INDO-UHF-CI Calculations of the Electronic Structure of Formaldehyde-Hydrogen Systems*

Kimiko MIZUTANI, Toyoo IZUMI,** and Shiro MATSUMOTO

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received October 29, 1976)

The electronic structures were calculated for the ground and several excited states of systems composed of a formaldehyde molecule and a hydrogen atom at various relative positions by means of an INDO-UHF-CI method, in order to elucidate the hydrogen-abstracting process of excited carbonyl compounds. The results were presented and discussed by means of the adiabatic potential energy curves, by means of configuration analysis using the various states of the non-interacting component species as reference, and by means of electron-density maps. The results showed in a concrete way that the process may proceed through an intermediate charge-transfer state, and the electron-density maps had features suggesting an attractive force acting on the positively charged hydrogen atom.

There have been increasing efforts to understand the mechanisms of chemical reactions in terms of the electronic structures of the molecular systems concerned.[1] The analyses have mostly been restricted to reactions between molecules in their ground states, although the principle may be the same for the cases when one or both of the partners are in excited states.

In the present work, electronic structures were calculated for systems composed of a formaldehyde molecule and a hydrogen atom at various relative positions in an attempt to get some insight into the nature of the hydrogen abstraction reaction of excited ketone molecules, as that reaction is one of the most clear-cut and best investigated chemical processes of excited states.[2] The process has, though, been described and discussed based only on the qualitative features of the electronic structures of the excited ketone molecules.[2,14c,15] For a more detailed understanding of the process, it seemed essential to compute the electronic structures of the combined system for a series of relative positions of the reactants. Since the calculation seemed, unfortunately, to be beyond the power of moderate computational facilities for real systems investigated experimentally, a model calculation was undertaken.

Ground and excited states of formaldehyde have been the subject of semiempirical calculations[3] of various precisions as well as of *ab initio* calculations.[4] The electronic states of the HCHO–H_2O system were calculated by Iwata and Morokuma.[5] In the case of the HCHO–H system, open shell or shells are involved in all the states, including the ground state. One way of treating the system would be a configuration interaction (CI) calculation using the configuration state functions (CSF's) constructed by the molecular orbitals (MO's) calculated for isolated HCHO plus an MO localized on the additional H atom. However, another method was attempted in this work; that is, the whole system was treated as a quasi-molecule by an SCF procedure. The method takes into account all the interactions between the components in a direct way at any internuclear distance. The resulting wavefunctions may be too complicated to be interpreted directly, but their expansions with the CSF's of the components (configuration analysis)[6] would help to grasp the characteristics of the states pictorially. As the RHF treatment will encounter the problem of orbital orthogonalization,[7] and as the wavefunction must be computed for a variety of geometries, the calculation was done by the INDO-UHF procedure[9] in order to obtain approximate wavefunctions without using too much computer time. Similar procedures have been used by several authors for similar purposes.[1d,1e] A fairly limited configuration interaction has been taken to improve the qualities of the excited states as well as of the ground state and to secure correct dissociation behavior[10b] of each state. In such a limited CI procedure, the SCF orbitals may be superior to the isolated HCHO and H orbitals for the state mainly composed of the ground-state configuration, as Brillouin's theorem[10c] states. For excited states, the situation was more subtle, but again the SCF orbitals seemed to be a better choice, as many terms cancelled each other out in the CI matrix element calculations. To visualize the results further, electron-density maps were drawn for some typical geometries. The conclusions obtained therefrom were in general agreement with those obtained by other methods of analysis; one interesting feature was that the maps were indicative of the direction of the force exerted on the approaching H atom.

Method of Calculation

The geometry of HCHO was taken to be planar (Fig. 1), and the dimensions were those given by the microwave analysis by Takagi.[8] They were fixed throughout this calculation. The position of the additional H atom will be defined below using the coordinate system given in Fig. 1. The method of INDO-UHF calculation was the same as that given in Ref. 9. The configuration interaction was confined to the 18 doublet CSF's*** resulting from the excitation of the π, n, and

* A part of this work was presented at the Symposium on Molecular Structure, Osaka, November 1975.

a), b), c), d) These configuration state functions are independent-spin-state pairs.

h orbitals to the π^* virtual orbital. Here, the π, π^*, and n orbitals were named by analogy with the orbitals of isolated HCHO, and h denotes the orbital with its main component on the approaching H atom. These CSF's are summarized in Table 1, together with the numbering used below. The primitive UHF determinantal wavefunctions are not exact spin eigenfunctions, and the generation of exact state functions therefrom requires complicated procedures.[10] In view of the rather semi-quantitative nature of this work and various approximations already done in INDO calculation, no effort was made to spin-project the UHF determinantal wavefunctions; when their linear combinations were essential, as when three singly occupied orbitals existed, the following simple approximation was

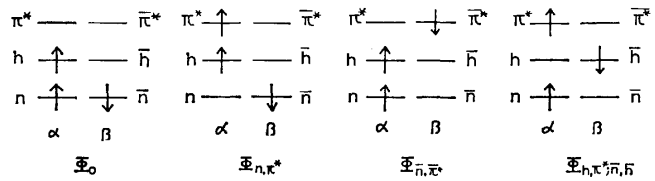

Fig. 2. Three independent arrangements of electrons resulting from $n\pi^*$ excitation.

taken tentatively for the doublet wavefunctions. First, let it be assumed that the orbital functions for the α- and β-spins coincide as in RHF calculations. Corresponding to the excitation of an n electron in the ground configuration, Φ_0, to the π^* orbital, for example, there may result three independent determinantal wavefunctions: Φ_{n,π^*}, $\Phi_{\bar{\pi},\bar{n}^*}$, and $\Phi_{h,\pi^*;\bar{n},\bar{h}}$ (Fig. 2). Two independent combinations of these determinants, which are exact doublets,[11] may be taken as

$$\Psi_a = (\Phi_{n,\pi^*}+\Phi_{\bar{n},\bar{\pi}^*})/\sqrt{2}, \quad (1)$$

$$\Psi_b = (-\Phi_{n,\pi^*}+\Phi_{\bar{n},\bar{\pi}^*}+2\Phi_{h,\pi^*;\bar{n},\bar{h}})/\sqrt{6}. \quad (2)$$

In the UHF case, orbital forms for α- and β-spins generally differ; however, if the differences are not too serious, Ψ_a and Ψ_b can be taken as representing approximately two doublet CSF's. For the estimation of the matrix elements of interaction between these CSF's, Slater's rule[12] was invoked, and the one- and two-electron integrals therein were again evaluated according to the prescription of the INDO method.

Configuration analysis was done in essentially the same way as the original paper[6] with necessary adaptations to doublets. The reference states were those of a hypothetical system composed of non-interacting component species. Here, two combinations,

$$\Psi_a^\circ = (\Phi_{n,\pi^*}^\circ+\Phi_{\bar{n},\bar{\pi}^*}^\circ)/\sqrt{2}, \quad (1')$$

$$\Psi_b^\circ = (-\Phi_{n,\pi^*}^\circ+\Phi_{\bar{n},\bar{\pi}^*}^\circ+2\Phi_{h,\pi^*;\bar{n},\bar{h}}^\circ)/\sqrt{6}. \quad (2')$$

represent exact doublets, as the orbital functions for α- and β-spins coincide in this case. The superscript, o, on Φ means the reference state. On the other hand, the CSF's assumed above for the real system are contaminated by the quartet character. A third linear combination,

$$\Psi_c^\circ = (-\Phi_{n,\pi^*}^\circ+\Phi_{\bar{n},\bar{\pi}^*}^\circ-\Phi_{h,\pi^*;\bar{n},\bar{h}}^\circ)/\sqrt{3},$$

is orthogonal to both Ψ_a° and Ψ_b° and represents a CSF quartet.[11] Thus, it would be appropriate to expand any state function, Ψ, in terms of this type of trio,

$$\Psi = \cdots + C_1(\Phi_{n,\pi^*}^\circ+\Phi_{\bar{n},\bar{\pi}^*}^\circ)/\sqrt{2} + C_2(-\Phi_{n,\pi^*}^\circ+\Phi_{\bar{n},\bar{\pi}^*}^\circ+2\Phi_{h,\pi^*;\bar{n},\bar{h}}^\circ)/\sqrt{6} + C_3(-\Phi_{n,\pi^*}^\circ+\Phi_{\bar{n},\bar{\pi}^*}^\circ-\Phi_{h,\pi^*;\bar{n},\bar{h}}^\circ)/\sqrt{3} + \cdots. \quad (3)$$

Equation 3 may be rewritten as:

$$\Psi = \cdots + f_1\Phi_{n,\pi^*}^\circ + f_2\Phi_{\bar{n},\bar{\pi}^*}^\circ + f_3\Phi_{h,\pi^*;\bar{n},\bar{h}}^\circ + \cdots, \quad (4)$$

with

$$f_1 = C_1/\sqrt{2} - C_2/\sqrt{6} - C_3/\sqrt{3},$$
$$f_2 = C_1/\sqrt{2} + C_2/\sqrt{6} + C_3/\sqrt{3}, \quad (5)$$
$$f_3 = 2C_2/\sqrt{6} - C_3/\sqrt{3}.$$

The coefficients, f_1, f_2, and f_3 are determined by means of the Ψ function, Φ_{n,π^*}°, $\Phi_{\bar{n},\bar{\pi}^*}^\circ$, and $\Phi_{h,\pi^*;\bar{n},\bar{h}}^\circ$ functions by the use of equations similar to those given in Ref. 6. The three Eqs. 5 are then solved to give

$$C_1 = (f_1+f_2)/\sqrt{2},$$
$$C_2 = (-f_1+f_2+2f_3)/\sqrt{6},$$
$$C_3 = (-f_1+f_2-f_3)/\sqrt{3}.$$

The C_3 coefficients are measures of the spin-contamination of the Ψ function.

Results and Discussion

Potential Curves and Configuration Analysis. The adiabatic potential curves obtained for several low-lying states are given in Figs. 3—5 for three modes of approach of the H atom. The results of configuration analysis along these curves are shown in Tables 2—6. In these figures, potential curves correlating to Ψ_5°, Ψ_7°, Ψ_8°, Ψ_9°, Ψ_{10}°, Ψ_{12}°, *etc.* for $R=\infty$ are not shown in order to avoid confusion. Each state, except for the one denoted as CT_1 in the figures, was found to dissociate rationally to an H atom and an HCHO molecule in its ground or in some of its excited states, which are shown beside each potential curve. The irreducible representation of each state is also indicated there. The CT symbol (charge transfer) is used here to denote states in which an electron in the h orbital is transferred to one of the empty orbitals of the HCHO component. As several different CT states arise, they are distinguished by subscripts, 1, 2, ···. They were found to dissociate to an H^+ and an $HCHO^-$ in its ground or various excited states. In the CT_1 state, the transferred electron occupies the LUMO π^* and has been found to play an important role in the chemical process under consideration. The BCT symbol (back charge transfer) indicates the states in which two electrons occupy the h orbital.

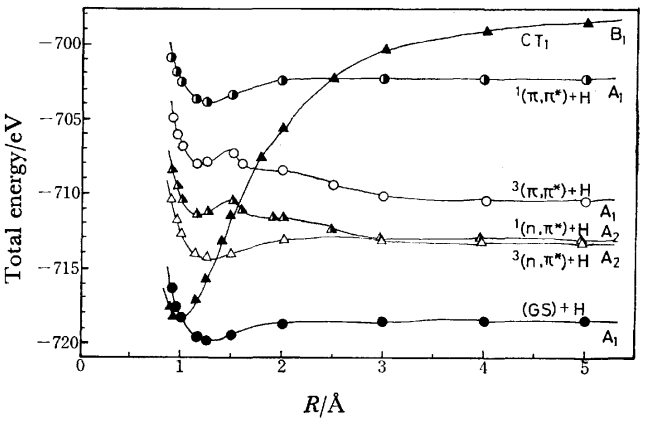

Fig. 3. Potential energy curves of ground and lower excited states of HCHO–H system; approaching H on X-axis. Beside each curve are given the states of components to which the state dissociates and the irreducible representation in C_{2v} point group.

When the H atom approaches along the X-axis (Fig. 3), the CT_1 curve drops sharply as R is reduced, but it merely crosses the lower potential curves. Even finite speed motions of the H atom will not cause transitions between these states. As a consequence, the H atom will not be attracted strongly by an $n\pi^*$ or $\pi\pi^*$ excited HCHO molecule in these geometries. A shallow minimum found in each potential curve at an R value of $\approx$1.2 Å is also seen in the ground-state potential curve; it might represent an attraction which is the cause of a stable ketyl radical formation from an H atom and an HCHO in the ground state. Another notable point in this nuclear configuration is that the potential curves of the $[^3(n\pi^*)+H]$ and $[^1(n\pi^*)+H]$ states closely approach at an R value of 2.84 Å, where the two states exchange characters rather abruptly, but continuously (Fig. 3 and Table 2). This is a case of pseudo-crossing,[13] and the transition between these adiabatic states may become possible by finite-speed motions of the H atom relative to the HCHO molecule. This observation is interesting because it seems to represent a mechanism by which singlet-triplet transitions of molecules are promoted through the formation of charge-transfer complexes with other species having odd electrons.

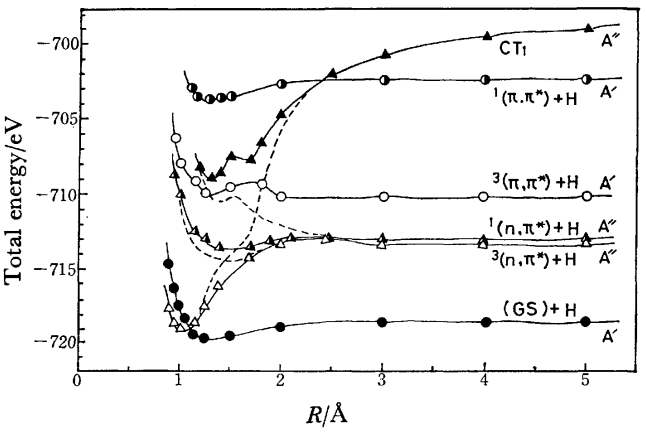

Fig. 4. Potential energy curves of ground and lower excited states of HCHO–H system; approaching H on Y-axis. Beside each curve are given the states of components to which the state dissociates and the irreducible representation in C_s point group.

When the H approaches along the Y-axis to the HCHO in the $^1(n\pi^*)$ or $^3(n\pi^*)$ excited state, the energy of the system decreases remarkably as a result of the strong configurational mixing with the CT_1 state (Fig. 4 and Table 3). The broken lines in Fig. 4 are intended to express these facts schematically. The transition to the ground state is, however, impossible in this mode of approach.

When the H atom is on the Z-axis, it is the $[^3(\pi\pi^*)+H]$ state which shows a marked decrease in energy as a result of the configurational mixing. The situation is

complicated here because of the abundance of states involved, but the results of configuration analysis may be summarized schematically as follows. The CT_1 state first interacts with $[^1(\pi\pi^*)+H]$ in the region of R= 2.5—3.0 Å, and its character is transferred to the latter. The second state then interacts with $[^3(\pi\pi^*)+H]$ in the region of R=2.2−1.3 Å; the lower state acquires a CT_1 character, and its energy drops remarkably as R becomes smaller, until it reaches near that of the ground state, where a third pseudo-crossing to the latter state occurs. The lowest adiabatic state is seen to have a CT_1 character as the main one for $R \lesssim 1.0$ Å. Another feature of these geometries is that the BCT_6 character seems to be an important cause of the energy decrease of the $[^3(\pi\pi^*)+H]$ state in the region of R=3.0−2.2 Å.

The importance of the charge-transfer type of intermediate states has frequently been suggested for quench-

a) [³(nπ*)+H] (H on X-axis)

R(Å)	2.845	2.4	2.0	1.5	1.25
C_3	0.0056	−0.0003	0.0009	0.0024	0.0011
C_3'	−0.00007	0.0005	−0.0021	−0.011	−0.019

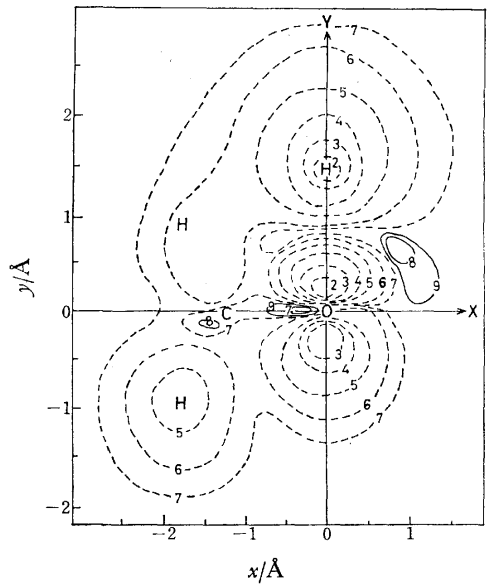
b) [³(nπ*)+H] (H on Y-axis)

R(Å)	2.5	2.0	1.5	1.25
C_3	−0.0075	−0.012	−0.32	−0.32

c) [³(ππ*)+H] (H on Z-axis)

R(Å)	2.5	2.0	1.5	1.25
C_3''	0.025	0.059	0.32	0.25

C_3, C_3', and C_3'' are the coefficients in Eq. 3 for the $(\pi)^2(n)(h)(\pi^*)$, $(\pi)(n)(h)(\pi^*)^2$, and $(\pi)(n)^2(h)(\pi^*)$ configurations of the reference system respectively.



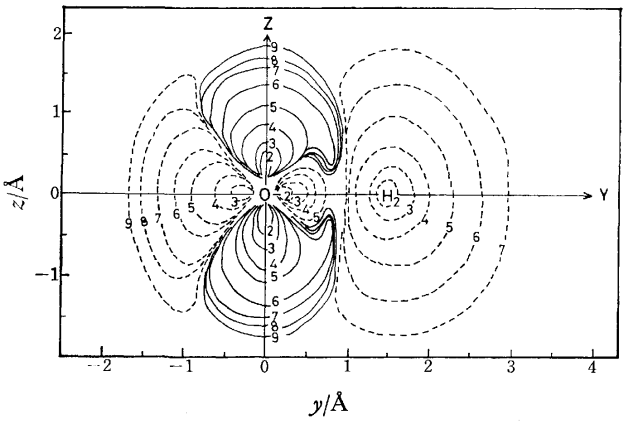


Fig. 6. Change in electron density upon ³(nπ*) excitation; approaching H on Y-axis. Full lines indicate increase and broken lines decrease in electron density. The numbers 1, 2, ···, 9 beside the contours indicate electron density change of 2.0, 1.0, 0.5, 0.2, 0.05, 0.01, 0.002, 0.0005, and 0.0001 electrons/Å³, respectively. a) XY-plane, b) YZ-plane.

ing and photochemical redox processes,[14] and potential curves have been deduced[14a] to describe them in a general but semi-quantitative way. The present straightforward calculation yielded a more concrete picture of the process. One point of criticism that might affect the quantitative aspects of the results was, however, the spin-contaminations of the wavefunctions used. The C_3 coefficients were moderate for the X-approach, but took appreciable values at certain geometries for the Y- and Z-approaches (Table 7). This will considerably obscure the quantitative aspects of the C_1 and C_2 coefficients of the same configuration at those geometries. An inspection showed that the main contribution to the large values in Tables 7b and 7c came from the expansion of CT_1 CSF, and showed the necessity of at least a partial spin-projection in a more quantitative work.

Electron-density Maps. The chemical process could be perceived more visually through inspections of the electron-density maps. The electron-density distributions of the total valence electrons for the system of an HCHO in the ground state and of an H atom on the X-axis were not much different from that of an isolated HCHO, except for a slight electron density in the regions between the two components. This may be the cause of a shallow minimum seen in the [(GS)+H] curve of Fig. 3. The same was found to be true for the system of the ³(nπ*) HCHO and the H atom on the X-axis, in which case charge-transfer cannot occur because of symmetry reasons.

The electron density was also not much different from that of the isolated system with the H on the Y-axis when the HCHO component was in the ground state, but an essential change was seen when the HCHO was excited to the ³(nπ*) state. The difference in the electron densities between the two states is shown in Fig. 6a. In most of the XY-plane, the electron densities are taken off perpendicularly to both sides of the plane upon excitation, whereas small regions of increased electron density appear near the O atom on the CO-axis and in the first quadrant. As there is only a weak attraction exerted on the H atom in the ground state, the separated charge upon excitation may be responsible

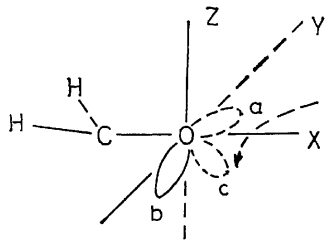

Fig. 7. Inferred path of H toward ($n\pi^*$) excited HCHO in a quasi-static approach. a, b: Leaves of n orbital. c indicates O–H bond orbital in ketyl radical.

for determining the remarkable attraction exerted on the H in this nuclear configuration. One may see that the projection of the vector of the attraction force on the XY-plane is not toward the carbonyl oxygen, but toward a region which is an extension of the CO-axis, as may be seen in Fig. 6a. A similar contour map on the YZ-plane is given in Fig. 6b. The positively charged H atom is seen to be attracted by the negative charge generated on both sides of the XY-plane upon $n\pi^*$ excitation.

By reference to the results obtained above, one may guess the way the H atom is abstracted from a hydrogen donor by $n\pi^*$ excited HCHO. The excited state of HCHO is known to be bent. Let the two H atom of HCHO be above the XY-plane (Fig. 7). When the H being abstracted approaches along a path on the XZ-plane, no charge-transfer contribution may be expected to lower the potential energy of the system, just as in the cases shown in Figs. 3 and 5. The most favorable path of statical approach seems again to be nearly along a leaf (a in Fig. 7) of the n orbital at first, then gradually curving to the final place in the ketyl radical (at an end of c in Fig. 7). The electron-density increase may be more pronounced in the negative Z-direction than in the positive Z-direction, as compared with the pattern in Fig. 6b, as a result of the bent structure of HCHO. The attraction force on the positively charged H may be directed toward the region of the outweighted negative charge. In this case, a less symmetric nuclear arrangement will allow the transition from the CT_1 mixed state to the ground state at a potential curve crossing point similar to the one seen in Fig. 4.

From Fig. 5 it may seem that the $^3(\pi\pi^*)$ excited HCHO could also abstract hydrogen from a hydrogen donor approaching from the Z-direction if a non-adiabatic transition occurred between the potential curves of $[^3(\pi\pi^*)+H]$ and $[(GS)+H]$ around a geometry of $R\approx 1.1$ Å.

The present calculation does not seem to account for the fact[15] that carbonyl compounds with $^3(\pi\pi^*)$ as the lowest triplet have, in general, less reactivities toward hydrogen abstraction than those with $^3(n\pi^*)$ as the lowest triplet. One explanation seems to be as follows. According to Slater's rule, the CI matrix element between two CSF's is calculated, if they are different in one spin-orbital pair, as the energy of the overlap density of the pair orbitals in the field generated by the nuclei and the electrons in the orbitals other than this pair. The CI matrix element between $[(\pi\pi^*)+H]$ and CT_1 is, then, mainly determined by the overlap density between the π and the h orbital, whereas the matrix element between $[(n\pi^*)+H]$ and CT_1 is determined by that between the n and the h orbitals. The carbonyl compounds commonly used in the hydrogen abstraction reaction contain large conjugated π systems, and the overlap between π and h orbitals may be comparatively smaller than in the present case. The orbital overlap between n and h may be affected only slightly by the conjugation due to the local nature of the n orbital. In the carbonyl compounds with the lowest CT-triplet,[15] this effect may even become prominent.

Infrared Spectra of 1,3-Butadiene Adsorbed on Alumina-supported Metal Catalysts at Various Temperatures

Yuko SOMA

College of General Education, University of Tokyo, Komaba, Tokyo 153

(Received November 22, 1976)

The infrared spectra of 1,3-butadiene adsorbed on Pd, Ni, and Co catalysts were measured while changing the adsorption temperature. These catalysts behaved differently in butadiene adsorption, and π-adsorbed butadiene was the major adsorbed species below 0 °C on Pd and Ni. This π-species was easily hydrogenated to produce butene at the same temperature.

There have been many infrared spectroscopic studies of hydrocarbons, especially olefins, adsorbed on transition metals.[1-3] The spectra of chemisorbed olefins have been measured mostly using supported metals at room temperature, and have been demonstrated to be of a complex nature caused by the existence of various dissociatively adsorbed hydrocarbons on the metal surface. Although π-bonded olefins on metal catalysts have been considered to be the intermediates of such reactions as hydrogenation, there has been no definite evidence from infrared spectroscopic measurements of the species on the metal surface. Recently π-adsorbed ethylene on Pd was observed from the difference in the spectra of the adsorbed species before and after hydrogenation[4] or in a low-temperature measurement.[5]

The hydrogenation reaction of 1,3-butadiene on transition metals has been studied in detail by Bond, Wells, and their co-workers.[6] According to their investigations, the reaction rate is proportional to the first order of the hydrogen pressure, while it is nearly proportional to the zero order of the butadiene pressure, like other olefin hydrogenation reactions. The composition of hydrogenated products (1-butene, *trans*- and *cis*-2-butene) varies depending on the metals and on the method of preparing the catalysts; this suggests the importance of the configurations of the adsorbed butadienes on the surface in deciding the compositions of hydrogenated products, kinds of butene. They considered three types of adsorbed butadiene: mono-π-bonded species, and *trans*- and *cis*-di-π-bonded species. Therefore, the direct measurement of the infrared spectra of adsorbed species will be helpful in understanding the mechanism and selectivity of the reaction.

The infrared spectra of butadiene adsorbed on Ni at room temperature were investigated by Erkelens,[3] and only methylene-rich polymeric species were observed. On Pd metal, no absorption band for adsorbed species appeared at room temperature, but that of polymerized species was observed after hydrogen addition.[2]

In this paper the infrared spectra of butadiene adsorbed on alumina-supported Ni, Pd, and Co catalysts will be reported in the temperature range between room temperature and −80 °C. At low temperatures, the side reactions were supressed and the spectra of π-bonded butadiene were clearly observed. The differences between the three metal catalysts in the adsorption of 1,3-butadiene were demonstrated to be of interest in connection with their catalytic properties in the hydrogenation reaction.

Experimental

Nickel or cobalt catalyst was prepared from a suspension of alumina in an aqueous solution of each metal nitrate, which was decomposed in air at 450 °C. Palladium particles were deposited on alumina in a $PdCl_2$ solution with the addition of formaldehyde and sodium hydroxide. Each of these catalysts contains about 9 wt % metal.

These catalysts were used in the shape of discs for the infrared measurements. For room-temperature measurements, the disc was evacuated at 420 °C for 2 h in an infrared cell and then reduced in hydrogen for 3 h at the same temperature. About 60 Torr of gaseous butadiene was placed in contact with the Ni catalyst for 15 min, but with Co catalyst for 20 h, and the spectra were measured after the cell was evacuated to 10^{-3} Torr. The cryogenic cell for low-temperature measurements was similar to that used by Avery.[2] As the highest temperature which could be attained with this cell was about 300 °C, the disc was evacuated and reduced at 400 °C in an glass vessel; the disc was then transferred to the cryogenic cell and was reduced again at 300 °C. The catalyst was placed in contact with gaseous butadiene for about 30 min; the butadiene was then removed by trapping and evacuation to 10^{-3} Torr. The adsorption of butadiene on an alumina support is negligible under these experimental conditions.

The 1,3-butadiene(*h*-butadiene) (Tokyo-Kasei Co.) and 1,3-butadiene-1,1,4,4-d_4(CD_2=CH−CH=CD_2) (MSD Co.) were purified by passing it through a heated palladium thimble.

Gas chromatography with a DMF–alumina column was used for the analysis of gaseous hydrocarbons.

Results

Palladium. Figure 1 shows a spectrum of $\Delta^{1,3}$-C_4H_6 chemisorbed on Pd-Al_2O_3 at −32 °C, together with the band frequencies of Fe–butadiene complexes and free butadiene. It is evident that the spectrum is quite different from that of gaseous butadiene, but corresponds to that of Fe–butadiene complexes except for a broad band at 1653 cm^{-1}. The assignment of the bands of chemisorbed $\Delta^{1,3}$-C_4H_6 can be made on the basis of the results for the Fe–C_4H_6 complex reported by Davidson *et al*:[7] 1433 for $\nu_{C=C}$, 1224 cm^{-1} for ν_{C-C}, and 1473 and 1376 cm^{-1} for CH_2 scissors vibrations. (π_d)* The existence of the band at 1653 cm^{-1} shows that a part of the chemisorbed butadiene has a

* π_s and π_d show two adsorbed species of butadiene on Pd below 0 °C. These structures will be shown in the 'Discussion' section.

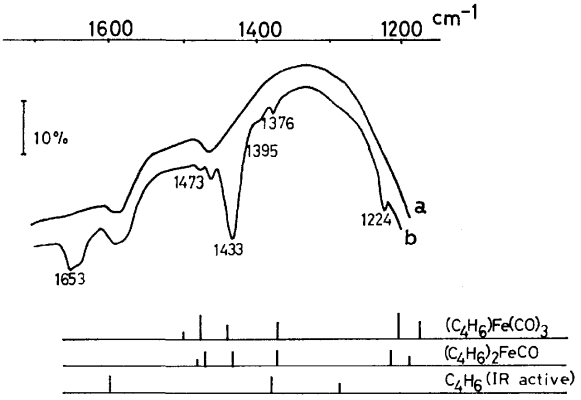

Fig. 1. IR spectrum of $\Delta^{1,3}$-C_4H_6 adsorbed on Pd–Al_2O_3 at −32°C(b), (a) Pd-Al_2O_3 background. The lines under the spectra show the positions and band intensities of Fe–C_4H_6 complexes and gaseous C_4H_6.

free C=C double bond and has another C=C bond interacting with the surface Pd. (π_s)*

The existence of two kinds of adsorbed species (π_d, π_s) is consistent with the fact that the band intensity at 1653 cm^{-1} relative to that at 1433 cm^{-1} varies with the butadiene coverage and the temperature. The ratio of these peak intensities was about 0.34 when a small amount of butadiene was adsorbed at −80 °C, while the value reached 0.60 when adsorption was saturated at −25 °C. If it is assumed that the band at 1433 cm^{-1} is due to both π_s and π_d species, while the band at 1653 cm^{-1} is due only to the π_s species, the relative amount of the π_s species can be estimated to be small at a low butadiene coverage, but to increase with a rise in the adsorption temperature. The rate of the decrease of the absorbance at 1653 cm^{-1} upon D_2 addition is 1.2 times faster than that of the absorbance at 1433 cm^{-1} on both Pd and Ni at −50 °C. These observations indicate that the π_s species is less stable than the π_d species.

When hydrogen was introduced on butadiene chemisorbed over a Pd catalyst at −50 °C, new bands attributable to the formation of a methyl group and a co-ordinated C=C double bond appeared, as is shown in Fig. 2. These bands which appeared upon hydrogen addition (indicated by arrows in Fig. 2c) are closely related to the bands of butene in K[$PtCl_3$(*trans*-C_4H_8)],[9] except for a part of the band at 1650 cm^{-1} which disappeared easily upon evacuation and the band at 1580 cm^{-1}. The only gaseous products were butenes and *n*-butane, and the butenes adsorbed on Al_2O_3 showed a band at 1580 cm^{-1}, so the above two bands may be attributed to gaseous butene and to butene adsorbed on Al_2O_3 respectively. It may be concluded that the π-species of chemisorbed butadiene was hydrogenated to form chemisorbed butene, a part of which was liberated into the gas phase or adsorbed on Al_2O_3.

At room temperature, no spectrum of butadiene adsorbed on Pd was observed, in agreement with the result by Avery,[2] whereas weak bands due to the formation of a methyl group were observed after hydrogen addition.

Nickel. The spectrum of $\Delta^{1,3}$-C_4H_6 chemisorbed on Ni at low temperatures (−78—0 °C) is almost

identical to that chemisorbed on Pd. The spectrum changed, however, as is shown in Fig. 3, when the temperature was raised, and new bands appeared which could not be removed by room-temperature evacuation. The spectra at room temperature are shown in Fig. 4, while the observed frequencies and their assignments are listed in Table 1. The two adsorbed species can be distinguished from each other on the basis of their behavior

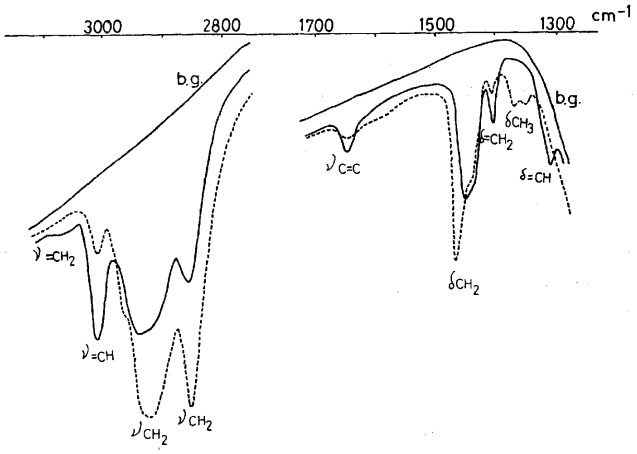

Fig. 4. IR spectrum of $\Delta^{1,3}$-C_4H_6 adsorbed on Ni-Al_2O_3 at room temperature(——) and that after hydrogen was introduced (-----). b. g.; Ni-Al_2O_3 background.

Table 1. Observed frequencies of 1,3-butadiene chemisorbed on Ni-Al_2O_3 at room temperature, the intensity changes of these bands upon hydrogen addition, and the band assignments

CH_2=CH-CH=CH_2 cm^{-1}	New bands appearing after H_2 addition cm^{-1}	Intensity changes after H_2 addition	Assignments
3075		decreased	$\nu_{=CH_2}$
3010		decreased	$\nu_{=CH}$
	2960 sh		ν_{CH_3}
2925		increased	ν_{CH_2}
2854		increased	ν_{CH_2}
1650		decreased	$\nu_{C=C\ free}$
	1467		δ_{CH_2}
1440		decreased	$\delta_{=CH_2}$ or $\nu_{C=C\ ads.}$
1407		decreased	$\delta_{=CH}$
	1370		δ_{CH_3}
1308		decreased	$\delta_{=CH_2}$

CD_2=CH-CH=CD_2 cm^{-1}	New bands appearing after D_2 addition cm^{-1}	Intensity changes after D_2 addition	Assignments
3006		decreased	$\nu_{=CH}$
2955		decreased	ν_{-CHM-}

upon hydrogen addition; the intensity of one increases, while that of the other decreases. The former bands can be assigned to the CH_2 stretching (2925, 2854) and CH_2 scissors (1467 cm^{-1}) of polyethylene. The latter bands are located at 3010, 1650, 1440, 1407, and 1308 cm^{-1} and may be assigned as is shown in Table 1. The weak band at 1370 cm^{-1} and the shoulder at about 2960 cm^{-1} may be due to the methyl group. In the case of butadiene-d_4, the bands at 3006, 2955, 2300, 2125, 1645, and 1403 cm^{-1} decreased in intensity upon hydrogen addition.

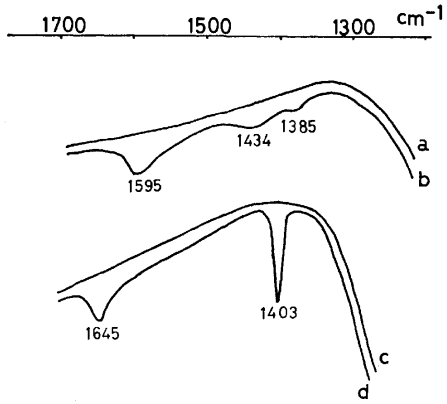

Fig. 5. IR spectra of CD_2=CH-CH=CD_2 adsorbed on Ni-Al_2O_3.
a, c) Background. b) Adsorption at −29°C. d) Adsorption at room temperature.

The adsorbed species, the amount of which decreased upon hydrogen addition at room temperature, can be considered to be different from those (π_d, π_s) observed below 0 °C, because the former species shows sharp bands at 1407 and 1308 cm^{-1} which were not observed in the π_d and π_s species of *h*-butadiene. Furthermore, the spectra of butadiene-d_4 changed remarkably with a change in the adsorption temperature, as is shown in Fig. 5. The free C=C double bond stretching band was observed at 1595 and 1645 cm^{-1} in low-temperature and room-temperature spectra respectively. This fact supports the above-mentioned deduction, since the adsorption of butadiene-d_4 produces, probably, the same species as *h*-butadiene adsorption.

The rate of butadiene hydrogenation to butene was zero-order to the butadiene pressure, and proportional to the hydrogen pressure, on the Pd and Ni catalysts in the low-temperature range (−60—10 °C) and on Co between 0 and 100 °C. The number of active sites of butadiene hydrogenation can be estimated from the amount of the C_4 species ($C_4H_8+C_4H_{10}$) formed by the addition of hydrogen to chemisorbed butadiene. As is shown in Table 2, the amount of C_4 species desorbed from the Ni catalyst by hydrogen decreases with an increase in the adsorption temperature, though the amount of butadiene adsorbed has a tendency to increase because of polymerization on the surface. At −31.5 °C almost all of the Ni atoms on the surface are active in hydrogenation, but at higher temperatures, polymerization on the surface destroys the active sites

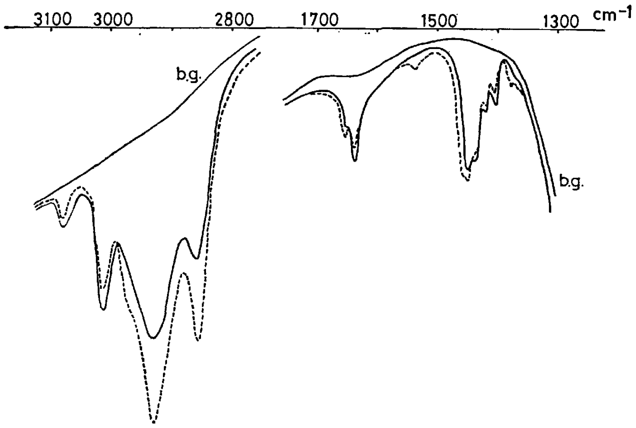

Fig. 6. IR spectrum of $\Delta^{1,3}$-C_4H_6 adsorbed on Co–Al_2O_3 at room temperature(——) and that after hydrogen was introduced(----). b. g.; Co–Al_2O_3 background.

for hydrogenation to butene. The number of active sites at room temperature is less than 10% of the surface Ni atoms.

Cobalt. Figure 6 shows the spectrum of butadiene chemisorbed on Co–Al_2O_3 at room temperature and that after hydrogen addition. The adsorption at room temperature was very slow, and the catalyst had to be in contact with butadiene for 20 h to obtain a sufficient intensity of the spectrum of the adsorbed species. When butadiene was in contact for 20 h, several weak bands appeared at 2960, 2920, 2860, 1460, and 1370 cm^{-1} on Al_2O_3 without metal. Though the spectra of chemisorbed species on Co–Al_2O_3 resemble, as a whole, those on Ni at room-temperature adsorption, some significant differences can be noted. The difference between Ni and Co spectra can be clearly seen in Fig. 7.

Discussion

Palladium. When pre-adsorbed butadiene on Pd was removed by introducing hydrogen below 0 °C, the gaseous products were butadiene, butene, and butane. Thus, butadiene may be considered to be non-dissociatively adsorbed on Pd in this temperature range. The observed similarity between the spectrum of butadiene chemisorbed on the Pd surface and that of the Fe complex may indicate that one type of adsorbed butadiene on Pd has the following structure, as butadiene in the Fe complex has a *cis* configuration with the two C=C bonds π-bonded to Fe:[7)]

π_d; 
It may be considered there exists another species which has a free C=C stretching band at 1653 cm^{-1}. The only band which were distinct to this species was the band at 1653 cm^{-1}, so it is reasonable to consider this species to have a structure similar to that of the above species, π_d. Thus, the following structure may be considered:

$$\pi_s;\quad CH_2{=}CH{-}CH{=}CH_2 \text{ (M coordinated below the terminal C=C)}$$

It has been reported that the butadiene in the $[PdCl_2(C_4H_6)]_2$ complex is monodentate at −40 °C and that it gives the free C=C stretching band at 1660 cm^{-1} and a strong band around 1440 cm^{-1}.[8)] Because the C=C stretching band is presumed to exhibit the largest shift with the change in the nature of π-bonding between butadiene and a metal atom, it is not unreasonable that the remaining bands of this π_s butadiene could not be observed from π_d butadiene.

Nickel. Butadiene chemisorbed on Ni below 0 °C must have structures similar to those chemisorbed on Pd, judging from the agreement of the spectrum; those were π_s and π_d.

However, the spectrum at room temperature is different from that below 0 °C. The former spectrum is explained as showing the co-existence of two adsorbed species; one is polyethylene, whose intensity increased upon hydrogen addition:

$$\text{polymer: } -(CH_2)_n-$$

From the spectra it was deduced that the other species had C=C, CH_2=, and CH= groups in *h*-butadiene and C=C, CD_2=, =CH, –CHM–, and –CD_2M groups in butadiene-d_4. Although the stretching bands due to –CHM– and –CH_2M groups in *h*-butadiene could not be observed, those bands were considered to overlap with the strong bands of polyethylene. The species with these bands most probably has the structure:

$$\sigma:\ CH_2{=}CH{-}\underset{\mid}{\overset{}{CH}}{-}\underset{\mid}{CH_2}$$
$$\qquad\qquad\ \ M\quad\ M$$

Cobalt. There are one σ-type species and one

polymeric species on Ni, whereas on Co there is still another adsorbed species which decreased in intensity upon hydrogen addition at room temperature, as is shown in Fig. 7. The third species has the bands at 1640 and 1420 cm^{-1} for C_4H_6 and at 1599 cm^{-1} for butadiene-d_4. As the bands of the species on Co agree with those on Pd or Ni in the low-temperature range, and are assigned to π-adsorbed species (π_s, π_d), the two kinds of π-adsorbed species remain stable at room temperature on Co, though they are unstable on Pd and Ni.

The observed species of 1,3-butadiene chemisorbed on alumina-suported Pd, Ni, and Co catalysts can be summarized as follows:

	Low temperatures (−50—0 °C)	Room temperature
Pd	$\pi_s+\pi_d$	—
Ni	$\pi_s+\pi_d$	polymer+σ
Co	—	polymer+σ+π_s+π_d

The σ-type species was easily hydrogenated at room temperature and can be considered to be a precursor of polyethylene and/or 1-butene.

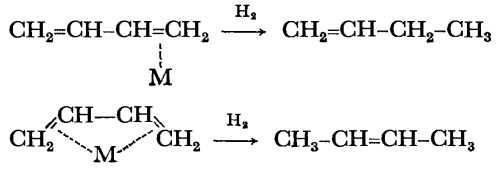
The π-species which were observed on Pd and Ni at low temperatures and on Co at room temperature were composed of two species (π_s, π_d), and the π_s species was less stable than the π_d species. These π-adsorbed species covered almost all of the Ni surface atoms at low temperatures (−35 °C), as is shown in Table 2, and were easily hydrogenated by hydrogen to form adsorbed butene at the same temperature (Fig. 2).

Table 2. Desorption products of adsorbed C_4H_6 on Ni-Al_2O_3, which were removed by the addition of H_2[a)]

T °C	Amounts of desorbed species ($C_4H_8+C_4H_{10}$) mol/g-cat	(C_4H_6) mol/g-cat	Amounts of surface Ni atoms[b)] mol/g-cat
−31.5	8.37×10^{-5}	0.77×10^{-5}	9.78×10^{-5}
2	3.69	0.62	
29.8	0.71	0.54	

a) 75 Torr of C_4H_6 was adsorbed for 30 min at the above temperature and evacuated to 0.03 Torr, and then 25 Torr of hydrogen was introduced to hydrogenise and remove the adsorbed species. The gaseous desorption products were C_4H_6, C_4H_8, and C_4H_{10}. b) The Ni surface area was estimated from the amount of H_2 adsorbed at 0 °C.

The π_s species may be considered to be a precursor of 1-butene, and the π_d species, to be that of 2-butene in butadiene hydrogenation.



$CH_2=CH-CH=CH_2 \xrightarrow{H_2} CH_2=CH-CH_2-CH_3$

$CH_2=CH-CH=CH_2 \xrightarrow{H_2} CH_3-CH=CH-CH_3$

π-Bonded ethylene was observed by IR measurement on Al_2O_3-supported Pd or Pt catalysts at low temperatures (−86 °C) as the main adsorbed species on the surface,[5)] whereas the main adsorbed species were σ-bonded or dissociatively adsorbed species at room temperature.[1,4)] In the butadiene adsorption, also σ-type and polymerized species were shown to be formed on Ni only above room temperature, while π-bonded species were observed at low temperatures. These facts indicate that π-bonded species of olefins which are considered to be precursors of hydrogenation reaction, become predominant on transition metals at low temperatures, where the reactivity of the metal catalysts is lowered. It is interesting that Pd, Ni, and Co behave differently from each other in butadiene adsorption; the difference in the stability of π-adsorbed species on Pd and Ni from that on Co, and the existence of polymerized species on Ni and Co, which decreases the active sites for hydrogenation reaction.

Wells and his co-workers discriminate various Ni or Co catalysts as Type A or Type B for butadiene hydrogenation.[6)] According to them, the 1,2-addition of hydrogen is preferred on a Type A catalyst, while on a Type B catalyst 1,4-addition occurs mainly. All the catalysts used here (Ni, Co, and Pd) showed Type A behavior; more than 50% of the butene produced was 1-butene, although the *trans*: *cis* ratio was high on Pd (7—8), but low on Ni and Co, (2—3). Type B behavior could not be observed even when the reduction temperature was raised above 400 °C; this might be because of the small metal particle size of these catalysts (less than 60 Å).

The author is grateful to Professor T. Onishi and Professor M. Nishikawa for their helpful discussions.

Determination of Magnetic Susceptibilities of Diamagnetic Liquids by an Improved Viscometer Method

Kazuo SUEOKA and Toshio IKEDA*

Department of Chemistry, Johsai University, Sakado, Saitama 350-02
**Department of Chemistry, Shizuoka University, Shizuoka 420*

(Received December 25, 1976)

An improved viscometer method is presented for the determination of the magnetic susceptibility of a liquid with a complete exclusion of the oxygen effect. The method was found to be excellent even in determining the magnetic susceptibilities of diamagnetic liquids, giving results accurate to within ±0.05%. The influence of air (or oxygen) was also discussed.

Previously, one of the present authors reported a viscometer method[1] for the determination of the magnetic susceptibilities of paramagnetic liquids by measuring the rate of flow of liquid through the capillary of a viscometer of the Ostwald type under the action of an external magnetic field. In the present study, the measuring device was improved using a modified Ubbelohde viscometer so that one may determine accurately the diamagnetic susceptibilities of liquids as well even by using an electromagnet of a comparatively small size. The diamagnetic susceptibilities of some organic liquids measured with the use of the improved cell under nitrogen were found to be in good agreement with those values reported in the literature within a range of deviation such as was pointed out by Eggleston *et al.*[2]

Theoretical

A modified capillary viscometer of the Ubbelohde type (Fig. 1) is placed in a magnetic field so that the lower end of the capillary is in the center of a gap between the pole pieces of an electromagnet, while its capillary part extends vertically, through the inhomogeneous region, outside of the field. Then, a liquid in the capillary of the cell is forced to flow down by the action of gravity downwards and by that of the magnetic force upwards (or downwards, as the case may be), both acting simultaneously on the liquid when it passes through the inhomogeneous region of the field.

The Hagen-Poiseuille expression for the flow of a liquid may be written as

$$\frac{1}{t_H} = \frac{\pi r^4}{8lv\eta}\left(\rho g\tilde{h} + \frac{1}{2}\kappa H^2\right), \tag{1}$$

where t_H is the time required by the liquid of a certain volume, v, to flow down in the presence of the field through a capillary with a certain radius, r, and a certain length, l; g is the acceleration of gravity; h is the mean effective head of the liquid; the ρ, η, and κ symbols represent the density, the viscosity coefficient, and the volume magnetic susceptibility of the liquid respectively; H denotes the local magnetic field strength near the center of the pole-pieces gap of the magnet. Denoting by t_0 the time of flow of the liquid in the absence of an external magnetic field, one may write $1/t_0 = \pi r^4 \rho g\tilde{h}/8lv\eta$. Since η is practically independent of the field of such an order of strength as is used here, we obtain from Eq. 1 the following relation:

$$\frac{t_0 - t_H}{t_H} = \frac{\kappa H^2}{2\rho g\tilde{h}} = \frac{\chi H^2}{2g\tilde{h}}, \tag{2}$$

where χ represents the mass magnetic susceptibility of the liquid. Equation 2 is the basic equation for determining the magnetic susceptibility in the present method. As is clear in Eq. 2, the time, t_H, should be longer than t_0 for diamagnetic liquids, while it is shorter for paramagnetic liquids. Upon taking into consideration the fact that the present type of viscometer is so made that the mean effective head, h, is controlled automatically to an exactly fixed value in every measurement, one may always be allowed to write

$$\frac{t_0 - t_H}{t_H\chi} = K, \tag{3}$$

so long as t_H is measured under the same field strength, H, where K is a constant characteristic of the cell used and is dependent on H, but entirely independent of the nature of the liquid. If once the constant, K, is determined for a certain standard liquid substance, such as water, whose magnetic susceptibility is known accurately, the susceptibilities of all the other liquid substances can be determined by merely measuring the two corresponding quantities, t_0 and t_H, of the sample to be studied.

Experimental

Materials. Commercial nitrogen with a purity of more than 99.9% was dried by passing silica gel and phosphorus pentaoxide through. The water was purified by sub-boiling distillation from a pure quartz still after deionization. The benzene, carbon tetrachloride, methanol, 2,2,4-trimethylpentane, and cyclohexane were Dotite Primasol solvents, while the toluene, dioxane, ethyl acetate, heptane, hexane, 2-propanol, and acetone were Dotite Spectrosol solvents obtained from the Dojindo Co. The other solvents, such as, acetic acid, ethanol, and nitrobenzene, were of the Wakō Guaranteed Reagent grade. These organic solvents were used without further purification.

Capillary Cell. A capillary viscometer cell of a modified Ubbelohde type, equipped with a thermostat jacket, was fixed in the pole gap of a magnet so that the lower end of its capillary part was located at the center of the pole gap of the magnet, while its upper part extended vertically out of the magnetic field through the inhomogeneous region of the field. Figure 1 shows the experimental equipment, where a capillary cell made of Pyrex glass is fixed upright in duplicated water jacket cabinets made of poly(vinyl chloride). The cabinets are covered with foam polystylene to which a glass window, W,

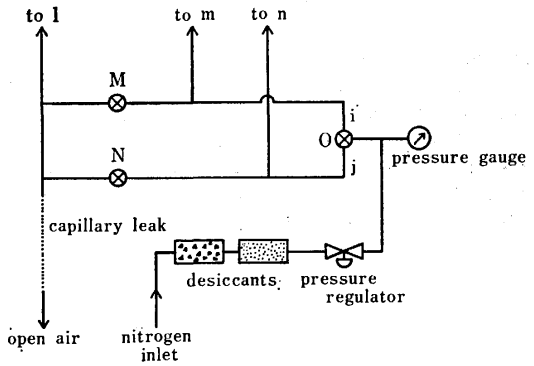

Fig. 2. Connection diagram of the operation tube.

is attached at the level of the upper globular part, C, of the cell.

Magnet. A Weiss-type 100-kg electromagnet manufactured by Nihon Kohmitsu Kenkyusho was used. The magnet pole pieces, about 20 mm in tip diameter, were set at a separation of 8 mm. The magnetic field was controlled using a stabilized dc source (±0.01%) up to 4 A, corresponding to a maximum field of 18800 Oe. The magnetic-field strength was calibrated with a Yokogawa gauss meter, type 3251, at the center of the pole gap.

Measuring. Prior to measuring, the liquid sample which was to be put in the cell was saturated with nitrogen by passing nitrogen through the liquid for about 10 min, and the residual inside space of the cell was fully filled with nitrogen by the aid of an operation tube (Fig. 2) connected to the cell. After this, until the measurement came to an end, nitrogen was continually allowed to flow through the operation tube so that the liquid in the cell was never exposed to air again. When it was necessary to shift the liquid sample up to the globular part, C, of the cell, a moderate pressure slightly higher than the exterior was applied by introducing nitrogen through the operation tube during the measurements,

Table 1. Operation of M, N, and O valves

	M	N	O
Removing air	close	open	i
Shifting up liquid	close	close	j
Measuring	open	open	j

while the inside pressure was kept constant. The direction of the flow of nitrogen was controlled, as occasion called for, by operating three magnetic valves made of Teflon in the way indicated in Table 1. The time of flow of the liquid was measured to an accuracy of ±0.01 s using a viscometer of the Shibayama Scientific Co. provided with an electric detector connected to an electronic clock for monitoring the passage of the meniscus of the liquid. The temperature around the cell was controlled at 20±0.01 °C by circulating thermostated water. The measurement of the flow time was repeated alternately in the presence or in the absence of the magnetic field, and the value of $(t_0-t_H)/t_H$ was calculated for each step. The observed values were found to become closely reproducible after several repetitions of measurements in the beginning. Twenty or fifty measurements were averaged to calculate the magnetic susceptibility.

Results and Discussion

The results are shown in Fig. 3. In all cases a perfect linear relation may be seen passing through the point of origin. These results can be expressed by the following experimental formula:

$$\frac{t_0-t_H}{t_H} = \alpha H^2, \tag{4}$$

where α should, in comparison with Eq. 2, be proportional to the mass susceptibility, χ, of the liquid in such a way that $\alpha=\chi/2gh$; this has proved to be true experimentally as well, as may be seen in Table 2. Thus, Eq. 3 was well confirmed.

The susceptibilities were calculated by the aid of Eq. 3 for some liquids, taking water as a standard reference. The results are shown in Fig. 4 and Table 3. The observed values of χ are found to be reproducible within ±0.05% and are in good agreement with the

literature values. However, strictly speaking, most of them are slightly larger than the literature values, except for acetone and cyclohexane.

As is shown in Fig. 5 for benzene, the observed value of $(t_0-t_H)/t_H$ was practically attained within about 2 min after nitrogen was passed through; this is its final steady state value, observed after the complete removal of air from the cell. Since, in the present work, the passage of nitrogen was carried out for a sufficiently long time (more than 10 min), the influence of air that was found in the cell in the beginning, including the liquid sample, could be assumed to be reduced to the limits of accuracy of this method, *i.e.*, within $\pm 0.05\%$.

Eggleston *et al.*[2] pointed out experimentally that most of the diamagnetic susceptibilities reported in the past are in error by an amount corresponding to the effect due to dissolved air. The magnetic susceptibility of a liquid dissolving air may be expressed in the following relationship:

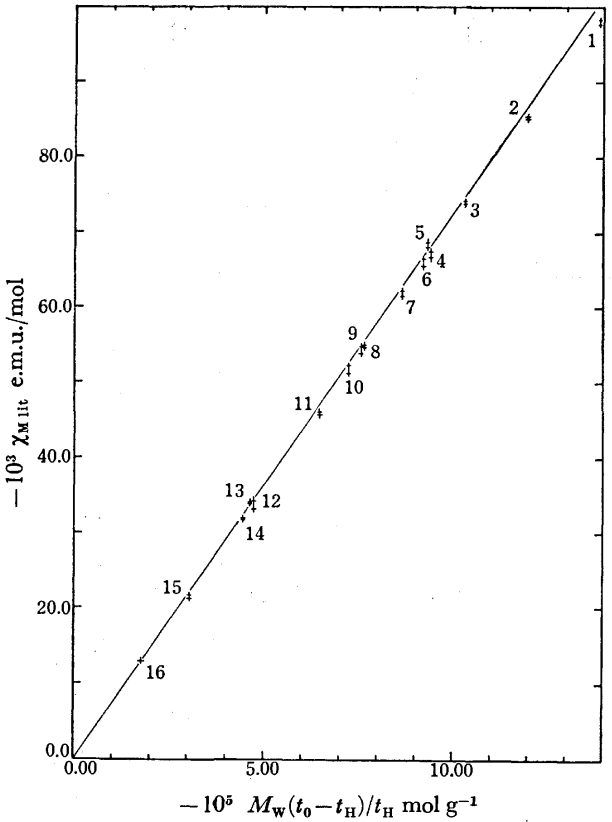

Fig. 4. Relationship between the $(t_0-t_H)/t_H$ value found at a fixed magnetic-field strength of 18800 Oe and the literature values of the magnetic susceptibility of the liquids. Fig. 5. Effect of atmospheric air in the cell on the flow time of benzene. (The broken line shows the level to be observed under ideal conditions when the air in the cell is completely removed. Such ideal conditions might be nearly attained, for example, by means of the freeze-pump technique and finally by saturation with nitrogen using the operation tube.)

$$\chi = \chi^\circ + \frac{\rho_{air}}{\rho}\beta\chi_{air}, \qquad (5)$$

where χ° and χ_{air} are the mass magnetic susceptibilities of a deaerated pure liquid and of air respectively, β is the solubility of air in the liquid, and ρ and ρ_{air} are the densities of the liquids and of air respectively. Since χ and χ° for diamagnetic liquids are opposite in sign to χ_{air}, and since the last term of Eq. 5 is of an order of magnitude of about 10^{-8} e.m.u., χ should be observed to be less than χ° by a fraction as small as 1.0—1.4% in most of the organic liquids studied here. This estimate is in nice agreement with the deviation found from the data reported in the past with regard to the susceptibilities of liquids of the same kinds as studied here. On the other hand, the influence of the dissolved air upon the χ value of water, which was adopted as the standard reference here, is only 0.14%. Thus, it seems certain that most literature values for organic liquids are spoiled by the dissolved air, except those given by Eggleston *et al.*,[2] who were unique in making measurements of the susceptibility with sufficient care to deaerate the sample. The values of the present work (Table 3) are found to be very close to those χ values, -0.7081 and -0.8665×10^{-6} e.m.u., given by Eggleston *et al.*[2] for benzene and heptane respectively, though there still remaining deviations of about 0.2—0.3%.

In order to get reliable results, it is preferable to make measurements in as strong a magnetic field as possible, not to speak of the necessity of a severe regulation of the temperature, because even a slight change in the temperature may cause a considerable change in the viscosity and, consequently, in the flow time. The advantages of the present method are: (1) The extensively homogeneous region of the magnetic field is not needed, because the meniscus of the liquid at the lower end of capillary does never shift throughout the measurement of the flow time; (2) the outside diameter of the cell near the lower end of the capillary part in the pole gap is so small that there is no need to use an electromagnet of a large scale; a small size magnet such as used here is sufficient; (3) the influence of air (or oxygen) that spoils the measurement of the diamagnetic susceptibility can be eliminated almost completely; and (4) it has been confirmed experimentally that an occasional slight shock or vibration in the table on which the magnet is mounted has practically no appreciable effect on the observed values.

Effect of the Third Virial Coefficient on the Intensity of Light Scattered by Mixed Aqueous Solution of Poly(vinylpyrrolidone) and Sodium Dodecyl Sulfate

Masayuki NAKAGAKI and Saburo SHIMABAYASHI

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received January 10, 1977)

It was found that the reduced intensity of scattered light, R_θ, increases and then decreases with polymer concentration, becoming maximum for a certain concentration of the polymer, when the third virial coefficient, A_3, is positive. The theoretical concentration of polymer for the maximum R_θ is $(3A_3M_2)^{-1/2}$, where M_2 is the molecular weight of the polymer. This was observed in the case of the aqueous solution of poly(vinylpyrrolidone) (PVP) mixed with sodium dodecyl sulfate (SDS). In the mixed solution, PVP and SDS form a complex which behaves like a polyelectrolyte with or without a simple salt of low concentration. Such a solution often has higher-order virials. The value of the polymer concentration for the maximum scattered light intensity agreed with the theoretical value.

Turbidity or intensity of scattered light increases, for the first approximation, in proportion to the concentration of colloidal or macromolecular solutes. This is utilized as a method of chemical analysis such as nephelometry of turbidimetry. According to the fluctuation theory, however, the intensity of scattered light does not necessarily increase but sometimes decreases with the solute concentration under certain conditions. The possibility of decrease of turbidity with increase of polymer concentration is of particular interest in relation to physiological problems such as the transparency of eye lenses. The lens of a human eye is transparent in the normal condition of water content (62%), but the lens becomes turbid when the content of water increases to 80—90%. Thus the lens of high content of macromolecules (protein) is less turbid than that of low content of the protein.

In this paper, the effect of solute concentration on the reduced intensity of the scattered light is discussed theoretically and the results are compared with those obtained by using the mixed system of poly (vinylpyrrolidone) (PVP) and sodium dodecyl sulfate (SDS) in aqueous solution.

Theoretical

The reduced scattering intensity, R_θ, for unpolarized incident beam is defined as follows:

$$R_\theta = \left(\frac{r^2 I_\theta}{I_0}\right) \Big/ (1+\cos^2\theta), \tag{1}$$

where r is the photometric distance, and I_0 and I_θ are the intensity of the incident light and scattered light, respectively, per unit volume at the scattering angle of θ. The term $(r^2 I_\theta / I_0)$ is the Rayleigh ratio.

According to fluctuation theory, the intensity of the scattered light depends on the fluctuation both of the density of solvent and of the concentration of solute. The former component is assumed to be constant regardless of solute concentration when solute concentration is sufficiently low. The latter component of the reduced intensity of the scattered light, R_θ, is proportional both to $(\partial\pi/\partial c_2)^{-1}$ and to $(\partial n_{12}/\partial c_2)^2$, where π is the osmotic pressure, n_{12} the refractive index of the solution, and c_2 the concentration of the solute. Thus,

$$\frac{Kc_2}{R_\theta} = \frac{1}{RT}\cdot\frac{\partial\pi}{\partial c_2}, \tag{2}$$

where R and T are the gas constant and the absolute temperature, respectively, of the solution. K is a constant defined as follows:

$$K = 2\pi^2 n_1^2 \left(\frac{\partial \bar{n}_{12}}{\partial c_2}\right)^2 \Big/ N_A \cdot \lambda_0^4, \tag{2-a}$$

where N_A is the Avogadro number, n_1 the refractive index of the solvent, and λ_0 the wavelength of the incident beam *in vacuo*. The left-hand side of Eq. 2 is, therefore, a quantity which can be determined as a function of θ and c_2.

The interference factor, $P(\theta)$, should be introduced into the equation of R_θ when the light scattering by large particle is considered. By expanding both terms $(\partial\pi/\partial c_2)$ and $P(\theta)$ in power series, we obtain the following equation which is used to analyse the data of the light scattering in a polymer solution:[1]

$$\frac{Kc_2}{R_\theta} = \frac{1}{M_2}\left(1+\frac{16\pi^2 n_1^2}{3\lambda_0^2}\langle R_G^2\rangle \sin^2(\theta/2)\right) + 2A_2c_2, \tag{3}$$

where M_2 is the molecular weight of the solute (polymer), $\langle R_G^2\rangle$ the mean-square value of the radius of gyration of polymer coil in the solution, and A_2 the second virial coefficient.

When the scattering angle, θ, is zero, the interference factor is equal to unity. In order to consider the effect of polymer concentration, the term $(\partial\pi/\partial c_2)$ in Eq. 2 is expanded to the third virial, and we obtain[2,3]

$$Kc_2/R_0 = \frac{1}{M_2} + 2A_2c_2 + 3A_3c_2^2, \tag{3-a}$$

where A_3 is the third virial coefficient. From this, the reduced intensity, R_0, of the scattered light at $\theta=0°$ is given by

$$R_0 = Kc_2 \Big/ \left(\frac{1}{M_2}+2A_2c_2+3A_3c_2^2\right), \tag{4}$$

and the differential of R_0 by c_2 by

$$\frac{\partial R_0}{\partial c_2} = \frac{K\left(\frac{1}{M_2}-3A_3c_2^2\right)}{\left(\frac{1}{M_2}+2A_2c_2+3A_3c_2^2\right)^2}. \tag{5}$$

Case 1: When $A_2=0$ and $A_3=0$, Eqs. 4 and 5

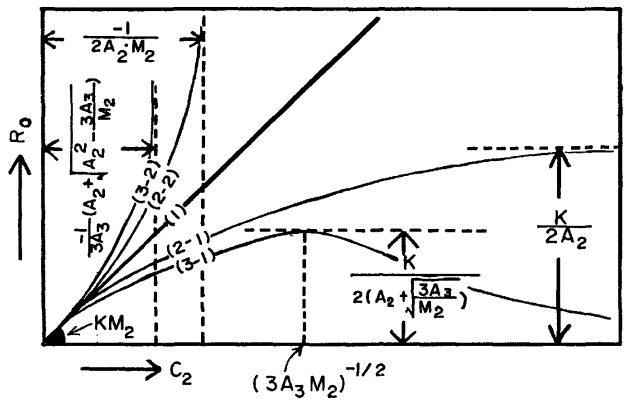

Fig. 1. Schematic diagram for the relationship between the reduced intensity of the scattered light, R_0, and solute concentration, c_2.
curve(1): $A_2=0$ and $A_3=0$, (2-1): $A_2>0$ and $A_3=0$,
(2-2): $A_2<0$ and $A_3=0$, (3-1): $A_2\geqq 0$ and $A_3>0$
(3-2): $A_2\leqq 0$ and $A_3<0$:

become as follows:

$$R_0 = KM_2c_2, \tag{6}$$

$$\frac{\partial R_0}{\partial c_2} = KM_2. \tag{7}$$

The relationship between R_0 and c_2 is shown in Fig. 1 as straight line (1), the slope of which is KM_2 as shown by Eq. 7.

Case 2: When $A_2\neq 0$ and $A_3=0$, Eqs. 4 and 5 become as follows:

$$R_0 = Kc_2\Big/\left(\frac{1}{M_2}+2A_2c_2\right), \tag{8}$$

$$\frac{\partial R_0}{\partial c_2} = \left(\frac{K}{M_2}\right)\Big/\left(\frac{1}{M_2}+2A_2c_2\right)^2. \tag{9}$$

In this case, R_0 increases monotonically with c_2. The initial slope (slope at $c_2\to 0$) is KM_2 as in case 1. If A_2 is positive, R_0 and $\partial R_0/\partial c_2$ approach $K/(2A_2)$ and zero, respectively, with increasing c_2. On the other hand, if A_2 is negative, both R_0 and $\partial R_0/\partial c_2$ diverge to infinity when c_2 approaches $-1/(2A_2M_2)$. These relationships are shown in Fig. 1 by curves (2-1) and (2-2) for $A_2>0$ and <0, respectively.

Case 3: When $A_3\neq 0$, the initial slope for the relationship between R_0 and c_2 is KM_2 as in cases 1 and 2. If $A_3>0$ and $A_2\geqq 0$, R_0 has a maximum value, according to Eq. 5, where

$$c_{2,\max} = (3A_3M_2)^{-1/2}, \tag{10}$$

and

$$R_{0,\max} = \frac{K}{2\left(A_2+\sqrt{\frac{3A_3}{M_2}}\right)}. \tag{11}$$

This relation is shown by curve (3-1) in Fig. 1. Thus, the reduced intensity of the scattered light, R_0, decreases in spite of the increase in the concentration of polymer, c_2, when c_2 is larger than $c_{2,\max}$. This is in contrast to the case $A_3=0$ in cases 1 and 2. If $A_3<0$ and $A_2\leqq 0$, both R_0 and $\partial R_0/\partial c_2$ tend to infinity at

$$c_2 = -\frac{1}{3A_3}\left(A_2+\sqrt{A_2^2-\frac{3A_3}{M_2}}\right). \tag{12}$$

This relation is also shown by curve (3-2) in Fig. 1.

From Eq. 4, the specific reduced intensity of the scattered light R_0/c_2 is given by

$$\frac{R_0}{c_2} = K\Big/\left(\frac{1}{M_2}+2A_2c_2+3A_3c_2^2\right), \tag{13}$$

and its differential by the solute concentration $\partial(R_0/c_2)/\partial c_2$ by

$$\frac{\partial}{\partial c_2}\left(\frac{R_0}{c_2}\right) = \frac{-2K(A_2+3A_3c_2)}{\left(\frac{1}{M_2}+2A_2c_2+3A_3c_2^2\right)^2}. \tag{14}$$

According to Eq. 13, R_0/c_2 becomes KM_2 irrespective of the values of A_2 and A_3 when c_2 approaches zero. As for the inclination of the (R_0/c_2) *vs.* c_2 curves given by Eq. 14,

$$\frac{\partial}{\partial c_2}(R_0/c_2) = 0, \tag{15}$$

for $A_2=0$ and $A_3=0$, and R_0/c_2 is constant regardless of the value of c_2. When $A_2>0$ and $A_3\geqq 0$, we have

$$\frac{\partial}{\partial c_2}(R_0/c_2) < 0, \tag{16}$$

and R_0/c_2 decreases monotonically with c_2, while for $A_2<0$ and $A_3\leqq 0$,

$$\frac{\partial}{\partial c_2}(R_0/c_2) > 0, \tag{17}$$

and R_0/c_2 increases monotonically with c_2.

Straight line (1) shows the proportionality of the scattering intensity R_0 to the polymer concentration c_2. Thus, R_0/c_2 becomes constant. This is in the case of a solution with θ-solvent.

Curves (2-1) and (3-1) show the dependence of the scattering intensity, R_0, on the polymer concentration, c_2, in a good solvent. In these cases, the polymer coil expands enough and the degree of fluctuation of concentration is relatively small, because of positive A_2 and A_3 in a good solvent. R_0, shown by curve (2-1) or (3-1), therefore, deviates negatively from the straight line (1) in Fig. 1, R_0/c_2 decreasing with c_2. Particularly in the case of curve (3-1) where A_3 is not equal to zero but positive, the repulsion between expanded polymer coils suppresses the concentration fluctuation so that the scattering intensity decreases with the increase of the polymer concentration at high concentration region.

Curves (2-2) and (3-2), on the other hand, show the dependency of R_0 on c_2 in a poor solvent. R_0 deviates positively from the straight line (1) and R_0/c_2 increases with c_2 because of the negative values of A_2 and A_3 and the large fluctuation in a poor solvent. Both the reduced intensity and the specific reduced intensity of the scattered light tend to infinity at a critical polymer concentration. This is the critical opalescence due to the two-phase separation of the polymer solution at the polymer concentration higher than the critical value.

So far, only typical conditions for the real solution have been considered. From a mathematical viewpoint, other conditions such as $A_2>0$ and $A_3<0$, or $A_2<0$ and $A_3>0$, should be considered, but discussion was not made.

Experimental

Material and Solution. Poly(vinylpyrrolidone) (hereafter called PVP) and sodium dodecyl sulfate(SDS) are the same as those reported.[4] The materials were dissolved in twice distilled water. The molecular weight of PVP, M_P, was kept constant throughout the experiment, but that of complex, $M_{complex}$, changed with the concentration of SDS; the relation is given by Eq.19-a.

The membrane equilibrium should be attained before the measurement since PVP and SDS form a complex in aqueous solution, the complex behaving like a polyelectrolyte.[5] Visking Cellulose Tubing was used with an initial inner solution of PVP mixed with SDS, and initial outer solution of SDS. The method of the membrane equilibrium is the same as that reported.[4]

After the membrane equilibrium has been attained, a solution of concentration of PVP–SDS complex, $c_{complex}$, at a given concentration of free SDS, c_s^f, can be prepared, if the outer solution is used as a solvent or as a diluting agent for the inner solution of PVP–SDS complex, since chemical potential of SDS in the inner solution is equal to that in the outer solution at the membrane equilibrium. The amount of SDS bound to PVP of unit weight can also be kept constant when c_s^f is kept constant through the dilution process. A solution, in which the amount of SDS is bound to PVP at the membrane equilibrium, can be prepared by adjusting the concentration of SDS of both sides of the membrane before the membrane equilibrium is attained. The dependence of the scattering intensity, R_θ, both on the scattering angle, θ, and on the concentration of complex, $c_{complex}$, was measured under the conditions of a constant concentration of free SDS, c_s^f. This system will be called the dialysed system.

The same measurement was carried out under the conditions of a constant concentrations of total SDS, c_s^t, in order to compare the results with those of the dialysed system. Concentration c_s^t indicates the sum of concentrations of free SDS and of bound SDS in a solution of PVP mixed with SDS. This system will be called the undialysed system.

Measurements of the Reduced Intensity of Scattered Light and the Increment of Refractive Index. Methods of measurement of refractive index increment are the same as those reported.[4] In order to measure the scattering intensity, a Shimadzu Electrophotometric Light Scattering Photometer PG-21 was used at 436 nm and at 25 °C. The reduced intensity of the scattered light, R_θ, is experimentally given as follows.

$$R_\theta = \phi_\theta \frac{G_\theta}{G_0} \tag{18}$$

where G_θ and G_0 are intensity of electric current in a phototube at scattering angle of θ and of zero degree, respectively. ϕ_θ is an empirical coefficient depending both on a scattering angle, θ, and the refractive index of the solvent, n_1.[6]

Results

Dependence of the Reduced Intensity of Scattered Light on Polymer Concentration. The concentrations of PVP and the PVP–SDS complex are denoted by c_P and $c_{complex}$, respectively, in order to distinguish them from the concentration of "polymer," c_2. The relationship between c_P and $c_{complex}$ is given by

$$c_{complex} = (1+y)c_p, \tag{19}$$

where y is the weight of SDS bound per unit weight of PVP. The relationship between the molecular weight of PVP, M_P, and that of the complex, $M_{complex}$, is given by

$$M_{complex} = (1+y)M_p \tag{19-a}$$

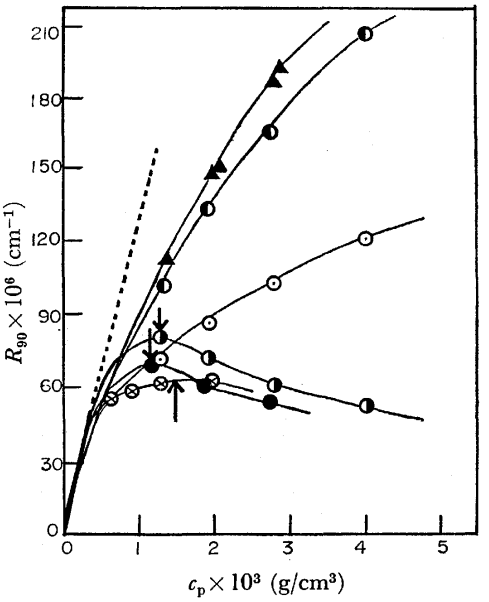

Fig. 2. Relationship between concentration of PVP, c_p and reduced intensity of scattered light at 90°, R_{90}. These are undialysed systems, and each concentration of total SDS, c_s^t, is kept constant through the measurement. Concentration of total SDS, c_s^t(mM): ▲ 0.0, ◐ 2.0, ⊙ 4.0, ⊗ 6.0, ● 8.0, ◑ 10.0.

Empirical relationship between PVP concentration, c_P, and the reduced intensity of the scattered light measured at 90°, R_{90}, are given in Fig. 2, where total concentration of SDS, c_s^t, is kept constant. This is the result obtained by the undialysed system. When c_s^t is small, *viz.*, in the case of 0 mM(▲), 2 mM(◐), and 4 mM(⊙), R_{90} increases with c_P, but when c_s^t is large, *viz.*, in the case of 6 mM(⊗), 8 mM(●) and 10 mM(◑), R_{90} decreases in spite of the increase in c_P. In the case of the undialysed system in which c_s^t is kept constant throughout the measurement (Fig. 2), it should be noted that PVP and SDS form a complex with each other, so that $M_{complex}$ as well as the amount of SDS bound per unit weight of PVP, y, decrease with c_p. It is thus difficult to analyse the effect of c_s^t, $c_{complex}$, and $M_{complex}$ on the reduced scattering intensity, R_{90}, and to explain the results. However it may be emphasized that the anomalous decrease of the scattered light intensity with the increase in the polymer concentration is observed even under simple experimental conditions.

On the other hand, it is easy in the case of the dialysed system to analyse the change of R_{90} with the concentration of PVP, c_P, since the free concentration of SDS, c_s^f, the amount of bound SDS, y, and the molecular weight of the complex, $M_{complex}$, can be kept constant throughout the measurement of R_{90}.

Since the value of y as a function of c_s^f is known,[4,5] the relationship between R_{90} and $c_{complex}$ can be obtained (Fig. 3). Each symbol indicates the experimental value. When c_s^f is large, R_{90} decreases in spite

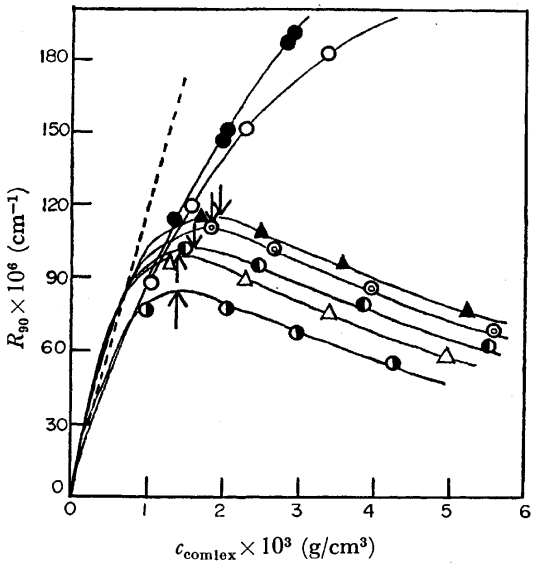

Fig. 3. Relationship between complex concentration, c_{comlex}, and reduced intensity of scattered light at 90°, R_{90}. These results are of the dialysed system, and concentration of free SDS, c_s^f, is kept constant through the measurement. Each arrow mark shows the maximum point of each curve, which is calculated by Eq. 10 as same as in the case of Fig. 2. The dotted line shows the initial slope for the aqueous solution of PVP without SDS.
Concentration of free SDS, c_s^f(mM): ● 0.00, ○ 2.00, ◑ 5.37, △ 6.82, ◐ 8.68, ◎ 15.58, ▲ 19.16.

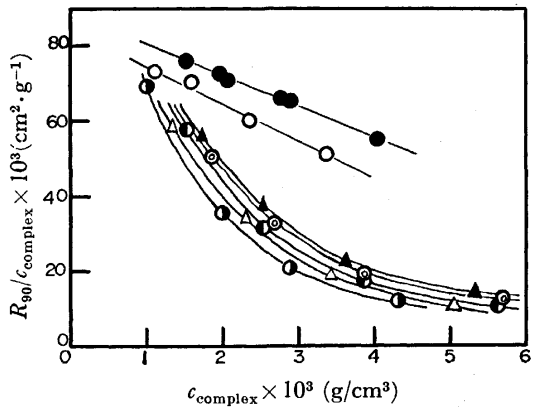

Fig. 4. Relationship between concentration of complex, $c_{complex}$, and specific reduced intensity of scattered light, $R_{90}/c_{complex}$. These results are of the dialysed system.
Concentration of free SDS, c_s^f(mM): ● 0.00, ○ 2.00, ◑ 5.37, △ 6.82, ◐ 8.68, ◎ 15.58, ▲ 19.16.

of the increase in the concentration of the complex, $c_{complex}$, in the region of high concentration of $c_{complex}$ as in the case of the undialysed system (Fig. 2). The anomalous behavior can thus be observed in both the dialysed and undialysed systems.

The relationship between the specific reduced intensity of the scattered light, $R_{90}/c_{complex}$, and $c_{complex}$ is shown in Fig. 4 on the basis of the data of Fig. 3 for the dialysed system. In the case of low concentration of free SDS, c_s^f, such as 0 mM(●) and 2 mM(○), $R_{90}/c_{complex}$ decreases linearly with $c_{complex}$, but in the case of high concentration of free SDS, such as 5.37 mM(◑) and higher, $R_{90}/c_{complex}$ decreases rapidly even in the region of low concentration of the complex, $c_{complex}$. Neither a maximum nor a minimum like that shown in Fig. 3 can be observed. The theoretical deduction has been verified experimentally.

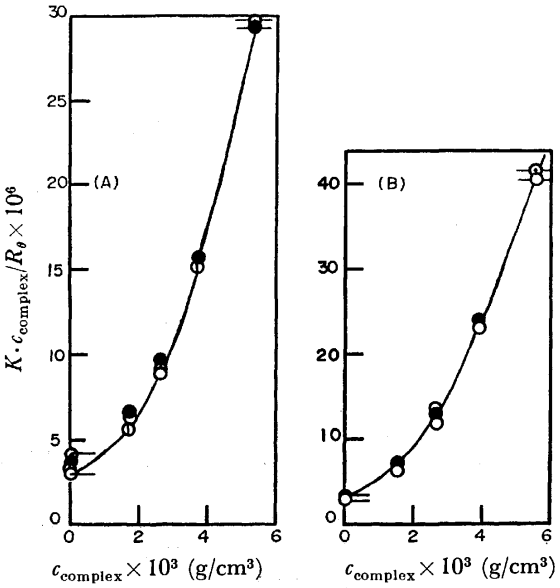

Fig. 5. Relationship between concentration of complex, $c_{complex}$, and $Kc_{complex}/R_\theta$. Different angles of the scattering, θ, are shown by different symbols. The solid line is the theretical curves calculated by Eq. 3-a.
Curve: (A)c_s^f=19.16mM, (B)c_s^f=8.68mM. Scattering angle: ○ 0°, ⦶ 45°, ● 90°, ⊙ 135°.

Dependence of Kc_2/R_θ on c_2 at Various θ. Dependence of Kc_2/R_θ on c_2 is shown in Fig. 5 for the dialysed system, for given θ-values as θ=0°(○), 45°(⦶), 90°(●) and 135°(⊙), where the data at θ=0° is quoted from the Zimm Plot for the solution of PVP-SDS complex.[7] The pairs of short bars in Fig. 5, drawn at both the lowest and highest concentration of the complex, show the range of $Kc_{complex}/R_\theta$ from θ=0° through θ=135° at the respective complex concentrations. We see that the effect of θ is relatively small, the dependence of $Kc_{complex}/R_\theta$ on $c_{complex}$ being approximately independent of θ. The conclusion is also applicable to the other data of both the dialysed and undialysed systems not shown in Fig. 5. The shapes of the curves show that the virial coefficients A_2 and A_3 of Eq. 3-a are both positive.

Discussion

Determination of Virial Coefficients, A_2 and A_3. Eq. 3-a can be rewritten as follows for the experimental determination of A_2 and A_3:

$$\frac{1}{c_2}\left(\frac{Kc_2}{R_0}-\frac{1}{M_2}\right)=2A_2+3A_3c_2. \qquad (20)$$

Virial coefficients, A_2 and A_3, can thus be determined from a linear relationship between $(Kc_2/R_0-1/M_2)/c_2$ and c_2.

In the case of the dialysed system such as shown in Fig. 6, the subscript "2" in Eq. 20 should be read as

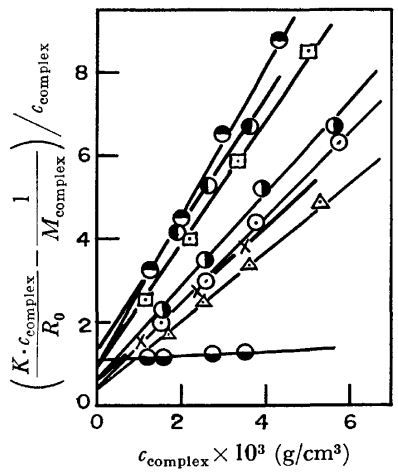

Fig. 6. The relationship between $c_{complex}$ and $(Kc_{complex}/R_0-1/M_{complex})/c_{complex}$. Both A_2 and A_3 can be estimated from the intercept and the slope of each straight line, as shown in Eq. 20. These results are for the dialysed system.
Concentration of free SDS(mM): ◒ 2.00, ◐ 3.73, ◓ 5.37, ⊡ 6.82, ◑ 8.68, ⊙ 10.64, × 13.40, △ 19.16.

the subscript "complex." The free concentration of SDS, c_s^f, is kept constant for each line, all lines in Fig. 6 being straight. The virial coefficients, A_2 and A_3, are thus obtained for each concentration of free SDS, c_s^f, for each molecular weight of the complex. A_2 and A_3 are of the PVP–SDS complex in aqueous solution of free SDS.

On the other hand, in the case of the undialysed system, subscript "2" in Eq. 20 should be assumed to be "p". The relationship between $(Kc_P/R_0-1/M_P)/c_P$ *vs.* c_P at constant c_s^t becomes a straight line as in the case of the dialysed system (Fig. 6), in spite of the variation in the molecular weight of the complex when c_P changes at constant c_s^t. Apparent values of A_2 and A_3 are determined from these straight lines.

The dependence of A_2 and A_3 on c_s^f for the dialysed system(●) and that of the apparent A_2 and A_3 on c_s^t for the undialysed system(⊙) are shown in Fig. 7. In the region of low concentration of SDS, c_s^f or c_s^t, the

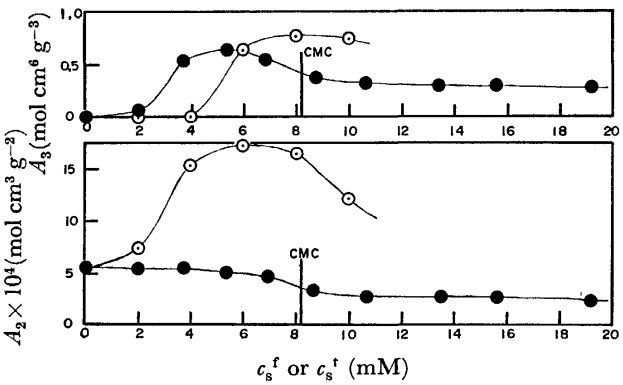

Fig. 7. The relationship between virial coefficients, A_2 or A_3, and concentration of SDS, c_s^f or c_s^t, for dialysed and undialysed system, respectively.
⊙ Undialysed system *versus* c_s^t, ● dialysed system *versus* c_s^f.

third virial coefficient, A_3, is negligible, increasing with SDS concentration (Fig. 7). This is of particular interest, since the positive third virial coefficient is responsible for the anomalous decrease in R_0 or R_θ with the increase in c_2.

Comparison of Observed R_{90} with Calculated R_0.
A comparison between experimental R_{90}-values and theoretical R_0-values is made herewith on the basis of the results where the effect of θ on R_θ is small (Fig. 5).

Solid curves in Figs. 2, 3, and 5 indicate the theoretical value of R_0 calculated by means of Eq. 4 using the values of A_2 and A_3 given in Fig. 7. Arrows (↑) in Figs. 2 and 3 show the maximum value of the reduced scattering intensity calculated by Eqs. 10 and 11. Agreement of the experimental R_{90}-values with the theoretical R_0-curves, and of the experimental maximum values with the theoretical ones (arrows) is good. It can therefore be concluded that the anomalous behaviour in Figs. 2 and 3 can be explained as the contribution of the third virial coefficient to the reduced scattering intensity.

The maximum point of the curve for $c_s^f=2$ mM of the dialysed system is not shown in Fig. 3, since the concentration of the complex at the maximum point is higher because of the smallness of A_3. In the case of 0 mM of c_s^f, that is an aqueous solution of PVP without SDS, R_{90} or R_0 increases with the polymer concentration ($c_{complex}$ on the abscissa should read c_P in this case) and does not have a maximum point since A_3 is zero and the curve corresponds to curve (2-1) in Fig. 1. Broken lines in Figs. 2 and 3 indicate initial slopes for the curve of 0 mM of SDS (*i.e.* aqueous solution of PVP without SDS). Even when A_3 is zero, deviation from the broken line increases with the polymer concentration because of the contribution of the effect of the second virial coefficient, A_2. The initial slope, KM_2, is constant for all the curves in Figs. 1 and 2, since the molecular weight is assumed to be constant (M_2 or M_p). However, the initial slopes for the curves in Fig. 3, $KM_{complex}$, are variable and not constant since the molecular weight of the complex, $M_{complex}$, depends on the amount of SDS bound to PVP, y, which also depends on the concentration of free SDS, c_s^f, as shown by Eqs. 19 and 19-a. Thus, the initial slope, $KM_{complex}$, depends on y or c_s^f. The initial slope for the respective curves are not shown in Fig. 3 in order to avoid confusion.

Estimation of the Effect of the Interference Factor.
In a rigorous sence it is wrong to compare R_{90} with R_0, since R_{90} is not equal to R_0 due to the interference factor, $P(\theta)^{-1}$. The effect of $P(\theta)^{-1}$, given by the following equation or the term in parenthesis on the right-hand

$$P(\theta)^{-1}=1+\frac{16\pi^2 n_1^2}{3\lambda_0^2}\langle R_G^2\rangle \sin^2(\theta/2), \qquad (21)$$

side of Eq. 3, should be evaluated at $\theta=90°$ of the present experimental conditions in order to check the difference between R_{90} and R_0.

Assuming that θ is equal to 90° and a radius of gyration of PVP, $\langle R_G^2\rangle^{1/2}$, in water is 210 Å,[6,7] Eq. 21 is evaluated to be 1.12. The maximum value of $\langle R_G^2\rangle^{1/2}$ of the complex of PVP–SDS is *ca.* 1.5 times

that of PVP in water, since the intrinsic viscosity of the complex at the highest amount of SDS bound to PVP is 3.5 times that of PVP in water.[5] Assuming that $\theta=90°$ and $\langle R_G^2\rangle^{1/2}=315$ Å, the value of Eq. 21 is found to be 1.27. Thus, $1.12 \leqq P(90°)^{-1} \leqq 1.27$.

The relative difference of $Kc_{complex}/R_{90}$ against $Kc_{complex}/R_0$ is, therefore, assumed to be greater than 12% and less than 27% in the region of very low concentration of the polymer. However, in the region of high concentration of the polymer, the relative difference decreases with polymer concentration, because of the contribution of higher order virials such as $2A_2c_{complex}$ and $3A_3c_{complex}^2$ as shown by Eqs. 3 and 3-a. All the data of θ (Fig. 5) lie nearly on the theoretical curve for $\theta=0°$ calculated by means of A_2 and A_3 and Eq. 3-a. We might compare the experimental results obtained for $\theta=90°$ with the theoretical ones deduced for $\theta=0°$.

Comparison of the Theory of Debye and Bueche with Ours. Debye and Bueche[8] showed that R_θ increases and then decreases with c_2, and the concentration of polymer at the maximum value of R_θ is proportional to $M_2^{-1/2}$, not depending on the virial coefficients. However, the second and third virial coefficients are important for expressing the concentration, $c_{2,max}$, of the maximum value, $R_{0,max}$, of the reduced scattering intensity, as shown by means of Eqs. 10 and 11.

Hydrogen Isotope Effect on the Radical Addition of the Hydrogensulfite Ion to Allyl Alcohol in Aqueous Solutions

Teijiro MIYATA, Akihisa SAKUMOTO, and Masamitsu WASHINO
Japan Atomic Energy Research Institute, Takasaki, Gunma 370-12
(Received September 6, 1976)

A study of the radiation-induced addition of HSO_3^- to allyl alcohol was carried out in D_2O–H_2O mixtures. It was found that a linear relationship held between the apparent rate constant of $NaHSO_3$ consumption and the atom fraction of deuterium in the mixture, and that the hydrogen atom abstraction from HSO_3^- by $HOCH_2\dot{C}H$-$CH_2SO_3^-$ was the rate-determining step. The kinetic isotope effect of this abstraction was 4.38.

In a previous paper,[1] we proposed the following mechanism for the radiation-induced addition of the hydrogensulfite ion (HSO_3^-) to allyl alcohol in aqueous solutions:

Initiation,

$$A + HSO_3^- \longrightarrow AH + \dot{S}O_3^-, \quad (1)$$

Propagation

$$\dot{S}O_3^- + CH_2{=}CHCH_2OH \longrightarrow HOCH_2\dot{C}HCH_2SO_3^-, \quad (2)$$

$$HOCH_2\dot{C}HCH_2SO_3^- + HSO_3^- \longrightarrow HOCH_2CH_2CH_2SO_3^- + \dot{S}O_3^-, \quad (3)$$

Termination

$$HOCH_2\dot{C}HCH_2SO_3^- + CH_2{=}CHCH_2OH \longrightarrow HOCH_2CH_2CH_2SO_3^- + CH_2{=}CH\dot{C}HOH, \quad (4)$$

where A represents the active species which contribute to the initiation. This addition reaction involves the hydrogen abstraction from HSO_3^- represented by Eq. 3. It follows, then, that a hydrogen isotope effect may be found if this abstraction reaction is the rate-determining step.[2]

The present study was undertaken to get direct evidence for the rate-determining step by means of the determination of the hydrogen isotope effect of the addition reaction. The reaction system employed was radiation-induced addition in D_2O–H_2O mixtures of various D_2O concentrations. The determination was made possible by finding the relationship between the atom fraction of deuterium in the mixture and the over-all rate constant of sodium hydrogensulfite consumption.

Experimental

The D_2O (Shōwa Denkō, 99.75 mol% D_2O) used was distilled twice under an atomosphere of nitrogen: first in the presence of a trace of potassium permanganate acidified with sulfuric acid and then in the absence of additives. The H_2O used was redistilled before use. The other reagents used were similar to those described previously.[1]

Solutions were prepared by dissolving 0.25 mol/l of Na_2SO_3, 0.50 mol/l of $NaHSO_3$, and 1.47 mol/l of allyl alcohol in D_2O–H_2O mixtures containing up to 100% of D_2O.

The irradiation vessel and analytical procedure used in this work were analogous to those described previously.[1] The pH measurements were carried out using a Tōa Denpa Model HM-5A pH meter with ordinary glass electrodes. The standardization of the pH meter in water solutions was made with conventional buffer solutions of an appropriate acidity. A 3450-curie Co-60 γ-source was used, and the dose rate was determined by the Fricke dosimeter in light water, taking $G(Fe^{3+})=15.6$.

Results and Discussion

Rate-determining Step. In aqueous solutions, $NaHSO_3$ dissociates into Na^+ and HSO_3^-, which is in equilibrium with the hydrogen ion, in the following two ways:

$$HSO_3^- \rightleftharpoons H^+ + SO_3^{2-}, \quad (5)$$

$$HSO_3^- + H^+ \rightleftharpoons H_2SO_3. \quad (6)$$

Accordingly, DSO_3^- is formed in D_2O instead of HSO_3^- being formed in H_2O. In the D_2O–H_2O mixture, a part of the HSO_3^- is assumed to be displaced with DSO_3^- in proportion to the D_2O concentration in the mixture.

The total G-value of the active species, A, produced from the radiolysis of D_2O is reported to be slightly higher than that from H_2O.[3] The concentration of DSO_3^- in D_2O can be estimated to be higher than that of HSO_3^- in H_2O since weak acids are less dissociated in D_2O than in H_2O.[4] These facts lead to the assumption that the rate of $NaHSO_3$ consumption may be greater in the D_2O–H_2O mixtures than in H_2O.

In order to evaluate the effects of D_2O on the addition reaction, the solutions were irradiated by Co-60 γ-rays at a dose rate of 8.45×10^{15} eV/cm^3 s and at room temperature. The conversion of $NaHSO_3$ decreased with the increase in the atom fraction of deuterium in the mixture, as is shown in Fig. 1. This result disagrees with the above assumption.

The addition reaction involves DSO_3^- as well as HSO_3^- in the D_2O–H_2O mixtures, as is represented in

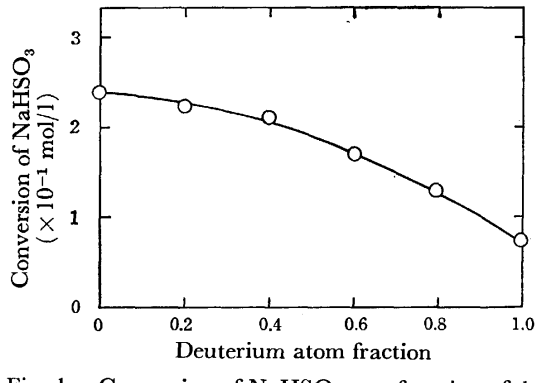

Fig. 1. Conversion of $NaHSO_3$ as a function of deuterium atom fraction in the mixture.

Eqs. 1 and 3, where the hydrogen-atom abstraction from these ions takes place. The hydrogen-atom abstraction causes an appreciable isotope effect.[2] On the basis of these findings, it is reasonable to assume that the above disagreement results from the isotope effect of these hydrogen-atom abstractions.

Reaction 1 plays a minor role in the isotope effect because most of the species formed in other reactions which involve A can initiate the addition reaction.[1] On the other hand, Reaction 3 involves $HOCH_2\dot{C}HCH_2SO_3^-$, which takes part both in the propagation shown by Reactions 2 and 3 and in the termination shown by Reaction 4. In addition, the chain length of the addition reaction is as large as 344,[1] and it is susceptible to small changes in the rate of Reaction 3 provided this reaction is the rate-determining step of the propagation. Consequently, it can be assumed that Reaction 3 is the rate-determining step of the propagation and mainly causes the isotope effect.

Total Concentration of HSO_3^- and DSO_3^- in D_2O–H_2O Mixtures. The concentration of HSO_3^- in an aqueous $NaHSO_3$ solution containing Na_2SO_3 at pH 5—7 is given by[1]

$$[HSO_3^-] = \frac{[NaHSO_3]+[Na_2SO_3]}{1+(K_5/a_H)(f_{HSO_3^-}/f_{SO_3^{2-}})}, \quad (7)$$

where $[NaHSO_3]$ and $[Na_2SO_3]$ are the initial concentrations of $NaHSO_3$ and Na_2SO_3; K_5, the dissociation constant of HSO_3^-; a_H, the activity of the hydrogen ion; and $f_{HSO_3^-}$ and $f_{SO_3^{2-}}$, the activity coefficients of HSO_3^- and SO_3^{2-}.

The dissociation constant of a weak acid in a D_2O–H_2O mixture is expressed by[5] Eq. 8:

$$K_N = K_H \frac{0.302n^3+1.37n^2(1-n)+2.04n(1-n)^2+(1-n)^3}{(1-n)+0.302(K_H/K_D)n}, \quad (8)$$

where K_N, K_H, and K_D refer to the dissociation constants of the weak acid in the D_2O–H_2O mixture, H_2O, and D_2O respectively, and where n is the atom fraction of deuterium in the mixture. In the case of HSO_3^- as the weak acid, K_H/K_D in Eq. 8 can be estimated to be 3.68 from the relationship[4] between K_H/K_D and $-\log K_H$, in which the K_H for HSO_3^- is 1.02×10^{-7}.[6] Substituting these values into Eq. 8, we obtain the K_N values shown in Table 1.

Table 1. Dissociation constants of HSO_3^-[a] in D_2O–H_2O mixtures

n[b]	0	0.2	0.4	0.6	0.8	1.0
$K_N\times10^8$	10.2	8.18	6.46	5.00	3.78	2.77

a) HSO_3^- at n=0, DSO_3^- at n=1, and the mixture of HSO_3^- and DSO_3^- at n 0.2 to 0.8. b) The atom fraction of deuterium in the mixture.

Using electrodes standardized for H_2O solutions, the pL, the generalized equivalent of pH (where L includes all the isotopically different hydrogen ions), in a mixture of the deuterium atom fraction of n is given by pL=(meter reading)+0.40n.[7] In addition, since the dielectric constant of D_2O is very close to that of H_2O,[8] it may be assumed that $f_{HSO_3^-}/f_{SO_3^{2-}}$ ratio is equal to that of $f_{DSO_3^-}/f_{SO_3^{2-}}$ and that these ratios are independent of the atom fraction of deuterium in the mixture. Hence, the value of 1.468[1] can be used as $f_{HSO_3^-}/f_{SO_3^{2-}}$ in Eq. 7 at the concentrations of 0.25 mol/l of Na_2SO_3 and 0.50 mol/l of $NaHSO_3$ in the D_2O–H_2O mixtures. Substituting these values into Eq. 7, we obtain the total concentration of HSO_3^- and DSO_3^-, $[\mathbf{HSO_3^-}]$, in the D_2O–H_2O mixtures (Table 2). As can be seen in Table 2, the total concentration increased slightly with the increase in the atom fraction of deuterium in the mixture.

Table 2. Total concentrations of HSO_3^- and DSO_3^-, $[\mathbf{HSO_3^-}]$, in D_2O–H_2O mixtures

n[a]	pH_{obs}	pH_{corr}	$[\mathbf{HSO_3^-}]$ (mol/l)	$\frac{[\mathbf{HSO_3^-}]}{[NaHSO_3]}$[b]

1.0	6.50	6.90	0.567	1.13

a) The atom fraction of deuterium in the mixture. b) The concentration ratio between $\mathbf{HSO_3^-}$ and the initial $NaHSO_3$.

Rate Constant in D_2O–H_2O Mixtures. The rate equation for the addition of HSO_3^- to allyl alcohol in an aqueous solution is expressed by[1]

$$-\frac{d[NaHSO_3]}{dt} = \frac{gIk_3[HSO_3^-]}{100k_4[\text{Allyl Alcohol}]}, \quad (9)$$

where g is the G-value of A; I, dose rate (eV/cm^3 s); k_3 and k_4, the rate constants for Reactions 3 and 4 respectively; and [Allyl Alcohol], the concentration of allyl alcohol. Equation 9 can be rewritten as

$$-\frac{d[NaHSO_3]}{dt} = \frac{gIk_3}{100k_4}\cdot\frac{[HSO_3^-][NaHSO_3]}{[NaHSO_3][\text{Ally Alcohol}]}. \quad (10)$$

Since the $[HSO_3^-]/[NaHSO_3]$ ratio is independent of the concentration of $NaHSO_3$ in H_2O,[1] the $[\mathbf{HSO_3^-}]/[NaHSO_3]$ ratio may also be assumed to be independent of the concentration of $NaHSO_3$ in the D_2O–H_2O mixtures. However, this ratio depends on the atom fraction of deuterium in the mixture, as is apparent from Table 2. The conversion of $NaHSO_3$ is equal to that of allyl alcohol.[1] Hence, the rate equation in the D_2O–H_2O mixtures is derived as:

$$\frac{dx}{dt} = \alpha k_n\cdot\frac{(a-x)}{(b-x)}, \quad (11)$$

where

$$k_n = \frac{gIk_3}{100k_4}, \quad (12)$$

$\alpha=[\mathbf{HSO_3^-}]/[NaHSO_3]$ at a concentration of D_2O given by the n of the atom fraction of deuterium, a and b are the initial concentrations of $NaHSO_3$ and allyl alcohol respectively, and x is the concentration of $NaHSO_3$ that reacts in time t. The integration of Eq. 11 yields

$$k_n = \frac{1}{\alpha t}\left\{(b-a)\ln\left(\frac{a}{a-x}\right)+x\right\}, \quad (13)$$

from which k_n can be obtained by substituting the values presented in Fig. 1 and Table 2. Table 3 presents the k_n values thus obtained.

Kinetic Hydrogen Isotope Effect. Taking the ratio

Table 3. Over-all rate constants for the addition of HSO^-_3 to allyl alcohol in D_2O–H_2O mixtures

n[a]	0	0.2	0.4	0.6	0.8	1.0
$k_n \times 10^4$ (mol/l s)	2.30	1.99	1.88	1.38	1.05	0.554

a) The atom fraction of deuterium in the mixture.

of k_n given by Eq. 12 for H_2O to that for the D_2O–H_2O mixture leads to the following equation:

$$\frac{k_H}{k_n} = \frac{g_H I_H k_{3H} k_{4n}}{g_n I_n k_{3n} k_{4H}}, \quad (14)$$

where the subscripts H and n refer to the values for H_2O and those for the D_2O–H_2O mixture respectively. Equation 14 can be simplified as

$$\frac{k_H}{k_n} = \frac{g_H k_{3H}}{g_n k_{3n}}, \quad (15)$$

since it can be assumed that I_H/I_n is nearly unity, because the electron density is nearly equal in both H_2O and D_2O, and since there are no solvent effects on Reaction 4.

The radiation-induced addition of HSO_3^- to allyl alcohol in aqueous solutions is initiated by the active species, the hydrogen atom, the hydroxyl radical, and the hydrated electron, produced from the radiolysis of water.[1] Hence, g in Eq. 12 is assumed to be equal to the sum of the G-values of these three active species. At pH about 6, g_H is 5.20 and the g for D_2O, g_D, is 5.48,[3] while no precise value of g_n is known. Since the formation of ions and excited molecules will occur in the same pattern in both H_2O and D_2O,[9] it is reasonable to assume that g_n is $g_H+(g_D-g_H)n$. Using these values and the k_n values given in Table 3, we can obtain $k_n(g_H/g_n)$.

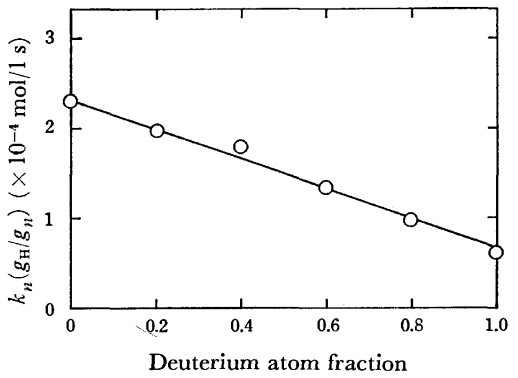

Fig. 2. k_n (g_H/g_n) as a function of deuterium atom fraction in the mixture.

Figure 2 shows the plot of $k_n(g_H/g_n)$ against n. It is apparent from this figure that a good linear relationship holds between these terms. This means that the magnitude of the kinetic isotope effect of Reaction 3 is equal to k_{3H}/k_{3D}, which can be calculated from the k_H, k_D, g_H, and g_D values. According to Eq. 15, k_{3H}/k_{3D} is 4.38 at the dose rate of 8.45×10^{15} eV/cm^3 s since $k_H=2.30\times10^{-4}$ mol/l s, $k_D=0.554\times10^{-4}$ mol/l s, $g_H=5.20$, and $g_D=5.48$. Similar values of 4.46 and 4.41 were obtained at the dose rate of 1.35×10^{16} eV/cm^3 s and 1.69×10^{16} eV/cm^3 s. Thus, the kinetic isotope effect is independent of the dose rate.

It has been reported[10] that there are two isomeric forms of HSO_3^-, (I) and (II), in aqueous solutions:

(I) (II)

This means that two types of hydrogen-atom abstraction should be taken into account; one is the abstraction from the O–H bond, and the other is that from the S–H bond.

Since the stretching vibration of O–H is higher than that of S–H, it seems reasonable to predict that a greater isotope effect is found in the former case than in the latter case. In fact, a value of about 8 for the isotope effect has been reported at 30 °C in the hydrogen-atom abstraction by 2,2-diphenyl-1-picrylhydrazyl (DPPH) from the O–H bond in such phenols as 2,6-di-*t*-butyl phenol and 4-bromophenol,[11] while the value of 5.4 has been reported for a similar abstraction by the same radical from the S–H bond in benzenethiol at 25 °C.[12] The kinetic isotope effect found in the hydrogen-atom abstraction from HSO_3^- is closer to that for benzenethiol than for phenols.

The simplest interpretation of the kinetic isotope effects[2] is based on the assumption that, on passing from the reactants to the transition state, the zero-point energy associated with the stretching vibration of the bond which is concerned in the abstraction is lost. It is thus predicted that

$$k_H/k_D = \exp(\Delta E_0/RT), \quad (16)$$

where ΔE_0 is the difference between the zero-point energy of the bond attached to deuterium and that attached to hydrogen.

The S–H stretching vibration of $HS_2O_5^-$ in an aqueous $K_2S_2O_5$ solution is 2532 cm^{-1}, while the S–D stretching vibration of $DS_2O_5^-$ in the D_2O solution of $K_2S_2O_5$ is 1843 cm^{-1}.[10] Hence, Eq. 16 becomes

$$k_H/k_D = \exp(985/RT). \quad (17)$$

At 25 °C, according to Eq. 17, k_H/k_D is 5.3, which is comparable with the kinetic isotope effect ($k_H/k_D=5.4$) for the hydrogen-atom abstraction from benzenethiol described above.

According to the theory of a three-center transition-state model,[13] the magnitude of the primary isotope effect in a hydrogen-transfer reaction varies with the symmetry of the transition state, which depends on the nature of the substrate and that of the acceptor of the hydrogen. For the determination of the hydrogen-abstraction reaction in the rate-determining step, more work is clearly needed.

The authors wish to thank Dr. Nobutake Suzuki for his valuable discussions.

(Received November 10, 1976)

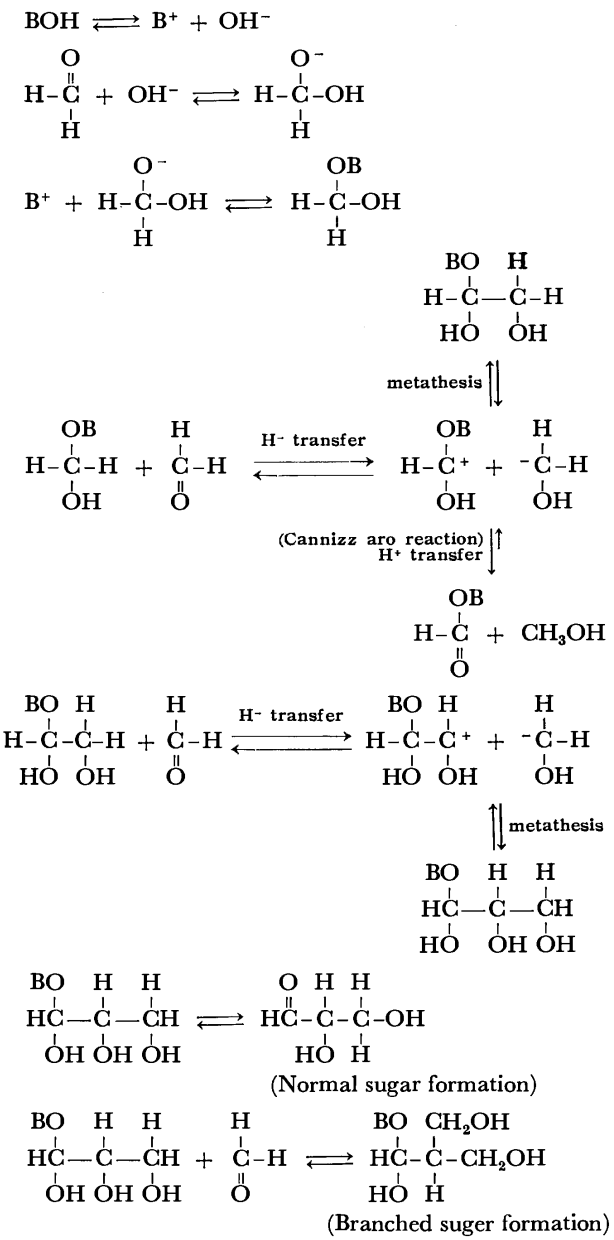
By using the previously developed analytical method of oxidation-reduction potential measurement, the formose reaction homogeneously-catalyzed by calcium formate-potassium hydroxide at pH 10.5—12.0 was found to proceed as effectively as that heterogeneously-catalyzed by calcium hydroxide. Other calcium salts, including chloride, bromide, acetate, and propionate, could be used in place of calcium formate. Kinetic studies with the calcium formate–KOH system showed a linear dependence of the concentration of the dissolved calcium ion species on the induction period (T_{min}) and the formose-forming period ($T_{max}-T_{min}$) at a given pH. From the results, the relationships, $T_{min}=a[CaOH^+]+c$ and $T_{max}-T_{min}=a[CaOH^+]+b[Ca(OH)_2]+c$, were obtained, suggesting that $CaOH^+$ is the principal catalytic species in the induction step, while both $CaOH^+$ and $Ca(OH)_2$ (or OH^-) are present in the formose-forming step. The effects of various factors on both steps and the sugar yield were also examined.

In a preceding paper,[1] which dealt with an examination of various factors affecting the formose reaction carried out with solid $Ca(OH)_2$ in a batch-reactor, it was suggested that the dissolved calcium ion is an essential catalyst for either the induction and the sugar-forming step, and that the hydroxide anion plays a significant role as a catalyst for the latter step. In order to obtain more information on the nature of catalysis in the formose reaction, it appeared necessary to investigate the reaction with a simpler system, such as a homogeneous one, which can excluded the complexity caused by the undissolved $Ca(OH)_2$.

Although Weiss *et al.*, in their studies of the formose reaction using a continuously stirred tank-reactor (CSTR), regarded the reaction as a homogeneously-catalyzed one,[2-4] both the undissolved and dissolved $Ca(OH)_2$ coexist in the reaction mixture. The homogeneously-catalyzed formose reaction has been briefly investigated using alkali-metal hydroxides, organic bases, and other catalysts.[5-12] These reactions, however, usually need a longer period and a higher temperature than the $Ca(OH)_2$-catalyzed formose reaction, and with alkali hydroxides the Cannizzaro reaction of formaldehyde occurs to a large extent. Among those investigations, only a report by Fujino *et al.*[12] concerns the calcium salt-catalyzed formose reaction in a homogeneous system, for which a glucose-calcium complex is used as a catalyst.

On the basis of kinetic studies using CSTR and on the basis of the fact that the reaction rate decreases dramatically when the pH is either too low or too high, Weiss and John have reported that $CaOH^+$ is the principal catalyst.[4] They have also proposed a simplified metathesis mechanism involving $CaOH^+$; it is shown by Scheme 1, where B^+ denotes $CaOH^+$. However, a question arises whether the $CaOH^+$ species is an effective catalyst in both induction and formose-forming steps, because these authors did not perform separate analyses of the two steps.

The purpose of this paper is to explore the standard experimental conditions for the formose reaction catalyzed homogeneously by calcium salts and to obtain evidence for the active catalytic species participating in



Scheme 1.

the induction and the formose-forming steps. The oxidation-reduction potential (ORP) measurement of the reaction system is applied to the analysis of the reaction. The method has been proved to be useful for the separate analysis of each step by observing an ORP minimum at the end of the induction period and a maximum at the end of the formose-forming step.[1,13,14]

Experimental

Procedure. The apparatus and the experimental procedure are virtually the same as those described previously.[14] Formaldehyde solutions were prepared from paraformaldehyde by refluxing for 4 h, followed by the filtration of the insoluble substances. The pH of the reaction was maintained by adding concentrated aqueous potassium hydroxide or formic acid. The reactor was flushed with nitrogen which had been bubbled through saturated aqueous barium hydroxide. The temperature was controled by means of a cooler dipped in a water bath to avoid the significant temperature rise which would otherwise occur in the formose-forming step. The formaldehyde consumption, the sugar yield, the concentration of the dissolved calcium ion species, and the ORP were measured by the method described in the previous paper.[14] The calcium salts and other reagents were of an analytical grade.

To examine the effect of the pH on the concentration of the calcium ion, an aqueous formaldehyde solution prepared at a desired concentration was maintained at 60 °C in a three-necked flask and nitrogen was passed through the solution. After the pH of the solution had been adjusted by carbonate-free concentrated KOH, calcium formate was added and stirred until precipitates appeared. A turbid supernatant was filtered through asbestos, and the filtrate was analyzed for the calcium ion by the EDTA method, using NN-reagent as an indicator.[15] The results are shown in Fig. 1.

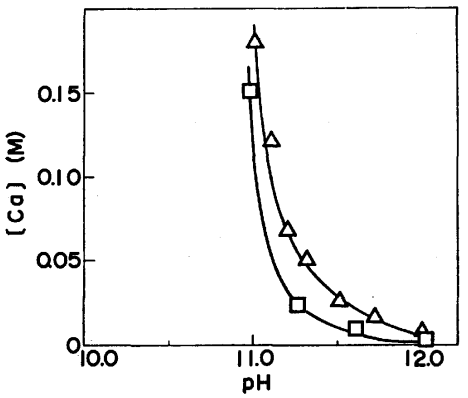


Fig. 1. Relationship between [Ca] and pH.
Temperature, 60 °C; Under N_2; [HCHO]: □, 0 M; △, 1 M; $Ca(HCOO)_2$ was used as the source of Ca^{2+} (See Experimental).

Results and Discussion

The following terms are adopted in this paper: [HCHO], [$Ca(HCOO)_2$], and [Ca], the concentrations of formaldehyde, calcium formate, and the dissolved calcium ion species respectively; T_{min}, the length of the induction step, namely, the time from the start to the ORP minimum; T_{max}, the time from the start to the ORP maximum, and $T_{max}-T_{min}$, the length of the formose-forming step (see the preceding paper[1]).

The Formose Reaction Homogeneously Catalyzed by the Calcium Ion. The reactant solution was prepared by dissolving a given amount of calcium formate into an aqueous formaldehyde solution and by adjusting the pH by the addition of concentrated aqueous KOH. After the reaction had been started at 60 °C, the pH of the mixture was maintained by adding concentrated aqueous KOH; the subsequent reaction was followed by ORP measurement and analyzed as usual. We have previously shown that the ORP of the reaction mixture increases from the minimum at the beginning of the formose-forming period up to the maximum at its end in the pH-uncontrolled reaction.[13,14] In the experiments at a constant pH, however, the increase in ORP in this period was found to be very small.

As is shown in Table 1, in a certain range of pH and [Ca] the formose reaction did occur. At pH 10.5 (Runs 1—3), T_{min} and $T_{max}-T_{min}$ were reduced with an increased [Ca], indicating that the rates of both the induction and formose-forming processes are dependent on the amount of the dissolved calcium ion species. At higher pHs, the situation became considerably different. At pH 11.0 (Run 4), even though [Ca] was the same as that of Run 1, in which the reaction was very slow, T_{min} and $T_{max}-T_{min}$ were as fast as Run 2, in which [Ca] was three times higher. At pH 11.5 (Run 5), although part of the calcium ion separated out as solid $Ca(OH)_2$, the rate was comparable to that of Run 3,

in which [Ca] was about seven times higher. The results suggest that the catalytic function of the dissolved calcium ion species increases with an increased pH. As will be discussed later, the active species catalyzing the formose reaction is believed to be $CaOH^+$.

At pH 12.0, most of the dissolved calcium ion species separated out as the solid $Ca(OH)_2$ and the reaction rate became very slow. As is shown in Fig. 1, when calcium formate was used as the source of the calcium ion, [Ca] decreased sharply above pH 11.0 in both the presence and absence of formaldehyde with an increased pH. The slow-down of the $Ca(OH)_2$-catalyzed formose reaction at a high pH[1,4] can now be ascribed to the deficiency of the dissolved calcium ion species. It follows that a high concentration of the catalyst cannot be employed for the homogeneously-catalyzed formose reaction carried out at an elevated pH. However, we found that the formose reaction took place smoothly even at pHs above 12, with the appearance of both an ORP minimum and a maximum, when an ion-exchange resin, Amberlite IR 120 (Ca^{2+}), was used as the catalyst in place of $Ca(OH)_2$ or a calcium salt-KOH system. The pH dependence of T_{min} and T_{max} in the formose reaction with the resin had a relation parallel to that of the $CaOH^+$ distribution in an aqueous $Ca(OH)_2$ solution shown in Fig. 4.

Next, a homogeneous formose reaction using other calcium salts was examined. If the formose reaction is mainly dependent on the dissolved calcium ion concentration and on the pH, it will not be much affected by the nature of the counter anion of calcium salts. The results summarized in Table 2 indicate that this is indeed the case. So far as the sugar formation is concerned, the formose reaction with these calcium salts was virtually the same as that with calcium formate-KOH or with calcium hydroxide. However, the reaction rate estimated by T_{min} and T_{max} showed a tendecy to decrease with a decrease in the dissociation ability of the calcium salts.

Effects of pH in a Homogeneously Catalyzed Formose Reaction. As is shown in Table 1 (Runs 1, 4, and 5), the induction period is shortened with an increase in the pH in the range from pH 10.5 to 11.5 in the homogeneous system. The pH dependence of the formose-forming period and the sugar yield was examined, after the homogeneous formose reaction using calcium formate had been started at pH 11.0, by varying the pH at T_{min} and by determining $T_{max}-T_{min}$ and the sugar yield. The results are shown in Figs. 2 and 3. The formose-forming step was shortened at

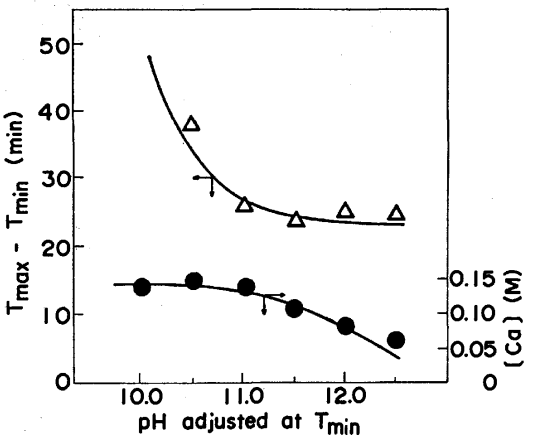

Fig. 2. Effect of pH variation at T_{min} on $T_{max}-T_{min}$ and [Ca].
[HCHO]=1.0 M; [$Ca(HCOO)_2$]=0.15 M; Starting pH=11.0 (Under these conditions, T_{min} was *ca.* 22 min).

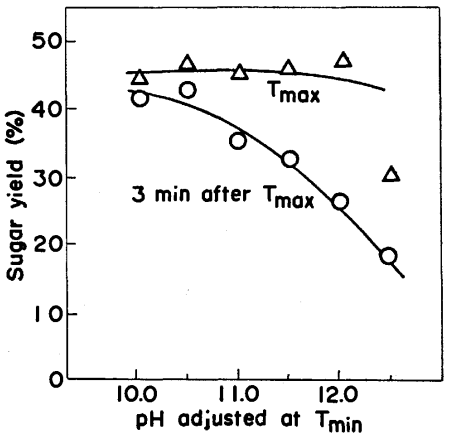

Fig. 3. Effect of pH variation at T_{min} on the sugar yield.
Reaction conditions; same as those in Fig. 2.

higher pHs, although [Ca] came to decrease at pHs above 11.5 as a result of the precipitation of the solid $Ca(OH)_2$. On the other hand, the sugar yield practically remained unchanged upon pH variation except for at pH 12.5, but the decomposition of the sugars occurring after T_{max} became more significant with an increased pH. The results indicate that the hydroxide ion may be as an effective catalyst in the formose-forming step as the dissolved calcium ion species.

Active Catalytic Species in the Formose Reaction Homogeneously Catalyzed by Calcium Ions. In view of the

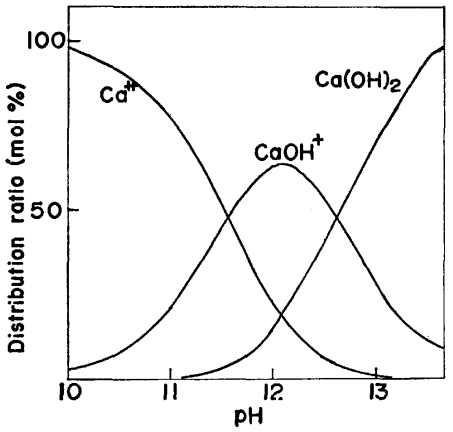

Fig. 4. Calculated distribution of dissolved Ca^{2+}, $CaOH^+$, and $Ca(OH)_2$ at different pHs.

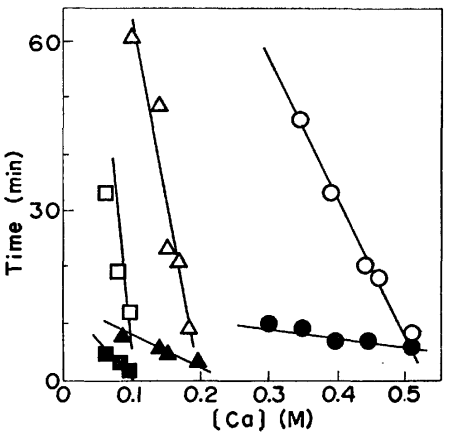

Fig. 5. Relationship between T_{min} or $T_{max}-T_{min}$ and [Ca] at different pHs.
[HCHO]=1.0 M; Catalyst, $Ca(HCOO)_2$; Temp, 60°C; T_{min}: ○,△ and □, pH 10.5, 11.0 and 11.5, respectively; $T_{max}-T_{min}$: ●,▲, and ■, pH 10.5, 11.0, and 11.5, respectively.

importance of the dissolved calcium ion species and the pH in the formose reaction, the distribution of $Ca(OH)_2$, $CaOH^+$, and Ca^{2+} in solution at different pHs was calculated (Fig. 4) on the basis of the acid-base equilibria of $Ca(OH)_2$:[17]

$$Ca^{2+} + H_2O \rightleftarrows CaOH^+ + H^+ \quad (pK_{a_1}=11.57),$$

$$CaOH^+ + H_2O \rightleftarrows Ca(OH)_2 + H^+ \quad (pK_{a_2}=12.63).$$

The Weiss proposal that $CaOH^+$ might be the active catalyst in the formose reaction catalyzed by calcium hydroxide now becomes very plausible. The calculated distribution of $CaOH^+$ at different pHs could not be applied exactly to our experimental data because of the differences of the conditions employed. However, the distribution was proved to be very useful for interpreting the experimental facts thus far obtained, provided that the pH of the maximum distribution of $CaOH^+$ under either heterogeneously- or homogeneously-catalyzed formose reaction conditions is shifted to *ca.* 11.5 from the calculated pH of 12. An example is given by a comparison of Runs 3 and 5 in Table 1. Although the initial concentration of the dissolved calcium ion species in Run 5 is considerably lower than that in Run 3, the rate of the induction and the formose-forming steps are comparable in both cases. This can be qualitatively explained by assuming that the concentrations of the active catalytic species, namely, $CaOH^+$, are almost equal in both runs.

(1) $CaOH^+$ as the Catalyst in the Induction Step: More quantitative experiments became necessary for proving the role of $CaOH^+$ as the catalyst. Figure 5 shows plots of T_{min} as a function of [Ca] at different pHs (10.5, 11.0, and 11.5) in a homogeneously-catalyzed formose reaction using $Ca(HCOO)_2$–KOH. An approximate linear relation was obtained at each pH. This relation led us to express T_{min} by

$$T_{min} = af_i[Ca] + c, \qquad (1)$$

where a and c are constants, and where f_i is the molar fraction of $CaOH^+$ in the dissolved calcium ion species at pH=i. The values of af_i and c are obtained from the slope and the interception of each line respectively. The same plots were made for the formose reaction catalyzed by $CaCl_2$–KOH, and a linear relation was again obtained at each pH. The c value was 130 min for the $Ca(HCOO)_2$–KOH system (105 for the $CaCl_2$–KOH system). When $a=-2000$ min M^{-1} (-2056), f_i is 0.12 (0.10), 0.33 (0.30), and 0.67 (0.69) at pH 10.5, 11.0, and 11.5 respectively. These f_i values are in fairly good agreement with the calculated values of Fig. 4. The constants, a and c, would depend on the reaction conditions, such as [HCHO] and the reaction temperature. Thus, Eq. 1 can be simplified to

$$T_{min} = a[CaOH^+] + c. \qquad (2)$$

Equation 2 means that the induction period is shortened linearly with an increase in the concentration of $CaOH^+$ at the same [HCHO] and pH in a certain range of [Ca].

(2) Effective Catalytic Species in the Formose-forming Step: We have suggested in the preceding paper and this paper that the OH^- as well as $CaOH^+$ participates in the catalysis in the formose-forming step in either a heterogeneous or homogeneous formose reaction.[1] Weiss and John have concluded, from their experiments using CSTR, that the rate of the formose reaction at the intermediate conversion level of formaldehyde, which is regarded as the actual formose-forming step, is first-order for calcium hydroxide ($r_F=k_F[Ca(OH)_2]$).[4] However, since their reaction system was heterogeneous, both dissolved and undissolved calcium hydroxide must contribute to the reaction rate. In order to clarify the role of the dissolved calcium ion species in the formose-forimng step, $T_{max}-T_{min}$ was plotted as a function of [Ca] at different pHs (10.5, 11.0, and 11.5) in the homogeneously catalyzed formose reaction.

The results, shown in Fig. 5, indicate that $T_{max}-T_{min}$ and [Ca] have a linear relation at different pHs. Similar relations were obtained with the $CaCl_2$–KOH system. These relations, however, are not simple as in Eq. 1, but can be expressed by

$$T_{max} - T_{min} = af_i^a[Ca] + bf_i^b[Ca] + c, \qquad (3)$$

where af_i^a, bf_i^b, and c are constants and where f_i^a and f_i^b are the molar fractions of $CaOH^+$ and $Ca(OH)_2$ respectively in the dissolved calcium ion species at pH=i. The experimental data eventually gave the following values:

a, -133 min M^{-1} for the $Ca(HCOO)_2$–KOH system (-67 for the $CaCl_2$–KOH system); b, -537 min M^{-1} (-33); c, 14.1 min (3.7); $f^a_{10.5}$, 0.12 (0.10); $f^a_{11.0}$, 0.33 (0.30); $f^a_{11.5}$, 0.67 (0.69); $f^b_{10.5}$, 0 (0); $f^b_{11.0}$, 0.03 (0.03); $f^b_{11.5}$, 0.07 (0.09). The f_i^a and f_i^b values are in fairly good agreement with the values calculated from Fig. 3. Thus, Eq. 3 can be simplified to

$$T_{max} - T_{min} = a[CaOH^+] + b[Ca(OH)_2] + c, \quad (4)$$

which means that, under these conditions, both dissolved $CaOH^+$ and $Ca(OH)_2$ act as effective catalytic species in the formose-forming step.

Equation 4 implies that the formose-forming step may occur when either $CaOH^+$ or $Ca(OH)_2$ is present in solution. For example, the reaction occurs at pH 10.5, where, practically, $[Ca(OH)_2]=0$. Furthermore, $Ca(OH)_2$ can be replaced merely by the OH^- ion. In fact, as was shown in Fig. 2, the formose-forming step still occurs even at pH values above 12, where [Ca] becomes very small due to the precipitation of the solid $Ca(OH)_2$. However, for such a case and for the formose reaction heterogeneously-catalyzed by $Ca(OH)_2$, one cannot neglect the possibility that the solid $Ca(OH)_2$ also participates in the catalysis in the formose-forming step, as has been proposed by Weiss *et al.*[2-4]

Equations 1—4, on the other hand, can be extrapolated to limiting values of c when [Ca] or $[CaOH^+]=0$. Since the reaction does not, of course, occur without a dissolution of the calcium ion species, it can be said that the c values have no significant physical meaning, but merely imply the feasibility of the induction and the formose-forming steps under the conditions employed.

Sugar Yield in the Homogeneously-Catalyzed Formose Reaction. The effects of [Ca] on the sugar yield at T_{max} and at 3 min after T_{max} at different pHs are illustrated in Fig. 6. The sugar yield at T_{max}, where sugars formed are most accumulated,[1] has a tendency to increase with an increase in [Ca], but the decomposition of the sugars is more accelerated with an increase in [Ca] at the same pH. The latter finding

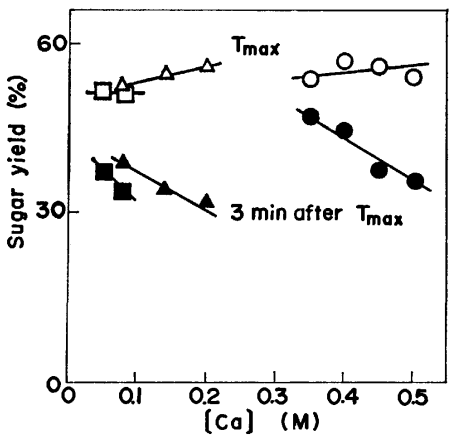

Fig. 6. Effect of [Ca] on the sugar yield.
[HCHO]=1.0 M; Catalyst, $Ca(HCOO)_2$; Temp, 60 °C; pH: ○,●, 10.5; △,▲, 11.0; □,■, 11.5.

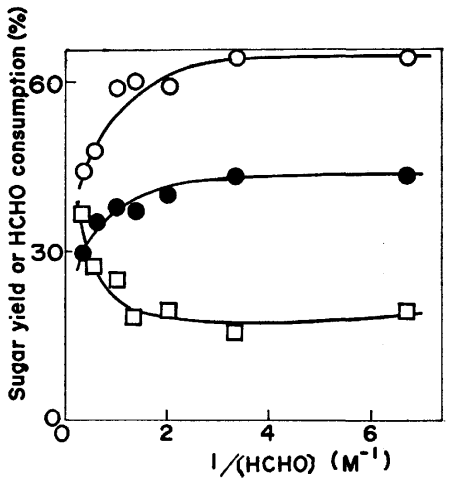

Fig. 7. Effect of the formaldehyde concentration on the sugar yield.
[$Ca(HCOO)_2$]=0.15 M; pH=11.0; Temp, 60 °C; ○, sugar yield at T_{max}; ●, sugar yield at 3 min after T_{max}; □, HCHO consumption at T_{min}.

suggests that the dissolved calcium ion species participate in the sugar decomposition like the hydroxide anion, which may take less part.

The sugar yield was found to be strongly affected by the initial [HCHO] in the present homogeneous system. This is shown in Fig. 7. At a constant [Ca], the sugar yield decreases with an increase in [HCHO] at relatively high [HCHO] values. As may be seen from Fig. 7, the decrease in the sugar yield is due to the increased consumption of formaldehyde by the Cannizzaro reaction in the induction step.

Syntheses of Gramicidin S Analogs Containing δ-Aminovaleric Acid.[1] [5-1′-δ-Aminovaleric Acid]-Gramicidin S and [5-1′, 5′-1-Bis-(δ-Aminovaleric Acid)]-Gramicidin S

Shōsuke Sōfuku, Akio Yoshida, Hiroki Baba, and Ichiro Muramatsu

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Tokyo 171

(Received December 7, 1976)

Gramicidin S (GS) analogs, [5-1′-δ-aminovaleric acid]-GS dihydrochloride (XIII) and [5-1′, 5′-1-bis(δ-aminovaleric acid)]-GS dihydrochloride (XIX), were synthesized. Both peptides are the analogs in which one or two L-prolyl-L-valyl residues of GS are replaced with one or two δ-aminovaleric acid residues. The spectra of optical rotatory dispersion (ORD) and circular dichroism (CD) of XIII and XIX were measured. The molar optical rotation of XIII is smaller than that of GS, but its ORD spectrum resembles that of GS. Analog XIII shows some antimicrobial activity, but not the analog XIX.

Analogs of gramicidin S (GS) containing δ-aminovaleric acid (δAva) residue have been synthesized in order to investigate the role of amide bond in the three-dimensional structure and antibiotic activity of GS. When one or two dipeptide residues of the antibiotic are replaced by δAva, one or two amide groups turn into ethylene groups, the chain length and ring size remaining unaltered. However, if the replaced amide group of GS participates in the hydrogen bond essential to the proper secondary structure of the original molecule, the replacement would lead to the impracticability of hydrogen bond formation, giving rise to the deformation of the ring structure and the loss of the biological activity.

In previous papers,[1,2] the syntheses and properties of [δAva$^{4-5,4'-5'}$]-GS and [δAva$^{4-5}$]-GS were reported. It has been deduced that the stabilization of the ring structure of GS needs the existence of D-phenylalanyl-L-prolyl residue, although it does not take part in intramolecular hydrogen bond formation. The NH groups of L-valyl residues seem to participate in the intramolecular hydrogen bonds, stabilizing the pleated sheet structure of GS.[3,4]

In this paper, we describe the syntheses of [δAva$^{5-1'}$]-GS and [δAva$^{5-1',5'-1}$]-GS, giving the results of antimicrobial assays and optical rotatory dispersion (ORD) and circular dichroism (CD) measurements. Both peptides are the analogs in which one or two L-prolyl-L-valyl residues participating in the hydrogen bonds in GS are replaced by δAva. The analogs are devoid of one or two amide groups in the corresponding residues of GS. The modification would be of use for a study of the conformation of GS.

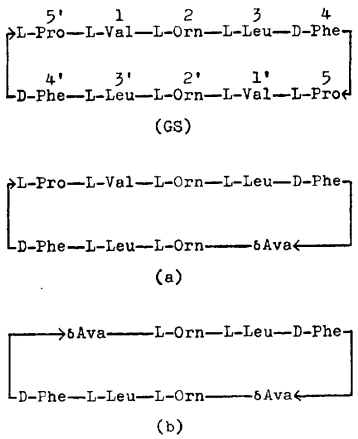

Fig. 1. Structures of gramicidin S (GS), [δAva$^{5-1'}$]-GS (a), and [δAva$^{5-1'}$, $^{5'-1}$]-GS (b).

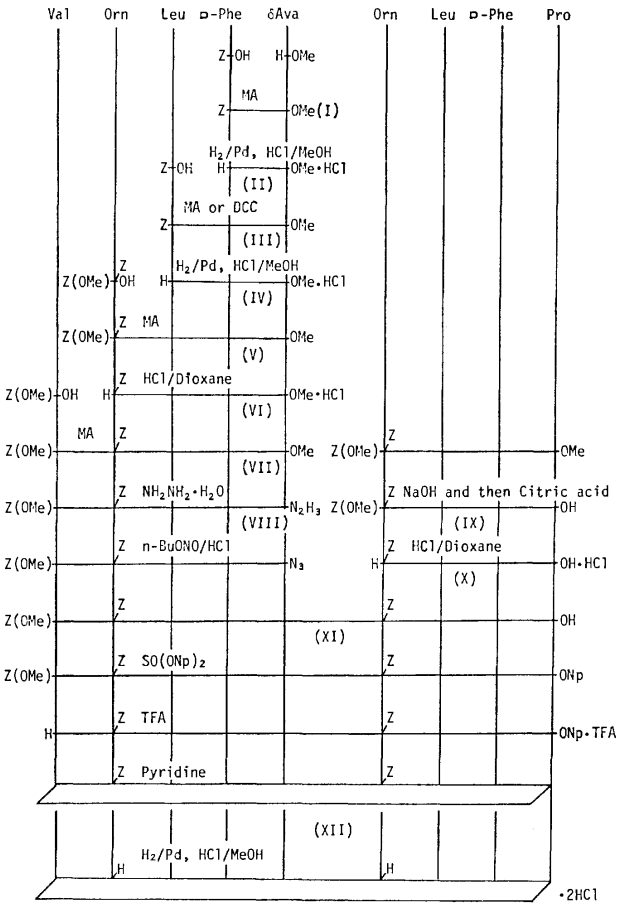
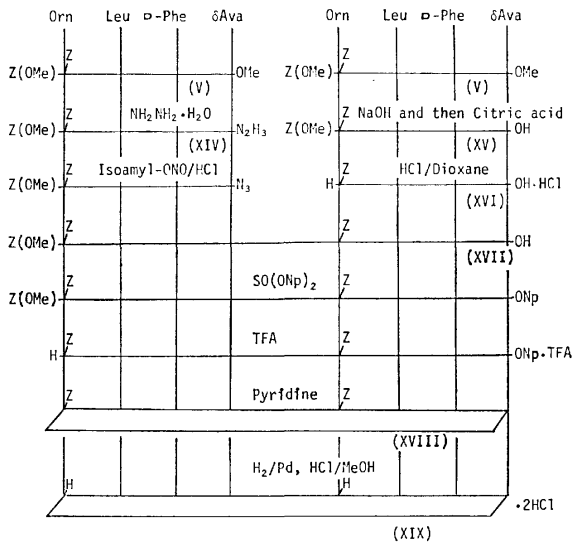
The analogs were synthesized according to Schemes 1 and 2. The cyclization reactions were carried out by using the *p*-nitrophenyl esters of liner peptides XI and XVII. The reaction procedures were the same as in the cyclization.[2] The cyclic peptides XII and XVIII were obtained in 61 and 14% yields, respectively. In analogy with the yields of cyclization in the syntheses of [δAva$^{4-5}$]-GS (71%)[2] and [δAva$^{4-5,4'-5'}$]-GS



Scheme 1.



Scheme 2.

(32%),[1] the results might reflect the relative stability of the conformation favorable for cyclization of each active ester. [δAva$^{5-1'}$]-GS dihydrochloride (XIII) and [δAva$^{5-1',5'-1}$]-GS dihydrochloride (XIX) were obtained by hydrogenolysis of the benzyloxycarbonyl groups on the ornithyl residues of XII and XVIII. The purity of the synthetic analogs was confirmed by means of dansyl chloride (1-dimethylamino-5-naphthalenesulfonyl chloride) procedure,[2] paper electrophoresis, and amino acid analysis.

Table 1. Antimicrobial activity of GS and its analogs

Test organisms	Minimum inhibitory concentration[a] (μg/ml)		
	GS·2HCl	XIII[b]	XIX[c]
Staphylococcus aureus ATCC 6538p	6.3	50	>100
Streptococcus pyogenes N. Y. 5	6.3	25	>100
Sarcina lutea ATCC 9341	6.3	>100	100
Corynebacterium diphtheriae P. W. 8	1.6	3.2	>100
Bacillus subtilis ATCC 6633	6.3	25	>100
Escherichia coli B	>100	>100	>100
Proteus vulgaris OX 19	>100	>100	>100

a) Agar dilution method. b) [δAva$^{5-1'}$]-GS·2HCl.
c) [δAva$^{5-1',5'-1}$]-GS·2HCl.

Results of the antimicrobial assay of these analogs for several microorganisms are given in Table 1. ORD and CD spectra are shown in Figs. 2 and 3. The minimum value in ORD spectrum of XIII (1.4×10^{-4} M) is observed at 232 nm. Although the molar optical rotation of XIII is smaller than that of GS, its ORD spectrum shape resembles that of GS. The analog XIII exhibits some antimicrobial activity against several microorganisms. CD spectrum of XIII has two troughs near 200 nm. The trough at 203 nm corresponds to that

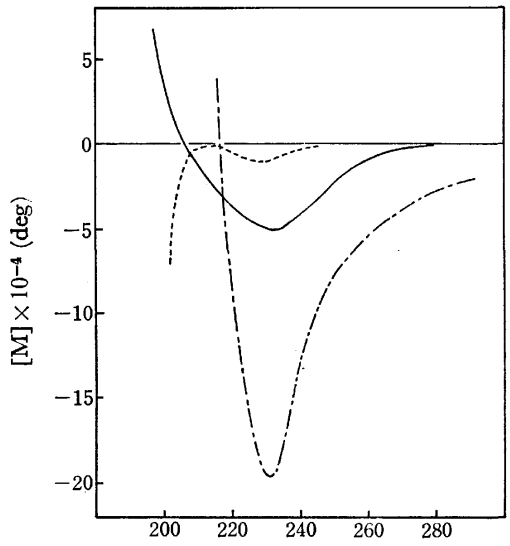


Fig. 2. ORD spectra of [δAva$^{5-1'}$]-GS·2HCl (XIII), [δAva$^{5-1',5'-1}$]-GS·2HCl (XIX), and gramicidin S 2HCl (GS) in water; XIII (——), XIX (----), and GS (- · -). Measurements were made using a 1 mm quartz cell at room temperature.

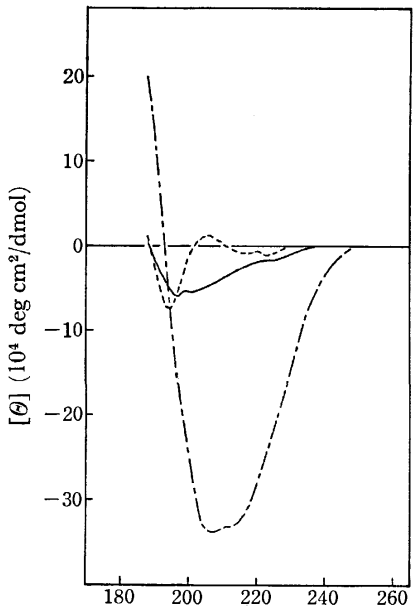

Fig. 3. CD spectra of [δAva$^{5-1'}$]-GS·2HCl (XIII), [δAva$^{5-1',5'-1}$]-GS·2HCl (XIX), and gramicidin S 2HCl (GS) in water; XIII(——), XIX(----), and GS(- · -). Measurements were made using 0.5 mm and 0.1 mm (XIX) quartz cells at room temperature.

of CD spectrum of [δAva$^{4-5}$]-GS,[2] which has a GS-like conformation. The trough in shorter wave length region is not observed in the spectrum of GS; it might arise from the partially flexible structure of XIII. The ORD and CD spectra of XIX (9.5×10^{-4} M) differ from both those of GS (1.3×10^{-4} M) and those of other GS analogs containing δAva.[1,2] Analog XIX shows no antimicrobial activity.

[MeVal^{1}]-GS and [MeVal$^{1,1'}$]-GS[5] were synthesized by Abe *et al.*[6] From the lack of amide hydrogen between L-prolyl and L-valyl residues, these analogs are comparable with analogs XIII and XIX. XIII shows antimicrobial activity and ORD spectrum similar to those of [MeVal^{1}]-GS.[6] If the part of ornithyl-leucyl-D-phenylalanyl-prolyl-valyl-ornithyl-leucyl[7] in the primary structure of XIII has a fixed secondary structure containing two hydrogen bonds and β-turn (D-phenylalanyl-prolyl),[4] analog XIII possibly exists in a GS-like conformation which can be illustrated by use of CPK model.

Experimental[5]

The purity of the synthetic compounds was confirmed by thin-layer chromatography (TLC) on silica gel plates using the following solvent systems (v/v): Solv. 1, $CHCl_3$–MeOH–AcOH–pyridine (95: 5: 3: 4); Solv. 2, $CHCl_3$–MeOH–AcOH (95: 5: 3); Solv. 3, $CHCl_3$–MeOH (9: 1); Solv. 4, *n*-BuOH–AcOH–pyridine–H_2O (4: 1: 1: 2); Solv. 5, *n*-BuOH–AcOH–H_2O (4: 1: 1). The molecular weight was determined with a Hitachi molecular weight apparatus model 115, using methanol. Amino acid analyses were performed with a JEOL automatic amino acid analyzer, after hydrolyzing samples with 6 M HCl in evacuated sealed ampoules for 20 h at 110 °C. ORD and CD spectra were measured with a JASCO model J-20 spectrometer and are represented in terms of molar optical rotation and molar ellipticity, respectively.

Z-D-Phe-δAva-OMe (I). The peptide was synthesized according to the method of Anderson *et al.*[8] Et_3N (1.39 ml, 10 mmol) was added to a solution of isobutyl chloroformate (1.44 ml, 11 mmol) in THF (20 ml) at −10 °C. After 3 min, a solution of Z-D-Phe-OH (2.99 g, 10 mmol) in THF was added dropwise to the above solution at −15 °C. After the reaction mixture had been stirred for 15 min, a mixture of H-δAva-OMe·HCl[2] (1.68 g, 10 mmol) and Et_3N (1.39 ml) in $CHCl_3$ (20 ml) was added. The reaction mixture was further stirred at −15 °C for 1 h and at room temperature overnight. After filtration, the filtrate was concentrated *in vacuo*. The residue was dissolved in ethyl acetate, and the solution was washed successively with 0.5 M HCl, water, 5% $NaHCO_3$, and water, and then dried over Na_2SO_4. After removal of the drying agent, the solution was concentrated *in vacuo* and the residue was recrystallized from ethyl acetate and petroleum ether. Yield, 3.38 g (81.9%); mp 103—104 °C; $[\alpha]_D^{20}$ +3.2° (*c* 4, MeOH).

Found: C, 67.14; H, 6.87; N, 6.99%. Calcd for $C_{23}H_{28}N_2O_5$: C, 66.97; H, 6.84; N, 6.79%.

H-D-Phe-δAva-OMe·HCl (II). I (4.13 g, 10 mmol) in MeOH (30 ml) containing methanolic 1.2 M HCl (10 ml) was hydrogenolyzed in the presence of Pd black (0.5 g) for 2 h. After removal of the catalyst and concentration of the filtrate *in vacuo*, white precipitate was obtained by trituration of the oily residue with diethyl ether in a theoretical yield.

Z-Leu-D-Phe-δAva-OMe (III). *a*) DCC (2.06 g, 10 mmol) was added to a mixture of II (3.15 g, 10 mmol) and Z-Leu-OH·DCHA[9] (4.48 g, 10 mmol) in $CHCl_3$ (50 ml) at 2—3 °C in an ice-salt bath.[10] The reaction mixture was stirred at this temperature for 3 h and then at room temperature overnight. After evaporation of the solvent *in vacuo* and addition of ethyl acetate to the residue, insoluble substance was removed by filtration. The filtrate was treated in a way similar to that for the synthesis of I. The pure product was obtained by recrystallization from ethyl acetate, EtOH and hexane. Yield, 3.7 g (70.3%); mp 145.5 °C; $[\alpha]_D^{20}$ +10.5° (*c* 2, MeOH). *b*) Z-Leu-OH obtained from the corresponding DCHA salt (14.73 g, 33 mmol) was combined with 30 mmol of II by a method similar to that for the synthesis of I. The product was recrystallized from ethyl acetate and petroleum ether. Yield, 12.42 g (77.8%); mp 144—145 °C; $[\alpha]_D^{22}$ +11.6° (*c* 2, MeOH).

Found: C, 66.46; H, 7.39; N, 8.01%. Calcd for $C_{29}H_{39}N_3O_6$: C, 66.26; H, 7.48; N, 7.99%.

H-Leu-D-Phe-δAva-OMe-HCl (IV). III (10.51 g, 20 mmol) was hydrogenolyzed by the method for II. The product was obtained in a theoretical yield.

Z(OMe)-Orn(Z)-Leu-D-Phe-δAva-OMe (V). This was prepared from IV (20 mmol) and Z(OMe)-Orn(Z)-OH obtained from the corresponding DCHA salt[11] (13.47 g, 22 mmol). The coupling method was similar to that for the preparation of I. The reaction mixture was concentrated *in vacuo*. The residue was dissolved in $CHCl_3$, and the solution was washed successively with water, 5% citric acid, water, 5% $NaHCO_3$, and water, and then dried over Na_2SO_4. After removal of the drying agent, the filtrate was concentrated *in vacuo*, and the residue was recrystallized from MeOH (600 ml). Yield, 12.52 g (77.9%); mp 182—183 °C; $[\alpha]_D^{22}$ +5.5° (*c* 1, DMF); TLC: R_f 0.64 (Solv. 3).

Found: C, 64.30; H, 7.10; N, 8.79%. Calcd for $C_{43}H_{57}N_5O_{10}$: C, 64.24; H, 7.15; N, 8.71%.

H-Orn(Z)-Leu-D-Phe-δAva-OMe·HCl (VI). V (1.85 g, 2.3 mmol) was added to 2 M HCl–dioxane (25 ml) containing anisole (0.6 ml). The solution was stirred at room temperature for 3 h and then evaporated *in vacuo*. The oily residue was triturated with diethyl ether and the resulting white precipitate was collected by filtration. After drying, the product weighed 1.42 g (89.1%).

Z(OMe)-Val-Orn(Z)-Leu-D-Phe-δAva-OMe (VII). Z(OMe)-Val-OH obtained from the corresponding DCHA salt[11] (1.16 g, 2.5 mmol) was introduced to a mixed anhydride in a way similar to that for the preparation of I. To this THF solution (19 ml) was added a solution of VI (1.42 g, 2.1 mmol) and Et_3N (0.29 ml) in DMF (15 ml) at −15 °C. The reaction mixture was stirred at this temperature for 1 h and at room temperature overnight and then filtered. The filtrate was concentrated to dryness *in vacuo*. The residue was washed on a filter funnel with water, 5% citric acid, water, 5% $NaHCO_3$, and water. The dried crude product was recrystallized from MeOH and diethyl ether. Yield, 1.2 g (63.2%); mp 193.5—195 °C; $[\alpha]_D^{18}$ +6.5° (*c* 1, DMF).

Found: C, 63.97; H, 7.41; N, 9.46%. Calcd for $C_{48}H_{66}N_6O_{11}$: C, 63.84; H, 7.36; N, 9.31%.

Z(OMe)-Val-Orn(Z)-Leu-D-Phe-δAva-NHNH$_2$ (VIII). $NH_2NH_2·H_2O$ (80%, 12.5 g) was added to a solution of VII (2.72 g, 3.0 mmol) in DMF (50 ml) and the resulting solution was stirred at room temperature for 4.5 d. The hydrazide precipitated by addition of water (400 ml) was filtered, washed with water, and dried. Yield, 2.68 g (98.9%); mp 213.5—215 °C; $[\alpha]_D^{20}$ +7.0° (*c* 1, HMPA).

Found: C, 62.05; H, 7.28; N, 12.07%. Calcd for $C_{47}H_{66}N_8O_{10}$: C, 62.51; H, 7.36; N, 12.41%.

Z(OMe)-Orn(Z)-Leu-D-Phe-Pro-OH (IX). Z(OMe)-Orn(Z)-Leu-D-Phe-Pro-OEt[2] (1.63 g, 2.0 mmol) was saponified in a mixture of MeOH (10 ml), dioxane (10 ml), and 1 M NaOH (4 ml) at room temperature for 3 h. After filtration of the reaction mixture, an oily product resulting by the addition of 5% citric acid (25 ml) in an ice bath was separated from the aqueous layer by decantation. The product was reprecipitated from MeOH, 5% citric acid, and excess water, washed with water, and dried. Yield, 1.46 g (92.5%); TLC: R_f 0.64 (Solv. 1).

H-Orn(Z)-Leu-D-Phe-Pro-OH·HCl (X). HCl–dioxane (8.6 M, 5 ml) was added to a solution of IX (1.46 g, 1.85 mmol) in dioxane (10 ml) containing anisole (0.22 ml). The solution was stirred at room temperature for 1 h. After the solvent had been evaporated *in vacuo*, the product was obtained by trituration with diethyl ether and decantation; yield, 1.19 g (97.5%).

Z(OMe)-Val-Orn(Z)-Leu-D-Phe-δAva-Orn(Z)-Leu-D-Phe-Pro-OH (XI). VIII (1.63 g, 1.8 mmol) was suspended in DMF (20 ml), followed by addition of 8.16 M HCl–dioxane (0.88 ml) and butyl nitrite (0.25 ml, 2.2 mmol) at −40 °C.[12] After the reaction mixture had been stirred at −20——30 °C for 15 min, Et_3N (1 ml) was added at −60 °C, followed by the addition of a mixture of X (1.19 g, 1.8 mmol) and Et_3N (0.5 ml) in DMF (15.5 ml) at −20——30 °C. The reaction mixture was stirred at this temperature for 1 h and at 0 °C for 66 h and then poured into cold water (500 ml). The resulting precipitate was collected by filtration, and washed with water, 5% citric acid, and water. The dried crude product (2.61 g) was recrystallized from DMF and diethyl ether. Yield, 1.53 g (56.7%); mp 226—227 °C; $[\alpha]_D^{24}$ −21.6° (*c* 0.5, DMF); TLC: R_f 0.52 (Solv. 1).

Found: C, 63.00; H, 7.25; N, 10.23%. Calcd for $C_{80}H_{107}N_{11}O_{17}\cdot 2H_2O$: C, 62.77; H, 7.31; N, 10.06%.

cyclo(-Val-Orn(Z)-Leu-D-Phe-δAva-Orn(Z)-Leu-D-Phe-Pro-) (XII). The cyclic peptide was prepared in the same way as described.[2] The reaction of XI (1.05 g, 0.7 mmol) with bis(*p*-nitrophenyl)sulfite (1.59 g) in a mixture of DMF (18 ml) and pyridine (8 ml) at room temperature for 43 h gave the *p*-nitrophenyl ester of XI. After the removal of Z(OMe)-group of this ester with TFA (7 ml) containing anisole (1.12 ml), cyclization of the resulting peptide ester was carried out in pyridine (467 ml) at 58—60 °C. The solution was concentrated *in vacuo*. The residue was dissolved in aq MeOH and passed through Dowex-1 (OH^- form) and Dowex-50 (H^+ form). After evaporation of the effluent, the product (628 mg) was recrystallized from aq MeOH. Yield, 561 mg (61.1%); mp 126—130 °C; $[\alpha]_D^{24}$ −158.0° (*c* 0.3, EtOH); TLC: R_f 0.5 (Solv. 2); mol wt, found: 1331 (calcd for $C_{71}H_{97}N_{11}O_{13}$: 1313).

Found: C, 64.09; H, 7.56; N, 11.03%. Calcd for $C_{71}H_{97}N_{11}O_{13}\cdot CH_3OH$: C, 64.31; H, 7.57; N, 11.46%.

cyclo(-Val-Orn-Leu-D-Phe-δAva-Orn-Leu-D-Phe-Pro-)·2HCl (XIII). Benzyloxycarbonyl groups of XII (394 mg, 0.3 mmol) were hydrogenolyzed in MeOH (10 ml) containing 1 M HCl (0.9 ml) in the presence of Pd-black (100 mg) for 7.5 h. After removal of the catalyst, the filtrate was concentrated *in vacuo*. The residue was washed with diethyl ether by decantation and then dissolved in water. The solution was filtered through active charcoal and the filtrate was lyophilized. Yield, 293 mg (77.4%); mp 228—231 °C (dec); $[\alpha]_D^{24}$ −157.0° (*c* 1, EtOH); TLC: R_f 0.82 (Solv. 4). Paper electrophoresis: migration distance −12 cm, *cf.* −12 cm for GS [HCOOH: AcOH: H_2O=4: 15: 180 v/v (pH 1.9), 600 V, 12—14.5 mA, 2 h, Toyo no. 50 (15×40 cm)]. Amino acid ratios: Val, 0.95; Orn, 2.00; Leu, 2.07; Phe, 2.00; Pro, 1.05; δAva, 0.96 (recovery 90%).

Found: C, 52.57; H, 7.15; N, 11.90%. Calcd for $C_{55}H_{87}N_{11}O_9Cl_2\cdot 6H_2O\cdot HCl$: C, 52.35; H, 7.99; N, 12.21%.

Z(OMe)-Orn(Z)-Leu-D-Phe-δAva-NHNH₂ (XIV). A solution of V (2.01 g, 2.5 mmol) and 80% $NH_2NH_2\cdot H_2O$ (4.7 g) in DMF (15 ml) was stirred at room temperature for 3 d. The solution was concentrated *in vacuo* to a volume of *ca.* 10 ml. White precipitate was obtained by the addition of excess water to the concentrate. The filtered and dried product weighed 1.94 g (96.5%). Mp 203.5—205.5 °C. A sample for analysis was obtained by crystallization from MeOH–ethyl acetate–diethyl ether. Mp 205.5—207.5 °C; $[\alpha]_D^{21}$ +8.4° (*c* 1, DMF).

Found: C, 62.47; H, 7.25; N, 12.46%. Calcd for $C_{42}H_{57}N_7O_9$: C, 62.75; H, 7.15; N, 12.19%.

Z(OMe)-Orn(Z)-Leu-D-Phe-δAva-OH (XV). A solution of V (2.41 g, 3 mmol) in a mixture of dioxane (50 ml) and MeOH (30 ml) containing 1 M NaOH (9 ml) was stirred at room temperature for 2.5 h. To this was added 1 M NaOH (3 ml) and the stirring was continued. Another portion (3 ml) of the alkali solution was added 1 h later. Four h after the last addition, the solution was acidified with citric acid (3.15 g) and concentrated *in vacuo*. On the addition of water to the residue, precipitate appeared immediately. After filtration and drying, the precipitate was recrystallized from MeOH. Yield, 1.80 g (75.9%); mp 165—167 °C; $[\alpha]_D^{21}$ +5.0° (*c* 1, DMF); TLC: R_f 0.18 (Solv. 3).

Found: C, 64.03; H, 7.19; N, 9.18%. Calcd for $C_{42}H_{55}N_5O_{10}$: C, 63.86; H, 7.02; N, 8.87%.

H-Orn(Z)-Leu-D-Phe-δAva-OH·HCl (XVI). XV (1.58 g, 2 mmol) was treated with a solution of 2.2 M HCl–dioxane (20 ml) containing anisole (0.65 ml) at room temperature for 2 h. The product was obtained in a theoretical yield following the procedure in the preparation of X.

Z(OMe)-Orn(Z)-Leu-D-Phe-δAva-Orn(Z)-Leu-D-Phe-δAva-OH (XVII). XIV (1.61 g, 2 mmol) and XVI (1.32 g, 2 mmol) were subjected to the same treatment as that for XI, except for the use of isopentyl nitrite (0.42 ml) instead of butyl nitrite. The reaction mixture was stirred at 0 °C for 70 h and filtered. The precipitate and the residue obtained from the filtrate after concentration *in vacuo* were combined, and washed with 5% citric acid and water. Recrystallization of the dried crude product from DMF and MeOH gave 1.65 g (59.0%) of the pure product. Mp 218—220 °C; $[\alpha]_D^{24}$ +3.4° (*c* 0.6, DMF).

Found: C, 64.10; H, 7.48; N, 9.79%. Calcd for $C_{75}H_{100}N_{10}O_{16}$: C, 64.45; H, 7.21; N, 10.02%.

cyclo(-Orn(Z)-Leu-D-Phe-δAva-Orn(Z)-Leu-D-Phe-δAva-) (XVIII). This cyclic peptide was synthesized following the same procedure as described for the prepararion of XII. From XVII (1.40 g, 1 mmol), 194 mg of crude product was obtained. Upon recrystallization from aq MeOH, 174 mg (14.3%) of the pure product was obtained. Mp 274—275 °C; $[\alpha]_D^{24}$ −20.7° (*c* 0.1, EtOH); TLC: R_f 0.46 (Solv. 3); mol wt, found: 1142 (calcd for $C_{66}H_{90}N_{10}O_{12}$: 1216).

Rhodium Complex Catalyzed Hydrogenation of α,β-Unsaturated Aldehydes to Unsaturated Alcohols

Tsutomu MIZOROKI, Katsumi SEKI, Shun-ichi MEGURO, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama Meguro-ku, Tokyo 152

(Received January 14, 1977)

Rhodium complexes were found to be effective in catalyzing selective hydrogenation of cinnamaldehyde to cinnamyl alcohol in the presence of strongly basic amine such as triethylamine or *N*-methylpyrrolidine under oxo reaction conditions. The selectivity of analogous hydrogenation of aliphatic unsaturated aldehyde was poorer than that of aromatic aldehyde. When a catalytic amount of triphenylphosphine was added, the selectivity was drastically changed to exclusive formation of hydrocinnamaldehyde. In order to elucidate the nature of rhodium-amine interaction, $Rh_2Cl_2(CO_4)$ was immobilized on a cross-linked chloromethylated polystyrene which was functionalized with pyrrolidine, the polymer amine acting as a tertiary amine. The polymer–rhodium complex was found to be stable and to effect the selective hydrogenation of cinnamaldehyde, while addition of triphenylphosphine seemed to liberate the rhodium complex from the polymer. It is concluded that a rhodium–amine–carbonyl complex is responsible for the selective hydrogenation of α,β-unsaturated aldehyde to the unsaturated alcohol.

Hindered unsaturated aldehydes having highly substituted carbon-carbon double bonds can be hydrogenated to the corresponding unsaturated alcoholes.[1] For unhindered α,β-unsaturated aldehydes such as cinnamaldehyde and crotonaldehyde, however, a very limited number of catalysts are known to be effective, *i.e.* platinum and palladium supported on carbon combined with zinc and iron(II) chlorides,[2] although no mechanistic study has been reported. On the other hand, a number of transition metal complexes have been reported to catalyze hydrogenation of olefin and aldehyde under mild reaction conditions.[3] No efficient homogeneous catalyst is known for preferential hydrogenation of these unsaturated aldehydes to the unsaturated alcohols using molecular hydrogen. In the presence of a tertiary amine, rhodium complex catalysts are much more active than cobalt carbonyls for oxo-alcohol syntheses without accompanying hydrogenation of olefin.[4,5] This suggested that rhodium complexes would be effective in the presence of carbon monoxide and tertiary amine for the selective hydrogenation of α,β-unsaturated aldehyde. Kogami *et al.* examined cobalt carbonyl catalyst in the presence of amine for hydrogenation of cinnamaldehyde and its derivatives under oxo reaction conditions, no preferential hydrogenation to the unsaturated alcohols being found.[6]

This work was undertaken to elucidate the necessary conditions for selective hydrogenation of cinnamaldehyde and croton aldehyde to the unsaturated alcohols with rhodium complex catalyst in the presence of tertiary amine under oxo reaction conditions, and to study the interaction of amine with rhodium atom in its coordination sphere by immobilizing $Rh_2Cl_2(CO)_4$ on an aminated polystyrene.

Experimental

Materials. Tetracarbonyldichlorodirhodium (I), $Rh_2Cl_2(CO)_4$, was prepared from $RhCl_3 \cdot 3H_2O$ and carbon monoxide[7] (Found: C, 11.2; Cl, 18.8%. Calcd for: C, 12.4; Cl, 18.2%). Commercial $RhCl_3 \cdot 3H_2O$, carbon monoxide (98%) and all the α,β-unsaturated aldehydes and amines (Tables 2 and 3) were used without purification. Benzene of extra pure grade guaranteed for UV spectrometry (Wako Pure Chemicals Industry Ltd.) was used as a solvent to avoid the effect of contaminants such as thiophene.

Aminated polystyrene was prepared by an appropriate modification of the method used for the amination of chloromethylated polymers.[8] A cross-linked chloromethylated polystyrene (divinylbenzene 3%. Mitsubishi Chemical Industry Ltd.) was washed with dioxane and water under nitrogen atmosphere, and dried at 50—60 °C in a vacuum (Found: H, 6.9; C, 75.2; Cl, 15.6%. Total 97.7%). The chloromethylated polystyrene (50 g) were aminated with pyrrolidine (100 g) in dioxane (150 ml) under nitrogen atmosphere at room temperature for 48 h. The resulting polymer was washed three times with a water–dioxane solution of hydrogen chloride to remove the excess pyrrolidine and then three times with an aqueous sodium carbonate solution to liberate the amine chemically linked to the polymer. Subsequently the aminated polystyrene was washed thoroughly with water and methanol and dried at 20 °C in a vacuum (Found: H, 9.1; C, 84.3; N, 5.4; Cl, 1.1%. Total 99.9%).

Reaction Procedure. All the reactions were carried out with use of a stainless steel autoclave (100 ml) equipped with a magnetic stirrer. A benzene solution (20 ml) of a tertiary amine (2.5—40 mmol) and one of α,β-unsaturated aldehydes (20—23 mmol) and $RhCl_3 \cdot 3H_2O$ (0.13 mmol) or $Rh_2Cl_2(CO)_4$ (0.065 mmol) were placed in the autoclave under nitrogen atmosphere, followed by introduction of carbon monoxide and hydrogen at room temperature. The autoclave was then heated up to the desired temperature within 10—15 min, and the temperature was kept constant. After a given period of run, the autoclave was rapidly cooled with water to room temperature, and gaseous materials were purged out. The products were quantitatively analyzed by a gas chromatograph equipped with a 4 meter column of DC-550, polyethylene glycol, or ethylene glycol succinate polyester using an appropriate substance as internal standard. The hydrogenation products were isolated by a preparative gas chromatograph, and identified by NMR, IR, or mass spectroscopy, when necessary.

Results and Discussion

General Features of Reaction. The results for cinnamaldehyde using $RhCl_3 \cdot 3H_2O$ as a catalyst are shown in Table 1. In the absence of carbon monoxide

Table 1. Hydrogenation of cinnamaldehyde catalyzed by rhodium complex

or triethylamine, small amounts of hydrogenated products are obtained, no cinnamyl alcohol being detected. Addition of triethylamine, however, significantly increases not only the catalytic activity but the selectivity to cinnamyl alcohol under the oxo reaction conditions, giving no hydroformylation products. Addition of primary or secondary amine in place of tertiary amine was ineffective in giving hydrogenation products. This is presumably caused by the formation of highly stable Rh(III)–amine complexes.[9] On the other hand, the addition of a catalytic amount of triphenylphosphine strikingly increases the selectivity for the hydrogenation of the carbon-carbon double bond to give hydrocinnamaldehyde. Triphenylamine has little effect, while triphenylarsine decreases the catalytic activity. $RhCl(PPh_3)_3$ is a highly active catalyst for preferential hydrogenation of the carbon-carbon double bond under the same conditions. The results indicate that both carbon monoxide and tertiary amine play important roles for the selective hydrogenation to cinnamyl alcohol with rhodium complex catalyst.

Although $RhCl_3 \cdot 3H_2O$ exhibits only a low activity at lower temperatures, it can be activated by treatment with carbon monoxide (30—50 kg/cm²) at 90 °C for 60 min before introduction of hydrogen, so that cinnamaldehyde can be hydrogenated even at 60 °C. When $Rh_2Cl_2(CO)_4$ is used as the catalyst, the selective hydrogenation takes place more readily without pretreatment, suggesting that $RhCl_3$ is reduced during the course of hydrogenation.

Effect of Tertiary Amine. The effect of tertiary amine in the hydrogenation of cinnamaldehyde is given in Table 2. Two features of amine effect are observed. Firstly, highly basic amines such as triethylamine (pK_b= 3.3), *N*-methylpyrrolidine (pK_b=3.8) and *N*-methylpiperidine (pK_b=2.8) are effective not only for catalytic activity but also for preferential hydrogenation to cinnamyl alcohol. *N,N*-Dimethylbenzylamine (pK_b= 5.1) is not effective, and less basic amines such as *N,N*-dimethylaniline (pK_b=8.9) and pyridine (pK_b=8.9) give no cinnamyl alcohol at all. Such a trend in the effectiveness of tertiary amines was also reported for oxo-alcohol synthesis from hexene or octene catalyzed by rhodium catalysts combined with tertiary amine and water.[4] Secondly, both catalytic activity and selectivity to cinnamyl alcohol substantially depend on the amount of amine, this being pronounced in the presence of large excess of triethylamine or *N*-methylpyrrolidine (amine/Rh=100—200 in mol). It is interesting to see the effect of diamines, since the interaction between rhodium atom and diamines could be strengthened by their chelate effect. The diamines (Table 2) are clearly effective for selective hydrogenation, but they are required in a large amount to increase the yield of cinnamyl alcohol, and no chelate effect is observed. *p,p'*-Bis(dimethylamino)diphenylmethane as well as *N,N*-dimethylaniline give no cinnamyl alcohol. The interaction between rhodium complex and amine will be discussed on the basis of the hydrogenation using $Rh_2Cl_2(CO)_4$ catalyst immobilized on an aminated polystyrene.

Effects of Carbon Monoxide and Hydrogen. Effects of carbon monoxide and hydrogen on the conversion of cinnamaldehyde and selectivity of hydrogenation are shown in Figs. 1 and 2. Under the conditions specified in Fig. 1, the highest conversion of cinnamaldehyde is obtained at 20 kg/cm² of carbon monoxide, where the selectivity to hydrocinnamyl alcohol is also the highest. The selectivity to cinnamyl alcohol increases with increase in the pressure of carbon monoxide, the formation of hydrocinnamaldehyde being significantly retarded by carbon monoxide. The increase in hydrogen pressure under a constant pressure of carbon monoxide (40 kg/cm²) increases the conversion of cinnamaldehyde,

a) Under low hydrogen pressure, it was supplied during the reaction to keep the pressure constant.

while the consecutive hydrogenation of cinnamyl alcohol produced is much slower than that of cinnamaldehyde. (Fig. 2). Thus, in the presence of carbon monoxide, the hydrogenation of the CHO group can be preferentially enhanced. This was verified by separate runs of hydrogenation of hydrocinnamaldehyde and cinnamyl alcohol under the same conditions specified in Fig. 1. Under 30—50 kg/cm² of carbon monoxide, hydrocinnamaldehyde was almost quantitatively hydrogenated to hydrocinnamyl alcohol (90%), while the extent of hydrogenation of cinnamyl alcohol was less than 25% in the same period.

The highest conversion to hydrocinnamyl alcohol is obtained at 20 kg/cm² of carbon monoxide (Fig. 1), considerable amounts of hydrocinnamaldehyde being formed under lower pressures of hydrogen (10, 20 kg/cm²) (Fig. 2). Strohmeier and Weigelt reported that 2-methyl-2-propanol is rapidly isomerized to

isobutyraldehyde with $RhH(CO)(PPh_3)_3$ as a homogeneous catalyst in trifluoroethanol at 70 °C[10] (CH_2=$C(CH_3)CH_2OH \longrightarrow [(CH_3)_2C$=$CHOH] \longrightarrow (CH_3)_2CHCHO$). Thus, the isomerization of cinnamyl alcohol to hydrocinnamaldehyde should be taken into account for the formation of hydrocinnamyl alcohol. With the present catalyst system, it seems likely that carbon monoxide retards the isomerization of cinnamyl alcohol as well as hydrogenation of the carbon-carbon double bond, since the selectivity of hydrocinnamyl alcohol is considerablely low under higher pressures (40—60 kg/cm²) of carbon monoxide (Fig. 1), gradually increasing even under high pressures of hydrogen (Fig. 2). However, we have no evidence for the course of formation of hydrocinnamyl alcohol.

Hydrogenation of Other α,β-Unsaturated Aldehydes. The results for other α,β-unsaturated aldehydes are given in Table 3. *N*-Methylpyrrolidine was used as the modifier, and the catalyst solutions were treated with carbon monoxide (40—50 kg/cm²) at 90 °C for 60 min before the hydrogenation at 40—60 °C by introduction of hydrogen. α-Methyl cinnamaldehyde as well as cinnamaldehyde are hydrogenated to the unsaturated alcohol selectively, while in the case of aliphatic unsaturated aldehydes such as croton aldehyde, 2-hexenal, or 2-ethyl-2-hexenal, the unsaturated alcohols produced are further hydrogenated to the saturated alcohols. All attempts to increase the selectivity to *trans*-2-buten-1-ol by over 50% using $Rh_2Cl_2(CO)_4$ as the catalysts were unsuccessful. Acrylaldehyde, presumably oligomerized before hydrogenation, gave only a trace amount of propionaldehyde.

Immobilization of Rhodium Complex. Since a large amount of tertiary amine is required for the selective hydrogenation of cinnamaldehyde, and little evidence on the nature of interaction of amine with rhodium atom in its coordination sphere is available, attempts to isolate a rhodium–amine complex from the product solution being unsuccessful, we attempted to immobilize $Rh_2Cl_2(CO)_4$ on a cross-linked chloromethylated polystyrene functionarized with pyrrolidine, *i.e.* $\{\text{-}C_6H_4\text{-}CH_2\text{–}NC_4H_8$. When a deep red benzene solution of $Rh_2Cl_2(CO)_4$ is added to the pale yellow polymer swollen in benzene at room temperature under nitrogen atmosphere, the complex is rapidly adsorbed on the polymer, the deep red colour disappearing within a few minutes. A pale dark brown polymer was separated by filtration. The immobilized rhodium complex was used as a catalyst for the hydrogenation of cinnamaldehyde without addition of any other amine. The results are summarized in Table 4, the amounts of the polymer used for immobilizing $Rh_2Cl_2(CO)_4$ (0.065 mmol) being 0.65—5.2 g (2.5—20 mmol equivalents of N). After the runs, the immobilized rhodium complex suspended in a colourless product solution was washed twice with benzene and separated by filtration in the air before

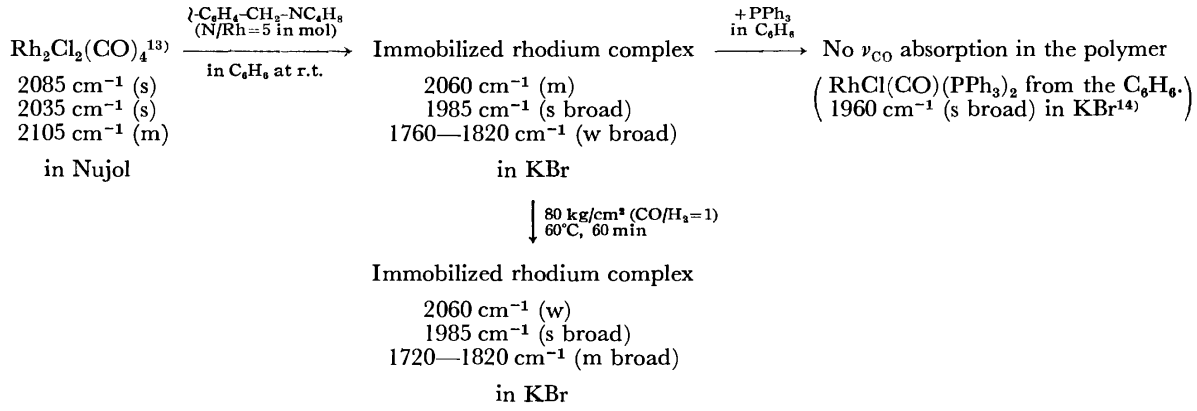
Table 5. IR absorptions of rhodium carbonyl complexes



analysis of hydrogenation products of cinnamaldehyde, since some of them were adsorbed on the polymer. The results obtained from the corresponding homogeneous catalyst system using *N*-methylpyrrolidine under the same conditions are given in parentheses in Table 4. Selective hydrogenation is again observed in heterogeneous catalyst system, although its catalytic activity and selectivity are slightly lower than those in homogeneous one. The polymer catalysts recovered in the air from runs 3, 5, and 4 reproduce almost the same activity and selectivity (runs 5, 6, and 7 respectively), indicating that the rhodium complexes are fairly air-stable, retaining original linkage to the aminated polystyrene after the runs. Addition of catalytic amounts of triphenylphosphine ($PPh_3/Rh=2$—3), however, gave exclusively hydrocinnamaldehyde and no cinnamyl alcohol at all (comparison of run 1 with runs 8 and 10) as observed in homogeneous catalyst system (Table 1). Since the product solutions were pale yellow in the runs with triphenylphosphine, some part of the rhodium complex seem to have been eluted from the polymer. In fact, the polymer catalyst recovered from run 10 was almost inactive for hydrogenation, although the one recovered from run 8 had some activity for selective hydrogenation (comparison of run 9 with run 2).

The interaction of $Rh_2Cl_2(CO)_4$ with the polymer was investigated by IR. The immobilized complex ($N/Rh=5$)[11] showed three absorptions, 2060(m), 1985(s broad), and 1720—1820 (w broad) cm^{-1}, in carbonyl stretching region. The last broad absorption, which was not observed in the parent rhodium complex, $Rh_2Cl_2(CO)_4$ (2105(m), 2085(s), and 2035(s) cm^{-1}), could be assigned to bridged carbonyls, suggesting the formation of a polynuclear rhodium carbonyl.[12] After treatment of the immobilized rhodium complex with $CO-H_2$ mixture ($CO/H_2=1$) in benzene under 80 kg/cm^2 at 60 °C for 60 min, the first absorption became weaker and the last one (1720—1820 cm^{-1}) relatively increased. On the other hand, all these absorptions disappeared after the treatment with triphenylphosphine ($PPh_3/Rh=3$) in benzene either in the presence or absence of the $CO-H_2$ mixture. From the benzene solution, $RhCl(CO)(PPh_3)_2$ (Found: C, 63.0; H, 4.25%. Calcd for: C, 64.3; H, 4.38%. $\nu_{CO}=1960$ (s broad) cm^{-1}), was isolated and recrystalized from benzene–methanol, indicating that triphenylphosphine coordinates to rhodium atom much more strongly than the amine. The IR absorptions of carbonyls are summarized in Table 5.

From a comparison of these IR absorptions of immobilized complexes with the effects of amine and triphenylphosphine shown in Table 4, it is evident that under oxo reaction conditions the rhodium–amine–carbonyl complex catalyzes the selective hydrogenation of α,β-unsaturated aldehyde to the unsaturated alcohol, while $RhCl(CO)(PPh_3)_2$ is effective only for the preferential hydrogenation of the carbon-carbon double bond to give the saturated aldehyde.

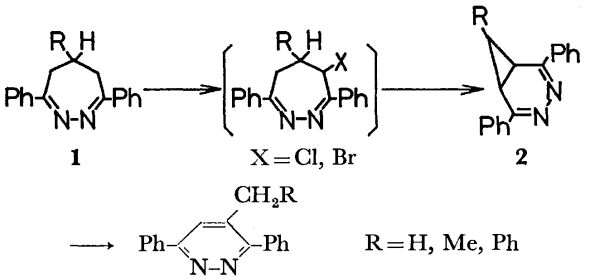
(Received January 18, 1977)

5,5-Bis(ethoxycarbonyl)-5,6-dihydro-3,7-diaryl-4*H*-1,2-diazepines (**4**) were prepared by the condensation of α-bromoacetophenone azines with diethyl malonate in the presence of sodium ethoxide. Halogenation of **4** afforded 7,7-bis(ethoxycarbonyl)-2,5-diaryl-3,4-diazanorcaradiene, 4,6-dihalodihydrodiazepines, 1-halodiazanorcaradienes, and/or 4,4,6,6-tetrachlorodihydrodiazepine, whose relative yields depended upon the reaction conditions. Dehalogenation of the halogenated products was also investigated.

It has been reported that the treatment of 3,7-diphenyl-5,6-dihydro-4*H*-1,2-diazepines (**1**) with halogenation-reagents resulted in ring contraction to pyridazines. The isolation of 3,4-diazanorcaradienes (**2**, R=H,[2)] Ph[3)]) has been cited as evidence for their intermediacy in the contraction reaction which presumably proceeds by a halogenation-dehydrohalogenation process. However, halogenated intermediates have not been isolated (Scheme 1).



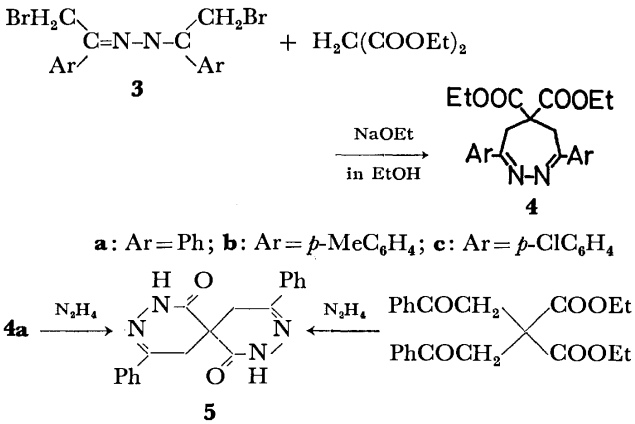
Scheme 1.

This paper is concerned with the preparation of 5,5-bis(ethoxycarbonyl)-5,6-dihydro-3,7-diaryl-4*H*-1,2-diazepines, and with their halogenations which afforded halogenated intermediates and diazanorcaradienes in good yields.

Results and Discussion

Preparation of 5,5-Bis(ethoxycarbonyl)-5,6-dihydro-3,7-diaryl-4H-1,2-diazepines (4). 5,5-Disubstituted 5,6-dihydro-4*H*-1,2-diazepines have not been reported in literature. α-Bromoacetophenone azine (**3a**)[4)] which was prepared by the bromination of acetophenone azine, would be expected to react with active methylene compounds, affording the corresponding 5,6-dihydro-4*H*-1,2-diazepines. In fact, **3a** reacted with diethyl malonate in the presence of sodium ethoxide to give the expected 5,5-bis(ethoxycarbonyl)-5,6-dihydro-3,7-diphenyl-4*H*-1,2-diazepine (**4a**). Similarly, 3,7-di(*p*-tolyl) and 3,7-bis(*p*-chlorophenyl) derivatives, **4b** and **4c**, were prepared from the corresponding azines, **3b** and **3c**, respectively.

Structural elucidation of **4** was accomplished on the basis of spectral data and the results of microanalyses,



Scheme 2.

a) All **4** are colorless prisms.

* To whom correspondence should be addressed.

which are given with the yields and melting points in Table 1.

Treatment of **4a** with hydrazine hydrate in acetic acid afforded 5,5′-spirobi(1*H*-3-phenyl-4,5-dihydropyridazin-6-one) (**5**), which was identical with an authentic sample prepared from diethyl diphenacylmalonate and hydrazine hydrate (Scheme 2).

Bromination. When **4a** was treated with an equimolar amount of bromine in methanol at room temperature, 7,7-bis(ethoxycarbonyl)-2,5-diphenyl-3,4-diazanorcaradiene (**7a**), mp 120—121 °C, was obtained in excellent yield. The reaction of **4a** with two molar amounts of bromine in methanol gave 5,5-bis(ethoxycarbonyl)-4,6-dibromo-5,6-dihydro-3,7-diphenyl-4*H*-1,2-diazepine (**8a**) and/or 1-bromo-7,7-bis(ethoxycarbonyl)-2,5-diphenyl-3,4-diazanorcaradiene (**9**); whose relative yields greatly depended upon the reaction time. That is, the reaction for 10 min gave **8a** and **9** in 83 and 16% yields respectively, whereas the reaction for 2 h exclusively produced **9**. On the other hand, the reactions of **4a** with two molar amounts of bromine in methylene dichloride, chloroform, and acetic acid, and with excess *N*-bromosuccinimide (NBS) in carbon tetrachloride did not give **8a** and **9**, but instead **7a** was only formed.

Similarly, the reaction of 3,7-di(*p*-tolyl)- **4b** and 3,7-bis(*p*-chlorophenyl)dihydrodiazepine **4c** with two molar amounts of bromine in methanol for 5 min afforded the corresponding dibromides **8b** and **8c** respectively. In these cases, the corresponding 1-bromodiazanorcaradines were not obtained.

Hydrolysis of **7a** with ethanolic potassium hydroxide afforded the half ester **10**, which on heating in ethanol or ethanol-d_1 underwent decarboxylation to give 7-*exo*-ethoxycarbonyl-2,5-diphenyl-3,4-diazanorcaradiene (**11**) or its 7-deuterio derivative **11**-d_1 respectively. When **10** was heated at 130—140 °C without solvent, ring opening occurred to yield 4-ethoxycarbonylmethyl-3,6-diphenylpyridazine (**12**) (Scheme 3).

The structures of all products, **7**—**12**, were confirmed on the basis of their spectral data.

Although the monobromide **6** has not been isolated, it is clear that the diazanorcaradienes **7a** and **9** are formed *via* internal nucleophilic displacement of the monobromide **6** and dibromide **8** respectively as delineated in Scheme 3.

Chlorination. The treatment of **4a** with an equimolar amount of sulfuryl chloride in methylene dichloride at room temperature afforded traces of an unidentified compound, together with recovery of **4a**. However, **4a** reacted with two molar amounts of sulfuryl chloride to give 5,5-bis(ethoxycarbonyl)-4,6-dichloro-5,6-dihydro-3,7-diphenyl-4*H*-1,2-diazepine (**13**) and/or 7,7-bis(ethoxycarbonyl)-1-chloro-2,5-diphenyl-3,4-diazanorcaradiene (**14**); whose relative yields depended upon the reaction time again. Further chlorination of the dichloride **13** with sulfuryl chloride afforded the 4,4,6,6-tetrachlorodihydrodiazepine **15** in good yield. The tetrachloride **15** was formed directly from chlorination of **4a** with excess sulfuryl chloride or chlorine gas. Structural elucidation of **13**—**15** was accomplished on the basis of their spectral data.

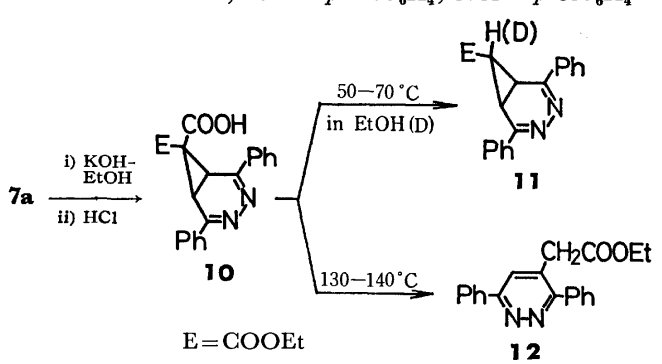
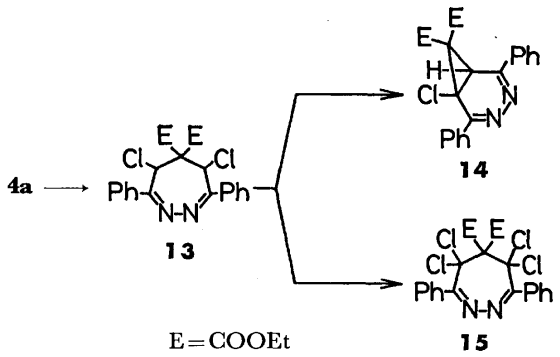


Scheme 3.



Scheme 4.

It is considered that activation of the methylene groups at positions 4 and 6 in **4** to halogenation is attributable to the electron-withdrawing azine and ethoxycarbonyl groups. As shown above. 7,7-bis(ethoxycarbonyl)diazanorcaradienes, **7**, **9**, and **14**, were isolated in good yields respectively; this fact suggests that the diazanorcaradienes are stabilized by the extended π-electron conjugation.

Dehalogenations of the Halogenated Products. When dibromides, **8a**—**8c**, were treated with sodium iodide in boiling acetone for 2 h, the corresponding diazanorcaradienes, **7a**—**7c**, were obtained in good yields. Although the dichloride **13** was unchanged under similar conditions, **13** was also converted to **7a** on prolonged heating with sodium iodide in ethanol. Similarly, treatment of the tetrachloride **15** with sodium iodide in boiling acetone afforded the 1,6-dichlorodiazanorcaradiene **16** quantitatively (Scheme 5).

Scheme 5.

Next, we have investigated the dehalogenation with zinc dust in boiling ethanol. In contrast to the above dehalogenation using sodium iodide, the dihalides, **8a** and **13**, did not give the diazanorcaradines **7a**, but instead the dihydrodiazepine **4a**, 3,6-diphenylpyridazine (**17**), and diethyl malonate were formed in the respective yields shown in Scheme 6. As illustrated in Scheme 6, these reactions proceed through two different pathways from the organozinc halide; one is direct decomposition by ethanol to give **4a**, and the other is ring contraction, followed by decomposition to afford **17** and diethyl malonate.

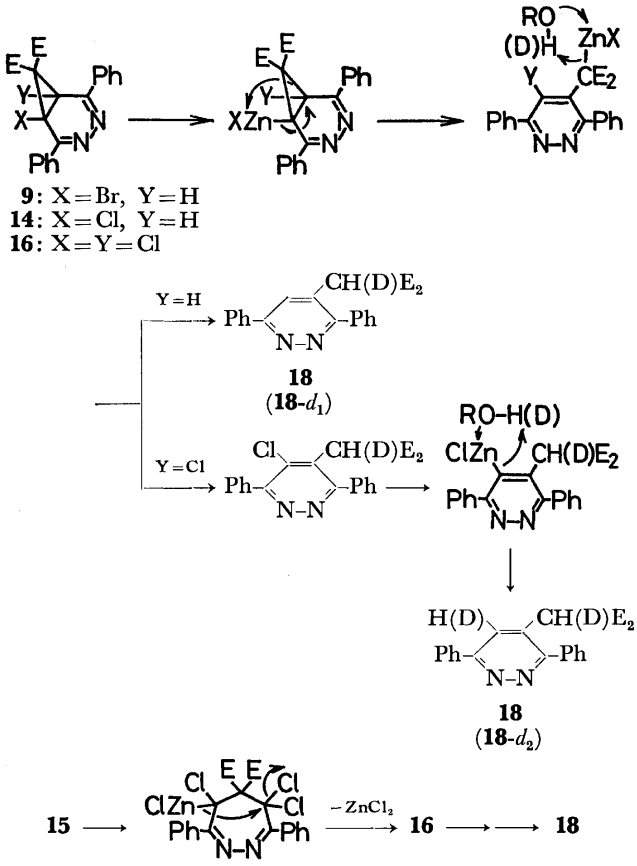
Scheme 6.

On the other hand, similar treatments of halogenated diazanorcaradienes, **9**, **14**, and **16**, afforded 4-[bis(ethoxycarbonyl)methyl]-3,6-diphenylpyridazine (**18**) in 47, 51, and 13% yields respectively. The pyridazine **18** was also obtained in 16% yield from the tetrachloride



9: X=Br, Y=H
14: X=Cl, Y=H

Scheme 7.

15. The dehalogenation of **14** and **15** with zinc dust in boiling ethanol-d_1 afforded the pyridazines, **18**-d_1 and **18**-d_2, respectively.

On the basis of the above results, the pathways for the formation of **18** from **9** and **14**—**16** are interpreted as depicted in Scheme 7.

Experimental

All the melting points are uncorrected. The NMR spectra were determined with a Hitachi R-20 Model spectrometer, with TMS as the internal standard. The IR spectra were measured as KBr disks, and the MS were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV.

α-Bromoacetophenone Azines (3). α-Bromoacetophenone azine (**3a**), mp 151—152 °C (lit,[4] mp 151—152 °C), was prepared by the bromination of acetophenone azine. Similarly, α-bromo-*p*-methylacetophenone azine (**3b**) and α-bromo-*p*-chloroacetophenone azine (**3c**) were prepared from the corresponding acetophenone azine.

3b: mp 182—183 °C; IR 1590 cm^{-1} (C=N). Found: C, 51.23; H, 4.15; N, 6.75%. Calcd for $C_{18}H_{18}N_2Br_2$: C, 51.19; H, 4.27; N, 6.63%.

3c: mp 186—187 °C; IR 1597 cm^{-1} (C=N). Found: C, 41.14; H, 2.67; N, 6.31%. Calcd for $C_{16}H_{12}N_2Br_2Cl_2$: C, 41.47; H, 2.60; N, 6.05%.

5,5-Bis(ethoxycarbonyl)-5,6-dihydro-3,7-diaryl-4H-1,2-diazepines (4). A solution of the azine **3a** (3.94 g, 0.01 mol) in benzene (50 ml) was added to a solution of diethyl malonate (3.2 g, 0.02 mol) and sodium ethoxide (1.4 g, 0.02 mol) in

ethanol (20 ml), and then the reaction mixture was refluxed for 1 h. The mixture was poured into water (100 ml) and the benzene layer was separated and evaporated *in vacuo* to leave crystals. Recrystallization from ethanol gave 3.0 g (77%) of the dihydrodiazepine **4a**.

Similarly, 3,7-di(*p*-tolyl) and 3,7-bis(*p*-chlorophenyl) derivatives, **4b** and **4c**, were prepared from the corresponding azines, **3b** and **3c**, respectively. The yields, physical data, and results of microanalyses of **4** are given in Table 1.

5,5'-Spirobi(1H-3-phenyl-4,5-dihydropyridazine-6-one) (5). A solution of the dihydrodiazepine **4a** (3.92 g, 0.01 mol) and hydrazine hydrate (1.0 g, 0.02 mol) in acetic acid (50 ml) was heated at 60—70 °C for 2 h. The mixture was poured into water (10 ml) and was allowed to stand at room temperature to give crystals. Recrystallization from ethanol gave 0.66 g (20%) of **5**, mp 315 °C (dec), as colorless prisms. NMR (pyridine-d_5) δ 3.19, 3.90 (each 2H, C**H**$_2$, J=17.4 Hz), 7.2—8.1 (10H, m, aromatic protons), 12.86 ppm (2H, br, N**H**).

Found: C, 68.78; H, 4.88; N, 17.02%. Calcd for $C_{19}H_{16}N_4O_2$: C, 68.66; H, 4.85; N, 16.86%.

The spirobipyridazinone **5** was identical with an authentic sample prepared by the following manner. A solution of diethyl diphenacylmalonate (1.33 g) and hydrazine hydrate (0.5 g) in acetic acid (10 ml) was heated at 60—70 °C for 2 h, and a similar work-up gave 0.65 g (59%) of **5**.

Bromination of the Dihydrodiazepines 4. *i*) A solution of bromine (0.8 g, 5 mmol) in methanol (40 ml) was added, drop by drop, over a period of 1 h to a suspension of the dihydrodiazepine **4a** (1.96 g, 5 mmol) in methanol (20 ml), and then the reaction mixture was stirred at room temperature for 2 h. The mixture was added to water (200 ml), and was extracted with benzene (40 ml×2). The benzene extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo* to leave crystals, which on recrystallization from petroleum ether (bp 60—80 °C) afforded 1.91 g (98%) of 7,7-bis(ethoxycarbonyl)-2,5-diphenyl-3,4-diaza-2,4-norcaradiene (**7a**), mp 120—121 °C, as yellow prisms. IR 1725, 1735 cm^{-1} (C=O); NMR ($CDCl_3$) δ 0.82, 1.35 (each 3H, t, CH_2CH_3), 3.38 (2H, s, ≥C**H**), 3.89, 4.40 (each 2H, q, C**H**$_2$Me), 7.3—7.7 (6H, m), 7.9—8.3 ppm (4H, m); MS *m/e* 390 (M^+).

Found: C, 70.79; H, 5.69; N, 7.18%. Calcd for $C_{23}H_{22}N_2O_4$: C, 70.75; H, 5.68; N, 7.18%.

Bromination of **4a** in acetic acid, chloroform, and carbon tetrachloride under similar conditions afforded **7a** in excellent yields respectively.

ii) Bromine (3.2 g, 0.02 mol) was added to a suspension of the dihydrodiazepine **4a** (3.92 g, 0.01 mol) in methanol (60 ml), and the reaction mixture was stirred at room temperature. The mixture changed to a solution and then yellow crystals separated out after about 5 min. Filtration gave crystals which were washed with methanol (30 ml). Recrystallization from ethanol afforded 4.5 g (83%) of 5,5-bis(ethoxycarbonyl)-4,6-dibromo-5,6-dihydro-3,7-diphenyl-4*H*-1,2-diazepine (**8a**), mp 150—151 °C, as yellow prisms. NMR ($CDCl_3$) δ 1.15 (6H, t, CH_2CH_3), 4.18 (4H, q, C**H**$_2$Me), 5.73 (2H, s, ≥C**H**), 7.3—7.7 (6H, m), 7.9—8.3 ppm (4H, m); MS *m/e* 548, 550, 552, 554 (M^+).

Found: C, 50.22; H, 4.04; N, 5.15%. Calcd for $C_{23}H_{22}N_2O_4Br_2$: C, 50.20; H, 4.04; N, 5.09%.

The filtrate and methanol washing were combined, poured into water (300 ml), and extracted with benzene (80 ml×2). The benzene extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo* to leave 0.74 g (16%) of crystals. Recrystallization from petroleum ether (bp 60—80 °C) afforded 1-bromo-7,7-bis(ethoxycarbonyl)-2,5-diphenyl-3,4-diazanorcaradiene (**9**), mp 133—134 °C, as yellow prisms. NMR ($CDCl_3$) δ 0.87, 1.44 (each 3H, t, CH_2CH_3), 3.88 (1H, s, ≥C**H**), 3.95, 4.54 (each 2H, q, C**H**$_2$Me), 7.3—7.7 (6H, m), 7.9—8.3 ppm (4H, m); MS *m/e* 468, 470 (M^+).

Found: C, 59.01; H, 4.52; N, 5.94%. Calcd for $C_{23}H_{21}N_2O_4Br$: C, 58.86; H, 4.51; N, 5.97%.

Similar reactions of the dihydrodiazepines **4b** and **4c** with bromine in methanol for 5 min afforded the corresponding dibromodihydrodiazepines **8b** and **8c** in 75 and 86% yields respectively.

8b: Mp 151—152 °C, yellow prisms. NMR ($CDCl_3$) δ 1.21 (6H, t, CH_2CH_3), 2.41 (6H, s, C**H**$_3$), 4.20 (4H, q, C**H**$_2$Me), 5.70 (2H, s, ≥C**H**), 7.2—8.1 ppm (8H, m).

Found: C, 51.89; H, 4.52; N, 4.85%. Calcd for $C_{25}H_{26}N_2O_4Br_2$: C, 51.92; H, 4.53; N, 4.84%.

8c: Mp 149—150 °C, yellow prisms. NMR ($CDCl_3$) δ 1.17 (6H, t, CH_2CH_3), 4.07 (4H, q, C**H**$_2$Me), 5.60 (2H, s, ≥C**H**), 7.3—8.1 ppm (8H, m).

Found: C, 44.63; H, 3.28; N, 4.50%. Calcd for $C_{23}H_{20}N_2O_4Br_2Cl_2$: C, 44.61; H, 3.26; N, 4.52%.

iii) When a mixture of **4a** (1.96 g, 5 mmol) and bromine (1.6 g, 10 mmol) in methanol (30 ml) was stirred at room temperature for 1 h, the precipitated dibromide **8a** dissolved. After the reaction mixture was stirred for another 1 h, it was evaporated *in vacuo* to leave crystals which on recrystallization from petroleum ether gave 2.31 g (98.5%) of the 1-bromodiazanorcaradiene **9**.

7-exo-Ethoxycarbonyl-2,5-diphenyl-3,4-diphenyl-3,4-diazanorcaradine (11). After a solution of the 7,7-bis(ethoxycarbonyl)-diazanorcaradiene **7a** (3.9 g) in ethanol (50 ml) was stirred with potassium hydroxide (4.0 g) at room temperature for 3 h, the mixture was acidified with dil. hydrochloric acid to give 2.5 g (70%) of the half ester **10**. A solution of the half ester **10** (1.0 g) in ethanol (5 ml) was warmed at 50—70 °C for 15 min, and then allowed to stand at room temperature, giving 0.47 g (54%) of the mono(ethoxycarbonyl)diazanorcaradiene **11**, mp 233—234 °C, as yellow needles. NMR ($CDCl_3$) δ 1.35 (3H, t, CH_2CH_3), 1.41 (1H, t, ≥C**H**, J=4.2 Hz), 3.25 (2H, d, 2×≥C**H**, J=4.2 Hz), 4.34 (2H, q, C**H**$_2$Me), 7.3—7.7 (6H, m), 7.9—8.3 ppm (4H, m); MS *m/e* 318 (M^+).

Found: C, 75.35; H, 5.61; N, 8.92%. Calcd for $C_{20}H_{18}N_2O_2$: C, 75.45; H, 5.70; N, 8.80%.

A similar treatment of **10** with ethanol-d_1 gave the 7-deuterio derivative **11**-d_1, mp 233—234 °C, in 60% yield. NMR ($CDCl_3$) δ 1.35 (3H, t, CH_2CH_3), 3.22 (2H, s, ≥C**H**), 4.43 (2H, q, C**H**$_2$Me), 7.3—7.7 (6H, m), 7.9—8.3 ppm (4H, m); MS *m/e* (rel. intensity %) 319 (M^+, 88), 318 (15), 246 (M^+−COOEt, 12).

4-Ethoxycarbonylmethyl-3,6-diphenylpyridazine (12). The half ester **10** (1.0 g) was heated at 130—140 °C (bath temperature) for 5 min, and then the residue was recrystallized from ethanol to give 0.54 g (63%) of the pyridazine **12**, mp 139—140 °C, as colorless prisms. NMR ($CDCl_3$) δ 1.20 (3H, t, CH_2CH_3), 3.72 (2H, s, C**H**$_2$), 4.15 (2H, q, C**H**$_2$Me), 7.85 (1H, s, pyridazine ring proton), 7.4—8.3 ppm (10H, m); MS *m/e* 318 (M^+).

Found: C, 75.31; H, 5.68; N, 8.72%. Calcd for $C_{20}H_{18}N_2O_2$: C, 75.45; H, 5.70; N, 8.80%.

Chlorination of the Dihydrodiazepine 4a. A solution of **4a** (1.96 g, 5 mmol) and sulfuryl chloride (1.35 g, 10 mmol) in methylene dichloride (40 ml) was stirred at room temperature for 5 min, and then the solvent was removed *in vacuo*. The residue was triturated with methanol (10 ml) and filtration gave crystals which on recrystallization from petroleum ether (bp 60—80 °C) afforded 2.97 g (64%) of 5,5-bis(ethoxycarbonyl)-4,6-dichloro-5,6-dihydro-3,7-diphenyl-4*H*-1,2-di-

azepine (**13**), mp 112—113 °C, as colorless prisms. NMR ($CDCl_3$) δ 1.15 (6H, t, CH_2CH_3), 4.18 (4H, q, CH_2Me), 5.73 (2H, s, $\geq CH$), 7.3—7.7 (6H, m), 7.8—8.3 ppm (4H, m); MS *m/e* 460, 462, 464 (M^+).

Found: C, 59.70; H, 4.78; N, 6.05%. Calcd for $C_{23}H_{22}N_2O_4Cl_2$: C, 59.88; H, 4.81; N, 6.07%.

The methanol filtrate was poured into water and extracted with benzene (40 ml×2). The benzene extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo* to give crystals. Recrystallization from petroleum ether (bp 60—80 °C) afforded 1.27 g (30%) of 7,7-bis(ethoxycarbonyl)-1-chloro-2,5-diphenyl-3,4-diazanorcaradiene (**14**), mp 130—131 °C, as yellow prisms. NMR ($CDCl_3$) δ 0.86, 1.41 (each 3H, t, CH_2CH_3), 3.88 (1H, s, $\geq CH$), 3.94, 4.50 (each 2H, q, CH_2Me), 7.3—7.7 (6H, m), 7.9—8.3 ppm (4H, m); MS *m/e* 424, 426 (M^+).

Found: C, 64.77; H, 4.92; N, 6.57%. Calcd for $C_{23}H_{21}N_2O_4Cl$: C, 65.02; H, 4.98; N, 6.59%.

The same reaction for 2 h afforded 1.87 g (88%) of **14**.

*5,5-Bis(ethoxycarbonyl)-5,6-dihydro-3,7-diphenyl-4,4,6,6-tetrachloro-4H-1,2-diazepine (**15**).* A solution of the dichloride **13** (0.46 g, 1 mmol) and sulfuryl chloride (0.27 g, 2 mmol) in methylene dichloride (10 ml) was stirred at room temperature for 2 h. The reaction mixture was evaporated *in vacuo* to leave crystals which on recrystallization from ethanol afforded 0.45 g (85%) of the tetrachloride **15**, mp 143—144 °C, as colorless prisms. NMR ($CDCl_3$) δ 1.21 (6H, t, CH_2CH_3), 4.35 (4H, q, CH_2Me), 7.3—7.7 (6H, m), 7.8—8.1 ppm(4H, m); MS *m/e* 528, 530, 532, 534, 536 (M^+).

Found: C, 51.82; H, 3.72; N, 5.22%. Calcd for $C_{23}H_{20}N_2O_4Cl_4$: C, 52.09; H, 3.81; N, 5.28%.

The tetrachloride **15** was directly obtained from chlorination of the dihydrodiazepine **4a** with excess sulfuryl chloride or chlorine gas. A solution of **4a** (1.96 g, 5 mmol) and sulfuryl chloride (2.7 g, 20 mmol) in methylene dichloride (40 ml) was stirred at room temperature for 2 h. A similar work-up of the reaction mixture as above gave 1.68 g (63%) of the tetrachloride **15**.

Chlorination of **4a** with excess chlorine gas in methanol, acetic acid, carbon tetrachloride, chloroform, and methylene dichloride afforded **15** in 45, 79, 79, 87, and 47% yields respectively.

Dehalogenation of the Dihalodihydrodiazepines with Sodium Iodide. *i*) A solution of the dibromide **8a** (1.1 g, 2 mmol) and sodium iodide (0.75 g, 5 mmol) in acetone (20 ml) was refluxed for 2 h. The reaction mixture was poured into water (100 ml) and extracted with benzene (40 ml×2). The benzene extract was washed with sodium thiosulfate aqueous solution, water, and dried over sodium sulfate, and then evaporated *in vacuo* to leave 0.76 g (97%) of the diazanorcaradiene **7a**.

Similarly, treatment of the dibromides **8b** and **8c** with sodium iodide in boiling acetone afforded 7,7-bis(ethoxycarbonyl)-2,5-di(*p*-tolyl)- (**7b**) and 7,7-bis(ethoxycarbonyl)-2,5-bis(*p*-chlorophenyl)-3,4-diaza-2,4-norcaradiene (**7c**) in 83 and 90% yields respectively.

7b: Mp 128—129 °C, yellow prisms. NMR ($CDCl_3$) δ 0.86, 1.36 (each 3H, t, CH_2CH_3), 2.45 (6H, s, CH_3), 3.35 (2H, s, $\geq CH$), 3.88 4.41 (each 2H, q, CH_2Me), 7.2—8.1 ppm (8H, m).

Found: C, 71.71; H, 6.20; N, 6.67%. Calcd for $C_{25}H_{26}N_2O_4$: C, 71.75; H, 6.26; N, 6.69%.

7c: Mp 165—166 °C, yellow prisms. NMR ($CDCl_3$) δ 0.85, 1.35 (each 3H, t, CH_2CH_3), 3.25 (2H, s, $\geq CH$), 3.85, 4.36 (each 2H, q, CH_2Me), 7.3—8.1 ppm (8H, m).

Found: C, 60.10; H, 4.36; N, 6.08%. Calcd for $C_{23}H_{20}N_2O_4Cl_2$: C, 60.14; H, 4.38; N, 6.09%.

ii) A solution of the dichloride **13** (0.92 g, 2 mmol) and sodium iodide (0.75 g, 5 mmol) in ethanol (20 ml) was refluxed for 24 h. A similar work-up as above afforded 0.75 g (96%) of the diazanorcaradiene **7a**.

*7,7-Bis(ethoxycarbonyl)-1,6-dichloro-2,5-diphenyl-3,4-diaza-2,4-norcaradiene (**16**).* A solution of the tetrachloride **15** (1.06 g, 2 mmol) and sodium iodide (0.75 g, 5 mmol) in acetone (20 ml) was refluxed for 2 h. A similar work-up as above and recrystallization of the product from petroleum ether (bp 60—80 °C) gave 0.88 g (97%) of the 1,6-dichlorodiazanorcaradiene **16**, mp 118—119 °C, as yellow prisms. NMR ($CDCl_3$) δ 0.89, 1.45 (each 3H, t, CH_2CH_3), 4.0, 4.5 (each 2H, q, CH_2Me), 7.3—7.7 (6H, m), 7.9—8.3 ppm (4H, m); MS *m/e* 458, 460, 462 (M^+).

Found: C, 60.09; H, 4.38; N, 6.15%. Calcd for $C_{23}H_{20}N_2O_4Cl_2$: C, 60.15; H, 4.38; N, 6.10%.

Dehalogenation of the Dibromide 8a with Zinc Dust. A solution of **8a** (1.1 g) in ethanol (40 ml) was refluxed with zinc dust (1.0 g) for 2 h. The reaction mixture was filtered and the residue was washed with hot ethanol (30 ml). The ethanol filtrate and washing were combined, concentrated to about 30 ml, and allowed to stand at room temperature. Filtration gave 0.2 g (43%) of 3,6-diphenylpyridazine (**17**), mp 223 °C (lit,[5] mp 222 °C), as colorless prisms. The filtrate was further concentrated to about 5 ml to give 75 mg (9.6%) of the dihydrodiazepine **4a**. The solution which was removed **4a** was chromatographed on silica gel to give 0.12 g (38%) of diethyl malonate.

A similar treatment of the dichloride **13** with zinc dust afforded the dihydrodiazepine **4a**, pyridazine **17**, and diethyl malonate; the yields are shown in Scheme 6.

*Dehalogenation of the 1-Bromodiazanorcaradiene **9** with Zinc Dust.* A solution of **9** (0.94 g) in ethanol (30 ml) was refluxed with zinc dust (1.0 g) for 2 h. A similar work-up as above afforded 0.38 g (47%) of 4-bis(ethoxycarbonyl)methyl-3,6-diphenylpyridazine (**18**), mp 131—132 °C, as colorless needles. IR 1740, 1760 cm^{-1} (C=O); NMR ($CDCl_3$) δ 1.23 (6H, t, CH_2CH_3), 4.25 (4H, q, CH_2Me), 4.93 (1H, s, $\geq CH$), 7.4—7.8 (6H, m), 8.0—8.4 (4H, m), 8.23 ppm (1H, s, pyridazine ring-H); MS *m/e* 390 (M^+).

Found: C, 70.82; H, 5.69; N, 7.21%. Calcd for $C_{23}H_{22}N_2O_4$: C, 70.75; H, 5.68; N, 7.18%.

Similarly, the chlorodiazanorcaradiene **14**, tetrachloride **15**, and dichlorodiazanorcaradiene **16** afforded the pyridazine **18** in 51, 16, and 13% yields respectively. Treatments of **14** and **15** with zinc dust in ethanol-d_1 under similar conditions afforded the pyridazines **18**-d_1 and **18**-d_2 in 54 and 13% yields respectively. **18**-d_1: NMR (DMSO-d_6) δ 1.20 (6H, t, CH_2CH_3), 4.20 (4H, q, CH_2Me), 7.4—7.8 (6H, m), 8.25 ppm (1H, s, pyridazine ring-H); MS *m/e* 391 (M^+). **18**-d_2: NMR (DMSO-d_6) δ 1.20 (6H, t, CH_2CH_3), 4.20 (4H, q, CH_2Me), 7.4—7.8 (6H, m), 8.0—8.4 ppm (4H, m); MS *m/e* 392 (M^+).

Substitution on Carbenoid Carbon of α-Halocyclopropyllithium. A Novel Stereoselective Synthesis of Geminally Substituted Cyclopropanes

Katuzi KITATANI, Hajime YAMAMOTO, Tamejiro HIYAMA, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received January 27, 1977)

The halogen atom of the title carbenoids is susceptible to displacement by butyllithium. 1-Butyl-1-lithiocyclopropanes are formed, in which the butyl group occupies the less hindered site (*trans* or *exo* position). The new reaction provides a means for the preparation of geminally disubstituted cyclopropanes with high degree of stereoselectivity.

In contrast to the view that the halogen atom on cyclopropane carbon is not easily displaced by nucleophiles,[1] it was found that the halogen atom of α-halocyclopropyllithium undergoes a displacement reaction, the process being applicable to the synthesis of *gem*-disubstituted cyclopropanes.

Addition of 1,1-dibromo-2-phenylcyclopropane (**1a**) to excess butyllithium at −95 °C, followed by aqueous work-up, afforded 1-butyl-2-phenylcyclopropane (**2a** and **3a**, 90: 10). The product distribution changes with reaction time, as shown in Fig. 1, according to Scheme 1. Apparently the decrease of the initially predominant *trans*-lithiocarbenoid **4**[2,3] is accompained by an increase of the *trans*-alkylated cyclopropyllithium **6**, whereas the concentration of the thermodynamically favored carbenoid **5** remains almost constant. The bulky phenyl substituent probably prevents the conversion of **5** into **7**. When the temperature is raised, however, the conversion occurs along with partial isomerization to **4** which would account for **6** to some extent.

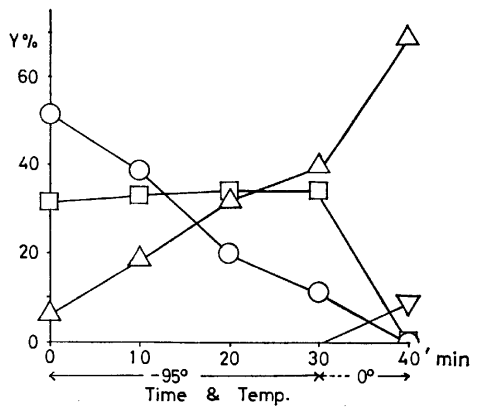

Fig. 1. Products distribution *vs.* reaction time in the reaction of **1a** with 3.3 molar eq of *n*-BuLi (as determined by GLC after methanol quenching). The reaction time was counted after completion of the addition of **1a** which required 5 min. ○: *cis*-1-Bromo-2-phenylcyclopropane corresponding to **4a**; □: *trans*-1-Bromo-2-phenylcyclopropane corresponding to **5a**; △: **2a** which corresponds to **6a**; ▽; **3a** which corresponds to **7a**.

Synthetic utility of cyclopropyllithium (**6**) and (**7**) was subsequently found in the reaction with several electrophiles. The results are summarized in Table 1. Stereoselectivity (91—100%) was excellent as compared with that (86%) obtained in the dibutylcuprate reaction.[1d] The reaction of the cyclopropyllithium with methyl iodide resulted in the formation of an iodocyclopropane **2f** in sharp contrast to the reaction of cyclopropylcopper species[1d] which afforded methylated cyclopropanes **2g** and **3g**. They were obtained by the reaction of **6** and **7** with dimethyl sulfate. Similarly **1b** afforded **2h** as the sole product.

More hindered 7,7-dibromonorcarane (**1c**) gave a mixture of *exo*-7-butylnorcarane (**2i**) and *exo*-7-bromo-

Table 1. Preparation of *gem*-disubstituted cyclopropanes

Dihalocyclopropane	R′–X	Products	Yield (%) of **2** and **3**	**2**:**3**

1c	MeOH	**2i**	24	100:0[c]

a) By-products **2a** and **3a** were obtained (see Experimental). Complete absence of **3c** isomer is attributed to the preferential protonolysis of **7** to **3a**. The proton source is still obscure. b) 1,1-Dibutyl-2-phenylcyclopropane (**8**) was also obtained. c) *exo*-7-Bromonorcarane formed as a by-product.

norcarane. The stereochemical outcome strongly suggests the large steric hindrance of the tetramethylene chain prohibiting the attack of butyl anion to the carbenoid of type **5** and the large barrier in the configurational isomerization of carbenoid **5** to **4**.

Extension of the reaction of **4** and **5** with anionic species other than butyl anion was not successful with the exception of that of lithium phenylthiolate complexed with tetramethylethylenediamine which afforded *trans*-1-phenyl-2-phenylthiocyclopropane (**9**) in 25% yield.

Experimental

All the temperatures are uncorrected. The IR spectra were obtained on a Shimadzu spectrometer 27-G, MS on a Hitachi RMU-6L, and PMR on JEOL JNM-PMX 60, Varian EM-360, or Varian HA-100D spectrometer. Butyllithium from Aldrich Chemical Co. Ltd. was used. Tetrahydrofuran (THF) was dried on benzophenone ketyl and freshly distilled before use. Tetramethylethylenediamine was dried on KOH and distilled. All the reactions were performed under nitrogen atmosphere. The cold bath was prepared by mixing liquid nitrogen with a solvent (−95 °C: toluene; −126 °C: methylcyclohexane).

1-Butyl-2-phenylcyclopropanes (2a and 3a).[3] *A Standard Procedure*: A solution of **1a** (0.40 g, 1.5 mmol) in THF (3 ml) was cooled to −78 °C and added to a stirred solution of *n*-BuLi (3.7 ml of 1.33 M in hexane, 5.0 mmol) in THF (30 ml) at −95 °C during 5 min. After 30 min the cold bath was removed and the reaction mixture was rapidly warmed to 0 °C in 10 min. This procedure is pertinent to the preparation of **2a**—**g** and their isomers if any. Work-up followed by preparative TLC (silica gel, hexane, R_f 0.7—0.8) afforded a mixture of **2a** and **3a** (0.20 g, 80% yield). Each isomer was identified by comparison of spectral data with those of authentic sample.

1-Butyl-1-deuterio-2-phenylcyclopropanes (2b and 3b). Addition of deuterium oxide (0.1 ml) to cyclopropyllithium (**6**) and (**7**) followed by work-up and preparative TLC (silica gel, hexane, R_f 0.7—0.8) afforded a mixture of **2b** and **3b** (0.20 g, 76% yield, 73% deuterium content). Bp 65—68 °C (bath temp)/15 Torr; IR (neat): 1605, 1495, 1455, 1370, 1025, 745, 695 cm^{-1}; MS: *m/e* (%), 175 (M^+, 16), 174 (M^+−1, 8), 119 (68), 117 (100), 104 (93), 91 (38); PMR (CCl_4): δ 0.5—2.0 (m, 12H), 6.7—7.5 (m, 5H, Ph).

1-Butyl-r-1-trimethylsilyl-c-2-phenylcyclopropane (2c). Addition of Me_3SiCl (0.24 g, 2.3 mmol) to the reaction mixture obtained from **1a** (0.42 g, 1.5 mmol) and 5.0 mmol of *n*-BuLi, followed by work-up and preparative TLC (silica gel, hexane, R_f 0.7—0.8), afforded **2c** (0.17 g, 46%). Bp 106—111 °C (bath temp)/3 Torr; IR (neat): 1600, 1490, 1245, 1030, 835, 780, 755, 730, 700 cm^{-1}; MS: *m/e* (%), 246 (M^+, 5), 172 (49), 129 (35), 117 (60), 104 (69), 73 (100); PMR (CCl_4): δ −0.30 (s, 9H, Me_3Si), 0.5—1.8 (m, 11H), 1.97 (dd, J=6, 8 Hz, 1H, PhC<u>H</u>), 7.1—7.3 (m, 5H, Ph). Found: C, 78.1; H, 10.9%. Calcd for $C_{16}H_{26}Si$: C, 78.0; H, 10.6%. By-products **2a** (7%) and **3a** (7%) were also obtained.

r-*1-Benzoyl-1-butyl-c-2-phenylcyclopropane (2d).* Dibromocyclopropane (**1a**) (0.41 g, 1.5 mmol) was subjected to the reaction with *n*-BuLi as above. Benzoyl chloride (0.35 g, 2.5 mmol) was then added. Work-up and preparative TLC (silica gel, hexane–ether 20:3, R_f 0.5—0.6) afforded **2d** (0.19 g, 45%). Mp 69.5—70.5 °C (hexane); IR (Nujol): 1660, 1455, 1064, 785, 770, 715, 690 cm^{-1}; MS: *m/e* (%), 278 (M^+, 17), 235 (36), 105 (100), 91 (18), 77 (47); PMR (CCl_4): δ 0.5—2.6 (m, 12H), 6.7—7.7 (m, 10H). Found: C, 86.6; H, 8.2%. Calcd for $C_{20}H_{22}O$: C, 86.3; H, 8.0%. By-products were **2a** (7%) and **3a** (6%).

1-Butyl-r-1-methylthio-c-2-phenylcyclopropane (2e). Quenching the cyclopropyllithium (**6** and **7**) with dimethyl disulfide (0.21 g, 2.3 mmol) and work-up afforded **2e** (0.18 g, 55% yield). A small amount of its stereoisomer **3e** was detected by GLC and identified by MS. Physical properties of **2e**: bp 120—124 °C (bath temp)/3 Torr; IR (neat): 1600, 1495, 1030, 770, 700 cm^{-1}; MS: *m/e* (%), 222 (M^++2, 1.5), 220 (M^+, 21), 205 (30), 173 (100), 129 (71), 115 (79); PMR (CCl_4): δ 0.7—1.7 (m, 11H), 1.66 (s, 3H, SMe), 2.13 (dd, J=6, 7 Hz, 1H, PhC<u>H</u>), 7.0—7.3 (m, 5H, Ph). Found: C, 75.7; H, 9.4%. Calcd for $C_{14}H_{20}S$: C, 76.0; H, 9.6%.

1-Butyl-r-1-iodo-c-2-phenylcyclopropane (2f).[3] Iodine (0.46 g, 1.8 mmol) in THF (2 ml) was added to the cyclopropyllithium prepared as above, and the resulting mixture was stirred at 0 °C for 1 h and subjected to work-up. Preparative TLC (silica gel, hexane, R_f 0.5—0.6) of the crude product afforded **2f** (0.26 g, 59% yield) besides 2,2-dibutyl-1-phenylcyclopropane (**8**) (38 mg, 10%).

Treatment of the cyclopropyllithium with excess methyl iodide (1 ml) at 0 °C gave **2f** (58%) and **8** (14%).

1-Butyl-1-methyl-2-phenylcyclopropanes (2g and 3g).[3] Dibromocyclopropane **1a** (0.28 g, 1.0 mmol) was treated with 3.3 mmol of *n*-BuLi and then dimethyl sulfate (0.20 g, 1.5 mmol). Work-up and preparative TLC (silica gel, hexane, R_f 0.7—0.8) afforded an oil (0.15 g). The ratio of **2g** to **3g** was estimated by GLC assay (10% HVSG on Celite 545, 122 °C, 0.8 kg/cm^2, naphthalene as an internal standard).

c-*2-Benzyloxymethyl-r-1-butyl-1-methylcyclopropane (2h).*[3] To *n*-BuLi (2.5 ml of 1.98 M hexane solution, 5.0 mmol) in THF (20 ml) was added a cooled solution of **1b** (0.48 g, 1.5 mmol) in THF (2 ml) at −95 °C. After 30 min the reaction mixture was warmed rapidly to 0 °C. Dimethyl sulfate (0.21 ml, 2.3 mmol) was then added. Work-up and preparative TLC afforded **2h** (0.14 g, 40%).

exo-*7-Butylnorcarane (2i).*[4] A cooled solution (−78 °C) of **1c** (0.25 g, 0.99 mmol) in a mixture[5] of THF–ether–hexane (50:5:18, 3 ml) was added to a solution of *n*-BuLi (1.7 ml, of 1.92 M in hexane, 3.2 mmol) in the same solvent mixture (22 ml) at −126 °C. After 7 h the reaction mixture was quenched with methanol and subjected to work-up affording

2i (24% yield by GLC, R_f (hexane) 0.8—0.9); bp 90—100 °C (bath temp)/20 Torr; IR (neat): 1450, 1370, 1112, 1064 cm^{-1}; MS: *m/e* (%), 152 (M^+, 12), 109 (24), 95 (51), 81 (65), 67 (100), 55 (46), 41 (51); PMR (CCl_4): δ 0.4—0.6 (m, 3H), 0.6—2.1 (m, 17H). By-product, *exo*-7-bromonorcarane,[6] was also obtained (53% yield by GLC, R_f (hexane) on silica gel TLC 0.7—0.8).

trans-*1-Phenyl-2-phenylthiocyclopropane (9)*. The dibromocyclopropane **1a** (0.41 g, 1.5 mmol) in THF (3 ml) was added to a THF (15 ml) solution of *n*-BuLi (0.82 ml of 1.95 M hexane solution, 1.6 mmol) and tetramethylethylenediamine (0.19 g, 1.6 mmol) cooled to *ca.* −95 °C Subsequently a THF (10 ml) solution of PhSLi (3.3 mmol, prepared from thiophenol and *n*-BuLi)[7] and tetramethylethylenediamine (0.42 g, 3.6 mmol) which had been cooled to −78 °C was added dropwise in a period of 8 min. After 30 min the whole was allowed to warm to 0 °C and then worked up. Preparative TLC (silica gel, hexane, R_f 0.3—0.4) of the crude product afforded **9** (85 mg, 25%). Bp 100—105 °C (bath temp)/1 Torr; IR (neat): 1603, 1582, 1493, 1480, 1085, 1020, 733, 685 cm^{-1}; MS: *m/e* (%), 228 (M^++2, 1.8), 226 (M^+, 30), 115 (100), 109 (8), 91 (49), 77 (98); PMR (CCl_4): δ 1.1—1.6 (m, 2H), 2.0—2.4 (m, 2H,) 6.9—7.3 (m, 10H). Found: C, 79.4; H, 6.2%. Calcd for $C_{15}H_{14}S$: C, 79.6; H, 6.2%.

Financial support (Grant-in-Aid No. 185188) by the Ministry of Education, Japanese Govenment, is acknowledged.

Substituent Effects on Dissociation Constants of *trans*-3-Hydroxy-6-styryl-4-pyrones

Hiromichi Besso,* Kimiaki Imafuku, and Hisashi Matsumura

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received February 18, 1977)

The dissociation constants of 6-substituted 3-hydroxy-4-pyrones and *trans*-6-(substituted styryl)-3-hydroxy-4-pyrones were measured spectrophotometrically in 50% aqueous methanol at 25 °C. The results are correlated to the substituent constants σ, the following equations being obtained: $pK_a = 8.57 - 1.53\sigma$ and $pK_a = 8.54 - 0.23\sigma$. The transmission coefficient through the styryl group was found to be 0.150 for the 3-hydroxy-6-styryl-4-pyrone system.

Choux and Benoit[1] measured the dissociation contants of 6-substituted 3-hydroxy-4-pyrones in water at 25 °C, and obtained the following Hammett equation:

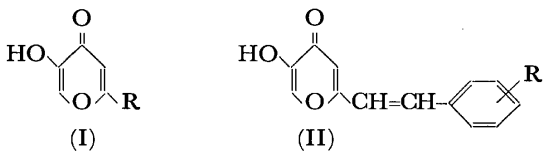
$$pK_a = 8.01 - 1.63\sigma \quad (r=0.978). \qquad (1)$$

However, little is known about the substituent effects for 3- or 5-hydroxy-4-pyrones. We report herewith on the substituent effects of 3-hydroxy-4-pyrones having styryl groups in the 6-position.

Studies were made on the substituent effects on dissociation constants of 4- and 5-styryltropolones.[2,3] The transmission of electronic effects from one aromatic ring to another through the ethylene linkage between them has been investigated in detail. It is of interest to compare the reaction constants of 4- and 5-styryltropolones with that of 3-hydroxy-6-styryl-4-pyrones. We found that the electronic effects of substituents in the benzene ring are transmitted through the ethylene linkage to 4-pyrone nucleus, the effects being comparable to those of 4-hydroxystilbenes.

Results and Discussion

Dissociation Constants. The dissociation constants of 6-substituted 3-hydroxy-4-pyrones (I) and 6-(substituted styryl)-3-hydroxy-4-pyrones (II) were determined spectrophotometrically in 50% aqueous methanol at 25 °C. The results are summarized in Tables 1 and 2.



(I) (II)

Ia R=H IIa R=H IIe R=*p*-Cl
Ib R=CH_3 IIb R=*p*-OCH_3 IIf R=*m*-NO_2
Ic R=COOH IIc R=*p*-CH_3 IIg R=*p*-NO_2
Id R=CH_2Cl IId R=3′,4′-$(OCH_3)_2$

Table 2. Dissociation constants of 6-(substituted styryl)-3-hydroxy-4-pyrones

No.[a]	R	σ[b]	pK_a
1	*p*-OCH_3	−0.27	8.60
2	*p*-CH_3	−0.17	8.58
3	3′,4′-$(OCH_3)_2$	−0.15	8.57
4	H	0.00	8.55
5	*p*-Cl	0.23	8.52
6	*m*-NO_2	0.71	8.37
7	*p*-NO_2	0.78 (1.27)[c]	8.26

a) Numbers correspond to those in Fig. 1.
b) Ref. 5. c) σ^- Value.

The pK_a values of these 4-pyrones are smaller than those of phenols ($pK_a = 10.02$ for phenol),[4] since the carbonyl group of 4-pyrones causes a decrease in the pK_a values by its electron withdrawing effect.

Substituent Effects. The pK_a values of 6-substituted 3-hydroxy-4-pyrones (I) and 6-(substituted styryl)-3-hydroxy-4-pyrones (II) were plotted against the Hammett substituent constants σ.[5,6] As an example, the Hammett plot of the latter is shown in Fig. 1. The following Eqs. 2 and 3 were obtained by the least squares method for systems (I) and (II), respectively (except for the *p*-nitro group in Eq. 3).

$$pK_a = 8.57 - 1.53\sigma \quad (r=0.998), \qquad (2)$$

$$pK_a = 8.54 - 0.23\sigma \quad (r=0.983). \qquad (3)$$

The plot of the *p*-nitro group deviates from the straight line given by Eq. 3 (Fig. 1). The deviation might be

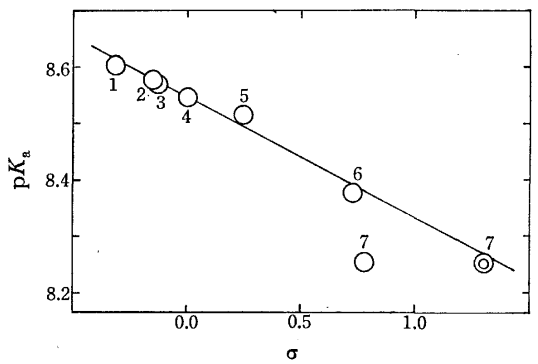

Fig. 1. The Hammett plot of pK_a's of 3-hydroxy-6-styryl-4-pyrones.
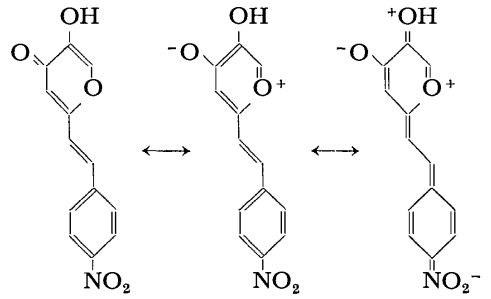
◎; Plotted against σ^- (1.27).

* Present address: Wakunaga Pharmaceutical Co., Ltd., Koda-machi, Takata-gun, Hiroshima 729-64.

attributed to the resonance interaction between the *p*-nitro group and the hydroxyl group in the 3-hydroxy-4-pyrone. Application of the σ^--value (1.27)[6] for the *p*-nitro group gives good linearity (Fig. 1). A similar resonance effect was also observed in the dissociation of *trans-p*-nitro-4-hydroxystilbene.[7] In 4- and 5-styryltropolones, the resonance effect might be present only in 5-styryltropolones, but this was not confirmed since 5-(*p*-nitrostyryl)tropolone was not available.



Reaction Constants. The reaction constants of 6-substituted 3-hydroxy-4-pyrones (I) and 6-(substituted styryl)-3-hydroxy-4-pyrones (II) are 1.53 and 0.23, respectively. These values are comparable to those of phenols (2.55)[8] and 4-hydroxystilbenes (0.37),[7] respectively. The reaction constant of 3-hydroxy-6-styryl-4-pyrones lies between 0.13 and 0.60 constants of 4- and 5-styryltropolones, respectively. The difference can be attributed to the tautomerism of tropolones.

Transmission Coefficients. When the reaction constants for the same reaction of two series of aromatic compounds, which are parents, and styryl-substituted compounds are denoted by ρ_M and ρ_S, respectively, the transmission coefficient π of the styryl group can be defined as follows:

$$\pi = \rho_S/\rho_M.$$

The transmission coefficients π for several systems are given in Table 3. The π-value of 3-hydroxy-6-styryl-4-pyrone system is 0.150, and comparable to that of 4-hydroxystilbenes. We found that the electronic effects of the substituents in the benzene ring are transmitted through the styryl group in the order, 4-styryltropolones <4-hydroxystilbenes≒3-hydroxy-6-styryl-4-pyrones< 5-styryltropolones.

Experimental

All the melting points were measured on a Yanagimoto micromelting point apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, and the NMR spectra on a Hitachi-Perkin-Elmer R-24 spectrometer (60 MHz).

The pK_a values of 4-pyrones were measured spectrophotometrically in 50% aqueous methanol at 25 °C by the method of Albert and Serjeant.[9] The UV spectra were taken on a Hitachi EPS-3T spectrophotometer, while the pH values were measured with a Hitachi-Horiba F-7 pH meter.

Materials. All 6-substituted 3-hydroxy-4-pyrones were prepared according to the method given in references: Ia, mp 117—118 °C (lit,[10] 118 °C); Ib, mp 152 °C (lit,[11] 152—153 °C); Ic, mp 270 °C (lit,[12] 273—274 °C); Id, mp 166—167 °C (lit,[13] 166—167 °C).

6-(Substituted styryl)-3-hydroxy-4-pyrones were obtained by the Wittig reaction. Phosphonium salt was prepared by the reaction of 5-hydroxy-2-chloromethyl-4-pyrone[13] with triphenylphosphine in benzene, 58% yield. Phosphonium salt (1.1 mmol) and benzaldehyde (1 mmol) were added to a sodium ethoxide (2 mmol) solution, and the resulting mixture was stirred for 2 h at room temperature under nitrogen atmosphere. After 2 M hydrochloric acid had been poured into the reaction mixture, the products were extracted with chloroform. Chloroform was evaporated off and the residue was chromatographed on silica gel column [Wakogel C-100 (60 g) and B-10 (10 g)] with chloroform to afford 3-hydroxy-6-styryl-4-pyrones, which were recrystallized from benzene. The yields, mp's spectral and analytical data are as follows: IIa; Yield, 34%; mp 183—185 °C; IR (KBr) 3180, 1660, 970 cm^{-1}; NMR ($CDCl_3$) δ: 7.85 (s, 1H), 7.7—7.2 (m, 6H), 6.66 (d, 1H, J=17.3 Hz), 6.45 (s, 1H), 8.3—7.6 (br, 1H). Found: C, 73.18; H, 4.77%. Calcd for $C_{13}H_{10}O_3$: C, 72.89; H, 4.71%. IIb: Yield, 32%; mp 187.5—189 °C; IR (KBr) 3100, 1655, 975 cm^{-1}; NMR ($CDCl_3$) δ: 7.79 (s, 1H), 7.35 (d, 1H, J=15.3 Hz), 7.5—6.8 (m, 4H), 6.49 (d, 1H, J=15.3 Hz), 6.36 (s, 1H), 3.82 (s, 3H), 8.0—7.5 (br, 1H). Found: C, 68.98; H, 4.95%. Calcd for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%. Preparation of Perfluoroalkylated Benzoheterocyclic Compounds Using Hexafluoro-1,2-epoxypropane

Nobuo Ishikawa and Shigekuni Sasaki

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 22, 1977)

Utilizing the high reactivity of hexafluoro-1,2-epoxypropane (HFPO, hexafluoropropylene oxide), several new benzoheterocyclic compounds containing CF_3 and C_2F_5 were prepared as follows: (1) 2-(pentafluoroethyl)benzoxazoles by treating 2-aminophenols with HFPO/Et_3N, followed by dehydrating cyclization, (2) 3-(trifluoromethyl)-2*H*-1,4-benzoxazin-2-ones, 3-(trifluoromethyl)-2(1*H*)-quinoxalinone and 2-fluoro-2-(trifluoromethyl)-2,3-dihydro-1,4-benzothiazin-3-one by reactions of ortho-bifunctional benzenes with HFPO, and (3) 2-(pentafluoroethyl)-4*H*-3,1-benzoxazin-4-one by treating anthranilic acid with HFPO/Et_3N.

A number of heterocyclic compounds containing a perfluoroalkyl group, especially CF_3, are known pharmaceutically and agrochemically.[1] However, knowledge of the structure of this kind of compound is limited, because the introduction of a perfluoroalkyl group into a heterocyclic ring is usually not easy.[2,3]

On the other hand, it is well known that nucleophiles readily attack the central carbon atom of HFPO, resulting in the formation of α-substituted tetrafluoropropionyl fluoride, which further reacts with an additional molecule of the nucleophile, forming an ester or an amide,[4-6] thus

$$CF_3\text{-}\underset{\diagdown O \diagup}{CF}\text{-}CF_2 \xrightarrow[(-F^-)]{Nu^-} CF_3\text{-}\underset{Nu}{CF}\text{-}CF{=}O \xrightarrow[(-F^-)]{Nu^-} CF_3\text{-}\underset{Nu}{CF}\text{-}\overset{O}{\overset{\diagup}{C}}\diagdown Nu,$$

where NuH=ROH, RSH, or RNH_2.

HFPO is also known to isomerize to pentafluoropropionyl fluoride under the action of a base.[7] The present authors have reported a convenient preparative method for esters and amides of pentafluoropropionic acid by reactions of HFPO and alcohols, thiols or amines in acetonitrile in the presence of triethylamine,[8] thus

$$HFPO \xrightarrow{Base} CF_3CF_2CF{=}O$$

$$HFPO + R\text{-}XH \xrightarrow{Et_3N} CF_3CF_2\text{-}\underset{O}{\overset{\|}{C}}\text{-}XR,$$

where X=O, S, NH. They have also reported that non-fluorinated carboxylic acids are readily converted into their fluorides by treating them in a HFPO-triethylamine system,[9] thus

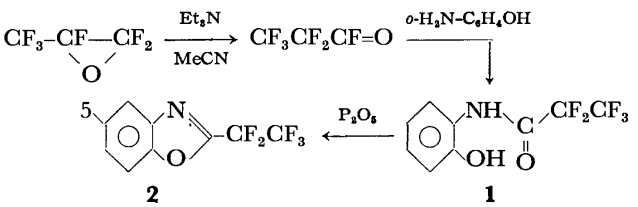
$$HFPO + \underset{O}{\overset{\|}{R}}COH \xrightarrow{Et_3N} C_2F_5CO_2H + \underset{O}{\overset{\|}{R}}CF.$$

The reactivities of HFPO described above were applied to the preparation of benzoheterocyclic compounds and several kinds of new heterocyclic compounds which contain a trifluoromethyl or a pentafluoroethyl group were obtained.

Results and Discussion

Preparation of 2-(Pentafluoroethyl)benzoxazoles. According to the method of preparation for pentafluoropropionyl amides,[8] 2-(pentafluoropropionylamino)phenol (**1**) was obtained in a good yield by the reaction between *o*-aminophenol and HFPO–triethylamine in acetonitrile. The structure of **1** was evident from its IR and ^{19}F NMR data. In the IR spectrum, a broad band due to an OH group, and a characteristic band due to the C=O of an amide group were observed at 3320 and 1695 cm^{-1}, respectively. In the ^{19}F NMR spectrum two signals due to CF_3 and CF_2 groups appeared at 6.0 and 45.3 ppm.*

The dehydrating ring closure of **1** was carried out by heating in diphosphorus pentaoxide at 200—230 °C, affording 2-(pentafluoroethyl)benzoxazole (**2**) in an 84% yield. In the IR spectrum of this compounds, the characteristic absorption bands for **1** due to OH and C=O disappeared, and a new band due to C=N appeared at 1615 cm^{-1}.

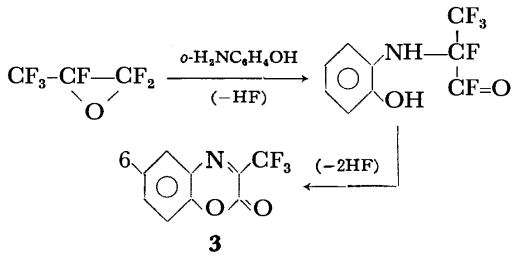


2-Amino-4-methyl- and 2-amino-4-chlorophenols, containing an electron donor or attractive group on the benzene ring, also gave 5-substituted 2-(pentafluoroethyl)benzoxazoles by a similar procedure. Although a number of 2-trifluoromethylbenzoxazoles are known,[10] no 2-pentafluoroethyl derivatives have been reported in the literature, The synthetic route described here appears to be a useful method for preparing this kind of compound.

Preparation of 3-(Trifluoromethyl)-2H-1,4-benzoxazin-2-ones, 3-(Trifluoromethyl)-2(1H)-quinoxalinone and 2-Fluoro-2-(trifluoromethyl)-2,3-dihydro-1,4-benzothiazin-3-one. When 2-aminophenol was allowed to react with HFPO in dioxane, without any base, it readily gave 3-(trifluoromethyl)-2*H*-1,4-benzoxazin-2-one (**3**) in an 85% yield, together with a small amount (7%) of 2-(pentafluoropropionylamino)phenol (**1**).** The reaction must be as follows:

* All the ^{19}F-chemical shifts throughout this article are given in δ ppm upfield from external trifluoroacetic acid.

** These yields are based on the ^{19}F-NMR signal intensities.



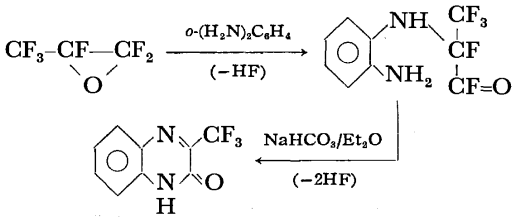
3

Thus, the amino group of *o*-aminophenol first attacks the central carbon atom of HFPO, as usual, and the resulting fluoroformyl group condensed with the ortho hydroxy group forming an oxazine ring. On the other hand, pentafluoropropionyl fluoride, formed by the isomerization of HFPO, pentafluoropropionated 2-aminophenol giving a small amount of **1**. When acetonitrile was used as the solvent, **3** and **1** were formed in yields of 45 and 22%, respectively. This probably means that the ionic isomerization of HFPO is accelerated by the polar solvent.

The structure of **3** was established from its spectral data. In the ^{19}F NMR spectrum, only one singlet signal was observed at −6.9 ppm, which means that there are no hydrogen or fluorine atoms around the CF_3 group. The IR spectrum indicates a characteristic band at 1765 cm^{-1} due to ester bonding, and the mass spectrum showed the expected parent peak at *m/e* 215.

6-Methyl- and 6-chloro-3-(trifluoromethyl)-2*H*-1,4-benzoxazin-2-ones were also obtained in good yields from 2-amino-4-methyl- and 2-amino-4-chlorophenols, respectively.

Like 2-aminophenol, *o*-phenylenediamine with HFPO gave another heterocyclic compound. In this case, however, more isomerization of HFPO to pentafluoropropionyl fluoride occurred becauseof the higher basicity of phenylenediamine compared to 2-aminonophenol. Thus, the reaction between *o*-phenylenediamine and HFPO in dioxane gave only a 30% yield of 3-(trifluoromethyl)-2(1*H*)-quinoxalinone (**4**). Then using diethyl ether as a solvent, together with sodium hydrogencarbonate to remove the hydrogen fluoride formed, the yield was increased to 84%. Bases stronger than sodium hydrogencarbonate were not used because they accelerate the isomerization of HFPO, and lower the yield of **4**.



4

The structure of **4** was also elucidated from spectral data (Table 1).

o-Aminobenzenethiol and HFPO in *N,N*-dimethylacetamide provided another heterocyclic compound, 2-fluoro-2-(trifluoromethyl)-2,3-dihydro-1,4-benzothiazin-3-one (**5**). The mercapto group, which is more nucleophilic than the amino group, first attacked the central carbon atom of HFPO, and an intramolecular

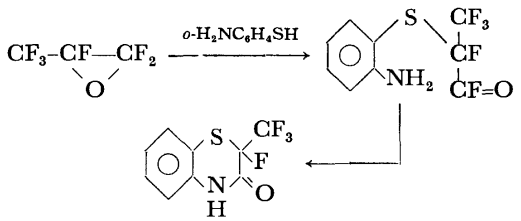
a) Upfield from external CF_3CO_2H.

amide linkage was subsequently formed.

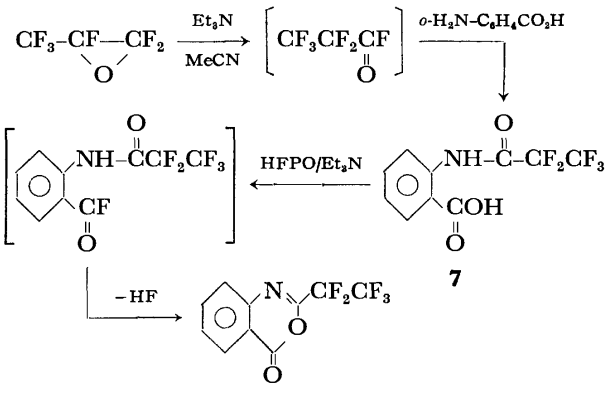


5

When dioxane or acetonitrile was used instead of *N,N*-dimethylacetamide, the formation of another product, which appeared to contain only a CF_3 group, was observed in the ^{19}F NMR spectrum. This compound was not isolated for identification.

In the ^{19}F NMR spectrum for **5**, two signals, a doublet and a quartet were observed, the mutual coupling constant being $J=10.2$ Hz. This indicates that a fluorine atom and a trifluoromethyl group are geminally attached to one carbon atom.

Preparation of 2-(Pentafluoroethyl)-4H-3,1-benzoxazin-4-one. The reaction of anthranilic acid with two molar amounts of HFPO in acetonitrile, in the presence of triethylamine, afforded 2-(pentafluoroethyl)-4*H*-3,1-benzoxazin-4-one (**6**) in a good yield. The reaction proceeded as follows:



7

6

When an equimolar amount of HFPO was used in this reaction, 2-(pentafluoropropionylamino)benzoic acid (**7**) was obtained.

The structures of these products were obvious from their spectra (Table 1). In particular, in the IR spectrum of **7**, the characteristic bands due to OH and NH groups appeared over 2400—3500 and at 3250 cm^{-1}, respectively, which were not observed in the spectrum of **6**.

Experimental

2-(Pentafluoropropionylamino)phenol (1). 2-Aminophenol (2.18 g, 20 mmol), triethylamine (2.02 g, 20 mmol) and acetonitrile (20 ml) were placed in a glass pressure vessel, which was then cooled to −75 °C in a Dry Ice–acetone bath. Liquefied HFPO (3.32 g, 20 mmol) was introduced into the vessel, and the whole system was brought to room temperature. After stirring for 30 min at that temperature, the reaction mixture was poured into water (200 ml) and the precipitated material was collected by filtration. By treating the precipitate with dilute aqueous hydrochloric acid to remove any basic material, crude 2-(pentafluoropropionylamino)phenol, (mp 113—116 °C, 4.02 g, 79%) was obtained. Recrystallization from benzene gave a pure product, mp 116.5—118 °C. When 2-amino-4-methyl- and 2-amino-4-chlorophenol was used instead of unsubstituted 2-aminophenol, 4-methyl- and 4-chloro-2-(pentafluoropropionylamino)phenols were obtained (Table 1), respectively.

2-(Pentafluoroethyl)benzoxazole (2). A mixture of 2-(pentafluoropropionylamino)phenol (2.55 g, 10 mmol) and diphosphorus pentaoxide (2.84 g, 20 mmol) in a distilling flask was heated gently to 220 °C. An oily product having a boiling point of 166—167 °C was distilled out, and an additional amount of the product was obtained by vacuum distillation of the residue. Almost pure 2-(pentafluoroethyl)benzoxazole (2.00 g, 84%) was thus obtained.

Following a similar procedure, 5-methyl and 5-chloro derivatives of **2** were obtained from 2-(pentafluoropropionylamino)-4-methyl- and -4-chlorophenols, respectively (Table 1).

3-(Trifluoromethyl)-2H-1,4-benzoxazin-2-one (3). Into a pressure vessel containing 2-aminophenol (1.09 g, 10 mmol) and dioxane (20 ml), liquefied HFPO (1.91 g, 11.5 mmol) was introduced as described above. After 3 h of stirring at room temperature, the reaction mixture was thrown into water, and the precipitated product was collected by filtration. An additional amount of the product was obtained from the filtrate by extraction with diethyl ether. Crystallization of the combined material from hexane gave a crude product (1.42 g, 66%), which was purified by recrystallization, mp 77—78 °C.

From 4-methyl- and 4-chloro-2-aminophenols, 6-substituted derivatives of **3** were obtained by the same procedure (Table 1).

3-(Trifluoromethyl)-2(1H)-quinoxalinone (4). A mixture of *o*-phenylenediamine (1.08 g, 10 mmol) and sodium hydrogen carbonate (2.54 g, 30 mmol) in diethyl ether (30 ml) was allowed to react with HFPO (2.09 g, 12.6 mmol) for 3 h at room temperature. A solid product was separated by filtration, washed with water, and dried to give crude benzodiazinone (1.27 g), mp 230—232 °C. Concentration of the parent solution yielded an additional product (0.53 g), mp 232—233.5 °C. The combined material (1.80 g, 84%) was recrystallized from benzene to give pure **4**, mp 233—234.5 °C.

2-Fluoro-2-(trifluoromethyl)-2,3-dihydro-1,4-benzothiazin-3-one (5). 2-Aminophenol (2.50 g, 20 mmol) in *N,N*-dimethyl acetamide (20 ml) was allowed to react with HFPO (3.82 g, 2.3 mmol) for 3 h at room temperature. The reaction mixture was poured into water and extracted with diethyl ether. The extract was washed with water, dried over magnesium sulfate and concentrated. The residue was recrystallized from benzene, yielding crude crystals of **5** (1.29 g, 26%), mp 177—178 °C. Further crystallization gave pure material, mp 181.5—182.5 °C.

2-(Pentafluoropropionylamino)benzoic Acid (7). Anthranilic acid (2.74 g, 20 mmol) and triethylamine (2.02 g, 20 mmol) in acetonitrile (20 ml) were allowed to react with HFPO (3.03 g, 18.3 mmol) in the usual manner. After 15 min of stirring at room temperature, the reaction mixture was poured into water and the precipitate formed was separated by filtration. By washing the precipitate with dilute aqueous hydrochloric acid, a crude product (2.53 g) was obtained. An additional amount of the product (1.13 g) was obtained by extraction of acidified aqueous layer with diethyl ether. The combined material was recrystallized from benzene, providing **7** (3.62 g, 70%), mp 166—169 °C. Further crystallization gave a pure product, mp 168—169 °C.

*2-(Pentafluoroethyl)-4*H*-3,1-benzoxazin-4-one* (**6**). (*a*): Anthranilic acid (1.37 g, 10 mmol) and triethylamine (3.03 g, 30 mmol) in acetonitrile (20 ml) were allowed to react with HFPO (3.40 g, 20.5 mmol) for 30 min at room temperature. The reaction mixture was worked up as usual. The residue from an ether extract was treated with pentane, and the insoluble material was removed by filtration. Evaporation of the solvent yielded a crude product (2.37 g, 89%), which was recrystallized to give pure material, mp 48—49 °C. (*b*): 2-(Pentafluoropropionylamino)benzoic acid (2.83 g, 10 mmol) and triethylamine (2.02 g, 20 mmol) in acetonitrile (15 ml) were allowed to react with HFPO (1.84 g, 11.1 mmol) as usual. The reaction mixture was worked up to give crude 2-(pentafluoroethyl)-4*H*-3,1-benzoxazin-4-one (2.45 g, 92%), mp 46—48 °C.

The Absolute Configuration of Sepiapterin

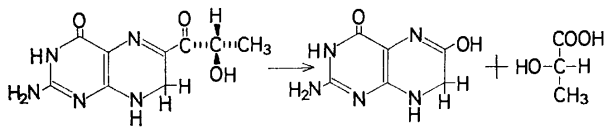
Sadao MATSUURA, Takashi SUGIMOTO, and Motoo TSUSUE*

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464
**Biological Laboratory, Kitasato University, Sagamihara City 228*

(Received March 31, 1977)

The absolute configuration of sepiapterin was determined to be 2-amino-7,8-dihydro-6-(*S*)-lactoyl-4(3*H*)-pteridinone from an analysis of the L-lactic acid produced from sepiapterin by oxidation cleavage in a sodium borate solution.

Sepiapterin, the yellow pigment contained in the eye of *Drosophila melanogaster*, was first isolated in 1954 by Forrest and Mitchel[1] and later by Viscontini and Möhlman[2] from a *sepia* mutant of the insect. Structural elucidation by Nawa[3] revealed the pigment to be 2-amino-7,8-dihydro-6-lactoyl-4(3*H*)-pteridinone (I). Sepiapterin possesses a chiral carbon at the 2-position of the side chain and has been found to be optically active,[2,4] as expected. Although no optically-active sepiapterin has been synthesized (with the exception of the recent work of Pfleiderer, see below), its racemate was produced by an unusual method starting from 2-amino-7,8-dihydro-4(3*H*)-pteridinone and 3-hydroxy-2-oxobutanoic acid.[5] It has been found that, of the



I

racemic sepiapterin isomers, only the enantiomer with the same configuration as naturally occurring sepiapterin is reduced by sepiapterin reductase.[5] However, from these results, it was not possible to reach a final determination of the configuration. Recently, Pfleiderer reported that the oxidation of 5,6,7,8-tetrahydrobiopterin yielded sepiapterin, which was found to be identical with natural sepiapterin in every respect, and thus, the configuration of the chiral carbon of sepiapterin was determined to be the (*S*)-configuration, the same as for biopterin.[7]

In this paper, an alternative approach for determining the absolute structure of sepiaterin is reported, which involves cleavage of the lactoyl group to lactic acid. Sepiapterin is known to undergo oxidative degradation to give lactic acid and 7,8-dihydroxanthopterin in a 4% sodium borate solution under aerobic conditions.[3] Since the 2-position of the side chain is not involved in the degradation reaction, its configuration is maintained throughout the reaction. Thus, it is possible to determine the absolute configuration of sepiapterin by examining the configuration of the lactic acid produced.

First, the oxidative degradation reaction was reinvestigated under a variety of conditions. It was found that sepiapterin remained practically unchanged in a phosphate buffer at pH 10.0. However, it was converted to 7,8-dihydroxanthopterin fairly slowly in a 4% sodium borate solution, as has been reported.[3] This reaction was found to be markedly enhanced by the addition

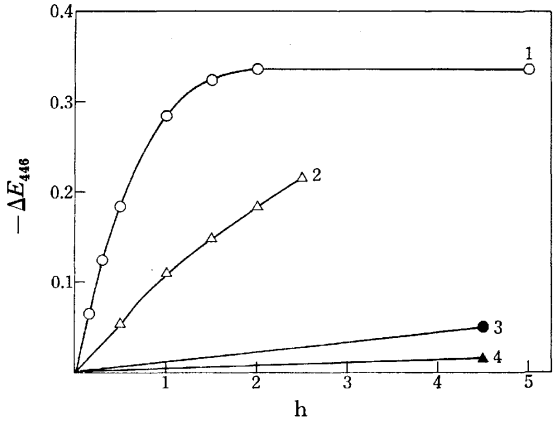


Fig. 1. Oxidative degradation of sepiapterin at 25 °C under aerobic conditions in the dark place. The initial concentration of sepiapterin was 50 μM and the reaction was monitored by reading the absorbance at 446 nm.
1: In 4% sodium borate containing cupric sulfate (25 μM).
2: In 4% sodium borate containing sodium hydroxide (0.1 M).
3: In 4% sodium borate.
4: In a 0.05M phosphate buffer at pH 10.0.

of sodium hydroxide or more effectively by a trace amount of copper(II) sulfate. This reaction was conveniently monitored spectroscopically (see Fig. 1).

Both L- and D-lactic acids can be assayed using an enzymatic method with L- and D-lactic acid dehydrogenases (LDH and D-LDH), respectively.[8] Therefore, the experimental conditions were examined using the enzymatic method in order to determine the lactic acid produced during the degradation reaction. This method employs NAD (nicotinamide-adenine dinucleotide) as a hydrogen acceptor; the amount of lactic acid can be calculated from the increment of the absorbance at 340 nm (ΔE_{340}). It was observed that the LDH activities were hindered by borate ions present in the solution (see Fig. 2), probably because the cofactor NAD is masked by borate ions due to the formation of a complex at the ribosyl moiety. However, the hindrance effects disappear upon the addition of an excess amount of D-ribose to the solution prior to the addition of NAD and the enzyme (Fig. 2).

Using the present method, a 1.03 ± 0.01 molar amount of L-lactic acid and no D-lactic acid were detected from the degradation solution of sepiapterin.

From these data, it is evident that the configuration at the chiral 2-position of the side chain of sepiapterin is

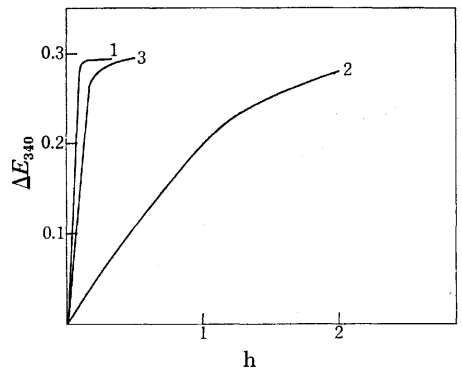

Fig. 2. Effects from borate ions and D-ribose on the dehydrogenation of L-lactic acid by a LDH–NAD system. The reaction was carried out at 25 °C in an assay solution composed of a glycine–hydrazine buffer (800 μl), 50 mM NAD (50 μl), 1 mM DL-lactic acid (100 μl), LDH (5 mg/ml; 10 μl), and distilled water (50 μl) or 4% sodium borate (50 μl).
1: In the absence of sodium borate and D-ribose.
2: In the presence of sodium borate (4%; 50 μl).
3: In the presence of sodium borate (4%; 50 μl) and D-ribose (10 mg).

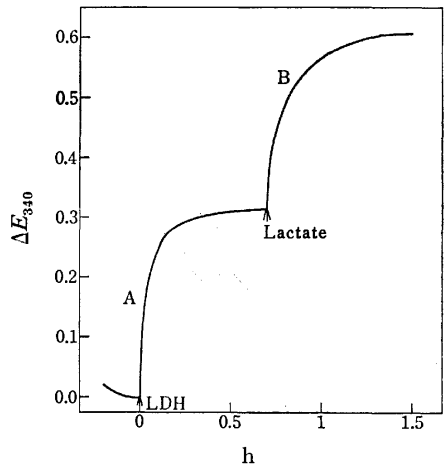

Fig. 3. Determination of L-lactic acid by a LDH–NAD system. First, the acid contained in 50 μl of the oxidative degradation solution (equivalent to 50 μmol of sepiapterin) was dehydrogenated by the system (curve A). When the reaction was complete (40 min), 50 μmole of lithium L-lactate was added (curve B) (for details, see experimental).

the (*S*)- or L-configuration as shown in the formula (I). The present conclusion is consistent with that of Pfleiderer.[7]

Experimental

Sepiapterin was obtained from *D. melanogaster sepia* by a method previously described.[4] NAD, LDH (EC.1.1.1.27; from rabbit muscle; 5 mg/ml, 550 U/mg), and D-LDH (EC. 1.1.1.28; from *Lactobacillus leichmanni*; 1 mg/ml, 300 U/mg) were purchased from Boehringer Mannheim.

Oxidation Degradation of Sepiapterin. A solution of sepiapterin (0.290 mg) in 4% sodium borate (1.22 ml; the concentration of sepiapterin was 1.00 mM) was stirred in air in the dark at 25 °C for 48 h. The sepiapterin degradated to 7,8-dihydroxanthopterin which was further oxidized to xanthopterin by air during the reaction. After completion of the reaction, the solution was adjusted to exactly 1.22 ml with water and used directly for the analysis of lactic acid.

Determination of L-Lactic Acid. The assay solution was composed of a glycine–hydrazine buffer (100 ml contains 7.5 g of glycine, 5.2 g of hydrazine sulfate, 0.2 g of EDTA $Na_2H_2 \cdot 2H_2O$, 51 ml of 2M-NaOH, and water to make the solution 100 ml; 840 μl), D-ribose (10%; 100 μl), NAD (50 mM; 50 μl), and 50 μl of the above reaction solution (equivalent to 50.0 μmol of sepiapterin). The assay solution was placed in both the sample and reference quartz cells which were maintained at 25 °C by a thermostatically-controlled cell holder. Then, to the sample cell was added 10 μl of LDH (5 mg/ml, 550 U/mg), and the increment of the absorbance at 340 nm (ΔE_{340}) was recorded. Within 40 min, the reaction was complete and the ΔE_{340} was found to be 0.305 (ΔE^1). Then, 50 μl of a lithium L-lactate solution (1.00 mM; equivalent to 50.0 μmol) was added to the sample cell. In about the same time as above, an additional ΔE_{340} of 0.296 (ΔE^2) was observed (Fig. 3). The amount of L-lactic acid contained in 50 μl of the oxidative degradation solution (equivalent to 50.0 μmol of sepiapterin) was determined using the following calculation:

$$\frac{0.305(\Delta E^1)}{0.296(\Delta E^2)} \times 50.0\ \mu\text{mol} = 51.5\ \mu\text{mol}.$$

By repeating the same procedures several times, it was concluded that 1.03 ± 0.01 mol of L-lactic acid was produced from sepiapterin. When D-LDH was used in place of LDH in the above procedures, no appreciable increase in absorbance at 340 nm was observed.

The Intramolecular Hydrogen Abstraction Reaction in the Photolysis of Aminated 1,4-Naphthoquinones

Kazuhiro MARUYAMA, Tadashi KOZUKA, and Tetsuo OTSUKI

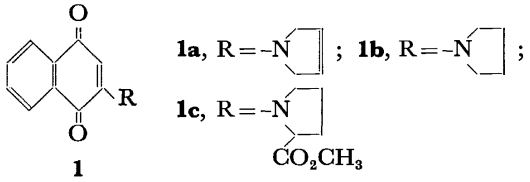
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received February 14, 1977)

Photolysis of aminated 1,4-naphthoquinones **1a**—**c** in liquid phase was investigated. After photolysis and successive autoxidation, 2-(3-pyrrolin-1-yl)-1,4-naphthoquinone **1a** gave 2-(1-pyrrolyl)-1,4-naphthoquinone **3** quantitatively. However, in the reaction, 2-(1-pyrrolydinyl)-1,4-naphthoquinone **1b** and 2-(2-methoxycarbonyl-1-pyrrolidinyl)-1,4-naphthoquinone **1c** afforded the corresponding hetero-ring opened products; 2-(4-oxobutylamino)-1,4-naphthoquinone **5** and 2-(4-methoxycarbonyl-4-oxobutylamino)-1,4-naphthoquinone **8** in good yields. Possible mechanisms for the formation of **3**, **5**, and **8** are presented.

The photochemistry of aminoquinones having a β-aminoenone grouping (–N–C=C–C=O) in the molecule is of interest from the synthetic viewpoint of antibiotics such as mytomycin and streptrigrin, but only a few investigations have been made.[1-3]

We describe herewith the synthesis and photochemistry of quinones **1**.

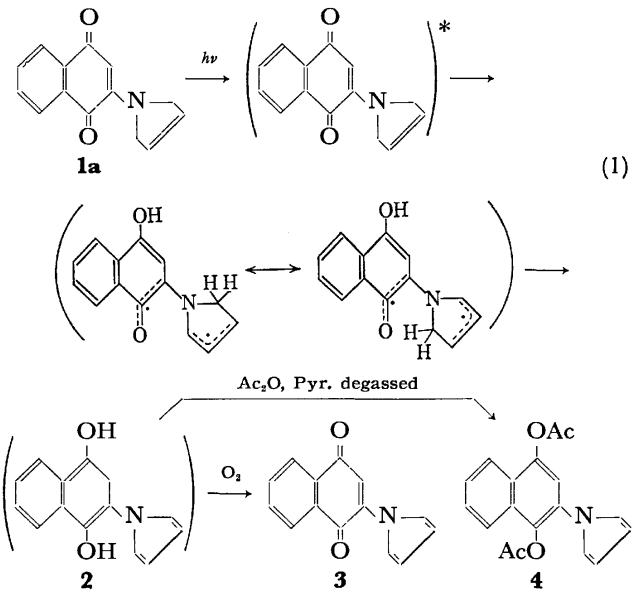


Results and Discussion

Compounds **1a**—**c** were prepared from the corresponding amines and 1,4-naphthoquinone by standing overnight in methanol. After purification by column chromatography and recrystallization, the spectral data of all the aminated 1,4-naphthoquinones were found to be consistent with the assigned structures.

Photolysis of 2-Aminated 1,4-Naphthoquinones ***1a—c.*** Irradiation of a solution of the quinone **1a** (8.88×10^{-3} M) in benzene for 1 h and bubbling the resulting solution with air for several minutes gave quinone **3** quantitatively. The ^{1}H-NMR spectrum ($CDCl_3$) of **3** showed two characteristic triplets, centered at 7.31(2H) and 6.42(2H) ppm. The quinone vinyl singlet, 6.84(1H) ppm, shifted to the lower field, suggesting the presence of 1-substituted pyrrole ring. Compound **3** was identified by comparison with the authentic sample prepared by dehydrogenation of **1a** with Pd–C.

The photochemical process was followed by measuring the UV spectrum of degassed benzene solution of **1a** during the course of irradiation. As the reaction proceeds the absorbance of the peak at 276 and 460 nm diminishes and the peak at 318 and 332 nm increases, exhibiting isosbestic points at 302 and 342 nm (Fig. 1). On the other hand, we examined the same reaction by ^{1}H-NMR spectrometry irradiating of a degassed C_6D_6 solution of **1a**. The examination revealed that the reaction proceeded quite smoothly. As the methylene and olefinic protons of 3-pyrroline ring diminish, two characteristic triplets due to the pyrrole ring protons and phenolic hydroxy protons (2H) grow. This indicates that an unstable compound **2** is produced in the reaction. Unstable **2** was trapped as its diacetate **4** by treatment with acetic anhydride in pyridine under degassed conditions. It was confirmed that the change in concentration of reactant **1a** (<0.2 M) gave no essential change on the course of reaction. Thus, the reaction of **1a** to **2** can be explained by a mechanism involving initial intramolecular hydrogen abstraction by carbonyl, followed by subsequent free rotation of C–N bond and secondary intramolecular hydrogen transfer as shown by Eq. 1.



(1)

Aminated quinone **1b** dissolved in benzene (2.20×10^{-3} M, for 1.5 h) is also highly photosensitive. After the usual work-up **1c** gave **5** (78%), together with small amount of **3** (2%) and **6** (3%). The structure of **5** was compatible with its spectral data; ν_{NH}: 3340, ν_{CO}: 1720 cm^{-1}; ^{1}H-NMR: 6.00 (br s, 1H, NH), 9.77 (s, 1H, CHO) ppm. Treatment of **5** with methanolic hydrogen chloride yielded acetal **7**. Structure **3** was confirmed by the spectral data and comparison with the authentic sample. The structure **6** was assigned on the basis of the spectral data, but compound **6** is unstable against light in solution. When the solution, after UV irradiation of **6** in chloroform, was left to stand overnight under contact with air, the color of solutions turned light yellow from purple red, the absorption spectrum of **6**

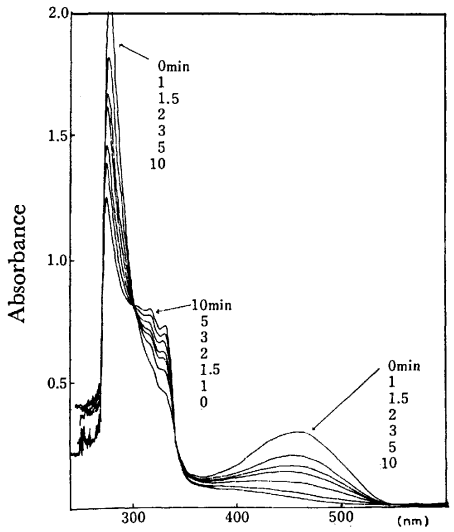


Fig. 1.

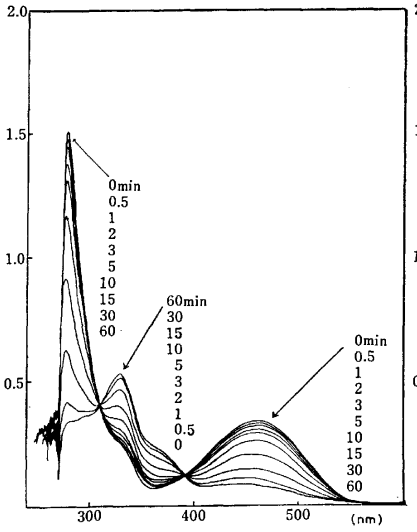

Fig. 2.

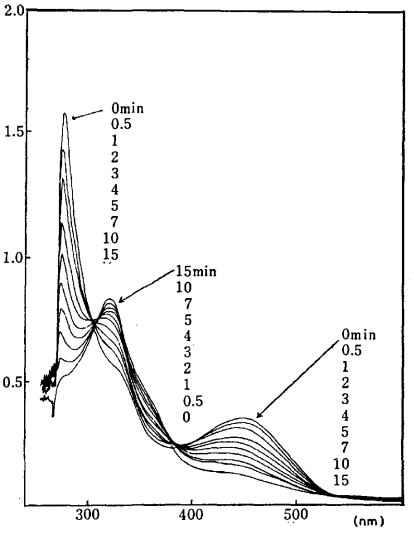

Fig. 3.

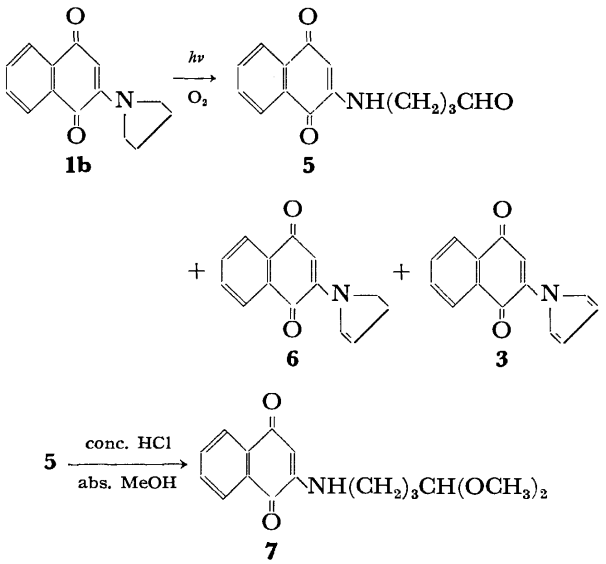
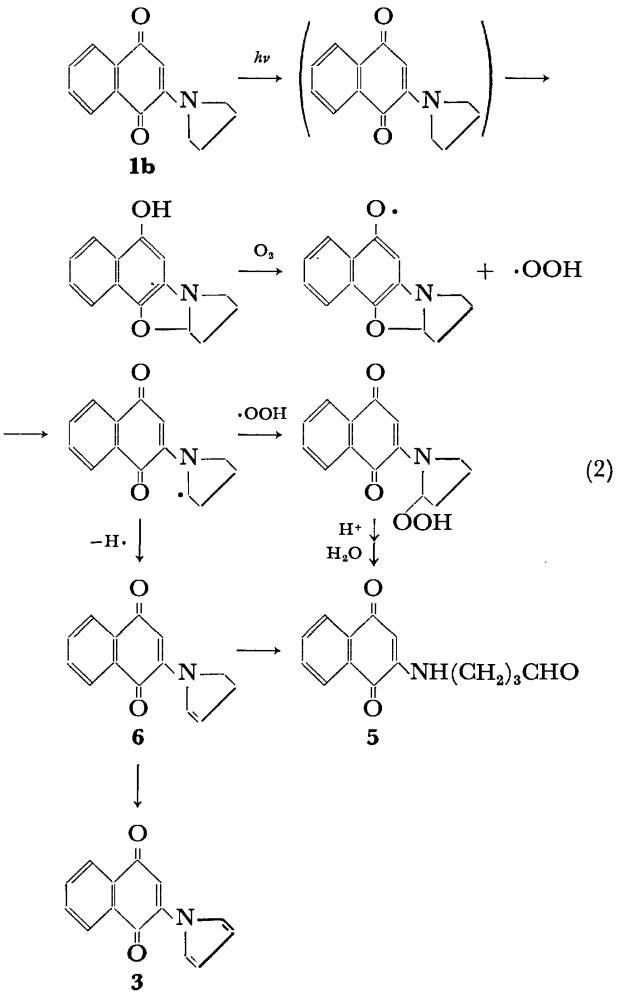
UV spectra of **1a**—**c**(benzene), before irradiation and during irradiation. A strictly degassed solution of **1a**—**c** was irradiated in a UV cell (1 cm×1 cm) by high pressure Hg arc lamp (300 W) through VY-42 glass filters (1 cm×3). In this experiment a glass filter was employed to eliminate the light of wavelength shorter than 400 nm.

(λ_{max}: 520 nm) disappearing, and new peaks corresponding to **3** and **5** appearing at 256, 270, and 441 nm. Presumably compound **6** changes to **3** and **5** by photolysis followed by air oxidation.



Photolysis of **1b** in degassed benzene was followed by UV spectroscopy. The orange yellow solution finally became colorless. Two isosbestic points at 309 and 392 nm appeared, indicating that the reaction is simple and clean (Fig. 2). The first order kinetic plot of the reaction showed a straight line (Fig. 4). When the reaction vessel was opened and aerated with bubbling of air, the solution turned yellow. The UV spectrum of the resulting solution was essentially the same as that of the benzene solution of **5**, λ_{max} (benzene): 278 and 440 nm (log ε: 4.24 and 3.52). Apparent maximum absorption of UV spectrum of the final solution is at



(2)

λ_{max} (benzene): 330 nm (log ε: *ca.* 3.8). From the results the photolysis of **1b** and successive air-oxidation

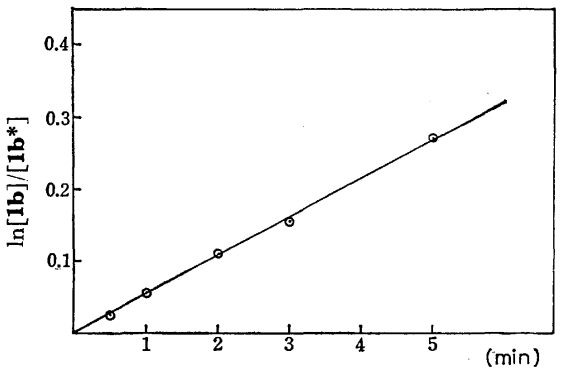


Fig. 4. First order kinetic plot in the photolysis of **1b** (solvent: benzene).
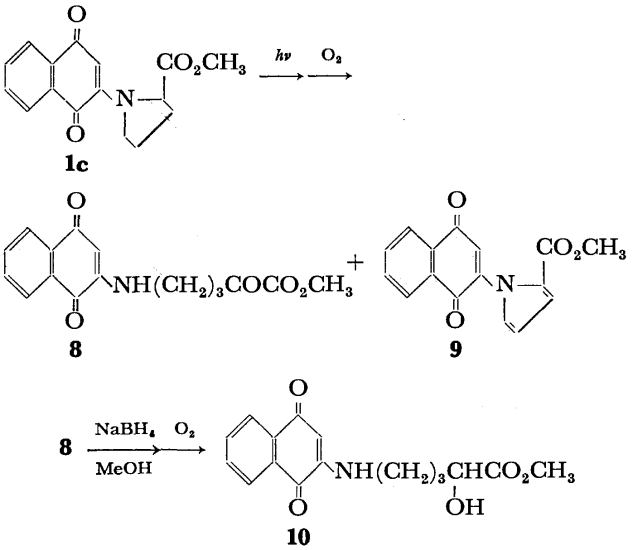
[**1b**]; absorbance(at 460 nm) before irradiation of **1b**.
[**1b***]; absorbance(at 460 nm) during irradiation of **1b**.

can be formulated as shown in Eq. 2. However, the detailed mechanism for the hetero-ring opening still remains unclarified.

Compounds **8** and **9** were obtained in 30 and 6%, respectively, after irradiation of **1c** (2.50×10^{-3} M) in benzene for 3 h and subsequent aeration. Structures **8** and **9** were assigned on the basis of their spectral data. Compound **8** was reduced to **10** by treatment with sodium borohydride in methanol.

Photolysis of **1c** in deaerated benzene was also followed by UV spectroscopy. No isosbestic point was observed during the course of reaction, suggesting that the reaction is complex (Fig. 3). This is in line with the lower yield of the identified products.



Experimental

Photolysis of 1a. A benzene solution of 2-(2-pyrrolin-1-yl)-1,4-naphthoquinone **1a**[4] (8.88×10^{-3} M) was irradiated without degassing with a high pressure Hg arc lamp through water layer. Aeration of the solution after 1 h gave 2-(1-pyrrolyl)-1,4-naphthoquinone **3** quantitatively; mp 164.5—164.7 °C. IR (KBr); 1670 cm^{-1}. Mass: *m/e*=223 (M^+). ^{1}H-NMR ($CDCl_3$); 6.43 (t, 2H), 6.84 (s, 1H), 7.31 (t, 2H), 7.71, 8.08 (m, 4H) ppm. UV max ($CHCl_3$); 256, 305, 395 nm (log ε: 4.31, 3.95, 3.54). Found: C, 75.03; H, 3.87; N, 6.09%. Calcd for $C_{14}H_9O_2N$: C, 75.32; H, 4.06; N, 6.28%.

During the course of irradiation the ^{1}H-NMR spectra of **1a** in degassed C_6D_6 indicated the formation of single product; *i.e.*, highly oxygen-sensitive compound **2**, which was identified by the subsequent acetylation with acetic anhydride–pyridine under degassed conditions as diacetate **4** (86%); mp 138—139 °C. IR (KBr); 1755 cm^{-1}. Mass: *m/e*=309 (M^+). ^{1}H-NMR ($CDCl_3$): 2.30 (s, 3H), 2.46 (s, 3H), 6.32 (t, 2H), 6.95 (t, 2H), 7.37, 7.57, 7.91 (m, 5H) ppm. Found: C, 69.61; H, 4.94; N, 4.68%. Calcd for $C_{18}H_{15}O_4N$: C, 69.89; H, 4.89; N, 4.53%.

Photolysis of 1b. By irradiating (1.5 h) of dry benzene solution of 2-(1-pyrrolidinyl)-1,4-naphthoquinone **1b**[5] (2.20×10^{-3} M) with a high pressure Hg arc lamp through a filter solution of 5,7-dimethyl-2*H*-3,6-dihydro-1,4-diazepine perchlorate, three products **5**, **6**, and **3** were isolated: 2-(4-oxobutylamino)-1,4-naphthoquinone **5** (78%): mp 146—147 °C. IR (KBr); 3340, 2825, 2725, 1680 cm^{-1}. Mass: *m/e*=243 (M^+). ^{1}H-NMR ($CDCl_3$); 2.04 (m, 2H), 2.63 (t, 2H), 3.23 (m, 2H), 5.69 (s, 1H), 6.00 (br s, 1H), 7.64, 8.02 (m, 4H), 9.77 (s, 1H) ppm. UV max ($CHCl_3$); 243, 270, 337, 441 nm (log ε: 4.07, 4.33, 3.50, 3.51). Found: C, 68.60; H, 5.33; N, 5.30%. Calcd for $C_{14}H_{13}O_3N$: C, 69.12; H, 5.39; N, 5.76%. 2-(2-Pyrrolin-1-yl)-1,4-naphthoquinone **6** (3%); mp 141—143 °C. IR (KBr); 1660, 1613, 1586, 1550 cm^{-1}. Mass: *m/e*=225 (M^+). ^{1}H-NMR ($CDCl_3$); 2.72 (tdd, 2H), 3.79 (t, 2H), 5.46 (m, 1H), 5.73 (s, 1H), 7.88 (m, 1H), 7.68, 8.01 (m, 4H) ppm. UV max ($CHCl_3$); 243, 250, 273, 520 nm (log ε: 4.08, 4.09, 4.29, 3.67). 2-(1-Pyrrolyl)-1,4-naphthoquinone **3** (2%): *vide supra.*

Acetalization of **5** gave 2-(4,4-dimethoxybutylamino)-1,4-naphthoquinone **7** (75%): mp 91—93 °C. IR (KBr); 3330, 1685 cm^{-1}. ^{1}H-NMR ($CDCl_3$); 1.74 (m, 4H), 3.22 (m, 2H), 3.35 (s, 6H), 4.38 (t, 1H), 5.71 (s, 1H), 6.06 (br s, 1H), 7.66, 8.05 (m, 4H) ppm. UV max ($CHCl_3$); 242, 271, 330, 440 nm (log ε 3.79, 4.06, 3.23, 3.20).

Photolysis of 1c. A chloroform solution of 2-(2-methoxycarbonyl-1-pyrrolydinyl)-1,4-naphthoquinone **1c**[6] (2.50×10^{-3} M) was irradiated with a high pressure Hg arc lamp through a filter solution of copper(II) sulfate. After irradiation for 3 h, two products, **8** and **9**, were isolated: 2-(4-Methoxy carbonyl-4-oxobutylamino)-1,4-naphthoquinone **8** (30%) mp 181—183 °C. IR (KBr); 3330, 1730, 1676 cm^{-1}. Mass: *m/e*=301 (M^+). ^{1}H-NMR ($CDCl_3$); 2.01 (m, 2H), 3.04 (t, 2H), 3.30 (q, 2H), 3.92 (s, 3H), 5.78 (s, 1H), 6.00 (br s, 1H), 7.07, 8.08 (m, 4H) ppm. UV max ($CHCl_3$); 242, 270, 331, 444 nm (log ε: 4.11, 4.35, 3.53, 3.49). Found: C, 63.91; H, 4.87; N, 4.69%. Calcd for $C_{16}H_{15}O_2N$: C, 63.78; H, 5.02; N, 4.65%. 2-(2-Methoxycarbonyl-1-pyrrolyl)-1,4-naphthoquinone **9** (6%): mp 116—120 °C. IR (KBr); 1708, 1687 cm^{-1}. Mass: *m/e*=281 (M^+). ^{1}H-NMR ($CDCl_3$); 3.74 (s, 3H), 6.40 (m, 1H), 6.90 (m, 1H), 7.12 (m, 1H), 6.86 (s, 1H), 7.79, 8.14 (m, 4H) ppm. UV max ($CHCl_3$); 248, 254, 298 (log ε: 4.20, 4.20, 3.63).

The reduction of **8** with sodium borohydride gave 2-(4-hydroxy-4-methoxycarbonylbutylamino)-1,4-naphthoquinone **10** (74%): mp 126—127 °C. IR (KBr); 3515, 3345, 1735, 1725, 1680 cm^{-1}. Mass: *m/e*=303 (M^+). ^{1}H-NMR ($CDCl_3$); 1.86 (m, 4H), 3.26 (q, 2H), 3.81 (s, 3H), 4.24 (br s, 1H), 5.72 (s, 1H), 6.06 (br s, 1H), 3.05 (br s, 1H), 7.65, 8.04 (m 4H) ppm. UV max ($CHCl_3$); 242, 271, 330, 445 (log ε: 4.19, 4.42, 3.69, 3.63).

Intramolecular Catalytic Substitution Reaction of *N*-(ω-Bromoalkyl)-pyridinium Bromide with Potassium Cyanide

Masahide YAMADA, Tohru SAKAKIBARA, Tetsuyoshi TAKAMOTO, and Rokuro SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 24, 1976)

It was found by means of NMR spectrometric and potentiometric titration technique that the intramolecular catalytic substitution of *N*-(ω-bromoalkyl)pyridinium bromide with KCN proceeds in the range $n=2$—6 of methylene chain on the pyridinium salt and the intermolecular substitution in $n=7$ and 9, and the addition of cyanide anion to the pyridine ring takes place only for $n=1$.

Our recent interest has been focused on the reaction selectivity resulting from the conversion of a bimolecular into an intramolecular reaction in view of entropy point. In the enzymatic reaction involving a typical intramolecular catalytic process, the formation of an adsorptive complex of enzymes with an appropriate substrate results in high reaction selectivity through a favorable orientation of reaction site on the catalytic center. Thus a substrate severely constrained in the complex should be a good model of the activated key-intermediates for our study.

The counter-anion of quaternary ammonium and phosphonium salts has been shown to behave as a nucleophile in phase-transfer catalyzed reaction.[1] When a reaction site and a nucleophile are involved in a quaternary salt at the same time, an intramolecular substitution might take place smoothly at the reaction site with significant interactions to the quaternary center.[2] In this paper we wish to report the reaction of pyridinium salts having a general formula $Py^+(CH_2)_n$-$CH_2Br \cdot Br^-$ ($n=1$—9) with potassium cyanide in aqueous solution.

The key-intermediary pyridinium salts (**1a**—**1h**) were prepared by the direct quaternization of pyridine with a series of the corresponding α,ω-dibromoalkanes. Successful induction of reactions of these salts with potassium cyanide, sodium acetate, and sodium azide was proved by IR and/or NMR spectroscopy. Since NMR spectroscopic studies have shown that methylene protons bearing a cyano group can be clearly recognized at higher field, potassium cyanide was used as a nucleophile for examining details of the substitution. The reaction of pyridinium salts (0.5 mol/l) with potassium cyanide (0.55 mol/l) in deuterium oxide at 64.5 °C was monitored by NMR spectroscopy with regard to the changing intensities at δ 3.2—3.4 (CH_2Br) and 2.6—2.8 (CH_2CN). Since the series of the substitution product, *N*-(ω-cyanoalkyl)pyridinium bromide, is too hygroscopic for isolation and characterization, one of them (**3b**) was immediately treated with sodium borohydride[3] to give *N*-(3-cyanopropyl)-1,2,3,6-tetrahydropyridine.

In order to let an intramolecular reaction take place, a very dilute solution is used. With respect to the amount of cyanide anion left during the course of reactions, potentiometric titration was employed for tracing in the 0.02 mol/l concentration scale since it has much sharper responses than in NMR spectrometry. As shown in Fig. 1, the rate of the substitution reaction decreases along with the sequence **1e**≈**1f**≥**1h**≈**1g**≥**1d**≈**1c**≈**1b** as in the NMR study. In the case of **1a** ($n=1$), however, addition of cyanide anion to the pyridine ring took place, since the unstable product[4] obtained in chloroform–water system only was no longer a quaternary salt as confirmed on the basis of the absorption band of cyano group and C–C double bond in the IR spectrum. Such a difference between **1a** and **1b**—**1h** can be explained as follows. It is very hard for a four-membered cyclic intermediate to form on **1a** for the intramolecular catalytic substitution; in addition quaternary pyridinium salts are liable to undergo nucleophilic additions.[4] Thus the intramolecular catalytic substitution proceeds primarily if the cyclic intermediate is available, whereas addition takes place if not. Thus the case of $n=5$ or 6 (**1e** or **1f**)

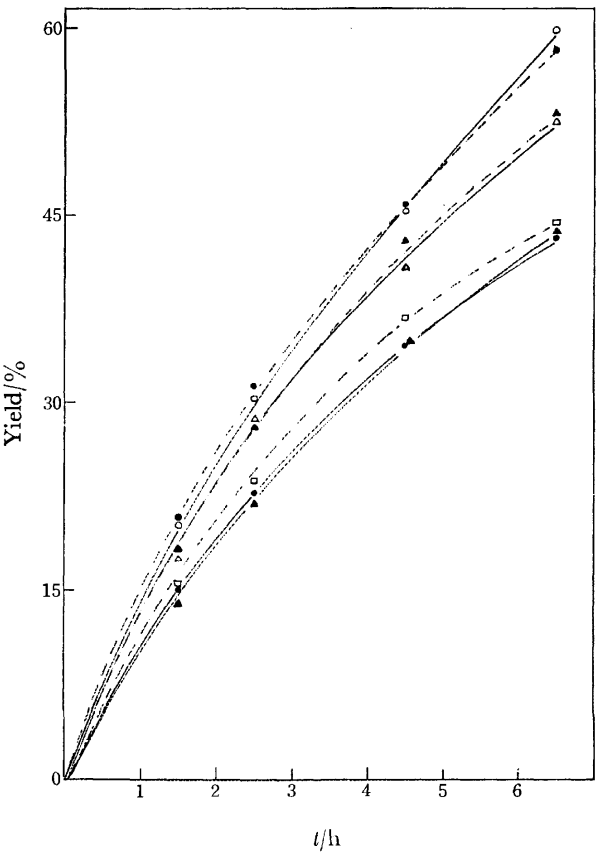

Fig. 1. Relationship between the yield and reaction time; **1** (0.020 mol/l) and potassium cyanide (0.021 mol/l) —●— **1b**; —▲— **1c**; ---□--- **1d**; —○— **1e**; ---●--- **1f**; —△— **1g**; ---▲--- **1h**.

showed the highest reaction rate through the maximum interaction between the catalytic center and the reaction site (Fig. 1). However, no first order reaction rate constant could be obtained from the results, since an ion-exchange equilibrium might take place between cyanide and bromide anions giving rise to the dependence of the reaction rate on the concentration of *N*-(ω-bromoalkyl)pyridinium cyanide (**2**). The reaction rate of **1b** and **1e**, in fact, were accelerated by addition of potassium cyanide and fairly retarded with potassium bromide as expected from the above assumption (Table 1).

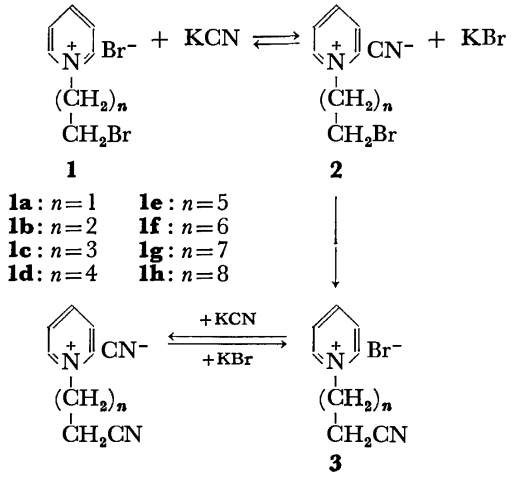
Table 1. Effect of the added salts to the yield[a] of *N*-(ω-cyanoalkyl)pyridinium salts

Concn. of salts mol/l	Starting material[b]	Reaction time (h) 0.5	1.5	2.5	3.5	4.5
KCN 0.021	**1b**	5.8	15.2	23.2	—	34.9
	1e	7.8	20.3	30.2	—	45.4
	1h	6.3	18.6	28.0	—	43.3
KCN 0.091	**1b**	17.0	43.0	60.7	69.4	78.6
	1e	29.1	55.1	70.1	78.2	86.6
	1h	20.7	48.6	67.1	74.2	79.1
KCN 0.181	**1b**	23.1	53.0	71.2	83.5	—
	1e	40.8	77.3	92.0	97.1	—
	1h	24.3	52.7	70.9	79.9	—
KCN 0.021 KBr 0.20	**1b**	4.1	11.0	—	—	—
	1e	4.8	15.0	—	—	—
	1h	6.0	18.7	—	—	—

a) Determined by the potentiometric titration. b) 0.020 mol/l was used in all cases.

Although there is no such effect of potassium bromide on **1h**, the reaction rate approached that of **1b** when potassium cyanide was added up to 0.19 mol/l. The reason for **1h** being more reactive than **1b** might be the term of the positive micellar effect[5] (cmc of **1h**: *ca.* 0.019 mol/l at 25 °C).[6]

The results show that the quaternary nitrogen atom plays a considerable catalytic role with favorable interactions to an appropriate reaction site even in aqueous solution. Such an idea might thus be applied to regio-specific substitutions in view of the intramolecular catalysts.



Experimental

Instruments. NMR and IR spectra were recorded with a Varian T-60 and Hitachi EPI-S2 spectrometers, respectively. The potentiometric titration was carried out with a Toa HM-5A potentiometer.

N-(ω-Bromoalkyl)pyridinium Bromide (1). After a mixture of pyridine (3.16 g, 0.05 mol) and α,ω-dibromoalkane (0.10 mol) had been refluxed in ethanol (50 ml) for 5 h, the solvent and excess α,ω-dibromoalkane were removed by means of evaporation, decantation, and extraction with ethyl acetate. The α,ω-bispyridinium salts was crystallized from 2-propanol (60 ml) (in the case of **1a**—**1e**) and from acetone (**1f**—**1h**) crystalline **1** deposited in an icebox after the solvent was concentrated to half. Recrystallization from ethanol (**1a**, **1b**, and **1c**) or 2-propanol (**1d** and **1e**) or acetone (**1f**, **1g**, and **1h**) gave pure salts. All these did not show clear melting points because of being too hygroscopic. Analytical data, **1a**; Found: C, 31.85; H, 3.58; N, 5.30%. Calcd for $C_7H_9NBr_2$: C,31.49; H, 3.40; N, 5.25%. **1b**; Found: C, 34.22; H, 3.58; N, 5.30%. Calcd for $C_8H_{11}NBr_2$: C, 34.19; H, 3.98; N, 4.99%. **1c**; Found: C, 36.96; H, 4.84; N, 5.01%. Calcd for $C_{10}H_{15}NBr_2$: C, 38.86; H, 4.89; N, 4.53%. **1e**; Found: C, 41.14; H, 5.22; N, 4.23%. Calcd for $C_{11}H_{17}NBr_2$: C, 40.89; H, 5.30; N, 4.34%. **1f**; Found: C, 42.82; H, 5.13, N, 3.95%. Calcd for $C_{12}H_{19}NBr_2$: C, 42.75; H, 5.68; N, 4.16%. **1g**; Found: C, 44.76; H, 6.45; N, 4.10%. Calcd for $C_{13}H_{21}NBr_2$: C, 44.46; H, 6.03; N, 3.99%. **1h**; Found: C, 46.36; H, 6.41; N, 3.91%. Calcd for $C_{14}H_{23}NBr_2$: C, 46.05; H, 6.35; N, 3.84%.

Reduction of N-(3-Cyanopropyl)pyridinium Bromide (3c). A solution of *N*-(3-bromopropyl)pyridinium bromide (**1c**) (1.12 g, 4 mmol) and potassium cyanide (0.286 g, 4.4 mmol) in water (30 ml) was heated in a water bath for 6 h. After evaporation of water, the residue was dissolved in methanol (30 ml) and treated with sodium borohydride (1.52 g, 40 mmol) below 5 °C. After being stirred for 1 h, the reaction product obtained by evaporation was dissolved in water and then extracted with ether several times. The extracts were evaporated to give syrup which was chromatographed with silica gel (Wako C300) using a solvent system ethyl acetate–acetone 10: 1 (500 ml) and then 5: 1 (500 ml). The fractions eluted by the system 5: 1 were combined and distilled in a Ball Tube Oven at 150 °C/26 Torr. The compound was very unstable in the air. Found: C, 72.29; H, 9.34: N, 18.71%. Calcd for $C_9H_{14}N_2$: C, 71.95; H, 9.39; N, 18.65%. IR(KBr) 2250 (CN) and 1610 cm^{-1} (C=C); NMR ($CDCl_3$) δ 5.67 (m, 2H, $J_{CH=CH}$=1 Hz, CH=CH) and 2.99 (s, 2H, NCH_2–CH=).

Reaction of 1 with Potassium Cyanide. NMR Study: A deuterium oxide solution of **1** (1.0 mol/l) and a potassium cyanide solution (1.1 mol/l) were prepared and then 0.2 ml of each was mixed in NMR tube at 5 °C. The mixture was kept at 64.5±2 °C in a Kugelrohr Oven and the intensities at δ 3.2—3.4 (CH_2Br) and 2.6—2.8 (CH_2CN) were measured at every 0.5 h.

Potentiometric Titration: An aqueous solution of **1** (0.2 mol/l) and that of potassium cyanide (0.21 mol/l) were prepared, and 10 ml of each was mixed and made up to 100 ml with water in a measuring flask. The solution was kept at 64.5 ±0.5 °C in a water bath. Two 5 ml portions of the solution were taken at regular time intervals, cooled immediately in ice–methanol bath and then titrated with silver electrode.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (8), 2177—2178 (1977)

An ESR Study of Photo-Induced Electron Transfer Reaction between Zinc(II)-Tetraphenylporphyrin and *p*-Benzoquinone in Solutions

Masayuki SHIOZAWA, Haruhiko YAMAMOTO, and Yuzaburo FUJITA*

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 24, 1976)

Synopsis. The titled reaction was studied, by means of the ESR technique at room temperature, as a model reaction of the primary process in the photosynthesis. Two kinds of radicals were observed in dichloromethane upon illumination with light of the porphyrin excitation; the zinc-tetraphenylporphyrin cation radical and the semiquinone neutral radical.

Since Tollin and Green[1] first observed the ESR signal of the semiqunone anion radical, Q^-, upon the illumination of ethanolic solutions containing chlorophyl (Chl) and *p*-benzoquinone (Q) at room temperature, both rise and decay processes of intermediates have been investigated in order to clarify the primary process of the photo-induced one-electron transfer from Chl to Q by using either ESR or the flash-photolysis technique. However, now there is a large discrepancy in the intermediates observed by two groups of workers using the former and latter techniques;[2] the latter group[3] has observed both Chl^+ and Q^- radicals, while the former group[4] has not yet succeeded in detecting Chl^+ at room temperature. Accordingly, the following proposals for the electron-transfer mechanism in the systems have been advocated:

1) Both Chl^+ and Q^- are in reality produced by the direct electron transfer from Chl to Q, but the lifetime of Chl^+ is shortened by a fast decay process with either ethanol[3] or an unknown material, X.[2]

2) Q^- and solvent radicals are formed by the electron transfer within a ternary complex among Chl, Q, and ethanol in which Chl acts as a photosensitizer.[4]

The identification of Chl^+ by flash photolysis is complicated by the overlap of the spectra of other species, such as Chl^T and Q^-; therefore, the unambiguous identification of Chl^+ by ESR at room temperature seems to be desirable. It is considered that the use of an appropriate solvent, in which the Chl^+ formed can exist with a longer lifetime, will lead to the easy detection of Chl^+ by ESR. Moreover, in this study zinc(II)-tetraphenylporphyrin, ZnTPP, was used as a model compound for chlorophyl, because the ESR spectrum of the $ZnTPP^+$ cation radical had been reported to reveal a well-defined hyperfine structure.[5]

ZnTPP and its π-cation radical, $ZnTPP^+$, were prepared by the method of Fajer *et al.*[5] *p*-Benzoquinone was purified by sublimation. The ethanol and dichloromethane used as solvents were purified by distillation. Unless otherwise specified, the concentrations of ZnTPP and Q were 10^{-4} and 10^{-1} M respectively. All the samples were thoroughly degassed by repeated freeze-degas-thaw cycles on a vacuum line prior to the measurements. The ESR spectra were recorded on a JEOL PE-1X spectrometer at room temperature. In most of the measurements, the sample in the cavity of ESR spectrometer was illuminated with light of wavelengths longer than 520 nm from a 650 W tungsten filament lamp, using a colored glass filter (Toshiba V-052).

When the solution of ZnTPP and Q in ethanol was illuminated with yellow light (>520 nm), only an ESR signal of the semiquinone anion radical, Q^-, was observed; this is in agreement with Quinlan's results.[6]

On the other hand, upon the illumination (>520 nm) of the solution of ZnTPP and Q in dichloromethane, the ESR spectrum shown in Fig. 1a was obtained. It was composed of two overlapped signals—one with a broad singlet (Signal I, g=2.0027) on the high-field side on the spectrum, and another with a rather well-resolved hyperfine structure (Signal II, g=2.0046) on the low-field side. The existence of the two kinds of radicals was confirmed by the method of microwave-power saturation; at higher microwave power levels, the intensity of Signal I increased, whereas that of Signal II decreased and its hyperfine structure became obscure (Fig. 1b). Both signals decayed completely within a second after light-off. In the dark, none of the signals were detected. Also, no signals were observed in either solvent with either ZnTPP or Q alone upon illumination with yellow light. More than a threefold increase in the porphyrin concentration resulted in a change in the spectrum of Fig. 1 to that in Fig. 2a, in which Signal I appeared as a partially resolved spectrum. Signal I did not saturate until moderately high microwave power levels (20 mW) as is shown in Fig. 2b. This saturation behavior clearly differs from that of the semiquinone radical saturable at higher levels than 4 mW, and rather resembles that of $ZnTPP^+$. The hyperfine coupling constant, which is inaccurate because of the poor S/N ratio, was estimated to be 1.7 G and compared with that of $ZnTPP^+$ (g=2.0025, a= 1.6 G) prepared by electrochemical oxidation in dichloromethane. In a preliminary experiment by flash photolysis, an intermediate species with a lifetime of a few milli seconds was detected; its absorption spectrum was not inconsistent with that of $ZnTPP^+$ reported previously.[5] Thus, Signal I was reasonably assigned to $ZnTPP^+$.

On the other hand, p-benzoquinone alone in dichloromethane showed an ESR signal assignable to the neutral semiquinone radical, QH (g=2.0046, 18-line signal), upon illumination with light longer than 420 nm. This signal showed a well-resolved 15-line hyperfine structure at the modulation amplitude of 0.63 G, as is shown in Fig. 3, and its ESR parameters were in good agreement with those of Signal II.

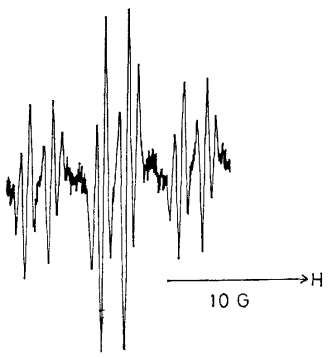

Fig. 3. ESR spectrum of the solution of Q in dichloromethane upon illumination (>420 nm).
Modulation amplitude 0.63 G.
Microwave power 4 mW.

As has been described above, on the illumination (>520 nm) of the solution of ZnTPP and Q in dichloromethane, the $ZnTPP^+$ and QH radicals are produced, whereas in ethanolic solutions only the p-benzoquinone anion radical is observed. These facts imply that there is a great difference in the lifetimes of the $ZnTPP^+$ produced in the two solvents, *i.e.*, a difference in the decay processes of $ZnTPP^+$. Barashkov and Chibisov[3] have proposed the following decay processes of Chl^+ and Q^- in ethanol on the basis of the kinetic results obtained by flash photolysis:

$$Chl^+ + Q^- \longrightarrow Chl + Q, \quad k = 2.0\times10^9\ M^{-1}\ s^{-1}, \tag{1}$$

$$2Q^- \longrightarrow Q + Q^{2-}, \quad k = 2\times10^7\ M^{-1}\ s^{-1}, \tag{2}$$

$$Chl^+ + Q^{2-} \longrightarrow Chl + Q^-, \quad k = 5.5\times10^5\ M^{-1}\ s^{-1}, \tag{3}$$

$$Chl^+ + C_2H_5OH \longrightarrow Chl + C_2H_5OH^+, \quad k = 8.6\times10^2\ M^{-1}\ s^{-1}. \tag{4}$$

Therefore, we examined the reactivity of $ZnTPP^+$, prepared by electrochemical oxidation in dichloromethane, toward both ethanol and hydroquinone in view of the similarity of Chl and ZnTPP. On the addition of hydroquinone to the solution, $ZnTPP^+$ was quickly reduced to reproduce ZnTPP stoichiometrically. Therefore, a decay process similar to (3) seems to be operative in our system, also. However, in the case of ethanol, only a trace amount of $ZnTPP^+$ decreased rapidly to reproduce ZnTPP. This fact indicates that a decay process similar to (4) is not important, but some decay process other than (4), such as a reaction with an unknown material, X, proposed by Hales and Bolton[2] may play a role in an ethanolic solution:

$$Chl^+ + X \longrightarrow Chl + X^+, \quad k > 10^3\ s^{-1}\ \text{(with X in excess)}. \tag{5}$$

The lifetime of $ZnTPP^+$ in ethanol may be shortened by a process similar to (5), but in dichloromethane the absence of decay processes similar to (4) and (5) may explain why $ZnTPP^+$ is not detected in an ethanolic solution.

Our present results indicate that the decay processes differ greatly in the solvents used; that is, they depend on the environment of the primarily produced radicals. A similar investigation using micellar systems in which ZnTPP is incorporated is now in progress.

A Semi-empirical NDDO Method for All-valence-electron Systems. II. Extension to Compounds Containing Nitrogen and/or Oxygen

Osamu KIKUCHI and Akira MAEDA

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

(Received December 2, 1976)

Synopsis. A semi-empirical NDDO method is extended to compounds containing nitrogen and/or oxygen, and is applied to the evaluation of the molecular geometries and excitation energies of the compounds and of the heats of reactions relating to them. The agreement between the calculated and observed values is comparable with that previously attained for hydrocarbons except for the conformations of NH_3 and CH_3NH_2.

In the previous paper,[1] a semi-empirical NDDO method was applied to the evaluation of the molecular geometries and excitation energies of a variety of hydrocarbons, and of the heats of reactions among them. It was shown that the NDDO method gave at the same time well-balanced values of the above three quantities. Here, the method will be extended to compounds containing nitrogen and/or oxygen. In the NDDO procedure, the off-diagonal core matrix element between AO's, μ and ν, on the different atoms,

$$H_{\mu\nu} = \frac{1}{2}S_{\mu\nu}(\beta_\mu+\beta_\nu),$$

and the core repulsion energies between atoms A and B,

$$E_{\text{core}}^{\text{AB}} = Z_A Z_B\left\{\frac{b}{R_{AB}^a}+c\right\} \qquad (R_{AB}<R_0),$$

are estimated empirically. The empirical parameters in these formulae were determined in the same way as in the previous paper.[1] The parameters obtained are listed in Tables 1 and 2. The equilibrium geometries, heats of reactions, and excitation energies of compounds containing nitrogen and/or oxygen were calculated using the parameters listed in Tables 1 and 2. They are

Nitromethane	$n\rightarrow\pi^*$	3.38	4.59
	$\pi\rightarrow\pi^*$	6.75	6.12

listed in Tables 3—5. All the bond lengths except the CN-type ones agree with the observed values within 0.05 A. The XOY types of bond angles are larger than the observed values by about 15°. The method fails to give the correct conformations of NH_3 and CH_3NH_2; it predicts the planar conformations. These defects were also found in the NINDO/2 method, which is at the same level of parametrization as the present method; the XOY types of bond angles were estimated to be 180° by MINDO/2.[6)] The agreement between the calculated and observed heats of reactions (average error, 9 kcal/mol) is comparable with that previously attained for hydrocarbons. The singlet excitation energies of several compounds were calculated by the CI method, in which only singly excited configurations were included. The calculated energies for the $n\rightarrow\pi^*$ types of excitations are smaller than the observed values about by 1 eV, while those for the $\pi\rightarrow\pi^*$ types differ from the observed values by about 0.5 eV. This somewhat large discrepancy comes from the empirical parameters which were chosen so as to give, at the same time, well-balanced values for the above three quantities. Better excitation energies can be obtained by the use of other sets of parameters which would simultaneously give poor molecular geometries and heats of reactions.[1)] The present NDDO results in Table 5 are felt to be satisfactory in comparison with the excitation energies[7)] estimated by the CNDO and MINDO/2 methods which are currently used in the theoretical studies of chemical reaction processes.

The authors wish to express their thanks to Professor Keizo Suzuki for his helpful suggestions.

Active Sites of MoO_3 and MoO_3-SiO_2 Catalysts for Isomerizaiton of Butenes. Characterization by Tracer Study

Hideshi HATTORI, Kazumasa MARUYAMA, and Kozo TANABE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 12, 1977)

Synopsis. Deuterium atom distribution of butenes in the coisomerization of *cis*-2-butene d_0/d_8 over MoO_3 and MoO_3–SiO_2 indicates that the reaction involves intermolecular hydrogen transfer for both catalysts. Butenvs produced over deuterium-exchanged MoO_3–SiO_2 contain deuterium atoms, those produced over deuterium-exchanged MoO_3 none.

Catalytic properties of MoO_3–SiO_2 and MoO_3 were investigated in view of surface acidity and basicity.[1] For the isomerization of butenes, it was suggested from the correlation of activity with acidity or basicity that the active sites on MoO_3–SiO_2 are acidic, while those on MoO_3 are basic. If the isomerization proceeds on the acidic sites, a hydrogen atom of butene is exchanged during the course of reaction. If the active sites are of Brönsted type, surface hydrogen atoms would be incorporated into the products. In the mechanism proposed for basic sites, the isomerization is initiated by the abstraction of a proton from butene to form the carbanion. In this case hydrogen atoms are not exchanged between butenes unless hydrogen atoms rapidly migrate over the surface.

Hightower and Hall investigated the isomerization of butene over Al_2O_3 and SiO_2–Al_2O_3 by means of a "tracer study" using deuterium as a tracer.[2] They developed a coisomerization technique, in which a mixture of nondeuterated and perdeuterated butene was used as a reactant. If the isomerization involves intermolecular hydrogen transfer, the product should contain both non-exchanged isotopic species d_0 and d_8, and mono-exchanged isotopic species d_1 and d_7. In the case of intramolecular hydrogen transfer, only non-exchanged isotopic species should be produced. The relative ratio of product from nondeuterated reactant to that from perdeuterated reactant shows an isotope effect when extraporated to zero conversion.

In the present work the coisomerization of butene over MoO_3–SiO_2 and MoO_3, and the reaction over the deuterium exchanged catalysts were carried out, the reaction mechanism and the nature of active sites being investigated.

Experimental

Molybdenum trioxide (MoO_3) was prepared by the precipitation from an aqueous solution of ammonium molybdate with nitric acid. MoO_3–SiO_2 was prepared by precipitation from a mixture of ammonium molybdate and tetraethyl orthosilicate with nitric acid. Precipitates were dried at 100 °C and finally calcined at 500 °C for 3 h in air. Details were described previously.[1]

A microcatalytic pulse reactor was used for the reaction. A catalyst (0.25 g) was evacuated at 500 °C prior to reaction. For the reaction over deuterium exchanged catalyst, surface hydrogen atoms were exchanged with deuterium atoms by exposing the catalyst evacuated to *ca.* 10 Torr of D_2O at 250 °C, the catalyst being evacuated at 500 °C for 1 h.

ca. 40 μmol of butene was passed over the catalyst in a helium carrier, and products were trapped by liquid nitrogen before being flash evaporated into a gaschromatographic column (Propylene carbonate on Uniport C in 10-m length, 8-mm o.d. Cu-tubing) operated at 0 °C. The separated products were collected in liquid nitrogen traps and subjected to mass spectroscopic analysis.

For the coisomerization, a mixture containing about equal amounts of nondeuterated and perdeuterated *cis*-2-butene was used as a reactant. The isotopic purity of the perdeuterated *cis*-2-butene was higher than 99.6%.

Results and Discussion

The isotopic profiles of butenes in the coisomerization and the reactions over deuterium exchanged catalysts are given in Table 1. The number of H (or D) atoms exchanged per molecule (AEM) was calculated by

$$\sum_{i=0}^{4} i \cdot N_i + \sum_{5}^{8} (8-i) N_i,$$

where N_i is a mole fraction of each isotopic species containing i deuterium atoms. An isotope effect (IE) was obtained by the relative reactivity of nondeuterated species to that of perdeuterated species, which was calculated by

$$\left(\sum_{0}^{3} N_i + \frac{1}{2} N_4\right) \Big/ \left(\sum_{5}^{8} N_i + \frac{1}{2} N_4\right),$$

where d_4 species in the product was assumed to be produced equally from d_0 and d_8 reactant.

Over both MoO_3 and MoO_3–SiO_2, the products in the coisomerization contained a considerable fraction of mono-exchanged d_1 and d_7 isotopic species. If there were no isotope effect, the AEM value at zero conversion would be 0.5 for the intermolecular hydrogen transfer, and would decrease when isotope effect becomes larger. AEM values of 1-butene close to 0.5 for both catalysts indicate that the isomerization to 1-butene involves intermolecular hydrogen transfer over both catalysts.

Considerable amounts of d_1 species were produced over deuterium exchanged MoO_3–SiO_2, (Table 2). This in addition to the existence of acidic sites on the surface[1] and the occurrence of intermolecular hydrogen transfer, strongly suggest that the active sites are of a Brönsted type and the isomerization to 1-butene proceeds *via* a carbenium ion intermediate. The number of H (or D) atoms exchanged per molecule in *trans*-2-butene was smaller than that in 1-butene. If the carbenium ions are weakly bonded to the surface, *trans*-2-butene may be produced from the carbenium ion by release of either the hydrogen atom that came from the surface or the hydrogen atom that was originally the vinyllic

MoO_3–SiO_2	1	16.9	72.3	24.8	3.0	0.1	0	0.311
	t	36.2	81.1	17.9	1.0	0	0	0.199
	c	46.9	86.3	13.0	0.7	0	0	0.144
MoO_3	1	7.2	100	0	0	0	0	0
	t	11.5	100	0	0	0	0	0
	c	81.3	100	0	0	0	0	0

hydrogen of *cis*-2-butene. This might result in a smaller number of exchanged hydrogen atoms in *trans*-2-butene.

On the other hand, no deuterium was incorporated into the products over deuterium exchanged MoO_3. Surface H (or D) atoms should not participate in the reaction. The active sites on MoO_3 were poisoned not by ammonia but by carbon dioxide, suggesting that MoO_3 is of a basic type of catalyst.[1] The reaction could be initiated by the abstraction of the allylic proton in *cis*-2-butene by basic sites. If the proton migrates over the surface very rapidly, intermolecular hydrogen transfer would occur.

On introducing an oxygen pulse to MoO_3 after the six pulses of butene, the activity was restored to the level of the second butene pulse. The activity was also recovered almost completely by allowing the catalyst to stand in the reactor overnight at room temperature with no carrier gas flowing. The results suggest that surface Mo^{6+} ions rather than Mo^{5+} ions participate in the reaction, though the amplitude of Mo^{5+} signal in the ESR spectrum decreases only slightly by exposure to oxygen at 250 °C. The Mo^{5+} ions may be produced by a loss of oxygen atoms attached to Mo^{6+} ions. By allowing the catalyst to stand overnight, oxygen atoms seem to diffuse from the bulk to the surface and Mo^{6+} ions are reproduced. The abstraction of protons from butene molecules seems to be performed much more easily by oxygen ions than by metal cations. Thus, it is suggested that the active sites on MoO_3 consist of pairs of oxygen ions and Mo^{6+} on the surface, at least in the initial stage of the reaction.

Radical Reaction in a Silent Electric Discharge of Ethylene

Junichi Itoh, Kazuto Takimoto, and Satoru Tsuda

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima 730

(Received February 24, 1977)

Synopsis. In the silent electric discharge of ethylene, it was revealed, by studying the effects of various scavengers on the formation of gaseous products, that the radical reaction plays an important role, unlike as in the reaction in radiolysis. Furthermore, the existence of several intermediates was directly or indirectly demonstrated by using an ESR technique and by adding iodine as a radical scavenger.

In a silent electric discharge as well as radiolysis, various active species, that is, cations, anions, excited molecules, and dissociated atoms (or free radicals), are produced by the collision of electrons with molecules. Paal and Foldiak[1] have reported that a gaseous-discharge reaction at 0.5—1.0 mA under 10 kV in a discharge tube of the Giemens-ozonizer type corresponds to the radiolysis at 10^7—10^8 rad/h.

The present authors have studied the discharge reaction of aqueous solutions.[2] This investigation is further extended to a gas phase to reveal the correlation between the discharge reaction and radiolysis. Ethylene was selected as the objective gas since the radiolysis of the gas has been studied in detail and the reaction mechanism has been relatively well clarified.[3,4] In the radiolysis of ethylene, only ethane is formed through the radical reaction, whereas hydrogen, acetylene, and butane are produced through the molecular dissociation and the ionic reaction.[3,4] Our purpose in this work is to reveal the molecular dissociation and the subsequent radical reaction and also to confirm the intermediate in the silent electric discharge of ethylene.

Experimental

The research-grade ethylene was used after several distillations. Purified nitrogen monoxide and iodine were used as radical scavengers. On the other hand, ethanol was employed as a positive ion scavenger. The identification and the determination of the gaseous products were performed by using a Hitachi RMU-6D mass spectrometer and a Hitachi 730 type gas chromatograph respectively.

In the discharge of ethylene below an atmospheric pressure, a linear relationship was confirmed between the applied potential and the current over 0.3 mA. Every experiment was, therefore, performed under the following conditions: a duration of 20 s at 0.5 mA and an ethylene pressure of 100 Torr. The energy (W) dissipated electrically by the discharge was estimated from the equation by Fuji and Takemura.[5]

The intermediates formed by the discharge of ethylene were trapped on the silica gel in a discharge tube of an ozonizer type as is shown in Fig. 1. The silica gel was prepared by the hydrolysis of sodium silicate, which had been baked at 600 °C for 6 h in air. Their intermediates were identified by the ESR technique.[6]

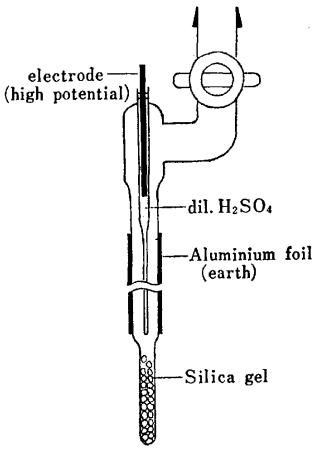

Fig. 1. Schematic diagram of discharge tube.

Results and Discussion

The major gas products formed by the silent electric discharge of ethylene were C_2H_2, H_2, n-C_4H_{10}, C_3H_8, CH_4, C_2H_6, C_3H_6, and $CH_2{=}CHC_2H_5$. The trace gas products were i-C_4H_8, *trans*-2-C_4H_8, *cis*-2-C_4H_8, $CH_3CH{=}C(CH_3)_2$, n-C_5H_{12}, i-C_5H_{12}, $CH_3C(CH_3)_2C_2H_5$, $CH_3CH(CH_3)_2$, $C_2H_5CH(CH_3)C_2H_5$, n-C_6H_{14}, and C_6H_6.

When ethanol was added as a positive ion scavenger, the yield of methane decreased with an increase in the additive amount of ethanol (0—8 mol %), whereas the formation of the other products was scarcely affected within the range of experimental error.

Figure 2 shows the effect of nitrogen monoxide on the

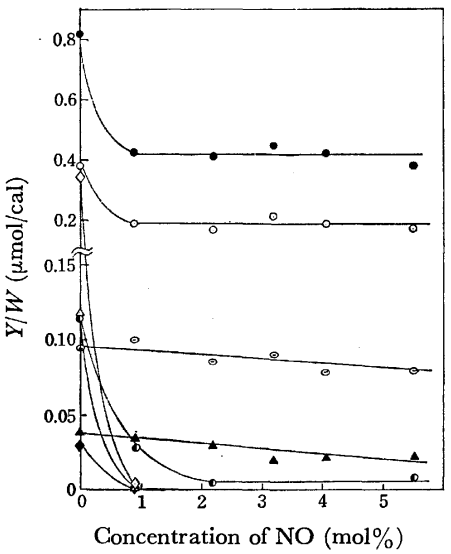

Fig. 2. Effect of nitrogen monoxide on the formation of each product.
●: Acetylene, ○: hydrogen, ◇: butane,
△: propane, ◐: ethane, ⊖: methane,
▲: propylene, ◆: 1-butene.

formation of each product. This suggests that all of the ethane, propane, butane, and 1-butene and a part of the hydrogen and acetylene is formed by the radical reaction.

The decompositions of ethylene excited by the discharge can be represented as follows:

$$C_2H_4^* \longrightarrow C_2H_2 + H_2, \quad (1)$$

$$\longrightarrow C_2H_2 + 2H, \quad (2)$$

$$\longrightarrow C_2H_3 + H. \quad (3)$$

The dissociation probabilities of Reactions 1 and 2 were calculated from the yields of the hydrogen and acetylene formed by the electric discharge of the ethylene–nitrogen monoxide system:

$$(1):(2) = 0.44:0.56 \text{ at } 100 \text{ Torr } C_2H_4,$$

$$0.38:0.62 \text{ at } 355 \text{ Torr } C_2H_4.$$

Meisels and his co-worker[4] estimated the relative probability of Reaction 3 by assuming the $(C_2H_3)/(1\text{-}C_4H_8)=3.3$ ratio. By using this ratio tentatively, the dissociation probabilities of the three reactions could be calculated:

$$(1):(2):(3) = 0.36:0.45:0.19 \text{ at } 100 \text{ Torr } C_2H_4,$$

$$(1):(2):(3) = 0.26:0.42:0.32 \text{ at } 355 \text{ Torr } C_2H_4.$$

On the other hand, Meisels and his co-worker[4] have reported that the relative dissociation probabilities for ethylene excited by slow electrons at $E/P=26.9$ V/cm Torr and at the ethylene pressure of 50 Torr were as follows:

$$(1):(2):(3) = 0.38:0.46:0.16.$$

The relative probabilities for ethylene discharged at 100 Torr happened to agree closely with those for ethylene irradiated by slow electrons at $E/P=26.9$ V/cm Torr and at the ethylene pressure of 50 Torr. This seems to support our previous conclusion[7] that the silent electric-discharge reaction corresponds to that by slow electrons.

Janzen and others have detected some radicals produced in a microwave discharge by using a technique called "spin trapping."[8] So far as we know, the detection technique of radicals by using a discharge tube of the ozonizer type such as is shown in Fig. 1, has hardly even been used. However, we succeeded in detecting hydrogen and the ethyl radical directly by using this technique.

When the silica gel evacuated at 300 °C for 10 h was discharged at 8 kV in the presence of argon gas, only a broad singlet centered at about $g=2.0036$ was observed, as is shown in Fig. 3(a). On the other hand, silica gel discharged under an ethylene pressure of about 20 Torr

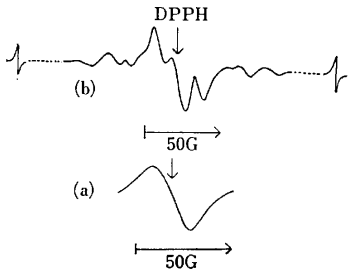

Fig. 3. ESR spectra of ethylene discharged at 77 K on the silica gel.
(a) Argon–silica gel, (b) ethylene–silica gel.

showed the ESR spectrum shown in Fig. 3(b). A hydrogen atom with a coupling constant of about 500 G and an ethyl radical which are superimposed on the broad singlet described above could be detected.

Furthermore, the existence of some radicals participating in the radical reaction was evidenced by the results of an analysis of the iodides resulting from the radical scavenging by iodine: $C_2H_5I=0.160$, $C_2H_3I=0.029$, $n\text{-}C_4H_9I=0.011$, $CH_3I=0.004$, and $n\text{-}C_3H_7I=0.001$, where each unit is μmol/cal. However, HI and CH_2I could not be detected.

In conclusion, if the discharge reaction of ethylene is compared with the radiolysis reaction, the final products in both reactions are similar to each other. However, the dominant reactions in the radiolysis are the ionic reaction and the molecular decomposition.[3] On the contrary, in the discharge reaction the radical reaction and the molecular decomposition play important roles.

Ligand-Substitution Reaction of Bis(acetylacetonato)copper(II) and Bis(acetylacetonato)zinc(II) with 2-(2-Pyridyl)benzimidazole

Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi 1-2-58, Shinagawa-ku, Tokyo 140

(Received November 16, 1976)

Synopsis. The reaction of bis(acetylacetonato)-copper(II) with 2-(2-pyridyl)benzimidazole (**1**) in ethanol was studied by means of absorption, fluorescence, and ^{1}H NMR spectroscopies, and it was found that one of the acetylacetonate anions in the complex is replaced by the anion of **1**. Bis-(acetylacetonato)zinc(II) reacts with **1** in a similar manner. Neither acetylacetonate reacts with 2-(3-pyridyl)- or 2-(4-pyridyl)benzimidazole.

It is well known that bis(β-diketonato)copper(II) complexes behave as Lewis acid and form addition compounds with nitrogen bases.[1] Several five-coordinate addition compounds of square planar bis(β-diketonato)copper(II) complexes with heterocyclic nitrogen bases have been isolated.[2] A stable 2,2'-bipyridine adduct of bis(hexafluoroacetylacetonato)-copper(II)[3] and a reaction product of bis(acetylacetonato)copper(II) with ethylenediamine[4] have been isolated, and their structures were determined by means of X-ray analysis. It has been reported that bis(acetylacetonato)zinc(II) forms stable addition compounds with 4,4'-bipyridine and pyrazine.[5] In all these cases no ligand-substitution occurs. This paper describes a new mixed ligand copper(II) complex formed by ligand-substitution between bis(acetylacetonato)copper-(II) and 2-(2-pyridyl)benzimidazole.

Experimental

Three 2-pyridylbenzimidazoles 2-(2-pyridyl)- (**1**), 2-(3-pyridyl)- (**2**), and 2-(4-pyridyl)benzimidazole (**3**), were prepared according to the literature.[6] Commercial bis(acetylacetonato)copper(II) and -zinc(II) (**4** and **5**) were purified by recrystallization from chloroform and ethanol, respectively. To a hot ethanol solution (50 ml) of **1** (0.98 g, 1/200 mol), was added a hot ethanol solution (500 ml) of **4** (1.31 g, 1/200 mol). The resulting green solution was concentrated to about 200 ml in a water bath, giving almost black crystals upon cooling. Found: C, 57.19; H, 4.09; N, 11.78%. Calcd for substitution product, $CuC_{17}H_{15}N_3O_2$: C, 57.19; H, 4.21; N, 11.77%. Calcd for adduct, $CuC_{22}H_{23}N_3O_4$: C, 57.82; H, 5.07; N, 9.20%.

The absorption, fluorescence, and ^{1}H NMR spectra were recorded with Hitachi spectrophotometers, Model 356, and MPF-2, at 25 °C and a Varian XL-100 spectrometer at 28 °C, respectively.

Results and Discussion

Figure 1 shows the absorption spectra of ethanol solutions of **1** in the presence of various amounts of **4**. Two isosbestic points are observed at 327 and 304 nm, indicating the existence of a stoichiometric complex-forming equilibrium. A new absorption band at about 350 nm can be ascribed to the complex formed, because neither **1** nor **4** has an absorption band in this region.

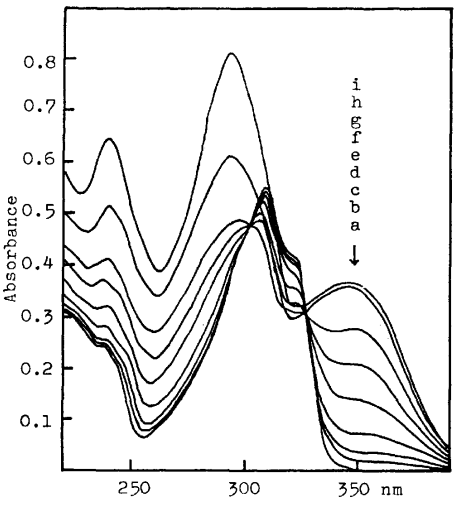

Fig. 1. The absorption spectral change of **1** (2.43×10^{-5} M) in ethanol in the presence of various amounts of **4**. The values of molar ratio, **4**/**1**, are: a, 0; b, 0.044; c, 0.088; d, 0.176; e, 0.352; f, 0.528; g, 0.704; h, 1.056; i, 1.408.

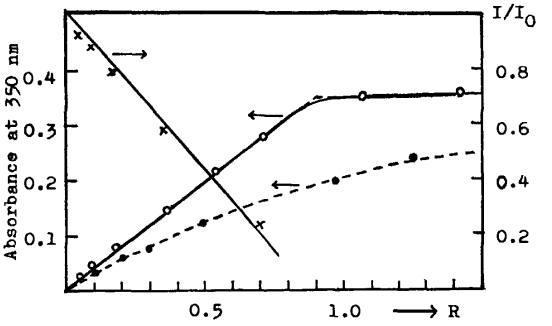

Fig. 2. Plots of absorbance at 350 nm and of relative fluorescence intensity (I/I_0; I_0 is the intensity observed in the absence of **4**), against the molar ratio, **4**/**1**:——, **1**—**4**;----, **1**—**5**.

In Fig. 2, the increments in the absorbance at 350 nm are plotted *versus* the molar ratio (R). The absorbance increases linearly with R until it ceases to increase at $R=1$. It can be concluded, therefore, that 1 : 1 complex with a large stability constant is formed. The high stability of this complex and the result of elemental analysis of the almost black crystals obtained from an ethanol solution of the 1 : 1 mixture of **1** and **4**, indicate that it is not merely an addition product of **1** and **4**, but a mixed ligand complex in which **1** coordinates to the Cu(II) ion as a bidentate ligand replacing an acetylacetonate anion in **4**. Consistent with this conclusion, the absorption spectrum of an ethanol solution of the almost black crystals was very similar to that

of the 1 : 1 mixture of **1** and **4**, though the latter shows stronger absorbance at shorter wavelengths, $\lambda<300$ nm, because of the contribution from acetylacetone molecules liberated by the ligand-substitution.

The fluorescence spectra of these solutions showed a marked decrease in intensity without any sign of the appearance of a new band in the presence of **4**. A plot of the observed intensities at 358 nm *versus* R yielded a straight line which crosses the abscissa at about $R=1$. This observation indicates that the complex formed is nonfluorescent and that the fluorescence emission originates only from the free molecules of **1**.

The ^{1}H NMR spectrum of **1** in $CDCl_3$ gave a broad signal due to the imidazolic proton at δ 11.3 and complex signals with fine structures due to the aromatic protons over the range of δ 7.2—8.7. The addition of a few drops of a dark blue chloroform solution of **4** to this solution gave a green color and, at the same time, a broadening of the aromatic proton signals, accompanied by the appearance of new weak signals at δ 2.04, 2.22, 3.57, and 5.52. These new signals can be ascribed to acetylacetone molecules liberated by the ligand-substitution, because these δ values are very close to those assigned to acetylacetone.[7]

For the system of **1** and bis(acetylacetonato)zinc(II) (**5**) in ethanol, a very similar absorption spectral behavior was observed, a smaller complex formation constant being inferred from the plot of the absorbance increase at 350 nm *versus* R (Fig. 2). This system showed a quite different fluorescence spectral change. The zinc-complex is strongly fluorescent; the new fluorescence band at about 420 nm can be ascribed to the zinc-complex because its intensity increases linearly as the absorbance at 350 nm increases.

The nonfluorescent property of the copper-complex can be interpreted in terms of the paramagnetism of the copper(II) ion, which may induce intersystem crossing in the excited state. The zinc-complex, on the other hand, is diamagnetic and fluorescent. In this connection, Bark and Rixon have studied the application of the zinc complex of **1** to the fluorimetric determination of zinc.[8]

The corresponding mixed complexes did not appear to be formed between **4** and **2** (or **3**) in ethanol, because the absorption spectra of the mixtures are almost the same as the sums of those of their components and because the fluorescence quenching of **2** and **3** in the presence of **4** was negligible.

The acetylacetonate anion in **4** is replaced only by the anion of **1** but not by those of **2** and **3**. This fact indicates the necessity of appropriate positioning of the imidazolic NH group and the pyridine nitrogen atom in order to function as a bidentate ligand. It can also be said that the ionizable property of the imidazolic proton in **1** is very important in the ligand-substitution reaction, because such substitution reactions did not occur between **4** and ethylenediamine or between bis(hexafluoroacetylacetonato)copper(II) and 2,2′-bipyridine.[3,4]

A mixed ligand copper(II) complex, Cu(acac)-(OCH_3), was prepared directly by treating **4** with sodium hydroxide in methanol. The methoxo ligand can be replaced by a pyrazolate anion and the resultant copper(II) complex has been proposed to have a dimeric structure on the basis of its antiferromagnetic properties.[9] This fact suggests that the possibility of a dimeric structure of the present mixed ligand complex cannot be discounted.

No double coordination of the anion of **1** to the copper(II) ion was observed. This indicates the relative instability of $Cu(\mathbf{1}^-)_2$ compared with $Cu(acac)(\mathbf{1}^-)$ from an energy point of view, probably because of the van der Waals' interaction between two anions of **1**, which is bulkier than the acetylacetnate anion.

The apparently smaller stability constant inferred for the zinc-complex may be ascribed to the smaller difference between the affinities of the two ligands in question to the zinc(II) ion.

1,3-Dithian-2-one Tosylhydrazone. Synthesis and Carbenoid Decomposition

Naruyoshi OBATA

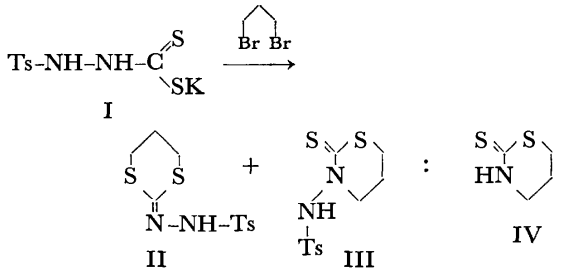
Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received January 12, 1977)

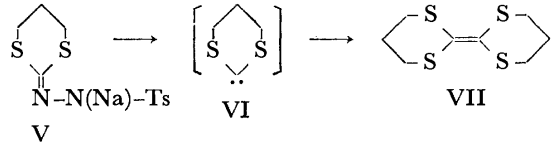
Synopsis. 1,3-Dithian-2-one tosylhydrazone was prepared by the reaction of potassium 3-tosyldithiocarbazate and 1,3-dibromopropane. Carbenoid reactions of the tosylhydrazone were investigated.

Much attention has been paid on the synthesis of 1,3-dithiane derivatives and their application in organic synthesis as a nucleophile of acyl anion equivalent.[1] In the carbene analog, however, only a few acyclic dithiocarbenes[2-4] and ethylenedithiocarbene[2] to give fragmentation products have been reported. As compared with these carbenes, trimethylenedithiocarbene is of great interest both in its reactivity and as synthetic tool. In this paper I present a convenient synthesis of 1,3-dithian-2-one tosylhydrazone (II) and its carbenoid decomposition under several conditions.

Potassium 3-tosyldithiocarbazate (I) prepared[3] from tosylhydrazine and carbon disulfide in the presence of KOH in methanol was alkylated with 1,3-dibromopropane. After chromatography on silica gel were obtained tosylhydrazone (II) and 3-(tosylamino)tetrahydro-1,3-thiazine-2-thione (III) in 36 and 28% yields, respectively, along with 11% recovery of tosylhydrazine. The structures of II and III were established by the elemental analysis and spectroscopic data. The structure of III was confirmed by reduction with zinc in acetic acid to give tetrahydro-1,3-thiazine-2-thione (IV) in 74% yield, the structure of which was determined by direct comparison with a sample prepared by the authentic route.[5]



Sodium salt (V) was prepared from II and NaH in hexane and was subjected to carbenoid decomposition, the Bamford-Stevens reaction.[6] Thermal decomposition of V in pyridine and in DMF at 90—95 °C for 2 h gave 2,2'-bi(1,3-dithianylidene) (VII) in 36 and 29% yields, respectively. Similarly, irradiation of V in DMF with 500 W high-pressure mercury lamp yielded VII in 23% yield along with unknown products. The structure of VII was established by elemental analysis and mass and NMR spectra.



The formation of the dimer VII seems to be a good indication that trimethylenedithiocarbene (VI) is a real intermediate[7] in both thermal and photochemical reactions of V. This carbene is in marked contrast to ethylenedithiocarbene[2] in reactivity, which gave no dimerization product but only fragmentation products, ethylene and carbon disulfide.

Experimental

Reaction of Potassium 3-Tosyldithiocarbazate (I) with 1,3-Dibromopropane. A solution of KOH (1.74 g, 0.031 mol) in methanol (10 ml) was added to I (9.32 g, 0.031 mol) prepared by the method of Schöllkopf and Wiscott[3] and the mixture was stirred at 50 °C for 10 mim. To this solution was added dropwise 1,3-dibromopropane (8.08 g, 0.04 mol) in methanol (10 ml) during a period of 1 h under stirring and the mixture was stirred for 2 h at room temperature. Removal of the solvent and addition of benzene caused precipitation. After filtration, the filtrate was concentrated and the residue was chromatographed on silica gel. Elution with benzene gave 1,3-dithian-2-one tosylhydrazone (II) (3.28 g, 36%), mp 172—173 °C from hexane–CH_2Cl_2.

Found: C, 43.72; H, 4.64; N, 9.48%; mol wt: 302 (mass). Calcd for $C_{11}H_{14}O_2N_2S_3$: C, 43.71; H, 4.67; N, 9.72%, mol wt: 302.4. IR(KBr): 3160 (νN–H) and 1520 cm^{-1} (νC=N). NMR($CDCl_3$): δ 2.16 (m, 2H), 2.42 (s, 3H), 3.04 (m, 4H), 7.50 (s, 1H), and 7.80 (d, 2H). Elution with benzene–CH_2Cl_2 (2: 1) gave 3-(tosylamino)tetrahydro-1,3-thiazine-2-thione (III) (2.65 g, 28%), mp 100—101 °C from hexane–CH_2Cl_2.

Found: C, 43.79; H, 4.72; N, 9.78%; mol wt: 302 (mass). Calcd for $C_{11}H_{14}O_2N_2S_3$: C, 43.71; H, 4.67; N, 9.27%; mol wt: 302.4. IR(KBr): 3140 (νN–H) and 1540 cm^{-1} (νC=S). NMR($CDCl_3$): δ 2.42 (s+t, 5H), 3.00 (t, 2H), 4.10 (t, 2H), 7.28 (d, 2H), 7.70 (d, 2H), and 9.46 (d, 2H). Further elution with CH_2Cl_2 gave tosylhydrazine (0.66 g, 11%).

Redution of III with Zinc in Acetic Acid. 1.0 g Zn was added to a solution of III (0.40 g, 1.3 mmol) in AcOH (15 ml) and the resulting mixture was refluxed for 3 h. After filtration, the filtrate was concentrated and dried under reduced pressure. The residue was chromatographed on silica gel. Elution with CH_2Cl_2 gave tetrahydro-1,3-thiazine-2-thione (IV) (0.13 g, 74%), mp 132—133 °C from hexane–CH_2Cl_2 (lit,[5] mp 132 °C).

Thermal Decomposition of Sodium Salt of Tosylhydrazone (V) in Pyridine. A solution of V (1.0 g, 3.3 mmol) in pyridine (20 ml) was heated at 90—95 °C for 2 h with stirring under argon. After evaporation of the solvent under reduced pressure, CH_2Cl_2 solution of the residue was washed with water and dried with $MgSO_4$. After eveporation of CH_2Cl_2, the residue was chromatographed on silica gel. Elution with benzene gave 2,2'-bi(1,3-dithianylidene) (VII) (0.28 g, 36%), mp 140—141 °C from CH_2Cl_2–hexane (lit,[8] mp 140.8—141.6 °C).

Found: C, 40.43; H, 5.12%; mol wt: 236 (mass). Calcd for $C_8H_{12}S_4$: C, 40.68; H, 5.12%; mol wt: 236.4. NMR($CDCl_3$): δ 2.16 (m, 4H) and 2.94 (t, 8H).

Photochemical Decomposition of V in DMF. A solution of

V (1.0 g, 3.3 mmol) in DMF (20 ml) was irradiated with 500 W highpressure mercury lamp for 5 h at room temperature under argon. After a similar work-up to that mentioned above, chromatographing on silica gel of the mixture gave VII (0.18 g, 23%).

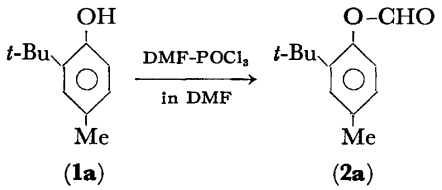
Vilsmeier Reaction of Phenols. I. Synthesis of Aryl Formates[1)]

Syoji MORIMURA, Hideo HORIUCHI, and Keisuke MURAYAMA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo 140

(Received January 27, 1977)

Synopsis The reaction of phenol and *o*-*t*-butylphenols with *N*,*N*-dimethylformamide–phosphoryl chloride complex in dimethylformamide afforded the corresponding formates in fairly good yields. The scope and limitation of *o*-formylation of highly sterically hindered phenols with the complex were also examined.



(**1a**) (**2a**)

Vilsmeier reagents have been shown to be effective in formylating the benzene nuclei of phenol derivatives. For example, the preparation of vanillin by the formylation of guaiacol with *N*-methylformanilide–phosphoryl chloride complex has been disclosed in an early patent.[2)] Furthermore, it has been shown that the hydroxyl group of picric acid is replaced by a chlorine atom when treated with (chloromethylene)dimethylammonium chloride.[3)] However, examples of formylation of the phenolic hydroxyl group by Vilsmeier reagent have not yet been reported. During the course of our study on the hindered phenol-type antioxidants, we have found that dimethylformamide–phosphoryl chloride (DMF–$POCl_3$) complex reacts with phenol derivatives to afford the formates in fairly good yields.

When 2-*t*-butyl-*p*-cresol (**1a**) was treated with DMF–$POCl_3$ complex in DMF at 80 °C for 5 h, the formate (**2a**) was obtained in 78% yield after hydrolysis of the reaction mixture. No product arising from the formylation of the benzene nucleus was isolated. The structure of **2a** was confirmed by the satisfactory analytical values and the following spectral data. The IR spectrum did not show OH absorption but exhibited the characteristic absorption at 1750 cm^{-1} for the ester carbonyl group. The NMR spectrum indicated the presence of three aromatic protons.

o-*t*-Butylphenols, **1b**—**g**, listed in the Table 1 also gave the corresponding formates, **2b**—**g**, when treated with DMF–$POCl_3$ complex. In the case of 6-*t*-butyl-*m*-cresol (**1d**), formation of the formate (**2d**) accompanied the production of 6-*t*-butyl-4-formyl-*m*-cresol (**3d**) as the minor product. The aldehyde **3d** showed carbonyl and hydroxyl absorptions at 1667 and 3320 cm^{-1} respectively in the IR spectrum, and the NMR spectrum exhibited two singlets at 7.50 and 7.28 ppm due to the isolated aromatic protons. Bis(5-*t*-butyl-4-hydroxy-2-methylphenyl sulfide (**1f**) is less reactive toward the complex, and a considerable amount of monoformate (**3f**) was obtained together with the diformate (**2f**) even when the reaction period was extended up to 24 h.

Further reactions with *o*,*o*′-disubstituted phenols such as 6-*t*-butyl-2,4-xylenol (**1h**) and 2,6-di-*t*-butyl-*p*-cresol (**1i**) were investigated in order to examine the limitation of the present method of formylation. The former phenol (**1h**) gave the formate (**2h**) in a low yield, whereas the latter (**1i**) was recovered after being treated with DMF–$POCl_3$ complex for 20 h at 85—95 °C. Employment of drastic reaction conditions (25 h at 120—125 °C) on the above reaction of **1i** resulted in the elimination of the *t*-butyl group, giving 2-*t*-butyl-4-methylphenyl formate (**2a**) in 76% yield.

6-*t*-Butyl-4-formyl-*m*-cresol (**3d**) was not formylated by DMF–$POCl_3$ complex. The inertness of this phenol is probably based on the deactivation due to the electron-

TABLE 1. REACTION OF DMF–$POCl_3$ COMPLEX WITH PHENOLS

Phenol	Reactant ratio (phenol: complex) (molar ratio)	React. temp (°C)	React. time (h)	Product	Yield (%)
2-*t*-Butyl-*p*-cresol (**1a**)	1:1.5	78—80	5	Formate (**2a**)	78
4,6-Di-*t*-butyl-*m*-cresol (**1b**)	1:1.5	80—90	3	Formate (**2b**)	82

withdrawing formyl function.

In connection with the formation of the formates from the hindered phenols, the formylation of phenol (**1j**) was also investigated. It had previously been reported that *p*-hydroxybenzaldehyde (**3j**) was obtained in a low yield when **1j** was heated with an equimolar mixture of DMF and $POCl_3$.[4] In the present work, the reaction was carried out using excess DMF as the solvent, and phenyl formate (**2j**) was obtained in 59% yield. The aldehyde, **3j**, was not isolated.

The formates of hindered phenols prepared in this work were shown to be useful for preventing the degradation of several synthetic polymers.[5]

Experimental

*Reaction of DMF–$POCl_3$ Complex with Phenols (**1a—1i**).* An example is cited for the reaction with 2-*t*-butyl-*p*-cresol (**1a**). Similar procedures were used in the reactions with other phenols. The products, **2b**, **3d**, and **2f**, were purified by recrystallization from ethanol, and **2e**, **3f**, and **2g** from benzene. Purification of the oily products, **2c**, **2d**, and **2i** was effected by distillation under reduced pressure. Results of elemental analyses of the products are given in Table 2. To a stirred solution of 16.4 g (0.1 mol) of **1a** in 40 ml of DMF, 22.6 g (0.15 mol) of $POCl_3$ added dropwise at 0—5 °C. After being stirred for 1 h at room temp, the mixture was heated slowly to 80 °C and kept at 78—80 °C for 5 h. To this reaction mixture were added 300 ml of hexane and then 240 ml of 10% aqueous sodium acetate at 0—5 °C with stirring. The hexane solution was separated, washed successively with clod aqueous $NaHCO_3$ and ice-water, and dried over Na_2SO_4. The solvent was removed under reduced pressure at temp below 50 °C, and the residue was recrystallized from ether to give 14.4 g (78%) of the formate, **2a**, mp 39.5—40.5 °C. IR (Nujol) 1750 cm^{-1} (C=O). NMR (CCl_4) δ 1.35 (s, 9H, -C-($C\underline{H}_3$)$_3$), 2.32 (s, 3H, -$C\underline{H}_3$), 6.84 (d, J=8.0 Hz, 1H, C_6-$\underline{H}$), 7.06 (d-d, J=8.0 and 2.0 Hz, 1H, C_5-$\underline{H}$), 7.22 (d, J=2.0 Hz, 1H, C_3-$\underline{H}$), 8.29 (s, 1H, -C$\underline{H}$O).

The authors are grateful to Dr. Ko Arima, Director of this Laboratories, for his encouragement throughout this study. They are also indebted to the members of the Analytical Section of this Laboratories for the elemental analyses and the spectral data.

A New Synthesis of 4-Methoxy-6-valeryl-5,6-dihydro-2-pyrone*

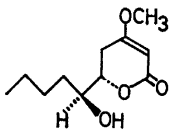
Akira TAKEDA, Eiichiro AMANO, and Sadao TSUBOI

Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

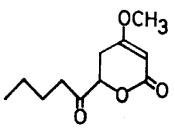
(Received February 2, 1977)

Synopsis. The reaction of ethyl 2-acetoxy-3-oxoheptanoate with γ-bromo-β-methoxy-*cis*-crotonate in the presence of sodium ethoxide afforded diethyl 3-methoxy-5-hydroxy-5-valeryl-2-hexenedioate (**7**) in 65% yield. Treatment of **7** with a dilute aqueous NaOH in acetone gave (±)-4-methoxy-6-valeryl-5,6-dihydro-2-pyrone, a key intermediate leading to pestalotin, in 41% yield.

Several reports have appeared on the synthesis of the pestalotin (**1**),[1-7] a gibberellin synergist isolated by Kimura and Tamura from the culture broth of *Pestalotia cryptomeriaecola* Sawada. First total synthesis of optically active pestalotin was accomplished by Seebach and Meyer[6] by the asymmetric reduction of (±)-4-methoxy-6-valeryl-5,6-dihydro-2-pyrone (**2**) in *ca.* 10% optical yield. They obtained dihydropyrone **2** *via* its 1,3-dithiane derivative. This paper deals with a convenient, alternative synthesis of dihydropyrone **2**.

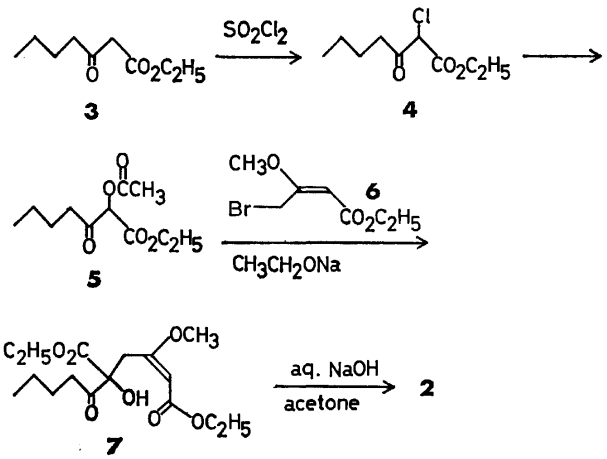


1



2

Chlorination of ethyl 3-oxoheptanoate (**3**) with sulfuryl chloride gave ethyl 2-chloro-3-oxoheptanoate (**4**) in 88% yield. This was converted into ethyl 2-acetoxy-3-oxoheptanoate (**5**)[9] by the action of potassium acetate in 61% yield. Reaction of the ester **5** with ethyl γ-bromo-β-methoxy-*cis*-crotonate (**6**) in the presence of sodium ethoxide afforded diester **7** in 65% yield. Treatment of **7** with a weak aqueous NaOH in acetone gave the desired dihydropyrone **2** in 41% yield. The spectral data (IR, NMR) of this product support its structure. Reduction of **2** with sodium borohydride in aqueous dioxane gave a mixture of (±)-pestalotin and (±)-epipestalotin in 90% yield.



* Presented at the 32nd National Meeting of the Chemical Society of Japan, Tokyo, April 1975.

Experimental

Melting points and boiling points are uncorrected. UV spectra were taken with a Hitachi Model EPS-3T recording spectrophotometer, IR spectra with a Hitachi Model EPI-S2 spectrometer, NMR spectra (60 MHz) with a Hitachi Model R-24 spectrometer, and MS spectra with a Hitachi Model RMS-4 mass spectrometer (70 eV). Analytical and preparative TLC were carried out on silica gel PF_{254} (E. Merck AG, Darmstadt) with layers of 0.25 mm and 1.0 mm thickness, respectively. Compounds **3** and **6** were prepared according to the methods of Anderson *et al.*[10] and Ellestad *et al.*,[3] respectively.

Ethyl 2-Chloro-3-oxoheptanoate (4). To a solution of ethyl 3-oxoheptanoate (**3**) (80 g, 0.47 mol) in 90 ml of dichloromethane was added slowly 63.5 g (0.47 mol) of sulfuryl chloride at a temperature below 45 °C. After the addition was over the mixture was refluxed for 2 h. Removal of the solvent left a clean oil which, on distillation, gave 84.5 g (88%) of **4**; bp 130—135 °C/30 Torr; IR (neat) 1750—1710 (C=O), 1630 (C=C), and 1600 cm^{-1} (enolic C=O); NMR ($CDCl_3$) δ 0.90 (t, 3H, J=6 Hz, $C\underline{H}_3(CH_2)_3$–), 1.0—1.7 (m, 4H, $CH_3(C\underline{H}_2)_2CH_2$–), 1.30 (t, 3H, J=7.5 Hz, $CO_2CH_2C\underline{H}_3$), 2.61 (t, 2H, J=6 Hz, –$C\underline{H}_2CO$–), 4.25 (q, 2H, J=7.5 Hz, $CO_2C\underline{H}_2CH_3$), and 4.72 ppm (s, 1H, –C<u>H</u>Cl–).

Ethyl 2-Acetoxy-3-oxoheptanoate (5). This compound was prepared according to the procedure given by Henecka.[8] To a mixture of potassium acetate (106 g, 1.08 mol), acetic acid (300 ml) and acetic anhydride (20 ml) was added 81.8 g (0.4 mol) of **4** at 110 °C. The mixture was stirred at 135 °C for 6 h. The solvent was removed *in vacuo*, and the residue was neutralized with dilute aqueous $NaHCO_3$. The organic layer was extracted with ether, washed with water, and dried over $MgSO_4$. After removal of the solvent the residue was distilled to give 56.3 g (61%) of **5**: bp 129—135 °C/8 Torr (lit,[9] bp 138—140 °C/17 Torr); IR (neat) 1750—1715 (C=O); NMR ($CDCl_3$) δ 0.91 (t, 3H, J=6 Hz, $C\underline{H}_3(CH_2)_3$–), 1.28 (t, 3H, J=7.5 Hz, $CO_2CH_2C\underline{H}_3$), 1.0—1.8 (m, 4H, $CH_3(C\underline{H}_2)_2CH_2$–), 2.14 (s, 3H, –$OCOC\underline{H}_3$), 2.56 (br, t, 2H, J=6.5 Hz, $CH_3(CH_2)_2C\underline{H}_2$–), 4.18 (q, 2H, J=7.5 Hz, $CO_2C\underline{H}_2CH_3$), and 5.29 ppm (s, 1H, –C<u>H</u>$CO_2C_2H_5$); MS (70 eV) *m/e* (rel intensity) 188 (4), 185 (4), 146 (39), 104 (83), 85 (100), 76 (26), 57 (98).

Diethyl 3-Methoxy-5-hydroxy-5-valeryl-2-hexenedioate (7). Sodium (1.15 g, 0.05 mol) was dissolved in 75 ml of absolute ethanol, 11.5 g (0.05 mol) of the ester **5** being added dropwise at 0—5 °C. The mixture was stirred for 2.5 h at room temperature, and to this was added dropwise 11.2 g (0.05 mol) of ethyl γ-bromo-β-methoxy-*cis*-crotonate (**6**) at 5 °C. The resulting mixture was brought to room temperature, and then stirred for 1 h. After it was made weakly acidic, the solvent was removed. The residue was extracted with ether, and the ethereal layer was washded with water and dried over $MgSO_4$. Removal of the solvent left a clean oil which, on

distillation, gave 10.2 g (65%) of **7**: bp 168—170 °C/0.06 Torr: IR (neat) 3455 (OH), 1740 (ester C=O), 1720 (ketone C=O), 1680 (conjugated ester C=O), and 1630 cm^{-1} (C=C); NMR ($CDCl_3$) δ 0.90 (t, 3H, J=6 Hz, $C\underline{H}_3(CH_2)_3CO$–), 1.25 (t, 6H, J=7.5 Hz, 2 $CO_2CH_2C\underline{H}_3$), 1.00—1.90 (m, 4H, $CH_3(C\underline{H}_2)_2CH_2CO$–), 2.3—2.8 (m, 4H, $-C\underline{H}_2C(OCH_3)$=CH– and $CH_3(CH_2)_2C\underline{H}_2CO$–), 3.56 (s, 3H, $C\underline{H}_3O$–), 4.18 (q, 4H, 2 $CO_2C\underline{H}_2CH_3$), 4.90 (s, 1H, O<u>H</u>), and 5.19 ppm (s, –C<u>H</u>=C〈).

Found: C, 57.90; H, 7.92%. Calcd for $C_{16}H_{26}O_7$: C, 58.17; H, 7.93%.

4-Methoxy-6-valeryl-5,6-dihydro-2-pyrone (2). To a solution of 1.0 g, (3 mmol) of **7** in 90 ml of acetone was added 60 ml of 0.2 M aqueous NaOH at room temperature during a period of 3 min. After being stirred for 2 h, the mixture was poured into a large amount of water. Acetone was removed *in vacuo*. The residue was extracted with ether, washed with water, and then dried over $MgSO_4$. Removal of the solvent left 0.27 g (41%) of **2**: mp 82—83 °C (from hexane) (lit,[6] mp 83 °C): IR (KBr) 1705 (C=O), 1690 (shoulder, conjugate C=O), and 1620 cm^{-1} (C=C); NMR ($CDCl_3$) δ 0.90 [t, 3H, $C\underline{H}_3(CH_2)_3$–), 1.10—1.90 (m, 4H, $CH_3(C\underline{H}_2)_2$-CH_2CO–), 2.50—3.00 (m, 4H, $-C\underline{H}_2C(OCH_3)$=CH– and $CH_3(CH_2)_2C\underline{H}_2CO$–), 3.72 (s, 3H, $C\underline{H}_3O$–), 4.70 (t, 1H, –COC<u>H</u>–O–), and 5.13 ppm (s, 1H, –C<u>H</u>=C〈).

Reduction of **2** *with Sodium Borohydride.* To a solution of dihydro-2-pyrone **2** (88 mg, 0.42 mmol) in 0.3 ml of 75% aqueous dioxane was added dropwise a solution of $NaBH_4$ (17 mg, 0.42 mmol) in 0.3 ml of 75% aqueous dioxane with stirring at 25 °C. After being stirred for 3 h the mixture was acidified with dilute H_2SO_4, and extracted with chloroform. The chloroform extract was dried over $MgSO_4$, and evaporated to yield 80 mg (90%) of an oil which showed one spot at TLC (benzene: ethyl acetate=1: 1, R_f=0.35). This was subjected to preparative TLC for analysis and spectral determinations: IR (neat) 3430, 1710—1670, and 1630 cm^{-1}; NMR ($CDCl_3$) δ 0.9 (t, br, 3H), 1.1—1.7 (m, br, 6H,) 1.95—2.2 (s, br, 1H, OH), 2.20 (m, 1H, ring methylene), 2.81 (m, 1H, ring methylene), 3.72 (m, br, 1H, –C<u>H</u>(OH)–), 3.74 (s, 3H, CH_3O–), 4.28 (m, 1H, ring >H<u>C</u>–O–), and 5.14 ppm (d, 1H, =C<u>H</u>); MS (70 eV) *m/e* (rel intensity) 214 (M^+), 127 (base peak); UV λ_{max} 233 nm (ε=12000, 95% EtOH).

Found: C, 61.86; H, 8.22%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%.

The authors wish to express their gratitude to Dr. Yasuo Kimura, The University of Tokyo, for the supply of IR and NMR spectra of pestalotin.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (Grant No. 647079).

Mono *S*-Acylated 1,8-Naphthalenedithiol. Isolation and Characterization of Tetrahedral Intermediate in the Intramolecular Acyl Transfer Reaction

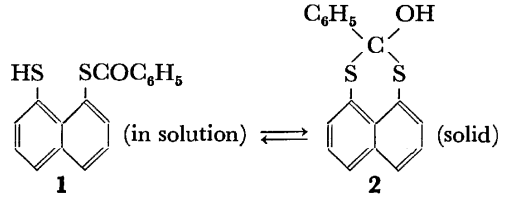
Makoto TAKAGI, Ryoji ISHIHARA, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 8, 1977)

Synopsis. The tetrahedral intermediate in the intramolecular acyl transfer reaction of mono-*S*-acylated 1,8-naphthalenedithiol was found to be sufficiently stable to allow isolation or direct characterization by spectroscopy. Formation of carbenium ion from the intermediate is suggested in sulfuric acid.

Mono-*S*-benzoylation of 1,8-naphthalenedithiol with benzoyl chloride in pyridine under nitrogen afforded the compound with correct data of elemental analysis after purification by column chromatography on silica gel or by simple recrystallization (60—75% yield as monobenzoate). Its IR spectra (Nujol mull), however, show a strong ν_{O-H} band around 3300 cm^{-1} but no absorption for $\nu_{C=O}$ or ν_{S-H}. The crystals obtained from carbon tetrachloride or benzene–petroleum ether gave a slightly yellowish coloration and mp 121—123 °C. Recrystallization from methanol or ethanol afforded white crystals with 1/4 molecule of the solvent (mp of the methanol adduct, 80—81.5 °C), which on evacuation at 70 °C over P_2O_5 turned to the same yellowish material. Mass spectra showed M^+ at *m/e* 296 (relative intensity, 19%) and $C_7H_5CO^+$ at *m/e* 105 (100%). In contrast to the IR spectra in solid state, the solution spectra in chloroform show a strong carbonyl band at 1675 cm^{-1} indicating the presence of normal functional group for ArSCOPh. In the ^1H NMR spectra in $CDCl_3$, only a sharp singlet for S–H (1H, δ 3.97 from TMS) was present besides the complex multiplets for aromatic protons (11H, δ 7.05—8.15). The sample recrystallized from methanol and ethanol showed additional broad singlets for O–H protons centered at δ 2.60 and δ 3.05, respectively, as well as the normal proton signals for methyl and ethyl groups. The signal for S–H was not affected appreciably by the presence of alcohol when the measurements were made at relatively low sample concentrations (5%). The results indicate that monobenzoylated 1,8-naphthalenedithiol can exist in two isomeric forms, 8-benzoylthio-1-naphthalenethiol (**1**) and 2-phenylnaphtho[1,8-*de*][1,3]dithian-2-ol (**2**). The latter is isolable as solid only by a fortuitous stabilization in the crystal lattice, the former structure being energetically favorable in solution.



A similar attempt for the preparation of the monoacetyl derivative by the reaction with acetic anhydride yielded a viscous oil after purification on silica gel (25% yield as monoacetate).[1] This preparation gave the exact result in elemental analysis for the expected thioester. However, the IR spectra (neat) showed only a weak carbonyl band at 1690 cm^{-1} and strong ν_{O-H} band at 3300 cm^{-1}, indicating the presence of substantial amount of O–H containing species. Thus, the NMR spectra in $CDCl_3$ consist of two sets of signals, which most probably arise from the two structural isomers **3** and **4** (Fig. 1), analogous to those for the monobenzoate derivative. In contrast to the benzoyl

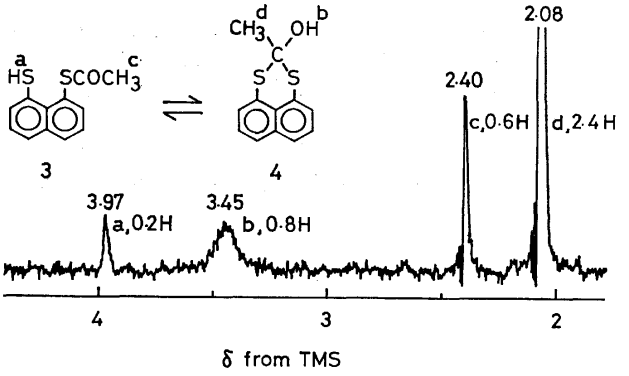


Fig. 1. NMR spectrum of monoacetylated 1,8-naphthalenedithiol ($CDCl_3$).

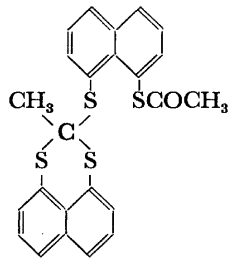
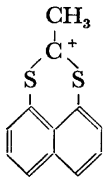
derivative, the cyclic isomer **4** is more favored as compared to **3** in the ratio *ca.* 4: 1. This is understandable if we recall the fact that the resonance stabilization associated with the conjugation between carbonyl and phenyl groups is eliminated on going from **1** to **2**. The equilibrium is also dependent on the nature of the solvent. In deuteriated methanol only one species, probably **4**, was observed in the NMR spectrum (one methyl signal in the high-field side, δ 2.03; however, the possibility that the two isomers are in rapid equilibrium in NMR time scale can not be excluded), and the carbonyl band at 1670 cm^{-1} was very weak in intensity. It is reasonable that the hydroxylic medium favors the formation of **4**, since the latter would be more stabilized than **3** in virtue of hydrogen bonding interaction with the solvent.

Another property related to the stability of the cyclic structure is the behavior in a strong acid. As an example, **3** (**4**) dissolves in 96% sulfuric acid with intense bluish-violet coloration, showing a single methyl signal at δ 2.75 (ppm from external TMS) and multiplet at δ 7.0—8.0. The former is featured by a considerable down-field shift as compared to that of **3** or **4**. Dilution of the solution with cold water gave only a trace of

recovered **3** (**4**), affording **5** as white crystalline solid. Compound **5** (mp 130—131 °C; $\nu_{C=O}$, 1690 cm^{-1}; NMR in $CDCl_3$, δ 1.78 (s, 3H), 2.23 (s, 3H), 7.1—8.0 (m, 12H), confirmed also by EA and molecular weight measurement by osmometer) was isolable as a by-product by monoacetylation in 20% yield. This is presumably formed by acid catalysed bimolecular condensation of **3** and **4** during the course of isolation. The solution of **5** in H_2SO_4 gave identical NMR signals to those of **3** (**4**). Though the evidences are preliminary, they seem to indicate the formation of carbenium ion **6**[2] in sulfuric acid solution.



5



6

It is interesting that the structures of **2** and **4** embody the tetrahedral addition intermediate from the ester (RCOSR') and the nucleophile (R'SH) of interest in acyl transfer mechanism, whose isolation and characterization have only recently been successfully carried out for a specifically designed polyfunctional compound directed to the study of enzyme-like catalysis for acyl transfer processes.[3] The facile formation of the tetrahedral intermediate for the present compounds is undoubtedly related to the unique spatial disposition of the two aromatic thiyl groups around the hemiacylal carbon. For the monoacylated analogues derived from aliphatic 1,3-dithiols,[4] no such intermediates were detected.[5]

References

1) A photochemical method has been described for the preparation of monoacyl derivative of 1,8-naphthalenedithiol (Ref. 4), but the ordinary acylation practice proved to be more convenient for large scale synthesis.

2) **6** seems to be the first example of dithiyl-substituted carbenium ion from 1,8-naphthalenedithiol.

3) G. A. Rogers and T. C. Bruice, *J. Am. Chem. Soc.*, **96**, 2481 (1974).

4) M. Takagi, S. Goto, and T. Matsuda, *J. Chem. Soc., Chem. Commun.*, **1976**, 92.

5) In sulfuric acid, however, the aliphatic analogues were found to behave somewhat similarly. 1,3-Dithiol is a structural unit of coenzyme dihydrolipoic acid which functions as an acetyl carrier in pyruvate dehydrogenase. In this connection, thermodynamic stability of the tetrahedral addition intermediate exhibited by mono-*S*-acetylated 1,8-naphthalenedithiol should not be overlooked. However, implications based on a simple structural analogy between the aromatic and aliphatic 1,3-dithiols should not be made.

(Received February 18, 1977)

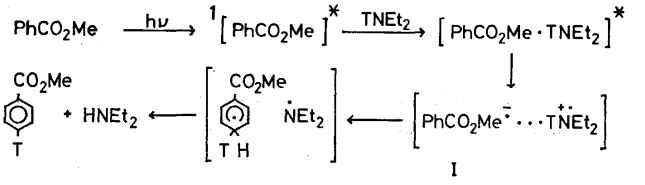
Synopsis. Methyl benzoate was tritiated at both nuclear and methyl positions on irradiation with diethylamine-*N*-*t* in benzene and with triethylamine–tritiated water in acetonitrile.

In a previous paper we demonstrated that irradiation of benzonitrile with diethylamine-*N*-*t* or a triethylamine–tritiated water mixture causes tritium uptake in the nucleus of benzonitrile, and proposed a mechanism involving the exciplex between benzonitrile and the amines.[1] In this paper we wish to report on our studies of methyl benzoate: irradiation of methyl benzoate with diethylamine-*N*-*t* and a triethylamine–tritiated water mixture, as well as 1-propanethiol-*S*-*t*,[2] brings about the incorporation of tritium not only in the nucleus but also in the methyl group of the ester.

Results and Discussion

A mixture of methyl benzoate, benzene, and diethylamine-*N*-*t* was irradiated with a 1 kW high pressure mercury arc lamp for 30 h. The aromatic compounds were separated by fractional distillation and submitted to tritium assay. Methyl benzoate was degraded by the known procedures[3] in order to determine the tritium distribution. Light induced tritiation of methyl benzoate was also carried out with triethylamine and tritiated water in acetonitrile. Methyl benzoate was recovered and degraded in a similar way.

The rates of nuclear tritiation of methyl benzoate relative to benzene (k_N/k_B) and relative to the methyl group of the ester (k_N/k_M) and the tritium distribution in the nucleus of the ester are shown in Table 1. The relative rate, k_N/k_B, is high and the order of reactivity among the nuclear positions is *para*≫*ortho*>*meta* in the tritiation with both diethylamine-*N*-*t* and the mixture of triethylamine and tritiated water. These results are similar to those obtained for benzonitrile,[1] suggesting the following mechanism for the tritiation of methyl benzoate with diethylamine-*N*-*t*:



The singlet excited methyl benzoate forms an exciplex with the amine, which collapses to a radical cation and a radical anion (I). Triton transfer from the former to the latter produces a radical pair of a cyclohexadienyl radical and a diethylaminyl radical, which in turn disproportionates, leading to the tritiation of methyl benzoate. In the tritiation with triethylamine triton is transferred to the radical anion, I, from tritiated water.

In order to estimate the nature of the postulated radical anion, its charge density was calculated by the molecular orbital method using the CNDO/2 approximation.[4] The geometry of I was assumed to be planar with the benzene ring and the methyl group apart and was constructed by using the standard bond lengths and angles.[5] The results show that the charge on the *meta* carbons is slightly positive ($C_{meta}=+0.006$), while those on the *ortho* and *para* carbons are greatly negative ($C_{ortho}=-0.057$ and $C_{para}=-0.119$). Although the geometry used for the calculation was not optimized, the charge distribution pattern itself did not change seriously for small variant in the geometry. The similarity between the charge density and the tritium distribution pattern may be taken as indicating the intermediacy of the methyl benzoate radical anion, I, in the tritiation.

More remarkable is the methyl tritiation, of which specific mention must be made. The finding that no tritiation occurred at both methyl and nuclear positions on irradiation of methyl benzoate with tritiated water in the absence of triethylamine suggests that the methyl tritiation proceeds through the radical anion, I, or at least through the exciplex between methyl benzoate and the amines. The radical anion, I, might take intramolecularly a proton from the methyl group, producing a carbanion (II), which then undergoes a set of triton capture and protium loss, leading to methyl

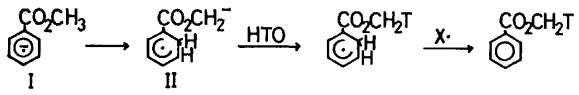
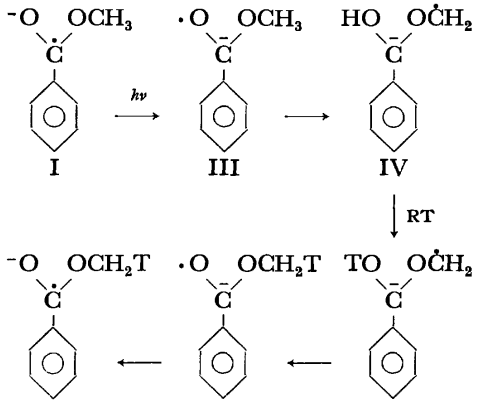
tritiation. If these reaction pathways were operating,



the use of methyl-*t* benzoate as the starting ester would lead to the incorporation of tritium in the nucleus. Thus, a mixture of methyl-*t* benzoate, triethylamine, water, and acetonitrile was exposed to light from the 1 kW lamp for 30 h. For the recovered methyl benzoate, no incorporation was observed in the nucleus and the mechanism involving the proton (triton) transfer from the methyl group to the nucleus is improbable.

Under illumination the radical anion, I, might be excited to a higher electronic state represented by structure III. The excited radical anion, III, could intramolecularly abstract a hydrogen atom from the methyl group to afford another radical anion (IV), in which the proton on the hydroxy group would be exchangeable with tritons in the system. The resulting radical anion-*O*-*t* would decay to the starting radical anion, I, containing a triton at the methyl group.



Although no direct evidence was obtained for this mechanism, it is rationalized by the aforementioned circumstantial evidence; the tritiation with tritiated water proceeds only in the presence of triethylamine and the extent of the tritiation of the methyl group relative to that of the nucleus is not much affected by varying the triton donors. Accordingly, we suppose the above mechanism most probable.

Experimental

Materials. Benzene, triethylamine, and methyl benzoate were purified by distillation or vacuum distillation. Diethylamine-*N*-*t* was prepared by the method reported.[1] Methyl-*t* benzoate was prepared in the usual way from the reaction of methanol-*t* (1.72 g, 53.8 mmol, 51.5 mCi/mol) with benzoyl chloride (7.19 g, 51.2 mmol) in hexane (20 ml) in the presence of pyridine (4.5 ml), and distilled *in vacuo* (6.08 g, 87%, 43.5 mCi/mol, radiochemical yield: 71%).

Tritiation of Methyl Benzoate with Diethylamine-N-t. A mixture of diethylamine-*N*-*t* (1.18 g, 16.2 mmol, 2.19 Ci/mol), methyl benzoate (10.6 g, 77.7 mmol), and benzene (6.06 g, 77.7 mmol) was irradiated in a Pyrex tube under nitrogen for 30 h with a 1 kW high pressure mercury arc lamp. The reaction mixture was washed with 1 M sulfuric acid and water to remove the amine, and the aromatic compounds were separated by distillation. Benzene and methyl benzoate were further purified by fractional distillation and submitted to tritium assay (benzene, 3.64×10^{-3} mCi/mol; methyl benzoate, 0.581 mCi/mol). Methyl benzoate was hydrolyzed with a sodium hydroxide solution. Benzoic acid, isolated and purified by recrystallization, was submitted to tritium assay (0.554 mCi/mol).

Tritiation with Triethylamine and Tritiated Water. A solution of methyl benzoate (2.64 g, 19.4 mmol), triethylamine (1.46 g, 14.4 mmol), and tritiated water (2 ml, 111 mmol, 335 mCi/mol) in acetonitrile (10 ml) was irradiated in a Pyrex tube under argon for 30 h with a 1 kw lamp. Triethylamine, acetonitrile, and water were removed by distillation, and the residual methyl benzoate was washed with watre and fractionally distilled. Methyl benzoate purified and benzoic acid obtained by hydrolysis of the ester were submitted to tritium assay (methyl benzoate, 0.541 mCi/mol; benzoic acid, 0.477 mCi/mol).

Irradiation of Methyl Benzoate with Tritiated Water. A solution of methyl benzoate (5.28 g, 38.8 mmol) and tritiated water (4 ml, 222 mmol, 123 mCi/mol) in acetonitrile (20 ml) was irradiated for 30 h with a 1 kW lamp and treated in a similar way to that above mentioned. No tritium was found to be incorporated in methyl benzoate.

*Irradiation of Methyl-*t *Benzoate in the Presence of Triethylamine and Water.* A solution of methyl-*t* benzoate (7.92 g, 58.2 mmol, 3.63 mCi/mol), triethylamine (4.37 g, 43.2 mmol), and water (6 ml, 333 mmol) in acetonitrile (30 ml) was irradiated with a 1 kW lamp. No tritium was found to be incorporated in benzoic acid obtained after the usual work-up.

Degradation of benzoic acid for the determination of tritium distribution and tritium activity measurements were carried out as reported.[1]

5-Fluorouracil Derivatives. II.[1] A Convenient Synthesis of 5-Fluoro-2′-deoxyuridine

Shoichiro OZAKI, Tsutomu KATAKAMI, and Mineo SANEYOSHI*

Research Center, Mitsui Toatsu Chemicals, Inc., 1190 Kasama-cho, Totsuka-ku, Yokohama 247

**Faculty of Pharmaceutical Sciences, Hokkaido University, Sapporo 060*

(Received February 21, 1977)

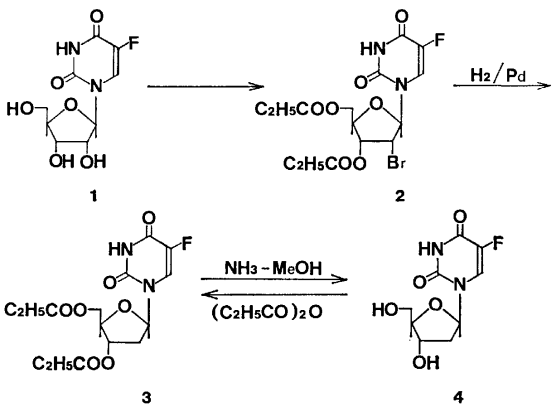
Synopsis. The reaction of 5-fluorouridine with propionyl bromide in acetonitrile afforded 3′,5′-di-*O*-propionyl-2′-bromo-5-fluoro-2′-deoxyuridine (**2**). Compound **2** was then hydrogenated, using Pd–C as the catalyst, to afford 3′,5′-di-*O*-propionyl-5-fluoro-2′-deoxyuridine (**3**). Compound **3** was deacylated with methanolic ammonia to give 5-fluoro-2′-deoxyuridine (FUDR). In this way, FUDR, a good antitumor agent, can easily be prepared from 5-fluorouridine by three steps in a 48.9% total yield.

5-Fluoro-2′-deoxyuridine (FUDR, **4**) was first prepared by enzymic procedures[2] and then by the chemical condensation method using a mercury-process.[3] In the latter process, methyl 2-deoxy-D-ribofuranoside was converted to the 3,5-di-*O*-*p*-toluoyl derivative, which was treated with HCl to give 3,5-di-*O*-*p*-toluoyl-2-deoxy-D-ribosyl chloride. 5-Fluorouracil-mercury was synthesized from 5-fluorouracil and mercury(II) acetate. The condensation of 3,5-di-*O*-*p*-toluoyl-2-deoxy-D-ribosyl chloride with 5-fluorouracil-mercury and the subsequent deacylation of the condensation product yielded **4** in a 30.8% total yield. Autitumor activities of **4** were demonstrated in several experimental tumors[4,5] and by clinical studies.[6]

Compound **4**, an approved drug for clinical use, has a remarkable anti-tumor activity with low toxicity. Unfortunately, this material was too expensive, because an industrial synthetic method had not yet been found.

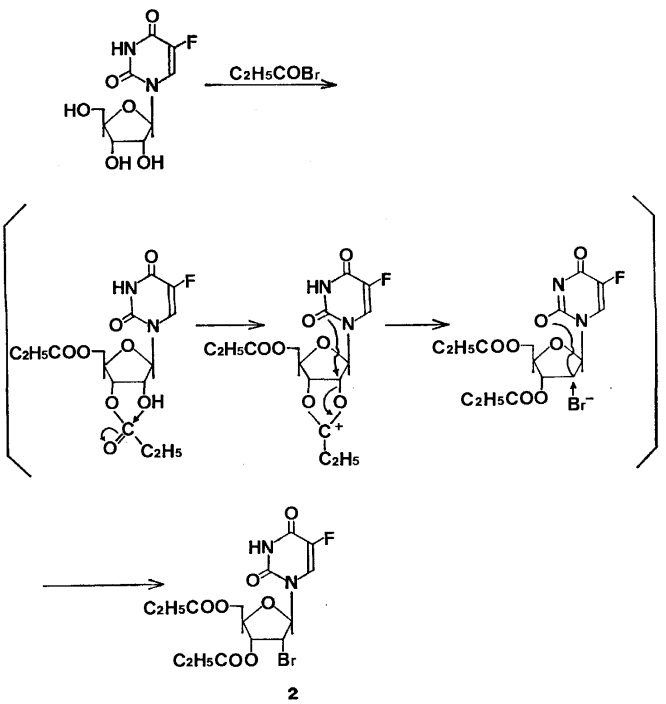
In this paper, we wish to report a convenient and industrial method for the synthesis of **4** starting from 5-fluorouridine (**1**), which can be prepared[7,8] easily from trimethylsilylated 5-fluorouracil and 1-acetyl-2,3,5-tribenzoylribose.

2′-Deoxyuridine was synthesized by Marumoto *et al.*[9] from uridine. When this synthetic procedure was applied to 5-fluorouridine (**1**), **4** was obtained from **1** *via* three steps in a 48.9% total yield. The synthetic route is illustrated in Scheme 1.



Scheme 1.

5-Fluorouridine (**1**) was suspended in acetonitrile, and the mixture was heated. Propionyl bromide was then added to the mixture at reflux to afford, after the usual work-up, 3′,5′-di-*O*-propionyl-2′-bromo-5-fluoro-2′-deoxyuridine (**2**) with a mp of 160—162 °C. This reaction may take place by means of the following mechanism,[9] even though no intermediate was isolated.



2

Compound **2** was hydrogenated on Pd–$BaSO_4$ as a catalyst at 1 atm 20 °C for 4 h to afford 3′,5′-di-*O*-propionyl-5-fluoro-2′-deoxyuridine (**3**) in a crystalline form in a 85.9% yield.

Compound **3** was also obtained by the reaction of authentic **4** with propionic anhydride, which was identical with the above sample. Compound **3** was deacylated with methanolic ammonia at 5 °C for 14 h to afford **4**. The structures of **2**, **3**, and **4** were confirmed by elemental analysis, IR, and NMR. The properties of the synthesized **4** were in good accord in all respects with those of an authentic **4** (obtained from PCR Inc. Gainesville, Florida, USA) and showed no depression in mixed mp. It may be concluded that this synthetic method is a convenient and inexpensive method to produce **4**.

Experimental

3′,5′-Di-O-propionyl-2′-bromo-5-fluoro-2′-deoxyuridine (2).

Into a boiling suspension of 5-fluorouridine (1310 mg, 5 mmol) in acetonitrile (60 ml), was added propionyl bromide (3 ml, 30 mmol) over a 30-min period. The stirring was then continued for a further 3 h. After the reaction mixture had been cooled, the solvent was evaporated, the residue was dissolved in methanol, and the solution was again evaporated to dryness. The residue was purified by column chromatography on silica gel using a benzene–methanol (4: 1) solvent. The crude product was crystallized from methanol to afford **2** (1764 mg, 80.8%): mp 160—161 °C. R_f=0.43 (benzene 4: methanol 1); IR (KBr) 3220, 3000, 1737 (s), 1710, 1475, 1392, 1357, 1289, 1270, 1212, 1180, 1162, 1098, 1068, 1040, 875, 812, cm^{-1}; NMR (60 MHz, CD_3OD) 1.12 (6H, t, J=7 Hz, CH_3), 2.44 (4H, q, J=7 Hz, CH_2), 4.36 (3H, m, OCH_2 and C_4'-H), 4.75 (CH_3O in CD_3OD+C_3'-H), 5.20 (1H, m, C_2'-H). Found: C, 40.96; H, 4.15; Br, 18.65; F, 4.25%. Calcd for $C_{15}H_{18}BrFN_2O_7$: C, 41.21; H, 4.15; Br, 18.28; F, 4.35%.

3',5'-Di-O-propionyl-5-fluoro-2'-deoxyuridine (3). *a*): To a suspension of a 5% Pd–$BaSO_4$ catalyst (40 mg) in water (10 ml), was added a solution of **2** (169 mg, 0.364 mmol) and sodium acetate (89 mg, 1.09 mmol) in methanol (20 ml). The mixture was shaken in a hydrogen atmosphere at 1 atm and 23 °C for 4 h. The catalyst was then removed by filtration, and the filtrate was concentrated. The resulting sirup was mixed with water (10 ml) and extracted with chloroform. The chloroform layer was dried (Na_2SO_4) and evaporated. The residue was crystallized from ethanol to afford **3** (123 mg, 85.9%): mp 122—123 °C. TLC R_f=0.46 (benzene 4: methanol 1); IR (KBr) 3240, 3100, 3020, 1730 (s), 1685, 1470, 1372, 1290, 1280, 1260, 1200, 1180, 1142, 1076, 1012, 968, 927, 892, 866, 810, 789, 765 cm^{-1}. Found: C, 50.33; H, 5.38; F, 5.25; N, 7.71%. Calcd for $C_{15}H_{19}FN_2O_7$: C, 50.28; H, 5.34; F, 5.30; N, 7.82%.

b): A mixture of **4** (246 mg, 1 mmol), propionic anhydride (0.5 ml, 4 mmol), and anhydrous pyridine (20 ml) was heated at 110 °C for 2 h. The solvent was then evaporated *in vacuo*, and the residue was purified by column chromatography on silica gel (using 4: 1 benzene–methanol as the eluting solvent). Crude **3** was crystallized from ethanol to give pure **3** (277 mg, 77%): mp 122—123 °C.

5-Fluoro-2'-deoxyuridine (4). 3',5'-Di-*O*-propionyl-5-fluoro-2'-deoxyuridine (218.6 mg, 0.61 mmol) in 20% methanolic ammonia (20 ml) was kept overnight at 5 °C. The reaction mixture was then concentrated to afford an oily substance. The oil was crystallized from methanol to afford **4** (177 mg, 70.5%); mp 150 °C. The sample was confirmed by IR, elemental analysis, and a mixed mp determination (150 °C) to be the same as the authentic **4**.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (8), 2199—2200 (1977)

The Reaction of Copper(I) Methyltrialkylborates with Allylic Halides or 2-Propynylic Halides

Norio MIYAURA, (the late) Mitsuomi ITOH, and Akira SUZUKI*
Faculty of Engineering, Hokkaido University, Sapporo 060
(Received March 7, 1977)

Synopsis. The reactions between copper(I) methyltrialkylborates (readily obtainable from organoboranes) and allylic halides or 2-propynylic halides were found to give corresponding alkylation products. These reactions provide novel synthetic routes to 1-alkenes or 1,2-alkadienes from organoboranes.

Recently we have reported that lithium methyltrialkylborate readily undergoes a cation exchange reaction by copper(I) halide to give copper(I) methyltrialkylborate (**1**), which successfully reacts with acrylonitrile, ethyl acrylate, 1-acyl-2-vinylcyclopropane,[1] benzylic bromides,[2] and aroyl chlorides.[3]

In an attempt to develop reaction of such borate complexes, we examined the possibility of alkylation reactions of 2-propenylic halides and 2-propynylic halides. No reaction occurs between allyl bromide and lithium methyltrialkylborates at room temperature, whereas when copper(I) borates (**1**) are used instead of lithium borates, the reaction proceeds smoothly to give corresponding products as shown in Eqs. 1. and 2.

$$R_3B + MeLi \longrightarrow [R_3BMe]Li \xrightarrow{CuX} \underset{\mathbf{1}}{[R_3BMe]Cu} + LiX \quad (1)$$

$$\mathbf{1} + CH_2{=}CHCH_2X' \longrightarrow RCH_2CH{=}CH_2 + R_2BMe + CuX' \quad (2)$$

The yields of alkylation products are dependent upon the copper(I) halides and allyl halides employed, as revealed in the case of copper(I) methyltrihexylborate in Table 1. In general, allyl chloride gives good yields of products. This reaction is applicable to representative organoboranes and 2-propenylic chlorides. The reaction appears to proceed through an allylic rearrangement as the main path, judging from the results obtained in the reaction of copper(I) methyltripropylborate with cinnamyl chloride, and it was noted that the attack of the methyl group in the borate complex may not be involved.

In the same way, copper(I) methyltrialkylborates react with 2-propynylic halides to give corresponding 1,2-alkadienes (Eq. 3). Some of the representative results are summarized in Table 1. Although the latter

$$\mathbf{1} + R'{-}C{\equiv}C{-}CH_2Br \longrightarrow \underset{\mathbf{2}}{\overset{R}{\underset{R'}{\diagdown\!\!\diagup}}C{=}C{=}CH_2} + \underset{\mathbf{3}}{\overset{Me}{\underset{R'}{\diagdown\!\!\diagup}}C{=}C{=}CH_2} \quad (3)$$

reaction provides a convenient synthetic procedure of 1,2-alkadienes from organoboranes, the formation of undesirable products (**3**) by the attack of methyl groups in borates reduces yields of desired products (**2**).

It is becoming increasingly evident that copper(I) methyltrialkylborates have a considerably high utility in organic synthesis. The applicability of this new alkylating agent to coupling and addition reactions is under further investigation.

Experimental

a) Reactions were carried out for 2 h by using a 20% excess of borate complexes at room temperature. b) Based on 2-propenylic or 2-propynylic halides employed.

* To whom all correspondences should be addressed.

2-propynylic halides are commercially available. The organic compounds used in the experiments were purified by distillation before use. Trialkylboranes were prepared by the usual procedure.[5]

The IR and NMR spectra were taken on a Hitachi-Perkin-Elmer Model 125 spectrophotometer and a Hitachi R-22 spectrometer at 90 MHz using tetramethylsilane as the internal standard, respectively.

General Procedure. The following procedure for the preparation of 8-chloro-1-octene is representative. A dry 50 ml-flask was charged under dry nitrogen atmosphere with 1.72 g (12 mmol) of copper(I) bromide and 6 ml of dry tetrahydrofuran. To this mixture was added lithium methyltris(5-chloropentyl)borate[2,4] (12 mmol in THF) at 0 °C, and the mixture was stirred for 5 min. Then allyl chloride (0.815 ml, 10 mmol) was gradually added and the mixture was stirred for further 2 h at room temperature. The residual organoborane was oxidized with 5.4 ml of 3 M NaOH and 5.4 ml of 30% H_2O_2 at room temperature for 2 h. The product was extracted with ether. The combined extract was washed with water and then dried over anhydrous sodium sulfate. The ether solution thus obtained was analyzed by VPC, revealing the formation of 8-chloro-1-octene (9.1 mmol, 91%). An analytically pure sample was obtained by preparative VPC with Varian autoprep Model-2800.

Identification of the Products. 1-Nonene and 1-undecene were identified by direct comparison with authentic samples which were commercially available from Tokyo Kasei Kogyo Co., Ltd. 1,2-Octadiene and 1,2-undecadiene were characterized by comparison with samples prepared by the methods reported by Meisters[6] and Moore,[7] respectively.

8-Chloro-1-octene: n_D^{24} 1.4508. Found: C, 65.31; H, 10.15%. Calcd for $C_8H_{15}Cl$: C, 65.52; H, 10.31%. Mass; m/e=146, 148 (M^+). IR (neat): 3055, 1630, 910 cm^{-1}. NMR (CCl_4); τ, 8.6 (8H, s), 7.99 (2H, t, J=7.0 Hz), 6.51 (2H, t, J=6.5 Hz), 4.85—5.15 (2H, m), 4.0—4.45 (1H, m).

3-Phenyl-1-hexene: n_D^{24} 1.4999. Found: C, 89.75; H, 9.91%. Calcd for $C_{12}H_{16}$: C, 89.94; H, 10.06%. Mass: m/e=158 (M^+). IR (neat): 1630, 1600, 915 cm^{-1}. NMR (CCl_4); τ, 9.10 (3H, t, J=6.3 Hz), 8.50—8.95 (2H, m), 8.15—8.45 (2H, m), 6.78 (1H, q), 4.90—5.15 (2H, m), 3.85—4.25 (1H, m), 2.82 (5H, s).

3-Phenyl-1,2-heptadiene: n_D^{24} 1.5637. Found: C, 90.77; H, 9.42%. Calcd for $C_{13}H_{16}$: C, 90.64; H, 9.36%. Mass: m/e=172 (M^+). IR (neat): 1945, 1600, 1496, 695 cm^{-1}. NMR (CCl_4): τ, 9.05 (3H, t, J=6.5 Hz), 8.3—8.8 (4H, m), 7.40—7.70 (2H, m), 4.96 (2H, m). 2.5—2.9 (5H, m).

3-Phenyl-1,2-butadiene: n_D^{24} 1.5612. Found: C, 92.35; H, 7.68%. Calcd for $C_{10}H_{10}$: C, 92.26; H, 7.74%. Mass; m/e=130 (M^+). IR (neat): 1945; 1600, 1500, 965, 695 cm^{-1}. NMR (CCl_4): τ, 7.93 (3H, t, J=2.6 Hz), 4.90—5.50 (2H, m), 2.55—2.90 (5H, m).

Photo-induced Cycloaddition of 1-Nitrocyclooctene and Cyclopentadiene

Keiichi YOKOYAMA, Masao KATÔ, and Ryoji NOYORI

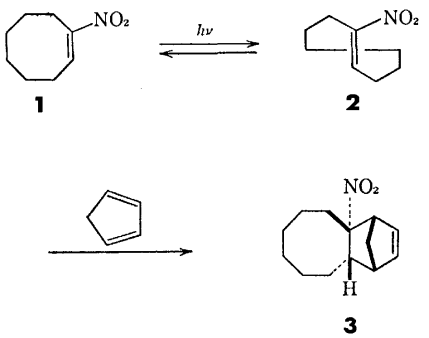
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received April 4, 1977)

Synopsis. Irradiation of 1-nitrocyclooctene produces first the strained *trans* isomer, which in turn undergoes thermal Diels-Alder reaction with cyclopentadiene affording the tricyclic adduct.

As a part of our investigation of the photochemical behavior of medium-sized cycloalkene derivatives,[1] a reaction of 1-nitrocyclooctene (**1**) has been examined.[2]

In the dark and below room temperature, no appreciable reaction took place between the nitro olefin **1** and cyclopentadiene. However, when the mixture immersed in a Dry Ice bath was irradiated by a high-pressure mercury arc through a Pyrex filter (n-π^* excitation), smooth reaction occurred and after 4 h the 1:1 cycloadduct **3** was obtained in *ca.* 40% yield. The norbornene type structure as well as the endo stereochemistry of the nitro group was deduced from the NMR signals of the vinylic protons;[3] both proton



signals appeared as a doublet of doublets with J=6 and 3 Hz with a rather great chemical shift difference, $\Delta\delta$ 0.42 ppm, due to the presence of anisotropic influence of the neighboring nitro group.[4] Unlike photoreaction of 1-acetylcyclooctene[1f,g] or 1-carbomethoxycyclooctene,[5] no double-bond migration was observed with this eight-membered olefin.

Apparently the cycloaddition forming **3** involves the initial photo-induced *cis* to *trans* isomerization of the nitro olefin, **1**→**2**,[6] followed by thermal Diels-Alder reaction with cyclopentadiene.[7] The evidence for the intermediacy of the strained ground-state molecule **2** was obtained by a standard technique. Thus a solution of **1** in methylcyclohexane was first irradiated at −78 °C for 3 h. After the light source was removed, an excess of cold cyclopentadiene was added and the mixture was allowed to warm up to ambient temperature, which produced the cycloadduct **3**. The product to recovered **1** ratio indicated that the *trans* olefin **2** exists in rather high concentration (at least 28%) in the photo-equilibrium mixture produced by the photolysis of **1**.

Experimental

Photolysis of 1-Nitrocyclooctene (1) in Cyclopentadiene. The nitro olefin **1** was prepared by the known procedure,[8] bp 87—88 °C (3 Torr). The UV spectrum in hexane solution exhibited absorption maxima at 257 (ε 8470) and 345 nm (weak). A solution of **1** (550 mg, 3.54 mmol) in freshly distilled cyclopentadiene (50 ml) was placed in three Pyrex tubes (15×180 mm), flushed with nitrogen, and immersed in a Dry Ice–CH_3OH bath. Then irradiation was effected externally with a 200 W hign-pressure mercury arc for 4 h. The photolysate was concentrated at room temperature under reduced pressure and the residue was chromatographed on a silica gel plate (Merck Kieselgel GF_{254}, 10:1 hexane–ether). The fraction slightly less polar than **1** was extracted to give 2α-nitro-(1β, 2α,9β,10β)-tricyclo[8.2.1.$0^{2,9}$]tridec-11-ene (**3**) (236 mg; 32%). The yield based on the unrecovered starting olefin was *ca.* 40%. In addition, several unidentified products were produced.[2] A sample of **3** for analysis was obtained by recrystallization from hexane, mp 76.0—76.5 °C (uncorrected). IR (CCl_4) 1610 (C=C), 1534, 1354, 1335 cm^{-1} (NO_2); NMR (CCl_4 containing tetramethylsilane as internal standard) δ 1.2—3.2 (broad signal with four envelopes), 5.88 (dd, J=6 and 3 Hz, vinylic proton at C_{11}), and 6.30 (dd, J=6 and 3 Hz, vinylic proton at C_{12}); MS (70 eV) *m/e* 221 (M^+), 190, 175, 147, 91, and 66 ($M^+ - C_5H_6$, *retro*-Diels-Alder process).

Found: C, 70.45; H, 8.74; N, 6.24%. Calcd for $C_{13}H_{19}O_2N$: C, 70.55; N, 8.65; N, 6.33%.

Dark Reaction of the Trans *Isomer of 1 and Cyclopentadiene.* A methylcyclohexane solution (25 ml) of **1** (256.6 mg, 1.66 mmol) in Pyrex tubes was cooled in a Dry Ice–CH_3OH bath and irradiated under nitrogen for 3 h. After the lamp had been turned off, to the photolysate was added cyclopentadiene (*ca.* 20 ml) and the mixture was warmed up spontaneously to room temperature with stirring. The volatile substances were removed by evaporation. TLC separation of the residual mixture afforded **3** (77 mg; 22% yield) and unchanged **1** (141 mg; 55% recovery).

Utilizing Emulsification in the Synthesis of Dihydro-*exo*-dicyclopentadienyl Ethers and Their Esters

Akira HATANO and Yoshiyuki IWASE

Mitsui Petrochemical Industries, Ltd., Waki-cho, Kuga-gun, Yamaguchi 740

(Received December 17, 1976)

Synopsis. Alcohols and carboxylic acids were subjected to an addition reaction with dicyclopentadiene, using dodecylbenzenesulfonic acid both as the emulsifying agent and the acid catalyst. Dihydro-*exo*-dicyclopentadienyl ethers and their esters were syntheized in good yields and found to be free of undesirable side reactions.

It is important to investigate the method of synthesizing dicyclopentadienyl ethers and their esters because of the usefulness of these compounds as plasticizers and drying oils. There are two known methods for preparing these compounds. One involves the reaction of a carboxylic acid with hydroxy-dihydro-*exo*-dicyclopentadiene and an alkaline metal alcoholate with dihydro-*exo*-dicyclopentadienyl halide.[1] The other method consists of an electrophilic addition reaction[2] of dicyclopentadiene with an alcohol or a carboxylic acid by using the difference in the reactivities[3] of the two double bonds in dicyclopentadiene in the presence of an acid catalyst, although the yields for this method are generally low.

The present paper describes an alternative method of preparing these compounds with a view to obtaining satisfactory yields. The necessary procedures are also dealt with.

Results and Discussion

Bruson *et al.* have reported on the preparation of dihydro-*exo*-dicyclopentadienyl ether[4] by the electrophilic reaction of an alcohol with dicyclopentadiene, and of dihydro-*exo*-dicyclopentadienyl ester by a similar reaction involving a carboxylic acid with dicyclopentadiene.[5]

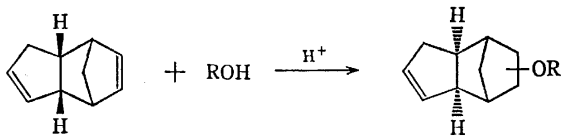

Table shows the results of this experiment. It is noted that the amount of acid catalyst required in the reaction of dicyclopentadiene with a carboxylic acid is rather small in comparison with that in the reaction of dicyclopentadiene with an alcohol, since in the former case it is needed only as a co-catalyst. As can be readily seen, both alcohols charaterized by poor or no solubility in dicyclopentadiene, as well as carboxylic acids, gave the addition products in very low yields. It is assumed that the most important cause of the limited yields in the heterogeneous system is due to the poor or no solubility of these compounds in dicyclopentadiene. In particular, the heterogeneous system causes side reactions *i.e.*, partial cationic polymerization[6] of dicyclopentadiene or a dehydratic condensation reaction[7] of alcohol in the presence of concentrated sulfuric acid.

To avoid this and to increase the yield, it was thought that a compound that would homogenize the heterogeneous system and at the same time act as a catalyst for the reaction would be worth testing. The refore, use was made of dodecylbenzenesulfonic acid, a strong acid capable of emulsifying action. The results show that the emulsifying action homogenized the heterogeneous system and restrained side reactions at the same time, thus increasing the yield and permitting the use of

a) The amount of the catalyst was calculated on the basis of one mol of dicyclopentadiene. b) Given in the ratio of the percentage of the amount obtained from GLPC (without **1c** and **2c** isolated) to that calculated from the mol of dicyclopentadiene used. c) Heterogeneous system in the reaction. d) Homogeneous system in the reaction. e) BF_3OEt_2 was used.

smaller amounts of the acid catalyst. From the above data, it was concluded that an acid with emulsifying action and capable of catalyzing the reaction, such as dodecylbenzenesulfonic acid, gives the addition product in better yields for carboxylic acids, as well as for alcohols, even when these are poorly soluble or insoluble in dicyclopentadiene.

Experimental

The NMR spectra were recorded on a Nippon Denshi Kogaku Model JNM-4H-100 spectrometer in parts per million (ppm) from internal tetramethylsilane. The IR spectra were obtained on a Nippon Bunko Model DS-701 D spectrometer using neat liqids between KBr disks. The mass spectra were measured on a Nippon Denshi Model D-100 spectrometer with an electron bombarding energy of 75 eV.

*Preparation of Ethylene Glycol Mono(dihydro-*exo*-dicyclopentadienyl) Ether.* Dodecylbenzenesulfonic acid (8.15 g, 0.025 mol) was added dropwise to the stirred ethylene glycol (31 g, 0.5 mol) at room temperature. The dicyclopentadiene (66 g, 0.5 mol) was added dropwise and the mixture was rapidly stirred until it was emulsified. The emulsified mixture was then heated to 100 °C and the reaction proceeded for 4 h. The reaction mixture was cooled to room temperature and benzene (100 g) was added to the stirred mixture. The mixture was poured into 3% aqueous sodium chloride (500 g) containing sodium hydroxide (1.4 g, 0.035 mol) to neutralize the acid, and left standing to separate out the oil layer. The layer was washed four times with a portion of 3% aqueous sodium chloride (500 g), dried over sodium sulfate, and distilled *in vacuo*. Bp 105—106 °C/0.5 Torr, Yield: 76% (from GLPC).

*Preparation of Dihydro-*exo*-dicyclopentadienyl Acetate.* Dodecylbenzenesulfonic acid (6.5 g, 0.02 mol) was added slowly to acetic acid (30 g, 0.5 mol), and cooled to 10 °C, followed by dropwise addition of dicyclopentadiene (66 g, 0.5 mol). The stirred mixture was heated to 100 °C and allowed to react for 5 h. The reaction mixture was cooled to room temperature, ethyl ether (100 g) was added and the mixture was poured into water (500 g) to separate out the oil layer. The oil layer was neutralized with sodium carbonate, washed a few times with a portion of water (500 g), dried over sodium sulfate, and vacuum distilled. Bp 96—97 °C/5 Torr, Yield: 82% (from GLPC.).

Preparation of the addition products using other alcohols or carboxylic acids was similar in principle to the procedure described above.

Photolysis of Benzenesulfonic Acid[1)]

Yoshiro OGATA,* Katsuhiko TAKAGI, and Shin YAMADA
Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya 464
(Received August 2, 1976)

Synopsis. Photolysis of benzenesulfonic acid(**1**) in an aqueous solution gave sulfurous acid, SO_2, and/or sulfuric acid as inorganic products in a total yield of 38.6% based on the consumed **1** along with organic products. The organic products are mainly acidic tarry material containing sulfur(8.7%) together with a small amount of biphenyl (1%). Photolysis of an alkaline solution of **1** afforded a considerable amount of benzene (16%) and biphenyl(<1%). The photolysis is started by the C–S bond fission of **1** to give Ph· and $\cdot SO_3H$ radicals. The quantum yield for decomposition of **1** in acidic conditions is 0.26.

Sodium alkylbenzenesulfonate is known to be an environmental pollutant. The studies on the photochemical decomposition of the sulfonate have recently been increasing,[2)] but little is known about the mechanism and intermediates of the photolysis except for photolysis of sulfonate ester[3)] and sulfonanilide.[4)] The present paper deals with the attempts to obtain on the subject, in particular, the mechanism for photolysis of benzene sulfonic acid as a model of the surfactant.

Results and Discussion

Irradiation of Alkaline Aqueous Sodium Benzenesulfonate. The photolysis of an aqueous mixture of benzenesulfonic acid (**1**) and two equivalents of NaOH was carried out by bubbling N_2 gas in order to introduce volatile materials into a trapping tube containing ethyl ether cooled at −50 °C. After irradiation for 24 h, GLC analysis of the ether solution showed formation of benzene in a 16% yield on the basis of starting **1**. The irradiated reaction mixture was found to contain a trace amount of biphenyl (<1%) by GLC up to 250 °C.

Irradiation of Aqueous Benzenesulfonic Acid (1). Aqueous benzenesulfonic acid (**1**) was irradiated with a high-pressure mercury lamp under N_2. Evolved gas was identified to be SO_2 by the fuchsine test. The photolysis of **1** was carried out by bubbling N_2 in order to introduce the evolved gas into a trapping tube containing 10% H_2O_2. The evolved SO_2 was converted into H_2SO_4 by aqueous H_2O_2 and titrated with standard aqueous alkali. The yield of resulting SO_2 was 9.6% based on the consumed **1**. The irradiated solution was extracted with ether. The aqueous layer, containing unreacted **1** and other acidic materials, was concentrated *in vacuo*, esterified by CH_2N_2, and then analyzed by GLC. Only a peak of methyl benzenesulfonate was observed (35% recovery). The aqueous layer contains H_2SO_3 and/or H_2SO_4 in a total yield of 29.0%.

On the other hand, the organic layer of the ether extract contains biphenyl (1%, mp and mixture mp 69—70 °C). No formation of benzene was observed even under conditions similar to those for sodium benzenesulfonate. In contrast to sodium benzenesulfonate, the resulting phenyl radical formed by homolysis of the C–S bond may form complex products; the H_2SO_3 (and probably H_2SO_4) may attack the phenyl radical, inhibiting the formation of benzene.

Addition of 6-fold excess H_2O_2 to the system markedly increased the consumption of **1**. About 97% of **1** disappeared after 11 h to afford CO_2 (8%), H_2SO_4 (34%), phenol (<1%) *etc.*

No reaction occurred in the dark with the same system. Hence the acceleration by H_2O_2 may be due to the oxidation induced by ·OH radical from H_2O_2. The quantum yield for decomposition of **1** in water was 0.26 with 254 nm light.

Attempt to Characterize Tarry Material. Irradiation of **1** under acidic conditions yielded only a small amount of volatile product, biphenyl (1%), most part of the product being a black tarry material (95 wt % based on the consumed **1**). The structure of the substance is still obscure on account of its contaminant and experimental difficulties. After elimination of **1** and H_2SO_4, the tarry substance was found to contain 8.7 wt % of sulfur atom, the total amount of sulfur in recovered and isolated materials reaching 91%.

Attempts were made to isolate organic substance from the residue. Chromatography of the tarry material with a SiO_2 column yielded an yellow oil (5 wt %), giving two GLC peaks. However, the two components were too small in quantity for further purification. They were thus analyzed by GLC-MS, the results of which indicated their molecular weight to exceed 300 with no aromatic fragment ions (*e.g.*, *m/e* 77 and 91). The structure has not been identified yet. A remaining solid was obtained by the column chromatography.

Mechanism. The photoproducts, *e.g.*, benzene and biphenyl, indicate that the primary process may be the fission of C–S bond. The sum of yields of fission products ($SO_2+H_2SO_4$) in Eq. 1 reaches 38.6% based on the consumed **1**; thus Eq. 1 should be the main primary path for the decomposition. The fate of the resulting Ph· and $\cdot SO_3H$ radicals may be as follows:

$$PhSO_3H\ (\mathbf{1}) \xrightarrow{h\nu} Ph\cdot + \cdot SO_3H \quad (1)$$

$$Ph\cdot + \mathbf{1} \longrightarrow Ph_2 + \cdot SO_3H \quad (2)$$

$$Ph\cdot + RH \longrightarrow PhH + \cdot R \quad (3)$$

$$\cdot SO_3H \longrightarrow SO_2 + \cdot OH \quad (4)$$

$$\cdot OH + \mathbf{1} \longrightarrow \text{(OH, H, } -SO_3H\text{ (2))} \quad (5)$$

$$\mathbf{2} \longrightarrow Ph\cdot + H_2SO_4 \quad (6)$$

$$\mathbf{2} \longrightarrow \text{further reaction (tarry materials)} \quad (7)$$

$$2\cdot OH \longrightarrow H_2O_2 \quad (8)$$

$$H_2O_2 + SO_2 \longrightarrow H_2SO_4 \quad (9)$$

(RH: Hydrogen sources)

It may be concluded that the homolysis of excited **1** to (Ph· + ·SO_3H) is more plausible than the heterolysis into phenyl cation because of the formation of biphenyl but not phenol in both acidic and basic media. Water cannot be a hydrogen source for phenyl radical to benzene in Eq. 3, since the bond energy of C–H for benzene (112 kcal/mol) is lower than that of O–H for H_2O (120 kcal/mol).[5] Intermediary products such as **2** may play the role of hydrogen donor in Eq. 3.

It is of interest to note that the formation of benzene is favored in alkaline media. A plausible reason is as follows. In acidic media, ·SO_3H collapses into SO_2 and ·OH which subsequently oxidizes **1**, whereas in alkaline media, ·SO_3H exists as metastable ·SO_3^- species[6] which expels only slowly ·OH radical. The anion radical ·SO_3^- is known to add to unsaturated bonds, *e.g.*, aromatic ring according to Eq. 10.[7] Species **3** in Eq. 10 as well as **2** in Eq. 5 can be H· source for benzene formation.

$$\cdot SO_3^- + \diagdown C{=}C \diagup \longrightarrow \underset{\text{(3)}}{-\overset{\cdot}{C}-\overset{|}{C}-SO_3^-} \qquad (10)$$

Intermediacy of phenyl radical was also confirmed by the formation of benzene in the photolysis of **1** in the presence of a hydrogen donor such as 2-PrOH even under acidic conditions. The observed biphenyl may be formed either by the coupling of two Ph· or by an attack of Ph· on a phenyl ring of the starting **1** followed by a collapse to biphenyl and ·SO_3H radical (Eq. 2).

Another fragment, ·SO_3H, can be succesively decomposed to SO_2 and hydroxyl radical (Eq. 4). Hydration of SO_2 gives H_2SO_3, which is easily converted by H_2O_2 into H_2SO_4. Formation of H_2SO_4 from SO_2 and H_2O_2 was actually observed (Eq. 9). The resulting ·OH radical may couple to form H_2O_2 and also may attack **1** and other materials to give derivatives of **2** and oxidized tarry materials.[8]

It is less probable that $PhSO_3H$ is cleaved to ·OH and $PhSO_2$·, and then collapses to Ph· and SO_2, since the fission of $PhSO_2$· to Ph· and SO_2 is endothermic.[9]

The following results suggest that the reactive state is a singlet: (i) No quenching by a triplet quencher, *i.e.*, molecular oxygen, and (ii) no heavy atom effect by *n*-BuBr as a solvent.

Experimental

Melting points were measured on a hot plate with a Ynagimoto micro melting point apparatus and were corrected. IR spectra were measured with a Perkin-Elmer Model 337 spectrophotometer. A Yanagimoto GCG 550F gas chromatograph was used with two 2 m×2.5 mm columns, one packed with 2.5% PEG 20 M on a Chamelite CS and the other with Bentone 34+DIDP on a Chromosorb. A Shimadzu GC-MS 7000 was used for GLC-MS spectra.

A Typical Photolysis of Sodium Benzenesulfonate in Alkali. An aqueous solution (500 ml, 2.2×10^{-2} M) of **1**(2 g) with two equivalents of NaOH was irradiated with a 300 w Halos high pressure Hg lamp. Volatile materials evolved were introduced with N_2 gas as a carrier into a trapping tube containing ethyl ether at −50 °C. After irradiation for 24 h, GLC analysis of the ether solution indicated the formation of benzene (16% based on the starting **1** used). Biphenyl(<1%) was detected by GLC of the irradiated aqueous solution.

A Typical Photolysis of Benzenesulfonic Acid(1). An aqueous solution (200 ml, 5×10^{-2} M) of **1**(1.65 g) was irradiated under N_2 for 16 h using a 100 w Halos high pressure Hg lamp. Evolved SO_2 was identified by the color change of a fuchsine solution. The yield of evolved SO_2 was 9.6% based on the consumed **1** using titrimetry with a 0.01 M NaOH after its conversion into H_2SO_4 with aqueous H_2O_2. After the completion of irradiation, the solution was extracted with ether (200 ml). Biphenyl was obtained after evaporation of ether (20 mg, mp and mixture mp 69—70 °C).

The aqueous layer was subdivided into three equal portions. The first portion was used for the measurement of the conversion of **1**. After concentration under reduced pressure, it was esterified with CH_2N_2. The conversion of **1** was found to be 65% by GLC. The data were checked by a blank experiment in the dark.

The yield of H_2SO_3 and/or H_2SO_4 in the second portion (29.0%) was determined as $BaSO_4$ (0.13 g) by addition of $BaCl_2$ after treatment of excess H_2O_2.

The third portion was condensed *in vacuo* to give a black tarry material (0.5 g) contamintated with **1** (0.17 g). The yield of this was 95 wt % based on the consumed **1**.

Column Chromatography. The tarry material (0.5 g) was passed through a column of 50 cm×2.0 cm packed with SiO_2. A mixture of benzene and methanol was used as an eluant. The eluate, a mixture of two components not separable, showed the following spectra: IR(cm^{-1}) 1725(C=O); NMR(CCl_4) δ 0.7—1.8, 4.0—4.3, and 7.2—7.6; *m/e* 362, 265, 247, 176, 149, 121, 99, 70, 69, and 43. The elemental analysis of the black solid. Found; C, 59.00; H, 3.83; O, 27.68; S, 9.49%.

Quantum Yield. An aqueous 5×10^{-6} M solution of **1** in a 10 mm thick quartz cell(10 ml) was irradiated with a 30 w low-pressure Hg lamp (254 nm). A ferrioxalate actinometer was used.[10]

Quenching Study. A 4.6×10^{-2} M solution of **1** saturated with a quencher, molecular oxygen, was irradiated with a 300 w high-pressure Hg lamp for 8 h. The conversion of **1** was 54%, which was similar to that(50% for 8 h) in the experiment in the absence of the quencher.

Synthesis of 4′-Vinylbenzo-15-crown-5 from Benzo-15-crown-5

Kiyoshi KIKUKAWA, Kazuhiko NAGIRA, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

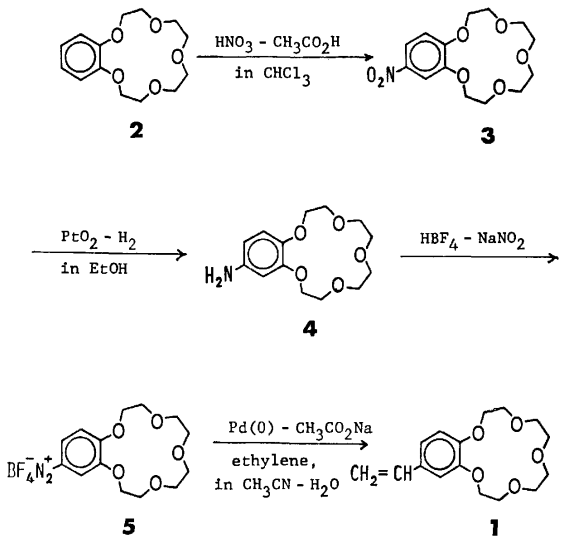
(Received March 22, 1977)

Synopsis. 4′-Vinylbenzo-15-crown-5 was conveniently synthesized in 30% yield by the reaction of diazotized 4′-aminobenzo-15-crown-5 with ethylene (6—10 kg/cm²) in the presence of zerovalent palladium at room temperature.

Vinylbenzocrown ethers are useful monomers for the preparation of the polymers attached with crown ethers.[1] 4′-Vinylbenzocrown ethers have been synthesized using 4-acetyl- or 4-formylcatechol as a starting material.[1,2]

We recently reported a novel catalytic arylation of olefins with arenediazonium salts in the presence of zerovalent palladium.[3] In view of the higher reactivity of ethylene with arylpalladium reagents, the reaction can be expected to be a convenient method to replace an amino group in primary aromatic amines with a vinyl group. It is interesting to apply this method to the vinylation of benzocrowns, since nitrobenzocrowns and thus aminobenzocrowns are readily available from the parent crown ethers.[4]

4′-Vinylmonobenzo-15-crown-5 (**1**) was synthesized using monobenzo-15-crown-5 as a starting material in the overall yield of 20—25% (Scheme 1). 4′-Aminobenzo-15-crown-5 (**4**) which is labile to air oxidation, and its diazonium salt (**5**) were used without isolation for the subsequent reactions.



Scheme 1.

Experimental

4′-Nitrobenzo-15-crown-5 (3). This compound was prepared in 70—80% yields according to the procedure described by Smid *et al.*[4] with some modifications. Thus, the reaction mixture was neutralized with aq NaOH and the crude product was recrystd from methanol.

4′-Aminobenzo-15-crown-5 (4) and the Diazonium Salt (5). In a glass autoclave, 7.79 g of **3** in 200 ml ethanol was hydrogenated to **4** at 30—40 °C for 8 h in the presence of 0.1 g of platinum oxide under hydrogen pressure of 8—10 kg/cm². After the reaction, the catalyst was filtered off under nitrogen and the ethanol was evaporated under reduced pressure. To the residue were added 30 ml of 42% HBF_4 and 140 ml of water to give a suspension of the less soluble salts. The mixture was cooled to 0 °C in an ice bath and then 1.7 g of $NaNO_2$ in 20 ml water was added dropwise at 0—5 °C under efficient stirring. The diazonium salt was soluble in water.

4′-Vinylbenzo-15-crown-5 (1). The diazotized soln was placed in a glass autoclave (500 ml), and then 100 ml of acetonitrile, 10.3 g of sodium acetate and 3.0 g of bis(dibenzylideneacetone)palladium(0) were added to the soln. After ethylene was introduced to a pressure of 6—10 kg/cm², the soln was stirred at room temp for 2 days. The reaction mixture was extracted with ether, and the extract was washed with satd aq $NaHCO_3$ soln followed by satd aq NaCl soln, and dried over anhyd $MgSO_4$ with the addition of 4-*t*-butylcatechol as an inhibitor. The mixture was filtered, and the filtrate was evaporated under reduced pressure. The residue was extracted several times with hot hexane, and after removal of a small amount of less soluble dibenzylideneacetone, concentration of the hexane soln gave **1** as white crystals. Yield 30% from **3**, mp 40—45 °C. Recrystallization from hexane gave pure **1**, mp 43.5—44.2 °C, which did not exhibit any depression of the mp on admixture with the authentic specimen prepared *via* 4′-acetylbenzo-15-crown-5.[1] NMR ($CDCl_3$) δ=4.0 (16H, m, $-CH_2-$), 5.3 (2H, m, vinyl $=CH_2$), 6.6 (1H, m, vinyl $-CH-$), 6.9 (3H, m, aromatic H).

Isolated Molecule Approach to the Orbital Study of Chemical Reactions. I. Bimolecular Nucleophilic Substitution

Hiroshi FUJIMOTO and Nobuhiro KOSUGI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 22, 1976)

A method of analyzing chemical interactions between two systems is presented and applied to the bimolecular nucleophilic substitution of methylfluoride by fluoride ion. In order to get a clear insight into the mechanisms of chemical interactions, the interacting system has been represented by a combination of various electron configurations of the reactants involved. The matrix elements necessary for the configuration interaction have been obtained by transforming the MO's of the isolated reactants into a set of orthogonalized functions. The change in the energy and the redistribution of the electrons due to the interaction in the reaction have been calculated by the use of the *ab initio* (STO-3G) MO's and have been divided into the Coulomb, exchange, delocalization, and polarization interactions. A comparison of the results with the results of the SCF CI calculations of the composite system has shown the utility of the method in studying weak and moderately strong interactions between two systems.

The bimolecular nucleophilic substitution (S_N2) reaction of aliphatic systems is one of the most extensively investigated reactions in organic chemistry.[1] Since Hughes and Ingold,[2] numerous experiments have attempted to study the mechanism of the reactions. It is now well-established that the attacking base approaches the substrate from the back, displacing the leaving group. Thus, the Walden inversion is characteristic of S_N2 reactions. It has been suggested that the carbon atom of a substrate under attack will take a nearly sp^2 planar structure at the transition state, although no stable intermediate has ever been trapped.

Recent developments in quantum mechanical methods of calculating the electronic structure of sizable molecules have led us to consider the detailed molecular mechanisms of organic reactions. In particular, *ab initio* MO methods have been accepted as a way of studying the basic nature of chemical reactions in recent years. Although it is unlikely, at present, that such methods can supply us with quantitatively reliable results on the magnitude of the activation energy and the geometry of transition state complex for systems with many degrees of freedom, an extensive configuration interaction with a large set of basis functions will lead to an improvement of the calculations.[3] In this respect, MO approaches to chemical reactions seem to be promising.

The perturbation theory is a convenient tool to deal with weakly interacting systems. The energy and the electron density are separated into several interaction terms and are interpreted in relation to chemical and physical concepts of molecular interaction.[4] In this paper, we will present the result of our calculation of the electron reorganization in a model S_N2 reaction. A direct evaluation of the interaction integrals and configuration energies is attempted. Our primary aim is to develop a theoretical method of studying molecular interactions, furnished both with the accuracy of *ab initio* calculations and with the accessibility of perturbation theories to the nature of chemical reactions.

Description of Chemical Interactions

In order to study the molecular mechanism of S_N2 reactions, we have chosen methylfluoride and fluoride ion as the substrate and the attacking base respectively.[5] The geometry of the reacting system was taken to be as is given in Fig. 1, after Veillard.[5c] In an early stage of the reaction, the electronic structure of the composite system can be represented by a wave function which is a linear combination of various electron configurations of the reactants involved:[4]

$$\Psi = \sum_p C_p \Psi_p . \qquad (1)$$

Some of the most important configurations are illustrated in Fig. 2. The wave functions of these electron configurations are given by the Slater determinants, as usual. The original configuration contains only the occupied MO's of the isolated reactants:

$$\Psi_0 = |a_1 \cdots a_i \cdots a_m b_1 \cdots b_k \cdots b_n \bar{a}_1 \cdots \bar{a}_i \cdots \bar{a}_m \bar{b}_1 \cdots \bar{b}_k \cdots \bar{b}_n| ,$$

where a and $\bar{a}$ are the spinorbitals of methylfluoride ($m=9$) with spin α and spin β respectively, and where

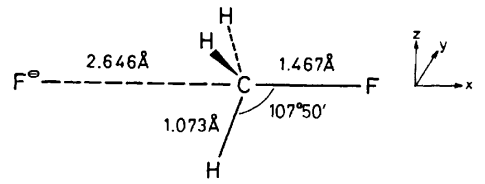

Fig. 1. A sketch of reaction model after Veillard.[5c]

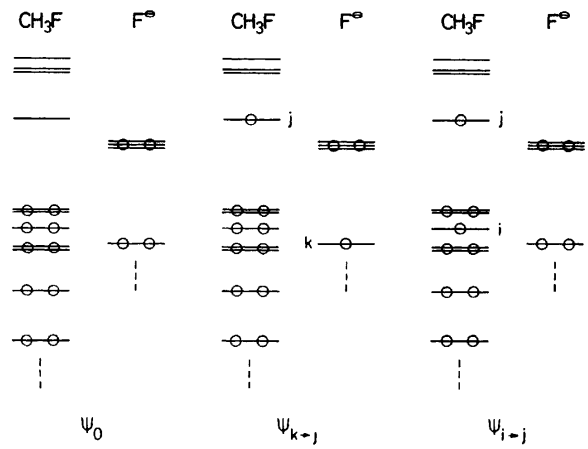

Fig. 2. An illustration of some electron configurations.

b and $\bar{b}$ are the spinorbitals of the fluoride ion ($n=5$). Similarly, we have:

$$\Psi_{k\to j} = 1/\sqrt{2}\,(|a_1\cdots a_m b_1\cdots a_j\cdots b_n\bar{a}_1\cdots\bar{a}_m\bar{b}_1\cdots\bar{b}_k\cdots\bar{b}_n| + |a_1\cdots a_m b_1\cdots b_k\cdots b_n\bar{a}_1\cdots\bar{a}_m\bar{b}_1\cdots\bar{a}_j\cdots\bar{b}_n|),$$

$$\Psi_{i\to j,i\to j} = |a_1\cdots a_j\cdots a_m b_1\cdots b_n\bar{a}_1\cdots\bar{a}_j\cdots\bar{a}_m\bar{b}_1\cdots\bar{b}_n|.$$

It should be noted here that, in general, the MO's a_i and b_k are not mutually orthogonal.

Among the various electron configurations appearing in Eq. 1, Ψ_0 is the dominant term, and the expansion coefficients, C_p, can be obtained as the solution of the simultaneous equations:

$$(\boldsymbol{H}-E\boldsymbol{S})\boldsymbol{C} = 0, \tag{2}$$

in which:

$$H_{p,q} = \int \Psi_p^* H \Psi_q \mathrm{d}\tau,$$

$$S_{p,q} = \int \Psi_p^* \Psi_q \mathrm{d}\tau.$$

The Hamiltonian operator for the interacting system is given by:

$$H = \sum_i -1/2\Delta_i + \sum_i\sum_\alpha -Z_\alpha/r_{i\alpha} + \sum_{i<j}\sum 1/r_{ij} + \sum_{\alpha<\beta}\sum Z_\alpha Z_\beta/R_{\alpha\beta}, \tag{3}$$

where the familiar notations are used.[4b] In obtaining the matrix elements in Eq. 2, it is convenient to carry out a certain transformation of the basis MO's into a set of orthogonalized orbitals and/or corresponding orbitals.[6,7] Thus, all the integrals can be calculated exactly in the framework of the method of the MO calculation employed. In the present calculation, we used an SCF LCAO MO approximation, all the necessary atomic integrals being evaluated by expanding the basis Slater atomic orbiatls in three-term Gaussian functions (STO-3G).[8,9] No polarization function was adopted.

Calculation of Matrix Elements

Here we may mention briefly the method of calculating the integrals appearing in the secular equations. First, we consider overlap integrals. A wave function, $\boldsymbol{\phi}$, is a subset of the MO's chosen from the occupied and unoccupied MO's of methylfluoride and the fluoride ion:

$$\boldsymbol{\phi} = (\phi_1\phi_2\cdots\cdots\phi_N) \qquad (N=m+n=14)$$

where the one-electron function, ϕ_i, corresponds to one of the a's or b's of the isolated reactants. In a similar manner, $\boldsymbol{\phi}'$, $\boldsymbol{\varphi}$, and $\boldsymbol{\varphi}'$ span other subsets:

$$\boldsymbol{\phi}' = (\phi_1'\phi_2'\cdots\cdots\phi_N'),$$
$$\boldsymbol{\varphi} = (\varphi_1\varphi_2\cdots\cdots\varphi_N),$$
$$\boldsymbol{\varphi}' = (\varphi_1'\varphi_2'\cdots\cdots\varphi_N').$$

Now the overlap integral between two configurations, p and q, is given by:

$$\Psi_p = |\phi_1\cdots\cdots\phi_N\bar{\phi}_1'\cdots\cdots\bar{\phi}_N'| = A(\boldsymbol{\phi}\cdot\bar{\boldsymbol{\phi}}')/N_p,$$
$$\Psi_q = |\varphi_1\cdots\cdots\varphi_N\bar{\varphi}_1'\cdots\cdots\bar{\varphi}_N'| = A(\boldsymbol{\varphi}\cdot\bar{\boldsymbol{\varphi}}')/N_q,$$
$$S_{p,q} = 1/(N_p\cdot N_q)\cdot|\boldsymbol{S}_{\phi,\varphi}|\cdot|\boldsymbol{S}_{\bar{\phi}',\bar{\varphi}'}|, \tag{4}$$

where $\boldsymbol{S}$ is an MO overlap matrix:

$$\boldsymbol{S}_{\phi,\varphi} = \int {}^+\boldsymbol{\phi}\cdot\boldsymbol{\varphi}\mathrm{d}\tau = (s_{i,j}), \tag{5}$$

$$s_{i,j} = \int \phi_i\varphi_j \mathrm{d}v.$$

When the wave functions, Ψ_p and Ψ_q are given by the linear combinations of Slater determinants, $S_{p,q}$ is the sum of the overlap integrals between the determinantal wave functions. The normalization factors, N_p, for the wave functions due to the intermolecular MO overlap are immediately derived from Eq. 4,[10]

$$\Psi_0 = 1/\sqrt{(2N)!}\cdot 1/|\boldsymbol{S}_{0,0}|\cdot A(\boldsymbol{\phi}_0\cdot\bar{\boldsymbol{\phi}}_0), \tag{6}$$

$$\Psi_{k\to j} = 1/\sqrt{(2N)!}\cdot 1/(2|\boldsymbol{S}_{0,0}|\cdot|\boldsymbol{S}_{k\to j,k\to j}| + 2|\boldsymbol{S}_{0,k\to j}|^2)^{1/2}\cdot\{A(\boldsymbol{\phi}_0\cdot\bar{\boldsymbol{\phi}}_{k\to j}) + A(\boldsymbol{\phi}_{k\to j}\cdot\bar{\boldsymbol{\phi}}_0)\}, \tag{7}$$

$$\Psi_{i\to j,i\to j} = 1/\sqrt{(2N)!}\cdot 1/|\boldsymbol{S}_{i\to j,i\to j}|\cdot A(\boldsymbol{\phi}_{i\to j}\cdot\bar{\boldsymbol{\phi}}_{i\to j}), \tag{8}$$

where:

$$\boldsymbol{S}_{0,0} = \int {}^+\boldsymbol{\phi}_0\cdot\boldsymbol{\phi}_0\mathrm{d}\tau,$$

$$\boldsymbol{S}_{0,k\to j} = \int {}^+\boldsymbol{\phi}_0\cdot\boldsymbol{\phi}_{k\to j}\mathrm{d}\tau,$$

$$\boldsymbol{S}_{i\to j,i\to j} = \int {}^+\boldsymbol{\phi}_{i\to j}\cdot\boldsymbol{\phi}_{i\to j}\mathrm{d}\tau,$$

$$\boldsymbol{\phi}_0 = (a_1\cdots a_i\cdots a_m b_1\cdots b_k\cdots b_n),$$
$$\boldsymbol{\phi}_{k\to j} = (a_1\cdots a_m b_1\cdots a_j\cdots b_n),$$
$$\boldsymbol{\phi}_{i\to j} = (a_1\cdots a_j\cdots a_m b_1\cdots b_n).$$

The corresponding electron density can be calculated by means of the following equation:

$$\rho_{p,q} = 1/(N_p\cdot N_q)\{|\boldsymbol{S}_{\bar{\phi}',\bar{\varphi}'}|\cdot(\boldsymbol{\varphi}\hat{\boldsymbol{S}}_{\phi,\varphi}{}^+\boldsymbol{\phi}) + |\boldsymbol{S}_{\phi,\varphi}|\cdot(\bar{\boldsymbol{\varphi}}'\hat{\boldsymbol{S}}_{\bar{\phi}',\bar{\varphi}'}{}^+\bar{\boldsymbol{\phi}}')\}, \tag{9}$$

where $\hat{\boldsymbol{S}}_{\phi,\varphi}$ is the minor of $\boldsymbol{S}_{\phi,\varphi}$ with respect to the particular MO's concerned, ϕ and φ.

Next let us consider the energy matrix between various electron configurations. As has been mentioned above, $\boldsymbol{\varphi}$ is not generally orthogonal to $\boldsymbol{\phi}$. Now, let us assume that $\boldsymbol{\varphi}$ can be converted into a set of orbitals, $\boldsymbol{\lambda}$, by a certain transformation, $\boldsymbol{X}$, to give rise to:

$$\boldsymbol{\lambda} = \boldsymbol{\varphi}\boldsymbol{X}, \tag{10}$$

which satisfies the condition that:

$$\boldsymbol{1} = \int {}^+\boldsymbol{\phi}\cdot\boldsymbol{\lambda}\mathrm{d}\tau. \tag{11}$$

Therefore, we obtain:

$$\boldsymbol{X} = \boldsymbol{S}_{\phi,\varphi}{}^{-1}. \tag{12}$$

The matrix element between two configurations is given by:

$$H_{p,q} = \int|\phi_1\cdots\phi_N\bar{\phi}_1'\cdots\bar{\phi}_N'|H|\varphi_1\cdots\varphi_N\bar{\varphi}_1'\cdots\bar{\varphi}_N'|\mathrm{d}\tau$$
$$= \int|\phi_1\cdots\phi_N\bar{\phi}_1'\cdots\bar{\phi}_N'|H|\lambda_1\cdots\lambda_N\bar{\lambda}_1'\cdots\bar{\lambda}_N'|\mathrm{d}\tau/|\boldsymbol{S}_{\phi,\varphi}{}^{-1}|\cdot|\boldsymbol{S}_{\bar{\phi}',\bar{\varphi}'}{}^{-1}|$$
$$= \int|\phi_1\cdots\phi_N\bar{\phi}_1'\cdots\bar{\phi}_N'|H|\lambda_1\cdots\lambda_N\bar{\lambda}_1'\cdots\bar{\lambda}_N'|\mathrm{d}\tau\cdot|\boldsymbol{S}_{\phi,\varphi}|\cdot|\boldsymbol{S}_{\bar{\phi}',\bar{\varphi}'}|. \tag{13}$$

We can define here the bond order matrix, $\boldsymbol{P}^{\alpha}$ for electrons with the α spin and $\boldsymbol{P}^{\beta}$ for electrons with the β spin:

$$\boldsymbol{P}^{\alpha}_{p,q} = (\boldsymbol{c}_{\varphi}\boldsymbol{X})^{+}\boldsymbol{c}_{\phi} = \boldsymbol{c}_{\varphi}\boldsymbol{S}_{\phi,\varphi}{}^{-1+}\boldsymbol{c}_{\phi}, \tag{14}$$

$$\boldsymbol{P}^{\beta}_{p,q} = \boldsymbol{c}_{\bar{\varphi}}\boldsymbol{S}_{\bar{\phi}',\bar{\varphi}'}{}^{-1+}\boldsymbol{c}_{\bar{\phi}'}, \tag{15}$$

where $\boldsymbol{c}$ is the LCAO coefficient matrix of the basis AO's $\boldsymbol{\chi}$:

$$\boldsymbol{\phi} = \boldsymbol{\chi}\boldsymbol{c}_{\phi}, \tag{16}$$

$$\boldsymbol{\varphi} = \boldsymbol{\chi}\boldsymbol{c}_{\varphi}. \tag{17}$$

By the use of the partial bond order, P_{rs}, between the AO's χ_r and χ_s defined as the (r,s) element of the matrix $\boldsymbol{P}$, we obtain:

$$\begin{aligned} H_{p,q} = {} & [\sum_{r}\sum_{s}(P^{\alpha}_{rs}+P^{\beta}_{rs})(t_{rs}+v_{rs}) \\ & + \sum_{r}\sum_{s}\sum_{t}\sum_{u}(P^{\alpha}_{rs}P^{\alpha}_{tu}+P^{\beta}_{rs}P^{\beta}_{tu})/2 \\ & \cdot\{(rs|tu)-(rt|su)\} + \sum_{r}\sum_{s}\sum_{t}\sum_{u}P^{\alpha}_{rs}P^{\beta}_{tu}(rs|tu) \\ & + \sum_{\alpha<\beta}\sum Z_{\alpha}Z_{\beta}/R_{\alpha\beta}]\cdot\boldsymbol{S}_{p,q}, \end{aligned} \tag{18}$$

where:

$$t_{rs} = \int \chi_r(1)(-1/2\Delta_1)\chi_s(1)\mathrm{d}v_1,$$

$$v_{rs} = \int \chi_r(1)(\sum_{\alpha} -Z_{\alpha}/r_{1\alpha})\chi_s(1)\mathrm{d}v_1,$$

and:

$$(rs|tu) = \iint \chi_r(1)\chi_t(2)(1/r_{12})\chi_s(1)\chi_u(2)\mathrm{d}v_1\mathrm{d}v_2.$$

When the wave functions Ψ_p and Ψ_q are represented by linear combinations of the Slater determinants, the matrix element, $H_{p,q}$, is given by the sum of the integrals obtained in a similar manner.[11]

Results of Calculation

Figure 3 shows the relative spacings of the MO's of methylfluoride and the fluoride ion in an isolated state.

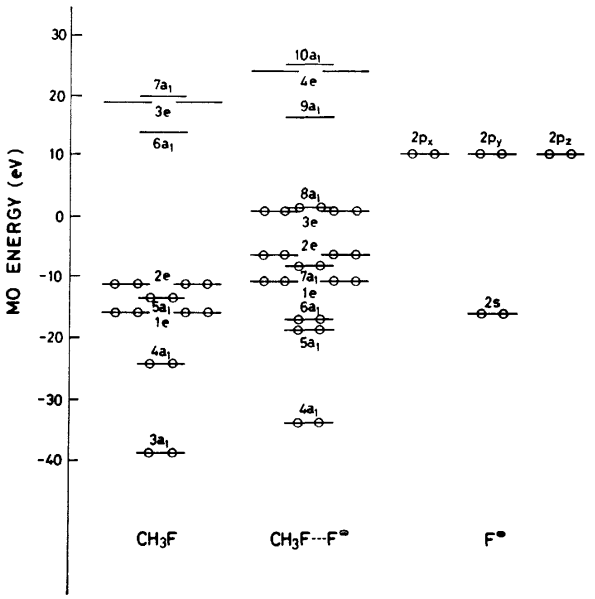

Fig. 3. Orbital diagram of interaction between methylfluoride and fluoride ion. Orbital exponents were taken after Hehre *et al.*[20]

The SCF MO levels of the composite system are also given in Fig. 3, although they are not necessary for our isolated-molecule approach to chemical interactions. They are used later in order to compare our results with the usual supermolecule calculation of the interacting system by the aid of configuration analysis. The matrix elements of Eq. 2 are given in Tables 1 and 2 with regard to some mono- and diexcited and electron-transferred configurations. It may be seen that the transferred configuration in which an electron is moved from the $2p_x$ of the fluoride ion to the LUMO of methylfluoride is located low only 4.02 eV above Ψ_0 and has a large off-diagonal element 0.80 eV. The pi-type interaction between the $2p_y$ or $2p_z$ of the fluoride ion and the $3e$ MO's of methylfluoride is found to be weaker than the sigma-type interaction. Ditransferred configurations can scarcely contribute to the stabilization of the system.

Table 1. The energies $(H_{p,p}-H_{0,0})$ of monoexcited and monotransferred configurations (upper) and diexcited and ditransferred configurations (lower) above Ψ_0 (in eV)

		—	0.003	—

a) The same as in Table 1.

The locally diexcited configurations in methylfluoride possess large off-diagonal matrix elements with Ψ_0, although they lie very high. These integrals originate, however, principally from intramolecular electron repulsions and, hence, should be further partitioned into several terms in evaluating the intermolecular interaction energy. The values in parentheses indicate the intramolecular parts. One may see that the enhancement of diexcited configurations due to the intermolecular interaction is negligibly small in this case.[12] The large matrix element, 1.26 eV, for the monoexcited configuration, $\Psi_{5a\to 6a}$, signifies a strong polarization of methylfluoride under the influence of the electrostatic field of the fluoride ion.

The coefficients of the ground-state wave function are given approximately by:

$$C_0 = 1 - \sum_{p\neq 0} (H_{0,p}-S_{0,p}H_{0,0})S_{0,p}/(H_{0,0}-H_{p,p}) - 1/2\sum_{p\neq 0}(H_{0,p}-S_{0,p}H_{0,0})^2/(H_{0,0}-H_{p,p})^2, \quad (19)$$

$$C_p = (H_{0,p}-S_{0,p}H_{0,0})/(H_{0,0}-H_{p,p}) + \sum_{q\neq 0,p}(H_{p,q}-S_{p,q}H_{0,0}) \cdot (H_{0,q}-S_{0,q}H_{0,0})/\{(H_{0,0}-H_{p,p})\cdot(H_{0,0}-H_{q,q})\}. \quad (20)$$

They are listed in Table 3. The monotransferred configuration in which an electron is shifted from the $2p_x$ of the fluoride ion to the $6a_1$ MO of methylfluoride is found to be dominant among the various electron configurations except for Ψ_0. The electron transfer from the $2p_y$ and $2p_z$ of the fluoride ion to the $3e$ MO's of methylfluoride is not effective. The present calculation indicates that the reaction is initiated by the attack of the 2p orbitals of the anion. The participation of the 2s orbital is found to be minor at the beginning of the reaction.

The electron density of the composite system can be divided into several terms:

$$\rho = \rho(CH_3F) + \rho(F^-) + \rho_K + \rho_\Pi + \rho_D + \cdots, \quad (21)$$

where $\rho(CH_3F)$ and $\rho(F^-)$ mean the electron densities of the isolated methylfluoride and fluoride ion respectively, and where ρ_K, ρ_Π, and ρ_D represent the exchange, polarization, and delocalization interactions respectively. The polarization density covers the locally excited electron configurations, while the delocalization density consists of the electron-transferred configurations involved in Table 3. The exchange density is defined by:

$$\rho_K = \rho_{0,0} - \rho(CH_3F) - \rho(F^-). \quad (22)$$

The exchange, polarization, and delocalization densities are illustrated in Fig. 4. The exchange interaction brings about a negative difference density between the attacking anion and the substrate, since both of the reactants possess closed-shells. On the other hand, the electron delocalization from the anion to methylfluoride produces a positive density in the intermolecular region. The competition between the exchange interaction and the delocalization interaction seems to govern the appearance of the new chemical bond to be formed between the reagent and the reactant. The polarization of methylfluoride induced by the electrostatic field of the fluoride ion causes a drift of electrons from carbon to fluorine to increase the polarity of the bond to be broken.

The energy of the interacting system is divided in a similar manner[4b] for the ground-state of the interacting

Table 3. The expansion coefficients of the ground-state wave function of the interacting system obtained by perturbation calculations[b]

system:

$$E_g = E(CH_3F) + E(F^-) + \varepsilon_Q + \varepsilon_K + \varepsilon_{II} + \varepsilon_D + \cdots, \quad (23)$$

where $E(CH_3F)$ and $E(F^-)$ are the energies of the isolated reactants and where ε_Q, ε_K, ε_{II}, and ε_D mean the Coulomb, exchange, polarization, and delocalization energies respectively. We have $\varepsilon_Q = -0.271$ eV, $\varepsilon_K = 0.110$ eV, $\varepsilon_{II} = -0.081$ eV, and $\varepsilon_D = -0.198$ eV for this system.

Configuration Analysis

An alternative way of calculating the coefficients in Eq. 1 is the configuration analysis of the SCF MO wave function of the interacting systems.[10,13] The given SCF wave function, Ψ, of the composite system can be expanded in terms of the various electron configurations, Ψ_p, of the reactants. Table 4 presents the result of the analysis of the wave function without CI. A comparison of the results given in Table 4 with those in Table 3 indicates that a single determinantal wave function describes the basic feature of the interaction pretty well in this case.[14] The inclusion of CI with the diexcited configurations of the composite system in which a pair of electrons are removed from an occupied MO and placed in an unoccupied MO improves the wave function appreciably, as is shown in Table 5. That is, the diexcited configurations in methylfluoride are recovered. The changes in the occupation numbers of the MO's of methylfluoride and the fluoride ion due to the interaction are given in Table 6.[15] The results confirm our conclusion that the electron delocalization from the $2p_x$ orbital of the fluoride ion to the $6a_1$ MO of methylfluoride plays the key role in the early stage of the S_N2 reaction.[16]

Discussion

As the first attempt to test the validity of our analysis, we carried out a preliminary evaluation of the expansion coefficients by the use of a perturbation formalism. The breakdown of the energy and the electron density was made tentatively by utilizing the coefficients. It may be unnecessary to say that they can be replaced by those derived from a configuration analysis of an SCF wave function of the interacting system. In this respect, the present method retains the flexibility of adapting to any degree of sophistication in the MO methods. Attempts to get information about the aspects of complicated chemical reactions by means of elaborate MO calculations seem to be getting more and more frequent in organic chemistry with the progress of computing facilities. On the other hand, the concept of orbital interaction based on rather simplified reaction models has provided us with some governing principles of chemical reactions.[17] Though qualitative in nature, the approach offers a promise of uncovering new insights into chemical reactions. In this study, we preferred a configuration interaction approach[4b] to the one-electron-orbital interaction approach,[17] because the former is expected to be capable of elucidating the characteristics of chemical interactions in a more acceptable manner both chemically and physically.

We have focused our attention mainly on the development of a method of relating the qualitative but lucid theory of molecular interactions to up-to-date computations of chemically interacting systems in a quantitative way. The numerical results presented here with regard to an S_N2 reaction do not necessarily give us novel information about the nature of the reaction. One may recognize, however, that further applications and possible refinements to fit for various kinds of reactions, involving open-shells, external perturbations,[18]

and so on, will verify the utility of our method for studying the molecular mechanisms of chemical reactions.

It has been demonstrated in this calculation that our isolated-molecule approach gives us a wave function which is comparable to the one obtained by the SCF CI calculation of the composite system. The usual SCF MO method possesses a serious drawback in that it fails to give a stable solution for weakly interacting systems. Therefore, it is necessary to employ the multiconfiguration SCF MO method in place of the single configuration SCF MO method to study weak interactions. On the contrary, our present method is quite useful in dealing with loosely bound systems, such as the early stages of chemical reactions and dissociation processes. Applications to strongly interacting systems by enlarging the basis electron configurations are in progress.

Finally, it should be noted that the destabilization of an interacting system due to the necessary distortion of the reactants in the course of the reaction must be an important source of activation energy, though the distortion is likely to take place in such a way as to promote further electron delocalization.[19] Accodingly, in order to obtain a reasonable activation energy from an MO calculation, it seems to be important to employ a basis set which is able to reproduce the energy change for a wide range of molecular deformations of the reactants.

This work was supported in part by a Grant-in-Aid from the Ministry of Education. The computation was carried out on a FACOM 230-75 of the Data Processing Center, Kyoto University. We are grateful to Mr. Tsutomu Minato for his assistance in our STO-3G MO calculations.

^{14}N Nuclear Quadrupole Resonances of the Molecular Complexes of Urea

Hisao NEGITA, Tsuneo KUBO, and Michio MAEKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received February 9, 1977)

The ^{14}N nuclear quadrupole resonance (NQR) was studied on three kinds of molecular complexes of urea, such as the urea-hydrogen peroxide complex (H_2O_2 complex), the urea-sodium chloride-water complex (NaCl complex), and the urea-sodium bromide-water complex (NaBr complex). The ^{14}N quadrupole coupling constants and asymmetry parameters are as follows: $|e^2Qq/h|=3493.8$ kHz and $\eta=0.3456$ for the H_2O_2 complex; $|e^2Qq/h|=3597$ kHz and $\eta=0.293$ for the NaCl complex, and $|e^2Qq/h|=3636.7$ kHz and $\eta=0.2778$ for the NaBr complex. From the temperature dependence of the resonance frequencies, it is considered that the hydrogen bonds in the H_2O_2 complex are stronger than those in the NaCl complex. The electron densities at nitrogen atoms in these complexes were derived from the corresponding NQR parameters, and were compared with those in urea.

The molecular complexes of urea have been investigated by various spectroscopic methods.[1,2] The NQR method is particularly useful for investigating the charge distributions in these complexes. However, only a few ^{14}N NQR data on molecular complexes have been reported thus far. Therefore, we planned to examine ^{14}N NQR in molecular complexes of urea, such as the urea–hydrogen peroxide complex (H_2O_2 complex), the urea–sodium chloride–water complex (NaCl complex), and the urea–sodium bromide–water complex (NaBr complex). On the basis of the ^{14}N NQR in these complexes, the strength of the hydrogen bonds and the charge distributions at the nitrogen atoms were compared with those in urea itself.

Experimental

The ^{14}N NQR spectra of the H_2O_2 complex, the NaCl complex, and the NaBr complex were obtained by the use of a frequency-modulated spectrometer described previously.[3] The resonance frequencies were measured by means of a heterodyne-type frequency meter, the frequency of which was checked by means of a frequency counter, TR-5104, from the Takeda Riken Co. Measurements were carried out at several temperatures between the temperature of liquid nitrogen and room temperature. The temperatures were measured by the use of a copper-constantan thermocouple.

Preparation of Samples. The sample of the H_2O_2 complex was obtained by cooling a solution of urea in 30% hydrogen peroxide, in a molar ratio of 2 : 3, the solution had been heated for a few minutes at a temperature of about 60 °C.[4] Found: C, 12.96; H, 6.39; N, 30.02; H_2O_2, 34.6%. Calcd for the H_2O_2 complex: C, 12.77; H, 6.43; N, 29.78; H_2O_2, 36.2%.

The sample of the NaCl complex was prepared by slowly evaporating an equimolar solution of urea and sodium chloride.[5] Found: C, 9.48; H, 4.39; N, 21.81; Cl, 25.4%. Calcd for the NaCl complex: C, 8.80; H, 4.43; N, 20.52; Cl, 26.0%.

The sample of the NaBr complex was obtained from an equimolar solution of urea and sodium bromide. Found: C, 6.62; H, 3.24; N, 15.66; Br, 43.4%. Calcd for the NaBr complex: C, 6.64; H, 3.34; N, 15.48; Br, 44.2%. All the samples were ground into powder after drying, and about a 20-g portion of the samples was used for the measurement.

Results and Discussion

Generally a pair of ^{14}N NQR frequencies, ν_- and ν_+, are observed for a species of nitrogen atoms:

$$\nu_\pm = \frac{|e^2Qq|}{4h}(3\pm\eta), \tag{1}$$

where $|e^2Qq/h|$ and η are the quadrupole coupling constant and the asymmetry parameter respectively. In the H_2O_2 complex and the NaBr complex, a pair of resonance lines was found, as is shown in Fig. 1. The quadrupole coupling constants and asymmetry parameters derived from these frequencies are listed in Table 1. In the case of the NaCl complex, four resonance lines were found, as is shown in Fig. 1. However, these lines could not be paired because both higher and lower lines of the two pairs were closely spaced. Accordingly, the quadrupole coupling constant and the asymmetry parameter were derived from the average values of ν_- and ν_+; they are listed in Table 1.

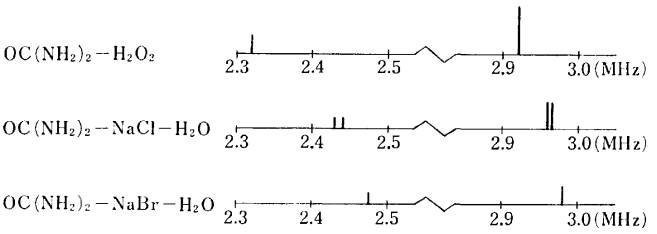

Fig. 1. NQR absorption lines in urea complexes at liquid nitrogen temperature.

TABLE 1. NQR PARAMETERS IN UREA COMPLEXES

Complex	ν_-/kHz	ν_+/kHz	$\lvert e^2Qq/h\rvert$/kHz	η
$OC(NH_2)_2$-H_2O_2	2318.4	2922.3	3493.8	0.3456
$OC(NH_2)_2$-NaCl-H_2O	2428.7 2439.1	2958.8 2964.5	3597	0.293
$OC(NH_2)_2$-NaBr-H_2O	2474.8	2980.1	3636.7	0.2778

Figure 2 shows the temperature dependence of the resonance frequencies of the ν_+ lines in the H_2O_2 complex, the NaCl complex, and urea.[6] In the case of the NaCl complex, the intensities of the ν_+ lines decrease gradually as the temperature rises, and become too weak to be observed at 181 K. The temperature dependence in the H_2O_2 complex is slightly smaller than that in urea, as is shown in Fig. 2. In the case of the H_2O_2 complex, each nitrogen atom of the urea molecule makes two hydrogen bonds, N–H···O, with lengths of 2.94 Å and 3.04 Å,[4] as is shown in Fig. 3,

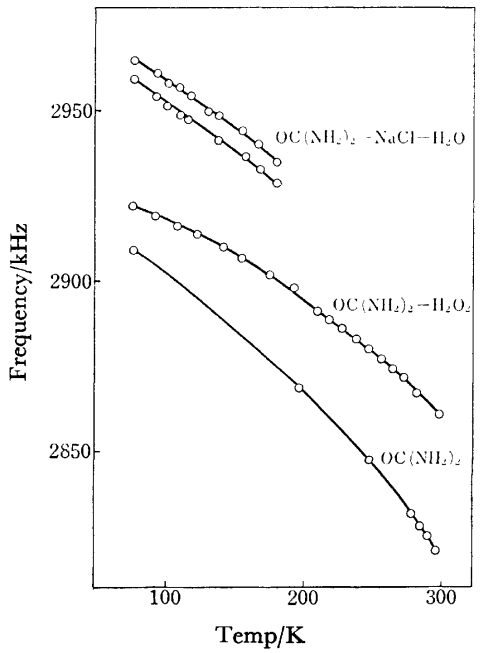

Fig. 2. The temperature dependence of the resonance line, ν_+, in urea-sodium chloride-water, urea-hydrogen peroxide, and urea.

whereas those in urea are 2.99 and 3.04 Å.[7] The smaller temperature dependence in the H_2O_2 complex can be explained by the difference in the hydrogen-bond distance between the H_2O_2 complex and urea. That is, the hydrogen bonds in the H_2O_2 complex are slightly stronger than in urea. On the other hand, Fig. 2 shows that the temperature dependence in the NaCl complex is nearly equal to that in urea. This suggests that the hydrogen bonds in the NaCl complex are nearly equal to those in urea and are weaker than in the H_2O_2 complex.

In the H_2O_2 complex, the hydrogen bonds are not very strong, as is shown in Fig. 3. Therefore, the electronic state of nitrogen in the NH_2 group may be considered to be nearly equal to that in urea, and we assumed the nitrogen σ-bond orbitals to be sp^2-hybrids. In the case of the NaCl complex, there are two crystallographically nonequivalent nitrogen atoms, and each nitrogen atom forms only one hydrogen bond with a chloride ion of sodium chloride, the length of which is 3.05 or 3.22 Å.[5] However, the electronic state of nitrogen in the NH_2 groups may be considered not

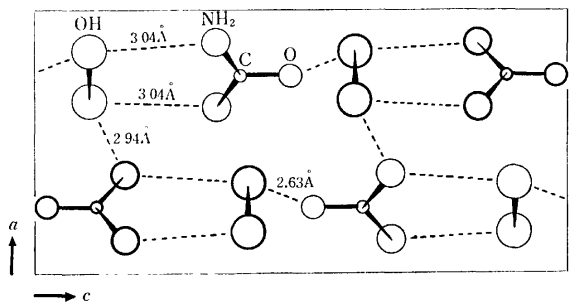

Fig. 3. The crystal structure of urea-hydrogen peroxide (b-axis projection).

to be largely different from that in urea, and we assumed that the nitrogen σ-bond orbitals are sp^2-hybrids. As is shown in Table 1, the quadrupole coupling constant and the asymmetry parameter in the NaBr complex are nearly equal to those in the NaCl complex. Therefore, we assumed sp^2-hybridization for nitrogen, as above.

The electron densities of the nitrogen atoms in these complexes can be calculated by means of the following equations derived by Lucken:[8]

$$2\eta \cdot |e^2Qq/e^2Qq_p| = 3(c-b)(1-\cot^2\gamma), \quad (2)$$

$$(1-\eta/3) \cdot |e^2Qq/e^2Qq_p| = a - c, \quad (3)$$

where a is the electron density in the lone-pair orbital; b and c are the σ-electron densities in the N–C and N–H bonds respectively; 2γ is the $\angle$HNH bond angle, approximately 120°, and $|e^2Qq_p/h|$ is the quadrupole coupling constant due to one 2p-electron of a nitrogen atom. In the case of the H_2O_2 complex, the NaCl complex, and the NaBr complex, it is assumed that $|e^2Qq_p/h|$ is 9 MHz and that the σ-electron density for the N–C bond is the same as that for the N–C bond in urea (1.206);[8] therefore, the values of the a and c parameters can be evaluated. Table 2 lists the values thus obtained. The σ_{NH} values in these complexes decrease in the order of the H_2O_2 complex, the NaCl complex, and the NaBr complex, showing that the strength of the hydrogen bond decreases in this order.

TABLE 2. ELECTRON DENSITIES IN UREA AND ITS MOLECULAR COMPLEXES

Compound	σ_{NH}	Lone-pair
$OC(NH_2)_2$	1.331	1.679
$OC(NH_2)_2$–H_2O_2	1.340	1.684
$OC(NH_2)_2$–NaCl–H_2O	1.323	1.684
$OC(NH_2)_2$–NaBr–H_2O	1.318	1.685

On the other hand, the σ_{NH} value in the H_2O_2 complex is larger than that in urea. This suggests that the hydrogen bonds in this complex are stronger than those in urea, which is parallel to the conclusion from the temperature dependence of the resonance frequencies.

Statistical Thermodynamics of Liquid Mixtures

Kazuo TOKIWANO* and Kiyoshi ARAKAWA
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
**Faculty of Engineering, Hokkaido University, Sapporo 060*
(Received February 10, 1977)

A statistical thermodynamic theory of binary liquid mixtures has been worked out on the basis of the equivalent free volume defined without use of lattice model. A liquid mixture is regarded as a mixture of hard spheres immersed in a uniform background potential. The total free energy is expressed as the sum of terms given by the analytical solution of the generalized Percus-Yevick equation for the hard sphere mixture and the term resulting from the uniform background potential. Thermodynamic functions are in a simple form convenient for practical applications. The nature of the equivalent free volume for the mixture which consists of molecules differing in size is elucidated. The energy interaction parameters and excess thermodynamic functions for eight binary mixtures composed of nonpolar molecules are calculated, and the results are discussed.

Since the designation of "regular solution" by Hildebrand and Scott[1] attempts have been made to develop a statistical theory of liquid mixtures. The most remarkable theories are those presented by Prigogine and co-workers,[2] and Flory.[3] Prigogine *et al.* presented the theories based on the average potential model, and Flory introduced the interactions between surface-sites of molecules, using the corresponding state theorem. These theories have been used by many workers during the last two decades.[4] However, the basic assumptions underlying the theories seem to require further examination.

The most important problem in the statistical theories of liquid mixtures is to estimate the "entropy of mixing" for the mixtures composed of molecules differing in size. A cell or lattice model has been used for estimation, but no rigorous treatment has been given so far. The solution for mixtures of hard spheres was first given by Lebowitz,[5] who succeeded in obtaining an analytical and explicit solution of the generalized Percus-Yevick equation.

Snider and Herrington[6] made a direct application of the Lebowitz solution to binary mixtures on the basis of the Longuet-Higgins and Widom model[7] which was proposed first for pure fluids. For the excess thermodynamic functions of binary mixtures of nonpolar molecules, they obtained good agreement between the calculated and experimental values. Marsh and others tested Snider and Herrington's treatment for several binary mixtures[8] and Kreglewski *et al.* carried out a statistical thermodynamic treatment along the same line.[9] However, the physical nature of those theories remains unclarified.

The equivalent free volume for mixtures of hard spheres has been defined on the basis of the Lebowitz solution without assuming any specified lattice.[10] We indicate in the present work that all molecules constituting a liquid mixture hold the same magnitude of the "equivalent free volume" in spite of their different sizes. A simple and convenient formulation of thermodynamic functions for liquid mixtures is attempted in terms of equivalent free volume.

For calculation, molecular parameters for each component are usually determined from the thermodynamical data for pure species. However, the energy interaction parameter between different species, which is necessary for the calculation of various excess thermodynamic functions, can not be obtained directly. The data for one of excess functions are used to determine the parameter. Excess enthalpy or excess Gibbs free energy has been used so far for the determination of the parameter. Snider and Herrington[6] calculated the energy interaction parameter for binary mixtures from the experimental values of excess Gibbs free energy. We have determined it from the observed values of excess volume obtained more easily than for the other thermodynamic functions such as excess heat *etc.* The results are satisfactory. Their significance is discussed in this paper.

Theory

The Liquid Model. For the formulation of the theory, the liquid mixture consisting of various species of molecules is regarded as a mixture of hard spheres immersed in a uniform background potential resulting from the attractive forces between molecules. Longuet-Higgins and Widom[7] applied the model to liquid Argon. The model has later been applied to pure liquid and solutions by several workers[6,9-11] including the present authors.

The Free Energy and Entropy. In the liquid model, the translational part of the total partition function for the mixture becomes identical with the partition function for the mixture of hard spheres with no attraction between themselves. In a previous paper,[10] an analytical expression was given on the translational partition function for mixtures of hard spheres on the basis of the Lebowitz solution for the Percus-Yevick equation. A partition function Z_0 at a given volume V and temperature T for an assembly of r components is expressed as

$$Z_0 = \frac{N!}{\prod_{i=1}^{r} N_i!} \prod_{i=1}^{r} \left[\left(\frac{2\pi m_i kT}{h^2} \right)^{3/2} \left(e \frac{Vf_m}{N} \right) \right]^{N_i}. \quad (1)$$

The Helmholtz free energy F_0 becomes

$$F_0 = -kT \sum_{i=1}^{r} N_i \ln \left(\frac{2\pi m_i kT}{h^2} \right)^{3/2} - NkT \ln \left(e \frac{Vf_m}{N} \right) - T\Delta S_{\text{id.mix.}}. \quad (2)$$

The equivalent free volume fraction f_m is given by

$$f_m = (1-\xi) \exp \left[-\frac{9}{\pi} \frac{V}{N} \frac{1}{(1-\xi)^2} (2XY - 2XY\xi + X^3) \right], \quad (3)$$

and the packing fraction for the mixture, ξ, by

$$\xi = \sum_{i=1}^{r} \frac{\pi}{6} \frac{N_i}{V} R_i^3, \tag{4}$$

where N_i is the number of molecules, m_i the mass, R_i the diameter of hard spheres for i-th species, $N(=\sum_{i=1}^{r} N_i)$ the total number of molecules, and

$$X = \sum_{i=1}^{r} \frac{\pi}{6} \frac{N_i}{V} R_i^2, \quad Y = \sum_{i=1}^{r} \frac{\pi}{6} \frac{N_i}{V} R_i. \tag{5}$$

The ideal entropy of mixing $\Delta S_{\text{id. mix.}}$ is

$$\Delta S_{\text{id.mix.}} = k \ln[N!/\prod_{i=1}^{r} N_i!]. \tag{6}$$

Equation 2 (or Eq.1) is seen to have a form which is identical with that given in the usual free volume theories. Thus we have the "equivalent free volume,"

$$v_f = V f_m / N. \tag{7}$$

Hence, f_m has been defined as the "equivalent free volume fraction,"[10] which is an extension of the case of a one-component fluid[11] to mixtures. No cell or lattice model is presupposed in the definition of the equivalent free volume.

Equation 2 indicates that the equivalent free volume v_f is the same for all the species in the mixture, in spite of their different sizes. The physical meaning of this remarkable fact will be discussed, in comparison with the interpretation of "free volume" made in the usual free volume theories of solutions.[12]

Let us assume that the attractive forces give rise to a uniform background potential, taking the liquid model proposed by Longuet-Higgins and Widom[7] into consideration. A uniform background potential is given by $U_{\text{BG}} = -N^2(\sum_{i=1}^{r}\sum_{j=1}^{r} x_i x_j a_{ij})/V$, where $x_i(=N_i/N)$ is the mole fraction of i-th species, a_{ii} the energy constant for the pure component, and $a_{ij}(i \neq j)$ the additional one for the mixture.[13] Thus, the free energy is written as

$$F = F_0 - \frac{N^2}{V}(\sum_i \sum_j x_i x_j a_{ij})$$

$$= F_{\text{id,m}} - NkT \ln(f_m) - \frac{N^2}{V}(\sum_i \sum_j x_i x_j a_{ij}), \tag{8}$$

where $F_{\text{id, m}}$ is the free energy of the mixture of ideal gases which is given by[14]

$$F(V, T, N_1 \cdots N_r)_{\text{id,m}} = -NkT \sum_i x_i \ln\left(\frac{2\pi m_i kT}{h^2}\right)^{3/2} - NkT \ln\left(e\frac{V}{N}\right) - T\Delta S_{\text{id.mix.}}. \tag{9}$$

The first term $F_{\text{id, m}}$ in the right-hand side of Eq. 8 is the ideal term, the second one $-NkT \ln(f_m)$ is the contribution from the repulsive interaction between molecules in the fluctuational thermal motions, and the third one is that from the uniform background potential in which the molecules constituting the mixture are immersed.

The entropy S is expressed as

$$S = S_{\text{id,m}} + Nk \ln(f_m), \tag{10}$$

where $S_{\text{id, m}}$ is given by

$$S(V, T, N_1 \cdots N_r)_{\text{id,m}} = Nk \sum_i x_i \ln\left(\frac{2\pi m_i kT}{h^2}\right)^{3/2} + \frac{3}{2}Nk + Nk \ln\left(e\frac{V}{N}\right) + \Delta S_{\text{id.mix.}}. \tag{11}$$

The Equation of State. Differentiating Eq. 8 with respect to V at constant T, we have

$$pV = NkT + NkT\frac{V}{f_m}\left(\frac{\partial f_m}{\partial V}\right)_{T,N} - \frac{N^2}{V}(\sum_i \sum_j x_i x_j a_{ij}) \tag{12}$$

$$= NkT\chi_m(\xi) - \frac{N^2}{V}(\sum_i \sum_j x_i x_j a_{ij}), \tag{13}$$

where

$$\chi_m(\xi) = \frac{1}{(1-\xi)^3}\left[(1-\xi)^2 + \frac{18}{\pi}\frac{V}{N}(XY - XY\xi + X^3)\right]. \tag{14}$$

$\chi_m(\xi)$ is the compressibility factor given by Lebowitz.[5]

Excess Thermodynamic Functions. Various excess molar quantities are given in the following. The excess volume V^E is given by

$$V^E = V - \sum_i x_i V_i, \tag{15}$$

where V_i and V are the molar volume for the pure fluid of i-th species and that for the mixture, respectively.

The excess free energy F^E is given by

$$F^E = F - \sum_i x_i F_i + T\Delta S_{\text{id.mix.}}, \tag{16}$$

where F_i is the free energy for the pure fluid of i-th species. Thus F^E is derived as follows by means of Eq. 8.

$$F^E = -N_A kT \sum_i x_i \ln\left(\frac{f_m V}{f_i V_i}\right) - \left[\frac{N_A^2}{V}\sum_i \sum_j x_i x_j a_{ij} - \sum_i x_i \frac{N_A^2}{V_i} a_{ii}\right], \tag{17}$$

where f_i is the equivalent free volume fraction for the pure fluid of i-th species and N_A Avogadro's number.

For the excess entropy, using Eq. 10 we obtain

$$S^E = S - \sum_i x_i S_i - \Delta S_{\text{id.mix.}}$$

$$= N_A k \sum_i x_i \ln\left(\frac{f_m V}{f_i V_i}\right). \tag{18}$$

Ignoring the difference between the energy and enthalpy of a liquid at ordinary pressure, we obtain the excess enthalpy H^E from Eqs. 17 and 18.

$$H^E = F^E + TS^E = -\left[\frac{N_A^2}{V}\sum_i \sum_j x_i x_j a_{ij} - \sum_i x_i \frac{N_A^2}{V_i} a_{ii}\right]. \tag{19}$$

Eqs. 17 and 19 can be expressed in terms of ξ, using the equation of state at vanishing pressure.[11,15] Equating the right-hand side of Eq. 13 to zero, we obtain

$$(N_A^2/V)\sum_i \sum_j x_i x_j a_{ij} = N_A kT\chi_m(\xi) \quad \text{(for a mixture)}, \tag{20}$$

$$(N_A^2/V)a_{ii} = N_A kT\chi(\xi_i) \quad \text{(for a pure fluid)}, \tag{21}$$

where ξ_i is the packing fraction for the pure fluid of

species i. $\chi(\xi_i)$ is the compressibility factor for a one-component fluid of hard spheres.[16] Eqs. 17 and 19 are rewritten as follows:

$$F^E = -N_A kT \sum_i x_i \ln\left(\frac{f_m V}{f_i V_i}\right) - N_A kT[\chi_m(\xi) - \sum_i x_i \chi(\xi_i)], \quad (22)$$

and

$$H^E = -N_A kT[\chi_m(\xi) - \sum_i x_i \chi(\xi_i)]. \quad (23)$$

The f_i[11] and $\chi(\xi_i)$[16] are given as

$$f_i = (1-\xi_i)\exp\left[-\frac{3\xi_i(2-\xi_i)}{2(1-\xi_i)^2}\right] \quad (24)$$

and

$$\chi(\xi_i) = \frac{(1+\xi_i+\xi_i^2)}{(1-\xi_i)^3}, \quad (25)$$

respectively, where

$$\xi_i = \frac{\pi}{6}\frac{N_A}{V_i}R_i^3. \quad (26)$$

It is confirmed that the free energy of a pure fluid of species i is derived from Eq. 8 for the mixture when $x_i=1$ and all $x_j=0$ for $i\neq j$. For the case of a one-component fluid, we see that f_m (Eq. 3) is reduced to f_i (Eq. 24) and that U_{BG} for the mixture becomes $U_{BG}=-N_A^2 a_{ii}/V_i$, which is the uniform background potential for a pure fluid.[7]

Calculation and Results

The binary liquid mixtures chosen in this work consist of nonpolar molecules which are regarded as approximately spherical. Calculations have been made for equimolar mixtures.

Determination of a_{ii} for a Pure Component. The energy parameter a_{ii} for a pure fluid is determined from the observed values of molar volume V_i and those of the heat of vaporization $\Delta H_{vap.}$ at a given temperature, using the relation

$$a_{ii} = (V_i/N_A^2)(\Delta H_{vap.} - N_A kT). \quad (27)$$

The values of $\chi(\xi_i)$, ξ_i, and f_i are calculated by means of Eqs. 21, 26, and 24, respectively.

For the determination of a_{ii}, we have used the observed values of $\Delta H_{vap.}$ and of V_i at 25 °C, except for the case of neopentane for which boiling-point data have been used. Experimental data of V_i and $\Delta H_{vap.}$, and the calculated values of a_{ii} are given in Table 1, where a_{ii} is expressed in kcal cm³/mol². All the experimental data refer to ordinary pressure.

Calculation of the Energy Interaction Parameter between Different Species, a_{12}, and Excess Thermodynamic Functions. Experimental data and calculated values are given in Table 2. For a binary mixture we have

$$\xi = (x_1\xi_1 V_1 + x_2\xi_2 V_2)/V, \quad (28)$$

and

$$a_{12} = \left[N_A kT\chi_m(\xi)\frac{V}{N_A^2} - (x_1^2 a_{11} + x_2^2 a_{22})\right]\frac{1}{2x_1x_2}. \quad (29)$$

By means of Eq. 28, ξ is calculated from the observed value of excess volume V^E at 25 °C (at 0°C for the systems including neopentane). a_{12} is then obtained by means of Eqs. 29, 14, and 5.

Table 1. Energy parameter a_{ii} for pure components

	T (°C)	$V_{i,obsd}$ (cm³/mol)	$\Delta H_{vap.}$ (kcal/mol)	a_{ii} (kcal cm³/mol²)
CCl_4	25	97.09[a]	7.83[b]	702.7
C_6H_6	25	89.41[a]	8.09[a]	670.4
c-C_6H_{12}	25	108.75[a]	7.89[a]	794.3
$C_6H_5CH_3$	25	106.85[a]	9.08[a]	906.9
$C(CH_3)_4$	9.5	119.67[a]	5.44[c]	583.8

a) J. Timmermans, "Physico-Chemical Constants of Pure Organic Compounds," Elsevier Publ. Co., Amsterdam (1950, 1965). b) See Ref. 1. c) N. A. Lange, "Lange's Handbook of Chemistry," McGraw-Hill, New York (1973).

The calculated values of H^E are obtained by Eqs. 23, 14, and 21, those of TS^E being obtained by Eqs. 18, 3, and 24. The agreement between the calculated and observed values is good.

The values of a_{12} calculated from the observed values of excess enthalpy H^E are also given in Table 2 for a comparison with those obtained from the excess volume. In calculating ξ from H^E_{obsd}, Eq. 23 has been used replacing V by $(x_1\xi_1V_1+x_2\xi_2V_2)/\xi$. The agreement between the values of a_{12} from V^E_{obsd} and those from H^E_{obsd} is very good.

Other excess functions V^E_{calcd} and TS^E_{calcd} obtained from H^E_{obsd} are also given.

Equivalent Free Volume Fraction. We have calculated the values of equivalent free volume fraction f_i and f_m using Eqs. 24 and 3. The values of f_i (the free volume fraction for the pure liquid i), packing fraction ξ_i and equivalent free volume are given in Table 3. A free volume refers to $V_i f_i (=Nv_f(\text{cm}^3/\text{mol}))$. The values of f_m which are identical for all components constituting the mixture, ξ and Vf_m are given in Table 4.

Discussion

Equivalent Free Volume Fraction for Mixtures. The concept of the equivalent free volume fraction was investigated for the case of a one-component hard-sphere fluid.[11] The same argument is applied to the case of mixtures.

As shown in Eqs. 1, 2, and 8, the free volume available for the molecule within the liquid mixture is Vf_m. The equivalent free volume fraction f_m given by Eq. 3 consists of a factor $(1-\xi)$ and an exponential factor. The former is equal to the fraction of void space for the total volume V, and the latter is supposed to come from the volume exclusion effect of hard sphere molecules in their thermal motions, similar to the case of a one-component fluid.[11]

The further problem is associated with the fact that the molecules constituting a mixture differ in size. We see from Eq. 2 that Vf_m is identical for all species of molecules included in the mixture, where f_m is determined from the diameters and number densities of all the constituents (Eq. 3). In other words, the same magnitude of the equivalent free volume, $v_f=Vf_m/N$, is as-

Table 2. Energy interaction parameter a_{12} and excess thermodynamic functions for equimolar mixtures at 25°C (at 0 °C for $CCl_4+C(CH_3)_4$ and $C_6H_6+C(CH_3)_4$)
a_{12} is in kcal cm³/mol², V^E in cm³/mol, and H^E and TS^E in cal/mol.

signed to all the molecules included in a liquid mixture in spite of the difference in their diameters.

In the usual free volume theories of solutions, it is important to know how the available total free volume is shared between molecules differing in size. However, the determination whether the free volume is shared equally between the molecules or shared unequally between them is made with some *ad hoc* assumptions.[2,12,17] The present treatment starting from Eqs. 2 and 8, considered to be equivalent to the free volume theory of fluids, suggests that the available total free volume for a fluid mixture is shared equally between the molecules.

We see from Tables 3 and 4 that the values of the equivalent free volume fraction are in the range 5—9×10^{-3} in most cases of pure fluids and mixtures, and that the values of free volume are in the range 0.55—0.93 cm³/mol. We obtain $f_1<f_m<f_2$ in most cases, where subscripts 1 and 2 refer to pure components constituting the mixture. The values of packing fraction ξ are in the range 0.48—0.50 and we have $\xi_1<\xi<\xi_2$. The values for the systems including neopentane differ considerably from those shown above. This might be attributed to the fact that the temperature of measurement is near the boiling point of $C(CH_3)_4$.

The Generalized van der Waals Equation of State and the Longuet-Higgins and Widom Model. Longuet-Higgins and Widom[7] proposed the following equation of state for pure fluids.

$$pV = p_0V - aN^2/V, \tag{30}$$

where p_0 is the pressure exerted by hard cores taken to be the true 3-dimentional hard-sphere pressure rather than the value $NkT/(V-b)$ as in the original van der Waals theory.

The equation of state Eq.13, which was presented for binary mixtures by Snider and Herrington,[6] is an extention of the generalized van der Waals equation of state Eq. 30 to mixtures.

The liquid model of Longuet-Higgins and Widom rests on the following view for fluid. The repulsive forces between molecules play the most important role in determining the short range behavior of molecules in a liquid, the attractive forces merely maintaining the liquid density. This view seems to be essentially correct, as stated also by Leland, Rowlinson and Sather[13]. The Lebowitz solution is an analytical solution of the generalized Percus-Yevick equation for hard sphere mixtures, giving the "entropy of mixing" for mixtures on the theoretically more sound ground than the lattice theories of fluids.[18] Snider and Herrington used the equation of state of hard spheres obtained from the Lebowitz solution, but they did not elucidate the nature of the Lebowitz solution, giving very lengthy expressions untractable for practical use.[20]

Energy Parameters and Excess Functions. The values of a_{12} from V^E_{obsd} are in extremely good agreement with those from H^E_{obsd} (fifth and eighth columns, Table 2). The values do not differ from each other by more than about 0.5%, except in the case of the systems including neopentane. The energy interaction parameter a_{12} between different species has been introduced for extending a uniform background potential for pure fluids to mixtures ($U_{BG} = -N_A^2 \sum_i \sum_j x_i x_j a_{ij}/V$). The striking agreement between the values of a_{12} from V^E_{obsd} and those from H^E_{obsd} shows the reality of that parameter and the effectiveness of the present treatment.

In order to determine a_{12}, data for one of excess thermodynamic functions must be used. Usually, the experimental data of H^E or that of the excess Gibbs free energy is used. The results shown in Table 2 permit us to calculate the values of a_{12} from the measured values of V^E (or density). This is very useful in practical applications since the density can be measured more easily than other thermodynamic quantities such as excess heat.

The agreement between the values of H^E calculated from V^E_{obsd} and the experimental values is fairly good. This is ascribed to the good agreement between the values of a_{12} from V^E_{obsd} and those from H^E_{obsd}. Reasonable values of H^E and S^E as well as a_{12} can be obtained from V^E_{obsd}.

In the present treatment, a_{ii} has been regarded as unchanged with the variation of temperature. In order to determine the values, the observed values of $\Delta H_{vap.}$ and V_i at 25 °C were used. The values of a_{ii} for C_6H_6 calculated from the data of $\Delta H_{vap.}$ and V_i at various temperatures are given in Table 5. The standard deviation of errors in the values of a_{ii} is about 7 kcal cm³/mol² (about 1.1% to the mean values) in the range 10—50 °C. The values of a_{ii} can be regarded to be constant in this range. In the range, 0—80.1 °C (boiling point), it is about 14.4 kcal cm³/mol² (about 2.2%).

Temperature Dependence of Excess Functions and Energy Parameters. The calculation of excess functions for the binary mixtures of CCl_4, C_6H_6 and *c*-C_6H_{12} at 20—

a) See Table 2, footnote a. b) See Table 5, footnote a. c) See Table 2, footnote c. d) See Table 2, footnote b. e) See Table 2, footnote g. f) See Table 2, footnote h. g) See Table 2, footnote i. h) Estimated from the heats of mixing as reported in the following works: G. Scatchard, L. B. Ticknor, J. R. Goates, and E. R. McCartney, *J. Am. Chem. Soc.*, **74**, 3721 (1952); R. Thacker and J. S. Rowlinson, *Trans. Faraday Soc.*, **50**, 1036 (1954); W. R. Moore and G. E. Styan, *Trans. Faraday Soc.*, **52**, 1556 (1956); see also Table 2, footnote j. i) See Table 2, footnote k.

40 °C has been carried out (Table 6). For the values of V_i and V^E we used the observed ones at each temperature. Concerning the values of a_{ii}, we used those given in the fifth column of Table 1 regarding as unchanged with the variation in temperature. The results obtained from the data of H^E_{obsd} are also included in Table 6.

We see that the calculated values for the various excess functions reproduce the trend of the temperature dependence in the observed values, but not necessarily the absolute magnitude. The values of the energy parameter a_{12}, which has been treated as a constant, are practically constant in the range 20—40 °C.

Concluding Remarks

A statistical thermodynamic theory of binary liquid mixtures has been worked out using the notion of the equivalent free volume fraction.

(a) The total free energy is expressed as the sum of three terms: the translational term of an ideal-gas mixture, the term resulting from the equivalent free volume fraction, and the energy term resulting from the uniform background potential.

(b) The equivalent free volume fraction is found to be identical for all species of molecules constituting the mixture, *viz.*, the same magnitude of equivalent free volume is assigned to all the molecules in spite of their different sizes, which is in sharp contrast to the cases in usual free volume theories.

(c) Concerning the energy parameter of mixtures, the form of a quadratic sum of a_{ij} has been used. The values of the energy interaction parameter a_{12} calculated from the values of V^E_{obsd} are found to be in good agreement with those from H^E_{obsd}. This result shows the reality of a_{12} and permits us to calculate the values of a_{12} from V^E_{obsd}.

(d) The agreement between the experimental and calculated values of various excess thermodynamic functions is found to be good on the whole, except for the case of the systems including neopentane.

18) Estimation of the "entropy of mixing" has been the most important problem in the lattice theories of fluid mixtures consisting of molecules differing in size. A f.c.c. lattice is presupposed usually for each component fluid before mixing and the lattice is assumed to remain unchanged in the solution. However, it is unreasonable to assume that a mixture of the molecules can be packed in the same way as in each component fluid when the difference in diameter of the molecules is fairly large.[15,19]

Switching in Copper-Phthalocyanine Films

Yoshihiko SADAOKA and Yoshiro SAKAI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received February 10, 1977)

Bistable switching between two impedance states was observed in copper-phthalocyanine films. The *turn-on* can be interpreted in terms of the steady thermal breakdown model. The stable high conductivity in the *on-state* is attributed to the partly carbonized copper-phthalocyanine which was formed by Joule heating along the filamentary paths. The *J-V* characteristic in the *off-state* and the threshold-field strength were found to be expressed as $J \propto V^6/d^{3.8}$ and $E_{th} \propto 1/d^{0.46}$ respectively.

The memory- and threshold-switching phenomena have recently received considerable attention as a practical application of organic semiconductors.[1,2] Although similar phenomena have been reported in thin films of inorganic semiconductors,[3-5] our understanding of switching is still incomplete, particularly in organic semiconductors.

In the present work the preswitching conduction and the memory-switching characteristics have been investigated in thin films of α-copper-phthalocyanine (CuPc).

Experimental

Pure copper-phthalocyanine was prepared by repeated sublimations *in vacuo* at 380 °C, followed by washing with acetone to remove any thermal decomposition products.

The geometry of the cell was of a sandwich type, where copper-phthalocyanine was deposited from a Pyrex crucible on a cleaned glass substrate with a silver electrode which had been evaporated through an etched stainless steel mask. The upper electrodes (Al) were deposited by vacuum evaporation through the mask. The vacuum evaporation was performed at pressures below 10^{-6} Torr. The film of CuPc was confirmed to be α-type crystalline by the methods described in a preceding paper.[6]

The film thickness of the copper-phthalocyanine, as measured with the aid of an interferometer, varied over the range of 10^{-6}—10^{-4} cm. The current-voltage characteristics were obtained by applying step voltages using a high-voltage dc power supply (John-Fluke, model 412 B), an electrometer, and a picoammeter (Takeda Riken, models TR8651 and TR8641 respectively). A series resistor ($10^6\Omega$) was used to limit the current flow in the circuit. The measurements were performed at a pressure of *ca.* 10^{-3} Torr.

The states of the film before and after the switching were observed using a scanning electron microscope (Hitachi and Akashi, model MSM-4).

Results and Discussion

In the Al–CuPc–Ag cell, the current with the forward-bias voltage (Ag(+), Al(−)) was much higher than that with the backward-bias voltage in the high-field region (Fig. 1). Its marked asymmetry can be explained by a pin-structure at the CuPc–Al junction, a detailed discussion of which has been given by Tantzscher and Hamann.[7] In the present paper the results with the backward-bias voltages will not be discussed.

Initially the film has a very high resistance (*off-state*), and the non-linear current-voltage characteristic is observed, as is shown in Fig. 1, as long as the applied voltage is lower than a certain value (threshold voltage;

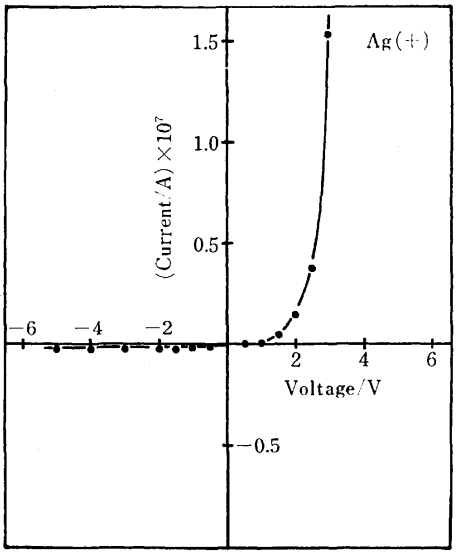

Fig. 1. A typical *V-I* characteristic in the Ag–CuPc–Al cell. Film thickness 1.7×10^{-5} cm.

V_{th}). When the applied voltage exceeds V_{th}, the current abruptly increases, and simultaneously the field drops, so that a new low-resistance state (*on-state*) with a memory effect appears. This new state can be easily quenched by applying a short current pulse (pulse width, 10 μs, maximum voltage, 180 V) from a capacitor of 0.047 μF. The scanning electron microscopic inspection of the film in the *on-state* shows that this state is accompanied by the formation of conducting channels (Fig. 2). The upper electrode (Al) was partly molten (A), and the region of CuPc (B) transformed by the localized Joule heating was confirmed in this figure, so

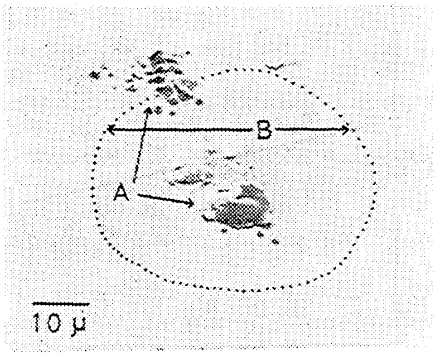

Fig. 2. Scanning electron microscope picture of damaged region. A) Partly molten electrode (Al), B) transformed region.

that it may be presumed that a temperature higher than 660 °C (the melting point of aluminium) has been temporarily attained in this region.

Souma[8] has reported that, when CuPc was heated at 625 °C, the carbonization and/or the condensation occurred and the conductivity increased rapidly. It has also been reported that poly-CuPc has a conductivity about 10^6 times larger than that of the monomer, and the activation energy (E) in $\sigma=\sigma_0 \exp(-E/kT)$ was estimated to be 0.06 eV[9] in a sample previously heated to 450 °C. In the present work, the activation energy in the high-conductivity state was estimated to be 0.05 eV from the temperature dependence of the current obtained in the range of 15—70 °C. Since this value is in fair agreement with the value for poly-CuPc, the conducting channels may be made up of the poly-CuPc.

Although many authors[10-12] have reported that the stable *on-state* in some organic compounds arises from the formation of metallic filaments or carbonized paths, the exact mechanism for the formation of such filaments is not clear.

The various models proposed to explain the memory-switching process for chalcogenide glass, *etc.* can be classified into two categories: (1) the electronic effect and (2) the thermal effect. In the former case, the *on-state* without a memory effect is formed first, and the *lock-on* occurs after a certain time by the excessive current flow in this state, while in the latter case, the switching occurs by means of the local Joule heating in the *off-state*.

The measurement of the thickness dependence of the threshold-field strength, E_{th}, which equals V_{th}/d, is a very powerful method of distinguishing between the thermal effect and the electronic effect.[13] If the switching is caused by the electronic mechanism, as explained by the space-charge-overlap model[14] or the one-carrier space-charge limited-current (SCLC) model,[15] in which the concentrations of the injected carriers are sufficient to exceed the critical concentration, the threshold-field strength can be expressed as $E_{th} \propto$ (thickness). Since Fig. 3 shows that E_{th} is not proportional to the thickness, the electronic model can be excluded.

On the other hand, according to the steady-state thermal-breakdown model,[16] the *turn-on* occurs when the temperature derivative of the power input exceeds that of heat loss. Below the critical point, Eq. 1 holds:

$$J \cdot V = \lambda(T - T_0), \tag{1}$$

where J is the current density; V, the applied voltage; λ, a constant external thermal conductivity, and T_0, the ambient temperature. At the critical point where thermal breakdown commences, the following equations are given:

$$\partial(J_c \cdot V_c)/\partial T = \lambda, \tag{2}$$

$$J_c \cdot V_c = \lambda(T_c - T_0), \tag{3}$$

where J_c and V_c are the critical current density and the voltage for breakdown respectively, and where T_c is the critical temperature.

To resolve these relations, the voltage and the thickness dependence of the current density in the preswitching state were observed (Figs. 4 and 5). The results are experimentally expressed as $J \propto V^{6.0}$ and $J \propto 1/d^{3.8}$ respectively in the high-field region, while the relation

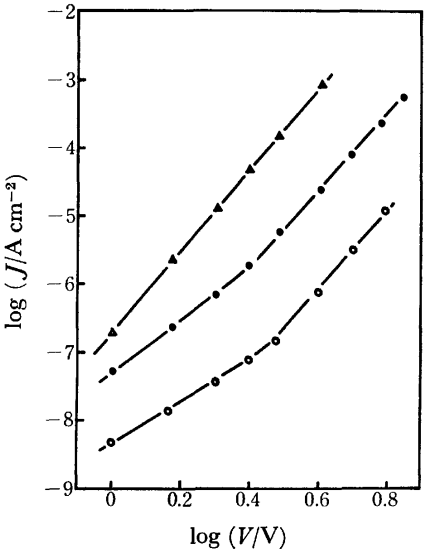

Fig. 4. The voltage dependence of the current. △) 0.18 μm, ●) 0.48 μm, ○) 1.2 μm.

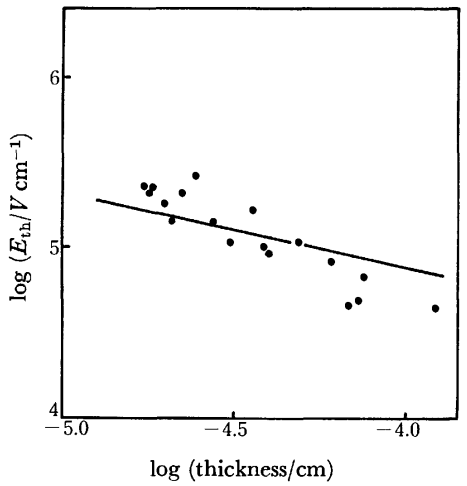

Fig. 3. The relation between log(E_{th}) and log(thickness).

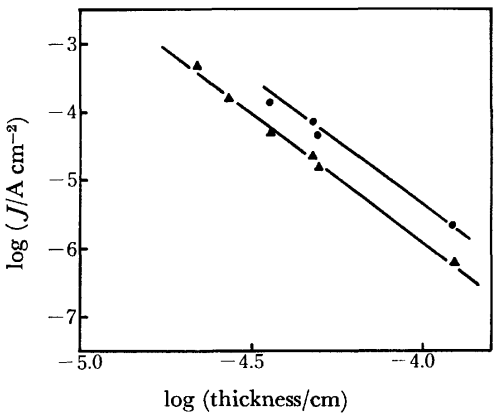

Fig. 5. The thickness dependence of the current. ▲) 4 V, ●) 5 V.

between the current density and the applied voltage expected from the scaling law[17] ($J \propto V^{l+1}/d^{2l+1}$) was confirmed in the low-field region for thicker films. Since the observed J-V characteristics were reversible with an increase and then a decrease in the voltage, the possibility of a thermal effect may be excluded. The high value of l in the high-field region may be attributed to the other conduction components, such as the emission limited current (ELC). A quantitative analysis of the J-V characteristics for ELC under the conditions of SCLC flow was reported by the Frank and Simmons.[18] According to this analysis, the transition from SCLC to ELC for the M–I–M junction can be expected to occur when a negative charge begins to appear on the cathode as well as inside the insulator, and the contact changes from an Ohmic to a blocking one with an increase in the voltage. As is shown in Fig. 6, the straight line in the plot of log J *vs.* $(V/d)^{1/2}$ indicates that the high-field conduction is predominantly governed by ELC in the preswitching state.

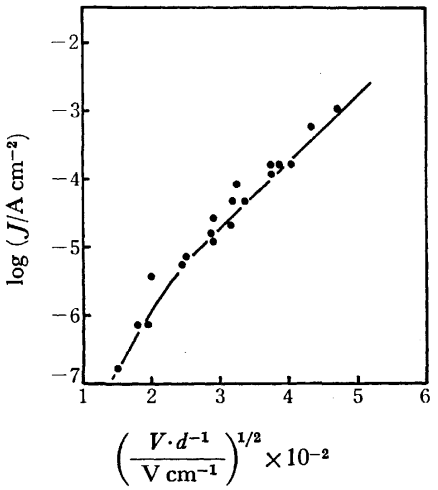

Fig. 6. The plots of log J *vs.* $(V/d)^{1/2}$.

If it is assumed that the I-V characteristic is expressed as Eq. 4* and that the *on-state* is formed filamentarily as is shown in Fig. 2, the critical current density in the area of the filamental paths is proportional to the current density geometrically obtained (J_G):

$$J_G = C \cdot \frac{V^{6.0}}{d^{3.8}} \exp(-\phi/kT), \tag{4}$$

$$J_c \propto J_G \tag{5}$$

where C is a constant; ϕ, the activation energy, and k, the Boltzmann constant.

The substitution of Eqs. 4 and 5 into Eqs. 1, 2, and 3 gives:

$$V_c^{7.0}/d^{3.8} \propto \frac{T_c^2}{\phi} \exp(\phi/kT_0) = \text{constant}. \tag{6}$$

Thus,

$$(V_c/d)^{7.0} = K \cdot d^{-3.2}, \tag{7}$$

where K is a constant.

* If the ELC relation ($J_G \propto \exp(V/d)^{1/2}$) is used, the relation between E_{th} and d is expressed as $\log E_{th} = -0.5 \log d + \text{constant}$ instead of by Eq. 8.

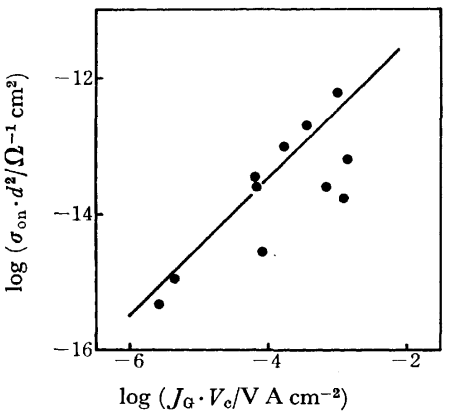

Fig. 7. The plots of $\log(\sigma_{on} \cdot d^2)$ *vs.* $\log(J_G \cdot V_c)$.

Since V_c/d is equal to E_{th}, Eq. 8 is obtained:

$$\log E_{th} = -0.46 \log d + \text{constant}. \tag{8}$$

The solid line in Fig. 3, drawn with a slope of −0.46, is in fair agreement with the experimental data. In addition, Fig. 7 shows that $\sigma_{on} \cdot d^2$ is proportional to $J_G \cdot V_c$, where σ_{on} is the conductance of the sample in the *on-state*. Since $\sigma_{on} \cdot d^2$ is proportional to the volume of the conducting paths and $J_G \cdot V_c$ is the heat evolved by the current, this result is also evidence in support of the thermal-breakdown mechanism.

One of us (Y. Sadaoka) thanks the Sakkokai Foundation for a grant.

Proton Transfer between Styrene Molecular Anion and Ethanol in Rigid Organic Matrices

Shoji Noda, Yasumi Fujii, and Hiroshi Yoshida

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received February 18, 1977)

The proton transfer from ethanol to styrene molecular anion was studied by examining the yield of the anion and α-methylbenzyl radical generated in γ-irradiated 2-methyltetrahydrofuran–ethanol mixed matrix at 77 K by means of optical absorption measurements. The radical yield was found to increase in proportion to the ethanol fraction at the expense of the anion yield. The maximum radical yield, 2.2, was identical with the yield of scavengeable electron in ethanol matrix where no anion was observed. Upon photobleaching the anion was transformed into the radical in the matrix. The transformation efficiency was constant, *ca.* 0.6, for the ethanol fraction 0.3—0.9. It is concluded that the radical arises from the anion through the proton transfer from ethanol to the β-carbon of vinyl group of the styrene anion. The proton transfer occurs readily only when a specific solvent site around the anion is populated by ethanol molecules. Otherwise, the proton transfer does not occur at all because of the restricted translational motion in the rigid matrix.

The proton transfer to aromatic radical anions in alcoholic solutions has been studied by means of pulse radiolysis technique[1] and its rate constant has been found to depend on the nature of the anion as well as the solvent. The proton transfer generally proceeds slowly because of a small pre-exponential factor in the rate constant. It has been observed to occur also in rigid alcoholic matrices at 77 K.[2–4] A steric factor is expected to affect significantly the rate of the proton transfer in the rigid matrices, since the translational motion of reactants are highly restricted. Styrene molecular anion (styrene anion) is transformed into α-methylbenzyl radical *via* proton transfer in γ-irradiated alcoholic matrices,[2–4] whereas it is stably trapped in aprotic rigid matrix of 2-methyltetrahydrofuran (MTHF) at 77 K.[2] In order to elucidate microscopically the mechanism of the proton transfer to an anion radical we have studied the transformation of the styrene anion into the α-methylbenzyl radical in the rigid matrices of MTHF–ethanol mixtures. The anion and the radical give distinct optical absorption spectra distinguishable from each other, so that the transformation can advantageously be followed by the optical spectrophotometric method.

Experimental

MTHF was distilled several times and treated with Na–K alloy. GR grade ethanol (Tokyo Kasei Chemical Ind., Ltd.) was used without further purification. Styrene was washed with aqueous solution of NaOH, distilled, dried with CaH_2, dehydrated with baked BaO and stored. It was distilled in a vacuum immediately before use. Sample solutions were degassed by a freeze-pump-thaw technique, transferred to an optical absorption cell of quartz or an ESR sample tube of quartz and sealed off in a vacuum of 10^{-5} Torr. γ-Irradiation was carried out at 77 K at a dose rate of 2 Mrad/h or 1 Mrad/h mostly to a dose of 0.2 Mrad. Optical absorption spectra were recorded with a conventional recording spectrophotometer (Hitachi, ESP-3A or Shimadzu, MPS-50L) and electron spin resonance (ESR) spectra with a conventional X-band spectrometer (JEOL, JES-3M) both at 77 K. The samples were annealed, when necessary, above 77 K with a controlled flow of cold nitrogen gas.

Results and Discussion

Yield of Styrene Anion and α-Methylbenzyl Radical. When an MTHF matrix containing styrene is irradiated at 77 K with γ-rays, the styrene anion is generated through the electron attachment to styrene, giving optical absorption bands at 415 and 600 nm.[2,3,5] Shida and Hamill reported that when a matrix of ethanol dissolving styrene is irradiated, α-methylbenzyl radical is exclusively detected by its absorption band with a maximum at 320 nm. Formation of the α-methylbenzyl radical in the ethanol matrix was evidenced by means of the fluorescence spectrophotometric method: the observed emission spectrum with the 0-0 band at 470 nm and the excitation spectra in visible and UV regions are essentially the same as those for the α-methylbenzyl radical generated by dissociative electron attachment to (1-chloroethyl)benzene in γ-irradiated organic matrices.[6] Williams and his co-workers[2] demonstrated by ESR studies a two-step mechanism for the formation of the α-methylbenzyl radical from styrene in the ethanol matrix, an electron attachment to styrene followed by proton transfer from a solvent molecule. Based on this mechanism, the stable trapping of the styrene anion in the MTHF matrix is attributed to the nature of MTHF solvent which cannot act as a proton donor.

A typical optical absorption spectrum recorded for the irradiated matrix of MTHF–ethanol mixtures con-

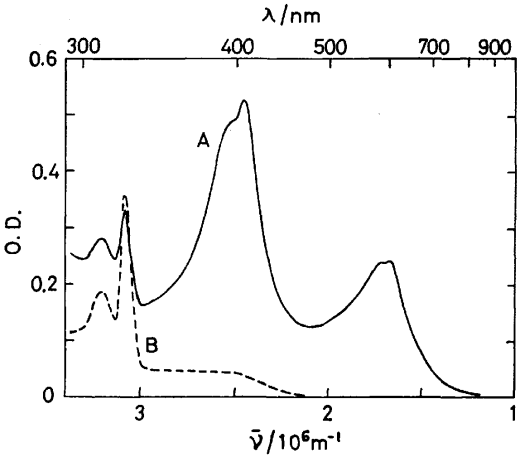

Fig. 1. Optical absorption spectra of a MTHF–ethanol mixed matrix (50 : 50 in mole) containing 50 mmol dm^{-3} styrene irradiated by γ-rays to 200 krad at 77 K (A) before and (B) after photobleaching with white light. Optical path-length: 0.2 cm.

taining styrene, for a solvent composition 50 : 50 in mole, is shown in Fig. 1A. The formation of trapped electron was completely depressed by 30 mmol dm^{-3} of styrene, the observed spectrum consisting of the band with the maximum at 320 nm due to α-methylbenzyl radical and the bands at 415 and 600 nm both due to the styrene anion. Figure 2 shows the relative yields of the radical and the anion monitored at 320 and 415 nm, respectively, as a function of the mole fraction of ethanol, X_{EtOH}, in the mixed matrix. The radical yield increases in proportion to X_{EtOH}, while the yield of the anion decreases linearly. This indicates, in accord with the two-step mechanism, that the radical is generated at the expense of the anion.

No transformation was observed from the anion into the radical after the irradiation as long as the matrix was kept at 77 K in the dark. This indicates that the proton transfer occurs so rapidly that it is completed during the course of γ-irradiation.

Proton Transfer in Rigid Matrix. The proton transfer reaction in a fluid solution is expected to follow the rate equation, $d[Radical]/dt = k[Anion][C_2H_5OH]$. If we ignore subsidiary reactions such as ion recombination, the ethanol concentration would affect not the ultimate yield of the α-methylbenzyl radical but the rate of the radical formation. However, the proton transfer in the rigid matrix showed a different feature. The change in X_{EtOH} caused the change in the radical yield as shown in Fig. 2.

The translational motion of molecules is highly restricted in the rigid matrix. Only the anion with an ethanol molecule (or molecules) located properly around it might undergo the proton transfer, but not the anion having no ethanol molecule in a proper location. Assuming that at the maximum the solvent site can be adequately populated by n ethanol molecules for the reaction, the probability is given by $(1-X_{EtOH})^n$ for the site being all populated by MTHF molecules, or for an anion not undergoing the proton transfer reaction.

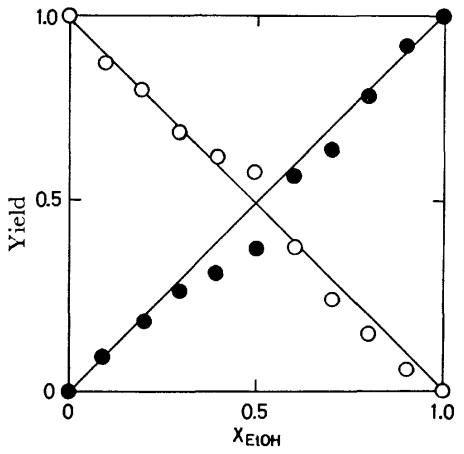

Fig. 2. Dependence of the yield of (○) styrene anion and (●) α-methylbenzyl radical upon the ethanol fraction in the MTHF-ethanol mixed matrix. The yields were corrected, so that their maximum value is 1.0. Straight lines indicate the dependence expected from Eq. 1 for $n=1$. Styrene concentration: 50 mmol dm^{-3}. γ-Irradiation: 200 krad.

Thus, the radical yield is given by $[Radical]=[Anion]_0 \cdot \{1-(1-X_{EtOH})^n\}$, where $[Anion]_0$ denotes the anion yield in the MTHF matrix or $X_{EtOH}=0$. Since the G-value of scavengeable electrons is almost the same in the MTHF and ethanol matrices,[7] the dependence of the radical yield on X_{EtOH} is given by

$$\frac{[Radical]}{[Radical]_{max}} = 1 - \frac{[Anion]}{[Anion]_0} = 1 - (1-X_{EtOH})^n \quad (1)$$

where $[Radical]_{max}$ denotes the radical yield for $X_{EtOH}=1$.

If $n>1$, the radical yield *vs.* X_{EtOH} curve should be convex upward. For instance, $[Radical]/[Radical]_{max}$ is calculated to be 7/8 for $n=3$ and $X_{EtOH}=1/2$. The reaction in a fluid solution is an extreme case: an anion has a chance to encounter all the ethanol molecules present in the solution suitably for the proton transfer, so that n is effectively infinite, and that $[Radical]/[Radical]_{max}=1$ except for $X_{EtOH}=0$. The result shown in Fig. 2 can be interpreted by n of unity, indicating that the proton transfer to the styrene anion occurs from an ethanol molecule located very close to and specifically with respect to a reactive site of the anion. This is consistent with the pulse radiolysis result in fluid solution which shows that the slow proton transfer is associated with a small pre-exponential factor of the rate constant.[1] It is also indicated that the linear decrease in the anion yield with X_{EtOH} is entirely due to the transformation of the anion into the radical and not to the recombination between the anion and a cation.

Site of Proton Attachment. The attachment of a proton to the β-carbon of the vinyl group in the styrene anion directly results in the formation of α-methylbenzyl radical. Alternatively, the α-methylbenzyl radical could be generated, when the intramolecular hydrogen transfer occurs in the phenethyl radical primarily formed by the proton attachment to the α-carbon of the vinyl group. Such an intramolecular hydrogen transfer was suggested from the observation of α-methylbenzyl radical when dissociative electron attachment to (2-chloroethyl)benzene occurred in γ-irradiated rigid matrices.[6,8]

In order to confirm the possibility of the latter mode of α-methylbenzyl radical formation, the stability of the phenethyl radical was examined in the MTHF matrix by the ESR method. Upon photolyzing (2-bromoethyl)benzene in the matrix at 77 K with UV light, a seven-line spectrum extending over 15 mT was observed, distinctly differing from the spectrum assigned to α-methylbenzyl radical,[2] and probably due to the phenethyl radical. It was found to decay with no change in its spectral shape when warmed to 100 K.

When the MTHF matrix containing (2-bromoethyl)benzene was irradiated with γ-rays at 77 K, the observed spectral shape consisted of the superposition of the well-known spectrum of MTHF radical,[9] and that attributable to the phenethyl radical. The change in the spectral shape upon warming to 100 K was found to be due to the decay of only the latter spectrum by examining the difference in spectral shape before and

after the warming. In this case the phenethyl radical seems to be formed by dissociative electron attachment to (2-bromoethyl)benzene.

From these photolysis and radiolysis studies it is obvious that the radical is too stable for the intramolecular hydrogen transfer to occur. Thus, the α-methylbenzyl radical is concluded to be generated exclusively by the direct mode of formation, the proton attachment to the α-carbon, the indirect mode being excluded. It is inferred that the proton transfer to the styrene anion in the mixed matrix occurs when an ethanol molecule happens to be properly located close to the β-carbon of the anion. Based on MO calculations, electron density is the highest as this carbon atom in the anion, so that it is expected to be the most reactive toward the proton attachment.

According to the present optical absorption study, the *G*-value of the α-methylbenzyl radical in the γ-irradiated ethanol matrix was determined to be 2.2 by using the extinction coefficient, 1.5×10^4 mol^{-1} dm^3 cm^{-1} at the absorption maximum for benzyl radical.[10] It is almost identical to the *G*-value of scavengeable electron in the ethanol matrix.[7] This coincidence of the *G*-values supports the view that the α-methylbenzyl radical arises from the styrene anion generated by the electron attachment to styrene, and that the proton transfer to the anion occurs almost exclusively to the β-carbon.

Photobleaching of Styrene Anion. Upon photobleaching with white light from an incandescent lamp ($\lambda>400$ nm), the styrene anion in the mixed matrix could be completely eliminated, being transformed partially into the α-methylbenzyl radical (Fig. 1B). The efficiency of this photoinduced transformation (the ratio of the increment of the radical yield to the yield of the photobleached anion) increases with increasing X_{EtOH} to reach a plateau value of *ca.* 0.6 (Fig. 3). The plateau could be determined by the competition for electrons photoreleased from the styrene anions between the dissociative electron scavenge reaction of ethanol[11,12] and the non-dissociative electron scavenge reaction of styrene associated with an ethanol molecule suitable for the proton transfer. Both the dissociative and non-dissociative scavenge reactions proceed at a rate proportional to the ethanol concentration in the mixed matrix, so that the transformation efficiency is independent of the ethanol concentration. The rate of non-dissociative scavenge reaction proportional to the ethanol concentration implies that only one ethanol molecule can be located in the solvent site adequate for the proton transfer, consistent with $n=1$ in Eq. 1.

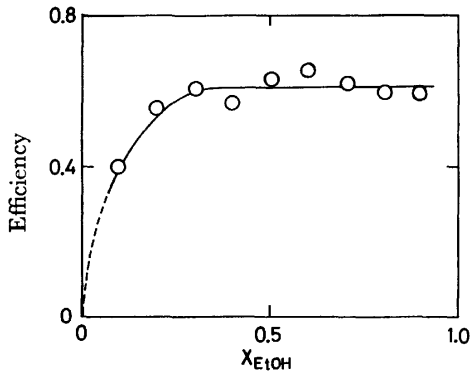

Fig. 3. Efficiency of photoinduced transformation of styrene anion into α-methylbenzyl radical as a function of the ethanol fraction in the MTHF–ethanol mixed matrix. Photobleaching was carried out with white light at 77 K after irradiating the matrices containing 50 mmol dm^{-3} styrene to the dose of 200 krad.

The fall of efficiency at low values of X_{EtOH} can be attributed to an increasing contribution of charge recombination reaction between the photoreleased electrons and positive ions, since the rate becomes low for both scavenge reactions.

So far the discussion has been given on the assumption that ethanol is perfectly missible in MTHF and *vice versa*, so that the mixed matrix is microscopically homogeneous. Sawai and Hamill studied the optical absorption spectra of trapped electrons in γ-irradiated MTHF–methanol mixed matrix and interpreted the spectral feature in terms of the microscopically homogeneous mixing of the two solvent components.[13]

8) Dissociative electron attachment to (2-chloroethyl)-benzene leads to the formation of phenethyl radical. The observed α-methylbenzyl radical was therefore suggested to arise from the phenethyl radical.[6] However, the α-methylbenzyl radical was detected by the sensitive fluorescence spectrophotometric method, the formation of the phenethyl radical not being examined. It seems to us that the main product from (2-chloroethyl)benzene is the phenethyl radical and that the α-methylbenzyl radical is generated by a subsidiary reaction in the γ-irradiated matrices.

Ultrasonic and Volumetric Investigation of Aqueous Solutions of Amides

Fumio KAWAIZUMI, Makoto OHNO, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 21, 1977)

The ultrasonic velocity and density of aqueous solutions of *N*-methylformamide, *N*,*N*-dimethylformamide, and *N*,*N*-dimethylacetamide have been measured at 25 and 35 °C over the entire concentration range. The compressibility, excess compressibility, partial molar compressibility, partial molar volume, and pressure dependence of the partial molar volume have been calculated. The concentration dependences of the velocity and density are highly nonlinear, and the velocity maxima are observed in all the amide solutions at *ca.* 20 mol%. Minima in the partial molar volume exist in solutions of DMF and DMAA, but not in that of MFA. On taking account of the results for viscosity, the velocity maxima are ascribed to the complex formation, and the minima in the partial molar volume, to the competition between the volume increase due to the complex formation and the volume decrease due to the breaking-down of the water structure. The pressure dependence of the partial molar volume shows that amides and water have strong interactions, even in the low-mole-fraction regions for each component.

Numerous investigators have studied solute-solvent interaction in nonelectrolytic aqueous solutions from the point of view of their ultrasonic and volumetric behavior. In binary liquid mixtures, the nonlinear variation in the ultrasonic velocity with the concentration has been frequently observed, but the systems showing a velocity maximum are limited to aqueous solutions, except for the very rare case of the liquid paraffin–carbon tetrachloride system.

From among the many nonelectrolytes known to form aqueous solutions with a velocity maximum at a certain concentration, the present authors chose amides. The ultrasonic velocities and densities of aqueous solutions of *N*-methylformamide(MFA), *N*,*N*-dimethylformamide (DMF), and *N*,*N*-dimethylacetamide (DMAA) will be reported.

The aqueous solutions of amides have the following characteristic features concerning their ultrasonic and volumetric properties. First, the ultrasonic velocity and the density of pure amides have values similar to those of water. Secondly, in a solution of DMF, the maximum has been observed in the concentration dependence of the velocity as well as in that of the density. Nonelectrolytes showing a similar solution behavior include some kinds of amines (ethylenediamine and benzylamine[1]), acetic acid, dioxane,[2] and pyridine.[3]

The ultrasonic velocities in aqueous solutions of DMF[4] and DMAA[5] have been reported by Endo, and the densities of the aqueous solutions of DMF[6] and DMAA,[7] by Arakawa *et al.* and Assarsson and Eirich. We have undertaken the re-determination of the velocities and densities of these three aqueous solutions of amides in order to obtain consistent data. For instance, the density of DMAA given by Assarsson and Eirich[7] is 0.9350 g/ml at 25 °C. This value is not compatible with our result (0.9367_0 g/cm^3) nor with the value of 0.9366 g/cm^3 found in the literature.[8] The data by Assarsson and Eirich[7] are, as they themselves say, not accurate enough to establish whether or not a small minimum in the partial molar volume exists, as in alcohol–water systems, at a very low mole fraction of the amides.

Experimental

Materials. The MFA(guaranteed grade) and DMF (spectral grade), obtained respectively from the Tokyo Kasei Co., Ltd., and Nakarai Chemicals were used without further purification. The DMAA (guaranteed grade) was purified by distillation under reduced pressure.

Apparatus and Procedures. Measurements of the sound velocity were carried out at a fixed frequency of 4 MHz by means of an improved ultrasonic interferometer. This interferometer has the great advantage that a good parallelism between the reflector and the quartz surface can be attained by the aid of the screws and the springs, while in the interferometer used hitherto in our laboratory, the parallelism was mechanically determined. The parallelism is established by the application of the pulse-echo method. The measurement of the sound velocity was reproducible within 0.4 m/s. Further accuracy has been obtained by finely polishing the surface of the reflector. The density has been measured by using a 20-ml pycnometer. The density data are accurate to ±3 units in the fifth decimal place. Measurements were done at 25 and 35 °C.

Results and Discussion

Density and Velocity. The experimental results of the density and the ultrasonic velocity as a function of the composition are summarized in Tables 1—3. In all three aqueous solutions of amides studied in this work, the density as well as the ultrasonic velocity shows a high nonlinear dependence on the concentration. In the MFA system, the density maximum exists in the vicinity of 20 mol% of MFA. In the DMF and DMAA systems, sinuous but slight variations of the density have been observed in the low-concentration region of amide. After passing this region, the concentration dependence of the density is marked, but in a linear fashion. The aqueous solutions of alcohols, which exhibit a marked nonlinear dependence on the concentration in many physical properties, do not show such a clearly sinuous variation or a maximum point in relation to the concentration dependence of the density. All three amide systems show velocity maxima in the concentration range of 15—20 mol%, this range corresponds to the region where the decreases of density begin. The concentration dependence of the ultrasonic velocity in general, and also the position of the maximum, correspond well with the viscosity results of many kinds of aqueous solutions of amides.[7] Assarsson and Eirich, considering phase diagrams and heat of mixing in amide–water systems,[9] have related the observed maximum of viscosity to the formation of the complex. The veloc-

ity maximum has been reported in the aqueous solutions of tetrahydrofran, 1,4-dioxane, and *t*-butyl alcohol in the concentration range of 3—8 mol%.[10] These compounds form solid clathrates of 17 hydrates. In these cases, there is no doubt of the relationship between the occurrence of the velocity maximum and the formation of a "compound" (hydrate or other).

Generally speaking, the velocity maximum in solutions do not always necessiate the formation of a "compound." However, in the aqueous solutions of amides concerned in this work, the resemblance between the concentration dependence of the ultrasonic velocity and that of the viscosity indicates that the velocity maximum arises from the formation of the complex, therefore, the position of the velocity maximum indicate its composition. However, the structure of the complex formed in amide–water systems may not be similar to those in an ordinary clathrate like 17 hydrate or $8X \cdot 136H_2O$.

Compressibility. From the values of the velocity and density, the adiabatic comprssibility, κ_s has been calculated. The concentration dependence of κ_s is shown in Fig. 1. DMAA gives a similar dependence of the compressibility. Concerning Fig. 1 two facts should be mentioned: the appearance of the minimum and the temperature-independent point. The former

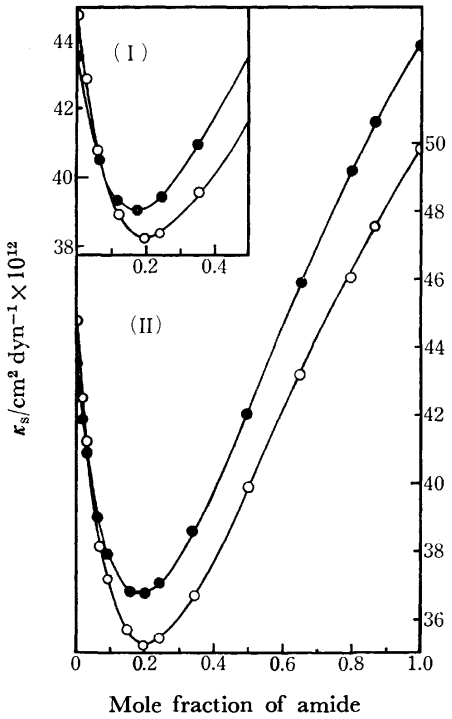

Fig. 1. Concentration dependence of adiabatic compressibility of the aqueous solutions of MFA (I) and DMF (II).
○: 25 °C, ●: 35 °C.

corresponds to the occurrence of the maximum in the velocity (and also in the density for the MFA system). The latter corresponds to the appearance of the common intersection in the relation of the temperature dependence of the velocity in solution. The phenomenon of the common intersection in the velocity has often been observed in many nonelectrolytic aqueous solutions.[4,5,11,12] Endo[4,5] has argued that this phenomenon is due to the clathrate formation and that the concentration of the common intersection should give the composition of the clathrate. The measurements of the ultrasonic velocity of Endo are quite extensive in terms of materials and the temperature range. However, his discussion of the common intersection has the crucial defect that comparisons with other properties which have intimate relations to the ultrasonic velocity, such as the density and the ultrasonic absorption coefficients, are disregarded. The relation between the common intersection and the partial molar volume will be discussed below.

The excess adiabatic compressibility, κ_S^E has been calculated from κ_S, and the molar volumes, V, of the mixtures and the pure components, A and B by means of this equation:

$$\kappa_S^E = \kappa_S - \frac{1}{V}(X_A V_A \kappa_{S,A} + X_B V_B \kappa_{S,B}).$$

The results are shown in the Fig. 2. κ_S^E's are always negative, and the values decrease as the $-CH_2-$ group increases. The temperature coefficients change their sign at a certain concentration in all systems.

Partial Molar Volume and Partial Molar Compressibility. From the density data given in Tables 1—3, the characteristic behavior of the partial molar volume of amides in solutions represented in Fig. 3 is obtained. The relation of the partial molar volume to the composition at 35 °C falls on the curves shown in Fig. 3. Similarly, as for κ_S^E, the curves become steeper as the number of the $-CH_2-$ group increases. The behavior of the aqueous solutions of amides shown in Fig. 3 closely resembles that of aqueous solutions of alcohols[13] and amines.[14] Sometimes the position of the minimum in the partial molar volume *vs.* composition relation roughly coincides with the common intersection of the ultrasonic velocity (therefore, the compressibility), for example, in aqueous solutions of tetramethylurea[11] and ethers.[12] The comparison of Fig. 1 with Fig. 3 shows that, for

DMA and DMAA, this coincidence holds, but for MFA this is not the case.

Figure 4 shows the apparent molar compressibility, ϕ_{κ_s}, at 25 °C as calculated by means of this equation:

$$\phi_{\kappa_s} = \frac{1000(\kappa_s - \kappa_{s,1})}{c} + \kappa_{s,1}\phi_v,$$

where the subscript 1 refers to the solvent, c is the concentration in molarity, and ϕ_v is the apparent molar volume. According to Fig. 4, at an infinite dilution the ϕ_{κ_s} values are in this order: MFA, DMF, DMAA: that is to say, as a molecule has more $-CH_2-$ groups, the more rigid it becomes. The order of the rigidity, however, is inverted in the concentration range above *ca.* 10 mol%.

As an inversion of the order of the values of ϕ_{κ_s}, the common intersection in the ultrasonic velocity, and the minimum in the partial molar volume, occur in a similar region of the concentration, these phenomena may have some interrelations. However, any interpretations of these phenomena must be consistent with the appearances of the velocity maximum and the viscosity maximum observed in the concentration range beyond 20 mol%.

As has been mentioned above, the maximum in ultrasonic velocity has been ascribed to the complex formation. The following is a tentative interpretation of the partial molar volume as a function of the concentration. The complex formed by the hydrogen-bonding between amide and water has a rigid, but bulky structure. Therefore, the complex formation gives rise to an increase in the apparent volume of amide. The minimum in the partial molar volume may, then, be attributed to the competition between the volume increase due to the complex formation and the volume decrease due to the breaking-down of the water structure.

The relationship of the common intersection in the ultrasonic velocity with the other phenomena is not clear at present. The coincidence of the minimum position in the partial molar volume with the common intersection in the ultrasonic velocity is part of the complicated nature of the aqueous solutions. However, with regard to the aqueous solutions of amides studied in this work, the composition of the common intersection of the ultrasonic velocity can not be considered to indicate that of the "compound" formed in solution.

Pressure Dependence of the Partial Molar Volume.
For the partial molar volume of a solute, its pressure dependence can be calculated from the following equation:[16]

$$\frac{\partial \overline{V}_2}{\partial p} = -\kappa \overline{V}_2 - (1-X)V\frac{\partial \kappa}{\partial X}.$$

The results of calculation are given in Fig. 5. In a dilute solution of amides, the three curves in Fig. 5 intersect with one another, and this intersection corresponds to the inversion of the order of ϕ_{κ_s} in Fig. 4. In a dilute region, $\partial\overline{V}_2/\partial p$ is very large. As the concentration of a solute increases, the variation in $\partial\overline{V}_2/\partial p$ gradually decreases. For small molecules, the variation in $\partial\overline{V}_2/\partial p$ with the concentration ceases in more dilute solutions than in case of large molecules, and in the pure state of amide, the order of $\partial\overline{V}_2/\partial p$ for the three systems is, as it should be, MFA, DMF, DMAA. The strong dependence of $\partial\overline{V}_2/\partial p$ on the concentration in a dilute aqueous solution of amides indicates the strong solute-solvent interaction in solution. Calculations using the data at 35 °C have given, for all three systems, more negative values than those shown in Fig. 5. The negative values of $\partial\overline{V}_2/\partial p$ are equivalent to the negative values of K_x, where K_x is the relative partial specific compression of the solute,[15] and where the amide is taken as a solute. A negative K_x value signifies the non-existence of an incompressible region in the solution. However, this does not contradict with the complex formation between amides and water, because the hydrogen-bonding interactions are not so strong as to

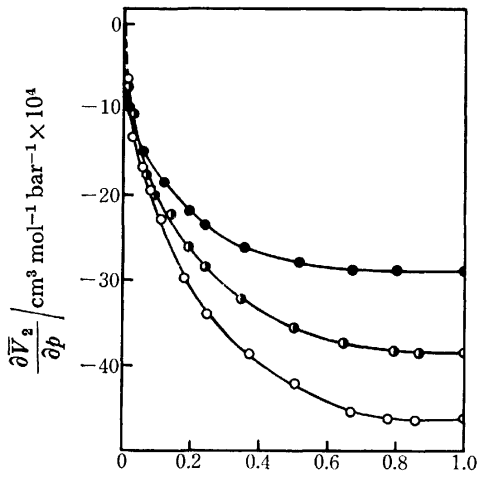

Fig. 5. Concentration dependence of $\partial\overline{V}_2/\partial p$ at 25 °C.

○: DMAA–water system.

the coulombic ones typically observed in the form of ionic hydration.

The pressure dependence of the partial molar volume of the solvent can be obtained in a similar way; the results are shown in Fig. 6. The values of $\partial \overline{V}_1/\partial p$ and its concentration dependence are in the order of DMAA, DMF, and MFA. For solutions of DMAA and DMF, $\partial \overline{V}_1/\partial p$ are positive in the water-rich region. The marked dependence of $\partial \overline{V}_1/\partial p$ on the concentration in the water-rich region shows that, when a small amount of water is dissolved in amides, water molecules interact very strongly with amide molecules.

In summing up the results of Figs. 5 and 6, it is evident that strong interactions exist between water and amides, even in low-mole-fractions for each component.

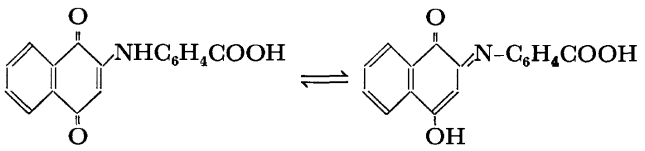
The Dimorphism and Electronic and Vibrational Spectra of 2-Anilino-1,4-naphthoquinones

Yoshio MATSUNAGA, Nobuhiko MIYAJIMA, and Atushi TOGASHI
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 23, 1977)

Dimorphic forms were isolated for over ten derivatives of 2-anilino-1,4-naphthoquinone, 2-anilino-3-chloro-1,4-naphthoquinone, and 2-anilino-3-bromo-1,4-naphthoquinone carrying substituents on the phenyl ring. One of the two forms exhibits a relatively sharp vibrational band near 3300 cm^{-1}, the other, a relatively broad band at a lower wave number. The spectra in the region from 700 to 1700 cm^{-1} are often markedly different from each other. In several instances, the two forms are differently colored. This difference is attributed to the appearance of, or a change in the intensity of, an intermolecular charge-transfer absorption band. Not only the dimorphic forms, but also most of the derivatives examined, could be classified into two groups on the basis of the location and the sharpness of the vibrational band appearing in the region from 3150 to 3350 cm^{-1}.

A large number of the condensation products of 1,4-naphthoquinone and its 2,3-dihalo derivatives with various anilines have been synthesized and examined for possible use as vat dyestuffs and as bactericides.[1-9] Among them, 2-(*p*-carboxyanilino)-1,4-naphthoquinone was isolated as yellow and red crystals by Hauschka.[7] The tautomerism involving *p*-quinonoid and *o*-quinonoid forms:



was pointed out as a possible cause of the marked difference in color. However, he added that the spectroscopic study failed to provide concrete evidence in support of this assumption. Because of the recent work on a related compound by Bloom and Dudek, a further study of the suggested tautomerism seemed to be desirable. These authors found that the electronic absorption spectrum of 4,8-dianilino-1,5-naphthoquinone is solvent-dependent.[10] In polar, associating solvents, the lowest-energy absorption appearing at 661 nm is of maximum intensity and decreases with a decrease in the solvent-associating ability. Further evidence for the existence of a tautomeric equilibrium in solution has been provided by their work on the proton magnetic resonance of the ^{15}N-substituted compound.

As we have reported for the dimorphic forms of *o*- and *p*-anisyl-*p*-benzoquinones,[11] there is another possible explanation for the difference in color. The molecule consists of an electron-donating and an accepting moieties; therefore, the color of the crystal may depend upon the intermolecular charge-transfer absorption, the location and the intensity of which can be modified, to some extent, by the mode of molecular stacking. No matter which is the cause, the dimorphism is certainly influenced by the kind and the position of substituent, and one may isolate more dimorphic forms by examining closely related compounds. Spectroscopic studies of many pairs of such modifications may be fruitful in deciding the origin of this phenomenon. Accordingly, a careful examination of various 2-anilino-1,4-naphthoquinones and its 3-chloro and 3-bromo derivatives was set up.

Experimental

Materials. The naphthoquinone and its 2,3-dichloro derivative were obtained commercially. The 2,3-dibromo-1,4-naphthoquinone was prepared following the method reported by Miller.[12] The condensation reaction between the naphthoquinones and anilines was carried out in boiling ethanol unless otherwise stated. The isolation of dimorphic forms was attempted by sublimation in a vacuum and by recrystallization from appropriate solvents, and under various conditions. Hereafter, X denotes the substituent on the phenyl group, and Y, the atom attached to the 3 position of the quinone.

Measurements. The vibrational spectra in the rock-salt region were recorded on a Jasco IR-G infrared spectrophotometer as Nujol mineral oil or hexachlorobutadiene mulls.

The diffuse reflectance of solid samples was measured using a Beckman DK-2A spectroreflectometer in the range from 325 to 700 nm. The anilinoquinone crystals were pulverized with sodium chloride in a concentration of the order of one weight percent. The spectra were recorded as the difference between the mixture and pure sodium chloride and were plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance. In all the figures in this paper, the electronic spectra are plotted taking the maxima of the lowest-energy absorption arbitrarily as 1.00.

Results

2-(Carboxyanilino)-1,4-naphthoquinones (X=COOH, Y=H). The vibrational spectra of the yellow form and the red form of the *p*-derivative obtained by vacuum sublimation are presented in Fig. 1. There is a marked difference in the region from 3150 to 3350 cm^{-1}. The yellow form exhibits a sharp absorption band at 3310 cm^{-1}, and the red form, a rather broad one at 3220 cm^{-1}. They may be assigned to the N–H or O–H stretching vibration. As their locations are known to be strongly affected by hydrogen bonding, it is difficult to decide whether or not the shift is an indication of the tautomerism. For example, 2-hydroxy-1,4-naphthoquinone, which is isomeric with 4-hydroxy-1,2-naphthoquinone, shows a very broad O–H stretching band at 3150 cm^{-1}, suggesting the presence of strong hydrogen bonding. On the other hand, 2-amino-3-hydroxy-1,4-naphthoquinone gives a sharp band at 3450 cm^{-1} and a broad one at 3300 cm^{-1}. As is shown in Fig. 1, the dimorphic forms significantly differ from

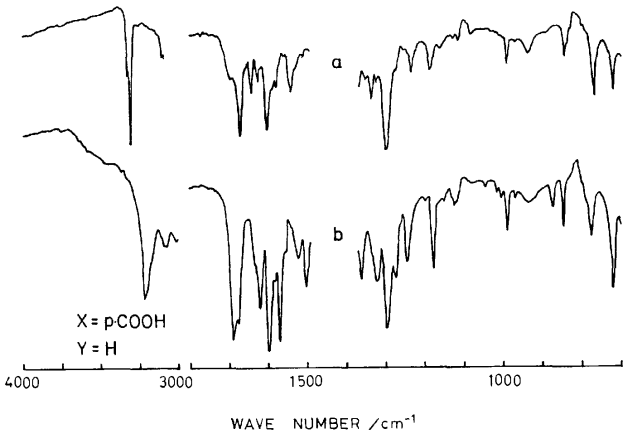


Fig. 1. Vibrational spectra of 2-(*p*-carboxyanilino)-1,4-naphthoquinone: (a) the yellow form and (b) the red form.

each other also in the pattern of the region from 1000 to 1700 cm^{-1}.

The electronic spectra of the yellow and red forms are given in Fig. 2. The absorption maximum is located at 435 nm in the yellow form and at 510 nm in the red form. As the location of the shoulder appearing in the former spectrum coincides exactly with the maximum in the latter, our yellow sample may be contaminated with a small amount of the red form. The maximum in the yellow form is close to the one observed in an acetone solution, 450 nm. No appreciable change was detected either in the location or in the intensity when methanol, ethyl acetate, chloroform, and pyridine were employed as the solvents. The temperature-dependence measured in the last mentioned solvent revealed that the absorption maximum decreases and shifts a little bit to the short wavelength side when the temperature is elevated, *e.g.*, 464 nm at 18 °C and 457 nm at 66 °C. The isosbestic points appearing at 360 and 422 nm probably arise from this shift. The present molecule is flexible, and the electronic transition considered is of the charge-transfer type; therefore, the temperature-dependence may be interpreted in terms of the thermal excitation of the distortion modes, as has been suggested by Kordes *et al.*[13]

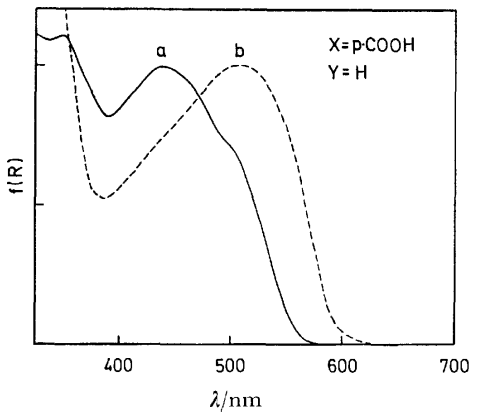

Fig. 2. Electronic spectra of 2-(*p*-carboxyanilino)-1,4-naphthoquinone: (a) the yellow form and (b) the red form.

In accordance with the observation by Hauschka, the *o*-derivative is obtainable as orange-red crystals, and the *m*-derivative, as red crystals. In the region near 3300 cm^{-1}, no vibrational band is found for the former compound, but a sharp band at 3280 cm^{-1} is found for the latter. The electronic spectrum of the *o*-derivative has a maximum at 475 nm, and the *m*-derivative, one at 520 nm.

Other 2-Anilino-1,4-naphthoquinones (Y=H). Among the sixteen compounds examined, only the *p*-methoxy and *m*-ethoxy derivatives were found to be dimorphic. When the condensation reaction between the quinone and *p*-anisidine was carried out in boiling ethanol, reddish violet crystals were deposited. The same form could be obtained by recrystallization under various conditions and also by sublimation in a vacuum. This stable form gives a broad vibrational band at 3215 cm^{-1}. Because of the reasoning to be presented later, the preparation was repeated in cold media with the hope of isolating the unstable form. A bluish violet product of the condensation in ethanol at room temperature showed a sharp band at 3325 cm^{-1} in addition to the above-mentioned broad one. The whole vibrational pattern, which is more complicated than that of the reddish violet form, suggested the coexistence of two forms. Since the transformation was suspected to be accelerated by the solvent, the reaction in cold water, in which the product is hardly soluble, was also attempted. This time, the product gave no broad band near 3200 cm^{-1}; however, the purity did not seem to be high, as the spectrum consists of rather broad bands. Thus, the unstable form could not be isolated. The *m*-ethoxy derivative prepared in boiling ethanol was reddish brown and showed a band at 3320 cm^{-1}. Upon sublimation in a vacuum the color turned dark red, and the vibrational spectrum was considerably modified. The above-mentioned sharp band was replaced by a broad one at 3255 cm^{-1}. The difference in the electronic spectrum is not large for this compound; the maximum is at 500 nm in both forms. These two compounds were initially prepared by Grossmann, but he did not note the dimorphism.[8]

For all the other derivatives, we saw no indication of dimorphism. On the basis of the vibrational band in the region from 3150 to 3350 cm^{-1}, they can be classified into two groups. The first group consists of the following derivatives, exhibiting a sharp band near 3300 cm^{-1}: X=H (3310 cm^{-1}), *m*-Me (3305), *p*-Me (3325), *o*-MeO (3300), *m*-MeO (3320), *o*-EtO (3330), *p*-EtO (3320), and 3,4-Me_2 (3315). On the other hand, a broad band was observed near 3200 cm^{-1} only with the halo derivatives—namely, *m*-Cl (3180 cm^{-1}), *p*-Cl (3185), *m*-Br (3180), *p*-Br (3200), and *p*-I (3200). The *p*-ethyl and *m*-carboxy derivatives are exceptional. A band with an intermediate breadth was found at 3280 cm^{-1}. Grossmann noted that the color of the *m*-methoxy derivative appreciably varies with the kind of solvent; that is, the pyridine solution is light yellow, the benzene solution is orange red, and the ethanolic solution is bluish red.[8] Nevertheless, we found that the absorption spectrum in pyridine is identical with that in ethanol. The maximum at room temperature is at 470 nm in both solvents.

2-Anilino-3-chloro-1,4-naphthoquinones (Y=Cl). Dimorphic forms could be isolated with the *m*-methyl, *p*-ethyl, 2,4-dimethyl, *m*-ethoxy, and *m*-carboxy derivatives. In the case of the *m*-methyl derivative, the form deposited from the reaction mixture gives a sharp vibrational band at 3300 cm^{-1}, while the other form, obtained by recrystallization from ethanol, gives a broad band at 3245 cm^{-1}. A mixture of the two forms was obtained by sublimation in a vacuum. The difference in the other region is less significant compared with the case shown in Fig. 1 (X=*p*-COOH, Y=H). The former form is dark reddish violet and gives an absorption maximum at 485 nm and a shoulder at 515 nm. The latter is bright reddish violet, and its maximum is located at 510 nm.

The crystals of the *p*-ethyl derivative, separated from the reaction mixture and also purified by vacuum sublimation, are reddish violet and give a sharp vibrational band at 3270 cm^{-1}, while the crystals deposited from acetone are similarly colored, but give a broader band at 3235 cm^{-1}. In both the dimorphs, the absorption maxima are located at 515 nm.

The 2,4-dimethyl derivative, as prepared in boiling ethanol, was found to be a mixture of two forms. The reddish brown form isolated by recrystallization from ethanol shows a sharp vibrational band at 3305 cm^{-1}. The color turns reddish violet upon vacuum sublimation, and the sharp band is replaced by a broad one appearing at 3250 cm^{-1}. The splitting of the carbonyl stretching vibrational band is observed only in the former form. The electronic absorption maximum is at 495 nm in the form obtained by recrystallization and at 505 nm in the form obtained by sublimation.

The *m*-ethoxy derivative is dimorphic; that is, the vibrational spectrum of the crystals as prepared in ethanol differs from that of the crystals obtained by vacuum sublimation or by recrystallization from ethanol. The former form gives a sharp band at 3325 cm^{-1}, and the latter, a broad one at 3240 cm^{-1}. The electronic spectra are essentially the same, both having a maximum at 500 nm.

Two forms distinctly differnt in color were isolated for the *m*-carboxy derivative. The crystals deposited from the reaction mixture are yellow or yellowish orange. Upon vacuum sublimation the color turned scarlet.

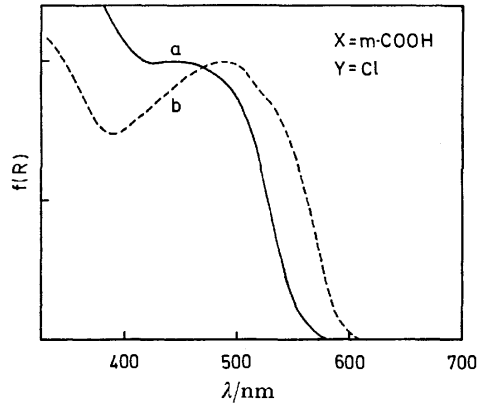

Fig. 3. Electronic spectra of 2-(*m*-carboxyanilino)-3-chloro-1,4-naphthoquinone: (a) the yellow form and (b) the scarlet form.

Although Buu-Hoi carried out his preparation in the same solvent, the color he described seems to be in agreement with the latter.[9] The former form shows a sharp vibrational band at 3340 cm^{-1}, and the latter, a broad one at 3275 cm^{-1}. The electronic spectra of these dimorphs are presented in Fig. 3. The maxima are located at 450 and 490 nm respectively. In addition, the scarlet form gives a shoulder at 525 nm. Both a sharp vibrational band at 3325 cm^{-1} and a broad one at 3225 cm^{-1} were observed with the *p*-propyl derivative, suggesting the existence of two forms. Unfortunately, we could not separate them.

Only one form each was obtained for the seventeen other derivatives examined. Among them, the following six derivatives give sharp vibrational bands near 3300 cm^{-1}: X=2,3-Me_2 (3295 cm^{-1}), 2,4,5-Me_3 (3290), *o*-MeO (3340), *o*-EtO (3320), *o*-COOH (3300), and *p*-COOH (3300). Broad bands are observable with the following eleven, including the unsubstituted compound: X=H (3245 cm^{-1}), *o*-Me (3240), *p*-Me (3220), 2,4-Me_2 (3225), 3,4-Me_2 (3250), *m*-MeO (3220), *p*-MeO (3245), *p*-EtO (3235), *m*-Cl (3225), *p*-Cl (3230), and *p*-I (3260). In this series, not only the halo derivatives, but also some alkyl and alkoxy derivatives, are classified into the second group. Therefore, it is apparent that the form with a broad vibrational band near 3200 cm^{-1} favors the substitution with the chlorine atom at the 3 position of the naphthoquinone. When the X derivative with Y=H belongs to the first group and the corresponding derivative with Y=Cl belongs to the second group, it is likely that the effect of the X substituent is nearly matched by the effect of the Y substituent. Assuming that the chance of finding dimorphs is high with these two derivatives, they were particularly carefully examined.

2-Anilino-3-bromo-1,4-naphthoquinones (Y=Br). With the *p*-ethyl, 2,3-dimethyl, 3,4-dimethyl, and *o*-ethoxy derivatives, dimorphic forms could be isolated. A broad vibrational band appearing at 3240 cm^{-1} was observed with the crystals of the *p*-ethyl derivative as prepared in boiling ethanol and also with those recrys-

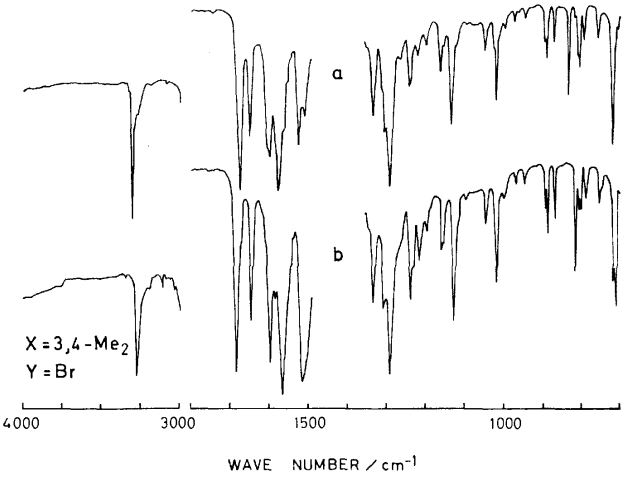

Fig. 4. Vibrational spectra of 2-(3,4-dimethylanilino)-3-bromo-1,4-naphthoquinone: (a) the form deposited from the reaction mixture and (b) the form isolated by recrystallization from aqueous ethanol.

tallized from the same solvent. By adding water to the cold solution and then letting stand the mixture overnight, crystals showing a sharper band at 3275 cm^{-1} were deposited. In the electronic spectra, the maximum is at 510 nm in the former form and shifts to 495 nm in the latter.

The difference in the vibrational spectrum is small in the dimorphic forms of the dimethyl derivatives, as is exemplified by the 3,4-derivative shown in Fig. 4. The reaction products show a band at 3280 cm^{-1} in both cases. A sharp band appears at 3305 cm^{-1} upon the vacuum sublimation of the 2,3-derivative. The crystals deposited from the reaction mixture show an electronic absorption maximum at 505 nm, while the crystals obtained by sublimation show a maximum at 485 nm. On the other hand, the form showing a sharp band at 3310 cm^{-1} was isolated by recrystallization from aqueous ethanol in the case of the 3,4-derivative. The maximum in the electronic spectrum is at 505 nm for both of the dimorphs.

The two forms for the *o*-ethoxy derivative do not differ much from each other in the vibrational spectrum; that is, the crystals deposited from the reaction mixture exhibit a sharp band at 3340 cm^{-1}, while the crystals obtained by sublimation in a vacuum or by recrystallization from benzene show a sharp band at 3325 cm^{-1}. The absorption maximum in the electronic spectrum is at 515 nm in the former form and at 530 nm in the latter. Nevertheless, the two spectra can be almost superposed on each other.

The presence of dimorphic forms was noted for the *m*- and *p*-methyl derivatives, but they could not be separated. A sharp band was observed at 3325 cm^{-1} with the crystals of the former compound deposited from the reaction mixture, and also with those recrystallized from ethanol. Upon vacuum sublimation, an additional band appeared at 3225 cm^{-1}. On the other hand, the synthesis, recrystallization, and vacuum sublimation yielded the form showing a broad band at 3225 cm^{-1} for the latter. However, the appearance of an additional sharp band at 3335 cm^{-1} was noted when the crystals were deposited from a cold aqueous ethanolic solution.

The following six derivatives of the anilinobromonaphthoquinone are classified into the first group: X= *p*-Pr (3280 cm^{-1}), *o*-MeO (3355), *m*-EtO (3330), *m*-COOH (3280), *p*-COOH (3320), and 2,4,5-Me_3 (3295). The second group consists of X=H (3245 cm^{-1}), *o*-Me (3255), *m*-MeO (3225), *p*-MeO (3255), *p*-EtO (3250) 2,4-Me_2 (3265), and 2,5-Me_2 (3225). The halo derivatives expected to be members of this group were not included in this study, as the observation of dimorphism with them seemed to be very unlikely. It may be added that the locations are generally at higher wave numbers compared with those of the corresponding derivatives in the chloronaphthoquinone series.

To supplement the above results, we carried out spectral measurements of the condensation product between two moles of 2,3-dichloro-1,4-naphthoquinone and one mole of 3,3′-dimethoxybenzidine. The color of this particular compound has been reported to be red in hot xylene and to turn reddish violet upon cooling.[14] However, we could record no unusual temperature dependence with this system.

Discussion

In order to examine the relative stabilities of the possible tautomeric forms within the framework of the HMO method, we compared the bonding energies of the two forms of the unsubstituted anilinonaphthoquinone. This approach has been employed by Kuder as a criterion of the tautomeric stability of hydroxyarylazo compounds.[15] The bonding energy is given by the difference between the total π-electron energy and the energy of the π-electrons localized on atomic *p*-orbitals. The latter is defined by $\sum_{i=1}^{n} s_i\alpha_i$, where n is the number of atomic centers, s_i is the number of electrons contributed by the i atom to the π-electron system, and α_i is the Coulomb integral for the i atom. The tautomeric form with the larger bonding energy or bonding energy per electron may be considered to be more stable. The heteroatom parameters, h_x and k_{xy}, in the Coulomb and resonance integrals, $\alpha_x=\alpha+h_x\beta$ and $\beta_{xy}=k_{xy}\beta$, were the same as those used by Kuder, namely, $h_{NH}=1.50$, $h_O=1.00$, k_{C-N}(the bond to naphthoquinone)$=0.90$, k_{C-N}(the bond to phenyl group)$=0.70$, and $k_{C=O}=1.00$ for the *p*-quinonoid form and $h_N=0.50$, $h_O=1.00$, $h_{OH}=2.00$, $k_{C=N}=1.10$, $k_{C-N}=0.90$, $k_{C=O}=1.00$, and $k_{C-O}=0.80$ for the *o*-quinonoid form. The effect of an intramolecular hydrogen bond, O···H–N, was also considered by taking the following parameters: $\alpha'_{NH}=\alpha_{NH}-0.20\beta$, $\alpha'_{O-H}=\alpha_O+0.20\beta$, $\beta_{O-H-N}=0.20\beta$. The bonding energies computed in terms of the carbon-carbon resonance integral, β, are shown below:

	p-Quinonoid	*o*-Quinonoid
No hydrogen bond	24.851	24.823
With a hydrogen bond	24.967	—

Consequently, the *p*-quinonoid form appears to be more stable than the *o*-quinonoid form, regardless of the hydrogen bond. It has been argued by Kuder that a difference in bonding energy per electron in excess of 0.002β leads to the presence of only one tautomer. This criterion suggests that only the *p*-quinonoid form of the anilinonaphthoquinone will be seen if the hydrogen bond is formed.

The above-mentioned situation may be affected, to some extent, by the introduction of a substituent on the phenyl group. However, our observations cannot be correlated with the nature of the substituents. Not only the derivative with an electron-withdrawing group, but also the one with an electron-donating group on the same position were found to be dimorphic: *e.g.*, X= *p*-COOH and *p*-MeO with Y=H and X=*m*-COOH, *m*-EtO, and *m*-Me with Y=Cl. Furthermore, the electronic spectrum not being sensitive to the nature of solvents and its small temperature-dependence seem to be inconsistent with the presence of a tautomeric equilibrium in solutions. The molar absorption coefficient of the band in the visible region is in the range from 2600 to 5400, depending mainly upon the kind and position of the X substituent. This absorption may be attributed to an intramolecular charge-transfer transi-

tion. The difference in vibrational spectrum must, then, be due to a change in the molecular configuration. The change appears to be large in the case shown in Fig. 1 (X=*p*-COOH, Y=H) and small in the case shown in Fig. 4 (X=3,4-Me_2, Y=Br). In other cases, the difference varies between these extremes. The band appearing in the region from 3150 to 3350 cm^{-1} can now be definitely assigned to the N–H stretching vibration. The shift implies that the strength of the hydrogen bond varies with the configuration. As the mode of stacking is governed by the molecular configuration, the difference in color between dimorphic forms may be attributed largely to changes in the location and the intensity of the intermolecular charge-transfer absorption between the electron-donating moiety of a molecule and the accepting moiety of the neighboring molecule.

Threshold Switching in Anthracene Thin Films

Yoshihiko SADAOKA, Yoshiro SAKAI, and Kohhei KISHI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received February 23, 1977)

Threshold switching was observed in anthracene thin films (<3 μm) using a circuit with a high protective resistance. On the other hand, when the protective resistance was small, the switching was erratic and irreproducible. In the latter case, the switching was occasionally accompanied by filamentary damages caused by the excess current focused at the electrically weak spots, and the threshold voltage was poorly dependent on the protective resistance. The threshold-switching characteristics for thin films are interpretable in terms of the transition from the trap-limited SCLC to the trap-filled SCLC. The thermal breakdown model is not adaptable.

In general, switching phenomena may be classified into two categories: memory and threshold switching. The threshold switching has no memory effect, and a *turn-off* can be achieved below the critical voltage, called the holding voltage. This type of switching has been observed in several organic thin films.[1,2] On the other hand, many authors[3-5] have reported memory-switching characteristics which arise from the formation of a metallic filament or a carbonized conducting channel. However, our understanding is still incomplete.

The purpose of this study is to report that a non-destructive switching in anthracence can be observed by means of circuit with an appropriate protective resistor and to discuss the mechanism of the switching.

Experimental

Pure anthracene was prepared by a method similar to that described by Nakada[6] and was then further purified by zone melting. The geometry of the cell was of the sandwich type, where anthracene was deposited on a glass substrate with an evaporated silver electrode through an etched stainless steel mask. The temperature of the substrate was controlled in the range from −70 to −50 °C.

The film thickness of anthracene was varied in the range of 5×10^{-6}—1.0×10^{-3} cm. The thickness was measured with the aid of an interferometer when the films were thin, while for the thicker films an ac bridge was used. Silver was deposited as the upper electrode by vacuum evaporation through the mask. The area of the electrode was *ca.* 0.01 cm².

The *I-V* characteristics were observed by means of the circuit described in a previous paper.[7] The protective resistor in the circuit can be varied in the range of 10^3—10^8 Ω in order to control the current which flows in the sample.

The states of the sample before and after the switching were observed using a scanning-electron microscope and an optical microscope.

Results and Discussion

Initially the anthracene film has a very high resistance, but when a certain value of voltage (threshold voltage, V_{th}) is applied, the current increases drastically; simultaneously, the voltage applied to the sample descreases and a new high conductivity state is formed. Figure 1 shows the relationship between the protective resistance, R_p, and the resistance, R_A, at the high conductivity state formed by applying the threshold voltage. It may be observed that the value of R_A increases with the protective resistance; consequently, non-linear current-voltage characteristics can be predicted in the high conductivity state.

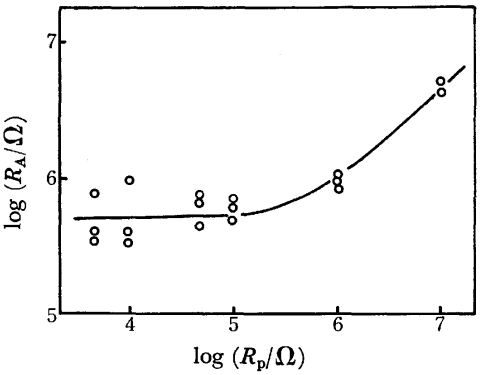

Fig. 1. Relationship between R_p and R_A.

More than 500 thin films were used for the current-voltage-characteristic measurements. When N_s and N represent respectively the total number of cells used in the measurements for a given protective resistor and the number of the cells with which the threshold switching without any structural changes were observed, the ratio of N/N_s increases with the value of the protective resistor, while the value of V_{th} is poorly dependent on the value of the protective resistor. Erratic and irreproducible switching characteristics, accompanied by structural changes, were occasionally observed. In these cases a stable high conductivity state with a memory effect was observed. The results of a scanning-electron-microscopic inspection of the cell after the erratic memory switching are shown in Fig. 2. The transformed area may be formed by the localized excessive current flow at the weak spots in the film.

The current-voltage relation in single crystals of anthracene, expressed as $I \propto V^n$, where $n>2$ in the high-field region, has been explained on the assumption that current carriers are trapped by the local states exponentially distributed within an energy region; the reduction of the value of n with the density of the trapping centers has previously been reported by Thomas *et al.*[8] On the other hand, Williams *et al.*[9] interpreted the precipitous transition from the ohmic region to the cubic region for the carbon fiber diode in terms of the trap-filled-limit.

Since, in this work, it is confirmed that the current obeys the scaling law in the preswitching state (Figs. 3 and 4), the current-voltage relation obtained in the high-field region may be expressed as:

$$J_{off} \propto \frac{V^{l+1}}{d^{2l+1}} \exp(-\phi/kT), \quad (1)$$

where J_{off} is the current density in the preswitching state; d the film thickness: ϕ, the activation energy; k, the Boltzmann constant, T, the temperature, and l, the constant. The averaged value of l was, from the results shown in Figs. 3 and 4, estimated to be 1. This behavior can be interpreted in terms of the space-charge-limited current in an insulator with a single type of traps.

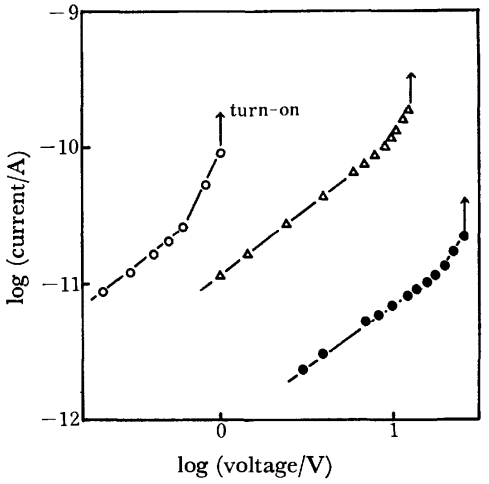

Fig. 3. Current-voltage characteristics in the *off state* for three different thickness.

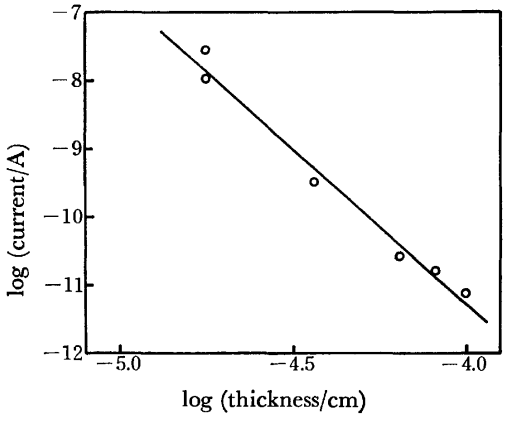

Fig. 4. Relation between the current and the film thickness in the *off state*.

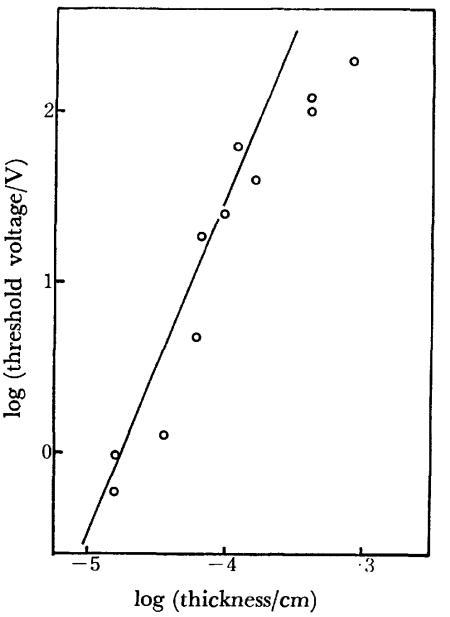

Fig. 5. Relation between the threshold voltage and the film thickness.
Solid line; $V_{th} \propto d^2$.

It is well known that the causes of switching and/or breakdown proposed by many authors can be classified into two categories; (1) the thermal effect and (2) the electronic effect. In order to determine which of these effects is the cause of the switching in the case of anthracene, the relation between the threshold voltage, V_{th}, and the film thickness, d, was observed. The results are plotted in Fig. 5. This figure shows that V_{th} is proportional to d^2.

In the thermal-breakdown model, the temperature of the film may be expected to be uniform for a thin film, so the switching conditions can be determined by the use of Eqs. 2, 3 and 4. These equations are induced by assuming that the thermal breakdown occurs when the temperature derivative of the power input exceeds that of the heat loss:[10]

$$J \cdot V = \lambda(T - T_0), \quad (2)$$

$$\partial(J \cdot V)/\partial T = \lambda, \quad (3)$$

$$J_c \cdot V_c = \lambda(T_c - T_0), \quad (4)$$

where λ is a constant external thermal conductivity; T_0, the ambient temperature; J_c, the current density at the critical temperature (T_0), and V_c, the breakdown voltage. The substitution of the current density in Eq. 1 into Eqs. 2, 3, 4 and subsequent rearrangement give:

$$V_c^{l+1} \propto d^{2l+1}. \quad (5)$$

However, the experimental results shown in Fig. 5 do not agree with this equation, unless $l=\infty$. Therefore, the possibility of the thermal breakdown was excluded.

On the other hand, the space-charge-limited-current (SCLC) in the preswitching state has been taken into consideration in some electronic models.[11,12] In these models, the *turn-on* can be achieved when the space-charge density in the film reaches a critical value. In this case, the relationship between the threshold voltage

and the film thickness is given by:

$$V_{th} \propto d^2. \quad (6)$$

The experimental results agree well with this expected relation deduced from the electronic model. Furthermore, the trap density, N_t, was estimated to be 10^{15}—10^{16} cm^{-3} by assuming that the *turn-on* condition is equivalent to the transition condition from the trap limited space-charge-limited current (SCLC) to the trap-filled SCLC. In this case, V_{th} is expressed as:

$$V_{th} = ed^2N_t/2\varepsilon\varepsilon_0. \quad (7)$$

The trap density thus obtained is comparable to the value, $(3-7)\times10^{13}$ cm^{-3}, obtained by Garrett *et al.*,[13] and to that 10^{13}—10^{19} cm^{-3}, obtained by Thomas *et al.*[8]

On other hand, a typical current-voltage relationship in the high-conductivity state is shown in Fig. 6. The square law holds in the high-field region, while in the low-field region the current is lower than the value estimated by extrapolation from the high-field region on the assumptions that the current obeys the square law and that this deviation from the square law increases with a decrease in the applied voltage. The *turn-off* can be achieved when the applied voltage decreases below *ca.* 1 volt. In the square law region, it was found that the current is proportional to d^{-3}. Therefore, the current density, J_{on}, in the high-conductivity state is expressed by the scaling law, l being 1:

$$J_{on} = \alpha \cdot V^2/d^3, \quad (8)$$

where α is a constant. It was confirmed by the analysis* of an equivalent circuit that the observed R_A is proportional to $R_p^{1/2}$ when a high protective resistance is used in the measurement circuit, whereas R_A is poorly dependent on R_p when a low protective resistance is used. These analytical results are in good agreement with the observed data plotted in Fig. 2.

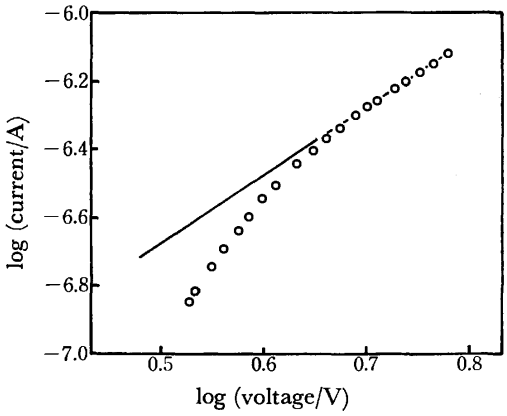

Fig. 6. Current-voltage characteristic in the *on state* solid line; $I \propto V^2$.

* Since the resistance in the preswitching state is much larger than that of the protective resistance, V_{th} is approximately equal to the total applied voltage. When the *turn-on* occurs, the voltage applied to the cell is equal to $V_{th}\cdot R_A/(R_A+R_P)$.

From the results thus obtained, it may be concluded that the threshold switching observed in thinner films is based on the transition from the trap-limited SCLC to the trap-filled SCLC, without any structural changes.

For thicker films (>3 μm), no reproducible threshold switching was observed. In these films, an instantaneous increase of current was observed when measurements were carried out using a circuit with a high protective resistor (10^8 Ω). On the other hand, a high-conductivity state with a memory effect was observed when a lower protective resistor was used. In this case, the relationship between V_{th} and the thickness is expressed as $V_{th} \propto d^n$, $0.5<n<1$; this relation can be introduced by the thermal-breakdown model (Eq. 5), while the current-voltage characteristics in the pre-breakdown region are expressed as $I \propto V^m$, ranging in value of m from 1 to 2 for these thicker samples.

It is well known[14,15] that the thickness dependence of V_{th} for the thick films is different from that for the thin films and that the thermal breakdown occurs in thicker films, while in thinner films the switching caused by the electronic mechanism is predominant, especially for amorphous semiconductors. The results for thicker anthracene films reported in this paper are consistent with those obtained by Garrett *et al.*[13]

One of us (Y. Sadaoka) thanks the Sakkokai Foundation for a grant.

Shock Tube Study of the H–D Exchange Reaction between Acetylene and Deuterium

Hiroo OGURA

Institute of Space and Aeronautical Science, Tokyo University, Komaba, Meguro-ku, Tokyo 153

(Received March 5, 1977)

H–D exchange reaction between acetylene and deuterium has been investigated in a single-pulse shock tube in the temperature range 1200—1500 K. Empirically, in the C_2HD appearance the order with respect to acetylene was 0.25 ± 0.09, and that with respect to deuterium 1.14 ± 0.15. The rate constant of 1.39 th order for the C_2HD increase was obtained as; $k(\mathrm{cm^{1.17}\ mol^{-0.39}\ s^{-1}})=(24.4\pm7.5)\times10^{11}\exp((-51200\pm2400)/RT)$. The isotopic distributions of acetylene and hydrogen as determined by mass spectrometry suggest that C_2D_2 and H_2 are formed by the subsequent reactions of C_2HD and HD, respectively. A free-radical chain mechanism initiated by the same bimolecular reaction of acetylene, *viz.* $2C_2H_2\rightarrow C_4H_3+H$, as in the pyrolysis and hydrogenation of acetylene was proposed. A steady-state treatment of the proposed mechanism shows that the empirical rate and concentration dependence of the C_2HD increase are in line with those of the steady-state rate.

The H–D exchange reaction between acetylene and deuterium has been studied by several investigators. Shock tube techniques were employed in all the experimental studies.

Kuratani and Bauer[1] derived empirical power rate formulas by the analysis of the infrared emission profiles of C_2H_2 and C_2HD, and proposed that C_2HD and C_2D_2 were produced from the same molecular complex $C_2H_2D_2$*. Besides, Bauer *et al.*[2–4] discussed the structure and thermodynamic property of $C_2H_2D_2$*.

Gay *et al.*[5] studied the pyrolysis of acetylene combining a shock tube with a TOF mass spectrometer and found C_4H_3 radical. They proposed a radical mechanism for the isotopic exchange reaction between C_2H_2 and C_2D_2, suggesting that this might be the case for the H–D exchange reaction between C_2H_2 and D_2.

Benson and Haugen[6] proposed a free-radical chain mechanism by the analysis of both kinetic and thermodynamic data available. By a single-pulse shock tube Skinner *et al.*[7] studied the reaction of the C_2H_2–D_2 system in the temperature range 1069—1280 K. They found that the amount of C_2D_2 was less than one half of C_2HD amount, C_2H_3D being the most abundant among ethylene isomers. From these observations, they supported the radical chain mechanism postulated by Benson and Haugen, but did not execute the quantitative analysis of kinetic date obtained.

The pyrolysis and hydrogenation of acetylene proceed *via* the free-radical chain mechanism initiated by the same bimolecular reaction of acetylene; $2C_2H_2\rightarrow C_4H_3+H$, C_4H_3 radical being responsible for the formation of 1-buten-3-yne and H atom for the production of ethylene.[8] On the other hand, the H atom could also lead to the H–D exchange reaction between acetylene and deuterium in the C_2H_2–D_2 system. As in the pyrolysis and hydrogenation of acetylene, the H–D exchange between acetylene and deuterium would occur by a free-radical chain mechanism. The study of the H–D exchange reaction in the C_2H_2–D_2 system could provide another test for the mechanism of hydrogenation of acetylene.

Experimental

Apparatus and Procedure. The H–D exchange reaction between acetylene and deuterium was investigated in a 4-cm single-pulse shock tube. A full description of the shock tube and the details of operation have been given previously.[8,9]

Shock tube was evacuated to below 1×10^{-4} Torr before each run, leak and outgassing rate being *ca.* 6×10^{-5} Torr/min. Prior to the opening of the tube for the renewal of the diaphram, the entire tube was pressurized with helium above the atmospheric pressure to avoid the exposure of the tube to the air. The shocks were fired within five minutes after the introduction of sample gases. Helium was used as the driver gas.

Materials. Three mixtures with the composition of $C_2H_2/D_2/Ar=10/10/80$; 5/10/85; and 10/5/85 were prepared in a 5-l glass vessel. The mixed gases were allowed to stand at a room temperature for about one day and analyzed by gas chromatography to check trace amount of oxygen prior to shock heating. All analyses showed that the oxygen in the sample mixtures was less than 10 ppm. The procedure of purification of acetylene, deuterium, and argon was identical with that in the pyrolysis and hydrogenation experiments.

Analytical. The isotopic distribution of acetylene was determined with a Hitachi Model RM-50 mass spectrometer. Details of the mass spectral analyses were described elsewhere. In some runs the isotopic distribution of hydrogen was determined at the same time. For this purpose, the bulb containing sample gas was condensed by liquid nitrogen, while the uncondensables were transferred into another evacuated bulb, which served for the measurement of the isotopic distribution of hydrogen. The removal of hydrocarbons by the procedure mentioned above could minimize the interference in the hydrogen peaks due to the fragmentation of the hydrocarbons. The relative intensity among the hydrogen isotopes was determined using an equilibrium mixture of hydrogen isotopes, which was prepared by platinum-black catalyzed reaction between H_2 and D_2.

Results

Three mixtures were subjected to shock heating in the temperature range 1000—1600 K, and then analyzed by mass spectrometry. The total densities behind the reflected shock waves were $(2.35\pm0.11)\times10^{-5}$ mol/cm^3, the average reaction time(dwell time) being *ca.* 800 μs in all runs.

Isotopic Distributions. Several shocks were fired with the mixture of 10% C_2H_2 and 10% D_2 in argon. The isotopic distribution of hydrogen together with that of acetylene was determined by mass spectrometry. The ionization potential was maintained at 50 eV for the

measurement of hydrogen isotope mass spectra, while at *ca.* 12 eV for that of acetylene isomers. The results of mass spectral analyses are summarized in Table 1.

As shown in Table 1, approximately equal amounts of C_2HD and HD, and those of C_2D_2 and H_2 are produced, the yields of the latter being much less than one half of the former.

Rate of H–D Exchange Reaction. The relative amounts of acetylene isomers were determined throughout all runs. In this case the ionization potential was kept at 50 eV. The rates of C_2HD and C_2D_2 appearance were derived from the relative amounts of acetylene isomers, neglecting the decrease of the total acetylene concentrations due to the pyrolysis and hydrogenation of acetylene occurring simultaneously with the H–D exchange reaction. The rates were defined as $[C_2HD]/\tau$ and $[C_2D_2]/\tau$, where τ is the dwell time. The rates at temperatures below 1200 K were too slow to allow a quantitative analysis and were ruled out The rates of the H–D exchange reaction of acetylene are shown in Fig. 1 in the case of the mixture of $C_2H_2/D_2/Ar=5/10/85$. The rates of C_2HD appearance increase linearly with temperature at temperatures below 1400 K, while they deviate from a linear line at temperatures above 1400 K. The ratio of $[C_2D_2]/[C_2HD]$ is dependent on temperature. This indicates that the formation of C_2D_2 by the subsequent reaction of C_2HD and the reverse reaction of C_2HD to reform C_2H_2 cannot be neglected at temperatures above 1400 K for the mixture of $C_2H_2/D_2/Ar=5/10/85$.

1473	0.701	0.259	0.040	770	10/10/80
1480	0.690	0.274	0.036	700	10/10/80

a) T_5 is the temperature behind the reflected shock wave. b) The total amount of acetylene is normalized to be 1.000. c) τ is the dwell time. d) The composition of the mixture.

The rates of C_2D_2 increase scatter considerably at lower temperatures. Some of the results of the relative yields of acetylene isomers for the mixture of $C_2H_2/D_2/Ar=10/10/80$, as determined at an ionization potential of 50 eV, are presented in Table 2. Apparent greater C_2D_2 abundance in Table 2 may result from the contamination of nitrogen, since at the lower ionization potential of 12 eV the fragmentation of nitrogen can be neglected(Table 1). However, the relative yields of C_2HD seem little affected by the ionization potential employed. Thus the kinetic analysis of the data obtained was made only for the rates of C_2HD increase.

The rates of C_2HD appearance obtained from the three shock heated mixtures are shown in Fig. 2. We see that the rates of C_2HD formation are strongly dependent on deuterium and slightly dependent on acetylene concentration.

In the above definition of rate, the rates of C_2HD increase are well defined only when the successive exchange of C_2HD to C_2D_2 (alternatively C_2H_2) is negligibly slow. The rates of C_2D_2 formation were less than one tenth of those of C_2HD increase in the temperature range up to 1500 K in the mixtures of $C_2H_2/D_2/Ar=10/10/80$ and $10/5/85$ and up to 1400 K for the mixture of $C_2H_2/D_2/Ar=5/10/85$.

An empirical power rate formula was derived by the least-squares method in the temperature range mentioned above, where the rates of C_2HD formation increase monotonically with temperature and successive exchange of C_2HD is negligibly slow:

$$d[C_2HD]/dt = k_1[C_2H_2]^{0.25\pm0.09}[D_2]^{1.14\pm0.15}, \quad (1)$$

$$k_1 = (24.4\pm7.5)\times10^{11}\exp((-51200\pm2400)/RT), \quad (2)$$

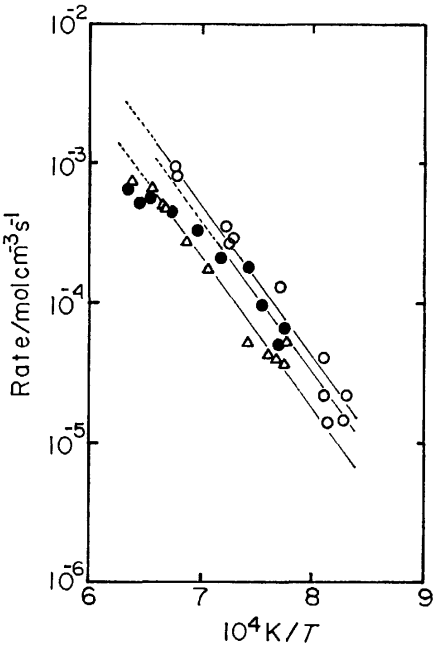

Fig. 2. Concentration dependence of the C_2HD increase.

where $d[C_2HD]/dt$ and k_1 are expressed in mol cm^{-3} s^{-1} and cm$^{1.17}$ mol$^{-0.39}$ s^{-1}, respectively, the activation energy being given in cal/mol. The errors denote the standard deviation of the least-squares method. The Arrhenius plots of the 1.39 th order rate constants are shown in Fig. 3.

Discussion

Mechanism of H–D Exchange Reaction. The isotopic distributions of acetylene and hydrogen(Table 1) are in line with those obtained by Skinner *et al.*,[7] who supported a free-radical chain mechanism. The very low ratios of $[C_2D_2]/[C_2HD]$ and $[H_2]/[HD]$, and the dependence of the former on temperature suggest that C_2D_2 and H_2 are produced successively by the reactions of C_2HD and HD, respectively.

Under the present experimental conditions, the H–D exchange reaction occurs simultaneously with the pyrolysis and hydrogenation of acetylene, the pyrolysis being predominant. The initiation step of the pyrolysis becomes an important source of radicals. The most probable free-radical chain mechanism for the H–D exchange reaction is outlined as follows:

$$2C_2H_2 \longrightarrow C_4H_3 + H, \quad (3)$$
$$H + D_2 \longrightarrow HD + D, \quad (4)$$
$$D + C_2H_2 \longrightarrow C_2HD + H, \quad (5)$$
$$H + HD \longrightarrow H_2 + D, \quad (6)$$
$$D + C_2HD \longrightarrow C_2D_2 + H. \quad (7)$$

The H and D atoms present in the system concurrently participate in the formation of ethylenes:

$$H + C_2H_2 \longrightarrow C_2H_3, \quad (8)$$
$$D + C_2H_2 \longrightarrow C_2H_2D, \quad (9)$$
$$C_2H_3 + D_2 \longrightarrow C_2H_3D + D, \quad (10)$$
$$C_2H_2D + D_2 \longrightarrow C_2H_2D_2 + D. \quad (11)$$

The termination occurs by the recombination or disproportionation reactions of the two vinyl radicals or by those of vinyl radicals with H or D atom.

A molecular complex mechanism was proposed by Kuratani and Bauer, which was essentially expressed as;

$$C_2H_2 + D_2 \longrightarrow C_2H_2 : D_2 \longrightarrow C_2H_2D_2^*, \quad (12)$$

where $C_2H_2 : D_2$ and $C_2H_2D_2^*$ were suggested to be the carbene and excited ethylene with V_d symmetry, respectively. In their scheme the $C_2H_2D_2^*$ rotates around the C=C bond to $C_2HD : HD$ or $C_2D_2 : H_2$ (alternatively $C_2H_2 : D_2$), and then decompose to C_2HD or C_2D_2. Accordingly, the ratios of $[C_2D_2]/[C_2HD]$ and $[H_2]/[HD]$ would be *ca.* 0.5 and would be substantially independent of temperature. These predictions from the molecular complex mechanism disagree with the observed isotopic distributions.[10]

Steady-state Rate. In the proposed mechanism the successive exchange reactions of C_2HD and HD and the backward reactions except for Reactions 8 and 9 can be neglected in the early stage of the exchange reaction, since the reaction times were extremely short, the yields of C_2D_2 and H_2 being far less than those of C_2HD and HD in the temperature range defined above. Reactions 9 and 11 can be also neglected, since C_2H_3D was the most predominant species among ethylene isomers.[8]

It is well known that the addition of H atom to acetylene yields vibrationally excited vinyl radical with subsequent dissociation to initial reactants or collisional stabilization to form thermal vinyl radical;[11–14]

$$H + C_2H_2 \longrightarrow C_2H_3^*, \quad (13)$$
$$C_2H_3^* \longrightarrow H + C_2H_2, \quad (14)$$
$$C_2H_3^* \xrightarrow{(+M)} C_2H_3, \quad (15)$$

where $C_2H_3^*$ and M are vibrationally excited vinyl

radical and a third body, respectively. Reactions 13—15 overall reduce to

$$H + C_2H_2 \rightleftharpoons C_2H_3, \quad (8')$$

where the reverse reaction is included, since C_2H_3D was formed in a considerable amount. In the case of the addition of D atom to C_2H_2, the above processes become as follows:[12,14]

$$D + C_2H_2 \longrightarrow C_2H_2D^*, \quad (16)$$

$$C_2H_2D^* \longrightarrow D + C_2H_2, \quad (17)$$

$$C_2H_2D^* \longrightarrow H + C_2HD, \quad (18)$$

$$C_2H_2D^* \xrightarrow{(+M)} C_2H_2D. \quad (19)$$

Practically, these steps reduce to Reactions 5 and 9. The reverse Reaction 9 can be neglected, for the yield of $C_2H_2D_2$ was small relative to C_2H_3D yield. Reactions 8 and 9 involve thermalized vinyl radicals, while in Reaction 5 the dissociation of the "hot" vinyl radical is significant. The formation of thermal vinyl radical from "hot" vinyl radical under our experimental conditions is estimated to be slow compared with exchange.[6]

As in the hydrogenation of acetylene, the termination reaction of H atom with C_2H_3 radical is insignificant, since the concentration of H atom is much lower than that of C_2H_3 radical. The simplified free-radical chain mechanism for the C_2HD(HD) appearance is thus represented as:

$$2C_2H_2 \longrightarrow C_4H_3 + H, \quad (3)$$

$$H + D_2 \longrightarrow HD + D, \quad (4)$$

$$D + C_2H_2 \longrightarrow C_2HD + H, \quad (5)$$

$$H + C_2H_2 \rightleftharpoons C_2H_3, \quad (8')$$

$$C_2H_3 + D_2 \longrightarrow C_2H_3D + D, \quad (10)$$

$$2C_2H_3 \longrightarrow C_4H_6. \quad (20)$$

For the termination, only the recombination reaction of two vinyl radicals is taken into account.

The steady-state assumption is applied to the simplified mechanism. The steady-state concentrations of H, D, and C_2H_3 radical are given by the following equations;

$$[C_2H_3]_{ss} = (k_3/2k_{20})^{1/2}[C_2H_2] = k_{21}[C_2H_2], \quad (21)$$

$$[H]_{ss} = (1/k_{8'})(k_3[C_2H_2] + k_{-8'}k_{21} + k_{10}k_{21}[D_2]), \quad (22)$$

$$[D]_{ss} = (1/k_5[C_2H_2])(k_4[H]_{ss}[D_2] + k_{10}[C_2H_3]_{ss}[D_2]), \quad (23)$$

where $k_{21}=(k_3/2k_{20})^{1/2}$. Rearranging Eq. 23, the following relation is derived:

$$d[C_2HD]/dt = d[HD]/dt + d[C_2H_3D]/dt \quad (23')$$

The rate of C_2H_3D formation is slower than that of HD increase. The rate of HD increase is approximately equal to that of C_2HD appearance, which is consistant with the observed isotopic distributions (Table 1). Thus the steady-state rate for C_2HD increase is given by

$$d[C_2HD]/dt = d[HD]/dt = k_4[H]_{ss}[D_2]. \quad (23'')$$

Equation 23″, if reduced to a power dependence on concentrations, predicts order with respect to acetylene and deuterium of 0 to 1 and 1 to 2, respectively.

The rate constants used in the derivation of an apparent power rate formula for the C_2HD increase are listed in Table 3. The pressure dependent bimolecular rate constant of Reaction 8′ is uncertain. The rate constant is assumed to have the same activation energy as that in high pressure limit with a correction in frequency factor.[13] Assuming the same activation energy as that of the observed rate (Eq. 2), an apparent power rate formula for the C_2HD increase is given by

$$d[C_2HD]/dt(\text{mol cm}^{-3}\text{ s}^{-1}) = k_{24}[C_2H_2]^{0.31}[D_2]^{1.39}, \quad (24)$$

$$k_{24}(\text{cm}^{2.10}\text{ mol}^{-0.70}\text{ s}^{-1}) = 1.16\times10^{14}\exp(-51200/RT). \quad (25)$$

The absolute values of the steady-state rate agree with those of the empirical power rate (Eqs. 1 and 2) within the error limit of 40%, and the power dependence of the steady-state rate is in good agreement with the observed rate within the present experimental errors.

The empirical power rate expression for the increase of C_2HD obtained by Kuratani and Bauer in the temperature range 1300—1600 K is given by

$$d[C_2HD]/dt = ((k_\alpha+k_\beta)/2.64)[C_2H_2]^{0.24}[D_2]^{1.0}, \quad (26)$$

where,

$$k_\alpha(\text{cm}^{0.72}\text{ mol}^{-0.24}\text{ s}^{-1}) = 4.2\times10^8\exp(-33800/RT)$$

and

$$k_\beta(\text{cm}^{0.72}\text{ mol}^{-0.24}\text{ s}^{-1}) = 1.6\times10^8\exp(-29300/RT).$$

The dependence of the rates on the concentrations seems essentially the same between the two power rate expressions (Eqs. 1 and 26), in spite of the different definition of rate, that is, their rates are the initial rates, on the other hand, our rates are the mean rates during the reaction times. The absolute rates obtained by them and those of the present agree within a factor of 2.

The steady-state rate of C_2H_3D production is directly derived from Eq. 21;

$$d[C_2H_3D]/dt(\text{mol cm}^{-3}\text{ s}^{-1}) = k_{10}k_{21}[C_2H_2][D_2], \quad (27)$$

where,

$$k_{10}k_{21}(\text{cm}^3\text{ mol}^{-1}\text{ s}^{-1}) = 1.3\times10^{12}\exp(-36600/RT). \quad (28)$$

Table 3. The rate constants relating to the H-D exchange reaction and the formation reaction of ethylene

Reaction	Rate constant (s^{-1} or $cm^3\,mol^{-1}\,s^{-1}$)	Ref.	λ[a]
3	$3.5\times10^{13}\exp(-47400/RT)$	9	1.0
4	$6.5\times10^{13}\exp(-8560/RT)$	15	2.0
5	$3.1\times10^{13}\exp(-3700/RT)$	12	1.0
8′	$7.53\times10^{11}\exp(-2410/RT)$	13	1/7.2
−8′	$8.19\times10^{11}\exp(-50210/RT)$	b)	1/7.2
10	$5.39\times10^{11}\exp(-12900/RT)$	8	1.0
20	4.45×10^{12}	c)	1.0

a) λ is the correction factor for the frequency factor with the same activation energy as that given in the reference. b) This rate constant was calculated by the combination of the rate constant of Reaction 8′ with the equilibrium constant at 1300 K. c) The activation energy was assumed to be zero, and the frequency factor was calculated at 1300 K, taking the collision diameter of C_2H_3 radical as 4.23 Å.

Equation 27 indicates that as far as the rate of Reaction 8′ is fast enough to reach a steady-state concentration of C_2H_3 radical during the reaction time, the rates of Reactions 8′ and −8′ do not produce any change in the rate of ethylene formation together with the steady-state concentration of C_2H_3 radical (Eq. 21). However, the steady-state concentration of H(D) atom is affected by the rates of Reactions 8′ and by the rates of Reaction 8′ and its reverse reaction (Eq. 22). This indicates that the H–D exchange reaction is closely related to the C_2H_3 radical formation and ethylene formation. The following relation may hold well:[8]

$$[C_2H_3D]/[C_2H_2D_2] = (k_{10}/k_{11})([C_2H_3]/[C_2H_2D]) = (k_{8'}/k_9)([H]/[D]) = (k_5/k_4)([C_2H_2]/[D_2]). \quad (29)$$

In the above derivation, $k_{8'}=k_9$ and $d[HD]/dt \gg d[C_2H_3D]/dt$ are assumed. The ratios of $[C_2H_3D]/[C_2H_2D_2]$, observed and calculated from Eq. 29, are summarized in Table 4. The agreement between the observed and calculated appears considerably good. Therefore, the inclusion of H–D exchange propagation process into the ethylene formation scheme provides a reasonable explanation of the rate and isotopic distribution of ethylene.

TABLE 4. THE COMPARISON OF THE OBSERVED RATIO OF $[C_2H_3D]/[C_2H_2D_2]$ WITH THE CALCULATED VALUE

T_5/K[a]	$[C_2H_3D]/[C_2H_2D_2]$		γ[c]	$C_2H_2/D_2/Ar$[d]
	Obsd[b]	Calcd		
1271	5.86	2.90	2.02	10/10/80
1313	5.68	2.74	2.08	10/10/80
1388	3.86	2.49	1.55	10/10/80
1407	3.76	2.44	1.54	10/10/80
1480	1.89	2.25	0.84	10/10/80

a) T_5 is the temperature behind the reflected shock wave. b) Calculated value from Table 2 in Ref. 8. c) γ is the ratio of the observed value to the calculated one from Eq. 29. d) The composition of the mixture.

At temperatures above 1500 K, the formation of 1,3-butadiyne becomes comparable to that of ethylene or predominant. The butadiyne formation cannot be neglected in the H–D exchange reaction, since H atom is responsible simultaneously for the butadiyne formation:[9]

$$H + C_2H_2 \longrightarrow C_2H + H_2, \quad (30)$$

$$C_2H + C_2H_2 \longrightarrow C_4H_2 + H. \quad (31)$$

D atom present in the system can abstract H atom from acetylene molecule:

$$D + C_2H_2 \longrightarrow HD + C_2H, \quad (32)$$

$$C_2H + D_2 \longrightarrow C_2HD + D. \quad (33)$$

Reactions 32 and 33 construct a chain for the H–D exchange reaction between acetylene and deuterium. Furthermore, the yield of 1-buten-3-yne begins to decrease at temperatures around 1500 K, H atom being supposed to participate in the 1-buten-3-yne decrease. The validity of our mechanism should be limited to the temperature range where the formation of 1-buten-3-yne and ethylene is dominant and that of butadiyne is negligibly slow.

The author wishes to thank Professor Kenji Kuratani, Tokyo University, for his valuable advice and helpful discussions during the course of this study.

The Transition to Detonation from Deflagration in Ethylene–Oxygen Systems

Tadaaki INOMATA and Momotaro SUZUKI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received March 8, 1977)

The flames of ethylene and oxygen mixtures (initial pressure, 50—500 mmHg, and ethylene content, 20—40%) were studied, especially for the transition to detonation from deflagration. The flames may roughly be divided into four groups: **A**, a flame without any shock wave generation; **B**, a flame with a shock wave generation; **C**, a flame with many shock waves and much turbulence of the flame, and finally **D**, the detonation produced by the collision of a flame and a reflected shock wave at the bottom of the tube. The flame transit to detonation from deflagration is a linear relation between the velocities of the flames at the point of detonation and DID, or the distance from the point of ignition to the detonation for all the sorts of flames given above, in spite of several apparent differences.

Since Berthelot and Vieille, and Le Chatelier and Mallard observed the propagation of detonation waves in 1881,[1] numerous works on the velocities of detonation waves, the theory of the transition to detonation, *etc.* have been published.[2] In the investigation of the transition to detonation, Payman and Titman observed the process using a streak schlieren photograph and discussed the mechanism of the onset of detonation.[3] Later, Bone *et al.* and White and Martin[4] investigated this process, while Oppenheim and his co-workers studied the transition processes in especial detail.[5] They used the stroboscopic schlieren system with a laser light and observed the mechanism of the transition to detonation in hydrogen–oxygen systems, classifying the process into the following four sections: 1) the explosion in the vicinity of a flame front, 2) the action of a shock wave formed at the lip of a flame, 3) the ignition at a shock front, and 4) the shock merging ahead of a flame.

In the present investigation, the processes of the transition to detonation in ethylene–oxygen systems were studied and the factors involved in this transition were fully discussed.

Experimental

The experiments were performed with C_2H_4–O_2 mixtures, at an initial pressure of 50—500 mmHg, in a square, 4×4 cm cross section and a 162 cm-long detonation tube, fitted on both sides with optically flat 4×30 cm glass windows.

The optical observations have been made by means of stroboscopic schlieren photographs. This observation was accomplished using 30 cm mirrors Z-type schlieren system, an argon stroboflash lamp, and a drum camera. The ignition was effected by means of a hot-wire glow coil.

Results and Discussion

In several mechanisms of the transition to detonation in flames, a detonation is generally produced by an explosion of the flame itself or is effected by means of a shock wave. In this study, four cases of transition to detonation were observed: **A**, without any shock wave generation; **B**, with a shock wave generation and a little distortion of a flame; **C**, with many shock waves, with much production of flame turbulences, and **D**, by the collision of a flame and a reflected shock wave at the bottom of the tube.

Figure 1 shows diagrams of the concentrations of the ethylene *versus* the pressures of the total gas mixture in a 162 cm-long tube. The regions between curves are the ranges where flames of Type **A**, **B**, **C**, and **D** are found; Type **A** is generated very exceptionally.

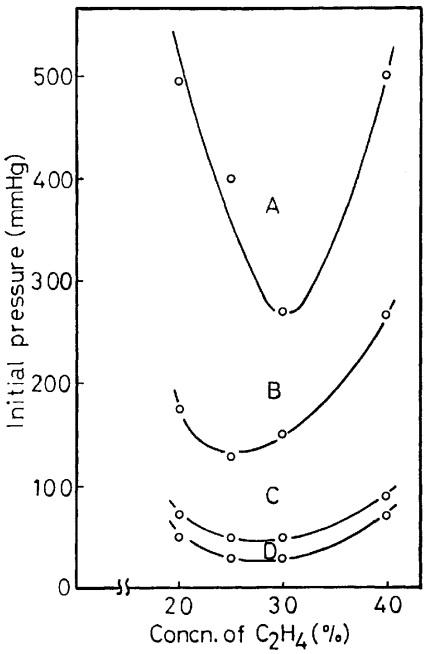

Fig. 1. Classification of propagation of flames.

In Fig. 2, a schlieren photograph of Type **A** is given. The flame has a dome shaped flame front until the region of the transition to detonation, without any sign of turbulence ahead of the flame. The surfaces of the flame are not uniform, but are blurred before the onset

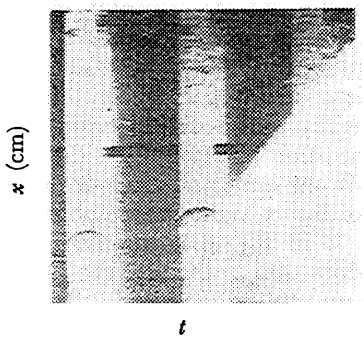

Fig. 2. Schlieren photograph of flame, type A.
x: Distance from ignition point, t: 25 μs/frame.

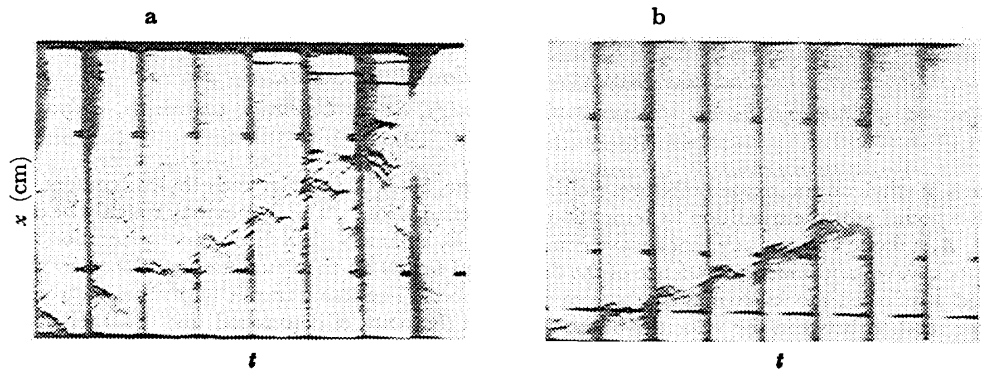

Fig. 3. Schlieren photograph of flame, type C.
x: Distance from ignition point, t: 25 μs/frame.

of detonation; this may be attributed to the cellular structure, or the local explosion started at a flame front with a high temperature and a high pressure conveyed from the reaction part. The only difference between the **A** and **B** types is the generation of shock waves. If shock wave is generated in Type **B**, the shock wave is very weak and cannot generate the detonation. Therefore, the transition to detonation occurs in a similar way in Types **A** and **B**.

Type **C**, depicted in Fig. 3, is most frequently observed. The four mechanisms reported by Oppenheim *et al.*[5] and mentioned above are also of this type. A detonation wave starts at a flame front or immediately ahead of a flame, as is shown in Fig. 3. In this type, the state of a flame front and the unburned mixture ahead of a flame change every time. Two forms of the onset of detonation are observed, one at the shock wave generated at the lip of a flame front (Fig. 3-a), and the other, in the vicinity of a flame front (Fig. 3-b).

The transition to detonation is essentially connected with the initial pressure of the gas mixture and the mixing ratio of the composition. Besides these, the detonation induction distance, DID, or the distances from the ignition of a flame to the point of detonation *versus* the initial gas pressures of mixture are shown in Fig. 4. The curves decrease against the pressures of the initial gas mixtures and approach constant values over 300 mmHg. These values seem rather small compares with the values which has been cited for hydrogen–oxygen,[6] methane–oxygen, and acetylene–oxygen[7] by other investigators, who have all reported constant values of a few atmospheres.

As DID change its value according to the values of the tube diameters and the condition of the tube wall, one can hardly expect constant values to be determined by, for example, initial pressures. Therefore, the absolute numerical values of these constants have not so much meaning as they seem to have.

For the generation of detonation, the turbulences of a wave front or the onsets of shock waves which make the velocities of flames higher are responsible; therefore, Types **B** and **C** in Fig. 4 correspond in these cases, but Type **A** does not. Actually, the DID of Type **A** does not concern initial pressures in higher region than a certain value, and consequently there is no effect on the state after the flame begins to move and there is still detonation. Therefore, the phenomena, such as

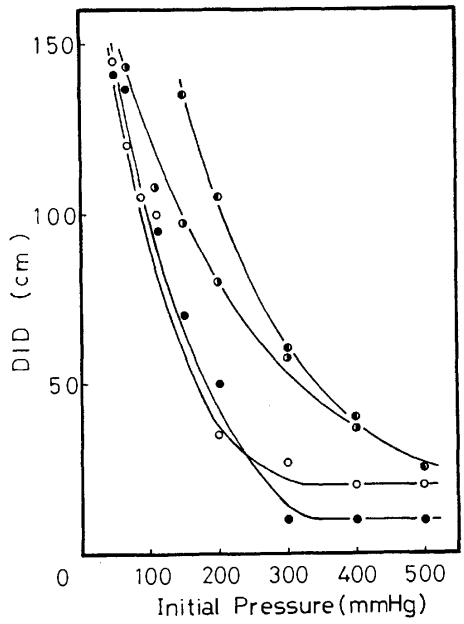

Fig. 4. Detonation induction distance of ethylene-oxygen mixture.
◑: 20% C_2H_4-80% O_2, ○: 25% C_2H_4-75% O_2,
●: 30% C_2H_4-70% O_2, ◐: 40% C_2H_4-60% O_2.

the turbulence of a flame or a shock wave after a flame begin to propagate, may not necessarilly always be responsible for the onset of detonation. Presumably an ignition energy of Type **A**, which maintains the system at the beginning, may be enough for the detonation.

Now the definite conditions, other than shock waves and turbulence, for which the detonation is responsible, can be considered. Figure 5 shows the relation of DID *versus* flame velocities immediately before the onset of detonation. The graph is linear for all sorts of flames at pressures of 70—500 mmHg and at compositions of the gas mixture of 20—40% ethylene, independent of the generation of shock waves or the turbulence of the flame. The flame which transits to detonation must have, at the very point of detonation, a definite value of a flame velocity. The flame in Type **A** which has enough flame velocity without any support of turbulence, transits to detonation by itself, while Types **B** and **C**, the velocities of which are insufficient to reach detonation, must get the support of turbulence of a flame to

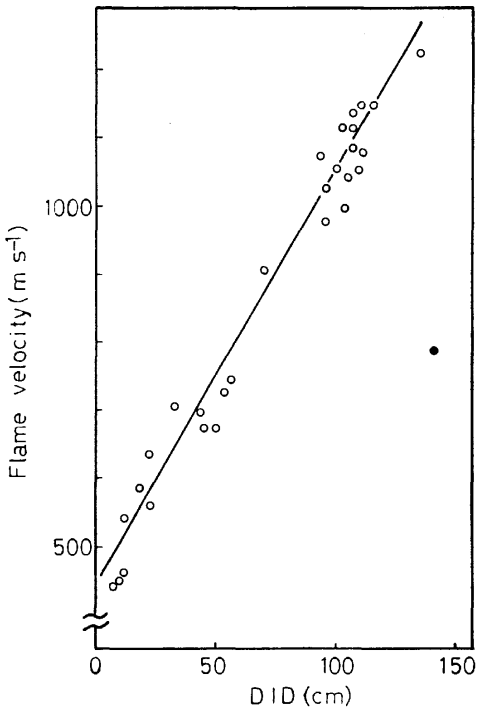

Fig. 5. Flame velocity at the detonation point.
○: Without the collision of reflected shock waves,
●: with the collision.

make the velocities higher. Thus, the velocity of the flame at the point of detonation is the largest factor in the detonation.

In Fig. 5 there is one point (the dot on the right of the diagram) which is outside the curves and which belongs to Type **D**. Figure 6 shows a typical example of this type. In Type **D** the detonation wave is generated after the collision of a flame and a reflected shock wave. The point outside the diagram in Fig. 5 does not contradict the theory. After the collision, the flame propagates in the region of higher pressures and higher temperatures, and the particle velocity becomes nil. If the tube is longer or the collision of a flame and a reflected shock wave does not occur, the dot in Fig. 5 will shift and find itself on the elongation of the straight line. In Type **D**, just before the detonation the turbulences in both the unburnt gas and the flame are less and the velocity of flame is slower than in Type **C**. Therefore, in Type **D** the detonation will be aroused through the collision of a flame and a reflected shock wave. After the collision, the flame propagates through the region of higher pressures. The value of this pressure, according to the theory, is 420 mmHg (observed 460 mmHg), and the velocity of flame at the point of the collision is 760 m s^{-1}. In Fig. 5, if the initial pressure is 460 mmHg, then the flame of 550 m s^{-1} is detonated and in Fig. 6 the actual flame velocity of 760 m s^{-1} will have enough energy for the detonation. Thus, the point of the dot in Fig. 5 elucidates the generation of detonation.

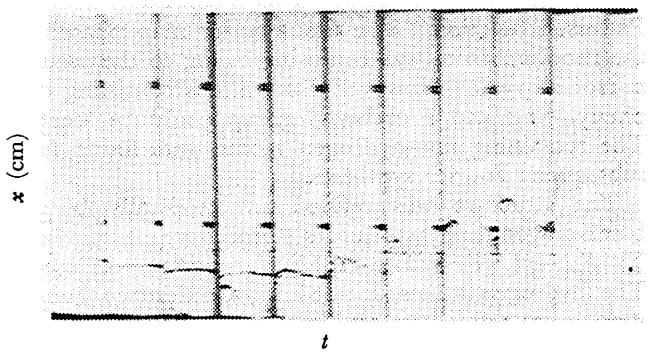

Fig. 6. Schlieren photograph of flame, type D.
x: Distance from ignition point, t: 25 μs/frame.

Another example is the initial gas flame of the pressure of 30 mmHg, which cannot be detonated by the collision of a flame and a reflected shock wave. The observed pressure of the reflected shock wave is 230 mmHg, the observed velocity of the flame is 510 m s^{-1} and the acceleration of the flame and the velocity of the shock wave are very similar to the flame of 50 mmHg. The flame with the initial pressure of 230 mmHg will be detonated with the flame velocity of 650 m s^{-1}, which can also be concluded from the theory. Therefore, if the flame is accelerated for some 10 m s^{-1} before the collision on the bottom plate, then the flame will detonated, but the flame collides with the plate, before that and will not be detonated with enough energy. Thus, in Type **D** the transition from the deflagration depends on a flame velocity which gains from the collision of the flame and the reflected shock wave.

At any rate, the velocity of the flame at the point of detonation and the DID are the predominating factors for the phenomena of the transition to detonation from deflagration, with or without any collision of a flame and a reflected shock wave.

The Molecular Structure of μ-Carbonyl-di-μ-diphenylmethylene-bis(π-cyclopentadienylrhodium), $[(\pi\text{-}C_5H_5)_2Rh_2\{C(C_6H_5)_2\}_2(CO)]$

Hiroshi UEDA, Yasushi KAI, Noritake YASUOKA, and Nobutami KASAI*

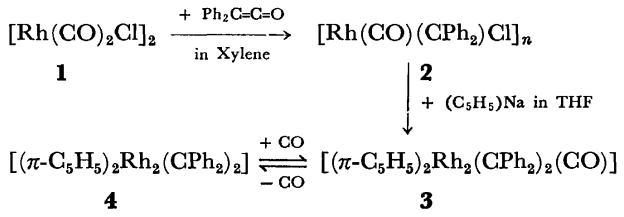
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received March 26, 1977)

The molecular structure of $[(\pi\text{-}C_5H_5)_2Rh_2\{C(C_6H_5)_2\}_2(CO)]$ has been determined from three-dimensional X-ray diffraction data ($R=0.040$ for 2394 reflections). The crystal belongs to the monoclinic system, space group A2/a, with four formula units in a cell of dimensions: $a=19.967(5)$, $b=10.343(1)$, $c=16.526(4)$ Å, and $\beta=123.05(2)°$. The molecule has C_2 symmetry: the two-fold axis passes through the bridge carbonyl group, being perpendicular to the Rh–Rh bond (Rh—Rh=2.548(1) Å). The diphenylcarbene moieties bridge between rhodium atoms. The planar cyclopentadienyl rings lie 1.94 Å from the nearest rhodium atom and exihibit the usual π-bonded geometry.

In recent years many transition metal-carbene complexes have been reported[1-4], in which the carbene ligands are stabilized by an adjacent oxygen or nitrogen atom. Recently, P. Hong and co-workers[5] have prepared some stable diphenyl-carbene complexes, which have no hetero atom adjacent to the carbene ligand.

The reaction between $[Rh(CO)_2Cl]_2$ (**1**) and diphenyl-ketene gives an insoluble, brick red complex $[Rh(CO)\{C(C_6H_5)\}_2Cl]_n$ (**2**). The reaction of **2** with cyclopentadienyl sodium in THF gives air stable, green, needle-like crystals **3**. The complex **3** in solution slowly loses the bridging carbonyl on heating, and finally changes into **4**. The reaction from **3** to **4** is reversible.



X-Ray molecular structures of **3** and **4** have been determined. This paper describes the crystal and molecular structure determination of **3**.

Experimental

The crystals used in this study were supplied by Professor N. Hagihara and co-workers. After preliminary X-ray work which showed that the crystal belongs to the monoclinic system, the unit-cell dimensions were determined by a least-squares fit using 2θ-values of 20 strong reflections measured on a G. E. single crystal orienter equipped on a Rigaku SG-2 goniometer.

Crystal Data. $C_{37}H_{30}ORh_2$, F. W. 696.5, $a=19.967(5)$, $b=10.343(1)$, $c=16.526(4)$ Å, $\beta=123.05(2)°$, $U=2860.0(9)$ Å^3, $D_m=1.60$ g cm^{-3}, $Z=4$, $D_c=1.62$ g cm^{-3}, μ(Mo)=11.2 cm^{-1}.

The systematic absences of reflections, hkl: $k+l=2n+1$ and $h0l$: $h=2n+1$, suggested the probable space group as A2/a (No. 16) or Aa (No. 9). Besides these diffraction aspects, the intensities of $h=2n+1$ layers were generally much weaker than those of $h=2n$ layers.

A single crystal with dimensions *ca.* $0.18\times0.21\times0.24$ mm was used to collect intensity data. Three-dimensional data were measured by means of the θ-2θ scan technique on a Rigaku automated, four-circle diffractometer using zirconium-filtered Mo $K\alpha$ radiation. The integrated intensity was determined by scanning over a peak at a rate of 4°min^{-1}, and subtracting the background by averaging the two values measured for 5 s at both ends of a scan. The scan width $\Delta(2\theta)$ of each reflection was computed by the equation: $\Delta(2\theta)=(2.0+0.70\tan\theta_c)°$, where θ_c is the calculated value of the Bragg angle for Mo $K\alpha_1$($\lambda=0.70926$ Å). The intensities of three standard reflections were measured after every 50 reflections. There was no evidence of crystal decomposition. After reflections up to $\sin\theta/\lambda=0.481$ were measured, reflections with $h=2n$ in the range $0.47\leqq\sin\theta/\lambda\leqq0.66$ were also collected since the intensities of high angle reflections with $h=2n+1$ were too weak to be measured. A total of 2394 independent reflections was obtained. Lorentz and polarization corrections were made in the usual manner, but no absorption correction was applied.

Structure Solution and Refinement

The structure was solved by using a three-dimensional Patterson function. A clue for the solution of the structure was obtained from the characteristic intensity distribution of the reflections mentioned above, from which it could be assumed that the space group A2/a was preferable and the y parameter of the rhodium atom nearly equal to zero. This is consistent with the Patterson function. The first Fourier map phased by the rhodium atom was confusing owing to the pseudo-mirror at $y=0$. However, light atoms consisting of a phenyl ring and a carbonyl group could be located. The remaining non-hydrogen atoms were found from subsequent Fourier syntheses.

The structure was refined anisotropically by the block-diagonal least-squares procedure minimizing $\Sigma(|F_o|-k|F_c|)^2$. The HBLS V program was used.[6] The hydrogen atoms, located by a difference Fourier map, were refined isotropically. The final R value is 0.040 for non-zero reflections. Atomic scattering factors used were those of Hanson, Herman, Lea and Skillman.[7] The positional and thermal parameters are given in Table 1.**

* To whom any correspondence should be addressed.

** The table of structure factors is kept as Document No. 7714 at the Chemical Society of Japan.

TABLE 1. ATOMIC POSITIONAL AND THERMAL PARAMETERS

Estimated standard deviations in parentheses. Anisotropic thermal parameters are expressed in the form $\exp\{-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)\}$ and isotropic thermal parameters $\exp\{-B\sin^2\theta/\lambda^2\}$.

Results and Discussion

The molecular structure and the numbering scheme of atoms are shown in Fig. 1. A stereoscopic drawing of the molecule is given in Fig. 2. Bond lengths and bond angles are listed in Table 2. Table 3 shows the equations of several least-squares planes.

The remarkable feature of the molecule is that it has C_2 symmetry; a crystallographic two fold axis passes through the bridging carbonyl groups, being perpendicular to the Rh–Rh bond. The diphenylmethylene moieties bridge between rhodium atoms instead of bonding to single rhodium atom. Each of the cyclopentadienyl group is π-bonded to a rhodium atom, and the two cyclopentadienyl rings are staggered about the Rh–Rh bond (Fig. 1).

The Rh–Rh single bond length 2.548(1) Å is significantly shorter than those in other π-cyclopentadienyl rhodium carbonyl complexes: 2.681(2) Å in $[(\pi\text{-}C_5H_5)_2Rh_2(CO)_3]$,[9] 2.62 Å in $[(\pi\text{-}C_5H_5)_3Rh_3(CO)_3]$,[10] 2.776(1) Å in $Rh_6(CO)_{16}$[11] and 2.690 Å in rhodium metal.[12]

The cyclopentadienyl rings are planar: the maximum deviation from the plane is ±0.001 Å. The C–C bond lengths and C–C–C bond angles are 1.411(16)—1.453 (14) (av. 1.425) Å, and 105.5(9)—109.7(9) (av. 108.0)°, respectively. Each ring makes an angle of 83° to the Rh–Rh bond and lies 1.94 Å away from the rhodium atom. The average Rh–C(C_5H_5) distance is 2.290(12) Å, which is comparable to the values of 2.24 Å in $[(\pi\text{-}C_5H_5)_3Rh_3(CO)_3]$, 2.26 Å in $[(\pi\text{-}C_5H_5)_2Rh_2(CO)_3]$, and 2.25 Å in $[(\pi\text{-}C_5H_5)Rh(CO)(C_2F_5)I]$.[13]

The Rh–C(1) bond lengths are 2.094(6) and 2.088 (6) (av. 2.091) Å, which are close to the Rh(III)–C-

(sp^3) distances of 2.08(3) in $[(\pi\text{-}C_5H_5)Rh(CO)(C_2F_5)I]$ and 2.08 Å in $[Rh_2I_2(SMe_2)_3Me_4]$.[14]

In the diphenylmethylene moiety, bond angles around the C(1) atom deviate from the tetrahedral angle: Rh–C(1)–Rh′ 75.1(2), Rh–C(1)–C(11) 122.1(4), Rh–C(1)–C(21) 110.2(4), Rh′–C(1)–C(11) 116.1(4), Rh′–C(1)–C(21) 118.4(4), C(11)–C(1)–C(21) 111.1(5)°. Bond lengths and bond angles in phenyl rings have normal values [C–C(av.)=1.38 Å and C–C–C(av.)=120.0°]. The two phenyl rings are roughly perpendicular to each other, the dihedral angle being 85.3°.

The Rh–C(2) bond length 1.995(9) Å is shorter than that of Rh–C(1). However, this distance is close to the values of 2.01 Å in $[(\pi\text{-}C_5H_5)_2Rh_2(CO)_3]$ and 2.00 Å in $[(\pi\text{-}C_5H_5)_3Rh_3(CO)_3]$. The bridging Rh–C(2)–Rh′ angle is 79.4(3)°, which is smaller than the corresponding angles of 84.0° in $[Rh_2(C_5H_5)_2(CO)_3]$, 81.9° in $[(\pi\text{-}C_5H_5)_3(CO)_3]$ and 82° in $[\{(PPh_3)_2Rh(CO)\}_2,2CH_2Cl_2]$.[15] The C–O length of the bridged carbonyl group, C(2)–O=1.152(10) Å, is comparable to the values of 1.15(4) and 1.18(4) Å in $[(\pi\text{-}C_5H_5)_3Rh_3(CO)_3]$ and 1.17 Å in $[\{(PPh_3)Rh(CO)\}_2,2CH_2Cl_2]$.

The overall molecular geometry of the present complex, except for the bridging carbonyl group, is similar to that of the diamagnetic complex $[(C_6H_5)_2PCo(C_5H_5)]_2$.[16] The molecular structure of the cobalt complex was described by the formation of a so-called "bent" metal-metal bond. However, this is not the case for the present complex because the bridging carbonyl group prevents the formation of the "bent" metal-metal bond. The $(CPh_2)_2$ bridging system is not planar: the dihedral angle between the two planes formed by Rh, Rh′, and C(1) and Rh, Rh′, and C(1)′ being decreased from 180 to 121° (Fig. 1(b)). The intra- and inter-molecular atomic contacts indicate that the magnitude of twisting of the phenyl rings is primarily determined by non-bonding intra-molecular interactions. The dihedral angles formed by the plane defined by C(1), C(1)′ and C(2) with phenyl rings 1 and 2 are 61.1, 31.8°, respectively. Because of the short C(1)···

TABLE 3. LEAST-SQUARES PLANES AND ATOM DEVIATIONS

Plane equations are of the form $AX+BY+CZ+D=0$, where X, Y, Z and D are measured in Å units: $X=ax+cz\cos\beta$, $Y=by$ and $Z=cz\sin\beta$.

Electronic Structures and Spectra of the Keto and Enol Forms of Acetylacetone

Hiroshi NAKANISHI, Hiroshi MORITA, and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received March 30, 1977)

Near and vacuum UV absorption spectra of acetylacetone were measured in the vapor phase and in several organic solvents at various temperatures. From the temperature dependence of the spectra, the equilibrium constant and enthalpy change between the keto and enol forms of acetylacetone were determined to be 25 at 20 °C and −4.3 kcal/mol, respectively, in the vapor phase. Rydberg excitation bands were observed at 47170 and 53300 cm^{-1} for the enol form, and $\approx$52000 cm^{-1} for the keto form. The estimated values of the quantum defect indicate that the Rydberg orbitals are 3s and 3p. A modified CNDO-CI method was applied to the valence-shell transitions. A weak band observed at $\approx$34000 cm^{-1} for the keto form was assigned to the first n-π^* transition, and relatively strong bands observed at 38020 and 56800 cm^{-1} for the enol form, to the first and second π-π^* transitions, respectively. Special attention was paid to the charge-transfer (CT) character pertinent to the intramolecular hydrogen bond in the excited states of the enol form. Configuration analysis of the wave functions revealed us that the first π-π^* band observed at 38020 cm^{-1} has the CT character.

Acetylacetone and its congeners in the enol form have a strong intramolecular hydrogen bond with the O···O distance of 2.38—2.55 Å as revealed from the X-ray diffraction[1] and gas-phase electron diffraction studies.[2,3] The electronic structures of the molecules in the ground states have been studied by the nonempirical[4-6] and semiempirical[6-8] calculations. The electronic absorption spectra of acetylacetone and its congeners in the near ultraviolet (UV) region have been measured by several authors[9-13] and have been compared with the spectra of their metal chelates.[12] The spectroscopic results so far obtained, however, are restricted only to the first allowed band and no spectral information is available for discussing the higher excitation bands of acetylacetone.

The charge-transfer (CT) mechanism of hydrogen bond between a proton donor and a proton acceptor is important.[14] Electronic structure of the symmetrical intramolecular hydrogen bond of the hydrogen maleate anion was investigated in previous papers[15,16] and the CT character pertinent to the hydrogen bond was discussed in detail for the ground and excited states from theoretical and experimental points of view.[16] For intermolecular hydrogen-bonded systems between acetic acid and some aliphatic amines, the CT band pertinent to the hydrogen bond was observed successfully in the vacuum ultraviolet (VUV) region by the present authors.[17]

In the present paper, in order to investigate the electronic structures of the keto and enol forms of acetylacetone, electronic absorption spectra in the near and vacuum UV (30000—61000 cm^{-1}) region have been measured with acetylacetone in the vapor phase and also in various solvents. The observed valence-shell transition and Rydberg excitation bands have been interpreted on the basis of theoretical results by a modified CNDO-CI method[18] and the configuration analysis[19] of the ground and excited states.

Experimental

Acetylacetone (Wako G. R. Grade) was distilled three times under reduced pressure immediately before use. Methanol (Kanto G. R. Grade) used as a solvent was purified by fractional distillation. Acetonitrile and heptane (Wako Spectro Grade) were fractionally distilled over diphosphorus pentaoxide and sodium metal wire, respectively. Perfluorohexane (Kishida G. R. Grade) was purified by vacuum distillation through a column filled with silica gel.

Near and vacuum UV absorption spectra were measured with a Cary recording spectrophotometer model 14, with a vacuum UV spectrophotometer constructed in our laboratory,[20] and in part with a JASCO VUV-3 recording spectrophotometer,[21] the cells of 0.1 mm—10 cm light path length being used. In the vapor phase measurement between 18—300 °C, temperature of the sample cell was regulated within ±0.5 °C by a thermoregulator.

Theoretical

The electronic structures of the keto and enol forms of acetylacetone and of its anion were calculated by the modified CNDO-CI method[18] to investigate the characters of the valence-shell transitions. The following one-center Coulomb repulsion integral (γ) and bonding parameter (β^0) were commonly used for all the 2s and 2p atomic orbitals (AO) of the methyl carbon atom of the enol form and the anion, and of all the carbon atoms of the keto form (molecular skeleton of which is not planar); γ(C)=12.78 eV and β^0(C)=−15.4 eV. The other semiempirical parameters used in the calculations were the same as reported previously,[16] the effect of excess formal charge in the anion being considered by the parametrization.[16] In the configuration interaction (CI) treatment, 80 singly excited π-π^* and σ-σ^* configurations and 70 singly excited π-σ^* and σ-π^* configurations were taken into account for the enol form and the anion, and 80 singly excited configurations, for the keto form.

Geometrical structures were taken for the keto form from the gas-phase electron diffraction study[2] and for the enol form from the X-ray diffraction study of tetraacetylethane[1,22] (hydrogen-bonded O···O distance, 2.424 Å), a linear symmetrical hydrogen bond being assumed. The molecular geometry of the anion was assumed to be the same as that of the enol form, except for the fact that the hydrogen-bonded hydrogen atom was removed.

The configuration analysis[19] was applied to the ground and two excited (B_1 symmetry) states of the enol

form. In order to elucidate the electronic structures of the symmetrical intramolecular hydrogen bond, the 35 molecular orbitals (MO) of the anion and the 1s orbital of the hydrogen-bonded hydrogen atom were adopted as the reference MO's, as for the case of the symmetrical hydrogen bond of the hydrogen maleate anion.[16] The ground state of the enol form was analyzed by the ground and 101 singly excited π-π^* and σ-σ^* reference configurations (with A_1 symmetry) and by all the doubly excited reference configurations derived from the above configurations, and the excited states of the enol form were analyzed by 99 singly excited π-π^* and σ-σ^* reference configurations (with B_1 symmetry) and 99×101 doubly excited reference configurations.

Results and Discussion

Electronic Absorption Spectra of Acetylacetone. Figure 1 shows near and vacuum UV absorption spectra in the 30000—61000 cm^{-1} region measured with acetylacetone in the vapor phase and in perfluorohexane at room temperature. As pointed out by the NMR[23] and IR[24,25] spectroscopic studies, acetylacetone predominantly exists as the enol form in the vapor phase and in nonpolar solvents at room temperature. Therefore, both spectra shown in Fig. 1 are due to the enol form. The difference between them in the frequency region higher than 45000 cm^{-1} can be explained by the fact that Rydberg transition bands in the vapor phase disappear in the condensed phase, *i.e.*, in perfluorohexane.[26] From this point of view, a weak band at 47170 cm^{-1} and a moderately strong band at 53300 cm^{-1} are assigned to the Rydberg transitions of the enol form.

The Rydberg excitation energy is expected to satisfy the following formula;[26]

$$h\nu = I_p - 109737/(n-\delta)^2, \quad (1)$$

where $h\nu$ is the excitation energy (cm^{-1}), I_p is the ionization potential (cm^{-1}), n is the principal quantum number, and δ is the quantum defect. The equation was applied to the 47170 cm^{-1} (5.85 eV) and 53300 cm^{-1} (6.61 eV) bands of the enol form by the use of the first I_p value (9.00 eV) obtained by photoelectron spectroscopy.[27] δ was determined to be 0.92 for the former band, and 0.62 for the latter band, corresponding to $n=3$. This strongly suggests that the 47170 cm^{-1} and 53300 cm^{-1} bands are due to the transitions to the 3s and 3p Rydberg orbitals, respectively, from the highest occupied π orbital.

In addition to the Rydberg transition bands, the enol form has valence-shell transition bands at 38020 cm^{-1} (4.72 eV) in the vapor phase or at 36770 cm^{-1} (4.56 eV) in perfluorohexane and at 56800 cm^{-1} (7.04 eV) in perfluorohexane. From Table 1 which shows the observed and theoretical values of the transition energies and oscillator strengths of the valence-shell transition bands, we can see that the bands at 4.72 and 7.04 eV are assigned to the first and second π-π^* transitions of the enol form, respectively.

In such polar solvents as acetonitrile and water, the amount of the keto form increases and the intensity of the 4.72 eV band pertinent to the enol form decreases with an approximate linear correlation with the dielectric constants of solvents. Figure 2 shows the intensity change of the band in several solvents.

Figure 3 shows the vapor phase absorption spectra of acetylacetone measured at various temperatures (20—204 °C) in the 30000—54000 cm^{-1} region. We can see that in the vapor phase the fraction of the keto form increases at higher temperatures. From the temperature dependence of the spectra in the 30000—35000 cm^{-1} region in Fig. 3, a weak band due to the keto form was found at $\approx$34000 cm^{-1} ($\approx$4.2 eV) in the vapor phase. The observed transition energy and oscillator strength are compared with the theoretical values in Table 1. We can see that the band is safely assigned to the first n-π^* transition of the keto form (calculated at 3.97 eV).

Let us turn to the Rydberg transition band of the keto form. In the region of 50000—54000 cm^{-1} in which the Rydberg transition bands of acetylacetone appear, spectral intensity increases at $\approx$52000 cm^{-1} with increasing temperature, whereas the bands at 47170 and 53300 cm^{-1} pertinent to the enol form decrease in intensity (see Fig. 3). This indicates that the band at $\approx$52000 cm^{-1} is ascribed to the keto form. By the aid of the equilibrium constant mentioned later, the 50000

a) Main electron configurations of the respective excited states are shown. (i,j)-k denotes the singly excited configurations, i-k and j-k, and i-(k,l), the singly excited configurations, i-k and i-l. b) The direction of the transition moment is shown in the parentheses, the x-axis being taken to be parallel to the O···H···O bond within the molecular (x-y) plane. c) The main component of the transition moment is shown in the parentheses, the x-axis being taken to be parallel to the C_2–C_4 line within the C_2–C_3–C_4 (x-y) plane (see Fig. 6(a)). d) Estimated from the observed intensity measured at 20 °C in the vapor phase by the aid of the equilibrium constant, K. e) Observed value in perfluorohexane. f) x- and z-components of the transition moment contribute comparably with the same sign to each other. g) x-Component of the transition moment contributes appreciably with the opposite sign to z-component.

—54000 cm^{-1} band can be resolved into the Rydberg bands of the keto form (≈52000 cm^{-1}) and the enol form (53300 cm^{-1}); the resolved spectra are also shown in Fig. 3. Equation 1 was applied to the ≈52000 cm^{-1} band of the keto form. From the first I_p value (9.60 eV) of the keto form,[27] δ was determined to be 0.92 corresponding to n=3, suggesting that the ≈52000 cm^{-1} band is due to the transition to the 3s Rydberg orbital from the highest occupied n orbital.

The UV absorption spectrum of the acetylacetonate anion[28] was also measured in 0.1 M NaOH aqueous solution; the result is shown in Fig. 2. Theoretical result tabulated in Table 2 clearly shows that the 34190 cm^{-1} (4.24 eV) band of the anion can be assigned to the first π-π^* transition calculated at 4.60 eV.

Electronic Structure of the Intramolecular Hydrogen Bond. Figure 4 shows the energy levels calculated by the modified CNDO-CI method for some low-lying π-π^* and σ-σ^* excited states of the enol form. In the figure, i–j represents a singly excited configuration caused by the one-electron excitation from the i-th occupied MO to the j-th vacant MO. The shapes of the MO's of the enol form are schematically shown in Fig. 5. The CT band characteristic of the intramolecular hydrogen bond, O···H···O corresponds to the transition from the nonbonding orbital to the antibonding orbital in the hydrogen bond. The 20–26 configuration corresponds to this transition. As is illustrated in Fig. 4, the 20–26 CT configuration interacts significantly with the 19–21 and 14–21 π-π^* configurations, and contributes to the first (calculated at 4.47 eV) and sixth (calculated at 9.02 eV) excited states. The 4.47 eV band is mainly composed of the 19–21 π-π^* (83.3%) and 20–26 CT (9.8%) configurations. The main configurations in other excited states of the enol form are also given in Table 1.

The character of the intramolecular hydrogen bond of acetylacetone can be clarified quantitatively by the configuration analysis; the results for the ground and the first π-π^* excited (calculated at 4.47 eV) states are tabulated in Table 3, together with the result for the first σ-σ^* excited (predicted at 8.38 eV) state. In the ground state, the hydrogen bond is composed of the symmetric covalent structure III (≈45.1%), the ionic structure V (≈42.9%), and the symmetric ionic structure I (≈11.0%). As is shown in a previous paper,[16] the CT structure corresponds to the antisymmetric covalent structure IV and antisymmetric ionic structure II. The antisymmetric covalent and ionic structures contribute fairly (≈9.7%) to the first π-π^* excited state, but contribute only little (≈1.4%) to the first σ-σ^* excited state predicted at 8.38 eV.

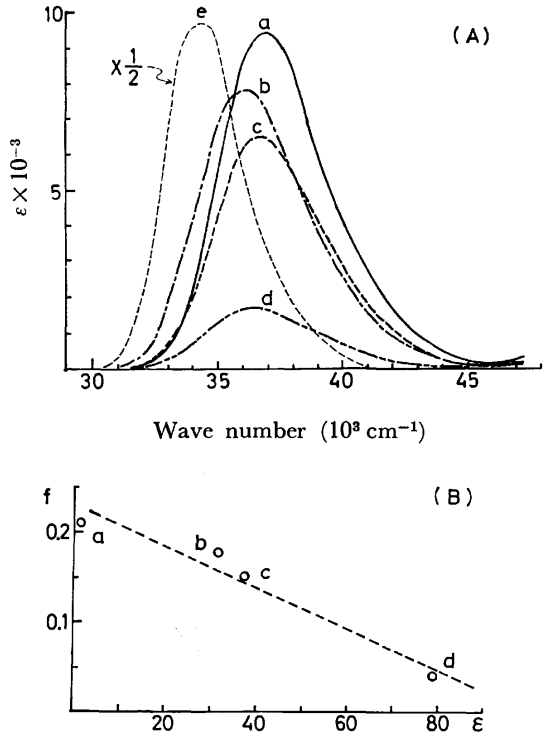

Fig. 2. (A) UV absorption spectra of acetylacetone measured at room temperature in (a) heptane, (b) methanol, (c) acetonitrile, (d) water, and (e) 0.1 M NaOH aqueous solution.
(B) Dependence of the oscillator strength (f) observed with the 36000—37000 cm^{-1} band in (a) heptane, (b) methanol, (c) acetonitrile, and (d) water upon the dielectric constant (ε) of the solvent used.

Electron Densities. Figure 6 shows electron densities for the ground states of the keto and enol forms of acetylacetone, and of its anion. The carbon and oxygen atoms in the five membered ring of the enol form are more polarized than the corresponding atoms in the keto form. By the removal of the hydrogen-bonded proton, electron densities in the anion increase in the whole region of the molecule compared to the corresponding ones in the enol form. Dipole moments of the keto and enol forms of acetylacetone were calculated to be 4.93 and 3.18 Debye, respectively, being in good agreement with the observed value for the enol form in the vapor phase (3.0 Debye).[29]

TABLE 2. TRANSITION ENERGIES ($^1\Delta E$(eV)) AND OSCILLATOR STRENGTHS (f) OBSERVED AND CALCULATED FOR THE ACETYLACETONATE ANION

a) The molecular structure was assumed to be the same to the one of the enol form of acetylacetone except for the fact that the hydrogen-bonded proton was removed.
b) The direction of the transition moment is shown in the parentheses, the x-axis being taken to be parallel to the O···O line within the molecular (x-y) plane.

Equilibrium Constant Between Keto and Enol Forms of Acetylacetone. The equilibrium constant (K) between the keto and enol forms of acetylacetone;

$$K = [\text{enol}]/[\text{keto}] \qquad (2)$$

was determined in the vapor phase from the temperature dependence of the absorption spectrum shown in Fig. 3. As already mentioned, gaseous acetylacetone

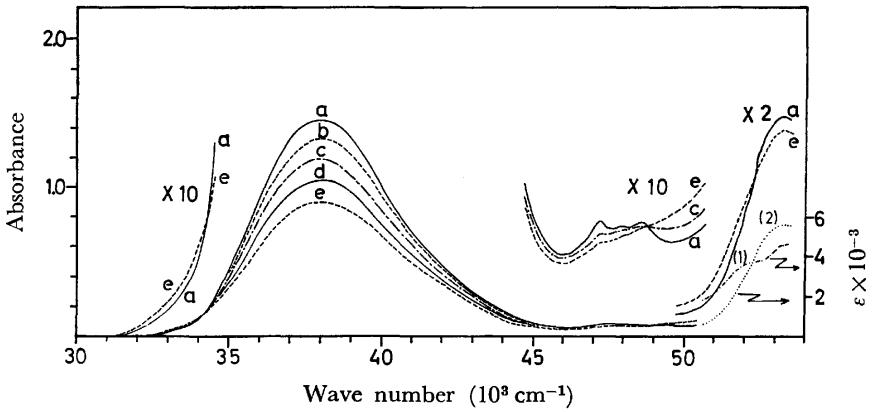

Fig. 3. Absorption spectra of acetylacetone in the vapor phase measured at (a) 20°, (b) 98°, (c) 120°, (d) 169°, and (e) 204 °C. From the mole fraction of the enol form, absorption spectrum in the 50000—54000 cm^{-1} region was resolved into two spectra ascribed to (1) the keto form and (2) the enol form of acetylacetone.

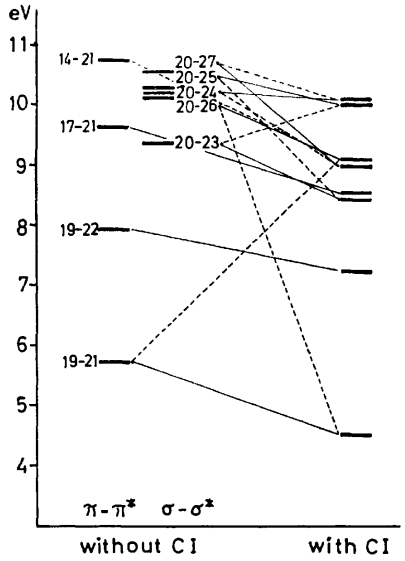

Fig. 4. Energy levels calculated with and without CI treatment for some lower π-π^* and σ-σ^* excited states of the enol form of acetylacetone.

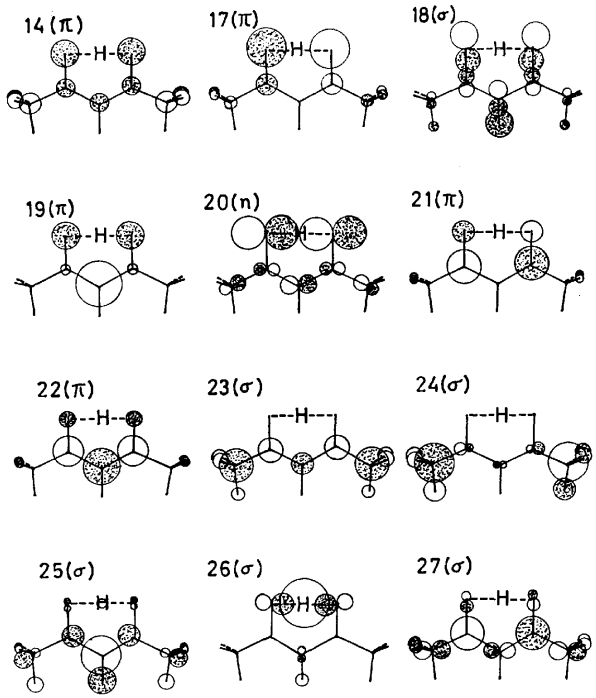

Fig. 5. Schematic shapes of some occupied and vacant MO's of the enol form of acetylacetone. The 20th MO is the highest occupied one.

at room temperature exists almost completely as the enol form. Strictly speaking, however, it may contain slightly the keto form. In view of this, we tried to determine accurately the mole fraction of the enol form and the K value from a linear relationship between $\ln K$ and $1/T$. In actuality, we evaluated K at 68, 120, 169, and 204 °C by combining the observed absorption intensity (at each temperature) at 38020 cm^{-1} and the molar extinction coefficients at the same wave number derived from several appropriate mole fraction values of the enol form at 20 °C, 90.0, 95.0, 96.2, 97.0, and 100%. The values of $\ln K$ obtained thus at 20—204 °C are plotted against $1/T$ (Fig. 7). We can see that the linear relationship is most satisfactorily held for the mole fraction of 96.2%. The K values for this case

Surface Oxidation of the Thin Films of Polycyclic Aromatic Hydrocarbons Studied by X-Ray Photoelectron Spectroscopy

Masamichi YAMADA, Isao IKEMOTO, and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received March 22, 1977)

The oxidation of the surfaces of thin films of perylene, pentacene, violanthrene, and mesonaphthodianthrene on exposure to oxygen or to the air was studied by means of X-ray photoelectron spectroscopy. A perylene film was found to be the least reactive toward oxygen among the above four hydrocarbons. In the cases of pentacene and violanthrene films, a single, broad O 1s peak grew up with time over the period of a few months as the exposure to the air was prolonged. On exposure to oxygen, a mesonaphthodianthrene film exhibited the O 1s spectrum which apparently consisted of two peaks located at the binding energies, 531.0 and 532.9 eV respectively, and the peak at 532.9 eV reduced its intensity irreversibly on heating the film in a high vacuum, suggesting that it was the one associated with a loosely bound oxygen.

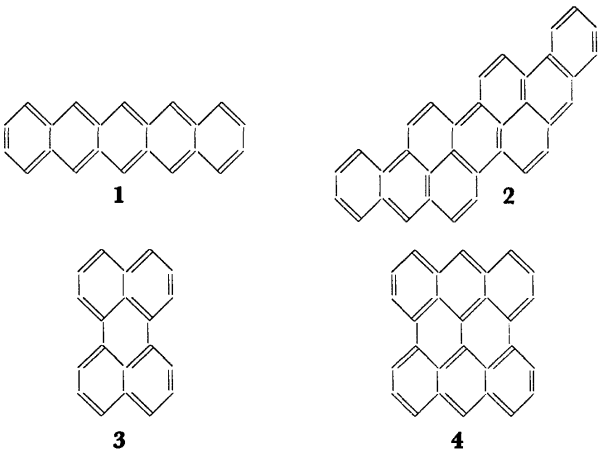
Semiconductive and photoconductive behavior of organic solids are often influenced considerably by the oxygen adsorption on the surface.[1] It is well known that the photoconductivity of anthracene crystal is significantly affected by oxygen.[2,3] In the cases of large polycyclic aromatic hydrocarbons such as mesonaphthodianthrene[4] and quaterrylene,[5]* their evaporated films were reported to exhibit quite different semiconductive behavior in the ordinary atmosphere as compared with those measured in a high vacuum. Generally, the surfaces of organic molecular crystals are rather unreactive to oxygen, so that one could consider that the oxygen species formed on their surfaces by the interaction with ambient oxygen would be primarily the oxygen molecules loosely bound on the crystal surface by physical adsorption. In effect, most of the observed oxygen effects on electrical properties of organic solids were found to vary reversibly depending on the ambient oxygen pressure. However, in some cases, the effects were not entirely reversible,[5] suggesting the formation of strongly-bound oxygen species or surface oxides.

Although a considerable amount of experimental results have been accumulated on the phenomena related to the influence of ambient oxygen on the electrical properties of organic solids,[1] little is known about the actual reactivities of the surfaces of organic crystals toward oxygen. In the present study, we have investigated the oxygen adsorption, or the surface oxidation of the thin films of polycyclic aromatic hydrocarbons by means of X-ray photoelectron spectroscopy.

Experimental

X-Ray photoelectron spectra were measured with McPherson ESCA 36 electron spectrometer employing Al K_α (1486.6 eV). The sample films were prepared by sublimation onto aluminum plates set inside the sample chamber of the spectrometer, which was kept at a vacuum of about 10^{-7} Torr by using a turbomolecular pump and a cryogenic pump. On each sample, the experiments were carried out according to the following steps. First, the C 1s and O 1s regions of Al K_α photoelectron spectrum were recorded immediately after the preparation of the sample film. A wide-scan spectrum was also recorded in order to see if the film was free from any impurity, and if the film was thick enough to prevent the appearance of any spectrum due to the substrate. After the above measurements, the cryogenic pump was switched off prior to the introduction of oxygen into the sample chamber. This inevitably caused a release of gases, including oxygen, from the cryopanel in the sample chamber. Thus, the C 1s and O 1s spectra were recorded again after this operation to examine the effects of the released gases. Then, the oxygen gas of a few hundred Torr was introduced into the sample chamber. After the sample film having been kept in this oxygen gas for 30 min, the oxygen gas was pumped out from the sample chamber to measure Al K_α photoelectron spectrum. In some cases, oxygen was again introduced into the sample chamber, and the film was continuously kept in the oxygen atmosphere for a night before the next measurement of the spectrum. After those experiments, the sample film was taken out of the spectrometer, and kept at a dark place in the ordinary atmosphere to examine the effect of prolonged exposure to the air. The C 1s and O 1s spectra of the sample film were observed occasionally over the period of a few months. Finally, a small amount of gold was deposited onto the sample surface for calibration of binding energies by use of Au $4f_{7/2}$ (84.0 eV) peak as the standard.

Experiments were done on four polycyclic aromatic hydrocarbons; pentacene(**1**), violanthrene(**2**),** perylene(**3**), and mesonaphthodianthrene(**4**).***



Results and Discussion

It is well known that pentacene, $C_{22}H_{14}$, is quickly oxidized in the solution by the interaction with the oxygen dissolved in the solvent, particularly under the

* Benzo[1,2,3-*cd*: 4,5,6-*c'd'*]diperylene.

** Dinaphtho[1,2,3-*cd*: 3',2',1'-*lm*]perylene.

*** Phenanthro[1,10,9,8-*opqra*]perylene.

action of visible light, to form a transannular peroxide.[6] However, it is quite stable in the crystalline state, so that the crystalline powder of pentacene can be kept in the ordinary atmosphere without significantly suffering the oxidation. The oxygen effect on the photoconductivity of a pentacene film was studied some years ago by one of the present authors.[7] It was observed that, when a pentacene film was exposed to an oxygen gas, the photocurrent through the film under a fixed light intensity gradually increased with time to the stationary-state value which was dependent on the pressure of the ambient oxygen. This oxygen effect was found to be almost reversible, suggesting that it was primarily associated with the oxygen molecules loosely bound on the surface.

The Al K_α photoelectron spectrum of a pentacene film before being exposed to the oxygen gas, did not exhibit any O 1s peak, showing only a strong and sharp C 1s peak (with the FWHM of about 1.7 eV) accompanied by weak satellite bands. When the film was exposed to the oxygen gas for about 30 min, a weak O 1s peak appeared in the photoelectron spectrum, and the intensity of this peak did not decrease at all even by keeping the film in a high vacuum (about 10^{-7} Torr) for a night. This fact indicates that, although the oxygen effect on photoconductivity is mostly reversible,[7] there are some oxygen species which can not be removed by a prolonged pumping from the surface of the pentacene film which has been once exposed to the oxygen gas.

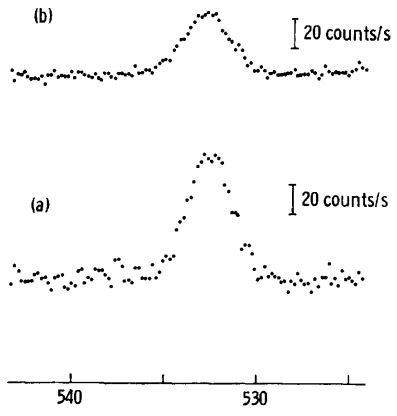


Fig. 1. (a): O 1s spectrum of the pentacene film after exposure to the air for 12 days, (b): O 1s spectrum of the violanthrene film after exposure to the air for 10 days.

On keeping the pentacene film in the air, the O 1s peak further grew up slowly with time. As shown in Fig. 1(a), the FWHM of this O 1s peak was 2.9 eV while a sample containing only a single kind of oxygen would give an O 1s peak with the FWHM of less than 2.0 eV under the same experimental conditions.[8] Thus the broadness of the observed O 1s peak is likely to indicate that there are more than one chemical states of oxygen atoms in the surface region of the pentacene film. In the photoelectron spectrum taken after 38 days' exposure to the air, the ratio of integrated intensity of the O 1s peak to that of the C 1s peak was found to be 0.099, which corresponds to the atom ratio, one oxygen atom per 22 carbon atoms,[9] in other words, one oxygen atom per one pentacene molecule. Since the escape depth of photoelectrons is of the order of two or three molecular layers of pentacene, the above results would possibly mean that every pentacene molecule on the surface is in the state bound with one oxygen molecule. The intensity ratios, O 1s/C 1s, obtained for the pentacene film at different stages of oxygen exposure are summarized in Table 1 together with the data concerned with other hydrocarbon films.

In the case of violanthrene, $C_{34}H_{18}$, the observed behaviors were a little different from those of a pentacene film. When a violanthrene film was exposed to the gases evolved from the cryopanel on turning off the cryogenic pump, there appeared a weak O 1s peak in the photoelectron spectrum of the film, but thereafter its intensity did not detectably increase on keeping the film in the oxygen gas for a night. The growth of the O 1s peak was so slow that we had to keep the film in the air for several days in order to attain an appreciable increase of its intensity. After the 38 days' exposure to the air, the intensity of O 1s peak relative to that of C 1s peak became 0.047, which corresponds to 0.7 oxygen atom per one violanthrene molecule. As in the case of a pentacene film, the observed O 1s peak was broad with the FWHM of about 3 eV as shown in Fig. 1(b).

The film of perylene, $C_{20}H_{12}$, was found to be the least reactive toward oxygen. Any O 1s peak did not appear in the photoelectron spectrum after the 10 min

Table 1. Variation of the intensity ratio, O 1s/C 1s

a) Ratio of the integrated intensity of the O 1s peak to that of the C 1s peak.

exposure to the oxygen gas. Even after having been kept in the air for six months, only a very weak O 1s peak appeared in the spectrum, its intensity relative to that of the C 1s peak being only 0.017.

The results described above demonstrate that the films of pentacene, violanthrene, and perylene are markedly different from each other as regards the reactivity toward oxygen. This difference seems to be closely related to the reactivity of the free molecule of each hydrocarbon. As it has been already mentioned, a pentacene molecule in the solution easily forms a transannular peroxide by the interaction with an oxygen molecule.[6] But a transannular peroxide will not be so easily formed in the bulk of a pentacene crystal since its formation requires a large distortion of crystal lattice. This is likely to be the reason why the pentacene crystal can be stably kept in the ordinary atmosphere. However, the situation can be different for the crystal surface, where the change of molecular arrangement can occur more easily than in the bulk. Thus one could consider that the oxygen-containing species formed on the surface of the film on exposing to the oxygen gas is the transannular peroxide of pentacene. One could also consider the formation of other oxides of pentacene such as a quinone or hydroxy compounds. But the observed O 1s peak is too broad to be attributed to any one of these oxides. Possibly, several different kinds of oxides coexist on the surface. In the case of violanthrene, a model like the transannular peroxide is hard to be considered because of the molecular geometry. Possibly, a quinone and/or hydroxy compounds would be the chemical species formed on the surface of the violanthrene film.

An interesting behavior was observed in the case of mesonaphthodianthrene, $C_{28}H_{14}$, which is also known to be very reactive to oxygen.[10] In the photoelectron spectrum of a fresh film, which was measured immediately after the preparation without breaking the vacuum, there appeared a weak O 1s peak at the binding energy of 531.0 eV (see the spectrum(a) of Fig. 2). This must be due to some impurity that originally existed in the powder of mesonaphthodianthrene. The above impurity is likely to be some stable oxide of mesonaphthodianthrene such as mesonaphthodianthrone.**** On exposure to oxygen, a new peak appeared on the higher binding-energy side (at 532.9 eV) of the first peak, as shown in the spectrum(b) of Fig. 2. This new O 1s peak can be attributed to the oxygen-containing species formed on the surface. The intensity of this new peak increased as the film was further exposed to the oxygen gas. However, at the same time, the intensity of the 531.0 eV peak increased by a larger extent, so that, after the 17 days' exposure to the air, the film showed the O 1s spectrum consisting of a strong peak at 531.0 eV and a shoulder at 532.9 eV (see the spectrum(d) of Fig. 2). After the 67 days' exposure to the air, the integrated intensity of the O 1s peak relative to that of the C 1s peak became 0.101 which corresponds to 1.3 oxygen atoms per one mesonaphthodianthrene molecule.

The O 1s spectrum of a mesonaphthodianthrene film once exposed to oxygen was found to vary with time. This behavior is illustrated by the spectra shown in Fig. 3. The spectrum(a) was obtained just after the exposure to oxygen for a night. The intensity of the 532.9 eV peak decreased when the film was kept in a high vacuum for 90 min, while that of the 531.0 eV

**** Phenanthro[1,10,9,8-*opqra*]perylene-7,14-dione.

peak remained almost the same. This change became faster on elevating the temperature of the film to 60 °C and settled in the state which gave the spectrum(c). Thereafter, the O 1s spectrum did not further change on heating the film to 100 °C (the spectrum(d)), nor on cooling down it to room temperature (the spectrum (e)).

From the observation described above, we can conclude that there are at least two different kinds of oxides; the first is the species responsible for the O 1s peak at the binding energy of 532.9 eV, and the second is the one responsible for the 531.0 eV peak. Possibly the former is a metastable surface oxide where an oxygen molecule is rather loosely bound to a mesonaphthodianthrene molecule, and the latter is a stable oxide of mesonaphthodianthrene. The semiconductivity of a mesonaphthodianthrene film is known to be influenced by the oxygen adsorption.[4] It was observed that the electrical conductivity gradually increased with time in the oxygen gas, and decreased when the ambient oxygen gas was removed. These changes were found to be very slow at room temperature. Matsunaga reported that a sharp ESR signal appeared as the mesonaphthodianthrene powder was exposed to the air, and the intensity of this ESR signal increased slowly with time over the period of a few days.[11] It is most likely that the metastable surface oxide detected by X-ray photoelectron spectroscopy has some connection with the phenomena mentioned above. But, at present, it is hard to derive a definite conclusion as regards the true nature of this oxide.

Factor Group Splitting and the Lowest Triplet State of Tetrachlorophthalic Anhydride Crystals

Mizuka SANO, Takatoshi NARISAWA, Mitsunobu MATSUKA, and Yasumasa J. I'HAYA

Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo 182

(Received April 22, 1977)

The electronic configuration of the lowest triplet state for tetrachlorophthalic anhydride (TCPA) was determined to be $B_2(\pi\pi^*)$ by means of Zeeman spectroscopy. The electronic origin for the singlet-triplet absorption of a TCPA single crystal was found in the region of 421.3 nm at 1.7 K. The first peak in the absorption spectrum was found to possess two components; the one observed at 23726.1 cm^{-1} corresponds to the transition to the B_u, and the other observed at 23728.5 cm^{-1} to that to the A_u triplet factor group state. The splitting between the two states is 2.4 cm^{-1}.

The lower excited triplet $n\pi^*$ and $\pi\pi^*$ states of aromatic carbonyls are closely spaced and change their energies differently under the influence of environments (solvents and/or host molecules) or substituent effects. The properties of these nearby triplet states have been the subject of numerous spectroscopic and related studies in recent years.[1] In previous papers we attempted to explain the excited triplet states of aromatic quinones.[2] As an extension of these studies, we take up tetrachlorophthalic anhydride (abbreviated to TCPA hereafter). TCPA is a typical electron acceptor and forms stable charge-transfer complexes with a number of aromatic compounds. Although much effort has been made in understanding spectroscopic properties of TCPA charge-transfer complexes, the excited triplet states of TCPA in a single crystal appear to be less understood.

The present study was undertaken in order to clarify the electronic configuration of the lowest triplet state of TCPA by means of Zeeman spectroscopy. In principle, the electronic configuration of a triplet state can be assigned by determining both the polarization in absorption and an effective route in the spin-orbit interaction. This is because the transition from the ground state to the triplet state in question is assumed to gain its intensity from the transition from the ground state to a perturbing singlet state through the spin-orbit coupling between the triplet state and the perturbing singlet state in the first-order spin-orbit interaction mechanism. In case that a perturbing triplet state is located closely to the triplet state in question, the intensity stealing from the transition between these triplet states must also be taken into consideration. In this work both the direction of polarization in the singlet-triplet absorption transition and the Zeeman intensity pattern were observed for thick TCPA single crystals.

Experimental

The experimental procedures were the same as described in the previous papers.[2] TCPA (Tokyo Kasei Organic Chemicals) was purified by zone-refining for 40 passes with additional 40 passes, and then grown into a single crystal from the melt. Crystal samples with suitable size, about 5×5 mm^2 in area and 3—18.4 mm in thickness, were taken from the crystal, and their faces were identified by the X-ray diffraction method. The reciprocal dispersion of an NLM-E2M spectrometer used for absorption measurements was 0.053 nm mm^{-1} at 420 nm in the 13th order of an Echelles grating. Phosphorescence of a crystal immersed in liquid helium was excited by 365 nm radiation from an ORC 1 kW superhigh-pressure mercury arc.

Results and Discussion

Figures 1 and 2 show the singlet-triplet absorption and the phosphorescence spectra of a TCPA single crystal at 1.7 K, respectively. The first peak in the absorption spectrum was found in the region of 421.3 nm and that in the phosphorescence spectrum at 422.2 nm (23677 cm^{-1}). The intensity of the first absorption peak was measured for the light polarized along each crystallographic axis. The polarization ratio I_a^*/I_c was found

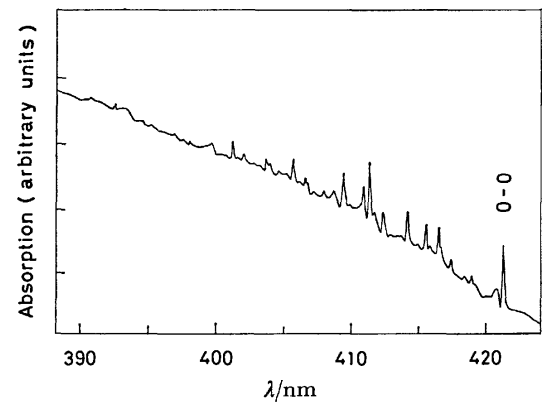

Fig. 1. The c-polarized singlet-triplet absorption spectrum of a TCPA crystal at 1.7 K; broad background due to a xenon arc light source.

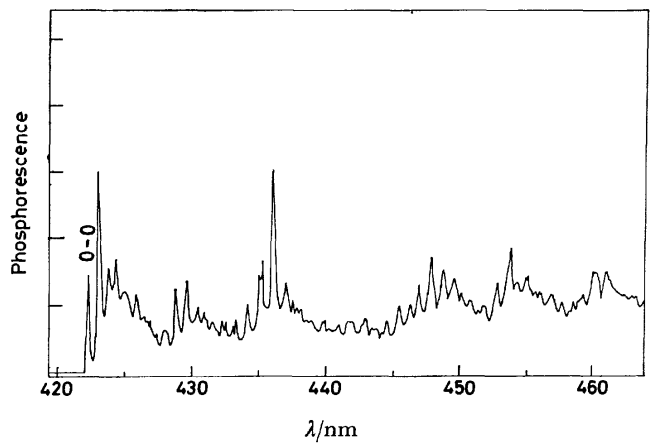

Fig. 2. The phosphorescence spectrum of a TCAP crystal at 1.7 K.

to be 0.53 and the ratio I_c/I_b to be 1.6. This peak was found to split into sublines upon the application of a magnetic field. From these results, the first peak is assigned to the origin of the lowest singlet-triplet transition for crystalline TCPA. Other intense, sharp absorption peaks were found at 24010.3, 24061.5, 24139.1, 24246.7, 24308.3, 24333.8, 24425.9, and 24641.5 cm^{-1} in the spectral region to 400 nm. No absorption peak was observed in the region between 400 and 380 nm, but a broad absorption band with polarization different from the first peak was found at 370 nm (27000 cm^{-1}).

Figure 3a shows the high-resolution absorption spectrum of the first peak for a 18.4 nm oriented crystal with the light propagating along the b axis and polarized along the c axis. The peak was found to possess two components, O_1 at 23726.1 cm^{-1} and O_2 at 23728.5 cm^{-1}. The intensity ratio of the O_1 to the O_2 components, $(I_1/I_2)_c$, was found to be 0.14. The intensity ratio obtained through the light propagating along the c axis, however, depended on the direction of polarization of light. The ratios were found to be 0.07 for the light polarized along the a* axis and 1/0.13 for the light polarized along the b axis.

Upon the application of a magnetic field of 50 kOe along the b axis, the O_2 component observed through the c-polarized light was found to split into two sublines with a separation of about 9.5 cm^{-1}, and the O_1 component remained unchanged, as shown in Fig. 3b. Upon the application of a magnetic field along the a* axis, there appeared five sublines in total, originating from both components, and their intensities were dependent on the polarization of light used for the observation (Fig. 4a).

All the experimental results mentioned above can be reasonably explained in terms of the scheme that the spatial symmetry of the lowest triplet state for TCPA belongs to $B_2(\pi\pi^*)$, and the O_1 and O_2 components in the absorption spectrum correspond to the transitions to

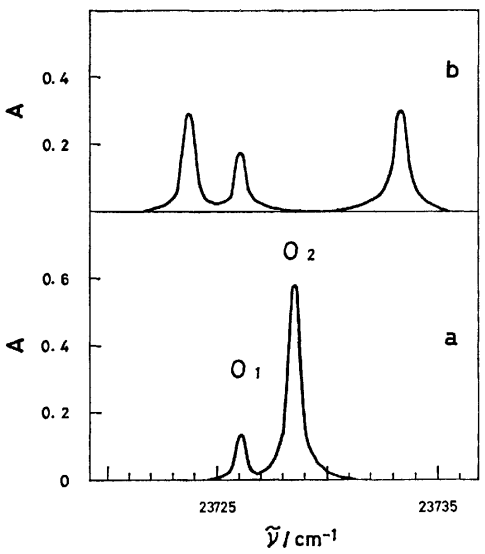

Fig. 3. The electronic origin of the c-polarized singlet-triplet absorption spectrum of a TCAP crystal at 4.2 K. (a) $H=0$, (b) $H=50$ kOe, H//b.

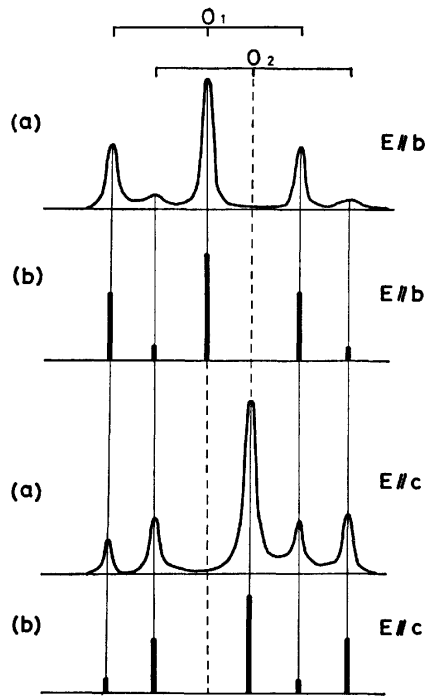

Fig. 4. Zeeman absorption patterns of a TCAP crystal. A magnetic field of 50 kOe was applied along the a* axis.
(a) The observed spectra, (b) the calculated intensities for the scheme of the x-polarized transition with the z-route in the spin-orbit coupling.

the B_u and A_u triplet factor group states, respectively.

The crystal structure of TCPA gives the space group symmetry C_{2h}^5 with four molecules per unit cell. The molecule in a crystal can be regarded as planar, belonging to the C_{2v} point group.[3] The molecular framework z-axis is taken as the molecular twofold axis, and the z,y-plane as the plane of the molecule. If we assume that only one route is active in mixing molecular singlet and triplet states through the spin-orbit coupling, the transition to the A_u state is expected to split into two wing sublines $I_{\pm 1}$, while that to the B_u state to remain unchanged, showing only the central subline I_0, when a magnetic field is applied along the b axis and the absorption is observed through the c-polarized light. The intensity ratio of I_0 to $I_{\pm 1}$ is expressed by

$$\left(\frac{I_0}{I_{\pm 1}}\right)_c = \frac{2m_u^2}{1-m_u^2}, \tag{1}$$

where m_u consists of the direction cosines of the molecular axes x, y, and z with respect to the b axis.[4] This ratio is just twice the absorption intensity ratio between the two factor group splitting components observed through the c-polarized light $(I_1/I_2)_c$. The absorption intensity ratios between the components obtained through the light polarized along each crystallographic axis are related to one another by the equation,

$$\left(\frac{I_1}{I_2}\right)_c = \left(\frac{I_1}{I_2}\right)_{a^*} = 1\Big/\left(\frac{I_1}{I_2}\right)_b. \tag{2}$$

This is just what we have observed for the TCPA crystals. The values of the ratio in Eq. 1 were calculated from the direction consines to be 1.1, 2.8, and

0.13 for x, y, and z routes in the spin-orbit coupling, respectively. The experimental finding is consistent only with the z route involved in the spin-orbit coupling (an A_2 representation in the C_{2v} point group).

The polarization ratio for the first peak, that is, the sum of the O_1 and O_2 components, can be explained in terms of the transition which is primarily out-of-plane polarized (a B_1 representation in the C_{2v} point group). Furthermore, the Zeeman absorption pattern obtained for the light polarized along the c axis or the b axis under the magnetic field directed along the a* axis can be most satisfactorily represented by the scheme that the absorption intensity is taken from the x-polarized transition and the effective route in the spin-orbit coupling is z, as shown in Fig. 4b. Therefore, it is concluded that the lowest triplet state for TCPA belongs to $B_2(\pi\pi^*)$.

The lowest singlet-singlet absorption band of TCPA in the region from 30000 to 32500 cm^{-1} has been assigned theoretically to the transition of $\pi\pi^*$ character. The next band in the region from 35000 to 38000 cm^{-1}, however, has not been explained in terms of a $\pi\pi^*$ transition.[5] The broad absorption band observed at 27000 cm^{-1} in the present study was found to be stronger than the lowest singlet-triplet absorption, but weaker than the singlet-singlet absoption in oscillator strength. Considering the intensity, the broadness, the direction of polarization (mainly z-polarized), and the location of the band in the spectrum, the absorption is tentatively ascribed to the transition to a triplet state of $n\pi^*$ character.

The triplet factor group splitting was observed only for the first absorption peak, which was the strongest in intensity among the peaks in the transition to the lowest triplet state. This result shows that the coupling between molecules in the TCPA crystals is interpreted on the basis of a weak coupling model, where the magnitude of each splitting is roughly proportional to the intensity of a peak.[6]

ENDOR Studies on Low-Symmetry Triphenylmethyl with *ortho*- or *para*-Methoxy Substituents

Kazuhiko Ishizu, Kazuo Mukai, Atsuko Shibayama, and Kyoko Kondo

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received January 21, 1977)

ENDOR observations were carried out for several triphenylmethyl derivatives with *ortho*- or *para*-methoxy substituents. The alteration of the spin-density distribution caused by steric hindrance, in particular, due to the low symmetrical substitution, was investigated. Using a revised MO parameter proposed by Kulkarni, McLachlan MO calculations were carried out and the twisting angles of the hindered phenyl groups are estimated.

Triphenylmethyl is one of the typical neutral radicals on which a number of ESR studies have been made. In the case of methoxy derivatives, however, the observed ESR hyperfine structures are often complicated by overlapping due to the small methoxy proton splitting, and, sometimes, by modulation of hindered rotation of the substituents.

To the authors' knowledge, the derivatives which have already been studied are chiefly those of higher molecular symmetry such as 4,4′,4″-trimethoxytriphenylmethyl[1] and 2,2′,2″,6,6′,6″-hexamethoxytriphenylmethyl.[2] In the present work, ENDOR studies of several methoxy derivatives of triphenylmethyl with low-symmetrical substitution, as shown in Fig. 1, are reported.

Perturbation of the spin density due to steric hindrance was measured in detail, and the conformation of the hindered phenyls was investigated in terms of McLachlan MO calculations including a correction for the Coulomb integral of the central methyl carbon due to Kulkarni.

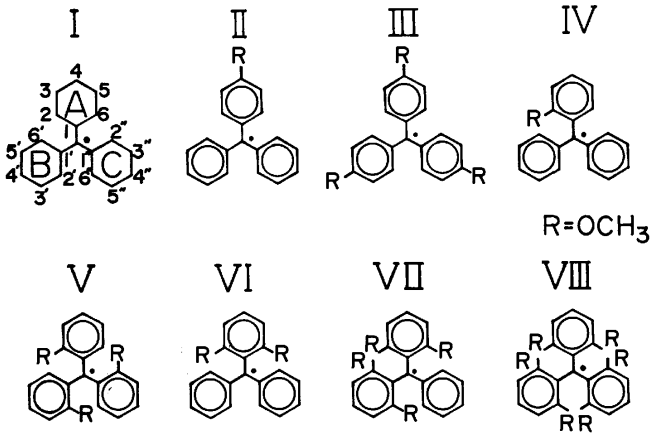

Fig. 1.

Experimental

Triphenylmethanols I, II, III, IV, and V, were synthesized by the Gomberg method,[3] and VI, VII, and VIII were prepared by reactions of 2,6-dimethoxyphenyllithium with benzophenone, ethyl benzoate and ethyl carbonate, respectively. The crude materials produced were purified by recrystallization in a hexane–benzene mixture; [I] mp 165 °C, [II] mp 61 °C, Found: C, 83.21; H, 6.34%. Calcd: C, 82.73; H, 6.25%. [III] Mp 85 °C, Found: C, 75.48; H, 6.31%. Calcd: C, 75.41; H, 6.33%. [IV] Mp 132 °C. Found: C, 83.92; H, 6.19%. Calcd: C, 82.73; H, 6.25%. [V] Mp 188 °C, Found: C, 75.64; H, 6.33%. Calcd: C, 75.41; H, 6.33%. [VI] Mp 137 °C, Found: C, 78.75; H, 6.11%. Calcd: C, 78.73; H, 6.29%. [VII] Mp 107 °C, Found: C, 72.53; H, 6.35%. Calcd: C, 72.61, H, 6.36%. [VIII] Mp 166 °C, Found: C, 67.91; H, 6.44%. Calcd: C, 68.17, H, 6.41%. Radicals VII and VIII were prepared by reduction of the corresponding carbonium ions, which are easily produced by dissolving the alcohols in 10% aqueous sulfuric acid.[2] Radicals I, II, III, IV, V, and VI were obtained by the Gomberg procedure applied to the corresponding chlorides, which were synthesized by treating the alcohols with thionyl chloride in dichloromethane.[4] ENDOR measurements were carried out in a toluene solution of the free radicals according to the procedure described previously.[5]

Results and Discussion

ENDOR Spectrum and the Hyperfine Splittings. A typical example of the ENDOR spectrum observed for 2-methoxytriphenylmethyl [IV] is shown in Fig. 2. Eight sets of the ENDOR signals seen in the figure (a—h) can be assigned with reference to the ENDOR spectrum of the parent triphenylmethyl as follows: signals (d), (g), and (h) are ascribed to the meta-, ortho- and para-ring protons of non-substituted phenyls (B, C) and (a), (b, c), (e), and (f) to the methoxyl protons and the meta-, ortho- and para-ring protons

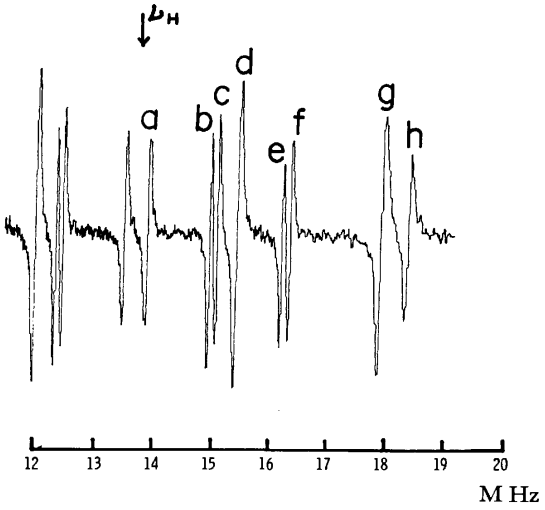

Fig. 2. ENDOR spectrum of 2-methoxytriphenmethyl [IV] recorded at −70 °C.

Table 1. Proton hyperfine coupling constants for triphenylmethyl (in G)

	A					B					C					$-OCH_3$
	2	3	4	5	6	2'	3'	4'	5'	6'	2''	3''	4''	5''	6''

VIII		1.07	2.35				1.07	2.35				1.07	2.35			0.16

of the substituted phenyl (A), respectively. The larger splitting of either (b) or (c) is assigned to position 5, since the methoxyl substitution causes a small reduction in the spin density at position next to the carbon atom, to which the methoxyl group is bonded. The coupling constants for the ring and the methoxyl protons under the same assumptions are summarized in Table 1, where splittings' assignments, in particular, those for the hindered triphenylmethyls IV and VIII are based on the prediction of the McLachlan MO calculation.

MO Calculation and the Steric Hindrance. In the HMO or McLachlan calculations for triphenylmethyls previously described, the value of the Coulomb integral for the central methyl carbon atom was taken to be equal to that of the aromatic ring carbon atom. This leads to equal spin densities at the ortho- and para-positions, which is contrary to experimental observations.

An improved choice of the parameter was proposed by Kulkarni, who employed the less electronegative value, $\alpha_{Me}=\alpha-1.2\beta$,[6] for the Coulomb integral of the methyl carbon atom. The resonance inhibition between the central methyl and the twisted phenyl $2p_\pi$ orbitals is represented by $\beta\cos\theta$ in which θ is the twisting angle.

In the present work, the inductive effect of the methoxyl group was ignored everywhere, and the hindrance of the phenyl group due to the ortho-substitution was taken into account. As an example, the dependence of the spin densities on the twisting angle (θ) calculated for VII suggested that the spin-density distribution on the substituted phenyls (A) and (B) decreases, but that on the non-substituted phenyl (C) increases, as the degree of steric hindrance in (A) and (B), θ, increases. The MO spin densities are in excellent agreement with the observed values obtained from the McConnel relation ($a^H=Q^H\rho^\pi$, $Q^H=-27$ G), under the assumption that each phenyl, A, B, and C, of VII is twisted outward by 65, 65, and 30°, respectively. The twisting angles of other hindered methyls shown in Table 2, give a satisfactory linear relation between the observed ring proton splitting and the MO spin densities calculated in the same manner, as is shown in Fig. 3. From the slope of the plot, the average value $|Q^H|$ was estimated to be 27.4 G, where the average value $|Q^{OCH_3}|$ is found to be 3.17 G, assuming $a^{OCH_3}=Q^{OCH_3}\cdot\rho_C^\pi$.

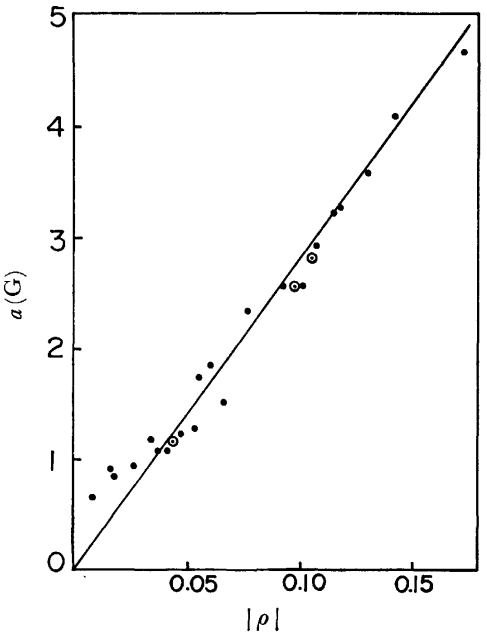

Fig. 3. Relation between the observed proton hyperfine coupling constants and the MO spin densities.
⊙ denotes the plots for mother triphenylmethyl.

Table 2. Twisting angles and MO π-bond orders for triphenylmethyl

	Twisting angle (θ)			Bond order		
	A	B	C	1-7	1'-7	1''-7
I	30°	30°	30°	0.333	0.333	0.333
IV	50°	30°	30°	0.249	0.338	0.338
V	35°	35°	35°	0.317	0.317	0.317
VI	70°	30°	30°	0.134	0.342	0.342
VII	65°	65°	30°	0.168	0.168	0.348
VIII	45°	45°	45°	0.278	0.278	0.278

Of interest is the fact that the twisting angle of the substituted phenyls of high symmetry [VIII] is much smaller than those seen for low symmetrical substitutions, such as VI and VII. This supports the hypothesis that an intramolecular odd-π-electron delocalization does affect the degree of steric hindrance in these molecules. In fact, the HMO bond order cited in Table 2 justifies the fact that the lowest value is predicted between the central methyl and the adjacent ring carbon of the substituted phenyl in derivative VI. On the other hand, the bond order for the non-substituted phenyl is increased by asymmetrical ortho-substitution. This means that the non-substituted phenyl of

derivatives VI and VII may have a more planar conformation compared with that of the parent triphenylmethyl in the true situation. Although the Kulkarni parameter predicts adequate spin densities, a rigorous explanation for the assumption of such a high electronegativity for the central methyl carbon still requires further investigation.[7,8] Other improved calculations for the triphenylmethyl were recently reported,[9,10] in which the resonance integral was chosen by taking into account the bond length of the triphenylmethyl perchlorate determined by X-ray analysis.[11] A tentative calculation for the present derivatives gave a qualitative explanation, but the agreement between the theoretical and experimental spin densities was not sufficient in comparison with the calculation of Kulkarni.

Vibration Spectra and Rotational Isomerism of Chain Molecules. VI.[1] 2-Chloro-, 2-Bromo-, and 2-Iodoethyl Methyl Ethers

Hiroatsu MATSUURA,* Motomichi KONO, Hiroshi IIZUKA, Yoshiki OGAWA, Issei HARADA, and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received April 13, 1977)

The Raman and infrared spectra of 2-chloro-, 2-bromo-, and 2-iodoethyl methyl ethers, $CH_3OCH_2CH_2X$ (X=Cl, Br, and I), were measured for the liquid, glassy, and crystalline states. The gaseous-state spectra of the chloride were also measured. The vibrational frequencies of these molecules were calculated by the use of the force constants transferred directly from unbranched ethers and alkyl halides. The rotational isomerism was studied and the following conclusions were obtained. (1) In the crystalline state, the molecule takes the form having the *trans* conformation about the CO–CC axis and the *gauche* conformation about the OC–CX axis. (2) In addition to this form (TG), three other forms (GG, TT, and GT) exist in the gaseous, liquid, and glassy states. (3) In the liquid state, the TG form is the most stable and the GT form is the least stable. (4) The less polar TT and GT forms are more favored and the more polar TG and GG forms are less favored in the gaseous state than in the liquid state.

In a series of previous papers, we reported the vibration spectra and rotational isomerism of chain molecules which include ethers,[1,2] paraffins,[3] sulfides,[1,4,5] and alkyl halides.[6] These studies gave us knowledge on the stable conformations of the chain molecules. For consistent elucidation of the conformational stabilities, it is important to examine rotational isomerism of molecules which contain two or more different kinds of chemical groups. Such studies are also important for confirming reliability and transferability of the force constants determined from observed vibrational frequencies.

In the present study, therefore, we deal with the rotational isomerism of 2-halogenoethyl methyl ethers, $CH_3OCH_2CH_2X$ (X=Cl, Br, and I), which contain oxygen and halogen atoms in a molecule. The study on these molecules also gives information on the effect of the two polar groups on the conformational stability. The vibrational spectra of 2-chloroethyl methyl ether have been measured by Hayashi[7] and the rotational isomerism has been discussed.

Experimental

2-Chloroethyl methyl ether was synthesized by treating ethylene glycol monomethyl ether with thionyl chloride, and 2-bromoethyl methyl ether by treating 2-bromoethanol with dimethyl sulfoxide. 2-Iodoethyl methyl ether was prepared from 2-chloroethyl methyl ether by treating with sodium iodide in acetone. The samples were distilled prior to the measurements.

The measurements of Raman spectra were made on a JEOL JRS-400D spectrophotometer with a Coherent Radiation CR-3 argon ion laser in the region below 1600 cm^{-1}. The Raman spectra of the chloride were measured for the gaseous, liquid, glassy, and crystalline states and those of the bromide and the iodide for the liquid, glassy, and crystalline states. A multireflection accessory and a gas cell with a heater were used for the measurements of the spectra in the gaseous state. The Raman spectra of the liquid state were recorded at various temperatures to examine the temperature dependence of Raman intensities. The glassy state was obtained by putting into liquid nitrogen the sample enclosed in an ampoule and cooling it rapidly, and the crystalline state by cooling the sample slowly or annealing it repeatedly.

The measurements of infrared spectra were made on a JASCO DS-402G grating spectrometer and a Hitachi EPI-G2 grating spectrometer in the region 1600—400 cm^{-1} and a Hitachi EPI-L grating spectrometer in the region 700—200 cm^{-1}. The infrared spectra of the chloride were measured for the gaseous, liquid, glassy, and crystalline states and those of the bromide and the iodide for the liquid, glassy, and crystalline states. For the measurements in the region below 700 cm^{-1}, the spectrometer was flushed with dry air to get rid of water vapor absorptions. The glassy state was obtained by depositing the sample onto a cooled window of KBr or KRS-5, and the crystalline state by annealing it repeatedly.

Normal Coordinate Treatment

The normal coordinate treatment of 2-halogenoethyl methyl ethers was carried out with a computer program NCTB2[8] and a HITAC 8700/8800 computing system at the Computer Center of the University of Tokyo. The force constants associated with the oxygen and halogen parts were transferred from the unbranched ethers[1,2,8] and alkyl halides.[6,8] The force constants for the C–C stretching and the methylene-methylene interactions were transferred from the corresponding alkyl halides. No further adjustment of the force constants was made. The transferred values were found to be accurate enough for determining the rotational isomerism of the molecules not only in the crystalline state but also in the glassy and liquid states.

Structural parameters and symmetry coordinates used in the calculation and the detailed results of the calculation are reported in a separate paper.[8]

Results

The Raman and infrared spectra of 2-halogenoethyl methyl ethers in various states are shown in Figs. 1—10 and the vibrational assignments based on the calculated potential-energy distributions are listed in Tables 1—3. Each of the molecules has five possible rotational isomers, TT, TG, GT, GG, and GG′, as given in Table 1 of Part I of this series,[2] where the first and second

a) VS: very strong, S: strong, M: medium, W: weak, VW: very weak, b: broad, sh: shoulder. The broadness of the band shapes in the gaseous state does not always allow us to correlate the individual bands in the liquid state to those in the gaseous state. Only approximate correlations are made in such cases and in other cases of similar situations. b) For the notation and definition of the local symmetry coordinates, see Ref. 16.

conformation symbols in each isomer designation are those for the CO–CC and OC–CX axes, respectively.

The following spectral features are observed for the three halogenoethers studied in this work. (1) The spectra have combined features of ethers and alkyl halides. (2) The number of the bands observed in the crystalline state is the smallest among the various states and corresponds to what is expected for one molecular form. (3) In the glassy and liquid states, additional bands appear in the spectra. The relative band intensities in the two states are considerably different. (4) Systematic variations of frequencies and intensities are observed with the change of the halogen atom.

In the following subsections, the rotational isomerism of the individual molecules is described. The results are summarized in Table 4.

a), b) See a) and b), respectively, of Table 1.

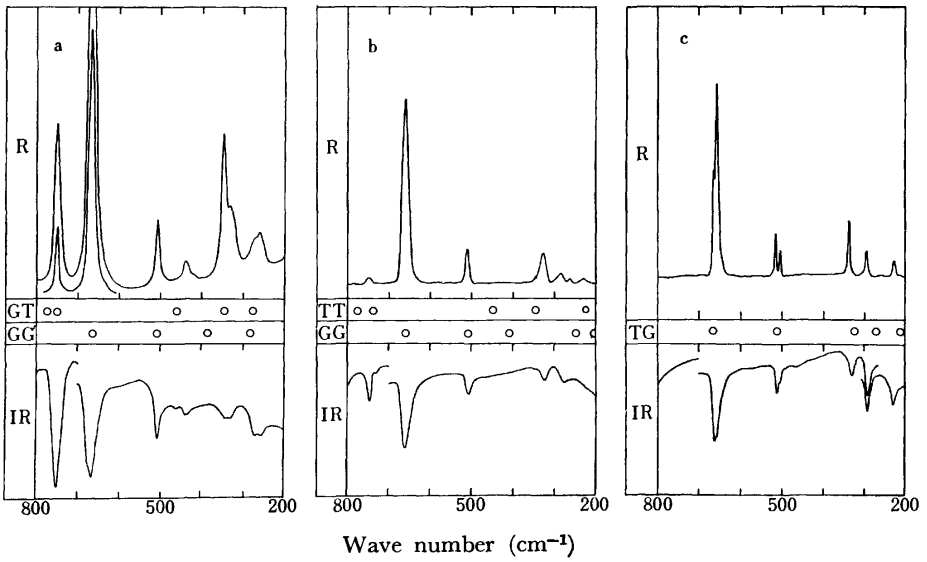

Fig. 3. Comparison of the observed and calculated frequencies of 2-chloroethyl methyl ether.
a: Liquid, b: glass, c: crystal.

parison of the observed and calculated frequencies are shown in Fig. 3.

In the crystalline state, the bands due to the CCl stretching vibration are observed at 658 and 665 cm^{-1} in the Raman spectrum and at 658 and 663 cm^{-1} in the infrared spectrum, the doublet being ascribed to the crystal field splitting. These frequencies indicate clearly that the OC–CCl axis is in the *gauche* conformation.[9] Figure 3 shows that the observed frequencies in the skeletal deformation region are explained only by the TG form. This conclusion agrees with the result of the previous study by Hayashi.[7]

In the glassy state, the bands due to the CCl stretching vibration of the *trans* OC–CCl axis appear at 748 cm^{-1} in the Raman spectrum and at 746 cm^{-1} in the infrared spectrum. The Raman band observed as a shoulder at 346 cm^{-1} is assigned to either one or both of the TT and GT forms. However, the bands assignable only to the TT or GT form are not observed definitely in the spectra. The Raman band at 264 cm^{-1} and the infrared band at 266 cm^{-1} are assigned only to the GG form. Thus, in the glassy state, the TG and GG forms and either one or both of the TT and GT forms exist. The TG form is dominant as seen from the relative band intensities.

The liquid-state spectra exhibit more bands than the glassy-state spectra. In the region below 550 cm^{-1}, the skeletal deformation bands of the individual rotational isomers are clearly observed; the bands at 507, 329, and 273 cm^{-1} are assigned to the TG form,** those at 493, 421, and 261 cm^{-1} to the GG form, those at 463, 348, and 282 cm^{-1} to the GT form, and those at 438 and 348 cm^{-1} to the TT form.

** The band at 273 cm^{-1} shifts to 285 cm^{-1} in the glassy state and to 295 cm^{-1} in the crystalline state. The result of the normal coordinate treatment indicates that the CH_2–CH_2 torsion contributes to this vibration to some extent, making the frequency shift upward on solidification. Similar frequency shifts are observed for the bromide (262 cm^{-1} in the liquid state and 287 cm^{-1} in the crystalline state) and the iodide (248 cm^{-1} in the liquid state and 276 cm^{-1} in the crystalline state).

Table 4. Rotational isomers of 2-halogenoethyl methyl ethers

	$CH_3OCH_2CH_2Cl$	$CH_3OCH_2CH_2Br$	$CH_3OCH_2CH_2I$
Gas	TG GG TT GT	—	—
Liquid	TG GG TT GT	TG GG TT GT	TG GG TT GT
Glass	TG GG TT[a] GT[a]	TG GG TT GT	TG GG TT GT
Crystal	TG	TG	TG

a) Either one or both of the TT and GT forms exist.

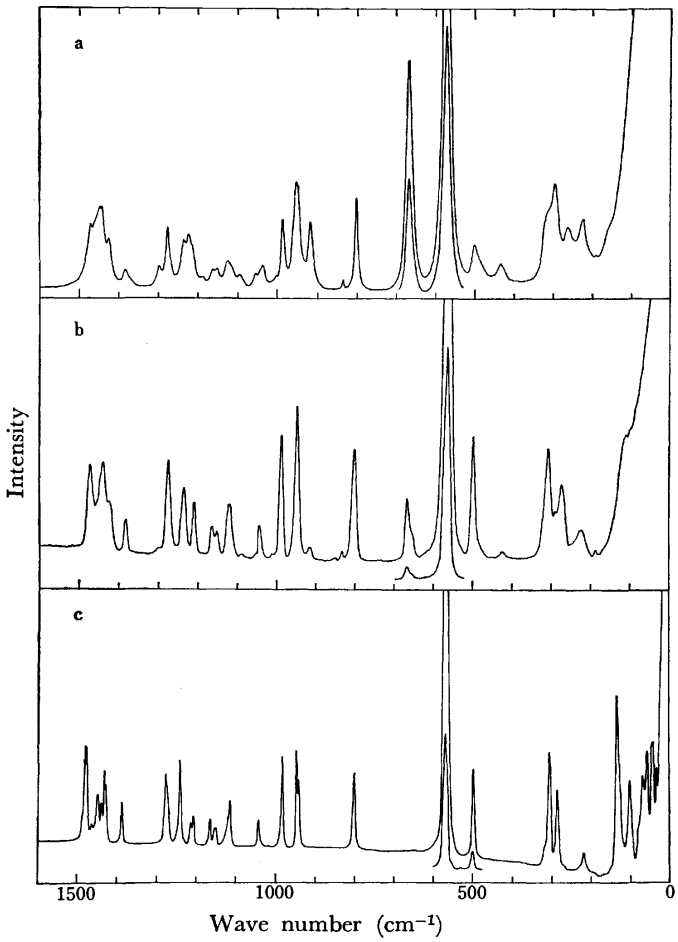

Fig. 4. Raman spectra of 2-bromoethyl methyl ether.
a: Liquid, b: glass, c: crystal.

In the gaseous state, the number of the observed bands is essentially the same as that in the liquid state, indicating the coexistence of the four forms of TG, GG, TT, and GT. However, the relative intensities of several bands are remarkably different between the two states. It is evident from Figs. 1 and 2 that the bands of the TT and GT forms become relatively stronger than those of the TG and GG forms in going from the liquid to the gas. This intensity alteration will be discussed later.

The existence of the GG′ form is unlikely. The result of the normal coordinate treatment for the GG′ form shows that a band due to the vibration of 385 cm^{-1} would be detectable in the Raman spectrum, if this form existed, since the mode of this vibration is a quasi-totally symmetrical deformation of the molecular skeleton. However, no Raman band is actually observed in the region 360—400 cm^{-1} in the liquid or gaseous state.

2-Bromoethyl Methyl Ether. The Raman and infrared spectra are shown in Figs. 4—6. A comparison of the observed and calculated frequencies shows that the spectra in the crystalline state can be explained only by the TG form. In the glassy-state spectra, there appear the bands which are assigned only to the GT form (914 and 669 cm^{-1}), TT form (658, 427, and 292 cm^{-1}), and GG form (482 cm^{-1}). The liquid-state spectra exhibit a similar spectral pattern but considerably different relative intensities. Thus, the four forms of TG, GG, TT, and GT are found to coexist in the glassy and liquid states.

2-Iodoethyl Methyl Ether. The Raman and infrared spectra are shown in Figs. 7—9. A comparison of the observed and calculated frequencies shows that the spectra in the crystalline state are explained only by the TG form, similarly to the cases of the chloride and the bromide. In the glassy- and liquid-state spectra, additional bands appear which are assigned only to the GT form (907 and 441 cm^{-1}), TT form (420 cm^{-1}) and GG form (469 and 397 cm^{-1}). Accordingly, the four forms of TG, GG, TT, and GT are found to coexist in the glassy and liquid states.

Temperature Dependence of the Raman Spectra in the Liquid State. The liquid-state Raman spectra measured at high and low temperatures are shown in Fig. 10. For the chloride, the relative intensities of the bands at 507, 329, and 273 cm^{-1} which are assigned to the TG form are strikingly stronger at the lower temperature. On the other hand, the band at 923 cm^{-1} assigned to the GT form loses its intensity as temperature is lowered. Similar spectral changes are observed for the bromide and the iodide; the bands assigned to the TG form of the bromide at 500, 307, and 262 cm^{-1} and that of the iodide at 489 cm^{-1} become stronger and the band assigned to the GT form of the bromide at 918 cm^{-1} and that of the iodide at 909 cm^{-1} become weaker as temperature is lowered. These spectral observations indicate that for the three molecules in common the TG form is the most stable and the GT form is the least stable in the liquid state.

In the glassy state, the bands of the TG form is dominant and those of the GT form are further weaker than in the cooled-liquid state. This spectral feature is consistent with the conformational stability obtained for the liquid state.

Discussion

The following results were obtained for the three halogenoethers studied in this work. (1) Only the TG form exists in the crystalline state. (2) In the glassy

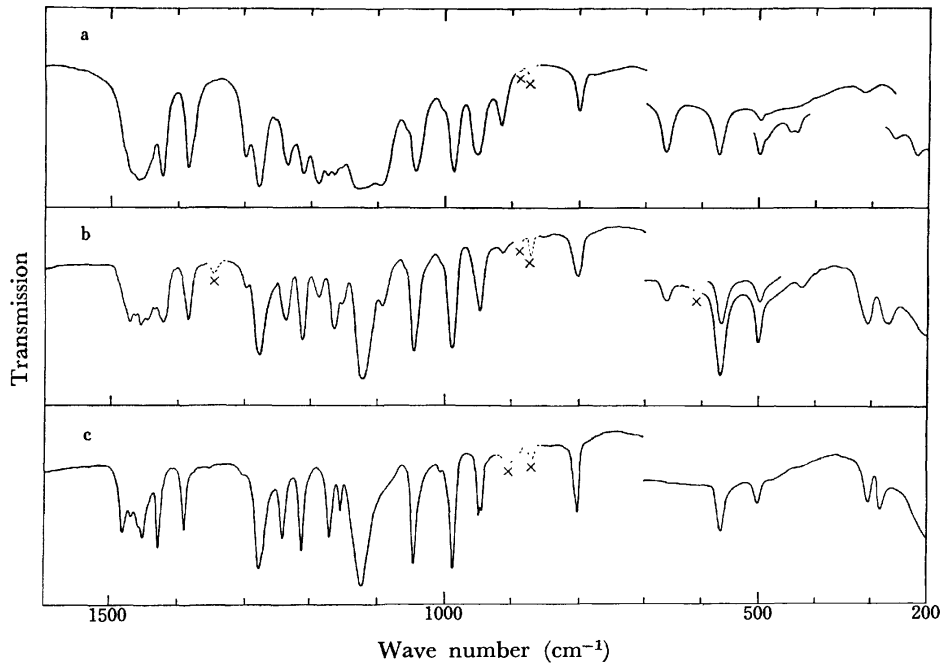

Fig. 5. Infrared spectra of 2-bromoethyl methyl ether.
a: Liquid, b: glass, c: crystal. ×: Bands due to impurities.

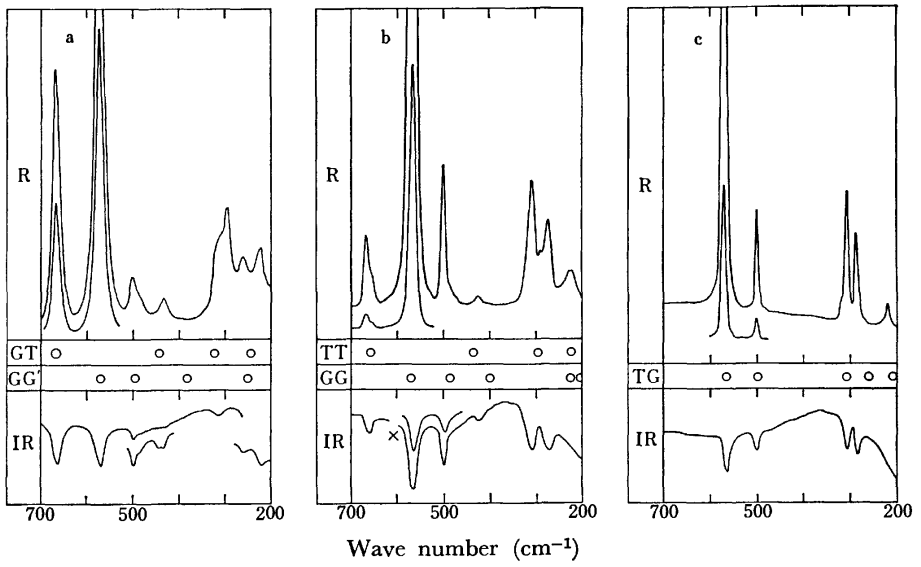

Fig. 6. Comparison of the observed and calculated frequencies of 2-bromoethyl methyl ether.
a: Liquid, b: glass, c: crystal. ×: Band due to impurity.

and liquid states, the GG, TT, and GT forms coexist in addition to the TG form. (3) The TG form is the most stable and the GT form is the least stable in the liquid state.

The stability of the *trans* conformation about the CO–CC axis over the *gauche* conformation is consistent with the results obtained for ethyl methyl ether,[10–12] diethyl ether,[13,14] and longer ethers.[1,2] The enthalpy difference between the *trans* and *gauche* conformations has been obtained as 1.1—1.5 kcal/mol for the former two ethers.

The OC–CX axis was found to be in the *gauche* conformation in the most stable isomer in the liquid state. This result may be compared with the previous findings that the *gauche* conformation about the CC–CX axis in butyl halides is more stable than the *trans* conformation in the liquid state[6] and that the *gauche* conformation about the OC–CC axis in longer chain ethers is as stable as the *trans* conformation in the liquid state.[2]

A comparison of the liquid-state Raman spectra of the three halogenoethers (Figs. 1, 4, and 7) indicates the systematic variation of the intensity ratio of the CX stretching band assigned to the *trans* OC–CX conformation to that assigned to the *gauche* OC–CX conformation. Namely, the intensity ratio, *I(trans)/I(gauche)*, is the smallest for the chloride and is the largest for the iodide. This observation suggests that the stability of the *trans* OC–CX conformation relative to that of the

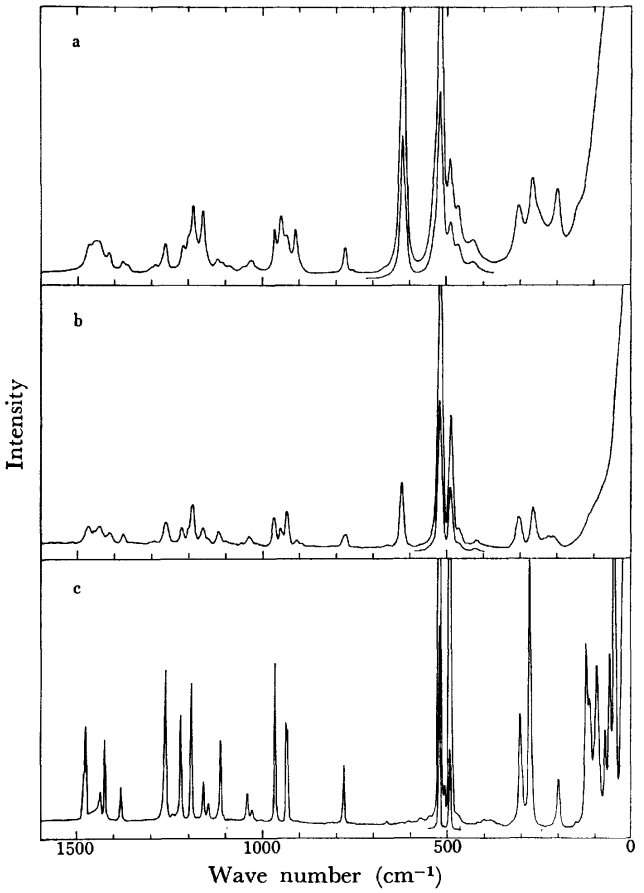

Fig. 7. Raman spectra of 2-iodoethyl methyl ether.
a: Liquid, b: glass, c: crystal.

gauche OC–CX conformation is larger in a molecule with a heavier halogen atom. The steric hindrance between the methylene group and the halogen atom accounts, at least in part, for the difference in conformational stability.

Each of the three halogenoethers contains two polar groups, the oxygen and halogen atoms, in a molecule. The five possible molecular forms are classified into two types on the basis of the polarity of the molecule. By assuming a simple vector summation, the dipole moment μ of the molecule is given by

$$\mu^2 = \mu_{CX}^2 + \mu_{COC}^2 - (2/\sqrt{3})\mu_{CX}\mu_{COC}$$

for the TT, GT, and GG′ forms and

$$\mu^2 = \mu_{CX}^2 + \mu_{COC}^2 + (2/\sqrt{3})\mu_{CX}\mu_{COC}$$

for the TG and GG forms, where μ_{CX} and μ_{COC} are the dipole moments of the CX and COC groups, respectively, and the all bond angles are assumed to be tetrahedral. Accordingly, the TT, GT, and GG′ forms are less polar and the TG and GG forms are more polar. For the chloride, as seen from Figs. 1 and 2, the bands assigned to the TT and GT forms (less polar) become relatively stronger than those of the TG and GG forms (more polar) in going from the liquid to the gas. The intensity ratio of the 751 cm^{-1} band to the 666 cm^{-1} band is reversed between the two states. These observations are consistent with the theoretical expectation that less polar conformations are better stabilized in less polar solvents or gas and that more polar conformations are better stabilized in more polar media.[15] It is thus clear that the *trans* OC–CX conformation of the halogenoethers is more favored in the gaseous state than in the liquid state. Similar intensity variations are observed in the spectra of the cyclohexane solution and the acetone solution.

In conclusion, the rotational isomerism of 2-halogenoethyl methyl ethers was determined from the vibrational s ectra. The satisfactory transferability of the force

constants from the ethers and the alkyl halides to the halogenoethers was also shown. These conclusions confirm that the combination of the systematic measurements of vibrational spectra and the systematic calculations of normal vibrations is a reliable method for studying the rotational isomerism of chain molecules. Theoretical studies on the stabilities of rotational isomers should be made on the basis of accumulated experimental data, by taking account of intramolecular and intermolecular interactions.

Erratum

Erratum in Table 2 of Part V.[1] For 764 M,sh listed in the column of R of Crystal read 764 M.

The Isotope Effect on the Quenching of the Cadmium Triplet State by Methanol

Shigeru TSUNASHIMA, Kuniko MORITA, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 15, 1976)

The isotope effect on the Cd-photosensitized emission of methanol has been investigated using CH_3OH, CH_3OD, CD_3OH, and CD_3OD. The relative quenching efficiencies for the 326.1 nm resonance line were 1 : 0.3 : 0.9 : 0.3 in the order of CH_3OH, CH_3OD, CD_3OH, and CD_3OD. The emission intensities from the intermediate complex between an excited cadmium and methanol were also measured. The band-shape was not affected by the substitution of D atoms. The intensity ratio was 1 : 3.1 : 1.1 : 3.1 in the order of CH_3OH, CH_3OD, CD_3OH, and CD_3OD, when the incomplete quenching was corrected. These results were explained by the following quenching processes:

$$Cd^* + CH_3OH \rightarrow Cd\cdots H\cdots O\,CH_3$$
$$\rightarrow Cd\cdots O\langle^{H}_{CH_3}$$

where Cd* represents $Cd(^3P_1)$ and/or $Cd(^3P_0)$. The D/H kinetic isotope effect on the former process was estimated to be 0.3

Recently, Luther *et al.* found a large isotope effect on the quenching of $Hg(^3P_0)$ atoms by methanol using CH_3OH, CH_3OD, CD_3OH, and CD_3OD; for example, the quenching efficiency of CH_3OH is about ten times that of CD_3OD.[1] They also found a HgH formation from CH_3OD, suggesting that the cleavage of the C–H bond in methanol is an important process, as is the cleavage of the O–H bond.[1] This observation, however, contradicts the reaction mechanism widely belived in which almost all the cleavage occurs at the O–H bond in the reaction of methanol photosensitized by triplet mercury, although the bond strength of the C–H is smaller than that of the O–H in methanol.[2]

In the case of the Cd-photosensitized reaction, the isotope effect was also found, as was briefly reported in a previous short communication; for example, the quenching efficiency of CH_3OH for the 326.1 nm resonance line was three times that of CD_3OD and CH_3OD.[3] Based on several assumptions, a reaction mechanism was proposed which explains the observed isotope effect on the quenching of the 326.1 nm resonance line and on the band emission at 395 nm.[3] This mechanism, however, was not consistent with the mechanism proposed by Luther *et al.* for the mercury photosensitization.

The present paper will report the details of the previous short communication, together with new results obtained with CD_3OH. The use of CD_3OH was expected to confirm some of the assumptions made previously.

Experimental

The apparatus and the procedure were essentially the same as those previously described.[4,5] The reaction cell and the cadmium lamp were kept in a furnace at 220±1 °C. Since Pyrex glass is known to be reactive to methanol vapor,[6] the use of Pyrex glass was avoided in constructing the vacuum lines which come in contact with methanol vapor. In order to minimize the effect of the possible D/H exchange reaction on the wall, the reaction system was treated with the same isotopic methanol before every run. All the experiments were carried out in the presence of an excess amount of argon. In order to minimize the pressure dependence of the absorption of the 326.1 nm resonance line, the total pressure in the reaction cell was kept constant.[4,5] The pressure of methanol was changed between 4 and 15% of the total pressure.

The isotopic methanols, CH_3OD, CD_3OH, and CD_3OD, were purchased from Merck Sharp and Dohme of Canada, Ltd. The nominal isotopic purities were more than 99%. All of the methanols were used after being degassed at −80 °C. High purity argon (Jonan Kyodo Sanso) was used after having been passed through a trap containing a molecular sieve, 4A, kept at −120 °C and a reduced copper furnace at 300 °C.

Results

In order to estimate the quenching efficiency for the $5^3P_1 \rightarrow 5^1S_0$ resonance line, the emission intensities at 326.1 nm were measured as a function of the pressure of methanol. The Stern-Volmer plots are shown in Fig. 1, where $I^\circ_{326.1}$ and $I_{326.1}$ are the emission intensities at 326.1 nm in the absence and in the presence of methanol respectively. Since the emission intensities were dependent on the irradiation time because of the accumulation of the reaction products, the $I_{326.1}$ values were obtained by extrapolation to zero irradiation time.

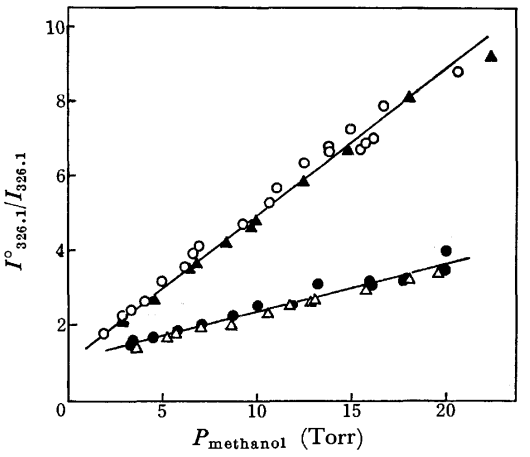

Fig. 1. Stern-Volmer plots for the quenching of the 326.1 nm resonance line by CH_3OH(○), CH_3OD(●), CD_3OH(▲), and CD_3OD(△).

Table 1. Observed isotope effect in the quenching of the 326.1 nm resonance line and the emission intensity at 395 nm

	CH_3OH	CH_3OD	CD_3OH	CD_3OD
H. Q. P. (Torr)[a]	2.4±0.2	7.6±0.7	2.7±0.1	8.0±0.3
Intercept (Torr)[b]	7.4±0.4	8.0±0.4	8.1±0.5	8.1±0.4
Slope (×100)[b]	3.9±0.4	4.3±0.5	4.6±0.4	4.5±0.4
Intensity[c]	1	3.1±0.3	1.1±0.1	3.1±0.3

a) Half-quenching pressure. b) Intercepts and slopes of the straight lines in Fig. 3. c) Total emission intensity at 395 nm, corrected for the incomplete quenching; see Text.

The effect of the argon pressure on the value of $I^{\circ}_{326.1}/I_{326.1}$ was negligibly small. The plots for the $I^{\circ}_{326.1}/I_{326.1}$ ratios *vs.* the methanol pressure lie on a straight line for each methanol. The half-quenching pressures were obtained from the slopes of the straight lines in Fig. 1 and are listed in Table 1.

As was stated in a previous paper,[5] a new band emission at 395 nm was obtained when the Cd–methanol mixture was irradiated with the 326.1 nm resonance line. The emission profile was not affected by the substitution of D atoms. The emission intensities, however, depended on the total pressure and the pressure of methanol. Figure 2 shows the results obtained with CD_3OD. Similar plots were also obtained with CH_3OH, CH_3OD, and CD_3OH. The values of $I_{326.1}[Me]/I_{395}$ were nearly independent of the methanol pressure, but depended on the total pressure, as is shown in Fig. 3. Here, I_{395} is the emission intensity at 395 nm and [Me] is the pressure of methanol. The values of the intercepts and the slopes of the straight lines in Fig. 3 are listed in Table 1.

The areas of the emission band at 395 nm were compared with that obtained with CH_3OH at the same total pressure and the pressure of methanol. When the incomplete quenching of the resonance line was corrected, the ratios of the total emission intensity at 395 nm were nearly independent of the total pressures (35—120 Torr) and also of the pressures of methanol (5—20 Torr). The ratios thus obtained are listed in Table 1.

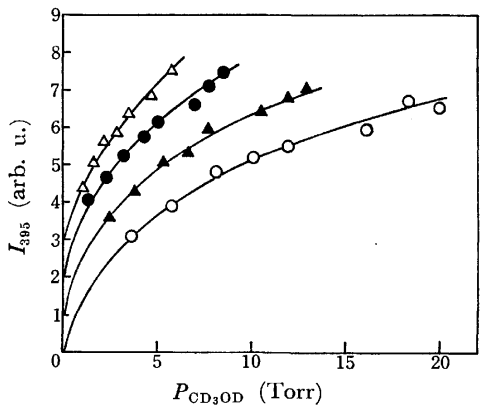

Fig. 2. The intensity of emission at 395 nm from the Cd-CD_3OD system as a function of the pressure of CD_3OD. The total pressures are 121(○), 80(▲), 53(●), and 35(△) in Torr. The plots are displaced upwards by one unit of I_{395} for clarity in the above order of the total pressure.

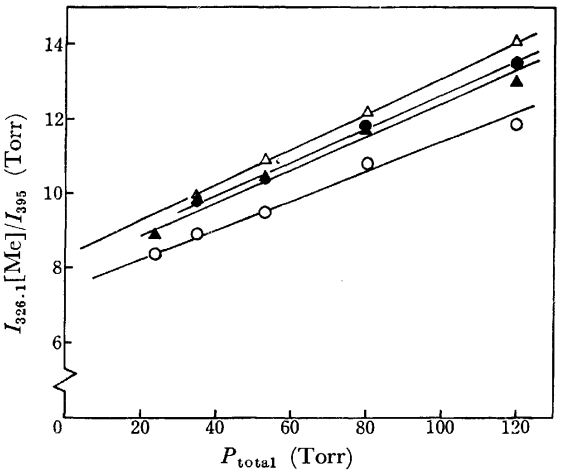

Fig. 3. Plots of $I_{326.1}$ [Me]/I_{395} as a function of the total pressure for CH_3OH(○), CH_3OD(●), CD_3OH(▲), and CD_3OD(△).

Discussion

Reaction Mechanism. As was shown in a previous paper,[4] the Stern-Volmer plots for the quenching of the Cd resonance line at 326.1 nm by ammonia were not linear at a low pressure of ammonia. In the cases of methanol, however, the Stern-Volmer plots give straight lines, as is shown in Fig. 1. This suggests that the reaction mechanism for the 326.1 nm and the 395 nm emissions is simpler than that considered in the case of ammonia.[4] Consequently, the following simplified reaction mechanism may be considered to explain the results obtained here:

$$Cd + h\nu(326.1) \longrightarrow Cd(^3P_1), \quad 1$$

$$Cd(^3P_1) \longrightarrow Cd + h\nu(326.1), \quad 2$$

$$Cd(^3P_1) + M \rightleftharpoons Cd(^3P_0) + M, \quad 3$$

$$Cd^* + Me \longrightarrow Products, \quad 4$$

$$Cd^* + Me \longrightarrow CdMe^*, \quad 5$$

$$CdMe^* \longrightarrow Cd + Me + h\nu(395), \quad 6$$

$$CdMe^* + Me \longrightarrow Cd + 2Me, \quad 7$$

$$CdMe^* + Ar \longrightarrow Cd + Me + Ar. \quad 8$$

Here, Cd* represents $Cd(^3P_1)$ or $Cd(^3P_0)$. Because the equilibrium between $Cd(^3P_1)$ and $Cd(^3P_0)$ is easily established under the present experimental conditions,[7] we cannot discriminate the reactions of these two states. The stationary concentration of $Cd(^3P_0)$ may be approximated as $(k_3/k_{-3})[Cd(^3P_1)]$.[4] CdMe* is a complex between Cd* and methanol(Me), which can emit

the band emission at 395 nm. In the case of ammonia, the formation of an "unstabilized" complex has been assumed; this complex dissociates into the triplet cadmium and methanol or is deactivated to an emissible complex through collision.[4] In the case of methanol, however, it is not necessary to assume the formation of the "unstabilized" complex, since the Stern-Volmer plots give a straight line. If the "unstabilized" complex is formed even in the case of methanol, the lifetime of the "unstabilized" complex must be long enough to be stabilized through collision under the present experimental conditions.

The steady-state treatment of the above mechanism gives the following relation for the quenching of the 326.1 nm resonance line:

$$I^{\circ}_{326.1}/I_{326.1} = 1 + k_q[\mathrm{Me}]/k_2. \quad (1)$$

Here, $I^{\circ}_{326.1}$ and $I_{326.1}$ represent the emission intensities observed at 326.1 nm in the absence and in the presence of methanol respectively. k_q is the sum of the quenching rate constants and is k_4+k_5 in the case of Cd*= Cd($^3P_1$). When Cd* represents a mixture of Cd($^3P_1$) and Cd($^3P_0$), k_4 and k_5 should be replaced by $k_4^1+(k_3/k_{-3})k_4^0$ and $k_5^1+(k_3/k_{-3})k_5^0$ respectively. Here, the superscripts 1 and 0 stand for the reactions of Cd($^3P_1$) and Cd($^3P_0$) respectively.

From the values of the half-quenching pressure listed in Table 1, the relative values of k_q can be estimated; they are listed in Table 2. The isotope effect on the efficiency of methanol has been observed for the quenching of Hg($^3P_0$) by Luther *et al.*[1] The relative values obtained by them are compared in Table 2 with those obtained in this study. In contrast with the case of Hg($^3P_0$)-photosensitization, the quenching efficiency of CD_3OD is 0.3 times that of CH_3OH and is close to that of CH_3OD.

Table 2. Isotope effects in the reaction of methanol[a]

	CH_3OH	CH_3OD	CD_3OH	CD_3OD
k_q(Cd)	1	0.31±0.04	0.88±0.10	0.30±0.03
k_q(Hg)[b]	1	0.31	0.093	0.088
k_5	1	0.93±0.09	0.91±0.09	0.91±0.09
k_8/k_6	1	1.0 ±0.1	1.1 ±0.1	1.1 ±0.1

a) Relative to the values obtained with CH_3OH. b) From Ref. 1.

The imprisonment lifetime of Cd($^3P_1$) is not known under the present experimental conditions. Breckenridge *et al.* have estimated the ratio of the imprisonment lifetime to the natural lifetime of Cd($^3P_1$) in the presence of argon.[8] According to their estimation, the ratio is 1.09 at 260 °C and increases with an increase in the vapor pressure of cadmium. In the present experiment, a smaller imprisonment lifetime may be expected, since the vapor pressure of cadmium in this study is lower than that in their studies.[8] When the lifetime of Cd($^3P_1$) in the present study is assumed to be equal to the natural lifetime, *i.e.*, 2.3×10^{-6} s, the quenching efficiency of CH_3OH can be estimated to be 0.4 Å^2. Because of the rough estimation, this value should be accepted as un upper limit. The cross section of methanol for quenching triplet cadmium is about twenty times smaller than that for quenching triplet mercury.[9]

For the intensity of the emission at 395 nm, I_{395}, the following equation can be derived from the above reaction mechanism:

$$I_{326.1}[\mathrm{Me}]/I_{395} = \alpha(k_2/k_5)(1+k_8[\mathrm{Ar}]/k_6+k_7[\mathrm{Me}]/k_6). \quad (2)$$

The factor, α, depends on the experimental conditions; the geometry of the apparatus, the slitwidth, the efficiency of the monochromator, and the sensitivity of the photomultiplier used. Substituting [Ar]=[M]−[Me] into Eq. 2, where [M] represents the total pressure, we can obtain Eq. 2′:

$$I_{326.1}[\mathrm{Me}]/I_{395} = \alpha(k_2/k_5)(1+k_8[\mathrm{M}]/k_6+(k_7-k_8)[\mathrm{Me}]/k_6). \quad (2')$$

As was stated in the Results section, the observed values of $I_{326.1}[\mathrm{Me}]/I_{395}$ are independent of the change in the pressure of methanol under the same total pressure. Therefore, the third term in the right-hand side of Eq. 2′ may be ignored. From the intercepts and the slopes of the straight lines in Fig. 3, the relative values of k_5 and k_8/k_6 can be estimated; they are listed in Table 2. As is shown in Table 2, the isotope effects on k_5 and k_8/k_6 are negligibly small.

Let us define quantum efficiency of the band emission at 395 nm as the number of photons emitted from the intermediate complex, CdMe*, per quenched Cd($^3P_1$) atom. Then this efficiency, Φ_{em}, may be expressed as follows:

$$\Phi_{em} = (k_5/k_q)/(1+k_8[\mathrm{M}]/k_6). \quad (3)$$

The quantum efficiency of the emission thus defined should be proportional to the emission intensity at 395 nm. Since the isotope effects on k_5 and k_8/k_6 were negligibly small, as is shown in Table 2, the total emission intensity should be inversely proportional to the quenching efficiency. This is indeed the case, as is shown in Tables 1 and 2. Thus, it may be said that the isotope effects observed in the Cd-photosensitized reaction of methanol are mainly due to the isotope effect on the quenching process.

Isotope Effect on the Quenching Process. In a previous short communication, the following three quenching processes were considered in an attempt to explain the results obtained with CH_3OH, CH_3OD, and CD_3OD:[3]

$$\mathrm{Cd}^* + \mathrm{CH_3OH} \rightarrow \mathrm{Cd\cdots H\cdots OCH_3} \quad (a)$$

$$\rightarrow \mathrm{Cd\cdots H\cdots CH_2OH} \quad (b)$$

$$\rightarrow \mathrm{Cd\cdots O\langle^{H}_{CH_3}} \quad (c)$$

The D/H kinetic isotope effects on the (a) and (b) processes are expected to be large. On the other hand, the effect on the (c) process is expected to be small because of the secondary effect. The band emissions have been observed at about 390 nm in the Cd-photosensitized reactions of water and ethers.[5] This fact suggests that the (c) process corresponds to Reaction 5, *i.e.*, the formation of a radiative intermediate complex. In fact, a very small isotope effect on k_5 was observed, as is shown in Table 2.

The observed quenching efficiency, k_q, may be set as equal to the sum of k_a, k_b, and k_c. If the secondary isotope effect can be neglected, we should obtain the following relation between the quenching efficiencies for the isotopic methanol:

$$k_{q,CH_3OH} + k_{q,CD_3OD} = k_{q,CH_3OD} + k_{q,CD_3OH}. \quad (4)$$

As is shown in Table 2, Eq. 4 is satisfied within the limits of experimental error. Since $k_{q,CH_3OH} \simeq k_{q,CD_3OH}$ and $k_{q,CH_3OD} \simeq k_{q,CD_3OD}$, the (b) process may not be important compared with the (a) and (c) processes. Moreover, the quantum yield of the emission at 395 nm has been estimated to be 0.0032.[5] The smallness of the quantum yield of the emission suggests that the (c) process cannot be the main process. Consequently, it may be said that the observed isotope effect on k_q is mainly due to the isotope effect on k_a. The D/H kinetic isotope effect on k_a can be estimated to be about 0.3.

Theoretical Estimation of D/H Kinetic Isotope Effect. The D/H kinetic isotope effect on the (a) process can be estimated by the use of the theory of the kinetic isotope effect:[10]

$$k_D/k_H = \exp\left[-(hc/2kT)\left\{\sum^{3n^\dagger-7}(\nu_i^\dagger(D)-\nu_i^\dagger(H)) - \sum^{3n-6}(\nu_i(D)-\nu_i(H))\right\}\right]. \quad (5)$$

Here, $\nu_i(D)$ and $\nu_i(H)$ are vibrational frequencies in cm^{-1}. The superscript † indicates the transition state. The h, c, k, and T symbols have their conventional significance. Equation 5 has been derived under a heavy-molecule approximation; *i.e.*, the changes in the molecular mass and moment of inertia have no significant influence upon the isotopic rate ratio.[10] The term of the symmetry-number ratio can be set as equal to unity in this reaction system, and so it is omitted in Eq. 5. An approximation, $1-\exp(-hc\nu/kT) \simeq 1$, has already been applied in Eq. 5. When the vibrational frequency is less than 1000 cm^{-1}, however, it is necessary to include the factor of $1-\exp(-hc\nu/kT)$. When the secondary isotope effect can be neglected, the contribution of all the vibrations except for the O–H stretching and two bending frequencies disappear in the reactant part of Eq. 5. Similarly, only a Cd–H–R stretching and two bending frequencies can contribute in the transition state. Here, R denotes the CH_3O radical.

In order to estimate the vibrational frequencies in the transition state, the following three models are considered:

Model a: The Cd atom is located apart from the methanol molecule and has no effect on the vibrational frequencies in the transition state. The reacting hydrogen atom is located in the neighborhood of the R radical. Thus, the two bending frequencies in the transition state may be set as equal to those in the reactant.

Model b: Much as in Model a, the Cd atom is located far from the methanol molecule, but the R–H bond is stretched so that the two bending frequencies in the transition state can be approximated as zero.

Model c: The R–H bond is stretched further, and the reacting hydrogen atom is located in the neighborhood of the Cd atom. The stretching frequency in the transition state is approximated by the Cd–H stretching. The two bending frequencies are also approximated as zero. In Models b and c the term which contains the two bending frequencies in the transition state may be approximated by m_D/m_H.[10] Here, m_D and m_H are the masses of the D and H atoms respectively.

Table 3. Frequencies used in the calculation of Eq. 5[a]

Atom transferred		H	D
O–H	Stretching	3682	2720
	Bending	1340	869
	Twisting	270[b]	191[c]
C–H	Stretching	2977	2227
	Bending	1430	1055
Cd–H	Stretching	1430[d]	1011[c]

a) In cm^{-1} unit. From H. D. Noether, *J. Chem. Phys.*, **10**, 693 (1942) unless otherwise cited. b) G. Herzberg, "Molecular Spectra and Molecular Structure II, Infrared and Raman Spectra of Polyatomic Molecules," D. Van Nostrand Co., Princeton (1945). c) Calculated using $\nu(D) = (1/\sqrt{2})\nu(H)$. d) G. Herzberg, "Molecular Spectra and Molecular Structure I, Spectra of Diatomic Molecules," D. Van Nostrand Co., Princeton (1950).

Table 4. Calculated D/H kinetic isotope effect

	Process (a)	Process (b)
Model a	0.25	0.33
Model b	0.16	0.22
Model c	0.29	0.41
Observed	0.31±0.04	

On the base of the above assumptions, the D/H kinetic isotope effect on the (a) process was calculated using the frequency assignments shown in Table 3. The results are listed in Table 4. For comparison, Table 4 also contains the results of a similar calculation of the (b) process. As is shown in Table 4, the observed D/H isotope effect on the (a) process is close to the case of Model c; *i. e.*, the reacting hydrogen atom is located in the neighborhood of the Cd atom in the transition state.

The present study suggested that the (a) process is the predominant process compared with the (b) and (c) processes in the Cd-photosensitized reaction of methanol. This coincides with the results obtained by Knight *et al.* and Pottie *et al.* in the case of mercury photosensitization.[2] However, it is different from the results obtained by Luther *et al.*[1]

Chromium(III) Complexes with Amino Acids. III. Chromium(III) Complexes with Acidic, Basic and Carbamoyl Amino Acids

Hisaya Oki and Yasuko Takahashi

Department of Chemistry, Faculty of Education, Fukui University, Fukui 910

(Received December 6, 1976)

Syntheses by both the isothermal matrix in a solid state and by the usual solution method have been tried for chromium(III) complexes with L- and DL-asparagine, L- and DL-aspartic acid, L- and DL-glutamine, L- and DL-glutamic acid, L- and DL-lysine, and L-ornithine. $[Cr(L\text{-}aspNH_2)_3]\cdot 2H_2O$, $[Cr(DL\text{-}aspNH_2)_3]\cdot 3H_2O$, $(NH_4)_2[Cr(L\text{-}asp)_2][Cr(D\text{-}asp)_2]\cdot 4H_2O$, and $(+)[Cr(L\text{-}lys)_2(NH_3)(H_2O)]Cl\cdot 4H_2O$ were obtained by the matrix method in the solid state, while $[Cr(L\text{-}aspNH_2)_3]\cdot 2H_2O$, $[Cr(DL\text{-}aspNH_2)_3]\cdot 2H_2O$, and $(+)[Cr(L\text{-}lys)_2(NH_3)(H_2O)]Cl\cdot 4H_2O$ were prepared by the usual solution method. The preparation of chromium(III) complexes with other amino acids was not successful. A new type of complex of chromium(III) containing terdentate DL-aspartic acid and a new mixed chromium(III) complex containing three different ligands (L-lysine, ammine, and aqua) were prepared.

Chromium(III) complexes containing terdentate amino acids have not yet been isolated. Amino acids which act as terdentate ligands are classified into amino dicarboxylic (acidic), diamino carboxylic (basic), and carbamoyl amino carboxylic acids (carbamoyl amino acid). In the chromium(III) complexes with L-asparagine,[1] L-aspartic acid,[2] L-glutamine, or L-lysine,[3] all the amino acids work as bidentate ligands. In the present work, attempts were made to prepare chromium(III) complexes with α-amino acids (L- and DL-aspartic acid, L- and DL-glutamic acid, L-ornithine, L- and DL-lysine, L- and DL-asparagine, and L- and DL-glutamine) by applying the methods described in Ref. 4, and to study the difference in complexation among neutral amino acids,[4,5] acidic, basic, and carbamoyl amino acids.

Experimental

Preparation of Chromium(III) Complexes. The methods of preparation are essentially the same as those reported in our previous papers.[4,5]

a) Preparation by Means of Solid State Reaction: The reaction temperature, the mole ratios of amino acids to the starting complex, $[Cr(NH_3)_6](NO_3)_3$, and the reaction time are listed in Table 1.

The reaction products with L- and DL-asparagine were dissolved in water, after which the solutions were kept standing at room temperature for one or two days. Tris(L-asparaginato) and tris(DL-asparaginato)chromium(III) were obtained as pink powder. By the same method, a complex with DL-aspartic acid was obtained as ammonium bis(DL-aspartato)chromate(III) after the solution had stood for two weeks. When the reaction product with L-lysine monohydrochloride was kept standing at room temperature for one or two days, bis(L-lysinato)ammineaquachromium(III) chloride was obtained as pink crystals. In the case of DL-lysine, a mixture of pink powder and free amino acid was obtained. However, the desired complexes could not be separated from the mixture. From the reaction products with L-aspartic acid, L- and DL-glutamine, and L-ornithine, oily substances were obtained, and crystallizations were not successful. In the case of the L- and DL-glutamic acid, the reaction products dissolved in water were kept standing at room temperature for four or five days to give purple crystals. However, the results of the elementary analysis of these crystals were coincident with the composition of neither a tris-type nor a dihydro-bridged dimer complex.

Table 1. Mole ratios of amino acids to the starting complex, the reaction temperature, and the reaction time

Amino acid	Mole ratio	Reaction temperature (°C)	Reaction time (min)
L-Asparagine	2.5	135	60
DL-Asparagine	2.5	135	60
DL-Aspartic acid	2.5	125	120
L-Lysine	5	135	35

b) Preparation by the Reaction in Solution: Hexaamminechromium(III) nitrate (3.4 g), and L-asparagine (4.0 g) were dissolved in water (50 ml), and the mixture was heated on a water-bath until pink crystals began to appear. The pink crystals were tris(L-asparaginato)chromium(III). By the same method, a complex with DL-asparagine was precipitated as a tris-type one. Hexaamminechromium(III) nitrate (3.4 g) and L-lysine monohydrochloride (5.4 g) were dissolved in water (50 ml), and the mixture was concentrated on a water-bath to one-fifth of its orginal volume. When the resulting solution was kept standing at room temperature for one or two weeks, bis(L-lysinato)ammineaquachromium(III) chloride were gradually deposited as pink crystals. In the case of DL-lysine or L-ornithine, a mixture of pink crystals and amino acid was obtained but the pink crystals could not be separated from the mixture.

Attempts to prepare of chromium(III) complexes with other amino acids were not successful, only oily substances were obtained in those cases.

The analytical data of these complexes are given in Table 2.

Apparatus. The absorption spectra were measured with a Hitachi 139 spectrophotometer. The IR spectra were measured with a Hitachi EPI-G3 infrared spectrophotometer in Nujol mull. The CD spectra were recorded on a JASCO Model ORD/UV-5 spectrophotometer with a CD attachment.

Results and Discussion

The absorption spectra of $[Cr(L\text{-}aspNH_2)_3]$ were measured in the solid state and in a perchloric acid solution. The spectrum of $[Cr(DL\text{-}aspNH_2)_3]$ was measured in the solid state, while those of $NH_4[Cr(DL\text{-}asp)_2]$ and $[Cr(L\text{-}lys)_2(NH_3)(H_2O)]Cl$ were measured in aqueous solutions. The numerical data of their maxima are summarized in Table 3. The values of the absorption maxima of $[Cr(L\text{-}aspNH_2)_3]$ in 20%$HClO_4$ and in

a) By the solid state reaction. b) By the reaction in solution.

the solid state differ from each other. The data suggest that this complex undergoes acid hydrolysis or some other chemical reaction in perchloric acid and that the behavior is similar to that of complexes with L- and DL-alanine.[4,5] The absorption maxima of $[Cr(L\text{-}aspNH_2)_3]$ and $[Cr(DL\text{-}aspNH_2)_3]$ in the solid state are nearly the same as those for chromium(III) complexes with neutral amino acids with the *fac*-structure. Thus, the present complexes of the tris-type have the *fac*-structure.

The spectrum of $NH_4[Cr(DL\text{-}asp)_2]$ is shown in Fig. 1. It may be seen that the second absorption band gives a lower molar extinction coefficient than does the first band and that the absorption curve of this complex is nearly the same as that of the corresponding *cis*(N)-*trans*(O_5) cobalt(III) complex.[6] The complex was adsorbed on an anion exchanger (Dowex 1X8, Cl-form). When a 0.01M NaCl solution was passed through a column of the exchanger, a pink solution was eluted. The spectrum of the eluted solution agreed with that of the original complex. Further, Nessler's reaction for this complex was positive. These results indicate that an ammonia molecule was not coordinated in this complex. In the complex of DL-aspartic acid, there are two possibilities whether both L- and D-aspartic acid are contained, or either. Concerning the geometrical isomers, the former type has one *trans*- and two *cis*-forms, while the latter has one *trans*- and one *cis*-form. The possible geometrical isomers are all shown in Fig. 2.

The reaction product in the solid state with L-aspartic acid was dissolved in water, and the solution was adsorbed on an anion exchanger (Dowex 1 X8, Cl-form). Upon elution with water, one violet band was seen. By eluting with 0.01M NaCl, two pink bands were completely separated. However, the isolation of compounds from these fractions was not carried out. The violet band described above was not adsorbed on a cation exchanger (Dowex 50W X2, H-form). Therefore, this

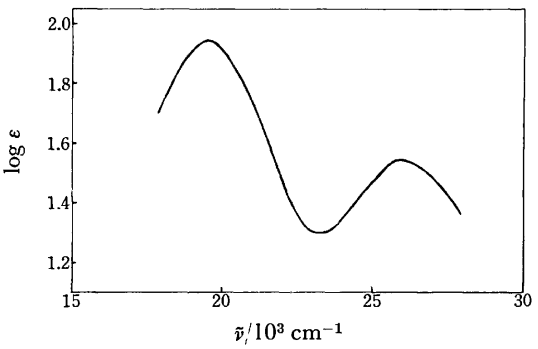

Fig. 1. The absorption spectrum of $(NH_4)_2[Cr(L\text{-}asp)_2]$-$[Cr(D\text{-}asp)_2]$.

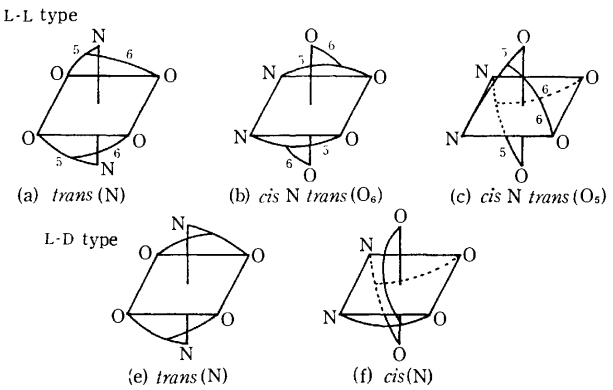

Fig. 2. The possible structures of bis(aspartato)chromate(III) ion.

band is considered to contain a noncharge species. The isolation of the compound from this fraction was also not carried out. By applying the method described above, the reaction product with DL-aspartic acid in the solid state was separated by chromatography. The results were similar to those for the complex with L-aspartic acid. Therefore, the chromium(III) ion was coordinated with two ions of either L- or D-aspartic acid in the bis(DL-aspartato)chromate(III) complex. The spectrum for the ammonium bis(DL-aspartato)-chromate(III) which had been eluted from the ion exchanger agreed with that of the first eluted band of the complex with L-aspartic acid. This complex shows no CD. Therefore, the bis(DL-aspartato)chromate(III) complex was concluded to consist of a racemic structure of $NH_4[Cr(L\text{-}asp)_2]$ and $NH_4[Cr(D\text{-}asp)_2]$. The geometrical structure of the first eluted band of the *cis*-type in the bis(L-aspartato)cobaltate(III) ion has been assigned to *cis*(N)-*trans*(O_5) [Fig. 2 (c)];[6] therefore, the structure of the bis(L-aspartato)chromate(III) ion is assigned to (c) in Fig. 2.

The absorption and CD spectra of $[Cr(L\text{-}lys)_2(NH_3)(H_2O)]Cl$ are shown in Fig. 3. In this complex, six geometrical isomers are possible; they are given in Fig. 4. It is obvious from Fig. 3 that the molar extinction coefficent of the first absorption band is nearly equal to that of the second absorption band, both showing no splitting. The maximum of the first absorption band of this complex is at a frequency nearly equal to those of *fac*-(amino acidato)chromium(III) complexes. The CD spectrum of this complex is shown in Fig. 3. Mizuochi *et al.*[3] reported that the bis(L-lysinato)diaquachromium(III) complex has a *cis* structure with respect to the nitrogen or the oxygen atoms of lysine. These facts lead to presume that the structure of $[Cr(L\text{-}lys)_2(NH_3)(H_2O)]^+$ has a *cis-cis* structure with respect to the nitrogen or the oxygen atoms, (f) in Fig. 4.

The CD spectra for $[Cr(L\text{-}aspNH_2)_3]$ and $[Cr(DL\text{-}aspNH_2)_3]$ were not measured, because these substances were not soluble in common solvents (H_2O, MeOH, EtOH, DMF and DMSO).

The chromium(III) complexes with acidic, basic, or

Mixture: pink crystal and amino acid. Purple: no pure purple compound.

carbamoyl amino acids were synthesized both in the solid state and in solution. These synthesized complexes are given in Table 4, together with a description of the preparation by the solution method when chromium(III) hydroxide and chromium(III) chloride are used as the starting materials as reported by Volshtein[1,2] and Mizuochi.[3] Only $(NH_4)_2[Cr(L\text{-asp})_2][Cr(D\text{-asp})_2]$ contained terdentate amino acids. Bis(L-aspartato)chromate(III) was not crystallized. Volshtein obtained $Ag_3[Cr(L\text{-asp})_3]$,[2] but the tris-asp complex was not isolated in the present work. When silver nitrate was added to solution eluted by chromatography, the tris-asp complex was not precipitated. The reason for this is not clear.

When a mixture of bis(L-lysinato)ammineaquachromium(III) chloride and L-lysine·HCl in water was heated on a water-bath, a tris-type complex was not prepared and only the starting substances were recovered. Mizuochi *et al.*[3] reported the method of preparing $[Cr(L\text{-lys})_2(H_2O)]Cl$, but not for $[Cr(L\text{-lys})_3]$. The absorption curves of crude pink complexes with DL-lysine and L-ornithine were similar to that of $[Cr(L\text{-lys})_2(NH_3)(H_2O)]Cl$; and therefore, those complexes may be bis-type complexes. Thus, the synthesis of a tris-type complex of basic amino acid seems to be difficult.

In the present work, tris(L- or DL-asparaginato)chromium(III) complexes were prepared by both methods, solid state and solution. These carbamoyl amino acids are regarded as neutral amino acids. In a previous paper, we reported that the solution containing hexaamminechromium(III) nitrate and neutral amino acid naturally neutralized during the course of reaction.[4] In the case of asparagine, the reacting solution is also expected to be naturally neutralized to yield a tris-type complex. However, tris-type complexes with L- and DL-glutamine, as well as asparagine, were not obtained. The reason for this is not clear.

No terdentate bis-type chromium(III) complex could be obtained, except for those with DL-aspartic acid. This might be due to the instability of seven- or eight-membered ring in a bis-type complex, except for the complexes of aspartic acid and asparagine.

In a previous paper,[5] we reported that the preponderance of the formation of one optical isomer is changed depending upon the kind of solvent dissolving the product of the solid state reaction; when reaction products were dissolved in methanol (+) isomers were obtained, while (−) isomers were obtained in ethanol. However, in the present work, the reaction products with amino acids used in the solid state reaction were all insoluble in ethanol. L- and DL-aspartic acid, L- and DL-lysine, L-ornithine and L-glutamine are soluble, but the other amino acids are insoluble in methanol. The complexes with L- and DL-aspartic acid, L-ornithine, and L-glutamine were prepared as oily substances. The complexes with L- and DL-lysine were obtained as pink crystals. However, the results of the elemental analysis of these complexes show a mixture of $[Cr(lys)_2(NH_3)(H_2O)]Cl$ and $[Cr(lys)_2(NH_3)_2]Cl$. These complexes could not be separated, and the relation between the formation of optical isomers and the solvent was not investigated.

The authors wish to thank Professor Muraji Shibata and his co-workers of Kanazawa University for the CD measurement. The authors also wish to thank Professor Ryokichi Tsuchiya of Kanazawa University for valuable discussions and suggestions. This work was financially supported by a Grant-in-Aid from the Ministry of Education.

Simultaneous Determination of the Atomic Ratio between C, H, O, and N by the Pyrolytic Sulfurization Method

Katsuya Tsuji, Kaoru Fujinaga, and Tadashi Hara

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received January 12, 1977)

From a sample subjected to pyrolytic sulfurization in a sealed quartz tube, the evolved gases, carbon disulfide, carbon monoxide, carbon dioxide, carbonyl sulfide, hydrogen sulfide, and a nitrogen molecule were simultaneously estimated. Determination of the atomic ratio between C, H, O, and N was carried out by means of three calibration curves obtained by use of glycine, L-glutamic acid, L-citrulline, and fumaric acid. They are applicable to carboxylic acids and the other compounds, but not to compounds including nitro and/or sulfo groups.

Various carboxylic acids were subjected to pyrolysis in sulfur(S) vapor and the reaction products such as hydrogen sulfide(H_2S), carbon dioxide(CO_2), and carbon disulfide(CS_2) were analyzed gas chromatographically, followed by determination of the chemical composition and functional group.[1] However, complete sulfurization of carboxylic acids apparently was not accomplished, since the amount of evolved CS_2 was much smaller than the expected one and a black carbonaceous residue remained. The method could not be applied to compounds other than carboxylic acids since the reaction products except for CO_2 were given in terms of the amount of CO_2 and the reaction in addition did not go to completion.

The present study was undertaken to establish an improved method in which a sample is subjected to pyrolytic sulfurization in a sealed quartz tube containing S, and the evolved gases such as H_2S, carbonyl sulfide (COS), CS_2, and a nitrogen molecule(N_2) are simultaneously estimated, followed by determination of the atomic ratio between C, H, O, and N. The calibration curves obtained from four compounds were applicable to carboxylic acids and other compounds, but not to the compounds including nitro and/or sulfo groups. Sulfurization seemed to be complete since no black carbonaceous residue remained. The present method gives more accurate results, no weighing being necessary during the procedure.

Experimental

Apparatus. A sampler, a displacement apparatus and an electric furnace were used. Gas chromatograms were taken on a Yanagimoto GCG-5DH and a Shimadzu GC-4B.

Reagents. Various purification methods including (1) vacuum sublimation, (2) contact with sulfuric acid, (3) nitric acid oxidation of sodium sulfide, (4) decomposition of sodium thiosulfate with hydrochloric acid, and (5) refluxing with magnesium oxide(MgO)[2] were examined, the last one being found the best. The procedure is as follows: 500 g S was gradually heated in a 500 ml four-holed flask with a reflux condenser, with an electric furnace, MgO being added after cessation of gas evolution. The temperature was held at *ca.* 450 °C, S being refluxed for 24 h. The melts were filtered at 120—150 °C through a sintered glass filter protected by a ribbon heater. About 450 g S was obtained as a filtrate to

which was added 4.5 g (1%) MgO, the contents being refluxed for 24 h. The operation was repeated six times, *ca.* 150 g S being finally obtained. The S obtained was dried at 150 °C for 3 h. A blank test was carried out using the sealed tube containing 20 mg S. Though slight peaks of air, COS and CS_2 were confirmed at the highest sensitivity of the Shimadzu GC-4B gas chromatograph, they were negligible in the present study.

The other reagents were of analytical grade. Helium was of commercial grade.

Materials. A transparent quartz tube was found suitable as the reaction tube, since an opaque tube gives a large peak owing to the N_2 present in foams. The maximal strength of the quartz tube was estimated to be *ca.* 390 atm at 950 °C from the relationship between the amount of S and the explosion temperature during the course of heating, and on the assumption that S is present as a diatomic molecule[3] at 950 °C. The internal pressure being *ca.* 20 atm, the operation was safely carried out.

The gas sampler E shown in Fig. 2 should be heat-resistant, strong and elastic. A silicone rubber tube is heat-resistant but mechanically weak, a poly(vinyl chloride) tube less heat-resistant, giving a number of impurity peaks. A Teflon tube meets all requirements and can be used more than 100 times at 55 °C, not giving any impurity peaks even at 120 °C.

Procedure. A transparent quartz tube, 3.8 mm i.d., 5.6 mm o.d. and 110 mm long, was treated for 5 h in a Bransonic-52 ultrasonic cleaner, washed, dried, and closed at one end by use of a town gas-oxygen flame, followed by being made narrow at *ca.* 50 mm from the closed end and being heated at 850 °C for 10 min.

Five mg of S was placed in the quartz tube and a definite volume of powdered sample was added to it with the sampler (Fig. 1), a definite length of capillary sample thus being prepared. The reaction tube was connected with the displacement apparatus (Fig. 2). A stream of helium regulated at a flow rate of 100 ml/min by a manometer M and valve I was passed through it to displace the air. Cock G and pinch cock J were closed. The internal pressure of the reaction tube (*ca.* 890 Torr) was balanced with the atmospheric pressure by operating cock G just before glass blowing, followed by sealing. The time required for sealing was *ca.* 15 s. The sealed tube was placed in a quartz case 11 mm i.d. × 90 mm and heated in an electric furnace for 10 min at 600 °C and for 30 min at 950 °C. The sealed tube was held at 90 °C for 5 min in an oven and inserted into a Teflon sampler E (Fig. 3) maintained at 55 °C. E was connected with the gas chromatograph by operating the cock A_1. The sealed tube was broken into pieces by driving a jack across the Teflon sampler and evolved gas was introduced into the gas chromatograph, the column temperature being raised immediately to the programmed one at a rate of 8 °C/min. The molecular sieve 5A column C_2 was separated from the flowing system in *ca.* 5 min after the introduction of evolved gas, and the constituents of relative higher boiling point, which come out of the silica gel column C_1, were analyzed with a thermal conductivity detector after passing through cock A_2.

The gas chromatograph was operated under the following conditions: A 1.5 m stainless steel column C_1 was charged with silica gel (80—100 mesh) and a 0.6 m stainless steel column C_2 with molecular sieve 5A (80—100 mesh), column temperature being programmed between 40 and 185 °C at a rate of 8 °C/min. The flow rate of helium was 30 ml/min at 185 °C. Davison grade 08 silica gel[4] was used instead of Deactigel.[5] The latter is known to be effective for the separation of S-containing compounds. In order to separate the individual constituents in the evolved gas, a combination

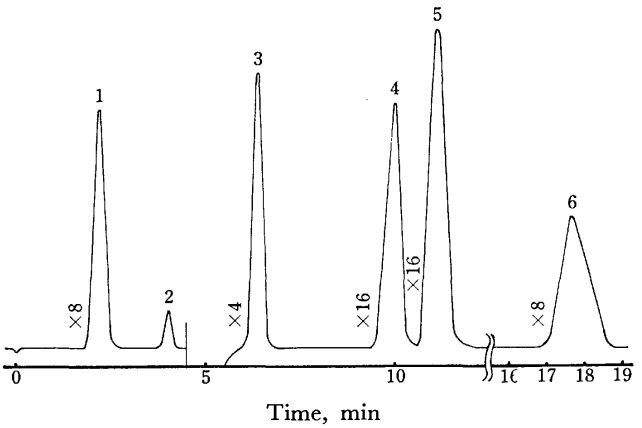

Fig. 4. Typical chromatogram of reaction products. 1: N_2, 2: CO, 3: CO_2, 4: COS, 5: H_2S, 6: CS_2.

of the silica gel column and the molecular sieve 5A column was utilized, by which N_2 was completely separated from carbon monoxide(CO). Glycine was chosen as an example and analyzed. Its chromatogram is shown in Fig. 4. All the peaks were identified by use of an authentic sample and their peak areas were estimated by the half-width method.

Results

Reaction Temperature and Reaction Time. The relationship between reaction products and reaction temperature (Fig. 5) or reaction time (Fig. 6) was examined using glycine. The composition of the reaction products was almost definite at a temperature in the range 750—1050 °C and in more than 20 min after the start of the reaction.

Pyrolytic Sulfurization. The sealed tube containing S and glycine was processed by five separate procedures (Table 1). The coefficients of variation in the values of (N/H), (C/H), and (O/H) were smaller in procedures C and E than in any other, and were thus re-examined using 5 mg S and 0.1—2.0 mg glycine. The results are given in Fig. 7 and Table 2. Procedure C was chosen since it gave a better result.

Amounts of Sample and S. Since the values of (N/H), (C/H) and (O/H) were approximately definite

in the reaction between a definite amount of S and 0.3—2.0 mg glycine, the compounds other than glycine were also sampled by the sampler (Fig. 1) so that their amounts would be in the range 0.3—2.0 mg. From the relation between the weight of sample and the peak area in the gas chromatogram, the amount of samples taken

was 0.3—1.0 mg. The relation between the amount of sample and the amounts of S was examined. The contents of N_2, CO, and CO_2 in the evolved gas were constant for the weight ratio of S to sample greater than 20. The contents of H_2S and COS decreased with an increase in the amount of S. Five mg of S was used.

Temperature of Gas Sampler. The effect of the internal temperature of the gas sampler E on the peak area of the reaction products was examined (Fig. 8). The peak area ratios of reaction products to N_2 were approximately constant at temperatures 50—120 °C. Thus the internal temperature of the gas sampler E

a) Individual peak area divided by the sum of all peaks. b) Estimated by Eqs. 4 and 5, respectively.

was held at 55 °C.

Correction Factors for the Relative Peak Area of CO_2, COS, and CS_2. The compound containing C, H, O, and N was subjected to pyrolytic sulfurization to form the following products: CO, CO_2, COS, and CS_2 from carbon atom, H_2S from hydrogen atom, CO, CO_2, and COS from oxygen atom and N_2 from nitrogen atom. In order to determine the composition of the compound, each peak area of N_2, C- and O-containing compounds was divided by the peak area of H_2S, and the atomic ratios between H and C or O or N were estimated from the calibration curves. The relationship between the peak areas of CO, CO_2, COS, and CS_2 and their mole numbers was used to estimate the sum of individual peak areas. Since the peak area of CO was negligibly small in comparison with that of CO_2, COS, and CS_2, no care was taken of the correction factor of CO. CO was sealed into a quartz tube containing S by use of the displacement apparatus (Fig. 2), and the gases evolved by the reaction were analyzed (Table 3). The major products were CO_2, COS, and CS_2, only a minute amount of CO remaining as an unreacted component. The reaction between CO and a diatomic S molecule[3] at 950 °C was assumed to proceed according to the following equations.

$$2CO + S_2 = 2COS, \quad (1)$$

$$2COS = CO_2 + CS_2. \quad (2)$$

CO_2 and CS_2 were formed in equimolecular amounts. On the basis of $K(CO_2)=1.00$, the correction factors were estimated by Eqs. 4 and 5, where $A'(CO)$, $A'(CO_2)$, $A'(COS)$ and $A'(CS_2)$ refer to percent peak area ratios of CO, CO_2, COS, and CS_2 to the sum of all peaks.

$$K(CO_2) = 1.00, \quad (3)$$

$$\frac{K(COS)}{K(CO_2)} = K(COS) = \frac{\{100-[A'(CO)+A'(COS)]\}}{2A'(CO_2)}, \quad (4)$$

$$\frac{K(CS_2)}{K(CO_2)} = K(CS_2) = \frac{A'(CS_2)}{A'(CO_2)}. \quad (5)$$

The value of $100-[A'(CO)+A'(COS)]$ corresponds to the amount of COS consumed. Thus the value of $A'(CO_2)$, $A'(COS)$, and $A'(CS_2)$ divided by $K(CO_2)$, $K(COS)$, and $K(CS_2)$ in that order imply their mole ratios. The correction factors thus obtained were used.

Calibration Curves. Glycine, L-glutamic acid, L-citrulline, and fumaric acid in high purity were analyzed and the numerical ratios of each atom were calculated as follows.

$$\left(\frac{C}{H}\right)_f = \frac{[A(CO)+A(CO_2)+A(COS)/1.26+A(CS_2)/1.52]}{2A(H_2S)}, \quad (6)$$

$$\left(\frac{O}{H}\right)_f = \frac{[A(CO)+2A(CO_2)+A(COS)/1.26]}{2A(H_2S)}, \quad (7)$$

$$\left(\frac{N}{H}\right)_f = \frac{A(N_2)}{A(H_2S)}. \quad (8)$$

Here, $A(CO)$, $A(CO_2)$, $A(COS)$, $A(CS_2)$, $A(H_2S)$, and $A(N_2)$ are referred to the individual peak areas in mm^2 at the chart speed of 5 mm/min. Simultaneous determination of the atomic ratio among C, H, O, and N was made by use of the calibration curves. Experimental values (f) are plotted against theoretical values (t) in Fig. 9.

Analysis of Various Compounds. Amino acids (Table 4) and other carboxylic acids (Table 5) were

analyzed. No difference between threonine and homoserine was found irrespective of their structural isomerism. Since S atom could not be determined, it was neglected in the composition of methionine. The method was applied to the compounds consisting of C and H as well as C, H, and N, satisfactory results being obtained (Table 6).

Discussion

Relative Correction Factors of CO_2, COS, and CS_2. Eqs. 1 and 2 for the reaction between CO and S were supported by Stock *et al.*[6,7] We found CO_2, COS, and CS_2 as the reaction products. The relative correction factors of CO_2, COS, and CS_2 were determined on the assumption that the reaction between CO and S proceeds in accordance with Eqs. 1 and 2, which were confirmed as follows: The N_2 gas containing 30—100 vol % CO was prepared by use of a N_2 bomb and a CO bomb equipped with a needle-valve and a flow-meter, respectively, and the mixed gas was sealed into a reaction tube containing 20 mg S, followed by heating at 950 °C and analysis of the gases produced (Fig. 10). The peak area ratios of CO, COS, and CS_2 to CO_2

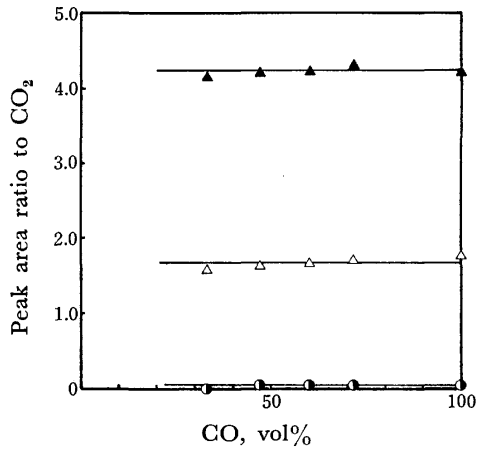

Fig. 10. Relationship between the amount of CO and the peak area ratios using a Yanagimoto GCG-5DH gas chromatograph. ◑: CO/CO_2, ▲: COS/CO_2, △: CS_2/CO_2.

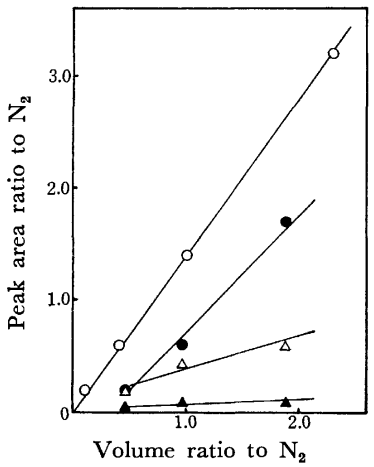

Fig. 11. Effect of CS_2* on the peak area ratios. * CS_2 added by the quartz capillary. (○) Mixture of N_2 and SO_2, (●) mixture of N_2, SO_2 and CS_2, (△) produced CO_2, (▲) produced COS.

were found to be constant irrespective of change of vol% CO. By taking it for granted that the reaction products are restricted to CO_2, COS, and CS_2, Eqs. 1 and 2 are concluded to hold for the reaction between CO, and S under the above conditions. Since CO_2 was produced as shown in Eq. 2, the reaction between CO_2 and S was examined, and the reaction mixture was found to contain the following: CO_2, COS, and sulfur dioxide(SO_2) as the major component, and CO and CS_2 as a trace component. Thus the reaction between CO_2 and S is supposed to proceed primarily as follows.

$$2CO_2 + \frac{3}{2}S_2 = 2COS + SO_2. \quad (9)$$

If we take Eqs. 2 and 9 into consideration, the formation of SO_2 is expected for the reaction between CO and S. However, no SO_2 was found. This is understandable if we accept the equation which was experimentally confirmed (Fig. 11).

$$CS_2 + SO_2 = CO_2 + \frac{3}{2}S_2. \quad (10)$$

The amount of SO_2 decreases by addition of CS_2 to SO_2, CO_2 and COS being simultaneously formed. Though the equation was also

$$3CS_2 + 2SO_2 = 2COS + CO_2 + S_2, \quad (11)$$

described for the formation of CO_2 and COS from CS_2 and SO_2, it was not acceptable since the amount of COS was confirmed experimentally to be about one-fifth that of CO_2, irrespective of the mole ratio of COS: CO_2=2 : 1. Assuming the conversions in Eqs. 2, 9, and 10 to be α, β, and γ, we have equilibrium fractions of each component based on a unit mass of COS as follows:

$$\underset{1-\alpha}{2COS} = \underset{0.5\alpha}{CO_2} + \underset{0.5\alpha}{CS_2}, \quad (2)'$$

$$\underset{0.5\alpha(1-\beta)}{2CO_2} + \frac{3}{2}S_2 = \underset{0.5\alpha\beta}{2COS} + \underset{0.25\alpha\beta}{SO_2}, \quad (9)'$$

$$\underset{0.5\alpha-0.25\alpha\beta\gamma}{CS_2} + \underset{0.25\alpha\beta(1-\gamma)}{SO_2} = \underset{0.25\alpha\beta\gamma}{CO_2} + \frac{3}{2}S_2. \quad (10)'$$

From the values $K_{eq}=2.67\times10^4$ at 1200 K and $K_{eq}=2.24\times10^4$ at 1300 K for Eq. 10,[8] the value of γ becomes approximately equal to 1. The fraction of CS_2 is equal to $0.5\alpha-0.25\alpha\beta\gamma=0.5\alpha-0.25\alpha\beta$ and that of CO_2 to $0.5\alpha(1-\beta)+0.25\alpha\beta\gamma=0.5\alpha-0.25\alpha\beta$. This implies that Eq. 2 holds even in the introduction of Eqs. 9 and 10.

Adaptability of Calibration Curves. The space velocity of a reactant gas was very large in the high temperature range, and the reaction between a sample gas and S could not go to completion.[1] Pyridine derivatives in particular were less decomposable and much carbonaceous residue remained after the reaction. By the present method, pyridine and quinoline derivatives were easily decomposed, no carbonaceous residue remaining. The reaction seems to proceed completely and stoichiometrically (Tables 4, 5, and 6).

The calibration curves obtained from four compounds were applicable to various compounds. However, they cannot be applied to aromatic sulfonic acids and nitro compounds. SO_2 was formed in a batchwise apparatus and a flow-type apparatus,[9] but not by the present method. This seems to be due to the difference in the reaction conditions. SO_2 formed in the former case moves quickly to the low temperature zone with other gases, remaining unreacted, while that in the present case is made to react with CS_2 at 950 °C according to Eq. 10. This is reasonable if we take the relationship between ΔG° and TK into consideration (Fig. 12). Compounds deviated from the calibration curves are given in Table 7. Since the amounts of CO_2 and COS formed according to Eqs. 9 and 10 were considered in Eqs. 6 and 7, the deviation seems to arise from other reasons. The amount of H_2S formed was unexpectedly small and the formation of water(H_2O) was always observed in a sample for which analytical data deviated markedly from the calibration curves. Detection of H_2O was carried out under the following conditions: A 2.2 m Porapak-Q (80—100 mesh) column, initial temperature 60 °C, operated at the rate of 5 °C/min. H_2O was assumed to be formed by the reactions (Eqs. 12, 13, and 14) between SO_2 and H_2S or H_2 from the results of the following experiment. The reaction between SO_2 and H_2 in the presence of S was examined in a similar manner to that given before. The amount of SO_2 decreased with an increase in the amount of H_2 while that of H_2O increased in the opposite way.

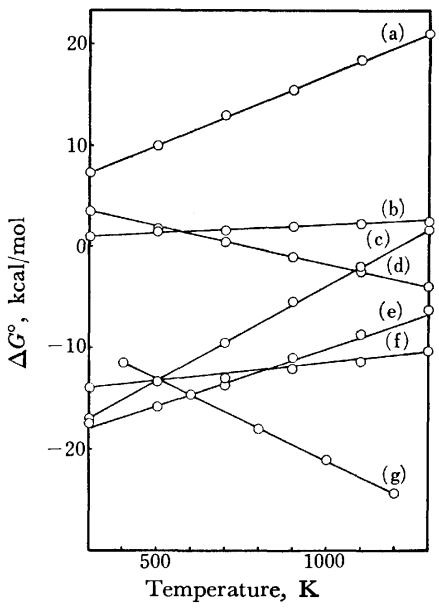

Fig. 12. Relationship between ΔG° and temperature. a: Eq. 9, b: Eq. 2, c: Eq. 1, d: Eq. 12, e: Eq. 13, f: Eq. 14, g: Eq. 10.

Table 7. Compounds deviated from the calibration curves

Compound	Formula	
	Theoretical	Found[a]
2,6-Dimethylphenol	$C_8O_1H_{10}$	$C_{8.5}O_{1.2}H_{10}$
8-Quinolinol	$N_1C_9O_1H_7$	$N_{1.3}C_{9.6}O_{1.1}H_7$
m-Nitroaniline	$N_2C_6O_2H_6$	$N_{2.8}C_{6.4}O_{2.4}H_6$
Sodium 1-naphthalenesulfonate	$C_{10}O_3S_1Na_1H_7$	$C_{9.0}O_{5.3}H_7$

a) Calculated from two runs for each sample.

$$H_2 + \frac{1}{2}S_2 = H_2S, \quad (12)$$

$$H_2S + \frac{1}{2}SO_2 = H_2O + \frac{3}{4}S_2, \quad (13)$$

$$H_2 + \frac{1}{2}SO_2 = H_2O + \frac{1}{4}S_2. \quad (14)$$

Since no correction was made for the formation of H_2O in the present method, the erroneous data of H and O in Eqs. 6, 7, and 8 seem to bring about the deviation from the calibration curves. Some phenols also produced H_2O, causing deviation from calibration curves. Two paths for the formation of H_2O were expected, one leading to Eq. 13 or 14 by way of Eq. 9 and the other based on a direct dehydration reaction instead of a decarbonylation reaction in the thermal decomposition of the sample. Since the conversion of Eq. 9 was found to be fairly low, the path involving Eq. 9 is less expected than that involving a dehydration reaction.

Comparison of the Present Method with Previous One. From a comparison with the method described previously, the characteristics of the present method are summarized as follows: 1) No carbonaceous residue was observed, 2) A large amount of COS was found, 3) No SO_2 was detected, 4) Weighing is unnecessary, 5) No information was obtained on the functional group. 1) and 5) indicate that the reaction is complete. All the compounds containing oxygen atom gave CO, CO_2, and COS, making the determination of atomic ratio complicated. We examined the catalytic disproportionation of COS[10] in the presence of a quartz powder with the intention of obtaining simple products, but no satisfactory results were obtained.

Stereochemistry of Cobalt(III) Complexes with Thioethers. I. Circular Dichroism Spectra of Complexes with Bi- or Terdentate Thioethers

Kazuaki YAMANARI, Jinsai HIDAKA,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 21, 1977)

Five (bidentate-*N,S* or *-O,S*)bis(ethylenediamine)cobalt(III) complexes have been optically resolved and their absolute configurations deduced from their circular dichroism (CD) spectra, where bidentate-*N,S* or *-O,S* are $NH_2(CH_2)_2S^-$, $NH_2(CH_2)_2SR$ (R=CH_3 and C_2H_5), and $CH_3S(CH_2)_nCO_2^-$ (n=1 and 2). The chromatographic, CD, and NMR behaviors suggest that the thioether donor atoms are coordinated stereoselectively producing the *Δ*-(*S*) or *Λ*-(*R*) complexes. Three (terdentate-*N,S,O*)[1,1,1-tris(aminomethyl)ethane]cobalt(III) complexes of $NH_2(CH_2)_2SCH_2CO_2^-$, $NH_2(CH_2)_2S(CH_2)_2CO_2^-$, and L-$CH_3SCH_2CH(NH_2)CO_2^-$ have been prepared and the complexes of the former two ligands optically resolved; the absolute configurations have been discussed on the basis of the CD spectra.

Some bis(ethylenediamine)cobalt(III) complexes with a bidentate ligand containing a sulfur donor atom, such as 2-aminoethanethiol, mercaptoacetic acid, and the related thioethers, have been prepared and the absorption spectra have been discussed.[1-5] The contribution of the coordinated sulfur atom of the thioether ligands to CD spectra would be an interesting study. However, no report seems to have appeared on the circular dichroism (CD) spectra of these complexes.

Two series of mixed cobalt(III) complexes with a bi- or a terdentate ligand containing a thioether donor atom, [Co(bidentate-*N,S* or *-O,S*)$(en)_2$]$^{n+}$ and [Co(terdentate-*N,S,O*)(tame)]$^{2+}$ have been prepared and resolved into optical antipodes, and their absorption and CD spectra are discussed in relation to the absolute configurations. Abbreviations used for the ligands are as follows: Haet, 2-aminoethanethiol $NH_2(CH_2)_2SH$; mea, 2-(methylthio)ethylamine $NH_2(CH_2)_2SCH_3$; eea, 2-(ethylthio)ethylamine $NH_2(CH_2)_2SC_2H_5$; Hmta, (methylthio)acetic acid $CH_3SCH_2CO_2H$; Hmtp, 3-(methylthio)propionic acid $CH_3S(CH_2)_2CO_2H$; Haeta, (2-aminoethylthio)acetic acid $NH_2(CH_2)_2SCH_2CO_2H$; Haetp, 3-(2-aminoethylthio)propionic acid $NH_2(CH_2)_2S(CH_2)_2CO_2H$; L-Hsmc, *S*-methyl-L-cysteine $CH_3SCH_2CH(NH_2)CO_2H$; en, ethylenediamine $NH_2(CH_2)_2NH_2$; tame, 1,1,1-tris(aminomethyl)ethane $CH_3C(CH_2NH_2)_3$; *d*-H_4tart, *d*-tartaric acid $C_4O_6H_6$.

Experimental

Preparation of Ligands. 1,1,1-Tris(aminomethyl)ethane: This ligand was prepared by the method of Fleischer *et al.*[6] Found: C, 26.61; H, 8.19; N, 18.34%. Calcd for $C_5H_{15}N_3\cdot 3HCl$: C, 26.51; H, 8.01; N, 18.55%.

(2-Aminoethylthio)acetic Acid: A solution of 77.2 g of 2-aminoethanethiol in 250 cm^3 of water was mixed with a solution of 94.5 g of monochloroacetic acid and 56.1 g of potassium hydroxide in 200 cm^3 of water with vigorous stirring at 80—85 °C on a water bath. The mixed solution was stirred for *ca.* 1 h and cooled in an ice bath. 185 cm^3 of 60% perchloric acid was then added and the resulting deposit, $KClO_4$, was filtered off. The filtrate was concentrated in a vacuum evaporator until it became oily and the deposit, $KClO_4$, was again filtered off. This filtrate was cooled in a refrigerator overnight. The white needles precipitated were recrystallized from a small amount of ethanol and dried in a vacuum desiccator over $CaCl_2$. The second crop was obtained by standing the above filtrate in a refrigerator for several weeks. The total yield: 70%. Found: C, 30.71; H, 6.28; N, 9.09; S, 20.41; Cl, 11.55%. Calcd for $C_4H_9NSO_2\cdot 0.5HCl$: C, 30.52; H, 6.08; N, 8.90; S, 20.37; Cl, 11.26%.

3-(2-Aminoethylthio)propionic Acid. This was prepared as described above, except that 3-bromopropionic acid was used instead of monochloroacetic acid. The yield: 75%. Found: C, 25.52; H, 5.39; N, 5.87; S, 13.07; Br, 33.84%. Calcd for $C_5H_{11}NSO_2\cdot HBr\cdot 0.5H_2O$: C, 25.11; H, 5.48; N, 5.86; S, 13.41; Br, 33.41%.

Preparation and Resolution of Complexes. (2-Aminoethanethiolato)bis(ethylenediamine)cobalt(III) Complexes, [Co(aet)$(en)_2$]$Cl_2\cdot H_2O$: The chloride salt was prepared by the method of Hori.[1]

(+)$_{589}$-[Co(aet)$(en)_2$]$(ClO_4)_2$: The racemic chloride monohydrate (1 g) and the resolving agent $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ (0.99 g) were dissolved in 10 cm^3 of water at 60 °C. On scratching the side of the flask with a glass rod, the brown diastereomer (+)$_{589}$-[Co(aet)$(en)_2$]$[Sb_2(d\text{-tart})_2]\cdot 2H_2O$ appeared. The mixture was cooled in an ice bath for *ca.* 10 min and then filtered off. The precipitate was washed with ice cold water, ethanol and acetone. Found: C, 20.05; H, 3.71; N, 8.66%. Calcd for (+)$_{589}$-[Co(aet)$(en)_2$]$[Sb_2(d\text{-tart})_2]\cdot 2H_2O=C_{14}H_{26}N_5SO_{12}CoSb_2$: C, 20.34; H, 3.66; N, 8.47%. The diastereomer (0.8 g) was ground in a mortar; water (60 cm^3) was added and then excess sodium perchlorate (5 g), and the mixture was stirred for 10 min. After filtration, the solution was evaporated to 10 cm^3 and cooled in an ice bath. The needle-shaped crystals were removed by filtration and washed with 50% ethanol and acetone. The yield was 0.3 g. Found: C, 15.96; H, 4.91; N, 15.31%. Calcd for (+)$_{589}$-[Co(aet)$(en)_2$]$(ClO_4)_2=C_6H_{22}N_5SO_8Cl_2Co$: C, 15.87; H, 4.88; N, 15.42%.

[2-(Methythio)ethylamine]bis(ethylenediamine)cobalt(III) Complexes, [Co(mea)$(en)_2$]$Cl_3\cdot H_2O$: The racemic complex was derived from the reaction of [Co(aet)$(en)_2$]$Cl_2\cdot H_2O$ and methyl iodide according to the method of Hori.[1]

(+)$_{589}$-[Co(mea)$(en)_2$]$Cl_3\cdot H_2O$: The racemic chloride monohydrate (1.91 g) and the resolving agent $Na_2[Sb_2(d\text{-tart})_2]\cdot 2H_2O$ (1.54 g) were dissolved in 10 cm^3 of water at 50 °C. After being cooled to room temperature, the mixed solution was allowed to stand overnight in a refrigerator. The less soluble diastereomer deposited as orange precipitate was recrystallized from a small amount of hot water. Found: C, 20.40; H, 3.83; N, 8.06%. Calcd for (+)$_{589}$-[Co(mea)$(en)_2$]$Cl[Sb_2(d\text{-tart})_2]\cdot 2H_2O=C_{15}H_{33}N_5SO_{14}ClCoSb_2$: C, 20.53; H, 3.79; N, 7.98%. The diastereomer was converted into the optically active chloride salt by use of

* Present address: Department of Chemistry, The University of Tsukuba, Ibaraki, 300-31.

an anion exchange resin (Dowex 1X8, Cl^- form). Found: C, 22.47; H, 7.24; N, 17.20%. Calcd for $(+)_{589}$-$[Co(mea)(en)_2]Cl_3 \cdot H_2O \cdot 1/3C_2H_5OH = C_6H_{27}N_5SOCl_3Co \cdot 1/3C_2H_5OH$: C, 22.46; H, 7.13; N, 17.08%.

[2-(Ethylthio)ethylamine]bis(ethylenediamine)cobalt(III) Complexes, $[Co(eea)(en)_2]Cl_3 \cdot 2H_2O$: This complex was obtained according to the above procedure, with use of ethyl iodide instead of methyl iodide.

$(+)_{589}$-$[Co(eea)(en)_2]^{3+}$: The resolution procedure was similar to that for $[Co(mea)(en)_2]Cl_3 \cdot H_2O$. Found: C, 20.54; H, 4.33; N, 7.28%. Calcd for $(+)_{589}$-$[Co(eea)(en)_2]Cl[Sb_2(d\text{-tart})_2] \cdot 4.5H_2O = C_{16}H_{40}N_5SO_{16.5}ClCoSb_2$: C, 20.52; H, 4.31; N, 7.48%. The optically active chloride salt was obtained by use of an anion exchange resin (Dowex 1X8, Cl^- form). The CD spectrum of this complex was measured with the eluate, the concentration being calculated from the CD intensity referring to that of the diastereomer.

[(Methylthio)acetato]bis(ethylenediamine)cobalt(III) Complexes, $[Co(mta)(en)_2]Cl_2$: This complex was prepared by the reaction of methyl iodide and $[Co(SCH_2CO_2)(en)_2]Cl$, the latter being prepared according to the literature.[2]

$(+)_{589}$-$[Co(mta)(en)_2]Cl_2 \cdot 1.5H_2O$: The racemic chloride (0.71 g) was dissolved in 2 cm^3 of water at 40 °C. Freshly precipitated silver tartrate, $Ag_2(d\text{-}H_2tart)$ (0.27 g), was added and the mixture was stirred for 10 min. The silver chloride was filtered off, washed with water (1 cm^3). Then *d*-tartaric acid (0.15 g) was added to the filtrate and washing. The mixed solution was cooled in an ice bath. The red diastereomer thus precipitated was recrystallized from 2 cm^3 of hot water by addition of ethanol. Found: C, 29.45; H, 5.76; N, 9.02%. Calcd for $(+)_{589}$-$[Co(mta)(en)_2](d\text{-}H_3tart)_2 \cdot 2H_2O = C_{15}H_{35}N_4SO_{16}Co$: C, 29.13; H, 5.70; N, 9.06%. The diastereomer was converted into the optically active chloride salt by use of an anion exchange resin (Dowex 1X8, Cl^- form). Found: C, 21.93; H, 6.25; N, 14.85%. Calcd for $(+)_{589}$-$[Co(mta)(en)_2]Cl_2 \cdot 1.5H_2O = C_7H_{24}N_4SO_{3.5}Cl_2Co$: C, 22.00; H, 6.33; N, 14.66%.

[3-(Methylthio)propionato]bis(ethylenediamine)cobalt(III) Complexes, $[Co(mtp)(en)_2]Cl_2$: This complex was prepared according to the method described above, except that $[Co(SCH_2CH_2CO_2)(en)_2]Cl$ was used instead of $[Co(SCH_2CO_2)(en)_2]Cl$.

$(-)_{589}$-$[Co(mtp)(en)_2]Cl_2 \cdot 0.5H_2O$: The racemic chloride (1.16 g) and the resolving agent $Na_2[Sb_2(d\text{-tart})_2] \cdot 2H_2O$ (0.93 g) were dissolved in 4 cm^3 water at 50 °C. After the solution had been cooled to room temperature, the diastereomer deposited was filtered and recrystallized from a small amount of hot water by addition of ethanol. Found: C, 20.48; H, 4.03; N, 6.29%. Calcd for $(-)_{589}$-$[Co(mtp)(en)_2][Sb_2(d\text{-tart})_2] \cdot 5H_2O = C_{16}H_{37}N_4SO_{19}CoSb_2$: C, 20.80; H, 4.04; N, 6.05%. The optically active chloride salt was obtained by use of an anion exchange resin (Dowex 1X8, Cl^- form). Found: C, 25.33; H, 6.44; N, 14.92%. Calcd for $(-)_{589}$-$[Co(mtp)(en)_2]Cl_2 \cdot 0.5H_2O = C_8H_{24}N_4SO_{2.5}Cl_2Co$: C, 25.41; H, 6.40; N, 14.81%.

[(2-Aminoethylthio)acetato][1,1,1-tris(aminomethyl)ethane]cobalt(III) Complexes, $[Co(aeta)(tame)]Cl_2 \cdot 0.5H_2O$: 1,1,1-Tris(aminomethyl)ethane (3.4 g) and sodium hydroxide (1.8 g) were added at 0°C to a green solution of tricarbonatocobaltate(III) prepared by the method of Shibata[7] in a 3.6 g scale of $CoCl_2 \cdot 6H_2O$. The mixture was then heated to 40 °C and stirred for 1.5 h. After addition of 3 g of (2-aminoethylthio)acetic acid hemihydrochloride, the solution was stirred at *ca.* 60 °C for 3 h, whereupon the solution turned from violet to red. 6 M acetic acid was then added until gas evolution ceased and the stirring was continued for 2 h at 80 °C. The resulting red solution was evaporated *in vacuo* and then cooled. The chloride salt thus precipitated was recrystallized from a small volume of water by addition of ethanol. Found: C, 27.52; H, 6.25; N, 14.77%. Calcd for $[Co(aeta)(tame)]Cl_2 \cdot 0.5H_2O = C_9H_{24}N_4SO_{2.5}Cl_2Co$: C, 27.70; H, 6.20; N, 14.35%.

$(+)_{589}$-$[Co(aeta)(tame)]Cl_2 \cdot 1.5H_2O$: The racemic chloride (0.39 g) was dissolved in 5 cm^3 of water at 40 °C. Potassium tris(L-cysteinesulfinato-*N*,*S*)cobaltate(III) 6-hydrate, $K_3[Co(L\text{-}cysu)_3] \cdot 6H_2O$[8] (0.22 g) dissolved in 5 cm^3 of water was added with stirring. The mixed solution was kept in a refrigerator for *ca.* 1 h. The orange yellow diastereomer precipitated was filtered and then recrystallized from a large amount of water. Found: C, 23.73; H, 5.59; N, 11.28%. Calcd for $(+)_{589}$-$[Co(aeta)(tame)]_3[Co(L\text{-}cysu)_3]_2 \cdot 14H_2O \cdot 2KCl = C_{45}H_{127}N_{18}S_9O_{44}Cl_2Co_5K_2$: C, 23.91; H, 5.66; N, 11.15%. The optically active chloride salt was obtained by use of an anion exchange resin (Dowex 1X8, Cl^- form). Found: C, 24.97; H, 6.20; N, 13.18%. Calcd for $(+)_{589}$-$[Co(aeta)(tame)]Cl_2 \cdot 1.5H_2O \cdot 1/4KCl = C_9H_{26}N_4SO_{3.5}Cl_2Co \cdot 1/4KCl$: C, 25.32; H, 6.14; N, 13.13%.

[3-(2-Aminoethylthio)propionato][1,1,1-tris(aminomethyl)ethane]cobalt(III) Complexes, $[Co(aetp)(tame)]Br_2 \cdot 1.5H_2O$: This complex was prepared according to the method described above, with use of 3-(2-aminoethylthio)propionic acid monohydrobromide instead of (2-aminoethylthio)acetic acid hemihydrochloride. Found: C, 23.45; H, 5.90; N, 11.35%. Calcd for $[Co(aetp)(tame)]Br_2 \cdot 1.5H_2O = C_{10}H_{28}N_4SO_{3.5}Br_2Co$: C, 23.48; H, 5.52; N, 10.96%.

$(-)_{589}$-$[Co(aetp)(tame)]^{2+}$: The racemic bromide was optically resolved by the same method as that for $[Co(aeta)(tame)]Cl_2$. The CD spectrum of this complex was measured with the eluate and the concentration was calculated from the optical density referring to that of the racemic complex.

Trinitro[1,1,1-tris(aminomethyl)ethane]cobalt(III), $[Co(NO_2)_3(tame)]$: 1,1,1-Tris(aminomethyl)ethane trihydrochloride (4.5 g) and sodium hydroxide (2.4 g) were dissolved in 15 cm^3 of water and the mixture was transferred to a separatory funnel. The solution was added dropwise to a solution of $Na_3[Co(NO_2)_6]$[9] (8.1 g) in 20 cm^3 of water at 70 °C. A yellow precipitate was formed readily and removed by filtration. The crude product was recrystallized from a small amount of hot water. The yield was 2 g. Found: C, 19.05; H, 4.92; N, 26.78%. Calcd for $[Co(NO_2)_3(tame)] = C_5H_{15}N_6O_6Co$: C, 19.12; H, 4.81; N, 26.75%.

Trichloro[1,1,1-tris(aminomethyl)ethane]cobalt(III), $[CoCl_3(tame)] \cdot 0.75H_2O$: Trinitro[1,1,1-tris(aminomethyl)ethane]cobalt(III) (2.5 g) was added to 80 cm^3 of ethanol saturated with hydrogen chloride and gently stirred until the evolution of nitrogen oxide ceased. The solution was kept standing overnight at room temperature. The deep blue precipitate was filtered off and washed with ethanol and ether repeatedly until the washings became colorless. The reaction proceeded almost quantitatively; the yield was 1.9 g. Found: C, 20.13; H, 5.43; N, 14.25%. Calcd for $[CoCl_3(tame)] \cdot 0.75H_2O = C_5H_{16.5}N_3O_{0.75}Cl_3Co$: C, 20.29; H, 5.62; N, 14.20%.

(S-Methyl-L-cysteinato)[1,1,1-tris(aminomethyl)ethane]cobalt(III) Chloride, $[Co(L\text{-}smc)(tame)]Cl_2$: Trichloro[1,1,1-tris(aminomethyl)ethane]cobalt(III) (0.9 g) was suspended in water (10 cm^3); silver perchlorate (1.98 g) was added and the mixture was shaken for 10 min. The resulting solution was filtered in order to remove the silver chloride. The solution obtained by dissolving *S*-methyl-L-cysteine (0.41 g) and sodium hydroxide (0.13 g) in 10 cm^3 of water was then added. The mixed solution was heated to 70 °C and stirred for 3 h. The reaction mixture was poured into a column of SP-Sephadex C-25 (3×40 cm, Na^+ form). The adsorbed band was eluted with 0.15 M NaCl solution at the rate of *ca.* 0.5 cm^3/min. The second orange-red eluate was evaporat-

ed and the deposit, NaCl, was filtered off. To the filtrate was added a large amount of ethanol. The crude product thus obtained was recrystallized from a minimum quantity of water by addition of ethanol, and washed with ethanol and then acetone, and dried in a vacuum desiccator. Found: C, 21.09; H, 4.65; N, 11.31%. Calcd for [Co(L-smc)(tame)]-$Cl_2 \cdot 2NaCl = C_9H_{23}N_4SO_2Cl_2Co \cdot 2NaCl$: C, 21.70; H, 4.65; N, 11.25%.

Measurements. The electronic absorption spectra were measured on a Shimadzu UV-200 spectrophotometer in aqueous solution. The CD spectra were recorded with a Jasco MOE-1 spectropolarimeter, with a cell of 1 cm path-length. A Jasco DIP-4 digital polarimeter was used to check the optical rotations. The proton magnetic resonance spectra were recorded in deuterium oxide on a Varian XL-100-15 NMR spectrometer with DSS as an internal reference. All measurements were carried out at room temperature.

Results and Discussion

Absorption Spectra. The first absorption maximum of $[Co(aet)(en)_2]^{2+}$, which belongs to $[Co(N)_5(S)]$ type having a thiolato group, appears at 20800 cm^{-1} with a shoulder on the low energy side (Fig. 1 and Table 1). The spectrum is very similar to the spectra of [Co(L-cyst)(en)$_2$]I, [Co(L-Hcyst)(en)$_2$]ICl, and [Co(L-cystee)(en)$_2$]I_2[4] (L-H_2cyst=L-cysteine and L-Hcystee=L-cysteine ethyl ester), in which the sulfur containing ligands are coordinated through the amino and thiolato groups. Based on the approximate C_{4v} symmetry, the lower energy band is assigned to the transition $^1A_1 \rightarrow {}^1E$, and the higher band to $^1A_1 \rightarrow {}^1A_2$. The ligand field strength of the thiolato group is very weak and falls close to iodide in the spectrochemical series.

On the other hand, the complexes $[Co(mea)(en)_2]^{3+}$ and $[Co(eea)(en)_2]^{3+}$ which belong to $[Co(N)_5(S)]$ type having a thioether donor atom, show a single band at 20500 cm^{-1} (Fig. 2 and Table 1). The energy corresponds to that for the $[Co(N)_5(O)]$ type complexes, $[Co(gly)(en)_2]^{2+}$, $[Co(L\text{-}ala)(en)_2]^{2+}$, and [Co(sar)-$(en)_2]^{2+}$ (gly=glycinate, L-ala=L-alaninate, and sar=*N*-methyl glycinate). As seen in Fig. 3, the first absorption maxima of the thioether complexes [Co(mta)-$(en)_2]^{2+}$ and [Co (mtp)$(en)_2]^{2+}$, which belong to [Co-$(N)_4(O)(S)$] type, appear at 20000 and 20100 cm^{-1},

		21.2(−2.15)
	27 (2.36)[c]	27.2(+0.99)
	34.6(3.93)	33.7(+2.93)
	44.5(4.15)	44 (+7.38)[c]

a) The wave numbers are given in 10^3 cm^{-1} unit. b) The racemate. c) A shoulder.

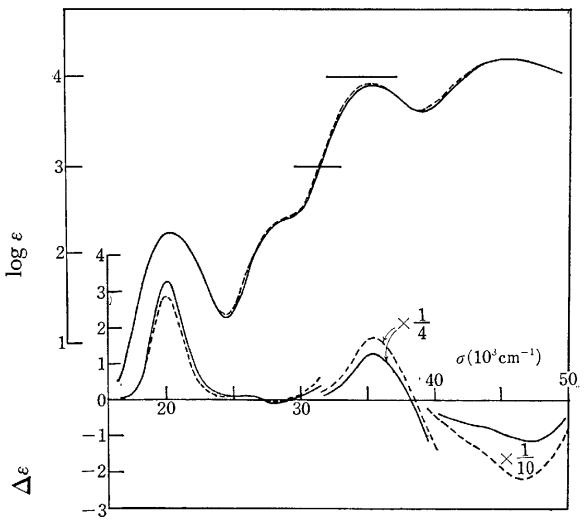

Fig. 2. Absorption and CD spectra of $(+)_{589}$-[Co-(mea)(en)$_2$]Cl_3 (——) and $(+)_{589}$-[Co(eea)(en)$_2$]Cl_3 (----).

respectively, in line with that of $[Co(ox)(en)_2]^+$ which belongs to a $[Co(N)_4(O)_2]$ type. Thus, the thioether R–S–R seems to lie close to the COO^- group in the spectrochemical series. The three tame complexes also belong to the $[Co(N)_4(O)(S)]$ type having the first absorption maxima at 20300—20400 cm^{-1} (Fig. 4 and

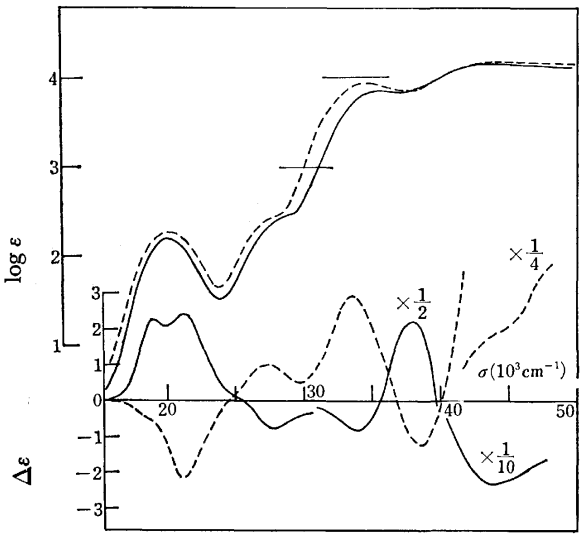

Fig. 3. Absorption and CD spectra of $(+)_{589}$-[Co(mta)(en)$_2$]Cl$_2$ (——) and $(-)_{589}$-[Co(mtp)(en)$_2$]Cl$_2$ (----).

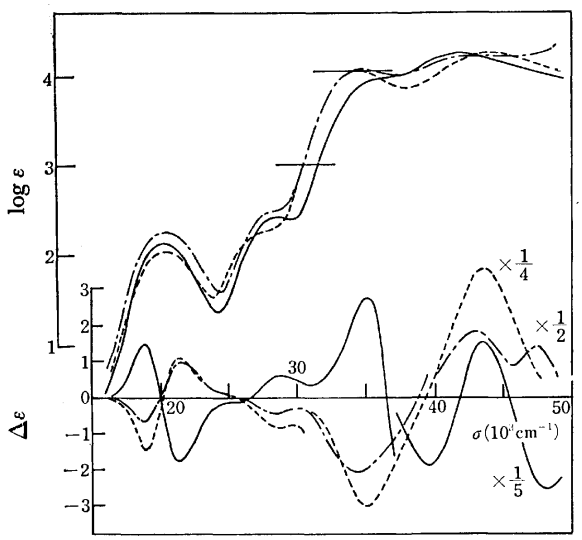

Fig. 4. Absorption and CD spectra of $(+)_{589}$-[Co(aeta)(tame)]$^{2+}$ (——), $(-)_{589}$-[Co(actp)(tame)]$^{2+}$ (------), and $(-)_{589}$-[Co(L-smc)(tame)]$^{2+}$ (----).

Table 2). These maxima are somewhat shifted to higher energy than those of the bis(ethylenediamine) complexes.

In the near-ultraviolet region, the complexes show intense bands ($\log \varepsilon \approx 4.0$). Such bands appear always for the cobalt(III) complexes containing sulfur donor atoms,[10-12] and are considered to be the charge transfer bands due to the lone-pair electrons on the sulfur donor.

CD Spectra of the Bis(ethylenediamine) Complexes. The optical isomer of the complex containing a thiolato group, $(+)_{589}$-[Co(aet)(en)$_2$](ClO$_4$)$_2$ which has only a chirality due to the skew pair of chelate rings, exhibits three weak CD bands in the first absorption band region (Fig. 1). Based on the assignment of the absorption components, two low energy positive bands can be assigned to be the split components of $^1A_1 \rightarrow {}^1E$ and a higher energy negative one $^1A_1 \rightarrow {}^1A_2$. This complex can be assigned to Λ configuration on the basis of the sign of $^1A_1 \rightarrow {}^1E$ components.

Table 2. Absorption and CD data of [Co(terdentate-*N,S,O*)(tame)]$^{2+}$ complexes

Complex	σ_{max}[a] ($\log \varepsilon$)	σ_{ext}[a] ($\Delta\varepsilon$)
$(+)_{589}$-[Co(aeta)-(tame)]Cl$_2$	20.3 (2.12) [b]	18.8 (+1.46)
		21.3 (−1.75)
	28.6 (2.41) [b]	28.8 (+0.61)
	35.7 (3.93) [b,c]	35.1 (+2.79)

$(-)_{589}$-[Co(L-smc)-(tame)]Cl$_2$	20.4 (2.05)	18.7 (−1.39)
		21.2 (+1.08)
	28 (2.25) [c]	28.4 (−0.79)
	34.7 (4.02)	34.8 (−11.9)
	44.4 (4.21)	43.5 (+14.3)

a) The wavenumbers are given in 10^3 cm^{-1} unit. b) The racemate. c) A shoulder.

For each of the four complexes containing a thioether donor atom, four optical isomers, Λ-(*R*), Λ-(*S*), Λ-(*R*), and Λ-(*S*), are possible; both chiralities due to the skew pair of chelate rings (Λ and Λ) and due to the coordinated sulfur atom ((*R*) and (*S*)) contribute to the CD spectra. The optical isomers of the [Co(N)$_5$(S)] type, $(+)_{589}$-[Co(mea)(en)$_2$]$^{3+}$, and $(+)_{589}$-[Co(eea)(en)$_2$]$^{3+}$ which were obtained from the less soluble diastereomers, show one strong positive CD band in the first absorption band region and two weak CD bands of positive and negative signs in the second d-d absorption band region (Fig. 2). The CD spectra are strikingly similar to each other, indicating that the *S*-alkyl groups of both the complexes are in analogous environments. A similar trend has been found for some *N,N'*-dialkylethylenediaminediacetato complexes[13] which have two asymmetric nitrogen donor atoms. The complexes belonging to the [Co(N)$_4$(O)(S)] type, $(+)_{589}$-[Co(mta)-(en)$_2$]$^{2+}$ and $(-)_{589}$-[Co(mtp)(en)$_2$]$^{2+}$, show two CD bands of the same sign in the first absorption band region (Fig. 3). The chiralities arising from the skew pair of chelate rings can be assigned to the present four complexes on the basis of the CD sign in the first absorption band region;[14] namely, Λ,Λ,Λ, and Λ configurations for $(+)_{589}$-[Co(mea)(en)$_2$]$^{3+}$, $(+)_{589}$-[Co(eea)(en)$_2$]$^{3+}$, $(+)_{589}$-[Co(mta)(en)$_2$]$^{2+}$, and $(-)_{589}$-[Co(mtp)(en)$_2$]$^{2+}$, respectively.

The NMR spectra of the resolved complexes show a single peak in the *S*-methyl proton region (Fig. 5). In the chromatographic separation of isomers of each resolved complex, all the fractions had the same CD spectra. The results and molecular model examination suggest that the thioether ligands are coordinated stereoselectively. The *S*-alkyl group in the configuration Λ-(*R*) or Λ-(*S*) has appreciable nonbonded atomic

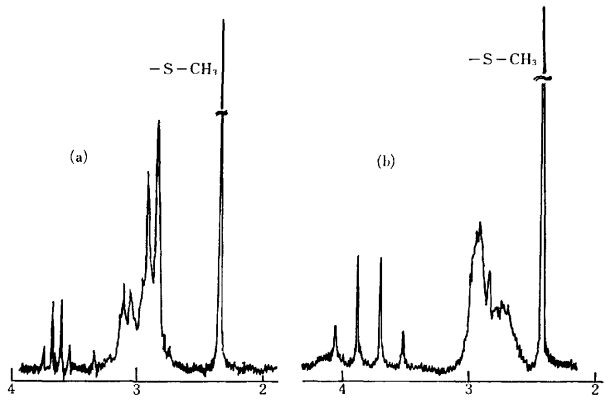

Fig. 5. The NMR spectra of $(+)_{589}$-$[Co(mea)(en)_2]Cl_3$ (a) and $(+)_{589}$-$[Co(mta)(en)_2]Cl_2$ (b) in D_2O.

interactions with the adjacent en chelate ring in contrast to that in the configuration Δ-(*S*) or Λ-(*R*). Thus, it is concluded that the configurations of the resolved complexes are Δ-(*S*) or Λ-(*R*).

In the region of the lower energy thioether charge transfer band, the mea and eea complexes show only one CD band; on the other hand, the mta and mtp complexes show two CD bands of opposite signs. Namely, for the $[Co(N)_5(S)]$ type, the Λ-(*R*) and Δ-(*S*) complexes show (+) and (−) bands, respectively. The Λ-(*R*) complex of the $[Co(N)_4O(S)]$ type shows (−) and (+) CD bands from low energy side, and Δ-(*S*) one (+) and (−).

CD Spectra of the tame Complexes. 1,1,1-Tris-(aminomethyl)ethane is a typical tripod-like ligand and coordinates facially to a Co(III) ion. When three remaining coordination sites are occupied by the three non-equivalent ligating atoms, a kind of chirality due to the arrangement of these donor atoms is expected;[15,16] this kind of chirality contributes dominantly to the CD spectra of $[Co(NH_2CHRCO_2)NH_3(tame)]^{2+}$.[15] In the present system, the terdentate-*N,S,O* ligands occupy the three remaining coordination sites but there is no chirality arising from the skew pair of chelate rings. These complexes have a chirality due to the arrangement of three different donor atoms and another due to the central donor sulfur atom, though both chiralities are associated with each other.

Three tame complexes, $(+)_{589}$-$[Co(aeta)(tame)]^{2+}$, $(-)_{589}$-$[Co(aetp)(tame)]^{2+}$, and $(-)_{589}$-$[Co(L\text{-}smc)(tame)]^{2+}$, exhibit two CD bands of opposite signs in the first absorption band region (Fig. 4): L-smc and aetp $(-)_{589}$-complexes show (−) and (+) bands in the order of increasing energy, but aeta $(-)_{589}$-one shows the reverse CD pattern. As is shown in Fig. 6, the optical isomers of the aeta and aetp complexes have the structure (a) or (b), while the L-smc complex takes the structure (c) because of the complete stereoselectivity due to the L-smc ligand. The arrangement chirality of (b) and (c) are the same but that of (a) is the opposite. Accordingly, by analogy of the CD patterns absolute configurations are assigned as (a) for $(+)_{589}$-$[Co(aeta)(tame)]^{2+}$ and (b) for $(-)_{589}$-$[Co(aetp)(tame)]^{2+}$.

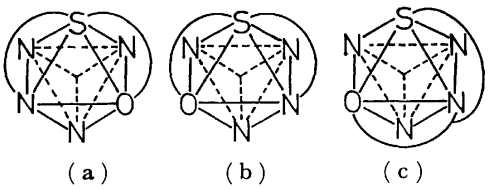

Fig. 6. Optical isomers of [Co(terdentate-*N,S,O*)-(tame)]$^{2+}$, (a) and (b), and the structure of $(-)_{589}$-$[Co(L\text{-}smc)(tame)]^{2+}$ (c).

In the lower energy thioether charge transfer band region, the aeta $(+)_{589}$- and aetp $(-)_{589}$-complexes show a positive and a negative band, respectively, which corresponds to the fact that the two complexes have the opposite absolute configurations.

The Absolute Configuration and Circular Dichroism of the $(-)_{260}$-Diammine((*S*)-1-*N*-methyl-1,2-propanediamine)platinum(II) Ion, $(-)_{260}$-$[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]^{2+}$

Yasuji NAKAYAMA, Keiji MATSUMOTO, Shun'ichiro OOI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received March 12, 1977)

The optical resolution of $[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]Cl_2$ is effected by using silver di-μ-(+)-tartrato(4−)-bis(antimonate(III)) ($Ag_2[Sb_2(+)\text{-tart}_2]$) as the resolving agent. X-Ray structure analysis of the less soluble diastereoisomeric salt, $(+)_{350}$-$[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})][Sb_2(+)\text{-tart}_2]\cdot H_2O$, revealed that the asymmetric secondary nitrogen is of the *R* configuration. The crystal is orthorhombic, with a $P2_12_12_1$ space group, $a=19.302(7)$ Å, $b=14.791(4)$ Å, $c=7.925(2)$ Å, and $Z=4$. The structure was determined from counter intensity data and refined to *R* 0.049 using the least-squares method for 1955 independent non-zero reflections. The Pt atom has a square-planar coordination with 4 N atoms and both the N–CH_3 and C–CH_3 groups are equatorial with respect to the chelate ring. The circular dichroism spectrum of *R*-$[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})](ClO_4)_2$, which was obtained from the less soluble di-μ-(+)-tartrato(4−)-bis(antimonate(III)) salt, is presented and discussed on the basis of the distribution of the possible conformers, the relative abundances of which were infered from ^{13}C NMR data.

Since Ito *et al.* studied the circular dichroism (CD) of a number of Pt(II) and Pd(II) complexes,[1] few studies have been made on this subject. Recently, Bosnich and Sullivan have reported the CD and stereochemistries of several Pt(II) chelates of *N*-substituted diamines,[2] and the absolute configuration of $(-)_{280}$-dichloro-((*S*)-1-*N*-methyl-1,2-propanediamine)platinum(II) has been determined by Ball *et al.*[3] Yokoho *et al.* and Matsumoto *et al.* attempted the resolution of dissymmetric Pt(II) complexes into enantiomeric forms in order to work out the CD-structure relationship for these complexes.[4,5] In the course of the present study, the optical resolution of the *N*-racemic $[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]Cl_2$ was successful with the final result being the isolation of the $(-)_{260}$-enantiomer in perchlorate form. This paper deals with the absolute configuration and the CD spectrum of the title complex.

Experimental

Preparations of Compounds. (*S*)-1-*N*-methyl-1,2-propanediamine (N^1-Me-(*S*)-pn) was prepared following the method of Saburi *et al.*[6] $[Pt(NH_3)_2(rac\text{-pn})](ClO_4)_2$ and $[Pt(NH_3)_2(rac\text{-chxn})]Cl_2$ were obtained using similar methods to those described in Ref. 1 (pn=1,2-propanediamine; chxn=1,2-cyclohexanediamine).

$(-)_{260}$-$[Pt(NH_3)_2(Meen)](ClO_4)_2$ (Meen=*N*-methylethylenediamine): $(-)_{260}$-$[Pt(NH_3)_2(Meen)]Cl_2$ was obtained following the method of Goddard and Basolo.[7] This chloride was then converted to a perchlorate using $AgClO_4$ in a perchloric acid solution. The resulting perchlorate was washed with methanol and recrystallized from acetone–ethanol acidified slightly with perchloric acid.

Found: C, 7.20; H, 3.14; N, 11.07%. Calcd for $[Pt(NH_3)_2(CH_3NH(CH_2)_2NH_2)](ClO_4)_2$: C, 7.18; H, 3.21; N, 11.16%.

$(+)_{350}$-$[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]\,[Sb_2(+)\text{-tart}_2]\cdot H_2O$ ($[Sb_2(+)\text{-tart}_2]^{2-}$=di-$\mu$-(+)-tartrato(4−)-bis(antimonate(III))ion): $[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]Cl_2$ was prepared using a method similar to that reported by Bosnich and Sullivan.[2] A solution of $[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]Cl_2$ (1.15 g in 20 ml of water) was added dropwise to the solution of $Ag_2[Sb_2(+)\text{-tart}_2]$ (2.12 g in 500 ml of water) and the mixture was stirred at 60 °C for 2 h in the dark. AgCl was then filtered off and the filtrate was rotary evaporated to *ca.* 50 ml. Colorless crystals were separated out and they were then recrystallized from hot water containing a drop of perchloric acid.

Found: C, 16.50; H, 2.84; N, 6.29%. Calcd for $[Pt(NH_3)_2(CH_3NHCH_2CH(CH_3)NH_2)]\,[Sb_2(C_4H_2O_6)_2]\,H_2O$: C, 16.54; H, 2.76; N, 6.43%.

$(-)_{260}$-$[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})](ClO_4)_2$: Conversion of the preceding salt to the perchlorate was carefully carried out in acidic media, since the rate of racemization of the assymmetric secondary nitrogen is known to be very slow at low pH values.[8] The di-μ-(+)-tartrato(4−)-bis(antimonate(III)) salt (0.40 g) was dissolved in 100 ml of water acidified with a drop of perchloric acid. This solution was passed through an anion-exchange column in the perchlorate form (Dowex 1-X8, 50—100 mesh) at a speed of one drop every 5 s. The effluent was rotary evaporated to near dryness. The residue was dissolved in a minimum amount of acetone and then *ca.* 15 ml of 1-propanol was added. Colorless plate-like crystals were obtained and these were recrystallized three times from acetone acidified slightly with perchloric acid.

Found: C, 9.53; H, 3.52; N, 10.92%. Calcd for $[Pt(NH_3)_2(CH_3NHCH_2CH(CH_3)NH_2)](ClO_4)_2$: C, 9.30; H, 3.49; N, 10.85%.

Spectral Measurements. The FT ^{13}C NMR spectra were recorded at 15.04 MHz with broad-band proton decoupling on a JEOL JNM-FX60 Spectrometer, dioxane being used as an internal reference (the values of chemical shifts given in the text have been converted to the TMS scale). The signal from the solvent, D_2O, was used as an internal lock. Usually, 4096 data points were taken over a 1-kHz spectral width. Electronic spectra were obtained with a Hitachi EPS-3T Recording Spectrometer. A JASCO J-20 Automatic Recording Spectrometer was employed for the CD spectra. All measurements were performed at room temperature. In the case of $(-)_{260}$-$[Pt(NH_3)_2(N^1\text{Me-}(S)\text{-pn})](ClO_4)_2$, the solutions were acidified slightly with DCl (NMR) or with $HClO_4$ (CD) in order to prevent the active complex ion from racemizing.

X-Ray Data Measurement. The crystallographic data for $(+)_{350}$-$[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})][Sb_2(+)\text{-tart}_2]\cdot H_2O$ are as follows: $M=870.6$, orthorhombic, space group $P2_12_12_1$, $a=19.302(7)$ Å, $b=14.791(4)$ Å, $c=7.925(2)$ Å, $Z=4$, $D_m=2.55$ g cm^{-3}, $D_c=2.56$ g cm^{-3}, $\mu(MoK\alpha)=87.6$ cm^{-1}. The space group was determined from oscillation and Weissenberg photographs. The unit cell dimensions were obtained by a least-squares analysis of 29 θ values measured on a Phillips diffractometer using $MoK\alpha$ radiation.

The intensities were measured using the ω-2θ scan method on a Phillips PW1100 four-circle diffractometer employing a

graphite monochromator and Mo$K\alpha$ radiation (λ=0.71069 Å) with a crystal of dimensions 0.14×0.16×0.18 mm³. A scan speed of 0.017° s⁻¹, a scan width of (0.8+0.2 tan θ)°, and two 20 s background counts were employed. Three standard reflections (800, 060, 004) monitored every 4 h throughout the period of data collection, showed no significant intensity variations. A total of 1955 intensity peaks with $I_t-2\sqrt{I_t}>I_b$ were measured in the $6°\leq 2\theta \leq 55°$ range (I_t is the intensity (counts/s) measured at the top of the peak, and I_b is the mean background intensity (counts/s) obtained from preliminary background measurements for 5 s on each side of the peak). A spherical absorption correction (r=0.08 mm) was applied.

Structure Determination and Refinement. The crystal structure was solved by the heavy-atom technique, and the positional and thermal parameters were refined by the least-squares method, the function minimized being $\sum w\Delta F^2$. In the final stage of refinement, the weighting scheme, w=0.8 for $F_o<32.3$, w=1 for $32.3\leq F_o\leq 161.3$, and $w=(161.3/F_o)^2$ for $F_o>161.3$, was used to render $\sum w\Delta F^2$ approximately constant over the entire ranges of F_o and (sin θ/λ). All parameter shifts in the final cycle refinement were $<0.2\sigma$. The final R value was 0.049. The atomic scattering factors for neutral Pt, Sb, O, N, and C were taken from Ref. 9. The real and imaginary parts of the anomalous dispersion corrections were applied for Pt and Sb atoms.

The atomic coordinates given in Table 1 correspond to the absolute crystal structure which was determined on the basis of the known configuration of the $[Sb_2(+)$-$tart_2]^{2-}$ ion. The observed and calculated structure factors are available at the Chemical Society of Japan (Document No. 7713). The computer programs used are as follows: RSSFR-4, HBLS-4, and DAPH, all of which were adapted to the FACOM 270-30 computer of Osaka City University.

Results and Discussion

X-Ray Structure. The absolute configuration of $(-)_{260}$-$[Pt(NH_3)_2(N^1$-Me-(*S*)-pn)$]^{2+}$ is shown in Fig. 1. The bond lengths and angles are given in Table 2 along with selected interatomic distances. The Pt atom has a square-planar coordination of four nitrogen atoms. The secondary nitrogen atom has *R* absolute configuration and the N–CH_3 group is equatorial. The C–CH_3 group is also disposed equatorially, imposing a δ conformation on the chelate ring. The Pt–N bond lengths range from 2.03 to 2.07 Å with an average value of 2.05 Å, wheras the N–Pt–N bond angle in the chelate ring is 84.1°. These values are comparable to those found in $(+)_{350}$-$[Pt(NH_3)_2(Me_3en)][Sb_2(+)$-$tart_2]\cdot H_2O$ (2.07 Å, 84.4°),[4] $(+)_{350}$-$[Pt(R$-pn)$(Me_2en)][Sb_2(+)$-$tart_2]\cdot 2H_2O$ (2.06 Å, 84.2°),[5] and $[Pt(en)_2][(+)$-

a) The numbers refer to the following equivalent positions: 1; x, y, z, 2; $1-x$, $(1/2)+y$, $(1/2)-z$, 3; x, y, $1+z$.

tart] (2.043 Å, 83.2°),[10] but the Pt–N bond length appears to be slightly longer than that in $(-)_{280}$-[Pt-Cl_2(N^1-Me-(S)-pn)] (2.021 Å, 83.1°).[3] The torsional angle in the N(1)–C(2)–C(3)–N(2) fragment is 52°. The equation for the plane defined by the four nitrogen atoms is

$$-0.936X - 0.350Y - 0.020Z = -4.961,$$

and the deviations of the atoms from this plane are as follows: 0.04 for Pt, 0.04 for N(1), −0.04 for N(2), −0.04 for N(3), 0.04 for N(4), −0.45 for C(1), −0.62 for C(2), 0.05 for C(3), and 1.06 Å for C(4). (The X, Y, and Z coordinates in Å refer to the crystallographic axes.)

Every complex cation is surrounded tetrahedrally by four $[Sb_2(+)\text{-tart}_2]^{2-}$ anions at (x,y,z), $((1/2)-x, -y, (1/2)+z)$, $(-(1/2)+x, (1/2)-y, -z)$, and $(1-x, (1/2)+y, (1/2)-z)$. The $[Sb_2(+)\text{-tart}_2]^{2-}$ anion selects the N(S) and N(S), N′(S)–C(R) isomers yielding the least soluble diasteroisomeric salts $(+)_{350}$-[Pt$(NH_3)_2$(Me_3-en)][$Sb_2(+)$-tart$_2$]·H_2O[4] and $(+)_{350}$-[Pt(R-pn)(Me_2-en)][$Sb_2(+)$-tart$_2$]·$2H_2O$,[5] respectively. In the present case, however, the N(R)–C(S) isomer is preferred by the same anion as the counter ion for the less soluble diastereoisomeric salt, $(+)_{350}$-[Pt$(NH_3)_2$(N^1-Me-(S)-pn)][$Sb_2(+)$-tart$_2$]·H_2O. The geometry and dimensions of the $[Sb_2(+)\text{-tart}_2]^{2-}$ anion agree well with those for $K_2[Sb_2(+)\text{-tart}_2]\cdot 3H_2O$.[11]

CD Spectrum. The absorption and CD spectra of R-[Pt$(NH_3)_2$(N^1-Me-(S)-pn)]$(ClO_4)_2$ are shown in Fig. 3, in which the CD spectrum of the racemic compound is also given. The N(R) isomer is stable with respect to racemization in a 0.01 M perchloric acid solution; actually no appreciable change in the CD curve was observed over a period of 24 h. The electronic spectrum of this complex bears a close resemblance to that of [Pt(R-pn)$_2$]Cl_2, and accordingly, the peak at 35000 cm^{-1}, on the basis of D_{4h} symmetry, can

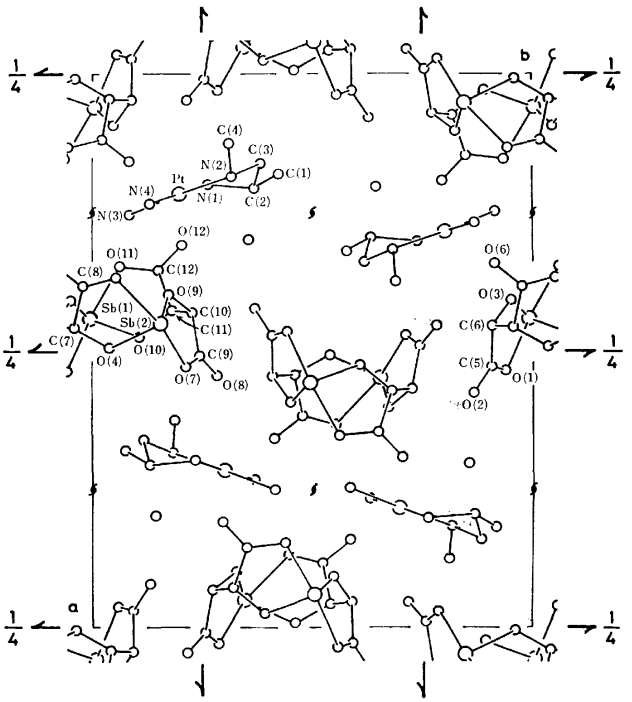

Fig. 2. The crystal structure of $(+)_{350}$-[Pt$(NH_3)_2$(N^1-Me-(S)-pn)]·[$Sb_2(+)$-tart$_2$]·H_2O viewed down the c axis. The atoms denoted as O(1), O(2), O(3), O(6), C(5), and C(6) are related with the corresponding ones in Table 1 by a unit translation in y.

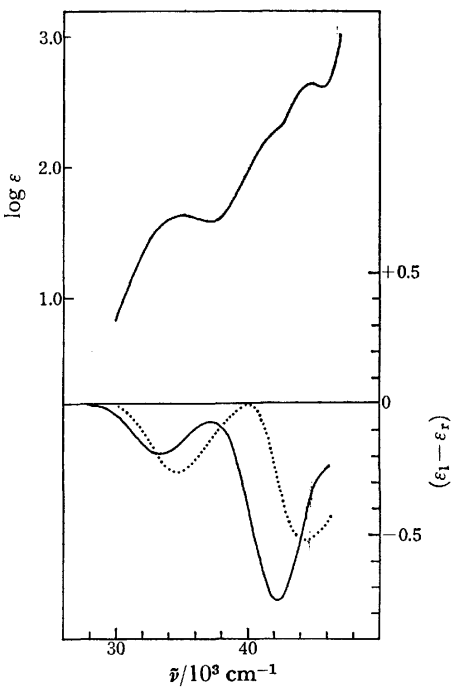

Fig. 3. The absorption (top) and CD (bottom) spectra of $(-)_{260}$-[Pt$(NH_3)_2$(N^1-Me-(S)-pn)]$(ClO_4)_2$: ——, and the CD spectrum of *rac*-[Pt$(NH_3)_2$(N^1-Me-(S)-pn)]Cl_2: ·····.

be assigned to $^1A_{1g} \rightarrow {}^3A_{2g}$, ^3E_g and those at 41500 (shoulder) and 44500 cm^{-1} to $^1A_{2g}$ and ^1E_g transitions.[1] The CD spectra are different from each other, showing marked influence of the vicinal effect of the asymmetric nitrogen.

The optical activity due to the chelate ring of N^1-Me-(*S*)-pn may arise from (i) the vicinal effect of the chiral secondary nitrogen, (ii) the conformational effect of the chelate ring, and (iii) the vicinal effect of the asymmetric carbon. Bosnich and Sullivan have shown that the first and the resultant of the remaining two effects are additive in the rotational strength for *R*- and/or *S*-$[PtCl_2(N^1\text{-Me-}(S)\text{-pn})]$.[2] Such additivity can be anticipated to be valid in the CD of the *R*-$[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]^{2+}$ considered here. The CD curve of the racemic N^1-Me-(*S*)-pn complex was subtracted from that of the N(*R*) isomer. The resulting curve (the dotted line in Fig. 4) should be regarded as representing the CD due to the vicinal effect of the *R* asymmetric nitrogen. It is noteworthy that this curve agrees well with the CD of $(-)_{260}$-$[Pt(NH_3)_2(Meen)](ClO_4)_2$ (Fig. 4). The CD band at 31000 cm^{-1} may be assigned to the $^3A_{2g}$ transition.[1]

According to the ^{13}C NMR studies of Bagger[12] and Erickson *et al.*,[13] rapid ring inversion ($\delta \leftrightarrow \lambda$) occurs in the 5-membered chelate ring composed of the Pt(II) and *N*-substituted 1,2-diaminopropane. The present ^{13}C NMR data for *C*-methyl carbons in some relevant complexes are given in Table 3. The β-carbon resonances in $[Pt(NH_3)_2(\text{rac-chxn})]Cl_2$ and the *C*-methyl carbon resonances in $[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]X_2$ and $[Pt(NH_3)_2(\text{rac-pn})]Cl_2$ were readily identified by comparison with the corresponding resonances in complexes of the $[Pt(bipy)(diamine)]Cl_2$ type.[13] Each of these signals is accompanied by two ^{195}Pt satellites. The $^3J_{Pt-C}$ value obtained from the spacing of the satellites is the weighted average of the coupling constants of the conformer with the equatorial C–CH_3 group and that with the axial group; ring inversion changes the equatorial C–CH_3 into an axial one or *vise versa*. Following Erickson *et al.*, the coupling constants $^3J_{Pt-C}$ of 0 and 50 Hz were assigned to the axial and equatorial conformers, respectively.[13] The mol fractions of the equatorial conformer calculated from the observed $^3J_{Pt-C}$ values are listed in the last column of Table 3.

The four possible conformers (I—IV) in $[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]^{2+}$ are illustrated in Fig. 5. The resonances at 16.3 and 16.7 ppm in the racemic N^1-Me-(*S*)-pn complex are attributable to the N(*R*) and the N(*S*) isomer, respectively. The relative abundances of the equatorial and axial C–CH_3 conformers for each of the N(*R*) and N(*S*) isomers indicate that the equatorial conformer is more stable than the axial. The I : II abundance ratio (86 : 14) is greater than that of III : IV (70 : 30), which reflects a greater conformational energy difference between I and II than between III and IV.

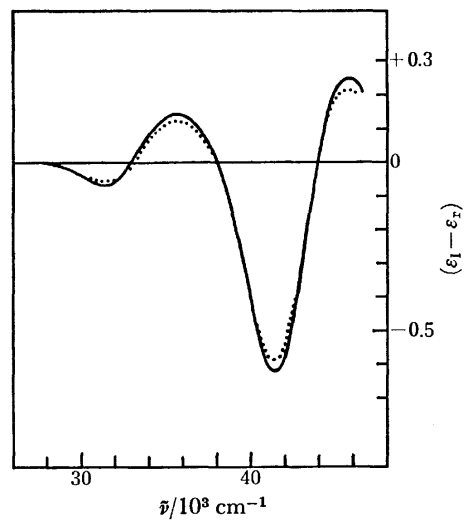

Fig. 4. The calculated curve of $[\Delta\varepsilon(R\text{-}[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})](ClO_4)_2) - \Delta\varepsilon(rac[Pt(NH_3)_2(N^1\text{-Me-}(S)\text{-pn})]Cl_2)]$: ·····, and the CD spectrum of $(-)_{260}$-$[Pt(NH_3)_2(\text{Me-en})](ClO_4)_2$: ——.

a) The mol fraction of the equatorial C–CH_3 conformer. b) Making use of the CD data presented in Ref. 1, Hawkins predicted that the ratio of n_{eq} to n_{ax} is of the order of 3 : 1 (Ref. 14, p. 204). c) Ref. 12; *R*,*R*-bn: (2*R*,3*R*)-2,3-butanediamine. d) These were utilized to check the appropriateness of the $^3J_{Pt-C}$ values assigned to the equatorial C–CH_3 conformer.

The chelate ring of the pn or its derivative has been thought to preferentially assume the conformation with equatorial C–CH_3 even for the planar complex.[14] However, in case there is a significant amount of axial conformers in the system, the CD of the Pt(II) chelate of the pn or its analogue must be reconsidered with the relative populations of the δ and λ conformers being taken into account.

As described above, the additivity found by Bosnich and Sullivan for the CD of *R*- and *S*-[$PtCl_2$(*N*¹-Me-(*S*)-pn)] is probably applicable to the case of *R*-[Pt-$(NH_3)_2$(*N*¹-Me-(*S*)-pn)]$^{2+}$. Thus, the CD curves for the conformers I and II can be represented by $x\Delta\varepsilon$-$[V_N(R)]+x\Delta\varepsilon[eq]$ and $(1-x)\Delta\varepsilon[V_N(R)]+(1-x)\Delta\varepsilon$-[ax] respectively, where $\Delta\varepsilon[V_N(R)]$ is the CD arising from the vicinal effect of N(*R*)–CH_3, $\Delta\varepsilon[eq]$ and $\Delta\varepsilon[ax]$ denote, respectively, the CD due to the (*S*)-pn ring with equatorial C–CH_3 and that with axial C–CH_3, and x is the mol fraction of conformer I. A calculation gives $(1/2)(x+y)\Delta\varepsilon[eq]+[1-(1/2)(x+y)]\Delta\varepsilon[ax]$ for the CD of the racemic compound and $\Delta\varepsilon[V_N(R)]+(1/2)(x-y)\cdot(\Delta\varepsilon[eq]-\Delta\varepsilon[ax])$ for that of the calculated curve in Fig. 4 (y=the mol fraction of conformer III). The chelate ring of the (*S*)-pn has two asymmetry factors: the chirality of the chelate ring conformation and the asymmetric carbon atom. For the Co(III) complex in which one bidentate ligand has two asymmetric centers, it has been demonstrated that the two centers act additively for the CD of the complex.[15] Although the situation is somewhat different, the conformational and vicinal effects are expected to be nearly additive for the rotational strength induced by the (*S*)-pn ring. Then $\Delta\varepsilon[eq]$ and $\Delta\varepsilon[ax]$ may be written as $\Delta\varepsilon[eq]\simeq\Delta\varepsilon[\delta]+\Delta\varepsilon[V_C(S)_{eq}]$ and $\Delta\varepsilon[ax]\simeq\Delta\varepsilon[\lambda]+\Delta\varepsilon[V_C(S)_{ax}]$, where $\Delta\varepsilon[\delta$(or $\lambda)]$ is the CD due to the conformational effect of the δ(or λ) chelate ring and $\Delta\varepsilon[V_C(S)_{eq}]$ or $\Delta\varepsilon[V_C$-$(S)_{ax}]$ is the CD ascribed to the vicinal effect of the equatorial or axial C(*S*)–CH_3.[16] However, $\Delta\varepsilon[V_C(S)_{eq}]$ is known to be small[17] and hence, $\Delta\varepsilon[eq]\simeq\Delta\varepsilon[\delta]$. Thus, the calculated curve can be approximated by

$$\Delta\varepsilon[V_N(R)]+(x-y)\Delta\varepsilon[\delta]-(1/2)(x-y)\Delta\varepsilon[V_C(S)_{ax}].$$

Since x=0.86 and y=0.70 (Table 3), this formula becomes

$$\Delta\varepsilon[V_N(R)]+0.16\Delta\varepsilon[\delta]-0.08\Delta\varepsilon[V_C(S)_{ax}].$$

The CD of [$Pt(NH_3)_2$(*S*,*S*-chxn)]Cl_2 shows two negative bands with intensities $\Delta\varepsilon(^3E_g)=-0.40$ (35000 cm^{-1}) and $\Delta\varepsilon(^1E_g)=-0.86$ (45000 cm^{-1}), and that of [$Pt(NH_3)_2$(*S*-pn)]Cl_2 has two minima with $\Delta\varepsilon(^3E_g)=-0.22$ (35200 cm^{-1}) and $\Delta\varepsilon(^1E_g)=-0.51$ (44800 cm^{-1}).[1,18] The CD curve of the former compound can be considered to display an approximate δ conformational effect, $\Delta\varepsilon[\delta](\simeq\Delta\varepsilon[\delta]+2\Delta\varepsilon[V_C(S)_{eq}])$, whereas that of the latter compound may be approximated by $(2x-1)\Delta\varepsilon[\delta]+(1-x)\Delta\varepsilon[V_C(S)_{ax}]$ which becomes $0.52\,\Delta\varepsilon[\delta]+0.24\Delta\varepsilon[V_C(S)_{ax}]$ upon the substitution of 0.76 for x (Table 3; x=the mol fraction of the equatorial conformer). If the $\Delta\varepsilon$ value of the latter CD curve is divided by 0.52, we obtain $\Delta\varepsilon[\delta]+0.46\Delta\varepsilon[V_C(S)_{ax}]$, which gives a curve with two extrema of $\Delta\varepsilon(^3E_g)=-0.42$ (35200 cm^{-1}) and $\Delta\varepsilon(^1E_g)=-0.98$ (44800 cm^{-1}). These $\Delta\varepsilon$ value are in agreement with the corresponding ones for the *S*,*S*-chxn complex. This indicates that the vicinal effect is small compared with the conformational effect: $0.46|\Delta\varepsilon[V_C(S)_{ax}]|\simeq(1/2)|\Delta\varepsilon[V_C(S)_{ax}]|\ll|\Delta\varepsilon[\delta]|$. Therefore, the calculated curve can be taken as representing

$$\Delta\varepsilon[V_N(R)]+0.16\Delta\varepsilon[\delta].$$

The secondary nitrogen in $(-)_{260}$-[$Pt(NH_3)_2$(Me-en)]$^{2+}$ is sure to be of *R* configuration from a comparison of the Cotton effect for this complex with that for $(+)_{260}$-[$Pt(NH_3)_2(Me_3en)$]$SbCl_5$, the absolute configuration of which was determined by the X-ray method[19] (Me_3en= *N*,*N*,*N*′-trimethylethylenediamine). The N–CH_3 group in the *R*-Meen complex is considered to favor the equatorial disposition in view of the steric interaction with solvent molecules (and/or with some anions in the solution) which may be located at the axial positions of the complex cation. This disposition of the N–CH_3 imposes a δ conformation on the chelate ring in contrast to the λ conformation induced by the axial N–CH_3. Accordingly, the CD curve of the *R*-Meen complex is presumably represented by the formula

$$\Delta\varepsilon[V_N(R)]+z\Delta\varepsilon[\delta]$$

(z=the difference between the mol fraction for the equatorial N–CH_3 conformer and that of the axial conformer, which is greater than zero in this case). Although the good agreement between the calculated curve and the CD spectrum of the *R*-Meen complex is accidental, this agreement supports the fact that the δ conformational effect is partly responsible for the calculated curve,[20] and moreover, this curve receives little contribution from the vicinal effect of the asymmetric carbon.

As mentioned above, $\Delta\varepsilon[\delta]$ may be very similar to the CD of [$Pt(NH_3)_2$(*S*,*S*-chxn)]$^{2+}$ and, hence, may have relatively intense ^3E_g and ^1E_g CD bands. If the curves shown in Fig. 4 are corrected for the δ conformational contribution, the intensities of the ^3E_g and ^1E_g components due to the N(*R*) vicinal effect will have some, not insignificant, enhancement. However, the signs of the Cotton effects are taken to be those characteristic of the N(*R*)–CH_3 group.

This research was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education. The authors wish to express their thanks to Drs. Kousuke Kusuda and Sabu Kasai of Osaka City University for the ^{13}C NMR measurements.

(Received March 14, 1977)

In order to establish a reliable and rapid method for the determination of rubidium in biological materials using atomic absorption spectroscopy, chemical interference as well as ionization interference due to co-existing elements and some organic substances was studied. In the presence of potassium of sufficient concentration, most of the interference was found to be negligible. The temperature of the sample solutions proved to be a possible source of error. The process of sample preparation was examined, including a determination of the loss of rubidium in dry ashing. The accuracy and precision of the method was tested by analyzing NBS SRM 1577 Bovine Liver. The rubidium contents of typical biological materials—foodstuffs, human tissues and urine—were determined by the present method and a possible relationship between the rubidium and potassium concentrations is indicated.

Rubidium is an element the behavior of which in biological systems is similar to that of potassium.[1] However, its data on the transfer of this element from the environment to man and on its distribution in the human body are relatively few.[2,3] Rubidium has a natural radioactive isotope, ^{87}Rb, the half-life of which is 4.8×10^{10} years and the abundance of which is 27.85 %.[4] The radioactivity of ^{87}Rb is calculated to be 52.9 disintegrations per min per milligram of rubidium, which cannot be neglected from the standpoint of radiological health problems. The development of rapid and precise methods for the determination of natural rubidium in biological and environmental materials has recently become urgent.

Rubidium has usually been determined using emission spectrography, X-ray fluorescence analysis, or neutron activation techniques,[5] which require rather complicated equipment and are not considered to be very convenient methods in most laboratories. Flame emission spectrometry, which is claimed to be simple and of satisfactory sensitivity, is subject to unavoidable interference due to the neighboring strong potassium lines even when spectrometers of high spectral resolution are used.[6,7] This problem necessitates wavelength scanning which is time consuming.

Only a few papers have been reported on the determination of rubidium in biological materials by atomic absorption spectroscopy. In this report, in order to establish a rapid method of atomic absorption spectroscopic determination of rubidium, the chemical interference due to the co-existing elements and acids, as well as the ionization interference effect, was studied. It was confirmed that rubidium in typical biological materials can be rapidly determined, free from the effect of interference, using the proposed method, which was proven using a biological standard material.

Experimental

Instrument. Perkin-Elmer Model 303 and 403 atomic absorption spectrophotometers were used with 10-cm slot burner heads for air-acetylene flames. An Osram rubidium discharge lamp covered with filter paper having an 8 mm × 8 mm square aperture was used. Thus, about a two-fold increase in intensity was obtained supposedly due to the integration of the emitted light by reflection. A UV-cut filter (Hoya Glass Works, Tokyo, O-56) was placed just in front of the entrance slit of the Model 303 instrument. A Hitachi 056 strip chart recorder was employed. A Medical Spectrometer (Tokyo Shibaura Electric Co.) with a well-type NaI(Tl) detector was used for gamma scintillation counting.

Reagents. Rubidium chloride and cesium chloride were purchased from E. Merck AG. and used in most of the experiments. A 1000 μg cm^{-3} rubidium stock solution for quantitative determination was prepared by dissolving 1.415 g of Johnson Matthey "Specpure" rubidium chloride in 1000 ml of distilled water. The rubidium-86(tracer with a half-life of 18.66 d, supplied as a chloride, a specific activity of 0.833 mCi/mg-Rb) was obtained from the Radiochemical Centre, U. K., and diluted before use. Most of the other reagents used were of JIS Special Grade or Analytical Grade.

Results and Discussion

Optimum Operating Conditions. Typical operating conditions adopted are summarized in Table 1. The light beam, 2, 6, and 15 mm in height above the burner, approximately sampled the primary, interconal and outer zones, respectively. A comparatively small variation in absorbance was observed over the range of acetylene flow rate examined in the presence of potassium at a height of 7 mm (Fig 1). Some enhancement of the rubidium absorbance was observed when the acetylene cylinder pressure was reduced below 5 kg/cm^2. This effect, which occurred up to 30% of the relative absorbance, was suspected to be due to acetone vapor liber-

ated from absorbing beds.

Comparison between Atomic Absorption and Emission Spectroscopy. The effect of the spectral band width on the signal-to-noise ratio of the rubidium absorbance signal in the presence of potassium was negligible as expected from theoretical considerations,[8] as is shown in Table 2. The peak-to-background ratio of the emission spectrum seriously deteriorated when wider slit widths were used, revealing the need for time-consuming scanning employing a narrow slit width (Fig. 2). Furthermore, it should be born in mind that many molecular emission bands such as the CrO 777.8- and 781.2-nm bands, the LaO 775.9-nm band, the FeO 777.5-nm band and the VO 785.1-nm band can interfere with the rubidium 780.0-nm line.[8,9]

The Effect of Other Alkali and Alkaline-earth Metals. Lithium, sodium, potassium, and cesium, as chlorides at concentrations greater than 100 μg cm^{-3} caused the rubidium absorbance to increase. In the interconal zone, the enhancement reached saturation at metal concentrations of greater than 1000 μg cm^{-3} while the saturation point shifted to the range from 2500 to 5000 μg cm^{-3} in the outer zone (Fig. 3). In the case of cesium, the rubidium absorbance apparently increases linearly with the concentration of cesium at concentrations greater than 1000 μg cm^{-3}. This was proven to be due to the rubidium impurity in the cesium chloride used (0.40 μg/mg of Cs as determined by atomic absorption) and the absorbance corrected for the reagent blank disclosed saturation at cesium concentrations greater than 500 μg cm^{-3}. The degree of enhancement was compared for these elements on a molar basis. The order was found to be Li<Na<K<Cs, which agrees with the inverse order of their ionization energies: 5.39 eV for Li, 5.14 eV for Na, 4.34 eV for K, and 3.89 eV for Cs.[8] The effect was more marked in the outer zone (Fig. 3). Flame temperatures in the outer zone were found to be higher than in the lower part for an air-acetylene flame closely matched to the flame conditions used here.[10] From these results, it is concluded

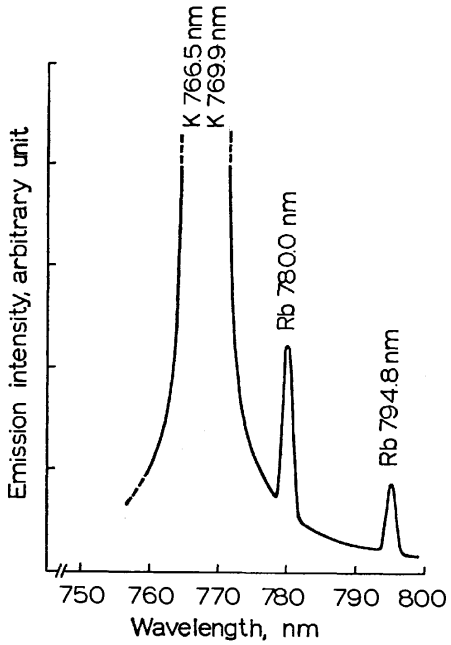

Fig. 2. A typical emission spectra of rubidium in the air-acetylene flame in the presence of potassium obtained by scanning. 2 μg cm^{-3} Rb+2000 μg cm^{-3} K (0.1 mol dm^{-3} HCl). Spectral band width: 1.4 nm; Scanning speed: 10 nm/min.

that the suppression of rubidium ionization by other easily ionized alkali metals[11,12] is the essential mechanism of this effect.

Alkaline-earth metals show a less pronounced but similar effect and the enhancement was found to be Mg<Ca<Sr<Ba, which is the inverse of their ionization energies: 7.65 eV for Mg, 6.11 eV for Ca, 5.69 eV for Sr, and 5.21 eV for Ba.[8] Magnesium, calcium, and strontium at greater than 1000 μg cm^{-3}, however, exhibited a slight suppression of the rubidium absorbance which had been enhanced at lower concentration levels. This negative interference was not observed in the outer zone (Fig. 4). It appears that the alkaline-earth metals were ionized to some extent in air-acetylene flames exhibiting ionization interference and that, at higher concentrations (2500 to 5000 μg cm^{-3}), they caused chemical interference by retarding the atomization of rubidium, possibly through occlusion in and/or adsorption to clotlets in the primary and interconal zones.

The enhancements of alkali and alkaline-earth metals at 10—20 mmol dm^{-3} were compared, with the resulting order in the interconal zone: Li, Mg<Ca< Sr<Ba<Na<K<Cs. This is in good agreement with the inverse order of the ionization energies for all these elements except lithium.

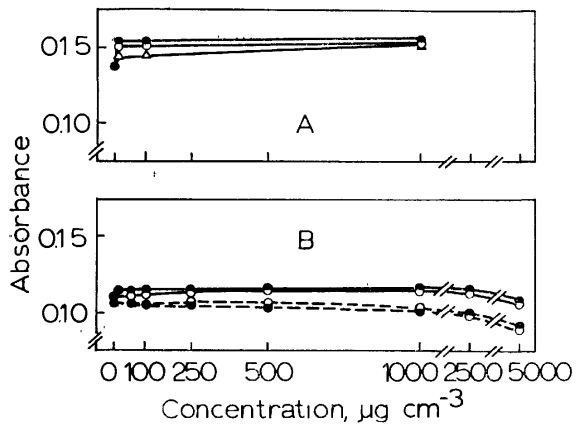

Fig. 5. Effect of transition metals and aluminium.

(B) 5 μg cm^{-3} Rb+Al as nitrate (●), as chloride (○).
—— interconal zone; ---: primary zone.

The Effect of Several Transition Metals and Aluminium. Iron, chromium, zinc, and copper at concentrations of 10 to 1000 μg cm^{-3} exhibited small positive interference while the effect of manganese was negligible at concentrations below 100 μg cm^{-3} (Fig. 5). Aluminium, as a nitrate at concentrations in the range from 100 to 2500 μg cm^{-3}, exhibited a small enhancement although it noticeably lowered the rubidium absorbance at 5000 μg cm^{-3} as either a nitrate or a chloride. For systems containing 1000 μg cm^{-3} of potassium, sodium showed no influence on the rubidium absorbance up to 1000 μg cm^{-3} and virtually no effect was observed for calcium, iron, copper, zinc, manganese, and aluminium up to 1000 μg cm^{-3} (Fig. 6). A small negative interference due to magnesium was observed in the presence of potassium. The use of nitric acid proved favorable when aluminium is present in sample solutions.

The Effect of Mineral Acids. No appreciable effect due to nitric acid was observed. Hydrochloric and perchloric acid exhibited slight enhancement at 0.1 mol dm^{-3} but a negative interference of about −30% at

2 mol dm^{-3} was observed (Fig. 7). This interference was inferred to be due to the formation of the diatomic molecule, RbCl, in the flame.[13] Phosphoric acid severely interfered causing a −50% decrease in signal even at 0.2 mol dm^{-3}. With sulfuric acid, the absorbance decreased and the aspiration rate of the sample solution was found to be reduced. In the presence of 1000 μg cm^{-3} of potassium, the negative interference for these acids at a concentration of 0.1 mol dm^{-3} was negligible, except for phosphoric acid in which case the interference was reversed to only −22% at 0.2 mol dm^{-3}. Precipitation occurred in solutions containing potassium and of perchloric acid concentrations greater than 0.5 mol dm^{-3}, which perturbed the rubidium absorbance measurements (Fig. 8).

The Effect of Phosphates. Phosphates at concentrations in the form of P below 2500 μg cm^{-3}, including free orthophosphoric acid, exhibited interference, except when the counter cation was potassium (Fig. 9). For an added potassium concentration of 1000 μg cm^{-3}, the interference of phosphoric acid, ammonium phosphate and calcium phosphate was reversed to from −3 to −5% at a P concentration of 1000 μg cm^{-3}. For the purpose of suppressing the phosphate interference, potassium should be added so as to render the K/P ratio greater than two.

The Effect of Silicates. No systematic study on the effect of silicates was carried out but some interference was observed. Since silicates exist in considerable amounts only in plant materials, this interference is expected to be negligible for most biological materials.

The Effect of Organic Acids and Their Ammonium Salts. Several ammonium salts of organic acids are used for separating alkali elements from matrices by ion-exchange column chromatography. In this connection, the effects of formic, acetic, lactic and tartaric acids and their ammonium salts were examined and the results are shown in Fig. 10. Trichloroacetic acid was selected since it is used for precipitating proteins from biological fluids. Acetic acid enhanced the rubidium absorbance while its trichloro derivative caused a severe reduction especially in the presence of 1000-μg cm^{-3} potassium concentrations. The effect of trichloroacetic acid is assumed to be due to liberated chlorine which tends to form RbCl. Ammonium formate, ammonium acetate and ammonium lactate in concentrations up to 0.5 mol dm^{-3} in the presence of 1000 μg cm^{-3} of potassium caused only a negligible effect and these are the most probable cases for practical application. These organic

substances, however, should be decomposed prior to nebulization, because they can clog the burner slot.

The Effect of the Solution Temperature. At higher sample solution temperatures, a considerable increase in absorbance was observed (Fig. 11). This phenomenon was accompanied by an increase in the rate of sample aspiration through a capillary. If sample and standard solutions of different temperatures are measured, considerable error will result.

Sensitivity and Detection Limit. Typical analytical curves for rubidium with potassium added are shown in Fig. 12. The slight non-linearity can be attributed to self-absorption in the light source. It is not expected that this can be avoided by replacing the discharge lamp with a hollow cathode, because no essential difference was observed between Na and K analytical curves obtained using metal discharge lamps and those obtained using hollow-cathode lamps. This non-linearity excludes the use of the standard addition method in precision analysis.

Only less than a 1% reduction in sensitivity was observed when further addition of sodium, calcium and phosphorus, each at 500 μg cm^{-3}, were made. The sensitivity for rubidium under these conditions was calculated to be 0.08 μg cm^{-3} for 1% absorption (0.0044 absorbance). The detection limit obtained by digital signal averaging over about 10 s was 6.5 ng cm^{-3}.

TABLE 3. LOSS OF RUBIDIUM DURING DRY ASHING AND PREPARATION OF SILICA-FREE SAMPLE SOLUTIONS DETERMINED BY Rb-86

Material	Wet weight (g)	Ashing temperature (°C)	Ashing time (h)	Recovery (%)
Cabbage	100	450	24	99.6
		550	3	94.5
Beef	100	450	24	99.8
		500	8	97.1

Cabbage was homogenized using a Waring blender, transferred to a porcelain dish, mixed thoroughly with a quantity of Rb-86 tracer and dried at 100 °C prior to ashing in a muffle furnace. Beef was minced, mixed with a quantity of Rb-86 tracer, and treated in a similar manner.

Decomposition of Biological Materials. The loss of rubidium during dry ashing and the conventional procedure for removing silica using concentrated hydrochloric acid (Table 3) was compared with the loss during

				Mean ± s. d.	
				18.6 ± 0.20	

a) Dried at 90°C for 24 h. The ash was taken up in 10.00 cm^3 of 0.1 mol dm^{-3} HNO_3. b) Mean of five measurements with relative standard deviation of 0.6% for an approximately 10 s digital integration ("100 AVR").

acid digestion (the recovery found, 99.7%). No appreciable rubidium loss was found for dry ashing. When extremely accurate determinations are required, a temperature of 450 °C should be used.

Preparation of Samples. Fifty to two hundred grams of fresh vegetables and cerials were dried at 90 °C for 24 h and ashed. Silica was removed as usual. The edible parts of about 50 g of fresh fish and shellfish were selected and processed as stated above without the removal of silica. About 50 g of meat was processed in the same manner. Two hundred milliliters of milk was evaporated in a porcelain evaporating dish on a water bath and then ashed. Urine sampled for 24 h, about 1.5 dm^3, was digested by repeated treatment with concentrated nitric acid and 30% hydrogen peroxide with heating, then evaporated to dryness and dissolved with distilled water. Regarding human tissue, about 10 g of fresh material was used. Finally, sample solutions were adjusted to 0.1 mol dm^{-3} using nitric or hydrochloric acid and the content of potassium was determined by atomic absorption or by emission in order to confirm that the concentration was in the range of 1000 to 5000 μg cm^{-3}. As necessary, potassium was added to sample solutions.

Accuracy and Precision. A biological reference material, NBS SRM 1577 Bovine Liver, was analyzed and the results are summarized in Table 4. The sample solution contained roughly 1300 μg cm^{-3} of potassium. The analytical results were in good agreement with the certified value.

Rubidium Content of Biological Materials. Some analytical results for typical biological materials made using the present method are listed in Tables 5 and 6. The values of the rubidium content found for these samples were in the range from 0.4 to 7 μg/g fresh weight. Higher figures were found for meat and milk than those for vegetables and fish. This relationship was again found when the results were compared on a potassium weight basis: 2—3 μg-Rb/mg-K for meat and milk as compared to 0.2—0.6 μg-Rb/mg-K for vegetables and fish. Human lung, liver, and spleen were found to contain slightly higher concentrations than the other tissues examined. The Rb/K ratios fall in the range 1.5—3.5 μg-Rb/mg-K for human tissues. From these results it may be inferred that mammals including man concentrate rubidium more than potassium during the incorporation of these alkali metals from precursors.

A Temperature-Jump Study of the Formation Reactions of Nickel(II)–Pyridine Complexes in Aqueous Solutions

**Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730*

(Received March 26, 1977)

A temperature-jump study reveals two relaxation phenomena in aqueous nickel(II)–pyridine solutions. One is observed in a metal-rich and low-concentration system, while the other is found only in a ligand-rich and high-concentration system. The relaxation processes are ascribed to the complex formation reactions:

$$Ni^{2+} + py \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ni(py)^{2+} \quad \text{and} \quad Ni(py)_2^{2+} + py \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Ni(py)_3^{2+}$$

The rate constants reported are: 3.6×10^3 M^{-1} s^{-1} for k_1 and k_3, 37 s^{-1} for k_{-1}, and 760 s^{-1} for k_{-3}, at 25 °C. The effect of the coordinated pyridine molecules on the reactivity of the metal is discussed.

Considerable information now exists on the kinetics of the complex formation reactions of metal ions with organic and inorganic ligands.[1,2] In particular, much effort has been directed toward characterizing the solvent lifetimes within the inner coordination spheres of the metal ions. However, these studies have been concerned almost entirely with the formation reactions of mono-ligand complexes, and considerably less is known about the kinetics of multi-ligand complexes, in particular, of unidentate ligands. This is because a fundamental difficulty exists in these studies. For obtaining kinetic information on these complexes, experiments have to be made on solutions in a ligand-rich concentration range. However, this condition generally produces many kinds of complexes in solution and introduces a complication in reaction analysis.

In the present study, complex formation reactions in the aqueous nickel(II)–pyridine system were investigated to begin with. Although many studies[1,2] have been made on the kinetics of the reactions of Ni^{2+} with unidentate and multidentate heterocyclic amines, few systematic studies have been made on the nickel(II)–pyridine system, especially from the above point of view. Any information obtained will be helpful in elucidating the detailed reaction mechanism of the formation of multidentate complexes.

Experimental

Pyridine of a reagent grade was dried over KOH and distilled once. The other chemicals used were of a reagent grade and were used without further purification. Distilled water was degassed by boiling it immediately before use. Sample solutions were prepared by mixing appropriate amounts of aqueous stock solutions of $Ni(NO_3)_2$, pyridine and, when necessary, Bromothymol Blue as a colorimetric pH-indicator. The ionic strength, I, was brought to the desired level by the addition of KNO_3. The pH was adjusted by the addition of NaOH and/or HNO_3.

The temperature-jump apparatus used and the experimental procedure have been described elsewhere.[3] The only change in the apparatus was that the cathode follower previously used was replaced by a 1 : 1 probe (Iwatsu 117B2). This improvement has resulted in an increase in the signal-to-noise ratio by a factor of two. The relaxation measurement was carried out at 25±1 °C.

Results

The experimental conditions and the kinetic data obtained are summarized in Table 1. All the solutions studied showed a single relaxation phenomenon. The reciprocal relaxation times, τ_1^{-1} and τ_2^{-1}, quoted in Table 1 represent an average of at least four experiments. The maximum errors are about ±10 and 15%, respectively. As is shown in Table 1, the kinetic studies were carried out for two different concentration ranges.

0.100	0.360	6.89		14.7

a) The equilibrium constants used:[5] pK_H=5.44, $\log K_1$ =1.91, $\log K_2$ = 1.28, and $\log K_3$ = 0.52, at 25 °C and I=0.6. b) Converted to $[H^+]$ by the use of γ_H =0.825 and 0.806 at I=0.10 and 0.30, respectively. c) Solutions contain 2×10^{-5} M Bromothymol Blue indicator (pK_{In} = 7.10, I=0.1).[6]

One has relatively low concentrations, mostly in the metal-rich region (I=0.10), and the other, high concentrations in the ligand-rich region (I=0.30).

The low concentration system contained Bromothymol Blue indicator, and the temperature-jump relaxation phenomenon was observed by following the absorbance at the wavelength of 617 nm. A representative relaxation effect is shown in Fig. 1. Blank solutions of the nickel-indicator and pyridine-indicator systems showed no relaxation effect in the same time range.

On the other hand, the indicator method is not effective in the ligand-rich region, because the amplitude of the relaxation signal decreases with an increase in the concentration of pyridine. Therefore, the experiments in this region were carried out at high concentrations and without a pH-indicator. The wavelength of the observation was 605 nm, where the nickel–pyridine solution exhibits an absorbance maximum. Figure 2 shows a representative relaxation effect. A solution containing only 0.1 M $Ni(NO_3)_2$ at pH=6.8 showed no relaxation effect in the same time range.

The above results indicate that the relaxation times in Table 1 are really associated with nickel–pyridine interactions.

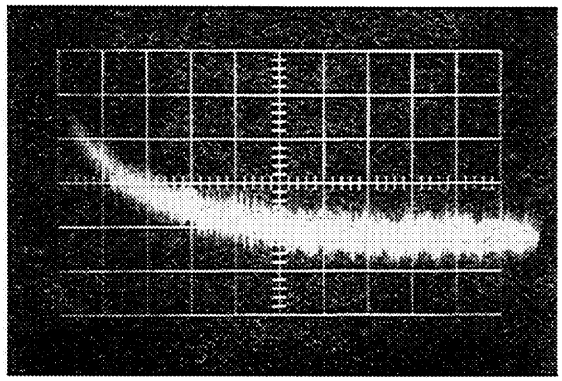

Fig. 1. Relaxation effect in nickel-pyridine system: $\Sigma Ni=9.92\times10^{-3}$ M, Σ py$=2.54\times10^{-3}$ M, pH=7.23, I=0.10 with 2×10^{-5} M Bromothymol Blue as an indicator. The abscissa scale is 10 ms per division, and the vertical scale is in arbitrary unit of absorbency. The relaxation effect corresponds to an increase in absorbance with time.

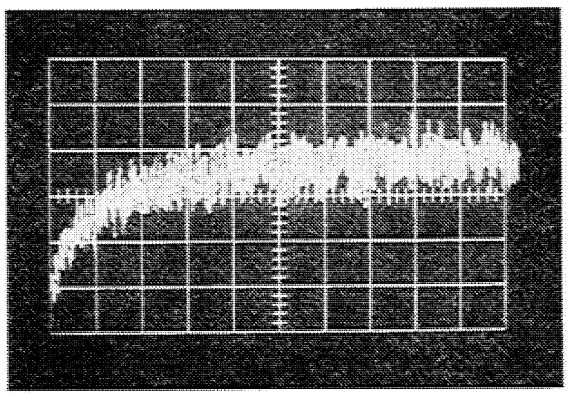

Fig. 2. Relaxation effect in nickel-pyridine system: Σ Ni$=0.100$ M, Σ py$=0.257$ M, pH=6.89, I=0.30. The abscissa scale is 0.5 ms per division, and the vertical scale is in arbitrary unit of absorbency. The relaxation effect corresponds to a decrease in absorbance with time.

Treatment of Data

Under the experimental conditions studied, the formation of nickel(II)–pyridine complexes may proceed most generally by the following reaction mechanism:

$$Hpy^+ \overset{\text{fast}}{\rightleftharpoons} H^+ + py \qquad K_H,$$

$$Ni^{2+} + py \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ni(py)^{2+} \qquad K_1, \qquad (1)$$

$$Ni(py)^{2+} + py \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Ni(py)_2^{2+} \qquad K_2, \qquad (2)$$

$$Ni(py)_2^{2+} + py \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Ni(py)_3^{2+} \qquad K_3, \qquad (3)$$

where py denotes the pyridine molecule and where K_H, K_1, K_2, and K_3 are the equilibrium constants for the corresponding reactions. If the relaxation process is ascribed to one of the reactions, (1—3), the corresponding relaxation time is given by:

$$\frac{1}{\tau} = k_n\{[Ni(py)_{n-1}^{2+}] + [py]\} + k_{-n}, \quad n=1,\ 2,\ \text{or}\ 3, \qquad (4)$$

where the brackets indicate the molar concentration at equilibrium. The protolytic reactions of pyridine and the pH-indicator (when it is added in solution) reach equilibrium much faster than the metal complex reactions (1—3), and they can be assumed to be in equilibrium at all times. However, the contributions of these equilibria to the relaxation times can be ruled out under the experimental conditions studied,[4] and so this effect has been ignored in Eq. 4.

The equilibrium constants used are listed in the footnote of Table 1. The values of the constants at I=0.6 were used without further corrections to the present systems at I=0.10 and 0.30. This approximation may not cause serious errors in the results because of the charge types of the reactions concerned. The equilibrium concentrations of various species in solution were calculated from the ΣNi, Σpy, and pH values in Table 1 by using these equilibrium constants.

Table 1 shows the two concentration-dependent relaxation times (τ_1 and τ_2), which were observed in very different concentration ranges. Since these relaxation times could be ascribed to different processes, they will be discussed separately.

Low-concentration Time (τ_1). An examination of the equilibrium concentrations shows that the predominant species in the solution are Ni^{2+}, py, and $Ni(py)^{2+}$. Then, the relaxation process can be attributed primarily to the complexation reaction (1). As is shown in Fig. 3, a graph of τ_1^{-1} *vs.* $[Ni^{2+}]+[py]$ plot gives a straight line. The slope and intercept of this line correspond to the rate constants k_1 and k_{-1}, respectively. The ratio of these values, 97±13, conforms with the equilibrium constant for this process. The rate constants obtained are shown in Table 2.

High-concentration Time (τ_2). The relaxation time was observed only in the solutions at high nickel concentrations with a pyridine-rich region. When the concentration of pyridine decreases further than those

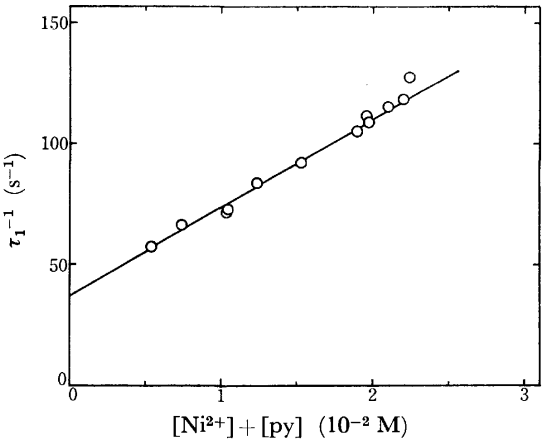

Fig. 3. $1/\tau_1$ *vs.* $[Ni^{2+}]+[py]$ plot of nickel-pyridine system at 25 °C, $I=0.10$.

Table 2. Kinetic results for the formation of nickel-pyridine complexes at 25 °C

n	$k_n(M^{-1}s^{-1})$	$k_{-n}(s^{-1})$
1	$(3.6\pm0.3)\times10^3$	37±4
3	$(3.6\pm1.5)\times10^3$	760±280

studied here, the amplitude of the relaxation effect decreases rapidly. This fact indicates that the relaxation process could not be ascribed to Reaction 1. In fact, the τ_1^{-1} value expected in this concentration range was estimated to be lower by a factor of 0.25—0.41 than the τ_2^{-1} value in Table 1. Therefore, the investigation was carried out by associating the relaxation process with one of the reactions, (2 or 3). By using Eq. 4, it was found that only the case of $n=3$ is consistent with the present data.[7] As is shown in Fig. 4, a graph of τ_2^{-1} *vs.* $[Ni(py)_2^{2+}]+[py]$ plot gives a straight line. From the slope and intercept of this line, the rate constants k_3 and k_{-3} were obtained; they are also shown in Table 2. The ratio of these values gives $K_3=4.7\pm2.7$, which is close to the corresponding value used.

In the system of interest here, an additional complication is introduced by the fact that the contribution of Reaction 2 to the relaxation process must be taken into account. By a relaxation treatment coupling the two reactions, (2 and 3), we obtain:[8]

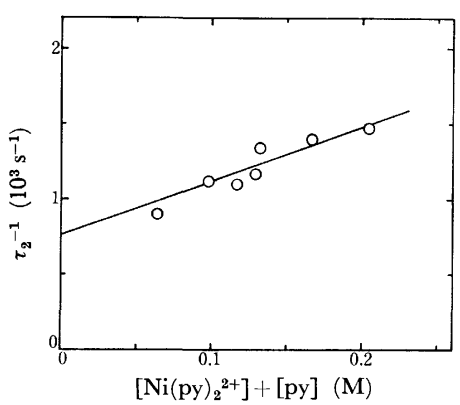

Fig. 4. $1/\tau_2$ *vs.* $[Ni(py)_2^{2+}]+[py]$ plot of nickel-pyridine system at 25 °C, $I=0.30$.

$$\frac{1}{\tau}=\frac{a_{11}+a_{22}}{2}+\left[\left(\frac{a_{11}-a_{22}}{2}\right)^2+a_{12}a_{21}\right]^{1/2}, \quad (5)$$

where $a_{11}=k_2\{[Ni(py)^{2+}]+[py]\}+k_{-2}$, $a_{12}=k_2[Ni(py)^{2+}]-k_{-2}$, $a_{21}=k_3\{[Ni(py)_2^{2+}]-[py]\}$, and $a_{22}=k_3\{[Ni(py)_2^{2+}]+[py]\}+k_{-3}$. The relaxation time was calculated by means of Eq. 5, with the k_3 and k_{-3} values in Table 2, together with appropriately assumed k_2 values and by use of the relation $k_{-2}=k_2/K_2$. Thus, the k_2 value in the range, $(2—5)\times10^3$ M^{-1} s^{-1}, is proven to affect the relaxation time only 8% at most. Therefore, the relaxation process can be ascribed solely to Reaction 3.

Discussion

The k_1 value in Table 2 is close to the corresponding rate constants reported for the reactions of Ni^{2+} with neutral unidentate ligands[1,2] and is also consistent with the first-order rate constant of the water exchange of the nickel ion measured by NMR.[9,10] This result indicates that the formation reaction of $Ni(py)^{2+}$ proceeds *via* the Eigen mechanism,[11] which involves the loss of a water molecule in the rate-determining step. Table 2 shows also that the value of k_3 is the same as that of k_1. This result leads one to conclude that the formation reaction of the $Ni(py)_3^{2+}$ complex proceeds by a mechanism similar to that cited above and that the rate of water release from $Ni(py)_2^{2+}$ is close to that of Ni^{2+}. This conclusion is similar to that already reached by Hammes and Steinfeld[8] for the consecutive formations of nickel(II)–imidazole complexes, although they obtained a slightly decreasing tendency of $k_1>k_2>k_3$.

On the other hand, the dissociation rate constants, k_{-1} and k_{-3}, are very different from each other; these values determine the corresponding stability constants of the complexes. It is interesting to note that the k_{-3} value is much higher than the k_{-1} value, even taking into account the fact that the chance of the liberation of a pyridine molecule from $Ni(py)_3^{2+}$ is three times larger than that from $Ni(py)^{2+}$. The conclusion remark is that the pyridine molecules coordinated to the nickel ion enormously enhance their own lability, but little affect the lability of the coordinated water molecules. This fact suggests that the crowding of the bulky ligand molecules in the inner coordination sphere loosens solely the Ni–N bonds and facilitates their rupture. The dissociation rate constants of the mono-, bis-, and tris-imidazole–nickel(II) complexes[8] and those of the mono- and tris-(2,2′-bipyridine)–nickel(II) complexes[12] also support this idea, although in the latter complexes the absolute values of the rate constants are extremely low as a result of the stabilization effect of chelation.

Transition-metal Complexes of Pyrrole Pigments. XIV.[1] An Electron Spin Resonance Study of Bis(3,3′,5,5′-tetramethyldipyrromethenato)manganese(II)†

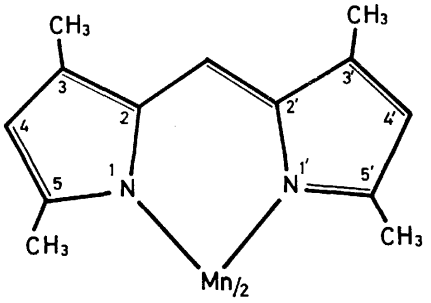
Yoshihisa MATSUDA and Yukito MURAKAMI*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 13, 1977)

Bis(3,3′,5,5′-tetramethyldipyrromethenato)manganese(II) in single crystalline and powdered sample states was investigated by means of K-band ESR spectroscopy. The spectral shape for the single crystal depends highly on the angle between the external magnetic field and the crystal axes. Anisotropic parameters D and E evaluated by the simulation method are 0.12 ± 0.01 and 0.032 ± 0.004 cm^{-1}, respectively. These values are considerably larger than those expected for the distorted tetrahedral manganese(II) complexes formed with four equivalent donor atoms. An origin of these large anisotropic parameters has been discussed.

Some bivalent and trivalent manganese complexes of dipyrromethenes were observed previously to show d→d transition bands of unusual high intensity.[2] The high transition probabilities can be attributed to mixing of the excited states of different spin-multiplicity into the ground electronic state through the simple spin-orbit coupling interaction, or else to the strong covalent interaction between manganese and aromatic nitrogen atoms. The ground state of high spin manganese(II) complexes should have d-electrons distributed in a manner of spherical symmetry, *i.e.*, it is in the sextet S-like state. Bis(3,3′,5,5′-tetramethyldipyrromethenato)-manganese(II) (**1**), referred to TMD-Mn(II) hereafter,



1

shows d→d bands of unusual high intensity ($\varepsilon\simeq160$) with some broadening.[2] This spectral feature indicates that the above mentioned effects are significant for the complex. The purpose of this paper is to discuss the electronic structure of TMD-Mn(II) and to characterize the anisotropic nature of the ground state by means of ESR spectroscopy applied to both single crystalline and powdered samples.

Experimental

The preparative procedure for TMD-Mn(II) has been reported previously.[2] Single crystals were grown by cooling down the saturated hexane solution from refluxing to room temperature.

ESR spectra were recorded on a JEOL JES-3K K-band spectrometer, equipped with a 100-kHz field modulation unit and with a modulation amplitude of 20 G, for both single

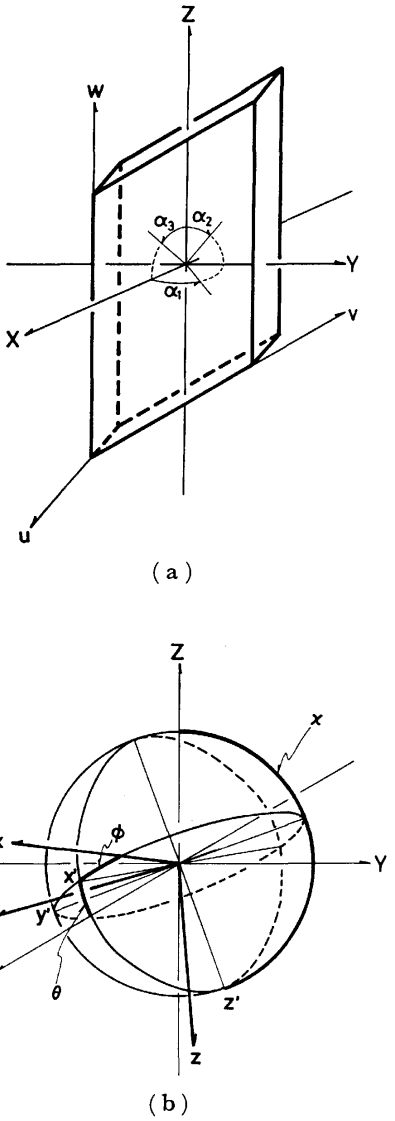


Fig. 1. (a) Correlation between crystal axes (u, v, and w) and experimental axes (X, Y, and Z) about which magnetic field is rotated: Z//w, X⊥vw-plane; α_1,α_2, and α_3 represent rotation angles about Z, X, and Y, respectively. (b) Correlation between molecular axes (x, y, and z) and coventional axes (X, Y, and Z) defined in Fig. 1a: rotations about X-, y′-, and z-axes by χ, θ, and ϕ (Eulerian angles), respectively, in this sequence convert X, Y, and Z coordinates to x, y, and z.

† Contribution No. 400 from this Department.

crystalline and powdered samples. The manganese(II) ion diffused thermally into magnesium oxide was used to provide the reference signals for measurements. The lack of crystallographic data for the single crystal made it difficult to establish *a priori* the relevant axes for ESR measurements in connection with the molecular coordinates. The Cartesian coordinates X, Y, and Z were set up for convenience with respect to the rhombohedral single crystal as shown in Fig. 1a. The crystal axes u, v, and w, defined as shown in Fig. 1a, have no ordinary crystallographic meaning. The Z-axis is parallel to the w-axis, and the X-axis is perpendicular to the vw-plane, while the Y-axis is perpendicular to both X and Z. The single crystal was mounted on a sample holder in a manner that the magnetic field can be applied effectively in a direction perpendicular to one of X, Y, and Z axes, and rotations were performed about these axes for ESR measurements. The rotation angles about these axes (α_1, α_2, and α_3) are defined as shown in Fig. 1a.

Computational Procedures

The ordinary ESR signals for the d^5 system are interpreted by the spin Hamiltonian

$$\mathscr{H} = g\beta H\cdot S + D[S_z^2 - S(S+1)/3] + E[S_x^2 - S_y^2] + AS\cdot I + \text{higher order terms} \quad (1)$$

The contribution of higher order terms is usually very small, in fact confirmed to be so in this work, and can be neglected. In addition, the hyperfine term was neglected due to the absence of such hyperfine ESR structures for the present undiluted chelate system. Then, Eq. 1 is simplified as follows for the six spin states ($m_s = 5/2 \text{——} 5/2$)

$$\mathscr{H} = g\beta H\cdot S + D[S_z^2 - S(S+1)/3] + E[S_x^2 - S_y^2] \quad (2)$$

Computations were performed by substituting sets of D and E values of reasonable magnitude. The level splittings were evaluated by solving the Hamiltonian for every 10° of both Θ and Φ, where Θ and Φ are the polar angles for the direction of magnetic field in the molecular coordinate system (x, y, and z), and the magnetic field intensities at resonance were consequently obtained. The numerical calculations were carried out on a Facom 230-60 computer of the Computer Center of Kyushu University. The anisotropic parameters D and E were obtained roughly from comparison of the ESR spectrum for powdered sample and the calculated resonance positions for the applied magnetic field parallel to the anisotropic axes (molecular axes) as shown in Figs. 3 and 4. The D and E parameters were then reexamined whether or not one set of parameters allows the existence of the corresponding set of reasonable θ, ϕ, and χ values (Fig. 1b), which provide satisfactory elucidation of the ESR spectra for the single crystal.

Results

ESR spectra observed for the single crystal are shown in Fig. 2 for rotation about the Z-axis as an example. The spectra consist of a set of five strong peaks and some weaker ones. Consequently, it is obvious that manganese occupies only a single kind of coordination sites in the unit cell. The spectra depend highly on the rotation angles α_1, α_2, and α_3.

A spectrum for the powdered sample is given in Fig. 3. The spectrum showing a strong peak at $g_{eff} \simeq 2.0$ and weaker one at $g_{eff} \simeq 4.0$ is characteristic of those having anisotropic parameters $D \lesssim h\nu$ and $E \simeq 0.3D$, as clarified by Dowsing and Gibson.[3] The correlation between resonance position and E/D is illustrated in Fig. 4 for the cases that the magnetic field is applied parallel to the x, y, and z axes. Upon comparison of this with Fig. 3, the D and E/D values are estimated as 0.12 cm^{-1} and 0.25, respectively. Resonance positions for magnetic field parallel to the x, y, and z axes are given in Fig. 3 by arrows. The final D and E values evaluated by the computational procedure mentioned in the preceding section are 0.12 ± 0.01 and 0.032 ± 0.004 cm^{-1}, respectively (refer to Figs. 5 and 6).

The computational results due to the manipulation of Eq. 2 are given in Fig. 5 as the correlation between resonance magnetic field and polar coordinates Θ and Φ. The allowed transitions ($\Delta m_s = 1$) are denoted by solid lines, and the forbidden transitions with $\Delta m_s = 2$ and $\Delta m_s > 2$ are represented by broken lines, respectively.

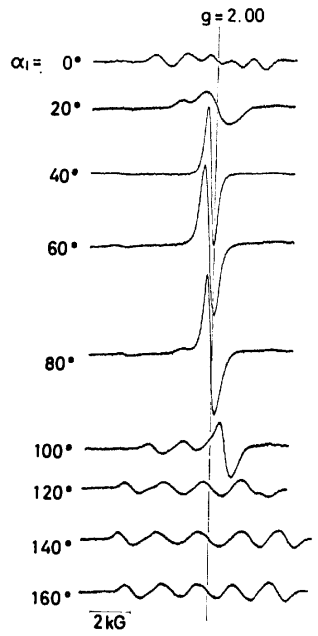

Fig. 2. Single crystal ESR spectra at room temperature (K-band): the magnetic field is rotated about the Z-axis (Fig. 1a) by α_1.

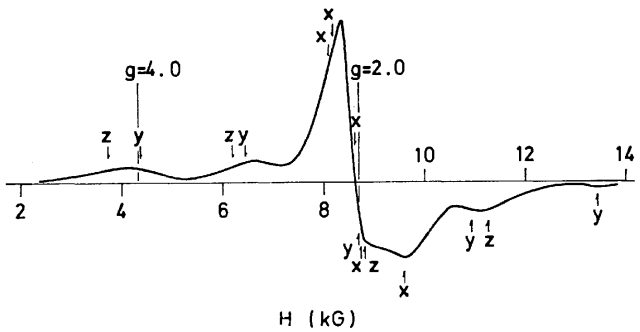

Fig. 3. K-band ESR spectrum of the powdered sample at room temperature. Arrows indicate the predicted resonance positions under the magnetic fields directed along the molecular axes (x, y, and z).

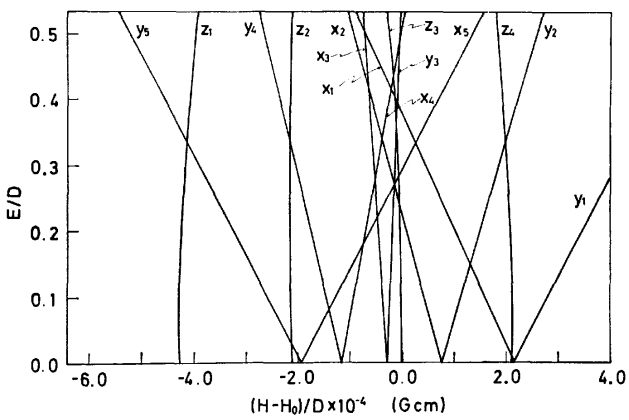

Fig. 4. Correlation between zero-field splitting parameters and resonance positions: $H_0=h\nu/g_0\beta$. Suffixed numbers refer to the transitions: 1, $-5/2\leftrightarrow-3/2$; 2, $-3/2\leftrightarrow-2/1$; 3, $-1/2\leftrightarrow1/2$; 4, $1/2\leftrightarrow3/2$; 5, $3/2\leftrightarrow5/2$.

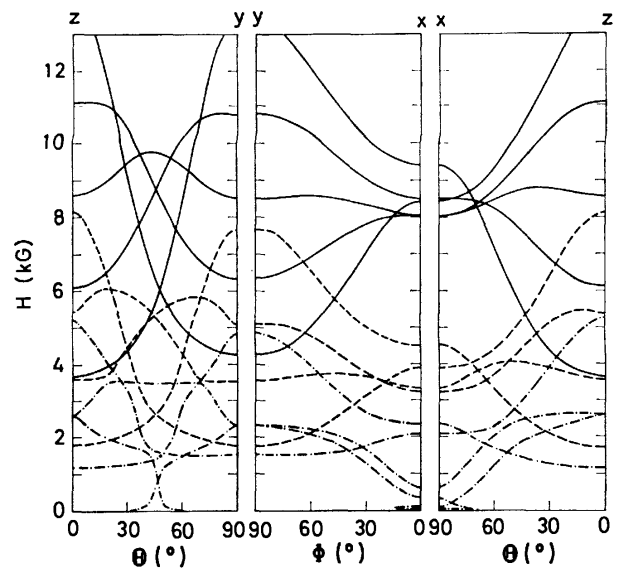

Fig. 5. Predicted ESR transitions for $S=5/2$ with $D=0.12$ cm^{-1}, $E=0.032$ cm^{-1}, and $h\nu=0.81$ cm^{-1}: ——, transitions for $\Delta m_s=1$; ----, transitions for $\Delta m_s=2$; —·—·, transitions for $\Delta m_s>2$.
θ, polar angle between z-axis and magnetic field; Φ, polar angle between x-axis and magnetic field projected on xy-plane.

Subsequently, the Eulerian angles θ, ϕ, and χ were evaluated as 7.7°, 43.3°, and 153.0°, respectively. The calculated correlations between resonance positions and rotation angles (α_1, α_2, and α_3) are illustrated in Fig. 6 along with the experimental results. The agreements between calculated and experimental data are quite satisfactory.

Discussion

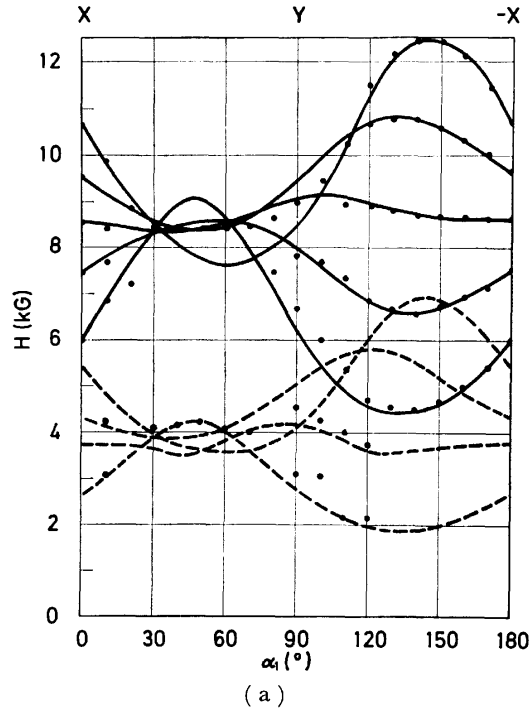
Several investigators have reported on the coordination structures of manganese(II) complexes in which the central metal is subject to either regular or distorted tetrahedral ligand field. Since the bivalent manganese is in general favorably placed in the octahedral ligand field, the steric effect may provide primarily a cause for the tetrahedral coordination. Moreover, the distorted tetrahedral coordination is less common for this metal ion. Most of these distortions have been caused by the structural nature of host lattice, which gives a geometrically distorted configuration of four equivalent donor atoms.[4] The rest has been due to the intramolecular repulsive interaction among ligands, where the coordination of electronically different donor atoms takes place. In those cases, the configuration of donor atoms is close to the regular tetrahedron. The anisotropic parameters D and E for manganese(II) placed in those geometrically distorted ligand fields are very close to zero and the corresponding g-value is nearly the free electron value.[4]

On the other hand, the tetrahedral manganese(II) complexes are reported to be subject to the profoundly large anisotropy in a few cases.[5] In those cases, two kinds of electronically different donor atoms are involved for the formation of a complex. Nevertheless, the mechanism responsible for the occurrance of this large anisotropy has not been clearly elucidated. Some iron(III) complexes show anisotropy larger than manganese(II) complexes. Cole and Garrett studied the large anisotropy of the aquapentachloroiron(III) anion, and attributed the origin of the large D value to the tetragonal distortion of coordination geometry.[6]

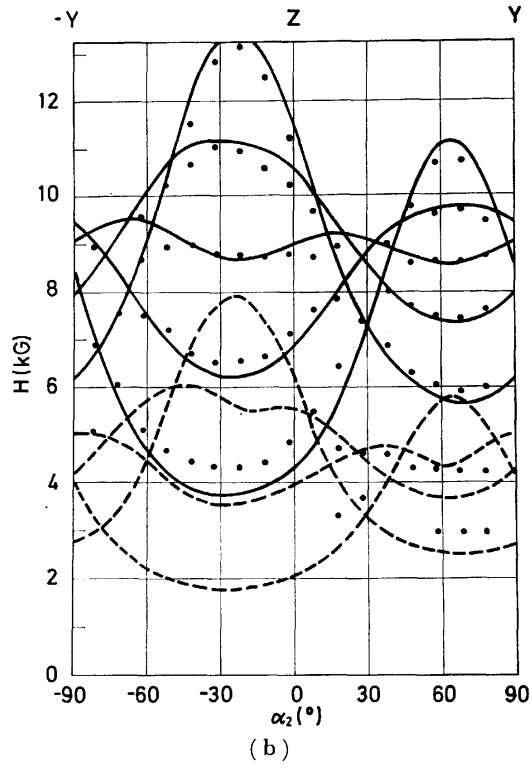
Judging from the existence of nonzero D and E values, TMD-Mn(II) is obviously in a distorted tetrahedral coordination structure. The electronic property is, however, identical with each other among all the four nitrogen donor atoms due to the resonance interaction within each dipyrromethene molecule. In any case, the bulky methyl groups placed at the 5- and 5′-positions in the present ligand hinder the planar alignment of four nitrogen atoms. Since there is no significant steric reason against attaining the regular tetrahedral geometry, manganese(II) must assume this coordination geometry unless other factors come into play. When the coordinate bonds between manganese(II) and nitrogen atoms attain highly covalent character, the configuration of nitrogen donor atoms can be expected to deviate from the regular tetrahedron toward the planar structure. These effects have been observed for dipyrromethene complexes of transition metals having a partially filled d-shell.[7]

The small D and E values for the geometric distortion can be explained in terms of the splitting of the sextet ground state caused by higher order perturbation due to spin-orbit coupling. On the other hand, TMD-Mn(II) gained the uniquely large D and E values for the complex having four equivalent donor atoms. These large D and E values may be attributed to the strong σ-bonding interaction. The existence of profound σ-bonding between manganese and nitrogen atoms tends to distort the coordination geometry from tetrahedral toward tetragonal, causing the mixing of the excited quartet into the sextet ground state. The π-bonding interaction between the central metal atom and the ligand molecules may be partly responsible for such tetragonal distortion.

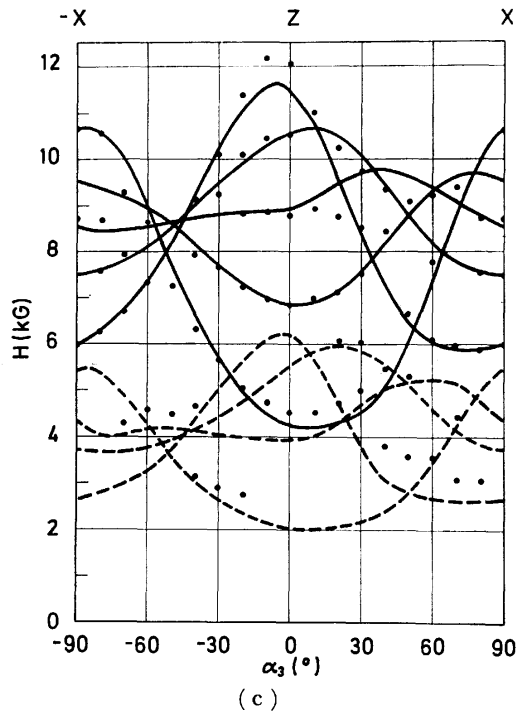
In conclusion, the eminent covalent interaction between manganese(II) and donor atoms caused the



(a)



(b)



(c)

Fig. 6. Resonance positions for single crystal under the magnetic field rotated by α_1 (a), α_2 (b), and α_3 (c) (refer to Fig. 1a). Solid and broken lines denote the calculated resonance positions ($\Delta m_s = \pm 1$ and ± 2, respectively) for $D = 0.12$ cm^{-1}, $E = 0.032$ cm^{-1}, and $h\nu = 0.81$ cm^{-1}, and solid circles indicate the observed values.

distortion of ligand alignment from the regular tetrahedron, and gives out the nonspherical distribution of d-orbitals. The latter effect is accompanied with spin-orbit interaction with the excited configurations. This mechanism must be responsible for the profound anisotropy existing in the N_4-pseudotetrahedral manganese complex, as well as for the exceedingly high intensity of ligand field bands due to spin forbidden transitions.[2]

(Received April 19, 1977)

A complete series of ten complexes, $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ (en=ethylenediamine; tn=trimethylenediamine; tmd=tetramethylenediamine) was obtained by preparing four new complexes, $[Co(en)(tmd)_2]^{3+}$, $[Co(tn)_2(tmd)]^{3+}$, $[Co(tn)(tmd)_2]^{3+}$, and $[Co(en)(tn)(tmd)]^{3+}$. The new complexes were resolved into optical isomers by SP-Sephadex column chromatography. The absorption and circular dichroism spectra of all the complexes were recorded and discussed.

Ten complexes are expected for a series of complexes of the type, $[M(AA)_x(BB)_y(CC)_z]^{n+}$ (x, y, z=0, 1, 2, or 3; $x+y+z=3$), where AA, BB, and CC denote different bidentate ligands. However, no example of such a complete series has been reported. In a series of ten complexes, $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ (en=ethylenediamine; tn=trimethylenediamine; tmd=tetramethylenediamine), there remain four unknown complexes, $[Co(en)(tmd)_2]^{3+}$, $[Co(tn)_2(tmd)]^{3+}$, $[Co(tn)(tmd)_2]^{3+}$, and $[Co(en)(tn)(tmd)]^{3+}$, all of which contain a seven membered chelate ring. Recently we prepared two tmd complexes, $[Co(en)_2(tmd)]^{3+}$ [1] and $[Co(tmd)_3]^{3+}$,[2] and resolved them into optical isomers. The en, tn, and tmd ligands are the most representative diamines which form a five-, six-, and seven-membered chelate ring, respectively. The collective data on a complete series of complexes of these diamines will be useful in elucidating such properties as the electronic state and the optical activity of a cobalt(III) complex. This paper is concerned with the preparation and resolution of the four unknown tmd complexes and with the comparison of absorption and circular dichroism spectra of all the complexes of the present series.

Experimental

Ligands. The ligands, en, tn, and tmd were obtained from Wako Pure Chemical Industries Co. and used without further purification.

$[Co(en)(tn)(tmd)]Cl_3\cdot 0.5H_2O$. To a solution of *trans*-$[CoCl_2(en)(tn)]ClO_4$[3] (2.0 g, 5.5 mmol) in *N,N*-dimethylformamide(DMF)(100 cm^3) was added a solution of tmd (0.5 g, 5.5 mmol) in DMF (100 cm^3), and the solution was stirred for 5 h at room temperature. The resultant reddish brown solution was diluted with a 10^{-2} M HCl solution, and passed through an SP-Sephadex column (ϕ 2.7×5 cm). A small portion of the Sephadex charged with the product was poured on the top of an SP-Sephadex column (ϕ 2.7×120 cm), and the adsorbed complexes were eluted with a 0.2 M Na_2SO_4 solution adjusted to pH 2 with HCl. The column showed six bands; pink (very small amount), pink, yellow, orange, violet, and red-violet bands from bottom to top of the column. The effluent of the fourth orange band was diluted with a 10^{-2} M HCl solution and poured again on an SP-Sephadex column (ϕ 1.5×3 cm). The adsorbed complex was eluted with a 1.0 M KBr solution adjusted to pH 2 with HBr, and the effluent was concentrated to dryness in a vacuum desiccator over P_2O_5–NaOH. The residue was extracted with methanol and the extract was mixed with diethyl ether to give an orange precipitate. The precipitate (crude complex bromide) was filtered off and dissolved in a small amount of 10^{-2} M HCl. To this solution was added a solution of $K_3[Co(CN)_6]$ in 10^{-2} M HCl to precipitate hardly soluble hexacyanocobaltate(III) salt of the complex. This salt was filtered off, washed with water, and mixed with the anion exchanger (BIORAD AG 1×8, 200—400 mesh, in the chloride form) in 10^{-2} M HCl. After the mixture had been stirred for several hours, the resin was filtered off, and the filtrate was passed through a column of the anion exchanger of the same type as the above to ensure the conversion into chloride. The effluent was evaporated to dryness under reduced pressure. Recrystallization from 10^{-2} M HCl by the addition of ethanol gave orange crystals. The yield depends on the purity of the starting material, *trans*-$[CoCl_2(en)(tn)]ClO_4$ which is usually contaminated with *trans*-$[CoCl_2(en)_2]ClO_4$ and *trans*-$[CoCl_2(tn)_2]ClO_4$.

Found: C, 27.24; H, 8.02; N, 20.92%. Calcd for $CoC_9H_{31}N_6O_{0.5}Cl_3$=$[Co(en)(tn)(tmd)]Cl_3\cdot 0.5H_2O$: C, 27.25; H, 7.88; N, 21.19%.

Resolution of $[Co(en)(tn)(tmd)]^{3+}$. A solution containing about 120 mg (0.3 mmol) of $[Co(en)(tn)(tmd)]Cl_3\cdot 0.5H_2O$ was poured on an SP-Sephadex column (ϕ 2.7×120 cm) and the adsorbed band was eluted with a 0.18 M sodium $(+)_{589}$-tartratoantimonate(III) solution. Two bands, the $(-)_{589}$- and $(+)_{589}$-isomers, were eluted in this order. Each isomer was isolated as bromide by the same method as that for the racemic complex chloride except that the anion exchanger was used in the bromide form. The complex was recrystallized from 10^{-2} M HBr by the addition of methanol. The complex chloride was hygroscopic. Found: C, 19.68; H, 5.79; N, 15.22%. Calcd for $CoC_9H_{34}N_6O_2Br_3$=$(+)_{589}$-$[Co(en)(tn)(tmd)]Br_3\cdot 2H_2O$: C, 19.41; H, 6.15; N, 15.09%.

$[Co(tn)_2(tmd)]Br_3\cdot 3.5H_2O$. To a solution of *trans*-$[CoCl_2(tn)_2]ClO_4$[4] (4.2 g, 11 mmol) in DMF (300 cm^3) was added a solution of tmd (1 g, 11 mmol) in DMF (200 cm^3) with stirring. The solution was stirred for 1 h at room temperature, and the product was chromatographed by a method similar to that for $[Co(en)(tn)(tmd)]^{3+}$. By developing the adsorbed band with a 0.2 M Na_2SO_4 solution adjusted to pH 2 with HCl, the column gave five bands, blue-violet, violet, reddish orange, violet, and pink in the order of elution. The effluent of the third reddish orange band was reloaded on an SP-Sephadex column (ϕ2.7×5 cm) after dilution with 10^{-2} M HCl. The adsorbed complex was eluted with a 1.0 M KBr solution adjusted to pH 2 with HBr. The eluate was concentrated to a small volume in a rotary evaporator, and the concentrate was kept in a refrigerator to give reddish orange crystals. These were filtered off, and recrystallized from 10^{-2} M HBr. Yield: about 50%. Found: C, 20.02; H, 6.17; N, 14.10%. Calcd for $CoC_{10}H_{39}N_6O_{3.5}Br_3$=$[Co(tn)_2(tmd)]Br_3\cdot 3.5H_2O$: C, 20.08; H, 6.57; N, 14.05%.

Resolution of $[Co(tn)_2(tmd)]^{3+}$. The resolution was

achieved by a method similar to that for $[Co(en)(tn)(tmd)]^{3+}$. The separation of optical isomers was incomplete, but the initial and the final fractions of the eluted complex showed negative and positive CD bands, respectively in the region of the first absorption band. The initial fractions of the effluent were collected, and chromatographed repeatedly until no further increase in dissymmetry factor ($\Delta\varepsilon/\varepsilon$) was observed. The isolation of the optical pure isomer was not attained, because of its small amounts. The quantitative CD curve of the complex was determined with the aid of the ε value of the racemate.

Preparation and Resolution of $[Co(en)(tmd)_2]^{3+}$. A solution of tmd (5.28 g, 60 mmol) and en (1.8 g, 30 mmol) in dimethyl sulfoxide (DMSO) (400 cm³) was added to a solution of $Co(NO_3)_2 \cdot 6H_2O$ (8.8 g, 30 mmol) and tmd·2HBr (3.75 g, 15 mmol) in DMSO (400 cm³) with stirring. The cobalt ions were oxidized by bubbling a stream of air through the solution for 9 h at room temperature. The resultant dark red solution was diluted with 10^{-2} M HCl and poured on SP-Sephadex. The adsorbed complexes were chromatographed by a method similar to that for $[Co(en)(tn)(tmd)]^{3+}$ with a 0.2 M Na_2SO_4 solution adjusted to pH 2 with HCl. The column gave nine bands; blue-violet, red, yellow, orange, pink, orange, pink, orange, and red-violet bands from bottom to top of the column. The effluent of the fourth orange band was a mixture of $[Co(en)(tmd)_2]^{3+}$ and other tris-diamine complexes as described below, and it was used for optical resolution without isolating the complex racemate. The effluent was reloaded on an SP-Sephadex column ($\phi 2.7 \times 120$ cm) after dilution with 10^{-2} M HCl, and the adsorbed band was eluted with a 0.15 M sodium $(+)_{589}$-tartratoantimonate(III) solution. The column gave four pairs of bands (Δ and Λ), yellow ($[Co(en)_3]^{3+}$), yellowish orange ($[Co(en)_2(tmd)]^{3+}$), orange ($[Co(en)(tmd)_2]^{3+}$), and orange (not characterized) bands in the order of elution. Each eluate of the third pair of the orange bands was passed through an SP-Sephadex column ($\phi 1.5 \times 3$ cm) after dilution with 10^{-2} M HCl and the adsorbed complex was eluted with a 1.0 M NaCl solution adjusted to pH 2 with HCl. The isomers were precipitated as hexacyanocobaltate(III) by the addition of $K_3[Co(CN)_6]$ in 10^{-2} M HCl. These salts were converted into chlorides by the use of the anion exchanger as described for $[Co(en)(tn)(tmd)]^{3+}$. Orange crystals were obtained by recrystallizing from 10^{-2} M HCl and methanol. Yield: about 1%. Found: C, 28.62; H, 8.16; N, 19.94%. Calcd for $CoC_{10}H_{34}N_6OCl_3 = (-)_{589}$-$[Co(en)(tmd)_2]Cl_3 \cdot H_2O$: C, 28.61; H, 8.11; N, 20.03%.

$[Co(tn)(tmd)_2]Cl_3$. To a solution of $Co(NO_3)_2 \cdot 6H_2O$ (8.8 g, 30 mmol) and tmd·2HBr (7.6 g, 30 mmol) in DMSO (800 cm³) were added a solution of tmd (6.68 g, 76 mmol) and tn (1.12 g, 15 mmol) in DMSO (1200 cm³) and active charcoal (1 g). The air oxidation of the cobalt ions was carried out for 50 h at room temperature. The reaction mixture was filtered to remove the charcoal. The filtrate was diluted with 10^{-2} M HCl and passed through an SP-Sephadex column ($\phi 7 \times 30$ cm). By developing the adsorbed band with a 0.5 M HCl solution, the column showed seven bands; violet, orange, blue-violet, red, blue-violet, reddish orange, and red-violet in the order of elution. The effluents of the first violet and the second orange bands were collected and reloaded on an SP-Sephadex column ($\phi 5.5 \times 30$ cm) after dilution with 10^{-2} M HCl, and the adsorbed band was eluted with a 0.2 M Na_2SO_4 solution adjusted to pH 2 with HCl. Five bands, violet, violet, orange, brown, and reddish brown were eluted in this order. The effluent of the third band was further loaded on an SP-Sephadex column ($\phi 2.7 \times 120$ cm) after dilution with 10^{-2} M HCl, and the adsorbed complexes were eluted with a 0.15 M sodium $(+)_{589}$-tartratoantimonate(III) solution. The column showed five separate bands; orange ($[Co(tn)_3]^{3+}$), reddish orange ($[Co(tn)_2(tmd)]^{3+}$), red ($[Co(tn)(tmd)_2]^{3+}$), and two purplish red ($(+)_{589}$- and $(-)_{589}$-$[Co(tmd)_3]^{3+}$) bands in the order of elution. The red crystals of $[Co(tn)(tmd)_2]Cl_3$ were obtained from the effluent of the third red band by a method similar to that for $[Co(en)(tn)(tmd)]^{3+}$. Yield: about 0.3%. Found: C, 31.38; H, 8.02; N, 20.22%. Calcd for $CoC_{11}H_{34}N_6Cl_3 = [Co(tn)(tmd)_2]Cl_3$: C, 31.78; H, 8.24; N, 20.22%.

Resolution of $[Co(tn)(tmd)_2]^{3+}$. The resolution was achieved by a method similar to that for $[Co(tn)_2(tmd)]^{3+}$. The bands of enantiomers were separated incompletely, so that the chromatography was repeated until no further increase in dissymmetry factor ($\Delta\varepsilon/\varepsilon$) was observed. No isolation of the isomer was made.

Resolution of $[Co(en)_2(tn)]^{3+}$ *and* $[Co(en)(tn)_2]^{3+}$. The racemic complexes were prepared by the method of Ogino and Fujita[5] and resolved by a method similar to that for $[Co(en)(tn)(tmd)]^{3+}$. The separation of bands of Δ- and Λ-$[Co(en)_2(tn)]^{3+}$ was complete, but that of Δ- and Λ-$[Co(en)(tn)_2]^{3+}$ was not, and the chromatography was repeated to obtain the optically pure isomer. Each isomer adsorbed on SP-Sephadex was eluted with a 1.5 M $NaClO_4$ solution and the effluent was evaporated in a vacuum desiccator over P_2O_5 to give orange crystals. These were recrystallized from a small amount of water by the addition of ethanol. Found: C, 14.32; H, 4.88; N, 14.31%. Calcd for $CoC_7H_{30}N_6O_{14}Cl_3 = (+)_{589}$-$[Co(en)_2(tn)](ClO_4)_3 \cdot 2H_2O$: C, 14.31; H, 5.15; N, 14.30%. Found: C, 17.13; H, 5.06; N, 14.93%. Calcd for $CoC_8H_{28}N_6O_{12}Cl_3 = (+)_{589}$-$[Co(en)(tn)_2](ClO_4)_3$: C, 16.99; H, 4.99; N, 14.86%.

Other complexes, $[Co(en)_3]^{3+}$, $[Co(en)_2(tmd)]^{3+}$, $[Co(tn)_3]^{3+}$, and $[Co(tmd)_3]^{3+}$ were prepared and resolved by the methods given in Table 1.

Measurements. Absorption and circular dichroism spectra were obtained on a Hitachi 323 spectrophotometer and a JASCO J-20 spectropolarimeter, respectively.

Results and Discussion

Preparation and Resolution of the Complexes. All of the new complexes contain the seven-membered chelate ligand. Since such large chelate ligands as tmd tend to coordinate to two metal ions to form polymeric complexes,[5] the reactions were carried out in dilute solutions as described in the Experimental part. Nonaqueous solvents such as DMSO are known to be useful for preparing complexes containing large chelate rings.[5] However, in the reactions of *trans*-$[CoCl_2(en)(tn)]^+$ or of *trans*-$[CoCl_2(tn)_2]^+$ with tmd in DMSO, a partial reduction of Co(III) to Co(II) takes place and disproportionation occurs to yield all possible complexes. Such a reduction may be avoided by use of DMF instead of DMSO, and no disproportionation is observed in the reactions. The perchlorates of the above dichloro complexes as well as the corresponding bis-en complex are fairly soluble in DMF and will be good starting materials for preparing mixed tris-diamine complexes. However, the reactions between *trans*-$[CoCl_2(en)_2]ClO_4$ and tn, and between *trans*-$[CoCl_2(tn)_2]ClO_4$ and en in DMF are accompanied by disproportionation, although no reduction seems to occur. For the preparation of both $[Co(en)(tmd)_2]^{3+}$ and $[Co(tn)(tmd)_2]^{3+}$, *trans*-$[CoCl_2(tmd)_2]^+$ should be useful as a starting material.

*: (+) or (−) at NaD line (589 nm); a: sodium $(+)_{589}$-tartrate; b: sodium $(+)_{589}$-tartratoantimonate(III); c: see the text; d: barium $(+)_{589}$-tartrate; e: sodium nitro-$(+)_{589}$-camphorate; f: $(-)_{589}$-K[As(cat)$_3$] (cat=catecholate ion=1,2-benzenediolate ion); g: silver $(+)_{589}$-tartratoantimonate(III).

However, this complex may be obtained only a little as a by-product in the preparation of $[Co(tmd)_3]^{3+}$.[2] Attempts to obtain this dichloro complex enough for reactions have all been unsuccessful. Hence, the two bis-tmd complexes of en or tn were prepared by oxidizing mixtures of Co(II) and the corresponding diamines in DMSO and isolated by the aid of SP-Sephadex column chromatography. The yields were extremely low, less than 1%. The same reactions in DMF result in the formation of hardly soluble black precipitates which appear to be a peroxo complex, and the reactions do not proceed further.

The complexes containing the tmd chelate ligand decompose gradually in neutral water, but stable in acidic solutions. The four new tmd complexes behave as monomeric tripositive ions in SP-Sephadex column chromatography; these complexes adsorbed on SP-Sephadex are easily eluted with 0.1—0.2 M Na_2SO_4 solutions.[5]

All the complexes, $[Co(en)_x(tn)_y(tmd)_z]^{3+}$ except $[Co(tn)_3]^{3+}$ can be resolved into their antipodes by SP-Sephadex column chromatography. By elution with sodium $(+)_{589}$-tartratoantimonate(III), the complexes containing the en ligand give *Λ* isomers first, while those of the series, $[Co(tn)_y(tmd)_z]^{3+}$, *Δ* isomers reversely. For $[Co(tn)_2(tmd)]^{3+}$ and $[Co(tn)(tmd)_2]^{3+}$, the separation of enantiomers on a column is insufficient, and repeated chromatography is necessary to obtain optically pure isomers. The $[Co(tn)_3]^{3+}$ complex cannot be resolved by SP-Sephadex column chromatography, but done completely by a modified Sephadex(D-$(-)_{589}$-tartrate form) column chromatography using a sodium L-$(+)_{589}$-tartrate solution as the eluent.[6] The data on optical resolution for all the complexes are given in Table 1.

Absorption and Circular Dichroism Spectra. Figures 1 to 4 show the absorption and circular dichroism spectra of the present series of complexes, $[Co(en)_x(tn)_y(tmd)_z]^{3+}$, and Table 2 lists the numerical data. Both the d-d and the charge-transfer absorption bands shift to longer wavelengths as the number of ring members

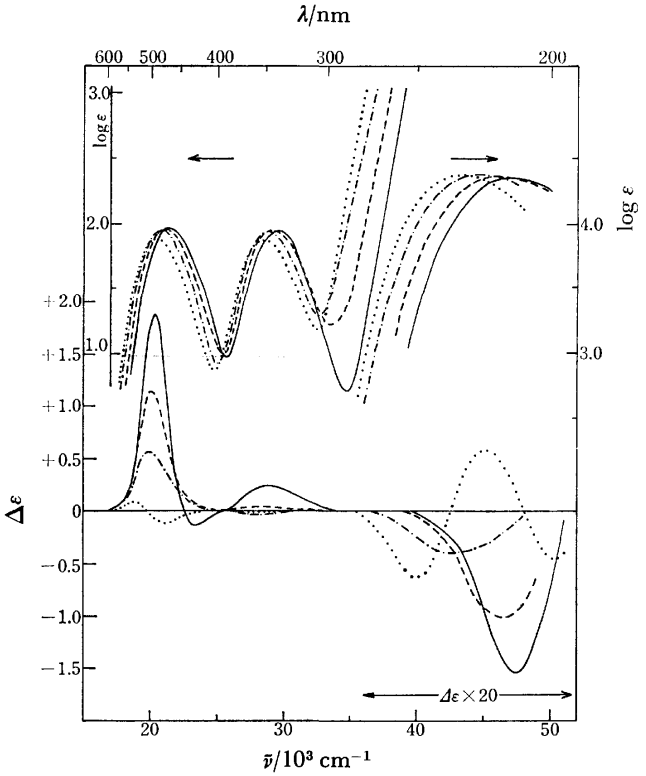

Fig. 1. Absorption and CD spectra of a series of *Λ*-$[Co(en)_x(tn)_y]^{3+}$ complexes; $(+)_{589}$-$[Co(en)_3]^{3+}$ (——), $(+)_{589}$-$[Co(en)_2(tn)]^{3+}$ (----), $(+)_{589}$-$[Co(en)(tn)_2]^{3+}$ (—·—), and $(-)_{589}$-$[Co(tn)_3]^{3+}$ (·····).

of the ligands increases. In Fig. 5 are plotted the maximum positions of these absorption bands against the number of ring members. The magnitude of shifts becomes smaller with increase in the number of ring members. In particular, the charge-transfer band of $[Co(tmd)_3]^{3+}$ shifts very little as compared with that of $[Co(tn)_3]^{3+}$, and those bands in the complexes, $[Co(tn)_y(tmd)_z]^{3+}$, are at nearly the same wavelengths. A similar shift of absorption bands due to the increase

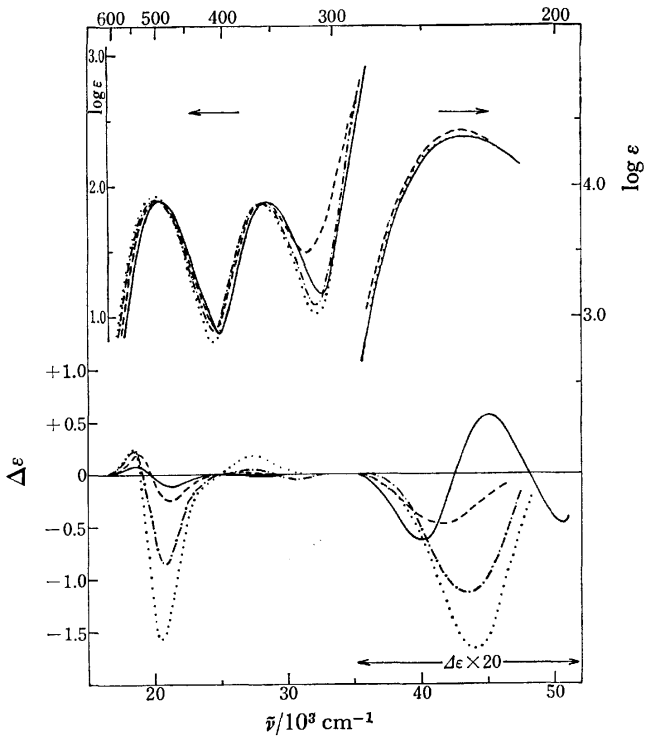

Fig. 3. Absorption and CD spectra of a series of Λ-$[Co(tn)_y(tmd)_z]^{3+}$ complexes; $(-)_{589}$-$[Co(tn)_3]^{3+}$ (——), $(-)_{589}$-$[Co(tn)_2(tmd)]^{3+}$ (----), $(-)_{589}$-$[Co(tn)(tmd)_2]^{3+}$ (—·—), and $(-)_{589}$-$[Co(tmd)_3]^{3+}$ (·····).

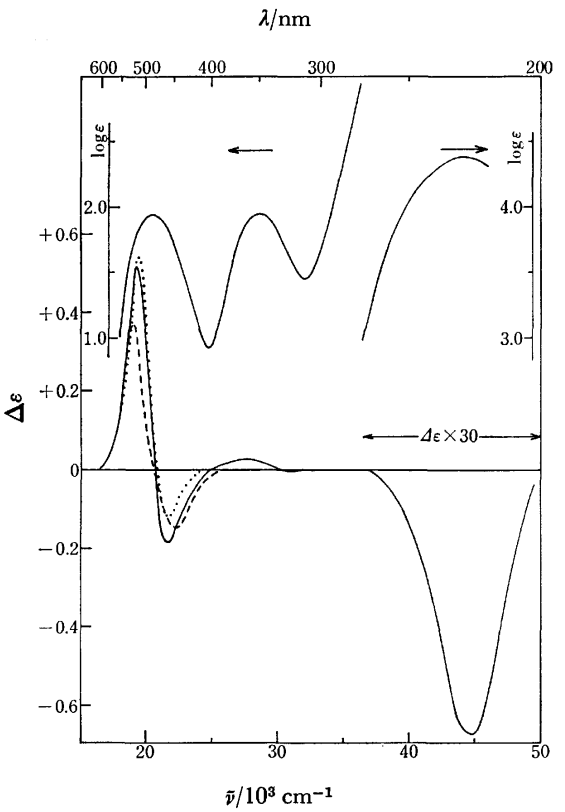

Fig. 4. Absorption and CD spectra of Λ-$(-)_{589}$-$[Co(en)(tn)(tmd)]^{3+}$ (——). Calculated CD curves of Λ-$[Co(en)(tn)(tmd)]^{3+}$ from $1/2\{\Lambda\text{-}[Co(en)_2(tn)]^{3+} + \Lambda\text{-}[Co(tn)_2(tmd)]^{3+} + \Lambda\text{-}[Co(en)(tmd)_2]^{3+}\} - 1/6\{\Lambda\text{-}[Co(en)_3]^{3+} + \Lambda\text{-}[Co(tn)_3]^{3+} + \Lambda\text{-}[Co(tmd)_3]^{3+}\}$ (·····) and $1/3\{\Lambda\text{-}[Co(en)_3]^{3+} + \Lambda\text{-}[Co(tn)_3]^{3+} + \Lambda\text{-}[Co(tmd)_3]^{3+}\}$ (----).

in the ring members was observed for the complexes of the type, $[Co(am)(en)_2]^{2+}$ (am=amino acidate ion); the first absorption bands of $[Co(gly)(en)_2]^{2+}$, $[Co(\beta\text{-ala})(en)_2]^{2+}$, and $[Co(amb)(en)_2]^{2+}$ (amb=4-aminobutanoic acidate ion) are at 20.5, 20.2, and 19.8×10^3 cm^{-1}, respectively.[7]

Although accurate intensity of absorption bands may be determined with difficulty, the apparent intensities (not band area) of the first absorption bands decrease in the order of the complexes of the ligands, en>tmd>tn; the intensities are not proportional to the number of ring members. Such a regular trend is not seen for the second and the charge-transfer absorption bands.

Figures 1—3 show the circular dichroism spectra of three series of complexes, $[Co(en)_x(tn)_y]^{3+}$, $[Co(en)_x(tmd)_z]^{3+}$, and $[Co(tn)_y(tmd)_z]^{3+}$, respectively. Of these complexes, the absolute configurations of $(+)_{589}$-$[Co(en)_3]^{3+}$, $(-)_{589}$-$[Co(tn)_3]^{3+}$, $(+)_{589}$-$[Co(en)_2(tn)]^{3+}$, and $(+)_{589}$-$[Co(tmd)_3]^{3+}$ have been determined by X-ray work to be Λ, Λ, Λ, and Λ, respectively (Table 1). Since the CD spectra of each series show a gradual change in the region of the first absorption band, the configurations of the other complexes shown in Figs. 1—3 can be assigned to Λ. The signs of the main CD bands in this region depend on the number of ring members. However, these nine complexes exhibit all positive CD components at a longer wavelength side

of the first absorption band. The strengths of these components are diminished in the presence of Na_2SO_4, and complementarily the negative CD components are enhanced (Table 2). The signs of the CD bands at the longest wavelengths in the charge-transfer region are all negative. All these observations have been reported for some complexes of the present series (Table 1). The CD spectrum of $(-)_{589}$-$[Co(en)(tn)(tmd)]^{3+}$ shown in Fig. 4 satisfies the above observations, and can be assigned to the same absolute configuration, *A*. The gradual changes of the CD spectra shown in Figs. 1—3 indicate that the CD spectrum of a mixed tris-diamine complex in the region of the first absorption band can be approximated by a sum of the contributions from three pairs of the chelate rings in chiral configuration. For example, the CD curve of [Co(en)(tn)-

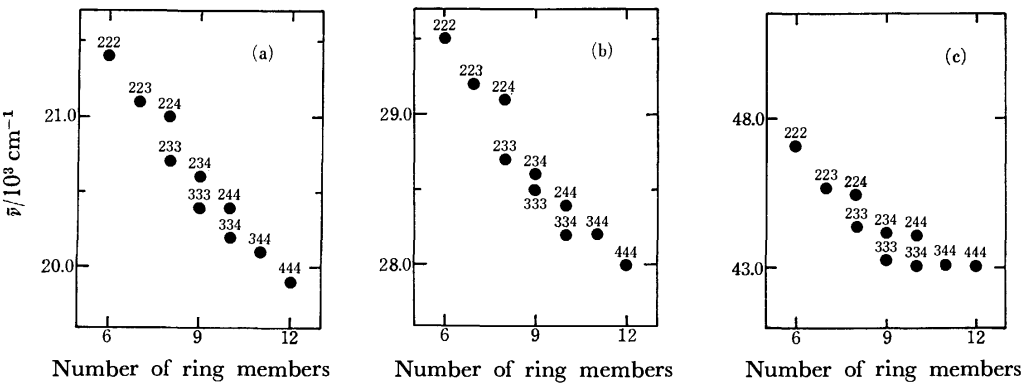

Fig. 5. Positions of (a) the first, (b) the second, and (c) the charge-transfer absorption bands of $[Co(en)_x(tn)_y(tmd)_z]^{3+}$. In the Figs. 2, 3, and 4 indicate en, tn, and tmd in the complex, respectively. For example, 234 denotes $[Co(en)(tn)(tmd)]^{3+}$.

$(tmd)]^{3+}$ which involves three pairs of chiral configurations, en-tn, en-tmd, and tn-tmd may be evaluated from the observed CD spectra of the following six complexes; $[Co(en)(tn)(tmd)]^{3+}=1/2\{[Co(en)_2(tn)]^{3+}+[Co(tn)_2(tmd)]^{3+}+[Co(en)(tmd)_2]^{3+}\}-1/6\{[Co(en)_3]^{3+}+[Co(tn)_3]^{3+}+[Co(tmd)_3]^{3+}\}$. The calculated CD curve of $[Co(en)(tn)(tmd)]^{3+}$ shown in Fig. 4 agrees well with the observed one. If the CD spectrum of a tris-chelate complex can be approximated by a sum of the contributions from each chelate ring, the CD curve of $[Co(en)(tn)(tmd)]^{3+}$ is obtained by the following equation; $[Co(en)(tn)(tmd)]^{3+}=1/3\{[Co(en)_3]^{3+}+[Co(tn)_3]^{3+}+[Co(tmd)_3]^{3+}\}$(or $1/3\{[Co(en)_2(tn)]^{3+}+[Co(tn)_2(tmd)]^{3+}+[Co(en)(tmd)_2]^{3+}\}$). The calculated CD curve is also given in Fig. 4. This curve agrees less satisfactorily with the observed spectrum compared with that approximated by the sum of the contributions of three pairs of the chelate rings.

(Received April 25, 1977)

A series of optically active cobalt(III) ammine complexes containing (*S,S*)-1,3-diphenyl-1,3-propanediamine (dppn) or (*S,S*)-1,2-diphenyl-1,2-ethanediamine (stien) were prepared. The sign of circular dichroism (CD) of $[Co(NH_3)_4(S,S\text{-dppn})]Br_3$ depends on solvents in the first absorption band region. The CD magnitude of *trans*-$[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$ varies significantly with solvent variations in the same energy region. The CD curve of the vicinal effect of (*S,S*)-dppn derived from the two diastereomers of *cis*-$[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$ is different from the CD spectra of both $[Co(NH_3)_4(S,S\text{-dppn})]^{3+}$ and *trans*-$[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$. The CD spectra of the (*S,S*)-stien complexes are insensitive to solvent variations and the vicinal contributions of the (*S,S*)-stien calculated from a variety of the (*S,S*)-stien complexes are similar to one another.

It has been suggested that circular dichroism (CD) of metal complexes are sensitive to environment around a metal ion, *i.e.* conformational change of ligands, the deviation of ligating atoms from the octahedral positions, and interactions between solute and solvent. Recently, cobalt(III) complexes containing six-membered chelate rings have been investigated to show remarkable variations in CD spectra with change in solvent.[1–3] These variations have been primarily ascribed to the flexibility of six-membered chelate rings.

Such a conformational flexibility will differ depending on the kind of substituent on six-membered chelate rings. In a previous paper,[4] we have reported that the CD sign of $[Co(NH_3)_4(S,S\text{-dppn})]Br_3$ in water is opposite to that of $[Co(NH_3)_4(R,R\text{-ptn})](ClO_4)_3$(*R,R*-ptn=(*R,R*)-2,4-pentanediamine) in water in the first absorption band region, although both the diamine ligands are expected to have the same λ-skew conformation. In order to investigate further detailed features of the dppn chelate ligand, we have prepared a series of complexes of the type $[Co(NH_3)_{2n}(S,S\text{-dppn})_{3-n}]^{3+}(n=0, 1, 2)$. This paper will report the preparation and the CD spectra of these complexes together with those of the corresponding (*S,S*)-1,2-diphenyl-1,2-ethanediamine (stien) complexes.

Experimental

Preparation of Ligands. The optically active diamines used were prepared by the methods previously reported; (*S,S*)-dppn[4] and (*S,S*)-stien.[5]

Preparation of the Complexes. *(1)* $[Co(NH_3)_4(S,S\text{-}dppn)]Br_3\cdot H_2O$: Method 1). Sodium hydroxide (2 g) in water (5 cm³) was added dropwise to a suspension of (−)$_D$-dppn-di-*O*-benzoyltartrate (0.6 g) in cold water (5 cm³). The released dppn was extracted with chloroform (20 cm³). After removal of the chloroform under reduced pressure, the oily residue was dissolved in 5 cm³ of dimethyl sulfoxide (DMSO). The solution was mixed with a DMSO solution (10 cm³) of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (0.46 g) and allowed to stand at room temperature for 10 h with stirring. The resultant solution was passed through a column ($\phi 3\times 20$ cm) of an SP-Sephadex ion exchanger. After washing with water, the adsorbed band was eluted with a 0.5 M aqueous solution of potassium bromide. The first eluted orange yellow band was $[Co(NH_3)_6]^{3+}$. The second orange yellow eluate was concentrated to give orange crystals, which were recrystallized from warm water (50 °C) acidified with a few drops of 60% hydrobromic acid. Yield; 0.1 g. Found: C; 29.67, H; 5.36, N, 13.78%. Calcd for $[Co(NH_3)_4(S,S\text{-dppn})]Br_3\cdot H_2O$ ($C_{15}H_{32}N_6OBr_3Co$): C; 29.48, H; 5.28, N; 13.76%.

Method 2). A DMSO solution (30 cm³) of racemic dppn (1.4 g) was added to a DMSO solution (50 cm³) of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (2.3 g). The solution was allowed to stand at 50 °C for 4 h with stirring, diluted to 1 dm³ with water and acidified with concd hydrochloric acid. A red precipitate of by-products was filtered off and the orange filtrate was passed through a column ($\phi 5\times 30$ cm) of an SP-Sephadex C-25 ion exchanger. After washing with water, the adsorbed band was eluted with a 0.3 M aqueous solution of potassium bromide. The orange yellow eluate was concentrated to give orange crystals, which were recrystallized from water (25 cm³) by adding ethanol (25 cm³) and by cooling the solution in a refrigerator. Yield: 0.9 g. Found: C; 28.98, H; 5.36, N; 13.63%. Calcd for $[Co(NH_3)_4(dppn)]Br_3\cdot 1.5H_2O$ ($C_{15}H_{33}N_6O_{1.5}Br_3Co$): C; 29.05, H; 5.36, N; 13.55%.

An aqueous solution of the orange yellow crystals was passed through a column ($\phi 4\times 60$ cm) of an SP-Sephadex C-25 ion exchanger. After washing with water, the adsorbed band was eluted with a 0.36 M aqueous solution of sodium (+)$_D$-tartratoantimonate(III). When the adsorbed band was separated into two bands, the eluent was changed to a 0.3 M aqueous solution of potassium bromide. The first eluted orange yellow band was concentrated to give orange crystals, which were the same compound as that prepared by method 1) on the basis of the elemental analysis and the CD spectra. Found: C; 29.24, H; 5.31, N; 13.90%.

The second orange yellow eluate was concentrated to give crystals, the CD spectrum of which is mirror image of that of the first eluted complex. Found: C; 29.47, H; 5.29, N; 14.00%. Calcd for $[Co(NH_3)_4(dppn)]Br_3\cdot H_2O$($C_{15}H_{32}N_6OBr_3Co$): C; 29.48, H; 5.28, N: 13.76%.

(2) $[Co(NH_3)_4(R,S\text{-}dppn)]Br_3$: A DMSO solution (5 cm³) of (*R,S*)-dppn prepared from (*R,S*)-dppn·2HCl (1.6 g) was mixed with a DMSO solution (20 cm³) of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (2.3 g). The resultant solution was warmed at 70 °C for 10 min with stirring, diluted with water (100 cm³) and acidified with concd hydrochloric acid. A red orange precipitate of by-products was filtered off and the orange filtrate was

* A part of the Ph.D. thesis submitted by S. Arakawa to Tohoku University, 1976.

passed through a column ($\phi 5 \times 30$ cm) of an SP-Sephadex C-25 ion exchanger. After washing with water, the adsorbed band was eluted with a 0.3 M aqueous solution of potassium bromide. The first eluted orange band was $[Co(NH_3)_6]^{3+}$. The second orange eluate was concentrated to give orange crystals, which were recrystallized from hot water (200 cm^3) acidified with a few drops of 47% hydrobromic acid. Yield; 0.7 g. Found: C; 29.98, H; 5.38, N; 13.39%. Calcd for $[Co(NH_3)_4(R,S\text{-dppn})]Br_3 \cdot H_2O$ ($C_{15}H_{32}N_6OBr_3Co$): C; 29.48, H; 5.28, N; 13.76%.

(3) $[Co(NH_3)_4(S,S\text{-}stien)](ClO_4)_3 \cdot 4H_2O$: (*S,S*)-Stien (1.0 g) was added to a DMSO solution (50 cm^3) of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (2.24 g). The resultant solution was allowed to stand at room temperature for 20 h, and passed through a column ($\phi 5 \times 30$ cm) of an SP-Sephadex C-25 ion exchanger. After washing with water, the adsorbed band was eluted with a 0.5 M aqueous solution of sodium perchlorate. The first eluted red band was $[Co(NH_3)_5(H_2O)]^{3+}$. The second yellow orange eluate was concentrated to give orange crystals, which were recrystallized from ethanol. Yield; 0.4 g. Found: C; 23.99, H; 5.00, N; 11.39%. Calcd for $[Co(NH_3)_4(S,S\text{-stien})](ClO_4)_3 \cdot 4H_2O$ ($C_{14}H_{36}N_6O_{16}Cl_3Co$): C; 23.69, H; 5.11, N; 11.84%.

(4) trans- *and* cis-$[Co(NH_3)_2(S,S\text{-}dppn)_2]^{3+}$: When *trans*-$[CoCl_2(S,S\text{-dppn})_2]Cl \cdot HCl \cdot H_2O$[4] (600 mg) was dissolved in liquid ammonia, the color of solution changed from green to orange instantly. After removal of liquid ammonia at room temperature, the residue was mixed with 2 M hydrochloric acid (10 cm^3) and then dissolved in DMSO. The resultant solution was passed through a column ($\phi 4 \times 45$ cm) of an SP-Sephadex C-25 ion exchanger. After washing with a mixture of water and DMSO (4 : 1), the adsorbed band was eluted with a 0.15 M solution of sodium $(+)_D$-tartratoantimonate(III) in a mixture of DMSO and water (1 : 4). When the adsorbed orange band was separated into two bands (I and II in the order of elution), the eluent was changed to a 0.7 M solution of sodium perchlorate in a mixture of water and methanol (2 : 1). The slowly eluted band, II, was further separated into two bands (IIa and IIb). The eluate of I was concentrated to give crystals, which were recrystallized from a mixture of acetone and ethanol (1 : 5), filtered off, and washed with ethanol and diethyl ether. Yield; 0.2 g. Found: C; 40.33, H; 5.39, N; 9.41%. Calcd for $[Co(NH_3)_2(S,S\text{-dppn})_2](ClO_4)_3 \cdot 3H_2O$ ($C_{30}H_{48}N_6O_{15}Cl_3Co$): C; 40.09, H; 5.39, N; 9.36%. This complex was assigned to the *trans* isomer on the basis of the PMR and CD spectra.

The eluate IIa was diluted about ten times with water and passed through a column ($\phi 2 \times 20$ cm) of an SP-Sephadex C-25 ion exchanger. The adsorbed band was eluted with 1 M hydrochloric acid. Orange crystals (20 mg) were obtained by concentrating the eluate. Found: C; 53.77, H; 6.52, N; 12.47%. Calcd for $[Co(NH_3)_2(S,S\text{-dppn})_2]Cl_3 \cdot H_2O$ ($C_{30}H_{44}N_6OCl_3Co$): C; 53.78, H; 6.62, N; 12.54%. This complex was assigned to the *cis-Λ* isomer on the basis of the CD spectrum.

The precipitate formed by concentrating the eluate IIb was filtered off and dissolved in a mixture of water and methanol (2 : 1). The solution was passed through a column ($\phi 2 \times 20$ cm) of an SP-Sephadex C-25 ion exchanger. The adsorbed band was eluted with 1 M hydrochloric acid. The orange eluate was evaporated to almost dryness and the residue was again dissolved in methanol. The solution was filtered and the filtrate was concentrated to give orange crystals, which were recrystallized from a mixture of methanol and water. Yield; 0.2 g. Found: C; 51.97, H; 6.49, N; 12.26%. Calcd for $[Co(NH_3)_2(S,S\text{-dppn})_2]Cl_3 \cdot 2H_2O$ ($C_{30}H_{46}N_6O_2Cl_3Co$): C; 52.37, H; 6.74, N; 12.21%. This complex was assigned to the *cis-Λ* isomer on the basis of the PMR and CD spectra.

(5) trans- *and* cis-$[Co(NH_3)_2(S,S\text{-}stien)_2]^{3+}$: To liquid ammonia (50 cm^3) was added *trans*-$[CoCl_2(S,S\text{-stien})_2]ClO_4 \cdot H_2O$[1] (0.57 g). The color of the solution changed from green to orange instantly. After removal of liquid ammonia at room temperature, the residue was mixed with 2 M hydrochloric acid (10 cm^3) and then dissolved in DMSO. The resultant solution was passed through a column ($\phi 4 \times 45$ cm) of an SP-Sephadex C-25 ion exchanger. After washing with a mixture of DMSO and water (1 : 4), the adsorbed band was eluted with a 0.15 M solution of sodium $(+)_D$-tartratoantimonate(III) in a mixture of DMSO and water (1 : 4). When the orange band was separated into two bands, the eluent was changed to a 0.7 M solution of sodium perchlorate in a mixture of water and methanol (2 : 1). The first eluted orange band was concentrated to give crystals, which were recrystallized from methanol. Yield; 0.3 g. Found: C; 40.40, H; 5.13, N; 9.82%. Calcd for $[Co(NH_3)_2(S,S\text{-stien})_2](ClO_4)_3(C_{28}H_{38}N_6O_{13}Cl_3Co)$: C; 40.33, H; 4.83, N; 10.08%. This complex was assigned to the *trans* isomer on the basis of the CD spectrum.

The second orange eluate was concentrated to give orange precipitate. The product was dissolved in a mixture of water and DMSO (4 : 1) and rechromatographed with a column ($\phi 4 \times 45$ cm) of an SP-Sephadex C-25 ion exchanger. The adsorbed band was eluted with a 0.15 M solution of sodium $(+)_D$-tartratoantimonate(III) in a mixture of DMSO and water (1 : 4). When the orange band was separated into two bands, the eluent was changed to a 0.5 M aqueous solution of sodium chloride. The first eluted band was concentrated to give orange precipitate. Recrystallization from a mixture of water and methanol (1 : 4) gave orange crystals, which were filtered off and washed with ethanol. Yield; 20 mg. Found: C; 49.42, H; 6.45, N; 12.35%. Calcd for $[Co(NH_3)_2(S,S\text{-stien})_2]Cl_3 \cdot 3H_2O$ ($C_{28}H_{44}N_6O_3Cl_3Co$): C; 49.60, H; 6.54, N; 12.40%. This complex was assigned to the *cis-Λ* isomer on the basis of the CD spectrum.

The second eluted band was concentrated to give orange precipitate, which was recrystallized from water. Yield; 0.1 g. Found: C; 49.74, H; 6.78, N; 12.75%. Calcd for $[Co(NH_3)_2(S,S\text{-stien})_2]Cl_3 \cdot 3H_2O$ ($C_{28}H_{44}N_6O_3Cl_3Co$): C; 49.60, H; 6.54, N; 12.40%. This complex was assigned to the *cis-Λ* isomer on the basis of the CD spectrum.

Measurements. Visible and ultraviolet absorption spectra were recorded on a Hitachi 323 spectrophotometer. CD spectra were obtained with JASCO J-20 and J-40 spectropolarimeters. PMR spectra were recorded on Varian A-60 and HA-100 spectrometers in deuterated solvents using tetramethylsilane (TMS) as the internal standard. All the solvents for optical measurements are of spectroscopic grade and used without further purification.

Results and Discussion

Conformation of the Chelate Rings and Geometrical Isomers of the Complexes. The PMR spectral data for the methylene and methine resonances of the (*R,S*)- and (*S,S*)-dppn complexes are summarized in Table 1 together with those of the (*R,S*)- and (±)-ptn platinum(II) and platinum(IV) complexes. Appleton and Hall[6] suggested that the chair conformation is preferred in the (*R,S*)-ptn platinum complexes and the skew conformation in the (±)-ptn platinum(IV) complex on the basis of the coupling constant $J_{Pt\text{-}N\text{-}C\text{-}H}$. The coupling constants, J_{AX} and J_{AB} of the (*R,S*)-dppn

Table 1. The methylene proton (H_A, H_B) resonances and the coupling constants with the methine proton (H_X) of the dppn and ptn complexes (δ/ppm)

	H_A	H_B	J_{AX}
$[Co(NH_3)_4(R,S\text{-dppn})](ClO_4)_3$	3.01	2.17	11
$[Pt(NH_3)_2(R,S\text{-ptn})]Cl_2$[6]	2.03	3.08	11.0
$[Pt(H_2O)_2(R,S\text{-ptn})_2](ClO_4)_4$[6]	2.68	3.75	11.0
$[Co(NH_3)_4((\pm)\text{-dppn})](ClO_4)_3$	2.62		8
trans-$[Co(NH_3)_2(S,S\text{-dppn})_2](ClO_4)_3$	2.70		8
cis-Λ-$[Co(NH_3)_2(S,S\text{-dppn})_2](ClO_4)_3$	2.53, 2.78		8
$[Pt((\pm)\text{-ptn})(NH_3)_2]Cl_2$[6]	2.87		5.5
$[Pt((\pm)\text{-ptn})(NH_3)_2(H_2O)_2](ClO_4)_4$[6]	3.42		7.5

Solvent: $(CD_3)_2CO$ for dppn complexes and D_2O for ptn complexes. Internal references: TMS for dppn complexes and DSS for ptn complexes.

cobalt(III) complexes are similar to those of the (*R,S*)-ptn platinum complexes. The constants, J_{AX} of the ((±) or *S,S*)-dppn cobalt(III) complexes are also similar to that of $[Pt((\pm)\text{-ptn})(NH_3)_2(H_2O)_2](ClO_4)_4$ as seen in Table 1. It is, therefore, concluded that the (*R,S*)-dppn and the (*R,R* or *S,S*)-dppn chelate rings take chair and skew conformations, respectively. In a previous paper,[4] it was clarified from the CD spectrum of *trans*-$[CoCl_2(S,S\text{-dppn})_2]^+$ that the (*S,S*)-dppn takes a λ-skew conformation upon coordination.

The assignment of the geometrical isomers of $[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$ was made on the basis of the PMR spectral patterns (Table 1). This assignment will be supported by the elution order of the isomers of $[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$ in SP-Sephadex column chromatography; *trans*>*cis*-Λ>*cis*-Δ. This order is the same as that for the corresponding isomers of the (*R,R*)-ptn complexes.[3]

Circular Dichroism Spectra. The CD data of the (*S,S*)-dppn and (*S,S*)-stien complexes in the first absorption band region are summarized in Table 2 together with the absorption data.

(1) $[Co(NH_3)_4L]^{3+}$(L=(S,S)-dppn and (S,S)-stien): The CD spectra of the complexes, $[Co(NH_3)_4L]^{3+}$ in water are shown in Fig. 1. Both the complexes give only a negative CD band in the first absorption band region. The (*S,S*)-stien is known to take a δ-gauche conformation, the two phenyl groups on the asymmetric carbons adopting equatorial orientation.[7,8] A single negative CD sign of the (*S,S*)-dppn complex predicts that the chelate ring also takes a δ-skew conformation. However, this conformation is unlikely for the (*S,S*)-dppn because the two phenyl groups on the asymmetric carbons become axial orientation. The (*S,S*)-dppn chelate is expected to be stable in the λ-skew conformation with two equatorial phenyl groups. The designation of the absolute configuration for both the diamines is opposite to each other for the same conformation on the basis of the sequence rule.[9] The CD pattern of $[Co(NH_3)_4(S,S\text{-dppn})]^{3+}$ in water is also different from either CD curve of the vicinal contribu-

* Solvent: 1) water, 2) methanol, 3) DMSO, and 4) KBr matrix.

tion of (*S,S*)-dppn calculated from the two diastereomers, *Δ*- and *Λ*-[Co(*S,S*-dppn)$_3$]$^{3+}$ or from *Δ*- and *Λ*-[Co(en)$_2$(*S,S*-dppn)]$^{3+}$.[4,10] One explanation for the CD spectrum of [Co(NH$_3$)$_4$(*S,S*-dppn)]$^{3+}$ can be based on the flexibility of the (*S,S*)-dppn ligand in connection with the observation that the cobalt(III) complexes containing 2,4-pentanediamine are susceptible to solvent effect.[3]

The solvent effect on the CD spectra of both the (*S,S*)-dppn and the (*S,S*)-stien complexes is shown in Figs. 2 and 3, respectively. The former complex shows a marked solvent effect in the first absorption band region. The CD pattern in KBr matrix resembles that of the vicinal contribution of (*S,S*)-dppn derived from the *Δ*- and *Λ*-[Co(*S,S*-dppn)$_3$]$^{3+}$ complexes in DMSO. On the other hand, [Co(NH$_3$)$_4$(*S,S*-stien)](ClO$_4$)$_3$ shows little variations. The pattern is the same as that of the vicinal contribution of (*S,S*)-stien derived from the two diastereomers of *Δ*- and *Λ*-[Co(*S,S*-stien)$_3$]$^{3+}$.[1] Several explanations have been proposed for the solvent effect; 1) the conformational change of the diamine chelate ring, 2) asymmetric deviation of the coordinated nitrogen atoms from the octahedral positions, 3) asymmetric interaction of the solvent molecule with the solute. These factors are not independent of one another. The fact that the CD spectrum of [Co(NH$_3$)$_4$(*S,S*-dppn)]$^{3+}$ is much more susceptible to solvent ef-

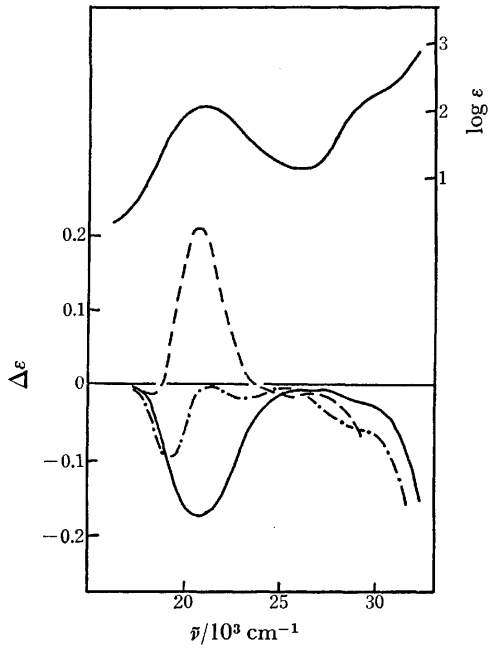

Fig. 2. Absorption and CD spectra of [Co(NH$_3$)$_4$(*S,S*-dppn)]Br$_3$ in water (——), in DMSO (—·—), and KBr matrix (----).

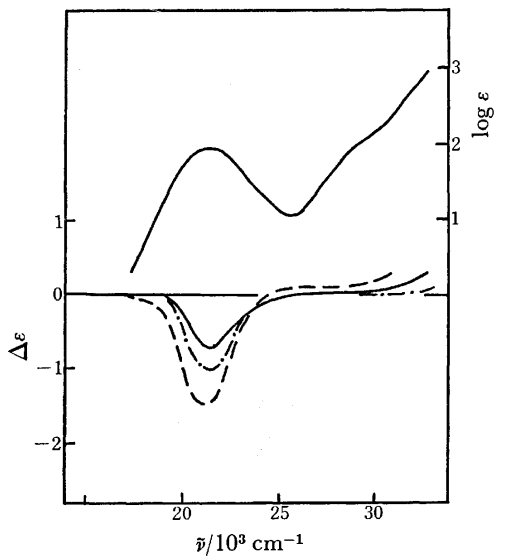

Fig. 3. Absorption and CD spectra of [Co(NH$_3$)$_4$(*S,S*-stien)](ClO$_4$)$_3$ in water (——), in DMSO (—·—), and KBr matrix (----).

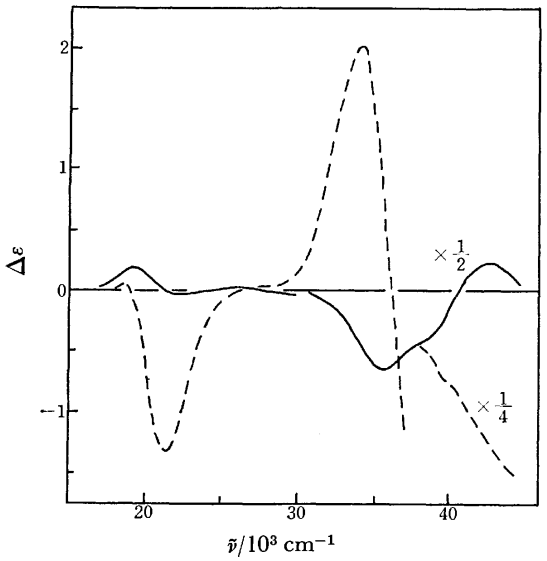

Fig. 4. CD spectra of *trans*-[Co(NH$_3$)$_2$(*S,S*-dppn)$_2$]-(ClO$_4$)$_3$ (——) and *trans*-[Co(NH$_3$)$_2$(*S,S*-stien)$_2$](ClO$_4$)$_3$ (----) in methanol.

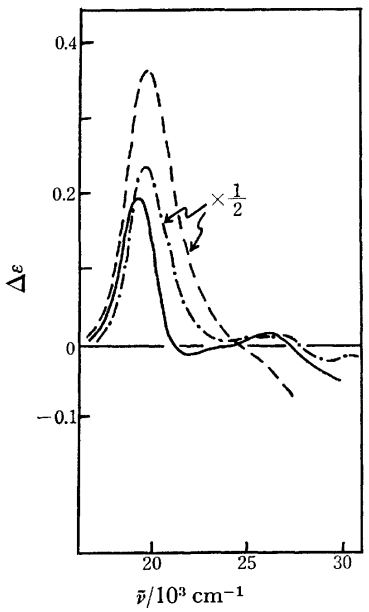

Fig. 5. CD spectra of *trans*-[Co(NH$_3$)$_2$(*S,S*-dppn)$_2$]-(ClO$_4$)$_3$ in methanol (——), in DMSO (—·—), and KBr matirx (----).

fect than that of the corresponding stien complex indicates that the variations may be associated with the flexibility of the six-membered chelate ring. However, the main factor for the solvent variations is not clear at present.

(2) trans-[*Co(NH$_3$)$_2$L$_2$*]$^{3+}$ *(L=(S,S)-dppn and (S,S)-stien)*: The CD spectra of the complexes, *trans*-[Co(NH$_3$)$_2$L$_2$]$^{3+}$ in methanol are shown in Fig. 4. Both the complexes give two CD peaks in the first absorption band region and the sign of the main component is positive for the former and negative for the latter. These patterns coincide with the anticipation that the (*S,S*)-dppn takes a λ-skew conformation and the (*S,S*)-stien a δ-gauche form. The CD strength of the (*S,S*)-dppn complex in the second absorption band region is very weak, in contrast to that of the corresponding (*R,R*)-ptn complex.[11]

The solvent effect on both the (*S,S*)-dppn and the (*S,S*)-stien complexes is shown in Figs. 5 and 6, respectively. The CD strength of the (*S,S*)-dppn complex varies significantly with the solvent variations in the first absorption band region. On the other hand, the CD spectrum of the (*S,S*)-stien complex is rather insensitive to the solvent variations. The CD pattern of *trans*-[Co(NH$_3$)$_2$(*S,S*-dppn)$_2$]$^{3+}$ is entirely different from that of [Co(NH$_3$)$_4$(*S,S*-dppn)]$^{3+}$ in water, while the (*S,S*)-stien complex gives the same pattern as that of [Co(NH$_3$)$_4$(*S,S*-stien)]$^{3+}$. The difference in the CD behavior between the (*S,S*)-dppn and the (*S,S*)-stien complexes may be related with the difference in the conformational behavior of the chelate rings.

(3) cis-[*Co(NH$_3$)$_2$L$_2$*]$^{3+}$*(L=(S,S)-dppn and (S,S)-stien)*: Figures 7—10 show the CD spectra of the isomers of *cis*-[Co(NH$_3$)$_2$L$_2$]$^{3+}$ and the calculated configurational and vicinal (per mole of the ligands) contributions to the CD spectra. The *cis* 1 in Figs. 7 and 9

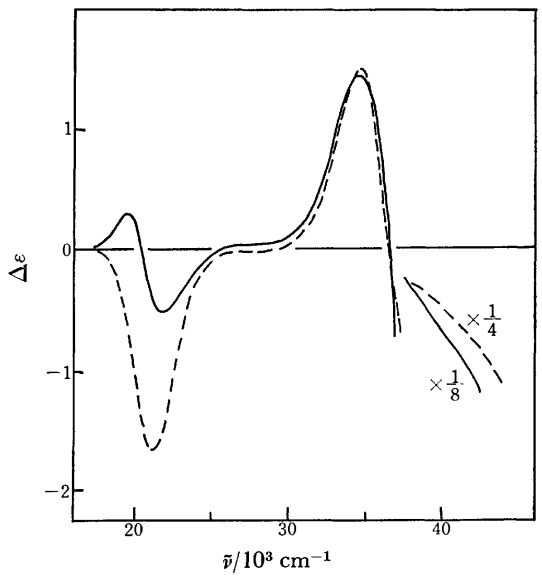

Fig. 9. CD spectra of *cis* 1 (——) and *cis* 2 (----) of [Co(NH$_3$)$_2$(*S,S*-stien)$_2$]Cl$_3$ in 0.02 M aqueous hydrochloric acid.

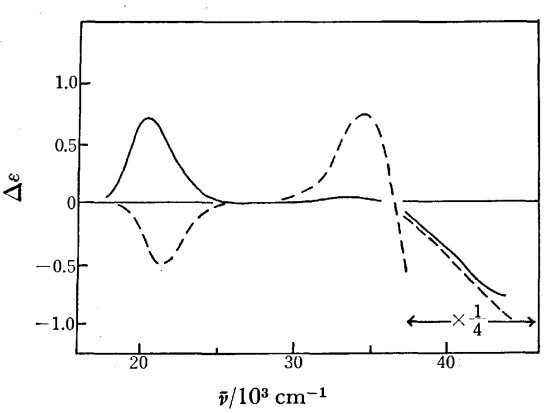

Fig. 10. The configurational (*Λ*) (——) and the vicinal (----) contribution in the CD calculated from the spectra of the two diastereomers of *cis*-$[Co(NH_3)_2(S,S\text{-stien})_2]Cl_3$ in methanol.

were obtained from the first orange eluate and the *cis* 2 from the second orange yellow eluate. The absolute configuration of each isomer can be assigned on the basis of the empirical rule.[12] The calculated configurational contribution of the CD spectra shown in Fig. 8 also supports the assignment: *cis* 1 to *Λ* and *cis* 2 to *Δ*.

Boucher and Bosnich[11] reported that the calculated vicinal contribution of (*R,R*)-ptn derived from the two diastereomers of *cis*-$[Co(NH_3)_2(R,R\text{-ptn})_2]^{3+}$ is entirely different from the CD spectrum of *trans*-$[Co(NH_3)_2(R,R\text{-ptn})_2]^{3+}$. Mizukami *et al.*[13] also claimed that the vicinal contribution of (*R,R*)-ptn derived from $[Co(R,R\text{-ptn})_3]^{3+}$ differs from the CD spectrum of $[Co(NH_3)_4(R,R\text{-ptn})]^{3+}$. The calculated vicinal contribution of (*S,S*)-dppn derived from the two diastereomers of *cis*-$[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$ also differs from the CD spectra of both *trans*-$[Co(NH_3)_2(S,S\text{-dppn})_2]^{3+}$ and $[Co(NH_3)_4(S,S\text{-dppn})]^{3+}$. The spectral pattern of the calculated vicinal contribution, however, is similar to that obtained from the CD spectra of *Δ*- and *Λ*-$[Co(S,S\text{-dppn})_3]^{3+}$ in Fig. 8, although the CD strength of the former is weak compared with that of the latter.

The vicinal contribution of the (*S,S*)-stien chelate ring in Fig. 10 is almost the same as the CD spectra of both $[Co(NH_3)_4(S,S\text{-stien})]^{3+}$ and *trans*-$[Co(NH_3)_2(S,S\text{-stien})_2]^{3+}$. This is common to five-membered chelate ring systems such as 1,2-propylenediamine cobalt(III) complexes.[14]

The Effect of a Solvent on the Carbonylation of Methanol Catalyzed by Rhodium Complexes in the Presence of Methyl Iodide

Toshio MATSUMOTO, Kunio MORI, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received March 13, 1976)

In the synthesis of acetic acid by the carbonylation of methanol catalyzed by $RhCl_3 \cdot 3H_2O$ or $Rh_2Cl_2(CO)_4$ in the presence of methyl iodide, it was found that ketone solvents, such as acetophenone and benzophenone, keep both the catalytic activity and selectivity high, even at an elevated temperature. The kinetic results in acetophenone are in agreement with the mechanism proposed by Paulik and Roth.[11] The effect of the ketone solvent was discussed by taking account of the competitive oxidative addition of hydrogen iodide with methyl iodide.

The oxidative addition of aryl iodide to nickel(0),[1,2] palladium(0),[3-8] and rhodium(I)[9,10] has been shown to play an important role in the catalytic carbonylation and arylation of olefin. It has been reported that, in the carbonylation of iodobenzene catalyzed by palladium-black in a basic medium to give methyl benzoate, the oxidative addition of iodobenzene to a palladium(0) complex is the rate-determining step, a step which is considerably influenced by ligands weakly bonded to the palladium complex.[4] Recently the oxidative addition of methyl iodide was demonstrated to be the rate determining step in the carbonylation of methanol catalyzed by rhodium compounds in liquid[11,12,16] and gas-phase reactions.[13-15] In this methanol carbonylation, the effect of ligands (including solvents) should also be reflected in its rate, as may be seen in the palladium-catalyzed carbonylation of iodobenzene. It was observed, however, that, when methanol was used as the solvent, the selectivity was very low (<20%) because of the formation of dimethyl ether in considerable amounts. The formation of dimethyl ether made it very difficult to elucidate the kinetic results. Thus, we examined the effects of the solvents in increasing the selectivity, and found that both the rate and the selectivity are highest in a ketone solvent, such as acetophenone or benzophenone.

During the preparation of this paper, a kinetic study of the carbonylation of methanol in an acetic acid solvent was reported,[16] and it was also noticed that much dimethyl ether was formed on initiating the carbonylation in a pure methanol solvent. The effect of solvents, however, was not described.

The purpose of this work is to investigate the effect of the solvent on the rate and selectivity of the rhodium complex-catalyzed carbonylation of methanol in the presence of methyl iodide and to discuss the role of solvents.

Experimental

Materials. Dichlorotetracarbonyldirhodium(I), $Rh_2Cl_2(CO)_4$, was prepared from $RhCl_3 \cdot 3H_2O$ and carbon monoxide according to the literature[17] (Found: C, 11.2; Cl, 18.8 %. Calcd: C, 12.4; Cl, 18.2%.). $RhCl_3 \cdot 3H_2O$ (Koso Chemical Co., Ltd,), carbon monoxide (>98%), methanol (>99%), methyl iodide (Tokyo Kasei's extra pure grade), and all the solvents used in this work were obtained from commercial sources. The solvents listed in Table 1 were checked by gas chromatography before use, and were used without purification.

Procedure. All the carbonylations were carried out using a Ti–Mn alloy autoclave (100 ml) equipped with a magnetic stirrer. A given amount of $RhCl_3 \cdot 3H_2O$ or $Rh_2Cl_2(CO)_4$ (0.125—1.00 mmol) and a mixture of methyl iodide (5—20 mmol), methanol (50—250 mmol) and a solvent (20 ml) were placed in the autoclave. Carbon monoxide was then introduced up to the desired pressure (7—90 kg/cm^2). Subsequently the autoclave was heated up to a reaction temperature within 15—20 min, the temperature and the pressure being kept constant for 1—4 h. The autoclave was then cooled rapidly to room temperature with water, and the carbon monoxide was purged out. The product solution was analyzed by gas chromatography. The reaction rate was measured as follows. A rhodium catalyst and a solution were placed in the autoclave, and it was heated up to a reaction temperature before introducing carbon monoxide. The carbonylation was initiated by introducing carbon monoxide. The pressure was kept constant during the reaction by supplying carbon monoxide from a high-pressure gas reservoir (100 ml). The amount of carbon monoxide consumed was measured by means of the pressure decrease in the gas reservoir.

Analysis. The product solutions were quantitatively analyzed by means of gas chromatography. A glass column (3 mmϕ, 3 m, carrier gas of H_2) of diethylene glycol succinate polyester on Celite was used at 100—200 °C for carboxylic acids with an internal standard substance (C_6H_5Br or 1-$C_{10}H_7Br$). For the determination of the methyl acetate, methanol, and methyl iodide, a copper column (3 mmϕ, 3 m, carrier gas of H_2) of 3,3′-oxy-dipropionitrile on an insulating brick was used at 70 °C with dibutyl ether as the internal standard substance.

Results and Discussion

Effect of Solvents. The carbonylation of methanol catalyzed by $RhCl_3 \cdot 3H_2O$ and methyl iodide was examined in various solvents under the same reaction conditions. The results are summarized in Table 1. The use of the solvents with a carbonyl group improved the yield and selectivity of the carbonylation of methanol. The yield and selectivity of more than 100% in the methyl benzoate solvent seemed to be caused by the hydrolysis of methyl benzoate or by its ester exchange with acetic acid. This idea was supported by the detection of benzoic acid in the reaction product.[25] The methyl iodide was restored almost completely after the carbonylation except in the case of the *N,N*-dimethylacetamide solvent. Acetophenone was employed to show the effectiveness of the ketone solvents in Table 2. The addition of acetophenone significantly increases

a) Total AcOH = AcOH + $AcOCH_3$. b) Defined in Table 1. c) The amount of $(CH_3)_2O$ formed was calculated as follow: $(CH_3)_2O = 1/2 \times ([CH_3OH]_{\text{init.}} - [\text{AcOH}] - 2[AcOCH_3] - [CH_3OH]_{\text{resid.}})$.

the amount of total acetic acid, retarding the formation of dimethyl ether, at a smaller volume ratio of methanol to acetophenone. The effect of acetophenone on the rate of carbonylation at 156 °C is shown in Fig. 1; anisole or toluene was added to keep the concentrations of the methyl iodide, the rhodium catalyst, and the methanol constant. In both cases, the rates effectively increase with an increase in the volume ratio of acetophenone added and reach a constant rate (138 mmol/h) above the ratio of 1. In no runs was any metallic substance detected in the product solutions.

A kinetic study of the carbonylation was undertaken in the acetophenone solvent. The amounts of carbon monoxide absorbed during the reaction are plotted against the time at various amounts of the rhodium catalyst and methyl iodide under 30 kg/cm² of carbon monoxide at 112 °C in Figs. 2 and 3. The total consumption of carbon monoxide almost corresponded to

the amount of total acetic acid produced in each run. Accordingly, the rates of carbonylation are independent of the feed of methanol. The rate is first order with respect to the amount of methyl iodide, and also with respect to that of the rhodium catalyst. The rate was also independent of the pressure of carbon monoxide (10—90 kg/cm²). These kinetic relations were independently confirmed in the higher-temperature range.

Effect of Temperature. The effect of the temperature was examined in stable solvents, such as acetophenone, benzophenone, anisole, and toluene (Figs. 4 and 5). Benzonitrile and chlorobenzene, which gave a high selectivity at 140 °C, as is shown in Table 1, were not investigated in detail, since the hydrogenolysis of benzonitrile and the oxidative addition of chlorobenzene seemed to interfere with the carbonylation of methanol at higher temperatures. In the toluene sol-

vent, the selectivity is very low because of the formation of dimethyl ether in considerable amounts. At 173 °C, the rates in the ketone solvents were 6 to 8 times larger than in anisole and 13 to 18 times larger than in toluene. There was no essential difference between $RhCl_3 \cdot 3H_2O$ and $Rh_2Cl_2(CO)_4$ with respect to the rate and selectivity of carbonylation, as is shown in Fig. 4. Arrhenius plots of the rates in ketone solvents gave good linearities, from which the apparent activation energy was estimated to be 19 kcal/mol (Fig. 6).

□ In benzophenone, ● in acetophenone, ○ in anisole, and ⊙ in toluene.

To examine whether or not low rates in anisole or toluene at elevated temperatures were caused by an irreversible deactivation of the catalyst, the dependence of the rates on temperature was reinvestigated. The rate in anisole initially measured at 173 °C for 30 min under the conditions specified in Fig. 5 was 75±10 mmol /h. After the temperature had been lowered to 156 °C within 5 min, the rate was measured again for 45 min to give the value of 65±5 mmol/h. The temperature was, then, further lowered to 140 °C within 5 min; the rate measured for 40 min was 32±5 mmol/h. These rates were almost entirely consistent with those obtained by the separate experimental runs shown in Fig. 6, namely, 80, 67, and 40 mmol/h at 173, 156, and 140 °C respectively. The rates obtained in toluene by the same manner were 52(50), 40(38), and 15(16) mmol/h at 156, 140, and 112 °C respectively; the rates given in Fig. 6 are shown in parentheses. These results indicate that the catalytic activity is reproducible with

respect to the reaction temperature. It seems most likely that there is no essential change in the mechanism, since the kinetic behavior in anisole or toluene is almost the same as in acetophenone, even at higher temperatures.

The effect of hydrogen on the methanol carbonylation was examined in the acetophenone solvent using $RhCl_3 \cdot 3H_2O$. Under a lower pressure of carbon monoxide (P_{H_2} 40 kg/cm^2, P_{CO} 10 kg/cm^2, 140 °C), acetophenone was hydrogenated to give ethylbenzene and a trace amount of styrene, while practically no hydrogenation of acetophenone was observed under a higher pressure of carbon monoxide (P_{CO}>20 kg/cm^2). Neither acetaldehyde nor ethanol was detected in the product solutions in any case. The treatment of methyl iodide without methanol under 60 kg/cm^2 of a H_2–CO (H_2/CO=1) mixture gave only a trace amount of acetic acid, but no acetaldehyde, and more than 80% of the methyl iodide was recovered in the product solution.

Role of the Solvent. The kinetic results suggest that the carbonylation of methanol in ketone solvents proceeds *via* a scheme similar to that proposed by Roth *et al.*[12] Recently a more elaborate scheme has been reported by Forster.[18] The most reasonable rate-determining step is the oxidative addition of methyl iodide to the rhodium(I) complex, assuming that the equilibrium between methyl iodide and hydrogen iodide ($CH_3OH + HI \rightarrow CH_3I + H_2O$) is much shifted to the formation of methyl iodide during the carbonylation. Figure 6 shows that the rates at lower temperatures (<140 °C) are almost the same in any solvent examined, indicating no essential role of solvent molecules as ligands.[19] Accordingly, the active species in ketone solvents is probably the same as that observed by Forster during a catalytic carbonylation of methanol in a heptanoic acid solvent, using $RhCl_3 \cdot 3H_2O$ as the catalyst precursor.[18] The reaction scheme with this species is illustrated.[20] It was reported that the oxidative addition of alkyl halide to a rhodium(I) complex such

$$[Rh(CO)_2I_2]^- \xrightarrow{CH_3I} [CH_3Rh(CO)_2I_3]^- \xrightarrow{CO}$$

$$[CH_3CORh(CO)_2I_3]^-\ ^{21)} \xrightarrow[-AcOCH_3 \text{ or } AcOH]{+CH_3OH \text{ or } H_2O}$$

$$[HRh(CO)_2I_3]^- \xrightarrow[+Solvent\text{-}HI]{+Solvent} [Rh(CO)_2I_2]^-$$

$$Solvent\text{-}HI + CH_3OH \rightleftharpoons CH_3I + Solvent + H_2O$$

as $RhCl(CO)(PPh_3)_2$ and $RhCl(CO)_2(PPh_3)$ proceeds *via* electrophilic attack of alkyl halide.[22–24] Since hydrogen iodide is less crowded and more electrophilic, a small amount of hydrogen iodide in the solution should be competitive with the methyl iodide for the oxidative addition. The equilibrium concentration of hydrogen iodide should increase with elevating the temperature, because the formation of methyl iodide is exothermic. In ketone solvents, hydrogen iodide may be effectively solvated so as to prevent its oxidative addition to the rhodium(I) complex.

25) The product solution contained AcOH (35.5 mmol), $AcOCH_3$ (19.2 mmol), C_6H_5COOH (19.5 mmol), and no methanol, indicating that 20—24 mmol of methyl benzoate were consumed during the carbonylation to give benzoic acid.

Studies of Peptide Antibiotics. XXXVI.[1] Synthesis and Biological Activity of [5,5′-Leucine]-gramicidin S[2]

Okitoshi ABE, Yoko UTSUMI, and Nobuo IZUMIYA*

Laboratory of Chemistry, Fukuoka Dental College, Nishi-ku, Fukuoka 814

**Laboratory of Biochemistry, Fuculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812*

(Received April 25, 1977)

An analog of gramicidin S, in which 5,5′-proline residues were replaced by leucine, was prepared in order to investigate the effect of the introduction of hydrophobic side groups on the antibacterial activity and on the conformation. Also the solubility problems encountered during the synthesis of this analog are described. No significant effect was observed on the cyclization reaction by the replacement of 5,5′-proline to leucine residues. This analog exhibited comparable biological activity and the similar conformation to the natural gramicidin S. These studies suggested that the imino groups of 5,5′-proline residues have no significant roles on both antibacterial activity and conformation of this antibiotic.

Synthetic analogs of gramicidin S (GS, Fig. 1) in which 5,5′-Pro residues are replaced by Gly,[3] Sar,[4] β-Ala,[5] α-aminoisobutyric acid (Aib),[6] or Phe[7] have been reported by Izumiya and his collaborators. Some of them, such as [5,5′-Gly]-,[3] [5,5′-Sar]-,[4] and [5,5′-Phe]-GS,[7] exhibited substantial biological activities. On the other hand, very weak or no antibacterial activity was observed on the other two analogs, *i.e.* [5,5′-β-Ala]-[5] and [5,5′-Aib]-GS.[6]

In this study was synthesized an analog in which 5,5′-Pro residues of the natural GS were replaced by Leu residues, namely [5,5′-Leu]-GS. Leucine residue possesses bulky hydrophobic side chain and its effect on the antibacterial activity has also been studied. In addition, as a strategy of the synthesis of this analog, the sequence of the linear intermediate was selected such a way that the 3- or 3′-Leu located to the carboxyl terminus in consideration of its similarity to the biosynthetic intermediate of GS.[8] The problems caused by this sequence are also discussed. Possibility of racemization during the cyclization reaction was overcome by the employment of the azide procedure.[9,10]

The intermediate peptides were protected on the α amino terminus by the *t*-butoxycarbonyl group (Boc–), on the δ amine of ornithines by the benzyloxycarbonyl group (Z–), and on α carboxyl groups by the ethyl ester (–OEt). Selective deprotection of Boc-group was

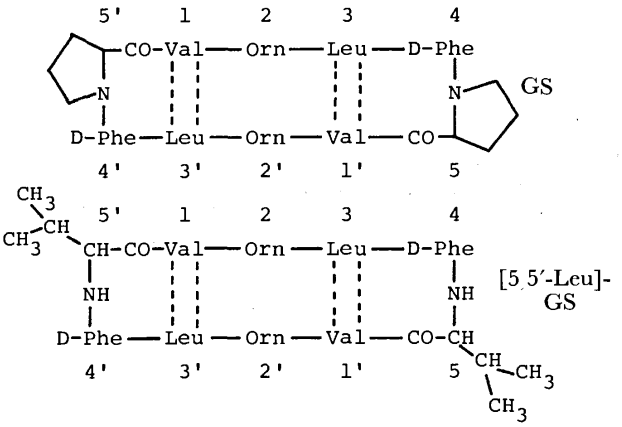

Fig. 1. Structure of GS (upper) and [5,5′-Leu]-GS (bottom).

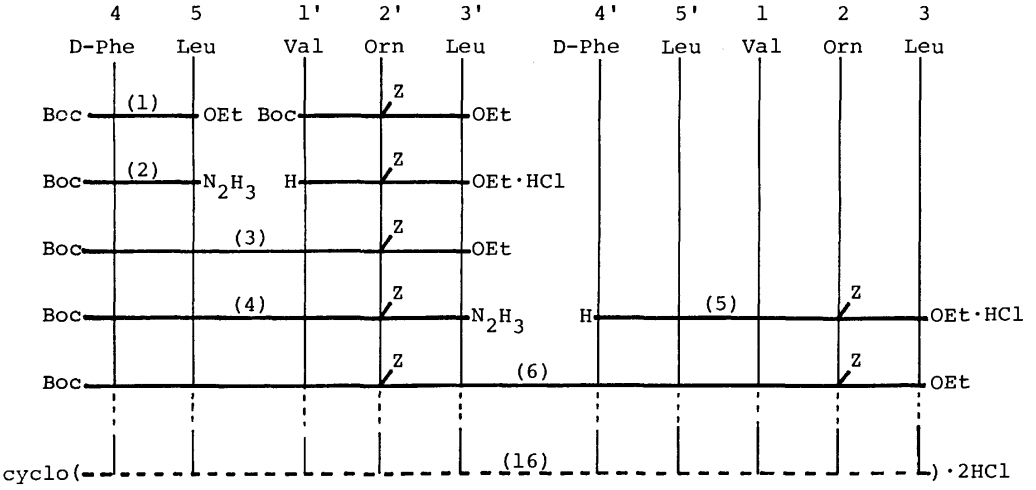
carried out with hydrogen chloride in formic acid and of Z-group by hydrogenolysis in the presence of palladium black. As for the coupling reaction, the azide procedure of Curtius[9] and of Honzl and Rudinger[10] were mainly employed.

Scheme 1 indicates a route for the synthesis of the protected decapeptide (**6**) with 3-Leu as the carboxyl terminus. This route was designed to imply the similarity of the amino acid sequence to that of the bio-



Scheme 1. Synthesis of [5,5′-Leu]-GS with 3-Leu as carboxyl terminus.

synthetic intermediate of GS.[8]

The first dipeptide derivative (**1**) was obtained by the mixed anhydride method with isobutyl chloroformate as the coupling reagent. Product **1** was obtained in 65% yield and then converted without difficulty to its hydrazide (**2**) by the addition of 20 molar excess of hydrazine hydrate. Boc-pentapeptide ester (**3**) was obtained by the coupling of the product **2** with H–Val–Orn(Z)–Leu–OEt[11] using azide procedure[9] in 80% yield. First problem was encountered in the following step, conversion of the ester (**3**) to the hydrazide (**4**). At first the same condition as described for the preparation of **2** was employed, however, the reaction was incomplete. Therefore, the amount of hydrazine was increased to 40 molar excess and also the reaction time prolonged. On standing for eight days, precipitates were formed and the reaction mixture was revealed to contain almost no ester on a thin-layer plate, yielding 82% of the product **4**. Deblocking of Boc-group from **3** yielded the product **5** in 96%.

The second problem was in the coupling of the product **4** with **5**. Compound **4**, sparingly soluble in common organic solvents, was dissolved on two hours of stirring in the mixed solvent DMF–DMSO (1 : 1, v/v) and the coupling was carried out using the azide procedure of Honzl and Rudinger.[10] The product was revealed to be a mixture of several components and all the efforts for their separation and purification resulted in vain, mainly because of their insolubility. No better result was obtained when the coupling reaction was repeated several times. These facts forced to change the strategy of the synthetic route.

In the alteration of the synthetic route, first to be considered was the use of the intermediate peptide derivatives synthesized in Scheme 1. As shown in Scheme 2, two peptide derivatives, Boc–Val–Orn(Z)–Leu–OEt and the dipeptide derivative (**1**), could be successfully used. Conversion of the Boc-tripeptide ester to its hydrazide (**7**) with 20 molar excess of hydrazine hydrate and deblocking of the Boc-group of the compound **1** were performed without trouble. Subsequent coupling of **7** with **8** was carried out by means of the azide procedure to produce Boc-pentapeptide ester (**9**) in the yield of 54%. The next step, conversion of ester (**9**) to its hydrazide (**10**), was much easier than the corresponding step (**3** to **4**) in Scheme 1. It took two days to complete the reaction with 40 molar excess of hydrazine hydrate. Decapeptide derivative (**12**) was also obtained without difficulty in pure form by the azide method and the yield was fairly good (88%).

In the synthetic route of Scheme 2, the most troublesome step was the conversion of **12** to the hydrazide (**13**). The amount of hydrazine was increased from 40 to 80 and finally to 200 molar equivalents. Under the final condition, the product **13** was obtained in good yield (96%).

After removal of Boc-group from **13**, the product **14** was cyclized by the azide procedure as described in Experimental part. Crude cyclic peptide thus obtained was dissolved in aqueous methanol and passed through a column of Dowex 50X8. Recrystallization from methanol–water gave the pure Z-protected cyclic petide (**15**) in the yield of 58%. Hydrogenolysis of **15** produced the final product, [5,5′-Leu]-GS (**16**), in the yield of 67%. Homogeneity of **16** was ascertained by paper and thin-layer chromatographies with various solvent systems, paper electrophoresis, elemental analysis and by amino acid analysis. Also the final product was subjected to antibacterial test and ORD measurements.

In general, from the standpoint of synthesis, deblocking of Boc-groups with hydrogen chloride in formic acid was performed without any trouble. On the contrary,

the conversion of the esters to their hydrazides produced several difficulties in some cases. And the insolubility of some hydrazides made the subsequent reaction difficult. Although the imino acid proline was replaced by the amino acid leucine, the cyclization step by the azide method was carried out without trouble and resulted in good yield.

Antibacterial activities of [5,5′-Leu]-GS measured in both nutrient agar and synthetic medium are listed in Table 1. Compared to natural GS, the synthetic analog exhibited considerable inhibitory activities against some organisms tested. From these data, the 5,5′-Pro residues of the natural GS seem to be exchangeable to bulky hydrophobic amino acid residues such as Leu without any significant effect on the antibacterial activity. In Table 2 are listed antibacterial activities of the 5,5′-position substituted GS analogs reported thus far. These data also indicate the insignificance of 5,5′-Pro residues of GS on its antibacterial activity.

The ORD curves of [5,5′-Leu]-GS measured in both ethanol and 8 M urea were presented in Fig. 2. In both media the synthetic analog exhibited similar curves as those of the natural GS with a negative trough at 234—235 nm. The fact that no shift of the trough had been observed even in the strong denaturing reagent such as 8 M urea suggested the rigid and stable conformation of the synthetic analog as well as the natural GS molecule, which has the intramolecular antiparallel β-form with four hydrogen bondings between the valyl and the leucyl residues.[13] Correlation between the rigid structure and the antibacterial activity is also suggested.

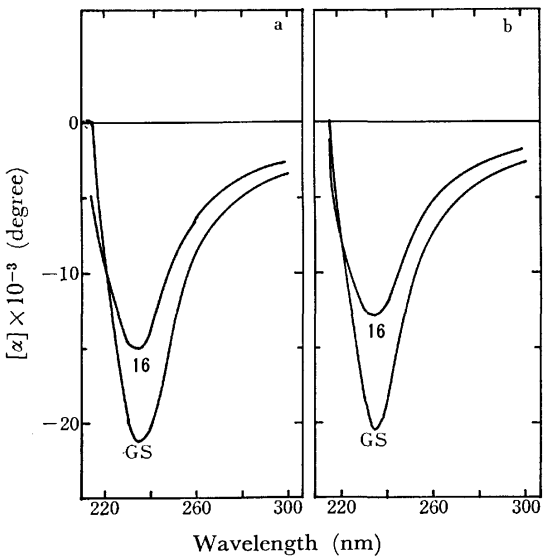

Fig. 2. ORD curves of [5,5′-Leu]-GS (**16**) and natural GS.

Experimental

All melting points are uncorrected. Prior to elemental analysis, all the compounds were dried over P_2O_5 to a constant weight at 80 °C and 2 Torr. TLC was carried out on silica gel G (Merck) with the following solvent systems: R_f^1, chloroform–MeOH (5 : 1, v/v), R_f^2, chloroform–MeOH–AcOH (95 : 5 : 1, v/v), R_f^3, chloroform–MeOH (9 : 1, v/v), R_f^4, 1-butanol (BuOH)–AcOH–pyridine–H_2O (4 : 1 : 1 : 2, v/v), R_f^5, BuOH–AcOH–pyridine–H_2O (15 : 3 : 10 : 12, v/v). Paper chromatography (PPC) was performed on Toyo Roshi No. 52 paper with the solvent system, either R_f^4 or R_f^5. The optical rotations were determined with a polarimeter at the 589 sodium line. Amino acid analysis was carried out on the sample which had been hydrolyzed for 24 h in a evacuated sealed tube at 110 °C.

*Boc-D-Phe-Leu-OEt (**1**).* To a solution of Boc-D-Phe-OH (2.65 g, 10 mmol) in THF (20 ml), were added triethylamine (TEA, 1.40 ml) and isobutyl chloroformate (1.31 ml, 10 mmol) at 0—4 °C. The mixture was stirred for 10 min at 0—4 °C and to this was added a solution of H-Leu-OEt·*p*TsOH[14] (3.31 g, 10 mmol) and TEA (1.4 ml) in chloroform (20 ml). After the mixture was stirred overnight at a room temp, the solvent was evaporated *in vacuo* and the residue was taken up in AcOEt. The AcOEt solution was then washed successively with 0.5 M citric acid, 4% sodium hydrogen carbonate and water, and then dried (Na_2SO_4). The solvent was evaporated *in vacuo* and the product was precipitated by the addition of ether and petroleum ether. Recrystallization was carried out from ether–petroleum ether; yield, 2.64 g (65%); mp 111—112 °C; $[\alpha]_D^{25}$ −4.6° (*c* 1, DMF); R_f^1 0.96.
Found: C, 64.96; H, 8.44; N, 7.04%. Calcd for $C_{22}H_{34}N_2O_5$: C, 65.00; H, 8.43; N, 6.89%.

*Boc-D-Phe-Leu-N_2H_3 (**2**).* Hydrazine hydrate (2.91 ml, 60 mmol) was added with stirring to the solution of **1** (1.22 g, 3 mmol) in DMF (6 ml) and the mixture was left to stand at a room temp. After stirring for 48 h, the reaction mixture showed a single spot, which was distinguished from that of **1**, on a TLC plate. Excess hydrazine was evaporated

in vacuo, and then the product was precipitated with water (200 ml). The precipitates were washed with water and desiccated overnight (P_2O_5); yield, 1.03 g (87%); mp 163—164 °C; $[\alpha]_D^{25}$ −12.0° (*c* 1, DMF); R_f^1 0.77.

Found: C, 61.13; H, 8.30; N, 14.28%. Calcd for $C_{20}H_{32}N_4O_4$: C, 61.20; H, 8.22; N, 14.28%.

Boc-D-Phe-Leu-Val-Orn(Z)-Leu-OEt (**3**). In a mixture of glacial AcOH (40 ml) and 1 M HCl (3 ml) was dissolved **2** (0.59 g, 1.5 mmol) and the solution was cooled to −5 °C. To the solution was added, with stirring, a cold concentrated aq solution of sodium nitrite (0.103 g, 1.5 mmol). After 10 min, the azide was precipitated by the addition of cold water (200 ml) and the precipitates were filtered, washed successively with ice-cold water, 5% sodium hydrogen carbonate, and again with water. After brief drying (P_2O_5), the azide was added to the solution of H-Val-Orn(Z)-Leu-OEt·HCl[11] (0.815 g, 1.5 mmol) and TEA (0.21 ml, 1.5 mmol) dissolved in DMF (10 ml). After standing overnight at 0 °C and then for 2 days at a room temp, the reaction mixture was concentrated *in vacuo* and the product was precipitated on adding water. The crude product was recrystallized with EtOH–ether; yield, 1.04 g (80%); mp 237—238 °C (dec); $[\alpha]_D^{20}$ −14.0° (*c* 1, DMF); R_f^1 0.98, R_f^2 0.98.

Found: C, 63.45; H, 8.19; N, 9.71%. Calcd for $C_{46}H_{70}N_6O_{10}$: C, 63.72; H, 8.14; N, 9.69%.

Boc-D-Phe-Leu-Val-Orn(Z)-Leu-N$_2$H$_3$ (**4**). A solution of **3** (0.867 g, 1 mmol) and hydrazine hydrate (1.94 ml, 40 mmol) in DMF (20 ml) was left to stand for 8 days at a room temp and hydrazide precipitated in the reaction mixture was filtered, washed with water and with a small amount of EtOH, and then dried (P_2O_5); yield ,0.72 g (82%); mp 237—238 °C (dec); $[\alpha]_D^{20}$ −11.8° (*c* 1, DMF); R_f^1 0.98, R_f^2 0.94, R_f^5 0.98.

Found: C, 60.55; H, 9.86; N, 12.50%. Calcd for $C_{44}H_{68}N_8O_9$: C, 60.52; H, 10.16; N, 12.83%.

H-D-Phe-Leu-Val-Orn(Z)-Leu-OEt·HCl (**5**). Compound **4** (434 mg, 0.5 mmol) was dissolved in 0.075 M HCl in formic acid (8.0 ml) and allowed to stand for 2 h at a room temp. After the reaction mixture was evaporated to dryness *in vacuo*, the product was solidified by the addition of ether; yield, 387 mg (96%); mp 231 °C (dec); $[\alpha]_D^{20}$ +4.0° (*c* 1, DMF); R_f^1 0.66, R_f^2 0.10, R_f^5 (PPC) 0.95.

Found: C, 60.48; H, 7.95; N, 10.23%. Calcd for $C_{41}H_{63}N_6O_8Cl\cdot 1/2H_2O$: C, 60.61; H, 7.94; N, 10.34%.

Boc-(D-Phe-Leu-Val-Orn(Z)-Leu)$_2$-OEt (**6**). To a solution of **4** (175 mg, 0.2 mmol) in a mixed solvent of DMF (25 ml) and DMSO (25 ml) were added 3.97 M HCl in dioxane and then isoamyl nitrite (0.031 ml, 0.22 mmol) at −30 °C. After 30 min of stirring at −10 °C, hydrazide test[15] of the reaction mixture turned negative. And the mixture was neutralized by the addition of TEA (0.084 ml, 0.6 mmol). After 5 min at 0 °C, a solution of **5** (176 mg, 0.22 mmol) was added to the mixture. After stirring for 3 days at 4 °C, 0.5 M citric acid (100 ml) was added to the reaction mixture concentrated *in vacuo* to *ca.* 30 ml, and the mixture was kept at 4 °C for 3 h. The colloidal product, which was hard to filter, was collected by centrifugation at 4000×*g* for 10 min and washed with water several times. The resulting residue was dried over P_2O_5.

Boc-Val-Orn(Z)-Leu-N$_2$H$_3$ (**7**). To a solution of Boc-Val-Orn(Z)-Leu-OEt[11] (1.03 g, 1.7 mmol) in DMF (3 ml), hydrazine hydrate (1.65 ml, 34 mmol) was added and allowed to stand overnight at a room temp. After the excess hydrazine had been evaporated *in vacuo*, water (50 ml) was added to the mixture.Precipitates formed were filtered, washed with water, and dried (P_2O_5); yield ,988 mg (98%); mp 209—210 °C; $[\alpha]_D^{20}$ −19.2° (*c* 0.5, AcOH); R_f^1 0.70, R_f^5 0.95.

Found: C, 59.05; H, 8.22; N, 14.21%. Calcd for $C_{29}H_{48}O_7N_6$: C, 58.76; H, 8.16; N, 14.18%.

H-D-Phe-Leu-OEt·HCl (**8**). The compound **1** (813 mg, 2 mmol) was dissolved in 0.113 M HCl in formic acid (21.2 ml) and allowed to stand at a room temp. After 30 min, the solution was evaporated *in vacuo*. The addition of ether and subsequent evaporation were repeated several times and the oily product was obtained; yield of the oil, 686 mg (100%); R_f^1 0.73.

Boc-Val-Orn(Z)-Leu-D-Phe-Leu-OEt (**9**). The compound was obtained from **7** (890 mg, 1.5 mmol) and **8** (686 mg, 2 mmol) by the azide procedure[10] as described for the preparation of **6**. The product was crystallized twice from AcOEt–ether–petroleum ether; yield, 701 mg (54%); mp 211—213 °C; $[\alpha]_D^{20}$ −12.9° (*c* 1, DMF); R_f^3 0.73.

Found: C, 63.47; H, 8.10; N, 9.63%. Calcd for $C_{46}H_{70}O_{10}N_6$: C, 63.72; H, 8.14; N, 9.69%.

Boc-Val-Orn(Z)-Leu-D-Phe-Leu-N$_2$H$_3$ (**10**). The compound **9** (607 mg, 0.7 mmol) was dissolved in DMF (10 ml) and hydrazine hydrate (1.36 ml, 28 mmol) was added. After standing for two days at a room temp, the solvent was evaporated *in vacuo* to a small volume and water was added to the residue. After brief standing at 4 °C, the precipitates were filtered and dried over P_2O_5; yield, 622 mg (96%); mp 207—209 °C; $[\alpha]_D^{20}$ −11.3° (*c* 0.5, DMF); R_f^1 0.67.

Found: C, 61.61; H, 8.21; N, 13.00%. Calcd for $C_{44}H_{68}O_9N_8$: C, 61.95; H, 8.04; N, 13.14%.

H-Val-Orn(Z)-Leu-D-Phe-Leu-OEt·HCl (**11**). Deblocking of Boc-group from **9** (780 mg, 0.9 mmol) was performed by the similar method described in the preparation of **5** by the action of 0.13 M HCl in formic acid (7.6 ml); yield, 694 mg (96%); mp 211—213 °C; $[\alpha]_D^{20}$ +3.8° (*c* 1, DMF) R_f^3 0.17.

Found: C, 61.17; H, 7.92; N, 10.36%. Calcd for $C_{41}H_{63}O_8N_6Cl$: C, 61.29; H, 7.90; N, 10.46%.

Boc-(Val-Orn(Z)-Leu-D-Phe-Leu)$_2$-OEt (**12**). This compound was prepared from **10** (512 mg, 0.6 mmol) and **11** (627 mg, 0.78 mmol) by the similar method described for the preparation of **3**, except that a mixed solvent, DMF–DMSO (5 : 1, v/v), was used in this case. Crude product was recrystallized from MeOH; yield, 839 mg (88%); mp 239—241 °C; $[\alpha]_D^{20}$ −13.4° (*c* 0.5, DMF); R_f^1 0.93.

Found: C, 63.57; H, 7.97; N, 10.58%. Calcd for $C_{85}H_{126}O_{17}N_{12}\cdot H_2O$: C, 63.57; H, 8.08; N, 10.53%.

Boc-(Val-Orn(Z)-Leu-D-Phe-Leu)$_2$-N$_2$H$_3$ (**13**). To the compound **12** (250 mg, 0.157 mmol) dissolved in DMF (10 ml), was added 200 molar equivalents of hydrazine hydrate (1.52 ml, 31.4 mmol) and allowed to stand at a room temp for 2 days and treated as described for the preparation of **2**; yield, 226 mg (96%); mp >250 °C; $[\alpha]_D^{20}$ −14.6° (*c* 0.5, DMF–DMSO (2 : 1, v/v)); R_f^2 0.01, R_f^3 0.41.

Found: C, 63.20; H, 8.01; N, 12.20%. Calcd for $C_{83}H_{124}O_{16}N_{14}$: C, 63.33; H, 7.94; N, 12.46%.

H-(Val-Orn(Z)-Leu-D-Phe-Leu)$_2$-N$_2$H$_3$·2HCl (**14**). The compound **13** (200 mg, 0.127 mmol) was treated with 0.12 M HCl in formic acid (2.5 ml) at a room temp. After an hour, the reaction mixture was evaporated *in vacuo*, AcOEt added to the residue and evaporation repeated. To the residue was added ether and the mixture was kept at 4 °C; yield, 199 mg (100%); mp >250 °C; $[\alpha]_D^{20}$ −32.2° (*c* 0.2, DMF–DMSO (2 : 1, v/v)); R_f^1 0.41.

Found: C, 60.11; H, 7.74; N, 12.53%. Calcd for $C_{78}H_{116}O_{14}N_{14}\cdot 2HCl\cdot H_2O$: C, 59.86; H, 7.73; N, 12.53%.

cyclo(*-(Val-Orn(Z)-Leu-D-Phe-Leu)$_2$-*) (**15**). To the solution of **14** (193 mg, 0.13 mmol) in DMF–DMSO (2 : 1, v/v, 6 ml) was added at −30 °C, 2.7 M HCl in AcOEt (0.096 ml) and then 10% isoamyl nitrite in DMF (0.182 ml,

0.13 mmol). The reaction mixture was stirred at −20 °C until hydrazide test[15] became negative. After 15 min of stirring, the resulting pale yellow solution was added at 0 °C to pyridine (65 ml) and the mixture was kept stirring at 0 °C. After 3 days, pyridine and DMF were evaporated *in vacuo* from the mixture and 5 M citric acid (80 ml) was added. White precipitates formed were filtered, washed with water and dried (P_2O_5). The crude product (199 mg) was dissolved in a mixture of MeOH (100 ml) and H_2O (10 ml), and passed through a column (1.5×7.0 cm) of Dowex 50x8 and the elution was performed with the same solvent. The combined eluates were evaporated *in vacuo*. The white residue was filtered with the aid of small amount of water and dried over P_2O_5. The product (125 mg) was recrystallized from MeOH–H_2O; yield, 109 mg (58%); mp >250 °C; $[\alpha]_D^{20}$ −122° (*c* 0.2, DMF); R_f^3 0.53.

Found: C, 64.01; H, 7.82; N, 11.17%; mol wt,[16] 1441. Calcd for $C_{78}H_{112}O_{14}N_{12}\cdot H_2O$: C, 64.17; H, 7.87; N, 11.51 %; mol wt, 1460.

cyclo*(−(Val–Orn–Leu–*D*-Phe–Leu)$_2$−)·2HCl* (**16**).

The compound **15** was dissolved in 0.07 M HCl in EtOH (1.2 ml) and hydrogenolysis was performed in the presence of palladium black. After 2 h, additional 0.07 M HCl was added to the reaction mixture and the hydrogenolysis was continued overnight at 4 °C. After the catalyst had been filtered and washed several times with EtOH, the filtrate was evaporated to dryness and the residual solid was collected with the aid of ether. The crude product was recrystallized from EtOH–ether; yield, 29 mg (67%); mp 251—255 °C; $[\alpha]_D^{20}$ −156° (*c* 0.2, DMF); R_f^3 0.01, R_f^4 0.91, R_f^4 (PPC) 0.92. Amino acid ratios in acid hydrolyzate; Val 2.16, Orn 2.00, Leu 4.00, Phe 2.30.

Found: C, 56.52; H, 8.24; N, 12.33%. Calcd for $C_{62}H_{100}O_{10}N_{12}\cdot 2HCl\cdot 4H_2O$: C, 56.47; H, 8.40; N, 12.75%.

Electrophoresis Electrophoresis on Toyo Roshi No. 52 paper was carried out with a solvent system, formic acid–AcOH–MeOH–H_2O (1 : 3 : 6 : 10, v/v, pH 1.8) at 500 V/30 cm for 3 h. As shown in Fig. 3, [5,5′-Leu]-GS migrated more slowly toward cathode than the control GS, *i.e.* the former migrated 7.4 cm and the latter 8 cm by length.

ORD Measurements These were performed with a JASCO spectropolarimeter Model ORD/UV-5 over a range 215—300 nm. A cell of the path length 0.1 cm was used and the runs were at ambient temperature. Patterns in EtOH and 8 M urea are shown in Fig. 2.

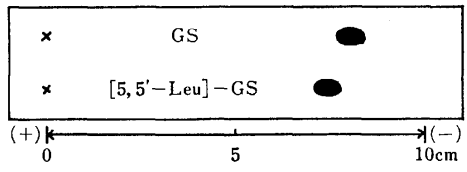

Fig. 3. Paper electrophoresis of [5,5′-Leu]-GS (**16**) and natural GS.

Microbiological Assays. The results of the assay and the microorganisms employed are listed in Table 1. The minimum amount of the compound necessary for the complete inhibition of growth was determined by a dilution method using a bouillon agar medium and a synthetic medium. As shown in Tables 1 and 2, [5,5′-Leu]-GS (**16**) was found to exhibit a considerable antibacterial activity against *Bacillus subtilis* and *Staphylococcus aureus*.

The authors are indebted to Dr. K. Kuromizu for his useful suggestions and discussions, Mr. Y. Shimohigashi for ORD measurements ,and the staffs of Takeda Chemical Industries, Ltd., for the biological assays.

The Photobromination of β-Styrenesulfonamides and Syntheses of 2-Arylacetylene-1-sulfonamides

Kiyoshi HASEGAWA, Syuzi HIROOKA, Hiroshi KAWAHARA, Atsushi TANAKA, Masahiro NOMURA, and Yutaka HORI

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka 933

(Received November 4, 1976)

The photobromination of *trans*-β-styrenesulfonamides in acetic acid at 16—18 °C gave about 75 : 25 mixtures of *threo* (*cis* adducts)- and *erythro*-1,2-dibromo-2-arylethane-1-sulfonamides (*trans* adducts). A similar photobromination of *cis*-β-styrenesulfonamide afforded a 33 : 67 mixture of the *threo* (*trans* adduct)- and the *erythro*-dibromides (*cis* adduct). The diastereomers could be separated by fractional recrystallization. The *cis* adducts were shown to be formed neither by secondary isomerization nor by (presumably) ionic addition. The *trans* dehydrobromination of the *threo*- and the *erythro*-dibromides with Et_3N gave (*Z*)- and (*E*)-β-bromo-β-styrenesulfonamides respectively, which underwent further facile dehydrobromination with aqueous 1 M NaOH at 45—50 °C to afford 2-arylacetylene-1-sulfonamides. They were also prepared from (*Z*)-α-chloro-β-styrenesulfonamide by an analogous procedure.

Triple bonds are more subject to nucleophilic attack than are double bonds.[1] It was, therefore, of interest to synthesize new 2-arylacetylene-1-sulfonic acids and -sulfonyl chlorides and to investigate their reactions with nucleophiles.

Rondestvedt, Jr. previously reported that the sulfonation of phenylacetylene or its acetylide was unsuccessful and the dehydrobromination of β-bromo-β-styrenesulfonic acid and -sulfonyl chloride gave only decomposed products involving no sulfonyl group.[2] He assumed that the *cis* configuration with respect to H and Br atoms makes the dehydrobromination difficult. Since then, acetylenesulfonic acid derivatives have not been studied.

Since an alkali-soluble sulfonamide group would promote dehydrobromination by alkali, we attempted to synthesize 2-arylacetylene-1-sulfonamides (**5**) from β-bromo- (**3**) and α-chloro-β-styrenesulfonamides (**4**). This paper will describe the stereochmistry of 1,2-dibromo-2-arylethane-1-sulfonamides (**2**), **3**, and **4**, and the synthesis of **5** from them.

Results and Discussion

Photobromination of trans- *and* cis-*β-Styrenesulfonamides.* It is known that bromine adds to *trans*-β-styrenesulfonyl chloride in CCl_4[2-4] or to *trans*-β-styrenesulfonamide (*trans*-**1a**, R=H) in acetic acid[2,3] by (presumably) a free-radical mechanism which is catalyzed by light and inhibited by oxygen. However, the stereochemistry of these adducts has not been estabilshed.

According to the procedure of Bordwell *et al.*,[3] *trans*-**1** was photobrominated by sunlight irradiation at 16—18 °C for 30 min. All of the crude products was shown by NMR spectroscopic and high-speed liquid chromatographic analyses to be mixtures of the *threo*- and *erythro*-**2**, predominantly the *threo*. On the contrary, *cis*-β-styrenesulfonamide (*cis*-**1a**) gave a mixture of the diastereomers in which the *erythro* predominated. Table 1 shows the distribution of the diastereomers and their NMR spectroscopic data. The stereochemical relationships are presented in Scheme 1. As the *erythro*-dibromides (R= H, CH_3, and NO_2) are more soluble in benzene than the *threo*, the two isomers could be separated by fractional recrystallization (Table 2). However, the *p*-halogeno-substituted dibromides could not be separated into their diastereomers. The *threo* and *erythro* configurations were assigned to **2** on the basis of the coupling constants (J_{AB}) and the configuration of **3** produced from **2** by *trans* elimination. It is known that the magnitude of the vicinal coupling constant (J_{AB}) depends upon the dihedral angle involved.[5] The diastereomers which have the larger coupling constants were assigned to the *erythro*-**2**, since it seems evident, from a consideration of the steric repulsion by large bromine atoms, that the

a) Lit,[3] mp 161—162 °C. b) They are mixtures of *threo-* and *erythro*-**2**. *threo*(%) : *erythro*(%); (**2c**) = 75 : 25 and (**2d**) = 73 : 27.

conformers shown in Scheme 1 will contribute more heavily to the rotational isomers of the *erythro-* and *threo*-**2**. Figure 1 shows the NMR spectra of *threo-* and *erythro*-**2a** in their methine-field regions. As the AB patterns of both diastereomers could be clearly distinguished, the evaluation of the signal intensities gave an

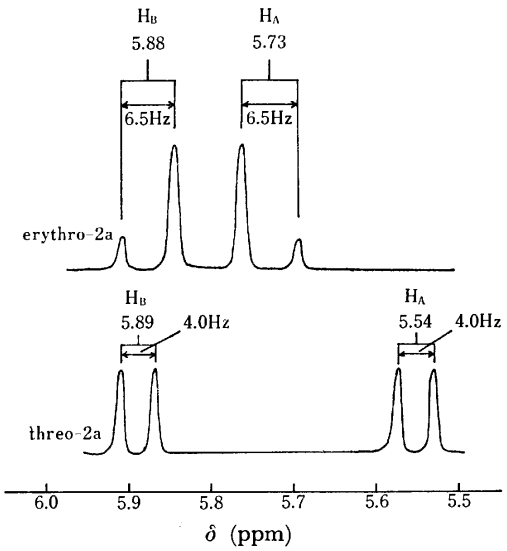

Fig. 1. NMR spectra of *threo-* and *erythro*-**2a** in methine region (DMSO-d_6).

estimate of the amounts of each isomer present. Our conclusion, to be drawn from the subsequent discussion of the configuration of **3**, also supports the stereochemical assignment based upon the coupling constants. The IR spectra of *threo*-**2b**—**e** showed a pair of NH_2 bands at a lower frequency region than the NH_2 bands of the *erythro* isomers.

As Bordwell and Rondestvedt, Jr., reported previously,[3] the addition was accelerated by light irradiation. Upon sunlight irradiation at 16—18 °C, the addition was completed within 5 min, but in the dark **2** was prepared in yields of less than 8%. The influence of the reaction time and the temperature on the stereochemistry of the addition was studied in order to find out whether the *cis* adducts were formed in the addition step or whether they arose from the subsequent isomerization of the initially formed *trans* adducts. Under the conditions used, the absence of isomerization between *trans-* and *cis*-**1** prior to the addition was proved by a blank test. The results summarized in Table 3 show that the isomerization of the products is negligible even at high temperatures and that the addition becomes non-stereospecific as the temperature increases. The *cis* addition under sunlight irradiation is a striking feature; however, its explanation must await the results of mechanical studies.

Syntheses of **5** *by Dehydrobromination.* The stereospecific *trans* dehydrobromination of *threo-* and *erythro*-**2**

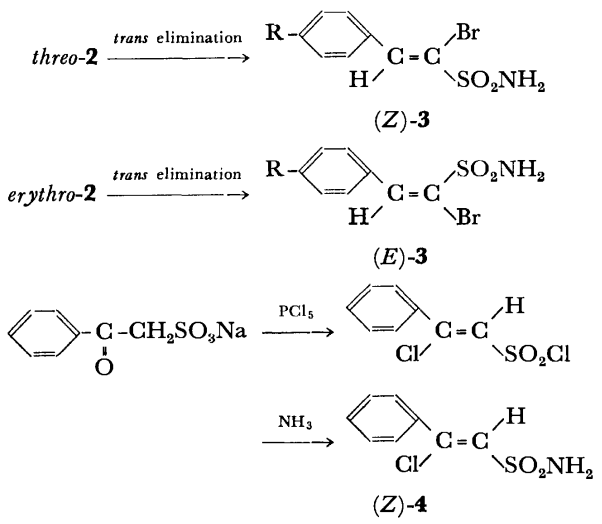
a) The experiments were carried out under the conditions described in Table 1. b) *trans*-**1a**. c) *cis*-**1a**.



with Et_3N gave *Z* and *E* isomers of **3** respectively. On the other hand, the *Z* isomer of **4** was prepared by the route described below. The results are summarized in Table 4. The *Z* and *E* configurations were assigned to **3** and **4** on the basis of the NMR data and the relative rate measurement of the dehydrobromination from them. The vinyl protons of **3** and **4** resonate about 0.30 ppm upfield from the chemical shifts calculated by the application of the NMR rules[6] of additivity. Since no substituent shielding constants for the SO_2NH_2 group have been reported, the value for the SO_2R group was used. The error must be caused by the shield effect of the NH_2 group. The dehydrobromination experiments of both isomers of **3** in five equiv of aqueous 1 M NaOH at 40 °C for 30 min revealed that not only (*Z*)-**3** is capable of undergoing a facile *β-trans* elimination to

(*Z*)-**3** : δ_{CH}(ppm)=5.25+1.38+1.16+0.55=8.34

(*E*)-**3** : δ_{CH}(ppm)=5.25+1.38+0.45+0.93=8.01

(*Z*)-**4** : δ_{CH}(ppm)=5.25+1.55+0.36+0.13=7.29

give **5**, but, surprisingly, (*E*)-**3** also. The only difference is that the *cis* elimination is slower than the *trans* process. The **5a** sulfonamide was also prepared by the dehydrochlorination of (*Z*)-**4** under the same conditions as held with **3**. The extent of the elimination was measured by the increase in **5** at the expense of **3** and **4** in high-speed liquid chromatography. The configuration and *p*-substituent effects on the elimination are as follows: (*Z*)-**3**; R(reaction %)=NO_2(100) > Cl(23) > Br(22) > H(16) > CH_3(5), (*E*)-**3a**; H(8), and (*Z*)-**4**; H(14). This order is in accord with the idea that electron-attracting groups facilitate elimination reactions.[7] The reason for the greater ease of

a) Yield after recrystallization from benzene.

the *cis* elimination from (*E*)-**3a** is the previous isomerization to (*Z*)-**3a** and/or the enhanced leaving ability of HBr from such a system when activated by an electron-attracting sulfonyl group.[8] As *cis*-**1a** is known to readily isomerize to *trans*-**1a** upon treatment with aqueous 1 M NaOH,[9] we attempted to detect (*Z*)-**3a** in the reaction mixture of (*E*)-**3a** by high-speed liquid chromatography, but it could not be found. However, this fact does not exclude the idea of the previous isomerization of (*E*)-**3a** if the *trans* elimination proceeds more rapidly than the isomerization.

We concluded that the **3a** sulfonamide (mp 132—133 °C[2] and 130—131 °C[3]), which was previously prepared by the dehydrobromination of the **2a** dibromide (mp 161—162 °C[3]) and by the amidation of β-bromo-β-styrenesulfonyl chloride,[2] has the *Z* configuration, judging from the physical properties and the spectral data.

The **5** sulfonamides were readily synthesized by treating **3** (Path A), (*Z*)-**4** (Path B), or **2** (Path C) with 4—5 equiv of aqueous 1 M NaOH for 5 h at 45—50 °C (Table 5). Both sulfonamides, **2** and **3**, were used without separation into their stereoisomers. The structures of **5** were determined on the basis of the analytical and spectral data. The IR spectrum of **5** displayed a strong absorption band at 2180—2190 cm^{-1} due to the C≡C bond. The **5** sulfonamides are stable enough to be stored for a year.

Experimental

The melting points and the IR, UV, NMR, and mass spectra were measured by the same apparatus as has been reported previously.[9] The high-speed liquid chromatographic analysis was carried out using a JASCO-FLC 150 apparatus on a 0.5 m×2.1 mm column packed with JASCO-DAC SV-O2 (Solvent: methanol (20—40%)-water). The melting points are uncorrected.

cis-*β-Styrenesulfonamide* (cis-*1a*). It was prepared in 100% purity by the method previously described by us.[9] Mp 122—122.5 °C (lit,[10] 96—98 °C).

threo- *and* erythro-*1,2-Dibromo-2-arylethane-1-sulfonamides* (threo *and* erythro-*2*). *General Procedure*: To a solution of *trans*-**1** (0.0010 mol) in purified acetic acid (15 ml) we added an equimolar amount of bromine at 16—18 °C, after which the solution was kept in sunlight at 16—18 °C. Acetic acid in aliquots irradiated for, 5, 30, and 60 min was evaporated *in vacuo* below 30 °C to leave a residue, which was solidified by the addition of ice water. Fractional recrystallization succeeded in separating the *threo* and *erythro* isomers except for the *p*-halogeno-substituted ones. The spectral data for *threo*- and *erythro*-**2a**: *threo*-**2a**: IR(KBr); 3400 and 3300 (NH_2), 1360, 1320, 1160, and 1130 (SO_2), 725 and 700 cm^{-1}. NMR (DMSO-d_6) δ: 5.54 (d, 1, H_A), 5.89 (d, 1, H_B), J_{AB}=4.0 Hz, 7.30—7.50 (m, 5, C_6H_5), and 7.50—7.60 (m, 2, NH_2). MS *m/e*: 343 (M^+). *erythro*-**2a**: IR(KBr); 3400 and 3300 (NH_2), 1350, 1160, and 1145 (SO_2) and 710 cm^{-1}. NMR (DMSO-d_6) δ: 5.73 (d, 1, H_A), 5.88 (d, 1, H_B), J_{AB}=6.5 Hz, 7.30—7.50 (m, 5, C_6H_5), and 7.50—7.60 (m, 2, NH_2). MS *m/e*: 343 (M^+).

(Z,E)-*β-Bromo-β-styrenesulfonamides* ((Z)-*3*, (E)-*3*). *General Procedure*: To a solution of *threo*-**2** (0.00050 mol) in benzene (100 ml) we added Et_3N (0.0020 mol), after which the solution was stirred for 1 h at room temperature. Triethylammonium bromide, which was immediately precipitated, was filtered out, and the filtrate was evaporated to dryness *in vacuo* to leave (*Z*)-**3**. The yields were more than 80%.

Isomers, (*E*)-**3**, were prepared from *erythro*-**2** by using the technique described in the synthesis of (*Z*)-**3**. The spectral data for (*Z*)- and (*E*)-**3a**: (*Z*)-**3a**: IR(KBr); 3350 and 3240 (NH_2), 1330 and 1160 (SO_2) cm^{-1}. NMR(DMSO-d_6) δ; 7.40—7.68 (m, 5, C_6H_5), 7.76—7.86 (m, 2, NH_2), and 8.01 (s, 1, CH). MS *m/e*; 262 (M^+). (*E*)-**3a**: IR(KBr); 3350 and 3240 (NH_2), 1330, 1170, 1160, and 1150 (SO_2) cm^{-1}. NMR(DMSO-d_6) δ; 7.28—7.48 (m, 5, C_6H_5), 7.60 (s, 1, CH), and 7.68 (s, 2, NH_2). MS *m/e*; 262 (M^+).

The dehydrobromination of **2c** (*threo* 75%) and **2d** (*threo* 73%) gave **3c** (*Z* 75%) and **3d** (*Z* 73%) respectively. The (*Z*)- and (*E*)-**3c**, and (*Z*)-**3d** could be separated by crystal forms, but (*E*)-**3d** could not be freed of (*Z*)-**3d**.

(Z)-*α-Chloro-β-styrenesulfonamide* ((Z)-*4*). Sodium benzoylmethanesulfonate (5.0 g, 0.023 mol) was refluxed with PCl_5 (18.7 g, 0.090 mol) for 10 h. The product was worked up in a way analogous to that reported in the synthesis of β-styrenesulfonyl chloride[11] and distilled under reduced pressure to give α-chloro-β-styrenesulfonyl chloride; bp 60—110 °C/3 mmHg (58% yield). Without further purification, it was converted to (*Z*)-**4** by treatment with a 28% ammonia solution. The *E* isomer could not be detected.

2-Arylacetylene-1-sulfonamides (*5*). *Paths A and C*: *General Procedure*: A solution of **3** (Path A) or **2** (Path C) in aqueous 1 M NaOH (50 ml, 0.050 mol) was stirred for 5 h at 45—50 °C and then acidified with concd HCl under cooling to give **5**. Recrystallization from benzene afforded thin plates.

Path B: Sulfonamide **5a** was prepared from (*Z*)-**4** and 1 M NaOH by using the procedure described for Paths A and C.

The spectral data for **5a**: IR(KBr); 3320 and 3210 (NH_2), 2180 (C≡C), 1330, 1180, and 1150 (SO_2) cm^{-1}. NMR (DMSO-d_6) δ; 7.55—7.60 (m, 5, C_6H_5) and 8.24 (s, 2, NH_2). MS *m/e*; 181 (M^+).

Diphosphine–Rhodium Complex-Catalyzed Hydroformylation of α,β-Unsaturated Esters

Masato TANAKA, Teruyuki HAYASHI, and Ikuei OGATA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received December 14, 1976)

The product distribution in the hydroformylation of α,β-unsaturated esters (ethyl acrylate, methyl methacrylate, methyl crotonate, and methyl tiglate) catalyzed by $Rh_2Cl_2(CO)_4$ was studied at 150 °C under 100 atm of synthesis gas ($CO/H_2=1/1$) in the absence or presence of various additional phosphorus ligands. In order to attain a high selectivity of α-formylation (>80%), the addition of shorter methylene-chained diphosphines ($R_2P(CH_2)_nPR_2$, R=phenyl or cyclohexyl, $n=2$—4) to the reaction system was essential, while the use of $Rh_2Cl_2(CO)_4$ alone or in combination with triphenylphosphine or a longer diphosphine, $Ph_2P(CH_2)_5PPh_2$, resulted in a very low α-selectivity. The effects of the reaction variables on the product distribution were also examined for acrylate and methacrylate using $Ph_2P(CH_2)_4PPh_2$ and $Ph_2P(CH_2)_2PPh_2$, respectively, as additional ligands.

Among many types of polar olefins, α,β-unsaturated esters have received much attention as substrates for hydroformylation. The selective β-formylation of the ethylenic linkage of acrylates, followed by cyclization to afford γ-butyrolactone, has been accomplished by the use of a cobalt carbonyl catalyst.[1] On the other hand, it has been noted in a patent claim that a rhodium catalyst favors α-formylation, though the selectivity attained is not very high.[2] The composition of the products from ethyl acrylate under a wide range of the reaction conditions has also been examined in detail by the use of cobalt[3] as well as rhodium catalyst.[4] In the hydroformylation of methyl methacrylate by a rhodium catalyst, the addition of a large amount of a phosphorus ligand to the reaction system or a much elevated pressure of synthesis gas as high as 1000 atm is required for selective α-formylation.[5,6] Methyl crotonate undergoes formylation mainly on the β-carbon, and a relatively large amount of the hydrogenation by-product is also formed.[5]

In this report, the authors will describe the hydroformylation of various α,β-unsaturated esters by the use of the diphosphine–rhodium catalyst system, and it will be shown that this catalyst system is extremely efficient for selective α-formylation.

Experimental

Materials. Benzene and ethylbenzene were distilled under nitrogen. All of the substrates were commercial products, and were freshly distilled under nitrogen of a reduced pressure before use. Triphenylphosphine and 1,2-bis(diphenylphosphino)ethane were used as purchased. Tetracarbonyldi-μ-chlorodirhodium,[7] 1,3-bis(diphenylphosphino)propane,[8] 1,4-bis(diphenylphosphino)butane,[9] 1,5-bis(diphenylphosphino)pentane,[9] 1,2-bis(dicyclohexylphosphino)ethane,[10] 1,4-bis(dicyclohexylphosphino)butane,[11] and 1,2-bis(5*H*-dibenzophospholyl)ethane[12] were prepared by the previously reported methods.

Reaction Procedure. A 37-ml Schlenk-tube-type high-pressure reaction vessel, made of stainless steel (SUS 316), was charged under a nitrogen atmosphere with 3 ml of a solvent (ethylbenzene for ethyl acrylate and benzene for the other substrates), 1.3 mg of tetracarbonyldi-μ-chlorodirhodium (6.7×10^{-6} mol with respect to the rhodium atom), a desired amount of a phosphine, and 1.5 ml of a substrate. The reaction vessel was then sealed and flushed with carbon monoxide. Then, carbon monoxide and hydrogen were introduced up to their given partial pressures. The temperature was elevated in an oil bath. The reaction solution was then agitated magnetically.

Analysis of the Products. An aliquot of the reaction mixture was analyzed by gas chromatography. A Shimadzu model GC-3B gas chromatograph, equipped with a stainless steel column packed with diethylene glycol succinate polyester on Neopak AS (3 mm i.d.×2.5 m) was used at an oven temperature of 120 °C for most cases. The remainder of the reaction mixture was submitted to distillation, and the products were identified spectroscopically. The IR and NMR spectra were recorded on a Shimadzu IR 27G apparatus, and a JEOL C-60HL apparatus, respectively.

Results

The reaction was carried out at 150 °C under 100 atm of synthesis gas ($CO/H_2=1/1$), with $Rh_2Cl_2(CO)_4$ as a catalyst precursor, in the absence or presence of a variety of phosphines. The phosphorus-to-rhodium ratio of 4 : 1 was used in every case. The boiling points and spectral data of the products are summarized in Table 1. The NMR spectra of some α-formylated isomers show that these isomers are present in equilibrium with the corresponding enol forms. The approximate ratio of enol to aldehyde under the conditions of the NMR measurement (carbon tetrachloride solution, 31.5 °C) is also shown in the table.

Hydroformylation of Ethyl Acrylate. The results are summarized in Table 2. The catalytic activity of the rhodium complex was, in the absence of a phosphine, very low, and ethyl β-formylpropionate was mainly formed. The addition of triphenylphosphine to the reaction system much improved the α-selectivity, though the reaction was still sluggish. In contrast, when carried out in the presence of α,ω-bis(diphenylphosphino)-alkanes, $Ph_2P(CH_2)_nPPh_2$ ($n=2$—4), the reaction proceeded extremely fast, and the α-carbon was formylated almost exclusively. It was also found that the extent of the competitive hydrogenation was enhanced by the use of these diphosphines. As the carbon chain between the two phosphorus atoms of the diphosphine got longer from C_2 to C_4, the amount of the hydrogenation by-product much decreased and the α-selectivity became slightly higher. However, when the still longer diphosphine, $Ph_2P(CH_2)_5PPh_2$, was used, a very low α-selectivity was caused, and the competitive hydrogenation intensively occurred again. In addition, a much

a) Reaction conditions: 150 °C, 100 atm (CO/H_2=1/1), phosphorus/rhodium=4/1. b) α, β and dihydro stand for ethyl α-formylpropionate, ethyl β-formylpropionate, and ethyl propionate, respectively. c) α-Selectivity denotes $100\times\alpha/(\alpha+\beta)$. d) DBP stands for the 5*H*-dibenzophospholyl group.

longer reaction time was required for complete conversion in the case of this diphosphine.

The electronic effects on the product distribution were examined by the use of dicyclohexylphosphino analogues of 1,2-bis(diphenylphosphino)ethane and 1,4-bis(diphenylphosphino)butane. These effects are apparently not separable from steric effects, and no clear trends in either the reaction rate or the extent of the competitive hydrogenation could be found. The α-selectivity remained practically unchanged upon the exchange of the phenyl groups for the cyclohexyl ones.

The effect of the structure of the diphosphine was further studied using 1,2-bis(5H-dibenzophospholyl)-ethane, some rhodium complexes of which efficiently catalyzed the hydroformylation of olefinic hydrocarbons.[13] However, for ethyl acrylate, this diphosphine was much inferior in its catalytic activity as well as in its α-selectivity to 1,2-bis(diphenylphosphino)ethane.

Hydroformylation of Methyl Methacrylate. The results of the hydroformylation of methyl methacrylate are collected in Table 3. Unlike ethyl acrylate, methyl methacrylate was rapidly hydroformylated in the absence of phosphines. The β-isomer was mainly formed, accompanied by a considerable amount of the hydrogenation by-product. The addition of tertiary phosphines to the reaction system much retarded the reaction and increased the content of the α-isomer. In addition, it suppressed the competitive hydrogenation except the reaction with 1,3-bis(diphenylphosphino)-propane. The highest α-selectivity accomplished by the use of 1,2-bis(diphenylphosphino)ethane, 81.4%, was lower than that observed in the reaction of ethyl acrylate, probably because of the steric hindrance of the α-methyl substituent. 1,2-Bis(dicyclohexylphosphino)ethane and 1,4-bis(dicyclohexylphosphino)butane, which caused high α-selectivities similar to the diphenylphosphino counterpart in the reaction of ethyl acrylate, gave inferior results for methyl methacrylate. Probably, this is also attributable to the steric hindrance due to the presence of the α-methyl substituent on the double bond as well as to the large ligand cone angle[14] of the bis(dicyclohexylphosphino)alkanes.

Hydroformylation of Methyl Crotonate. The results are shown in Table 4. In comparison with the reactions of ethyl acrylate and methyl methacrylate, the hydroformylation of methyl crotonate gave very diverse results for the product distribution depending on the nature of the added ligands. Competitive hydrogenation was often the main reaction. Nevertheless, some of the diphosphines, such as $Ph_2P(CH_2)_{2(or\ 4)}PPh_2$ and $Cy_2P(CH_2)_2PCy_2$, showed high α-selectivities, suppressing the formation of the β- and γ-isomers which were the main products when the reaction was carried out either in the absence of any additional ligands or in the presence of triphenylphosphine.

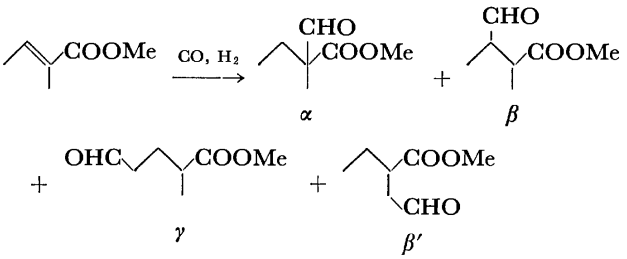
a) Reaction conditions: 150 °C, 100 atm ($CO/H_2=1/1$), phosphorus/rhodium=4/1. b) Total yield of the four aldehydes based on the amount of methyl tiglate charged (see the text). c) α-Selectivity denotes the percentage of methyl α-formyl-α-methylbutyrate in the total amount of the four aldehydes formed.

are shown in Table 5. Unlike the other substrates examined, a significant amount of unidentified high boiling by-product(s) was formed, especially in the absence of phosphine. As concerns the aldehyde formation, after comparing the gas chromatogram of the reaction mixture with that of methyl crotonate, the authors presume that all of the possible four isomeric aldehydes were produced. However, only the α-isomer could be isolated and identified. The other isomers could not be separated in a pure state because of the similarity of their boiling points. The α-selectivity, which was very low without added phosphines, was markedly enhanced by the use of the diphosphines.



Effects of the Reaction Variables. Tables 2 and 3 show that 1,4-bis(diphenylphosphino)butane and 1,2-bis(diphenylphosphino)ethane are the most beneficial α-formylating ligands for ethyl acrylate and methyl methacrylate respectively. Therefore, using those most beneficial combinations of the ligand and the substrate, the effects of the reaction variables, such as the phosphorus-to-rhodium ratio, the reaction temperature, and the partial pressures of carbon monoxide and hydrogen, on the product distribution were briefly examined in order to search for the optimum conditions for selective α-formylation and to shed more light on the role of the diphosphines during the course of the reaction. The results are illustrated in Figs. 1—5.

Figure 1 shows that, in the reaction of ethyl acrylate, the decrease in the amount of the diphosphine slightly lowered the α-selectivity. Competitive hydrogenation was almost completely inhibited at phosphorus-to-rhodium ratios smaller than 2. A similar but more profound influence on the α-selectivity was also observed for methyl methacrylate (Fig. 2), while the effect on the hydrogenation by-product formation was just the reverse of that with ethyl acrylate, and, at the ratio of 2, the extent of hydrogenation was markedly intensive.

Lowering the reaction temperature increased the α-

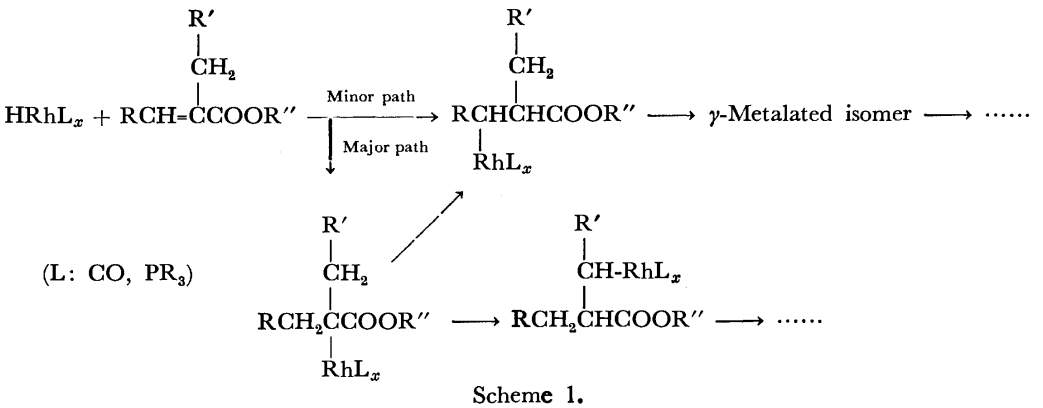
selectivity and decreased the extent of hydrogenation for ethyl acrylate as well as methyl methacrylate (Fig. 3); therefore, it provides a very favorable condition for selective α-formylation. For example, when ethyl acrylate was allowed to react with synthesis gas (100 atm, $CO/H_2=1/1$) at 100 or 75 °C by the use of 1,4-bis(diphenylphosphino)butane (phosphorus/rhodium=4/1), the reaction was completed within 12 or 65 min respectively, and ethyl α-formylpropionate was obtained in a 92.6 or 95.1% yield (98.5 or 99.3% α-selectivity) respectively.

For both the substrates, the α-selectivity and the amount of hydrogenation by-product increased and decreased respectively with an increase in the carbon monoxide pressure up to *ca.* 50 atm; thereafter it remained practically unchanged (Fig. 4).

As Fig. 5 shows, the effect of the hydrogen pressure on the α-selectivity was smaller than, but similar to, that of the carbon monoxide pressure for both ethyl acrylate and methyl methacrylate. On the other hand, concerning the hydrogenation by-product formation, acrylate and methacrylate behaved differently from each other on a variation in the hydrogen pressure. Thus, for acrylate, a higher pressure suppressed the competitive hydrogenation. The influence of the hydrogen pressure on methacrylate was the reverse.

Discussion

As has been described above, the rhodium–diphosphine system is a very beneficial catalyst for the selective α-formylation of α,β-unsaturated esters. As concerns the isomer distribution, Takegami and his co-workers[4] have examined the hydroformylation of ethyl acrylate catalyzed by rhodium carbonyl under various reaction conditions. On the basis of the results, they have suggested that the extent of the skeletal isomerization of the α-metalated intermediate, which is preferably formed initially, is an important factor in deciding the product distribution. With the present catalyst system, the effects of the reaction variables on the α-selectivity in the reaction of ethyl acrylate were qualitatively the same as the above authors had observed. In addition, γ- and/or β′-isomers were also produced in the reaction of crotonate and tiglate. These results seem to indicate that such an isomerization occurs also with the diphosphine–rhodium catalysts (Scheme 1). The α-selectivity for methyl methacrylate was more sensitive to the reaction conditions than for ethyl acrylate. This can also be reasonably explained from the point of view of the skeletal isomerization; *i.e.*, the possibility of the skeletal isomerization of the α-metalated intermediate from methacrylate is greater than that from acrylate, because the former has two carbons onto which the rhodium can migrate through isomerization, while the latter has only one such carbon. However, judging from the extremely high α-selectivity and its low sensitivity to the reaction conditions compared with those reported by Takegami *et al.*, it might be better to consider that the extent of the skeletal isomerization is not so great with the present catalyst system. The shorter carbon-chained (C_2–C_4) diphosphines may coordinate tightly to rhodium because of their chelating power, and may thus stabilize the α-metalated intermediate predominantly formed initially, retarding the possible skeletal isomerization prior to the CO insertion. This may be at least one of the reasons why the high α-selectivity is realized by the use of these shorter-chained diphosphines as additional ligands, though the possibility that the chelation of the diphosphines facilitates the CO insertion itself, considering the unexpected acceleration of the reaction of ethyl acrylate by the shorter-chained diphosphines, can not be ruled out. Such a retardation of skeletal isomerization due to the stabilization of the reaction intermediates caused by the addition of a phosphine to the reaction system is also observed in the palladium-catalyzed isomerization of straight-chained acyl halides to the corresponding branched-chained ones.[15]



Scheme 1.

On the other hand, the α-selectivity varied sensitively depending on the chain length of the diphosphine. Moreover, the effect of the chain length on the α-selectivity appeared in a different manner from substrate to substrate. These results indicate that the size and the conformation of the chelate ring have much to do with the α-selectivity and the reaction rate. Concerning the hydrogenation of olefinic compounds, Kagan and his co-workers[16] have reported that the catalytic activity of some diphosphine–rhodium complexes heavily depends on the combination of the diphosphine and the substrate.

In consideration of the effect of the size and the conformation of the chelate ring formed by α,ω-bis(diphenylphosphino)alkanes in the present reaction system, it may be reasonable to assume that any factors weakening the coordination of a diphosphine as a bidentate ligand are harmful to a high α-selectivity, because the addition of a diphosphine is essential for selective α-formylation. The chelate ring formed by the coordination of a diphosphine with a longer methylene chain linking the two diphenylphosphino groups should become progressively less stable as the rings become larger. Moreover, the so-called medium rings, such as the eight-membered ring formed by 1,5-bis(diphenylphosphino)pentane, suffer a further destabilization due to the transannular steric repulsion. Therefore, it is likely that the longer-chained diphosphine functions as a monodentate ligand with a free phosphorus end. The low α-selectivity observed with 1,5-bis(diphenylphosphino)pentane, which lies on a level with that with $Rh_2Cl_2(CO)_4$ alone or in the presence of triphenylphosphine, may be because of the above reasons.

The reaction with 1,3-bis(diphenylphosphino)propane also caused a relatively low α-selectivity, with the exception of the case of ethyl acrylate. This may be explained as follows: 1,3-bis(diphenylphosphino)propane forms a six-membered ring on chelating coordination, the ring being preferably of a chair form. As is well known in the cyclohexane chemistry, there arises a serious steric repulsion between 1,3-diaxial substituents of chair-formed cyclohexanes. Regarding the present six-membered ring containing a rhodium and two phosphorus atoms, a pair of phenyl groups bonded to the separate phosphorus atoms cannot help occupying the 1,3-diaxial position. This may weaken the coordination of the diphosphine and bring about the formation of some non-α-selective catalytic species in which the diphosphine does not effectively chelate the rhodium. The relatively lower α-selectivity for methyl methacrylate as well as for methyl crotonate with 1,3-bis(diphenylphosphino)propane than that with 1,2-bis(diphenylphosphino)ethane or 1,4-bis(diphenylphosphino)butane may be ascribable to the partial participation of these non-α-selective species. However, the above-mentioned tendency for this diphosphine to cause a lower α-selectivity did not appear explicitly in the case of ethyl acrylate. In consideration of this point, careful attention should be paid to the reaction rate: the reaction without any additional ligand or in the presence of triphenylphosphine proceeded very sluggishly. On the other hand, the reaction with the shorter diphosphines was extremely fast. Judging from this great difference in the reaction rate between these two cases, it may be reasonable to consider that the species in which 1,3-bis(diphenylphosphino)propane does not effectively chelate the rhodium can scarcely participate in the reaction to such a great extent as to influence the results, while the species with the chelating diphosphine effects a rapid and highly α-selective formylation. This may be the reason why a high α-selectivity was attained for ethyl acrylate even by the use of 1,3-bis(diphenylphosphino) propane.

As another factor playing an important role during the reaction, a steric interaction of the substrate with the catalyst should be taken into account. The introduction of a methyl group into the α-position of acrylate (methyl methacrylate) lowered the α-selectivity, probably because of the increased steric repulsion around the α-carbon to be preferentially metalated. However, unexpectedly, the introduction of a methyl group into the β-carbon (methyl crotonate) also lowered the α-selectivity. Moreover, 1,2-bis(5*H*-dibenzophospholyl)-ethane, in which the rotation of the phenyl groups around the phenyl-to-phosphorus-bond axis is inhibited by the connection of the two phenyl groups on each phosphorus atom to each other at the ortho position, caused a much poorer activity and a far lower α-selectivity in the hydroformylation of ethyl acrylate than the more flexible 1,2-bis(diphenylphosphino)ethane. These results suggest that a delicate steric interaction between the substituents of the catalyst ligands and those of the substrates should be taken into consideration. The steric requirement for the coordination of a substrate should be more severe as the steric bulk of both the substrate and the other ligands increases. This is

supported by the fact that the α-selectivity for methyl methacrylate and crotonate varied more sensitively with the structure of the catalyst than that for ethyl acrylate. However, the mode and the extent of this kind of steric interaction must be very dependent on the conformation of the ligand, and more precise knowledges about the real structure of the catalyst under the reaction conditions will be necessary in order to develop a more subtle argument.

Finally, concerning the electronic aspects, the authors did not find any direct and distinct evidence that the variation in the α-selectivity as well as in the reaction rate observed with various diphosphines, including such powerful electron donors as α,ω-bis(dicyclohexylphosphino)alkanes, was dependent on the electronic factor of the diphosphines. Probably, this is because the steric factors much more seriously affect the results.

The authors wish to thank Mr. Tohru Arakawa and Mr. Hirokatsu Takyu for their experimental assistance.

Catalysis and Mechanism of the Isomerization of a Δ^5-3-Keto Steroid

Tadashi OKUYAMA, Akira KITADA, and Takayuki FUENO

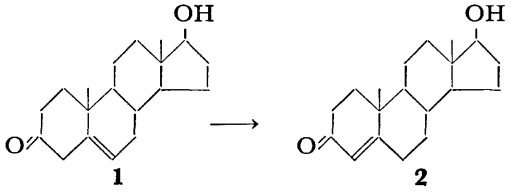
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 25, 1977)

The acid- and base-catalyzed isomerizations of Δ^5- to Δ^4-testosterone have been kinetically studied in aqueous solution. Solvent isotope effects of $k_{H_3O^+}/k_{D_3O^+}=0.69$ and $k_{OH^-}/k_{OD^-}=3.1$ were obtained. It was thus concluded that the acid-catalyzed isomerization proceeds through rate-determining enolization but the base-catalyzed reaction through rate-determining protonation of an enolate ion. It was found that primary amines efficiently catalyze the isomerization *via* an iminium ion intermediate. Possible bifunctional catalysis was suggested for the high catalytic activity of polyfunctional primary amines.

The isomerization of β,γ-unsaturated ketones to their conjugated isomers has been shown to be catalyzed by both acids[1–6] and bases.[4,6] The acid-catalyzed isomerization involves the formation of a dienol intermediate followed by protonation at the γ carbon to give an α,β isomer.[3,5] A similar pathway through a dienolate anion intermediate has been presented for the base-catalyzed reaction.[4,6] The rate-determining step of these reactions seems to depend on the ketone structure.[5,6] Recently, a primary amine has been found to efficiently catalyze the isomerization through a dienamine intermediate.[7,8] Closely related enzymatic reactions have received considerable attention.[9,10] The Δ^5-3-keto steroid isomerase from *P. testosteroni* has most extensively been studied, although the mechanism for this reaction has yet to be fully elucidated.[9]

In this paper, acid- and general base-catalyzed isomerization of Δ^5-(**1**) to Δ^4-testosterone (**2**) has been investigated to determine the rate-determining step.



1 **2** (1)

Various primary amines, including polyfunctional amines, have been examined for their catalytic activities.

Experimental

Materials. Δ^5-Testosterone (**1**) was prepared by the isomerization of testosterone (**2**) catalyzed by potassium *t*-butoxide in *t*-butyl alcohol.[11] Crude products were recrystallized from acetone to give white plates melting at 160 °C. Calcd for $C_{19}H_{28}O_2$: C, 79.17; H, 9.72%. Found: C, 79.40; H, 9.72%.

Inorganic salts of reagent grade were used without further purification. Organic buffers were distilled or recrystallized before use. Freshly boiled, glass distilled water was used for all the rate determinations.

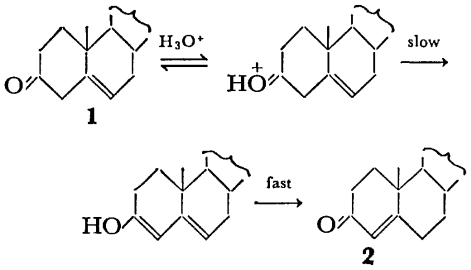
Kinetics. Rates were measured at 30±0.1 °C in aqueous buffer solutions containing 1% methanol, ionic strength being maintained at 0.50 with the addition of KCl. Three ml of buffer solution was equilibrated at 30 °C in a stoppered quartz cuvette inserted in a water-jacketted cell holder. Into the buffer solution was injected 30 μl of stock solution of **1** in methanol (4×10^{-3} M) with use of a microsyringe. After thorough mixing, the reaction was monitored spectrophotometrically using a Shimadzu spectrophotometer UV-200. First-order plots were linear over 90% conversion as monitored at 245 nm (λ_{max} of **2**) in the absence of primary amines.

Values of pH of buffer solutions and reaction mixtures were determined with a Hitachi-Horiba pH meter CTE F-5 calibrated in +0.01 pH unit.

To determine solvent isotope effects, D_2O and DCl and NaOD solutions supplied by E. Merck (isotopic purity >99.5 %) were used. Protic methanol was used for the preparation of the stock solution of **1**. Thus, deuterium purity of the reaction mixture was >98%.

Results and Discussion

Acid-catalyzed Isomerization. The rates of isomerization of **1** were measured in HCl (H_2O) and DCl (D_2O) solutions. An inverse isotope effect of $k_{H_3O^+}/k_{D_3O^+}=0.69\pm0.02$ was observed (Table 1). The result is consistent with the rate-determining enolization and in agreement with that observed for androst-5-ene-3,17-dione.[3]



1 **2** (2)

With 3-cyclohexen-1-one a normal isotope effect was found, indicating the rate-determining protonation of

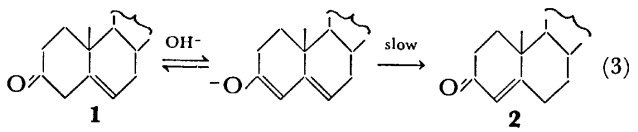
a dienol intermediate.[5a] The reason for the mechanistic difference of the latter reaction was nicely interpreted by the conformational aspects.[6]

Base-catalyzed Isomerization. The rate of the isomerization of **1** were compared in NaOH (H_2O) and NaOD (D_2O) solutions (Table 2). The isotope effect is normal $k_{OH^-}/k_{OD^-}=3.13\pm0.14$, indicating an equilibrium formation of a dienolate ion intermediate, followed by the rate-determining protonation of the intermediate by water.



This observation is consistent with the preferential α-protonation (deconjugation) of a dienolate anion in *t*-butyl alcohol.[11,12] That is, even in aqueous solution the base-catalyzed isomerization proceeds by the rate-determining protonation or the dienolate anion undergoes the preferential α-C protonation. A similar observation has recently been made with 3-cyclohexen-1-one.[6]

General Base Catalysis. The isomerization was also carried out in various buffer solutions. The observed rates were strongly dependent on buffer concentrations. Buffer-dependent rate constants were partitioned into the acid- and base-catalytic constants in a usual way as seen in Fig. 1. The acid-catalytic term was negligible at pH>7 except for primary amine buffers. The general base catalytic constants obtained are given in Table 3 and the Brønsted plots are shown in Fig. 2 ($\beta=0.48$). The apparent general base catalysis observed here must be a consequence of combined specific hydroxide and general acid catalyses since the rate-determining step is protonation (Eq. 3). In the same way, the apparent general acid catalysis

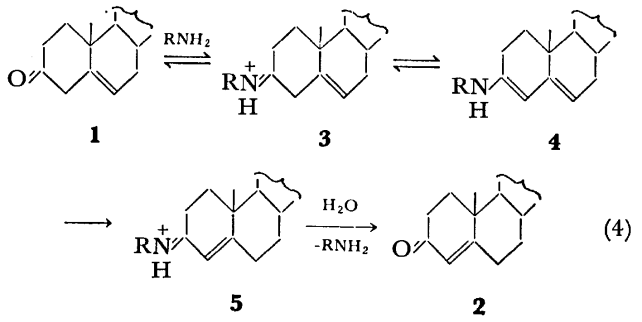
is actually specific oxonium-general base catalysis. Thus, the reasoning previously made by Jones and Wigfield[4] that the phenolic group of the enzyme acts as a general acid because of insufficient base catalytic activity of phenolate anion is weak.

Primary Amine Catalysis. The reactions in primary amine buffers showed some induction period with higher concentrations, and rates showed non-linear buffer de-

pendence. With 2-aminoethanol as a buffer, the rate constants obtained with low buffer concentrations (< 0.06 M) showed an acid-catalytic term as is seen in Fig. 1(b). With primary amine buffers of lower pK_a, the anomalous behavior was more apparent and the transient intermediate formation was observed by the scannings of UV spectra of the reaction mixture. An intermediate having the absorption maximum at ≈280 nm appeared rapidly, followed by slower decay for all the primary amines of $pK_a<9$ studied here. Similar observations were noted previously with trifluoethylamine[7] and glycylglycine[8] and the intermediate of λ_{max} ≈280 nm was identified as an α,β-unsaturated iminium ion of type **5**.



(4)

Kinetics of the primary amine-catalyzed isomerization of 3-methyl-3-cyclohexen-1-one has recently been investigated with trifluoroethylamine as a buffer, and a mechanism similar to Eq. 4 has been presented by Pollack and Kayser.[7] Some kinetic results preliminarily obtained with our system are consistent with the mechanism 4.[13] Because of the kinetic complexity and the publication of Pollack's data, thorough kinetic investigation of the present system was abandoned.

We compared relative catalytic effects of various primary amines. For the sake of kinetic simplicity,

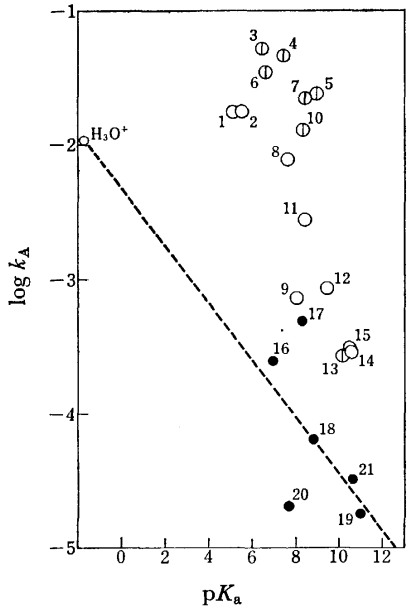


Fig. 3. Amine catalysis of the isomerization of **1**. For numbering see Table 4. ○, Primary amines. ⓓ, Polyfunctional primary amines. ●, Sceondary and tertiary amines.

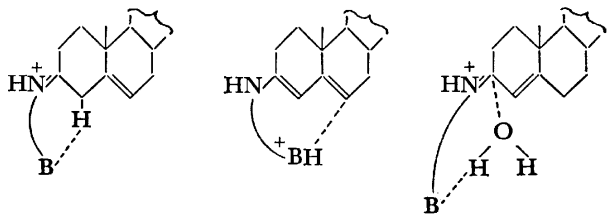
Rubber Co., Cleveland (1968), unless otherwise noted. c) R. L. Pecsok, R. A. Garber, and L. D. Shields (*Inorg. Chem.*, **4**, 447 (1965)) report pK_a=4.22, 8.95, 9.79 at 26 °C. d) D. B. Rorabacher, W. J. MacKeller, F. R. Shu, and S. M. Bonavita (*Anal. Chem.*, **43**, 561 (1971)) report pK_a=3.39, 6.75, 9.31, 10.09 at 25 °C. e) D. B. Rorabacher, W. J. MacKeller, F. R. Shu, and S. M. Bonavita (*Anal. Chem.*, **43**, 561 (1971)) report pK_a=2.40, 4.70, 8.50, 9.65, 10.36 at 25 °C.

very low concentrations of amines (≦0.02 M) were employed to determine the catalytic constants at pH near neutrality. To maintain pH constant (pH=6.6± 0.1), phosphate buffer of 0.1 M was used. Under these conditions, the formation of **2** (245 nm) was of the first-order in rate. From the rate increase by the addition of an amine, the apparent catalytic constant k_A was calculated and given in Table 4.

Logarithms of k_A are plotted against pK_a of the conjugate acid in Fig. 3. A reference line was drawn through the points for usual general acids because the acidic term of primary amine catalysis is important in mechanism 4.[7,13] Points for primary amines show large upward deviations from the reference line by the magnitude of *ca.* 2 in the log unit. The reaction in a 1-M buffer of *N,N*-dimethylethylenediamine of neutral pH would be more than 10^5 times as rapid as the uncatalyzed reaction at the same pH. A primary amine effectively attacks the β,γ-unsaturated ketone as a nucleophile to give an iminium ion followed by rapid isomerization to the α,β-unsaturated iminium ion, which is finally hydrolyzed to give the α,β-unsaturated ketone

(Eq. 4). During the conversion of the iminium intermediate, a second molecule of an amine or an external buffer acts as a general base or acid.

When a bifunctional primary amine having a second base group is used as a catalyst, intramolecular base (acid) catalysis may operate in manners like **6**—**8** in each step of Eq. 4.



6 **7** **8**

Some polyfunctional primary amines were examined and are included in the plots of Fig. 3. Small such effects seem to be actually operative, though not definite. Intramolecular catalysis similar to **8** was previously found in the dehydration of a carbinolamine (the reverse of the present reaction).[14] Although the catalysis like **6** may also be possible, the step that follows (γ protonation) would hardly be catalyzed intramolecularly because of the remoteness of an acid group (**7**). Thus, whether or not the bimolecular catalysis by primary amines is actually effective depends on the rate-determining step of the overall reaction. Further details on this problem is now under investigation.

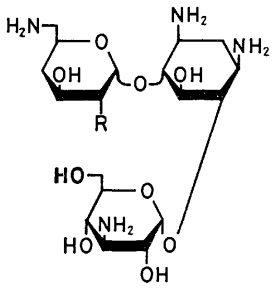
(Received March 1, 1977)

4′-Deoxykanamycin (**9**) was prepared from kanamycin *via* *N*-benzyloxycarbonylation, 4″,6″-*O*-cyclohexylidenation, selective benzoylation at 2′,3′, and 2″-hydroxyl groups, 4′-*O*-mesylation, 4′-iodination, 4′-hydrogenation, and removal of the protective groups. 4′-Deoxykanamycin B (**19**) was analogously prepared from kanamycin B. 4′-*O*-Tosyl derivative of kanamycin B was also led to **19**. Selective formylation of the 3′-hydroxyl group of a protected kanamycin B derivative with *N*,*N*-dimethylformamide-tosyl chloride followed by mesylation of the unstable 3′-*O*-formyl derivative also led to 4′-deoxykanamycin B. Throughout the syntheses, the 4′-hydroxyl group of the protected kanamycins was found to be least reactive for benzoylation among the 2′,3′,4′, and 2″-hydroxyl groups. The ^{13}C NMR spectrum of **9** was also measured. It was concluded that 4′-deoxygenation of antibiotics structurally related to kanamycin caused the resonances of ^{13}C-6′ downfield shift.

As reported[2] previously, 4′-deoxykanamycin (**9**) synthesized by a condensation method has been found to have antibacterial activity in the similar strength as that of parent antibiotic, kanamycin and moreover to have activity against some strains of *Pseudomonas aeruginosa*. Naito *et al.*[3] have also prepared **9** starting from kanamycin *via* the 4′,6′-carbamate formation[4] followed by selective liberation of the 4′-hydroxyl group or *via* the 4′-*O*-acetyl migration to the 6′-amino group. This paper describes another synthesis of 4′-deoxykanamycin (**9**) starting from kanamycin and three processes for the synthesis of 4′-deoxykanamycin B (**19**) strating from kanamycin B.



9 R=OH
19 R=NH_2

In preliminary experiments we have found that the 4′-hydroxyl groups of kanamycin, kanamycin B and their derivatives were least reactive for benzoylation among the 2′,3′,4′, and 2″-hydroxyl groups. We, therefore, utilized this finding for the syntheses of **9** and **19**.

Synthesis of 4′-Deoxykanamycin (9). Tetrakis(*N*-benzyloxycarbonyl)kanamycin (**1**) was treated with 1,1-dimethoxycyclohexane in *N*,*N*-dimethylformamide (DMF) in the presence of *p*-toluenesulfonic acid. The 4″,6″-*O*-cyclohexylidenation was achieved almost quantitatively without formation of other mono-*O*-cyclohexylidene or di-*O*-cyclohexylidene derivatives. This exclusive 4″,6″-*O*-cyclohexylidenation was rather unexpected, because in a similar treatment of a *N*-protected kanamycin B derivative, the 3′,4′-*O*-cyclohexylidenation occurred[5] more or less in addition to the 4″,6″-*O*-cyclohexylidenation.

Treatment of the 4″,6″-*O*-cyclohexylidene derivative (**2**) with 6 mol equivalents of benzoyl chloride in pyridine gave a mixture of tri- and tetra-*O*-benzoyl (**4**) derivatives. If the amount of benzoyl chloride used

* A mixture of epimers

was reduced, the production of tri-*O*-benzoyl derivatives was increased with the decrease of **4**. However, the apparent increase of tri-*O*-benzoyl derivatives did not necessarily mean the yield increase of the desired 2′,3′,2″-tri-*O*-benzoyl derivative (**3**), since **3** was found to be contaminated with other minor tri-*O*-benzoyl isomer(s) and this made the purification of **3** difficult even by column chromatography (**3** and the isomer(s) had the same mobility). The contamination was shown by the PMR spectrum of the mesylated mixture of the tri-*O*-benzoylated products; that is, in the spectrum, at least two peaks assignable to the methyl protons of mesyls were observed, indicating that the tri-*O*-benzoyl products were a mixture of the position isomers. By increasing the amount of benzoyl chloride up to 6 mol equivalents for **2**, a mixture of **3** and **4** was formed exclusively. The tetra-*O*-benzoyl isomer (**4**), which was formed concomitantly in high proportion, could be converted again to **2** in 90% yield by treatment with sodium methoxide. The doubtless structure of **3** was deduced from the fact that **3** was led to 4′-deoxykanamycin after a sequence of reactions described below.

Mesylation of **3** gave 4′-*O*-mesyl (**5**, 65%) and 5,4′-di-*O*-mesyl (**6**, 9.5%) derivatives. It should be noted that mesylation of an *N*-ethoxycarbonyl-kanamycin B

derivative[6] (compound **5** in that literature) gave 3′,4′-di-*O*-mesyl derivative in 96% yield without formation of the 5-*O*-mesyl derivative. This means that 4′-*O*-mesylation of **3** is somewhat hindered by the neighboring groups (possibly by 3′-*O*-benzoyl and 6′-*N*-benzyloxycarbonyl groups) and consequently the mesylation can occur at the 4′- and 5-hydroxyl groups in a similar level. Tosylation of **3**, in contrast to mesylation, occurred scarcely. Treatment of **5** with 50% (w/v) sodium iodide in DMF at 100 °C gave an epimeric mixture of 4′-iodo derivatives (**7**). This displacement reaction required 40 h heating. Since the similar iodination of **22** and **26** described later required a shorter reaction period for completion, the displacement reaction of **5** was considered to be somewhat hindered by the groups in the vicinity of the 4′-mesyloxy group. Hydrogenolysis of **7** with Raney nickel gave the 4′-deoxy derivative (**8**), which, after deblocking, gave 4′-deoxykanamycin (**9**).

The structure of **9** was confirmed by acidic solvolysis of the tetrakis(*N*-benzyloxycarbonyl) derivative of **9**. One of the alcoholyzed products which showed the same mobility was identified to the anomeric mixture of benzyl 6-benzyloxycarbonylamino-4,6-dideoxy-D-*xylo*-hexopyranosides (**10**) which consumed periodate, indicating that **10** has a pair of vicinal diols. Acidic hydrolysis of **9** followed by paper chromatography also supported the conclusion (Chart 1).

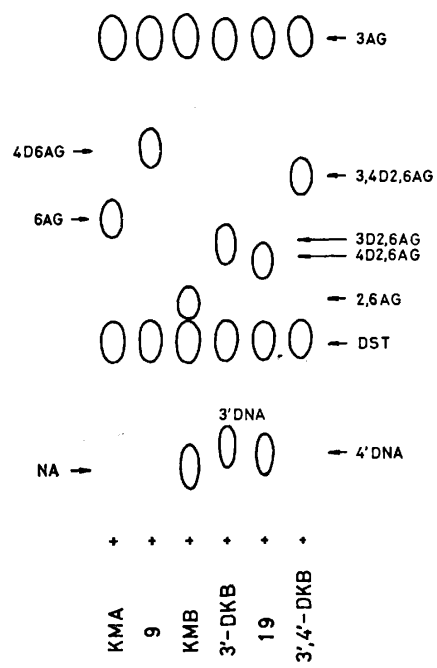

Chart 1. The paper chromatogram of acidic hydrolyzates (6M HCl 100 °C 0.5 h for KMA and **9**, and 6.5 h for other compounds) of kanamycin (KMA), 4′-deoxykanamycin (**9**), kanamycin B (KMB), 3′-deoxykanamycin B (3′-DKB), 4′-deoxykanamycin B (**19**), and 3′,4′-dideoxykanamycin B, descending for 3 days. Abbreviations are: NA (neamine), DST (2-deoxystreptamine), 3AG (3-amino-3-deoxy-D-glucose), 6AG (6-amino-6-deoxy-D-glucose), 2,6AG (2,6-diamino-2,6-dideoxy-D-glucose); the denotions of 3D, 3′D, 4D, 4′D, and 3,4D mean that the numbered positions of the parent compounds (cited after the letter D) are deoxygenated.

Table 1. The ^{13}C chemical shifts[a] of kanamycin (KMA),[b] 4′-deoxykanamycin (**9**), 3′-deoxykanamycin B(3′-DKB),[c] and 3′,4′-dideoxykanamycin B(3′,4′-DKB) (all as free bases)

a) In ppm downfield from TMS calculated as $\delta^{TMS} = \delta^{dioxane} + 67.4$ ppm. b) Shift assignments were based on the shifts of kanamycin (pH 9.6) reported.[8] c) The shifts were substantially the same with those reported by Koch *et al.*[9] d) The values of C-3′ and C-5′ may well be reversed. e) Shift assignments of C-3′ and C-4′ were made based on the corresponding shifts[10] of gentamicin C_{1a} and gentamin C_{1a}.

^{13}C NMR spectral studies were further made. The data of **9**, kanamycin, 3′-deoxykanamycin B (tobramycin), and 3′,4′-dideoxykanamycin B[7] were shown in Table 1. By the spectrum of **9**, the presence of two deoxy groups (δ 36.3 at C-2 and 4′) was clearly shown. Comparison of the C-6′ resonances of kanamycin and 3′-deoxykanamycin B with those of **9** and 3′,4′-dideoxykanamycin B showed downfield shifts $\approx$3 ppm of the latter. By taking the shift difference ($\Delta\delta$) between C-6′ and C-2 of structurally related antibiotics as a measure of downfield shift (the shift of C-2 was selected as a standard because the shift was thought to remain relatively constant throughout kanamycin series), following results were obtained: kanamycin ($\Delta\delta$ 6.1), 3′-deoxykanamycin B (6.0),[9] 3′,4′-dideoxykanamycin B (9.1), gentamicin C_{1a} (9.4),[10] ribostamycin (6.0),[11] 4′-deoxyneamine (9.1),[12] and seldomycin factor 5 (9.2).[13] These results show that the lack of 4′-hydroxyl group causes downfield shift of the resonance of C-6′ by $\approx$3 ppm. This fact is useful to discern the presence of 3′- or 4′-deoxy group. Similar downfield shifts were reported[14] on mannose and galactose, in which the C-4 resonances shifted downfield ($\Delta\delta$ 2.5—5.3) on 6-deoxygenation.

Synthesis of 4′-Deoxykanamycin B. Pentakis(*N*-benzyloxycarbonyl)kanamycin B (**11**), which was prepared from kanamycin B, was treated with 1,1-dimethoxycyclohexane similarly as described for **2** to give the 4″,6″-*O*-cyclohexylidene derivative (**12**).[15] In this reac-

* A mixture of epimers

tion, undesirable 3′,4′-*O*-cyclohexylidenation was inevitable, but this product was mostly hydrolyzed to **12** by addition of water.[5] Benzoylation of **12** with benzoyl chloride gave a mixture of 3′,2″-di-*O*-(**13**) and 3′,4′,2″-tri-*O*-benzoyl (**14**) derivatives, from which **13** was readily separated by chromatography. Mesylation of **13** gave 4′-*O*-mesyl derivative (**15**) and subsequent iodination gave 4′-iodo derivative (**17**). Hydrogenation of **17** with tributyltin hydride[16] or with hydrogen-Raney nickel gave the 4′-deoxy derivative (**18**). Finally, removal of the protecting groups gave 4′-deoxykanamycin B (**19**).

The structure of **19** was confirmed by another synthesis, that is, the 4′-*O*-tosyl derivative[17] (**22**) of 2″-*O*-benzoyl-4″,6″-*O*-cyclohexylidene-pentakis(*N*-ethoxycarbonyl)kanamycin B (**20**), was led to **19**. Iodination of **22** gave the 4′-iodo derivative (**27**) and it was hydrogenated with Raney nickel to give the 4′-deoxy derivative (**28**), which after deblocking gave 4′-deoxykanamycin B (**19**) identical with that obtained by the first synthesis. Paper chromatogram of the acidic hydrolyzates of **19** was shown in Chart 1.

To further improve the synthesis of **19**, we tried to protect the 3′-hydroxyl group of **20** by formylation with *N*,*N*-dimethylformamide in the presence[18] of tosyl chloride. Treatment of **20** in DMF with tosyl chloride in the presence of pyridine gave a product (**24**) which was considered to be a mono-*O*-formyl compound. Since the compound could not be purified by column chromatography owing to its instability, **24** was mesylated without purification and the mesyl derivative (**25**) was treated with aqueous ammonia to remove the formyl group. The 4′-*O*-mesyl derivative (**26**) was thus obtained in a yield of 62% from **20**. This formylation reaction did not proceed smoothly, if pyridine was omitted, and higher temperature and longer reaction period were required for completion of the reaction and the yield of **26** was much lower. The structure of **26** was confirmed by leading it to **27** by treatment with sodium iodide. Above results indicate that the formylation occured at 3′-hydroxyl group fairly selectively, although the mode of acylation was different from that of benzoylation for the preparation of **13**. In the above 4′-*O*-sulfonylation step, if tosyl chloride was used instead of mesyl chloride, the 4′-*O*-tosylation hardly occurred. This suggests that the 3′-*O*-formyl group of **24** fairly prevents the 4′-*O*-tosylation as in the case of 3′-*O*-benzoyl group in **3** described before.

The structure of **19** was further confirmed by determination of $\Delta[M]_{TACu}$[19] values (Table 2). TACu can form complex only with a pair of vicinal amino and hydroxyl groups having relative spacial orientations of $\approx 60°$ dihedral angle and the $\Delta[M]_{TACu}$ shows a value

Table 2. The $\Delta[M]_{TACu}$[19] values measured at 20 °C

of $\approx\pm900°$. The accordance of the difference of the $\Delta[M]_{TACu}$ values between kanamycin and kanamycin B with that between 3′-deoxy- and 4′-deoxykanamycin B (**19**) shows that a copper complex was formed between 2′-amino and 3′-hydroxyl groups in **19**.

Antibacterial activities of 4′-deoxykanamycin[2] (**9**) and 4′-deoxykanamycin B (**19**) are shown in Table 3.

Experimental

PMR spectra were recorded at 60, 90, and 100 MHz with Hitachi R-24A, Varian EM-390, and Varian XL-100 spectrometers, respectively. ^{13}C NMR spectra were recorded on a Varian XL-100 spectrometer with Varian 620-L data processing system (25.2 MHz) in $\approx$0.5 M deuterium oxide solution containing dioxane as internal reference. Thin-layer chromatography (TLC) was performed on Wakogel B-5 unless otherwise stated or on E. Merck silica gel 60 F_{254}. Paper chromatography (PPC) was carried out on Toyo-Roshi paper No. 50 with 1-butanol–pyridine–water–acetic acid=6 : 4 : 3 : 1, descending for 7—8 days unless otherwise stated and spots were visualized by 0.5% ninhydrin in pyridine. For column chromatography, silica gel (Wakogel C-200) was used. For experiments at lower than 0 °C, cooling assembly of Haake constant circulator KS60W was used. Reprecipitation was carried out by adding the last-cited solvent to a solution of the first-cited solvent (or the mixture of the first and the second-cited solvents).

*Tetrakis(*N*-benzyloxycarbonyl)kanamycin (**1**).* To an ice-cold suspension of kanamycin sulfate (54.2 g as kanamycin·H_2SO_4·H_2O) and anhydrous sodium carbonate (52 g) in aqueous acetone (1 : 1, 1 l), benzyl chloroformate (50 ml) was gradually added under vigorous stirring and the mixture was stirred for 1.5 h in the cold. Precipitates occurred were filtered, washed with water and then with ether to give a solid of **1**, 78.0 g (90%), $[\alpha]_D^{25}$ +68° (*c* 2, DMF); IR (KBr): 1690, 1530 cm^{-1}; PMR (DMSO-d_6) δ: 5.05 (8H s, C_6H_5-CH_2).

Found: C, 58.89; H, 6.18; N, 5.41%. Calcd for $C_{50}H_{60}N_4O_{19}$: C, 58.81; H, 5.92; N, 5.49%.

*Tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidenekanamycin (**2**).* To a solution of **1** (297 mg) in dry DMF (3 ml), anhydrous *p*-toluenesulfonic acid (11 mg) and 1,1-dimethoxycyclohexane (0.07 ml, $\approx$1.5 mol equivalents for **1**) were added and the solution was heated at 50 °C under reduced pressure (25—30 Torr) for 1 h. The resulting solution showed, on TLC with $CHCl_3$–EtOH (6 : 1), a single spot at R_f 0.5 (*cf.* **1**, R_f 0.12). The solution was poured into aqueous sodium hydrogencarbonate solution with stirring and the precipitates occurred were filtered, washed with water, and dried. The solid was reprecipitated from dioxane–water, 314 mg (98%), $[\alpha]_D^{20}$ +60° (*c* 1, DMF).

Found: C, 60.78; H, 6.14; N, 4.82%. Calcd for $C_{56}H_{68}N_4O_{19}$: C, 61.08; H, 6.22; N, 5.09%.

*2′,3′,2″-Tri-*O*-(**3**) and 2′,3′,4′,2″-Tetra-*O*-benzoyl-tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidenekanamycin (**4**).* To an ice-cold solution of **2** (39.4 g) in dry pyridine (800 ml), benzoyl chloride (8.35 ml, 2 mol equivalents for **2**) was added and the solution was kept in the cold for 1 h. Another benzoyl chloride (8.35 ml) was added and the solution was kept in the cold for further 1 h. Benzoyl chloride (8.35 ml) was again added and the solution was kept at room temperature overnight. The resulting solution showed, on TLC with $CHCl_3$–2-propanol (IPA) (40 : 1), spots of **3** (R_f=0.15) and **4** (R_f=0.2) in almost equal color strength. After addition of water (20 ml) followed by heating at 40 °C for a while, the solution was concentrated. The chloroform solution (1.2 l) of the residual syrup was washed with 5% aqueous potassium hydrogensulfate, 2% aqueous sodium hydrogencarbonate, and water, dried ($MgSO_4$), and concentrated. The pale-brown solid was chromatographed over silica gel with the same solvent system to give a colorless solid of **3**, 24.3 g (48%) and **4**. Since **4** thus obtained was contaminated with color impurities, it was purified by column chromatography again as described above and the pale-yellow solid obtained was reprecipitated from $CHCl_3$–ether–hexane to give a colorless solid of **4**, 341 mg (50%).

3: $[\alpha]_D^{25}$ +106° (*c* 1, $CHCl_3$).

Found: C, 65.61; H, 5.79; N, 3.77%. Calcd for $C_{77}H_{80}N_4O_{22}$: C, 65.43; H, 5.70; N, 3.96%.

4: $[\alpha]_D^{25}$ +109° (*c* 1, $CHCl_3$); PMR ($CDCl_3$): the areal ratio of the signals at δ 6.8—7.7 ($CH_2C_6\underline{H}_5$ and *m* and *p* of COC_6H_5) and those at δ 7.7—8.2 (*o* of COC_6H_5) were $\approx$4 : 1.

Found: C, 66.16; H, 5.69; N, 3.74%. Calcd for $C_{84}H_{84}N_4O_{23}$: C, 66.48; H, 5.58; N, 3.69%.

*Conversion of **4** to **2**.* To a solution of **4** (68.5 mg) in dioxane (1.4 ml), 1 M sodium methoxide in methanol (0.14 ml) was added and the solution was kept at room temperature for 1.5 h. After addition of Dowex 50Wx8 (H form, pretreated with methanol) the mixture was filtered and the filtrate was concentrated to give a syrup. Washing the syrup thoroughly with water gave a solid (45.0 mg, 90%) identical with **2**.

*2′,3′,2″-Tri-*O*-benzoyl-tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidene-4′-*O*-mesylkanamycin (**5**).* To a solution of **3** (20.0 g) in dry pyridine (300 ml), mesyl chloride (3.32 ml, $\approx$3 mol equivalents for **3**) were added and the solution was kept at 50 °C overnight. The solution showed, on TLC with $CHCl_3$–IPA (25 : 1), three spots of R_f 0.22 (**3**), 0.3 (major, **5**) and 0.45 (**6**). After addition of water (3.8 ml), the solution was concentrated *in vacuo* and the chloroform solution (600 ml) of the residual syrup was washed with 5% aqueous potassium hydrogensulfate, 2% aqueous sodium hydrogencarbonate, and water, dried ($MgSO_4$), and concentrated. The brown solid (21.3 g) was vigorously stirred with benzene (100 ml) and the mixture was centrifuged. The solid was treated likewise twice more to give a colorless solid of **5**, 13.8 g (65%). The benzene-soluble part (6.4 g), which was a mixture of **3**, **5**, and **6**, was repeatedly chromatographed over silica gel with $CHCl_3$–IPA to give a colorless solid of **6**, 2.1 g (9.5%).

5: $[\alpha]_D^{22}$ +120° (*c* 1, $CHCl_3$); PMR ($CDCl_3$): δ 2.85 (3H s, SO_2CH_3).

Found: C, 62.81; H, 5.62; N, 3.52; S, 2.07%. Calcd for $C_{78}H_{82}N_4O_{24}S$: C, 62.81; H, 5.54; N, 3.75; S, 2.15%.

6: $[\alpha]_D^{25}$ +82° (*c* 1, $CHCl_3$); PMR ($CDCl_3$): δ 2.87 and 2.96 (each 3H s, SO_2CH_3).

Found: C, 60.26; H, 5.26; N, 3.37; S, 3.83%. Calcd for $C_{79}H_{84}N_4O_{26}S_2$: C, 60.45; H, 5.39; N, 3.57; S, 4.08%.

*2′,3′,2″-Tri-*O*-benzoyl-tetrakis(*N*-benzyloxycarbonyl)-4″,6″-*O*-cyclohexylidene-4′-deoxy-4′-iodokanamycin (**7**).* A mixture of **5** (5.00 g) and sodium iodide (50 g) in DMF (100 ml) was heated at 100 °C for 40 h in an atmosphere of nitrogen. The solution, which solidified on cooling, was shaken with chloroform and the organic layer was concentrated *in vacuo* with several additions of toluene (to remove DMF) to give a residue. The solution of the residue in chloroform was washed with aqueous sodium thiosulfate and water, dried ($MgSO_4$), and concentrated. The brown solid was chromatographed over silica gel with $CHCl_3$–IPA (45 : 1) to give a pale-yellow solid, 3.34 g (65%). The solid contained two components, on checked by TLC, of R_f 0.3 (major) and 0.4 (the 3′-epimer); $[\alpha]_D^{23}$ +102° (*c* 1, $CHCl_3$).

Found: C, 60.70; H, 5.41; N, 3.69; I, 8.17%. Calcd for $C_{77}H_{79}N_4O_{21}I$: C, 60.71; H, 5.23; N, 3.68; I, 8.33%.

2',3',2''-Tri-O-benzoyl-tetrakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidene-4'-deoxykanamycin (8). A solution of **7** (2.38 g) in dioxane–methanol (1 : 1, 14 ml) containing a few drops of triethylamine was hydrogenated with hydrogen under pressure (50 lb/in^2) with Raney nickel at room temperature. After 1 h, the catalyst was replaced with fresh one and the mixture was treated likewise for further 1 h, then the procedure was repeated again. Filtration followed by evaporation gave a solid, which was chromatographed over silica gel with $CHCl_3$–IPA (45 : 1) to give a solid of **8**, 1.93 g (89%). The solid was reprecipitated from dioxane–water, $[\alpha]_D^{20}$ +160° (*c* 0.5, $CHCl_3$).

Found: C, 66.33; H, 5.87; N, 3.85%. Calcd for $C_{77}H_{80}N_4O_{21}$: C, 66.18; H, 5.77; N, 4.01%.

4'-Deoxykanamycin (9). To a solution of **8** (502 mg) in dry dioxane–methanol (1 : 1, 10 ml), 1 M sodium methylate in methanol (0.5 ml) was added and the solution was kept at room temperature for 4.5 h. Dowex 50Wx8 (H form) resin pretreated with methanol was added and the neutral solution was filtered and the filtrate was concentrated. The solid was washed with vigorous stirring with ether and then with hot acetone to give a solid, 304 mg (78% as debenzoyl product). A suspension of the solid in 80% aqueous acetic acid (11 ml) was heated at 80 °C for 1 h. The resulting clear solution was concentrated *in vacuo* to give a solid (295 mg). The decyclohexylidenated product was suspended in a mixture of dioxane–acetic acid–water (2 : 2 : 1, 20 ml) and the mixture was hydrogenated with atmospheric hydrogen in the presence of palladium black at room temperature for 20 min. Filtration followed by evaporation *in vacuo* gave a pale-brown syrup, which was chromatographed over CM-Sephadex C-25 (NH_4 form) with aqueous ammonia (0.02→0.15 M, gradually increased). The ninhydrin-positive fractions were concentrated to give a solid, 121 mg (62% as monocarbonate hemihydrate), $[\alpha]_D^{20}$ +137° (*c* 1, H_2O) (lit[2] +129° as 2/3 hydrate; +134°[3] as free base); PPC: $R_{f\ kanamycin}$ 1.2, TLC: $R_{f\ kanamycin}$ 1.7 (Avicel (microcrystalline cellulose powder, Funakoshi Co.), BuOH–EtOH–$CHCl_3$–17% NH_3=4 : 4 : 2 : 3, doubly developed).

Found: C, 42.45; H, 7.30; N, 10.08%. Calcd for $C_{18}H_{36}N_4O_{10}\cdot H_2CO_3\cdot 1/2H_2O$: C, 42.29; H, 7.29; N, 10.38%.

Benzyl 6-Benzyloxycarbonylamino-4,6-dideoxy-α- and β-D-xylo-hexopyranosides (10). A suspension of **9** (51.1 mg as $H_2CO_3\cdot 1/2H_2O$ salt) and anhydrous sodium carbonate (57 mg) in aqueous methanol (1 : 1, 1 ml) was treated with benzyl chloroformate (0.07 ml) in a similar manner as described to give tetrakis-(*N*-benzyloxycarbonyl)-4'-deoxykanamycin (85 mg, 89%). This was suspended in 2 M hydrogen chloride in benzyl alcohol (1.5 ml) and the mixture was heated at 100 °C for 15 min. The resulting clear solution showed, on TLC with $CHCl_3$–EtOH (10 : 1), three spots of R_f 0.05 (2-deoxystreptamine), 0.30 (3-amino-3-deoxy-D-glucose), and 0.38 (**10**). Basic lead carbonate (0.8 g) was added and the mixture was vigorously stirred for hours. Centrifugation followed by concentration of the upper layer gave a syrup, which was chromatographed over silica gel with $CHCl_3$–EtOH (40 : 1) to give a colorless solid of **10**, 32 mg (98%). PMR ($CDCl_3$–D_2O): δ 1.36 (≈0.7H q, J≈12 Hz, H-4_{ax} (α-anomer)), 1.39 (≈0.3H q, H-4_{ax} (β-anomer)), 1.75—2.05 (1H, m H-4_{eq}), 4.24 (≈0.3H d, J=7.5 Hz, H-1 (β)), 4.53 (≈1.4H AB q, J_{AB}=11.5 Hz, $C_6H_5C\underline{H}_2OC(1)(\alpha)$), 4.69 (≈0.6H AB q, J_{AB}=11.5 Hz, $C_6H_5C\underline{H}_2OC(1)(\beta)$), 4.93 (≈0.7H d, J=4.0 Hz, H-1(α)), 5.85 (2H s, $C_6H_5C\underline{H}_2OCO$).

Periodate Oxidation of 10. A sample of **10** (≈1 mg) was dissolved in a drop of dioxane and a drop of 0.01 M aqueous metaperiodate solution was added. The solution was checked by TLC with $CHCl_3$–EtOH (10 : 1). After keeping at room temperature for 10 min, the solution showed a spot of R_f 0.33 (**10**) and that of 0.43 in almost equal color strength, and after 1 h, the former spot disappeared. The latter spot was active for triphenyltetrazolium chloride, a reagent for reducing substances.

Pentakis(N-benzyloxycarbonyl)kanamycin B (11). Kanamycin B sulfate was treated similarly as described for **1** to give **11** in a yield of 85%, $[\alpha]_D^{25}$ +72° (*c* 1, DMF).

Found: C, 60.13; H, 5.81; N, 6.05%. Calcd for $C_{58}H_{67}N_5O_{20}$: C, 60.36; H, 5.85; N, 6.07%.

Pentakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidenekanamycin B (12). A mixture of **11** (6.65 g), 1,1-dimethoxycyclohexane (1.7 ml, 2 mol equivalents for **11**), and anhydrous *p*-toluenesulfonic acid (220 mg) was treated in a similar manner as described for **2**. The resulting sloution showed, on TLC with $CHCl_3$–EtOH (10 : 1), two spots of R_f 0.3 (**12**) and 0.7 (dicyclohexylidene isomer, major) (*cf.* **11**, R_f 0.12). After addition of water (0.05 ml, 0.5 mol equivalent for **11**), the solution was kept at room temperature overnight. The formation of **12** became major. Aqueous sodium hydrogencarbonate (480 mg) was added with vigorous stirring and the mixture was concentrated *in vacuo* with several additions of toluene. The residual colorless solid (5.9 g) was stirred with hot benzene (30 ml×3), centrifuged, and dried to give pure **12**, 5.67 g (80%). The benzene-soluble portion (217 mg) contained the dicyclohexylidene derivative as a major component.

12: $[\alpha]_D^{25}$ +62° (*c* 1, DMF) (lit,[15] +47° in pyridine).

Found: C, 62.43; H, 6.18; N. 5.68%. Calcd for $C_{64}H_{75}N_5O_{20}$: C, 62.28; H, 6.12; N, 5.67%.

3',2''-Di-O- (13) and 3',4',2''-Tri-O-benzoyl-tetrakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidenekanamycin B (14). To a solution of **12** (495 mg) in dry pyridine (10 ml), benzoyl chloride (0.12 ml, 2.5 mol equivalents for **12**) was added and the solution was kept at room temperature overnight. This reaction conditions were established by mesylating the product followed by examining its PMR spectrum several times, as in the preparation of **3**. The solution showed, on TLC (E. Merck) with $CHCl_3$–methyl ethyl ketone (MEK) (3 : 1), two spots of R_f 0.15 (**13**) and 0.22 (**14**) in almost equal strength. Work up as described for **3** gave a mixture of **13** and **14** (611 mg). The solid (195 mg) was chromatographed over silica gel (E. Merck silica gel 60, prepacked column 2.5×25 cm) with $CHCl_3$–MEK (3 : 1) to give **13** (81.6 mg, 44%), **14** (56.9 mg, 29%) and a mixture of **13** and **14** (25.7 mg).

13: mp 237—238 °C, $[\alpha]_D^{25}$ +112° (*c* 0.8, $CHCl_3$).

Found: C, 64.70; H, 5.75; N, 4.82%. Calcd for $C_{78}H_{83}N_5O_{22}$: C, 64.94; H, 5.80; N, 4.86%.

14: mp 139—140 °C, $[\alpha]_D^{25}$ +96° (*c* 1, $CHCl_3$).

Found: C, 65.74; H, 5.74; N, 4.45%. Calcd for $C_{85}H_{87}N_5O_{23}$: C, 66.01; H, 5.67; N, 4.53%.

3',2''-Di-O-benzoyl-pentakis(N-benzyloxycarbonyl)-4'',6''-O-cyclohexylidene-4'-O-mesylkanamycin B (15). A solution of **13** (197 mg) and mesyl chloride (0.05 ml, 5 mol equivalents for **13**) in dry pyridine (4 ml) was kept at room temperature for 2 h. The solution showed, on TLC (E. Merck) with $CHCl_3$–MEK (3 : 1), two spots of R_f 0.23 (**15**) and 0.44 (minor, di-*O*-mesyl derivative). Work up as described for **5** gave a solid (195 mg), which was chromatographed over silica gel with $CHCl_3$–MEK (3 : 1) to give a solid of **15**, 155 mg (75%) and a solid of 5,4'-di-*O*-mesyl derivative (**16**), 18 mg (8.3%).

15: mp 211—212 °C, $[\alpha]_D^{25}$ +97° (*c* 1, $CHCl_3$); PMR ($CDCl_3$): δ 2.78 (3H s, CH_3SO_2).

Found: C, 62.66; H, 5.73; N, 4.58; S, 1.88%. Calcd for $C_{79}H_{85}N_5O_{24}S$: C, 62.40; H, 5.63; N, 4.61; S, 2.11%.

16: mp 162—163 °C, $[\alpha]_D^{25}$ +70° (*c* 0.5, $CHCl_3$); PMR ($CDCl_3$): δ 2.78 and 3.07 (each 3H s, CH_3SO_2).

Found: C, 59.86; H, 5.43; N, 4.46; S, 4.01%. Calcd for $C_{80}H_{87}N_5O_{26}S_2$: C, 60.10; H, 5.49; N, 4.38; S, 4.01%.

*3′,2″-Di-O-benzoyl-pentakis(N-benzyloxycarbonyl)-4″,6″-O-cyclohexylidene-4′-deoxy-4′-iodokanamycin B (**17**).* Compound **15** (147 mg) was treated with sodium iodide (1.5 g) in DMF (3 ml) at 100 °C for 40 h. Work up as described for **7** gave a mixture of 4′-iodo epimers (R_f 0.2 and 0.38 (minor) with $CHCl_3$–MEK=3 : 1), 68 mg (45%).

*3′,2″-Di-O-benzoyl-pentakis(N-benzyloxycarbonyl)-4″,6″-O-cyclohexylidene-4′-deoxykanamycin B (**18**).* To a solution of **17** (35.6 mg) in dry dioxane (0.7 ml), tributyltin hydride (0.07 ml) and α,α′-azobisisobutyronitrile (≈3 mg) were added and the solution was heated at 80 °C for 2 h under the atmosphere of nitrogen. The solution showed, on TLC with $CHCl_3$–MEK (3 : 1), a single spot at R_f 0.2. Concentration gave a residue, which was chromatographed over silica gel with $CHCl_3$–MEK (3 : 1) to give a solid, which was reprecipitated from chloroform–ether, 26.5 mg (81%), mp 247—248 °C, $[\alpha]_D^{25}$ +120° (*c* 0.8, $CHCl_3$).

Found: C, 65.62; H, 5.84; N, 4.85%. Calcd for $C_{78}H_{83}N_5O_{21}$: C, 65.67; H, 5.86; N, 4.91%.

*4′-Deoxykanamycin B (**19**).* *A. From **18***: Compound **18** (26.5 mg) was treated likewise as described in the preparation of 4′-deoxykanamycin (**9**) to yield **19**, 7.0 mg (64% as dicarbonate), $[\alpha]_D^{20}$ +117° (*c* 0.5, H_2O); PPC: $R_{f\ \text{kanamycin B}}$ 1.2 (*cf.* tobramycin, 1.3); PMR (D_2O): δ 1.0—1.5 (2H two overlapped q, $J\approx12$ Hz, H-2_{ax}, H-$4'_{ax}$), 1.75—2.1 (2H m, H-2_{eq}, H-$4'_{eq}$), 4.99 (1H d, J=3.5 Hz, H-1′ or 1″), 5.35 (1H d, J=3.5 Hz, H-1′ or 1″).

Found: C, 40.75; H, 6.96; N, 11.90%. Calcd for $C_{18}H_{37}N_5O_9\cdot2H_2CO_3$: C, 40.61; H, 6.99; N, 11.84%.

*B. From **28***: Compound **28** (97.4 mg) was treated similarly as described[17] (preparation of **10** from **7** in that litrature) to give **19**, 20.0 mg (35% as dicarbonate) and a ureylene derivative,[20] 15.6 mg.

*2″-O-Benzoyl-4″,6″-O-cyclohexylidene-pentakis(N-ethoxycarbonyl)-3′-O-(**21**), 4′-O- (**22**), and di-O-tosylkanamycin B (**23**).* A solution of **20**[17] (4.17 g) and *p*-toluenesulfonyl chloride (3.90 g, 5 mol equivalents for **20**) in dry pyridine (50 ml) was kept at room temperature overnight. The solution showed, on TLC with $CHCl_3$–IPA (15 : 1), three spots of R_f 0.30 (**21**, major), 0.36 (**22**), and 0.38 (**23**). After addition of water, the reaction mixture was treated likewise as descibed[17] (preparation of **5** in that literature) to give **21** (2.76 g, 58%; mp 149—150 °C (lit, [17]149—150 °C), $[\alpha]_D^{20}$ +88° (*c* 1, MeOH) (lit,[17] +88°)), **22** (0.60 g, 12.5%), and **23** (0.36 g, 6%).

22: mp 152—153 °C (dec), $[\alpha]_D^{20}$ +118° (*c* 1, DMF); PMR ($(CD_3)_2SO$): δ 2.42 (3H s, CH_3(Ts)).

Found: C, 53.78; H, 6.15; N, 5.88; S, 2.85%. Calcd for $C_{53}H_{75}N_5O_{23}S$: C, 53.84; H, 6.40; N, 5.93; S, 2.71%.

23: $[\alpha]_D^{25}$ +79° (*c* 1, MeOH); PMR ($CDCl_3$): δ 2.47 (6H s, CH_3(Ts)).

Found: C, 54.08; H, 6.12; N, 5.36; S, 4.71%. Calcd for $C_{60}H_{81}N_5O_{25}S_2$: C, 53.92; H, 6.11; N, 5.24; S, 4.80%.

*2″-O-Benzoyl-4″,6″-O-cyclohexylidene-pentakis(N-ethoxycarbonyl)-4′-O-mesylkanamycin B (**26**).* To a cold (−20 °C) solution of **20** (101 mg) in dry DMF (1 ml) containing dry pyridine (0.048 ml, 6 mol equivalents for **20**), tosyl chloride (38.2 mg) was added and the solution was kept for 2 h in the cold. The solution showed, on TLC with $CHCl_3$–IPA (10 : 1), a single spot at R_f 0.2 (mainly **24**) (*cf.* **19**, R_f 0.1). Concentration of the solution below 30 °C gave a syrup, which was dissolved in chloroform. The solution was washed with 5% aqueous sodium hydrogencarbonate and water, dried ($MgSO_4$), and concentrated *in vacuo* with several additions of toluene to give a colorless solid (114 mg). The solid was vigorously stirred with ether and filtered. The solid (108 mg) contained a trace amount of di-*O*-formyl(?) product (R_f 0.21). To a solution of the solid in pyridine (2 ml), mesyl chloride (0.024 ml, 3 mol equivalents for **20**) was added and the solution was kept at room temperature for 4 h. The solution showed, on TLC (E. Merck), a single spot at R_f 0.49 (mainly **25**) *cf.* mono-*O*-formyl product, R_f 0.42). Work up as described for **5** gave a solid (112 mg). A solution of the solid in dioxane (1 ml) and 28% aqueous ammonia (0.1 ml) was kept at room temperature for 15 min. The solution showed, on TLC, a single spot at R_f 0.40. Concentration followed by washing of the residue with water gave a solid (100 mg). The solid was washed with ethyl acetate (1 ml×2) with vigorous stirring to give a colorless solid of **26**, 68 mg (62% based on **20**). The ethyl acetate-soluble part (30 mg) is mainly composed of **20**. Compound **26** has fairly low solubility in usual organic solvents.

26: $[\alpha]_D^{25}$+105° (*c* 1, DMF); PMR (Py-d_5): δ 3.43 (3H s, CH_3SO_2).

Found: C, 51.14; H, 6.44; N, 6.16; S, 2.88%. Calcd for $C_{47}H_{71}N_5O_{23}S$: C, 51.03; H, 6.47; N, 6.33; S, 2.90%.

*2″-O-Benzoyl-4″,6″-O-cyclohexylidene-4′-deoxy-pentakis(N-ethoxycarbonyl)-4′-iodokanamycin B (**27**).* *A. From **22***: A mixture of **22** (517 mg) and sodium iodide (5.0 g) in DMF (10 ml) was heated at 100 °C for 3 h. Work up as described for **7** gave a solid of **27**, 359 mg (72%), $[\alpha]_D^{20}$ +78° (*c* 1, MeOH).

Found: C, 48.69; H, 5.91; N, 6.01; I, 10.80%. Calcd for $C_{46}H_{68}N_5O_{20}I$: C, 48.55; H, 6.02; N, 6.15; I, 11.15%.

*B. From **26***: A mixture of **26** (49.3 mg) and sodium iodide (500 mg) in DMF (1 ml) was heated at 100 °C for 10 h. Work up as described in A gave **27**, 46.8 mg (92%). Compounds **27** obtained by A and B were identical in every respect.

*2″-O-Benzoyl-4″,6″-O-cyclohexylidene-4′-deoxy-pentakis(N-ethoxycarbonyl)kanamycin B (**28**).* Compound **27** (49.6 mg) was treated as described for **8** to give a solid of **28**, 37.3 mg (85%), mp 256—257 °C, $[\alpha]_D^{20}$ +93° (*c* 1, MeOH),

Found: C, 54.47; H, 6.73; N, 6.65%. Calcd for $C_{46}H_{69}N_5O_{20}$: C, 54.59; H, 6.87; N, 6.92%.

The authors are grateful to Dr. Hiroshi Naganawa of Institute of Microbial Chemistry for collaboration on ^{13}C NMR spectral studies.

(Received March 1, 1977)

5-*O*-[3-*O*-(2-Amino-2-deoxy-α-D-glucopyranosyl)-β-D-ribofuranosyl]-3′-deoxyparomamine was prepared by two different routes. The first route involves glycosylation of a protected 1-*N* : 6-*O*-carbonyl-3′-deoxyparomamine with a protected 3-*O*-(2-amino-2-deoxy-α-D-glucopyranosyl)ribofuranosyl bromide and subsequent removal of the protecting groups. In the second route, 1-*N* : 6-*O*-carbnyl-3′-deoxyparomamine was glycosylated with a protected ribosyl bromide having 3-*O*-benzylthiocarbonyl group to give a pseudotrisaccharide and, after de-3-*O*-benzylthiocarbonylation, the product was further condensed with a protected 1-bromide of 2-amino-2-deoxy-D-glucose. This synthesized lividomycin B analogue showed only very weak antibacterial activity and the role of the 6″-amino group of lividomycin in the action was suggested.

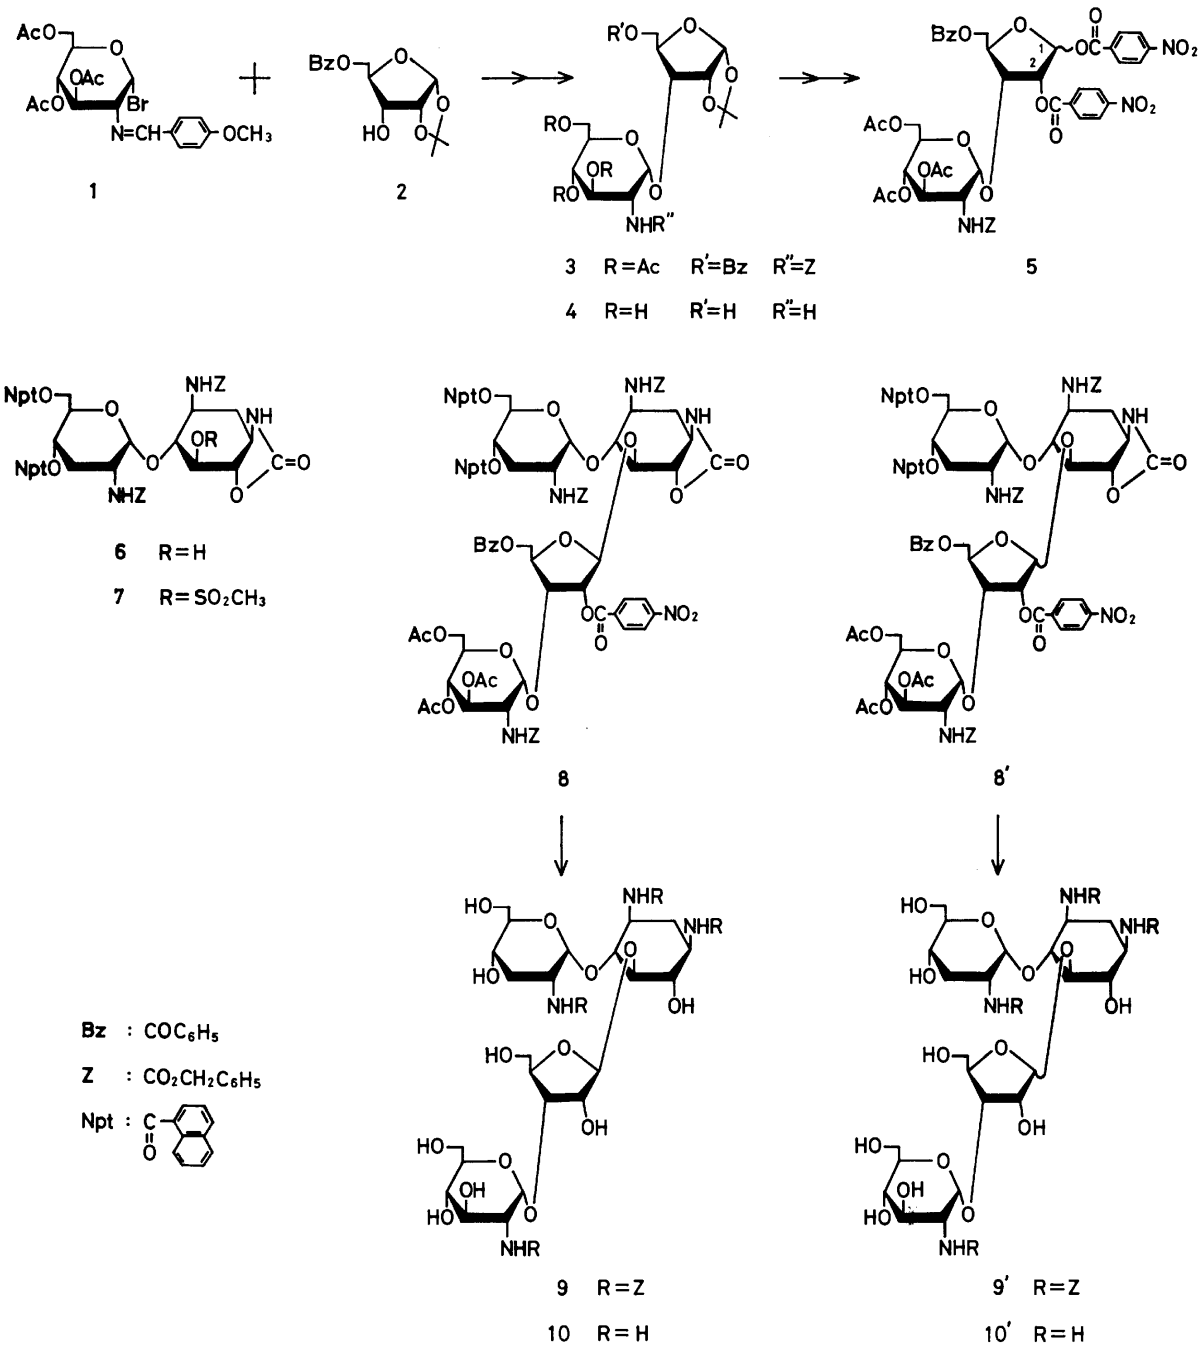
Lividomycin B[1] is an aminoglycoside antibiotic which belongs to a pseudotetrasaccharide. Since its pseudotrisaccharide[2] portion which lacks the 2,6-diamino-2,6-dideoxy-L-idopyranose moiety has only very weak antibacterial activity, this diaminohexose moiety has been suggested to enhance the antibacterial activity in a great extent. However, it has not yet been certain, which amino group in this diaminohexose moiety has the predominant role to increase the activity. Therefore, we attempted to replace this diaminohexose moiety of lividomycin B with 2-amino-2-deoxy-D-glucose.

Among two synthetic routes considered, we at first prepared this lividomycin B analogue by condensation of a disaccharide with a pseudodisaccharide. The disaccharide was prepared by condensation of 3,4,6-tri-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylidene)amino-α-D-glucopyranosyl bromide[3] (**1**) with 5-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-ribofuranose[4] (**2**) in benzene in the presence of mercury(II) cyanide as catalyst. Acid hydrolysis of the *N*-(*p*-methoxybenzylidene) group of the condensation product followed by *N*-benzyloxycarbonylation gave the protected disaccharide (**3**) in 54% yield (based on **2**). The high yield formation of the α-D-glucoside may be ascribed in part to the presence of the 2-*N*-(*p*-methoxybenzylidene) group.[5] To confirm the α-D-glucoside linkage of **3**, the *O*-acyl and *N*-benzyloxycarbonyl groups of **3** were removed. The PMR spectrum and the optical rotation of the deacylated product (**4**) substantiated the α-D-glucoside linkage. Then, the isopropylidene group of **3** was removed by 95% formic acid treatment without affecting the glucosyl bond and the *O*-acyl groups, and the resulting free hydroxyl groups at C-1 and 2 were *p*-nitrobenzoylated to give **5**. The presence of the 2-*O*-(*p*-nitrobenzoyl) group prevents undesirable orthoester[6] formation in the subsequent glycosylation. Treatment of **5** with hydrogen bromide in dichloromethane gave the corresponding 1-bromide.

The protected pseudodisaccharide, namely 3,2′-bis(*N*-benzyloxycarbonyl)-1-*N* : 6-*O*-carbonyl-3′-deoxy-4′,6′-di-*O*-(α-naphthoyl)paromamine (**6**), which is moderately soluble in organic solvents, was prepared by treatment of tris(*N*-benzyloxycarbonyl)-3′-deoxyparomamine[7] with sodium hydride in *N*,*N*-dimethylformamide (DMF)[8] followed by regioselective acylation with α-naphthoyl chloride. The positions of the α-naphthoyl groups in **6** were confirmed by the hydrolysis of mono-*O*-mesyl derivative (**7**) of **6**. Paper chromatography of the acidic hydrolyzate of **7** gave no detectable 2-deoxystreptamine, whereas the same treatment of **6** gave 2-deoxystreptamine, indicating that the 5-hydroxyl group of **6** was mesylated. Condensation of **6** with the abovementioned 1-bromide of **5** was carried out in dichloromethane in the presence of mercury(II) cyanide, and, the condensation products having β-D (**8**) and α-D (**8′**) glycoside linkages were separated by silica gel chromatography in yields of 33 and 47%, respectively. Treatment of **8** and **8′** with sodium benzylate in benzyl alcohol removed all the *O*-acyl groups and, simultaneously cleaved the 1,6-carbamate into 1-benzyloxycarbonylamino and 6-hydroxyl groups to give **9** and **9′**, respectively. Hydrogenolysis of **9** and **9′** with palladium black removed the benzyloxycarbonyl groups and gave the desired pseudotetrasaccharide (**10**) and its α-D-anomer (**10′**), respectively.

The anomeric configurations of **10** and **10′** were identified by their PMR spectra, and their pseudotetrasaccharide structures were supported by paper chromatography of their methanolyzates.

In another route, the pseudodisaccharide derivative (**6**) was successively glycosylated with a protected ribofuranosyl bromide and then with the glucosamine derivative (**1**). The aforementioned protected ribose **2** was led to 3-*O*-benzylthiocarbonyl derivative (**11**) by treatment with benzylthiocarbonyl chloride in pyridine. This protecting group[9] was chosen because of its easy elimination by oxidation with hydrogen peroxide to liberate the free hydroxyl group at C-3 of the ribose moiety. Acidic solvolysis of **11** to remove the isopropylidene group followed by *p*-nitrobenzoylation gave methyl 3-*O*-benzylthiocarbonyl-2-*O*-(*p*-nitrobenzoyl)-β-D- and α-D-riboside (**12** and **12′**). The structures of **12** and **12′** were confirmed by their PMR spectra as well as by those of the debenzylthiocarbonylated product (**13** and **13′**) of **12** and **12′**. In the spectrum of **12′** a virtual coupling[10] between H-1 and 3 was observed and it was further observed that 2-*O*→3-*O*-(*p*-nitrobenzoyl) migration gradually occurred when the solu-

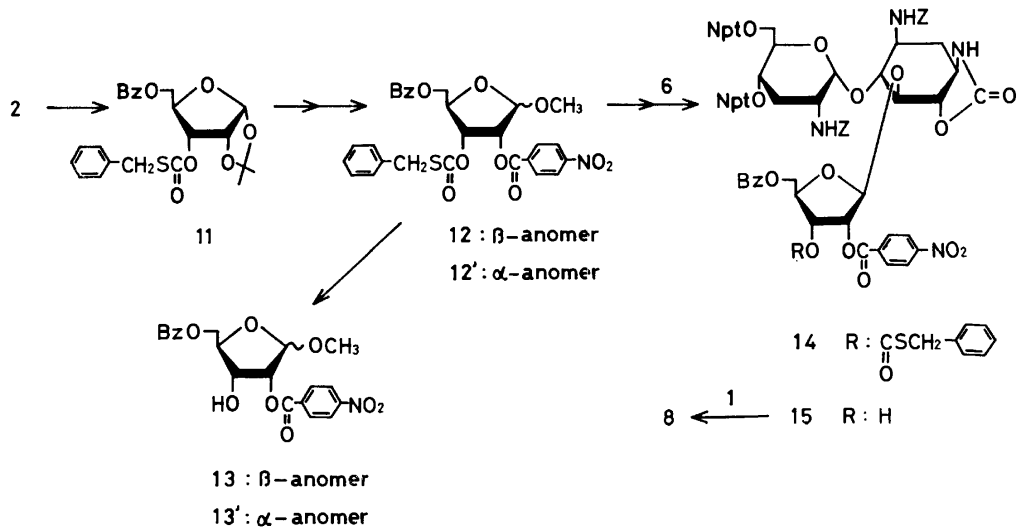


tion (in pyridine-d_5 containing deuterium oxide) of **13** and **13'** were allowed to stand (see Experimental).

Treatment of **12** with hydrogen bromide in acetic acid gave the 1-bromide, which was used without purification, for coupling with **6** in a manner described above to give the condensation product (**14**) in 66% yield. The β-anomeric configuration (at C-1") of **14** could not be determined at this stage, but was made clear at the last step which gave **10** identical with that prepared by the alternative route aforementioned. Removal of the benzylthiocarbonyl group with hydrogen peroxide in acetic acid gave the product (**15**) having a free hydroxyl group at C-3". In this reaction, a slight amount of 3"-*O*-(*p*-nitrobenzoyl) derivative was formed by migration. The structure of **15** was confirmed by recovery of **14** from **15** with the benzylthiocarbonyl chloride treatment. The condensation of **15** with **1** was achieved in benzene in the presence of silver reagents to give **8**, in 30% yield, which was led to the desired product (**10**).

The overall yield of **10** by the second route was lower than that by the first route. However, it should be noted that the first route gave a larger amount of the α-riboside (**8'**) than the desired β-riboside (**8**). In the second route no α-riboside was obtained.

The synthesized pseudotetrasaccharide (**10**) showed much weaker antibacterial activities than lividomycin B and this result suggested that the 6"'-amino group



of lividomycin B has a predominant role in increasing the antibacterial activity. The corresponding α-anomer (**10′**) showed no antibacterial activity.

Experimental

Thin-layer chromatography (TLC) was carried out on Wakogel B-5 with sulfuric acid spray for detection unless otherwise stated. For column-chromatography, silica gel (Wakogel C-200) was used. Descending paper chromatography was performed on Toyo-Roshi Paper No. 50 with 1-butanol–pyridine–water–acetic acid (6 : 4 : 3 : 1), and spots were visualized by spraying 0.5% ninhydrin in pyridine. PMR spectra were recorded at 60 and 90 MHz with Hitachi R-24A and Varian EM-390 spectrometers, respectively.

*5-O-Benzoyl-1,2-O-isopropylidene-α-D-ribofuranose (**2**).* The compound was prepared in a different way from the reported one.[4] 5-*O*-Benzoyl-1,2-*O*-isopropylidene-D-*erythro*-pentofuranos-3-urose[11] (2 g) dissolved in methanol was treated with sodium borohydride in a usual manner to give **2** as needles (from ethyl acetate–diisopropyl ether, 1.7 g, 86%), mp 81—82 °C (lit,[4] 78—79 °C), $[\alpha]_D^{26}$ +32° (*c* 1, $CHCl_3$) (lit,[4] +20.05° in $CHCl_3$).

*3-O-(3,4,6-Tri-O-acetyl-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranosyl)-5-O-benzoyl-1,2-O-isopropylidene-α-D-ribofuranose (**3**).* To a solution of 3,4,6-tri-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylidene)amino-α-D-glucopyranosyl bromide[3] (**1**, 1.34 g) in dry benzene (18 ml), 5-*O*-benzoyl-1,2-*O*-isopropylideneribofuranose[2] (**2**, 0.58 g,) mercury(II) cyanide (1.3 g), and calcium sulfate (Drierite 2.7 g) were added and the mixture was stirred at room temperature overnight. After addition of chloroform (100 ml), the mixture was centrifuged. The organic layer separated was washed with aqueous sodium hydrogencarbonate and water, dried (Na_2SO_4), and concentrated. The resulting syrup was dissolved in a mixture of methanol (36 ml) and 50% aqueous acetic acid (16 ml) and the solution was kept at room temperature for 4 h. After addition of powdered sodium carbonate (7.1 g), the solution was concentrated. The residue was extracted with acetone and the extract was concentrated to dryness. To an ice cold solution of the residue in aqueous acetone (3 : 10, 50 ml), sodium carbonate (900 mg) and benzyl chloroformate (1.8 g) were added and the mixture was stirred for 1 h in the cold. Evaporation followed by extraction with chloroform and evaporation of the solvent gave a syrup. Since **2** which remained unreacted had the same mobility with that of **3** on column chromatography, **3** was separated after acetylation of the remaining **2**. A mixture of the syrup and acetic anhydride (2 ml) in pyridine (40 ml) was allowed to stand at 37 °C overnight. Evaporation, extraction of the residue with chloroform, washing of the solution (aqueous potassium hydrogensulfate, aqueous sodium hydrogencarbonate, and water), drying (Na_2SO_4), and evaporation of the solvent gave a syrup. The syrup was chromatographed over silica gel with benzene–ethyl acetate (8 : 1) to give **3** (syrup), 748 mg (54%), $[\alpha]_D^{20}$ +102° (*c* 1, $CHCl_3$); IR (KBr): 1740, 1720 cm^{-1}; PMR ($CDCl_3$) δ: 1.22 and 1.53 (each 3H s, $C(CH_3)_2$), 1.94, 2.00, and 2.02 (each 3H s, Ac), 5.07 (1H d, J=3.5 Hz, H-1′), 5.91 (1H d, J=3.5 Hz, H-1).

Found: C, 58.67; H, 5.78; N, 1.78%. Calcd for $C_{35}H_{41}NO_{15}$: C, 58.74; H, 5.77; N, 1.96%.

*3-O-(2-Amino-2-deoxy-α-D-glucopyranosyl)-1,2-O-isopropylidene-α-D-ribofuranose (**4**).* A solution of **3** (100 mg) in methanol containing 5% ammonia (5 ml) was kept at room temperature overnight and the solution was concentrated. To a solution of the residue in dioxane (2 ml), water (1 ml) and two drops of acetic acid were added and the mixture was hydrogenated with palladium black in an atmospheric pressure of hydrogen. After filtration, the filtrate was concentrated to give a syrup, which was chromatographed over CM-Sephadex C-25 (NH_4 form) with 0.05 M aqueous ammonia to give a ninhydrin-positive solid of **4** as hemihydrate, 20 mg (40%), $[\alpha]_D^{18}$ +165° (*c* 0.5, H_2O); PMR (D_2O) δ: 1.43 and 1.61 (each 3H s, $C(CH_3)_2$), 2.78 (1H q, $J_{1',2'}$=3.7 Hz, $J_{2',3'}$=9.5 Hz, H-2′), 4.95 (1H m, H-2), 5.12 (1H d, J=3.7 Hz, H-1′), 5.96 (1H d, J=3.8 Hz, H-1).

Irradiation of H-2′ collapsed the doublet of H-1′ to a singlet and irradiation of H-1′ collapsed the quartet of H-2′ to a doublet (J=9.5 Hz). Irradiation of H-1 (δ 5.96) collapsed the multiplet of H-2 to an incomplete triplet ($J \approx 1.9$ Hz).

Found: C, 46.75; H, 6.96; N, 3.70%. Calcd for $C_{14}H_{25}NO_{19} \cdot 1/2H_2O$: C, 46.66; H, 7.27; N, 3.89%.

*3-O-(3,4,6-Tri-O-acetyl-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranosyl)-5-O-benzoyl-1,2-bis-O-(p-nitrobenzoyl)-D-ribofuranose (**5**).* A solution of **3** (621 mg) in 95% aqueous formic acid (30 ml) was kept at room temperature for 3.5 h. Concentration *in vacuo* at room temperature gave a syrup. The chloroform solution of the syrup was washed with aqueous sodium hydrogencarbonate and water, dried (Na_2SO_4), and concentrated. To a solution of the resulting syrup in dry pyridine (8 ml), *p*-nitrobenzoyl chloride (626 mg) was added and the solution was kept at room temperature overnight.

After addition of water (0.1 ml), the solution was concentrated. The chloroform solution (50 ml) of the residue was washed with aqueous potassium hydrogensulfate, aqueous sodium hydrogencarbonate, and water, dried (Na_2SO_4), and concentrated. The resulting syrup was chromatographed over silica gel with benzene–ethyl acetate (10 : 1) to give a syrup of **5**, 572 mg (68%), $[\alpha]_D^{23}$ +72° (*c* 1, $CHCl_3$); IR (KBr): 1725, 1520 cm^{-1}.

Found: C, 56.82; H, 4.65; N, 4.02%. Calcd for $C_{46}H_{43}N_3O_{21}$: C, 56.73; H, 4.45; N, 4.31%.

*3,2′-Bis(*N*-benzyloxycarbonyl)-1-*N*:6-O-carbonyl-3′-deoxy-4′,6′-di-O-(α-naphthoyl)paromamine (6).* To an ice-cold solution of 1,3,2′-tris(*N*-benzyloxycarbonyl)-3′-deoxyparomamine[7] (3.0 g) in DMF (60 ml), 50% oily suspension (600 mg) of sodium hydride was added under nitrogen atmosphere and the mixture was stirred vigorously for 2.5 h. After addition of acetic acid (0.8 ml), the mixture was poured into ice-water. The precipitates of 1,6-carbamate were filtered and dried (2.35 g). To a cold (−20 °C) solution of the solid in pyridine (45 ml), α-naphthoyl chloride (610 mg×3) was added and the solution was kept at −10 °C for 9 h (3 h×3). After concentration, the residue was dissolved in chloroform. The solution was washed (with aq $KHSO_4$, aq $NaHCO_3$, and H_2O) as described for **3** to give a solid, which was chromatographed over silica gel with chloroform–ethanol (50 : 1) to give a solid of **6**, 2.78 g (76%), $[\alpha]_D^{22}$ +69° (*c* 1, $CHCl_3$); IR (KBr): 1775 cm^{-1} (shoulder, cyclic carbamate).

Found: C, 67.31; H, 5.26; N, 4.64%. Calcd for $C_{51}H_{47}N_3O_{13}$: C, 67.32; H, 5.21; N, 4.62%.

*3,2′-Bis(*N*-benzyloxycarbonyl)-1-*N*:6-O-carbonyl-3′-deoxy-5-O-mesyl-4′,6′-di-O-(α-naphthoyl)paromamine (7).* To a solution of **6** (180 mg) in dry pyridine (4 ml), methanesulfonyl chloride (200 mg) was added and the solution was kept at room temperature overnight. The solution showed, on TLC with chloroform–methanol (30 : 1), a single spot at R_f 0.33. Work up in a usual manner gave a solid of **7**, 172 mg (88%), $[\alpha]_D^{24}$ +49° (*c* 1, $CHCl_3$); IR (KBr): 1180, 1350 (Ms) cm^{-1}; PMR: δ of SO_2CH_3: 3.07 (in $CDCl_3$), 3.18 (in $CDCl_3$–CD_3OD=1 : 1), 3.43 (in C_5D_5N).

Found: C, 63.00; H, 5.16; N, 4.16; S, 3.47%. Calcd for $C_{52}H_{49}N_3O_{15}S$: C, 63.21; H, 5.00; N, 4.25; S, 3.25%.

Acidic Methanolysis of 7. A solution of **7** in 2 M methanolic hydrogen chloride was heated at 80 °C for 40 h. As a control experiment, **6** was similarly treated. Paper chromatography of the methanolyzate of **7** gave no 2-deoxystreptamine, whereas that of **6** did.

*5-O-[3-O-(3,4,6-Tri-O-acetyl-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranosyl)-5-O-benzoyl-2-O-(*p*-nitrobenzoyl)-β-* and *α-D-ribofuranosyl]-3,2′-bis(*N*-benzyloxycarbonyl)-1-*N*:6-O-carbonyl-3′-deoxy-4′,6′-di-O-(α-naphthoyl)paromamine (8 and 8′).* *A. From 5 and 6*: To a cold (−10 °C) solution of **5** (1.75 g) in dry dichloromethane (50 ml), hydrogen bromide was introduced until saturation and the solution was kept at −10 °C for 30 min. Colorless needles of *p*-nitrobenzoic acid was deposited. Filtration followed by concentration of the filtrate at room temperature gave a syrup, which was dissolved in dichloromethane (11 ml). To the solution, **6** (516 mg), mercury(II) cyanide (1.85 g), and calcium sulfate (Drierite 3.75 g) were added and the mixture was vigorously stirred at room temperature overnight. On TLC with chloroform–ethanol (30 : 1), the reaction mixture showed two marked spots at R_f 0.37 (**8**), 0.29 (**8′**). The mixture was filtered with aid of chloroform. The filtrate was concentrated to give a syrup, which was chromatographed over silica gel with chloroform–ethanol (100 : 1) to give a solid of **8**, 316 mg (33% from **6**) and a solid of **8′**, 456 mg (47% from **6**).

Compound **8**: $[\alpha]_D^{20}$ +51° (*c* 1, $CHCl_3$): IR(KBr): 1780 (s), 1725, 1530 cm^{-1}.

Found: C, 62.59; H, 5.05; N, 4.05%. Calcd for $C_{90}H_{85}N_5O_{30}$: C, 62.97; H, 4.99; N, 4.08%.

Compound **8′**: $[\alpha]_D^{20}$+69° (*c* 0.5, $CHCl_3$): IR(KBr): 1780 (s), 1725, 1530 cm^{-1}.

Found: C, 63.04; H, 5.05; N, 4.04%.

B. From 1 and 15: To a solution of **1** (222 mg) in dry benzene (4 ml), **15** (194 mg), freshly prepared silver carbonate (230 mg), silver perchlorate (23 mg), and calcium sulfate (Drierite 550 mg) were added and the mixture was stirred at room temperature overnight in a dark place. The reaction mixture was filtered with aid of chloroform (20 ml) and the filtrate was concentrated. The residue was dissolved in a mixture of chloroform (2 ml), methanol (4 ml), acetic acid (1 ml) and water (1 ml), and the solution was kept at room temperature overnight. After addition of powdered sodium carbonate (930 mg), the mixture was concentrated *in vacuo*. The residue was extracted with chloroform and the extract was washed with water, dried (Na_2SO_4), and concentrated to give a solid. To a cold (0 °C) solution of the solid in aqueous acetone (1 : 2, 6 ml), benzyl chloroformate (150 mg) and sodium carbonate (600 mg) were added and the mixture was stirred at 0 °C for 1.5 h. After evaporation of the mixture was extracted with chloroform. The solution was washed with water, dried (Na_2SO_4), and evaporated to give a solid, which was chromatographed over silica gel with chloroform–ethanol (60 : 1) to give a solid of **8**, 77 mg (30% based on **14**), $[\alpha]_D^{23}$ +52° (*c* 1, $CHCl_3$). Recovered **15** by the chromatography was 80 mg (41%).

Found: C, 62.61; H, 5.11; N, 3.87%. Calcd for $C_{90}H_{85}N_5O_{30}$: C, 62.97; H, 4.99; N, 4.08%.

*1,3,2′-Tris(*N*-benzyloxycarbonyl)-5-O-[3-O-(2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranosyl)-β-* and *α-D-ribofuranosyl]-3′-deoxyparomamines (9 and 9′).* To a solution of **8** (42 mg) in dry dioxane (0.17 ml), 0.27 M sodium benzylate in benzyl alcohol (0.63 ml, benzyl alcohol was dried over molecular sieves 4A) were added and the solution was kept at 37 °C for 2 h. After addition of chloroform (27 ml), the organic solution was washed thoroughly with water, dried (Na_2SO_4), and concentrated to give a syrup. The syrup was chromatographed over silica gel with chloroform (to elute the alcohol remained) and then with chloroform–ethanol (4 : 1) to give **9**, 23 mg of solid (83%), $[\alpha]_D^{19}$ +58° (*c* 0.4, MeOH).

Found: C, 56.65; H, 5.89; N, 4.94%. Calcd for $C_{55}H_{68}N_4O_{22}\cdot H_2O$: C, 57.19; H, 6.11; N, 4.85%.

Compound **9′** was obtained from **8′** in a similar manner as described above in a yield of 83%; $[\alpha]_D^{19}$ +113° (*c* 0.5, MeOH).

Found: C, 56.90; H, 5.98; N, 4.88%.

5-O-[3-O-(2-Amino-2-deoxy-α-D-glucopyranosyl)-β- and *α-D-ribofuranosyl]-3′-deoxyparomamines (10 and 10′).* A mixture of **9** (80 mg) in aqueous dioxane (1 : 3, 4 ml) containing two drops of acetic acid was hydrogenated with palladium black in an atmospheric pressure of hydrogen. On TLC (E. Merck, silica gel 60 F_{254}) with chloroform–methanol–17% aqueous ammonia (1 : 4 : 3), the solution showed a major spot at R_f 0.51 (in the case of **10′**, R_f 0.59). Concentration of the solution gave a solid, which was chromatographed over CM-Sephadex C-25 (NH_4 form) with 0.05 M aqueous ammonia to give **10** as a solid of monocarbonate, 34 mg (73%); PPC, $R_{f\ \text{Hydromycin B}}$ 1.49, $[\alpha]_D^{23}$ +77° (*c* 0.7, H_2O); PMR (D_2O+DCl, pH ≈3) δ: 5.34 (1H d, J≈4 Hz, H-1′ or 1‴), 5.36 (1H s, H-1″), 5.53 (1H d, J=3.0 Hz, H-1′ or 1‴).

Found: C, 43.27; H, 7.28; N, 8.26%. Calcd for $C_{23}H_{44}N_4O_{14}\cdot H_2CO_3$: C, 43.50; H, 6.99; N, 8.45%.

Compound **10′** was obtained from **9′** in a similar manner

as described above in a yield of 77.5% as monocarbonate; PPC, R_f lividomycin B 1.63, $[\alpha]_D^{23}$ +119° (*c* 0.7, H_2O); PMR (D_2O)δ: 4.95 (1H d, $J\approx4$ Hz), 5.13 (1H d, $J\approx2.7$ Hz), 5.23 (1H d, $J\approx3$ Hz) (each anomeric proton); in D_2O+DCl (pH≈3): δ: 5.34 (1H d, $J\approx3$ Hz), 5.35 (1H d, $J\approx4$ Hz), and 5.48 (1H d, $J\approx2.5$ Hz) (each anomeric proton).

Found: C, 43.63; H, 7.22; N, 8.29%.

Acidic Methanolysis of ***10*** *and* ***10′***. A solution of **10**, **10′**, or lividomycin B in 0.4 M methanolic hydrogen chloride was heated at 65 °C for 25 h, and the solution was examined by TLC (E. Merck, silica gel 60 F_{254}) with chloroform–methanol–17% aqueous ammonia (2 : 2 : 1). The methanolyzates of **10** and **10′** gave the same TLC pattern. From the comparison of the R_f values of the spots on the chromatograms with those of the hydrolyzate of lividomycin B and other reference substances, assignments of the spots were made: R_f 0.12 (2-deoxystreptamine), 0.25 (3′-deoxyparomamine), 0.52 [methyl 3-O-(2-amino-2-deoxy-α-D-glucopyranosyl)riboside], 0.58 (methyl 2-amino-2-deoxy-D-glucoside), 0.62 (methyl 2-amino-2,3-dideoxy-D-glucoside).

*5-O-Benzoyl-3-O-benzylthiocarbonyl-1,2-O-isopropylidene-α-D-ribofuranose (****11****).* To a solution of **2** (3.0 g) in pyridine (50 ml), benzylthiocarbonyl chloride (3 ml) was added and the solution was kept at room temperature overnight. After addition of water (0.5 ml), the solution was concentrated and the chloroform solution of the residue was washed (with aq $KHSO_4$, aq $NaHCO_3$, and H_2O), dried (Na_2SO_4), and concentrated. The residue was recrystallized from methanol to give colorless needles, 4.2 g (93%), mp 68—69 °C, $[\alpha]_D^{23}$ +141° (*c* 1, $CHCl_3$); PMR ($CDCl_3$) δ: 1.38 and 1.60 (each 3H s, $C(CH_3)_2$), 4.17 (2H s, CH_2S), 5.94 (1H m, J=5 Hz, H-1).

Found: C, 62.27; H, 5.47; S, 7.12%. Calcd for $C_{23}H_{24}O_7S$: C, 62.15; H, 5.44; S, 7.12%.

*Methyl 5-O-Benzoyl-3-O-benzylthiocarbonyl-2-O-(p-nitrobenzoyl)-β- and α-ribofuranosides (****12*** *and* ***12′****).* To a solution of **11** (3.5 g) in dry dichloromethane (21 ml), 0.4 M methanolic hydrogen chloride (50 ml) was added and the solution was kept at room temperature for 40 h. Pyridine (3 ml) was added and the solution was concentrated with intermittent additions of pyridine to give a syrup. To a solution of the syrup in pyridine (30 ml), a solution of *p*-nitrobenzoyl chloride (3.3 g) in dichloromethane (8 ml) was added and the solution was kept at room temperature for 3 h. On TLC with benzene–ethyl acetate (30 : 1), the solution showed two spots at R_f 0.54 (major **12**) and 0.50 (minor, **12′**). Work up as described for **11** gave a syrup, which was chromatographed over silica gel with benzene–ethyl acetate (100 : 1) to give a pale-yellow syrup of **12**, 2.96 g (66%), and pale-yellow needles (recrystallized from methanol) of **12′**, 1.05 g (24%).

Compound **12**: $[\alpha]_D^{24}$ +90° (*c* 1, $CHCl_3$).

Found: C, 59.52; H, 4.50; N, 2.41; S, 5.41%. Calcd for $C_{28}H_{25}NO_{10}S$: C, 59.25; H, 4.44; N, 2.47; S, 5.65%.

PMR ($CDCl_3$) δ: 3.43 (3H s, OCH_3), 4.07 (2H s, CH_2S), 5.15 (1H s, H-1), 5.6—5.85 (2H m, H-2,3). In pyridine-d_5: δ 5.38 (1H s, which sharpend on irradiation at δ 6.0, H-1), 6.0 [1H d, $J_{2,3}$=5 Hz, with small splittings ($J_{1,2}\approx1$ Hz), which disappeared, on irradiation at δ 5.38, to give a sharp d, H-2], 6.08 (1H t, $J_{2,3}=J_{3,4}$=5 Hz, H-3). On irradiation at δ 4.8, the triplet of H-3 collapsed to a doublet.

Compound **12′**: mp 110—110.5 °C, $[\alpha]_D^{20}$ +147° (*c* 1, $CHCl_3$).

Found: C, 58.95; H, 4.46; N, 2.39; S, 5.45%. Calcd for $C_{28}H_{25}NO_{10}S$: C, 59.25; H, 4.44; N, 2.47; S, 5.65%.

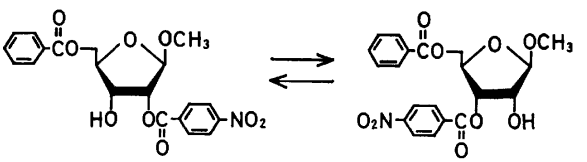
PMR (in $CDCl_3$ at 90 MHz) δ: 3.49 (3H s, OCH_3), 4.13 (2H AB q, J_{gem}=13 Hz, CH_2S), 5.2—5.45 (2H m, H-1,2), 5.55—5.75 (1H m, H-3). Since any signal distance of H-1,2 multiplet and that of H-3 multiplet did not accord each other, the occurrence of virtual coupling[10] between H-1 and H-3 was suggested. To clarify this, the solvent was changed: among the solvents tested, pyridine-d_5 was found most suitable and the signals of **12′** assignable to H-1,2, and 3 were separated each other without virtual coupling as follows: δ (at 90 MHz) 3.46 (3H s), 4.27 (2H s, CH_2S), 4.7—5.0 (3H, H-4,5,5′), 5.60 (1H d, $J_{1,2}$=4.7 Hz, H-1), 5.78 (1H q, J=4.7 and 7.2 Hz (=$J_{2,3}$), H-2), 6.12 (1H double q, J=7, ≈2, and ≈1 Hz, H-3). Irradiation at δ 4.8, the multiplet of H-3 collapsed to a doublet (J=7 Hz).

*Methyl 5-O-Benzoyl-2-O-(p-nitrobenzoyl)-β- and α-D-ribofuranosides (****13*** *and* ***13′****).* To a solution of **12** (or **12′**) (100 mg) in chloroform (1 ml), acetic acid (3 ml) and 30% aqueous hydrogen peroxide (1 ml) was added and the solution was kept at room temperature overnight. The solution was pound, with stirring, into an ice–water (150 ml) containing sodium hydrogencarbonate (4.5 g). The mixture was extracted with chloroform and the solution was washed with water, dried (Na_2SO_4), and concentrated to give a solid of **13** (or **13′**).

Compound **13**: Yield 67 mg (91%), colorless needles (from benzene–hexane), mp 134—135 °C, $[\alpha]_D^{23}$ +6° (*c* 1, $CHCl_3$).

Found: C, 57.46; H, 4.63; N, 3.23%. Calcd for $C_{20}H_{19}NO_9$: C, 57.55; H, 4.59; N, 3.36%.

PMR (pyridine-d_5) δ: 3.45 (3H s, OCH_3), 5.34 (1H s, H-1), 5.80 (1H d, J=4.4 Hz, H-2). On addition of D_2O followed by keeping the solution at room temperature for 1 h, the doublet of H-2 (δ 5.79) was gradually weakened with concomitant increase in intensity of a quartet at 5.91 (J=4.0 and 7.0 Hz, H-3 of **13m**) although the singlet of H-1 (δ 5.40) remained unchanged. This shows that an acyl migration occurred as shown below.



13 **13m**

Compound **13′**: Yield 58 mg (79%), pale-yellow needles (from benzene–hexane); mp 73.5—74.5 °C, $[\alpha]_D^{23}$ +80° (*c* 0.8, $CHCl_3$).

Found: C, 57.73; H, 4.63; N, 3.38%. Calcd for $C_{20}H_{19}NO_9$: C, 57.55; H, 4.59; N, 3.36%.

PMR (pyridine-d_5) δ: 3.55 (3H s, OCH_3), 5.53 (1H d, $J_{1,2}$=4.5 Hz, H-1), 5.70 (1H q, J=4.5 and 5.9 Hz(=$J_{2,3}$), H-2). On addition of water, the signal pattern was gradually changed possibly by the similar migration described above, but the migration was much slower than that for **13**.

*5-O-[5-O-Benzoyl-3-O-(benzylthiocarbonyl)-2-O-(p-nitrobenzoyl)-β-D-ribofuranosyl]-3,2′-bis(N-benzyloxycarbonyl)-1-N : 6-O-carbonyl-3′-deoxy-4′,6′-di-O-(α-naphthoyl)paromamine (****14****).*
To a solution of **12** (1.9 g) in dry dichloromethane (5 ml), hydrogen bromide saturated in acetic acid (6 ml) was added and the solution was kept at room temperature for 1 h. The solution was concentrated *in vacuo* and the resulting syrup was dissolved in dichloromethane (40 ml). The solution was washed as fast as possible with aqueous sodium hydrogencarbonate and water, dried (Na_2SO_4), and concentrated to give a syrup. Immediately, to a solution of the syrup in dichloromethane (9 ml), **6** (1.0 g), mercury (II) cyanide (1.9 g) and calcium sulfate (Drierite, 3.8 g), were added and the mixture was vigorously stirred at room temperature overnight. The reaction mixture was filtered with aid of chloroform and the filtrate was concentrated. The resulting syrup was chromato-

graphed over silica gel with chloroform–ethyl acetate (5 : 1) to give a solid of **14**, 1.05 g (66% based on **6**), $[\alpha]_D^{23}$ +33° (*c* 0.5, $CHCl_3$); IR (KBr): 1780, 1725, 1530 cm^{-1}.

Found: C, 64.50; H, 4.89; N, 3.79; S, 2.38%. Calcd for $C_{78}H_{68}N_4O_{22}S$: C, 64.81; H, 4.74; N, 3.88; S, 2.22%.

5-O-[*5*-O-*Benzoyl-2*-O-(p-*nitrobenzoyl*)-β-D-*ribofuranosyl*]-*3,2'*-*bis*(N-*benzyloxycarbonyl*)-*1*-N : *6*-O-*carbonyl-3'-deoxy-4',6'-di*-O-(α-*naphthoyl*)*paromamine* (**15**). To a solution of **14** (600 mg) in acetic acid (18 ml), 30% aqueous hydrogen peroxide (2.1 ml) was added and the solution was kept at room temperature overnight. On TLC with chloroform–ethanol–acetic acid (150 : 5 : 1), the solution showed two spots at R_f 0.49 (major, **15**) and 0.41 (trace, 3″-*p*-nitrobenzoate isomer?). The solution was concentrated at room temperature and the residue was dissolved in chloroform. The solution was washed with water, dried (Na_2SO_4), and concentrated. The resulting solid was chromatographed over silica gel with chloroform–ethanol–acetic acid (500 : 10 : 1) to give a solid of **15**, 424 mg (79%), $[\alpha]_D^{23}$ +18° (*c* 0.5, $CHCl_3$).

Found: C, 65.03; H, 4.96; N, 4.17%. Calcd for $C_{70}H_{62}N_4O_{21}$: C, 64.91; H, 4.82; N, 4.33%.

Synthesis of Streptolidine Lactam, a Guanidine-containing Amino-acid Lactam Moiety of Streptothricin Antibiotic Group

Mitsuhiro KINOSHITA and Yoshiharu SUZUKI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received March 5, 1977)

Streptolidine lactam (**3**) present in streptothricin antibiotics was stereospecifically synthesized. 3,4-Anhydro-1,2 : 5,6-di-*O*-isopropylidene-D-iditol (**4**) was converted into the 3,4-bis(benzyloxycarbonylamino)-3,4-dideoxy-D-mannitol derivative **7** *via* the 3,4-diazido-3,4-dideoxy-D-mannitol derivative **6**. De-*O*-protection of **7** followed by two-stage oxidation with periodate–bromine afforded 2,3-bis(benzyloxycarbonylamino)-2,3-dideoxy-D-*arabono*-1,4-lactone (**8**), which was transformed into the azide lactone **9**. Selective hydrogenolysis of **9** with Raney Ni gave the *N*-protected amino sugar lactam **10**. *O*-Tetrahydropyranylation of **10** followed by hydrogenolysis afforded the *O*-protected amino sugar lactam **12**. Treatment of **12** with cyanogen bromide in water gave the *O*-tetrahydropyranylated streptolidine lactam **13**, which on mild acid hydrolysis afforded **3** (hydrochloride). The amino sugar lactam **14** obtained by hydrogenolysis of **9** with palladium black was also treated with cyanogen bromide to yield **3** (hydrobromide). Acid hydrolysis of **3** gave streptolidine (**2**)(dihydrochloride) identical with that derived from the antibiotics.

The ingenious studies on construction of the streptolin-streptothricin group of *streptomyces* antibiotics by Van Tamelen *et al.*[1] revealed the presence of a lactam ring in the streptolidine unit **A** of the intact antibiotic **1**.[2] Borders *et al.*[3] verified the lactam structure by comparison of the PMR spectra of antibiotic LL-AC-541 belonging to the streptothricin family and of streptolidine(**2**), a common degradation product of various streptothricin type antibiotics.

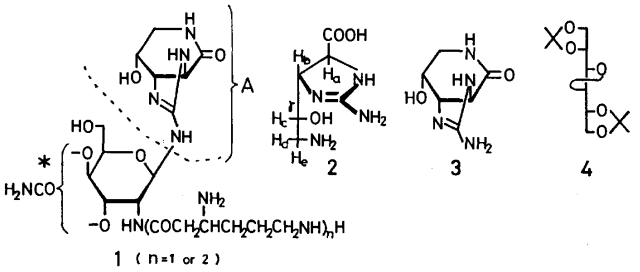

Chart 1.

During the course of synthetic studies on streptothricin antibiotics, we found it necessary to synthesize the streptolidine lactam **3** which corresponds to the cyclic guanidine-containing lactam moiety **A**, for use in a streptothricin antibiotic synthesis and for a biological test in connection with the role of **A** in the biological activity of the antibiotics.[1,5] This paper presents the first synthesis of **3** and its *O*-protected derivative **13**. Streptolidine(**2**) has been synthesized independently by Kusumoto *et al.*,[6] and Goto and Ohgi[7] *via* the amino sugar lactam **14** from D-ribose and D-xylose.[8] In the synthesis of streptolidine lactams, we also adopted the condensation reaction of amino sugar lactam with cyanogen bromide[6,7] for the cyclic guanidine ring formation. Consideration was given to the following points: (i) protection of the free hydroxyl group of the amino sugar lactam **14** stabilizes the lactam ring during the condensation reaction and (ii) the use of equivalent amounts of the pure amino sugar lactam and cyanogen bromide for the reaction minimizes any side reactions which might be caused by excess cyanogen bromide. The *O*-protected amino sugar lactam **12** and free lactam **14** were synthesized in moderate overall yields through the new stereospecific route from the 3,4-anhydro-D-iditol derivative **4** prepared from D-mannitol.[9,10]

* The indicated pattern for the carbamate group substitution has been shown to be most likely vaild for streptolin-streptothricin group (**1**) by Borders *et al.*[4]

Results and Discussion

Starting material, 3,4-anhydro-1,2 : 5,6-di-*O*-isopropylidene-D-iditol(**4**),[9] prepared *via* *trans*-3,4-didehydro-3,4-dideoxy-1,2 : 5,6-di-*O*-isopropylidene-D-*threo*-hexitol[10] from D-mannitol, was subjected to azidolysis with sodium azide in the presence of ammonium chloride in aqueous methyl cellosolve and the resulting azido hydroxy compound, without purification, was *O*-mesylated in the usual way, affording 3-azido-3-deoxy-1,2:5,6-di-*O*-isopropylidene-4-*O*-mesyl-D-talitol(**5**) in 61% overall yield from **4**. The mesylate **5** was allowed to react with sodium azide in DMSO to give 3,4-diazido-3,4-dideoxy-1,2 : 5,6-di-*O*-isopropylidene-D-mannitol (**6**) in 47% yield. Hydrogenolysis of **6** over palladium black in methanol followed by *N*-benzyloxycarbonylation with benzyl chloroformate in pyridine at −20 °C afforded 3,4-bis(benzyloxycarbonylamino)-3,4-dideoxy-1,2 : 5,6-di-*O*-isopropylidene-D-mannitol (**7**) in 77% yield. De-*O*-isopropylidenation of **7** with warm aqueous acetic acid followed by periodate oxidation with 1.2 equivalent of sodium periodate in aqueous acetone and subsequent oxidation with bromine in aqueous dioxane at room temperature gave 2,3-bis(benzyloxycarbonyl-

amino)-2,3-dideoxy-D-*arabono*-1,4-lactone (**8**) in 59% yield. *O*-Mesylation of **8** in the usual way followed by treatment with sodium azide in DMSO at 100 °C afforded 5-azido-2,3-bis(benzyloxycarbonylamino)-2,3,5-trideoxy-D-*arabono*-1,4-lactone (**9**) in 61% yield.

Selective hydrogenolysis of the azido group in **9** over Raney Ni in methanol led directly[11] to 5-amino-2,3-bis-(benzyloxycarbonylamino)-2,3,5-trideoxy-D-*arabono*- 1,5-lactam (**10**) in 63% yield after recrystallization. The 4-*O*-(tetrahydro-2-pyranyl) derivative **11** (an epimeric mixture about the 2-position of the pyran) was obtained by treatment of **10** with dihydropyran and a catalytic amount of *p*-toluenesulfonic acid in DMF at 37—40 °C in 80% yield after recrystallization. Hydrogenolysis of **11** over 10% palladium on charcoal in methanol at 50 psi affroded, after silica gel column chromatography, an almost pure sample of the *O*-protected sugar lactam **12**, whose IR spectrum($CHCl_3$) showed a δ-lactam band at 1660 cm^{-1}, in 77% yield. Treatment of **12** in water with 0.95 equivalent of cyanogen bromide gave the *O*-protected cyclic guanidine lactam **13** as a crystalline hydrobromide in 51% yield after recrystallization. The ring proton coupling constants in the PMR spectrum of the hydrobromide of **13** were very similar to those of the spectral data[3] reported for the lactam structure of the streptolidine moiety in antibiotic LL-AC541 (Table). Treatment of the hydrobromide with silver carbonate followed by mild hydrolysis with 0.5 M hydrochloric acid afforded the hydrochloride of streptolidine lactam(**3**) as needles in 87% yield after recrystallization. The PMR spectrum of **3** also shows peaks consistent with the lactam structure.

On the other hand, hydrogenolysis of **9** over palladium black in methanol gave, after silica gel column chromatography, an almost pure sample of 2,3,5-triamino-2,3,5-trideoxy-D-*arabono*-1,5-lactam(**14**)[6,7] in 71 % yield. *N*-benzyloxycarbonylation of **14** with *N*-(benzyloxycarbonyloxy)succinimide[14] in aqueous DMF yielded **10** in 90% yield. Treatment of **14** in water with one equivalent of cyanogen bromide for 2 h at room temperature afforded the crystalline hydrobromide of **3** in 62% yield after recrystallization. The CD curve of **3** shows the positive Cotton effect at 220 nm. In the plain negative ORD curve of **3**, however, no first positive extremum expected for the positive Cotton effect in the CD spectrum is observed. The ORD curves of streptothricin and its family show a first extremum at 227 nm in positive field through negative field.[12] This indicates that the ORD curve of **3** is more strongly affected by back ground rotation[13] than those of the antibiotics.

Hydrolysis of **3** with 3 M hydrochloric acid overnight at room temperature gave the crystalline dihydrochloride of **2** (85% yield) identical in IR, PMR (Table), and optical rotation with those derived from streptothricin antibiotics. The stereochemistry of synthetic **3** was thus completely confirmed.

In preliminary microbial tests, the synthetic streptolidine lactams **13** and **3** showed no inhibition against test microorganisms sensitive to the streptothricin antibiotic group at the concentration of 100 μg/ml.

TABLE. COMPARISON OF 90 MHz PMR DATA (D_2O)[a] OF SYNTHETIC STREPTOLIDINE LACTAM (**13** and **3**) AND STREPTOLIDINE (**2**) WITH THE REPORTED PMR DATA (100 MHz, D_2O)[a,b] OF ANTIBIOTIC LL-AC541 AND NATURAL STREPTOLIDINE

a) All chemical shifts are based on external reference of TMS. b) See Ref. 3.

Experimental

Melting points were detemined on a micro hot-stage and are uncorrected. IR spectra were taken on a Hitachi 225 spectrophotometer, PMR spectra on Varian A-60D and EM-390 spectrometers using TMS as internal and external standard. Specific rotations were determined with a Zeiss Photoelectric Polarimeter. CD and ORD spectra were taken on a JASCO J-20 spectropolarimeter. TLC was performed on Wakogel B-5 and colum chromatography on Wakogel C-200. Paper chromatography was conducted on Toyoroshi No. 525 with 1-butanol–acetic acid–water (3 : 1 : 1). Paper electrophoresis was carried out with a Savant IV-5000A in formic acid–acetic acid–water (1 : 3 : 36). Unless otherwise stated, hydrogenolysis was conducted at room temperature over catalyst under bubbling with hydrogen. In general, concentration was carried out under reduced pressure below 40 °C.

1) 3-Azido-3-deoxy-1,2 : 5,6-di-O-isopropylidene-4-O-mesyl-D-talitol (5). A solution of 3,4-anhydro-1,2 : 5,6-di-*O*-isopropylidene-D-iditol (**4**)[9] (36.0 mg) in 80% aqueous methyl cellosolve (1 ml) was heated with sodium azide (78.8 mg) and ammonium chloride (32.6 mg) at 120 °C for 7 h. The reaction mixture was evaporated after filtration and the residue was extracted with ethyl acetate. The dried extract was evaporated to afford a pale brown syrup. The syrup (40 mg) was mesylated with mesyl chloride (0.012 ml) in dry pyridine (0.8 ml) at room temperature for 1 h. Work-up in the usual way gave a brown syrup, which was chromatographed on silica gel with benzene–acetone (20 : 1) to afford **5** (32.6 mg, 60%) as a colorless syrup: $[\alpha]_D^{17}$ −26° (*c* 0.78, $CHCl_3$); $\nu_{max}^{CCl_4}$ 2105 (N_3), 1370 and 1180 cm^{-1} (sulfonate).

Found: C, 42.94; H, 6.25; N, 11.22; S, 8.53%. Calcd for $C_{13}H_{23}N_3O_7S$: C, 42.73; H, 6.34; N, 11.50; S, 8.78%.

2) 3,4-Diazido-3,4-dideoxy-1,2 : 5,6-di-O-isopropylidene-D-mannitol (6). Sodium azide (365 mg) was added to a solution of **5** (379.4 mg) in dry DMSO (7.6 ml) and the mixture was heated at 120 °C for 3.5 h. The reaction mixture was poured into cold water and extracted with chloroform. The extracts were washed with saturated NaCl solution, dried, and evaporated. The residual brown syrup was chromatographed on silica gel with benzene–acetone (40 : 1) to afford **6** (153.3 mg, 47%) as a colorless syrup: $[\alpha]_D^{28}$ +15° (*c* 0.67, $CHCl_3$), $\nu_{max}^{CCl_4}$ 2100 cm^{-1} (N_3); δ ($CDCl_3$), 1.40 and

1.46 [each s, 6H, $(CH_3)_2C$], and 3.60—4.39 (m, 8H).

Found: C, 46.49; H, 6.55; N, 26.54%. Calcd for $C_{12}H_{20}N_6O_4$: C, 46.14; H, 6.45; N, 26.91%.

*3) 3,4-Bis(benzyloxycarbonylamino)-3,4-dideoxy-1,2 : 5,6-di-O-isopropylidene-*D*-mannitol (7).* A sample of **6** (220 mg) was hydrogenolysis in methanol (6 ml) for 3 h over palladium black. The resulting colorless syrup (200 mg) was dissolved in dry pyridine (4 ml) and cooled to −20 °C, and benzyl chloroformate (0.375 ml) was added to this solution under stirring. After being stirred at −20 °C for 1.5 h, the reaction mixture was diluted with water and extracted with chloroform. The extracts were washed with saturated NaCl solution, dried and evaporated. The residue was subjected to silica gel column chromatography with benzene–acetone (20 : 1) to give **7** (288.6 mg, 77%) as a colorless syrup: $[\alpha]_D^{28}$ +13° (*c* 3.74, $CHCl_3$); δ ($CDCl_3$), 1.32 and 1.42 [each s, 6H, $(CH_3)_2C$], 3.75—4.45 (m, 8H), 5.12 (s, 4H, $PhCH_2$), 5.59—5.86 (br, 2H, NH), and 7.34 (s, 10H, Ph).

Found: C, 63.46; H, 6.88; N, 5.19%. Calcd for $C_{28}H_{36}N_2O_8$: C, 63.62; H, 6.87; N, 5.30%.

*4) 2,3-Bis(benzyloxycarbonylamino)-2,3-dideoxy-*D*-arabono-1,4-lactone (8).* A solution of **7** (82.0 mg) in acetic acid (1.6 ml) was diluted with water (0.8 ml) and warmed at 60 °C for 1 h. The solution was evaporated and the residue was co-evaporated with ether in order to remove acetic acid. The residual solid (70 mg) was dissolved in a mixture of acetone (2.1 ml) and water (0.28 ml), and solid sodium metaperiodate (39.9 mg) was added to the solution in small portions with stirring under ice-cooling. After 1 h, acetone (2 ml) was added to the mixture. The precipitate was filtered off and evaporated to give a colorless solid. Bromine (0.032 ml) was added dropwise to the ice-cooled solution of the solid in dioxane (2.5 ml) and water (0.77 ml), and the mixture was stirred for 1 h. After being kept at room temperature for 3 h, a saturated $Na_2S_2O_3$ solution (4.5 ml) was added to the reaction mixture under ice-cooling. The resulting mixture was extracted with ethyl acetate and extracts were washed with saturated NaCl solution and saturated $NaHCO_3$ solution, dried, and evaporated. The residual solid was dissolved in a small amount of ethyl acetate and filtered in order to remove sulfur. Evaporation of the filtrate afforded a pale yellow solid, which was chromatographed on silica gel with chloroform–methanol (10 : 1) to give a colorless solid. Recrystallization from ethyl acetate and petroleum ether (bp 30—60 °C) afforded needles of **8** (38.6 mg, 59%): mp 149.0—150.5 °C (dried for 24 h at 60 °C in 1 Torr over CaH_2); $[\alpha]_D^{26}$ −51° (*c* 0.89, CH_3OH): ν_{max}^{KBr} 1800 (γ-lactone), 1680 (amide I), and 1530 cm^{-1} (amide II).

Found: C, 59.82; H, 5.44; N, 6.70%. Calcd for $C_{21}H_{22}N_2O_7 \cdot 1/2H_2O$: C, 59.570 H, 5.48; N, 6.62%.

*5) 5-Azido-2,3-bis(benzyloxycarbonylamino)-2,3,5-trideoxy-*D*-arabono-1,4-lactone (9).* A sample of **8** (34.0 mg) was mesylated with mesyl chloride (0.0254 ml) in pyridine (1 ml) at room temperature for 1 h. Work-up in the usual way followed by silica gel column chromatography with benzene–acetone (6 : 1) afforded an almost pure sample of the mesylate (36.1 mg, 89%); δ ($CDCl_3$), 3.85 (s, 3H, CH_3SO_3), 4.02—4.62 (5H, H-2,3,4,5-CH_2), 4.91 (s, 4H, $PhCH_2$), 5.31—5.90 (br, 2H, NH), and 7.15 (s, 10H, Ph). The mesylate (11.5 mg) was treated with sodium azide (6.1 mg) in dry DMSO (0.3 ml) at 100 °C for 0.5 h. Work-up in the suual way followed by silica gel column chromatography with benzene–acetone (10 : 1) gave colorless crystals of **9** (6.8 mg, 68%): mp 84.0—85.0 °C (dried for 24 h at 60 °C in 1 Torr over CaH_2); $[\alpha]_D^{26}$ +20° (*c* 1.72, CH_3OH), $\nu_{max}^{CHCl_3}$ 2100(N_3), 1790(γ-lactone), 1710 (amide I), and 1500 cm^{-1} (amide II).

Found: C, 56.36; H, 4.84; N, 15.63%. Calcd for $C_{21}H_{21}N_5O_6 \cdot 1/2\ H_2O$: C, 56.24; H, 4.95; N, 15.62%.

*6) 5-Amino-2,3-bis(benzyloxycarbonylamino)-2,3,5-trideoxy-*D*-arabono-1,5-lactam (10).* (a) A sample of **9** (37.5 mg) was hydrogenolyzed in methanol with Raney Ni R-100 (Nikko Scientific and Chemical Industries Ltd.) for 4 h. Recrystallization of the crystalline product from methanol gave **10** (22.0 mg, 63%) as fine needles: mp 208—209 °C $[\alpha]_D^{25}$ −122° (*c* 0.84, DMF); ν_{max}^{KBr} 3370 (OH), 3310 (NH), 1680 (amide I), 1650 (δ-lactam), and 1530 cm^{-1} (amide II).

Found: C, 60.74; H, 5.56; N, 10.34%. Calcd for $C_{21}H_{23}N_3O_6$: C, 61.01; H, 5.61; N, 10.16%.

(b) A sample of **9** (231.5 mg) was hydrogenolyzed in methanol (8.5 ml) over palladium black for 5 h. During this period a fresh catalyst was added every hour. Evaporation of the filtered solution afforded the crude triamino sugar lactam **14** as a pale yellow syrup. A solution of *N*-(benzyloxycarbonyloxy)succinimide (283 mg) in DMF (1 ml) was added to a solution of the syrup in DMF (3 ml) and water (0.5 ml). After being kept at room temperature for 1 h, the reaction mixture was neutralized with triethylamine and evaporated. The residue (pale brown semisolid) was chromatographed on silica gel with chloroform–methanol (10 : 1) to give **10** (127.3 mg, 60% overall yield from **9**): mp 203—207 °C; $[\alpha]_D^{20}$ −127° (*c* 0.79, DMF). This sample was identical with that obtained in (a) on mixture melting point.

*7) 5-Amino-2,3-bis(benzyloxycarbonylamino)-2,3,5-trideoxy-4-O-(tetrahydro-2-pyranyl)-*D*-arabono-1,5-lactam (11).* A mixture of **10** (107.2 mg), dihydropyran (0.54 ml), *p*-toluenesulfonic acid (4.8 mg), and dry DMF (1.75 ml) was warmed at 37—40 °C for 2 h. The reaction mixture was neutralized with triethylamine and evaporated. The residual pale brown syrup was chromatographed on silica gel with chloroform–methanol (25 : 1) to afford **11** (124.6 mg, 97%) as a colorless solid. Crystallization took place on slow evaporation of the methanol solution, giving colorless needles of **11** (80% overall yield): mp 163—166 °C; $[\alpha]_D^{20}$ −59° (*c* 1.28, $CHCl_3$); δ ($CDCl_3$), 1.12—1.90 (m, 6H, 3′,4′,5′-CH_2), 3.10—4.76 (m, 8H, 5,6′-CH_2, H-2′, 2, 3, 4), 5.05 (s, 4H, $PhCH_2$), 5.50—6.33 (br, 3H, NH), and 7.30 (s, 10H, Ph).

Found: C, 62.65; H, 6.26; N, 8.53%. Calcd for $C_{26}H_{31}N_3O_7$: C, 62.76; H, 6.28; N, 8.45%.

*8) 2,3,5-Triamino-4-O-(tetrahydro-2-pyranol)-2,3,5-trideoxy-*D*-arabono-1,5-lactam (12).* A sample of **11** (150.8 mg) was hydrogenolyzed in methanol (3 ml) at 50 psi for 4 h using 10% Pd/C catalyst (total 180 mg). The catalyst was divided into four 45 mg-portions, one portion being added every hour during the reaction period. Filtration followed by removal of solvent afforded a pale yellow-green syrup. Chromatography over silica gel (0.7 g) with chloroform–methanol–17% aqueous ammonia (20 : 20 : 1) gave almost pure **12** (53.2 mg, 77%) as a colorless syrup: $\nu_{max}^{CHCl_3}$ 3580—3140 (NH_2), 3400 (NH), and 1660 cm^{-1} (δ-lactam).

9) O-(Tetrahydro-2-pyranyl)streptolidine Lactam (13) Hydrobromide. Cyanogen bromide (23.5 mg, 0.95 equiv) was added to a solution of **12** (53.2 mg) in water (0.5 ml) and the mixture was allowed to stand at room temperature for 5 h. Evaporation of the reaction mixture afforded a pale yellow solid, which was crystallized on slow evaporation of the methanol solution to give colorless needles of the hydrobromide of **13** (40.1 mg, 51%): mp 295 °C (dec); $[\alpha]_D^{20}$ −128° (*c* 0.975, H_2O); ν_{max}^{KBr} 3100 (NH), 1670 (lactam and guanidium I), and 1590 cm^{-1} (vw, guanidium II).

Found: C, 39.44; H, 5.76; N, 16.60%. Calcd for $C_{11}H_{18}N_4O_3 \cdot HBr$: C, 39.41; H, 5.71; N, 16.72%.

10) Streptolidine Lactam (3) Hydrochloride. A solution of **13** hydrobromide (37.5 mg) in water (0.9 ml) was treated with Ag_2CO_3 (15.4 mg, 0.5 equiv) for 10 min. Additional

Ag_2CO_3 (7 mg) was added to the mixture and the precipitates were filtered and washed with water (1 ml). The combined filtrates (1.9 ml) were acidified with 2M HCl (0.6 ml), and kept at room temperature for 0.5 h. The reaction mixture was neutralized (pH 7) with Amberlite CG-4B and evaporated after filtration to afford colorless crystals. Recrystallization from methanol–acetone (1 : 1) gave a pure sample of the hydrochloride of **3** (20.0 mg, 87%) as needles: mp 146—147.5 °C; $[\alpha]_D$ −124°, $[\alpha]_{436}$ −250°, and $[\alpha]_{365}$ −386° (*c* 0.99, H_2O at 16 °C); $[\theta]_{220}$ +3794 (*c* 0.11, H_2O at 18 °C); ν_{max}^{KBr} 1680 (lactam and guanidium I), and 1600 cm^{-1} (sh, guanidium II).

Found: C, 34.72; H, 5.58; N, 26.76%. Calcd for $C_6H_{10}N_4O_2 \cdot HCl$: C, 34.78; H, 5.37; N, 27.12%.

11) Preparation of Streptolidine Lactam (3) Hydrobromide from Triamino Sugar Lactam (14). A crude sample of **14** (Exp. 6b) was chromatographed through a short column of silica gel with chloroform–methanol–17% aqueous ammonia (6 : 6 : 1) to afford a practically pure sample of **14** in 72% yield. Cyanogen bromide (30.0 mg, 1 equiv) was added to a solution of the sample (39.7 mg) of **14** in water (0.4 ml), and the mixture was kept at room temperature for 2 h and then neutralized (pH 7) with Amberlite CG-4B, and evaporated. The pale yellow crystalline residue (70 mg) was recrystallized twice from methanol–acetone to give **3** hydrobromide (42 mg, 60%): mp 147—148 °C; $[\alpha]_D$ −102°, $[\alpha]_{436}$ −210°, and $[\alpha]_{365}$ −329° (*c* 0.638, H_2O at 19 °C); ν_{max}^{KBr} 1680 (lactam and guanidium I) and 1600 cm^{-1} (guanidium II). The PMR spectrum (D_2O) of the sample was identical with that of **3** hydrochloride.

Found: C, 29.02; H, 4.66; N, 22.00%. Calcd for $C_6H_{10}N_4O_2 \cdot HBr$: C, 28.70; H, 4.42; N, 22.31%.

12) Streptolidine (2) Dihydrochloride. A solution of **3** hydrochloride (10.5 mg) in 3 M HCl (0.2 ml) was allowed to stand at room temperature for 22 h. The solution was evaporated and the crystalline residue was washed with a mixture of methanol–acetone (2 : 1) to afford **2** dihydrochloride (11.0 mg, 83%). Recrystallization from water–ethanol gave an analytical sample: mp 175—180 °C (dec) [lit,[15] mp 173—190 °C (dec)]; $[\alpha]_D$ +52°, $[\alpha]_{436}$ +126°, $[\alpha]_{365}$ +195° (*c* 0.988, H_2O at 16 °C) [lit,[15] $[\alpha]_D^{22}$ +56.8° (*c* 2.35, H_2O)]; ν_{max}^{KBr} 1725 (COOH), 1680 (guanidium I), 1580 cm^{-1} (guanidium II). R_f-values on paper chromatopraghy and mobility of paper electrophresis of the synthetic product and the natural one were identical.

Found: C, 27.70; H, 5.21; N, 21.41%. Calcd for $C_6H_{12}N_4O_3 \cdot 2HCl$: C, 27.60; H, 5.41; N, 21.46%.

The authors wish to thank Dr. Shinpei Aburaki for the measurements of PMR, CD, and ORD spectra, Mr. Nakada for the microanalyses, and Mr. Yoichi Niimura for his technical assistance. We are also indebted to Dr. Masa Hamada, Institute of Microbial Chemistry, for the microbiological test.

Ketyl Radicals Formed in Grignard Reaction. IV.[1] Sterically Hindered Ketyl Radicals in Nuclear Replacement and Conjugate Addition

Masao Ōkubo

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840

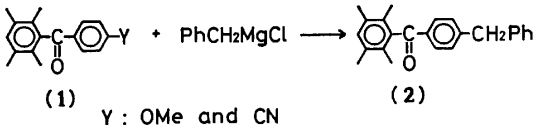
(Received March 9, 1977)

The reaction in which 4′-methoxy and 4′-cyano substituents on 2,3,5,6-tetramethylbenzophenone are effectively replaced by benzyl- and *t*-butylmagnesium chloride was examined by means of ESR measurements. Both the original and the "replaced" ketyl radicals were identified, and an electron-transfer mechanism similar to that of S_{RN}-type reactions was proposed. Some sterically hindered $\alpha\beta$-enones were also found to form detectable amounts of ketyl radicals. The factors governing the production ratio of the normal and the conjugate adduct were discussed.

Several reports have been given on evidence for the electron-transfer(ET) mechanism of Grignard reaction.[2,3] The course of the reaction of PhMgBr with benzophenone is affected greatly by the steric hindrance of *ortho*-methyl groups; the group on the former reagent tends to form benzopinacol whereas the same group on the latter to form the nuclear phenylated product.[1] The formation of these "abnormal" products can be explained by the ET-mechanism *via* ketyl radicals. Not only the mode of appearance but also the spin-distribution on the radicals have turned out to be dependent upon the magnitude of the steric effect. Thus, similar steric effects are expected to be operative in the Grignard reactions of the several different types of ketones. This paper gives the results of the ESR studies on the two "abnormal" Grignard reactions: 1) the nuclear replacement of anionoid substituents on hindered benzophenones, and 2) the conjugate addition to the *ortho*-methyl derivatives of chalcone, 2-benzoylbenzofuran, and 3-benzylidenecamphor.

Results and Discussion

Nuclear Replacement of Hindered Benzophenones. Recently the ET-mechanism for the nuclear *ortho*-phenylation of benzoylmesitylene in the reaction with PhMgBr was proposed.[4] Benzophenone itself undergoes unclear *t*-butylation, which has been explained also by the ET-mechanism.[5] Fuson and his co-workers pointed out that some anionoid substituents (methoxyl, cyano, and acetoxyl) were effectively available for the analogous nuclear alkylation or arylation.[6] As the first step in the present work, the "replacement" reaction of the 4′-MeO and 4′-CN substituents of 2,3,5,6-tetramethylbenzophenone (benzoyldurene) with $PhCH_2MgCl$ (Scheme 1) was examined by ESR technique.



Scheme 1.

For the sake of simple analysis of ESR spectra, the 2,3,5,6-tetramethylphenyl(duryl) group is advantageous since it gives no resolvable splitting[7] as a result of the inhibition of spin-delocalization due to the twisting of the group out of the plane of the carbonyl group.[8] Though all the spectra were not fully-resolved, they can be analyzed by considering only the hydrogen atoms of the unhindered aryl groups. The structure and the coupling constants of the radicals identified are summarized in Table 1.

When the two 4′-substituted benzoyldurenes(**1**) were treated with five equivalents of $PhCH_2MgCl$ in tetrahydrofuran(THF) in a vacuum and at room temperature, the colorless (Y=OMe) or pale yellow (Y=CN) solution turned first pink and then reddish brown rapidly. Replacement product(**2**) was obtained after 1 h in a good yield. The highest radical concentrations, observed after 30 min after mixing, were estimated to be *ca.* 6 mol% based on the concentration of the original ketones. The ESR spectrum (Fig. 1a) obtained after the reaction solution had turned reddish brown, was independent of the 4′-substituents. When $PhCD_2MgCl$ is used, the spectrum changes to the one which has weak narrow quintets (Fig. 1b). The spectrum is thus ascribed to a ketyl radical (Rp)· which has been "replaced" by the benzyl group. The large coupling constant of the benzylic hydrogen, a_{α}^{H} (Table 1), seems to reflect the fact that the $Q_{C-CH_2}^{H}$ value (27.2) is larger than the Q_{C-H}^{H} value (23.7).[9]

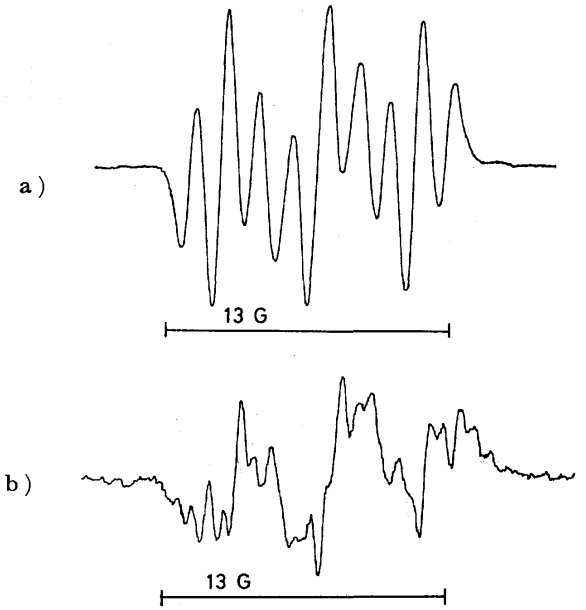


Fig. 1. ESR Spectra obtained in the benzyl-MgCl reaction of 4′-MeO- and 4′-CN-benzoyldurene: (a) usual benzyl-MgCl was used, (b) benzyl-α-d_2-MgCl was used.

Table 1. Coupling constants of Grignard ketyls of some benzoyldurenes

No.	Structure of ketyls	Coupling constants (G) a_p^H	a_o^H	a_m^H	a_α^H	Spectrum corresponding to Fig.
1		—	4.44	1.39	4.0	Fig. 1a
2		—	4.44	1.39	$a_\alpha^D=0.62$	Fig. 1b
3		—	4.44	1.52	—	Fig. 2
4		—	4.44	1.52	—	(Fig. 2)
5		—	4.44	1.46	—	Fig. 3
6		5.69	4.38	1.32	—	Fig. 4
7		2.91	5.83	1.39	—	Fig. 4

When PhMgBr was used instead of $PhCH_2MgCl$, the solution turned pink, the coloration becoming deep purple. The radical concentration increased gradually and reached *ca.* 30 mol% of the original ketone after 5 h. A partially resolved spectrum (Fig. 2) was obtained. It was identical with that of the Mg-ketyl prepared by use of Mg-amalgam. However, only the original ketone was recovered when the deeply colored solution was hydrolyzed after 1 h. Thus, the pink coloration observed transiently in the initial stage of the $PhCH_2MgCl$ reaction can be ascribed to the ketyl radical of **1**.

t-Butylmagnesium chloride reacts similarly with **1** (Y=OMe) giving *para*-*t*-butylated ketone in a high yield.[10] A color change similar to that of $PhCH_2MgCl$ reaction was observed though the radical concentration was low (*ca.* 2 mol%). This low radical concentration is recognizable as a result of the higher reactivity

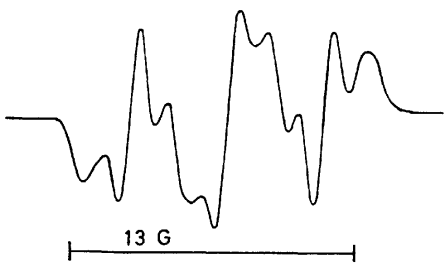

Fig. 2. ESR Spectrum obtained in the phenyl-MgBr and/or Mg-amalgam treatment of 4′-MeO-benzoyldurene.

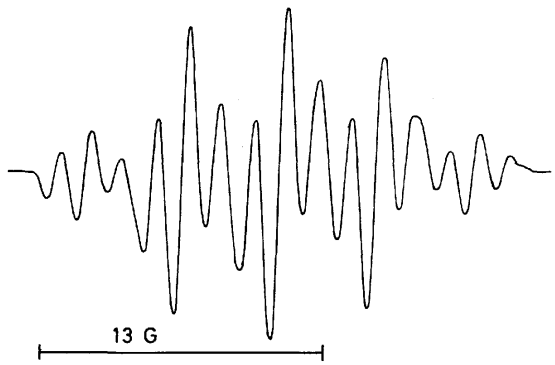

Fig. 3. ESR Spectrum obtained in the *t*-butyl-MgCl reaction of 4′-MeO-benzoyldurene.

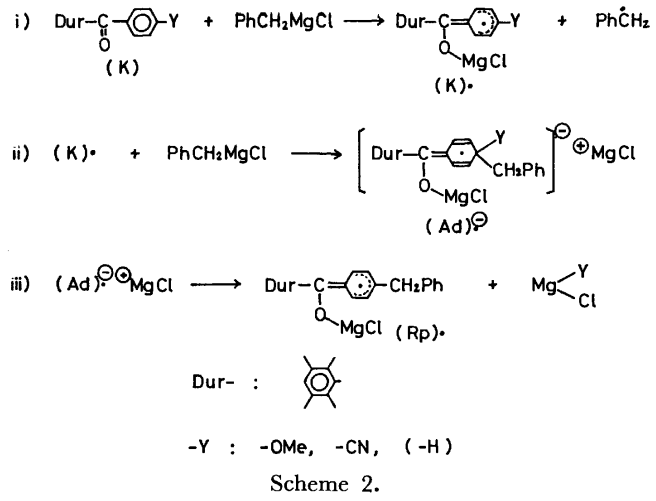
of *t*-butyl reagent than that of benzyl reagent.[2] The obtained ESR spectrum is shown in Fig. 3. Since the spectrum differs from that of the original ketyl of **1**, it can be ascribed to that of the "replaced" ketyl radical (Table 1). The difference between the values of a_m^H of No. 1, 3, and 5 is understood as that between the magnitudes of electron-repelling ability of the respective substituents.

Since both the original and the "replaced" ketyl radicals were identified and the low radical concentration in the $PhCH_2MgCl$ and/or *t*-BuMgCl reaction is attributable to the high reactivity of these reagents, the replacement reaction can be explained by the ET-mechanism shown in Scheme 2.

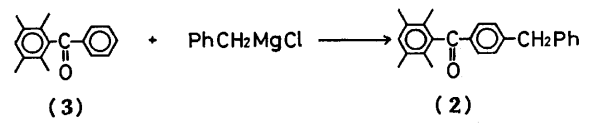
The benzyl radical produced in step i) is in the coordi-



Scheme 2.

nating state to the Mg atom, and would be less reactive than the ordinarily generated "free" radicals; the radical does not necessarily react with the ketyl radical (K)· in the recombination manner. In fact, most part of the benzyl radical escapes out of the solvent cage and abstracts hydrogen from the THF molecule.[11] Since neither benzyl methyl ether nor benzyl cyanide was detected, the substituent Y would be eliminated as anoin Y^- and the process can be formulated by the sequence of steps ii) and iii). The formation of the adduct radical anion species $(Ad)^{\cdot-}$ ^+MgCl is possible since the O–Mg linkage in (K)· is covalent due to the largest electronegativity of Mg among the alkali and alkaline-earth elements; (K)· should thus be neutral. The formation of such an aggregated state[4] is compatible with the observation of the highly aggregated Grignard species in the presence of oxygen-containing compounds.[12]

The postulate on the formation of $(Ad)^{\cdot-}$ ^+MgCl is rationalized by the following study on the nuclear substitution reaction of benzoyldurene itself (**3**) with $PhCH_2MgCl$ (Scheme 3).[13] The *para*-benzylated product (**2**) was isolated (yield 23%) after the reaction solution had been left to stand at room temperature for 4 h. The ESR spectrum consists of thirteen lines (Fig. 4) and is not influenced by the use of $PhCD_2MgCl$, in contrast with the case of **1**. The original ketyl of **3** has thirteen lines with the relative strength of 1 : 2 : 1 : 2 : 5 : 4 : 2 : 4 : 5 : 2 : 1 : 2 : 1, whereas the adduct radical anion (Scheme 2; $(Ad)^{\cdot-}$, Y=H) shows also thirteen lines but with different relative strength of 1 : 2 : 2 : 2 : 3 : 4 : 4 : 4 : 3 : 2 : 2 : 2 : 1 (*cf.* Table 1, No. 6 and 7). The spectrun (Fig. 4) with the apparent relative strength of 1 : 1.9 : 1.2 : 1.0 : 2.4 : 2.6 : 1.6 : 2.6 : 2.4 : 1.0 : 1.2 : 1.9 : 1 was reconstructed by superposing the stronger signals of the original ketyl (No. 6) on the weaker ones of the adduct radical anion (No. 7). The $(AdH)^{\cdot-}$ species does not undergo the hydrogen-transfer (Scheme 4a)[4] as easily as the $(Ad)^{\cdot-}$ species undergoes the Y^--transfer. Thus, the $(AdH)^{\cdot-}$ becomes detectable, but not the "replaced" radical (Rp)·. The formation of **2** would be caused by the air-oxidation of AdH during the course of isolation (Scheme 4b).[5]



Scheme 3.

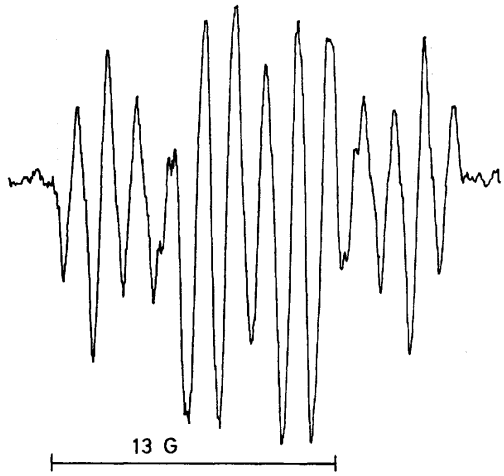


Fig. 4. ESR Spectrum obtained in the benzyl-MgCl and/or benzyl-α-d_2-MgCl reaction of benzoyldurene.

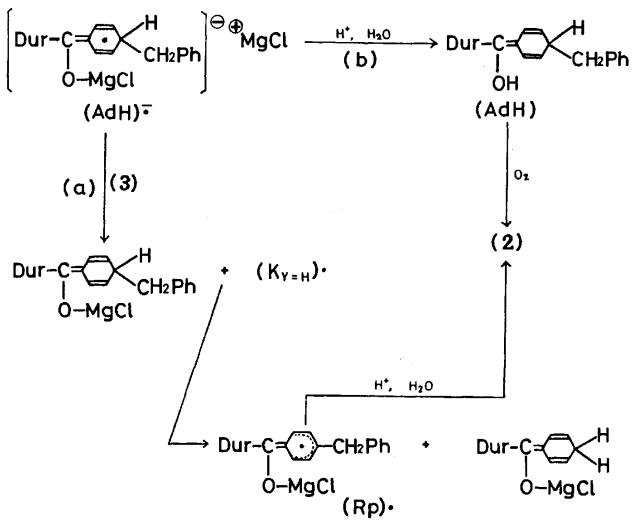

Scheme 4.

If we compare the reaction profiles of **1** with those of **3**, the former reaction is characterized in terms of "replacement", the latter in terms of "addition." The definitive ease of the former reaction is consistent not only with the high spin-density on the unhindered aryl groups,[8] but also with the formation of $(Ad)^{\cdot-}$ favoring the elimination of Y^-. Such an intermediacy of the radical anion species resembles what was postulated in a number of S_{RN}-type reactions.[14] The electrolytically reductive elimination,[15,16] as well as the Grignard replacement,[17] of the anionoid substituents from benzonitrile derivatives have also been reported.

In order to estimate the effect of 4′-anionoid substituents on the ET-process, the initial concentrations of ketyl radicals produced on the PhMgBr treatment of 4′-F-, 4′-Cl- and 4′-MeO-benzoylmesitylenes were

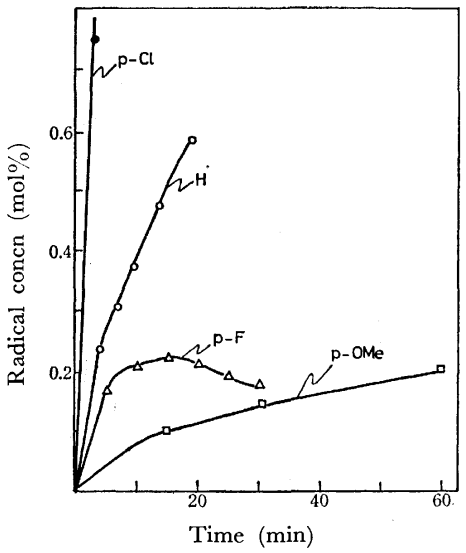

Fig. 5. Radical concentrations at the initial stage of the phenyl-MgBr treatment of benzoylmesitylenes.

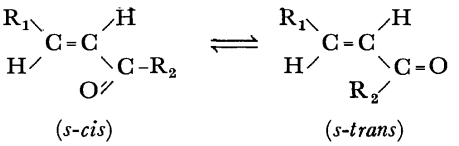
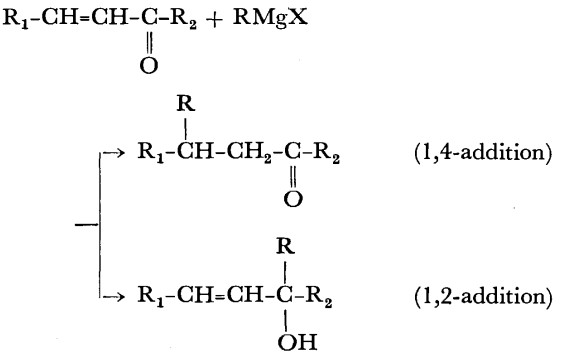
compared. Despite the high radical concentrations, no replacement product was obtained after this treatment for 1 h. The radical concentrations, measured by the over-modulation technique, were tentatively corrected on the basis of the relative total width of the well-resolved spectra, respectively (see Experimental). As shown in Fig. 5, the chloro derivative accelerates and the methoxy derivative retards the ET-velocity, whereas the fluoro derivative greatly reduces the radical concentration. However, the estimation by means of visible spectral absorbance verified the high ET-velocity of the fluoro derivative comparable to that of the chloro derivative. The seemingly low radical concentration, as well as the noticeably reduced fluidity of the deeply colored solution, suggests the presence of aggregated diamagnetic dimers which might be formed by the coordination of unhindered fluorine atoms to Mg atom. Probably such an additional coordination through the lone-pair electrons of substituents, when it is located on a position appropriate for the reactivity of the Grignard reagent used, favors the replacement reaction. In fact, the introduction of anionoid substituents such as methoxyl group[18] or bromine atom[19] on the *ortho*-position of benzophenones is effective for the nuclear *ortho*-phenylation in the "replacement" manner.

Considering the difference between the markedly slow *ortho*-phenylation of benzoylmesitylene[4] and the rather rapid *para*-benzylation of benzoyldurene,[13] the C_{phenyl}–Mg linkage is stronger than the C_{benzyl}–Mg linkage.

Conjugate Addition to αβ-Enones. The earliest systematic work by Kohler[20] on the mode of the Grignard addition to open-chain αβ-enones (Scheme 5) reveals the steric effect of R_1, R_2, and R. If R_2 is H(aldehydes), only the normal 1,2-addition takes place. As R_2 becomes bulkier, the conjugate 1,4-addition becomes predominant. This is understandable since the bulky R_2 favors the *s-cis* conformation which is appropriate for the six-membered cyclic structure of transition state. When R_1 is phenyl and R_2 is ethyl, some alkylmagnesium bromides and benzylmagnesium chloride gave 68—70% yields of the conjugate adducts whereas phenylmagnesium bromide gave only the 40% yield.[20] This reveals the strength of C_{phenyl}–Mg linkage, which may be loosened only slightly in the transition state, making it suitable for normal addition.





Scheme 5.

Even in the PhMgBr reaction, chalcone(**4**) has been reported to give the conjugate adduct almost exclusively.[20] Though the product resulting from the radical dimerization at the β-carbon has been reported,[21] detection of the Grignard ketyl of **4** could not be made because it should react more rapidly than benzophenone[1] owing to its less-crowded molecular structure resulting from the interposition of the –CH=CH– group. Thus, the present author used the sterically hindered chalcones (Table 2) which have one or two mesityl groups instead of the phenyl groups. Attempts to detect ketyl radicals at room temperature in the PhMgBr reaction were unsuccessful even with the use of these chalcones. The electrolytic reduction method was applied. Though all the radical anions of **5**, **6**, and **7** were short lived and the ESR spectra obtained

Table 2. Beta-hydrogen coupling constants and apparent life-times of chalcones

	Chalcones	a^H_β	Order[a] of life-time

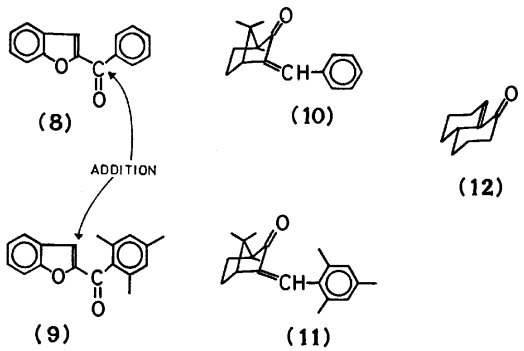
(**5**)		13.3—13.9	2
(**6**)		—[b]	(4)
(**7**)		14.1—15.2	1

a) The radical anion which has the apparently longest life-time is indicated by 1. b) The radical anion is very short-lived and a^H_β could not be determined.

were poorly resolved, they consisted of the widely separated two equivalent parts due to the large β-H coupling constants.[22,24] The observed a_β^H values accompanied by the order of the apparent life-times are summarized in Table 2.

The a_β^H values of **5** and **7** larger than the value of **4** indicate that the spin-delocalization is suppressed by the mesityl substitution. The life-times in cases of **5** and **7** longer than those of **4** and **6** can be explained by the steric hindrance due to the β-mesityl group against the dimerization at the β-carbon.[22] However, all the chalcones **4**—**7** gave the conjugate adducts in the PhMgBr reaction.

In the o-MeC_6H_4MgBr treatment, **5** solely produced the short-lived Grignard ketyl detectable at room temperature; a_β^H=17.7—18.9 G.[25] This is attributable to the following: 1) slower addition process of the o-tolyl reagent than that of the phenyl reagent,[1] 2) lower spin-density on the β-carbon than that of **7**, and 3) the steric hindrance due to the β-mesityl group against addition. The explanation suggests the existence of a correlation between the mode of addition and the spin-distribution. This is supported by the HMO-calculation which shows the high spin-density on the β-carbon comparable to that on the carbonyl-carbon.[24] This is exemplified also by the following examples.



2-Benzoylbenzofuran(**8**) reacts in the normal mode, and its trimethyl derivative(**9**) in the conjugate mode.[26] The latter displays a pink color of the Grignard ketyl for *ca.* 1 h in the o-MeC_6H_4MgBr treatment at room temperature; a_β^H=7.8 G. The fair stability as well as the large a_β^H is explained in terms of the nuclear phenylation of benzoylmesitylene.[4]

The bridged cyclic enones, 3-benzylidenecamphor(**10**) and its trimethyl derivative(**11**), gave the conjugate adducts exclusively.[27] On the treatment of **10** and **11** with o-MeC_6H_4MgBr, the fairly long-lived ketyl radical of the latter camphor was detected at room temperature; a_β^H=4.3 G. The small coupling constant is explicable by the incomplete co-planarity of the grouping O=C–C=CH–; the mode of addition in this case is governed solely by the rigid *s-cis* conformation.

It can be suggested that 1) the spin-distribution in the ketyl radical, 2) the conformation of $\alpha\beta$-enones, and 3) the strength of C–Mg linkage are the three main factors governing the mode of the Grignard addition to $\alpha\beta$-enones. The result showing that $\Delta^{8,8a}$-1-octalone (**12**) gave only the 43% yield of the conjugate adduct in the PhMgBr reaction[28] is partly attributable to the strong C_{phenyl}–Mg linkage which favors the normal 1,2-addition.

General Discussion. Holm[2] studied the behavior of some alkyl Grignard reagents in the electrolytic oxidation and their thermographically-measured kinetic behavior in the reaction with benzophenone, and discussed the correlation between the two kinds of behavior on the basis of the ET-mechanism. House and Weeks[29] utilized the *cis-trans* isomerization of enone-radical anion, as well as the skeletal rearrangement of radical anion, as means to distinguish the ET-mechanism from the direct nucleophilic attack mechanism in the reaction with methyl-carbanionic reagents. The effect of the strength of C–Mg linkage has not been taken into account. The steric effect would be an additional factor affecting the boundary between the two mechanisms. However, the fact that the steric hindrance of both ketones and Grignard reagents makes it possible to detect the intermediate ketyl radicals by the ordinary ESR technique suggests the possibility of the ET-mechanism of Grignard reaction.

Experimental

Materials. All the benzoyldurenes and benzoylmesitylenes were prepared from durene and mesitylene respectiveley by the Friedel-Crafts reaction with the corresponding benzoyl chlorides.[4,6] Chalcones **4**—**7** were prepared by the aldol condensation of the corresponding benzaldehydes and acetophenones.[20] 2-Benzoylbenzofurans **8** and **9**[26] and 3-benzylidenecamphors **10** and **11**[27] were prepared according to the reported methods. Commercial halogen compounds, including benzyl-α-d_2 chloride, were used for the preparation of Grignard reagents.

Procedures. Grignard reagents in THF were prepared as usual, and stored in sealed bottles under N_2 atmosphere. The preparation of samples for ESR measurements were similar to those described previously;[1,8] the molar concentrations of ketones and Grignard reagents were 1.4×10^{-4} and 7.0×10^{-4}, respectively.

Radical concentrations were determined by the over-modulation technique using a reference solution of galvinoxyl in THF.[1] The values obtained by the PhMgBr treatment of benzoylmesitylenes (Fig. 5) were corrected on the basis of the total widths of the resolved spectra: benzoylmesitylene 20.9 G, chloro derivative 16.3 G, fluoro derivative 29.6 G, and methoxy derivative 16.8 G. In order to obtain a well-resolved spectrum, a small portion of the reaction mixture in the measurement cell was diluted by the vaucum distillation of THF from the reaction vessel; the spectra (Figs. 1—4) were not resolvable any further. The visible absorption measurement was also carried out.[1]

For the electrolytic reduction of chalcones **4**—**7**, a similarly shaped simple glass apparatus equipped with two platinum-wire electrodes(the one on the top, anode, and the other at the bottom, cathode, of the cell) was used. Tetrabutylammonium perchlorate(1.0 M) and one of the chalcones (0.2 M) were dissolved in acetonitrile and the apparatus was degassed and sealed off. Since all the radical anions of **4**—**7** were short-lived, the cathode-part of the cell was placed at the center of the ESR cavity. When direct current (0.2 V) was supplied, the green or blue color of radical anions appeared. The apparent life-times(Table 2) were compared based ron the relative time in which the radical anion had been

detected by ESR after the direct current was cut off.

Reaction products were separated by means of TLC and/or column chromatography, and identified by their mp and NMR spectra.

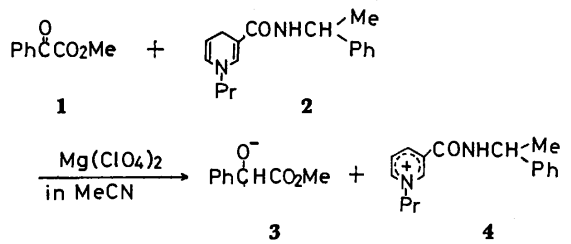
(Received April 16, 1977)

Kinetics for the reduction of methyl benzoylformate (**1**) with *N*-α-methylbenzyl-1-propyl-1,4-dihydronicotinamide (**2**) in the presence of magnesium perchlorate in acetonitrile at 25 °C has been studied. The reaction follows first-order in **1**, first-order in **2**, and zero-order in magnesium ion when [**2**] ≪ [**1**], [$Mg(ClO_4)_2$]. When [**2**] = [$Mg(ClO_4)_2$] ≪ [**1**], the kinetics is best explained by Eqs. 6 and 7. The results indicate that **2** and magnesium ion form a complex, which reacts with **1** at the rate-determining step. It is concluded that magnesium ion activates **2** to promote the release of an electron.

It has been reported that biomimetic reduction of α-keto esters by a model of NAD(P)H takes place in acetonitrile in the presence of magnesium or zinc perchlorate.[1] In addition to the promotion of the reduction, these metal salts also catalyze the asymmetric induction with a chiral model of NAD(P)H.[1] Lithium perchlorate is effective, although the efficiency is much less than that of magnesium or zinc perchlorate, to promote the reduction, but the stereospecificity is absolutely absent with this lithium salt.[2]

In a preceeding paper of this series,[2] we proposed a mechanism of stereospecific magnesium ion-catalyzed reduction of methyl benzoylformate (**1**) with *N*-α-methylbenzyl-1-propyl-1,4-dihydronicotinamide (**2**), where the importance of the initial formation of a complex between **2** and magnesium ion was suggested.



However, the existence of the complex prior to the reduction of **1** remained equivocal, and in order to confirm the previously proposed mechanism we studied the kinetics of the reduction.

Results and Discussion

Kinetics was followed at 25 °C by observing the decrease in the intensity of absorption at 354 nm. The absorption is characteristic of **2**. Pseudo-first-order rate constants, k_{obsd}, under various concentrations of **1** and of magnesium perchlorate are listed in Tables 1 and 2. In Tables 1 and 2 are also listed second-order rate constants, k_{calcd}, calculated by dividing k_{obsd} by the concentration of **1**. The result clearly indicates that the reaction kinetics is first-order in **1**, first-order in **2**, and zero-order in magnesium perchlorate under the conditions employed. The independency of the reaction rate from the concentration of magnesium perchlorate rules out the possibilities of initial formation of a complex between **1** and magnesium ion and of termolecular reaction with free reagents.

[**2**] × 10^4, M	[$Mg(ClO_4)_2$] × 10^3, M	[**1**] × 10^3, M	k_{obsd} × 10^2, min^{-1}	k_{calcd}, $M^{-1}\,min^{-1}$
2.00	3.91	11.92	8.16±0.30	6.84±0.31
2.00	6.06	11.74	7.86±0.30	6.70±0.30
1.99	6.03	12.21	8.26±0.31	6.76±0.30
2.00	11.91	11.92	8.53±0.31	7.15±0.31
2.00	23.81	12.34	8.36±0.31	6.77±0.30
2.00	35.70	12.40	8.00±0.30	6.45±0.30

It may be safely assumed that the first dissociation of magnesium perchlorate is practically complete in acetonitrile under the conditions where the concentrations of the salt are 10^{-2}—10^{-3} M.[3,4] Thus, the present result is best interpreted, in agreement with the previously suggested mechanism, with the following reaction scheme:

$$Mg(ClO_4)_2 \overset{K_1}{\rightleftharpoons} Mg(ClO_4)^+ + ClO_4^-$$

$$Mg(ClO_4)^+ + \mathbf{2} \overset{K_2}{\rightleftharpoons} \mathbf{2}\cdot Mg(ClO_4)^+$$

$$\mathbf{2}\cdot Mg(ClO_4)^+ + \mathbf{1} \xrightarrow{k_3} \mathbf{3}\cdot Mg^+ + \mathbf{4}\cdot ClO_4^-$$

It should be noted that the absorption at about 354 nm is not affected appreciably by the presence of magnesium perchlorate.[2] That is, what we can observe by measuring the intensity of this absorption is the sum of concentrations of free and complexed **2**. This is an important point, because otherwise the observed kinetics does not predict the above scheme.

The validity of the proposed scheme can be tested

in another way: when initial concentrations of **2** and magnesium perchlorate are set to be equal, Eq. 1 holds because the equilibrium constant K_1 has been assumed to be very large:

$$[\mathbf{2}]_T = [Mg(ClO_4)^+]_T, \quad (1)$$

where the subscript T denotes the sum of concentrations of free and complexed species.
Since

$$K_2 = [\mathbf{2}\cdot Mg(ClO_4)^+]/[Mg(ClO_4)^+][\mathbf{2}]$$
$$= [\mathbf{2}\cdot Mg(ClO_4)^+]/[\mathbf{2}]^2, \quad (2)$$

therefore

$$[\mathbf{2}]_T = [\mathbf{2}] + K_2[\mathbf{2}]^2. \quad (3)$$

When Y is defined by Eq. 4

$$Y = (1 + 4K_2[\mathbf{2}]_T)^{1/2} \quad (4)$$

the kinetic expression according to the proposed reaction scheme can be written as in Eq. 5,

$$-d[\mathbf{2}]_T/dt = k_3[\mathbf{2}\cdot Mg(ClO_4)^+][\mathbf{1}]$$
$$= K_2k_3[\mathbf{2}]^2[\mathbf{1}]$$
$$= k_3[\mathbf{1}](Y-1)^2/4K_2. \quad (5)$$

Finally, we obtain Eqs. 6 and 7 under the conditions of $[\mathbf{2}]=[Mg(ClO_4)_2]\ll[\mathbf{1}]$

$$(Y-1)^{-1} - \ln(Y-1) = k_3[\mathbf{1}]t/2 + C, \quad (6)$$

$$C = (Y_0-1)^{-1} - \ln(Y_0-1), \quad (7)$$

where Y_0 is the value of Y at $t=0$.

The values for K_2 and k_3 were obtained by computer-assisted iteration with the Newton's method[5] and the result is summarized in Table 3. The excellent agreement between the values for k_3 and k_{calcd} proves the validity of the proposed reaction scheme. The value for K_2 also agrees with the idea that practically all molecules of **2** in the reaction system are complexed by magnesium ion under the conditions with which the pseudo-first-order kinetics was studied.

Hughes and Prince reported that the rate of reduction of 2-pyridinecarbaldehyde exibits a half-order dependence on total metal salt concentration.[6] Indeed, our kinetic result obtained under the conditions of $[\mathbf{2}]=[Mg(ClO_4)_2]\ll[\mathbf{1}]$ is very well processed by a two-third order dependence on total concentration of **2**. Therefore, it may provide another possibility that the rate depends on the first-order in **2** and a half-order in magnesium perchlorate. However, such a kinetics comes out only when the dissociation constant of magnesium perchlorate in acetonitrile is very small. If this were the case, the kinetics under the conditions of $[\mathbf{2}]<[Mg(ClO_4)_2]\ll[\mathbf{1}]$ should deviate from the first-order in **2** in contrast to the observed result. Thus, the assumption that K_1 has a large value has been proved to be valid.

The kinetics has revealed that the complex, $\mathbf{2}\cdot Mg(ClO_4)^+$, is the reacting species and the role of magnesium ion is not only to activate the substrate but also to activate the model compound.[7] In this way, **2** releases an electron, a proton, and an electron, successively. This conclusion is different from that proposed by Gase and his coworkers, who assigned free **2** as a reacting species.[8]

Lithium perchlorate gave a quite complex kinetics which could not be interpreted. The reaction rate depended on the concentration of lithium ion even in the region of 15×10^{-3} M against 2×10^{-4} molar concentration of **2**. The result may probably due to the formation of various types of aggregates in concordance with the idea previously proposed in a simplified form.[2]

Partial support in the form of a Scientific Resarch Grant from the Ministry of Education, Japan, is acknowledged.

Experimental

Materials. Acetonitrile was distilled once on phosphorus pentaoxide and kept over molecular sieves 4A. Magnesium and lithium perchlorates were dried at 120 °C *in vacuo* for 5 h and used immediately. Preparations of methyl benzoylformate and *N*-α-methylbenzyl-1-propyl-1,4-dihydronicotinamide were described previously.[9]

Procedure. Acetonitrile was flushed with dry argon prior to the use. In a glove-box filled with dry argon, solutions for kinetic studies were prepared and placed in a UV-cell (1 cm) equipped with a silicone-rubber stopper. Kinetics was followed spectrophotometrically with a Union Giken SM-401 spectrophotometer, the cell-compartment of which was filled with dry argon and kept at 25.0+0.1 °C. The order of incubation of reagents did not affect the kinetics.

Kinetics. In the presence of a large excess of magnesium perchlorate, the reactions gave good first-order plots over three half-lives ($r>0.9997$). In the presence of a small amount of magnesium perchlorate, the kinetics over 75% conversion of the reaction was processed well with Eqs. 6 and 7. Iterations of K_2 and k_3 by a FACOM 230 OS2/VS with a FORTRAN IV program gave constants which reproduced experimentally obtained plots exactly.

Synthesis of α Substance-I_B in *Saccharomyces cerevisiae*[1,2]

Haruhiko Aoyagi and Nobuo Izumiya

Laboratory of Biochemistry, Faculty of Science 33, Kyushu University, Higashi-ku, Fukuoka 812

(Received April 18, 1977)

Two hexapeptides, H–Arg–Gly–Pro–Phe–Pro–Ile–OH (**1a**) and H–Arg–Pro–Gly–Phe–Pro–Ile–OH (**1b**), have been proposed for a factor inducing sexual agglutination in the yeast and were synthesized by a conventional method. Compound **1a** was completely identical with the natural peptide in thin-layer chromatography, mass spectrometric measurements, and biological assay on agglutination. Compound **1b** showed the same biological activity as **1a** though distinct differences in the chemical data were observed. Strong bitterness of the **1a** and **1b** was discovered.

Sakurai *et al.*[3] reported the isolation of a peptidyl factor named α substance-I from α type cells (H15 strain) of heterothallic yeast *Saccharomyces cerevisiae*. The active principle induces sexual agglutinability in opposite a (ei) type cells (H22 strain) prior to the mating reaction. It was later found that the factor could be separated into two components by further purification and one of them was designated as α substance-I_B (abbreviated as I_B).[4] Sakurai *et al.* intended to determine the amino acid sequence of I_B by means of mass spectrometry and postulated a tentative structure as H–Arg–Gly–Pro–Phe–Pro–Ile–OH (**1a**). In the beginning, however, an alternate structure of H–Arg–Pro–Gly–Phe–Pro–Ile–OH (**1b**) for I_B could not be excuded because of presence of the unexpected fragment ions. We intended to ascertain the correct structure of the I_B by the syntheses of the supposed hexapeptides, **1a** and **1b**.

The present paper deals with the syntheses of **1a**·2AcOH and **1b**·2AcOH by a conventional method and the comparison of the synthetic peptides with the natural I_B by thin-layer chromatography, mass spectrometry and biological assays.

The syntheses of **1a**·2AcOH and **1b**·2AcOH are outlined in Figs. 1 and 2. The mixed anhydride method[5] was employed through all coupling reactions and the removal of Boc groups of the intermediates was performed by the action of hydrogen chloride in ethyl acetate. The protected hexapeptide **8a** prepared from Z–Arg(NO_2)–OH and **7a**·HCl was hydrogenated in the presence of palladium black, and the desired product (**1a**) was obtained as diacetate by lyophilization. The similar procedure was employed for the preparation of **1b**. The intermediate **8b** contained minor by-products and was purified by silica gel column chromatography, and the desired product (**1b**) was obtained as diacetate. The homogeneity of **1a**·2AcOH and **1b**·2AcOH was confirmed by paper and thin-layer chromatography, paper electrophoresis and elemental analysis.

For the comparison of the synthetic peptides with natural I_B, thin-layer chromatography was performed at first using four different systems, the result being given in Table 1. In all cases, the **1a**·2AcOH revealed com-

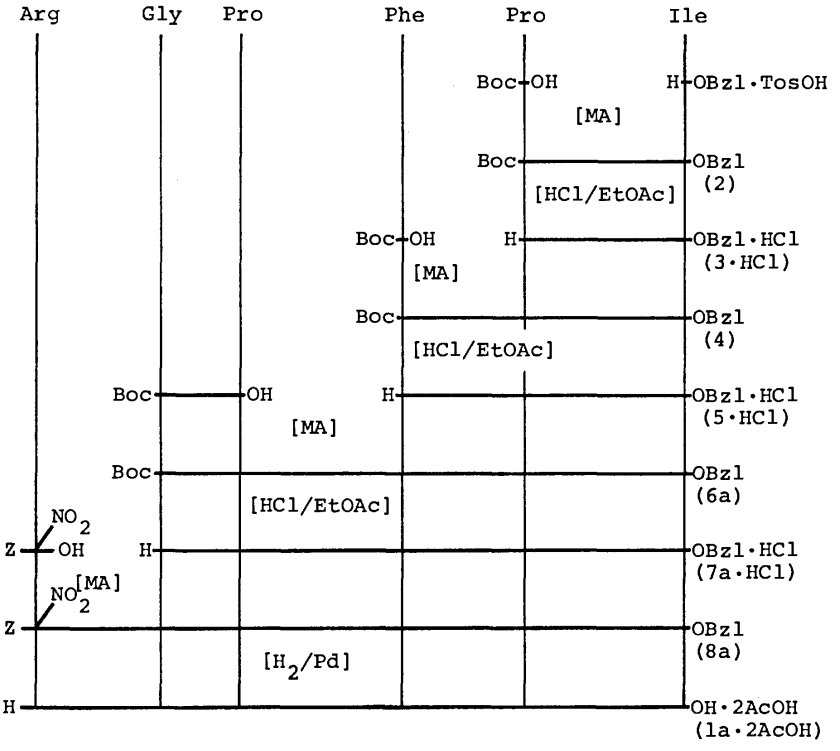

Fig. 1. Synthesis of the hexapeptide, **1a**.

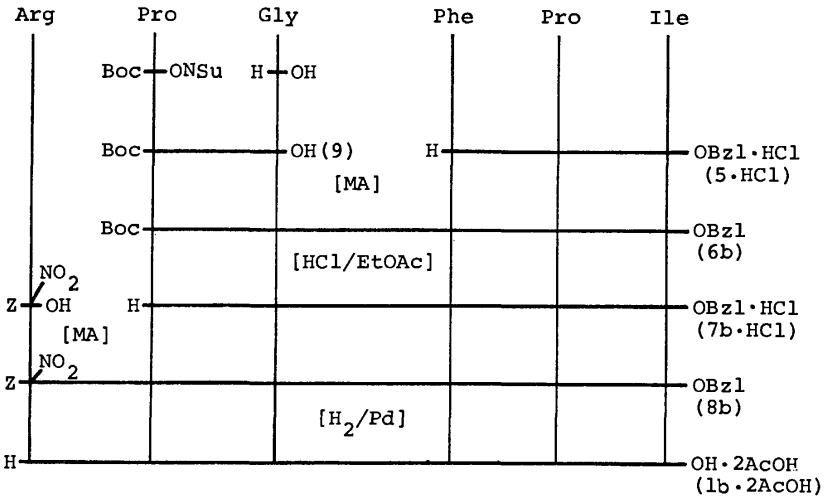

Fig. 2. Synthesis of the hexapeptide, **1b**.

Table 1. Thin-layer chromatography of natural and synthetic peptides

Solvent	Carrier	R_f[a]		
		I_B	**1a**·2AcOH	**1b**·2AcOH
1-BuOH–AcOH–H_2O (4 : 1 : 5, upper phase)	Silica gel[b]	0.18	0.18	0.17
1-BuOH–AcOH–pyridine–H_2O (15 : 3 : 10 : 12)	Silica gel[b]	0.59	0.59	0.57
1-BuOH–1-PrOH–0.2 M AcOH (2 : 1 : 3, upper phase)	Silica gel[b]	0.11	0.11	0.09
1-BuOH–1-PrOH–0.2 M AcOH (2 : 1 : 3, upper phase)	Cellulose[c]	0.58	0.58	0.63

a) The chromatograms were stained with ninhydrin followed by chlorine–toluidine. b) The plates coated with siligel gel GF_{254} (Merck) in 0.25-mm thickness were used. c) The plates coated with cellulose (Merck) in 0.1-mm thickness were used.

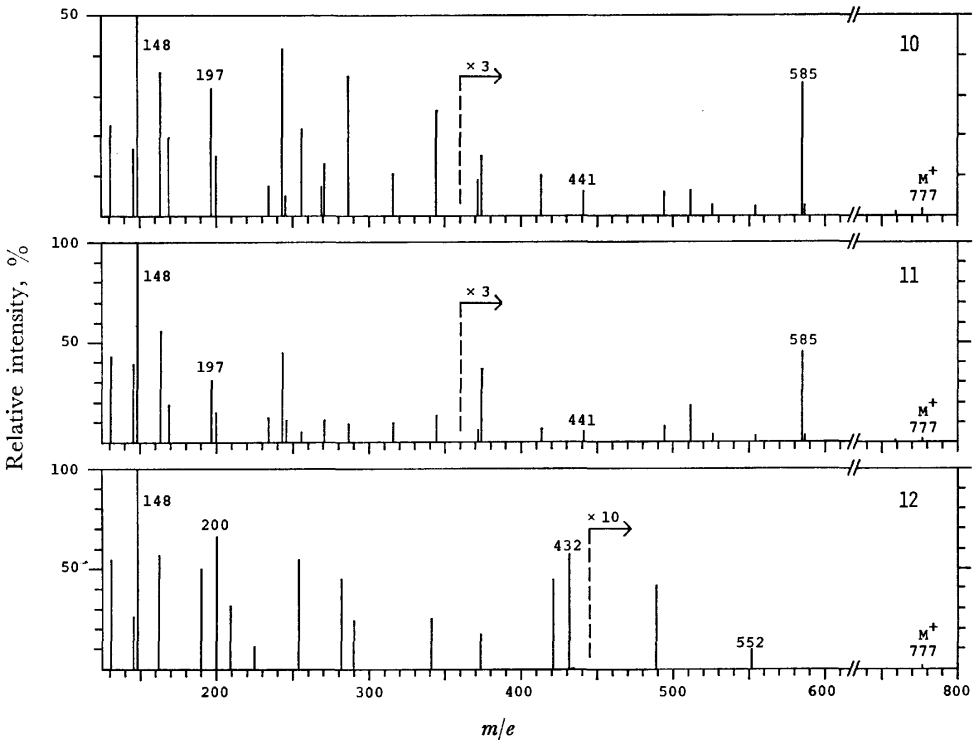

Fig. 3. Mass spectra of the derivative (**10**) of I_B and the derivatives (**11** and **12**) of the hexapeptides (**1a** and **1b**).

plete identity with I_B. The difference between R_f's of **1b**·2AcOH and I_B obvious.

Prior to comparison of mass spectra, the N-terminal arginine residues in I_B, **1a**·2AcOH, and **1b**·2AcOH were converted to α-*N*-acetyl-δ-*N*-pyrimidyl-ornithines and the C-terminus to methyl esters according to the literature.[6] The spectra of the derivatives, which named [Ac–Orn(Pyr)[1]]–I_B–OMe (**10**), [Ac–Orn(Pyr)[1]]–**1a**–OMe (**11**) and [Ac–Orn(Pyr)[1]]–**1b**–OMe (**12**), respectively, from I_B, **1a**, and **1b** are shown in Fig. 3. Compound **11** showed ion peaks at *m/e* 777 (M^+), 585, 441, 197, and 148, which were exactly the same as those observed for the corresponding **10** from I_B. On the contrary, the spectra of **12** were quite different in fragmentation pattern from those of **10** and **11**. From these results, the identity of **1a** with I_B was verified unambiguously.

The biological activities of the natural and synthetic peptides to induce agglutinability in a (ei) type cells were examined, and the I_B and **1a**·2AcOH showed the activity in the same degree at dosages at 2—20 ng/ml. Contrary to our expectation, the **1b**·2AcOH also showed almost the same activity as I_B, the finding suggesting that a strict structure is not always required for activity. This phenomenon is interesting because the replacement of amino acid residue by another in a biologically active peptide gives generally an influence for activity of the peptide.

Recently, Ribadeau Dumas *et al.* elucidated the whole primary structure of bovine β-casein,[7] which contained the partial sequence of –Arg[202]–Gly–Pro–Phe–Pro–Ile[207]–Ile–Val–OH[209] in the C-terminal portion. It is noteworthy that the part of –Arg[202]–Gly–Pro–Phe–Pro–Ile[207]– is identical with the I_B, On the other hand, two Japanese groups isolated the peptides having the structures of H–Arg–Gly–Pro–Pro–Phe–Ile–Val–OH (**13**)[8] and H–Gly–Pro–Phe–Pro–Val–Ile–OH (**14**)[9] from the enzymatic hydrolyzate of casein as bitter principles. Neither amino acid sequence of **13** nor that of **14** can be found in any part of the primary structure of casein, but both peptides are very similar to C-terminal portion of casein and I_B. We observed that the synthetic **1a**·2AcOH and **1b**·2AcOH showed strong bitter taste in almost the same threshold value. From these results, we assume that the partial structure of a substance corresponding to **13** will be H–Arg–Gly–Pro–Phe–Pro–Ile–, and that of **14** will be H–Gly–Pro–Phe–Pro–Ile–.

Experimental

Melting points are uncorrected. The ratio in parentheses after a solvent system was indicated by vol. TLC was carried out on silica gel G (Merck) with the solvent systems: R_f^1, $CHCl_3$–MeOH (5 : 1); R_f^2, 1-BuOH–AcOH–pyridine–H_2O (15 : 3 : 10 : 12). Paper chromatography was carried out on Toyo Roshi No. 52 paper with the solvent system: R_f^3, 1-BuOH–AcOH–pyridine–H_2O (4 : 1 : 1 : 2). Optical rotations were measured on a Union high sensitivity polarimeter PM-71. Amino acid analyses were performed with a Hitachi amino acid analyzer, KLA-5.

*Boc–Pro–Ile–OBzl (**2**).* To a chilled solution of Boc–Pro–OH (3.23 g, 15 mmol) and TEA (2.10 ml, 15 mmol) in THF (30 ml) was added isobutyl chloroformate (1.97 ml, 15 mmol) at −5 °C. After 15 min, a chilled solution of H–Ile–OBzl·TosOH (5.90 g, 15 mmol) and TEA (15 mmol) in $CHCl_3$ (30 ml) was added. The mixture was left to stand overnight at room temperature, evaporated *in vacuo*, and the oily residue was dissolved in EtOAc. The solution was washed successively with 4% $NaHCO_3$, 10% citric acid and water, and then dried (Na_2SO_4). The solvent was evaporated *in vacuo*; yield of an oil, 6.06 g (96%); R_f^1 0.91.

*Boc–Phe–Pro–Ile–OBzl (**4**).* Compound **2** (5.86 g, 14 mmol) was dissolved in 3.0 M hydrogen chloride in EtOAc (50 ml). The solution was allowed to stand for 40 min at room temperature and then evaporated; yield of oily H–Pro–Ile–OBzl·HCl (**3**·HCl), 4.87 g (98%). Then, **4** was prepared from Boc–Phe–OH (3.58 g, 13.5 mmol) and **3**·HCl (4.79 g, 13.5 mmol) as described for **2**; the yield of oily **4**; 7.20 g (94%); R_f^1 0.90.

*Boc–Gly–Pro–Phe–Pro–Ile–OBzl (**6a**).* Compound **4** (5.66 g, 10 mmol) was treated with 3.0 M hydrogen chloride in EtOAc (35 ml) as described for **3**·HCl; yield of oily H–Phe–Pro–Ile–OBzl·HCl (**5**·HCl), 4.75 g (95%). Then, **6a** was prepared from Boc–Gly–Pro·OH[10] (1.22 g, 4.5 mmol) and **5**·HCl (2.26 g, 4.5 mmol) as described for **2**; yield of oily **6a**, 3.00 g (93%); R_f^1 0.69.

*H–Gly–Pro–Phe–Pro–Ile–OBzl·HCl (**7a**·HCl).* Compound **6a** (2.88 g, 4 mmol) was treated as described for **3**·HCl. The oily product was solidified by the addition of ether; yield, 2.13 g (80%); mp 145—148 °C; $[\alpha]_D^{20}$ −69.8° (*c* 1, DMF); R_f^1 0.35, R_f^2 0.85.

Found: C, 61.28; H, 6.94; N, 10.48%. Calcd for $C_{34}H_{46}O_6N_5Cl\cdot 1/2H_2O$: C, 61.38; H, 7.12; N, 10.53%.

*Z–Arg(NO_2)–Gly–Pro–Phe–Pro–Ile–OBzl (**8a**).* This compound was prepared from Z–Arg(NO_2)–OH (1.06 g, 3 mmol) and **7a**·HCl (1.99 g, 3 mmol) as described for **2**. The product was recrystallized from EtOAc–ether; yield, 2.09 g (72%); mp 99—103 °C; $[\alpha]_D^{20}$ −58.0° (*c* 1, DMF); R_f^1 0.71, R_f^2 0.92.

Found: C, 59.31; H, 6.44; N, 14.41%. Calcd for $C_{48}H_{62}O_{11}N_{10}\cdot H_2O$: C, 59.24; H, 6.63; N, 14.40%.

*H–Arg–Gly–Pro–Phe–Pro–Ile–OH·2AcOH (**1a**·2AcOH).* Compound **8a** (389 mg, 0.4 mmol) was dissolved in a mixture of MeOH (5 ml), AcOH (2 ml) and water (3 ml), and treated with hydrogen in the presence of Pd black overnight. The filtrate of the reaction mixture was evaporated and the evaporation was repeated several times on the addition of water. The residue was dissolved in water and lyophilized to leave a solid; yield, 312 mg (95%); mp 102—108 °C; $[\alpha]_D^{21}$ −87.6° (*c* 1, H_2O). The homogeneity of **1a** was confirmed by ninhydrin and Sakaguchi reagent on paper electrophoresis and paper chromatography; R_f^3 0.88. Amino acid ratios in an acid hydrolyzate; Pro 2.12, Gly 1.00, Ile 0.98, Phe 0.96, Arg 0.97.

Found: C, 54.18; H, 7.53; N, 15.55%. Calcd for $C_{33}H_{51}O_7N_9\cdot 2CH_3COOH\cdot H_2O$: C, 53.93; H, 7.46; N, 15.30%.

*Boc–Pro–Gly–OH (**9**).* To a solution of glycine (1.13 g, 15 mmol) and TEA (15 mmol) in water (70 ml) at 5 °C was added Boc–Pro–ONSu[11] (3.89 g, 12.5 mmol) in dioxane (50 ml). The mixture was stirred for 30 min at 5 °C and overnight at room temperature. After the dioxane was evaporated, the aqueous solution was acidified with 10% citric acid and extracted with EtOAc. The organic layer was washed with water, dried and evaporated to leave a solid. The product was recrystallized from EtOAc–ether; yield, 2.37 g (70%); mp 159—160 °C; $[\alpha]_D^{20}$ −60.8° (*c* 1, DMF); R_f^1 0.22.

Found: C, 52.78; H, 7.40; N, 10.14%. Calcd for $C_{12}H_{20}O_5N_2$: C, 52.93; H, 7.40; N, 10.29%.

*Boc–Pro–Gly–Phe–Pro–Ile–OBzl (**6b**).* This compound was prepared from **9** (0.95 g, 3.5 mmol) and **5**·HCl (1.76 g,

3.5 mmol) as described for **2**; yield of an oil, 2.47 g (98%); R_f^1 0.72.

*H-Pro-Gly-Phe-Pro-Ile-OBzl·HCl (**7b**·HCl).* Compound **6b** (2.16 g, 3 mmol) was treated as described for **3**·HCl. The oily product was solidified by the addition of ether; yield, 1.70 g (84%); mp 91—94 °C; $[\alpha]_D^{20}$ −39.6° (*c* 1, DMF); R_f^1 0.34, R^2 0.82.

Found: C, 60.38; H, 7.07; N, 10.34%. Calcd for $C_{34}H_{46}O_6N_5Cl\cdot H_2O$: C, 60.56; H, 7.18; N, 10.39%.

*Z-Arg(NO$_2$)-Pro-Gly-Phe-Pro-Ile-OBzl (**8b**).* This compound was prepared from Z-Arg(NO$_2$)-OH (0.88 g, 2.5 mmol) and **7b**·HCl (1.68 g, 2.5 mmol) as described for **2**. The oily product was obtained in 2.30 g. For purification, a half (1.15 g) of the product was dissolved in a solvent of $CHCl_3$–MeOH–AcOH (95 : 5 : 1), applied on a column (2.4 × 84 cm) with silica gel, and eluted with the same solvent. The fractions with the desired product were evaporated to leave an oil which was solidified by the addition of ether, the remainder (1.15 g of the product) being purified by the same procedure. Recrystallization from EtOAc–ether gave 0.92 g (38%) of pure **8b**; mp 98—105 °C; $[\alpha]_D^{20}$ −33.8° (*c* 1, DMF); R_f^1 0.68; R_f^2 0.91.

Found: C, 59.79; H, 6.59; N, 14.40%. Calcd for $C_{48}H_{62}O_{11}N_{10}\cdot 1/2H_2O$: C, 59.80; H, 6.59; N, 14.53%.

*H-Arg-Pro-Gly-Phe-Pro-Ile-OH·2AcOH (**1b**·2AcOH).* Compound **8b** (386 mg, 0.4 mmol) was treated as described for **1a**·2AcOH; yield of a solid, 314 mg (95%); mp 107—112 °C; $[\alpha]_D^{21}$ −56.2° (*c* 1, H_2O); R_f^3 0.89. Amino acid ratios in an acid hydrozate: Pro 2.11, Gly 1.00, Ile 0.97, Phe 0.96, Arg 0.95.

Found: C, 53.67; H, 7.45; N, 15.52%. Calcd for $C_{33}H_{51}O_7N_9\cdot 2CH_3COOH\cdot H_2O$: C, 53.93; H, 7.46; N, 15.30%.

*Comparison of the Natural Peptide (I_B) and Synthetic Peptides (**1a** and **1b**).* *TLC*: TLC was carried out using four different systems, the results being shown in Table 1.

Mass Spectrometric Measurements: The I_B, **1a**·2AcOH, and **1b**·2AcOH were modified according to the literature,[6] and the measurements were performed on a Hirachi RMU-6L at 70 eV. The results are shown in Fig. 3.

Agglutinability Assays: The activities of I_B, **1a**·2AcOH, and **1b**·2AcOH to induce agglutinability in a (ei) type cells (H 22 strain) were assayed according to the literature.[3] The I_B and **1a**·2AcOH showed the activity in the same degree at 2—20 ng/ml. Compound **1b**·2AcOH also showed the same activity.

Bitterness Evaluation. Each synthetic peptide (**1a**·2AcOH or **1b**·2AcOH) was dissolved in water and a series of solution of decreasing concentration were prepared. The degree of bitterness was organoleptically determined by a panel of five men in our laboratory according to the literature.[12] Compounds **1a**·2AcOH and **1b**·2AcOH showed the bitter taste in the same degree at 0.13—0.25 mM (0.1—0.2 mg/ml).

We wish to express our thanks to Professor S. Tamura, University of Tokyo, for his helpful discussion, and to Dr. A. Sakurai, Institute of Physical and Chemical Research, Saitama, for TLC and agglutinability assays for the comparision of the synthetic peptides with I_B. We also thank to Drs. A. Isogai and K. Aizawa, University of Tokyo, for the measurements of mass spectra.

^{13}C-NMR-Spektren von thermischen Oligomeren des Cyclopentadiens

Kiyoshi NAKAGAWA, Shoji IWASE, Yasutaka ISHII,
Sawako HAMANAKA, und Masaya OGAWA
Abteilung für Angewandte Chemie, Technische Fakultät der Universität Kansai, Senriyama, Suita, Osaka 564

(Received April 11, 1977)

Die zwei Isomere des Dicyclopentadiens und vier Isomere des Tricyclopentadiens werden isoliert und ihre ^{13}C-NMR-Spektren werden vorgelegt, wobei die Trimerisationsstufe des Cyclopentadiens systematisch in allen Einzelheiten behandelt wird. Die ^{13}C-NMR-Spektren von Oligomeren des Cyclopentadiens werden durch Vergleich mit Spektren von Vergleichssubstanzen zugeordnet. Es ist beachtenswert, dass zwei neue Stereoisomere des Tricyclopentadiens isoliert und nachgewiesen werden.

Die Oligomere des Cyclopentadiens erregen von früher her die Aufmerksamkeit.[1] Die Entstehung des Tricyclopentadiens spielt eine bedeutende Rolle für alle folgenden Oligomerisationsprozesse. Die Addition des dritten Cyclopentadiens an den Cyclopentenring des *endo-* oder *exo*-Dicyclopentadiens wurde bisher noch nicht systematisch untersucht. Die ^{13}C-NMR-Spektroskopie hat sich in den letzten Jahren zu einem leistungsfähigen Hilfsmittel des organischen Chemikers entwickelt. In der vorliegenden Arbeit werden die ^{13}C-MNR-spektroskopischen Daten einer oligomeren Reihe von Cyclopentadien interpretiert, wobei die Trimerisationsstufe des Cyclopentadiens ausführlich diskutiert wird.

Ergebnisse und Diskussion

*^{13}C-NMR-Spectren von Dicyclopentadienen **1** und **2**.*

Das ^{13}C-NMR-Spektrum von **1**, das schon von Johnson und Jankowski berichtet wurde[2], konnte nicht vollständig zugeordnet werden. Die in der Tabelle 1 angegebenen Zuordnungen der ^{13}C-Signale von **1** und **2** ergeben sich aus folgenden Gesichtspunkten. Bei Verbindung **7** liegen drei ^{13}C-Signale um 5 bis 43.7 ppm bei tieferem Feld als bei **1**. Der Substituenteneinfluss der Hydroxylgruppe auf die chemische Verschiebung des C-1-Signals ist α-Effekt von $\Delta\delta_\alpha=43.7$ ppm (vgl. ^{13}C-NMR-Spektren von Cyclopentanol[3] und 2-Hydroxynorbornan[4]). Daher entspricht dem C-1-Atom das Signal bei $\delta=34.7$ ppm. Der Einfluss der Hydroxygruppe auf das C-2- oder C-7a-Signal ist β-Effekt von $\Delta\delta_\beta=5$ oder 11.7 ppm. Charakteristisch getrennt von dem C-7a-Signal (sp^3-Kohlenstoff) erscheint das C-2-Signal (sp^2-Kohlenstoff). Somit entspricht dem C-2-Atom das Signal bei $\delta=132.1$ ppm, so dass das Signal bei $\delta=41.3$ ppm dem C-7a-Atom entspricht. Bei Verbindung **8** liegen zwei sp^3-Kohlenstoff-Signale *ca.* 5 ppm bei höherem Feld als bei **1**. Da diese Hochfeldverschiebungen aufgrund der Hydrierung von Norbornendoppelbindung sind, entsprechen den C-4- und C-7-Atomen diese zwei sp^3-Kohlenstoff-Signale bei $\delta=$ 45.3 und 46.3 ppm in **1**, wobei die Verschiebungsdifferenz zwischen C-4 und C-7 nicht zu unterscheiden ist. Bei Verbindung **9** wird das Signal des C-4-Atoms (γ-ständiges Kohlenstoffatom zu Cyclopentendoppelbindung in **8**) mit 1.7 ppm nach tieferem Feld im Vergleich zu **8** verschoben, während das δ-ständige C-7-Atom durch Hydrierung der Cyclopentendoppelbindung nahezu unbeeinflusst bleibt. Das Signal bei $\delta=45.3$ ppm muss also C-4 zugeordnet werden und das

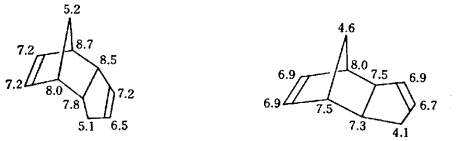
a), b) Tauschbare Zuordnungen.

Signal bei $\delta=46.3$ ppm entspricht C-7 in **1**. Somit können die Verschiebungen bei 135.6 und 54.8 ppm C-3 und C-3a in **1** zugeordnet werden.

Die Zuordnung der Signale von C-5, C-6, und C-8 in Verbindung **2** ergibt sich, wenn man berücksichtigt, dass C-5 und C-6 durch sterischen Kompressionseffekt des Cyclopentenringes nicht beeinflusst werden, während C-8 durch diesen Effekt nach höherem Feld verschoben wird. Für C-5 und C-6 in **2** beobachtet man die Tieffeldverschiebungen im Vergleich zu **1**.

Wie bei **1** können die Signale von anderen Kohlenstoffatomen in **2** durch Vergleich mit Spektren von Vergleichssubstanzen **10** und **11** zugeordnet werden. Die Ergebnisse sind in Tabelle 1 zusammengefasst.

Longitudinale Relaxationszeiten T_1 von Dicyclopentadienen. Wenn Relaxationsvorgänge durch intramolekulare C-H-Dipol-Dipol-Wechselwirkungen beherrscht werden, sollte die longitudinale Relaxationszeit T_1 von ^{13}C charakterisch von der Anzahl direkt an Kohlenstoff gebundener Wasserstoffatome abhängen.[5] T_1 von Dicyclopentadienen sind in Schema 1 zusammengefasst. Diese Ergebnisse unterstützen die oben erwähnten Zuordnungen der ^{13}C-chemischen Verschiebungen von Dimeren des Cyclopentadiens.



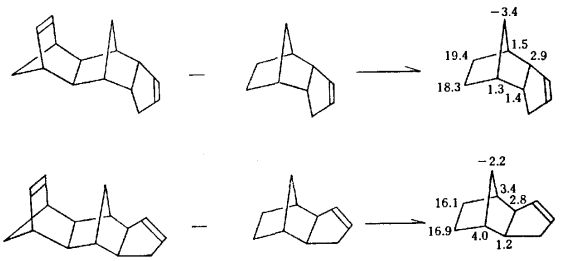
Schema 1. T_1 von Dimeren des Cyclopentadiens (in Sek).

*^{13}C-NMR-Spektren von Tricyclopentadienen **3** und **4**.*

Lässt man frisch destilliertes Cyclopentadien bei normaler Temperatur stehen, so erstarrt es zum *endo*-Dicyclopentadien, aber das *exo*-Dicyclopentadien tritt bei höherer Temperatur in Erscheinung.[1d] Die Angliederung des dritten Cyclopentadiens ist eine 1,4-Addition von Monomeren an die Norbornendoppelbindung oder Cyclopentendoppelbindung des *endo*- oder *exo*-Dicyclopentadiens (s. Tabelle 2). Unter den denkbaren 14 Isomeren sind 4 Isomere molekülmässig unwahrscheinlich.

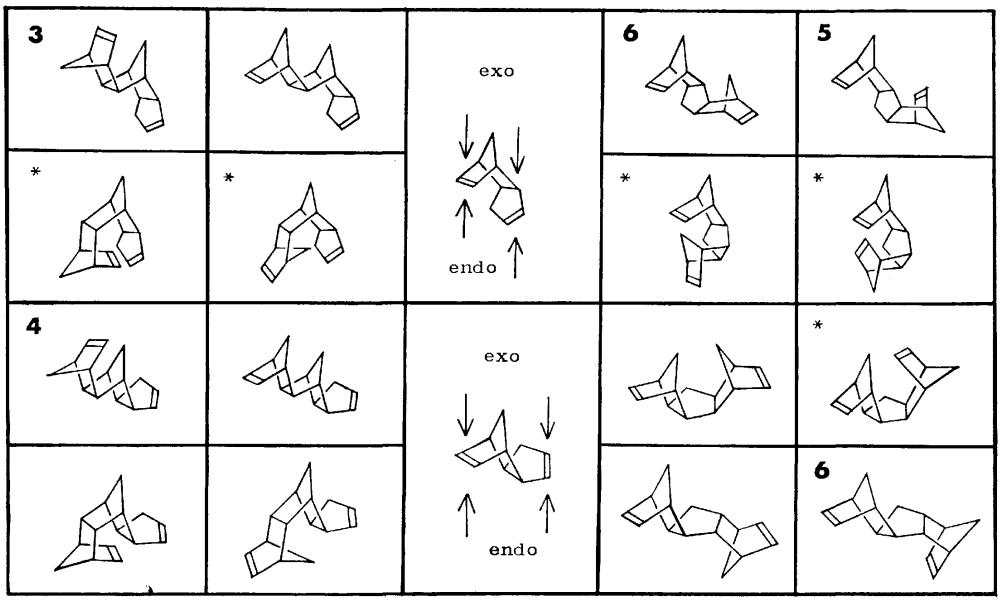
Was die Norbornendoppelbindung betrifft, kommt man zu dem Schluss, dass Cyclopentadien in *exo*-Stellung addiert wird.[1d] Innerhalb der *exo*-Stellung bleibt noch die Entscheidung für die gegenseitige Lage der Brücken zu treffen. Diese Alternative zwischen *exo-endo*- und *exo-exo*-Addition von Cyclopentadien an die Norbornendoppelbindung wurde von Soloway,[6] Stille und Frey[7] und de Vries und Winstein[8] entschieden. Daher kann man sagen, dass *exo-endo*-Addukte **3** und **4** bevorzugt gebildet werden.[1f,1g]

Somit können die ^{13}C-Signale von Norbornanringen (C-3a, C-4, C-4a, C-8a, C-9, C-9a, und C-10) in **3** und **4** mit Hilfe von Schema 2 zugeordnet werden, wobei man Norbornenring als symmetrischen Substituenten betrachten kann und daher die ^{13}C-chemischen Verschiebungen des Norbornanringes in **3** oder **4** durch Norbornenring symmetrisch beeinflusst werden.



Schema 2. Einfluss von Norbornenring auf die ^{13}C-chemischen Verschiebungen Norbornanring in **3** order **4**.

TABELLE 2. DENKBARE TRICYCLOPENTADIENE



* Stereochemisch unmögliche Verbindungen.

Tabelle 3. ^{13}C-Chemische Verschiebungen (δ in ppm, $\delta_{TMS}=0$) und Multiplizitäten der tricyclopentadiene **3** und **4**

	3	**4**
C-1	31.3(t)	38.9(t)
C-2	132.0(d)	132.4(d)
C-3	131.2(d)	131.5(d)
C-3a	56.0(d)	58.8(d)
C-4	41.3(d)	42.4(d)
C-4a	44.8(d)	48.6(d)
C-5 oder C-8	46.9(d), 47.2(d)	46.6(d)
C-6 oder C-7	135.7(d), 136.3(d)	135.2(d), 135.4(d)
C-8a	40.4(d)	49.6(d)
C-9	42.7(d)	44.8(d)
C-9a	44.4(d)	46.6(d)
C-10	38.9(t)	26.8(t)
C-11	53.3(t)	53.2(t)

Andererseits können die ^{13}C-Signale von Norbornenringen (C-5, C-6, C-7, C-8, und C-11) durch Vergleich der ^{13}C-chemischen Verschiebungen von **1** und **2** zugeordnet werden. Die ^{13}C-Signale von Cyclopentenringen (C-1, C-2, und C-3) können durch Vergleich der Verbindungen **8** und **10** zugeordnet werden. Die Ergebnisse sind in Tabelle 3 zusammengefasst.

*^{1}H- und ^{13}C-NMR-Spektren von Tricyclopentadienen **5** und **6**.* Was die Addition des dritten Cyclopentadiens an die Cyclopentendoppelbindungen der Dimere betrifft, ist es bisher noch nicht möglich, zwischen der *endo-* und *exo-* Stellung zu entscheiden. Die Isolierung einheitlicher Isomere des Cyclopentadiens ist zwar mit Schwierigkeiten verbunden, aber doch ist es uns gelungen, zwei neue Isomere, **5** und **6**, neben **3** und **4** durch geeignete Variation der Versuchsbedingungen zu isolieren (s. exp. Teil).

Die Elementaranalysen und das in den Massenspektren von **5** und **6** beobachtete Auftreten eines Molekul-Ions bei $m/e=198$ weisen beide Verbindungen als Trimere des Cyclopentadiens aus. In den IR-Spektren von **5** und **6** treten C=C-Valenzschwingungen des Norbornenringes auf, aber keine C=C-Valenzschwingungen des Cyclopentenringes (s. Tabelle 4), was die folgende Tatsache zeigt, dass **5** und **6** zueinander Stereoisomere sind, die durch Addition von Cyclopentadien an Cyclopentendoppelbindungen der Dimere gebildet werden.

Dem Nachweis, dass die neuen Trimere im Verhältnis der Stereoisomere zueinander stehen, schliesst sich eine weitgehende Klärung der konfigurativen Verhältnisse an. Tabelle 5 bietet Daten für Zusammensetzung der Tricyclopentadiene bei der Reaktion von Cyclopentadien an *endo-* oder *exo*-Dicyclopentadien(s. exp. Teil). Da die Norbornendoppelbindung bei weitem reaktiver als die Cyclopentendoppelbindung ist, tritt Trimer **4** auf als Nebenprodukt bei der ersten Reaktion durch *exo-endo*-Addition von Cyclopentadien an Norbornendoppelbindung des *exo*-Dicyclopentadiens, das infolge der Isomerisierung des *endo*-Dicyclopentadiens entsteht, und tritt Trimer **3** auf als Nebenprodukt bei der zweiten Reaktion durch *exo-endo*-Addition von Cyclopentadien an Norbornendoppelbindung des *endo*-Dicyclopentadiens, das infolge der leichten Dimerisierung des Cyclopentadiens entsteht. Es ist bemerkenswert, dass kein Trimer **6** bei der ersten Reaktion nachgewiesen wird und dass kein Trimer **5** bei der zweiten Reaktion gefunden wird. Dieses Resultat führt zwangsläufig zu der Folgerung, dass Trimer **5** durch Addition von Cyclopentadien an Cyclopentendoppelbindung des *endo*-Dicyclopentadiens gebildet wird und dass Trimer **6** durch Addition von Cyclopentadien an Cyclopentendoppelbindung des *exo*-Dicyclopentadiens gebildet wird. Eine Fülle zusätzlicher Informationen steuern die NMR-Messungen bei.

Tabelle 4. Die charakteristischen Absorptionsbanden der IR-spektren von Tricyclopentadienen

Tricyclopentadiene	C=C (cm^{-1})	
	Norbornenring	Cyclopentenring
3	1570	1620
4	1570	1617
5	1568	—
6	1570	—

Tabelle 5. Die Zusammensetzung der Trimere bei der Reaktion von Cyclopentadien und *endo-* oder *exo*-Dicyclopentadien in Benzol (180 °C 1 Stde.)

Reaktionen	Zusammensetzung der Trimere (%)			
	3	**4**	**5**	**6**
Cyclopentadien + *endo*-Dicyclopentadien	66.8	16.0	17.2	0.0
Cyclopentadien + *exo*-Dicyclopentadien	14.6	74.5	0.0	10.9

Das ^{1}H-NMR-Spektrum von Tricyclopentadien **5** (s. Abb. 1) oder **6** (s. Abb. 2) weist ein oder zwei Multipletts für olefinische Protonen des Norbornenringes ($\delta=$ 5.65—6.10) und kein Multiplett für olefinische Protonen des Cyclopentenringes($\delta=5.20$—5.60) auf, was mit dem Ergebn s der Tabelle 4 übereinstimmt. Die olefinischen Protonen des Norbornenringes von **5** sind äquivalent und die von **6** sind nicht äquivalent. Somit kann man sagen, dass Trimer **5** die symmetrische Verbindung ist und dass Trimer **6** die asymmetrische Verbindung ist. Aus alledem ergibt sich, dass das symmetrische Trimer **5** durch *exo-endo*-Addition von Cyclopentadien an Cyclopentendoppelbindung des *endo*-Dicyclopentadiens gebildet wird und dass das asymmetrische Trimer **6** nicht durch *exo-endo*-Addition von Cyclopentadien an Cyclopentendoppelbindung des *endo*-Dicyclopentadiens ge-

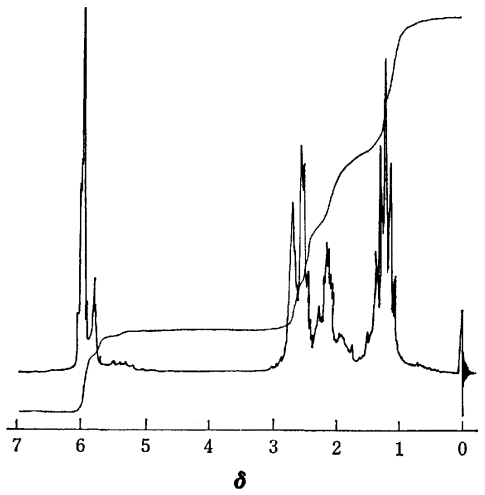


Abb. 1. 100 MHz ^{1}H-NMR-Spektrum von Tricyclopentadien **5** in CCl_4(Reinbeit; 80%).

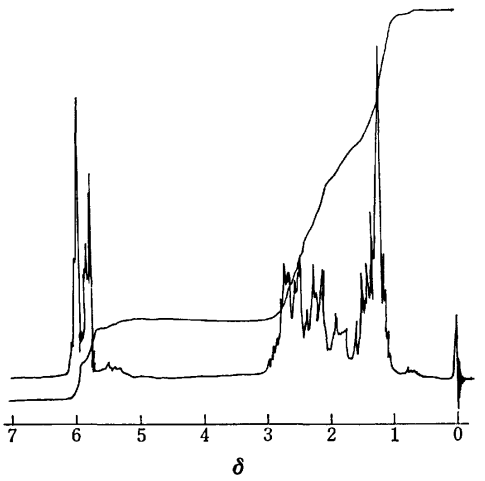

Abb. 2. 100 MHz ^{1}H-NMR-Spektrum von Tricyclopentadien **6** in CCl_4(Reinbeit; 71%).

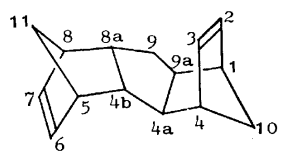
bildet wird, sondern durch *endo-endo*-Addition von Cyclopentadien an Cyclopentendoppelbindung des *exo*-Dicyclopentadiens. Es ist schwer, die anderen Wasserstoffe, mit Ausnahme der Brücken-Methylene ($\delta = 1.05$—1.50), vollständig zuzuordnen, da die Signalgruppen überlappen.

Daher kann man nur sieben ^{13}C-Signale für die symmetrische Verbindung **5** erwarten. In der Tat beobachtet man sieben Signale im ^{13}C-NMR-Spektrum von **5**. Die Zuordnung der Signale von **5** ergibt sich, wenn man die Ergebnisse der Tabelle 1 und die Off-Resonance-Technik benutzt(s. Tabelle 6). Das ^{13}C-NMR-Spektrum der asymmetrischen Verbindung **6** weist die Existenzen von sp^2-Kohlenstoffatomen der *exo*- und *endo*-Norbornentypen und Brücken-Kohlenstoffatome der *exo*- und *endo*-Norbornentypen auf(s. Tabelle 6), was mit der Struktur **6** in Tabelle 2 übereinstimmt. In diesem Fall sind die unsicheren Zuordnungen von C-1, C-4, C-4a usw. kein grosses Problem. Die in dieser Arbeit angegebenen Zuordnungen der ^{13}C-NMR-Spektren von thermischen Oligomeren des Cyclopentadiens werden nach Einführungen von Deuterium und anderen Substituenten festgestellt werden.

TABELLE 6. ^{13}C-CHEMISCHE VERSCHIEBUNGEN (δ IN ppm, $\delta_{TMS} = 0$) UND MULTIPLIZITÄTEN DER TRICYCLOPENTADIENE **5** UND **6**



5

Angesichts der vielen theoretischen Möglichkeiten der Tricyclopentadiene ist es besonders auffällig, dass nur vier Vertreter bekannt sind. Offenbar findet bei der Bildung der Tricyclopentadiene eine weitgehende Stereoauslese statt. Da sich in ähnlicher Weise Argumente für die Konstitution der höheren Oligomere des Cyclopentadiens beibringen lassen, bilden dieso Ergebnisse den Schlüssel für das Verständnis des Aufbaues der ganzen oligomeren Reihe.

Experimenteller Teil

Die Aufnahme der ^{1}H-NMR-Spektren erfolgte mit einem JEOL-Gerät PS-100 in CCl_4(TMS als innerer Standard), während die Massenspektren mit LEOL-Gerät JMS-OlSG aufgenommen wurden(75 eV). Die IR-Spektren wurden mit einem Shimadzu-Gerät IR-27G aufgenommen. Zur Aufnahme der Puls-Fourier-Transform-^{13}C-NMR-Spektren diente ein JPS-EC-100 von JEOL-Gerät mit einer Messfrequenz von 25.15 MHz, wobei die Reproduzierbarkeit der ^{13}C-chemischen Verschiebungen ± 0.05 ppm beträgt. Alle Substanzen wurden als 50%-ige Lösungen in $CDCl_3$ gemessen(TMS als innerer Standard). Das Deuteriumsignal des Lösungsmittels diente als Lock(Lockfrequenz 15.36 MHz). Die FT-^{13}C-NMR-Spektren wurden unter Akkumulation von 200 Pulsinterferogrammen bei einer Pulsbreite von 12.5 μsek(Pulswinkel 45°) und einem Pulsintervall von 6 sek durch Fourier-Transformation des akkumulierten Interferogramms mit einem JEC-6-Rechner erhalten(Spektrumbreite 5 kHz; Datenpunkte 16382). Die in den Tabellen 1, 3, und 6 angegebenen Multiplizitäten berhen auf Off-Resonance-Technik. Die Messung von T_1 beruhte auf Inversion-Wiederherstellung-^{13}C-Experimenten (180°-t-90°), wobei ein JEOL-Auto-T_1-Programm verwendet wurde. Die Genauigkeit von T_1 beträgt ± 0.7 sek.

Darstellung und Isolierung der Verbindungen 1—6. Dimer **1** wurde durch Dimerisierung des Cyclopentadiens, das durch thermische Zersetzung des verkäuflichen *endo*-Dicyclopentadiens gewonnen wurde[9], bei Zimmertemperatur gewon-

nen, während Dimer **2** nach der Methode von Bartlett und Goldstein gewonnen wurde.[10] Trimere **3**—**6** wurden auf folgende Weise gewonnen. Frisch destilliertes Cyclopentadien wurde unter N_2 im Autoklaven 5 Stdn. auf 150 °C erhitzt. Nach der Entfernung des Dicyclopentadiens wurde das Produktgemisch durch Behandeln mit siedendem Methylalkohol, in dem Tetracyclopentadien und die höheren Oligomere unlöslich sind, von dem Tricyclopentadien völlig befreit.[1b] Nach dem Umkristallisieren aus Methylalkohol erhielt man Trimer **3** (*m/e* 198, 132, 66). Durch Rektifikation der Mutterlauge erhielt man Trimer **5** ($C_{15}H_{18}$, Ber. C, 91.0; H, 9.0%. Gef. C, 90.9; H, 9.1%. *m/e* 198, 132, 66). Äquimolare Mengen frisch destillierten Cyclopentadiens und Dimer **2** wurden unter N_2 im Autoklaven 2 Stdn. auf 250 °C erhitzt. Durch Umkristallisieren aus Methylalkohol und Rektifikation der Mutterlauge erhielt man Trimere **4** und **6** (Gef. C, 91.1; H, 8.9%. *m/e* 198, 132, 66).

Darstellung der Verbindungen ***7***—***11***. α-1-Hydroxy-dicyclopentadien **7** wurde nach der Methode von Rosenblum gewonnen.[11] 5,6-Dihydro-dicyclopentadien **8** oder **10** wurde durch Hydrierung der Norbornendoppelbindung von **1** oder **2** mittels Raney-Nickel-Katalysators bei Zimmertemperatur unter Wasserstoffdruck von 140 kg/cm² gewonnen. 2,3,5,6-Tetrahydro-dicyclopentadien **9** oder **11** wurde durch Hydrierung der Cyclopentendoppelbindung von **8** oder **10** mittels Raney-Nickel-Katalysators bei 150 °C unter Wasserstoffdruck von 140 kg/cm² gewonnen. Alle diese Verbindungen wurden mit Hilfe von ^{1}H-NMR-Spektren bestätigt.

Reaktion von Cyclopentadien und endo- *oder exo-Dicyclopentadien.* Äquimolare Mengen(5×10^{-2} Mol) frisch destillierten Cyclopentadiens und *endo*- oder *exo*-Dicyclopentadien wurden in 160 ml Benzol unter N_2 im 300 ml Autoklaven 1 Std. auf 180 °C erhitzt. In dieser Reaktionsbedingung waren Ausbeuten von Trimeren 2—3% und wurden keine weiteren Oligomere des Cyclopentadiens nachgewiesen. Gaschromatographische Bestimmung des Mengenverhältnisses der Isomere des Tricyclopentadiens erfolgte mit einem Shimazu-Gerät GC-3AF mit Flammenionisationsdetektor; Säulenfüllung: PEG 6000 10 wt%; Säulendimension: 3 mm$\phi \times$ 3 m; Trägergas: N_2.

Photolytic Oxidation of Alkylbenzenesulfonic Acids by Aqueous Sodium Hypochlorite[1]

Masao NAKAMURA and Yoshiro OGATA*

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 4, 1976)

Photolyses of alkylbenzenesulfonic acids, such as benzene-, *p*-toluene-, and *p*-ethylbenzenesulfonic acids, in aqueous solution by sodium hypochlorite have been studied. In the presence of a large excess of hypochlorite, benzenesulfonic acid is completely photolyzed to give carbon dioxide and sulfuric acid. Irradiation of an equimolar mixture of substrate and hypochlorite in an aqueous solution yields the corresponding alkylbenzene, alkylphenol, arylalkyl alcohol and arylalkylaldehyde, some of which may be produced by an attack of the oxidant on alkyl chain. In some cases, small amounts of diaryl sulfones and chlorinated compounds are also detected.

Interest has recently centered on the decontamination of surfactants, sodium alkylbenzenesulfonate in particular, from waste water. Practically, the removal of surfactants has been done by biochemical or physical (*e.g.* adsorption) methods and sometimes by irradiation of sunlight or ultraviolet light in the presence of oxygen or appropriate oxidizing agents such as alkali hypochlorite and hydrogen peroxide. However, these methods are often insufficient for certain surfactants.

Matsuura and Smith[2,3] reported from kinetic and product analysis (GLC) studies that the photochemical autoxidation of aqueous alkali dodecylbenzenesulfonate (DBS) gives products containing formaldehyde, formic acid and acetaldehyde, which are finally oxidized to CO_2. On the other hand, a loss of surface activity of some surfactants by hypohalite on UV irradiation was observed.[4]

Recently, an effective industrial process[5] was developed for the photo-oxidative removal of several organic contaminants in waste water by aqueous alkali hypochlorite in excess, by which most organic materials are completely decomposed into CO_2, HCl and H_2O. Decontamination of organic compounds in waste water was accomplished by the combined use of irradiation with UV light in the presence of Cl gas or hypochlorite and activated sludge treatment.[6]

However, there is no detailed information on the intermediary products and reaction mechanism for the hypohalite oxidation. Some products might cause secondary pollution. We have examined the intermediary products and mechanism for the UV photolyses of anionic surfactants by aqueous sodium hypochlorite. As model compounds of alkylbenzenesulfonate type surfactants, simple sulfonates such as benzene-, *p*-toluene-, and *p*-ethylbenzenesulfonic acids were chosen. They were photolyzed under conditions of short irradiation time and a nearly equivalent amount of sodium hypochlorite. Analyses were carried out by means of GLC-mass spectra along with a comparison of the retention times of products with those of authentic samples by GLC.

Experimental

Gas chromatograms were recorded with a Yanagimoto Model GCG550 chromatograph employing a flame ionization detector and a 1.5 m × 3 mm copper column packed with Silicone OV17 5% on Celite. The mass spectra were measured with a Shimadzu Model GCMS-7000 mass spectrometer.

Materials. *Sodium Hypochlorite*: The aqueous solution of sodium hypochlorite was prepared as follows. Gaseous chlorine was bubbled into an aqueous 1 M-NaOH with ice-cooling, and the sodium chloride precipitated was filtered off. The solution can be stored for severl days in a refrigerator. The concentration was determined by iodometry before use.

Alkylbenzenesulfonic Acids: All the alkylbenzenesulfonic acids were commercial products of the best grade.

Irradiation of Benzenesulfomic Acid. A mixture of benzenesulfonic acid (0.099 M), aqueous sodium hypochlorite (0.103 M), and 1 M-NaOH solution (100 ml) were diluted with distilled water until the total volume became 400 ml. The solution was degassed with nitrogen and irradiated by quartz-filtered UV light employing a 300 W high pressure mercury lamp, nitrogen being bubbled at room temperature. Irradiation was stopped before complete disappearance of sodium hypochlorite. After irradiation, the excess sodium hypochlorite was removed with sodium sulfite, the aqueous solution being extracted with 100 ml ether. The aqueous layer was acidified to pH 2—3 with HCl and again extracted with 100 ml ether. The combined extracts, after being dried over anhydrous sodium sulfate, were concentrated, and then analyzed by means of GLC and GLC-mass spectrometry. The work-up for other alkylbenzenesulfonic acids is similar to that mentioned above.

Estimation of Evolved Carbon Dioxide. Carbon dioxide produced by photolysis was kept absorbed in the aqueous alkaline solution. The solution was acidified with sulfuric acid, carbon dioxide being expelled by N_2 stream from the reaction mixture. The CO_2 evolved was absorbed by aqueous 0.05 M-$Ba(OH)_2$ and determined by titration with 0.1 M-HCl.

Estimation of Sulfate Ion. Analysis of sulfate ion in the products was achieved gravimetrically by adding excess aqueous barium chloride to the acidified reaction mixture, barium sulfate precipitated being weighed.

Results and Discussion

Irradiation of an aqueous solution of benzenesulfonic acid in the presence of a 20-fold equivalent of sodium hypochlorite gives, after complete disappearance of hypochlorite, carbon dioxide and sulfate, their yields by photolysis being 95.7 and 83.5%, respectively. Benzenesulfonic acid is decomposed almost completely to give CO_2 and inorganic materials.

In the photolysis of an equimolar mixture of benzene-

* To whom all correspondence should be addressed.

sulfonate and hypochlorite by means of quartz-filtered UV light (>180 nm) for a short time, the yield of CO_2 was only *ca.* 3%. The organic products extracted with ether are given in Table 1. The products were identified by direct comparison of the GLC peaks with those of the authentic samples and also the parent ion peak and its pattern of fragmentation in mass spectra. Crystals of mp 128.5—129° C (lit, mp 128—129 °C) were isolated by condensation of the ether extract, and identified by GLC using three different columns (Silicone OV17 5% on Celite, Apiezon grease L 3% on Celite and PEG 20M 10% on Chromosorb) as diphenyl sulfone.

Table 1. Partial mass spectra of photo-oxidation products of benzensulfonic acid[a)]

Parent ion peak *m/e*	Fragment ion peak	Compound	Relative mole ratio

122	107 91 79 77 51 43	1-Phenyl-ethanol	0.41
120	105 91 77 51 43	Acetophenone	3.26
122	107 91 79 77 51 39	2-Phenyl-ethanol	5.97
122	107 94 91 77 39	*p*-Ethylphenol	2.15

a) Initial concentration: *p*-ethylbenzenesulfonic acid 23.0 mM, NaOCl 22.5 mM; pH≈11; room temperature. Conversion of ethylbenzenesulfonic acid into products was *ca.* 7%.

The results of photolysis of *p*-toluene- and *p*-ethylbenzenesulfonate, with equimolar hypochlorite by quartz-filtered light, are given in Tables 2 and 3, respectively. Reports[7)] on mass spectrometry are cited for identification of the products.

The photolytic oxidation of alkylbenzenesulfonic acid with hypochlorite gives rise mainly to alkylbenzene, alkylphenol, arylakyl alcohol, and arylalkyl aldehyde. Small amounts of chlorinated compounds such as monochlorophenols were also detected.

Typical conversion curves for the photodecomposition of aqueous sodium hypochlorite in the presence and absence of benzenesulfonic acid are shown in Fig. 1. Decomposition is rather fast with light of over 180 nm, and is accelerated by the addition of benzenesulfonic acid which probably acts as a sensitizer.

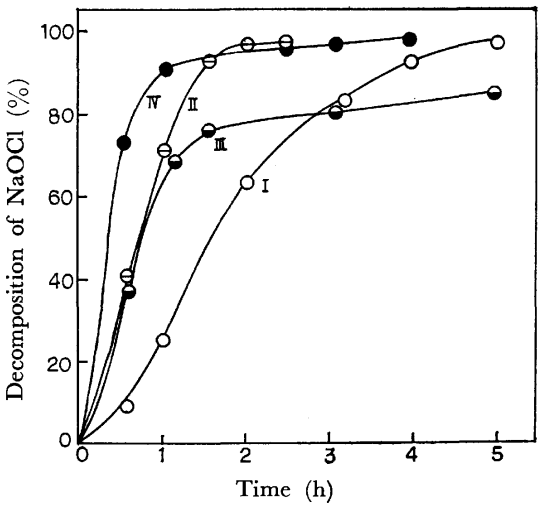

Fig. 1. Photodecomposition of aqueous sodium hypochlorite at room temperature and pH≈11 in the presence and absence of $PhSO_3H$.

Curve	Initial concentration (mM) NaOCl	Initial concentration (mM) $C_6H_5SO_3H$	Light
I	89.5	0	>300 nm
II	89.5	0	>180 nm
III	83.4	84.2	>300 nm
IV	102.7	98.8	>180 nm

The photodecomposition of aqueous hypochlorite has been studied, but the overall mechanism of photochemical decomposition does not seem to have been clarified. Earlier workers[8)] showed that the products of the photolysis of aqueous hypochlorite are oxygen, chloride and chlorate ions and that the amount of decomposed hypohalite is proportional to the light energy absorbed. Recently, Buxton and Subhani[9)] demonstrated with flash photolysis technique that the primary products of the photolysis of hypochlorite ion at 365 nm are O (triplet oxygen atom), O^-, Cl, and Cl^- and that, at 313 and 253.7 nm, O (singlet oxygen atom) and Cl^- are also produced. The stoichiometry is expressed as follows.

$$ClO^- \xrightarrow{h\nu} Cl^- + O\ (^3P) \quad (1a)$$
$$ClO^- \xrightarrow{h\nu} Cl + O^- \quad (1b)$$
$$ClO^- \xrightarrow{h\nu} Cl^- + O\ (^1D). \quad (1c)$$

We employed quartz-filtered light (>180 nm) for *p*-ethylbenzenesulfonic acid in which non-selective oxidation on α- and β-carbon atoms of alkyl chain with little chlorination was observed (Table 3). Thus, the photo-oxidation should proceed mostly by an attack of oxygen atom produced from hypochlorite by the above mechanism (1a and 1c) to give the observed products.

A probable mechanism for an initial stage in the photolysis is as follows (R: H, *p*-Me, *p*-Et).

$$RC_6H_4SO_3H \xrightarrow{h\nu} RC_6H_4\cdot + \cdot SO_3H, \quad (1)$$
$$\cdot SO_3H \xrightarrow{h\nu} SO_2 + \cdot OH, \quad (2)$$
$$SO_2 + O + H_2O \xrightarrow{h\nu} H_2SO_4. \quad (3)$$

Formation of sulfur dioxide from benzenesulfonic acid (Eqs. 1 and 2) was confirmed by the Fuchsine test for the photolysis of aqueous benzenesulfonic acid alone. As regards Eq. 3, we have reported on the photo-oxidation of aqueous sulfur dioxide to sulfuric acid with H_2O_2 and O_2.[10] There are other reports[11] which support this kind of photo-oxidation.

The aryl and hydroxyl radicals produced might undergo reactions as follows in view of the observed products.

1) Phenyl radical:

$$Ph\cdot + \cdot OH \longrightarrow PhOH, \quad (4)$$
$$2Ph\cdot \longrightarrow Ph\text{-}Ph. \quad (5)$$

2) *p*-Tolyl radical:

$$\cdot C_6H_4CH_3 \longrightarrow C_6H_5CH_2\cdot, \quad (6)$$
$$C_6H_5CH_2\cdot + \cdot OH \longrightarrow C_6H_5CH_2OH, \quad (7)$$
$$\cdot C_6H_4CH_3 \text{ (or } C_6H_5CH_2\cdot \text{ or another radical)} + C_6H_5CH_2OH \longrightarrow C_6H_5CH_3 \text{ (etc.)} + C_6H_6\dot{C}HOH, \quad (8)$$
$$C_6H_5\dot{C}HOH + O \longrightarrow C_6H_5CHO + \cdot OH, \quad (9)$$
$$\cdot C_6H_4CH_3 + \cdot OH \longrightarrow HOC_6H_4CH_3. \quad (10)$$

3) *p*-Ethylphenyl radical:

$$\cdot C_6H_4CH_2CH_3 \longrightarrow C_6H_5\dot{C}HCH_3, \quad (11)$$
$$\cdot C_6H_4CH_2CH_3 \longrightarrow C_6H_5CH_2CH_2\cdot, \quad (12)$$
$$C_6H_5\dot{C}HCH_3 + \cdot OH \longrightarrow C_6H_5CH(OH)CH_3, \quad (13)$$
$$C_6H_5CH_2CH_2\cdot + \cdot OH \longrightarrow C_6H_5CH_2CH_2OH, \quad (14)$$
$$\cdot C_6H_4CH_2CH_3 + SH \longrightarrow C_6H_5CH_2CH_3 + S\cdot, \quad (15)$$
$$C_6H_5\dot{C}HCH_3 + SH \longrightarrow C_6H_5CH_2CH_3 + S\cdot, \quad (16)$$
$$C_6H_5CH_2CH_2\cdot + SH \longrightarrow C_6H_5CH_2CH_3 + S\cdot, \quad (17)$$
(SH: $C_6H_5CH(OH)CH_3$, $C_6H_5CH_2CH_2OH$)
$$S\cdot + O \longrightarrow C_6H_5COCH_3 \text{ or } C_6H_5CH_2CHO, \quad (18)$$
$$\cdot C_6H_4CH_2CH_3 + \cdot OH \longrightarrow HOC_6H_4CH_2CH_3. \quad (19)$$

The aryl radical, $RC_6H_4\cdot$, produced might abstract a hydrogen atom from its own alkyl chain to give aryl-alkyl radical *via* successive internal *o*- and *m*-H atom shifts (Eqs. 6, 11, and 12), giving alcohols and carbonyl compounds. Aryl radical can also abstract a hydrogen atom from another molecule to give alkylbenzene (Eqs. 8 and 15), but the yield is very low and the contribution of intermolecular H-atom abstraction seems to be small. Polymerization of aryl radical might be impossible in consideration of the absence of $(-C_6H_4-R)_2$ except biphenyl. The product distribution shows that the H-abstraction is preferable to coupling of $RC_6H_4\cdot$ with hydroxyl radical to form alkylphenol. The absence of products formed by chlorine addition to radicals or by chlorination of the side chain suggests that the hydrogen abstraction by Cl· is unimportant. Higher yields of *p*-alkylphenol than *o*- and *m*-substituted phenols may be due to the greater resonance stability of *p*-$RC_6H_4\cdot$ radical. The higher yield of $PhCH_2CH_2OH$ than $PhCH(OH)CH_3$ is of interest, since the radical stability in the latter is greater. This suggests that the attack of ·OH on these arylalkyl radicals is very fast, giving a statistical distribution of the OH position of alcohols. The unsubstituted phenol formation, though small, from ethylbenzenesulfonate but not from toluenesulfonate implies easier elimination of the larger alkyl chain to give the phenyl radical.

There are reports stating that (i) benzyl phenyl sulfone can be formed by coupling of benzyl and phenylsulfonyl radicals produced from phenyl radical and SO_2[12] and (ii) the ESR evidence of methylsulfonyl radical photochemically formed from methyl radical and SO_2.[13] The results suggest the following mechanism for this diaryl sulfone formation.

$$Ph\cdot + SO_2 \xrightarrow{h\nu} PhSO_2\cdot, \quad (20)^{14}$$
$$\text{(or } PhSO_3H \xrightarrow{h\nu} \cdot PhSO_2\cdot + \cdot OH), \quad (21)$$
$$PhSO_2\cdot + \cdot Ph \longrightarrow PhSO_2Ph, \quad (22)$$
$$Ph\cdot + PhSO_3H \longrightarrow PhSO_2Ph + \cdot OH, \quad (23)$$
$$PhSO_2\cdot + PhSO_3H \longrightarrow PhSO_2Ph + \cdot SO_3H. \quad (24)$$

The phenol produced might subsequently be chlorinated to give mono- and di-chlorinated phenols. In fact, mono- and di-chlorophenols were formed on irradiation of a mixture of phenol and aqueous sodium hypochlorite (Table 4). However, the poor yield of chlorinated phenol in the photo-oxidation of alkylbenzenesulfonate shows that an attack of Cl species is not important.

We found that the photo-oxidation by aqueous hypochlorite proceeds even by Pyrex-filtered light (>300

Table 4. Partial mass spectra of photo-oxidation products of phenol[a]

Parent ion peak *m/e*	Fragment ion peak	Compound	Relative mole ratio
128	130 95 94 66 65 55 39	Monochloro-phenols	1

a) Initial concentration: phenol 49.6 mM, NaOCl 46.0 mM; pH≈11; room temperature.

nm), where a grater variety of products were observed, since the substrate cannot be excited and thus only a random attack of oxygen atom predominates. In photo-oxidation employing a Pyrex filter, slightly larger amounts of various chlorinated compounds were also detected. An attack of Cl· on the unexcited substrate might become significant in this case.

Coenzyme Models. IX. Micellar Catalysis of Isoalloxazine (Flavin) Oxidation of Dithiol*

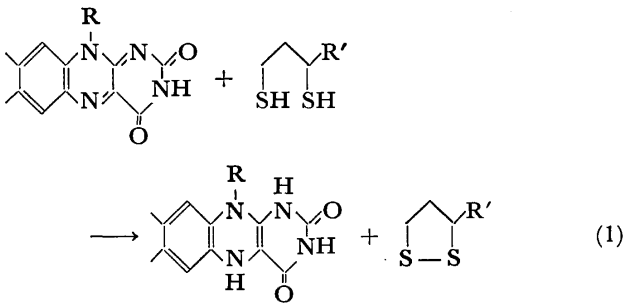
Seiji SHINKAI and Toyoki KUNITAKE

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received January 31, 1977)

The influence of micelles on the reaction of isoalloxazines and 1,4-butanedithiol(BDT) was studied. The pK_a of BDT was lowered by 0.3 pK unit in the presence of the hexadecyltrimethylammonium bromide(CTAB) micelle, indicating the formation of "hydrophobic ion pairs." The apparent second-order rate constant for the reaction of 3-methyl-10-ethylisoalloxazine and BDT increased by 18-fold on addition of CTAB(3 mM). The UV-visible spectrum of 3-hexadecyl-10-butylisoalloxazine in the presence of the CTAB micelle was similar to that in organic solvents, the rate being enhanced by more than 400-fold as compared with that in a nonmicellar system. Anionic(SDS) and nonionic(Brij-35) micelles suppressed the reaction. The results show that the flavin oxidation of dithiol is facilitated by the environments of the CTAB micelle.

Reduction of flavins by dihydrolipoic acid is one of the interesting oxidation-reduction reactions catalyzed by flavoenzymes(*e.g.*, lipoamide dehydrogenase). Gascoigne and Radda[1] found that dihydrolipoic acid reacts with flavins in the absence of enzyme to produce lipoic acid and reduced flavins(Eq. 1). The subsequent examination established the fact that flavin oxidation of dithiol is of first-order in dithiol concentration and buffer-catalyzed, while that of monothiol is of second-order in monothiol concentration, not being subjected to buffer-catalysis.[2-4]



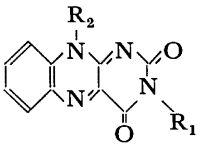
(1)

We have found that the reactivity of some coenzymes and their model compounds are markedly affected by the microenvironments of micelles and polysoaps.[5-7] This is of interest from the viewpoint that the reactivity of coenzymes must a priori be very susceptible to the microenvironments of apoenzymes. In particular, the nucleophilic reactivity of some anions (including thiolate anions such as glutathione and coenzyme A) is drastically enhanced in the presence of the cationic hydrophobic aggregates.[7,8] This unusual activation of anions is conceivably derived from the formation of a "hydrophobic ion pair" between the surfactant cation and the anionic nucleophile.[9,10] Since flavins are reduced by dissociated species of dithiol,[1-3] it occurred to us that the efficiency of this biologically important reaction would be markedly affected by the hydrophobic environment.

In this paper, we wish to report on the micellar effect on the reaction of isoalloxazines and 1,4-butanedithiol(BDT: an analogue of dihydrolipoic acid). Isoalloxazines chosen are 3-methyl-10-ethylisoalloxazine(**1**) and 3-hexadecyl-10-butylisoalloxazine(**2**).

* Contribution No. 418 from this department.

Isoalloxazine:



(**1**) $R_1=CH_3-$, $R_2=CH_3CH_2-$

(**2**) $R_1=CH_3(CH_2)_{15}-$, $R_2=CH_3(CH_2)_3-$

Surfactant:

CTAB, $CH_3(CH_2)_{15}N^+(CH_3)_3Br^-$

SDS, $CH_3(CH_2)_{11}OSO_3Na$

Brij-35, $CH_3(CH_2)_{11}(CH_2CH_2O)_{23}OH$

Experimental

Materials. 3-Methyl-10-ethylisoalloxazine(**1**) and 10-butylisoalloxazine were supplied by Professor F. Yoneda(for preparation, *cf.* Ref. 11). 3-Hexadecyl-10-butylisoalloxazine was obtained by treating 10-butylisoalloxazine(130 mg: 0.5 mmol) with hexadecyl iodide(176 mg: 0.5 mmol) at room temperature in *N,N*-dimethylformamide containing excess powdered K_2CO_3(500 mg). The progress of the reaction was monitored by the TLC method (silica gel–ethyl acetate). The insoluble parts were filtered off after two days, and the solvent was evaporated *in vacuo*. The residual brown oil was extracted with carbon tetrachloride, the extract being washed with an aqueous solution of 0.1 M NaOH and water, dried over anhydrous K_2SO_4. The reaction mixture was concentrated to dryness, and the yellow residue was recrystallized from ethanol–acetonitrile; mp 77—80 °C. Found: C, 72.15; H, 9.44; N, 10.98%. Calcd for $C_{30}H_{46}N_4O_2$: C, 72.83; H, 9.37; N, 11.33%.

1,4-Butanedithiol was distilled under N_2 stream before use: bp 98—102 °C/17 mmHg (lit,[12] bp 74.5 °C/10 mmHg). Hexadecyltrimethylammonium bromide was recrystallized from ethanol before use, and other surfactants(sodium dodecylsulfate, Brij-35) were used without further purification.

Titration of 1,4-Butanedithiol. The spectrophotometric titration was carried out under anaerobic conditions with a Thunberg cuvette. Absorbance at 240 nm(thiolate anion) was chosen. The detailed procedure has been described.[7,13]

Kinetics. All the kinetic measurements were carried out anaerobically at 30±0.1 °C at a calculated ionic strength (μ=0.06 with KCl) unless otherwise stated. The reactions were followed spectrophotometrically by monitoring the reduction of isoalloxazine (λ_{max}, 433 nm for **1** and 440 nm for **2**). The stock solution of BDT was prepared in ethanol just before the experiment. Since excess BDT was present in all the cases, the pseudo first-order behavior was observed. The pH of the reaction mixture was confirmed

not to vary from pH measurements (TOA Digital pH Meter, Model HM-15A) before and after the reaction.

Results

Spectrophotometric Titration of 1,4-Butaneditiol(BDT). Prior to the kinetic measurements, the equilibrium constants for the –SH ionization(K_a) were estimated in the absence and presence of the CTAB micelle. Since the critical micelle concentration (CMC) for CTAB is estimated to be about 8×10^{-4} M under the present conditions,[14] the titration for the latter system was conducted in the presence of 3 mM CTAB. The results are shown in Fig. 1.

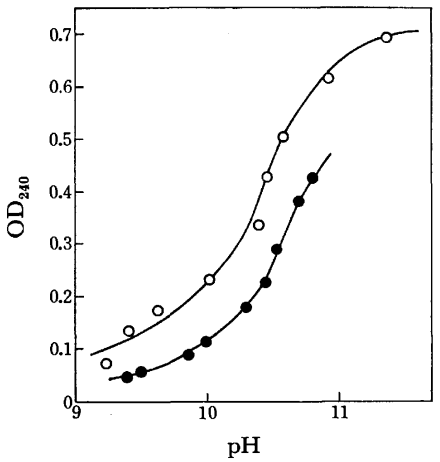


Fig. 1. Spectrophotometric titration of 1,4-butanedithiol. [1,4-Butanedithiol]$=2.20\times10^{-4}$ M, $\mu=0.06$ with KCl.
(○), [CTAB]$=3.0\times10^{-3}$ M; (●), CTAB was not added.

Under the anaerobic conditions at pH 9.2—11.4, only one inflection point was observed. The titration curve monitored by the absorbance(OD) at 240 nm(thiolate anion) is expressed by Eq. 2, where ε is the molar absorption coefficient of thiolate anion. The linear correlation between a_H and $1/OD_{240}$ is indicated by Eq. 3.

$$OD_{240} = \varepsilon[BDT]\left(\frac{K_a}{K_a+a_H}\right) \quad (2)$$

$$\frac{1}{OD_{240}} = \frac{1}{\varepsilon[BDT]} + \frac{a_H}{\varepsilon[BDT]K_a} \quad (3)$$

Good linear relationships($r>0.99$) were observed for the treatment of the experimental data by Eq. 3. From the slope and the intercept, K_a and ε were determined: in the presence of CTAB (3 mM), $pK_a=10.4$, $\varepsilon=3.41\times10^3$ $M^{-1}cm^{-1}$; in the absence of CTAB, $pK_a=10.7$, $\varepsilon=3.30\times10^3$ $M^{-1}cm^{-1}$. According to Benesch and Benesch,[15a] the molar absorption coefficients for aliphatic thiolate anions are $(4—6)\times10^3$ $M^{-1}cm^{-1}$. The observed inflections may correspond to the first dissociation(K_{a1}) of two SH groups.[15b] The pK_{a1} value was lowered in the presence of the CTAB micelle by *ca.* 0.3 pK unit.

Absorption Spectra of Isoalloxazines. Figure 2 shows absorption spectra of oxidized and reduced forms of isoalloxazines. The isoalloxazine **1** shows an absorption maximum at 433 nm($\varepsilon=14200$ $M^{-1}cm^{-1}$). the reduction by BDT giving a tight isosbestic point at 323 nm. The spectra were hardly affected by addition of CTAB above CMC. At the completion of the reaction, admittance of O_2 regenerated **1** quantitatively. In the presence of the CTAB micelle(λ_{max} 440 nm, $\varepsilon=11500$ $M^{-1}cm^{-1}$), the spectrum of **2** shows distinct shoulders at 420 nm and 460—470 nm(Fig. 2), isosbestic points for the reduction by BDT appearing at 278, 324, 367, and 385 nm. Since similar shoulders are observable in organic solvents(acetonitrile, dioxane), the isoalloxazine ring of **2** should be present in the hydrophobic region of the micelle.

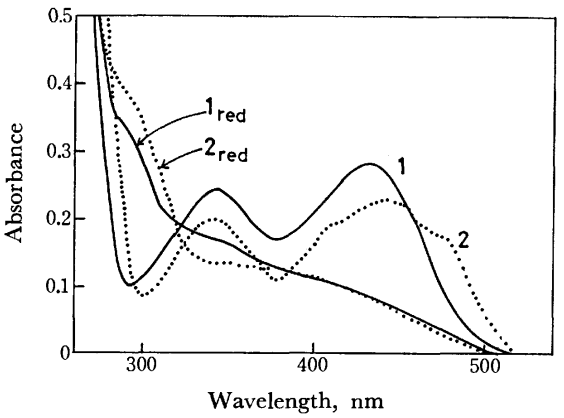

Fig. 2. Spectra of oxidized and reduced forms of isoalloxaznes. [isoalloxazine]$=2.0\times10^{-5}$ M, [CTAB]$=3.0\times10^{-3}$ M, pH 10.05.
——, **1** and reduced **1** ($\mathbf{1}_{red}$); ----, **2** and reduced **2** ($\mathbf{2}_{red}$). Reduction was performed with 1.04×10^{-3} M 1,4-butanedithiol.

Rate Measurements. With excess BDT, isoalloxazine concentration as a function of time gave good pseudo

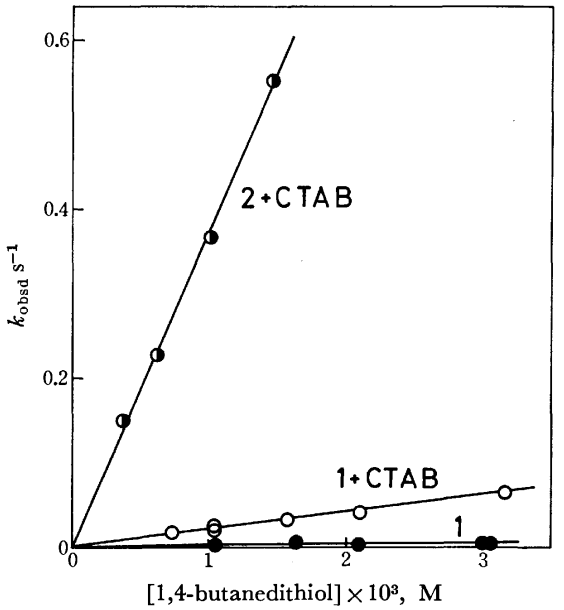

Fig. 3. Pseudo-first order rate constant (k_{obsd}) *vs.* [1,4-butanedithiol].
[Isoalloxazine]$=(1—3)\times10^{-5}$ M, [CTAB]$=3.0\times10^{-3}$ M, pH 10.05+0.02.

first-order plots up to 3 half-lives under all reaction conditions in the present work. When the concentration of BDT was varied, plots of pseudo first-order rate constants(k_{obsd}) against the BDT concentration showed linearity(Fig. 3), indicating that the reaction is of first-order with respect to the concentrations of isoalloxazine and BDT. The apparent second-order rate constants(k_2') can be obtained by dividing k_{obsd} by the total concentration of BDT.

The apparent second-order rate constants at pH 10.05+0.02 are given in Table 1. At this pH, the rate constant for the reaction of **1** and BDT was accelerated by a factor of 23 by the CTAB micelle. The rate for the reaction of **2** and BDT is further accelerated, being more than 400 times greater than that of **1** and BDT in a nonmicellar system. The results suggest that the cationic environments remarkably improve the electrophilicity of isoalloxazine ring and/or the reductive activity of the thiolate anion.

The apparent second-order rate constants for the reaction of **1** and BDT are plotted against the concentration of CTAB in Fig. 4. The plots give a sigmoidal curve: around the CMC, the rate constants rose rapidly with increasing the CTAB concentration. At optimal CTAB concentration(*ca.* 5 mM), 35 times rate augmentation was observed. In contrast, addition of anionic (SDS) and nonionic(Brij-35) surfactants suppressed the reaction above their CMC (Fig. 5). Thus,

TABLE 1. APPARENT SECOND-ORDER RATE CONSTANTS AND pH_{max}

Isoalloxazine	CTAB mM	k_2' at pH 10.05 $M^{-1}s^{-1}$	$k_{2'max}$ $M^{-1}s^{-1}$	pH_{max}
1	0	0.904	1.78	10.9
1	3.0	21.0	32.0	10.4
2	3.0	375	447	10.3

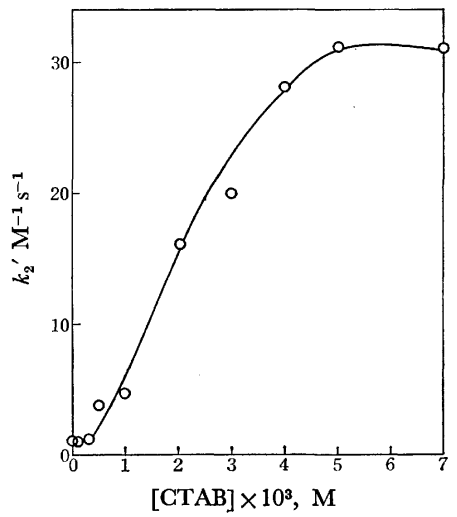

Fig. 4. Apparent second-order rate constants for the reaction of **1** and 1,4-butanedithiol plotted as a function of CTAB.
[**1**]=3.01×10⁻⁵ M, [1,4-butanedithiol]=1.05×10⁻³ M, pH 10.05±0.02, μ=0.06 with KCl.

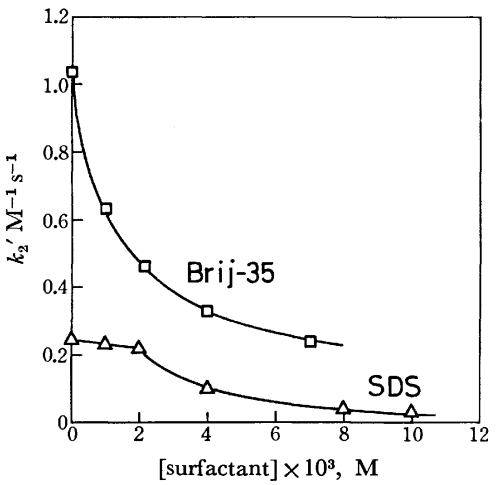

Fig. 5. Apparent second-order rate constants for the reaction of **1** and 1,4-butanedithiol plotted as a function of anionic (SDS) and nonionic (Brij-35) surfactants. (△), SDS, pH 9,10±0.03; (□), Brji-35, pH 10.05± 0.02. Other reaction conditions are recorded under Fig. 4.

only the cationic micelle acts as a catalyst for the reaction of **1** and BDT.

Effects of pH, Salt Concentration, and Buffer Concentration. The logarithm of the apparent second-order rate constant is plotted as a function of pH in Fig. 6. Plots of log k_2' *vs.* pH give bell-shaped curves.[3,4] The pH values(pH_{max}) and the rate constants($K_{2'max}$) at the rate maxima are summarized in Table 1. We see that the pH_{max} values are lowered by 0.5—0.6 pK unit on addition of CTAB(3 mM). The maximal rate constant for the reaction of **1** and BDT is enhanced 18 times in the presence of the CTAB micelle and that of **2** 250 times, as compared with that for **1** and BDT in a nonmicellar system.

The rate of micelle-catalyzed system is influenced by

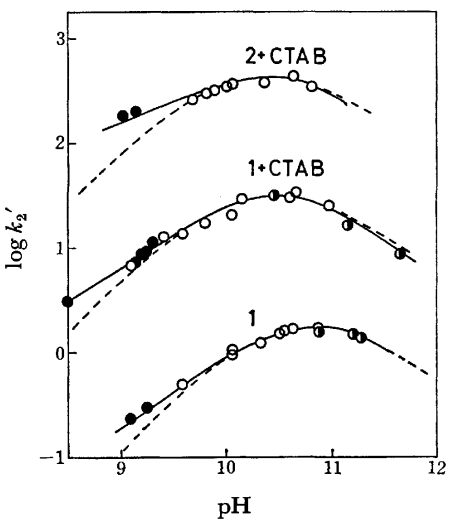

Fig. 6. pH Dependence.
[CTAB]=3.0×10⁻³ M. pH was adjusted with KOH (◑), carbonate (○), and borate (●). Ionic strength was maintained at 0.06 with KCl. Dotted curves (theoretical pH-rate profiles) are obtained from Eq. 6.

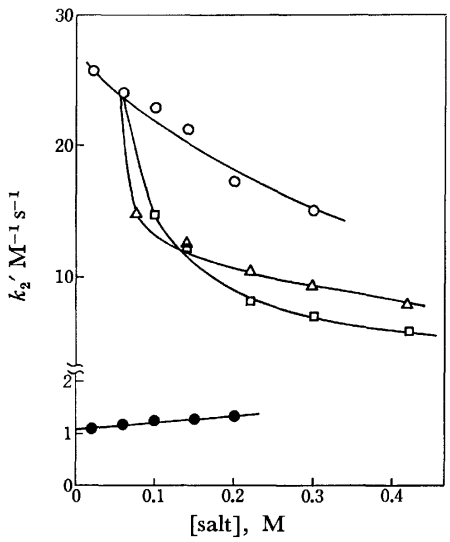

Fig. 7. Effect of ionic strength and buffer concentration on the reaction of **1** and 1,4-butanedithiol.
pH 10.05±0.03, [CTAB]=3.0×10^{-3} M. (○), Carbonate; (●), carbonate without CTAB; (□), KCl; (△), K_2SO_4. pH of the latter two systems was maintained with 0.06 M carbonate.

the salt concentration of the reaction medium. The second-order rate constants for the reaction of **1** and BDT in the presence of the CTAB micelle are suppressed by increase in salt concentration (KCl, K_2SO_4; Fig. 7). Increase in the carbonate buffer($KHCO_3$–K_2CO_3) concentration does not retard the reaction as conspicuously as KCl and K_2SO_4. As shown by Gascoigne and Radda[1] and Loechler and Hollocher,[3] the flavin oxidation of dithiol is subjected to general catalysis. In the present system, the reaction of **1** and BDT in a nonmicellar system was slightly accelerated with increasing carbonate buffer concentration(black circles in Fig. 7); third-order rate constant for general catalysis(*i.e.*, slope for the plots of black circles), 1.3 $M^{-2}s^{-1}$. Supposedly, the micelle-catalyzed reaction is also subjected to general catalysis. The increase in carbonate buffer concentration would provide two opposing effects: the rate deceleration due to the increased ionic strength and the rate acceleration due to the increased local concentration of bicarbonate ion as an acid around the micelle surface. As a result, the rates would become less susceptible to the change in buffer concentration.

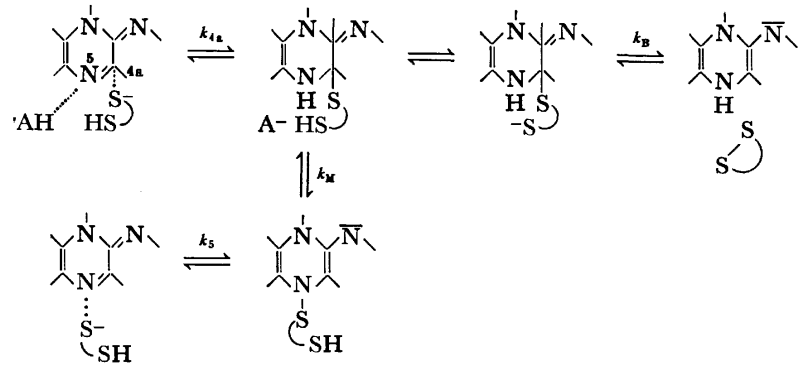
Discussion

Micellar catalysis provides suitable model systems of the enzymatic catalysis.[16,17] Micelles can influence rates and equilibria of biologically important reactions. The micellar environment evaluated with the fluorescent emission is akin to that of the active site of enzymes.[17,18] Thus, it seems significant to assess the influence of the micellar enviroments on the enzyme-like reactions, especially on the coenzyme-dependent reactions.

One of the most significant findings on the micellar catalysis would be the unusual enhancement of nucleophilicity of a variety of anionic species when they are bound to the cationic micellar and polymer micellar phase.[8,10] In studies on nucleophilic reactions of thiolate anions, we found that the thiolate anion bound to the cationic micellar phase is very susceptible to air oxidation.[7,13] This suggests that the formation of the hydrophobic ion pair would enhance not only the nucleophilicity but the reactivity as a reducing agent. This led us to investigate the effect of micellar environments on the oxidation-reduction reactions containing thiol groups.

The most plausible mechanism for the reaction of flavins and dithiols is the formation of adduct followed by the nucleophilic attack of intramolecular thiolate anion. The free radical mechanism can be disregarded on the basis of kinetic evidence.[3,4] Two kinetically equivalent mechanisms were suggested: (i) nucleophilic attack by thiolate anion on C(4a), aided by a general acid catalysis at N(5)(k_{4a} process in Eq. 4), and (ii) nucleophilic attack on N(5)(k_5 process) followed by 5→4a migration of RS^+(k_M process).**

According to Loechler and Hollocher,[3] buffer catalysis is observed only when the 4a-addition(*i.e.*, k_{4a} process) is involved in the rate-limiting step. This is based on the fact that the negative charge on N(5) developed by 4a-addition is energetically unfavorable ($pK_a\approx24$), unless the adduct formation is aided by acid catalysis. The present system is buffer-catalyzed in the absence and probably in the presence of the CTAB micelle(Fig. 7). Therefore, mechanism (i) is not incompatible with the present kinetic situation. 5-Addition(*i.e.*, mechanism (ii)) is presumed not to be buffer-



(4)

** This mechanism was proposed for the reaction of flavins and monothiols.[4]

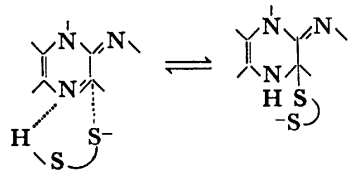
catalyzed, since the anionic charge is developed on N(1), the pK_a of which is much lower ($\approx$6.6).[19] If 5-adduct is formed, 5→4a migration of RS^+ becomes obligatory prior to breakdown(k_B process). Since the reaction which yields the cationic charge in the transition state is extremely suppressed by the cationic micelle,[5,6] the migration should be significantly inhibited by the CTAB micelle. However, the CTAB micelle acts as catalyst for the isoalloxazine oxidation of BDT. Thus, mechanism (ii) is unlikely in the present system.

Similar reaction orders and pH-rate profiles observed for the micellar and nonmicellar systems indicate that the reaction mechanism is not essentially changed by the micelle. The result of spectrophotometric titration of BDT shows that the pK_{a1} is lowered by 0.3 pK unit in the presence of the CTAB micelle. pH_{max} values (Table 1) are lowered by 0.5—0.6 pK unit. The lowering of pK_a is generally observed for anionic species bound to the cationic micelle,[9,13,20] and such anions are greatly activated with no apparent exceptions. For example, the nucleophilic reaction of coenzyme A and *p*-nitrophenyl acetate is accelerated by a factor of 290 in the presence of the CTAB micelle, the pK_a being lowered by 0.5 pK unit as compared with the corresponding value in a nonmicellar system.[7] On the other hand, spectral data(Fig. 2) indicate that **1** is not much concentrated in the micellar phase. Thus, the rate increase for the reaction of **1** and BDT would be attributed to the concentration of BDT in the micellar phase and to the enhanced nucleophilicity of BDT anion therein.

The 18—23 fold rate augmentation in **1** oxidation of BDT seems rather small. It has been shown that **1** oxidation of monothiols shows a remarkable rate enhancement by a factor of 10^2—10^5 times.[21] Some mechanistic difference between monothiol and dithiol may cause the different susceptibility to the micellar catalysis. Possible interpretation might be as follows. (i) The k_B process is presumed to be rate-limiting for flavin oxidation of monothiol.[3,4] Since the k_B process is a simple nucleophilic attack on flavin–S– by RS^-, the rate would directly reflect the enhanced nucleophilicity of RS^-. On the other hand, the k_{4a} process, a rate-limiting step for dithiol,[3] is a nucleophilic attack concerted with acid catalysis. In most cases, the cationic micelle retards acid catalyzed reactions.[5,6,22,23] Therefore the total reaction rate would not be greatly enhanced despite the favorable influence on the nucleophilicity. (ii) The monoanion of BDT is subjected to micellar activation to a smaller extent due to the intramolecular hydrogen bond with the undissociated SH group. There is a precedent that reactivity of naked anion in aprotic environment is efficiently quenched by a single intramolecular hydrogen bonding.[24] Micellar desolvation of anion stabilized by intramolecular hydrogen bonding might be considerably difficult.

Isoalloxazine **2** is scarcely soluble in an aqueous solution. The isoalloxazine ring of **2** resides in relatively hydrophobic region of the micelle(Fig. 2). Both **1**+CTAB and **2**+CTAB systems employ similar pH_{max} (10.4 and 10.3, respectively), indicating that both systems oxidize similar species of BDT. Thus, a mechanistic change in the **2**+CTAB system is hardly expected. The rate increase in this system could be derived from the concentration effect of **2** in the micellar phase and the facilitation of flavin oxidation due to the change in the oxidation potential of **2**. The latter conjecture is supported by the fact that flavin oxidation is more facile in dipolar aprotic solvents[25] to which the cationic micellar environment is said to be akin.[17]

The requirement of a general acid catalysis for 4a-addition is discussed by Bruice *et al.*[4,26,27] in detail on the basis of the libido rule of Jencks.[28] Since H_3O^+ catalysis is *completely* inhibited by the cationic micelle when the substrate is buried in the micellar phase,[6] H_3O^+ dependent processes (k_3 and k_6 in Loechler and Hollocher's scheme) should be disregarded in the cationic micellar system. Thus, acid species present in the cationic micellar solution are H_2O, buffer acid, and intramolecular SH group. When the reaction system is buffered by H_2O–OH^-, intramolecular SH group would play the role of a general acid(Eq. 5).



(5)

If the reaction is of first-order in BDT monoanion as expressed by $v_{obsd}=k_2[HS(CH_2)_4S^-][isoallozaxine]$, the corresponding pH-rate profile is given by

$$k_2' = k_2 a_H K_{a1}/(a_H^2 + a_H K_{a1} + K_{a1}K_{a2}) \quad (6)$$

where k_2 denotes a true second-order rate constant. Theoretical curves(Fig. 6, dotted line) derived from Eq. 6*** show that the experimental data satisfy Eq. 6 at $pH > pH_{max}$, while the observed rate is greater at $pH < pH_{max}$. In the latter pH region, buffer acid would significantly contribute to the observed rate.

In conclusion, the reactivity of BDT as a reducing agent is remarkably enhanced in the presence of the cationic micelle, and the electrophilicity of isoalloxazines can be affected by the micellar environements.

The authors express their thanks to Professor F. Yoneda for his valuable discussion. They also express their appreciation to Miss R. Ando for technical assistance.

5-Fluorouracil Derivatives. I. The Synthesis of 1-Carbamoyl-5-fluorouracils

Shoichiro OZAKI,* Yoshimasa IKE, Haruo MIZUNO, Katsutoshi ISHIKAWA, and Haruki MORI

Research Center, Mitsui Toatsu Chemicals, Inc. Kasama-cho, Totsuka-ku, Yokohama 247

(Received February 21, 1977)

The toxicity and tumor affinity of 5-fluorouracil (**1**) have been modified by the introduction of a carbamoyl group. Carbamoylation by three general methods were studied extensively: (i) The reaction of **1** with isocyanate, (ii) the reaction of 1-chloroformyl-5-fluorouracil with amine, and (iii) the reaction of **1** with carbamoyl chloride. These three methods usually give 1-carbamoyl-5-fluorouracils (**2**). 3-Carbamoyl-5-fluorouracils were not obtained by any method. The **2** substances take a hydrogen-bonded structure in chloroform, a non hydrogen-bonded structure in DMSO at 80 °C, and mixed structures in DMSO at 25 °C. Thirty-six homologues shown by **2** were prepared all of these compounds showed antitumor activity. Of them, 1-hexylcarbamoyl-5-fluorouracil (HCFU) appeared to be the most promising antitumor agent when administered orally in that HCFU retains well balanced lipo- and hydro-philicity, is stable in acid in the stomach, and moreover, decomposed moderately in a tumor. Isocyanate was obtained from the reaction of amine with trichloromethyl chloroformate (TCF) by simply heating these two reagents in toluene; this offers a convenient new method for synthesizing isocyanate from amine. Several new isocyanate were obtained from amino acids.

As the combination of long-standing research on isocyanate chemistry[1] and the synthetic work on 5-fluorouracil derivatives, searching for useful products, the reaction of isocyanate with 5-fluorouracil (**1**) has been studied in detail; it has led to the discovery of the powerful antitumor agents.[2]

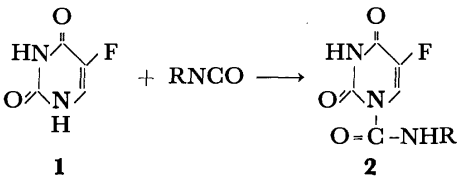
1, though an effective antitumor agent,[3] has a strong toxicity and poor tumor affinity. Chemical modifications of **1** by introducing β-cyanoethyl,[4] 2-tetrahydrofuryl,[5] 2-oxo-3-tetrahydrofuryl,[6] β-amino-β-carboxyethyl,[7] methyl,[8] hydroxy,[9] benzyloxy,[9] 2,3-dihydroxypropyl,[10] acyl,[11] alkyl- and aryl- sulfonyl,[11] and alkoxycarbonylmethyl[12] groups have been reported. However many of these masked compounds have no or only weak activities toward tumors, because the chemical bonds between **1** and the substituents are too strong to undergo biodegradation. Some of the 5-fluorouracil derivatives retaining weakly bonded substituents, though, show no difference in action toward tumors when compared with **1** itself.

In order to adapt the biological activities of **1** for practical purposes, especially for oral administration, hundreds of new structual analogs have been synthesized. The antitumor activities of these compounds were examined at the Pharmacology Division, National Cancer Center Research Institute, Tokyo. Some of the screening results for biological activity have been published.[13,14] In the present paper we wish to report the synthesis of 1-carbamoyl-5-fluorouracils (**2**) in detail.

Although the reaction of uracil and isocyanate has been reported to be sluggish,[15] the treatment of uracil with methyl isocyanate in a dimethyl sulfoxide solution gave 1-methylcarbamoyluracil.[16] We have extensively explored the reactions of **1** with isocyanate, with phosgene and amine, and with carbamoyl chlorides, and have obtained a number of **2** substances by three general synthetic methods.

Results and Discussion

Method 1. The reaction of **1** with isocyanates affords **2**.



1 **2**

Scheme 1.

This reaction was originally carried out in *N,N*-dimethylformamide. However, our thorough study of the solvent effect revealed that pyridine (Method 1-A) was the best solvent and that the reaction proceeded almost quantitatively. In other solvents, such as *N,N*-dimethylacetamide (Method 1-B) and dimethyl sulfoxide (Method 1-C), however, the yield does not exceed 70% as is shown in Table 1. The best reaction temperature is 90—100 °C. The best molar ratio of isocyanate/**1** is 1.5. The reaction is catalyzed by organic bases, such as triethylamine, triethylenediamine, and DBU (1,8-diazabicyclo[5.4.0]undecene-7).

This method gives products of the best quality and in good yields as well. 1-Arylcarbamoyl-5-fluorouracil is obtained only by this method. It is known[11] that

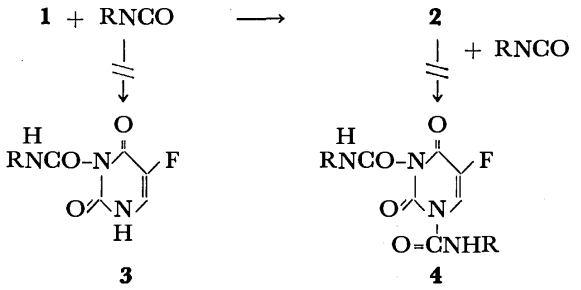
Table 1. Solvent effects on the conversion of 5-fluorouracil to 1-hexylcarbamoyl-5-fluorouracil[a]

Solvent	Conversion[b] (%)
Pyridine	99
N,N-Dimethylformamide	70
N,N-Dimethylacetamide	70
Dimethyl sulfoxide	40
Hexamethylphosphoric triamide	60
o-Dichlorobenzene	40
Triethylamine	trace
N,N-Dimethylaniline	60
Quinoline	60
Acetonitrile	70
Nitromethane	70

a) The n-$C_6H_{13}NCO$-to-5-fluorouracil molar ratio was 1.5. The reaction was carried out at 90 °C for 2 h. b) The conversion was measured by comparing the TLC spots of premixed 5-fluorouracil and **22**.

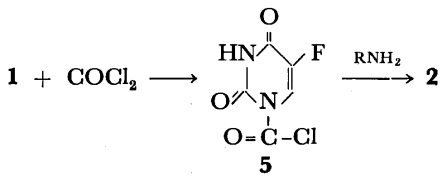
* To whom correspondence should be addressed.

the reaction of **1** with an electrophile like alkyl chloride introduces substituents at the 3- and 1-positions of **1**. However, 3-carbamoyl-substituted 5-fluorouracils (**3** and **4**) were not obtained by the treatment of 5-fluorouracils with isocyanate, even when a higher temperature, a large excess of isocyanate, or a catalyst such as triethylamine was employed. This may result from the acidic character of the proton on the nitrogen at the 3-positions of **1** and **2**, or from the easy dissociation of once-formed carbamoyl groups at the 3-positions of **3** and **4**.



Scheme 2.

Method 2. Phosgene can be condensed with **1**, but the resulting 1-chloroformyl-5-fluorouracil (**5**) is too unstable to be isolated; nevertheless, it is stable enough in a basic solvent such as pyridine at low temperatures. Accordingly, **5** treated with aliphatic amines *in situ* afforded **2**.



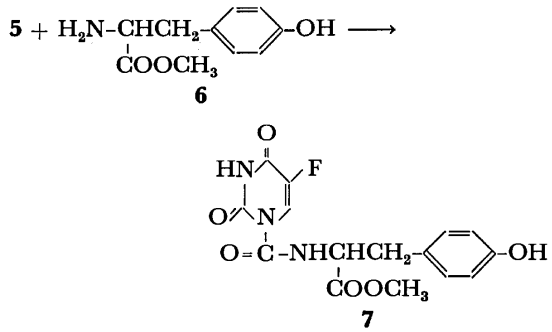
Scheme 3.

On the contrary, aromatic amine does not react with **5**, indicating that a strong basicity is necessary for the amine to react with **5**.

In this reaction, a small amount of triethylamine increases the yield, while excess amines lower the yield, because of the following further reaction:

$$2 + RNH_2 \longrightarrow 1 + RNHCONHR$$

Method 2, shown in Scheme 3, is a convenient method to prepare **2**, as amine is more easily available than isocyanate. One more practical advantage is that amines retaining a hydroxy moiety, like thyrosine, **6**, can condense with **5**.

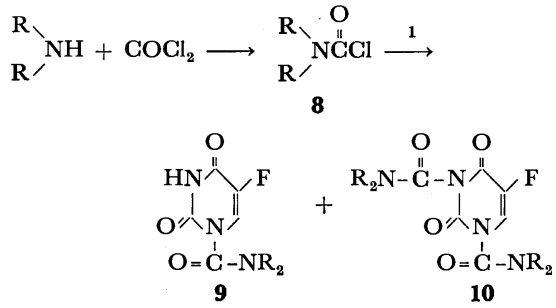


Scheme 4.

The carbamoyl uracil (**7**) can not be obtained by Method 1, because hydroxy isocyanate can not be prepared.

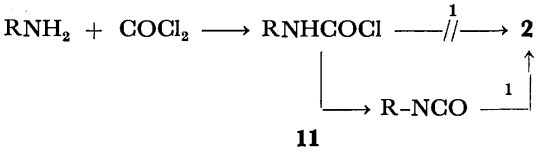
Method 3. Amine and phosgene condense to give carbamoyl chloride. The carbamoyl chloride of secondary amine (**8**) reacted with **1** to give 1-(*N*,*N*-disubstituted carbamoyl)-5-fluorouracil (**9**).

When an excess of carbamoyl chloride (**8**) was employed, 1,3-dicarbamoyl-5-fluorouracil (**10**) was also produced, along with 1-carbamoyl-5-fluorouracil (**9**).



Scheme 5.

The carbamoyl chloride of primary amine (**11**) and **1** do not give **2**, even in the presence of triethylamine at low temperatures, but they do give **2** in low yields at a high temperature (80 °C).



Scheme 6.

The nucleophilicity of **1** is too weak to attack the carbonyl of **11** at low temperatures. At a high temperature (80 °C), **11** decomposes to isocyanate, and eventually the isocyanate reacts with **1** to give **2**.

The structure of **2** was confirmed by elemental analysis and by its infrared and NMR spectra.**

In a polar solvent like dimethyl sulfoxide, the **2** substances take two mixed structures at room temperature, as is shown in Fig. 1 and Table 3. These two structures are presumed to be a hydrogen-bonded[16] **12** and a non hydrogen-bonded structure, **13**.

With an increase in the temperature, **13** predominates over **12**, as polar dimethyl sulfoxide affects the hydrogen bond unfavorably. At 80 °C, for example, 1-hexylcarbamoyl-5-fluorouracil (**22**) mostly exists in the form of

** The position of substituents was clearly distinguished on the basis of UV at varying pH and NMR spectra of 1-alkoxymethyl-, 3-alkoxymethyl-, and 1,3-bis(alkoxymethyl)-5-fluorouracils. The NMR spectra of 1-substituted uracils showed a sharp doublet at around 7.5 ppm due to C_6–H (coupling with F), while non-substituted and 3-monosubstituted uracils gave the corresponding triplets (coupling with F and N_1–H) at around 8 ppm. A fuller account will be given in detail in the third article of this series. The NMR spectrum of **2** showed a doublet due to C_6–H, indicating the 1-carbamoyl structure.

Table 2. 1-Carbamoyl-5-fluorouracils  ($R^1=H$)

Compd	R_2	Synthetic method	Yield %	Mp °C	Molecular formula	Found (Calcd) % C	H	F	N

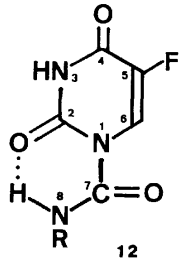
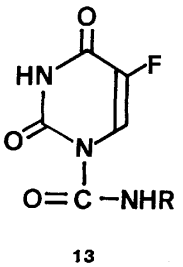
a) Prepared from hexamethylene diisocyanate. b) Prepared from *m*-xylene-α,α'-diyl diisocyanate. c) 1,3-Bis-(diethylcarbamoyl)-5-fluorouracil.



12



13

13. In a poorly solvating chloroform, only the **12** structure is observed at 25 and 60 °C. The ratio of **12** to **13** can be calculated based on the peak-intensity ratio of two doublets at 8.38 ppm (J=8 Hz, C_6–H of **12**) and at 7.70 ppm (J=6 Hz, C_6–H of **13**), or the ratio of two broad triplets at 9.11 ppm (J=6 Hz, N_8–H of **12**) and 5.68 ppm (J=6 Hz, N_8–H of **13**).

In contrast to the fact that the **2** substances decompose gradually in neutral water, they are generally resistant to acid hydrolysis because of their hydrogen bonding. Especially alkylcarbamoyl compounds like **22** are strongly resistant to acid hydrolysis. Indeed, their dormant nature in acid conditions suggests a possible application as oral administrative drugs which can survive acid in the stomach.

1-Alkylcarbamoyl-5-fluorouracil (**2**) can be absorbed into the blood. The lipophilic alkyl group of **2** helps it reach tissues or a tumor, and it moderately decomposes into **1** or other metabolites in tumor cells where the pH is nearly neutral.

The antitumor activities of **2** were evaluated by Hoshi *et al.*[13,14] by oral administration along with two reference compounds, **1** and 1-(2-tetrahydrofuryl)-5-fluorouracil (FT-207). The compounds tested in the L-1210 system were methyl-, ethyl-, isopropyl-, phenyl-, hexyl- and cyclohexyl-carbamoyl-5-fluorouracil; the therapeutic ratios ($ILSmax/ILS_{30}$) of these compounds were 1.9, 2.2, 2.3, 1.0, 4.5, and 3.3 respectively, while

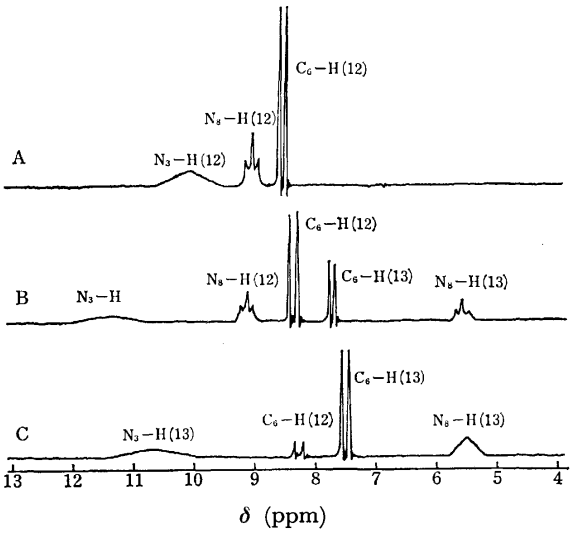


Fig. 1. Partial ^1H NMR spectra of 1-hexylcarbamoyl-5-fluorouracil.
A: In $CDCl_3$ solvent at 25 °C (hydrogen-bonded structure 12),
B: in DMSO-d_6 solvent at 25 °C (60% 12 and 40% 13),
C: in DMSO-d_6 solvent at 80 °C (non hydrogen-bonded structure 13).

those of the two reference compounds were 1.7 and 1.0. Among these compounds **22** showed the most effective results. The therapeutic ratio in the C-1498 system of **22** was 11, while those of **1** and FT-207 were 3.3 and 2.5 respectively. **22** was also showed activities toward solid tumors like Nakahara Fukuoka sarcoma and adenocarcinoma-755, and ascites tumors like sarcoma-180A, and was moderately active against Ehrlich ascites carcinoma. This compound had a wider tumor spectrum than **1** and FT-207 upon oral administration.

a) Hydrogen-bonded. b) Non-hydrogen-bonded. c) (h/h+nh)×100. d) Not detected. e) DMSO-d_6. f) $CDCl_3$. g) Pyridine-d_5.

In one continuing research on antitumor drugs a convenient new method of preparing isocyanate was also found. Isocyanates are obtained by the treatment of amines with trichloromethyl chloroformate (TCF)[17] in toluene at 100—110 °C, followed by distillation. In this reaction, the use of amine hydrochloride is preferable to avoid the formation of 1,3-disubstituted urea. When free amine is used, amine and TFC must be added to the solution so that the TCF is in excess in solution. Otherwise, heating at a high temperature for a long time is necessary for disubstituted ureas to react with TCF. By this method, several new isocyanates, **52**—**55**, were prepared.[18]

Experimental

The melting points were recorded on a Büchi melting-point aparatus and are uncorrected. Most 1-alkylcarbamoyl-5-fluorouracils (**2**) melt instantaneously at 95—170 °C and solidify. This melting point is likely to be overlooked, how-

ever. Nevertheless, differential thermal and gravimetric analysis revealed that **2** dissociated to **1** and isocyanates in this melting region, and a loss in weight of the isocyanates was observed. **1** decomposes at 280—283 °C. Therefore, in patents[2] in 1975, we mistakenly observed some decomposition temperatures of **2** to be 280—283 °C. The ^{1}H NMR spectra were recorded on a JEOL-60HL apparatus and the ^{13}C NMR spectra at 15 MHz on a JEOL-FX-60 apparatus. The IR spectra were obtained on a JASCO IR-A-1 apparatus. The mass spectrum was recorded on a Varian CH 7 apparatus. Microanalysis was done by the staff of the Analytical Laboratories of the Mitsui Toatsu Research Center.

*1-Hexylcarbomoyl-5-fluorouracil (**22**) (HCFU). Method 1-A. Reaction in a Pyridine Solution*: Hexyl isocyanate (19.08 g, 0.15 mol) and **1** (13.0 g, 0.1 mol) were heated in 40 ml of pyridine at 90 °C for an hour. The reaction mixture was then cooled to room temperature. About 30 ml of the pyridine were evaporated at 50 °C under reduced pressure. To the resulting residue, 50 ml of ethanol were added at 55 °C. Then the solution was kept at 0—5 °C overnight. Cyrstalline **22** (22.5 g, 87.4%) was thus obtained. As a second crop 2.90 g of product was obtained: mp 110—111 °C.

^{13}C NMR 157.27 (d, $J_{C_4-F}=1.87$ Hz, C-4), 150.35 (s, C-2), 149.31 (s, C-7), 140.90 (d, $J_{C_5-F}=16.05$, C-5), 123.43 (d, $J_{C_6-F}=2.47$ Hz, C-6), 41.52 (s, C-9), 31.38 (s, C-10), 29.11 (s, C-11), 26.51 (s, C-12), 22.55 (s, C-13), 13.97 (s, C-14).

MS *m/e* (rel. intensity) 257 (0.49) (M^+), 131 (7.9), 130 (88.4), 128 (1.3), 126 (1.7), 114 (2.0), 113 (1.3), 112 (14.5), 100 (4.9), 99 (70.7), 88 (5.6), 87 (37.4), 86 (2.2), 85 (27.0), 84 (19.8), 83 (1.9), 82 (6.0), 74 (1.3), 71 (3.4), 70 (7.5), 69 (8.6), 68 (1.7), 67 (4.2), 60 (27.0), 59 (8.5), 58 (16.6), 56 (56.2), 55 (49.9), 54 (4.6), 53 (8.0), 51 (2.0), 46 (1.9), 44 (9.5), 43 (35.4), 42 (35.4), 41 (87.4), 40 (7.8), 39 (8.3), 38 (27.0), 37 (2.6), 32 (4.6), 31 (11.4), 30 (11.4), 29 (49.9), 28 (73.8), 27 (43.7), 26 (4.2). IR (KBr) 3320, 3230, 3080, 2920, 1720—1740 (s), 1680, 1660, 1510, 1445, 1340, 1272, 1200, 1090, 1042, 802, 770, 750 cm^{-1}. UV ($CHCl_3$), λ_{max} 258, E 451, $\varepsilon=1.16\times10^4$.

Method 1-B. Reaction in a Dimethylacetamide Solution: Hexyl isocyanate (19.1 g, 0.15 mol), **1** (13.0 g, 0.1 mol) and triethylamine (1.0 g) in 52 ml of *N,N*-dimethylacetamide were heated at 90 °C for 3 h. The reaction mixture was then cooled and stirred into dilute aqueous hydrochloric acid (pH 1; 100 ml). The resulting precipitate was filtered, washed with water, and dried *in vacuo* to yield 21.4 g (83.1%) of crude **22,** which was then recrystallized from ethanol as white crystals.

Method 2. Into a cold (5 °C) solution containing **1** (1.30 g, 0.01 mol) in 40 ml of pyridine, phosgene (2.97 g, 0.03 mol) was bubbled over a 1 h period at 10 °C. Nitrogen gas was passed through to expel the excess phosgene. Hexylamine (1.01 g, 0.01 mol) was then added, and the mixture was stirred 1 h. The resulting pyridine hydrochloride was filtered off, and the reaction mixture was evaporated to dryness. The residue, taken up in 50 ml of chloroform, was washed twice with 30 ml of a dilute hydrochloric acid solution. The chloroform sloution was then dried (Na_2SO_4) and evaporated to afford **22** (2.05 g, 80.0%).

*1-Phenylcarbamoyl-5-fluorouracil (**33**). Method 1-C. In a Dimethyl Sulfoxide Solution*: To a solution containing **1** (10.4 g, 0.08 mol) in 100 ml of dimethyl sulfoxide, phenyl isocyanate (14.3 g, 0.12 mol) was added, and the mixture was stirred at room temperature for 1 h. When the milky reaction mixture was then filtered, fine precipitates were obtained. The precipitates were suspended in hot ethanol and filtered again to afford **33** (16.2 g, 81.4%); mp 280 °C.

*1-[α-Ethoxycarbonyl-β-(p-hydroxyphenyl) ethylcarbamoyl]-5-fluorouracil (**42**). Method 3.* To a cold pyridine solution containing a 0.04 molar amount of 1-chloroformyl-5-fluorouracil (**5**), a solution of L-thyrosine ethyl ester hydrochloride (9.80 g, 0.04 mol) in triethylamine (12.14 g) was added at 0 °C over a period of 2 h. The pyridine hydrochloride thus formed was filtered off. The filtrate was evaporated to dryness, and the residue, dissolved in 200 ml of chloroform, was washed twice with 200 ml of dilute hydrochloric acid. The chloroform layer was evaporated and column chromatographed on silica gel C-200. Elution with benzene–ethyl acatate (10 : 1) gave 5.10 g (25.8%) of **42**; mp 76.5—78 °C.

*1-Diethylcarbamoyl-5-fluorouracil (**47**). Method 3.* To 1.3 g (0.01 mol) of **1** dissolved in 20 ml of *N,N*-dimethylacetamide was added 0.48 g (0.01 mol) of 50% sodium hydride in mineral oil. Subsequently, diethylcarbamoyl chloride (1.36 g, 0.01 mol) in 5 ml of *N,N*-diethylacetamide was added, drop by drop, at 30 °C. After stirring at 30 °C for 5 h, the reaction mixture was left to stand overnight at room temperature and then filtered; the filtrate was subsequently evaporated *in vacuo*. The chloroform extract of the residue yielded 2.14 g of a crude product which was washed with diethyl ether to afford pure **47** (1.73 g, 75.5%); mp 157—160 °C.

*1,3-Bis(diethylcarbamoyl)-5-fluorouracil (**51**). Method 3.* To **1** (2.6 g, 0.02 mol) in 30 ml of *N,N*-dimethylformamide was added powdered potassium carbonate (3.32 g, 0.024 mol), and then a mixture of diethylcarbamoyl chloride (7.06 g, 0.052 mol) and 20 ml of *N,N*-dimethylformamide. The reaction mixture was heated at 80 °C for 2 h. The product was extracted into chloroform after the removal of the solvent *in vacuo*. The extract was washed with water, dried (Na_2SO_4), and evaporated to give a viscous oil. The oil was triturated with 5 ml of ethanol, and ether was added to complete the crystallization. The crystal was washed with ether to afford **51** (1.18 g, 31.0%); mp 147—148 °C.

*L-α-Ethoxycarbonyl-β-phenylethyl Isocyanate (**52**).* TCF (16.0 g, 0.07 mol) is added, drop by drop, to a mixture of L-phenylalanine ethyl ester hydrochloride (16.0 g, 0.07 mol) and active carbon (0.1 g) in 200 ml of toluene. The reaction mixture was gradually being heated to 80 °C over a 1 h period, the addition of the TCF being adjusted so as to finish at the time when the temperature reached 80 °C. The reaction was continued for an additional 2 h at 100—110 °C. The subsequent removal of the toluene and distillation of the reaction mixture gave **52** (13.75 g, 89.6%); bp 141—142 °C (5 mm); IR (neat), 2980, 2250(vs), 1735(s), 1208(s), 1197, 1025, 700 cm^{-1}; NMR (neat), 1.12 (3H, t, $J=8$ Hz), 2.95 (2H, d, $J=6$ Hz), 4.09 (2H, q, $J=8$ Hz), 4.0—4.2 (1H, m,) 7.21 (5H, s). Found: C, 65.54; H, 5.91; N, 6.14%. Calcd for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.39%.

*L-α-Ethoxycarbonyl-β-(methylthio)propyl Isocyanate (**53**).* Into a mixture of methionine ethyl ester hydrochloride (14.96 g, 0.07 mol), active carbon (0.01 g), and 200 ml of toluene, TCF (10.4 g, 0.0525 mol) was added dropwise with stirring. Then the reaction mixture was gradually heated up to reflux, and the reflux was continued for 2 h. The subsequent distillation of the reaction mixture gave 7.37 g (51.8%) of **53** as a colorless liquid: bp 133 °C (7 mm); IR (neat), 2995, 2950, 2270(s), 1752(s), 1450, 1225(s), 1040 cm^{-1}; NMR (neat), 1.32(3H, t, $J=8$ Hz), 2—2.2(2H, m), 2.1(3H, s), 2.67(2H, t, $J=7$ Hz), 4.3(2H, q, $J=8$ Hz), 4.2—4.4(1H, m). Found: C, 46.89; H, 6.52; N, 6.66; S, 15.46%. Calcd for $C_8H_{13}NO_3S$: C, 47.27; H, 6.45; N, 6.89; S, 15.74%.

*α-Methoxycarbonyl-β-methylbutyl Isocyanate (**54**).* TCF (19.8 g, 0.1 mol) was added, drop by drop, to a mixture of L-leucine methyl ester hydrochloride (26.62 g, 0.13 mol), active carbon (0.2 g), and toluene (200 ml). The mixture was

gradually heated to reflux, and heating at reflux was continued for 2 h. The subsequent distillation of the reaction mixture afforded 15.51 g (69.7%) of **54** as a colorless liquid; bp 74 °C (5 mm); n_D^{25} 1.4322; IR (neat), 3420, 2960, 2270(s), 1755, 1445, 1280, 1220 cm^{-1}; NMR (neat) 0.93(6H, d, J= 6 Hz), 1.67 (3H, m), 3.78 (3H, s), 4.05 (1H, t, J=8 Hz). Found: C, 56.61; H, 7.65; N, 7.43%. Calcd for $C_8H_{13}NO_3$: C, 56.31; H, 7.65; N, 8.18%.

*β-(Ethoxycarbonyl)ethyl Isocyanate (**55**).* The treatment of β-alanine ethyl ester hydrochloride (15.3 g, 0.1 mol) with TCF (19.8 g, 0.1 mol) in the usual way in **52** afforded 10.2 g (71.2%) of **53** as a colorless liquid; bp 69 °C (8 mm); IR (neat) 3000, 2280, 1750, 1390, 1200 cm^{-1}.

*Phenethyl Isocyanate (**56**).* Into a solution of TCF (19.8 g, 0.1 mol) in 200 ml of toluene, phenethylamine (24.15 g, 0.2 mol) and active carbon (0.1 g) were added, drop by drop, with strring. Then the reaction mixture was gradually heated to 50 °C and TCF (9.9 g, 0.05 mol) was added, drop by drop. The reaction was subsequently continued for 2 h at 100—110 °C. The removal of the solvent and distillation of the residue afforded 25.0 g (85.3%) of **56**: bp 124—126 °C (33 mm).

*Benzyl Isocyanate (**57**).* The treatment of benzylamine (21.4 g, 0.2 mol) with TCF (30.0 g, 0.15 mol) in the same way in was used for **56** afforded 23.0 g (86.4%) of **57**; bp 95 °C (19 mm).

The authors wish to thank Drs. K. Kuretani and A. Hoshi, National Cancer Center Research Institute in Tokyo, for the evaluation of the antitumor activity, and also Mitsui Toatsu Chemicals, Inc., and Mitsui Pharmaceuticals, Inc. (The Pharmaceutical Division of Mitsui Toatsu Chemicals, Inc.) for permission to publish this paper.

Studies on Separation of Amino Acids and Related Compounds. VIII.[1] Preparative Separation of Isomeric L-Aspartyl-L-phenylalanine Methyl Esters and Related Dipeptide Esters by Ion-Exchange Chromatography

Akira YASUTAKE, Haruhiko AOYAGI, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, 33 Kyushu University, Higashi-ku, Fukuoka 812

(Received February 21, 1977)

Authentic peptides, α- and ω-isomers of L-aspartyl (or L-glutamyl)-L-phenylalanine (or L-tyrosine) methyl ester, were synthesized by conventional methods. Among these eight peptides, α-L-glutamyl-L-phenylalanine methyl ester showed the tendency to convert to the corresponding dipeptide anhydride even under mild conditions. The experiments on a small column of Dowex 50 cation exchange resin were carried out with a model mixture composed of the α- and ω-isomers, and the optimum conditions for the complete separation of both isomers were determined. A synthetic mixture composed of the α- and ω-isomers was prepared readily through the coupling of benzyloxycarbonyl-L-aspartic acid (or glutamic acid) anhydride with L-phenylalanine (or L-tyrosine) methyl ester and subsequent hydrogenation. The synthetic mixture was separated by the use of a large ion exchange column and each isomer was obtained in a good yield.

In 1969, Mazur *et al.* discovered that α-APM[2] was 100—200 times sweeter than sucrose.[3] Although Davey *et al.* synthesized α-APM in 1966 by the hydrogenation of Z–Asp(OBzl)–Phe–OMe,[4] the large-scale preparation of α-APM by a simpler method has been desired. As described in a previous paper,[1] we have developed a convenient procedure for the separation of the α- and β-isomers of H–Asp–His–OH by column chromatography with Dowex 50.

In the present study, we attempted to separate in quantity α- and β-APM from a synthetic mixture by similar chromatographic methods. The synthetic mixture was prepared easily as shown in Fig. 1 by coupl ing and subsequent hydrogenation of the resulting mixture containing Z–Asp(OH)–Phe–OMe and Z–Asp(Phe–OMe)–OH. Additionally, we intended to separate α- and β-ATM, α- and γ-GPM, and α- and γ-GTM, from corresponding synthetic mixtures

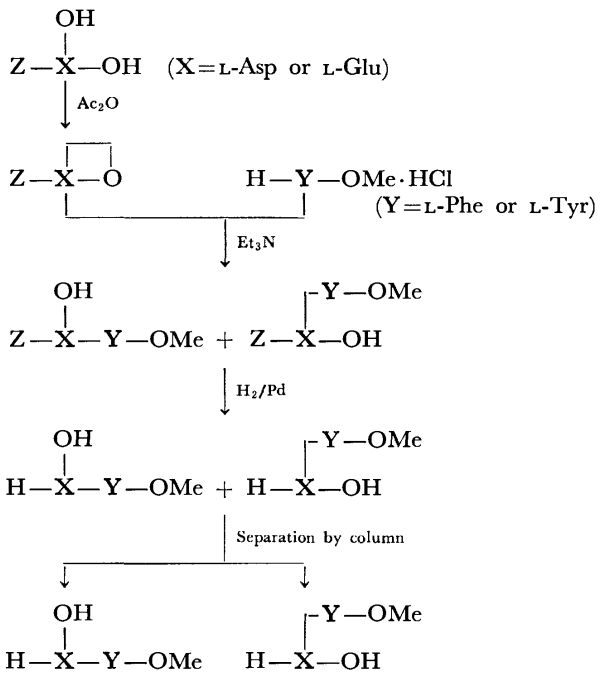

Fig. 1. Preparation of a synthetic mixture composed of α- and ω-dipeptide ester and subsequent saparation of the mixture.

which were also prepared by the coupling and hydrogenation procedure outlined in Fig. 1. These dipeptide esters are considered as interesting compounds from the standpoint of possible structure-taste relationships related to α-APM.

Experimental

TLC was carried out on Merck silica gel G, and PPC on Toyo Roshi No. 52 paper. R_f (TLC) and R_f (PPC) values are reported for the following solvent system: 1-butanol–acetic acid–pyridine–water (15 : 3 : 10 : 12, v/v). Material possessing a free terminal amino group (*e.g.*, α-APM) was detected by spraying with 0.2% ninhydrin solution in 80% ethanol, followed by heating at 100 °C. Material having blocked amino groups (*e.g.*, dipeptide anhydride) was detected by spraying with 10% H_2SO_4, followed by heating on a hot plate. $[\alpha]_D$ was measured with a Union high sensitivity polarimeter PM-71 (Kyoto).

*Authentic Peptides. Z-Asp(OBzl)-Phe-OMe (**1**), Z-Asp(OBzl)-Tyr-OMe (**3**), Z-Glu(OBzl)-Phe-OMe (**5**), Z-Glu(Phe-OMe)-OBzl (**6**), Z-Glu(OBzl)-Tyr-OMe (**7**)*: Mazur *et al.* prepared these compounds by the coupling of the Z-amino acid *p*-nitrophenyl ester, *e.g.*, Z–Asp(OBzl)–ONp, and H–Phe(or Tyr)–OMe in yields of 57—97%.[3] We prepared these compounds by the coupling of a mixed anhydride[5] of the Z-amino acid with H–Phe(or Tyr)–OMe in yields of about 70% as described for the preparation of **2**. Melting points and specific rotations of the products agreed with literature values[3] with the exceptions of mp 99—100 °C for **5** (lit, 78—80 °C), $[\alpha]_D^{20}$ −6.4° for **7** (*c* 2, MeOH) (lit, −44°). We observed that the synthesis of Z–Asp(OH)–OBzlNO_2[6] was easier than that of Z–Asp(OH)–OBzl;[7] therefore, the intermediate compounds (**2** and **4**) were prepared as follows.

*Z-Asp(Phe-OMe)-OBzlNO_2 (**2**)*: To a chilled solution of Z–Asp(OH)–OBzlNO_2 (4.02 g, 10 mmol) and triethylamine (1.4 ml, 10 mmol) in tetrahydrofuran (25 ml) was added isobutyl chloroformate (1.31 ml, 10 mmol) at −10 °C. After 15 min, a chilled solution of H–Phe–OMe·HCl (2.16 g, 10 mmol) and triethylamine (1.4 ml, 10 mmol) in chloroform (20 ml) was added. The reaction mixture was left to stand at room temperature overnight, evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate (300 ml). The solution was washed successively with 4% $NaHCO_3$, 2% HCl and water, dried (Na_2SO_4), and evaporated. The crystals were collected with the aid of ether; yield, 3.84 g (68%); mp 162—164 °C; $[\alpha]_D^{20}$ −40.9° (*c* 1, MeOH).

Found: C, 61.73; H, 5.16; N, 7.28%. Calcd for $C_{29}H_{29}O_9N_3$: C, 61.80; H, 5.19; N, 7.46%.

Z-Asp(Tyr-OMe)-OBzlNO$_2$ (4): This compound was prepared from Z-Asp(OH)-OBzlNO$_2$ (10 mmol) and H-Tyr-OMe·HCl (10 mmol), as described for the preparation of **2**; yield, 4.18 g (72%); mp 163—164 °C; $[\alpha]_D^{20}$ −40.4° (*c* 1, MeOH).

Found: C, 60.04; H, 5.06; N, 7.19%. Calcd for $C_{29}H_{29}O_{10}N_3$: C, 60.10; H, 5.04; N, 7.25%.

Z-Glu(Tyr-OMe)-OBzl (8): This compound was prepared from Z-Glu(OH)-OBzl[8] (10 mmol) and H-Tyr-OMe·HCl (10 mmol), as described above; yield, 3.50 g (64%); mp 149 °C; $[\alpha]_D^{20}$ −9.2° (*c* 1, MeOH).

Found: C, 65.54; H, 6.05; N, 5.07%. Calcd for $C_{30}H_{32}O_8N_2$: C, 65.68; H, 5.88; N, 5.11%.

α-APM, β-APM, α-ATM, β-ATM, α-GPM, γ-GPM, α-GTM: These compounds were prepared by the hydrogenation of **1**—**7**, as described for the preparation of γ-GTM. Their specific rotations agreed with literature values[3] with the exceptions of $[\alpha]_D^{20}$ +6.1° (*c* 2, H_2O) for β-APM (lit, +4°)[3] and $[\alpha]_D^{20}$ +15.8° for γ-GPM (*c* 2, H_2O) (lit, +21°).[3]

γ-GTM: A solution of **8** (0.55 g, 1 mmol) in a mixture of methanol (12 ml) and acetic acid (3 ml) was treated with hydrogen in the presence of palladium black, and the filtrate was evaporated *in vacuo*. The resulting solid was recrystallized from hot water; yield, 0.30 g (93%); mp 197—199 °C; $[\alpha]_D^{20}$ +6.9° (*c* 2, H_2O), $[\alpha]_D^{20}$ +39.2° (*c* 2, AcOH); R_f (TLC) 0.68, R_f (PPC) 0.54.

Found: C, 55.40; H, 6.23; N, 8.51%. Calcd for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.22; N, 8.64%.

H-α-Glu-Phe-OH Anhydride (9): α-GPM (62 mg, 0.2 mmol) was dissolved in methanol (10 ml) previously saturated with ammonia, and the solution was allowed to stand at room temperature for 2 days. The solvent was removed by evaporation, the residue was dissolved in water (10 ml), and the solution was acidified with 1 M HCl (0.2 ml). After the solution was evaporated to dryness, the resulting crystals were collected by the filtration with the aid of cold water; yield, 42 mg (71%); mp 235—236 °C (dec); $[\alpha]_D^{20}$ +28.8° (*c* 1, AcOH); R_f (TLC) 0.75.

Found: C, 60.54; H, 5.93; N, 10.18%. Calcd for $C_{14}H_{16}O_4N_2$: C, 60.56; H, 5.84; N, 10.14%.

Column Chromatography. A column was packed with Dowex 50X8 (200—400 mesh) equilibrated with a specified eluting solvent. The eluting solvents used were aqueous pyridinium acetate at different concentrations and pHs as follows; S_1=0.1 M at pH 4, S_2=0.2 M at pH 4, S_3=0.2 M at pH 5, S_4=1 M at pH 5. A mixture of dipeptide esters was applied to a column and eluted with one of these eluting solvents at room temperature. An aliquot (0.5 ml) of each fraction was subjected to a test to determine the amount of ninhydrin-positive material present using the Yemm and Cocking method.[9]

Results and Discussion

Column Chromatography of a Model Mixture Containing Isomeric Dipeptide Esters. Preliminary experiments on a model mixture were performed as follows with a small column in order to find the optimum conditions for the separation. A model mixture was prepared by dissolving 0.01 mmol each of α- and β-APM in water (0.5 ml). Other model mixtures (α- and β-ATM, α- and γ-GPM, and α- and γ-GTM) were prepared similarly. The model mixture was applied to a column (0.9×20 cm) and eluted with a specified eluting solvent,

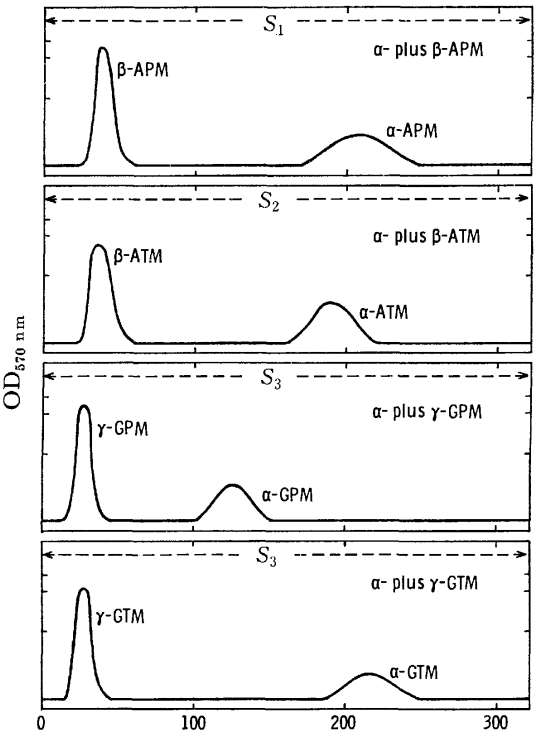

Fig. 2. Chromatography on a 0.9×20 cm column of Dowex 50 of model mixtures. For example, α- plus β-APM represents a model mixture composed of α-APM and β-APM (total, 0.02 mmol).

2-ml fractions being collected at a flow rate of 20 ml/h. The peptide in each fraction was identified by means of TLC or PPC after concentration of the corresponding fraction by evaporation.

We applied pyridinium acetate in various concentrations and pHs to determine necessary separation conditions of the α- and ω-isomers in a model mixture. An example with satisfactory results is shown in Fig. 2. When higher concentrations of pyridinium acetate and more alkaline pHs were used, the distance of separation between the α- and ω-isomers was diminished.

As seen in Fig. 2, the α-isomer was eluted more slowly than the corresponding ω-isomer in every case. We can give no definite explanation for this phenomenon, but we can point out that the same phenomenon was observed in the previous study in which H-β-Asp-His-OH or H-γ-Glu-His-OH was eluted faster than the corresponding α-dipeptide.[1]

Preparative Separation of α-APM and β-APM from a Synthetic Mixture. A synthetic mixture was prepared according to Fig. 1 and each isomer was separated with a large column. To a solution of Z-Asp-OH anhydride[10] (2.49 g, 10 mmol) in tetrahydrofuran (10 ml) was added a solution of H-Phe-OMe·HCl (2.38 g, 11 mmol) and triethylamine (1.54 ml, 11 mmol) in chloroform (20 ml) while stirring at room temperature. After stirring overnight, the reaction mixture was evaporated to dryness and the residue was dissolved in a mixture of methanol (40 ml) and acetic acid (10 ml). The solution was treated with hydrogen in the presence of palladium black. The filtrate was evaporated to dry-

Table 1. Elution data for preparative separation of synthetic mixture

Material	Elution solvent	Eluate volume (ml)	Portion for evaporation (ml)	Peptide present
Mixture of				
α- and β-APM	S_1	0—1000	580—980	β-APM
	S_3	1000—2000	1340—1760	α-APM
α- and β-ATM	S_2	0—1000	660—900	β-ATM
	S_3	1000—2000	1620—1900	α-ATM
α- and γ-GTM	S_3	0—1000	300—520	γ-GTM
	S_4	1000—1600	1400—1700	α-GTM
α- and γ-GPM	S_3	0—500	300—420	γ-GPM
	S_4	500—1200	900—1100	α-GPM[a]

a) α-GPM was converted into H-Glu-Phe-OH anhydride mostly after evaporation of the portion (900—1100 ml).

Table 2. Yields and physical constants of peptides

Peptide	Yield (%)	Melting point (°C dec)	$[\alpha]_D^{20}$ (c 1)		R_f	
			H_2O	AcOH	TLC	PPC
β-APM	32	181—182	+6.2°	+40.4°	0.69	0.67
α-APM	37	239—242	+0.2°	+33.0°	0.74	0.72
β-ATM	31	200—202	+14.8°	+38.4°	0.65	0.55
α-ATM	34	266—268	+5.2°	+36.2°	0.69	0.61
γ-GTM	27	201—202	+7.0°	+39.0°	0.69	0.55
α-GTM	34	215—217	+15.6°	+46.0°	0.72	0.76
γ-GPM	27	160—162	+1.2°	+38.4°	0.69	0.71
H-α-Glu-Phe-OH anhydride	31	234—236	—[a]	+28.6°	0.76[b]	
Authentic α-GPM[c]		105—109	+1.2°	+45.2°	0.74[b]	0.80

a) H-α-Glu-Phe-OH anhydride was slightly soluble in water, hence an accurate determination of $[\alpha]_D$ in water was difficult. b) When chloroform-methanol-acetic acid (25 : 5 : 1, v/v) was used as a solvent on TLC, R_f values were 0.54 for H-α-Glu-Phe-OH anhydride and 0.14 for authentic α-GPM. c) Data of this peptide synthesized by the conventional method are given as reference values.

ness, and the resulting powder (a synthetic mixture) was used in the next step.

The powder was dissolved in S_1 (20 ml) and put on a column (2.7×50 cm) of Dowex 50. The sample was eluted with 1000 ml of eluant S_1 at a flow rate of 40 ml/h, and 20-ml fractions were collected. Then, the eluant was changed to S_3 in order to shorten elution time, and 1000 ml of S_3 was eluted. The eluting solvents used in this study are summarized in Table 1. The elution pattern is shown in Fig. 3 as a representative example among similar experiments. A portion of 580—980 ml was evaporated in a bath at about 50 °C *in vacuo*, the evaporations being repeated several times by the additions of water.

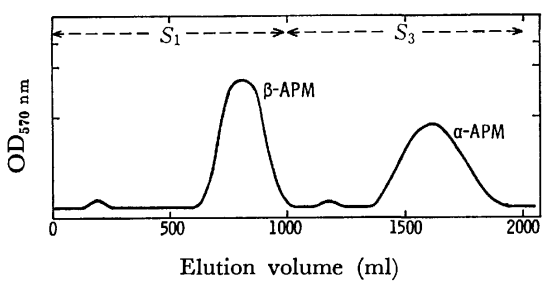

Fig. 3. Chromatography on a 2.7×50 cm column of Dowex 50 of a synthetic mixture (10 mmol) composed of α-and β-APM.

The residual product was recrystallized from hot water; yield of β-APM, 0.95 g (32% from Z-Asp-OH anhydride), the data being shown in Table 2. A portion of 1340—1760 ml was treated similarly; yield of α-APM, 1.09 g (37% from Z-Asp-OH anhydride).

As mentioned above, we could isolate pure α- and β-APM in good yields from a synthetic mixture by the use of a column with ion-exchange resin. Ariyoshi *et al.* prepared a similar synthetic mixture by the coupling of L-aspartic acid anhydride (1 equivalent) and H-Phe-OMe (4 equivalents); this procedure is advantageous because it avoids the hydrogenation step as seen in Fig. 1, but suffers from the contamination of the product with excess H-Phe-OMe and polymers that are produced by over reaction of L-aspartic acid anhydride.[11] The same investigators reported the isolation of α-APM hydrochloride, which was less soluble than β-APM hydrochloride, by means of fractional crystallization from their synthetic mixture.[11]

Preparative Separations of α-ATM and β-ATM, and α-GTM and γ-GTM, from Each Synthetic Mixture. Each synthetic mixture was prepared from Z-Asp-OH anhydride (10 mmol) and H-Tyr-OMe·HCl (11 mmol), and from Z-Glu-OH anhydride[12] (10 mmol) and H-Tyr-OMe·HCl (11 mmol), respectively, as described for the preparation of the synthetic mixture containing α- and β-APM. Subsequently, each mixture was subjected to column chromatography as described for the

isolation of α- and β-APM, the data of eluting solvents being summarized in Table 1. Each isomer was obtained in yields of 0.97 g (31%) for β-ATM, 1.06 g (34%) for α-ATM, 0.87 g (27%) for γ-GTM and 1.09 g (34%) for α-GTM. The physical constants are summarized in Table 2.

Preparative Separation of H–α-Glu–Phe–OH Anhydride and γ-GPM from a Synthetic Mixture. The synthetic mixture prepared from Z–Glu–OH anhydride (10 mmol) and H–Phe–OMe·HCl (11 mmol) was treated on a column as described above. A portion of the eluate (300—420 ml) yielded 0.84 g (27%) of pure γ-GPM (see Tables 1 and 2). It was observed that a portion of the 900—1100 ml fraction contained α-GPM; however, the residual powder obtained after evaporation of this fraction was a mixture of H–α-Glu–Phe–OH anhydride as a major product and α-GPM as a minor product. The residual powder was collected by filtration with the aid of cold 0.1 M HCl to remove α-GPM, and subsequently washed with cold water; yield of H–α-Glu–Phe–OH anhydride, 0.91 g (31%); mp 234—236 °C (dec) (see Table 2).

At the beginning stages of this experiment, we had assumed that the product with mp 234—236 °C was either Pyroglu–Phe–OMe or H–α-Glu–Phe–OH anhydride. Since the results of IR and NMR of the product indicated no presence of methyl ester group, we compared the product with authentic H–α-Glu–Phe–OH anhydride(**9**), and were able to identify the product as the anhydride. We discovered that the H–α-Glu–Phe–OH anhydride was produced during evaporation of the eluate and the amount produced was dependent upon the temperature of the bath and the extent of reduced pressure during the evaporation. For example, the residual powder after evaporation at 30 °C with a good aspirator at 15—20 mmHg was a 3 : 7 mixture of the anhydride to α-GPM. Since these results suggested the lability of α-GPM compared with other dipeptide esters, we carried out the following experiments.

Stability of Dipeptide Esters. Authentic dipeptide methyl esters (eight kinds) were stored in bottles at room temperature for about 4 months, and each was examined by TLC and PPC. The results indicated that α-GPM was converted mostly into H–α-Glu–Phe–OH anhydride and only a small amount of the original peptide ester remained. On the contrary, the seven other peptide esters remained unchanged after 4 months.

The experiment was also carried out in solution. 25 μmol of each of the pure authentic dipeptide esters (eight kinds) was dissolved in S_4 (1 ml), and the solution was allowed to stand at 25 °C. Aliquots withdrawn at selected intervals up to 6 days were subjected to TLC, and examined for the appearance of new peptides. After 6 days, an incubation solution of α-GPM contained an appreciable amount (about 20%) of H–α-Glu–Phe–OH anhydride, and each solution of α-APM, α-ATM, and α-GTM also contained some amounts (5—10%) of new products which are presumably the corresponding dipeptide anhydrides. On the contrary, each solution of ω-dipeptide esters was stable producing no new product.

No definite explanation for the marked tendency of α-GPM to convert to the corresponding anhydride can be given at present. Recently, Furda *et al.* examined the relative stabilities of α-APM and its hydrochloride in aqueous solution, and detected the presence of H–α-Asp–Phe–OH anhydride as a major product.[13]

Sweetness Evaluation. The sweetness of these compounds was organoleptically determined by panel evaluation in our laboratory according to the literature.[14] α-APM and α-ATM, isolated from the synthetic mixture, had intense sweet tastes similar to the corresponding authentic samples. Other β-aspartylpeptide esters and all glutamylpeptide esters, including γ-GTM which was prepared newly in this study, showed weak bitter tastes. Mazur *et al.* reported the intense sweet tastes of α-APM and α-ATM, and the bitter tastes of many β-aspartyl and glutamylpeptide esters.[3]

(Received Feberuary 28, 1977)

The reactions of 1-methoxycarbonyl-2-imidazolidinone, 3-acetyl-1-methoxycarbonyl-2-imidazolidinone and 1-methoxycarbonyl-*cis*-perhydrocyclopenta[*d*]imidazol-2-one with butylamine were studied in the absence and presence of various metal ions. Certain bivalent ions such as Mg^{2+}, Ca^{2+}, and Mn^{2+} enhanced an electrophilic reactivity of the methoxycarbonyl group and facilitated the transfer reaction of this group to butylamine, especially when the imidazolidinone moiety of substrates bears the methoxycarbonyl group at one N-position and a hydrogen atom at the other N-position. Whereas monovalent ions such as Na^+ and Ag^+, and bivalent ions such as Zn^{2+} and Cu^{2+}, had no appreciable effect on the reactivity, and exhibited almost the same reactivity patterns as those observed in the reactions in the absence of metal ions. A possible explanation is given in terms of the stability of coordination complexes which are formed by the interaction between the imidazolidinone moiety of substrates and added ions.

It has been postulated that a carboxylated biotin-enzyme, most probably carboxylated at the 1-N position of the biotin moiety of the enzyme, is a key intermediate in the biotin-enzyme-promoted carboxylations, and that the carbonyl group is transferred from this intermediate to a nucleophilic carbon of acyl-CoA or α-keto acids.[1,2] In order to elucidate the chemical mechanism of these enzymatic carboxylations, many model studies have been carried out by use of compounds related to biotin.[3] However, no definitive information has yet been obtained. We have recently investigated the chemistry of 1-methoxycarbonyl-2-imidazolidinone and its derivatives in a hope to gain a more insight into the chamical functions of biotin in the enzymatic carboxylations.[4]

Upon treatment with an amine, 1-methoxycarbonyl-2-imidazolidinone (**1**) is preferentially converted into 1-alkylcarbamoyl-4-methoxycarbonylethylenediamine (**2**), and the transfer of the methoxycarbonyl group to the amine is not observed.[4] Consequently, this experiment does not become in any sense a model reaction for the enzymatic carboxylations. On the other hand, it has been found that certain metal ions such as Mg^{2+} and Mn^{2+} are required for the enzymatic carbonylations.[5] These metal ions also depress the decarboxylation of 1-carboxy-2-imidazolidinone.[6] On the bases of these findings, we studied the effects of several metal ions on the reactivities of **1** and its derivatives in their reactions with butylamine. The addition of some ions including Mg^{2+} and Mn^{2+} to the reaction system exerted a dramatic change in the reactivity patterns and promoted the transfer of the methoxycarbonyl group from **1** and its derivatives to butylamine. The results are summarized in this paper.

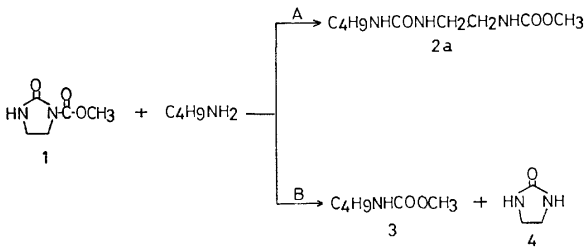
Results and Discussion

*Reaction of **1** with Butylamine.* Treatment of **1** with butylamine in the absence and presence of various metal ions gave the products listed in Table 1. The results of Table 1 demonstrate that the reaction takes place through two different paths, depending on the constituents of the reaction system (Scheme 1). In the absence of metal ions, 1-butylcarbamoyl-4-methoxycarbonylethylenediamine (**2a**) was obtained as a sole product (path A). The addition of monovalent ions such as Na^+ and Ag^+ and some bivalent ions such as Zn^{2+} and Cu^{2+} to the reaction system did not alter the above reactivity pattern. However, the addition of Mg^{2+}, Ca^{2+}, and Mn^{2+} brought about a dramatic change in the reactivity pattern and resulted in the formation of methyl butylcarbamate (**3**) and 2-imidazolidinone (**4**) (path B).

TABLE 1. REACTION OF **1** WITH BUTYLAMINE IN THE PRESENCE OF METAL IONS[a]

Added salt	Reaction path	Products, %		
		2	**3**	**4**
None	A	95	—[b]	—
AgCl	A	96	—	—
NaCl	A	94	—	—
$CuCl_2$	A	88	—	—
$ZnCl_2$	A	86	—	—
$MgCl_2$	B	—	74	67
$MnCl_2$	B	—	63	40
$CaCl_2$	B	—	62	56

a) The reaction was carried out by refluxing an equimolar mixture of **1** and a metal chloride in butylamine for 17 h. b) The dash(—) signifies that the product was unable to be isolated.



Scheme 1.

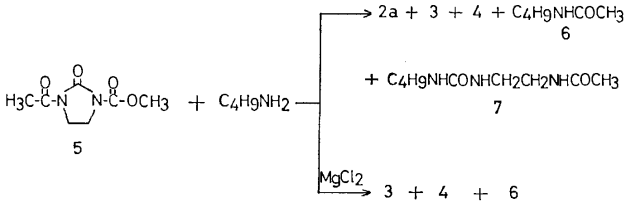
The methoxycarbonyl transfer reaction of path B occurs by an attack of butylamine on the carbonyl carbon of the methoxycarbonyl group of **1**. An analogous transfer reaction did not take place upon treatment of **2a** with butylamine in the presence of Mg^{2+} under the similar conditions.

Table 2. Reaction of **5** with butylamine in the presence of magnesium chloride[a)]

Added salt	Products, %				
	2	**3**	**4**	**6**	**7**
None	17	66	42	55	24
$MgCl_2$	—[b)]	71	67	85	—

a) The reaction was carried out by refluxing an equimolar mixture of **5** and magnesium chloride in butylamine for 17 h. b) The dash(—) signifies that the product was unable to be isolated.

Reaction of 3-Acetyl-1-methoxycarbonyl-2-imidazolidinone (5) with Butylamine. The reaction of **5** with butylamine was carried out in the absence and presence of Mg^{2+}. The products isolated are listed in Table 2. In the absence of metal ion, the reaction yielded **2a**, **3**, **4**, *N*-acetylbutylamine (**6**), and 1-acetyl-4-(butylcarbamoyl)ethylenediamine (**7**). In contrast, the reaction in the presence of Mg^{2+} afforded **3**, **4**, and **6**. These results show that the reactivity pattern is also altered by the addition of Mg^{2+}; *i.e.*, the production of ring-opening compounds, **2a**, and **7**, is completely depressed by the addition of Mg^{2+}.



Scheme 2.

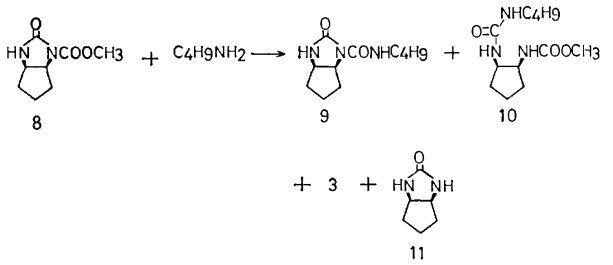
*Reaction of 1-Methoxycarbonyl-*cis*-perhydrocyclopenta*[d]*imidazol-2-one (8) with Butylamine.* The reaction of **8** with butylamine was studied somewhat in detail. The results are summarized in Table 3 and Scheme 3. In the absence of metal ions, **3**, 1-butylcarbamoyl-*cis*-perhydrocyclopenta[*d*]imidazol-2-one (**9**), *N*,*N*′-disubstituted *cis*-1,2-diaminocyclopentane (**10**), and *cis*-perhydrocyclopenta[*d*]imidazol-2-one (**11**) were obtained. For this reaction, a main reaction was an attack of butylamine on the 1-methoxycarbonyl carbon to produce **9**. Whereas the methoxycarbonyl transfer to produce **3** and **11** *via* the same mode of attack became a side-reaction. This observation implies that a leaving ability of the *cis*-perhydrocyclopenta[*d*]imidazol-2-one anion is lower than that of methoxide anion.

Table 3. The reaction of **8** with butylamine in the presence of various metal ions[a)]

Added salt	Products, %			
	3	**9**	**10**	**11**
None	7	55	15	13
AgCl	8	51	20	7
$CuCl_2$	10	52	17	15
$MgCl_2$	66	28	—[b)]	38
$MnCl_2$	68	22	—	44

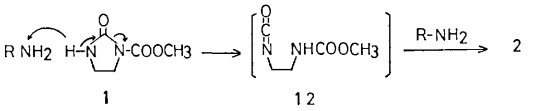
a) The reaction was carried out by refluxing an equimolar mixture of **8** and a metal chloride in butylamine for 17 h. b) The dash(—) signifies that the product was unable to be isolated.

No essential change in the reactivity pattern was observed by the addition of Ag^{+} and Cu^{2+}. However, the addition of Mg^{2+} again brought about a considerable change in the reactivity pattern. The formation of **10** was completely depressed, and the methoxycarbonyl transfer leading to **3** was highly facilitated.

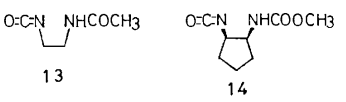


Scheme 3.

Discussion. In a previous paper,[4)] we have studied the reactions of **1**, **5**, and **8** with nucleophilic reagents in the absence of metal ions, and proposed probable pathways for these reactions. The reaction of **1** with an amine proceeds by way of the isocyanate intermediate (**12**) which has been produced by the removal of an acidic NH proton on the imidazolidinone ring of **1** by amine.



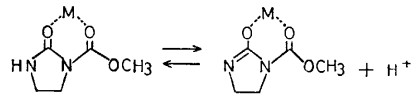
Compound **5** bears no acidic proton on the ring. For this compound, the methoxycarbonyl or acetyl group is removed at the first step by the nucleophilic attack of an amine on their carbonyl carbons. 1-Acetyl-2-imidazolidinone and **1** thus produced are converted into **7** and **2** *via* the corresponding isocyanate intermediates, **13** and **12**. These pathways explain the formation of all the products isolated. Finally, **8** is of special interest from the viewpoint that it has a more close structural resemblance to biotin than do **1** and **5**. Although **8** bears an acidic NH proton on the imidazolidinone ring, its 1-methoxycarbonyl group is attacked to produce **3**, **9**, and **11** in moderate yields. Obviously, **10** is produced *via* the isocyanate intermediate **14**.



The above reactivity patterns observed in the absence of metal ions change upon the addition of certain bivalent ions such as Mg^{2+}, Ca^{2+}, and Mn^{2+} to the reaction mixtures. These ions enhance an electrophilic reactivity of the methoxycarbonyl group and facilitate breaking of the N–$COOCH_3$ bond, especially when the imidazolidinone moiety of substrates bears the methoxycarbonyl group at one N-position and a hydrogen atom at the other N-position. In the case of **5** which bears

no hydrogen on the nitrogen atoms of the imidazolidinone moiety, the compound is, as pointed out above, at first transformed into **1** and 1-acetyl-2-imidazolidinone regardless the addition of metal ions. Since both of the products have a hydrogen on the N-position of the imidazolidinone moiety, **1** is preferentially converted into **3** and **4**, and 1-acetyl-2-imidazolidinone into **4** and **6** upon the addition of Mg^{2+}.

There is little doubt that the formation of coordination complexes as represented in formula 15 by chelating interaction between metal ions and imidazolidinone moiety is responsible for these changes. The formation of stabilized chelate ring depresses the conversion of the imidazolidinone derivatives, **1**, **5**, and **8** into the corresponding isocyanate intermediates, **12**, **13**, and **14**. It also enhances an electrophilic reactivity of the methoxycarbonyl group by its increased polarization.



$M = Mg^{2+}, Ca^{2+}, Mn^{2+}$

15

The experimental results suggest that the formation of stabilized chelate rings is favored by an association of the imidazolidinato ligand with bivalent ions, Mg^{2+}, Ca^{2+}, and Mn^{2+}, that belong to the hard metal ions in Pearson's classification.[7]

Bivalent ions, Zn^{2+} and Cu^{2+}, that belong to the borderline class in his classification and all monovalent ions do not give stabilized chelate rings.

Experimental

Materials. 1-Methoxycarbonyl-2-imidazolidinone (**1**), mp 178—179 °C, 3-acetyl-1-methoxycarbonyl-2-imidazolidinone (**5**), mp 143—144.5 °C, and 1-methoxycarbonyl-*cis*-perhydrocyclopenta[*d*]imidazol-2-one (**8**), mp 153.5—154.5 °C, were prepared by the methods described previously.[4]

*Reaction of **1**, **5**, and **8** with Butylamine.* The reaction of an imidazolidinone, **1**, **5**, or **8**, with butylamine in the absence of metal ion were conducted by refluxing a solution of 2 mmol of the respective imidazolidinone in 10 ml of butylamine for 17 h, and the products were isolated and identified by the procedures described previously.[4]

The reactions in the presence of metal ions were carried out as follows: A mixture of 2.08 mmol of an imidazolidinone, **1**, **5**, or **8**, and 2.08 mmol of a metal ion (as chloride) in 10 ml of butylamine was refluxed for 17 h. An excess of butylamine was removed by distillation, and the residue was subjected to a chlomatographic separation on silica gel column: chromatographic separations were successfully accomplished by use of the solvent systems[4] employed for the reactions in the absence of metal ions.

The products were identified by the comparisons of melting points and spectral properties such as IR, NMR, and mass spectra with those of the respective authentic specimens.

A Macrocyclic Enzyme Model System. Catalytic Properties of 10-Amino-[20]paracyclophane in the Deacylation of *p*-Nitrophenyl Carboxylates

Yukito MURAKAMI,* Junzo SUNAMOTO, Hiroki KONDO, and Hiroshi OKAMOTO

**Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812*

Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852

(Received April 21, 1977)

The catalytic efficiency of 10-amino[20]paracyclophane in the deacylation of *p*-nitrophenyl carboxylates was investigated in 10.9 or 20.8% (v/v) aqueous ethanol at $\mu=0.10$ (KCl). The present catalyst exhibited marked catalytic effects not only in the free amine but in the ammonium form. The observed saturation-type kinetics is consistent with a reaction mechanism which involves pre-equilibrium complexation between the aminoparacyclophane and the substrate at a 1 : 1 molar ratio, followed by pseudo-intramolecular catalysis effected by the amino group of the macrocycle. Studies on the inhibition effect by 1-dodecanol and the modification of the catalyst by 2,4-dinitrofluorobenzene confirmed the effective binding ability of the present paracyclophane toward hydrophobic substrates. The free amine form of the catalyst acted as an effective nucleophile to give the acylated aminoparacyclophane as confirmed by the product analysis. On the other hand, the protonated amine form also enhanced the ester degradation, retaining a turnover behavior. On the basis of the kinetic solvent isotope effect and the exceedingly minor kinetic effect of [10-oxo[20]paracyclophan-22(23)-ylmethyl]trimethylammonium chloride in the ester degradation in the neutral pH region, a plausible reaction mechanism has been discussed.

[20]Paracyclophanes are synthetic macrocycles designed to have a hydrophobic cavity of sizable diameter into which an appropriate hydrophobic substrate can be incorporated. Upon formation of the inclusion complex, the cleavage of an ester bond of the incorporated substrate is subjected to the catalysis by a functional group or groups placed on the edge of a macrocyclic skeleton. The previously developed catalysts in this series, *i.e.*, 10-hydroxy-11-hydroxyimino[20]paracyclophane (**1**)[1,2] and substituted 10-hydroxyimino[20]paracyclophanes,[3] have shown characteristic enzyme-like behavior in the deacylation of *p*-nitrophenyl carboxylates bearing a long aklyl chain. In those systems, the reaction had to be carried out at relatively high pH's to observe moderate catalysis because of relatively high pK_a values of the hydroxyimino group. Another macrocycle, 10-amino[20]paracyclophane (**2**), was prepared previously by Murakami *et al.*[4] and investigated as for its catalytic efficiency in this work. Since a free amino group is expected to act as either a nucleophile or a general base and a protonated amino group as either a general acid or an electrostatic catalyst in a moderate pH region, some novel catalysis different from those demonstrated by the hydroxyimino group would be expected in this study.

Amino acid residues as components constituting many enzymes often bear primary amine substituents. These amino groups play indispensable roles in the enzymatic reactions in one way or another. While the aminolysis of carboxylic esters is one of the most thoroughly investigated reactions,[5] the catalytic roles of amino groups seem less understood in the enzymatic reactions in spite of their importance. In the present investigation, the catalytic functions of an amino group placed in the hydrophobic field are to be clarified to obtain a clue to development of more elaborated enzyme model systems.

Experimental

Materials. 10-Amino[20]paracyclophane (**2**) was prepared by a three-step procedure from 11-hydroxy[20]paracyclophan-10-one and isolated as the hydrochloride form.[4] Preparation of [10-oxo[20]paracyclophan-22(23)-ylmethyl]-trimethylammonium chloride (**3**) was described previously.[3] *p*-Nitrophenyl dodecanoate (PNPL) and hexadecanoate (PNPP) were the same as those described previously.[1,2] 2,4-Dinitrofluorobenzene was obtained as a guaranteed reagent from Nakarai Chemicals, Ltd. 1-Dodecanol was also obtained as a guaranteed grade from Nakarai Chemicals, Ltd. and distilled *in vacuo* before use. Deuterium oxide (99.75%) and ethanol-d_1 (99%) were the products of E. Merck AG and Commissariat al' Energie Atomique de France, respectively, and used without further purification.

Kinetic Measurements.[6] The deacylation rates of *p*-nitrophenyl carboxylates were determined by measuring the absorption at 400 nm either on a Hitachi 124 recording spectrophotometer or on a Shimadzu-Bausch & Lomb Spectronic 88 equipped with a Riken Denshi SP-G3 recorder. The procedure for the kinetic measurements was essentially the same as those described previously.[1,2] Each run was initiated by adding an appropriate amount of a substrate dissolved in ethanol to a reaction medium which was pre-equilibrated at an appropriate temperature in a thermostatted cell set in the spectrometer. The reaction medium was prepared by mixing appropriate amounts of 10-amino[20]paracyclophane, ethanol, potassium chloride, and buffer salts. The initial substrate concentration was always maintained at 1.00×10^{-5} M in order to make critical comparisons of kinetic data possible, since the hydrolytic rates of *p*-nitrophenyl carboxylates bearing a long alkyl chain

were reported to vary by the change in their initial concentrations.[7,8]

pH Measurements. The pH and pD values of reaction mixtures were measured with a TOA HM-5A pH meter equipped with a TOA GS-135C combined electrode. The pH meter was calibrated by using a combination of appropriate aqueous buffer solutions. The pH values thus determined were converted into stoichiometric hydrogen ion concentrations (−log[H+]) by titrating perchloric acid with standard sodium hydroxide in the same solvent as used for the kinetic runs (10.9 or 20.8% (v/v) aqueous ethanol). The difference between pH in 20.8% (v/v) aqueous ethanol and pD in 20.8% (v/v) ethanol-d_1–79.2% (v/v) deuterium oxide was directly estimated from the pH-meter readings measured in phosphate buffer for both solvent systems.

Product Analysis.[9] A solution of **2** (14 mg) and PNPL (50 mg) dissolved in a mixture of aqueous borate-carbonate buffer (pH 9.4, μ=0.1 with KCl, 800 ml) and ethanol (200 ml) was stirred at 40 °C for 58 h, and the mixture was extracted with ether (150 ml×6). The ether extracts were washed with water (200 ml×2), dried over sodium sulfate, and evaporated to give an oil. The oily material was chromatographed on a column (2.4×15 cm) of silica gel (Wakogel C-100) with dichloromethane–benzene (1 : 1) as an eluant to afford *ca.* 4 mg of the acylated amine (**4**). The authentic sample was prepared independently as follows for the identification of the product. A solution of **2** (20 mg) and dodecanoyl chloride (100 mg) in dry ether (25 ml) was stirred under reflux for 8 h. The cooled solution was washed with 5% aqueous sodium carbonate (20 ml×3), 5% aqueous sodium hydroxide (20 ml×5), and then water (30 ml×2) in this sequence. The usual work-up gave an oily material (*ca.* 40 mg) which was applied on a chromatographic column in a manner as described above. The amide fraction eluted with dichloromethane–benzene (1 : 1) was further purified by a Hitachi 635 liquid chromatograph equipped with a column of Hitachi gel 3019. Methanol was used as eluant and components eluted were detected by UV absorption at 254 nm. Spectral data identified the acylated amine (**4**) with the isolated authentic sample (*ca.* 5 mg). IR (neat): 3280 (NH str.), 1635 (amide C=O str.), and 1552 cm^{-1} (amide NH bend. and CN str.). NMR ($CDCl_3$, TMS): δ 7.11 (s, aromatic), 5.13 (broad d, NH), 3.51 (m, *H*CNHCO), 2.64 (t, benzyl methylene), 2.16 (t, CH_2CO), and 1.9—0.8 (m, methylene).

Results

The deacylation reaction of *p*-nitrophenyl carboxylates was investigated in aqueous ethanol both in the absence and in the presence of **2** as listed in Table 1. The initial concentration of a substrate was adjusted at 1.00×10^{-5} M and total amount of **2** was in the same concentration range. The pseudo-first-order rate constants were obtained from the early stage, since good first-order correlations were observed for that range under the present conditions. While **2** showed little catalytic effect in the degradation of substrates bearing a comparatively short alkyl chain in a manner as observed with **1**,[1,2] it showed marked rate acceleration in the reaction of carboxylic esters bearing a longer alkyl chain, such as PNPL and PNPP. The extents of rate acceleration in the ester decomposition are 1380- and 4750-fold for PNPL and PNPP, respectively, relative to their spontaneous hydrolyses as shown in Table 2.

pH-Rate profiles for the reaction between **2** and PNPL in 20.8% (v/v) aqueous ethanol and in 20.8% (v/v) ethanol-d_1–79.2% (v/v) deuterium oxide are a characteristic sigmoid type for which the acid dissociation process is responsible (Fig. 1). This feature is consistent with the presence of two forms for the present catalyst, *i.e.*, protonated (**2a**) and free amine species (**2b**), the latter being far more effective (Eq. 1). Figure 2 shows the solvent isotope effect on the specific base catalyzed hydrolysis of PNPL, plotted as log k_{hyd} *vs.* −log [H+] or −log [D+].

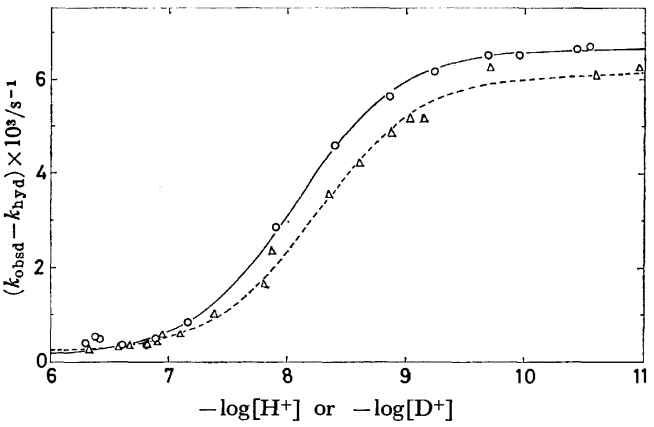

Fig. 1. pH-Rate profiles for the deacylation of PNPL as catalyzed by **2** in 20.8%(v/v) aqueous ethanol (○) and in 20.8%(v/v) ethanol-d_1–79.2%(v/v) deuterium oxide (△) at 40.0±0.1 °C and μ=0.10 (KCl) with the initial concentrations: PNPL, 1.00×10^{-5} M; **2**, 0.998×10^{-5} M. Solid lines are theoretical curves calculated by using parameters given in Table 3.

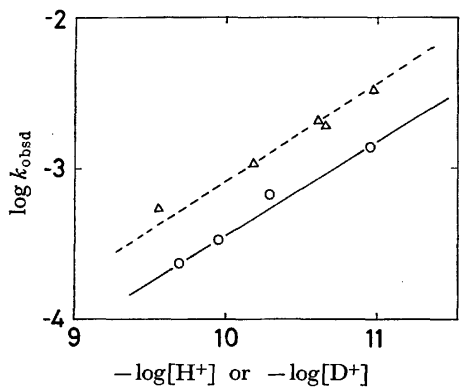

Fig. 2. pH-Rate profiles for the hydrolysis of PNPL as catalyzed by the specific base (hydroxide ion) in 20.8 %(v/v) aqueous ethanol (○) and in 20.8%(v/v) ethanol-d_1–79.2%(v/v) deuterium oxide (△) at 40.0± 0.1 °C and μ=0.10 (KCl) with the initial PNPL concentration of 1.00×10^{-5} M. The kinetic solvent isotope effect ($k^{(H)}/k^{(D)}$) is 0.47.

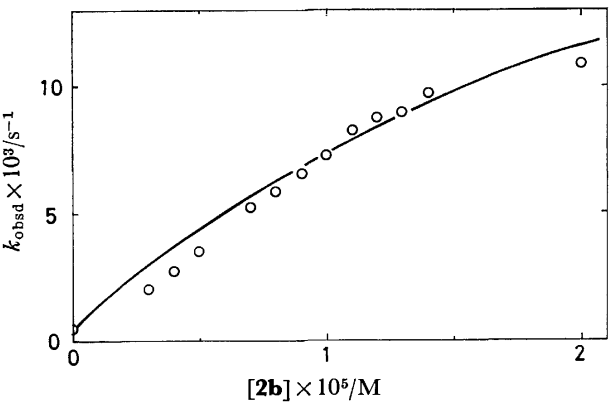

Fig. 3. Saturation-type kinetics for the reaction of PNPL with **2b** in 20.8% (v/v) aqueous ethanol at 40.0±0.1 °C, $\mu=0.10$ (KCl), and $-\log[H^+]=9.95$ with the initial substrate concentration of 1.00×10^{-5} M. Solid line is the theoretical curve calculated by using parameters listed in Table 5.

that the kinetic pK_a value decreases with the decrease in an ethanol content, even though it is little effected by a small change in the alkyl-chain length of the substrates. The equilibrium solvent isotope effect ($pK_a^{(D)}-pK_a^{(H)}$) is 0.20. The kinetic solvent isotope effects for reactions of PNPL with **2a** and **2b**, $k^{(H)}/k^{(D)}$, are 0.67 and 1.09, respectively.

The saturation-type kinetics was observed as exemplified by the correlation between concentration of aminocyclophane **2b** and rate constant for the deacylation of PNPL (Fig. 3). These results are consistent with a reaction mechanism which involves pre-equilibrium complexation of the aminoparacyclophane and the substrate at a 1 : 1 molar ratio, followed by the pseudo-intramolecular catalysis effected by the amino group of the paracyclophane.

The addition of 1-dodecanol resulted in the depression of the catalytic efficiency of **2** in the degradation of PNPL and PNPP, while the alcohol alone (10^{-4} M, 10-fold amount of the substrates) did not show any effect on the hydrolysis of both substrates.

The extent of inhibition by 1-dodecanol increased with the increase in its concentration, and both PNPL- and PNPP-systems show a similar behavior (Fig. 4). On the other hand, 2,4-dinitrofluorobenzene (DNFB) in-

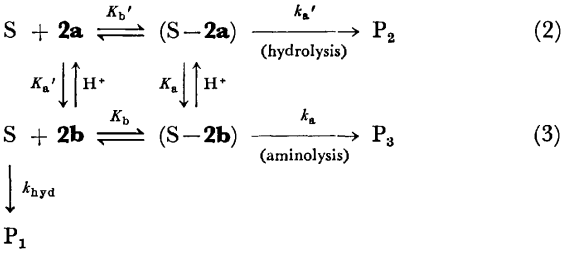
a) $[PNPL]_0=1.00\times10^{-5}$ M; solvent, 20.8%(v/v) aqueous ethanol; μ=0.10(KCl); $-\log[H^+]=9.26$; 40.0±0.1 °C.

hibited the aminoparacyclophane-catalyzed reaction in a manner different from 1-dodecanol. The pre-incubation of **2** with DNFB resulted in an appreciable reduction of the catalytic efficiency as listed in Table 4. Examination of the effects of incubation time and DNFB concentration on the reaction rate confirms that the amino group of **2** reacted quantitatively with DNFB at a 1 : 1 molar ratio in 24 h. It must be noted that the dinitrophenylated aminoparacyclophane reduced the rate of PNPL decomposition even below the catalyst absence level.

Discussion

10-Amino[20]paracyclophane is characterized by two functions: a hydrophobic binding site formed by polymethylene chains and a benzene ring, and a catalytic center provided by an amino group. In fact, dinitrophenylation of **2** with DNFB, which is the potent re-



P_1: Carboxylate and *p*-nitrophenolate ions,

P_3: *p*-nitrophenolate ion and acylated **2**.

Scheme 1.

agent to modify an essential amino group of enzymes,[10] resulted in the complete disappearance of catalytic effect. Accordingly, it is evident that the amino group placed on the paracyclophane skeleton plays an indispensable role in the catalytic degradation of the carboxylic esters. Formation of an inclusion complex between **2** and the substrate was confirmed by the inhibition experiment with 1-dodecanol. The catalytic efficiency exhibited by **2** gradually decreases with the increase in inhibitor concentration as shown in Fig. 4. Since the inhibitor and the substrate (PNPL or PNPP) bear a hydrophobic alkyl chain of similar length, they can compete with each other in occupying the hydrophobic cavity of the catalyst.

In consistent with the pH-rate correlation (Fig. 1) and the saturation-type kinetics (Fig. 3), the reaction scheme is given by Scheme 1 in a manner similar to those applied to the hydroxyiminoparacyclophane catalysis described previously.[2] This reaction scheme means that the pre-equilibrium complexation of the aminoparacyclophane with the substrate at a 1 : 1 molar ratio is followed by the pseudo-intramolecular catalysis to decompose the substrate. Reactions 2 and 3 in Scheme 1 can be treated separately by analyzing the kinetic data obtained in sufficiently lower and higher pH regions, respectively, relative to the pK_a value of the catalyst. The binding constant K_b and the rate constant for substrate decomposition k_a were computed by the nonlinear least-squares method to obtain best fit to the kinetic data (see Appendix). The rate constants of simple hydroxide-catalyzed hydrolysis (k_{hyd}) were obtained independently from kinetic runs in the absence of the catalyst (Table 5).

Nucleophilic Catalysis in the Higher pH Region.[11] In general, the free amine takes part in the decomposition of carboxylic esters in two different ways;[5] the general base catalysis to give the same product as observed in the corresponding spontaneous hydrolysis, and the direct nucleophilic attack of the amino group on the ester carbonyl to give the acylated amine. When both substrate and amine bear long hydrocarbon chains, the overall rate of ester degradation was accelerated drastically due to the mutual hydrophobic interaction which facilitate to place the amino group in a close vicinity of the ester carbonyl.[7,12] At the same time, the aminolysis becomes the major reaction among competing ones. Similar proximity effect is expected for the present paracyclophane system and the amino group attacks on the ester carbonyl as confirmed by the prod-

Table 5. Kinetic parameters for the deacylation reactions of PNPL and PNPP as catalyzed by **2b**[a]

Substrate	$-\log[H^+]$	$k_{hyd}\times10^4/s^{-1}$	$k_a\times10^2/s^{-1}$	$K_b\times10^{-3}/M^{-1}$	U[b]

PNPP	10.29	*ca.* 0.1—0.5	1.38	100	2.76×10^{-6}

a) $[PNPL]_0=1.00\times10^{-5}$ M and $[PNPP]_0=0.996\times10^{-5}$ M; solvent, 20.8% (v/v) aqueous ethanol; 40.0±0.1 °C; μ=0.10 (KCl). b) A residual sum of squares for the computational procedure, see Appendix.

uct analysis. The observed small isotope effect on the specific rate constant, $k_{(2b)}^{(H)}/k_{(2b)}^{(D)}=1.09$ for PNPL as shown in Table 3, is consistent with the direct nucleophilic attack by the amino group. For the nucleophilic displacement, the kinetic solvent isotope effect is usually very close to unity: phenyl acetate with imidazole, 1.07;[13] *p*-nitrophenyl acetate with imidazole, 1.0;[13] and *p*-nitrophenyl acetate with trimethylamine, 0.9.[14]

The ester degradation was even slower than the corresponding spontaneous hydrolysis in the presence of the dinitrophenylated aminoparacyclophane. This means that the modified paracyclophane can still incorporate the substrate and the incorporated substrate is less susceptible to the nucleophilic attack by hydroxide ion due to the steric hindrance effect exerted by the bulkyl substituent. A similar state of affairs has been noted by Bender *et al.* for the reaction between phenyl acetates and dodecamethylcyclohexaamylose.[15] Since the present and related paracyclophanes may be regarded to exist largely in a monomeric form under the kinetic conditions,[3] the inclusion complex is most plausibly formed at a 1 : 1 molar ratio as shown in Scheme 1. The cyclic skeleton of **2b** shows a profound tendency to bind the substrates in a manner similar to those observed for other [20]paracyclophanes.[1-3] Thus, there is no doubt that [20]paracyclophane skeleton provides an effective hydrophobic binding site for carboxylic esters bearing a long alkyl chain.

Another prominent feature found in the present study is that the acyl transfer rates as catalyzed by the amino group (**2b**) are comparable to those by the hydroxyimino group (**1**); $k_a=1.82\times10^{-2}$ s^{-1} at 43.1 °C and pH 10.3 for PNPL, and 4.45×10^{-2} s^{-1} at 39.9 °C and pH 10.7 for PNPP with the hydroxyimino group in 10.9% (v/v) aqueous acetone.[1] This result seems to be rather surprising since the basicity of the hydroxyimino group of **1** is greater than that of the amino group of **2b** by an order of approximately 10^4. The large basicity as well as the additional α-effect should in general enhance the nucleophilic reactivity of the hydroxyimino group relative to the amine. The complexation of **2b** with the substrate bearing a long alkyl chain may provide a profound hydrophobic reaction field for the amino group of **2b**. This field effect (microsolvent effect) as well as the proximity effect seems to enhance the nucleophilicity of the amino group in the present system.

Rate Acceleration in the Neutral pH Region. The present paracyclophane gave out an appreciable catalysis in the degradation of PNPL and PNPP in a pH region where the amino group is protonated predominantly and the spontaneous hydrolysis of the substrate esters proceeds to a negligible extent. In an alkaline region where **2b** is the dominant species, the rate plots always deviated downwards, relative to the linear first-order correlation line, because the catalytic amino group was consumed along with the progress of reaction. On the other hand, the rate plots deviated upwards in the neutral pH region in a manner as observed in the spontaneous hydrolysis of PNPP over the whole pH range. In the cases of the hydrophobic substrates, such as PNPL or PNPP, the substrate becomes progressively free from the intermolecular aggregation along with the progress of reaction because of the decrease of substrate concentration.[8] The kinetic behavior mentioned above suggests that the deaggregated substrate is more favorably incorporated into the paracyclophane. In the neutral pH region, in addition, it is clear that the catalytic group is not consumed during the course of reaction. The protonated amino group most plausibly plays a catalytic function by either of the following two mechanisms in the hydrolysis of carboxylic esters. The first one is the electrostatic catalysis effected by the positively charged ammonium group which stabilizes the anionic tetrahedral intermediate. The alkaline hydrolysis of acetylcholine proceeds 32 times as fast as that of 2-(dimethylamino)ethyl acetate.[16] This acceleration effect was attributed to the electrostatic stabilization of the anionic tetrahedral intermediate by the positively charged ammonium group of the former species. An appropriate spatial orientation of an ammonium group relative to an ester carbonyl was suggested to be responsible for the development of such electrostatic catalysis.[17] In a previous work,[3] [10-hydroxyimino[20]paracyclophan-22(23)-ylmethyl]trimethylammonium chloride was found to enhance the deacylation of PNPL and PNPP in an alkaline solution due to an electrostatic effect provided by the positively charged ammonium group. In order to examine the possibility of electrostatic catalysis by the protonated amino group of **2a**, the kinetic effect of [10-oxo[20]paracyclophan-22(23)-ylmethyl]trimethylammonium chloride (**3**) in the degradation of PNPL was investigated under the following conditions: pH 7.28; solvent, 20.8% (v/v) aqueous ethanol; temp, 40.0 °C; ionic strength, 0.10 with KCl; initial concentration of PNPL, 1.00×10^{-5} M.[9] The observed first-order rate constants (2.33×10^{-5} s^{-1} with 0.88×10^{-5} M of **3**, and 2.92×10^{-5} s^{-1} with 1.53×10^{-5} M of **3**) are much smaller than those observed in the presence of **2a**, even though they are larger than that of the spontaneous hydrolysis (*ca.* 1.3×10^{-5} s^{-1}) under the same conditions. Thus, it is concluded that contribution of electrostatic effect may be ruled out under the present experimental conditions, even if the structural difference between **2a** and **3** needs to be taken into consideration. In addition, the observed solvent isotope effect (0.67) seems

to support this view, since no isotope effect would be expected for the electrostatic catalysis which involves no proton transfer process. An alternative mechanism is the general acid catalysis[18] in which the ammonium group of **2a** attacks on the ester carbonyl as a general acid and the nucleophilic attack of a water molecule is facilitated accordingly. Even though the solvent deuterium isotope effect is usually greater than unity for this mechanism, there are other examples in which the isotope effect is smaller than unity: the dehydration step of oxime formation, 0.30;[19] the acid-catalyzed addition of thiol to aldehyde, 0.59.[20] Thus, the protonated amino group most plausibly attacks on the ester carbonyl as a general acid catalyst. This work presents undoubtedly a novel type of catalysis in any sense played by the protonated amino group placed on the hydrophobic cyclic skeleton in the hydrolysis of carboxylic esters.

In brief summary, the present aminoparacyclophane demonstrated marked catalytic effects on the deacylation of *p*-nitrophenyl carboxylates bearing a long alkyl chain not only in the free base but also in the protonated form. The nucleophilic attack of the free amino group of **2** on the ester carbonyl takes place pseudo-intramolecularly upon complexation with the substrate, which afforded the acylated aminocyclophane. On the other hand, the general acid catalysis is exercised by the protonated amino group of **2** in the deacylation of the same substrates. Even though its absolute catalytic efficiency is not so large as that of the free base group, a characteristic turnover behavior was observed.

Appendix

Determination of Kinetic Parameters for Saturation-type Kinetics. When the reaction is carried out in a sufficiently high pH region relative to the pK_a value of the catalyst, the predominant catalyst species is **2b** and Scheme 1 can be simplified to Scheme 2.

$$\mathrm{S} + \mathrm{C} \overset{K_b}{\rightleftharpoons} (\mathrm{S-C}) \overset{k_a}{\rightleftharpoons} \mathrm{P}$$
$$\Big\downarrow k_{hyd}$$
$$\mathrm{P'}$$

Scheme 2.

The kinetic parameters given in Scheme 2 are evaluated by the following computations. Abbreviations are made here for convenience.

S: a substrate species
C: a catalyst species (**2b**)
S–C: a substrate-catalyst inclusion complex
P and P′: products
K_b: a binding constant
k_a: a catalytic rate constant for the aminolysis step
k_{hyd}: a rate constant for spontaneous or simple alkaline hydrolysis
k_ϕ: an overall rate constant

Mass balances in consistent with Scheme 2 are established as follows.

$$[\mathrm{S}]_T = [\mathrm{S}] + [\mathrm{S-C}] \tag{4}$$

$$[\mathrm{C}]_T = [\mathrm{C}] + [\mathrm{S-C}] \tag{5}$$

The binding constant is given by

$$K_b = \frac{[\mathrm{S-C}]}{[\mathrm{S}][\mathrm{C}]} \tag{6}$$

Combination of Eqs. 4, 5, and 6 gives

$$[\mathrm{S-C}] = \frac{1}{2}\left[[\mathrm{S}]_T + [\mathrm{C}]_T + \frac{1}{K_b} - \left\{\left([\mathrm{S}]_T + [\mathrm{C}]_T + \frac{1}{K_b}\right)^2 - 4[\mathrm{S}]_T[\mathrm{C}]_T\right\}^{1/2}\right] \tag{7}$$

The overall rate can be expressed as follows:

$$k_\phi[\mathrm{S}]_T = k_{hyd}[\mathrm{S}] + k_a[\mathrm{S-C}] \tag{8}$$

$$k_\phi = \left(1 - \frac{[\mathrm{S-C}]}{[\mathrm{S}]_T}\right)k_{hyd} + \frac{[\mathrm{S-C}]}{[\mathrm{S}]_T}k_a \tag{9}$$

The equation derived by combination of Eqs. 7 and 9 is nonlinear with respect to parameters K_b and k_a. An iterative calculation was performed to minimize the residual sum of squares (U):

$$U = \sum_{i=1}^{n}\{k_\phi(\mathrm{obsd})_i - k_\phi(\mathrm{calcd})_i\}^2,$$

where n is the number of observations at different concentrations of the catalyst and i is the observation-number index.

All calculation processes were programmed by means of the Fortran language for use with a FACOM 270-20/30 electronic computer of the Computation Center of Nagasaki University.

A New Method for Measuring Surface Acidity. The Titration of Silica–Alumina with the Indicator Itself[1]

Jun-ichiro TAKE, Haruyuki KAWAI,[2] and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 23, 1976)

A new method has been proposed for measuring the surface acidity of solid acids. The method involves the titration of a solid acid with the indicator itself in a nonpolar solvent; it determines the number of acid sites from the amount of the indicator chemisorbed at saturation. The titration of silica-aluminas with 4-anilinoazobenzene ($pK_a=1.5$) itself yielded an acid content smaller than the butylamine titration method with the same indicator. This difference in acid content was ascribed to the difference in the base strength of the titrants. Similarly, titration with *trans*-azobenzene ($pK_a=-2.9$)itself produced an acid content smaller than that with 4-anilinoazobenzene itself.

Walling's[3] and the butylamine titration (or Benesi's)[4] methods have been employed for measuring the acidic properties of solid acid surfaces in nonpolar solvents. The former is for measuring the acid strength from the color change in indicators adsorbed on surfaces. The latter method, for measuring the acid-strength distributions, can be interpreted in the following way: it is primarily designed to determine the number of acid sites capable of chemisorbing each H_0 indicator on the basis of the amount of butylamine which must be added until the chemisorbed indicator changes in color. In our recent studies[5–7] it was pointed out that the assumption underlying the latter method is not valid from a practical point of view. This argument is based on the fact that neither the amine nor the any indicator reaches an adsorption equilibrium with the acid sites under the conventional conditions of operation.

Since butylamine is much more basic than the usual indicators, it may reasonably be inferred that the acid sites capable of chemisorbing the amine are not all capable of chemisorbing indicators, and also that the amine chemisorbed is less mobile than the chemisorbed indicators. The former inference is equivalent in essence to the generalized one that acid sites on a solid acid vary in number depending on the base strength of the base used. When no asdorption equilibrium is attained, a substantial part of the amine added may be chemisorbed on acid sites incapable of chemisorbing an indicator, and thus wasted. Consequently, the butylamine titration method may overestimate the number of acid sites.

Therefore, if solid acid surfaces are titrated with indicators themselves different in base stregth, accurate information may be obtained on acid-strength distributions from both the amount chemisorbed at saturation and the base strength of each indicator. The amount of a chemisorbed indicator at saturation will correspond to the number of acid sites capable of chemisorbing the indicator. The base strength of the indicator (*e.g.*, its pK_a value) will determine an arbitrary scale of the acid strength of the acid sites. Also this method will not require, in principle, that the adsorption be at equilibrium, if only the amount of a chemisorbed indicator itself is measurable even in the presence of the physically adsorbed indicator.

The present study was undertaken in order to see whether or not the titration of solid acid surfaces worked out in practice with an indicator itself, and also to examine whether or not the above inference was valid. This attempt was carried out with silica–alumina catalysts as solid acids, silica gel as an inert diluent of the catalysts, and 4-anilinoazobenzene or *trans*-azobenzene as an indicator.

Experimental

Materials. The original and Na-poisoned silica-alumina catalysts (SA-1, SA-1-Na-2 and -3) were described elsewhere.[8] The additional catalyst (SA-1-Na-4) was prepared by the impregnation of SA-1 with an aqueous solution of sodium hydroxide. Its surface area and Na^+- content were 452 m^2/g and 0.807 mg-ion/g respectively. The silica gel (S-3) was taken from the same batch as was used earlier.[6] The 4-anilinoazobenzene (BADA, $pK_a=1.5$) and *trans*-azobenzene (TAB, $pK_a=-2.9$) were of a GR and an EP grade respectively, and both were purified by recrystalization from ethanol. Their solutions in cyclohexane were prepared in the way described previously.[6] Thoroughly purified cyclohexane was sealed in a small Y-shaped glass ampoule under a vacuum;[6] its volume (around 3 ml) was determined from the difference in the weight of the ampoule before and after sealing. Gaseous nitrogen from a cylinder was also purified.[6]

Apparatus. The specially designed UV-cell, which provides two light-paths rectangular to each other, was shown in a previous paper.[6] A single wafer was used in each of the present runs, so that concurrent spectral measurements were possible of both the wafer and the liquid phase. The spectra were recorded on a Shimadzu multipurpose recording spectrophotometer, Model MSP-50L, at room temperature. The control was atmospheric air.

Procedures. Most of the procedures have been described in detail earlier.[6] In most experiments, the powdered catalysts were diluted with inert S-3 powder (for a reason to be stated later) by mixing them well for 2—5 min in a mixing grinder; they were then pressed into self-supporting wafers.

A wafer was activated in the cell at 450 °C and at pressures of 10^{-4} to 10^{-5} mmHg for 2 h after pretreatment in air at 550 °C for 5 h. After the introduction of the sealed cyclohexane, the background spectra were recorded of both the liquid phase and the wafer, plus the liquid phase. The background spectra of the wafer itself were obtained as a difference between the two spectra. A known, small amount of each indicator solution (around 0.3 or 0.5 ml) was added to the cell, and then the cell was allowed to stand at 60 °C for at least 4 days before spectral measurements. This addition was repeated until the amount of a chemisorbed indicator became virtually constant. A previous study[6] showed that the BADA adsorbed on non-acidic sites transmigrated

effectively onto acid sites when it was allowed to stand as above. In the present titration, therefore, the added indicator can be regarded as being approximately in an adsorption equilibrium.

Results

Spectra of BADA and Molar Absorption Coefficients. BADA shows a band at 386 nm in cyclohexane, at 440 nm on S-3, and at 545 nm on SA-1. The bands at 440 and 545 nm are ascribable to species hydrogen-bonded to non-acidic sites and chemisorbed on acid sites respectively.[6] The molar absorption coefficients were determined for each species from the Beer plots. They are listed in Table 1. The values for adsorbed species were obtained with undiluted wafers (*ca.* 25 mg). For each species, an excellent linearity was confirmed up to an absorbance of at least 2 at an absorption maximum. This critical absorbance corresponded to surface concentrations of around 3.5×10^{-3} and of around 7×10^{-3} mmol/g for chemisorbed and hydrogen-bonded BADA respectively.

Table 1. Molar absorption coefficients of BADA

System	Molar absorption coefficient	
	Symbol	$\varepsilon\times10^{-4}$
In cyclohexane	$\varepsilon_{l,386}$	2.78
On S-3	$\varepsilon_{p,440}$	2.00
	$\varepsilon_{p,545}$	0.07
On SA-1 or	$\varepsilon_{c,545}$	3.72
SA-1-Na-4	$\varepsilon_{c,440}$	0.29

With S-3 wafers, the BADA remained in part unadsorbed in the liquid phase, even on the first addition (about 3×10^{-5} mmol). Also, no spectral evidence was found to indicate the presence of chemisorbed BADA, not even at the above critical surface concentration. The adsorption isotherm of hydrogen-bonded BADA followed the Freundlich equation well. With undiluted SA-1 wafers, the spectra showed not only the presence of chemisorbed BADA alone on the surface, but the absence of BADA in the liquid phase, even at a surface concentration of about 8×10^{-3} mmol/g, indicating that the chemisorption was far from saturation even at this surface concentration. The same things were noted with undiluted SA-1-Na-4 wafers. Therefore, it was necessary for the titration of the catalysts with BADA itself to reduce greatly the amount of acid sites in a wafer. For this purpose, it seemed advisable to dilute the catalysts with inert S-3. This is the reason for the use of a diluted wafer.

Evaluation of the Amount of Chemisorbed BADA. The spectra of diluted wafers showed the coexistence of both chemisorbed and hydrogen-bonded BADA, even on the first addition of $3—5\times10^{-5}$ mmol. When the addition was repeated, the BADA increased gradually in both the liquid-phase and surface concentrations. Hence, the material balance is given by the following equations:

$$m_0 = m_a + m_l, \tag{1}$$

$$m_a = m_p + m_c, \tag{2}$$

where m is the amount of BADA; the 0, a, l, p, and c subscripts denote the BADA added, adsorbed, remaining in the liquid phase, hydrogen-bonded, and chemisorbed respectively. The m_l quantity is readily determinable from the data on both the liquid-phase concentration of BADA and the cumulative volume of cyclohexane added; hence, the m_a can be determined from Eq. 1. The absorbances at the absorption maxima of both adsorbed species (A_{λ_m}) are given by Eqs. 3 and 4:

$$A_{545} = \frac{1}{S}(\varepsilon_{c,545}m_c + \varepsilon_{p,545}m_p), \tag{3}$$

$$A_{440} = \frac{1}{S}(\varepsilon_{c,440}m_c + \varepsilon_{p,440}m_p), \tag{4}$$

where S is the cross section of a wafer; ε, the molar absorption coefficient, and m, in mmol.[6]

It is well known that molar absorption coefficients often vary at high concentrations.[9] When diluted wafers were titrated, the chemisorbed BADA increased in the net surface concentration by a factor of 10 to 50 over the critical concentration below which the Beer law was valid. On the other hand, the concentration of hydrogen-bonded BADA was never beyond the range of the validity of the Beer law. Then, it does not seem to be reasonable to evaluate the amount of chemisorbed BADA directly from Eqs. 3 and 4 with the ε_c and ε_p values given in Table 1. With the assumption that the ratio of $\varepsilon_{c,440}$ to $\varepsilon_{c,545}$ is constant over an extended range of surface concentrations (Eq. 5), Eq. 6 is derived from Eqs. 2, 3, and 4:

$$\frac{\varepsilon_{c,440}}{\varepsilon_{c,545}} = \alpha \text{ (constant value)}, \tag{5}$$

$$m_c = m_a - m_p = m_a - \frac{S(A_{440}-\alpha A_{545})}{\varepsilon_{p,440}-\alpha\varepsilon_{p,545}}. \tag{6}$$

This assumption seems to be reasonable and much more practical than the assumption of the Beer law over an extended range of surface concentrations. For BADA, the value of α was as low as 0.078. Also, the second term ($\alpha\varepsilon_{p,545}$) in the denominator of Eq. 6 was neglected because of its negligibly small value. Thus, the amount of chemisorbed BADA was determined according to Eq. 6.

Adsorption Isotherms of Chemisorbed BADA. The adsorption isotherms were obtained by plotting the amount chemisorbed on a catalyst of a unit weight, M_c (mmol/g), against the liquid-phase concentration, as is exemplified in Fig. 1. Each isotherm conformed well to the Langmuir equation, as is illustrated in Figs. 1 and 2. The solid lines in Fig. 1 denote isotherms derived from the Langmuir equation. Figure 2 shows the Langmuir plots of the isotherm data given in Fig. 1. The isotherm data at zero concentration were excluded from the Langmuir plots because the lower limit for the detectable liquid-phase concentration was about 3×10^{-4} mmol/l. The amount of chemisorbed BADA at saturation (*i.e.*, the number of acid sites capable of chemisorbing BADA) was determined from the Langmuir plots in the usual way. The results are listed in Table 2. Acid contents determined by other methods were also collected in this table for comparison.

with TAB, less basic than BADA, was preliminarily examined. Table 3 summarizes the absorption spectra of TAB, together with the relevant molar absorption coefficients determined from the Beer plots. An inspection of this table leads to the conclusion that the strong bands at 435 nm on SA-1 and at 318 nm on S-3 are due to TAB chemisorbed on acid sites and adsorbed in the neutral (probably, hydrogen-bonded) form on non-acidic sites respectively. The amount of chemisorbed TAB was determined according to the equation corresponding to Eq. 6. For TAB, α was 0.21 and the second term ($\alpha\varepsilon_{p,435}$) in the denominator was again neglected.

a) nm; (vs), very strong; (s), strong; (vw), very weak; (b), broad.

When a diluted SA-1 wafers was titrated, even the first addition of TAB (about 5 mmol) effected the saturation of the chemisorption, as evidenced by the fact that repeated additions brought about no increase in the amount of chemisorbed TAB. The amount of chemisorbed TAB in each addition was, therefore, taken as the amount of acid sites for TAB. The value listed in Table 2 is the one averaged over four additions.

The adsorption isotherm of chemisorbed TAB was determined with an undiluted SA-1 wafer (Fig. 3). In this titration, TAB was detected in the liquid phase, even at a low surface concentration. In addition, no spectral evidence was observed to show the presence of hydrogen-bonded TAB at any stage of the titration. Figure 3 also shows that the isotherm fits the Langmuir equation. The acid content evaluated from the Langmuir plot is also listed in Table 2.

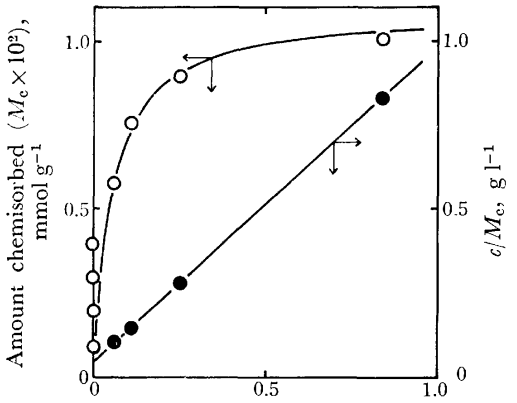

Fig. 3. Adsorption isotherm (○) and Langmuir's plot (●) for TAB chemisorption on SA-1.

Discussion

Table 2 indicates that there are fewer acid sites on SA-1 when TAB is used than when BADA is used, as was expected. This difference can be explained in terms of the difference in the base strength of the two indicators, since TAB is smaller in molecular size than BADA. A similar phenomenon was observed with S-3. Silica gel S-3 behaved as a non-acid to BADA. but as an acid to 4-(1-naphthylamino)azobenzene (pK_a=4.0), which is more basic than BADA. This is also very similar to the well-known fact that even alcohols such as 1-butanol behave as acids toward potasium hydroxide, yielding alkoxide anions. Thus, the present observations substantiate the inference that acid sites on a solid acid vary in number depending on the base strength of the base used.

Also, Table 2 points out that the present titration with BADA itself gives an acid content smaller than the butylamine titration method with BADA for every catalyst used. Two explanations may be offered for this difference. The first is that the observed difference results from the difference in molecular size between BADA and butylamine as titrants. If the acid sites were present mainly in small surface pores which are accessible to butylamine molecules, but inaccessible to BADA molecules larger than the amine, or if such pores were predominant in the surfaces, titration with BADA itself would yield an acid content smaller than the butylamine titration method with BADA. The second is in terms of the difference in the base strengths of the two titrants, as has been described in the Introduction.

The acid-content data shown in the last column of Table 2 give a clue for determining which explanation is valid. These values (for Lewis plus Brønsted acid sites) were determined from the integrated IR absorption intensities for the Lewis-bound pyridine (1455 cm^{-1}) and Brønsted-bound pyridine (1540 cm^{-1}) bands,[10] using the apparent integrated molar absorption coefficients reported by Hughes and White.[11] The IR spectra were recorded after a catalyst wafer had been exposed to pyridine vapor and then evacuated at 150 °C for 1 h.[10] When an undiluted SA-1 wafer was pretreated with pyridine in the same way as above, its UV spectra revealed that such a wafer was capable of chemisorbing only a small amount of BADA. This fact implies that the prechemisorbed pyridine has occupied almost all the acid sites capable of chemisorbing BADA. It should be noted here that pyridine is substantially the same in molecular size as butylamine. According to the first explanation, therefore, the IR-pyridine method would produce an acid content larger than the present titration method. On the other hand, according to the second explanation, almost the same acid contents will be obtained by both methods. Table 2 shows clearly that the two methods yielded almost the same acid content for each catalyst except for SA-1-Na-3. This fact proves the second explanation and, hence, our inference to be valid, although the cause of the exceptional value for SA-1-Na-3 is not clear at present.

Tiration with TAB produced the same acid content for both diluted and undiluted SA-1 wafers, as is shown in Table 2. In the case of the former wafer, its acid content was obtained without the determination of the adsorption isotherms, as has been described above. These facts imply that the present titration method does not necessarily require the time-consuming determination of adsorption isotherms.

The authors are grateful to Mr. Akira Watanabe for his help in part of the measurements, and to Dr. Yasukazu Saito for his valuable discussion.

Emission Spectra of Phenol, Anisole, and Phenetole by Controlled Electron Impact

Masaharu Tsuji,* Teiichiro Ogawa, Yukio Nishimura,* and Nobuhiko Ishibashi

Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received November 2, 1976)

Upon the impact of an electron beam (100—450 eV) on PhOH, $PhOCH_3$, $PhOC_2H_5$, $PhCOCH_3$, and $(Ph)_2CO$ at low pressures, the S_1 emission of the parent molecule (not from $PhCOCH_3$ and $(Ph)_2CO$) and the photoemissions from such fragments as H, CH, CO, CO^+, and OH were observed in the 200—520 nm region. It was concluded that the S_1 emission of the parent molecule originates through both the $S_0 \rightarrow S_1$ and $S_0 \rightarrow S_2$ (cascade) $\rightarrow S_1$ excitation processes and that the direct excitation into the lower vibronic levels of S_1 is responsible for the appearance of the vibrational structures. Most excited species including $CO^+(A)$ from PhOH were confirmed to be primarily produced; however, $CO^+(A)$ from $PhOCH_3$, $PhOC_2H_5$, and $PhCOCH_3$, and CO(b) from $PhCOCH_3$ were found to be produced competitively through one-electron and two-electron excitation processes in relation to the intensity measurements. The relative contribution of the two-electron excitation process in producing $CO^+(A)$ increased with a larger substituent, and it was larger than that for CO(b) in $PhCOCH_3$.

The spectroscopic analysis of the optical emission resulting from the collision of an electron with molecules at a low pressure provides direct information about the energy states not only of ionic products, which have been well investigated by mass spectrometry, but also of radical and neutral ones. In the previous papers,[1-7] we have reported the emission spectra of various aromatic molecules in the ultraviolet and visible regions as studied by means of the crossed electron-beam and molecular-jet method. Many aromatic molecules showed the characteristic S_1 emission of the parent molecule, and in the case of naphthalene[5] the cascading processes from S_2 and S_3 to S_1 were concluded to be mainly responsible for the S_1 emission. Photoemissions from several excited fragments were also observed; most of them were confirmed to be primarily produced in relation to their intensity measurements. The formation of $CO^+(A)$ from three isomers of dimethoxybenzenes[6] was an exceptional case, which involves a secondary reaction, and the results were interpreted in terms of the competition between the one-electron and the two-electron excitation processes. However, no studies have been carried out on the emission spectra and the mechanism of the dissociative excitation of monosubstituted benzene with an oxygen atom, except for our previous communications on anisole[1] and nitrobenzene.[4] In this paper, we will describe the emission spectra of phenol, anisole, phenetole, acetophenone, and benzophenone under a controlled electron-impact excitation (100—450 eV) and will discuss the mechanism of the S_1 emission of the parent molecule and that of the formation of the excited species.

Experimental

The apparatus and the experimental conditions were essentially identical with those described previously.[3] The electron-beam current in the collision chamber ranged between 10 and 3000 μA for electron energies from 100 to 450 eV. The pressure of the sample gases in the collision chamber, which was proportional to that in the gas reservoir, was estimated to be of the order of 10^{-3} Torr.

The photoemission in the 200—520 nm region was detected by the use of a JASCO CT-50 scanning spectrometer in the first order of a 1200 grooves/mm grating blazed at 300 nm. The spectra were recorded at a resolution of about 4 Å (FWHM). An EMI 9558QB photomultiplier and a Burr-Brown 3421K OP amplifier were used for recording the spectra. The current and pressure dependences of the emission intensities were measured with the aid of a HTV R585 photomultiplier, and the output pulses from the photomultiplier were amplified and counted by means of an NF-PC 545A photon counter. The absence of changes in the observed spectra when a suppressor electrode was put just above the electron target or when an aluminum target was replaced by a golden one reinforced the conclusion that the excitation by secondary electrons ejected from the target was negligible.

The reagents were obtained either from the Wako Pure Chemical Co. or from Kishida Chemical Ind. They were subjected to several freeze-pump-thaw cycles to remove dissolved atmospheric gases.

Results

A typical emission spectrum of phenol excited by an electron beam of 300 eV at 2 mA is shown in Fig. 1. The continuous features with discrete structures in the 275—340 nm region were assigned to the $S_1(^1B_1) \rightarrow S_0$ $(^1A_1)$ transition of the parent molecule. No appreciable alteration in the shape or position of the S_1 emission was found by changing the excitation energies between 100 and 450 eV. Prakash[8] measured photographically the fluorescence spectrum of phenol at the vapor phase excited by the radiation from a condensed iron spark and analyzed the observed S_1 emission in the 275—303 nm region. He found the 0-0 band at 2751 Å; this band was very weak because of the self-absorption by the unexcited molecules. In the present spectrum, taken under a very low pressure, where such a self-absorption effect and collisional deactivation within the lifetime of the excited species are expected to be negligible, the 0-0 band appears intensively at the shortest wavelength. Although our spectrum is less resolved, several features at the shorter wavelengths can be interpreted as an overlapping of some fluorescence bands given by Prakash.

Since energetic electrons bring about not only the excitation but also the dissociation of target molecules, photoemissions from the excited fragments can be ob-

served. The Balmer series of the hydrogen atom ($H_{\beta-\eta}$) and the two systems of CH, the 4300 Å system ($A^2\Delta$-$X^2\Pi$) and the 3900 Å system ($B^2\Sigma^-$-$X^2\Pi$), were identified in the 384—486 nm region. The features around 306 nm and the bands at 283, 298, 313, and 331 nm, superimposed upon the intense S_1 emission of the parent molecule, were assigned to the 3064 Å system of OH ($A^2\Sigma^+$-$X^2\Pi$) and the third positive system of CO ($b^3\Sigma^+$-$a^3\Pi$). The bands at 451, 484, and 520 nm were assigned to the Ångström system of CO ($B^1\Sigma^+$-$A^1\Pi$). The numerous other bands were ascribed to the comet tail system ($A^2\Pi$-$X^2\Sigma^+$) and the first negative system ($B^2\Sigma^+$-$X^2\Sigma^+$) of CO^+.

Figures 2 and 3 show the emission spectra of anisole and phenetole excited by an electron beam of 300 eV at 1 mA. The S_1 emission of the parent molecule, the shape and position of which were independent of the excitation energy (100—450 eV), can be observed at the identical wavelength region in the case of phenol, and the 0-0 band is found at 275 nm in both spectra. Their vibrational structures are very similar to those of phenol, although the fraction of the unresolved continuum becomes larger with an enlargement of the substituent. Several features of anisole at the shorter wavelengths can be interpreted as an overlapping of some fluorescence bands measured and assigned by Prakash and Singh in the vapor phase.[9] The S_1 emission of phenol, anisole, and phenetole are more diffuse than the spectrum of benzene,[3] while they are sharper than the spectrum of naphthalene.[5] Photoemissions from

the same atomic and diatomic fragments can be identified in both spectra.

The striking optical features of benzene monoderivatives with a carbonyl group are the appearance of strong phosphorescence instead of fluorescence in the solution and in the low-temperature matrix.[10] In the electron-impact excitation of acetophenone and benzophenone at low pressures, no photoemission from the excited parent molecule could be observed, just as in the case of the optical excitation; all the observed bands were attributed to the photoemissions from the excited fragment species: H, CH, CO, and CO^+. Both spectra were similar to the emission spectrum of nitrobenzene,[4] except for the absence of the band systems of NO and CN.

The current and pressure dependences of the photoemission intensities of the parent molecule and the fragment species were measured in order to elucidate the reaction mechanism. Figure 4 shows such intensity measurements on anisole. The band intensities of the parent molecule, H, and CH are proportional both to the electron-beam current and to the gas pressure, just as in the cases of other aromatic molecules.[2-7] However, the band intensity of CO^+(A) varies non-linearly with the electron-beam current, although it is proportional to the gas pressure. The pressure dependence of the intensity of CO^+(A) from CO[11] and CH_3OH[7] has been found to be linear at a low pressure, and a similar linear relationship has been presumed on $PhNO_2$[4] and $Ph(OCH_3)_2$.[6] The present observation of the linearity in anisole indicates the validity of the previous assumption.

The photoemission intensities of the parent molecule, H, and CH produced from phenol, phenetole, and acetophenone, and that of OH from phenol were also proportional to the electron-beam current. However, their pressure dependence could not be measured in the present study because of the low vapor pressures of these compounds. Figure 5 shows the dependence

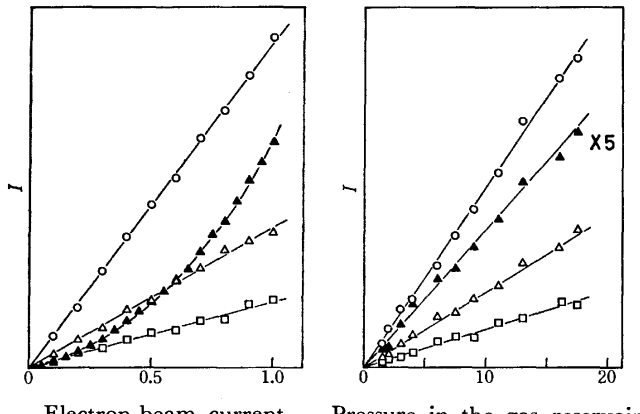

Fig. 4. Dependence of band intensities (I, arbitrary units) from anisole on the electron-beam current (mA) and on the pressure in the gas reservoir (mmHg). Electron energy 300 eV, electron-beam current in the measurement of the pressure dependence 50 μA.

of the photoemission intensity of CO^+(A) from phenol and phenetole, and that of CO(b) and CO^+(A) from acetophenone, where the intensities in the right figure are normalized at the value of 1 mA. A significant deviation from the linearity is observed in the intensity of CO^+(A) from phenetole, and that of CO(b) and CO^+(A) from acetophenone, while a linear relationship is established in the intensity of CO^+(A) from phenol.

The non-linearity of the photoemission intensity (I) may be interpreted by considering the quadratic term with respect to the electron-beam current [e]:

$$I = K_1[e] + K_2[e]^2, \quad (1)$$

where K_1 and K_2 are constant. It is convenient to divide this equation by the electron-beam current and to plot $I/[e]$ as a function of [e]:

$$I/[e] = K_1 + K_2[e]. \quad (2)$$

The current dependence of the emission intensities of CO^+(A) and CO(b) described in this form is given in Figs. 6 and 7. The reasonable fit to a straight line in all cases indicates the validity of this equation. The measurement of the intensity of CO(b) from the other

compounds was difficult because of the weak intensity and the band overlapping with the intense S_1 emission of the parent molecule.

Discussion

The Emission of the Parent Molecule. There is a significant difference in the excitation into the neutral states between the photon and the electron. The former pumps molecules resonantly into one or a few specific vibronic levels; on the other hand, the latter excites them simultaneously into all the vibronic levels below the electron energy. Therefore, phenol, anisole, and phenetole are expected to be primarily excited into any of the S_1, S_2, and higher singlet states under the impact of fast electrons. However, photoemission can be observed almost exclusively from the S_1 state; this indicates that the radiationless transition occurs with a high efficiency at higher excited singlet states under a very low pressure.

The probability of excitation by fast electrons into an upper state, s, with an energy, E_s, is known to be proportional to $M_s^2=f_sR/E_s$ in the case of an optically allowed transition according to the Bethe theory,[12-14] where f stands for the optical oscillator strength, which can be obtained from the energy-loss (absorption) spectrum, and where R is the Rydberg constant. The efficiency of the radiative transition from an excited state is given by the fluorescence quantum yield Φ, which can be measured in an optical excitation. Hence, the relative contribution of the S_1 emission from the various primary excitation processes can be estimated by the product, $\Phi_s(S_1)M_s^2$. Although the energy-loss spectra of phenol, anisole, and phenetole have not been reported, it is justifiable to use the oscillator strengths obtained by the ultraviolet absorption spectra, because the oscillator strengths obtained through the two methods agreed well with each other.[15] Kimura and Nagakura[16] measured the f values of these molecules in the vapor phase and found them to be 0.020—0.028 for $S_0\rightarrow S_1$ (E_1=4.59 eV), 0.132—0.188 for $S_0\rightarrow S_2$ (E_2=5.75—5.82 eV), and 0.529—0.636 for $S_0\rightarrow S_3$ (E_3=6.60—6.70 eV). These values show that the $S_0\rightarrow S_2$ and $S_0\rightarrow S_3$ excitation is 5—6 and 13—22 times stronger than the $S_0\rightarrow S_1$ excitation. The quantum yield of the S_1 emission as a function of the excitation energy has, to our knowledge, been measured only on phenol in dilute solutions in the 280—200 nm region;[17] the quantum yield in a nonpolar solvent is almost constant within the first absorption band ($\Phi_1(S_1)=7.5\times10^{-2}$) and within the second one ($\Phi_2(S_1)=3.0\times10^{-2}$). The non-zero value of the quantum yield in the S_2 region shows the existence of some contribution of the S_1 emission, followed by a fast internal conversion from S_2 to S_1. Assuming that the value of the quantum yield in a dilute solution can be carried over to that in the low-pressure vapor, the relative contribution of the S_1 emission from the two excited states is obtained as follows: $\Phi_1(S_1)M_1^2$: $\Phi_2(S_1)M_2^2$ $=1.0:2.1$. This result indicates that the contribution of the S_1 emission through the $S_0\rightarrow S_2$ excitation, followed by the fast internal conversion from S_2 to S_1, is larger than that through the direct $S_0\rightarrow S_1$ excitation. The routes of the S_1 emission of anisole and phenetole are probably similar to that of phenol.

From the investigations of the resonance fluorescence of aromatic molecules, the S_1 emission has been established to become increasingly diffuse as the molecules are excited into the higher vibronic levels.[18] For instance, no vibrational fine structure could be observed when toluene was excited into the higher vibronic levels at 1189 cm^{-1} above the 0-0 level of the $S_0\rightarrow S_1$ transition.[19] The present S_1 emissions of phenol, anisole, and phenetole exhibit some vibrational structures on a broad continuum, and it is reasonable to consider that the vibrational structure and the continuum come from different origins; the direct excitation into the lower vibrational levels of the S_1 state is responsible for the vibrational structure and the excitation into the higher levels for the continuum photoemission. The density of the vibrational levels increases with a larger substituent; therefore, the fraction of the broad continuum increases in the order of phenol, anisole, and phenetole.

It has been found that the predominant process of the S_1 emission of benzene[20-22] contrasts with that of naphthalene.[5,23] The former emission exhibits a sharp vibrational structure[3] and arises mostly from the lower vibrational levels of the S_1 state. The latter emission is very broad, shifts to the red in comparison with the resonance fluorescence obtained at low excitation energies, and occurs mostly from the highly excited vibrational levels of the S_1 state populated through rapid internal conversion from the primarily excited S_2 and S_3 states. In the present study, it was concluded that the S_1 emission of phenol originates through both the $S_0\rightarrow S_1$ and $S_0\rightarrow S_2$ (cascade)$\rightarrow S_1$ excitation processes; probably this is the case for anisole and phenetole also.

The S_1 emission could not be observed from acetophenone and benzophenone. In these carbonyl compounds, the lowest excited singlet state is of the n,π^* type, and a rapid intersystem crossing to the triplet state occurs. The quantum yields of the intersystem crossing in these molecules have been reported to be unity in benzene at room temperature.[24]

The Kinetic Study of the Reaction. In the crossed electron-beam and molecular-jet method, most emitting excited species produced from aromatic molecules have been confirmed to be primary products in terms of the

current and pressure dependences of the emission intensity.[2-7] In the present study, the intensities of the parent molecule, H, and CH from phenol, anisole, phenetole, and acetophenone have been found to be proportional to the electron-beam current. Their intensities from anisole were also found to be proportional to the gas pressure, and similar linear relationships can be expected to hold for the other molecules, because their pressures in the reaction chamber were still lower than that in the case of anisole. Therefore, it can be concluded that the formation of excited parent molecule, H, and CH from such compounds proceeds through a primary collision of an electron with a molecule.

It has been found that the current dependence of the band intensity of $CO^+(A)$ from small molecules, such as CO[6] and CH_3OH,[7] differs from that from larger aromatic molecules, such as $PhNO_2$[4] and $Ph(OCH_3)_2$;[6] the former was linearly proportional, while the latter was non-linear. The linear relationship of the band intensities of $CO^+(A)$ and OH from phenol shows that these fragments are also primary products. However, since the intensities of $CO^+(A)$ from anisole, phenetole, and acetophenone, and CO(b) from acetophenone are represented by Eq. 1, a secondary collision with another electron participates in the formation of such excited fragments.

Several similar relationships have been pointed out, and the excited species which show non-linear relationships have been classified in the following two groups:[6] (a) fragments which are produced through the scission of two skeletal bonds—*e.g.*, CN(anilines[4]) and CO^+ (dimethoxybenzenes[6]) and (b) a new chemical bond is created on its formation—*e.g.*, HCl^+(chlorobenzene[7]) and HBr^+(bromobenzene[7]). The formation of CO^+ (A) from anisole and phenetole can be classified in Group (a). It should be noticed that aromatic molecules with a large substituent containing an oxygen atom give fragments abundantly produced in the non-linear process.

For the interpretation of the empirical Eq. 1, the following reaction scheme is assumed:

$$\mathrm{M} + \mathrm{e} \xrightarrow{k_1} \mathrm{CO}^{+}{}^{*}, \quad \mathrm{M} + \mathrm{e} \xrightarrow{k_2} \mathrm{X}$$

$$\mathrm{X} + \mathrm{e} \xrightarrow{k_3} \mathrm{CO}^{+}{}^{*}, \quad \mathrm{X} + \mathrm{e} \xrightarrow{k_4} \mathrm{Y}$$

$$\mathrm{X} \xrightarrow{k_5} \mathrm{Z}$$

$$\mathrm{CO}^{+}{}^{*} \xrightarrow{k_6} \mathrm{CO}^{+}(\mathrm{X}) + h\nu,$$

where M and CO^+* denote a target molecule and the $A^2\Pi$ state of CO^+. X, which stands for some unidentified neutral or ionic intermediates, disappears upon another collision with an electron, producing CO^+* or other products (Y). It is also removed from the reaction zone mainly by the evacuation process, where the removed species are represented as Z.[25] The radiative lifetime of CO^+*, reported as 2.1—3.8 μs,[26] is short enough to emit radiation within the observation region. A similar reaction scheme is applicable to the formation of CO(b) from acetophenone. The observed emission intensity is proportional to $k_6[CO^+*]$:

$$I = ak_6[CO^+*], \tag{3}$$

where a is a proportionality constant. The rates of the formation of CO^+* and X are represented as follows:

$$d[CO^+*]/dt = k_1[M][e] + k_3[X][e] - k_6[CO^+*], \tag{4}$$

$$d[X]/dt = k_2[M][e] - k_3[X][e] - k_4[X][e] - k_5[X]. \tag{5}$$

Since the photoemission was observed in a flowing system at the stationary state, the steady-state conditions hold; therefore, the following equations can be derived:

$$[X] = k_2[M][e]/\{(k_3+k_4)[e]+k_5\}, \tag{6}$$

$$I = ak_1[M][e] + ak_2k_3[M][e]^2/\{(k_3+k_4)[e]+k_5\}. \tag{7}$$

If $(k_3+k_4)[e] \ll k_5$, an equation identical with the one obtained empirically, Eq. 1, is derived by substituting $ak_1[M]/k_5=K_1$ and $ak_2k_3[M]/k_5=K_2$. Therefore, we can conclude that $CO^+(A)$ and CO(b) are produced competitively through one-electron and two-electron excitation processes where most of the X is removed by the evacuation process. The relative contribution of the two-electron excitation process to the one-electron excitation process, K_2/K_1, was evaluated, by means of the slope and the intercept of the straight line, as 1.0: 2.0 : 5.2 : 0.39 for $CO^+(A)$ from anisole, acetophenone, and phenetole, and for CO(b) from acetophenone, respectively. The relative contribution of the two-electron excitation process in the formation of $CO^+(A)$ from dimethoxybenzenes has been attributed to the difference in the intra-molecular interaction of two adjacent groups.[6] In the present study, an increase in the mass of the substituent, taking phenol as a limiting case, enhances the relative rate (K_2/K_1) of the two-electron excitation process. In the competitive formation of $CO^+(A)$ and CO(b) from acetophenone, the relative rate of the two-electron excitation process for producing $CO^+(A)$ is about 5 times faster than that for producing CO(b).

The authors wish to thank Professor Fumiyuki Nakashio and Dr. Minoru Toyoda for their discussions. They are also indebed to Professor Tomoo Oyama for the use of his CT-50 monochromator.

The Formation of $VOSO_4$ on the Surface of V_2O_5 in the Oxidation of SO_2 as Studied by ESR

Yoshiya KERA and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 27, 1976)

To obtain information on the arrangements of the $VOSO_4$ phase in the surface layer of the V_2O_5 single crystal, the angular dependencies of an asymmetric ESR spectrum which has been found in the crystal under the conditions of SO_2 oxidation and assigned to the $VOSO_4$ phase were examined in detail. Two types of the angular dependency of the spectrum on the static magnetic field were clearly differentiated from each other. In the main spectrum, the direction of $g_{//}$ was completely consistent with the b-axis of the V_2O_5 crystal, while, on the other hand, in the minor spectrum, it took rather random orientations. From comparisons of the crystal structures between V_2O_5 and $VOSO_4$, it was deduced, preliminarily, that the α-$VOSO_4$ phase with a layer structure, was regularly aligned along the layer of the V_2O_5 lattice and that the β-$VOSO_4$ phase without a layer structure took a relatively random orientation to the lattice.

Vanadium oxides, which were promoted with alkali metals and/or supported on silica and alumina gels, have been used as catalysts in the production of sulfuric acid and organic acids. Numerous investigators have attempted to make clear their catalytic properties and reaction mechanisms, especially in SO_2 oxidation.[1] Their results, however, seem to conflict with each other. This is because of some changes in the surface states to which catalysts are subjected in preparation[2] and working.[3] On the other hand, a simple and reversible change in the ESR spectrum was found in the highly purified V_2O_5 single crystal under the conditions of SO_2 oxidation. It was previously reported that, at lower temperatures, the $VOSO_4$ phase existed stably, while at higher temperatures oxygen vacancies remained in the surface layer under the conditions of SO_2 oxidation.[4]

In the present study, in order to obtain information on the structure of the $VOSO_4$ formed in the surface layer of the V_2O_5 crystalline lattice, the angular dependencies of the asymmetric ESR spectrum on the static magnetic field were examined in detail. The growth of $VOSO_4$ in the surface layer of V_2O_5 crystal will be preliminarily discussed.

Experimental

Preparation and Treatment of V_2O_5 Single Crystal. The V_2O_5 powder which was used as the starting material was obtained by the thermal decomposition of NH_4VO_3 (special grade, Wako Pure Chem. Co.) at 600 °C for 3 h in an air stream. The purification of the V_2O_5 powder was carried out chemically according to the procedures reported by McCarley *et al.*[5] The V_2O_5 single crystal was prepared by a zone-melting method in a Pt boat. The crystal was cut out in a size (mm^3) of about $1.4\times0.5\times9$ (wt 0.021 g) and was placed in a quartz tube (4 mm in outer diameter) for the reaction and for ESR measurement. The sample was preliminarily heated at about 500 °C for 1 h under evacuation. After the sample had then cooled to room temperature, a gaseous mixture (SO_2 : air = 37 : 20) of 500 mmHg* was introduced and the tube was sealed. The inner volume of the sealed tube was 6 cm^3. The reaction temperature was kept at 617 °C (±1 °C). At time, the reaction tube was taken out from the furnace, and the intensities and line shapes of the ESR spectrum were checked.

* 1 mmHg = 1.333×10^2 Pa.

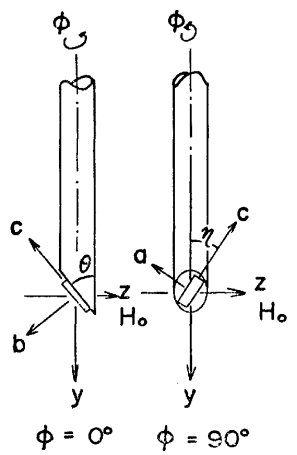

Fig. 1. Rotating operations and relations among crystal axes, experimental coordinates and H_0.

After treatment for 312 h, the crystal was taken out from the reaction tube and was cut out again in a size (mm^3) of about $1.4\times0.3\times4$, in order to measure the angular dependencies of the ESR spectrum.

Rotation Apparatus and Crystal Settings. A quartz rod, the end of which was cut out at a given angle (the angle is denoted as θ) to the rod axis, was mounted on a rotating divice around the vertical axis (the angle of the rotation is denoted as ϕ). In this experiment, six quartz rods, the θ values of which equal 0, 30, 45, 60, and 90° respectively, were used. The accuracy in θ was about 1°. The crystal was placed on the cut plane of the rod at a given angle between the long axis of the elliptical-cut plane of the rod and the c-axis of the crystal (the angle is denoted in η). The relations among the crystal axes and the laboratory coordinates are illustrated in Fig. 1. The three ways of rotation were chosen as follows:

θ: rotation angle around the x-axis (experimental coord.) at $\phi=0°$

ϕ: rotation angle around the y-axis (experimental coord.)

η: rotation angle around the b-axis (crystal axis).

η was determined by use of a micrometerscope (10X) with a graduator; the accuracy was about 1°. ϕ was changed from 0 to 180° at 5° intervals, and accuracy in ϕ was about 0.5°.

ESR Measurements. The ESR measurements were carried out at 77 K by means of a home made X-band spectrometer. The modulation frequency was 455 kHz. The microwave frequency was determined by means of a wave meter,

and the calibration of the magnetic field was done by the use of DPPH and Mn(II) ions doped in MgO. The determination of the concentration of the unpaired electron was done by comparing the integrated intensities with those of a known amount of the $CuSO_4 \cdot 5H_2O$ single crystal. The growth of the spectrum was estimated by comparing the intensities with the DPPH. For the check of the line shape, the spectrum was observed in several different directions of the magnetic field in each measurement.

Results

V_2O_5 Single Crystals Heated in SO_2+Air. No ESR signal was found initially in the V_2O_5 crystal, which was prepared from cautiously purified V_2O_5 powder. The crystal exposed to a gaseous mixture of SO_2 and air at 617 °C for 32 h, however, showed an asymmetric ESR signal. The intensity increased with the time up to about 180 h. The growth of the spectrum with the time is illustrated in Fig. 2. Finally, the spin concentration increased up to about 2×10^{17}. The line shape did not change with the time.

Angular Dependencies of ESR Spectrum. Sharp Signal: When both θ and η are fixed at zero, the change in the spectrum with ϕ is demonstrated in Fig. 3. The figure shows clearly that a strong sharp signal is gradually moving toward a low field as the direction of the magnetic field changes from H_0//b to H_0//a in the ba-plane of the crystal. Besides this, a minor signal, which seems to consist of more than one component, was seen, but the angular behavior is not clear. The sharp signal also behaved similarly when θ was fixed at 0 and at a η of any value from 0 to 90°. When η was fixed at 0° and the θ was of any value between 0 and 90°, the moving range of the sharp component with ϕ was not constant; the larger θ was, the narrower the moving range became. In the limiting case of $\eta=0°$ and a θ value close to 0°, the sharp signal seems always to be at the lowest magnetic field during the change in ϕ, as is demonstrated in Fig. 4. These results for the sharp signal clearly indicate that the ***g***-tensor has approximately an axial symmetry, that the direction of $g_{//}$ coincides with the b-axis of the crystal, and that $g_\perp$ is in the ac-plane.

The g-values of the sharp signal at each θ are plotted against ϕ in Fig. 5. The full lines are the theoretical one, calculated using the values of $g_{//}=1.924$ and $g_\perp=1.970$ obtained by the least-square treatment of the data by the use of the familiar equation, $g^2=g_{//}^2\cos^2\delta+g_{//}^2\sin^2\delta$, where δ denotes the angle between $g_{//}$ and H_0.

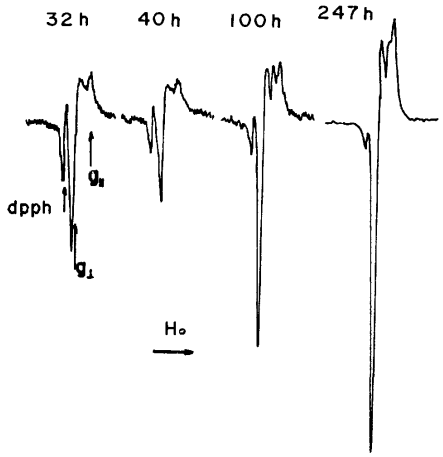

Fig. 2. Change in the intensity of ESR spectrum in V_2O_5 single crystal during SO_2 oxidation reaction.

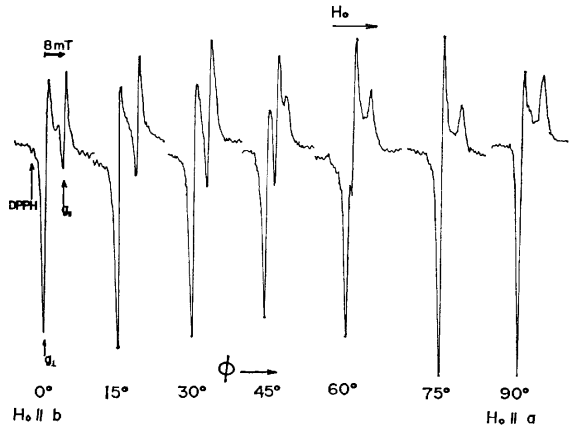

Fig. 3. Change in ESR spectrum with change in the direction of H_0 in the crystal ab-plane from H_0//b to H_0//a.

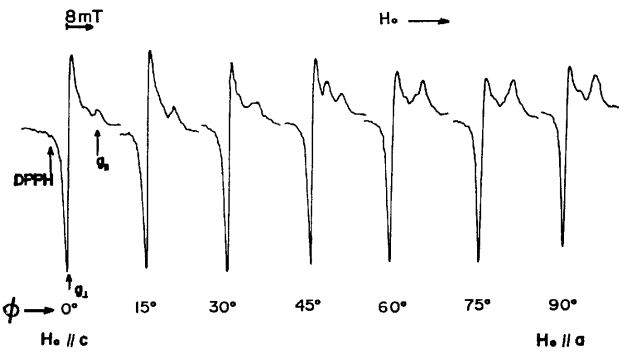

Fig. 4. Change in ESR spectrum with the change in the direction of H_0 in the crystal ac-plane from H_0//c to H_0//a.

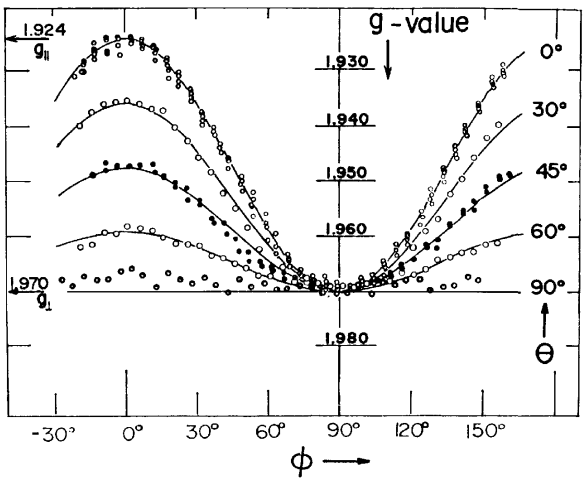

Fig. 5. Angular dependency of the sharp signal on θ. Figure shows following cases: at $\theta=0°$ with $\eta=0$, 30, 45, 60, and 90°; at $\theta=45°$ with at $\eta=0$ and 45°; and with $\theta=30$, 60, and 90° only at $\eta=0°$.

In the case of $\theta=0°$, at η values of 0, 30, 45, 60, and 90°, and in the case of $\theta=45°$, at η values of 0° and 45°, the results are given together. In the other cases, only results at $\eta=0°$ are given. Except in the case of $\theta=90°$, the g-values concentrate close to the theoretical curves. The fluctuations of the g-values in the case of $\theta=90°$ seem to due to the overlap of some minor components, as will be discussed below.

Other Minor Signals: It may be seen in Fig. 4 that the other minor signals in the spectrum move from a low to a high field with the change in the direction of the H_0 in the ac-plane from $H_0//c$ to $H_0//a$. As several components overlap complicatedly and seem to move independently of each other, the centers of the groups of these signals can not be preciesly determined. In the case of $\theta=90°$ and $\phi=0°$, however, the g-values estimated from the distances between the center of the group and that of DPPH can be plotted against ϕ, as is shown in Fig. 6. A periodical change is seen, especially near the maximum point in the figure. The dotted

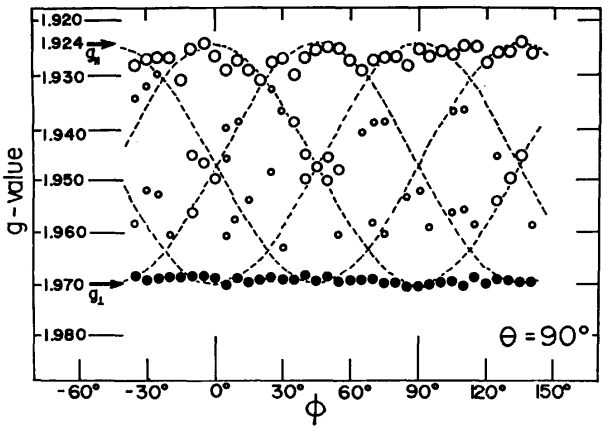

Fig. 6. Angular variations of the minor signal with the change in H_0 in the ac-plane. Dotted lines denote the theoretical calculations under the assumptions that $g_{//}$ is in the ac-plane and is parallel to a-, c-axis and the axes deviated by ±45° from a- or c-axis. Closed circles denote the values of the sharp signal. Large open circles denote the values of relatively clear signal and the small circles that of not so clear signal.

lines are the theoretical ones, calculated by the use of the same equation and parameters as those used in the case of the sharp signal. To obtain a good fit, several directions of g were tried parallel to the a- and c- axes and deviating by ±45° from the axes in the ac-plane; the best fit was thus obtained. It may be seen in the figure that there are also other groups of points which are not distributed on any of the dotted lines. This may indicate that there are other components which have $g_{//}$ components out of the ac-plane. Nearly the same periodicities as in the case of the H_0 change in the ac-plane (*cf.* Fig. 6) were also seen near the c- and a-axes in the case of the H_0 variations in the ab- and bc-planes of the V_2O_5 crystal. However, the minor signals can not be determined practically because they are extensively disturbed by the sharp signal.

Discussion

Possible Structures of the $VOSO_4$ Formed in the V_2O_5 Crystal in the Oxidation of SO_2 with Air. Many investigators have found several types of ESR spectra in the V_2O_5 crystal, in some cases by the addition of metal impurities.[6-10] The results have always indicated that the direction of $g_{//}$ coincides with the b-axis, and the spectra show hfs due to V (IV) ions which are diluted inside the V_2O_5 lattice and are sufficiently isolated from each other. Therefore, the sharp and asymmetric spectrum in the present study can not be ascribed to these species. On the other hand, the possibilities of ascribing this ESR spectrum to some lower vanadium oxide compounds (*e.g.*, V_3O_7, V_6O_{13}, and VO_2) can also be excluded. On the contrary, existence of the $VOSO_4$ phase has been strongly supported by previous study.[4]

Two types of crystal structures have been reported in $VOSO_4$:[11] the α-form (tetragonal) and the β-form (orthorhombic). The α-form has the layer structure shown in Fig. 7,[12] and the vanadium-oxygen bond (V=O) takes only one direction, which coincides with the c-axis in the crystal. In the β-form, the layer structure is completely destroyed, as is shown schematically in Fig. 8.[13] The vanadium-oxygen bond (V=O) takes two directions deviating by about ±22° from the a-

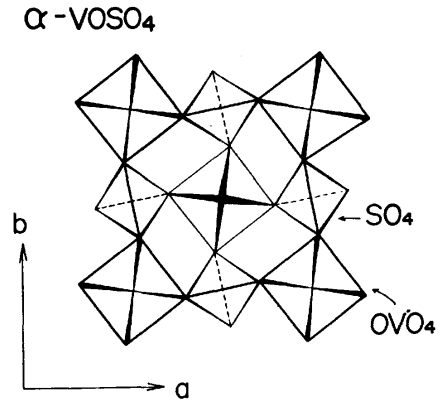

Fig. 7. A schematic representation of α-$VOSO_4$ crystal structure by Ladwig.[12] A layer structure is kept, although crystal coordinate differ from that in V_2O_5.

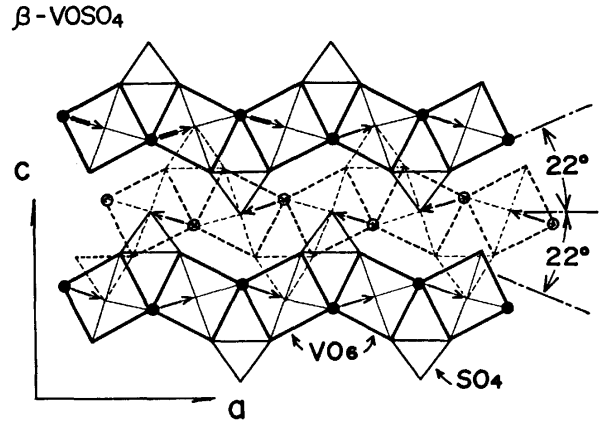

Fig. 8. A schematic representation of the crystal structure of β-$VOSO_4$ by Kierkegaard *et al.*[13]

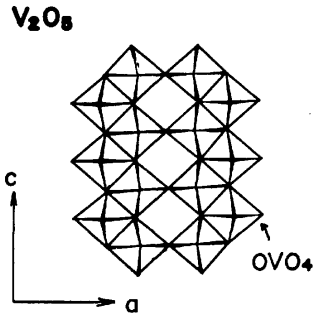

Fig. 9. A schematic representation of V_2O_5 crystal structure by Byström *et al.*[14] and Bachmann *et al.*[15] Construction of a sheet from zig-zag double chains.

axis on the ac-plane of the crystal. On the other hand, V_2O_5 is orthorhombic (Pnmn) and has a layer structure, as is shown in Fig. 9.[14,15] All the V=O bonds are alined on a straight line, which is parallel to the b-axis.

α-$VOSO_4$ in the crystalline state could be realized from the V_2O_5 crystal, keeping the layer structure in such a manner that the oxygen ions in the four corners of the VO_5 square-pyramid unit of V_2O_5 are simply replaced by the oxygen atoms of the four SO_4^{2-} tetrahedrons. On the other hand, in the β-$VOSO_4$ the same replacement of the oxygen of the VO_5 unit by the oxygen of SO_4^{2-} could occur only after the destruction of the layer structure. Therefore, we can expect that the growth of the α-phase in the V_2O_5 crystal occurs more easily than that of the β-phase.

Arrangement of the $VOSO_4$ Phases in the V_2O_5 Lattice under the SO_2 Oxidation. The directions of the V=O bond, which are coincident with the $g_{//}$ of the $\boldsymbol{g}$-tensor in these crystals, may be clearly summarized as follows: in V_2O_5 and α-$VOSO_4$, it takes only one direction, parallel to the b-axis, but in β-$VOSO_4$, a pair of directions, deviating from the a-axis by about $\pm 22^\circ$ on the ac-plane. The $\boldsymbol{g}$-tensor should have the same value in both α- and β-$VOSO_4$ because they have the same local field around the vanadyl ion.

The alignments of the V=O bond and principal axes of the $\boldsymbol{g}$-tensor in the $VOSO_4$ crystal can be primarily known from the crystal structure. By connecting the crystal structures with the results of the $\boldsymbol{g}$-tensor analysis, therefore, the possible arrangements of $VOSO_4$ phase in the V_2O_5 lattice can be discussed.

The finding that the axis for the $g_{//}$ of the sharp signal in the spectrum was completely coincident with the b-axis of the V_2O_5 crystal strongly suggests that the $VOSO_4$ formed in the V_2O_5 lattice is the α-form. Both α-$VOSO_4$ and V_2O_5 have the same layer structure, except only for such differences that the oxygen atoms in the four corners of the VO_5 square-pyramid in V_2O_5 are replaced by the oxygen atoms of the SO_4^{2-} tetrahedron in α-$VOSO_4$. The change from V_2O_5 to α-$VOSO_4$ seems to be possible in the crystalline states in such a manner that the oxygen atoms in the four corners of the VO_5 square-pyramidal unit in V_2O_5 are simply replaced by the oxygen atoms of the four SO_4^{2-} tetrahedrons; then the layer structure and the direction of V=O bonds are kept unchanged in the α-$VOSO_4$ lattice.

In the case of the minor components of the spectrum, as has been preliminarily described above, the axis for $g_{//}$ exists on the ac-plane and on the other planes as a pair of $\boldsymbol{g}$-tensors, which take an angle of about 45° toward each other. From the correspondence of the directions of the $\boldsymbol{g}$-tensor with that of the V=O bond in β-$VOSO_4$, the minor components can possibly be ascribed to β-$VOSO_4$. Besides, the possibility of the growth of α-$VOSO_4$ on dislocation or some other imperfection of the crystal can not, of cause, be ruled out.

It can reasonably be expected that a clear-cut and reversible transformation between the formation and decomposition of the $VOSO_4$ phase in the V_2O_5 crystalline lattice occurs more favorably in the case of the α-$VOSO_4$ than the β-$VOSO_4$ phase. The fact that a surface brilliance always remained after repetitions of the formation and the decomposition of the $VOSO_4$ phase in the V_2O_5 lattice[4] also suggests strongly that, in the cleaven plane (the ac-plane) of the V_2O_5, α-$VOSO_4$ phase easily grows with a topochemical relation. From this suggestion, the important role of the ac-plane in catalysis can be understood in the case of SO_2 oxidation as well as in the case of CO oxidation.[16]

Indirect Chemiluminescence from the Air Oxidation of Ketones and Carboxylic Acids in Alkaline Aprotic Solvents Containing 9,10-Diphenylanthracene and 9,10-Dibromoanthracene

Isao KAMIYA and Takashi SUGIMOTO

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 15, 1977)

A number of ketones and carboxylic acids have been examined for direct and indirect chemiluminescence with 9,10-diphenylanthracene and 9,10-dibromoanthracene by air oxidation. From the finding that the efficiency of the chemiluminescence was dramatically influenced by the class of the C–H bond adjacent to the carbonyl group, it was concluded that the molecules with a –COCH– group surely give an excited product during air oxidation in alkaline aprotic solvents. The reaction scheme was consistent with the evidence that most simple carboxylic acids exhibited no chemiluminescence, probably because the C–H bond adjacent to the carboxyl group is no more acidic, but keto acids exhibited emission. In several compounds, however, the chemiluminescent reaction was retarded by other functional groups.

In the previous studies of the chemiluminescence from the air oxidation of 3,5-dihalogeno-4-hydroxyphenylpyruvic acid[1] and succinylfluorescein[2] in alkaline aprotic solvents, a mechanism involving dioxetane intermediate was proposed for the luminescent reactions, and the reaction pathway leading to the dioxetanes which will be formed by the oxygenation of the anion of these compounds, formed by the loss of a proton from the carbon adjacent to the carbonyl or  group, was discussed as a possible mechanism for the generation of the excited products.

These results suggest that other simple molecules with a –COCH– group should also follow the same reaction pathways, involving a dioxetane, to yield a product in an excited state. In order to test this hypothesis, we carried out a preliminary study to investigate the chemiluminescent reaction of several carbonyl compounds by means of the indirect chemiluminescence technique with 9,10-diphenylanthracene(DPA) and 9,10-dibromoanthracene(DBA); we found that excited acetone and benzoic acid, mainly in the triplet state, were generated by air oxidation of 3-methyl-2-butanone and benzoin respectively in dimethyl sulfoxide(DMSO) or *N*,*N*-dimethylformamide(DMF) containing potassium *t*-butoxide (*t*-BuOK) as the base.[3]

In the present study, we have examined a number of simple ketones and carboxylic acids for the chemiluminescence from the air oxidation under the same experimental condition in order to test the validity of, and to broaden the scope of this interesting reaction mechanism.

Results and Discussion

The indirect chemiluminescence was observed upon adding a *t*-BuOK solution in *t*-BuOH to an aerated solution of ketones in DMSO or DMF containing DPA or DBA. However, no direct chemiluminescence could be detected on an appreciable scale except with some aromatic ketones (see below). The intensity of the indirect chemiluminescence with DBA was markedly higher than with DPA, in spite of the much higher fluorescence efficiency of the latter. From these findings, we concluded that the excited species, predominantly in the triplet rather than the singlet state, were produced during the air oxidation of the ketones, because DBA is more capable of converting the energy of excited triplet species into singlet energy than is DPA because of the increased spin-orbit coupling and mixing of singlet and triplet states by the heavy-atom effect.[4]

The features of the chemiluminescent reaction were affected by the experimental conditions— *i.e.* the temperature, solvents, and the concentrations of the ketones,

Table 1. Relative intensities (i_M) and 1/4-lifetimes ($t_{1/4}$) of the indirect chemiluminescence of aliphatic ketones with DBA in a DMSO-*t*-BuOK system at 313 K, and the colors of the spent reaction solutions[a]

Compound		i_M[b]	$t_{1/4}$(s)	Colors of spent reaction solns
$CH_3COCH(CH_3)_2$	(**1**)[c]	1.0	40	colorless
$CH_3COCH(CH_3)CH_2CH_3$	(**2**)	1.2	40	colorless
$CH_3COCH_2CH(CH_3)_2$	(**6**)	0.3	20	reddish brown
$CH_3COCH_2CH_2CH(CH_3)_2$	(**7**)	0.2	15	reddish brown
$CH_3COCH_2CH_3$	(**8**)	0.5	10	dark red
$CH_3COC(CH_3)_3$	(**12**)	0.0	—	light brown
$CH_3COCH(OH)CH_3$	(**5**)	0.0	—	yellowish brown
$(CH_3)_2CHCOCH(CH_3)_2$		0.2	20	colorless
$CH_3CH_2CH_2COCH_2CH_2CH_3$		0.1	15	brown
$CH_3CH_2CH_2COCH(CH_3)_2$		0.0	—	colorless
$CH_3CH_2COCH_2CH_3$		0.1	15	light reddish brown
$CH_3(CH_2)_{20}CO(CH_2)_{20}CH_3$		0.0	—	colorless
CH_3COCH_3		0.0	—	dark orange

a) The intensity of the emission peak from **1** was defined as 1.0. b) The ratios of the (total) light emission were given approximately by $i_M \cdot t_{1/4}$. c) The quantum yield for the indirect chemiluminescence of **1** at an infinite concentration of DBA was estimated to be 2.1×10^{-7} einstein mol^{-1} (the details of the measurement will be reported in the next paper).

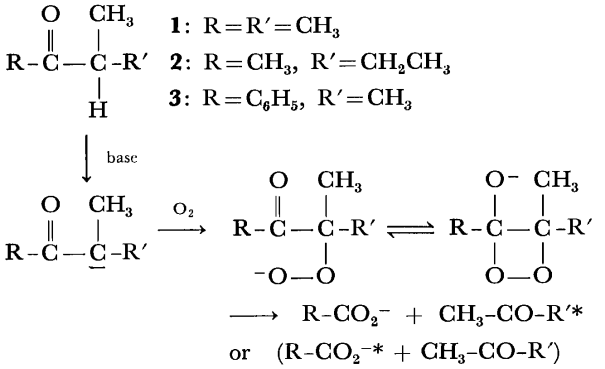
Table 2. The values of i_M and $t_{1/4}$ of the indirect chemiluminescence of aromatic ketones with DBA in a DMSO-*t*-BuOK system at 313 K, and the colors of the spent reaction solutions

Compound		i_M[a]	$t_{1/4}$(s)	Colors of spent reaction solns
$C_6H_5COCH(CH_3)_2$	(**3**)[b]	200	20	colorless
$C_6H_5COCH(OH)$-C_6H_5	(**4**)	25	5	colorless
$C_6H_5CO(CH_2)_2CH_3$	(**10**)	15	12	brown
$C_6H_5CO(CH_2)_4CH_3$	(**11**)	15	12	orange
$C_6H_5COCH_2CH_3$	(**9**)	7	10	dark orange
$C_6H_5COCH_3$		1.0	10	brown
$C_6H_5CH_2COCH_2C_6H_5$		0.5	10	brown
$C_6H_5COCH_2C_6H_5$		0.0	—	yellow
$C_6H_5COCH_2COC_6H_5$		0.0	—	colorless
$(C_6H_5)_2CHCOCH_3$		0.0	—	colorless

a) The values of i_M were also estimated by comparison with the i_M value from **1**, which was defined as 1.0. b) The quantum yield for the indirect chemiluminescence of **3** at an infinite concentration of DBA was estimated to be 2.6×10^{-5} einstein mol^{-1}.

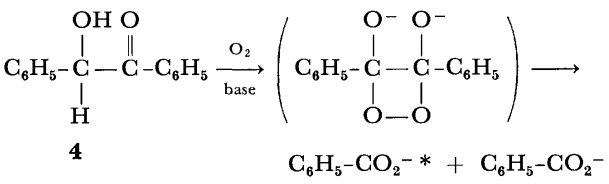
t-BuOK, and the fluorescers, and also, more essentially, by the chemical structure of the ketones. In general, the intensity was much higher with aromatic ketones than with aliphatic ketones. The relative intensities of the emission peaks (i_M) and the times for the decay of intensities to one fourth of the maxima ($t_{1/4}$), as measured in a DMSO solution with equal concentrations of ketones, *t*-BuOK, and DBA at 313 K, are listed in Tables 1 and 2 for aliphatic and aromatic ketones respectively, together with the colors of the spent reaction solutions. The results in the tables clearly show that the efficiency of the emission is dramatically influenced by the class of the C–H bond adjacent to the carbonyl group, as was expected.

3-Methyl-2-butanone(**1**) and 3-methyl-2-pentanone (**2**), which possess a tertiary C–H bond, exhibited the most intensive chemiluminescence among all the aliphatic ketones examined. Among the aromatic ketones, isopropyl phenyl ketone(**3**) exhibited the most intensive emission; it could be easily observed even by the naked eye in a dark place. These ketones, **1**, **2**, and **3**, absorbed equimolar amounts of oxygen and yielded acetone, 2-butanone, and both acetone and benzoic acid respectively, as the main products. Thus, the chemiluminescent reaction of these ketones can be explained reasonably by the following mechanism:



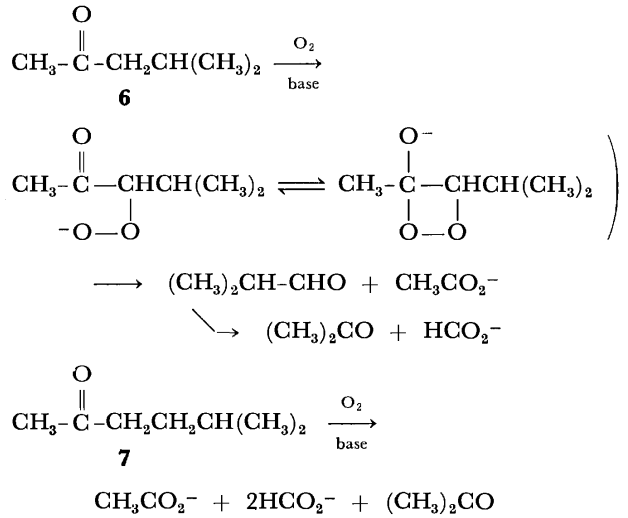
A similar reaction mechanism has been proposed for the decomposition of α-hydroperoxy ketones, which are known to be intermediates in the autoxidation of the parent ketones.[5]

Benzoin(**4**), whose emission was fairly intensive but rapidly decayed, yielded benzoic acid as the main product in a 59% yield (based on the two moles of the acid). This result implies that excited triplet benzoic acid is generated by the oxidation of benzoin, presumably *via* a dioxetane intermediate:



Acetoin(**5**), though it absorbed equimolar oxygen upon oxidation, showed no appreciable indirect chemiluminescence with DBA or DPA. This is probably because a large amount of energy, greater than the sum of the reaction enthalpy and activation energy, would be required to excite the acetic acid produced. Therefore, it is more reasonable to assert that excited triplet acetone and 2-butanone, rather than excited triplet acetic acid, are generated in the air oxidation of **1** and **2** respectively. However, it is difficult to decide which, acetone or benzoic acid, is the excited species in the case of **3**.

4-Methyl-2-pentanone(**6**), 5-methyl-2-hexanone(**7**), and 2-butanone(**8**), whose C–H bond adjacent to the carbonyl group is not tertiary but secondary, showed a much weaker emission than **1** and **2**. Similarly, ethyl phenyl ketone(**9**), phenyl propyl ketone(**10**), and pentyl phenyl ketone(**11**) exhibited a medium indirect chemiluminescence emission. In the system of **6** and **7**, where the molar ratios of absorbed oxygen to the ketones were about 2 : 1 and 3 : 1 respectively, acetone was formed, though in low yields. The difference in the amounts of absorbed oxygen and the formation of acetone can be best explained by the following consecutive reaction mechanism, in which the aldehydes formed by the initial oxidation undergo a sequential oxidation reaction to give acetone:



However, no aldehydes could be detected in the spent reaction solutions of these ketones, probably because they were quickly consumed by sequential oxidation or by other concurrently proceeding reactions, such as addition and polymerization. In fact, the spent reaction solutions were colored probably because of the concurrent reactions (see Tables 1 and 2). The aromatic ketones, **9**, **10**, and **11**, reacted similarly and gave benzoic acid in yields of 38, 57, and 23% respectively. Thus it may be reasonable to decide that excited triplet benzoic acid is generated from **9**, **10**, and **11** in the same way as it is from benzoin. However, we cannot exclude the possibility that aldehydes in the excited state are generated from **8**.[b]

Such ketones as 3,3-dimethyl-2-butanone(**12**), acetone, and acetophenone, whose C–H bond adjacent to the carbonyl group is primary, exhibited little or very feeble emission.

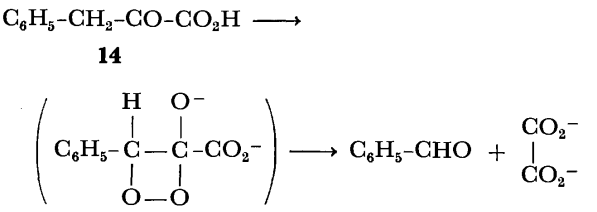
We also examined the chemiluminescent reaction of carboxylic acids. With simple carboxylic acids, such as acetic acid, propionic acid, isobutyric acid, phenyl acetic acid, diphenylacetic acid, and α(and β)-naphthylacetic acids, neither direct nor indirect chemiluminescence could be detected. However, β-benzoylpropionic acid(**13**) and β-phenylpyruvic acid(**14**), which possess a carbonyl group in addition to a carboxyl group, exhibited indirect chemiluminescence with the emission characteristics shown in Table 3. The results obtained from these keto acids also support our reaction scheme for the luminescent reaction shown above.

TABLE 3. THE VALUES OF i_M AND $t_{1/4}$ OF THE INDIRECT CHEMILUMINESCENCE OF CARBOXYLIC ACIDS WITH DBA IN A DMSO-*t*-BuOK SYSTEM AT 313 K, AND THE COLORS OF THE SPENT REACTION SOLUTIONS

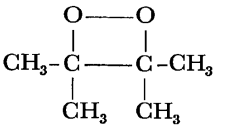
Compound		i_M[a]	$t_{1/4}$(s)	Colors of spent reaction solns
$C_6H_5COCH_2CH_2$-COOH	(**13**)	1.0	40	dark orange
$C_6H_5CH_2COCOOH$	(**14**)	2.5	60	dark brown

a) The values were estimated by comparison with the i_M value from **1**, which was defined as 1.0.

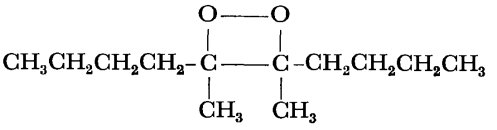
β-Phenylpyruvic acid(**14**) exhibited a direct chemiluminescence whose spectral distribution was similar to that of the fluorescence spectrum of benzaldehyde. This implies that both excited singlet and triplet benzaldehydes are produced, presumably *via* a dioxetane intermediate:



Cilento *et al.* have proposed the same reaction mechanism for the oxidation of the phenylthio ester of 3-indoleacetic acid.[7] β-(*p*-Hydroxyphenyl)pyruvic acid (**15**) also exhibited both direct and indirect chemiluminescence. It should be noted here that the intensity of the indirect chemiluminescence of **15** with DPA was higher than that with DBA, while the total intensity of the emissions was lower compared to the case of **14**. Ethyl *p*-hydroxyphenyl ketone(**16**) also exhibited both direct and indirect chemiluminescence with emission features similar to those from **15**. The relative intensities of the direct and the indirect chemiluminescence with DPA and DBA are listed in Table 4. These results indicate that the substitution of a hydroxyl group at the 4 position of the benzene ring in aromatic ketones increases the yield of the excited singlet product, but causes a reduction in the total yield of excited products. An analogous substitution effect was observed in the cleavege of dioxetanes. Turro and coworkers reported that tetramethyl-1,2-dioxetane(**17**) gave excited triplet acetone in high yields and a little amount of excited singlet acetone.[8] On the other hand, it has been shown that relatively low and nearly equal yields of excited singlet and triplet 2-hexanone were formed upon the cleavage of 3,4-dibutyl-3,4-dimethyl-1,2-dioxetane(**18**).[18]



17



18

Ethyl *o*-hydroxyphenyl ketone(**19**) exhibited neither direct nor indirect chemiluminescence, probably because the reaction route is entirely altered by the substituent.

TABLE 4. RELATIVE INTENSITIES[a] OF THE DIRECT AND INDIRECT CHEMILUMINESCENCE IN THE SYSTEMS OF **14**, **15**, AND **16**

Compound		Direct CL	Indirect CL		Colors of spent reaction solns
			DPA	DBA	
$C_6H_5CH_2COCOOH$	(**14**)	1.0	1.2	2.5	dark brown
p-$HOC_6H_4CH_2COCOOH$	(**15**)	0.3	0.6	0.3	light yellow
$C_6H_5COCH_2CH_3$	(**9**)	0.0	0.5	7	dark orange
p-$HOC_6H_4COCH_2CH_3$	(**16**)	0.4	0.6	0.4	colorless
o-$HOC_6H_4COCH_2CH_3$	(**19**)	0.0	0.0	0.0	bright yellow

a) These values were also estimated by comparison with the i_M value from **1**, which was defined as 1.0.

Table 5. The emission features (i_M and $t_{1/4}$) of the indirect chemiluminescence with DBA of the *p*-substituted isopropyl phenyl ketones, and the colors of the spent reaction solutions

Substituent (and compound)		i_M[a)]	$t_{1/4}$(s)	Colors of spent reaction solns
p-CH_3	(**20**)	180	20	colorless
p-OCH_3	(**21**)	50	20	colorless
p-Cl	(**22**)	50	15	light yellow
p-Br	(**23**)	20	18	yellowish brown
p-F	(**24**)	0	—	colorless
p-SCH_3	(**25**)	0	—	colorless

a) The values were also estimated by comparison with the i_M value from **1**, defined as 1.0.

In Table 5, the relative intensities of the indirect chemiluminescence of several substituted isopropyl phenyl ketones with DBA are listed. We can find that the emission efficiencies of the *p*-methyl(**20**), *p*-methoxy (**21**), *p*-chloro(**22**), and *p*-bromo derivatives(**23**) decrease in this order. The *p*-fluoro(**24**) and *p*-methylthio derivatives(**25**) exhibited little emission.

Summarizing the results of the present study, we conclude that excited products are surely generated *via* dioxetane intermediates in the air oxidation of those molecules with a –COCH– group in alkaline aprotic solvents and that the dioxetanes are formed by the oxygenation of the anion formed by the loss of the proton from the carbon atom adjacent to the carbonyl group. However, it should be kept in mind that the luminescent reaction is debased by the competitive and sequential processes brought about by other functional groups.

Recently, we have found that several aldehydes with a –CHCHO group exhibited similar indirect chemiluminescence with DPA and DBA under comparable experimental conditions.[10)]

Experimental

The commercially available ketones (except the substituted isopropyl phenyl ketones), carboxylic acids, and fluorescers, DPA and DBA (Nihon Kasei, extra pure grade) were used without further purification. The substituted isopropyl phenyl ketones(**21**, **22**, **23**, **24**, and **25**) were synthesized by Friedel-Crafts condensation of the appropriately substituted benzene with isobutyric anhydride in carbon disulphide under reflux, using aluminum chloride as the catalyst. The products were purified by fractional distillation under reduced pressure (except for **25**, which was purified by recrystallization from hexane and melted at 42—43 °C): **20**, bp 132.5—133.5 °C/27 mmHg; **21**, bp 116—117 °C/2 mmHg; **22**, bp 89—92 °C/3 mmHg; **23**, bp 85—87 °C/3 mmHg; **24**, bp 49.5—50 °C/3 mmHg. The structures of these compounds were confirmed by means of their ^1H NMR spectra.

The concentrations of the solution of the ketones or carboxylic acids in DMSO (*A*), the solution of *t*-BuOK in *t*-BuOH (*B*), and the solution of DPA or DBA in DMSO (*C*) were usually 3.0×10^{-4}, 3.3×10^{-2}, and 1.0×10^{-3} mol l^{-1} respectively.

A mixed solution composed of 1 ml of *A* and 1 ml of *C* was placed in a quartz cell, which was kept at 313 K by means of a thermostatically controlled cell holder. The intensity of the indirect chemiluminescence at 430 nm (the peak of the spectral distribution) was measured immediately after adding 0.2 ml of *B* into the mixed solution on a Hitachi MPF-2A type fluorescence spectrophotometer, with the exciting source off.

The reaction products, acetone, 2-butanone, benzoic acid, and the *p*-substituted benzoic acids, were detected as follows:

General Procedures for the Isolation of Benzoic Acid and Its p-Substituted Derivatives. A solution of *t*-BuOK (2.3 g) in DMF (70 ml) was saturated with oxygen by stirring vigorously under the gas. A solution of isopropyl phenyl ketone (1.50 g) in DMF (30 ml) was then added to the solution through a dropping funnel, and the mixture was stirred under oxygen at 17—18 °C for 15 min, during which period 280 ml of oxygen was absorbed. After being diluted with water (100 ml), the solution was evaporated to dryness under reduced pressure. The residue, dissolved in water (20 ml) and acidified with hydrochloric acid, gave benzoic acid (1.13 g, 92%); mp 122—123 °C (recrystallized from water).

In a similar way, benzoic acid was isolated from the oxidation solution of the following compounds (the yield of the acid is shown in parentheses); benzoin (59%); phenyl propyl ketone (38%); pentyl phenyl ketone (57%); ethyl phenyl ketone (23%); β-benzoylpropionic acid (50%).

The substituted isopropyl phenyl ketones (**20**, **21**, **22**, **23**, **24**, and **25**) were similarly oxidized and gave, respectively, the following *p*-substituted benzoic acids, which were all recrystallized from water and identified by means of their melting points: *p*-methylbenzoic acid (80%, mp 182—183 °C), *p*-methoxybenzoic acid (68%, mp 183.5—185 °C), *p*-chlorobenzoic acid (90%, mp 241—242 °C), *p*-bromobenzoic acid (40%, mp 255—256 °C), *p*-fluorobenzoic acid (50%, mp 184.5—186 °C), and *p*-(methylthio)benzoic acid (90%, mp 193.5—194 °C).

General Procedures for the Detection of Acetone and Other Ketones. A solution of *t*-BuOK (2.5 g) in DMF (100 ml) was saturated with oxygen as above. After adding 3-methyl-2-butanone (0.74 g), the solution was stirred under oxygen at 23 °C for 30 min, during which period 220 ml of oxygen was absorbed. To the solution, 1 M HCl (20 ml) and then 2,4-dinitrophenylhydrazine (1.0 g) in methanol (300 ml) were added. The solution was stirred at 25 °C for 30 min and then under reflux for 20 min. Evaporation to dryness under reduced pressure and trituration with water (30 ml) gave a yellow solid. The crystallization of the solid from methanol gave yellow needles (1.15 g) of acetone 2,4-dinitrophenylhydrazone, identified with an authentic sample by a mixed mp (125—126 °C) and by TLC developed by a mixture of benzene (15 v/v) and ethyl acetate (5 v/v) on a Merck pre-coated silica gel 60 F_{254} plate.

In a similar way, we detected acetone from an oxidation solution of **3**, **6**, and **7** and 2-butanone from **2**, both as the 2,4-dinitrophenylhydrazones; they were identified by means of TLC as above.

Yields of Excited Triplet Products Generated from the Air Oxidation of 3-Methyl-2-butanone and Isopropyl Phenyl Ketone in a Dimethyl Sulfoxide Solution Containing Potassium *t*-Butoxide

Isao KAMIYA

Department of Chemistry, College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

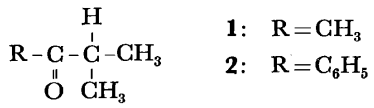
(Received April 12, 1977)

An attempt has been made to evolve the kinetic scheme in order to evaluate the yields (ϕ^*_{react}) of excited triplet products generated from the air oxidation of 3-methyl-2-butanone (**1**) and isopropyl phenyl ketone (**2**). Expressions for the total light emission and quantum yield of the indirect chemiluminescence (CL) can be derived, from which the rates of energy transfer from excited triplet products to singlet 9,10-dibromoanthracene (DBA), k_{TS}, and ϕ^*_{react} were determined on the basis of the CL intensity measured for various DBA concentrations. The values of k_{TS} from **1** and **2** (4×10^8 and 1×10^9 l mol^{-1} s^{-1}) are in fair agreement with the values proposed by several investigators who measured the indirect CL from the thermal cleavage of 1,2-dioxetanes. The markedly small ϕ^*_{react} values (1×10^{-5} and 1×10^{-3}) result from the fact that the CL arises from a minor reaction.

In previous studies,[1] Kamiya and Sugimoto have found that many simple ketones exhibit indirect chemiluminescence (CL) by air oxidation in alkaline aprotic solvents containing 9,10-diphenylanthracene (DPA) or 9,10-dibromoanthracene (DBA), and that the intensity for solvents containing DBA was markedly higher than for those containing DPA, in spite of the much higher fluorescence efficiency of DPA. The results indicate that excited species, mainly in the triplet state, are produced during the oxidation of the ketones, since DBA is more efficient at converting the energy of the excited triplet species into singlet energy than is DPA due to the heavy-atom effect.[2] Further, they observed that the CL intensity was dramatically affected by the class of C–H bonds adjacent to the carbonyl group; generally, the intensity increased in the order, primary <secondary<tertiary. The results suggest that the CL efficiency depends upon the tendency to loose a proton from the C–H bond. This argument was supported by evidence that the ordinary carboxylic acids, having a C–H bond adjacent to the carboxyl group, are very weakly acidic and exhibit neither direct nor indirect CL. However, such keto acids as β-benzoylpropionic and β-phenylpyruvic acids exhibit emission.

Summarizing their results, they concluded that excited products, predominantly in the triplet rather than in the singlet state, were surely generated during air oxidation of those compounds having a –CO–CH– group *via* dioxetane intermediates. These intermediates were generated by oxygenation of the anion of the compounds formed *via* the loss of a proton from the α-carbon atom.

The overall reaction in systems of several ketones is very complicated, since the molar ratios of the absorbed oxygen to the reactants were found to be greater than 2 and the spent reaction solutions were dark orange or red owing to other competitive and/or sequential reactions. However, two ketones, 3-methyl-2-butanone (**1**) and isopropyl phenyl ketone (**2**), which possess a tertiary C–H bond adjacent to the carbonyl group and exhibited relatively intense emission, showed rather simple reaction characteristics: an equimolar amount of oxygen was absorbed, and acetone and acetic acid, and acetone and benzoic acid were produced as main products from **1** and **2**, respectively. No color change was observed in the spent reaction solutions under the experimental conditions employed in this study. (See experimental section.)

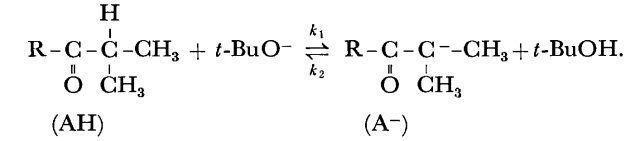


In the present study, an attempt has been made to evolve the kinetic scheme for indirect CL with DBA in order to evaluate the yields of the excited triplet products generated from **1** and **2**.

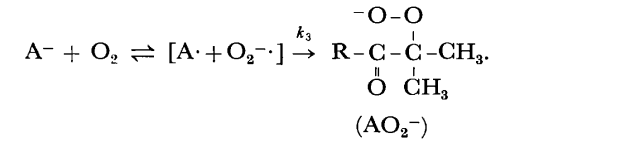
Results and Discussion

From the results described above, the following kinetic scheme appears plausible for indirect CL.

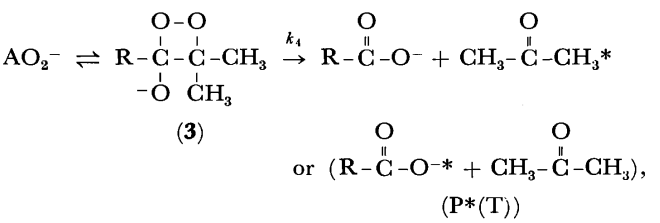
The ketones (AH) transfer their proton to the *t*-butoxide ion (*t*-BuO$^-$) when a potassium *t*-butoxide (*t*-BuOK) solution in *t*-butyl alcohol (*t*-BuOH) is added to solutions of **1** and **2**:



A possible mechanism for the reaction of A$^-$ with oxygen would be oxygenation *via* a *radical pair*:[3]



Of the decomposition processes of the hydroperoxy ketone anion (AO_2^-), one is cleavage *via* a dioxetane intermediate (**3**) generating two products, one in the excited state (mainly in the triplet state, P*(T)) and the other in the ground state;[4]



or, both in the ground state,

$$AO_2^- \rightleftharpoons \mathbf{3} \xrightarrow{k_5} R\text{-}\overset{O}{\overset{\|}{C}}\text{-}O^- + CH_3\text{-}\overset{O}{\overset{\|}{C}}\text{-}CH_3.$$

Other AO_2^- cleavage processes *via* acyclic intermediates[5] will compete with cleavage *via* the dioxetane intermediate. Let us write all the reactions together in the following scheme:

$$AO_2^- \rightleftharpoons AO_2H \rightarrow \text{(acyclic intermediate)} \xrightarrow{k_6} \text{products.}$$

In the presence of DBA, the following steps will occur:
triplet-singlet energy transfer from P*(T) to DBA,

$$P^*(T) + DBA \xrightarrow{k_{TS}} P + DBA^*(S),$$

triplet-triplet energy transfer form P*(T) to DBA,

$$P^*(T) + DBA \xrightarrow{k_{TT}} P + DBA^*(T)$$

(where DBA*(S) and DBA*(T) are the excited singlet and triplet states of DBA, respectively),
radiationless deactivation of P*(T),

$$P^*(T) \xrightarrow{k_7} P,$$

quenching of P*(T) by oxygen,

$$P^*(T) + O_2 \xrightarrow{k_8} P + O_2^*(\Delta),$$

fluorescence emission from DBA*(S),

$$DBA^*(S) \xrightarrow{k_f} DBA + h\nu,$$

radiationless deactivation of DBA*(S),

$$DBA^*(S) \xrightarrow{k_9} DBA,$$

and intersystem crossing from DBA*(S) to DBA*(T),

$$DBA^*(S) \xrightarrow{k_{10}} DBA^*(T).$$

Since the emission intensity with DPA was much lower than that with DBA (DPA and DBA are often used as monitors for excited singlet and triplet products, respectively[6]), the step for generating excited singlet products is ignored. Moreover, triplet-triplet annihilation of DBA*(T), DBA*(T)+DBA*(T)→DBA*(S)+DBA, is not taken into account, because the process has been reported to occur with low probability.[7]

According to the above scheme, the intensity of the indirect CL emission (I_{CL}) is given by:

$$I_{CL} = k_f[DBA^*(S)].$$

Using the steady-state approximation for which $d[P^*(T)]/dt=0$ and $d[DBA^*(S)]/dt=0$, I_{CL} can be written as

$$I_{CL} = \frac{k_4 k_{TS} \phi_f [DBA][AO_2^-]}{\{(k_{TS}+k_{TT})[DBA]+k_7+k_8[O_2]\}}, \quad (1)$$

where ϕ_f is the fluorescenec efficiency of DBA and is given by

$$\phi_f = k_f/(k_f+k_9+k_{10}).$$

If $[O_2]$ and [DBA] are maintained constant during the air oxidation, the total light emission is given by:

$$\int I_{CL}dt = \frac{k_4 k_{TS} \phi_f [DBA]}{\{(k_{TS}+k_{TT})[DBA]+k_7+k_8[O_2]\}} \times \int [AO_2^-]dt. \quad (2)$$

Furthermore, from the scheme we can write

$$-d[AH]/dt = k_1[AH][t\text{-}BuO^-] - k_2[A^-][t\text{-}BuOH], \quad (3)$$

$$d[A^-]/dt = k_1[AH][t\text{-}BuO^-] - k_2[A^-][t\text{-}BuOH] - k_3[A^-][O_2], \quad (4)$$

and

$$d[AO_2^-]/dt = k_3[A^-][O_2] - (k_4+k_5+k_6)[AO_2^-], \quad (5)$$

thence,

$$-\int d[AH] - \int d[A^-] - \int d[AO_2^-] = (k_4+k_5+k_6)\times \int [AO_2^-]dt = [AH]_0, \quad (6)$$

since

$$\int d[A^-] = \int d[AO_2^-] = 0$$

and

$$-\int d[AH] = [AH]_0,$$ where $[AH]_0$ is the initial ketone concentration.

Upon substituting Eq. 6 for Eq. 2, the total light emission is found to be:

$$\int I_{CL}dt = \frac{k_4 k_{TS}[DBA]\phi_f[AH]_0}{(k_4+k_5+k_6)\{(k_{TS}+k_{TT})[DBA]+k_7+k_8[O_2]\}}, \quad (7)$$

The curves of the emission intensity *versus* time (*I-t* curves) for the indirect CL upon adding a solution of *t*-BuOK in *t*-BuOH to solutions of **1** and **2** of various concentrations in dimethyl sulfoxide (DMSO) containing DBA, are illustrated in Figs. 1 and 2, respectively. The results indicate that both the intensity and total light emission are proportional to the initial concentration of the ketone ($[AH]_0$) when $[AH]_0$ is comparably low.[8] The *I-t* curves obtained by adding *t*-BuOK solutions of different concentrations to solutions of **1** and **2** are illustrated in Figs. 3 and 4, respectively. The results indicate that the peak of the emission increases and that duration of the emission decreases with increasing *t*-BuOK concentration, while the total light emission remains almost constant provided that $[AH]_0$ is kept constant. Thus, it may be concluded that the

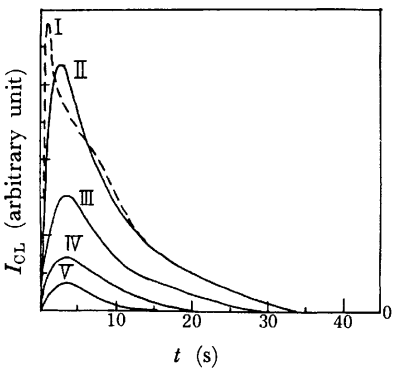


Fig. 1. Effect of the concentration of 3-methyl-2-butanone (**1**) on *I-t* curve of the indirect CL from **1** in a DMSO-*t*-BuOK/*t*-BuOH system containing DBA at 313 K. The initial concentration of **1** in 10^{-3} mol l^{-1}: I, 2.4; II, 1.2; III, 0.60; IV, 0.30; V, 0.15. The initial concentrations of *t*-BuOK and DBA are 3.0×10^{-3} and 5×10^{-4} mol l^{-1}, respectively.

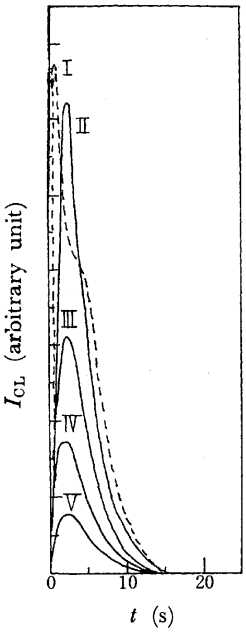

Fig. 2. Effect of the concentration of isopropyl phenyl ketone (**2**) on *I-t* curve of the indirect CL from **2** in a DMSO-*t*-BuOK/*t*-BuOH system containing DBA at 313 K. The initial concentration of **2** in 10^{-4} mol l^{-1}: I, 14; II, 7.0; III, 3.5; IV, 1.8; V, 0.9. The initial concentrations of *t*-BuOK and DBA are 3.0×10^{-3} and 5×10^{-4} mol l^{-1}, respectively.

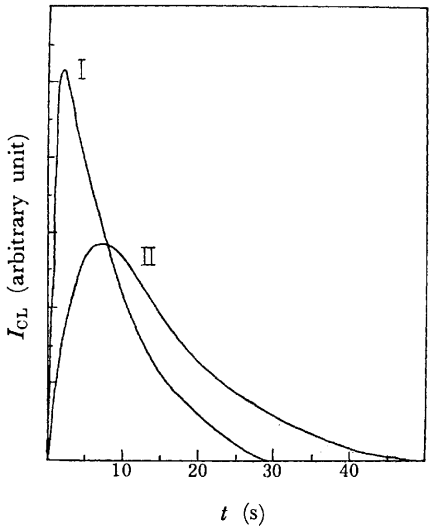

Fig. 3. Effect of the concentration of *t*-BuOK on *I-t* curve of the indirect CL from 3-methyl-2-butanone (**1**) in a DMSO-*t*-BuOK/*t*-BuOH system containing DBA at 313 K. The initial concentration of *t*-BuOK in 10^{-3} mol l^{-1}: I, 3.0; II, 0.75. The initial concentrations of **1** and DBA are 3.0×10^{-4} and 5×10^{-4} mol l^{-1}, respectively.

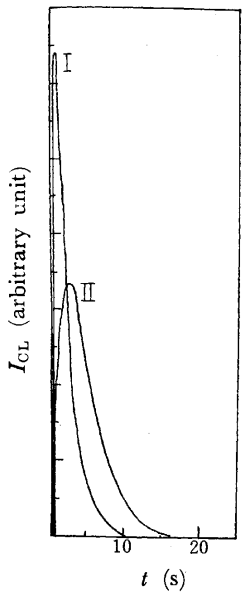

Fig. 4. Effect of the concentration of *t*-BuOK on *I-t* curve of the indirect CL from isopropyl phenyl ketone (**2**) in a DMSO-*t*-BuOK/*t*-BuOH system containing DBA at 313 K. The initial concentration of *t*-BuOK in 10^{-3} mol l^{-1}: I, 3.0; II, 0.75. The initial concentrations of **2** and DBA are 1.8×10^{-4} and 5×10^{-4} mol l^{-1}, respectively.

experimental results support the validity of Eq. 7.

From Eq. 7, the indirect CL quantum yield can be written as

$$\phi_{CL}=\frac{\int I_{CL}dt}{[AH]_0}=\frac{k_4k_{TS}[DBA]\phi_f}{(k_4+k_5+k_6)\{(k_{TS}+k_{TT})[DBA]+k_7+k_8[O_2]\}},$$

or

$$\frac{1}{\phi_{CL}}=\frac{1}{\phi^*_{react}\phi_{ET}\phi_f}\left(1+\frac{k_7+k_8[O_2]}{(k_{TS}+k_{TT})[DBA]}\right), \quad (8)$$

where

$\phi^*_{react}=k_4/(k_4+k_5+k_6)$ and $\phi_{ET}=k_{TS}/(k_{TS}+k_{TT})$.

The quantum yields for the indirect CL of **1** and **2** were determined from the *I-t* curves measured by varying the DBA concentration. (See experimental section.) Plots of $1/\phi_{CL}$ *versus* 1/[DBA] are shown in Figs. 5 and 6 for **1** and **2**, respectively. These linear plots indicate that Eq. 8 is plausible.

The values of the *abscissa intercept* ($1/\phi_{CL}$ at infinite DBA concentration, $1/\phi^\infty_{CL}$) were found from the figures to be 5.0×10^6 and 3.8×10^4 mol einstein^{-1} for **1** and **2**, respectively. Thus, the values of ϕ^∞_{CL} for **1** and **2** were calculated to be 2.0×10^{-7} and 2.6×10^{-5} eins mol^{-1}, respectively.

From Eq. 8, the value of $(k_7+k_8[O_2])/(k_{TS}+k_{TT})$ is given by the *line slope/intercept*, which is found from Figs. 5 and 6 to be $2.5\times10^3/5.0\times10^6=5.0\times10^{-4}$ and $7.5/3.8\times10^4=2.0\times10^{-4}$ mol l^{-1} for **1** and **2**, respectively. Considering that the stationary concentration of dissolved oxygen is lower than the initial concentration due to consumption during oxygenation, the decay rate of P*(T), $k_7+k_8[O_2]$, is assumed to be $\approx10^6$ s^{-1}, although

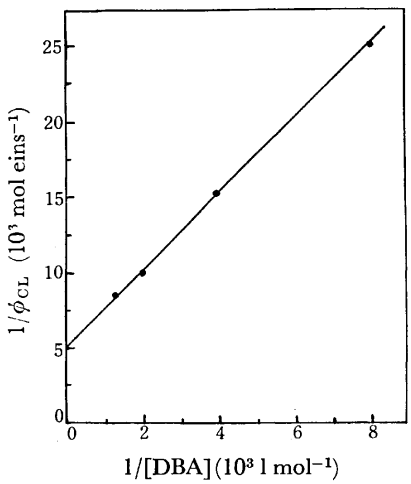

Fig. 5. Effect of the concentration of [DBA] on the quantum yield of the indirect CL from 3-methyl-2-butanone (**1**) in a DMSO-*t*-BuOK/*t*-BuOH system at 313 K. The initial concentrations of **1** and *t*-BuOK are 1.2×10^{-3} and 3.0×10^{-3} mol l^{-1}, respectively.

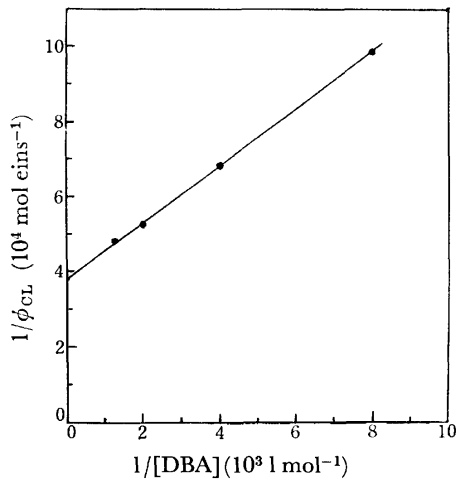

Fig. 6. Effect of the concentration of DBA on the quantum yield of the indirect CL from isopropyl phenyl ketone (**2**) in a DMSO-*t*-BuOK/*t*-BuOH system at 313 K. The initial concentrations of **2** and *t*-BuOK are 7.0×10^{-4} and 3.0×10^{-3} mol l^{-1}, respectively.

this value is an order of magnitude smaller than that proposed by Turro *et al.*[9] Then, using the value $\phi_{ET}=k_{TS}/(k_{TS}+k_{TT})=0.2$ reported by Wilson *et al.*,[6] the k_{TS} values for **1** and **2** were calculated to be 4×10^8 and 1×10^9 l mol^{-1} s^{-1}, respectively. These values are in fairly good agreement with the values reported by Belyakov and Vassilév,[10] Turro *et al.*[9] and Wilson *et al.*[6] for the rate of energy transfer from triplet carbonyl compounds to singlet DBA.

The yield of the excited triplet product (ϕ^*_{react}) can be written as:

$$\phi^*_{react} = \phi^{\infty}_{CL}/\phi_{ET}\phi_f.$$

Since $\phi^{\infty}_{CL}=2.0\times10^{-7}$ and 2.6×10^{-5} eins mol^{-1} (for **1** and **2**, respectively), $\phi_{ET}=0.2$, and $\phi_f=0.1$,[9] the values of ϕ^*_{react} for **1** and **2** were calculated to be 1×10^{-5} and 1×10^{-3}, respectively. These values are markedly lower than the yields of excited triplet products generated in the thermal cleavage of various 1,2-dioxetanes (0.5—0.02[11]). These very small values are presumably due to the fact that CL *via* a dioxetane intermediate arises from a minor reaction.[12]

Experimental

Commercially available 3-methyl-2-butanone, isopropyl phenyl ketone, DBA (all from Tokyo Kasei and of guaranteed reagent grade), and *t*-BuOK (from Merck, for synthesis) were used without further purification. Luminol (from Nakarai Kagaku) was recrystallized from dilute hydrochloric acid prior to use. All solvents, DMSO (from Merck, for spectroscopy) and *t*-BuOH (from Tokyo Kasei, extra pure grade), were used without further purification.

The luminescent reaction was initiated by adding 0.2 ml of a *t*-BuOK solution (in *t*-BuOH) to 2 ml of an aerated solution of **1** or **2** with stirring in a quartz cell ($10\times10\times45$ mm) which was situated in a thermostatically-controlled cell holder.

The CL intensity at 430 nm (the peak of the DBA fluorescence) *versus* time was measured on a Hitachi MPF-2A fluorescence spectrophotometer with no exciting source. The total light emission was determined graphically from the *I-t* curves.

A standard solution of luminol in anhydrous DMSO having an optical density at 359.5 nm (the absorption peak) of 0.010 (1.26×10^{-6} mol l^{-1}) was prepared, and the *I-t* curve of the CL initiated by adding 0.2 ml of a *t*-BuOK solution to 2 ml of the standard solution was measured on the same apparatus at 313 K.

Using the value of 1.28×10^{-2} eins mol^{-1} proposed by Lee *et al.* for the CL exhibited from the luminol solution,[13] the quantum yields for indirect CL from **1** and **2** were determined from the ratios of the total light emitted from the luminol solution to the total measured light emission from the ketone solutions.

Support for this research from a Scientific Research Grant from the Ministry of Education is gratefully acknowledged.

Stereochemistry of Cobalt(III) Complexes with Thioethers. III.[1] Vicinal Circular Dichroism due to the Chiral Sulfur Donor Atom

Kazuaki YAMANARI, Jinsai HIDAKA,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 21, 1977)

Two kinds of mixed type cobalt(III) complexes, [(2-aminoethylthio)acetato](L-methioninato)cobalt(III) chloride and [3-(2-aminoethylthio)propionato](L-methioninato)cobalt(III) chloride, have been prepared and chromatographically separated into seven and eight isomers, respectively. The characterization of isomers based on their electronic absorption and ^{1}H NMR spectra leads to the conclusion that there have been obtained four pairs of diastereomers due to the sulfur chirality of the coordinated L-methioninate. The circular dichroism spectra of isomers have been measured and discussed in relation to the absolute configurations. The vicinal CD contribution due to the chiral sulfur atom of L-methioninate has been estimated by applying an additivity rule for the three diastereomeric pairs.

A large number of investigations for the vicinal circular dichroism (CD) of asymmetric carbon[2] and nitrogen[3] atoms have been undertaken and the results have indicated that the vicinal chirality makes a relatively smaller CD contribution than the configurational one. The sulfur atom of a thioether ligand also becomes chiral by coordination to a metal ion,[4-8] leaving on itself a single lone-pair which can give a fixed configuration for the donor center at ordinary temperature. However, no optical resolution has been reported for the coordinated sulfur atom of cobalt(III) complexes with thioethers, though some examples were known for the complexes of other metals such as $[Pt^{IV}Cl_4(NH_2CH_2CH_2SCH_2CH_2NH_3)]Cl$.[9]

The present paper is concerned with the isolation of diastereomers arising from the chiral sulfur donor atom and the estimation of vicinal CD contribution due to the sulfur donor in two mixed-complex systems, [Co(terdentate-*N,S,O*)(L-met)]$^+$ [L-Hmet=L-methionine; terdentate-*N,S,O*=(2-aminoethylthio)acetic acid (Haeta), and 3-(2-aminoethylthio)propionic acid (Haetp)]. For the mixed complex six geometrical isomers, *tr.tr.tr.*, *trans(S)*, *trans(O)*, *trans(N)*, *cisciscis-I*, and *cisciscis-II*, are possible as seen in Fig. 1. As compared with [Co(terdentate-*N,S,O*)$_2$]$^+$ complexes,[1] isomer distribution is altered; *meridional* isomer becomes impossible and two *cisciscis* isomers, *cisciscis-I* and *-II*, appear in the present mixed type complexes. In addition, a pair of another type isomers are formally expected for each of the six geometrical isomers, arising from the absolute configuration (*R*) or (*S*) of the sulfur donor atom of coordinated L-methioninate ligand.

Experimental

Preparation and Separation of Isomers. [(2-Aminoethylthio)acetato](L-methioninato)cobalt(III) Chloride, [Co(aeta)(L-met)]Cl: To a hot solution (*ca.* 75 °C) of 9.0 g of cobalt(II) chloride hexahydrate in 60 cm^3 of water was added a mixed solution of 5.95 g of (2-aminoethylthio)acetic acid hemihydrochloride,[10] 5.65 g of L-methionine, and 0.75 g of sodium hydroxide dissolved in 80 cm^3 of water. Nine grams of lead dioxide was gradually added to the solution, and this was stirred at 70—75 °C for 40 min, whereupon the color of the solution became violet. The mixture was filtered to remove an excess of the lead dioxide after cooling to room temperature.

The filtrate was poured into a cation-exchange column of Dowex 50Wx8 (Na^+ form, 200—400 mesh, 4.5×40 cm). After the column had been swept with water, the adsorbed band was eluted with 0.15 M aqueous solution of sodium chloride at the rate of 1 cm^3 per min. Seven colored bands were eluted. It was confirmed from the measurements of the CD and electronic absorption spectra of these eluates, that the second eluate (brownish violet) was *tr.tr.tr.*-[Co(aeta)$_2$]$^+$, the third one (purple) *trans(S)*-[Co(L-met)$_2$]$^+$,[8] the fourth one (purple) *trans(O)*-[Co(aeta)$_2$]$^+$, and the seventh one (red) *trans(N)*-[Co(aeta)$_2$]$^+$,[1] and that the isomers of the desired complex, therefore, exist in the remaining three eluates, first, fifth, and sixth ones. It was also found that the first dark violet eluate is a single band (C-1), but the fifth and sixth reddish purple ones consist of bands more than two. The three eluates were concentrated separately in a vacuum evaporator, and then the deposit, NaCl, was filtered off. The complex in C-1 eluate was obtained by adding a large amount of ethanol to the concentrated solution and recrystallized from a small amount of water.

Each concentrated solution of the fifth and sixth eluates was again poured into a column of SP-Sephadex C-25 (K^+ form, 4.5×120 cm). The adsorbed band was eluted with 0.05 M aqueous solution of $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ (*d*-H_4tart $=C_4O_6H_6$) at the rate of 0.5 cm^3/min. For the column of the fifth eluate, five colored bands, a brownish red one (C-2), a violet one which was *trans(O)*-[Co(L-met)$_2$]$^+$,[8] a reddish

purple one (C-3), a brownish red one (C-4), and another brownish red one which was *trans(N)*-[Co(L-met)$_2$]$^+$,[8] were eluted in this order. On the other hand, for the column of the sixth eluate four colored bands, a brownish red one (C-2), a red one (C-5), another red one (C-6), and a violet one (C-7), were eluted in this order. CD measurements showed that each band consists of a single species. The desired eluates, C-2 to C-7, were concentrated separately in a vacuum evaporator, and the deposit, $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$, was filtered off. The concentrated eluate was poured into an anion exchange column of Dowex 1x8 (Cl^- form) and converted into the chloride salt. The desired complex was obtained by adding a large amount of ethanol to the eluate. The product was recrystallized from a minimum quantity of water by adding a small amount of ethanol and washed with ethanol and then acetone, and dried in a vacuum desiccator over $CaCl_2$. Found for C-1: C, 28.09; H, 4.79; N, 7.34%. Calcd for [Co(aeta)(L-met)]Cl=$C_9H_{18}N_2S_2O_4ClCo$: C, 28.69; H, 4.82; N, 7.44%. Found for C-2: C, 27.69; H, 4.76; N, 7.09%. Calcd for [Co(aeta)(L-met)]Cl·0.5H_2O·1/10 KCl=$C_9H_{19}N_2S_2O_{4.5}ClCo$·1/10 KCl: C, 27.49; H, 4.87; N, 7.12%. Found for C-3: C, 25.79; H, 5.30; N, 6.54%. Calcd for [Co(aeta)(L-met)]Cl·2H_2O·1/10 KCl=$C_9H_{22}N_2S_2O_6ClCo$·1/10 KCl: C, 25.72; H, 5.28; N, 6.67%. Found for C-4: C, 26.42; H, 5.35; N, 6.60%. Calcd for [Co(aeta)(L-met)]Cl·1.5H_2O·3/10 KCl=$C_9H_{21}N_2S_2O_{5.5}ClCo$·3/10 KCl: C, 25.37; H, 4.97; N, 6.57%. Found for C-6: C, 24.99; H, 4.94; N, 6.86%. Calcd for [Co(aeta)(L-met)]Cl·1.5H_2O·3/10 KCl=$C_9H_{21}N_2S_2O_{5.5}ClCo$·3/10 KCl: C, 25.37; H, 4.97; N, 6.57%. Found for C-7: C, 26.15; H, 5.36; N, 6.93%. Calcd for [Co(aeta)(L-met)]Cl·2H_2O=$C_9H_{22}N_2S_2O_6ClCo$: C, 26.19; H, 5.37; N, 6.79%.

[3-(2-Aminoethylthio)propionato](L-methioninato)cobalt(III) Chloride, [Co(aetp)(L-met)]Cl: The preparation and separation of isomers were carried out according to the method similar to that for the corresponding [Co(aeta)(L-met)]Cl complex, by use of Haetp·HBr·0.5H_2O[10] instead of Haeta·0.5HCl.

Nine colored bands were eluted. From the measurements of the electronic absorption and CD spectra, it was confirmed that the first eluate (brownish violet) is *tr.tr.*-[Co(aetp)$_2$]$^+$, the third one (purple) *trans(S)*-[Co(L-met)$_2$]$^+$,[8] the fourth one (purple) *trans(O)*-[Co(aetp)$_2$]$^+$, and the sixth one (brownish red) *trans(N)*-[Co(aetp)$_2$]$^+$.[1] Thus, the second eluate (dark violet, D-1), the fifth one (purple, D-2), the seventh one (reddish purple, D-3+D-4), the eighth one (purple, D-5), and the ninth one (red, D-6) were the desired isomers. These eluates were concentrated separately in a vacuum evaporator, and then the deposit, NaCl, was filtered off.

Each concentrated filtrate was again poured into a column containing SP-Sephadex C-25 (K^+ form, 4.5×120 cm). The adsorbed band was eluted with 0.05 M aqueous solution of $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ at the rate of about 0.5 cm^3/min. For the column of the seventh eluate, three bands, a brownish red one (D-3), a purple one which was *trans(O)*-[Co(L-met)$_2$]$^+$,[8] and a red one (D-4), were eluted in this order. For the other columns there was apparently a single band. However, careful CD measurements showed that D-4 and D-6 bands consist of two bands, which were designated as D-4a and D-4b for D-4 eluate, and D-6a and D-6b for D-6 one according to the elution order though the separation of the latter two isomers was insufficient. The desired eluate was concentrated in a vacuum evaporator and the deposit, $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$, was filtered off, and then converted into the chloride salt by using an anion exchange resin (Dowex 1x8, Cl^- form). To the eluate a large amount of ethanol and acetone was added. The product was recrystallized from a minimum quantity of water by adding ethanol and acetone, and washed with acetone and then diethyl ether, and dried in a vacuum desiccator over $CaCl_2$. The isomers obtained were contaminated with a small amount of potassium chloride or sodium chloride, because of the relatively lower yields of isomers as compared with those of [Co(L-met)$_2$]$^+$ and [Co(aetp)$_2$]$^+$ complexes. The CD spectra of D-4a, D-4b, D-6a, and D-6b isomers were measured with the eluates, and their concentrations were calculated from the optical densities referring to that of the mixture, D-4 or D-6. Found for D-1: C, 23.88; H, 4.72; N, 5.49%. Calcd for [Co(aetp)(L-met)]Cl·2H_2O·1.4NaCl=$C_{10}H_{24}N_2S_2O_6ClCo$·1.4NaCl: C, 23.61; H, 4.76; N, 5.51%. Found for D-2: C, 27.76; H, 5.36; N, 6.47%. Calcd for [Co(aetp)(L-met)]Cl·2H_2O·1/5KCl=$C_{10}H_{24}N_2S_2O_6ClCo$·1/5KCl: C, 27.19; H, 5.48; N, 6.34%. Found for D-3: C, 29.38; H, 5.12; N, 6.84%. Calcd for [Co(aetp)(L-met)]Cl·0.5H_2O·0.13KCl=$C_{10}H_{21}N_2S_2O_{4.5}ClCo$·0.13KCl: C, 29.33; H, 5.17; N, 6.84%. Found for D-4 (=mixture of D-4a and D-4b): C, 27.68; H, 5.61; N, 5.89%. Calcd for [Co(aetp)(L-met)]Cl·1.5H_2O·CH_3OH·2/5KCl=$C_{10}H_{23}N_2S_2O_{5.5}ClCo$·$CH_3OH$·2/5KCl: C, 27.54; H, 5.67; N, 5.84%. Found for D-5: C, 28.01; H, 5.08; N, 6.56%. Calcd for [Co(aetp)(L-met)]Cl·H_2O·3/10NaCl=$C_{10}H_{22}N_2S_2O_5ClCo$·3/10NaCl: C, 28.17; H, 5.20; N, 6.57%. Found for D-6 (=mixture of D-6a and D-6b): C, 26.17; H, 5.23; N, 6.13%. Calcd for [Co(aetp)(L-met)]Cl·2H_2O·2/5KCl=$C_{10}H_{24}N_2S_2O_6ClCo$·2/5KCl: C, 26.30; H, 5.30; N, 6.13%.

Measurements. The electronic absorption spectra were measured on a Shimadzu UV-200 spectrophotometer in aqueous solution. The CD spectra were recorded with a JASCO MOE-1 spectropolarimeter. The ^1H NMR spectra were measured in deuterium oxide on a Varian XL-100-15 spectrometer with DSS as the internal reference. All measurements were made at room temperature.

Results and Discussion

Absorption Spectra and Structural Assignments. In the [Co(aeta)(L-met)]$^+$ complex, seven isomers were obtained. Their absorption spectra, are shown in Fig. 2

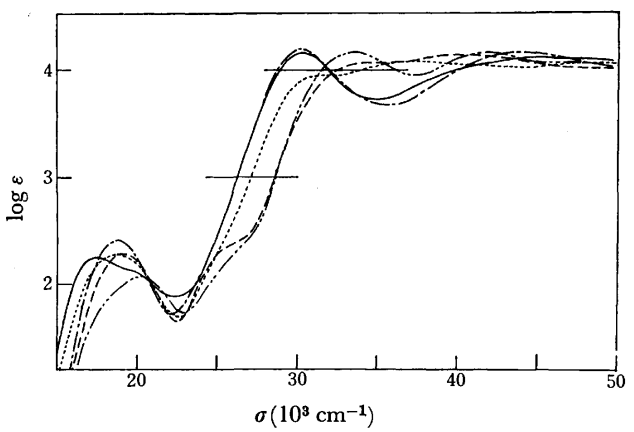

Fig. 2. Absorption spectra of the isomers of [Co(aeta)(L-met)]Cl: C-1 (——), C-2 (– – – –), C-3 (— — —), C-6 (——), and C-7 (- - - -); the spectra of C-4 and C-5 isomers are similar to those of C-2 and C-6 ones, respectively.

Table 1. Absorption data of isomers of [Co(aeta)(L-met)]Cl and [Co(aetp)(L-met)]Cl

Isomer	Assignment	σ_{max}[a] (log ε) First d-d band	Second d-d band	Charge transfer band region

a) The wave numbers are given in 10^3 cm^{-1} unit. b) A shoulder. c) The wave number cannot be determined.

and Table 1. The spectral behavior of the present isomers is very similar to that of $[Co(aeta)_2]^+$, and this is due to the fact that both complexes have the same chromophore $[Co(N)_2(O)_2(S)_2]$. Furthermore both complexes have the geometrical isomers of the same types. Therefore, the interpretation of the electronic absorption spectra described in the previous paper[1] could be applied for the present isomers in the same manner.

Of seven isomers, the long wavelength thioether charge transfer bands for C-1 (30300 cm^{-1}, log ε=4.16) and C-3 (30300 cm^{-1}, log ε=4.18) locate at lower energy side than those for the other five isomers. This indicates that the former two isomers have two ligating sulfur atoms in *trans* positions and the latter five in *cis* positions. The isomers C-1 shows a broad first absorption band with a shoulder at high energy side, while C-3 shows a sharp peak. Therefore, C-1 and C-3 can be assigned to *tr.tr.tr.* and *trans(S)* structures, respectively.

On the other hand, of the latter five isomers, C-2 and C-4 show a shoulder at low energy side of the major peak at 20200 and 19900 cm^{-1}, respectively, and C-7 shows a band at 18800 cm^{-1} with a vague shoulder at high energy side, while C-5 and C-6 apparently a sharp peak at 19100 and 19200 cm^{-1}, respectively. From these absorption patterns it was affirmed that C-2 and C-4 isomers are *trans(N)*, C-5 and C-6 *cisciscis*, and C-7 *trans(O)*. As shown in Fig. 1, there exists the only one geometrical isomer for the *trans(N)* geometry. Accordingly, C-2 and C-4 isomers with *trans(N)* structure should be diastereomers due to the sulfur atom chirality (*R*) or (*S*) of the coordinated L-methioninate. For the *cisciscis* form, two geometrical isomers, *cisciscis-I* and *cisciscis-II*, are expected, but it is impossible to decide the configuration of C-5 and C-6 isomers from their electronic absorption spectra. In order to achieve the assignments, NMR spectra of C-5 and C-6 isomers were measured in D_2O by adding a small amount of DCl; the spectra are entirely similar to each other all over the measured region. Furthermore, in the region of amine protons, there are four peaks at 6.35, 5.85, 5.18, and 4.48 ppm from DSS for both isomers. These results indicate that both isomers have either *cisciscis-I* or *cisciscis-II* structure. The C-5 and C-6 isomers, therefore, are diastereomers due to the sulfur atom chirality (*R*) or (*S*) of the coordinated L-methioninate. Referring to the characterization of *cisciscis-I* and *cisciscis-II* isomers for the $[Co(aetp)(L\text{-met})]^+$ complex, which will be described below, the C-5 and C-6 isomers are assigned finally to have the *cisciscis-I* structure (see Figs. 1 (e) and (f)).

In the $[Co(aetp)(L\text{-met})]^+$ complex, eight isomers were obtained chromatographically and their absorption spectra are shown in Fig. 3 and Table 1. These isomers can be assigned in the same manner described above; D-1 is *tr.tr.tr.*, D-2 *trans(S)*, D-3 *trans(N)*, D-4a and D-4b *cisciscis*, D-5 *trans(O)*, and D-6a and D-6b *cisciscis*. It is reasonable from their chromatographic behavior to consider that D-4a and D-4b (or D-6a and D-6b) have the same geometrical structure.

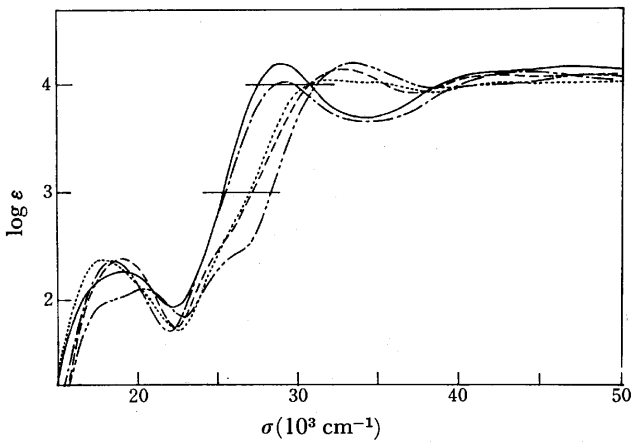

Fig. 3. Absorption spectra of the isomers of [Co(aetp)-(L-met)]Cl: D-1 (——), D-2 (– – –), D-3 (— — —), D-4a (——), and D-5 (----); the spectra of D-4b, D-6a, and D-6b isomers are similar to that of D-4a one.

The assignment of *cisciscis-I* and *cisciscis-II* was made on the basis of ^{1}H NMR spectra. D-4 complex which is a mixture of D-4a and D-4b isomers, showed a methine signal at 3.91 ppm from DSS, and D-6 one which is a mixture of D-6a and D-6b, showed at 3.45 ppm. This very large difference of the chemical shift between D-4 and D-6 isomers is explained on the basis of C–O deshielding effect[11] as follows; in the *cisciscis-I* structure, the methine proton is located just above a line drawn down the C–O bond of the other ligand and will be deshielded by the anisotropy associated with the C–O bond, while in the *cisciscis-II* form, this effect does not occur. From these reasons, D-4 and D-6 isomers can be assigned to the *cisciscis-I* and *cisciscis-II* structures, respectively. In addition, in the region of the amine protons, D-4 isomer showed three peaks at 4.31, 5.03, and 6.19 ppm, whereas D-6 isomer one peak at 5.97 ppm from DSS. Since the *cisciscis-I* structure has each of two amine groups in the deshielded and shielded positions and the *cisciscis-II* one has two amine groups in the shielded positions, it is also expected that D-4 isomer is *cisciscis-I* and D-6 one *cisciscis-II*. The similar consideration was applied for the assignment of *cisciscis-I* structure of the C-5 and C-6 isomers of [Co(aeta)(L-met)]$^+$. Thus, four diastereomeric pairs, C-2 and C-4, C-5 and C-6, D-4a and D-4b, and D-6a and D-6b, are discovered, which are arising from the chiral sulfur donor atom of the coordinated L-methioninate.

The structural assignments described above were able to be made mainly on the basis of electronic absorption spectra. This indicates that the absorption spectral behavior in the mixed type complexes is similar on the whole to that of the bis(terdentate-*N,S,O*) type complexes. However, there appear some interesting differences in details. Firstly, two *trans(N)* isomers of $[Co(aeta)_2]^+$ and $[Co(aetp)_2]^+$ show no splitting in the first absorption band region, but four *trans(N)* isomers of the present mixed type complexes and of the $[Co(L\text{-met})_2]^+$ complex exhibit an explicit shoulder at low energy side of the major peak. Two bis(terdentate) type *trans(O)* isomers show more explicit shoulder at high energy side of the major peak than the *trans(O)* isomers of the mixed type and $[Co(L\text{-met})_2]^+$ complex. These differences indicate that the sulfur atom in the linear terdentate-*N,S,O* ligands has a strong ligand field strength than that in L-methioninate. Secondly, the thioether charge transfer band positions of the mixed type *trans(O)* isomers apparently differ from those of the bis type *trans(O)* isomers: 31300 cm^{-1} for [Co(aeta)(L-met)]$^+$ (C-7); 31900 cm^{-1} for [Co(aetp)(L-met)]$^+$ (D-5); 35100 cm^{-1} for $[Co(aeta)_2]^+$; 34200 cm^{-1} for $[Co(aetp)_2]^+$. The present mixed complexes have two kinds of sulfur atoms, one in the ligand aeta$^-$ or aetp$^-$ and the other in L-met$^-$. The *trans(O)* isomer of $[Co(L\text{-met})_2]^+$ shows the thioether charge transfer band at 32700 cm^{-1}, a considerably lower energy position than that of $[Co(aeta)_2]^+$ or $[Co(aetp)_2]^+$. Therefore, the thioether charge transfer bands due to two kinds of sulfur atoms appear separately in this case. In fact, C-7 isomer shows another intense band at 37500 cm^{-1} and D-5 one at 34500 cm^{-1} (sh), which correspond roughly to the positions of the bis type complexes.

CD Spectra. CD spectra of fifteen mixed type complexes are shown in Figs. 4—9 and Table 2. The CD patterns hardly change with the substitution of the aetp ligand for the aeta one, especially in the first absorption band region. This suggests that the difference in size of the *S*-carboxylate chelate ring has not large effect on the CD spectra as in the case of the bis(terdentate-*N,S,O*) type complexes.[1] In contrast to this, drastic changes were reported for the cobalt(III) complexes of bis(terdentate-*O,N,O*) type.[12]

The *tr.tr.tr.* isomers show two CD bands in the first absorption band region; the low energy band has a positive sign and the high energy negative (Fig. 4). This is good agreement with the fact that both isomers have *Λ* configurations[13] according to the ring pairing method.[14]

a) The wave numbers are given in $10^3\,cm^{-1}$ unit. b) A shoulder. c) CD spectra were measured for the eluates.

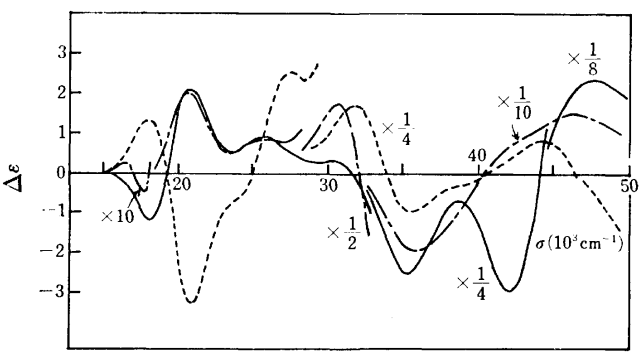

Fig. 7. CD spectra of *trans(N)* complexes: [Co(aeta)-(L-met)]Cl, C-2 (——) and C-4 (----); [Co(aetp)-(L-met)]Cl (——).

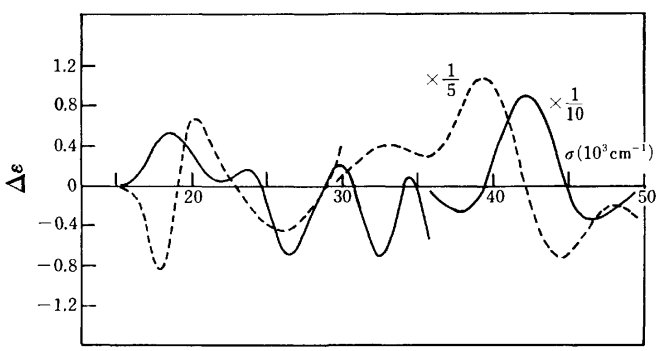

Fig. 8. CD spectra of *cisciscis-I*-[Co(aeta)(L-met)]Cl, C-5 (——) and C-6 (----).

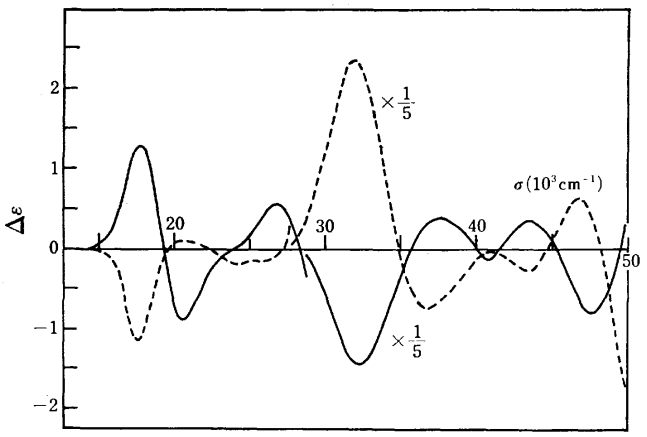

Fig. 9. CD spectra of *cisciscis-I*-[Co(aetp)(L-met)]$^+$, D-4a (——) and D-4b (----).

The two *trans(S)* isomers (Fig. 5) exhibit the same pattern as that of the *tr.tr.tr.* isomers in the first absorption band region. Since both *trans(S)* isomers also have *A* absolute configuration but the $^1A \rightarrow {}^1A + {}^1B_b(C_2)$ transition should be in higher energy for this geometry, this result indicates that CD spectral pattern cannot be always related to the ring pairing method for the complexes containing L-methioninate. A similar case has been reported for another system.[15]

Both *trans(O)* isomers exhibit a major positive CD band at high energy side, though a weak positive or negative band occurs in low energy (Fig. 6). This may suggest that the high energy positive band represents a composite transition $^1A \rightarrow {}^1B_a + {}^1B_b(C_2)$. However, these mixed *trans(O)* isomers have formally no configurational chirality according to the ring pairing method. Thus it may be more reasonable to consider that the CD contributions due to the chiral sulfur donor atoms become dominant.

For the *trans(N)* isomers, this viewpoint becomes more important; two *trans(N)* isomers of the aeta complex, C-2 and C-4, exhibit completely enantiomeric CD patterns in the first absorption band region (Fig. 7), which can be attributed mainly to the enantiomeric configurations of chiral sulfur atom of the coordinated L-methioninate. In the case of the aetp complex, the only one *trans(N)* isomer was obtained. Its CD spectral pattern is similar to that of C-2 isomer and its structure is considered to be same as that of C-2. The D-4a *cisciscis-I* isomer shows the CD spectrum almost enantiomeric to the D-4b *cisciscis-I* isomer (Fig. 9).

Of the fifteen mixed type complexes, eight ones which are classified into diastereomeric pairs, C-2 and C-4, C-5 and C-6, D-4a and D-4b, and D-6a and D-6b, have of course a definite configuration, (*R*) or (*S*), with respect to the chiral sulfur donor atom of L-methioninate. Furthermore, the remaining five isomers except two *tr.tr.tr.* ones take also a definite configuration of the chiral sulfur atom of L-methioninate on the basis of the following reasons; firstly, all fractions of each isomer on the chromatographic separation shows the same CD spectra. Secondly, ^1H NMR spectra of these isomers showed a single peak in the *S*-methyl proton region (Fig. 10). Thirdly, corresponding geometrical isomers of the mixed aeta and aetp complexes show very similar CD spectra, and stereomodel examination reveals that the isomers except *tr.tr.tr.* one prefer (*S*) configuration, since the S-CH_3 group in (*R*) configuration interacts with the chelate ring of the other ligand.

For the present mixed type complexes, there are two kinds of chiral sulfur atoms, one in the ligand aeta$^-$ or aetp$^-$, and the other in L-met$^-$. Therefore, the CD signs in the thioether charge transfer band region cannot

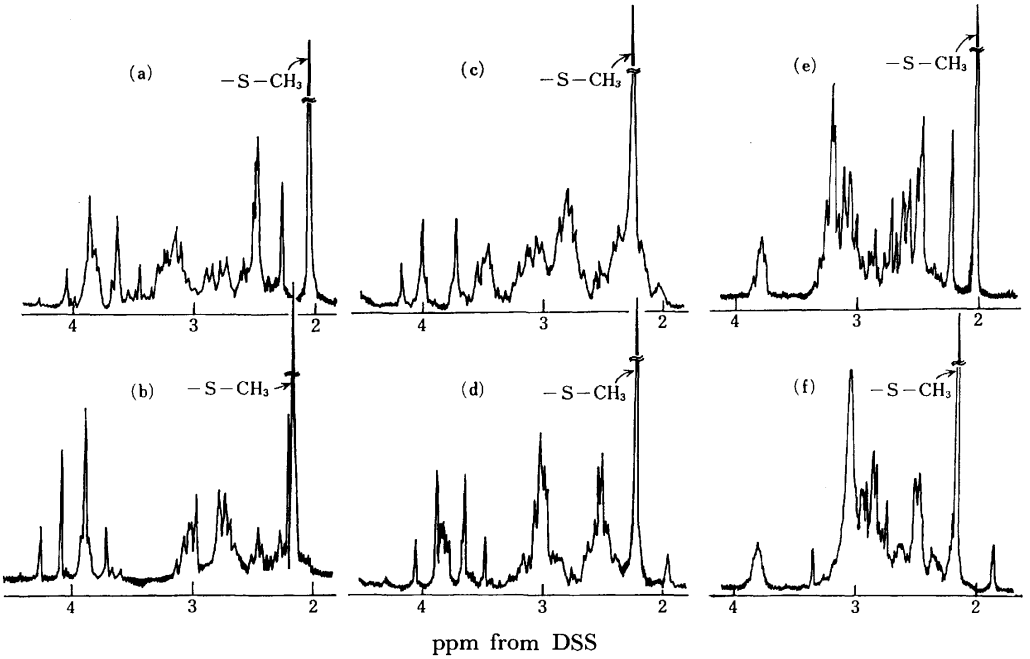

Fig. 10. The ^1H NMR spectra of the isomers of [Co(aeta)(L-met)]Cl, [(a) *trans(N)*=C-2, (b) *trans(N)*=C-4, (c) *trans(S)*, and (d) *trans(O)*] and [Co(aetp)(L-met)]Cl [(e) *trans(N)* and (f) *trans(O)*].

be simply related to the absolute configurations. However, some correlations are found for the *trans*(*S*) and *trans*(*N*) isomers. Namely, both *trans*(*S*) isomers show two CD bands, (+) and (−) from low energy side, and both *trans*(*N*) isomers (C-2 and D-3) also two CD bands of opposite signs (Table 2).

CD Contribution due to the Chiral Sulfur Donor Atom. In order to estimate the vicinal CD contribution of the chiral sulfur donor atom of L-methioninate, an additivity rule was applied to the CD spectra of the diastereomeric pairs C-2 and C-4, C-5 and C-6, and D-4a and D-4b isomers; the chiral sulfur contribution can be obtained by subtracting the observed CD of one isomer from that of the counterpart, while the overall CD contribution due to the remaining factors such as the chiral carbon atom of L-methininate and the chiral sulfur atom of the terdentate-*N,S,O* ligand and/or the configurational chirality due to the skew pair of chelate rings can be obtained by summing up the two observed CD curves. The calculated CD curves are shown in Figs. 11—13.

In the case of *trans*(*N*)-[Co(aeta)(L-met)]$^+$ (Fig. 11), the CD contribution of the chiral sulfur donor atom of L-methioninate is very large in the first absorption band region ($\Delta\varepsilon=-1.24$ at 18000 cm^{-1} and $\Delta\varepsilon=+2.72$ at 20700 cm^{-1}). Similarly, for the *cisciscis-I*-[Co(aeta)-(L-met)]$^+$ and -[Co(aetp)(L-met)]$^+$ complexes (Figs. 12 and 13), their L-methioninate sulfur vicinal CD are

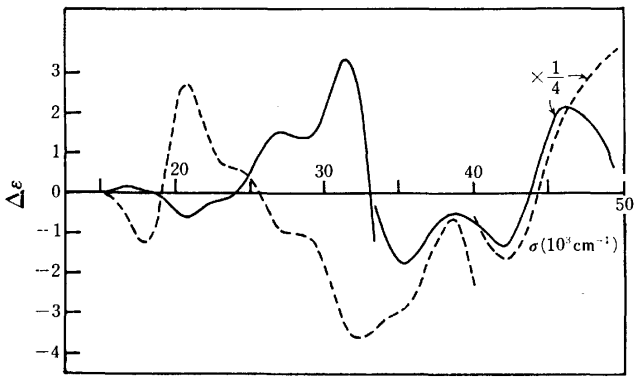

Fig. 11. Curve analysis of *trans(N)*-[Co(aeta)(L-met)]Cl complexes: $1/2\times\{\Delta\varepsilon(\text{C-2})+\Delta\varepsilon(\text{C-4})\}$ (——) and $1/2\times\{\Delta\varepsilon(\text{C-2})-\Delta\varepsilon(\text{C-4})\}$ (----).

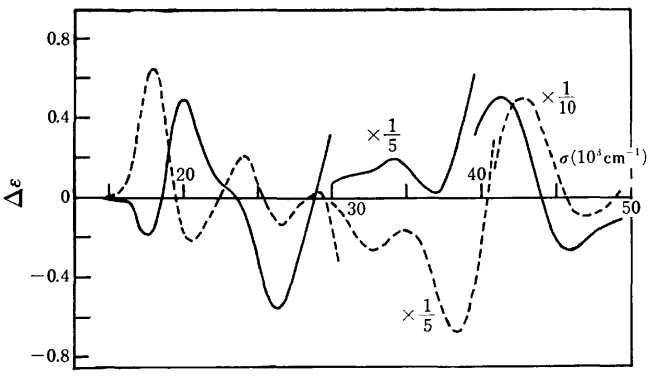

Fig. 12. Curve analysis of *cisciscis-I*-[Co(aeta)(L-met)]Cl complexes: $1/2\times\{\Delta\varepsilon(\text{C-5})+\Delta\varepsilon(\text{C-6})\}$ (——) and $1/2\times\{\Delta\varepsilon(\text{C-5})-\Delta\varepsilon(\text{C-6})\}$ (----).

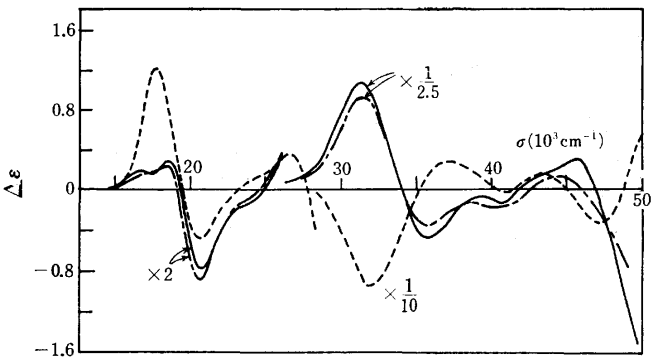

Fig. 13. Curve analysis of *cisciscis-I*-[Co(aetp)(L-met)]$^+$ complexes: $1/2\times\{\Delta\varepsilon(\text{D-4a})+\Delta\varepsilon(\text{D-4b})\}$ (——), $1/2\times\{\Delta\varepsilon(\text{D-4a})-\Delta\varepsilon(\text{D-4b})\}$ (----), and D-4 mixture of diastereomers (———).

dominant in the first absorption band region. It is interesting to note that the observed CD curve of the D-4 mixture is very similar to the calculated contribution of chiralities other than the sulfur atom chirality of L-methioninate. This indicates that the D-4 complex is composed of equal amounts of D-4a and D-4b isomers.

In conclusion, the sulfur chirality of the coordinated L-methioninate has large vicinal CD contribution even in the first absorption band region. In this respect, there are some differences between the chiral sulfur and nitrogen[3] donor atoms. Therefore, care must be taken in relating the CD spectra to the absolute configurations of the complexes containing L-methioninate ligand.

Cobalt(III) Complexes Containing Large Chelate Rings. II.[1] Syntheses and Properties of Cobalt(III)–Ammine Complexes Containing α,ω-Alkanediamines

Hiroshi OGINO

Departemnt of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received March 17, 1977)

Reactions of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with $H_2N(CH_2)_nNH_2$ (N–N) in dimethyl sulfoxide were examined by changing the number of methylene groups in N–N (n=2—5, 7, 8, 10, 12, and 14). Complexes of the $Co(NH_3)_4$-(N–N)$^{3+}$ type were found to be formed for n=2—4, 12, and 14, but, not for n=5, 7, 8, and 10. In addition to these products, a number of new cobalt(III) complexes were isolated.

In the previous paper, a number of new cobalt(III) complexes were isolated as products of the reactions of $[CoCl_2(en)_2]Cl$ with α,ω-alkanediamines $H_2N(CH_2)_n$-NH_2 (N–N) in dimethyl sulfoxide (DMSO), where en denotes 1,2-ethanediamine.[1] Among them, complexes of the $[Co(en)_2(N–N)]X_3$ and $[Co_2(en)_4(N–N)_2]$-X_6 types which contain large chelate rings were found.

Recently, $[Co(NH_3)_{6-2p}(en)_p]X_3$ (p=0, 1, 2, and 3) and $[Co(NH_3)_5(enH)]X_4$ were isolated as products of the reaction of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with en in DMSO.[2] It seemed that it would be interesting and worthwhile to know, when this reaction is applied to various diamines, what kinds of products are formed. If a diamine with a long methylenic chan is used, the formation of the complexes containing large chelate rings might be expected. In this paper, the products of the reactions of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with α,ω-alkanediamines (N–N) in DMSO are examined. The diamines, $H_2N(CH_2)_nNH_2$, used in this work are n= 2 (en), 3 (tn), 4 (tmd), 5 (pmd), 7 (hepn), 8 (ocn), 10 (den), 12 (don), and 14 (tden).

Several attempts have been made to prepare cobalt(III) complexes in non-aqueous solvents.[3] The results indicate that the non-aqueous solvents are useful for obtaining novel cobalt(III) complexes. The present study will also help to understand the features of the reactions of cobalt(III) complexes in such a solvent.

Experimental

Preparation of Cobalt(III) Complexes. All the cobalt(III) complexes were obtained from the products of the reactions of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with N–N in DMSO. The species formed in the reactions were separated by the use of an SP-Sephadex C-25 column (ϕ5×40 cm). Usually, KBr solutions were used as the eluents. In order to isolate the products, each eluate was concentrated to a small volume by means of a rotary evaporator.

When it was difficult to obtain bromide salt because of its high solubility, the eluate was diluted with water and then poured into another SP-Sephadex column. The adsorbed species was then eluted with an appropriate eluent, *e.g.*, a HCl, $LiClO_4$, or NaI solution. When a $LiClO_4$ solution was used as the eluent, the column was washed first with a dilute HCl solution to remove potassium ions; otherwise, the deposition of insoluble $KClO_4$ crystals in the column was unavoidable. The eluate was then concentrated again. The addition of ethanol or ethanol–ether to the resulting solution was often necessary to ensure crystallization.

The elution of highly charged species with KBr solutions sometimes caused a crystallization of the bromide salt in the column. In such a case, the eluent was changed to a sodium acetate–acetic acid solution and the eluate was concentrated. Then, the bromide salt was obtained by the addition of an HBr solution to the concentrated eluate.

The analytical data for the complexes prepared in this work are summarized in Table 1.

1) Products of the Reaction of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with en. To 100 ml of a DMSO solution containing 9.2 g of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ (0.02 mol) were added 1.2 g of en (0.02 mol). The solution was kept at 85 °C for 20 min. The resulting deep yellowish orange solution was neutralized with concd HCl and diluted to 1.5 l with water. This was poured into a Sephadex column, and then the column was washed with water. When the adsorbed bands were developed with NaBr solutions, the column showed three bands; reddish orange (a trace amount), yellow, and yellowish orange, in the order of elution. The first and second species were eluted with a 0.25 M NaBr solution. The first reddish orange species was found to be $Co(H_2O)(NH_3)_5^{3+}$. When the second yellow eluate was concentrated, crystals of $[Co(NH_3)_6]Br_3$ appeared; they were filtered off, and the filtrate was diluted with water and then poured into a Sephadex column. The adsorbed species were eluted with a 0.08 M Na_3PO_4 solution. The single band was progressively separated into three bands. The eluates were labeled F1, F2, and F3, in the order of elution. Each eluate was neutralized with a HCl solution and poured into a Sephadex column. The F1 species was eluted with a 0.3 M HCl solution. The concentration of the eluate gave yellow crystals, which were characterized as $[Co(en)_3]Cl_3 \cdot 3H_2O$ by the measurements of the infrared, electronic, and PMR spectra. The F2 and F3 species were eluted out with 0.5 M KI solutions. The concentration of these eluates gave *cis*-$[Co(NH_3)_2(en)_2]I_3$ and $[Co(NH_3)_4(en)]I_3$ respectively. The *cis* configuration of $[Co(NH_3)_2(en)_2]I_3$ was confirmed by the measurement of the PMR spectrum.

The last yellowish orange species was eluted with a 0.7 M NaBr solution. When the eluate was concentrated with a rotary evaporator, yellowish orange crystals of $[Co(NH_3)_5$-$(enH)]Br_4$ were obtained. Yield: 0.6 g.

The yield of the products was found to be in the order: $Co(NH_3)_6^{3+} > Co(NH_3)_4(en)^{3+} > Co(NH_3)_2(en)_2^{3+} > Co$-$(NH_3)_5(enH)^{4+} > Co(en)_3^{3+}$

When a mixture of 0.6 g of en (0.01 mol) and 2.6 g of $en \cdot 2HClO_4$ (0.01 mol) was used in place of 1.2 g of en, 0.8 g of $[Co(NH_3)_5(enH)]Br_4$ was obtained. The other products were found to be $[Co(NH_3)_{6-2p}(en)_p]Br_3$ (p=0—3).

When 100 ml of a DMSO solution containing 6.8 g of $[Co$-$(NH_3)_6](ClO_4)_3$ and 0.9 g of en was kept at 90 °C for 10 min, 30 mg of $[Co(NH_3)_5(enH)]Br_4$ was obtained from the reaction products.

2) $[Co(NH_3)_5(en)]Br_3$. Crystals of $[Co(NH_3)_5(enH)]$-Br_4 (0.2 g) were dissolved into 4 ml of 1.5 M aqueous ammonia. Solid NaBr was added to the solution until a small amount

Table 1. Summary of analytical data for the complexes prepared in this work

Complex	C, %		H, %		N, %

a) This sample was isolated from the products of the reaction of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with en in DMSO.
b) The analytical results were not improved by repeated crystallizations. The salt might contain a small amount of $[(NH_3)_4Co(N\text{-}N)_2Co(NH_3)_4]Br_6$.

of crystals of $[Co(NH_3)_5(en)]Br_3$ appeared. Ethanol and then ether were added to insure the crystallization.

3) Products of the Reaction of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with tn, tmd, pmd, hepn, ocn, den, don, or tden. To a DMSO solution containing $[Co(H_2O)(NH_3)_5](ClO_4)_3$ were added the title N–N. The solution was then treated with the way described in 1). The species adsorbed on a Sephadex column were eluted with KBr solutions.

a) Products of the Reaction with tn: To 100 ml of a DMSO solution containing 9.2 g of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ (0.02 mol) were added 1.5 g of tn (0.02 mol). Four bands were observed on a Sephadex column. The lowest reddish orange species was found to be a small amount of $Co(H_2O)(NH_3)_5^{3+}$. The upper three bands were of yellowish orange colors. The eluates were labeled F1, F2, and F3 in the order of elution. F1 was found to contain a mixture of $Co(NH_3)_{6-2p}(tn)_p^{3+}$ (p=0, 1, 2, and 3). The concentration of the eluate yielded crystals of $[Co(NH_3)_6]Br_3$. The filtrate was diluted, and then the solution was poured into a Sephadex column. After the column had been washed with dil HCl, the adsorbed species were eluted out with a 0.5 M $LiClO_4$ solution. The concentration of the solution gave crystals of $[Co(NH_3)_{6-2p}(tn)_p](ClO_4)_3$ (p=1, 2, and 3). The separation of $[Co(NH_3)_4(tn)](ClO_4)_3$, $[Co(NH_3)_2(tn)_2](ClO_4)_3$, and $[Co(tn)_3](ClO_4)_3 \cdot H_2O$ was achieved by fractional crystallization. From F2, crystals of $[Co(NH_3)_5(tnH)]Br_4$ were obtained. The concentration of F3 gave orange crystals which were considered to contain $[(NH_3)_5Co(tn)Co(NH_3)_5]Br_6$ as the main component

(see Table 1).

b) Products of the Reaction with tmd: To 100 ml of a DMSO solution containing 9.2 g of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ (0.02 mol) were added 1.8 g of tmd (0.02 mol). The Sephadex column showed six bands. The lowest species was found to be a small amount of Co^{2+}. Then, the band of a small amount of $Co(H_2O)(NH_3)_5^{3+}$ followed. The eluates of the other four bands were labeled F1, F2, F3, and F4 in the oder of elution. The concentration of F1 gave $[Co(NH_3)_6]Br_3$. The filtrate contained $Co(NH_3)_4(tmd)^{3+}$, which could be crystallized as the perchlorate salt. When F2 was concentrated, crystals of $[Co(NH_3)_5(tmdH)]Br_4$ were obtained. The KBr medium in F3 was replaced by $LiClO_4$ with the aid of a Sephadex column. Upon the evaporation of the solution, crystals of $[Co(NH_3)_4(tmdH)_2](ClO_4)_5$ were precipitated. The concentration of F4 gave yellowish orange crystals, which were considered to consist of $[(NH_3)_5Co(tmd)Co(NH_3)_5]Br_6$ and a small amount of $[(NH_3)_4Co(tmd)_2Co(NH_3)_4]Br_6$ (see Table 1).

c) Products of the Reaction with den: To 750 ml of a DMSO solution containing 9.2 g of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ (0.02 mol) were added 3.4 g of den (0.02 mol). The Sephadex column showed the presence of a small amount of Co^{2+}, $Co(H_2O)(NH_3)_5^{3+}$, and many yellow-to-orange species. From the fractions with yellow to orange colors, the following salts were obtained, in the order of elution (the yield (%), based on $[Co(H_2O)(NH_3)_5](ClO_4)_3$, is given in parentheses): $[Co(NH_3)_6]Br_3$ (25), $[Co(NH_3)_5(denH)]Br_4$ (26), $[Co(NH_3)_4(denH)_2]Br_5$ (9), $[Co(NH_3)_3(denH)_3]Cl_6\cdot 2H_2O$ (0.3),[4] $[(NH_3)_5Co(den)Co(NH_3)_5]Br_6\cdot 2H_2O$ (7),[5] and $[(NH_3)_4Co(den)_2Co(NH_3)_4]Br_6\cdot 3H_2O$ (9).[5]

Even after these species had been eluted out, several species remained in the column. These species could be crystallized as bromides. One of the species was found to be $[Co_2(NH_3)_8(den)(denH)_2]Br_8\cdot 2H_2O$. Yield: 3%.[5]

d) Products of the Reaction with don: To 700 ml of a DMSO solution containing 6.9 g of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ (0.015 mol) were added 3.0 g of don (0.015 mol). The Sephadex column showed many bands. Crystals of $[Co(NH_3)_6]Br_3$, $[Co(NH_3)_4(don)]Br_3$, $[Co(NH_3)_5(donH)]Br_4$, $[Co(NH_3)_4(donH)_2](ClO_4)_5$,[4] and $[(NH_3)_5Co(don)Co(NH_3)_5]Br_6$ were obtained, in that order of elution. Even after these species had been eluted out, several species remained in the column.

e) Products of the Reaction with pmd, hepn, ocn, or tden: To 1000 ml of a DMSO solution containing 4.6 g of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ (0.01 mol) were added 0.01 mol of N–N (1.0 g for pmd, 1.3 g for hepn, 1.4 g for ocn, and 2.3 g for tden). From the eluates, various complexes containing pmd, hepn, ocn, or tden, which are shown in Table 1, were isolated as crystals. $[Co(NH_3)_6]Br_3$ was also obtained, regardless of the kind of N–N used. No formation of $Co(NH_3)_4(N–N)^{3+}$ was observed for any of the diamines except the tden. The $[Co(NH_3)_4(tden)]^{3+}$ ions moved faster than $Co(NH_3)_5(tdenH)^{4+}$, but slower than $Co(NH_3)_6^{3+}$. The formation of more positively charged species than six was not observed in any of the diamines under the conditions employed.

Apparatus. The electronic spectra were recorded with a Union Giken SM-401 or a Hitachi EPS-3 recording spectrophotometer. The PMR spectra were recorded with a Varian A-60 spectrometer.

Results and Discussion

Product Distribution. The analytical results given in Table 1 are in good agreement with the formulas assigned to the products isolated in this work. All these products are yellow to yellowish orange in color; hence, they must be of the CoN_6 type (*vide infra*). This is also consistent with the assigned formulas. Furthermore, these complex ions show reasonable flow rates on Sephadex columns.[1]

A semi-quantitative determination of the product distribution of the reactions in question was also carried out; the results are shown in Table 2. Complex ions, $Co(NH_3)_6^{3+}$ and $Co(NH_3)_5(\underline{N}–NH)^{4+}$,[6] were always formed as the products, regardless of the kind of N–N. The pH titration of the solutions containing $Co(NH_3)_5(\underline{N}–NH)^{4+}$ with standard NaOH solutions reveals that the complex ions are mono-basic acid. The value of pK increases with the increase in the number of methylene groups in the N–N.[7]

Table 2 shows that the change in the concentration of the reactants affects the product distribution considerably. The formation of highly charged species becomes significant with the increase in the concentration of the reactants. This is a trend similar to that found in the reactions of $[CoCl_2(en)_2]Cl$ with N–N in DMSO.[1]

Table 2. Product distribution of the reactions of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with N–N in DMSO[a]

	N–N used	en	tn[b,c]	tn	tmd[b,d]	tmd	pmd	hepn	ocn	den[e]	don[e]	tden

a) The reactants were allowed to react at 85 °C for 20 min, unless otherwise stated. The numerical values given in this table denote the yield (%) based on $[Co(H_2O)(NH_3)_5](ClO_4)_3$. The f symbol denotes that the product indicated is formed. b) The reactants were allowed to react at 92 °C for 20 min. c) The recovered $Co(H_2O)(NH_3)_5^{3+}$ amounted to 8% of the initial $Co(H_2O)(NH_3)_5^{3+}$. d) The recovered $Co(H_2O)(NH_3)_5^{3+}$ amounted to 14% of the initial $Co(H_2O)(NH_3)_5^{3+}$. e) The species with charges higher than 6+ were formed in considerable amounts. f) The product is not sufficiently pure (see Table 1). g) The product indicated is considered to be formed, but no pure sample has been isolated. h) The yield was calculated by means of the following relation: Yield = 2 × (mol of the indicated product) × 100/(mol of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ used as the starting material).

The formation of $Co(NH_3)_4(N-N)^{3+}$, which contains an N–N chelate ring, is observed for en, tn, tmd, don, or tden, but not for pmd, hepn, ocn, or den. These facts support the previous conclusion in which the medium-size chelate ring is unstable.[1)]

In the en and tn systems, $Co(NH_3)_2(N-N)_2^{3+}$ and $Co(N-N)_3^{3+}$ were formed, and the formation of complexes more positively charged than four was not significant. The yield of $Co(NH_3)_5(\underline{N}-NH)^{4+}$ was also low. However, when the diamines with more methylene groups than tn were used, the formation of appreciable amounts of $Co(NH_3)_5(\underline{N}-NH)^{4+}$ was observed. Furthermore, the formations of $Co(NH_3)_4(\underline{N}-NH)_2^{5+}$ and $(NH_3)_5Co(N-N)Co(NH_3)_5^{6+}$ were also significant. These tendencies become notable with the increase in the number of methylene groups, as is shown in Table 2. These facts indicate that, when the methylenic chain of N–N is long, the N–N tends to coordinate to a cobalt(III) ion as a unidentate ligand, or to two cobalt(III) ions as a bridging ligand, rather than as a chelate ligand. In the systems of the diamines higher than tn, Co^{2+} ions were always formed during the reactions in DMSO. Their amounts increased with the increase in the reaction time and with the elevation of the reaction temperature. In the en and tn systems, the formation of Co^{2+} ions was found to be negligible.

Mechanism of the Reaction of $[Co(H_2O)(NH_3)_5](ClO_4)_3$ with N–N in DMSO. When a DMSO solution containing $[Co(H_2O)(NH_3)_5](ClO_4)_3$ is heated, the aqua ligand in $Co(H_2O)(NH_3)_5^{3+}$ is known to be replaced by DMSO.[3g)] Here, it is assumed tentatively that the formation of $Co(DMSO)(NH_3)_5^{3+}$ occurs prior to the attack of $Co(H_2O)(NH_3)_5^{3+}$ by N–N; that is, the reaction occurs in the following sequence:

$$Co(H_2O)(NH_3)_5^{3+} + DMSO \longrightarrow Co(DMSO)(NH_3)_5^{3+} + H_2O, \quad (1)$$

$$Co(DMSO)(NH_3)_5^{3+} + N\text{–}N \longrightarrow Co(NH_3)_5(\underline{N}-N)^{3+} + DMSO. \quad (2)$$

Upon the acidification of the solution, the $Co(NH_3)_5(\underline{N}-N)^{3+}$ complex should be converted into $Co(NH_3)_5(\underline{N}-NH)^{4+}$. This explains the formation of $[Co(NH_3)_5(\underline{N}-NH)]X_4$.

As has been mentioned above, the product distributions of the en and tn systems are quite different from those for the higher N–N systems. The products indicate that the predominant reactions in the systems of en and tn can be expressed as follows:

$$Co(NH_3)_5(\underline{N}-N)^{3+} \rightarrow Co(NH_3)_4(N-N)^{3+} + NH_3, \quad (3)$$

$$Co(DMSO)(NH_3)_5^{3+} + NH_3 \rightarrow Co(NH_3)_6^{3+} + DMSO, \quad (4)$$

$$Co(NH_3)_4(N-N)^{3+} + N\text{–}N \rightarrow Co(NH_3)_2(N-N)_2^{3+} + 2NH_3, \quad (5)$$

$$Co(NH_3)_2(N-N)_2^{3+} + N\text{–}N \rightarrow Co(N-N)_3^{3+} + 2NH_3, \quad (6)$$

$$Co(NH_3)_6^{3+} + N\text{–}N \rightarrow Co(NH_3)_5(\underline{N}-N)^{3+} + NH_3. \quad (7)$$

Reaction 7 was comfirmed by the product survey of the direct reaction of $Co(NH_3)_6^{3+}$ with en in DMSO (see Experimental section). The occurrence of Reactions 3, 5, and 6 reveals that the successive substitution of the ammonia molecules from $Co(NH_3)_5(\underline{N}-N)^{3+}$ with en or tn molecules leads to the formation of $Co(NH_3)_{6-2p}(N-N)_p^{3+}$ containing the diamine chelate(s), where $1 \leq p \leq 3$. In the systems of the higher N–N's, however, Reactions 5 and 6 are absent. The successive substitution of ammonia molecules from $Co(NH_3)_5(\underline{N}-N)^{3+}$ with these N–N molecules leads to the formation of

a) From Ref. 8. b) From Ref. 1. c) From Ref. 10. d) From Ref. 3i. e) The sample is not pure (see Table 1). f) The intensities are given per complex ion, *i.e.*, per two cobalt(III) ions.

$Co(NH_3)_{6-p}(\underline{N}\text{–}N)_p^{3+}$:

$$Co(NH_3)_5(\underline{N}\text{–}N)^{3+} + (p-1)N\text{–}N \longrightarrow Co(NH_3)_{6-p}(\underline{N}\text{–}N)_p^{3+} + (p-1)NH_3, \quad (8)$$

where $p>1$. Upon the acidification of the solution, the $Co(NH_3)_{6-p}(\underline{N}\text{–}N)_p^{3+}$ complex should be converted into the highly charged $Co(NH_3)_{6-p}(\underline{N}\text{–}NH)_p^{(3+p)+}$ complex. This would explain the formation of $Co(NH_3)_4(\underline{N}\text{–}NH)_2^{5+}$ and $Co(NH_3)_3(denH)_3^{6+}$. Reaction 8 is absent in the systems of en and tn, This result and the occurrence of Reactions 3, 5, and 6 show the remarkable tendency for the en or tn to take the chelate form.

The formation of the dimeric complex can be expressed as:

$$Co(DMSO)(NH_3)_5^{3+} + Co(NH_3)_5(\underline{N}\text{–}N)^{3+} \longrightarrow (NH_3)_5Co(N\text{–}N)Co(NH_3)_5^{6+} + DMSO. \quad (9)$$

The amount of the dimer becomes appreciable with the increase in the number of methylene groups in the N–N. In the N–N with a long methylenic chain, a close approach between two positively charged cobalt(III) ions is not necessary. This would favor the formation of the dimer.

Spectral Properties of the Complexes. The numerical data for electronic absorption spectra of the complexes are summarized in Table 3. The positions of the first absorption bands of all the complexes prepared in this work are located around 21000 cm^{-1}. Therefore, it can be concluded that all the complexes have CoN_6 moieties. The increase in the number of en chelate(s) in $Co(NH_3)_{6-2p}(en)_p^{3+}$ causes shifts in the absorption maxima to shorter wavelengths,[9] while those of the other N–N chelate(s) shift to longer wavelengths. The absorption bands of $Co(NH_3)_4(N\text{–}N)^{3+}$ shift to longer wavelengths as the methylenic chain of the N–N becomes longer; hence, the ligand-field strength for N–N chelates is in this order: en>$(NH_3)_2$>tn>tmd≃don≃tden. The successive substitution of ammonia molecules in $Co(NH_3)_6^{3+}$ with monoprotonated diamines causes shifts in the absorption maxima to longer wavelengths. However, the absorption positions for $Co(NH_3)_5(\underline{N}\text{–}NH)^{4+}$ and $Co(NH_3)_4(\underline{N}\text{–}NH)_2^{5+}$ are almost independent of the kind of diamine. The absorption positions of the dimeric complexes are also insensitive to the kind of diamine.

The author wishes to thank Professor Nobuyuki Tanaka, Tohoku University, and Professor Junnosuke Fujita, Nagoya University, for their encouragement and support.

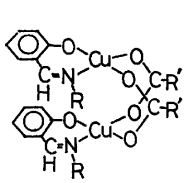
(Received May 23, 1977)

The crystal structure of di-μ-propionato-*O,O'*-bis[*N*-*p*-tolylsalicylideneaminatocopper(II)] was determined by X-ray diffraction method using the data collected by counter diffractometer techniques. The space group is $P\bar{1}$ and the cell constants are $a=12.565(2)$, $b=13.040(2)$, $c=12.230(2)$ Å, $\alpha=107.73(1)$, $\beta=115.72(1)$, $\gamma=100.18(1)°$, and $Z=2$. The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method to an R factor of 0.029. The crystal is composed of one-dimensional chains extended along the c axis, where the two copper atoms coordinated by the Schiff bases are bridged by two propionate groups. The magnetic property was discussed on the basis of the crystal structure.

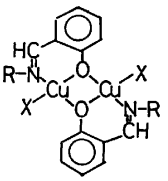
Recently, Tokii *et al.*[1] found that bis(*N*-R-salicylideneaminato)copper(II), Cu(Sal·*N*-R)$_2$ reacts with copper(II) carboxylates, Cu(R'COO)$_2$, to form a series of the complexes with the formula, [Cu(Sal·*N*-R)R'-COO], where R=phenyl and *p*-tolyl and R'=ethyl. These complexes show antiferromagnetic behavior and the temperature dependence of the magnetic susceptibility (80—300 K) is well expressed by the Bleaney-Bowers equation 1[2]

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1 + \frac{1}{3}\exp\left(\frac{-2J}{kT}\right)\right]^{-1} + N\alpha, \qquad (1)$$

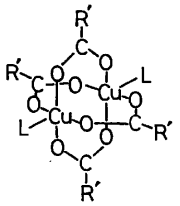
where $-2J$ is equal to the energy separation between the lowest singlet and triplet levels, which gives the degree of the magnetic interaction. By the best fit of the observed cryomagnetic data to Eq. 1, assuming $N\alpha=60\times10^{-6}$ emu/mol, they evaluated the values of $-2J=101$ cm^{-1} and $g=2.14$ for [Cu(Sal·*N*-*p*-tolyl)C$_2$H$_5$-COO]. On the basis of the magnetic properties and the IR spectral data, they concluded that the complexes possess the binuclear structure shown in **1**.[3]



1



2



3

Binuclear copper(II) complexes with monatomic bridges and with triatomic bridges as shown in **2** and **3** have been studied extensively. However, the binuclear structure consisting of only two triatomic bridges as shown in **1** is rare so far. Only one example of the copper complex of this structure has been reported.[4] Hence, in this study, the crystal structure of [Cu(Sal·*N*-*p*-tolyl)C$_2$H$_5$COO], was determined by the single-crystal X-ray diffraction method, in order to clarify the structure and to discuss the magnetic property in more detail in relation to the structure.

Experimental

Dark green crystals of the title complex were prepared according to Ref. 1. Most of the crystals were twins, and accordingly a crystal which had been confirmed to be a single-crystal by the Weissenberg photographs was used for the measurement of the cell parameters and intensities. Preliminary Weissenberg photographs revealed no systematic absences and showed the triclinic symmetry. The cell parameters and intensities were measured on a Syntex $P\bar{1}$ automated diffractometer with monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å). The crystal used was ground to a sphere of radius 0.225 mm. The cell parameters were determined by the least-squares refinement from 15 reflections within a range of $24<2\theta<35°$. The values are $a=12.565(2)$, $b=13.040(2)$, $c=12.230(2)$ Å, $\alpha=107.73(1)$, $\beta=115.72(1)$, $\gamma=100.18(1)°$, and $V=1604.3(4)$ Å^3. The density $D_m=1.43(1)$ g/cm^3 obtained by floatation in hexane-carbon tetrachloride solutions agrees well with the density $D_c=1.435$ g/cm^3 calculated for two dimer units per cell. Of the two possible triclinic space groups, the centrosymmetric space group $P\bar{1}$ was assumed on the basis of its more frequent occurrence. Successful solution and refinement in this space group support this choice.

Intensity data were collected by the θ-2θ scan technique with a variable scan rate of 4.0 to 24.0 °/min. Three standard reflections were monitored every 50 reflections, and their intensities showed a good stability. A total of 4154 independent reflections with $2\theta<45°$ were collected. 3421 reflections with I greater than $3\sigma(I)$ were considered as "observed" and were used for the structure analysis, where $\sigma(I)$ was calculated for each reflection on the basis of counting statistics. The Lorentz and polarization corrections were applied, but no absorption correction was made on account of $\mu r=0.33$.

Solution and Refinement of the Structure

The structure was solved by the heavy atom method. The positions of the copper atoms were obtained from a three-dimensional Patterson synthesis. Successive Fourier syntheses and difference Fourier syntheses revealed all the nonhydrogen atoms. Refinement was carried out by the block-diagonal least-squares method. In the course of refinement, it became apparent that the carbon atom C(6) of the ethyl group was subjected to disorder. A difference Fourier map revealed two largest chemically reasonable peaks in the vicinity of C(6). Thus, in further refiements two partial atoms, C(6A) and C(6B), were used. The occupancy factors, 0.4 and 0.6 for C(6A) and C(6B) respectively, were based on the peak heights. The bolckdiagonal least-squares refinement introducing anisotropic thermal pa-

rameters yielded discrepancy factors $R_1=\Sigma||F_o|-|F_c||/\Sigma|F_o|=0.045$ and $R_2=[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}=0.067$. At this stage, a difference Fourier map revealed all the hydrogen atoms except for those bound to the disordered carbon atom C(6). Further refinement including the hydrogen atoms yielded final values of 0.029 and 0.042 for R_1, and R_2, respectively. The final shift in the atomic parameters of the nonhydrogen atoms averaged 0.05σ with a maximum of 0.42σ, with the exception of several parameters of the disordered carbon atom C(6) which were undergoing poorly damped oscillations of 0.05—2.15σ. A final difference Fourier map showed no important features, the highest peak being 0.25 e/Å^3 except for some peaks of 0.26—0.29 e/Å^3 corresponding to the hydrogen atoms bound to C(6).

In the least-squares refinement the function minimized was $\Sigma w(|F_o|-k|F_c|)^2$, and the weighting scheme was

I) $-x, -y, -z$. II) $-x, -y, 1-z$.

cally independent copper(II) atoms, two *N*-*p*-tolylsalicylideneamine ligands, and two propionate groups. The structure essentially agrees with that proposed by Tokii *et al.* The copper atoms Cu(1) and Cu(2) are bridged by two propionate groups in a "*syn-syn*" configuration, and each copper atom is coordinated by the amino nitrogen and the phenolic oxygen atoms of *N*-*p*-tolylsalicylideneamine and by the two oxygen atoms of propionate groups with the distances of the normal Cu–O and Cu–N in-plane coordination. These four coordinating atoms slightly deviate from the least-squares plane (plane A and A′ in Table 5). Such a slight distortion from a plane toward the tetrahedron has been reported for a number of copper complexes. In addition to these coordinations, the phenolic oxygen atoms coordinate to neighbouring copper atoms from the apical direction with the bond distances of 2.371(3) and 2.519(3) Å, respectively.

I) $-x$, $-y$, $-z$. II) $-x$, $-y$, $1-z$. a) Equations have the from $AX+BY+CZ=D$ where X, Y, and Z are Cartesian axes lying along a×c*, b, and c*, respectively.

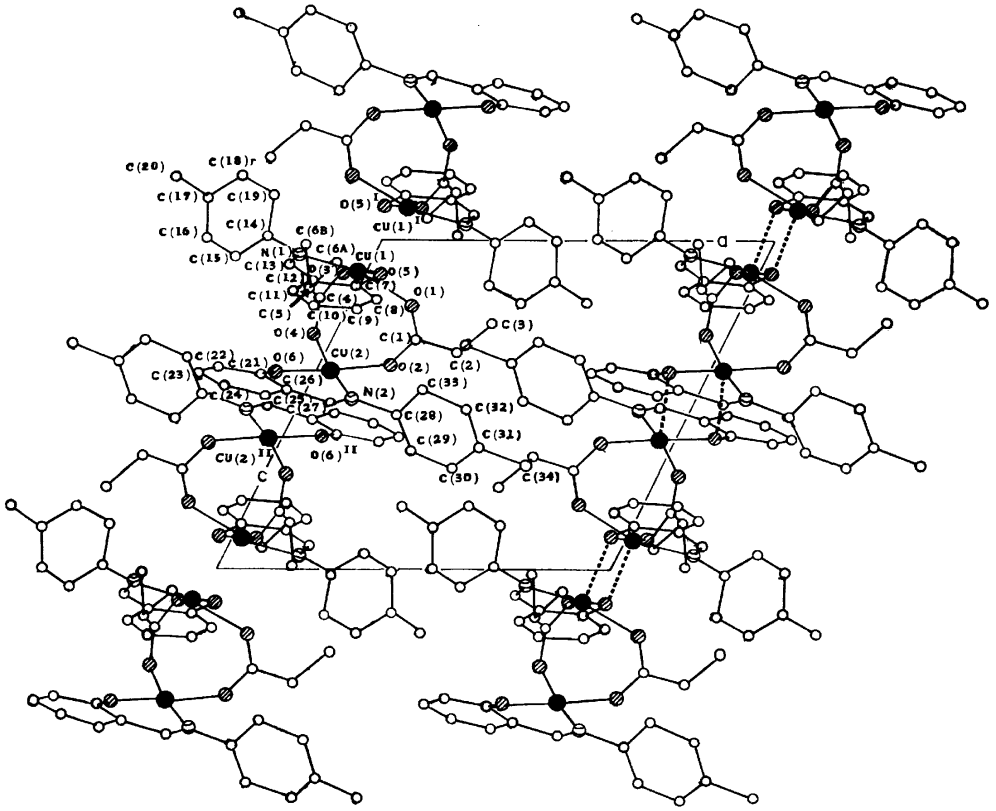

Fig. 2. A view of the packing along the b axis.

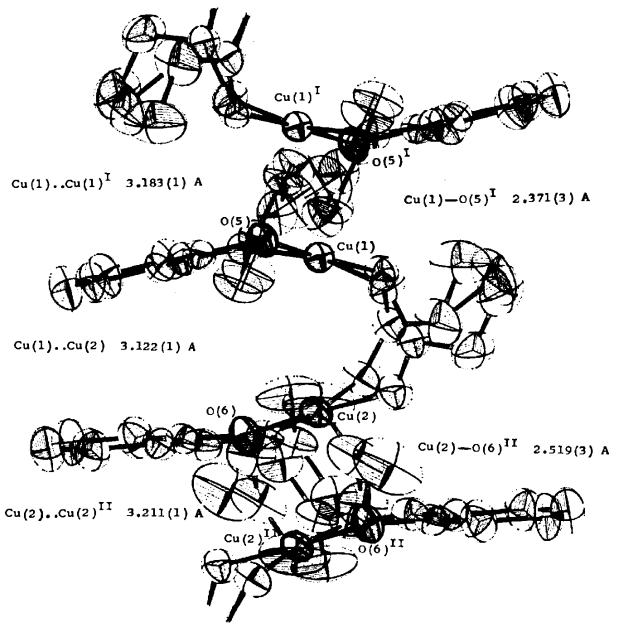

Fig. 3. A portion of the chain structure.

(A view of the packing along the b axis is shown in Fig. 2.) The apical O–Cu–basal atom angles for Cu(1) vary from 84.7(1) to 102.5(1)° and those for Cu(2) vary from 86.1(1) to 100.6(1)°, implying that the coordination sphere about each copper atom is a distorted square pyramid. The C–O distances O–C–O and O–C–C angles of the propionate groups are normal,[7–11] with average values of 1.246 Å, 126.2 and 116.9°, respectively. The $\begin{matrix}O\\O\end{matrix}\!\!>$C–C planes retain their planarity (Table 5). Such planarity was also observed for dimeric copper(II) carboxylates.[12–16] The Cu(1)–Cu(2) distance is 3.122(1) A, being longer than the Cu–Cu distances of dimeric copper(II) carboxylates (*ca.* 2.5—2.8 Å). When the number of bridging carboxylate groups is reduced from 4 to 2, the metal-metal distance becomes longer. Such a tendency was also found in the rhodium(II)[17] and molybdenum(II)[18] complexes with structures similar to the present one. The two basal planes of the distorted square pyramids around copper atoms incline toward each other making a dihedral angle of 35.9°, whereas those of copper(II) carboxylates are parallel. The Cu–O–C angles of the carboxylate groups have a mean value of 129.0°, larger than the angles observed in copper(II) acetate (a mean value of 123.1°). The above facts imply that a reduction of the number of bridging carboxylate groups weakens the binding force between the two copper atoms and opens the carboxylate group bridges.

The binuclear units are linked in a mode of out-of-plane coordination by the phenolic oxygens of upper and lower binuclear units, forming a one-dimensional polymeric chain along the c axis. The chains are separated from each other with the shortest interchain contact (excluding hydrogen atoms) of 3.594(19) Å. Consequently, any interchain magnetic interactions should be very small. There are two types of magnetic interaction between copper ions in the one-dimensional chain (Fig. 3). One is the magnetic interaction *via* two triatomic bridges of the propionate groups (Cu(1)–

Cu(2) 3.122(1) Å), and the other is the interaction *via* monatomic out-of-plane bridges of the phenolic oxygen atoms (Cu(1)–Cu(1)^{I} 3.183(1) Å, Cu(2)–Cu(2)^{II} 3.211(1) Å). Because the Cu–Cu separations of both types are longer than 3 Å, a direct interaction can not be maintained. Therefore, a "superexchange" mechanism should be operative in this system. Considered from the fact that the magnetic behavior of the present complex can be explained by a binuclear model, it is reasonable that the observed magnetic interactions are within each binuclear unit and inter-dimer interactions are negligible. It has been known that the out-of-plane interaction in copper(II) complexes is very weak compared to the interaction *via* triatomic carboxylate bridges.[19,20] Accordingly, it is natural that the antiferromagnetic behavior of the present complex can be explained mainly by a pairwise interaction between Cu(1) and Cu(2) *via* two triatomic carboxylate bridges. This view seems to be compatible with the fact that the $2J$ value of the present complex is about one third of that of copper(II) carboxylate (for example, $2J=-284$ cm^{-1} for copper(II) acetate monohydrate,[21] $2J=-300$ cm^{-1} for anhydrous copper(II) propionate[22]).

The authors are grateful to Dr. Yuzo Nishida of Kyushu University for his kind advice and help in the operation of the Syntex P$\bar{1}$ diffractometer. Thanks are also due to Professor Tetsuya Komori of Kyushu University for allowing us to use the diffractometer.

ESR Study of the *t*-Pentyl Derivative of Yang's Biradical

Kazuo MUKAI, Koichi YORIMITSU, and Tadashi MISHINA

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received January 17, 1977)

Synopsis. An asymmetrical *t*-pentyl derivative of Yang's biradical was prepared, and the ***g***- and ***D***-tensor values of the biradical were determined from an analysis of an asymmetric ESR spectrum of a frozen solution containing the biradical. The result may be understood by assuming that the benzene ring onto which two pentyl groups are substituted is twisted more than the other two benzene rings. On the other hand, the fluid solution ESR spectrum shows seven hyperfine splittings due to six equivalent meta ring protons in the three benzene rings of the pentyl derivative.

Yang's biradical (I) is a ground-state triplet molecule which has structural three-fold symmetry and degenerate partially-filled levels.[1,2] The evidence for the triplet state (S=1) has been demonstrated by the ESR observation of zero-field splitting in rigid media.[3,4] The triplet ground state has actually been confirmed by susceptibility measurements,[5] that is, the susceptibility of powder samples of Yang's biradical follows the Curie-Weiss law with a paramagnetic Curie constant of 1.0 K·emu/mol and a Weiss constant of −4 K in the temperature region between 4.2 and 300 K. In a previous paper, Mukai *et al.* analyzed the toluene rigid-matrix ESR spectrum of Yang's biradical, obtained with $D=34.1$ G and $E=2.3$ G,[6] as the characteristic spectrum of a non-axially symmetrical triplet. This result was explained by assuming that at least one of the twist angles of the three benzene rings is different from the other two rings in the low-temperature rigid matrix. It was suggested that both Jahn-Teller distortion and the asymmetric environment due to frozen solvent molecules may contribute to such a molecular distortion in Yang's biradical. In that publication, the effect of asymmetric deuterium substitution on molecular distortion in Yang's biradical was also reported, indicating that the effect is negligible.

In work reported here, for the purpose of obtaining further information about the molecular distortion, a less symmetrical di-*t*-pentyl derivative (see Fig. 1(a)) of Yang's biradical was synthesized, and the effect of the pentyl substitution on the unpaired spin distribution and symmetry of Yang's biradical was studied.

Experimental

2,6-Di-*t*-butylphenol is commercially available. 2,6-Di-*t*-pentylphenol (bp 100—110 °C/2 mmHg) was synthesized by the reaction of phenol with 2-methyl-2-butene in the presence of aluminium phenoxide as a catalyst in an autoclave according to the method of Kolka *et al.*[7] The bisphenol precursor of the di-*t*-pentyl derivative (see Fig. 1(a)) of Yang's biradical was synthesized from 2,6-di-*t*-butylphenol and 2,6-di-*t*-pentylphenol, following a method similar to that used with the bisphenol precursor of Yang's biradical.[1] Mp 245—247 °C. Found: C, 82.55; H, 10.15%. Calcd for $C_{45}H_{66}O_3$: C, 82.53; H, 10.16%. UV spectrum ($\lambda_{max}=266$ nm, $\log\varepsilon=4.24$; 412 nm, $\log\varepsilon=4.57$ in cyclohexane).

ESR spectra were obtained in the X band using a JES-ME-3X spectrometer equipped with a Takeda-Riken microwave frequency counter, which was used to measure the klystron frequency. The ESR splittings were determined using $(KSO_3)_2NO$ ($a^N=13.05\pm0.03$ G) as a standard. The *g*-values were measured relative to the value of Li-TCNQ powder, calibrated with $(KSO_3)_2NO$ ($g=2.0054$).[8]

Results and Discussion

The initial slight oxidation of the bisphenol precursor of the di-*t*-pentyl derivative of Yang's biradical in toluene gives a five line hyperfine pattern ($a_m^H=1.30\pm0.04$ G and $g_{iso}=2.00442\pm0.00003$) due to the equivalent four meta ring protons of the monoradical precursor. As the oxidation process proceeds further, the spectrum of the monoradical is altered to a seven-line spectrum with an equivalent splitting constant of $a=0.86\pm0.04$ G and with $g_{iso}=2.00447\pm0.00003$, as shown in Fig. 1(b). This spectrum is believed to be due to the magnetically equivalent six meta ring protons of the di-*t*-pentyl derivative of Yang's biradical. The g_{iso}-value for the pentyl derivative is in good agreement with that ($g_{iso}=2.00451\pm0.00003$) for Yang's biradical.[6] The hyperfine splitting constant (a_m^H) due to the meta ring hydrogen atoms of the pentyl derivative is also the same as that ($a_m^H=0.91\pm0.04$) for Yang's biradical, to within experimental error.

When a solution containing the biradical is frozen into rigid glass at 77 K, one can observe dipolar splittings, as is shown in Fig. 2. Assuming non-axial symmetry, the zero-field splitting parameters *D* and *E* and the ***g***-tensor values were tentatively estimated from the

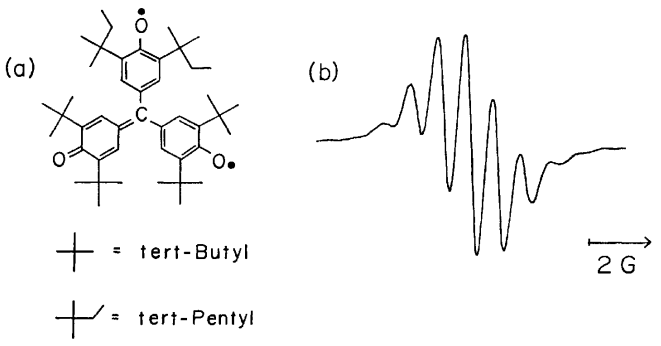

Fig. 1. (a) Molecular structure of the di-*t*-pentyl derivative of Yang's biradical, and (b) ESR spectrum of the biradical in toluene at 20 °C.

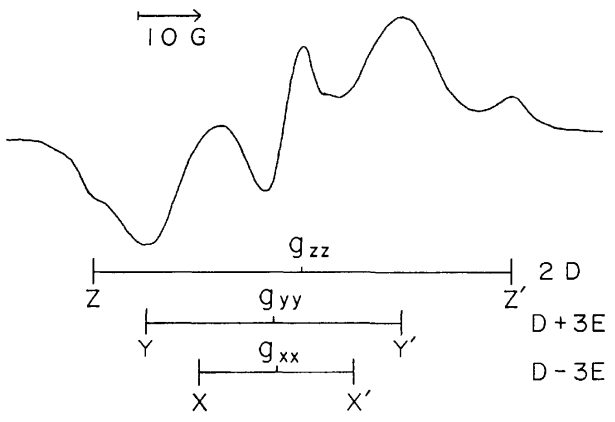

Fig. 2. ESR spectrum of the di-*t*-pentyl derivative of Yang's biradical in toluene at 77 K.

positions of the three pairs of turning points ZZ', YY', and XX' in Fig. 2, as performed for Yang's biradical in Ref. 6. The separation of the two outermost lines (ZZ') is $2D=66.6\pm0.4$ G. Due to the delocalization of each unpaired electron, the principal Z-axis of the D-tensor, corresponding to a maximum separation $2D$, is probably parallel to the $2p_z$ orbital of the center triphenylmethyl carbon atom. The remaining pairs, YY' and XX' ,are separated by $(D+3E)=40.6\pm1.2$ G, and $(D-3E)=24.5\pm1.2$ G, respectively. The E values calculated from the separations ,YY' and XX', assuming $D=33.3$ G, are 2.4 and 2.9 G, respectively. These values will give lower and higher limits of the E value, considering the overlapping of the two inner pairs of lines. The average value is $E=2.7\pm0.4$ G. Corresponding separations for Yang's biradical are $ZZ'=68.3\pm0.4$ G, $YY'=40.0\pm1.2$ G, and $XX'=26.0\pm1.2$ G, respectively.[6] The experimental errors in the absolute values of these separations were estimated by considering the overlapping of the lines. On the other hand, comparing the rigid-matrix ESR spectra of Yang's biradical and its pentyl derivative, the relative decrease in the $ZZ'=2D$ separation and the relatively small increase in the $YY'=D+3E$ separation in the pentyl derivative compared to those of Yang's biradical are obvious. Therefore, it appears reliable that the values, $D=33.3$ G and $E=2.7$ G, show a relatively small decrease and increase, respectively, compared with the values ($D=34.1$ G and $E=2.3$ G) for Yang's biradical reported previously. The frequency centers of these three pairs of absorption lines, ZZ', YY', and XX', give $g_{zz}=2.0025\pm0.0002$, $g_{yy}=2.0053\pm0.0002$, and $g_{xx}=2.0050\pm0.0002$, respectively. The average $g_{av}=1/3(g_{xx}+g_{yy}+g_{zz})=2.0043\pm0.0002$ is in agreement with the isotropic $g_{iso}=2.00447\pm0.00003$ value measured at room temperature, indicating that the g-tensor values obtained by the above analysis are consistent.

Yang's biradical may be considered to be triphenylmethyl derivatives. A molecular model indicates that the main steric interaction in Yang's biradical operates between the ring protons, although weak interactions can be seen between the substituted tertiary butyl groups. Thus, the radical most probably adopts a propeller configuration, with a twist angle of about 30°.[2] By substituting a tertiary pentyl group for the tertiary butyl group, the steric interaction between the substituted groups increases to some extent. Consequently, the benzene ring onto which the pentyl groups are substituted will be twisted more than the other two benzene rings. This results in a decrease in the D-parameter and an increase in the E-parameter in the pentyl derivative in comparison to those for Yang's biradical. Therefore, in addition to both Jahn-Teller distortion and the asymmetric environment due to the frozen solvent molecules, as is observed for Yang's biradical, the asymmetric pentyl substitution may also contribute to the molecular distortion found for the pentyl derivative of Yang's biradical in the low-temperature rigid matrix.

On the other hand, the fluid-solution ESR spectrum of Yang's biradical exhibits seven equally-spaced lines due to the six equivalent protons in the biradical.[3,6] The results of NMR and ENDOR studies[4,9] in solution also indicate that the six ring protons are magnetically equivalent, resulting in a hyperfine splitting for the six meta ring protons. The ESR spectrum of the pentyl derivative at 20 °C also appears to correspond to the hyperfine interaction with six equivalent meta ring protons. The difference in the proton splittings for the pentyl derivative is expected to be less than the line widths.

We are very grateful to Prof. Kazuhiko Ishizu for his encouragement.

Variations in the Vibrational Structures of Fluorescence Spectra of Naphthalene and Pyrene in Water and in Aqueous Surfactant Solutions

Akira NAKAJIMA

Department of Electronic Engineering, Saitama Institute of Technology, Fusaiji, Okabemachi, Ohsatogun, Saitama 369-02

(Received December 27, 1976)

Synopsis. Variations in the vibrational structures of the fluorescence spectra of naphthalene and pyrene in water and in aqueous solutions of sodium dodecyl sulfate (SDS) have been studied by comparison with those in various organic solvents. The results were applied to the determination of the critical micelle concentration of SDS.

In studies on the effect of solvent polarity on vibrational structures in the absorption and fluorescence spectra of condensed aromatic hydrocarbons,[1-5] remarkable intensity enhancement of the forbidden vibronic bands in various organic polar solvents was observed for some aromatic hydrocarbons.

The electronic spectra of condensed aromatic hydrocarbons in aqueous solutions might be important in view of solvent effects.[6,7] However, they have not been studied much. It is of interest to examine whether a similar band enhancement is observed in water, a highly polar solvent.

On the other hand, in view of recent interest in the spectroscopic studies in micellar systems,[8-10] the effects can be applied to micellar solutions to provide useful information on the micellar interior and permit determination of the critical micelle concentration (CMC).

In this work, the fluorescence spectra of naphthalene and pyrene have been investigated in water and in aqueous solutions of sodium dodecyl sulfate (SDS), a typical anionic surfactant.

Experimental

Naphthalene and pyrene were purified by recrystallization, sublimation, and zone-refining. SDS was repeatedly recrystallized from methanol. Water was distilled three times. All the organic solvents were of spectroscopic grade. The aqueous solutions of the aromatic hydrocarbons were prepared in the following way. Small amounts of the hydrocarbons were immersed in given quantities of water and the mixtures were treated with an ultrasonic cleaner to accelerate dissolution. In order to eliminate the undissolved microcrystals, the saturated solutions were carefully filtered with finest Whatman glass fiber papers, diluted with water, treated with an ultrasonic apparatus, and allowed to stand for a day before spectroscopic measurements. The solutions contained various amounts of SDS, the concentrations of hydrocarbons being constant. This was confirmed by measuring the absorbances at strong UV bands which were found to be *ca.* 2×10^{-5} and 3×10^{-7} M for naphthalene and pyrene, respectively. The fluorescence spectra were recorded on a Hitachi MPF-2A spectrofluorometer and the absorption spectra on a Hitachi EPS-3 spectrophotometer.

Results and Discussion

The fluorescence spectra of naphthalene and pyrene have been observed in organic solvents of varying polarities (Figs. 1 and 2). In the vibrational structures of these spectra, the intensities of the forbidden vibronic bands A, B, and C increase remarkably with the solvent polarity relative to the intensity of the allowed vibronic

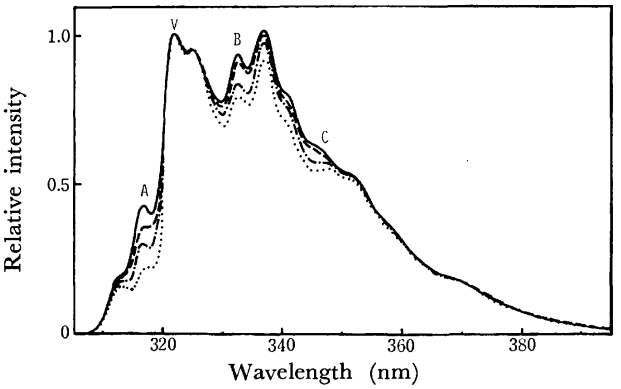

Fig. 1. Fluorescence spectra of naphthalene in several organic solvents. Solvent: cyclohexane (·····), diethyl ether (·-·-·), 1,2-dichloroethane (----), and acetonitrile (——).

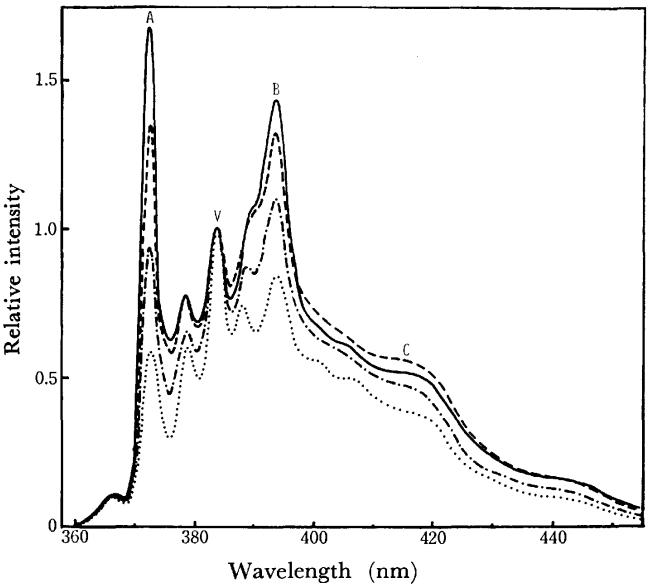

Fig. 2. Fluorescence spectra of pyrene in several organic solvents. Solvent: cyclohexane (·····), diethyl ether (·-·-·), 1,2-dichloroethane (----), and acetonitrile (——).

band V, which is almost insensitive to the solvents.[1,2,4] Thus, these aromatic hydrocarbons can be employed as fluorescent probes for the characterization of their environments.

The fluorescence spectra of naphthalene (Fig. 3) and pyrene (Fig. 4) have been studied in aqueous solutions of various concentrations. The vibronic bands are considerably broadened in water as compared with those in organic solvents, the red shifts being small. Relatively large broadenings indicate the specific solvent effects of water. The relative intensities of bands A, B, and C are markedly enhanced in water, which is reasonable considering its high polarity. In aqueous surfactant solutions, the spectra at lower SDS concentrations are practically the same as those in pure water, whereas at higher SDS concentrations the band intensities are reduced to those as observed in a much less polar solvent. The CMC can thus be determined by means of the present medium effects.

The intensity enhancement can be expressed in terms of the intensity ratio of band A to band V, I_A/I_V. In

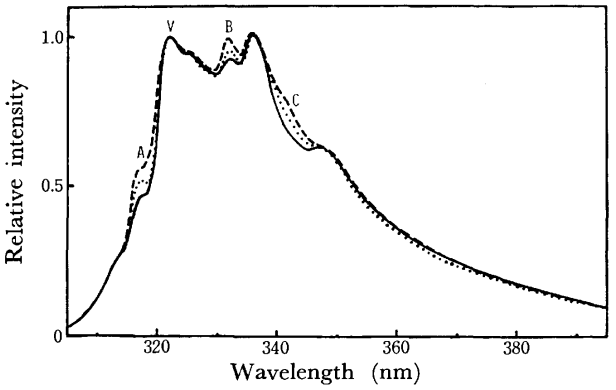

Fig. 3. Fluorescence spectra of naphthalene in water and in aqueous SDS solutions. SDS concentration: 0 and 5.22×10^{-3} M (----), 1.22×10^{-2} M (·····), and 1.86×10^{-2} M (——).

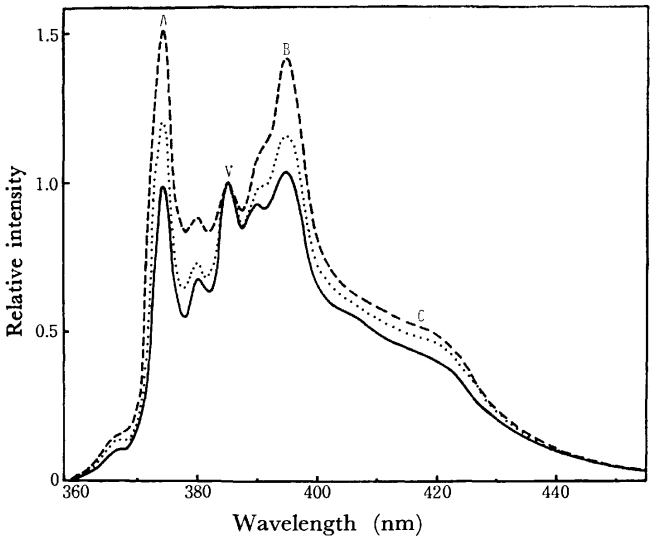

Fig. 4. Fluorescence spectra of pyrene in water and in aqueous SDS solutions. SDS concentration: 0 and 1.30×10^{-3} M (----), 8.16×10^{-3} M (·····), and 4.99×10^{-2} M (——).

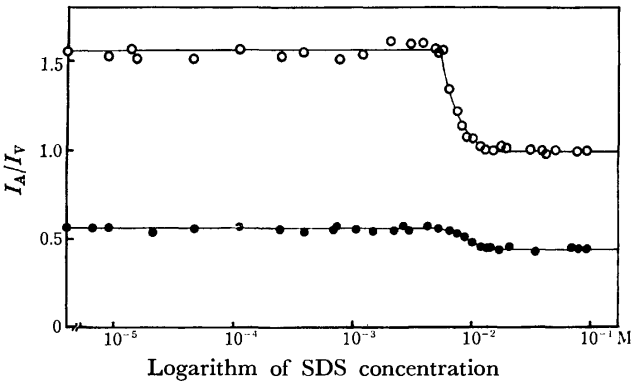

Fig. 5. Plots of relative intensities, I_A/I_V, *vs.* SDS concentration for naphthalene (●) and pyrene (○) probes.

Fig. 5, the ratios are plotted against the concentration of SDS. Changes in ratio occur in the relatively narrow concentration range, on either side of which the ratios remain constant. The concentration at which the breaks are observed may be taken as the CMC of SDS. Its values are estimated as 0.0065 and 0.007 M for naphthalene and pyrene, respectively (Fig. 5). These values are in rough agreement with those reported,[11,12] being slightly smaller. In the presence of aromatic hydrocarbons, the micellar formation may be more or less influenced; thus, the CMC values are somewhat reduced by the induction effects of probes.

In view of the band intensities in pyrene, the environment in the interior of micelle is considerably less polar than in ethanol but a little more polar than in diethyl ether. Such a weak polar environment might be caused by the influence of the ionic atmosphere around the micelles as well as the polarization of the surrounding water. In the case of naphthalene, however, a comparison of spectra indicates that the environment in micellar solution is much more polar than in organic polar solvents, implying that the probe molecules are preferably located near the micellar surface.[13]

ESR and ENDOR Study of the Carbonization of Rubrene

Yoshio YAMADA and Yuzo SANADA*

National Research Institute for Pollution and Resources, Kawaguchi, Saitama 332

(Received January 18, 1977)

Synopsis. An ESR spectrum of the radical produced during the carbonization of rubrene was measured and analyzed from an ENDOR spectrum and using computer simulations.

It is well-known that the initial thermal reactions of organic materials are of particular importance in determining the course of the subsequent carbonization and graphitization processes.[1-3] The reaction mechanism and the precursor of the carbon produced have been investigated by X-ray diffraction,[1] mass spectrometry,[3] chromatography,[4] *etc.* Singer and Lewis[5] have pointed out that the electron spin resonance (ESR) spectrometer is a powerful tool for obtaining information about the individual steps of the carbonization process when pyrolysis is carried out in an inert solvent such as *m*-quinquephenyl. In many cases, however, it appears rather difficult to analyze the many ESR spectral lines due to radicals of large molecular size.[6]

The purpose of the present study is to identify the radicals produced during initial carbonization by combining the ESR technique with electron nuclear double resonance (ENDOR) and to clarify the reaction process involving the mechanism of radical formation. This paper is concerned with the structure of the radical formed by the pyrolysis of rubrene, *i.e.*, 5,6,11,12-tetraphenylnaphthacene ($C_{42}H_{28}$), and with the associated reaction mechanism. The reason why rubrene was selected as the starting material is that the carbonization reaction rate is moderate compared with that of naphthacene.

Experimental

Rubrene and *m*-quinquephenyl were purchased from the Aldrich Chem. Co., Inc., and the K & K Laboratories, Inc., respectively. The preparation of the sample and the procedure for ESR measurement are described elsewhere.[6] The ENDOR spectra were obtained using a Japan Electron Optics Laboratory ES-EDX1 ENDOR spectrometer.

Results and Discussion

Rubrene dissolved in *m*-quinquephenyl in a weight ratio of 1 : 10 began to exhibit a large number of ESR spectral lines for pyrolysis at 450 to 470 °C. Figure 1(a) shows the spectrum observed at 150 °C for the heat treatment of rubrene at 500 °C for 5 min. This spectrum consists of about 57 lines with the same interval of 0.44 G, which are overlapped by a broad line. The spectrum illustrated in Fig. 1(a) is spread over about 25 G. The spin concentration is of the order of about 1.2 species per 1000 molecules of rubrene heat-treated at 450 °C. A similar spectrum was observed also when only rubrene was pyrolyzed at 425 °C for 1 h or at 450 °C for 10 min and then dissolved in *m*-quinquephenyl. Accordingly, it appears reasonable that the *m*-quinquephenyl used in this experiment does not participate in the rubrene carbonization.

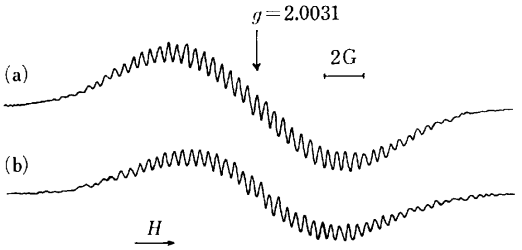

Fig. 1. (a) Experimental ESR spectrum of the radical produced when rubrene was heat-treated in *m*-quinquephenyl at 500 °C for 5 min. The spectrum was measured at 150 °C. (b) The calculated spectrum. Line spape is Gaussian, with a peak to peak linewidth of 0.35 G. The spectrum consists of 8 equivalent protons with a^H=0.884 G, 6 protons with 1.230, 4 protons with 1.724, 2 protons with 1.964, and 2 protons with 2.412.

When the rubrene was treated in *m*-quinquephenyl at 500 °C for a period longer than 5 min, the intensity of the broad line gradually increased but the relative intensity of the hyperfine spectral lines scarcely changed. Also, when the spectra were measured at various temperatures between 130 and 190 °C, the line widths became sharper with increasing temperature, whereas no significant variation of the intensity ratio was observed in this temperature range. Assuming a single radical on the basis of these observations, one can explain the odd lines of the hyperfine structure in terms of the interaction with even hydrogen nuclei.

An ENDOR spectrum was recorded at 150 °C for the sample heat-treated in *m*-quinquephenyl at 500 °C for 5 min (Fig. 2). Five pairs of lines which were reduced to hyperfine splitting constants of 0.884, 1.230, 1.724, 1.964, and 2.412 G, were observed above and below the free-proton frequency.

On the basis of the values of the splitting constants determined from the ENDOR signal, the ESR spectrum was simulated using the SESRS computer program of Stone and Maki.[8] As a result, two calculated spectra were found to fit the observed spectrum best by trial and error. One consists of 8 equivalent protons at a^H= 0.884 G, 6 protons at 1.230, 4 protons at 1.724, 2 protons at 1.964, and 2 protons at 2.412. The other is composed of 8 protons at 0.884 G, 6 protons at 1.230, 4 protons at 1.724, 4 protons at 1.964, and 2 protons at 2.412. The former spectrum is represented in Fig. 1(b).

* Present address: Faculty of Engineering, Hokkaido University, Sapporo 060.

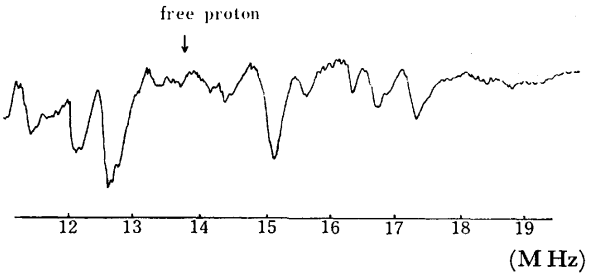

Fig. 2. ENDOR spectrum of the radical produced when rubrene was heat-treated in *m*-quinquephenyl at 500 °C for 5 min. The spectrum was measured at 150 °C.

π-Radicals, such as perinaphthenyl, are generally known to be stable at the intermediate stage of early carbonization.[7] These radicals always contain an odd number of carbon atoms. In this case, since carbon-carbon bond cleavage within the benzene and/or naphthacene ring in the rubrene is impossible at as low a temperature as 500 °C, the radical produced from the rubrene is considered to be located in the carbon-frame composed of 11 rings, such as bi-naphthacene.

In order to confirm the existence of a biradical, on the other hand, the lines due to the $\Delta M_s = \pm 2$ transition were examined and temperature variations of the spectrum were measured over the range 123—373 K, for which a single line was observed. No line corresponding to this transition was found at low field, but the absorption intensity significantly decreased with decreasing temperature. This result may suggest the existence of a biradical. Also, it can be considered that dimerization of the radical causes a reduction in the signal intensity.[10] But the large molecular size of the radical formed in the carbonization of rubrene may make dimerization difficult in the solid phase at the low temperature tested. Accordingly, identification of the radicals is expected after further experimentation.

As an approach to estimating the molecular weight of the reaction product, the mass spectrum of the sample carbonized at 450 °C with no solvent was observed. New intense peaks appeared in the range 608—684, in addition to a group of peaks at $m/e=532$, which were assigned to the unreacted parent molecular ion.[9] The thermal reaction of rubrene involves the elimination of substituted phenyl groups, subsequent polymerization and aromatization to a condensed aromatic layer. The development of such a plane as the precursor of carbon is thought to result in a well-ordered graphite product, the *c*-spacing of which is 3.356 Å.[11]

Preparation of Vitamin E Using Cation Exchange Resin Complexes of Metal Ions

Yoji TACHIBANA

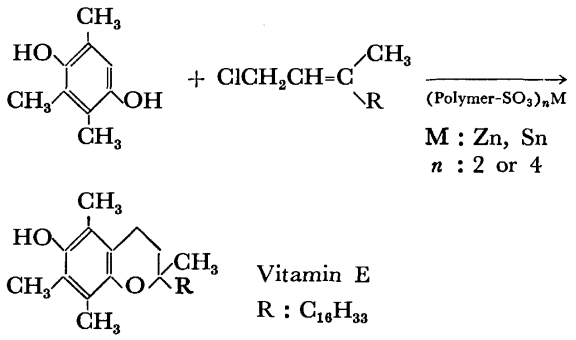
Ueda Factory, Nisshin Chemical Co., Ltd., Kamishiojiri, Ueda, Nagano 386

(Received February 17, 1977)

Synopsis. A series of cation exchange resin complexes of metal ions were prepared. These resins are effective catalysts for the preparation of vitamin E and were recycled for use several times with little activity loss. The effect of solvents and metal ions on the reaction is discussed.

Incresed attention has recently been paid to anchoring homogeneous transition metal catalysts to polymers. Heterogenized catalysts have some advantages over their homogeneous counterparts such as (1) the ease in separation from the product,[1-5] (2) enhanced size and positional selectivity,[6] and (3) the ability to carry out sequential catalytic reactions.[7] In this respect, insoluble polymers also have been used widely in organic synthesis,[8] for example, as protecting groups[9-11] or in esterification.[12-13]

The cation exchange resins were employed for the preparation of vitamin E, but their catalytic activity was very low. The present paper describes the preparation of cation exchange resin complexes of metal ions and the use of these materials as catalyst for the preparation of vitamin E.



It was shown that the catalysts can be used as heterogenous catalysts. Furthermore, the investigation of the preparation of vitamin E using the resin complexes as catalysts was prompted by the following advantages offered by resins: the ability to remove the catalyst from the reaction product by simple filtration, thus avoiding contamination of the latter and generating economic savings effected by repeated use of the resin, which exhibits good stability of activity. The stabilities of the catalysts decrease in the order $Sn^{4+}>Sn^{2+}>Zn^{2+}$. This agrees well with the stability order for chelate rings. In benzene, the catalysts were recycled several times with little loss in activity. However, in highly polar solvents such as acetonitrile, repeated use of the catalysts was not possible. This may be due to the elimination of metal ions from the resin by strong solvation. With recycling of the catalyst, a decrease in activity was observed. This is ascribed to the elimination of metal ions through reactions. The catalysts can be regenerated to their initial activity by the addition of the amount of metal ions equal to that lost in the reactions. The results are summarized in Table 1 and Fig. .

One practical limitation of this method is the very low catalytic activity and the inability to employ recycling when phytol or isophytol is used. In the course of the reaction, about 70% of the metal ions in the resin catalyst were detected. This strongly indicates that the catalytic species is a metal halide. These reactions were effectively assisted by the addition of a trace amount of a protonic acid, such as *p*-toluenesulfonic or methanesulfonic acid. This may be due to the promotion of cyclization in the reaction.[14] From the results, a plausible mechanism for this catalytic

system is shown below. The detailed nature of the catalytic process reported here requires further clarification and work in progress is aimed at exploring the synthetic utility of this technique.

$$2\,\text{Polymer-SO}_3\text{H} + \text{ZnCl}_2 \longrightarrow (\text{Polymer-SO}_3)_2\text{Zn} + 2\text{HCl}$$

or,

trimethylhydroquinone + phytyl chloride + ZnCl_2

$$\xrightarrow[\text{H}^+(\text{HCl or Polymer-SO}_3\text{H})]{} \text{Vitamin E} + \text{ZnCl}_2 + \text{HCl}$$

Experimental

GLC and atomic absorption spectra were recorded on a Hitachi 023 gas chromatograph equipped with a flame ionizer detector and a Hitachi 208 atomic absorption spectrometer, respectively.

General Procedure. Zinc chloride (12.3 g, 0.09 M) was dissolved in 100 ml of ethyl acetate. Amberlyst 15 in hydrogen ion form (30 g, 4.8 meq/g dry resin) was added to the solution and the mixture was maintained at 40 °C for 2 h and allowed to stand overnight at room temperature. The resin complex was filtered and washed well with acetone to remove hydrogen chloride and unbounded zinc chloride. A theoretical amount of zinc ions were shown to be bounded to the resin (analyzed by atomic absorption spectroscopy). A benzene solution (100 ml) containing 30 g of trimethylhydroquinone, 65 g of phytyl chloride and 30 g of the catalyst was allowed to reflux for 3 h. After standing overnight, the catalyst was filtered off and washed with acetone. The filtrate was concentrated under reduced pressure and the residue was subsequently distilled. The product thus obtained was analyzed by GLC. The catalyst could be recycled for use in the next reaction.

The author wishes to thank the Nisshin Chemical Co., Ltd., for permission to publish this report. The author is also grateful to Drs. K. Nakagawa and H. Fukawa of the Central Research Laboratory, Nisshin Flour Milling Co., Ltd., for their interest throughout this work.

Adsorption of Phosphate on Synthetic Silica–Alumina Possessing Lewis-acid Sites

Kazuto TAKIMOTO, Akira FUJITA, and Satoru TSUDA
Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima 730

(Received February 24, 1977)

Synopsis. It was confirmed from measurements of the adsorption isotherms of phosphates in aqueous solutions that there were adsorption sites with very high reactivity on the surface of silica–alumina. The concentration of adsorption sites which is estimated from the adsorption amount extrapolated to zero equilibrium concentration is nearly twice the concentration of Lewis-acid sites for silica–alumina of higher alumina content. Furthermore, the concentration of phosphate adsorbed on the surface of various silica–alumina is relatively well correlated with the concentration of Lewis-acid sites.

It is well known that inorganic phosphates play an important role in the abnormal growth of phytoplankton in an area of the sea or a lake, which is called red tide. Nishimura[1] has reported that the average concentration is 0.015 ppm for P and 0.14 ppm for N in a given sea area. The pollution source of the phosphates is mainly domestic sewage. Even in the effluent of so-called secondary sewage treatment, phosphate in concentrations of 3 to 5 ppm as P is usually detected.[2] Complete phosphate removal, which is relatively easy and economical compared with that of nitrogen, may offer the best solution for returning aquatic environments to their pristine state.[3] Although many workers have widely studied phosphate removal,[4–6] some clay minerals containing aluminium atoms are reported to be effective for the removal of phosphate at the very low concentrations described above. The aluminium atoms responsible for the phosphate removal are not the internal atoms of the adsorbent but the surface atoms. Therefore, it is expected that the concentration of Lewis-acid sites associated with surface aluminium atoms correlates with that of the phosphate adsorbed. To the authors' knowledge, no work has been done from such a viewpoint.

In the study reported here, synthetic silica–alumina samples having strong Lewis-acid sites, which also react with electron-donating polyaromatic hydrocarbons[7] were used as adsorbents. The object of the present paper is to clarify the correlation between the concentration adsorbed of Lewis-acid sites, the concentration of phosphate and the alumina content of the silica–alumina samples.

Experimental

Aluminium isopropoxide and tetraethyl orthosilicate purified under reduced pressure were mixed in various proportions and were hydrolyzed for 12 h. The gels thus obtained were treated at 600 °C for 8 h. The particles which passed through 100 mesh sieve were used as adsorbents. Each silica–alumina sample is represented as % silica–alumina which indicates the alumina content in wt%. The surface area of these silica–alumina samples were measured by means of the BET method. The concentration of Lewis-acid sites on the surface of the silica–alumina samples was measured by the Leftin method,[8] after heating *in vacuo* at 400 °C for 2 h.

The phosphate was adsorbed onto various silica–alumina samples at 20 °C. The adsorbents were suspended in aqueous KH_2PO_4 solutions having concentrations in the range from 1 to 10 mmol/l and the mixture were stirred for 48 h. It was confirmed that the adsorption equilibrium was reached within 48 h. After centrifugation, the phosphate concentration in the supernatant solutions was determined by the molybdenum blue method.[9]

Results and Discussion

The isotherms for the adsorption of phosphate onto the silica–alumina samples are shown in Fig. 1. The phosphate is only slightly adsorbed on samples ranging from pure silica gel to 25% silica–alumina, whereas adsorption clearly occurs on samples ranging from 40% silica–alumina to pure alumina. Thus, adsorption is enhanced with increasing alumina content. For pure alumina, however, the adsorption concentration, is slightly lower than that for 90% silica–alumina.

The phosphate adsorption concentration is fairly large even near zero equilibrium concentration in the cases from 50% silica–alumina to pure alumina. This result suggests that highly reactive sites responsible for the adsorption exist on the surface.

In order to confirm this, the Muljadi adsorption isotherm[10] and the Langmuir isotherm for alumina are shown in Fig. 2. The Langmuir theory assumes that all the adsorption sites are equivalent. This theory is

not applicable to the present results obtained at low phosphate concentrations. On the contrary, the adsorption isotherm obtained is in rather good accord with the Muljadi isotherm. Muljadi and his co-workers[10] have revealed that there are two types of adsorption sites on the surface of kaolinite, gibbsite and pseudo-boehmite.

The concentration of highly-reactive sites estimated from the phosphate adsorption concentration extrapolated to zero equilibrium concentration is shown in Table 1. Since the reactive sites responsible for the adsorption are essentially surface aluminium atoms, it can be expected that the concentration of Lewis-acid sites is a good parameter for estimating the phosphate adsorption. The Lewis-acid sites associate with bare aluminium atoms due to the removal of water which is produced by a reaction between adjacent hydroxyl groups on the surface. The concentration of highly-reactive sites is nearly twice that of Lewis-acid sites for silica–aluminas of higher alumina content. This difference may be due to the following reason: there are weakly and strongly-bonded hydroxyl groups on the surface of silica–alumina, corresponding to strong and weak basic sites, respectively.[11] The phosphate can easily exchange with weakly-bonded hydroxyl groups in the aqueous solution, forming a surface complex with aluminium atoms. In the case of the strongly bonded groups, the ability of the phosphate to exchange with the hydroxyl groups may be less.

On the other hand, the weakly-bonded hydroxyl groups may be preferentially eliminated by heat treatment at 400 °C for 2 h *in vacuo*, forming weak Lewis-acid sites. All hydroxyl groups on the surface are not eliminated by the heat treatment.[12] Therefore, it is believed

Table 1. The relation between the concentration of phosphate adsorbed and the concentration of Lewis-acid sites

Silica–alumina	Specific surface area (m^2/g)	Concentration of phosphate adsorbed ($\times 10^{-4}$ mmol/m^2)	Concentration of Lewis-acid sites ($\times 10^{-4}$ mmol/m^2)
Alumina	164.3	8.95	4.72
90% S.A	323.6	9.47	4.02
75% S.A	178.4	8.42	3.41
60% S.A	142.7	4.21	1.99
50% S.A	343.7	1.89	1.89
40% S.A	97.4	0.42	1.80
25% S.A	118.5	0	0.88
10% S.A	309.1	0	0.34
Silica gel	378.9	0	0.13

that strongly-bonded hydroxyl groups which form Lewis-acid sites with difficulty, have possibly an exchange ability in the aqueous solution, although this ability is weak. Another reason may be the positively-charged spots proposed by Cloos *et al.*[13]

Table 1 indicates that the concentration of Lewis-acid site increases with the alumina content in silica–alumina. However, the adsorption concentration is zero up to 25% silica–alumina and, thereafter, it increases with the alumina content. This should be due to the negatively-charged surface caused by the isomorphous replacement of four-fold coordinating aluminium atoms into the tetrahedral silica framework. As the alumina content in silica–alumina is increased, the surface negativity decreases due to the increase in Al–OH cations with alumina content.[13]

Asymmetric Shape of Charge-transfer Absorption in Crystalline Ion Radical Salts

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received Aplil 6, 1977)

Synopsis. Using the one-dimensional Hubbard model, we proposed an asymmetric band shape for the charge-transfer transition between ion radicals in crystalline ion radical salts. The charge-transfer band of the anion radical salts derived from 2,3-dicyano-*p*-benzoquinone was explained in terms of such a model.

In a number of solid ion radical salts, the planar ion radical molecules are known to form, in themselves, a face-to-face stacking into infinite one-dimensional columns so as to make a large overlap between their half-filled molecular orbitals.[1-3] In this case, since any individual radical molecule interacts through charge-transfer most strongly with two other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution but shows a charge-transfer transition between ion radicals in the low-energy region.[1-3]

The 2,3-dicyano-*p*-benzoquinone (*p*-H_2QCy_2) and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (*p*-Cl_2QCy_2) molecules are known to be strong electron acceptors and to form stable anion radical salts with some diamagnetic alkali metal cations. Several years ago,[2] we measured the diffuse reflection spectra of the solid anion radical salts of Na^+ *p*-$H_2QCy_2^{\cdot-}$, K^+ *p*-$H_2QCy_2^{\cdot-}$, Na^+ *p*-$Cl_2QCy_2^{\cdot-}$ and K^+ *p*-$Cl_2QCy_2^{\cdot-}$, and found strong absorptions due to the charge-transfer transition between anion radicals in the low-energy region. The observed spectra of the charge-transfer absorptions are reproduced in Fig. 1, where the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, was plotted against wave number. In the case of the Na^+ *p*-$Cl_2QCy_2^{\cdot-}$ salt (see (a) or Fig. 1), the peak position of the charge-transfer band is around 12600 cm^{-1} and its band shape is found to be almost symmetrical with respect to the axis of peak energy. On the other hand, the solid-state spectrum of the Na^+ *p*-$H_2QCy_2^{\cdot-}$ salt (see (c) of Fig. 1) shows the charge-transfer band with the peak position around 10700 cm^{-1}. However, its band shape is not symmetrical with respect to the axis of peak energy, but has a shoulder in the higher-energy region. Regardless of the species of the counter cations, these distinct differences are also observed for the K^+ *p*-$Cl_2QCy_2^{\cdot-}$ and K^+ *p*-$H_2QCy_2^{\cdot-}$ salts as are shown in (b) and (d) of Fig. 1. When we first reported those solid-state spectra,[2] we could not fully explain why the anion radical salts derived from *p*-H_2QCy_2 have asymmetric charge-transfer band with a shoulder in the higher-energy region.

In order to understand the character of this charge-transfer absorption in more detail, we studied in a previous paper the transition energy and the theoretical line shape of such absorption by the use of one-dimensional Hubbard model and the Green's function method.[3] For half-filled band system of simple ion

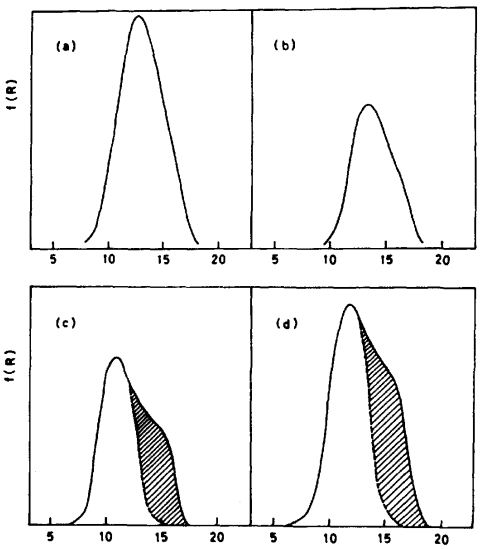

Fig. 1. The observed charge-transfer absorptions of solid anion radical salts as studied by diffuse reflection method (see Ref. 2); (a) Na^+ *p*-$Cl_2QCy_2^{\cdot-}$, (b) K^+ *p*-$Cl_2QCy_2^{\cdot-}$, (c) Na^+ *p*-$H_2QCy_2^{\cdot-}$ and (d) K^+ *p*-$H_2QCy_2^{\cdot-}$. radical salt, we consider non-alternant one-dimensional stack of ion radical molecules with paramagnetic state. We assumed a δ-function for each elementary transition in which the spin and the wave vector of an electron are conserved. The intermolecular charge-transfer absorption, $\sigma(\omega)$, at very low temperature is given by

$$\sigma(\omega) \propto \frac{e^2}{4}\frac{I^2}{\omega^2\sqrt{\omega^2-I^2}}\sqrt{4T^2-\omega^2+I^2}, \qquad (1)$$

where I is the intra-site Coulomb repulsion energy, and $T(<0)$ is the transfer matrix element between nearest neighbor sites in such one-dimensional column.

The theoretical charge-transfer absorption has a sharp divergent peak at the energy $\omega=I$, where the spectrum has a van Hove singularity in the lower energy side. The spectrum has no absorption in the energy region $\omega<I$, but has an absorption intensity in the region $\omega>I$. The intensity is the greatest at $\omega=I$, and decreases progressively with the increase of ω. The highest energy of the absorption takes place at $\omega=\sqrt{I^2+4T^2}$, where the intensity falls down to zero. The spectrum has a shoulder in the region $I<\omega<\sqrt{I^2+4T^2}$. These spectroscopic features are illustrated in Fig. 2.

In this model, the line width, $\sqrt{I^2+4T^2}-I$, of the charge-transfer absorption is solely caused by the ex-

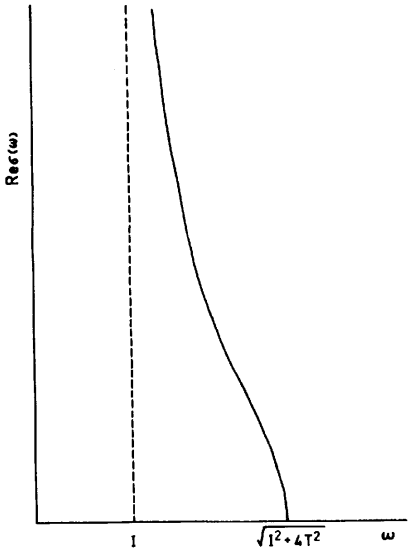

Fig. 2. The theoretical absorption line shape of Eq. 1 due to the charge-transfer transition between ion radical molecules in one-dimensional Hubbard model. See text and Ref. 3.

istence of non-zero transfer matrix element, T. However, as has been mentioned in the previous paper,[3] the actual elementary absorption is not a simple δ-function but involves finite width. Therefore, the actual charge-transfer absorption will have extra width and become more smoothed. If the band width due to the transfer matrix element is much smaller than that of the elementary absorption, the charge-transfer absorption will be governed predominantly by the band shape of the elementary absorption, so that we can well expect almost symmetrical line shape of the charge-transfer absorption with the peak position at $\omega=I$. The charge-transfer absorption of the Na^+ p-$Cl_2QCy_2^-$ and K^+ p-$Cl_2QCy_2^-$ salts should correspond to this case. In the case of the Na^+ p-$Cl_2QCy_2^-$ salt (see (a) of Fig. 1), the observed absorption peak value, 12600 cm^{-1}, corresponds to $I=12600$ cm^{-1}. The band width due to the transfer matrix element, $\sqrt{I^2+4T^2}-I$, will be very small compared to that of the elementary absorption, 4000 cm^{-1}, and the $|T|$ value appears less than 1000 cm^{-1}. In a similar way, $I=13300$ cm^{-1} is estimated for the K^+ p-$Cl_2QCy_2^-$ salt, and the $|T|$ value of this salt will again be less than 1000 cm^{-1}. In both of these salts, we can well see that a narrow band system with strong electron correlation (*i.e.*, $|T|\ll I$) takes place in one-dimensional column of the p-$Cl_2QCy_2^-$ anion radicals.

On the other hand, we consider the case when the band width due to transfer matrix element is comparable to or larger than that of the elementary absorption. In this case, the peak position of the charge-transfer absorption is still at $\omega=I$, but the line shape is no longer symmetrical with respect to $\omega=I$. Because of asymmetric component of Fig. 2, the charge-transfer absorption will have a distinct shoulder in the energy region $\omega>I$, and the total band width will arise partly from the width due to the elementary absorption but partly from the width due to the non-zero transfer matrix element. As are shown in (c) and (d) of Fig. 1, the charge-transfer absorption of the Na^+ p-$H_2QCy_2^-$ and K^+ p-$H_2QCy_2^-$ salts should correspond to this case. In the case of the Na^+ p-$H_2QCy_2^-$ salt, the observed absorption peak value, 10700 cm^{-1}, thus corresponds to $I=10700$ cm^{-1}. As for the band shape, note that the effect of transfer matrix element gives no contribution to the absorption intensity in the region $\omega<I$. Therefore, we divide, for the sake of simplicity, the observed charge-transfer absorption into symmetrical and asymmetrical parts by subtracting, with respect to $\omega=I$, the lower-energy side from the higher-energy side. This is shown in (c) of Fig. 1, where the unshaded and shaded parts are the symmetrical and asymmetrical ones, respectively. Then, the band width of the shaded part will come mostly from the width due to the non-zero transfer matrix element, $\sqrt{I^2+4T^2}-I$, and this width is found to be of the order of 3000 cm^{-1} or less. By putting $I=10700$ cm^{-1} into this relation, the magnitude of the transfer matrix element is estimated to be $|T|\lesssim 4300$ cm^{-1}. Similarly, in the case of the K^+ p-$H_2QCy_2^-$ salt, it is found that $I=11700$ cm^{-1} and $\sqrt{I^2+4T^2}-I\lesssim 3000$ cm^{-1}, so that the magnitude of the transfer matrix element is estimated to be $|T|\lesssim 4500$ cm^{-1}.

On the basis of these considerations, we can well understand the spectroscopic features of the charge-transfer absorptions characteristic of the Na^+ p-$H_2QCy_2^-$ and K^+ p-$H_2QCy_2^-$ salts as well as of the Na^+ p-$Cl_2QCy_2^-$ and K^+ p-$Cl_2QCy_2^-$ salts. The magnitude of $|T|$ of the p-H_2QCy_2 anion radical salts appears to be considerably larger than that of the p-Cl_2QCy_2 anion radical salts. This result is also strongly supported by the following reason. The p-Cl_2QCy_2 anion radical molecule includes bulky chlorine substituents, while the p-H_2QCy_2 anion radical molecule does not. Therefore, in one-dimensional stacking of anion radicals, the p-H_2QCy_2 anion radicals will stack, in themselves, more closely than do the p-Cl_2QCy_2 anion radicals, so that the magnitude of $|T|$ of the p-H_2QCy_2 anion radical salts will be definitely larger than that of the p-Cl_2QCy_2 anion radical salts.

At the present time, it is desirable to make sure of the magnitudes of $|T|$ of those anion radical salts by another approach. For this purpose, it will be quite useful to measure the exchange interaction parameters in their magnetic properties and the energy gaps in their semiconductivities. However, more useful approach is to measure absolute intensity of the charge-transfer absorption, because the total intensity will be roughly proportional to $|T|^2$. In this respect, the intensites of the charge-transfer absorptions of the p-H_2QCy_2 anion radical salts may be much stronger than those of the p-Cl_2QCy_2 anion radical salts.

A Modified Method of Discrete Fourier Transform Application to Electron Spin Resonance Spectral Data

Toshio NISHIKAWA and Kazuo SOMENO

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received February 18, 1977)

Synopsis. With the development of signal processing techniques, the spectral data obtained from analytical instruments have been collected and searched with the aid of a digital computer. Recognition of the spectrum as a wave pattern is adequate in such situations. The previous study[1] demonstrated signal processing based on this idea, involving the discrete Fourier transform (DFT) applied to ESR spectral data, and the advantages of this method with respect to memory capacity and searching speed. In that study, however, the spectral data were limited to symmetrical traces from organic free radicals in solution, in which case the ESR spectra exhibit isotropic hyperfine structure. This paper describes some modifications of the method rendering it applicable to asymmetrical traces, thus, for general use.

Modification of the Procedure

For the ESR spectral data, which are considered as a time series, values of $f(nT)$ $(0 \leq n \leq N-1)$ consisting of N samples, the discrete Fourier transform (DFT), $F(k\Omega)$ $(0 \leq k \leq N-1)$, may be calculated using the Fourier processing algorithm. The notation and details of formulation are the same as in a previous paper.[1]

Mathematically, $f(nT)$ and $F(k\Omega)$ are complex numbers, but for an actual DFT sequence, the real part of $F(k\Omega)$ is even and the imaginary part is odd due to the nature of the DFT,[2] since the values of $f(nT)$ are real numbers as obtained from experiment. In a method presented previously,[1] only the imaginary parts of $F(k\Omega)$ appear due to the nature of the symmetrical ESR pattern, and these are stored in the file. The present method, which is intended for application to asymmetrical patterns, however, requires both the real and imaginary parts of the DFT terms in addition to the k-values. This requires 50% more storage than the previous method.

For the file search, the known DFT, $P(k\Omega)$, and the unknown DFT, $Q(k\Omega)$, are treated in an expression for the absolute value and the argument,

$$\left.\begin{array}{ll} \text{known:} & P(k\Omega) = |P_k| \exp(ip_k) \\ \text{unknown:} & Q(k\Omega) = |Q_k| \exp(iq_k) \end{array}\right\}, \quad (1)$$

although the comparison procedure should be modified.

For the shift between the known and unknown traces, the absolute values, $|P_k|$ and $|Q_k|$, may be directly compared, since the absolute values of the DFT are invariant for the shifted traces.

On the other hand, the argument cannot be compared as it is. The comparison procedure is modified by utilizing the relationship that the shift in the time domain results in rotation of the argument in the frequency domain. In other words, the difference in argument angles due to the shift is linearly related to the difference in the magnetic fields to the order k, if the microwave frequency is assumed to remain unchanged. The arguments for unknown data are modified in the following manner:

$$\left.\begin{array}{l} q'_k = q_k - (k/k_{max})(q_{k_{max}} - p_{k_{max}}),\ k_{max} \neq 0 \\ q'_{k_{max}} = p_{k_{max}} \end{array}\right\}. \quad (2)$$

These equations indicate that the DFT arguments are rotated proportionally to the k/k_{max} ratio, so that the argument for an unknown k_{max} th DFT becomes equal to that for the known. Then, the modified argument q'_k can be compared with the standard argument p_k.

Results and Discussion

The applicability of the modified method was tested on asymmetrical ESR spectra. The hyperfine structure of the dialkyldithiocarbamate complex in solution is asymmetrical, because the line widths are dependent on the magnetic quantum number, m_I, of the central metal nucleus due to insufficient averaging for the anisotropy.[3,4]

The examples of ESR spectra were measured on diethyldithiocarbamate of Cu(II) in toluene under different conditions, such as for different signal heights, shifts, and signal-to-noise ratios. Traces 1a and 2a in Fig. 1 are taken as examples of known and unknown spectra, respectively.

The number of sampling points, N, is 512, since N should be a power of 2 for fast Fourier transform computation.[2] The DFT waveforms obtained are shown

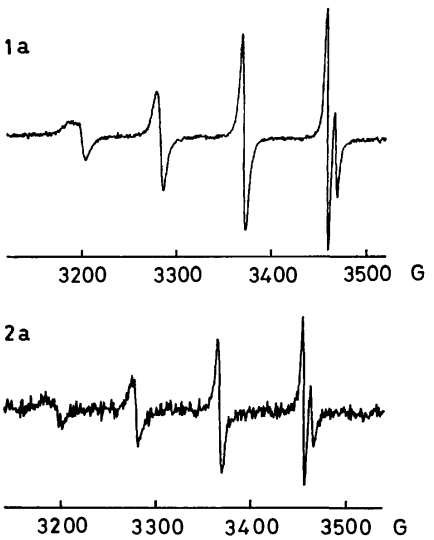

Fig. 1. Original spectral traces of Cu(II) diethyldithiocarbamate. 1a and 2a, assumed as known and unknown, are contrasted in respect of signal height, shift, and S/N ratio.

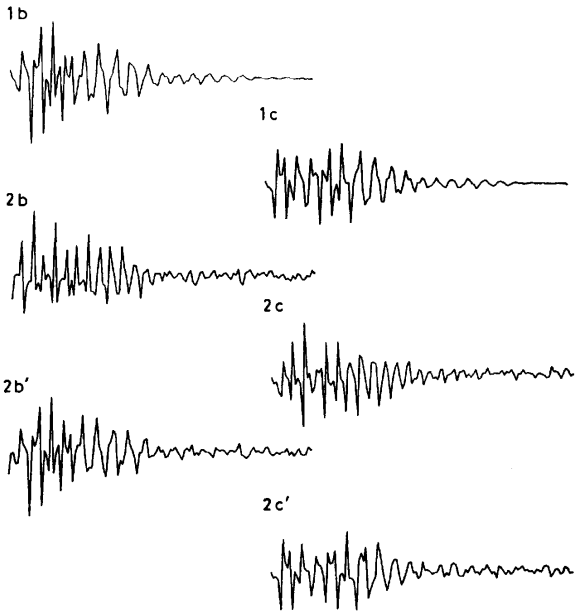

Fig. 2. DFT plots corresponding to 1a and 2a. 1b, 2b, and 2b′ are real-part plots and 1c, 2c, and 2c′ are imaginary-part plots. 2b′ and 2c′ are modified DFT plots.

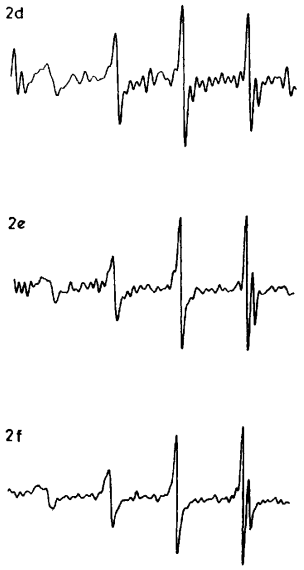

Fig. 3. The reproduced traces by inverse Fourier transform on modified DFT's 2b′ and 2c′. 2d, 2e, and 2f are transformed from 20, 40, and 60 DFT terms in the largest order, respectively.

in Fig. 2. Plots 1b and 1c are the real and imaginary parts, respectively, corresponding to 1a, and plots 2b and 2c the real and imaginary parts, respectively, corresponding to 2a. As comparisons between 1b and 2b, and between 1c and 2c indicate, these are completely different.

To obtain the unknown argument, q'_k, in Eq. 2, a problem arises from multi-valued arctangent function. Although the argument should change linearly with the magnetic field, the actual angle may differ by 2π radians.

Moreover, since the argument, p_k, is computed using the FORTRAN statement, "ATAN2(AIMAG(P(K)), REAL(P(K)))", p_k will fall within the range $-\pi$ to π. Such angles were corrected using the fact that the advanced trace shift corresponding to greater magnetic field results in a gain of the argument, as was discussed previously.[1)]

In comparing known and unknown data for search, another problem occurs: when angle p_k is near π or $-\pi$ radians, the comparison may be unsuccessfull because of deviation errors and the discontinuity of the arctangent function in these regions. For this reason, the DFT are returned as real and imaginary numbers. Therefore, the parameters obtained for the unknown data can be compared with those for the standard data.

Modified DFT plots for the unknown trace, 2a, are shown as 2b′ and 2c′ in Fig. 2. It is seen that 2b′ is almost identical with 1b, and, similarly, 2c′ with 1c, although small differences are present.

The inverse Fourier transform using some of the largest terms may reproduce the original pattern as described previously.[1)] This is demonstrated for the largest twenty, forty, and sixty DFT terms in Fig. 3. Fairly good reproduction is realized for sixty terms, but the number of terms required for an asymmetrical trace is greater than that for a symmetrical trace. The symmetrical wave pattern would be more sinusoidal, requiring fewer DFT terms. On the other hand, an asymmetrical wave pattern, being composed of higher DFT terms, might be less favorable to Fourier processing. Fourier processing, however, might still be effective with respect to data normalization for search and with a reduction of computer memory compared with the storage of original spectral values. It is believed that the present method may be applicable, in general, to analytical spectral data, as well as ESR data.

(Received April 4, 1977)

Synopsis. The ESR spectra of the title compounds were measured at 77 K. From the results, it was concluded that an unpaired electron is localized in the d_{yz} orbital of the cobalt atom of the complexes.

In the last several years we have investigated the electronic structures of low-spin square planar cobalt(II) complexes in terms of their ESR spectra. Very recently we found that 6,13-diaryl-1,8-dihydrodibenzo[*b,i*][1,4,8,11]tetraazacyclotetradecene, **1**(a) and **1**(b), shown in Fig. 1, can be readily obtained from the reaction mixture of 4-aryl-1,2-dithiolium salt and *o*-phenylenediamine.[2)] In this study we have synthesized the cobalt(II) complexes with **1**(a) and **1**(b) and measured their ESR spectra. This is the first report on the ESR spectra of low-spin square planar cobalt(II) complexes with a 14-membered tetraazacyclotetradecene.

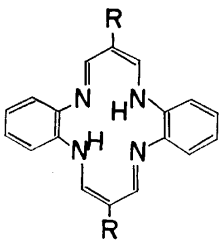

Fig. 1. Tetraaza-macrocyclic ligands. **1**(a): R=phenyl
1(b): R=*p*-tolyl

Experimental

Preparation of the Ligands. The ligand, **1**(a)(or **1**(b)), was obtained from the reaction mixture of 4-phenyl(or 4-*p*-tolyl)-1,2-dithiolium hydrogensulfate and *o*-phenylenediamine.[2)]

Preparation of the Cobalt(II) Complexes. A DMF solution(15 ml) containing cobalt(II) acetate tetrahydrate (0.001 mol) and the ligand(0.001 mol) was refluxed at 150 °C for 3 h. On cooling the solution, the complex was separated as dark violet needles.

Measurements. ESR spectra were obtained with a JEOL ESR spectrometer model JES-ME-3X at 77 K. For the ESR measurements, cobalt(II) complexes were diluted in the corresponding nickel(II) complexes. DPPH was employed as a standard marker. Magnetic susceptibilities were measured at room temperature by the Faraday method, Pascal's constants being used for diamagnetic correction.

Results and Discussion

The magnetic moments of the cobalt(II) complexes with **1**(a) and **1**(b) were 2.28 BM and 2.30 BM at room temperature, respectively, indicating that these complexes are of low-spin type. These cobalt(II) complexes are stable against air in the solid state.

The ligands, **1**(a) and **1**(b), are 14-membered tetraazamacrocyclic ligands with 16 π-electrons, while porphyrins are 16-membered tetraaza-macrocyclic ligands with 18 π-electrons. Therefore it is interesting to compare the electronic states of the complexes of **1**(a) and **1**(b) with those of cobalt(II) porphyrins.

In Fig. 2, the ESR spectrum of cobalt(II) complex with **1**(a) is shown, which is very similar to that of **1**(b). One absorption (g_1=4.256) with eight hyperfine structures due to ^{57}Co was observed in the range 1000—2200 G(G=10^{-4} T). In the range of 3700—4500 G, two absorptions(g_2=1.71, g_3=1.53) were observed, their

c) Unresolved.

hyperfine splittings being smaller than that observed for g_1. It should be noted that this ESR pattern is quite different from that of Co-tpp,[3] where H_2tpp represents $\alpha,\beta,\gamma,\delta$-tetraphenylporphyrin. The latter complex shows an axial pattern with $g_{//}=1.798$ and $g_{\perp}=3.322$, and the hyperfine splitting observed for $g_{//}$ is very large. (*cf.* Table 1).

Recently we have investigated the ESR spectra of low-spin cobalt(II) complexes in detail[4] and found that square planar cobalt(II) complexes can be classified into two types, Type-I and Type-II, in terms of their ESR parameters, as shown in Table I. These two types are different from each other in two points, (1) the anisotropy of $\boldsymbol{g}$-tensors and (2) the value of $|A_z|$. The origin of such differences was attributed to the different ground state configurations, $(d_{x^2-y^2})^2(d_{xz})^2(d_{yz})^2(d_{z^2})^1$ for Type-I and $(d_{x^2-y^2})^2(d_{z^2})^2(d_{xz})^2(d_{yz})^1$ for Type-II.[4,*)]

As clearly seen in Table I, the cobalt(II) complexes with **1**(a) and **1**(b) belong to Type-II, and their ESR parameters can be elucidated in terms of our calculated results[4] based on the $(d_{x^2-y^2})^2(d_{z^2})^2(d_{xz})^2(d_{yz})^1$ ground state configuration.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (9), 2487—2488 (1977)

^{13}C-NMR-Spektren von mono- und disubstituierten Cyclohexenen

Kiyoshi NAKAGAWA, Michimasa SAWAI, Yasutaka ISHII, und Masaya OGAWA

Abteilung für Angewandte Chemie, Technische Fakultät der Universität Kansai, Senriyama, Suita-shi, Osaka 564

(Received December 17, 1976)

Synopsis. ^{13}C-NMR-Spektren von mono- und disubstituierten Cyclohexenen werden vorgelegt. Für die ^{13}C-chemischen Verschiebungen von disubstituierten Cyclohexenen gelten gute Additivitäten, sofern nicht sterische Wechselwirkungen auftreten und daraus einige Gesetzmässigkeiten abgeleitet werden können, die in der Konfigurations- und Konformationsanalyse von Bedeutung sind.

Was die ^{13}C-NMR-Spektren von Cyclohexenderivaten betrifft, werden nur die Monoalkylcyclohexene vorgelegt.[1] In der vorliegenden Arbeit werden ^{13}C-NMR-spektroskopische Daten einer Reihe mono- und disubstituierter Cyclohexenderivate interpretiert.

Resultat und Diskussion

4-Substituierte Cyclohexene werden durch Diels-Alder-Reaktionen von Butadien mit monosubstituierten Äthylenen gewonnen.[2] Die Zuordnung der ^{13}C-Signale von 4-substituierten Cyclohexenen beruhen auf ^{1}H-Off-Resonance-Entkopplung und Substituenteneinfluss auf den Cyclohexenring. Die ^{13}C-chemischen Verschiebungen von 4-substituierten Cyclohexenen sind in Tabelle 1 zusammengefasst. Trägt man α-Effekte von 4-substituierten Cyclohexenen gegen die von CH_3X auf, so stellt man eine lineare Korrelation fest. Da viele α-Effekte von CH_3X bekannt sind[3], kann man α-Effekte von unbekannten 4-substituierten Cyclohexenen schätzen.

Bei der Diels-Alder-Reaktionen von Isopren mit monosubstituierten Äthylenen können zwei Regioisomeren entstehen.[2] Diese Regioisomeren werden nicht durch gebräuchliche Methoden getrennt. Aber die Zuordnung der ^{13}C-Signale von den Regiosiomeren wird im Gemisch erreicht, da die ^{13}C-NMR-Spektren die chemischen Verschiebungen der C-Atome nicht nur direkter, sondern auch deutlicher anzeigen als ^{1}H-NMR-Spektren. In Tabelle 2 und 3 sind die berechneten und beobachteten ^{13}C-chemischen Verschiebungen von 4- und 5-substituierten 1-Methylcyclohexenen zusammengestellt.

Tabelle 2 und 3 zeigen die guten Additivitäten. Man erhält die linearen Korrelationen zwischen den α-Effekten von CH_3X und denen von 4- und 5-substituierten 1-Methycyclohexenen.

Bei der Diels-Alder-Reaktionen von *trans*-1,3-Pentadien mit monosubstituierten Äthylenen können Stereo- und Regioisomeren entstehen.[2] Da die *meta*-Isomeren nur in geringem Anteil entstehen, sind die Isolierung dieser Isomeren schwer. Demnach behandeln wir die *ortho*-Isomeren. Jedes *ortho*-Isomer kann als Gleichgewicht zweier Konformeren auftreten. In der Regel ist das diaxiale Konformer thermolabiler als das diäquatoriale Konformer, was dafür spricht, dass das diäquatoriale Konformer gegenüber dem diaxialen Konformer bevorzugt ist. Für *ortho-cis*-Isomere erwartet man das zeitmittlere Spektrum. Im Vergleich zum *ortho-trans*-Isomer erlei den die Signale von C-3, -4, -5, -6, Methylkohlenstoff und Substituentskohlenstoff in ortho-cis-Isomeren die erwarteten Hochfeldverschiebungen infolge des sterischen Kompressionseffektes. In Tabelle 4 sind die berechneten und beobachteten ^{13}C-chemischen Verschiebungen von 4-substituierten 3-Methyl-cyclohexenen zusammengestellt. Wegen der

Experimenteller Teil

Zur Aufnahme der PFT-^{13}C-NMR-Spektren diente ein PS-100 von JEOL-Gerät mit einer Messfrequenz von 25.15 MHz. Alle Substanzen wurden als 50%-ige Lösung in $CDCl_3$ gemessen(TMS als innerer Standard). ^{1}H-Rauschentkopplung-PFT-^{13}C-NMR-Spektren wurden unter Akkumulation von 200 Pulsinterferogrammen bei einer Pulsbreite von 12.5 µsek (Pulswinkel 45°) und einem Pulsintervall von 6 sek durch Fourier-Transformation des akkumulierten Interferogramms mit einem JEC-6-Rechner erhalten(Spektrumbreite 5 kHz; Datenpunkte 8191). Die mono- und disubstituierten Cyclohexene wurden durch bekannte Diels-Alder-Reaktionen von acyclischen Dienen mit monosubstituierten Äthylenen gewonnen(150°—200 °C; 2—7 Stdn.). Vgl. Tabelle 5.

Photochromism of 2,2,4,6-Tetraphenyl-1,2-dihydro-1,3,5-triazine

Taro HAYASHI

Institute of Physical and Chemical Research, Wako, Saitama 351

(Received September 17, 1976)

Synopsis. 2,2,4,6-Tetraphenyl-1,2-dihydro-1,3,5-triazine shows temperature dependent photochromism only in a solid state at temperatures above *ca.* −70 °C under UV(320—380 nm) irradiation, giving several absorption maxima in the visible region, but no change in the IR spectrum. *N*-Substituted derivatives show no photochromism.

It was briefly reported by Lottermoser[1] that 2,2,4,6-tetraphenyl-1,2-dihydro-1,3,5-triazine (TPDT) exhibits photochromism in a solid state. No investigation has been made since the phenomenon was confirmed by von Walthers.[2] In this note the specificity of the photochromism of TPDT is reported.

TPDT turned brownish pink on irradiation in a solid state with the light 320—380 nm of sunlight or a Xenon lamp, the coloration reaching a limit with continual irradiation. TPDT which showed λ_{max} 257 and 325 nm (broad; assigned to an n,π^*-transition[3]) in a solid state before irradiation showed λ_{max} 430, 447, 487, 502, 533, 565, and 584 nm in a solid state after irradiation (Fig. 1).

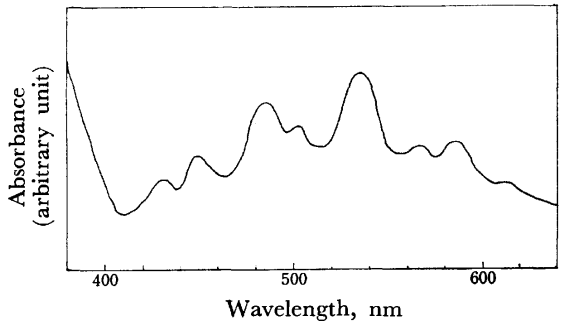

Fig. 1. The electronic absorption spectrum of TPDT measured in a solid state after irradiation at room temperature (the paraffin paper method).

It seems that the absorption at 325 nm indicates the start of photochromism. The color hardly faded at all at room temperature in the dark and also under irradiation with visible light, but it reverted thermally to the original colorless state in the dark slowly at temperatures above room temperature, somewhat rapidly with a rise in temperature. TPDT showed no change in the IR spectrum in the range 650—4000 cm^{-1} on irradiation in solid state, showing no ESR signal in both solid state not irradiated and solid state irradiated. The photochromic characteristic was lost by repetition of photochromic treatment.

It was found that TPDT exhibits photochromism only in solid state, since TPDT exhibits photochromism neither in solutions at various temperatures nor in rigid glasses in mixed solvents such as isopentane–methylcyclohexane(1 : 1) at *ca.* −196 °C. In addition, no absorption of the light in the visible region was recorded at room temperature on high density excitation by the 337 nm light of a nitrogen laser pulse with a nanosecond time-resolved spectrosco pytechnique.[4] The result indicates that TPDT does not yield even a transient colored species with a short lifetime on irradiation in solution. Very few compounds have been reported[5,6] which exhibit photochromism only in a solid state.

The photochromism of TPDT is temperature dependent. It was not observed at low temperatures below *ca.* −70 °C down to *ca.* −196 °C. A weak photochromic coloration was first observed at *ca.* −70 °C, deepening with a rise in temperature to about room temperature. No such temperature dependence seems to have been reported.[6]

TPDT containing a solvent of crystallization, such as acetone, benzene and chloroform, exhibited photochromism accompanied by the absorption of light in visible region, similar to that of TPDT free from a solvent of crystallization. TPDT containing methanol or ethanol as a solvent of crystallization, in which formation of a hydrogen bond between the alcohol and NH of TPDT was confirmed by IR analysis, exhibited no photochromism. Salts of TPDT, such as hydrochloride, and *N*-substituted TPDT, such as *N*-methyl-, *N*-ethyl-, and *N*-nitroso-TPDT, exhibited no photochromism. This shows that the photochromism of TPDT requires the presence of free H in NH.

The results suggest that the mechanism of the photochromism of TPDT is of a new type[6] attributed to an intermolecular interaction in a crystalline structure, presumably an interaction between free H in NH and excited C=N, rather than an intramolecular change of the molecular structure.

Experimental

The crystals of 2,2,4,6-tetraphenyl-1,2-dihydro-1,3,5-triazine(TPDT), $C_{27}H_{21}N_3$, were prepared according to the method of von Walthers;[2] colorless fine crystalline powder, mp 197—198 °C; $\lambda_{max}^{C_2H_5OH}$ 242($\varepsilon=3.62\times10^4$), 307($\varepsilon=1710$), 330 nm ($\varepsilon=1100$), $\lambda_{max}^{C_6H_6}$ 274($\varepsilon=6.84\times10^4$), 310(sh)($\varepsilon=1170$), 333 nm ($\varepsilon=884$); IR(KBr) 3405(m, ν_{NH}), 1685(w), 1612 cm^{-1}(m, ν_{CN}); NMR(δ ppm) 6.12 (1H, NH; missing on treatment with D_2O), 7.20—8.60 (aromatic protons). TPDT exhibits no thermochromism both in solid state and in solution. TPDT containing methanol, ethanol, benzene, acetone, or chloroform as solvent of crystallization was obtained as colorless fine crystals by recrystallization of TPDT from the solvents respectively; $C_{27}H_{21}N_3\cdot CH_3OH$(IR 3190 cm^{-1}, m, ν_{NH} (hydrogen-bonded)), $C_{27}H_{21}N_3\cdot C_2H_5OH$ (IR 3155 cm^{-1}, m,) $C_{27}H_{21}N_3\cdot CH_3COCH_3$(IR 3420 cm^{-1}, m, ν_{NH}), $C_{27}H_{21}N_3\cdot 1/3\ C_6H_6$ (IR 3415 cm^{-1}, m), $C_{27}H_{21}N_3\cdot 1/5\ CHCl_3$ (IR 3415 cm^{-1}, m). *N*-Methyl-TPDT, mp 198—200 °C, and *N*-ethyl-TPDT, mp 218—219 °C, were prepared[7] from alkyl iodide and TPDT-potassium which was obtained by heating TPDT with metallic potassium in dioxane. *N*-Nitroso-TPDT, $C_{27}H_{20}ON_4\cdot 2H_2O$, mp 171—173 °C, was prepared by a reaction of an aqueous

solution of sodium nitrite with TPDT-hydrochloride, $C_{27}H_{21}N_3 \cdot HCl$, obtained from TPDT and 2M HCl.

The electronic absorption spectra were measured with a Cary 14 spectrophotometer. The spectrum in a solid state was recorded with a thin layer of the specimen on paraffin paper obtained by rubbing crystals of the specimen on paraffin paper with an agate pestle and also with KBr disk. The infrared spectra were recorded with a Hitachi 215 grating spectrophotometer. The nuclear magnetic resonance spectrum was recorded with a Varian HA 100D spectrometer. The electron spin resonance was recorded with a JES 3B electron spin resonance spectrometer of Japan Electron Optics Laboratory.

The author wishes to express his gratitude to Dr. H. Midorikawa, Dr. K. Yamamoto, Dr. T. Kobayashi, and Dr. R. Nakagaki, Institute of Physical and Chemical Research, and Dr. K. Maeda, Ochanomizu University, for their kind help throughout this work.

Para Tolylation of Pyridine by Photolysis of Di-*p*-Tolyl Sulfone and Related Compounds

Takeshige NAKABAYASHI, Toyokazu HORII, Shunichi KAWAMURA, and Masayuki HAMADA

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

(Received February 16, 1977)

Synopsis. Di-*p*-tolyl sulfone, sulfoxide and sulfide, *p*-toluoyl peroxide, and *p*-iodotoluene were respectively photolyzed in pyridine with a mercury arc lamp. It was found that all the compounds decompose photochemically to yield the isomeric *p*-tolylpyridines (α, β, and γ). The isomer distribution ratios ($\beta > \alpha > \gamma$) obtained with the sulfone differ from those ($\alpha > \beta > \gamma$) with the other compounds. The presence of acetone in the reaction system remarkably promoted the photochemical conversion of both the sulfone and sulfoxide.

Kharasch and Khodair[1] first reported that the photolysis of diaryl sulfone, sulfoxide, and sulfide in benzene produces aryl radicals which afford the corresponding biphenyl derivatives in good yields. They proposed the following intermolecular mechanism: the photolytic cleavage of the C–S bond of the sulfone, sulfoxide, or sulfide gives the aryl radical which, in turn, reacts with benzene to form the intermediate arylcyclohexadienyl radical, and finally the corresponding biphenyls are produced by the hydrogen atom abstraction from the intermediate. The mechanism was confirmed by Nakai *et al.*[2] in the photolysis of a benzene solution of diphenyl-1,1′-$^{14}C_2$ sulfone. Khodair *et al.*[3] reported that the photolysis of a series of symmetrical and unsymmetrical aromatic sulfones in benzene solutions gives rise to only the corresponding monosubstituted biphenyls but no disubstituted biphenyls. Diphenyl sulfone in selected aromatic solvents undergoes photolysis to afford the corresponding isomeric biphenyl derivatives (*o*-, *p*-, and *m*-).[4] This also supports the above mechanism involving the attack of aryl radical on aromatics used as the solvent. In the course of studies on the photolysis of aromatic sulfones, it was found[5] that the photolysis of diphenyl sulfone in a pyridine solution gives rise to three isomeric phenylpyridines whose isomer distribution ratios ($\beta > \alpha > \gamma$) differ from those ($\alpha > \beta > \gamma$) for a free-radical phenylation of pyridine. The purpose of the present work is to examine whether or not the order of the isomer distribution ratios of *p*-tolylpyridines produced by the photolysis of di-*p*-tolyl sulfone in pyridine coincides with that obtained with the diphenyl sulfone.

Di-*p*-tolyl sulfone (1.5 mmol, 369.5 mg) in 100 ml of pyridine or pyridine–acetone (1 : 1 in volume) was irradiated for 20 h or 50 h at room temperature, with a 400-W medium pressure mercury arc lamp. After irradiation, the unchanged sulfone and isomeric *p*-tolylpyridines produced in the reaction mixture were identified and estimated by gas chromatography. For the sake of comparison, di-*p*-tolyl sulfoxide and sulfide, *p*-toluoyl peroxide, and *p*-iodotoluene were photolyzed in the same way as for the sulfone. The results are summarized in Table 1. We see that acetone photosensitized the degradation of both sulfone and sulfoxide in pyridine solutions, but decreased markedly the yield of the isomeric *p*-tolylpyridines with sulfoxide. The isomer distribution ratios of the *p*-tolylpyridines were hardly or not at all affected by the acetone present in the reaction mixture. Either di-*p*-tolyl sulfoxide or sulfide was photolyzed in acetone to give *p*-tolyl radical which abstracts a hydrogen atom from acetone affording toluene in a good yield. Accordingly, the low yields of the *p*-tolylpyridines both with the sulfoxide and sulfide in the presence of acetone seem to be ascribed to the competitive formation of toluene with the *p*-tolylpyridines. The isomer distribution ratios ($\beta > \alpha > \gamma$) with the sulfone differ from those ($\alpha > \beta > \gamma$) obtained with the other compounds (Table 1), being comparable to those with diphenyl sulfone.[5] The gross isomer distribution ratios

a) Determined by estimation of the unchanged starting compounds. b) Based on the amount which actually underwent photolysis and on the assumption that 1 mole of the starting compound gives 1 mole of *p*-tolylpyridines. c) Preliminary work indicated that authentic *p*-tolylpyridines do not isomerize mutually under our reaction conditions. d) Not determined.

in a free-radical phenylation of pyridine are essentially independent of the source of phenyl radicals.[6,7] Abramovitch and Saha[8] reported that in the reaction with *p*-tolyl radical generated by the Gomberg-Hey reaction, the isomer distribution ratios of *p*-tolylpyridines are $\alpha=58.0\%$, $\beta=26.2\%$, and $\gamma=15.7\%$. This suggests that the *p*-tolylation of pyridine with compounds other than the sulfone proceeds *via* simple *p*-tolyl radical generated from the radical sources themselves under UV irradiation. Although the reason for the characteristic result obtained with the sulfone is ambiguous, we propose the following mechanism based on the fact that the yield of the *p*-tolylpyridines with the sulfone does not decrease substantially even in the presence of acetone : the sulfone in pyridine interacts on UV irradiation with pyridine to form a sulfone-pyridine complex[9] which decomposes exclusively into the *p*-tolylpyridines giving the isomer distribution ratios of $\beta>\alpha>\gamma$.

Experimental

Materials. Commercial di-*p*-tolyl sulfone (mp 160 °C), di-*p*-tolyl sulfoxide (mp 96—97 °C), and *p*-iodotoluene were purified by recrystallization or preparative gas chromatography. *p*-Toluoyl peroxide (mp 134—135 °C, dec : lit[10] 136—137 °C, dec) was prepared by the method given in literature from the reaction of *p*-toluoyl chloride with sodium peroxide and purified by recrystallization from ethanol. Di-*p*-tolyl sulfide (mp 56—57.5 °C) was supplied by Dr. S. Tamagaki, Osaka City University. Pyridine and acetone were of spectroscopic grade and used without further purification. Authentic α-*p*-tolylpyridine was prepared from the corresponding bromopyridine according to the procedure of Abramovitch and Saha.[11] Authentic β-*p*-tolylpyridine was prepared by a slight modification of the procedure since it was found that a mixture of β-*p*-tolylpyridine and 4-methyl-1-(3-pyridyl)-1-cyclohexene was produced by the procedure; additional dehydrogenation of the above mixture was carried out with elemental sulfur at 200 °C. The two *p*-tolylpyridines thus obtained were purified by preparative gas chromatography on a 5 m×3 mm column packed with 20% OV-210 on Shimalite W (210 D), using a JEOL Chromatograph, JGC-650. Authentic γ-*p*-tolylpyridine was prepared by the dehydrogenation of γ-*p*-tolyl-1,2,3,6-tetrahydropyridine obtained from *p*-α-dimethylstyrene, ammonium chloride, and formaldehyde.[12] The compound was purified by recrystallization twice from hexane (mp 90—91 °C, lit,[12] 90—91 °C).

General Procedure for the Photolysis of Di-p-Tolyl Sulfone and Related Compounds. The procedure for the sulfone is described here as a typical run. A 0.015 M-solution of di-*p*-tolyl sulfone in 100 ml of pyridine or pyridine–acetone (1 : 1 in volume) was placed in a quartz cylinder. The solution was irradiated for 50 h or 20 h at room temperature, with a 400 W-medium pressure mercury arc lamp. After the irradiation, the photolysate was transferred to a round-bottomed flask, acetone or pyridine being removed by means of a rotary evaporator. The residue was treated with benzene in order to remove benzene-insoluble materials. The benzene solution was washed with water and dried over anhydrous sodium sulfate. After most of the solvent had been evaporated, the oily residue was placed in a volumetric flask, adjusted to an appropriate volume with acetone, and subjected to GLC analysis to determine the unchanged sulfone and isomeric *p*-tolylpyridines produced in the reaction. All the GLC analyses were carried out with use of a Shimadzu Gas Chromatograph GC-3AF equipped with a flame ionization detector. The unchanged sulfone and isomeric *p*-tolylpyridines obtained were identified by comparison of their retention times with those of authentic specimens, their amounts being estimated by use of calibration curves for the authentic compounds. A 3 m× 3 mm column packed with 5% OV-210 on Shimalite W (210 D) was employed in the GLC analyses.

Reaction of Dioxygen Complexes with Catechols

Shigeaki MUTO, Kazuaki TASAKA, and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 22, 1977)

Synopsis. The square planar dioxygen complexes $MO_2(PPh_3)_2$(M=Pt, Pd) reacted with catechols at low temperature to give H_2O_2 and the corresponding catecholato complexes, characterized by their physical properties, in high yields. A similar treatment of $PtO_2(PPh_3)_2$ with *o*-substituted anilines afforded the corresponding adducts and H_2O_2 in moderate yields.

A number of reports have appeared on the formation of catecholato complexes by oxidative addition of *o*-quinones to metal complexes having mainly d^6, d^8, and d^{10} electron configurations.[1-7] We have found that these complexes can also be obtained in high yields by an other route. In this paper we deal with the reaction of dioxygen complexes with catechols which results in the selective formation of catecholato complexes and H_2O_2. The reactivity of dioxygen complexes toward *o*-substituted anilines was also studied, the reactions of square planar dioxygen complexes $MO_2(PPh_3)_2$-(M=Pt, Pd)[8-10] with catechlos being carried out in CH_2Cl_2 or CH_2Cl_2–EtOH(1 : 1 by volume) solvent at low temperature. Hydrogen peroxide formed during the course of reaction was transferred under vacuum (*ca.* 10^{-2} Torr) and then titrated by the conventional iodometric method. The transfer efficiency for H_2O_2 was about 98 percent.

Table 1. Yield of H_2O_2 and catecholato complexes in the reaction of dioxygen complexes with phenols or aromatic diamines at 2 °C[a]

Dioxygen complex (1.97×10^{-2} M)	Phenol or diamine (8.25×10^{-2} M)	Yield (%) H_2O_2	Yield (%) Catecholato complex
$PtO_2(PPh_3)_2$	**1a**[b]	85.1	87.8
	1a[b]	1.22[c]	87.8
	1b	68.3	77.6
	1c	66.5	75.7
	o-Aminophenol	83.2	64.0
	o-Phenylenediamine	57.6	51.5
	Hydroquinone	5.34	
	p-Aminophenol	7.40	
	p-Phenylenediamine	—[d]	
$PdO_2(PPh_3)_2$[e]	**1a**	72.1	68.9
	1b	65.7	63.7
	1c	59.1	65.7
	o-Aminophenol	36.5	
	o-Phenylenediamine	3.58	
	p-Aminophenol	4.44	
	p-Phenylenediamine	—[d]	

a) All the reactions were carried out in 4 ml of CH_2Cl_2-EtOH(1 : 1 by volume) under N_2 for 1 h. b) Reacted in 4 ml of CH_2Cl_2. c) Treated with catalase prior to titration. d) No peroxide was detected by iodometry. e) $[PdO_2(PPh_3)_2]$ was 1.68×10^{-2} M.

$PtO_2(PPh_3)_2$ reacted with catechol(**1a**), 4-*t*-butylcatechol(**1b**), and 3,5-di-*t*-butylcatechol(**1c**) under nitrogen atmosphere to give peroxide in 66—85% yields based on the dioxygen complexes (Table 1). The fact that the amount of peroxide formed considerably decreases by treatment with catalase prior to titration indicates that the peroxide transferred is principally H_2O_2. H_2O_2 was also obtained in moderate yields in the reaction of $PtO_2(PPh_3)_2$ with *o*-aminophenol and *o*-phenylenediamine. Similarly reaction of $PdO_2(PPh_3)_2$ with **1a**, **1b**, and **1c** gave H_2O_2 in 59—72% yields. No H_2O_2 is formed under N_2 in the absence of $MO_2(PPh_3)_2$. This suggests that the peroxide titrated was driven from the coordinated molecular oxygen of $MO_2(PPh_3)_2$. The yields of H_2O_2 obtained in the reactions of the dioxygen complexes with *p*-substituted phenols were much less than those obtained by use of the corresponding *o*-isomers. A possible explanation may beth at catechol dianions are suitable ligands for the formation of these complexes.

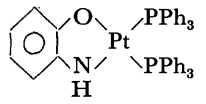
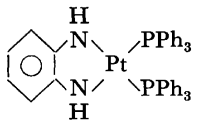
a) The IR spectra were calibrated with polystyrene film. w weak, m medium, s strong, sh shoulder.
b) Overlapping with the strong PPh_3 band. c) In CH_2Cl_2 solution.

δ 7.26(m, 30H, PPh_3), δ 6.43(br d, 2H, C_6H_2), δ 1.23 (s, 9H, 5-Bu^t), δ 0.99(s, 9H, 3-Bu^t). **2e**: δ 7.24(m, 30H, PPh_3), δ 6.33(br s, 2H, C_6H_2), δ 1.23(s, 9H, 5-Bu^t), δ 0.92(s, 9H, 3-Bu^t).). The infrared spectra (Table 2) of the complexes are similar to each other. The parent catechols show intense hydroxyl absorption at *ca.* 3500 cm^{-1}, but none in the 4000—3100 cm^{-1} region. In the 1800—1500 cm^{-1} region no bands were observed except for a weak band at 1570—1551 cm^{-1} which seems to be the characteristic of the reduced form of the ligand as reported for $Pt(C_6Cl_4O_2)(PPh_3)_2$.[5] All the complexes exhibited intense IR absorption at 1098 cm^{-1} characteristic of the coordinated PPh_3. Other new bands in the complexes were observed at *ca.* 1260, 1093, and 998 cm^{-1} where the parent catechols show no characteristic absorption. The results support the structures illustrated above.



3



4

3 and **4** were obtained in moderate yields as brown and reddish brown crystals, respectively, by similar reactions of $PtO_2(PPh_3)_2$ with *o*-aminophenol and *o*-phenylenediamine. Analytical data of complexes **3** and **4** are as follows: **3** Found: C, 61.47; H, 4.48; N, 1.44%. Calcd for $C_{42}H_{35}ONP_2Pt$: C, 61.01; H, 4.28; N, 1.66%. **4** Found: C, 60.51; H, 4.54; N, 3.17%. Calcd for $C_{42}H_{36}N_2P_2Pt$: C, 61.08; H, 4.40; N, 3.39%. IR(Nujol) **3**: 3410, 1572, 1291, 1270, 1098, and 997 cm^{-1}, **4**: 3400, 1567, 1298, 1098, and 997 cm^{-1}. Complex **4** is unstable in solution at ambient temperature, decomposing in a few hours to give black precipitates. However, the NMR spectrum of **4** in $CDCl_3$ solution exhibits a singlet absorption at 5.25 and a multiplet at 7.21 ppm. This also indicates the formula $Pt(C_6H_4NHO)(PPh_3)_2$ and $Pt(C_6H_4N_2H_2)(PPh_3)_2$ for **3** and **4**, respectively.

Experimental

Melting points were determined on a Yazawa hot-stage apparatus and are uncorrected. IR spectra were recorded as Nujol mulls on a Nippon Bunko IR-G spectrophotometer (4000—400 cm^{-1}), calibrated with polystyrene film. ^1H NMR spectra were measured in $CDCl_3$ solution on a JEOL JMN PMX 60 spectrometer.

Preparation of Catecholato Complexes. The general procedure for the preparation of catecholato complexes is as follows. Excess catechol(0.22 g, 2.0 mmol) dissolved in EtOH (10 ml) was added dropwise to a stirred solution of $PtO_2(PPh_3)_2 \cdot 1.5C_6H_6$(0.44 g, 0.5 mmol) in CH_2Cl_2(2 ml) at 0 °C. The solution was then stirred for 1 h at 0 °C. At the end of the reaction, the mixture containing an appreciable amount of precipitates was filtered and washed twice with EtOH. Recrystallization from $CHCl_3$ gave yellow crystals in 88% yield. A similar procedure for the preparation of other complexes was employed(yields were 50—80%). Infrared data for individual complexes are given in Table 2.

The authors wish to thank Dr. E. Niki, the University of Tokyo, for his valuable discussions.

Friedel-Crafts Reaction of Benzene with 2-Phenylbutanedioic Anhydride

Iwao HASHIMOTO and Ryozo TAKATSUKA

Department of Industrial Chemistry, Wakayama Technical College, Noshima, Nada-cho, Gobo 649-15

(Received March 1, 1977)

Synopsis. The $AlCl_3$-catalyzed acylation of benzene with 2-phenylbutanedioic anhydride was found to give a mixture of 3-benzoyl-2-phenylpropanoic acid, isomeric 3-benzoyl-3-pehnylpropanoic acid, and 3-oxoindan-1-carboxylic acid. The distribution of the products was affected markedly by the amount of $AlCl_3$ or solvents used.

It has been reported in earlier publications[1-5] that the acylation of benzene with 2-phenylbutanedioic anhydride (**1**) gave only the intermolecular acylation products, 3-benzoyl-2-phenylpropanoic acid (**2**) and 3-benzoyl-3-phenylpropanoic acid (**3**), in low yields (6.9 and 7.5%, respectively). However, the reaction mechanism discussed on the basis of such low yields does not appear to afford a rational mechanism, and furthermore, there is the possibility of intramolecular acylation of **1** itself. In the present work, the acylation of benzene with **1** was studied in more detail and the solvent effect was examined.

Results and Discussion

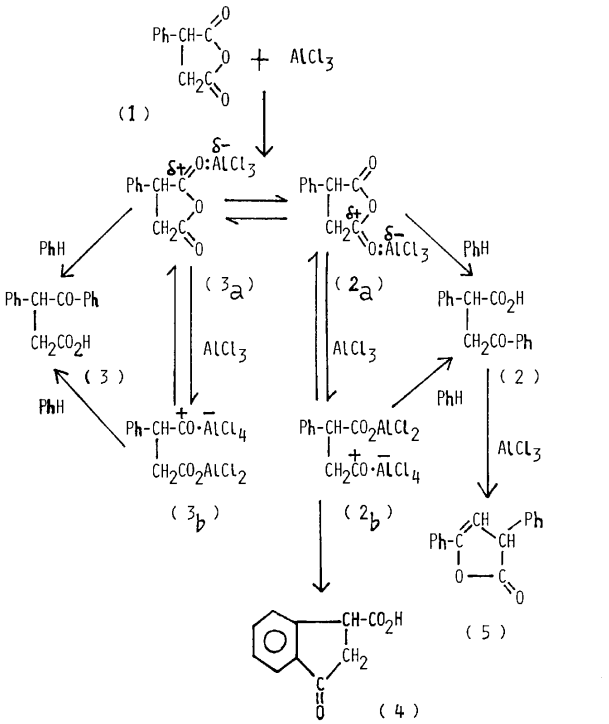
Ten mmol of **1** reacted almost quantitatively with 20 mmol of $AlCl_3$ in a large excess of benzene (550 mmol) to give a mixture of **2** and **3**, in which the yield of **3** was about twice as much as that of **2**.

When acylation using a lesser amount of benzene (10 mmol) was carried out in the presence of 20 mmol of $AlCl_3$ in 1,2-dichloroethane, a considerable amount of **4**, an intramolecular acylation product, was formed along with **2** and **3**. A high yield (93%) of **4** was also obtained in the absence of benzene using 1,2-dichloroethane as a solvent. These facts indicate that both inter- and intramolecular acylations occur competitively in the reaction system. A decrease in the amount of $AlCl_3$ in 1,2-dichloroethane resulted in a greater decrease in the yield of **3** than those of **2** and **4**, or higher (**2**+**4**)/(**3**) ratio.

Acylation in nitrobenzene gave the same products, accompanied by a small amount of 2,4-diphenyl-3-buten-4-olide (**5**). However, the yield of **3** was low even with a greater amount (30 mmol) of $AlCl_3$ and it was always less than that of **2**.

These results suggest the following reaction paths: In the presence of a sufficient amount (20 mmol) of $AlCl_3$, the acylating agent should be the acyl halide complexes (**2b** and **3b**), because one molecule of dibasic acid anhydride requires two molecules of $AlCl_3$ to form an acyl halide complex.[6] The electrophilic reactivity of **3b** having an electron-attracting phenyl group closer to the acylium cation may be greater than that of **2b**, hence, **3** is formed preferentially, even though the concentration of **3b** is lower than that of species **2b** (or **2a**).

However, for an insufficient amount of $AlCl_3$ (10 mmol), complexes of the entire anhydride molecule



Scheme 1.

coordinated with one molecule of $AlCl_3$ (**2a** and **3a**) should appear as the actual acylating agents.[7] The concentration of the complex, **2a**, in which $AlCl_3$ is added to the oxygen atom separated from the phenyl group, should be higher than that of **3a** (or **3b**). Complex **2a** should afford **2** and **4** upon acylation, although **4** may be formed preferentially *via* **2b**. Therefore, a decrease in the amount of $AlCl_3$ leads to an increase in the ratio (**2**+**4**)/(**3**).

Since nitrobenzene is a polar solvent, the polarized complexes (**2b** and **3b**) should be strongly solvated by nitrobenzene to form bulky acylating species. Such bulky acylating species may be unfavorable for the electrophilic attack on the benzene molecule, hence, the yields of **2** and **3** become low. Furthermore, the complex formation between nitrobenzene and $AlCl_3$ may decrease the effective amount of $AlCl_3$ and thus unfavorably affect the formation of **3a** (or **3b**) with the result that the yield of **3** is low.

The reaction of isolated **2** with $AlCl_3$ in nitrobenzene gave **5** *via* the enolization of **2**.

Experimental

General Procedure for the Acylation of Benzene with 2-Phenylbutanedioic Anhydride (1). To a solution of benzene and $AlCl_3$ in $ClCH_2CH_2Cl$ was gradually added a solution of **1** in $ClCH_2CH_2Cl$. The reaction mixture was stirred at 25 °C for 5 h, poured onto crushed ice containing 6 ml of concd

HCl, and then extracted with ether. After removal of the solvent, the crude keto carboxylic acids were methylated with an ethereal solution of diazomethane. The resulting esters were analyzed by means of GLPC employing a Yanagimoto G 800 T Model chromatograph on a 1.5 m×3 mm column packed with Apiezon Grease M (5 wt%) with a He flow of 40 ml/min at 205 °C. Benzyl benzoate was used as an internal standard.

The authors are very grateful to Professor Yoshiro Ogata of Nagoya University for valuable discussions concerning this work.

An Efficient Synthesis of Bicyclo[3.1.0]hex-3-en-2-one

Masaji ODA,* Yoshinori KANAO, Masaji KASAI, and (the late) Yoshio KITAHARA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received March 19, 1977)

Synopsis. Bicyclo[3.1.0]hex-3-en-2-one is synthesized in fair yield in five steps from 4-cyclopentene-1,3-dione-furan Diels-Alder adduct.

Although a good number of derivatives of bicyclo-[3.1.0]-hex-3-en-2-one (**1**) have been described, there is only one paper dealing with the synthesis of the parent componnd.[1] The preparation starts from 2-cyclopentenone and the total yield is poor. We have recently reported the preparation of 4-cyclopentene-1,3-dione-furan Diels-Alder adduct (*exo*-10-oxatricyclo[5.2.1.$0^{2,6}$]-dec-8-en-3,5-dione) (**2**).[2] In view of ready thermal cycloreversion of furan–Diels-Alder adducts[3] and of high reactivities of 1,3-diones, the adduct (**2**) could be a versatile synthetic intermediate for cyclopentenoids. We here describe an efficient synthesis of the parent compound (**1**) from **2**.

Treatment of **2** with a slight excess of triethyloxonium tetrafluoroborate[4] in the presence of triethylamine in methylene chloride afforded the enol ether (**3**) in quantitative yield. The enol ether (**3**) was then converted into the cyclopentenone derivative (**4**) by reduction with lithium aluminum hydride and following acid hydrolysis of the resulting hydroxy enol ether with aqueous acetic acid in 54% overall yield.

Cyclopropanation of **4** using dimethylsulfoxonium methylide[5] in dimethyl sulfoxide gave the cyclopropyl ketone (**5**) in 84% yield. The configuration of the cyclopropane ring is tentatively assigned to be *anti* to the 2,5-dihydrofuran moiety on the basis of steric hindrance.

As expected, the thermal cycloreversion of **5** to **1** was fairly easy: on heating in a short-path distillating apparatus[6] at 120—140 °C at the pressure of 200 mmHg, **5** gave almost pure material of **1** in 76% yield.

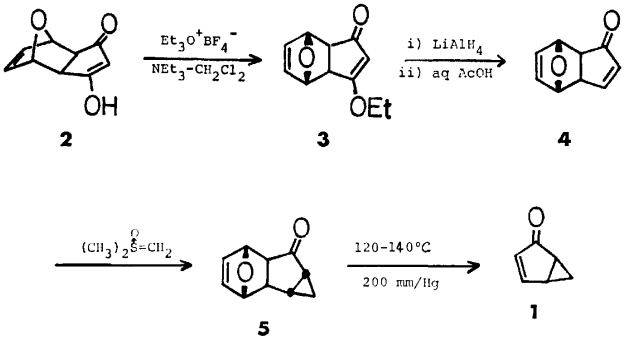

Chart.

Experimental

Melting points were uncorrected. IR spectra were recorded with a Hitachi 215 grating spectrometer and PMR with a Varian A-60A and a JEOL PMX-60 spectrometers. Microanalyses were performed at the Microanalytical Laboratory in this department.

*5-Ethoxy-10-oxatricyclo[5.2.1.$0^{2,6}$]deca-4,8-dien-3-one (**3**).* To a solution of 10-oxatricyclo[5.2.1.$0^{2,6}$]deca-8-en-3,5-dione (**2**)[2] (10.0 g, 61 mmol) and triethylamine (7.88 g, 78 mmol) in methylene chloride (100 ml) was added rapidly triethyloxonium tetrafluoroborate (14.0 g, 74 mmol) at room temperature. After stirring for one hour, the reaction mixture was washed with water (30 ml×5), dried over $MgSO_4$, and the solvent evaporated off under reduced pressure to give 11.7 g (100%) of **3** as solids. Recrystallization from benzene gave pure materials, mp 137—138 °C. IR (KBr) 1674, 1582 cm^{-1}; PMR ($CDCl_3$) δ 6.53 (2H, s), 5.37 (1H, s), 5.12 (1H, br. s), 5.04 (1H, br. s), 4.14 (2H, q, J 7.0 Hz), 2.88 (1H, d, 5.6), 2.57 (1H, d, 5.6), 1.44 (3H, t, 7.0). Found: C, 68.66; H, 6.54%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

*9-Oxatricyclo[5.2.1.$0^{2,6}$]deca-4,8-dien-3-one (**4**).* To a suspension of lithium aluminum hydride (1.14 g, 30 mmol) in ether (150 ml) was added dropwise a solution of the crude **3** (11.7 g, 61 mol) in tetrahydrofuran (150 ml) under stirring in an ice-bath. The mixture was then stirred at room temperature for two hours. Water (10 ml) was cautiously added to the reaction mixture under ice-cooling and then 20 g of $MgSO_4$. The solids were filtered with suction and washed with tetrahydrofuran (50 ml×3), and the filtrate concentrated to leave 11.2 g of oil which on standing mostly crystallized. The crude product was then dissolved in 60% aqueous acetic acid (50 ml) and the solution was allowed to stand at room temperature for two days. The mixture was added with methylene chloride (250 ml), and the organic layer was washed with water (50 ml×3), saturated aqueous sodium carbonate until no more carbon dioxide evolved, and finally with brine, and the organic layer dried. Removal of the solvent left 8.6 g of pale yellow oil. Chromatography on silica gel (100 g) using benzene–ethyl acetate as eluent afforded 4.9 g (54%) of **4**, mp 69—70 °C. IR (KBr) 1692, 1584 cm^{-1}; PMR ($CDCl_3$) δ 7.65 (1H, ddd, J 5.6, 2.5, 0.5 Hz), 6.5 (2H, m), 6.24 (1H, dd, 5.6, 1.3), 4.99 (1H, m), 4.78 (1H, m), 3.01 (1H, ddd, 5.0, 2.5, 1.3), 2.39 (1H, d, 5.0). Found: C, 72.99; H, 5.44%. Calcd for $C_9H_8O_2$: C, 72.96; H, 5.44%.

*11-Oxatetracyclo[6.2.1.$0^{2,7}$.$0^{4,6}$]undec-9-en-3-one (**5**).* To a solution of dimethylsulfoxonium methylide prepared *in situ* from trimethylsulfoxonium iodide (4.0 g, 18 mmol) and sodium hydride (450 mg, 18.8 mmol) in dimethyl sulfoxide (25 ml) was added **4** (2.40 g, 16 mmol) under nitrogen atmosphere at room temperature. After one hour, ice-water (150 ml) was added and the mixture extracted with methylene chloride (50 ml×3), and the organic layer was washed with water (25 ml×2), and dried. After removal of the solvent, the residue was passed through a short silica gel column (30 g) to afford 2.20 g (84%) of **5**, mp 46—48 °C. IR (KBr) 1712 cm^{-1}; PMR (CCl_4) δ 6.4 (2H, m), 4.9 (2H, m), 2.28 (1H, d, J 6.0 Hz), 2.1—1.8 (3H, m), 1.15 (1H, dddd, 8.5, 7.5, 4.5, 1.3), 0.61 (1H, dt, 4.5, 4.0). Found: C, 74.10; H, 6.33%. Calcd for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22%.

*Bicyclo[3.1.0]hex-3-en-2-one (**1**).* The cyclopropyl ketone (**5**) (207 mg) was heated in a short-path distillating apparatus[6] at 120—140 °C under the reduced pressure of

200 mmHg. After about 20 min, 91 mg (76%) of almost pure **1** was distilled. IR (liquid film) 1712, 1692, 1568 cm^{-1}; UV (MeOH) λ 210 (sh, ε 4940), 251 (2060), 325 nm (90). PMR data were identical with the reported ones.[1)]

The Structure of Sendanolactone, a New Triterpenoid from *Melia azedarach* L. *var. japonica* Makino

Masamitsu Ochi, Hiyoshizo Kotsuki, Takashi Tokoroyama,* and Takashi Kubota**

Faculty of Science, Kochi University, Asakura, Kochi 780

**Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558*

***School of Medicine, Kinki University, Sayama-cho, Osaka 589*

(Received March 24, 1977)

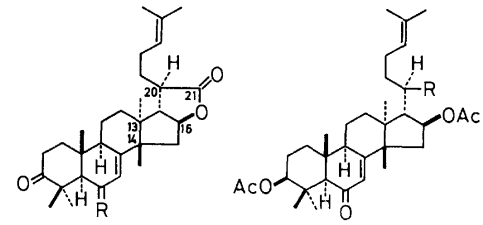
Synopsis. Sendanolactone, a new tetracyclic triterpenoid from the bark of *M. azedarach* L. *var. japonica* Makino, was determined as 3,6-dioxo-13α,14β,17α-lanosta-7,24-dien-21,16β-olide on the basis of chemical and spectroscopic evidence.

In the course of an investigation of limonoids of *M. azedarach* L. *var. japonica* Makino,[1] a new tetracyclic triterpenoid was obtained. In this paper, the isolation and structural elucidation of this compound designated as sendanolactone is treated.

Sendanolactone (I), $C_{30}H_{42}O_4$, mp 208.5—209 °C, $[\alpha]_D^{14.5}$ −30° (*c* 0.1, EtOH), was isolated in a 0.008% yield from an methanol extract of the bark of *M. azedarach* L. *var. japonica* Makino by partitioning and careful silica gel column chromatography. The IR, UV, and NMR spectra of I indicate the presence of the following groups: one γ-lactone (1780 cm^{-1}), one six-membered ring ketone (1715 cm^{-1}), one α,β-unsaturated ketone [1655 and 1625 cm^{-1}; 246 nm (ε 16400)], five tertiary methyls [δ 1.00, 1.13, 1.34 (3H each, s), and 1.38 (6H, s)], two vinylic methyls [δ 1.64 and 1.72 (3H each, br s)], and one trisubstituted double bond [δ 5.11 (1H, m)]. The reduction of I with sodium borohydride in methanol, followed by acetylation, gave II, $C_{35}H_{52}O_7$, mp 204.5—205 °C, and III, $C_{36}H_{54}O_7$, mp 154.5—155 °C. The UV spectra of both products still showed the presence of the conjugated enones. The NMR spectrum of II indicates signals due to two acetate groups [δ 2.00 and 2.07 (3H each, s)] and a methyl ester [δ 3.62 (3H, s)], whereas that of III shows the presence of three acetate groups [δ 1.99, 2.04, and 2.07 (3H each, s)] and an acetylated hydroxymethyl [δ 4.03 (2H, d, J=4 Hz)], instead of the methyl ester. The formation of these products is explained as follows. The opening of the γ-lactone ring due to transesterification occurs concurrently with the reduction of the saturated ketone both in II and III during the sodium borohydride treatment, and further reduction of the resultant methoxycarbonyl group ensued in the latter.

These facts and the analogy with the structures of the triterpenes isolated from the *Melia* species[2] suggest a euphane or tirucallane skeleton for I, the side chain of which contains a double bond between C_{24} and C_{25}.

The location of the conjugated enones was proven by the following data. The NMDR experiments of I show the presence of a $-CO-CH_A=\overset{|}{C}-\overset{|}{C}H_B-$ grouping [δ_A 5.78 (1H, d, J=3 Hz) and δ_B 2.96 (1H, m)], in which the dihedral angle between H_A and H_B is roughly 90°. In the NMR spectrum of I, the signal due to the methine proton adjacent to the carbonyl appears as a sharp singlet (δ 2.46). Consequently, the conjugated enone



I R = O II R = CO_2Me

IV R = H,H III R = CH_2OAc

must be located on the B-ring (7-en-6-one). Possible locations of γ-lactone are C_{21}–C_{23} and C_{21}–C_{16}. The NMR spectrum of I contains a signal due to the methine proton on an oxygenated carbon as a doublet of paired doublets (J=10, 10, and 8 Hz) at δ 4.18. This observation indicates that the oxy linkage of the lactone is at C_{16} and is β-oriented. From biogenetic considerations, it would be most reasonable to place the remaining carbonyl in I at C_3. This was verified by the following evidence. The NMR spectrum of I includes signals due to the methyls at C_4 and C_{10} at a rather low field [δ 1.38 (6H) and 1.33 (3H)], while those of II and III exhibit the corresponding signals at a somewhat higher field [II: δ 1.21 (6H) and 1.23 (3H); III: δ 1.19 (6H) and 1.21 (3H)]. Moreover, the solvent shifts ($\Delta=\delta^{CDCl_3}-\delta^{C_6D_6}$) of these signals in I, given in Table 1, are consistent with the case of 3,6-dione.[3]

Table 1. Solvent shifts ($\Delta=\delta^{CDCl_3}-\delta^{C_6D_6}$) of C_4 and C_{10}-methyls in I

	δ^{CDCl_3}	$\delta^{C_6D_6}$	Δ
C_4-α-Me	1.38	1.64	−0.26
C_4-β-Me	1.38	1.42	−0.04
C_{10}-Me	1.33	0.82	+0.51

Therefore, sendanolactone must be represented by structure I.[4] The proposed structure is quite analogous to that of kulactone (IV)[2e] isolated from *M. azedarach* L., the typical variety, except for the presence of the ketonic group at C_6, and the spectral data of I are in good agreement with those of IV, except for the environment of the conjugated enone.

The structure of sendanolactone was eventually established from an X-ray analysis as 3,6-dioxo-13α,14β,17α-lanosta-7,24-dien-21,16β-olide (I),[5] which is in full agreement with the structure derived from the chemical and spectral data mentioned above.

Sendanolactone is the first compound of the euphane

series which has an oxygen substituent at C_6.

Experimental

All mps are uncorrected. The IR and UV spectra were recorded on a JASCO model IR-S and a Hitachi EPS-3T spectrophotometer, respectively. The NMR spectra were determined, using a JEOL PS-100 spectrometer, in $CDCl_3$ solutions with TMS as an internal standard unless otherwise stated. A Rex Optical Works model NEP-2 apparatus was used for the rotation measurement.

Isolation. Air-dried bark of *M. azedarach* L. *var. japonica* Makino (6 kg), collected in Kochi, in July 1974, was cut into small pieces and extracted with methanol (50 l) for one month. The methanol extract was concentrated up to about 5 l and washed with petroleum ether. The methanol layer was again concentrated up to 1 l, diluted with water (2 l), and extracted with ether. The ether layer was dried over Na_2SO_4 and evaporated to dryness. The residue (32 g) was repeatedly subjected to chromatography over silicic acid. Elution with $CHCl_3$–MeOH (49 : 1) gave sendanolactone (I) (470 mg): needles from methanol; mp 208.5—209 °C, $[\alpha]_D^{14.5}$ −30° (*c* 0.1, EtOH); MS *m/e* 466 (M^+). Found: C, 76.89; H, 9.12%. Calcd for $C_{30}H_{42}O_4$: C, 77.21; H, 9.07%.

Reduction of I With $NaBH_4$. To a solution of I (200 mg) in methanol (50 ml) were added excess amounts of $NaBH_4$ (200 mg). The mixture was stirred for 30 min at 0 °C. The solution was then concentrated, diluted with water (100 ml), and extracted with ether. The ether layer was washed with water, dried over Na_2SO_4, and evaporated to dryness. The residue was subjected to chromatography over silicic acid; subsequent elution with $CHCl_3$–MeOH (99 : 1) gave a diol and a triol.

The diol (84 mg) was acetylated with acetic anhydride (2 ml) and pyridine (2 ml) and then worked up in the usual manner to afford II (65 mg): needles from methanol, mp 204.5—205 °C; IR (Nujol) 1735 and 1660 cm^{-1}; UV (EtOH) 244 nm (ε 16700). Found: C, 71.93; H, 9.06%. Calcd for $C_{35}H_{52}O_7$: C, 71.88; H, 8.96%.

The triol (40 mg) was acetylated in the same manner as described above to give III (21 mg): needles from aqueous ethanol, mp 154.5—155 °C; IR (Nujol) 1740 and 1670 cm^{-1}; UV (EtOH) 245 nm (ε 12700). Found: C, 72.16; H, 9.06%. Calcd for $C_{36}H_{54}O_7$: C, 72.21; H, 9.09%.

We are grateful to Drs. M. Shiro and H. Nakai of Shionogi Research Laboratory for carring out the X-ray analysis and to Dr. Y. Hirose and Mr. H. Naoki of the Institute of Food Chemistry for recording the mass spectrum.

A Convenient and General Preparation of Diphenyl Tellurium Dicarboxylates

Seizo TAMAGAKI, Isao HATANAKA, and Seizi KOZUKA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received March 24, 1977)

Synopsis. A number of diphenyl tellurium dicarboxylates were readily prepared from diphenyl telluroxide and carboxylic acids or anhydrides. Some of them were also derived through the carboxylate exchange from readily available tellurium carboxylates.

While several diaryl tellurium dicarboxylates have been prepared either by the reaction between the corresponding tellurium dichlorides and metal carboxylates[1] or *via* the lead tetraacetate oxidation of tellurides,[2] little attention has been paid to the preparation in which telluroxides serve as starting materials.

$$Ar_2TeCl_2 + 2AgOCOR \longrightarrow Ar_2Te(OCOR)_2 + 2\,AgCl$$

$$Ar_2Te + Pb(OAc)_4 \longrightarrow Ar_2Te(OAc)_2 + Pb(OAc)_2$$

Herein we wish to present facile methods for the preparation of a number of tellurium dicarboxylates from diphenyl telluroxide.

Results and Discussion

Diphenyl telluroxide, easily prepared from diphenyl tellurium dichloride by aqueous sodium hydroxide hydrolysis,[3] was allowed to react with an equiv of acetic anhydride in chloroform for 30 min at room temperature and evaporation of the solvent and recrystallization of the resulting residue from chloroform–hexane gave a crystalline product (I) almost quantitatively.

a) From carboxylic anhydrides. b) From carboxylic acids. c) By carboxylate exchange reaction. The values indicated are unreacted amounts of the starting diacetate, which were determined by NMR measurements 5 minutes after diphenyl tellurium diacetate was mixed with two moles of acids. d) $\nu_{C=O}$ (KBr) cm^{-1}. e) Spectra were measured in $CDCl_3$. Line positions are reported in δ (ppm).

Likewise, other commercially available acid anhydrides could be employed for the synthetic purposes and the treatment of diphenyl telluroxide with sulfonic anhydride such as *p*-toluenesulfonic anhydride afforded diphenyl tellurium bistoluenesulfonate (II) in good yield.

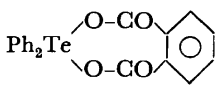
$$Ph_2Te{=}O + (TolSO_2)_2O \longrightarrow Ph_2Te(OSO_2Tol)_2 \qquad (II)$$

Various dicarboxylates thus obtained were satisfactorily characterized by elemental analyses, and IR and NMR spectra. The data are summarized in Table 1.

When desired carboxylic anhydrides are not available on hand, instead the corresponding carboxylic acids may be used as well. Thus, treatment of the telluroxide with 2 equiv of acetic acid in chloroform at room temperature resulted in the formation of the tellurium diacetate (I) quantitatively.

$$\text{b)}\ Ph_2Te{=}O + 2AcOH \xrightarrow{\text{r.t., 30 min}} I + H_2O$$

Quite recently McWhinnie *et al.*[4] have reported that sodium salt of ortho-phthalic acid reacts with diaryl tellurium dichlorides to give dimeric tellurium phthalates. It is of particular interest, however, that the methods described here are applicable to dicarboxylic anhydrides and acids such as phthalic, maleic, malonic, and succinic acids giving quantitative yields of monomeric or oligomeric esters. Especially, the melting point of monomeric compound III (mp: 181—185 °C) is markedly different from that of the dimeric ester (mp: 108—110 °C) provided by McWhinnie *et al.*



(III)

MW(obsd): 438

The application of this method to propiolactones failed to give discrete monomeric compounds, but led to the formation of oligomeric compounds with molecular weight larger than 1000.

$$Ph_2Te{=}O + O{=}C(CH_2)O \longrightarrow -(Ph_2Te{-}OCOCH_2CR_2O)-_{n=3-4}$$

(R = H, Ph)

Meanwhile, although McWhinnie's attempt to obtain a pure product from formic acid was unsuccessful, the preparation of diphenyl tellurium diformate was attained in a nearly quantitative yield by the reaction of the telluroxide with a slight excess of formic acid. Alternatively, the same formate ester could be given by the ligand exchange reaction of the corresponding diacetate with a large excess of formic acid. In general, less acidic carboxylic acids tend to be more readily expelled from the tellurium center than more acidic ones do.

$$\text{c)}\ Ph_2Te(OAc)_2 + 2HCOOH \xrightarrow{\text{r.t., 10 min}} Ph_2Te(OCOH)_2$$

The methods described are quite simple and hence convenient because a variety of carboxylic acids and anhydrides is commercially available and can be directly used without conversion into their sodium or silver salts.

Experimental

A typical procedure was as follows: diphenyl telluroxide and an equimolar amount of carboxylic anhydrides or acids were dissolved in dry chloroform. The reaction mixture was allowed to react at room temperature for 30 min. After evaporation of the solvent, the residue was recrystallized from chloroform–hexane. A similar procedure was also employed for carboxylate exchange reactions by using excess of desired carboxylic acids. Yields and physical properties of products are listed in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (9), 2503—2504 (1977)

Alicyclic Terpenoids from Cyclocitryl Phenyl Sulfides. V. A Synthesis of Ferruginol

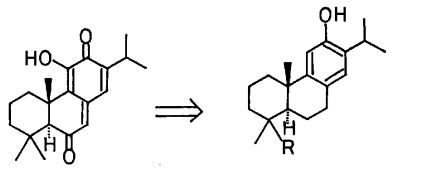
Sigeru TORII,* Kenji UNEYAMA, and Kazuhide HAMADA

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

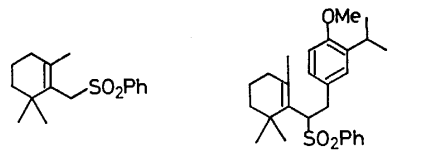
(Received April 30, 1977)

Synopsis. Ferruginol a precursor for taxodione synthesis, was prepared by the coupling of C(10) units between 2-(phenylsulfonylmethyl)-1,3,3-trimethylcyclohexane and 3-isopropyl-4-methoxybenzyl bromide followed by desulfonation and acid-catalyzed cyclization.

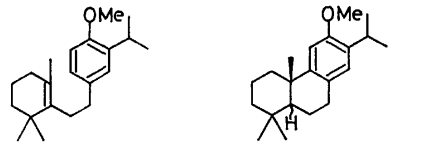
Taxodione (**1**), a tumor-inhibitory diterpene, has been isolated from *Taxodium distichum* Rich (Taxodiaceae) by Kupchan *et al.*[2] Because of its significant tumor-inhibitory activity, its synthesis attracted our attention. Mori *et al.* succeeded the transformation of podocarpic acid into **1** *via* ferruginol (**2**) by several modifications on B and C rings.[3] Matsumoto *et al.* prepared **1** starting from 2,3-dimethoxyisopropylbenzene by C→B →A ring construction[4a] and also from abieta-8,11,13-trienoate (**3**).[4b] Recently, the same authors reported a new route to **1** from methyl ether of **2**.[5]



1 2 R=Me ; 3 R=CO_2H



4 5



6 7a cis ; 7b trans

Considering the synthetic design of **1**, ferruginol (**2**) must be one of the desirable precursors of **1** and therefore should be prepared by a simple and practical method, since the reported syntheses involved many steps and unsatisfactory yields.[6] Here, we describe an efficient synthesis of **2** by the coupling of C(10) units between 2-(phenylsulfonylmethyl)-1,3,3-trimethylcyclohexene (**4**) and 3-isopropyl-4-methoxybenzyl bromide followed by desulfonation and acid-catalyzed cyclization.

The sulfone, **4**, is a synthon of cyclocitral and can react effectively with carbonyls, halides, and epoxides[7] as a nucleophile. Thus, the reaction of **4** with 3-isopropyl-4-methoxybenzyl bromide afforded **5** in 92% yield on treatment with butyllithium in THF at −70 C°. Desulfonation of **5** was accomplished selectively in 80% yield, without reducing the anisole ring, by the action of potassium in liquid ammonia at −65 °C. Cyclization of **6** thus obtained was performed quantitatively by stirring in AcOH–H_2SO_4 (9 : 1) to afford **7** as a mixture (6 : 4) of *cis*-**7a** and *trans*-**7b**. The isomers were separated by VPC and identified spectroscopically with those reported.[8] Demethylation of *trans*-**7b** with boron tribromide in dichloromethane gave **2** as a sole product. The spectral data of **2** was consistent with those reported.[3,6g]

Experimental

Melting point is uncorrected. IR spectra were determined with a JASCO IRA-1 infrared spectrophotometer. NMR spectra were obtained at 100 MHz with a JEOL FX-100 spectrometer and the chemical shift values are expressed in δ value (ppm) relative to Me_4Si in $CDCl_3$. The mass spectra were determined at 70 eV with a Finnigan 3300F.

*2-[1-Phenylsulfonyl-2-(3-isopropyl-4-methoxyphenyl)ethyl]-1,3,3-trimethylcyclohexane (**5**).* To a solution of 181 mg (0.65 mmol) of **4** in 2 ml of dry THF was added 0.63 ml (0.98 mmol) of BuLi–ether at −70 °C under N_2. After 5 min tsirring, the reaction mixture was treated with 3-isopropyl-4-methoxybenzyl bromide (221 mg, 0.91 mmol) dissolved in 2 ml of dry THF and stirred at −70 °C for 2 h. After adding 2 ml of saturated NH_4Cl, the organic substances were extracted three times with ethyl acetate. The combined extracts were washed with saturated NaCl, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (SiO_2, benzene–AcOEt/10 : 1) to afford **5** (359 mg, 92%) as colorless crystals: mp 116—117 °C; IR (Nujol) 1506 (Ar), 1306, 1156 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 7.82—7.30 (5H, m, $ArSO_2$), 6.80—6.52 (3H, m, Ar), 3.98 (1H, dd, J=6 and 8 Hz, $CHSO_2$), 3.75 (3H, s, CH_3O), 3.55—3.00 (3H, m, CH_2Ar, CH), 2.30—1.92 (2H, m, CH_2C=), 2.14 (3H, s, CH_3), 1.70—1.18 (4H, m, CH_2), 1.11 (3H, d, J=7 Hz, CH_3), 1.08 (3H, d, J=7 Hz, CH_3), 0.99 (3H, s, CH_3), 0.36 (3H, s, CH_3); MS *m/e* (rel. intensity) 440 (m^+, 1), 299 (M^+-SO_2Ph, 69), 163 (81), 137 (71), 123 (100). Found: C, 73.66; H, 8.08%. Calcd for $C_{27}H_{36}O_3S$: C, 73.60; H, 8.24%.

*2-[2-(3-Isopropyl-4-methoxyphenyl)ethyl]-1,3,3-trimethylcyclohexene (**6**).* To a solution of 132 mg of **5** in 2 ml of dry THF and 20 ml of liq. NH_3 was added 100 mg of potassium at −70 °C and the mixture was vigorously stirred at −70—−65 °C for 2 h. After quenching with 1 ml of EtOH and evaporating the solvent under reduced pressure, 2 ml of saturated NH_4Cl was added to the residue and the organic substance was extracted with ether. The combined ether extracts were washed with saturated NaCl, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (SiO_2, hexane–benzene/10 : 1), affording **6** (72 mg, 80%). Subsequent elution with hexane–AcOEt (10 : 1) provided **5** (10 mg, 8%): IR (neat) 2840 (MeO), 1610 (Ar), 1500,

1460, 1240 cm^{-1}; NMR ($CDCl_3$) δ 7.02 (1H, d, J=2 Hz, ArH), 7.00 (1H, dd, J=9 and 2 Hz, ArH), 6.75 (1H, d, J=9 Hz, ArH), 3.80 (3H, s, CH_3O), 3.28 (1H, sept, J=7 Hz, CH), 2.44—2.70 (2H, m, CH_2Ar), 2.10—2.37 (2H, m, CH_2), 1.82—2.02 (2H, m, CH_2), 1.67 (3H, s, CH_3C=), 1.30—1.72 (4H, m, CH_2), 1.22 (6H, d, J=7 Hz, CH_3), 1.05 (6H, s, CH_3); MS *m/e* 300 (M^+, 8), 163 (100). Found: C, 84.04; H, 10.76%. Calcd for $C_{21}H_{32}O$: C, 83.94: H, 10.73%.

12-Methoxyabieta-8,11,13-triene (7). Into 46 mg of **6** was added a mixture of AcOH (1.8 ml) and concd H_2SO_4 (0.2 ml) under ice cooling. The reaction mixture was stirred vigorously at 5 °C for 5 min and at 15—18 °C for 20 h. After adding 5 ml of ice water, the organic substance was extracted with hexane–ether (1 : 5). The combined extracts were washed with saturated $NaHCO_3$ and saturated NaCl, dried (Na_2SO_4), and concentrated *in vacuo*. The residue was chromatographed (SiO_2, hexane–benzene 10 : 1), affording **7** (45 mg, 99%) as a mixture (6 : 4) of *cis*-**7a** and *trans*-**7b**. Both isomers were separated by VPC (SE-30, 3 m, 4ϕ, 210 °C) and identified in comparison with the reported spectral data.

Ferruginol (2). To a solution of 1.4 mg of **7b** in 1.5 ml of dry CH_2Cl_2 was added 10 mg of BBr_3 at −70 °C under stirring. The mixture was stirred for 1 h while the reaction temperature was allowed to rise to −30 °C and then at 15—18 °C for additional 1 h. After adding 0.02 ml of saturated $NaHCO_3$, the mixture was dried (Na_2SO_4) and concentrated under reduced pressure. The residue was chromatographed (SiO_2, benzene), affording **2** (1.1 mg, 84%) as a sole product. The NMR and IR spectra were consistent with those reported.

The authors are grateful to Messrs M. Oka and K. Nara, Kuraray Co., Ltd. for mass spectral analysis.

Photochemical Dimroth Rearrangement of 1,4-Diphenyl-5-amino- and 4-Phenyl-5-anilino-1,2,3-triazoles[1]

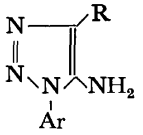
Yoshiro OGATA, Katsuhiko TAKAGI, and Eiji HAYASHI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

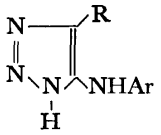
(Received May 14, 1977)

Synopsis. Irradiation of 1,4-diphenyl-5-amino-1,2,3-triazole (**1a**) gives 4-phenyl-5-anilino-1,2,3-triazole (**2a**) and the reverse photochemical reaction is possible. Hence, the reaction is reversible, the ratio of **1a** : **2a** in equibrium being 1.2—1.7, which is different from the ratio 0.33 in the thermal reaction (Dimroth rearrangement). The mechanism is discussed on the basis of spectral data and analogous reactions.

Dimroth discovered a rearrangement of 1-aryl-5-amino-1,2,3-triazoles(**1**) to 5-anilino-1,2,3-triazoles(**2**) in boiling pyridine or in boiling ethanolic sodium ethoxide.[2] The rearrangement is essentially complete in the above solvent,[3] but in some other solvents or in melts, **1** gives an equilibrium mixture of **1** and **2** in which the acidic isomer(**2**) usually predominates.[4,5] The reverse thermal reaction of **2** to **1** (retro-Dimroth rearrangement) leading to the equilibrium state was also reported.[6]



(**1**)



(**2**)

We wish to report here a photo-equilibrium between the amino(basic) isomer(**1**) and the anilino (acidic) isomer(**2**).

Results and Discussion

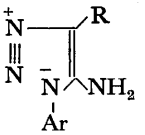
1,4-Diphenyl-5-amino-1,2,3-triazole(**1a**)[7] (2.0 g) in absolute ethanol(250 ml) was irradiated with a 100-W high-pressure mercury lamp for 40 h under N_2. The irradiated products were separated by TLC, and the rearrangement product(**2a**) (34.9%), unreacted **1a** (53.5%) and unidentified products(12.1 wt%) were obtained.

On the other hand, the irradiation of **2a** (1.9 g) under N_2 in absolute ethanol (200 ml) for 40 h gave a mixture of **1a** (36.6%), unreacted **2a** (30.7%) and unidentified products (32.7 wt%). The longer irradiation, which is sufficient for establishment of the equilibrium, afforded an equilibrium mixture containing **1a** and **2a** in a mole ratio of 1.53 by means of preparative TLC. Whereas, the irradiation of **2a** gave an equilibrium mixture of isolated **1a** and **2a** in the ratio of 1.20. The slight difference in the ratio may be due to the difference of extent of side reactions from **1a** and **2a**.

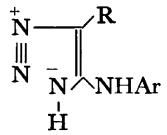
The amount of acidic isomer(**2a**) was determined by acidimetry with aq KOH at appropriate time intervals. As a result, the ratio of **1a** : **2a** became constant approaching to 1.70. This ratio is close to that obtained above by TLC analysis.

Generally, **1a** is favored in the photo-equilibrium of **1a** : **2a**. It is in contrast to the thermal reaction in which the equilibrium mixture consists of a larger amount of **2** than that of **1**, *i.e.*, the reported equilibrium ratio of 0.33 in melts,[6] while the ratio for photolysis in ethanol is 1.2—1.7, and suggests the difference in mechanism between thermal and photochemical reactions.

The thermal Dimroth rearrangement was postulated to involve a diazonium intermediates(**3** or **4**).[5] In the case of photolysis, this mechanism is not suitable, because the diazonium intermediate(**3** or **4**) is expected to react



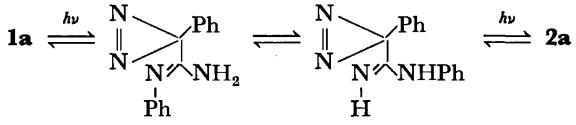
(**3**)



(**4**)

with the solvent.[8] In our attempt for spectral detection of the intermediates (**3** and **4**), the UV peak around 400 nm[9] and IR absorption in a range of 2150—2170 cm^{-1},[9] which are characteristic to diazonium group (C–N_2^+; *e.g.*, a diazonium ketone has UV peaks at 410 and 417 nm[10] and IR peak at 2137 cm^{-1} [10]), could not be detected at room temperature. These facts also disfavor the intermediacy of **3** and **4** possessing a diazonium group. But the possibility cannot completely be precluded at present, since the diazonium intermediate should be diluted and short-lived.

It is likely that this photo-rearrangement of **1** to **2** involves a valence isomerization which is characteristic to the photolysis of aromatic compound;[11] *i.e.*, the photolysis may proceed *via* diarines (**5** and **6**), and may



(**5**) (**6**)

involve a process of ring contraction and expansion together with a proton shift of **5** to **6**. A similar mechanism was suggested for five-membered hetero aromatics such as the photo-rearrangement of 3,5-diphenylisoxazole to 2,5-diphenyloxazole *via* a three-membered azirine which was detected spectroscopically.[12]

Experimental

Materials. 1,4-Diphenyl-5-amino-1,2,3-triazole(**1a**) and 4-phenyl-5-anilino-1,2,3-triazole(**2a**) were prepared by the method of Libers;[7] **1a**, mp 171—172 °C (lit,[7] 169—171 °C), λ_{max}(EtOH) 268 nm (log ε 4.18), IR (KBr)(cm^{-1}) 1620(s), 1265(s); NMR (DMSO-d_6, internal TMS) δ 7.95

(m, 3H), 7.72(s, 5H), 7.32(m, 2H), 6.82(s, 2H). **2a**, mp 167—168 °C (lit,[7] 167—169 °C); λ_{max}(EtOH) 238 nm(log ε 4.24), 360 nm(sh); IR(KBr)(cm^{-1}) 1580(s); NMR (DMSO-d_6, internal TMS) δ 8.14(s, 1H), 7.94(m, 2H), 7.50(m, 4H), 7.38(s, 1H), 7.20(d, 3H), 6.90(t, 1H).

*Photolysis of 1,4-Diphenyl-5-amino-1,2,3-triazole(**1a**).* **1a**(2.0 g) in absolute ethanol(250 ml) was irradiated with a 100-W high-pressure mercury lamp for 40 h, and the reaction mixture was evaporated to yield a brown crystalline solid which was separated and analyzed by TLC.

*Photolysis of 4-Phenyl-5-anilino-1,2,3-triazole(**2a**).* **2a** (1.9 g) in absolute ethanol(200 ml) was irradiated similarly, and condensed *in vacuo* to yield brown tarry material which was analyzed by TLC.

TLC Analysis. TLC was carried out on a plate (200×200 mm) uniformly coated with Kieselgel 60PF$_{254}$ (1 mm thickness) by using a mixture of benzene–ethyl acetate (3 : 1) as an eluant. The TLC analysis afforded three substances from the reaction mixture of **1a**(200 mg). The first (R_f=0.52) was unreacted **1a**(107 mg), the second (R_f=0.65) was **2a**(69.8 mg), and the rest (R_f=0.75) was unidentified(20.4 mg). Four substances were obtained from the reaction mixture of **2a**(200 mg). The first (R_f=0.52) and **1a**(73.2 mg), the second (R_f=0.85) (30.0 mg) was unidentified. Identification of the isolated products was done by means of comparison of UV, IR, and NMR spectra with those of authentic specimen.

Actinometry. An ethanol solution (200 ml) of **1a** (503 mg) was irradiated with a 300-W high-pressure mercury lamp, and aliquots (10 ml) were pipetted out at 2 h intervals and titrated by 0.0146 M KOH using phenolphthalein as an indicator. The final aliquot was that of 40 h irradiation.

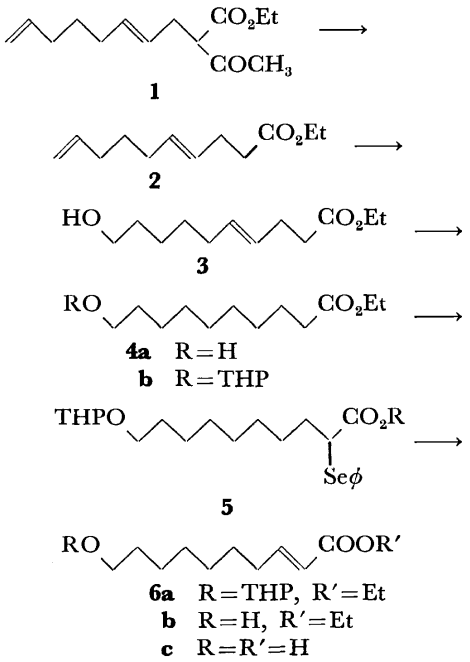
(Received May 18, 1977)

Synopsis. Ethyl 2-acetyl-4,9-decadienoate obtained by palladium catalyzed reaction of butadiene and ethyl acetoacetate was converted to 4,9-decadienoate. Hydroboration of the terminal olefin gave 10-hydroxy-4-decenoate. After hydrogenation and protection of the hydroxyl group, the double bond was created at the conjugated position by introduction of phenylseleno group and subsequent oxidative removal to give 10-hydroxyl-2-decenoic acid.

Royal jelly is a nutrient of queen bee *lavae*. Investigation of the lipids of royal jelly has revealed that their free acid fraction contained a complex mixture of C_{10} acids which are called royal jelly acids. The structure of the main component of the royal jelly acids was determined by Butenandt and Rembold as 10-hydroxy-2-decenoic acid.[1] Several synthetic methods for this physiologically interesting acid have been reported.[2] These syntheses are based on chain elongation of the shorter compounds *via* somewhat lengthy steps. We now wish to report a simple synthetic method for this acid starting from an easily available butadiene telomer which has the right carbon numbers and suitable functional groups for the synthesis of the acid.

Butadiene and ethyl acetoacetate react to give 2-acetyl-4,9-decadienoate (**1**)[3] in 80% yield (bp 91—93 °C/2 Torr) using palladium acetate and triphenylphosphine as a catalyst. It is apparent that this easily prepared compound has an ideal structure for the construction of the royal jelly acid, which was synthesized by the following sequences.



The acetyl group was removed by treatment of the ester **1** (63.5 g, 267 mmol) with sodium ethoxide in absolute ethanol (5.3 g, 78 mmol, 241 ml) to give, in 86% yield, ethyl 4,9-decadienoate **2**: bp 83 °C/1 Torr; NMR (CCl_4) δ 4.7—6.15 (m, 5H, olefin), 4.05 (q, J=7.0 Hz, 2H), 1.75—2.45 (m, 6H), 1.45—1.75 (m, 2H), 1.2 (t, J=7.0 Hz, 3H); IR (neat) 1735, 970, 910 cm^{-1}. Then the terminal double bond was converted to alcohol by hydroboration[4] using 1.1 equivalent of bis(1,2-dimethylpropyl)borane in dry THF and subsequent oxidation with 30% hydrogen peroxide in 3M sodium hydroxide solution to give, in 82% yield, 10-hydroxy-4-decenoate **3**: bp 118 °C/1 Torr; NMR (CCl_4) δ 5.3—5.6 (bt, 2H, olefin), 4.1 (q, J=7.0 Hz, 2H), 3.55 (bt, J=6.0 Hz, 2H), 3.2 (br, 1H, -OH), 2.3 (bs, 4H), 1.85—2.2 (br, 2H), 1.25 (t, J=7.0 Hz, 3H); IR (neat) 3600—3200, 1735, 975 cm^{-1}. The isomerization of the double bond at the position 4 of the ester **3** to the conjugated position would complete the synthesis. However, the attempted isomerization with various catalysts such as strong base, $RhCl(PPh_3)_3$, platinic acid, gave no clear result. Thus the double bond was hydrogenated by using palladium on carbon to give the saturated ester **4a** in 90% yield. The hydroxyl group was protected by converting to tetrahydropyranyl ether **4b** in 77% yield: NMR (CCl_4) δ 4.55 (br, 1H), 4.1 (q, J=7.0 Hz, 2H), 3.15—3.80 (m, 4H), 2.0—2.4 (m, 2H), 1.24 (t, J=7.0 Hz, 3H); IR (neat) 1738, 1040 cm^{-1}. Generation of the anion of saturated ester **4b** (900 mg, 3 mmol) with lithium isopropylcyclohexylamide (3.6 mmol) in dry THF at −78 °C was followed by the reaction of phenylselenenyl bromide[5] (991 mg, 4.2 mmol) to give, in 47% yield after column chromatography, the selenide **5**: NMR (CCl_4) δ 7.0—7.6 (m, 5H, phenyl), 4.4 (br, 1H), 3.95 (q, J=7.0 Hz, 2H), 3.2—3.7 (m, 5H), 1.12 (t, J=7.0 Hz, 3H). The purified selenide **5** (636 mg, 1.4 mmol) was oxidized with sodium periodate[5] (899 mg, 4.2 mmol) in aqueous methanol to give, in 81% yield after column chromatography, the desired unsaturated ester **6a**: NMR (CCl_4) δ 6.83 (dt, J=15.6 and 6.0 Hz, 1H, olefin), 5.67 (d, J=15.6, 1H, olefin), 4.4 (br, 1H), 4.10 (q, J=7.0 Hz, 2H), 3.2—3.7 (m, 4H), 1.8—2.4 (br, 2H), 1.25 (t, J=7.0 Hz, 3H). The removal of tetrahydropyranyl ether from ester **6a** (337 mg, 1.1 mmol) with copper sulfate (400 mg) in a mixture of methanol (8 ml) and water (2 ml) under reflux gave quantitatively the ethyl ester of royal jelly acid **6b**: NMR (CCl_4) δ 6.83 (dt, J=15.8 and 6.0 Hz, 1H, olefin), 5.67 (d, J=15.6, 1H, olefin), 4.10 (q, J=7.0 Hz, 2H), 3.50 (dt, 2H), 1.8—2.4 (br, 3H), 1.25 (t, J=7.0 Hz, 3H); IR (neat) 3100—3600, 1720, 1650, 980 cm^{-1}. The coupling constants of 15.6 and 15.8 for the olefinic protons of **6a** and **6b**

support the trans configuration of the olefins. Hydrolysis of the ester with 10% potassium hydroxide in aqueous methanol produced the royal jelly acid **6c** which was identified by its melting point, 63—64 °C (reported 64—65 °C).[2a]

(Received January 17, 1977)

The exciplex (at room temperature) and EDA complex (at low temperature) fluorescence was observed in 3-methylpentane solution of 1,4-dicyanonaphthalene with several alkylbenzenes and alkylnaphthalenes. The fluorescence behavior provides evidence for an identical fluorescent state of the exciplex and EDA complex.

Intermolecular electron donor-acceptor (EDA) interaction leads to the formation of molecular complexes stable in the ground state and also the exciplexes stable only in the excited state. Formation of an exciplex can be observed in the fluorescence quenching of the component molecule and/or in the appearance of a new red-shifted fluorescence band. By transient absorption spectroscopy both the singlet excited states of the EDA complex and the exciplex are seen to show absorption bands of cation and anion radicals of the electron donor and acceptor, which indicates their strong charge transfer (CT) character in the excited state.[2]

Itoh and Mimura[3] and others[4,5] reported on the exciplex and EDA complex formation in the nonpolar solution of 9,10-dicyanoanthracene (DCA) and several naphthalene and benzene derivatives, demonstrating an experimental evidence for an identical fluorescent state of the exciplex and EDA complex. Similar evidence was reported for the identical fluorescent state in the tetracyanobenzene and *p*-xylene system by Gaweda and Prochorow.[6] This paper describes further examples of evidence for their identical fluorescent state in the simple EDA system of 1,4-dicyanonaphthalene (DCN) and alkylbenzenes (alkylnaphthalenes).

Experimental

1,4-Dicyanonaphthalene was prepared from naphthalene by bromination and cyanogenation, and purified several times by silica gel chromatography (solvent; benzene–hexane) and recrystallization. The sample has no fluorescent impurity in solution as verified by thinlayer chromatography. Purification of alkylbenzenes, alkylnaphthalenes, and solvents was carried out as reported.[4,5]

Measurement of fluorescence spectra was carried out with Hitachi MPF-2A and MPF-4 spectrophotometers, and that of absorption spectra with Cary 11 and Hitachi 323 spectrophotometers. Determination of fluorescence polarization was described previously.[4] The fluorescence lifetimes and time-resolved fluorescence spectra were determined by analyzing exponential decay curves measured with an oscilloscope and a coaxial N_2 gas laser.

Results and Discussion

The exciplex fluorescence in the 3-methylpentane (MP) solution of 1,4-dicyanonaphthalene (DCN) and alkylbenzenes was observed at room temperature. Figure 1 shows the fluorescence and fluorescence excitation spectra of MP solution of DCN and pentamethylbenzene (PMB) at room temperature. The fluorescence maxima and lifetimes of the exciplexes in

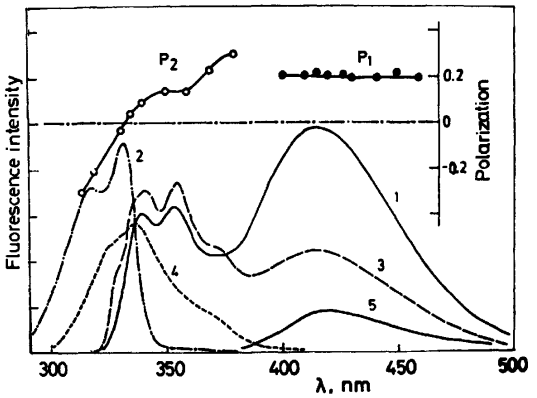

Fig. 1. Fluorescence and fluorescence excitation spectra, and their polarizations of MP solutions of DCN and PMB. *Spectra* 1 (excited at 310 nm) and 2 (monitored at 450 nm) are fluorescence and excitation spectra at room temperature, respectively (Concentration: DCN, 3×10^{-6} M: PMB, 1.5×10^{-2} M). *Spectra* 3 (excited at 310 nm) and 5 (excited at 370 nm) are fluorescence spectra at 77 K, and 4 (monitored at 450 nm) is a fluorescence excitation spectrum. P_1 (excited at 370 nm) and P_2 (monitored at 420 nm) are fluorescence and excitation polarizations at 77 K, respectively (Concentration: DCN, 9×10^{-7} M; PMB, 1×10^{-3} M).

Table 1. Fluorescence maxima and lifetimes of the exciplex (at room temperature) and the EDA complex (at 77 K) in MP solution of DCN and alkylbenzenes and alkylnaphthalenes

Donor	Exciplex		EDA complex	
	λ, nm	τ, ns[a]	λ, nm	τ, ns[a]
Hexamethylbenzene	430	86	430	71
Pentamethylbenzene	416	69	415	66
Durene	413	69	405[b]	50
Mesitylene	390	43	400[b]	40
p-Xylene	390	38	400[b]	37
Toluene	376[c]	15[c]	—	—
1,5-Dimethylnaphthalene	440	59	434	58
2-Methylnaphthalene	436	52	430	50
Naphthalene	430	51	427	48

a) Errors are approximately ± 1 ns. b) Determined by time-resolved fluorescence spectra. c) Determined in the concentrations of DCN = 6×10^{-6} M and toluene = 1.1 M.

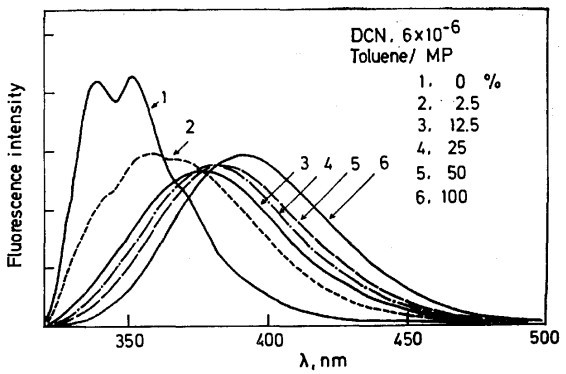

Fig. 2. Fluorescence spectra of MP solutions of DCN and toluene at room temperature.

MP, summarized in Table 1, show a slight concentration dependence of the electron donor. In the DCN and toluene system, however, the fluorescence maxima and lifetimes show remarkable concentration dependence (Fig. 2). Data of these exciplexes determined in almost the same concentrations of electron donor ($\approx 10^{-1}$ M) and acceptor ($\approx 10^{-6}$ M) are given in Table 1. The concentration dependence is due to the increasing solvent polarity with donor concentration.[7]

The exciplex fluorescence was gradually quenched with decrease in temperature. Almost the same fluorescence band as that of exciplex increases in intensity with further decrease in temperature. The temperature region of the decrease and increase of the long wavelength fluorescence is dependent on the concentrations of donor and acceptor. The fluorescence spectra of the MP solution of DCN with low concentration of alkylbenzene show no exciplex fluorescence band at room temperature but a similar fluorescence to that of the exciplex at low temperature. The fluorescence and excitation spectra of MP solution of DCN and PMB at 77 K are also shown in Fig. 1. The absorption spectra of the MP solution of DCN–alkylbenzene system at room temperature are completely superimposed by those of the component molecules, while the spectra show the EDA complex formation at low temperature as shown in Fig. 3 (DCN–PMB). The electronic absorption spectra at 77 K are similar to the corresponding excitation spectra monitored at long wavelength fluorescence

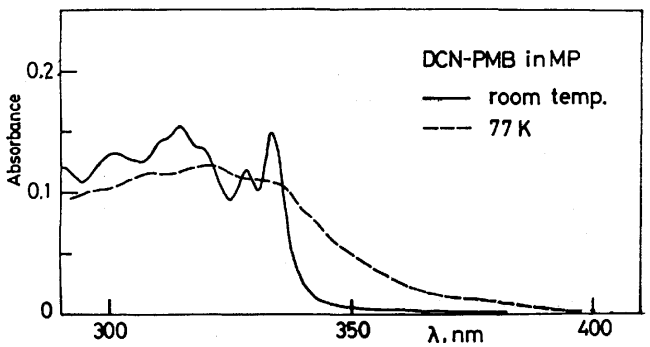

Fig. 3. Electronic absorption spectra of an MP solution of DCN and PMB at room temperature and 77 K (Concentration: DCN, 1.6×10^{-5} M; PMB, 7.5×10^{-3} M). Volume change at 77 K was corrected.

(Fig. 1). From the absorption and fluorescence excitation spectra in the MP solutions of DCN–alkylbenzenes, the long wavelength fluorescences at room temperature and at low temperature are ascribed to the exciplex and to the EDA complex, respectively. The absorption and excitation spectra indicate a small absorption band in the EDA complex at 350—400 nm as will be mentioned later. The fluorescence maxima and fluorescence lifetimes of the EDA complex in the MP solution at 77 K are summarized in Table 1. In the EDA complexes of DCN with durene, mesitylene and *p*-xylene, fluorescence maxima were determined with time-resolved fluorescence spectra because of their low solubility in MP at 77 K. The DCN–toluene system shows no detectable EDA complex formation.

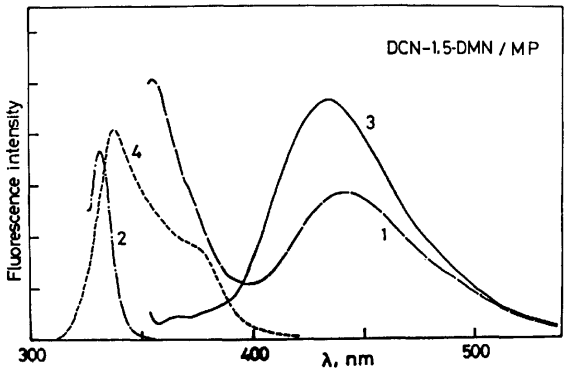

Fig. 4. Fluorescence and excitation spectra of MP solutions of DCN and 1,5-dimethylnaphthalnene. *Spectra* 1 (excited at 335 nm) and 2 (monitored at 450 nm) are fluorescence and excitation spectra at room temperature, respectively (Concentration: DCN, 2×10^{-6} M; 1,5-DMN, 2.2×10^{-2} M). *Spectra* 3 (excited at 340 nm) and 4 (monitored at 450 nm) are fluorescence and excitation spectra at 77 K, respectively (Concentration: DCN, 2×10^{-6} M; 1,5-DMN, 3.4×10^{-3} M).

The DCN and methylnaphthalene system shows exciplex formation at room temperature with the excitation of DCN and the EDA complex formation at low temperature, spectra of which are shown in Fig. 4 (DCN–1,5-dimethylnaphthalene). With the excitation of electron donor, however, no exciplex fluorescence but only alkylnaphthalene fluorescence was observed. The excitation spectra monitored at long wavelength fluorescence of the EDA complex of DCN–DMN (Fig. 4) give a similar absorption band at 350—400 nm to that in DCN–PMB.

The fluorescence maxima and lifetimes of both exciplex and EDA complex increase with decreasing ionization potential of alkylbenzene (alkylnaphthalene), indicating an increase of CT character of their fluorescent state with decreasing ionization potential of the electron donor. The fluorescent behavior in DCN–alkylbenzene (alkylnaphthalene) is similar to that in the DCA–alkylbenzene (alkylnaphthalene).[4,5] The fluorescence of the EDA complex in the DCN–alkylbenzene system at 77 K shows positive polarization with excitation at 370 nm, and negative with excitation at 320 nm. On the other hand, the electronic absorption spectra

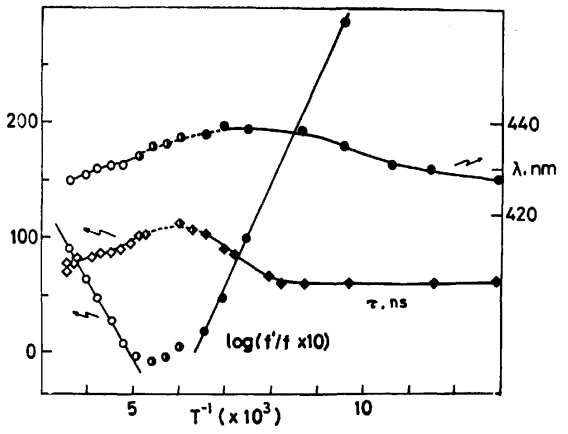

Fig. 5. Temperature dependence of fluorescence maxima (—○— exciplex and —●— EDA complex) and lifetimes (—◇— exciplex and —◆— EDA complex) in MP solutions of DCN and PMB, and of intensity ratio of the long wavelength fluorescence (f′ at λ_{max} 415 nm) and DCN fluorescence (f at λ_{max} 355 nm); —◑—, —◈— and —◑— are fluorescence indistinguishable from each other between exciplex and EDA complex.

and the excitation spectra of the EDA complex give a small absorption band at 350—400 nm. The results indicate that the absorption is a CT band between DCN and the electron donor. In the DCA–alkylbenzene system reported previously, small positive polarization with the local excitation of DCA and rather small fluorescence lifetimes of the EDA complex as well as the exciplex suggest that the fluorescent states mostly consist of the locally excited state of DCA.[5] The results of the EDA complex and the exciplex in DCN–alkylbenzene (alkylnaphthalene) show marked CT character in their fluorescent states.

The fluorescence maxima and lifetimes of the long wavelength fluorescence of MP solution of DCN–PMB at serveral temperatures, plotted in Fig. 5, both show continuous variation from room temperature to 77 K. On the other hand, the temperature dependence of intensity ratio of the long wavelength fluorescence to the DCN fluorescence completely differ between exciplex

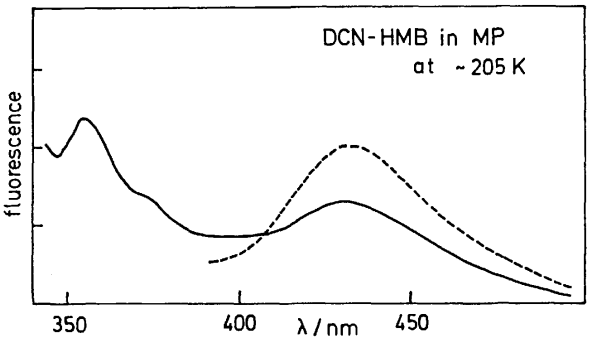

Fig. 6. Fluorescence spectra of an MP solution of DCN and HMB at 205 K in the excitations at 320 nm (——) and at 380 nm (------), (concentration; DCN, 3×10^{-6} M and HMB, 6×10^{-3} M).

and EDA complex.[4] If the exciplex and EDA complex have different fluorescence behavior, different fluorescence should be observed in the intermediate temperature (200—140 K). However, no distinguishable fluorescence is observed between exciplex and EDA complex in DCN–HMB system at ≈205 K, the fluorescence being observed in the excitation of DCN absorption band and CT band of the complex (Fig. 6). Appearance of one fluorescence species in this temperature region and the continuous change in fluorescence maxima and lifetime indicate an identical fluorescent state of the exciplex and EDA complex.[3]

NMR Studies of Picolyl-type Carbanions. IV.[1] Anions Produced by Reactions of 2-Substituted Pyridines with Butyllithium

Kazuyori KONISHI and Kensuke TAKAHASHI*

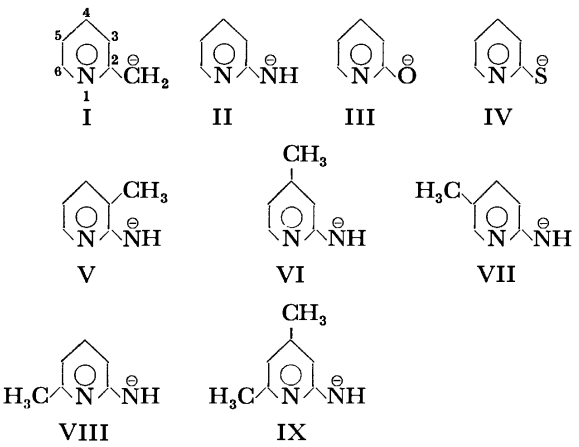
The Industrial Technology Center of Mie Prefecture, Takajaya-komori-cho, Tsu 514

**Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466*

(Received January 26, 1977)

The ^{13}C and ^{1}H NMR spectra of 2-pyridylmethyl (α-picolyl), 2-pyridylamino, 2-pyridyloxy, and 2-pyridylthio anions were observed in polar solvents with lithium as a counter ion. The chemical shifts are compared with the electron densities calculated using the PPP and CNDO/2 MO methods. A linear relationship was obtained between the ^{13}C chemical shifts and π-electron densities. The charge distributions on the anions are discussed, and it is found that the 2-pyridylamino anion and its methyl derivatives can be regarded as delocalized anions with the same significance as a series of picolyl anions.

In the benzyl carbanion, a simple Hückel MO theory predicts that the excess charges are distributed at the α-, *o*-, and *p*-positions, respectively.[2] Therefore, it is reasonable to consider that carbanions which have more electronegative atoms at the *o*- or *p*-positions are more stable than the benzyl carbanion. Picolyl-type carbanions have been studied as models of these carbanions.[1,3,4] This study was extended to anions having α-atoms of nitrogen, oxygen, and sulfur. The anions prepared are numbered from II to IX as follows: (I, which was reported previously,[3,4] is presented for comparison.)



Experimental

The procedures used in this study are similar to those described in previous reports.[3,4] All the starting materials are commercially available. These materials were used after vacuum sublimation.

The ^{13}C NMR spectra were measured using a Hitachi R-20B spectrometer operating in the CW mode at 15.085 MHz. Sample concentrations were about 1.0 mol/l or more. Chemical shifts were evaluated with solvent peaks used as an internal reference. These peaks were taken to be 26.4 ppm for tetrahydrofuran (THF) and 37.0 ppm for hexamethylphosphoramide (HMPA) with respect to TMS. In the ^{1}H NMR spectra, the solvent peaks used as an internal reference were taken to be 1.79, 2.15, 2.58, and 3.28 ppm from TMS for THF, TMEDA (*N,N,N',N'*-tetramethylethylenediamine), HMPA, and DME (1,2-dimethoxyethane), respectively.

The PPP and CNDO/2 MO calculations were carried out using the Okitac-4300C and Hitachi-8450 computer systems installed at The Industrial Technology Center of Mie Prefecture and at Nagoya Institute of Technology, respectively, using modified versions of programs taken from the book of Kikuchi.[5] All the parameters used in the calculation were taken from this book and other references.[6,7] The skeletal coordinates of the anions were taken to be the same as those of pyridine.[8] The bond lengths between the 2-carbon and the α-atom used in the calculation are 1.39, 1.36, 1.31, and 1.75 Å for I, II, III, and IV, respectively.

Results and Discussion

Typical spectra of the anions are shown in Figs. 1 and 2. The ^{1}H and ^{13}C chemical shifts of both the anions and the starting materials are given in Tables 1 and 2. The results are of first order analysis.

NMR Spectra of the Anions. Typical PMR (^{1}H NMR) spectra of the anions are shown in Fig. 1. The well-separated signals permitted easy assignment. For example, the spectrum of the aromatic proton region of II, shown in Fig. 1(a), consists of four parts. The peaks appear as a doublet, a triplet, a doublet, and a triplet in passing from lower to higher field, with an integrated ratio of 1 : 1 : 1 : 1. They can, therefore, be identified as signals due to the 6-, 4-, 3-, and 5-protons. Typical CMR (^{13}C NMR) spectra are shown in Fig. 2. The signals were assigned in several ways, such as by comparison with the PMR spectra and by substitution of a methyl group for a hydrogen atom in the pyridyl ring.

From an inspection of the PMR spectra of VI, VIII, and IX shown in Fig. 1(b)—(d), the reaction sites of the starting materials having a 2-amino and 4- or 6-methyl groups with butyllithium were confirmed using chemical-shift considerations. The metal-proton exchange reaction occurred at the 2-amino group, indicating that the 2-amino group is more reactive than the 6-methyl group. The methyl protons in these anions show upfield shifts similar to the ring protons, but the shifts are about 0.1 ppm and are smaller than about 0.6 ppm in α-picolyl anions.[4] In the PMR spectra of II, V, and VII in HMPA shown in Fig. 1(a), (e)—(f), one relatively broad signal is observed in the range of 3.4—3.7 ppm. This signal may be attributed to the 2-NH.

Chemical Shift and Charge Density. In the CMR spectra of I—IV, the 5-carbon of each anion is the most shielded of the ring carbons, *i.e.*, its signal appears at a

Table 1. The proton chemical shifts of the anions and the starting materials, at 60 MHz and 31.5 °C in ppm[a]

a) Errors are estimated to be within ± 0.3 ppm. b) Assignment uncertain.

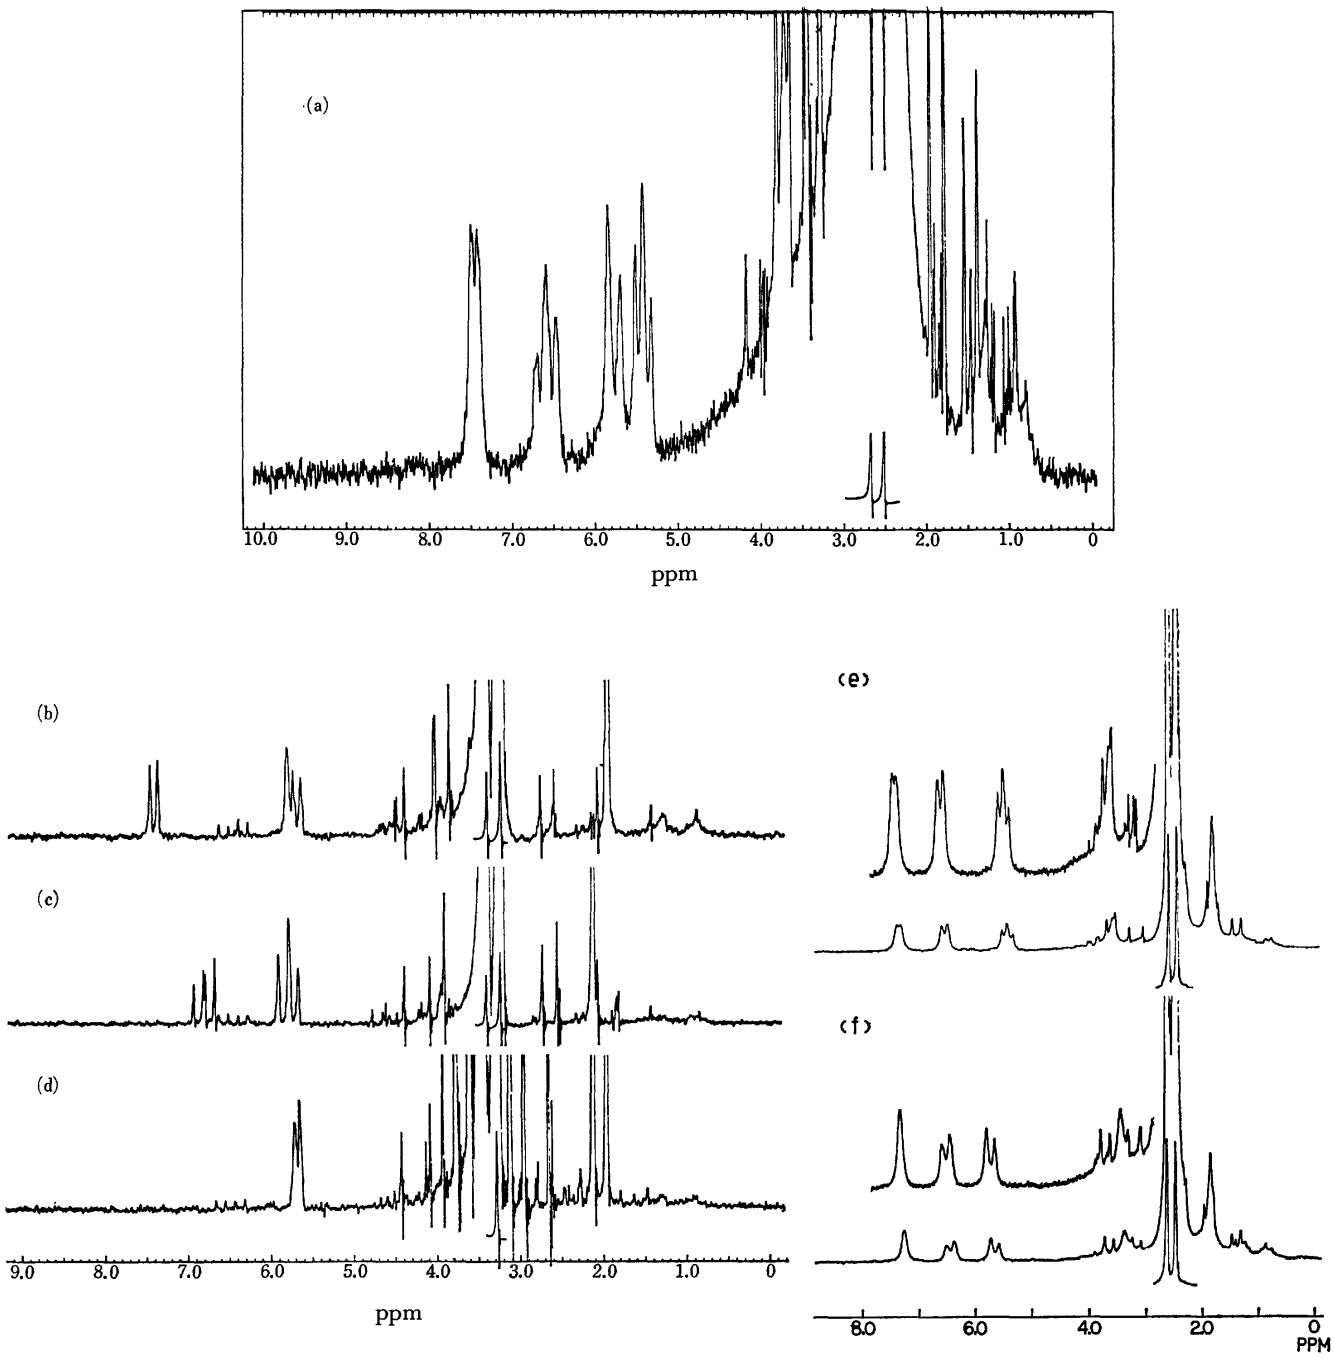

Fig. 1. PMR spectra of pyridylamino anions; (a) II in HMPA, (b) VI, (c) VIII, (d) IX in DME, and (e) V, (f) VII in HMPA.

higher field. In addition, the 5-carbon signals of I and II are shifted appreciably in the upfield direction relative to those of the starting materials. In the PMR spectra, the same tendency is observed for the 5-protons. It is apparent that the excess charges transferred from the α-atom to the pyridyl ring in I and II have the strongest influence at the 5-position, *i.e.*, the 5-carbon and proton chemical shifts are most affected by the charges. The 5-carbon and proton signals appear at higher field in the increasing order, IV, III, II, and I. Thus, it may be possible to consider that the excess charges transferred onto the ring increase in the same order.

In order to clarify the relationship between the carbon or proton chemical shifts and the π-electron densities, these densities were calculated using the PPP and CNDO/2 MO methods for I—IV and I—III, respectively. The π-electron densities calculated using the PPP method are plotted against the carbon chemical shifts in Fig. 3. The plot is linear although the 2-carbons and the methylene carbon of I deviate from linearity. One cause of this deviation may be the hybridization change in the α-atoms. On the other hand, in Fig. 4 are plotted the π-electron densities

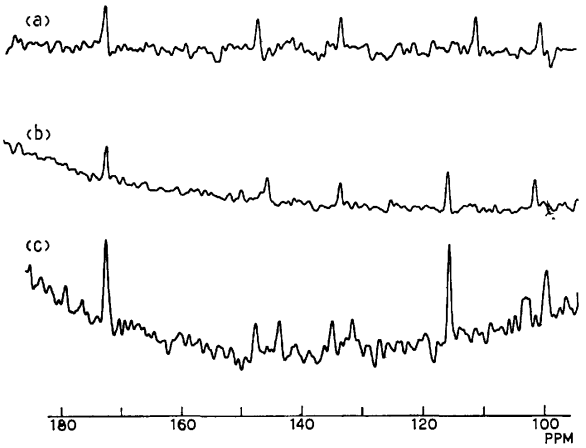

Fig. 2. CMR Spectra of the aromatic carbon region of pyridylamino anions; (a) II, (b) V in HMPA (proton noise decoupling), and (c) V in HMPA (off resonance decoupling).

calculated using the CNDO/2 method. The plot of the 4-carbons deviates considerably from linearity, as compared with the plot of the others, that is, the densities are underestimated. The cause of this is unclear at present. Next, the relation between the ring-proton chemical shifts for each anion in I—III and the π-electron densities of the adjacent carbons calculated using the PPP method is linear, and the plot of I is most distinctly linear.

The charge distributions on I—IV are discussed on the basis of the relationship shown in Fig. 3. This relationship implies that, in spite of changes in the α-atoms, the π-electron densities of the ring carbons in these anions can be evaluated from the carbon chemical shifts using an identical scale. The δ-values of the ring-carbon chemical shifts of each anion increase in the order 5-, 3-, 4-, 6-, and 2-carbons, indicating that the π-electron densities decrease in the same order. Of these anions, the 6-carbon chemical shifts are almost the same, the shift range is about 3 ppm, and, of course, is smaller than about 18 ppm for the 5-carbons. This may be due to the strong induction effect caused by the neighboring nitrogen atom. Here, from an assignment of both the 3- and 4-carbon signals of IV, the calculated charge densities distinguish the 3- from the 4-carbon. In this sense, this assignment may be uncertain. Therefore, at least in I—III, the π-electron distribution patterns are clearly analogous, *i.e.*, I—III are anions of the same type. The ring nitrogens in I—III are expected to follow the same tendency as the 5-carbons, over which the charges transferred from the α-atoms are largely distributed and the π-electron densities increase in the order III, II, and I. The π-electron densities of the ring nitrogen calculated using both the PPP and CNDO/2 methods also increase in the order III, II, and I.

The PMR spectra of I in THF were temperature dependent; chemical shifts of the ring protons at −25 °C were 0.10—0.15 ppm upfield from the 31.5 °C values. This variation is larger than those for benzyllithium and 1- and 2-naphthylmethyllithium.[9] This relatively large temperature dependence shows that solvent separation in I occurs to an appreciable extent. In addition to this fact, the ring proton and carbon signals in HMPA move to higher field in comparison with those in THF, *i.e.*, the excess charges on the α-atom are transferred more into the ring for HMPA than for

α-H			1.064 1.061			1.035				

THF. In this sense, I is more stable in HMPA than in THF. Consequently, I exists as either solvent separated ion pairs or free ions in HMPA. The ring protons of II—III and the ring carbons of II in HMPA are also more shielded than those in THF. The 5-proton chemical shift of each anion in I—III shows the largest variation with a change in solvents from THF to HMPA, and the magnitudes are 0.21, 0.35, and 0.51 ppm for III, II, and I, respectively. For the 5-carbon chemical shifts of both I and II, the same tendency is observed, and the magnitudes are 5.4 and 3.1 ppm. With a change in solvents, the densities at the 5-position vary greatly. In HMPA, the PMR spectral patterns of II and III are similar to that of I. From these results for II and III in polar solvents and the relationship among I—III as shown in Fig. 3, it is possible to consider that II and III also exist as analogous ions in HMPA, as does I, and, furthermore, so may IV.

The 5-carbons in V and VII show upfield shifts of about 10 ppm similar to that in II. This magnitude is smaller than about 25 ppm in I, but much larger than about 0 ppm in III and IV. This suggests that the excess charges on the α-nitrogen atoms are appreciably transferred onto the pyridyl rings with a change in starting materials to lithium salts in polar solvents. Therefore, anions II and V—IX, whose α-atoms are nitrogens, can be regarded as delocalized anions with the same significance as a series of picolyl anions.

Synthetic Zeolites as Catalysts for the Ring Conversion of γ-Butyrolactone into 1-Substituted 2-Pyrrolidinones

Kou HATADA* and Yoshio ONO

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 31, 1977)

Synthetic zeolites were found to be effective catalysts for the synthesis of 1-substituted 2-pyrrolidinone by the reaction of γ-butyrolactone with amines. 1-Propyl-2-pyrrolidinone was obtained in the equilibrium yield with practically 100% selectivity over copper exchanged Y-zeolite at 280 °C. The effects of reaction temperature, contact time and partial pressures of the reactants were examined. A reaction mechanism is proposed for the ring transformation based on the kinetic studies of the reaction of γ-butyrolactone with propylamine.

Transformation of heterocycles into compounds containing a ring system differing from that of starting substance provides a convenient method for the synthesis of some heterocycles. As an example, 2-pyrrolidinone can be obtained by the reaction of γ-butyrolactone and ammonia.[1] Usually, the reaction is carried out in a liquid phase under pressure. The ring transformations of cyclic ethers or lactones into the corresponding cyclic imines or lactams can be effectively carried out in a vapor phase by using synthetic zeolites as catalysts.[2-7] Over copper-exchanged Y zeolites, 2-pyrrolidinone was obtained from γ-butyrolactone in 80—90% yield.[4] We have carried out the synthesis of 1-substituted 2-pyrrolidinones from γ-butyrolactone in a vapor phase with use of zeolites as catalysts. A detailed study has been carried out on the kinetics of the reaction and a reaction mechanism is proposed in the case of the reaction of γ-butyrolactone with propylamine to form 1-propyl-2-pyrrolidinone.

Experimental

Measurements. All the boiling points are uncorrected. The determination of infrared spectra was made on a Shimadzu IR-6 spectrophotometer. The NMR spectra were recorded in tetrachlorometane solution with a spectrometer using tetramethylsilane as an internal reference. Gas chromatograms were obtained using a 2 m column packed with a 10% PEG-6000 on Shimalite-F operating at 200 °C.

Materials. γ-Butyrolactone (Tokyo Chemical Industry) was distilled just before each reaction. Amines (Wako Pure Chemical Industry) were used without purification.

Catalyst. NaY-zeolite (Linde SK-40) was used as the starting material for all the catalysts. Various cation forms of zeolites were prepared by the conventional cation exchange procedure using salt solutions. The cation exchanged zeolites were pelleted without a binder and crushed and sized into 9—16 mesh.

Apparatus and Procedure. A continuous flow reactor was used under atomspheric pressure. The reactor is a silica tubing (13 mm i.d.) placed in a vertical furnace. Prior to the reaction, the catalyst in the reactor was heated in an air stream at 500 °C (or 450 °C for HY) for 60 min. The liquid reactants were pumped with microfeeders into the preheating zone of the reactor containing 10 ml quartz or α-alumina (about 24 mesh). The gaseous materials were fed through flowmeters. Nitrogen was used as a diluent for regulating the initial pressure of reactants. Reaction products collected in the receiver maintained at 0 °C was withdrawn at certain intervals during the run and were analyzed by gas chromatography. 2-Pyrrolidinone, 1-methyl-2-pyrrolidinone and 1-ethyl-2-pyrrolidinone were identified by comparison of their infrared spectra with that of authentic samples. Other products were assignd by IR, NMR, and the elemental analysis methods.

Results and Discussion

Catalytic Activity of Various Cation Forms of Zeolite. The catalytic activities of various cation forms of Y-zeolite for the reaction of γ-butyrolactone and propylamine were compared under the following conditions:

* Present address: Faculty of Education, Saitama University, Urawa, Saitama 338.

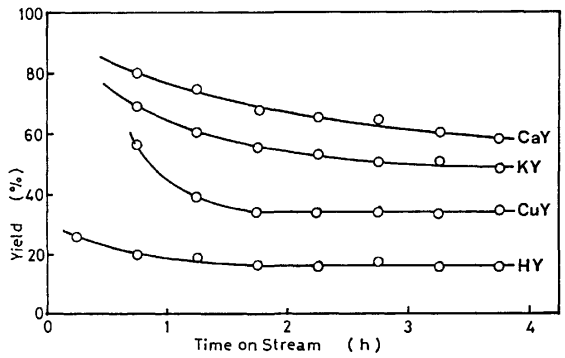

Fig. 1. Change in the yield of 1-propyl-2-pyrrolidinone over various zeolites at 280 °C.

reaction temperature 280 °C, catalyst weight 1 g, flow rate of reactants; γ-butyrolactone 24×10^{-3} mol/h, propylamine 122×10^{-3} mol/h, flow rate of nitrogen 99×10^{-3} mol/h. The catalytic activities decreased with time (Fig. 1). The activity and selectivity for the production of 1-propyl-2-pyrrolidinone on various cation forms of zeolites are given in Table 1. The values refer to the data obtained after the reaction had proceeded for 3 h. Besides 1-propyl-2-pyrrolidinone, a small amount of *N*-propyl-4-hydroxybutyramide was produced. Selectivity is defined as follows.

$$\text{Selectivity (\%)} = \frac{\text{mol of pyrrolidinone produced}}{\text{mol of } \gamma\text{-butyrolactone reacted}} \times 100.$$

The highest yield of the pyrrolidinone was obtained over CaY (calcium exchanged Y zeolite), followed by alkaline cation forms (Table 1). The best selectivity for the pyrrolidinone was observed for CuY, the most stable catalyst for the reaction (Fig. 1). Thus, CuY was used exclusively for further investigations. Though the activity decreased gradually with stream hours, it is completely recovered by calcining the used catalyst under air stream at 500 °C.

Reaction of γ-Butyrolactone with Various Amines. The reactions of γ-butyrolactone (I) with various primary amines were carried out with CuY as a catalyst

Table 1. Activity and selectivity for the reaction of γ-butyrolactone over various Y-zeolites

Cation	Conversion of I %	Yield of III %	Selectivity for III %

Ni	35	27	77
Co	23	16	70
Zn	16	6	38

Catalyst 1 g. Reaction temperature 260 °C. Feeding rate of I 24.0×10^{-3} mol/h. Reactant ratio II/I=5.08. Total feed (I+II+N_2) 225×10^{-3} mol/h.

at 280 °C. The results are summarized in Table 2. The yield of 2-pyrrolidinones depends on the nature of the amines, but the selectivity of the reaction is quite high. In addition to neat amines, the amine in aqueous solution can be used for the synthesis.

The yield of 2-pyrrolidinone in the reaction of I with ammonia was lower than that with primary amines. This may be caused by the difference in the basicity of ammonia and primary amines. The steric effect also seems to be important for the reactions; the yield of 2-pyrrolidinones depends on the starting amine in the following order.

$$CH_3NH_2 \approx C_3H_7NH_2 > C_4H_9NH_2 > C_5H_{11}NH_2 > C_6H_{13}NH_2 > PhNH_2$$

$$C_4H_9NH_2 > \text{Iso-}C_4H_9NH_2 > s\text{-}C_4H_9NH_2 > t\text{-}C_4H_9NH_2$$

Since the basicity of alkylamines hardly depends at

Catalyst Cu–Y 3 g. Reaction temperature 280°C. Total feed(I+amine+N_2): 245×10^{-3} mol/h. *P*: partial pressure. *R*: feeding rate. a) 40% aqueous solution. b) 70% aqueous solution.

all on the kind of alkyl group, the difference in the yield of 2-pyrrolidinone seems mainly to be caused by the steric effect. The bulkier the alkyl group, the less the reactivity of amine toward I. Since propylamine (II) has a high reactivity toward I with high selectivity, the various parameters determining the yield of 1-propyl-2-pyrrolidinone (III) were examined by using propylamine as a strating amine.

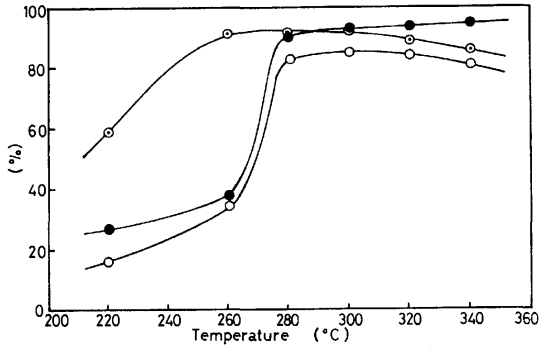

Fig. 2. Effect of reaction temperature on the catalytic behavior of CuY in the reaction of γ-butyrolactone with propylamine.
●: Conversion of γ-butyrolactone, ○: yield for 1-propyl-2-pyrrolidinone, ⊙: selectivity for 1-propyl-2-pyrrolidinone.

Influence of the Reaction Temperature. Figure 2 shows the temperature dependence of the yield of III by the reaction of I with II. The yield of III increases with temperature up to 320 °C, decreasing slightly above 320 °C. Thus, the optimum temperature seems to lie around 300 °C.

Effect of Contact Time. Effect of the contact time (W/F) on the yield of III from I and II over CaY and CuY was examined. W/F is defined as follows.

$$W/F = \frac{\text{Weight of catalyst (g)}}{\text{Total feed (I+II+N}_2\text{) (mol/h)}}$$

The results are illustrated in Fig. 3. The partial pressure of I was kept constant at 0.098 atm and that of II was varied in the range 0.088—0.497 atm. The yield of III increased with contact time, reaching a constant value which does not depend on the nature of the catalyst. Thus, the reaction seems to proceed until equilibrium is reached. The apparent equilibrium constant (K_P)

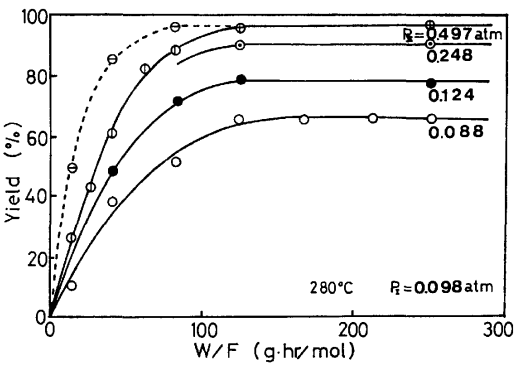

Fig. 3. Effect of contact time (W/F) on the yield of 1-propyl-2-pyrrolidinone over CuY (——) and CaY (------).

values estimated from the data in Fig. 3 are given in Table 3. The K_P value does not depend on the initial reaction conditions, suggesting that the reaction proceeds nearly to equilibrium.

Reaction Kinetics. The kinetics of the reaction of I and II was studied with CuY as a catalyst. Reaction kinetics was examined in the temperature range 240—280 °C under small contact time conditions for the reaction of I and II. The effect of the partial pressure of I (P_I) on the reaction rate was examined by keeping the partial pressure of II (P_{II}) at 0.348 atm. The partial pressure of nitrogen was adjusted to keep the contact time constant. The result is given in Fig. 4.

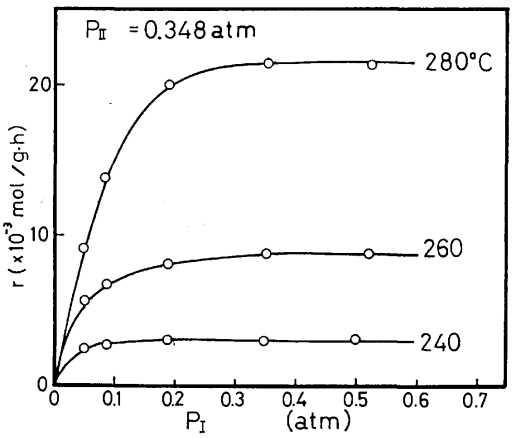

Fig. 4. Dependence of the reaction rate on the partial pressure of γ-butyrolactone.

Table 3. Apparent equilibrium constant of the reaction of γ-butyrolactone with propylamine

Catalyst	Feeding rate of reactant I ×10⁻³ mol/h	Feeding rate of reactant II ×10⁻³ mol/h	Formation rate of III ×10⁻³ mol/h	Yield of III %	Apparent equilibrium constant K_p
CuY, CaY	24.0	121.6	23.0	95.8	5.4
CuY	24.0	60.8	21.6	90.0	5.0
CuY	24.0	30.4	18.5	77.1	5.6
CuY	24.0	21.5	15.8	65.8	5.3

Catalyst 3 g. Reaction temperature 280 °C. Total feed (I+II+N_2) 245×10⁻³ mol/h.

$$K_p = \frac{P^*_{III} \cdot P^*_{H_2O}}{P^*_I \cdot P^*_{II}} = \frac{P^{*2}_{III}}{P^*_I \cdot P^*_{II}}$$

P^*: partial pressure at the reactor exit.

The dependence of the rate (r) on the partial pressure of I can be expressed by

$$r = k_I \cdot \frac{K_I P_I}{1+K_I P_I}, \quad (1)$$

were k_I and K_I are constants. By rearrangement, we have

$$\frac{P_I}{r} = \frac{1}{k_I K_I} + \frac{P_I}{k_I}, \quad (2)$$

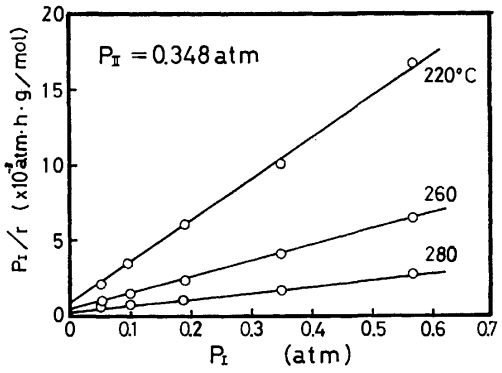

Fig. 5. P_I/r *vs.* P_I plot.

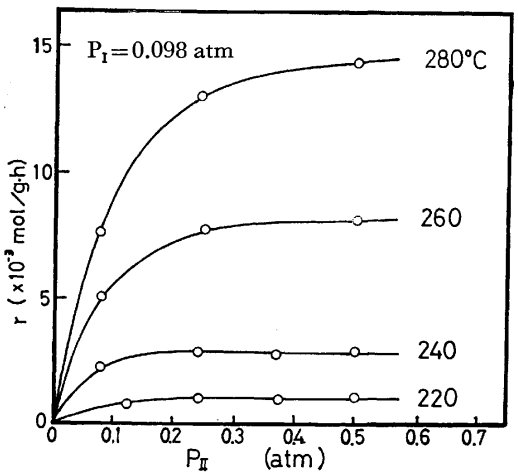

Fig. 6. Dependence of the reaction rate on the partial pressure of propylamine.

Straight lines are obtained by plotting P_I/r against P_I (Fig. 5). The slope and the intercept give the values of $1/k_I$ and $1/k_I K_I$, respectively.

The dependence of the reaction rate on the partial pressure of II was examined by keeping P_I at 0.098 atm (Fig. 6). It was found to be represented also by

$$r = k_{II} \cdot \frac{K_{II} P_{II}}{1+K_{II} P_{II}}, \quad (3)$$

which, on rearrangement, gives

$$\frac{P_{II}}{r} = \frac{1}{k_{II} K_{II}} + \frac{P_{II}}{k_{II}}. \quad (4)$$

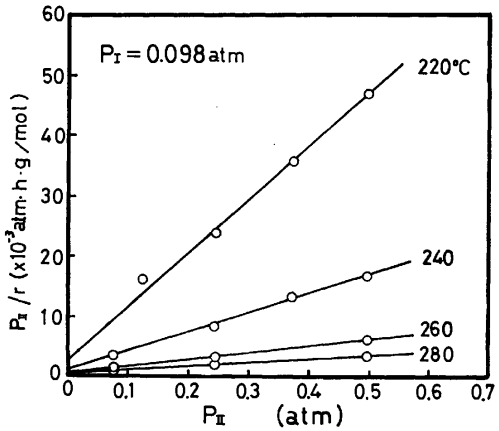

Fig. 7. P_{II}/r *vs.* P_{II} plot.

The relation was checked (Fig. 7) and the values of k_{II} and K_{II} were obtained.

Thus, the following kinetic expression is obtained from Eqs. 1 and 3:

$$r = k \cdot \frac{K_I P_I}{1+K_I P_I} \cdot \frac{K_{II} P_{II}}{1+K_{II} P_{II}}, \quad (5)$$

where

$$k_I = k \cdot \frac{K_{II} P_{II}}{1+K_{II} P_{II}} \quad \text{and} \quad k_{II} = k \cdot \frac{K_I P_I}{1+K_I P_I}.$$

From the values of k_I, k_{II}, K_I, and K_{II}, obtained experimentally, the value of k was determined uniquely. The values of K_I, K_{II} are given in Table 4.

Equation 5 indicates that there are independent adsorption sites for I and amine and that the reaction of the adsorbed I and adsorbed amine is rate determining. The activation energy of the reaction, the heats of adsorption of I and II were determined to be 23 kcal/mol, 9.0 kcal/mol, and 9.9 kcal/mol, respectively.

It was also confirmed that rate does not depend on the partial pressure of water or III, by addition of water or III to the feeding reactant.

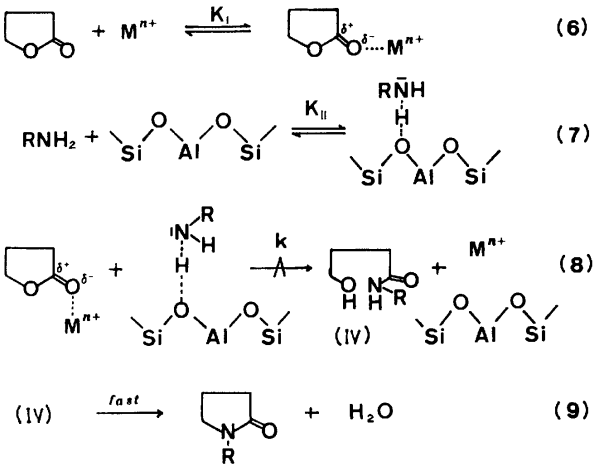
Reaction Mechanism. The reaction kinetics represented by Eq. 5 suggests that there is an independent adsorption site for each reactant. In a previous work on the reaction of I and ammonia, it was postulated that polarization of the carbonyl group of I to the strong electrostatic field in the neighborhood of the metal cation is essential. The same should hold for the reaction with primary amines. The adsorption sites for I are probably metal cations.

The adsorption site for primary amines might be the oxygen ions next to aluminum cations in the zeolitic framework. Dissociative adsorption of ammonia has been observed on the oxide ions of alumina surface.[8]

TABLE 4. KINETIC PARAMETERS FOR THE REACTION OF γ-BUTYROLACTONE AND PROPYLAMINE OVER CuY

Temperature (°C)	k_I (×10^{-3} mol/g·h)	K_I (atm^{-1})	k_{II} (×10^{-3} mol/g·h)	K_{II} (atm^{-1})	k (×10^{-3} mol/g·h)
220	—	—	1.11	45.2	—
240	3.66	32.1	3.15	24.9	4.1
260	9.28	26.3	9.62	20.8	12.1
280	23.25	21.5	16.39	15.3	20.9

Thus, we proposed the following reaction mechanism.



Equations 6 and 7 represent the adsorption of I and primary amine on metal cation and oxygen anion in the zeolite framework, respectively. The activated reactants react with each other to form an acid amide like intermediate IV (Eq. 8), the step being rate determining. The dehydration of the intermediate to the lactam is fast. This mechanism is in line with Eq. 5, if we put the adsorption equilibrium constant of I and primary amine, K_I and K_A and the rate constant of the elementary reaction (Eq. 8), k. This mechanism also expresses the effect of the kind of amines on their reactivity toward I. The elementary reaction (Eq. 8) should be faster, if the basicity of the amine increases; primary normal alkylamines react more readily with I than ammonia. The large steric effect is expected since the reaction occurs on the surface of zeolite. The interaction between the carbonyl group of I and the lone pair of the amine may need very specific special arrangement.

Low activity of hydrogen form of the zeolite (HY) should be noted since the origin of catalytic activity of the zeolite is very often ascribed to the protonic acidity of the zeolite. In the case of the reaction studied, protonic acid probably reacts with amines to form ammonium ions.

$$NH_2R + H^+ \rightleftharpoons NH_3R^+.$$

This explains the low activity of HY.

Application of Infrared ATR Spectroscopy to Liquid Crystals. I. Surface-Induced Orientation in Thin Films of Nematic MBBA[1]

Aritada HATTA

Laboratory of Interface Science of Metals, Faculty of Engineering, Tohoku University, Aramaki Aoba, Sendai 980

(Received February 8, 1977)

Infrared dichroism of nematic liquid *N*-(*p*-methoxybenzylidene)-*p*-butylaniline (MBBA) was measured using a conventional transmission method and an ATR method. In the former, KBr windows were used as substrates. The degree of orientation order of the homogeneous structure, which was achieved by a rubbing procedure, was obtained to be $S=0.40$. Using the measured dichroic ratios, the angles between the transition moments and the long axis of the molecule were calculated. The calculated values are in satisfactory agreement with the molecular conformation already suggested. In the ATR method, In_2O_3-coated glass plates were used as substrates. Rubbing of the In_2O_3 surface gave a uniform homogeneous orientation with an S value of 0.57. An In_2O_3 surface treated with dimethyldichlorosilane gave a homeotropic texture with an S value of 0.53. The directions of the transition moments relative to the long axis of the molecule closely agreed with those obtained from transmission spectra.

The orientation of the thin liquid-crystal film in contact with the solid surface is very often determined by the orientation of the liquid-crystal molecules interacting with the solid surface. Therefore, if the interaction between the molecules and the solid surface is very strong, the surface orientation can greatly contribute to the long-range ordering of the liquid crystal. Such an orientation behavior is not only a phenomenon of fundamental interest, but is also a practical problem for application to display elements.[2] In this connection, it is interesting to observe the infrared dichroism arising from molecular orientation in thin films of the liquid crystals in contact with various substrate surfaces.

The effects of temperature[3] and electric field[4] on molecular orientation have been investigated by the infrared dichroism method. All of these studies, however, have resorted to the use of the transmission method. Absorption measurements on liquid crystals using transmission techniques are often difficult because of the strong absorption and, therefore, extremely thin films are required. This difficulty does not arise when the ATR method[5] is used, because the observed intensities are determined by an electric-field penetration into the sample of a few microns and are independent of the sample thickness.

The most significant advantage of using the ATR method is that the electric fields exist in all spatial directions at the reflecting interface. Therefore, the ATR technique is capable of giving information about any orientational state of the liquid crystal.

Vergoten and Fleury[6] have recently reported infrared and Raman spectra of *N*-(*p*-methoxybenzylidene)-*p*-butylaniline (MBBA) in the solid state and in nematic and isotropic liquids. However, no infrared dichroism measurements have yet been reported.

The objective of this report is to show the versatility of the infrared ATR method in studying the structure of oriented liquid films of MBBA induced by the surface effect of the substrate.

Experimental

ATR spectra were recorded using a JASCO model IR-G grating spectrophotometer equipped with a double-beam ATR attachment and a conventional AgCl polarizer. Two trapezoidal prisms made from high-purity monocrystalline silicon were used as internal reflection elements in an optically-balanced double-beam system; one prism was put in the sample beam and the other in the reference beam.

The prisms were cut and polished so as to provide an internal reflection angle of incidence of 40° and give one reflection. The Si prism used has a constant transmittance (55%) from 2.5 to 6.6 μ. Beyond 6.6 μ, however, the transmittance of silicon falls off due to impurities and lattice bands, for example, three weak bands appear between 6.6 and 8 μ and a strong band appears at 9 μ. Careful balancing of the sample and reference beams provided a flat background level over the 2.5—10 μ wavelength range with sufficient sensitivity. In the present study, mainly the 6—10 μ range was investigated.

The sandwich cell shown in Fig. 1 was used for the ATR measurements. The sample of the liquid crystal is sandwiched between the Si prism and a substrate plate which is separated from the prism by a polyester spacer. The substrate chosen for the present study was an In_2O_3-coated conducting glass plate. The substrate was in contact with the wall of a brass box containing a nichrome wire heater. The tempera-

ture of the liquid crystal was controlled by a conventional on-off power supply. The accuracy of the temperature was ±2 °C. Guaranteed-grade MBBA reagent was obtained from Tokyo Chemical Industry Co. and was used without further purification.

To obtain homeotropic alignment, the substrate of the In_2O_3-coated glass plate was immersed in a 5% toluene solution of $(CH_3)_2SiCl_2$, following the experimental procedure given by Uchida *et al.*[14] After standing for 30 min at room temperature, the substrate was taken out of the solution and then rinsed with toluene to remove the remaining $(CH_3)_2SiCl_2$. The substrate thus treated was dried at 100°C for 1 h.

Results and Discussion

First, the transmission spectra of oriented MBBA at 30 °C will be discussed. The MBBA sample was held between two KBr windows whose surfaces were rubbed in one direction with a buff.

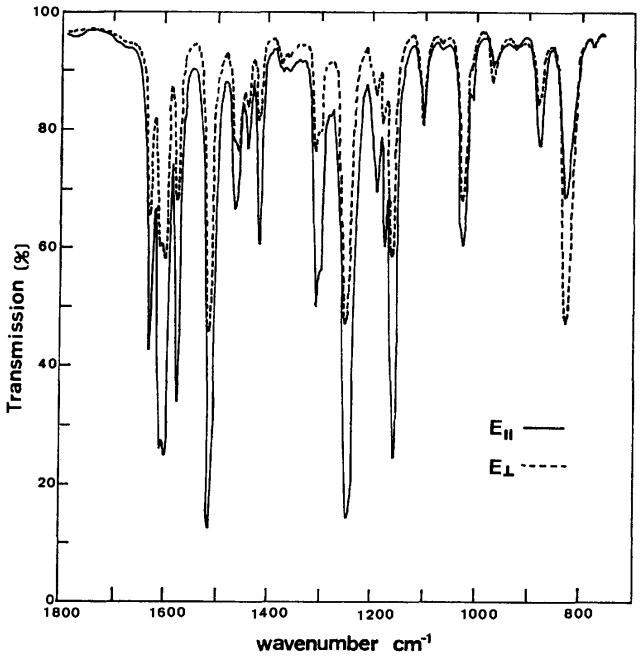

Fig. 2. The polarized transmission spectra of oriented thin MBBA film at 30 °C. $E_{//}$ and $E_{\perp}$ refer to the electric vector of radiation polarized parallel and perpendicular to the optic axis (rubbing direction), respectively.

Spectra were taken for radiation with the electric vector polarized parallel and perpendicular to the rubbing direction. Because of the high degree of absorption, no spacer was used between the windows. The polarized transmission spectra for MBBA are shown in Fig. 2. The observed dichroic ratios and vibrational assignments for several important bands are given in Table 1.

The degree of orientational order in liquid crystals is generally defined by the degree of order, S[7]

$$S = \frac{1}{2}(3\cos^2\alpha - 1), \tag{1}$$

where α is the angle between the long axis of the molecule and the optical axis of the uniformly oriented liquid crystal.

Table 1. Observed frequencies, vibrational assignments, and dichroic ratios for homogeneously-oriented MBBA (S=0.40; α=39.2°)

Observed (cm^{-1})	Assignment	R	β[a]
1630	C=N stretching	2.03	29.4°
1600	phenyl ring stretching	2.51	19.3°
1578	phenyl ring stertching	2.85	10.2°
1520	phenyl ring stretching	2.52	19.0°
1250	C–O–C asym. stretching	2.51	19.2°
1160	phenyl C–H in-plane deformation	2.63	16.4°
1030	CH_3–O stretching (C–O–C sym. str.)	1.34	44.8°
830	phenyl C–H out-of-plane deformation	0.50	90.0°[b]

a) The angle between the direction of the transition moment and the long axis of the molecule. b) Assumed.

On the other hand, the dichroic ratio is given by[8]

$$R = \frac{k_{//}}{k_{\perp}} = \frac{4\cos^2\beta\cos^2\alpha + 2\sin^2\beta\sin^2\alpha}{2\cos^2\beta\sin^2\alpha + \sin^2\beta(1+\cos^2\alpha)}. \tag{2}$$

In Eq. 2, $k_{//}$ and $k_{\perp}$ are the absorption coefficients measured with the infrared radiation polarized parallel and perpendicular to the optical axis, respectively. The angle β designates the angle between the long axis and the vibrational transition moment of the molecule. The coordinate system defined above is shown in Fig. 3. In this figure, all the long axes of the molecules are assumed to be inclined at a common angle α with respect to the optical axis. Furthermore, the molecules are assumed to rotate freely about their own long axes.

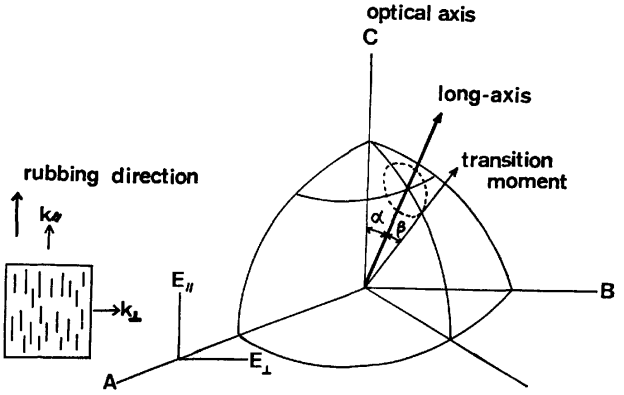

Fig. 3. Uniaxial orientation of the long-axis of the molecule around the optical axis and of the transition moment around the long-axis of the molecule.

From Eqs. 1 and 2, the degree of order is expressed in the simple form,

$$S = \frac{R-1}{S_\beta(R+2)}, \tag{3}$$

where

$$S_\beta = \frac{1}{2}(3\cos^2\beta - 1).$$

Thus, the degree of order is expressed in terms of R and

S_β. Accordingly, if the angle β is known for a given vibrational band, the value of S can be obtained from its R value. Furthermore, by using the S value obtained above, the β value can be calculated for any other vibrational band.

According to Eq. 1, the S value in Eq. 3 should vary from -0.5 to 1, the former corresponding to liquids oriented with the long axes of molecules perpendicular to the rubbing direction and the latter to liquids oriented with the long axes parallel to that direction. If the liquid crystal is isotropic, that is $R=1$, the S value becomes zero.

On the other hand, there is a high tendency for nematic molecules to line up with their long axes parallel to the direction of rubbing[3,9] and, therefore, the optical axis of the uniaxial liquid crystal can be assumed to coincide with the rubbing direction, as shown in Fig. 3. Accordingly, we may consider only the case in which the long axis of the molecule is oriented preferably parallel to the optical axis of the liquid so that the long axis has a positive S value. If the vibrational transition moment is oriented along the long axis of the molecule, Eq. 3 reduces to $S=(R-1)/(R+2)$. Because R varies between 1 and infinity in this case, the degree of order varies from 0 and 1, the former corresponding to an isotropic liquid and the latter to a liquid oriented parallel to the optical axis. On the other hand, when the transition moment is directed perpendicular to the long axis, the degree of order is given by $S=2(1-R)/(R+2)$. In this case, R would vary from 0 and 1, and then S is positive with a maximum value of 1 which also corresponds to a completely parallel liquid. Consequently, the degree of order S varies from 0 and 1 provided the $k_{//}$ component of the absorption coefficients is taken to be parallel to the optical axis of MBBA molecule.

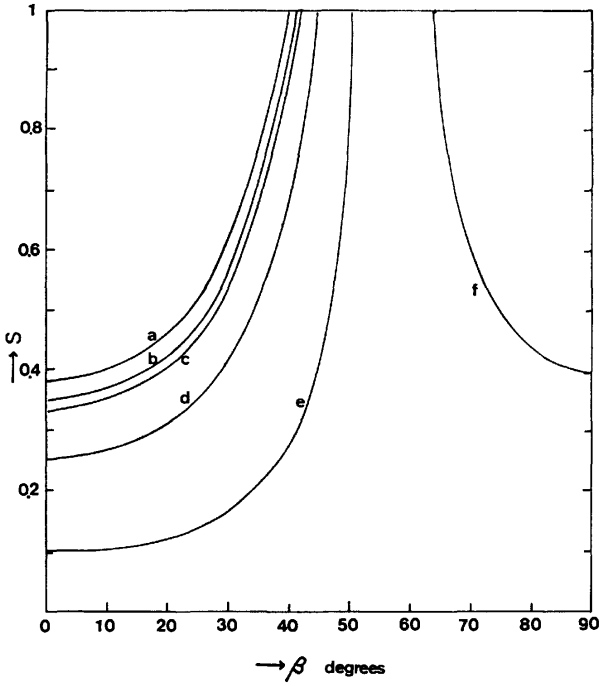

Fig. 4. The degree of orientation order S as a function of angle calculated from experimental dichroic ratio. a: 1578 cm^{-1}, b: 1160 cm^{-1}, c: 1600 cm^{-1}, d: 1630 cm^{-1}, e: 1030 cm^{-1}, f: 830 cm^{-1}.

The S values estimated from Eq. 3 are plotted against β in Fig. 4, using the R values listed in Table 1. The plots vary in a characteristic way and provide useful information about molecular structure: they afford the relative direction of the transition moment of the molecule and can, therefore, give confirmation of assignments already given. It is evident from Fig. 4 that the angle for the 1578 cm^{-1} band must have the lowest value; its transition moment is oriented nearly parallel to the direction of the long axis of the molecule. In contrast to this band, the 830 cm^{-1} band very probably has a much different direction of transition moment from that of the above band.

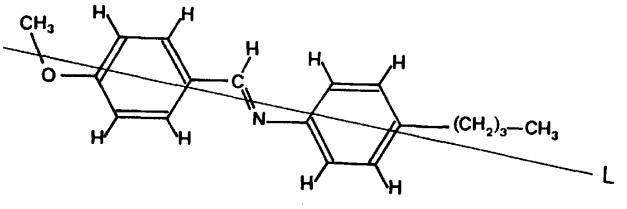

Fig. 5. Structural model for MBBA. L is the approximate direction of the long-axis of the molecule (from Ref. 10).

Based on the NMR study, Pines and Chang[10] suggested the structure of the MBBA molecule as shown in Fig. 5, where the long axis **L** is shown as the line passing through the centers of the co-planar benzene rings. If the transition moment of the 830 cm^{-1} band is assumed to be perpendicular to the long axis, *i.e.*, $\beta=\pi/2$, the S value is found, from Fig. 4, to be 0.40. From Eq. 1, the value of α is calculated to be 39.2°. If an S value of 0.40 is used, one can estimate β values for the remainder of the vibrational bands. The results are presented in Table 1.

The angle β between the transition moment of the phenyl ring stretching mode at 1578 cm^{-1} and the long axis of the molecule is calculated to be 10.2°, which is in excellent agreement with the experimental value of 9° given by Pines and Chang.[10] The above-mentioned value $S=0.40$ is rather low compared with the 0.62 value obtained from optical anisotropy measurements.[11] Nevertheless, in view of the fact that a sample in the form of very thin film was used, the uniformity of orientation may be affected by the container surfaces.

Saupe and Maier[7] have pointed out that the observed dichroic ratios contain a contribution from the anisotropy in the refractive indices, *viz.*, birefringence, $\Delta n=n_e-n_o$, where the extraordinary index n_e and ordinary index n_o correspond to the directions parallel and perpendicular to the optical axis of the medium, respectively: the correction factor to the dichroic ratio should increase with increasing S. If we conveniently assume that the birefringence of MBBA[12] obtained at 6328 Å is applicable to the present case, the corrected S value is found to be 0.44. In this case, however, the resulting β value for the 1578 cm^{-1} band is as large as 22°, which cannot be considered reasonable in view of the structural model mentioned above. Therefore,

the birefringence in the infrared region is probably small compared with that in the visible region. Support for this deduction is given by the ATR measurements of highly-oriented MBBA.

In the ATR method,[13] electromagnetic fields interacting with the absorbing medium are present in three directions at the reflecting interface and then the measurement of the reflectivity losses provides information about the anisotropy of the medium. In this respect, the ATR method is valuable for all types of oriented liquid crystals. However, no ATR spectra of liquid crystals have yet been reported. Brief mention is made of a procedure for the determination of the orientation of MBBA induced by substrate surfaces.

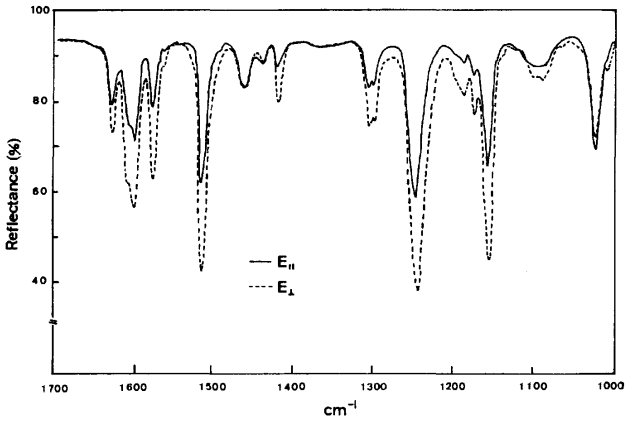

Fig. 6. The ATR spectra of uniformly homogeneous MBBA kept at 25 °C, measured with the electric vector of the radiation polarized parallel (solid line) and perpendicular (broken line) to the plane of incidence.

Figure 6 shows the polarized ATR spectra of a 25-μ sandwich of nematic MBBA between indium-oxide coated glass and a single reflection silicon prism. The temperature of the liquid cell was maintained at 25 °C and the incident angle was 40°. In order to obtain homogeneous orientation, the In_2O_3 surface was rubbed with alumina in one direction. The rubbed substrate was positioned to form the liquid cell so that the direction of rubbing coincided with the x-axis of the prism (see Fig. 8).

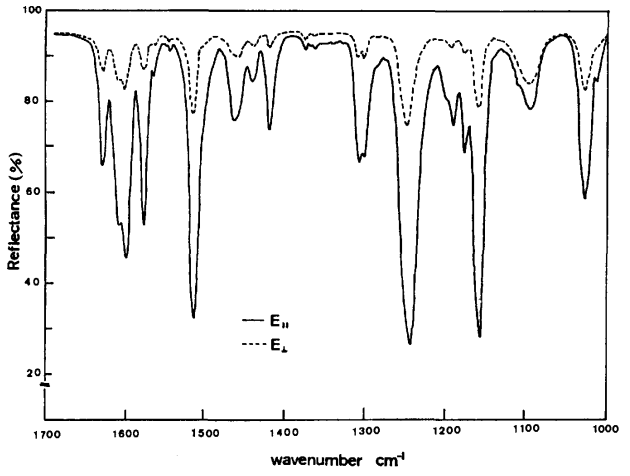

Fig. 7. The ATR spectra of homeotropic MBBA kept at 25 °C, measured with the electric vector of the radiation polarized parallel (solid line) and perpendicular (broken line) to the plane of incidence.

Figure 7 shows the polarized ATR spectra of homeotropically-oriented MBBA film at a constant temperature of 25 °C with the long axis of the molecule perpendicular to the substrate. This homeotropic structure was attained when the surface of the In_2O_3 coated glass was treated with dimethyldichlorosilane[14] or lecithin. The dichroic behavior exhibited in Fig. 7 shows clearly that the sample is quite well oriented, in agreement with the literature.[14] The observed dichroic ratios, D, taken from Figs. 6 and 7 are listed in Table 2.

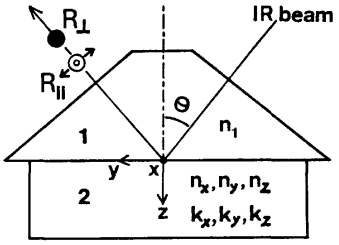

Fig. 8. Coordinate system for the attenuated total reflection from anisotropic absorbing medium. 1: Silicon prism, 2: anisotropic liquid crystal.

Table 2. Observed dichroic ratios, calculated β values, and S values for homogeneous and homeotropic liquids of MBBA

Wavenumber (cm^{-1})	Homogeneous			Homeotropic		
	D_{obsd}	k_x/k_z	β	D_{obsd}	k_z/k_x	β
1630	0.74	2.556	31.6°	4.35	2.277	32.6°
1600	0.53	3.568	20.9°	5.72	3.144	22.1°
1578	0.42	4.502	11.0°	7.18	4.068	10.0°
1520	0.51	3.708	19.6°	5.90	3.258	20.9°
1250	0.51	3.708	19.6°	5.74	3.156	22.0°
1160	0.46	4.110	15.5°	6.48	3.625	16.3°
1030	1.19	1.589	43.6°	3.29	1.606	42.4°
	$S=0.57$; $\alpha=32.4°$			$S=0.53$; $\alpha=34.0°$		

We now consider the two-phase system having a flat boundary shown in Fig. 8. In the figure, medium **1** is the Si ATR prism (refractive index of 3.42)[15] from which the infrared radiation is incident on medium **2**, which is a semi-infinite absorbing liquid crystal. The plane of incidence is the yz plane, the x-axis being perpendicular to this plane.

When total reflection occurs, the electromagnetic wave penetrates into medium **2** beyond the reflecting interface. For bulk material in which the thickness is much greater than the penetration depth of the evanescent wave, the change in reflection absorbance is respectively expressed for radiation polarized perpendicular and parallel with respect to the plane of incidence,[16] as

$$\ln\left(\frac{R_0}{R_\perp}\right) = pk_x$$

and

$$\ln\left(\frac{R_0}{R_{//}}\right) = qk_y + rk_z, \tag{4}$$

with

$$p = \frac{4n_{x1}^2}{\tan\theta(1-n_{x1}^2/\sin^2\theta)^{1/2}(1-n_{x1}^2)},$$

$$q = r(1-n_{z1}^2/\sin^2\theta), \tag{5}$$

and

$$r = \frac{4n_{y1}n_{z1}}{\tan\theta(1-n_{z1}^2/\sin^2\theta)^{1/2}(1-n_{z1}^2/\sin^2\theta+n_{y1}^2n_{z1}^2\cot^2\theta)}.$$

In Eq. 4, R_0 is the reflectivity when the absorption of medium **2** is zero and k_x, k_y, and k_z are the components of the absorption coefficient along the x, y, and z axes, respectively. In Eq. 5, θ is the incident angle and n_{x1}, n_{y1}, and n_{z1} are the components of the ratio of the refractive index of medium **2** to that of medium **1**.

From Eq. 4, the experimental dichroic ratio D, obtained from ATR spectra can be written as

$$D = \frac{q}{p}\left(\frac{k_y}{k_x}\right) + \frac{r}{p}\left(\frac{k_z}{k_x}\right). \tag{6}$$

In a particular case where the liquid is isotropic, *i.e.*, where $k_x=k_y=k_z$, D becomes $(q+r)/p$. Since the nematic liquid crystal has a uniaxial symmetry about the optical axis, the Eq. 6 can be reduced to a simpler expression.

If the molecules are oriented normal to the Si prism surface (homeotropic orientation), one finds $k_x=k_y$ from Fig. 8, and Eq. 6 reduces to

$$D = \frac{q}{p} + \frac{r}{p}\left(\frac{k_z}{k_x}\right). \tag{7}$$

If the molecules are oriented parallel to the x axis (homogeneous orientation), one has $k_y=k_z$ and then obtains

$$D = \frac{q+r}{p}\left(\frac{k_z}{k_x}\right). \tag{8}$$

Thus, if the values of p, q, and r can be calculated from Eq. 5, the value of the degree of order, S, can be obtained as a function of β in the manner described above for the case of transmission spectra. One should note that the k_z/k_x in Eq. 7 corresponds to the R in Eq. 3 in the case of homeotropic orientation, while in the case of homogeneous orientation the k_x/k_z in Eq. 8 corresponds to the R in Eq. 3. In order to calculate coefficients p, q, and r, however, it is necessary to know the anisotropic refractive indices in the infrared region for truly-oriented MBBA, however, no data are available at present.

On the other hand, in the visible region, detailed determinations of the birefringence and indices of refraction of MBBA at two wavelengths have been made by Haller, Huggins, and Freiser.[12] Their results are $n_o=1.54$ and $\Delta n=0.22$ at 6328 Å. These values are in good agreement with those obtained by Labrunie and Valette[17] at the same wavelength. Therefore, the values of p, q, and r were calculated assuming the above values.

Using an appropriate β value and the D value observed for any one vibration band, we can determine the degree of order S by the combined use of Eq. 3 and Eq. 7 or 8 corresponding to the case of homeotropic or homogeneous orientation. The β values for any other vibration can be derived using the S value thus determined. In the present study, the S value was changed independently for the homeotropic and the homogeneous cases so as to obtain agreement of the resulting β values for all vibration bands listed in Table 2 for both cases, because the β values cannot be altered by changes of orientation and the degree of orientation order. However, no set of reasonable S values could be obtained that fit the corresponding β values for both cases. Therefore, the most reasonable set of β values was obtained by changing only Δn, because the contribution of Δn to the calculated β and S values is much more sensitive than that of n_o. For these calculations, a least-squares refinement gave S values of 0.57 for the uniform homogeneous orientation and 0.53 for the homeotropic orientation. In these cases, the values of α are calculated to be 32.4 and 34.0° for the homogeneous and homeotropic cases, respectively. As a result of the above calculations, the most probable birefringence was obtained to be 0.05. In view of the experimental accuracy, however, a birefringence of 0.10 should also be considered to give good fit to the observations. The values of β obtained for the two liquid crystals are presented in Table 2, together with the values of k_z/k_x and k_x/k_z. The values of the degree of order S thus derived are compatible with the value of 0.62 for MBBA given by Chang.[11] In addition, values of β for the vibrational bands investigated here are in satisfactory agreement with those obtained by the transmission method mentioned previously.

It should be noted that the dichroisms observed for the two types of oriented film both arise from orientations of the liquid crystal very near the Si surface. In spite of this fact, dichroic analysis revealed a high degree of orientation, as mentioned above, which strongly suggests that the influence of the silicon surface on the orientational structure is much weaker than the aligning forces of the wall of the substrate side.

For practical reasons, several techniques for obtaining uniform orientation of liquid crystals have been investigated.[18] In order to understand the alignment mechanism, it is important to elucidate the structure of the liquid crystal as well as the surface structure of the substrate.[14,19] The infrared ATR technique permits experiments directed towards these problems.

Another important objective of the present ATR study on liquid crystals was to observe the molecular orientation under electric fields. This has been partly completed and the results of the experiment will be reported in the near future.

The author wishes to thank the Ōsaka Titanium Co., Ltd., for providing a high-purity single crystal of Si. The author also wishes to thank Professor W. Suĕtaka of Tohoku University, for help in the preparation of the manuscript.

The Heat of Solution of Poly(oxyethylene) Dodecyl Ethers in Dodecane

Takayasu MIURA* and Masao NAKAMURA

Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka 259-12

(Received February 9, 1977)

The heats of mixing of nonionic surfactants, poly(oxyethylene) dodecyl ethers $C_{12}H_{25}(OC_2H_4)_nOH$ (n=0—5) with a nonpolar liquid, dodecane were measured directly with a twin conduction microcalorimeter. A discontinuity appears on the heat of mixing *vs.* concentration curve except for n=0, the concentration of which decreases exponentially with n. This was regarded as the critical micelle concentration. It was deduced from the heat of solution at infinite dilution, $\Delta_s h_2^{\ominus}$, that the poly(oxyethylene) chain is in a cyclic state in dodecane due to intramolecular hydrogen bonding of the terminal OH group with an oxygen atom in the chain. In addition, the energy of the solute-solvent interaction, $\Delta_t u_2^{\ominus}$, was estimated from $\Delta_s h_2^{\ominus}$ and the heat of evaporation of the solute, $\Delta_e h^0$. As a consequence, the interaction energies of the OH group with nonpolar hydrocarbon are similar, regardless of whether or not the OH group is intramolecularly hydrogen bonded.

The use of nonionic surfactants in nonaqueous solutions has been developed,[1] but the dissolved states are not well understood.[2] In a previous paper,[3] the molecular state of poly(oxyethylene) dodecyl ethers, a typical series of nonionic surfactants were deduced, in the vapor phase, in which the poly(oxyethylene) chains are not extended but in cyclic states due to the intramolecular hydrogen bonding of the terminal OH group with an oxygen atom in the chain. Poly(oxyethylene) chains are also expected to be in cyclic states in a nonpolar liquid, because the vapor phase may be regarded as the most nonpolar medium. Dodecane may be the most desirable solvent in nonpolar liquids for poly(oxyethylene) dodecyl ethers, because the hydrophobic dodecyl group cannot be discerned from the solvent dodecane. In the present paper, the dissolved states of nonionic surfactant molecules in nonpolar liquids are elucidated by calorimetrically determining the heats of mixing of poly(oxyethylene) dodecyl ethers with dodecane.

Experimental

Poly(oxyethylene) dodecyl ethers, $C_{12}H_{25}(OC_2H_4)_nOH$ (n= 1, 2, 3, 4, and 5), and 1-dodecanol (corresponding to n=0) were kindly provided by Nihon Surfactant Kogyo K. K., which have the same order of purity as those used in a previous paper.[3] The solvent was prepared by distilling G. R. grade dodecane (Wako Junyaku Co.) after drying over a sodium wire for one week.

The heats of mixing were measured with a twin conduction microcalorimeter using a mixing device for ampoules (Oyodenki Kenkyujo Co., CM-502).[4] The temperature of the cells was maintained at 29.00±0.05 °C by circulating thermostatically-controlled water around the apparatus installed in an air thermostat. A small glass ampoule containing a weighed amount of solute was immersed in 25 cm³ of dodecane in the cell. After the establishment of thermal equilibrium, the ampoule was crushed and the liquid was stirred for 1 min. The difference in temperature between the two cells, one ampoule in either cell being empty, was recorded. This difference is due to the liberation or absorption of heat which accompanies the mixing of the solute and dodecane. The heat was estimated similarly using the method described by Murakami and Fujishiro.[5]

Results and Discussion

Critical Micelle Concentration. When n_1 mol of solvent and n_2 mol of solute are mixed, the heat of mixing, ΔH, is given by

$$\Delta H = n_1 \Delta h_1 + n_2 \Delta h_2, \quad (1)$$

where $\Delta h_i = h_i^0 - h_i$ and h_i and h_i^0 are the partial molar enthalpy in the solution and the molar enthalpy in the pure state, respectively, of component i. Then,

$$\Delta h_2 = \left(\frac{\partial \Delta H}{\partial n_2}\right)_{T,p,n_1}, \quad (2)$$

where T is the absolute temperature and p the pressure. The relations between ΔH and n_2 measured for poly(oxyethylene) dodecyl ethers with dodecane are shown in Figs. 1—6, when the amount of solvent dodecane is 25 cm³. Since T, p, and n_1 are maintained constant under the present experimental conditions, the tangent at any point on the curves in Figs. 1—6 is equal to Δh_2 at that concentration.

For 1-dodecanol (n=0), ΔH is proportional to n_2 and, therefore, Δh_2 is constant over the measurement range, as shown in Fig. 1. This means that such concentrations

are dilute enough so that the solutions can be regarded as ideal dilute solutions. Thus, the value of Δh_2 estimated from the inclination is equal to the heat of solution at infinite dilution, $\Delta_s h_2^{\ominus}$.

For $n=1$—5, ΔH is not proportional to n_2 and Δh_2 is not constant even in the same concentration region where the solution of 1-dodecanol is ideally dilute, as shown in Figs. 2—6. In such a concentration region, the solution not only deviates from the condition of an ideal dilute solution, but also there appears a discontinuous point on the curve of ΔH *vs.* n_2, where ΔH decreases abruptly with increasing concentration, regardless of n. Such discontinuous phenomena have been found by Hutchinson *et al.*[6] for aqueous sodium alkyl sulfates solutions. They have shown that the discontinuity concentration, DC, is in good agreement with the critical micelle concentration, CMC. Then, the observed DC is also assumed to correspond to the CMC of poly(oxyethylene) dodecyl ethers in dodecane, the values of which are listed in Table 1.

The plot of log DC was found to decrease linearly with n, the number of oxyethylene units in a poly(oxyethylene) chain, as shown in Fig. 7. Such a relationship resembles those between CMC for aqueous solutions and the number of methylene groups in a hydrophobic alkyl chain of a homologous series of surfactants.[7] According to the theory of micellization,[8] the linear relation means that each methylene group of the homologs makes an equal energy contribution, when an alkyl group is transferred from the aqueous solution into a micelle. The linear relation between log DC and n, therefore, confirms the assumption that the DC corre-

sponds to the CMC. In addition, the state of an oxyethylene unit in the lipophobic chain would not be different depending whether it exists in micelle or in dodecane.

Hutchinson *et al.* have also shown that the discontinuous change in the heat of mixing per mol of solute at the CMC corresponds to the heat of micellization.[6] The values of the heat of micellization, which are listed in Table 1, were estimated by dividing the abrupt changes in ΔH at the DC by n_2. They exhibit no tendency to increase linearly with n, which is expected from the linear relation between log CMC and n. These may not always reflect equilibrium properties, because of the complexity of the dissolving process of the surfactant, especially around the CMC, involving the alternate formation and destruction of micelles. Actually, both endothermic and exothermic parts were often found in a chart at such concentrations. Even if the heat of micellization cannot always be obtained correctly, the measurement of the heat of mixting is recommended as the preferred method for determining the CMC, especially for organic solutions.

Heat of Solution at Infinite Dilution. From Eq. 2, the heat of solution at infinite dilution, $\Delta_s h_2^\ominus$, is expressed by

$$\Delta_s h_2^\ominus = \lim_{n_1 \to 0} \Delta h_2 = \lim_{n_1 \to 0} \left(\frac{\partial \Delta H}{\partial n_2} \right)_{T,p,n_1} . \quad (3)$$

Then, $\Delta_s h_2^\ominus$ can be obtained from the initial slope of the straight lines passing through the origin in Figs. 1—6. The values thus estimated are listed in Table 1. It was found that $\Delta_s h_2^\ominus$ increases linearly with n in the range 2—5, as shown in Fig. 8. This means that all oxyethylene units in a poly(oxyethylene) chain of n= 2—5 are in equal states in dodecane, as has been described previously for the heats of evaporation of these compounds.[3] From the slope of the line, it requires *ca.* 0.8 kcal mol^{-1} for the oxyethylene unit to transfer a poly(oxyethylene) dodecyl ether from the pure liquid state to the dodecane solution for n=2—5.

The straight line in Fig. 8 passes through the origin, which is *ca.* 5.6 kcal mol^{-1} less than the value for 1-dodecanol (n=0). These phenomena suggest that the terminal OH group of the poly(oxyethylene) chain is

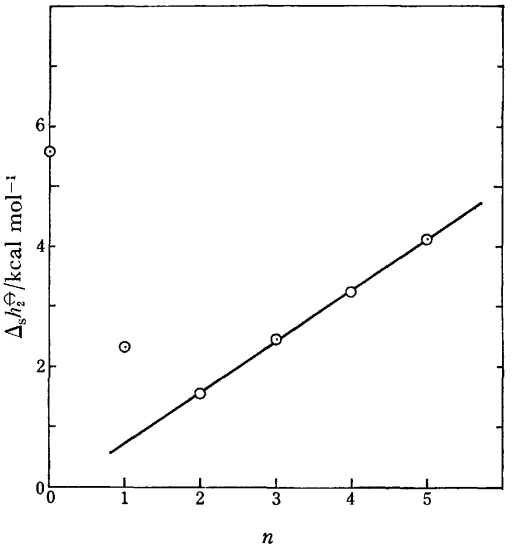

Fig. 8. Heat of solution at infinite dilution $\Delta_s h_2^\ominus$ *vs.* n plot for $C_{12}H_{25}(OC_2H_4)_nOH$ in dodecane at 29 °C.

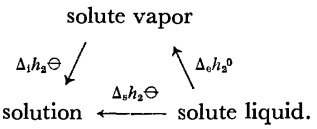
not in the same state as the alcoholic OH group dissolved in dodecane, because both the alcoholic and terminal OH groups in their pure states are considered not to be so different energetically but to interact with one of the neighboring molecules due to intermolecular hydrogen bonding. As already deduced for the vapor phase,[3] for the nonpolar dodecane solution the terminal OH group of the poly(oxyethylene) chain is believed to interact with an oxygen atom in the chain and thus the chain is in a cyclic state due to intramolecular hydrogen bonding. A signal due to intramolecular hydrogen bonding has been observed by means of infrared spectroscopy for similar substances, the monomer and dimer of ethylene glycol and their monomethyl ethers, in nonpolar carbon tetrachloride.[9,10] Because an energy of 5.6 kcal mol^{-1}, the difference between $\Delta_s h_2^{\ominus}$ for 1-dodecanol and the straight line for $n=2$—5, corresponds exactly to that of 1 mol of a hydrogen bond[11] (although this is slightly less than the corresponding value for evaporation, 6.2 kcal mol^{-1}), almost all the molecules would be in cyclic states due to intramolecular hydrogen bonding.

The value of $\Delta_s h_2^{\ominus}$ for $n=1$ is *ca.* 1.5 kcal mol^{-1} higher than that expected from the linear relation for $n=2$—5. This increase in energy can be interpreted from the fact that the molecule of $n=1$ can only form a 5-membered ring, for intramolecular hydrogen bonding. The 5-membered ring is expected to have a higher energy for hydrogen bonding than 8-membered or larger rings,[12] because it has been found that the infrared absorption-band shift of the OH group due to the 8-membered ring is appreciably larger than that due to the 5-membered ring.[10]

Solute-solvent Interaction. The heat of condensation of 1 mol of solute from the vapor phase to solution at infinite dilution, $\Delta_i h_2^{\ominus}$, may be expressed in terms of the heat of evapration, $\Delta_e h_2^0$, and the heat of solution at infinite dilution, $\Delta_s h_2^{\ominus}$, as

$$\Delta_i h_2^{\ominus} = \Delta_s h_2^{\ominus} - \Delta_e h_2^0, \tag{4}$$

according to the Born-Harber cycle:



When the interaction between solute molecules is neglected in the vapor phase, the interaction energy of the solute with the surrounding solvent molecules in the solution, $\Delta_i u_2^{\ominus}$, can be expressed as

$$\Delta_i u_2^{\ominus} = \Delta_i h_2^{\ominus} + RT, \tag{5}$$

where R is the gas constant. $\Delta_i u_2^{\ominus}$ is considered to be the most suitable measure of the affinity for a given solute and solvent combination. The values of $\Delta_i u_2^{\ominus}$ for poly(oxyethylene) dodecyl ethers in dodecane listed in Table 1 were calculated from the data for $\Delta_s h_2^{\ominus}$ in the present paper and those for $\Delta_e h_2^0$ from a previous paper.[3] The relationship between $\Delta_i u_2^{\ominus}$ and n is shown in Fig. 9. A linear relation holds not only for $n=2$—5, as in Fig. 8, but also for $n=0$ for which the value of $\Delta_i u_2^{\ominus}$ falls near the straight line. This reveals that the

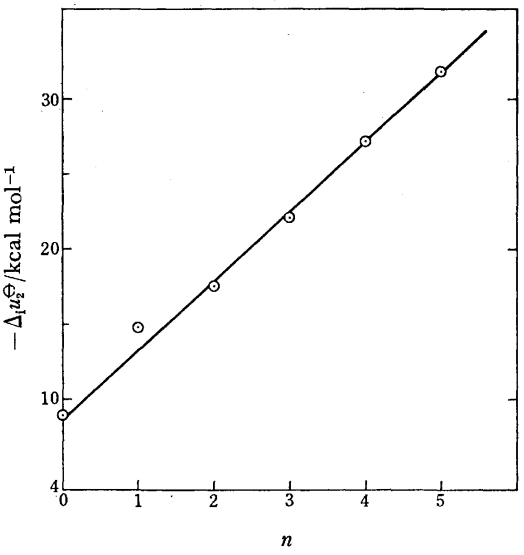


Fig. 9. Intraction energy with dodecane $\Delta_i u_2^{\ominus}$ *vs.* n plot for $C_{12}H_{25}(OC_2H_4)_nOH$ at 29 °C.

interaction of an alcoholic OH group with dodecane is indistinguishable from that of the terminal OH group of the poly(oxyethylene) chain for $n=2$—5. Thus, it is concluded that the energy of interaction of the OH group with dodecane does not depend on whether it is free or intramolecularly bonded to an ether oxygen atom. If this is true, the upward deviation of $n=1$ from the straight line can be ascribed to changes in the energy of the intramolecular hydrogen bond in the 5-membered ring and/or in the rate for the 5-membered ring to free an OH group, when the molecules are transferred from the vapor phase to the dodecane solution. The slope of the straight line gives an energy of *ca.* −4.7 kcal mol^{-1}, which is the interaction energy of an oxyethylene unit with dodecane. Since the cohesive energy of a hydrocarbon is estimated to be *ca.* −0.8 kcal mol^{-1} of the methylene group,[13] the interaction energy of an ether oxygen atom with dodecane results in an energy of *ca.* −3.1 kcal mol^{-1}, provided that the additivity holds for the interaction energy in oxyethylene unit.

The authors wish to express their thanks to Professor Kiiti Kosiyama for his encouragement throughout this work.

Dye-sensitization on the Photocurrent at Zinc Oxide Electrode in Aqueous Electrolyte Solution

Michio MATSUMURA, Yoichi NOMURA, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 10, 1977)

The dye-sensitized photocurrents generated from the electrochemical systems <zinc oxide|aq solution|platinum> have been studied. The action spectra for the photocurrent, its dependence on the concentration of the dye solution and other experimental results have revealed that the photocurrent is caused by the dye adsorbed on the electrode, not from that dissolved in the liquid phase. From the analysis of the decay of the photocurrent with the time of illumination, the quantum yield for the electron injection from the excited dye has been determined. Rose Bengal showed the quantum yield of 22%. The influence of halide ions on the photocurrent has also been studied.

"Wet-type" photocells, consisting of a semiconductor electrode, an aqueous solution, and a metal counter electrode, are attracting growing attention as a device to convert light energy into electrical or chemical energy.[1-4] The photovoltaic effect in such cells arises essentially from generation of electrons and holes in the illuminated semiconductor electrode and their efficient separation by the built-in electric field inside the space charge layer of the semiconductor. One of the characteristics of the "wet" cells is that the photocurrent is accompanied by redox reactions of the solute or the solvent in the electrolyte solution.

When the electrolyte solution contains a dye, a photocurrent often flows by the excitation of the dye with photon energy less than the band gap of the semiconductor. In this case, the current is called the dye-sensitized photocurrent, on which many reports have been made.[5-9]

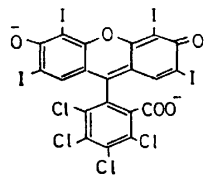
We have succeeded in constructing a dye-sensitized semiconductor photo-cell having an energy conversion efficiency of 1.5% under monochromatic illumination.[10] In order to increase the energy conversion efficiency further, it will be necessary to increase both the quantity of light absorbed by the dye and the quantum yield of electron injection from the excited dye. For this purpose, it is essential to deepen our understanding on the mechanism of electron transfer in such systems. In this paper, we describe some of our results on such problems.

Experimental

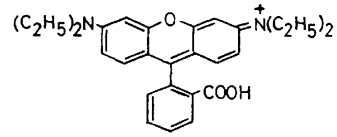
Zinc oxide sinter disks were used as the electrodes. They were prepared by moulding zinc oxide powder by compression and heating at 1300 °C in the air for 1 h. It was found that the adsorptive activity of the zinc oxide sinter for the dye depends on the source of the zinc oxide powder. In the following experiments, we made the sinter out of zinc oxide powder obtained from Kanto Chemical Co. without any purification or pre-treatment. The sinter had low adsorptive activity but gave a reproducible photocurrent. One of the surfaces of the zinc oxide disk was coated with indium by employing the evaporation method so as to make an ohmic contact, and a copper wire was attached with silver paste. The structure of the electrode was mostly the same as that described previously.[9,10] Before each measurement, the electrode was polished with silicon carbide abrasive, etched with hydrochloric acid or nitric acid, washed with water, and dried.

The potential of the semiconductor electrode *versus* the reference electrode (SCE) was controlled by use of a Hokutodenko HA-101 potentiostat and the current was measured with a Yokogawa-Hewlett-Packard 4304B electrometer. A 500 W xenon lamp of Ushio Electric Inc. was used as the light source. The light was monochromatized by use of a Japan Jarrel-Ash, 0.25 m Ebert type monochromator. The light intensity was measured with an Eppley, bismuth-silver type thermopile. A Shimadzu MPS-50L Spectrometer was used for the measurements of absorption spectra.

All the solutions used contained 0.2 M (mol·dm^{-3}) Na_2SO_4 or KNO_3 as the supporting electrolyte. Oxygen was removed by bubbling high purity nitrogen gas through the solutions before measurement. All chemicals were of reagent grade and used without further purification. The structual formulas of the dyes used are given below:



Rose Bengal.



Rhodamine B.

Results

Figure 1 shows the dye-sensitized photocurrent-potential curves for the case of Rose Bengal. The anodic current was negligible in the dark, while it rose up under illumination in the wavelength range of the absorption band of Rose Bengal. When the solution contained no dye, the photocurrent was less than 0.03

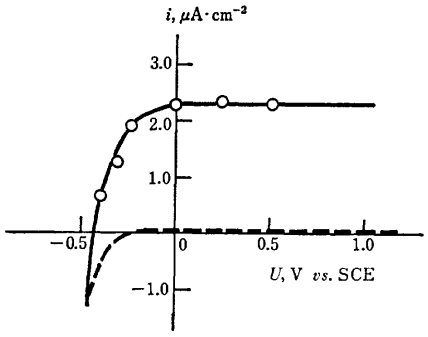


Fig. 1. Current-potential curves in the presence of 6.5×10^{-7} M Rose Bengal and 0.2 M Na_2SO_4, ——dark current, ——under illumination (λ 562 nm).

$\mu A \cdot cm^{-2}$ under illumination at the same wavelength and at the electrode potential of 0.35 V. Since the photocurrent decayed during the course of illumination, the photocurrent curve was plotted by using the value obtained immediately after the light had been turned on. The photocurrent appeared at the electrode potential more positive than −0.5 V *vs.* SCE, which nearly agreed with the flat band potential of the zinc oxide electrode reported by Lohmann,[11] and became constant at the potential more positive than 0.0 V. Therefore, most of the experiments were made at 0.35 V.

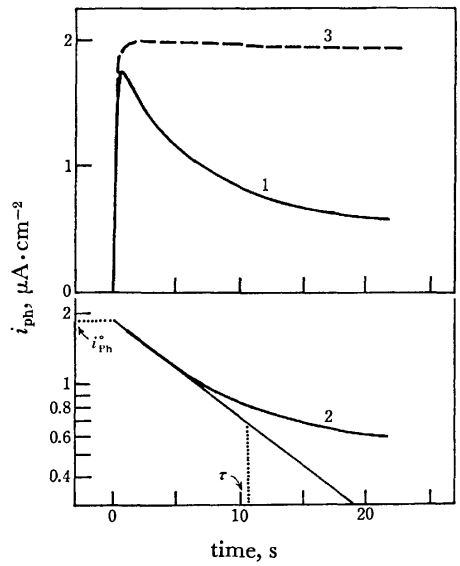

Fig. 2. The change of the photocurrent *vs.* time. Curve 1, for the solution of 6.7×10^{-7} M Rose Bengal and 0.2 M KNO_3. Curve 2, the logarithmic plot of the same result. Curve 3, for the case where 0.1 M KI is added.

The photocurrent decayed rather quickly with time as shown in Fig. 2. The photocurrent was not restored to the initial value, if the electrode was kept in the dye solution for a few minutes. The photocurrent fell down to zero when the light was turned off, and no overshoot to the cathodic side was observed. The decay of the photocurrent was suppressed or stopped by adding a reducing agent, *e.g.*, potassium iodide, as shown by curve 3. The logarithm of the photocurrent gave a straight line for the first several seconds as shown by curve 2, from which we can obtain the initial value of the photocurrent, i^0_{ph}, and the decay time constant, τ, namely the period of illumination for which the current decays to 1/e.

The surface of the zinc oxide electrode faintly colored pink, if it was dipped into the Rose Bengal solution. After prolonged illumination in the same solution at closed circuit, the color changed to brown-red. The color was not removed by washing with water. On the other hand, no color change occurred when the elctrode was illuminated at open circuit or at closed circuit in the presence of a reducing agent.

Figure 3 shows the photocurrent action spectrum obtained for a solution containing a sufficient amount of potassium iodide. Almost the same action spectrum was obtained for a solution without any reducing agent

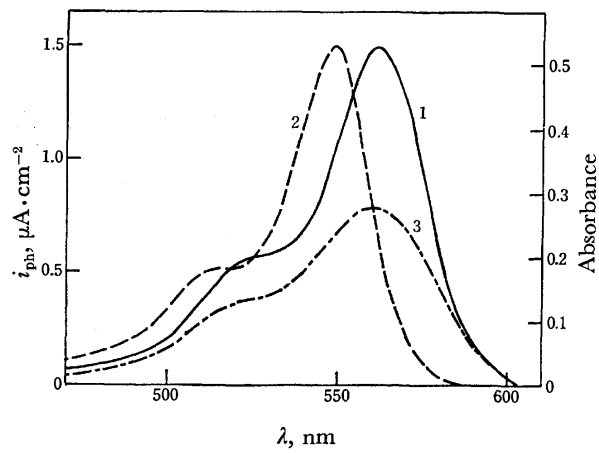

Fig. 3. (1) The action spectrum for the photocurrent for the solution of 5.3×10^{-7} M Rose Bengal and 0.1 M KI at the electrode potential: 0.35 V *vs.* SCE. (2) Absorption spectrum of the same solution, measured with a 10 cm cell. (3) Diffuse reflectance spectrum of the dye adsorbed on zinc oxide powder. The dye was adsorbed in the aqueous solution of 1.4×10^{-5} M Rose Bengal.

by scanning rapidly under weak illumination. The peak of the action spectrum for the photocurrent shifted by 13 nm toward the longer wavelength from that of the absorption spectrum of the dye solution, and nearly coincided with that of the reflection spectrum of the dye adsorbed on zinc oxide powder.

The initial value of the photocurrent increased proportionally with the illumination intensity, while the decay time constant was inversely proportional to it (Fig. 4). The value of i^0_{ph} and τ scarcely changed over the electrode potential range 0.0—1.0 V. Figure 5 shows the change of i^0_{ph} and that of τ with the concentration of Rose Bengal in the solution. The i^0_{ph} value increased with the concentration of the dye and ap-

proached a constant. The τ was constant for the concentration of Rose Bengal up to 10^{-6} M, and increased by the concentration above 10^{-6} M.

The photocurrent for Rhodamine B increased by addition of halide ions to the dye solution, while the dependence of the decay time constant of the photocurrent on the concentration of the halide ions was more complicated (Fig. 6a and b).

Discussion

The mechanism of the dye-sensitized photocurrent can be explained by the energy diagram such as shown in Fig. 7, for the case of an n-type semiconductor. The

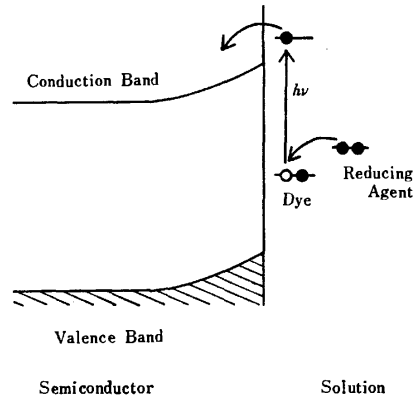

Fig. 7. A model for the electron injection.

electron injection from an excited dye (D*) into a conduction band is suggested by the fact that only those dyes whose excited energy levels are considerably higher than the conduction band of the semiconductor at the interface can act as effective sensitizers.[12] The electron deficient dye (D^+) may undergo irreversible reaction, causing the color change of the electrode. The total reaction scheme can be represented as follows:

$$D + h\nu \longrightarrow D^*, \quad (1)$$

$$D^* \longrightarrow D^+ + e(\text{electrode}), \quad (2)$$

$$D^+ \longrightarrow \text{reaction product}. \quad (3)$$

It has been tacitly assumed by many authors so far that the dye-sensitized photocurrent is caused by the dye adsorbed on the electrode and not by that dissolved in solution. However, there has been no strong evidence for this. Now, we can pick up the following three facts as such evidence from our experimental results.

1. The shift of the action spectrum for the photocurrent from the absorption spectrum of the solution, as shown in Fig. 3, indicates that the photocurrent is caused mainly by the dye adsorbed on the electrode.

2. From the initial value of the photocurrent shown in Fig. 2, the apparent quantum yield of the photocurrent (η), defined as the number of electrons transferred divided by the number of incident photons, can be calculated to be 1.8%, which means that at least 1.8% of the photons are absorbed by the dye. If the photocurrent is assumed to be caused only by the dye in the bulk of the solution, 3 mm of the light path length in the solution is required to make the absorption factor of the light 1.8% at λ=562 nm. However, the same photocurrent was observed with a light path length of 0.2 mm or shorter. This result indecates that the contribution of the dye in the solution is small or negligible.

3. As shown in Fig. 5, the photocurrent indicates the tendency of saturation at a relatively low concentration of the dye, *i.e.*, 5×10^{-6} M. It would be difficult to explain this by attributing the photocurrent to the dissolved dye. From our preliminary experiments, the adsorption isotherm of the dye adsorbed on the electrode surface has been found to be saturated at about the same low dye concentration as above.

The Decay Curve of the Photocurrent and the Quantum Yield of Electron Injection from the Excited Dye. The photocurrent of some semiconductor-aqueous solution

photocell decays with time owing to the deposition of opaque substance on the surface of the electrode, produced by the reaction with the holes generated. The photocurrent in the case of zinc oxide electrode does not decay, because in this case the products, zinc ion and oxygen, do not accumulate on the surface.[13]

In the case of the dye-sensitized photocurrent for zinc oxide, the photon energy is less than the band gap, and so it is clear that the decay is not caused by the reaction of the electrode itself, since no free hole exists in the electrode. The decay of the photocurrent should then be attributable either to the decrease of the number of the unoxidized dye molecules (or ions) adsorbed on the electrode or to an accumulation of the deteriorated dye (Reactions 1—3).

The influence of the dye (D_{soln}) or the reducing agent (R_{soln}) in solution on the decay of the photocurrent, as shown in Figs. 2 and 5, is explained by the following dye regeneration processes:

$$D^+ + D_{soln} \longrightarrow D + D^+_{soln}, \quad (4)$$

$$D^+ + R_{soln} \longrightarrow D + R^+_{soln}. \quad (5)$$

Process 4 can be achieved either by the electron transfer or by the exchange of D^+ and D_{soln}. The decay of the photocurrent is suppressed if the reaction velocities for processes 4 and 5 are greater than those for processes 2 and 3.

When the solution contains no reducing agent, the number of dye molecules (or ions), N, per unit area of the electrode surface will change according to

$$dN/dt = -\eta_0 SN + kC(N_0 - N), \quad (6)$$

where η_0 is the quantum yield of the electron injection from the excited dye, S the frequency of excitation of a dye molecule (or ion), N_0 the number of the dye molecules (or ions) per unit area of the electrode before illumination, C [M] the concentration of the dye in the solution, and k the rate constant. The second term of the right hand side of Eq. 6 corresponds to the restoring rate of the oxidized dye on the electrode surface by Reaction 4.

When the concentration of the dye in the solution is very low, the second term of Eq. 6 can be neglected, and N can be written as

$$N = N_0 \exp(-\eta_0 St). \quad (7)$$

The photocurrent, assumed to be proportional to N, can be written as

$$i_{ph} = i^0_{ph} \exp(-\eta_0 St), \quad (8)$$

and, hence

$$\eta_0 = 1/\tau S. \quad (9)$$

The exponential decay of the photocurrent, as observed experimentally at the initial stage, coincides with Eq. 8.

The dependence of τ on the concentration of the dye shown in Fig. 5b can be explained as follows. When the concentration of the dye is high, the second term of Eq. 6 cannot be neglected. Therefore, Eqs. 7—9 are valid only in the range of the concentration where τ does not depend on C. Figure 5 shows that such a condition is satisfied when C is lower than 10^{-6} M.

The absorbance of the dye on the electrode can be written as

$$\log I_0/I = 1000\varepsilon N/N_A, \quad (10)$$

where ε [M^{-1} cm^{-1}] is the molar extinction coefficient of the dye, N_A the Avogadro constant, I_0 the number of the photons incident on a unit area of the dye layer on the electrode per second, and I the number of the photons transmitted through the same layer. Since the absorption of light by the dye layer is small, the equation can be approximated as

$$(I_0 - I)/I_0 = 1000(\ln 10)\varepsilon N/N_A, \quad (11)$$

and

$$I_0 - I = SN. \quad (12)$$

From these equations, S can be written as

$$S = 1000(\ln 10)\varepsilon I_0/N_A. \quad (13)$$

The relation that τ is inversely proportional to I_0, as shown in Fig. 4b, can be derived from Eqs. 9 and 13.

The quantum yield η_0 for Rose Bengal was determined to be 22% by applying Eqs. 9 and 13 to the experimentally obtained photocurrent decay curves. The quantum yield was obtained for the illumination at the peak wavelength, and the molar extinction coefficient was assumed to be the same as that at the peak of the absorption spectrum of the solution. The reflection factor of light at the surface of the electrode was estimated to be 0.7 from the comparison of the reflected light intensity with that from magnesium oxide powder. This means that seven tenths of the incident light, which passes through the dye layer toward the inside of zinc oxide sinter, is reflected and passes again through the dye layer on the surface of the electrode. Therefore, we employed the value of measured number of photons incident upon the sample multiplied by 1.7 for I_0 in Eqs. 10—13.

Effect of Halide Ions on the Dye-sensitized Photocurrent. Hauffe *et al.*[14] found that the dye-sensitized photocurrent at a zinc oxide electrode was increased by addition of halide ions to the dye solution. The results shown in Fig. 6a indicate similar effects of the halide ions on the photocurrent. The increase in the photocurrent becomes greater in the sequence $Cl^- < Br^- < I^-$. This order is the same as that of the electron donating ability of the ions, *i.e.*, the oxidation potential increases in the reverse order.

Essentially, the visible spectra of the dye solution were not changed by addition of halide ions. Therefore, the effect of halide ions can be explained by assuming the formation of the exciplex between the excited dye and halide ions, the exciplex injecting an electron into the electrode efficiently. It is expected that the $1/\tau$ increases with the quantum yield of electron injection (Eq. 9). The result for chloride and bromide ions (Fig. 6b) is consistent with the expectation and supports the mechanism mentioned above. By addition of ioide ion, τ as well as i^0_{ph} increased. Iodide ion suppresses the deterioration of the dye by supplying an electron to the oxidized dye as described earlier. Therefore, in this case, the decrease of $1/\tau$ is attributable to the restoration of the oxidized dye by iodide ion, but not to the decrease of the quantum yield of electron injection.

Hauffe *et al.* proposed the reduced dye formation by the electron transfer from halide ions to the excited

dye, the reduced dye injecting an electron into the electrode. According to their mechanism, the dye should not deteriorate, in contradiction with the experimental results that the decay is faster in the presence of chloride and bromide ions.

The authors wish to express their gratitude to Wireless Research Laboratory, Matsushita Electric Industrial Co., Ltd. for the supply of zinc oxide sinter disks at the early state of this work. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 911504).

Studies of the Measurement of the Intermicellar Concentration of Surfactants by Gel Filtration

Tsunetaka SASAKI,* Misako YASUOKA,** and Hitoshi SUZUKI***

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received February 21, 1977)

Equations are derived which are used to calculate the intermicellar concentration (C_s) of a surfactant from measurements of the elution volumes of micelles, the elution front and the intermicellar monodisperse molecules or ions. These quantities are obtained by the gel filtration of a surfactant charged in band form through a gel column previously filled with the same surfactant at a lower concentration. The C_s values found are not constant, but increase and the increase becomes less pronounced with the concentration (C) of the surfactant, both for sodium dodecyl sulfate and α-dodecyl-ω-hydroxyhexa(oxyethylene). This confirms that the concentration $C-C_s$ of the micelles which move during the gel filtration is smaller than the usually-employed concentration $C-C_m$ of micelles in a stationary state, where C_m denotes the critical micelle concentration.

Many problems remain unsolved regarding the properties of aqueous surfactant solutions, especially the dissolution state of the surfactants.[1] The intermicellar concentration of the aqueous surfactant, for instance, is usually believed to be constant for a solution of concentration C above the critical micelle concentration (CMC), C_m, and the micellar concentration is equated with $C-C_m$.[2,3] Here, constancy of the intermicellar solution is assumed from the constancy of the surface tension of the aqueous surfactant solution above the CMC[4] or from the result of equilibrium dialysis.[5] However, the surface tension of, for instance, a sodium dodecyl sulfate (SDS) solution shows a gradual decrease with increasing concentration of the SDS above the CMC.[1,6] Also, equilibrium dialysis cannot be applied to such a system, consisting of single ions and micelles with rapid equilibrium established between them, since the micelles eventually pass through a semipermeable membrane, if the intermicellar concentration or the activity increases above the CMC.[7]

T. Sasaki *et al.* have studied the dissolution state of aqueous surfactant solutions by gel filtration[8] and have found the method to be suitable also for the study of intermicellar concentrations. The present paper describes studies of the measurements of intermicellar concentrations of the aqueous solutions of SDS and α-dodecyl-ω-hydroxyhexa(oxyethylene) ($D(EO)_6$).

Experimental

Materials. SDS was prepared from 1-dodecanol and chlorosulfuric acid according to the Dreger method[9] and was purified by extraction with diethyl ether and recrystallization from ethanol. $D(EO)_6$ of more than 99% purity, as measured by gas chromatography, was obtained from the Nikko Chemical Company. Both SDS and $D(EO)_6$ were confirmed to be free from surface-active impurities by the absence of a minimum in the surface tension *vs.* concentration curve. Distilled water was used after degassing by boiling.

Apparatus. The gel filtration apparatus is shown in Fig. 1. In this figure, Sephadex G-50 fine gel from Pharmacia

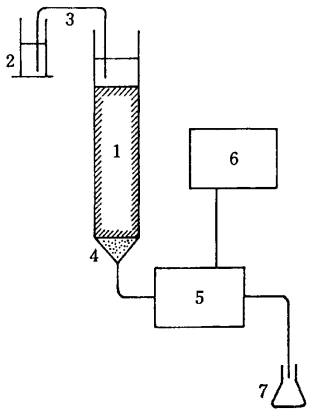

Fig. 1. Gel filtration apparatus.
(1) Gel column, (2) reservoir vessel, (3) siphon, (4) glass wool, (5) differential refractometry monitor, (6) recorder, (7) weighing vessel.

Products was packed in gel column 1 after sufficient swelling in water. The gel beds used were of 1.18 cm inner diameter and 24 and 30 cm in length. For the measurements, a given amount (8 to 30 cm^3) of sample solutions of varying concentrations was placed in vessel 2, from which the solution was introduced through a siphon onto the gel column that had previously been filled with the same solution at a different concentration which is hereafter abbreviated to a preset solution. The sample solution was then eluted by similarly introducing water from vessel 2 through the siphon onto the gel column. This ensures elution under a constant hydrostatic pressure. The rate of liquid flow was 30 and 24 cm^3/h in the cases of SDS and $D(EO)_6$, respectively. The monitor used for the sample flow was a flow-type differential refractometer (LDC-Mitsumi Model 1103 refractomonitor) which detects and records the change of the refractive index at the outlet of the gel column due to the concentration change. The whole apparatus, with the exception of the recorder, was maintained in an air thermostat at 30 ± 1 °C for SDS and 25 ± 1 °C for $D(EO)_6$.

Principle of the Intermicellar Concentration Measurements. Figure 2 shows the elution profile of a surfactant solution of concentration C, which is larger than C_m, charged in band form and eluted with water through a gel column previously swollen with water. As is seen, the tail part of the elution curve forms two steps, corresponding to the fast- and slow-flowing tails of the micelles and the intermicellar single molecules or ions, respectively.

At the elution front, fast-flowing micelles precede the inter-

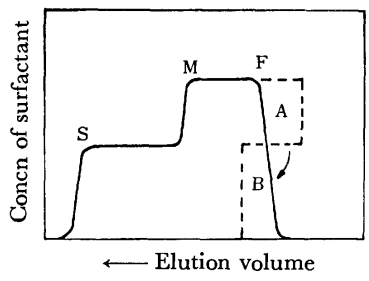

Fig. 2. Elution profile of a surfactant solution.

micellar solution. However, since micelles without the intermicellar solution containing single molecules or ions are unstable, A in Fig. 2 decomposes to form intermicellar molecules or ions, B, with which the rest of the micelles are brought into equilibrium, as is shown in Fig. 2. Because of such a docomposition, the micellar front moves slower than the micelles eluting without decomposition or than the tail of the micelles. Now, if the gel column is previously filled with a preset solution of the same surfactant at concentration C', which is lower than C_m, decomposition of the sample solution at the elution front decreases and the difference in elution rate between the micellar front and tail may become smaller. Then the preset concentration which makes this difference zero is considered to be the intermicellar concentration.

Actually, the concentration of such a preset solution,which contains only single molecules or ions, is not available when the intermicellar concentration C_s is larger than C_m. Therefore, in the present experiment, the concentration of the preset solution, C', was first made slightly lower than C_m. This also avoids the change in structure of the gel due to the change in the solution concentration as elution proceeds. Figure 3 shows the principle of the calculation of C_s. Figure 3(a) shows the state of the preset solution and the sample solution before elution and Fig. 3(b) represents the behavior of the solution during elution. In this figure, R_f, R_m, and R_s denote the elution rates of the solution front, of the tails of micelles, and of the intermicellar molecules or ions, respectively, C is the total concentration of the surfactant, and A_t and A_0 are the cross-sectional area of the gel column through which the

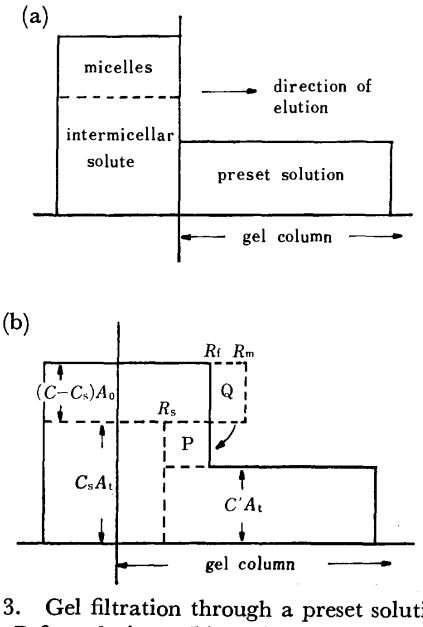

Fig. 3. Gel filtration through a preset solution.
(a) Before elution, (b) during elution.

intermicellar solute and micelles flow, respectively.

In Fig. 3(b), the broken lines indicate the elution profile of each component of solutions of concentrations C and C', the former being assumed to flow without micelle decomposition. Actually, however, as shown by the arrow, part Q of the micellar front of the solution of concentration C decomposes and fills up the solute gap, P. Thus, the entier elution profile assumes the form represented by the solid lines. From this consideration, we obtain

$$(R_m-R_f)(C-C_s)A_0 = (R_f-R_s)(C_s-C')A_t. \quad (1)$$

Taking into account that

elution rate $R \propto$ elution volume V^{-1}

and that

cross sectional area $A \propto$ elution volume V, } (2)

Eq. 1 can be rewritten as

$$C_s = \frac{(V_f-V_m)(C-C')}{V_s-V_m} + C', \quad (3)$$

where V_m, V_f, and V_s represent the elution volumes of the micelles, the solution front and the intermicellar single molecules or ions, respectively. Equation 3 enables us to calculate C_s from measurements of V_m, V_f, and V_s for a solution of concentration C eluted through the gel column filled with a preset solution of concentration C'. Here, V_m and V_s can be measured from the elution tail of the corresponding constituent.

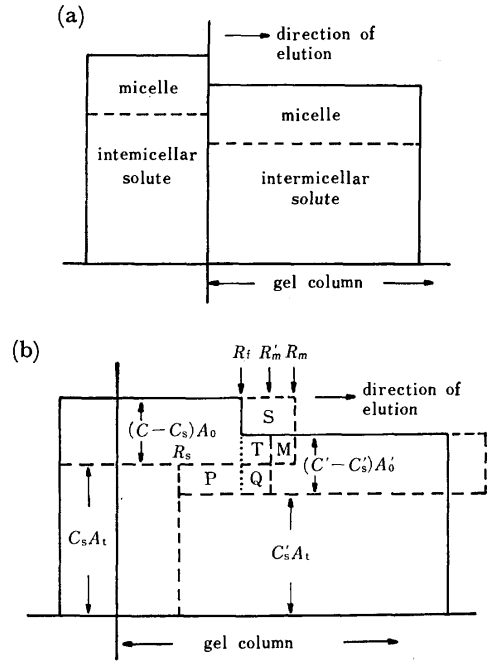

Fig. 4. Gel filtration through a preset solution.
(a) Before elution, (b) during elution.

Furthermore, in case the concentration C' of the preset solution is larger than C_m, so that $C_m<C'<C$, the elution diagram becomes somewhat more complicated, as is shown in Fig. 4. Here, R_m' and C_s' represent the elution rates of the micelles and the intermicellar concentration of the preset solution, respectively, and A_0' denotes the cross-sectional area of the gel column available for micellar flow of the preset solution. The broken lines indicate both the elution tail of the preset solution when eluted alone and the elution front of the solution

of concentration C, assumig that the micelles do not decompose. The solid lines indicate the actual elution front.

From this diagram, it is confirmed that the frontal part of the micelles S+(overlapped)M decomposes to fill up the solute gaps, P and Q, or that the S+M+T part fills up parts P and Q+T. Thus, we obtain

$$(R_m-R_f)(C-C_s)A_o = (R_f-R_s)(C_s-C_s')A_t + (R_m'-R_f)(C'-C_s')A_o'. \quad (4)$$

Again, applying Eq. 2, Eq. 4 can be rewritten as

$$C_s = \frac{C(V_f-V_m)-C'(V_f-V_m')+C_s'(V_s-V_m')}{V_s-V_m}, \quad (5)$$

where the primes indicate preset solution quantities. Equation 5 enables us to calculate the intermicellar concentration, C_s, of the sample solution from measurements of V_f, V_m, and V_s for a solution of concentration C passing through the gel filled with a preset solution of concentration C', intermicellar concentration C_s' and elution volume V_m'. Thus, we can obtain the intermicellar concentration of a surfantant of successively higher concentrations, C.

Results and Discussion

Intermicellar concentration obtained, C_S, is plotted against the total concentration for the aqueous SDS and $D(EO)_6$ solutions in Figs. 5 and 6, respectively. It is seen that C_s increases with increasing concentration of the surfactants both for SDS and $D(EO)_6$, but the increase becomes less marked with the concentration. It is worthwhile to refer to the fact that, according to

the results of EMF measurements,[1] the intermicellar concentration of Na^+ ions increases while that of dodecyl sulfate ions, DS^-, decreases with the total concentration above the CMC as shown in Fig. 7, where the curve for C_S is also depicted. As is seen, the C_S curve is situated between the Na^+ and DS^- curves. This means that the micelles in the stationary state have a net negative charge, but when the micelles precede the intermicellar Na^+ and DS^- ions during elution, they are constrained to move as electrically-neutral units. This requirement is satisfied by the dissociation and the detachment of a part of the excess negative DS^- ions of the micelles and at the same time by the attachment of Na^+ ions to the micelles from the intermicellar solution, thus leaving the solution also electrically neutral.

Actually, Fig. 7 indicates that the amounts of DS^- ion detachment and Na^+ ion attachment are roughly equal and the following relation results,

$$C_{Na} - X = C_{DS} + X = \frac{C_{Na}+C_{DS}}{2} = C_s, \quad (6)$$

where C_{NS} and C_{DS} express the intermicellar concentration of Na^+ and DS^- ions, respectively, and X is the amount of DS^- ions detached from and Na^+ ions attached to micelles. Equation 6 may be the physical meaning of the intermicellar concentration C_S, although the actual intermicellar concentrations in the stationary state are C_{Na} and C_{DS} for Na^+ and DS^- ions, respectively, both of which are different from C_s. Furthermore, the micellar concentration of SDS in the stationary state, or more strictly, the concentration of DS^- ions in the form of micelles is expressed by $C-C_{DS}$, which is larger than the usually-employed value of $C-C_m$,[3] while the concentration of micelles which move during the gel filtration is $C-C_s$ which is considerably smaller than $C-C_{DS}$ and is slightly smaller than $C-C_m$, as is seen from Fig. 7. The difference in concentration of the micelles in the stationary and in the gel filtration states results from the requirement that the micelles be negatively charged in the former case and electrically neutral in the latter case.

The situation may be far simpler in the case of $D(EO)_6$, since it produces no ions. Here also, the micellar concentration is $C-C_s$, and not $C-C_m$. As is seen in Fig. 6, the former is smaller than the latter. It may

also be mentioned that, strictly speaking, $C-C_s$ is the concentration of those micelles which move during gel filtration, while the micellar concentration in the stationary state may differ from $C-C_s$, as in the case of SDS. Although this concentration has not yet been determined experimentally, the value may prove to be close to $C-C_s$, because of the nonionic nature of $D(EO)_6$.

The Behavior of Aqueous Solution of Sodium Deoxycholate in Capillary Flow

Gohsuke SUGIHARA, Mitsuru TANAKA, and Ryohei MATUURA*

Department of Chemistry, Faculty of Science, Fukuoka University, Nishi-ku, Fukuoka 814
**Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812*

(Received March 9, 1977)

Primary micelles form secondary, polymer-like aggregates in a capillary flow of aqueous solution of sodium deoxycholate (SDC). The formation of the polymer-like aggregate is promoted by mechanical action, degradation being simultaneously caused by shearing stress. The viscosity of the SDC solution in the capillary flow attains equilibrium value between polymerization and degradation. The viscosity changes a great deal with the time of observation and pH. Under given conditions the SDC solution behaves as a non-Newtonian fluid obeying a power-law.

The flow of colloid-dispersed systems is of practical and theoretical interest as regards transportation through pipe and humors in a capillary *in vivo*. The motion of material *in vivo* can be classified into two types, permeation through an interface (membrane) and the flow in a capillary. Flow systems accompanied by reactions are of special interest. Attention has been paid to the variation in particle size or particle structure during the course of flow which considerably affects the flowing characteristics.

Sodium deoxycholate (SDC), a bile salt which is a surfactant *in vivo*, was chosen. Vochten and Joos[1] studied the viscosity of SDC solutions with an Ubbelohde type viscometer. They measured the viscosity at pH=7 for SDC of constant concentration containing NaCl in different concentrations, and found that the viscosity varies with time. Fontell performed viscosity measurement of aqueous solutions of various bile salts and pointed out that micelles at higher concentrations are voluminous and anisometric, indicating the formation of a secondary structure by the interlinking of primary micelles.[2] However, Fontell ignored the time dependency in the viscosity of the aqueous solution of SDC. We have regarded the viscous behavior in the capillary flow as a process of polymer-like aggregation of primary micelles. The aggregation is accelerated by mechanical action, degradation being caused by shearing stress simultaneously. Blow and Rich[3] observed this phenomenon for the first time by viscosity measurement with an Ostwald-type viscometer. However, they did not carry out analysis.

We have investigated aqueous solutions of SDC in detail, and found that the solution has a rheologically complex character, which might be clarified by means of an improved method of viscosity measurement on non-Newtonian flow.

The present study was carried out with the use of horizontal viscometers in order to clarify the effect of shearing stress on the flow and to correlate the result with SDC concentration, pH, and temperature.

Experimental

Horizontal viscometers were so constructed as to enable us to observe flow volume and flow time of the solution by connecting a 2 cm^3 mess-pipet to the capillary. Two viscometers were used: (a) capillary length 10 cm, and inner diam. 1.64×10^{-2} cm and (b) capillary length 10 cm, inner diam. 1.66×10^{-2} cm. The Reynold number was less than 60 under hydraulic pressure of 100 cm. The viscosity measurement was carried out by immersing the viscometer in a thermostated water bath, putting the SDC solution in the viscometer and giving an arbitrary shearing stress. The temperature was kept constant within ±0.01 °C.

A pressure-generator was set up by combination of two water-tanks (20 dm^3), U-tube for manometer (180 cm in height) and cocks. This makes it possible to give an arbitrary difference of pressure and observe both forward and backward processes by use of T-cocks. For the simultaneous measurement of viscosity and pH, the horizontal viscometer was fitted with a combination-type electrode (Hitachi-Horiba 6028-10T for test tube) near the exit of capillary (Fig. 1). The variation of pH with time was measured with a Hitachi-Horiba pH meter, model F-5 and recorded automatically with a recorder (QPD-54, Hitachi).

The solutions were prepared as follows. Aqueous SDC and inorganic salt solutions (buffer) were prepared separately with concentration twice higher than necessary for the experiments. Both solutions were kept at a constant temperature. The

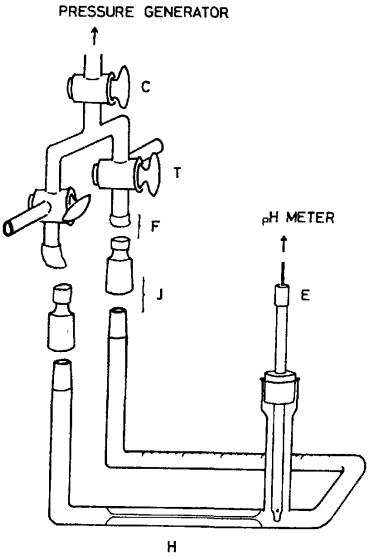

Fig. 1. Horizontal viscometer for the simultaneous measurement of pH and viscosity.
Key C: cock, T: T-cock, F: flexible pipe ,J: glass joint, H: horizontal viscometer, E: combination-type electrode (for test-tube use).

same amount of each was mixed in a vessel, and the mixture was freed from dust by a Millipore 47 mm membrane filter. 5 cm^3 of filtered solution was immediately put into the viscometer immersed in thermostated bath, and then subjected to incessant flow. The pH of the solutions was adjusted to 6.8, 7.0, or 7.2 by the Sørensen buffer solution.

SDC (E. Merck Co.) was thrice crystallized from ethanol and dried at 110 °C *in vacuo* for a day. Twice distilled water was used. Other chemicals were of guaranteed reagent-grade.

Results and Discussion

Correlation of Viscosity with Flow Time. After the initial Newtonian flow the viscosity rises abruptly, showing a characteristic peak and stationary value (Fig. 2). The viscosity is expressed in time (s) required

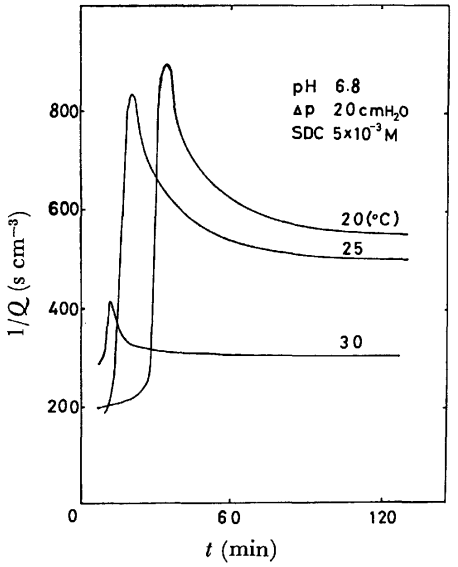

Fig. 2. An example of viscosity change with time in the capillary flow.

for the flow of the unit volume of liquid. The abrupt rise in viscosity with time seems to be correlated with various factors. The reproducibility is not always good because of sensitivity to the delicate difference of running or existence of impurity. We might interpret the initial part of the curve as follows. It is assumed that the polymer-like aggregation of SDC takes place by crystallization or phase transition. The growth of crystalline nuclei may be hindered by thermal and mechanical motions. The temperature of the whole system is kept constant during the observation, but minute, local variation is unavoidable. The rate of producing nuclei depends largely on the temperature nearer to that of phase transition, increasing rapidly with a lowering temperature. Thus, there is a possibility for effective nuclei to exist whose rate of production and growth exceed that of collapse during the minute, local variation of temperature. Once the effective nuclei are produced, polymer-like aggregation is accelerated in the field of flow. On the other hand, the degradation of the aggregates proceeds in the flow. The curves in Fig. 2 can be regarded as the result of polymerization and degradation.

The time-dependent equation of the number-average degree of polymerization $P_{(t)}$ at time t is[5]

$$P_{(t)} = \frac{qe^{qkt}}{e^{qkt}-1+qT/(t+T)}, \quad (1)$$

where T denotes the half-life of particle (monomer) number, k the rate constant of degradation of polymer-like aggregates, and $q=2g-1$, g being the limiting degree of polymerization. If we denote the mass of primary particle (monomer) by m and the Avogadro number by N, the time-dependent weight average molecular weight $[M]_{w,t}$ is given by[5]

$$[M]_{w,t} = \frac{2mNqe^{qkt}}{e^{qkt}-1+qT/(t+T)}, \quad (2)$$

where parameters T, q, and k have the same meaning as in Eq. 1. These parameters and m should be determined by separate experiments. No complete analysis can be carried out from only the curves shown in Fig. 2. We see from Eqs. 1 and 2 that $P_{(t)}$ and $[M]_{w,t}$ attain the values q and $2mNq$, respectively, after a sufficiently long time. These two values correspond to the dynamic equilibrium after the peak in Fig. 2.

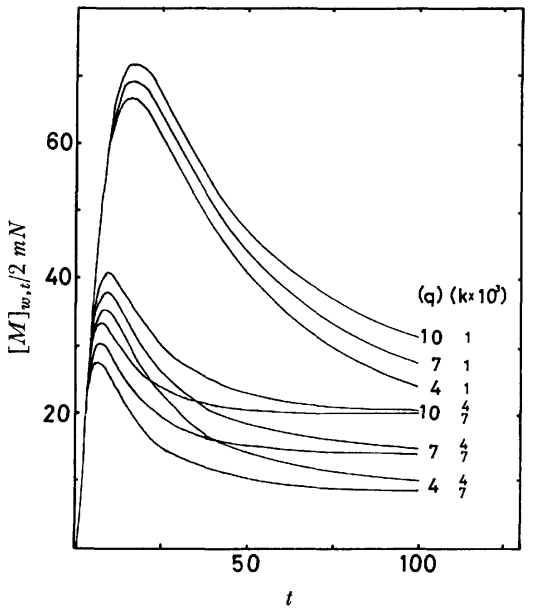

Fig. 3. Simulation curves for the relation between the weight-average degree of polymerization, computed with various values of each parameter and time t.

Figure 3 shows simulation curves computed by substituting appropriate values for the parameter in Eq. 2. The equilibrium value varies with concentration of SDC, temperature and pH. This is of dynamic equilibrium related directly to shearing stress or shear rate. The value of dynamic equilibrium does not depend on the history (the half-life T and the rate constant of degradation k) but on only the limiting degree of polymerization g determined by given conditions. Thus only the treatment of dynamic equilibrium is required for the analysis of the characteristics of the

flow system.

Apparent and Real Viscosity in Dynamic Equilibrium. The behavior of capillary flow of aqueous SDC solution was investigated by examining the relation between the value of dynamic equilibrium and various conditions. All systems in Fig. 2 behave as non-Newtonian flow.

In the case of non-Newtonian flow the coefficient of viscosity η is a function of shearing stress p_t or shear rate $\dot{e}_t$:

$$\eta = \frac{p_t}{\dot{e}_t} = \frac{g(\dot{e}_t)}{\dot{e}_t} = \frac{p_t}{f(p_t)}. \quad (3)$$

The shearing stress P and shear rate V on the wall-surface of capillary are

$$P = \frac{R\Delta p}{2l}, \quad (4)$$

$$V = \frac{4Q}{\pi R^3}, \quad (5)$$

where R is the radius of capillary, l the length, Δp the pressure difference on the unit area of cross-section of liquid cylinder in the capillary, and Q the amount of flowing liquid per unit time. Q is expressed as a function of P (or Δp) as follows.[6]

$$Q = (2l/\Delta p)^3 \int_0^P p_t^2 f(p_t) dp_t = (\pi R^3/P^3) \int_0^P p_t^2 f(p_t) dp_t. \quad (6)$$

It is desirable to find the relation between the measured Q and Δp, but the type of function $f(p_t)$ is unknown. The function can be obtained, if we use the following equation.[6-9]

$$f(P) = V(3/4 + (1/4)\, d \log Q/d \log P). \quad (7)$$

If we determine the slope of the curve $\log P$-$\log Q$, we obtain the second term in parenthesis. Since P is proportional to Δp, we can use $\log \Delta p$ instead of $\log P$.

In the Newtonian flow $d \log Q/d \log P$ is equal to unity and we have $f(P) = V$. While V in Newtonian flow gives a real shear-rate on the capillary-wall, V in non-Newtonian flow gives only an apparent one. Thus, P/V gives the apparent viscosity η_a. The real coefficient of viscosity η is given by $P/f(P)$.

When the non-Newtonian flow is of a power function type, $f = kp_t^n$, we obtain the following equation from Eqs. 6 and 4.

$$Q = \frac{\pi R^3 k}{n+3} P^n = \frac{\pi k R^{n+3}}{(n+3)(2l)^n} (\Delta p)^n. \quad (8)$$

Thus we have $d \log Q/d \log P = n$. Hence Eq. 7 gives the relation $f(P) = (3+n)V/4$. The value of real viscosity η is given by

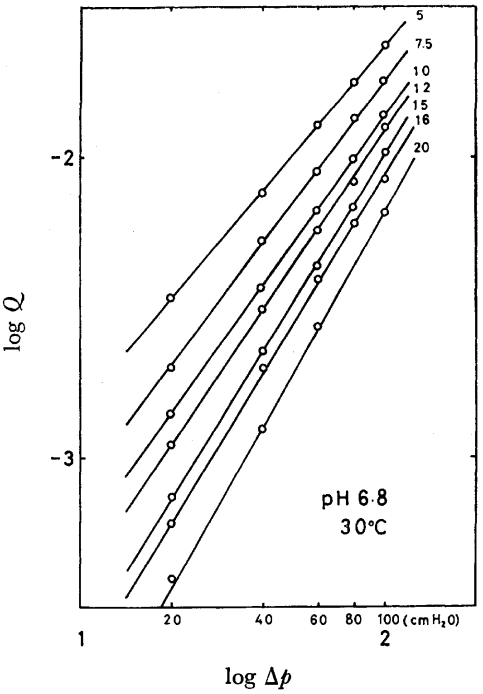

Fig. 4. The plot of $\log \Delta p$ *vs.* $\log Q$ at pH 6.8 and 30 °C. The figures at the right hand of curves indicate the concentration of SDC in mM. The slope of the straight line gives the power n in Eq. 8.

$$\eta = \frac{4}{n+3} \eta_a. \quad (9)$$

Straight lines are obtained by plotting $\log Q$ against $\log \Delta p$ in dynamic equilibrium (Fig. 4). This indicates that the flow of the SDC solution is non-Newtonian and of the power function type. The values n obtained from the slopes of $\log \Delta p$-$\log Q$ curves are given in Table 1. The value of n may give a criterion of the deviation from Newtonian type, or a degree of non-Newtonian. Although the real physical meaning of n is not known, it seems to correspond to the degree of interaction among aggregated particles. We see from Table 1 that the value of n is larger in higher concentration range for any temperature and pH.

Relation between Real Viscosity, Concentration of SDC, and Shearing Stress at Various Temperatures and pH. The dynamic equilibrium value of real viscosity η at pH 7.0 and 25 °C is shown in Fig. 5, in which (a) is the plot of η *vs.* concentration of SDC and (b) the plot of η *vs.* shearing stress, where the pressure difference Δp (cm

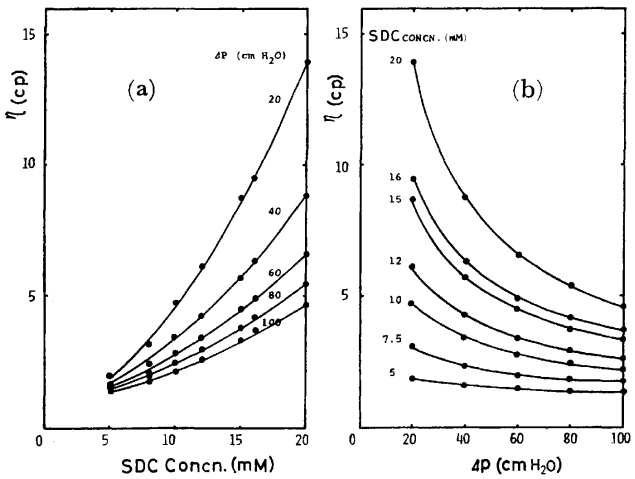

Fig. 5. The correlation of the real viscosity (cp) with SDC concentration (mM) and pressure difference Δp (cm H_2O) at pH 7.0 and 25 °C. (a) The plot of SDC concentration *vs.* η, where numerical values indicate the pressure difference Δp in cm H_2O. (b): The plot of Δp *vs.* η, where numerical values indicate the SDC concentration in mM.

H_2O) is used instead of the real shearing stress. Numericals at the end of respective curves refer to the pressure difference (in cm H_2O) in (a) and to the concentration (in mM** (mol m^{-3})) of SDC in (b). Though the value of η varies with pH and temperature, all the results are similar. Decrease in shearing stress tends to increase the viscosity, and the higher the concentration of SDC, the greater the dependence of real viscosity on shearing stress. The values of η of the 1.00×10^{-2} M** solution and 1.60×10^{-2} M solution in the dynamic equilibrium under various conditions are given in Table 2.

Effect of Shearing Stress on the Molecular Weight of Polymer-like Aggregate. As shown in Fig. 5, the shearing stress (Δp) considerably affects viscosity and the molecular weight of the polymer-like aggregate in dynamic equilibrium.

The dimension of polymer-like aggregate can be estimated from the molecular weight determined by viscometry. If the reduced values η_{sp}/c and $\ln \eta_r/c$ are plotted against c (in grams of SDC per 100 cm^3) and extrapolated to $c=0$, both curves intersect at the same point of ordinate (Fig. 6). The coincidence of intercept of the two curves affords a reasonable value as the limiting viscosity number $[\eta]$.

The correlation of $[\eta]$ with Δp illustrates the fact that decrease in shearing stress tends to increase considerably $[\eta]$ or the dimension of polymer-like aggregate. The plot of log Δp *vs.* $[\eta]$ gives straight lines (Fig. 7). We see that the product $[\eta]\,\Delta p^{\beta}$ is constant, where β is a

** Throughout this paper 1M=1 mol dm^{-3} and 1 mM=1 mol m^{-3}.

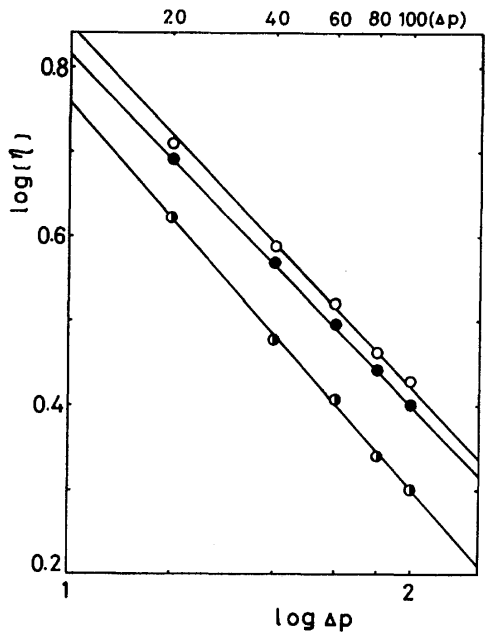

Fig. 7. The relation between log Δp and log $[\eta]$.
Key ○ pH 6.8, 25 °C, ● pH 7.2, 20 °C, ◑ pH 6.8, 30 °C. Empirical formula is expressed as follows.
at pH 6.8, 20 °C $\log[\eta]=-0.46\log(\Delta p)+1.33$
at pH 6.8, 25 °C $\log[\eta]=-0.46\log(\Delta p)+1.31$
at pH 6.8, 30 °C $\log[\eta]=-0.46\log(\Delta p)+1.22$
at pH 7.0, 20 °C $\log[\eta]=-0.37\log(\Delta p)+1.20$
at pH 7.2, 20 °C $\log[\eta]=-0.42\log(\Delta p)+1.24$

constant.

The intercept of the log (Δp) *vs.* log $[\eta]$ curve might be utilized as an index of limiting dimension of the aggregate at the pressure difference $\Delta p=1$ cm H_2O. Though the physical meaning of the slope or the power of pressure difference cannot be grasped, the value seems to correspond to pH. Temperature seems to have no effect on the slope. When pH is constant, curves at various temperatures have the same slope.

In the case of linear polymer the molecular weight is estimated by the relation $[\eta]=KM^{\alpha}$. However, this relation is not applicable to the SDC system, since the parameters K and α are unknown. The molecular weight of SDC aggregates can be estimated roughly by use of the computed data for q-value and the data for m obtained by means of light scattering. We assume that q is 5—10 (Fig. 3) and mN or the micellar weight of primary micelle is 2.6×10^4 at 36.5 °C. Thus from Eq. 2, the value of $[M]_{w,t}$ in dynamic equilibrium is estimated to be 2.6×10^5 to 5.2×10^5. The micellar weight of the polymer-like aggregate is calculated to be several millions at 10 °C.[10]

pH Change with Flow. The SDC solution undergoes specific hydrolysis when it forms a gel.[4,11] This can be explained by a kinetic consideration that the abrupt rise of pH is due to the hydrolysis of SDC. When gel formation takes place, the pH rise is linear against logarithm of the reaction time t in the early stage with the same slope of unity. If we denote the initial concentration of the reactant deoxycholate ion by C, the concentration of the product by x, the rate constant by k, and the ionic product of water by K_w, we obtain the relation

$$pH = \log t + \log(kC/K_w), \qquad (10)$$

where it is assumed that $x \ll C$ in the initial stage of reaction and therefore only the first term of the expansion of $\ln[C/(C-x)]$ is taken. Equation 10 gives the relation $\mathrm{d\,pH/d\log}\,t=1$. It was found that the rate constant varies from 1.6×10^{-7} to 20×10^{-7} ($\mathrm{min^{-1}}$) at temperatures 5—35 °C, the activation energy of hydrolysis being calculated to be 14 kcal. We studied the behavior of the counter ions Na^+ and H^+ through the measurement of their activity change with concentration. We have concluded that the adsorption of proton on the micelle surface (or hydrolysis) is necessary for the structure-making of micelle or gel, and that the counter ion Na^+ undergoes exchange with a proton on micelle (gel) formation, and the proton exchanged contributes to the formation of hydrogen bond between deoxycholate molecules.[11]

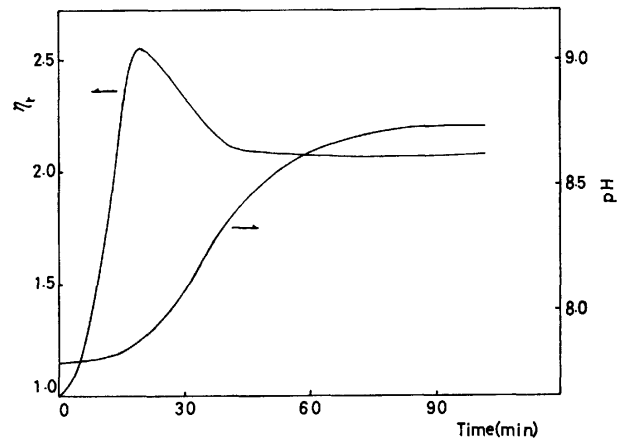

Fig. 8. The time-dependent changes of viscosity and pH which were caused simultaneously in the capillary flow. 1.6×10^{-2} M solution of SDC with addition of 0.5 M NaCl at 15 °C under $\Delta p=80$ cm H_2O.

A special viscometer (Fig. 1) was used in order to determine the pH change accompanied by the change in viscosity. The solution containing SDC of given concentration and 0.5 M NaCl showed a specific rise in pH when viscosity began to rise. However, the rise in pH was gradual, no peak being observed as in viscosity. The dynamic equilibrium in viscosity and pH was reached at the same time. Figure 8 shows an example of both changes in pH and viscosity with time. The measurement of pH shifts was carried out for different concentrations of SDC, shear-rates and temperatures. The results show that the pH shift is independent of concentration and shear-rate, but depends on temperature. On the other hand, viscosity is affected distinctly by shear-rate, concentration and temperature. The characteristic pH behavior indicates that the secondary aggregation or polymerization is not parallel to hydrolysis. The value of pH in equilibrium corresponds to that of the system (Fig. 2, the preceding paper[11]) and the range of pH shifts corresponds to the deviation from the straight line with slope 1/2 extrapolated from the singly dispersed region. The mixing of two solutions (SDC and NaCl) indicates that the SDC

solution is diluted with NaCl solution, the micelles being broken abruptly due to the shift of equilibrium. After micelles are broken by dilution, new micelles are formed again. In this state the environment of new micelles and singly dispersed species are now rich in sodium ions, almost all the counterions being sodium ions. Micelles of a more stable structure are then formed gradually, the counterions of Na^+ being replaced by protons. This can be considered a relaxation phenomena. Though the exchange reaction is slow, it can be accelerated by mixing or by being carried out in a field of flow. Alternatively, in the early stage of the capillary flow when no rise of viscosity appears, the exchange reaction takes place and stable primary micelles are formed by hydrogen bonding. As soon as sufficient protons are adsorbed on deoxycholate ions in the micelle, the primary micelles begin to associate secondarily forming polymer-like aggregates.

The indispensable role of hydrogen bond in the formation of SDC aggregate was revealed by other studies on pH and pNa behavior of aqueous solution of SDC[11] and the sol-gel transition under high pressure.[12]

We would like to acknowledge the valuable suggestions given by Prof. Dr. Kinsi Motomura, Kyushu University. We are indebted to Mr. Yoshio Aogame, Miss Machiko Hiraishi, Mr. Kiyofumi Hiramatsu, and Mrs. Makiko Taka, Fukuoka University, for their technical assistance.

Comparison of Experimental and Calculated Oscillator Strengths for Condensed Ring Compounds

Tetsutaro YOSHINAGA, Hiroshi HIRATSUKA, and Yoshie TANIZAKI
Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received March 18, 1977)

The electronic absorption spectra of eighteen aromatic condensed ring compounds (C_{2v} or D_{2h}) were studied by means of comparison between the calculated and experimental results in terms of three fundamental factors: the electronic transition energy, the direction of the electronic transition moment, and the oscillator strength. The three experimental factors were obtained from the component spectra polarized to the long and short axes of the molecule, which were determined by means of the dichroism analysis technique. The calculated oscillator strengths were obtained by the dipole-length, dipole-velocity, and mixed-dipole methods. From the comparison between experimental and calculated results, it was found that the mixed-dipole method gives the best fit of the values to the experimental ones.

As is well known, the electronic absorption spectrum is assigned on the basis of comparison between calculated and experimental results for three fundamental factors: the electronic transition energy, the direction of the electronic transition moment, and the oscillator strength. In most cases, however, the experimental results to be compared with the theory are not always valid for these items, since the results are obtained through band spectra in which most bands are composed of two or more overlapping transition bands. In order to make more precise assignments, therefore, it is necessary to separate the overlapping bands. One of the most useful methods for separating such bands for some symmetrical molecules is dichroism analysis using a stretched PVA [poly(vinyl alcohol)] film.

For a planar molecule of C_{2v} symmetry, for instance, the polarization direction of the π-π^* electronic transitions are restricted to directions parallel or perpendicular to the C_2 axis in the molecular plane. In such cases, the directions of polarization can easily be distinguished from one another by the use of the dichroism analysis. By means of this method, an absorption spectrum observed in non-stretched PVA film can be divided into two kinds of spectra in which the polarization directions are orthogonal to each other. When the divided spectra thus obtained are employed as experimental data, the comparison with the calculated results will become more precise in terms of the three factors mentioned above.

As for the theoretical calculation of the oscillator strength, the dipole-length method[1] has been extensively used. In recent years, however, the mixed-dipole method[2] and the dipole-velocity method[3-5] have also been employed, and comparisons of calculated with experimental values have been reported.

The first purpose in the present study is to determine the oscillator strength experimentally using the component spectra for many symmetrical molecules, such as condensed-ring compounds. The second purpose is to compare the oscillator strengths obtained by the dipole-length, mixed-dipole, and dipole-velocity methods with the experimental values.

Experimental

Materials. The chemical structures and the names of the compounds used are shown in Fig. 1, along with the sample number to be referred to throughout this work.

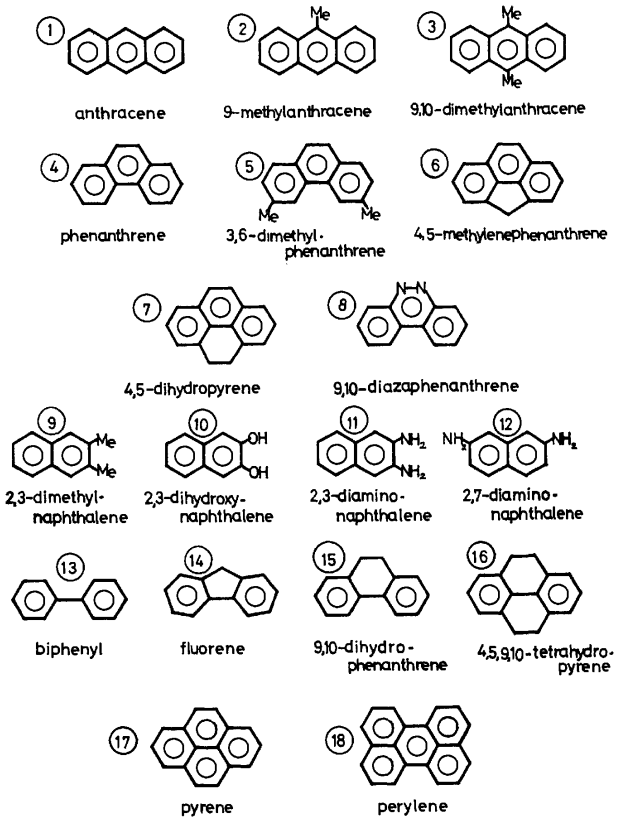

Fig. 1. Name, structures, and numbers for the compounds. (In Table 1, these numbers are employed instead of respective name of compound.)

The anthracene (U.P.; ultra-pure reagent), 9-methylanthracene (G.R.; guaranteed reagent), 9,10-dimethylanthracene (G.R.), 3,6-dimethylphenanthrene (G.R.), 4,5-methanophenanthrene (G.R.), 2,3-dimethylnaphthalene (G.R.), 2,3-naphthalenediol (G.R.), 2,3-naphthalenediamine (E.P.; extra pure reagent), 2,7-naphthalenediamine (E.P.), pyrene (U.P.), biphenyl (E.P.: >99%, G.C.), fluorene (U.P.), 9,10-dihydrophenanthrene (G.R.), and 4,5,9,10-tetrahydropyrene (G.R.) were commercially obtained from the Tokyo Kasei Kogyo Co., Ltd. The phenanthrene(fluorescence grade) and 5,6-phenanthroline were obtained from the Aldrich Chemical Company. Highly purified perylene was kindly offered by the Inokuchi Laboratory at the Institute for Solid State Physics, the University of Tokyo. The biphenyl, 2,3-dimethyl-

naphthalene, and other naphthalene derivatives were repeatedly recrystallized from the respective appropriate solvents. For 9,10-dihydrophenanthrene and 4,5,9,10-tetrahydropyrene, further purification was made by the Tokyo Kasei Kogyo Co., Ltd., at our request. For other compounds, no purification was made.

Measurement. The measurement of the polarized absorption spectra and the determination of the component spectra were carried out using the methods previously reported.[6]

After the assignment of the electronic transition bands for the component spectra had been established, the experimental oscillator strength (f^{exp}) for the respective bands were determined by means of the well-known formula:*

$$f^{exp} = 4.32 \times 10^{-9} \int \varepsilon_\sigma d\sigma$$

where σ is the wave number in cm^{-1} and where ε_σ is the molar extinction coefficient in the PVA substrate. In the present work, however, we used ε_σ in ethanol instead of that in PVA, since the absorption curves in the PVA film generally resemble those in ethanol. In fact, for some compounds, such as anthracene, and phenanthrene, it was found that the ε_σ values in PVA were nearly equal to those in ethanol.

Calculation

The MO calculations were carried out using the Pariser-Parr-Pople SCF CI method.[7,8] The one- and two-center electron repulsion integrals were evaluated by the Pariser-Parr equation[7] and the Nishimoto-Mataga equation[9] respectively. The valence-state ionization potentials (I_p(r)) and the electron affinities (E_a(r)) were as follows: I_p(C)=11.16 eV, E_a(C)=0.03 eV, I_p(–N=)=14.12 eV, E_a(–N=)=1.78 eV, I_p(–NH_2)=24.80 eV, E_a(–NH_2)=8.04 eV, I_p(–OH)=33.00 eV, and E_a(–OH)=11.47 eV.

For the "methyl" group, the hyperconjugation effect was taken into account after Morita,[10] and the following values were used: $I_p(H_3)$=10.08 eV and $E_a(H_3)$=0.19 eV, the resonance integrals were β(C–C')=–2.24 eV and β(C'–H_3)=–5.27 eV where the primed carbon is for methyl carbon. For the methylene group, the same parameters were used as for the methyl group. All the molecules, including biphenyl, were regarded as planar. The geometrical structure of fluorene was determined by reference to the crystal structure.[11]

The theoretical oscillator strengths, f^{cal}, were calculated by means of the following equations:[2,3]

$$f_l = 1.085 \times 10^{11}\, \sigma M_l^2 \quad (1)$$

$$f_v = 1.463 \times 10^{5}\, D_v^2/\sigma, \quad (2)$$

$$f_m = (f_l \cdot f_v)^{1/2}, \quad (3)$$

$$M_l = \langle \Psi_p | \sum_i r_i | \Psi_q \rangle,$$

$$D_v = \langle \Psi_p | \sum_i \mathrm{grad}\, i | \Psi_q \rangle,$$

where σ is the transition energy in cm^{-1}, for which the calculated values were used. The calculation methods using Eqs. 1, 2, and 3 are referred to as the dipole-length, dipole-velocity, and mixed-dipole methods respectively. In these calculations, Slater's atomic orbitals were employed, and the overlap integrals were not neglected. Moreover, all the elements of the transition density matrix were included.

* In general, f^{exp} is little affected by the medium. However, we neglected this correction in the present work, since there is some disagreement about this matter. See also Ref. 5 and especially the Ref. 17 in the Ref. 5.

Results

Table 1 shows the experimental and calculated results for the allowed transitions of eighteen compounds. Roman numerals represent the calculated transition numbers. For example, in the case of anthracene (Sample Number 1), the I st, II nd, and VI th transitions are allowed, while the others are forbidden, in the region above 200 nm. Even if a transition is allowed, when the corresponding absorption is too low to be determined, the relevant columns for the experimental transition energy and also the oscillator strength (f^{exp}) are left blank, as may be seen for the 1st transition of Sample No. 5, for example. Moreover, even if a transition energy is determined, when not all of the band is observed, f^{exp} can not be determined and the relevant column is blank (see the Xth transition of Sample No. 5).

In Table 1, the transition directions are designated by x and y for the long and short axes of the molecule respectively, and Platt's notations are shown in parentheses. The oscillator strengths calculated by the dipole-length, dipole-velocity, and mixed-dipole methods are denoted by f_l, f_v, and f_m respectively.

According to Table 1, the calculated transition energies as well as the transition directions agree very well with the experimental values. As for the oscillator strength, however, the calculated values are considerably different from the experimental ones in some cases. Moreover, some considerable differences between f_l and f_v are observed.

Figure 2 shows the distributions of the experimental (f^{exp}) and calculated (f^{cal}) oscillator strengths for the about seventy transitions listed in Table 1. In the figure, the abscissa is divided into sections at 0.1 intervals: for example, the f^{exp} value, 1.54, of the VI th transition of Sample No. 1 is placed in the column between 1.5 and 1.6. Thus, the distributions for f^{exp}, f_l, f_v, and f_m are obtained as shown in Figs. 2(a), (b), (c), and (d) respectively. The f^{exp} and f^{cal} values did not exceed 1.6 and 2.6 respectively. Nearly 90% of all the f values fall in the range of $0<f<1$. The frequencies within $0<f<0.1$ are 30—40% and are the greatest in all classes.

Now, let us investigate the relation between the f^{exp} and f^{cal} values. First, let us select sample molecules in Table 1 for which the π-electron approximation will be completely valid in the present calculation; that is, the five molecules of Samples No. 1, 4, 8, 17, and 18 have a planar structure and no substituent groups. The ratios of the oscillator strength, $R(=f^{cal}/f^{exp})$, for the corresponding transitions are plotted in Fig. 3, in which the abscissa is the same as in Fig. 2 and in which the ordinate represents the frequency of R values. In Fig. 3, the R values for $f^{exp}<0.1$ are marked by oblique lines to distinguish them from the others.

According to Fig. 3(c) all the values of $R_v(=f_v/f^{exp})$

TABLE 1. COMPARISON OF EXPERIMENTAL AND CALCULATED OSCILLATOR STRENGTHS

a) The calculated oscillator strengths, f_l, f_v, and f_m, represent the values from the dipole-length method, the dipole-velocity method, and the mixed-dipole method respectively. b) Where x and y show the polarization directions paralle to and perpendicular to the molecular long axis respectively; the signs in parentheses are Platt's notations. c) Circles indicated in the first column show the selected samples.

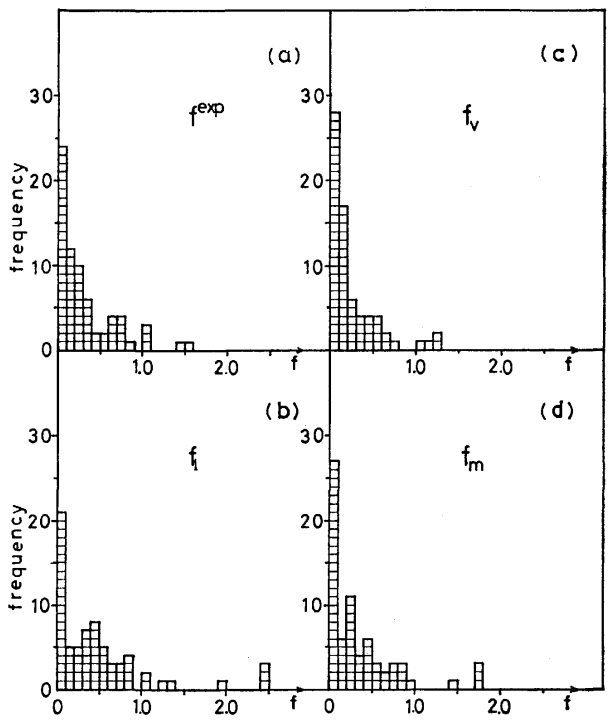

Fig. 2. Distributions of absolute oscillator strength for f^{exp} (a), f_l (b), f_v (c), and f_m (d); The ordinate, the number of frequencies and the abscissa, the absolute oscillator strength classed at 0.1 intervals.

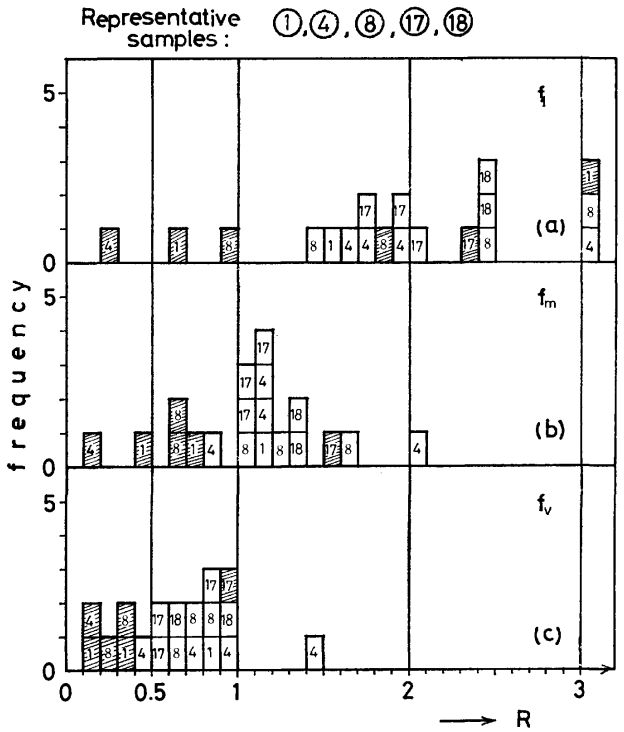

Fig. 3. Distributions of relative oscillator strength; (f_l/f^{exp}) (a), (f_m/f^{exp}) (b), and (f_v/f^{exp}) (c) for the representative compounds. The ordinate, the frequencies and the abscissa, the relative values, $R=(f^{cal}/f^{exp})$ at 0.1 intervals. The shaded parts represent the R values for $f^{exp}<0.1$.

except one ($R_v=1.5$, the VIth transition of Sample No. 2) are less than unity, and most of those for $f^{exp}<0.1$ are less than those for $0.1<f^{exp}$. On the other hand, Fig. 3(a) shows that the values of $R_l(=f_l/f^{exp})$ are scattered widely around 3. The values of $R_m(=f_m/f^{exp})$ shown in Fig. 3(b) fall between the former two values, and it is noticed that the values for $0.1<f^{exp}$ are concentrated in the range of 1.0—1.5.

Figure 4 shows the distributions of the R values for all the transitions in Table 1. The interrelation among R_v, R_m, and R_l is similar to that for the selected samples in Fig. 3.

From these results, the following relations are generally obtained:

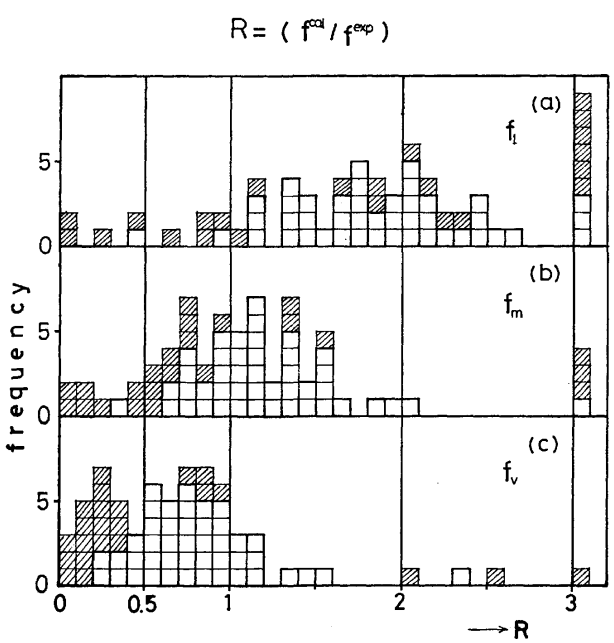

Fig. 4. Distributions of relative oscillator strength, $R=f^{cal}/f^{exp}$, for all compounds used in the present work. The shaded parts represent the R values for $f^{exp}<0.1$.

$$f_v \lesssim f^{exp} \lesssim f_l, \text{ and } f_v \lesssim f_m \lesssim f_l.$$

Moreover, in the comparison of the experimental and calculated values, since, in practical absorption spectra, intensity-borrowing phenomena usually occur, even if the calculated values are exact ones, for weak intensity bands the $f^{cal}<f^{exp}$ relation is to be expected. In fact, in the figures of distributions of the R values for f_m and f_v, the shaded parts ($f^{exp}<0.1$) mainly lie in the classes with relatively low values.

Discussion

In the present investigation, we determined the experimental oscillator strength (f^{exp}) from the component spectra obtained by the application of the dichroism analysis, thinking that the f^{exp} value to be compared with the calculated value should be determined for the corresponding single electronic band. That the f^{exp} values thus obtained are quite reasonable can be shown by the following example. For the first band of anthracene, the experimental oscillator strength has been given as 0.10—0.11.[13-15] It is well known that this band is composed of ^1L_a and ^1L_b bands. According to Table 1 (Sample No. 1), they are $f^{exp}(L_a)=0.0763$ and $f^{exp}(L_b)=0.0194$, the sum of these values gives 0.096, which is very close to the above conventional value. For the strong second band (^1B_b) of anthracene, the conventional values reported are 1.4—2.8;[13,15,16] among them, the value of $f=1.56$ is considered as the best one.[5] Table 1 shows that $f^{exp}(^1B_b)=1.545$. Since it is known that this band is a little overlapped, the value of $f=1.56$ may be regarded as reasonable.

In view of the above, the f^{exp} values which used to be compared with f^{cal} in the studies of the oscillator strength were not always reliable. However, if the band in question is not overlapped, such as the first band of linear polyenes, its f^{exp} value is reliable.

From the study of the oscillator strength for the linear polyenes, biphenyl linear polyenes, *etc.*, Chong *et al.*[3,4] found that the f_l/f^{exp} ratio ranges from 2 to 5, whereas f_v/f^{exp} varies from 1 to 0.5; they concluded that f_v is much better than f_l. The same conclusion was derived from the study of naphthalene, anthracene, *etc.* by McHugh and Gouterman.[5] They obtained a quantity relatively independent of the overlapped bands and intensity borrowing by integration over the complete experimental absorption curve. Using these quantities, they compared M_l and D_v (see Eqs. 1—3) and found that D_v is superior to M_l and that consequently, f_v is superior to f_l, in comparison with the experimental (f^{exp}) value. Furthermore, they concluded that f_v is superior to the f_m employed by Hansen.[2]

On the other hand, as is shown in our results, both f_v and f_m are much better than f_l in comparison with the experimental (f^{exp}) values; moreover, f_m is superior to f_v, as is shown in Figs. 3 and 4. It is natural from the forms of Eqs. 1—3 that f_m falls between f_l and f_v. According to Hansen,[2] when the doubly excited configuration is taken into account, f_l and f_v are considerably changed, while f_m shows less sensitivity. This means that even if the electron correlation is taken into account, f_m is still superior to f_l and f_v.

Incidentally, one advantage of employing f_m is that the transition energy is unnecessary in the calculation. Therefore, in contrast to f_l and f_v, one can avoid the problem of whether to use the experimental or theoretical transition energy in the calculation of the oscillator strength. (In this connection, Chong *et al.* used the experimental values.)

De Bruijn[17] calculated f_l and f_v by considering the overlap integral and CI for alternant hydrocarbons. He concluded that a complete CI does not give much improvement in f^{cal} and that the failure in f^{cal} is partly attributable to the deficiency of the simpler MO-levels and partly to the neglect of the polarization of the σ-electrons. He pointed out that the overlap integral is effective in the f_v calculation. Especially, from a comparison of f_l and f_v for the S_j-S_o transitions of naphthalene and anthracene, he concluded that the inference of Chong *et al.* is not generally valid. However, as has been already pointed out, these considerations do not seem appropriate, since the f^{exp} values employed in his study have some problems.

Finally, it should be emphasized here that the inclusion of the off-diagonal terms of the transition density matrix in the calculation of the oscillator strength, especially by the dipole-length method, sometimes becomes very important, though the off-diagonal elements have been disregarded in almost all cases.[18,19] An example is indicated for the very weak transitions on the longest-wavelength sides of the first bands for pyrene, phenanthrene, biphenyl, *etc.*, which are well known to be ^1L_b bands. (Ex.: for pyrene, $f^{exp}=1.4\times10^{-3}$). For these transitions, the conventional calculated values are always zero; *i.e.*, f_l(diagonal)=0.000. On the other hand, relatively good values for the corresponding f^{exp} values are obtained by the inclusion of off-diagonal terms. (Ex.: for pyrene,

f_l(diag.+off-diag.)$=3.4\times10^{-3}$.) (See Table 1.) The same relation holds for naphthalene, which was not taken up in the present study. This may also be extended to a general case; that is, the inclusion of the off-diagonal terms gives a non-zero finite value for a transition which is group-theoretically allowed, but f_l(diagonal) is zero.

ESR Studies of the Photoreduction of Quinones. II. The Reinterpretation of Semiquinone Intermediates from Halogenated *p*-Benzoquinones in Ethanol

Yoshihiko KAMBARA, Hiroshi YOSHIDA, and Bengt RÅNBY*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
**Institute of Polymer Technology, Royal Institute of Technology, Stockholm 70, Sweden*

(Received March 22, 1977)

A reinterpretation was made of the electron spin resonance spectrum of semiquinone intermediates during the photolysis of a flowing solution of tetrachloro-*p*-benzoquinone (chloranil) in ethanol. The photoinduced spectrum with a width of 0.06 mT with an unresolved hyperfine structure was found to be identical with the spectrum of the semiquinone anion generated by reducing chloranil in an alkaline ethanol solution. This and other observations indicated that the photoinduced spectrum was due to the chloranil semiquinone anion formed primarily by the one-electron transfer to chloranil from the solvent ethanol, rather than to the semiquinone radical. The photoinduced one-electron transfer reaction was found, though qualitatively, to proceed more efficiently for chloranil and fluoranil, with a larger electron affinity, than for *p*-benzoquinone and dichloro-*p*-benzoquinones.

Because of the interesting nature of semiquinone intermediates and their important role in biological systems, the photochemistry of quinones has attracted much attention.[1] One of the quinones, tetrachloro-*p*-benzoquinone (chloranil), had thus far been studied by means of the flash-photolysis and the electron spin resonance methods.[2-6] However, controversy still remains as to the identification of semiquinone intermediates upon photolyzing chloranil in alcoholic solutions. Kemp and Porter observed an optical absorption at 420 nm in their laser-flash-photolysis study of the ethanol solution and attributed it to the semiquinone radical resulted from the hydrogen abstraction of the triplet excited chloranil from the solvent.[2] Wong *et al.* observed an ESR spectrum with an unresolved hyperfine structure by flash-photolyzing chloranil in 2-propanol and attributed it also to the semiquinone radical,[4] mainly by the analogy to other simple quinones, such as *p*-benzoquinone and duroquinone, from which semiquinone radicals has been inferred to be the photoinduced intermediates in alcoholic solutions.[7-9] On the contrary, Hales and Bolton assigned a similar ESR spectrum recorded from the solution in ethanol or methanol to the chloranil semiquinone anion on the basis of the measured *g*-values.[3] In the flash-photolysis study, Kawai *et al.* reported the formation of both the semiquinone anion and the radical from chloranil in ethanol.[5]

We also found the generation of the ESR spectra of both the anion and the radical recorded during the continuous photolysis of *p*-benzoquinone and its methyl-substituted derivatives in methanol and ethanol,[10-11] and have recently revealed that the *p*-benzosemiquinone anion is generated by a photoinduced one-electron transfer from the solvent to the quinone and that the *p*-benzosemiquinone radical results from a subsidiary reaction between the quinone and hydroquinone.[12] These results raised a question as to our previous interpretation of an ESR spectrum observed during the photolysis of chloranil in alcoholic solutions[6]—that the transient intermediate involved was the semiquinone radical.

Our primary concern in the present investigation is the reinterpretation of the ESR spectra of chloranil semiquinone intermediates. Experimental evidence will be given that the photoinduced one-electron transfer takes place for chloranil and other halogenated *p*-benzoquinones in ethanol, just as for *p*-benzoquinone.[12]

Experimental

Chloranil, fluoranil (tetrafluoro-*p*-benzoquinone), 2,5-, and 2,6-dichloro-*p*-benzoquinones of an analytical grade were purified by sublimation several times, and their purity was checked from their melting point. Ethanol of a specrtoscopic grade was usually used as received, without further purification. Occasionally ethanol was purified as has been described before,[12] but the purification of the solvent caused no change in the results. Sodium ethoxide of an analytical grade was used as received.

The photogenerated semiquinone intermediates were studied by observing their ESR spectrum during the continuous photolysis of a solution of the quinones (usually 1×10^{-3} mol dm^{-3}) flowing through a flat quartz cell in the ESR resonant cavity after being purged with helium gas for at least half an hour to remove any dissolved oxygen. The photolysis was carried out with unfiltered light from a super-high pressure mercury arc (Philips, SP-500), except when otherwise mentioned. The effective volume of the cell was 0.045 cm^3, which results in the total photolysis time of 30 ms when the solution flows, for example, at the rate of 1.5 cm^3 s^{-1}. A more detailed description of the experimental apparatus has been given in our previous papers.[12,13] The solution sealed in a quartz sample tube was studied under photolyzing light, but no good ESR signal could be recorded because of the rapid depletion of the quinones.

Results and Discussion

Photolysis of Chloranil. Figure 1A shows a typical ESR spectrum recorded during the photolysis of chloranil in neutral ethanol. It indicates no resolved hyperfine structure with a spectral width (peak-to-peak in the derivative spectral curve, ΔH_{msl}) of 0.06 mT, and agrees with the spectra in our previous investigation, where the widths were precisely determined to be 0.055, 0.062, and 0.063 mT in 2-propanol, ethanol, and methanol respectively.[6] It is essentially the same as

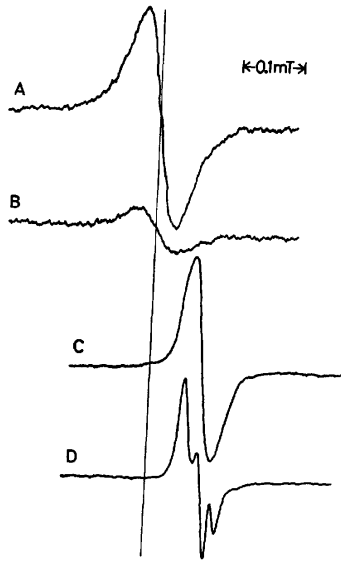

Fig. 1. ESR spectra of semiquinone intermediates generated from chloranil (1×10^{-3} mol dm^{-3}) in ethanol at room temperature (A) during photolysis, or by the addition of (B) 1×10^{-3}, (C) 3×10^{-3}, or (D) 1×10^{-2} mol dm^{-3} of sodium ethoxide. Solutions are flowing at the rate of 0.15 cm^3 s^{-1} for (A) and (B), and are sealed in sample tubes for (C) and (D).

the spectrum reported by Wong *et al.* (0.058 mT in 2-propanol)[4] and that reported by Hales and Bolton (0.08 mT in ethanol and methanol).[3]

When the solution was made alkaline with a small amount of sodium ethoxide, it gave an ESR spectrum without photolyzing light, as is shown in Fig. 1B. This "dark spectrum" showed a *g*-value and width exactly identical with those of the photospectrum in the neutral solution. Successive ESR recording under the photolyzing light, the other conditions being the same, gave a much more intense spectrum without any change in the *g*-value and the width, and confirmed the identity of the dark spectrum with the photospectrum. Thus, the photospectrum is attributable to the chloranil semiquinone anion, the same entity as that in alkaline ethanol,[3,14] resulting from photoinduced one-electron transfer from the solvent ethanol to chloranil. Previously we assigned the photospectrum to the semiquinone radical resulting from the hydrogen abstraction of excited chloranil from the solvent, on the basis of the observed difference in *g*-value between the photospectrum and the dark spectrum.[6] However, such an assignment has been found to be incorrect, as will be described below.

When the solution was made acidic with acetic acid, the photospectrum did not change in shape, but only decreased in intensity. Dissolved oxygen also reduced the intensity. By analogy with the semiquinone anion formation from *p*-benzoquinone previously studied,[12] these observations may be interpreted in terms of the inhibiting effect of oxygen and acid on the photoinduced one-electron transfer to chloranil, and in terms of the protonation of the semiquinone anion being too slow to compete with its decay reaction. When the flow rate was changed from 2 to 0.15 cm^3 s^{-1}, the intensity decreased monotonically. This result indicates a lifetime of the semiquinone anion equal to, or less than, some tens miliseconds under the present conditions. Otherwise, the intensity should have increased as a result of the accumulation of the generated semiquinone anion during the longer photolysis time. The observed decrease in the intensity may be attributed to the depletion of chloranil. Some stable photoproduct seems to have been deposited on the cell surface and to have screened the solution from the photolyzing light at low flow rates, so that no quantitative measurement could be made of the effect of the flow rate.

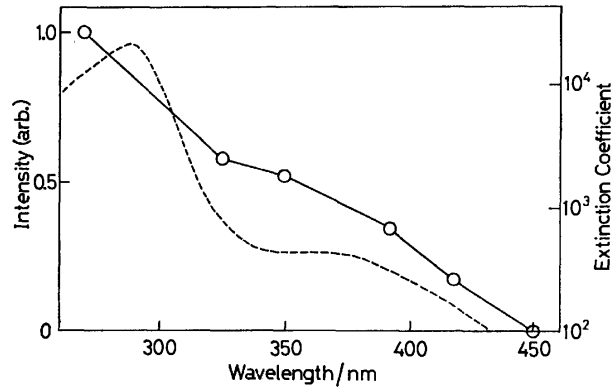

Fig. 2. Dependence of the intensity of ESR spectrum observed during the photolysis of flowing (0.15 cm^3 s^{-1}) solution of 1×10^{-3} mol dm^{-3} chloranil in ethanol on the wavelength of photolyzing light examined by discriminating the light with long-pass filters. Optical absorption spectrum of chloranil in ethanol reported in Ref. 15 is shown by dashed line for comparison.

When the shorter wavelength region of the light was successively descriminated by long-pass filters, the intensity of the spectrum decreased as is shown in Fig. 2. The intensity observed without a filter was plotted at 270 nm, which was effectively the shortest wavelength of the light source used. The plot at 325 nm shows the intensity observed with a filter of a 50% transmission at this wavelength, and so forth. The light of wavelengths longer than 450 nm is found to be ineffective to generate the photospectrum. The optical absorption spectrum of chloranil in ethanol was studied with a conventional recording spectrophotometer, and was found to agree with that reported by Shcheglova *et al.*,[15] though it gradually changed even in the absence of light under oxygen-free conditions. Taking into account this optical absorption spectrum and the spectral distribution of the light sourse supplied by the manufacturer, the relative quantum efficiency of the semiquinone anion formation can be calculated from the data in Fig. 2:

Wavelength (nm)	Efficiency
295—330	0.1
330—370	0.02
370—405	1.0
405—450	0.8

Admitting the uncertainty in the above values mainly caused by the tailing of the filters (though this uncertainty was taken into account in calculating the efficien-

cy), one can notice that the longer-wavelength region of the absorption spectrum is effective for the semiquinone anion formation. This observation is consistent with the previous result that the *p*-benzosemiquinone anion was the most efficiently generated by the light of wavelengths at the $n\pi^*$ band of *p*-benzoquinone.[12]

Chloranil in Alkaline Ethanol. The dark formation of the chloranil semiquinone anion by adding sodium ethoxide was studied in more detail for a fixed concentration of chloranil, 1×10^{-3} mol dm^{-3}, sealed in sample tubes under a vacuum. For concentrations of sodium ethoxide lower than 2×10^{-3} mol dm^{-3}, the ESR spectrum was the one due to the semiquinone anion. However, the spectrum changed, as is shown in Fig. 1C, when the ethoxide concentration was raised to 3×10^{-3} mol dm^{-3}. It narrowed to the width of 0.04 mT and was shifted to a resonant field higher by 0.09 mT (the *g*-value was smaller by 0.0006). We had assigned this shifted spectrum incorrectly to the chloranil semiquinone anion.[6] The increase in ethoxide concentration caused a further change in the spectral shape, it becoming complex, as is shown in Fig. 1D.

Sasaki *et al.* studied the reduction of chloro-*p*-benzoquinone by ethoxide and found that the semiquinone anion primarily formed was further transformed into the diethoxy-*p*-benzosemiquinone anion.[16] The present spectral change in the reduction of chloranil may be interpreted analogously: the substitution of one of the chlorine atoms in the chloranil semiquinone anion with an ethoxyl group may have caused the narrowing and shift of the spectrum. Further substitution resulted in the complex and resolved hyperfine structure shown in Fig. 1D, though no exact interpretation has been made. Because chlorine isotopes make the hyperfine structure complicated and unresolved, the decrease in the number of chlorine nuclei involved should resolve the hyperfine structure. Because of the large spin-orbit coupling of the chlorine atom, it is also conceivable that the loss of the chlorine nucleus caused the change in the *g*-value and, therefore, the shift in the resonant magnetic field.

Assignment of Semiquinone Intermediates. Hales and Bolton compared spectral parameters between the photoinduced ESR spectrum in neutral alcohols and that of the semiquinone anion generated from chloranil in alkaline alcohols in the dark, and concluded that the photoinduced spectrum was also due to the semiquinone anion.[3] Later Wong *et al.* argued that the difference in the *g*-value between the semiquinone anion and the semiquinone radical might be too small to give an unequivocal identification of semiquinone intermediates.[4] In the present investigation, however, the identity of the photospectrum with that of the authentically generated semiquinone anion was proven almost unequivocally, especially by the photolysis of the alkaline solution, where the semiquinone anion was present even in the dark. In addition, it was strongly suggested that the photoinduced one-electron transfer took place between an ethoxide ion and chloranil.

Wong *et al.* assigned the photospectrum to the chloranil semiquinone radical by analogy with other simple quinones, such as *p*-benzoquinone and duroquinone.[4] Since Porter's pioneering work by the flash photolysis-optical absorption method,[7] the photochemical generation of semiquinone radicals from these quinones in alcohols has been widely accepted. ESR studies seem to have supported such a view by detecting photospectra unquestionably attributable to the corresponding semiquinone radicals from their resolved hyperfine structure.[8,9] Recently, however, we reported ESR evidence that the semiquinone anion is a unique intermediate generated by photolyzing the fresh solution of the simple non-halogenated quinones in alcohols, and that the ESR spectra of the semiquinone radicals may, when observed, have resulted from a subsidiary reaction between the quinones and the corresponding hydroquinones.[10,12] Therefore, we believe that the photochemical analogy mentioned above is no longer pertinent.

Naturally it is a difficult task to identify an ESR spectrum without a resolved hyperfine structure, such as shown in Fig. 1A. Perhaps the ENDOR study will give a firm answer to the question of whether the photoinduced semiquinone intermediate is an anion or a radical, when the measurements are carried out during the photolysis, by proving the absence (or the presence) of a proton hyperfine splitting. In such a study, attention should be paid to eliminate the perplexing effect of the corresponding hydroquinone in the chloranil solution.

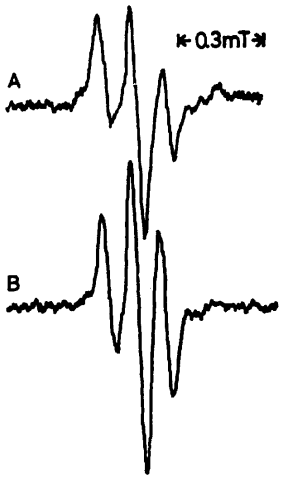

Fig. 3. ESR spectra of semiquinone intermediates observed during the photolysis of the solution, flowing at a rate of 1.5 cm^3 s^{-1}, of 1×10^{-3} mol dm^{-3} (A) 2,5-dichloro-*p*-benzoquinone or (B) 2,6-dichloro-*p*-benzoquinone in ethanol at room temperature.

Photolysis of Other Halogenated p-*Quinones.* When 2,5- and 2,6-dichloro-*p*-benzoquinones were photolyzed in ethanol at a comparatively high flow rate of the solution, the spectra with three hyperfine lines shown in Fig. 3 were recorded. The observed hyperfine splittings were 0.23 and 0.20 mT, essentially the same as those determined for the 2,5- and 2,6-dichloro-*p*-benzosemiquinone anions generated by the air oxidation of the corresponding hydroquinones.[17] Therefore, the semiquinone anions are believed to form from these dichloro-*p*-benzoquinones, as from chloranil, by photoinduced

one-electron transfer reactions. With a decrease in the flow rate, the spectra decreased in their intensity and were distorted simply because of an overlapping of the broad spectrum without a resolved hyperfine structure. The latter spectrum is thought to be due to the semiquinone radicals, which are generated preferentially at a low flow rate through the photoreaction between dichloro-*p*-benzoquinones and their corresponding hydroquinones, because of the depletion of the quinone concentration and the increase in the concentration of the product hydroquinones. Such a dependence on the flow rate is just the same as that reported previously for *p*-benzoquinone.[12]
