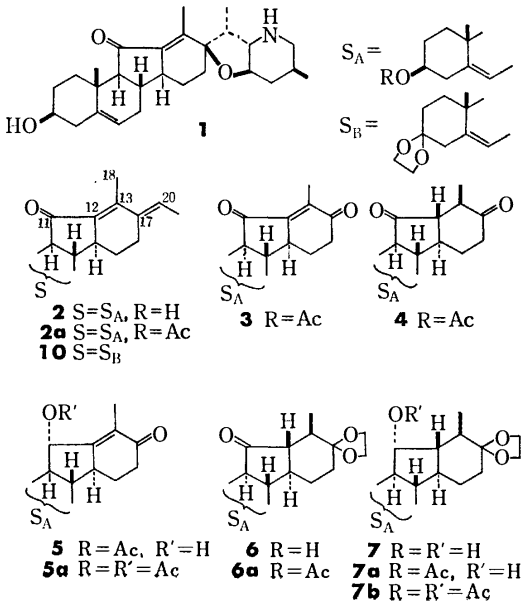
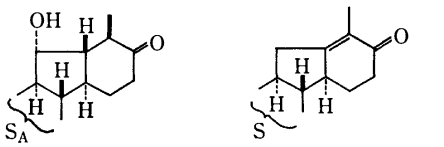
As the first step for the synthesis, it was undertaken to prepare 17-oxo-Δ^{12}-etiojervanes, important intermediates for the objective epoxy compounds. Jervine (**1**) was degraded by a known procedure, *via* trienone[4] (**2a**), into Δ^{12}-11,17-diketone[5] (**3**), which on treatment with zinc and acetic acid afforded 11,17-diketone[5] (**4**), a known compound with established configurations,[6] in a 67% yield together with a small amount (3%) of 11α-hydroxy-Δ^{12}-17-ketone (**5**), mp 249—250.5 °C. The α-hydroxy configuration at C_{11} of the latter (**5**) was deduced from facile conversion (82%) into its 3,11-diacetate (**5a**), mp 168—170 °C, under mild conditions. The major product (**4**) was then transformed, *via* the corresponding 17-ethylene acetal, amorphous, into a known compound, 3β-hydroxy-11,17-diketone 17-acetal[7] (**6**), in an 81% yield, which on reduction with sodium in isopropyl alcohol gave 3β,11α-diol (**7**), mp 157—159 °C, in a 69% yield.



The assigned α-configuration to the 11-hydroxyl group of **7** was based on the chemical shift (δ 0.98) of the 19-methyl protons (δ_{calcd} 0.99 for 11α-OH and 1.26 for 11β-OH).[8] Acetylation of 3β,11α-diol (**7**) under controlled conditions (0 °C, 1.5 h) effected monoacetylation to give, after chromatography, 3-monoacetate (**7a**), mp 235—236 °C, in a 57% yield with 3,11-diacetate (**7b**), mp 172—173 °C (12%), and the starting diol (**7**) (8%). The 3-monoacetate (**7a**) was smoothly deacetalized with *p*-toluenesulfonic acid in aqueous acetone to yield 17-ketone (**8**), mp 216.5—217.5 °C, and was also oxidized with chromic acid to 11-ketone (**6a**), mp 188—190 °C, in good yields, respectively. The latter (**6a**) proved to be identical with a known compound with established configurations,[6,7] indicating that each of compounds **6**—**8** possesses a β-oriented hydrogen atom at C_{12}.



8 R=Ac

9 S=S_A, R=H
9a S=S_A, R=Ac
15 S=S_B

Compound **8**, 17-oxo-11α-alcohol, when treated with phosphoryl chloride and pyridine, underwent dehydration with concomitant double bond migration to give Δ^{12}-17-ketone (**9a**), mp 172—173 °C, in a low yield (38%), which was readily hydrolyzed with base (KOH) to the corresponding 3β-alcohol (**9**), mp 174—175 °C, quantitatively. In accordance with the formula, compound **9a** exhibited absorption maxima at 246 nm (ε 12000) and at 1665 cm^{-1} in the UV and IR spectra and displayed two three-proton singlets due to the 19- and 18-methyl protons at δ 1.04 and 1.73 in the NMR spectrum. This Δ^{12}-17-ketone (**9a**) was also obtained by treatment of 11α-acetoxy-Δ^{12}-17-ketone (**5a**) with zinc and acetic acid in a 73% yield. Likewise, 11α-hydroxy-17-ketone 17-acetal (**7a**), when treated with phosphoryl chloride under the same conditions as 17-ketone (**8**) and then with hydrochloric acid in aqueous dioxane, was converted into Δ^{12}-17-ketone (**9**) in a 74% yield. Compound **9** is one of the most important intermediates for preparation of the aimed 12,13-epoxides. However, the afore-mentioned process involved 11 steps and the over-all yield from jervine

amounted to only 4%. In order to improve the yield of compound **9** or its analogues, we searched an alternate route.

3β-Hydroxy-trienone[4] (**2**) was transformed *via* a known process into 3-oxo-trienone 3-acetal[9] (**10**), which was treated with aluminium hydride in tetrahydrofuran. The reduction proceeded without saturation of the double bonds[10] and, after chromatography, gave the corresponding 11α- and 11β-alcohols (**11** and **12**), mp 142—144 and 138—141 °C, in 59 and 21% yields, respectively. The configurations of C_{11} in these alcohols were assigned as shown in the formulas on the basis of chemical shifts of the protons at C_{19} and C_{11}; 19-CH_3, δ 1.10 for **11** and 1.30 for **12**;[3a,8] H at C_{11}, δ 4.66 (d J=7 Hz) for **11** and 4.90 (d J=7 Hz) for **12**.[3a] The result is interesting in the sense that the hydride reduction has led to predominant formation of 11α-alcohol (**11**), and we have such a precedent.[3a] The 11α-alcohol (**11**) was readily converted into its 11-acetate (**11a**), mp 171—174 °C, quantitatively, which on oxidation with sodium periodate in 75% aqueous dioxane (the Lemieux-Johnson oxidation)[11] afforded 11α-acetoxy-Δ^{12}-17-ketone (**13a**), mp 189—191 °C, in a 71% yield. This 17-ketone (**13a**) was also obtained by the Lemieux-Johnson oxidation of 11α-alcohol (**11**) into 11α-hydroxy-Δ^{12}-17-ketone (**13**), mp 186—188 °C, followed by acetylation in a 70% yield. Likewise, 11β-alcohol (**12**) was oxidized under the same conditions as **11** to give 11β-hydroxy-Δ^{12}-17-ketone (**14**), mp 169—170 °C in a 52% yield. These 11β-alcohols (**12** and **14**) were not converted into the respective 11-acetates under the same conditions as the corresponding 11α-alcohols (**11** and **13**). An attempted reduction to remove the oxygen functions at C_{11} of 11α-acetoxy- or 11β-hydroxy-Δ^{12}-17-ketone (**13a** or **14**) with zinc and acetic acid[12] produced a multi-component mixture containing 3-deacetalized compounds. However, the Birch reduction of these compounds (**13a** and **14**) effected the relevant reduction to give a desirable product, Δ^{12}-17-ketone (**15**), mp 163—165 °C, in 86 and 73% yields, respectively. The over-all yield of **15** amounted to 19%.

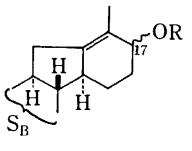
14 11α-H, R=H



16 17β-H, R=H
16a 17β-H, R=Ac
17 17α-H, R=H
17a 17α-H, R=Ac

Reduction of Δ^{12}-17-ketone (**15**) with sodium borohydride produced Δ^{12}-17α-alcohol (**16**), mp 132—133 °C, in a 95% yield as a sole isolable compound. On the other hand, when aluminium hydride was used as the reduction reagent, its 17-epimer, Δ^{12}-17β-alcohol (**17**), mp 92—94 °C, was obtained in a 6% yield along with the 17α-epimer (**16**) (88%). The configurations of 17-hydroxyl groups were drawn from the optical rotations and spectral patterns of protons at C_{17}; $[\alpha]_D$ −25.7° for **16** and −77.3° for **17**;[13] H at C_{17}, δ 4.12 (br W_H=18 Hz) for **16** and 3.96 (br W_H=8 Hz) for **17**.[14] These Δ^{12}-17-alcohols (**16** and **17**) were readily transformed into the respective 17-acetates (**16a** and **17a**), mp 142—143 and 138—141 °C, quantitatively; H at C_{17}, δ 5.35 for **16a** and 5.21 for **17a**.[14] Prior to epoxidation of the 12,13-double bond, it was desirable to modify the Δ^5-3-ketone 3-acetal grouping into a Δ^4-3-carbonyl system, which leads to decrease of electrophilicity of the 5,6-double bond. However, all attempts to hydrolyze the 3-acetal group under various conditions (with *p*-toluenesulfonic acid in aqueous acetone under reflux or at room temperature, with anhydrous magnesium sulfate in wet benzene,[15] with trityl tetrafluoroborate in dry dichloromethane,[16] and so on) failed, giving complex mixtures. This suggested that the relevant epoxidation must be carried out under carefully controlled conditions.

Epoxidation of Δ^{12}-17α-alcohol (**16**) with perbenzoic acid in benzene afforded 12α,13α-epoxy-17α-alcohol (**18**), mp 158—161 °C, as a main product (75%) with small amounts (3 and 6%) of 12β,13β-epoxy- and 5β,6β,12α,13α-diepoxy-17α-alcohols (**19** and **20**), mp 136—138 and 123—125 °C. The major product (**18**) was also obtained by oxidation of **16** with *t*-butyl hydroperoxide in the presence of bis(acetylacetonato)-oxovanadium(IV) in a 57% yield as a sole compound, which could be isolated from complex mixtures. The 12α,13α- and 12β,13β-epoxy configurations were assigned to compounds **18** and **19** on the premise that (i) peracid epoxidation of olefins takes place by an electrophilic attack mainly from a less-hindered (α) side,[17] and (ii) epoxidation of allyl alcohols in the presence of the transition metal leads to preferential formation of epoxides with the group at the same side as the hydroxyl group.[18] On the other hand, the epoxy-configurations of diepoxide (**20**) were deduced as shown by the formula from the chemical shift of 19-methyl protons; δ_{obsd} 0.99, δ_{calcd} 0.81 for 5α,6α,12α,13α-diepoxide and 1.02 for 5β,6β,12α,13α-diepoxide.[3a,8,19] Compound **18** was then converted into 17-acetate (**18a**), mp 212—213 °C, and oxidized with chromium(VI) oxide in pyridine to 12α,13α-epoxy-17-ketone (**21**), mp 139—140 °C, in good yields.[20] The latter (**21**) was also produced by direct oxidation of Δ^{12}-17-ketone (**15**) with hydrogen peroxide in alkaline aqueous methanol in an 86% yield. Reduction of the 17-ketone (**21**) produced two 17-epimeric alcohols, the original 17α-alcohol (**18**) and 12α,13α-epoxy-17β-alcohol (**22**), mp 144—146 °C, which were isolated in 65 and 25% yields from the mixture. The latter (**22**) readily formed 17-acetate (**22a**), mp 144—147 °C, quantitatively. The NMR spectra of these 17-epimeric alcohols were in good accord with the assigned configurations: H

at C_{17}, δ 3.76 (br W_H=28 Hz) for **18** and 4.06 (br W_H=7 Hz) for **22**; δ 5.04 (do d J=10 and 5 Hz) for **18a** and 5.16 (br W_H=6 Hz) for **22a**.

24

Epoxidation of Δ^{12}-17β-alcohol (**17**) with *t*-butyl hydroperoxide in the presence of bis(acetylacetonato)-oxovanadium(IV)[18] proceeded smoothly to give a new epoxide, 12β,13β-epoxy-17β-alcohol (**23**), mp 130—132 °C, in an 83% yield, which formed 17-acetate (**23a**), mp 132—135 °C, in a good yield. Oxidation of **23** with chromium(VI) oxide in pyridine afforded 12β,13β-epoxy-17-ketone (**24**), mp 184—186 °C, in an 80% yield, which was reconverted by treatment with sodium borohydride into the original 17β-alcohol (**23**) only in a 38% yield, the major product being 12β,13β-epoxy-17α-alcohol (50%). The latter was readily converted into 17-acetate (**19a**), mp 142—144 °C, and was naturally identical with the afore-mentioned epoxy-alcohol (**19**). A series of these reactions correlating all 17-hydroxy- and 17-oxo-12,13-epoxides (**18**—**24**) were consistent with the assigned epoxy configurations to the respective compounds. Confirmatory evidence was presented by comparison of the ORD curves of two epoxy-ketones (**21** and **24**), which exhibited negative and positive Cotton effects (a=−119° and +125°), respectively (Fig. 1).

Finally we examined collectively the chemical shifts of 19-methyl protons of etiojervanes described in this paper. We now add the contributions of new functional groups shown in Table 1 to *Table 2 in the Ref. 8.* These data, coupled with those in *Table 1 of the Ref. 3a*, would be valuable in confirming certain stereochemical points as well as promoting the structure determination of new derivatives. For example, 3β-hydroxy-Δ^{12}-17-ketone (**9**) was oxidized with hydrogen peroxide in an alkaline solution to give 12α,13α-epoxy-17-ketone (**25**), mp 173.5—175 °C, in a 57% yield. This epoxide (**25**) exhibited the ORD curve with a negative Cotton effect (a=−99°) and the NMR signal due to the 19-methyl protons at δ 1.02; δ_{calcd} 1.00 for 12α,13α-epoxide and 1.09 for 12β,13β-epoxide.

Fig. 1.

Table 1. The contribution ($\Delta\delta$) of functional groups to the chemical shift of the 19-methyl protons of etiojervanes

Groups	A-T[a]	B-T[a]
Reference shifts	0.74[a]	0.79[a]
Functional groups (No of examples)	$\Delta\delta$[b]	$\Delta\delta$[b]
11β-OH, Δ^{12}, $\Delta^{17(20)}$ (1)	0.32	—
11α-OH, Δ^{12}, $\Delta^{17(20)}$ (1)	0.12	—
11α-OAc, Δ^{12}, $\Delta^{17(20)}$ (1)	0.16	—
11β-OH, Δ^{12}, 17=O (1)	0.34	—
11α-OH, Δ^{12}, 17=O (2)	0.16	—
11α-OAc, Δ^{12}, 17=O (2)	0.20	—
12β,13β-O-[c] (5)	0.06	—
12α,13α-O-[c] (5)	—	−0.01[d]
12β,13β-O-, 17=O (1)	0.12	—
12α,13α-O-, 17=O (2)	—	−0.02[d]

a) *Cf.*, Table 2 in Ref. 8. b) "$\Delta\delta$" means deshielding effect. c) The abbreviations "12β,13β-O- and 12α, 13α-O-" denote "12β,13β-epoxy and 12α,13α-epoxy", respectively. d) The negative sign means "up-field shift".

Experimental

All the mps were uncorrected. The homogenity of each compd was always checked by TLC over silica gel (Wakogel B-5) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid and/or iodine. The optical rotations, ORD curves, UV and IR spectra were measured in chloroform, dioxane, ethanol, and Nujol, respectively, unless otherwise stated. The NMR spectra were obtained in chloroform-*d* at 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. The abbreviations "s, d, t, q, br, do, and sh" in the NMR and IR spectra denote "singlet, doublet, triplet,

quartet, broad, double, and shoulder," respectively.

3β-Hydroxy-12β-etiojerv-5-ene-11,17-dione 3-Acetate (4), 3β,-11α-Dihydroxyetiojerva-5,12-dien-17-one 3-Acetate (5), and Its 3,11-Diacetate (5a). A soln of 3β-hydroxyetiojerva-5,-12-diene-11,17-dione 3-acetate[5] (**3**, 22 g) in glacial acetic acid (1730 ml) was heated with zinc powder (27.5 g) at 90 °C for 30 min under stirring, when the yellow soln had become colorless. The reaction mixture was worked up according to the known procedure[5] to give crystalline residue (32 g), showing two spots, which was separated by chromatography over alumina (Merck, standard, 340 g). Eluates with benzene–hexane (3 : 1), benzene, and benzene–ether (3 : 1) afforded **4** (14.8 g), mp 164—166 °C (diisopropyl ether) (lit,[4] 171—172 °C). Eluates with chloroform gave **5** (0.65 g), mp 246—248 °C (acetone), which was recrystallized from acetone for analysis; mp 249—250.5 °C and $[\alpha]_D$ −61°; MS, *m/e* 344 (M^+); UV, λ_{max} 249 nm (ε 15000); IR, ν_{max} 3495, 1722, 1648 (br), 1250, 1041, and 1031 cm^{-1}; NMR, δ 1.14, 1.90, and 2.07 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 4.67 (1H, br W_H=24 Hz, $\underline{H}$ at C_3), 4.73 (1H, d J=7 Hz, $\underline{H}$ at C_{11}), and 5.46 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 73.24; H, 8.19%. Calcd for $C_{21}H_{28}O_4$:C, 73.22; H, 8.19%.

A soln of **5** (1.44 g) in acetic anhydride (Ac_2O, 7.2 ml) and pyridine (Py, 14.4 ml) was allowed to stand at room temp for 24 h. The reaction mixture was poured into ice-water and extracted with chloroform. The chloroform soln was washed with 2 M hydrochloric acid, 5% aq sodium hydrogencarbonate and water, dried over anhyd sodium sulfate, and evaporated to leave amorphous residue (2.02 g), which was crystallized from acetone to yield **5a** (1.33 g), mp 167—170 °C. This was recrystallized for analysis from acetone; mp 168—170 °C and $[\alpha]_D$ −93°; MS, *m/e* 326 (M^+−CH_3COOH), 284, 266, and 251; UV, λ_{max} 244 nm (ε 15000); IR ν_{max} 1724, 1670, 1249, 1238, 1042, and 1033 cm^{-1}; NMR, δ 1.19 and 1.68 (each 3H, s, 19- and 18-C$\underline{H}_3$), 2.05 and 2.07 (each 3H, s, 2OCOC$\underline{H}_3$), 4.63, and 5.47 (each 1H, br W_H=22 and 9.5 Hz, 2$\underline{H}$ at C_3 and C_6), and 6.12 (1H, d J=8 Hz, $\underline{H}$ at C_{11}). Found: C, 71.38: H, 7.81%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%.

3β-Hydroxy-12β-etiojerv-5-ene-11,17-dione 17-Ethylene Acetal (6). A soln of **4** (20 g) in ethylene glycol (80 ml) was refluxed with *p*-toluenesulfonic acid (PTS, 1.0 g) in benzene (1600 ml) for 21 h, water being removed with a Dean-Stark apparatus. After being cooled, the soln was worked up as usual to leave crude acetal (23.7 g), which, without purification, was refluxed in methanol (670 ml) containing potassium hydroxide (70 g) for 1 h under nitrogen. The reaction mixture was worked up as usual to leave crystalline residue, which was recrystallized from hexane–benzene to give **6** (16.3 g), mp 160—162 °C (lit,[7] 165—167 °C).

3β,11α-Dihydroxy-12β-etiojerv-5-en-17-one 17-Ethylene Acetal (7), Its 3-Acetate (7a), and 3,11-Diacetate (7b). To a refluxing soln of **6** (10.0 g) in isopropyl alcohol (1400 ml) was added in small protions sodium metal (51 g) during 2 h. The mixture was further refluxed for 20 min under stirring, when it had become homogeneous. After being cooled, the mixture was combined with water (300 ml) and concentrated under reduced pressure to leave oily residue, which was mixed with water and extracted with chloroform. The extracts were worked up as usual to leave amorphous residue, which on trituration with aq ethanol afforded **7** (6.98 g), mp 156—158 °C. This was recrystallized from the same solvent mixture for analysis; mp 157—159 °C and $[\alpha]_D$ −34°; MS, *m/e* 348 (M^+), 330, 315, 286, and 259; IR, ν_{max} 3370, 1089, and 1050 cm^{-1}; NMR, δ 0.94 (3H, d J=7 Hz, 18-C$\underline{H}_3$), 0.98 (3H, s, 19-C$\underline{H}_3$), 3.48 (1H, br W_H=26 Hz, $\underline{H}$ at C_3), 3.94 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.05 and 5.32 (each 1H, br W_H=8 and 10 Hz, 2$\underline{H}$ at C_{11} and C_6). Found: C, 70.65; H, 9.39%. Calcd for $C_{21}H_{32}O_4 \cdot C_2H_5OH$: C, 70.01; H, 9.71%.

Compd **7** (125 mg) was dissolved in Py (1.26 ml) and Ac_2O (0.33 ml) under cooling with ice and then allowed to stand at room temp for 1.5 h. After being poured into ice-water, the mixture was extracted with chloroform. The extracts were worked up as usual to leave oily residue (164 mg), showing three spots on TLC, which was separated by chromatography over silica gel (Merck, 9 g). Eluates with benzene–ether (5 : 1) were crystallized and recrystallized from hexane to give **7b** (18 mg), mp 172—173 °C and $[\alpha]_D$ −15°; MS, *m/e* 432 (M^+), 372, 357, 312, and 297; IR, ν_{max} 1731, 1240 (br), 1086, 1043, and 1018 cm^{-1}; NMR, δ 0.77 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 1.07 (3H, s, 19-C$\underline{H}_3$), 2.00 and 2.02 (each 3H, s, 2OCOC$\underline{H}_3$), 3.92 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.53 (1H, br W_H=20 Hz, $\underline{H}$ at C_3), and 5.37 (2H, br W_H= 10 Hz, 2$\underline{H}$ at C_{11} and C_6). Found: C, 69.24; H, 8.27%. Calcd for $C_{25}H_{36}O_6$: C, 69.42; H, 8.39%.

Eluates with benzene–ether (3 : 1) were crystallized and recrystallized from diisopropyl ether to give **7a** (80 mg), mp 235—236 °C and $[\alpha]_D$ −43°; MS, *m/e* 390 (M^+), 330, 268, and 242; IR, ν_{max} 3540, 1725, 1253, 1085, 1035, and 1023 cm^{-1}; NMR, δ 0.95 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$), 1.00 (3H, s, 19-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 3.94 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O) 4.10, 4.60, and 5.38 (each 1H, br W_H=9, 22, and 9 Hz, 3H at C_{11}, C_3, and C_6). Found: C, 70.84; H, 8.83%. Calcd for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78%. Eluates with benzene–ether (1 : 1) were crystallized and recrystallized from aq ethanol to give the starting material (**7**, 10 mg), mp 156—158 °C, which was identical with an authentic sample.

To a pasty mixture, prepared by addition of chromium-(VI) oxide (500 mg) into Py (5 ml) at 0 °C under stirring, was added a soln of **7a** (20 mg) in Py (0.8 ml), and the whole mixture was stirred at room temp for 22 h. The reaction mixture was worked up as usual to yield an oily material, which was purified by chromatography over silica gel (Merck, 1 g). Eluates with benzene–ether (5 : 1) afforded 12β-etiojerv-5-en-3β-ol-11,17-dione 3-acetate 17-ethylene acetal (**6a**, 10 mg), mp 188—190 °C (diisopropyl ether), which was identical with an authentic sample[6,7] (IR, NMR, TLC, and mixed mp).

3β,11α-Dihydroxy-12β-etiojerv-5-en-17-one 3-Acetate (8). A soln of **7a** (1.91 g) in acetone (300 ml) and water (30 ml) was refluxed with PTS (150 mg) for 3 h under stirring. The soln was worked up as usual to leave crystalline residue (1.68 g), showing a single spot, which was recrystallized from acetone to give **8** (1.61 g), mp 216.5—217.5 °C and $[\alpha]_D$ −139°; MS, *m/e* 286 (base, M^+ −CH_3COOH), 271, 268, and 253; IR, ν_{max} 3615, 1728, 1696, 1250, and 1036 cm^{-1}; NMR, δ 1.03 (3H, s, 19-C$\underline{H}_3$), 1.11 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 2.06 (3H, s, OCOC$\underline{H}_3$), 4.13 (1H, do d J=4 and 6 Hz, $\underline{H}$ at C_{11}), 4.63 and 5.43 (each 1H, br W_H=23 and 9 Hz, 2$\underline{H}$ at C_3 and C_6). Found: C, 72.97; H, 8.73%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

3β-Hydroxyetiojerva-5,12-dien-17-one 3-Acetate (9a).
(i) Compd **5a** (204 mg), dissolved in glacial acetic acid (14 ml), was stirred vigorously with zinc powder (440 mg) at 90 °C for 30 min. The mixture, after being cooled, was filtered to remove excess of the zinc powder, which was washed with chloroform. The filtrate and chloroform washings were combined, evaporated, diluted with water, and then extracted with chloroform. The extracts were worked up as usual to leave an amorphous substance (172 mg), which was crystallized from acetone to yield **9a** (127mg), mp 172—173 °C. This was recrystallized for analysis from

acetone; mp 172—173 °C and $[\alpha]_D$ −93.4°; MS, *m/e* 328 (M^+), 268, 253; UV, λ_{max} 246 nm (ε 12000); IR, ν_{max} 1731, 1665, 1248, and 1035 cm^{-1}; NMR, δ 1.04, 1.73, and 2.05 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 4.66 and 5.45 (each 1H, br W_H=21 and 9 Hz, 2$\underline{H}$ at C_3 and C_6). Found: C, 76.96; H, 8.52%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

(ii) To a soln of **8** (1.5 g) in dry Py (39 ml), cooled at 0 °C, was added dropwise phosphoryl chloride ($POCl_3$, freshly distilled, 1.95 ml) during 1 min under stirring, and the mixture was kept at room temp for 9 min. The reaction mixture was poured into ice–water (*ca.* 500 ml) and extracted with chlorofrom, and the chloroform soln was worked up as usual to give a crystalline substance, which was recrystallized from acetone to give **9a** (540 mg), mp 172—173 °C, identical with an authentic sample.

*3β-Hydroxyetiojerva-5,12-dien-17-one (**9**).* (i) Compd **9a** (6.49 g) was refluxed in methanol (160 ml) containing 5% potassium hydroxide for 1 h under nitrogen. The reaction mixture was worked up as usual to leave a crystalline substance (6.04 g), which was purified by chromatography over silica gel (Merck, 60 g). Eluates with benzene - ether (1 : 3) afforded **9** (5.07 g), mp 172—174 °C (acetone), which was recrystallized for analysis from acetone; mp 174—175 °C and $[\alpha]_D$ −106°; MS, *m/e* 286 (M^+), 268, and 253; UV, λ_{max} 246 nm (ε 12000); IR, ν_{max} 3440, 1643, and 1065 cm^{-1}; NMR, δ 1.03 and 1.73 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.57 and 5.42 (each 1H, br W_H=23 and 9 Hz, 2$\underline{H}$ at C_3 and C_6). Found: C, 79.70; H, 9.14%. Calcd for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15%.

(ii) A soln of **7a** (5.68 g) in Py (57 ml) was treated with $POCl_3$ (5.7 ml) at room temp for 12 min (*cf.*, dehydration of **8**). The reaction mixture was worked up as mentioned above to leave an amorphous material (5.62 g), which was dissolved in dioxane (300 ml) and water (110 ml), and treated with concd hydrochloric acid (25 ml) at room temp for 25 h under stirring. The mixture was concentrated to 200 ml below 65 °C under reduced pressure, diluted with water, and then allowed to stand overnight, when crystalline substances (3.75 g) precipitated. These were collected by filtration and recrystallized from acetone to yield **9** (3.09 g), mp 169—170 °C, identical with an authentic sample.

*11α-Hydroxy-17-ethyletiojerva-5,12,17(20)-trien-3-one 3-Ethylene acetal (**11**), Its 11-Acetate (**11a**), and Its 11β-Ol Epimer (**12**).* (i) To an ice-cooled, stirred suspended mixture of lithium aluminium hydride (LAH, 3.40 g) in dry tetrahydrofuran (THF, 120 ml) was added dropwise 95% sulfuric acid (2.3 ml) under a stream of nitrogen, and the mixture was further stirred at room temp for 1 h and then kept in a refrigerator. The supernatant THF soln contained 0.75 M aluminium hydride. To a soln of 17-ethyletiojerva-5,12,17(20)-triene-3,11-dione 3-ethylene acetal[9] (**10**, 5.0 g) in THF (60 ml) cooled with ice was added slowly the above THF soln (25 ml) under stirring, and the whole mixture was stirred at room temp for 3 h. After addition of ethanol and 6 M aq ammonia to decompose excess of the hydride, the reaction mixture was filtered to remove aluminium hydroxide, which was washed with ethanol. The filtrate and ethanol washings were combined, concentrated, diluted with water, and extracted with chloroform. The extracts were washed with water, dried, and evaporated to leave oily residue, which was separated by chromatography over alumina (Merck, 200 g). Eluates with benzene–ether (3 : 1 and 2 : 1) gave the starting trienone (**10**, 77 mg). Eluates with benzene–ether (1 : 1) afforded crystalline substances, which were collected by filtration and recrystallized from benzene–ether to yield **12** (1.06 g), mp 138—141 °C and $[\alpha]_D$ −2.0°; MS, *m/e* 356 (M^+), 341, 338, and 323; UV, λ_{max} 260 (sh), 252, and 244 (sh) nm (ε 7000, 11000, and 10000); IR, ν_{max} 3540, 1110, and 1095 cm^{-1}; NMR, δ 1.30 and 1.93 (each 3H, s, 19- and 18-C$\underline{H}_3$), 1.72 (3H, d J=7 Hz, 21-C$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.90 (1H, d J=7 Hz, $\underline{H}$ at C_{11}), 5.30 (1H, br W_H=11 Hz, $\underline{H}$ at C_6), and 5.60 (1H, q J=7 Hz, $\underline{H}$ at C_{20}). Found: C, 77.54; H, 8.99%. Calcd for $C_{23}H_{32}O_3$: C, 77.49; H, 9.05%.

Eluates with ether afforded **11** (2.96 g), mp 142—144 °C and $[\alpha]_D$ +6.9°; MS, *m/e* 356 (M^+), 341, 338, 323, and 239; UV, λ_{max} 258 (sh), 250, and 242 (sh) nm (ε 7000, 10000, and 9000); IR, ν_{max} 3350, 1110, and 992 cm^{-1}; NMR, δ 1.10 and 1.90 (each 3H, s, 19- and 18-C$\underline{H}_3$), 1.72 (3H, d J=7 Hz, 21-C$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.66 (1H, d J=7 Hz, $\underline{H}$ at C_{11}), 5.36 (1H, br W_H=11 Hz, $\underline{H}$ at C_6), and 5.56 (1H, q J=7 Hz, $\underline{H}$ at C_{20}). Found: C, 77.58; H, 9.10%. Calcd for $C_{23}H_{32}O_3$: C, 77.49; H, 9.05%.

(ii) Compd **11** (205 mg) was treated with Ac_2O (1 ml) and Py (2 ml) at room temp overnight under stirring. The reaction mixture was worked up as usual to give **11a** (228 mg), mp 171—174 °C (benzene–ether) and $[\alpha]_D$ −37.5°; MS, *m/e* 398 (M^+), 338, and 323; UV, λ_{max} 259 (sh), 250, and 244 (sh) nm (ε 9500, 14800, and 13600); IR, ν_{max} 1720, 1245, 1108, and 1092 cm^{-1}; NMR, δ 1.16 and 1.72 (each 3H, s, 19- and 18-C$\underline{H}_3$), 1.69 (3H, d J=7 Hz, 21-C$\underline{H}_3$), 2.03 (3H, s, OCOC$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.37 (1H, br W_H=12 Hz, $\underline{H}$ at C_6), 5.60 (1H, q J=7 Hz, $\underline{H}$ at C_{20}), and 6.10 (1H, d J=7 Hz, $\underline{H}$ at C_{11}). Found: C, 75.01; H, 8.43%. Calcd for $C_{25}H_{34}O_4$: C, 75.34; H, 8.60%.

*11α-Hydroxyetiojerva-5,12-diene-3,17-dione 3-Ethylene Acetal (**13a**) and Its 11-Acetate (**13a**).* (i) A soln of **11a** (850 mg) in 75% aq dioxane (70 ml) was stirred with osmium tetraoxide in dioxane (0.74 ml) (OsO_4 : dioxane=1.0 g : 80 ml) at room temp for 30 min, when the colorless soln gradually became dark-brown. To the soln was added sodium periodate (0.88 g) during 30 min, and the mixture was stirred at room temp for 22 h, when white precipitates separated out and were removed by filtration. The filtrate was concentrated, diluted with water, and extracted with chloroform repeatedly. The chloroform soln was washed with water, dried and evaporated to leave amorphous residue, which was purified by chromatography over silica gel (Merck, 34 g) with mixtures of benzene and ether to give **13a** (584 mg), mp 189—191 °C (benzene–ether) and $[\alpha]_D$ −79.7°; MS, *m/e* 386 (M^+) and 326; UV, λ_{max} 244 nm (ε 11000); IR, ν_{max} 1732, 1658, 1240, and 1093 cm^{-1}; NMR, δ 1.18, 1.66, and 2.06 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.97 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.40 (1H, br W_H=9 Hz, $\underline{H}$ at C_6), and 6.10 (1H, d J=7 Hz, $\underline{H}$ at C_{11}). Found: C, 71.03; H, 7.38%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%.

(ii) Compd **11** (2.20 g) was oxidized in the same manner as **11a** to give **13** (1.48 g), mp 186—188 °C (benzene–ether) and $[\alpha]_D$ −44.1°; MS, *m/e* 344 (M^+); UV, λ_{max} 249 nm (ε 12000); IR, ν_{max} 3480, 1665, 1110, and 1095 cm^{-1}; NMR, δ 1.14 and 1.90 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.98 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.78 (1H, d J=7 Hz, $\underline{H}$ at C_{11}), and 5.43 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 73.30; H, 8.10%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

Compd **13** (4.16 g) was treated with Ac_2O (21 ml) and Py (42 ml) at room temp overnight under stirring to give **13a** (4.64 g), which was identical with an authentic sample.

*11β-Hydroxyetiojerva-5,12-diene-3,17-dione 3-Ethylene Acetal (**14**).* The Lemieux-Johnson oxidation of **12** (105 mg) was carried out in the same manner as that of **11** and gave **14** (51 mg), mp 169—170 °C (benzene–ether); MS, *m/e* 344

(M+); UV, λ_{max} 247 nm (ε 10600); IR, ν_{max} 3360, 1640, 1118, and 1100 cm^{-1}; NMR, δ 1.32 and 1.90 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.98 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.00 (1H, d J=7 Hz, $\underline{H}$ at C_{11}), and 5.30 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 73.45; H, 8.40%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

*Etiojerva-5,12-diene-3,17-dione 3-Ethylene Acetal (**15**).*
(i) To a blue-colored soln of lithium (2.0 g) in liquid ammonia (*ca.* 300 ml) cooled with Dry Ice-Acetone was added **13a** (4.7 g) in THF (15 ml), and the mixture was stirred at the temp for 15 min. The reaction mixture, on addition of ammonium chloride (20 g), became colorless and was then allowed to stand at room temp to remove the ammonia. The residue was submitted to filtration to remove ammonium chloride, the latter being washed with ethanol. The filtrate and ethanol washings were combined, concentrated, diluted with water, and extracted with chloroform, repeatedly. The extracts were worked up as usual to give crystalline residue, which on recrystallization from ether yielded **15** (3.43 g), mp 163—165 °C and $[\alpha]_D$ −81.5°; MS, *m/e* 328 (M+); UV, λ_{max} 247 nm (ε 9200); IR, ν_{max} 1658 and 1110 cm^{-1}; NMR, δ 1.06 and 1.73 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.98 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.42 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 76.65; H, 8.68%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

(ii) The Birch reduction of **14** (8.00 g) was carried out in the same manner as that of **13a** and produced **15** (5.58 g), which was identical with the afore-mentioned sample.

*17α-Hydroxyetiojerva-5,12-dien-3-one 3-Ethylene Acetal (**16**), Its 17β-Ol Epimer (**17**), and Their 17-Acetates (**16a** and **17a**).*
(i) A soln of **15** (1.00 g) in methanol (100 ml) was stirred with sodium borohydride (1.8 g) at room temp for 35 min. After addition of a small amount of acetic acid, the mixture was neutralized with 5% aq sodium hydrogencarbonate, concentrated, diluted with water, and extracted with chloroform, repeatedly. The chloroform soln gave crystalline residue, which was recrystallized from ether to yield **16** (950 mg), mp 132—133 °C and $[\alpha]_D$ −25.7°; MS, *m/e* 330 (M+) and 312; IR, ν_{max} 3360, 1110, and 1090 cm^{-1}; NMR, δ 0.98 and 1.65 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.94 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.12 and 5.35 (each 1H, br W_H=18 and 10 Hz, 2$\underline{H}$ at C_{17} and C_6). Found: C, 75.93; H, 9.12%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%.

Compd **16** (0.11 g) was treated with Ac_2O (0.7 ml) and Py (1.4 ml) at room temp for 1 d under stirring to give **16a** (0.12 g), mp 142—143 °C (benzene-ether) and $[\alpha]_D$ −10.6°; MS, *m/e* 372 (M+) and 312; IR, ν_{max} 1734, 1237, 1107, 1092, 1019, and 976 cm^{-1}; NMR, δ 0.99, 1.54, and 2.06 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.94 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.35 (2$\underline{H}$, br W_H=10 Hz, 2$\underline{H}$ at C_6 and C_{17}). Found: C, 74.05; H, 8.62%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%.

(ii) To an ice-cooled and stirred soln of LAH (0.8 g) in THF (40 ml) was added dropwise concd sulfuric acid (0.7 ml) under a stream of nitrogen, and the mixture was then kept in a refrigerator. To a soln of **15** (2.00 g) in THF (20 ml) was added slowly the above supernatant THF soln (25 ml) under nitrogen, and the whole mixture was stirred at room temp for 2 h. The mixture, after being worked up as described before, gave amorphous residue, which was separated by chromatography over silica gel (Merck, 65 g). Eluates with benzene-ether (2 : 1) afforded a mixture, showing two spots, which was further separated by preparative TLC over silica gel (Wakogel B-5, 35 plates of 20×20 cm^2) with benzene-ether (2 : 1). A less polar fraction afforded **17** (0.11 g), mp 92—94 °C (benzene-ether) and $[\alpha]_D$ −77.3°; MS, *m/e* 330 (M+), 312, and 297; IR, ν_{max} 3500, 3260, 1190, 1035, 1015, and 970 cm^{-1}; NMR, δ 0.98 and 1.71 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.94 (5H, s, OC$\underline{H}_2$C$\underline{H}_2$O and $\underline{H}$ at C_{17}), and 5.36 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 75.93; H, 9.34%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%. A more polar fraction afforded **16** (1.77 g), which was obtained from eluates with benzene-ether (1 : 1) and ether, and proved to be identical with an authentic sample.

Compd **17** (14 mg) was acetylated with Ac_2O (0.4 ml) and Py (0.8 ml) at room temp for 3 d to give **17a** (15 mg), mp 138—141 °C (acetone) and $[\alpha]_D$ −89.7°; MS, *m/e* 372 (M+) and 312; IR, ν_{max} 1738, 1238, 1108, 1090, 1020, and 957 cm^{-1}; NMR, δ 1.00, 1.59, and 2.05 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.95 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.21 and 5.39 (each 1H, br W_H=8 and 10 Hz, 2$\underline{H}$ at C_{17} and C_6). Found: C, 74.18; H, 8.63%. Calcd for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66%.

*Epoxidation of **16**.* (i) To a soln of **16** (100 mg) in dry benzene (10 ml) was added perbenzoic acid (50 mg, purity 95%), and the mixture was stirred at room temp for 30 min. After addition of 5% aq sodium thiosulfate, the mixture was concentrated and shaken with water and chloroform. The chloroform soln was washed with 5% aq sodium hydrogencarbonate and water, dried and evaporated to leave amorphous residue, which was separated by chromatography over silica gel (Merck, 4.0 g). Eluates with benzene-ether (3 : 1) gave a crystalline substance (4 mg), which was recrystallized from benzene to give 17α-hydroxy-12β,13β-epoxyetiojerv-5-en-3-one 3-ethylene acetal (**19**), mp 136—138 °C and $[\alpha]_D$ −63.8°; MS, *m/e* 346 (M+) and 328; IR, ν_{max} 3500, 1106, and 1022 cm^{-1}; NMR, δ 1.04 and 1.40 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.96 (5H, s, OC$\underline{H}_2$C$\underline{H}_2$O and $\underline{H}$ at C_{17}), and 5.36 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 72.48; H, 8.75%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

Eluates with benzene-ether (2 : 1) gave the 12α,13α-epoxy epimer (**18**, 75 mg), which was recrystallized for analysis from benzene-ether: mp 158—161 °C and $[\alpha]_D$ −57.0°; MS, *m/e* 346 (M+) and 328; IR, ν_{max} 3440, 1110, 1100, and 1035 cm^{-1}; NMR, δ 1.00 and 1.40 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.76 (1H, br W_H=28 Hz, $\underline{H}$ at C_{17}), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.38 (1H, br W_H=11 Hz, $\underline{H}$ at C_6). Found: C, 72.89; H, 8.74%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. Eluates with benzene-ether (1 : 1) afforded the 5β,6β,12α,13α-diepoxide (**20**, 10 mg), mp 123—125 °C (benzene-ether) and $[\alpha]_D$ −28.6°; MS, *m/e* 362 (M+) and 347; IR, ν_{max} 3460, 1100, 1040, and 957 cm^{-1}; NMR, δ 0.99 and 1.38 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.14 and 3.72 (each 1H, br W_H=5 and 24 Hz, 2$\underline{H}$ at C_6 and C_{17}), and 3.90 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O). Found: C. 69.44; H, 8.43%. Calcd for $C_{21}H_{30}O_5$: C, 69.58; H, 8.34%.

Compd **18** (300 mg) and **19** (10 mg) were treated with Ac_2O and Py (1.5 and 3 ml, and 0.15 and 0.3 ml) to give the respective acetates (**18a**, 276 mg and **19a**, 8 mg). Compd **18a**, mp 212—213 °C (acetone) and $[\alpha]_D$ −44.7°; MS, *m/e* 388 (M+) and 328; IR, ν_{max} 1737, 1240, 1107, 1092, and 1030 cm^{-1}; NMR, δ 1.00, 1.26, and 2.12 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.04 (1H, do d J=5 and 10 Hz, $\underline{H}$ at C_{17}), and 5.37 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 70.82; H, 8.31%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%. Compd **19a**, mp 142—144 °C (ether) and $[\alpha]_D$ −53.0°; MS, *m/e* 388 (M+) and 328; IR ($CHCl_3$), ν_{max} 1732, 1248, 1110, 1095, and 1025 cm^{-1}; NMR, δ 1.04, 1.29, and 2.06 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.04 and 5.37 (each 1H, br W_H=14 and 10 Hz, 2$\underline{H}$ at C_{17} and C_6). Found: C, 70.34; H, 8.83%. Calcd for $C_{23}H_{32}O_5$·

0.5 $(C_2H_5)_2O$: C, 70.56; H, 8.76%.

(ii) To a refluxing, green-colored soln of **16** (200 mg) in dry benzene (3 ml) containing bis(acetylacetonato)-oxovanadium(IV) (2.7 mg) was added rapidly *t*-butyl hydroperoxide (0.12 ml), when the soln became yellow-colored. The soln was then refluxed for 20 min and cooled. The reaction mixture was washed with 5% aq sodium hydrogensulfite, until the mixture became colorless, and then with water, dried and evaporated to leave a resinous material, which was purified by chromatography over silica gel (Merck, 8.0 g) to yield **18** (120 mg), mp 157—159 °C, from eluates with benzene–ether (1 : 2). This was identical with the afore-mentioned sample.

*12α,13α-Epoxyetiojerv-4-ene-3,17-dione 3-Ethylene Acetal (**21**).* (i) A soln of **15** (200 mg) in methanol (14 ml), containing 4 M aq sodium hydroxide (0.4 ml) and 30% aq hydrogen peroxide (0.8 ml), was allowed to stand in a refrigerator for 3 d. The reaction mixture was concentrated and shaken with water and chloroform, and the chloroform soln was washed with 5% aq sodium thiosulfate and water, dried and evaporated to give amorphous residue, which was purified by chromatography over silica gel (Merck, 7.0 g). Eluates with benzene–ether (2 : 1) gave a crystalline substance, which was recrystallized from benzene–ether to give **21** (180 mg), mp 139—140 °C and $[\alpha]_D$ −67.1°; ORD (dioxane), $[\Phi]_{326}^{trough}$ −5600°, $[\Phi]_{280}^{peak}$ +6300°, $a=-119°$; MS, *m/e* 344 (M^+); IR, ν_{max} 1712, 1211, 1117, 1102, 1032, 974, and 943 cm^{-1}; NMR, δ 1.00 and 1.34 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.38 (1H, br W_H= 10 Hz, $\underline{H}$ at C_6). Found: C, 73.22; H, 8.25%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

(ii) A soln of **18** (50 mg) in Py (2 ml) was mixed with a suspended mixture of chromium(VI) oxide (0.5 g) in Py (5 ml), and then stirred at room temp for 5 h. The reaction mixture was filtered through Florisil (3.0 g), which was washed with ether. The filtrate was diluted with water and extracted with ether. The ether soln and ether washings were combined and worked up as usual to give **21** (45 mg), mp 139—142 °C (ether), which was identical with the aforementioned sample.

*Reduction of **21** with Sodium Borohydride.* A soln of **21** (330 mg) in methanol (38 ml) was treated with sodium borohydride (660 mg) at room temp for 20 min. The reaction mixture was worked up as usual to give a mixture of alcohols, which was separated into two fractions by chromatography over silica gel (Merck, 10 g). A less-polar fraction eluted with benzene–ether (2 : 1) gave 12α,13α-epoxyetiojerv-5-en-17β-ol-3-one 3-ethylene acetal (**22**, 82 mg), mp 144—146 °C (benzene) and $[\alpha]_D$ −63.1°; MS, *m/e* 346 (M^+) and 328; IR, ν_{max} 3480, 1120, 1103, 1033, 1003, and 970 cm^{-1}; NMR, δ 1.00 and 1.38 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.94 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 4.06 and 5.37 (each 1H, br W_H=7 and 10 Hz, 2H at C_{17} and C_6). Found: C, 73.03; H, 8.76%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. A more-polar fraction eluted with benzene–ether (1 : 1 and 1 : 2) gave 17α-alcohol (**18**, 215 mg), mp 159—162 °C (benzene), which was identical with the sample described above.

Compd **22** (45 mg) was treated with Ac_2O (0.5 ml) and Py (1.0 ml) to give 17-acetate (**22a**, 45 mg), mp 144—147 °C (ether) and $[\alpha]_D$ −39.7°; MS, *m/e* 388 (M^+) and 328; IR, ν_{max} 1742, 1237, 1098, 1028, 1010, and 968 cm^{-1}; NMR, δ 1.02, 1.26, and 2.09 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.93 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.16 and 5.34 (each 1H, br W_H=6 and 10 Hz, 2H at C_{17} and C_6). Found: C, 71.33; H, 8.20%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%.

*Epoxidation of **17**.* Compd **17** (80 mg) was oxidized with *t*-butyl hydroperoxide (0.05 ml) in the presence of bis(acetylacetonato)oxovanadium(IV) (2 mg) under reflux for 20 min. The reaction mixture was worked up as described before to yield 12β,13β-epoxyetiojerv-5-en-17β-ol-3-one 3-ethylene acetal (**23**, 55 mg), mp 130—132° C (ether) and $[\alpha]_D$ −58.4°; MS, *m/e* 346 (M^+) and 328; IR ($CHCl_3$), ν_{max} 3570, 1110, 1062, 1024, 990, and 972 cm^{-1};NMR, δ 1.04 and 1.45 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.81 (1H, br W_H=12 Hz, $\underline{H}$ at C_{17}), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), and 5.40 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 72.48; H, 8.75%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

Compd **23** (14 mg) was treated with Ac_2O (0.15 ml) and Py (0.3 ml) to give 17-acetate (**23a**, 11 mg), mp 132—135 °C (ether) and $[\alpha]_D$ −38.0°; MS, *m/e* 388 (M^+), 360, 345, and 328 cm^{-1}; IR ($CHCl_3$), ν_{max} 1733, 1245, 1110, 1090, 1025, and 973 cm^{-1}; NMR, δ 1.06, 1.37, and 2.14 (each 3H, s, 19- and 18-C$\underline{H}_3$, and OCOC$\underline{H}_3$), 3.98 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O), 5.14 and 5.40 (each 1H, br W_H=12 and 10 Hz, 2H at C_{17} and C_6). Found: C, 70.68; H, 7.99%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%.

*12β,13β-Epoxyetiojerv-5-ene-3,17-dione 3-Ethylene Acetal (**24**).* Compd **23** (30 mg) in Py (2 ml) was oxidized with chromium (VI) oxide (0.35 g) in Py (3.5 ml) at room temp for 4 h. The reaction mixture was worked up as usual to give an amorphous substance, which was purified by preparative TLC over silica gel (Wakogel B-5, 3 plates) with benzene–ether (2 : 1) to give **24** (24 mg), mp 184—186 °C (ether) and $[\alpha]_D$ −13.4°; ORD (dioxane), $[\Phi]_{280}^{trough}$ −8500°, $[\Phi]_{324}^{peak}$ +4000°, a=+125°; MS, *m/e* 344 (M^+); IR ($CHCl_3$), ν_{max} 1706, 1230, 1110, 1090, and 1028 cm^{-1}; NMR, δ 1.10 and 1.42 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.96 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$-O), and 5.39 (1H, br W_H=10 Hz, $\underline{H}$ at C_6). Found: C, 72.89; H, 8.45%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.15%.

*Reduction of **24** with Sodium Borohydride.* Compd **24** (18 mg) was treated with sodium borohyride (36 mg) in methanol (4 ml) at room temp for 30 min. The reaction mixture was worked up as described before to give amorphous residue, which was separated into two fractions by preparative TLC over silica gel (Wakogel B-5, 2 plates) with benzene–ether (5 : 1). Less and more polar fractions gave **23** (9 mg), mp 133—135 °C (ether) and **19** (7 mg), mp 136—138 °C (diisopropyl ether), respectively, which were identical with the corresponding authentic sample.

*3β-Hydroxy-12α,13α-epoxyetiojerv-5-en-17-one (**25**).* A soln of **9** (295 mg) in methanol (28 ml) was mixed with 30% aq hydrogen peroxide (1.64 ml) in 4 M aq sodium hydroxide (0.84 ml), and then allowed to stand in a refrigerator (5 °C) for 46 h. The reaction mixture was concentrated, diluted with water, and extracted with chloroform. The chloroform soln was worked up as usual to leave amorphous residue (249 mg), showing a single spot, which on trituration with acetone crystallized, and was then recrystallized from acetone to give **25** (177 mg), mp 173.5—175 °C and $[\alpha]_D$ −92.3°; ORD (dioxane), $[\Phi]_{326}^{trough}$ −5530°, $[\Phi]_{280}^{peak}$ +4410°, $a=-99.4°$; MS, *m/e* 302 (M^+), 284, and 269; IR, ν_{max} 3480, 1703, and 1062 cm^{-1}; NMR, δ 1.02 and 1.37 (each 3H, s, 19- and 18-C$\underline{H}_3$), 3.59 and 5.43 (each 1H, br W_H=24 and 10 Hz, 2H at C_3 and C_6). Found: C, 75.23; H, 8.61%. Calcd for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67%.

12,13-Epoxy-*C*-nor-*D*-homosteroids. IV.[1] The Reaction of 11-Oxygenated 17α-Acetyl-12α,13α-epoxyetiojervanes with Boron Trifluoride Etherate[2]

Akio MURAI, Hiroshi SASAMORI, and Tadashi MASAMUNE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received July 10, 1976)

The titled compounds were treated with boron trifluoride etherate in benzene at room temperature. 11α-Hydroxy-12α,13α-epoxide (**1**) underwent rapid cleavage of the epoxy ring at both C_{13} and C_{12} to give 11α-hydroxy-13β-fluoro-12α-alcohol (**2**), 13α-hydroxy-12βH-11-ketone (**3**), 17-deacetyl-Δ^{12}-11-ketone (**4**), and an acetophenone derivative (**5**) in comparative yields. The same acid treatment of 11α-acetoxy-12α,13α-epoxide (**1a**) yielded 11α-acetoxy-13β-fluoro-12α-alcohol (**2a**) as a single isolable product, while that of 11-unsubstituted 12α,13α-epoxide (**16**) afforded 12β-fluoro-13α-alcohol (**17**) besides **5**, a major product. Evidently, compounds **2a** and **17** are products formed by the epoxy ring opening at C_{13} and C_{12}, respectively. Interestingly, compounds **2** and **2a**, when treated with bases, produced a rearranged 13α-pregnane derivative (**12**) *via* 11α,12α-dihydroxy-$\Delta^{13(17)}$-20-ketone (**10**), in good yields. On the other hand, the epoxy cleavage of 11-oxo-12α,13α-epoxide (**13**) led to predominant formation of rearranged products, bicyclo[3.3.1]nonane-2,9-dione and hydrooxepin derivatives (**14** and **15**). It is emphasized that the epoxy cleavage reactions proceeded more slowly and took place at C_{13} rather than at C_{12} with increase of electronegativity of the 11-substituents.

In the previous paper[3] we reported the synthesis and stereochemistry of 17α-acetyl-12,13-epoxyetiojervanes. As a continuing study aimed at the preparation of biologically active normal steroids from jervine, we have examined reactions of several 11-oxygenated 17α-acetyl-12α,13α-epoxyetiojervanes with boron trifluoride etherate, keeping in mind the Coxon and coworkers' result, a low yield of formation of hecogenin acetate by the acid treatment of the corresponding 12α,13α-epoxy-*C*-nor-*D*-homospirostan.[4] Contrary to the expectation, the reactions have not led to the desirable rearrangement but have resulted in formation of many compounds including interesting rearranged products such as bicyclo[3.3.1]nonane-2,9-dione and hydrooxepin derivatives.[5]

Treatment of 17α-acetyl-12α,13α-epoxyetiojerv-4-en-11α-ol-3-one (**1**), the most readily available 12,13-epoxides, with boron trifluoride etherate in benzene at room temperature for 30 s afforded a multi-component mixture, from which four compounds (**2**—**5**) were isolated after careful chromatography in 20, 10, 10, and 11% yields, respectively. The major product (**2**), mp 153—155 °C, was assigned structure **2** on the following evidence. The mass [*m/e* 364 (M^+), 346, 345, 344, 326 (M^+-HF-H_2O), and 301 ($M^+-HF-COCH_3$)] and NMR spectra [δ 2.37 (3H, s, 21-C$\underline{H}_3$), 3.34 (2H, br W_H=28 Hz, $\underline{H}$ at C_{17} and O$\underline{H}$) and 5.96 (1H, s, O$\underline{H}$)] revealed the presence of one fluorine atom, one acetyl (at C_{17}) and two hydroxyl groups. These spectra, as coupled with the UV [λ_{max} 239 nm (ε 10000)] and IR spectral data (ν_{max} 1703 cm^{-1}), indicated that the A ring and 17-side chain remained unchanged. The NMR spectrum also exhibited two three-proton singlets due to the 19- and 18-methyl protons at δ 1.26 and 1.50, a one-proton singlet ($\underline{H}$ at C_4) at δ 5.76 and also one doublet (J=8 Hz) due to a proton on the carbon atom (at C_{11}) bearing the hydroxyl group at δ 4.02. Compound **2**, when acetylated with acetic anhydride at room temperature and also oxidized with the Jones reagent, was converted into the corresponding monoacetate and hydroxy ketone (**2a** and **6**), mp 140—142 and 188—190 °C, in 95 and 85% yields, respectively. The latter (**6**) displayed a strong absorption maximum at 1753 cm^{-1} in the IR spectrum, proving that the secondary hydroxyl group in question existed in a five-membered C ring. These facts were consistent with the assigned formula (**2**) and also with an alternate formula (**2'**). Compound **2** was then treated with periodic acid in aqueous dioxane at room temperature for 18 h, when one mole of the acid had been consumed. The resulting single product, mp 128—130 °C, isolated in a 75% yield, was formulated as lactol (**7**) rather than keto aldehyde (**8**) on the spectral data (Exp). Moreover, compound **2** readily formed the corresponding acetonide (**9**), oil, by treatment with acetone and acid ($HClO_4$) at room temperature in a quantitative yield. All these results indicate that the compound is represented by structure **2** with a *cis*-glycol partial formula, excluding the alternate structure (**2'**), and also establish the previously assigned 12α,13α-epoxy configuration to the starting epoxide (**1**).

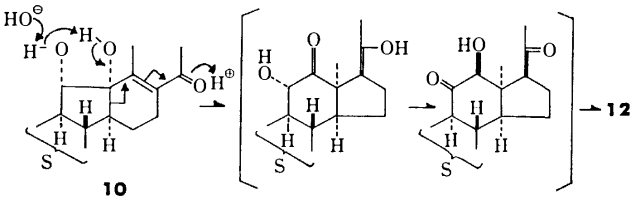
7 **8** **9**

The configuration of the fluorine atom at C_{13} was deduced from analogous examples[4,6] as well as consideration of the 11-carbonyl frequency of hydroxy ketone (**6**) as discussed below. The relevant absorption maximum was observed at a higher wave number (ν_{max} 1753 cm^{-1}) than that (ν_{max} *ca.* 1735 cm^{-1}) of usual 11-oxo-12α-etiojervanes without any substituent at C_{12}. The Dreiding model indicates that the D ring of **6** would probably adopt a half-chair or a twist-boat (bowsprit and flagpole at C_{14} and C_{17}) conformation with both the 17α-acetyl and 13β-fluoro substituents pseudo-equatorial. If the D ring assumes another twist-boat form (bowsprit-flagpole at C_{13} and C_{15}), the pseudo-equatorial 17α-acetyl group would readily form hydrogen-bonding with the 12α-hydroxyl group and show the absorption maximum at a lower wave number than at the observed (ν_{max} 1715 cm^{-1}). With either one of the afore-mentioned conformations with the fluorine atom pseudo-equatorial, the carbon-fluorine and 11-carbonyl bonds were located to be 1,3-diaxial-like and hence the carbonyl absorption would be susceptible to hypsochromic effect owing to the nearby dipole (C–F bond). Furthermore the 12α-hydroxyl group was disposed almost perpendicular to the 11-carbonyl bond and would exert no influence on the frequency in question. This presumption is reasonable and supports the above β-assignment to the fluorine atom. Here we emphasize that fluorohydrin (**2**) would result from a nucleophilic attack of a fluoride anion, probably contained in the reagent,[6b] to the epoxy ring at C_{13}.

11α-Hydroxy-fluorohydrin (**2**) was then treated with potassium carbonate in aqueous methanol at room temperature for 1 h. Contrary to the expectation that the starting epoxide (**1**) would be regenerated, compound **2** underwent dehydrofluorination to give $\Delta^{13(17)}$-20-ketone (**10**), mp 173—174 °C, in a quantitative yield, which on treatment with acetone and acid ($HClO_4$) formed the corresponding acetonide (**11**), oil, in a good yield. The latter (**11**) was also obtained by treatment of acetonide **9** with potassium carbonate under the same conditions as mentioned above. In accordance with the assigned structures, compound **10** exhibited an absorption maximum at 245 nm (ε 17000) and two three-proton singlets due to the 19- and 18-methyl protons at δ 1.20 and 1.87 in the UV and NMR spectra, and compound **11** showed absorption maxima at 1383 and 1372 cm^{-1} and two three-proton singlets due to the acetonide methyl protons at δ 1.50 and 1.56 in the IR and NMR spectra. However, prolonged treatment of fluorohydrin **2** or the α,β-unsaturated ketone (**10**) with the base (K_2CO_3) afforded a new compound (**12**), mp 164—166 °C, in low yields (7—28%) along with the unsaturated ketone (**10**). This new nompound could be obtained from the starting fluorohydrin (**2**), $\Delta^{13(17)}$-20-ketone (**10**) and also 11-acetoxy-fluorohydrin (**2a**) by treatment with potassium hydroxide in ethanol at room temperature for *ca.* 2 h in quantitative yields.

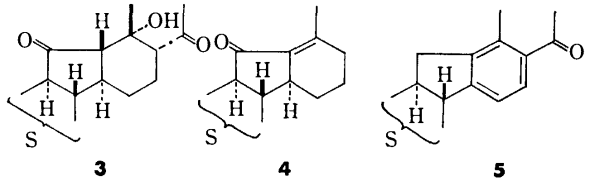
Compound **12** had the same molecular formula $C_{21}H_{28}O_4$ as the α,β-unsaturated ketone (**10**). The mass spectrum suggested the presence of hydroxyl and acetyl groups at *m/e* 344 (M^+), 326 (M^+-H_2O), 311, and 301 (base, M^+-COCH_3). However, the NMR spectrum exhibited three three-proton singlets at δ 1.25, 1.37, and 1.60, the former two singlets being assignable to the 19- and probably 18-methyl protons but the last (δ 1.60) being not attributed to the acetyl methyl protons. This singlet would be ascribed to methyl protons of a partial formula CH_3-(C)(OH)-O-,[7] in which (C) denotes a quarternary carbon. The IR spectrum displayed three absorption maxima at 1714, 1665, and 1614 cm^{-1} in the double bond region and also due to (a) hydroxyl group(s) at 3600 and 3440 cm^{-1}. The above two absorptions (1665 and 1614 cm^{-1}) revealed the existence of the Δ^4-3-carbonyl system, which was supported by the UV [λ_{max} 237 nm (ε 10000)] and NMR spectra [δ 5.69 (1H, s, H at C_4)]. Hence, the remaining oxygen atom would have to constitute a carbonyl group (ν_{max} 1714 cm^{-1}) on a straight chain or a six-membered ring. Moreover, a one-proton singlet was observed at a low field (δ 4.33), which was ascribed to a proton on the carbon atom flanked by a carbonyl group and an oxygen atom. These facts, combined with the chemical shift (δ 1.25 or 1.37) of the 19-methyl protons, indicate that the compound is represented most favorably by the 13α-pregnane formula (**12**) with an oxo group at C_{11} and a hemi-acetal group formed by the 12-hydroxyl and 17-acetyl groups. Presumably, formation of the 13α-pregnane (**12**) (Scheme 1) would take place *via* (i) intramolecular Michael addition of a carbanion at C_{14}, generated by cleavage of the bond at C_{12}–C_{14}, into a partially positive β-carbon at C_{13} of the α,β-unsaturated carbonyl system ($\Delta^{13(17)}$-20-one) and (ii) subsequent tautomerization at C_{11} and C_{12} as well as epimerization at C_{17} of the resulting 13α-pregnane derivative (iii) followed by conversion into the hemi-acetal structure.



Scheme 1. Pathway for formation of 13α-pregnane (**12**).

The second product (**3**) mp 175.0—176.5 °C, had the same molecular formula $C_{21}H_{28}O_4$ as the starting epoxide (**1**) and was formulated as structure **3**. In good accord with the structure, the IR spectrum revealed the presence of five-membered carbonyl and hydroxyl groups at 1732 and 3480 cm^{-1}, and the NMR spectrum showed two three-proton singlets at δ 1.20 and 1.58, which could be attributed to the 19- and 18-methyl protons. These chemical shifts indicate that the hydroxyl group is attached to the carbon at C_{13},

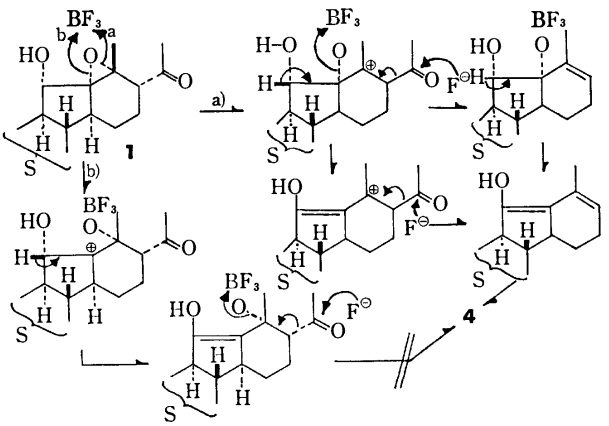
and also that the C and D rings are *trans*-fused (12βH) (19-CH_3, δ_{obsd} 1.20; δ_{calc} 1.21 for 12βH, and 1.26 for 12αH).[8] In view of the fact that the corresponding 12-epimer (12αH) was not isolated, compound **3** would probably be formed by cleavage of the epoxide ring at C_{12} with concomitant hydride shift of the β-oriented hydrogen at C_{11} to the carbon atom at C_{12}.



3 **4** **5**

The third product (**4**), mp 112—115 °C, had a molecular formula of $C_{19}H_{24}O_2$, indicative of elimination of a $C_2H_4O_2$ (CH_3CO+OH) moiety from the starting epoxide (**1**) and was assigned formula **4**. Removal of the 17-acetyl group was revealed by the absence of a three-proton singlet near δ 2.3 in the NMR spectrum. The UV and IR specta [λ_{max} 247 nm (ε 13000), and ν_{max} 1708 and 1639 cm^{-1}] showed the presence of a new α,β-unsaturated carbonyl group (Δ^{12}-11-one) besides the Δ^4-3-carbonyl system (ν_{max} 1668 and 1639 cm^{-1}). This was confirmed by appearance of two three-proton singlets due to 19- and 18-methyl protons at δ 1.24 and 2.15 as well as a one-proton singlet (H at C_4) at δ 5.77 in the NMR spectrum. This compound (**4**) was also produced by treatment of hydroxy ketone (**3**) with base (KOH) in refluxing methanol though in a low yield. The transformation of hydroxy ketone (**3**) into Δ^{12}-11-ketone (**4**) evidently takes place by retro-aldol reaction, initiated by attack of hydroxide ion to the acetyl carbonyl group, and subsequent migration of the resulting double bond (at C_{13}–C_{17}). On the other hand, the α,β-unsaturated ketone (**4**) was *not* obtained by the boron trifluoride treatment (including work-up) of hydroxy ketone (**3**) under the same conditions as those for formation of the compround (**4**) from epoxide **1**. Probably, formation of compound **4** would be formed by initial cleavage of the epoxy ring at C_{13} followed by degradation of the resulting cationic glycol *via* several pathways as shown in Scheme 2.

The fourth product (**5**), mp 143—145 °C, was assigned reasonably a substituted acetophenone structure



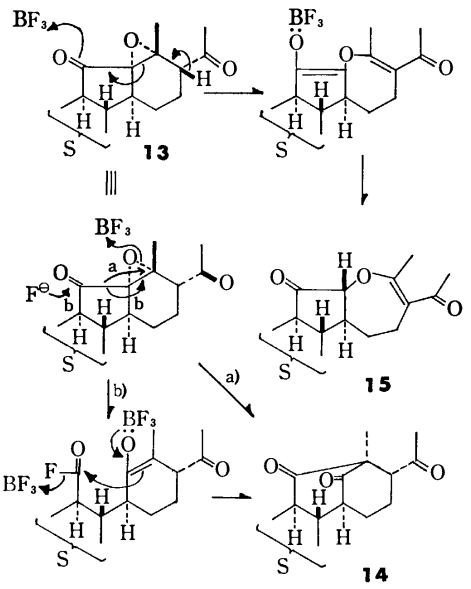
Scheme 2. Pathway for formation of Δ^{12}-11-ketone (**4**).

(**5**) on the basis of the spectral data (Exp). We only mention that the chemical shift (δ 1.32) of 19-methyl protons was in good accord with that of the corresponding veratramine derivatives.[9]

11α-Acetoxy-12α,13α-epoxide (**1a**), 11-acetate of 11α-alcohol **1**, was similarly treated with boron trifluoride etherate in benzene at room temperature. The reaction proceeded slowly and afforded fluorohydrin, as an only isolable product in a 60% yield, after 15 min, when the starting epoxide (**1a**) was recovered unchanged in a 10% yield. The sole product, mp 143—145 °C, was identified as 11-acetate (**2a**) of the 11α-hydroxy-fluorohydrin (**2**) as described before. It should be noted that no product, considered to be formed by initial cleavage of the epoxy ring at C_{12}, was isolated, when the starting epoxide passed from 11α-alcohol (**1**) to 11α-acetate (**1a**).

11-Oxo-12α,13α-epoxide (**13**) was then treated with excess of the Lewis acid under almost the same conditions as mentioned above. The epoxide cleavage proceeded only slowly and, after 140 min, gave a complex mixture, from which three compounds (**6**, **14**, and **15**) were isolated by column chromatogrphy in 25, 20, and 20% yields, respectively. The first product, mp 190.5—191.5 °C, was identified as 11-oxo-fluorohydrin (**6**). The second product (**14**), mp 227—228 °C, had the same molecular formula $C_{21}H_{26}O_4$ as the starting epoxide (**13**). The mass [*m/e* 342 (M^+) and 299(M^+ $-COCH_3$)], UV [λ_{max} 234 nm (ε 14000)], IR [ν_{max} 1667 and 1619 cm^{-1}], and NMR spectra [δ 2.19 (3H, s, 21-CH_3) and 5.72 (1H, s, H at C_4)] indicated that the 17-acetyl and Δ^4-3-carbonyl groups were left unchanged. In view of the absence of a hydroxyl group (no absorption near 3400 cm^{-1}), the remaining two oxygen atoms would have to exist as two carbonyl groups, which were observed as two absorption bands at 1742 and 1716 cm^{-1}, the latter being overlapping with that of the acetyl carbonyl group. The mass spectrum [*m/e* 271 (M^+-CH_3CO-CO)] suggested that one of the two carbonyl groups would be readily removable. The NMR spectrum also exhibited two three-proton singlets due to the 19- and 18-methyl protons at relatively low fields (δ 1.07 and 1.48) as well as a broad one-proton signal (W_H=8 Hz) at δ 3.54 besides that (20 Hz) due to the 17β-proton at δ 3.18. The signal (δ 3.54) would be attributed to a proton on the carbon atom (C_{14}) adjacent to the carbonyl group. All these spectral data revealed the presence of a bicyclo[3.3.1]nonane-2,9-dione[10] moiety and hence the compound was formulated most favorably as structure **14**.

The third product, mp 198—200 °C, also had the same molecular formula $C_{21}H_{26}O_4$ as the starting epoxide (**13**) and was assigned formual **15** on the basis of the following spectral data. The UV spectrum [λ_{max} 245 nm (ε 14000)] showed that an α,β-unsaturated carbonyl or an analogous system was newly formed besides the original Δ^4-3-carbonyl group [δ 5.78 (1H, s, H at C_4)]. The mass spectrum, unlike those of other 17-acetyletiojervanes, displayed a fragmentation peak caused by removal of a CH_2CO moiety at *m/e* 300 instead of that (M^+-CH_3CO) at *m/e* 299, but the NMR spectrum still exhibited a six-proton

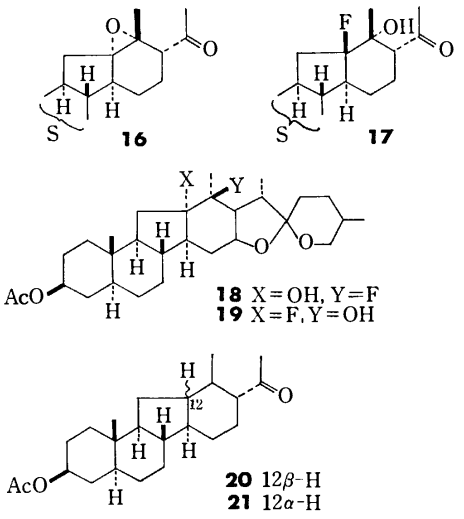


Scheme 3. Pathway for formation of compounds **14** and **15**.

singlet at δ 2.10, which was assignable to the 18-methyl and acetyl-methyl protons. The IR spectrum revealed the presence of two carbonyl groups, besides the Δ^4-3-carbonyl group (ν_{max} 1674 and 1618 cm^{-1}), at higher wave numbers (ν_{max} 1750 and 1714 cm^{-1}) as compared with those of five-membered carbonyl and 17-acetyl groups of usual 17-acetyl-11-oxoetiojervanes (ν_{max} *ca.*, 1735 and 1705 cm^{-1}). These carbonyl absorptions, coupled with an absorption due to a vinyl ether at 1044 cm^{-1}, were ascribed to α-alkoxy five-membered carbonyl and vinylogous ester carbonyl groups, respectively. Moreover, a broad one-proton doublet (J =10 Hz) was observed at δ 5.42 along with a 19-methyl proton singlet at δ 1.23. The relevant low field peak could be assigned to a proton on the carbon atom flanked by a carbonyl group and an oxygen atom. These results indicated the existence of a partial formula O=C(at C_{11})-CH-O-C(CH_3)=C-C(=O)CH_3, which led to assignment of formula **15** to the compound.

The formation of these two compounds (**14** and **15**) was rationalized as described in Scheme 3.[11] While we have analogous precedents[12] regarding the novel elimination-rearrangement involving the C-C bond cleavage of an epoxide ring of the 11-oxo-12,13-epoxide (**13**) to give the seven-membered ether ring compound (**15**), the transformation of epoxide **13** into compound **14**, a rearrangement of α,β-epoxy-carbonyl system into a bicyclo[3.3.1]nonane-2,9-dione system under acidic conditions, is most noteworthy and would probably be the first example as for such rearrangements. It should be emphasized that all these products again resulted from cleavage of the epoxide ring at C_{13}, apart from that whether the respective reactions are concerted or step-wise.

The same treatment of 11-unsubstituted 12α,13α-epoxide (**16**) only for 30 s produced two compounds (**5** and **17**) in 60 and 12% yields, the starting epoxide (**16**) being not detected on TLC. The major product, mp 141—143 °C, was identified as acetophenone (**5**), and would be formed by cleavage of the epoxide ring at C_{13} and/or C_{12} followed by dehydration and dehydrogenation. The minor product (**17**) had a molecular formula of $C_{21}H_{29}O_3F$ and was assigned 12β-fluoro-13α-hydroxy structure (**17**) on the basis of the following facts. (i) The molecular formula and spectral data indicated product **17** to be a fluorohydrin formed by simple cleavage of the epoxy ring. (ii) The product (**17**) underwent no dehydrofluorination, the starting material being recovered unchanged, under the same basic (K_2CO_3) conditions as those under which 13β-fluoro-12α-alcohols (**2** and **2a**) were readily converted into $\Delta^{13(17)}$-20-ketone (**10**). (iii) 13β-Fluoro-12α-hydroxy-etiojervanes and *C*-nor-*D*-homospirostan[4] (**2**, **2a**, **6**, and **18**) exhibited signals due to the 18-methyl protons at δ 1.50, 1.58, 1.47, and 1.58, respectively, which 12α-fluoro-13β-hydroxy-*C*-nor-*D*-homospirostan[4] (**19**) and the product in question displayed the corresponding signals at higher fields, δ 1.27 and 1.29. Moreover, compounds **2**, **2a**, and **6** showed signals due to the protons at C_{17} near δ 3.30 (W_H= 24—20 Hz), δ 3.34, 3.30, and 3.27, respectively, while compound **17** displayed the 17-proton at δ 2.89 (W_H= 18 Hz). All these facts revealed that the substituent at C_{13} in product **17** was not a fluorine atom but a hydroxyl group, and hence the product (**17**) is represented favorably by structure **17**. This structure was also supported by the ORD curves; **17**, a=+90°; 17α-acetyl-12β-etiojervan-3β-ol 3-acetate[13] and its 12α-epimer[14] (**20** and **21**), a=+53° and +34°.[15] Compound **17** evidently resulted from the epoxide ring cleavage at C_{12}. In summary, we again emphasize that the epoxide opening reactions proceeded more slowly and took place at C_{13} rather than at C_{12} with increase of electronegativity of the 11-substituents.



Experimental

All the melting points were uncorrected. The homogenity of each compound was always checked by TLC on silica gel (Wakogel B-5) with various solvent systems, and the spots were developed with cerium(IV) sulfate in dil sulfuric acid and/or iodine. The optical rotations, UV, and IR spectra

were measured in chloroform, ethanol, and chloroform, respectively, unless otherwise stated. The NMR spectra were obtained in deuterochloroform at 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. The abbreviations "s, d, and br" in the NMR spectra denote "singlet, doublet, and broad", respectively.

*Treatment of 17α-Acetyl-12α,13α-epoxy-11α-hydroxyetiojerv-4-en-3-one (**1**) with Boron Trifluoride Etherate (BF_3).* A solution of **1** (900 mg) in anhydrous benzene (93 ml) was stirred with BF_3 (2 ml), freshly distilled over calcium hydride, at room temperature (temp.) for 30 s. The solution was mixed with ether (50 ml), washed with 5% aqueous sodium hydrogencarbonate ($NaHCO_3$) and water, dried over anhydrous sodium sulfate, and evaporated to leave amorphous residue (877 mg), which was chromatographed over silica gel (Merck 70—230 mesh, 26 g) with mixtures of benzene and ether. Benzene–ether (5 : 1) eluates gave etiojerva-4,12-diene-3,11-dione (**4**, 74 mg), mp 112—115 °C (from hexane–methanol) and $[\alpha]_D$ +97°; MS, *m/e* 284 (M^+) and 269; UV, IR, and NMR, in the text. Found: C, 79.98; H, 8.58%. Calcd for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51%.

Benzene–ether (3 : 1) eluates gave 17-acetyletiojerva-4,12,14,16-tetraen-3-one (**5**, 92 mg), mp 143—145 °C (from hexane–acetone) and $[\alpha]_D$ +148°; MS, *m/e* 308 (M^+), 293, and 265; UV, λ_{max} 295 nm (ε 4000) and 239 (13000); IR (Nujol), ν_{max} no OH, 1680—1650 (broad), and 1615 cm^{-1}; NMR, δ 1.32, 2.42, and 2.56 (each 3H, s, 19-, 18-, and 21-C<u>H</u>$_3$), and 5.85 (1H, s, <u>H</u> at C_4), 7.04 and 7.56 (each 1H, ABq J=8 Hz, 2<u>H</u> at C_{15} and C_{16}). Found: C, 81.55; H, 7.73%. Calcd for $C_{21}H_{24}O_2$: C, 81.78; H, 7.84%.

Benzene–ether (2 : 1) eluates afforded 17α-acetyl-13α-hydroxy-12β-etiojerv-4-ene-3,11-dione (**3**, 90 mg), mp 175.0—176.5 °C (from isopropyl ether–acetone) and $[\alpha]_D$ +26°; MS, *m/e* 344 (M^+), 326, and 301; UV (MeOH), λ_{max} 236 nm (ε 14,000); IR (Nujol), ν_{max} 3480, 1732, 1692, 1675, and 1610 cm^{-1}; NMR, δ 1.20, 1.58, and 2.25 (each 3H, s, 19-, 18-, and 21-C<u>H</u>$_3$), 4.01 (1H, s, O<u>H</u>), and 5.78 (1H, s, <u>H</u> at C_4). Found: C, 73.06; H, 8.27%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

Benzene–ether (1 : 1) eluates afforded 17α-acetyl-11α,12α-dihydroxy-13β-fluoro-13-epietiojerv-4-en-3-one (**2**, 180 mg), mp 153—155 °C (from ether) and $[\alpha]_D$ +38°; MS and UV (MeOH), in the text; IR (Nujol), ν_{max} 3400—3480 (broad), 1703, 1660, and 1610 cm^{-1}; NMR, in the text. Found: C, 69.53; H, 8.15%. Calcd for $C_{21}H_{29}O_4F$: C, 69.20; H, 8.02%.

Compound **3** (15 mg) was refluxed in methanol containing 5% potassium hydroxide. After being cooled, the mixture was made neutral with 10% aqueous acetic acid, evaporated and shaken with water and chloroform. The chloroform solution was washed with water, dried and evaporated to leave amorphous residue (13 mg), which was separated by preparative TLC over silica gel (Wakogel B-5F, one plate with 20×20 cm^2) with a 3 : 1 mixture of benzene and ether to yield **4** (4 mg), mp 112—114 °C. This was identical with the afore-mentioned sample in IR, NMR, and TLC.

*Treatment of 17α-Acetyl-12α,13α-epoxy-11α-hydroxyetiojerv-4-en-3-one 11-Acetate (**1a**) with BF_3.* A solution of **1a** (196 mg) in anhydrous benzene (18 ml) was stirred with BF_3 (0.4 ml) at room temp for 15 min. The reaction mixture was worked up as described above to leave amorphous residue (206 mg), showing one major and one minor spot, which was separated by chromatography over silica gel (7 g). The major fraction, eluted with benzene–ether (3 : 1) afforded 11-acetoxy-fluorohydrin (**2a**, 103 mg), mp 143—145 °C (from isopropyl ether–acetone) and $[\alpha]_D$ +75°; MS, *m/e* 406 (M^+), 388, 386, 346, 326, and 283; UV, λ_{max} 238 nm (ε 10000); IR, ν_{max} 3420, 1737, 1717, 1663, 1614, and 1243 cm^{-1}; NMR, δ 1.24, 1.58, 2.32, and 2.12 (each 3H, s, 19-, 18-, 21-C<u>H</u>$_3$, and OCOC<u>H</u>$_3$), 3.30 and 5.42 (each 1H, br W_H=24 and 12 Hz, 2<u>H</u> at C_{17} and C_{11}), 5.56 and 5.75 (each 1H, s, O<u>H</u> and <u>H</u> at C_4). The minor fraction, eluted with benzene–ether (1 : 1), gave acetate (20 mg), mp 198—200 °C (from ether), which was identified as the starting epoxide (**1a**) (IR, NMR, TLC, and mixed mp).

*Treatment of 17α-Acetyl-12α,13α-epoxyetiojerv-4-en-3,11-dione (**13**) with BF_3.* Compound **13** (180 mg) in benzene (20 ml) was treated with BF_3 (0.28 ml) at room temp for 140 min. The reaction mixture was worked up as mentioned above to leave amorphous residue (182 mg), which was separated into three fractions by preparative TLC over silica gel (Wakogel B-5F, 9 plates) with a 3 : 1 mixture of benzene and ether. A most mobile fraction gave a crystalline substance, which was recrystallized from isopropyl ether–acetone to yield a bicyclo[3.3.1]nonane-2,9-dione derivative (**14**, 35 mg), mp 227—228 °C and $[\alpha]_D$ +95°; MS, IR (Nujol), and NMR, in the text. Found: C, 73.26; H, 7.66%. Calcd for $C_{21}H_{26}O_4$: C, 73.66; H, 7.66%.

A middle fraction afforded 11-oxo-fluorohydrin (**6**, 47 mg), mp 190.5—191.5 °C (from isopropyl ether–acetone) and $[\alpha]_D$ +182°; MS, *m/e* 362 (M^+), 342, 319, and 299; UV, λ_{max} 234 nm (ε 12,000); IR, ν_{max} 3380, 1753, 1699, 1644, and 1615 cm^{-1}; NMR, δ 1.21, 1.47, and 2.33 (each 3H, s, 19-, 18-, and 21-C<u>H</u>$_3$), 3.24 (1H, br W_H=20 Hz, <u>H</u> at C_{17}), 5.72 and 5.77 (each 1H, s, O<u>H</u> and <u>H</u> at C_4). Found: C, 69.38; H, 7.58%. Calcd for $C_{21}H_{27}O_4F$: C, 69.62; H, 7.51%.

A least mobile fraction gave an oxepin derivative (**15**, 35 mg), mp 198—200 °C (from isopropyl ether) and $[\alpha]_D$ +160.5°; MS, *m/e* 342 (M^+), 300 ($M^+ - CH_2CO$), 282, and 267; UV, IR (Nujol), and NMR, in the text. Found: C, 73.36; H, 7.69%. Calcd for $C_{21}H_{26}O_4$: C, 73.66; H, 7.66%.

*Treatment of 17α-Acetyl-12α,13α-epoxyetiojerv-4-en-3-one (**16**) with BF_3.* Compound **16** (500 mg) in benzene (50 ml) was stirred with BF_3 (0.72 ml) at room temp for 30 s. The reaction mixture was worked up as usual to leave an amorphous material, which was separated into two fractions by chromatography over silica gel (Merck 70—230 mesh, 30 g) with benzene–ether mixtures. Eluates with benzene–ether (5 : 1) gave a crystalline substance (284 mg), mp 141—143 °C (from hexane–acetone), which was identical with acetophenone (**5**) in IR, NMR, TLC, and mixed mp. Eluates with benzene–ether (3 : 1) afforded 17α-acetyl-12β-fluoro-13α-hydroxyetiojerv-4-en-3-one (**17**, 66 mg), mp 157—159 °C (from ether) and $[\alpha]_D$ +83°; ORD, $[\Phi]_{306}^{peak}$ +4750°, $[\Phi]_{282}^{trough}$ −4250°, a=+90°; MS, *m/e* 348 (M^+), 333, 328, and 310; UV, λ_{max} 237 nm (ε 10000); IR, ν_{max} 3460, 1696, 1657, and 1616 cm^{-1}; NMR, δ 1.17, 1.25, and 2.26 (each 3H, s, 19-, 18-, and 21-C<u>H</u>$_3$), 2.89 (1H, br W_H= 18 Hz, <u>H</u> at C_{17}), 4.32 and 5.75 (each 1H, s, O<u>H</u> and <u>H</u> at C_4). Found: C, 72.19; H, 8.54%. Calcd for $C_{21}H_{29}O_3F$: C, 72.38; H, 8.39%.

*Oxidation of Fluorohydrin **2**.* (i) A solution of **2** (20 mg) in dry acetone (3 ml) was stirred with the Jones reagent (0.2 ml) for 2 h under cooling with ice. After addition of ethanol to decompose excess of the reagent, the solution was evaporated and shaken with water and chloroform. The chloroform solution was worked up as usual to leave a crystalline substance, showing a single spot, which was recrystallized from isopropyl ether–acetone to give 11-oxo-fluorohydrin (**6**, 16 mg), mp 188—190 °C, which was identical with the above-mentioned sample in IR, NMR, TLC, and mixed mp.

(ii) A solution of **2** (20 mg) in dioxane (1.5 ml) was stirred with periodic acid (50 mg as $HIO_4 \cdot 2H_2O$) in water (0.5 ml) at room temp for 18 h. The solution was diluted with water, extracted with chloroform, and the chloroform solution, after being worked up as usual, gave a crystalline material, showing a single spot. This was recrystallized from ether to give lactol (**7**, 14 mg), mp 128—130 °C; MS, *m/e* 362 (M^+), 347, and 342; IR, ν_{max} 3570, 3440, 1715, 1665, and 1615 cm^{-1}; NMR, δ 1.24, 1.33, and 2.26 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 3.70 (1H, s, O$\underline{H}$), 5.40 (1H, d J=8 Hz, $\underline{H}$ at C_{11}), and 5.73 (1H, s, $\underline{H}$ at C_4), and no absorption near δ 1.0.

*11-Acetate (**2a**) and 11,12-Acetonide (**9**) of Fluorohydrin **2**.* (i) Compound **2** (15 mg) was treated with acetic anhydride (0.15 ml) and pyridine (0.3 ml) at room temp for 24 h under stirring. The reaction mixture was worked up as usual to give **2a** (17 mg), mp 140—142 °C (from isopropyl ether–acetone), which was identical with the sample obtained from **1a** (IR, NMR, and mixed mp).

(ii) A solution of **2** (10 mg) in acetone (2 ml) was stirred with 60% aqueous perchloric acid (0.1 ml) for 1.5 h. The solution was made alkaline with 5% aqueous $NaHCO_3$, evaporated and extracted with chloroform. The chloroform solution, after being worked up as usual, gave acetonide (**9**), oil, showing a single spot on TLC; MS, *m/e* 405 (M^++1), 389, and 384; IR, ν_{max} 1715, 1664, 1614, 1384, and 1373 cm^{-1}; NMR, δ 1.23, 1.40, 1.53, and 2.26 (3H, 6H, 3H, and 3H, each s, 19-, 18-, and 21-C$\underline{H}_3$, and acetonide 2C$\underline{H}_3$ or *vice versa*), 4.71 (1H, br W_H=12 Hz, $\underline{H}$ at C_{11}), and 5.76 (1H, s, $\underline{H}$ at C_4).

*Alkali Treatment of 11-Hydroxy-fluorohydrin (**2**), Its 11-Acetate (**2a**), and Its 11,12-Acetonide (**9**).* (i) Compound **2a** (18 mg) was stirred with potassium carbonate (200 mg) in a mixture of methanol (6 ml) and water (2 ml) at room temp for 2 h under nitrogen. The reaction mixture, after being worked up as usual, left amorphous residue (17.5 mg), showing two spots, which was separated into two fractions by preparative TLC over silica gel (Wakogel B-5F, one plate). A less polar fraction gave a crystalline substance, which on recrystallization from hexane–acetone afforded $\Delta^{13(17)}$-20-ketone (**10**, 10 mg), mp 173—174 °C and $[\alpha]_D$ −26°; MS, *m/e* 344 (M^+), 326, 311, and 301; UV, in the text; IR, ν_{max} 3620, 3440, 1680 (shoulder), 1662, and 1613 cm^{-1}; NMR, δ 1.20, 1.87, and 2.29 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 3.32 (2H, br, s, 2O$\underline{H}$), 3.61 (1H, br W_H=15 Hz, $\underline{H}$ at C_{11}), and 5.78 (1H, s, $\underline{H}$ at C_4). Found: C, 72.89; H, 8.12%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%. A more polar fraction was identified as 13α-pregnane (**12**, 1 mg), by comparison with the sample described later (MS and TLC).

When compound **2a** (12.8 mg) was treated with the base under the same conditions for 1 h as mentioned above, the product (10 mg), mp 170—172 °C, showed a single spot and was identified as **10**.

Compound **10** (7.3 mg) was stirred with acetone (2 ml) containing perchloric acid (60%, 0.1 ml) at room temp for 1 h. The mixture was worked up as usual to leave oily residue, showing a single spot, which was purified by preparative TLC to yield acetonide (**11**, 8.0 mg), oil and $[\alpha]_D$ −43°; MS, *m/e* 384 (M^+), 369, and 326; UV, λ_{max} 241 nm (ε 16000); IR, ν_{max} no OH, 1664, 1615, 1383, and 1372 cm^{-1}; NMR, δ 1.16, 1.50, 1.56, 1.86 and 2.30 (each 3H, 19-, 18-, and 21-C$\underline{H}_3$, acetonide 2C$\underline{H}_3$, or *vice versa*), 4.18 (1H, d J= 8 Hz, $\underline{H}$ at C_{11}), and 5.80 (1H, s, $\underline{H}$ at C_4). This acetonide (**11**, 16 mg) was obtained by treatment of **9** (17 mg) with potassium carbonate.

(ii) A solution of **2a** (20 mg) in ethanol (5 ml) containing 5% potassium hydroxide was stirred at room temp for 100 min. The solution was made neutral with 10% aqueous acetic acid under cooling, evaporated below 40 °C, and shaken with water and chloroform. The chloroform solution was worked up as usual to leave an oily material, showing a single spot, which was purified by preparative TLC to give a 13α-pregnane derivative (**12**, 13 mg), mp 164—166 °C (isopropyl ether–acetone) and $[\alpha]_D$ +64°; MS, UV, IR, and NMR, in the text; NMR (C_5D_5N), δ 1.30, 1.58, and 1.74 (each 3H, s, 19-, 18-, and 21-C$\underline{H}_3$), 4.50 and 5.76 (each 1H, s, 2$\underline{H}$ at C_{12} and C_4).[16]

Found: C, 73.08; H, 8.12%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

Treatment of **2** (5.3 mg) and **10** (4.7 mg) with potassium hydroxide under almost the same conditions as mentioned above afforded **12** (5.0 and 4.7 mg, respectively), and that of **10** (9.7 mg) with potassium carbonate also gave **12** (2.7 mg) along with the starting material (**10**, 4.7 mg) after preparative TLC.

The Reactions of 1,3-Indandiones and 1,3(2*H*)-Phenalenediones with Lead Tetraacetate

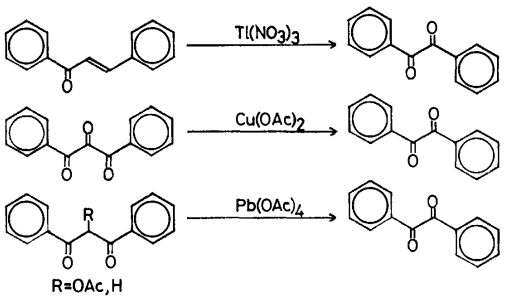
Keiichi Ezoe and Kazu Kurosawa

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860

(Received July 23, 1976)

The reaction of 1,3-indandione with lead tetraacetate gave phthalic anhydride and 2,2-diacetoxy-1,3-indandione. The reaction of 2,2-dihydroxy-1,3-indandione gave phthalic anhydride. The reactions of 1,3(2*H*)-phenalenedione and 2,3-dihydroxy-1-phenalenone yielded acenaphthenequinone and 1,8-naphthalenedicarboxylic anhydride. The reactions of acenaphthenequinone and 2,2-dihydroxy-1,3-phenalenedione gave 1,8-naphthalenedicarboxylic anhydride with higher yields. The reactions of [2-^{14}C]-labeled compounds showed that the middle carbon atom was lost.

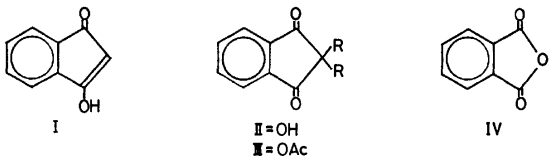
Mckillop and his co-workers[1] have reported that the reaction of chalcones with thallium(III) nitrate gave benzils with the loss of one carbon atom. Roberts *et al.*[2] reported that the decarbonylation of 1,3-diphenyl-1,2,3-propanetrione with cupric acetate in refluxing acetic acid yielded benzil with the loss of the center carbonyl group, as evidenced by the decarbonylation of the ^{14}C-labeled trione. Moriyama[3] also reported that the oxidation of 2-acetoxy-1,3-diphenyl-1,3-propanedione-2-^{14}C with lead tetraacetate gave inactive benzil and active carbon dioxide, again indicating that the middle carbon was lost. However, the oxidation of β-hydroxychalcone-α-^{14}C with lead tetraacetate gave radioactive benzil (the relative specific radioactivity was 0.53) and carbon dioxide (the relative specific radioactivity was 0.06 as barium carbonate), thus suggesting that binary reaction mechanisms may operate in this case. We therefore examined the reactions of 1,3-indandiones and 1,3(2*H*)-phenalenediones with lead tetraacetate, which are cyclic analogues to the 1,3-diphenyl-1,3-propanediones, in the hope of clarifying the reaction pathways.



Scheme 1.

Results

When 1,3-indandione (I)[4] was oxidized with lead tetraacetate in boiling benzene, two compounds (III-(7%) and IV(12%)) were obtained. The NMR spectrum of III ($C_{13}H_{10}O_6$; mp 174—175 °C) indicated the presence of two acetoxyl groups [δ 2.14(s, 6H)] and aromatic protons [δ 7.98 (m, 4H)]. The IR spectrum of this compound suggested the presence of two carbonyl groups [ν_{max} 1745 (CO) and 1765 cm^{-1} (OAc)]. These spectroscopic properties indicated that this product has the structure of 2,2-diacetoxy-1,3-indandione. The second compound (IV) was found to be phthalic anhydride, which was identified by comparison of its IR spectrum and its melting point with those of an authentic specimen.



The yields of III and IV were slightly improved by increasing the amount of lead tetraacetate. These results are shown in Table 1.

The reaction of 2,2-dihydroxy-1,3-indandione (II)[5] with lead tetraacetate in boiling benzene gave only IV (43%).

The reaction of 1,3(2*H*)-phenalenedione (VI)[6] with lead tetraacetate in various molar ratios in boiling acetic acid gave two products (IX, mp 272—273 °C and X, mp 259—260 °C). IX and X were shown to be 1,8-naphthalenedicarboxylic anhydride and acenaphthenequinone respectively, by comparison of their melting points and their IR spectra with those of authentic specimens.

When 2,3-dihydroxy-1-phenalenone (VIII)[6] was oxidized with one equivalent of lead tetraacetate in boiling acetic acid, two compounds (IX and X) were obtained. However, when VIII was oxidized with three equivalents of lead tetraacetate, only IX was obtained.

The reaction of 2,2-dihydroxy-1,3-phenalenedione (VII)[7] with lead tetraacetate in boiling acetic acid gave IX as the sole product.

Table 1. Oxidations of 1,3-indandione (I) and 2,2-dihydroxy-1,3-indandione (II) with lead tetraacetate in boiling benzene

Compound	Reaction conditions: Molar ratio	Reaction conditions: Time (min)	Products: (Isolated yield, %) III	IV	CO_2

a) Not measured.

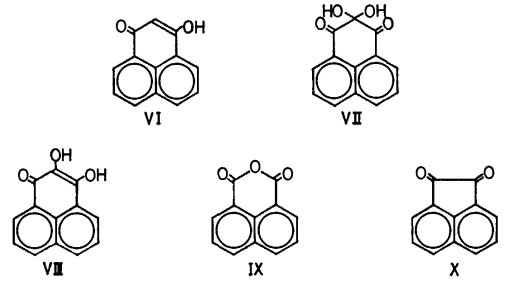
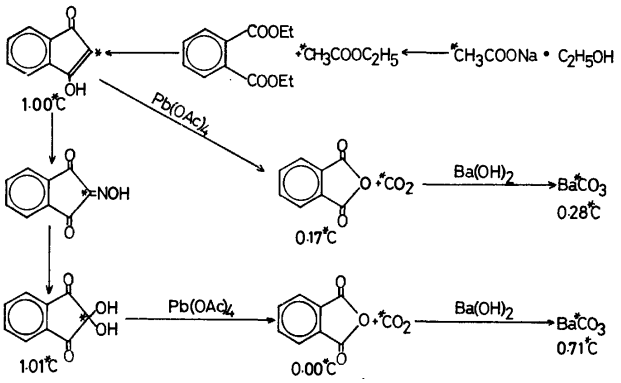
The oxidation of acenaphthenequinone with one equivalent of lead tetraacetate in boiling acetic acid gave IX (70%) after 20 min. The yields of the products obtained by the above reactions are summarized in Table 2.

In order to establish the nature of the decarbonylation reaction, the reactions were repeated using [2-^{14}C]-labeled compounds, *i.e.*, [2-^{14}C]-I, [2-^{14}C]-II, [2-^{14}C]-VI, [2-^{14}C]-VII, and [2-^{14}C]-VIII. The results are summarized in Schemes 2 and 3.

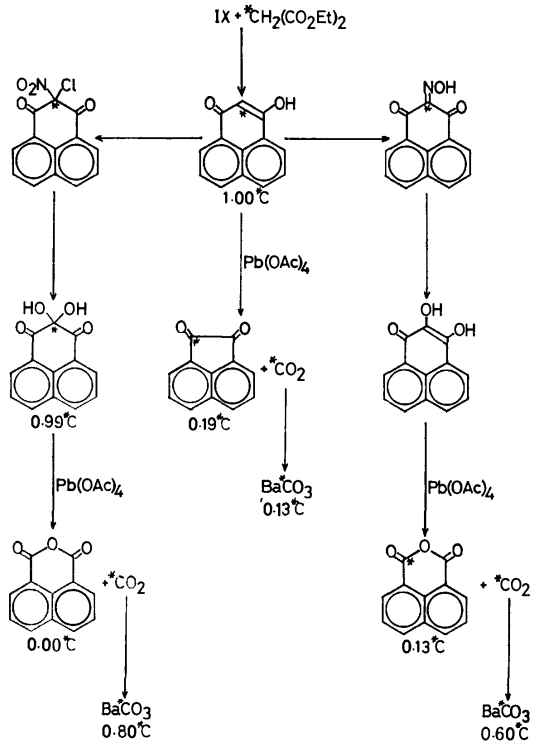


1,3-Indandione-2-^{14}C was synthesized by the reaction of diethyl phthalate with ethyl acetate-2-^{14}C. When 1,3-indandione-2-^{14}C was oxidized with lead tetraacetate, radioactive IV (the relative specific radioactivity was 0.17) and carbon dioxide (the relative specific radioactivity was 0.28 as barium carbonate) were obtained. On the other hand, the oxidation of 2,2-dihydroxy-1,3-indandione-2-^{14}C gave inactive IV and active carbon dioxide (the relative specific radioactivity was 0.71 as barium carbonate) (Scheme 2).

1,3(2*H*)-Phenalenedione-2-^{14}C was synthesized by the reaction of 1,8-naphthalenedicarboxylic anhydride with diethyl malonate-2-^{14}C. When 1,3(2*H*)-phenalenedione-2-^{14}C was oxidized with lead tetraacetate, radioactive X (the relative specific radioactivity was 0.19) and carbon dioxide (the relative specific radioactivity was 0.13 as barium carbonate) were obtained. When 2,3-dihydroxy-1-phenalenone-2-^{14}C was oxidized with lead tetraacetate, radioactive IX (the relative specific radioactivity was 0.13) and carbon dioxide the relative specific radioactivity was 0,60 as barium carbonate) were obtained. The oxidation of 2,2-dihydroxy-1,3-phenalenedione-2-^{14}C gave inactive IX and active carbon dioxide (the relative specific radiocativity was 0.80) (Scheme 3).



Scheme 2. Synthesis and decarbonylation reactions of 1,3-indandiones[2-^{14}C] (the figures under the formulae refer to the specific activities of the compounds relative to 1,3-indandione).



Scheme 3. Synthesis and decarbonylation reactions of 1,3(2*H*)-phenalenediones[2-^{14}C] (the figures under the formulae refer to the specific activities of the compounds relative to 1,3(2*H*)-phenalenedione).

Discussion

The conversion of I to III can readily be explained in terms of successive acetoxylations at the α-carbon adjacent to the carbonyl group. The conversion of I to IV involves the loss of 83% of C(2), suggesting that there may be binary reaction pathways.

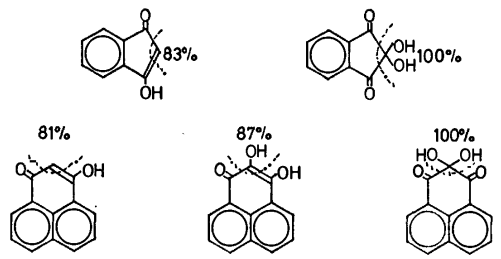
In the case of the reaction of II with lead tetraacetate, the yield of IV was increased by increasing the molar

ratio of the oxidant. From the tracer experiment, it was shown that the decarbonylation of C(2) is involved in the oxidation of II with lead tetraacetate, as indicated by the complete loss of the radioactivity.

When VI was oxidized with lead tetraacetate, the yield of X was decreased by increasing the molar ratio of the oxidant. It seems that X is an intermediate, as the oxidation of X with one equivalent of lead tetraacetate gave IX in better yield (70%). However a longer reaction time (20 min) was needed to consume the lead tetraacetate than in the case of VI. Therefore, we must eliminate the possibility that the reaction proceeds *via* X. The experiment on the ^{14}C-labeled compound showed that the reaction pathway involved the decarbonylation of C(2) atoms by 81%.

The oxidation of VIII with one equivalent of lead tetraacetate gave both IX and X, but that with three equivalents of lead tetraacetate gave only IX (62%). The experiment on the ^{14}C-labeled compound again indicated that the decarbonylation of C(2) was involved by 87% in this case.

The oxidation of VII gave IX (68%) without redox disproportionation, which was reported to occur in the reactions of VII[6] in boiling water or at high temperature, and completed by one equivalent of the oxidant. This reaction pathway involved the complete loss of C(2) atoms as shown by the tracer experiment (Scheme 4).



Scheme 4. The loss of the carbon (2-position) in 1,3-diones.

The above data indicate that the reaction pathway for the oxidation of the 1,3-diones and the enediol are fairly complicated ones, as indicated by the presence of the portion of the radioactivity in the product.

In the case of trione, on the other hand, on change in the yields of IV in the oxidation of II was observed when acetic acid was used as a solvent. The oxidations of VIII required only one equivalent of the oxidant and lost the C(2) completely. The above two facts suggest that the radical mechanism is favored in this case. However, no conclusive evidence is available to distinguish the radical and ionic mechanisms which operate in the reaction.

Experimental

The NMR spectra were recorded for the deuteriochloroform and trifluoroacetic acid solutions with a Hitachi R 24 NMR spectrometer, with tetramethylsilane as an internal reference. The IR spectra were recorded for the chloroform solution and KBr disk with a JASCO IRA-1 grating spectrometer. The melting points were determined with a Yanagimoto hot-stage apparatus. The radioactivities were recorded, for samples crystallized to a constant specific radioactivity, with an Aloka liquid scintillation spectrometer. The scintillator consisted of DPO(6 g), POPOP (0.275 g), and naphthalene (Dojin Laboratories, Kumamoto) dissolved in dioxane. Barium carbonate samples were suspended in a gel made up with 4% W/V CAB-O-SIL (Beckmann Instruments Inc., U.S.A.). Sample counts were repeated twice; the maximum observed error was within 0.5%.

Oxidations of 1,3-Indandiones with Lead Tetraacetate. The typical procedure of the oxidation of 1,3-indandiones is as follows. A mixture of 1,3-indandione (2 mmol), lead tetraacetate (4—8 mmol), and benzene (30 ml) was heated under reflux for the period of time shown in Table 1. Nitrogen was passed through the reaction mixture, and the evolved gases were passed into saturated aqueous barium hydroxide, aqueous potassium permanganate, and again saturated aqueous barium hydroxide. The precipitated barium carbonate was collected by centrifugation, washed with water, and dried. After the removal of insoluble materials by filtration, the benzene was evaporated *in vacuo* and the products were purified on TLC with chloroform as an eluting solvent. I gave 2,2-diacetoxy-1,3-indandione (III), mp 174—175 °C, 6.8%, (Found: C, 59.34; H, 3.99%. Calcd for $C_{13}H_{10}O_6$: C, 59.54; H, 3.84%, δ: 7.98 (m, 4H) and 2.14 (s, 6H, OAc), ν_{max}: 1745 and 1750 cm^{-1}), phthalic anhydride (IV) (mp 130—131 °C) and carbon dioxide. II yielded IV (mp 130—131 °C) and carbon dioxide.

Oxidation of 1,3(2H)-Phenalenediones with Lead Tetraacetate. A typical procedure of the oxidation of 1,3(2*H*)-phenalenediones is as follows. A mixture of 1,3(2*H*)-phenalenedione (2 mmol), lead tetraacetate (2—6 mmol), and hot acetic acid (30 ml) was heated under reflux for a period of time shown in Table 2. The carbon dioxide which evolved was converted to barium carbonate as described previously. After the removal of the acetic acid *in vacuo*, the residue was treated with 2M hydrochloric acid (60 ml) and extracted with chloroform. The chloroform solution was dried over sodium sulfate and evapolated under reduced pressure, and the products were separated on TLC with chloroform as an eluting solvent, giving the 1,8-naphthalenedicarboxylic anhydride (IX) (mp 272—273 °C) and/or acenaphthenequinone (X) (mp 259—260 °C). VII yielded IX (mp 272—273 °C) and carbon dioxide. VIII yielded IX (mp 272—273 °C), carbon dioxide and/or X (mp 259—260 °C).

Oxidation of Acenaphthenequinone (X). A mixture of acenaphthenequinone (2 mmol), lead tetraacetate (2 mmol), and acetic acid (30 ml) was heated under reflux for 20 min. After cooling, the crystals which precipitated were collected by filtration, giving IX (mp 272—273 °C).

1,3-Indandione-2-^{14}C. Into a mixture of diethyl phthalate (72 g) and powdered sodium (14.3 g) was dropped ethyl acetate-2-^{14}C (70 g) (which was prepared from acetic-2-^{14}C acid (250 μCi, Radiochemical Centre, Amersham, England) in absolute ethyl alcohol (1.43 g) over a period about 90 min). The material in the flask was refluxed gently during the addition of ethyl acetate mixture. The heating was continued for 6 h, and ether (30 ml) was added after cooling. As much of the sodium salt as possible was collected on a filter and then washed with ether, using as small a volume as possible. The total yield of the dry, yellow sodium salt was 55 g (71%). The sodium salt (55 g) was added to hot water (750 ml). The solution was cooled to 70 °C and under vigorous agitation the sodium salt was decomposed with a sulfuric acid solution (three parts of concentrated sulfuric acid and one part of water) (50 ml). The mixture was cooled to 15 °C and filtered. The 1,3-indandione thus obtained was a pale yellow solid (mp 127—

129 °C, 29 g, 61.3%, specific radioactivity 0.176 μCi/mmol).

2,2-Dihydroxy-1,3-indandione-2-^{14}C. To 1,3-indandione-2-^{14}C (5 g) dissolved in dilute sodium hydroxide (200 ml) was added sodium nitrite (2.5 g); then the mixture was cooled to 0 °C. Hydrochloric acid was added dropwise until the solution became distinctly acidic, whereupon the ice-bath was removed and the mixture was stirred for 30 min at room temperature. The solution was filtered and a yellow amorphous powder (5.9 g, 100%) was obtained. The oxime was recrystallized from acetic acid and formed yellowish green plates; mp 200—201 °C (decomp.). A mixture of selenious acid and the oxime (5 g) was refluxed for 3 h, and the clear solution was cooled to room temperature and saturated with sulfur dioxide. The solid which separated was filtered off and the filtrate was concentrated by distillation to *ca.* 50 ml and filtered. The filtrate was boiled with active carbon, filtered again, concentrated to 20 ml, and allowed to stand at room temperature. The crude 2,2-dihydroxy-1,3-indandione-2-^{14}C was filtered, and the mother liquor was concentrated to obtain a second crop; total yield 3.7 g (73%). It was purified by recrystallization from hot water with the aid of active carbon. Long colorless prisms of 2,2-dihydroxy-1,3-indandione-2-^{14}C were obtained, mp 241—243 °C (decomp.). The specific radioactivity was 0.178 μCi/mmol.

*1,3(2*H*)-Phenalenedione-2-*^{14}C. To a stirred mixture of diethyl malonate-2-^{14}C (75 ml, 250 μCi, Radiochemical Centre, Amersham, England) and 1,8-naphthalenedicarboxylic anhydride (25 g) was added zinc chloride (25 g); then the mixture was heated to *ca.* 170—175 °C for 6 h. The cooled reaction mass, after the addition of hot water (50 ml), was crushed to a powder and filtered. The residue was stirred with aqueous ammonia (one part of ammonia and four parts of water, 250 ml) for 15 min, and filtered. The filtrate was treated with active carbon, again filtered, and acidified with acetic acid. The solution was allowed to stand at room temperature for one hour, and filtered. The crystals obtained were washed with water, mp 254 °C (decomp.) (20.0 g, 81%, specific radioactivity 0.369 μCi/mmol).

2,3-Dihydroxy-1-phenalenone-2-^{14}C. 1,3(2*H*)-Phenalenedione-2-^{14}C (9.8 g) was dissolved in dilute sodium hydroxide (5%, 200 ml). After the addition of sodium nitrite (3.8 g), the mixture was cooled to 0 °C. Hydrochloric acid (17%) was added dropwise until the solution became distinctly acidic, whereupon the ice-bath was removed and the mixture was stirred for 30 min at room temperature. The solution was filtered and then washed with water and dried in *vacuo*, yielding the oxime (11.25 g, *ca.* 100%). The oxime (2.25 g) was dissolved into a mixture of acetic acid (10 ml), formalin (6.5 ml, 40%), and hydrochloric acid (2 ml). The mixture was refluxed for 4 h, and the solution was cooled and water (30 ml) was added. The solution was filtered to obtain 2,3-dihydroxy-1-phenalenone-2-^{14}C (1.7 g, 80%, mp 256 °C (xylene)). The specific radioactivity could not be obtained because of the deep coloration of the sample solution.

2,2-Dihydroxy-1,3-phenalenedione-2-^{14}C. A mixture of 1,3-(2*H*)-phenalenedione-2-^{14}C (1.96 g), sodium chloride (0.7 g), acetic acid (20 ml), and nitric acid (5 ml) was heated at 100 °C and stirred for 10 min. After cooling, the precipitates were collected, washed with ether, and dried. This gave 2-chloro-2-nitro-1,3-phenalenedione-2-^{14}C (1.8 g, 69%). The compound (1.0 g) was heated in nitrobenzene (10 ml) at 140 °C for 15 min; then the solution was cooled and the precipitates were washed with ether. This gave 2,2-dihydroxy-1,3-phenalenedione-2-^{14}C (0.62 g, 81%, mp 263 °C (decomp.), specific radioactivity 0.367 μCi/mmol).

Oxidation of [2-^{14}C]-*Compounds by Lead Tetraacetate.* [2-^{14}C]-Compounds were oxidized by the method described previously for the oxidation of the unlabeled compounds.

1,3-Indandione-2-^{14}C (292 mg) gave phthalic anhydride, mp 129—131 °C (35.6 mg, 12%, specific radioactivity 0.030 μCi/mmol), and carbon dioxide, which was converted to barium carbonate (116.7 mg, 29.6%, specific radioactivity 0.048 μCi/mmol).

2,2-Dihydroxy-1,3-indandione-2-^{14}C (356 mg) gave phthalic anhydride, mp 129 °C (127.7 mg, 43.2%, no radioactivity), and carbon dioxide, which was converted to barium carbonate (67.5 mg, 17%, specific radioactivity 0.124 μCi/mmol).

1,3(2*H*)-Phenalenedione-2-^{14}C (329 mg) gave acenaphthenequinone, mp 260 °C (11.5 mg, 3.2%, specific radioactivity 0.071 μCi/mmol), and carbon dioxide, which was converted to barium carbonate (24.3 mg, 6.2%, specific radioactivity 0.049 μCi/mmol).

2,3-Dihydroxy-1-phenalenone-2-^{14}C (424 mg) gave 1,8-naphthalenedicarboxylic anhydride, mp 274 °C (247.3 mg, 62.4%, specific radioactivity 0.049 μCi/mmol), and carbon dioxide, which was converted to barium carbonate (225.5 mg, 57%, specific radioactivity 0.222 μCi/mmol).

2,2-Dihydroxy-1,3-phenalenedione-2-^{14}C (456 mg) gave 1,8-naphthalenedicarboxylic anhydride, mp 274 °C (270 mg, 68%, no radioactivity), and carbon dioxide, which was converted to barium carbonate (11.47 mg, 2.9%, specific radioactivity 0.299 μCi/mmol).

(Received July 26, 1976)

The reaction of dimethyl sulfoxide–trifluoroacetic anhydride complex with anilines, phenols, and thiophenols was studied, and the following results were obtained. (1) The yields of a methylthiomethylated product were improved with anilines. The reaction proceeded without significant amount of tar, the unreacted anilines being easily recovered. (2) Selective *ortho*-methylthiomethylation took place with phenols in good yields at lower temperature, *para*-methylthiomethylation occurring at higher temperature. (3) Methylthiomethylation took place with thiophenols on a sulfur atom of thiophenol at room temperature in a simple process.

Sulfides and sulfoxides are activated with electrophiles to produce the reactive sulfonium salts. These electrophiles include dicyclohexylcarbodiimide+acid,[1] acetic anhydride,[2] acetyl chloride,[3] phosphorus pentoxide, polyphosphoric acid,[4] sulfur trioxide–pyridine,[5] diphenylketene–*p*-tolylimine+acid,[6] *etc.*

By employing sulfides activated with chlorine or *N*-chlorosuccinimide, Corey and Kim[7] carried out the mild oxidation of aliphatic alcohols to ketones. Gassman and co-workers[8–10] described *ortho*-methylthiomethylation of anilines by using *N*-chloroanilines and dialkyl sulfide. However, *N*-chloroanilines with electron-donating groups are unstable and easily oxidized to tar. Thus the reaction does not proceed without disturbance even though the improved dimethyl sulfide–chlorine method[11] is employed. Similar difficultics arise with the *ortho*-methylthiomethylation of phenols.

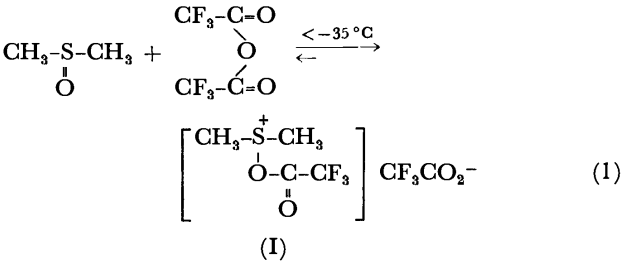
As for the reaction of activated sulfoxides, Claus and coworkers[12,13] reported that dimethyl sulfoxide and phosphorus pentoxide complex reacted with anilines to produce *N*-arylsulfimides. The dimethyl sulfoxide–phosphorus pentoxide system presented difficulties in purification of the product during the course of work-up. Swern and co-workers[14] also succeeded in preparing sulfimides by employing dimethyl sulfoxide–trifluoroacetic anhydride. Burdon and Moffatt[15,16] reported acid-catalyzed *ortho*-methylthiomethylation of phenols with dimethyl sulfoxide, dicyclohexylcarbodiimide, and anhydrous orthophosphoric acid. The yields were moderate, 1,3-benzoxathian and phenyldicyclohexyl urea being produced as by-products.

Dimethyl sulfoxide–trifluoroacetic anhydride system is expected to overcome these difficulties and improve the yields in alkylation of the anilines and the phenols owing to a good leaving group, *i.e.* trifluoroacetate.

No report has been found concerning the reaction of thiophenol with the activated sulfoxide and sulfide, except for the formation of diphenyl disulfide with dimethyl sulfide and dicyclohexylcarbodiimide.[15] The dimethyl sulfoxide–trifluoroacetic anhydride complex reacted with a variety of the substituted thiophenols to give methylthiomethyl phenyl sulfide in good yields.

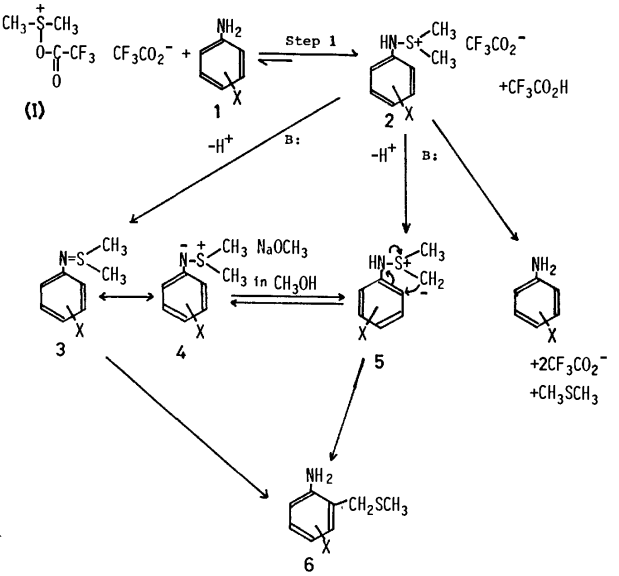
Results and Discussion

Trifluoroacetic anhydride (TFAA) reacts with dimethyl sulfoxide (DMSO) readily to afford the complex I at low temperature as formulated in Eq. 1. In methylene chloride as solvent, it appears as a white precipitate (see Experimental). Trifluoroacetoxyl group on the sulfur atom facilitates the substitution of sulfur atom being attacked by nucleophiles.



(I) (1)

ortho-*Methylthiomethylation of Aniline.* In general, the 'activated DMSO' reacts with a variety of anilines to afford azasulfonium compounds (**2**) followed by conversion into ylids (**5**) on treatment with base.[10] The ylid rearranges smoothly at lower temperature to the desired *o*-substituted aniline *via* Sommelet-Hauser type rearrangement as shown in Scheme 1. Alternatively, it may also be possible that the treatment of base leads to the abstraction of hydrogen on N atom of compound **2** to afford sulfimide (**3**), which rearranges to the corresponding product (**6**) in base. On the other hand, compound **2** is anticipated to decompose back to the starting aniline (**1**). If this process



Scheme 1.

is involved, a complete conversion can not be considered to be attained.

7

Substituted anilines (X=NO_2, CN, CO_2CH_3, Cl, CH_3, OCH_3) were alkylated on the *ortho* position with 1.2 equivalent of the complex I. In each case, the reaction proceeded without significant amount of tar, the unreacted aniline being easily recovered as shown in Table 1.

TABLE 1. *ortho*-METHYLTHIOMETHYLATION OF *para*-SUBSTITUTED ANILINES

Compd	X	Yield (%)[a] 6	Yield (%)[a] 7	Recovered anilines (%)
1a	NO_2	55	5	40

1e	H	54	1	45
1f	CH_3	45	16	33
1g	OCH_3	27	7	66

a) Isolated yield based on the starting anilines.

In the case of anilines substituted by the strong electron-withdrawing group (*i.e.* *p*-nitroaniline), sulfimide **3** is preferred to the ylid form, since the hydrogen of the amino group is prone to be abstrated rather than the methyl hydrogen, and required to be refluxed with triethylamine in dry toluene to cause *o*-alkylation. On the other hand, it is enough to keep the reaction mixture below room temperature in the case of the rearrangement of azasulfonium compounds derived from anilines substituted by electron-donating group (*i.e.* *p*-toluidine and *p*-anisidine).

Sodium methoxide in absolute methanol was employed in each rearrangement of the azasulfonium compounds. *N*-Trifluoroacetylation took place instead of the desired rearrangement, when the compound derived from *p*-anisidine was treated with triethylamine. Potassium *t*-butoxide in THF was examined in a similar procedure to give *N*-trifluoroacetylation product, but the yield of *o*-alkylation decreased to a few %. Methanol is presumed to facilitate the protonation and counter anion exchang[12] from **3** to **5** through structure **4**, and **5** rearranges spontaneously even at low temperature below −50 °C.

In step 1, trifluoroacetic acid is generated, and is thought to protonate the aniline, while the protonated aniline is considered not to attack complex I. Attempts were made to remove the acid generated. In the presence of one equivalent of 2,6-lutidine, *p*-chloroaniline was reacted with the complex followed by the usual procedure. GLC analysis shows the formation of *o*-substitution product (20%) and acylation product (27%), and recovery of unreacted aniline (30%), indicating that 2,6-lutidine was not effective. In the same manner, *p*-toluidine was reacted in the presence of potassium carbonate. GLC analysis suggests that acylation predominated. Two equivalent of *p*-chloroaniline to the complex I afforded *o*-substituted product in 45% yield, attempts being unsuccessful.

Trifluoroacetylation took place as the sole side reaction (Eq. 2). However, it was possible to depress it with a choice of solvent system. Trifluoroacetylation is more unfavorable than the alkylation of aniline in a less polar solvent, though the process of alkylation is complicated. Less polar solvent (toluene) was preferred to methylene chloride in the reaction of *p*-anisidine which has higher basicity; Methylene chloride–acetonitrile (1/1=v/v) solvent was preferred in the reaction of *p*-chloroaniline which is less basic (Table 2).

o-Monosubstituted anilines were also alkylated on the *ortho* position in a similar manner. Table 3 gives the yields of *o*-alkylation of the *o*-monosubstituted anilines. Methylene chloride–acetonitrile (1/1=v/v) was used as the solvent, toluene being used in the case of *o*-anisidine. *o*-Anisidine was alkylated in 52% yield in toluene as compared with 24% in methylene chloride.

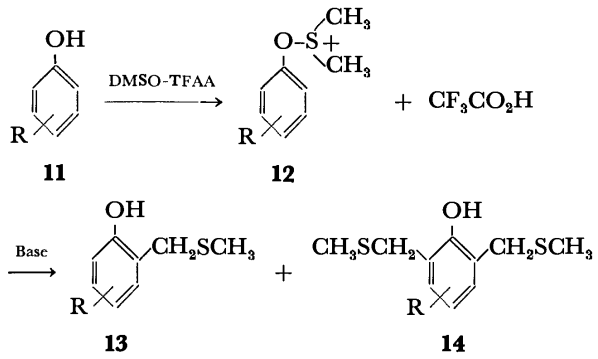
Methylthiomethylation of the Phenols. To a solution of the DMSO-TFAA complex formed below −60 °C was added the substituted phenol **11** to produce oxysulfonium compound **12**, followed by conversion into *ortho*-alkylated phenols **13** and **14** through the ylid intermediate on treatment with base. Scheme 2 shows the reaction path.



Scheme 2.

Various substituted phenols were alkylated as shown in Table 4, yields higher than those of the precedent works being marked.[15,20]

When the DMSO-TFAA complex and phenol were treated with sodium methoxide in absolute methanol, the desired product **13** was not obtained. Triethylamine was found to be the suitable base. In the reaction quenched 7 min after addition of the base, 0.5 equivalent of complex I to phenol marked a higher yield than one equivalent. This indicates that phenol was protonated and blocked by trifluoroacetic acid generated in the course of the reaction. It was thus necessary to eliminate the acid. 2,6-Lutidine, which has little nucleophilicity and is able to trap proton, was considered to be effective. Table 5 gives the yield from *o*-cresol and the effect of 2,6-lutidine. In the absence of triethylamine, 2,6-lutidine did not work as the base in the rearrangement, but a combination of 2,6-lutidine and triethylamine was recognized to be a good base. Optimum yield was attained in methylene chloride-hexane (1/1=v/v).

On the other hand, phenol reacted with DMSO-TFAA in acetonitrile at room temperature to produce viscous liquid instantaneously. NMR analysis (in $CDCl_3$) showed a singlet (6H) at δ 2.68 and a multiplet (4H) at δ 7.24—7.36. The liquid was refluxed with triethylamine in acetonitrile for 5 h to afford 4-methylthiomethylphenol in 23% yield (Eq. 3): NMR (CCl_4) δ=1.84 (s, 3), 3.44 (s, 2), and 6.44—7.08 ppm (q, 4). Anisol which also produced viscous liquid in a similar procedure was refluxed in acetonitrile with triethylamine to afford 4-methylthiomethylanisol (Eq. 4). The yield was low, but unreacted anisol was recovered: NMR (CCl_4) δ=1.88 (s, 3), 3.46 (s, 2), 3.64 (s, 3), 6.56—7.01 (q, 4).

Hirose and Ukai reported on the conversion of dimethyl-*p*-hydroxyphenylsulfonium perchlorate **17** into methyl *p*-hydroxyphenyl sulfide (**18**) by heating in an aqueous saturated potassium chloride solution.[17] The acetonitrile solution of DMSO-TFAA and phenol was refluxed in an aqueous saturated potassium chloride solution for 5 h. No methyl *p*-hydroxyphenyl sulfide was detected. Dimethyl-*p*-hydroxyphenylsulfonium perchlorate was prepared according to the method of Hirose and Ukai,[17] and treated with triethylamine in acetonitrile at room temperature. The sole product was identified with methyl *p*-hydroxyphenyl sulfide **18**. The results exclude the possibility of oxysulfonium intermediate **12** and dimethyl-*p*-hydroxyphenylsulfo-

* Yield was determined as cresol after desulfurization by Raney-Ni.

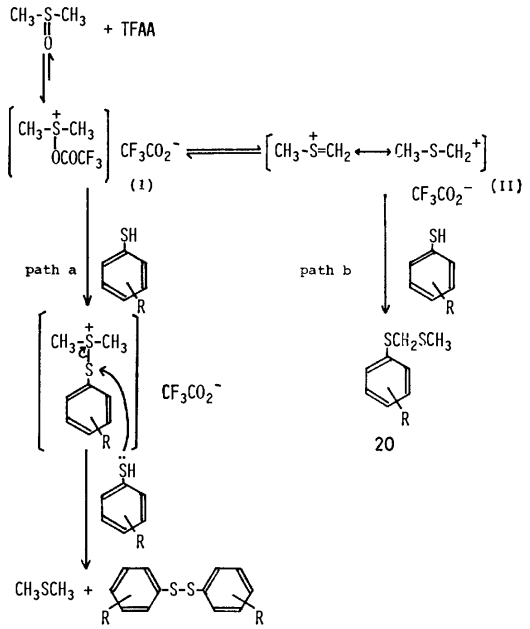
nium intermediate in the *para* alkylation reaction of phenol. It seems that methylmethylenesulfonium cation (Pummerer type intermediate) is the attacking species to phenol and anisol.

Methylthiomethylation on Sulfur Atom of Thiophenols. Complex I reacted with thiophenol below −50 °C under the usual conditions. Thiophenol was oxidized to give diphenyl disulfide, DMSO being reduced to dimethyl sulfide quantitatively. It is assumed that dimethylphenylthiosulfonium species was attacked by unreacted thiophenol along path a as shown in Scheme 3.



Scheme 3. Generation of the Pummere type intermediate.

On the other hand, complex I is expected to be transformed into carbonium ion following deprotonation (Pummerer type intermediate) (II). Trifluoroacetoxy anion (the counter anion) in the complex I has very weak nucleophilicity. Thus a certain nucleophile is considered to be able to trap this intermediate carbonium ion. *p*-Methylthiophenol gave methylthiomethyl *p*-methylphenyl sulfide **20** in good yield (59% isolated) and bis(*p*-methylphenyl) disulfide (21% yield) in a simple procedure: TFAA and thiophenols were added to an acetonitrile solution of DMSO successively at room temperature, and the reaction mixture was evaporated. The reaction was completed instantaneously, and dimethyl sulfide and trifluoroacetic acid formed were removed by evaporation of the solvent. No additional base was required. The yield decreased from 59 to 21% in the presence of triethylamine, because of the decomposition of complex I.

Several substituted thiophenols were alkylated (Table 6). DMSO-TFAA complex is the effective reagent for methylthiomethylation.

Experimental

*Preparation of 4-Chloro-2-methylthiomethylaniline (**6d**) from* p-*Chloroaniline. (Procedure A)* Dimethyl sulfoxide (1.4 g, 18 mmol) was dissolved in 20 ml of dry methylene chloride–acetonitrile (1/1=v/v), and the solution was stirred with a magnetic stirrer under nitrogen atmosphere and cooled below −70 °C in a Dry Ice–acetone bath. Trifluoroacetic anhydride (TFAA, 2.5 g, 12 mmol) was added dropwise to the solution maintained below −30 °C. The reaction was exothermic and a white precipitate immediately appeared. To the solution was gradually added *p*-chloroaniline (1.28 g, 10 mmol) in 10 ml of acetonitrile. A white precipitate soon disappeared and the solution which became homogeneous was kept stirring for 5 h. Sodium methoxide (30 mmol) in 15 ml of absolute methanol was added to the reaction mixture dropwise below −50 °C. The solution was allowed to warm to room temperature and was kept overnight (*ca.* 12 h). The resulting mixture was diluted with 40 ml of 10% aqueous sodium hydroxide. The organic layer was separated, the aqueous phase extracted three times with 70 ml portions of methylene chloride, and the organic layers were combined with the original organic phase, dried over anhydrous magnesium sulfate, filtered, and concentrated *in vacuo* to yield yellow oil. The resulting oil was dissolved in 100 ml of acetonitrile with 5 ml of triethylamine, and refluxed for 15 h. The solution was evaporated in order to remove the solvent and triethylamine to give a brown oil. Column chromatography on silica gel gave acylated aniline, *p*-chloroaniline, and 4-chloro-2-methylthiomethylaniline: 1.27 g isolated (eluant: benzene–hexane=1/1, v/v); mp 79—80 °C (lit, mp 78—79 °C[12]); NMR (CCl_4) δ=2.00 (s, 3), 3.62 (s, 2), 4.07 (s, 2), 6.5—7.1 (m, 3) (identical with the lit[12]).

*Preparation of 4-Nitro-2-methylthiomethylaniline (**6a**) from* p-*Nitroaniline. (Procedure B)* DMSO (1.4 g, 18 mmol) in 90 ml of dry methylene chloride–acetonitrile (1/1=v/v) was stirred and kept below −70 °C in a Dry Ice–acetone bath under nitrogen atmosphere. TFAA (2.5 g, 12 mmol) was added dropwise to the solution maintained below −30 °C throughout the course of addition. No white precipitate appeared. To the solution was gradually added *p*-nitroaniline (1.38 g, 10 mmol) and DMSO (3 ml) dissolved in 20 ml of acetonitrile. It was kept stirring for 7 h, and sodium methoxide (50 mmol) in 25 ml of absolute methanol was added dropwise below −40 °C. The reaction mixture was allowed to warm to room temperature and kept overnight (10 h). After the usual workup, yellow crystals and oil were obtained. They were dissolved in 100 ml of dry toluene with 5 ml of triethylamine, and refluxed for two days. This solution was evaporated to give crude solid. Column chromatography on silica gel gave 4-nitro-2-methylthiomethylaniline: 0.99 g isolated (eluant: benzene); mp 75—76 °C (lit, mp 75—

77 °C[12]); NMR ($CDCl_3$) δ=2.06 (s, 3), 3.72 (s, 2), 4.92 (s, 2), 6.64—8.12 (m, 3) (identical with lit[12]). The crystals obtained before reflux were identified with *N*-nitrophenyl dimethyl sulfimide: mp 164—167 °C (lit, mp 166—167 °C[14]); NMR ($CDCl_3$) δ=2.72 (s, 3), 6.66—8.04 (q, 4) (identical with lit[14]).

*Preparation of 4-Methyl-2-methylthiomethylaniline (**6f**) from* p-*Toluidine. (Procedure C)* DMSO–TFAA complex was prepared in 20 ml of methylene chloride and acetonitrile from 18 mmol of DMSO and 12 mmol of TFAA as described in procedure A. *p*-Toluidine (1.07 g, 10 mmol) in 10 ml of acetonitrile was added dropwise below −50 °C. The solution was stirred for 3 h. Sodium methoxide (30 mmol) in absolute methanol 15 ml was added slowly, and the solution was kept overnight at room temperature (*ca.* 10 h). The usual work-up gave a dark oil. Column chromatography on silica gel gave 4-methyl-2-methylthiomethylaniline: 0.752 g isolated (eluant: benzene–hexane=1/1, v/v); mp 43—44 °C (lit, mp 42—45 °C[12]); NMR (CCl_4) δ=1.91 (s, 3), 2.21 (s, 3), 3.58 (s, 2), 3.79 (s, 2), 6.42—6.86 (m, 3) (identical with values in lit[12]).

*Preparation of 2-Methylthiomethylaniline (**6e**) from Aniline.* The reaction was carried out according to procedure A. Methylene chloride (20 ml) solution of the DMSO–TFAA complex (DMSO 36 mmol and TFAA 24 mmol) and 20 ml of methylene chloride solution of aniline (20 mmol) were employed. Column chromatography on silica gel gave 2-methylthiomethylaniline: 0.83 g isolated (eluant: benzene–hexane=1/1, v/v); NMR (CCl_4) δ=1.94 (s, 3), 3.64 (s, 2), 4.01 (s, 2) 6.60—7.12 (m, 4) (identical with lit[12]), and *N*-trifluoroacetylaniline **7e**: MS (20 eV), *m/e*, 189; NMR ($CDCl_3$) δ=7.14—7.50 (m, 5), 7.80 (s, 1); IR (KBr) 1710 cm^{-1}; mp 90.0—90.5 °C.

*Preparation of 4-Methoxy-2-methylthiomethylaniline (**6g**) from* p-*Anisidine.* The reaction was carried out according to procedure C. The DMSO–TFAA complex was prepared in dry toluene. Column chromatography on silica gel gave 4-methoxy-2-methylthiomethylaniline: 0.49 g (eluant: benzene–hexane); NMR (CCl_4) δ=1.92 (s, 3), 3.53 (s, 2), 3.63 (s, 3), 3.68 (s, 2), 6.46 (s, 3) (identical with lit[10]).

*Preparation of 4-Cyano-2-methylthiomethylaniline (**6b**) from* p-*Cyanoaniline.* The reaction was carried out according to procedure B. Column chromatography on silica gel gave 4-cyano-2-methylthiomethylaniline: 0.94 g isolated; mp 84—86 °C; NMR ($CDCl_3$) δ=2.00 (s, 3), 3.68 (s, 2), 4.7 (s, 2), 6.5—7.2 (m, 3) (identical with values in lit[18]).

*Preparation of 4-Carbomethoxy-2-methylthiomethylaniline (**6c**) from* p-*Carbomethoxyaniline.* The reaction was carried out according to procedure B. Column chromatography on silica gel gave starting aniline, acylated aniline, and 4-carbomethoxy-2-methylthiomethylaniline: 1.03 g isolated (eluant: benzene); mp 85—87 °C; NMR ($CDCl_3$) δ=2.00 (s, 3), 3.80 (s, 2), 3.82 (s, 3), 4.80 (s, 2), 7.4—8.0 (m, 3) (identical with values in lit[18]).

*Preparation of 6-Chloro-2-methylthiomethylaniline (**9b**) from* o-*Chloroaniline.* The reaction was carried out according to procedure A. The oil obtained after quenching with 10% aqueous sodium hydroxide was refluxed in 100 ml acetonitrile with 5 ml of triethylamine for 10 h. Column chromatography on silica gel gave 6-chloro-2-methylthiomethylaniline: 1.33 g isolated (eluant: benzene–hexane=1/1, v/v); NMR (CCl_4) δ=1.85 (s, 3), 3.57 (s, 2), 4.48 (s, 2), 6.51—7.18 (m, 4) (identical with values in lit[12]).

*Preparation of 6-Methoxy-2-methylthiomethylaniline (**9d**) from* o-*Anisidine.* DMSO (1.4 g) was dissolved in 100 ml of dry toluene, and the solution was cooled below −70 °C in a Dry Ice–acetone bath under nitrogen atmosphere. TFAA (2,5 g) was added. Methylene chloride solution of *o*-anisidine (10 mmol) was added dropwise. The precipitate soon disappeared, and the solution was kept standing for 5 h. Sodium methoxide (30 mmol) in 15 ml of methanol was added below −50 °C. The cooling bath was removed in order to warm the reaction mixture upto room temperature. After quenching with 10% aqueous sodium hydroxide, the reaction mixture was dissolved in 100 ml of acetonitrile and refluxed for several hours with 5 ml of triethylamine. Preparative thin layer chromatography (Merck Silica gel 60 PE_{254}) gave 6-methoxy-2-methylthiomethylaniline: 0.95 g isolated (eluant: benzene–hexane=1/1, v/v); NMR (CCl_4) δ=1.87 (s, 3), 3.57 (s, 2), 3.76 (s, 3), 4.04 (s, 2), 6.56—7.16 (m, 3); MS (20 eV), *m/e*, 183.

*Preparation of 6-Nitro-2-methylthiomethylaniline (**9a**) from* o-*Nitroaniline.* The reaction was carried out according to procedure B. Column chromatography on silica gel gave 6-nitro-2-methylthiomethylaniline: 0.812 g isolated (eluant: benzene–hexane=1/1, v/v); mp 80—82 °C; NMR ($CDCl_3$) δ=2.00 (s, 3), 3.70 (s, 2), 6.5—7.2 (m, 3), 8.0 (s, 2); MS (20 eV), *m/e*, 198, 151, and 105.

*Preparation of 6-Methyl-2-methylthiomethylaniline (**9c**) from* o-*Toluidine.* The reaction was carried out according to procedure A. Preparative thin layer chromatography (Merck Silica gel 60 PE_{254}) gave 6-methyl-2-methylthiomethylaniline: 0.802 g isolated (eluant: benzene–hexane=1/2, v/v); NMR (CCl_4) δ=1.86 (s, 3), 2.08 (s, 3), 3.53 (s, 2), 3.90 (s, 2), 6.56—7.16 (m, 3) (identical with values in lit[12]).

*Preparation of 2-Methylthiomethylphenol (**13c**) from Phenol. (General Procedure)* DMSO–TFAA complex was prepared from DMSO (28 mmol) and TFAA (14 mmol) in 10 ml of dry methylene chloride below −60 °C. White precipitate appeared immediately. Phenol (2.7 g, 29 mmol) and 2,6-lutidine (1.6 g 15 mmol) dissolved in 4.5 ml of DMSO and 10 ml of methylene chloride was added dropwise, and the solution was stirred for 3 h. After triethylamine (2 ml) had been added, the solution was allowed to warm up to room temperature overnight. The reaction mixture was poured into 70 ml of dil. hydrochloric acid, the organic layers were separated, and the aqueous phase was extracted three times with 50 ml portions of methylene chloride. The organic layers were combined, and dried over magnesium sulfate, filtered, and concentrated *in vacuo*. Column chromatography on silica gel gave 2-methylthiomethylphenol: 0.452 g isolated (eluant: benzene–hexane=1/1, v/v); NMR (CCl_4) δ=1.86 (s, 3), 3.58 (s, 2), 6.40—6.96 (m, 4) (identical with values in lit[19]); IR (neat), 3350 cm^{-1} (O–H).

*Preparation of 4-Methyl-2-methylthiomethylphenol (**13b**) from* p-*Cresol.* The reaction was carried out according to the general procedure. *p*-Cresol (0.99 g), DMSO (0.7 ml), and TFAA (1.04 g) were employed. The resulting oil was purified by preparative thin layer chromatography (Merck Silica gel 60 PF_{254}), which gave 0.28 g of mono substituted cresol and 0.06 g of disubstituted cresol (eluant: benzene–hexane=1/1, v/v). 4-methyl-2-methylthiomethylphenol: NMR (CCl_4) δ=1.88 (s, 3), 2.18 (s, 3), 3.58 (s, 2), 6.52 (m, 3) (identical with values in lit[20]); IR (neat), 3350 cm^{-1} (O–H) 4-methyl-2,6-bismethylthiomethylphenol: NMR (CCl_4) δ= 1.92 (s, 6), 2.20 (s, 3), 3.62 (s, 4), 6.78 (s, 2); IR (neat), 3300 cm^{-1} (O–H).

*Preparation of 4-Chloro-2-methylthiomethylphenol (**13d**) from* p-*Chlorophenol.* The reaction was carried out according to general procedure. DMSO (0.4 ml), TFAA (0.50 g), and *p*-chlorophenol (0.75 g) were employed. The resulting oil was separated by preparative thin layer chromatography (Merck Silica gel PF_{254}, eluant: benzene–hexane=1/1, v/v) to give 0.20 g of 4-chloro-2-methylthiomethylphenol:[21]

NMR (CCl_4) δ=1.96 (s, 3), 3.62 (s, 2), 6.96—7.20 (m, 3); IR (neat), 3310 cm^{-1} (O-H), and 0.06 g of 4-chloro-2,6-bis(methylthiomethyl)phenol: NMR (CCl_4) δ=1.92 (s, 6), 3.60 (s, 4), 6.96 (s, 2); IR (neat), 3290 cm^{-1} (O-H)

*Preparation of 4-Methoxy-2-methylthiomethylphenol (**13a**) from* p-*Methoxyphenol.* The reaction was carried out according to general procedure. DMSO (6 mmol), TFAA (2.3 mmol), and *p*-methoxyphenol (5 mmol) were employed. Preparative thin layer chromatography (Merck Silica gel 60 PF_{254}, eluant: benzene–hexane=1/1, v/v) gave 4-methoxy-2,6-bis(methylthiomethyl)phenol (0.08 g) and 4-methoxy-2-methylthiomethylphenol (0.23 g). Mono-alkylated product:[21] NMR (CCl_4) δ=1.94 (s, 3), 3.64 (s, 2), 3.68 (s, 3), 6.52—6.80 (m, 3); IR (neat), 3340 cm^{-1} (O-H) dialkylated product: NMR (CCl_4) δ=1.98 (s, 6), 3.68 (s, 4), 3.74 (s, 3), 6.60 (s, 2); IR (neat), 3340 cm^{-1} (O-H)

*Preparation of 2-Methyl-6-methylthiomethylphenol (**13e**) from* o-*Cresol.* The reaction was carried out according to general procedure. DMSO (10 mmol), TFAA (6 mmol), and *o*-cresol (5 mmol) were used. Column chromatography on silica gel (eluant: benzene–hexane=1/1, v/v) gave 6-methyl-2-methylthiomethylphenol (0.412 g):[20] NMR (CCl_4) δ=1.92 (s, 3), 2.24 (s, 3), 3.64 (s, 2), 6.56—7.00 (m, 3); IR (neat), 3360 cm^{-1} (O-H).

*Praparation of 2,4-Dimethyl-6-methylthiomethylphenol (**13f**) from 2,4-Xylenol.* According to the general procedure, 2,4-xylenol was converted into methylthiomethylated phenol. DMSO (20 mmol), TFAA (12 mmol), and 2,4-xylenol (10 mmol) were used. The resulting oil was separated by column chromatography on silica gel (eluant: benzene–hexane=1/1, v/v) to give 0.75 g of 4,6-dimethyl-2-methylthiomethylphenol:[2b] NMR (CCl_4) δ=1.88 (s, 3), 2.14 (s, 6), 3.60 (s, 2), 6.24—6.76 (m, 2); IR (neat), 3350 cm^{-1} (O-H).

*Reaction of Dimethyl-*p*-hydroxyphenylsulfonium Perchlorate with Triethylamine.* Dimethyl-*p*-hydroxyphenylsulfonium perchlorate was prepared by the method[17] of Hirose and Ukai; 78% yield, mp 158—159 °C (lit, mp 155—157 °C); NMR (CD_3CN–$CDCl_3$) δ=3.06 (s, 6), 7.00—7.75 (q, 4).

Triethylamine was added to 20 ml acetonitrile solution of dimethyl-*p*-hydroxyphenylsulfonium perchlorate at room temperature. White precipitates appeared instantaneously. After evaporation of the solvent, the reaction mixture was washed with 100 ml of water and extracted three times with 60 ml portions of chloroform. The organic phase was dried over anhydrous magnesium sulfate and concentrated *in vacuo* to yield white crystals which were identified with methyl *p*-hydroxyphenyl sulfide: mp 85—86 °C (lit, mp 86—87 °C[17]); NMR (CCl_4) δ=2.38 (s, 3), 4.18 (s, 1), 6.61—7.17 (q, 4).

*Preparation of Methylthiomethyl Phenyl Sulfide (**20b**) from Thiophenol. (General Procedure)* DMSO (10 mmol) wa dissolved in 10 ml of dry acetonitrile at room temperature. TFAA (2.1 g, 10 mmol) in 5 ml acetonitrile was added to the solution at room temperature with stirring. Thiophenol (10 mmol) was added. The reaction was completed instantaneously, and the reaction mixture was evaporated in order to remove the solvent. The resulting yellow liquid was separated by preparative thin layer chromatography (Merck Silica gel 60 PF_{254}, eluant: hexane) to give methylthiomethyl phenyl sulfide (1.0 g, 59% yield): NMR (CCl_4) δ=2.19 (s, 3), 3.95 (s, 2), 7.12—7.46 (m, 5); MS (20 eV), *m/e*, 170 and 61.

Preparation of Methylthiomethyl p-*Chlorophenyl Sulfide (**20c**) from* p-*Chlorothiophenol.* The reaction was carried out according to general procedure. Preparative thin layer chromatography (Merck Silica gel 60 PF_{254}, eluant: hexane) gave methylthiomethyl *p*-chlorophenyl sulfide: 0.94 g isolated: NMR (CCl_4) δ=2.18 (s, 3), 3.93 (s, 2), 7.30 (s, 4); MS (20 eV), *m/e*, 204 and 61.

Preparation of Methylthiomethyl p-*Methylphenyl Sulfide (**20c**) from* p-*Methylthiophenol.* The reaction was carried out according to general procedure. Preparative thin layer chromatography (Merck Silica gel 60 PF_{254}, eluant: hexane) gave methylthiomethyl *p*-methylphenyl sulfide: 1.1 g isolated; NMR (CCl_4) δ=2.16 (s, 3), 2.31 (s, 3), 3.82 (s, 2), 6.98—7.29 (q, 4); MS (20 eV), *m/e*, 184 and 61.

(Received July 26, 1976)

The title pyrimidoazepines when treated with phosphoryl chloride underwent rearrangement to the vinylpyrrolo-pyrimidines *via* probable intermediates 5-(2-benzylaminoethyl)-4-chloro-6-vinylpyrimidines. Reduction and subsequent dehydrogenation of the products led to the preparation of 4-ethyl-7*H*-pyrrolo[2,3-*d*]pyrimidines and their 5,6-dihydro derivatives. The structures are discussed on the basis of pK_a values, UV and NMR spectra.

Tetrahydroazepines fused with various heterocycles have been actively synthesized in recent years mainly because of their pharmacological usefulness.[2] We have reported[3] the synthesis of a variety of substituted 4-hydroxy-6,7,8,9-tetrahydro-5*H*-pyrimido[4,5-*d*]azepines (*e.g.* **1**) by the condensation of *N*-substituted 5-ethoxycarbonyl-1-azacycloheptan-4-ones with various formamidine derivatives. These 4-hydroxypyrimidoazepines have been converted to the versatile 4-chloro derivatives by the usual method[4] (*i.e.* with $POCl_3$ in the presence of $PhNEt_2$ as a catalyst), leading to the preparation of 6,7,8,9-tetrahydro-5*H*-pyrimido[4,5-*d*]azepines bearing various substituents at the 2,4,7-positions.[3]

On carrying out the above chlorination without catalyst, however, we had noticed a considerable decrease in the yield of the desired 4-chloro compounds along with the simultaneous formation of a certain by-product. We wish to report here the structure of the by-product which was found to form through a rare type of rearrangement, since such a ring transposition of heterocycles has been a topic of current interest.[5]

The present investigation showed that refluxing **1a** in $POCl_3$ (without $PhNEt_2$) for 2—5 h also gave the expected 4-chloro compound[3] **2a** in a reasonable yield (60—70%). The UV spectra of the monocations of **2a** and its dechlorinated derivative[6] **3** did not differ appreciably from those of the neutral species (see Table 1). This implied that the first protonation took place on the azepine ring nitrogen in **2a** and **3** (*cf.* UV spectra and pK_a values of pyrimidine[7,8] and benzylamine[9,10]).

Prolonged heating of **1a** (*e.g.* for 34 h) with $POCl_3$ and subsequent chromatographic separation of the reaction mixture over alumina, however, resulted in formation of **2a** (40%) and a minor amount of intensely blue-fluorescent (under UV light) colorless prisms. The latter compound had the molecular formula $C_{15}H_{15}N_3$ (thus its yield was 30%). The IR spectrum indicated absence of OH, NH, or C=O group but showed characteristic absorptions at 1635, 980, and 930 cm^{-1}, indicative of the presence of a vinyl group. In contrast to **2a** and **3** the by-product had the longest wavelength UV absorption maximum at 324 nm which, on protonation (pK_a 5.94), showed a hypsochromic shift of *ca.* 20 nm with an increased intensity (Table 1); this is reminiscent of the UV spectra of 4-aminopyrimidines (see below). Since 4-vinylpyrimidine has been reported[11] to exhibit a strong, blue fluoresecnce under UV light, the presence of a vinyl group attached to a 4-aminopyrimidine nucleus was thought to account for the intense fluorescence and the UV of the by-product. The NMR spectrum of the by-product markedly differed from that of **2a** (Table 2) in the following respects: 1) a down-field shift (1.0 ppm) of the benzyl methylene singlet (at δ 4.59) of the by-product and 2) splitting of the complex azepine ring methylene absorptions (8H) of **2a** into a quasi-A_2B_2 methylene signal (4H; centered at δ 3.20) and a typical ABX vinyl signal (at δ 6.60, 6.28, and 5.54). The remaining absorptions in the spectrum of the by-product were two singlets at δ 7.27 (5H; Ph) and 8.39 (1H; pyrimidine ring proton); no deuterium-exchangeable proton was present. Combination of these spectral data led to the structure **4a** 7-benzyl-4-vinyl-6,7-dihydro-5*H*-pyrrolo[2,3-*d*]pyrimidine for the by-product; the assignments of the NMR signals are shown in Table 2.

Heating the 2-methylpyrimido-azepine (**1b**) with $POCl_3$ analogously produced a mixture of the chloro compound[3] (**2b**) and the similar rearranged product (**4b**); yields of **2b** and **4b** (from **1b**) *vs.* reaction time are shown in Table 3. The UV and NMR spectra of **2b** and **4b**, which closely resembled those of **2a** and **4a**, respectively, were consistent with the structures (see Tables 1 and 2). The pK_a of **4b** (6.95) was one unit higher than that of **4a**, while the pK_a difference between **2b** and **2a** was 0.35. This can be explained in terms of the large base-strengthening effect of a methyl group (usually 0.8 unit) when it is α- or γ- to ionizing nitrogen.[12]

The 2-phenyl derivative **1c**, made by the condensation of 1-benzyl-5-ethoxycarbonyl-1-azacycloheptan-4-one with benzamidine, gave only the 4-chloro compound **2c** in good yield when treated with boiling $POCl_3$ for 2—5 h. Heating of **1c** with $POCl_3$ at an elevated temperature (160 °C) in a sealed tube, however, produced the similar rearranged product **4c** in 38% yield; the physical properties of **4c**, recorded in Tables 1 and 2, were in conformity with the structure. The same reaction of the 2-amino compound[3] **1d** with $POCl_3$ yielded a mixture of several intractable products.[13]

The structure **4a** was confirmed by examining the spectra of the hydrogenated derivative **5a** readily obtainable as colorless prisms with the molecular formula of $C_{15}H_{17}N_3$. Its IR and NMR spectra (Table 2) clearly showed the conversion of the vinyl group of **4a** to an ethyl group, indicating the structure 7-benzyl-4-ethyl-6,7-dihydro-5*H*-pyrrolo[2,3-*d*]pyrimidine for **5a**.

a) Measured with a Hitachi EPS 3T Recording Spectrophotometer. b) Inflections in italics. c) Dication (++), monocation (+), neutral species (0), monoanion (−). d) Analytical wavelength in nm (*cf.* Ref. 23). e) Approx. value because the neutral species is hardly soluble in water. f) In 95 v/v% ethanol. g) In 0.01 M buffers containing 25 v/v% ethanol because the neutral species is hardly soluble in the buffers alone. h) Approx. i) From Ref. 16. j) No pK_a values have been reported. k) The acidic $pK_a>14$.

The close resemblance of the UV of **5a** (pK_a 6.68; Table 1) to those of structurally similar 4-dimethylaminopyrimidine (pK_a 6.35)[14] further supported the structure; the longest wavelength absorption maxima of the neutral species of both compounds showed about 7 nm hypsochromic shift (with increased intensities) on protonation. The 2-methyl- and 2-phenyl-4-vinylpyrrolo-pyrimidine **4b** and **4c** were also readily reduced to the 4-ethyl derivatives **5b** and **5c**, respectively. Those spectral properties evidently supported the structures (see Tables 1 and 2 for UV and NMR spectra).

Synthesis of a variety of substituted pyrrolo[2,3-*d*]-pyrimidines ("7-deazapurines") and their 5,6-dihydro derivatives has been drawing an increasing interest in view of their biological importance recently.[15] When our dihydropyrrolopyrimidine **5a** was heated in decalin in the presence of 10% Pd-C, a mixture of 7-benzyl-4-ethyl-7*H*-pyrrolo[2,3-*d*]pyrimidine (**6a**) and the debenzylated derivative (**6b**) (in 27 and 33% yields, respectively) was produced, the latter (**6b**) being presumably derived from **6a** by reduction with the hydrogen absorbed on the catalyst. The fully aromatic structures for **6a** and **6b** were confirmed by

Table 2. ^{1}H-NMR spectra[a]

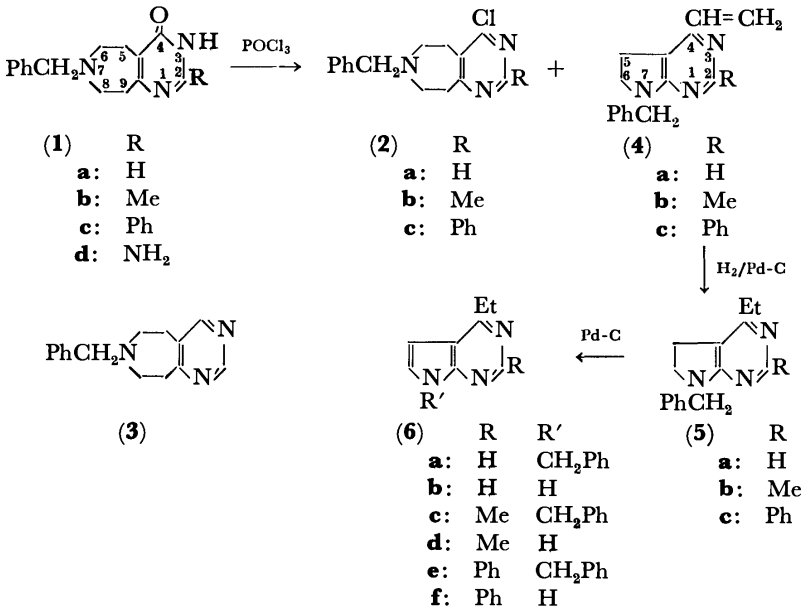
a) Measured with a Hitachi High Resolution NMR Spectrometer, R-20A (60 MHz). b) In $CDCl_3$ with TMS as an internal standard, except for compounds **2a**, **2b**, and **6e** (in CCl_4). Suffixes: b, broad; s, singlet; d, doublet; dd, double doublet; t, triplet; q, quartet; m, multiplet; J, coupling constants (Hz). c) For C_6H_5-2. d) For PhCH_2-7. e) For $C_6H_5CH_2$-7. f) Values from Ref. 3 for comparison. g) For Me-2. h, i) For CH_2=CH-4 (*trans* and *cis* with respect to the nucleus, respectively). j) CH_2=C*H*-4. k) For H_2-5. l) For H_2-6. m) For CH_3CH_2-4. n) For CH_3CH_2-4. o) For H-5. p) For H-6. q) For H-6. Becomes doublet on D_2O exchange. r) For H-7; D_2O exchangeable.

the down-field shifts of the coupled doublets (1H each, J=3.5 Hz) due to H-5 and 6 and of the benzyl methylene singlet (in the case of **6a**) in the NMR spectra (see Table 2). The UV spectra of **6b** (Table 1) resembled those of the parent substance[16] (Table 1) and of pyrrolo[2,3-*e*]pyrimidine ("9-deazapurine"),[17] but differed slightly from those of purine[18] by having an extra absorption band in 285—315 nm region. The basic and acidic pK_a values of **6b** were in the similar order to those of 9-deazapurine (pK_a 4.24, 13.16).[17] The 2-methyl compound **5b** also gave a mixture of **6c** and **6d** in 10 and 80% yields, respectively; the physical properties of those products shown in Tables 1 and 2 were similar to those of **6a** and **6b**. The 2-phenyl compound **5c** produced likewise **6e** and **6f** (in 31 and 64% yields, respectively).

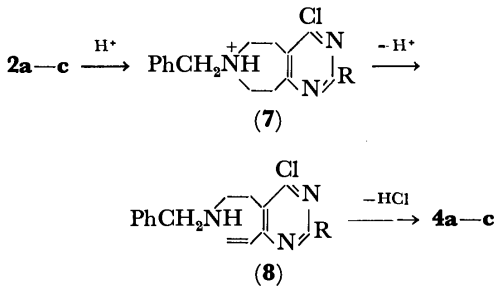
A Reaction Pathway for the Formation of the Rearrangement Products ***4***. It was found that the 4-chloro compounds **2a**—**c** also produced mainly **4a**—**c**, when heated with $POCl_3$. The compound **4b** was obtained on heating the monohydrochloride of **2b** at 130 °C in *N*,*N*-dimethylformamide. Thus the rearrangement products **4a**—**c** were most likely formed through the protonated tetrahydropyrimido-azepines **7**, which afforded the ring-opened intermediate 5-(2-benzylaminoethyl)-4-chloro-6-vinylpyrimidines (**8**) through



Scheme 1.

TABLE 3. ISOLATED YIELDS OF **2b** AND **4b** FROM **1b**

Chlorinating agents	React. time (h)	**2b** (%)	**4b** (%)
$POCl_3 + PhNEt_2$	2	70	10
$POCl_3$	5	50	20
$POCl_3$	8	25	40
$POCl_3$	13	0	45



Scheme 2.

Hofmann-type degradation[19] (or retrograde Michael reaction[20]). This ring-opening would preferably take place at the N(7)–C(8) [not N(7)–C(6)] bond of **7**, because the C(9) methylene group (which is α- and γ- to the pyrimidine ring nitrogens) is expected to be more acidic than that of C(5).[21] The intermediate **8** would then yield the final products **4a**—**c** by the intramolecular cyclization between the 5-(2-benzylaminoethyl) and 4-chloro groups of the pyrimidine ring (Scheme 2). 4-Vinylpyrimidines have been reported[11] to polymerize easily. The main reason for the moderate yields thus far of the rearranged products **4a**—**c** appeared to be likewise a facile addition polymerization of the vinyl functional group of the products (or of the intermediate **8**), since a considerable amount of a colorless rubberlike substance always accompanied during the preparation and purification of **4a**—**c**.

Many rearrangements have been known[5] involving fission of a heterocyclic ring and ring closure in the alternative direction catalyzed by base, heat, light or miscellaneous reagents. The present rearrangement seems, to our knowledge, to be a rare example of acid-catalyzed thermal ring transposition of fused heterocycles.[22]

Experimental

The microanalyses were carried out in this department using a Yanagimoto CHN Corder, MT-2. The solid materials for the analysis were dried over P_2O_5 for 2—4 h at 25 °C/20 Torr unless otherwise specified. Each of the analytical samples gave a single spot on thin-layer chromatography (silica gel and alumina). The IR spectra were taken with a JASCO IRA-1 Diffraction Grating IR Spectrophotometer. The measurements of ionization constants were carried out spectrophotometrically in 0.01 M buffers by the usual method.[23]

The Reaction of ***1a*** *with Phosphoryl Chloride.* A mixture of 1.0 g of **1a** and 15 ml of $POCl_3$ was refluxed under N_2 for 34 h. After evaporation of the $POCl_3$ at 40 °C/15 Torr, the residue was triturated with 20 ml of cold water, then diluted with 20 ml of cold chloroform. The aqueous layer was carefully brought to pH 8 with Na_2CO_3 at 5 °C. After separation, the aq. layer was extracted with $CHCl_3$. The combined organic layer was washed with brine, dried over K_2CO_3, and evaporated *in vacuo*, giving 1.14 g of a brown viscous liquid, which consisted mainly of **2a** and **4a** (in a ratio of 3 : 2 by NMR; the ratio was 9 : 1 after 9 hours' refluxing). This was chromatographed over alumina (Merck, Activity I; 60 g) and eluted with benzene (which was gradually changed up to 20% ether/benzene), giving first 0.48 g (40%) of **2a** as colorless prisms (from benzene/light petroleum, bp 30—70 °C), mp 65—67 °C (lit,[3] 67—68 °C), then 0.28 g (30%) of **4a** as colorless prisms (from ether/light petroleum), mp 71—73 °C. IR ($CHCl_3$): 1635, 1592, 1582, 1320, 980, 930, and 855 cm^{-1}. Found: C, 76.02; H, 6.50; N, 17.53%. Calcd for $C_{15}H_{15}N_3$: C, 75.91; H, 6.37; N, 17.71%.

7-Benzyl-6,7,8,9-tetrahydro-5H-pyrimido[4,5-d]azepine (***3***). A suspension of 100 mg of **2a** and 100 mg of sodium acetate in 5 ml of abs. EtOH was hydrogenated over 30 mg of 10%

Pd-C under atmospheric pressure, followed by the usual work-up procedure, giving 65 mg (74%) of **3** as colorless prisms (from light petroleum), mp 65—66 °C (lit,[3] 66.5—67.5 °C).

*The Reaction of **1b** with Phosphoryl Chloride.* One gram of **1b** was refluxed in 15 ml of $POCl_3$ and the same procedure as that described for **1a** was followed; the reaction time and the isolated yields of the products are shown in Table 3. The chloropyrimidoazepine (**2b**) was a colorless liquid (bp 170 °C/0.7 Torr[3]), which gave the monohydrochloride with HCl/ether as colorless flakes (from EtOH), mp 204—205 °C dec. Found (for material dried at 80 °C): C, 59.18; H, 6.09; N, 12.97%. Calcd for $C_{16}H_{18}N_3Cl \cdot HCl$: C, 59.28; H, 5.91; N, 12.96%.

The pyrrolo-pyrimidine **4b** was colorless needles (from benzene/light petroleum), mp 96—97 °C. IR ($CHCl_3$): 1635, 1590, 1390, 1340, 980, and 930 cm^{-1}. Found: C, 76.58; H, 6.92; N, 16.30%. Calcd for $C_{16}H_{17}N_3$: C, 76.45; H, 6.82; N, 16.72%.

*The Reaction of **2b** Hydrochloride with Phosphoryl Chloride.* A suspension of 100 mg of **2b** hydrochloride in 2 ml of $POCl_3$ was refluxed under N_2 for 12 h, followed by the same procedure as above, giving 80 mg of the crude reaction mixture as an amber liquid, which consisted mainly of unreacted **2b** and the rearranged **4b** in a ratio of 8 : 2 (by NMR).

*Heating of **2b** Hydrochloride in* N,N-*Dimethylformamide.* A solution of 0.32 g of **2b** hydrochloride in 10 ml of dry DMF was heated under N_2 at 130 °C for 5 h. The volatile was removed at 80 °C/15 Torr and the residue was dissolved in a cold mixture of $CHCl_3$ and 5% aq $NaHCO_3$ (10 : 10 ml). After separation, the aq layer was extracted with $CHCl_3$. The combined organic layer was dried over K_2CO_3 and evaporated *in vacuo*, giving a pale amber liquid (0.48 g). This was chromatographed over silica gel (40 g) into 15 ml fractions with $CHCl_3$ (which was gradually changed up to 2% MeOH/$CHCl_3$) as an eluent. The fractions 8—22 gave 0.10 g (43%) of a colorless solid which consisted mostly of **4b** (by NMR). Recrystallization from benzene/light petroleum afforded pure **4b** as colorless prisms, mp 94—95 °C.

*7-Benzyl-4-hydroxy-2-phenyl-6,7,8,9-tetrahydro-5*H*-pyrimido[4,5-*d*]azepine (**1c**).* To a cold solution of 1.15 g of sodium in 60 ml of dry MeOH were added 3.12 g of 1-benzyl-5-ethoxycarbonyl-1-azacycloheptan-4-one hydrochloride[24] and 2.62 g of benzamidine hydrochloride (monohydrate). The mixture was refluxed under N_2 for 4.5 h. After evaporation of the solvent *in vacuo*, the residue triturated with 80 ml of cold water was carefully taken to pH 6 with cold 6M-HCl and stirred at 25 °C for 1 h. The precipitate was collected and recrystallized from 80% EtOH, giving 2.50 g (75%) of **1c** as pale yellow needles, mp 197—199 °C. IR ($CHCl_3$): 3400—3000, 1630, 1600, and 1500 cm^{-1}. Found (for material dried at 80 °C): C, 75.41; H, 6.57; N, 12.62%. Calcd for $C_{21}H_{21}N_3O$: C, 75.10; H, 6.39; N, 12.68%.

*7-Benzyl-4-chloro-2-phenyl-6,7,8,9-tetrahydro-5*H*-pyrimido[4,5-*d*]azepine (**2c**).* A mixture of 0.42 g of **1c** and 15 ml of $POCl_3$ was refluxed under N_2 for 5 h. The volatile was removed *in vacuo* and the residue was triturated in 50 ml of cold water. The mixture was taken to pH 9 with Na_2CO_3 at 5 °C and extracted with benzene. The dried (over K_2CO_3) extract was evaporated *in vacuo*, giving 0.37 g (81%) of **2c** as colorless prisms, mp 117—119 °C, after recrystallization from benzene/light petroleum. IR ($CHCl_3$): 1560, 1520, and 1359 cm.$^{-1}$ Found: C, 72.33; H, 6.06; N, 12.03%. Calcd for $C_{21}H_{20}N_3Cl$: C, 72.08; H, 5.76; N, 12.06%.

*7-Benzyl-2-phenyl-4-vinyl-6,7-dihydro-5*H*-pyrrolo[2,3-*d*]pyrimidine (**4c**).* A suspension of 0.33 g of **1c** in 20 ml of $POCl_3$ was heated in a sealed tube at 160—170 °C for 13 h. The same procedure described above for **4a** and **4b** was followed, giving the crude reaction mixture which contained mostly **4c** and a trace of **2c**. Chromatographic purification over alumina (25 g) with $CHCl_3$ as an eluent gave 0.12 g (38%) of **4c** as pale yellow prisms (from benzene/light petroleum), mp 145—146 °C. IR ($CHCl_3$): 1635, 1580, 1560, 1370, 1350, 1320, 980, 930, and 880 cm^{-1}. Found: C, 80.56; H, 6.23; N, 13.16%. Calcd for $C_{21}H_{19}N_3$: C, 80.48; H, 6.11; N, 13.41%.

*7-Benzyl-4-ethyl-6,7-dihydro-5*H*-pyrrolo[2,3-*d*]pyrimidine (**5a**).* The vinyl compound **4a** (60 mg) was hydrogenated in 4 ml of abs. EtOH over 30 mg of 10% Pd-C. The usual work-up procedure yielded 49 mg (81%) of **5a** as colorless prisms (from light petroleum), mp 41—42 °C. Found: C, 75.42; H, 7.20; N, 17.31%. Calcd for $C_{15}H_{17}N_3$: C, 75.28; H, 7.16; N, 17.56%.

*7-Benzyl-4-ethyl-2-methyl-6,7-dihydro-5*H*-pyrrolo[2,3-*d*]pyrimidine (**5b**).* The vinyl compound **4b** (100 mg) was similarly hydrogenated, giving 81 mg (80%) of **5b** as colorless prisms (from light petroleum), mp 72—73 °C. Found: C, 75.46; H, 7.67; N, 16.10%. Calcd for $C_{16}H_{19}N_3$: C, 75.85; H, 7.56; N, 16.59%. The picrate: yellow prisms (from EtOH), mp 138—139 °C. Found: C, 54.65; H, 4.54; N, 16.81%. Calcd for $C_{22}H_{22}N_6O_7$: C, 54.77; H, 4.60; N, 17.42%.

*7-Benzyl-4-ethyl-2-phenyl-6,7-dihydro-5*H*-pyrrolo[2,3-*d*]pyrimidine (**5c**).* The similar hydrogenation of 100 mg of **4c** gave 85 mg (85%) of **5c** as colorless needles (from ether/light petroleum), mp 89—90 °C. Found: C, 79.69; H, 6.84; N, 13.07%. Calcd for $C_{21}H_{21}N_3$: C, 79.96; H, 6.72; N, 13.32%.

*Dehydrogenation of **5a**.* A mixture of 60 mg of **5a** and 30 mg of 10% Pd-C was refluxed in 1 ml of dry decalin under N_2 for 17 h. The catalyst was filtered off and washed with hot benzene. The filtrate combined with washings was concentrated at 20 °C/15 Torr to *ca.* 1 ml and set aside at 0 °C overnight, depositing 8 mg of *4-ethylpyrrolo[2,3-*d*]-pyrimidine (**6b**).* The filtrate was chromatographed over silica gel (5.5 g) and eluted with benzene, then with $CHCl_3$ (which was gradually changed up to 2% MeOH/$CHCl_3$), giving first 17 mg (27%) of *7-benzyl-4-ethylpyrrolo-[2,3-*d*]pyrimidine (**6a**)* as a colorless liquid, then 5 mg of more **6b** as a colorless crystalline powder. Recrystallization of the latter (**6b**; 33% total yield) from benzene/light petroleum gave colorless needles, mp 99—100 °C. IR ($CHCl_3$): 3430, 3200, 3150, 1580, 1345, and 890 cm^{-1}. Found: C, 65.53; H, 6.44; N, 28.55%. Calcd. for $C_8H_9N_3$: C, 65.28; H, 6.16; N, 28.55%. The benzyl compound **6a** gave the picrate as yellow prisms (from EtOH), mp 153—154 °C. Found: C, 54.28; H, 3.92; N, 18.31%. Calcd for $C_{21}H_{18}N_6O_7$: C, 54.08; H, 3.89; N, 18.02%.

*Dehydrogenation of **5b**.* A mixture of 70 mg of **5b**, 40 mg of 10% Pd-C, and 1.2 ml of dry decalin was refluxed under N_2 for 10 h. The similar work-up procedure as above was followed, giving 36 mg (80%) of *4-ethyl-2-methylpyrrolo-[2,3-*d*]pyrimidine (**6d**)* and 7 mg (10%) of the 7-benzyl derivative (**6c**). The latter was a colorless liquid. IR ($CHCl_3$): 2910, 2840, 1580, 1440, and 1400 cm^{-1}. It gave the picrate as yellow prisms (from EtOH), mp 137—138 °C. Found: C, 55.33; H, 4.20; N, 17.63%. Calcd for $C_{22}H_{20}N_6O_7$: C, 55.00; H, 4.20; N, 17.49%.

The former (**6d**) was colorless needles (from benzene/light petroleum), mp 141—142 °C. IR ($CHCl_3$): 3460, 3120, 1580, 1390, and 885 cm^{-1}. Found: C, 67.30; H, 7.22; N, 26.32%. Calcd for $C_9H_{11}N_3$: C, 67.05; H, 6.88; N, 26.07%.

*Dehydrogenation of **5c**.* Fifty milligrams of **5c** upon

similar dehydrogenation gave 15 mg (64%) of *4-ethyl-2-phenylpyrrolo[2,3-d]pyrimidine (6f)* and 10 mg (31%) of the 7-benzyl derivative (**6e**). The latter (**6e**) was colorless needles (from light petroleum), mp 46—47 °C. IR ($CHCl_3$): 1600, 1575, 1560, 1390, and 1370 cm^{-1}. Found: C, 80.11; H, 6.24; N, 13.17%. Calcd for $C_{21}H_{19}N_3$: C, 80.48; H, 6.11; N, 13.41%. The former (**6f**) was colorless needles (from ether/light petroleum), mp 139—140 °C. IR ($CHCl_3$): 3480, 3200, 3140, 1580, 1380, 900, 800, and 690 cm^{-1}. Found: C, 74.91; H, 5.96; N, 18.49%. Calcd for $C_{14}H_{13}N_3$: C, 75.31; H, 5.87; N, 18.82%.

Synthesis of Riparіochromene B and C[1]

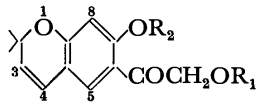
Masao TSUKAYAMA

Department of Applied Chemistry, Faculty of Engineering, Tokushima University, Minami-Josanjima, Tokushima 770

(Received August 3, 1976)

Condensation of 7-hydroxy-2,2-dimethylchroman with benzoyloxyacetonitrile gave 7-hydroxy-6-benzoyloxyacetyl-2,2-dimethylchroman (**3**) which was converted into 7-hydroxy-6-acetoxyacetyl-2,2-dimethylchroman (**7**) in four steps. Dehydrogenation of **7** with DDQ in dried toluene afforded riparіochromene B (**1**). Riparіochromene B was also synthesized by oxidative cyclization of 2,4-dihydroxy-5-(3-methyl-2-butenyl)-ω-acetoxyacetophenone (**13**) which was prepared from resorcinol and acetoxyacetonitrile in two steps. Riparіochromene C (**2**) was synthesized from resorcinol by the same method as that described above.

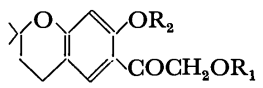
Riparіochromene B and riparіochromene C have recently been isolated from Australian *Eupatorium riparium* Regel along with several other chromenes, and these structures have been determined to be respectively 7-hydroxy-6-acetoxyacetyl-2,2-dimethylchromene (**1**) and 7-hydroxy-6-isobutyryloxyacetyl-2,2-dimethylchromene (**2**) which have an acyloxyacetyl substituent at the 6-position on the basis of spectral evidence.[2] In the present paper, the syntheses of **1** and **2** are reported to confirm the proposed structures of natural riparіochromene B and C.



(**1**) $R_1=CH_3CO$ $R_2=H$
(**2**) $R_1=(CH_3)_2CHCO$ $R_2=H$
(**8**) $R_1=R_2=CH_3CO$
(**11**) $R_1=(CH_3)_2CHCO$ $R_2=CH_3CO$

Fig. 1.

The condensation of 7-hydroxy-2,2-dimethylchroman[3] with benzoyloxyacetonitrile in the presence of freshly-fused zinc chloride gave 7-hydroxy-6-benzoyloxyacetyl-2,2-dimethylchroman (**3**), which produced a dark-brown reaction in the ferric chloride color test. Chroman **3** was easily converted into a 7-(benzyloxy) chroman derivative (**4**) upon treatment with benzyl chloride. Compound **4** was hydrolyzed with diluted hydrochloric acid in ethanol to give a 6-(hydroxyacetyl) chroman derivative (**5**) which showed absorption bands attributable to an alcoholic hydroxyl group in the IR spectrum and no proton signals from the benzoyl group in the NMR spectrum. The hydrolysis of **4** with a diluted alkali, however, did not afford the desired chroman derivative **5**. Compound **5**, after being converted into a 6-(acetoxyacetyl)chroman derivative (**6**)



(**3**) $R_1=C_6H_5CO$ $R_2=H$
(**4**) $R_1=C_6H_5CO$ $R_2=C_6H_5CH_2$
(**5**) $R_1=H$ $R_2=C_6H_5CH_2$
(**6**) $R_1=CH_3CO$ $R_2=C_6H_5CH_2$
(**7**) $R_1=CH_3CO$ $R_2=H$
(**9**) $R_1=(CH_3)_2CHCO$ $R_2=C_6H_5CH_2$
(**10**) $R_1=(CH_3)_2CHCO$ $R_2=H$

Fig. 2.

with acetyl chloride in a large quantity of pyridine cooled by ice, was subjected to hydrogenolysis over palladium on charcoal in methanol to afford a 7-(hydroxy)chroman derivative (dihydroriparіochromene B) (**7**), which produced a light-brown reaction in the ferric chloride color test and indicated an intramolecular hydrogen-bonded hydroxyl group in the NMR spectrum. The dehydrogenation[4-6] of **7** with boiling in DDQ (2,3-dichloro-5,6-dicyano-*p*-benzoquinone) in dried toluene afforded the desired chromene (**1**) (mp 146—147 °C) (lit, mp 145—146 °C).[2] This compound was further converted into the acetate of riparіochromene B (**8**).

According to the procedure described above, **5** was treated with isobutyryl chloride to give a 6-(isobutyryloxyacetyl)chroman derivative (**9**). The subsequent hydrogenolysis of **9** afforded a 7-(hydroxy)chroman derivative (dihydroriparіochromene C) (**10**). The dehydrogenation of **10** with DDQ gave the desired chromene (**2**) (mp 109.5—110.5 °C) (lit, mp 109—110 °C).[2] Chromene **2** was also converted into the acetate of riparіochromene C (**11**).

Chromenes **1** and **2** thus synthesized were respectively confirmed to be identical to natural riparіochromene B and C on the basis of a mixed melting-point determination and NMR, IR, and UV spectral comparisons.

In order to provide an alternate approach to the synthesis of chromenes **1** and **2**, another route was investigated. The condensation of resorcinol with acetoxyacetonitrile or isobutyryloxyacetonitrile in the presence of freshly-fused zinc chloride easily gave ω-(acyloxy)acetophenones (**12**) or (**16**), respectively, which showed a positive reaction in the ferric chloride color test and was supported by IR and NMR spectra. The BF_3-catalyzed condensation of 2-methyl-3-buten-2-ol[7] with **12** or **16** afforded 3- or 5-(3-methyl-2-butenyl)-ω-(acyloxy)acetophenones (**13** and **14**) or (**17** and **18**), respectively, which were isolated by column chromatography. All these compounds showed positive reactions in the ferric chloride color test, and these structures were supported by NMR spectra. The major product **13** or **17**, in each condensation, was boiled with DDQ in dried toluene for conversion into chromene **1** or **2**, which was confirmed to be identical with the riparіochromene B or C synthesized above, respectively. The minor products **14** and **18** in the condensation were similary treated to give compounds **15** and **19**, whose structures were revealed by their NMR spectra to be chromenes.

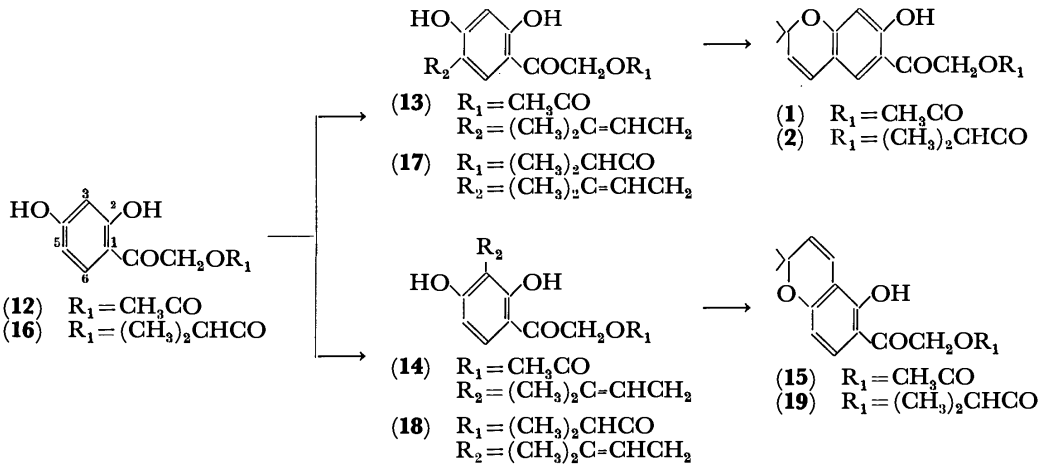


Fig. 3.

Experimental

All the melting points are uncorrected. The IR spectra were taken on a Hitachi 215 Spectrophotometer and the UV spectra on a Hitachi 124 Spectrophotometer. The NMR spectra were measured with a JOEL PS-100 Spectrometer (100 MHz), using tetramethylsilane as an internal standard (δ, ppm). Column chromatography was carried out on Kieselgel 60 (70—230 mesh) (Merck).

7-Hydroxy-6-benzoyloxyacetyl-2,2-dimethylchroman (3). 7-Hydroxy-2,2-dimethylchroman (10.6 g), anhydrous benzoyloxyacetonitrile (14.5 g), and freshly-fused zinc chloride (4 g) were successively added in dried ether (60 ml), and a rapid stream of dried hydrogen chloride was bubbled into the mixture with stirring and cooling in an ice-salt bath for 7 h. The reaction mixture was allowed to stand for 24 h in a refrigerator, and then the solvent was decanted. The residual solid, after being washed with dried ether (80 ml), was boiled in water (80 ml) for 1 h and cooled to give a white precipitate, which was collected and recrystallized from methanol as colorless needles (**3**) (15.2 g, 75%): mp 141—142 °C; IR ν_{max}^{KBr} 1720, 1665 cm^{-1}; NMR ($CDCl_3$) δ 1.36 (s, 6H, 2×CH_3), 1.83 (t, 2H, J=7 Hz, C_3-H), 2.73 (t, 2H, J=7 Hz, C_4-H), 5.48 (s, 2H, CH_2), 6.32 (s, 1H, arom. H), 7.3—7.6 (m, 4H, arom. H), 8.0—8.3 (m, 2H, arom. H), 11.66 (s, OH). Found: C, 70.55; H, 5.85%. Calcd for $C_{20}H_{20}O_5$: C, 70.57; H, 5.92%.

7-Benzyloxy-6-benzoyloxyacetyl-2,2-dimethylchroman (4). Compound **3** (10.2 g), benzyl chloride (7.0 g), potassium iodide (9.0 g), and dried potassium carbonate (15.0 g) were successively added to dried acetone (150 ml). After the mixture was heated under reflux for 7 h, the solvent was evaporated under reduced pressure, and the residual substance was poured into cold water. The white precipitate thus formed was collected and recrystallized from ethanol to give colorless needles (**4**) (11.6 g, 90%): mp 146—147 °C; IR ν_{max}^{KBr} 1725, 1662 cm^{-1}; NMR ($CDCl_3$) δ 1.36 (s, 6H, 2×CH_3), 1.83 (t, 2H, J=7 Hz, C_3-H), 2.73 (t, 2H, J=7 Hz, C_4-H), 5.11 (s, 2H, $C\underline{H}_2C_6H_5$), 5.34 (s, 2H, CH_2), 6.45 (s, 1H, C_8-H), 7.3—7.6 (m, 8H. arom. H), 7.79 (s, 1H, C_5-H), 8.0—8.2 (m, 2H, arom. H). Found: C, 75.36; H, 6.04%. Calcd for $C_{27}H_{26}O_5$: C, 75.33; H, 6.09%.

7-Benzyloxy-6-hydroxyacetyl-2,2-dimethylchroman (5). Compound **4** (8.6 g) with *ca.* 18% hydrochloric acid (80 ml) in ethanol (400 ml) was refluxed for 8 h, and then the organic solvent was removed under reduced pressure. The precipitate was recrystallized from methanol to give colorless needles (**5**) (2.7 g, 40%): mp 142—143 °C; IR ν_{max}^{KBr} 3480, 1643 cm^{-1}; NMR ($CDCl_3$) δ 1.37 (s, 6H, 2×CH_3), 1.83 (t, 2H, J=7 Hz, C_3-H), 2.75 (t, 2H, J=7 Hz, C_4-H), 4.63 (s, 2H, CH_2), 5.05 (s, 2H, $C\underline{H}_2C_6H_5$), 6.43 (s, 1H, C_8-H), 7.36 (s, 5H, arom. H), 7.87 (s, 1H, C_5-H). Found: C, 73.63; H, 6.74%. Calcd for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79%.

7-Benzyloxy-6-acetoxyacetyl-2,2-dimethylchroman (6). To a solution of **5** (1.0 g) in dried pyridine (25 ml) was added acetyl chloride (1.5 ml) drop by drop with stirring and cooling in an ice bath, and the mixture was stirred with cooling for 6 h. The reacted mixture was poured into ice-cold water (20 ml) to give a white precipitate, which was collected and recrystallized from methanol as colorless needles (**6**) (0.76 g, 65%): mp 111—112 °C; IR ν_{max}^{KBr} 1740, 1662 cm^{-1}; NMR ($CDCl_3$) δ 1.32 (s, 6H, 2×CH_3), 1.78 (t, 2H, J=7 Hz, C_3-H), 2.72 (t, 2H, J=7 Hz, C_4-H), 2.14 (s, 3H, CH_3CO), 5.06 and 5.10 (each s, 2H, $C\underline{H}_2C_6H_5$ and $COCH_2O$), 6.41 (s, 1H, C_8-H), 7.41 (s, 5H, arom. H), 7.76 (s, 1H, C_5-H). Found: C, 71.90; H, 6.68%. Calcd for $C_{22}H_{24}O_5$: C, 71.72; H, 6.57%.

7-Hydroxy-6-acetoxyacetyl-2,2-dimethylchroman (Dihydroripariochromene B) (7). Compound **6** (0.74 g) was hydrogenated over palladium on charcoal (10%; 0.18 g) in methanol until the uptake of hydrogen ceased. The solvent was removed under reduced pressure, and the residue was recrystallized from methanol to give colorless plates (**7**) (0.37 g, 70%): mp 131—132 °C; IR ν_{max}^{KBr} 1745, 1645 cm^{-1}; NMR ($CDCl_3$) δ 1.34 (s, 6H, 2×CH_3), 1.81 (t, 2H, J=7 Hz, C_3-H), 2.71 (t, 2H, J=7 Hz, C_4-H), 2.21 (s, 3H, CH_3CO), 5.24 (s, 2H, CH_2), 6.31 (s, 1H, C_8-H), 7.30 (s, 1H, C_5-H), 11.80 (s, OH). Found: C, 64.87; H, 6.59%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

7-Hydroxy-6-acetoxyacetyl-2,2-dimethylchromene (Riparіochromene B) (1). A mixture of **7** (0.11 g) and DDQ (0.10 g) in dried toluene (50 ml) was heated under reflux for 10 h, and then the solvent was removed under reduced pressure. The residual substance was purified by column chromatography over silica gel with chloroform to give chromene **1**, which was recrystallized from carbon tetrachloride as colorless needles (40 mg, 40%): mp 146—147 °C (no depression in a mixed melting-point determination with natural riparіochromene B); IR ν_{max}^{KBr} 1750, 1652 cm^{-1}; UV λ_{max}^{EtOH} nm (log ε) 257 (4.51), 286 (3.95), 347 (3.85). NMR ($CDCl_3$) δ 1.41 (s, 6H, 2×CH_3), 2.20 (s, 3H, CH_3CO), 5.20 (s, 2H, CH_2), 5.54 (d, 1H, J=9 Hz, C_3-H), 6.23 (d, 1H, J=9 Hz, C_4-H), 6.30 (s, 1H, C_8-H), 7.15 (s, 1H, C_5-H), 12.20 (s, OH). Found: C, 65.09; H, 5.79%. Calcd for

$C_{15}H_{16}O_5$: C, 65.21; H, 5.84%.

7-Acetoxy-6-acetoxyacetyl-2,2-dimethylchromene (Acetate of Ripariochromene B) (8). After a mixture of **1** (54 mg), acetic anhydride (1 ml), and pyridine had been allowed to stand over 24 h at room temperature, cold water was added to the mixture and it was again allowed to stand overnight in a refrigerator. The mixture was extracted with ether and the ethereal solution was washed with a saturated aqueous solution of sodium chloride, dried over sodium sulfate, and the solvent was evaporated. The residue was recrystallized from a mixture of benzene and hexane to give colorless needles (**8**) (58 mg, 93%): mp 109—110 °C; IR ν_{max}^{KBr} 1770, 1735, 1675 cm^{-1}; NMR ($CDCl_3$) δ 1.46 (s, 6H, $2\times CH_3$), 2.19 (s, 3H, CH_3CO), 2.35 (s, 3H, C_7-CH_3CO), 5.10 (s, 2H, CH_2), 5.64 (d, 1H, J=10 Hz, C_3-H), 6.29 (d, 1H, J=10 Hz, C_4-H), 6.53 (s, 1H, C_8-H), 7.46 (s, 1H, C_5-H). Found: C, 64.25; H, 5.68%. Calcd for $C_{17}H_{18}O_6$: C, 64.14; H, 5.70%.

7-Benzyloxy-6-isobutyryloxyacetyl-2,2-dimethylchroman (9). Isobutyryl chloride (1.5 ml) was added to a solution of **5** (0.86 g) in dried pyridine (25 ml). After stirring in an ice bath for 10 h, the mixture was worked up in the same manner, as in the case of **6**, to give chroman **9**, which was recrystallized from methanol as colorless needles (0.76 g, 73%): mp 93—94 °C; IR ν_{max}^{KBr} 1740, 1680 cm^{-1}; NMR ($CDCl_3$) δ 1.23 [d, 6H, J=7 Hz, $(CH_3)_2CH$], 1.32 (s, 6H, $2\times CH_3$), 1.77 (t, 2H, J=7 Hz, C_3-H), 2.71 (t, 2H, J=7 Hz, C_4-H), 2.65 [m, 1H, $(CH_3)_2CH$], 5.06 and 5.09 (each s, 2H, $CH_2C_6H_5$ and $COCH_2O$), 6.40 (s, 1H, C_8-H), 7.40 (s, 5H, arom. H), 6.77 (s, 1H, C_5-H). Found: C, 72.86; H, 6.84%. Calcd for $C_{24}H_{28}O_5$: C, 72.70; H, 7.12%.

7-Hydroxy-6-isobutyryloxyacetyl-2,2-dimethylchroman (Dihydroripariochromene C) (10). Compound **9** (0.44 g) was hydrogenated over palladium on charcoal and the reacted mixture was worked up in the same manner, as in the case of **7**, to give colorless plates (**10**) (0.26 g, 70%): mp 113—114 °C; IR ν_{max}^{KBr} 1738, 1640 cm^{-1}; NMR ($CDCl_3$) δ 1.24 [d, 6H, J=7 Hz, $(CH_3)_2CH$], 1.33 (s, 6H, $2\times CH_3$), 1.80 (t, 2H, J=7 Hz, C_3-H), 2.70 (t, 2H, J=7 Hz, C_4-H), *ca.* 2.67 [m, 1H, $(CH_3)_2CH$], 5.22 (s, 2H, CH_2), 6.30 (s, 1H, C_8-H), 7.30 (s, 1H, C_5-H), 11.80 (s, OH). Found: C, 66.62; H, 7.50%. Calcd for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24%.

7-Hydroxy-6-isobutyryloxyacetyl-2,2-dimethylchromene (Ripariochromene C) (2). A mixture of **10** (102 mg), DDQ (85 mg), and dried toluene (30 ml) was heated under reflux for 9 h. The reacted mixture was worked up in the same manner, as in the case of **1**, to give chromene **2**, which was recrystallized from carbon tetrachloride as colorless needles (30 mg, 30%): mp 109.5—110.5 °C (no depression in a mixed melting-point determination with natural ripariochromene C); IR ν_{max}^{KBr} 1740, 1645 cm^{-1}; UV λ_{max}^{EtOH} nm (log ε) 257 (4.39), 287 (3.77), 348 (3.72); NMR ($CDCl_3$) δ 1.26 [d, 6H, J=7 Hz, $(CH_3)_2CH$], 1.45 (s, 6H, $2\times CH_3$), 2.73 [m, 1H, $(CH_3)_2$-CH], 5.24 (s, 2H, CH_2), 5.57 (d, 1H, J=9 Hz, C_3-H), 6.25 (d, 1H, J=9 Hz, C_4-H), 6.33 (s, 1H, C_8-H), 7.18 (s, 1H, C_5-H), 12.05 (s, OH). Found: C, 67.37; H, 6.58%. Calcd for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62%.

7-Acetoxy-6-isobutyryloxyacetyl-2,2-dimethylchromene (Acetate of Ripariochromene C) (11). A mixture of **2** (54 mg), acetic anhydride (1 ml), and pyridine was worked up in the same manner, as in the case of **8**, to give colorless needles (**11**) (56 mg, 91%): mp 124—125 °C; IR ν_{max}^{KBr} 1775, 1740, 1685 cm^{-1}; NMR ($CDCl_3$) δ 1.24 [d, 6H, J=7 Hz, $(CH_3)_2$-CH], 1.46 (s, 6H, $2\times CH_3$), 2.35 (s, 3H, CH_3CO), 2.70 [m, 1H, $(CH_3)_2CH$], 5.07 (s, 2H, CH_2), 5.63 (d, 1H, J=10 Hz, C_3-H), 6.29 (d, 1H, J=10 Hz, C_4-H), 6.52 (s, 1H, C_8-H), 7.48 (s, 1H, C_5-H). Found: C, 65.88; H, 6.32%. Calcd for $C_{19}H_{22}O_6$: C, 65.88; H, 6.40%.

2,4-Dihydroxy-ω-(acetoxy)acetophenone (12). Resorcionl (20 g), acetoxyacetonitrile (26.5 g), and zinc chloride (8 g) were successively added to dried ether (100 ml), and a rapid stream of dried hydrogen chloride was bubbled into the mixture with stirring in an ice-salt bath for 2 h. The mixture, after being treated in the same manner as in the case of **3**, was heated in water–methanol (1 : 9; 300 ml) for 1.5 h at 60 °C, and the solvent was distilled out under reduced pressure. The residue was recrystallized from chloroform to give colorless plates (**12**) (15 g, 40%), producing a light-brown reaction in the ferric chloride color test: mp 167—168 °C; IR ν_{max}^{KBr} 1740, 1610 cm^{-1}; NMR (DMSO) δ 2.13 (s, 3H, CH_3CO), 5.24 (s, 2H, CH_2), 6.30 (bs, 1H, C_3-H), 6.35 [q, 1H, (J=2.5, 9 Hz) C_5-H], 7.68 (d, 1H, J=9 Hz, C_6-H), 10.63 (s, C_4-OH), 11.54 (s, C_2-OH). Found: C, 57.03; H, 4.77%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

5-(3-Methyl-2-butenyl)-2,4-dihydroxy-ω-(acetoxy)acetophenone (13) and 3-(3-Methyl-2-butenyl)-2,4-dihydroxy-ω-(acetoxy)acetophenone (14). To a mixed solution of **12** (5.0 g) and boron trifluoride etherate (3.3 g) in dried dioxane (70 ml) was gradually added a solution of 2-methyl-3-buten-2-ol (2.1 g) in dried dioxane (15 ml) and the mixture was heated at 50—60 °C for 3 h. The reacted mixture was cooled to room temperature, poured into cold water, and taken up in ether. The ethereal solution was washed with an aqueous solution of sodium hydrogen carbonate, dried over sodium sulfate, and the solvent was evaporated to give a yellow oil, which was chromatographed over a silica-gel column with chloroform with separation of compounds A (R_f=0.19) and B (R_f=0.07). Compound B was recrystallized from benzene as colorless needles (**13**) (1.8 g, 20%): mp 129—130 °C; IR ν_{max}^{KBr} 1740, 1630 cm^{-1}; NMR ($CDCl_3$) δ 1.77 (bs, 6H, $2\times CH_3$), 2.23 (s, 3H, CH_3CO), 3.24 (d, 2H, J=7 Hz, CH_2CH=), 5.24[8] (s, 2H, CH_2), *ca.* 5.24[8] [1H, $(CH_3)_2C$=CH], 6.31 (s, 2H, C_3-H, C_4-OH), 7.25 (s, 1H, C_6-H), 11.93 (s, C_2-OH). Found: C, 64.77; H, 6.43%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

Compound A was recrystallized from benzene as colorless needles (**14**) (0.4 g, 6%), producing a positive reaction in the ferric chloride color test: mp 147—148 °C; IR ν_{max}^{KBr} 1725, 1630 cm^{-1}; NMR ($CDCl_3$) δ 1.74 (s, 3H) and 1.80 (s, 3H) [$(CH_3)_2C$=CH], 2.22 (s, 3H, CH_3CO), 3.39 (d, 2H, J=7 Hz, CH_2CH=), 5.22[8] (s, 2H, CH_2), *ca.* 5.22[8] [1H, $(CH_3)_2C$=CH], 6.32 (d, 1H, J=9 Hz, C_5-H), 6.37 (s, C_4-OH), 7.83 (d, 1H, J=9 Hz, C_6-H), 12.45 (s, C_2-OH). Found: C, 64.68; H, 6.41%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

Another Synthesis of Ripariochromene B (1). A mixture of **13** (0.30 g), DDQ (0.32 g), and dried toluene (120 ml) was heated under reflux for 2 h. The reacted mixture was worked up in the same manner as in the case of chromene **1**. The chromene thus obtained was recrystallized from carbon tetrachloride as colorless needles (**1**) (0.18 g, 65%): mp 146—147 °C (no depression in a mixed melting-point determination with the ripariochromene B synthesized above).

5-Hydroxy-6-acetoxyacetyl-2,2-dimethylchromene (15). A mixture of **14** (57 mg), DDQ (68 mg), and dried toluene (20 ml) was worked up in the same manner described above. The chromene thus obtained was crystallized from petroleum ether (35—40 °C) as colorless prisms (**15**) (24 mg, 42%): mp 117—118.5 °C; IR ν_{max}^{KBr} 1755, 1660 cm^{-1}; NMR ($CDCl_3$) δ 1.44 (s, 6H, $2\times CH_3$), 2.21 (s, 3H, CH_3CO), 5.23 (s, 2H, CH_2), 5.56 (d, 1H, J=10 Hz, C_3-H), 6.32 (d, 1H, J=10 Hz, C_4-H), 6.67 (d, 1H, J=10 Hz, C_8-H), 7.38 (d, 1H, J=10 Hz, C_7-H), 12.32 (s, OH). Found: C, 65.10; H,

5.90%. Calcd for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84%.

*2,4-Dihydroxy-ω-(isobutyryloxy)acetophenone (**16**).* A mixture of resorcinol (10.4 g), isobutyryloxyacetonitrile (18 g), and zinc chloride (6 g) in dried ether (200 ml) was worked up in the same manner as in the case of **12** to give colorless prisms (**16**) (10 g, 40%): mp 116—117 °C; IR ν_{max}^{KBr} 1710, 1635 cm^{-1}; NMR (DMSO) δ 1.15 [d, 6H, J=7 Hz, $(CH_3)_2$-CH], 2.63 [m, 1H, $(CH_3)_2CH$], 5.23 (s, 2H, CH_2), 6.28 (bs, 1H, C_3-H), 6.33 [q, 1H, (J=2.5, 9 Hz) C_5-H], 7.68 [d, 1H, (J=9 Hz) C_6-H], 10.57 (s, C_4-OH), 11.46 (s, C_2-OH). Found: C, 60.46; H, 5.74%. Calcd for $C_{12}H_{14}O_5$: C, 60.50; H, 5.92%.

*5-(3-Methyl-2-butenyl)-2,4-dihydroxy-ω-(isobutyryloxy) acetophenone (**17**) and 3-(3-Methyl-2-butenyl)-2,4-dihydroxy-ω-(isobutyryloxy)acetophenone (**18**).* A mixed solution of **16** (8.0 g), boron trifluoride etherate (3.6 g), and 2-methyl-3-buten-2-ol (2.1 g) in dried dioxane (150 ml) was worked up in the same manner as in the case of **13** to give **17** and **18**. Compound **17** was recrystallized from benzene as colorless needles (1.8 g. 20%): mp 122—123 °C; IR ν_{max}^{KBr} 1720, 1650 cm^{-1}; NMR ($CDCl_3$) δ 1.27 [d, 6H, J=7 Hz, $(CH_3)_2$-CH], 1.74 [bs, 6H, $(CH_3)_2C$=CH], 2.74 [m, 1H, $(CH_3)_2CH$], 3.23 [d, 2H, J=7 Hz, CH_2CH=], 5.23[8] (s, 2H, CH_2), *ca.* 5.23[8] [1H, $(CH_3)_2C$=CH], 6.29 (s, 1H, C_3-H), 6.47 (s, C_4-OH), 7.25 (s, 1H, C_6-H), 11.96 (s, C_2-OH). Found: C, 66.88; H, 7.29%. Calcd for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24%.

Recrystallization of **18** from benzene gave colorless needles (0.4 g, 5%): mp 147—148 °C; IR ν_{max}^{KBr} 1713, 1625 cm^{-1}; NMR ($CDCl_3$) δ 1.25 [d, 6H, J=7 Hz, $(CH_3)_2CH$], 1.73 (s, 3H) and 1.79 (s, 3H) [$(CH_3)_2C$=CH], 2.73 [m, 1H, $(CH_3)_2CH$], 3.40 (d, 2H, J=7 Hz, CH_2CH=), 5.24[8] (s, 2H, CH_2), *ca.* 5.24[8] [1H, $(CH_3)_2C$=CH], 6.35 (d, 1H, J=9 Hz, C_5-H), 6.39 (s, C_4-OH), 7.36 (d, 1H, J=9 Hz, C_6-H), 12.45 (s, C_2-OH). Found: C, 66.50; H, 7.12%. Calcd for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24%.

*Another Synthesis of Riparіochromene C (**2**).* A mixture of **17** (0.30 g), DDQ (0.29 g), and dried toluene (120 ml) was worked up in the manner described above to give colorless needles (**2**) (0.18 g, 60%): mp 109.5—110.5 °C (no depression in a mixed melting-point determination with the riparіochromene C synthesized above).

*5-Hydroxy-6-isobutyryloxyacetyl-2,2-dimethylchromene (**19**).* A mixture of **18** (102 mg), DDQ (113 mg), and dried toluene (120 ml) was worked up in the manner described above to give colorless prisms (**19**) (53 mg, 52%): mp 72—73.5 °C; IR ν_{max}^{KBr} 1735, 1640 cm^{-1}; NMR ($CDCl_3$) δ 1.26 [d, 6H, J=7 Hz, $(CH_3)_2CH$], 1.44 (s, 6H, 2×CH_3), 2.73 [m, 1H, $(CH_3)_2CH$], 5.22 (s, 2H, CH_2), 5.55 (d, 1H, J=10 Hz, C_3-H), 6.32 (d, 1H, J=10 Hz, C_4-H), 6.68 (d, 1H, J=10 Hz, C_8-H), 7.38 (d, 1H, J=10 Hz, C_7-H), 12.33 (s, OH). Found: C, 67.36; H, 6.72%. Calcd for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62%.

The author wishes to express his deep gratitude to Professor Shûichi Hayashi and Dr. Mitsuru Nakayama, Hiroshima University, for their guidance and encouragement throughout the course of this work, and also to Dr. Thorleif Anthonsen, Norway Institute of Technology, for supplying the samples of natural riparіochromene B and C.

Skeletal Rearrangement of Furanoeremophilane-6β,10β-diol into Farfugin A, Farfugin B, and 6-[(4*R*)-Chloropentyl]-3,5-dimethylbenzofuran[1]

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received August 5, 1976)

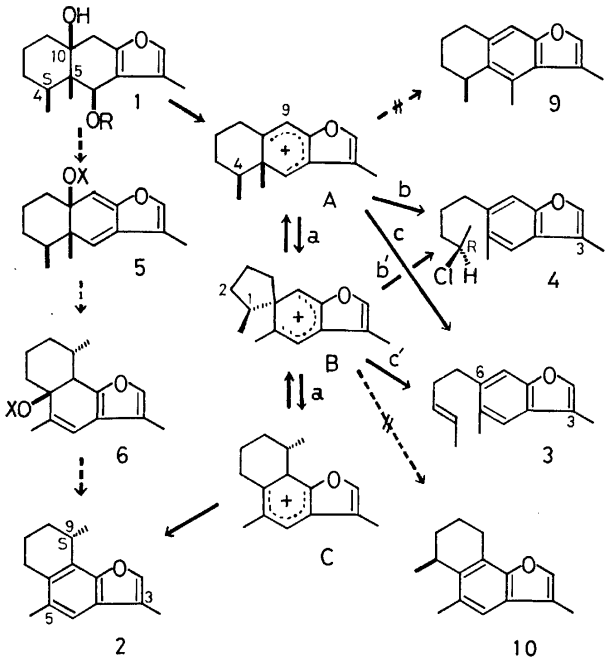
Treatment of furanoeremophilane-6β,10β-diol (**1**; R=H) with phosphoryl chloride in pyridine at 110 °C gave farfugin A (**2**; yield: 23%), farfugin B (**3**; y: 34%), and 6-[(4*R*)-4-chloropentyl]-3,5-dimethylbenzofuran (**4**; y: 15%). A mechanism of formation of these three compounds (**2**, **3**, and **4**) is discussed.

Furanoeremophilane-6β,10β-diol (**1**; R=H)[2] is a sesquiterpene of eremophilane-type isolated from *Ligularia japonica* Less., while farfugin A (**2**)[3] and farfugin B (**3**)[3] are benzofuran derivatives contained in *Farfugium japonicum* (L.) Kitam. In connection with a structure investigation of **1** (R=H), we found that farfugin A, farfugin B, and another benzofuran (**4**) were formed on dehydration of **1** (R=H) with phosphoryl chloride. In the present paper we wish to report the mechanism of these skeletal rearrangements.

The diol (**1**; R=H) was treated with phosphoryl chloride in pyridine at 110 °C under nitrogen to give three benzofuran derivatives (**2**, **3**, and **4**). The two products, **2** (yield: 23%), mp 78—79 °C, $[\alpha]_D$+32° (EtOH), and **3** (y: 34%), an oil, proved to be identical with farfugin A (**2**) and farfugin B (**3**), respectively. The molecular formula $C_{15}H_{19}OCl$ of the third product (**4**; y: 15%), an oil, $[\alpha]_D$—20° (EtOH), was determined by elemental analysis and mass spectrometry. The UV spectrum of **4** is superimposable with that of **3**; this suggests the presence of a benzofuran moiety in **4** similar to that in **3**. The IR spectrum of **4** indicates the presence of a C-Cl group (795 cm^{-1}) and the absence of a *trans* -CH=CH- system. The PMR spectrum of **4** shows a doublet (J=7.5 Hz) at δ 1.50 due to a secondary methyl (CH_3-CHCl-) and a multiplet at δ 4.0 due to a proton on the chlorine-bearing carbon (CH_3-CHCl-), while a multiplet at δ 5.45[3b] due to a *trans* olefin system (-CH=CH-) observed for **3** is absent. The other PMR spectral data of **3** are closely related to those of **4**. The observation shown above led to the structure **4** for the third product. The absolute configuration at the chlorine-substituted carbon in **4** (with negative sign of $[\alpha]_D$) was deduced to be (*R*) by application of Brewster rule.[4]

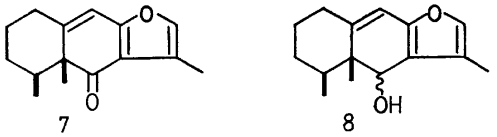
A similar treatment of 10β-hydroxy-6β-methoxyfuranoeremophilane (**1**; R=CH_3)[2] and 6β-acetoxy-10β-hydroxyfuranoeremophilane (**1**; R=Ac)[2] yielded also the three benzofuran derivatives (**2**, **3**, and **4**) (detected by TLC). When **1** (R=H) was treated with trace of hydrochloric acid in acetone at room temperature, the formation of these compounds (**2**, **3**, and **4**) was observed by TLC examination along with tarry products.

The fact that both **2** and **4** are optically active is of interest in view of the mechanism of these skeletal rearrangements. The absolute configuration at $C_{(4)}$ of the diol (**1**; R=H) and the absolute stereochemistry at $C_{(9)}$ of farfugin A (**2**) have recently been reported to be both (*S*).[2b,5] The configuration of the migrating center was thus shown to be retained before and after the transformation. The formation of **2** from **1** would be explained by two successive 1,2-alkyl shifts involving a spiro intermediate (**B**),[6] or by a 1,5-sigmatropic shift[7] *via* **5** and **6** (X=$POCl_2$ or other phosphate esters) (Scheme 1).



Scheme 1.

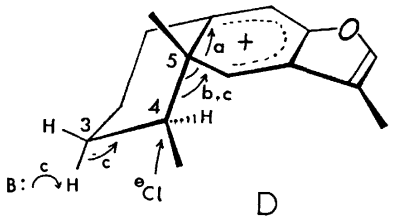
Reduction of furanoeremophil-9-en-6-one (**7**)[2b] with lithium aluminium hydride gave the corresponding alcohol (**8**), which was treated with phosphoryl chloride under the same conditions described for **1** (R=H). The three benzofuran derivatives (**2**, **3**, and **4**) were fairly obtained in a similar ratio to that observed for the rearrangement products of **1** (R=H). This fact strongly suggests that these three benzofurans are formed from an intermediate cyclohexadienyl cation (**A**),[8] which could be produced from **8** by elimination of a hydroxyl (or its equivalents). The pathway through the cation **A** would thus be favorable rather than the route involving 1,5-sigmatropic shift.



The presence of two stage 1,2-alkyl shifts through a spiro intermediate in the dienone-phenol rearrangement of a cyclohexadienyl cation has elegantly been demonstrated.[9,10] In an acid-catalyzed dienone-phenol rear-

rangement the medium affects the products.[11,12] A preferential migration, especially favored under the anhydrous conditions, of the more highly substituted carbon atom in the rearrangement was demonstrated.[9-12]

The mechanism of the rearrangement of **1** into **2**, **3**, and **4** could therefore be well rationalized as follows. The elimination of hydroxyls (or their equivalents) from **1** would give rise to the cyclohexadienyl cation **A** (depicted as **D**), which would then suffer rearrangements to form the three benzofuran derivatives (**2**, **3**, and **4**). (a) A migration of $C_{(4)}$-$C_{(5)}$ bond in **A** gives a spiro intermediate (**B**)[9-11] which would be further rearranged into another cation (**C**). An elimination of a proton from **C** affords farfugin A (**2**) whose configuration at $C_{(9)}$ is (*S*) (pathway a). Two processes could account for the formation of both **4** and **3**. (b and/or b') A S_N2 type substitution by Cl^- is effected at the secondary methyl carbon of **A** (path b) and/or of **B** (path b') with concomitant aromatization of ring B. These pathway would give the (4*R*)-4-chloropentyl side chain in **4**. (c and/or c') An abstraction of $C_{(3a)}$-H from **A** with aromatization of ring B would lead to a formation of the *trans*-3-pentenyl side chain[3b] in farfugin B (**3**) (path c). An alternative route involving an elimination of $C_{(2)}$-H from **B** accompanied with aromatization could produce a mixture of isomers with the *cis* and *trans* side chains. The *cis*-isomer would then isomerize under the reaction conditions to give **3** (path c'). A choice between the two routes (between b and b', and between c and c') for each formation of **4** and **3**, remained undecided (*cf.* **D** and Scheme 1).



D

In the rearrangement of the diol (**1**; R=H), benzofuran derivatives such as **9**[13] and **10** might be expected to be produced form **A** and **B**, respectively. This was, however, contrary to the observation. This evidence could be interpreted by the preferential migration (or bond-scission) of the more highly substituted carbon atom[9-12] ($C_{(4)}$ of **A**, or $C_{(1)}$ of **B**), whose rearrangement would be especially pronounced in anhydrous conditions ($POCl_3$-pyridine), to afford **2** (**3**, and **4**).

In conclusion, the conversion of **1** into **2**, **3**, and **4** can be best explained by an intermediacy of the cyclohexadienyl cation **A** as in the case of dienone-phenol rearrangement.[14]

Experimental

IR spectra were measured using a Hitachi EPI-G2 spcetrometer. Optical rotation was measured on a JASCO DIL-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV. PMR spectra were measured using a JEOL PS-100 (100 MHz). Thin layer chromatography (TLC) was carried out on Kieselgel PF_{254} (E. Merck, Darmstadt). For column chromatography Wakogel 200 (Wako Pure Chemical Co.) was used. All mps were determined on a hot block and reported uncorrected.

Treatment of Furanoermophilane-6β,10β-diol (***1*** : *R=H*) *with Phosphoryl Chloride.* To a solution of the diol (**1** : R=H; 67 mg)[2] in pyridine (2 ml), phosphoryl chloride (0.2 ml) was added dropwise with stirring, and the mixture was heated under nitrogen at 110 °C (bath temperature) for 1 h. The cooled reaction mixture was poured into a mixture of ice and water and extracted with ether. The organic layer was washed with 2 M hydrochloric acid and then with water, dried over anhydrous sodium sulfate, and evaporated to give a residue, which was chromatographed on a column of silica gel. Elution with petroleum ether gave farfugin A (**2**; 13 mg; y: 23%) and farfugin B (**3**; 19 mg; y: 34%) successively. These compounds (**2** and **3**) proved to be identical (by IR, UV, PMR, TLC, and mass spectrometry) with natural farfugin A[3b] and farfugin B[3b] respectively. Further elution with the same solvent yielded 6-[(4*R*)-4-chloropentyl]-3,5-dimethylbenzofuran (**4**; 10 mg; y: 15%), an oil, $[\alpha]_D$ −20° (*c* 1.0, EtOH); IR (liquid) 1630, 1580, 1132, 1090, and 795 cm^{-1}; UV (EtOH) λ_{max} 252 nm (ε 10600), 258 (sh), 276 (sh), 282 (3400), 285 (3300), and 292 (3800); PMR ($CDCl_3$) δ 1.50 (3H, d, J=7.5 Hz; $C\underline{H}_3$-CHCl-), 2.19 (3H, d, J=1.2 Hz; $C_{(3)}$-CH_3), 2.40 (3H, s; $C_{(5)}$-CH_3), *ca.* 4.0 (1H, m; CH_3-C$\underline{H}$Cl-), *ca.* 7.2—7.3 (3H, $C_{(2)}$-H, $C_{(4)}$-H, and $C_{(7)}$-H), and *ca.* 2.5—3.0 [6H, -$(CH_2)_3$-]; mass spectrum *m/e* 252 and 250 (M^+; in an intensity ratio of *ca.* 1 : 3) and 159 (base peak). Found: C, 71.70; H, 7.58; Cl, 14.42%. Calcd for $C_{15}H_{19}OCl$: C, 71.84; H, 7.64; Cl, 14.14%. Other benzofuran derivatives such as **9** and **10** were not obtained.

Gas chromatographic examination before effecting the column chromatographic separation showed that the ratio of these products (**2**, **3**, and **4**) was 1.0 : 1.5 : 0.4 based on the integrated area of the peak for each product [column: Diasolid H-523, 5(mm)×1.5(m); column temperature: 170 °C; detection: FID; carrier gas: N_2, 66 ml/min; instrument: Shimadzu GC-4A PF].

Treatment of 10β-Hydroxy-6β-methoxyfuranoeremophilane (***1*** : *R=*CH_3) *and 6β-Acetoxy-10β-hydroxyfuranoeremophilane* (***1*** : *R=Ac*) *with Phosphoryl Chloride.* A methoxy alcohol (**1**; R=CH_3; 5 mg)[2] or an acetoxy alcohol (**1**; R=Ac; 5 mg)[2] was treated with phosphoryl chloride (0.05 ml) in pyridine (0.5 ml) at 110 °C for 1 h. In each case the reaction mixture gave, after the work-up described above, a residue which was shown to be a mixture of the three benzofuran derivatives (**2**, **3**, and **4**) by TLC examination.

Acid-Catalyzed Rearrangement of the Diol (***1***; *R=H*). To a solution of the diol (**1**; R=H; 5 mg)[2] in dry acetone (0.5 ml) was added a drop of concentrated hydrochloric acid at room temperature. The reaction mixture was treated as usual to give a residue, which was examined by TLC to show the formation of the three benzofurans (**2**, **3**, and **4**) and of tarry products formed probably by degradation of the furan ring.

Reduction of Furanoeremophil-9-en-6-one (***7***) *with Lithium Aluminium Hydride and Successive Treatment with Phosphoryl Chloride.* Lithium aluminium hydride (100 mg) was added to a solution of the ketone (**7**; 40 mg)[2b] in ether (10 ml), and the mixture was stirred under nitrogen at room temperature for 1 h. The excess of lithium aluminium hydride was decomposed with water, and the mixture was extracted with ether. The ethereal layer was washed with water and brine, and then dried over anhydrous sodium sulfate. On

removal of the solvent, an unstable oily alcohol (**8**; ν_{OH} 3500 cm^{-1}; one spot on TLC) was obtained, which without further characterization was dissolved in pyridine (0.5 ml). After addition of phosphoryl chloride (0.1 ml), the resulting mixture was heated under nitrogen at 110 °C for 1 h. The reaction mixture was treated as usual to give a residue, which was subjected to separation by preparative TLC to afford the three benzofurans (**2**, **3**, and **4**). The ratio of these products (**2**, **3**, and **4**) was determined to be 1.0 : 1.3 : 0.3 by gas chromatography (under the same conditions mentioned above) before effecting the TLC separation.

Reaction of 1,1-Diiodoethane with Copper Powder in the Presence of Olefins and/or Alkylbenzenes

Nariyoshi KAWABATA,* Nobuyuki YAMAGISHI, and Shinzo YAMASHITA

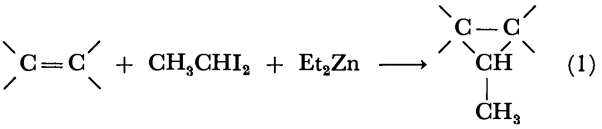
Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received August 13, 1976)

The treatment of 1,1-diiodoethane with copper powder in the presence of 1-heptene gave a 1.3 : 1 mixture of *cis*- and *trans*-1-methyl-2-pentylcyclopropane in 11% yield. The treatment in the presence of cyclohexene gave a 1 : 1.7 mixture of *endo*- and *exo*-7-methylbicyclo[4.1.0]heptane in 32% yield, together with 1-ethylcyclohexene in 8% yield, which was shown to be derived mainly from isomerization of the *endo*-isomer. These reactions were concluded to proceed *via* organocopper intermediate rather than free methylcarbene. The treatment of 1,1-diiodoethane with copper powder in the presence of alkylbenzene gave a mixture of *o*- and *p*-ethyl(alkyl)benzene contrary to the corresponding reaction of methylcarbenoid of zinc which gave cycloheptatriene derivatives.

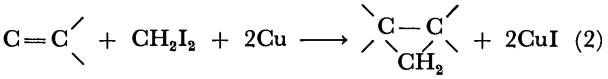
This paper describes an α-elimination of iodine from 1,1-diiodoethane by the reaction with copper powder. Although α-elimination reactions provide the best route to most classes of carbenes and carbenoids,[1] only a few publications are available on the α-elimination of halogen from 1,1-dihaloalkane. Alkyl- and dialkylcarbenes are distinguished from other classes of carbenes by the predominance of intramolecular reactions leading to olefins and cyclopropane derivatives. Kirmse and Wächtershäuser[2] reported that the treatment of 1,1-diiodoalkane with sodium, lithium, and magnesium afforded predominantly cyclopropane derivatives, whereas the treatment with zinc and copper produced olefins *via* rearrangements of the Wagner-Meerwein type, but these workers did not refer to the α-elimination of 1,1-diiodoethane. The α-elimination of iodine from 1,1-diiodoalkane by zinc-copper couple was reported to give predominantly olefins.[3] The reaction of 1,1-diiodoethane with zinc-copper couple was reported to give ethylene.[4]

The α-elimination reactions of 1,1-dihaloalkanes in the presence of olefins give the corresponding cyclopropane derivatives by intermolecular cycloaddition of alkylcarbene or carbenoid to olefins.[4-6] Previously we have proposed an improved method for preparing methylsubstituted cyclopropane derivatives by the reaction of olefins with 1,1-diiodoethane and diethylzinc.[7]



(1)

Recently we found that the reaction of diiodomethane with copper powder in the presence of olefins gave the corresponding cyclopropane derivatives in good yields.[8]



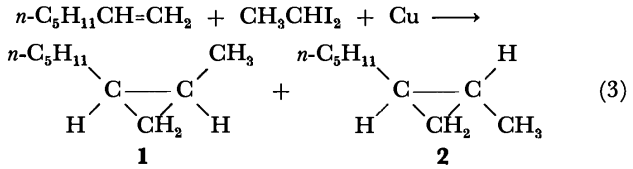
(2)

As an extension of this work, we have investigated the reaction of 1,1-diiodoethane with copper powder in the presence of olefins and/or alkylbenzenes.

Results and Discussion

The reaction of 1,1-diiodoethane with copper powder was carried out in toluene at 75 °C for 24 h. Gas chromatographic analysis of the liquid layer showed that 74% of 1,1-diiodoethane remained unchanged in the reaction mixture under the conditions. In the gaseous products was shown the formation of ethylene in 2% yield, but ethane was not detected. The experimental results indicate that 1,1-diiodoethane reacted with copper powder under the conditions. Methylcarbene or methylcarbenoid of copper would be reactive intermediates. The absence of ethane in the gaseous products indicates that the methylcarbene or carbenoid did not undergo the hydrogen abstraction under the conditions.

The treatment of 1,1-diiodoethane with copper powder in the presence of 1-heptene gave a 1.3 : 1 mixture of *cis*- and *trans*-1-methyl-2-pentylcyclopropane in 11% yield based on the olefin.



(3)

1 **2**

Isomeric olefins were not detected in the reaction mixture which would be expected from the insertion of free methylcarbene into C–H bonds. Therefore, the α-elimination of iodine from 1,1-diiodoethane by copper powder may proceed *via* an organocopper intermediate (methylcarbenoid of copper) rather than free methylcarbene.

Since the *cis*-isomer **1** was obtained predominantly over the *trans*-isomer **2**, the methylcarbenoid of copper was concluded to show essentially the *syn*-selectivity[9] in the cycloaddition with olefins as the methylcarbenoid of zinc.[7]

1,1-Diiodoethane was allowed to react with copper powder in the presence of cyclohexene to give a 1 : 1.7 mixture of *endo*- and *exo*-7-methylbicyclo[4.1.0]heptane in 32% yield, together with 1-ethylcyclohexene (**5**) in 8% yield based on the olefin.

Table 1. Formatiom of ethyl(alkyl)benzene by reaction (5)

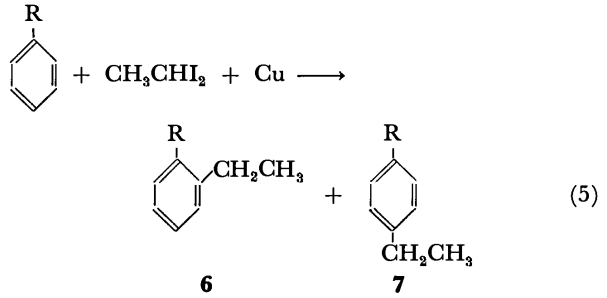
R	Copper (mmol)	Alkylbenzene (ml)	1,1-Diiodoethane (mmol)	Temp (°C)	Time	Yield (%)[a]	Isomer ratio (*p*/*o*)
H	72.0	15.0	32.0	75	17 day	1	—
CH_3	18.0	4.0	8.1	100	95 h	3	2.1
CH_3CH_2	72.0	15.0	31.3	125	40 h	27	2.4

a) Based on 1,1-diiodoethane.

Heating of an isolated mixture (77 : 23) of **3** and **5** in the presence of copper (I) iodide gave a 4 : 96 mixture of **3** and **5**. On the other hand, the *exo*-isomer **4** did not isomerize to **5** under the conditions. Therefore, **5** was concluded to be derived mainly from the isomerization of **3** during the reaction (Eq. 4) rather than the insertion of free methylcarbene into C–H bonds. When **5** was supposed to be completely derived from the isomerization of **3**, the reaction (Eq. 4) was led to give a nearly equimolar amount of **3** and **4**. In any case, the *endo*-isomer **3** did not predominate over the *exo*-isomer **4** in the reaction (Eq. 4), contrary to the corresponding reaction of methylcarbenoid of zinc. The reaction (Eq. 1) with cyclohexene gave a 1.5 : 1 mixture of **3** and **4**.[7]

In order to compare the behavior of the organocopper intermediate (methylcarbenoid of copper) with that of the methylcarbenoid of zinc generated from 1,1-diiodoethane and diethylzinc in the reaction with alkylbenzene, we also studied on the reaction of 1,1-diiodoethane and copper powder in the presence of alkylbenzene.

1,1-Diiodoethane was found to react with copper powder in alkylbenzene to give mixtures of *o*- (**6**) and *p*-ethyl(alkyl)benzene (**7**) as are given in Table 1. *m*-Ethyl(alkyl)benzene was not significantly detected in the reaction mixture (see experimental for details). Cycloheptatriene derivatives were not detected in the above reaction mixtures.

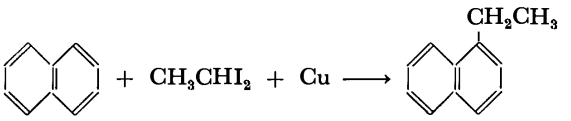


(5)

6 **7**

These experimental results form a sharp contrast with those observed in the reaction of methylcarbenoid of zinc with alkylbenzene. In the latter reaction, the ring expansion reaction was predominant to afford cycloheptatriene derivatives.[10]

The reaction of the methylcarbenoid of zinc with naphthalene gave 7-methyl-2,3-benzobicyclo[4.1.0]-hepta-2,4-diene (**8**).[10] On the other hand, the treatment of 1,1-diiodoethane and copper powder in the presence of naphthalene in ethylbenzene gave α-ethylnaphthalene in 12% yield at 125 °C based on naphthalene together with *o*- and *p*-diethylbenzene. β-Ethylnaphthalene and **8** were not detected in the reaction mixture.



(6)

Since cycloheptatriene derivatives and **8** were not formed by the reactions (Eqs. 5 and 6), the following route should be excluded: the cycloaddition of the methylcarbenoid of copper to the aromatic carbon-carbon unsaturated bond to afford bicyclo[4.1.0]-hepta-2,4-diene derivatives followed by isomerization to ethylbenzene derivatives. The *ortho-para* orientation in the reaction (Eq. 5) and the predominant formation of α-ethylnaphthalene in the reaction (Eq. 6) show the electrophillic nature of the reaction of 1,1-diiodoethane and copper powder with alkylbenzene to afford ethylbenzene derivatives, but further experiments are required to discuss the mechanism of the substitution.

Experimental

Gas chromatographic analyses were carried out on a Shimadzu GC-4A or GC-4B gas chromatograph. NMR spectra were obtained with a Varian Model T-60-A spectrometer using carbon tetrachloride as the solvent and tetramethylsilane as the internal standard. IR spectra were recorded on a Hitachi Model 215 or Japan Spectroscopic Model 402 G spectrophotometer.

Materials. 1,1-Diiodoethane was prepared according to the procedure of Letsinger and Kammeyer.[11] Diethylzinc was prepared according to the procedure of Holler.[12] Active zinc-copper couple was prepared according to the procedure of Shank and Shechter.[13] The ordinary commercial grade of copper powder (particle size was 5—15 μ) provided by Nakarai Chemicals Ltd., Kyoto was used without further purification. Olefins, alkylbenzenes, and solvents were purified by distillation. Nitrogen was purified by being passed through a tube containing copper turnings in a furnace at 170 °C. Authentic samples of ethylene and ethane were prepared by hydrolyses of vinylmagnesium bromide and ethylmagnesium bromide, respectively. Authentic samples of **1**,[14] **2**,[14] **3**,[7] and **4**[7] were prepared by conventional methods, respectively. Commercial authentic samples and other chemicals were used without further purification.

Reaction of 1,1-Diiodoethane with Copper Powder. Copper powder (2.28 g, 36.0 mmol) was allowed to react with a small amount (0.10 g, 0.4 mmol) of iodine in 4.0 ml of toluene at room temperature in a flask equipped with a gas burrette and a magnetic stirrer. After the brown color of iodine disappeared, 1,1-diiodoethane (4.51 g, 16.0 mmol) was added, and the mixture was heated at 75 °C for 24 h with stirring. The total amount of the evolved gas was determined by the gas burrette, and the gaseous products were analyzed by gas chromatography. The liquid layer was also analyzed by gas chromatography after elimination of the inorganic ma-

terials from the reaction mixture by filtration. Results are given in the text.

Reaction of 1,1-Diiodoethane with Copper Powder in the Presence of 1-Heptene. Copper powder (2.28 g, 36.0 mmol) was allowed to react with a small amount (0.10 g, 0.4 mmol) of iodine in 6.0 ml of toluene at room temperature in a flask equipped with a reflux condenser and a magnetic stirrer. After the brown color of iodine disappeared, 1,1-diiodoethane (4.31 g, 15.3 mmol) and 1-heptene (0.88 g, 9.0 mmol) were added, and the mixture was heated at 85 °C for 91 h with stirring. After the reaction, inorganic materials were removed by filtration, and the organic layer was analyzed by gas chromatography. Yields were determined by the gas chromatographic analyses of the reaction mixture. The structures of the products **1** and **2** were determined by comparison of their retention times with those of authentic samples in gas chromatography using two types of different liquid phase, *i.e.*, Silicone DC 550 and Apiezon Grease L. Results are given in the text.

Reaction of 1,1-Diiodoethane with Copper Powder in the Presence of Cyclohexene. Copper powder (3.42 g, 54.0 mmol), iodine (0.15 g, 0.6 mmol), 1,1-diiodoethane (7.03 g, 24.9 mmol), and cyclohexene (1.04 g, 12.7 mmol) were reacted in 9.0 ml of benzene at 75 °C for 304 h in a similar way. Yields were determined by gas chromatographic analyses of the reaction mixture. Products **3**, **4**, and **5** were isolated by collection from the organic layer by gas chromatography. Structures of **3** and **4** were determined by comparison of their IR spectra with those of authentic samples. The structure of **5** was determined by its NMR spectrum. NMR (CCl_4) τ: 4.68 (1 H, m), 7.7—8.8 (8 H, m), 8.09 (2 H, q, J=7 Hz), and 9.01 (3 H, t, J=7 Hz).

A 77 : 23 mixture of **3** and **5** (0.14 g, 1.2 mmol) collected by gas chromatography was heated at 75 °C for 40 h in the presence of copper(I) iodide (0.95 g, 2.5 mmol) in 2.5 ml of benzene. Gas chromatographic analysis of this reaction mixture showed the presence of a 4 : 96 mixture of **3** and **5**, and **4** was not detected in this reaction mixture.

An isolated sample of **4** (0.09 g, 0.8 mmol) collected by gas chromatography was heated at 75 °C for 40 h in the presence of copper(I) iodide (0.65 g, 1.7 mmol) in 1.7 ml of benzene. Gas chromatographic analysis of this reaction mixture showed the presence of **4** without **3** and **5**.

Reaction of 1,1-Diiodoethane with Copper Powder in the Presence of Alkylbenzene. The reaction of 1,1-diiodoethane with copper powder in the presence of alkylbenzene was carried out in a similar way. Products were isolated by collection from the organic layer by gas chromatography. Structures were determined by comparison of their IR spectra with those of authentic samples. Yields were determined by gas chromatographic analyses of the reaction mixture. Results are given in the text.

Reaction of 1,1-Diiodoethane with Copper Powder in the Presence of Naphthalene. The reaction of copper powder (3.82 g, 60.0 mmol), 1,1-diiodoethane (8.12 g, 28.8 mmol), iodine (0.20 g, 0.8 mmol), and naphthalene (2.56 g, 20.0 mmol) was carried out in 10.0 ml of ethylbenzene at 125 °C for 22 h. Gas chromatographic analysis of the reaction mixture showed the formation of α-ethylnaphthalene in 12% yield based on naphthalene, together with *o*- and *p*-diethylbenzene. The sturcture of α-ethylnaphthalene was determined by comparison of the IR spectrum of an isolated sample collected by gas chromatography with that of an authentic sample.

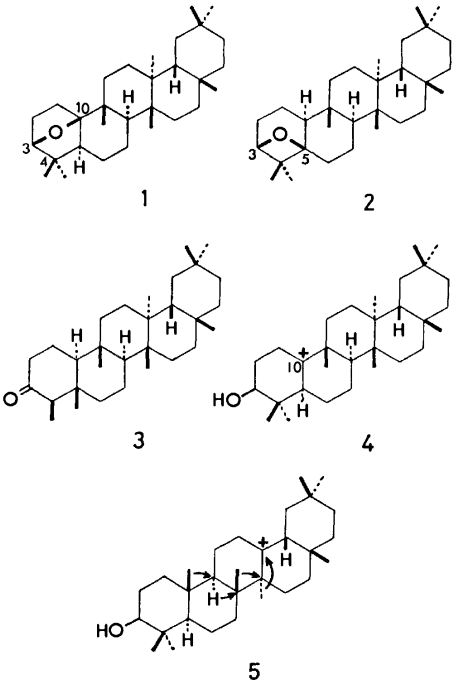
(Received August 13, 1976)

Dendropanoxide (**1**) was synthesized by the reaction of 3β,4β-epoxyfriedelane (**19**) with boron trifluoride etherate in ether at −10 °C. In the rearrangement reaction, 4α-fluorofriedelan-3β-ol (**20**), D : B-friedo-olean-5(10)-en-3β-ol (**21**), β-amyrin (**22**), and D : B-friedo-olean-5-en-3β-ol (**23**) were also produced.

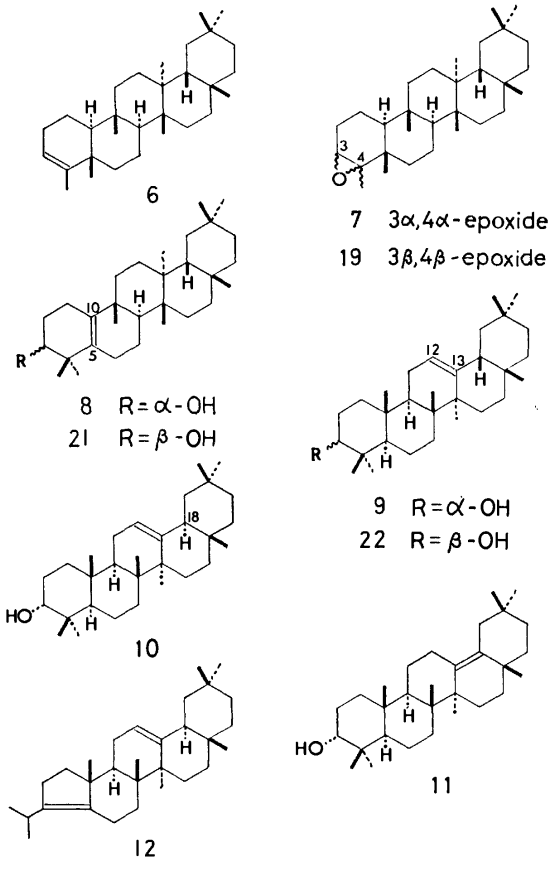
A triterpene oxide, named dendropanoxide,[2] isolated from *Dendropanax trifidus* Makino (=*Gilibertia trifida* Makino, Araliaceae) is also known as epoxyglutinane[3] and campanulin[4] and distributed in a number of plants of Araliaceae and Ericaceae families.[5] Although two alternative structures, D : B-friedo-olean-3,10-oxide (**1**)[3,4,6] and D : B-friedo-olean-3,5-oxide (**2**),[2,3,5] had been proposed, the D : B-friedo-olean-3β,10β-oxide structure (**1**) was recently assigned for this triterpene oxide by X-ray study.[7]

From an interest in biogenetic relationship between dendropanoxide (**2**) and friedelin (**3**),[8] conversion of **3** into **1** was attempted. Dendropanoxide (**1**) may arise by the following biogenetic pathways.[9] An alunusane (glutinane) type intermediate (**4**) may be derived by a sequence of 1,2-shifts of methyl groups and a hydrogen atom from a protonated β-amyrin type intermediate (**5**) which is originated from squalene. A cationic center at C-10 of the resulting intermediate (**4**) then may suffer an attack by an oxygen atom of the C-3 hydroxyl group from β-side, followed by deprotonation in the last step to give dendropanoxide (**1**).

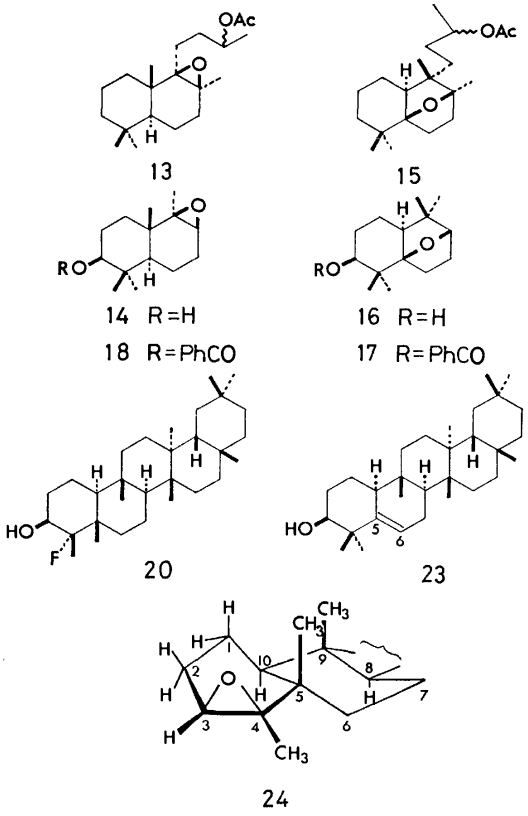


It has been reported that friedel-3-ene (**6**) affords only 3α,4α-epoxyfriedelane (**7**)[10] on epoxydation because of a preferential attack of oxidizing reagents from α-side, and that a treatment of the α-epoxide (**7**) with stannic chloride[10a] or boron trifluoride etherate[10b] gave D : B-friedo-olean-5(10)-en-3α-ol (**8**),[10] olean-12-en-3α-ol (**9**),[10b] 18α*H*-olean-12-en-3α-ol (**10**),[10b] olean-13(18)-en-3α-ol (**11**),[10b] and 18α*H*-A-neo-oleana-3(5),12-diene (**12**).[10b]

Recently Hadley and Halsall[11] reported a boron trifluoride-catalyzed rearrangement of epoxides (**13** and **14**) to give five-membered oxides (**15** and **16**, respectively) in both norlabdane and decalin series. In connection with a study on the rearrangement of tetramethyldecalin derivatives, we found also the formation of a five-membered oxide (**17**) by a similar treatment of an epoxide (**18**).[12] It is therefore suggested that a treatment of 3β,4β-epoxyfriedelane (**19**) with boron trifluoride etherate would produce, by epoxide opening followed by 1,2-methyl shift, the intermediate cation (**4**) (or its equivalent species) which would then afford dendropanoxide (**1**). In the case of shionane derivatives, a conversion of 3β,4β-epoxyshionane into dihydrobaccharis oxide was re-



cently achieved.[13] In the present paper, the formation of dendropanoxide (**1**) as well as 4α-fluorofriedelan-3β-ol (**20**), D : B-friedo-olean-5(10)-en-3β-ol (**21**), β-amyrin (**22**), and D : B-friedo-olean-5-en-3β-ol (**23**) by treatment of 3β,4β-epoxyfriedelane (**19**) with boron trifluoride etherate is described.



It was reported that 3β,4β-epoxyshionane was formed as a minor product together with 3α,4α-epoxyshionane on epoxidation of shion-3-ene.[14] Friedelin (**3**) was transformed *via* friedelan-3β-ol[8a,b] into friedel-3-ene (**6**)[8a,b] by the known procedures. Epoxidation of **6** with *m*-chloroperbenzoic acid gave two epoxides in a ratio of about 2 : 1. One epoxide, mp 234—236 °C, obtained as a major product, was shown to be identical with 3α,4α-epoxyfriedelane (**7**).[10] The other one, $C_{30}H_{50}O$, mp 237—250 °C,* therefore, is corresponding to 3β,4β-epoxyfriedelane (**19**), whose structure was supported by the spectral data (IR, PMR, and mass spectra) and the elemental analysis. Neither hydroxyl nor carbonyl group was observed in the IR spectrum. The PMR spectrum showed a multiplet ($W_{1/2}$ 3 Hz) signal at δ 2.90[14] due to the methine proton attached to a carbon atom (C-3) on the epoxide ring terminus; the corresponding signal of 3α,4α-epoxide (**7**) appeared at δ 2.86.

Treatment of 3β,4β-epoxyfriedelane (**19**) with boron trifluoride etherate in ether at −10 °C gave a complex mixture, which showed four spots on silver nitrate-impregnated silica gel TLC besides a spot attributed to the starting epoxide (**19**). The reaction mixture was separated by silver nitrate-impregnated silica gel column chromatography and by subsequent separation procedures described below into five components (**a**—**e**).

The least polar component **a** (yield: *ca.* 22%) was an oxide, $C_{30}H_{50}O$, mp 206—208 °C, $[\alpha]_D$ +71°, and was found to be identical in all respects with dendropanoxide (**1**), obtained by isolation from *Dendropanax trifidus* Makino according to Kimura's procedure[2], and with authentic D : B-friedo-olean-3β,10β-oxide (**1**), isolated from *Rhododendron macrophyllum* by Block and Constantine.[5,6] The second component **b** (y: *ca.* 1.7%) was identified to be the starting β-epoxide (**19**).

The third component **c** (y: *ca.* 21%) was a fluoride, $C_{30}H_{51}OF$, mp 223.5—224.5 °C. The presence of a secondary hydroxyl group was shown by the PMR spectrum (δ 3.72, 1H, dt, J=6 and 3 Hz) and by the IR spectrum (3450, 1100, and 1030 cm^{-1}). The fluoro alcohol was treated with potassium hydroxide in ethanol under reflux temperature to generate the starting β-epoxide (**19**). These observations led to the conclusion that the fluoro alcohol should be formulated as 4α-fluorofriedelan-3β-ol (**20**). The formation of a fluorohydrin in the reaction of an epoxide with boron trifluoride etherate is often encountered[15].

The fourth component **d** (y: *ca.* 23%) was found to be a mixture of three compounds. The mixture was subjected to fractional recrystallization from acetone to afford an alcohol, $C_{30}H_{50}O$, mp 236.5—237.5 °C. The physical and spectral data were completely identical with those of authentic D : B-friedo-olean-5(10)-en-3β-ol (**21**),[2-6] prepared by isomerization of dendropanoxide (**1**) with hydrochloric acid in ethanol,[2-6] and of the specimen derived from friedelin (**3**) by the known procedure.[16] On evaporation of the solvent, the mother liquor of the fractional recrystallization gave a residue. Although a separation of the residue by TLC under various conditions was attempted, it was not satisfactorily achieved. Then the residue was examined by high performance liquid chromatography (HPLC) and three peaks were detected at 18.0, 19.7, and 20.5 min, the shortest one of which was shown to be attributed to D : B-friedo-olean-5(10)-en-3β-ol (**21**). In the PMR spectrum of the residue obtained from the mother liquor, two signals due to olefinic protons at δ 5.20 and 4.87 besides tertiary methyl signals at δ 0.76—1.20 were observed. The mass spectrum showed two prominent peaks at *m/e* 218 and 205 with relative intensities 100 and 46%, respectively, together with the molecular ion peak at *m/e* 426. It is well known that a characteristic peak at *m/e* 218 due to a retro-Diels-Alder fragmentation is observed in pentacyclic Δ^{12}-triterpenes such as β- or α-amyrin.[17] From this fact as well as the PMR spectrum, in which an olefin proton of β-amyrin resonates at δ 5.20, it was concluded that one component in the residue must be β-amyrin itself. The validity of the conclusion was verified by direct comparison of the retention time (20.5 min) with that of authentic β-amyrin (**22**) in the HPLC examination. The structure of the third compound present in the residue of the mother liquor is left undetermined because of lack of the material and of difficulty of the separation.

* Due to thermal fragility, no sharp melting point was observed (*Cf.* Experimental).

The most polar component **e** (y: *ca.* 14%), eluted from the column, $C_{30}H_{50}O$, mp 208.5—209.5 °C, $[\alpha]_D$ +63.8°, proved to be identical with the authentic D : B-friedo-olean-5-en-3β-ol (**23**)[3,5,6] prepared by the reaction of 4α-bromofriedelin with silver acetate[16] and also by the isomerization of dendropanoxide (**1**) with boron trifluoride.[5,6]

The A-ring of the β-epoxide (**19**) is suggested to be in a conformation depicted as in **24**. The formation of dendropanoxide (**1**) from **19** can be explained by a mechanism involving a non-concerted process. The conversion of friedelin (**3**) into dendropanoxide (**1**) *via* the β-epoxide (**19**) was thus achieved.

Experimental

General Procedure. Melting points were determined on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncorrected. Infrared (IR) spectra were determined on a Hitachi EPI-G2 infrared spectrometer. Mass spectra were measured using a Hitachi RMU-6 mass spectrometer operating at 70 eV with a direct inlet system. High resolution mass spectra were measured using a Hitachi RMH-2 mass spectrometer operating at 70 eV. Proton magnetic resonance (PMR) spectra were measured in a deuteriochloroform solution using a JEOL JNM PS-100 (100 MHz) or a Hitachi R-20B (60 MHz) spectrometer. Chemical shifts are expressed in δ value downfield from TMS as an internal standard and coupling constants in Hz. Optical rotation was measured with a JASCO DIP-SL polarimeter. High performance liquid chromatography (HPLC) analyses were determined on a Waters liquid chromatograph model ALC-GPS 202—401. Analytical and preparative thin layer chromatographies (TLC) were carried out on Kieselgel G nach Stahl (E. Merck) and Kieselgel 60 PF_{254} (E. Merck), respectively. Column chromatography was carried out on Wakogel C-200 (Wako Pure Chem. Ind.).

Preparation of 3β,4β-Epoxyfriedelane (19). To a solution of friedel-3-ene (**6**; 1.97 g) in benzene, *m*-chloroperbenzoic acid (1.74 g) in benzene was added with stirring at room temperature, and the solution was allowed to stand overnight. The reaction was stopped by addition of 10% sodium sulfite solution and the organic layer was washed with saturated sodium hydrogencarbonate solution and then with brine. After drying over sodium sulfate, evaporation of the solvent gave a residue, which was chromatographed on silica gel to afford 3α,4α-epoxide (**7**; 1.06 g), mp 234—236 °C, [IR (KBr) 865 cm^{-1}; PMR δ 0.82, 0.95, 1.07, 1.18, 1.19 (each 3H, s, *t*-CH_3), 1.00 (9H, 3×*t*-CH_3), and 2.86 (1H, t, J=2.5 Hz, $C_{(3)}$-H); mass spectrum *m/e* 426] and 3β,4β-epoxide (**19**; 0.49 g) as colorless needles (crystallized from acetone). The epoxide (**19**) showed no sharp melting point; on heating in a capillary, it began to melt at 237—240 °C and melted completely at 250 °C. In a sealed tube, it sublimed at 245—250 °C. IR (KBr) 1000, 890, 790, and 760 cm^{-1}; PMR δ 0.80, 0.96, 1.07 (each 3H, s, *t*-CH_3), 1.01 (9H, s, 3×*t*-CH_3), 1.18 (6H, s, 2×*t*-CH_3), and 2.90 (1H, m, $W_{1/2}$ 3 Hz, $C_{(3)}$-H); mass spectrum *m/e* 426 (M^+, 42%), 411 (33), 408 (8), 393 (8), 218 (100), and 205 (83); Found: C, 84.54; H, 11.88%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

Reaction of 3β,4β-Epoxyfriedelane (19) with Boron Trifluoride Etherate. To a solution of 3β,4β-epoxide (**19**; 300 mg) in anhydrous ether (200 ml) kept at −10 °C, boron trifluoride etherate (4 ml) was added with stirring, and the progress of the reaction was monitored by TLC. After 30 min, the starting material was almost consumed and the reaction was stopped by addition of a saturated potassium hydroxide methanolic solution (200 ml). The usual treatment gave a residue, which was subjected to column chromatography on silica gel (70 g) impregnated with silver nitrate (12 g) and the following solvents were used (each fraction 100 ml): frs 1 and 2, petroleum ether; frs 3—5, petroleum ether–benzene (5 : 1); frs 6—8, (4 : 1); frs 9—15, (3 : 1); frs 16—21, (2 : 1); frs 22—41, (1 : 1); frs 42—47, (1 : 2); frs 48—57, benzene; frs 58—63, benzene–ether (3 : 1).

Fractions 9—15, on evaporation of the solvents, afforded dendropanoxide (**1**; component **a**; 65 mg), mp 206—208 °C (recrystallized from acetone), mixed mp 206—208 °C; IR (KBr) 1100, 1010, 995, 980, and 955 cm^{-1}; PMR δ 0.91, 0.95, 0.97, 1.00, 1.02, 1.15, 1.17, 1.20 (each 3H, s, *t*-CH_3), and 3.75 (1H, d, J=4.8 Hz, $C_{(3)}$-H); $[\alpha]_D$ +71° (*c* 0.97, $CHCl_3$); mass spectrum *m/e* 426 (M^+, 15%), 411 (65), 344 (8), 343 (8), 205 (24), and 137 (100). Found: C, 84.64; H, 12.01%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

Fractions 25 and 27—30 yielded 3β,4β-epoxide (**19**; component **b**; 5 mg) and 4α-fluorofriedelan-3β-ol (**20**; component **c**), respectively, on evaporation of the solvents.

Fractions 31—39 were evaporated to give a mixture, which was separated by column chromatography on silver nitrate-impregnated silica gel (10 g) into the fluoro alcohol (**20**; component **c**) and a component **d**. The fluoro alcohol (**20**) obtained from fractions 27—30 and fractions 31—39 were combined and weighed 64 mg, mp 223.5—224.5 °C (recrystallized from chloroform–methanol); IR (KBr) 3450, 1100, and 1030 cm^{-1}; PMR δ 0.88, 0.96, 1.18 (each 3H, s, *t*-CH_3), 1.00, 1.02 (each 6H, s, 2×*t*-CH_3), and 3.72 (1H, dt, J=6 and 3 Hz, $C_{(3)}$-H); mass spectrum *m/e* 446 (M^+, 15%), 431 (18), 426 (20), 411 (14), 293 (36), 273 (36), and 205 (100); MW 446.3977 (by high resolution mass spectrometry). Calcd for $C_{30}H_{51}OF$: MW 446.3922.

A residue obtained from fractions 40—57 contained component **d** (by TLC examination). This residue and the component **d** from fractions 31—39 were combined (in total, weighed about 70 mg), and fractionally recrystallized from acetone to give D : B-friedo-olean-5(10)-en-3β-ol (**21**; component $\mathbf{d}_1$; 38 mg), mp 236.5—237.5 °C; IR (KBr) 3450, 1630, and 1040 cm^{-1}; PMR δ 0.95, 1.02 (each 9H, s, 3×*t*-CH_3), 1.05, 1.20 (each 3H, s, *t*-CH_3), 3.45 (1H, dd, J=9.5 and 4.5 Hz, $C_{(3)}$-H), and the absence of olefinic proton signal; mass spectrum *m/e* 426 (M^+, 17%), 411 (17), 408 (11), 393 (7), and 205 (100). Found: C, 84.72; H, 12.08%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

The mother liquors of fractional crystallization were combined and evaporated to give a residue, which was examined by PMR, mass spectrometry, and HPLC: PMR δ 5.20 and 4.87 (olefinic protons); mass spectrum *m/e* 218 (100%) and *m/e* 205 (46%); HPLC (μ-porasil, elution with 10% ether–hexane at flow rate 1.0 ml/min) 18.0, 19.7, and 20.5 min. The retention times of D : B-friedo-olean-5(10)-en-3β-ol (**21**) and β-amyrin (**22**) under the same conditions were 18.0 and 20.5 min, respectively. Therefore, the presence of β-amyrin (**22**; component $\mathbf{d}_2$) in the mother liquor received support. The structure of the third component ($\mathbf{d}_3$; with retention time 19.7 min) contained in the mother liquor remains undetermined.

On evaporation of the solvents, fractions 58—63 gave D : B-friedo-olean-5-en-3β-ol (**23**; 41 mg), mp 208.5—209.5 °C (crystallized from chloroform–methanol); IR (KBr) 3450, 1630, 1095, and 825 cm^{-1}; PMR δ 0.87, 0.97, 1.06, 1.11 1.18 (each 3H, s, *t*-CH_3), 1.02 (6H, s, 2×*t*-CH_3), 3.45 (1H, m, $W_1/_2$ 6 Hz, $C_{(3)}$-H), and 5.63 (1H, dd, J=4 and 1.8 Hz, $C_{(6)}$-H); $[\alpha]_D$ +63.8° (*c* 1.1, $CHCl_3$); mass spectrum

m/e 426 (M^+, 4%), 411 (2), 408 (2), 393 (2), 274 (100), 259 (66), and 205 (45). Found: C, 84.25; H, 11.99%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

*Treatment of 4α-Fluorofriedelan-3β-ol (**20**) with Base.* 4α-Fluorofriedelan-3β-ol (**20**; 44 mg) in 5% potassium hydroxide ethanolic solution (20 ml) was heated under reflux for 21 h. The usual work-up and recrystallization from acetone gave 3β,4β-epoxyfriedelane (**19**; 17 mg).

*Isomerization of Dendropanoxide (**1**).* *(a) With Hydrochloric Acid in Ethanol*: Dendropanoxide (**1**; 103 mg) was dissolved in ethanol (20 ml) and conc hydrochloric acid (0.8 ml). The solution was heated under reflux for 30 min and then left at room temperature overnight. The reaction mixture, after the usual treatment, was purified by preparative TLC to afford D : B-friedo-olean-5(10)-en-3β-ol (**21**; 55 mg).

(b) With Boron Trifluoride Etherate: Boron trifluoride etherate (1.4 ml) was added to dendropanoxide (**1**; 631 mg) in ether (110 ml) at room temperature and the reaction mixture was allowed to stand at room temperature for 22 h. Work-up in a usual manner and a separation by column chromatography on 20% silver nitrate-impregnated silica gel using benzene as eluent gave D : B-friedo-olean-5(10)-en-3β-ol (**21**; 417 mg) and D : B-friedo-olean-5-en-3β-ol (**23**; 50 mg).

The authors wish to thank Professor J. H. Block and Professor G. H. Constantine, Jr., Oregon State University, for a generous gift of the authentic sample of D : B-friedo-olean-3β,10β-oxide (**1**) and also Dr. Hidehiro Ishizuka and Dr. Kazuyuki Aizawa for the measurements of PMR (100 MHz) spectra and high resolution mass spectra, respectively.

Mechanism of the Chemiluminescence of Lucigenin. II. The Charge-transfer Structure of Lucigenin and Reduction of 10,10′-Dimethyl-9,9′-biacridinium Dication by Electron Transfer from Nucleophiles

Koko MAEDA, Toshi KASHIWABARA, and Mizue TOKUYAMA

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

(Received August 26, 1976)

Lucigenin (10,10′-dimethyl-9,9′-biacridinium dinitrate, $DBA^{2+}2NO_3^-$) was found to be a CT complex between DBA^{2+} and NO_3^-. In the reaction of lucigenin with several nucleophiles in the absence of molecular oxygen or oxidizing agents the following four types of products were obtained, depending upon the relative power of the nucleophiles to donate electrons to DBA^{2+}: (1) salts of DBA^{2+} ($DBA^{2+}2X^-$) which are the CT complex between DBA^{2+} and the nucleophiles, such as Cl^-, Br^-, SCN^-, and I^-, (2) the cation radical $DBA^{+\cdot}$ produced by one-electron transfer from nucleophiles, such as $C_6H_5COCH_2^-$ and $CH_3COCH_2^-$, to DBA^{2+}, (3) the biradical $DBA^{\cdot}_2$ produced by two-electron transfer from nucleophiles such as OH^-, CN^-, CCl_3^-, and $C_6H_5S^-$ and (4) 10,10′-dimethyl-9,9′-bi(dihydroacridinylidene) produced from $DBA^{\cdot}_2$. Only the nucleophiles of (3), which produced $DBA^{\cdot}_2$ brought about the luminescence of lucigenin in the presence of oxygen, and $DBA^{\cdot}_2$ also showed luminescence in organic solvents in the presence of oxygen. From these findings it was concluded that the first process of the chemiluminescent reaction of lucigenin was the electron transfer reduction of DBA^{2+} by the nucleophiles to form the biradical $DBA^{\cdot}_2$.

Numerous studies concerning the mechanism of the chemiluminescenec of lucigenin($DBA^{2+}2NO_3^-$, **1**) with hydrogen peroxide in an aqueous alkaline solution have been carried out.[1] It has been established that *N*-methylacridone, the end product of the luminescence, is a light emitter.[1g] Totter has suggested a mechanism for the luminescence involving two successive, two equivalent reductions and autoxidation. From the results of an ESR study Janzen and collaborators have proposed[2] the mechanism shown in Scheme 1 involving *N*-methylacridone ketyl, **3**. Maeda and Hayashi have previously reported that crystals of **1** exhibited a weak ESR absorption,[3a] and Maeda, Hayamizu, and Hayashi have shown that an aqueous sodium hydroxide solution of **1** produced a compound[3b] with the same UV and IR spectra as 10,10′-dimethyl-9,9′-bi(dihydroacridinylidene), **5**, but in contrast to **5**, the product exhibited an ESR absorption both in solid state and in solution and luminescence with molecular oxygen in solutions of organic solvents. These findings suggest a radical mechanism of the luminescence involving a reduction process of **1** by a hydroxide ion. In order to obtain further information on the radical mechanism of the chemilumnescence of **1**, its reactions with the various nucleophiles shown in Table 1 were studied. This paper deals with the results of the reactions and discusses the mehanism involving a reduction process of DBA^{2+}.

5

Experimental

Measurements. Measurements of electronic absorption spectra were carried out using a Shimadzu UV 200 spectrophotometer with oxygen-free solutions which were purged with prepurified nitrogen. The IR spectra were measured on a JASCO IR-G infrared spectrophotometer. The ESR spectra and spin concentrations were obtained by a JES p-10 type ESR spectrometer (100 kHz modulation) equipped with a JES 1D-2 type integrator with deaerated solutions and solids. The proton NMR spectra were measured with a JEM C-60-HL NMR spectrometer. The fluorescence spectra were obtained with a Hitachi EPF-2A fluorescence spectrophotometer with deaerated solutions.

Materials. Lucigenin, **1**, was synthesized by the method of Decker and Dunnant[4] from *N*-methylacridone which was obtained from acridine. Purification of **1** was achieved by recrystallization from water and then ethanol to give amber crystals. NMR(D_2O); δ 5.07(6H, s, N–CH_3), δ 7.26—8.52 (16H, m, aryl proton). 10,10′-Dimethyl-9,9′-bi(dihydroacridinylidene), **5**, was prepared by the reduction of *N*-methylacridone with zinc and acetic acid, and recrystallized from pyridine to give lemon yellow fine crystals.

Results and Discussion

The addition of aqueous solutions containing the nucleophiles of group (a) in Table 1 to an aqueous

Concentration of **1**: 1×10^{-4} mol l^{-1}.

solution of **1** in the presence of oxygen brought about the luminescence of **1**, but the addition of the nucleophiles of group (b) in Table 1 under the same conditions did not result in any luminescence. On the other hand, a DMF solution of **1** exhibited luminescnce in the presence of oxygen with or without the nucleophiles of group (b) in Table 1. In order to obtain some information about the difference in behavior between the nucleophiles of group (a) and (b) of Table 1 for the chemiluminescence of **1**, reactions of these nucleophiles with **1** were studied in oxygen-free solutions in which no luminescence was exhibited. It was found that the following four types of products, $DBA^{2+}2X^-$, $DBA^{+}X^-$, $DBA^{\cdot}$, and DBA, **5**, were produced, depending upon the kind of nucleophiles and reaction conditions, as described below.

I. Salts of 10,10′-Dimethyl-9,9′-biacridinium Dication, DBA^{2+} $2X^-$. When solids of potassium or sodium salts of Cl^-, Br^-, SCN^-, and I^-, the nucleophiles of group (b) in Table 1, were added to an aqueous solution of **1** (1×10^{-2} mol l^{-1}) in amounts equivalent to twice the molar quantity of **1**, salts of DBA^{2+} with the nucleophilic anions added, $DBA^{2+}2Cl^-$(**6**), $DBA^{2+}2Br^-$(**7**), DBA^{2+} $2SCN^-$(**8**), and DBA^{2+} $2I^-$(**9**), as by elemental analysis of Cl, Br, S, and I, were separated out. The colors of salts **1**, **6**, and **7** were amber, while the colors of salts **8** and **9** were orange and dark red, respectively. The deepened colors of salts **8** and **9** caused by the replacement of NO_3^- by SCN^- or I^-, which has a larger nucleophilicity[5] than NO_3^-, suggest the formation of a CT complex between DBA^{2+} and SCN^- or I^-, as has been reported for the salts of pyridinium,[6] tropylium[7] and quinolinium[8] cations.

The crystals of **1** exhibited weak ESR absorption(g= 2.003, the line width was 12.5 G) and those of **6**, **7**, **8**, and **9** also exhibited weak ESR absorption(g=2.003). The spin concentrations of **1**, **8**, and **9** are shown in Table 2. The intensities of these signals increased two or three times upon irradiation with an incandescent lamp for about 1 h and reverted to their original intensities after standing in the dark at room temperature. These findings suggest that lucigenin is also

Table 2. The spin concentrations and colors of the CT complexes $DBA^{2+}2X^-$ measured in the absence of the light

X^-	Spin mol^{-1}	Color

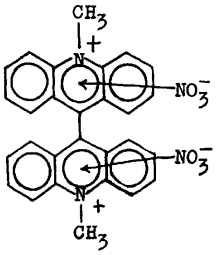
SCN^-	1.5×10^{19}	orange
I^-	1×10^{20}	dark red

the CT complex **1′** shown below, although the degree of charge transfer was less than those in **8** and **9**.



1′

Confirmation of the CT structure of these salts was carried out by measurements of their absorption spectra. For example, the absorption spectra of **9** measured in mixed solvents of DMSO, $CHCl_3$, and CH_2Cl_2 showed a broad band in a longer wavelength region than 500 nm, which was not observed in water, as shown in Fig. 1. The band was attributed to charge transfer from I^- to DBA^{2+}, since the absorbance of the band was intensified for a decrease in the polarity of the mixed solvent and disappeared in water. This fact appears to indicate a shift of equilibrium in solutions, shown in Scheme 2, which favors an ionic species in polar solvents. Comparison of the CT absorption of **1**, **6**, **7**, **8**, and **9** measured in ethanol, DMSO, and DMF,

respectively, showed that the degree of charge transfer from the nucleophiles to DBA^{2+} increased in the following order, $NO_3^-<Cl^-\approx Br^-<SCN^-<I^-$ and for a decrease in the Z value[9] of the solvents, $H_2O<$ethanol$<$DMSO$<$DMF. The spectra of the salts of **1**, **8**, and **9** observed in DMF are shown in Fig. 2.

The formation of similar CT complexes of DBA^{2+} was also observed in oxygen-free solutions in reactions of **1** with the nucleophiles of group (a) in Table 1. By the evaporation of a solvent immediately after adding to an aqueous solution of **1** (7.8×10^{-3} mol l^{-1}) the nucleophiles in amounts equivalent to twice the molar quantity of **1**, crystals of various CT complexes of DBA^{2+} containing the added nucleophiles were obtained. After treatment of the crystals with benzene to remove the small quantity of a by-porduct, a reduction product which appeared later, the CT complexes were purified by recrystallization from water and then from ethanol. The absorption spectra of these complexes measured in water agreed with those of **1**, **8**, and **9** in the shorter wavelength region below 500 nm, but showed an additional weak broad band in the longer wavelength region above 500 nm. The broad band is considered to be due to charge transfer between nucleophiles and DBA^{2+}, because the absorbance of

Tabte 3. The spin concentrations and colors of the CT complexes obtained from **1** and nucleophiles

Nucleophile	Spin mol^{-1}	Color	Type of the fine structure of the ESR spectrum in Fig. 3
$(C_2H_5)_3N$	1×10^{20}	brown	B
$CH_3COCH_2^-$	2×10^{20}	brown	B
CCl_3^-	4×10^{20}	brown	B
$C_6H_5COCH_2^-$	4×10^{20}	bluish brown	B
NH_3	6×10^{20}	reddish brown	B
$C_6H_5S^-$	7×10^{20}	reddish brown	A

OH^-	4×10^{21}	reddish brown	A
t-BuO^-	2×10^{22}	reddish brown	A

the band measured in water was intensified in DMF. These complexes exhibited strong ESR absorptions (g=2.003) both in solid state (line widths were about 11.4 G) and in oxygen-free solutions of DMF and C_6H_6. The colors and spin concentrations of the ESR abosrption in solid state are shown in Table 3. The intensities of the ESR signals increased upon irradiation and reverted to the original intensities after standing in the dark at room temperature. These properties of the complexes are comparable to those of **1**, **8**, and **9**, although the degrees of charge transfer from the nucleophiles of group (a) in Table 1 to DBA^{2+} are larger than those from SCN^- and I^- (the nucleophiles of group (b) in Table 1) and NO_3^-. ESR spectra of the CT complexes containing the nucleophiles of group (a) in Table 1 measured in oxygen-free solutions showed fine structures which are classified into two groups, A and B, shown in Fig. 3. Although it is now difficult to explain the two types of the fine structures, it is observed that (1) the CT complexes which exhibited a spectrum of type A (the spacing was 1.6 G) had spin concentrations larger than those of the CT complexes which exhibited a spectrum of type B (the spacing was 3.0 G) as shown in Table 3 and (2) fine structure of type A is similar to that of the ESR spectrum[2a] which was attributed to the radical cation of DBA^{2+} produced by the one-electron reduction of DBA^{2+}. From these findings it is conceivable that both in solid state and in less polar solvents, the equilibrium

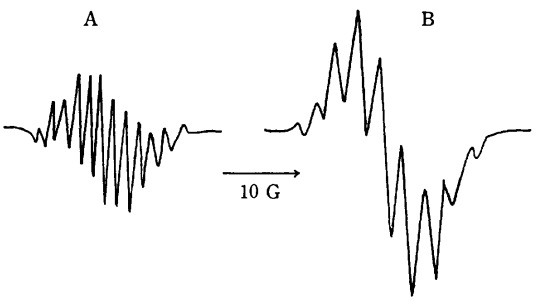

Fig. 3. Two types of ESR spectra of $DBA^{2+}2X^-$ in the oxygen-free DMF solution.
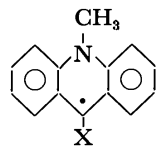
X^- showing type A: $C_6H_5S^-$, CN^-, OH^-, t-BuO^-.
X^- showing type B: $(C_2H_5)_3N$, $CH_3COCH_2^-$, CCl_3^-, $C_6H_5COCH_2^-$, NH_3.

shown in Scheme 2 might be further shifted more to the right-hand side in CT complexes having a fine structure of type A than in CT complexes having a fine structure of type B. Counter anions in CT complexes having a structure of type A, $C_6H_5S^-$, CN^-, OH^-, and *t*-BuO^-, might have a larger electron-donating power than the neutral or anionic nucleophiles in CT complexes having a structure of type B, $(C_2H_5)_3N$, $CH_3COCH_2^-$, CCl_3^-, $C_6H_5COCH_2^-$, and NH_3.

II. 10,10'-Dimethyl-9,9'-bi(dihydroacridinyl) Biradical DBA and 10,10'-Dimethyl-9,9'-bi(dihydroacridinylidene) Produced by Two-electron Transfer from Nucleophiles to DBA^{2+}. Although aqueous solutions of **1**, **8**, and **9** did not exhibit chemiluminescence in the presence of oxygen or hydrogen peroxide, the addition of nucleophiles of group (a) in Table 1 to these solutions produced luminescence. Luminescence of the salts was also observed in aqueous solutions containing organic solvents such as ethanol, DMSO, DMF, and pyridine in the presence of oxygen or hydrogen peroxide. It has already been reported by Janzen[2] that the addition of the potassium or sodium salts of the nucleophiles, CN^-, *t*-BuO^-, and S^{2-}, included in group (a) in Table 1, to solutions of **1** in DMSO, DMF, or aqueous DMSO in the presence of oxygen resulted in luminescence, as in the case of the addition of OH^-, and radical **10** corresponding to ketyl radical **3** was formed as an intermediate. If the mechanism involving **3** or **10** is correct, the nucleophiles



X: CN, *t*-BuO, S^-

10

of group (a) in Table 1 which exhibited luminescence in the presence of oxygen, might produce a radical corresponding to **10** in oxygen-free solutions *via* the addition at the 9,9'-positions of DBA^{2+}. This assumption was examined by measuring the variation of the absorption spectrum of **1** for the addition of the nucleophiles of group (a) in Table 1. When various amounts of the nucleophiles were added to a solution of **1** (1.6×10^{-4} mol l^{-1}) in oxygen-free aqueous ethanol (50 : 50 vol%), a new broad band appeared in the wavelength range longer than 500 nm, and the absorbance of the band increased with an increase in the nucleophile amount. Two examples are shown in Figs. 4 and 5. The broad band can reasonably be attributed to charge transfer in the salts formed between DBA^{2+} and the nucleophiles. When the nucleophiles were added to a more dilute solution of **1** (8×10^{-5} mol l^{-1}) in oxygen-free aqueous ethanol, the mixture gradually turned reddish brown and then became turbid owing to the formation of an insoluble product. The evolution of the absorption spectrum of **1** was followed in dilute solutions of **1** until turbidity appeared. No broad CT band was observed, but each spectrum showed a decrease in the absorbance of the band of DBA^{2+} at 370 nm accompanied by the increase of a band at 423 nm and two isosbestic points near 380 and 480 nm. The time-resolved absorption spectra of mixtures of

The spectra were measured immediately after mixing of *t*-BuOK.

1 and $(C_2H_5)_3N$ and CN^-(NaCN) are shown in Figs. 6 and 7 as examples. A similar variation of the UV spectrum of **1** was also observed by mixing the nucleophiles in aqueous DMF and in aqueous pyridine. The variations in these solvents were faster than those in the aqueous ethanol, although they were similar. The absorption maximum at 423 nm shown in Figs. 6 and 7 agrees with that of 10,10'-dimethyl-9,9'-bi(dihydroacridinylidene), **5**. These facts and the formation of the CT complexes described above appear to show that the reaction of DBA^{2+} with the nucleophiles was the reduction of DBA^{2+} with the nucleophiles by electron

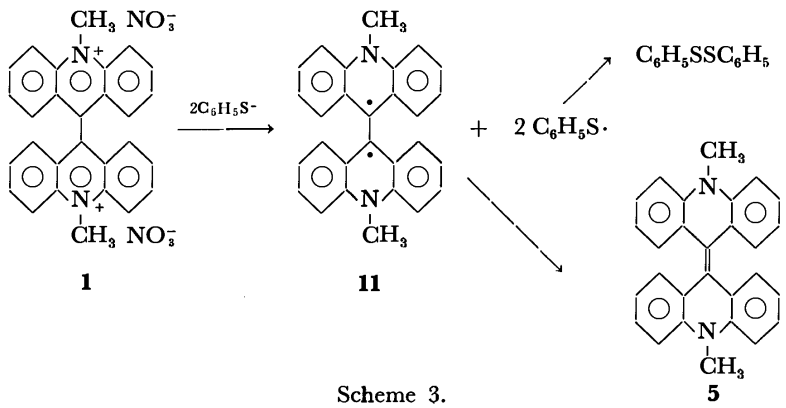
transfer *via* the formation of CT complexes rather than the formation of a radical **10** *via* the formation of pinacol **2**.[10]

The reduction of DBA^{2+} with the nucleophiles was further confirmed on the basis of the following reaction. When sodium benzenethiolate (8×10^{-4} mol) was added to an aqueous solution of **1** (4×10^{-4} mol in 45 ml) over 2 h with stirring in nitrogen, orange yellow fine crystals of the reduction product (83%) were separated out. The crystals were filtered and diphenyl disulfide (mp 60.5—61.5 °C from ethanol, 82%), the amount of which was comparable to that of the reduction product, was isolated from the filtrate. The crystals showed an absorption spectrum with a maximum at 423 nm in benzene and a green fluorescence in benzene with a maximum at 504 nm. These spectra and the IR spectrum agreed with those of **5**. The crystals decomposed at 360 °C and the results of elemental analysis[11] corresponded to **5**. However, the crystals exhibited an ESR absorption (g=2.003) in both solid state and solution. The spin concentration in solid state was 6×10^{20} spin mol^{-1}. Repeated recrystallization of the crystals from pyridine or benzene eventually gave lemon yellow crystals which exhibited no ESR absorption and were identified to be **5**. From these facts it is believed that the crystals were a mixture of **5** and a radical which is reasonably assumed to be biradical 10,10′-dimethyl-9,9′-bi(dihydroacridinyl), **11**.[12] It appears that **5** was produced from biradical **11** by bonding of the two spins and diphenyl disulfide was produced by dimerization of phenylthiyl radicals formed by one-electron oxidation of benzenethiolate



Scheme 3.

TABLE 4. THE YIELDS OF THE REDUCTION PRODUCTS OF DBA^{2+} OBTAINED FROM **1** AND NUCLEOPHILES

Nucleophile	Yield (%)
$(C_2H_5)_3N$	70

t-BuO$^-$	84
OH^-	86
S^{2-}	92
CN^-	93

anions by DBA^{2+}, as shown in Scheme 3. Because the ESR spectrum of **11** measured in C_6H_6 showed no signals attributable to a triplet state, it appears that there was little interaction between the two spins, and the two dihydroacridinyl groups in biradical **11** were twisted about the C_9–$C_{9'}$ bond. A similar reduction product of DBA^{2+} was isolated by the addition of other nucleophiles, as shown in Table 4, and it exhibited an ESR absorption which had a spin concentration of $(5—10)\times10^{20}$ spin mol^{-1}, depending upon the kind of nucleophile and the reduction condition. The spin concentration showed that the amount of biradical **11** included in the reduction product was little. Chemiluminescence was visually observed in the reduction product in organic solvents such as ethanol, benzene and pyridine in the presence of oxygen,[13] while no luminescence was observed in a pure sample of **5** under the same conditions. Therefore, when sodium dithionite ($Na_2S_2O_4$) which has a strong reducing power was used as a nucleophile, the reduction product isolated (88%) was mostly **5** and exhibited hardly any ESR absorption or chemiluminescence. Thus, it is reasonable to consider that the chemiluminescence of the reduction products is connected with the oxygenation of biradical **11**.

No reduction of DBA^{2+} in water occurred by NO_3^- and the nucleophiles of group (b) in Table 1, but occurred upon irradiation. When a dilute aqueous solution of **1** ($(5—10)\times10^{-4}$ mol l^{-1}) was irradiated with a high-pressure mercury lamp or an incandescent lamp in a nitrogen atomosphere, a solid product was gradually deposited on the wall of the reaction vessel. For example, the yield of the product was about 10% after irradiation by a 400 watt high-pressure mercury lamp for 25 h. The reduction product obtained photochemically exhibited luminescence in organic solvents in the presence of oxygen in a manner similar to the reduction products obtained by the chemical reduction of DBA^{2+} described above. The reduction of DBA^{2+} under irradiation with NO_3^- and I^- in **1** and **9** in both ethanol and DMSO was followed by observing the variation of the absorption spectra of DBA^{2+}, respectively. The variation of the spectrum of **1** in ethanol shown in Fig. 8 is similar to those shown in Figs. 6 and 7.[14] It is believed that because the electron-donating powers of nucleophiles NO_3^- and I^-(group (b) in Table 1) are weaker than those of nucleophiles of group (a) in Table 1, the former does not reduce DBA^{2+} without irradiation in water, but the latter does reduce DBA^{2+} without irradiation by the electron transfer mechanism. As described above, a DMF solution of

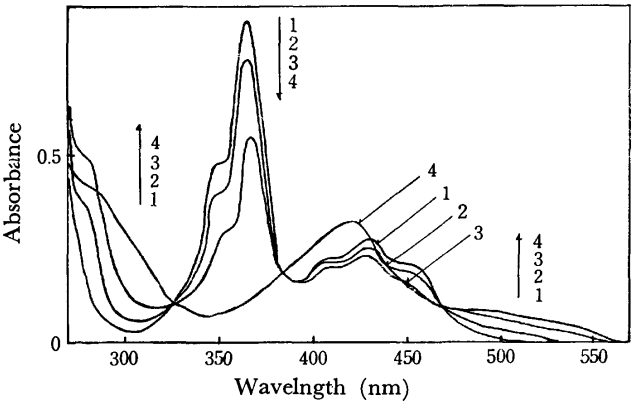

Fig. 8. The variation of the absorption spectrum of **1** in ethanol under irradiation.
Irradiation: A 400 watt high-pressure mercury lamp.

1: Before irradiation, 2: after irradiation for 1 min, 3: after irradiation for 3 min, 4: after irradiation for 5 min.

1 exhibited luminescence in the presence of oxygen without any other nucleophiles. This fact can be explained in terms of the electron-donating power of NO_3^- which is stronger in DMF than in water. Therefore, in the DMF solution of **1** the equilibrium of Scheme 2 was shifted greatly to the right-hand side. This explanation is further supported by the fact that a DMF solution of **1** exhibited a green fluorescence visually similar to that of **1** in water, but, in contrast to the fluorescence in water, the excitation spectrum of the fluorescence in DMF was not consistent with the absorption spectrum of DBA^{2+}, but was consistent with that of **5**, the reduction product of **1**.

III. Cation Radical DBA^{+} Produced by One-electron Transfer from Nucleophiles to DBA^{2+}. It has previously been reported[3b] that an aqueous solution of **1** containing acetone turned blue upon the addition of aqueous sodium hydroxide. It was found that a similar blue color also appeared in aqueous alkaline solutions of **1** containing $RCOCH_3$ in which R was C_6H_5, C_2H_5, and H. It appears that the blue color is due to a substance produced by the reduction of DBA^{2+} with $RCOCH_2^-$ which was formed from $RCOCH_3$ and OH^-. For example, upon the addition of an ethanolic solution of acetophenone (1.74 g in 15 ml) containing aqueous sodium hydroxide (1 ml of 0.3 mol l^{-1}) to an aqueous solution of **1** (0.25 g in 45 ml) with stirring in nitrogen the solution turned blue. After 2 h, the solvent was evaporated under reduced pressure. When the residue was repeatedly extracted with water and washed with a small amount of benzene, a blue compound was obtained. The residue was soluble in benzene, pyridine, DMF, and ethanol and exhibited a strong ESR absorption in both solid state and solution (g=2.003). By evaporating the combined aqueous extracts a salt of DBA^{2+} involving $C_6H_5COCH_2^-$ as a counter ion(0.111 g) was obtained, which was recrystallized from water giving bluish-brown crystals. The salt showed an absorption spectrum having a CT absorption band in the longer wavelength range below 500 nm and showed an ESR

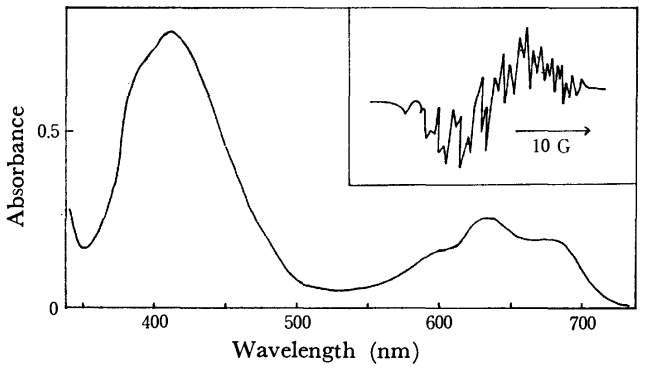

Fig. 9. The absorption spectrum of **12** in benzene and the ESR spectrum in oxygen-free DMF.

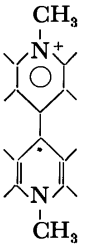
absorption both in solid state and solution. The ESR spectrum of the salt measured in an oxygen-free DMF solution was similar to the ESR spectrum of type B shown in Fig. 3.

The absorption spectrum of the blue compound **12** in benzene and the ESR spectrum in oxygen-free DMF are shown in Fig. 9. The absorption spectrum of **12** is different from that of the salt of DBA^{2+}, but resembled those of methylviologen cation radical **13**[15] and biisoquinolinium cation radical **14**,[16] which were one-electron reduction products of the parent dications, methylviologen and biisoquinolinium, respectively, although the absorption maxima of **12** (blue; 600, 630, and 680 nm in benzene) are shifted to wavelengths longer than those of **13** (royal blue; 560, 610, and 670 nm in CH_3CN[15]) and **14** (orange red; 460, 500, and 538 nm in CH_3OH[16]). Similarly to **13** which was reoxidized to the original dication by oxygen or iodine, **12** was also reoxidized to the original dication DBA^{2+} in both DMF and methanol upon the addition of an equimolar amount of iodine, because a residue obtained by evaporation of the solvents showed an absorption spectrum in water which agreed with that of DBA^{2+}. When **12** was chromatographed on silica gel using benzene as the eluent in nitrogen atmosphere, the blue color of **12** on silica gel faded and **5** was isolated as yellow crystals from the eluate. In addition, a small amount of solid which was identified to be a salt of DBA^{2+} by comparing its absorption spectrum with that of DBA^{2+}, was isolated when water was used as the second eluent. From these findings it can reasonably be assumed that the blue compound **12** is the one-electron reduction product of DBA^{2+}, DBA^{+} $C_6H_5COCH_2^-$. The cation radical corresponds to **13** and **14**, which have a common partial structure, **15**. The



15

results of the elemental analysis of $DBA^{+}C_6H_5COCH_2^-$ (Found: C; 84.84, H; 5.70, N; 5.78%. Calcd for $C_{36}H_{29}N_2O$: C, 85.54, H; 5.74; N; 5.55%) and its IR spectrum, which appears to be the superposed spectra of **5** and acetophenone, also supported the structure of **12** for the blue compound. The formation of **5** and DBA^{2+} from **12** by chromatography on silica gel was considered to be due to the disproportionation reaction shown in Scheme 4. The blue color observed in the reaction of DBA^{2+} with $CH_3COCH_2^-$, $C_2H_5COCH_2^-$, and $HCOCH_2^-$, which were formed from the corresponding ketones or acetaldehyde and hydroxide ion, was also attributed to the formation of the cation radical DBA^{+}.

The rate of formation of **12** in solutions depended upon the reaction conditions, such as the kind of solvents and the concentrations of DBA^{2+} and $C_6H_5COCH_2^-$. When the concentrations of **1** and $C_6H_5COCH_2^-$ were rather high, the absorption spectrum of

Solvent: C_2H_5OH-H_2O (50 : 50 vol%).
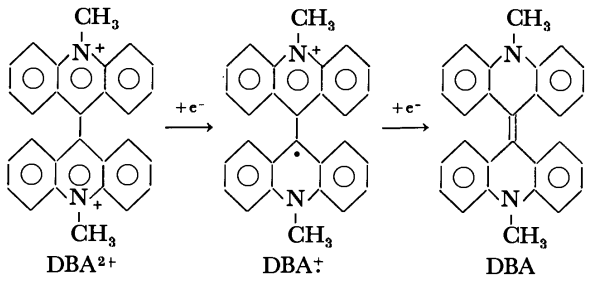
Concentration of **1**: 8.0×10^{-5} mol l^{-1}.
Concentration of $C_6H_5COCH_3$: 8.4×10^{-2} mol l^{-1}.
Concentration of NaOH added into the solution of $C_6H_5COCH_3$: 5.0×10^{-4} mol l^{-1}.
—— Before mixing, ---- immediately after mixing, — — — 10 min after mixing, ——— 40 min after mixing.

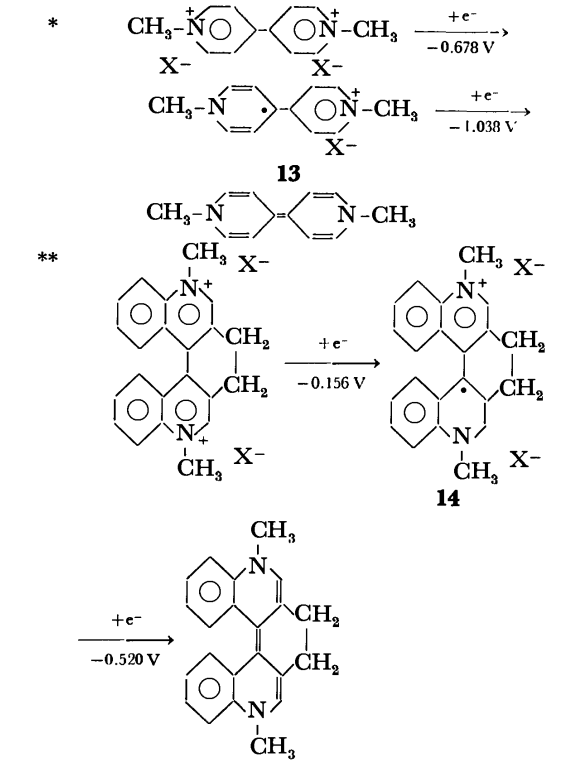
12 immediately appeared after mixing solutions of **1** and the nucleophiles, as shown Fig. 10. However, when the concentration of the nucleophiles was lower, CT absorption appeared immediately after mixing and then the absorption spectrum gradually changed to that of **12**, as is shown in Fig. 11.

In order to explain the fact that only nucleophile $RCOCH_2^-$ formed the cation radical DBA^+, one- and two-electron half-wave reduction potentials of DBA^{2+} in **1**, shown in Scheme 5, were measured polarographically[17] to be −0.035 and −0.43 V, respectively. In a manner similar to methylviologen dication*[18] and biisoquinolinium dication**,[16] the reduction potentials showed that the one-electron reduction in the first step from the dication to the corresponding cation radical **12** occurred more easily than that in the second step from the cation radical, **12**, to **5**. Although most of the oxidation-reduction potentials of the nucleophiles used in the present study are not known, it is reasonable to assume that the electron-donating power of nucleophiles $RCOCH_2^-$ to DBA^{2+} was stronger than those of NO_3^-, SCN^-, and I^- which gave CT complexes in an aqueous solution, but weaker than those of CN^-, OH^-, and CCl_3^- which gave DBA^{2+} as a reduction product. Therefore, the nucleophile $RCOCH_2^-$ formed the cation radical DBA^+ because of the difficulty in the second reduction step from DBA^+ to the two-electron reduction product.



Scheme 5.

The results obtained in I, II, and III are summarized below and the mechanism of the chemiluminescence of lucigenin, **1**, is reasonably concluded to be that described below.



1. Lucigenin($DBA^{2+}2NO_3^-$) is a CT complex between DBA^{2+} and NO_3^-. Nucleophiles, such as Cl^-, Br^-, SCN^-, and I^-, give CT complexes upon their introduction into an aqueous solution of **1**.

2. The first process of the chemiluminescent reaction of **1** in an aqueous solution in the presence of oxygen is a reduction-oxidation reaction in which DBA^{2+} is reduced by two-electron transfer from OH^- to the biradical $DBA^{:}$ *via* the cation radical $DBA^{+\cdot}$. The biradical forms dioxetane[19] by oxygenation and then produces excited *N*-methylacridone, the light emitter. The mechanism of the chemiluminescence of **1** is shown in Scheme 6.

$$\underset{\mathbf{1}}{DBA^{2+}2NO_3^-} \xrightarrow{OH^-} \underset{\text{cation radical}}{(DBA^{+\cdot})} \xrightarrow{OH^-} \underset{\mathbf{11}}{DBA^{:}} \xrightarrow{O_2} \text{dioxetane}$$

$$\longrightarrow \underset{\mathbf{4^*}}{N\text{-methylacridone}^*} \longrightarrow h\nu + \underset{\mathbf{4}}{N\text{-methylacridone}}$$

Scheme 6.

3. Several nucleophiles which have strong electron-donating powers, such as CN^-, $t\text{-}BuO^-$, $C_6H_5S^-$, CCl_3^- and NH_3, also give the biradical which exhibits luminescence in organic solvents in the presence of oxygen. Nucleophiles which have weak electron-donating powers, such as $C_6H_5COCH_2^-$ and $CH_3COCH_2^-$, give cation radicals by one-electron transfer *via* CT complexes, but do not produce the biradical, and consequently exhibit no luminescence in the presence of oxygen.

The authors wish to express their deep gratitude to Professor Emeritus Taro Hayashi of Ochanomizu University for helpful discussions throughout this investigation. They wish also to express their gratitude to Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research, Tokyo for his kind help, and to Dr. Kikuko Hayamizu of the National Chemical Laboratory for Industry, Tokyo, and Mrs. Makiko Onishi for their experimental assistance in the early stages of this investigation. This work was partially supported by a grant for Scientific Research from the Ministry of Education (No. 964095).

ESR Studies of Dibenzenesulfenamidyl Radicals[1]

Yozo MIURA, Noboru MAKITA, and Masayoshi KINOSHITA
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received September 2, 1976)

Dibenzenesulfenamidyl radicals (**2**) were generated by the oxidation of dibenzenesulfenamides (**1**), and their ESR and visible spectra were measured. The ESR spectra were split into a 1 : 1 : 1 triplet by the interaction with the nitrogen nucleus (a_N=11.26—11.49 G); in some spectra, each of the triplet was further split by the interaction with the ring protons ($a_{o\text{-}H}=a_{p\text{-}H}$=0.48—0.70, $a_{m\text{-}H}$=0.18—0.22 G). The *g*-values lay in the range of 2.0080—2.0083. From the results, it was concluded that the unpaired electron is distributed mainly on the nitrogen and the two sulfur atoms. Kinetic studies of the decay of **2** indicated that **2** decays with second-order kinetics and is not sensitive to the atmospheric oxygen.

A number of nitrogen-centered free radicals have so far been prepared, and extensive ESR studies for such radicals have been undertaken.[2] Some of them can be readily isolated as pure crystals: 2,2-diphenyl-1-picrylhydrazyl (DPPH),[3] 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (1,3,5-triphenylverdazyl),[4] *etc.*

About fifty years ago, Lecher *et al.* reported that dibenzenesulfenamide (**1a**) in benzene gives a purple solution on treatment with lead dioxide or silver oxide.[5] They inferred from the coloration that a new class of nitrogen-centered free radicals, dibenzenesulfenamidyl radical (**2a**), had been generated. This radical possesses an interesting structure in which two divalent sulfur atoms are adjacent to the radical center. Barton *et al.* have recently found that tribenzenesulfenamide (**3a**) affords **2a** on photolysis or pyrolysis.[6] ESR studies on dibenzenesulfenamidyl radicals (**2**), however, have been rare. In this paper, the authors wish to report a detailed ESR investigation of **2**.

Results and Discussion

Generation of Radicals. Eighteen dibenzenesulfenamides (**1**) were prepared according to a procedure similar to that in the literature.[5] The compounds **1** in benzene all afforded immediately a purple solution on treatment with lead dioxide and potassium carbonate, and the solution showed a strong ESR signal. The ESR parameters for the radicals are listed in the table. The radicals are also generated by the photolysis of **1**, with or without the assistance of di-*t*-butyl peroxide. In general, nitrogen-centered free radicals are easily converted to the corresponding nitroxide radicals. However, even if the present radicals were treated under exposure to the atmosphere, the corresponding nitroxide radicals were not detected. The compounds **1** were not oxidized to **2** by the atmospheric oxygen, but they were subject to photolysis under exposure to the sunlight to give **2**.

Visible Spectra of Radicals. It is important to prove that the radicals **2** are responsible for the purple colors. For example, a visible spectrum of **2a** in benzene shows a λ_{max} at 538 nm, which is responsible for the purple color. The absorbance at this point was plotted against the intensity of the ESR signal (Fig. 1). The good linearity of the plot indicates that the purple color is attributable to the radical. The absorption maxima of **2** are summarized in the table.

ESR Spectra of Radicals. The ESR spectra of **2** were recorded in degassed benzene in order to make them well-resolved. The radical **2a** gave a broad 1 : 1 : 1 triplet spectrum, indicating that the splitting is due to the interaction with the nitrogen nucleus. For the radical, the reported value of a_N is 11.4 G (in cyclohexane),[6] which is in good agreement with this experimental value. The *para*-substituted radicals, **2b** and **2d**, also gave a similarly broad 1 : 1 : 1 triplet spectrum. On the other hand, in the cases of **2c**, **2f**, **2g**, and **2o**, each of the triplet was further split by the interaction with the ring protons, although the splittings were not well-resolved (Fig. 2). In the spectra of **2h**, **2i**, **2k**, **2l**, and **2p**—**r**, however, the splittings were well-resolved (Figs. 3 and 4), and thus the values of a_H were easily determined. The spectra of **2e**, **2j**, **2m**, and **2n** were split by the interaction with the fluorine nuclei and the methyl protons, respectively. However, the spectra were complicated due to superposition with the splittings due to the ring protons,

TABLE. ESR AND VISIBLE SPECTRAL DATA OF DIBENZENESULFENAMIDYL RADICALS (2) IN BENZENE AT ROOM TEMPERATURE

Radical	Coupling constant (G)				g-Value	λ_{max} (nm)
	a_N	$a_{o\text{-H}}$	$a_{m\text{-H}}$	$a_{p\text{-H}}$		
2a	11.41				2.0082	538
2b	11.45			—	2.0082	545
2c	11.45	0.48	0.20	—	2.0082	541
2d	11.26			—	2.0080	497

and thus poorly resolved. Consequently, the values of a_H and a_N of the radicals could not be determined.

As found in the table, the values of a_N lie in the range of 11.26 to 11.49 G and are almost uninfluenced by the substituents. The values of a_H are very small, indicating that the spin densities of the rings are not large. The unpaired electron is, therefore, distributed mainly on the nitrogen and the two sulfur atoms. The *g*-values of **2** lie in the range of 2.0080 to 2.0083;[7] these are large for a nitrogen-centered free radical.[8] This can be explained in terms of the presence of sulfur atoms possessing a large spin-orbit coupling parameter in the π-system.[9]

Decay Kinetic Studies of Radicals. The radicals **2** are rather long-lived in non-polar solents such as benzene and hexane, and give diaryl disulfide and nitrogen in quantitative yields as final decomposition products. Kinetic studies of the decay of **2** were undertaken at 23 °C in the dark. The results are illustrated in Fig. 5.

According to Barton *et al.*,[6] a small quantity of **3a** is generated by the coupling reaction of **2a** with phenylthiyl radical in the course of decomposition of **2a**. Since **3a** already decomposes at relatively low temperature (78 °C) into the original radicals, **2a** and phenylthiyl radical, if tribenzenesulfenamides (**3**) are

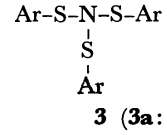
○; Dibenzenesulfenamidyl radical (**2a**) in degassed benzene, ●; **2a** in benzene exposed to the atmosphere, ◑; 4,4′-dichlorodibenzenesulfenamidyl radical (**2f**) in degassed benzene, ◐; 4,4′-dinitrodibenzenesulfenamidylradical (**2d**) in degassed benzene.

generated in the present kinetic system, the analyses of the kinetic studies may become difficult.



3 (**3a**: Ar=C_6H_5)

In order to examine whether **3** was generated or not in the present system, thin layer chromatographic analysis was performed for every solution after the kinetic measurement was completed. The substance **3**, however, was not detected at all. Furthermore, the benzene solution of 0.015 mol/l of **3a** gave only 3.0×10^{-6} mol/l of **2a** at 23 °C in the dark (the concentration of **1a** used for the kinetic investigation was 0.054 mol/l). From these results, it seems that **3** scarcely affects the present kinetic studies.

From the figure, it was found that the radicals **2** decay with second-order kinetics (the rate constant **2a**: 1.1, **2d**: 6.8, **2e**: 2.0 l/mol s) and are not sensitive to the atmospheric oxygen. The decay rates decrease in the order of **2d**>**2e**>**2a**, indicating that introduction of electron-withdrawing groups destabilizes the radicals.[2] This may be explained as follows: electron-withdrawing groups stabilize the corresponding hydrazines by reducing the dipolar repulsion between the nirogen atoms.[10] The hydrazines have not yet been isolated, in spite of many attempts,[5] probably because they are very unstable.

Experimental

All melting points were uncorrected. IR and visible spectra were recorded on a Jasco Model IR-G Spectrometer and a Hitachi Recording Spectrometer Model ESP-3T, respectively. Thin layer chromatographic analyses were performed on alumina (Merck Art 1064), using hexane as eluent, and detected by UV-irradiation.

ESR Measurement. ESR spectra were recorded with a JES-ME 3X Spectrometer, equipped with 100 kHz field modulation, at room temperature (23 °C).

Sample preparation was performed as follows: a) dibenzenesulfenamide (**1**, 10 mg) was treated with lead dioxide (0.5 g) and potassium carbonate (0.5 g) in benzene (1.0 ml), and the inorganic compounds were removed by filtration. 0.4 ml of the filtrate was placed in an ESR tube and degassed by three freeze-and-thaw cycles, and then sealed; b) a solution of **1** (5 mg) and di-*t*-butyl peroxide (0.02 ml) in benzene (0.4 ml) was placed in an ESR tube and degassed as above, and then sealed. ESR spectra were recorded under UV-irradiation from a distance of 40 cm using a high pressure mercury lamp (JES-UV-1, 100 W).

Kinetic Studies. Sample preparation was performed according to the procedure b (di-*t*-butyl peroxide was not added). The solution was UV-irradiated for *ca.* 3 min as described above, and the lamp was turned off. Decay rates of radicals were measured at 23 °C in the dark by monitoring the intensity of the ESR signals. Integrations of ESR signals were achieved with a Model JES-ID-2 Integrator, using a benzene solution of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl[4] as a standard.

Materials. The benzene used for the ESR measurements was purified by the usual method: it was shaken with concd sulfuric acid, and washed with dilute potassium carbonate and then water. After drying over anhydrous magnesium sulfate, it was distilled from sodium wire. Commercially available di-*t*-butyl peroxide, benzenethiol, 2-methyl-, 4-methyl-, 4-*t*-butyl-, and 4-chlorobenzenethiols were used without further purification. 4-Fluoro-, 4-bromo-, 2,4-dimethyl-, and 2,4-dichlorobenzenethiols were prepared by treatment of the appropriate benzenes with chlorosulfonic acid, followed by reduction with zinc dust and sulfuric acid.[11,12] 2-Chloro-, 2-bromo-, 3-chloro-, 3-bromo-, 2-methyl-4-chloro-, 2,3-dichloro-, 2,5-dichloro-, and 3,5-dichlorobenzenethiols were prepared from the appropriate diazotized anilines.[13] 4-Nitrobenzenethiol was prepared by the procedure of Price *et al.*[14]

All dibenzenesulfenamides (**1**) except 4,4′-dinitrodibenzenesulfenamide (**1d**) were prepared according to a procedure similar to that in the literature;[15] **1d** was obtained by a modified method. A typical procedure for the preparation of **1** is described below.

Dibenzenesulfenamide (1a). Chlorine gas was passed into dry chlorofrom (200 ml) at −5—0 °C. To the solution was added dropwise benzenethiol (25 g, 0.23 mol) over a period of 1 h, and for an additional 1 h the gas was passed at the same temperature. After chloroform was evaporated, the resulting red oil was distilled, giving pure benzenesulfenyl chloride; 56—57 °C/3 Torr, 24.7 g (0.17 mol). Ammonia gas was passed into dry ether (600 ml) at −40——50 °C under stirring. To the solution was added dropwise the sulfenyl chloride in dry ether (200 ml) over a period of 2 h. After completion of the addition, the passing of ammonia gas was stopped, and the temperature was gradually raised to room temperature. The formed ammonium chloride was filtered off, and ether was evaporated, giving purple crystals, which were recrystallized from hexane; mp 127—128 °C lit,[15] 127—128 °C), 11.8 g (0.051 mol, 60%).

2-Methyl-(87—88 °C/4 Torr), 4-methyl-(76—78 °C/3 Torr), 4-*t*-butyl-(124—126 °C/7 Torr), and 2,4-dimethylbenzenesulfenyl chlorides (76—78 °C/3 Torr) were purified by distillation. On the other hand, the other sulfenyl chlorides

were used for the following steps without any purification after the removal of chloroform.

*4,4'-Ditoluenesulfenamide (**1b**).* Mp 98—100 °C (petroleum ether), 29%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 64.18; H, 5.97; N, 5.55%. Calcd for $C_{14}H_{15}NS_2$: C, 64.37; H, 5.77; N, 5.36%.

*4,4'-Di-t-butyldibenzenesulfenamide (**1c**).* Mp 89—91 °C (petroleum ether), 28%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 69.75; H, 7.67; N, 4.21%. Calcd for $C_{20}H_{27}NS_2$: C, 69.50; H, 7.89; N, 4.05%.

*4,4'-Difluorodibenzenesulfenamide (**1e**).* Mp 127—129 °C (hexane), 54%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 53.33; H, 3.14; N, 5.24%. Calcd for $C_{12}H_9NF_2S_2$: C, 53.51, H, 3.37; N, 5.20%.

*4,4'-Dichlorodibenzenesulfenamide (**1f**).* Mp 132—133 °C (benzene–hexane, lit,[16] 137—140 °C), 71%.

*4,4'-Dibromodibenzenesulfenamide (**1g**).* Mp 138—139 °C (methanol), 53%. IR (KBr): 3270 cm^{-1} (NH). Found C, 36.87; H, 2.37; N, 3.70%. Calcd for $C_{12}H_9NBr_2S_2$: C, 36.85; H, 2.32; N, 3.58%.

*3,3'-Dichlorodibenzenesulfenamide (**1h**).* Mp 122—123 °C (benzene–hexane), 24%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 47.49; H, 2.95; N, 4.83%. Calcd for $C_{12}H_9NCl_2S_2$: C, 47.68; H, 3.01; N, 4.64%.

*3,3'-Dibromodibenzenesulfenamide (**1i**).* Mp 115—117 °C (benzene–hexane), 24%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 37.11; H, 2.23; N, 3.77%. Calcd for $C_{12}H_9NBr_2S_2$: C, 36.85; H, 2.32; N, 3.58%.

*2,2'-Ditoluenesulfenamide (**1j**).* Mp 128—130 °C (petroleum ether), 39%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 64.27; H, 5.72; N, 5.31%. Calcd for $C_{14}H_{15}NS_2$: C, 64.37; H, 5.77; N, 5.36%.

*2,2'-Dichlorodibenzenesulfenamide (**1k**).* After the removal of ether from the filtrate, to the residue (oil) hexane was added, giving crystalline **1k**, which was recrystallized from methanol, and benzene–hexane; mp 167—169 °C, 21%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 47.57; H, 2.95; N, 4.72%. Calcd for $C_{12}H_9NCl_2S_2$: C, 47.68; H, 3.01; N, 4.64%.

*2,2'-Dibromodibenzenesulfenamide (**1l**).* After the removal of ether from the filtrate, to the residue (oil) hexane was added, giving crystalline **1l**, which was recrystallized from methanol, and benzene–hexane; mp 173—174 °C, 31%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 36.86; H, 2.25; N, 3.61%. Calcd for $C_{12}H_9NBr_2S_2$: C, 36.85; H, 2.32; N, 3.58%.

*2,2',4,4'-Dixylenesulfenamide (**1m**).* Mp 116—118 °C (petroleum ether), 49%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 66.33; H, 6.65; N, 5.05%. Calcd for $C_{16}H_{19}NS_2$: C, 66.39; H, 6.62; N, 4.84%.

*2,2'-Dimethyl-4,4'-dichlorodibenzenesulfenamide (**1n**).* Mp 144—146 °C (chloroform), 48%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 50.63; H, 3.90; N, 4.21%. Calcd for $C_{14}H_{13}NCl_2S_2$: C, 50.91; H, 3.98; N, 4.24%.

*2,2',4,4'-Tetrachlorodibenzenesulfenamide (**1o**).* After the removal of ether from the filtrate, the crystalline residue was refluxed in methanol (100 ml) for 10 min (not soluble completely) and cooled. The crystals separated were filtered and recystallized from benzene; mp 185—186 °C, 23%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 38.75; H, 1.86; N, 3.78%. Calcd for $C_{12}H_7NCl_4S_2$: C, 38.83; H, 1.91; N, 3.76%.

*2,2',3,3'-Tetrachlorodibenzenesulfenamide (**1p**).* After the removal of ether from the filtrate, to the oily residue hexane was added, giving crude **1p**, which was filtered, and refluxed in methanol (50 ml) for 10 min (not soluble completely) and cooled. The crystals separated were filtered and recrystallized from benzene–hexane; mp 197—198 °C, 26%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 38.94; H, 1.91; N, 3.76%. Calcd for $C_{12}H_7NCl_5S_2$: C, 38.83; H, 1.91; N, 3.76%.

*2,2',5,5'-Tetrachlorodibenzenesulfenamied (**1q**).* After the removal of ether from the filtrate, to the oily residue hexane was added, giving crude **1q**, which was filtered, and refluxed in methanol (50 ml) for 10 min (not soluble completely) and cooled. The crystals separated were filtered and recrystallized from benzene–hexane; mp 197—198 °C, 20%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 39.06; H, 1.73; N, 3.72%. Calcd for $C_{12}H_7NCl_4S_2$: C, 38.83; H, 1.91; N, 3.76%.

*3,3',5,5'-Tetrachlorodibenzenesulfenamide (**1r**).* Mp 185—186 °C (benzene–chloroform), 16%. IR (KBr): 3270 cm^{-1} (NH). Found: C, 38.75; H, 1.86; N, 3.78%. Calcd for $C_{12}H_7NCl_4S_2$: C, 38.83; H, 1.91; N, 3.76%.

*4,4'-Dinitrodibenzenesulfenamide (**1d**).* By a procedure similar to **1a**, 4-nitrobenzenethiol was treated with chlorine and ammonia gases. After the removal of ether from the filtrate, the obtained residue was recrystallized from benzene–hexane, giving 4-nitrobenzenesulfenamide; mp 104—106 °C (lit,[17] 103 °C), 49%.

4-Nitrobenzenesulfenyl chloride, which was prepared from 5.5 g (0.032 mol) of 4-nitrobenzenethiol, was added dropwise at −10—−5 °C under stirring to a solution of 4-nitrobenzenesulfenamide (5.5 g, 0.032 mol) and triethylamine (4.0 g) in acetonitrile (100 ml). After completion of the addition, the reaction mixture was stirred for an additional 30 min at 0 °C, and filtered. After the removal of acetonitrile, the resulting residue was recrystallized repeatedly from methanol, giving yellow brown needles [it was very difficult to obtain pure crystals of **1d**, because bis (4-nitrophenyl) disulfide was always contaminated]; mp 167—169 °C (lit,[17] 155 °C), 0.30 g (9.3 mmol, 3.2%). IR (KBr); 3270 cm^{-1} (NH). Found: C, 44.64; H, 2.64; N, 12.88%. Calcd for $C_{12}H_9N_3O_4S_2$: C, 44.57; H, 2.89; N, 13.00%.

*Tribenzenesulfenamide (**3a**).* The compound was prepared according to the literature,[6] mp 62—64 °C (lit,[6] 68 °C).

A Synthesis of 3′-Deoxybutirosin B

Isamu WATANABE, Akio EJIMA, Tsutomu TSUCHIYA, Daishiro IKEDA, and Sumio UMEZAWA

Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

(Received September 9, 1976)

3′-Deoxybutirosin B (**13**) was prepared from 3′-deoxyparomamine (**1**), D-ribose and (*S*)-4-amino-2-hydroxybutyric acid (AHBA). The synthesis involves replacement of the 6′-hydroxyl group of 3′-deoxyparomamine with azido group, 1,6-carbamate ring formation, condensation with tri-*O*-(*p*-nitrobenzoyl)-α,β-D-ribofuranosyl bromide, selective cleavage of the carbamate ring, and acylation of the free amino group at C-1 with AHBA.

In a previous paper,[1] we described the synthesis of 3′-deoxybutirosin B (**13**), a compound having a remarkable activity against resistant bacteria, starting from ribostamycin. In this paper we describe a second synthesis of **13** by condensation of a 3′-deoxyparomamine derivative with a protected ribosyl bromide. The starting material 3′-deoxyparomamine[2] (**1**) is conveniently obtained by hydrolysis of lividomycins,[3] an antibiotic complex produced by *streptomyces lividus*.

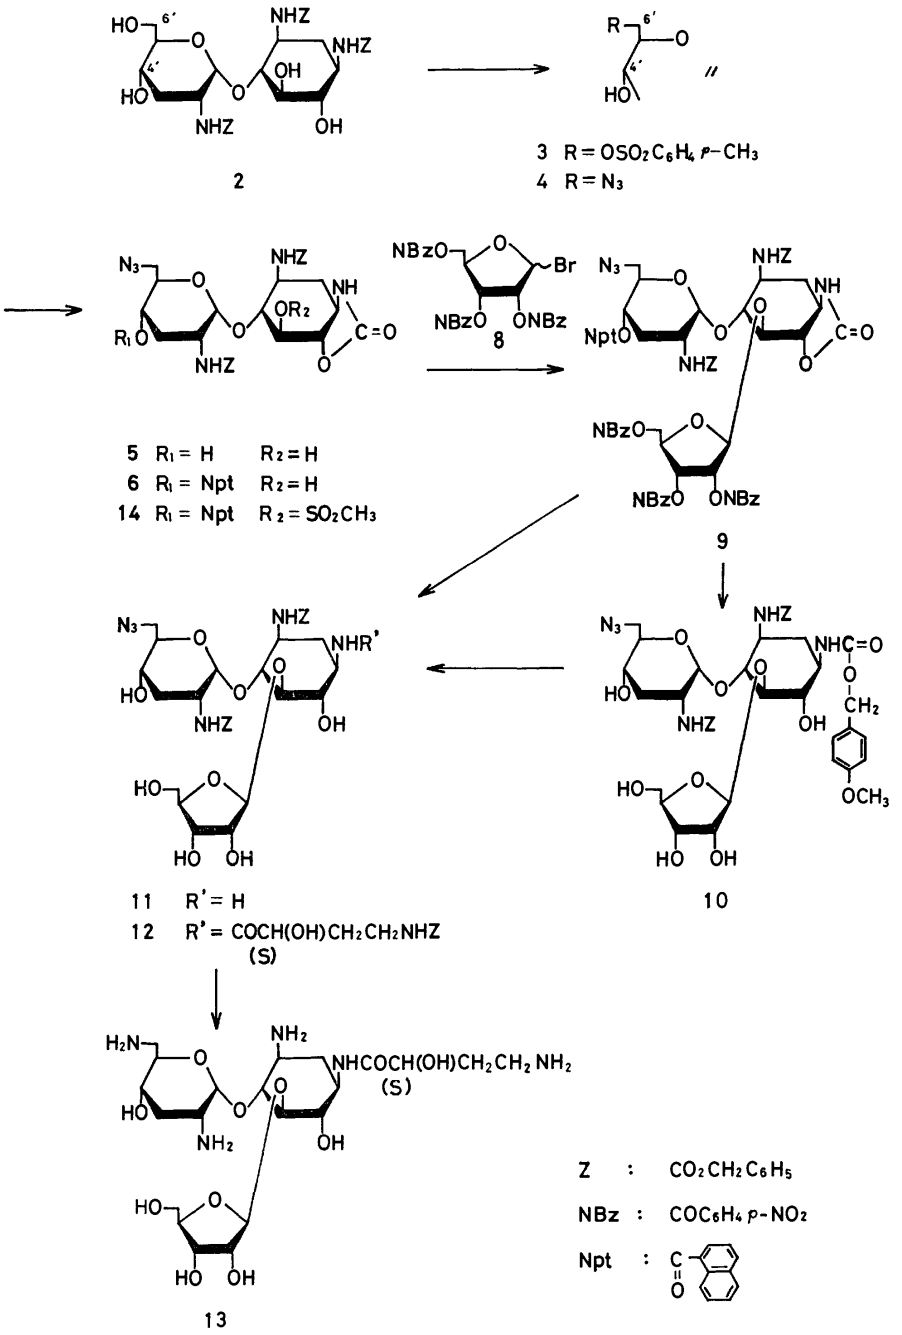
For attaining the synthesis, three key steps were required: 1) replacement of the 6′-hydroxyl group with an amino group, 2) selective ribosylation of the 5-hydroxyl group, and 3) selective amidation of the 1-amino group with (*S*)-4-amino-2-hydroxybutyric acid. The step (1) was performed by selective 6′-*O*-tosylation of a paromamine derivative followed by azidation and hydrogenation. For the step (2) the preparation of a 3′-deoxyparomamine derivative having a free hydroxyl group only at C-5 was required. For this purpose cyclic 1,6-carbamate[4] formation was utilized. Ito *et al.*[5] have reported the synthesis of ribostamycin by condensation of an *O*-benzoylribosyl chloride with a neamine derivative bearing two free hydroxyl groups at C-5 and C-6 to give 5-*O*-ribosyl glycoside as the major product. On the other hand, Hanessian *et al.*[6] have obtained a 6-*O*-ribosyl glycoside almost quantitatively by condensation of the ribosyl chloride with a protected paromamine derivative having two free hydroxyl groups at C-5 and C-6. In our experiences,[13] the 6-hydroxyl group is observed to be more reactive than the 5-hydroxyl group, therefore, we designed to protect the 6-hydroxyl group by cyclic 1,6-carbamate formation. The 1,6-carbamate suggested another advantage that the space around the 5-hydroxyl group is extended by the formation of the cyclic carbamate, favouring the 5-*O*-glycosylation, while commonly used 6-*O*-acyl groups may exert steric hindrance on the 5-hydroxyl group. For the step (3), the cyclic 1,6-carbamate was again useful because it is preferentially cleaved[4] to give the free amino group at C-1.

Tri-*N*-benzyloxycarbonyl-3′-deoxyparomamine (**2**) obtained by treatment of 3′-deoxyparomamine[2] (**1**) with benzyl chloroformate was tosylated. In spite of the presence of four hydroxyl groups in **2**, the 6′-*O*-tosyl derivative (**3**) was isolated in a yield of 68%. The position of the group was indicated by the difficulty of tritylation of **3**. Treatment of **3** with sodium azide in *N*,*N*-dimethylformamide (DMF) gave the 6′-azido derivative (**4**) quantitatively. Reaction of **4** with sodium hydride in DMF in a manner as described in previous papers[1,4,7] gave the cyclic carbamate derivative (**5**) in a yield of 80%. The presence of a carbamate group was confirmed by its IR spectrum.[8] Since **5** has two hydroxyl groups at C-5 and 4′, the hydroxyl group at C-4′ was protected in advance. For the purpose we utilized α-naphthoyl group, a bulky one, expecting its regioselective effect. The 4′-*O*-(α-naphthoyl) derivative (**6**) was obtained in a yield of 65%. The structure of **6** was confirmed by acidic hydrolysis of the mesyl derivative (**14**) of **6**. Hydrolysis of **6** gave 2-deoxystreptamine, whereas hydrolysis of **14** did not give 2-deoxystreptamine, indicating that the hydroxyl at C-5 of 2-deoxystreptamine moiety was mesylated.

The 5-*O*-ribosylation of **6** was next studied. Among the protected ribosyl halogenides tested, the anomeric mixture (*ca.* 1 : 1) of 2,3,5-tri-*O*-(*p*-nitrobenzoyl)-D-ribofuranosyl bromide (**8**), which was prepared *via* methyl 2,3,5-tri-*O*-(*p*-nitrobenzoyl)-β-D-ribofuranoside (**7**), was found suitable for the coupling partner to **6**, because **8** is stable to recrystallization from benzene and can be kept for months. The corresponding *O*-acetyl and *O*-benzoyl bromide were less stable. In addition, the presence of the *p*-nitrobenzoyl group at C-2 may be convenient in the glycoside formation in preventing[9] the formation of undesirable orthoester. After completion of our work, Khadem *et al.*[12] have reported the syntheses of **7** and **8** in the β-anomeric form by a method similar to ours. Condensation of **6** with **8** was carried out in dichloromethane in the presence of mercuric cyanide. In this reaction, the use of fairly decreased amount of dichloromethane (7—10 times v/w for **8**) was required to raise the yield of the condensation product (**9**). The use of benzene–dioxane, or nitromethane as the solvent or the use of Ag_2CO_3–$AgClO_4$ as the catalyst also decreased the yield.

Cleavage of the 1,6-carbamate as well as that of *O*-acyl groups was performed by use of a limited amount of barium hydroxide in dioxane, as reported in previous papers,[1,4,7] to give **11**. When, sodium *p*-methoxybenzylate was used as the base in this reaction, the 1,6-carbamate was cleaved to give the 1-*N*-(*p*-methoxybenzyloxycarbonyl) derivative (**10**). The 1-*N*-protecting group was selectively removed by the action of trifluoroacetic acid[10] in methoxybenzene to give **11** in high yield. The use of boiling acetic acid[10] decreased the yield of **11**.

(*S*)-4-Benzyloxycarbonylamido-2-hydroxybutyryl[11] group was then introduced to the free amino group at C-1 by *N*-hydroxysuccinimide ester method. Catalytic hydrogenolysis of the *N*-benzyloxycarbonyl groups



and the 6'-azido group of the amide (**12**) gave the 3'-deoxybutirosin B (**13**) in overall yield of *ca.* 6% based on **1**. The PMR spectrum of **13** was superimposable with that of 3'-deoxybutirosin B prepared[1] from ribostamycin.

Experimental

Thin-layer chromatography (TLC) was carried out on Wakogel B-5 with sulfuric acid spray for detection. For column chromatography, silica gel (Wakogel C-200) was used.

*1,3,2'-Tri-*N*-benzyloxycarbonyl-3'-deoxyparomamine (2).* A sample of 3'-deoxyparomamine[2] (**1**) was treated with benzyl chloroformate in a similar manner as reported[7] in benzyloxycarbonylation of lividomycin A to give a solid of **2** almost quantitatively, $[\alpha]_D^{22}$ +43° (*c* 0.5, dioxane).

Found: C, 60.70; H, 6.06; N, 5.63%. Calcd for $C_{36}H_{43}N_3O_{12}$: C, 60.92; H, 6.11; N, 5.92%.

*1,3,2'-Tri-*N*-benzyloxycarbonyl-3'-deoxy-6'-*O*-tosylparomamine (3).* To an ice-cold solution of **2** (9.78 g) in pyridine (200 ml), anhydrous *p*-toluenesulfonyl chloride (12.7 g, 5 mol equivalent for **2**) was added and the solution was kept at −10 °C overnight. The solution showed, on TLC with chloroform–ethanol (12 : 1), a major spot at R_f 0.53 and other several slight spots. After addition of water (2.5 ml), the solution was concentrated to give a yellow syrup. The chloroform solution (500 ml) of the syrup was washed with aqueous potassium hydrogensulfate, aqueous sodium hydrogencarbonate and water, dried (Na_2SO_4), and concentrated to give a slightly yellow syrup, which was recrystallized from hot dioxane–hexane to give colorless needles, 8.04 g (68%), mp 185—186 °C, $[\alpha]_D^{21}$ +33° (*c* 1, dioxane); PMR ($CDCl_3$–pyridine-d_5) δ: 2.33 (3H s, CH_3(Ts)).

Found: C, 59.89; H, 5.70; N, 4.87; S, 3.72%. Calcd

for $C_{43}H_{49}N_3O_{14}S$: C, 59.78; H, 5.72; N, 4.86; S, 3.71%.

*6'-Azido-1,3,2'-tri-*N*-benzyloxycarbonyl-3',6'-dideoxyparomamine (4).* A mixture of **3** (5.46 g) and sodium azide (4.2 g) in DMF (100 ml) was agitated at 60 °C for 7 h. Either prolonged or shorter reaction at that temperature decreased the yield of **4**. The solution showed, on TLC with chloroform–ethanol (12 : 1), a single spot at R_f 0.50. Filtration followed by concentration of the filtrate with additions of toluene gave a solid, which was dissolved in dioxane and, after filtration, the solution was concentrated to give a solid, 4.51 g (97%), $[\alpha]_D^{22}$ +90° (*c* 0.5, dioxane); IR (KBr): 2100 (N_3), 1690 cm^{-1} (carbamate).

Found: C, 58.87; H, 5.78; N, 11.20%. Calcd for $C_{36}H_{42}N_6O_{11}$: C, 58.85; H, 5.76; N, 11.44%.

*6'-Azido-3,2'-di-*N*-benzyloxycarbonyl-3',6'-dideoxyparomamine 1,6-Carbamate (5).* To an ice-cold solution of **4** (1.11 g) in DMF (22 ml), 50% oily sodium hydride (240 mg) was added and the mixture was vigorously stirred for 2.5 h in the cold under the atmosphere of nitrogen. The solution showed, on TLC with chloroform–ethanol (15 : 1), a single spot at R_f 0.2. After addition of acetic acid (0.35 ml), the resulting pale-brown gelatinous mixture was poured into water (400 ml). After the mixture had been kept in a refrigerator overnight, it was filtered, and the solid was washed with water. After drying, the solid was reprecipitated from dioxane–hexane to give a solid, 0.75 g (80%). $[\alpha]_D^{20}$ +73° (*c* 1, dioxane); IR (KBr): 2100, 1760 (cyclic carbamate), 1700 cm^{-1}.

Found: C, 55.67; H, 5.50; N, 12.91%. Calcd for $C_{29}H_{34}N_6O_{10}$: C, 55.59; H, 5.47; N, 13.41%.

*6'-Azido-3,2'-di-*N*-benzyloxycarbonyl-3',6'-dideoxy-4'-*O*-(α-naphthoyl)paromamine 1,6-Carbamate (6).* To a cold solution of **5** (1.03 g) in dry pyridine (20 ml) in ice–salt bath, α-naphthoyl chloride (370 mg, 1.2 mol equivalent for **5**) was added and the solution was kept at −10 °C overnight. On TLC with chloroform–ethanol (20 : 1), the solution showed spots at R_f 0.12 (slight, **5**), 0.33 (major, **6**), 0.40 (slight, 5-*O*-α-naphthoyl isomer?) and 0.57 (slight, di-*O*-α-naphthoyl isomer?). Working up in a usual manner gave a crude solid, which was chromatographed over silica gel with benzene–ethyl acetate (3 : 2, gradually changed to 1 : 1) to give a solid of **6**, 826 mg (65%), $[\alpha]_D^{23}$ +98° (*c* 1, dioxane); IR (KBr): 2100, 1750, 1730 cm^{-1}.

Found: C, 61.42; H, 5.24; N, 10.49%. Calcd for $C_{40}H_{40}N_6O_{11}$: C, 61.53; H, 5.17; N, 10.76%.

*6'-Azido-3,2'-di-*N*-benzyloxycarbonyl-3',6'-dideoxy-4'-*O*-(α-naphthoyl)-5-*O*-[2,3,5-tri-*O*-(p-nitrobenzoyl)-β-*D*-ribofuranosyl]paromamine 1,6-Carbamate (9).* To a suspension of **6** (108 mg) in dichloromethane (2.0 ml), calcium sulfate (Drierite, 600 mg, reactivated at 250 °C), mercuric cyanide (350 mg, dried at 90 °C *in vacuo*) and **8** (330 mg, 3.85 mol. equivalent for **6**) were added and the mixture was vigorously stirred at room temperature overnight. On TLC with chloroform–ethanol (30 : 1), the solution showed spots of R_f 0.27 (major), 0.23 (slight), and 0.19 (minor, α-anomeric isomer?), which were of all non-reducing ability (checked by triphenyltetrazolium chloride reagent). After filtration, the solution was washed with aqueous sodium hydrogencarbonate and water, dried (Na_2SO_4), and concentrated. The resulting solid was chromatographed over silica gel with chloroform–ethyl acetate (3 : 2) to give a solid of **9**, 119 mg (66%), mp 136—138 °C, $[\alpha]_D^{22}$ +25° (*c* 1, chloroform); IR (KBr): 2100, 1770 (cyclic carbamate), 1730, 1530, and 1350 cm^{-1} (NO_2).

Found: C, 58.04; H, 4.32; N, 8.99%. Calcd for $C_{66}H_{57}N_9O_{24}$: C, 58.28; H, 4.22; N, 9.27%.

*6'-Azido-3,2'-di-*N*-benzyloxycarbonyl-3',6'-dideoxy-1-*N*-(p-methoxybenzyloxycarbonyl)-5-*O*-(β-*D*-ribofuranosyl)paromamine (10).* To a solution of **9** (444 mg) in dioxane (40 ml) containing *p*-methoxybenzylalcohol (8.8 ml dried over Molecular Sieves 4A), 1 M sodium *p*-methoxybenzylate in the same alcohol (1.6 ml) was added and the solution was kept overnight at room temperature. On TLC with chloroform–ethanol (10 : 1), the solution showed a single spot at R_f 0.26. After addition of acetic acid (0.1 ml), the solution was concentrated and the syrup was dissolved in chloroform (150 ml). The solution was washed several times with water and concentrated to give a syrup. Evaporation (110 °C, 0.02 Torr) of the *p*-methoxybenzylalcohol remained in the syrup gave a thick syrup, which was chromatographed over silica gel firstly with chloroform (to elute the alcohol remained) and then with chloroform–ehtanol (12 : 1) to give a colorless solid of **10**, 175 mg (60%), mp 96—98 °C, $[\alpha]_D^{23}$ +38° (*c* 1, chloroform); IR (KBr): 2100, 1695, 1520 cm^{-1}; PMR ($CDCl_3$) δ: 3.69 (3H s, $CH_3O \cdot C_6H_4$).

Found: C, 56.12; H, 5.76; N, 9.08%. Calcd for $C_{42}H_{52}N_6O_{16}$: C, 56.24; H, 5.84; N, 9.37%.

*6'-Azido-3,2'-di-*N*-benzyloxycarbonyl-1-*N*-[(S)-4-benzyloxycarbonylamido-2-hydroxybutyryl]-3',6'-dideoxy-5-*O*-(β-*D*-ribofuranosyl)paromamine (12).* *A. From 9.* To a solution of **9** (94 mg) in dioxane (4.4 ml), 0.05 M barium hydroxide solution (1.5 ml, 1 mol equivalent for **9**) was added and the mixture was stirred at 60 °C for 30 min. To the resulting neutral solution, additional aliquots of the barium hydroxide solution (1.5 ml × 2) were added at intervals and the mixture was treated as above. On TLC with chloroform–ethanol (7 : 2), the solution showed a major spot at R_f 0.15. Introduction of carbon dioxide followed by filtration and concentration of the filtrate gave a residue, which was extracted with dioxane and the dioxane-soluble product (crude **11**, 65 mg) was isolated.

To a solution of the crude **11** in THF (0.8 ml), *N*-hydroxysuccinimide ester[11] (32 mg) of (*S*)-4-benzyloxycarbonylamido-2-hydroxybutyric acid and triethylamine (*ca.* 11 mg) were added and the solution was stirred at 0 °C for 1 h and then kept at room temperature overnight. On TLC with chloroform–methanol (7 : 1), the solution showed a major spot at R_f 0.31 and the spot at R_f 0.05 (**11**) almost disappeared. The solution was concentrated and the chloroform solution of the residue was washed successively with aqueous potassium hydrogensulfate, aqueous sodium hydrogencarbonate and water, dried (Na_2SO_4), and concentrated. The residue was then chromatographed over silica gel with chloroform–methanol (20 : 1) to give **12**, 24 mg (36% based on **9**), mp 94—96 °C, $[\alpha]_D^{22}$ +19° (*c* 0.25, chloroform); IR (KBr): 2100, 1700, 1530 cm^{-1}.

Found: C, 55.62; H, 5.81; N, 9.95%. Calcd for $C_{45}H_{57}N_7O_{17}$: C, 55.84; H, 5.94; N, 10.13%.

B. From 10. To a cold suspension (in ice–salt bath) of **10** (142 mg) in methoxybenzene (0.13 mg), trifluoroacetic acid (0.8 ml) was added and the mixture was stirred in the cold for a while. The resulting clear solution was kept in the cold for further 30 min. On TLC with chloroform–ethanol (7 : 2), the solution showed majorly a ninhydrin-positive spot (**11**, R_f 0.15). Concentration of the solution *in vacuo* followed by addition of methanolic ammonia to the concentrate until weakly alkaline gave a gelatinous mixture, which was chromatographed over silica gel with chloroform–ethanol (10 : 1) to give a solid of **11**, 102 mg (88%). Reaction of the solid with the active ester in a similar manner as described in A gave **12**, 71 mg (58%).

3'-Deoxybutirosin B (13). To a solution of **12** (64 mg) in dioxane (1.2 ml), water (1.0 ml) and a drop of acetic acid was added and the mixture was hydrogenated with

palladium black under an atmospheric pressure of hydrogen. Concentration of the solution gave a solid, which was chromatographed over CM-Sephadex C-25 (NH_4 form) with 0—0.4 M ammonia with gradient increase in concentration to give **13** as monocarbonate, 25 mg (63%), mp 147—149 °C, $[\alpha]_D^{23}$ +29° (*c* 1, water); IR (KBr): 1640, 1565 cm^{-1}.

Found: C, 44.22; H, 7.27; N, 11.71%. Calcd for $C_{21}H_{41}N_5O_{11}\cdot H_2CO_3$: C, 43.92; H, 7.20; H, 11.64%.

Methyl 2,3,5-Tri-O-(p-nitrobenzoyl)-β-D-ribofuranoside (7). To an ice-cold solution of D-ribose (2.0 g) in dry methanol (40 ml), 1 M methanolic hydrogen chloride (4.5 ml) was gradually added and the solution was kept at room temperature for 1 h. On TLC with benzene–ethanol (1 : 1), the solution showed spots at R_f 0.63 (major, β-riboside) and 0.44 (slight) (*cf.* D-ribose, R_f 0.54). Pyridine (12 ml) was added and the solution was concentrated with additions of toluene to give a syrup. To the solution of the syrup in pyridine (44 ml), *p*-nitrobenzoyl chloride (8.15 g) was added and the solution was kept at room temperature overnight. Water (1 ml) was added and the solution was concentrated. The chloroform solution of the syrup was successively washed with aqueous potassium hydrogensulfate, aqueous sodium hydrogencarbonate and water, dried (Na_2SO_4), and concentrated. Recrystallization of the solid from acetone gave pale-yellow needles, 4.9 g (60%), mp 169—170.5 °C, $[\alpha]_D^{27}$ +80° (*c* 1, choroform) [lit,[12]: mp 169.5—170 °C (from acetone–petroleum ether), $[\alpha]_D^{20}$ +79.7° (*c* 1.38, $CHCl_3$)]; IR (KBr): 1735, 1525, 1350 (NO_2) cm^{-1}; PMR ($CDCl_3$) δ: 3.53 (3H s, OCH_3), 5.32 (1H s, H-1).

Found: C, 53.23; H, 3.56; N, 7.03%. Calcd for $C_{27}H_{21}N_3O_{14}$: C, 53.03; H, 3.46; N, 6.87%.

2,3,5-Tri-O-(p-nitrobenzoyl)-α,β-ribofuranosyl Bromide (8). To an ice-cold solution of **7** (210 mg) in dichloromethane (1.1 ml), hydrogen bromide saturated in acetic acid (1.1 ml) was added and the solution was kept at room temperature for 1 h in the dark place. The solution was concentrated *in vacuo* and the resulting syrup was again dissolved in dichloromethane (20 ml). The solution was successively washed, as fast as possible, with water, aqueous sodium hydrogen carbonate, water again, dried (Na_2SO_4) and concentrated to give a pale-yellow solid. Recrystallization from benzene gave almost colorless needles, 170 mg (75%), mp 105—112 °C, $[\alpha]_D^{23}$ +61° (*c* 1, chloroform) [β-anomer:[12] mp 100—105 °C (from CH_2Cl_2), $[\alpha]_D^{20}$ +55.4° (*c* 1.58, $CHCl_3$)]; PMR ($CDCl_3$) δ: 6.56 (*ca.* 0.5 H s, β-H-1), 6.94 (*ca.* 0.5 H d, J= 4.5 Hz, α-H-1), 6.32 (*ca.* 3H s, C_6H_6).

Found: C, 49.85; H, 3.17; N, 5.87; Br, 10.88%. Calcd for $C_{26}H_{18}BrN_3O_{13}\cdot 1/2C_6H_6$: C, 49.80; H, 3.03; N, 6.01; Br, 11.43%.

6'-Azido-3,2'-di-N-benzyloxycarbonyl-3',6'-dideoxy-5-O-mesyl-4'-O-(α-naphthoyl)paromamine 1,6-Carbamate (14). To a solution of **6** (60 mg) in dry pyridine (2 ml), methanesulfonyl chloride (60 mg) was added and the solution was kept at room temperature for 4 h. The solution showed on TLC with chloroform–methanol (30 : 1) an single spot at R_f 0.48. Isolation of the product in a usual manner gave a solid of **14**, 58 mg (88%); $[\alpha]_D^{24}$ +86 ° (*c* 0.5, chlorofrom); IR (KBr): 1180 (ν_sSO_2), 1350 ($\nu_{as}SO_2$), 1770 cm^{-1}; PMR, δ of SO_2-CH_3: 3.10 ($CDCl_3$), 3.21 ($CDCl_3$–CD_3OD=1 : 1), 3.39 (C_5D_5N).

Found: C, 57.11; H, 5.00; N, 9.57; S, 3.44%. Calcd for $C_{41}H_{42}N_6O_{13}S$: C, 57.33; H, 4.93; N, 9.79; S, 3.73%.

The authors are grateful to Professor Hamao Umezawa, Director of Institute of Microbial Chemistry, for his support and encouragement.

Photolysis in Rigid Matrixes at Low Temperatures. An Intermediate of Photo-dehydrobromination

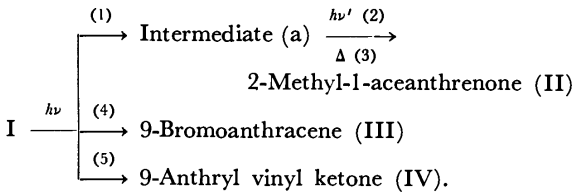
Satoshi HIRAYAMA

Faculty of Textile Science, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606

(Received March 8, 1976)

The intermediate of the photo-dehydrobromination of 9-(α-bromopropionyl)anthracene (I) to yield 9-anthryl vinyl ketone (IV) was detected by its electronic spectrum upon photolysis in polar solvent matrixes at 77 K. Approximately 80% of the initial photo-products is trapped as the intermediate. The remainder is observed as the final product IV formed directly from I. The intermediate is stable only below *ca.* 83 K in EPA. Above this temperature, it decomposes rapidly to form IV. No intermediate was detected for this reaction in the non-polar solvent matrixes at 77 K. Instead, a conformational change of IV with temperature was noticed. Based on the temperature and solvent effects on the stability of the intermediate, a loose structure where a hydrogen bromide is almost completely eliminated *via* a concerted mechanism is postulated for the intermediate. This is supported by the evidence that the main electrochemical reduction product of I is only 9-propionylanthracene. The temperature effects on the other photochemical reactions of I are also discussed in relation to the allowed molecular motions in rigid matrixes.

According to the previous results reported by the present author *et al.*,[1,2] the mechanisms of the intramolecular photochemical reactions of 9-(α-bromopropionyl)anthracene (I) can be summarized as follows:



The intermediate (a) to give II was rather stable and was readily detectable by its UV-absorption spectrum.[1,3]

The present detailed study of Reaction (5) in several matrixes at low temperatures has revealed that an intermediate to yield IV can also be detected spectroscopically at 77 K. Its stability is strongly dependent upon not only the temperature but also the nature of the matrix. Although no absorption due to the intermediate to give IV was detected in the non-polar solvent matrixes, an apparently different spectral change from that observed in the polar solvent matrixes was observed upon gradually softening the matrixes after the photolysis. This observation is explicable in terms of the presence of a second elementary process prior to giving IV, implying that Reaction (5) should involve at least one more transient state other than the newly found intermediate. These findings are of significance, since they will give us additional information as to the mechanism of the photo-dehydrohalogenation of α-haloketones.[4-6] A plausible structure of the intermediate will be given below, referring to the evidence demonstrated by the electrolysis of I.

Taken together with the previous results,[1-3] the present results also demonstrate that each of the Reactions (1) to (5) (revised (5), see below) shows a different temperature dependence. This appears to reflect a difference in the ease of the molecular motions which accompany each reaction mentioned above. Since the photochemistry of I involves rather a wide variety of molecular motions, it is expected that the present photochemical reactions will also provide the possibility of predicting what kind of molecular motion is allowed or prohibited in rigid matrixes upon photo-excitation.

Experimental

Materials. The preparation and purification of I have been described elsewhere.[1] Methylcyclohexane (MCH), isopentane (IP), ethanol (ET), diethyl ether, triethylamine (TEA), and 2-methyltetrahydrofuran (MTHF) were of a guaranteed grade from the Nakarai Chem. Co., Ltd. and were used after an ordinary distillation on a 30-cm Widmer column. Acetonitrile (ACN), a solvent used for the electrolysis of I, was repeatedly distilled over anhydrous aluminium chloride, sodium carbonate, and finally calcium hydride according to the method of Walter and Ramaley.[7] Dry tetrabutylammonium perchlorate (TBAP) or potassium perchlorate was used as a supporting electrolyte (*ca.* 0.1 M).

Procedures. The electonic absorption spectra at the controlled low temperatures were recorded in the same way as has previously been described.[8] For photolysis at low temperatures, a glass gas-inlet pipe at the bottom of a transparent Pyrex Dewar vessel, in which a reaction cell was set, was attached directly to the inlet of a metal Dewar vessel which served as a liquid-nitrogen reservoir. From the bottom of the Pyrex Dewar vessel, boiled cold nitrogen gas was admitted by means of a power resister in order to control the temperature in the range of 90—200 K. After the thermal equilibrium had been attained, the temperature was measured with a copper-constantan thermocouple which was directly immersed in the reaction cell. Photolysis at 77 K was performed by immersing the reaction cell directly in a transparent Pyrex Dewar vessel containing liquid nitrogen. The reaction cells were made of quartz and were 1.0 and 0.2 cm in path length. When the matrixes were unstable toward temperature variation, the cells of the smaller path length were employed. The irradiation source was an Ushio 100 W medium-pressure mercury-arc lamp. A Pyrex Dewar vessel or a water-cooled jacket made of Pyrex glass served as a glass cut-off filter. Since the photolysis of I is essentially independent of whether or not the solution is deaerated, the sample solutions were not degassed unless otherwise stated.

A conventional H-shaped electrolysis cell, the center of which was separated into two compartments by means of a sintered glass-plate, was employed to electrolyze I at a constant potential. Working and auxiliary electrodes were platinum plates of 2×2 cm. A reference-electrode (silver wire) compartment was isolated from the solution to be electrolyzed by means of a glass frit. The solutions were

deaerated by bubbling dry nitrogen gas through. To control the potential, a Hokuto Denko Model HA 101 potentiostat and a Hewlett Packard Model 3300 A function generator were used. Electrolysis products were analyzed by column chromatography on silica gel with benzene after removing the solvent and were identified by comparison (IR- and UV-absorption spectra) with the authentic samples.

For the studies of the cyclic voltammograms of I under a thoroughly degassed and dried condition, a cell similar to that which had previously been prepared for ECL observation was used.[9]

Results

Photolysis at Low Temperatures. Figure 1 shows the absorption spectra of I before and after photolysis in EPA (diethyl ether, isopentane, and ethanol, 5 : 5 : 2 by volume) at 77 K. All the spectra were taken at 77 K. As is shown in Fig. 1b, the absorption of I disappears with irradiation and, instead, we obtain the red-shifted broad band superposed upon by the sharp band with peaks at 364 and 384 nm. The absorbances of these broad and sharp bands increase only with irradiation and, after the thorough consumption of the reactant (spectrum (b)), continued irradiation causes no further spectral change at 77 K. Upon warming the matrix, however, the broad band disappears and changes into a sharp spectrum with the 0-0 band at 384 nm (spectrum (c)). Since IV is the sole photolysis product in EPA at 77 K, as has previously been verified,[1,2] the (c) spectrum is solely due to IV.

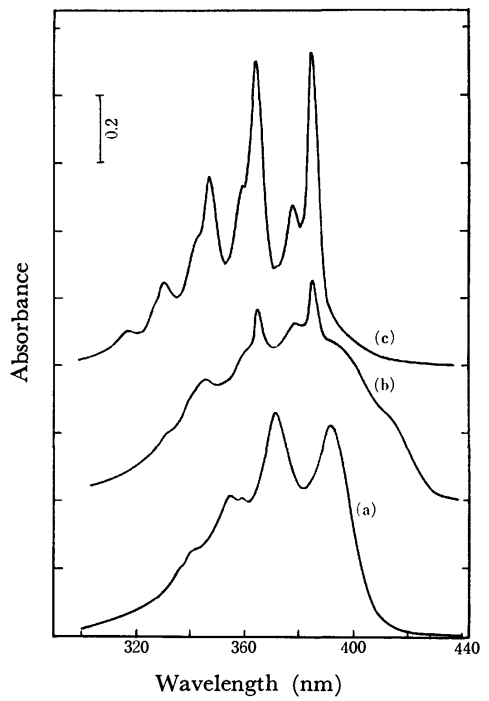


Fig. 1. Photolysis of I (7.1×10^{-5} M) in EPA at 77 K. (a) Before irradiation, (b) after irradiation for 3 h, (c) the spectrum observed at 77 K immediately after warming the sample with the (b) spectrum to room temperature. The (c) spectrum is due to IV. For the sake of clarity, the base line (right-hand side) of each spectrum is shifted by an appropriate amount of absorbance in Figs. 1, 3, 4, and 5.

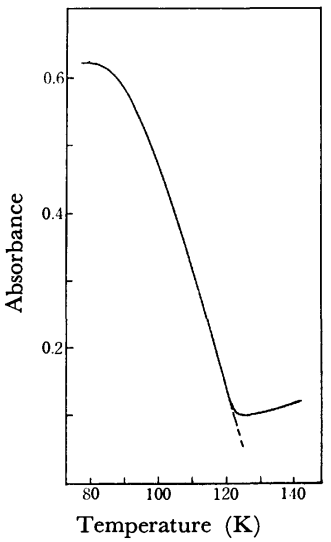

Fig. 2. Change in the absorbance (at 395 nm) of the intermediate with temperature.
A rise in the absorbance at around 123 K is caused by the opacity of the matrix on softening. This figure shows that the intermediate is stable only below 82—83 K. Temperature-rise time: *ca.* 4 min (77—83 K); *ca.* 5 min (83—123 K).

Therefore, the broad band on the longer-wavelength side can reasonably be attributed to an intermediate (hereafter called intermediate (b)) to give IV.

Figure 2 shows how labile the intermediate (b) is against a rise in the temperature. The change in the absorbance of the intermediate formed in EPA was monitored at 395 nm against the temperature by allowing the matrix to grow warmer, and was displayed on an X-Y recorder. From this curve it is apparent that the intermediate (b) is stable only below 82—83 K. In fact, no absorption due to the intermediate (b) was observed during the photolysis of I in EPA at 93 K. At 77 K, however, the intermediate was very stable and no absorption change was observed after allowing the photolyzed solution to stand in the dark at 77 K for several hours. A similar phenomenon was also observed in other transparent-matrix-forming polar (or slightly polar) solvents such as MTHF, ET, and TEA.

The presence of the small sharp peaks before warming the matrix, as is shown in Fig. 1b, implies that a part of the photoeliminated hydrogen bromide molecules can escape from the solvent cage, probably because of excess excitation energy, and that IV is formed directly from I. The percentage of this escape is calculated to be *ca.* 20%[10] in EPA and does not differ significantly in MTHF, ET, TEA, and in EPA.

In contrast, in a non-polar and rather soft MCHIP matrix (methylcyclohexane and isopentane, 3:1 by volume),[11] no absorption similar to that which was observed in EPA was detected, in spite of almost a 100% yield of IV.[2] The results of the spectral change upon photolysis are shown in Fig. 3. The (c) spectrum was obtained at 77 K once after warming the photolyzed solution with the (b) spectrum to room temperature. Although the absorption due to the in-

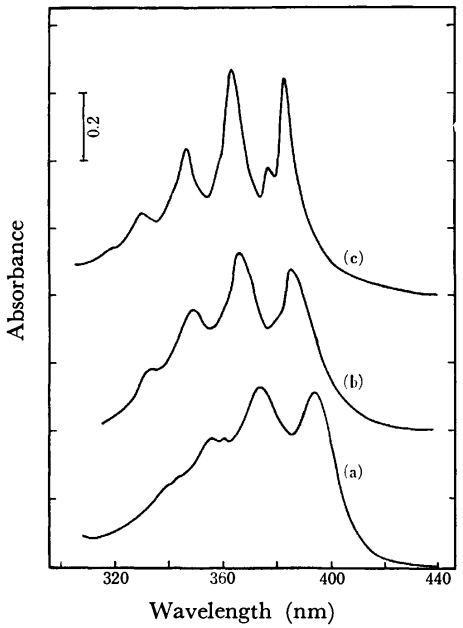

Fig. 3. Photolysis of I (5.3×10^{-5} M) in MCHIP at 77 K.
(a) Before irradiation, (b) after irradiation for 3 h, (c) the spectrum observed at 77 K immediately after warming the sample with the (b) spectrum to room temperature. The (c) spectrum is due to IV. No absorption due to the intermediate (b) is observable.[11,13]

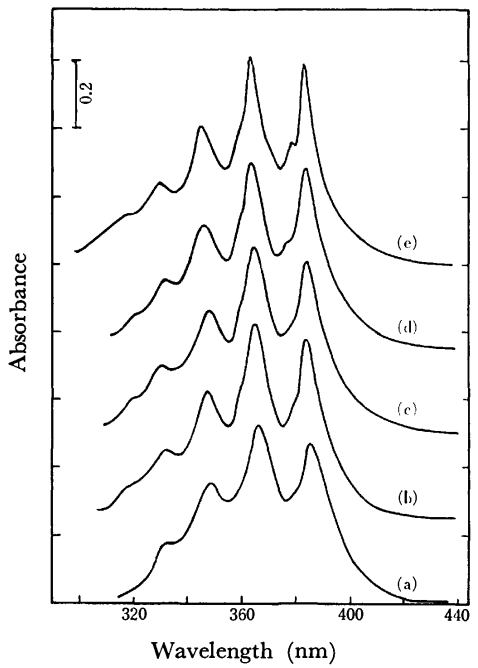

Fig. 4. Temperature dependence of the absorption spectrum of the photo-product formed in MCHIP at 77 K.
(a) 77 K, (b) 98 K, (c) 114 K, (d) 127 K, (e) 144 K. The (e) spectrum apparently differs in the sharpness of the bands from the other spectra.

termediate (b) cannot be observed in MCHIP, the absorption spectra of the photolyzed solution apparently differ between before and after softening the matrix.

Figure 4 shows at what temperature this spectral change occurs. After thorough photolysis in MCHIP at 77 K, the absorption spectra were recorded upon warming the matrix to several constant temperatures. In the neighborhood of 140 K, a rather broad band is seen to change into a sharp band with a greater molar extinction coefficient. Since the medium at these temperatures is fluid enough to allow free molecular motions,[12] the observed spectral change cannot be explained in terms of a change in the rigidity of the matrix with temperature. A possible cause of this spectral change will be discussed later,[13] in relation to a conformational change in IV.

A similar spectral change was also detected during

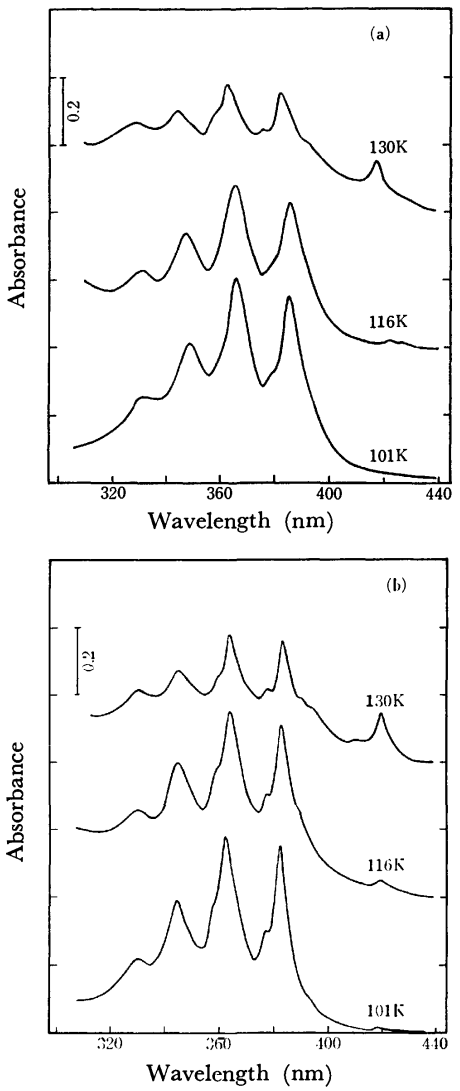

Fig. 5. Absorption spectra of the photo-products of I formed at several low tempratures.
(a) Immediately after photolysis;
(b) after warming to room temperature.
The samples were photolyzed at the indicated temperatures and their spectra were observed at 77 K (Fig. 5a) and were then warmed once to room temperature before the second observation at 77 K (Fig. 5b). All the spectra in Fig. 5b are sharper in shape than the corresponding spectra in Fig. 5a. The small peaks at 418 nm are due to II,[2,8]

the photolysis of I in MCHIP at temperatures higher than 77 K. The results are shown in Fig.5. Comparing Fig.5a with 5b, a difference in the sharpness of the bands can be seen particularly at 383 nm.

In the first instance, a radical species derived from the homolysis of the C–Br bond may be considered as an appropriate candidate for the intermediate (b). However, no ESR signal was observed upon photolysis at 77 K in either polar- or non-polar-solvent matrixes. Thus, Reaction (5) does not appear to involve a radical mechanism but to proceed *via* a concerted elimination mechanism.[6]

In order to confirm this from a different point of view, the electrolysis of I was carried out.

Electrolysis. The cyclic voltammograms of I before and after electrolysis at a constant potential are shown in Fig. 6. A similar result was obtained under a thoroughly degassed and dried condition.

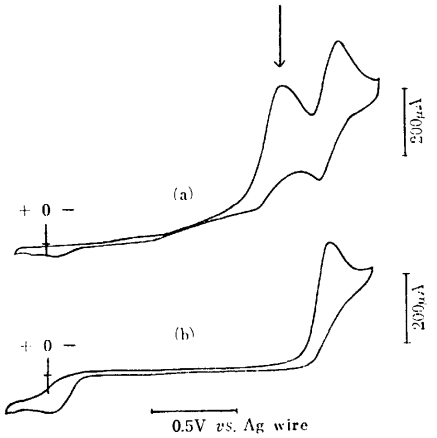

Fig. 6. Cyclic voltammograms of I (2.7×10^{-3} M) and its electrolysis products in ACN.
(a) Before electrolysis;
(b) after electrolysis for 30 min at the constant potential indicated by the arrow. Supporting electrolyte: TBAP, Sweep rate: 86 mV/s.

Based on product analysis by column chromatography, the main electrolysis product was only 9-propionylanthracene (V, 9-CH_3CH_2CO-A, more than 95% of the detected products), a product of bromine atom replacement. Thus, the first and second peaks in Fig.6a correspond to the reduction-wave peaks of I and V respectively.[14] The fact that the loss of a bromide ion from the $[I]^{\cdot-}$ anion radical is rapid is demonstrated by the absence of an anodic wave of the reoxidation of $[I]^{\cdot-}$. This is the case even at low temperatures where the anion radical might be stabilized.[16] Similar results were obtained with both TBAP and potassium perchlorate, the latter of which has no hydrogen atom to donate.

Referring to the previously reported reduction reaction mechanism of organic halides,[17] the present result may be interpreted by the following mechanism;

$$I + e \longrightarrow [I]^{\cdot-} \longrightarrow 9\text{-}CH_3\dot{C}HCO\text{-}A + Br^-,$$

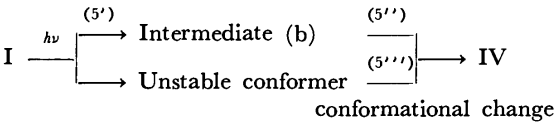
$$9\text{-}CH_3\dot{C}HCO\text{-}A \xrightarrow{\text{solvent}} V,$$

$$V + e \longrightarrow [V]^{\cdot-} \longrightarrow \text{rapid follow-up reactions.}^{15}$$

A 9-$CH_3\dot{C}HCO$-A radical, formed as a result of bromide ion elimination, immediately abstracts a hydrogen atom from the solvent to give V,[18] but not IV. Thus, the intermediacy of the ketonyl radical in the photolysis of I may reasonably be ruled out. In considering the detailed mechanism of Reaction (5), it is noteworthy that none of the main photolysis products[1] was found in the electrolysis products; the photochemistry of I in ACN is essentially the same as that in ET or in MCH.

Discussion

A Postulated Structure of the Intermediate (b). Summarizing the above-mentioned facts, Reaction (5) may be rewritten as follows:



Each process, of course, depends on the nature of the matrix.

We must now consider the structure of the intermediate (b) and the origin of the conformational change indicated in the above scheme. Based on the facts that no ESR signal was detected and that the main electrolysis product was solely V, a radical species such as 9-$CH_3\dot{C}HCO$-A can safely be excluded as an appropriate intermediate to give IV. Taking into account the fact that the intermediate is very labile toward a rise in the temperature from 77 K, completely unstable in soft matrixes, and gives a single product IV upon sofetening the matrix, a structure in which dehydrobromination has almost been completed appears to be most appropriate as a structure of the intermediate (b). A postulated structure is dipicted in Fig. 7a. The dotted-line bonds will be much weaker than the broken-line bonds. This structure is reminiscent of the structure frequently referred to as the four-membered *syn*-elimination transition state in the pyrolytic dehydrohalogenation reactions of organic halides.[6,20] Its loose structure could explain the broad absorption spectrum of the intermediate. Although the intermediacy of a tight radical pair formed as a result of homolysis of the C–Br bond may not be ruled

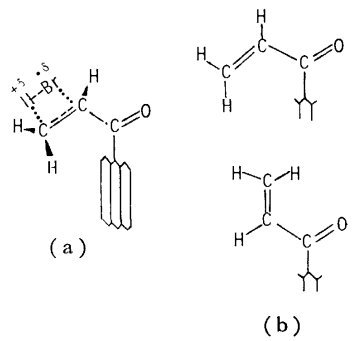


Fig. 7. A plausible conformation of the intermediate (b) (Fig. (a)) and two conformers of IV (Fig. (b)). It is not obvious which conformer is more stable.

out completely, we may expect, in such a case, the formation of V in an appreciable amount.[21] To the author's knowledge, this is the first case where an intermediate of photo-dehydrohalogenation has been detected by its electronic absorption spectrum.

Figure 7b shows two possible conformers of IV. Acrylaldehyde serves as the simplest model compound for the substituent of IV and *s-trans*-acrylaldehyde is reported to be more stable than *s-cis*-acrylaldehyde.[22] Thus, the conformational change in the substituent of IV from *cis* to *trans* or *vice versa* may give rise to the observed spectral change at around 140 K, where the potential barrier of the conformational change will come to be surmounted. The reason for the absence of a similar change in EPA or in MTHF may be that interactions between I or IV and solvent molecules (hydrogen-bonding, *etc.*)[23] can preferentially stabilize one of the conformers.

Allowed Molecular Motions in the Rigid Matrixes. It is very important and instructive to know what kinds of molecular motions are allowed in rigid matrixes, particularly upon photo-excitation. However, there are few such related works, except for detailed studies of *cis-trans* photoisomerization at low temperatures.[24] Fortunately, the present results provide the possibility of investigating a wide variety of allowed molecular motions in matrixes by observing the temperatures at which the photochemical and follow-up dark reactions of I are prohibited. The sequence of the prohibition of the present reactions is as follows, in increasing order:

(5′) (77 K) < (2) (77 K, very slow) < (5″) (85 K) < (4)[1] < (1) (100 K) < (5‴) (140 K) < (3)[1]

In parentheses are given the approximate lowest temperatures where the indicated reactions can still be observed. The first inequality means that the photodehydrobromination from the intermediate (a) is very slow, though detected at 77 K, as compared with Reaction (5′).[25] Reactions (3), (5″), and (5‴) are thermal reactions, the last of which is observed in MCHIP. From the above sequence, it can be said that:

i) The elimination of small molecules (*e.g.*, HX, N_2, CO_2) which is not accompanied by a large structural change will occur readily even at 77 K.[26,27] In the hard matrixes, however, the eliminated molecules cannot be expelled out of the solvent cage, but stay very near to the parent pieces; in a fortunate case, the intermediate(s) will be detected.

ii) A large rotational motion of a group equal to or greater than an acetyl (or propionyl) group is strongly prohibited at 77 K.[2]

iii) Compared with photochemical reactions, the corresponding thermal reactions (*i.e.*, the reaction to yield the same product(s)) are generally retarded much faster upon cooling, as is demonstrated by a comparison of Reactions (2) and (3).[1] This does not mean that the local heating due to irradiation may be of some help to the photolysis of I in the frozen matrixes.

Even for photochemical reactions, some amount of activation energy is necessary, and hence the prohibition of photochemical reactions in frozen matrixes does not always mean the prohibition of the necessary molecular motion due to the matrix rigidity. Hence, if a photolytic reaction which belongs to item i) cannot be detected in frozen matrixes, the activation energy of that reaction may be said to play a dominant role in the prohibition. On the basis of the temperature effect on its reaction, every photochemical reaction reported herewith seems principally rigidity-controlled and Reactions (3) and (5‴) are activation-energy controlled.

The Volumetric Behavior of Nitrobenzene in Electron Donating Solvents

Vojtech FRIED, Lewis P. MILLER, and Howard N. WACHTER[1)]

Department of Chemistry, Brooklyn College of the City University of New York, Brooklyn, New York 11210, U.S.A.

(Received April 12, 1976)

The excess volumes of 18 binary solutions containing nitrobenzene as a weak electron acceptor and various mono- and polysubstituted aromatic donors were evaluated at 25 °C. The partial molal volume of nitrobenzene in these solvents was also evaluated. There is no quantitative correlation between the volumetric behavior of the solutions and the electron donor acceptor abilities of the solution constituents. The results, however, clearly prove that isomers of higher cohesive energy affect the volumetric behavior of solutions less than their lower cohesive energy counterparts. An attempt is made to interpret this observation in terms of the steric effect and the cohesive energy of donors.

It is well known that solutions with strong specific interactions, such as H_2O+HCl, $H_2O+H_2SO_4$, H_2O+HNO_3, acetone+chloroform, methylacetate+chloroform, water+hydrazine and many others frequently exhibit negative deviations from ideal behavior ($G^E<0$, $\gamma_1<1$).[2)] There are systems for which the reasons for negative deviations from ideal behavior are not as obvious as in the above mentioned solutions. The 2,3-dimethyl-2-butene+carbon tetrachloride solution is a good example of this kind of a system.[3)] By comparing the negative G^E values of this system with the positive G^E values of the very similar 2,3-dimethyl-2-butene+tetrachloroethylene system one must conclude that the diametrically different thermodynamic behavior of the two solutions is due to charge transfer interactions in the $C_2(CH_3)_4+CCl_4$ system. The chlorines in the CCl_4 molecule have the ability to withdraw π-electrons from the electron rich double bond of the donor molecule $[(CH_3)_2C=C(CH_3)_2]$; this charge transfer interaction may eventually lead to complex formation between the donor and acceptor molecules. The chlorines in the C_2Cl_4 molecule do not possess such ability. These chlorines saturate themselves with electrons by withdrawing them from the double bond of the C_2Cl_4 molecule itself. Consequently, the C_2Cl_4 molecule cannot act as an electron acceptor and is unable to participate in complex formation. The partially double bond character of the C–Cl bond in the C_2Cl_4 molecule (the C–Cl bond is shorter than in the CCl_4 molecule) gives strong support for such interpretation.

Electron charge transfer interactions account for the thermodynamic behavior in far more numerous systems than suspected in the past. Deviations of solutions from ideal behavior is frequently due to charge transfer interactions between the solution constituents. Complex formation in binary mixtures of carbon tetrachloride with aromatic donor molecules has been extensively studied and is well established.[3–10)] The great majority of these systems exhibit positive G^E values in spite of the charge transfer interaction in the solution. This seems to be contradictory and can be explained by the following reasoning. When only charge transfer interactions exist in a solution, or when these interactions control the behavior of a solution, then G^E is expected to be negative. The discrepancy arises from the practical impossibility of separating the specific and nonspecific interactions in solutions from each other. There is no rigorous method, theoretical or experimental, which can quantitively distinguish the contributions to thermodynamic behavior of liquid solutions due to specific and nonspecific interactions. Data appearing recently in the literature[11–13)] indicate that simultaneous thermodynamic and structural investigtions might yield some qualitative insight into this extremely important problem.

This work is concerned with the excess volumes and partial molal volumes of nitrobenzene (electron acceptor) in 18 eletron donating solvents.

Results and Discussion

The purity of the chemicals employed in this investigtion, the experimental technique used for density measurements, and the density *versus* concentration data were reported elsewhere.[14)]

The molar volumes of the solutions, v, evaluated from experimental densities, d, by using the formula

$$v=\frac{x_1M_1+x_2M_2}{d} \tag{1}$$

where M_i and x_i are the molecular weight and mole fraction of the two solution constituents, were fitted by a least-squares method to a polynomial of the form:

$$v=\sum_{i=0}^{i} b_i x_1^i \tag{2}$$

The number of constants necessary to obtain the best fit was chosen so that the deviation of the experimental molar volumes from the correlated volumes was within the limit of experimental error (±0.003 $cm^3\ mol^{-1}$). Most systems required four constants to obtain such accuracy. The constants for the 18 systems are summarized in Table 1. The slight fluctuation in the molar volume of pure nitrobenzene ($v_2\equiv b_0$) is explained by the fact that for each system a freshly distilled and dried sample was used. It was practically impossible to obtain samples exactly of the same purity. The average value of $b_0=102.723$ $cm^3\ mol^{-1}$ is, however, very close to the literature value.[15)]

The assumption was made that in dilute donor solutions the specific interactions control the behavior of the solutions. If this assumption was correct then the constant $b_1\left(\equiv\frac{v-b_0}{x_1}\right)$ could be considered as a measure of charge transfer interactions, at least in dilute solutions. As the data in Table 1 indicate, the systems with little or no specific interactions at all

a) Average value 102.723 $cm^3\ mol^{-1}$.

have very small b_1 values (bromobenzene+nitrobenzene, chlorobenzene+nitrobenzene, and benzonitrile+nitrobenzene). The small b_1 values of these systems may, however, also result from the fact that their molar volume ratios v_2/v_1 (see Table 2) are very close to unity. Because of this and also because the other 15 systems do not show any obvious correlations between complex formation and the b_1 values, the assumption made above cannot be recommended (see further discussion). The volume of mixing per mole of solution for the 18 systems was calculated from the formula:

$$v_{mix} = v^E = v - x_1v_1 - x_2v_2$$
$$= x_1x_2\left[\left(-b_2-\frac{3}{2}b_3\right)-\frac{b_3}{2}(x_1-x_2)\right] \quad (3)$$

where b_2 and b_3 are the constants listed in Table 1,

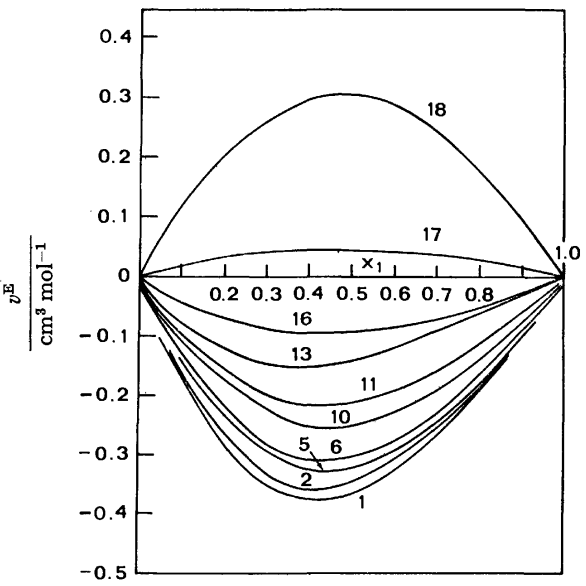

Fig. 1. Excess volume as a function of donor mole fraction at 25 °C. Systems: *p*-xylene(1), 1,3,5-trimethylbenzene(2), toluene(5), isobutylbenzene(6), *o*-xylene (10), *n*-butylbenzene(11), benzene(13), chlorobenzene (16), bromobenzene(17), aniline(18). Nitrobenzene is the acceptor in all the solutions.

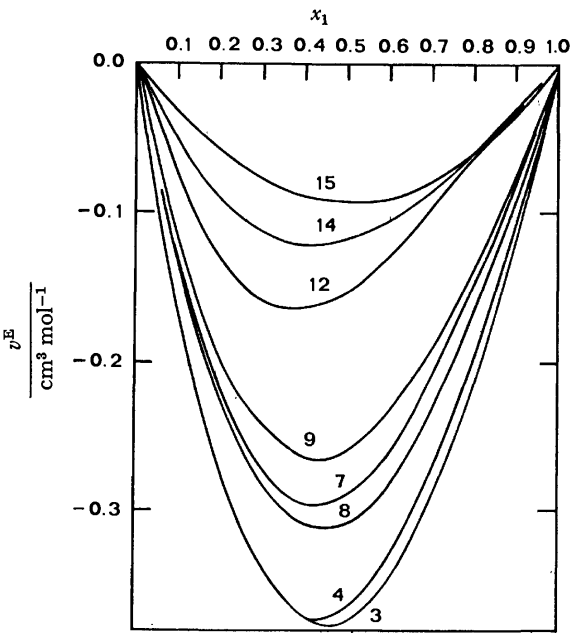

Fig. 2. Excess volume as a function of donor mole fraction at 25 °C. Systems: *m*-xylene(3), isoproylbenzene(4), ethylbenzene(8), 1,2,4-trimethylbenzene (7), *n*-proplybenzene(9), styrene(12), 1,2,3,4-tetramethylbenzene(14), benzonitrile(15). Nitrobenzene is the acceptor in all the solutions.

v_1 and v_2 are the molar volumes of the donor and acceptor respectively, and x_1 and x_2 are their respective mole fractions. The v^E *vs.* x_1 data for 18 systems are shown in Figs. 1 and 2, respectively. The binary systems containing bromobenzene, chlorobenzene and benzonitrile are again readily distinguishable from all the other solutions. The b_3 values of these systems are very small and consequently their v^E *vs.* x_1 curves are symmetrical. The curves representing the other systems, except the one for the aniline system, are more or less skewed, depending on their b_3 values, and have minima between $x_1=0.4$ and $x_1=0.5$. The skewed shape is indicative of specific interactions. The bromobenzene, chlorobenzene and benzonitrile systems seem to be the only solutions within this group with little or no specific interactions at all. The question of how much specific interaction there is in a solution cannot be answered from the shape of the curve alone. Only qualitative observations can be made from these curves and from the data listed in Table 2. Some of them are as follows:

1. The longer the chain of the substituent on the donor the smaller is $|v^E|$. In the series of donors, toluene, ethylbenzene, propylbenzene and butylbenzene, the toluene system exhibits the largest and the butylbenzene system the smallest $|v^E|$. This is just the opposite of the conclusion for NMR studies that the longer the chain of the substituent on the donor the greater the extent of complexation in the solution.

The difference in v^E for the toluene and ethylbenzene systems in 0.020 $cm^3\ mol^{-1}$ at equimolar concentration. For the ethylbenzene and propylbenzene systems the difference amounts to 0.045 $cm^3\ mol^{-1}$ and remains very much the same for the *n*-propylbenzene and butylbenzene systems.

2. The v^E *vs.* mole fraction data indicate that the branched donors have a more profound effect on $|v^E|$ than do the unbranched donors:

$$(v^E_{\text{isopropyl}}-v^E_{\text{propyl}})=(v^E_{\text{isobutyl}}-v^E_{\text{butyl}})=0.095\ \text{cm}^3\ \text{mol}^{-1}$$

3. The monosubstituted ethylbenzene affects v^E less than its disubstituted isomers, *m*- and *p*-xylenes (for *o*-xylene see below). This is in agreement with NMR measurements, according to which polysubstituted donors are superior to their monosubstituted counterparts in complex formation.

4. Donors having substituents in neighboring (*ortho*) positions have in general a smaller effect on v^E than similar donors with substituents in non-neighboring positions. The *o*-xylene system when compared with the other two xylene systems illustrates this fact. This is also seen from comparison of the 1,2,4-trimethylbenzene and the 1,3,5-trimethylbenzene systems. The relatively small $|v^E|$ values of the 1,2,3,4-tetramethylbenzene system very clearly proves the "neighboring substituent effect". The steric effect of the *ortho* substituted donors, as well as their stronger intermolecular forces, indicated by higher enthalpies of vaporization, may be responsible for the diametrically different volumetric behavior of the

a) In all the systems nitrobenzene is the acceptor. b) The average value $v_2=102.723\ cm^3\ mol^{-1}$. c) Given just for comparison. 1,2,3,5-Tetramethylbenzene has lower cohesion energy than 1,2,3,4-tetramethylbenzene. 1,2,4-Trimethylbenzene has lower cohesion energy than 1,2,3-trimethylbenzene. The specific enthalpies of vaporization were evaluated from vapor pressure-temperature data at the respective boiling points of the donors.

ortho substituted donor solutions. The heat of vaporization per gram, l_{vap}, for some of the donors is listed in Table 2. As these data indicate, donors having substituents in neighboring positions exhibit larger l_{vap} values; consequently they must have larger intermolecular forces and exhibit smaller molar volumes.

It may be argued that $|v^E|$ values will depend on both the electron donor ability of the base and the intermolecular forces in the base.

Addition of acceptor molecules to the pure donor will result in charge transfer interaction and consequently in a lowering of the volume of the solution. Due to these interactions it might be reasonable to expect that the distance between the donor and acceptor molecules will be shorter than between two donor molecules. NMR measurements show that the three xylene isomers have approximately the same donor ability and therefore it is expected that the lowering of the molar volume of the solution caused by charge transfer interactions will be the same regardless of whether or not the donor is *ortho* or non *ortho* substituted.

The *ortho* substituted donors, due to their larger cohesive forces, represent more densely packed solvents (see v_1 in Table 2). For donor and acceptor molecules to interact they must approach each other. Molecules of the solvent must separate from each other in order to make space for the approaching nitrobenzene molecule. Because of the closer packing of molecules in the *ortho* substituted donors, relatively larger separation is required. Thus, the volume increase in these solvents will be larger than in the other donors. The charge transfer interaction effect and the separation effect when combined together will therefore result in smaller $|v^E|$ values for the *ortho* substituted solvents.

Similar arguments can also be used for the other systems studied and especially for the ethylbenzene and styrene systems. The relatively high cohesion energy in styrene is probably responsible for the unexpectedly smaller $|v^E|$ value for the styrene-nitrobenzene system.

5. There is no obvious correlation between $|v^E|$ and v_1/v_2. For the three isomeric xylenes v_1/v_2 is approximately the same and yet $|v^E|$ of the *o*-xylene system differs significantly from $|v^E|$ of the other two xylene systems. The chlorobenzene and toluene systems have very close v_1/v_2 values and yet their $|v^E|$ differ substantially. Similar conclusions can be made for the C_9H_{12} isomeric solutions and for the $C_{10}H_{14}$ isomeric solutions (see Table 2).

6. There is no obvious correlation between $|v^E|$ and the polarity of the donor molecules. Systems containing the polar *m*-xylene and the nonpolar *p*-xylene exhibit roughly the same $|v^E|$ values. Solutions of nonpolar 1,3,5-trinitrobezne seem to be more nonideal than solutions of polar 1,2,4-trimethylbenzene.

7. Of the 18 systems presented here only the two containing bromobenzene and aniline exhibit positive v^E values. The large positive values of v^E for the aniline system (0.305 cm^3 mol^{-1} at $x_1=x_2=0.5$) is probably due to some structure breaking in the aniline. Aniline is known as a highly associated liquid. The nitrobenzene molecules break some of the bulky aniline conglomerates into smaller units and separate them from each other. Consequently, there is a volume increase during mixing.

A number of methods have been suggested for the determination of partial molal volumes from density measurements.[16,17] In this investigation we have used a method which establishes an empirical equation to describe the experimental molar volumes of the solution as a function of mole fraction

$$v = b_0 + b_1x_1 + b_2x_1^2 + b_3x_1^3 \quad (2)$$

where $v_2 \equiv b_0$. It is then simple to evaluate the derivatives at any point and therefore to determine the partial molal quantity. In this way we obtain for the partial molal volume of the acceptor (nitrobenzene)

$$\bar{v}_2 = v_2 - b_2x_1^2 - 2b_3x_1^3 \quad (4)$$

The constants b_2 and b_3 are those listed in Table 1.

The function $\bar{v}_2-v_2$ for the 18 systems is plotted against x_1 in Fig. 3. The limiting values of $\bar{v}_2-v_2$ for $x_1\rightarrow 1$, listed in Table 2, are of theoretical significance. Friedman and Sheraga[18] derived a very simple but illustrative theory that evaluates the contribution of nonpolar groups to the partial molal volume in dilute aqueous alcoholic solutions from the limiting values. We were unable to apply this theory to our systems.

The presence of an inflection point on the v^E *vs.* x_1

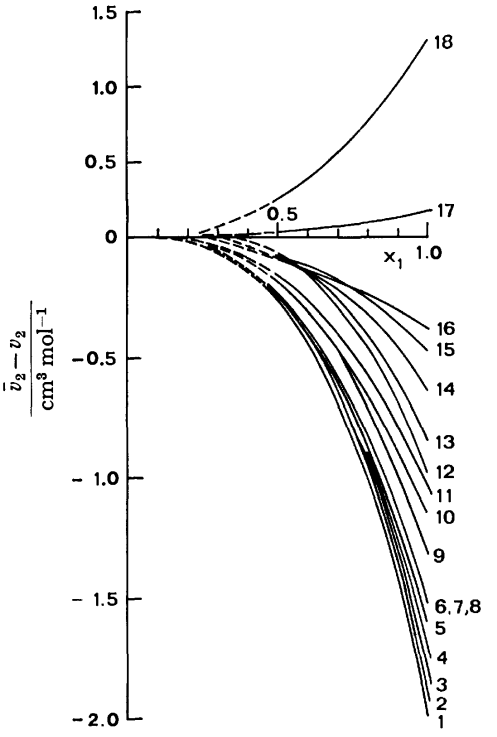

Fig. 3. Partial molal volume of nitrobenzene in electron donating slovents as function of donor mole fraction at 25 °C. Systems: *p*-xylene(1), isopropylbenzene(2), *m*-xylene(3), 1,3,5-trimethylbenzene(4), toluene(5), ethylbenzene(6), 1,2,4-trimethylbenzene (7), isobutylbenzene(8), *n*-propylbenzene(9), *o*-xylene(10), *n*-butylbenzene(11), styrene(12), benzene(13) 1,2,3,4-tertamethylbenzene(14), chlorobenzene(15), benzonitrile(16), bromobenzene(17), aniline(18).

curve indicates the occurrence of extrema on the partial molal volume *vs.* x_1 curves (minimum for one component and maximum for the other component). No such inflection points were observed for our systems. Consequently, no extrema are expected on the $\bar{v}_2$ *vs.* x_1 curves. Frequently, such extrema occur in the limits of low ($x_1 \rightarrow 0$) and high concentrations ($x_1 \rightarrow 1$). We investigaed these regions thoroughly and found no evidence of extrema for these systems.

Since there is direct relationship between v^E and $\bar{v}_2$, all the conclusions drawn from the excess volumes apply equally to the partial molal volumes.

Condensed State Spectra and Phase Transitions of Charge Transfer Autocomplexes

Jānis FREIMANIS, Andrejs MĀLMANIS, and Jānis DRĒGERIS

Institute of Organic Synthesis, Latvian Academy of Sciences, Riga 226006, U. S. S. R.

(Received January 8, 1976)

The results of a spectroscopic study of super-cooled melts and crystalline layers of charge-transfer autocomplexes are reported. Samples obtained by sublimation *in vacuo* or by melting of the complex between transparent plates undergo a "liquid-solid" phase transition. Amorphous films produce absorption bands identical with those obtained from solutions, whereas crystalline layers are colored depending on intermolecular CT interaction. In some cases transparent crystalline films with pronounced optical anisotropy were obtained.

Vacuum-sublimed solid thin films are widely used for studying optical and electrophysical properties of organic compounds. Difficulties encountered in such studies are connected with the fact that the state of organic matter changes with time. Polychromism and polymorphism in donor–acceptor compounds (also in monomolecular ones) have been reported in a number of cases.[1-11] Only few of these have, however, been analysed from a structural point of view.[3,6,7,10] Another difficulty arises in connection with the fact that thin-layer samples are liable not only to polymorphic transitions of the "crystal-crystal" type, but also to "supercooled amorphous phase - crystal" transitions. Melting has been also found to produce considerable changes in the optical properties of certain donor–acceptor compounds.[12,15]

Polychromic changes of 2,4-dinitro-4′-diethylaminodiphenylamine and 2,4,6-trinitro-4′-diethylaminodiphenylamine have been reported previously.[2] The present work deals with a spectroscopic study of phase states, as well as of charge-transfer phenomena of molecular donor–acceptor autocomplexes (AC), particularly in thin-layer condensed films. Molecular autocomplexes of the naphthoquinone and nitroaryl series I,II,III have been investigated.

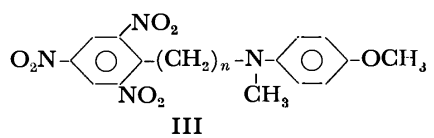
II



III

a) n=1, b) n=2.

Thin layers of these compounds were obtained by sublimation or melting *in vacuo*.[3] In this procedure the majority of compounds condense on the base in an unstable form, deposited as an amorphous, usually sticky, transparent and homogeneous film. Mechanical interference or standing leads to transition of the layers in to a final, stable form. Both forms have been examined by means of electron diffraction pattern.

Amorphous layers have been recently obtained even for naphthacene,[16] whereas production of so-called specular non-crystalline dye layers from solution is well known. In our case the amorphous layers obtained may be considered as unstable supercooled melts. The optical density and hence the extinction coefficient of such layers can be calculated within a certain error, accounting for a 1.1-fold expansion of most cyclic organic compounds on melting (Ref. 17 as well as calculations based on available data on specific volume changes of many substances on melting).

Amorphous films of complexes I and II crystallize after a certain time. A change of color of the film can be observed with phase transition and formation of fissures. Free parts of the base appearing between crystallites can be observed by means of a microscope. This necessitates in some cases great care in securing conditions for minimum light scattering in the final crystalline layer (*cf.* Experimental).

Let us first consider visible absorption in naphthoquinone AC. Figure 1a and Table 1, as well as the shape of experimental curves[18] show close similarity between the absorption curves of solutions and those of amorphous layers of the substances. It can be inferred that the long wavelength band of amorphous films is most likely due to intermolecular n-π^* or π-π^* (in the case of II) charge transfer, as is in the case for liquid[18,19] or solid[20] solutions of these compounds. There is, however, a general increase in intensity ever the whole visible spectrum in the case of non-crystalline layers.

This is apparently due to the fact that in sublimed layers the molecules are free from a solvent shell and thus may possess a somewhat different donor or acceptor ability of their molecular fragments, as well as different conditions of intermolecular orbital overlap.

The spectra of crystalline naphthoquinone autocomplex films show further increase in visible absorption (Figs. 2—3 and Table 1). X-Ray data on complex Ic[21] and on the prototype of autocomplexes

Table 1. Optical characteristics of the solutions and sublimated layers of autocomplexes

Compound	Solution		Amorphous layer		Crystalline layer	
	ν_{max}	ε	ν_{max}	ε	ν_{max}	ε
Ia	17.3	490	17.5	≈1050[a]	of Fig. 3B	
Ib	16.7	410	17.0	≈680	16.0	≈1160
Ic	16.7	410	16.8	≈890	18.7	≈4000
Id	18.4	185	19.0	≈600	19.0	≈850
	≈23.5	150	23.0	≈600		
Ie	18.5	225	19.0	≈550	17.8	≈810
	≈23.5	170	23	≈530		
II	18.8	1700	18.3	≈1850	17.8	≈3650
IIIa	≈27 i	1250	24.0	≈2800		
IIIb	20.6	1490	19.8	≈6060[b]	19.3	≈7070[b]

ν_{max} in $cm^{-1} \times 10^{-3}$, ε—molar extinction coefficient. i—inflexion. Bands with ν_{max} 27×10^3 cm^{-1} are cited only. a) Supercooled melt between two glass plates. b) Sublimed films with a different degree of crystallinity.

Id, e[22] show a packing of molecular donor and acceptor fragments in infinite stacks of type DADADA..., as is usual for binary CTC. This leads to the conclusion that the observed changes in absorption with phase transition of the autocomplexes is due to the appearance of an additional band of intermolecular charge transfer (ICT). A phase transition alone could not have produced such considerable changes in visible absorption. This is seen clearly from a comparison of UV spectra obtained from solutions and from solid layers of 2-chloro- and 2-methyl-1,4-naphthoquinones which correspond to the acceptor fragments of autocomplexes Ia—e (Fig. 3B, C). Some possible differences in simple van der Waals intermolecular interactions in amorphous and crystalline states should not be neglected, but these would be considerably small.

The position of the ICT band of the crystal can be determined from differential spectra and depends only very little on absorption background (Figs. 2 and 3A). The intensity of the ITC band peak which characterizes electronic transitions in the crystal can only be approximately estimated, owing to different light scattering in the crystalline and the corresponding amorphous film. Each sample may also contain, in addition to its basic phase, inclusion of the other phase. Thus the accuracy of intensity measurements is estimated to be within ±5%. Intermolecular charge

transfer in AC Ic is primarily caused crystallographically. It was shown that[23,24] in crystalline autocomplex II we might expect intramoleclar donor-acceptor interaction but the orientation of the nearest planes of donor and acceptor fragments of adjoining molecules in the crystal should not favor intermolecular charge transfer. Hence, the very high intensity of the CTC band in the differential spectrum (Fig. 3A, curve c) may be due either to compression of the horseshoe-shaped molecules II in the process of crystallization of the amorphous phase, or to additional intermolecular interaction within the crystal, *e. g.* through contacts C–O . . . Cl. In the case of Ic and II the interatomic distances of adjacent molecules in the lattice are practically equal to those caused by van der Waals interaction[21,23]; nevertheless distinct n-π^* charge transfer is suggested for analogous halogenquinones by de Gaultier *et al.*[25]

It could be shown in the case of autocomplexes Ia,b that the optical properties of crystalline films largely depend on the mode of preparation. Crystallization of a melt of Ia between glass plates, or fast sublimation of Ib leads to the formation of blue microcrystalline layers. Their spectra clearly show an ICT band in the region of (14—16) $\times 10^3$ cm^{-1} (Figs. 3 B, C, curves b, d).

A crystalline melt of quinone Ia between a quartz and a mica plate, or that of an analogue of Ib between glass plates has much larger crystalline particles. These particles are, in the case of a layer of Ia, distributed non-homogeneously, and the sample is always unevenly colored. Violet and blue patches can be observed simultaneously. The resultant spectrum is shown in Fig. 3Bc. These shades merge into each other on a change in the angle of vision, or on observing the film through a polarizing microscope with a white light source and a rotating object-table. Quinone Ib produces a more homogeneous layer, and change of the angle of vision leads to a change of shade of the whole sample. At the same time, the band in the region (14—16) $\times 10^3$ cm^{-1} is less characteristic of this compound, unlike the other analogue of Ia, as can be seen from curves "c" in Figs. 3B, C and from the corresponding differential spectra "c"—"a".

It follows that in microcrystalline samples of AC Ia,b the orientation of separate single crystals, and, hence, that of the planes of molecular donor-acceptor pairs, with respect to the plane of the base is essentially different from the one in the macrocrystalline sample of quinone Ib. The inhomogeneous macrocrystalline sample of Ia shows a non-uniform distribution of single crystals both with respect to orientation and to location within the area of the film.

The absorption spectrum of a siblimed nitroaryl AC IIIa film has a bathochromically shifted long wave (length) edge, as compared to that of solution (Fig. 4A, curves a, b). Analysis of first Gaussian components shows that the low-frequency absorption edge is shifted towards lower energy values by at least 4×10^3 cm^{-1}. This indicates a high microcrystal inclusion or oligomolecular associate percentage in a "freshly" sublimed film, intermolecular interaction taking place between each part of such inclusions. Thus the well defined 22.5×10^3 cm^{-1} band in the differential spectrum of amorphous phase *vs.* solution indicates not only changes in intermolecular interaction between

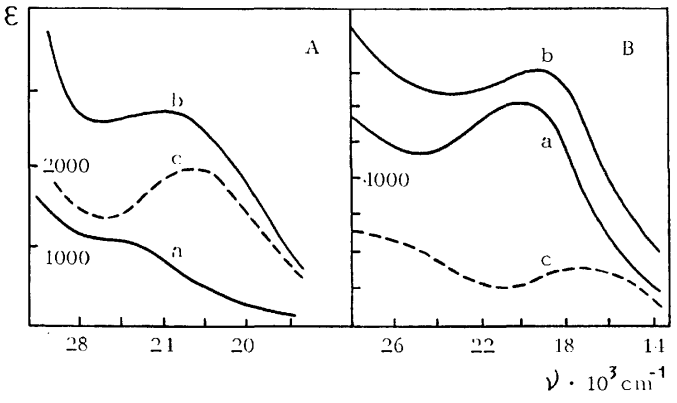

Fig. 4. Absorption of nitroaryl autocomplexes.
A—spectra of IIIa.

functional groups in the absence of solvent, but also contribution of the intermolecular charge transfer, as demonstrated by X-ray studies.[24,26]

A freshly sublimed film of the three-member-bridged autocomplex IIIb hardly differs optically from a film that has been kept for several weeks. Only a considerable intensity increase of the CT band and a slight bathochromic peak shift can be observed, as compared with that of solution (Fig. 4B and Table 1). In this case the differential spectrum also shows an absorption component due to intermolecular interaction; both samples are likely to contain both the amorphous and the crystalline phases, only in different proportions. The ICT band is estimated to be in the region $(17—18) \times 10^3\ cm^{-1}$ in this case.

As expected, owing to different polarization values of the molecules and their fragments in the solid phase the variochromic ICT band shift do not always follow the simple Mulliken relations (spectra of pairs of compounds differing only in one structural element, such as IIIa, b; Id, e; Ie, c; Ia, b). This, too, can be easily explained by the fact that the differential spectra can demonstrate only intermolecular CT absorption as a whole, which undoubtedly depends on the different grain orientation at the base for different compounds.

Experimental

Compounds I—III were synthesized according to the methods reported.[27-30] Samples for absorption measurements were prepared by sublimation of AC I—III *in vacuo* on a glass base at room temperature. The sublimation process is controlled visually. The heater of the evaporator is switched off[31] as soon as the melting point of the autocomplex has been reached. A thermogravimetric experiment on Ib demonstrated that this substance is not decomposed by melting. The heating rate of a compound in the evaporator varied from 3 to 20 min, the vacuum being about 10^{-5} Torr, depending on the desired type of film. For the preparation of an amorphous coating, comparatively rapid sublimation is usually necessary; only in the case of complex Ib and amorphous layer could be prepared by slow sublimation. However, in this case the film itself must be sufficiently thick. Microcrystalline layers were obtained immediately in the course of sublimation from substances Ic and II only if the evaporator was heated very slowly. A microcrystalline film from AC Ib is formed only by very rapid sublimation of a small sample.

The method of melting the sample *in vacuo* between transparent windows was used when the vacuum-deposited films turned out to scatter light after crystallization (Ib, and sometimes Ia). For this purpose a supercooled amorphous layer is prepared between two glass plates. In a few hours the melt crystallizes into a microcrystalline (Ia) or a large-grained sample (Ib). Large-grained samples of Ia could be obtained by melting the complex between a glass and a mica plate. Films of AC IIIa, b could not be obtained by the melting procedure owing to decomposition.

The authors express their gratitude to E. Chirkowa and M. Kaminsky for thermographic analysis of AC Ib; to J. Kalnačs for structure analysis by electron diffraction; to L. Berzina, D. Novicka, E. Silinš for their assistance and to Ya. Eiduss for valuable advice.

Kinetic Studies on the Decolorization Reaction of Rosaniline in Aqueous Acidic Medium*

Sudhir K. SINHA** and Sarvagya S. KATIYAR

Department of Chemistry, Indian Institute of Technology, Kanpur, India

(Received March 12, 1976)

The reaction responsible for the decolorization of rosaniline in acid medium has been studied spectrophotometrically. The rate-determining step has been found to be the reaction of the protonated dye cation with water molecule. Kinetic data have been analyzed on the basis of rate equations which were derived considering the complete protolytic scheme involving all the steps of the reaction of rosaniline in acid and alkaline media. The rate constant k_1 for the ion-molecule reaction has been found to be independent of the dye concentration and hydrogen ion concentration. The apparent rate constant k at various hydrogen ion concentrations has been utilized for calculating the equilibrium constant for the fast protonation step. Effect of ionic strength in the range 0—0.27 indicates no substantial effect on the rate constant k_1. Anomalous solvent effects were obtained suggesting the solvated nature of the reactants. The average energy of activation for the reaction of rosaniline in aqueous medium corresponded to 10.52 kcal. Chemical and kinetic evidence has been presented to prove the participation of water molecule in the rate-determining step.

The mechanism for the color fading of the basic triphenylmethane dyes in acidic medium put forward by Biddle and Porter[1] indicates that in the rate-determining step the dye cation reacts with proton giving

$$R_3\overset{+}{C}\text{-}R_2 + H^+ \overset{\text{slow}}{\rightleftharpoons} R_3\text{-}\overset{+}{C}\text{-}R_2H^+$$
(R_1 on the carbon in both)

a protonated product. Later on working with malachite green Katiyar[2] found almost linear dependence of rate constant on the proton concentration as well as increase in rate constant with the increase in ionic strength of the medium and decrease in rate with decrease in dielectric constant of the medium. These data apparently agreed with the mechanism given by Biddle and Porter. However, it was difficult for us to conceive the idea of a protonation rection of an amino group being slower than the reaction of the protonated dye cation with water. A careful analysis of the data on the variation of the rate constant with hydrogen ion concentration in the color fading reaction of rosaniline as well as the earlier data[2] showed that the values of the so-called bimolecular rate constant obtained by dividing the apparent rate constant with $[H^+]$ are not identical. This raised suspicion as to the validity of the ion-ion step as the rate determining step in the reaction-leading to decolorization of triphenylmethane dyes in acid solutions.

In some of the investigations,[3-7] all the possible reactions of the dye with various other species present in the aqueous acidic solutions have been considered in interpreting the observed kinetic data. But in these studies where the reaction was treated as an ion-molecule reaction, the authors did not make any attempt to find out the effect of dielectric constant or ionic strength on the reaction rate. Existing literature also revealed complete absence of such studies on the ion-molecular type reaction of triphenylmethane dyes. Apart from this, no direct chemical evidence has been cited for the suggested mechanism.

In view of the above mentioned facts, we decided to undertake the investigation of the reaction of color fading of rosaniline (C.I. Basic violet 14), a primary member of the triphenylmethane dyes, in acidic medium. These studies have been utilized to establish the nature of the reacting species and to provide a possible explanation for the misleading effect of dielectric constant and ionic strength on the reaction rate.

Experimental

Materials. Rosaniline hydrochloride (C. I. No. 42510, Basic violet-14) was obtained from Eastman Organic Chemicals. Paraffin wax used for coating the inside of the reaction vessels was a B. D. H. laboratory grade material (congealing point 60—62 °C). Dioxane, a B. D. H. analytical grade reagent was purified further[8] before use. All other chemicals needed for buffer solutions were either B. D. H. AnalaR or E. Merck "pro analysi" grade reagents. Deionized all glass distilled water was used for all the experiments.

Methods. Investigations were carried out spectrophotometrically using Beckman DU or Cary model 14 spectrophotometers by the method described earlier.[9]

Rosaniline has an absorption maximum at 546 nm in water solution. It follows Beer's law at 546 nm satisfactorily up to the concentration of 2.5×10^{-5} M ($\varepsilon'=66500$). It was observed that the absorption maximum remains unchanged by the addition of a neutral electrolyte such as 1.0 M solution of KCl. All the measurements, when pure water was used as solvent, were made at 546 nm and the concentration of the dye taken was less than 2.5×10^{-5} M. The decolorization reaction of rosaniline in the presence of acid was found to be reversible in nature. In the presence of small amounts of acid (pH>4), therefore, the fading reaction did not proceed to completion. The backward reaction was minimized by taking the concentration of acid in large excess (pH<2) over that of the dye (2.5×10^{-5} M), which shifted the equilibrium to the side of the product. Further, the kinetic data were recorded in the first few minutes of the reaction.

Fitting of data to straight lines by method of least squares and calculations of the standard derivations to assess the error limits were done with the help of an I. B. M. 7044 digital computer.

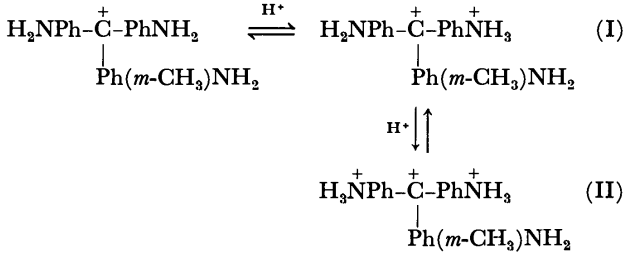
Results and Discussion

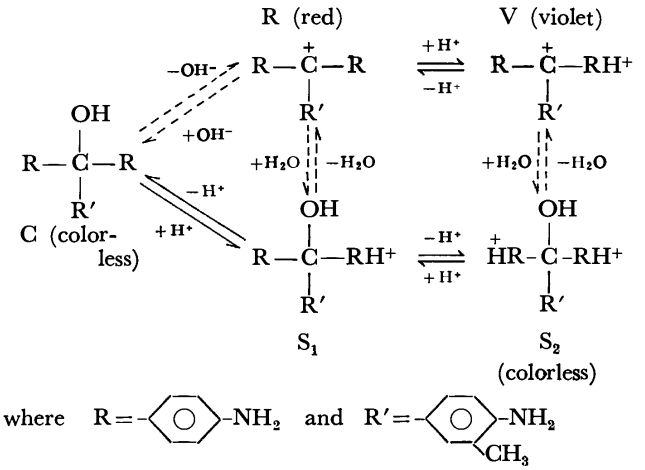
Chemical and Kinetic Evidence for the Reactant and Product. In order to get a direct chemical evidence for the nature of reactants, we carried out the protonation of rosaniline in complete absence of water. It was observed that when pure dry HCl gas was passed into a solution of rosaniline (4×10^{-4} M) in pure dry acetonitrile, the solution instantaneously changed its color from red to reddish violet. Further passage of dry HCl gas changed the color to yellowish green, which remained stable in the absence of moisture. These colored species are due to the protonation of the first and second amino groups respectively. Earlier spectral investigations[10,11] also indicated that out of three amino groups only two get protonated. That one *p*-amino grouping is never protonated in all these cases is due to the fact that only one of the benzene rings is involved in resonance interactions, thus giving a difference in base strength of one amino group with respect to the other two. It has been also reported that 68% of the carbonium ions from crystal violet add two protons in 1 M hydrochloric acid.[12] These protonations of amino groups in rosaniline may be represented as follows:



A drop of water in the violet (I) or green (II) solution thus obtained changed them to colorless solution. This demonstrates that colorless product is obtained from the reaction of water with the protonated species and not from the protonation of the dye.

Now in order to establish the rate-determining step, the rate of decolorization of the protonated species in the presence of water was compared with the rate of unprotonated rosaniline in aqueous acidic medium under identical conditions. The overall rate constants, k, for these protonated and unprotonated solutions were found to be 0.207 and 0.202 min^{-1} respectively at pH 1.35. Similarly at pH 2.4, k corresponedd to 0.026 and 0.018 min^{-1} for these protonated and unprotonated rosaniline solutions. It is thus esablished that under the identical conditions of temperature, solvent and hydrogen ion concentration the rates of reaction responsible for the decolorization of protonated and unprotonated dye are the same within reasonable limits. This finding augments the earlier evidence that water is one of the reactants and further proves that the rate-determining step in the decolorization reaction of basic triphenylmethane dye in aqueous-acidic medium is definitely not the protonation process, but is the reaction of water molecule with the protonated dye cation giving protonated carbinol, whose existence is reported in the literature.[13-15]

Rate Expression for the Decolorzation of Rosaniline. Evidence presented above shows that protonation of rosaniline is the fast equilibrium step and subsequent reaction of water molecule with the protonated dye cation is the slow rate-determining step. On the basis of the protolytic scheme given by Cigen[3] and taking into account only the protonation of one amino group, as the concentration of acid used in all the cases was not that much as to cause further protonation, all the steps of the reaction of the rosaniline in acid and alkaline media can be shown as follows. The solid lines in the scheme indicate that the reactions proceed instantaneously whereas broken lines indicate that the reactions take place with measurable velocity.



Now let us define the following constants:

$K_1=\dfrac{[V]}{[R][H^+]}$, where [R] is the concentration of rosaniline

k_1 = pseudo first order rate constant for the reaction; $V+H_2O\rightarrow S_2$

k_2 = first order rate constant for the reaction; $S_2\rightarrow H_2O+V$.

The investigations were carried out spectrophotometrically. Therefore, the concentrations of the dye are given in the form of specific absorptions. The following symbols are used:

ε_R, ε_V = The molar absorptivity of R and V respectively.

e_R, e_V = The specific absorbance of a solution containing only R and V respectively.

e_0, e_t, e_∞ = The specific absorbance of the solution at times 0, t and at equilibrium.

C_M = The total concentration of rosaniline.

If protonation equilibrum is achieved instantaneously, one can obtain the following equations by the method of Cigen.

$$\frac{[H^+]}{(e_R-e_0)}=[H^+]\cdot\frac{1}{(e_R-e_V)}+\frac{1}{K_1(e_R-e_V)} \quad (1)$$

And the overall rate constant k at pH<2 is given as

$$k=\frac{1}{t}\ln\frac{e_0-e_\infty}{e_t-e_\infty}=k_1\frac{K_1[H^+]}{1+K_1[H^+]}+k_2 \quad (2)$$

neglecting the other equilibrium terms except the protonation and subsequent water addition step. Thus a plot of $[H^+]/(e_R-e_0)$ against $[H^+]$ will give a straight line. The intercept, C, of this line on the Y axis and its slope, m, give $(e_R-e_V)=1/m$ and thus giving $K_1=m/C$ hence, the value of K_1 can be obtained from Eq. 1.

The value of k_1, the rate of hydration, can be obtained from the slope of a plot of k *versus* $K_1[H^+]/(1+K_1[H^+])$ and that of k_2 from the intercept of this plot.

Effect of Rosaniline Concentration on the Reaction Rate. The dependence of rate on the concentration of rosaniline was studied by recording the kinetic runs at varying dye concentrations in the range 19.6×10^{-6} M to 3.9×10^{-6} M and a fixed amount of hydrochloric acid (1.89×10^{-2} M). Value of e_∞ was obtained by measuring the absorbance after the lapse of four hours. Analysis of the results from the graphical method yielded linear first order plots with almost the same slope, giving a constant value of k for all the rosaniline concentrations as shown in Table 1. This indicates that the value of k is independent of the initial concentration of rosaniline. As the equilibrium constant k_1 and the hydrogen ion concentration are constant, the value of k_1, the true rate constant for hydration, will remain unchanged for all rosaniline concentrations in accordance with Eq. 2. Thus, k_1 is independent of initial concentration of rosaniline. Since the concentration of the reactant, namely, water is in great excess as compared to that of the dye, the first order nature of the reaction is in agreement with the suggested mechanism.

Effect of Hydrogen Ion Concentration on Reaction Rate. As in the aqueous solution of the dye there exist more than one species, it is not possible to determine the values of ε_R, ε_V, e_R, e_V directly from the measured absorption curves. For simplicity, aqueous solution of dye of pH 6.5 was taken. In such a solution, the concentration of the red form, R, is about 80—90% of the total dye concentration. If the apparent molar extinction coefficient of such a solution is denoted by ε'_R and the specific extinction by e'_R, then $e'_R/e_R = e'_V/e_V$. From this relation and Eq. 1, the value of K_1 can be determined by substituting e'_R, the measured specific extinction, for e_R and e'_V for e_V. For the determination of equilibrium constant the rates of decolorization of rosaniline were measured at various hydrogen ion concentrations at constant ionic strength. The equilibrium $R + H^+ \rightleftharpoons V$ is reached instantaneously during the mixing, whereupon the color of the solution fades owing to the reaction $V + H_2O \rightleftharpoons S_2$. By determining the fading rate and extrapolating the extinction to $t=0$, e_0 was obtained. The measurements were carried out at the wavelength, 546 nm, where the absorption curve of the red component has a sharp maximum. The plots of $\log(e_t - e_\infty)$

vs. time at various hydrogen ion concentrations were linear indicating the first order nature of the reaction as expected from Eq. 2. The values of apparent rate constants, k, were found to increase with increasing concentration of the acid (Table 2). In order to find out the equilibrium constant K_1 of the protonation step using Eq. 2, a plot of $[H^+]/(e_R'-e_0)$ against $[H^+]$ was made as shown in Fig. 1. The slope and intercept from this graph gave a value of $18.1\pm0.15\ M^{-1}$ for the equilibrium constant K_1. As is evident from Eq. 2, a plot of $K_1[H^+]/(1+K_1[H^+])$ *vs.* k should give a straight line with slope equal to k_1 and intercept k_2. Such plot shows the linear variation of $K_1[H^+]/(1+K_1[H^+])$ with k giving the value of $k_1=1.7\times10^{-2}\ s^{-1}$ and $k_2=0.40\times10^{-3}\pm0.05\times10^{-3}\ s^{-1}$ which are independent of the hydrogen ion concentrations (Fig. 2). It is evident from the values of k_1 and k_2 that the rate of forward reaction is much greater than that of backward reaction under the experimental conditions but still k_2 is quite significant. Hence, in all the measurements of k_1, the backward reaction has been taken into account.

Effect of Ionic Strength on the Rate Constant k_1. Usually for a reaction between an ion and a neutral molecule, the electrostatic effects are small in very dilute solution. If the reacting species in the rate determining step in the present case are ionic type the rate constant should increase with increase in ionic strength.[9,16] The effect of ionic strength ion dipole interaction can be expected from considerations of interactions of the ion atmosphere with the dipole moment of the reactant molecule in the free state and in the complex.[17]

Studies were done taking fixed concentration of the dye ($0.72\times10^{-5}M$) and varying HCl concentration at a constant ionic strength of 0.27. The values of rate constants and equilibrium constants obtained from Eqs. 1 and 2 are reported in Table 3. It is of interest to note that the equilibrium constant K_1 is $34.9\pm0.15\ M^{-1}$ and it is considerably higher that the value obtained at $\mu=0.091$ which is $18.13\pm0.15\ M^{-1}$ (Table 2). The equilibrium constant at higher ionic strength increases as expected, since the effect of ionic strength on the association constant follows the Bjerrum-Brønsted relationship.[18] The values of k_1 at $\mu=0.27$ was found to be $2.08\times10^{-2}\ s^{-1}$. Comparing this value to k_1 obtained at $\mu=0.091$ ($1.7\times10^{-2}\ s^{-1}$), it is evident that it does not change much in accordance with the equation valid for ionic reactions,[9,16] and given below:

$$\ln k = \ln k_0 + \frac{2Z_AZ_BA\sqrt{\mu}}{1+\beta a_1\sqrt{\mu}} \qquad (3)$$

The increase in the value of k_1 even after a three-fold increase in ionic strength is too small to get any meaningful quantitative correlation. In view of the limitation that the acid concentration cannot be decreased above pH 2 and the overall rate becomes faster with increase in ionic strength, the study could not be extended to higher ionic strength. But, the above studies clarifies the cause of apparent increase of the overall rate constant with increase in ionic strength which led to the false inference about the nature of reactants, by previous workers. No doubt the overall rate constant k is markedly dependent on the ionic strength of the medium but this is because of the change in value of K_1 and the rate constant k_1 is only slightly effected. Thus, the above observations further supports the nature of reacting species as given in the protolytic scheme.

Effect of Dielectric Constant on the Rate Constant k_1. Experiments were carried out at different dioxane-water compositions keeping the ionic strength of the solution constant using suitable HCl-KCl mixtures in all the experiments. It was observed that the wavelength of maximum absorption shifted to 543 nm in dioxane-water mixtures, the studies were therefore carried out at 543 nm. The values of e_R' were determined prior to the experiment at each solvent percentage. Rate constants and equilibrium constants at different dixane-water concentrations are sum-

marized in Table 4. It is of interest to note that the values of equilibrium constant K_1 increase with increase in solvent percentage or decrease in dielectric constant of the medium. It corresponded to 11.43 M^{-1} in 5%, 18.01 M^{-1} in 10% and 21.23 M^{-1} in 15% dioxane-water mixture. This increase in equilibrium constant with decrease in dieletric constant is understandable and is in accordance with the formulation discussed elsewhere. Figure 2 represents the plot of $K_1[H^+]/(1+K_1[H^+])$ *vs.* k, the total reaction rate. As expected from Eq. 2, the plot is a fairly straight line. It may be seen from Fig. 3 that the slope increases in 5% to 10% and then decreases in 15%, 2.8×10^{-2} s^{-1} in 10% and $1.7\times10^{-2}s^{-1}$ in 15% dioxane-water mixture, even though total rate generally decreases with decrease in dielectric constant of the medium. Several treatments are available for interpreting the influence of the solvent on electrostatic force which modifies the rate process between ion and dipolar molecules. The equation derived by Amis and Jaffe[20] and modified by Amis[21] is as follows:

$$\ln k_D' = \ln k_\infty' + \frac{Z_A m_0 \varepsilon}{kTr^2 D} \qquad (4)$$

where k_D' and k' are specific reaction rates at dielectric constant D and m_0 is the moment at $\mu=0$. Further modification of the Eq. 4 was done by Quinlan and Amis[22] to obtain a relation which also predicts linear dependence of $\ln k'_{\mu=0}$ on $1/D$. Laidler and Landskroener[23] proposed a relation for such type of reaction based on Kirkwood[24] and Kirkwood and Westheimer's[25] theory which also predicts that the dependence of $\ln k'$ on $1/D$ should be linear. Thus,

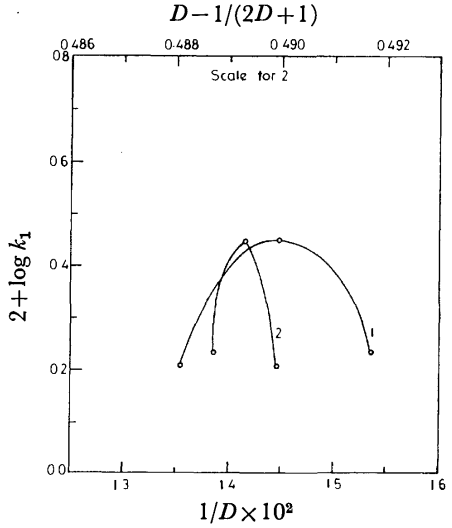

Fig. 4. Variation of $\log k_1$ as a function of dielectric constant (D) of the medium at 25 °C.
1 : $1/D$; 2 : $(D-1)/(2D+1)$.

almost all the models suggest that on the basis of electrostatic considerations the plot of $\ln k'$ *vs.* $1/D$ should be linear with positive slope if the charge on the reacting ion is positive for reaction between an ion and a neutral molecule. Figure 4 represents the dependence of $\log k_1$ on $1/D$. The plot, contrary to expectation, does not show any linear behavior and after 10% dioxane-water composition, the slope also becomes negative. The inconsistency with the predicted behavior can be analyzed on the basis of Laidler and Eyring[26] equation according to which the plot of $\ln k_1$ *vs.* $1/D$ will be straight line only when the Kirkwood term in the equation is only slightly affected with change in dielectric constant of the medium and the change in ϕ's (the non-electrostatic term) is insingnificant. In the present case, since the reacting species are water and protonated triphenylmethane carbonium ion, the effect on Kirkwood term due to change in dielectric constant is apparently significant.

For a bimolecular reaction of dipolar molecule (A) with dipolar molecule (B) the specific velocity constant is given as follows:

$$A + B \rightarrow M^* \rightarrow X + Y$$

$$\ln k' = \ln\left(\alpha\frac{\bar{k}T}{h}K_0^*\right) - \frac{1}{\bar{k}T}\frac{D-1}{2D+1}\left(\frac{\mu_A^2}{a_A^3}+\frac{\mu_B^2}{a_B^3}-\frac{\mu_{M^*}^2}{a_{M^*}^3}\right) + \frac{\phi_A+\phi_B-\phi_{M^*}}{\bar{k}T} \quad (5)$$

where k' is the specific velocity constant, α is the transmission coefficient, $\bar{k}$ is the Boltzmann constant, h is Planck's constant, T is the temperature in degrees Kelvin, D is the dielectric constant of the final solution, and for dilute solutions D is effectively the dielectric constant of the pure solvent. a_B is the average distance of closest approach of B to A, a_A is the average distance of closest approach of A to B, ϕ_A, ϕ_B and ϕ_{M^*} are the sum of the non-electrostatic terms considered by Laidler and Eyring.[26] K_0^* is defined by Laidler and Eyring as $K_0^*=F'_{M^*}/F_AF_B$, where F_A and F_B are the partition function of A and B and F'_{M^*} is the part of the partition function of complex, F_M which refers to the degrees of translational freedom corresponding to decomposition. According to this equation, if the non-electrostatic terms are negligibly small, a plot of $\ln k'$ *vs.* $(D-1)/(2D+1)$ should give a straight line. Laidler and Eyring[26] used Eq. 5 to interpret the solvent effects on the hydrolysis of esters. They plotted $\ln k'$ *vs.* $(D-1)/(2D+1)$ for acid and alkaline hydrolysis of some esters and obtained good straight line plots. Figure 4 (plot 2) represents the variation of $\log k_1$ with $(D-1)/(2D+1)$. It may be seen that this plot is also not linear. There are several reactions[27] where the solvent effect cannot be accounted for satisfactorily by electrostatic considerations only. Basic triphenylmethane dyes, as reported earlier,[9] exhibit specific solvent effect also in the case of carbinol formation in alkaline medium. The explanation of specific effects can be formulated in terms of the non-eletrostatic terms, ϕ's. Probably, the most important factor contributing to these terms is the solvating power of the solvents.

Effect of Temperature on Rate Constant k_1. Kinetic runs were further carried out at 20 and 30 °C maintaining the ionic strength for the solution constant using suitable HCl-KCl mixture. The data obtained are summarized in Table 5. It is interesting to note that increase in temperature decreased the value K_1 from 25.33 M^{-1} at 20 °C to 19.71 M^{-1} at 30 °C. This indicates that the equilibrium is shifted towards the reactants. Thus, even if the total rate increases with increase in temperature, the values of e_0 and e_∞ are also increased. This decrease in equilibrium constant with increase in temperature is well expected for the exothermic reaction of protonation of amino group. From the slopes of the plots of $K_1[H^+]/(1+K_1[H^+])$ *vs.* k at 20 and 30 °C the values of rate constants k_1 were obtained and were found to be 1.12×10^{-2} s^{-1} at 20 °C and 2.03×10^{-2} s^{-1} at 30 °C. Taking the value of k_1 at 25 °C equal to 1.7×10^{-2} s^{-1} as obtained earlier in aqueous medium, although this value is at slightly different ionic strength but the change due to this can be ignored as discussed earlier, dependence of $\log k_1$ on $1/T$ was plotted. This plot shows a fairly good straight line indicating that ΔE remains constant in this narrow temperature range. The average value of apparent ΔE was found to be 10.52 kcal. These studies suggest that the protolytic scheme is valid at higher temperatures also. Raising the temperature has the effect of displacing the equilibrium constant towards

the colored, dehydrated form. The dissociation constant increases with temperature if they are defined as acid constants that is, as $1/K_1$. Due to specific solvent effect exhibited by the system, the different contributions to the energy of activation and thereby the true energies and entropies of activation could not be calculated.

Synthesis and Spectra of 3-Benzyl(or *p*-tolyl)-5-methyl-2-(substituted benzothiazol-2′-ylimino)-4-thiazolidones

Radhey SHYAM* and I. C. TIWARI

Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi 221005, India

(Received April 8, 1974)

Some 3-benzyl(or *p*-tolyl)-5-methyl-2-(substituted benzothiazol-2′-ylimino)-4-thiazolidones were prepared. Their structures and the purity of the compounds were corroborated by their analytical and spectral data. Screening tests on these compounds showed the 4-chloro and 6-bromo analogues to be the most active as CNS depressants, muscle relaxants and anticonvulsants.

Certain thiocarbamides and their cyclic analogues are known to possess good pharmacological activity.[1] An interesting structural variation is the cyclisation of thiocarbamides to thiazolidones.[2,3] A number of disubstituted 4-thiazolidones have been prepared[4] and it has been observed that many of these compounds inhibit convulsions in cats and rats.[5] Various other Δ^4-thiazolidones have been reported[6] and the greatest effort has been made in the synthesis of heterocyclic analogues of thiazolidones.[7,8]

In extending the work, we synthesized 3-benzyl (or *p*-tolyl)-5-methyl-2-(substituted benzothiazol-2′-ylimino)-4-thiazolidones by the cyclisation of *N*-benzyl (or *p*-tolyl)-*N*′-(substituted)benzothiazol-2-yl thiocarbamides with α-chloropropionic acid under anhydrous conditions. The structures and the purity of the compounds were determined with the help of NMR, IR, and TLC. The compounds were also tested for their pharmacological activity.

Experimental

All melting points were measured by the capillary method and are uncorrected. A *Varian-A60D* was used for recording NMR spectra, a *Perkin-Elmer 257* for IR and a *Coleman Analyzer* for analyses.

N-Benzyl-N′-(4-methyl)benzothiazol-2-yl Thiourea (1). A mixture of 4-methyl-2-aminobenzothiazol (4.1 g), benzyl isothiocyanate (3.7 ml) and dry benzene (40 ml) was refluxed on a water-bath for about 5 h at 80—90 °C. The residue was filtered and washed with ether followed by a little 40% HCl solution. The product was crystallised from 80% ethanol, yield 73%, mp 170 °C. TLC: R_f=0.79 (benzene-ether, 3 : 1). Calcd for $C_{16}H_{15}N_3S_2$: N, 13.42; S, 20.45%. Found: N, 13.41; S, 20.54%. IR ν_{max}^{Nujol} cm^{-1}: 3180(⟩N-H), 3035m(⟩N-H), 1560s(⟩C=N- or ⟩C=C⟨), 1200s(⟩C=S), NMR($CDCl_3$) δ(J=Hz): 2.35(3H, s), 5.08 (2H, d, J=5.0), 7.80(1H, broad), 10.95(1H, broad) and 7.50 for aromatic protons (8H, m).

Similarly, other substituted-2-aminobenzothiazoles were converted into their respective thioureas by treating with benzyl isothiocyanate and *p*-tolyl isothiocyanate.

3-Benzyl-5-methyl-2-(4′-methylbenzothiazol-2′-ylimino)-4-thiazolidone (2). *N*-Benzyl-*N*′-(4-methyl) benzothiazol-2-yl thiourea (3.13 g) was dissolved in absolute alcohol (35 ml) and to this was added α-chloropropionic acid (1.5 ml) and anhydrous sodium acetate (2.5 g). The mixture was refluxed on a water-bath for 8—10 h and poured into cold water. On standing overnight, a solid mass precipitated. It was filtered and recrystallised from 80% ethanol into shining needles of (**2**), yield 67%, mp 149 °C. TLC: R_f= 0.79 (benzene-ether, 3 : 1). Calcd for $C_{19}H_{17}N_3OS_2$: N,

MED=Minimum effective dose. MIC=Minimum inhibitory concentration. CNS=Central Nervous System.
a) S. Nos. correspond to the serial number of the compounds in Table 1.

11.44; S, 17.44%. Found: N, 11.42; S, 17.52%. IR ν_{max}^{Nujol} cm^{-1}: 1720s(>C=O), 1552s(>C=C< or >C=N-). NMR ($CDCl_3$) δ(J=Hz): 1.75(3H, d, J=7.5), 2.75(3H, s), 4.17 (1H, q, J=7.5), 5.21(2H, s) and 8.25 for aromatic protons (8H, m).

Likewise, other substituted benzothiazolyl thiazolidones were synthesised. Their structures were confirmed by their analytical, spectral and R_f values as recorded in Table 1.

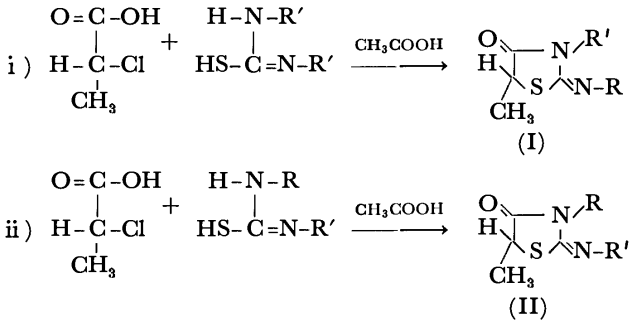
Hydrolysis of 3-Benzyl-5-methyl-2-(4′-methylbenzothiazol-2′-ylimino)-4-thiazolidone (2). 3-Benzyl-5-methyl-2-(4′-methylbenzothiazol-2′-ylimino)-4-thiazolidone (1.83 g), concd HCl (2 ml) and ethanol (20 ml) were refluxed on a water-bath for 8—10 h. After distilling off the ethanol, the reaction mixture was poured into cold water and filtered. The residue was washed with water and crystallised from ethanol to afford 3-benzyl-5-methyl-2,4-thiazolidindione (**3**), yield 76%, mp 186 °C. Calcd for $C_{11}H_{11}NO_2S$: N, 6.33; S, 14.47%. Found: N, 6.53; S, 14.58%. IR ν_{max}^{Nujol} cm^{-1}: 1730s(>C=O), 1720(>C=O), 1552s(>C=C< or >C=N-). On neutralisation with ammonium hydroxide the filtrate gave 4-methyl-2-aminobenzothiazole, melting at 136 °C.

3-Benzyl-5-methyl-2,4-thiazolidindione (3). A mixture of *S*-dibenzyl thiourea (6.0 g), α-chloropropionic acid (2.0 ml) and glacial acetic acid (10 ml) was refluxed on a water-bath for 5 h and then allowed to cool. Addition of excess cold water gave a solid mass which was washed with water and dried. It was crystallised from 80% ethanol, yield 69%, mp 186 °C. Calcd for $C_{11}H_{11}NO_2S$: N, 6.33; S, 14.47%. Found: N, 6.21; S, 14.53%. IR ν_{max}^{Nujol} cm^{-1}: 1732s(>C=O), 1716s(>C=O) and 1565s(>C=C< or >C=N-).

Discussion

The structure of 3-benzyl(or *p*-tolyl)-5-methyl-2-(substituted-benzothiazol-2′-ylimino)-4-thiazolidones was assigned on the basis of the elemental analyses, spectral data and the nature of their degradation products. NMR spectrum of compound (**2**) in $CDCl_3$ shows a singlet at δ 2.75 for the benzene ring methyl protons. A doublet (J=7.5Hz) for the thiazolidone ring methyl protons at δ 1.75 and a quartet (J=7.5Hz) for the thiazolidone ring single proton at δ 4.75 were observed. A singlet at δ 5.21 was assigned to >N–$CH_2C_6H_5$ protons. The aromatic protons resonated at δ 8.25 as a multiplet. A strong IR peak at 1720 cm^{-1} for the >C=O group is the characteristic of lactam group.

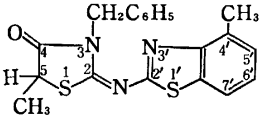
Actually, the possibility of two isomeric products may be assumed here from the two possible tautomeric forms of thiocarbamides undergoing reactions with α-chloropropionic acid. The compound 3-benzyl-5-methyl-2-(4′-methylbenzothiazol-2′-ylimino)-4-thiazolidone after hydrolysis affords a residue which was identified as 3-benzyl-5-methyl-2,4-thiazolidindione by comparing with an authentic sample of the thiazolidindione (**3**) by the mixed melting point method.



R=(substituted)benzothiazol-2-yl-
R′=benzyl or *p*-tolyl-

The structure of 3-benzyl-5-methyl-2,4-thiazolidindione (**3**) is also supported by its IR spectrum which shows an additional peak at 1730 cm^{-1} for the carbonyl group attached to position-2 of the thiazolidindione ring.

Hence the hydrolysis as well as spectral data show the attachment of 2-amino-(substituted)benzothiazoles residue at position-2 and benzyl or *p*-tolyl residue at position-3, thereby confirming the structure as type I but not as type II. Therefore, these findings agree with structure III for compound (**2**).



(III)

Screening Results. The selected compounds have been tested for their pharmacological activities at Bristol Laboratories, Syracuse, New York. The com-

pound 3-benzyl-5-methyl-2-(4′-chlorobenzothiazol-2′-ylimino)-4-thiazolidone was found to be active as a CNS depressant and muscle relaxant and 3-benzyl-5-methyl-2-(6′-bromobenzothiazol-2′-ylimino)-4-thiazolidone as a CNS depressant, muscle relaxant and anticonvulsant.

Thanks are due to Prof. P. N. Bhargava, for his keen interest and Prof. G. B. Singh and Dr. R. S. Dwivedi for providing facilities. The financial assistance provided by CSIR, New Delhi to R.S. and by PGIIM, B.H.U. to I.C.T. is gratefully acknowledged.

Fluorination with Substituted (Difluoroiodo)arenes

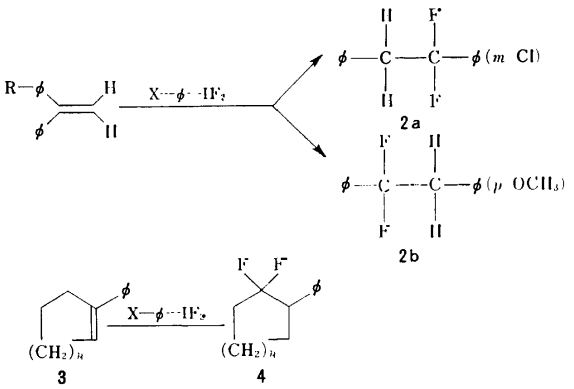
Ana GREGORČIČ and Marko ZUPAN*

"*J. Stefan*" *Institute and Department of Chemistry, University of Ljubljana, 61000 Ljubljana, Yugoslavia*

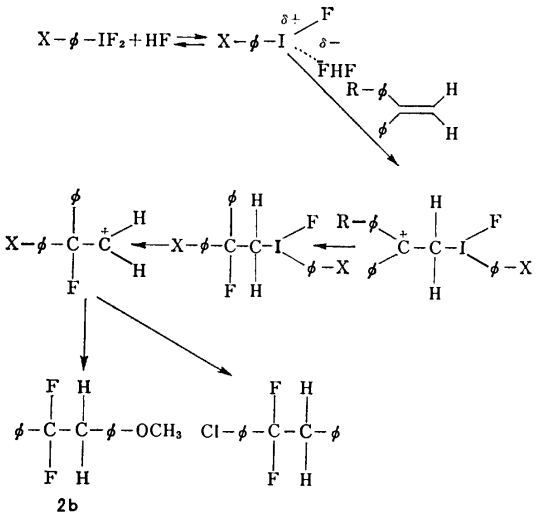
(Received January 21, 1976)

The reaction of substituted (difluoroiodo)arenes with 1-phenyl-1-(*m*-chlorophenyl)ethylene results in 1,1-difluoro-1-(*m*-chlorophenyl)2-phenylethane, with 1-phenyl-1-(*p*-methoxyphenyl)ethylene in 1,1-difluoro-1-phenyl-2-(*p*-methoxyphenyl)ethane, and with 1-phenylcyclopentene and 1-phenylcyclohexene in rearranged *gem*-difluoro compounds. The reaction with norbornene results in three products: fluoronortricyclane (9—12%), 2-*exo*-7-*syn*-difluoronorbornane (75—86%), and 2-*exo*-7-*anti*-difluoronorbornane (5—15%) depending upon the substituent on the phenyl ring in (difluoroiodo)arenes.

The addition of chlorine to olefinic double bonds using (dichloroiodo)benzene as a halogenating agent has received (difluoroiodo)arenes attention from several workers.[2-5] The corresponding received much more limited attention as fluorinating agents, possibly because of the difficulties involved in their preparation and storage. Three methods are of particular interest for the preparation of (difluoroiodo)arenes. The first is the method of Dimroth and Bockemüller[6] or the modified one of Garvey *et al.*[7] in which the appropriate iodosoarene is treated with 46% hydrogen fluoride in acetic acid. The method of Carpenter[8] involves one-step reaction of mercuric oxide and aqueous hydrofluoric acid with (dichloroiodo)benzene in dichloromethane. The dichloromethane solution is then used directly for fluorination. The third procedure[9] involves the electrolysis of an acetonitrile solution of silver(I) fluoride. We developed a method for the synthesis of various (difluoroiodo)arenes, using xenon difluoride as fluorinating agent in dichloromethane solution, in the presence of anhydrous hydrogen fluoride at room temperature.[10] We have recently found that (difluoroiodo)methane reacts with phenylalkenes in the presence of hydrogen fluoride as a catalyst to form the corresponding 1-fluoro-2-iodo-1-phenylalkanes,[11] and not the rearranged *gem*-difluoro compounds observed in similar fluorination reactions with (difluoroiodo)arenes.[8,12] We now report the study of fluorination of various phenylalkenes and norbornene with substituted (difluoroiodo)arenes.



Scheme 1.



Scheme 2.

Results and Discussion

(Difluoroiodo)arenes have already been used for fluorination of 1,1-diphenylene[12] and styrene[8], giving *gem*-difluoro compunds. Carpenter[8] showed that hydrogen fluoride or some other strong acid such as trifluoroacetic acid is necessary as a catalyst in the fluorination reaction, and proposed an ionic mechanism with the phenonium ion as the intermediate. We obtained evidence which supports the phenonium ion intermediate by the fluorination of 1-phenyl-1-(*m*-chlorophenyl)ethylene (**1a**), 1-phenyl-1-(*p*-methoxyphenyl)ethylene (**1b**) with substituted (difluoroiodo)-arenes (Scheme 1). The reactions resulted in 1,1-difluoro-1-(*m*-chlorophenyl)-2-phenylethane (**2a**) and 1,1-difluoro-1-phenyl-2-(*p*-methoxyphenyl) ethane (**2b**), respectively. The structures of the products were estabished on the basis of their NMR data (δF-100 ppm (t, J_{FH}=15 Hz)) for **2a** and (δF-105.2 ppm (t, J_{FH}=16.5 Hz)) for **2b**, which correspond to those of *gem*-difluoro compounds. In the mass spectrum the fragments for the product **2a** were the tropylium ion *m/e* 91 and the difluorochlorobenzylium ion *m/e* 161, indicating phenyl group migration. On the other hand, product **2b** showed as fragments the methoxytropylium ion *m/e* 121 and the difluorobenzylium ion *m/e* 127, which indicates *p*-methoxyphenyl group migration. The fluorination of the phenyl-substituted cycloolefins, 1-phenylcyclopentene (**3a**) and 1-phenylcyclohexene (**3b**), with (difluoroiodo)arenes also resulted in the formation of *gem*-difluoro compounds (**4**) (Scheme 1), which could be identified by their NMR and mass spectral data. We were unable to detect any trace of

iodofluoro compounds. In the light of these experiments we suggest a mechanism similar to that proposed by Carpenter[8] (Scheme 2). It might be expected that in the presence of hydrogen fluoride, substituted (difluoroiodo)arenes behave as electrophiles (reactions were completely quenched when no hydrogen fluoride was added), adding to an olefin, thus forming a carbonium ion, which is then attacked by the fluoride ion. In the next step, dissociation of the carbon iodine bonds results in the formation of carbonium ion, accompanied by phenyl group or *p*-methoxyphenyl group migration.

The reaction of a bicyclic olefin, norbornene, has been utilized for elucidating the mechanism and stereochemistry of various reactions.[13-18] It is possible (from the identification of the products) to discriminate the three possible mechanistic pathways leading to the products; (i) a concerted *cis*-molecular addition, (ii) a free radical reaction, (iii) a reaction path proceeding *via* cationic intermediates.

We have studied the fluorination reaction of various substituted (difluoroiodo)arenes with norbornene. Reactions resulted in the formation of three products, which could be separated by preparative GLC. The first product shows in its ^{19}F NMR (rel to CCl_3F) spectrum a doublet of triplet at −218.2 ppm, and in H NMR spectrum at $\delta = 5.05$ ppm a doublet of triplet signal which corresponds to the proton bonded on the same carbon atom as the fluorine atom, with the characteristic geminal F-H coupling constant of 69 Hz. The product **6** was synthesised independently by addition of hydrogen fluoride to norbornadiene,[19] which made it possible to determine the structure of the first product as fluoronortricyclane (**6**). Both of the remaining products showed a similar mass spectrum with the molecular peak *m/e* 132, which suggests the structure of the difluoro compounds. The basic peak for both of the products *m/e* 81 corresponds to the splitting off of the fragment $-CHF_2$. In the mass spectra of both compounds, the fragments were *m/e* 99, 86, 85, 72, which correspond to the splitting off of $-CH_2F$, $-C_2H_3F$, $-C_2H_4F$, and C_3H_5F fragments, respectively. From the extraordinary similarity of the mass spectra we concluded that the two compounds are remarkably alike. The product obtained in the lower yield (5—13%), shows in its ^{19}F NMR spectra two signals; one at −176.2 ppm as doublet of multiplet, corresponding to an *exo*-bonded fluorine atom, and the other at −232.3 ppm as doublet of triplet, which corresponds to fluorine bonded at C7. In the proton spectrum we have observed two signals for hydrogen atoms at lower field, the first at $\delta = 4.28$ ppm as doublet of multiplet, corresponding to an *endo*-bonded hydrogen atom, and the second signal at $\delta = 5.48$ ppm as doublet, which corresponds to a hydrogen atom at C7 (see Experimental).

The main product formed in the fluorination of norbornene with substituted (difluoroiodo)arenes shows an NMR spectrum very similar to that of the previously described one.[18] In the ^{19}F spectrum we observed a signal at −179.5 ppm as doublet of multiplet and the second at −223.5 ppm as doublet of multiplet. In the proton NMR we observed two protons at a lower field, one at 5.1 ppm as a doublet of doublet and the other at 5.21 ppm as a doublet. From the data we were unable to decide the stereochemistry at position C7. However, from a detailed comparison of the NMR spectra with the literature ones[18] the stereochemistry on C7 could be confirmed. If we compare the chemical shifts for protons bonded at C7 in various substituted norbornane derivatives[18] we see that the one in the 2-*exo*-7-*anti* isomer is at a lower field than the one in the 2-*exo*-7-*syn* isomer. The chemical shift for the proton at C2 is at a higher field in the 2-*exo*-7-*anti* isomer (but not in all cases) than in the 2-*exo*-7-*syn* isomer. Tanner and Van Bostelen[18] established the stereochemistry at the Carbon 7 also by chemical transformations, *i.e.*, dehydrofluorination and reduction. From the data mentioned above, we can conclude that the main product, formed in 75—86% yield, is 2-*exo*-7-*syn*-difluoronorbornane (**7**), and the third product, obtained in 5—13% yield, is 2-*exo*-7-*anti*-difluoronorbornane (**8**) (Scheme 3).

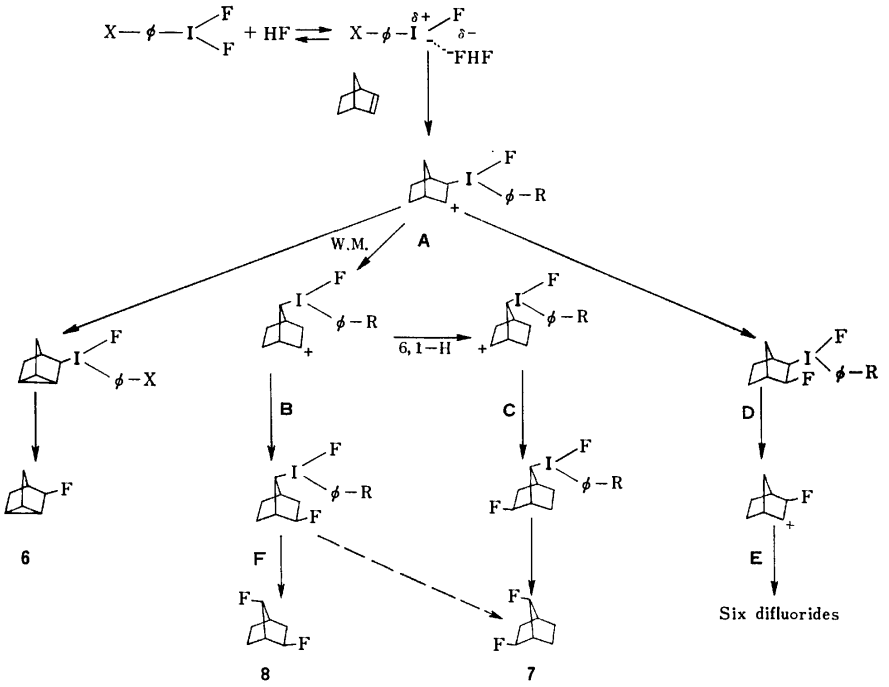
Scheme 3.

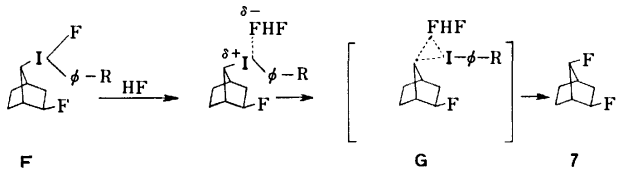
We have studied the effect of groups bonded to benzene ring on the distribution of the products formed in the reaction of norbornene with substituted (difluoroiodo)arenes. The ratios of the products were established by VPC. Each reaction was repeated several times the average data being presented in Scheme 3. We observed no isomerisation of the products under the reaction and isolation conditions or during the course of isomerisation. The data (Scheme 3) show a very high yield (86%) of 2-*exo*-7-*syn*-difluoronorbornane (**7**) formed in the reaction with the *m*-nitro derivative. On the other hand, with electron donating substituents bonded to the benzene ring of (difluoroiodo)arenes, we observed a lower amount of product **7** and a higher amount of compound **8**.

The formation of three products could be explained by the reaction of norbornene with the polarized molecule of (difluoroiodo)arenes with hydrogen fluoride, thus primarily forming the carbonium ion A (Scheme 4) which undergoes the Wagner-Meerwein rearrangement, in turn forming ions B, which could be attacked by the nucleophile, leading to the product F. The S_N2 substitution of the aryliodo function by fluoride anion can produce 2-*exo*-7-*anti*-difluoronorbornane (**8**). Carbonium ion B can undergo the hydride 6—1 shift, thus forming carbonium ion C, followed by nucleophilic attack of fluoride anion and



Scheme 4.

S_N2 substitution of aryliodo function, resulting in the formation of 2-*exo*-7-*syn*-difluoronorbornane (**7**). The next possibility for an explanation of the formation of difluoro compounds could be the attack of fluoride anion on the primarily formed carbonium ion A, thus forming the adduct D, and dissociation of carbon–iodine bond leading to formation of fluorocarbonium ion E, which would rearrange by Wagner-Meerwein and hydride shift, resulting in six difluoro compounds. The β-fluorocarbonium ion E formed in the reaction of xenon difluoride with norbornene undergoes rearrangement, thus forming six difluoro compounds[20] after fluoride anion attack. From the results we could eliminate this reaction pathway. However, we suggest another possible explanation for the formation of product **7** in a high yield (Scheme 5). The intermediately formed compound F can be polarized by hydrogen fluoride and *via* the transition state G results in difluoro compounds.



Scheme 5.

Experimental

IR spectra were recorded with a Perkin-Elmer 257 spectrometer, ^1H and ^{19}F NMR spectra with a Jeol JNM-PS-100 from CCl_4 solution with TMS or CCl_3F as an internal reference. Mass spectra and high resolution measurements were taken on a CEC-21-110 spectrometer. Gas-Liquid partition chromatography was carried out on a Varian Aerograph Model 1800 and TLC on Merck PSC-fertigplatten SILICA GEL F-254.

Materials. Pure samples of olefins were prepared by known methods: 1-phenyl-1-(*m*-chlorophenyl)ethylene,[21] 1-phenyl-1-(*p*-methoxyphenyl)ethylene,[21] 1-phenylcyclopentene,[22] 1-phenylcyclohexene.[22] Other commercial olefins were distilled or purified by VPC to conform with published physical and spectral data. Substituted iodobenzenes were prepared by known methods from corresponding amino derivatives and distilled before use. Dichloromethane was purified[23] and stored over molecular sieves. Hydrogen fluoride of Fluka Purum quality was used, and xenon difluoride was prepared by the photosynthetic method[24] with a purity better than 99.5%.

Substituted (Difluoroiodo)benzenes. Substituted iodobenzene (1.1 mmol) was dissolved in dichloromethane (5 ml) at room temperature. Anhydrous HF (1—3 mmol) was introduced into the reaction mixture and pure XeF_2 (1.1 mmol) was added under stirring. After a few second the colourless solution turned dark green, xenon gas being evolved. Gas evolution ceased after 45 min (for *p*-OCH_3, or 3 h for the *m*-NO_2 derivative) and the reaction appeared to be complete. The solution was used for fluorination of olefins.

General Procedure for Fluorination with Substituted (Difluoroiodo)-arenes: To a solution of the previously prepared substituted (difluoroiodo)arenes was added 1 mmol of olefin under stirring at room temperature. After 2 h the reaction mixture was diluted with dichloromethane (15 ml), washed with 10 ml of 5% $NaHCO_3$, dried over anhydrous Na_2SO_4, the solvent being evaporated *in vacuo*. The crude products were separated by preparative TLC or GLC.

1,1-Difluoro-1-(m-chlorophenyl)-2-phenylethane (2): The product was separated by preparative TLC (silica gel, methanol : chloroform = 1 : 9) yield 50% of oily product. NMR δF-100 ppm (t), δH = 3.25 (t), ppm, $\delta\phi$ = 7.2 (m) ppm, J_{FH} = 15 Hz. Mass spectrum: calcd for $C_{14}H_{11}ClF_2$ *m/e* 252.0517, found *m/e* 252.0510, *m/e*: 254 (M^++2,4%), 252 (M^+, 12%), 215 (40), 179 (40), 178 (46), 163 (10), 161 (30), 91 (100), 89 (18), 77 (20), 76 (20), 75 (16), 51 (25).

1,1-Difluoro-1-phenyl-2-(p-methoxyphenyl)ethane (2b): The

product was separated by preparative TLC (silica gel, methanol : chloroform = 1 : 9), yield 55% of yellow oily product. NMR δF-105.0 (t) ppm, δH = 3.3 (t) ppm, δOCH_3 = 3.7 (s) ppm, $\delta\phi$ = 7.2 (m) ppm, J_{FH} = 16.5 Hz. Mass spectrum: calcd for $C_{15}H_{14}F_2O$ *m/e* 248.1008, found *m/e* 248.1008, *m/e*: 248 (100%, M^+), 209 (46), 197 (40), 165 (46), 139 (40), 127 (46), 121 (60), 77 (40).

1-Phenyl-2,2-difluorocyclopentane (***4a***): The product was separated by preparative TLC (silica gel, cyclohexane: chloroform = 4 : 1), yield 60% of yellow oily product. NMR δF-101.3 (m) ppm, $\delta\phi$ = 7.3 (m) ppm, δH = 2 (m) ppm. Mass spectrum: calcd for $C_{11}H_{12}F_2$ *m/e* 182.0902, found *m/e* 182.0911, *m/e*: 182 (M^+, 3%), 155 (14), 154 (100, 153 33 (33), 152 (21), 117 (47), 115 (50), 77 (10), 76 (17).

1-Phenyl-2,2-difluorocyclohexane (***4b***): The product was separated by preparative TLC (silica gel, methanol: chloroform = 1 : 9), yield 63% of yellow oily product. NMR δF-103.5 (m) ppm, $\delta\phi$ = 7.5 (m) ppm, δH = 1.7 (m) ppm. Mass spectrum: calcd for $C_{12}H_{14}F_2$ *m/e* 196.0125, found *m/e* 196.0160, *m/e*: 196 (M^+, 35%), 176 (9), 173 (9), 158 (14), 154 (55), 153 (21), 152 (13), 130 (22), 129 (17), 128 (30), 127 (100), 117 (37), 104 (30), 91 (33), 77 (38), 69 (48), 68 (55), 58 (34).

Products Formed in the Fluorination of Norbornene: Separated by preparative GLC (Chromosorb Regular 100-DDP 10%, ϕ 3/8′ × 2 m, stainless steel column).

Fluoronortricyclane (***6***): Yield 8% of volatile, white waxy solid product, mp (sealed capillary) 44—45 °C, lit,[19] 48—50 °C. NMR (CCl_4): δF-218.2 (dt) ppm, δH = 5.05 (dt) ppm, J_{FH} = 69 Hz. Mass spectrum: calcd for C_7H_9F *m/e* 112.0688, found *m/e* 112.0697.

2-exo-7-syn-Difluoronorbornane (***7***): Yield 68% of volatile, white waxy solid product, mp (sealed capillary) 116—119 °C, lit,[18] 95—97 °C. NMR (CCl_4): δF2-179.5 (dm) ppm, δF7-223.5 (dm) ppm, δH_2 = 5.1 (dd) ppm, δH7 = 5.2 (d) ppm, J_{F2H2} = 60 Hz, J_{F2H} = 40 Hz, J_{F7H7} = 63 Hz, J_{F7H} = 12.6 Hz. Mass spectrum: calcd for $C_7H_{10}F_2$ *m/e* 132.0752. Anal. calcd for $C_7H_{10}F_2$: C, 63.60; H, 7.63; found C, 63.32; 7.40.

2-exo-7-anti-Difluoronorbornane (***8***): Yield 6% of volatile, waxy solid product, mp (sealed capillary) 101—102 °C, lit,[18] 107—110 °C. NMR (CCl_4): δF2-176.2 (dm) ppm, δF7-232.3 (dt) ppm, δH2 = 4.28 (dm) ppm, δH7 = 5.48 (d) ppm, J_{F2H2} = 60 Hz, J_{F2H} = 30 Hz, 7.5 Hz, J_{F7H7} = 65 Hz, J_{F7H} = 3 Hz. Mass spectrum calcd for $C_7H_{10}F_2$ *m/e* 132.0750, found *m/e* 132.0753. Anal. calcd for $C_7H_{10}F_2$: C, 63.60; H, 7.63, found C, 63.44; H, 7.70.

We thank Prof. J. Slivnik for the supply of XeF_2 and Prof. J. Marsel for the use of facilities. Financial assistance from the Boris Kidrič Foundation and the "KRKA" Pharmaceutical Co., Novo mesto, is acknowledged.

The Position Dependence of the SCF Screened Potential in Several Pseudo-Jahn-Teller Nonbenzenoid Aromatic Hydrocarbons

Tsuguo KOYANAGI and Hiroyuki YAMAGUCHI

Department of Chemistry, Kumamoto University, Kurokami, Kumamoto 860

(Received August 16, 1976)

Synopsis. The SCF screened potentials of pentalene, heptalene, and *s*-indacene were calculated by using the SCF screened potential MO CI method. The characteristics of the screened potential in the nuclear arrangement belonging to the lower molecular symmetry group, C_{2h}, are similar to those of the polyene.

Recently, Terasaka *et al.*[1] have shown that there are two kinds of screening (screening and anti-screening) in molecules such as polyene in which there exists a strong bond alternation, while there is only one kind of screening in molecules such as benzene and azulene which do not show a clear bond alternation.

The purpose of this paper is to investigate the position dependence of the SCF screened potential in pseudo-Jahn-Teller nonbenzenoid hydrocarbons, such as pentalene (I), heptalene (II), and *s*-indacene (III), by using the SCF screened potential MO CI method in combination with the variable bond-length technique.[1,2] It may be possible to use the results of such calculations to deepen our understanding of the aromatic characteristics of nonbenzenoid aromatic hydrocarbons.

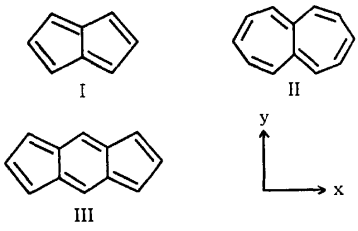

Fig. 1. Numbering of molecules and choice of axes.

Method of Calculation

A procedure that combines the SCF screened potential with the variable bond-length technique[1,2] is used in the Pariser-Parr-Pople SCF MO CI method.[3,4] At each step of the SCF calculation, the new bond lengths are obtained from the corresponding bond orders.[5] The screened potential is evaluated by using the bare potential (Mataga-Nishimoto[6]) obtained from the new bond lengths. This screened potential is thus used in the calculation of the next SCF step. The calculation is repeated until self-consistency is reached. As the starting geometrical structures for iterative calculation, we adopt various distorted structures in which bond lengths are distorted, so that the set of displacement vectors may form a basis for an irreducible representation of the full symmetry group, D_{2h}, of molecules I, II, and III. In the case of I, for example, there are 3, 2, 2, and 2 distinct bond distortions belonging to a_g, b_{1g}, b_{2u}, and b_{3u} respectively. If self-consistency is achieved at two or more different nuclear arrangements, the total energies should be compared with each other in order to determine which one is most favorable. The total energy is assumed to be the sum of the π-electron energy and the σ-electron energy, the latter being calculated by using the harmonic oscillator model, with the force constant equal to 714 kcal/Å.[7] All the singly-excited states are considered in the calculation of the RPA porlarization part.

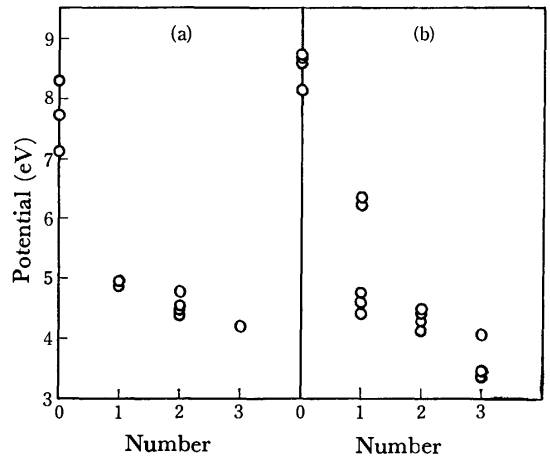

Fig. 2. The SCF screened potentials in pentalene plotted *vs.* the number; (a) the nuclear arrangement D_{2h}, (b) the nuclear arrangement C_{2h}.

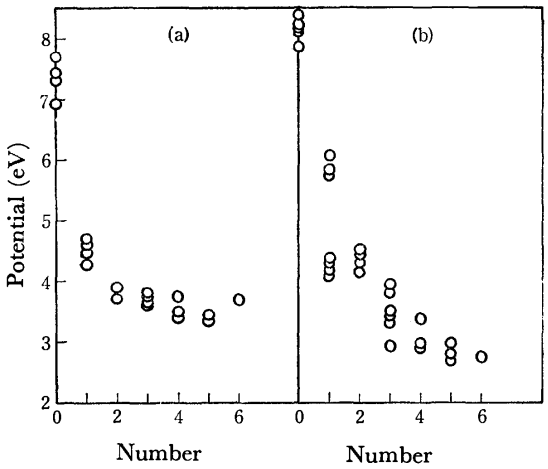

Fig. 3. The SCF screened potentials in heptalene plotted *vs.* the number; (a) the nuclear arrangement D_{2h}, (b) the nuclear arrangement C_{2h}.

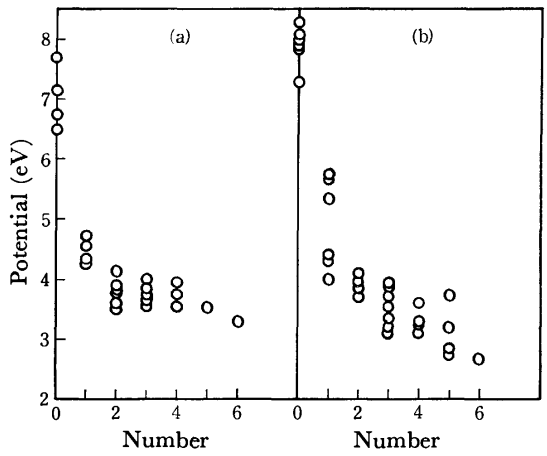

Fig. 4. The SCF screened potentials in *s*-indacene plotted *vs.* the number; (a) the nuclear arrangement D_{2h}, (b) the nuclear arrangement C_{2h}.

Results and Discussion

The starting bond distortions, belonging to the a_g, b_{2u}, and b_{3u} representations, all converge into the unique self-consistent set of bond lengths belonging to the molecular symmetry group D_{2h}, while the distortions belonging to b_{1g} converge into another set of bond lengths belonging to C_{2h}. The nuclear arrangement belonging to C_{2h} is energetically more favored than that belonging to D_{2h}. The stabilization energies for I, II, and III are predicted to be 8.2, 12.0, and 2.2 kcal/mol respectively. There exists a strong bond alternation in the peripheral carbon skeleton of the nuclear arrangement, C_{2h}. There is no bond alternation in the peripheral carbon skeleton of the nuclear arrangement, D_{2h}. The above results are almost the same as the results obtained by using the bare potential SCF CI method.[8]

In Figs, 2, 3, and 4, the SCF screened potentials, V, in the nuclear arrangements, D_{2h} and C_{2h}, of I, II, and III are plotted against a number that indicates the kind of screened potential, that is, 0: one-center potentials V_{11}, V_{22}, V_{33},$\cdots$; 1: the nearest two-center potentials V_{12}, V_{23}, V_{34},$\cdots$, *etc.* There is only one kind of screened potential at each of the numbers in the D_{2h} structures of I, II, and III (*cf.* Fig. 9 of Ref. 1). There is one kind of screened potential at the even numbers in the C_{2h} structures of these molecules. However, under the influence of the bond-length alternation, there are two kinds of screened potentials, screening and anti-screening, at the odd numbers in the C_{2h} structures of I, II, and III. Such characteristics of the screened potentials in the C_{2h} structures of I, II, and III show a tendency similar to those of the polyene shown in Fig. 7 of Ref. 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (2), 523—524 (1977)

Effect of Pressure on Interfacial Tension between Oil and Water

Norihiro MATUBAYASI, Kinsi MOTOMURA, Shoji KANESHINA,
Makoto NAKAMURA, and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received August 23, 1976)

Synopsis. The interfacial tension of hexane, octane, carbon tetrachloride and benzene against water was measured as a function of pressure up to 150 MPa at 303.15 K, using a newly designed apparatus. The interfacial tension showed definite increase with pressure and positive volume change was found on interface formation.

Several experimental studies have been carried out on the effect of pressure on interfacial tension between oil and water, but no coincidence of the results has been exhibited because of the lack of precaution for precise measurement.[1-6] It is necessary for the thermodynamic study of the interface to measure the exact pressure dependence of interfacial tension.

Experimental

A pendant drop method was adopted for measuring interfacial tension. This method is very satisfactory for the accurate evaluation of the interfacial tension between oil and water, but some precaution should be kept for precise measurement. We have newly designed an apparatus suitable for organic liquid/water interface. A schematic diagram of the apparatus designed here is shown in Fig. 1. The pressure vessel is a cylinder of stainless steel (SUS 27) 110 mm in o.d., 25 mm in i.d., and 420 mm in height, in which two quartz windows 12 mm thick and 20 mm in diameter are installed so that we can take the picture of pendant drop profiles by the camera. In order for the pendant drop cell to be free from contamination, which is caused by desorption of surface active impurities from the vessel, the cell is made of quartz, which consists of the syringe, the barrel shaped optical part, the drop forming tip, and the cylinder. The capacity of the cell is about 20 cm^3; the syringe and cylinder are filled out with water and organic liquid, respectively; and the pendant drop is formed by making use of the difference on their isothermal compressibility. Pressure was generated by means of a high pressure hand-pump and measured with a Heise bourdon gauge. Temperature was kept constant at 303.15 K by circulating thermostated water in the jacket of the pressure vessel.

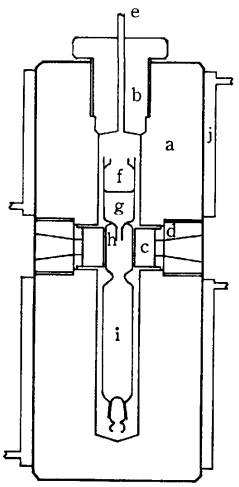

Fig. 1. Schematic diagram of the apparatus. a) Cylinder; b) flange; c) quartz window; d) window plug; e) pressure tubing with which the pressure pump and bourdon gauge are connected; f) plunger; g) syringe in which water is filled; h) drop forming tip; i) cylinder in which oil is filled; j) jacket.

Water used was refluxed with $KMnO_4$ and distilled. Organic liquids were purified by the usual method and the purity was checked by evaluating the interfacial tension at the atmospheric pressure. Water and organic liquids were stored together so that mutual solubilities were attainable.

Since the mutual solubilities of water–organic liquid systems are negligibly small, we used the density and compression data of pure water and organic liquids for the calculation of interfacial tension.[7-11]

The pendant drop cell was filled with water and organic liquid before it was set in the pressure vessel. Measurements of the interfacial tension were made under the condition of increasing pressure. For each rise in pressure, the apparatus was allowed to stand for 30 min so as to remove errors brought about by the adiabatic compression. Then the enlarged photograph of pendant drop was taken by the camera at each pressure. The dimensions of profile were determined to a precision of μm by Nikon Measurescope. The interfacial tension was calculated by using an equation proposed by Andreas *et al.*[12] and Fordham's correction factor was applied within a precision of ± 0.1 mN m^{-1}.[13]

Results and Discussion

The interfacial tension-pressure (γ-p) curves observed for organic liquid–water system are shown in Fig. 2. It is seen that the interfacial tension increases with an

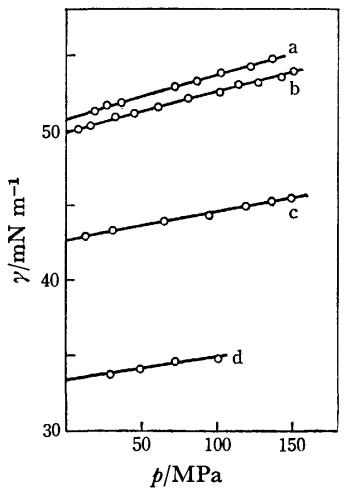

Fig. 2. The variation of the interfacial tension with pressure. a) octane/water; b) hexane/water; c) carbon tetrachloride/water; d) benzene/water.

increase in pressure and the slope of the curve is almost constant all over the pressure range investigated. The experimental equation expressing the interfacial tension as a function of the pressure is then formulated as

$$\gamma = a + bp \quad (1)$$

The constants a and b were determined by the method of least squares. The values of a and b evaluated are given in Table 1. It is apparent that the slope of γ-p curve

Table 1. The constants of the Eq. 1 resulting in the best fit to the experimental data

	a/mN m^{-1}	b/mN m^{-1} MPa^{-1}
Octane	50.89	0.0287
Hexane	49.94	0.0259
Carbon tetrachloride	42.68	0.0188
Benzene	33.42	0.0138

varies regularly with the value of interfacial tension, which is known to be correlated directly with the mutual solubility between organic liquid and water.[14] Some of these systems have been studied by several investigators. For benzene–water system, Hassan *et al.* observed for the slope to be negative,[3] Michaels *et al.* reported that the slope is positive at lower temperatures and negative at higher temperatures,[2] and Harvey observed that the γ-p curve has a minimum when temperature is low.[4] On the other hand, Jennings obtained the linear γ-p which bears a positive but very small slope.[5] The slopes obtained by these investigators are definitely small compared with those given in Table 1. Taking into consideration that they used pendant drop cells made of stainless steel with which water and organic liquids were in contact, it seems likely that the discrepancy among them can be ascribed to contamination by surface-active impurities, because it is found that the slope of γ-p curve is diminished by the adsorption of surface-active substances.[15]

According to the thermodynamics, the variation of interfacial tension with pressure at constant temperature is shown to be given by the equation

$$(\partial\gamma/\partial p)_{T,\sigma} = (\partial V/\partial\sigma)_{T,p} \quad (2)$$

where V is the volume of the organic liquid–water system and σ the interfacial area.[16] The right-hand side of the above equation expresses the volume change ΔV accompanied by the interface formation. Applying this equation to the present data we see ΔV being positive, as shown in Table 1 as b.

Electronic States of the 4,4′-Dinitrobiphenyl-Benzidine Complex

Masashi TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received August 25, 1976)

Synopsis. The charge transfer complex composed of 4,4′-dinitrobiphenyl and benzidine was studied by measuring and analyzing the UV crystalline spectra. The deep coloration of this complex was found to be due to the charge transfer bands appearing at 21000 and 25000 cm^{-1}, while the long axes of the component molecules are known to be perpendicular to each other.

Common electron donor-acceptor complexes crystallize in the plane-to-plane stacking of the molecules and are much more deeply colored than the component compounds. Nevertheless, 4,4′-dinitrobiphenyl has been known to form a complex with benzidine in a stack in which the 4,4′-dinitrobiphenyl molecules is arranged at right angles to each benzidine molecule and the complex becomes deeply red in color while the component molecules are light yellow.[1,2] Therefore, it is very interesting to determine whether or not the deep coloration of this complex is due to the appearance of broad, weak charge-transfer absorption. The author measured the polarized reflection and absorption spectra of the complex crystal and analyzed them theoretically.

Experimental and Theoretical

Single crystals of the complex were kindly supplied by the Research Institute for Polymers and Textiles. The crystals showed developed planes of (100) and (101). These planes were identified by X-ray examination. The reflection spectra at normal incidence and the transmission spectra were measured with spectrophotometers constructed in this laboratory. The absorption spectra obtained by the Kramers-Kronig[3] transformation of the reflection spectra are shown in Fig. 2 and the polarized transmission spectra in Fig. 3.

As Davydov splitting was not observed in these spectra, exciton treatment was not developed in this study and the electronic energy levels of the complex were calculated assuming a 1: 1 dimer type complex of 4,4′-dinitrobiphenyl and benzidine molecules, although the actual composition is 4: 1. The calculation of the dimer were made by taking into account the configuration interaction between the ground (Φ_0), locally-excited (LE; $\Phi_{at\to aj}$) and charge-transfer (CT; $\Phi_{at\to bj}$) configurations. These matrix elements were estimated in the zero differential overlap approximation, except for the elements between the Φ_0 and $\Phi_{at\to bj}$ configurations,[4]

$$(\Phi_0|H|\Phi_{at\to bj}) = -\sqrt{2}K(\phi_a{}^i|\phi_b{}^j)$$

where K is a constant and was taken to be 10.0. The atomic Coulomb integrals were estimated by the Nishimoto-Mataga method.

The molecular orbitals ϕ_a^i and the orbital energies were given using the PPP approximation. The results of the calculation are shown in Table 1.

The computation was carried out on the Facom 230-60 computer at the Nagoya University Computation Center.

Results and Discussion

Crystals of the 4,4′-dinitrobiphenyl–benzidine complex belong to the C_c space group.[5] The unit cell contains four of the complex groups $[O_2N\cdot C_6H_4\cdot C_6H_4\cdot NO_2]_4\cdot[H_2N\cdot C_6H_4\cdot C_6H_4\cdot NH_2]$. Figure 1 shows a projection of the unit cell along b on to the ac plane. The benzidine molecules lie along b and are thus seen end-on. Each dinitrobiphenyl molecule shown on the projection represents four molecules lying parallel to one another and separated by $(1/4)b$ or 3.7 Å. These dinitrobiphenyl molecules must all lie with their long axes very nearly on the $(40\bar{2})$ planes, while the benzidine molecules must lie almost wholly on these planes.

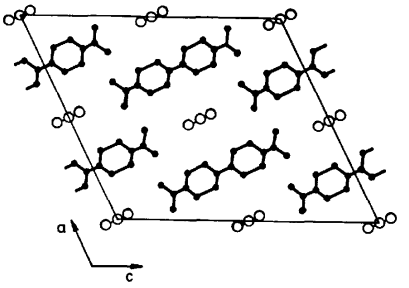

Fig. 1. A projection of the unit cell along b on to the ac plane.

Figure 2 shows the polarized absorption spectra of the crystal obtained by K-K analysis of the reflection spectra. In the b-axis spectrum, the long-axis polarized state of benzidine is located at about 32000 cm^{-1}. The long-axis state of 4,4′-dinitrobiphenyl is observed at

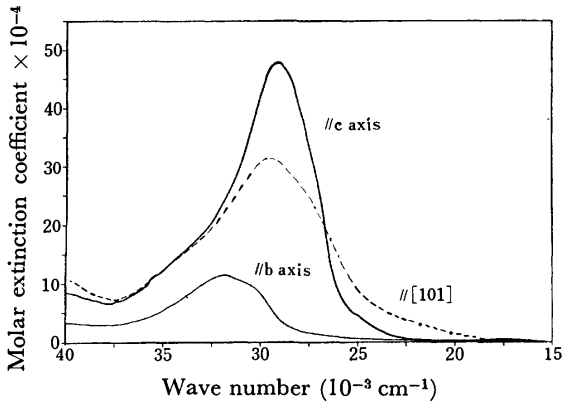

Fig. 2. The polarized absorption spectra of the crystal obtained by the Kramers-Kronig analysis of the reflection spectra.

29000 cm^{-1} in the c- and [101]-axis spectra. Two broad, weak shoulders occur in the vicinity of 17500 to 25000 cm^{-1} in the [101]-axis spectrum.

Figure 3 shows the polarized absorption spectra of the crystal obtained by the transmission method. Two peaks are observed at 21000 and 25000 cm^{-1} in the [101]-axis spectrum.

Table 1 shows that the first and second bands at about 21000 and 25000 cm^{-1} are assigned to the CT bands from the occupied MO of the benzidine molecule

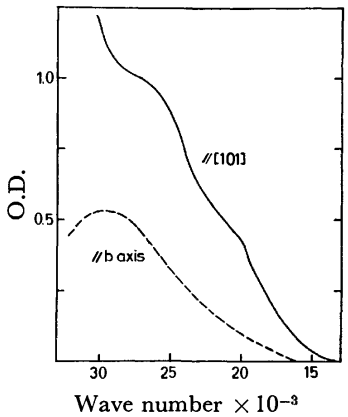

Fig. 3. The polarized absorption spectra of the crystal obtained by the transmission method.

to the vacant MO of the dinitrobiphenyl molecule. As these CT configurations do not mix strongly with the ground and LE configurations, the absorption intensities to these CT states are nearly forbidden and weak, as is shown in Figs. 2 and 3. In the third and fourth states, the large mixing between the LE configuration $\Phi(\phi_1^{10}\rightarrow\phi_1^{11})$ of the dinitrobiphenyl molecule and the CT configuration $\Phi(\phi_2^{7}\rightarrow\phi_1^{10})$ from the occupied MO of benzidine to the vacant MO of dinitrobiphenyl is due to the nearly degenerate configuration energies and the transition moments of these states depend mainly on the transition moments of the LE configuration $\Phi(\phi_1^{10}\rightarrow\phi_1^{11})$ of the dinitrobiphenyl molecule. The LE configuration $\Phi(\phi_1^{10}\rightarrow\phi_1^{11})$ is polarized parallel to the long axis of the dinitrobiphenyl molecule. Therefore, the 29000-cm^{-1} band observed in the c- and [101]-axis spectra may be assigned to the long-axis state of dinitrobiphenyl. The fifth state consists of the LE configuration $\Phi(\phi_2^{8}\rightarrow\phi_2^{9})$ polarized parallel to the long axis of the benzidine molecule and the 32000-cm^{-1} band in the c-axis spectrum can be assigned to the long-axis state of benzidine.

In the ground state, mixing with the charge-transfer configurations is small and the stabilization of the ground state appears to be due to the quadrupole interaction rather than to the charge-transfer and polarization effects. Accordingly, this dinitrobiphenyl–benzidine complex forms an inclusion compound and can be crystallized in various molecular ratios.

The author would like to thank Mr. Kazuaki Harata of the Research Institute for Polymers and Textiles for supplying the crystal of the 4,4′-dinitrobiphenyl–benzidine complex.

An Improved Gas Circulation Pump

Isao YASUMOTO and Keizo NAGAI*

Department of Chemistry, Yonago Technical College, Yonago 683

**Department of Electrical Engineering, Yonago Technical College, Yonago 683*

(Received September 11, 1976)

Synopsis. A gas circulation pump made of glass has been constructed, which works at less than one atmosphere. The pumping speed of the present pump is approximately 4 l/min.

The study of the gas-solid reactions on the surface of catalysts requires in many cases a technique for circulating gas in a closed system.

This report will describe an improved design of a gas circulation pump[1-4] and present some experimental results performed with this new pump. The design was found to be satisfactory and to have a number of advantages, such as:

(1) The pump works at any pressure less than one atmosphere.

(2) A high pumping speed can be obtained.

(3) Piston overshooting does not occur.

(4) The pump can be baked at 500 °C. The pressure of 1×10^{-5} Torr is obtainable.

(5) Modern electronics can be applied to the switching circuit of the pump.

The pump consists of a cylinder, a piston with a coil, and four sets of valves with coils of the same design (Figs. 1 and 2). The cylinder is a Pyrex tube 18 mm in inside diameter and 66 cm in length and is placed horizontally. The closely fitting piston is a piece of Pyrex tube enclosing a ferrite rod 12 mm wide and 100 mm long.

The coil for the piston consists of 10000 turns of an enamelled copper wire 0.5 mm in diameter and is fixed on a slider, which is driven on rails by means of a reciprocating slider-crank mechanism with a 50 watt DC servomotor. The piston accordingly makes a smooth back-and-forth motion over the distance of about 53 cm

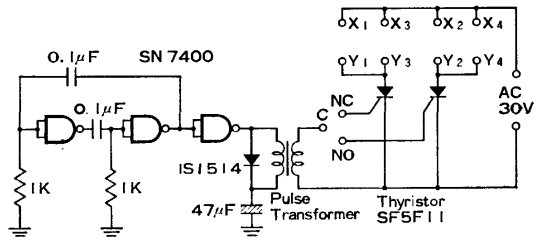

Fig. 2. The switching circuit. C, NC, and NO-terminals of the switch. X_i and Y_i; terminals.

at the repetition rate set at 15 cycle/min without danger of overshooting. The exciting current for the coil was found to be about 0.4 amperes (corresponding to 30 W). The rise in the temperature of the cylinder during a continuous operation was negligibly small.

The valve has a glass bulb which encloses a ferrite rod 4 mm wide and 22 mm long (Fig. 3). The bulb

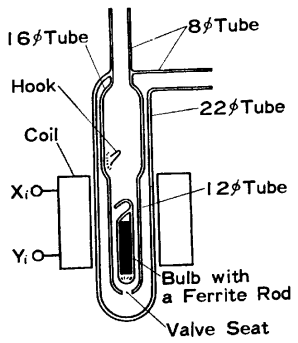

Fig. 3. The schematic sketch of the valve. X_i and Y_i; terminals of the coil.

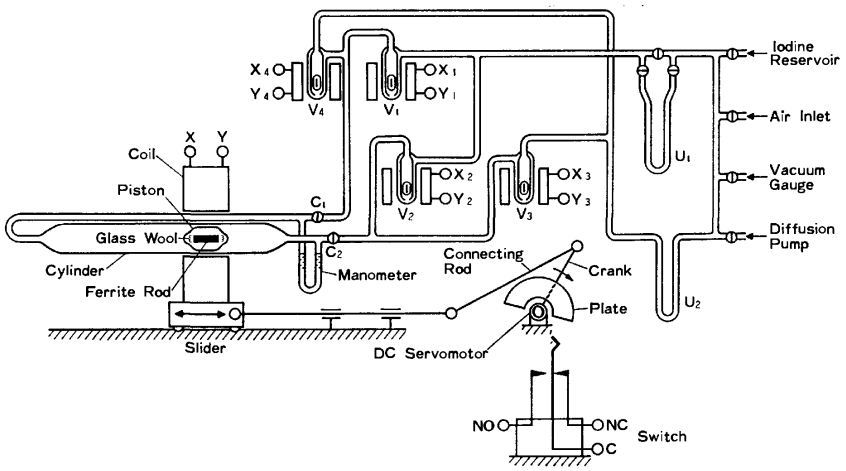

Fig. 1. The circulation pump with the vacuum line.

end and the valve seat are ground together to form a ball joint of about 7 mm in radius.

The coil for the valve consists of 5000 turns of an enamelled copper wire 0.5 mm in diameter. The proper exciting current was about 0.5 amperes (corresponding to 15 W) and the rise in the temperature around the valve was approximately 5 °C after a prolonged operation.

The concerted action of the valve system with the motion of the piston is achieved by attaching to the crank shaft a semicircular plastic plate which pushes the lever of a switch, owing to its thickness, during one half period of time. A triggering signal turns thyristors on. The current through each thyristor excites alternately two pairs of coils: V_1 and V_3, and V_2 and V_4.

To bake out the pump the bulb is raised with the coil and hung on a hook, and then the five coils are all removed.

The pump works at any pressure of gas in theory, but at low pressure the migration of gaseous molecules by diffusion predominates. For the purpose of investigating this phenomenon, the series of procedures described below were repeated.

Dry air of a certain pressure is admitted into the apparatus (Fig. 1) as a carrier gas for iodine vapor. The apparatus is equipped with two traps, U_1 and U_2: the former is filled with a quantity of sublimed iodine and cooled in a Dry Ice–acetone mixture and the latter is left at room temperature. The U_2-trap is then dipped in another Dry Ice–acetone mixture and cooled. When the refrigerant which cools the U_1-trap is removed, the temperature of iodine in the U_1-trap gradually rises to room temperature. Iodine vapor, flowing from the iodine trap, reaches the U_2-trap, either downstream *via* the circulation pump or directly upstream by diffusion, and condenses there. The lengths of these paths are roughly in the ratio of 8 to 1. Several minutes after, the refrigerant which cools the U_2-trap is removed, and the U_2-trap is photographed (Fig. 4).

Runs 1, 2, 3, and 4 were carried out under the pressures of 300, 100, 15, and 1 Torr of air, and their iodine deposits in the left arm of the trap were denser than in the right one. However, a new deposit appeared in the right arm in run 5, in which the pressure of 0.4 Torr of air was used. It looked as dense as the left arm deposit in run 6, which was done under the pressure of 0.3 Torr of air. The right arm deposit was denser than the left one in run 7, in which the pressure of 0.1 Torr of air was used; the diffusion of gas would have a considerable share in this case.

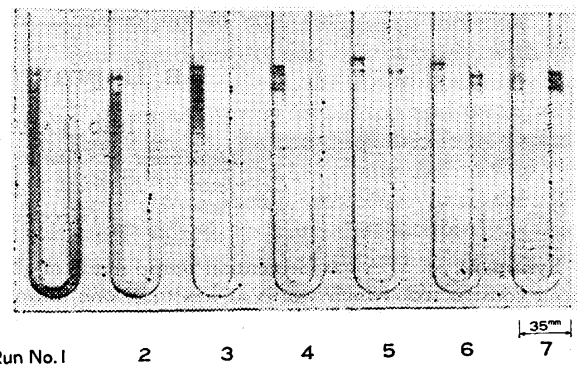

Fig. 4. The photographs of the U_2-trap containing iodine deposit.
Run No. —pressure of air: 1—300 Torr, 2—100 Torr, 3—15 Torr, 4—1 Torr, 5—0.4 Torr, 6—0.3 Torr, 7—0.1 Torr.

To estimate the circulating power of the pump, air was admitted into the apparatus up to 50 Torr. The circulating air was cut off by closing the taps of C_1 and C_2 and the pressure difference between the spaces in the front and the rear of the piston was measured with a manometer, while the piston was pulled slowly in one direction by the coil. The pressure difference was found to be roughly 14 Torr.

The Crystallization of $Pb_5Si_3O_{11}$ from the Glass in the PbO-SiO_2 System

Hiroshi HASEGAWA, Masahiko SHIMADA,* Fumikazu KANAMARU,* and Mitsue KOIZUMI*

Department of Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu, Shizuoka 432

**The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565*

(Received August 16, 1976)

Synopsis. A new compound, $Pb_5Si_3O_{11}$, is prepared by the crystallization of the glass in the PbO–SiO_2 system. $Pb_5Si_3O_{11}$ has an orthorhombic symmetry, and its lattice parameters are determined to be a_0=9.93 Å, b_0=8.31 Å, and c_0=34.4 Å.

During the course of a systematic study of the crystallizing phenomena of lead germanate glasses and of lead germanosilicate glasses,[1,2] it was found that a ferroelectric crystalline phase, $Pb_5Ge_3O_{11}$, was easily obtained from the $5PbO \cdot 3GeO_2$ glass, that the glass-ceramic product was transparent, and that a ferroelectric solid solution, $Pb_5Ge_{3-x}Si_xO_{11}$ ($0 \leq x \leq 2$), was precipitated from the $5PbO \cdot (3-X)GeO_2 \cdot XSiO_2$ glass ($0 \leq X \leq 2$).

Eysel *et al.*[3] reported that the single crystals of the $Pb_5(Ge, Si)_3O_{11}$ solid solution, containing up to 62% of Si replacing Ge, were prepared from the melt. Assuming that Si can be completely substituted for Ge in a nearly ideal fashion, the presence of $Pb_5Si_3O_{11}$ can be expected. As to the PbO–SiO_2 system, Ott and McLaren[4] obtained a corrected phase diagram by means of the crystallization of lead silicate glasses and suggested the existence of five compounds: Pb_4SiO_6, Pb_3SiO_5, Pb_2SiO_4, $Pb_3Si_2O_7$, and $PbSiO_3$. More recently, Smart and Glasser[5] studied the phase equilibria in this system and reported the existence of six compounds: Pb_4SiO_6, Pb_3SiO_5, Pb_2SiO_4, $Pb_3Si_2O_7$, $PbSiO_3$ and $Pb_5Si_8O_{21}$. However, the existence of the $Pb_5Si_3O_{11}$ compound has not been reported.

The purpose of this research is to ascertain the existence of $Pb_5Si_3O_{11}$ by using the crystallization of lead silicate glasses.

Experimental

Pure lead monoxide and silicic acid were carefully mixed. About 50 g of the mixture was preheated at 550 °C for 10 h, and then melted in a platinum crucible at 800 °C. After the melting has been completed, the melt was poured onto a steel mould and formed into a plate glass. The compositon of the glass was checked by chemical analysis. The specimen prepared in this way was placed in a platinum basket, heated in an electric furnace at temperatures from 350 to 650 °C for 1 to 340 h, and then quickly cooled to room temperature. The crystallized phases after the heat-treatment were identified by powder X-ray diffraction analysis.

Results and Discussion

A microcrystalline phase, denoted as "Phase X," was precipitated in the $5PbO \cdot 3SiO_2$ glass by heating at about 400 °C. This phase was stable up to 600 °C, but decomposed at a higher temperature into Pb_2SiO_4 and $PbSiO_3$. According to the phase diagram of this system reported by Ott and McLaren, the major crystalline phase precipitated from the $5PbO \cdot 3SiO_2$ glass might be $Pb_3Si_2O_7$. However, the powder X-ray diffraction pattern of Phase X was similar not to that of lead-barysilite, $Pb_3Si_2O_7$, reported by Billhardt,[6] but to that of ferroelectric $Pb_5Ge_3O_{11}$ as shown in Fig. 1.

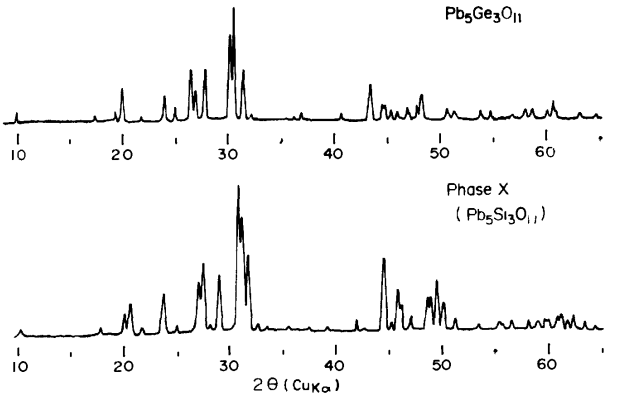

Fig. 1. X-Ray diffraction patterns of Phase X and $Pb_5Ge_3O_{11}$.

On the basis of the crystal structure of $Pb_5Ge_3O_{11}$, the crystal structure of Phase X was determined to be pseud-hexagonal and orthorhombic. Its lattice parameters were calculated to be a_0=9.93 Å, b_0=8.31 Å. and c_0=34.4 Å. The X-ray diffraction data of Phase X are tabulated in Table 1.

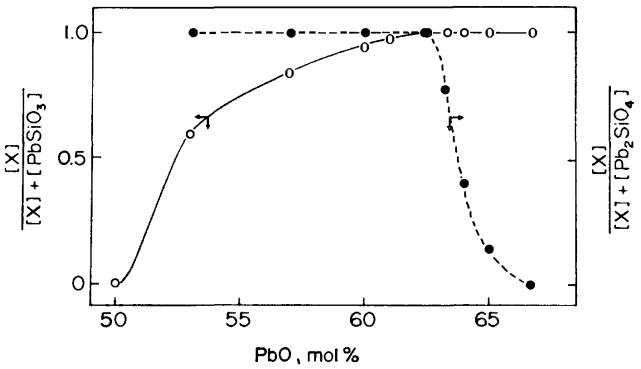

Fig. 2. Relative amounts of products after the crystallization of the glasses as functions of the PbO content of the glass.

Phase X was obtained only through the crystallization of glass. All the attempts to synthesize Phase X by the usual solid-state-reaction methods and by the solidification of the melts failed.

The chemical composition of Phase X was determined by using the following process. Powder glass samples with ten compositions, ranging from 50.1%PbO·49.9%SiO_2 to 66.7%PbO·33.3%SiO_2 in mol, were heat-treated at about 550 °C for 340 h, and the amounts of crystallized products were estimated from the intensities of the most intense peaks of Phase X, Pb_2SiO_4 and $PbSiO_3$. The crystallization of the glasses investigated was completed within about 5 h at 550 °C, so that our experimental conditions—at 550 °C for 340 h—are sufficient to reach the equilibrium state. A microscopic examination of crystallized products showed that the sample was completely crystalline. The relation between the amounts of each phase and the PbO contents of the glass is illustrated in Fig. 2. As is shown in this figure, in the range where the PbO content is less than 62.5%, the yield of Phase X increased with an increase in the PbO content, and in the range where the PbO content is more than 62.5%, mixtures of Phase X and Pb_2SiO_4 were observed. From these results, the chemical composition and the chemical formula of Phase X were determined to be 62.5%PbO·37.5%SiO_2 and $Pb_5Si_3O_{11}$.

In conclusion, in the present research the existence of a new crystalline phase, $Pb_5Si_3O_{11}$, has been confirmed by using the crystallization of lead silicate glasses.

The Crystal Structure of Nitratotriaquo(2,2′-bipyridine)copper(II) Nitrate $[Cu(NO_3)(H_2O)_3(bipy)]NO_3$*

Hisayoshi NAKAI,** Shun'ichiro OOI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received September 21, 1976)

Synopsis. The crystal structure of the title compound has been determined from three-dimensional X-ray data. The crystal is composed of the nitrate anions and the distorted-octahedral $[Cu(NO_3)(H_2O)_3(bipy)]^+$ cations, where the nitrato-groups act as a monodentate ligand and the three coordinated water molecules occupy a facet of the octahedron.

It has been found that the bis(2,2′-bipyridine)copper(II) complexes have a variety of stereochemistries: distorted trigonal bipyramid and *cis*- and *trans*-distorted octahedrons.[1-4] As a part of our structural studies on such complexes, a single crystal X-ray analysis has been carried out on $[Cu(NO_3)(H_2O)_3(bipy)]NO_3$.

Experimental

The crystals of $[Cu(NO_3)(H_2O)_3(bipy)]NO_3$ were easily prepared by adding a methanol solution of 2,2′-bipyridine (8 mmol in 20 cm³ of the solvent) to an aqueous solution of cupric nitrate (10 mmol in 30 cm³ of water), and were recrystallized from a water–methanol mixture. Found: C, 30.29; H, 3.75; N, 14.05%. Calcd for $[Cu(NO_3)(H_2O)_3(bipy)]NO_3$: C, 30.20; H, 3.55; N, 14.09%.

The lattice parameters were obtained by the least-squares refinement of the data from the higher-angle reflections of the (0*kl*), (*h*0*l*) and (*hk*0) Weissenberg photographs, on which aluminum powder lines were superimposed for calibration. Cu*K*α radiation (λ=1.5418 Å) was used throughout the diffraction study. The density was measured by the flotation technique, using a benzene–bromoform mixture. Of the two possible triclinic space groups, $P\bar{1}$ and P1, the former was chosen initially; it was subsequently verified by the successful refinements of the derived structure. Crystal data: $[Cu(NO_3)(H_2O)_3(bipy)]NO_3$, *F.W.*=397.8, triclinic $P\bar{1}$, a=9.52(1), b=7.80(1), c=13.62(2) Å, α=110.4(2), β=124.3(2), γ=77.3(1)°, Z=2, D_m=1.65, D_c=1.69 g·cm^{-3}, μ=25.3 cm^{-1} (for Cu*K*α radiation). The intensity data of 0*kl* to 5*kl*, and *h*0*l* to *h*4*l* were collected by the multiple-film equi-inclination technique from two cylindrically shaped crystals with approximate dimensions of 0.2×0.2×0.8 mm. The intensities of 2890 independent reflections were visually estimated by comparison with a standard scale; 374 of them were too weak to be measured and so were assumed to be zero. After the intensity data have been corrected for Lorentz-polarization, spot-extension, and absorption effects, the structure factors were placed on a common arbitrary scale by the least-squares method.

Structure Determination

The crystal structure was determined by the heavy-atom method. The position of the copper atoms was determined from a three-dimensional Patterson map, and a Fourier synthesis phased with the Cu atoms revealed all the atoms except the hydrogen atoms and those of the uncoordinated NO_3^- ion; the NO_3^- ion was found from the subsequent Fourier and difference Fourier maps. The structure was refined by the block-diagonal least-squares method, using the HBLS-IV program coded by Prof. Ashida. The weighting scheme used was: w=0.2 when F_o=0, and w=1.0 when F_o>0. The atomic scattering curves were taken from the International Tables for X-ray Crystallography,[5] the real part of the anomalous dispersion correction ($\Delta f'$=−2.1) being applied for the neutral copper atom. Refinement of the positional and thermal parameters, at first isotropic and subsequently anisotropic, reduced the R value to 0.124 for 2516 non-zero reflections, and no other significant peak was obtained in the final Fourier and difference Fourier maps. Final atomic coordinates and thermal parameters are listed in Table 1. The observed and calculated structure factors are listed in Table 2.***

Results and Discussion

The crystal is composed of the $[Cu(NO_3)(H_2O)_3(bipy)]^+$ cations and the nitrate anions. Figure 1 shows a schematic drawing of the complex cation. The coordination geometry about the copper atom is a tetragonally distorted octahedron: two nitrogen atoms of the bipy ligand[Cu–N(1)=2.02(1) and Cu–N(2)=1.99(1) Å], and two oxygen atoms of the coordinated water molecules[Cu–O(1)=1.99(1) and Cu–O(2)=

1.99(1) Å] define the equatorial plane, while the axial positions are occupied by the O(3) atom of the third coordinated water molecule[Cu-O(3)=2.36(1) Å], and by the O(11) atom of the nitrato-group[Cu-O(11)= 2.70 Å]. The copper atom is 0.12 Å distant from the equatorial plane, towards the O(3) atom. The angles of N(1)-Cu-O(11), N(1)-Cu-O(3), N(2)-Cu-O(11), and N(2)-Cu-O(3) are 84.9(4), 94.0(4), 93.2(4), and 91.7(4)° respectively.

The bipyridine ligand is in the *cis*-planar configuration with the maximum deviation of 0.04 Å, and the "bite" angle, N(1)-Cu-N(2), is 81.5°; the planarities of the two pyridine rings, A and B, are good with the maximum deviations of 0.02 and 0.01 Å respectively, and the dihedral angle between the A and B planes is 3°. The C(5)-C(6) bond length is 1.52(2) Å, and the aromatic C-C(1.38—1.43 Å) and C-N(1.35—1.38 Å) bond lengths are 1.41 and 1.36 Å on the average. It should be noted that the angles of C(4)-C(5)-C(6) and C(5)-C(6)-C(7) are larger than those of N(1)-C(5)-C(6) and C(5)-C(6)-N(2) by 8—10°; the same trend has been observed in the 2,2′-bipyridine[6] and its copper complexes.[1-4,7,8] The dihedral angle between the equatorial plane and the plane of the bipy ligand is 8°.

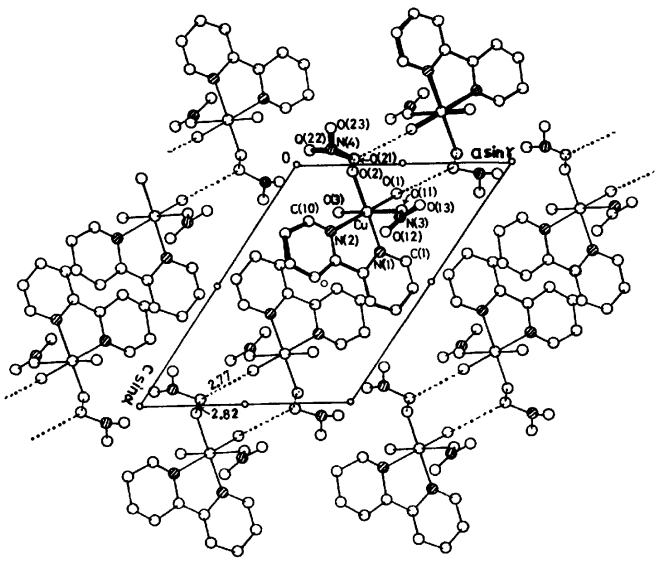

Fig. 2. Projection of the structure along the b axis. Dotted lines are hydrogen bonds.

The nitrato-group is planar and acts as a monodentate ligand. The O(11) is bonded to the copper atom (2.70 Å), while the O(13) is linked to the O(1)′[x,1+ y,z] by a hydrogen bond (2.76 Å). The plane of the nitrato-group makes the dihedral angles of 72° with the equatorial plane and of 79° with the plane of the bipy ligand.

The uncoordinated nitrate ion is also planar and is linked to the two water molecules by hydrogen bonds, which are indicated by the dotted lines in Fig. 2 [O(21) ···O(2)=2.82(2) and O(21)···O(11)″[1−x, 1−y, −z]= 2.77(2) Å]. The bond lengths of N(4)-O(21), N(4)-O(22), and N(4)-O(23) are 1.32(2), 1.27(2), and 1.22(2) Å respectively. The O-N(4)-O angles in the nitrate ion range from 119(1) to 121(1)°. The plane of the nitrate ion makes the angles of 74° with the plane of the coordinated nitrato-group and of 79° with the equatorial plane of the complex cation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (2), 533—534 (1977)

Absorption Spectra of Bis(sulfito) and Bis(thiosulfato) Complexes of Cobalt(III)

Keiji AKAMATSU, Jinsai HIDAKA,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received September 27, 1976)

Synopsis. It has been shown that the near ultraviolet "specific band" of a *trans* isomer of bis(sulfito) or bis(thiosulfato) cobalt(III) complexes is more bathochromic than the corresponding *cis* isomer. The *cis*-$[Co(SO_3)_2(en)_2]^-$ complex was optically resolved and its circular dichroism spectrum reported.

This note deals with "specific bands" of the *cis-trans* isomers of bis(aniono-*S*) cobalt(III) complexes, *i.e.*, bis(sulfito) and bis(thiosulfato) ones. It has been shown that the "specific bands" due to the aniono-*S* or aniono-*N* ligands such as SO_3^{2-} or NO_2^- are mostly of charge-transfer character,[1,2] but we retain the old name for convenience.

There had been a confusion as to the configuration assignment of tetraamminebis(sulfito)cobaltate(III) complex, but recent crystal structure[3] and other[4] studies of the *cis* isomer have solved the problem; thus the *cis-trans* assignment of Hofmann and Jenny,[5] and of Bailar and Peppard[6] are correct, while that of one of the present authors in 1952[7] incorrect. The isomers of the corresponding bis(ethylenediamine) complexes were assigned by infrared spectral[8] and lability[9] studies, and the result has been confirmed by the optical resolution of the *cis* isomer in the present study.

Results and Discussion

Figure 1 shows the visible and ultraviolet absorption spectra of bis(sulfito) and bis(thiosulfato) complexes, of which those of the *trans* bis(sulfito) complexes were measured in 0.1 M aqueous Na_2SO_3 solution to prevent the aquation due to the strong *trans* effect of sulfito ligand.[4] Table 1 presents the data of specific bands of the bis(aniono-*S*) complexes together with those of bis(aniono-*N*) ones for the purpose of comparison, and shows that the specific band of a *trans* isomer is in a longer wavelength region than that of the *cis* isomer is. It is remarkable that the specific bands of the *cis* isomers of tetraamminebis(sulfito)- and bis(ethylenediamine)-bis(sulfito) complexes split into distinct components. The *cis* isomer of bis(ethylenediamine)bis(thiosulfato) complex also shows a tendency to split in the specific band region (Fig. 1). A probable splitting of the specific band has been suggested for the *cis* isomers of dinitro-, diazido-, or diisothiocyanatobis(ethylenediamine) cobalt(III) complexes from their circular dichroism (CD) measurements.[1] Now, the *cis* isomer of $[Co(SO_3)_2(en)_2]^-$ was optically resolved and the CD spectrum is shown in Fig. 1. Since the major CD component of the first d-d transition in the longer wavelength region is negative for the obtained isomer, the absolute configura-

tion is Δ from a criterion of McCaffery *et al.*[18] The CD of Δ isomer shows a pattern of positive and then negative in the order of increasing energy in the specific band region. This sign pattern coincides well with those found for dinitro-, diazido-, and diisothiocyanatobis-(ethylenediamine) complexes in this region.[1]

Experimental

Preparations. *(1)* cis- *and* trans-$M[Co(SO_3)_2(NH_3)_4]$ *(M=Na, or* NH_4*)*: The *cis* isomer was prepared by the method of Bailar and Peppard.[6] Absorp. max. 10^{-3} σ/cm^{-1} (log ε): 22.12 (2.27), 34.13 (4.21), 37.59 (4.19). Found: H, 6.01; N, 20.12%. Calcd for *cis*-$NH_4[Co(SO_3)_2(NH_3)_4]\cdot 2.5H_2O$: H, 6.05; N, 19.99%.

To the filtrate from the *cis* isomer was added twice the volume of methanol and the resulting yellowish brown *trans* isomer was recrystallized from 0.1 M aqueous Na_2SO_3 and dried in air. Absorp. max. 10^{-3} σ/cm^{-1} (log ε): 23 sh (2.60), 30.68 (4.38). Found: H, 5.00; N, 14.99; S, 17.42%. Calcd for *trans*-$Na[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$: H, 4.99; N, 15.38; S, 17.60%.

(2) cis- *and* trans-$Na[Co(SO_3)_2(en)_2]$: The isomers were prepared as in literature.[19] Absorp. max 10^{-3} σ/cm^{-1} (log ε): *cis* 22.73 (2.40), 34.48 (4.35), 37.25 (4.36); *trans* 23.10 (2.62), 30.86 (4.46). Found: C, 9.00; H, 4.23; N, 10.38%. Calcd for *cis*-$Na[Co(SO_3)_2(en)_2]\cdot NaClO_4\cdot 3H_2O$: C, 8.91; H, 4.12; N, 10.40%. Found: C, 13.21; H, 4.63; N, 15.59%. Calcd for *trans*-$Na[Co(SO_3)_2(en)_2]$: C, 13.26; H, 4.46; N, 15.46%.

(3) Optical Resolution of cis-$Na[Co(SO_3)_2(en)_2]\cdot NaClO_4$: The resolving agent $(+)_{589}$-$[Co(ox)(en)_2]I$ (2.7 g, 6.0×10^{-3} mol) was suspended in 10 cm^3 of water, and converted into the acetate by treating with silver acetate (1.0 g, 6.0×10^{-3} mol). This solution was added to a solution of *cis*-$[Co(SO_3)_2(en)_2]\cdot NaClO_4\cdot 3H_2O$ (1.6 g, 3.0×10^{-3} mol) in 10 cm^3 of water. Red crystals, $(+)_{589}$-$[Co(ox)(en)_2]ClO_4$, appeared immediately. After filtration, the filtrate was evaporated at about 20 °C in a rotary evaporator to about half the initial volume. During the process, another crop of the red crystals (perchlorate of the resolving agent) precipitated, and this was filtered off. The filtrate was kept for a week in a refrigerator, when the less soluble reddish brown diastereomer gradually crystallized out. The diastereomer was converted into the sodium salt by using a cation exchanger SP-Sephadex C-25 (Na^+ form), and the eluate was evaporated. Sodium perchlorate was added to the concentrated solution to precipitate the active complex. CD extrema 10^{-3} σ/cm^{-1} ($\Delta\varepsilon$): 21.05 (−1.83), 23.81 (+0.42), 27.66 (−0.07), 34.25 (+25.7), 38.02 (−28.7). Found: C, 10.13; H, 4.46; N, 11.81%. Calcd for $Na[Co(SO_3)_2(en)_2]\cdot 2.5H_2O\cdot 0.5NaClO_4$: C, 10.25; H, 4.53; N, 11.96%.

(4) cis- *and* trans-$M[Co(S_2O_3)_2(en)_2]$ *(M=Na or Li)*: Ammonium thiosulfate (0.5 g) dissolved in 1 cm^3 of water was added to 10 cm^3 of dimethyl sulfoxide. To this solution 1 g of *cis*-$[CoCl_2(en)_2]Cl$ was added and the mixture was stirred for half an hour at about 70 °C; then this was cooled to room temperature. The precipitated dark green crystals were filtered off, and the filtrate was poured into an anion exchanger column (QAE-Sephadex A-25, Cl^- form; ϕ 2.6 cm, l 30 cm). The column was washed with water and eluted with 0.07 M aqueous LiCl or NaCl solution. A dark green (*trans*)[20] and a brownish violet (*cis*) band were eluted in this order. The *cis* eluate was condensed below 20 °C, and isolated as the lithium salt, while the *trans* one as the sodium salt. Absorp. max. 10^{-3} σ/cm^{-1} (log ε): *trans* 16.5 sh (1.76), 18.32 (1.92), 29.94 (4.43); *cis* 18.35 (2.22), 35.34 (4.20). Found: C, 11.17; H, 3.88; N, 13.39%. Calcd for *trans*-$Na[Co(S_2O_3)_2(en)_2]$: C, 11.26; H, 3.78; N, 13.13%. Found: C, 8.50; H, 4.72; N, 9.47%. Calcd for *cis*-$Li[Co(S_2O_3)_2(en)_2]\cdot 6H_2O\cdot 1.6LiCl$: C, 8.21; H, 4.83; N, 9.57%.

Measurements. The absorption spectra were measured by a Shimadzu UV-200 Spectrophotometer in 0.1 M aqueous Na_2SO_3 solution for the *trans*(SO_3) isomers, in 3% aqueous NH_3 solution for the *cis*-$NH_4[Co(SO_3)_2(NH_3)_4]$, and in H_2O for all the other complexes. The CD spectrum was recorded on a JASCO MOE-1 Spectropolarimeter.

The Halogenation and Nitration of the Optical Active Isomer of the α-Acetylacetonato(triethylenetetramine)cobalt(III) Complex

Kashiro KURODA, Kazumi YAMAGUCHI, and Noriko YAMAOKA

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime 790

(Received October 4, 1976)

Synopsis. The methylidyne hydrogen of the coordinated acetylacetonate ion in $(+)_D$-α-acetylacetonato(triethylenetetramine)cobalt(III) perchlorate has been replaced with halogens and with a nitro group with a complete retention of the configuration. The order of the molar rotations of the complexes has been found to be: acac-<Clacac-<Bracac-<Iacac-complex and acac-≃O_2Nacac-complex.*

Resolution into the optical-active antipodes from a synthesized metal complex is generally tedious, since we have no common knowledge as to a suitable resolving reagent for the specified complex. Therefore, if an active complex which has been resolved can be converted into its derivatives with a complete retention of the configuration, our labor in the preparation of the active complexes will be greatly reduced. This technique has been used for the preparation of some active complexes of cobalt(III).[1] However, when a substitution of a ligand is involved in the procedure, there is always a possibility of racemization during the reaction, and the verification of the optical purity of the product remains necessary.

We have found that $(+)_D$-$[Co(acac)(en)_2]^{2+}$* reacts with a slight excess of *N*-chlorosuccinimide in water and in a methanol(50%)–water mixture at *ca.* 40 °C with an increase in activity to form $(+)_D$-$[Co(Clacac)(en)_2]^{2+}$. The activity of the solution at t_∞ (practically, after 1 day) was the same as that of the solution with an equal concentration prepared with the isolated and recrystallized $(+)_D$-$[Co(Clacac)(en)_2](ClO_4)_2$. This means that the chlorination proceeds with a complete retention of the configuration under those conditions; accordingly, $(+)_D$-$[Co(acac)(en)_2](ClO_4)_2$ was treated with the other *N*-halogenosuccinimides and active halogenoacetylacetonato complexes have been obtained.[2] In order to make surer the halogenations with a retention of configuration, $(+)_D$-α-$[Co(acac)(trien)](ClO_4)_2$ was newly prepared and was treated with *N*-halogenosuccinimides. Furthermore, the nitration of the ligand in both active complexes was examined using a mixture of copper(II) nitrate trihydrate and acetic anhydride as a nitration reagent. Thus, a series of optically active halogenated and nitrated complexes were isolated as crystals.

Experimental

Preparation of $(+)_D$-α-$[Co(acac)(trien)](ClO_4)_2$. In 10 ml of water, 2.5 g of the racemic perchlorate salt and 1.0 g of potassium acetate were stirred for 10 min, and then the mixture was cooled. The precipitate($KClO_4$) was filtered off. Into the filtrate, 1.3 g (1/2 equiv. to the complex) of $(+)_D$-$NaAsOC_4H_4O_6$ in 3 ml of water was added. Since it took a long time for the first crystal to come out, a few pieces of $(+)_D$-$[Co(acac)(en)_2][(+)_D$-$AsOC_4H_4O_6]_2$[3] were added to induce the crystal growth. Thus, pale red crystals came out gradually. After the mixture had been placed in a refrigerator overnight, the precipitate was separated and washed with ethanol and ether. Yield, 1.8 g.

Into a suspension of 0.5 g of the diastereoisomeric salt in 30 ml of ethanol, 3 ml of aqueous 2 M $NaClO_4$ was added. The mixture was then stirred vigorously for 1 h at *ca.* 45 °C, whereupon the solid phase turned white. The solid($NaAsOC_4H_4O_6$) was subsequently filtered off, and the filtrate was evaporated to dryness. To the residue we added 5 ml of warm water, and, after the removal of a white insoluble material by filtration, a few drops of 6 M $HClO_4$ were added to the filtrate, which was then cooled. The bright red crystals which were thus precipitated were collected and washed with an ethanol(20%)–ether mixture and with ether. Yield, 0.3 g.

Preparation of $(+)_D$-$[Co(acac)(en)_2](ClO_4)_2$. The procedure of the preparation was described in the preceding report.[2]

Chlorination, Bromination, Iodination, and Nitration of the Active Complexes. The halogenations and the nitration of the active isomers were carried out by the methods used for the inactive complexes.[2]

Identification and Measurement of the Optical Rotations. Each complex was identified by making sure its absorption spectrum was identical with that of the respective inactive complex.[2] The rotation of the complexes was counted with a JASCO DIP 180 Polarimeter at 589, 577, 546, 435, and 405 nm, using a 0.1% aqueous solution for the first four wavelengths and a 0.02% solution for the last wavelength.

Results and Discussion

Sodium arsinyl tartrate, which is known as an excellent resolving reagent for $[Co(acac)(en)_2]^{2+}$,[3] is also useful for the resolution of α-$[Co(acac)(trien)]^{2+}$. The conversion of the diastereoisomeric salt into the perchlorate was carried out by utilizing the property of the perchlorate of being soluble in ethanol including a small amount of water.

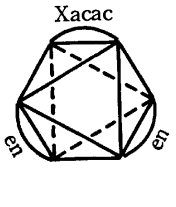
The molar rotations of the obtained complexes are shown in Table 1. As may be seen in the table, the rotatory characters of the trien complexes as well as of the en complexes are quite similar to each other; therefore, the chirality around the central cobalt must be same, and, since $(+)_D$-$[Co(acac)(en)_2]^{2+}$ has been established as having the *Λ*-configuration,[4] all of the trien complexes as well as the halogenated and nitrated en complexes can be concluded as having the *Λ*-configuration:

* The following abbreviations have been used in this report: en, ethylenediamine; trien, triethylenetetramine; acac, acetylacetonate ion (2,4-pentanedionate ion); Clacac, chloroacetylacetonate ion (3-chloro-2,4-pentanedionate ion); Bracac, bromoacetylacetonate ion; Iacac, iodoacetylacetonate ion; O_2Nacac, nitroacetylacetonate ion.

Table 1. Molar rotations of $(+)_D$-[Co(Xacac)$(en)_2$]-$(ClO_4)_2$ and $(+)_D$-α-[Co(Xacac)(trien)]$(ClO_4)_2$

Complex	$[M]_{589}$	$[M]_{577}$	$[M]_{546}$	$[M]_{435}$	$[M]_{405}$
$(+)_D$-[Co(Xacac)$(en)_2$]$(ClO_4)_2$					
acac	+2280°	+2900°	+3200°	−11500°	−11800°
Clacac	+2590°	+3260°	+3330°	−12700°	−13300°
Bracac	+2630°	+3280°	+3340°	−12800°	−13600°
Iacac	+2770°	+3330°	+3410°	−13500°	−14400°
O_2Nacac	+2090°	+2650°	+3750°	−11500°	−12600°
$(+)_D$-α-[Co(Xacac)(trien)]$(ClO_4)_2$					
acac	+2560°	+3280°	+4630°	−13700°	−13500°
Clacac	+3130°	+3900°	+4990°	−16000°	−15800°
Bracac	+3210°	+4060°	+5270°	−16800°	−16200°
Iacac	+3330°	+4200°	+5350°	−17800°	−16700°
O_2Nacac	+2240°	+2840°	+5050°	−15300°	−14600°

$(+)_D$-α-[Co(Xacac)(trien)]$^{2+}$



$(+)_D$-[Co(Xacac)$(en)_2$]$^{2+}$

The orders of the activities can be seen as:

acac-<Clacac-<Bracac-<Iacac-complex

and

acac-≃O_2Nacac-complex

in both en and trien complexes. Thus, the increase or the maintenance of rotation by the substitutions indicates that the reactions proceed without any bond rupture between the cobalt and the ligands, as has been verified in the chlorination of $[Co(acac)(en)_2]^{2+}$; hence, the method for obtaining these optical active isomers has been greatly simplified.

cis-2-Pentenyl Moiety from 5,6-Dihydro-2*H*-thiopyran. A Convenient Synthesis of *cis*-Jasmone

Sigeru Torii, Hideo Tanaka, and Yoshihisa Tomotaki

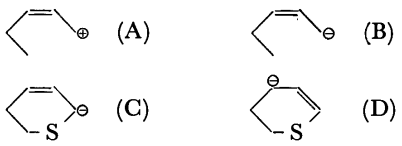
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received June 4, 1976)

Synopsis. A method for the synthesis of *cis*-jasmone from 5,6-dihydro-2*H*-thiopyran is described. Formation of *cis*-2-pentenyl moiety was achieved by reductive desulfurization of the 2*H*-thiopyran derivative obtained by the alkylation of 5,6-dihydro-2*H*-thiopyran with epichlorohydrin.

The construction of *cis*-2-pentenyl moiety has been the subject of jasmonoid syntheses.[1a-c] Preparation of the *cis*-pentenyl group by elaborated routes has been reported, *e.g.*, the partial hydrogenation of carbon-carbon triple bond,[1d] including the formation of 2-pentynyl group,[1e] the Wittig reaction of formylmethyl group with propylidenetriphenylphosphorane under salt-free condition ,[1f] and 1,5-sigmatropic rearrangement of 1-(1-propenyl)spiro[2.5]octan-4-one.[1g]

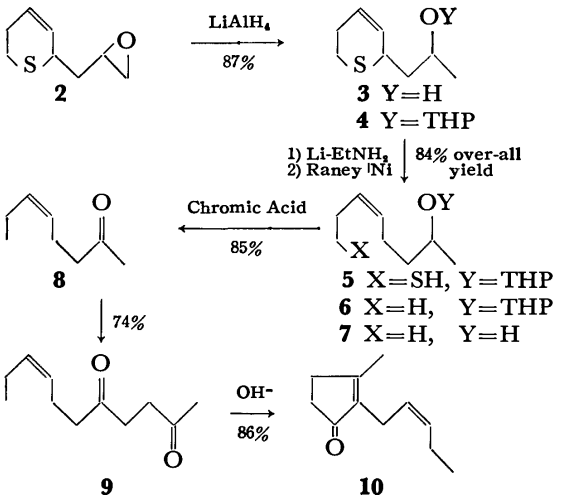
The dipole inversion (umpolung)[2] of *cis*-2-pentenyl cation (A) derived from *cis*-2-pentenyl halide would be *cis*-2-pentenide ion (B) which promises a novel approach for jasmonoid synthesis. A synthetic equivalent of the carbanion (B) is considered to be 5,6-dihydro-2*H*-thiopyran-2-ide ion (C). From our preliminary experiments, the regioselective alkylation of ambident carbanions (C) and (D) with epichlorohydrin has been found to occur exclusively at C-2 carbon atom.[3] This led us to investigate the novel synthesis of *cis*-jasmone.



Treatment of 5,6-dihydro-2*H*-thiopyran (**1**)[4] with 1.1 equivalents of *s*-butyllithium in tetrahydrofuran (THF) at −78 °C and subsequent addition of epichlorohydrin gave the 2-alkylated product **2** in 95% yield. Product **2** was contaminated with less than 2% of the corresponding 4-alkylated product. Reduction of **2** in THF at room temperature with lithium aluminum hydride afforded the alcohol **3**. Reductive desulfurization of the corresponding tetrahydropyranyl ether of **3** was performed by a two-step operation: treatment of **4** with lithium metal–ethylamine[5] at *ca.* −25 °C and subsequent reduction of the thiol **5** with Raney nickel (W-2)[6] in methanol at 25—28 °C, giving *cis*-7-tetrahydropyranyloxy-3-octene (**6**) in 84% over-all yield. Acetal exchange reaction of **6**[7] with *p*-toluenesulfonic acid–methanol and subsequent oxidation with chromic acid[8] gave *cis*-5-octen-2-one (**8**)[9] in 85% yield.

The conversion of the ketone **8** into *cis*-jasmone was achieved by Harper and Smith,[10] the preparation of dihydrojasmone from 2-octanone being established.[1] The cross-coupling of enolate anions from 2-octanone and acetone has been found to be promoted by copper(II) chloride in *N*,*N*-dimethylformamide.[11] According to the method of Ito *et al.* **8** could react with acetone to give diketone **9** in 74% yield. Refluxing of **9** in aqueous 2% potassium hydroxide afforded *cis*-jasmone in 86% yield.[12]

The *cis* double bonds of the products **8**, **9**, and **10** were analyzed by comparing their spectral data with those reported.[9,11,12] The results indicate that the *cis* double bonds of the intermediates **6** and **7** are retained during the course of conversion from **4** to **8**.



Experimental

Boiling points were indicated by air bath temperature without correction. NMR spectra were recorded on a Hitachi R-24 instrument. IR spectra were taken with JASCO model IRA-1 spectrometer. Analytical TLC was performed on commercial glass plates bearing 0.1—0.2 mm layer of Merck silica gel PF-254.

5,6-Dihydro-2H-thiopyran (1). An Inproved Method: A mixture of 4-hydroxytetrahydrothiopyran[13] (1.30 g, 11 mmol) and a catalytic amount of $KHSO_4$ was heated to 250—300 °C under N_2 for 10 min and then distilled. After work-up in the usual manner, 0.90 g (82%) of **1** was obtained; bp 74—75 °C/60 Torr (lit,[4] bp 35—36 °C/12 Torr); IR (neat) 3020 (HC=), 1652 cm^{-1}; NMR (CCl_4) δ 2.30 (m, 2H, CH_2–C=), 2.65 (m, 2H, CH_2–S), 3.04 (m, 2H, S–CH_2–C=), 5.75 (m, 2H, HC=CH).

2-(2,3-Epoxypropyl)-5,6-dihydro-2H-thiopyran (2). *s*-BuLi in pentane (1.5 M, 2.5 ml, 3.8 mmol) was added dropwise to a solution of **1** (350 mg, 3.5 mmol) in THF (15 ml) with stirring under N_2 at −78 °C for 1 h. To this mixture was added epichlorohydrin (336 mg, 3.6 mmol) with stirring at −78 °C for 1 h and at room temp for an additional 1 h. The reaction was terminated by a few drops of water. The mixture was treated in the usual manner and the residue was subjected to short-path distillation to give **2** (520 mg, 95%): bp 84—86 °C/9 Torr; IR (neat) 3024 (HC=), 1658 cm^{-1} (C=C); NMR (CCl_4) δ 3.38 (m, 1H, HC–S), 5.75 (m, 2H, HC=CH). Found:

C, 61.26; H, 7.82%. Calcd for $C_8H_{12}OS$: C, 61.50; H, 7.74%.

2-(2-Hydroxypropyl)-5,6-dihydro-2H-thiopyran (3). A THF solution (4 ml) of **2** (344 mg, 2.2 mmol) was added to a suspension of $LiAlH_4$ (100 mg, 2.6 mmol) in ether (12 ml) at 0 °C under N_2. The mixture was stirred at 0 °C for 2 h and at room temp for 11 h and quenched with water at 0 °C until a white precipitate formed. The white solid was filtered off and the filtrate was concentrated. The residue was chromatographed over silica gel (2 g) with hexane–THF (10: 1) to give **3** (340 mg, 87%): TLC R_f 0.30 (hexane–THF, 4: 1); IR (neat) 3360 (OH), 3020 (HC=), 1654 cm^{-1}; NMR ($CDCl_3$) δ 1.22 (d, J=6.5 Hz, 3H, CH_3), 1.55—1.94 (m, 2H), 2.29 (m, 2H, CH_2–C=), 2.69 (m, 2H, CH_2–S), 2.98 (s, 1H, OH), 3.41 (m, 1H, CH–S), 3.96 (m, 1H, CH–O), 5.75 (m, 2H, HC=CH). The analytical sample was prepared by short-path distillation at 50—55 °C/0.001 Torr. Found: C, 60.62; H, 9.07%. Calcd for $C_8H_{14}OS$: C, 60.72; H, 8.92%.

2-(2-Tetrahydropyranyloxypropyl)-5,6-dihydro-2H-thiopyran (4) was prepared from **3** (88 mg, 0.56 mmol) and dihydropyran (100 mg, 1.20 mmol) in benzene (2 ml) in the presence of *p*-toluenesulfonic acid (5 mg) in 89% yield: bp 67—72 °C/0.001 Torr; IR (neat) 3015 (HC=), 1652 cm^{-1} (C=C); NMR ($CDCl_3$) δ 1.20 (m, 3H, CH_3), 1.62 (m, 8H), 2.26 (m, 2H, CH_2–C=), 2.67 (m, 2H, CH_2–S), 3.17—4.20 (m, 4H, CH_2–O, CH–O, CH–S), 4.69 (m, 1H, O–CH–O), 5.73 (m, 2H, HC=CH). Found: C, 64.19; H, 9.22%. Calcd for $C_{13}H_{22}O_2S$: C, 64.42; H, 9.15%.

cis-*7-Tetrahydropyranyloxy-3-octene (6).* Lithium metal (11 mg, 1.6 mmol) was added at −25 °C to a solution of **4** (30 mg, 0.12 mmol) in $EtNH_2$ (3 ml), stirring being continued for 1 h. The mixture was quenched with water. After evaporation of the solvent, the residue was extracted with AcOEt, washed with brine, and concentrated, then subjected to column chromatography of silica gel with hexane–THF (10: 1) to give the thiol **5** (28 mg, 93%): TLC R_f 0.35 (hexane–THF, 10: 1); IR (neat) 3000 (HC=), 1654 cm^{-1} (C=C); NMR ($CDCl_3$) δ 1.16 (m, 3H, CH_3), 1.27—2.70 (m, 15H), 3.15—4.10 (m, 3H), 4.67 (m, 1H, O–CH–O), 5.41 (m, 2H, HC=CH). Without further purification a MeOH solution (2 ml) of **5** (28 mg, 0.11 mmol) was added to a suspension of Raney Ni (W-2) (60 mg) in MeOH (1 ml) over a period of 5 min at room temp. The mixture was stirred for 1 h at 25—28 °C, diluted with acetone, filtered and concentrated. The residue was chromatographed on silica gel (2 g) with hexane–THF (50: 1) to give **6** (22 mg, 90%): TLC R_f 0.62 (hexane–THF, 15: 1); IR (neat) 3040 cm^{-1} (HC=); NMR ($CDCl_3$) δ 0.95 (t, J=7.2 Hz, 3H, CH_3), 1.15 (m, 3H, CH_3), 1.30—2.33 (m, 12H), 3.20—4.07 (m, 3H), 4.69 (m, 1H, O–CH–O), 5.37 (m, 2H, HC=CH). The analytical sample was obtained by short-path distillation at 71—75 °C/1.0 Torr. Found: C, 73.36; H, 11.62%. Calcd for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39%.

cis-*5-Octen-2-ol (7).* To a MeOH solution (3 ml) of **6** (50 mg, 0.24 mmol) was added *p*-toluenesulfonic acid (5 mg) at 0 °C. After being stirred for 5 min at 0 °C, then 1.5 h at room temp the mixture was worked up in the usual manner to give the alcohol **7** (30 mg, 99%); bp 62—65 °C/13 Torr; TLC R_f 0.30 (hexane–THF, 10: 1); IR (neat) 3330 (OH), 3000 (HC=), 1652 cm^{-1} (C=C); NMR ($CDCl_3$) δ 0.96 (t, J=7.2 Hz, 3H, CH_3), 1.17 (d, J=6.2 Hz, 3H, CH_3), 1.20—2.35 (m, 7H), 3.76 (m, 1H, CH–O), 5.38 (m, 2H, HC=CH). Found: C, 75.05; H, 12.87%. Calcd for $C_8H_{16}O$: C, 74.97; H, 12.85%.

cis-*5-Octen-2-one (8).* To a solution of **7** (30 mg, 0.23 mmol) in ether (3 ml) was added aqueous chromic acid[8] (1.3 M, 0.1 ml) at 0 °C. The mixture was stirred for 30 min at 0 °C and for 1 h at room temp. The organic phase was separated and worked up in the usual manner to give **8** (25 mg, 85%); bp 110—115 °C/760 Torr (lit,[9] bp 54—57 °C/10 Torr), whose IR and NMR spectra were identical with those of the authentic compound.[9]

cis-*8-Undecen-2,5-dione (9).*[11] The compound **8** (30 mg, 0.24 mmol) was added dropwise to a solution of *i*-Pr_2NLi in THF (0.9 M, 1.3 ml, 1.2 mmol) at −78 °C under N_2. Stirring was continued for 15 min and then acetone (41 mg, 0.47 mmol) was added over a period of 10 min. The mixture was stirred for 15 min at −78 °C and then a solution of copper-(II) chloride (184 mg, 1.1 mmol) in DMF (1 ml) was added at −78 °C. The mixture was kept at −78 °C for 30 min, warmed to room temp, and stored for 30 min. The solution was poured into ice cooled aqueous 5% HCl (5 ml) and extracted with ether. The extract was worked up in the usual manner and the residue was subjected to preparative GLPC[14] to give **9** (32 mg, 74%), whose spectral data were in agreement with those of the authentic sample.[12]

cis-*Jasmone (10).* A solution of diketone **9** (20 mg, 0.11 mmol) in aqueous 2% KOH was refluxed for 3 h. After work-up in the usual manner, 17 mg (86%) of **10** was obtained, bp 105—110 °C/3 Torr (lit,[12] bp 93—97 °C/0.8 Torr), which was identified as *cis*-jasmone by comparison of the IR and NMR spectra of **10** with those reported.[12]

Geometrical Isomerism of 2,4-Dinitrophenylhydrazones of Some Pyruvic Esters

Takeo NASHIMA, Fumihide ISHIBASHI, Masayuki IWAMOTO,* Yoko AIHARA,**
Sumiko ANZAI,† and Goro YAMANO††
Department of Chemistry, Osaka Kyoiku University, Tennoji-ku Osaka 543

(Received June 16, 1976)

Synopsis. Visible, IR, and PMR spectra of 2,4-dinitrophenylhydrazones (DNPH) of some pyruvic esters were studied. It is suggested that each α-isomer with a higher R_f-value involves an intramolecular hydrogen bond between the imino hydrogen and the ester carbonyl group, to which the *Z*-structure is assigned. The *E*-structure is assigned to each β-isomer with a lower R_f-value.

Formation of various phenylhydrazones is usually utilized for the identification of pyruvic acid and its esters. The problem of geometrical isomerism of the hydrazones has been studied for many years by a number of investigators. However, only a few investigations deal with the geometrical isomerism of DNPH of pyruvic esters, *cf.* H. van Duin,[1] and P. Juvvik and B. Sundby.[2]

Van Duin[1] prepared DNPH of pyruvic esters by the reaction of the corresponding alcohols with DNPH of pyruvoyl chloride and separated two geometrical isomers of DNPH of each ester by partition column chromatography, and assigned *E*(*anti*)-structure to the isomer with the smaller retention volume (α-isomer) and *Z*(*syn*)-structure to the other (β-isomer). His assignment was based on the fact that the wavelength of the absorption maximum in the visible spectra for each α-isomer is very close to that for DNPH of normal ketones. Recently, Juvvik and Sundby[2] assigned, on the basis of the IR spectra (no data given), *E*-structure to DNPH of ethyl pyruvate obtained from the ester and the hydrazine reagent in an aqueous hydrochloric acid solution, no detail being given except for the UV-visible spectral data for the DNPH.

We report the results of the observations on the visible, IR, and PMR spectra for the geometrical isomers of DNPH of pyruvic esters. It is suggested that van Duin's assignment is inconsistent.

Experimental

Methyl and ethyl pyruvates (Sigma Chemical Co.) were distilled before use. Isopropyl and *t*-butyl pyruvates were prepared by esterification of pyruvic acid. DNPH of diethyl mesoxalate was prepared from 2,4-dinitrophenylhydrazine and the ester which was obtained by the oxidation of diethyl bromomalonate with dimethyl sulfoxide.

When DNPH of pyruvic esters were formed in an alcoholic sulfuric acid solution, followed by separation of the resulting mixture of isomers by means of column chromatography on

silica gel with benzene as an eluting solvent, the main product was the α-isomer with a higher R_f-value. On the other hand, the lower R_f-value was found for the main product of the reaction of pyruvic esters with the hydrazine reagent in a dilute aqueous hydrochloric acid solution with subsequent separation.

Results and Discussion

Melting points, elementary analyses, crystalline forms, and R_f-values of DNPH of pyruvic esters (**1**, α and β) together with those for diethyl mesoxalate (**2**) are summarized in Table 1.

The visible, IR, and PMR spectral data for **1** and, for comparison, for **2** and DNPH of acetone (**3**) are given in Table 2. We see that, (a) absorption maxima in the visible spectra for all the α-isomers lie at the longer wavelengths than those for all the corresponding β-isomers, (b) extinction coefficients at the absorption maxima for all the α-isomers are larger than those for all the corresponding β-isomers, (c) both N–H and C=O stretching bands in the IR spectra appear at wave numbers for all the α-isomers smaller than those for all the corresponding β-isomers, (d) all the α-isomers show NH signals in the PMR spectra at lower magnetic fields than all the corresponding β-isomers.

Infrared spectral data for **1**, **2**, and **3** in carbon tetrachloride at various concentrations are given in Table 3. We see that both N–H and C=O stretching bands for all the α-isomers appear at wave numbers smaller than those for all the corresponding β-isomers as in the case with Nujol mull. The observation may suggest that each α-isomer involves an intramolecular hydrogen bond between the imino hydrogen and the ester carbonyl group.

The results suggest that the *Z*-structure (**1**-*Z*) is assigned to the α-isomers and the *E*-structure (**1**-*E*) to the β-isomers. Similar suggestions were reported on the geometrical isomerism of DNPH of α-keto acids,[3,4] and of phenylhydrazones of α-keto acids,[5] pyruvamide,[6] and methyl[6] and ethyl[7] pyruvates. The assignment is just the opposite to that of van Duin. **3** gives an absorption maximum in the visible spectra at the wavelength close to those given by the α-isomers of **1** as was reported by him. However, **2** shows two absorption bands, the stronger band appearing at a longer wavelength than for **3**. Thus, the mere agreement of the wavelength, at which the maximum absorption in the UV-visible spectra occurs, cannot be taken to indicate the coincidence of geometrical structure. The IR and PMR spectral data for **2** and **3** also support our assignment (Tables 2 and 3).

Pseudohalogen Chemistry. V.[1] Homolytic Addition of Thiocyanogen Chloride to Some Haloalkenes on Irradiation with UV Light

Robert G. Guy and Ian Pearson

School of Natural Sciences, The Hatfield Polytechnic, P.O. Box 109, Hatfield, Hertfordshire, England

(Received July 5, 1976)

Synopsis. When irradiated with UV light, thiocyanogen chloride reacts with haloalkenes containing 1—4 halo substituents yielding α-chloro-β-thiocyanato compounds. Addition to unsymmetrical alkenes is regioselectively anti-Markownikov. A radical-chain mechanism, involving S_H2 displacement on the sulfur atom of thiocyanogen chloride and chlorine atoms as the adding/chain-carrying species, is proposed.

In earlier papers it was shown that, under heterolytic conditions in acetic acid, thiocyanogen chloride ($\overset{\delta-}{Cl}$–$\overset{\delta+}{SCN}$) behaves as an electrophile towards aliphatic alkenes[2] and α-arylalkenes[3] yielding α-chloro-β-thiocyanato compounds and the corresponding α-acetoxy-β-thiocyanato compounds; in the case of unsymmetrical alkenes preferential or exclusive Markownikov addition is observed.[4] Here we describe the homolytic reaction of thiocyanogen chloride with some alkenes previously shown to be unreactive under heterolytic conditions.[2-4]

Results and Discussion

UV irradiation of equimolar amounts of thiocyanogen chloride and *cis*-dichloroethylene under conditions previously shown to lead to homolytic substitution reactions with aralkyl hydrocarbons[5] (acetic acid or carbon tetrachloride solvent, an aerial atmosphere, ambient temperatures) resulted in slow reactions. Faster reactions were achieved, especially in acetic acid, by increasing the intensity of the radiation and, more strikingly, by using a nitrogen atmosphere (see Table 1).

Under these conditions, vinyl bromide, *cis*-dichloroethylene, *trans*-dichloroethylene, 1,1-dichloroethylene, trichloroethylene, and tetrachloroethylene all yielded α-chloro-β-thiocyanato compounds exclusively (see products **1**—**8** in Table 1); unsymmetrical alkenes yielded both regioisomers, with the anti-Markownikov isomer predominating in each case (see products **2**—**7** in Table 1). Reaction times and yields are recorded in Table 1. Neither tetraphenylethylene nor *trans*-1,2-dithiocyanatoethylene added thiocyanogen chloride, but, in the latter case, the recovered alkene consisted of the equilibrium mixture of *cis*- and *trans*-isomers. No telomers or crossed products, *i. e.* dichlorides or dithiocyanates, were observed.

Initiation: $ClSCN \xrightarrow{h\nu} Cl\cdot + \cdot SCN$ (1)

Addition: $Cl\cdot + \rangle C{=}C\langle \rightleftharpoons -\overset{|}{\underset{|}{C}}-\overset{|}{\underset{Cl}{C}}-\cdot$ (2)

Transfer: $-\overset{|}{\underset{Cl}{C}}-\overset{|}{\underset{\cdot}{C}}- + ClSCN \rightarrow -\overset{|}{\underset{Cl}{C}}-\overset{|}{\underset{SCN}{C}}- + Cl\cdot$ (3)

Photochemical induction of the reaction and its inhibition by aerial oxygen point towards a radical chain reaction, albeit of low chain length as indicated by the effect of the radiation intensity and the relatively long reaction times. The chemical results are consistent with the chain reaction shown in Eqs. 1—3 in which a chlorine atom, formed photochemically from thiocyanogen chloride[5] (Eq. 1), is the adding and chain-carrying species. Reversible addition of the chlorine atom to the alkene (Eq. 2), well-established in radical additions of molecular chlorine,[6] accounts for the observed isomerisation of *trans*-dithiocyanatoethylene. The transfer step (Eq. 3) involves S_H2 displacement on the electron-deficient sulfur atom of thiocyanogen chloride by the donor[7] chloroalkyl radical and the generation of a chlorine atom to carry on the chain; this accounts for (a) the exclusive formation of chlorothiocyanato compounds rather than the corresponding, thermodynamically more stable, chloroisothiocyanato compounds, (b) the preferential anti-Markownikov orientation of addition to unsymmetrical alkenes (*via* the more stable of the two possible chloroalkyl radicals), and (c) the lower rates of reaction as the donor characteristics of the chloroalkyl radical are reduced by the electronic and steric effects of further halo, thiocyanato and phenyl substituents.[7]

In contrast, homolytic additions of all other RSCl compounds examined so far have involved either exclusive displacement on the chlorine atom with RS· radicals as the adding/chain-carrying agent (*e. g.* Cl_3CSCl,[8] Cl_3CSO_2Cl,[9] F_5SCl[10]), or concurrent displacements on the chlorine and sulfur atoms with RS· and Cl· radicals respectively as competing adding/chain-carrying agents (*e.g.* F_3CSCl[11]). These differences, also noted in the homolytic substitution reactions of these compounds,[12] are consistent with the steric barrier to displacement at the sulfur atom increasing in the order $NCSCl < F_3CSCl < Cl_3CSCl$, Cl_3CSO_2Cl, F_5SCl.

Experimental

Alkenes. The haloalkenes and tetraphenylethylene were commercial samples purified until their physical constants agreed with those recorded in the literature. *trans*-1,2-Dithiocyanatoethylene was prepared as described.[13]

General Procedure. Reactions were carried out on an ≈0.4 M scale using the procedure described earlier[5] and the modifications recorded in the text and Table 1. Irradiation was continued until iodometric titrations showed at least 70% consumption of thiocyanogen chloride. Products were isolated as described.[5]

Identification of the Products. Adducts of the haloalkenes were identified as before by IR and NMR spectroscopy;[2-4] regioisomers were not separated, but isomer

The Reactions of β-Amino Enones with Hydroxylamine

Choji KASHIMA*, Yasuhiro YAMAMOTO, Yoshimori OMOTE, and Yoshihiko TSUDA

Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received August 27, 1976)

Synopsis. The reactions of *N*-substituted β-amino enones with hydroxylamine give two isoxazole isomers. The ratio of these isomers changes with the electron-withdrawing effect of the *N*-substituents.

Previously, we reported the synthesis of β-amino enones, such as 1-substituted 3-amino-2-buten-1-ones, from 3,5-dimethylisoxazole *via* 5-substituted 3-methylisoxazoles by hydrogenolysis.[1] These β-amino enones are isoelectronic with the β-diketones. Although the β-diketones exhibit behavior similar to keto and enol tautomers, the β-amino enones exhibit mainly behavior similar to amino derivatives of enones. Therefore, the reactions of β-amino enones with nucleophiles are quite interesting. Grignard reactions with β-amino enones give β-alkylated enones.[2] Also Kashima *et al.* have reported the regioselective reaction of β-amino enones with *N*-monosubstituted ureas to give 1-substituted 2(1*H*)-pyrimidinones.[3]

In the literature, it has been reported that 3,5-unsubstituted isoxazoles can be prepared from the corresponding β-amino enones and hydroxylamine.[4] However, the regioselectivity of β-amino enones in the reaction with hydroxylamine has never been reported. The reactions of 1-substituted 3-amino-2-buten-1-ones with hydroxylamine to give 3,5-disubstituted isoxazoles are presented here.

When a mixture of 5-amino-4-hexen-3-one (**4**) and hydroxylamine hydrochloride is refluxed in ethanol in the presence of potassium carbonate, two products, 3-ethyl-5-methyl- (**7a**) and 3-methyl-5-ethylisoxazole (**7b**) are expected. However, the only product was **7b** no trace of **7a** was detected in the NMR spectrum. These results suggest that the amino group of the hydroxylamine attacked the C-5 position of the amino enones as in Michael addition, and then the adducts were cyclized to isoxazoles by deamination and dehydration.

Here, the reactivity of the nucleophiles with the enones is considered to reflect the electron density at the reaction site. Fortunately, the electron densities of β-amino enones can be varied due to the electron-withdrawing effect of the acyl group on the nitrogen atom.[5] When 5-(methoxycarbonylamino)-4-hexen-3-one (**5**) and 5-(trichloroacetamido)-4-hexen-3-one (**6**) were treated with hydroxylamine under the same conditions, a mixture of **7a** and **7b** was obtained. The product ratio a/b from **6** is 3.0, while from **5** it is 0.5. From these results, it can be concluded that the product ratio a/b increases with an increase in the electron-withdrawing effect of the *N*-substituents (R').

Furthermore, various β-trichloroacetamido enones, 5-(trichloroacetamido)-1-phenyl-4-hexen-3-one (**8**), 5-(trichloroacetamido)-2,2-dimethyl-4-hexen-3-one (**10**) and 3-trichloroacetamido-1-phenyl-2-buten-1-one (**13**), were treated with hydroxylamine to give the corresponding isoxazoles, **9**, **11**, and **14**, respectively. As shown in Table, the results suggest that as the substituents, R, become more bulky, the product ratio a/b decreases.

Experimental

Materials. Using known methods, 4-amino-3-penten-2-one (**1**),[6] 3-amino-1-phenyl-2-buten-1-one (**12**)[7] and 5-(methoxycarbonylamino)-4-hexen-3-one (**5**)[5] were prepared. *N*-Acylated derivatived were also prepared from the corresponding β-amino enones and acyl chloride in pyridine.[5]

5-Amino-4-hexen-3-one (4). By hydrogenolysis in ethanol in the presence of platinum, **4** was prepared from 3-methyl-5-ethylisoxazole, recrystallized from hexane, mp 62—63 °C; yield 69%; NMR ($CDCl_3$): δ 1.18 (t, 3H, J=4.0 Hz), 1.91 (s, 3H), 2.26 (q, 2H, J=4.0 Hz), 4.99 (s, 1H), 6.2 ppm (broad s, 1H).

Found: C, 63.78; H, 9.64; N, 12.22%. Calcd for $C_6H_{11}NO$: C, 63.69; H, 9.80; N, 12.38%.

4-(Trichloroacetamido)-3-penten-2-one (2). From **1** and trichloroacetyl chloride, **2** was prepared and recrystallized from hexane, mp 74.5—75.5 °C; yield 64%; IR (KBr): 1740, 1645, 1615, 1480 cm^{-1}: NMR ($CDCl_3$): δ 2.22 (s, 3H), 2.43 (s, 3H), 5.59 (s, 1H), 13.5 ppm (broad s, 1H).

Found: C, 34.32; H, 3.23; N, 5.77%. Calcd for $C_7H_8NO_2Cl_3$: C, 34.39; H, 3.30; N, 5.73%.

5-(Trichloroacetamido)-4-hexen-3-one (6). From **4** and

trichloroacetyl chloride, **6** was prepared and recrystallized from hexane, mp 91—93 °C; yield 47%; IR (KBr): 3445, 1740, 1650, 1620, 1480 cm^{-1}; NMR ($CDCl_3$): δ 1.11 (t, 3H, J=6.8 Hz), 2.42 (s, 3H), 2.43 (q, 2H, J=6.8 Hz), 13.4 ppm (broad s, 1H).

Found: C, 37.33; H, 3.97; N, 5.56%. Calcd for $C_8H_{10}NO_2Cl_3$: C, 37.16; H, 3.90; N, 5.42%.

5-(Trichloroacetamido)-1-phenyl-4-hexen-3-one (8). From 5-amino-1-phenyl-4-hexen-3-one[1] and trichloroacetyl chloride, **8** was prepared, bp 170—176 °C/3 Torr; yield 77%; IR (liquid film): 3050, 1735, 1650, 1615, 1600, 1470 cm^{-1}; NMR ($CDCl_3$): δ 2.42 (s, 3H), 2.5—3.2 (m, 4H), 5.56 (s, 1H), 7.23 (s, 5H), 13.5 ppm (broad s, 1H).

Found: C, 50.79; H, 4.42; N, 4.18%. Calcd for $C_{14}H_{14}NO_2Cl_3$: C, 50.25; H, 4.22; N, 4.19%.

5-(Trichloroacetamido)-2,2-dimethyl-4-hexen-3-one (10). 3-Methyl-5-*t*-butylisoxazole was hydrogenated in ethanol in the presence of platinum to give 5-amino-2,2-dimethyl-4-hexen-3-one, which was recrystallized from hexane, mp 65—66.5 °C; yield; 95%; IR (KBr): 3300, 1620, 1595, 1530 cm^{-1}; NMR ($CDCl_3$): δ 1.15 (s, 9H), 1.98 (s, 3H), 5.2 (broad s, 1H), 5.23 (s, 1H), 9.7 ppm (broad s, 1H).

Found: C, 67.82; H, 10.76; N, 9.92%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92%. 5-Amino-2,2-dimethyl-4-hexen-3-one was acylated using trichloroacetyl chloride to give **10**, bp 109—113 °C/3 Torr; yield 79%; IR (liquid film): 1740, 1650, 1605, 1470 cm^{-1}; NMR ($CDCl_3$): δ 1.20 (s, 9H), 2.47 (s, 3H), 5.79 (s, 1H), 13.6 ppm (broad s, 1H).

Found: C, 41.93; H, 5.00; N, 4.82%. Calcd for $C_{10}H_{14}NO_2Cl_3$: C, 41.91; H, 4.92; N, 4.89%.

3-(Trichloroacetamido)-1-phenyl-2-buten-1-one (13). From **12** and trichloroacetyl chloride, **13** was prepared and recrystallized from hexane, mp 118—119 °C; yield 63%; IR (KBr): 1730, 1625, 1600, 1470 cm^{-1}; NMR ($CDCl_3$): δ 2.57 (s, 3H), 6.30 (s, 1H), 7.3—8.1 (m, 5H), 10.4 ppm (broad s, 1H).

Found: C, 47.07; H, 3.32; N, 4.46%. Calcd for $C_{12}H_{10}NO_2Cl_3$: C, 47.01; H, 3.29; N, 4.57%.

The Reaction of β-Amino Enones with Hydroxylamine Hydrochloride. A mixture of β-amino enone (3.2 mmol), hydroxylamine hydrochloride (8.0 mmol) and anhydrous potassium carbonate (3.9 mmol) in ethanol (10 ml) was refluxed for 6 h (in the cases of *N*-acyl derivatives, the refluxing time was 20 h). To the mixture, ether was added, and the organic layer was separated. The organic layer was washed with dilute hydrochloric acid and water, and dried over anhydrous sodium sulfate. After the solvent was removed, the product ratios were measured by the NMR spectra of the residual mixture. The products were identified from authentic samples using the spectral data.[1]

Metal Phosphinylides and Phosphinothioylides. VII.[1] The Structure of [Ph_2PX]M (X=O, S) in Solution and Their Disproportionation

Koshiro GODA, Hideyuki GOMI, Masaaki YOSHIFUJI, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 31, 1976)

Synopsis. The species [Ph_2PO]M in THF were found to exist as Ph_2P–O–M by ^{31}P-NMR, and [Ph_2PS]MgCl as Ph_2P–S–MgCl by Raman spectrum. The species [Ph_2PS]M undergo easy disproportionation by heating.

The species [Ph_2PX]M (X=O, S) have been prepared by the reaction of sodium or magnesium with diphenylphosphinic (**1a**)[2,3] or diphenylphosphinothioic chloride (**1b**)[3] (Method A) and by the reaction of butyllithium[3] or Grignard reagents[4] with diphenylphosphine oxide (**2a**) or sulfide (**2b**) (Method B).

$$\underset{\mathbf{1}}{Ph_2P(X)Cl} + M \longrightarrow \underset{\mathbf{3}}{[Ph_2PX]M} \qquad \text{(Method A)}$$

a, X=O; b, X=S

$$\underset{\mathbf{2}}{Ph_2P(X)H} + R'M \text{ (or M)} \longrightarrow \underset{\mathbf{3}}{[Ph_2PX]M} \qquad \text{(Method B)}$$

a, X=O; b, X=S

The following equilibrium is possible in a solution of **3**.

$$\underset{\mathbf{4}}{Ph_2P\text{–}X\text{–}M} \rightleftarrows \underset{\mathbf{4'}}{Ph_2P(X)M}$$

It was found from ^{31}P-NMR data that [$(EtO)_2PO$]M exists as $(EtO)_2P$–O–M in solution.[5] The present paper describes the results of a reexamination of the reactions of **1** with metals by means of ^{31}P-NMR and the structure of **3** in solution.

The reactions by Methods A and B were carried out in tetrahydrofuran (THF) at room temperature under nitrogen. The ^{31}P-NMR data are given in Tables 1 and 2. The yields of **3** were nearly quantitative based on the ^{31}P-NMR spectra, except for the case of M=MgCl in Method A (Table 1). We see that reactions of **1**, especially **1b**, with metals are very complicated,

TABLE 1. ^{31}P-NMR DATA OF REACTION MIXTURE OF **1** WITH METAL (M) IN THF (METHOD A)

M	X=O δ_P (ppm)	X=O Assignment	X=S δ_P (ppm)	X=S Assignment	Yield (%)[a]
none	−42.8	**1a**	−79.8	**1b**	
Li	−93.8	[Ph_2PO]-Li	16.2	Ph_2PPPh_2	2
			−37.0	$Ph_2P(S)$-$P(S)Ph_2$	20
			−59.8	$Ph_2P(S)SLi$	46
Mg	−17.7	[Ph_2PO]-MgCl	15.9	Ph_2PPPh_2	4
			−37.9	$Ph_2P(S)$-$P(S)Ph_2$	23
			−59.0	$Ph_2P(S)$-SMgCl	46

a) Based on the peak areas in the ^{31}P-NMR spectra.

TABLE 2. ^{31}P-NMR DATA OF [Ph_2PX]M IN THF (METHOD B)

RM or M	X=O δ_P (ppm)	X=O Assignment	X=S δ_P (ppm)	X=S Assignment
none	−22.9 (J=490 Hz)	**2a**	−20.8 (J=468 Hz)	**2b**
n-BuLi	−93.8	[Ph_2PO]-Li	−20.7	[Ph_2PS]-Li
n-BuMgCl	−90.0	[Ph_2PO]-MgCl	−14.3	[Ph_2PS]-MgCl
NaH			−22.3	[Ph_2PS]-Na
K			−25.0	[Ph_2PS]-K

indicating dimerization, desulfurization, and disproportionation of **3b**.[3] Thus, for the preparation of **3**, Method B is preferable to Method A.

The phosphorus atom in **3a** is trivalent (**4** type) in THF (Tables 1 and 2), except for the case of M=MgCl in Method A.[6] However, the structure of **3b** could not be determined, due to δ_P values being similar to those of **2b**. Thus, the Raman spectrum of [Ph_2PS]MgCl prepared by Method B was compared with spectra of some model compounds (Table 3). From the results the structure was determined to be **4** type. In the case of M=Li and Na, no Raman spectra could be obtained because of the emission of fluorescence.

TABLE 3. RAMAN SPECTRA

Compound	$\nu_{P=S}$ (cm^{-1})	ν_{P-S} (cm^{-1})
$Ph_2P(S)H$ (THF)	650	—
$Ph_2P(S)OMe$ (THF)	638	—
$Ph_2P(S)SMe$ (THF)	658	537
$Ph_2P(O)SMe$ (THF)	—	568
Ph_2PSEt (neat)	—	515
[Ph_2PS]MgCl (THF)	—	530

Easy disproportionation of **3b** was confirmed by the following experiments. Reaction of **1b** with lithium in THF at room temperature for 24 h afforded *S*-methyl diphenylphosphinodithioate (**5**) and methyldiphenylphosphine sulfide (**6**) in a ratio of 5:1 after treatment first with methyl iodide and then sulfur.

$$2[Ph_2PS]Li \longrightarrow \underset{\mathbf{5}}{Ph_2P(S)SLi} + Ph_2PLi$$

$$\downarrow MeI \qquad \downarrow MeI \qquad S_8 \downarrow MeI$$

$$\underset{\mathbf{6}}{2Ph_2P(S)Me} \qquad \underset{\mathbf{5}}{Ph_2P(S)SMe} \qquad \mathbf{6}$$

Refluxing of a mixture of **2b** and butyllithium in THF also gave **5** and **6** after a similar treatment (see Experi-

mental).

In this connection, a large contribution of metal diphenylphosphinodithioate is considered to take place in the reactions of $[Ph_2PS]M$ with THF.[7]

Experimental

^{31}P-NMR spectra were measured with a Hitachi R-20B-R-204 PB spectrometer using 85% phosphoric acid as an external standard. Raman spectra were taken with a JEOL-JSP-RS 4000 spectrometer.

Materials. Diphenylphosphinic (**1a**) and diphenylphosphinothioic chlorides (**1b**), diphenylphosphine oxide (**2a**) and sulfide (**2b**) were prepared by the methods described in a previous paper.[3] The following compounds were prepared by the reported methods: *O*-methyl diphenylphosphinothioate,[8] *S*-methyl diphenylphosphinodithioate,[9] and ethyl diphenylphosphinothioate.[10]

Preparation of S-Methyl Diphenylphosphinothioate. To a mixture of 13.4 g (57 mmol) of diphenylphosphinothioic acid and 2.5 g (63 mmol) of sodium hydroxide in 50 ml of THF was added 6 ml of methyl iodide, and the mixture was stirred for 3 h at room temperature. After washing with water and extraction with benzene, the extract was distilled *in vacuo*, bp 190 °C/0.2 Torr yield 13.0 g (92%). The distillate solidified on standing, mp 49.0—50.5 °C (from cyclohexane). IR (KBr): 1435, 1118 (P–Ph), 1202 (P=O), and 565 cm^{-1} (P–S); NMR (CCl_4): δ 2.10 (d, $J_{PSCH}=13$ Hz, 3H, SMe) and 7.2—8.0 (m, 10H, P–Ph); ^{31}P-NMR (THF): $\delta_P-38.6$ ppm.

Found: C, 62.91; H, 5.06; S, 13.05%. Calcd for $C_{13}H_{13}OPS$: C, 62.89; H, 5.28; S, 12.91%.

Disproportionation of $[Ph_2PS]Li$. A mixture of 1.405 g (6.4 mmol) of **2b**, 0.336 g (7.9 mmol) of lithium chloride, 12 mmol of butyllithium in hexane (8 ml), and 30 ml of THF was refluxed for 3 h and 1 ml of methyl iodide was added. The presence of methyldiphenylphosphine, **5**, and **6** was shown by means of gas chromatography (H 523 on Diasolid at 210 °C). Sulfur (0.38 g, 1.5 mmol) was added to the reaction mixture and the mixture was refluxed for several minutes. Only **5** and **6** were observed in the ratio 27: 73.

This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education. The authors thank Dr. Issei Harada and Mr. Shuji Imazeki for the measurement of Raman spectra.

Ullmann Condensation Reaction of Haloanthraquinone Derivatives with Amines in Aprotic Solvents

Sadao ARAI, Takamichi YAMAGISHI, Satoshi OTOTAKE, and Mitsuhiko HIDA

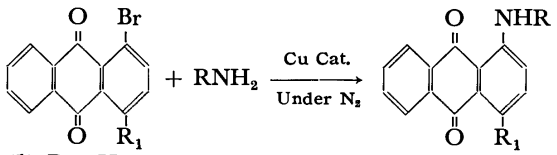
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received September 17, 1976)

Synopsis. Cuprous catalysts were more effective than cupric ones in the Ullmann condensation of haloanthraquinones with amines in aprotic media. In the presence of Cu(I) catalyst, amines with a hydroxyl group (3-amino-1-propanol and 2-aminoethanol) were more reactive than the higher basic butylamine.

In our previous papers we discussed the mechanism of the Ullmann condensation reaction of haloanthraquinones with amines.[1] The reaction rate and mechanism were found to be largely affected by the chemical structures of haloanthraquinones, amines, and ligands and by the valence state of copper catalysts.

This paper deals with the reactivities of haloanthraquinones, amines, and catalysts in aprotic media under nitrogen atmosphere.



(**1**) R_1=H
(**2**) R_1=NH_2

Results and Discussion

As shown in Table 1, cuprous salts were more effective than cupric ones. The catalytic activities of cuprous salts decreased with the increase of Cu(I)-halogen bond strength[2]: CuCl>CuBr>CuI. The reactivities of 1-bromoanthraquinone (**1**) and 1-amino-4-bromoanthraquinone (**2**) toward some kinds of amines with and without the catalyst are summarized in Table 2. Table 2 suggests that the character of the reaction is largely changed in the presence of the catalyst. Thus in the absence of cuprous catalyst the yields of the condensation products, though very low, increased with increasing basicity of the amines used. This fact can be easily understood by the nucleophilic character of this reaction.

Amines with a hydroxyl group, however, were more reactive than butylamine, stronger as a base, in the presence of cuprous bromide: butylamine<3-amino-1-propanol<2-aminoethanol. It is also noteworthy that 2-aminoethanol was more reactive toward 1-bromoanthraquinone (**1**) than toward 1-amino-4-bromoanthraquinone (**2**) in the absence of cuprous catalyst, but the reverse was found in the presence of the catalyst. Such unexpected results in the presence of the catalyst may be ascribed to the difference in the coordination of haloanthraquinones to cuprous species.

When the reactions of bromoanthraquinones with 2-aminoethanol were carried out in 1,2-dimethoxyethane by use of cuprous catalyst under nitrogen atmosphere, the blue cupric complex deposited. In 1,2-dimethoxyethane-methyl cellosolve solution the blue cupric complex did not deposit very much, since it was more soluble in this solvent. No cupric complex was formed without bromoanthraquinones.

Table 1. Comparison of the catalytic activity in the condensation of 1-bromoanthraquinone with 2-aminoethanol[a]

Catalyst	t/h	Yield (%)	Solvent
CuCl	2	21.6	THF–EtOH 4:1

$NH_2CH_2CH_2OH$	9.51	43.2	4.3	48.8	0.2

a) Reaction temp: 70 °C; Solvent: 1,2-dimethoxyethane–methyl cellosolve 4:1; [Substrate]$_0$=5×10^{-3} mol/l, [Amine]$_0$=5×10^{-1} mol/l, [Catalyst]$_0$=2×10^{-3} mol/l.

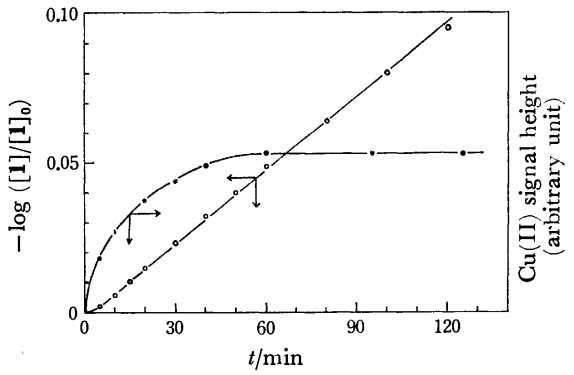

Fig. 1. Pseudo-first order plots and the time dependence of Cu(II) signal height; temp 70 °C under N_2 atmosphere, [substrate (**1**)]$_0$ 5×10^{-3} mol/l, [$NH_2CH_2CH_2OH$]$_0$ 5×10^{-1} mol/l, [CuBr]$_0$ 2×10^{-3} mol/l, solvent 1,2-dimethoxyethane-methyl cellolve 4:1.

The ESR spectra suggested that the Cu(II) species were formed[3] and their concentration increased up to a certain amount as the reaction proceeded (Fig. 1). The formation of the Cu(II) species can be understood by an electron transfer from Cu(I) to the haloanthraquinone. In the reaction system of 1-bromoanthraquinone with 2-aminoethanol using CuBr catalyst, the organic paramagnetic species, assumed to be a radical anion of 1-bromoanthraquinone, was indeed observed. As shown in Fig. 1, however, the reaction rate did not decrease in accordance with the formation of Cu(II) species, which is much less active than Cu(I) species.

The formation and the role of Cu(II) species is a very interesting and important problem of the Ullmann condensation reaction in aprotic media. Further examination of this problem will be reported in the near future.

Experimental

Materials and Solvents. 1-Bromoanthraquinone (**1**) was prepared from 1-aminoanthraquinone by Sandmeyer's bromination and purified by column chromatography on alumina (benzene as developing solvent) followed by recrystallization from benzene: λ_{max} (C_2H_5OH) 336 nm (ε 4980); mp 189.6—189.9 °C(cor) (lit, mp 192 °C[4]) (Found: C, 58.60; H, 2.20%). 1-Amino-4-bromoanthraquinone (**2**) was prepared by desulfonation of sodium 1-amino-4-bromoanthraquinone-2-sulfonate with 80% sulfuric acid. After being separated from the reaction mixture by column chromatography on alumina (benzene as developing solvent), it was recrystallized from acetic acid: λ_{max} ($CH_3OCH_2CH_2OCH_3$) 474 nm (ε 7100); mp 178.5—179.2 °C(cor) (lit, mp 170—176 °C[5]) (Found: C, 55.75; H, 2.56; N, 4.56%). 2-Aminoethanol and 3-amino-1-propanol were dried over sodium hydroxide and distilled under nitrogen atmosphere. Butylamine was dried over sodium and distilled under nitrogen atmosphere. Cuprous halides were prepared by the usual methods.[6] All solvents were purified by the usual methods and stored under nitrogen atmosphere.

Spectral Measurements. The UV and visible spectra were measured using a Shimadzu UV-200 spectrophotometer. The ESR spectra were taken on a JEOL JES-PE-3X instrument.

Reaction Procedure. A typical run is as follows. 1-Bromoanthraquinone and the solvent (THF–EtOH) were mixed in a flask. After this solution was brought to the reaction temp, the reaction was initiated by the addition of a homogeneous ethanol solution containing 2-aminoethanol and cuprous bromide. All above operations were performed under a dry and oxygen-free nitrogen atmosphere. At regular time intervals, 0.5 ml portions of the reaction solution was withdrawn and diluted in 25 ml of ethanol. The yields were determined spectrophotometrically.

Products. Products were obtained from the reaction mixture in a following manner. After the solvent was removed under reduced pressure, the reaction mixture was poured into water. After being filtered, washed with water, and dried, the precipitate was chromatographed. The separated amination product was recrystallized.

1-Amino-4-(β-hydroxyethylamino)anthraquinone: λ_{max} (C_2H_5OH) 616 nm (ε 16700); mp 195.3—196.4 °C(cor) (lit, 195—197 °C[7]) (Found: C, 67.68; H, 4.96; N, 9.63%).

1-(β-Hydroxyethylamino)anthraquinone: λ_{max}(C_2H_5OH) 503 nm (ε 6700); mp 175.6—175.8 °C(cor) (lit, 171—171.5 °C[7]) (Found: C, 71.86; H, 4.70; N, 4.99%).

1-Amino-4-(γ-hydroxypropylamino) anthraquinone: λ_{max} ($CH_3OCH_2CH_2OCH_3$) 615 nm (ε 15300); mp 211.7—212.3°C(cor); Found: C, 68.78; H, 5.43; N, 9.51%. Calcd for $C_{17}H_{16}O_3N_2$: C, 68.91; H, 5.44; N, 9.45%.

1-(γ-Hydroxypropylamino)anthraquinone: λ_{max}($CH_3OCH_2CH_2OCH_3$) 502 nm (ε 6800); mp 184.7—185.4 °C(cor); Found: C, 72.58; H, 5.37; N, 5.03%. Calcd for $C_{17}H_{15}O_3N$: C, 72.58; H, 5.37; N, 4.98%.

1-Amino-4-(butylamino)anthraquinone: λ_{max}(C_2H_5OH) 617 nm (ε 17600); mp 142.6—143.1 °C(cor); Found: C, 73.32; H, 6.01; N, 9.65%. Calcd for $C_{18}H_{18}O_2N_2$: C, 73.45; H, 6.16; N, 9.52%.

1-(Butylamino)anthraquinone: λ_{max}(C_2H_5OH) 507 nm (ε 7090); mp 85.9—86.7 °C(cor) (lit, 80—81 °C[8]); Found: C, 77.57; H, 6.20; N, 4.88%.

Acyl Cyanide. IV. The Reduction of Phenyl-substituted Carbamoyl Cyanides with Metal Hydrides

Akira Oku,* Jiro Inoue, Hiroyuki Ueda, and Fujio Mashio
Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received September 18, 1976)

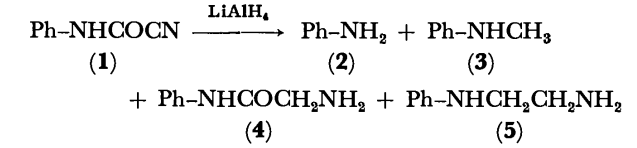
Synopsis. The reaction of phenylcarbamoyl cyanide with $LiAlH_4$ or $NaBH_4$ gave glycine anilide, *N*-phenylethylenediamine, and *N*-methylaniline. With the latter hydride, 4-amino-1,3-diphenyl-2-imidazolidinone was also formed. The reduction of diphenylcarbamoyl cyanide with $LiAlH_4$ gave *N*-methyldiphenylamine as the only reduction product.

The utilization of acyl cyanides (α-ketonitriles) as useful precursors in organic synthesis has been discussed in a number of literatures.[1] In contrast, carbamoyl cyanides, the nitrogen homologues of acyl cyanide, have not been extensively studied, and only a small quantity of information has accummulated about their chemical properties.[2]

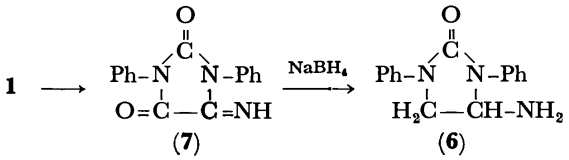
Among the chemical reactions of acyl cyanides it has been known that the reduction by lithium aluminum hydride generally gives β-amino alcohols, β-(acylamino) alcohols, or aldehydes depending on the reaction conditions.[3] Can analogous products be obtained in the reduction of carbamoyl cyanides with metal hydrides? Is there any difference between the reactions of mono- and di-substituted carbamoyl cyanides? In answer to these questions, we would like to present the results obtained from the reduction of phenylcarbamoyl cyanide (**1**) and diphenylcarbamoyl cyanide (**8**) with metal hydrides.

Results and Discussion

When phenylcarbamoyl cyanide (**1**) was treated with lithium aluminum hydride ($LiAlH_4$) in anhydrous ether, the following four products: aniline (**2**), *N*-methylaniline (**3**), glycine anilide (**4**), and *N*-phenylethylenediamine (**5**), were obtained. The time-dependent increase of **5** with a decrease in **4**, as observed by a VPC analysis, indicated that the product, **4**, was the reduction intermediate to produce **5**. In addition, the yield of **3** increased from 6 to 21% as the $[LiAlH_4]/[1]$ ratio increased from 1 to 5.



Analogously, when cyanide **1** was treated with sodium borohydride ($NaBH_4$) in tetrahydrofuran, the same products were produced. In addition, 4-amino-1,3-diphenyl-2-imidazolidinone (**6**) was isolated. The same product was also formed when 1,3-diphenyl-5-iminohydrantoin (**7**) was treated with the same hydride. Therefore, the base-induced condensation of cyanide **1** into **7** must occur under the present conditions[2a] competitively with the slow reduction. The yields of



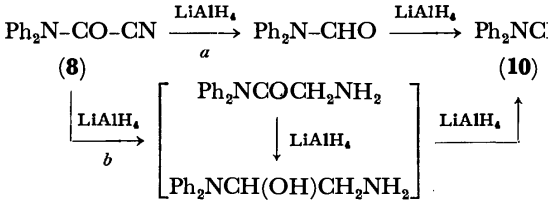
the other products depended significantly upon the reaction conditions, *i.e.*, the amounts of the reductant and additives such as $AlCl_3$,[4] and the time. For example, that the yield of aniline (**2**) decreased upon the lengthening in the reaction period indicates that **2** may be formed mainly by the hydrolysis of the unreacted **1**.[5] Indeed, the alkaline hydrolysis of **1** in aqueous NaOH proceeded very easily. However, the yield of **2** was only 30% at the maximum, and the main product was *N*,*N*′-diphenylurea. We found separately that a number of amines and alcohols induced **1** to undergo facile nucleophilic substitution.[6] Therefore, it seems reasonable that diphenylurea was formed by the reaction of **1** with aniline, which is the primary hydrolysis product of **1**.

Diphenylcarbamoyl cyanide (**8**)[7] seems to be an appropriate compound to examine in order to ascertain the difference in reaction behavior between monosubstituted (*e.g.*, **1**) and disubstituted (*e.g.*, **8**) carbamoyl cyanides. The results obtained from the reduction of **8** with $LiAlH_4$ are listed in Table 1. The only products detected by VPC were diphenylamine (**9**) and *N*-methyldiphenylamine (**10**). The former was apparently produced by the hydrolysis of **8** through the work-up process, as is evidently proved by Run 3. The latter, the only reduction product, must be formed by either Route *a* or Route *b*. Although conclusive evidence has not yet been obtained, it has been reported that

Table 1. Reduction of diphenylcarbamoyl cyanide (**8**) with $LiAlH_4$[a]

Run No.	Solvent	Product yield (%)		**8**
		Ph_2NH	Ph_2NCH_3	
1	Et_2O	38	58	0
2	THF	18	72	0
3	THF[b]	22	0	78

a) $[\mathbf{8}]/[LiAlH_4]=1.0$, 1 h each at −50 and 35 °C.
b) $LiAlH_4$ was hydrolyzed prior to the addition of **8**.



the cyanides, **1** and **8**, undergo a facile displacement of the cyano group by the appropriate nucleophiles.[3,6] Therefore, our tentative preference is Route *a*, where the displacement of the cyano group by the hydride anion takes place, as is evident in the case of acyl cyanides.[3]

Now, let us recall the reduction of **1** where *N*-methylaniline (**3**) was one of the major products. As has been reported recently,[6] cyanide **1** behaves as if it generates the phenyl isocyanate intermediate under various conditions (*i.e.*, it acts as a *carbamoylating reagent*). Also known is the reduction of phenyl isocyanate with $NaBH_4$, where **3** is the main product.[8] Nevertheless, the formation of **10** from **8** seems to present rational evidence in favor of the hypothesis that the derivation of **3** from **1** does not necessarily involve phenyl isocyanate as the intermediate.

In addition, it became evident in our study that amide carbonyl groups can undergo $NaBH_4$ reduction, at least when the vicinal substituent to the carbonyl is an unsaturated group such as CN or C=NH, though it has been our general understanding that amide carbonyls are resistant against that reagent.[9] Also proved is the transformability of the cyanocarbonyl group of carbamoyl cyanides into a methyl group by treatment with such metal hydrides as $LiAlH_4$ or $NaBH_4$.

Experimental

General. The NMR, mass, and IR spectra were taken on JEOL 4H-100, Hitachi RMU-6L, and JASCO IRA-1 spectrometers respectively. Some typical experimental procedures are shown below.

Reduction of Phenylcarbamoyl Cyanide (1) with $LiAlH_4$. To a solution of **1** (4.4 g, 30 mmol) in dry THF (100 ml) was added a suspension of $LiAlH_4$ (2.3 g, 60 mmol) in dry THF (30 ml) over a 40-min period at 5 °C. After stirring for 30 min, a mixture of THF (20 ml) and water (6 ml) was added and the decomposed mixture was filtered. The filtrate was dried over anhyd $MgSO_4$ and distilled under a vacuum. The first fraction (55 °C/3 Torr, 0.8 g) was found by VPC (Apiezon L, 10%, 1 m) to consist of aniline (**2**, 15%) and *N*-methylaniline (**3**, 10%). The third fraction (95—97 °C/1.5 Torr, 1.5 g, 37%) formed a picrate (mp 175—177 °C) which did not show any mp depression when mixed with an authentic picrate of *N*-phenylethyleneadimine. The fifth fraction (145—148 °C/1 Torr, 12 g, 27%) was a solid (mp 98—100 °C) containing a small amount of impurity with a higher mp. Therefore, the fraction was heated with Ac_2O in AcOH to give an acetylated product (98%); mp 195.5—196.5 °C (from ethanol). Found: C, 62.59; H, 6.29; N, 14.61%. Calcd for $C_{10}H_{12}N_2O_2$: C, 62.48; H, 6.29; N, 14.58%.

Reduction of 1 with $NaBH_4$. A mixture of **1** (4.4 g, 30 mmol) and dry $NaBH_4$ (1.2 g, 30 mmol) in dry THF (50 ml) was stirred for 4 h at 40 °C. The reaction mixture was poured into cold 5% NaOH, the solution was extracted with ether, and the extract was dried. After removing the solvent, the residue was analyzed by VPC to find that it consisted of **2**+**3** (22%), **4** (6.2%), and **5** (1%). After these were distilled off, the residue was chromatographed (silica gel, $CHCl_3$) to give a colorless solid of **6** (45%); mp 178 °C; P^+ (*m/e*) 253; IR (cm^{-1}) 1690 (C=O), 3400, and 3330 (NH); NMR (δ, $CDCl_3$) 1.90 (2H, bs), 3.57 (H, q, J_1=10, J_2=5.0 Hz), 4.14 (H, q, J_1=10, J_2=8.5 Hz), 5.23 (H, q, J_1=8.5, J_2=5.0 Hz), 7.0—7.65 (10H, m). Found: C, 71.35; H, 6.01; N, 16.40%. Calcd for $C_{15}H_{15}N_3O$: C, 71.12; H, 5.97; N, 16.60%.

Hydrolysis of 1 by Aq NaOH. A dioxane solution of **1** was hydrolyzed in 5% aq NaOH at 20 °C for 2 h. After a similar work-up, VPC and column chromatographic analysis of the product mixture showed it to consist of **4** (30%) and *N,N'*-diphenylurea (45%).

Reduction of Diphenylcarbamoyl Cyanide (8) with $LiAlH_4$. To a solution of **8** (2.22 g, 10 mmol) in dry ether (20 ml) was added a suspension of $LiAlH_4$ (0.4 g, 10 mmol) in dry ether (10 ml) over 10 min at −50 °C. After stirring the mixture for 1 h each at −50 and 35 °C, the mixture was decomposed under ice cooling by the addition of a cold mixture of THF (20 ml) and water (0.8 g), followed by the addition of a saturated NH_4Cl solution (30 ml). After work-up, the ethereal extract weighed 1.69 g and was analyzed by VPC (Apiezon L, 10%, 1 m, 200—250 °C). Diphenylamine (**9**, 38%, identified with an authentic sample) and *N*-methyldiphenylamine (**10**, 58%, NMR Me at δ 3.28, and by MS P^+ 183) were detectable products. See Table 1.

Treatment of 8 with Water-treated $LiAlH_4$. The same treatment of **8** as described above, but with the $LiAlH_4$ preliminarily decomposed by an equivalent mole of water, was carried out in order to examine the hydrolysis product. After work-up, the VPC of the reaction mixture proved that diphenylamine (**9**) was its only product (22%), together with the recovered **8** (78%).

The Palladium-catalyzed Phenylation of Enol Esters with Iodobenzene

Akira KASAHARA, Taeko IZUMI, and Naoki FUKUDA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

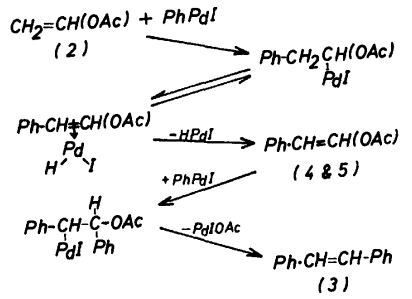
(Received October 12, 1976)

Synopsis. The palladium-catalyzed phenylation of olefins with iodobenzene has been extended to enol esters. In the presence of triethylamine and a catalytic amount of palladium acetate, vinyl acetate is phenylated with iodobenzene to produce, mainly, stilbene, accopanied by small amounts of (*E*)- and (*Z*)-styryl acetates.

Recently, the palladium-catalyzed substitution of vinylic hydrogen by aryl and vinyl halides has received wide attention.[1-5] Meanwhile, Heck[6] has reported the reaction of enol esters with the organo-palladium species generated from an arylmercury(II) compound and palladium salts. We are, therefore, intrigues by the palladium-catalyzed reaction of enol esters with iodobenzene (**1**) and wish to report herein the results of a study of this reaction.

Table 1 shows the results of the phenylation of enol esters with **1**. The reaction of vinyl acetate (**2**) with **1** gave stilbene (**3**) as the main product and (*E*)- and (*Z*)-styryl acetates (**4** and **5**) as the minor products. Since neither styrene nor acetophenone enol ester was found in the reaction mixture and since, in addition, a mixture of **4** and **5** reacted with **1** to give **3** under the same conditions, the compound **3** appears to be formed by the secondary phenylation of **4** and **5**, as despicted in Scheme 1. (Scheme 1).

The phenylation of isopropenyl acetate (**6**) gave three isomers of the diphenylated propene derivatives (**7**, **8**, and **9**) and two isomers of (*E*)- and (*Z*)-2-acetoxy-1-phenyl-1-propene (**10** and **11**). It has been reported[6] that the Heck reaction of **2** with phenylmercury(II) salt gave **4** and **5** as the main products and **3** and styrene as the minor products, while the Heck reaction of **6** afforded a mixture of **10**, **11**, and 2-acetoxy-3-phenyl-1-propene. The results obtained here indicate that the phenylation of **2** and **6** with **1** favors the formation of diphenylated olefin compounds more than the Heck reaction of **2** and **6**.



Scheme 1.

A common mechanism has been proposed for the arylation of olefins with aryl halides.[2,3] In the phenylation of **6** with **1**, the formation of 2,3-diphenyl-1-propene (**9**) may require that the phenylpalladium group is added to the double bond in both possible directions

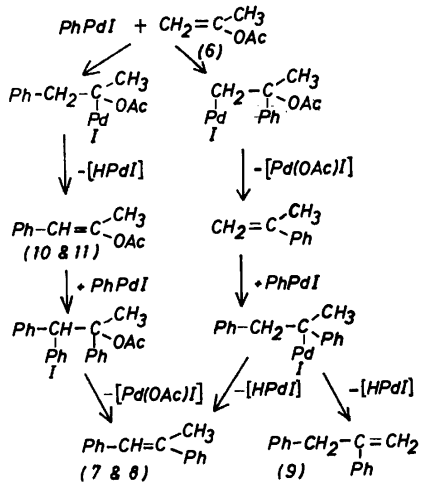


Scheme 2.

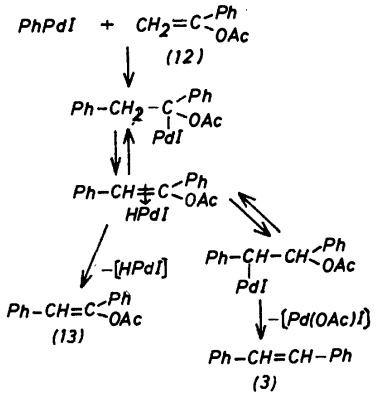
(Scheme 2).

The phenylation of acetophenone enol acetate (**12**) gave **3** and 1,2-diphenyl-1-acetoxyethene (**13**). The formation of **3** may require three intermediate steps, namely, the initial elimination, a readdition of the palladium hydride in the reverse direction, and another elimination of Pd(OAc)I, as shown in Scheme 3.

Experimental

Materials. Iodobenzene, vinyl acetate, and isopropenyl acetate of a commercial grade were used without further purification. The preparation of the following compounds has already been reported: (*E*)- and (*Z*)-styryl acetates[7] and acetophenone enol acetate.[9]

General Procedure for The Phenylation of Enol Acetate. A mixture of 2.04 g (10 mmol) of **1**, 12 mmol of enol acetate, 1.21 g (12 mmol) of triethylamine, 0.022 g (0.1 mmol) of palladium acetate, and 0.524 g (0.2 mmol) of triphenylphosphine in acetonitrile (10—15 ml) was heated in a sealed tube flushed with nitrogen at 100 °C for 8 h. The products



Scheme 3.

were isolated by diluting the cooled reaction mixtures with water and ether. The ether phase was separated, washed several times with water, dried over anhydrous magnesium sulfate, and concentrated. The products were generally analyzed by gas chromatography on a 1 m SE 30 (5% on celite) column with a Hitachi K-53 gas chromatograph, and identified by comparing the retention time on the gas chromatogram and the IR and NMR spectra with those of an authentic sample. The reactions carried out are listed in Table 1.

Carbonylation Reaction of Isoprene Catalyzed by Palladium(II) Acetate and Triphenylphosphine

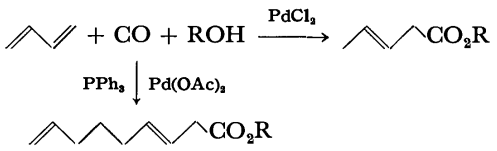
Jiro TSUJI and Hideyuki YASUDA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 4, 1976)

Synopsis. The carbonylation reaction of isoprene in alcohol catalyzed by palladium(II) acetate and triphenylphosphine gave 4-methyl-3-pentenoate selectively in a moderate yield. Unlike butadiene, no dimerization-carbonylation of isoprene to give C_{11} esters took place.

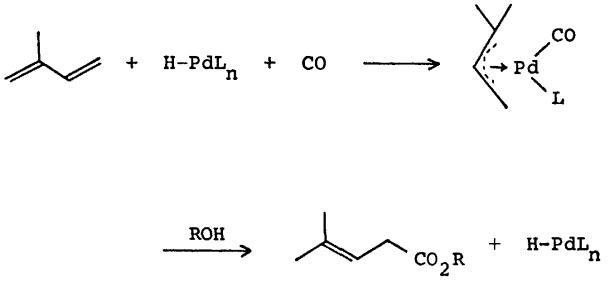
Palladium catalyzed carbonylation of butadiene in alcohol proceeds in two ways depending on the catalytic species. When palladium(II) chloride is used as the catalyst, 3-pentenoate is obtained selectively.[1] On the other hand, when halogen free palladium compounds such as palladium(II) acetate or palladium(II) acetylacetonate are used with triphenylphosphine as the catalyst, the dimerization-carbonylation occurs to give 3,8-nonadienoate exclusively.[2] Carbonylation of isoprene catalyzed by palladium(II) chloride in ethanol gave ethyl 4-methyl-3-pentenoate as the main product.[2]



In this paper we report on the carbonylation reaction of isoprene in alcohol which we carried out with use of palladium(II) acetate and triphenylphosphine as the catalyst, expecting the formation of C_{11} esters by the dimerization-carbonylation of isoprene. However, no dimerization took place, the product being a C_6 ester. The C_6 ester was a single compound with no contamination of isomeric C_6 esters. The structure of the ester was determined to be 4-methyl-3-pentenoate based on spectral data. The carbonylation of isoprene proceeded

much slower than that of butadiene under the same reaction conditions, taking roughly three times longer a period than that of butadiene. The structure of alcohols used as the reactant and solvent showed crucial effect on the carbonylation. As observed in the carbonylation of butadiene catalyzed by palladium(II) acetate, methanol was not a good solvent, hardly any carbonylation taking place in methanol. In ethanol, the ethyl ester was obtained after 60 h in 37% yield by using 1 mol % of the catalyst. *t*-Butyl alcohol seems to be an effective reactant and *t*-butyl 4-methyl-3-pentenoate was obtained as the sole product in 50% yield with 0.45 mol % of palladium(II) acetate. The ratio of palladium(II) acetate to triphenylphosphine is also an important factor, the ratio of 1: 6—7 giving the best result. With a lower ratio, palladium metal precipitated during the course of reaction. The reaction was carried out at 115 °C. A reaction temperature higher than 130 °C resulted in the decomposition of the catalyst into black palladium metal, no carbonylation taking place above this temperature.

The selective formation of 4-methyl-3-pentenoate can be explained by the following mechanism. At first the π-allyl complex is formed by the reaction of isoprene with palladium–hydride species. The selective attack of carbon monoxide at the unsubstituted side of the π-allylic complex then follows to give 4-methyl-3 pentenoate. Usually the reaction of isoprene with nucleophiles catalyzed by palladium(II) acetate and triphenylphosphine leads to the formation of a mixture of various substituted head-tail and tail-tail dimers.[3-6] It is interesting that in the carbonylation only one π-allylic complex is formed selectively, which is attacked by carbon monoxide, but not by another isoprene to lead to the dimer formation.



Experimental

A typical carbonylation reaction in *t*-butyl alcohol was carried out in the following way. A mixture of isoprene (2.72 g, 40 mmol), palladium(II) acetate (40 mg, 0.178 mmol, 0.45 mol% based on isoprene), triphenylphosphine (327 mg, 1.245 mmol) and *t*-butyl alcohol (10 ml) was put in a glass cylinder placed in a 50-ml autoclave and then carbon monoxide was introduced until the pressure reached 30 atm. The autoclave was placed in an oil bath kept at 120 °C and stirred with a magnetic stirrer. Gas absorption took place slowly. Gas chromatographic analysis of the reaction mixture showed the exclusive formation of 4-methyl-3-pentenoate and the presence of a very small amount of by-products. After 48 h, the product was subjected to distillation to give 3.40 g (50%) of *t*-butyl 4-methyl-3-pentenoate at 76—78 °C/19 Torr. NMR (CCl_4); 5.25 (m, 1, olefinic), 2.83 (d, 2, J=7 Hz, $-CH_2-CO$), 1.75, 1.64 (s, s, 6, $2CH_3$), 1.4 ppm (s, 9, *t*-Bu), IR (neat); 1715 cm^{-1}.

Similarly the ethyl ester (1.60 g, 37.6%) was obtained by the reaction of isoprene (1.98 g, 30 mmol) in ethanol (10 ml) with use of palladium(II) acetate (67 mg, 0.3 mmol) and triphenylphosphine (393 mg, 1.5 mmol) at 115 °C for 60 h. Bp 62—63 °C/18 Torr.

Gaseous Products from the Plasma Decomposition of Isomeric Xylenes

M. VENUGOPALAN and Thomas W. SCOTT

Department of Chemistry, Western Illinois University, Macomb, Illinois 61455, U. S. A.

(Received July 31, 1976)

Synopsis. The formation of methane and ethane on decomposition of the isomeric xylenes in Siemens-type discharges has been investigated. With increasing voltage the methane yield decreased, while the ethane yield increased; the C_2H_6/CH_4 mole ratios increased continuously but varied in the order *ortho*>*meta*>*para*.

A recent investigation[1] of the plasma decomposition of isomeric xylenes showed that ethane is the major gaseous product and that very little methane is formed in high-frequency (10—2450 MHz) electrical discharges. Under the experimental conditions extensive polymerization occurred.[1,2] Dimerization by elimination of hydrogen has been reported[3] to be the major reaction in low-frequency (50 Hz) electrical discharges in xylene vapors, but there is no published data on the gaseous products from such discharges.

In our preliminary investigations of isomeric xylene plasmas produced by low-frequency Siemens-type discharges significant amounts of methane and ethane were detected among the gaseous products.[4] Since methane was not a significant product in the high-frequency discharges,[1] it was desirable to re-investigate this aspect of the plasma chemistry of xylenes. In this paper we report on the yields of methane and ethane from 50 Hz xylene plasmas.

Experimental

Xylene vapor (99.9 per cent purity, Matheson Company) was pumped at a pressure of 7 Torr and a flow rate of 22 micromole s^{-1} through a 15 cm long Siemens co-axial-type Pyrex reactor with 5 mm inter-electrode separation. The plasma was produced by applying line frequency (50 Hz) high voltage from a transformer to electrodes which were (1) a thick copper wire dipping in salt solution inside the inner glass tube and (2) a thin copper wire wound outside the outer glass tube of the reactor. For the experimental conditions an approximate residence time of 0.75 s was calculated[5] for the xylene in the plasma zone where, depending on the applied voltage, 5—10 per cent of the input xylene was decomposed. The products were trapped at 77 K in a U-trap which was warmed to 215 K prior to the gas chromatographic analysis for CH_4 and C_2H_6. The analysis was performed *in situ* using a Gow-Mac chromatograph in conjunction with a 1.2 m long silica gel column at 273 K.

Results and Discussion

The yields of CH_4 and C_2H_6 found per mole of *o*-xylene entering the discharge tube are shown in Fig. 1. At the lower applied voltages the methane yield increased slightly to a maximum, but it then dereased almost linearly with increasing voltage while the ethane yield increased continuously. This behavior was less dominant in the case of the *meta* and *para* isomers

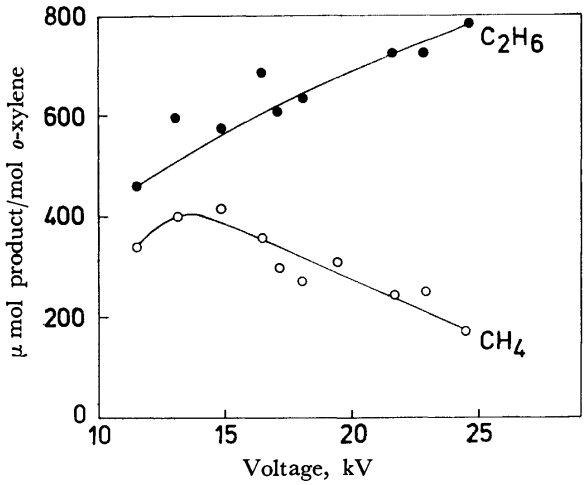

Fig. 1. Methane and ethane yields from *o*-xylene as functions of the applied voltage.

than the *ortho* isomer. The CH_4 and C_2H_6 yields varied in the order *ortho*>*meta*>*para* suggesting that these product yields depend on the proximity of the two methyl groups in the xylene molecule.

Some sort of xylene ion must form as a result of inelastic collisions between the electrons and xylene molecules in the plasma, but whether these ions or some derivative species are the reactive intermediates is not known. The energetics of xylene decomposition[6] suggests that both the C–H (*ca.* 77.5 kcal mol^{-1}) and C–C (87 kcal mol^{-1}) bonds in the xylene molecule may split under plasma conditions:

$$C_6H_4(CH_3)_2 \rightarrow CH_3C_6H_4CH_2^{\cdot} + {}^{\cdot}H \quad (1)$$

$$C_6H_4(CH_3)_2 \rightarrow CH_3C_6H_4^{\cdot} + {}^{\cdot}CH_3 \quad (2)$$

The formation of these free radicals is supported by the evidence from mass spectroscopy[7] and emission spectroscopy[8,9] of the xylene plasmas. If reaction (2) is the CH_3 radical source[10] and is followed only by the recombination reaction to form ethane

$$2\,CH_3^{\cdot} \rightarrow C_2H_6 \quad (3)$$

and the abstraction reaction to form methane

$$CH_3^{\cdot} + C_6H_4(CH_3)_2 \rightarrow CH_3C_6H_4CH_2^{\cdot} + CH_4 \quad (4)$$

then the fate of the methyl radicals produced in the xylene plasmas is somewhat exemplified by the C_2H_6/CH_4 mole ratios[11] shown in Fig. 2. The voltage dependence of the ratio suggests that reactions (2) and (3) are favored and reaction (4) is disfavored as the voltage is increased. The different ratios for the isomers at a given voltage indicate that the proximity of the two interacting methyl groups in the xylene molecule may be significant for methane production *via* reaction (4). This conclusion, however, excludes

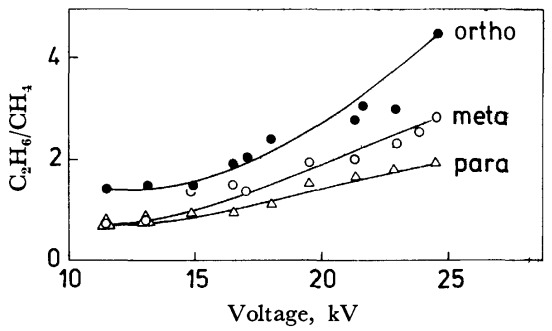

Fig. 2. Variation of the C_2H_6/CH_4 ratios with applied voltage for the three isomeric xylenes.

the loss of CH_3 radicals by their combination with $CH_3C_6H_4CH_2$ radicals to form the isomeric ethyltoluenes.

The authors are grateful to the Research Council, Western Illinois University, for a grant in support of this work.

Magnetic Properties of Oxovanadium(IV) Complexes with Bidentate ON Donor Schiff Bases*

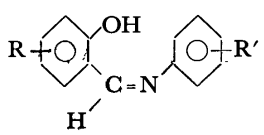
A. SYAMAL†

Department of Chemical Technology, The University of Bombay, Matunga Road, Bombay 400019, India

(Received April 27, 1976)

Synopsis. The magnetic properties of oxovanadium(IV) complexes of Schiff bases(I) are reported. Contrary to an earlier report that these complexes are involved in magnetic exchange, the complexes are found to be magnetically dilute. The complexes display μ_{eff} in the range 1.68—1.71 B. M. at 78—297 K with $\theta=2$—4 K, and exhibit 8 line ESR spectra.

The $3d^1$ oxovanadium(IV) ion belongs to $s=1/2$ system and the coupling of two $s=1/2$ spins of interacting pair of oxovanadium(IV) ions may lead to both antiferromagnetic and ferromagnetic spin-spin coupling. Many terdentate dibasic ONO or ONS donor Schiff base ligands have been utilized for the syntheses of dimeric or polymeric oxovanadium(IV) complexes with antiferromagnetic properties.[1] The terdentate dibasic character of these ligands force the oxovanadium(IV) ion to dimerise or polymerise leading to complexes with subnormal magnetic properties. The oxovanadium(IV) complexes of the bidentate monobasic, terdentate monobasic, quadridentate dibasic Schiff bases are usually magnetically dilute.[2] On the other hand, the copper(II) complexes of terdentate monobasic and quadridentate dibasic Schiff bases are usually involved in magnetic exchange.[3,4] Although most copper(II) complexes with bidentate monobasic Schiff bases are magnetically dilute, several examples of copper(II) complexes of bidentate monobasic Schiff bases involved in magnetic exchange are known.[3,4] This difference in magnetic properties has been attributed to the presence of out-of-plane magnetic interaction in copper(II) complexes. The absence of such out-of plane magnetic interaction in oxovanadium(IV) complexes is due to the non-participation of the vanadyl oxygen atom in magnetic exchange.[1] A recent cryomagnetic study[5] of an oxovanadium(IV) Schiff base complex containing a V=O···V=O··· chain indicates that the vanadyl oxygen bridges (*ca.* 170° exchange) do not contribute to the antiferromagnetic interaction due to the intraionic exchange *via* $\sigma(O_{p_z}-V_{d_{z^2}})$ or $\pi(O_{p_x,p_y}-V_{d_{xz},d_{yz}})$ pathway. In the above light one may expect that the oxovanadium(IV) complexes with bidentate monobasic Schiff bases



I. R=H, C_4H_4;
R′=H, Cl, SO_2NH_2.

will not exhibit the behaviour of antiferromagnetic exchange. However, the oxovanadium(IV) complexes of ON donor bidentate monobasic Schiff bases(I) have been reported to possess a magnetic moment of 1.54 B.M. at 297 K indicating the presence of antiferromagnetic exchange in these complexes.[6] Kuge and Yamada[7] have also prepared the oxovanadium(IV) complex of I (R=C_4H_4, R′=H) but they believe the complex to be magnetically dilute. Due to this disagreement between these two groups of workers, it was of interest to repeat the work. We report here the detailed magnetic(78—297 K), ESR and molecular weight measurements on the complexes.

Experimental

The oxovanadium(IV) complexes of I were prepared according to the method of Dutta and Sengupta.[6] However, the complexes were not recrystallised, and the complexes without recrystallisation gave satisfactory elemental analyses.

The magnetic susceptibilities of the complexes were determined by the Gouy method using mercury(II) tetrathiocyanatocobaltate(II) as the standard. Diamagnetic corrections of the metal and ligand atoms were calculated using a standard source.[8] The magnetic susceptibilities were corrected for the temperature independent paramagnetism using a value of 40×10^{-6} cgs unit. Electron spin resonance spectra were obtained with a Varian V-4502-12 X-band spectrometer using 100-kHz modulation and a 9-inch electromagnet. A minute polycrystalline sample of diphenylpicrylhydrazil (Aldrich Chemical Co., U. S. A.) free radical was used as a *g*-marker in a dual channel cavity and the frequency was monitored with the help of a frequency meter. Molecular weight measurements were made in $CHCl_3$ using a Hewlett-Packard Mechrolab Model 301 A Vapor Pressure Osmometer operating at 37 °C and calibrated with benzil.

Results and Discussion

The magnetic susceptibities and magnetic moment data of the complexes are presented in Table 1. The room temperature magnetic moments(1.69—1.71 B.M.) of the complexes are close to the spin-only value of 1.73 B.M. expected for a d^1 system. The magnetic data of the complexes indicate that the magnetic moments of the complexes remain almost constant in the temperature range 78—297 K. The complexes obey the Curie-Weiss law** with Weiss constant, θ in the range +2 to +4 K. A typical plot of reciprocal magnetic susceptibility *versus* temperature is given in Fig. 1. Thus the magnetic susceptibility data indicate the absence of magnetic exchange in

* ON represents oxygen and nitrogen donor bidentate Schiff bases(I).

these complexes. We synthesized these three complexes by several independent experiments and measured magnetic susceptibilities separately, and found deviation in the magnetic moment seldom greater than ±2%.

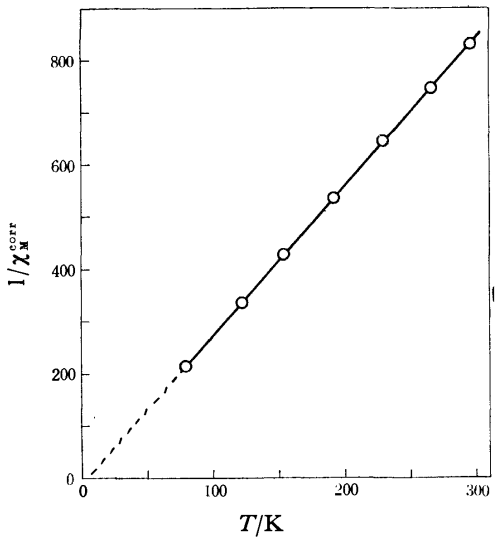

Fig. 1. The inverse magnetic susceptibility *vs.* temperature plot of VO(hydroxynaphthaldehyde-aniline)$_2$.

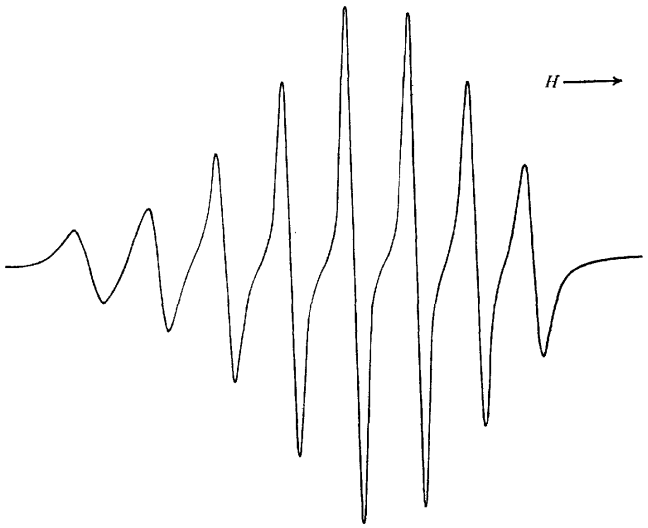

Fig. 2. The ESR spectrum of VO(hydroxynaphthaldehyde-aniline)$_2$ in chloroform.

We recorded the electeon spin resonace spectra of the complexes in dilute chloroform soution. The spectra of the complexes exhibit eight line spectra (^{51}V, I=7/2) with $g_{av}=1.98\pm0.01$ and average hyperfine splittings ⟨A⟩ around 100 gauss. A typical spectrum is presented in Fig. 2. The complexes do not exhibit any triplet state spectra ($\Delta Ms=\pm2$ transition) at around 1600 gauss. The ESR spectra of the complexes are typical of the spectra of magnetically dilute oxovanadium(IV) complexes.[2] The osmometric molecular weight measurements in chloroform solutions indicate the monomeric nature of the complexes. Thus the magnetic, ESR, and molecular weight data of the complexes indicate the absence of magnetic exchange in these complexes and the magnetic moments reported by Dutta and Sengupta[6] are in error. Our work agrees with the work of Kuge and Yamada[7] and proves conclusively that the complexes are spin-doublet species. On the basis of the experimental evdence presented a monomeric square pyramidal structure is suggested to these complexes.

Microdetermination of Furfural Using Bromine Monochloride

V. K. S. SHUKLA* and S. SHUKLA
Department of Pharmacology, M. L. N. Medical College, Allahabad, India

(Received January 29, 1976)

Synopsis. A simple micro procedure for the estimation of furfural with bromine monochloride has been presented. A 2—10 mg sample dissolved in distilled water is reacted with a known excess of bromine monochloride in acetic acid in an ice bath, and the excess reagent is back titrated iodometrically. The maximum deviation in the results is ±0.90%.

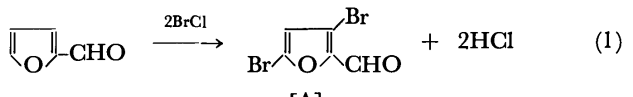
A number of methods are available for the quantitative determination of furfural depending upon the various analytical principles. Kruglikov and coworker[1] determined furfural titrimetrically with a potassium bromide-potassium bromate mixture. Spiridonova[2] reported a rapid method for the determination of furfural concentrations in non-aqueous solutions by titration with water. Similarly Nikitm and coworker[3] developed a rapid procedure for the determination of furfural by titration with water in the presence of isobutyl alcohol as a turbidity indicator. Larzlo and coworker[4] proposed a bromometric method for the determination of furfural. In the present work a new titrimetric method has been described for the microgram determination of furfural using bromine monochloride in a water-acetic acid medium.

Validity of the Reaction for the Quantitative Determination. Before applying the reaction for the determination of furfural the stoichiometry of the reaction was determined as follows: A 2—10 mg of the sample dissolved in water was reacted with a known amount of bromine monochloride solution in acetic acid. The reaction was allowed to proceed for about 15 min in an ice bath, after which the excess of the reagent was back-titrated iodometrically. Results obtained are presented in Table 1.

TABLE 1. DETERMINATION OF THE STOICHIOMETRY OF THE REACTION

Wt. of sample (mg)	Number of moles of BrCl consumed per mole of furfural
1.999	3.002
4.996	3.000
6.994	3.004
9.992	3.006

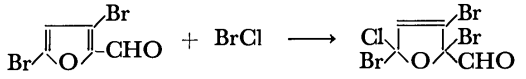
These results show that, 3 mol of BrCl are consumed per mole of furfural. The possible explanation for this is that 2 mol of BrCl are probably used for



(1)

[A]

substitution, and then this dibromination product (A) acts as diene (just as butadiene) to add one more mole of BrCl.



(2)

[A]

This is the 1,4 addition of BrCl, and probably Br will go to the carbon 2 due to the effect of the formyl group. Furan derivatives are known to undergo easy substitution (like (1)) and also to act as diene. The effect of coexistence of impurities such as other furan derivatives has not been examined.

Experimental

Procedure. An aliquot containing 2—10 mg of the sample solution in distilled water was placed in a 100 ml iodine flask. Five ml of glacial acetic acid followed by 5 ml of bromine monochloride[5] were introduced and the flask was stoppered and shaken well. The flask was placed in an ice bath and reaction mixture allowed to cool well for about 15 min. After the reaction was over the stopper was washed with 5 ml of distilled water followed by the same volume of 15% potassium iodide solution, and the liberated iodine was titrated with 0.02 M sodium thiosulfate solution using starch as an indicator. A blank experiment was also run under the identical conditions except for the use of the sample.

Results and Discussion

The proposed method has been applied for the determination of furfural, and the results of the determination are presented in Table 2. Excess of bromine monochloride should be controlled as it leads to higher results. Acetic acid is a good solvent and reaction medium for a large variety of compounds. Cooling of the reaction mixture is necessary for obtaining good results.

TABLE 2. MICRO DETERMINATION OF FURFURAL USING BROMINE MONOCHLORIDE

Sample No.	Taken (mg)	Found (mg)	No. of Determinations	Error (%)

The Synthesis of 4-Acetylaminoimidazole-5-sulfonamide and 1-Acetyl-5-acetylimidazole-4-sulfonamide

B. Robinson* and M. Uppal Zubair**,*

* *Manchester University, Oxford Street, Manchester, England*

** *Islamabad University, Islamabad, Pakistan*

(Received June 7, 1976)

Synopsis. The synthesis of mono- and di-, *N*-acetyl derivatives of 5-aminoimidazole-4-sulfonamide, from 5-nitroimidazole-4-sulfonamide, as analogues of 5-amino-1'-ribonucleotyl)imidazole-4-carboxamide, is described.

The l-ribonucleotides of several imidazoles are well-established[1] as intermediates in purine ribonucleotide anabolism, but as yet few structurally related compounds have received attention as potential anti-viral or oncolytic agents. Since one of the intermediates in *de novo* nucleic acid synthesis is 5-amino-1-(1'-ribonucleotyl)imidazole-4-carboxamide[2] (I), we have now synthesised the di- and mono-*N*-acetyl-5-amino-4-sulfonamide derivatives (II and III respectively), which by possible *in vivo* hydrolysis of the acetyl group and l-ribonucleotylation would become bioisosteric with the above-mentioned natural ribonucleotide and thereby exibit an antimetabolite relationship.

	R_1	R_2	R_3
I	$-CONH_2$	$-NH_2$	-Ribonucleotyl
II	$-SO_2NH_2$	$-NHCOCH_3$	$-COCH_3$
III	$-SO_2NH_2$	$-NHCOCH_3$	-H
IV	$-SO_2NH_2$	$-NO_2$	-H
V	$-SO_2NH_2$	$-NH_2$	-H

Many unsuccessful attempts have been made to introduce a sulfonamide moiety into the 4-position of an imidazole ring and to prepare 5-aminoimidazole-4-sulfonamide. Attempts to prepare 4-sulfonyl chlorides as potential intermediates failed[3] when imidazole-4-sulfonic acid, 2-methylimidazole-4-sulfonic acid and 5-methylimidazole-4-sulfonic acid[4] failed to react with phosphorus pentachloride, phosphorus pentachloride–phosphoryl chloride mixtures, thionyl chloride or chlorosulfuric acid.[5] Attempts to proceed *via* the sulfenamide starting from 1-methyl-4-nitro-5-mercaptoimidazole also failed,[5] as did an attempt[5] to introduce a sulfonyl chloride group directly by chlorosulfonation of 4-acetamidoimidazole. However, 5-bromoimidazole has been successfully chlorosulfonated to give 5-bromo-4-sulfonyl chloride, which was readily converted to the corresponding amide but attempts to subsequently replace the bromo substiuent by an amino group failed.[5] although unfortunately an attempt using sodamide was not made. Attempts to catalytically hydrogenate the nitro group to an amino group in 5-nitroimidazole-4-sulfonamide (IV) led only to the formation of decomposition products,[6] probably because the amino sulfonamide (V) is unstable.

We have repeated this hydrogenation with 5-nitroimidazole-4-sulfonamide (IV), under the catalytic action of platinum, at elevated temperature and pressure, in a solution of glacial acetic acid and acetic anhydride. Instead of isolating the free amine formed, which is unstable, its diacetyl derivative (II) was formed, by boiling under reflux the reaction mixture, under the atmosphere of nitrogen gas. Aqueous hydrolysis of compound (II) afforded the monoacetyl derivative, 5-acetamidoimidazole-4-sulfonamide (III). The structure of II was confirmed by its elemental analysis and by its infrared spectrum which in particular showed two carbonyl functions. The structure of III was established by its high resolution mass spectral analysis and by its infrared spectrum which showed only one carbonyl function.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. The IR spectra were recorded (solids as mulls in Nujol) with a Perkin-Elmer model 237 spectrophotometer, mass spectra were recorded with AEI MS-12 (low resolution) and MS-9 (high resolution) spectrometers.

5-Nitroimidazole-4-sulfonamide (IV). This compound was synthesised by the known method.[6]

5-Acetamido-1-acetylimidazole-4-sulfonamide (II). A mixture of IV (250 mg) and finely divided platinum (100 mg) in glacial acetic acid (5 ml) and acetic anhydride (15 ml), was hydrogenated at 50 p. s. i./50—60 °C. After hydrogen uptake had ceased (4 h), nitrogen was passed through the reaction mixture, the catalyst was rapidly removed by filteration and the filtrate was boiled under reflux for 1.5 h. After decolorisation (charcoal) the excess acetic acid and acetic anhydride were evaporated to afford a pale-yellow oil (50 mg) which crystallised from methanol to afford 5-acetamido-1-acetylimidazole-4-sulfonamide (II), as white prisms mp 250—252 °C; yield, 26 mg (8%).

Found: C, 33.9; H, 3.9; N, 22.7%. Calcd for $C_7H_{10}N_4O_4S$: C, 34.1; H, 4.0; N, 22.7%.

Mass spectrum: *m/e* 246 $(M)^+$; the infrared spectrum indicated the characteristic bands of the two carbonyl groups at 1710 and 1695 cm^{-1}.

5-Acetamidoimidazole-4-sulfonamide (III). A solution of II (25 mg) in water was boiled under reflux for 0.5 h. Evaporation of water and recrystallisation from methanol/ether afforded 5-acetamidoimidazole-4-sulfonamide (III) as white prisms; mp 220—221 °C; yield, 9 mg; 43%. High resolution mass spectral analysis showed a molecular ion at *m/e* 204.0319. Calcd for $C_5H_8N_4O_3S$ 204.031 the infrared spectrum indicated a characteristic band of a carbonyl group at 1675 cm^{-1}. The site of acetylation in this product is based[5] upon the similar partial hydrolysis of 1-

acetyl-4-acetamidoimidazole which affords 4-acetamidoimidazole.

Improvement of Zone-melting Apparatus: A New Apparatus with a High-precision Heater-temperature-controlling Mechanism

Yasuko ISHIZUKA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received March 31, 1976)

A new zone-melting apparatus with a high-precision heater-temperature-controlling mechanism has been designed and constructed. The apparatus can control the width of several melting zones at an equal temperature and thus can obtain smooth concentration profiles after zone refining. The effect of zone refining with this apparatus was examined with fair success, using phenanthrene and naphthalene as samples.

The zone-melting technique has been recognized as a useful method for purifying organic compounds, and many apparatuses for this purpose have been manufactured. Most of the automatic zone-melting apparatus have several heaters to refine the samples efficiently.[1] However, when the heater temperatures are not precisely controlled, the difference between them causes differences in the widths of the molten zones[2] and, consequently, a difference in the impurity transfer, which results in an inefficient refining. Thus, impurity concentration profiles after zone-refining experiments have bumps and are not smooth. To avoid this disadvantage, the heater temperatures must be controlled so as to have equal values in all operating zones. On the other hand, other causes of differences in the widths of molten zones over a long period of experiment, such as changes in the electric power added to the heaters, the ambient temperature, *etc.*, must also be borne in mind.

In this paper, the design and construction of a new zone-melting apparatus which has precisely controlled heaters, as well as a few results obtained by using it, will be reported.

Experimental

Heaters and their temperature controls: A unit of the heater consists of nichrome wire and the other elements shown in Fig. 1. The nichrome wire (NTK No. 3, 0.23ϕ, 110 cm length, Ishikawa Co., Tokyo) is wound around two Turner rings (22 mm o.d., 12 mm i.d. and 2 mm in thickness), and a sheet of mica is put between these two Turner rings as an electric shield. This part of heater is wound around with a glass wool ribbon and set inside two Turner lids. A chromel alumel thermocouple is inserted through a groove of the Turner lids into the inside so as to touch the glass wool ribbon. The temperature of the heaters thus constructed rise to *ca.* 440 °C if an electric voltage of 50 V is supplied.

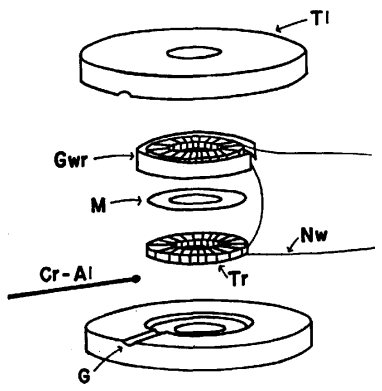

Fig. 1. Composition of a heater.
Tl: Turner lid. Gwr: Glass wool ribbon. Tr: Turner ring. M: Mica sheet. Nw: Nichrome wire. Cr-Al: Cr-Al thermocouple. G: Groove for a thermocouple.

Eighteen heaters are used in this zone-melting apparatus and are connected parallel. They are precisely controlled using eighteen thermocouples and three sets of an automatic temperature controller Model E-500 (Chino Works, Ltd., Tokyo) and a multicontroller Model P-885-6 (Chino Works, Ltd., Tokyo). The temperature of the automatic temperature controller is set 1—2 °C higher than the melting point of the sample. The heater temperature is measured for 12 s every 72 s; the electric voltage applied to the heaters is maintained until the next measurement time by means of a relay circuit memory system included in the multicontroller. When the heater temperature is lower than the setting temperature, the setting voltage which is preliminarily chosen is applied to the heater. On the other hand, when it is higher than the setting temperature, 80% of the setting voltage is applied. With this mechanism, the heater temperature is maintained constant and does decrease rapidly to temperature lower than the setting temperature, particularly for the samples with high melting points. By this mechanism the heater temperature is maintained within 100 ± 3 °C when it is set at 100 °C. This precision is mainly a result of the precision of the automatic temperature controller, Model E-500.

Apparatus: An apparatus with a device to prevent the breakage of the sample tube was previously constructed by the present author and his coworkers.[3] The new apparatus reported here is improved in several points: 1) No buffer is used to prevent the breakage of the sample tube. Instead, a vacant space which is considerably large in the sample tube and which is filled with an inert gas, is regarded as a buffer for the expansion of the sample at melting. 2) The sample tube moves twice the distance of two neighboring heaters to smooth out the difference in the performances of the two neighboring heaters which is caused by a slight difference in the structures of the heaters. 3) The sample tube rotates and the direction of rotation reverses periodically in order to stir the liquid zones vigorously.[4] 4) The sample tube moves in a slant-wise manner so as to prevent the formation of voids in the sample during the purification.[5]

A diagram of the apparatus is shown in Fig. 2. A Pyrex tube (10 mm o.d., 110 cm length) is used as a sample tube (St). 10—50 g of a sample is compactly packed into the tube, and then the tube is sealed with 1/2 atm of an inert gas. The sample tube is set so that the end filled with the sample is supported by a clamp (Cl) and the other end, filled with the inert gas, is supported by a support (S). Eighteen precisely controlled heaters (H1, H2,···, H18) and nineteen coolers (C) are alternately arranged; the distance between neighboring heaters is 5 cm. The part shown by a heavy line in

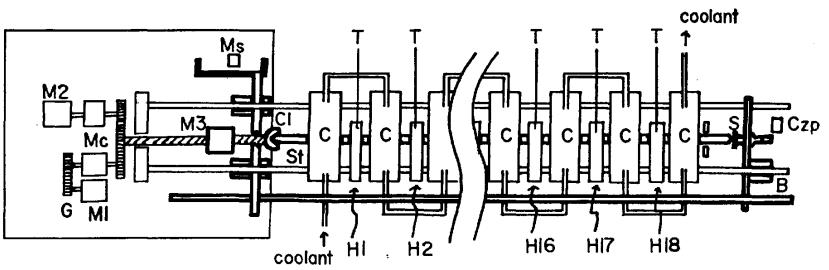

Fig. 2. Diagram of zone melting apparatus.
St: Sample tube. H: Heater. C: Cooler. T: Thermocouple. Cl: Clamp. S: Support. B: Ball bearing. Mc: Magnetic clutch. M1, M2: Motor. M3: Reversible motor. G: Gear. Ms: Microswitch. Czp: Counter for zone passes.

the figure is moved slowly 10 cm to the left by a motor (M1) and then rapidly returned to the initial position by another motor (M2). This alternating movement of the sample tube is controlled automatically by means of a microswitch (MS) and a pusher mechanism. The velocity of moving the tube to the left, which determines the solidifying velocity of the sample, can be selected by changing gears (G) at 150, 75, 50, 37.5, 30, or 18.8 mm/h. The time required for returning to the initial position is several seconds. Starting from H1 and H2, two heaters are switched on in the order of the number of heater every time the reciprocating movement stops. After all heaters are switched on, the sample tube continues the reciprocating movements for the needed time. Then two heaters are turned off in the order of the heater number every time the reciprocating movement stops until all the heaters are turned off. This mechanism of turning off the heaters makes the number of zone passes equal at every point of a refined sample. To stir the melted part of a sample, the sample tube is rotated around the axis of the tube by means of a reversible motor (M3, 100 r.p.m.), and the direction of the rotation is periodically reversed every 1, 1/2, or 1/3 s.

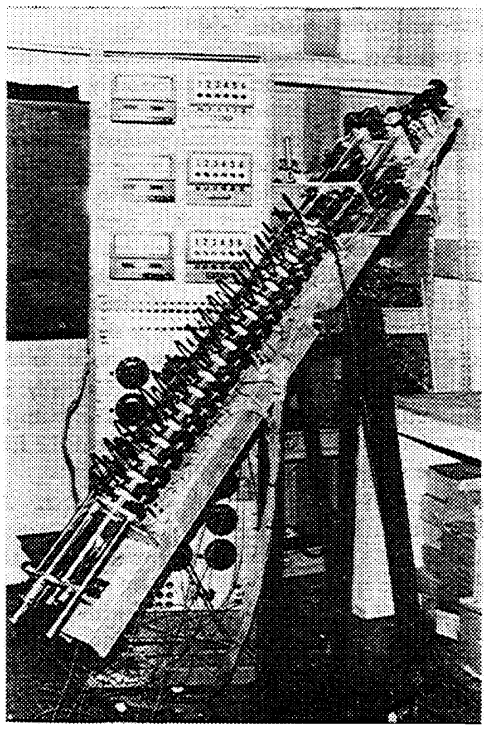

Fig. 3. Zone melting apparatus.

Figure 3 shows the temperature-controlled zone-refining apparatus in the front part and the controlling part in the rear part. The apparatus operates in a slant posture so as to make the vacant space of the sample tube higher than the sample. The slanting angle is continuously changed.

Results and Discussion

The zone-refining performance of the new apparatus was examined with two samples, naphthalene and phenanthrene. In both experiments the solidifying

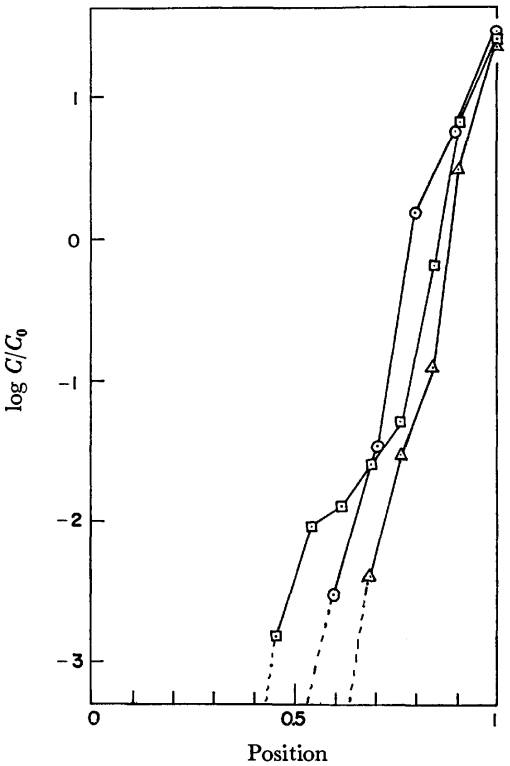

Fig. 4. Concentration (C) of 2-methylnaphthalene in the naphthalene sample after the zone refining. As for the abscissa the total sample length was regarded as 1.0 and each sample position was measured from the vacant space side. Initial concentration (C_0) was 1%. Detectable limit was 5 ppm.
—○—: 9 zone passes with the apparatus reported here.
—△—: 20 zone passes with the apparatus reported here.
—□—: 60 zone passes (33 mm/h solidifying speed) with the apparatus reported previously.[3]

velocity was kept at 50 mm/h, the slanting angle to a vertical line, at 50°, and the reversing cycle of the rotation, at 2 cycle/s.

2-Methylnaphthalene was doped in naphthalene (Kokusan Chemical Works Ltd., Tokyo) as an impurity so that the concentration of the impurity was 1%. The quantity of 2-methylnaphthalene in the refined sample was examined by means of a gas chromatograph equipped with F.I.D. A sample solution for the gas chromatograph was prepared using 200 mg of the refined samples taken every 5 cm starting from the vacant space side. As is shown in Fig. 4, the 2-methylnaphthalene in the naphthalene sample moves in the same direction as the movement of the melting zone. After only 9 zone passes, the concentration of the impurity decreases to less than 5 ppm in the first 40% of the naphthalene sample, starting from the vacant space in the sample tube, and then increases smoothly for the next 60% of the sample. Figure 4 also shows that naphthalene is more effectively refined with the new apparatus than with the apparatus previously reported.[3]

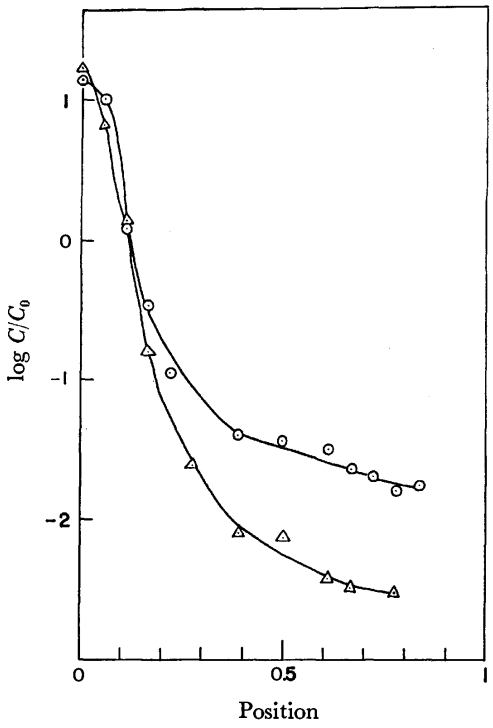

Fig. 5. Concentration (C) of anthracene in the phenanthrene sample after the zone refining. The abscissa is the same as explained in Fig. 4. Initial concentration (C_0) was 1%.
—○—: 304 zone passes, —△—: 774 zone passes.

The phenanthrene sample (Tokyo Kasei Kogyo Co., Ltd., Tokyo) includes 1% anthracene as a major impurity. The concentration of anthracene in the zone-refined sample is examined by means of the absorptivity of a 379 nm band of anthracene in a benzene solution. In this case, 100—250 mg of the refined sample, cut in the same way as the naphthalene sample, is used to make the benzene solution. Figure 5 shows the results after 304 and 774 zone passes. In this case, the impurity moves in the direction opposite to the movement of the melting zone. Both results show that phenanthrene samples are effectively refined and that anthracene as the impurity is smoothly distributed. In the 0.8—1 range in the figure, the phenanthrene samples are colored by other impurities.

The equal widths of the melting zones resulting from the equal temperatures realized by the high-precision controlling mechanism of the heater temperatures and the reverse rotation of a sample tube make the efficient refining possible. With this new apparatus, organic materials with high melting points can be refined effectively without the breakage of the sample tube.

The author wishes to thank Dr. Y. Mashiko, Mrs. N. I. Wakayama, and Mr. I. Takeda of this laboratory for their valuable advice.

The author is also indebted to Mr. K. Tsuji of the Institute for Solid State Physics, the University of Tokyo, for his valuable advice and technical help in the construction of the apparatus.

The Detemination of the Formation Constants of the Triiodide Ion in Water-Alcohol Mixed Solvents at Various Temperatures

Katumitu HAYAKAWA and Sumio NAKAMURA

Department of Chemistry, Faculty of Science, Kagoshima University, Koorimoto, Kagoshima 890

(Received April 26, 1976)

The formation constants of the triiodide ion were determined in water–alcohol mixed solvents by a spectrophotometric method at various temperatures. The formation reaction of the triiodide ion from an iodide ion and an iodine molecule is accompanied by a negative enthalpy change and a positive entropy change at various alcohol contents: $\Delta H°$/kJ mol^{-1}, −15.4 (in water) to −14.3 (in methanol) in the water-methanol system, −15.4 (in water) to −21.4 (in ethanol) in the water-ethanol system; $\Delta S_x°$/J K^{-1} mol^{-1}, 36 (in water) to 57 (in methanol) in the water-methanol system, and about 36 at various ethanol contents in the water–ethanol system. The enthalpy term is the dominant factor in the water-ethanol mixtures, whereas the entropy term is the dominant factor in the water-methanol mixtures. In order to explain the thermodynamic behavior, the changes in the solvation properties as well as the activity coefficients of solutes must be considered in both the mixture systems.

During the course of an investigation of the effect of solvents on the rate of the oxidation of the formate ion by iodine, it became necessary to know the formation constant of the triiodide ion in mixed solvents at various temperatures. Although the formation constant has been determined in some mixed solvents[1,2] and some organic solvents[3,4] at 25 °C, it has not been determined at various temperatures in mixed solvents. The present work was undertaken in order to determine the values of the formation constant in water–alcohol mixed solvents at various temperatures. The formation constant varies with the composition of the solvents, and it has been found that the variation in the solvation properties influences the formation constant of the triiodide ion.

Experimental

Materials. The iodine, potassium iodide, ethanol (99.5%), and methanol (99.5%) were obtained from Wako Pure Chemicals Industries. The ethanol was of Wako's super special grade, while the other chemicals were of a guaranteed grade. The solutions of the iodine were prepared by dissolving exactly weighed amounts of iodine purified by sublimation in the potassium iodide solution. The presence of iodide lowers the reactivities of iodine with solvents. The potassium iodide used was dried at 120 °C overnight, and the solutions were prepared by dissolving exactly weighed amounts of the salt in mixed solvents. The water used was double-distilled from potassium permanganate in an all-glass apparatus.

Measurements. The absorbance at 355 nm was measured by using a Hitachi 101 spectrophotometer with quartz cells with a light-path length of 10 mm in a thermostated holder, and using a Valhalla Scientific digital multimeter, Model 4440, as the digital output at various temperatures. The pH and the ionic strength in the solutions were uncontrolled.

The Determination of the Formation Constant of I_3^-. The formation constant of the triiodide ion was calculated from the dependence of the absorbance at 355 nm on the concentration of the iodide of the solution containing a constant concentration of iodine (*ca.* 25×10^{-6} mol dm^{-3}).

For Reaction 1, the apparent formation constant, K_c, is given by Eq. 2:

$$I_2 + I^- \rightleftarrows I_3^- \quad (1)$$

$$K_c = [I_3^-]/[I_2][I^-] = x/(a-x)(b-x) \quad (2)$$

where the brackets represent the respective concentrations, a and b are the total concentrations of iodine and potassium iodide respectively, and x is the equilibrium concentration of the triiodide ion. As potassium iodide does not absorb the light at 355 nm, the absorption coefficient at 355 nm, $A(\equiv D_1/l)$, is given by Eq. 3:

$$A = \varepsilon_0(a-x) + \varepsilon_1 x \quad (3)$$

where ε_0 and ε_1 are the molar absorption coefficients of iodine and the triiodide ion respectively, at 355 nm. From Eqs. 2 and 3,

$$\bar{\varepsilon} \equiv A/a = \varepsilon_0 + K_c b(\varepsilon_1-\varepsilon_0)/[1+K_c(a-x)+K_c b] \quad (4)$$

As b is much larger than $(a-x)$ in the present measurements, and as ε_1 is much larger than ε_0 at 355 nm,

$$1/\bar{\varepsilon} \approx (1/\varepsilon_1 K_c)(1/b) + 1/\varepsilon_1 \quad (5)$$

Therefore, K_c and ε_1 can be calculated by the intercept and slope of the $1/\bar{\varepsilon}$ *vs.* $1/b$ plot. All the plots were linear in various mixed solvents at $b \gg a$, and the intercept of each line was almost independent of the temperature.

Results and Discussion

The iodine solution in methanol and ethanol has an absorption band with a maximum absorbance near 355 nm.[1,5] However, the absorbance at 355 nm is not proportional to the concentration of iodine. This band is ascribed to a small amount of the triiodide ion formed by the reaction of iodine with alcohol.[5,6] The formations of I_5^-, I_7^-, I_9^-, *etc.* are neglected because of the low concentration of iodine in the present work (for example, $\log([I_5^-]/[I_2]^2[I^-]) = 1.8$ in ethanol[2]).

In aqueous solutions, Reaction 1 is accompanied by Reactions 6 and 7:[7-10]

$$I_2 + H_2O \rightleftarrows HIO + I^- + H^+ \quad (6)$$

$$3I_2 + 3H_2O \longrightarrow IO_3^- + 5I^- + 6H^+ \quad (7)$$

At pH≈7, Equilibrium 6 may be neglected.[9,10] Reaction 7 is sufficiently slow in the presence of excess potassium iodide.[9] In fact, the absorbance at 355 nm did not vary for 24 h in an iodine solution containing an excess of potassium iodide.

Table 1 gives the values of the apparent formation constants of the triiodide ion, K_c. The constant increases when the temperature is lowered and the alcohol content is increased. The values of K_c obtained in the present work are compared with those of other workers in

Fig. 1. Ramadan *et al.*[1] assigned the absorption bands at 360 and 294 nm to the iodine molecule, and obtained the molar absorption coefficient of the iodine molecule, ε_0, from the absorbance of the iodine–alcohol–water systems. However, this assignment is questionable, because the absorbances at 360 and 294 nm are not proportional to the concentration of iodine. The absorption bands may be ascribed to a small amount of the triiodide ion formed by the reaction of iodine with the alcohol.[6] The difference between the present results and those reported by Barraqué *et al.*[2] (Fig. 1) may be attributed to the difference in methods. Barraqué *et al.* used a potentiometric method.

Table 2 gives the values of the standard thermodynamic functions, $\Delta H°$, $\Delta S_c°$, and $\Delta G_c°$, of Reaction 1 and the molar absorption coefficient, ε_1, of the triiodide ion. In order to compare the formation constant in mixed solvents, it is necessary to use a measure which is independent of the conventional scale. For a solute A, the chemical potential, μ(A), is represented by either Eq. 8 or Eq. 9:

$$\mu(\mathrm{A}) = \mu_c°(\mathrm{A}) + RT\ln(C_\mathrm{A}/C°) + RT\ln y_\mathrm{A} \quad (8)$$

$$\mu(\mathrm{A}) = \mu_x°(\mathrm{A}) + RT\ln x_\mathrm{A} + RT\ln f_\mathrm{A} \quad (9)$$

where x_A is the mole fraction of A, C_A is the concentration of A, y_A, and f_A are the activity coefficients in

Table 2. The equilibrium characteristics and the absorption coefficient of the formation of triiodide in water–alcohol mixed solvents at 25 °C

a) At 355 nm.

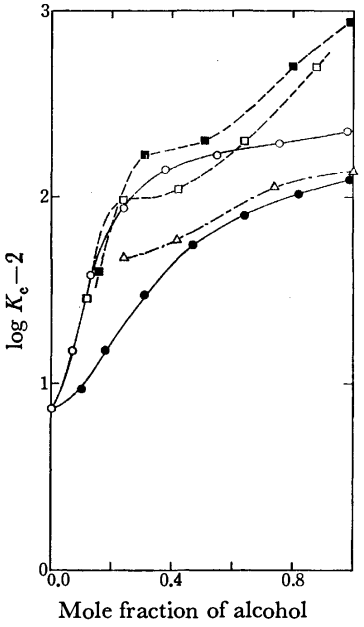

Fig. 1. Effects of the alcohol content on the formation constant of the triiodide ion at 25 °C. Open marks: water–ethanol mixture, closed marks: water–methanol mixture. Circle: the present work, square: by Ramadan *et al.*,[1] Triangle: by Barraqué *et al.*[2]

the respective concentration scale, and C° is the standard concentration, selected as 1 mol dm^{-3} in the present work. At an infinite dilution,

$$\mu_x^\circ(\mathrm{A}) = \mu_c^\circ(\mathrm{A}) + RT\ln\{(C_\mathrm{A}/C^\circ)/x_\mathrm{A}\} \quad (10)$$

Since $x_\mathrm{A} \approx C_\mathrm{A}(x_\mathrm{B}M_\mathrm{B} + x_\mathrm{C}M_\mathrm{C})/\rho$ in the B–C mixed solvents,

$$\mu_x^\circ(\mathrm{A}) = \mu_c^\circ(\mathrm{A}) + RT\ln\{\rho/(x_\mathrm{B}M_\mathrm{B} + x_\mathrm{C}M_\mathrm{C})C^\circ\} \quad (11)$$

where M_B and M_C are the molar masses of B and C respectively, while ρ is the mass of the 1 dm^3 solution. Since $\Delta G_c^\circ = \mu_c^\circ(\mathrm{I_3^-}) - \mu_c^\circ(\mathrm{I_2}) - \mu_c^\circ(\mathrm{I^-})$ for Reaction 1,

$$\Delta G_x^\circ = \mu_x^\circ(\mathrm{I_3^-}) - \mu_x^\circ(\mathrm{I_2}) - \mu_x^\circ(\mathrm{I^-})$$
$$= \Delta G_c^\circ - RT\ln\{\rho/(x_\mathrm{B}M_\mathrm{B} + x_\mathrm{C}M_\mathrm{C})C^\circ\} \quad (12)$$

Since $\Delta H_c^\circ = \Delta H_x^\circ (= \Delta H^\circ)$ and $\Delta S_c^\circ = (\Delta H_c^\circ - \Delta G_c^\circ)/T$,

$$\Delta S_x^\circ = (\Delta H_x^\circ - \Delta G_x^\circ)/T$$
$$= \Delta S_c^\circ + R\ln\{\rho/(x_\mathrm{B}M_\mathrm{B} + x_\mathrm{C}M_\mathrm{C})C^\circ\} \quad (13)$$

Table 2 shows also the values of ΔG_x° and ΔS_x° at 25 °C.

Figure 2 shows the dependence of these quantities on the mole fraction of alcohol. The values of ΔH° are nearly constant in the methanol–water mixtures, whereas in the ethanol–water mixtures they increase remarkably on the addition of the first portions of ethanol and become nearly constant beyond the 0.4 mol fraction. On the other hand, the values of ΔS_x° are nearly constant in the ethanol–water mixtures, while they increase in the methanol–water mixtures. The values of ΔS_c° increase with the ethanol content, whereas those of ΔS_x° are constant (Table 2). The increase in ΔS_c° may be due to the neglect of the entropy change on the mixing of the solvents.

Two factors can explain the variations in ΔS_x° and ΔH° with the alcohol content: one is the variation in the activity coefficients of the solutes with the alcohol content, and the other is the variation in the solvation properties with the alcohol content. The activity

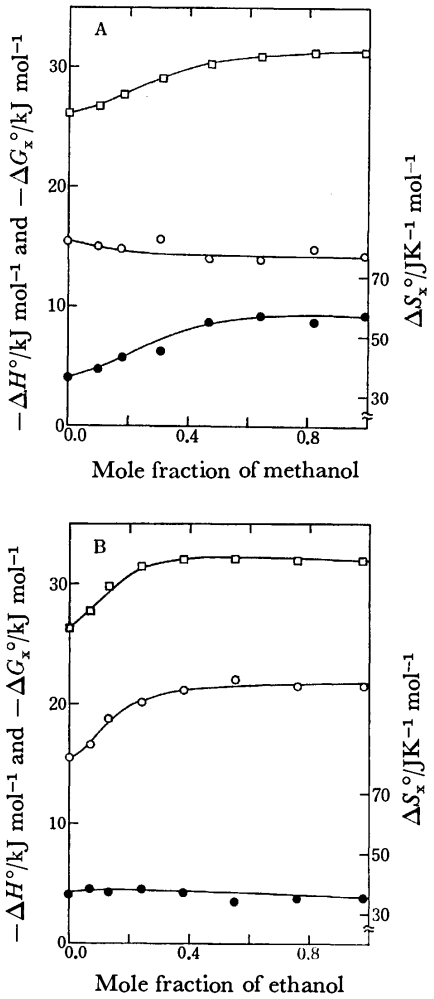

Fig. 2. The standard thermodynamic functions of the formation of the triiodide ion in water–alcohol mixed solvents. A: water–methanol mixtures, B: water–ethanol mixtures. □: ΔG_x°, ○: ΔH°, ●: ΔS_x°.

coefficients of $\mathrm{I_3^-}$ and $\mathrm{I^-}$ are nearly the same in a given solvent, because the two ions are univalent. The activity coefficient of $\mathrm{I_2}$ will be close to unity because it is a neutral molecule. Even if the activity coefficient varied from 1.0 to 0.5 with the alcohol content, the difference in ΔG_x° would be only about 2 kJ mol^{-1}. Thus, the activity coefficients of solutes cannot explain the effects of the solvent on ΔG_x°.

Next, the variation in the solvation properties, such as the structure of the solvation shell and the specific solvation, must be considered in both the mixture systems. ΔH° and ΔS_x° in Fig. 2 reflect the solvation energy of each solute and the structure of the solvation shell of each solute respectively, because μ_x° is based on the infinite dilution. For example, the curves of ΔH° in Fig. 2 indicate that the difference in the solvation energy between the reactants and the product in Reaction 1 is nearly constant in the methanol–water system, while it increases on the addition of a small amount of ethanol to water in the ethanol–water system. Ramadan *et al.*[1] ascribed the marked change in K_c by the addition of a small amount of organic solvents to the rearrangement of the structure of the solvent and a subsequent change in its solvation properties. In order

to make it clear why ΔS_x° is the dominant factor in the methanol–water system, while ΔH° is the dominant factor in the ethanol–water system, we need to know the structure of the solvation shell of each solute and the transfer-free energy of the solutes in various solvents. Thus, in order to explain the thermodynamic behavior of Reaction 1 in the two mixture systems, the changes in the solvation properties as well as the activity coefficients of the solutes must be considered.

An ESR Study of the 4,4′-Difluorobiphenyl Cation Radical*

Fujito NEMOTO, Kazuhiko ISHIZU, and Fumio SHIMODA**

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received May 10, 1976)

The ESR spectra of the 4,4′-difluorobiphenyl cation show resolved second-order splittings and a marked line-broadening attributable to the modulation of the ^{19}F anisotropic hyperfine interactions by the tumbling motion. This dipolar broadening is mainly observed for the lines associated with the triplet state ($I=1$) of the two equivalent ^{19}F nuclei. When the temperature is lowered, the wings of the triplet due to the two ^{19}F and the downfield second-order components become broad and finally disappear. The dipolar contributions to the line widths are calculated as a function of the correlation time for the molecular motion, τ_2. Furthermore, the ESR observation of the ^{13}C hyperfine structures is carried out, and the spin densities on each ring carbon and the fluorine atoms are experimentally determined. From the spin densities thus determined, the parameters in the equation

$$a_F = Q^F_{CF}\rho^\pi_C + Q^F_{F(FC)}\rho^\pi_F,$$

in which the ^{19}F hyperfine coupling constant is correlated to the π spin densities on the fluorine atom and the adjacent carbon atom, are estimated to be $Q^F_{CF}=39$ and $Q^F_{F(FC)}=324$ G.

Recently there have been a number of ESR and NMR studies of fluoro-substituted alkyl and aromatic radicals in solution. The objectives of these studies may mainly be classified as follows; (1) The ESR spectra of fluoro-substituted radicals show a viscosity-dependent selective line-width effect due to a relaxation process brought about by the modulation of the relatively large anisotropic fluorine splitting by the tumbling motion. The information about the motion of molecules in solution was extracted from the analysis of their temperature-dependent selective line width. The fluorinated alkyl radicals ordinarily have simple ESR spectra and show large fluorine hyperfine coupling constants, so that the line width of the spectra can be determined with great precision. Consequently, the temperature dependence and selective variations in line widths were studied in detail for fluorinated alkyl radicals.[1-3] There has been no detailed study of the fluoro aromatic radicals, however, because of the small values of the ^{19}F hyperfine splitting. (2) The hyperfine coupling constants, a_F, of fluorine atoms in fluoro-substituted aromatic radicals depend on both the spin density, ρ^π_C, at the adjacent carbon atom and the spin density, ρ^π_F, at the fluorine atom. There have been numerous investigations of the fluoro aromatic radicals, and a consistent functional relationship between the isotropic fluorine splitting and the π spin densities has been proposed.[11-19] Mainly, two types of equations have been examined;

$$a_F = Q^F_{CF}\rho^\pi_C \quad (1)$$

$$a_F = Q^F_{CF}\rho^\pi_C + Q^F_{F(FC)}\rho^\pi_F \quad (2)$$

Here, Q^F_{FC} is the π–σ contribution analogous to that of the aromatic C–H fragment. $Q^F_{F(FC)}$is the contribution from the π–σ polarization of the 1s and 2s electrons of fluorine by the spin density centered on the $2p_\pi$ orbital of fluorine.

The results of the ESR and NMR investigations indicate that the simple linear relationship, Eq. 1, may be inadequate to describe the data of fluorinated compounds. Equation 2 seems more realistic than Eq. 1 in that it allows for conjugation on the fluorine $2p_\pi$ orbital with the π electrons in the aromatic ring. The previously determined values of Q's in Eq. 2 are, however, scattered over a wide range because the π fluorine spin densities are usually not obtained by solution ESR studies; the simple LCAO MO approach to the calculation of the ρ^π_F is, then, not necessarily valid.

In the present paper, we wish to report the results of ESR studies of the 4,4′-difluorobiphenyl cation radical. The value of the ^{19}F hyperfine coupling constant is quite large (19.20 G) compared with those of the fluoro aromatic radicals, and a second-order splitting of ^{19}F and a temperature-dependent broadening of ^{19}F splitting were observed. Furthermore, the spin densities on each ring carbon and fluorine atom were experimentally determined based on the observation of the ^{13}C hyperfine splittings for ring carbons, and the Q values of Eq. 2 were discussed.

Experimental

4,4′-Difluorobiphenyl (mp 88—89 °C) was synthesized and recrystallized from ethanol. The cation radicals was generated by $SbCl_5$ oxidation in CH_2Cl_2 in a manner described before.[7] The ESR spectrum of the 4,4′-difluorobiphenyl cation radical was observed using a JEOL-ME-3X spectrometer operating with a 100 kHz magnetic field modulation. The magnetic field was calibrated by means of a perylene cation radical prepared in concentrated sulfuric acid.

Results and Discussion

Temperature-dependent Line Broadening of the ^{19}F Splittings. The high-resolution ESR spectrum of the 4,4′-difluorobiphenyl cation radical was observed in the temperature range from −90 to +20 °C. The spectrum observed at +10 °C is shown in Fig. 1-a. This spectrum consists of a large triplet of 19.20 G due to two ^{19}F nuclei (a_F), each line of which splits into a quintet of 2.76 G due to the four ring ortho-protons (a^H_2)[8]; the central component ($I_z=0$ lines) of the triplet further splits, by means of the second-order effect, into a doublet of 250 mG corresponding to the possible values ($I=1$, 0) of the resultant nuclear angular momentum for the two

* A Part of this work has been previously pulbished as a communication: F. Nemoto, F. Shimoda, and K. Ishizu, *Chem. Lett.*, **1975**, 567.

** Present address: Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730.

equivalent ^{19}F nuclei. As is well known, the second-order splitting of the $I_z=0$ component of the first-order triplet is $(a_F)^2/H_0$, where H_0 is the position of the center of the spectrum.[6] The expected value of $(a_F)^2/H_0$ is about 100 mG, taking $a_F=19.20$ and $H_0=3300$ G, but the observed splitting is larger than that theoretically expected. This is probably due to the line broadening attributed to the modulation of the ^{19}F anisotropic hyperfine interactions as a result of the tumbling motion, which makes the accurate measurement of the hyperfine splittings difficult.

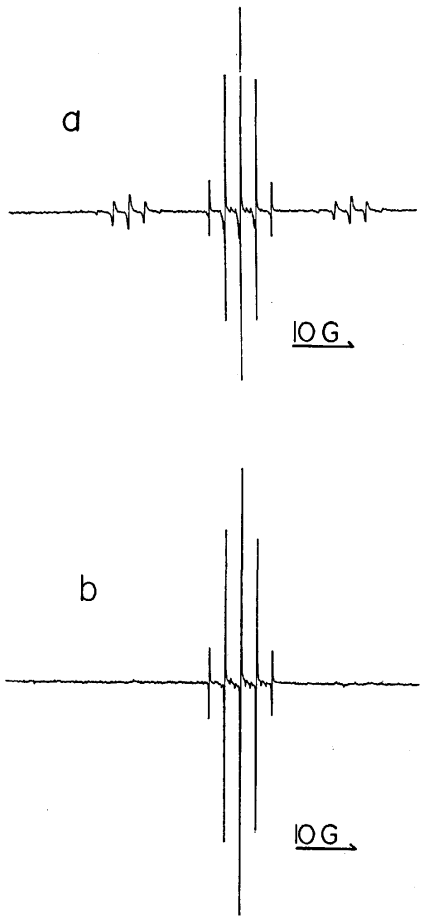

Fig. 1. The ESR spectra of 4,4'-difluorobiphenyl cation radical. a) +10 °C. b) −80 °C.

Upon a lowering of the temperature, the wing lines of the triplet due to the two ^{19}F, and the downfield second-order components ($I=1$, $I_z=0$) become broad and finally disappear, while the central quintet ($I=0$ lines) is unaffected, as is shown in Fig. 1-b.

For organic radicals in solution, it is well known[1-3] that the line width variations in the various second-order components are mainly due to a relaxation process brought about by the modulation of the anisotropic hyperfine coupling tensor by rotational Brownian motion; this theory is well established.[4,5]

The dipolar contribution to the line width of the (I, I_z) hyperfine components can be calculated as a function of the molecular rotational correlation time τ_2, using a spin Hamiltonian for a system undergoing dipolar relaxation.

Assuming a set of completely equivalent ^{19}F nuclei with an axially symmetric hyperfine tensor, the main term of the dipolar contribution to the line width is given by:[4,5]

$$T_{2d}^{-1} = \frac{A_{//}^2}{40}[(3I(I+1)+5I_z^2)J_0+(7I(I+1)-I_z^2)J_1] \quad (3)$$

where $J_0=\tau_2$, $J_1=\tau_2(1+\omega^2\tau_2^2)^{-1}$, and $A_{//}$ is the parallel component of the anisotropic part of the hyperfine tensor. From the line widths of the $I_z=\pm1$ lines, the correlation times, τ_2, are estimated using Lorentzians with line widths given by:

$$[T_2(I, I_z)]^{-1} = [T_{2d}(I, I_z)]^{-1} + T_{20}^{-1} \quad (4)$$

where T_{20} accounts for the other relaxation processes and T_{20}^{-1} is assumed to be 80 mG. The experimental value of $A_{//}$ is not known for the cation radical of 4,4'-difluorobiphenyl. Therefore, the estimation of $A_{//}$ was performed in the following way.

The anisotropic component of the ^{19}F hyperfine tensor for a $\rangle$C–F fragment may be described by the following equation[9,23]:

$$\boldsymbol{B}_F = \boldsymbol{B}_C^\pi\rho_C^\pi + \boldsymbol{B}_F^\pi\rho_F^\pi + \boldsymbol{B}_F^\sigma\rho_F^\sigma \quad (5)$$

where $\boldsymbol{B}_C^\pi$, $\boldsymbol{B}_F^\pi$, and $\boldsymbol{B}_F^\sigma$ are the anisotropic tensors due to the interaction of a fluorine nucleus with carbon $2p_\pi(\rho_C^\pi=1)$, fluorine $2p_\pi(\rho_F^\pi=1)$, and fluorine $2p_\sigma(\rho_F^\sigma=1)$ electrons respectively. The principal values of $\boldsymbol{B}_C^\pi$ and $\boldsymbol{B}_F^\pi$ have been calculated by Cook *et al.*[9] and Morton *et al.*[24] respectively. According to Iwasaki *et al.*,[23] Eq. 5 may be represented in this form:

$$\boldsymbol{B}_F = (\boldsymbol{B}_C^\pi+\boldsymbol{Q}_{CF}^F)\rho_C^\pi + (\boldsymbol{B}_F^\pi+\boldsymbol{Q}_{CF}^F)\rho_F^\pi \quad (6)$$

where $\boldsymbol{Q}_{CF}^F$ and $\boldsymbol{Q}_{FC}^F$ are the tensor polarization factors of the $F_{2p\sigma}$ electrons arising from the unit spin density in C_{2p_π} and F_{2p_π} respectively, and where the parameters, $\boldsymbol{Q}_{CF}^F$ and $\boldsymbol{Q}_{FC}^F$, have been experimentally determined.

Using Eq. 6, the value of $A_{//}$ in Eq. 4 was estimated to be 41 G based on the spin densities, ρ_C^π and ρ_F^π, determined from the ^{13}C hyperfine splittings for the ring carbons (see Table 2 and the following section). The values of τ_2 obtained are 1.5×10^{-10} s at −60 °C and 0.8×10^{-10} s at +10 °C. These correlation times are typical of those found for similar molecules in liquids by a study of the relaxation mechanism of ENDOR.[10]

Estimate of Q Values. As is shown in Fig. 2, four kinds of ^{13}C hyperfine splitting were recorded. The absolute values of these hyperfine coupling constants are much like those of the ring carbon atoms of the 4,4'-bitolyl cation radical, as has already been reported[7] (see Table 1). In previous works, it has been reported that the substitution of fluorine for hydrogen has little effect on the spin-density distribution.[9,11-14] The ^{13}C hyperfine coupling constants, therefore, can more easily be assigned than those of the 4,4'-bitolyl cation radical; $a_1^C=-0.78$, $a_2^C=1.90$, $a_3^C=-3.57$, and $a_4^C=6.92$ G. The experimental values of the ring spin densities were obtained from the ring proton hyperfine splittings, a_2^H, and the ^{13}C hyperfine splittings, a_1^C, based on the Colpa-Bolton[20] and the Karplus-Fraenkel[21] formulae:

$$a_1^H = Q_{CH}^H\rho_1^\pi + K_{CH}^H[\rho_1^\pi]^2 \quad (7)$$

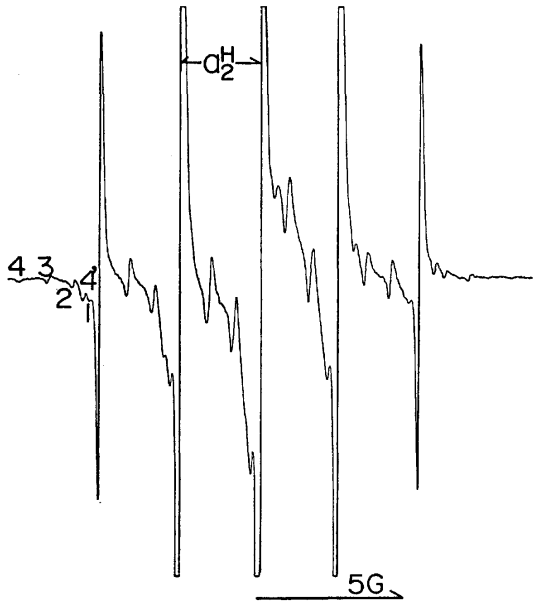

Fig. 2. The ^{13}C splitting of the ring carbon atoms of 4,4′-difluorobiphenyl cation radical. The figures denote the ring position.

$$a_1^C = (S^C + \sum_{k=1}^{3} Q^C_{C_1X_k})\rho_1^\pi + \sum_{k=1}^{3} Q^C_{X_kC_1}\rho_k^\pi \quad (8)$$

The parameters in Eq. 7 were taken as $Q^H_{CH}=-27$ and $K^H_{CH}=-12$ G, while the parameters in Eq. 8 were taken as $S^C=-12.7$ G, $Q^C_{C_1X_k}(Q^C_{C_1H}=19.5$, $Q^C_{C_1C_k}=14.4$ G), and $Q^C_{C_1C_k}=-13.9$ G. The experimental values of the spin density are summarized in Table 2. Here, the fluorine spin densities were obtained by the normalization of the total spin density. For comparison, Hückel- and McLachlan-type calculations were carried out, taking the Coulomb integral and resonance integral to be $\alpha_F=\alpha_C+2.5\beta_C$ and $\beta_{CF}=0.62\beta_C$.[11] The results are summarized in Table 2. As may be seen in Table 2, the values of the spin densities for the 4,4′-difluorobiphenyl cation radical are nearly the same as those for the 4,4′-bitolyl cation radical, and the similarity in the spin densities on the ring carbon atoms shows that the substitution of fluorine for hydrogen does not produce a large perturbation in the overall spin densities.

The evaluation of Q^F_{CF} and $Q^F_{F(CF)}$ in Eq. 2 requires the values of ρ^π_C and ρ^π_F. Nevertheless, there have been few studies in which ρ^π_C and ρ^π_F were experimentally determined, and the simple LCAO MO approach to the estimation of ρ^π_F is not necessarily valid.

Recently Icli and Kreilick[12,13] experimentally determined the values of both ρ^π_C and ρ^π_F for a series of fluorinated phenoxyl radicals based on the measurement of the paramagnetic chemical shift in NMR; they also examined Eq. 2. For a series of fluorinated phenoxyl radicals, the ratios of ρ^π_C to ρ^π_F at the adjacent carbon are nearly constant (0.07). This situation is not feasible for determining the individual values of Q^F_{CF} and $Q^F_{F(FC)}$, because two sets of data on ρ^π_F and ρ^π_C with very different ratios (ρ^π_F/ρ^π_C) should be chosen for obtaining accurate Q values.

On the other hand, for the 4,4′-difluorobiphenyl cation radical the ratio of ρ^π_F to ρ^π_C at the adjacent carbon is much larger (0.27) than those for other fluorinated aromatic radicals, and this situation is very favorable for estimating the values of Q^F_{CF} and $Q^F_{F(FC)}$ accurately. The estimation of the values of Q's was carried out using a_F and the spin densities, ρ^π_C and ρ^π_F, obtained for the 4,4′-difluorobiphenyl cation, together with those for the 4-(*p*-fluorophenyl)-2,6-di-*t*-butylphenoxyl radical.[13] The estimated values of the parameters are $Q^F_{F(FC)}=324$ and $Q^F_{CF}=39$ G.

In order to examine the validity of our parameters, we applied the present Q values to the fluorine coupling constants of several compounds previously studied. In Table 3, the experimental and calculated fluorine coupling constants are summarized. We found that our two-parameter equation, $a_F=324\rho^\pi_F+39\rho^\pi_C$, gives a consistent explanation in every case.

Based on the experimental finding that fluorine substitution has little effect on the ring spin densities except for the at the adjacent carbon,[9,11-14] we assumed that the original spin density, ρ^0_C, on the carbon atom in the parent molecule is shared by the carbon atom and the fluorine atom;

$$\rho^\pi_C + \rho^\pi_F = \rho^0_C \quad (9)$$

By substituting Eq. 9 into Eq. 2, we obtain:

$$a_F = [(Q^F_{F(FC)}-Q^F_{CF})K+Q^F_{CF}]\rho^0_C = Q_{eff}\rho^0_C \quad (10)$$

where K is the ratio of ρ_F^π to ρ_C^0 and $Q_{eff}=(285K+39)$ G, using our estimated values. This equation corresponds to Eq. 1.

In respect of Eq. 1, many investigators have reported that the experimentally or semiempirically determined values of Q are scattered over a wide range from molecule to molecule.[11-23] This is not surprising, because the K ratio is certainly not a constant for different molecules. Perhaps the K ratio depends on the double-bond character of the C–F bond, as has previously been proposed by Eaton *et al.*[11] For example, the fluorine hyperfine coupling constant of the 4,4'-difluorobiphenyl cation radical is about six times as large as that of the 4,4'-difluorobiphenyl anion radical,[22] but the spin densities of the anion and cation, based on the LCAO MO calculations, are nearly identical with each other. These results are analogous to the case of the hyperconjugation of the methyl group (see Tables 1 and 2). We can, therefore, consider that the value of Q_{eff} in Eq. 10 is related to the degrees of π-conjugation between the $2p_z$ orbital of fluorine atom and the $2p_z$ orbital of carbon which is adjacent to fluorine. That is, the large value of Q_{eff} represents the strong conjugation of the π system on the C–F fragment. As a result of this strong conjugation, the spin density on the fluorine atom and the K ratio increase. Indeed, the estimated value of Q_{eff} for the 4,4'-difluorobiphenyl cation is very large (100 G), and the corresponding K value reaches 0.21.

The numerical calculations were carried out mainly at the Computing Center of Ehime University.

Infrared Studies on Water Adsorption Systems with the Use of HDO. I. Molecular Sieves 13X and 4A

Masao HINO

Government Industrial Development Laboratory, Hokkaido, Higashi-Tsukisamu, Toyohira-ku, Sapporo 061-01

(Received July 12, 1976)

It was shown that the use of HDO molecules in IR studies on water adsorption system is advantageous for obtaining information as to whether 1) a band arises from the surface structural hydroxyl groups or from adsorbed water molecules, 2) a band arises from an overtone bending vibration, and 3) water molecules are adsorbed in a state of its two hydroxyl bonds being equivalent. The bands in the spectra of Molecular sieves–H_2O systems were assigned as follows. I) 13X–H_2O system. Bands at 3752, 3685, and 3647 cm^{-1} correspond to surface structural OH, bands at 3697, 3360, and 1650 cm^{-1} to asymmetrically adsorbed water molecules, band at 3230 cm^{-1} to overtone bending vibration of the same molecules. The band at 3590 cm^{-1} was found to arise from some other type of adsorbed water molecules. II) 4A–H_2O system. Bands at 3500, 3400, and 1660 cm^{-1} correspond to symmetrically adsorbed water molecules, band at 3280 cm^{-1} to overtone bending vibration of the same molecules. Another type of adsorbed water was suggested to be present.

Infrared spectroscopy has been widely employed in studies on surface and adsorbed species. However, analysis of the spectra has not always been easy to carry out. This is due to inevitable characteristics of the spectra of adsorption systems, such as the specific complexity of the spectra and the lack of means of spectral observation over a wide frequency range masked by strong absorption by adsorbents.

Thus, additional information from other sources is desirable. As an example, the use of partially deuterated compounds is considered to be effective. The use of this technique has been made for the spectral study on adsorption systems to some extent.[1] A number of investigations have been carried out on water adsorption systems. However, they were restricted to the measurement of the spectra of H_2O or D_2O adsorption systems. No work seems to have been made with the use of HDO.

In the present work, IR absorption spectra of hydroxyls and adsorbed water on Molecular sieves 13X and 4A are analyzed by the use of HDO. Although assignments of the spectral bands of these systems have been made to a certain extent,[2–14] more direct and conclusive evidences for the assignments are obtained by the use of the present technique.

Its applicability to other molecular adsorption systems will be suggested.

Experimental

Materials. Linde molecular sieves 13X and 4A (GASUKURO Ind. Co., Ltd.) were used. The crystallinity and purity of these materials were confirmed to be of a sufficiently high by X-ray diffraction analysis. The surface area of the 13X sieve was 717 m^2/g. In order to obtain extremely fine powder samples for IR experiments, the materials were ground in an agate motor with a small amount of water, and then suspended in deionized water. The particle size of the fine powders was found to be less than 1 μm in diameter by electron microscopic observation. D_2O (E. Merck, Darmstadt) of 99.75% in purity and deionized-distilled H_2O were used for IR experiments after being degassed.

Apparatus and Procedure. A JASCO Model 402-G IR spectrophotometer and a Pyrex glass cell were used for recording the spectra. The cell was essentially similar to that designed by Angell *et al.*[6] In order to prevent the contamination of the sample pieces by grease vapor, a Teflon greaseless valve was fixed directly to the top of the cell. The exchange of sample pieces was made by cutting and re-fixing the arm part of the cell.

The sample powders were pressed into disks under a pressure of 2.5 tons/cm^2, and then the disks were cut into pieces of 1×2 to 2.5 cm to fit the cell windows. The "thickness" was 12—80 mg/cm^2.

After the sample pieces had been set in the cell, they were evacuated at 500 °C for at least 3 h prior to experiments. Before the addition of each type of sample water for IR measurements, the surface of the sample as well as the inner wall of the cell were washed by the following procedure. The sample was exposed at room temperature to the saturated sample water vapor, and then pumped out at 180—200 °C for 10 min. This procedure was repeated five times. Finally, it was evacuated at 500 °C for 3 h. Spectral observation confirmed that the washing was sufficient. In the case of measurements of H_2O-adsorbent systems on a new sample piece, washing was omitted.

The experiments related to HDO were carried out in the presence of H_2O and D_2O. By mixing H_2O with D_2O at a molar ratio of a to b, HDO is obtained under the coexistence of other water in a ratio of about H_2O: HDO: $D_2O=a^2$: $2ab$: b^2.

All the spectra were measured at room temperature. Spectra on the desorption process were observed after the pretreated sample piece was first exposed to the saturated sample water vapor and then evacuated at various temperatures. Spectra on the adsorption process were measured by dosing small amounts of sample water at room temperature successively after the sample piece was evacuated at 500 °C.

The measurements were carried out mainly in the OD stretching region in place of the OH stretching region, since the former is not only higher in transparency but also flatter in background owing to the lack of weak absorption bands arising from the water vapor in the air.

Results

13X–Water System. D_2O, H_2O Systems: The spectra of 13X–D_2O and H_2O systems were measured for a comparison of the results with those of the HDO system (Figs. 1 and 2). The spectra observed were similar to those published.[17] On evacuation at 90 °C six absorption bands were observed at 2756, 2727, 2682, 2645, 2470, and 2395 cm^{-1} in the D_2O system, (these

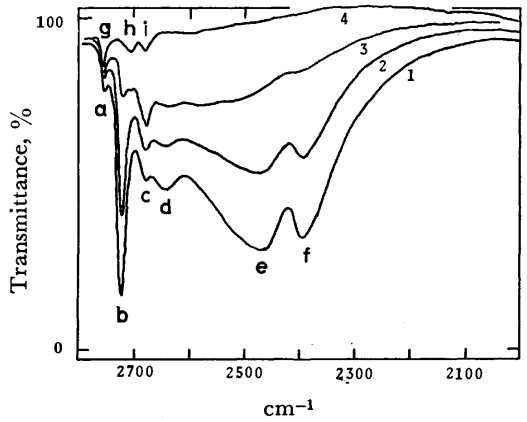

Fig. 1. Spectra of 13 X–D_2O system.
Evacuated for (1) 1 h at 90 °C, (2) 1 h at 120 °C, (3) 20 min at 170 °C, (4) 2 h at 500 °C. "Thickness" of the sample piece was 12 mg/cm².

bands as well as the corresponding bands in other systems will be referred to as a, b, c, d, e, and f). In the H_2O system the six bands corresponding to those in D_2O system were at 3752, 3697, 3645, 3590, *ca.* 3360, and 3230 cm^{-1}. In the latter system a single HOH bending vibration band was observed at 1650 cm^{-1}. Elevation of the evacuation temperature gave rise to a decrease in the intensity of all these bands except for a and c. After the final evacuation at 500 °C, three sharp bands remained at 2756, 2708, and 2683 cm^{-1} in the D_2O system (referred to as g, h, and i, respectively), and in the H_2O system at 3752, 3685, 3647 cm^{-1}.

HDO System: The spectra in OD stretching and bending regions are shown in Fig. 3. In this experiment, an H_2O–D_2O mixture in the ratio 3 to 1 was used except for curve 5, the contents being H_2O 56.3%, HDO 37.5% and D_2O 6.3%. In the number of OD chemical bond, the 75% belongs to HDO and the rest to D_2O. The OH stretching region of this system (Fig. 4) was measured employing another mixture in the ratio H_2O: D_2O = 1 : 5. The spectra of OD and OH stretching regions of this system were compared with those of D_2O and H_2O systems, respectively. All the correlations

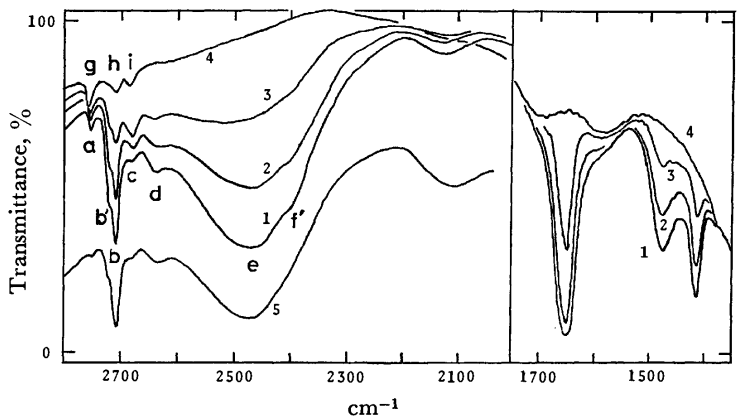

Fig. 3. Spectra of 13X–HDO system in the OD stretching and bending regions.
Evacuated for (1) 1 h at 95 °C, (2) 1 h at 120 °C, (3) 20 min at 165 °C, (4) 2 h at 500 °C after exposure to the vapor of H_2O–D_2O mixture of a molar ratio of 3 to 1, and (5) evacuated for 1 h at 90 °C after exposure to the vapor of H_2O–D_2O 7 to 1 mixture. Sample piece "thickness" 43 mg/cm².

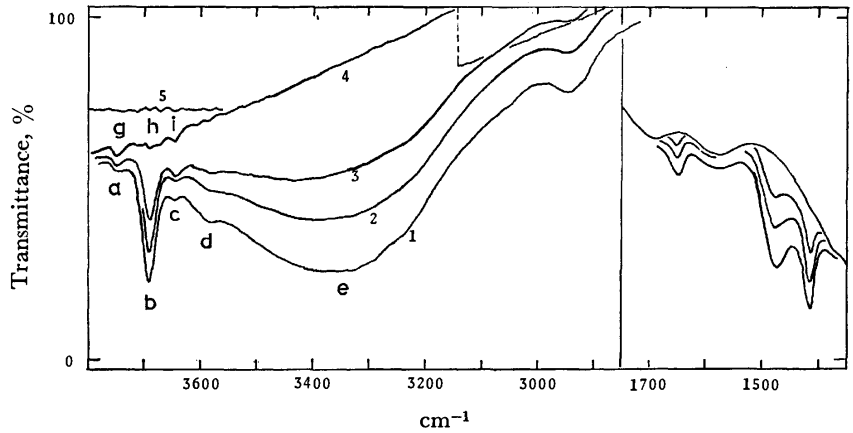

Fig. 4. Spectra of 13X–HDO system in the OH stretching and bending regions. Evacuated for (1) 1 h at 95 °C, (2) 1 h at 120 °C, (3) 20 min at 165 °C, (4) 3 h at 500 °C after exposure to the vapor of H_2O–D_2O 1 to 5 mixture. (5) Empty cell. Sample piece "thickness" 38 mg/cm².

between the spectra in the OH stretching region of HDO system and those of H_2O system were analogous to those between the spectra in the OD stretching region of the HDO system and those of D_2O system. The frequencies of the bands in OH stretching regions are parenthesized.

Bands a, c, and e in the spectra of HDO system appeared in the OD stretching region at 2756, 2680, and 2470 cm^{-1} (3750, 3645, *ca.* 3350 cm^{-1}) which were of nearly the same frequencies as those of the D_2O system. However, band b was observed at a distinctly different frequency from that of D_2O system, namely at 2710 cm^{-1} (3690 cm^{-1}). As for band d, even though the difference in frequency was not very great, *ca.* 7 cm^{-1}, the frequency 2638 cm^{-1} was not equal to that of the band in D_2O system. In the OH region, band d was so broad that the difference could not be detected decisively. It should be noted that no band f appeared in the spectra of this system. The fact that the shoulders at 2725 and 2395 cm^{-1} are due to the D_2O molecules contained in the mixed water as "impurity" was confirmed from another experiment, *viz.* the spectra after the adsorption of sample water followed by evacuation at 100 °C were measured in a series where the D content of the sample water was changed step by step from 0 to 100 atom %. The results showed that the intensities of both shoulders change in proportion to the D content. The spectrum in the OD stretching region obtained by the use of H_2O: D_2O=7.1: 1.0 mixed water is shown in Fig. 3, curve 5. A band somewhat broader and weaker appeared in both stretching regions, at 2945 cm^{-1} in the OH region and at 2120 cm^{-1} in the OD region. The weak absorption bands of g, h, and i were measured in the OD stretching region with a thick sample for the sake of comparison with those in D_2O system. The results showed that the three bands were exactly equal in wavenumber to those in D_2O system, and were 27% in intensity as compared with that of the latter which is almost equal to the D content, 25 atom %, of the mixed water used. In the bending vibration region, three absorption bands were observed at 1650, 1476, and 1415 cm^{-1}. The band at 1650 cm^{-1} is assigned to HOH bending vibration, because its frequency was quite the same as that of pure H_2O system and its intensity decreased with decrease of H_2O content in the mixed water (Figs. 3 and 4). Thus the other two arise from HDO.

The spectra measured on the adsorption process were almost the same as those on the desorption process. However, the intensity of the band d was so weak that the band was hardly observable on the adsorption process in the spectra of any of the systems.

4A-Water System. In this system the spectral measurements were carried out only on the adsorption process.

4A-D_2O, H_2O Systems: In the stretching region of the spectra of D_2O (H_2O) system (Figs. 5 and 6) three main bands were observed at 2578, 2515, and 2427 cm^{-1} (in H_2O system, at 3500, 3400, and 3280 cm^{-1}) and three weak bands at 2760, 2737, and 2645 cm^{-1} (in H_2O system, only the two former bands were detected at 3750 and 3715 cm^{-1}). In H_2O system one bending band was observed at 1660 cm^{-1}. These were similar to those reported by previous authors.[7,8]

4A-HDO System: The spectra obtained in the OD stretching and bending regions employing an H_2O–D_2O

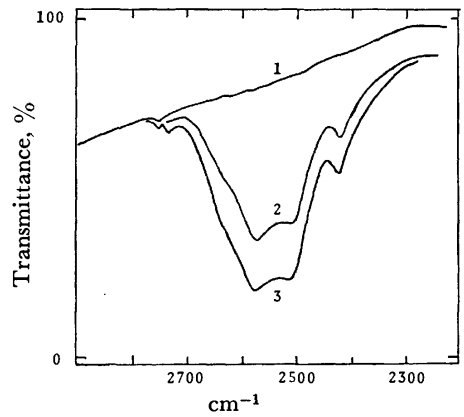

Fig. 5. Spectra of 4A–D_2O system.

(1) Evacuated for 3 h at 500 °C, (2) 18 μmol, (3) 36 μmol, (4) 54 μmol of H_2O–D_2O 3 to 1 mixture were readsorbed. Sample piece "thickness" 30 mg/cm².

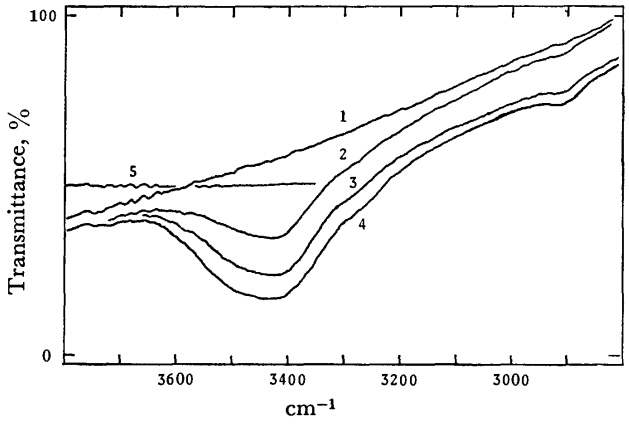

Fig. 8. Spectra of 4A–HDO system in the OH stretching region.
(1) Evacuated for 3 h at 500°C, (2) 18 μmol, (3) 36 μmol, (4) 54 μmol of H_2O–D_2O 1 to 5 mixture were readsorbed. (5) Empty cell. Sample piece "thickness" 30 mg/cm².

mixture in the ratio 3 to 1 and those in the OH stretching region employing another mixture in the ratio 1 to 5 are shown in Figs. 7 and 8, respectively. In each stretching region, a main single OD or OH stretching band of symmetric shape appeared at a frequency of 2530 or 3420 cm^{-1}. Their positions are located between two strong stretching bands appearing in the spectra of D_2O or H_2O system. A weak band was observed at 2705 cm^{-1} in the OD stretching region but not the fitting band in the OH region. As in the case of 13X-water system a new band was observed in each stretching region at 2140 cm^{-1} in the OD region and at 2910 cm^{-1} in OH region. Both bands at 2427 cm^{-1} in D_2O system and 3280 cm^{-1} in H_2O system disappeared from each corresponding region of the spectra of HDO system. Swellings around 2580, 2420 cm^{-1} (Fig. 7) and 3500, 3280 cm^{-1} (Fig. 8) arise obviously from D_2O or H_2O present in the water mixtures. Only one HOD bending band appeared at 1465 cm^{-1}. The 1660 cm^{-1} band corresponds to HOH bending vibration as previously described.

Table 1. Summary of the IR bands of molecular sieves–water systems

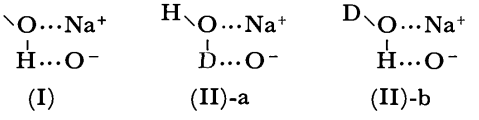
1), 3), 7), 12) OD(H) stretching of structural deuteroxyl groups. 2), 5), 10) Free OD(H) stretching, hydrogen-bonded OD(H) stretching and HOH (HOD) bending of asymmetrically adsorbed water (Type WX-I), respectively. 4), 13) OD(H) stretching of adsorbed water of Types WX-II and WA-II, respectively. 6), 15) DOD(HOH) overtone bending of Types WX-I and WA-I water, respectively. 8), 16) HOD overtone bending or combination of adsorbed HDO? 9) Combination of adsorbed H_2O. 11), 18) Arising from D_2O or H_2O impurities. 14) OD (H) stretching of symmetrically adsorbed water (Type WA-I). 17) HOH(HOD) bending of Type WA-I water.

The observed bands are summarized with their assignments in Table 1.

Discussion

13X-Water System. Discussion has been made as to whether various absorption bands, especially those of h, i, d, and b, arise from surface hydroxyl groups or from adsorbed water molecules.[15] The use of HDO gives more detailed information. If a band arises from the former, the wavenumbers of the corresponding two OH (or OD) vibration bands, one appearing in the H_2O (or D_2O) adsorption system and the other in the HDO adsorption system, should be exactly the same as each other, and if it arises from the latter the wave numbers would not be equal. Thus, the residual bands g, h, and i can be attributed to the stretching vibrations of surface hydroxyl groups, since their corresponding bands appear at the same frequency in the two systems. Bands a and c are also attributable to hydroxyl groups. They would be the same bands as g and i, respectively, because of equal frequency. However, the origin of band b differs from that of h. The fact that band b in HDO system appears in the OD stretching region at a frequency 16 cm^{-1} lower than that in D_2O system (as well as in the OH stretching region 7 cm^{-1} lower than that in H_2O system) indicates that the band does not arise from structural hydroxyl groups but from adsorbed water molecule. Band e is attributed to the OH stretching vibration of the water molecules hydrogen bonded to the surface. The absorption d was reported by Habgood,[5] Ward[9] and also by Kiselev *et al.*[12] However, no assignment was made. Only Uytterhoeven *et al.*[11] attributed the band to OH groups in ions of the type $Me^+(OH)$. However, the results in the present experiments indicate that its origin is not the structural OH groups but a certain type of adsorbed water molecule. Band f was considered by Ward[9] and Abramov *et al.*[14] to arise from the OH stretching of another type of water molecule adsorbed in a different way from the origin of band e. Kiselev *et al.*[12] attributed it to the overtone bending vibration of the water molecules, which are the origin of band e, enhanced by Fermi resonance. Our results support the assignment by Kiselev *et al.* The frequencies of the overtone bending vibrations of HDO would be near 2952 and 2830 cm^{-1} if they appear, since the fundamentals were observed at 1476 and 1415 cm^{-1}. However, since they differ a great deal from the frequency of any stretching vibration of HDO, no resonance would occur. Thus, if the band arises from the overtone bending vibration it would not appear in the spectra of HDO system, or would be only slightly observable at frequencies near 2952 and 2830 cm^{-1}. There is some uncertainty in the attribution of the observed 2945 cm^{-1} band to the overtone bending of HDO molecules. If we suppose that the 2945 cm^{-1} band is the overtone of 1476 cm^{-1} band, we cannot explain the reason why that of 1415 cm^{-1} band does not appear. However, at least the disappearance of band f from the spectra of HDO system is in line with the assignment by Kiselev *et al.* On the other hand, if Ward's assignment is accepted, no reason can be found for the disappearance of the band.

There were two bending vibrations in the adsorbed HDO molecules, but only one in adsorbed H_2O. This supports the schematic structure of water adsorption originally proposed by Bertsch and Habgood[3] (I). If the structure is adopted, the adsorbed HDO molecules would take either of the two forms onto the surface by equal chance as illustrated in (II)-a and (II)-b, then the adsorbed HDO molecules as well as the H_2O



molecules should yield the bending vibrations in accordance with the observed results. This adsorption model also supports the experimental fact on the stretching vibration of the adsorbed molecules. There were two OH (OD) stretching vibration bands, one of free OH (OD, band b) and the other of hydrogen bonded OH (OD, band e), in both spectra of H_2O (D_2O) and HDO systems.

4A-Water System. First, the band at 3280 cm^{-1} in the spectra of H_2O system (at 2427 cm^{-1} in the D_2O system) is assigned to the overtone bending of adsorbed H_2O (D_2O) in the same manner as in the discussion on 13X-water system, although there remains some doubt in attributing the 2910 cm^{-1} band in HDO system to the overtone of 1465 cm^{-1} band in analogy of the case of 13X-water system. Then, the existence of two strong OH (OD) stretching bands, presumably corresponding to the ν_3 and ν_1 vibrations, and one bending band in the spectra of H_2O (D_2O) system suggests that there exists only one adsorbed species with two equivalent hydroxyl bonds. This is also supported by HDO adsorption experiment. If HDO molecule is adsorbed in this manner, OH, OD stretching bands and HOD bending band arising from the adsorbed molecule should all be single. This is in line with the observed results.

The weak bands at 2737 and 2645 cm^{-1} (Fig. 5) are possibly assigned to the ν_3 and ν_1 vibrations of another adsorbed D_2O molecule, which may fit the origin of the weak 2705 cm^{-1} band in HDO system (Fig. 7). However, the reason is not clear why the bands corresponding to them, except for at 3715 cm^{-1} in H_2O system, do not appear in the OH regions.

Bands at 2945, 2120 cm^{-1} in 13X-HDO System and at 2910, 2140 cm^{-1} in 4A-HDO System. The frequency ratios of each couple of bands, 1.39 and 1.36, seem to suggest that they arise from OH and OD stretching vibrations of HDO molecules adsorbed. However, these assignments contradict the fact that the frequencies are too low and no band corresponding to them could be detected in the spectra of H_2O or D_2O adsorption systems. In order to investigate the origin of these bands the spectra of pure H_2O, D_2O and mixtures of D_2O and H_2O were measured in liquid phase. The results show that there is a band at 2140 cm^{-1} in the spectrum of pure H_2O, its intensity decreasing with a decrease in H_2O content. No band around 2945—2910 cm^{-1} was detected in the spectrum of either pure H_2O or D_2O, but a band appeared in the spectra of mixed waters at 2920 cm^{-1}. Simultaneously, an HOD bending band was observed at 1450 cm^{-1} in the latter spectra. From a comparison of the spectra of liquid water with those of adsorption systems, the band at 2120 or 2140 cm^{-1} is considered to arise from a combination band of adsorbed H_2O molecules existing in the mixed water. The band at 2945 or 2910 cm^{-1} can be attributed to a overtone bending or a combination band of adsorbed HDO molecule.

The present technique is widely applicable to spectral analyses of adsorption systems including XH_n type molecules, with the use of partially deuterated $XH_{n-1}D$ or XHD_{n-1} molecules. It is applicable, in some cases, to the compounds including the atomic groups of $-XH_n$ type.

The author thanks Dr. Toshio Sato for his helpful advice and Mr. Okio Nishimura for his assistance in electron microscopic techniques.

Radiation-induced Phase Transformations in $NdNb_{1-x}V_xO_4$

Tadao KENJO and Seishi YAJIMA

The Oarai Branch, The Research Institute for Iron, Steel and Other Metals, Tohoku University, Oarai-machi, Ibaraki 311-13

(Received July 12, 1976)

When $NdNb_{1-x}V_xO_4$ compounds were exposed to a fast neutron dose of 6.6×10^{18} *nvt*, their monoclinic-tetragonal transition temperatures were lowered; particularly the transition temperature for the compound with $x=0.3$ was lowered to a temperature below room temperature. The lowering of the transition temperatures was greater for samples containing more V^{5+} ions. Although the present work does not fully reveal why neutron-irradiation lowers the transition temperature, it does show that neither the internal stress due to radiation damage nor the change in valency state of Nb^{5+} or Nd^{3+} lowers the transition temperature.

In previous work it was found that when the $YNbO_4$ compounds containing various impurities were exposed to a fast-neutron dose, the monoclinic $YNbO_4$ lattice approached a tetragonal structure; the *a*/*c* ratio of the monoclinic lattice became closer to unity.[1] This radiation-induced structural change can be explained as being due to (1) the presence of the high-temperature phase (tetragonal form) which is formed by quenching by the thermal spike mechanism, or (2) a lowering of the transition temperature (T_t), as will be described in more detail in a later section. One can expect no changes in T_t from (1), while a lowering of T_t can be expected from (2). Therefore, a measurement of T_t for the irradiated samples would determine which explanation is valid. In previous work, however, the T_t of the irradiated samples could not be measured without recovery of the damage due to radiation because this process begins at a temperature below T_t. This work employed the doping method in order to lower T_t to a temperature below the recovery temperature. Vanadium oxide (V_2O_5) was chosen as a dopant which may lower the T_t of $LnNbO_4$ (Ln=a rare earth) for the reasons described below. (1) Vanadium belongs to the same family of the periodic table as niobium and thus their chemical properties are similar so that the substitution of Nb^{5+} by V^{5+} can be expected to be efficient. (2) The ABO_4 scheelite-type oxides appear to form a tetragonal structure when the ionic potential (Z/r, Z=ionic charge, r=ionic radius) of ions at the A site is small and that at the B site is great, *e.g.*, for $CaWO_4$, $BaMoO_4$ and $NaIO_4$,[2] while they appear to be distorted to a monoclinic structure in the opposite case, *e.g.*, for $LnNbO_4$ and $LnTaO_4$.[2,3] The V^{5+} dopant (Z/r of $Nb^{5+}=7.25$, Z/r of $V^{5+}=8.47$) enhances the mean ionic potential of the Nb^{5+} sites so that, for the above-mentioned reason, V^{5+} can be expected to stabilize the tetragonal structure of $LnNbO_4$ in such a way that the more V^{5+} ions that the $LnNbO_4$ samples contain, the greater will be the T_t lowering.

Neodymium was used as Ln because the T_t of $NdNbO_4$ is one of the lowest of the $LnNbO_4$ family[4] and because it is induced to only a weak radioactivity upon reactor irradiation.

Experimental

Samples were prepared by the usual ceramic technique, as described previously.[1] The oxide mixtures were milled in a mortar and pressed into $15\phi\times3$ mm pellets, which were then heated to 1400 °C in air for 15 h. The samples thus obtained were irradiated in the JMTR (Japan Material Testing Reactor) at a temperature of 150 °C by a fast-neutron flux ($E>1$ MeV) of 1.9×10^{13} *nv* for 4 days, for a total flux of 6.6×10^{18} *nvt*.

The lattice parameters of the irradiated and non-irradiated samples were calculated using the data obtained from X-ray powder patterns using KCl as an internal standard. Since no DTA peaks for the phase transformation were observed, a high-temperature X-ray diffractometer was used for the measurements of T_t.

The magnetic susceptibility was measured using a Gouy balance.

Results and Discussion

The crystal structure of V_2O_5-doped $NdNbO_4$ compounds was identified as a monoclinic-distorted scheelite structure; the X-ray diffraction powder patterns could be indexed according to the known data for monoclinic

$LnNbO_4$ structures.[4] Table 1 gives the lattice parameters for the irradiated (irr.) and non-irradiated (nonirr.) $NdNb_{1-x}V_xO_4$ samples. Since the dependence of the lattice parameters of the non-irradiated samples on the V_2O_5 concentration is smooth, the V_2O_5-doped $NdNbO_4$ samples can be regarded as solid solutions. The reduction in the unit cell volume with increasing V_2O_5 content is reasonable because V^{5+} is smaller than Nb^{5+}.

Table 1 indicates that the $NdNb_{1-x}V_xO_4$ compounds approach tetragonal structures (the compound with $x=0.3$ becomes tetragonal) when they are irradiated; a/c and $\sin\beta$ become closer to unity (these parameters become unity for $x=0.3$) with increasing irradiation. These lattice parameter changes due to irradiation can be explained as being due to (1) the presence of the high-temperature phase formed by the thermal spike mechanism, or (2) a lowering of T_t, as mentioned above. The problem to be solved is to determine which explanation is valid.

In the thermal spike process, small regions of the solid are heated for a very short time and followed by very rapid cooling. If the heating process raises the local temperature high enough for transformation to a high-temperature form, the thermal-spiked areas maintain the high-temperature structure, at least when the local temperature is higher than T_t. The high-temperature phase thus formed is quenched as a metastable phase if the cooling rate of the thermal-spiked regions is so high that the high-temperature structure formed cannot return to the low-temperature structure. Due to this thermal spike process the samples irradiated thus consist of a quenching-formed high-temperature phase and an unchanged low-temperature phase and the fractional portion of the former phase present increases with increasing irradiation dose.[3] The thermal-spiked region is expected to be a sphere of approximately a few tens of Å in diameter and the X-ray diffraction patterns for the high-temperature phase thus formed cannot be separated from those for the low-temperature phase, that is, the lattice parameters in this case denote mean values of the above two phases. The presence of the tetragonal structure thus formed renders the mean values of a/c and $\sin\beta$ closer to unity. This is observed in the case of $x=0.1$ and 0.2 (Table 1). When the whole region of the solid has been covered with rapidly-quenched high-temperature phase islands, the radiation-induced phase transformation is completed. This is the case for $x=0.3$. Thus, as far as the lattice parameters at room temperature are concerned, the thermal spike mechanism explains the radiation-induced structural changes in $NdNb_{1-x}V_xO_4$.

The radiation-induced structural changes can also be explained as being due to a lowering of T_t. The values of a/c and $\sin\beta$ for $LnNbO_4$ approach unity with increasing temperature and become unity at T_t, where the $LnNbO_4$ transforms from monoclinic to tetragonal form.[1,3] Therefore, if the T_t of $NdNb_{1-x}V_xO_4$ is lowered due to the irradiation, the a/c and $\sin\beta$ values at room temperature become closer to unity. This is the case for $x=0.1$ and 0.2. If T_t is lowered due to the irradiation to a temperature below room temperature, the crystal structure at room temperature is tetragonal. This is the case for $x=0.3$.

If the lattice parameter changes due to irradiation are ascribable to the fractional portion of the tetragonal phase formed by process (1), the transition temperature is unchanged upon irradiation because the process (1) does not change the T_t for the monoclinic phase and because the tetragonal phase formed by the rapidly-quenching process does not contribute to the T_t shift. On the other hand, if the lattice parameter changes are due to a lowering of T_t, the transition temperature is lowered by the irradiation. Therefore, measuring the T_t of the irradiated samples determines which explanation is valid.

The irradiated $NdNb_{0.7}V_{0.3}O_4$ sample has a tetragonal structure. If the tetragonal structure is ascribed to the thermal spike process, then when the irradiated $NdNb_{0.7}V_{0.3}O_4$ sample is cooled it maintains its tetragonal structure at any temperature below room temperature. On the other hand, if this structure is the result of the lowering of T_t to a temperature below room temperature, the tetragonal form is transformed into a monoclinic structure when the irradiated sample is cooled to a temperature that is lower than T_t but still high enough for the transformation rate. As is shown in the last line of Table 1, the values of $\sin\beta$ and a/c at 0 °C show small deviations from unity, or a slight distortion to the monoclinic form. The values at liquid N_2 temperature (the next to the last line in the same table) show greater deviations from unity. These findings indicate that the tetragonal structure in the irradiated $NdNb_{0.7}V_{0.3}O_4$ sample is due to a lowering of T_t to a temperature below room temperature, that is, explanation (2) is valid.

Figure 1 gives the temperature dependence of the lattice parameters for both irradiated (○) and non-irradiated (●) $NdNb_{0.8}V_{0.2}O_4$. From the figure, the T_t for the irradiated sample is found to be ≈290 °C and that the non-irradiated sample to be ≈330 °C.

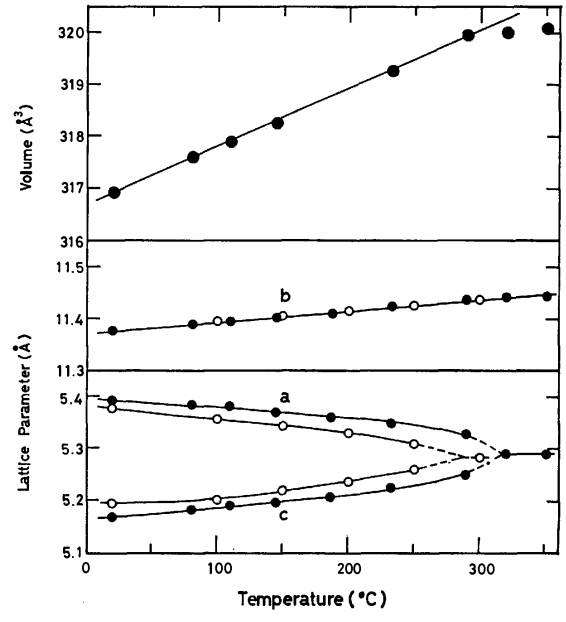

Fig. 1. Temperature dependence of lattice parameters of $NdNb_{0.8}V_{0.2}O_4$.
●: Non-irradiated, ○: irradiated.

TABLE 2. TRANSITION TEMPERATURES (T_t) FOR IRRADIATED AND NON-IRRADIATED $NdNb_{1-x}V_xO_4$

x	irr./nonirr.	T_t(°C)
0.1	nonirr.	520
	irr.	≈510
0.2	nonirr.	330
	irr.	290
0.3	nonirr.	170
	irr.	20

This indicates that the radiation-induced lattice distortion in $NdNb_{0.8}V_{0.2}O_4$ is also due to a lowering of T_t. Similarly, the high-temperature X-ray diffraction data indicate that the T_t of the $NdNb_{0.9}V_{0.1}O_4$ sample is also lowered upon irradiation, although the data are not given. Table 2 summarized the results of T_t for the irradiated and non-irradiated $NdNb_{1-x}V_xO_4$ samples, indicating that their transition temperatures are lowered when they are irradiated. Thus, it has been shown that the radiation-induced structural changes in $NdNb_{1-x}V_xO_4$ are due to a lowering of T_t, and not due to the rapidly-quenched tetragonal phase. Table 2 also indicates that the T_t lowering due to irradiation is greater in samples containing more V_2O_5 dopant. Although this cannot be explained at present, we suppose that the lattice distortion induced by the dopant plays a role in stabilizing the radiation damage.

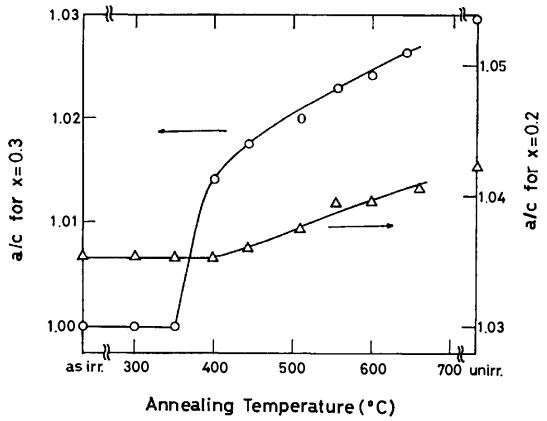

Fig. 2. Variation of a/c with annealing temperature in $NdNb_{0.8}V_{0.2}O_4$ (△) and $NdNb_{0.7}V_{0.3}O_4$ (○) irradiated.

To confirm that the sample does not recover from radiation damage while T_t is being measured, a study of the annealing of the irradiated samples was carried out. The samples were annealed successively at each temperature for 1 h in air. Figure 2 shows the variation of a/c for the irradiated $NdNb_{0.8}V_{0.2}O_4$ and $NdNb_{0.7}V_{0.3}O_4$ samples with the annealing temperature, indicating that the radiation damage recovery begins at ≈350 °C. Neither of the values of T_t for the two samples is higher than that. The data for the annealing of $NdNb_{0.9}V_{0.1}O_4$ could not be obtained because the a/c change due to irradiation is too small. However, the amount of damage recovery during the T_t measurements, if any, could be considered to be very small due to the fact that the lattice parameters of the irradiated sample are essentially the same before heating as those of the same sample after heating to 520 °C (520 °C= the T_t of $NdNb_{0.9}V_{0.1}O_4$). Thus, it has been shown that the T_t values for the irradiated samples involve no recovery effects of the radiation damage.

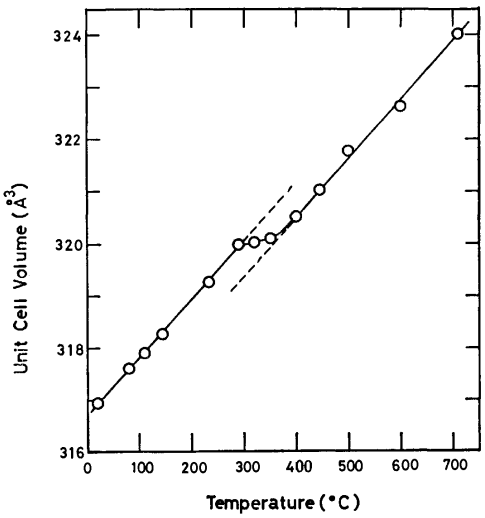

Fig. 3. Temperature dependence of unit cell volume of $NdNb_{0.8}V_{0.2}O_4$.

Several materials undergo similar shifts in transition temperatures when exposed to fast-neutron doses.[5-9,11-13] However, it is not yet clearly understood why their transition temperatures vary due to irradiation. Some workers have attributed this to the internal stress caused by radiation damage; the internal stress acts on T_t as if a pressure had been applied. However, this explanation may not be valid for the reason described below. As is shown in Fig. 3, the unit cell of $NdNb_{0.8}V_{0.2}O_4$, which is an example of $NdNb_{1-x}V_xO_4$, shrinks when it transforms from a monoclinic to a tetragonal structure. Therefore, if such an internal stress lowers T_t, it must act as a positive pressure on T_t, as predicted by the Clausius-Clapeyron equation. When a positive pressure is applied the crystal lattice shrinks. Therefore, such radiation-induced internal stress shrinks the unit cell, that is, the irradiation must result in the shrinking the unit cell. However, on the contrary, the unit cells of $NdNb_{1-x}V_xO_4$ expand when they are irradiated (Table 1). This contradiction strongly suggests that the internal stress due to the radiation damage, if at present at all, is not the dominant cause of the T_t lowering.

The experimental results of the neutron-irradiation of $BaTiO_3$[9] also appear to disprove the "internal stress theory." The $BaTiO_3$ compound is transformed from a tetragonal to a cubic structure at 130 °C. It undergoes T_t lowering when it is irradiated.[9] In a manner similar to the case of $NdNb_{1-x}V_xO_4$, a positive pressure must be assumed[10] as the internal stress to explain the T_t lowering due to the irradiation. However, in reality, the unit cell expands upon irradiation.[9] This contradicts the assumption that the internal stress acts as a positive pressure.

The radiation-induced lowering of T_t may be explained as being due to a change in the valency state. As described in the previous section, the $NdNbO_4$ compound appears to suffer a lowered T_t when replacing the Nb^{5+} ion with ions of greater ionic potential or

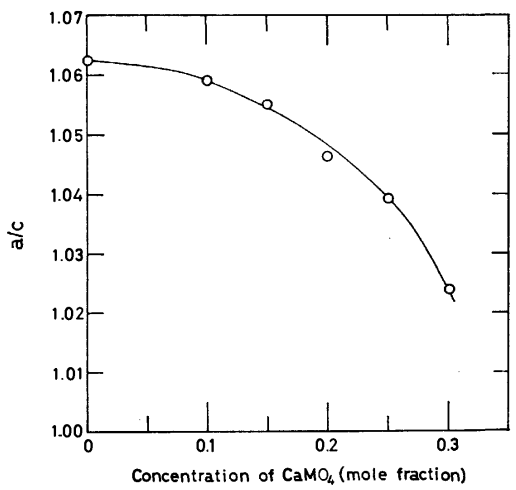

Fig. 4. Variation of a/c with concentration of $CaMoO_4$ in $NdNbO_4$.

when replacing the Nd^{3+} ions with ions of lower ionic potential. In fact, as shown in Fig. 4, the $CaMoO_4$ dopant for which the ionic potential of Ca^{2+} ($Z/r=2.02$) is smaller than that of Nd^{3+}($Z/r=2.88$) and that of Mo^{6+}($Z/r=9.68$) is greater than that of Nb^{5+}($Z/r=7.25$), lowers the a/c ratio of $NdNbO_4$, that is, it lowers the T_t of $NdNbO_4$. A similar effect on T_t occurs for a change in valency state. If electrons are transferred from Nb^{5+} to Nd^{3+} and are trapped there when the $NdNbO_4$ compound is irradiated, the irradiated $NdNbO_4$ compound contains $Nd^{2+}Nb^{6+}O_4$. It can be expected that the ionic potential of Nd^{2+} is smaller than that of Nd^{3+} and that the ionic potential of Nb^{6+} is greater than that of Nb^{5+}. Therefore, if irradiation induces the $Nd^{2+}Nb^{6+}O_4$ compound in the $NdNbO_4$ matrix, the effect on the T_t of $NdNbO_4$ may well be similar to that of the $CaMoO_4$-dopant, that is, the $Nd^{2+}Nb^{6+}O_4$ compound will lower the T_t of $NdNbO_4$.

The $Nd^{2+}Nb^{6+}O_4$ compound may be detected by measuring the magnetic susceptibility of the sample It is reasonable to expect that Nd^{2+} shares 4 Bohr magnetons/mol and Nb^{6+} 1 Bohr magneton/mol while the non-irradiated $NdNbO_4$ compound retains 3 Bohr magnetons/mol.[14] V^{5+} is diamagnetic. Therefore, if $Nd^{2+}Nb^{6+}O_4$ is present in the irradiated sample, the magnetic susceptibility of the irradiated sample will be greater than that of non-irradiated sample by 2 Bohr magnetons per mol due to the $Nd^{2+}Nb^{6+}O_4$ present. The $CaMoO_4$ doping data (Fig. 4) leads to the estimation that, if the radiation-induced $Nd^{2+}Nb^{6+}O_4$ compound lowers the T_t of a $NdNb_{0.7}V_{0.3}O_4$ sample, at least one tenth mole of $Nd^{2+}Nb^{6+}O_4$ must be present in the irradiated $NdNb_{0.7}V_{0.3}O_4$ samples. Such an amount of $Nd^{2+}Nb^{6+}O_4$ can readily be detected using a Gouy balance. Figure 5 gives the temperature dependence of the magnetic susceptibilities of irradiated (○) and non-irradiated (△) $NdNb_{0.7}V_{0.3}O_4$. However, no significant difference in the magnetic susceptibilities between the two is observed. Therefore, the change in the valency state is not an important cause of the radiation-induced lowering of T_t.

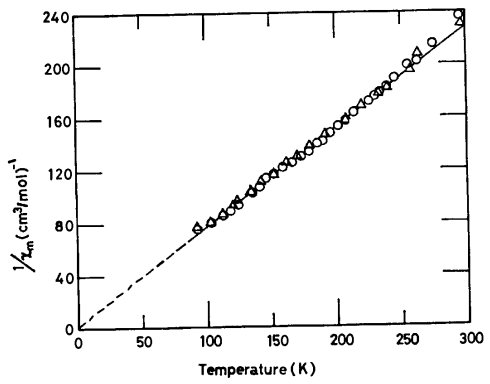

Fig. 5. Temperature dependence of inverse molar susceptibility in irradiated (○) and non-irradiated (△) $NdNb_{0.7}V_{0.3}O_4$ sample.

This study provides no definite explanation of the radiation-induced lowering of T_t, but it is supposed that this may be ascribed to disordering in the crystal lattice.

(Received September 2, 1976)

The Mössbauer absorption spectra of ^{119}Sn in single crystals of $(CH_3)_2SnF_2$ and $(CH_3)_2SnCl_2$ have been studied as a function of the orientation angles of the incident unpolarized gamma-ray beam with respect to the crystal axes, taking the absorber thickness effect into account. The analysis of the intensity ratios of the quadrupole splitting doublet yields the asymmetry parameter (η) and the orientation of the principal axes of the electric-field gradient with respect to the crystal axes. The value of η in $(CH_3)_2SnCl_2$ at 135 K was about 0.4, less than the value published previously. The sign of the ^{119}Sn quadrupole coupling constant (e^2qQ) in these compounds was found to be positive, as has been reported before.

Several parameters, such as the electric-field gradient (EFG) and the mean square-displacement (MSD) tensors at the sites of the resonant nuclei, can be obtained by means of the Mössbauer absorption spectra of the single-crystal samples.

Zory has discussed the analysis of the EFG in a single-crystal absorber containing ^{57}Fe and has applied his analysis to $FeCl_2 \cdot 4H_2O$ and evaluated all the EFG parameters.[1] This method has been successfully employed for the complete determination of all the parameters of the EFG tensor in the iron compounds, $Na_2[Fe(CN)_5NO] \cdot 2H_2O$,[2] $FeSO_4 \cdot 7H_2O$,[3] $FeSO_4 \cdot (NH_4)_2 SO_4 \cdot 6H_2O$,[3] *etc.*[4-6]

In these cases, the analysis of the quadrupole hyperfine anisotropy, however, was based on the thin absorber approximation. Unless the absorber is extremely thin, the analysis is complicated by the partial saturation of the absorption intensity in a polarized single crystal.

The general theory of polarization effects given by Housley *et al.*[7] has been developed recently by Gibb,[8] who treated the data of the $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ single crystal with polarization in the absorption cross section and obtained good results.

So far no Mössbauer experiments with single crystals containing tin have been performed except for $Fe\{(\pi\text{-}C_5H_5)(CO)_2\}_2 SnCl_2$,[9] with which the EFG tensor at tin has been evaluated and discussed by the use of a point-charge model. Therefore, in this paper we wish to report the results for Mössbauer absorption spectra by taking into account the absorber thickness effect in single crystals of $(CH_3)_2SnF_2$ and $(CH_3)_2SnCl_2$.

Experimental

A single crystal of $(CH_3)_2SnF_2$ was grown by the slow evaporation of its HF solution. A thin crystal plate of approximately 0.4×0.4 cm^2 could be obtained over about 8 weeks. The crystal habit has been described in detail.[10] An unusual feature is the dominance of the 001 plane, whose edges coincide with the crystallographic a direction. $(CH_3)_2SnF_2$ is a tetragonal crystal in the space group I4/mmm, with cell dimensions of $a=b=4.24$ Å and $c=14.16$ Å.[11] A unit cell contains two Sn atoms at the 2a positions (0, 0, 0) and (1/2, 1/2, 1/2), with a point symmetry of 4/mmm. The tin atoms are octahedrally surrounded by two methyl groups and four bridging fluorine atoms. These octahedra have the same orientation relative to the crystal axes. The local environment of the tin is shown in Fig. 1(a).

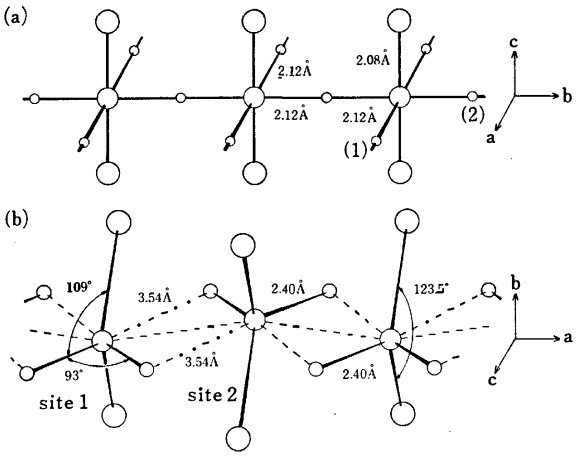

Fig. 1. The structure of (a) $(CH_3)_2SnF_2$ and (b) $(CH_3)_2SnCl_2$.
○: Me, ○: Sn, ○: Cl, and ○: F.

A large crystal of $(CH_3)_2SnCl_2$ was grown by the Bridgman method.[12] After it had been cut with a knife along the habit plane (011 and 01$\bar{1}$), we obtained a thin plate of approximately 0.7×0.7 cm^2 by the hand-polishing technique. $(CH_3)_2SnCl_2$ crystallizes in the orthorhombic space group of Imma, with unit cell dimensions of $a=8.78$, $b=7.75$, and $c=9.25$ Å.[13] The structure consists of a chain of molecules running parallel to the a axis, with the tin atoms in the distorted octahedrals. The tin and chlorine atoms in each chain are coplanar, and the methyl groups are not collinear with the tin atoms joined to their own neighbors by two bridging chlorine atoms (Fig. 1(b)).

The thickness of the crystal samples was determined by means of their weights and areas. The values of $(CH_3)_2SnF_2$ and $(CH_3)_2SnCl_2$ were 29 and 18 mg/cm^2 respectively for Sn. The crystal was mounted on a goniometer head, and the crystal axes were located by the X-ray diffraction method. Then the goniometer head was placed in a liquid nitrogen cryostat so the gamma ray might be incident perpendicularly to the crystal plate. The angle of the plate to the gamma ray was varied by the rotation of the goniometer head.

The Mössbauer spectra were obtained by the use of a constant-acceleration-type spectrometer. The gamma-ray source was 0.7 mCi ^{119}Sn in the barium stannate matrix and was used at room temperature. The absorber temperatures were 135 K for single-crystal samples and 100 K for powder. X-Rays from the source were shut out by a palladium foil 50 micron thick. The velocity scale was calibrated by the use of reference absorbers of $BaSnO_3$ and Sn foil. All the

spectra were analyzed by means of a least-squares computer fitting the Lorentzian-line shapes without constraints on the line positions, widths, and intensities by the use of HUC-III, HITAC-8700.

Method of Calculation

The Absorption Cross Section. The polarization of the absorption cross section can be described in terms of 2×2 density matrices such as:

$$\begin{pmatrix} \rho_{11}^{ij} & \rho_{12}^{ij} \\ \rho_{21}^{ij} & \rho_{22}^{ij} \end{pmatrix}$$

where sites are labeled by j and the hyperfine components of a resonance by i.[7] The normalization conditions are $\sum_i \rho_{11}^{ij} = \sum_i \rho_{22}^{ij} = 1$ and $\sum_i \rho_{12}^{ij} = \sum_i \rho_{21}^{ij} = 0$. The density matrix can always be diagonalized if the direction of observation is in a mirror or glide plane, along a 3-fold or higher rotation or a screw axis, and normal to a suitable 2-, 4-, 6-fold rotation axis. Furthermore, if there is only one resonant site per unit cell, then the density matrix can always be diagonalized for any observation direction.

$(CH_3)_2SnF_2$ has only one resonant site per unit cell, and $(CH_3)_2SnCl_2$ has three 2-fold rotation axes parallel to the a, b, and c axes. In these single crystals, therefore, the density matrix is diagonalized for the observation direction normal to the a axis.

If there are only two absorption lines in the spectrum, as in the case for the $I=1/2\rightarrow3/2$ nuclear transition, appropriate density matrix elements for a single site, j, have been shown to be:

$$\begin{aligned} \rho_{11}^{j} &= 1/2 \pm (1/4)w(1+\eta\cos 2\phi_j) \\ \rho_{22}^{j} &= 1/2 \pm (1/4)w(1-3\sin^2\theta_j - \eta\cos^2\theta_j\cos 2\phi_j) \\ \rho_{12}^{j} &= \rho_{21}^{j} = \pm(\eta/4)w\cos\theta_j\sin 2\phi_j \end{aligned} \quad (1)$$

where $w=[3/(3+\eta^2)]^{1/2}$, where the upper signs correspond to the $\pm1/2\rightarrow\pm3/2$ (π) transitions and the lower to the $\pm1/2\rightarrow\pm1/2$ (σ) transitions, and where θ_j and ϕ_j are polar angles with respect to the principal-axes system (PAS) of the EFG.

Let us transform Relation (1) from the θ_j and ϕ_j coordinates to the Θ and Φ coordinates, which define the crystal axes with respect to the incident radiation beams, as is illustrated in Fig. 2. Since the $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ directions are orthogonal with one another, the following expressions relate θ_j, ϕ_j to Θ, Φ, and the Euler angles $(\alpha_j, \beta_j, \gamma_j)$ which relate the j site to the axes $(\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c})$:

$$\begin{aligned} \sin\theta_j\cos\phi_j &= \sin\Theta\cos\Phi(\boldsymbol{b}\cdot\boldsymbol{x}_j) + \sin\Theta\sin\Phi(\boldsymbol{c}\cdot\boldsymbol{x}_j) \\ &\quad + \cos\Theta(\boldsymbol{a}\cdot\boldsymbol{x}_j) \equiv B_j \\ \sin\theta_j\sin\phi_j &= \sin\Theta\cos\Phi(\boldsymbol{b}\cdot\boldsymbol{y}_j) + \sin\Theta\sin\Phi(\boldsymbol{c}\cdot\boldsymbol{y}_j) \\ &\quad + \cos\Theta(\boldsymbol{a}\cdot\boldsymbol{y}_j) \equiv C_j \\ \cos\theta_j &= \sin\Theta\cos\Phi(\boldsymbol{b}\cdot\boldsymbol{z}_j) + \sin\Theta\sin\Phi(\boldsymbol{c}\cdot\boldsymbol{z}_j) \\ &\quad + \cos\Theta(\boldsymbol{a}\cdot\boldsymbol{z}_j) \equiv A_j \end{aligned} \quad (2)$$

where:

$$\begin{aligned} (\boldsymbol{b}\cdot\boldsymbol{x}_j) &= \cos\alpha_j\cos\beta_j\cos\gamma_j - \sin\alpha_j\sin\gamma_j \\ (\boldsymbol{c}\cdot\boldsymbol{x}_j) &= -\cos\alpha_j\cos\beta_j\sin\gamma_j - \sin\alpha_j\cos\gamma_j \\ (\boldsymbol{a}\cdot\boldsymbol{x}_j) &= \cos\alpha_j\sin\beta_j \\ (\boldsymbol{b}\cdot\boldsymbol{y}_j) &= \sin\alpha_j\cos\beta_j\cos\gamma_j + \cos\alpha_j\sin\gamma_j \\ (\boldsymbol{c}\cdot\boldsymbol{y}_j) &= -\sin\alpha_j\cos\beta_j\sin\gamma_j + \cos\alpha_j\cos\gamma_j \\ (\boldsymbol{a}\cdot\boldsymbol{y}_j) &= \sin\beta_j\sin\gamma_j \\ (\boldsymbol{b}\cdot\boldsymbol{z}_j) &= -\sin\beta_j\cos\gamma_j \\ (\boldsymbol{c}\cdot\boldsymbol{z}_j) &= \sin\beta_j\sin\gamma_j \\ (\boldsymbol{a}\cdot\boldsymbol{z}_j) &= \cos\beta_j \end{aligned} \quad (3)$$

From Eq. 2, it may be shown that Eq. 1 has the form of:

$$\begin{aligned} \rho_{11}^{j} &= 1/2 \pm (1/4)w\{1+\eta(B_j^2-C_j^2)/(1-A_j^2)\} \\ \rho_{22}^{j} &= 1/2 \pm (1/4)w\{1-3(1-A_j^2) \\ &\quad -\eta A_j^2(B_j^2-C_j^2)/(1-A_j^2)\} \\ \rho_{12}^{j} &= \rho_{21}^{j} = \mp(\eta/2)wA_jB_jC_j/(1-A_j^2) \end{aligned} \quad (4)$$

Absorption Areas. Since the ^{119}Sn first excited state has a spin of 3/2, as a result of the interaction of the nuclear quadrupole moment with the EFG, the resonance absorption line splits into two components, whose separation is given by:

$$\Delta E = (1/2)e^2qQ(1+\eta^2/3)^{1/2} \quad (5)$$

where eq is the EFG in the z (major-axis) direction, η the asymmetry about the z axis ($0\leq\eta<1$) and eQ the nuclear quadrupole moment of the first excited state of ^{119}Sn.

If the observed spectrum has the form of the individual, completely split components—*i.e.*, if the energy difference between components is larger than the absorption line width, then the absorption area, A_i, for the i-th component of the spectrum of the absorber with the effective cross section of T_a is given by:

$$A_i = \alpha f\pi K(T_{ia}) \quad (6)$$

where:

$$\begin{aligned} K(T_{ia}) &= T_{ia}\exp(-T_{ia}/2)[I_0(T_{ia}/2)+I_1(T_{ia}/2)], \\ T_{ia} &= b_iT_a, \end{aligned}$$

α is the fraction of the resonance quanta in the emission spectrum; f, the recoilless fraction of the source, $I_0(x)$ and $I_1(x)$, the zero- and the first-order Bessel function and imaginary argument respectively, and b_i, the relative intensity of the i-th component.[14] If we are considering a polarized absorber (such as a single crystal) with two independent polarizations of the cross section, ρ_{11}^i and ρ_{22}^i, then the area of the i-th component

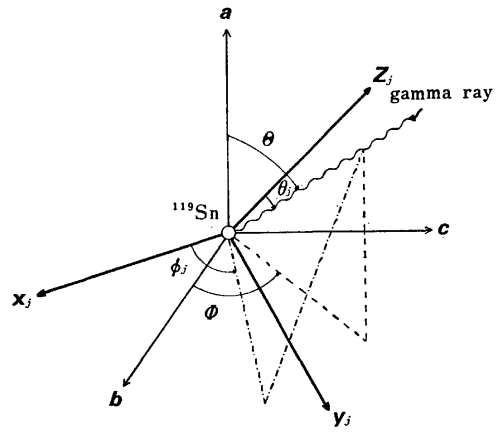

Fig. 2. The orientation of the incident radiation beam relative to the crystal axes (**a**, **b**, **c**) and the EFG axes ($\mathbf{x}_j$, $\mathbf{y}_j$, $\mathbf{z}_j$) of the j-th site in the unit cell.

is given by[8]:

$$A_i = \alpha f\pi[(1/2)K(\rho_{11}^i T_a)+(1/2)K(\rho_{22}^i T_a)] \quad (7)$$

Density Matrix for Two Sites in $(CH_3)_2SnCl_2$. If we let k_j stand for either x_j, y_j, or z_j, the symmetry relation between two sites in the unit cell is a 180° rotation about the a axis and can be written as:

$$\begin{aligned}(b\cdot k_1) &= -(b\cdot k_2)\\ (c\cdot k_1) &= -(c\cdot k_2)\\ (a\cdot k_1) &= (a\cdot k_2)\end{aligned} \quad (8)$$

Consequently, from Eqs. 2 and 8, for observation in the bc plane, *i.e.*, for $\Theta=90°$, the diagonal elements of the density matrix are the same for both sites. The resulting diagonal elements of the density matrix are:

$$\begin{aligned}\rho_{11} &= (1/2) \pm (1/4)w\{1+\eta(B'^2-C'^2)/(1-A'^2)\}\\ \rho_{22} &= (1/2) \pm (1/4)w\{1-3(1-A'^2)\\ &\quad -\eta A'^2(B'^2-C'^2)/(1-A'^2)\}\end{aligned} \quad (9)$$

where:

$$\begin{aligned}A' &= \cos\Phi(b\cdot z) + \sin\Phi(c\cdot z)\\ B' &= \cos\Phi(b\cdot x) + \sin\Phi(c\cdot x)\\ C' &= \cos\Phi(b\cdot y) + \sin\Phi(c\cdot y)\end{aligned}$$

Eq. 9 also holds for observation along the a axis; *i.e.*, $\Theta=0°$, where:

$$A' = (a\cdot z),\quad B' = (a\cdot x),\quad C' = (a\cdot y)$$

Note that these equations are ill-conditioned if $1-A'^2=0$; *i.e.*, $\beta=90°$ and $\alpha=\Phi$ in the first case, and $\beta=0°$ in the second.

Recoilless Fraction. When the recoilless fraction of the absorber is f', the effective cross section can be written as $T_a=\eta f'\sigma_0$, where n is the number of resonant nuclides per cm², and σ_0, a resonant cross section. Therefore, the effective cross section, T_a, depends on f'.

From the elementary theory of the Mössbauer-Lamb fraction, the dependence of the recoilless fraction on the mean-square amplitude of the vibration ($\langle u^2\rangle$) is given by:

$$f' = \exp(-\langle u^2\rangle/\lambda\!\!\!^{-2}) \quad (10)$$

where $2\pi\lambda\!\!\!^{-}=hc/E$, the gamma quatum wavelength, which for ^{119}Sn is 5.190×10^{-9} cm. For an axial-symmetric crystal, using the model for the angular distribution of MSD given by Kündig *et al.*,[15]

$$\langle u^2\rangle(\theta') = \langle u_\perp{}^2\rangle \sin^2\theta' + \langle u_{//}{}^2\rangle \cos^2\theta' \quad (11)$$

where $\langle u_\perp{}^2\rangle$ and $\langle u_{//}{}^2\rangle$ are components of the MSD tensor normal to and parallel to its principal axis, and θ', the polar angle made by the gamma-ray-propagation vector, k, with respect to the PAS of the MSD tensor. From Eqs. 10 and 11, the recoilless fraction for the powder sample is given by:

$$f' = \exp\{-(1\lambda\!\!\!^{-2})(\langle u_{//}{}^2\rangle+2\langle u_\perp{}^2\rangle)/3\} \quad (12)$$

By assuming a Debye model for the phonon spectrum, the temperature dependence of the recoilless fraction is given by the well-known expression[16]:

$$f' = \exp\{-(3E_R/2k\theta_D)[1+4(T/\theta_D)^2\int_0^{\theta_D/T} x\,dx/(e^x-1)]\} \quad (13)$$

in which, within the high-temperature limit, ($T\geq\theta_D/2$) takes the form of:

$$f' = \exp[(-6E_R/k\theta_D{}^2)T] \quad (14)$$

where E_R is the recoil energy of the free nucleus, and θ_D, the Debye temperature. Therefore, if the MSD or the Debye temperature is known, f' can be estimated from Eqs. 10, 12, and 13.

From Eq. 6, if a second spectrum is determined using a similar absorber k times as thick as the original one, the ratio of the intensity is determined as follows:

$$A_i'/A_i = K(kb_i\eta f'\sigma_0)/K(b_i\eta f'\sigma_0) \quad (15)$$

where $k=n'/n$.

Since A_i', A_i, n', and n are measurable, and since $K(x)$ is assumed to be a Lorentzian, the value of f' can be determined from Eq. 15.

Results and Discussion

$(CH_3)_2SnF_2$. The Mössbauer spectra were obtained at 135K for the single-crystal absorber mounted on the a axis normal to the observation axis. Figure 3 shows two typical experimental spectra. The upper spectrum is observed when the angle of the source radiation is 10° from the c axis of the crystal and the crystal thickness is 29.5 mg/cm² for Sn; the lower spectrum is observed when the direction of the radiation is 45° from the c axis and the crystal thickness is 41.0 mg/cm² for Sn.

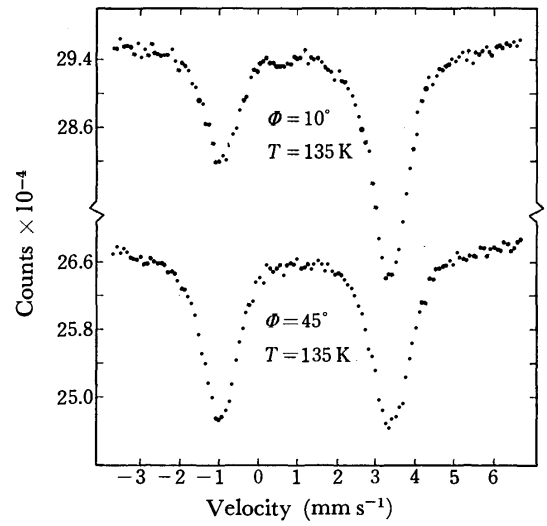

Fig. 3. The Mössbauer absorption spectra of $(CH_3)_2SnF_2$ single crystal absorber with the direction of observation normal to the a axis.

The room-temperature mean-square amplitude of vibration along the a axis, $\langle u_\perp{}^2\rangle$, and that along the c axis, $\langle u_{//}{}^2\rangle$, have been reported to be 0.0188 Å² and 0.0440 Å² respectively.[11] These values were substituted into Eq. 12 in order to estimate the value of f' at room temperature. Using this value of f', it was estimated from Eq. 14 that the Debye temperature, θ_D, is 115.7 K and that f' is 0.17 at 135 K.

Previously it was mentioned that the tin is surrounded by a octahedron composed of four fluorine atoms and two methyl groups. It will be noted that the C–Sn–C bond direction is assuredly a 4-fold axis, because the angles between the axes of the octahedron are 90°. Therefore, the Sn–C direction is taken as the z axis of the EFG, and the Sn–F(1) and Sn–F(2) directions, as the x and y axis respectively. The EFG is thus axially

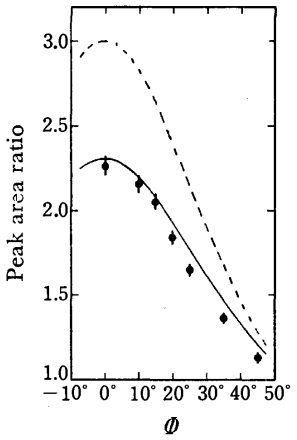

Fig. 4. The area ratio as a function of the observation angle Φ for $(CH_3)_2SnF_2$ single crystal at 135 K. The solid line is computed for $e^2qQ>0$, $\eta=0$, $f'=0.17$, $\alpha=0°$, $\beta=90°$, and $\gamma=90°$. The broken line is computed for neglecting polarization effects.

symmetric ($\eta=0$). Assuming that f' is isotropic, we calculated the area ratio, A_π/A_σ, as a function of the observation angle, Φ, in the bc plane using Eqs. 2, 3, 4, and 7. The assumption that f' is isotropic is supported by the work of Herber and Chandra,[17] who reported that the mean-square amplitudes of vibration of the tin atoms in $(CH_3)_2SnF_2$ were the same in all directions at 140K. The results are shown in Fig. 4. The solid line is the curve computed for $f'=0.17$, $\eta=0$, $\alpha=0°$, $\beta=90°$, and $\gamma=90°$. The broken curve is the line calculated neglecting the effects of polarization, as in Zory.[1] The agreement between the experimental and theoretical results means that the ratio of the high-energy experimental absorption area to the low energy one, A_H/A_L, is equal to A_π/A_σ and not A_σ/A_π. This implies that the $\pm3/2\rightarrow\pm1/2$ transition is higher in energy than the $\pm1/2\rightarrow\pm1/2$ transition, *i.e.*, the sign of the quadrupole interaction (e^2qQ) is positive, which is in accordance with the result obtained by the application of a large external magnetic field.[18]

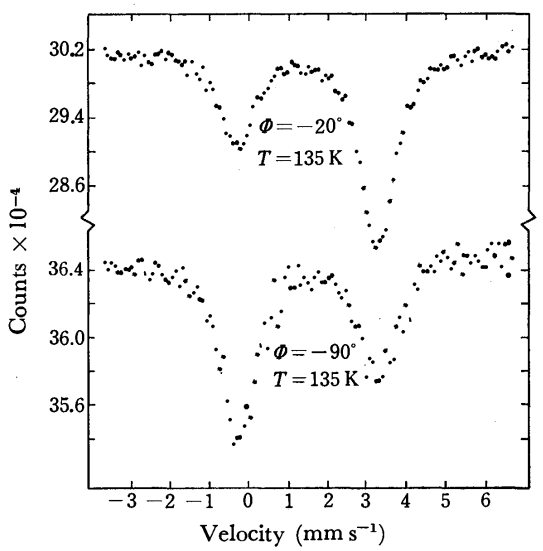

Fig. 5. The Mössbauer absorption spectra of $(CH_3)_2SnCl_2$ single crystal absorber with the direction of observation normal to the a axis.

$(CH_3)_2SnCl_2$. The single-crystal Mössbauer spectra were obtained at 135 K for gamma radiation in the bc plane. The spectra which were obtained for two cases are shown in Fig. 5. In the first case, the gamma ray direction from the b axis was −20° and the thickness was 19.2 mg/cm^2 for Sn, whereas in the second the values are −90° and 28.0 mg/cm^2 respectively.

An approximate value of f' was obtained by the area-ratio method using the powder sample at 100 K. Figure 6 illustrates the results. The low-energy experimental-absorption-area ratios $(A'/A)_L$, are plotted against n'/n. A reasonable fit to the data is obtained for $nf_L'\sigma_0=0.60$, which gives $f'_L=0.10$. A similar analysis for the high-energy experimental-absorption-area ratios $(A'/A)_H$ yields $f'_H=0.11$. Therefore, $f'_L+f'_H=0.21$ is obtained as the recoilless fraction of $(CH_3)_2SnCl_2$ at 100K. Substituting $f'=0.21$ into Eq. 14, the Debye temperature θ_D

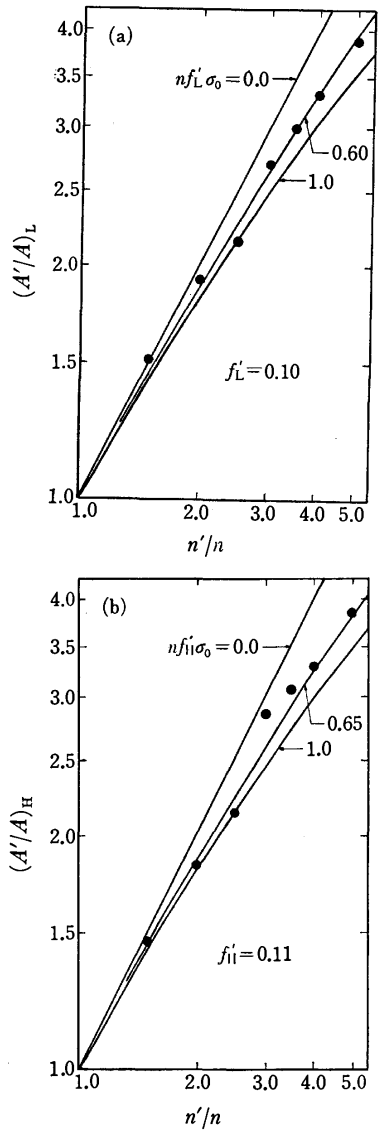

Fig. 6. The absorption area ratio against $(CH_3)_2SnCl_2$ powder absorber thickness ratio at 100 K. (a) The lower energy experimental area ratio $(A'/A)_L$ is plotted against n'/n. (b) The higher energy experimental area ratio $(A'/A)_H$ is plotted against n'/n.

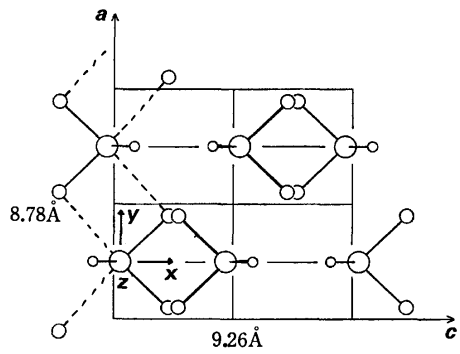

Fig. 7. Projection of the unit cell of $(CH_3)_2SnCl_2$ on the ac plane. ○: Sn, ○: Cl, and o: C.

is derived as 107.1 K, which is in good agreement with the literature value,[19] 108.3 K at 70 K. Using this value of θ_D, the value of f' at 135 K is found to be nearly equal to 0.12.

In the following discussion, we shall refer only to one site because the two sites are related by a 180° rotation about the a axis. The projection onto the crystallographic ac plane of the unit cell of $(CH_3)_2SnCl_2$ is shown in Fig. 7. Since the tin atom in the unit cell lies on the mirror plane parallel to the ac and bc plane and has C_{2v} symmetry, it can be expected that the principal axes of the EFG tensor lie parallel to the crystallographic a, b, and c axes. However, it is unclear which principal axes of the EFG the a, b, and c axes correspond to; furthermore, the value of η can not be determined from the point symmetry of the tin site itself. Erickson has reported that the sign of V_{zz} in $(CH_3)_2SnCl_2$ is negative.[20] The negative sign of V_{zz} (which corresponds to an excess of the negative charge along the z axis) in *trans*-R_2SnX_4 compounds can most logically be interpreted by assuming that tin-carbon bonds have a much larger p-electron density along the bond that do tin-halogen bonds along their bond axes. Therefore, it seems most likely that the V_{zz} direction is along the b axis.

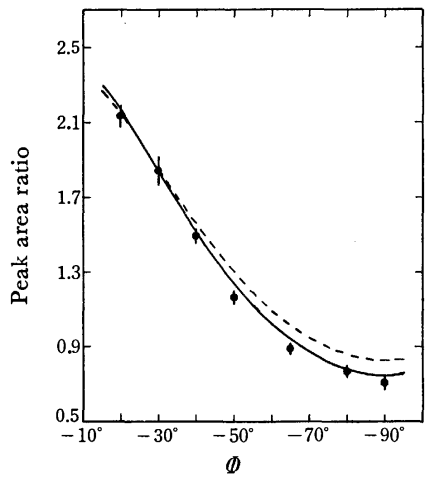

Fig. 8. The area ratio as a function of the observation angle Φ for $(CH_3)_2SnCl_2$ single crystal at 135 K. The dotted curve is computed for $\eta=0.6$, and solid curve for $\eta=0.4$, when $e^2qQ>0, f'=0.12$, $\alpha=0°$, $\beta=90°$, and $\gamma=90°$.

Equations 3, 7, and 9 were evaluated by means of a small computer program to give the density matrix elements for various values of α, β, γ, and η. We assumed that f' was approximately isotropic and that V_{xx} and V_{yy} were parallel to the crystallographic c axis and a axis respectively. The observation angle (Φ) curve for the area ratio was then found using Eq. 7. The results of $\eta=0.4$ and 0.6 are shown, along with the experimental values, in Fig. 8. The dotted curve is computed for $\eta=0.6$, and the solid curve, for $\eta=0.4$, when $f'=0.12$, $\alpha=0°$, $\beta=90°$, and $\gamma=90°$. The agreement between the experimental and calculated values is better when $\eta=0.4$ is used than when $\eta=0.6$ is used. The latter value, which was published previously,[20] must be overestimated. A more detailed value for η may be obtained by comparison with the results of other observations normal to the b axis or the c axis. As we have seen, the thickness of the sample has so profound an effect on the absorption spectra that precise area measurements are necessary to determine the value of η as well as e^2qQ.

We wish to express our sincere gratitude to Assistant Professors Toshihiko Kushi of Hiroshima University and Mitsuo Mishima of Shimane University for their valuable advice in analyzing the data.

Magnetic Circular Dichroism of the Thulium and Erbium Ethyl Sulfate Nonahydrate Crystals

Yoshifumi KATO, Toshikazu NAKAYA, and Toshiyuki NAGAI

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received July 26, 1976)

The magnetic circular dichroism and absorption spectra of the thulium and erbium ethyl sulfate nonahydrate crystals have been measured at low temperatures, down to 18 K. The analyses are made for five absorption bands of $Tm(C_2H_5SO_4)_3 \cdot 9H_2O$; the bands from the ground state, $^3H_6$, to the excited states $^3F_3$, $^3F_2$, $^1G_4$, $^1D_2$, and $^3P_1$ of Tm^{3+}, and for four bands of $Er(C_2H_5SO_4)_3 \cdot 9H_2O$; the bands from the ground state, $^4I_{15/2}$, to the excited states $^4S_{3/2}$, $^4F_{5/2}$, $^4F_{3/2}$, and $^2G_{9/2}$ of Er^{3+}. With the aid of the information about energy levels already obtained, the *g* values of the crystal levels relevant to absorptions are derived from the Faraday parameters; these are in good agreement with those obtained by other methods.

A certain amount of crystal field level data for rare earth crystals has been accumulated by the analysis of the absorption and fluorescence spectra and the Zeeman effect for these crystals.[1,2] By using the knowledge of these well established energy levels, it has been pointed out[3-6] that even when optical absorption bands are too broad to give resolved Zeeman patterns, fairly accurate estimates of the spectroscopic splitting factors (*g* value) in the ground and excited states can be obtained from the magnetic circular dichroism (MCD) spectra.

In the present work, the MCD measurements for five absorption bands of thulium ethyl sulfate nonahydrate, $Tm(C_2H_5SO_4)_3 \cdot 9H_2O$ (Tm(ES)), and four absorption bands of erbium ethyl sulfate nonahydrate, $Er(C_2H_5SO_4)_3 \cdot 9H_2O$ (Er(ES)), have been carried out at low temperatures and the *g* values derived from the MCD are compared with those obtained by other methods.

Experimental

The procedure of the preparation of the crystals is described in our previous paper.[6] All the absorption and MCD spectra were obtained by a JASCO J-10 spectrophotometer equipped with a permanent magnet of 3.6 kG. The measurements at low temperatures down to 18 K were performed using a metal Dewar vessel, as showh in Fig. 1. The temperature of the crystal packed into a sample cell attached to the tail of the liquid helium vessel was measured by using an Au-Co *versus* chromel thermocouple with one junction pressed directly against the crystal and found to be 80 ± 1 and 18 ± 2 K at liquid nitrogen and helium temperatures, respectively.

The product of the concentration and path length for a sample was determined from a comparison of the absorption strength of several isolated bands in the crystal with that of the corresponding aqueous solution at room temperature. While this procedure may produce errors in the estimate of the absorption coefficient and the molar ellipticity, this is not a serious matter,[6,7] because the important quantities in our discussion are always the ratios of the Faraday parameters to the dipole strength. The slit width was made as narrow as possible ($\approx$0.01 mm) to resolve an overlapping band, although there was a limitation owing to the characteristic resolving power of the instrument. When the incident light beam was directed along the principal axis of a uniaxial, crystal, no birefringence effect was observed in the present measurement; the base line was flat and well behaved with zero magnetic field. The MCD and absorption data thus obtained are considered to be accurate within 20 percent.

Results and Discussion

Energy Levels and Calculated g *Values.* The Tm^{3+} and Er^{3+} ions in ethyl sulfate have $4f^{12}$ and $4f^{11}$ electronic configurations respectively. According to the analysis of the crystal structure of rare earth ethyl sulfates,[8] the space group is $P6_3/m$ (C^2_{6h}) and the local symmetry about a rare earth ion is D_{3h} as far as the nearest-neighbor oxygen atoms of 9 crystalline waters are concerned. An ion state $|JM>$ placed in a crystal field splits into several crystal levels, designated by the crystal quantum numbers η, following Hellwege:[9] *e.g.*, the ground ion state of Tm(ES), $^3H_6$, and that of Er(ES), $^4I_{15/2}$, split into 9 and 8 crystal levels in D_{3h} symmetry, respectively.

In general, it is possible to evaluate theoretically the *g* values of crystal levels. Wong and Richman[10] made

the calculation of the crystal levels of Tm(ES) and their g values. They obtained the root mean square deviation of 118.9 cm^{-1} for 11 ion levels by the operator equivalent method and that of 10.8 cm^{-1} for 21 crystal levels by the first-order perturbation theory. Although the accuracy of the physical quantities calculated depends on that of the wave functions used, the results by Wong and Richman are considered to be fairly reliable. As there has been no calculation for the g values of Er(ES), we have made the crystal field calculation for this crystal[11] in which the configuration interaction for ion levels and complete J-mixing for crystal levels are taken into account by means of the tensor method.[12] This calculation has made it possible to fit 22 ion levels with the root mean square deviation of 78.2 cm^{-1} and to fit 50 crystal levels with that of 3.6 cm^{-1}. The calculated g values will be utilized in the comparison with those from MCD in the following section.

MCD Spectra. The general expressions for the MCD extensively used can be applied to a uniaxial crystal. The ellipticity accompaning an electronic transition is written as

$$\theta = -\frac{4}{3}\gamma N_a[Af_1/\hbar+(B+C/kT)f_0]H, \qquad (1)$$

where the explicit expressions for the Faraday parameters A, B, and C, are given by Stephens.[13,14] The ordinary conditions assumed in the derivation of Eq. 1 (Zeeman energy $\ll$zero-field state separation, line width, and kT) are satisfied in the present measurements. The ratios of the Faraday parameters to the dipole strength D $(=(1/d_a)|\langle a|\boldsymbol{m}|j\rangle|^2)$ are related to the g values of the ground a and excited j states in a transition as

$$|A/D| = |g_j-g_a|, \quad |C/D| = |g_a|, \qquad (2)$$

where the Zeeman splitting is taken as $2g\beta H$, since there are no multiplets except the doublet in the ethyl sulfate crystals. The selection rules in D_{3h} symmetry in case of an even and odd number of electrons are given in

$\pm3/2$	σ	π	σ
$\pm5/2$	σ, π	σ	—

Table 1,[15] while σ polarization can be observed in the present experiment. The energy level diagrams of Tm(ES) and Er(ES) relevant to the present analysis are given in Fig. 2.[1] The MCD and absorption spectra observed are shown in Figs. 3 and 4 for Tm(ES) and Er(ES), respectively. The absorption bands analyzed are five for Tm(ES): $^3H_6 \rightarrow {}^3F_3$, $^3F_2$, $^1G_4$, $^1D_2$, and $^3P_1$, and four for Er(ES): $^4I_{15/2} \rightarrow {}^4S_{3/2}$, $^4F_{5/2}$ $^4F_{3/2}$, and $^2G_{9/2}$.[16] The Faraday parameters derived from the method of moments[14,17] are given in Tables 2 and 3 for Tm(ES) and Er(ES), respectively. We consider that the parameter values by the graphical method by Bodoz *et al.*[18] and the curve fitting method by a least-squares procedure[19] can be also obtained with similar accuracy to those by the moment method when a careful application of these two methods is made.[19]

Discussion for Tm(ES). The lowest crystal level of the $^3H_6$ state of Tm(ES) is a non-degenerate level $\eta=0$. The population of the next level ($\eta=\pm1$), which is 32 cm^{-1} higher than the lowest level, is 8 percent of

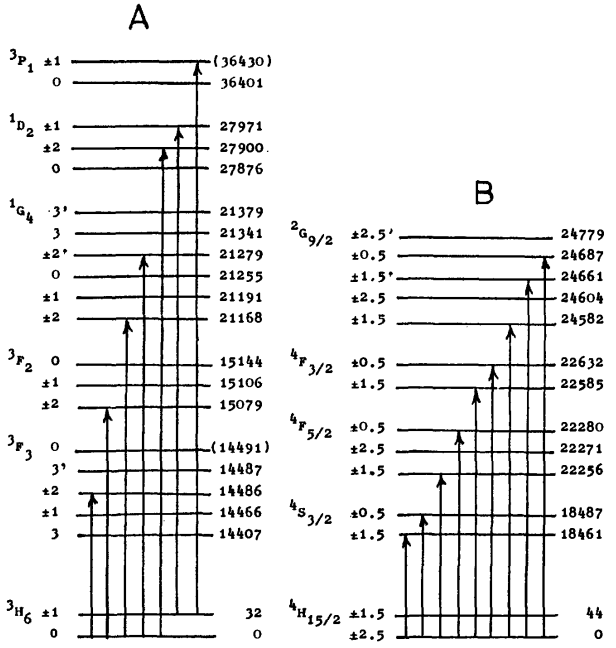

Fig. 2. Energy level diagrams of Tm(ES) (A) and Er(ES) (B) (Ref. 1). The units of energy are in cm^{-1}. The values in parentheses are not yet determined experimentally. Allowed transitions are indicated by arrows.

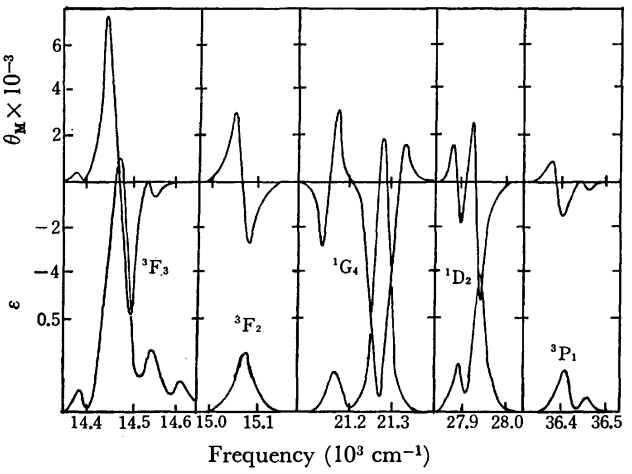

Fig. 3. Absorption and MCD spectra of Tm(ES) at 18 K. θ_M and ε are the MCD in molar ellipticity units (degree deciliter decimeter^{-1} mol^{-1}) per unit gauss and molar extinction coefficient, respectively.

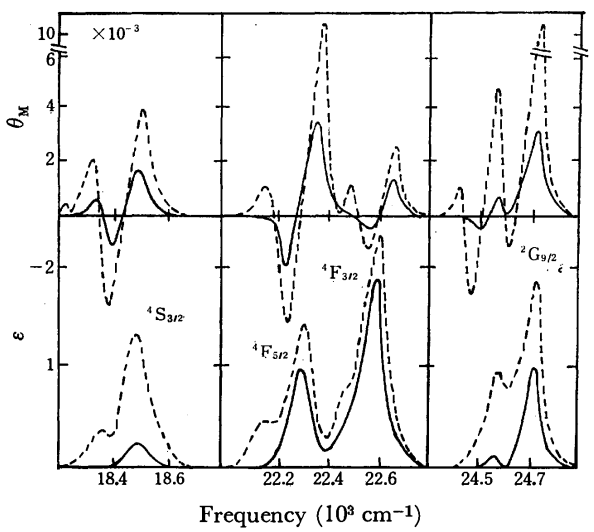

Fig. 4. Absorption and MCD spectra of Er(ES) at 18 K (solid line) and at 80 K (broken line). Notations and units are the same as in Fig. 3.

that of the latter at 18 K. As seen in Fig. 3, the $^3H_6 \rightarrow {}^1D_2$ band splits into two bands: each of these should correspond to the $^3H_6(\eta=0) \rightarrow {}^1D_2(\eta=\pm 2)$ and the $^3H_6(\eta=\pm 1) \rightarrow {}^1D_2(\eta=\pm 1)$ transitions (Fig. 2). Furthermore, the band at about 36400 cm^{-1} is readily seen to be the $^3H_6(\eta=\pm 1) \rightarrow {}^3P_1(\eta=\pm 1)$ transition from the selection rules (Table 1). Thus, the absolute value of g in the $^3H_6(\eta=\pm 1)$ level can be obtained separately from the C/D values in the two transitions from this level; its average value is 1.11 β. The absolute g values for the excited levels of these two bands are also obtained from the corresponding A/D values. However, for the $^3H_6 \rightarrow {}^3F_3$, $^3F_2$, $^1G_4$ bands, no evident transition from the $^3H_6(\eta=\pm 1)$ level is observed in the present measurements (Fig. 3). If it is assumed that these bands arise solely from the lowest level $^3H_6(\eta=0)$, then all the C/D values for these bands turn out to be zero, the B/D values are fixed, and the absolute g values of the excited levels are obtained from the corresponding A/D values. As a result, all the g values of the crystal levels observed are definitely settled. The g values derived from MCD are compared with those of other methods in Table 4; here the agreement among the three methods is fairly good within the accuracy estimated. The g values from MCD seem to be in better agreement with those by Zeeman effect than are the calculated values.

Discussion for Er(ES). All the crystal levels of Er(ES) are doubly degenerate due to the Kramers degeneracy. The lowest crystal level of the $^4I_{15/2}$ state of Er(ES) is $\eta=\pm 5/2$. The population of the next level ($\eta=\pm 3/2$) which is 44 cm^{-1} higher than the lowest level, is 3 percent of that of the latter at 18 K. Thus, we can assume that all the absorption bands at 18 K originate only from the lowest crystal level. However, from the energy level diagram (Fig. 2), each of the bands except the band at about 24580 cm^{-1} should be considered to consist of two transitions to the excited crystal levels ($\eta=\pm 3/2$ and $\pm 1/2$), owing to low dispersion of the instrument used. Therefore, the estimate of g values is not so straightforward. In the $^4I_{15/2} \rightarrow {}^2G_{9/2}$ band consisting of only one transition, the absolute g values for the $^4I_{15/2}(\eta=\pm 5/2)$ and $^2G_{9/2}(\eta=$

a) The absolute values. b) The data from Ref. 21. c) The data from Ref. 10.

$\pm3/2$) levels can be determined from the Faraday parameters. As seen in Table 3, the A/D values for each of the other four bands are almost constant and independent of temperature, but the C/D values over these bands are not consistent with each other and also are considerably different from the value of the $^4I_{15/2}(\eta=\pm5/2)\rightarrow{}^2G_{9/2}(\eta=\pm3/2)$ band. Therefore it will be difficult to extract useful information from these C/D values. When it is assumed that each A/D value of the above four bands is a simple sum of the values from the two transitions which are contained within a band, and the g value of the ground level is taken as 0.75, being the value from the Zeeman experiment,[20] the g values for the excited crystal level can be estimated. The g values thus obtained are compared with those of other methods in Table 5. The agreement between the g values from MCD and those of other methods is satisfactory, considering the above assumption.

TABLE 5. COMPARISON OF THE g VALUES IN Er(ES)

Level		Energy (cm^{-1})	g value		
Term	η		MCD[a]	Zeeman[b]	Calcd[c]
$^4I_{15/2}$	$\pm5/2$	0	0.86	0.75±0.03 0.74±0.02[d]	0.71
$^4S_{3/2}$	$\pm3/2$	18461	(2.47)	2.47±0.09	2.53
	$\pm1/2$	18487	1.00	—	0.84
$^4F_{5/2}$	$\pm3/2$	22256	(1.56)	1.56±0.15	1.57
	$\pm1/2$	22280	0.35	—	0.53
$^4F_{3/2}$	$\pm3/2$	22585	(1.05)	1.05±0.08	1.12
	$\pm1/2$	22632	0.28	—	0.37
$^2G_{9/2}$	$\pm3/2$	24582	1.82	−1.83±0.05	−2.26
	$\pm3/2'$	24661	(1.50)	−1.50±0.25	−0.96
	$\pm1/2$	24687	0.08	0.15±0.10	0.54

a) The absolute values. The values in parentheses are assumed ones. b) The data from Ref. 20. c) The data from Ref. 11. d) The value from paramagnetic resonance (Ref. 22).

In conclusion, it may be stated that with the aid of the knowledge of well-established energy levels, the g values of crystal levels can be estimated with considerable accuracy from MCD, and these values might be better than other calculated ones.

We wish to express our gratitude to Professor T. Kanda and his coworkers at Kobe University for their aid with the experiment at liquid helium temperature.

A Semi-empirical NDDO Method for All-valence-electron Systems. I. Hydrocarbons

Osamu KIKUCHI

Department of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

(Received August 5, 1976)

A semi-empirical NDDO method is applied to the evaluation of the molecular geometries and excitation energies of a variety of hydrocarbons, both saturated and conjugated, and of the heats of reactions among these hydrocarbons. Two-center electron repulsion integrals are evaluated by the simple formulae derived from the corresponding theoretical formulae. The off-diagonal core matrix elements and core-core repulsion energies are estimated empirically. It is shown that the method gives good estimates of the molecular geometries and excitation energies and permissible values for the heats of reactions.

The understanding of a chemical reaction process requires a knowledge of the potential energy surfaces for the lowest and excited states. The MO method to be used in the study of a reaction process should well reproduce three quantities at the same time; the molecular geometries, the heats of reaction, and the excitation energies of the molecules. Many semi-empirical methods for all-valence-electron systems have been reported,[1-5] and the recent MINDO/3 version, in which a large number of parameters are introduced, reproduces satisfactorily the ground-state properties of molecules.[3] However, little attention has been paid to the simultaneous evaluation of the above three quantities. This paper will search for a semi-empirical method, which is at the same level of parametrization as in the MINDO/2 method,[4] and which gives good estimates of the above three quantities.

Most of the semi-empirical methods for all-valence electrons are modified versions of the CNDO and INDO approximations, while only a few are those of the NDDO (Neglect of Diatomic Differential Overlap) approximation.[5] The NDDO approximation may be difficult to parametrize or for use in evaluating a large number of additional integrals semi-empirically. However, it represents a more logical solution of the problem[6] than the CNDO and INDO approximations. In this study, the NDDO approximation was used. Two-center integrals were evaluated by the simple formulae which were derived from the corresponding theoretical formulae. Parameters were chosen so as to give, at the same time, well-balanced values for the above three quantities. The method was applied to several hydrocarbons, and the results were compared with the observed values.

Method

The LCAO-MO's for valence electrons are determined from Roothaan's LCAO-SCF equation.[7] The atomic integrals necessary for the calculation are evaluated by the following methods.

One-center electron repulsion integrals are evaluated from the Slater-Condon parameters, F_K and G_K, as in MINDO/2.[4]

Two-center electron repulsion integrals are evaluated from the integrals related to the local diatomic coordinate. Consider the integrals between AO's of two atoms, A and B:

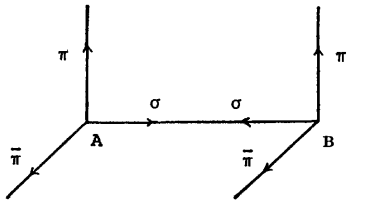

Fig. 1. Local diatomic coordinate and AO's of atoms A and B.

$$(\mu^A\nu^A|\lambda^B\sigma^B) \equiv \int \phi_\mu{}^A(1)\phi_\nu{}^A(1)\frac{1}{r_{12}}\phi_\lambda{}^B(2)\phi_\sigma{}^B(2)\mathrm{d}\tau_1\mathrm{d}\tau_2 \quad (1)$$

First, we transform the AO's, ϕ_μ's, into the local coordinate system of Fig. 1. The repulsion integrals of the original AO's can be expressed in terms of integrals between the transformed AO's. The integrals between the AO's of Fig. 1 are given by Roothaan.[8] In Roothaan's formulae, if the terms higher than the third order in $1/R_{AB}$ (R_{AB} is the distance between two atoms, A and B) are neglected, the integrals between the AO's of Fig. 1 are written as:

$$\begin{aligned}
&(s^As^A|s^Bs^B) \equiv \gamma_{AB}\\
&(\sigma^A\sigma^A|\sigma^B\sigma^B) = \gamma_{AB} + 6I_1\\
&(s^As^A|\sigma^B\sigma^B) = \gamma_{AB} + 3I_1\\
&(\sigma^A\sigma^A|\pi^B\pi^B) = \gamma_{AB} + \frac{3}{2}I_1\\
&(s^As^A|\pi^B\pi^B) = \gamma_{AB} - \frac{3}{2}I_1\\
&(\pi^A\pi^A|\pi^B\pi^B) = (\pi^A\pi^A|\bar{\pi}^B\bar{\pi}^B) = \gamma_{AB} - 3I_1\\
&(s^A\sigma^A|s^Bs^B) = (s^A\sigma^A|\sigma^B\sigma^B) = (s^A\sigma^A|\pi^B\pi^B) = I_2\\
&(s^A\pi^A|s^B\pi^B) = I_3\\
&(s^A\sigma^A|s^B\sigma^B) = I_4\\
&(\sigma^A\pi^A|\sigma^B\pi^B) = (\pi^A\bar{\pi}^A|\pi^B\bar{\pi}^B) = (s^A\pi^A|\sigma^B\pi^B) = 0
\end{aligned} \quad (2)$$

where s^A is the 1s or 2s AO of the A atom and where σ^A and π^A are the $2p\sigma$ and $2p\pi$ AO's of the A atom. They are defined in the local coordinate (Fig. 1). The I_i's are sub-integrals defined by Roothaan:

$$\begin{aligned}
I_1 &= [3S|3D\Sigma]\\
I_2 &= \frac{5}{2\sqrt{3}}[3S|3P\Sigma]\\
I_3 &= \frac{25}{12}[3P\Pi|3P\Pi]\\
I_4 &= \frac{25}{12}[3P\Sigma|3P\Sigma]
\end{aligned} \quad (3)$$

The sub-integral $[3S_a|3D\Sigma_b]$ is different from $[3S_b|3D\Sigma_a]$ when the A and B atoms are of different species. In the above formulae, this difference is neglected, though, and both are written as I_1.

The integrals between s orbitals, γ_{AB}, are calculated by using the Ohno-Klopman expression.[9] The sub-integrals, I_i's, are calculated by means of the following formulae:

$$\begin{aligned} I_1 &= 19.294 f R_{AB}\gamma_{AB}^4 \\ I_2 &= 1481.9 f R_{AB}\gamma_{AB}^3 \\ I_3 &= 0.5 I_4 = 52.263 f R_{AB}\gamma_{AB}^4 \end{aligned} \tag{4}$$

where $f=(F_2^A+F_2^B)/(F_0^A+F_0^B)$[5]. An explanation of these formulae is given in the Appendix. The values of the repulsion integrals calculated from (2) were compared with the theoretical values (Table 1). All two-center repulsion integrals (1) between the original AO's can be evaluated from the above integrals by means of:

$$\begin{aligned} &(s^A s^A|s^B s^B) = \gamma_{AB} \\ &(s^A s^A|s^B p_k^B) = a_{k\sigma} I_2 \\ &(s^A s^A|p_k^B p_l^B) = \delta_{kl}\gamma_{AB} + \frac{3}{2} I_1\{3a_{k\sigma}a_{l\sigma} - \delta_{kl}\} \\ &(s^A p_i^A|s^B p_k^B) = I_3\{\delta_{ik} + 3a_{i\sigma}a_{k\sigma}\} \\ &(s^A p_i^A|p_k^B p_l^B) = \delta_{kl}a_{i\sigma}I_2 \\ &(p_i^A p_j^A|p_k^B p_l^B) = \delta_{ij}\delta_{kl}\gamma_{AB} + \frac{I_1}{2}\{-6\delta_{ij}\delta_{kl} \\ &\qquad + 9\delta_{ij}a_{k\sigma}a_{l\sigma} + 9\delta_{kl}a_{i\sigma}a_{j\sigma}\} \end{aligned} \tag{5}$$

where s represents the s AO, and p_i, one of the $2p_x$, $2p_y$, and $2p_z$ AO's defined in the original coordinate. The $a_{i\sigma}$ is scalar product of two vectors, $\mathbf{e}_i$ and $\mathbf{e}_{AB}$, the unit vector directed along the i-axis and that directed from A toward B respectively. These expressions satisfy the correct transformation condition which ensures the invariance with respect to the rotation of axes.

TABLE 1. VALUES OF CARBON-CARBON TWO-CENTER REPULSION INTEGRALS FOR $R_{CC}=1.50$ Å.

Type	Values of integrals	
	Calcd using Slater AO's	Calcd from (2)—(4)
$(ss\|ss)$	9.21 eV	7.26 eV
$(s\sigma\|s\sigma)$	10.94	8.11
$(ss\|s\sigma)$	9.99	7.68
$(s\sigma\|\pi\pi)$	9.51	7.47
$(ss\|\pi\pi)$	8.82	7.05
$(\pi\pi\|\pi\pi)$	8.56	6.83
$(\pi\pi\|\bar{\pi}\bar{\pi})$	8.38	6.83
$(s\sigma\|ss)$	2.41	1.50
$(s\sigma\|s\sigma)$	2.77	1.50
$(s\sigma\|\pi\pi)$	2.23	1.50
$(s\sigma\|s\sigma)$	0.96	0.76
$(s\pi\|s\pi)$	0.78	0.38

The attraction $(\phi_\mu^A|V_B|\phi_\mu^A)$ between an electron in an AO ϕ_μ on the A atom and the core of the B atom was assumed to be:

$$(\phi_\mu^A|V_B|\phi_\mu^A) = -Z_B(\phi_\mu^A\phi_\mu^A|s^B s^B) \tag{6}$$

where $Z_B e$ is the core charge of the B atom. In the NDDO approximation, the attraction $(\phi_\mu^A|V_B|\phi_\nu^A)$ is also taken into account. This was assumed to be:

$$(\phi_\mu^A|V_B|\phi_\nu^A) = -Z_B(\phi_\mu^A\phi_\nu^A|s^B s^B) \tag{7}$$

by analogy with the diagonal parts. From these approximations, the core matrix elements between AO's on the same atom is written as:

$$H_{\mu\nu} = \delta_{\mu\nu}U_{\mu\mu} - \sum_{B(\neq A)} Z_B(\phi_\mu^A\phi_\nu^A|s^B s^B) \tag{8}$$

where $U_{\mu\mu}$ is the diagonal matrix element of ϕ_μ with respect to the one-electron Hamiltonian containing only the core of its own atom, the values of which are given by Baird and Dewar.[4] The off-diagonal elements between AO's on the different atoms are calculated by means of:

$$H_{\mu\nu} = \frac{1}{2}S_{\mu\nu}(\beta_\mu+\beta_\nu) \tag{9}$$

where $S_{\mu\nu}$ is the overlap integral and β_μ is a parameter which is empirically determined.

The core repulsion energy between the A and B atoms, *i.e.*, E_{core}^{AB}, must be equal to the electron-electron repulsion energy between the neutral atoms when $R_{AB}\to\infty$. $R_{AB}\to 0$, E_{core}^{AB} should tend to infinity. Many parametric expressions for E_{core}^{AB} which satisfy these conditions are possible. The following simple expressions are used in the present study:

$$\begin{aligned} E_{ore}^{AB} &= Z_A Z_B \gamma_{AB} && (R_{AB} > R_0) \\ E_{core}^{AB} &= Z_A Z_B\left\{\frac{b}{R_{AB}^a} + c\right\} && (R_{AB} < R_0) \end{aligned} \tag{10}$$

The constant, c, is determined by fitting values calculated from the two equations at $R_{AB}=R_0$. The a, b, and R_0 parameters are determined empirically.

Results and Discussion

The excitation energies of six hydrocarbons (CH_4, C_2H_6, C_3H_8, C_2H_4, C_4H_6, and C_2H_2) were calculated by the CI method, in which only singly excited configurations were taken into account in the evaluation of the singlet excited states. The relation between the values of β_μ and the excitation energies of these compounds was examined. The values of $\beta_{1s}(H)=-7.3$ eV, $\beta_{2s}(C)=-13.8$ eV, and $\beta_{2p}(C)=-9.5$ eV gave the best fit of the calculated excitation energies with the observed values. These β_μ values, however, were not appropriate for the estimation of the molecular geometries and heats of reactions. A compromise was thus made for the values of β_μ, and the values listed in Table 2 were used in all the calculations in this paper.

TABLE 2. VALUES OF β_μ(eV)

	1s(H)	2s(C)	2p(C)
β_μ	−7.5	−13.2	−9.3

In order to determine the parameters in the core-core repulsion energy (10), the calculated geometries of the above six hydrocarbons and the heats of reactions among them were compared with the observed values. The parameters were determined with the help of the

Table 3. Parameters in core-core repulsion formulae (10)[a]

	a	b	R_0
H-H	10.45	0.7436	2.642

a) The core-core repulsion energies calculated from the parameters are in eV units.

Davidon-Fletcher-Powell minimization technique.[10,11] They are listed in Table 3.

Molecular Geometry. The molecular geometries of typical hydrocarbons were calculated using the parameters determined above. They are listed in Table 4. The C–C and C=C bond lengths calculated agreed with the observed values within 0.03 Å (mean deviation; 0.01 Å), while the C≡C bond lengths were smaller than the observed values by 0.05 Å. The C–H bond lengths estimated agreed with the observed values within 0.01 Å. The bond angles also agreed well with the observed values (within 1 degree) except for the HCH angles; they were slightly smaller than the observed values. It seems that the present NDDO method predicts the geometries of hydrocarbons correctly.

a) Bond lengths in Å; bond angles in degrees. b) Geometries of CH(sp) and CH_2(sp^2, sp^3) groups were assumed to be those of acetylene, ethylene and cyclopropane. c) Estimated from Ref. 13.

Heats of Reactions. The heats of reactions among the above hydrocarbons were estimated by using the geometries obtained in the previous section (Table 5). The energy difference between *s-trans-* and *s-cis-*butadiene was correctly estimated. The agreement of the heats of the hydrogenations of unsaturated hydrocarbons with the observed values was not satisfactory, however, (the mean deviation for 8 examples was 7 kcal/mol). Considerable disagreements were found in the hydrogenations and additions related to ethylene or cyclic compounds. This comes form the fact that the calculated energy of ethylene is high (≈15 kcal/mol unstable) in comparison with other compounds, while those of cyclic compounds are quite low (stable).

Table 5. Calculated heats of reactions[a]

Reactions	Expt[14]	Calcd[b]
Hydrogenations		
acetylene → ethane	74.4	73.6

a) Heats of reactions in kcal/mol. b) The molecular geometries listed in Table 4 were used in the calculation.

Excitation Energy. The excitation energies of several hydrocarbons were calculated by the CI method using their calculated geometries. In the CI calculation, only singly excited configurations were taken into account. The excitation energies are listed in Table 6. The MINDO/2 method, which includes parameters comparable to the present NDDO method and gives good estimates for the molecular ground-state properties, gives poor excitation energies. This is an obstacle to its application to photochemical reactions. The excitation energies obtained by the NDDO method agree with the observed values within 0.5 eV, however; this deviation is permissible in studies of photochemical processes.

Since a properly parametrized version of NDDO should be superior to a similar parametric version of

INDO, it seems that the present NDDO method is not completed in its parametrization. However, it gives good estimates of the molecular geometries and excitation energies of hydrocarbons and permissible values of the heats of reactions among them. It may be fit for the evaluation of potential energy surfaces related to both thermal and photochemical reactions.

The author wishes to express his thanks to Professor Keizo Suzuki for his helpful suggestions.

Appendix

An explanation of Eqs. 4 will be given here. Consider the sub-integral $[3S|3D\Sigma]$ between carbon atoms. When $\rho \gg 1$ ($\rho \equiv R_{AB}(\zeta_A+\zeta_B)/a_0$, and when $R_{CC}=1.0$ Å corresponds to $\rho \simeq 6$), this is approximately expressed by:

$$[3S|3D\Sigma] \simeq \zeta/\rho^3 \qquad \text{(A-1)}$$

This means that the integral is approximated by a function of γ_{CC}^3 from the present semi-empirical point of view:

$$I_1 = c_1 R \gamma_{CC}^4 \qquad \text{(A-2)}$$

where $R\gamma_{CC}$ was introduced so that $I_1 \rightarrow 0$ when $R_{CC} \rightarrow 0$. To determine the coefficient, c_1, the sub-integral, $[3D\Delta|3D\Delta] \lesssim \zeta/\rho^5$, was approximated as a function of γ_{CC}^5:

$$[3D\Delta|3D\Delta] = c_2 \gamma_{CC}^5 \qquad \text{(A-3)}$$

If the present semi-empirical values of $[3D\Delta|3D\Delta]$ (namely$=4/27(pp'|pp') \propto F_2^C$) and γ_{CC} ($=F_0^C$) at $R_{CC}=0$ are used in (A-3), the relation between c_2 and the Slater-Condon parameters is obtained:

$$c_2 \propto (F_2^A+F_2^B)/(F_0^A+F_0^B)^5 \qquad \text{(A-4)}$$

where A and B represent two carbon atoms. The theorcoretical formulae indicate that the $[3S|3D\Sigma] \simeq [3D\Delta|3D\Delta]|\rho^2$ relation holds approximately.[8] Thus, the I_1 integral was expressed as:

$$I_1 = c_3 \frac{F_2^A+F_2^B}{(F_0^A+F_0^B)^5} R_{AB}\gamma_{AB}^4 \qquad \text{(A-5)}$$

The c_3 coefficient was determined by means of the following equation, the integral being evaluated at $R_{CC}=1.50$ Å:

$$(I_1^{theor}/I_1^{emp}) = (\gamma_{AB}^{theor}/\gamma_{AB}^{emp})^3 \qquad \text{(A-6)}$$

Though (A-5) is obtained from the carbon-carbon pair, (A-5) will be used for the integrals between other atomic pairs. The "F_2^H" value was estimated using the I_2 formula of (4) and an equation similar to (A-6); $F_2^H=7.802$ eV was obtained.

He I Photoelectron Spectra of Ethylene Carbonate and Related Compounds

Masafumi JINNO,* Iwao WATANABE, Yu YOKOYAMA, and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 7, 1976)

He I photoelectron spectra of ethylene carbonate, propylene carbonate, γ-butyrolactone, β-propiolactone and vinylene carbonate have been investigated. Assignments of an oxygen lone pair and nonbonding π orbitals have been made by means of analysis of vibrational structures and molecular orbital calculation. Many vibrational structures could be assigned to appropriate vibrational modes of the corresponding neutral molecules from a comparison with infrared and Raman spectra. Correlation among the orbital energies of the compounds is discussed.

Photoelectron spectral bands originating from the carbonyl oxygen lone pair and the nonbonding π orbitals of carbonyl compounds appear in the lower ionization energy range, lying sometimes close to each other. In the present report we deal with the photoelectron spectra of five heterocyclic carbonyl compounds, that is, ethylene carbonate and related compounds. The related compounds are derived from ethylene carbonate by the following substitution: 1) replacement of a hydrogen atom by a methyl group, 2) replacement of an esteric oxygen by a methylene group, 3) removal of an esteric oxygen, and 4) change of the single bond between the ethylenic carbons into a double bond. Their constitutional formulas are shown in Fig. 1.

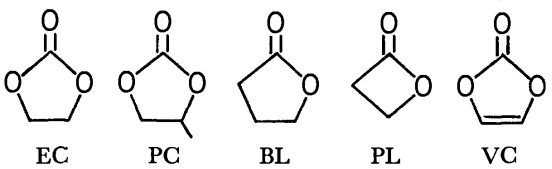

Fig. 1. Structural formulas of compounds investigated. EC: Ethylene carbonate, PC: propylene carbonate, BL: γ-butyrolactone, PL: β-propiolactone, VC: vinylene carbonate.

It has been proved that a comparison of a series of related compounds is useful for the assignment of their spectral bands to a particular molecular orbital, and that analysis of vibrational structures in some bands can be utilized for band assignment. By these means the effects of substitution on orbital energy and also orbital character could be clarified.

Experimental

He I resonance line at 58.4 nm emitted from a direct current discharge tube was used as an excitation light source. The discharge tube was so designed as to intensify the resonance line and to obtain photoelectron spectra of high signal-to-noise ratio. It has two coaxially aligned hollow electrodes and collimator capillaries to introduce the light produced within the whole discharge area into the ionization chamber. The photoelectron energy analyzer used was of a parallel plate type.[1] Xe gas was mixed with sample gas and used as an internal standard. A half width of Xe $2p_{3/2}$ peak was approximately 30 meV. The organic compounds used showed a tendency to broaden Xe peaks, probably due to in homogeneity of the surface potential caused by the adsorption of sample gas onto the analyzer electrodes.

Variation in room temperature caused a drift of the position of peaks, probably due to the variation in adsorption equilibrium caused by a change of the sample pressure. The ionization energy was therefore determined by measuring the sample peak and internal standard peak alternately several times. Coating of the electrode surface with graphite emulsion effectively lowered the background of the spectrum. Better resolution was obtained at a sample pressure above the pressure range in which there is a linear relation between sample pressure and spectral intensity. This might be related to the neutralization of the space charge in the ionization chamber by backscattered electrons and to the saturation of adsorbed sample gas.

Vinylene carbonate was synthesized from chloroethylene carbonate,[2,3] and purified by vacuum distillation. All the other compounds were chemicals of G. R. grade and used without purification. Samples in which residual water was detected were used after dehydration with anhydrous sodium sulfate or phosphorus pentoxide.

Laser Raman spectra of the three carbonates were taken for reference in the vibrational analysis of their photoelectron spectra.

Results and Discussion

Ethylene Carbonate and Propylene Carbonate. The lowest energy overlapping bands in the photoelectron spectra

TABLE 1. IONIZATION ENERGY AND VIBRATIONAL FREQUENCY OF ETHYLENE CARBONATE AND PROPYLENE CARBONATE

	Band	Ionization energy, eV		Vibrational frequency, cm^{-1}		Band assignment
		adiabatic	vertical	ion	molecule	
Ethylene carbonate	1 st	10.70	10.89	1530	1765—1790[a]	$n_O(5b_2)$
				910	1065 [b]	
	2 nd		11.38			$\pi(2a_2)$
	3 rd		11.45			$\pi(3b_1)$
Propylene carbonate	1 st	10.52	10.71	1520	1785[a]	$n_O(b_2)$[c]
				820	960[b]	
	2 nd		11.17			$\pi(a_2)$[c]
	3 rd		11.27			$\pi(b_1)$[c]

a) Carbonyl stretching vibration. b) Skeletal stretching vibration. c) Propylene carbonate does not belong to the point group C_{2v}. However, the respective orbitals can be associated with b_2, a_2, and b_1 orbitals of ethylene carbonate from electron distribution.

of ethylene carbonate and propylene carbonate have been assigned to three appropriate molecular orbitals as a result of analysis of vibrational structures and INDO molecular orbital calculation.[4] The ionization energies and vibrational frequencies are given in Table 1. Figure 2 shows the orbital energies and electron distributions of ethylene carbonate and propylene carbonate obtained from the molecular orbital calculation.

Several reports have appeared on the ionization energies of the carbonyl oxygen lone pair orbital of ethylene carbonate.[5-8] However, there are discrepancies among the reported values both for the adiabatic and vertical ionization energies. We pointed out that the vertical ionization energy corresponds not to the highest peak but to the second peak in the main vibrational progression, this conclusion being derived from the reasoning that the second peak should be the most intense if the relative intensity of the peaks in the vibrational progression is not modified by the slope of the adjacent bands.[4]

The adiabatic ionization energy and the frequency of carbonyl stretching vibration we determined are consistent with the results obtained by Sweigart and Turner[5] (10.70 eV and 1500 cm^{-1}), but not with those by McGlynn *et al.*[7,8] (10.40 eV and approx. 1900 cm^{-1}). Variation in room temperature during the course of measurement causes a change of sample pressure in the sample reservoir, leading to apparent drift of ionization energy. Since the lowest energy overlapping bands obtained by McGlynn *et al.* are identical with ours and they used the same energy reference (Xe $2p_{3/2}$ 12.130 eV) as we did, the only possible explanation for the discrepancies seems to be a drift in the ionization energy in their measurement. Contraction of the ionization energy scale with the Xe $2p_{3/2}$ peak as a base point would result in a lowering of the adiabatic ionization energy and at the same time an increase in the vibrational frequency. The direction of the shift of their values relative to ours is in line with the above inference. Contrary to their results, the frequency of the carbonyl stretching vibration of the neutral molecule is usually reduced on ionization from the carbonyl oxygen lone pair orbital.

The vibrational spacing of the subsidiary vibrational progression in the first band is 910 and 820 cm^{-1} for ethylene carbonate and propylene carbonate, respectively.[4] The vibration should correspond to one of the skeletal stretching modes. Two skeletal stretching vibrations appear in the Raman spectra of ethylene carbonate (980 and 1065 cm^{-1}) and propylene carbonate (1125—1150 and 960 cm^{-1}). In many cases the ionization from a molecular orbital with almost the same electron distribution gives nearly the same reduction ratio of vibrational frequency of a neutral molecule to the corresponding cation among different molecules. Thus the vibrational frequencies giving the common reduction ratio, which is calculated to be 0.85, are 1065 cm^{-1} (for ethylene carbonate) and 960 cm^{-1} (for propylene carbonate). Angell[9] denoted the skeletal stretching vibrations of 980 and 1065 cm^{-1} in infrared spectra of ethylene carbonate by ν_4 and ν_5, respectively, which belong to the irreducible representation A_1. Thus the analysis of photoelectron spectra shows that the skeletal stretching vibration of 960 and 1125—1150 cm^{-1} in the Raman spectrum of propylene carbonate should

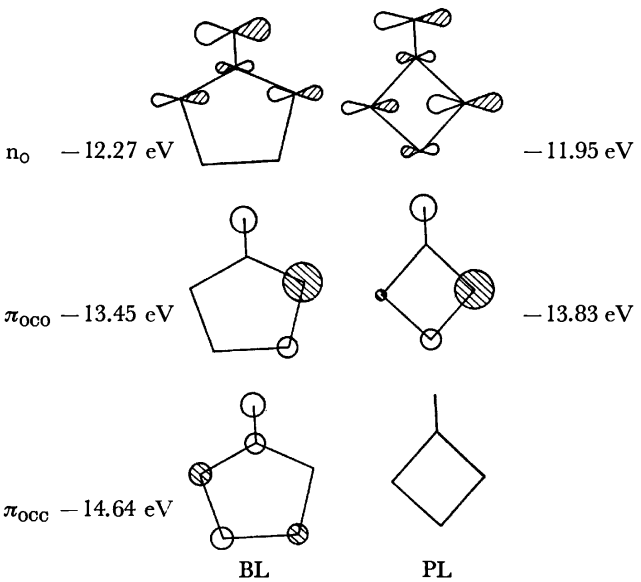

Fig. 3. Orbital energy and electron distribution of γ-butyrolactone(BL) and β-propiolactone(PL) obtained from INDO calculation. The esteric oxygen occupies the same position as shown in Fig. 1.

correspond to ν_5 and ν_4 in ethylene carbonate, respectively, *viz.*, a reversal in magnitude of the vibrational frequency of the two vibrational modes. This result shows that the methyl substituent effect on the frequency of skeletal stretching modes differs for ν_4 and ν_5. This effect could not be revealed by analysis of Raman or infrared spectra alone, even when the spectra for both carbonates were compared with each other.

γ-Butyrolactone and β-Propiolactone. Characteristic bands related to the ionization from the carbonyl oxygen lone pair and the nonbonding π orbitals were also studied for γ-butyrolactone and β-propiolactone in relation to ethylene carbonate. INDO molecular orbital calculation was made for these two lactones on the assumption of planar molecular configuration. The results are given in Fig. 3. The calculation shows that there are considerable differences between these compounds. Firstly, the lone pair orbital of γ-butyrolactone, $n_{O\gamma}$, is localized mainly on the two oxygen and one carbon atoms. On the other hand, that of β-propiolactone, $n_{O\beta}$, is fairly delocalized over all the skeletal atoms so that the electron density on the esteric oxygen atom is almost equal to that on the carbonyl oxygen atom. Secondly, γ-butyrolactone contains two π orbitals which can be thought to have a nonbonding character from the similarity in nodal plane to the nonbonding π orbitals of ethylene carbonate. They will be denoted by π_{OCO} and π_{OCC} according to the electron distribution. On the other hand, only one of the nonbonding π orbitals remains in β-propiolactone, which will be denoted by π'_{OCO}, corresponding to the orbital π_{OCO} in γ-butyrolactone.

The whole photoelectron spectra of γ-butyrolactone and β-propiolactone are shown in Fig. 4. The first band of γ-butyrolactone has several vibrational fine structures, as shown in Fig. 5. There are four main peaks with vibrational spacings of approximately 1530 cm^{-1}, which could be attributed to the excitation of the carbonyl stretching mode of the ion. The first band could be assigned to ionization from the carbonyl oxygen lone pair orbital, $n_{O\gamma}$. These spacings are almost equal to those of the n_O bands of ethylene carbonate and propylene carbonate. The three compounds give four

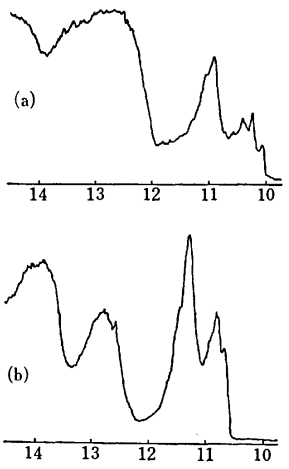

Fig. 4. (a) Photoelectron spectrum of γ-butyrolactone.
(b) Photoelectron spectrum of β-propiolactone.

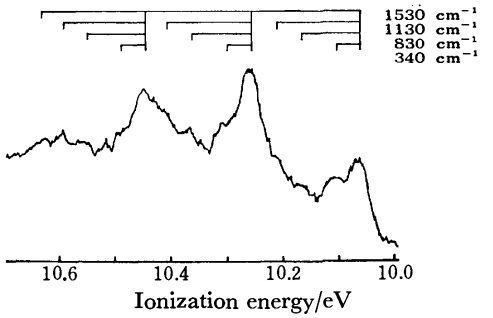

Fig. 5. First band of photoelectron spectrum of γ-butyrolactone.

sharp or prominent main peaks in the first band corresponding to the ionization from the lone pair orbitals. The number of fine structures shows that the change of geometry from neutral molecule to ion or the Franck-Condon factor seems to be almost equal to each other. It would be said that the degrees of localization of the lone pair orbital are almost equal among these molecules. There are further three weak peaks on the higher ionization energy side of each main peak of γ-butyrolactone, which are not seen in the spectrum of ethylene carbonate. Vibrational spacings from each main peak are approximately 340, 830, and 1130 cm^{-1} for the three peaks. From a comparison with the infrared and Raman spectra, the vibrational spacings of 1130 cm^{-1} might be attributed to the excitation of the skeletal stretching mode of the ion, which is 1170 cm^{-1} in the neutral molecule. Appearance of two more vibrational excitations for γ-butyrolactone should be attributed to the substitution of a methylene group for an oxygen atom in ethylene carbonate and, at the same time, change of molecular symmetry. The adiabatic and vertical ionization energies of the first band of γ-butyrolactone are 10.06 and 10.26 eV, respectively. The vertical one is identical to the value reported by Bain and Frost.[6]

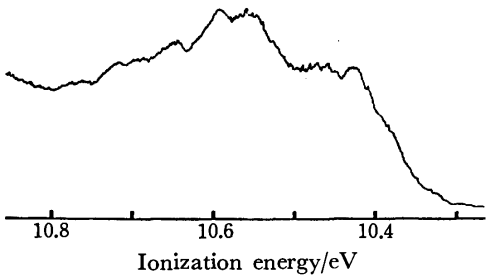

Fig. 6. First band of photoelectron spectrum of β-propiolactone.

The orbitals of the first band in the photoelectron spectrum of β-propiolactone are shown in Fig. 6. There are many peaks, but they are very complex and cannot be attributed to any harmonic vibrational progressions. This tendency has been reported as regards the photoelectron spectra of cycloalkanones.[10] Cyclobutanone gives a complex first band, while cyclopentanone clearly shows some vibrational progressions. The complexity may be due to the change in hybridization of the lone pair orbital of the carbonyl oxygen atom resulting from the strain of the ring. In fact, the results of molecular

orbital calculations shown in Fig. 3 indicate a marked change in electron distribution, *viz.*, the delocalization of $n_{O\beta}$ orbital over all the skeletal atoms. The somewhat unusual aspect of the first band of β-propiolactone seems to be associated with the result of infrared study by Durig,[11] which showed that the vibration of this molecule is very anharmonic.

The second band of γ-butyrolactone can be compared with the second band of β-propiolactone. Each second band has a shoulder on its higher ionization energy side. These peaks are fairly broad as compared with those in the first band. The second bands in the two spectra can be assigned to the ionization from the approximately nonbonding π orbital, π_{OCO} in γ-butyrolactone and π'_{OCO} in β-propiolactone from the results of molecular orbital calculation and the similarity in spectral shapes. Intensity ratios of the π band to the first band are almost equal for the two compounds, indicating that only one orbital is involved in the second band of γ-butyrolactone. The spacing between the shoulder and the main peak could not be attributed to any vibrational progression, since the peak for the adiabatic ionization cannot be distinguished. The vertical ionization energy of π_{OCO} orbital for γ-butyrolactone is 10.93 eV and that of π'_{OCO} orbital for β-propiolactone is 11.20 eV.

The molecular orbital calculation predicts that the second nonbonding π orbital, π_{OCC}, of γ-butyrolactone should exist approximately 1 eV below the first nonbonding π orbital, and that three σ orbitals cluster together with the second nonbonding π orbital in an energy range of approximately 2 eV. As a matter of fact, the photoelectron spectrum of γ-butyrolactone indicates that the third band begins to rise at 12 eV (approximately 1 eV higher than the second band), and that a number of bands overlap in the energy range 12—14 eV, supporting the prediction of the molecular orbital calculation. Thus the adiabatic ionization energy of the π_{OCC} orbital could be estimated to be 12 eV or higher. The results are summarized in Table 2.

Vinylene Carbonate. Vinylene carbonate is a cyclic carbonate ester of the hypothetical enediol and differs from ethylene carbonate in having a double bond in the ring structure. The molecule is considered to have a planar configuration and consequently C_{2v} symmetry in gaseous phase from the results of microwave spectroscopic study by Slayton *et al.*[12] Infrared and Raman spectroscopic studies for this molecule were carried out by Dorris *et al.*[13]

The photoelectron spectrum of vinylene carbonate gives three well separated prominent bands in the lower ionization energy region. Each of the three bands shows distinct vibrational progressions.

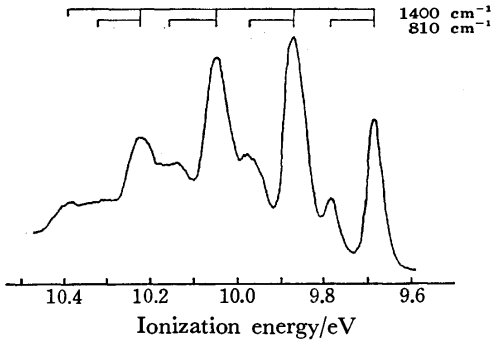

Fig. 7. First band of photoelectron spectrum of vinylene carbonate.

The first band (Fig. 7) has five main peaks with vibrational spacings of approximately 1400 cm^{-1}, each main peak being accompanied by one subsidiary peak. The spacings between the subsidiary and main peaks are approximately 810 cm^{-1}.

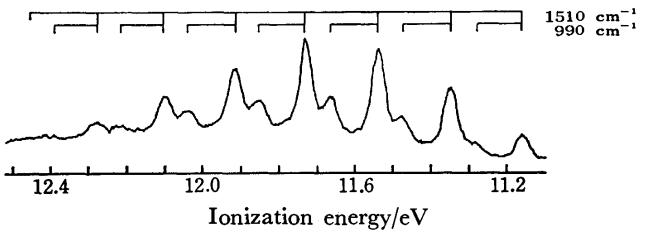

Fig. 8. Second band of photoelectron spectrum of vinylene carbonate.

The second band (Fig. 8) has at least eight main peaks with vibrational spacings of approximately 1510 cm^{-1} and subsidiary peaks approximately 990 cm^{-1} apart from each main peak.

The third band (Fig. 9) is on the slope of the next broad band, having at least four main peaks with vibrational spacings of approximately 1900 cm^{-1}. Each main peak is accompanied by three subsidiary peaks,

TABLE 2. IONIZATION ENERGY AND VIBRATIONAL FREQUENCY OF γ-BUTYROLACTONE AND β-PROPIOLACTONE

	Band	Ionization energy, eV		Vibrational frequency, cm^{-1}		Band assignment

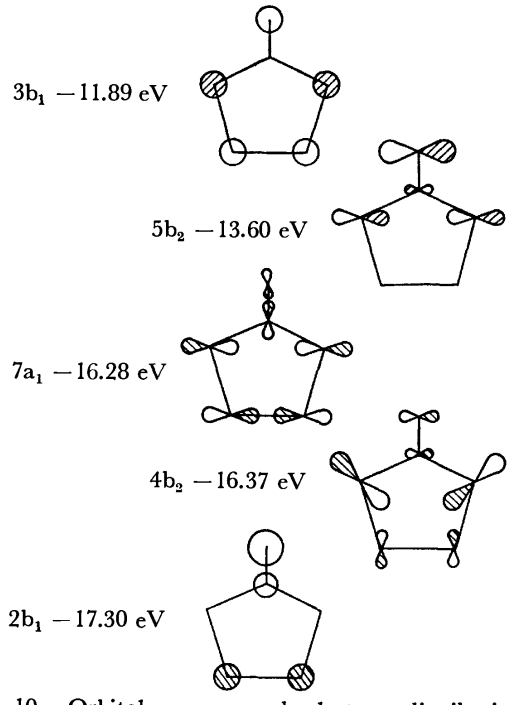

Fig. 10. Orbital energy and electron distribution of vinylene carbonate obtained from INDO calculation.

approximately 1530, 1140, and 710 cm^{-1} apart from each main peak.

INDO molecular orbital calculation shows possible orbitals to be assigned to these three bands (Fig. 10), which are denoted by $3b_1$, $5b_2$, $7a_1$, $4b_2$, and $2b_1$ after the notations for ethylene carbonate. The double bond in the ring structure changes the situations of some orbitals.

The $5b_2$ and $4b_2$ orbitals of vinylene carbonate are almost equal in energy to the $5b_2$ and $4b_2$ orbitals, respectively, of ethylene carbonate. However, introduction of the double bond into the ring structure results in the promotion of the $3b_1$ orbital energy above the $5b_2$ orbital energy. The results of calculation indicate that the $3b_1$ orbital should have the lowest ionization energy. This was confirmed by the following vibrational analysis of the photoelectron spectrum of vinylene carbonate. The vibrational spacings of approximately 1400 cm^{-1} in the first band would correspond to the excitation of the skeletal stretching mode reduced from 1625 cm^{-1} in the neutral molecule. The vibrational mode is mainly dominated by the vibration between the ethylenic carbons. Thus such a reduction suggests the ionization from an orbital having a bonding character between the ethylenic carbons, such as $3b_1$, $7a_1$, and $2b_1$ orbitals. Since the orbital energy of $3b_1$ orbital is raised higher than that of the highest occupied π orbital of ethylene (−10.5 eV) by introduction of vinylene group, the first band could be assigned to $3b_1$ orbital (*cf.* Section "Correlation of Orbital Energies of Five Compounds). The vibrational spacings of approximately 810 cm^{-1} could be ascribed to the skeletal breathing vibration in the ion reduced from 911 cm^{-1} in the neutral molecule. The adiabatic and vertical ionization energies can easily be determined to be 9.68 and 9.87 eV, respectively.

The results of calculation also predict that the second band corresponds to the ionization from the $5b_2$ orbital. The vibrational spacings of approximately 1510 cm^{-1} in the main vibrational progression would correspond to the carbonyl stretching mode in relation to the assignment in the previous sections. Thus the second can be assigned to the ionization from the $n_O(5b_2)$ orbital in accordance with expectation from the calculated orbital energy. The spacings of approximately 990 cm^{-1} would correspond to the skeletal stretching mode reduced from 1100 cm^{-1} in the neutral molecule. The skeletal stretching frequency of the ions is higher than that of ethylene carbonate. The reduction ratio of the frequency is approximately 0.90, indicating that the change in skeletal bonding strength is somewhat smaller than that of ethylene carbonate. The discrepancy would be caused by the existence of the double bond in the ring structure of vinylene carbonate. At least eight components appear in the main vibrational progression ascribed to carbonyl stretching, while there are only four components in the lone pair photoelectron band of ethylene carbonate. This implies that the molecular geometry is rather largely changed by the ionization from the $5b_2$ orbital than in ethylene carbonate. The change in carbonyl oxygen-carbon distance seems similar to that of ethylene carbonate where the reduction ratio is approximately 0.82. Many vibrational components are found in the band corresponding to the ionization accompanied by a drastic change of molecular symmetry, *e.g.* in the first band of ammonia (pyramidal to planar). It could thus be said that not only the carbonyl carbon-oxygen distance but also the C_{2v} symmetry in the neutral molecule change with the photoionization from the $5b_2$ molecular orbital of vinylene carbonate. The adiabatic and vertical ionization energies for the $5b_2$ lone pair orbital of vinylene carbonate are 11.16 and 11.73 eV, respectively. The vertical one differs from the value reported by Bain and Frost[6] by a unit of vibrational spacings, approximately 0.19 eV.

The vibrational spacings of approximately 1900 cm^{-1} in the third band are considerably large compared with the largest possible vibration of the neutral molecule. In this case, it is necessary to refer to the characters of molecular orbitals. From the results of calculation, any of the $7a_1$, $4b_2$, and $2b_1$ orbitals around −16.5 eV could be taken for the third band. Their orbital energies seem to be almost degenerate from molecular orbital calculation alone and it would be impossible to choose

an appropriate one among them. In this case the characteristic vibrational spacings mentioned above could be used as a clue to the assignment of the third band. A possible mode of vibration to be assigned to the vibrational spacings of approximately 1900 cm^{-1} is the carbonyl stretching or the skeletal stretching involving the carbon-carbon double bond stretching. The $7a_1$ molecular orbital has a strong bonding character between the double bond in the ring structure. It has also the same character for the carbon-oxygen double bond of the carbonyl group. If an electron is ionized from this orbital, these bonds would reduce their bonding character. As a result, the vibrational frequencies corresponding to these bonds should be reduced relative to those in the neutral molecule. This orbital is not suitable for explaining the high frequency in the ion. The same discussion can also be applied to the case of the $2b_1$ orbital. The $4b_2$ orbital reveals a bonding character in the carbon-oxygen double bond and an antibonding character in the carbon-carbon double bond. The ionization of an electron from such an orbital would cause a desirable change, *viz.*, carbon-carbon double bond in the ring should be stronger in the ion than in the neutral molecule. The vibrational spacings of approximately 1900 cm^{-1} could be attributed to the skeletal stretching mode of the ion, the wave number of which is 1625 cm^{-1} in the neutral molecule. Thus, the third band could be assigned to the ionization from the $4b_2$ orbital. Necessarily the vibrational spacings of approximately 1530 cm^{-1} could be attributed to the carbonyl stretching mode reduced from 1830 cm^{-1} in the molecule and the spacings of 1140 and 710 cm^{-1} could be attributed to the skeletal breathing and skeletal stretching mode which are 911 and 1100 cm^{-1}, respectively, in the neutral molecule. A study by means of group theory shows that five vibrational modes belonging to an irreducible representation A_1 are possible for six atoms except C–H vibrations. Four of them can be found in the third band showing that the $4b_2$ orbital is actually distributed on the whole skeletal structure. The other one is the carbonyl bending vibration which would not be excited through a photoionization process. The results are summarized in Table 3.

Correlation of Orbital Energies of Five Compounds. The vertical ionization energies of the oxygen lone pair and nonbonding π orbitals of the five compounds are shown in the form of a correlation diagram in Fig. 11. Propylene carbonate, γ-butyrolactone, and β-propiolactone do not belong to the point group C_{2v}. However, the π orbitals of these compounds can be associated with the b_1 or a_2 orbital of ethylene carbonate from a consideration of electron distribution.[4]

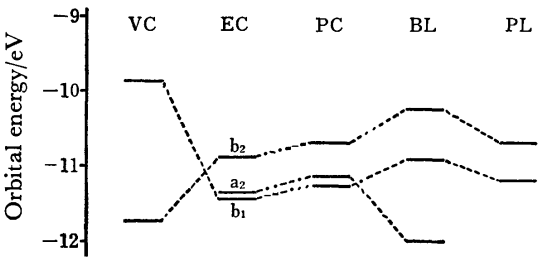

Fig. 11. Correlation diagram of observed orbital energies for ethylene carbonate and related compounds.

Oxygen Lone Pair Orbital n_O: The orbital of propylene carbonate is destabilized (0.18 eV) relative to ethylene carbonate due to the electron releasing effect of methyl group.[4] The orbital of γ-butyrolactone is destabilized (0.63 eV) as a result of the substitution of esteric oxygen with methylene, which is less electronegative than the former. The degree of orbital stabilization of β-propiolactone relative to γ-butyrolactone (0.44 eV) is approximately the same as that of cyclobutanone relative to cyclopentanone (0.36 eV), which was attributed to the hybridization change as well as an inductive effect of a methylene chain.[10] The orbital stabilization of vinylene carbonate relative to ethylene carbonate (0.84 eV) is in line with that of cyclopenten-3-one relative to cyclopentanone (approximately 0.2 eV), which could also be attributed to the greater electronegativity of sp^2-carbons as compared with sp^3-carbons.[14,15]

Nonbonding π Orbitals: The nonbonding π orbitals of propylene carbonate destabilize (approximately 0.2 eV) relative to the corresponding orbitals of ethylene carbonate due to the electron releasing effect of methyl group. γ-Butyrolactone and β-propiolactone belong to the point group C_s in a planar molecular configuration. When the molecular symmetry is lowered from C_{2v} to C_s, the representations B_1 and A_2 are changed to A″, and the b_1 and a_2 orbitals go over into a″ orbitals. Thus the accidentally degenerate b_1 and a_2 orbitals of ethylene carbonate can interact with each other to generate the π_{OCO} and π_{OCC} orbitals in γ-butyrolactone. Inspection into the electron distribution shows that the π_{OCO} orbital is more closely related to the b_1 orbital and the π_{OCC} orbital to the a_2 orbital. Destabilization of the π_{OCO} orbital (0.52 eV) could result from both the substitution of an esteric oxygen with methylene and the interaction, accompanied by the stabilization of the π_{OCC} orbital ($<$0.6 eV). π_{OCC} orbital stabilization of β-propiolactone relative to γ-butyrolactone (0.27 eV) could be explained by an inductive effect of a methylene chain.

In contrast to the n_O orbital the nonbonding $\pi(b_1)$ orbital of vinylene carbonate is destabilized (1.58 eV) relative to the corresponding orbital of ethylene carbonate. The destabilization could be explained by assuming that the two carbonates are a composite

molecule of a localized carbonate and a localized hydrocarbon groups (ethylene and vinylene groups, respectively) and that symmetric π orbitals of the carbonate and hydrocarbon groups combine in a reversed phase to produce the $\pi(b_1)$ orbital. The energy of the symmetric π orbitals of the vinylene group was taken as -10.51 eV from the energy of the highest occupied π orbital of ethylene.[16] That of the ethylene group (-15.4 eV) was adopted from the energy of ethane $1e_u$ orbital which belongs to the pseudo-π molecular orbitals built from e-type methyl orbitals.[17] The energy of the symmetric π orbital of the carbonate group cannot readily be estimated. However, it should be around -12 or -13 eV, since the energy level of an oxygen π orbital is found around this energy range in such molecules as water, formic acid *etc.* Thus, the symmetric π orbital of the vinylene group lies higher than the corresponding one of the carbonate group. In ethylene carbonate the b_1 orbital is somewhat destabilized relative to the orbital energy of the carbonate group due to the interaction between the orbitals of the ethylene and the carbonate groups. In vinylene carbonate, on the other hand, such an interaction leads to the destabilization of the b_1 orbital higher up than the orbital energy of the vinylene group.

The Sol-Gel Transition of Sodium Deoxycholate Solutions under High Pressures

Gohsuke SUGIHARA, Toshiaki UEDA, Shoji KANESHINA,* and Mitsuru TANAKA

Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Nishi-ku, Fukuoka 814
**College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810*

(Received August 11, 1976)

The effect of pressure on the sol-gel transition of sodium deoxycholate (SDC) solutions was investigated by the electric conductivity method up to 2000 atm in the temperature range from 10 to 65 °C. The gelation of SDC solutions is effected more easily at lower temperatures, at higher pressures, and at higher concentrations of SDC. The changes in the volume ($\Delta\bar{V}^{(\alpha\beta)}$), the enthalpy ($\Delta\bar{H}^{(\alpha\beta)}$), and the entropy ($\Delta\bar{S}^{(\alpha\beta)}$) of gelation were calculated thermodynamically. The values for $\Delta\bar{V}^{(\alpha\beta)}$, $\Delta\bar{H}^{(\alpha\beta)}$, and $\Delta\bar{S}^{(\alpha\beta)}$ are all negative under the conditions of this experiment. Therefore, it is concluded that the gel formation of SDC is attributable to intermolecular hydrogen bonds.

One of the most unique characteristics of sodium deoxycholate (SDC) is its specific hydrolysis, *i.e.*, the pH change in aqueous solutions, and another is its polymer-like aggregation. The relation between these two characteristics has been studied by the present authors[1-3] and by Rich and Blow.[4] The micelle formation of SDC in aqueous solutions is well known. The formation of polymer-like aggregates in the aqueous solution of SDC was described for the first time by Rich and Blow.[4,5] Under suitable conditions, the micelles of SDC aggregate secondarily to form a gelatinous complex with macromolecular dimensions in a solution. X-Ray diffraction studies of the fibers of this complex showed that the molecules assume an elongated helical configuration 3.6 nm in diameter. Botré *et al.*[6] have studied the stability of the polymer-like structure and the effect of cations on the sol-gel transition of deoxycholic acid in aqueous solutions. One of the present authors previously suggested that the polymer-like aggregates of SDC were formed by intermolecular hydrogen bonding between the 3α-hydroxyl group and the carboxyl group of SDC.[1] In spite of these studies, however, there remain many problems to be solved with respect to the gelation of bile salt solutions. In order to make clear the mechanism of gelation, it is useful to investigate the sol-gel transition as a function of the pressure as well as of the temperature and concentration, because the study of the pressure effect affords effective thermodynamic information. In this study we will examine the pressure effect on the sol-gel transition of SDC solutions by means of the electric conductivity method.

Experimental

Materials. The SDC (Merck Co.) was recrystallized from a mixed solvent of methanol and ethanol. All the other chemicals used were of a guaranteed reagent grade. The thrice-distilled water used was previously freed from CO_2 gas by passing the air through a soda-lime column.

Apparatus. The high-pressure apparatus used in the present study consists of a pressure generator and a pressure vessel. A screw- and hand-pump (Hikari Kikai Co.) was used as a pressure generator. The pressure vessel was made of stainless steel (SUS 27) so as to withstand pressures up to 3000 atm; 80 mm o.d., 20 mm i.d., and 250 mm height. The pressure generator and vessel were connected with a piece of flexible stainless steel tubing (1/8 in. o.d. and 0.024 in. i.d.). The prevention of oil leakage from the vessel and the connection between conductivity cell and electrical leads are devised in a manner described before.[7] The conductivity cell fitted with platinized platinum electrodes was made by modifying an injector. The specific conductivity of SDC solutions was measured by means of a Yanagimoto conductivity outfit, Model MY-8. The cell constant was checked with a KCl solution before and after applying high pressures; no change was observed. The pressures were measured within an accuracy of ±3.5 atm by means of a Heise pressure gauge. The thermostatted bath in which the pressure vessel was immersed was regulated within ±0.01 °C. The measurement of the conductivity was carried out in the temperature range from 10 to 65 °C, and in the pressure range from 1 to 2200 atm.

Procedure. The preparation of the SDC solution and of the gel was performed according to the method of Botré *et al.*[6] so as to confirm their results. The SDC gel was obtained by dissolving a known amount of SDC in water and by then adjusting the pH value to 6.85 at 20 °C by adding a small amount of HCl under continuous and con-

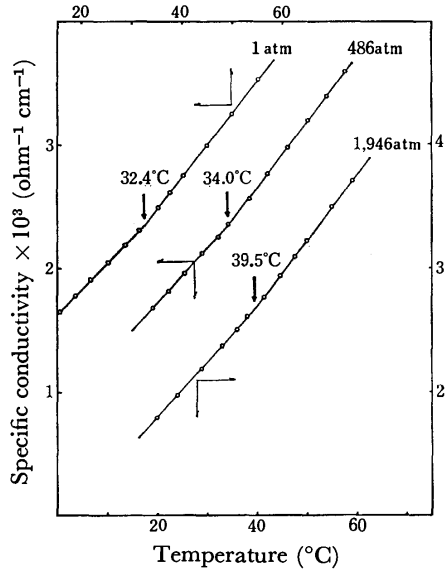

Fig. 1. The specific conductivity of SDC solution (3.180 × 10^{-2} mol/kg) as a function of temperature. The break in the slope indicates a transition.

stant stirring. All the gels obtained were stored at about 5 °C, and the gels used for measurements were permitted to stand for at least 20 h after the preparation.

The temperature of the sol-gel transition was decided as follows. The specific conductivity of an SDC solution with a given concentration was measured at various temperatures and at a desired constant pressure. The temperature was raised or lowered so slowly that the solution reached a sufficient equilibrium. It was confirmed by the constancy of the conductivity that the equilibrium was established after the thermostatted bath had been regulated at a constant temperature.

The specific conductivity measured at a constant pressure and concentration was plotted against the elevating temperature, resulting in the two straight lines which intersect each other at a certain temperature, as is shown in Fig. 1. The temperature corresponding to the break in these lines indicates the exact transition temperature,[6] which can be determined under various pressures as well as under atmospheric pressure. The strict determination of the transition temperature was performed by computing the intersection point of the two straight lines obtained by the least-squares method. The differences between the transition temperatures determined on elevating the temperature and on lowering the temperature were within 1 °C.

Results

Plotting the transition temperature at various concentrations of SDC against the pressure, straight lines are obtained, as is shown in Fig. 2. This figure shows a sol-gel phase diagram of the SDC–HCl solution system at different concentrations of SDC. The phase on the left-hand side of each curve is of a gel, while the phase on the right-hand side is of a sol. On the curves, the sol and gel phases may coexist in equilibrium.

In Fig. 3, the logarithm of the SDC concentration (in mole fraction) on the gelation at given pressures

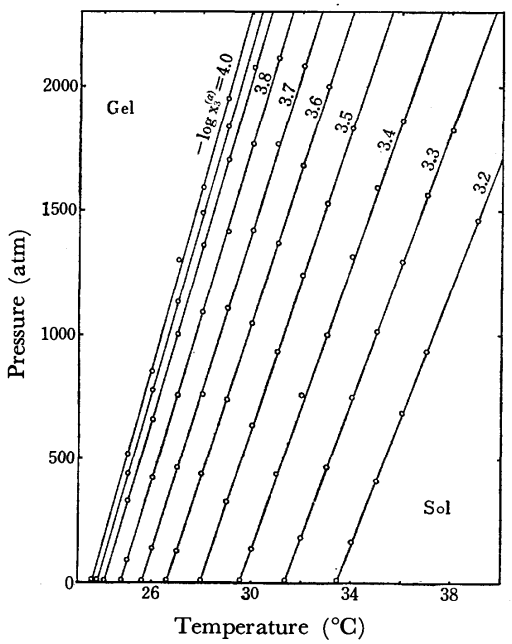

Fig. 2. Sol-gel phase diagram of SDC solutions at various concentrations. Numerical values indicate $-\log X_3^{(\alpha)}$. These relations are of Eq. 13 in the text.

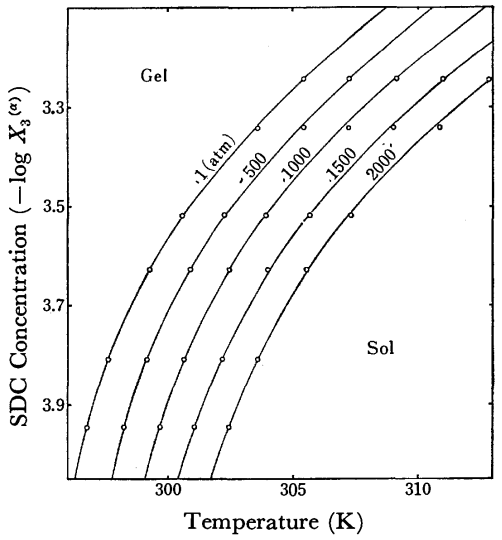

Fig. 3. Sol-gel phase diagram of SDC solutions at various pressures. Numerical values indicate pressure in atm. These relations are of Eq. 14 in the text.

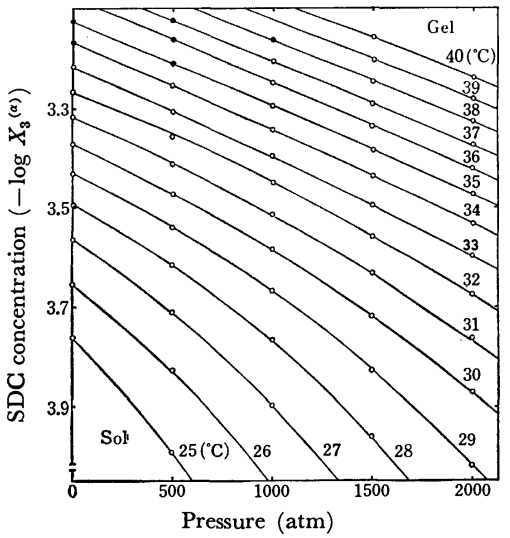

Fig. 4. Sol-gel phase diagram of SDC solutions at various temperatures. Numerical values indicate temperature in °C. These relations are of Eq. 15 in the text. (●: Extrapolated value in Fig. 3).

is plotted against the transition temperatures, which are taken from Fig. 2 by reading interpolated points on the curves. The region above each curve is of a gel, while that below each curve is of a sol.

In Fig. 4 the phase diagram is made by plotting the transition pressure against the logarithm of the SDC mole fraction at given temperatures. The regions above and below each isotherm refer to the gel and the sol phases respectively. It may be seen from Figs. 2, 3, and 4 that the gelation of SDC solutions is caused more easily at the lower temperatures, the higher pressures, and the higher concentrations of SDC.

Discussion

In order to analyze the above results, we will try to treat thermodynamically the gelation of SDC in an

aqueous dilute solution of HCl. The system under given conditions is in equilibrium between the sol phase (α) and the gel phase (β) and consists of three components; water (1), HCl (2), and SDC (3). The Gibbs free energy of each phase is expressed as follows:

$$G^{(\alpha)}[T, P, N_1^{(\alpha)}, N_2^{(\alpha)}, N_3^{s(\alpha)}, N_3^{m(\alpha)}] \quad (1)$$

$$G^{(\beta)}[T, P, N_1^{(\beta)}, N_3^{(\beta)}] \quad (2)$$

where T, P, and N denote the temperature, the pressure, and the number of moles, and where the superscripts, s and m, refer to singly dispersed SDC and micellar SDC respectively.

In the sol phase the Gibbs free energy is expressed by:

$$dG^{(\alpha)} = -S^{(\alpha)}dT + V^{(\alpha)}dP + \sum \mu_i^{(\alpha)} dN_i^{(\alpha)} \quad (3)$$

where $\mu_i^{(\alpha)}$ is the chemical potential of the i component in the sol phase. In the system under consideration, HCl is very diluted and the pH of solutions is adjusted to 6.85 at 20 °C. Since co-ions, *i.e.*, chloride ions, scarcely affect the gelation, the $N_2^{(\alpha)}/N_1^{(\alpha)}$ ratio can be regarded as constant. Hence, the aqueous dilute solution of HCl may be regarded as the solvent, and $N_{12}^{(\alpha)} = N_1^{(\alpha)} + N_2^{(\alpha)}$. Therefore, $X_{12}^{(\alpha)} = (N_1^{(\alpha)} + N_2^{(\alpha)})/(N_1^{(\alpha)} + N_2^{(\alpha)} + N_3^{(\alpha)}) = 1 - X_3^{(\alpha)}$. Here, $N_3^{(\alpha)}$ is the total number of moles of singly dispersed and micellar SDC, and $X_3^{(\alpha)}$ is the mole fraction of total SDC in the sol phase.

At equilibrium,

$$d\mu_3^{s(\alpha)} = d\mu_3^{m(\alpha)} = d\mu_3^{(\alpha)}. \quad (4)$$

Therefore,

$$dG^{(\alpha)} = -S^{(\alpha)}dT + V^{(\alpha)}dP + \mu_{12}^{(\alpha)}dN_{12} + \mu_3^{(\alpha)}dN_3^{(\alpha)} \quad (5)$$

and

$$d\mu_i^{(\alpha)} = -\bar{S}_i^{(\alpha)}dT + \bar{V}_i^{(\alpha)}dP + RT(\partial \ln a_i^{(\alpha)}/\partial \ln X_3^{(\alpha)})_{T,P} d \ln X_3^{(\alpha)} \quad (6)$$

where

$$\mu_i^{(\alpha)} = \mu_i^{\circ(\alpha)} + RT \ln a_i^{(\alpha)}.$$

It may be seen from Eqs. 5 and 6 that the state of solution could be completely defined by three variables, T, P, and $X_3^{(\alpha)}$, because $X_{12}^{(\alpha)} = 1 - X_3^{(\alpha)}$.

Next, in the overall gel phase (β) we obtain Eq. 7 from a consideration of the Gibbs-Duhem equation:

$$\bar{S}^{(\beta)}dT - \bar{V}^{(\beta)}dP + (1 - X_3^{(\beta)})d\mu_1^{(\beta)} + X_3^{(\beta)}d\mu_3^{(\beta)} = 0. \quad (7)$$

By analogy with Eq. 6,

$$d\mu_1^{(\beta)} = -\bar{S}_1^{(\beta)}dT + \bar{V}_1^{(\beta)}dP + RT\left(\frac{\partial \ln a_1^{(\beta)}}{\partial \ln X_3^{(\beta)}}\right)_{T,P} d \ln X_3^{(\beta)}, \quad (8)$$

and

$$d\mu_3^{(\beta)} = -\bar{S}_3^{(\beta)}dT + \bar{V}_3^{(\beta)}dP + RT\left(\frac{\partial \ln a_3^{(\beta)}}{\partial \ln X_3^{(\beta)}}\right)_{T,P} d \ln X_3^{(\beta)}. \quad (9)$$

At an equilibrium between α and β phases,

$$d\mu_{12}^{(\alpha)} = d\mu_1^{(\beta)} \text{ and } d\mu_3^{(\alpha)} = d\mu_3^{(\beta)}.$$

Hence, from Eqs. 7, 8, and 9,

$$\Delta\bar{S}^{(\alpha\beta)}dT - \Delta\bar{V}^{(\alpha\beta)}dP + RT\{(1 - X_3^{(\beta)})(\partial \ln a_{12}^{(\alpha)}/\partial \ln X_3^{(\alpha)})_{T,P} + X_3^{(\beta)}(\partial \ln a_3^{(\alpha)}/\partial \ln X_3^{(\alpha)})_{T,P}\} d \ln X_3^{(\alpha)} = 0. \quad (10)$$

Here, the changes in the entropy ($\Delta\bar{S}^{(\alpha\beta)}$) and volume ($\Delta\bar{V}^{(\alpha\beta)}$) on the gelation are:

$$\Delta\bar{S}^{(\alpha\beta)} = \{\bar{S}^{(\beta)} - (1 - X_3^{(\beta)})\bar{S}_{12}^{(\alpha)} - X_3^{(\beta)}\bar{S}_3^{(\alpha)}\} \quad (11)$$

and

$$\Delta\bar{V}^{(\alpha\beta)} = \{\bar{V}^{(\beta)} - (1 - X_3^{(\beta)})\bar{V}_{12}^{(\alpha)} - X_3^{(\beta)}\bar{V}_3^{(\alpha)}\} \quad (12)$$

If the concentration dependence of the activity coefficient in Eq. 10 is negligible in the vicinity of the equilibrium state, the following equations may be derived; these equations enable us to obtain $\Delta\bar{S}^{(\alpha\beta)}$, $\Delta\bar{V}^{(\alpha\beta)}$, and $\Delta\bar{H}^{(\alpha\beta)}$.

At a constant concentration of SDC,

$$\left[\frac{\partial P}{\partial T}\right]_{\ln X_3^{(\alpha)}} = \frac{\Delta\bar{S}^{(\alpha\beta)}}{\Delta\bar{V}^{(\alpha\beta)}} = \frac{\Delta\bar{H}^{(\alpha\beta)}}{T\Delta\bar{V}^{(\alpha\beta)}}. \quad (13)$$

At a constant pressure,

$$RT\left[\frac{\partial \ln X_3^{(\alpha)}}{\partial T}\right]_P = -\Delta\bar{S}^{(\alpha\beta)}. \quad (14)$$

At a constant temperature,

$$RT\left[\frac{\partial \ln X_3^{(\alpha)}}{\partial P}\right]_T = \Delta\bar{V}^{(\alpha\beta)}. \quad (15)$$

It should be noted that the analytical concentration can be used for the evaluation of the above thermodynamic quantity. The left-hand sides in Eqs. 13, 14, and 15 are experimentally determinable by using the results shown in Figs. 2, 3, and 4 respectively. From the slopes of the P *vs.* T curves in Fig. 2, we first obtained $\Delta\bar{S}^{(\alpha\beta)}/\Delta\bar{V}^{(\alpha\beta)}$ or $\Delta\bar{H}^{(\alpha\beta)}/T\Delta\bar{V}^{(\alpha\beta)}$ by using Eq. 13, *i.e.*, the Clausius-Clapeyron relation. The entropy change in the gelation is obtained from the slope of the $\log X_3^{(\alpha)}$ *vs.* T curve in Fig. 3 based on Eq. 14. The volume change, $\Delta\bar{V}^{(\alpha\beta)}$, is obtained from the slope of the $\log X_3^{(\alpha)}$ *vs.* P curve in Fig. 4. This estimation is based on Eq. 15. Actually, we obtained $\Delta\bar{V}^{(\alpha\beta)}$ by applying Eq. 15 to Fig. 4 and then estimated $\Delta\bar{S}^{(\alpha\beta)}$ and $\Delta\bar{H}^{(\alpha\beta)}$ by the use of Eq. 13 and Fig. 2.

The change in volume on gelation, $\Delta\bar{V}^{(\alpha\beta)}$, is shown as a function of the pressure at various temperatures in Fig. 5. The transition from a sol to a gel is accompanied by a decrease in the volume. The lower the temperature and the higher the pressure, the larger the degree of

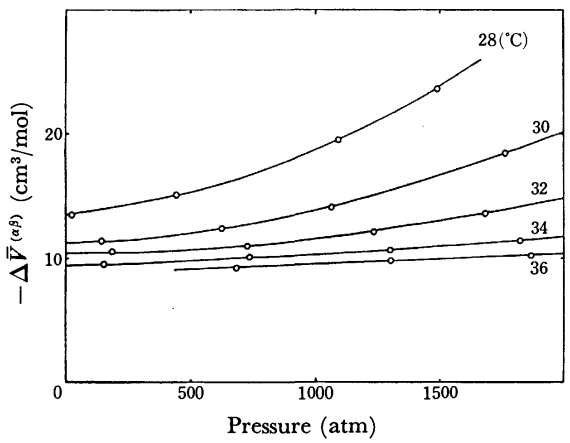

Fig. 5. The volume change of gel formation as a function of pressure at various temperatures. Numerical values indicate temperature in °C.

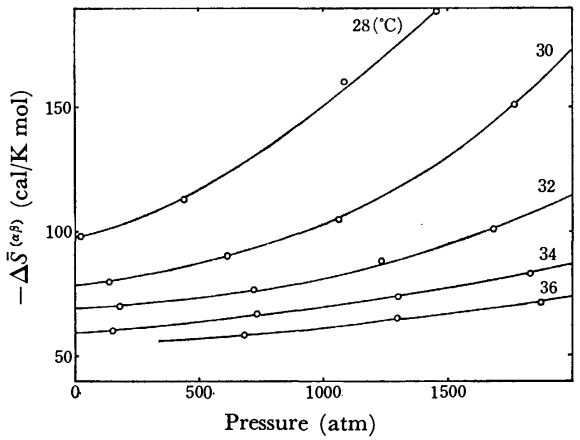

Fig. 6. The entropy change of gel formation as a function of pressure at various temperatures. Numerical values indicate temperature in °C.

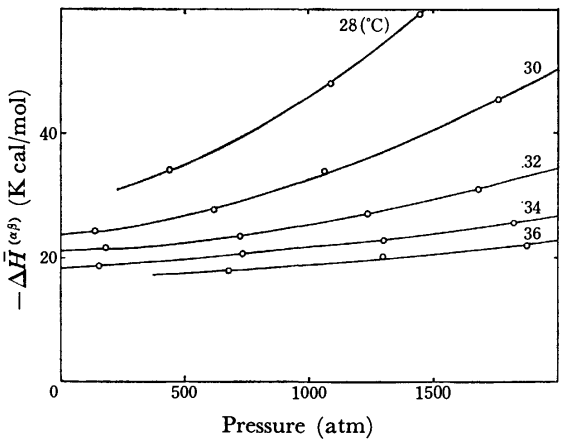

Fig. 7. The enthalpy change of gel formation as a function of pressure at various temperatures. Numerical values indicate temperature in °C.

volume decrease. The changes in the entropy ($\Delta\bar{S}^{(\alpha\beta)}$) and enthalpy ($\Delta\bar{H}^{(\alpha\beta)}$) of gel formation are shown as functions of the pressure at various temperatures in Figs. 6 and 7 respectively. The values of $\Delta\bar{S}^{(\alpha\beta)}$ and $\Delta\bar{H}^{(\alpha\beta)}$ are all negative under the conditions of this study and come to be negatively larger as the temperature is lowered and the pressure is raised.

Suzuki and his co-workers[8] have studied the effect of the pressure on the thermodynamically reversible gelation of gelatin, poly(vinyl alcohol), and methylcellulose in aqueous solutions. They have found that the formation of intermolecular hydrogen-bonded cross-links results in negative values of both the enthalpy and volume change on gelation. Taniguchi and Suzuki[9] have reported the effect of the pressure on the gel formation of 12-hydroxyoctadecanoic acid in CCl_4 and showed the enthalpy and volume changes on gelation to be negative.

In a thermodynamically reversible gel, the cross-links are known to be caused by secondary forces, such as hydrogen bonds, hydrophobic, and electrostatic interactions, rather than by covalent bonds. Of these, the hydrogen-bond formation is characterized by a negative change in the volume and an exothermic change in the enthalpy. On the other hand, the hydrophobic interactions (*i.e.*, the hydrophobic bonds) lead to positive changes in volume and entropy upon the gel formation. Therefore, the negative changes in the thermodynamic quantities on gelation are at least attributable to the cross-links of the intermolecular hydrogen bonds.

The enthalpy change per mole of the hydrogen bond is well known to be within the range from −4 to −4.5 kcal/mol.[10] The volume change per mole of the hydrogen bond has also been found to be −5.5 cm^3/mol in the gel formation of 12-hydroxyoctadecanoic acid in CCl_4,[9] −4.64 cm^3/mol for the association of 1-butanol in CS_2,[11] −3.0 to −3.4 cm^3/mol for the hydrogen-bond formation between phenol and dioxane in hexane,[12] and −7.0 cm^3/mol for the dimerization of formic acid.[13]

A molecule of SDC has, as a maximum, three sites for hydrogen bonds, *i.e.*, the 3α- and 12α-hydroxyl groups and the carboxyl group. Judging from the values of $\Delta\bar{V}^{(\alpha\beta)}$ and $\Delta\bar{H}^{(\alpha\beta)}$ shown in Figs. 5 and 7 and the respective values for hydrogen-bond formation per mole described above, the number of hydrogen bonds per mole of SDC in the gel formation can be roughly estimated to be about 3 or more if the gel formation involves the hydrogen-bond formation alone. The number of hydrogen bonds tends to increase as the temperature is lowered. This is probably attributable to the hydrogen bonds with solvent water.

Reaction of Pyridine Bases with Carboxylic Acids in Benzene

Katsumi HIROSE and Motoharu TANAKA*

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Nagoya 464

(Received August 20, 1976)

The reaction of pyridine bases with aliphatic monocarboxylic acids has been studied by means of the partition method. Partition was carried out at 25 °C between benzene and 0.10 mol dm^{-3} (Na, H) ClO_4 aqueous solution, the total concentration of pyridine base and that of carboxylic acid being less than 2×10^{-2} mol dm^{-3} and 1.0 mol dm^{-3}, respectively. Both (1: 1) and (1: 2) complexes (base to acid ratio) are formed in benzene, (1: 3) complex being additionally formed only for 2,4,6-trimethylpyridine. A linear free energy relationship is observed between the formation of the (1: 1) and (1: 2) complexes and the protonation in water of the corresponding bases except for sterically crowded 2,6-dimethyl derivatives of pyridine. The structure of the (1: 2) and (1: 3) complexes is discussed.

The reaction of bases with carboxylic acids in nonpolar solvents is important for understanding the nature of the acid-base reaction, since a carboxylic acid undergoes association in nonpolar solvents.[1] Several interesting features of the acid-base reaction, such as, the formation of higher hydrogen-bonded complexes and the proton transfer complex have been reported.[2] It was revealed that the hydrogen bond strength is parallel to the acidity and basicity of components.[3]

The system involving pyridine bases and carboxylic acids in organic solvents was initially studied by Barrow with use of IR spectroscopy. He revealed the stoichiometry of reaction products and discussed the extent of the proton transfer in relation to the acid strength of a carboxylic acid.[4] Since then, various physical methods, such as IR, visible, NMR, NQR, thermodynamic method and dipole moment measurement, have been applied to the reaction of the pyridine bases with carboxylic acids in solution or in solid state.[5-10] In the present paper, we describe the reaction of carboxylic acid with pyridines in reference to the effect of substituents. The structure of the (1: 2) and (1: 3) species (base to acid ratio) is discussed.

Experimental

Reagent. All the pyridine bases, *i.e.* pyridine, 3-bromopyridine, 2-methylpyridine, 4-methylpyridine, 2,6-dimethylpyridine and 2,4,6-trimethylpyridine were of G. R. grade. Carboxylic acids, *i.e.* butyric acid, valeric acid and hexanoic acid, were of G. R. grade, while decanoic acid was of chemical pure grade. The purification of pyridine bases, carboxylic acids and benzene (G. R.) as a solvent has been described elsewhere.[11,12]

Procedure. The partition was carried out in an incubator thermostated at (25±0.1) °C. Equilibrium is reached within 1 h. Concentrations were 0.1—1.0 mol dm^{-3} for the carboxylic acids and 2×10^{-3}—2×10^{-2} mol dm^{-3} for the pyridine bases. The ionic strength in the aqueous phase was maintained at 0.10 mol dm^{-3} with sodium perchlorate. Hydrogen ion concentration was measured with a Orion Ionalyzer Model 801 and a Beckman Research pH meter. A 1.00×10^{-2} mol dm^{-3} perchloric acid solution containing 0.09 mol dm^{-3} sodium perchlorate was employed as a standard of hydrogen ion concentration. Hydrogen ion concentration was estimated by correcting for a liquid-junction potential.[13] The total concentration of pyridine base in the aqueous phase was determined by colorimetry for 3-bromopyridine; for the other pyridine bases the total concentration in the organic phase was determined by acid-base titration in glacial acetic acid with Crystal Violet as an indicator.

Results

When a pyridine base, B, is extracted with a carboxylic acid, HA, in benzene, the extraction equilibrium between the organic and aqueous phases is written as

$$mB_w + n(HA)_o \rightleftharpoons (B_m(HA)_n)_o \quad (1)$$

where $B_m(HA)_n$ denotes an extracted species which involves m molecules of pyridine base and n molecules of carboxylic acid, and subscripts w and o refer to the aqueous and organic phases, respectively. Since the activity coefficient of each species in both phases is assumed to be kept constant,[14,15] the concentration equilibrium constant, $K_{ex(mn)}$, for Eq. 1 is kept constant.

$$K_{ex(mn)} = [B_m(HA)_n]_o[B]_w^{-m}[HA]_o^{-n} \quad (2)$$

The association between a pyridine base and a carboxylic acid is negligible in the aqueous phase.

When a pyridine base is extracted with a carboxylic acid in benzene, the total concentration of the pyridine base in the organic phase, $C_{B,o}$, is given by

$$C_{B,o} = \sum_{m=1}\sum_{n=0} m[B_m(HA)_n]_o \quad (3)$$

Substituting this relation into Eq. 2, we have

$$C_{B,o} = \sum_{m=1}\sum_{n=0} mK_{ex(mn)}[B]_w^m[HA]_o^n \quad (4)$$

If only species involving m molecules of pyridine base are present in the organic phase, the total concentration of the pyridine base in the organic phase can be written as

$$C_{B,o} = [B]_w^m\{\sum_{n=0} mK_{ex(mn)}[HA]_o^n\} \quad (5)$$

or

$$\log(C_{B,o}/\text{mol dm}^{-3}) = m\log([B]_w/\text{mol dm}^{-3}) + \log\{\sum_{n=0} mK_{ex(mn)}[HA]_o^n/\text{mol}^{1-m}\,\text{dm}^{3m-3}\} \quad (5')$$

$\log(C_{B,o}/\text{mol dm}^{-3})$ is linearly related with $\log([B]_w/\text{mol dm}^{-3})$ for a given concentration of monomeric carboxylic acid in the organic phase. From the slope of this linear relationship we find the number of the pyridine base involved in the extracted species. The plots of $\log([B]_w/\text{mol dm}^{-3})$ *vs.* $\log(C_{B,o}/\text{mol dm}^{-3})$ for the extraction of the six pyridine bases with decanoic acid are shown in Fig. 1. They give rise to straight lines

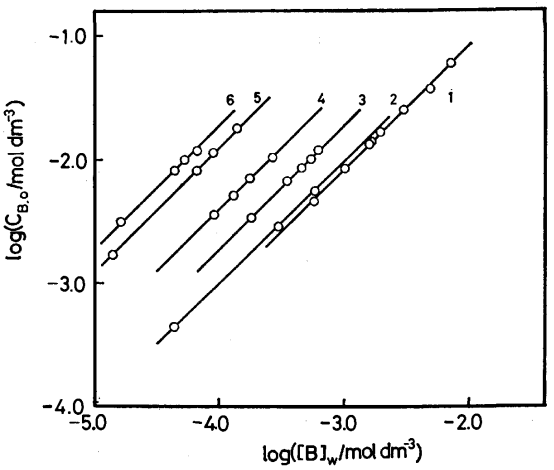

Fig. 1. Determination of the number of pyridine base involved in extracted species.
1: Decanoic acid–pyridine, 2: decanoic acid–3-bromopyridine, 3: decanoic acid–2-methylpyridine, 4: decanoic acid–4-methylpyridine, 5:decanoic acid–2,6-dimethylpyridine, 6: decanoic acid–2,4,6-trimethylpyridine.

with a slope of unity. We thus have extracted species involving only one molecule of pyridine base in benzene.

From Eq. 5 we obtain

$$C_{B,o}[B]_w^{-1} = \sum_{n=0} K_{ex(1n)}[HA]_o^n \quad (6)$$

By use of the distribution ratio, D, and the formation constant of pyridinium in the aqueous solution, K_{HB}, Eq. 6 is rewritten as

$$D\cdot\alpha_B = \sum_{n=0} K_{ex(1n)}[HA]_o^n \quad (7)$$

where α_B is the side reaction coefficient taking into account the protonation of the base:

$$\alpha_B = 1 + K_{HB}[H^+] \quad (8)$$

The $K_{ex(10)}$ in Eq. 7 is identical with the partition constant, $K_{D,B}$, of the pyridine base between benzene and aqueous solution in the absence of a carboxylic acid. In order to determine the number of carboxylic acid involved in the extracted species, $D\cdot\alpha_B$ was plotted against the concentration of the monomeric carboxylic acid in benzene. The latter was calculated from the partition constant and the dimerization constant in benzene[12]:

Acid	Partition constant*	Dimerization constant*
Butyric acid	0.11	182
Valeric acid	0.54	229
Hexanoic acid	1.9_1	251
Decanoic acid	500	260

* Hydration not corrected.

The results for the extraction of 4-methylpyridine with four carboxylic acids are shown in Fig. 2. Non-linearity of the plots indicates the presence of the extracted species involving more than one molecule of the carboxylic acid. Similar results were obtained for the other pyridine bases. Equation 7 can be rewritten as follows:

$$(D\cdot\alpha_B - K_{D,B})[HA]_o^{-1} = K_{ex(11)} + K_{ex(12)}[HA]_o + \cdots \quad (9)$$

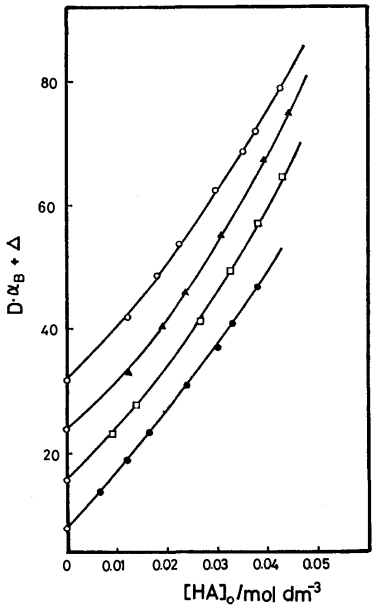

Fig. 2. Determination of the number of carboxylic acid involved in extracted species for 4-methylpyridine. The solid lines represent calculated values.
○: Decanoic acid (Δ=24), ▲: hexanoic acid (Δ=16), □: valeric acid (Δ=8), ●: butyric acid (Δ=0).

If only the first two terms on the right side are important, $(D\cdot\alpha_B - K_{D,B})[HA]_0^{-1}$ should be linearly related to the concentration of monomeric carboxylic acid in the organic phase. The plots of $[HA]_o$ *vs.* $(D\cdot\alpha_B - K_{D,B})$-$[HA]^{-1}$ for the extraction of 4-methylpyridine with the four carboxylic acids are shown in Fig. 3, in which we utilized the partition constants of the pyridine bases determined previously.[16] Straight lines with non-zero intercept (Fig. 3) indicate the presence of 1: 1 and 1: 2 complexes in the organic phase. The extraction constants of 1: 1 and 1: 2 complexes can be obtained from the intercept and the slope, respectively. Similar results were obtained for pyridine and its derivatives except for 2,4,6-trimethylpyridine. The formation of complexes

with the same compositions in nonpolar solvents such as carbon tetrachloride has been confirmed by IR study for the reaction of pyridine with several carboxylic acids.[4,6,8]

For 2,4,6-trimethylpyridine, the plot of $[HA]_o$ *vs.* $(D\cdot\alpha_B - K_{D,B})[HA]_o^{-1}$ is not linear (Fig. 4). This indicates the presence of higher complexes. Rearranging Eq. 9, we have

$$\{(D\cdot\alpha_B - K_{D,B})[HA]_o^{-1} - K_{ex(11)}\}[HA]_o^{-1} = K_{ex(12)} + K_{ex(13)}[HA]_o + \cdots \quad (10)$$

By plotting the values of the left side of Eq. 10 against $[HA]_o$ for 2,4,6-trimethylpyridine we obtain straight

	Decanoic acid	3.84	4.3_8	6.3

$\log(K_{ex(11)}/\text{mol}^{-1}\,\text{dm}^3)$, $\log(K_{ex(12)}/\text{mol}^{-2}\,\text{dm}^6)$, and $\log(K_{ex(13)}/\text{mol}^{-3}\,\text{dm}^9)$ values are estimated to be accurate to ±0.05, ±0.10, and ±0.2, respectively.

lines (Fig. 5). It is obvious that three species, *i.e.* 1:1, 1:2, and 1:3 complexes are present in benzene for 2,4,6-trimethylpyridine. The extraction constants are summarized in Table 1.

From the results, the equilibria of the pyridine bases with the carboxylic acids in benzene are formulated as follows:

$$B_o + (HA)_o \rightleftarrows (B\cdot HA)_o \qquad K_{11} \quad (11)$$

$$B_o + (HA)_{2,o} \rightleftarrows (B\cdot(HA)_2)_o \qquad K_{12} \quad (12)$$

$$(B\cdot(HA)_2)_o + (HA)_o \rightleftarrows (B\cdot(HA)_3)_o \qquad K_{13} \quad (13)$$

In addition, the dimerization of a carboxylic acid occurs in benzene:

$$2(HA)_o \rightleftarrows (HA)_{2,o}$$

The formation constant of complexes in benzene can be evaluated from the corresponding extraction constant by use of the partition constant of the pyridine base and the dimerization constant of the carboxylic acid.

Polar solutes, *i.e.* carboxylic acids and amines, form hydrates in a nonpolar solvent equilibrated with water.[17] Thus correction for hydration of pyridine base and carboxylic acid should be made in order to evaluate the true formation constant of complexes. We have information on the hydration of pyridine bases and carboxylic acids in benzene.[11,12] The formation constants corrected for the hydration of acids and bases are summarized in Table 2.

Table 2. Logarithmic formation constants of $(B\cdot HA)$, $(B\cdot(HA)_2)$, and $(B\cdot(HA)_3)$ complexes in benzene

Discussion

It has been suggested that the extent of formation of hydrogen-bonded complex between a series of bases and phenols or alcohols is a function of basicity of these bases.[18,19] We have observed the linear free energy relationship between the hydration of pyridine bases in benzene and the formation of the corresponding pyridiniums in aqueous solution,[11] a similar relationship being observed for the hydration of carboxylic acids.[12] The formation constants of 1 : 1, 1 : 2, and 1 : 3 complexes for a given pyridine base remain constant for the carboxylic acids studied (Table 2). This seems reasonable since the acidity of the four carboxylic acids does not differ appreciably from each other.

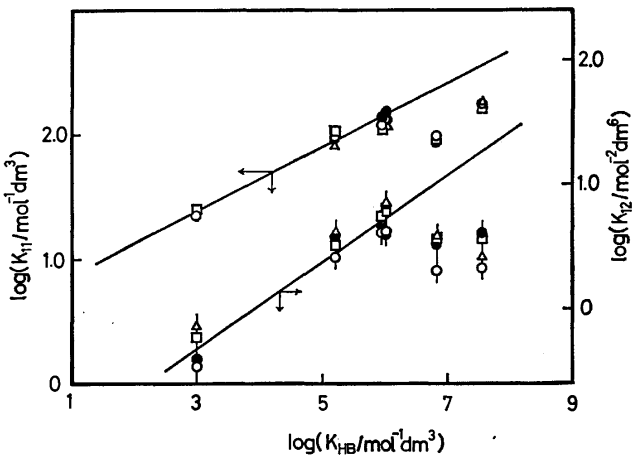

Fig. 6. Correlation between the logarithmic formation constants of the 1:1 and 1:2 complexes and the logarithmic formation constants of pyridinium in aqueous solution. Data of log K_{HB}'s were taken from Ref. 16.

Let us examine the correlation between the formation of 1 : 1 complex and the formation of the corresponding pyridinium. The plot of the logarithmic formation constant of 1 : 1 complex against $\log(K_{HB}/\text{mol}^{-1}\text{ dm}^3)$ is shown in Fig. 6. A linear correlation was obtained between $\log(K_{11}/\text{mol}^{-1}\text{ dm}^3)$ and $\log(K_{HB}/\text{mol}^{-1}\text{ dm}^3)$ except for sterically crowded 2,6-dimethyl derivatives of pyridine. The relationship is written as follows (dimensions are hereafter omitted for the sake of simplicity):

$$\log K_{11} = 0.25 \log K_{HB} + 0.62 \qquad (15)$$

A similar relationship has been obtained for the formation of the monohydrate of pyridines[11]:

$$\log \beta_{11}(\text{hydrate}) = 0.09 \log K_{HB} - 0.37 \qquad (15')$$

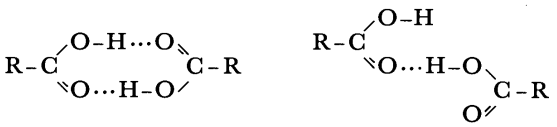
The coefficient of $\log K_{HB}$ in Eq. 15 is appreciably larger than that in Eq. 15'. In view of the fact that acidity of the carboxylic acid is much higher than that of water, it is reasonable that the extent of the complex formation of the pyridine bases with the carboxylic acids is greater than that of the hydration. The $\log K_{11}$ values for the sterically crowded 2,6-dimethyl derivatives of pyridine are smaller than that expected from $\log K_{HB}$.

We shall examine the correlation between the reaction of the pyridine base with the dimeric carboxylic acid and the formation of pyridinium. In Fig. 6 the logarithmic formation constant of the 1 : 2 complex for carboxylic acids is plotted against $\log K_{HB}$ of corresponding pyridiniums. The correlation is obviously good except for 2,6-dimethyl derivatives of pyridine. This relationship is expressed by

$$\log K_{12} = 0.35 \log K_{HB} - 1.44 \qquad (16)$$

We see that the formation of the 1 : 2 complex would occur to a negligible extent for the pyridine bases less basic than 3-brompyridine. A comparison of coefficients of $\log K_{HB}$ in Eqs. 15 and 16 suggests that the dimeric carboxylic acid is somewhat more acidic than monomeric carboxylic acid.

Let us consider the structure of the 1 : 2 complex. We have two possible structures of dimeric carboxylic acids:



cyclic dimer, c-$(HA)_2$ open dimer, o-$(HA)_2$

The following equilibrium might take place.

$$\text{o-}(HA)_2 \rightleftharpoons \text{c-}(HA)_2 \qquad K_{o-c} \qquad (17)$$

Pyridine bases are assumed to react only with the open dimer:

$$\text{o-}(HA)_2 + B \rightleftharpoons (B\cdot\text{o-}(HA)_2) \qquad K_{OB} \qquad (18)$$

Then the formation constant of the 1 : 2 complex can be written as:

$$K_{12} = [B\cdot\text{o-}(HA)_2][B]^{-1}([\text{o-}(HA)_2] + [\text{c-}(HA)_2])^{-1}$$
$$= K_{OB}(1+K_{o-c})^{-1} \qquad (19)$$

If K_{OB} is approximated as K_{11}, we have

$$K_{o-c} = K_{11}K_{12}^{-1} - 1 \qquad (20)$$

Thus the value of K_{O-C} can be calculated from values of K_{11} and K_{12} given in Table 2. Average values of K_{O-C} for the four carboxylic acids are as follows: butyric, 31; valeric, 28; hexanoic, 26; decanoic, 44. The proportion of the open dimer is roughly estimated to be *ca.* 3% of acid dimer. IR spectroscopic study and the slopes of the LFER given in Fig. 6 suggest strongly that the acidity of the open dimer should exceed the acidity of the monomeric carboxylic acid, *i.e.*

$$K_{OB} > K_{11}$$

Then the proportion of the open dimer should be less than 3%.

Combining Eqs. 16 and 19, we have

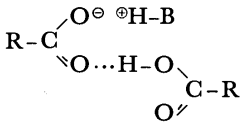
$$\log K_{OB} = 0.35 \log K_{HB} - 1.44 + \log(1+K_{o-c}) \qquad (21)$$

K_{OB} should be greater than K_{11} for all bases including a base of which K_{HB} is equal to 1. Then from Eqs. 15 and 21 we obtain

$$-1.44 + \log(1+K_{o-c}) > 0.62$$

or $$K_{o-c} > 119$$

The fraction of the open dimer in the total dimer concentration seems to be a little less than 1%. Since the estimations are consistent with the previous findings,[20] we can conclude that the open dimer of a carboxylic acid reacts with a pyridine base to form a 1 : 2 complex:



(22)

2,4,6-Trimethylpyridine forms the 1 : 3 complex with the four carboxylic acids in benzene. The formation of 1 : 3 complex in organic solvents has been found in several systems involving more acidic carboxylic acids or more basic amines.[21-24] The stronger the base, the the more extensive the polarization of -OH group in the 1 : 2 complex (formula 22) and the more basic the terminal -C=O becomes. Thus we have the 1 : 3 complex for the stronger bases, the situation being similar for stronger acids.

A Study of Catalysis by Metal Phosphates. IV.[1] The Alkylation of Phenol with Methanol over Metal Phosphate Catalysts

Fumio Nozaki and Isao Kimura

Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received August 26, 1976)

The catalytic methylation in the vapor phase over various metal phosphates has been investigated using a conventional flow reactor at temperatures ranging from 350 to 500 °C under atmospheric pressure. The $Ca_3(PO_4)_2$ catalyst was excellent in both its activity and its selectivity for ortho-methylation, giving predominantly *o*-cresol and 2,6-xylenol, whereas the BPO_4 or $CaHPO_4$ catalyst simultaneously promoted the formation of anisole. The activity of $Ca_3(PO_4)_2$ was significantly higher than that of the CaO or MgO catalyst. The influences of the reaction temperature, the contact time, and the calcination temperature of the catalyst upon the conversion of phenol, and the yields of the products were investigated in detail over the $Ca_3(PO_4)_2$ catalyst. The activities and the selectivities of various catalysts were discussed in connection with their acid-base properties. The mechanism of the participation of both the acidic and basic sites in the methylation was also discussed.

The alkylation of phenol in the ortho position has been of interest in recent years,[2] and the catalytic process using methanol as an alkylating reagent has been investigated by several workers.[3-7] The alkylation reactions of phenol or cresol using C_2—C_4 olefins or C_1—C_4 alcohols have also been studied over various catalysts.[8-10] However, no study of the phosphate catalyst has been reported.

Our preliminary study has revealed that calcium orthophosphate has a significant activity and an interesting selectivity for the alkylation of phenol with methanol in the vapor phase. The present paper will describe the behavior of metal phosphates as a catalyst. The correlation between the selectivity for the reaction and the acid-base character of the catalysts will also be discussed.

Experimental

Catalysts. The metal phosphate catalysts were obtained from guaranteed commercial reagents by the usual method of pellet-catalyst preparation, which involves wet mixing and extruding in order to mold the catalyst. All the catalysts were in the form of 1—2 mm pellets. The CaO and MgO catalysts used to characterize the phosphate catalysts were prepared by the thermal decomposition of the $Ca(OH)_2$ and $(MgCO_3)_4 \cdot Mg(OH)_2$ reagents respectively. Unless otherwise noted, the catalysts were activated before use by calcining at 500 °C for 3 h in a stream of air.

Apparatus and Procedure. A usual type of flow reactor consisting of a 18 mmϕ glass tube was used to perform the catalytic tests. Unless otherwise specified, the reactor contained 2 g of the catalyst. The reactor was vertically supported and externally heated in an electric furnace. The upper part of the reactor was packed with small glass beads, thereby vaporizing and preheating the reactants. A stream of nitrogen was passed through the catalyst bed at 500 °C for 1 h and then the temperature was lowered to the reaction temperature in a stream of nitrogen. A methanol-phenol mixture of a known composition was fed into the reactor at a constant rate by means of a microfeeder, and then carried by nitrogen to the catalyst bed. The outlet vapor was condensed in a trap cooled with an ice bath, and samples for analysis were collected periodically. The condensed liquid products were analyzed by means of a gas-chromatographic unit containing a 3-m column of Silicone DC-550. The column was operated at 150 °C, with hydrogen as the carrier gas. The products were identified by a comparison of their chromatograms with those of authentic samples. Besides the methylation of phenol, methanol was simultaneously consumed by the gasification which was a side-reaction, giving such non-condensable products as CO, CO_2, and CH_4. However, no detailed measurement of the non-condensable products has been made because they were formed to only a small extent throughout the catalytic tests in which the phosphates were used as catalysts. The conversion of phenol and the yields of the products were expressed in mol%. The liquid products obtained consisted mainly of *o*-cresol, 2,6-xylenol, anisole, 2,4,6-trimethylphenol, 2,4-xylenol, and small amounts of *m*, *p*-cresol. Very small peaks of unknown products were detected in the gas-chromatograms, but their formation was neglected in the calculation of the conversion and the selectivity. The selectivity for the ortho-methylation, S_o, was defined as follows:

$$S_o = \frac{\text{yield of } (o\text{-cresol}+2,6\text{-xylenol})}{\text{total conversion of phenol, } x}$$

The selectivity for anisole formation, S_A, and the selectivity to the other products (*m*- and *p*-cresol+2,4-xylenol+2,4,6-trimethylphenol), S_B, were defined as follows:

$$S_A = \frac{\text{yield of anisole}}{\text{total conversion of phenol, } x}$$

$$S_B = 1 - (S_o + S_A)$$

As an indication of the contact time in the flow reactor, we used W/F, defined as follows:

$$W/F = \frac{\text{catalyst weight (g)}}{\text{feed rate of the sum of reactants and nitrogen (mol/h)}}$$

The powdered catalyst samples calcined at 500 °C for 3 h in air were used for the measurements of their acidity and basicity. The acidities of the catalysts were measured by usual *n*-butylamine titration, using the Hammett indicators. According to the method of Tanabe *et al.*,[11] the basicities of the catalysts were measured by titrating them with a benzoic acid–benzene solution, using bromothymol blue ($pK_a=7.1$) and phenolphthalein ($pK_a=9.3$) as indicators.

Results and Discussion

Catalyst Activity and Change in Activity with the Process Time. The changes in the activity and selectivity during the course of the reaction were generally not serious, although the degree of the change depended on the species of the catalysts. Henceforth, in order to

Table 1. Activities and selectivities of various catalysts

Conditions: reaction temperature (t)=460 °C, W/F=14.5 g h/mol, feed molar ratio (m) of methanol/phenol/N_2=2.0/1.0/1.2.

Catalyst		$Ca_3(PO_4)_2$	$CaHPO_4$	$Ca(H_2PO_4)_2$	BPO_4	CaO	MgO
Conversion of phenol, x (%)		77.7	26.4	1.0	47.0	7.6	48.0
Selectivity, S_o (%)		88	28	0	46	75	80
Yield (%)	anisole	0.6	19.0	1.0	25.4	0.6	1.9
	o-cresol	38.2	7.4	0	17.8	5.7	30.5

	2,6-xylenol	30.3	0	0	3.8	0	7.9
	2,4-xylenol	3.1	0	0	0	0	1.8
	2,4,6-trimethylphenol	5.5	0	0	0	0	1.1
Conversion of methanol, x_M (%)		42.1	—	—	95.8	4.6	—
Selectivity for methylation, S_M (%)		93	—	—	25	83	—

compare the catalysts, we will use the activity data obtained around 1.5 h after the start of the reaction. The activities and the selectivities of various catalysts are shown in Table 1. It can be seen from Table 1 that the $Ca_3(PO_4)_2$ catalyst is excellent in activity and selectivity for ortho-methylation, leading to *o*-cresol and 2,6-xylenol. Another characteristic of the $Ca_3(PO_4)_2$ catalyst is the fact that it is liable to form highly methylated products, such as xylenol isomers and 2,4,6-trimethylphenol. The ortho-selectivity of the BPO_4 catalyst is far less than that of the $Ca_3(PO_4)_2$, since the BPO_4 gives rise to anisole in a large quantity even though it has a substantial activity. Both the $CaHPO_4$ and $Ca(H_2PO_4)_2$ are somewhat inferior to the other catalysts. The CaO and MgO catalysts have a low activity, though it is high in ortho-selectivity. Tanabe *et al.*[4,5] have already pointed out that the CaO or MgO catalyst has a high selectivity for ortho-methylation. In agreement with their papers, our experiment has also revealed that the CaO and MgO catalysts have a high selectivity, although their activities are far less than that of the $Ca_3(PO_4)_2$. In the cases of the other phosphate catalysts, the catalytic tests gave the following results; $Ni_3(PO_4)_2$: x=8%, S_O=38%, S_A=62%, $AlPO_4$: 9, 56, 44%, $CrPO_4$: 19, 21, 79% and $Zr_3(PO_4)_4$: 6, 33, 67%, respectively. The activities and the ortho-selectivities of these phosphate catalysts were appreciably inferior to those of the $Ca_3(PO_4)_2$; an additional characteristic of their behaviors as catalysts was the fact that scarcely any formation of *m,p*-cresol, 2,4-xylenol, or 2,4,6-trimethylphenol was found. As has been described in previous papers,[1,12] $Cd_3(PO_4)_2$ is an effective catalyst for the dehydrogenation of alcohols, by analogy with the $Ca_3(PO_4)_2$ catalyst. However, $Cd_3(PO_4)_2$ exhibited very little activity for the methylation of phenol. This seems to be the reason for the low thermostability of the $Cd_3(PO_4)_2$ catalyst.[12]

During the course of the methylation, the phenol is not entirely decomposed to form benzene or gaseous compounds. In contrast, methanol is consumed through two simultaneous reactions, the methylation of phenol and the gasification giving such non-condensable products as CO, CO_2, and CH_4. The effectiveness of the catalyst should be discussed not only in terms of the conversion of phenol, but also in terms of the fraction of methanol utilized as an alkylating reagent. An important characteristic of the $Ca_3(PO_4)_2$ catalyst to be noted here is that only a small % of the methanol converted is consumed for gasification. It must be generally accepted that the MO-Fe_2O_3 catalyst developed by Kotanigawa *et al.*[3] is more active than the $Ca_3(PO_4)_2$ catalyst. The MO-Fe_2O_3 catalyst, however, leads to significant amounts of gasification of methanol; hence, it can be said that the $Ca_3(PO_4)_2$ catalyst is more effective in the selectivity of methanol than the MO-Fe_2O_3 catalyst.

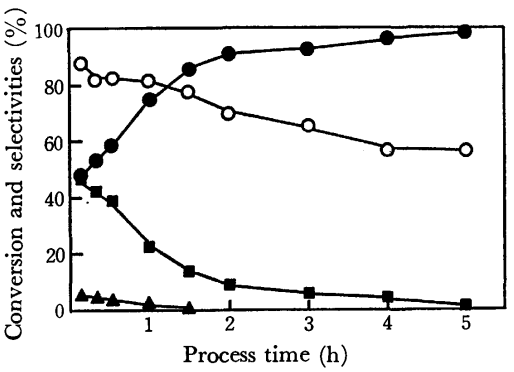

Fig. 1. Changes in activity and selectivity of $Ca_3(PO_4)_2$ catalyst with process time.
Conditions: t=460 °C, W/F=14.5 g h/mol, m=2.0/1.0/1.2.
○: Conversion of phenol (x), ●: selectivity for ortho-methylation (S_O), ▲: selectivity for anisole formation (S_A), ■: selectivity to the other products (S_B).

The change in the activity and selectivity of the $Ca_3(PO_4)_2$ catalyst with the process time are illustrated in Fig. 1. Both the activity and the selectivity change rapidly at the initial period, and then they gradually approach almost constant values. The selectivity for ortho-methylation, S_O, increases with the process time and approaches 100% after the reaction had been continued for 4 h. In contrast, the selectivity to the other products, S_B, decreases rapidly and is lowered to a very small value with an increase in the process time. The selectivity for anisole formation, S_A, is allowed to continue at a small value and then becomes practically negligible around 2 h after the start of the reaction. Consequently, only two products, *o*-cresol and 2,6-xylenol, are obtained after the reaction has been continued for 5 h or more. Such a decrease in activity

and change in selectivity as are shown in Fig. 1 might be due to the disappearance of active sites, leading to the formation of a highly methylated product or anisole by the deposition of a carboneous substance. After the reaction has been continued for several hours, however, the catalyst surface is brought into a situation favorable to ortho-methylation and the subsequent catalytic reaction reaches an almost steady state.

Effects of the Reaction Temperature and Contact Time. The effect of the reaction temperature on the conversion, the selectivity, and the yields of the products was investigated with the $Ca_3(PO_4)_2$ catalyst. The results are shown in Figs. 2 and 3; the data were obtained by using a fresh catalyst in each run and by analyzing the samples collected 1.5 h after the start of the reaction. The higher the reaction temperature, the higher the conversion and the yield of *o*-cresol, 2,6-xylenol, or 2,4,6-trimethylphenol became. The selectivity for ortho-methylation was approximately 80%, regardless

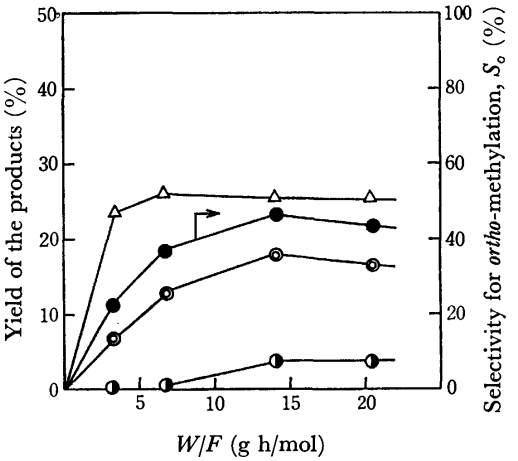

Fig. 5. Yield and selectivity over BPO_4 catalyst as a function of W/F.
Conditions and symbols are the same as for Fig. 4.

of the reaction temperature. The temperature providing the maximal yields of anisole and 2,4-xylenol were about 400 and 430 °C respectively. However, their yields did not exceed 5%.

The effects of W/F on the yields of the products are shown in Figs. 4 and 5. Figure 4 indicates that the $Ca_3(PO_4)_2$ catalyst gives, selectively, *o*-cresol and 2,6-xylenol in the low range of W/F. With an increase in W/F, the consecutive methylation of *o*-cresol to xylenols and trimethylphenol is gradually increased, but the formation of anisole is slight over the entire range of W/F. Figure 5 indicates that, in the case of the BPO_4 catalyst, the increase in W/F does not result in a remarkable increase in the yields of the products or in the selectivity for ortho-methylation. Anisole is predominantly formed over the whole range of W/F, but no definitive maximum in the yield of anisole is perceived throughout the experimental range of W/F. The yields of xylenol isomers were vanishingly small, and such highly methylated products as trimethylphenol were completely missing, even at the highest range of W/F.

Table 2. Acid-base properties of various catalysts

Catalyst	Acidity (mmol/g) $H_0 \leqq 3.3$	$H_0 \leqq 4.8$	$H_0 \leqq 6.8$	Basicity (mmol/g) $H_0 \geqq 7.1$
$Ca_3(PO_4)_2$	0	0	0.132	0.053
$CaHPO_4$	0	0.046	0.073	0
$Ca(H_2PO_4)_2$	0.196	—[b]	—[a]	0
BPO_4	0.220	—[b]	0.370	0
CaO	0	0	0.043	0.066

a) The acidity ($H_0 \leqq 6.8$) of $Ca(H_2PO_4)_2$ could not be measured quantitatively because of the formation of a precipitate. b) The measurements were not carried out.

Acid-Base Property of the Catalyst and the Catalytic Activity. The acid-base properties of the catalysts are shown in Table 2. The strong basic site with $H_0 \geqq 9.3$ was not found in any catalyst. Between the catalytic activities and the acid-base properties of the catalysts, no simple correlation can be observed by comparing Table 1 with Table 2. Excluding the case of the $Ca(H_2PO_4)_2$ catalyst, however, it is likely that anisole is produced over the BPO_4 or $CaHPO_4$ catalyst with acidic sites ($H_0 \leqq 4.8$) but no basic sites, and that the ortho-methylation can occur over the catalysts with both weak acidic sites ($H_0 \leqq 6.8$) and basic sites.

In order to make this aspect clearer, we have investigated the relationship between the catalytic activity and the acid-base property, using a series of $Ca_3(PO_4)_2$ catalysts calcined at various temperatures. The results are shown in Figs. 6 and 7. Both the acidic strength and the basic strength of the $Ca_3(PO_4)_2$ catalyst remained unaltered by a change in the calcination temperature, although either the acidity ($H_0 \leqq 6.8$) or the basicity ($H_0 \geqq 7.1$) varied, as is shown in Fig. 6. Figure 6 indicates that the acidity decreases monotonously with the rise in the calcination temperature, while the basicity has its maximum at the calcination temperature near 550 °C. Figure 7 indicates that the catalyst activity (the conversion of phenol) slightly increases with rise in the calcination temperature from 460 to 500 °C, passes

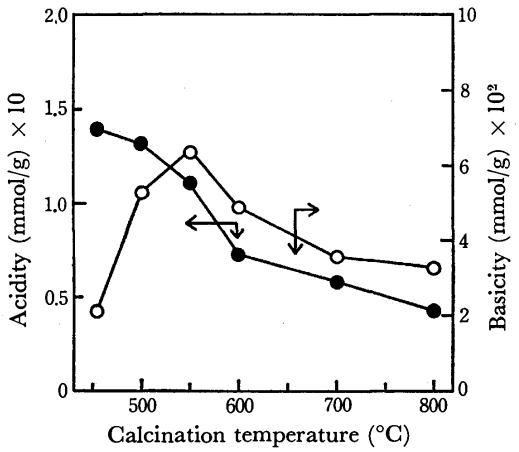

Fig. 6. Acidity and basicity of $Ca_3(PO_4)_2$ calcined at various temperatures.
●: Acidity (measured at $H_0=6.8$), ○: basicity (measured at $H_0=7.1$).

Conditions and symbols are the same as for Fig. 2.

through a maximum at about 500 °C, and then significantly decreases. In contrast, the selectivity for ortho-methylation remains almost constant at temperatures ranging from 500 to 800 °C, except for the low selectivity of the catalyst prepared at 460 °C. A comparison of Fig. 6 with Fig. 7 suggests that the catalytic activity may be correlated to both the acidity and basicity, whereas the ortho-selectivity essentially depends on whether or not the basic sites coexist with acidic sites.

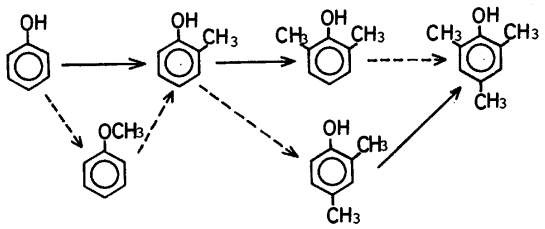
Reaction Pathway and Reaction Mechanism. By considering the fact that a maximal yield in the anisole formation is not observed in Fig. 4, the ortho-methylation giving *o*-cresol and 2,6-xylenol is expected to occur through a direct methylation of phenol, not through the formation of phenylethers, such as anisole or *o*-methylanisole, and their subsequent isomerization. In order to make more clear the reaction pathway of methylation, we have carried out additional catalytic tests between anisole, *o*-cresol or xylenols, and methanol. The results are summarized in Table 3. When anisole alone was passed through the $Ca_3(PO_4)_2$ catalyst under

Table 3. Catalytic reactions between anisole, *o*-cresol, 2,4-xylenol, or 2,6-xylenol and methanol over the $Ca_3(PO_4)_2$ catalyst
The conditions are the same as in Table 1, except for the methanol/reactant feed ratio.[a]

Reaction[a]	Anisole–methanol	*o*-Cresol–methanol	2,6-Xylenol–methanol	2,4-Xylenol–methanol
Conversion[b] (%)	48	40	25	66
	Yield of the product (%)			
Phenol	2	3	0	0
o-Methylanisole	6	3	0	0
o-Cresol	8	—	8	4
m,p-Cresol	0	0	0	1
2,6-Xylenol	16	23	—	0
2,4-Xylenol	5	7	0	—
2,4,6-Trimethylphenol	11	4	17	61

a) Feed molar ratio of methanol/anisole, methanol/*o*-cresol, *etc.*=1. b) Conversion of anisole, *o*-cresol, *etc.*

the same conditions as those described in Table 3, the anisole was rearranged, giving a small amount of *o*-cresol (in a 7.5% yield); it was partly demethylated to give phenol (in a 9.8% yield). From a comparison of Table 3 with the results shown in the other tables and figures, the following speculations are possible with respect to the reaction pathway of methylation: (1) the formation of *o*-cresol is due mostly to the direct methylation of phenol; (2) anisole is scarcely methylated at all to form *o*-methylanisole; (3) the isomerization of *o*-cresol to anisole or *m,p*-cresol is not observed; (4) xylenol isomers are formed by a consecutive methylation of *o*-cresol, whereupon it tends to form 2,6-xylenol rather than 2,4-xylenol, and (5) 2,4,6-trimethylphenol is formed by the further methylation of xylenol isomers, whereupon 2,4-xylenol is more readily methylated than 2,6-xylenol. Thus, the reaction pathway of methylation over the $Ca_3(PO_4)_2$ catalyst may be depicted as the following steps:



where the(→)arrow shows the main route of the methylation and(⇢), the sub-route. The behavior of $Ca_3(PO_4)_2$ as a catalyst was characterized by a selective formation of the ortho alkylated products. The reaction pathway described above is intrinsically consistent with the result obtained over the basic catalysts by Tanabe *et al.*[4] and by Enomoto *et al.*[7] Tanabe[13] and Enomoto *et al.*[7] have already pointed out that acidic catalysts, such as SiO_2–Al_2O_3 or condensed phosphoric acid, promote the reactions, giving phenylethers or *m*-alkylated products, while basic catalyst, such as MgO or ZnO–Fe_2O_3, promote the direct alkylation, giving the *o*-methylphenols without passing through phenylethers as an intermediate. According to their argument, the $Ca_3(PO_4)_2$ catalyst appears to be characteristically basic. This is not in conflict with our previous reports,[1,12] in which the $Ca_3(PO_4)_2$ has been characterized as a basic catalyst for the dehydrogenation of alcohols. However, it should be noted that the ortho-methylation of phenol depends not only on the basic sites, but also on the acidic sites, as has been mentioned above.

The acid-base properties of the colored phosphates, such as $Ni_3(PO_4)_2$ or $CrPO_4$, are difficult to measure by the titration method using Hammett indicators. Thus, instead of using the experimentally found values of the acid-base properties of the catalysts, the electronegativities (x_i) of the metal ions[14] in the phosphate or oxide catalysts were used as an indication of the acidic or basic strength, according to the theory proposed by Tanaka.[14] The selectivities for the ortho-methylation of various catalysts are shown in Fig. 8 as functions of the parameter, x_i. Figure 8 shows that the correlation between S_0 and x_i has a rough tendency to move towards a low selectivities with the increase in x_i. This

downward trend in the selectivity on x_i is intrinsically the same result as those reported by Tanabe *et al.*[10,13] On the other hand, the change in the activity depending on the variety of catalyst was too complicated to deal with quantitatively. In the limited case of the $Ca_3(PO_4)_2$ catalyst calcined at various temperatures, however, there was a rough correlation between the acid-base property (Fig. 6) and the catalyst activity (the conversion of phenol in Fig. 7), as is shown in Fig. 9. The upward trend in the activity with an increase in the term of (acidity)·(basicity) presumably suggests that the catalytic methylation is attributable to the mechanism involving both the acidic and basic sites. Further details of the reaction scheme and the catalyst structure must remain the subjects of future study.

(Received September 16, 1976)

The Photoemission from the organic compounds containing anthracene rings—anthracene, 9-methylanthracene, 9,10-dichloroanthracene and 9,9′-bianthryl—was measured. The photoelectron energetic responses of all these compounds were nearly the same. The resemblance of the photoelectron energy distribution curves and the spectral dependence of the quantum yield revealed the coincidence of the electronic structures of these compounds in a solid. The comparison between solid- and gas-phase photoelectron spectra showed that the optical excitation process is the most characteristic one in photoemission phenomena.

Anthracene is a typical compound in the research field of molecular crystals, like polycyclic aromatic hydrocarbons and solid rare gases. The various physicochemical properties of anthracene have been reported.[1,2] Among them, photoemission has recently been revealed to be a useful method for the investigation of the electronic structures of the solid state.[3–10]

We have measured the photoelectric response of anthracene and aromatic compounds containing anthracene-ring systems. The photoelectron energy distribution curves (EDCs) were obtained with a high accuracy by means of an electrical differentiation circuit.[7,11]

In this paper, we will compare the photoelectric effect among these compounds, and will also discuss the effect of the anthracene-ring on the photoemission behavior. We will also point out the resemblance of the photoelectron spectra between the gaseous and solid phases.

Experimental

Measurement. Monochromatic light obtained by a half-meter Seya-Namioka-type monochromator[12] was admitted into a chamber through a lithium fluoride window, which limited the measurement to $h\nu < 12$ eV. The energy distribution of the photoemitted electrons was measured by means of a spherical retarding electrode coated with colloidal graphite, Aquadag, on the inside. The small ac voltage (200 mV peak to peak, 4 Hz) was superimposed on the retarding potential in order to differentiate the I—V characteristic curves.[7,11] The spectral width of the monochromatized light was between 0.05 eV at 200 nm and 0.13 eV at 120 nm. In all, the experimental error is estimated to be less than 0.2 eV in measuring the EDCs.

As the total photocurrents were about 10^{-10} A or less, a preamplifier, a Cary 31 vibrating reed electrometer, had to be used to amplify the photocurrent. 4 Hz ac was adopted to differentiate the I—V characteristics, since the time response of the electrometer was not fast enough for a higher frequency to be used.

The spectral dependence of the quantum yield (SDQY) were measured by means of the same electrode, applying enough accelerating voltage between the emitter and the collector. The relative light intensity was also measured by means of a photomultiplier tube RCA 5819 with the aid of a coronene wavelength converter. As the stray light of the monochromator easily affects the photocurrent (this effect could not be neglected in the case of a low incident photon energy), filters, mainly a quartz filter (with a cut-off wavelength of 155 nm), were applied.

Samples. The samples used in this study were anthracene, 9-methylanthracene (9MeA), 9,10-dichloroanthracene (DClA), and 9,9′-bianthryl. Anthracene and 9MeA were deposited onto a cooled emitter (copper disk 12 mm in diameter) as a thin film by the sublimation method in a fairly low vacuum (10^{-3}—10^{-4} Torr) in order to prevent sample evaporation. After the preparation of the specimens, the emitter was introduced into the ionization chamber. During this operation, the specimen absorbed oxygen and water on its surface easily. The effect of this contamination will be discussed later.

DClA and 9,9′-bianthryl, on the other hand, were deposited onto the emitters under a pressure of less than 4×10^{-6} Torr by the sublimation method, this was possible because of their low vapor pressures.

The film thickness is an important factor in the quantitative photoemission measurements of organic crystals; a thinner film is not thick enough to prevent the penetration of light to the substrate, and the photocurrent due to the substrate is often observed, while a thicker film causes a charge-up effect which affects the EDCs. The thickness of the evaporated films in this work was from 40 to 100 nm in the first preparation. As the samples were sublimed successively from the surface of the thin film during the measurements, it was difficult to estimate the film thickness at each measurement.

Results

Energy Distribution Curves. Figures 1—4 show the photoelectron energy distribution curves of anthracene and its derivatives. Each EDC is indicated in arbitrary units, plotted as a function of the retarding potential, V; the numerical value beside each EDC is the incident photon energy. A dominant peak was observed in each EDC at about $V=0$ V. This peak position was independent of the incident photon energy. The kinetic energy of the photoejected electrons which are attributed to this dominant peak was less than 1 eV.

On the left side of the dominant peak (a large retardation voltage was applied) several structures were observed. These structures resemble each other. They come from the valence bands of each material as will be discussed later. On the right side of the peak, most EDCs except those of anthracene were cut sharply by

an effect of the escape function for passing electrons from a solid to a vacuum through the surface. However, long tails were found in some EDCs of anthracene. These long tails were caused by potential drops between the sample surface and the copper disk, since we were sometimes obliged to use thick specimens to avoid quick sample consumption.

The EDCs of 9MeA did not show any distinguishing peaks on the left side of the dominant peak. They showed only shoulders.** These results were perhaps due to the contamination of the specimen surface as will be discussed later, because the deposition of 9MeA was not performed under good conditions.

The threshold energy, E_{th}, can be obtained by using the well-known equation:

$$E_{th} = h\nu - E_w$$

** Moreover, the dominant peaks of 9MeA were much higher than the others.

where $h\nu$ is the energy of the incident photon and E_w is the band width of the EDCs. The threshold energies of these compounds are collected in Table 1.

Quantum Yield. Figure 5 shows the spectral dependence of the quantum yield of anthracene and its derivatives. All the SDQYs showed steep rises at about 6 eV. This is due to the effect of the escape function, which dominates the photoelectron-escape probability at the solid-vacuum interface. In the region between 6.5 and 7.5 eV, all the SDQYs had almost flat slopes. These flat slopes meant a small probability of photoelectron emission in spite of an increase in the light energy. Above 7.5 eV, the quantum yields increased gradually in accordance with the photon energy.

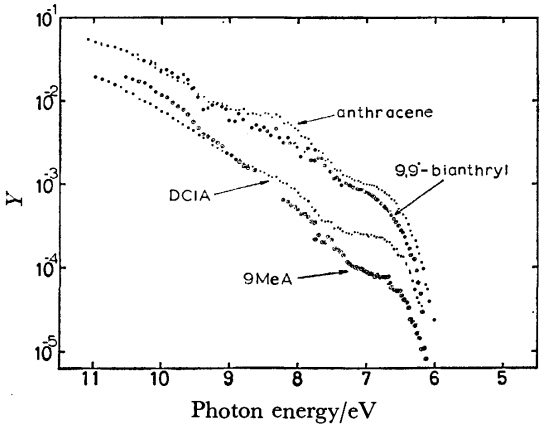

Fig. 5. Spectral dependence of quantum yield of these four compounds.

Anthracene and 9,9′-bianthryl showed the same yields throughout the energy region, while the photoelectric yield of DClA was about a half of that of anthracene. The photoelectric current of 9MeA varied with the exchange of specimens at the same intensity of the exciting light. This phenomenon was probably due to the surface conditions; one specimen was fairly clean and free from the contamination of the surface, while the others were not. As the surface contamination affects the photoelectric quantum yield, the SDQY of 9MeA shown in Fig. 5 is somewhat dubious.

Discussion

Energy Distribution Curves. Figures 6—8 show the replotted EDCs arranged with the first edges of each EDC on the same line. There are fixing peaks in this revised plot which vary the peak position with the incident quanta as shown in Figs. 1—4. These peaks

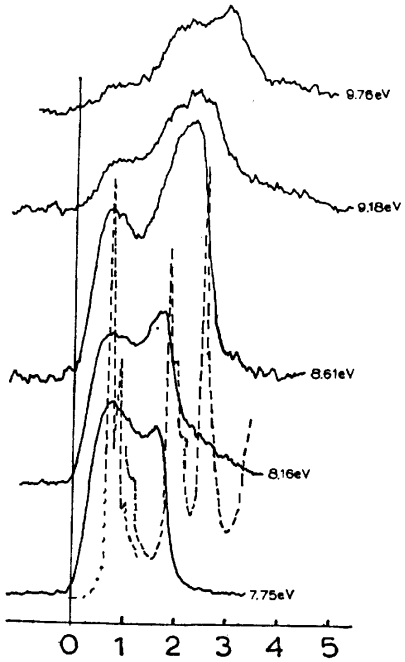

Fig. 6. EDCs of anthracene rewritten so that the first edge of each EDC should coincide. Abscissa is energy measured from threshold energy, 5.7 eV. Broken line indicates a molecular photoelectron spectrum of anthracene.[13] See description of text.

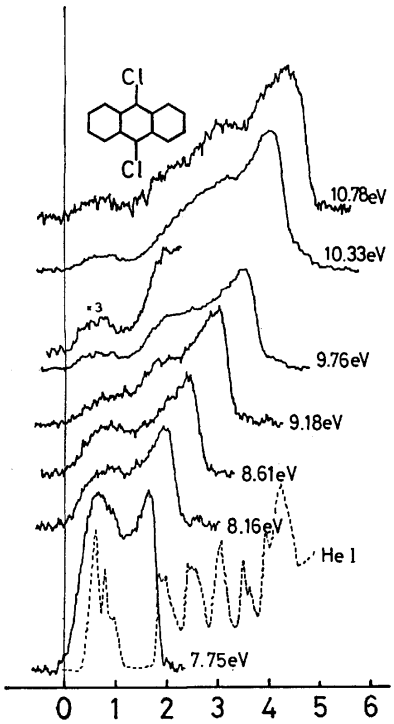

Fig. 7. EDCs (solid line) and molecular photoelectron spectrum (broken line) of DClA.[15] Abscissa is energy measured from threshold energy, 5.8 eV.

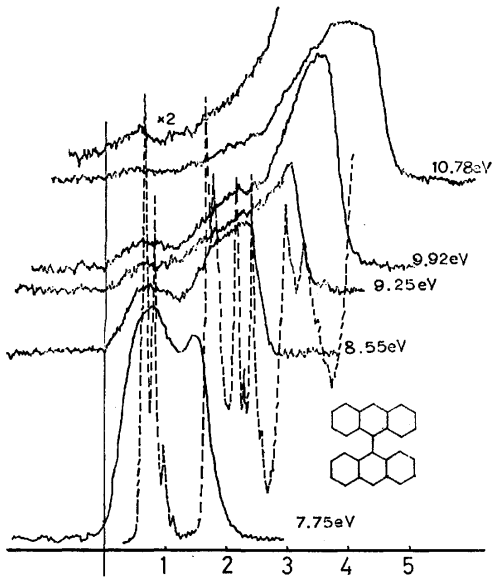

Energy from threshold energy in eV

Fig. 8. EDCs (solid line) and molecular photoelectron spectrum (broken line) of 9,9′-binathryl.[16] Abscissa is energy measured from threshold energy, 5.9 eV.

correspond to the valence electrons of each substance. This can be confirmed by a comparison of the broken lines in each figure;[13–16] this line is the molecular photoelectron spectrum, with a slight shift so that the first peaks of both spectra will coincide. The positions of the peaks or shoulders in the EDCs are in good agreement with the photoelectron spectra indicated by the broken lines. This fact indicates that the EDCs obtained by photoemission measurements reflect the state density of the valence band. The ionization potentials obtained by photoemission measurements (peak position) are collected in Table 2, which also lists the I_p's of gaseous anthracene and its derivatives. Table 3 summarizes the energy differences between the first ionization potential and the others.

On the other hand, the dominant peak, which was at the right side of each EDC and had a kinetic energy nearly 0 eV, has no corresponding photoelectron spectrum in the gas phase. This result suggests two possible explanations: The existence of auto-ionization levels in the conduction band, as Zagrubskii and Vilesov

a) Mean values were adopted.

proposed,[8] or a scattering mechanism of photoexcited electrons in the transport process, as estimated by Kochi *et al.*[5] and Schechtman.[10]

As for the first explanation, it is difficult to consider a characteristic level which uniformly results in the creation of electrons of nearly 0 eV in these compounds. According to Zagrubskii and Vilesov,[8] the vibrational excitation, ΔE_j, of the auto-ionizing state, M_j^*, has a dominant role in making the stationary peaks in the low-kinetic-energy region. The probability of auto-ionizing processes becomes more significant and the EDCs become structureless when ΔE_j is large. Moreover, ΔE_j is considerable in large molecules. It is, however, doubtful whether the ΔE_j of these compounds are the same. Moreover, the resemblance between the obtained results of anthracene and 9,9′-bianthryl (twice as large as anthracene) raises a question about their explanation.

The second explanation is more reasonable. In the solid state, there are various scattering processes, and such processes cause a decrease in the kinetic energy of the photoelectrons over a considerably wide energy range. Moreover, the peak ratio of this dominant peak depends strongly on the photon energy. These facts suggest that the scattering mechanism is the origin of the dominant peak.[17]

The result for 9MeA, which did not show any abrupt large peaks except for the dominant peak, can be understood in terms of the contamination of the solid surface especially with water. The effect of the contamination was checked by the use of DClA evaporated films. The film evaporated at room temperature showed several structures, as is shown in Fig. 4. The films prepared at about −30 °C, however, showed dull shapes, and their EDCs changed with the evacuating time; the structure became sharper. Moreover, the total photoelectric current increased. These facts suggest that the contamination mainly caused by the adsorption of water affects the measurements of the photoemission and that continuous evacuation reduces the contamination of the sample surface. Therefore, if we seek to account for the experimental conditions of 9MeA, low vacuum and a thin sample film which were inadequate to evaporate the contaminated layer of the film, it is probable that the intrinsic EDCs of 9MeA are not just like those of Fig. 2: This figure may be somewhat too vague.

When we consider the exceptional situations in the case of 9MeA, anthracene and its derivatives may be said to show the same EDCs, as may easily be seen in

the figures. This finding indicates that the photoelectron energetic responses of these compounds are nearly the same. This fact is useful in considering the mechanism of photoemission from organic crystals. As is well known, photoemission is constituted of three steps: photoelectron generation, electron-transport, and escape from the surface. When electron-transport process is the dominant process in photoemission, the EDCs obtained must be different, unrelated to the photoelectron generation, since the field with which an excited electron is affected differs with the compound. For example, though DClA has a large polarizability and chlorine atoms which have a large electronegativity so as to easily catch the electrons, the EDC patterns of DClA are analogous to those of anthracene. As for the escape process, the resemblance of the EDCs in spite of various experimental conditions may indicate that the electron escape probabilities of these compounds are the same. Therefore, the photoelectron generation process, which is considered to be the same as in the case of gas-phase photoexcitation, plays the dominant role in the photoemission of organic crystals. Electron transport does not affect the shape of the EDCs so much. They are slightly affected by the electron-escape process, mainly by the contamination of the surface, as is 9MeA.

As is shown by the broken lines in Figs. 6 and 8, though the ionization potentials of 9,9′-bianthryl were much more complicated than those of anthracene, the EDCs obtained were almost the same, within the limits of resolution of the analyzer. This result implies an analogy in the electronic states of the two compounds in the solid state. In the gas phase at high temperatures, two anthryl groups may rotate along the C–C axis and may perturb the molecular orbitals of each other. On the other hand, in the solid state the two anthryl groups, mainly π-electron systems, are independent of each other. This phenomenon was also observed in biphenyl derivatives[18] and *p*-terphenyl.[19]

Quantum Yield. The steep rise in SDQYs at about 6 eV is due to the effect of the escape function, which rules the electron transport from the surface into the vacuum. To this region we can apply the following relation in order to obtain the threshold energy;[5]

$$Y \propto (h\nu - E_{th})^3$$

The cube-root plot of these compounds shows linear relation between the photon energy and the cube root of the quantum yield. The threshold energies of the compounds obtained by this method are collected in Table 1; the threshold energies obtained from the EDCs are also listed in that table.

The values obtained from the cube root plot and from the EDCs show a good accordance. As to the comparison with other works, the threshold energy obtained by Lyons and Morris[3] shows a good agreement with our present results. That of 9MeA reported by Vilesov and Sukhov[9] seems somewhat small, though the method of obtaining the threshold energy reported by Marchetti and Kearns[6] gives a slightly large value because it considers the thermal excitation. Therefore, their values, which were larger than our present results by about 0.2 eV, nevertheless show a good agreement with ours in the trend among these compounds.

In the energy region higher than 7.5 eV, the quantum yield increased in accordance with increase in the photon energy. This is probably due to the photoelectrons from deeper levels. There are some dips in the SDQYs. Seki and his co-workers[17] suggested that these dips might be due to the change in the absorption coefficient. The basis of their conclusion was that the electron-attenuation length, L, is much shorter than the reciprocal of the absorption coefficient α, *i.e.*, $\alpha L \ll 1$; the photoelectrons observed might be produced mainly near the surface. Consequently, the SDQYs of this region depend on the spectral response of the absorption coefficient. However, our recent experiment on electron-attenuation length measurement has shown that the $\alpha L \ll 1$ relation does not always hold good. In some cases αL is nearly equal to unity or slightly larger than unity.[20,21] This fact is not always inconsistent with their postulate that the dips are due to the change in the absorption coefficient. However, particularly when αL is larger than unity, all the photoelectrons excited have a high probability of escaping into the vacuum. Therefore, we should conclude that the dips in the SDQYs are due not only to the spectral response of the absorption coefficient, but also to the beginning of the ionization of deeper levels.

The SDQYs of anthracene and 9,9′-bianthryl resembled each other and showed a larger photoelectron efficiency than that of DClA. The resemblance between them is considered in terms of electronic structures, as has previously been discussed. Though the SDQYs of DClA was about half that of anthracene, their inclination was analogous to that of anthracene. This analogy indicates that the skeletal structure of the molecules (the anthracene ring system) influences the SDQYs as in the EDCs. Moreover, the small quantum yield of DClA is probably due to the effect of the chlorine atom.[22]

The SDQY of 9MeA was not parallel with that of anthracene. The ratio of both SDQYs, 9MeA and anthracene, changed from 0.6 ($h\nu \simeq 10$ eV) to 0.1 ($h\nu \simeq 7$ eV). This fact seems inconsistent with previous discussion. However, the experimental conditions for measuring 9MeA were not good. In this case, as the contamination of the surface reduced the photoelectron-escape probability, we could not obtain the same SDQY. Moreover, the quantum yield of 9MeA changed with the evacuation time and with the conditions at sample preparation. Though we chose the largest photocurrent as the true photoelectron efficiency, there was still some probability of contamination due to the adsorption of water or oxygen.

Therefore, in view of the effect described above, all four SDQYs of anthracene and its derivatives show analogous structures. This fact also indicates that the electronic structures and photoelectric responses of these compounds are almost the same.

Conclusion

The external photoelectric responses of anthracene and its derivatives show the same behavior, and their EDCs correspond with the molecular photoelectron

spectra. The coincidence among the EDC of the same skeletal structure (anthracene ring system) implies that the original π-electronic state is the dominant factor in the energy distribution of photoemitted electrons. The resemblance of their SDQYs supports the above conclusion.

The authors wish to thank Professor Werner Schmidt, Institut für Organische Chemie, Universität München, for sending them the photoelectron spectrum of 9,9′-bianthryl.

The Microwave Spectrum, Structure, Quadrupole Coupling Constants, and Barrier to Internal Rotation of Methyldichlorosilane

Kunihiko ENDO,* Harutoshi TAKEO, and Chi MATSUMURA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received September 18, 1976)

The microwave spectra of the $^{35}Cl_2$, $^{35}Cl^{37}Cl$, and $^{37}Cl_2$ isotopic species of CH_3SiHCl_2 have been investigated in the frequency region from 12 to 40 GHz. The rotational constants and centrifugal distortion constants have been determined and were used to calculate the structure of the molecule. The structural parameters determined are:

r(Si-C) = 1.850 Å, ∠C-Si-Cl = 109.8°,

r(Si-Cl) = 2.040 Å, ∠Cl-Si-Cl = 108.8°.

A few high-J R-branch transitions are split into doublets because of the methyl internal rotation. These splittings give a barrier to internal rotation of 1.69±0.05 kcal/mol. An analysis of the $^{35}Cl_2$ quadrupole splittings leads to quadrupole coupling constants of $\chi_{aa}=-19.1\pm0.3$ MHz, $\chi_{bb}=5.4\pm1.3$ MHz, $\chi_{cc}=13.7\pm1.4$ MHz, $\chi_{bond}=-41.2\pm2.0$ MHz, and $\eta_{bond}=0.16\pm0.03$.

A comparison of the molecular structures in various substituted fluorosilane molecules reveals that both the Si-C and Si-F bond distances decrease upon the substitution of the fluorine atoms for the hydrogen atoms attached to the silicon.[1-4] Furthermore, it is interesting to note that the barrier to internal rotation decreases markedly with an increase in the number of fluorine atoms, while the barriers to internal rotation of various fluoroethane molecules have almost the same values.[5]

The chloro derivatives of methylsilane also provide a group of molecules that may be used to test the changes in the molecular constants with the substitution of the chlorine atoms for the hydrogen atoms. However, CH_3SiHCl_2 has not been studied by microwave spectroscopy, and only incomplete molecular structures have been determined for CH_3SiH_2Cl and CH_3SiCl_3. CH_3SiCl_3 was first investigated by Mockler *et al.*,[6] and the primitive molecular structure was presented on the basis of an analysis of the spectra of $CH_3Si^{35}Cl_3$ and $CH_3Si^{37}Cl_3$. Although the data for its isotopic species were added by Mitzlaff *et al.*,[7] they did not determine the molecular structure, since they failed to observe the silicon isotopic species. Recently the present authors suceeded in observing the spectrum of the ^{29}Si species, and the molecular structure has been analyzed.[8] Zeil *et al.* investigated the microwave spectrum of CD_3SiH_2Cl and presented the partial r_s structure of Si-Cl.[9] Though they recently reported about normal species, CH_3SiD_2Cl, and CD_3SiD_2Cl,[10] the molecular structure has not yet been determined.

The barrier to internal rotation of CH_3SiCl_3 has been obtained from the intensity measurement of the microwave spectral lines,[7] and that of CH_3SiH_2Cl has been determined by the observation of the far-infrared spectrum,[11] while the barrier height of CH_3SiHCl_2 in the vapor phase has not been obtained. In the present study, we measured the microwave spectrum of CH_3SiHCl_2 and determined the molecular structure and the barrier to internal rotation.

* Present address: College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157.

Experimental

The sample of CH_3SiHCl_2 was obtained from a commercial source and was used without further purification. The $CH_3SiH^{35}Cl^{37}Cl$ and $CH_3SiH^{37}Cl_2$ isotopic apecies were observed in their natural abundances. Since the sample decomposed gradually in the cell, it was continuously introduced into the cell and pumped out during the measurement. The spectrometer used in this reseach was a conventional 100 kHz Stark modulation type, with a 3 m X-band waveguide cell cooled with Dry Ice. The frequency accuracy is estimated to be ±0.1 MHz.

Analysis of the Spectra

The spectrum of CH_3SiHCl_2 was predicted from an approximate structure based on the structures of CH_3SiHF_2[3] and CH_3SiH_2Cl.[9] The χ_{bond} values (quadrupole coupling constants in coordinate system with z axis along the Si-Cl bond) were assumed to be the same as in CH_3SiH_2Cl. The predicted spectrum indicated that the c- and b-type transitions are allowed and that the b-type transitions are stronger if the large bond moments are assumed along the Si-Cl bonds. The prediction also showed that the b-type R-branch transitions with low K_{-1} numbers make the strongest series and have very small splittings due to hyperfine structures, and that they should have large Stark effects because of the nearly degenerate K-type doublet levels which are coupled with the μ_c dipole component. In fact, the clear K-doublet patterns for the $9_{09}\leftarrow8_{18}$ and $9_{19}\leftarrow8_{08}$ transitions were observed first under very small Stark modulation voltages. Between these two K-doublet lines, unusual spectral lines showing only Stark components were observed, as is shown in Fig. 1. These lines were identified as $9_{09}\leftarrow8_{08}$ and $9_{19}\leftarrow8_{18}$. Since this molecule lacks the μ_a component, these transitions are prohibited at the zero-field duration time of the square-wave modulation. On the other hand, the transitions are allowed at the other duration time in which the electric field is applied, because of the breakdown of the selection rule caused by the mixing of the energy levels by the μ_c component. This mechanism is illustrated schematically in Fig. 2. The similar transitions were observed also for $J=8\leftarrow7$, $J=10\leftarrow9$, and

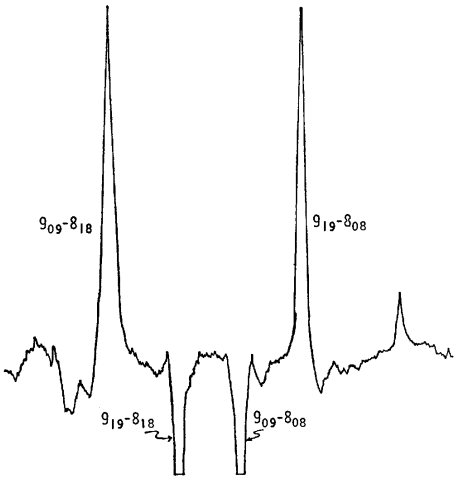

Fig. 1. The $9_{09}\leftarrow 8_{08}$, $9_{19}\leftarrow 8_{18}$ prohibited transitions.

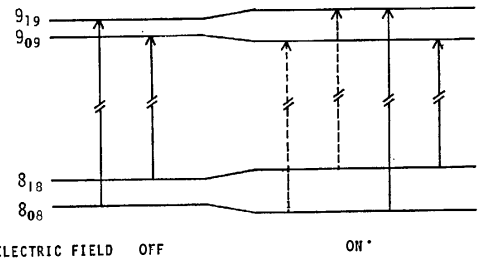

Fig. 2. Schematical illustration for breakdown of the prohibited transitions. Dotted lines represent prohibited transitions which is allowed only when an electric field is applied.

$J=11\leftarrow 10$ R-branch K-type doublets. Subsequently, Q-branch transitions were searched for in the region predicted from the rotational constants roughly determined by the R-branch transitions, and assigned by means of their characteristic hyperfine structures.

The unsplit frequencies of the observed transitions, which were obtained by a method to be described later, are listed in Table 1. The rotational constants and the centrifugal distortion constants of the $CH_3SiH^{35}Cl_2$ species were determined by a least squares fit calculation using the formula presented by Watson.[12] The determined constants are given in Table 2. The rotational constants of the $^{35}Cl^{37}Cl$ and $^{37}Cl_2$ species were determined by assuming the same centrifugal distortion constants as those of the $^{35}Cl_2$ species.

d_{WK}	0.109×10^{-4}		

The assignment was also confirmed by the observation of the double-resonance effects between the transitions of $7_{25}\leftarrow7_{16}$ and $8_{27}\leftarrow7_{16}$, and between those of $9_{36}\leftarrow9_{27}$ and $9_{27}\leftarrow8_{36}$. The spectral line of $8_{27}\leftarrow7_{16}$ or $9_{27}\leftarrow8_{36}$ was observed on a cathode ray tube, and the transition of $7_{25}\leftarrow7_{16}$ or $9_{36}\leftarrow9_{27}$ was saturated. About 30% of the intensity decrease was observed when the exact pumping frequency was applied.

Hyperfine Structure

The hyperfine structures of the spectrum due to the two chlorine nuclei were analyzed on the basis of the theory presented by Robinson and Cornwell.[13] A typical pattern of the hyperfine structure and an observed spectrum, when the moments of the two chlorine nuclei are identical, are given in Fig. 3. As is shown in the figure, the strongest line, which consists of four degenerate components, always exists at the unsplit value. Therefore, the unsplit values can be determined simply by measuring the strongest lines in the hyperfine structures. Although this degenerate line splits into four components when the two quadrupole coupling constants are not identical, as in the case of the $^{35}Cl^{37}Cl$ species, the strongest lines without splittings were always observed for the spectrum of $CH_3SiH^{35}Cl^{37}Cl$. Therefore, the unsplit frequencies of the spectrum were approximated by the center frequencies of the unresolved lines for this species.

The values of the χ tensor for $CH_3SiH^{35}Cl_2$ were determined from the analysis of the five Q-branch

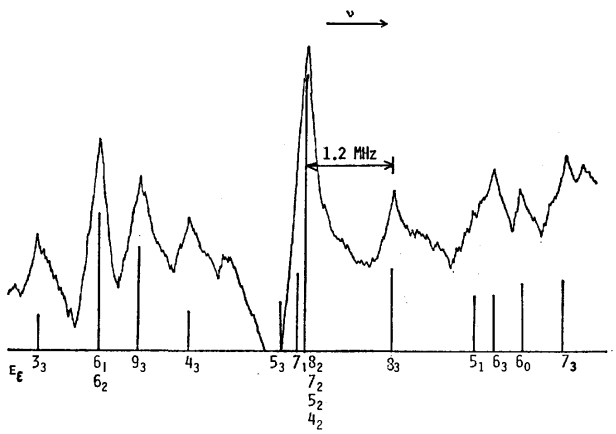

Fig. 3. Recorded spectrum and predicted hyperfine structure for the $6_{51}\leftarrow6_{42}$ transition in $CH_3SiH^{35}Cl_2$.

TABLE 3. QUADRUPOLE COUPLING CONSTANTS OF $CH_3SiH^{35}Cl_2$

χ_{aa}	−19.1±0.3 MHz
χ_{bb}	5.4±1.3 MHz
χ_{cc}	13.7±1.4 MHz
χ_{bond}	−41.2±2.0 MHz
η_{bond}	−0.16±0.03

transitions. The obtained values are listed in Table 3, along with the values of χ_{zz} and η. Since the off-diagonal elements of the tensor in the principal axis system of the molecule were not obtained, χ_{zz} and η were calculated by the use of the transformation coefficients determined from the structure obtained in the present study. In this coordinate system, the z axis is along the Si–Cl bond, the x axis is in the Cl–Si–Cl plane, and the y axis is perpendicular to these two. The obtained values of this χ_{zz} may be compared with that of SiH_3Cl ($eQq=-40.0$ MHz).[14]

Internal Rotation

The low-J lines in the spectrum of this molecule are of rigid asymmetric top. Some of the high-J R-branch transitions, however, shows splittings due to the interaction between the internal rotation and the over-all rotation. These splittings have been analyzed to determine the barrier to internal rotation using the structure shown in Table 5. Table 4 lists the frequencies, ν_A, the frequency differences, $\nu_A-\nu_E$, and the calculated values of V_3 for four transitions in $CH_3SiH^{35}Cl_2$. The splittings due to the quadrupole coupling are very small and are not observed for these transitions.

Durig and Hawley measured the vibrational spectra of gaseous and solid CH_3SiHCl_2,[11] and they estimated that the very weak band at 173 cm^{-1} in solid phase arose from the methyl torsion. This value leads to 2.09 kcal/mol as the barrier height; this value is consistent with our value considering that the barrier in the solid phase is always higher than that in the gas phase.[11]

Molecular Structure

Since only three isotopic species ($^{35}Cl_2$, $^{35}Cl^{37}Cl$, and $^{37}Cl_2$) were measured, and since the $^{37}Cl_2$ species gives

essentially the same informations as to the molecular structure as does the $^{35}Cl^{37}Cl$ species, it is necessary to assume some parameters in order to determine the molecular structure. The partial structures of the CH_3 and SiH groups were chosen as those to be assumed, because the probable errors in the assumed structures cause little errors in the other parameters. In principle, it is possible to determine the four parameters of the C-Si and Si-Cl bond lengths and the Cl-Si-Cl and C-Si-Cl angles from six rotational constants. Although this was tried first, the obtained values were changed appreciably by the small deviations of the rotational constants. Therefore, the Si-C length was also assumed for the analysis of the molecular structure. The C-Si bond distances in methylsilane and methylfluorosilanes have been determined precisely by the substitution method. Durig *et al.*[4] have revealed that both the Si-C and Si-F bond distances decrease with a further substitution of the fluorine atoms for the hydrogen atoms attached to the silicon. In Fig. 4 the change in the Si-C bond distances in methylfluorosilanes versus the number of fluorine atoms is plotted. A similar shortening of Si-C distances in methylcholorosilanes can also be expected by the substitution of the chlorine atoms for the hydrogen atoms, while the amount of the shortening

Table 5. Molecular structure of methyldichlorosilane

Assumed structural parameters			
r Si-C	1.850 Å	∠ Si-C-H	109.5°
r Si-H	1.467 Å	∠ C-Si-H	110.9°
r C-H	1.093 Å		
C_{3v} symmetry for methyl group			
Fitted structural parameters			
r Si-Cl	2.040 Å		
∠ C-Si-Cl	109.8°		
∠ Cl-Si-Cl	108.8°		
Calculated rotational constants (MHz)			
	A	*B*	*C*
$CH_3SiH^{35}Cl_2$	4342.18	2433.62	1706.04
$CH_3SiH^{35}Cl^{37}Cl$	4313.70	2371.20	1671.20
$CH_3SiH^{37}Cl_2$	4283.32	2310.85	1636.90

is expected to be about a half of that in the case of fluorine. Therefore, we estimated that the C-Si bond distance of methyldichlorosilane should be about 1.850 Å, which is the average value of the C-Si bond distances in methylsilane and methyldifluorosilane. This estimation is supported by the results of the structure analysis for the halogen derivatives of hydrocarbones. The Cl-Si length, and the C-Si-Cl and Cl-Si-Cl angles were determined, using this assumed value, by means of a least-squares method. The obtained values are listed in Table 5.

Discussion

The obtained Si-Cl bond distance is compared with those of chlorosilanes and other methylchlorosilanes in Fig. 4. Zeil *et al.* have presented two Si-Cl bond distances, 2.049±0.013 Å and 2.052±0.005 Å by combining the rotational constants of $CD_3{}^{28}SiH_2{}^{35}Cl$, $CD_3{}^{29}SiH_2{}^{35}Cl$, $CD_3{}^{30}SiH_2{}^{35}Cl$, and $CD_3{}^{28}SiH_2{}^{37}Cl$. When we choose 2.052 Å for the plot of Si-Cl bond distances in Fig. 4, it can clearly be seen that the Si-Cl bond distances decrease with the substitution of chlorine atoms for the hydrogen atoms and that the change is quite regular. It should be noted that the slopes of chlorosilanes and methylchlorosilanes have almost the same gradient.

In Table 6, the barrier of CH_3SiHCl_2 determined in this study is compared with a few values of methylsilanes and methylhalosilanes which have been determined by microwave and infrared spectroscopy. In the CH_3SiH_3,

Table 6. Comparison of barriers to internal rotation in methylhalosilane

Molecule	V_3(kcal/mol)	Method

CH_3SiH_2F, CH_3SiHF_2, CH_3SiF_3 series, it can clearly be observed that the substitution of a fluorine for a hydrogen causes a significant decrease in the barrier to internal rotation. The CH_3SiH_3, CH_3SiH_2Cl, CH_3SiHCl_2, CH_3SiCl_3 series, however, shows that the substitution of a chlorine for a hydrogen does not cause any significant effect on the barrier except CH_3SiCl_3. A similar comparison of the barriers for chloro and fluoroethanes has revealed that the substitution of a chlorine with a hydrogen increases the barrier, while the change in the barrier is small in the case of fluorine. Therefore, one might assume that the nonbonded Cl···H interaction is always larger than the nonbonded F···H interaction. From this point of view, it is very difficult to explain the remarkably low barrier of CH_3SiCl_3. Since the barrier of 0.58 kcal/mol for CH_3SiCl_3 was obtained by the microwave intensity method, it is probable that there was a confusion in the assignment of the tortional state; a careful re-investigation of the microwave spectrum may, therefore, be necessary.

The *cis-trans* Isomerization of 2-Butenes Caused by Sulfur Dioxide Adsorbed on Porous Vycor Glass. The Contribution of the Charge-transfer Complex

Kiyoshi Otsuka, Kiyoshi Eshima, and Akira Morikawa

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 8, 1976)

Sulfur dioxide adsorbed on porous Vycor glass enhances the *cis-trans* isomerization of 2-butenes selectively, but it poisons the double-bond migration. The correlation between the *cis-trans* isomerization and the sulfur dioxide–*cis*-2-butene charge-transfer complex observed on the glass were studied under various pressures of the reactants. The kinetic data of the reaction were well explained by the reaction mechanism in which the isomerization occurs *via* the addition and elimination of 2-butene molecules at the terminal of the polysulfone formed from sulfur dioxide and *cis*-2-butene in the adsorbed layer. It has been suggested that the copolymerization is initiated through the charge-transfer complex polarized in the strong electrostatic field of the exposed aluminum ions contained in the glass.

Porous Vycor glass, evacuated at a high temperature (>500 °C), is catalytically inactive for the isomerization of normal butenes at room temperature. However, the addition of a small amount of sulfur dioxide causes a considerably fast *cis-trans* isomerization of 2-butenes very selectively. In the gas phase, of course, sulfur dioxide exerts no effect upon the butene isomerization. Similar specific catalyses of the sulfur dioxide manifested in the adsorbed layer of various solid adsorbents have been reported in previous papers,[1,2] and it has been suggested that the geometrical isomerization of 2-butenes takes place by means of a mechanism in which the addition and subsequent elimination of the *cis*- or *trans*-2-butene molecule at the terminal of the formed polysulfone cause the isomerization. It has been suggested that the polysulfone formation may be initiated by the sulfur dioxide–olefin (1: 1) molecular complex,[2] though the kinetic data obtained over NaX zeolite[2] could not be tested in this point by observing the presence of the complex by means of ultraviolet spectroscopy because of its opacity in the ultraviolet-wavelength region.

In order to carry out a quantitative test of the contribution of the molecular complex, we have chosen porous Vycor glass as the adsorbent because of its good transparency in the wavelength range down to ≈ 210 nm. In the present work, we will first carry out a kinetic investigation of the geometrical isomerization of *cis*-2-butene over porous Vycor glass in the presence of sulfur dioxide. Then, examining the molecular complex in the adsorbed layer of the glass by means of the ultraviolet spectroscopic method, we intend to verify that the complex plays a significant role in the reaction. Finally, the nature of the active site on the glass will be discussed along with the kinetic data obtained over glass evacuated at various temperatures.

Experimental

Materials. The porous Vycor glass used was a glass plate (Corning No. 7930, surface area 150 m^2/g) $30\times8\times0.8$ mm in size. Similar samples were shown to contain ≈3% of B_2O_3, ≈0.4% of Al_2O_3, and less than 0.2% of Na_2O and K_2O inaddition to silica [information supplied by Corning Glass Works]. After having been calcined thoroughly at 700 °C in air, the glass was washed by distilled water and dried at 400 °C; then it was placed in the reactor.

The sulfur dioxide reagent was of an anhydrous grade of the Matheson Chemical Company. The *cis*-2-butene was a high-purity product of the Phillips Petroleum Company. The stated purity of 99.9% for *cis*-2-butene was verified by gas chromatography. Each compound was further purified by trap-to-trap distillation in a vacuum apparatus.

Apparatus. The appratus employed was a conventional mercury-free and grease-free gas-circulating system with a dead volume of 288 ml, capable of achieving a vacuum down to 10^{-6} Torr. A part of the reactor, where the glass was placed, was constructed from a quartz cell ($10\times10\times40$ mm) designed for spectrophotometric use. The pressure readings for the reactants were made with a glass Bourdon gauge.

Procedure. Prior to every run of the experiment, the glass placed in the reactor was calcined at 600 °C in dried oxygen and then evacuated for 2 h in a vacuum below 5×10^{-5} Torr at the same temperature. After introducing sulfur dioxide at 25 °C, the reaction was started by feeding in *cis*-2-butene and circulating the mixture gas through the reactor. A small amount of reacting gas was periodically collected and analyzed by gas chromatography. The temperature of the reactor was controlled within ±0.2 °C by using a water bath. The ultraviolet-spectra measurements were performed by means of a Shimadzu UV-200 spectrometer. The spectra were recorded by placing the glass without any adsorbate on the reference side of the light beam.

Results

The geometrical Isomerization of cis*-2-Butene Enhanced by Sulfur Dioxide.* Porous Vycor glass calcined in a vacuum at 600 °C exhibits a low catalytic activity in the two isomerizations of *cis*-2-butene, *i.e.*, the geometrical isomerization to *trans*-2-butene and the double-bond isomerization to 1-butene, at 25 °C. The initial rates of the former and latter reactions were 7.23×10^{-8} and 15.0×10^{-8} mol/g min respectively, at an initial pressure of *cis*-2-butene of 46 Torr.

The addition of a small amount of sulfur dioxide to the reaction system markedly enhanced the rate of geometrical isomerization, but it stopped the double-bond migration. Furthermore, no double-bond migration in the presence of sulfur dioxide was confirmed by using 100% 1-butene as the starting olefin.

The effects of the pressure of sulfur dioxide and *cis*-2-butene on the initial rate of the *trans*-2-butene

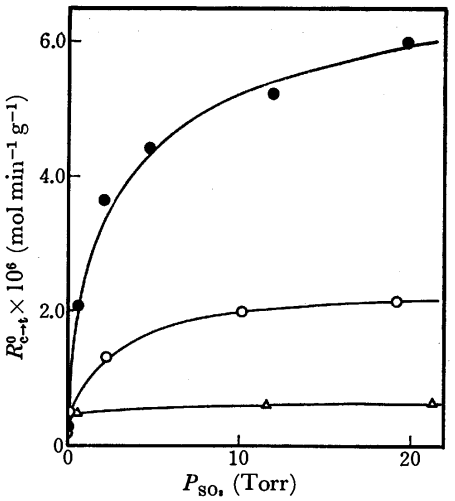

Fig. 1. Effect of the pressure of sulfur dioxide on the rate of geometrical isomerization: The pressure of *cis*-2-butene: (●), 107 Torr; (○), 6.2 Torr; (△), 0.9 Torr.

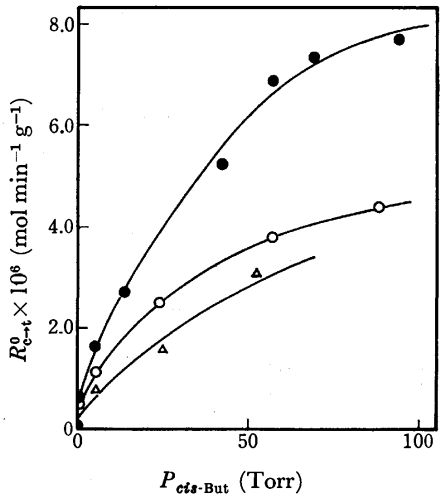

Fig. 2. Effect of the pressure of *cis*-2-butene on the rate of the isomerization: The pressure of sulfur dioxide: (●), 51 Torr: (○), 4.9 Torr; (△), 2.0 Torr.

formation, $R^0_{c\to t}$, at 25 °C are shown in Figs. 1 and 2. These figures exhibit that $R^0_{c\to t}$ can not be expressed by a simple function of the pressures of the two compounds.

The Charge-transfer Complex of Sulfur Dioxide with cis-*2-Butene.* Examples of the ultraviolet spectra of the glass with *cis*-2-butene, sulfur dioxide, and the two compounds adsorbed together on the glass are shown in Fig. 3. The (c)spectrum, taken 3—5 min after the coadsorption of sulfur dioxide and *cis*-2-butene, indicates new absorptions at around 240 and 330 nm. The absorbance of the spectra at wavelengths less than ≈250 nm increases with the time, as can be seen in the figure (Spectra(c)—(f)). After various durations of the coadsorption, the glass was evacuated in a vacuum for 2 h at 25 °C. The spectra of the glass taken after this treatment are shown in Fig. 4. The absorption due to adsorbed sulfur dioxide has disappeared after the evacuation, though a considerable portion of the spectra seen at the wavelengths less than ≈240 nm still remains.

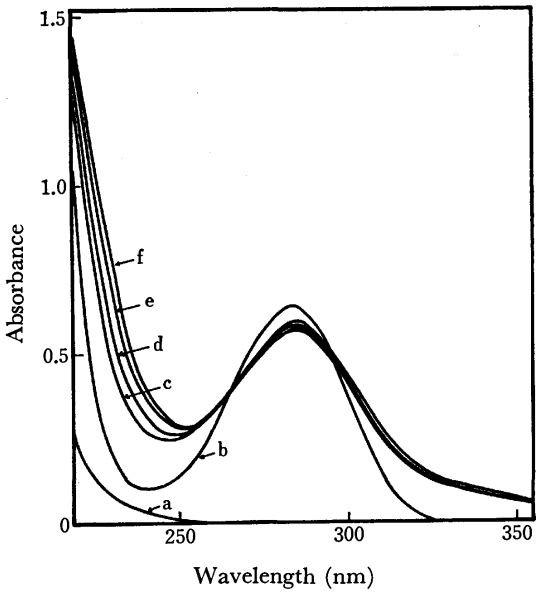

Fig. 3. The UV-spectra of the compounds adsorbed at 25 °C on the porous Vycor glass. (a) *cis*-2-butene (amount of adsorption is 2.40 ml STP/g); (b) sulfur dioxide (0.45 ml STP/g); (c)—(f) sulfur dioxide (0.45 ml STP/g) and *cis*-2-butene (2.4 ml STP/g) coadsorbed. The spectra (c)—(f) were recorded at various times after the addition of the both compounds: (c) 3—5 min, (d) 12—14 min, (e) 40—42 min, (f) 108—110 min. Scanning speed was 100 nm/min, scanning wavelength from 400 to 200 nm.

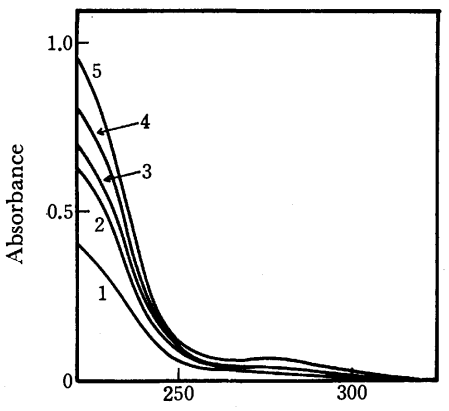

Fig. 4. The UV-spectra of the compound remained on the glass after the evacuation for 2 h: Sulfur dioxide and *cis*-2-butene had been coadsorbed before the evacuation for the following time; (1) 8 min, (2) 20 min, (3) 38 min, (4) 105 min, (5) 930 min.

It is assumed that the increase in the absorbance with the time for the spectra in Fig. 3 results from the accumulation of the unknown compounds, referred to as P_x hereafter, which corresponds to the spectra in Fig. 4. The D_{ctc} at various wavelengths, defined by the following equation (i):

$$D_{ctc} = D_{ob} - D_{SO_2} - D_{But} \quad \text{(i)}$$

are plotted against the duration of coadsorption, where D_{ob}, D_{SO_2}, and D_{But} are the optical density of the total absorption observed in the case of coadsorption

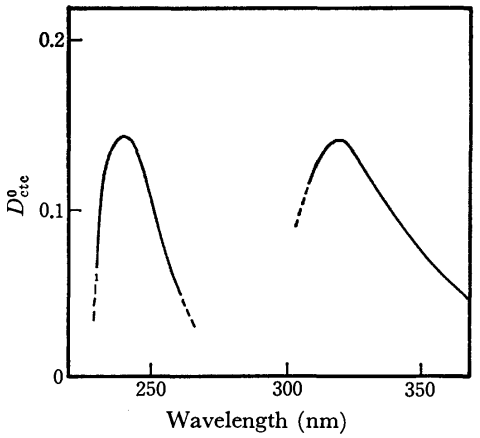

Fig. 5. Plot of D^0_{ctc} against wavelength.

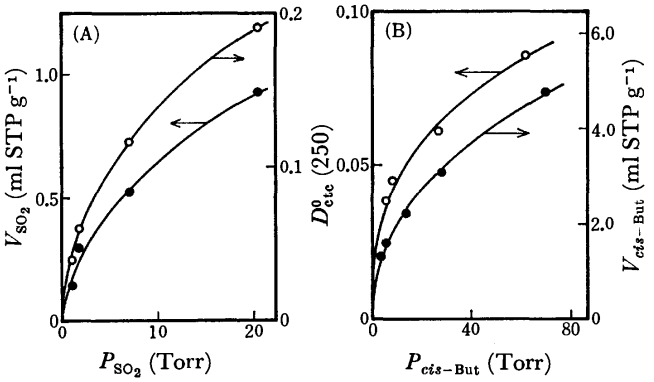

Fig. 6. (A) Plot of D^0_{ctc} (250) (open circles) and the amount of adsorbed sulfur dioxide (V_{SO_2}) (closed circles) against the pressure of sulfur dioxide: $P_{cis\text{-But}}$ =6.2 Torr. (B) Adsorption isotherm of *cis*-2-butene (closed circles) and the plot of D^0_{ctc} (250) against the pressure of *cis*-2-butene (open circles): P_{SO_2}=4.9 Torr.

(Spectra(c)—(f) in Fig. 3), the optical density for the sulfur dioxide (Spectrum(b)), and that for the *cis*-2-butene (Spectrum(a)) respectively. In order to exclude the contribution of P_x, the extrapolated values of D_{ctc} to the zero duration time of adsorption, D^0_{ctc}, were estimated. They are plotted against the wavelengths in Fig. 5.

The effects of the pressures of sulfur dioxide and *cis*-2-butene on D^0_{ctc} at 250 nm are indicated by open circles in Fig. 6. The adsorption isotherm of sulfur dioxide in the presence of *cis*-2-butene is also shown in Fig. 6-(A) by closed circles. The adsorption isotherm of the *cis*-2-butene in Fig. 6-(B) (closed circles) was obtained in the absence of sulfur dioxide.

Effect of the Evacuation Temperature. Following the usual pretreatment of the glass, water vapor was adsorbed at 25 °C under a pressure of 4.6 Torr. Then, the temperature of the glass was raised to a temperature at which the glass was allowed to stand for 1 h; thereafter the system was evacuated for 2 h at the same temperature. With the glass thus treated, the rate of the sulfur dioxide-enhancing isomerization was measured. The data are plotted against the evacuation temperature in Fig. 7.

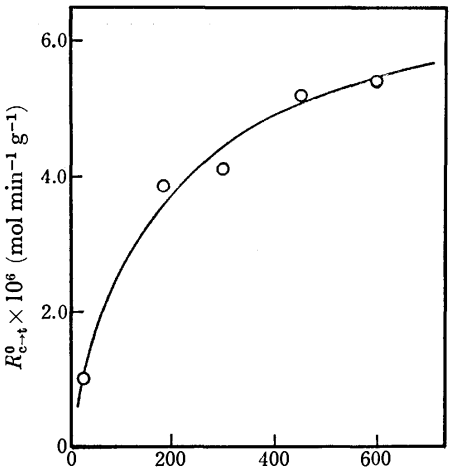

Fig. 7. Effect of evacuation temperature on the rate of the isomerization: reaction at 25 °C; P_{SO_2}=5.0 Torr, $P_{cis\text{-But}}$=90 Torr.

Discussion

The carbonium-ion mechanism, generally accepted for porous glass,[3,4] requires not only the occurrence of the *cis-trans* geometrical isomerization, but also the double-bond migration of normal butenes. The fact that no double-bond migration is observed in the presence of sulfur dioxide suggests that the geometrical isomerization of 2-butenes, enhanced by the addition of sulfur dioxide, proceeds by means of a new mechanism, different from that operative in the absence of sulfur dioxide; sulfur dioxide strongly inhibits the double-bond migration which proceeds on the glass without sulfur dioxide.

D_{SO_2} or D_{But}, the optical density obtained from the data of the individual adsorption of sulfur dioxide or that of *cis*-2-butene, can, in the case of the coadsorption of the two compounds, be used in calculating D_{ctc} by means of equation (i), for the following reasons: (1) The total coverage of the two adsorbates was less than 0.1 under the experimental conditions applied to the data in Fig. 3; (2) a small equilibrium quantity of the charge-transfer complex formed appears in a hexane solution;[5] (3) a much larger extinction coefficient of the complex compared to that of sulfur dioxide has been confirmed.[5]

The two absorption bands at ≈240 and ≈330 nm are seen in Fig. 5; the former was identified as the charge-transfer band of the sulfur dioxide–*cis*-2-butene molecular complex, and the latter, as the enhanced absorption of the sulfur dioxide brought about by the proximity of the π-donating *cis*-2-butene molecule.[2,5] In the following discussion, the D^0_{ctc} at 250 nm, D^0_{ctc} (250), has been adopted as the optical density due to the charge-transfer complex, because it is the most reliable value.

The curves of D^0_{ctc} (250) and the adsorption isotherm in Fig. 6-(A) or those in Fig. 6-(B) indicate a similar dependence on the pressure. Most of the sulfur dioxide or *cis*-2-butene adsorbed on the glass is physically adsorbed; this similar dependence implies that the

complex results from the reaction between the weekly adsorbed sulfur dioxide and *cis*-2-butene.

Role of the Charge-transfer Complex in the Reaction Mechanism. It has been suggested that the selective *cis-trans* isomerization is accompanied by the copolymerization of sulfur dioxide with 2-butenes on the solid surface.[2,6] Since the pressure readings of the reacting gases did not change during the isomerization, the formation of the polymer could not be confirmed in the present work. However, the unknown compound, P_X, giving the tailing spectra in Fig. 4 may possibly be the polysulfone formed from sulfur dioxide and *cis*-2-butene.

In the following discussion, we intend to examine the role of the charge-transfer complex along with the reaction mechanism shown below:[2]

$$SO_2 + \textit{cis}\text{-2-butene} \overset{K}{\rightleftharpoons} CTC \quad (1)$$

$$CTC \longrightarrow P_B + P_S \quad (2)$$

$$P_B \longrightarrow P_S + \textit{trans}\text{-2-butene} \quad (3)$$

$$P_B \longrightarrow P_S + \textit{cis}\text{-2-butene} \quad (4)$$

$$P_S \longrightarrow P_B + SO_2 \quad (5)$$

$$P_B + SO_2 \longrightarrow P_S \quad (6)$$

$$P_S + \textit{cis}\text{-2-butene} \longrightarrow P_B \quad (7)$$

$$P_B \longrightarrow \text{stabilized} \quad (8)$$

$$P_S \longrightarrow \text{stabilized} \quad (9)$$

where the mechanism is considered under a low conversion, using 100% *cis*-2-butene as the starting olefin; *CTC* is the charge-transfer complex, and P_B and P_S represent the terminal group of 2-butyl and sulfonyl radical of the active polysulfone respectively.

The steady-state treatment of P_S and P_B with Eq. 1—9 gives the following rate equation by assuming $k_9/2+k_5 \ll k_7[\textit{cis}\text{-2-butene}]$:

$$R^0_{c\to t} = \frac{2k_2k_3k_7[\textit{cis}\text{-2-butene}][CTC]}{k_7k_8[\textit{cis}\text{-2-butene}]+k_9(k_8/2+k_3+k_4+k_6[SO_2])} \quad \text{(ii)}$$

where the concentration for the each compound is assigned to that on the surface. Since it has been shown that the equilibrium constant of the formation of the charge-transfer complex is small in a hexane solution ($K=0.075\pm0.082$ l mol^{-1} at 25 °C),[5] a low concentration of *CTC* on the glass can reasonably be assumed, and the Lambert-Beer law holds for the optical density:

$$D^0_{ctc} = \varepsilon[CTC]l \quad \text{(iii)}$$

We may then rearrange Eq. ii to Eq. iv to see the effect of the concentration of adsorbed sulfur dioxide:

$$\frac{D^0_{ctc}}{R^0_{c\to t}} = A + B[SO_2] \quad \text{(iv)}$$

where

$$A = \frac{\varepsilon l}{2k_2k_3}\left\{k_8+\frac{k_9(k_8/2+k_3+k_4)}{k_7[\textit{cis}\text{-2-butene}]}\right\}$$

$$B = \frac{\varepsilon l}{2k_2k_3}\left\{\frac{k_6k_9}{k_7[\textit{cis}\text{-2-butene}]}\right\}.$$

Using the data of $R^0_{c\to t}$ in Fig. 1 and those of D^0_{ctc} (250) and V_{SO_2} in Fig. 6 at the *cis*-2-butene pressure of 6.2 Torr, where the concentration of the adsorbed *cis*-2-butene is assumed to be constant because of the low total coverage of the adsorbed compounds ($\theta<0.1$),

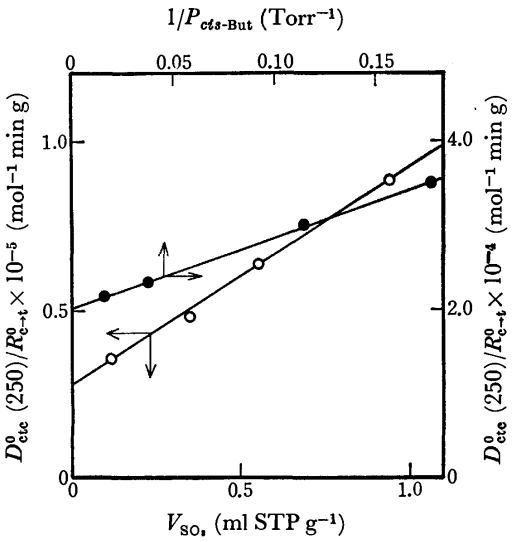

Fig. 8. Plot of (D^0_{ctc} (250)/$R^0_{c\to t}$) against the amount of sulfur dioxide adsorbed (○), or that against the inverse of *cis*-2-butene pressure (●).

$D^0_{ctc}(250)/R^0_{c\to t}$ is plotted against V_{SO_2} in Fig. 8 (open circles). A reasonably good linear relation is obtained between the variables.

Assuming that the *cis*-2-butene in the propagation step (7) is chemically adsorbed on the active site of the glass and that the adsorption isotherm can be represented by a Langmuir-type equation such as:

$$[\textit{cis}\text{-2-butene}] = \frac{b(P_{cis\text{-But}})}{1+b(P_{cis\text{-But}})} \quad \text{(v)}$$

we may rearrange Eq. ii to Eq. vi:

$$\frac{D^0_{ctc}}{R^0_{t\to c}} = C + D(P_{cis\text{-But}})^{-1} \quad \text{(vi)}$$

where

$$C = \frac{\varepsilon l}{2k_2k_3}\left\{k_8+\frac{k_9}{k_7}\left(\frac{k_8}{2}+k_3+k_4+k_6[SO_2]\right)\right\}$$

$$D = \frac{\varepsilon lk_9}{2k_2k_3k_7b}\left(\frac{k_8}{2}+k_3+k_4+k_6[SO_2]\right).$$

$D^0_{ctc}(250)/R^0_{c\to t}$, calculated from the data in Fig. 6 and Fig. 2 at a fixed pressure of sulfur dioxide (=4.9 Torr), is plotted against $1/P_{cis\text{-But}}$ in Fig. 8 (closed circles); the plot confirms the theoretically expected linear relation of the plot.

Consequently, the results in Fig. 8 confirm the previously predicted hypothesis[2] that the charge-transfer complex initiates the reaction by Process (2).

The Nature of the Active Site on the Porous Vycor Glass. Figure 7 shows that the catalytic activity of the glass increases with a rise in the evacuation temperature. In contrast to this result, if sulfur dioxide is absent, the activity of the glass decreases with the evacuation temperature from 400 to 700 °C;[7] this is consistent with the results reported by Blomfield and Little.[8] It has been suggested that the alumina contained in the porous Vycor glass is responsible for the catalytic activity of the glass.[3,4] West, Haller, and Burwell also suspected that most of the reported reactions over silica gel occur at impurity sites, most likely Al^{3+}.[9] In the studies of the isomerization of normal butenes over

silica–alumina, it has been found that the rate of reaction decreases as the concentration of hydroxyl groups on the catalyst is decreased by a rise in the evacuation temperature.[10,11] On the contrary, on an alumina catalyst, the reaction rate is inversely related to the surface density of hydroxyl groups,[10-12] suggesting that the active sites involve the exposure of aluminum ions, creating dual acid-base sites[12] when hydroxyl groups are removed. Hence, if the silica–alumina site on the porous Vycor glass is much more active than the exposed aluminum ion site for the normal butene isomerization in the absence of sulfur dioxide, the opposite dependences of the isomerization rates on the evacuation temperature in the presence and in the absence of sulfur dioxide can be explained by considering that the reaction in the absence of sulfur dioxide occurs on the silica–alumina-type site, while the one in the presence of sulfur dioxide proceeds on similar sites over an alumina catalyst.[11,12] It is probable that sulfur dioxide strongly adsorbs on the silica–alumina site and, accordingly, poisons the double-bond migration of the butenes. If the sulfur dioxide–*cis*-2-butene molecular complex approached the exposed aluminum ions, it would be polarized by the strong electrostatic field surrounding these cations toward the radical-ion structure $\dot{S}O_2CH(CH_3)\overset{+}{C}H(CH_3)$, and this could readily initiate the polysulfone formation and the accompaning geometrical isomerization.

The Microwave Spectrum of Dichlorodifluoromethane

Harutoshi TAKEO and Chi MATSUMURA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received October 12, 1976)

The microwave spectra of three isotopic species of dichlorodifluoromethane have been observed, and the following rotational constants have been obtained:

$A = 4118.90$ MHz, $B = 2638.70$ MHz, $C = 2233.72$ MHz for $^{12}C^{35}Cl_2F_2$
$A = 4092.07$ MHz, $B = 2582.30$ MHz, $C = 2185.54$ MHz for $^{12}C^{35}Cl^{37}ClF_2$
$A = 4115.73$ MHz, $B = 2638.95$ MHz, $C = 2232.86$ MHz for $^{13}C^{35}Cl_2F_2$.

The bond lengths and angles determined from them are r(C–Cl)=1.744 Å, r(C–F)=1.345 Å, ∠Cl–C–Cl=112°33′, and ∠F–C–F=106°14′. The nuclear quadrupole coupling constants in the C–Cl bond axis system are $\chi_{zz}=-82.7$ MHz and $\eta_{bond}=0.06$.

The chloro and fluoro derivatives of methane have been examined by many investigators,[1] and the molecular structures have been determined by microwave spectroscopy. Lide[2] pointed out that a clear bond shortening occurs upon the substitution of hydrogen atoms by halogen atoms in the series of CH_mCl_n and CH_mF_n, and that the shortening effect is larger in the fluoromethanes than in the chloromethanes. A similar effect can be expected in the series of chlorofluoromethanes, whereas only dichlorodifluoromethane has not been studied of the molecules with the general formula of $CH_lCl_mF_n$. The purposes of this research are to determine the structure of dichlorodifluoromethane precisely and to check the shortening effect in the series of methane derivatives with both fluorine and chlorine atoms.

Experimental

The sample of dichlorodifluoromethane was prepared by the fluorination of tetrachloromethane.[3] Since this reaction also produced trichlorofluoromethane, the sample was purified by gas chromatgraphy. The ^{13}C species was prepared by the same reaction from $^{13}CCl_4$.

The spectrometer used was a conventional Stark modulated type with a 100 kHz square-wave modulation. The X-13 and X-12 klystrons dipped in oil baths were used as 8—18 GHz microwave sources, while 18—36 GHz sources were obtained by the use of harmonic generators. A stability of the microwave frequency of within 0.005 MHz per minute was obtained, and the resolution was about 0.2 MHz with the sample pressure of 5 mTorr. The spectra were all observed with a sample cell cooled with Dry Ice.

Analysis of the Spectra

Hyperfine Structure. The hyperfine structure of the spectrum was predicted and analyzed by using the first-order perturbation theory for the rotational levels of an asymmetric-top molecule containing two nuclei of isotopic spin 3/2 presented by Robinson and Cornwell.[4] The calculated patterns of the hyperfine structures showed that the low-J transitions consist of many weak components with the selection rule of $\Delta F=0, \pm1$ and $\Delta\varepsilon=0, \pm2$, while in the high-$J$ transitions only $\Delta F=\Delta J$ transitions have strong intensities. This makes the hyperfine structures of high-J transitions simple and easy to be observed. Some typical patterns

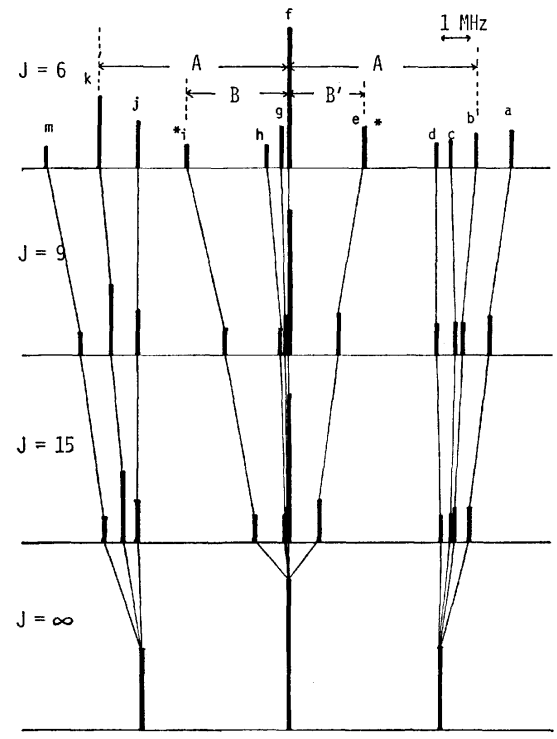

Fig. 1. The J dependance of hyperfine structures with identical nuclei of spin 3/2. The same values of $\langle eqQ \rangle_J$ are used for the calculation. For the notation of the alphabet attached to each component, see Table 1.

of the hyperfine structure in the high-J Q-branch series are shown in Fig. 1. It should be noted that the asterisked components in Fig. 1 shift greatly with the change in the J number, while the ratio of A to B depends only on J, not on the other quantum numbers nor on the quantities of the $\langle eqQ \rangle_J$ values of the upper and lower levels of the transition. The J number in the Q-branch transition can easily be assigned by the measurement of these values, even in the transition with the J number of 15 or more; in fact, $15_{6,10}$—$15_{5,11}$ was assigned without any other information.

The intensity alternation occurs in each hyperfine component depending on the spin weight due to fluorine nuclei. The intensity ratio by spin weight between ε=even and ε=odd components in the $(ee)\leftrightarrow(oo)$ transitions should be 1 to 3, and this ratio should change

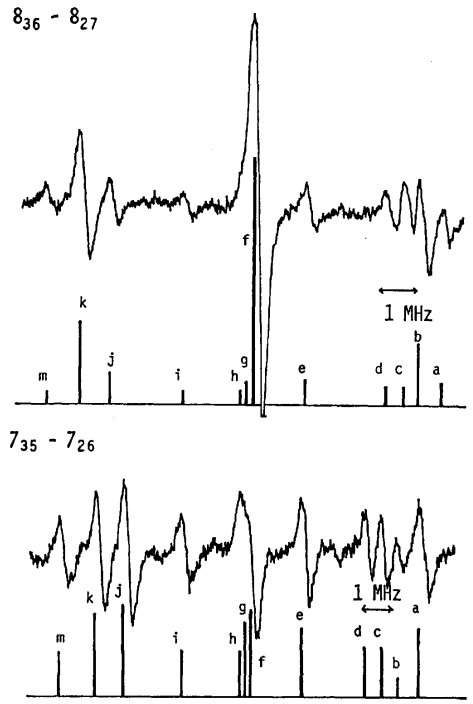

Fig. 2. The recorded and calculated hyperfine structures of $C^{35}Cl_2F_2$.

to 3 to 1 in the $(eo)\leftrightarrow(oe)$ transitions. This phenomenon was also helpful in the assignment of the transitions. The recorded hyperfine structures of the two transitions, which have different spin weights, are shown in Fig. 2. The figures also show that the strong component always exists at the unsplit position, and that it is the strongest in the transition of $(eo)\leftrightarrow(oe)$. Therefore, the measurements of only these components lead to the rotational constants, without any analysis of the hyperfine structures being necessary, if the second-order approximation is correct enough. In the hyperfine structures of the $C^{35}Cl^{37}ClF_2$ species, on the other hand, there are no such components at the exact unsplit positions because the two quadrupole moments are not identical. However, the shifts of the four components which degenerate in the spectrum of the $C^{35}Cl_2F_2$ species are quite small in this case; in fact, the strong sharp lines were always obtained in the hyperfine structure of $C^{35}Cl^{37}ClF_2$ species. It is believed that the difference between the observed peak position of this component and the hypothetical unsplit value is within 0.1 MHz. Therefore, these values were used for the determination of the rotational constants.

Assignment of the Spectrum. The Q-branch series were searched for first in the region predicted by the rotational constants of the assumed structure based on other halogenomethanes, and were assigned by using the method described above. The spectrum of the $C^{35}Cl^{37}ClF_2$ species was assigned first, since the degenerate K-type doubling transitions of this molecule have fairly large Stark effects compared with those of symmetric $C^{35}Cl_2F_2$ species because of the existance of a small μ_a component. The same transitions of the $C^{35}Cl_2F_2$ species were observed with Stark voltages about 1000 V/cm. This suggests that the dipole moment of the molecule is fairly small because of the cancellation of the C–Cl and C–F bond moments. The R-branch transitions were assigned by means of the values calculated from the structure refined by Q-branch transitions. The observed transitions used for the determination of the quadrupole coupling constants are listed in Table 1. The obtained values for the diagonal components of the quadrupole coupling constant tensor along the principal inertial axes are listed in Table 2, along with the diagonalized χ tensor, which was calculated using the molecular structure determined in this study with the assumption that the z axis coincides with the C–Cl internuclear line.

The frequencies of the observed transitions are listed in Table 3. The rotational constants and the centrifugal distortion constants were determined by a least-squares fit of all the transitions listed in Table 3. They are shown in Table 4.

of fluorine atoms, which were themselves obtained by the use of the first-moment equation for b-coordinates and the value of $I_c-I_a-I_b$ for the c-coordinates. They were also determined by a least-squares fit of all the observed rotational constants, the C–Cl length and the Cl–C–Cl angle being fixed to the previously determined values. The structural parameters obtained by the two methods are in good agreement with each other. They are listed in Table 5.

	∠F–C–F = 106°14′±23′		

a) Calculated from the first moment equation.
b) Calculated from the value of $I_c-I_a-I_b$.

Discussion

The obtained C–Cl and C–F bond distances are compared with those of other halogenomethanes in Fig. 3. The values indicated by black circles have been determined by using many isotopic data; they seem to be precise enough. On the other hand, the values indicated by white circles may have fairly large ambiguities because they were obtained from few isotopic data. As Lide[2] pointed out, the carbon-halogen distances in the CH_3Cl, CH_2Cl_2, $CHCl_3$ series and the CH_3F, CH_2F_2, CHF_3 series show a quite regular shortening upon further substitution of the hydrogen by the halogen, and the C–F shortening is more marked than the C–Cl shortening. In the figure we can see that the C–Cl shortening occurs as a fluorine is added to the molecule. The C–F shortening is also seen as a chlorine is added. It is interesting to note that the bond shortening upon the substitution of a fluorine is always more marked than that upon the substitution of a chlorine. The irregularities in $CClF_3$ and CCl_3F may be attributed to the improper analyses of their molecular structures, since the assumption of some structural parameters seem to be invalid for the analyses of these molecules. Therefore, the precise re-determination of the molecules

indicated by white circles in the figure is necessary for a further detailed discussion.

Gordy and Cook[5] have shown that the change in quadrupole coupling constants obtained by the pure nuclear quadrupole resonance is quite regular in the CCl_4, CCl_3F, CCl_2F_2, $CClF_3$ series and that the change can be interpreted in terms of hyperconjugation. The χ_{zz} obtained in the present study, however, is fairly large compared with the value expected from their figure. As far as we know, this value is the highest in the coupling constants obtained for chlorine nuclei

attached to carbon atoms. For a detailed discussion, it is desirable to determine the χ_{zz} by the analysis of the off-diagonal element of the χ tensor in the principal axis system, which can be obtained from the measurement of the second-order quadrupole effect. However, all the transitions measured in this study fit the calculated values within the limits of experimental errors without the second-order terms.

Two kinds of deuterium substituents of the galvinoxyl radical have been synthesized, and the effect of the deuterium substitution on the anomalous phase transition of the crystalline galvinoxyl radical at 82 K has been studied. The results, investigated by means of ESR and magnetic susceptibility measurements, indicate that the effect was not strong enough to induce any observable change in the transition.

In the previous papers,[1-3] we have reported that the galvinoxyl radical shows a first-order phase transition accompanying the pairing of magnetic spins at 82 K; the magnetic susceptibility is paramagnetic above the magnetic transition point, 82 K, where the susceptibility drops very sharply on cooling, while it is diamagnetic (weak paramagnetic) below this point. The anomaly at 82 K in the galvinoxyl has disappeared in the bisindophenoxyl radical, in which the centered methylidyne group (-CH=) of galvinoxyl is replaced by a nitrogen atom (-N=).[2] The magnetic susceptibility of the bisindophenoxyl radical exhibits a broad maximum at 54±2 K. This susceptibility can be explained approximately using a model which consists of a singlet ground state and a triplet state lying slightly above the ground state. On the other hand, the deuterated galvinoxyl radical, in which a centered methylidyne proton of galvinoxyl is replaced by a deuteron, showed a quite similar anomaly at 82 K.[4]

It has been reported that the deuterium substitution causes changes in the proton hyperfine splittings at the undeuterated positions of deuterated radicals.[5-9] Karplus *et al.*[10] have successfully analyzed the above results in terms of a model for the effect of the difference in the CH and CD out-of-plane bending motions. This vibration can affect the sigma-pi coupling, the pi-electron spin-density distribution, or both.

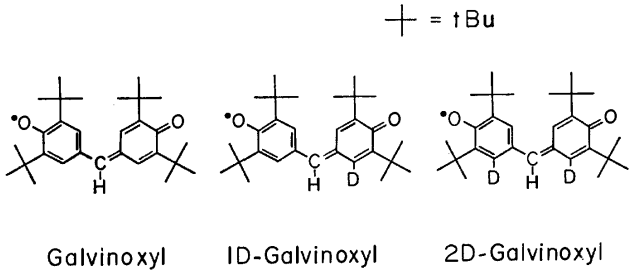

Fig. 1. Molecular structures of the galvinoxyl, 1D-galvinoxyl, and 2D-galvinoxyl radicals.

In the present paper, we have synthesized two mono- and di-deuterium derivatives, in which one and two of four *meta*-ring protons of the galvinoxyl radical are deuterated respectively (hereafter, they will be denoted as 1D- and 2D-galvinoxyl; see Fig. 1) and studied the magnetic properties of these radicals by means of ESR and magnetic susceptibility measurements.

Experimental

Materials. 2,6-Di-*t*-butylphenol and 2,6-di-*t*-butyl-4-methoxymethylphenol are commercially available. The synthesis of 2,6-di-*t*-butyl-3-deuteriophenol (bp 128—132°C/13 Torr) was reported previously.[11] The degree of deuterium substitution was determined as at least 95% from the NMR data of 2,6-di-*t*-butyl-3-deuteriophenol. 3,3′,5,5′-Tetra-*t*-butyldiphenylmethane-4,4′-diol, phenol (I) (mp 157.0—157.5 °C (lit, 154 °C)) was prepared according to the method of Kharash and Joshi.[12] 3,3′,5,5′-Tetra-*t*-butyl-2,2′-dideuteriodiphenylmethane-4,4′-diol, phenol (III), was also similarly prepared from 2,6-di-*t*-butyl-3-deuteriophenol by condensation with formaldehyde in a KOH–ethanol solution. Mp 157.5—158.0 °C. (Found: C, 81.57; H, 10.82%. Calcd for $C_{29}H_{42}D_2O_2$: C, 81.63; H, 10.87%). UV spectrum (λ_{max}=279 nm, logε=3.53 in ethanol). NMR spectrum ($\delta_{C(CH_3)_3}$=1.40 ppm (36), δ_{CH_2}=3.74 (2), δ_{OH}=4.86 (2). $\delta_{m\text{-}H}$=6.85 (2); δ in CCl_4, with TMS as the internal standard). 3,3′,5,5′-Tetra-*t*-butyl-2-deuteriodiphenylmethane-4,4′-diol, phenol (II), was prepared by the reaction of 2,6-di-*t*-butyl-3-deuteriophenol and 2,6-di-*t*-butyl-4-methoxymethylphenol in a KOH–methanol solution, according to the procedure used by Steelink *et al.*[13] to prepare 3,5-di-*t*-butyl-3′,5′-dimethyl-4,4′-dihydroxydiphenylmethane. Mp 156.0—157.0 °C. (Found: C, 82.22; H, 10.72%. Calcd for $C_{29}H_{43}D_1O_2$: C, 81.83; H, 10.66%). UV spectrum (λ_{max} =279 nm, logε=3.51 in ethanol). NMR spectrum ($\delta_{C(CH_3)_3}$ =1.41 ppm (36), δ_{CH_2}=3.76 (2), δ_{OH}=4.88 (2), $\delta_{m\text{-}H}$=6.89 (3); δ in CCl_4, with TMS as the internal standard.

The galvinoxyl (I), 1D-galvinoxyl (II), and 2D-galvinoxyl (III) radicals (see Fig. 1) were prepared according to the methods of Coppinger[14] and of Bartlett and Funahashi.[15] The diphenylmethane precursors, phenols (I)—(III), were oxidized

Table 1. Chemical and physical properties of galvinoxyl, 1D-, and 2D-galvinoxyls

	Mp (°C)	UV		Visible		Calcd (%)		Found (%)	
		λ_{max}	log ε	λ_{max}	log ε	C	H	C	H
Galvinoxyl	151.0—152.5	289nm	4.06	430nm	5.23	82.61	9.80	82.55	9.88
1D-Galvinoxyl	150.5—151.5	289	4.03	430	5.21	82.41	10.02	82.33	9.90

with PbO_2 in diethyl ether, with the temperature kept between 0 and 5°C under nitrogen gas throughout. The PbO_2 was then filtered off carefully, and the diethyl ether solvent was slowly evaporated under nitrogen gas. Very dark blue crystalline compounds of the galvinoxyl (I)—(III) remained in the round-bottomed flask. This flask was connected to a vacuum line (5×10^{-3} Torr) for two hours to remove the diethyl ether solvent completely. The chemical and physical properties of these radicals are summarized in Table 1. All these values show good accordance with each other within the limits of experimental error.

Apparatus. The susceptibility measurements were carried out with a Shimadzu-type MB-2 magnetic torsion balance, equipped with a low-temperature cryostat. The temperatures were measured using an AuCo-Cu thermocouple. Manganese Tutton salt was used for the calibration of the themometers and the field gradient. The ESR measurements were carried out using a JES-ME-3X spectrometer equipped with a Takeda-Riken microwave frequency counter. The ESR hyperfine splittings and g-values were measured relative to those of $(KSO_3)_2NO$ ($a^N=13.05\pm0.03$ G; $g=2.0054$[16]). The NMR spectra were taken on a JEOLCO 4H-100 100 MHz NMR spectrometer.

Results and Discussion

Initial slight oxidations of 3,3′,5,5′-tetra-*t*-butyldiphenylmethane-4,4′-diol and 3,3′,5,5′-tetra-*t*-butyl-2,2′-dideuteriodiphenylmethane-4,4′-diol, (I) and (III) phenols, with PbO_2 in toluene in a sealed, degassed system give ESR spectra consisting of triplet-triplet or triplet-doublet splittings respectively. We assign the spectra to the primary phenoxyl radicals (I-P) and (III-P) formed from the parent phenols by the abstraction of a phenolic hydrogen atom. The large triplet splittings ($a^H=9.58$ G for (I-P) and $a^H=9.57$ G for (III-P) at 15 °C) in the primary radicals are clearly due to the para methylene group, and the triplet or doublet splittings ($a^H=1.65$ G for (I-P) and 1.68 G for (III-P)) can be explained by the meta hydrogens. One group of large triplet splittings of (I-P) and (III-P) is shown in Figs. 2(a) and (b). The spectrum shown in Fig. 2(b) includes also a weak triplet signal arising from undeuterized phenol. The theoretical ratio (a^D/a^H) of the deuteron to the proton splittings expected on the basis of the magnetic moments and spins of the two nuclei is 0.1535; thus, we can expect 0.25 G as the deuteron hyperfine splitting for the (III-P) radical. However, the deuteron hyperfine splitting (a_m^D) due to the *meta*-ring deuteron of the (III-P) primary radical was not resolved, as is shown in Fig. 2(b). On the basis of the relative intensities and line widths of the ESR spectrum consisting of doublet and triplet splittings, it is estimated that the samples contain approximately 8% undeuterized protons. This value shows a good agreement with that of 5% estimated from the NMR spectrum. The spectrum of the primary radical (II-P) obtained by the PbO_2 oxidation of phenol (II) may be explained as resulting from the addition of the spectra from (I-P) and (III-P).

As the oxidation of the phenol (I) solution proceeds, a further absorption due to a secondary radical, galvinoxyl, appeared, and finally the spectrum was completely altered to a doublet-quintet spectrum with hyperfine splittings, $a_{CH}^H=5.77$ G and $a_m^H=1.41$ G.[17] The (II) and (III) phenols also show similar behavior; they give doublet-quartet and doublet-triplet spectra due to 1D- and 2D-galvinoxyl radicals. The deuteron hyperfine splittings were not resolved, as is to be expected from the results obtained for the primary radicals. Recordings of the 1D-galvinoxyl spectrum also include

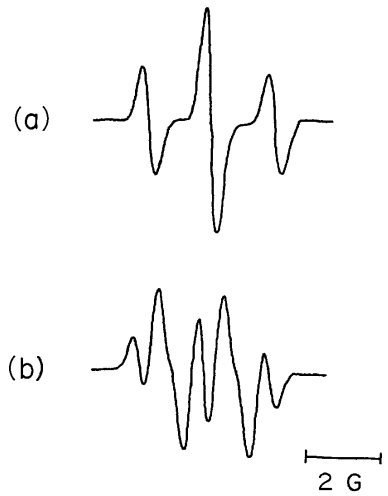

Fig. 2. ESR spectra of the primary radicals, (a) (I-P) and (b) (III-P), obtained by the PbO_2 oxidation of the phenols, (I) and (III), in toluene at 15 °C. One group of the three identical absorption groups is shown in Fig. 2(a) and (b), respectively.

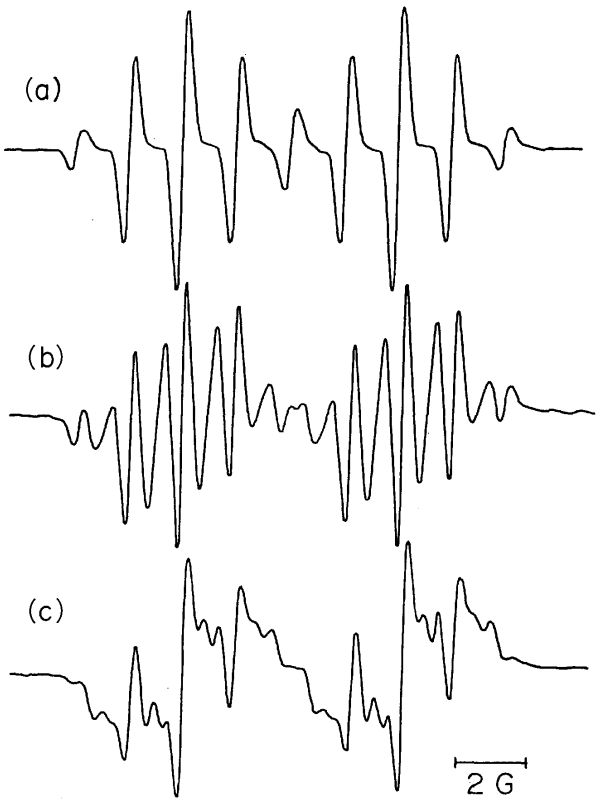

Fig. 3. ESR spectra of (a) galvinoxyl, (b) 1D-galvinoxyl, and (c) 2D-galvinoxyl radicals obtained by the PbO_2 oxidation of the phenols, (I), (II), and (III), in toluene at 20 °C.

Table 2. Hyperfine splittings and G-values of galvinoxyl, 1D-, and 2D-galvinoxyls

	$A^{H}_{-CH=}$ (G)	A^{H}_{m} (G)	G-value
Galvinoxyl	5.77±0.04	1.41±0.04	2.00434±0.00003
1D-Galvinoxyl	5.82±0.04	1.36±0.04	2.00433±0.00003
2D-Galvinoxyl	5.86±0.04	1.35±0.04	2.00431±0.00003

the doublet-quintet spectrum of undeuterated galvinoxyl, because the sample of the monodeuterated diphenylmethane precursor (phenol (II)) contains the diphenylmethane (phenol (I)) as an impurity. Similarly, the spectrum of the 2D-galvinoxyl radical sample also includes signals due to both 1D-galvinoxyl and galvinoxyl radical impurities. These spectra are shown in Fig. 3. The g-values of these radicals in toluene were also measured. All these values are listed in Table 2. Both the hyperfine splittings and the g-values of these radicals remain constant, within the limits of experimental error, indicating that deuterium substitution to the *meta*-ring proton of the phenyl rings does not significantly affect the unpaired electron distribution.

The molar susceptibilities obtained for the galvinoxyl radical are shown in Fig. 4 as a function of the temperature. The data have been corrected for a calculated diamagnetism of -0.276×10^{-3} emu/mol. The susceptibility of galvinoxyl follows the Curie-Weiss law with a Curie constant of 0.358 K emu/mol and a Weiss constant of 13.0±2.0 K in the temperature region between 86 and 300 K. At 85.1±2.0 K, χ_P rapidly decreases by 93% of its maximum value within about three degrees, and afterward falls off gradually until 55 K. The residual paramagnetic radical concentration, calculated from the susceptibility at 55 K assuming Curie law, is only 1.1%. As has been reported before, the anomaly in the galvinoxyl is thought to be a first-order phase transition, accompanied by a pairing of the magnetic spins.[2] It has also been reported before that the magnetic susceptibilities in the low-temperature region (5—50 K) obey the Curie-Weiss law, with different spin concentrations from about 10 to 30 mol % for the three independently-prepared samples; thus, the low-temperature susceptibilities are probably due to the residual unpaired galvinoxyl radicals with a spin of 1/2, the radicals being randomly located in the lattice. In the present work, poly crystals of the galvinoxyl radical were prepared by careful, slow evaporation from a saturated etherial solution under nitrogen throughout in order to decrease the quantity of residual unpaired spins. In fact, the residual radical concentration (1.1%) obtained is much smaller than the values (from about 10 to 30 mol %) reported before for the galvinoxyl.

The 1D- and 2D-galvinoxyl radical samples were similarly prepared. The magnetic susceptibilities of these

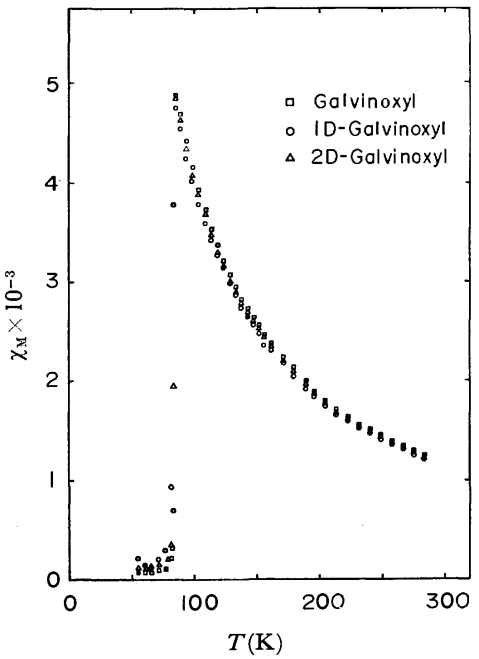

Fig. 4. Molar susceptibilities of the galvinoxyl (open square, □), 1D-galvinoxyl (open circle, ○), and 2D-galvinoxyl (open triangle, △) radicals versus temperature (55—300 K).

radicals between 55 and 300 K are shown in Fig. 4, together with those of the galvinoxyl radical. As is clear from the results shown in Fig. 4, the temperature dependences of the magnetic susceptibilities of the 1D- and 2D-galvinoxyl radicals are very similar to that of the galvinoxyl. The values of the Curie constants (C), the Weiss constants (θ), the radical concentrations, the transition temperatures (T_{max}), and the residual radical concentrations obtained in this work are summarized in Table 3. The small differences observed between these radicals for the radical concentrations above the transition temperature and the residual radical concentrations below it must be due to differences in the sample preparation. On the other hand, the expected change in the phase-transition temperature and the Weiss constant upon the deuterium substitution to the *meta*-ring protons of the galvinoxyl was not observed. It has been reported by ESR studies that the deuterium substitution to aromatic radicals can produce significant modifications in the proton hyperfine splittings (a^H) for ring positions other than that of substitution. The most notable effect is observed in the benzenide anion;[5,6] the equal hyperfine splittings (a^H=3.75 G) obtained at all positions in $C_6H_6^-$ are replaced in the benzenide-1-*d* anion by $a^H_2=a^H_3=3.95$ G, $a^H_4=3.49$ G and in the benzenide-2,6-d_2 anion by

Table 3. Results from susceptibility measurements of galvinoxyl, 1D-, and 2D-galvinoxyls

	C (emu K/mol)	θ (K)	Radical concentration (%)	T_{max} (K)	Residual para (%)
Galvinoxyl	0.358	13.0±2.0	95.0±2.0	85.1±2.0	1.1±0.5
1D-Galvinoxyl	0.343	13.2±2.0	90.9±2.0	84.3±2.0	3.2±0.5
2D-Galvinoxyl	0.347	13.6±2.0	92.1±2.0	84.9±2.0	1.7±0.5

$a_1^H = a_4^H = 4.16$ G, $a_3^H = 3.61$ G. Smaller changes are observed in deuterated naphthalenide anions[7] and in the *N*-deuterated dihydropyrazine cation and its methyl derivatives.[8] However, all the results obtained for the galvinoxyl, 1D-, and 2D-galvinoxyl radicals in the solid state and in solution indicate that the perturbations in electronic and magnetic properties resulting from the deuterium substitution are quite small in these radicals.

Charge-transfer Character in the Intramolecular Hydrogen Bond: Electronic Structures and Spectra of Hydrogen Maleate Anion and Related Molecules

Hiroshi MORITA, Kiyokazu FUKE, and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received October 18, 1976)

Ultraviolet absorption spectra were measured with aqueous solutions of maleic acid (H_2M) at various pH values and in concentrated sulfuric acid solutions. With the aid of the theoretical calculations of electronic structures by the modified CNDO-CI method, relatively strong bands observed at 193.5 nm for H_2M, at 210.0 nm for the hydrogen maleate anion (HM^-), and at 202.8 and ≈230 nm for the dinegative ion (M^{2-}) are assigned to the π–π^* transition bands. Special attention was paid to the charge-transfer (CT) character (pertinent to the strong intramolecular hydrogen bond) in the excited states of HM^-. Configuration analysis of the wave functions revealed us that the first π–π^* band of HM^- covered by the much stronger 210 nm band is rich in the CT character pertinent to the hydrogen bond.

In some hydrogen-bonded systems (X-H···Y), the charge-transfer (CT) force between a proton donor (X-H) and a proton acceptor (Y) has been recognized to be important as well as the electrostatic and exchange repulsion forces.[1–6] On the basis of the CT mechanism, the CT band characteristic of hydrogen bond is expected to appear in the ultraviolet (UV) or vacuum ultraviolet (VUV) region, and observation of the band is a direct proof of the CT mechanism of hydrogen bond.

The hydrogen maleate anion (HM^-) has a symmetrical intramolecular hydrogen bond ($(O\text{-}H\text{-}O)^-$) as revealed from the X-ray diffraction analysis[7] and from the studies by infrared spectroscopy.[8–10] One of the present authors observed an electronic absorption band of HM^- in aqueous solution at ≈210 nm and determined the direction of the transition moment (being parallel to the O-H-O bond) of the band.[11] From a theoretical calculation based on the π-electron approximation, the 210 nm band was suggested to be the CT band characteristic of the intramolecular hydrogen bond ($(O\text{-}H\text{-}O)^-$) of HM^-. Further theoretical studies have been carried out with the ground and excited states of HM^- by the non-empirical[12] and semi-empirical[13] methods. The potential energy curve of hydrogen bond calculated by the modified CNDO method[13] for HM^- agreed with the experimentally expected one.[8–10]

In the present study, in order to extend the previous works and to elucidate the electronic structures of the excited states of the hydrogen maleate anion, the absorption spectra of the maleic acid cation (H_3M^+), maleic acid (H_2M), HM^-, and maleate dinegative ion (M^{2-}) have been measured and their electronic structures have been calculated and analysed by the modified CNDO-CI method[14] combined with the configuration analysis method.[15] From the comparison between the theoretical and experimental results, the CT character (pertinent to the hydrogen bond) in some lower excited states of HM^- has been discussed in detail.

Experimental

Maleic acid (Wako G. R. grade) was purified by repeated recrystallizations from water. HM^- was prepared[10] by treating aqueous solution of maleic acid with potassium hydrogen carbonate ($KHCO_3$), and recrystallized three times from water. Methanol and acetonitrile (Wako spectrograde) were used as solvents without further purification. A buffer solution with pH=4.4 was prepared from aqueous solutions of acetic acid and sodium acetate.[16]

UV absorption spectra were measured with a Cary recording spectrophotometer model 14, a cell of 0.933 mm light path length being used. VUV absorption spectra were measured with a spectrophotometer constructed in our laboratory[17].

Theoretical

The electronic structures of H_3M^+, H_2M, HM^-, and M^{2-} were calculated by the modified CNDO-CI method presented in a previous paper.[14] The method has the characteristics that the semi-empirical electron repulsion, core resonance, and core potential integrals are separately evaluated for the σ- and π-orbitals. As in the case of formic and acrylic acids reported,[14] the one-center Coulomb repulsion integrals, γ's and bonding parameters, β^0's were commonly used for all the 2s and 2p atomic orbitals (AO) of the two oxygen atoms in the carboxyl group. Furthermore, in order to consider the effect of excess formal charge of the ions, the β^0 and γ values and the effective nuclear charge (Z) of the basis

TABLE 1. EFFECTIVE NUCLEAR CHARGE (Z), ONE-CENTER COULOMB REPULSION INTEGRAL (γ_{AA}(eV)), AND BONDING PARAMETER (β_A^0(eV)) FOR H, C, AND O ATOMS

	H	C		O[a]			
		σ-AO	π-AO	H_3M^+	H_2M	HM^-	M^{2-}

β_A^0	−12.0(−9.0)[b]	−17.9	−12.9	−31.8	−27.0	−23.0	−17.9

a) Value being employed for both the σ- and π-AO's. b) Employed only for HM^-.

AO's of oxygen and the hydrogen-bonded hydrogen atoms were modified from those of the neutral H_2M molecule. The parameters finally used are tabulated in Table 1. In the configuration interaction (CI) calculation, 24 singly excited π-π^* and σ-σ^* configurations and 25 singly excited π-σ^* and σ-π^* configurations were taken into account.

Geometrical structures were taken for H_2M and HM^- from the X-ray crystal analysis data[7,18] and assumed for H_3M^+ and M^{2-} to be the same as those of H_2M and HM^-, respectively, except for the fact that the additional proton was attached or removed.

The configuration analysis[15] was applied to the ground and two excited (B_1 symmetry) states of HM^-. The molecular orbitals (MO) of M^{2-} and 1s orbital of the hydrogen-bonded hydrogen atom were adopted as the reference MO's. The ground state of HM^- was analysed by the ground and 92 singly excited π-π^* and σ-σ^* reference configurations (with A_1 symmetry) and by all the doubly excited reference configurations derived from the above configurations, and the excited states of HM^- were analysed by 93 singly excited π-π^* and σ-σ^* reference configurations (with B_1 symmetry) and 93×92 doubly excited reference configurations.

Results and Discussion

Figure 1 shows the absorption spectra of HM^- in aqueous buffer solution with pH=4.4 and of M^{2-} in aqueous KOH solution with pH=11.0, the spectrum of M^{2-} being tentatively resolved into two components.

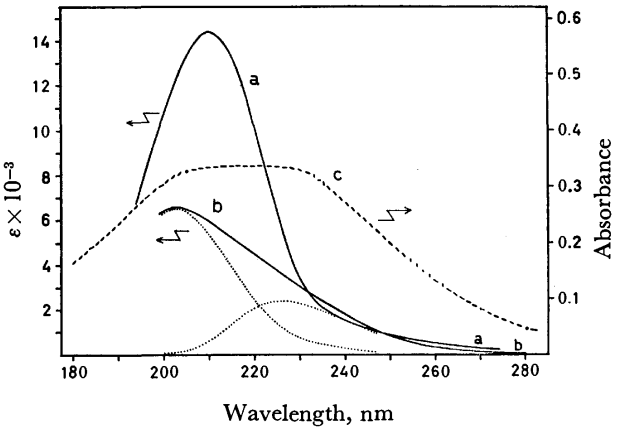

Fig. 1. Near and vacuum UV absorption spectra of (a) HM^- in aqueous buffer solution with pH=4.4, (b) M^{2-} in aqueous KOH solution with pH=11.0, and (c) HM^- crystalline powder. The composite band of M^{2-} is tentatively resolved by dotted lines.

This figure also shows the VUV spectrum observed with HM^- crystalline powder. Table 2 shows the transition energies, oscillator strengths, and directions of transition moments calculated by the modified CNDO-CI method, together with the observed values. Within the molecular (x-y) plane, the x-axis is parallel to the O-H-O hydrogen bond. From the comparison between the observed and calculated results, the 210.0 nm (5.90 eV) band of HM^- in aqueous solution and $\approx$220 nm band of HM^- crystalline powder can safely be assigned to the second

π–π^* transition (calculated at 6.73 eV), whereas the ≈230 nm (≈5.4 eV) and 202.8 nm (6.11 eV) bands of M^{2-}, to the second and third π–π^* transitions (calculated at 5.38 and 6.83 eV), respectively. The theoretical results indicate that the first π–π^* band is covered by the stronger second (and third) π–π^* band(s) for both HM^- and M^{2-}.

Figure 2 shows the UV absorption spectra measured with the sulfuric acid (H_2SO_4) solutions of maleic acid. From the dependency of the spectrum on the sulfuric acid concentration, spectrum b in 8.6% H_2SO_4 solution can be ascribed to the spectrum of H_2M. The theoretical result in Table 3 shows that the 193.5 nm (6.41 eV) band of H_2M is assigned to the first π–π^* transition (calculated at 5.87 eV). In more concentrated sulfuric acid, the spectrum shifts to longer wavelengths, showing a strong band at 220.5 nm (5.62 eV) (curve g in Fig. 2). The spectra of the concentrated sulfuric acid solutions e, f, and g show practically no change even after 15 days. Moreover, dilution of the 90.9% H_2SO_4 solution of maleic acid (solution g) with water gives a spectrum similar to that of the sulfuric acid solution of the corresponding acidity. These facts indicate that the species having the absorption band at 220.5 nm in concentrated sulfuric acid solution is not a reaction product but a cation in equilibrium with sulfuric acid; H_3M^+ or the acylium ion as observed with the concentrated H_2SO_4 solution of mesitoic acid.[19]

Let us investigate the electronic structure of HM^- in more detail. Figure 3 shows the energy levels calculated for some lower π–π^* and σ–σ^* excited states of HM^- compared with those of H_2M. In the figure, a singly excited configuration i–j represents one electron excitation from the i-th occupied MO to the j-th vacant MO. The shapes of MO's of HM^- are schematically shown in Fig. 4. The CT character pertinent to the intramolecular

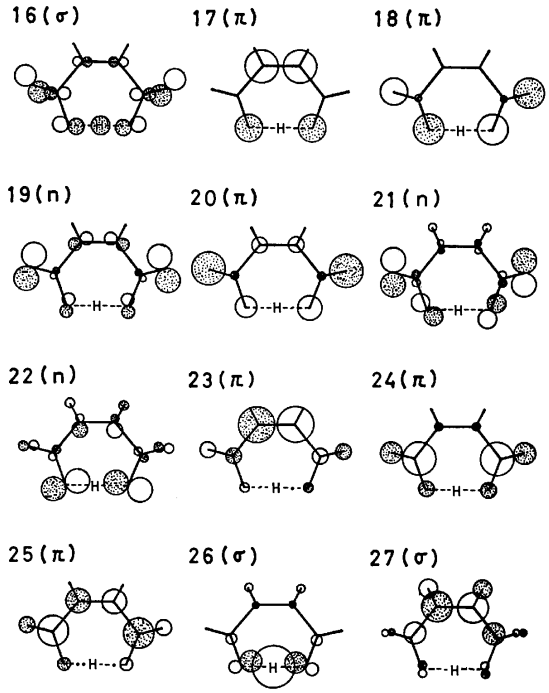

Fig. 4. Schematic shapes of some occupied and vacant MO's of HM^-. The 22th MO is the highest occupied one.

a) i and j denote the 22 occupied MO's of M^{2-}, and k and l, the 12 vacant MO's of M^{2-}. The 1s orbital of hydrogen-bonded hydrogen is numbered as the 35th vacant orbital. b) i–k and i,j–k,l denote the singly and doubly excited reference configurations, respectively. c) The ionic structure, $[(O^+H^-O)^- + (OH^-O^+)]$ is also involved. d) The result for the case where the excitation energies of all the CT and σ–σ^* configurations are lowered by 1.0 eV in the CI treatment is listed in the column (with parentheses). e) Doubly excited configurations, i,j–k, 35. f) The ground reference configuration coincides with the ground state of M^{2-}. g) Singly excited configurations, i–k.

hydrogen bond corresponds to the transition from the nonbonding orbital to the antibonding orbital in the hydrogen bond. The 21—26 and 22—26 configurations are easily seen to have the CT character pertinent to the hydrogen bond. The energy levels of the CT configurations calculated for HM^- are $\approx$3 eV lower than those for the corresponding CT configurations of H_2M. As is illustrated in Fig. 3, the CT configuration 22—26 of HM^- interacts strongly with the 17—23 π–π^* configuration. Consequently, the first and fourth π–π^* excited states of HM^- turn out to be considerably rich in the CT character pertinent to the hydrogen bond.

The conclusion was further clarified by the configuration analysis for the first π–π^* excited state of HM^-; the result is tabulated in Table 4, together with the results for the ground and the second π–π^* excited (assigned to the 210.0 nm band) states. Because of the symmetrical hydrogen bond in HM^-, the CT structure corresponds to the antisymmetric covalent structure, $[(O\text{–}H\cdots O)^- - (O\cdots H\text{–}O)^-]$ and the antisymmetric ionic structure, $[(OH^-O^+)^- - (O^+H^-O)^-]$. As is shown in Table 4, the antisymmetric covalent and ionic structures contribute considerably ($\approx$32%) to the first π–π^* excited state, revealing that the first π–π^* excited state is rich in the CT character in the hydrogen bond. Table 4 shows also the result for the case where the excitation energies of all the CT and σ–σ^* configurations are lowered by 1.0 eV in the CI treatment. The result shows that the quantitative CT character is sensitive to

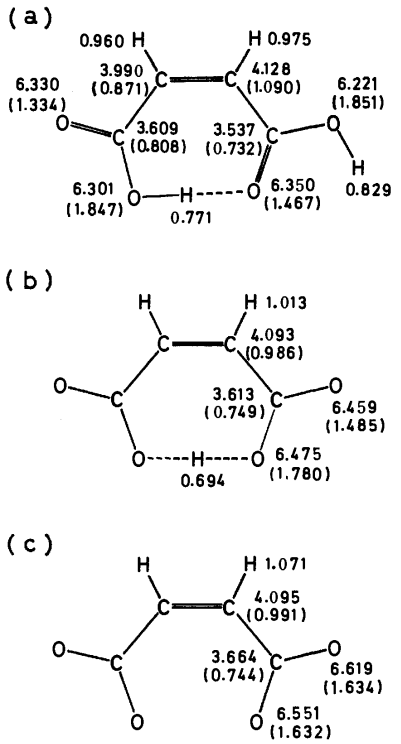

Fig. 5. Total and π-(in parentheses) electron densities calculated for the ground states of (a) H_2M, (b) HM^-, and (c) M^{2-}.

the relative position of the π-π^* (17—23) and CT (22—26) configurations; the CT character of the first π-π^* excited state increases to $\approx$50% by the energy lowering of the CT configuration.

The electron densities for the ground states of H_2M, HM^-, and M^{2-} are shown in Fig. 5. The excess formal charge in HM^- and M^{2-} is mainly distributed on the oxygen atoms.

Vibration Spectra and Rotational Isomerism of Chain Molecules. V.[1] 2,5-Dioxahexane, 2,5-Dithiahexane, and 2-Oxa-5-thiahexane

Yoshiki OGAWA, Masahiro OHTA, Masaaki SAKAKIBARA, Hiroatsu MATSUURA, Issei HARADA, and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 5, 1976)

The Raman and infrared spectra of 2,5-dioxahexane $CH_3OCH_2CH_2OCH_3$, 2,5-dithiahexane $CH_3SCH_2CH_2SCH_3$ and 2-oxa-5-thiahexane $CH_3OCH_2CH_2SCH_3$ were measured for the gaseous, liquid, glassy and crystalline states and were correlated with the normal-vibration calculations. The rotational isomerism was studied and the following conclusions were obtained. (1) The molecular form existing in the crystalline state is a non-extended form, in contrast with the cases of the unbranched ethers or sulfides containing one oxygen or sulfur atom which take the extended all-*trans* form. (2) Many forms coexist in the gaseous, liquid and glassy states. (3) The form existing in the crystalline state is the most stable in the liquid state. It was found that the repulsive force between non-bonded hydrogen atoms is one of the important factors influencing the conformational stabilities and for 2,5-dioxahexane the dipole-dipole interaction is another important factor. The stable conformations of these molecules were correlated with those of the polyether and polythioether chains. The stable isomers of 2-oxa-5-thiahexane could be explained on the basis of the knowledge of the conformational stabilities of the unbranched ethers and sulfides. The force constants of the ethers and sulfides were satisfactorily transferred to 2-oxa-5-thiahexane.

In previous papers,[1,2] we reported the vibration spectra and the rotational isomerism of the unbranched ethers and sulfides which contain one oxygen or sulfur atom, and obtained information on the conformational stability for these molecules. In the present paper, we extended our studies to 2,5-dioxahexane (ethylene glycol dimethyl ether) $CH_3OCH_2CH_2OCH_3$, 2,5-dithiahexane $CH_3SCH_2CH_2SCH_3$, and 2-oxa-5-thiahexane $CH_3OCH_2CH_2SCH_3$. The Raman and infrared spectra of these molecules in various states were analyzed and the rotational isomers existing in each state were determined on the basis of normal-vibration calculations.

The present results on the rotational isomerism will be discussed together with those previously obtained for the unbranched ethers and sulfides.[1-6] Discussions will also be made in relation to the stable conformations of polyethers[7,8] and polythioethers.[9]

Experimental

2,5-Dioxahexane was purchased from Tokyo Kasei Kogyo Co., Ltd. and was distilled prior to the measurements. 2,5-Dithiahexane was synthesized by the reaction

$$BrCH_2CH_2Br + 2CH_3SNa\ (aq) \xrightarrow{60\ ^\circ C,\ 6\ h} CH_3SCH_2CH_2SCH_3 + 2NaBr.$$

After the organic layer was dried over anhydrous sodium sulfate, 2,5-dithiahexane was obtained by the distillation under reduced pressure. 2-Oxa-5-thiahexane was synthesized by the following reactions

$$2HOCH_2CH_2Cl + (CH_3)_2SO_4 \xrightarrow[120\ ^\circ C,\ 5\ h]{CaCO_3} 2CH_3OCH_2CH_2Cl + H_2SO_4$$

and

$$CH_3OCH_2CH_2Cl + CH_3SNa\ (aq) \xrightarrow[60\ ^\circ C,\ 30\ h]{NaOH} CH_3OCH_2CH_2SCH_3 + NaCl.$$

After the organic layer was dried over anhydrous sodium sulfate, 2-oxa-5-thiahexane was obtained by the distillation (bp 134—135 °C).

The Raman and infrared spectra were measured for the gaseous, liquid, glassy, and crystalline states by the methods reported previously.[1,2] The glassy state for the Raman measurements was obtained by putting into liquid nitrogen the sample enclosed in an ampoule and cooling it rapidly, and that for the infrared measurements by depositing the sample onto a cooled window of KBr or KRS-5.

Normal Coordinate Treatment

Normal coordinate treatment was carried out with a computer program NCTB2[10] and a HITAC 8700/8800 computer system at the Computer Center of the University of Tokyo. The data of 2,5-dioxahexane and 2,5-dithiahexane were included in the least-squares refinement of the force constants of the unbranched ethers and sulfides.[1,2]

For 2-oxa-5-thiahexane, the force constants were transferred from the unbranched ethers and sulfides[1,2] except those for the OCH_2CH_2S part. The force constants for this part were initially transferred from the OCH_2CH_2O part and the stable forms of the rotational isomers were determined. The nine important force constants, the CC stretching and methylene-methylene interactions, were subsequently refined by the least-squares method from 56 Raman and infrared frequencies.

Detailed results of the calculations and the force constants are reported in a separate paper.[10]

Results

Figures 1—10 show the Raman and infrared spectra obtained. The observed frequencies and the vibrational assignments based on the calculated potential-energy distributions are listed in Tables 1—3. The observed spectra were analyzed with reference to the results of the normal coordinate treatment.

In the following subsections, the rotational isomerism

of the individual molecules is described.

2,5-Dioxahexane $CH_3OCH_2CH_2OCH_3$. Since this molecule has two C–O axes and one C–C axis associated with the rotational isomerism, there are ten possible rotational isomers as given in Table 1 of Part I of this series.[2] Of these, the GG'G form is rejected, because the distance between the two terminal methyl groups is too short for this form to be stable. However, the TGG' and GGG' forms are not simply ruled out, since the

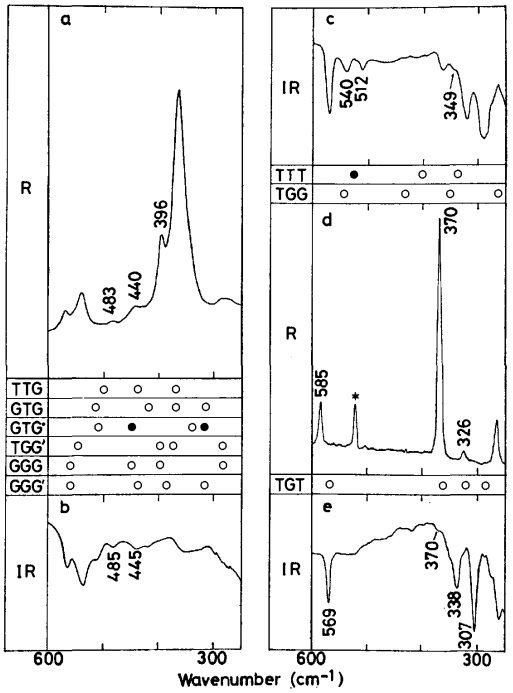

Fig. 3. Comparison of the observed and calculated frequencies of 2,5-dioxahexane in the 600—250 cm^{-1} region.

steric hindrance in the GG' sequence of the OC–C–OC part is expected to be smaller than that in the former case. The observed and calculated frequencies in the 600—250 cm^{-1} region are compared in Fig. 3.

A comparison between the observed spectra and the calculated frequencies indicates that the TGT form exists in the crystalline state. It should be noted that some of the low-frequency vibrations give frequencies depending to some extent on the state and the spectroscopic measurement. Namely, the infrared bands at 338 and 307 cm^{-1} in the crystalline state correspond to the infrared bands at 325 and 295 cm^{-1}, respectively, in the glassy state and the Raman bands at 585 and 326 cm^{-1} in the crystalline state correspond to the infrared bands at 569 and 338 cm^{-1}, respectively.

The infrared spectrum in the glassy state shows that the TGT, TTT, and TGG forms coexist in this state. The glassy state for Raman measurements could not be obtained, since the liquid sample enclosed in an ampoule cell turns quickly into crystal even when it is put into liquid nitrogen for rapid cooling. In the glassy-state infrared spectrum, many bands appear in addition to the bands which have been assigned to the TGT form. Of these, the infrared band at 512 cm^{-1} is also observed in the infrared spectrum of the liquid state, but not observed in the Raman spectrum of this state. On the other hand, the Raman band observed at 396 cm^{-1} in the liquid state is missing in the infrared spectrum of this state. These bands are reasonably assigned to the

TTT form which has the center of symmetry. Other additional frequencies such as 540 and 349 cm^{-1} are well explained by the calculated frequencies of the TGG form.

In the liquid state, the observed spectra are explained by the coexistence of the TGT, TTT, TGG, and TTG forms. The Raman bands at 483 and 440 cm^{-1} and the corresponding infrared bands at 485 and 445 cm^{-1} appear in the liquid state. These frequencies agree well with the calculated frequencies of the TTG form. The existence of other forms is not proved, since their frequencies and the Raman and infrared activities are not consistent between the calculated results and the spectral observations.

The liquid-state Raman spectra at room and lower temperatures and the liquid- and glassy-state infrared spectra in the 1050—900 cm^{-1} region are shown in Fig. 4. These spectra also prove the coexistence of the TGT, TTT, and TGG forms in the glassy state and of the TGT, TTT, TGG, and TTG forms in the liquid state. The Raman bands at 1032 and 1022 cm^{-1} and the infrared bands at 1039 and 1026 cm^{-1} in the glassy state are assigned to the TGT form, the Raman band at 996 cm^{-1} and the infrared band at 943 cm^{-1} in the glassy state to the TTT form, the Raman band at 985 cm^{-1} and the infrared band at 988 cm^{-1} to the TGG form, and the Raman bands at 970 and 923 cm^{-1} and the additional infrared bands at 971 and 923 cm^{-1} in the liquid state to the TTG form. The temperature dependence of the liquid-state Raman spectra and the non-existence of the TTG form in the glassy state near the liquid nitrogen temperature indicate that the rotational isomers become less stable in the order of the TGT, TTT, TGG, and TTG forms.

In the gaseous state, the spectra have essentially the same number of bands as in the liquid state (Figs. 1 and 2). However, in contrast with the liquid-state spectra, the Raman intensity of the 822 cm^{-1} band is stronger than that of the 848 cm^{-1} band in the gaseous state. The infrared intensity of the 868 cm^{-1} band, which is observed as a shoulder of the 852 cm^{-1} band in the liquid state, increases in the gaseous state. These spectral changes are related to the polarity of the molecules as will be mentioned later. The gaseous-state spectra are explained by the coexistence of the TGT,

a) VS: very strong, S: strong, M: medium, W: weak, VW: very weak, vb: very broad, b: broad, sh: shoulder. The broadness of the band shapes in the gaseous state does not always allow us to correlate the individual bands in the liquid state to those in the gaseous state. Only approximate correlations are made in such cases and in other cases of similar situations. b) The band is assigned preferentially to the isomer(s) given by boldface. For the notation and definition of the local symmetry coordinates, see Ref. 11.

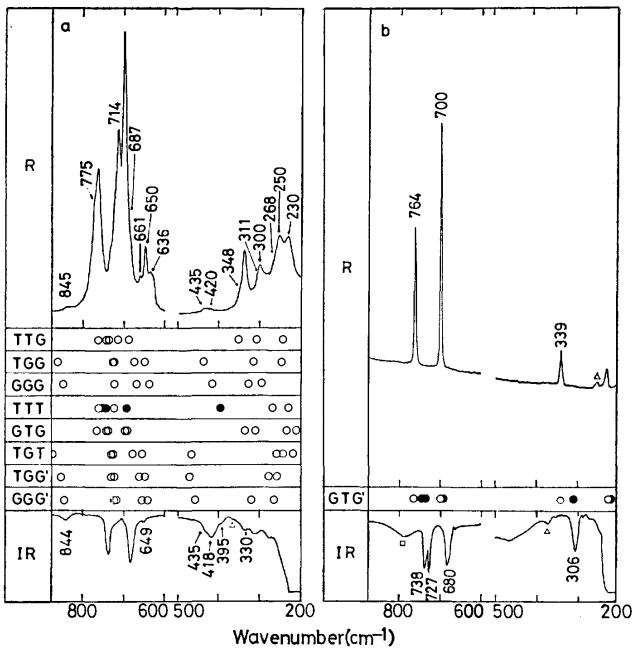

Fig. 7. Comparison of the observed and calculated frequencies of 2,5-dithiahexane in the 875—200 cm^{-1} region.
a: Liquid, b: crystal.
The symbols are explained in the caption of Fig. 1. For the forms which have the center of symmetry, the open and filled circles denote the Raman and infrared active vibrations, respectively.

TTT, TGG, and TTG forms similar to the liquid state.

2,5-Dithiahexane $CH_3SCH_2CH_2SCH_3$. This molecule has ten possible rotational isomers like the case of 2,5-dioxahexane. Of these, the GG'G form is rejected because of the reason stated for 2,5-dioxahexane. The observed and calculated frequencies in the 900—200 cm^{-1} region are shown in Fig. 7.

In the crystalline state, the Raman and infrared spectra are quite different from each other and the mutual exclusion rule holds as shown in Fig. 7. The TTT and GTG' forms are the possible candidates, since they possess the center of symmetry. Figure 7 shows that the calculated frequencies of the GTG' form are in good agreement with the observed frequencies of the crystalline state. The Raman and infrared activities expected for each vibration of this molecular form are also consistent with the spectral observations.

In the liquid state, the observed spectra are explained by the coexistence of the GTG', TTT, TTG, TGG, and GGG forms. Many bands appear in this state in addition to those existing in the crystalline state. As seen from Fig. 7, the Raman band at 268 cm^{-1} and the infrared band at 395 cm^{-1} are assigned to the TTT form, the Raman bands at 714, 348, and 300 cm^{-1} to the TTG form, the Raman bands at 650, 435 and 250 cm^{-1} and the infrared band at 435 cm^{-1} to the TGG form, and the Raman bands at 636 and 420 cm^{-1} and the infrared bands at 418 and 330 cm^{-1} to the GGG form.

The existence of the GTG form is uncertain, since all of its calculated frequencies are almost coincident

steric repulsions in this form are not much larger than those in the GTG' form. It is not probable that the TGT, TGG', and GGG' forms exist in the liquid state, since no bands are observed around their characteristic frequencies in the region 460—475 cm^{-1}.

As temperature is lowered in the liquid state, the Raman intensities of the bands assigned to the GTG' form increase relative to those of other bands (Fig. 5). Thus the GTG' form is found to be the most stable in the liquid state.

2-Oxa-5-thiahexane $CH_3OCH_2CH_2SCH_3$. This molecule has fourteen possible rotational isomers as listed in Table 1 of Part I of this series.[2] The existence of the GG'G form can be again rejected because of the very large steric hindrance. Figure 10 shows the observed and calculated frequencies in the 1000—200 cm^{-1} region.

The spectra in the crystalline state show that the

a), b) See a) and b), respectively, of Table 1.

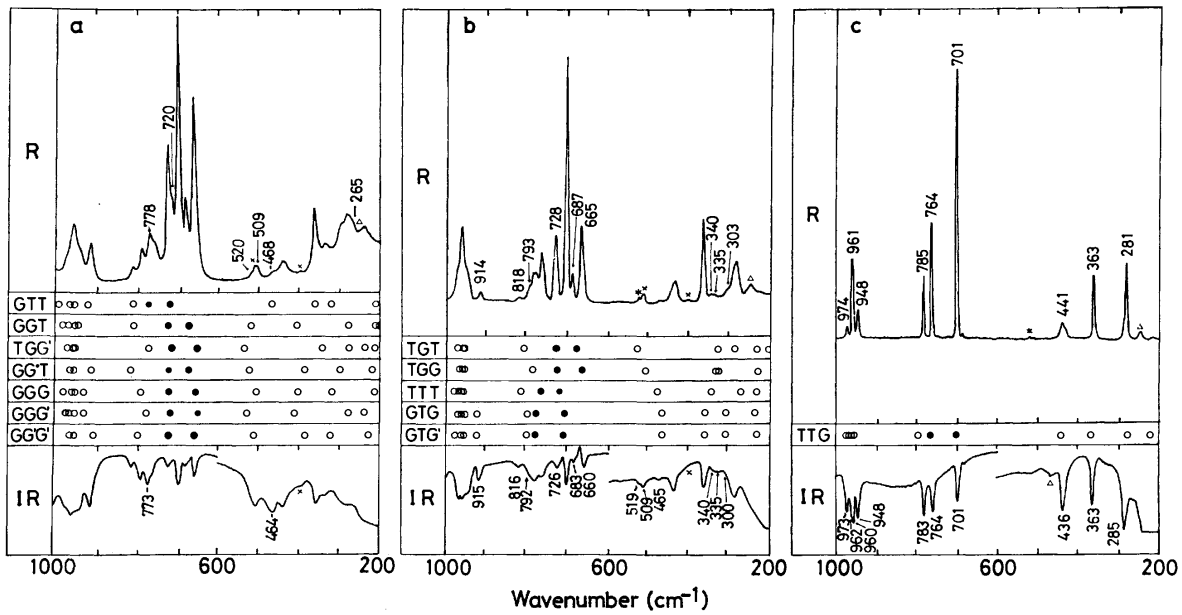

Fig. 10. Comparison of the observed and calculated frequencies of 2-oxa-5-thiahexane in the 1000—200 cm^{-1} region.
a: Liquid, b: glass, c: crystal.
The symbols are explained in the caption of Fig. 1. The filled circles denote the CS stretching vibrations.

TTG form exists. In the liquid state, the spectra have essentially the same number of bands as in the glassy state. The glassy- and liquid-state spectra are explained by the coexistence of the TTG, TTT, TGT, and TGG forms. One or both of the GTG and GTG' forms also exist in these states. In the liquid and glassy states, many bands appear in addition to those existing in the crystalline state. Of these bands observed in the liquid state, the Raman bands at 720, 468, and 265 cm^{-1} and the infrared band at 464 cm^{-1} are assigned to the TTT form, the Raman bands at 687 and 520 cm^{-1} and the infrared bands at 683 and 519 cm^{-1} to the TGT form, the Raman bands at 665 and 509 cm^{-1} and the infrared bands at 660 and 509 cm^{-1} to the TGG form, and the Raman bands at 914 and 303 cm^{-1} and the infrared bands at 915 and 300 cm^{-1} to one or both of the GTG and GTG' forms.

Each of the GGT, GGG, GG'T, GGG', and GG'G' forms has a characteristic frequency in the region 385—410 cm^{-1}. The weak Raman band at 400 cm^{-1} and the

Glass	**TGT TTT TGG**	—[a]	**TTG TGT TGG TTT** GTG or GTG′ (GTT) (GGT) (TGG′) (GG′T) (GGG) (GGG′) (GG′G′)
Crystal	**TGT**	**GTG′**	**TTG**

The isomers given by boldface are confirmed to exist. The existence of the isomers in parentheses is uncertain. For more details, see text. a) Spectral measurements were not made.

weak infrared band at 395 cm^{-1} are observed in the liquid-state spectra. However, these bands are attributed at least in part, to an impurity, because the Raman intensity of this band in the liquid state of the distillate with bp 135—136 °C is much stronger than that of the distillate with bp 134—135 °C. Since these bands are much weaker than those assigned to the TTG, TTT, TGT, TGG, and GTG or GTG′ forms, the populations of the GGT, GGG, GG′T, GGG′, and GG′G′ forms, if they exist, are much smaller than those of the former ones. The existence of the GTT and TGG′ forms is uncertain, since all of their calculated frequencies are almost coincident with those of the other forms mentioned above.

As temperature is lowered in the liquid state, the Raman intensities of the bands assigned to the TTG form increase relative to those of the bands assigned to the other forms. Accordingly, the TTG form is the most stable in the liquid state.

Rotational Isomerism. In Table 4, the rotational isomerism of the three compounds treated in this work is summerized.

The vibration spectra of 2,5-dioxahexane have been studied by several investigators.[3-5] Snyder and Zerbi[4] concluded that the TGT form exists in the crystalline state and the TGT, TTT, and other forms in the glassy and liquid states. Iwamoto[5] indicated the existence of the TGG and TTG forms in addition to that of the TGT and TTT forms in the liquid state on the basis of the comparison of the infrared spectra of pure liquid, liquid containing $HgCl_2$ and crystalline complex with $HgCl_2$. In the present work, these conclusions were further confirmed and the relative stabilities among the rotational isomers were determined.

The rotational isomerism of 2,5-dithiahexane has been discussed by Hayashi *et al.*[6] They found that the GTG′ form exists in the crystalline state and the GTG′ and GGG forms in the liquid state. The present work shows that in addition to these two forms the TTT, TTG, and TGG forms also exist in the liquid state. The isomerism of 2-oxa-5-thiahexane has first been studied in the present work.

The following results were obtained for the three compounds studied in this work in common. (1) The molecular form existing in the crystalline state is a non-extended form, in contrast with the cases of the unbranched ethers or sulfides containing one oxygen or sulfur atom which take the extended all-*trans* form.[1,2] (2) Many forms coexist in the gaseous, liquid and glassy states. (3) The form existing in the crystalline state is the most stable in the liquid state.

Discussion

In a previous paper,[2] the following results were reported for unbranched ethers containing one oxygen. (1) About the CO–CC axis, the *trans* conformation is more stable than the *gauche* conformation. (2) About the OC–CC axis, the *gauche* conformation is as stable as the *trans* conformation. (3) The repulsive force between nonbonded hydrogen atoms is one of the important factors influencing the stability of these conformations.

In the crystalline state, 2,5-dioxahexane exists in the TGT form which has the *gauche* conformation about the OC–CO axis. This form is also the most stable in the liquid state. These results are consistent with those obtained for the one-oxygen containing ethers mentioned above.

In addition to the stabilizing factor with regard to the repulsive force between the nonbonded hydrogen atoms in the TGT form, the dipole moment is suggested to be another important factor to stabilize this form in the crystalline and liquid states. For 2,5-dioxahexane, the observed frequencies for the same molecular vibrations are appreciably different between the Raman and infrared spectra in the crystalline state and between the infrared spectra in the crystalline and glassy states. The magnitudes of these frequency differences are much larger than those for the one-oxygen containing ethers.[2] These spectral observations may be due to the effect of dipole moment.

In the liquid state, as compared with the case in the gaseous state, polar molecular forms are more stabilized than non-polar forms.[12] In fact, as shown in Fig. 1, the intensities of the bands assigned to the TGT form (polar form) increase in the liquid state as compared with the gaseous state. However, the details in this point are left to be studied.

In connection with the TGT form of 2,5-dioxahexane in the crystalline state, it is important to examine the structure of polyether.[7,8] It has been shown that poly(oxyethylene) $(-OCH_2CH_2-)_n$ and poly(oxytri-

methylene) $(-OCH_2CH_2CH_2-)_n$ have several crystal modifications. In the most stable crystal modification, the molecule takes the TGT conformation for the series of O-C-C-O bonds in the former polymer and the TGGT conformation for the series of O-C-C-C-O bonds in the latter polymer. In other modifications, the poly(oxyethylene) molecule takes the TTT conformation, and the poly(oxytrimethylene) molecule takes the TTGTTTG'T and $(TTTT)_2$ conformations for the series of O-C-C-C-O-C-C-C-O bonds. The stabilizing factors for the TGT conformation of 2,5-dioxahexane are thus found to be strongly correlated to those of the TGT conformation of poly(oxyethylene) and the TGGT conformation of poly(oxytrimethylene).

In a previous paper,[1] the following results were reported for the one-sulfur containing sulfides. (1) About the CS-CC axis, the *gauche* conformation is slightly more stable than the *trans* conformation. (2) About the SC-CC axis, the *gauche* conformation is as stable as the *trans* conformation. (3) The repulsive force between nonbonded hydrogen atoms is an important factor influencing the conformational stability.

In the crystalline state, 2,5-dithiahexane exists in the GTG' form which has the *gauche* conformation about the two CS-CC axes. This form is also the most stable in the liquid state. These results are consistent with those obtained for the one-sulfur containing sulfides mentioned above.

The 2,5-dithiahexane molecule corresponds to the monomer unit of poly(thioethylene) $(-SCH_2CH_2-)_n$. Accordingly, the conformation of 2,5-dithiahexane in the crystalline state must be closely related to the chain conformation of poly(thioethylene). In fact, the poly(thioethylene) molecule takes the GTG'G'TG conformation for the series of S-C-C-S-C-C-S bonds according to the X-ray diffraction studies by Tadokoro *et al.*[9]

From the results for the unbranched ethers and sulfides stated above, the stable conformations of 2-oxa-5-thiahexane are expected to have the following factors. (1) About the CO-CC axis, the *trans* conformation is more stable than the *gauche* conformation. (2) About the OC-CS axis, the *gauche* conformation is as stable as the *trans* conformation. (3) About the CC-SC axis, the *gauche* conformation is slightly more stable than the *trans* conformation.

In the present study, 2-oxa-5-thiahexane was found to take the TTG form in the crystalline state. Most of the bands observed in the liquid state are explained by the existence of the four forms of TTG, TTT, TGT, and TGG, of which the TTG form is the most stable. These results are in good agreement with the above points for the stable conformations of this molecule.

In the present normal vibration calculations, 107 force constants were used for 2-oxa-5-thiahexane. However, the majority of the force constants was assumed to be the same as the corresponding force constants for the unbranched ethers and sulfides treated previously,[1,2] and only nine force constants characteristic of this molecule were determined by the least-squares method. The vibrational frequencies calculated from these force constants were indeed accurate enough to predict the rotational isomerism of this molecule.

Through the previous[1,2] and present studies on the vibration spectra and rotational isomerism of the unbranched ethers and sulfides, the following conclusions are drawn. (1) The force constants determined in these studies are satisfactorily transferable to similar molecules. (2) The conformational stabilities of the ethers and sulfides are consistently explained and it may be possible to predict stable isomers of similar molecules on the basis of the knowledge obtained in these studies. (3) The combined method of the systematic measurements of vibration spectra and the systematic normal vibration calculations is useful for the studies of the rotational isomerism of chain molecules. The measurement of Raman spectra is more important than that of infrared spectra. The former offers, without much difficulty, information on the low-frequency vibrations which are closely associated with the rotational isomerism. In addition, the temperature dependence of band intensities is more easily measured by the method of Raman spectroscopy.

V-51 and Mn-55 NMR Studies of Metal Carbonyls

Taku NAKANO*

Department of Chemistry, Faculty of Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 7, 1975)

The metal chemical NMR shifts of metal carbonyls are reported and discussed in relation to the bonding nature characteristic of carbonyl compounds of the $M(CO)_6$- and $Mn(CO)_5X$-types, where M is V or Mn, and X is a halogen or SCN. Theoretically evaluated chemical shift data based upon Ramsey's expression agree well with those observed for the $M(CO)_6$-type carbonyls. Regarding $Mn(CO)_5X$, the variation of the shifts for halogens is elucidated theoretically and revealed to be dependent upon the π-bonding nature between the metal and the halogen atom.

The stability of organometallic complexes in low oxidation states has been interpreted in terms of the formation of the covalent bonding between the metal atom and ligands, such as carbon monoxide and tertiary phosphines. This covalent bonding may be divided into σ-bonding and π-bonding parts; the latter is frequently called "back bonding" or "back donation." The basicity of carbon monoxide is relatively weak[1] and the coordination through a σ-bond is not enough to stabilize the complexes. On the other hand, the formation of the π-bond between the unfilled antibonding π-orbital on the carbon atom and the metal d-orbitals (d_{xy}, d_{yz}, d_{xz}) increases the double-bond character thereby strengthening the bonding between CO and the metal. Simultaneously, the back donation results in the dilution of the negative charge of the central metal, reducing the repulsive energy among the electrons. Cotton and Kraihanzel[2] calculated the force constants of the CO vibrations in a model system of metal carbonyls where both the σ- and π-bonds were taken into consideration. This led Graham[3] to the idea of the σ- and π-parameters in the bonding of metal carbonyls.

^{59}Co and ^{55}Mn NMR of metal carbonyls have been reported by Calderazzo *et al.*,[4] Onaka *et al.*,[5] and Bancroft *et al.*,[6] and ^1H NMR signals have been obtained for hydrides of metal carbonyl complexes.[7] ^{13}C NMR chemical shifts suggest the existence of a strong covalent bond between carbon and metal atoms.[8]

In order to investigate the bonding nature of metal carbonyls from the viewpoint of the magnetic character, $[V(CO)_6]^-$ and $[Mn(CO)_6]^+$ were chosen as typical compounds for the present study; they are highly symmetric and isotropic geometrically, electronically, and furthermore, magnetically. The ^{55}Mn chemical shifts of $Mn(CO)_5X$ with C_{4v} symmetry, as referred to below, are dependent on halogen atoms,[4] reflecting the bonding characters of the metal carbonyl derivatives.

The ^{51}V and ^{55}Mn chemical shifts were calculated using suitable molecular orbitals and the general formula derived by Ramsey;[9,10] the latter has been successfully applied to the calculation of ^{19}F chemical shifts by Saika and Slichter.[11]

Experimental

Metal Carbonyl Compounds. $Mn_2(CO)_{10}$ and $Na[V(CO)_6]$ were obtained from Pressure Chemical Company and Strem Chemicals Inc., respectively. Other metal carbonyl compounds were prepared by methods described in the literature.[12-19]

NMR Measurements. ^{51}V and ^{55}Mn NMR spectra were recorded on a Varian VF-16 spectrometer at 10.55 or 7.35, and 11.20 MHz, respectively.

A tetrahydrofuran or acetone solution, or a neat liquid of the metal carbonyls was sealed in glass tubes 15 mm in diameter. NMR measurements were carried out at 20°C.

The NMR signals of ^{51}V and ^{55}Mn of $KMnO_4$ were obtained in dispersion modes in order to avoid saturation. All other signals were recorded in absorption modes.

For the manganese compounds, potassium permanganate was used as the standard compound for the shifts and for the vanadium compounds, vanadium oxotrichloride was employed.

TABLE 1. CHEMICAL SHIFTS AND LINE WIDTHS OF METAL CARBONYLS

Compound	Solvent	Shift(ppm)	Width(Oe)
$[V(CO)_6]^-$	THF	2010±5	0.1
$[Mn(CO_6)]^+$	acetone	935±5	4.28
$HMn(CO)_5$	neat	2560±10	2.45±0.05
	THF	2630[a]	2.39[a]
	THF	2578[b]	2.28[b]
$Mn(CO)_5Cl$	THF	1003±10	0.30±0.01
	THF	1005[a]	0.182[a]
$Mn(CO)_5Br$	THF	1200±10	0.66
	THF	1160[a]	0.378[a]
$Mn(CO)_5I$	THF	1520±10	0.84±0.02
	THF	1485[a]	0.557[a]
$Mn(CO)_5SCN$	THF	1130±10	3.51

a) Values from Ref. 4. b) Values from Ref. 7.

Chemical Shift Data. The observed ^{51}V and ^{55}Mn chemical shift data are summarized in Table 1, together with those reported in the literature. All compounds examined give signals higher than that of the reference compound.

Calculation of the Chemical Shifts

The symmetries of the $M(CO)_6$- and $Mn(CO)_5X$-type compounds allow their electronic structures to be analyzed with the aid of the molecular orbital theory. The results can be compared with photoelectron and ultraviolet spectra.

The molecular orbitals of $[V(CO)_6]^-$ and $[Mn(CO)_6]^+$, and $Mn(CO)_5X$ reported by Beach and Gray[20] and Fenske and DeKock[21] were applied here to estimate the

* Present Address: Faculty of Pharmaceutical Sciences, University of Toyama, Gofuku, Toyama 930.

chemical shifts in these compounds.

According to Ramsey,[10] the chemical shift is expressed by the following formula,

$$\sigma = e^2/mc^2\langle 0|\sum_k (x_k^2+y_k^2)/r_k^3|0\rangle - 2\sum_n (1/(E_n-E_0))\{\langle 0|\sum_k m_{zk}^0|n\rangle\langle n|\sum_{k'} m_{zk'}^0/r_{k'}^3|0\rangle + \langle 0|\sum_k m_{zk}^0/r_k^3|n\rangle\langle n|\sum_{k'} m_{zk'}^0|0\rangle\}, \quad (1)$$

where

$$m_{zk}^0 = -e\hbar/2mci(x_k\partial/\partial y_k - y_k\partial/\partial x_k) \quad (2)$$

and $|0\rangle$ and $|n\rangle$ denote the ground state and the n th excited state wave functions of the molecule, respectively, with E_0 and E_n being the energies of the corresponding states. The other symbols have their usual meanings.

In order to simplify the system, we assumed that only the d-electrons of the central atoms contribute to the paramagnetic term; the core electrons are assumed not to contribute to the matrix elements $\langle 0|m_{zk}^0|n\rangle$ and $\langle 0|m_{zk}^0/r_k^3|n\rangle$. Contribution from 4p-electrons and the variation of the orbital exponents caused by the bond formation are neglected here.

$M(CO)_6$-type Carbonyls. Applying Eq. 1 to the $M(CO)_6$-type carbonyls, we obtain the following reduced equation for the chemical shift,

$$\sigma = \sigma_P + \sigma_D \quad (3)$$

$$\sigma_P = -8e^2\hbar^2/m^2c^2\langle 1/r^3\rangle_{3d}\sum_{i,j} C_i^2C_j^2/\Delta E(i,j) \quad (4)$$

$$\sigma_D = e^2/3mc^2\{\langle 1/r\rangle_{3d}P_{3d} + \langle 1/r\rangle_{4s}P_{4s} + \langle 1/r\rangle_{4p}P_{4p} + \sum_k^{\text{core}}\langle 1/r\rangle_k\}, \quad (5)$$

where C_i is the coefficient of the i th atomic d-orbital in the molecular orbital of t_{2g} or e_g symmetry and $\langle 1/r\rangle_k$ and $\langle 1/r^3\rangle_k$ are the average values of $1/r$ and $1/r^3$ for the k th orbital, respectively. Here, we assume that the $\langle r^n\rangle_k$ values are those of free atoms. P_i is the electron population of the corresponding orbital defined by Mulliken.[22] $\Delta E(i,j)$ is the transition energy between the i th and j th levels.

TABLE 2. CALCULATED VALUES FOR $\langle 1/r\rangle$, $\langle 1/r^3\rangle$, AND $\langle r^2\rangle$ IN ATOMIC UNITS

	Vanadium complexes	Manganese complexes
$\langle 1/r\rangle_{1s}$	22.395	24.385
$\langle 1/r\rangle_{2s}$	5.018	5.540
$\langle 1/r\rangle_{3s}$	1.507	1.680
$\langle 1/r\rangle_{4s}$	0.322	0.347
$\langle 1/r\rangle_{2p}$	4.625	5.075
$\langle 1/r\rangle_{3p}$	1.237	1.392
$\langle 1/r\rangle_{4p}$	0.191	0.200
$\langle 1/r\rangle_{3d}$	0.849	1.020
$\langle 1/r^3\rangle_{3d}$	2.0755	3.2484
$\langle r^2\rangle_{1s}$	0.0060	0.0050
$\langle r^2\rangle_{2s}$	0.1132	0.0937
$\langle r^2\rangle_{3s}$	1.0441	0.8508
$\langle r^2\rangle_{4s}$	14.7720	12.5757
$\langle r^2\rangle_{2p}$	0.0877	0.0728
$\langle r^2\rangle_{3p}$	1.1978	0.9489
$\langle r^2\rangle_{4p}$	39.0585	36.1045
$\langle r^2\rangle_{3d}$	3.9738	2.7711

On estimating the $\langle r^n\rangle_k$ values, the Richardson wave functions[23] for the radical parts of the metal orbitals were adopted as in the treatments of the calculations of the molecular orbitals.[20,21] The calculated values of $\langle 1/r\rangle_k$ and $\langle 1/r^3\rangle_k$ are listed in Table 2 together with the values of $\langle r^2\rangle_k$ which are used in the Appendix.

For the closure approximation in this system, one should consider that t_{2g} is the highest occupied orbital and e_g is the lowest vacant one, and that only the $\langle t_{2g}|\boldsymbol{m}|e_g\rangle$ and $\langle t_{2g}|\boldsymbol{m}/r^3|e_g\rangle$ components have non-zero values. Thus, the transition energy is between the $^1A_{1g}$ and $^1T_{1g}$ states. Though the electron transition between the t_{2g} and e_g levels is forbidden and is masked in the intensive charge-transfer bands, the values of ΔE_{av} were adopted from the results obtained by Beach and Gray,[20] employing Gaussian analysis of the electronic spectra. These values are 25500 cm^{-1} for $[V(CO)_6]^-$ and 41050 cm^{-1} for $[Mn(CO)_6]^+$.

TABLE 3. ESTIMATED CHEMICAL SHIFT VALUES FOR $[Mn(CO)_6]^+$ AND $[V(CO)_6]^-$

Compound	Calculated value (ppm) σ_D	σ_P	$\sigma=\sigma_D+\sigma_P$	Chemical shift	Experimental value (ppm) *vs.* $KMnO_4$ or K_3VO_4
$[Mn(CO_6)]^+$	1915	−6102	−4187	928	935±5
$KMnO_4$	1900	−7015	−5115		
$[V(CO)_6]^-$	1718	−5993	−4275	612	1480±5
K_3VO_4	1708	−6595	−4887		

The results are summarized in Table 3. The chemical shifts for the reference compounds are estimated in the Appendix.** The calculated values of σ_D are in good agreement with those obtained by Dickinson[24] in the Hartree-Fock approximation. Here, the following values are used: $P_{3d}=6.37$, $P_{4s}=0.00$, $P_{4p}=0.14$ for manganese and $P_{3d}=4.36$, $P_{4s}=0.06$, $P_{4p}=0.19$ for vanadium.[20]

In order to further improve the approximation, one should consider other non-zero matrix elements between the more highly-excited states and the ground state. The transition energies are assumed to be the difference between the orbital energies of the corresponding molecular orbitals, which are partly quoted in Table 4.

Thus, the paramagnetic part of Eq. 1 becomes

$$\sigma_P = -e^2\hbar^2/m^2c^2\langle 1/r^3\rangle_{3d}\{8C_{3e_g}^2C_{2t_{2g}}^2/\Delta E(3e_g, 2t_{2g}) + 4C_{3t_{2g}}^2C_{2t_{2g}}^2/\Delta E(3t_{2g}, 2t_{2g}) + 8C_{3t_{2g}}^2C_{2e_g}^2/\Delta E(3t_{2g}, 2e_g)\}, \quad (6)$$

where C_i is the coefficient of the d-orbital of the molecular orbitals, i denotes the symmetry of the corresponding orbital, and $\Delta E(i,j)$ is the difference in energy between the i and j levels.

The values obtained are given in Table 5, and the non-zero terms are listed with transition energies and calculated σ_P values. The values of σ_P are not very far

** The signal for vanadium oxotrichloride appears at a value 533 ppm below that for potassium vanadate.[25]

$$\sigma_P = -e^2\hbar^2/3m^2c^2\langle 1/r^3\rangle_{3d}\{8\sum_{i,j}^{b_1,b_1} C_i^2C_j^2/\Delta E(i,j) + 4\sum_{i,j}^{e,b_1} C_i^2C_j^2/\Delta E(i,j) + 12\sum_{i,j}^{e,a_1} C_i^2C_j^2/\Delta E(i,j) + 4\sum_{i,j}^{e,e} C_i^2C_j^2/\Delta E(i,j) + 4\sum_{i,j}^{e,b_1} C_i^2C_j^2/\Delta E(i,j)\}, \quad (7)$$

where $\sum_{i,j}^{k,l}$ means the summation of matrix elements between the orbitals of k and l symmetries, and $\Delta E(i,j)$ is the transition energy between the i and j levels. All possible excited states for a single electron transition from the ground state are considered. The values of σ_P resulting from the above calculation are listed in Table 7, together with the values of σ_D which are calculated from Eq. 5 for 3d-orbital populations of $P_{3d}(Cl)=5.687$, of $P_{3d}(Br)=5.723$, of $P_{3d}(I)=5.747$, those of the other P_is being unity.[21]

Table 7. Estimated chemical shift values for $Mn(CO)_5X$

Compound	Calculated value (ppm)		Observed (ppm)
	σ_D	σ_P	σ_P
$Mn(CO)_5Cl$	1897	−2722	−6009
$Mn(CO)_5Br$	1898	−2696	−5813
$Mn(CO)_5I$	1899	−2615	−5494

Though the calculated values for σ_P are almost one half of those obtained experimentally, the order of the chemical shifts for the halogen atom series is in agreement with that observed.

Discussion

The calculated values of the shifts of hexacarbonylmetal compounds based upon the molecular orbitals of Beach and Gray[20] agree well with the experimental results. This leads us to conclude that the paramagnetic term contributes dominantly to the shifts, and that the chemical shift directly reflects the nature of the chemical bond. This is more clearly revealed in the case of pentacarbonylmanganese halides and thiocyanate.

Though the calculated chemical shifts of pentacalbonylmanganese halides do not quite agree with the experimental values, it is clear that the dominant change of the shifts is due to the paramagnetic terms, while the diamagnetic terms vary only slightly. In the approximation described above, in which only the matrix elements involving the d-orbitals are taken into account, the calculated values of the paramagnetic terms are about one half of those observed. The paramagnetic terms under consideration involve only with the squares of the coefficients of the metal d-orbitals, so that the calculated values should be somewhat smaller than those obtained experimentally. In order to improve the agreement between the theoretical and experimental results, the cross terms between the d-orbitals of the metal and the orbitals of the ligand should be considered.***

The chemical shifts are linearly correlated with the electronegativity of the halogen and pseudohalogen; the shifts decrease with increasing electronegativity. In plotting the shifts versus the Schwarzenbach bond strength,[25] an appropriately linear relationship is obtained.

*** The theoretical treatmant will be reported elsewhere.

If halogen atoms withdraw electrons from the central metals, the diamagnetic shielding would decrease and the nuclei would be less shielded. However, the fact that the total 3d-orbital populations are essentially constant, as shown by the Fenske molecular orbitals, indicates that a variation in σ_D terms is unlikely. Thus, the order of the shifts for the various halogens can be elucidated using the paramagnetic term. Thus, the next problem is to determine which part should dominantly contribute to the paramagnetic term.

Table 8. Chemical shift values, σ_P, in parts of $Mn(CO)_5X$

Mixing		$Mn(CO)_5Cl$		$Mn(CO)_5Br$		$Mn(CO)_5I$	
		$\Delta E(i,j)$ (eV)	$-\sigma_P$ (ppm)	$\Delta E(i,j)$ (eV)	$-\sigma_P$ (ppm)	$\Delta E(i,j)$ (eV)	$-\sigma_P$ (ppm)
$2b_2$	$5b_1$	12.325	560.7	12.274	563.6	12.229	566.0
$4b_1$	$3b_2$	25.680	63.0	25.595	63.3	25.217	63.5
$2b_2$	9e	13.443	133.2	13.294	134.4	13.129	136.7
7e	$3b_2$	11.835	164.3	11.641	184.5	11.514	195.0
8e	$3b_2$	8.975	46.0	8.057	27.5	7.536	17.5
$9a_1$	9e	13.599	47.0	12.671	66.8	11.806	90.0
$8a_1$	9e	26.066	52.8	25.952	53.1	25.618	4.1
7e	$11a_1$	17.455	99.5	17.211	99.4	16.968	97.3
8e	$11a_1$	14.595	25.3	13.629	13.0	12.990	7.5
7e	$10a_1$	10.414	775.0	10.475	827.4	10.465	833.0
8e	$10a_1$	7.554	226.9	6.891	129.9	6.487	78.9
7e	$5b_1$	11.929	264.1	11.766	295.3	11.681	310.1
8e	$5b_1$	9.090	73.8	8.182	43.9	7.703	27.6
$4b_1$	9e	26.893	25.3	26.741	25.3	26.584	25.5
7e	9e	13.048	125.2	12.786	140.4	12.581	149.3
8e	9e	8.586	40.4	9.202	20.1	8.603	12.8

As shown in Table 8, which gives the parts of the paramagnetic terms, the variations of the paramagnetic shifts are caused mostly by terms involving mixing between the 8e and $10a_1$ levels. The summation of the other parts leads to almost the same values for three halogen derivatives. For the values of $\Delta E(i, j)$, no significant variations are found. On the other hand, the variation of the coefficients of the d-orbitals in the 8e orbitals plays an important role in the evaluation of matrix elements such as $\langle 8e|\boldsymbol{m}|10a_1\rangle$.

While the a_1 symmetric orbitals form the σ-bonds, the e symmetric orbitals form π-bonds between the metal and halogen atoms. Consequently we conclude that the π-bonding between metal and halogen atoms is a dominant cause of the chemical shifts, and the σ-bonding does not vary the values very much. This suggests that the Graham σ-parameter makes almost no contribution to the chemical shifts but that π-parameter must be closely related to these values.

It should be pointed out that the variation of the chemical shifts depends upon the π-bond which has been neglected so far in discussing the nature of halogen-metal bonds. If the ligands have the ability to form π-type bonds with the metal, this effect appears to be larger than that of the halogen ligands.

It should be emphasized that the values of the paramagnetic term increase in the order H<I<Br<Cl<CO; especially we note here that hydrogen has the

least tendency to form π-bond and carbon monoxide has the greatest. The π-bonding which seems to stabilize the low oxidation states in the metalcarbonyl can be estimated from the NMR chemical shifts. The π-bond formation in other halogen compounds can be predicted from these shifts.

For pentacarbonylmolybdenum halides reported by Takano,[26] a similar relation between the chemical shifts and the halogen atoms has been found, although the differences between the chemical shifts are less than those in the case of manganese compounds: 1584 ppm for $Mo(CO)_5Cl$, 1596 ppm for $Mo(CO)_5Br$, and 1709 ppm for $Mo(CO)_5I$ against potassium molybdate.

The author would like to express his sincere thanks to Professor Yukiyoshi Sasaki of The University of Tokyo and Professor Shigeyuki Aono of Kanazawa University for valuable discussions.

Appendix

Evaluation of the Chemical Shifts of $KMnO_4$ and K_3VO_4. The molecular orbitals of the $[MnO_4]^-$ ion have been calculated by several authors, but the computation of the energies is not yet adequate to explain the electronic structure accurately. The bonding between oxygen and manganese is covalent, and the electrons which contribute to the paramagnetism come from ligand oxygen; the d-electron population of the central manganese atom is 6.15 according to the molecular orbitals of Brown.[27]

Since the results of the calculation of the paramagnetism are not satisfactory, the shifts are estimated empirically as follows.

The magnetic susceptibility of $KMnO_4$, $\chi_g=0.175\times10^{-6}$ cm^3/g,[28] is divided into two parts, paramagnetic and diamagnetic terms, which in units of moles, is

$$\chi_M(KMnO_4) = \chi_M^D(KMnO_4) + \chi_M^P(KMnO_4) \quad (1)$$

and

$$\chi_M^D(KMnO_4) = \chi_M^D(Mn) + \chi_M^D(K^+) + \chi_M^D(4O^{2-}) \quad (2)$$

$$\chi_M^D(Mn) = -N(e^2/6mc^2)\sum_i\langle r^2\rangle_i, \quad (3)$$

where

$$\sum_i\langle r^2\rangle_i = \sum_i^{core}\langle r^2\rangle_i + P_{4s}\langle r^2\rangle_{4s} + P_{4p}\langle r^2\rangle_{4p} + P_{3d}\langle r^2\rangle_{3d}, \quad (4)$$

N is the Avogadro number, and P_i is the electron population of the i th orbital; $P_{4s}=0.24$, $P_{4p}=0.16$, $P_{3d}=6.15$.[27]

$\chi_M^D(4O^{2-})$ is estimated to be the difference of the sums of the empirical values for O^{2-} and O ($\chi_M^D(O^{2-})=-13.7\times10^{-6}$ and $\chi_M^D(O)=-5.3\times10^{-6}$ cm^3/mol[28]):

$$\chi_M^D(4O^{2-}) = (8-P_{3d}-P_{4s}-P_{4p}) \times (\chi_M^D(O^{2-})-\chi_M^D(O)) + 4\times\chi_M^D(O). \quad (5)$$

$\chi_M^D(Mn)=-26.82\times10^{-6}$ and $\chi_M^D(K^+)=-14.9\times10^{-6}$ cm^3/mol.[28] From Eq. 2, $\chi_M^D(KMnO_4)=-68.6\times10^{-6}$ cm^3/mol.

Since $\chi_M(KMnO_4)=\chi_g\times$(molecular weight)$=27.7\times10^{-6}$ cm^3/mol, Eq. 1 gives $\chi_M^P(KMnO_4)=96.36\times10^{-6}$ cm^3/mol.

The paramagnetic shift has the following relation to $\chi_M^P(KMnO_4)$:

$$\sigma_P = 2/N\times\langle 1/r^3\rangle_{3d}\chi_M^P(KMnO_4) \quad (6)$$

neglecting the contribution from 4p-electrons. $\sigma_P(KMnO_4)$ is calculated to be 7015 ppm.

For potassium vanadate, the values were calculated similarly using the following data: $P_{4s}=0.0148$, $P_{4p}=0.3519$, $P_{3d}=3.7167$,[30] and $\chi_g=-0.08\times10^{-6}$ cm^3/g.[31]

Thus, we obtain $\chi_M^P(K_3VO_4)=95.9$ cm^3/mol and evaluate the shift for potassium vanadate to be $\sigma_p(K_3VO_4)=6595$ ppm.

The shift of the diamagnetic term is found to be

$$\sigma_D = e^2/3mc^2\sum_i\langle 1/r\rangle_i,$$

where

$$\sum_i\langle 1/r\rangle_i = \sum_i^{core}\langle 1/r\rangle_i + P_{4s}\langle 1/r\rangle_{4s} + P_{4p}\langle 1/r\rangle_{4p} + P_{3d}\langle 1/r\rangle_{3d}. \quad (8)$$

The values in Table 2 are used for $\langle 1/r\rangle_i$s and the values of P_is as above, and we obtain $\sigma_D(KMnO_4)=1900$ ppm and $\sigma_D(K_3VO_4)=1708$ ppm.

Studies of the Ruthenium Complexes. XIII. Kinetic Studies of Electron-transfer Reactions between Aquapentaammineruthenium(II) and Halopentaammineruthenium(III) Comlexes

Akira OHYOSHI, Kenichiro YOSHIKUNI, Hidetoshi OHTSUYAMA, Tomohisa YAMASHITA, and Shigeyoshi SAKAKI

(Received February 14, 1976)

Kinetic measurements of the electron-transfer reactions from $Ru(OH_2)(NH_3)_5^{2+}$ to $RuX(NH_3)_5^{2+}$, where X=Cl, Br, and I, have been made in aqueous solutions. The reaction rate is independent of the hydrogen-ion concentration, while it is greatly influenced by the ionic strength of the reaction solution. The rate constants were determined to be 147, 172, and 293 $M^{-1}s^{-1}$ for the reaction systems of chloro- bromo- and iodopentaammineruthenium(III) ions respectively at 25 °C in a solution with an ionic strength of 0.0944 M. The activation parameters, (ΔH^* kcal mol^{-1}, ΔS^* cal K^{-1} mol^{-1}), were (19.4, 16), (18.9, 15), and (11.2, −10) respectively, for the same systems. From the facts that the reaction rate decreases in the order of I>Br>Cl and that the ionic strength of the solution strongly affects the reaction rate, it may be concluded that the present electron-transfer reactions proceed by means of an outersphere-type mechanism.

The reduction reactions of ruthenium(III) ammine complexes have been studied by use of such reductants as Cr(II),[1-3] V(II),[3] the Ru(II) complex,[4] and divalent rare earth ions.[3,5] Since the reduced ruthenium(II) ammines are labile, reactions such as aquation and reoxidation proceed successively to complicate the redox reactions. Electron-transfer reactions from aquapentaammineruthenium(II) to halopentaammineruthenium(III) ions are observed in the radiolysis[6] and the electrochemical reactions.[7,8] However, there have been few quantitative investigations with respect to the kinetics and the reaction mechanism.

The present report will deal with the reaction kinetics of halopentaammineruthenium(III) with the aquapentaammineruthenium(II) ion, and an attempt to elucidate the reaction mechanism will be made on the basis of the kinetic sequences. The reaction rate was spectrophotometrically determined in solutions with various hydrogen-ion concentrations and ionic strengths.

Experimental

Materials. The halopentaammineruthenium(III) halides were prepared from ruthenium trichloride by the previously reported procedures.[9] The complex *p*-toluenesulfonates were recrystallized from a saturated *p*-toluenesulfonate solution. The chemical purities of the products were confirmed spectrophotometrically.[9,10] The reductant, the $Ru(OH_2)(NH_3)_5^{2+}$ ion solution, was prepared from iodopentaammineruthium(III) and zinc amalgam in a deaerated solution with high-purity argon gas. The water was triply distilled.

Procedures. The reductant solution was rapidly added to a deoxygenated solution of the halopentaammineruthenium(III) ion. The pH and the ionic strength of this solution were adjusted with *p*-toluenesulfonic acid and its sodium salt. Before mixing, the solutions were thermostated in a water bath at constant temperatures. The reaction rates were determined by measuring the change in the absorbance at given wave numbers[9] as a function of the reaction time—for instance, at 30.5×10^3 cm^{-1} (ε=1930 M^{-1} cm^{-1}) for chloropentaammine, at 25.1×10^3 cm^{-1} (ε=1980 M^{-1} cm^{-1}) for bromopentaammine, and at 18.5×10^3 cm^{-1} (ε=2050 M^{-1} cm^{-1}) for iodopentaammine. The concentrations of reactants were chosen to be $(2—5)\times10^{-4}$ M for $RuX(NH_3)_5^{2+}$ and $(1—5)\times10^{-5}$ M for $Ru(OH_2)(NH_3)_5^{2+}$ in the reaction solution. A Shimadzu UV 200 spectrophotometer was used for all the experiments.

Results and Discussion

The progressive changes in the absorption spectrum are shown in Fig. 1 for the electron-transfer reaction of the chloropentaammine complex. The absorption band at 30.5×10^3 cm^{-1} of the original complexes[9] rapidly decreases as the reaction proceeds. The absorption band at 37.3×10^3 cm^{-1} of the reaction product,[1] $Ru(OH_2)(NH_3)_5^{3+}$, could not be observed since there is an intense absorption of *p*-toluenesulfonate in the region higher than 36×10^3 cm^{-1}. However, this product was identified in a separate experiment[10] in the absence of *p*-toluenesulfonate. Similar changes in the absorption spectrum were observed in the reactions of the other complexes.

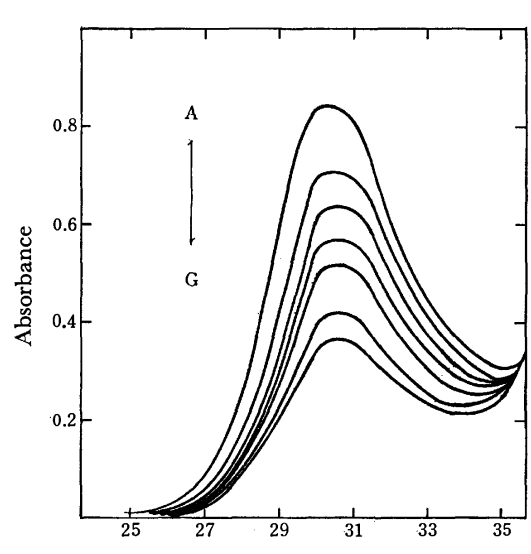

Fig. 1. Changes of absorption spectrum during reduction of $RuCl(NH_3)_5^{2+}$ with $Ru(OH_2)(NH_3)_5^{2+}$ at 30 °C. Curve A is the initial trace followed successively by traces at 25, 50, 85, 125, 180, and 220 (G) sec reaction.

Here, we assumed the following mechanism:

$$Ru^{III}X(NH_3)_5^{2+} + Ru^{II}(OH_2)(NH_3)_5^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ru^{II}X(NH_3)_5^{+} + Ru^{III}(OH_2)(NH_3)_5^{3+} \quad (1)$$

$$Ru^{II}X(NH_3)_5^{+} + H_2O \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Ru^{II}(OH_2)(NH_3)_5^{2+} + X^- \quad (2)$$

The rate constants have been given[8] as $k_2=6.3\ s^{-1}$, $k_{-2}=9.0\ M^{-1}\ s^{-1}$ for the chlorocomplex and $k_2=5.4\ s^{-1}$, $k_{-2}=5.9\ M^{-1}\ s^{-1}$ for the bromocomplex at 25 °C and at an ionic strength of 0.1 M. The rate formula with respect to the ruthenium complex in Reactions 1 and 2 can be expressed by Eqs. 3—6:

$$d[Ru^{III}X(NH_3)_5^{2+}]/dt = -k_1[Ru^{III}X(NH_3)_5^{2+}][Ru^{II}(OH_2)(NH_3)_5^{2+}] + k_{-1}[Ru^{II}X(NH_3)_5^{+}][Ru^{III}(OH_2)(NH_3)_5^{3+}] \quad (3)$$

$$d[Ru^{II}(OH_2)(NH_3)_5^{2+}]/dt = -k_1[Ru^{III}X(NH_3)_5^{2+}][Ru^{II}(OH_2)(NH_3)_5^{2+}] + k_{-1}[Ru^{II}X(NH_3)_5^{+}][Ru^{III}(OH_2)(NH_3)_5^{3+}] + k_2[Ru^{II}X(NH_3)_5^{+}] - k_{-2}[Ru^{II}(OH_2)(NH_3)_5^{2+}][X^-] \quad (4)$$

$$d[Ru^{II}X(NH_3)_5^{+}]/dt = k_1[Ru^{III}X(NH_3)_5^{2+}][Ru^{II}(OH_2)(NH_3)_5^{2+}] - k_{-1}[Ru^{II}X(NH_3)_5^{+}][Ru^{III}(OH_2)(NH_3)_5^{3+}] - k_2[Ru^{II}X(NH_3)_5^{+}] + k_{-2}[Ru^{II}(OH_2)(NH_3)_5^{2+}][X^-] \quad (5)$$

$$d[Ru^{III}(OH_2)(NH_3)_5^{3+}]/dt = k_1[Ru^{III}X(NH_3)_5^{2+}][Ru^{II}(OH_2)(NH_3)_5^{2+}] - k_{-1}[Ru^{II}X(NH_3)_5^{+}][Ru^{III}(OH_2)(NH_3)_5^{3+}] \quad (6)$$

In the initial period of the reaction, the concentration of $RuX(NH_3)_5^{+}$ may be negligibly small, because the rate of aquation (Eq. 2) is large as compared with that of the reverse reaction. In the initial stationary-state period, therefore, Eq. 3 can be simplified to Eq. 7:

$$-d[Ru^{III}X(NH_3)_5^{2+}]/dt = k_1[Ru^{III}X(NH_3)_5^{2+}][Ru^{II}(OH_2)(NH_3)_5^{2+}] \quad (7)$$

The plot of $\log[Ru^{III}X(NH_3)_5^{2+}]$ *vs.* the reaction time shows a good linearity for about 60 s after the initiation. The slope of the first-order plot is independent of the initial concentrations of the complex and the hydrogen ion. The rate constants, k_1 calculated from Eq. 7 as a function of the reactant and the hydrogen-ion concentration and of the ionic strength are listed in Table 1. The second-order rate constant, k_1, is independent of the concentrations of the reactants and the hydrogen ion, but increases with an increase in the ionic strength. Applying the simplified Brønsted-Bjerrum-Christiansen formulation,[11] the dependence of the k_1 value on the ionic strength was investigated. Figure 2 shows the relationship between k_1 and the ionic strength, I. The slope of the straight line is nearly +4; this fact suffices to show that the charge product of the reacting particles is four at the transition state of Reaction 1. This effect is similar to those in the reactions of $Ru(NH_3)_6^{2+}$ with $CoX(NH_3)_5^{2+}$, (X=Br, I) and $CoCl_2(en)_2^{+}$ ions.[2]

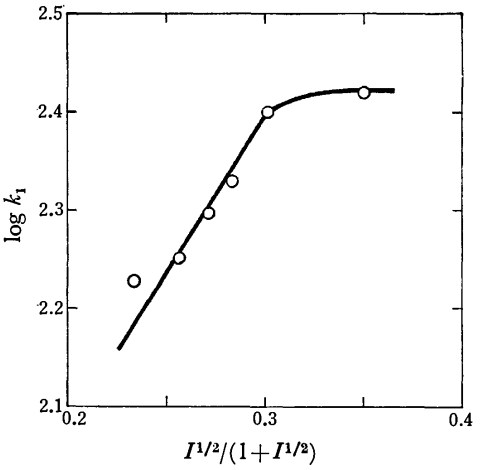

Fig. 2. Effect of ionic strength on the electron transfer reaction rate of $RuCl(NH_3)_5^{2+}$ with $Ru(OH_2)(NH_3)_5^{2+}$ at 30 °C, $[H^+]=0.0944$ M.

The curve-fitting method with various k_{-1} values was applied to the reaction between $RuCl(NH_3)_5^{2+}$ and $Ru(OH_2)(NH_3)_5^{2+}$ using the values of $k_1=147\ M^{-1}\ s^{-1}$, $k_2=6.3\ s^{-1}$, and $k_{-2}=9.0\ M^{-1}\ s^{-1}$. As is shown in Fig. 3, the experimental plot of the concentration variation for the $RuCl(NH_3)_5^{2+}$ species falls on the calculated curve when $k_{-1}\leqq 100\ M^{-1}\ s^{-1}$. The concentration variations of the other species in Reactions 1 and 2 were calculated by means of the numerical integration of Eqs. 3—6 using the same values of the rate constants. The results are also given in Fig. 3. The concentration of the intermediate, $[RuCl(NH_3)_5^{+}]$, is less than those of the other species by a factor of about 10^{-2}—10^{-3}, and it instantly reaches a maximum after the initiation of the reaction. The concentration of $[Ru(OH_2)(NH_3)_5]^{2+}$ decreases momentarily upon initiation, and then it increases very slowly.

The kinetic parameters for the electron-transfer reactions of the halogenopentaammineruthenium(III) complexes are exhibited in Table 2, along with those for the

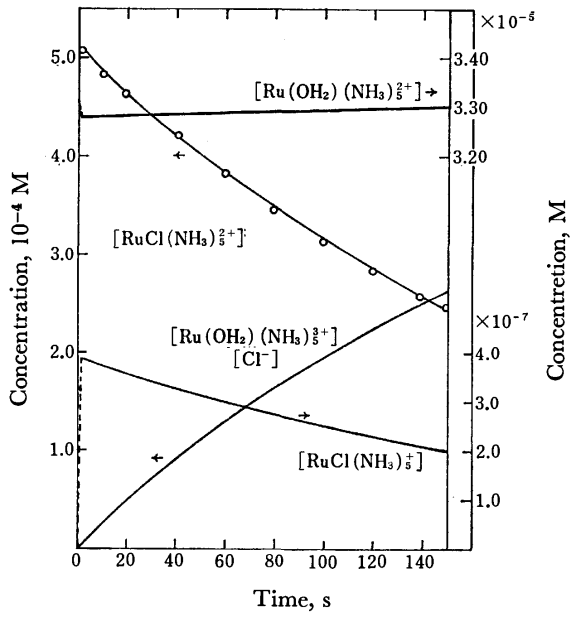

Fig. 3. Concentration variation of chemical species participating in the electron transfer reaction of $RuCl(NH_3)_5^{2+}$ with $Ru(OH_2)(NH_3)_5^{2+}$ at 25 °C, $[RuCl(NH_3)_5^{2+}]_{t=0}=5.10\times10^{-4}$ M, $[RuOH_2(NH_3)_5^{2+}]_{t=0}=3.32\times10^{-5}$ M, $I=[H^+]=0.0944$ M.
○: Experimental, —: calculated.

reference reactions. All the rate constants are determined in the solution with I=0.094 M. The order of the magnitude of the rate constants is chloropentaammine< bromopentaammine<iodopentaammine. This order is not the same as that of 3.5×10^4 M^{-1} s^{-1}>2.2×10^3 M^{-1} s^{-1}>2.6×10^2 M^{-1} s^{-1} estimated on the basis of the analysis of catalytic reactions involved in the process of the electron transfer between halogenopentaammines and Cr(II).[3] The relative rates (chloro: bromo: iodo) are 135: 8: 1 for the Cr(II) reaction and 57: 12: 1 for the reaction with Eu(II). On the other hand, the relative rates are 1: 1.7:—[12] for the V(II) reaction, and 1: 1.2: 2.0 at 25 °C or 1: 1.7: 2.4 at 30 °C for the present reaction with $Ru(OH_2)(NH_3)_5^{2+}$. The reactions of the ruthenium(III) halopentaammines with Cr(II) and Eu(II) are innersphere, while the reactions with V(II) are of the outersphere type.[3] This similarity in the relative reactivity may support the theory that the present reaction has an outersphere mechanism.

An outersphere process often occures when both reactants of the electron-transfer reaction are inert to substitution over the period required for the electron-transfer process. A typical reaction can be found in a homonuclear self-exchange electron transfer such as the reaction between $Ru(NH_3)_6^{3+}$ and $Ru(NH_3)_6^{2+}$ ions.[4] In the present study, all of the oxidants contain halide ligands which can interact with the reducing cation,

Table 2. Kinetic parameters for the electron-transfer reactions of halogenopentaammineruthenium(III) complexes

while the reductant has a water molecule in the coordination sphere which is weakly capable of reacting with the oxidizing cation. The rate constants for the aquation of halogenopentaammineruthenium(III) have been determined to be 3.28×10^{-4} s^{-1} for the chlorocomplex, 3.99×10^{-4} s^{-1} for the bromocomplex, and 1.64×10^{-4} s^{-1} for the iodocomplex at 54.5 °C.[13] These values are smaller than those of the pseudo-first-order rate constants for the correspondings electron-transfer reactions. The rate constants for the anations of the chloride and bromide ions to $Ru(OH_2)(NH_3)_5^{2+}$ have been determined to be 9.0 M^{-1} s^{-1} and 5.9 M^{-1} s^{-1} at 25 °C respectively.[8] These values are also smaller than those for the electron-transfer reactions. Thus, the substitution on either $RuX(NH_3)_5^{2+}$ or $Ru(OH_2)(NH_3)_5^{2+}$ is not rate-determing; hence, the outersphere mechanism is applicable to the present electron-transfer reactions.

In Table 2, the values of both ΔH^* and ΔS^* are practically the same for the reactions of chloro and bromopentaammines, and for the reactions of the $RuI(NH_3)_5^{2+}$-$Ru(OH_2)(NH_3)_5^{2+}$ and $Ru(NH_3)_6^{3+}$-$Ru(NH_3)_6^{2+}$ systems. This suggests that the energy change to form the reaction intermediate is the same for both the reaction systems. The electron-transfer reactions of halopentaammines with the simple metal ions are characterized by small values of ΔH^* and large negative values of ΔS^*. The reactions with Cr_{aq}^{2+} and Eu_{aq}^{2+} are regarded as of the innersphere type,[3,5] while the reaction with V_{aq}^{2+} is accounted for by the outersphere mechanism.[3] Hence, it is inadequate to distinguish the innersphere and outersphere mechanisms by only the aid of the activation parameters.

The Influence of a Co-ion on the Potential of a Liquid Ion-exchnger Membrane Electrode

Akinori Jyo, Kazumi Fukamachi, Wataru Koga, and Nobuhiko Ishibashi

Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received April 8, 1976)

The potential of a liquid ion-exchanger membrane electrode was affected by a co-ion, *i.e.*, an ionic species with the same charge sign as the ion-exchange site in the liquid membrane, when the co-ion in the sample was lipophilic. An aspect of the influence or interference of the co-ion on the response of the electrode is clarified theoretically, based on the three-region concept of the membrane potential. Theoretical predictions of the co-ion interference are illustrated by the measurement of potentials of a nitrate-sensitive nitrobenzene membrane electrode for sample solutions containing sodium nitrate, tetramethylammonium nitrate and the like. The co-ion interference became more important for increased extractability of the co-ion in the nitrobenzene–water system, specifically the order is $Rb^+ < Cs^+ < (CH_3)_4N^+$, and for a decrease in the concentration of the ion-exchanger in the membrane. Co-ion interference appeared for high concentration levels of the ion to be determined and produced a negative error in the activity measurement. The results are in good agreement with the theoretical predictions.

Recently, it has been pointed out both theoretically and experimentally that the interference of an ionic species with the charge sign opposite to that of the ion to be determined, the so-called co-ion, causes problems in the activity measurement of the ion using a liquid membrane electrode of the neutral carrier type.[1-4] According to the Teorell-Meyer-Sievers theory of membrane potentials,[5] the interference of a co-ion is anticipated in the response of a usual liquid ion-exchanger membrane electrode. Nevertheless, studies on the influence of a foreign ion on the response of such an electrode has been heretofore restricted to the interference of an ionic species with the same charge sign as the ion to be determined, the so-called counter ion. Little, therefore, is known about the effects of co-ion interference on the response of a liquid ion-exchanger membrane electrode.

In this report, the membrane potential of a liquid ion-exchanger membrane electrode is discussed theoretically in the case in which the co-ion in the sample solution is not completely rejected by the membrane, and the theoretical predictions are compared with experimental results.

Theoretical

We will analyze the membrane potential of the following membrane system with the help of a three-region concept of the membrane potential, *i.e.*, the regions of the two interfacial potential differences and of the diffusion potential in the membrane. The membrane system consists of a liquid ion-exchanger and two aqueous solutions. The membrane contains an electrolyte S-i, and is denoted by an asterisk. One aqueous solution marked by a prime contains an electrolyte A-i, and corresponds to the inner reference solution of an i ion-sensitive liquid ion-exchanger membrane electrode. The other solution designated by a double prime contains an electrolyte B-i and corresponds to the sample solution. We take the space coordinate x to be in the direction of the membrane thickness. The origin of the x-axis is placed at the membrane-reference solution interface. The x value of the other interface is denoted by d. The following assumptions are made:

(i) All the electrolytes dissociate completely in all phases.

(ii) The ion-exchange site S is confined to the membrane, and the concentration of ion-exchange sites in the membrane C_s^* is constant throughout.

(iii) While co-ion A in the reference solution is completely rejected by the membrane, co-ion B in the sample solution is not completely rejected by the membrane, and dissolves into the membrane with the ion i.

(iv) The concentrations are equal to the activities and vary linearly with x within the membrane.

(v) Electroneutrality holds.

First, the equation which expresses the diffusion potential in the membrane is derived. According to the Nernst-Planck equation, we can write this as:

$$\phi_n^* = -U_n^* C_n^* (\partial \tilde{\mu}_n^*/\partial x), \quad (n: A, B, i, S). \tag{1}$$

Assumptions (ii) and (iii) allow us to write the relation:

$$\phi_A^* = \phi_S^* = 0 \tag{2}$$

When no current flows,

$$I^*/F = \sum_n z_n \phi_n^* = 0 \quad (n: B, i). \tag{3}$$

From Eqs. 1, 2, and 3, the following relation can be obtained:

$$\partial \Psi^*/\partial x = -(RT/F)(\sum_n z_n U_n^* C_n^* \partial \ln C_n^*/\partial x)/(\sum_n z_n^2 U_n^* C_n^*) \quad (n: B, i). \tag{4}$$

Integrating Eq. 4 from $x=0$ to d under the foregoing assumptions, one obtains the relation in the case of $|z_n|=1$:

$$\Psi^*(0) - \Psi^*(d) = ((RT/z_i F)(U_i^* - U_B^*)/(U_i^* + U_B^*)) \times \ln (((U_i^* + U_B^*)C_i^*(d) - U_B^* C_s^*)/U_i^* C_s^*). \tag{5}$$

Next, we consider the interfacial potential differences. From the electrochemical equilibria at the respective boundaries, $x=0$ and $x=d$, we have the relations:

$$\Psi' - \Psi^*(0) = -(\mu^\circ - \mu^{\circ *})/z_i F + (RT/z_i F) \ln (C_i^*(0)/a_i')$$
$$\Psi^*(d) - \Psi'' = (\mu^\circ - \mu^{\circ *})/z_i F + (RT/z_i F) \ln (a_i''/C_i^*(d)) \tag{6}$$

From assumption (v) and the electrochemical equilib-

rium at the membrane-sample solution interface, $x=d$, we obtain the relation:

$$C_i^*(d) = (C_s^* + (C_s^{*2} + 4k_ik_B(a_i'')^2)^{1/2})/2. \quad (7)$$

Adding together Eqs. 5 and 6, and inserting Eq. 7, we obtain the desired equation which expresses the influence of the co-ion on the potential E_M of the liquid ion-exchanger membrane electrode:

$$E_M = \Psi' - \Psi'' = (RT/z_iF) \ln (a_i''/a_i') - (RT/z_iF) \ln ((C_s^* + (C_s^{*2} + 4k_ik_B(a_i'')^2)^{1/2})/2C_s^*) + ((RT/z_iF)(U_i^* - U_B^*)/(U_i^* + U_B^*)) \ln (((U_i^* + U_B^*) \times ((C_s^* + (C_s^{*2} + 4k_ik_B(a_i'')^2)^{1/2})/2) - U_B^*C_s^*)/U_i^*C_s^*). \quad (8)$$

Experimental

The influence of the co-ion on the potential E_M of the i ion-sensitive electrode was examined by EMF measurement of the following electrochemical cells:

+SCE/Reference Solution (A-i)/Liquid Membrane/ Sample Solution (B-i)/SCE− (9)

and

+SCE/Reference Solution (A-i)/Liquid Membrane/ Sample Solution (A-i, B-j)/SCE−, (10)

where j is a foreign ion with the same charge sign as the i ion. The j ion selected scarcely interferes with the activity measurement of the i ion. The interference effects of co-ions were examined for the response of nitrate-sensitive and methylephedrine-sensitive electrodes using cells (9) and (10), respectively. The liquid membrane in cell (9) was a nitrobenzene solution of the nitrate salt of crystal violet, and that in cell (10) was a nitrobenzene solution of the tetraphenylborate (TPB) salt of methylephedrine (MEP). The reference solutions in cells (9) and (10) were 1.00×10^{-2} M(M=mol dm^{-3}) solutions of sodium nitrate and methylephedrine hydrogenchloride, respectively. Electrolytes B-i used in cell (9) were sodium nitrate, rubidium nitrate, cesium nitrate and tetramethylammonium nitrate. Sodium nitrate, sodium iodide and sodium thiocyanate were used as the electrolyte B-j in cell (10). The procedures for the preparation of the membrane solutions and the EMF measurement have been described in detail elsewhere.[6-8]

Results and Discussion

Equation 8 can be reduced to a Nernstian equation, when $4k_ik_B(a_i'')^2$ is sufficiently smaller than the square of the concentration of the ion-exchanger in the membrane, C_s^{*2}. On the other hand, the second and third terms of Eq. 8 may contribute to E_M when $4k_ik_B(a_i'')^2$ is not much smaller than C_s^{*2} and co-ion B thus interferes with the activity measurement of the i ion using the i ion-sensitive electrode with the liquid ion-exchanger membrane. In most liquid ion-exchanger membrane electrodes, the mobilities of ions in the membrane are not so different for the ions of interest, whereas the partition coefficients of the ions differ greatly for these ions.[9-13] Accordingly, the effect of co-ion interference can be discussed in a first approximation, neglecting the contribution of the third term of Eq. 8 to E_M. Since the value of $(C_s^* + (C_s^{*2} + 4k_ik_B(a_i'')^2)^{1/2})/2C_s^*$ is always larger than unity when the co-ion enters the membrane, the observed potential E_M gives a lower activity of the i ion than true value. The co-ion interference thus leads to a negative error in the activity measurement of the i ion, whereas a positive error is measured in the usual interference of a foreign counter-ion species. From Eq. 8 the effect of co-ion interference can be summarized as follows:

(i) Co-ion interference becomes more important with decreasing concentration of the ion-exchanger in the membrane; conversely, the co-ion interference can be reduced by increasing the concentration of the ion-exchanger in the membrane.

(ii) Co-ion interference occurs at high activity levels of the objective ion i, whereas the interference of a foreign counter ion occurs at low activity levels of the i ion.

(iii) Co-ion interference increases with increasing extractability of the co-ion.

To illustrate the theoretical predictions, the nitrate-sensitive membrane electrode system (9) was selected because it is likely to fulfill most of the foregoing assumptions.[9-13]

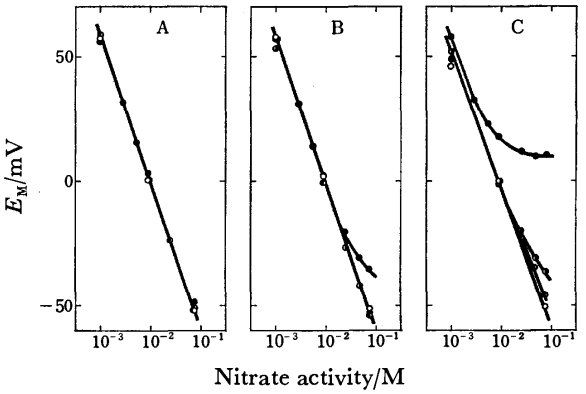

Fig. 1. The interference of a co-ion or cation in the response of the nitrate-sensitive electrode with the nitrobenzene membrane containing the nitrate salt of Crystal Violet as an ion-exchanger.
Concentration of the ion-exchanger in the membrane: (A) 1.0×10^{-3} M, (B) 1.0×10^{-4} M, (C) 1.0×10^{-5} M; Nitrate salt in the sample solution: $NaNO_3$ (○), $RbNO_3$ (◑), $CsNO_3$ (◐), $(CH_3)_4N\,NO_3$ (●); Temp: 24±1 °C.

In Fig. 1, the potentials of the nitrate-sensitive electrode are shown. The potential was stable in the concentration range above 10^{-3} M of the sample salt. Below 10^{-3} M, however, the potential was somewhat unstable in the initial stage of the measurement. In such cases, the stationary values observed after a delay of 15—20 min are used.

A membrane with a 10^{-3} M ion-exchanger showed a Nernstian response to all of nitrate salts up to 10^{-1} M. In the case of a membrane with a 10^{-4} M ion-exchanger, the response for tetramethylammonium nitrate differed from the ideal Nernstian response in the activity level above 10^{-2} M. A negative error was observed in accordance with theoretical predictions. A large deviation from Nernstian response was observed for the response of a membrane with a 10^{-5} M ion-exchanger. Except

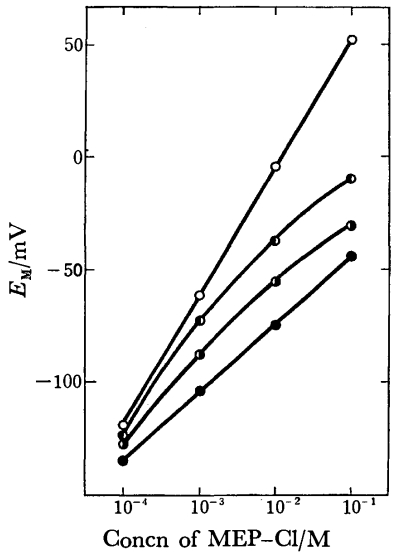

Fig. 2. The response of the methylephedrine-sensitive electrode for sample solutions containing methylephedrine hydrogenchloride (MEP-Cl) and sodium salts of inorganic anions.

Liquid membrane of the electrode: 1.0×10^{-4} M nitrobenzene solution of MEP-TPB; Sample solution: MEP-Cl only (○), MEP-Cl+0.5 M $NaNO_3$ (◐), MEP-Cl+0.1 M NaI (◑), MEP-Cl+0.1 M NaSCN (●); Temp: 20°C.

for the case of sodium nitrate, the responses were no longer Nernstian in the relatively high activity levels of the sample salt. In this case, the extent of the interference is distinguishable for the co-ion species. The order of increasing interference is $Rb^+<Cs^+<(CH_3)_4N^+$. This order is in agreement with the increasing extractability of the ions in the nitrobenzene–water system.[10] The results are thus in good agreement with the theoretical expectations. An example of co-ion interference for electrode response is shown for a sample solution containing mixed electrolytes A-i and B-j (cell (10)) in Fig. 2. The methylephedrine-sensitive electrode showed a nearly Nernstian response for a sample solution containing only methylephedrine hydrogenchloride (MEP-Cl).[8] In the presence of the sodium salt of nitrate, iodide or thiocyanate, the electrode response was no longer Nernstian. A negative error was observed. The order of increasing interference is also in agreement with the increasing extractability of the ions in the nitrobenzene–water system, *i.e.*, $NO_3^-<I^-<SCN^-$.[11]

Usually, it is considered that co-ions do not affect the response potential of a liquid ion-exchanger membrane electrode. As shown by this work, however, co-ions do, in some cases, interfere strongly with the activity measurement of the objective ion of the electrode, especially when a lipophilic ion is contained in the sample as a co-ion. In this connection, the recent study of Llenado on the calcium electrode response in the presence of ionic surfactants is interesting because it is anticipated that ionic surfactants may show this type of interference.[14] In conclusion, *the presented results suggest that co-ion interference should be considered in the analytical use of a liquid ion-exchanger membrane electrode, in addition to the consideration of the usual interference of foreign counter ions.*

A Study of the Structures of Aluminum Complexes with Isopropoxy and Methyl Groups Using Pulsed NMR and Chemical Ionization Mass Spectrometry

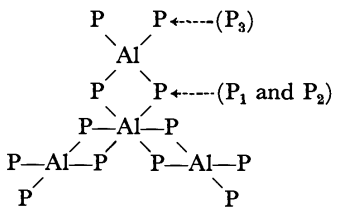
Masao UETSUKI and Yuzuru FUJIWARA

Central Research Laboratories, Kuraray Co., Ltd., Sakazu 2045, Kurashiki 710

(Received May 17, 1976)

The structures of aluminum complexes formed by the reaction of aluminum isopropoxide with trimethylaluminum was investigated by measuring the spin-lattice relaxation times, T_1 for ^1H and T_1* for ^{27}Al. The motion of the ligand of the complexes reflected upon the value of T_1, which was about twice as long at the terminal position as at the bridge position, and decreased with increasing molecular weight. Coordination symmetry about the aluminum nucleus of the complexes governed the value of T_1*, which was about ten times as long at the center of the tetrameric complexes as at the wing of the dimeric complexes. The ^{13}C NMR signals of the isopropoxy group varied with the configuration of the ligands, while those of the methyl group were either broad or not observable. Chemical ionization mass spectra of the complexes supported the tetrameric and the dimeric structures determined from the results of NMR measurements.

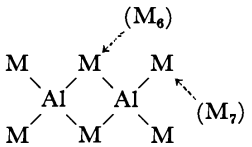
Aluminum alkoxides have a stable structure, while alkylaluminums are so reactive that they are utilized as a reducing reagent in various reactions.[1] A tetrameric structure, T^0, for aluminum isopropoxide was first proposed by Bradley,[2] and a dimeric one, D^2, for trimethylaluminum by Laubengayer *et al.*[3] ^1H NMR has been used effectively for the structure determination of these complexes.[4-6]



T^0

P=$(CH_3)_2CHO$-

M_w=817

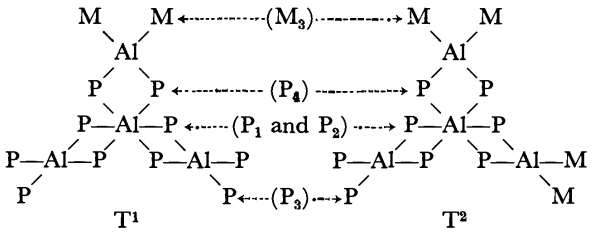


D^2

M=CH_3-

M_w=320

M_w indicates the molecular weight of the complexes. Using ^1H NMR spectroscopy, it has been found that aluminum isopropoxide reacts with trimethylaluminum to produce three kinds of tetranuclear complexes, T^1, T^2 and T^3, and two kinds of binuclear ones, D^0 and D^1.[7] Chemical shifts, spin-spin coupling constants between the protons, signal intensities and relative values of the spin-lattice relaxation times were measured to confirm the structures reported in a previous publication.[7]

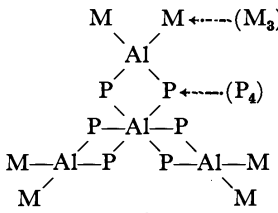


T^1

M_w=729

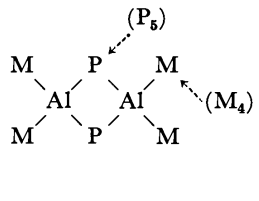
T^2

M_w=641



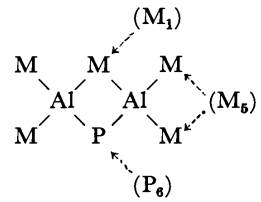
T^3

M_w=553



D_0

M_w=409



D^1

M_w=364

The remaining problems are summarized as follows. a) When ^1H NMR signals were obtained in the CW (continuous wave) mode, the spin-lattice relaxation time was measured using the progressive saturation method, so that the absolute values for T_1 could not be obtained, and relative values for T_1 could hardly be determined for NMR signals which are close to each other. b) As a result of overlapping of the NMR signals it was impossible to discriminate between the three kinds of tetranuclear complexes, T^1, T^2 and T^3. c) Since the NMR measurements were performed only on the protons of the ligands, no direct information was obtained concerning the aluminum nucleus of the complexes.

In the present work, the absolute values of T_1 for both ^1H and ^{27}Al were measured in the pulsed NMR mode to reconfirm the structures of the aluminum complexes and to study the remaining problems. ^{13}C NMR was also used to study the coordination mode of the ligand. The molecular weight of the complexes was examined using chemical ionization mass spectrometry, which is a useful technique for estimating the molecular size of such unstable compounds.

Experimental

Reagents. All the reagents used were obtained and purified by the same method as that described in Ref. 7.

Preparation of Samples. Aluminum isopropoxide and trimethylaluminum were dissolved separately in benzene, and solutions were mixed at 25 °C in an atmosphere of nitrogen in a dry box. The concentration was set so that the total amount of the solutes was 20 and 5.0 mol % in the solutions used to prepare the samples for pulsed NMR spectroscopy and chemi-

cal ionization mass spectrometry, respectively. Since a trace of oxygen in the solution which reacted with trimethylaluminum showed no observable effect upon the magnetic relaxation time, none of the samples were degassed.

Measurements of NMR and Mass Spectra. NMR spectra were measured with a Bruker SXP 4-100 spectrometer operating at 21.14 kG. Spin-lattice relaxation times for ^{1}H and ^{27}Al nuclei were measured at 28 °C using a partial relaxation technique with π- and $\pi/2$-pulses. The length of the π-pulses were 1.3×10^{-5} and 2.4×10^{-5} s for ^{1}H and ^{27}Al, respectively. Mass spectra were recorded using a Finnigan model 3300F quadrupole mass spectrometer equipped with a chemical ionization system. Methane was used as the reactant gas for the chemical ionization.

Results and Discussion

^{1}H NMR. The ^{1}H NMR spectra of the aluminum complexes showed four types of signals with hyperfine structures characteristic of the functional groups of the ligands; the methyl groups displayed a singlet pattern for τ=9.96—10.53, the isopropoxy methyl groups a doublet for τ=8.31—9.04, the isopropoxy methine groups a heptad for τ=5.27—5.70, and methane, a by-product of the reaction of aluminum isopropoxide with trimethylaluminum, a singlet at τ=9.85. For convenience, the signals of the isopropoxy methyl groups are denoted by P_1, P_2, P_3, P_4, P_5, and P_6 in the order of increasing τ values, and those of the methyl groups by M_1, M_2, M_3, M_4, and M_5 at 28 °C. Below −40 °C, the signal due to trimethylaluminum, M_2, splits into two singlet signals, which are designated as M_6 for the smaller value and as M_7 for the larger. On the basis of considerations of chemical-shifts, spin-spin coupling constants and signal intensities, these signals were assigned in Ref. 7 to T^0, T^1, T^2, T^3, D^0, D^1, and D^2.

In the present work, an attempt was made to reconfirm the signal assignments using the spin-lattice relaxation time, T_1. Typical ^{1}H NMR spectra measured using the partial relaxation technique are shown in Fig. 1, where the molar ratio of added trimethylaluminum and aluminum isopropoxide is 0.40: 0.60. The logarithm of the recovery rate of the signals was plotted against the delay time of the $\pi/2$-pulse after the π-pulse, and the linearity was sufficient to determine the T_1 values to within an accuracy of ±5% as listed in Table 1.

From the observed T_1 values, the isopropoxyl methyl signals can be classified into two groups, I (P_1, P_2, P_3 and P_4), and II (P_5 and P_6), which represent T_1 values of 0.35—0.97 and 3.2—4.0 s, respectively. In a similar manner, the methyl signals can also be classified into two groups, I (M_3), and II (M_2 and M_4), with T_1 values of 1.9 and 3.2—4.6 s, respectively. Since it is known

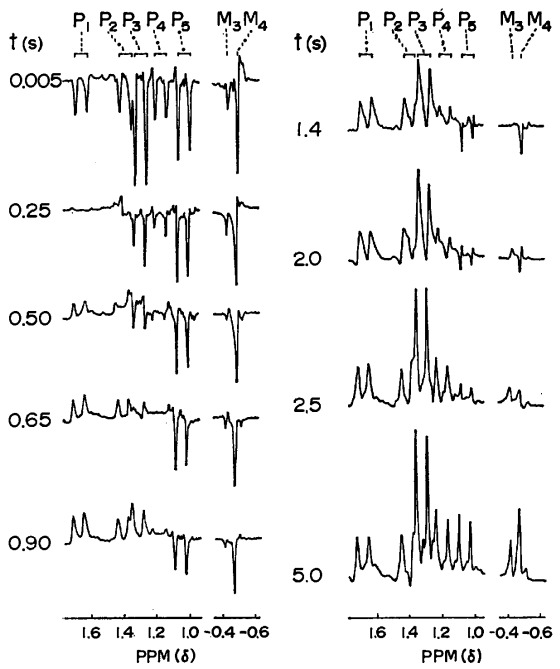


Fig. 1. ^{1}H NMR spectra of the methyl groups of the aluminum complexes in benzene at 28 °C. t is delay time of the $\pi/2$-pulse after the π-pulse. Trimethylaluminum and aluminum isopropoxide were mixed at the molar ratio 0.40: 0.60.

that aluminum isopropoxide and trimethylaluminum are tetrameric[2] and dimeric,[3] respectively, the signals of groups I and II are referred to the ligands of the tetra- and the binuclear aluminum complexes, respectively.

The M_2 signal, which is a singlet due to the rapid exchange of bridging and terminal methyl groups, M_6 and M_7, of dimeric trimethylaluminum D^2, has the longest T_1 value, 4.6 s. The bridging ligand is supposed to be less mobile and have a shorter value of T_1 than the terminal ligand. Since P_5 and M_4 have shorter T_1 values than P_6 and M_5, the former can be assigned to the ligand of D^0, and the latter to that of D^1. The results agree with those obtained from the change in the signal intensity with the ratio of the trimethylaluminum to aluminum isopropoxide concentrations.[7] The T_1 values of P_5 and P_6 show that the T_1 value of the isopropoxyl methyl group increases by about 0.6 s when the neighboring isopropoxyl group is substituted by a methyl group. The increase in the T_1 value is attributable to a decrease in the number of neighboring protons, which play the role of the energy carriers in the spin-lattice relaxation process.

The T_1 values of P_1 and P_2 are *ca.* 0.35 s, and P_3 has a

Table 1. Spin-lattice relaxation times for methyl protons of aluminum complexes in benzene at 28 °C

$Al(CH_3)_3$: $Al(isoPrO)_3$[a)]	Spin-lattice relaxation time (s)								
	P_1	P_2	P_3	P_4	P_5	P_6	M_2	M_3	M_4
0.00 : 1.00	0.35	0.35	0.65						
0.40 : 0.60	0.36	0.36	0.79	0.97	3.2			1.9	3.2
0.80 : 0.20					3.4	4.0	4.6		

a) Molar ratio.

T_1 value about twice as long as the former two. Therefore, P_1 and P_2 are assigned to the bridging isopropoxy group of the tetranuclear complexes, and P_3 to the terminal one. The splitting of the signal of the isopropoxy methyl group into the two signals, P_1 and P_2, suggests that the bridging group is less mobile than the terminal group, P_3. P_4 has a T_1 value *ca.* 0.6 s longer than P_1 or P_2, and is equivalent in molar intensity to M_3, which has a T_1 value about twice as long as P_4. Hence, P_4 and M_3 are assigned to the bridging isopropoxy group and the terminal methyl group, respectively, of one of the substituted wings of the tetranuclear structures, T^1, T^2 or T^3. The T_1 values of P_4 and M_3, as well as those of P_1, P_2 and P_3, become longer with an increase in the amount of trimethylaluminum. This phenomenon shows that the T_1 value increases with decreasing proton number of the neighboring ligands, a fact which supports the assumption that all three structures, T^1, T^2, and T^3, exist in the solution. If, for instance, only T^0 and T^3 existed, the T_1 values of P_1, P_2, P_3, P_4, and M_3 would not change with the ratio of the trimethylaluminum and aluminum isopropoxide concentrations.

As long as similar structures are considered, it is seen that the T_1 value is inversely proportional to the molecular weight. For instance, the ratio of the molecular weight of D^0 to that of D^1 is 0.89, while the ratio of the T_1 values of P_5 and P_6 is 0.85 when trimethylaluminum and aluminum isopropoxide are mixed at a molar ratio of 0.80: 0.20. When the ratio of the trimethylaluminum and aluminum isopropoxide concentrations is 0.40: 0.60, the mean molecular weight of the tetranuclear complexes is calculated from the T_1 value of P_3 to be 672 in comparison with that for a pure solution of aluminum isopropoxide, while from the T_1 values of M_3 and M_4, it is 689. The mean molecular weight decreases with an increase the number of methyl groups.

^{27}Al NMR. The aluminum nucleus forms the skelton of the polynuclear complexes, but little work has so far been undertaken on the structure of the complexes based on information about the aluminum nucleus itself. For this reason ^{27}Al NMR spectroscopy is an indispensable technique. However, ^{27}Al NMR signals are usually broad because of the $I=5/2$ spin and the large electric quadrupole moment,[8] so that they are not easily used to obtain detailed information. After the work of O'Reilly,[9] most studies using ^{27}Al NMR, which is a sensitive probe of the environment of the aluminum nucleus, have been developed by measuring line widths instead of direct measurements of the spin-lattice relaxation times.

^{27}Al NMR spectra of the reaction products of aluminum isopropoxide with trimethylaluminum are shown in Fig. 2, where aluminum sulfate dissolved in water is used as a chemical shift standard. Values of the chemical shift, ν, and the half-height width, $\Delta\nu$, are listed in Table 2. Aluminum sulfate shows up as a sharp line with a half-height width of 13.5 Hz indicating the formation of a monomeric structure involving six ligands in water. A single line of aluminum isopropoxide appeared at a frequency 2.69 ppm higher than that of aluminum sulfate with a half-height width of 102 Hz, although the tetrameric structure T^0 contains two kinds of the aluminum nuclei. Trimethylaluminum, the dimeric structure D^2 of which was determined from ^{1}H NMR spectra,[5,6] showed a broad signal with a half-height width of 1042 Hz at a frequency 537 ppm higher than that of aluminum sulfate. No signals other than those corresponding to the tetrameric or the dimeric structures were observed at molar ratios for trimethylaluminum and aluminum isopropoxide of 0.40: 0.60 and 0.80: 0.20, respectively. When trimethylaluminum and aluminum isopropoxide were mixed at a molar ratio of 0.60: 0.40, the ^{27}Al NMR spectrum displayed both narrow and broad lines corresponding to the tetra- and binuclear complexes, respectively. The coordination number of the aluminum nucleus of the tetranuclear complexes is six at the center and four in the wing. Hence, the aluminum nucleus at the latter position should show an NMR signal with a frequency close to that of the binuclear complexes, but no such signal was observed. As a result, the aluminum nuclei that represent the NMR signals are attributable to the

central nucleus of the tetranuclear complexes, T^0, T^1, T^2 and T^3, and to the nuclei forming the binuclear complexes, D^1 and D^2. The spin-lattice relaxation time for the aluminum nuclei situated in the wings of all the tetranuclear complexes and for those of the binuclear complex D^0 is believed to be too short to exhibit this NMR signal because of the low symmetry of the coordination structures.

In order to evaluate the spin-lattice relaxation time from the ^{27}Al NMR data, it is necessary to formulate an equation that describes the nuclear magnetization of aluminum in terms of the time interval t between the π- and $\pi/2$-pulses. The master equations for a nucleus with a spin quantum number I are expressed as

$$dP_1/dt = -W_{12}(P_1-P_2-\delta_{12})$$
$$dP_i/dt = W_{i-1,i}(P_{i-1}-P_i-\delta_{i-1,i}) - W_{i,i+1}(P_i-P_{i+1}-\delta_{i,i+1})$$

and

$$dP_n/dt = W_{n-1,n}(P_{n-1}-P_n-\delta_{n-1,n}), \quad (1)$$

where n is the total number of spin states given by $n=2I+1(=6)$, and i can take any integer between unity and n. P_i and $W_{i,i+1}$ denote the spin population of the i-th state and transition probability of the spin from the i-th state to the next higher state, respectively. $\delta_{i,i+1}$ denotes the difference in the spin populations between the i-th and $(i+1)$-th states at thermal equilibrium. For simplicity, it is assumed that both $W_{i,i+1}$ and $\delta_{i,i+1}$ are constants independent of i, and that the apparent value of the spin-lattice relaxation time is given by T_1^*, one half of the reciprocal of the transition probability. Then, the normalized value of the magnetization M for the ^{27}Al nucleus is given by

$$M = M(t)/M(\infty) = 1 - (2/105)(A+B+C), \quad (2)$$

where $A=\exp(-t/T_1^*)$, $B=2(26+15\sqrt{3})\exp[-(2-\sqrt{3})t/(2T_1^*)]$ and $C=2(26-15\sqrt{3})\exp[-(2+\sqrt{3})t/(2T_1^*)]$. A and C have smaller values than B, so that they are negligible within the practical accuracy of M. Hence Eq. 2 can be simplified to

$$M = 1 - 2\exp[-(2-\sqrt{3})t/(2T_1^*)]. \quad (3)$$

Experimental values of $\log 2(1-M)^{-1}$ lie along a straight line when plotted against the value of t. For a sample composed of a mixture of D^1 and D^2, it was difficult to obtain a straight line as a result of the overlapping of the broad signals, so that the apparent value of T_1^* was determined from the line width upon comparison with that of D^2. The T_1^* values are listed in the last column of Table 2.

Aluminum sulfate dissolved in water provided the longest T_1^* value, 2.2×10^{-3} s, of all the samples. T_1^* of the signal due to the tetranuclear complexes gradually increased with an increase in the amount of trimethylaluminum. This corresponds to a decrease in the molecular weight, as well as to a slight change in the coordination symmetry about the observable aluminum nucleus, supporting the assumption that it is the central nucleus alone that produces the NMR signal of the tetranuclear complexes. The T_1^* value is much shorter for the aluminum nucleus with the coordination number six, as can be seen from the following results of the binuclear complexes. When trimethylaluminum and aluminum isopropoxide were mixed at a molar ratio of 0.80: 0.20, the ^{27}Al NMR spectrum displayed a T_1^* value of 2.3×10^{-5} s, which was shorter than that for a pure solution of trimethylaluminum. This indicates that the aluminum nucleus of the binuclear complex D^1 produces an NMR signal at the same position as dimeric trimethylaluminum D^2. The T_1^* value would be too short to allow detection of the NMR signal of the aluminum nucleus between a pair of bridging isopropoxy groups and a pair of terminal methyl or isopropoxy groups.

^{13}C NMR. The coordination state of the ligand was examined by ^{13}C NMR, too, as is shown in Fig. 3, where tetramethylsilane was used as the chemical shift standard. The isopropoxy methyl and methine carbons produced ^{13}C NMR signals higher in frequency and narrower in width than those of the methyl carbons attached to the aluminum nucleus.

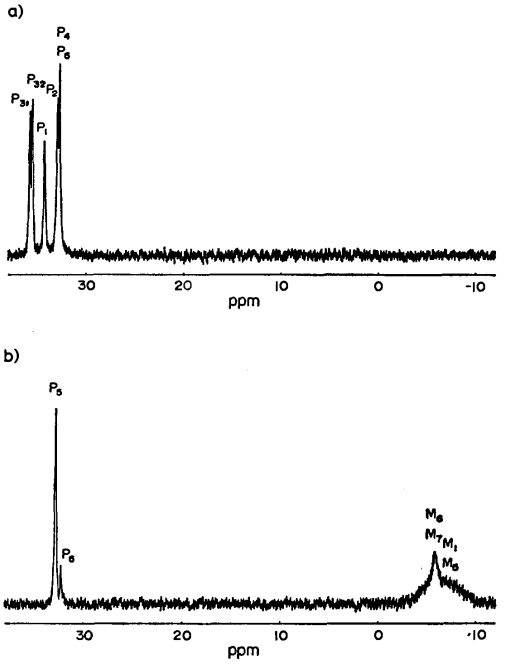

Fig. 3. ^{13}C NMR spectra of the mixture of trimethylaluminum and aluminum isopropoxide at the molar ratios a) 0.40: 0.60, and b) 0.80: 0.20 in benzene at 28 °C.

Four kinds of signals from the isopropoxyl methyl of the benzene carbon at 128.60 ppm, were observed in the ^{13}C NMR spectrum of a pure solution of aluminum isopropoxide. The signals at 34.27 and 33.00 ppm are assigned to the bridging ligand of tetrameric aluminum isopropoxide, T^0, and are designated by P_1 and P_2, respectively, in a similar manner to the case of ^{1}H NMR. The two signals at 35.75 and 35.53 ppm, which are close to each other in comparison with the other two signals, are assigned to the terminal ligand P_3 of T^0, and are indicated by P_{31} and P_{32}, respectively. The ^{1}H NMR signal from P_3 was, however, lower in frequency than the signals from P_1 and P_2, and did not split. On the other hand, the isopropoxy methine

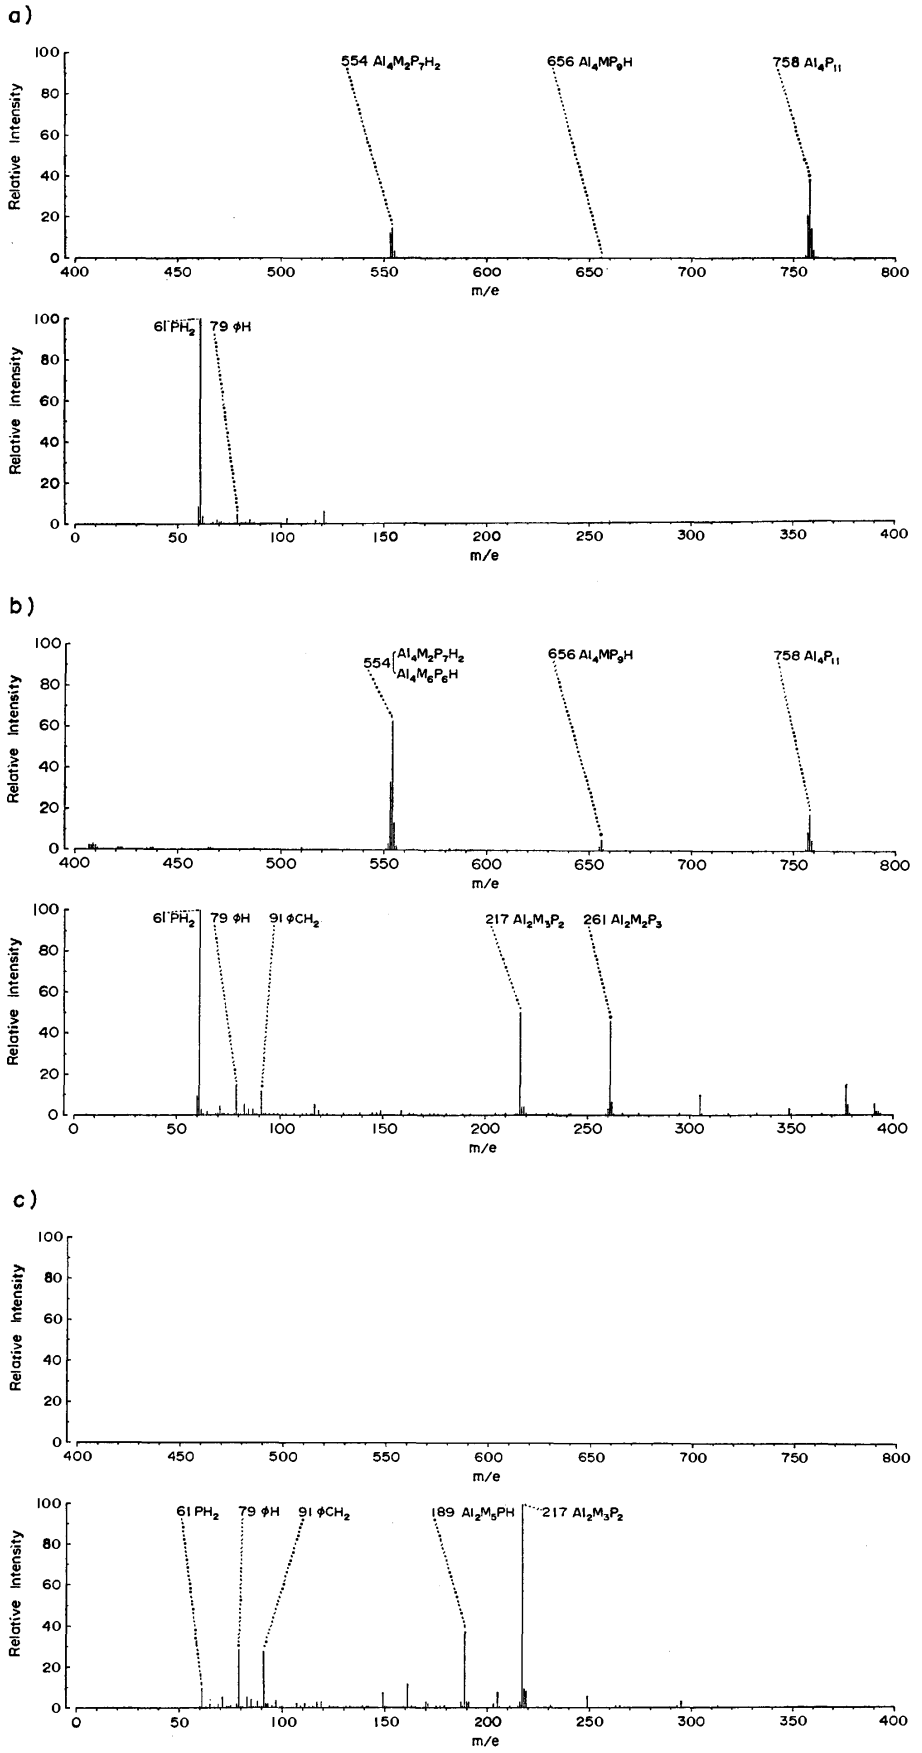

Fig. 4. Chemical ionization mass spectra of the mixture of trimethylaluminum and aluminum isopropoxide at the molar ratios a) 0.00: 1.00, b) 0.30: 0.70, and c) 0.90: 0.10 in benzene.

carbons of aluminum isopropoxide display only the two signals with equimolar intensity at 73.70 and 70.83 ppm, which are assigned to the terminal and bridging ligands respectively, so that splitting of the isopropoxy methyl, signal is attributed to the steric difference of the two methyl groups bonded to a methine carbon.

When trimethylaluminum was added to aluminum isopropoxide in benzene, a new signal from the isopropoxy methyl carbon appeared at 32.80 ppm, which was assigned to a mixture of the bridging ligands, P_4 of the substituted wing of the tetranuclear complexes T^1, T^2, and T^3, and P_5 of the binuclear complex D^0. However, the methyl groups of M_3 and M_4 attached to the aluminum nuclei bearing P_4 and P_5, respectively, produced no ^{13}C NMR signal. This phenomenon coincides with the result of the ^{27}Al NMR experiments that no NMR signal was detected due to these aluminum nuclei.

When the amount of trimethylaluminum exceeded 75.0 mol % in the benzene solution, signals from the tetranuclear complexes diminished to the point of disappearing, and a signal due to the isopropoxy methyl carbon, assigned to P_6 of the binuclear complex D^1, appeared at 32.21 ppm accompanied by the signals from the corresponding to methyl groups M_1 and M_5, which overlapped each other at -7.0 ppm with a half-height width of *ca.* 140 Hz. The methyl groups, M_6 and M_7, of dimeric trimethylaluminum D^2 also displayed an overlapping of the carbon signals at -5.9 ppm with a half-height width of *ca.* 20 Hz. Line broadening of the methyl carbons bonded to the aluminum nucleus corresponds to the exchange of the methyl groups and to the electric quadrupole moment of the adjacent aluminum nucleus, as well as to the spin-spin coupling between the ^{13}C and ^{27}Al nuclei.[10] Since the carbons of the ligands are located at positions closer to the aluminum nucleus in comparison with the protons, the ^{13}C NMR spectrum exhibits an intermediate character between the ^1H NMR and the ^{27}Al NMR data supporting these results.

Chemical Ionization Mass Spectrometry. In order to verify the NMR results mentioned above, it is desirable to determine the molecular weight of the aluminum complexes. However, these complexes are so unstable that it is very difficult to measure their molecular weights using ordinary methods. CIMS (chemical ionization mass spectrometry) is a useful technique for the molecular weight measurements of such unstable compounds, since ions are produced under a milder condition in CIMS than in electron impact mass spectrometry.

CIMS spectra of the reaction products of aluminum isopropoxide with trimethylaluminum are illustrated in Fig. 4. In the CIMS spectrum of aluminum isopropoxide, the large peak at an *m/e* of 758 corresponds to an ion of $[Al_4(isoPrO)_{11}]^+$, which is a fragment from a $Al_4(isoPrO)_{12}$ molecule. This indicates a tetrameric structure for aluminum isopropoxide, although no molecular ion $[T^0H]^+$ was detected at an *m/e* of 818. The peaks at *m/e* of 656 and 554 are assigned to $[Al_4(CH_3)(isoPrO)_9H]^+$ and $[Al_4(CH_3)_2(isoPrO)_7H_2]^+$, respectively, which are produced by the partial substitution of the isopropoxyl groups of T^0 by methyl groups of methane, the reactant gas. The isopropoxyl group of the ligand produces a peak at an *m/e* of 61, which is assigned to $[isoPrOH_2]^+$.

When trimethylaluminum and aluminum isopropoxide were mixed at a molar ratio of 0.30: 0.70, the peaks at *m/e* of 656 and 554 were enhanced indicating the progress of the substitution reaction of the isopropoxyl group by the methyl group for trimethylaluminum. The peak at an *m/e* of 554 might include a molecular ion $[Al_4(CH_3)_6(isoPrO)_6H]^+$ from the tetranuclear complex T^3, but no molecular ions were produced from the tetranuclear complexes, T^1 and T^2, as well as from T^0. The peaks at *m/e* of 261 and 217 are attributable to $[Al_2(CH_3)_2(isoPrO)_3]^+$ and $[Al_2(CH_3)_3(isoPrO)_2]^+$ binuclear ions, respectively. The former corresponds to the reaction product of D^0 with the isopropoxyl ion or to a fragment from T^1, T^2, or T^3, and the latter to a fragment from D^0.

At a molar ratio of trimethylaluminum and aluminum isopropoxide concentrations of 0.90: 0.10, no tetranuclear ions were detected in the CIMS spectrum, which displayed large peaks for binuclear ions at *m/e* of 217 and 189. The peak at an *m/e* of 189 is assigned to the $[Al_2(CH_3)_5(isoPrO)H]^+$ molecular ion from D^1. These results agree with the data obtained in the NMR experiments.

Conclusion

The structure of aluminum complexes formed by the reaction of aluminum isopropoxide with trimethylaluminum was investigated from three different angles: the ligand was examined using ^1H NMR and ^{13}C NMR, the central nucleus using ^{27}Al NMR, and the molecular weight employing chemical ionization mass spectrometry.

The spin-lattice relaxation time of ^1H is sensitive to the motion of the ligand; T_1 was shorter at the bridge position than at the terminal position, and inversely proportional to the molecular weight. This was used to estimate the mean molecular weight of the mixture of tetranuclear complexes, which were indistinguishable from one another using the chemical shift of the ^1H and ^{13}C NMR signals.

The coordination symmetry about the aluminum nucleus was reflected on the spin-lattice relaxation time of ^{27}Al, which was defined as one half of the reciprocal of the transition probability of the spin, T_1^*. The T_1^* value was longer at the center of the tetranuclear complex than at the binuclear complex, and was too short to produce an NMR signal for the aluminum nucleus between a pair of bridging isopropoxy groups and a pair of terminal methyl or isopropoxy groups.

The ^{13}C NMR data for the ligand represented an intermediate character between the data for ^1H NMR and ^{27}Al NMR; the ^{13}C NMR signal due to the isopropoxyl group reflected the configuration of the ligand in a manner similar to the ^1H NMR, while that of the methyl group was broad and was not observed with a methyl group attached to the aluminum nucleus that showed no NMR signal.

The chemical ionization mass spectra of the products of the reaction of aluminum isopropoxide with trimethylaluminum showed fragment ions from both the tetra- and the binuclear complexes as predicted from the NMR study. However, no molecular ions of tetrameric aluminum isopropoxide were observed.

All the results support the conclusions of previous work[7] that the terminal isopropoxy groups of tetrameric aluminum isopropoxide are replaced successively by the methyl groups of dimeric trimethylaluminum to form three kinds of tetranuclear and two kinds of binuclear complexes, and that, after the reactions, the resultant tetranuclear complex undergoes decomposition reactions leading to two kinds of binuclear complexes.

Chromium(III) Complexes with Amino Acids. II. Chromium(III) Complexes with L-α-Amino Acids

Hisaya Oki

Department of Chemistry, Faculty of Education, Fukui University, Fukui 910

(Received June 4, 1976)

As chromium(III) complexes with L-α-amino acids (alanine, aminobutyric acid, norvaline, norleucine, valine, isoleucine and leucine), $[Cr(ala)_3]$, (+)$[Cr(am\text{-}but)_3]$, $[Cr(OH)(am\text{-}but)_2]_2$, (+) and (−)$[Cr(norval)_3]$, (−)-$[Cr(norleu)_3]$, $[Cr(OH)(norleu)_2]_2$, $[Cr(val)_2(val\text{-}O)(NH_3)]$, (+)$[Cr(isoleu)_3]$, $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]$, $[Cr(OH)(isoleu)_2]_2$, (+) and (−)$[Cr(leu)_3]$, and $[Cr(OH)(leu)_2]_2$ were prepared by the matrix method in solid state, and $[Cr(ala)_3]$, $[Cr(am\text{-}but)_3]$, $[Cr(OH)(am\text{-}but)_2]_2$, (−)$[Cr(norval)_3]$, $[Cr(OH)(norval)_2]_2$, (−)$[Cr(norleu)_3]$, $[Cr(OH)(norleu)_2]_2$, (+)$[Cr(val)_3]$, $[Cr(val)_2(val\text{-}O)(NH_3)]$, $[Cr(OH)(val)_2]_2$, (+)$[Cr(isoleu)_3]$, $[Cr(OH)(isoleu)_2]_2$, and a mixture of diasteroisomers of $[Cr(leu)_3]$ were obtained by the usual method in solution. Some differences in the formation of the tris-type and hydroxo-dimer complexes appeared between the two methods. Especially, in the solid reaction, some complexes gave diastereoisomers with optically-active counter structures depending upon the kind of solvents used for preparation. All tris-type chromium(III) complexes with L-α-amino acids were of *fac*-structure.

In a previous paper,[1] systematic studies were reported on the effect of the length of the skeletal carbon chain or the presence of side chains in glycine and racemic amino acids upon the formation of complexes by the isothermal matrix method in solid state and by the usual method in solution in which hexaamminechromium(III) nitrate was used as the starting material. In the present work, attempts were made to prepare chromium(III) complexes with L-α-amino acids (alanine, aminobutyric acid, norvaline, norleucine, valine, isoleucine and leucine) by applying the same methods as described in Ref. 1 with respect to the preparation of racemic amino acids and to study the difference between racemic and L-amino acids in complexation. The studies of the formation of optical isomers of the complexes were also investigated.

Experimental

Preparation of Chromium(III) Complexes. There are two methods for the preparation of chromium(III) complexes with L-α-amino acids depending on the starting technique.

a) Preparation by Solid State Reaction: Hexaamminechromium(III) nitrate was mixed with the respective L-amino acid in a mortar. The mixture was heated at (150±1)°C in a Toyoroshi electronic drying oven. The molar ratio of the amino acids to the starting complexes was 3: 1 and the heating time was 20 min.

The reaction product containing L-alanine was dissolved in water. After removal of the residue by filtration, filtrate was kept standing at room temperature for one or two days. $[Cr(ala)_3]$ was gradually deposited as pink crystals. The main product of the residues was also $[Cr(ala)_3]$. Using a method similar to that described above, the di-μ-hydroxo-tetrakis(amino acidato)dichromium(III) complexes were obtained as light purple crystals, when the amino acid was L-α-aminobutyric acid, L-norleucine or L-leucine. The complex with L-norvaline was, however, obtained as (−) $[Cr(norval)_3]\cdot 3H_2O$. In the case of L-isoleucine, a mixture of pink and purple crystals was gradually deposited. The mixture was dissolved in DMF. After filtration, the filtrate was added dropwise to water, causing instant precipitation of (+)$[Cr(isoleu)_3]\cdot 3H_2O$ as pink crystals. The purple residue obtained by the above filtration was $[Cr(OH)(isoleu)_2]_2\cdot 6H_2O$.

The reaction products containing L-α-aminobutyric acid, L-norvaline, L-norleucine, L-valine, L-isoleucine and L-leucine were dissolved in methanol. After removal of the residues by filtration, the filtrates were kept standing at room temperature for two or three days. (+)$[Cr(am\text{-}but)_3]\cdot H_2O$, (+)$[Cr(norval)_3]\cdot 2H_2O$, $[Cr(norleu)_3]\cdot 3H_2O$, $[Cr(val)_2(val\text{-}O)(NH_3)]\cdot 2H_2O$, $[Cr(isoleu)_2(iaoleu\text{-}O)(NH_3)]\cdot 2H_2O$ and (+)$[Cr(leu)_3]\cdot 3.5H_2O$ were gradually deposited as pink crystals. After filtering the (+)$[Cr(am\text{-}but)_3]\cdot H_2O$ obtained above, the filtrate was kept standing at room temperature until completely dried, another type of $[Cr(am\text{-}but)_3]\cdot H_2O$ also being obtained as pink crystals. The former was soluble, whereas the latter was insoluble in water. The complexes $[Cr(val)_2(val\text{-}O)(NH_3)]\cdot 2H_2O$ and $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]\cdot$ were obtained by drying for 30 min the above-mentioned crystals deposited at 50°C.

When ethanol was used as the solvent, tris type complexes were obtained as pink crystals only for L-norvaline, L-norleucine and L-leucine. The CD sign of these optically active tris type complexes was, however, negative, which is opposite to that of the corresponding complexes obtained in methanol. Complexes with L-valine and L-isoleucine were also obtained as $[Cr(val)_2(val\text{-}O)(NH_3)]\cdot 2H_2O$ and $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]\cdot 2H_2O$, respectively, although they might have been contaminated by small amounts of tris type complexes. In the case of L-α-aminobutyric acid, only an oily substance was obtained, the crystallization having been unsuccessful. In the case of L-alanine, the reaction product was insoluble in both ethanol and methanol.

The analytical data for the complexes obtained by the above method are shown in Table 1, except for the dimer-complexes with isoleucine and norleucine. The IR spectra of these complexes were coincident with those of the corresponding complexes obtained by the solution method.

b) Preparation by Solution Reaction: Hexaamminechromium(III) nitrate (345 mg) and L-α-alanine (267 mg) were dissolved in hot water (5 ml) and the mixture was heated in a water bath until pink crystals began to appear and then was cooled to room temperature. The pink crystals obtained were $[Cr(ala)_3]$. By applying the method described above, the complexes with L-α-aminobutyric acid, L-norvaline and L-valine were all precipitated as pink crystals. The pink crystals containing L-norvaline were dissolved in DMF or DMSO. After filtration, the filtrate was added dropwise to water, causing instant precipitation of (−)$[Cr(norval)_3]\cdot 3H_2O$. The pink complex containing L-α-aminobutyric acid was washed with water and then with ethanol. In the case of L-valine, the pink crystals were

dissolvaed in ethanol. After filtration, $(+)[Cr(val)_3]\cdot 3H_2O$ was obtained from the residue and when the filtrate was allowed to stand at room temperature for three or four days, $[Cr(val)_2(val\text{-}O)(NH_3)]\cdot xH_2O$ was gradually deposited as red-purple crystals. By heating at 50°C for 30 min, the amount of crystal water contained was determined to be $x=2$. The IR spectrum of this complex was coincident with that of the corresponding complexes obtained for the solid state reaction.

By using a similar method, with the exception that 60 ml of water was employed insteaed of 5 ml of hot water, hydroxo-dimer complexes with L-α-aminobutyric acid, L-norvaline, L-norleucine, L-valine and L-isoleucine were obtained as purple crystals. However, the complexes with L-alanine and L-leucine were of tris-type. When 10 ml of water was employed, hydroxo-dimer complexes were obtained in the case of L-α-aminobutyric acid and L-valine, whereas only tris complexes were obtained for all the other amino acids. The tris complex containing L-norvaline was dissolved in methanol. After filtration, the filtrate was concentrated using a cooling dryer, causing the precipitation of $(-)[Cr(norval)_3]\cdot 3H_2O$. The residue thus obtained was identical to that obtained previously.

The analytical data of these complexes are shown in Table 2.

Apparatus. The UV spectra were measured with a Hitachi 139 spectrophtometer. The IR spectra were measured in a KBr disk with a Hitachi EPI-G3 infrared spectrophtometer. The CD spectra were recoded on a JASCO Model ORD/UV-5 spectrophtometer with a CD attachment.

Results and Discussion

UV Absorption Spectra. The absorption spectra of the chromium(III) complexes with L-α-amino acids of type $[Cr(L)_3]$ and $[Cr(L)_2(L\text{-}O)(NH_3)]$, where L denotes amino acids, were measured in DMSO, except for the complexes with alanine, aminobutyric acid and norleucine which were insoluble in DMSO. The spectra of the chromium(III) complexes with alanine and aminobutyric acid were measured in solid state and in perchloric acid. The spectrum of the tris(norleucinato)-chromium(III) complex was not measured, because the yield of this complexes was very small. Since the color of this complex was pink, the structure may be of facial form.

The numerical data for their absorption maxima are summarized in Table 3. These data suggest that the

complexes with L-alanine and L-α-aminobutyric acid undergo acid hydrolysis or some chemical reaction on dissolution in perchloric acid and that the behavior is similar to that of complexes with *dl*-alanine and *dl*-α-aminobutyric acid. Also it is seen that the absorpiton maxima of the other chromium(III) complexes are almost coincident with those of the corresponding chromium(III) complexes of tris-type with *dl*-amino acids.[1] This suggests that the chromium(III) complexes

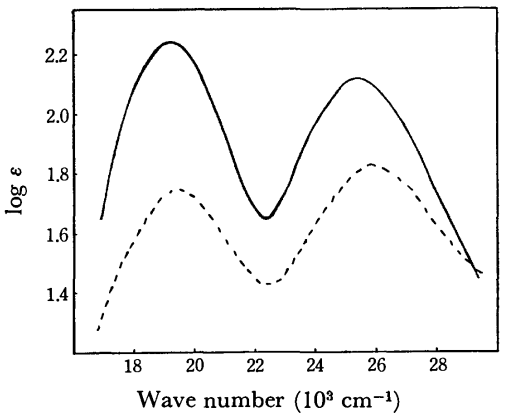

Fig. 1. The absorption spectra of $[Cr(isoleu)_3]$ (——) and $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]$ (------) in DMSO solution.
ε: M^{-1} cm^{-1}, M: mol dm^{-3}.

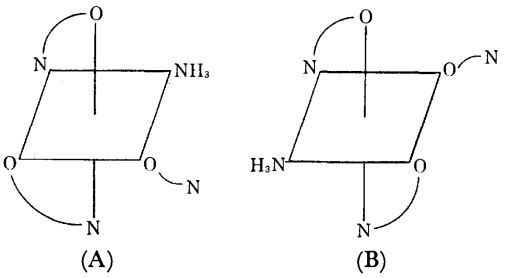

Fig. 2. The possible structures of $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]$.

of tris-type are of *fac*-structure.

The spectra of $[Cr(isoleu)_3]$ and $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]$ in DMSO are shown in Fig. 1. The absorption curve of the bis-type complex is similar to that of the tris-type, except that the first absorption band has a lower absorption coefficient than the second band of the bis-type complex. Therefore, this uggests that the coordinating structure of the bis-type complex is a cis-cis structure with respect to the nitrogen or oxygen atoms and the symmetry of this complex is lower than the C_{3v} of tris-type complex. Thus, for the bis-type complex, two geometrically possible isomers are considered, as shown in Fig. 2. When the reaction product was dissolved in water, instead of methanol, a mixture of *fac*- and hydroxo-dimer complexes were obtained. This suggests that the coordinating structure of this complex is that of (A) in Fig. 2. The absorption spectrum of $[Cr(val)_2(val\text{-}O)(NH_3)]$ was similar to that of $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]$. The structure of the bis(valinato) complex is also coincident with that of the bis(isoleucinato) one.

IR Spectra. Infrared absorption spectra were measured in the range of 4000 to 400 cm^{-1}. The spectra of $[Cr(isoleu)_3]$ and $[Cr(isoleu)_2(isoleu\text{-}O)(NH_3)]$ are shown in Fig. 3. It is seen from this firgure that the absorption peak which is assigned to the NH_2 deformation vibration appears at 1505 cm^{-1} in the bis-type complex, but that in the tris complex in which all amine groups were bonded to the chromium atom, this peak is shifted to 1600 cm^{-1}. Therefore, these results lead to the conclusion that the structure of this bis-type complex is that of (A) in Fig. 2. The bis-type

complex with L-valine also has an absorption peak at 1505 cm^{-1}. This suggests that the structure of this complex is similar to that of the bis-type complex with L-isoleucine.

CD Spectra. The circular dichroism for (+)[Cr(am-but)$_3$] and (+) and (−)[Cr(norval)$_3$] (Fig. 4), (−)[Cr(norleu)$_3$] and (+)[Cr(val)$_3$] (Fig. 5), and (+)[Cr(isoleu)$_3$] and (+) and (−)[Cr(leu)$_3$] (Fig. 6) were measured in DMSO. Although the separation of these optical isomers was not always perfect, the $\Delta\varepsilon_{(ext)}$ of the major components of the first absorption band were larger than those for the corresponding cobalt(III) complexes.[2] Therfore, it appears that these optical isomers were obtained as complexes with fairly high optical purity. Their configurations can be tentatively identified as *Λ* for (+) and *Δ* for (−) by comparing the CD curves of the present complexes with those of the *Λ*-tris(oxalato)[3] and *Λ*-tris(ethylendiamine)chromium[4] ions, respectively. Gillard *et al.* have reported that [Cr(ala)$_3$] which is insoluble in water is of *Λ*-form.[5] The IR spectrum of [Cr(ala)$_3$] obtained in the present work agrees with that published by the above authors.

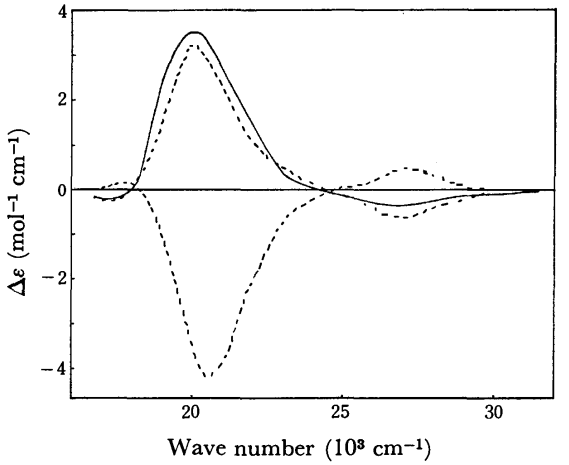

Fig. 6. The CD spectra of (+)[Cr(L-isoleu)$_3$] (——) and (+) and (−)[Cr(L-leu)$_3$] (------).
ε: M^{-1} cm^{-1}, M: mol dm^{-3}.

Douglas and Yamada have reported[6] that the lower solubility of (*β*)-*Λ*[Co(L-ala)$_3$] is not surprising since the molecules of the isomer might be expected to interact strongly through intramolecular hydrogen bonding which would be possible if the molecules were stacked directly above one another. The solubility of (+)[Cr(norval)$_3$] is appreciably lower than that of the corresponding (−) complex. Therefore, the tris(aminobutyrato) and tris(norleucinato)chromium(III) complexes, which are insoluble in both water and DMSO might be also of (+)-form. But, (+)[Cr(am-but)$_3$] which is soluble in water might be different from the other complexes in crystal structure. In general, the solubility of *fac*-(+)chromium(III) complexes with L-amino acids which do not have the side chain is lower than that of the (−) complexes. On the other hand, it is not difficult to understand that the solubility of (+)[Cr(val)$_3$], (+)[Cr(isoleu)$_3$] and (+)[Cr(leu)$_3$] is high, since the interaction through intramolecular hydrogen bonding would become weaker as these amino acids have a methyl group in the *β*- or *γ*-position. Since the spectra of [Cr(val)$_2$(val-O)(NH$_3$)] and [Cr(isoleu)$_2$-(isoleu-O)(NH$_3$)] were not observed, except for the small peaks which are regarded as due to vicinal effects, these complexes are considered to be mixturees of diastereoisomers.

◑: Complexes prepared by both methods.
○: Complexes prepared by the solution method.

The chromium(III) complexes with various L-α-amino acids of type $[Cr(L)_3]$, $[Cr(L)_2(L\text{-}O)(NH_3)]$ and $[Cr(OH)(L)_2]_2$ were synthesized in solid state and in solution (Table 4). The preparation of chromium(III) complexes with natural L-α-amino acids by the two methods may be characterized as follows.

i) *Solid State Reaction.* The complexes of tris-type structure were prepared for all amino acids, except for L-valine, but the complexes of dimer-structure were prepared only for amino acids other than L-alanine, L-norvaline and L-valine. As far as valine and isoleucine, which have a methyl group in the β-position, are concerned, a new type complex, $[Cr(L)_2(L\text{-}O)(NH_3)]$ was prepared. When water was used as the solvent, the complexes containing alanine and norvaline obtained were of tris-type, while the complexes containing aminobutyric acids and norleucine were of dimer structure. Complexes with L-α-amino acids are predominatly of tris- and dimer-type, alternatively, depending on the length of the carbon skeleton. This is also observed for the complexes with racemic amino acids prepared by the solution method.

Table 5. Optical isomers of the tris-chromium(III) complexes prepared

Amino acid	Solid reaction			Solution reaction
	MeOH	EtOH	H_2O	
Alanine	no	no	(+)	(+)
Aminobutyric acid	+	no	no	(+)
Norvaline	+	−	−	−
Norleucine	(+)	−	−	−
Valine	no	no	no	+
Isoleucine	no	no	+	+
Leucine	+	−	no	mixture

no: No tris-complex was obtained.
( ): The CD spectrum was not measured due to the low solubility.

The interesting relation between the formation of optical isomers and the solvent in which the reaction product was dissolved, which is shown in Table 5, together with that for complexes prepared by the solution method. These data suggest that the preponderance of the type of optical isomers is changed depending upon the kind of solvent used, specifically, when reaction products were dissolved in methanol, (+) isomers were obtained, while (−) isomer were obtained in ethanol. The reason may be due to the difference in the solubilities of the diastereoisomers, although this is still not clear from the present work. When water was used as the solvent, the complex with alanine was obtained as a (+) isomer, but those with norvaline and norleucine in which the length of carbon chain is longer than that of aminobutyric acid are obtained as (−) isomers. On the other hand, the complexes with L-amino acids which have a side chain have no clear tendency, since the complex with L-isoleucine are obtained as a (+) isomer, while the other complexes obtained are not in tris form.

When the differences between the racemic and L-amino acids in the complexation were compared, L-amino acids which have no side chains were similar to the racemic acid, except for norleucine. The complexes with L-amino acids which have a side chain were obtained as bis- (val), tris-, bis- and dimer-(isoleu), and tris- and dimer-structures (leu), while the complexes with the corresponding racemic amino acids were obtained only as dimer-type structures. No circular dichroism for tris-type structures with racemic amino acids was observed, while the complexes with L-amino acids were found to be optically active.

ii) *Solution State Reaction.* The chromium(III) complexes with L-amino acids were all prepared as tris-type structures. All complexes of dimer-structure were prepared, except for alanine and leucine. By changing the amount of water in which the mixture was dissolved, tris- or dimer-complexes were selectively obtained. The optical isomer obtained by the solution method is similar to that resulting from the solid reaction which was dissolved in water, except for L-α-aminobutyric acid, L-valine and L-leucine which were not prepared as tris-type complexes in solid state.

When the differences between racemic and L-amino acids in complexation were compared, no significant difference was observed for the solution method, except that the complexes with L-amino acids were obtained as optically-active complexes. However, a different result was obtained for the complex with valine, since *dl*-valine gave only a dimer-type complex, while L-valine gave tris-, bis- and dimer-structures.

The author wishes to thank Professor Muraji Shibata and his corworkers of Kanazawa University for the CD measurements. The author also wishes to thank Professor Ryokichi Tsuchiya of Kanazawa University for valuable discussions and suggestions. This work was finally supported by a grant-in-aid from the Ministry of Education.

The Absolute Configuration of the (+)$_{546}$-β-Oxalato[(6*R*,8*S*)-dimethyl-2,5,9,12-tetraazatridecane]cobalt(III) Ion, (+)$_{546}$-β-[Co(ox)(*N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet)]$^+$

Shigenobu YANO, Keizo FURUHASHI, and Sadao YOSHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Tokyo 113

(Received October 29, 1976)

The crystal and molecular structure of (+)$_{546}$-β-[Co(ox)(*N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet)]$^+$ has been determined from three-dimensional intensity data collected by counter methods. The structure has been refined by least-squares techniques to an *R* factor of 5.9% for 838 reflections above the background. The red violet crystals are orthorhombic, with a space group of $P2_12_12_1$, with $Z=4$ ($D_m=1.501$, $D_c=1.505$ g/cm^3), and with cell constants of $a=14.175(5)$, $b=18.591(2)$ and $c=7.747(4)$ Å. The complex ion has the Δ absolute configuration, which was determined by the Bijvoet method. The quadridentate ligand, *N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet, is coordinated to the Co *via* 4 N atoms in the *cis*-β configuration, yielding two terminal 5-membered chelate rings with the λ conformation and a central 6-membered ring with a chair conformation (both C–CH$_3$ groups are equatorial). The secondary N atoms have *R* chirality except for one terminal N atom, the absolute configuration of which is *S*. The N(*S*)–CH$_3$ group in the "out-of-plane" 5-membered ring is equatorial, whereas the N(*R*)–CH$_3$ group in the other ring has an axial disposition.

In recent years, metal complexes containing six-membered β-diamine with *C*-methyl groups have been under investigation.[1] However, only two complexes have been structurally elucidated by X-ray analysis. Kobayashi *et al.*, reported that each 2,4-pentanediamine chelate ring in the {Co[(*R*,*R*)-2,4-pentanediamine]$_3$}$^{3+}$ ion takes a skew-boat conformation, with both methyl groups in an equatorial position.[2] On the other hand, in the (+)$_{470}$-β-[Co(NO$_2$)$_2$(4-methyl-3,7-diazanonane-1,9-diamine)]$^+$ ion, the central six-membered chelate ring of the tetramine adopts a chair conformation, with an equatorial methyl group.[3] Thus, there are two probable conformations for the central 2,4-pentanediamine moiety of the tetramine in the [Co(ox)(*N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet)]$^+$ ion, where *N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet is (6*R*,8*S*)-6,8-dimethyl-2,5,9,12-tetraazatridecane.

Our present ligand, *N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet, has two *N*-methyl groups, it is of interest in elucidating the stereochemistry of this system.

The crystal structure of (+)$_{546}$-[Co(ox)(*N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet)]ClO$_4$, isolated by Dr. Fujio Mizukami,[4] has been determined by X-ray structure analysis in oder to establish the stereochemical configuration of the complex ion.

Experimental

The crystals of (+)$_{546}$-β-[Co(ox)(*N*,*N'*-Me$_2$-*R*,*S*-2,3'',2-tet)]ClO$_4$ were kindly supplied by Dr. Fujio Mizukami of the National Chemical Laboratory for Industry. The systematic absences observed on Weissenberg photographs are *h*00 for *h* odd, 0*k*0 for *k* odd, and 00*l* for *l* odd, all consistent with the $P2_12_12_1$ space group. The precise lattice conatsnts were obtained by the least-squares analysis of the 2θ angles of the reflections carefully measured on a Rigaku-Denki four-circle automatic X-ray diffractometer by the use of Mo*K*α radiation ($\lambda=0.7107$ Å). The values are $a=14.175(5)$, $b=18.591(2)$, and $c=7.747(4)$Å. The calculated density of 1.505 g/cm^3 for the four formula units in the unit cell agrees well with the density of 1.501 g/cm^3 measured by the floatation method in a mixture of carbon tetrachloride and dibromoethane. The crystal used in the data collection was an irregularly shaped plate with the approximate dimensions of 0.4×0.25×0.3 mm. The crystal was mounted with the c axis approximately parallel to the instrument axis. The intensity data ($2\theta\leqq60°$) were collected by the ω-2θ scan technique, using Mo*K*α radiation monochromated by a LiF crystal. The scan speed was 2°/min in 2θ, and the stationary-crystal, stationary-counter background counts of 10 s were taken at each end of the scan. As a general check on the electronic and crystal stability, the intensities of four standard reflections were monitored every 50 reflections during the collection of the intensity data, no significant variation was noted. A total of 838 indepent reflctions larger than 3σ were used for the structure determination, where σ is given by $|F|/2I_0[I_P+(B_1+B_2)(T_P/2T_B)^2]^{1/2}$ (I_P and I_0 are the total intensity and the net intensity respectively; B_1 and B_2 are the background counts, T_P and T_B are the times required for the measurements of the peak and background intensities).

Determination and Refinement of the Structure

In order to obtain a trial structure, a three-dimentional Patterson function was calculated. The coordinates of the cobalt and chlorine atoms were determined from the prominent peaks in the Patterson function. The remaining non-hydrogen atoms were located from a Fourier map phased by the heavy atoms. The conventional *R* value ($\sum||F_o|-|F_c||/\sum|F_o|$) was 0.561 at this stage. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[5] Refinement was carried out with a block-diagonal least-squares method in the isotropic mode. A weighting scheme, $\omega=1$ if $F_o\geq10.0$ and otherwise $\omega=0.2$, was employed. After several cycles of the refinement, the *R* value was reduced to 0.175 ($R'=(\sum\omega(|F_o|-|F_c|)^2/\sum\omega F_o^2)^{1/2}=0.196$). When the least-squares calculations were continued with anisotropic thermal parameters, the *R* and *R'* values reached 0.076 and 0.082 respectively. Differential synthesis showed no abnormal features except for the ambiguity in the positions of the hydrogen atoms. At this stage, the idealized positions of the hydrogen atoms were calculated using a C–H distance of 1.08 Å and H–C–H angles of 109°28'. These hydrogen atoms were included in the subsequent

refinement, but their positional and isotropic thermal parameters (given the value of $B=3.5$) were not refined. The final refinement converged at the R value of 0.059 ($R'=0.064$). The observed and calculated structure factors all listed in Table 1. Table 2 summarizes the final values of the positional and thermal parameters. The absolute configuration of the complex was determined by using the absorption-edge technique.[6] An equi-inclination Weissenberg photograph of the 1st-layer about c axis was taken with Cu$K\alpha$ radiation. Some Bijvoet pairs, hkl and $h\bar{k}l$, were found to show appreciable differences in intensity. These pairs and the observed inequality relationships are listed in Table 3, in which the structure amplitudes calculated on the basis of the Δ configuration of the complex are also given.

Description and Discussion of the Structure

There are four complex and four perchlorate ions per unit cell. Figure 1 gives a stereoscopic pair of view of the contents of a unit cell of this structure. The absolute configuration of the complex ion is represented by a perspective drawing in Fig. 2. The cobalt atom is situated at the center of a slightly distorted octahedron. The tetramine ligand, $(H_3C)NH$-$(CH_2)_2$-NH-$CH(CH_3)$-CH_2-$CH(CH_3)$-NH-$(CH_2)_2$-$NH(CH_3)$, is coordinated to the cobalt atom in the Δ-*cis*-β geometry. Each conformation of the three chelate rings for the tetramine is present in Fig. 3. The central -HN(2)-C(3)H(CH_3)-C(4)H_2-C(5)H(CH_3)-N(3)H- atoms and the cobalt atom form a six-membered chelate ring with a chair conformation, both of the C-CH_3 groups being equatorial. The H_3C(N1)-N(1)H-C(1)H_2-C(2)H_2-

C(N1)-O(2)	3.10(2)	C(N4)-O(1)	2.98(3)
		C(N4)-O(2)	3.38(3)

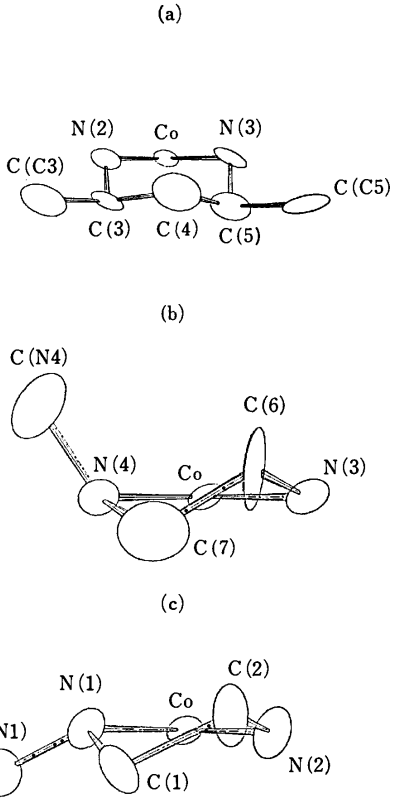

Fig. 3. A perspective drawing of the chelate rings; (a) central six-membered ring, (b) in-plane five-membered ring, and (c) out-of-plane five-membered ring.

N(2)H- fragment participates in the five-membered chelate ring with a λ gauche conformation, and the methyl group is equatorial. The other five-membered ring is composed of the -HN(3)-C(6)H_2-C(7)H_2-N(4)-H-C(N2)H_3 fragment with a metal atom and also has a λ conformation, but the methyl group is axial with respect to the chelate ring. Among the secondary nitrogen atoms, N(1)—N(4), the N(1) has *S* chirality, while the absolute configurations of the remainder are *R*. The two outer chelate rings have similar gauche conformations. The ring carbon atoms, C(1) and C(2), lie at −0.53 and 0.21 Å respectively from the plane formed by N(1), Co, and N(2). The corresponding deviations of C(7) and C(6) from the plane of N(4), Co, and N(3) are −0.41 and 0.33 Å. Close contacts between the *N*-methyl carbon atoms and other atoms in the complex (less than 3.5 Å) are listed in Table 4. These are similar values between the two *N*-methyl groups.

Four isomers can exist with respect to the orientation of the two *N*-methyl groups in relation to the *Δ-cis-β*

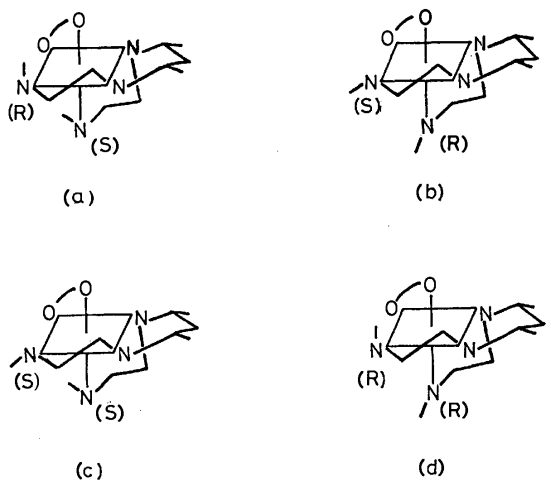

Fig. 4. Possible isomers of *Δ*-*β*-[Co(ox)(*N*,*N*′-Me$_2$-*R*,*S*-2,3″,2-tet)]$^+$.
(a) (N1(*S*), N4(*R*)), (b) (N1(*R*), N4(*S*)), (c) (N1(*S*), N4(*S*)), (d) N1(*R*), N4(*R*)).

form. They are (N1(*S*), N4(*R*)), (N1(*R*), N4(*S*)), (N1(*S*), N4(*S*)), and (N1(*R*), N4(*R*)), as shown in Fig. 4. The (N1(*S*), N4(*R*)) isomer to involve a smaller interaction than the other three forms, according to the molecular model study. This structural feature was supported by the present X-ray analysis. It is noteworthy that one *N*-methyl group has an axial orientation with that the equatorial orientation of the *N*-methyl group is preferable to the axial situation. This stereochemical feature can be attributed to severe steric interactions on the metal ion.

All the N–Co–N angles in five-membered chelate rings are less than 90°, and they have an average value of 86.0°. The N–Co–N angle in the central six-membered chelate ring is 91.7°. The bond distances and angles are given in Tables 5 and 6 respectively. The four Co–N distances are not significantly different from one another, and the average value (2.01 Å) is quite usual.

Absolute Configuration and Circular Dichroism. The stereochemical features which can contribute to the circular dichroism (CD) of a dissymmetric metal complex have been classified as follows: (1) a distribution of chelate rings about the metal ion (configurational effect), (2) the puckered dissymmetric conformation of individual chelate rings (conformational effect), and (3) the presence of asymmetric groups on the ligands, such as asymmetric carbon or asymmetric nitrogen atoms (vicinal effect). The latter two effects are considered to make minor contributions as compared with the configurational effect.

The CD spectrum of *Δ*-*β*-[Co(ox)(*N*,*N*′-Me$_2$-*R*,*S*-2,3″,2-tet)]$^+$ is shown in Fig. 5. The above results suggest the following conclusion: when the oxalato cobalt(III) complexes of 3,7-diaza-1,9-nonanediamine (2,3,2-tet) and its derivatives give two circular dichroism bands with opposed signs in the first absorption region,

an enantiomer which has a lawer-energy negative Cotton effect and a higher-energy positive one should be assigned the Δ configuration.

The calculation of the lattice constants, the Fourier synthesis the least-squares analysis, and drawings of the crystal or molecular structures were carried out on a HITAC 8700/8800 computer at the Computer Center of this University, using the RSCL3, ANSFR-2, HBLS-4, and ORTEP[7] programs of the UNICS system respectively.

The authors are grateful for Dr. Fujio Mizukami for providing crystals of $(+)_{546}$-β-[Co(ox)(N,N'-Me_2-R,S-2,3″,2-tet)]ClO_4. They also wish to thank Dr. T. Kodama for the operation of the diffractometer. This work was partially supported by a Grant-in-aid for Scientific Research from the Ministry of Education, Japan (No. 911502).

Polymer-supported Trichlorotitanium(III) Complexes and Their Dioxygen Adducts*

Yasuo CHIMURA, Masazo BEPPU, Satohiro YOSHIDA, and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 22, 1976)

Various polymer-supported trichlorotitanium(III) ($TiCl_3$) complexes were prepared in pyridine or THF from $TiCl_3$ and copolymers composed of 4-vinylpyridine (10, 20, and 65 mol%), divinylbenzene (0 and 20 mol%), and styrene. The ESR technique was employed for structural studies of titanium(III) species and their dioxygen adducts contained in the supported complexes. The supported complexes contained, as titanium(III) species, mainly (>88%) mixtures of $TiCl_3(pyr)_nL_{3-n}$ ($n=1$, 2, and 3), where pyr is a pyridyl group of the supports and L is a molecule of the solvents used in preparation. The relative amounts of the species having smaller n values increased with cross-linking, with a decrease in the content of pyridyl groups, and with pretreatment with tetrachlorotitanium(IV) ($TiCl_4$). On exposure to oxygen the supported complexes gave two or three kinds of dioxygen adducts (Ti(IV)-O_2^-) characterized by g_1, the principal g value along the axis of O–O bond. The g_1 values of three dioxygen adducts α, β, and γ were 2.027—2.028, 2.022—2.024, and 2.017—2.018, respectively. The probable structures of α, β, and γ, when L is THF, are $[TiCl_2(pyr)_3(O_2)]Cl$, $TiCl_3(pyr)_2(O_2)$, and $TiCl_3(pyr)L(O_2)$, respectively, their precursors being the titanium(III) species having the n values of 3, 2, and 1, respectively.

Many reports have appeared on dioxygen adducts of divalent cobalt and of lower valent transition metals of the group VIII.[1] Typical examples are $Co\{C_6H_5C(O^-)=CHC(CH_3)=NCH_2-\}_2(O_2)py$, $Ir(O_2)Cl(CO)\{P(C_6H_5)_3\}_2$, $Pt(O_2)\{P(C_6H_5)_3\}_2$, and $Ni(O_2)\{CNC(CH_3)_3\}_2$.

Dioxygen adducts of other metals are scarcely known. The main reason is that they react rapidly in solution with their original complexes (step b in the following scheme), even though they were once formed.

$$M + O_2 \underset{a}{\rightleftharpoons} M\text{-}O_2 \xrightarrow[b]{+M} \cdots \longrightarrow M\text{-}O\text{-}M \text{ or } M{=}O$$

Two devices have been developed to suppress step b: (1) dioxygen adducts are sterically protected by ligands with bulky substituents from reacting with their orginal complexes;[2] (2) metal complexes are attached to organic or inorganic polymers with coordinating groups so that no two metal complexes can approach each other. Misono *et al.*[3] reported that several cobalt(II) Shiff base complexes attached to poly-4-vinylpyridine gave 1:1 dioxygen adducts. Wang[4] reported the spectral evidence that oxygen was bound reversibly to the diethyl ester of heme embedded in a matrix of polystyrene and 1-phenethylimidazole. Leal *et al.*[5] showed recently that an iron(II) porphyrin attached to a modified silica gel adsorbed oxygen reversibly and was not oxidized to a μ-oxo dimer even at room temperature.

The ESR signals observed during the course of reaction of $TiCl_3$ with hydrogen peroxide in a flow system were ascribed to peroxy radical species of titanium.[6] No dioxygen adduct of titanium formed from a titanium(III) complex and molecular oxygen, however, has been observed in solution. We could detect a dioxygen adduct of $TiCl_3$, by binding $TiCl_3$ to a copolymer containing pyridyl groups and exposing it to oxygen.[7] The aim of the present work is to clarify the structures of titanium(III) species and of their dioxygen adducts contained in the supported $TiCl_3$ complexes.

* A part of this report was presented at the 35th Meeting of the Catalysis Society of Japan, Sendai, October 1974.

Experimental

Materials. All solvents were refluxed over sodium metal or calcium hydride, then distilled, and stored under nitrogen. Monomers 4-vinylpyridine, styrene, and divinylbenzene were distilled under reduced pressure immediately before use. The divinylbenzene contained about 45% ethylvinylbenzene and was employed when cross-linked polymers were desired. Trichlorotitanium(III) was used as a 0.1 M acetonitrile solution. Commercial oxygen and nitrogen gases were used without further purification.

Polymer Supports: The monomers (total 50 mmol) were copolymerized by the use of 2,2′-azobisisobutyronitrile (0.25 mmole) in benzene or ethanol (50 cm^3) under nitrogen at refluxing temperature for 5 h. The resulting polymers were either precipitated by addition of ethyl ether when they were linear and soluble or washed with benzene and methanol when cross-linked and insoluble. They were then dried *in vacuo* at 120°C and ground to powders of 100—300 mesh. The yields were 60—80%. The degree of cross-linking was assumed to be equal to the molar ratio of charged divinylbenzene to total monomers. The content of pyridyl groups (mol%) was calculated from nitrogen microanalysis.

Polymer-supported $TiCl_3$ Complexes: The acetonitrile solutions of $TiCl_3$ (0.072—0.146 mmol) were stirred with the polymer supports (0.180 g, 0.145—1.15 mequiv. N) dissolved or swelled in pyridine or THF (30 cm^3) under nitrogen at room temperature for 5 h. The solvents were then evaporated *in vacuo* when the supported complexes were prepared from cross-linked supports in pyridine or from soluble, linear ones in either of the solvents, while the solvent was decanted when prepared from cross-linked ones in THF. The resulting solids were then dried *in vacuo* at room temperature. The amounts of charged $TiCl_3$ were controlled to yield supported complexes containing about 5% of $TiCl_3$ based on the total aromatic rings of the supports. Thus, in order to prepare supported complexes with 20% cross-linking and 10, 20, and 65% pyridyl group in THF, 0.146, 0.100, and 0.080 mmol of $TiCl_3$, respectively, were charged. The amounts of $TiCl_3$ corresponding to 5% of the total aromatic rings of the supports were introduced when supported complexes were prepared in pyridine.

A support with 20% cross-linking and 65% pyridyl group (0.180 g, 1.02 mequiv. N) was stirred with $TiCl_4$ (0.29 mmol) in THF (30 cm^3) for 5 h, subsequently mixed with $TiCl_3$ (0.10 mmol) and worked up as described above.

Analysis of Titanium. The amounts of attached $TiCl_3$ were determined only in the case of supported complexes with cross-linking prepared in THF. The method was to titrate chelatometrically titanium ions not attached and dissolved in a supernatant liquid, and to subtract the titre from the amount of charged $TiCl_3$. A titanium(IV) ion is so apt to be hydrolyzed in water that a 50% aqueous ethanol solvent was employed, and EDTA added in excess was back-titrated at pH 5.5 with a 0.05 M zinc(II) solution by the use of xylenol orange as an indicator.

ESR Measurements. Fine solids of the supported complexes were transferred under nitrogen to ESR sample tubes equipped with three-way stopcocks. Their spectra were recorded under nitrogen at room temperature and 77 K with a JEOL-JES-3BS-X (X-band) spectrometer before and after contact with oxygen. The g values were calculated on the basis of that of manganese(II) ions doped into magnesium oxide, which was calibrated with an aqueous solution of peroxylamine disulfonate. The relative amounts of paramagnetic species were determined by the integration of their ESR spectra with a JEOL-JES-ID-2 integrator.

Results and Discussion

Polymer-supported $TiCl_3$ Complexes. The colors of polymer-supported $TiCl_3$ complexes depend upon the composition of supports and the solvents used in preparation (Table 1). Supported complexes without cross-linking are dark brown regardless of solvent. Those with 20% cross-linking change their colors from brown to light brown and from brown to light yellow with a decrease in the content of pyridyl groups, when they are prepared in pyridine and THF, respectively.

All the supported complexes gave two types (A and B) of ESR signals of titanium(III). Type A with g value of 1.96** was easily detected at room temperature and 77 K. Type B was very weak and broad at room temperature. On cooling down to 77 K it became strong showing g values of 1.87—1.91, but was much broader than type A. ESR spectra of a supported complex with 20% cross-linking and 65% pyridyl group prepared in pyridine recorded at room temperature and 77 K are shown in Fig. 1 as a typical example. Supported complexes without cross-linking showed, in addition to A and B signals, weak signals at $g \approx 4$ attributable to $\Delta M = \pm 2$ transitions of the triplet-state of a $TiCl_3$ dimer.[8,9]

The g values and relative amounts of the two types of signals are summarized in Table 1. Type A signals have almost constant g values throughout all the supported complexes. Their amounts are much smaller than those of type B signals, diminishing with cross-linking, a decrease in the content of pyridyl groups, the change of solvents from pyridine to THF, and pretreatment with $TiCl_4$. The g values of type B signals are greatly influenced by the solvents used in preparation, the composition of the supports, and pretreatment with $TiCl_4$. Supported complexes prepared in pyridine have larger g values than those prepared in THF except for those without cross-linking. Among supported complexes prepared in THF the g values decrease with a decrease in the content of pyridyl groups, while supported complexes prepared in pyridine have constant g values. Cross-linking makes the g value small when prepared in THF, while cross-linking has little effect when prepared in pyridine. Tetrachlorotitanium(IV) introduced prior to addition of $TiCl_3$ makes a small g value.

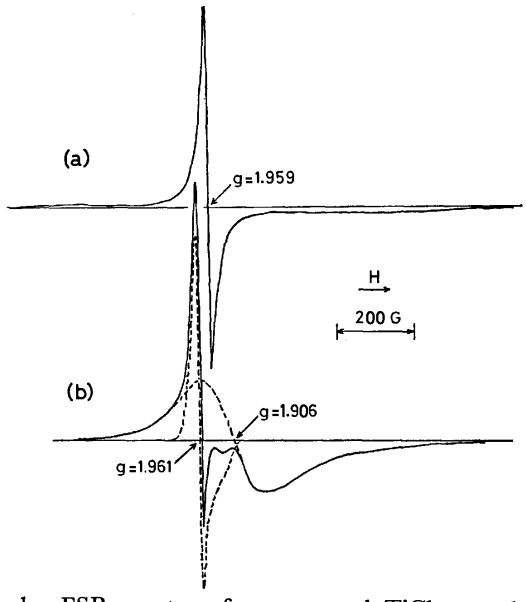

Fig. 1. ESR spectra of a supported $TiCl_3$ complex with 20% cross-linking and 65% pyridyl group prepared in pyridine, recorded under nitrogen at room temperature (a) and at 77 K (b).

When $TiCl_3$ is dissolved into pyridine, a sharp intense singlet signal at $g=1.96$[8] or 1.957[9] has been observed at room temperature along with a triplet-state spectrum of a $TiCl_3$ dimer. This signal has been ascribed to a $TiCl_3$ monomer whose structure, however, is unknown. The titanium(III) species giving type A signals has an analogous structure because of the similarity of g values and line widths between type A signals and the above signal in the pyridine solution. The titanium(III) species responsible for type A signals is coordinated only by the pyridyl groups of supports, since the g values of the signals depend neither upon the solvents used in preparation nor the composition of supports, the amounts of the signals decreasing with a decrease in chelating nature of the pyridyl groups.

Trichlorotitanium(III) forms hexacoordinated complexes of the type $TiCl_3L_3$, where L is a polar molecule such as acetonitrile, pyridine, acetone, or THF.[10] Further, $TiCl_3$ forms also hexacoordinated complexes of the type $TiCl_3L_2L'$ with two different non-halide ligands, where L and L' are acetonitrile, dioxane, THF, and 2-propanol.[11] Thus the following hexacoordinated titanium(III) species seem to be present in the supported complexes: $TiCl_3(pyr)_nL_{3-n}$ ($n=1$, 2, and 3), where pyr is a pyridyl group of the supports and L is a molecule of the solvents used in preparation.

In frozen solution at 77 K, $TiCl_3L_3$, where L is acetonitrile, pyridine, or THF, gave an ESR signal with $g_{//}=1.883$, $g_{\perp}=1.921$, $g_{av}=1.908$;[11] $g_1=1.86$, $g_2=$

** Each g value of the two types of signals was calculated at the center of each ESR signal, since the signal was a single line without peaks giving principal g values.

Table 1. *g* Values, relative amounts of two types of signals, and colors of polymer-supported $TiCl_3$ complexes

Expt. No.	Solvent used for preparation	Cross-linking %	Content of pyridyl groups %	*g* Value[a] type A	*g* Value[a] type B	Relative amount[a,b] type A/type B %	Color
1	pyridine	0	65	1.962	1.909	14	dark brown
2	pyridine	20	65	1.961	1.906	2	brown
3	pyridine	20	10	1.961	1.906	1	light brown
4	THF	0	65	1.959	1.908	10	dark brown
5	THF	20	65	1.960	1.901	2	brown
6	THF	20	20	1.959	1.883	1	light brown
7	THF	20	10	1.959	1.870	1>	light yellow
8[c]	THF	20	65	1.960	1.873	1>	yellow

1.89, $g_3=1.95$, $g_{av}=1.90$;[8] or $g_{//}=1.849$, $g_{\perp}=1.894$, $g_{av}=1.879$,[11] respectively, while it gave a very broad signal at room temperature.[12] Since the *g* values and the line widths of type B signals at room temperature and 77 K are similar to those of the above $TiCl_3L_3$ complexes, type B signals are ascribed to the $TiCl_3(pyr)_nL_{3-n}$ species.

In hexacoordinated titanium(III) complexes their *g* values increase with the increasing number of their ligands at higher order in the spectrochemical series.[11,13] The *g* values of the above $TiCl_3L_3$ complexes increase with the following order of L: THF<pyridine<acetonitrile. This is the same order of L in the spectrochemical series.[14]

The fact that supported complexes prepared in pyridine have larger *g* values than those prepared in THF indicates the presence of the $TiCl_3$ species having solvent molecules, *i.e.*, $TiCl_3(pyr)_nL_{3-n}$ ($n=1$ and 2), in the supported complexes. The decrease in the *g* values of supported complexes prepared in THF with a decrease in the content of pyridyl groups indicates the increase in the number of the $TiCl_3$ species having more solvent ligands, THF, with a decrease in the content of pyridyl groups. The decrease in the *g* values with cross-linking of the supports or with pretreatment with $TiCl_4$ indicates also the increase in the $TiCl_3$ species which have more solvent ligands, THF, with these changes in the conditions of preparation. Supported complexes prepared in pyridine would contain the $TiCl_3(pyr)_nL_{3-n}$ species having various values of *n*, as those prepared in THF contain, in spite of the small change of the *g* values with the change of the composition of the supports. The small change is ascribed to the similar effects of a pyridyl group (4-alkylpyridine) and pyridine upon the *g* value of a titanium(III) ion.

In conclusion, there are several $TiCl_3$ species with different environments (titanium(III) species responsible for type A signals and $TiCl_3(pyr)_nL_{3-n}$ ($n=1$, 2, and 3)) in polymer-supported $TiCl_3$ complexes, and the relative amounts of these titanium(III) species depend upon the composition of the polymer-supports (the content of pyridyl groups and the degree of cross-linking) and upon pretreatment with $TiCl_4$. In supported complexes with a high content of pyridyl groups, the pyridyl groups coordinate as chelate ligands to $TiCl_3$, and the number of the $TiCl_3$ species with two or three chelate pyridyl groups, *i.e.*, $TiCl_3(pyr)_nL_{3-n}$ ($n=2$ and 3), is large. On the other hand, such chelation is difficult in supported complexes with a low content of pyridyl groups and thus the $TiCl_3$ species with one pyridyl group, *i.e.*, $TiCl_3(pyr)L_2$, increase. Cross-linking makes supports rigid and their chelating nature weak. On addition of $TiCl_4$, the pyridyl groups coordinate as chelate ligands to $TiCl_4$ forming $TiCl_4(pyr)_2$, and thus the number of the pyridyl groups which can coordinate as chelates decreases and $TiCl_3$ added subsequently forms mainly $TiCl_3(pyr)L_2$.

Dioxygen Adducts of Polymer-supported $TiCl_3$ Complexes. By introduction of 1 atm of oxygen upon polymer-supported $TiCl_3$ complexes at room temperature, the intensities of both types of ESR signals became less than half of their original ones within a few minutes except for supported complexes without cross-linking. The colors of the supported complexes turned from brown or yellow to orange or yellowish orange at the same time. The decrease in intensities of both types of ESR signals and the change of color were very slow (half-life, *ca.* 2 h) in the case of supported complexes without cross-linking. This difference may be mainly caused by the difference in surface areas. Supported complexes with cross-linking are fine powders and may have greater surface areas than those without cross-linking which are fine pieces of films.

New sharp signals appeared at about $g=2.01$ as soon as the signals of titanium(III) diminished. The shapes of the new signals at 77 K were the same as those at room temperature. The new signals of two different supported complexes are given in Fig. 2. Each spectrum consists of two or three signals, each having three principal *g* values, *viz.*, $g_1=2.028$, $g_1'=2.023$, $g_2=g_2'=2.011$, $g_3=g_3'=2.004$ (Fig. 2a); $g_1=2.028$, $g_1'=2.022$, $g_1''=2.017$, $g_2=g_2'=g_2''=2.011$, $g_3=g_3'=g_3''=2.004$ (Fig. 2b). The new signals of all the supported complexes we examined had the following principal *g* values: $g_1=2.017$—2.028, $g_2=2.010$—2.011, and $g_3=2.003$—2.004 (Table 2). These values are nearly the same as those of O_2^- radicals on titanium dioxide.[15] Thus the new signals are ascribed to dioxygen adducts of support-

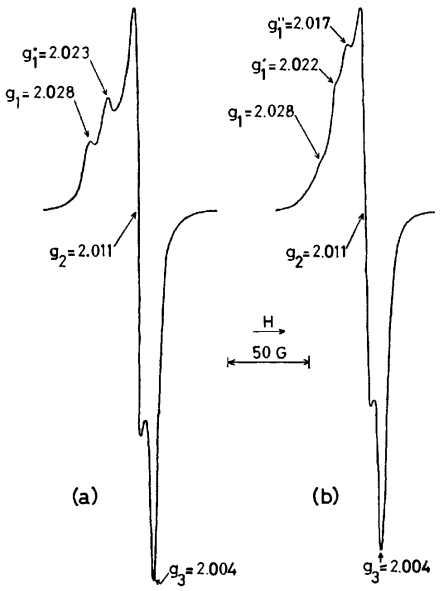

Fig. 2. New ESR signals of supported $TiCl_3$ complexes with 20% cross-linking and 65% (a) and 10% (b) pyridyl group prepared in THF, recorded under nitrogen at room temperature after contact with oxygen.

ed $TiCl_3$ complexes, whose electronic structure should be formally decribed as $Ti(IV)-O_2^-$.

The three principal g values of the dioxygen adducts of the supported complexes prepared from different supports in different solvents are given in Table 2. We denote principal g value along the axis of O–O bond by g_1. The g_1 values are greatly influenced by the conditions of preparation, whereas the g_2 and g_3 values remain nearly constant. The g_1 values can be classified into three groups: 2.027—2.028, 2.022—2.024, and 2.017—2.018. They correspond to three different $Ti(IV)-O_2^-$ species α, β, and γ, respectively, whose g_2 values as well as g_3 values are identical with each other. The g_1 peak of α is enhanced in supported complexes with a high content of pyridyl groups prepared in either of the solvents, becoming a shoulder in those with a low content of pyridyl groups. The g_1 peak of β behaves like that of α, but remains as a stronger peak than that of α when supported complexes are prepared from supports with a low content of pyridyl groups. The g_1 peak of γ appears only in supported complexes with a low content of pyridyl groups prepared in THF or pretreated with $TiCl_4$, being the strongest of the three peaks.

A few different O_2^- species have also been found on the surface of titanium dioxide. Naccache *et al.*[16] reported that two different O_2^- species were found on both anatase and rutile: $g_1=2.024$, $g_1'=2.020$, $g_2=g_2'=2.009$, $g_3=g_3'=2.003$ for anatase; $g_1=2.030$, $g_2=2.008$, $g_3=2.004$, $g_1'=2.020$, $g_2'=2.009$, $g_3'=2.003$ for rutile. Davydov *et al.*[17] found five different O_2^- species on anatase: $g_1^1=2.0330$, $g_1^2=2.0278$, $g_1^3=2.0254$, $g_1^4=2.0233$, and $g_1^5=2.0213$, the g_2 values as well as the g_3 values of which coincided with each other. However, the structures of the dioxygen adducts corresponding to these different g_1 values have not been described.

The structures of the dioxygen adducts α, β, and γ should be considered. These dioxygen adducts do not come mainly from the titanium(III) species responsible for type A signals, since the amounts of type A signals were small. There was no remarkable difference in the relative amounts of these dioxygen adducts of a supported complex with 0% cross-linking and 65% pyridyl group and that with 20% cross-linking and 65% pyridyl group, where the relative amounts of type A signals to type B signals were 14% and 2%, respectively. Adducts α and β were observed in supported complexes prepared in pyridine. They have no THF ligand though they appeared also in supported complexes prepared in THF. The relative amounts of the titanium(III) species $TiCl_3(pyr)_3$, $TiCl_3(pyr)_2L$, and $TiCl_3(pyr)L_2$ in supported complexes prepared in THF increased in this order with a decrease in the content of pyridyl groups. The relative amounts of α, β, and γ increased also in this order with a decrease in the content of pyridyl groups. Thus $TiCl_3(pyr)_3$, $TiCl_3(pyr)_2L$, and $TiCl_3(pyr)L_2$ might be the precursors of α, β, and γ, respectively.

The order of the g_1 values of α, β, and γ gives information on the structures of the dioxygen adducts. It has been shown both experimentally and theoretically that the g_1 value of a O_2^- radical coordinating to a cation approaches g_e (2.0023) more closely as the charge of the cation becomes more positive.[15] The g_1 values decreased in the order $\alpha>\beta>\gamma$, the negativity of titanium ions of the dioxygen adducts decreasing in the same order. Since a pyridyl group is more basic than THF or a chloride anion, a titanium ion which has more pyridyl

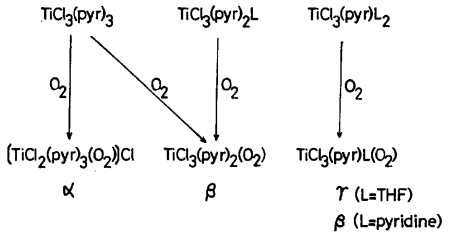
Table 2. Principal g values of dioxygen adducts of polymer-supported $TiCl_3$ complexes[a]

Expt. No.	Solvent used for preparation	Cross-linking %	Content of pyridyl groups %	g_1	g_1'	g_1''	g_2	g_3
1	pyridine	0	65	2.028	2.022	—	2.010	2.004
2	pyridine	20	65	2.028	2.023	—	2.010	2.003
3	pyridine	20	10	2.028 sh[b]	2.022	—	2.011	2.004
4	THF	0	65	2.028	2.024	—	2.010	2.004
5	THF	20	65	2.028	2.023	—	2.011	2.004
6	THF	20	20	2.027 sh	2.022 sh	2.017	2.010	2.004
7	THF	20	10	2.028 sh	2.022 sh	2.017	2.011	2.004
8[c]	THF	20	65	2.028 sh	2.022 sh	2.018	2.010	2.004

a) Measured under nitrogen at room temperature after contact with oxygen. b) Abbreviation: sh, shoulder.
c) Pretreated with $TiCl_4$.

groups becomes more negative. Thus the number of pyridyl groups coordinating to the titanium ions of the dioxygen adducts increases in the order $\gamma<\beta<\alpha$.

The tentative structures of α, β, and γ which agree with the above conclusions are shown in the following scheme along with their precursors. It is assumed that an oxygen molecule behaves as a unidentate ligand and a titanium ion is hexacoordinated.



Scheme.

These dioxygen adducts were very stable at 77 K, but decomposed slowly at room temperature under either nitrogen or oxygen. Among the dioxygen adducts γ was the most unstable, half-life of which was about 1 h under oxygen at room temperature.

The total yields of the dioxygen adducts after a five minute contact with 1 atm of oxygen at room temperature were measured at 77 K under nitrogen and found to be a few percent based on the titanium(III) species reacted with oxygen.

The oxygenation of supported $TiCl_3$ complexes was almost irreversible, since the decomposition of their dioxygen adducts was very slow in a vacuum or under nitrogen as compared with their rapid formation. The decomposition would imply not only the liberation of oxygen to yield the original titanium(III) species but also irreversible oxidation to titanium(IV) species.

The authors wish to express their thanks to Dr. Toshimitsu Suzuki of this department for the supply of $TiCl_3$.

The Liquid-phase Oxidation of Acetaldehyde with Metal Polyphthalocyanines. Solvent Effect

Yasukazu OHKATSU, Takao HARA, and Tetsuo OSA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 1, 1975)

Acetaldehyde was oxidized using metal polyphthalocyanines as catalysts. Metal polyphthalocyanines, especially Fe,Cu-polyphthalocyanine, were found to be useful oxidation catalysts for the selective formation of peracetic acid from acetaldehyde. The rate of oxidation was much affected by the nature of the solvents. The solvent is considered to take part in the initiation oxidation reaction in two ways: one is based on the prevention of the oxygen molecule from coordination with a metal polyphthalocyanine and subsequent activation, and the other is due to the solvation with the activated oxygen molecules on the catalyst. Preferable solvents were ethyl acetate, bromobenzene, benzene, and acetone.

Since metal phthalocyanines were discovered to carry oxygen molecules, they have been used as catalysts in the autoxidation of many organic compounds, the mechanism of their action on the oxidation reaction has also been investigated.[1-4] Kropf *et al.* reported that an active species, an oxygen complex derived from a metal pathalocyanine and molecular oxygen in the presence of a base such as pyridine, could abstract the hydrogen atom from a substrate to generate free radicals, resulting in the initiation of autoxidation.[5-7] Other investigators[8,9] proposed another mechanism for the action of metal phthalocyanines, especially the ability to decompose hydroperoxide homolytically to initiate autoxidation. Contrary to the oxidations using metal phthalocyanines, there are only a few papers available concerning the metal polyphthalocyanine-catalyzed autoxidation.[10-13] But studies of the metal polyphthalocyanine in comparison with its monomeric analogue are expected to throw some light on the elucidation to the chemical behavior of metal polyphthalocyanine as one of the macromolecular catalysts complexed with metal ions, the structure of which possesses a close similarity to hemoglobin. In our papers, various metal polyphthalocyanines were synthesized and shown to be effective catalysts for the autoxidation of cumene[11] and acrolein.[12,13]

In this paper, the liquid-phase oxidation of acetaldehyde was tried using various metal polyphthalocyanines as catalyst. The action of the catalyst and the effect of solvents on the oxidation are discussed in detail.

Experimental

Materials: Metal polyphthalocyanines were synthesized and purified according to the method descrided in an earlier paper.[13] The metal contents in Fe,Cu-polyphthalocyanine were analyzed by a spectrophotometric method; the ratio of iron to copper ions was 1.52. The metal polyphthalocyanine was sufficiently pulverized with a mortar before use. The oxidation rate with micro-crystals of metal polyphthalocyanine was, however, found to be essentially the same as that with the pulverized metal. Acetaldehyde was carefully distilled under nitrogen atmosphere to insure the complete removal of the oxidized materisls; solvents were used after conventional purification with careful drying.

Procedure and Analysis: The oxidation apparatus and oxidation process were described in the literature.[14]

Peroxide products were analyzed by an iodometric titration method determining individual concentrations of hydrogen peroxide, peracetic acid, and other peroxides such as acetoyl peroxide.[15] Other oxidation products were quantitatively determined by gas liquid chromatography.

Results and Discussion

Outline of Autoxidation: Purified samples of metal polyphthalocyanines have been shown to lack the ability to decompose a hydroperoxide, though they catalyzed the liquid-phase oxidation of organic compounds such as cumene and acrolein. The oxidation of acetaldehyde with a metal polyphthalocyanine also gave peracetic acid quantitatively in such solvents as benzene, ethyl acetate, and acetone (Table 1). This fact may be emphasized as one of the characteristic actions of metal polyphthalocyanines, because metal phthalocyanines and other catalysts such as metal acetylacetonates and naphthenates are known to decompose peracetic acid formed during the oxidation of acetaldehyde through a homogeneous mechanism.[16,17] The selectivity of peracetic acid in benzene and ethyl acetate as solvents was inclined to decrease with the reaction time. This may be ascribed to the formation of acetaldehyde monoperacetate in these solvents, followed by its heterogeneous decomposition. In acetone, the rate of oxidation was slower than in ethyl acetate, but the selectivity remained about 93% even after three hours. This suggests that metal polyphthalocyanines can be made use of as catalysts for the selective formation of peracetic acid, and shows that they have no ability to decompose peracetic acid, resulting in the initiation of autoxidation.

The rate of oxygen absorption, as shown in Table 2, was much affected by the nature of the solvent. The dielectric constants of the solvents are also listed in Table 2. The oxidation reaction seems to proceed much faster in a solvent which has an adequate polarity, such as ethyl acetate. There is, however, no linear relationship between the rate and the dielectric constant.

The role of solvents in an autoxidation reaction catalyzed by an organometallic complex can be considered in general in terms of the following two ways. First, the solvent may take part in the chain-propagating step to interrupt autoxidation:

$$CH_3COOO\cdot + RH \longrightarrow CH_3COOOH + R\cdot \quad (A)$$

in which RH denotes a solvent. Secondly, it may

Table 1. The oxidation products in the oxidation of acetaldehyde catalyzed by metal polyphthalocyanines

		Catalyst (solvent)		
		Fe, Cu (Benzene)	Fe, Cu (Ethyl acetate)	Fe (Acetone)

Table 3. The rate of oxygen absorption with and without catalyst in carboxylate solvents

Solvent	$-d(O_2)/dt, \times 10^5$ M s^{-1} (a) Uncatalyzed	(b) Catalyzed	Ratio of (b) to (a)
Ethyl acetate	0.89	13.7	15.4
Isopropyl acetate	0.89	5.84	6.6
Ethyl chloroacetate	0.1	2.45	28.0

Reaction conditions: temperature, 10 °C; catalyst, Fe,Cu-poly-Pc, 4.81×10^{-3}M; acetaldehyde, 4.52×10^{-1}M.

interact with the complexes as a catalyst to change their activity. Imamura found that the oxidation rate of acetaldehyde catalyzed by cobalt naphthenate depended substantially on the kind of solvents and concluded that the oxidation was probably governed by a reaction according to Eq. A in the case of the presence of a hydrocarbon solvent.[17]

If the solvent effect is observed only on the propagation and termination steps of a general autoxidation mechanism as discussed below, though ester solvents were mostly used in this paper, the relative rates of the oxidation in the presence of the catalyst to that in the absence of the catalyst must be same regardless of the kind of solvents. The ratio in Table 3 does not show any solvent effect on such chain steps. This fact also proposes that the solvent effect is operative in the initiation step rather than the chain steps in the present oxidation reaction using a metal polyphthalocyanine as catalyst.

Solvent Effect: The effect of solvents on the rate of oxidation was investigated in detail using various esters, such as acetates (CH_3COOR) and ethyl carboxylates ($R'COOC_2H_5$), as solvents. The oxidation rate in the presence of a metal polyphthalocyanine was considerably dependent on the kind of substituent groups R and R' (Table 4). It was found that there was a certain relation between the oxidation rates and the electronic properties of the substituents (R and R') in terms of their polar substituent constants σ^* for Taft's equation.

In the case of acetates (Fig. 1), the logarithm of the rates increased linearly with increase of σ^* of R in the range of $\sigma^* < -0.10$. The constants ρ^* can be calculated as 6.7 and -0.3 over the ranges of σ^* below and above -0.10, respectively, except for methyl acetate, which is very difficult to purify and constains a small amount of methanol which makes the metal polyphthalocyanine inactive (Table 2). A similar result was also obtained for the ethyl carboxylates, as illustrated in Fig. 1b;

Table 4. Solvent effect of various acetates and ethyl carboxylates on the oxidation rates

Solvent	Substituents R–	Substituents R'–	$-d(O_2)/dt \times 10^5$ M s^{-1}
Acetates			
methyl acetate	CH_3–		2.33

isopropyl acetate	$(CH_3)_2CH$–		5.84
benzyl acetate	$(C_6H_5)CH_2$–		2.58
ethyl acetate	C_2H_5–	CH_3–	13.7
Ethyl carboxylates			
ethyl propionate		C_2H_5–	6.10
ethyl chloroacetate		CH_2Cl–	2.45
ethyl isobutyrate		$(CH_3)_2CH$–	3.14
ethyl dichloroacetate		$CHCl_2$–	0.18

Reaction conditions: (acetaldehyde), 4.52×10^{-1}M; (Fe,Cu-poly-Pc), 4.8×10^{-3}M; temperature, 10 °C.

values of ρ^* were calculated as 4.4 and −1.0 for the straight lines of the left and right sides of ethyl acetate, respectively. For simplicity, a series of solvents having positive ρ^* value are hereafter called M, while the series having negative ρ^* are called N. Considering the absolute values of ρ^* for solvent series M and N, the values for the series M are much larger than those for series N. The ρ^*'s also have different signs for the two series of solvents. These facts imply that the mechanisms of solvent effects are different in these series. The rather large values of ρ^* for series M may suggest that such solvents take part as more polarized species in the initiation reaction.

Table 5. The constant k_1K_1 of the initiation reaction of acetaldehyde by various metal polyphthalocyanines

Metals	$-d(O_2)/dt \times 10^5$ M s	$k_1K_1 \times 10^2$ M^{-2} s^{-1}
Fe,Cu	21.6	7.2
Fe,Mo	12.1	2.0
Fe	8.6	1.1
Fe,Co	8.5	1.1
Cu,Co	1.1	0.0017

Reaction conditions: (CH_3CHO), 0.45M; (catalyst), 4.82×10^{-3}M; solvent, ethyl acetate; temperature, 10 °C.

A Possible Reaction Mechanism: In order to explain the results mentioned above and to explain the oxidation mechanism, especially the initiation reaction, in more detail, the oxidation reaction was investigated kinetically under reaction conditions including those shown in Figs. 1(a) and 1(b). The reactions were confirmed not to proceed under diffusion control of oxygen in the reaction system. The dependence of the rates of oxygen absorption on concentrations of acetaldehyde and the catalyst and on oxygen pressure was determined in three kinds of solvents, isopropyl acetate belonging to series M and ethyl acetate and ethyl monochloroacetate belonging to series N (Figs. 2a, 2b, and 2c).

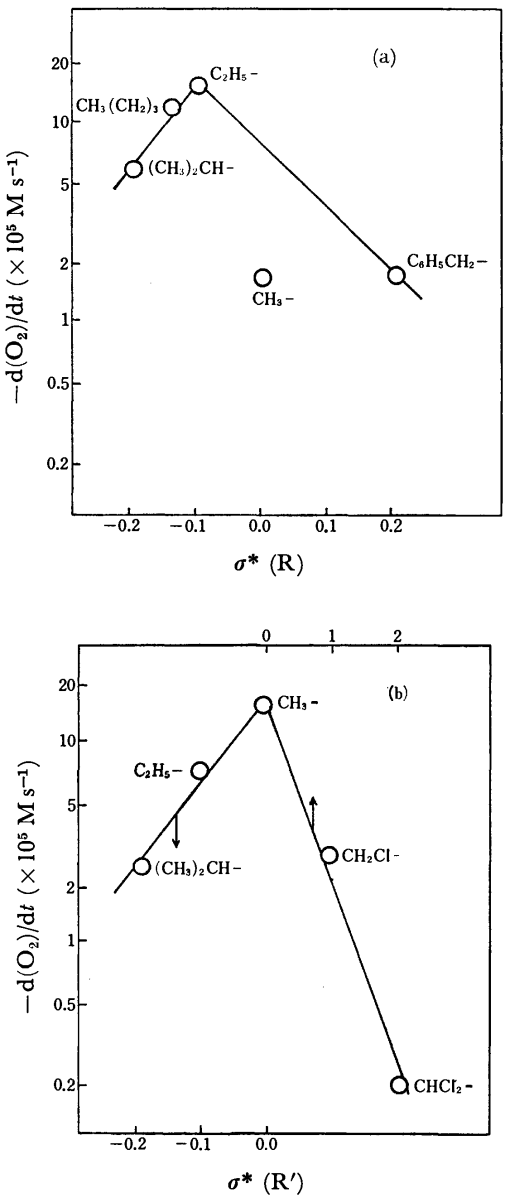

Fig. 1. The effects of the substituents R and R' of esters (R'COOR) as solvents on the rate of oxidation.

The rate equations, except for that obtained with a lower pressure of oxygen in isopropyl acetate, were equal and could be written as Eq. I:

$$-\frac{d(O_2)}{dt} = k(CH_3CHO)^{3/2}(\text{catalyst})^{1/2}(O_2)^{1/2} \quad \text{(I)}$$

in which k means a rate constant. This equation can be compared with the rate equation (II)

$$-\frac{d(O_2)}{dt} = k_p/(2k_t)^{1/2}(CH_3CHO)\cdot R_i^{1/2} \quad \text{(II)}$$

derived from the general elementary steps of autoxidation under no diffusion control of oxygen as follows;

initiation: $CH_3CHO \longrightarrow CH_3\dot{C}O$: R_i (1)

chain propagation:

$CH_3\dot{C}O + O_2 \longrightarrow CH_3COOO\cdot$ (2)

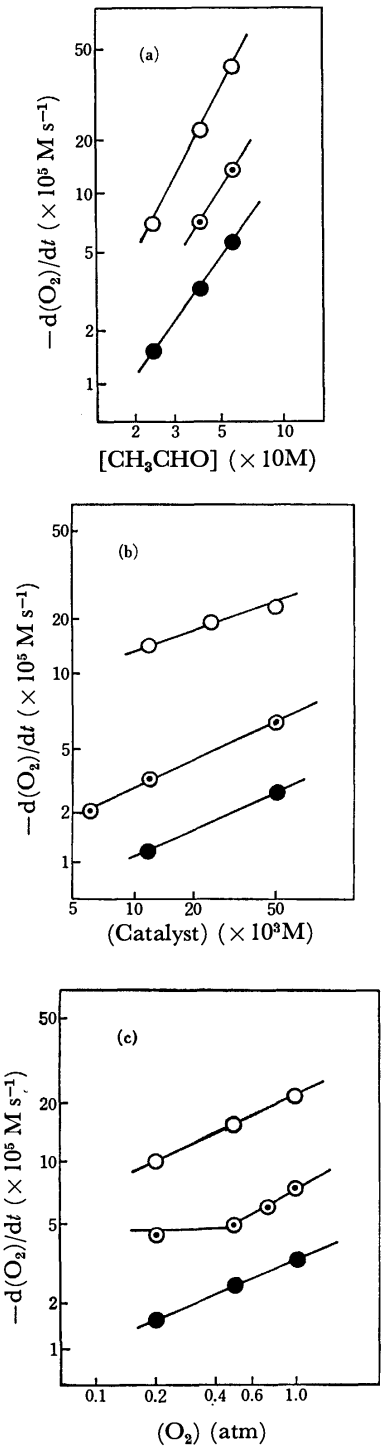

Fig. 2. Effects of concentrations of acetaldehyde, Fe, Cu-polyphthalocyanine, and oxygen on the oxidation rates.
Reaction conditions: (CH_3CHO), 0.45 M; (Fe,Cu-poly-Pc), 4.82×10^{-3} M; and O_2 pressure, 1 atm were used as standard. Temperature was 10°C.
○: Ethyl acetate, ⊙: isopropyl acetate, ●: ethyl chloroacetate.

$$CH_3COOO\cdot + CH_3CHO \xrightarrow{k_p} CH_3COOOH + CH_3\dot{C}O \quad (3)$$

$$\text{termination: } 2CH_3COOO\cdot \xrightarrow{k_t} \text{non-radical} \quad (4)$$

in which R_i represents the rate of initiation, and k_p and k_t represent the rate constants of Steps 3 and 4. Consequently the rate of initiation is obtained as

$$R_i = \{k/k_p/(2k_t)^{1/2}\}^2(CH_3CHO)(\text{catalyst})(O_2) \quad \text{(III)}$$

It is possible, therefore, to discuss the initiation mechanism as follows:

$$\text{Me-polyPc} + O_2 \rightleftarrows \text{Me}^+\text{-polyPc-}O_2^- \quad \text{(1-a)}$$

$$\text{Me}^+\text{-polyPc-}O_2^- + CH_3CHO \longrightarrow (\text{Me-polyPc-}O_2H) + CH_3\dot{C}O \quad \text{(1-b)}$$

When the equilibrium constant of Scheme 1-a and the rate constant of Scheme 1-b are assumed to be K_1 and k_1 respectively, the rate equation of initiation is

$$R_i = k_1K_1(CH_3CHO)(\text{catalyst})(O_2) \quad \text{(IV)}$$

at the stationary state. This equation is equal to Eq. III.

It is well known that such substrates as acetic acid and methanol are easily coordinated with a metal ion in the conjugated system of a metal phthalocyanine through the electron pair on the oxygen atom. In the above initiation mechanism, the solvents in series M are considered to have considerably stronger electron-donating substituents corresponding to the lower values of σ^*, resulting in the stronger coordination through their carbonyl oxygen. In other words, the degree of the electron density on the oxygen atom of the carbonyl group increases with the increase of the electron-donating ability of the substituents R and R′. The reaction 1-a is, therefore, considered to be competitive with the reaction between a metal polyphthalocyanine and a solvent as follows:

$$\text{Me-polyPc} \xrightarrow{O_2} \text{Me}^+\text{-polyPc-}O_2^- \quad \text{(1-a)}$$

$$\text{Me-polyPc} \xrightarrow{\text{RCOOR}'} \text{Me-polyPc-O=C}\begin{matrix}\text{OR}'\\ \text{R}\end{matrix} \quad \text{(1-a')}$$

As the σ^* values of the solvents become smaller, the equilibrium 1-a′ is much more shifted to the right side. The stronger interaction of a solvent with a metal ion will leave fewer chances for the O_2 molecule to be activated by coordination. This interaction can be explained by the higher values (6.7 and 4.4) of ρ^* in series M, which are considered to be based on the interaction of solvents with the polarized species as mentioned before.

Negative values of the reaction constant ρ^* were obtained in the solvents of series N. As the absolute values of ρ^* are smaller compared with those in series M, these solvents are considered to have a weaker interaction with the initiation reaction. According to the explanation with respect to solvents of series M, the larger value of σ^* has to facilitate the activation of the molecular oxygen by a metal ion. But in the case of the electron-attracting ability of the substituent becoming too large, the electron density on the oxygen atom decreases to a certain extent, and consequently the metal polyphthalocyanine-O_2 complex is not apt to react with acetaldehyde, because these kinds of solvents may solvate with such an activated oxygen complex, resulting in the prevention of the hydrogen-abstracting reaction from acetaldehyde (1-b). No

evidence to support this explanation is yet available, but this will be discussed in detail in our next paper.[18] A possible reaction mechanism is

$$\mathrm{Me^+\text{-}polyPc\text{-}O_2^-} \xrightarrow{CH_3CHO} \mathrm{Me^+\text{-}polyPc\text{-}O_2^-\text{-}CH_3CHO} \quad (1\text{-b})$$

$$\mathrm{Me^+\text{-}polyPc\text{-}O_2^-} \xrightarrow{solvent} \mathrm{Me^+\text{-}polyPc\text{-}O_2^-\text{-}solvent} \quad (1\text{-b}')$$

In this case, the lower absolute value of ρ^* may be explained by the above-mentioned Schemes 1-b and 1-b'.

It is concluded, as the sum of these two effects of solvents on the initiation mechanism, that such a solvent as ethyl acetate or ethyl propionate is an optimum one whose substituent shows an adequate degree of the electron-donating and -attracting abilities for the carbonyl group.

In the oxidation of acetaldehyde in isopropyl acetate, the partial pressure of oxygen had no influence on the rate of oxygen absorption in the range of the oxygen pressure below 400 Torr. This means that the activation of oxygen does not occur because of low concentration of oxygen dissolved and/or the more preferable conditions for the reaction 1-a' than 1-a, and suggests that Fe,Cu-polyphthalocyanine directly abstracts the hydrogen atom from aldehyde, as is well known.[19]

The constants k_1K_1 of Eq. IV are compared for various metal polyphthalocyanines. The rate equation can be written as when the R_i of Eq. IV is put into Eq. II.

$$-\frac{d(O_2)}{dt} = (k_1K_1)^{1/2}k_p/(2k_t)^{1/2}(CH_3CHO)^{3/2} \times (\text{catalyst})^{1/2}(O_2)^{1/2} \quad (V)$$

The rate constant k_p at 0 °C is reported to be 2.7×10^3 M^{-1} s^{-1} and the activation energy of k_p is assumed to be 4.2 kcal/mol, which is determined in the oxidation of decanal.[20] Then the approximate value of k_p at 10 °C is calculated to be 3.6×10^3 M^{-1} s^{-1}. On the other hand, the rate constant $2k_t$ at 0 °C is reported to be 1.04×10^8 M^{-1} s^{-1}. As $2k_t$ is considered not to be so influenced by the temperature, $k_p/(2k_t)^{1/2}$ can be obtained as 3.6×10^{-1} $M^{-1/2}$ $s^{-1/2}$ at 10 °C. The concentration of oxygen dissolved in ethyl acetate at 10 °C is reported to be 1.15×10^{-2} M.[21] Table 5 summarizes the calculated k_1K_1 values. The metal polyphthalocyanines are effective to activate the oxygen molecule in the order of Fe,Cu–≫Fe,Mo–>Fe–>Fe,Co–≫Cu, Co–polyphthalocyanines. Iron seems to be essential to such activation.

The authors would like to express their thanks to Prof. Teiji Tsuruta for giving fruitful advice on finishing this work.

The Liquid-phase Oxidation of Aldehydes with Fe,Cu-Polyphthalocyanine and Cobalt Tetra-*p*-tolylporphyrin

Yasukazu OHKATSU, Osamu SEKIGUCHI, and Tetsuo OSA

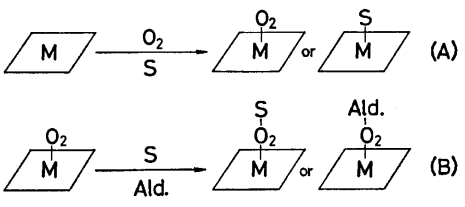
Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 1, 1975)

The effect of chemical species in a reaction system on the oxidation reaction of aldehydes was studied using Fe,Cu-polyphthalocyanine and cobalt tetra-*p*-tolylporphyrin as catalysts. Both catalysts activated the oxygen molecule on their central metals and then abstracted the hydrogen atom from aldehydes to initiate autoxidation. In this initiation step, every chemical species present in the reaction system, such as the solvent, the aldehyde, the oxygen molecule and the catalyst, is found to have an effect, one after another, either to accelerate or to retard the rate of initiation. The correlation of the nature of chemical species with such mutual interaction was discussed in detail.

There are only a few papers[1,2] about liquid-phase oxidations using metal polyphthalocyanines and porphyrins as catalysts. Imoto *et al.*[3] utilized polyphthalocyanines containing two kinds of transition metals in the oxidation of acetaldehyde ethylene acetal. Such polyphthalocyanines have been reported to show no activities except for polyphthalocyanines including both iron and manganese, or both manganese and another metal. The oxidation rates has a good correlation with the activated energies (ΔE) calculated from the dependence of the electroconductivity of the catalyst on the temperature. In other words, the oxidation activity of a polyphthalocyanine increased with the decrease in ΔE, namely, the enlargement of the π-electron conjugated system. They concluded that the central metal of a polyphthalocyanine was the active site, which contributed to the activation of oxygen and the decomposition of a hydroperoxide. We also investigated the effects of the kinds of transition metals on the oxidation rate, and found that iron was one of the essential metals and that Fe,Cu-polyphthalocyanine was most effective in the oxidation of acetaldehyde.[4]

In the oxidations of cumene,[5] acrylaldehyde,[6,7] and acetaldehyde,[4] the activity of a metal polyphthalocyanine was also found to be much affected by the nature of the solvents with respect to the activation of oxygen and the catalytic performance. The effect of solvents in the liquid-phase oxidation of acetaldehyde with a metal polyphthalocyanine complex was elucidated in terms of the interaction between the central metal ion of the complex and a solvent, or the interaction of the aldehyde and/or the solvent with the oxygen molecule activated on the complex:



In the above schemes, M means the transition metals, S means the solvent, and Ald. means acetaldehyde. This paper will described some of the evidence for the vaguuness of the proposed schemes, especially Scheme B, using several kinds of aldehydes. Cobalt tetra-*p*-tolylporphyrin was utilized as a catalyst in comparison with Fe,Cu-polyphthalocyanine.

Experimental

Materials. The Fe,Cu-polyphthalocyanine used as a catalyst was synthesized and purified according to the conventional method.[8] Cobalt tetra-*p*-tolylporphyrin was prepared by the use of pyrrole, *p*-tolualdehyde, and cobalt(II) acetate.[9] Solvents such as ethyl carboxylates and aldehydes, such as acetaldehyde, propionaldehyde, butyraldehyde, isobutyraldehyde, acryldehyde, cinnamaldehyde, and benzaldehyde, were purified by conventinal methods. The aldehydes were carefully purified just before use in order to remove the pre-oxidation products.

Procedure. The liquid-phase oxidation of aldehydes was carried out using an atmosphere-tight and oxygen-circulating reaction apparatus reported before.[10] The reaction was started by the first charge of a solvent and the purge of the system with oxygen, subsequently we added a catalyst and an aldehyde.

In some cases, oxygen was bubbled and circulated into a reaction solution containing a solvent and a catalyst thirty minutes before the start of oxidation, so that the oxygen complex was formed previously, and then an aldehyde was added.

The amount of oxygen absorbed was followed by means of a gas burett, sometimes a portion of the reaction solution was sampled out to detemined its content of a percarboxylic acid by an iodine method.[11]

Results and Discussion

The oxidation of an aldehyde is widely accepted to proceed through the following steps:

$$\mathrm{RCHO} \longrightarrow \mathrm{R\dot{C}O} \text{ (initiation rate, } R_i\text{)} \quad (1)$$

$$\mathrm{R\dot{C}O} + \mathrm{O_2} \xrightarrow{k_2} \mathrm{RCOO_2\cdot} \quad (2)$$

$$\mathrm{RCOO_2\cdot} + \mathrm{RCHO} \xrightarrow{k_p} \mathrm{RCOO_2H} + \mathrm{R\dot{C}O} \quad (3)$$

$$2\mathrm{R\dot{C}O} \xrightarrow{k_4} \quad (4)$$

$$\mathrm{R\dot{C}O} + \mathrm{RCOO_2\cdot} \xrightarrow{k_5} \text{inert products} \quad (5)$$

$$2\mathrm{RCOO_2\cdot} \xrightarrow{k_6} \quad (6)$$

In the autoxidation of saturated aldehydes and benzaldehyde using Fe,Cu-polyphthalocyanine or cobalt tetra-*p*-tolylporphyrin as a catalyst, the rate of oxidation was obtained as follows (see, Tables 1 and 2):

Table 1. Oxidation of isobutyraldehyde using Fe,Cu-polyphthalocyanine in ethyl acetate

$$-\frac{d(O_2)}{dt} = k(RCHO)^{3/2}(catalyst)^{1/2}(O_2)^{1/2} \quad (I)$$

It was ascertained that enough oxygen was present in a reaction system for Step 2 by other experiments using azobisisobutylonitrile under the radiation of UV as initiator.

These results give the rate of initiation:

$$R_i = K(RCHO)(catalyst)(O_2) \quad (II)$$

in which $K = \left\{\frac{k(2k_t)^{1/22}}{k_p}\right\}$

by the same treatment as that described in a previous paper.[4] This establishes that the initiation reaction consists of a reaction among an aldehyde, a catalyst, and oxygen.

Seven kinds of aldehydes were oxidized. Table 3 shows the rates of the oxidation of the aldehydes in combination with esters as solvents. Zaikov *et al.*[12] studied the oxidation of acetaldehyde, heptanal, octanal, pivaldehyde, and benzaldehyde in chlorobenzene at 0 °C. They concluded that the reason why these aldehydes were oxidized at similar rates under similar conditions was due to compensating changes in the rate constants for chain propagation (k_p) and chain termination ($2k_t$), that is to say, the values of $k_p/(2k_t)^{1/2}$ were almost constant, regardless of the kind of aldehydes.

The oxidation rates in Table 3, therefore, are estimated to parallel the initiation rates using Fe,Cu-polyphthalocyanine and tetra-*p*-polyporphyrin. The oxidation rates of some aldehydes are plotted in logarithm against Taft's σ^* values of alkyl groups of ethyl carboxylate (Fig. 1). Every aldehyde shows a similar type of figure; their slopes are calculated to be as is shown in Table 4.

The aldehyde with a conjugated double bond to the formyl group, such as acrylaldehyde and cinnamaldehyde, showed higher ρ^* values on the left-hand side of graph. This may be ascribed to the fact that the oxidation-rate equation cannot be written as Eq. I. In the autoxidation of acrylaldehyde,[13] for example, the equation is obtained as:

$$-\frac{d(O_2)}{dt} = \frac{R_i^{1/2}k_2k_p(acrylaldehyde)(O_2)}{k_p(2k_4)^{1/2}(acrylaldehyde)+k_2(2k_t)^{1/2}(O_2)} \quad (IV)$$

in which $k_p(2k_t)^{-1/2}=5.5\times10^{-2}$ $M^{-1/2}$ $s^{-1/2}$, and $k_2(2k_4)^{-1/2}=3.7\times10$ $M^{-1/2}$ $s^{-1/2}$ at 40 °C. This suggests that the reaction of the acyl radical of acrylaldehyde with oxygen is one of the rate-determining steps because of the stabilization of the acyl radical *via* the conjugated double bond:

Table 3. Rates of oxidation of aldehydes

Aldehydes	Rate of oxidation ($\times 10^5$ M s^{-1}) in solvent of						
	Ethyl isobutyrate	Ethyl butyrate	Ethyl propionate	Ethyl acetate	Ethyl acetyl-acetate	Ethyl chloro-acetate	Ethyl dichloro-acetate
Isobutyradehyde	20.1	26.5	25.5	22.4		11.3	
Butyraldehyde	15.3	20.0	23.2	21.2		8.50	5.95
Propionaldehyde	3.40	4.92	6.73	14.6		5.42	2.87
Acetaldehyde	3.14	4.58	6.10	13.7	4.75	2.45	6.79
Acrylaldehyde	0.38	1.57	2.07			1.50	0.015
Cinnamaldehyde	0.77	1.80	2.45			0.089	
Benzaldehyde	5.55	6.80 7.24	9.21 9.55	24.5		3.60	1.56
Acetaldehyde[a)]	14.1		12.3	11.8	3.05		
Benzaldehyde[a)]	21.6			15.4		7.03	

Reaction conditions: Fe,Cu-polyphthalocyanine, 5×10^{-4} M; aldehyde, 0.5 M; and 10 °C.
a) An equimolecular amount of cobalt tetra(*p*-methylphenyl)porphyrin was used in place of the polyphthalocyanine.

Table 4. Reaction constants, ρ^*, for solvents in the oxidation of aldehydes[a)]

Aldehydes	Left side		Right side	
	ρ^*	Relative value	ρ^*	Relative value
Isobutyraldehyde	3.23	0.74	−0.30	0.39
Butyraldehyde	3.01	0.69	−0.35	0.45
Propionaldehyde	3.70	0.85	−0.41	0.53
Acetaldehyde[b)]	4.35	1.00	−0.77	1.00
Acrylaldehyde	6.67		−1.10	
Cinnamaldehyde	5.50		−1.16	
Benzaldehyde[b)]	3.85		−0.66	

a) Reaction conditions: Fe,Cu-polyphthalocyanine, 5×10^{-4}M; aldehyde, 0.5M, and temperature, 10°C.
b) An equimolecular amount of cobalt tetra-*p*-tolylporphyrin was also used in place of the polyphthalocyanine. ρ^* values obtained: −0.77 for acetaldehyde and −1.11 for benzaldehyde.

$$CH_2=CH-\dot{C}=O \longleftrightarrow \dot{C}H_2-CH=C=O$$

Therefore, these aldehydes do not belong to the substrates, to which the correspondence of the oxidation rates to the initiation rates mentioned above can be applied.[13,14)]

According to the explanation presented in a previous paper,[4)] the reaction constant, ρ^*, of oxidation in ester solvents (R'COOR) with substituents (R and R') of lower σ^* values are most likely to be independent of the kind of aldehydes (see Scheme A). In such solvents as the reported as "left-side" in Table 4, almost constant values of ρ^* were obtained for all aldehydes except for acrylaldehyde and cinnamaldehyde, compared with those of the oxidation in solvents referred to as "right-side." This supports Scheme A, though it cannot positively be said to be true because of the incomplete constancy of ρ^* values: the small difference in the ρ^* values will be discussed hereafter.

On the other hand, a considerable difference among values of ρ^* was observed in solvents with higher σ^* values. This means some participation of solvent in the initiation reaction and suggests the effect of such solvents on the interaction with activated oxygen molecules on catalysts (Scheme B).

Table 5. Rates of oxygen absorbed in the oxidation of benzaldehyde with or without the pre-bubbling of oxygen

Solvents	Rates of oxygen absorbed $\times 10^5$ M s^{-1}	
	With pre-bubbling	Without pre-bubbling
Ethyl isobutyrate	7.66	5.55
Ethyl butyrate	10.3	7.24
Ethyl chloroacetate	3.83	3.60

Reaction conditions: Fe,Cu-polyphthalocyanine, 5×10^4M; benzaldehyde, 0.5 M, and temperature, 10 °C.

Other experimental data are shown in Table 5. In ethyl isobutyrate and ethyl butyrate, the oxidation rate corresponding to the initiation rate was higher when oxygen was bubbled into the reaction solution thirty minutes before the start of oxidation by the addition of an aldehyde, than when all of the reactants were charged at once to commence oxidation. This fact means not only that there occurs the competitive coordination of a solvent and an oxygen molecule with the complex, but also that an aldehyde has some interaction with such a coordination reaction. Ethyl chloroacetate belonging to a solvent as the "right side" did not show enough difference in the oxidation rate to be discussed. This supports the explanation mentioned above that the solvent is not considered to participate in the activation of the oxygen molecule, but to interact with the activated oxygen according to Scheme B. The coordination of carbonyl compounds such as an aldehyde and an ester with a metal complex is explained by the fact well known in the chemistry of the reaction of an alkyl metal complex with a carbonyl compound: an aldehyde is more reactive with the complex than an ester.[15)] The coordination of acrylaldehyde with cobaltous acetylacetonate through its carbonyl group has also been reported.[16)] It is not surprizing, therefore, that the formation of the oxygen complex is accelerated by the absence of the aldehyde, which will behave competitively as a ligand like an ester solvent. This pheno-

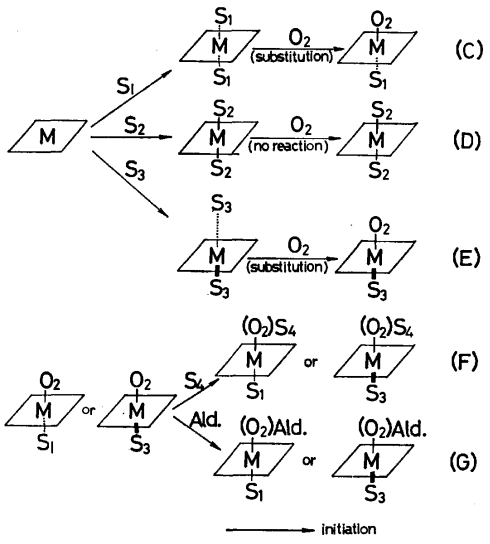
menon is not fully understood, but it may be related to the fact that the maximum points of the rate of oxidation seem to shift against the σ^* values of alkyl groups of esters, depending on the kind of aldehydes (see Fig. 1). The oxidation rates of all aliphatic aldehydes except for unsaturated ones are arranged against the σ^* values of the aliphatic residues as in Fig. 2. The lower the σ^* value was the higher the oxidation rate was. If an aldehyde is taken account of as a part of a solvent, this result seems to be the reverse of that shown in Fig. 1 with respect to the σ^* values of alkyl substituents of aldehydes. This may be explained as follows, not by the steric hindrance of aldehyde, but by the electron-donating property of aldehyde.

The value of σ^* of the alkyl residue has, in general, some relation with the steric hindrance factor (E_s). The E_s is considered to show the possibility for an aldehyde occupying the coordination site of oxygen sterically to prevent it from access to the site. However, this explanation is the just reverse of the inclination against σ^*, as is shown in Fig. 2.

In previous papers[5,7] we have reported that a strong electron-donating additive such as pyridine could accelerate the rate of oxidation if it is present in a catalytic amount. This was well interpreted by the idea that the additive could activate the oxygen molecule at the axial position through electron donation. The complexes used in this oxidation have vacant axial positions, which are probably solvated by a solvent in solution. The aldehyde with a stronger electron-donating power compared with an ester solvent may substitute the solvating ester or may occupy the coordination site in preference over the solvent molecule. Consequently, an aldehyde such as isobutyraldehyde is considered to assist the activation of oxygen, as does pyridine. The first coordination of an aldehyde with an electron-rich carbonyl group, that is, with an alkyl residue with a lower σ^* value makes its second coordination difficult because of the repulsion of electrons between the central metal of the complex given by the first aldehyde and of the carbonyl group of the second aldehyde approaching from the axial trans position. Thus, the electrophilic coordination and activation of the oxygen molecule at the second site is accomplished more easily, and the oxidation of isobutyraldehyde, for example, is initiated more easily and faster.

The difference as a catalyst between Fe,Cu-polyphthalocyanine and cobalt tetra-*p*-tolylporphyrin was also observed (Table 4 and Fig. 1). Though it is difficult to compare the two catalysts simply because of their probable different behavior in response to peracids, the latter catalyst, unlike the former, did not give mountain-shaped lines, but lost its oxygen-activating performance in the limited number of solvents used as the σ^* values of the ester solvents increase. This may be ascribed to the concept that cobalt tetra-*p*-tolylporphyrin is probably affected only with difficulty by solvents with electron-donating ability, compared with a metal polyphthalocyanine as may be seen in the comparable data of the effects of additives such as pyridine on the rate of oxidation.[2,7]

From the above-mentioned results and discussion, the behavior of chemical species present in the reaction system may be deduced in terms such scheme as shown on the next page. In the scheme, ------ indicates a weak coordination; ——, medium coordination; ——, strong coordination; S_1—S_3, an ester solvent and/or an aldehyde; S_4, the solvent, and Ald., an aldehyde. Fe,Cu-polyphthalocyanine and cobalt tetra-*p*-tolylpophyrin can initially activate an oxygen molecule to abstract the hydrogen atom from a substrate to be oxidized, and then initiate the autoxidation. The presence of a chemical species (S_1) which has a week interaction with the catalyst facilitates the coordination and activation of oxygen by substitution



(Scheme C), whereas a chemical species (S_2) with a medium interaction obstracts the coordination of oxygen by its occupation of both trans-positioned sites, depending on the capacity of electron donation (Scheme D). However, a chemical species (S_3) including an aldehyde to be oxidized with a suitable capacity can activate oxygen more easily than in the absence of such a species because of the delivery of an electron to the trans-position through the central metal of the catalyst Subsequently, the chemical species (S_4) solvating strongly to the coordinated oxygen inhibits the approach of an aldehyde to be oxidized, resulting in a decrease in the rate of oxidation (Scheme F). When an aldehyde can react with the activated oxygen, the autoxidation is initiated (Scheme G).

To utilize polyphthalocyanines and porphyrins as oxidation catalysts, we must carefully select the reaction conditions, especially the circumstances of the oxidation reaction.

We should like to express our thanks to Professor Teiji Tsuruta for his fruitful discussions and suggestion throughout our work of this paper.

The *O*-Alkylation of Phenols by Esters. II. The Steric Hindrance and Electronic Effect in the *O*-Alkylation of Phenol by Esters[1]

Taketoshi KITO, Kazumune YAMAMOTO, and Ichiro HIRAO

Laboratory of Industrial Chemistry, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kitakyushu-shi, Fukuoka 804

(Received Junuary 27, 1976)

The steric hindrance in the *O*-alkylation of PhOK by alkyl acetate (PhOK+AcOR→PhOR+AcOK) was examined by means of competitive reactions. As a result, the following sequence of the reactivities of alkyl acetates was obtained: $CH_3 \gg C_2H_5 > n\text{-}C_3H_7 \gtrsim n\text{-}C_4H_9 > s\text{-}C_4H_9 > i\text{-}C_3H_7 \gtrsim i\text{-}C_4H_9 > t\text{-}C_4H_9$ and $n\text{-}C_4H_9 > n\text{-}C_5H_{11} > i\text{-}C_5H_{11}$. The electronic effect in the *O*-alkylation was also examined by means of the competitive reaction of *p*-substituted (CH_3 or CH_3O) methyl benzoate and methyl benzoate with PhOK. The reactivity decreases in the following order: $C_6H_5COOMe > p\text{-}CH_3C_6H_4COOMe > p\text{-}CH_3OC_6H_4COOMe$. Therefore, it was concluded that the rate-determining step is the attack of the phenoxide anion on the carbon atom of the methyl group.

There have been few reports on the *O*-alkylation of phenols by alkyl alkanoates except by alkyl oxalate and methyl trichloroacetate.[2,3] On the other hand, dialkyl sulfates and *p*-toluenesulfonic esters, which are the esters of strong acids, are known as powerful *O*-alkylating agents of phenols. The present authors have previously reported[1] that alkali phenoxides react with alkyl alkanoates at high temperatures to give alkyl phenyl ether. For example, alkali salts of phenols (RC_6H_4OH; where R is H, *o*-CH_3, *m*-CH_3, *p*-CH_3, *o*-Cl, or *p*-Cl) react with the methyl ester of acetic acid, acrylic acid, or methacrylic acid to give the corresponding anisoles ($RC_6H_4OCH_3$). The runs using alkali phenoxides with ortho-substituent or those with electron-attracting substituents gave the corresponding anisoles in lower yields. In this paper, the effects of the alkyl and the acyl components in alkyl alkanoates on the *O*-alkylation were examined from the standpoint of the steric hindrance and the electronic effect.

Results and Discussion

Steric Hindrance. The reactions of potassium phenoxide with nine alkyl acetates were carried out. The results are summarized in Table 1.

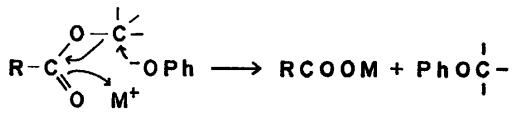
TABLE 1. YIELDS OF ALKYL PHENYL ETHERS[a]

R	Yield of ROPh (%)	
	200 °C[b]	250 °C[b]
CH_3	75.3	78.7
C_2H_5	42.1	56.6
n-C_3H_7	—	55.0
i-C_3H_7	4.8	35.6
n-C_4H_9	33.5	56.1
i-C_4H_9	3.3	18.9
s-C_4H_9	13.9	20.0
t-C_4H_9[c]	—	12.3
n-C_5H_{11}	17.1	37.9
i-C_5H_{11}	11.8	39.2

a) The reaction was carried out by using an excess of alkyl acetate (AcOR 0.5 mol and PhOK 0.05 mol). b) Reaction temp (Reaction time, 2 h). c) Many by-products were detected in the reaction mixture by gas chromatography.

In these esters, ethyl, propyl, and butyl acetates gave alkyl phenyl ethers in nearly equal yields. Branched alkyl acetates gave the ethers in lower yields.

In the previous paper,[1] the mechanism shown in Scheme 1 was suggested for the *O*-alkylation of alkali phenoxide by ester. According to this mechanism, not only the bulky alkyl component, but also the long-chain alkyl component, in alkyl acetate would hinder the attack of the phenoxide anion. However, we observed no great difference in yields when ethyl, propyl, and butyl acetates were used.



Scheme 1.

One method of evaluating the reactivity of each acetate towards potassium phenoxide is to compare the reaction rate constant in each reaction. However, there are few solvents which have high boiling points and which dissolve potassium phenoxide. Although potassium phenoxide is soluble in some aprotic polar solvents, such as *N*,*N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and hexamethyl phosphoric triamide (HMPA), the rate of the disappearance of the ester (methyl benzoate) in the initial period was abnormally great when the reaction was carried out at high temperatures in these solvents. This phenomenon must result from the side reactions: that is, the hydrolysis of the ester by the water contained in the solvents (it is difficult to remove the water completely from such solvents) and the decomposition of DMF into carbon monoxide and dimethylamine in the presence of the base (PhOK).[4] The latter product further reacts with the ester to produce undesirable products.

Competitive reactions were used to compare the reactivity of each acetate to potassium phenoxide. The merit of this method is that we can carry out the reactions of several kinds of alkyl acetates with potassium phenoxide under the same conditions.

The competitive reactions were carried out by heating potassium phenoxide with a mixture of three alkyl acetates, and then the three alkyl phenyl ethers formed were determined by gas chromatography. The results are shown in Table 2. As has already been mentioned,

Table 2. Competitive reactions of alkyl acetates with potassium phenoxide[a]

the phenoxide anion would attack the less hindered carbon atom adjacent to the ether oxygen. Therefore, the ester with a longer-chain alkoxyl group will give an alkyl phenyl ether in a lower yield. Thus, the reactivities of the esters may be supposed to decrease in the following order: $CH_3OAc > C_2H_5OAc > n$-C_3H_7-$OAc > n$-C_4H_9OAc. The branched alkyl acetate will give the alkyl phenyl ether in a yield lower than the normal alkyl acetate. From Table 2, the following sequence of the reactivities was obtained for the series of acetates: n-$C_4H_9 \gg s$-$C_4H_9 > i$-C_3H_7; $C_2H_5 > n$-$C_4H_9 > i$-C_3H_7; $C_2H_5 > n$-$C_4H_9 \gg i$-C_4H_9; $CH_3 \gg n$-$C_3H_7 > n$-C_4H_9; $C_2H_5 > n$-$C_3H_7 > n$-C_4H_9. It is preferable to use a mixture containing all the alkyl acetates in the competitive reaction, but it was difficult to determine each alkyl phenyl ether in the mixture by gas chromatography. The ratio of the yields in the same reaction will not be exactly equal to the ratio of the reactivities because the reaction rate is also dependent on the concentration of the ester. Under the present experimental conditions, the variation in the concentration of the ester can not be neglected when the yield of the alkyl phenyl ether is appreciably high. If a mixture containing excess amounts of esters is used to avoid the variation in the concentration during the reaction, the accurate determination of the products will become difficult. On the basis of the data shown in Tables 1 and 2, though, a reasonable order of the reactivities of alkyl acetates may be as follows: $CH_3 \gg C_2H_5 > n$-$C_3H_7 \gtrsim n$-$C_4H_9 > s$-$C_4H_9 \gtrsim i$-$C_3H_7 \gtrsim i$-$C_4H_9 > t$-C_4H_9 and n-$C_4H_9 > n$-$C_5H_{11} > i$-C_5H_{11}. Although the electronic effect, of course, influences the reactivity of the alkyl group, the reactivity might be controlled mainly by the steric hindrance.

It was reported previously[1] that ortho-substituted alkali phenoxides gave the corresponding ethers in lower yields. For example, potassium p- and m-methylphenoxide react with methyl methacrylate at 200 °C to afford anisole in 84.5 and 74.8% yields respectively. On the contrary, potassium o-methylphenoxide gave o-methylanisole in a 29.4% yield under the same conditions. Similarly, potassium o-chorophenoxide gave o-chloroanisole in a 13.9% yield, although potassium p-chlorophenoxide gave p-chloroanisole in a 48.9% yield. In Table 2, there are no examples of reactions using ortho-substituted phenoxide. The steric hindrance may also be caused by the interaction between the hydrogen atom on the ortho position of phenoxide and that of the alkoxyl group. In methyl acetate this interaction may be small, but the interaction will become important in ethyl and higher alkyl acetates. In fact, there was a great difference in the reactivity between methyl acetate and ethyl acetate, as is shown in Tables 1 and 2.

The steric hindrance of the acyl group was also examined; the results are summarized in Table 3. At a low temperature (150 °C), methyl pivalate and methyl decanoate gave anisole in lower yields than did the other esters. The decrease in the yield is attributable in part to the steric hindrance of the bulky group and the long chain.

Table 3. Relationship between the yield of anisole and the acid component of the methyl ester[a]

Ester RCOOMe	pK_a of RCOOH (25 °C)[a]	Yields of anisole (%) 150 °C	200 °C	250 °C[c]

The Electronic Effect of the Acyl Group on the Reactivity. The electronic effect of the acyl group in alkyl alkanoate was also examined; the results are shown in Table 3. However, it is difficult to isolate only the electronic effect from the results shown in Table 3.

King reported[5] that methyl benzoate is a good O-alkylating agents (see also Table 3). Therefore, the electronic effect was investigated by using methyl p-substituted benzoate. A mixture of methyl p-substituted benzoate, methyl benzoate, potassium phenoxide, and cyclohexane (a heat medium) was heated in an autoclave, and the residual methyl p-substituted benzoate and methyl benzoate and the anisole formed from this

TABLE 4. COMPETITIVE REACTIONS OF *p*-SUBSTITUTED METHYL BENZOATE AND METHYL BENZOATE WITH POTASSIUM PHENOXIDE[a)]

a) C_6H_5OK, 0.1 mol; reaction temp, 250 °C. b) $\sigma_p=-0.17$. c) $\sigma_p=-0.27$.

reaction were determined by gas chromatography. The results are shown in Table 4. As the steric hindrance of the *p*-substituents can be disregarded, the inductive effect and the resonance effect of these groups must become important in this reaction. Benzoic acid is the strongest acid, and *p*-anisic acid is the weakest one, of the three (the pK_a values of the acids at 25 °C are as follows: benzoic acid, 4.21; toluic acid, 4.37; *p*-anisic acid, 4.49[6)]). The electron-donating group on the para-position may increase both the electron densities on the oxygen atom of the carbonyl group (>C=O) and on the carbon atom of the methyl group (-$COOCH_3$). If the rate-determining step of this reaction is the nucleophilic attack of the phenoxide anion on the carbon atom of the methyl group, the electron-donating group may retard the attack of the phenoxide anion. On the contrary, if the rate-determining step is the activation of the phenoxide anion (although the oxygen atom of potassium phenoxide has an anionic character, it is neutralized by the potassium cation), the electron-donating group is advantageous for the *O*-alkylating reaction because the potassium cation may be neutralized to a greater extent by the oxygen atom of the carbonyl group and a more active phenoxide anion may be formed.

The molar ratios (potassium phenoxide: methyl benzoate: methyl *p*-substituted benzoate) and the reaction time were varied, and the yields of anisole from methyl benzoate and methyl *p*-substituted benzoate and its ratio were calculated. From the results listed in Table 4, the following facts became clear. The reactivities of both methyl toluate and anisate are lower than that of methyl benzoate, and the reactivity of methyl anisate is lower than that of methyl toluate. Therefore, the results lead to the conclusion that the attack of the phenoxide anion on the carbon atom adjacent to the ether linkage is more important than the formation of the active phenoxide anion.

The competitive reaction of methyl *p*-nitrobenzoate and methyl benzoate with potassium phenoxide was also carried out at 200 °C for 5 h and at 170 °C for 9 h. Under the former conditions, the yield of anisole was 15.2 and 83.6% of the methyl benzoate was recovered. On the contrary, only 8.6% of the methyl *p*-nitrobenzoate was recovered, while 91.4% of the methyl *p*-nitrobenzoate was consumed to produce unidentified by-products. In this case, a side reaction, which has no relation with the *O*-alkylation, most likely occurred.

Experimental

Competitive Reactions of Alkyl Acetates with Potassium Phenoxide. Because the experiments of other competitive reactions were carried out similarly, only one example will be given in detail.

An equimolar mixture (0.15 mol each) of methyl acetate, propyl acetate, and butyl acetate, and 0.05 mol of potassium phenoxide was placed in a 300-ml autoclave equipped with an electromagnetic stirrer. The reaction mixture was then heated at 250 °C for 2 h. It takes about 20 min to raise the temperature to 250 °C. After cooling, the reaction mixture was poured into water and the alkyl phenyl ether was extracted with ether (about 100 ml). To the ethereal solution, 0.05 mol of *N,N*-dimethylaniline (6.060 g) was then added as an internal standard compound and the anisole, propyl phenyl ether, and butyl phenyl ether were determined by gas chromatography (internal standard method; column, PEG 20M; temp, 200 °C).

Competitive Reactions of p-*Substitued Methyl Benzoate and Methyl Benzoate with Potassium Phenoxide.* To an equimolar mixture of methyl benzoate and methyl *p*-substituted benzoate, potassium phenoxide was added, after which the mixture was heated at 250 °C. After cooling, the anisole and the benzoates were extracted with ether (100 ml) and the molar ratios of anisole/methyl benzoate and methyl *p*-substituted benzoate/methyl benzoate were obtained by gas chromatography (column, PEG 20M; temp, 200 °C). The mole number of the anisole formed in this reaction must be equal to the sum of the mole numbers of the methyl benzoate and methyl *p*-substituted benzoate consumed in this reaction, because no product other than anisole was detected in the gas chromatogram. On the basis of this fact, the yields of anisole from methyl benzoate and from methyl *p*-substituted benzoate were calculated.

Identification of Alkyl Phenyl Ethers. Authentic alkyl phenyl ethers were prepared by Williamson ether synthesis,[7)] but *t*-butyl phenyl ether was prepared according to the directions described in "Organic Syntheses" (Vol. 45, p. 89). These ethers were identified by elementary analysis, NMR, and gas chromatography. The retention times of the alkyl phenyl ethers formed in this reaction were compared with those of authentic ethers. The two retention times were agreed within 2 s (the retention times of these ethers were from 124 s, CH_3OPh, to 333 s, *i*-$C_5H_{11}OPh$; column, PEG 20M, 30%; temp, 200 °C). Four ethers obtained from the reactions of potassium phenoxide and alkyl acetates (propyl, butyl, isobutyl, and *s*-butyl acetates) were isolated by gas chromatography and were identified by NMR (solvent, CCl_4).

Tautomerism of 4-Pyridones

Hiromichi Besso, Kimiaki Imafuku, and Hisashi Matsumura

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received June 18, 1976)

The tautomeric constants, K_t, of several 4-pyridones were determined by measurement of pK_a values. For 2-substituted 5-methoxy-4-pyridones, the K_t values were correlated to the substituent constants σ, the equation $\log K_t = 2.98 + 2.93\sigma_m - 6.18\sigma_o$ being obtained.

The tautomerism of simple 4-pyridones having chlorine atom[1] or methoxycarbonyl group[2] in an α-position to nitrogen atom has been investigated in detail. Gordon *et al.* showed that the tautomeric equilibrium of 4-pyridones is displaced in favour of 4-hydroxypyridine form by electron-withdrawing groups of α-position.

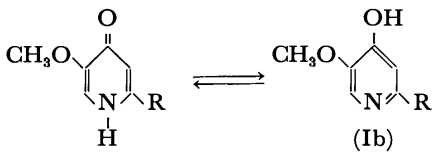
We report the tautomerism of several 2-substituted 5-methoxy-4-pyridones and discuss the substituent effects by the Hammett equation. Little is known about the application of the Hammett equation to 4-pyridones.

Results and Discussion

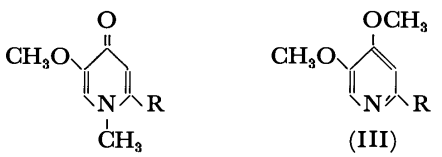
Dissociation Constants. The dissociation constants of 4-pyridones (I), *N*-methyl-4-pyridones (II), and 4-methoxypyridines (III) were determined spectrophotometrically in water at 20 °C. The results are summarized in Table 1, where pK_1 and pK_2 represent respectively the first and second dissociation constants for 4-pyridones (I), and pK_{NCH_3} and pK_{OCH_3} correspond to the dissociation constants for *N*-methyl-4-pyridones (II) and 4-methoxypyridines (III), respectively.

Table 1. Dissociation constants

Substituent	(I) pK_1	(I) pK_2	(II) pK_{NCH_3}	(III) pK_{OCH_3}
CH_3	3.42	11.29	3.39	7.10
H	3.04	11.08		
CH_2OH	3.06	10.48	3.06	5.89
CH_2OCH_3	2.99	10.23	2.88	5.42
CHO				4.25
$COOCH_3$	2.17	8.23	2.18	3.16



(Ia) (Ib)



(II) (III)

Since activity coefficients were not introduced into the calculation, the dissociation constants do not represent thermodynamic terms, giving only a relative measure of base strength.

The pK_a values of 4-pyridones and 4-methoxypyridines decrease by electron-withdrawing groups attached to 2-position, the degree of decrease for 4-methoxypyridines being the greatest of all. It is concluded that these changes are related to the distance between the substituent and the reaction site.

Tautomeric Ratio. The tautomeric constants K_t which represent the ratio of NH-form (Ia) to OH-form (Ib), are given by the following equation[3] (Table 2).

$$\log K_t = pK_{OCH_3} - pK_{NCH_3} \quad (1)$$

Table 2. Tautomeric constants

Substituent	$\log K_t$
CH_3	3.7
CH_2OH	2.8
CH_2OCH_3	2.5
$COOCH_3$	1.0

The K_t values for 4-pyridones are affected by the substituents in the 2-position, decreasing by electron-withdrawing groups.

UV Spectra. The UV spectra of neutral species of 5-methoxy-4-pyridones (I) having methyl, hydroxymethyl, and methoxymethyl groups in the 2-position are similar to those of their *N*-methyl derivatives (II), but differ a great deal from those of their *O*-methyl derivatives (III). That is to say, these 4-pyridones exist essentially in the NH-form (Ia). However, 5-methoxy-2-methoxycarbonyl-4-pyridone exists in both NH-form (Ia) and OH-form (Ib) in water (Fig. 1).

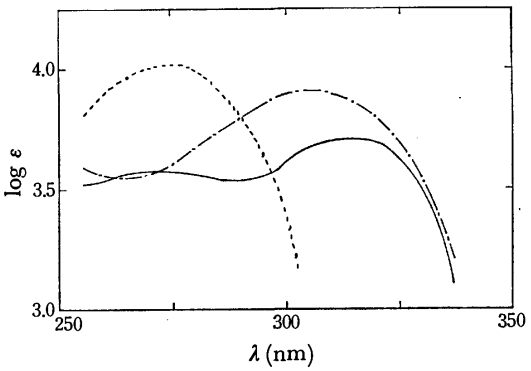


Fig. 1. The UV spectra of the neutral species of 5-methoxy-2-methoxycarbonyl-4-pyridone series.
——: 5-Methoxy-2-methoxycarbonyl-4-pyridone,
- - - -: 5-methoxy-2-methoxycarbonyl-1-methyl-4-pyridone,
……: 4,5-dimethoxy-2-methoxycarbonylpyridine.

Substituent Effects. The substituent constants σ_o for ortho-substituted pyridines were obtained from their dissociation constants by Clark and Perrin.[4] However, the σ_o values for hydroxymethyl and methoxymethyl groups are unknown. We obtained them by the following method. When the pK_a values of 2-substituted 4,5-dimethoxypyridines, 4-methoxypyridine (pK_a=6.62),[5] and 2-chloro-4-methoxypyridine (pK_a=1.93)[1] are plotted against the apparent substituent constants σ_o[4] for the 2-position and the substituent constants σ_m[6] for the 5-position, the plot gives a straight line, the following equation for 2,5-disubstituted 4-methoxypyridines being obtained by the least square methods.

$$pK_{OCH_3} = 6.75 - 6.07(\sigma_o+\sigma_m) \quad (r=0.992) \quad (2)$$

The regression of Eq. 1 gives the σ_o values which are 0.02 and 0.10 for hydroxymethyl and methoxymethyl groups, respectively.

The following Eqs. 3 and 4 are obtained for the proton gain and proton loss, respectively, of 2-substituted 5-methoxy-4-pyridones (I).[6,7]

$$pK_1 = 3.11 - 3.01\sigma_m \quad (r=0.989) \quad (3)$$

$$pK_2 = 10.77 - 4.94\sigma_o \quad (r=0.989) \quad (4)$$

Equations 5 and 6 are obtained for the proton gain of 2-substituted 5-methoxy-1-methyl-4-pyridones (II) and the proton loss of 2-substituted 4,5-dimethoxypyridines (III), respectively.

$$pK_{NCH_3} = 3.09 - 2.93\sigma_m \quad (r=0.978) \quad (5)$$

$$pK_{OCH_3} = 6.07 - 6.18\sigma_o \quad (r=0.985) \quad (6)$$

In Eq. 5, the value 0.01 obtained from the regression of Eq. 3 was assigned to the substituent constants σ_m for the hydroxymethyl group.

When Eqs. 4 and 5 are substituted into Eq. 1, the following equation is derived.

$$\log K_t = 2.98 + 2.93\sigma_m - 6.18\sigma_o \quad (7)$$

The electron-withdrawing groups in the 2-position stabilize the keto form for the carbonyl group and the hydroxy form for the nitrogen atom in the ring. In Eq. 7, the K_t values are defined as [NH]/[OH]. The ρ-value −6.18 for the substituent constants σ_o shows that the ratio of (Ib) increases with electron-withdrawing groups in the 2-position. In contrast, the ρ-value +2.93 for the substituent constants σ_m indicates the decrease of (Ib) owing to the stabilization of the carbonyl group by electron-withdrawing groups in the 2-position. Thus, Eq. 7 shows to what extent the substituents in the 2-position participate in the two reaction sites relating to the tautomerism of 4-pyridones. For 2-substituted 5-methoxy-4-pyridones, the electron-withdrawing substituents in the 2-position increase the ratio of the hydroxy form (Ib). Gordon *et al.*[2] showed that the K_t values are little affected by the substituents in β-position as compared with α-position, supporting our results.

It is concluded that most of the factors for the tautomerism of 4-pyridones are due to the electronic effect (including steric effect) of the substituents in the 2-position.

Experimental

All the melting points were measured on a Yanagimoto micro-melting point apparatus and are uncorrected. The IR spectra were taken on a JASCO IRA-1 spectrophotometer, and the NMR spectra on a Hitachi-Perkin-Elmer R-24 spectrometer (60 MHz).

The pK_a values of 4-pyridones, *N*-methyl-4-pyridones, and 4-methoxypyridines were measured specrophotometrically in water at 20 °C by the method of Albert and Serjeant.[8] The absorption spectra were taken on a Hitachi EPS-3T spectrophotometer, while the pH values were measured by a Hitachi-Horiba F-7 pH meter.

Materials. All the known compounds were prepared according to the methods described in references: 3-methoxy-4-pyridone, mp 170—172 °C (lit,[9] 173 °C); 5-methoxy-2-methyl-4-pyridone, mp 104—105 °C (lit,[10] 102—103 °C); 5-methoxy-1,2-dimethyl-4-pyridone, mp 145—147 °C (lit,[11] 150 °C); 4,5-dimethoxy-2-methylpyridine, bp 76—80 °C/1 Torr (lit,[10] 78—80 °C/1 Torr); 5-methoxy-2-hydroxymethyl-4-pyridone, mp 170—171°C (lit,[11] 172 °C); 5-methoxy-2-hydroxymethyl-1-methyl-4-pyridone, mp 203—205 °C (lit,[11] 203—205 °C); 4,5-dimethoxy-2-hydroxymethylpyridine, mp 117—118 °C (lit,[12] 117—118 °C); 5-methoxy-2-methoxymethyl-4-pyridone, bp 200—204 °C/1 Torr (lit,[13] 200 °C/1 Torr); 5-methoxy-2-methoxymethyl-1-methyl-4-pyridone, mp 58—59 °C (lit,[14] 59°C).

4,5-Dimethoxy-2-methoxymethylpyridine was obtained by methylation of 5-methoxy-2-methoxymethyl-4-pyridone[13] with diazomethane: Yield, 22%; mp 49—50 °C (from petroleum ether); IR ($CHCl_3$) 1590 cm^{-1} (C=C); NMR ($CDCl_3$) δ: 3.45 (s,3H), 3.95 (s,6H), 4.50 (s,2H), 6.97 (s,1H), 8.19 (s,1H). Found: C, 58.88; H, 7.13; N, 7.71%. Calcd for $C_9H_{13}NO_3$: C, 59.00; H, 7.15; N, 7.65%.

4,5-Dimethoxy-2-formylpyridine was obtained by manganese dioxide oxidation of 4,5-dimethoxy-2-hydroxymethylpyridine[12]: Yield, 59%; mp 136—137°C (from petroleum ether); IR ($CHCl_3$) 1730(C=O), 1580(C=C) cm^{-1}; NMR ($CDCl_3$) δ: 3.98(s,3H), 4.05(s,3H), 7.47(s,1H), 8.27(s,1H), 9.91(s,1H). Found: C, 57.57; H, 5.50; N, 8.41%. Calcd for $C_8H_9NO_3$: C, 57.48; H, 5.43; N, 8.38%.

5-Methoxy-2-methoxycarbonyl-4-pyridone was obtained by esterification of 5-methoxy-2-carboxy-4-pyridone[11] with methanol in the presence of dry hydrogen chloride: Yield, 15%; mp 174—177 °C (from ethyl acetate); IR ($CHCl_3$) 1730(C=O), 1615(C=O) cm^{-1}; NMR ($CDCl_3$) δ: 3.95(s,3H), 3.97(s,3H), 7.55(s,1H), 7.95(s,1H). Found: C, 52.17; H, 4.87; N, 7.71%. Calcd for $C_8H_9NO_4$: C, 52.46; H, 4.95; N, 7.65%.

5-Methoxy-2-methoxycarbonyl-1-methyl-4-pyridone was obtained from 5-methoxy-2-carboxy-4-pyrone[15] by *N*-methylation with methylamine and by esterification with methanol in the presence of hydrogen chloride: Yield, 21%; mp 147—149 °C (from benzene); IR ($CHCl_3$) 1750(C=O), 1620(C=O) cm^{-1}; NMR ($CDCl_3$) δ: 3.82(s,3H), 3.88(s,3H), 3.91(s,3H), 7.02(s,2H). Found: C, 54.65; H, 5.60; N, 7.11%. Calcd for $C_9H_{11}NO_4$: C, 54.82; H, 5.62; N, 7.10%.

4,5-Dimethoxy-2-methoxycarbonylpyridine was obtained by methylation of 5-methoxy-2-carboxy-4-pyridone[11] with a large excess of diazomethane: Yield, 29%; mp 125—126 °C (from ethyl ether); IR ($CHCl_3$) 1735(C=O,) 1580(C=C) cm^{-1}; NMR ($CDCl_3$) δ: 3.99(s,6H), 4.01(s,3H), 7.68(s,1H), 8.21 (s,1H). Found: C, 54.96; H, 5.69; N, 7.19%. Calcd for $C_9H_{11}NO_4$: C, 54.82; H, 5.62; N, 7.10%.

The Reaction of 4-Thiazoline-2-thione with Methyl Iodide. Solvent Effects and Pressure Effects

Yasuhiko KONDO, Masayuki SHINZAWA, and Niichiro TOKURA

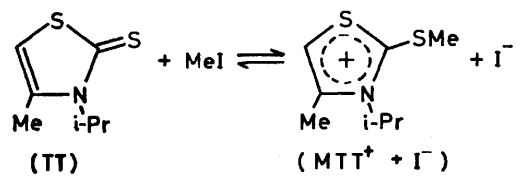
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received June 21, 1976)

Rate constants for the reaction of 3-isopropyl-4-methyl-4-thiazoline-2-thione with methyl iodide have been determined in several solvents at 1 atm. In acetonitrile and propylene carbonate, the reaction was studied at pressures up to 1500 atm by a conductivity method. A comparison of the activation volume and overall volume change of reaction, obtained from density measurements, suggests that the charge development at the transition state is only fractional. The results of CNDO/2 calculations support the argument.

In a previous paper[1] we called attention to the correlation of the solvent effect on reaction rates and activation volumes for a series of Menschutkin reactions. In particular, it was shown that the reaction in which the rate has a larger sensitivity to solvent characteristics exhibits a greater solvent effect on the activation volumes.

With the aim of determining the range of applicability of such correlations on reactions of the same charge type, we examined the solvent and pressure effects on the reaction of 3-isopropyl-4-methyl-4-thiazoline-2-thione (TT) with methyl iodide, since it is of the same charge type as the Menschutkin reaction[2] but with a different nucleophilic center. The results are given in this report.



Experimental

Materials. Propylene carbonate (Wako EP grade) was dried over freshly activated molecular sieves and distilled three times under reduced pressure. The other solvents (Wako guaranteed grade) were purified.[1,3] 3-Isopropyl-4-methyl-4-thiazoline-2-thione (TT)[2,4,5] was recrystallized three times from aqueous ethanol and dried *in vacuo* at 65 °C before use. [Found: H, 6.39; C, 48.29; N, 8.09%. Calcd for $C_7H_{11}NS_2$: C, 48.51; H, 6.40; N, 8.08%]

2-Methylthio-3-isopropyl-4-methylthiazolium iodide ($MTT^+ I^-$), prepared by refluxing TT and methyl iodide, was recrystallized three times from *N,N*-dimethylacetamide–ether mixture and dried *in vacuo* at 65 °C before use. [Found; I, 40.14%, Calcd for $C_8H_{14}INS_2$: I, 40.26%] *N*-Methylpyridinium iodide, prepared from pyridine and methyl iodide, was recrystallized three times from *N,N*-dimethylacetamide–ether mixture and dried *in vacuo* at 65 °C before use. [Found; I, 57.06%, Calcd for C_6H_8IN: I, 57.41%]

Kinetic Measurements. Equal volumes of a halide solution and a TT solution (*ca.* 0.01 M), or pyridine solution (*ca.* 0.01 M) were mixed rapidly in a stoppered flask, aliquots of the reaction mixture being withdrawn at intervals and titrated potentiometrically with a siver nitrate solution.[1] In acetonitrile and propylene carbonate, the rates were determined conductimetrically in glass cells immersed in the pressure vessel. The conductivity cell, capacity *ca.* 15 ml, was equipped with platinum electrodes (1 cm × 1 cm, 1 cm apart). Since no direct proportionality between conductance and ion concentration was observed in these solvents, the dependence of conductance on concentration, not corrected for solvent compression, was dermined for methylpyridinium iodide and MTT^+I^- solutions in both solvents under pressure (1, 300, 600, 900, 1200 and 1500 kg cm^{-2}) at 30 °C. Calculation of the rate constant was carried out after transforming the measured resistance into the concentration at atmospheric pressure. The activation volumes thus calculated should be taken as expressed in mole fraction unit. A few runs at atmospheric pressure were followed by titration of halide ion. The rate constants determined by these methods agreed within experimental error. The errors were estimated to be less than ±2% from duplicate or triplicate runs.

Density Measurements. The densities of the solution were measured in a glass dilatometer calibrated with doubly distilled water, having a bulb of *ca.* 40 ml capacity and two graduated stems. The apparent molal volumes were calculated by the equation

$$\phi_v = \frac{1000(d_0-d)}{cd_0} + \frac{M_2}{d_0} \qquad (1)$$

where the quantities have their usual meaning. The concentration of the solute was 0.01—0.02 M except for methyl iodide and pyridine for which it was 0.1—0.2 M. The errors were estimated to be less than ±0.4 cm^3 mol^{-1} from duplicate or triplicate runs.

Results and Discussion

Rate Law. A characteristic feature of the reaction of TT with methyl iodide is that the rate law changes according to the polarity of the solvent, since in low or medium dielectric solvents the reverse process has an effect on the observed rate.

In dipolar solvents such as acetonitrile (AN), propylene carbonate (PC), methanol, *N,N*-dimethylacetamide, and nitrobenzene, the rate law followed second order kinetics as expected, *i.e.*, first order in TT and in methyl iodide.

In cyclohexanone and bromobenzene the rate behavior was rather complicated, probably because of ion-pair and various kinds of higher aggregates formed in these solvents.[6,7]

For a comprehensive treatment of these two cases the following reaction schemes were postulated.

$$\underset{a-x}{TT} + \underset{b-x}{MeI} \underset{k_r}{\overset{k_f}{\rightleftarrows}} \underset{x_{fi}}{MTT^+} + \underset{x_{fi}}{I^-} \rightleftarrows \underset{x_{ip}}{MTT^+ I^-}$$

$$2\underset{x_{ip}}{MTT^+ I^-} \rightleftarrows \underset{x_q}{(MTT^+ I^-)_2}$$

$$\frac{dx}{dt} = k_f(a-x)(b-x) - k_r x_{fi}^2 \quad (2)$$

$$K = (k_f/k_r) \quad (3)$$

$$K_{ip} = x_{ip}/(x_{fi})^2 \quad (4)$$

$$K_q = x_q/(x_{ip})^2 \quad (5)$$

$$x = x_{fi} + x_{ip} + 2x_q$$
$$= x_{fi} + K_{ip}x_{fi}^2 + 2K_qK_{ip}^2x_{fi}^4 \quad (6)$$

At equilibrium the following equation holds,

$$k_f(a-x_e)(b-x_e) = k_r x_{fi,e}^2 \quad (7)$$

where the suffix, e, denotes the concentration at equilibrium.

In cyclohexanone the observed equilibrium constant, K_{obsd}, is defined by the equation

$$K_{obsd} = x_e^2/\{(a-x_e)(b-x_e)\}. \quad (8)$$

This is transformed into the following equation by combining Eqs. 3, 6, 7, and 8:

$$K_{obsd} = K(x_e^2/x_{fi,e}^2)$$
$$= K(1+K_{ip}x_{fi,e}+2K_qK_{ip}^2x_{fi,e}^3)^2 \quad (9)$$

By rearranging we have,

$$(K_{obsd}/K)^{1/2} = 1 + K_{ip}(Kx_e^2/K_{obsd})^{1/2} + 2K_qK_{ip}^2(Kx_e^2/K_{obsd})^{3/2} \quad (10)$$

The values of K_{obsd}, determined analytically after keeping the reaction mixtures at 30 °C for a sufficiently long time (usually for a week), and the corresponding values of x_e were substituted into Eq. 10. Several such equations were solved simultaneously to give $K=1.08\times10^{-2}$, $K_{ip}=1.11\times10^3$ M^{-1}, and $K_q=3.35$ M^{-1}.

The calculated values of K_{obsd} (on the basis of the above set of equilibrium constants) as a function of x_e are compared with the experimental values (Fig. 1).

The values of K_{ip} thus determined (1.11×10^3) seem to be in the correct order of magnitude, since the association constants of quaternary ammonium halides in methyl ethyl ketone which has a dielectric constant comparable with that of cyclohexanone, are in the range 400—1000 M^{-1}.[8]

The values of x_{fi} at a given time were obtained by solving the biquadratic equation 6 with respect to x_{fi} by the Newton-Raphson method for the measured values of x.

The integration of Eq. 11 was carried out after expanding the integrand into a power series of x as given by Eq. 12.

$$\int_0^x \frac{dx}{(a-x)(b-x)-x_{fi}^2/K} = \int_0^t k_f dt \quad (11)$$

$$\frac{1}{(a-x)(b-x)-x_{fi}^2/K} = \frac{1}{ab} + Bx + Cx^2 + Dx^3 \quad (12)$$

The forward rate constants thus obtained showed no systematic deviation from the average value over three fold changes of initial concentration of the reactants.

In bromobenzene, the assumption $x_q \gg x_{fi}$ and x_{ip} seems plausible, and leads to a simplified rate law.

$$x \approx 2x_q = 2K_qK_{ip}^2x_{fi}^4 \quad (13)$$

$$\therefore\ x_{fi} = (x/2K_qK_{ip}^2)^{1/4} \quad (14)$$

If we denote the observed equilibrium constant by K_{obsd}, we have the following relation from a combination of Eqs. 3, 7, and 14.

$$K_{obsd} = k_e^{1/2}/\{(a-x_e)(b-x_e)\}$$
$$= K(2K_qK_{ip}^2)^{1/2} \quad (15)$$

Under these conditions Eq. 2 is reduced to

$$\frac{dx}{dt} = x_f\{(a-x)(b-x) - K_{obsd}^{-1}x^{1/2}\}. \quad (16)$$

$$\int_0^x \frac{dx}{(a-x)(b-x)-K_{obsd}^{-1}x^{1/2}} = \int_0^t k_f dt \quad (17)$$

On the basis of Simposon's rule, graphical integrations were repeated for the assumed values of k_f and K_{obsd}, until the calculated set of x *vs.* t data agreed with the experimental values. The best sets for K_{obsd} and k_f were 47.5 M$^{-1/2}$, and 2.97×10^{-4} M^{-1} s^{-1}, respectively.

The equilibrium constant determined kinetically (47.5

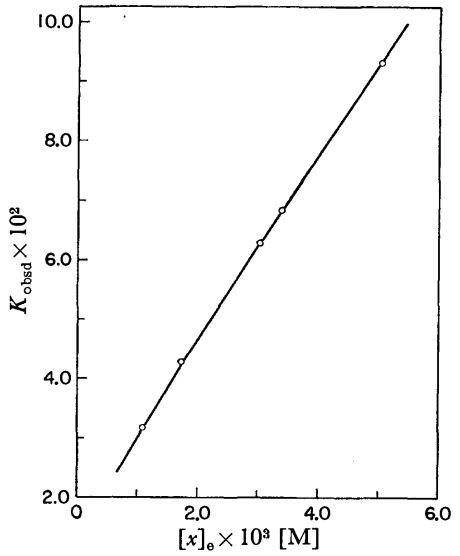


Fig. 1. Plots of K_{obsd} *vs.* $(x)_e$ at 30 °C.
○; Experimental, —; calculated with $K=1.08\times10^{-2}$, $K_{ip}=1.11\times10^3$(M^{-1}), $K_q=3.35$(M^{-1}).

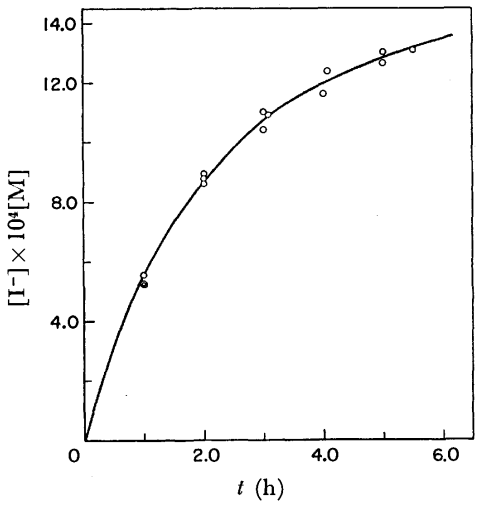

Fig. 2. Plots of (I^-) *vs.* t at 30 °C.
○; Experimental, —; calculated with $K_{obsd}=47.5$ (M$^{-1/2}$), $k_f=2.97\times10^{-4}$ (l mol^{-1} s^{-1}), $a=b=3.00\times10^{-2}$ (M).

$M^{-1/2}$) was in good agreement with the value determined analytically (46.5 $M^{-1/2}$). A comparison of the calculated values of x with the experimental ones is shown in Figure 2.

The values of k_f and K_{obsd} were also determined by direct differentiation of x with respect to t after expanding x into a power series of t as in $x=at+bt^2+ct^3$, followed by calculation of the value of K_{obsd} which gave a constant value of k_f throughout the run. The values determined by the two methods were in good agreement.

Solvent Effects on the Rate Constant, k_f. The rate constants, k_f, are summarized in Table 1, where k_x denotes the rate constant expressed in mole fraction unit as calculated from the rate constant, k_f, and the molar volume of the solvent, V_s, (expressed in liter) by the equation, $k_x=k_fV_s^{-1}$.

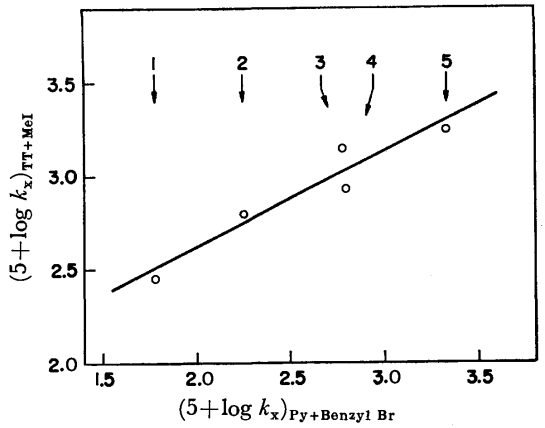

Fig. 3. Empirical correlations for the rate constants. Ordinate; present system, abscissa; pyridine+benzyl bromide, 1: bromobenzene, 2, cyclohexanone, 3; nitrobenzene, 4; methanol, 5; acetonitrile.

An empirical correlation exists[1] among log k_x values in spite of the different nucleophilic centers in the reactants (Fig. 3). The slope of the plots, which gives a relative sensitivity of the reaction to varying solvent characteristics, is smallest for the present reaction. This indicates that the charge development at the transition state is fairly small as compared with the quaternization reaction, or alternatively that charge delocalization in the thiazoline ring reduces the charge density on each atom, thus causing the reaction to be less sensitive to the solvent change.

The observation that the reverse rate process is also liable to solvent effects makes the first suggestion more plausible.

Table 1. Comparison of rate constants, k_f (30 °C)

Solvent	$k_f\times10^4$	$k_x\times10^2$
Propylene carbonate	20.5	2.40
Nitrobenzene	14.8	1.43
N,N-Dimethylacetamide	12.3	1.32
Acetonitrile	9.50	1.78
Methanol	3.48	0.849
Cyclohexanone	6.40	0.611
Bromobenzene	2.97	0.280

k_f; 1 mol^{-1} s^{-1}, k_x; s^{-1}.

Table 2. Comparison of the slopes

Reaction	$\Delta\log k/(\Delta\log k)_{Benzyl\ Br+Pyr}$

The apparent molal volumes of the solute, ϕ_v and the overall volume change in the reaction, $\Delta\phi_v$, are summarized in Table 4. In acetonitrile and propylene carbonate, the values of $\Delta\phi_v$ in the table would approximately be equal to the volume change of the reaction, $\Delta\bar{V}°$, since the association constants of the quaternary ammonium salts are usually small in these solvents.[9,10]

We see that the molal volumes of electrolytes are fairly small in acetonitrile as compared to those in propylene carbonate and that there is a near parallelism between the values of ΔV_0^* and of $\Delta\phi_v$, resulting in a nearly constant value of $(\Delta V_0^*/\Delta\phi_v)$.

ΔV_0^* is generally considered as the sum of two terms, Δ_1V^*, Δ_2V^*. The first term arises from changes in the molal volume of the reactant molecules as they form a transition state, while the latter is attributed to the volume change in the surrounding solvents due to electrostriction. A similar dissection of $\Delta\bar{V}°$ in terms of $\Delta_1\bar{V}°$ and $\Delta_2\bar{V}°$ is valuable for the following discussions.

Stewart and Weale[11] concluded that $\Delta_1\bar{V}°\approx0$, by combining the calculated values of Δ_1V^* for the forward and reverse Menschutkin reactions on the basis of a cylinder model. An alternative estimation of $\Delta_1\bar{V}°$ is possible by the substitution of the molal volume of methylpyridinium iodide by the molar volumes of neutral model compounds, *i.e.*, by the molar volume of toluene as a model compound for methylpyridinium ion, 107.4 cm^3 mol^{-1},[3] and of liquid xenon, 37.3 cm^3 mol^{-1} (−109 °C),[12] (or a little larger than this because of volume expansion due to temperature rise from −109 to 30 °C), as a model compound for iodide, thus leading to $\Delta_1\bar{V}°\approx107.4+37.3-(81.6+67.1)=-4$ to 0 (cm^3 mol^{-1}). Both estimates suggest that the major part

TABLE 4. APPARENT MOLALVOLUMES AND ACTIVATION VOLUMES (30 °C)

Reaction	Solvents	ϕ_v (cm^3 mol^{-1})			$\Delta\phi_v$	ΔV_0^*	$(\Delta V_0^*/\Delta\phi_v)$
		TT	MeI	MTT+I^-			
MeI+TT	AN	145.2	67.1	166.9	−45.4	−24.9	0.55
MeI+TT	PC	151.8	65.1	191.3	−25.6	−16.1	0.63

of the observed values of $\Delta\phi_v$ comes from the term, $\Delta_2\bar{V}°$.

The observed molal volume of a solute V_M is usually larger than the calculated van der Waals volume, V_W, and the ratio (V_M/V_W) is known to range from 1.3 to 2.2 because of the existence of empty space in the liquid.[13] Calculation of van der Waals volumes as proposed by Edward[13] gives the factor (V_M/V_W) of 1.8 and 2.0 for pyridine and methyl iodide in acetonitrile.

Stewart and Weale[11] estimated $\Delta_1V^* = -6.5$ cm^3 mol^{-1} for the forward Menschutkin reaction on the basis of the cylinder model. A combination of the value −6.5 and the above factor of 1.8 gives $\Delta_1V^* = -11.7$ cm^3 mol^{-1}, which is in reasonable agreement with the estimated value of −10.7 cm^3 mol^{-1} obtained by a completely different method.[14]

The values of $\Delta_2V^*/\Delta_2\bar{V}°$ would serve as indices of the degree of charge development at the transition state throughout the series of reactions of the same volume profile along the reaction coordinate, *i.e.*, a slightly modified version of the proposals.[15,16] Making use of the value of $\Delta_1V^* = -11.7$ cm^3 mol^{-1} and the above conclusion that $\Delta\phi_v \approx \Delta_2\bar{V}°$, we find that the value $(\Delta_2V^*/\Delta_2\bar{V}°)$ becomes nearly constant at 0.26—0.29 for both reactions. An exception is the reaction of TT with methyl iodide in propylene carbonate for which a rather large uncertainty should be included in the value of Δ_2V^* obtained above. Abraham estimated the above indices as 0.4—0.41 from a comparison of the transfer free energy of the activated complex with that of the product ion-pair.[17] Our value of 0.26—0.27 is intermediate between the value 0.2 as estimated previously[1] and the value given by Abraham.[17]

The relative sensitivity difference to change of solvent observed in the case of the reaction rate constants is manifested neither on the activation volumes nor on the values of $(\Delta V_0^*/\Delta\phi_v)$.

Thus, the desirability of acquiring reliable values of Δ_1V^* and $\Delta_1\bar{V}°$ is obvious.

CNDO/2 Calculation. CNDO/2 calculations[18] were carried out for estimated structures of the transition state using model compounds.[19–21] In order to save time it was assumed that the reaction proceeds through a transition state which has a structure closely resembling a product, *i.e.*, ∠N-C-I=180° for pyridine and methyl chloride, and ∠C(ring)-S-C(methyl)=101° for TT with methyl chloride. Thus only two bond distances r_{N-C} and r_{C-Cl} change during the course of reaction, the others remaining unchanged. The central CH_3 group was assumed to lie in a plane. Calculations were repeated until a minimum total energy was reached, by changing the value of Δr according to $r_{N-C}=1.47+\Delta r$ (or $r_{S-C}=1.80+\Delta r$) and $r_{C-Cl}=1.78+\Delta r$, where the numerals indicate normal bond distances of a model compound.[19–21]

Charge densities for the minimized structures as given in Figs. 4 and 5 suggest that electronic charges are more developed at the transition state for the reaction of pyridine with methyl iodide, which corresponds to the arguments put forward on the basis of the rate studies.

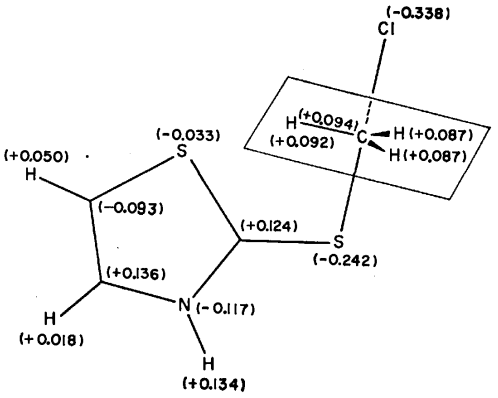

Fig. 4. Charge distribution for minized structure. $r_{C-S}=1.83$ Å, $r_{C-Cl}=1.81$ Å, $\mu=6.74$ D.

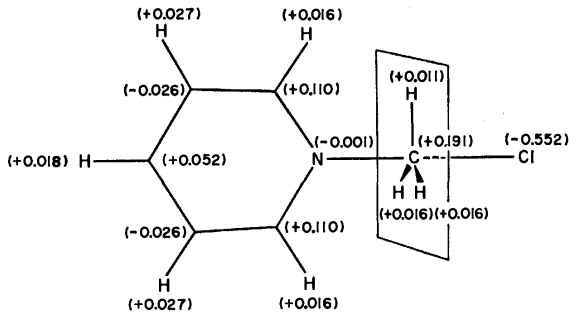

Fig. 5. Charge distribution for minimized structure. $r_{N-C}=1.59$ Å, $r_{C-Cl}=1.90$ Å, $\mu=10.7$ D.

Heydtman *et al.*[22] estimated the dipole moment of the activated complex to be 7.8 D by applying the Kirkwood approach[23] to the reaction of ω-bromoacetophenone with α-picoline. Eckert *et al.* derived a value of 5.9 D for the reaction of pyridine and methyl iodide by the same approach.[24] For the reaction of pyridine with

methyl iodide, the slope of the plots of $RT \ln k$ *vs.* $(D-1/2\ D+1)$ corresponds to 14.3 kcal mol^{-1}. This leads to the value 6.3 D for the dipole moment of the activated complex, when allowance is made for the empty space as mentioned above, *i.e.*, the factor of 1.8, and when radii are calculated from the molal volumes in Table 4 assuming a spherical molecule. A different application of the Kirkwood approach leads to a different dipole moment as described by Eckert.[25] Thus, the model CNDO/2 calculation provides an alternative way of estimating the dipole moment.

We are grateful to Dr. Michael H. Abraham, University of Surrey, England for helpful criticisms of the original version of this manuscript.

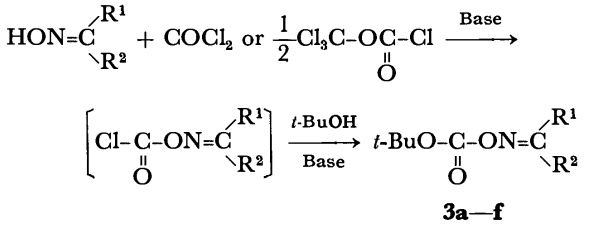
Peptides. VI. Some Oxime Carbonates as Novel *t*-Butoxycarbonylating Reagents[1)]

Masumi Itoh, Daijiro Hagiwara, and Takashi Kamiya,
Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Kashima-cho, Yodogawa-ku, Osaka 532
(Received July 15, 1976)

Several *t*-butoxycarbonyl derivatives of oximes were prepared through the corresponding oxime chloroformates. Of these, diethyl (*t*-butoxycarbonyloxyimino)malonate and 2-(*t*-butoxycarbonyloxyimino)-2-phenylacetonitrile were utilized for the preparation of *t*-butoxycarbonylamino acids under various conditions. The results are summarized in a table.

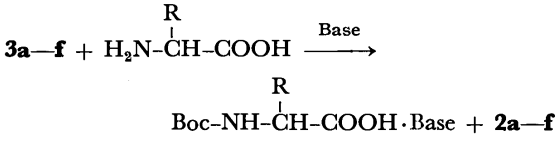
The *t*-butoxycarbonyl (Boc) group is one of the most important amino-protecting groups in peptide synthesis, and there have been many reagents proposed for its introduction.[2-18)] The most popular and still widely utilized one is *t*-butyl azidoformate (**1**),[2)] though it is toxic and relatively less reactive and should be prepared just before use. Most of the substitutes for **1** are, with a few exceptions, less attractive because of disadvantages such as difficult access or insufficient reactivity of the reagents, or cumbersome elimination of by-products from Boc-amino acids. The present authors wish to propose a new promising reagent, 2-(*t*-butoxycarbonyloxyimino)-2-phenylacetonitrile (**3c**), which is an easy-to-prepare, stable, and highly reactive crystalline material and affords contaminant-free Boc-amino acids in high yields by following a conventional procedure.

In the course of studies on the application of *N*-hydroxy compounds to peptide synthesis in our laboratory, it was noticed that some oximes could be suitable as the activator and carrier of Boc groups. Oximes are usually regarded as unstable compounds which are easily hydrolyzed or rearranged. However, certain ketoximes which possess electron-withdrawing substituents and have no hydrogen atoms on the α-carbon atoms are relatively stable and can be converted into their Boc derivatives through the corresponding chloroformates.



Scheme 1.

In practice those oximes were allowed to react first with phosgene or trichloromethyl chloroformate in the presence of *N,N*-dimethylaniline or pyridine in inert solvents, and the resultant chloroformates were treated *in situ* with *t*-butyl alcohol and pyridine to give Boc-oximes. Some of the derivatives prepared are listed in Table 1. Of these, diethyl (*t*-butoxycarbonyloxyimino)malonate (**3a**) was the most reactive one; it readily introduced the Boc group to amino acids within 1 to 3 h. Compound **3c** was a stable crystalline material and moderately reactive among the compounds listed in Table 1; it completed the reaction within 4 to 5 h. The other cardonates were so unstable that mainly **3a** and **3c** were subjected to further studies.



Scheme 2.

An advantage of **3c** over **3a** is the easy removal of 2-(hydroxyimino)-2-phenylacetonitrile (**2c**) from the reaction mixture. When **3a** is used it requires critical pH adjustment to 7.0 for the removal of diethyl (hydroxyimino)malonate (**2a**) from the reaction mixture. To simulate extraction conditions for the removal of **2a** and **2c**, their ethyl acetate solutions were shaken with water in the presence of sodium hydroxide, sodium hydrogencarbonate, or triethylamine. The oxime **2c** transferred only with sodium hydroxide but not with the others, suggesting an easy way for complete removal of **2c** from the reaction mixture. Both **3a** and **3c** were quite stable to competitive hydrolysis by sodium hydroxide or triethylamine in dioxane–water at room

a) The amino acids used, with the exceptions of glycine and D-phenylglycine, are of L-configuration. The reactions were carried out in 10 mmol scale with 1.1 equiv of the reagents at 20 to 25 °C unless stated otherwise. All products were purified following descriptions in the literatures, and optical rotations observed were within the limit of error in comparison with reported values. b) Five to 10 ml of organic solvents and water per 10 mmol amino acid were used unless cited below. Those with asterisks were removed *in vacuo* before the extraction of oximes; A: *t*-butyl alcohol/water, B: acetone/water, C: dioxane/water, D: methanol/water (70/70 ml), E: methanol/dioxane/water (15/5/10 ml), and F: dioxane/chloroform/water (20/10/10 ml). c) 40/100 ml. d) The difference of the melting points of the two N^{α}-Boc-N^{G}-nitro-L-arginine preparations will be due to polymorphism. e) Warmed for a while at 50 °C. f) At 40 °C. g) 14/20 ml. h) 30/20 ml. i) An equiv of **3c** was used. j) Sodium hydroxide was neutralized before the extraction.

temperature. Compound **3c** dissolves only partly in a solvent–water mixture at an initial stage of the reaction, but the mixture usually becomes homogeneous within 1 h. Yields of Boc-amino acids and conditions employed for each reaction are summarized in Table 2. In the case of L-tyrosine, two equivalents of sodium hydroxide and an equivalent of triethylamine were employed to obtain a clear solution, and a small amount of a side-product, *N,O*-bis-Boc-L-tyrosine, was detected on a thin layer chromatogram. However, the side-product could be eliminated effectively from *N*-Boc-L-tyrosine through salt formation with dicyclohexylamine. To secure a high yield and the purity of the products, other solvents than dioxane should be removed before the extraction of **2a** or **2c** from the reaction mixture. Omission of the removal of dioxane did not cause any trouble unless a large excess of it was used. The selection of a suitable solvent for the removal of **2a** or **2c** may be important

Table 3. Oxime carbonates prepared for the introduction of other amino protective groups

a) Prepared from the corresponding alkyl or aralkyl chloroformates with the oximes by following the conventional procedure.[28] b) Prepared by following a similar procedure to that described for **3c**. c) Hexane. d) Prepared by following the procedure for **3a**.

for the Boc-amino acids with lipophilic side chains. For example, in the preparation of Boc-L-phenylalanine with **3c**, the use of ethyl acetate or benzene lowered the yield, whereas the use of ether gave a satisfactory result. Possible contaminants, **2a** and **2c**, were detected on fluorescent indicator-impregnated silica gel plates.

In comparison with **1** and 2-(*t*-butoxycarbonylthio)-4,6-dimethylpyrimidine (**4**),[18] **3c** showed a much higher reactivity. In the preparation of Boc-glycine, for example, **3c** completed the reaction within 2 h at room temperature,[1] whereas both **1** and **4** required more than 20 h at 40 °C and room temperature, respectively. Furthermore, **3c** is less toxic (LD_{50} orally in mice: 8000 mg/kg) and the by-product **2c** is easily recovered and recycled.

This procedure is wholly applicable to the preparation of other *N*-protected amino acids, and the reagents prepared for such purposes are listed in Table 3. Examples of *N*-protected amino acids, prepared by similar procedures to those described in the experimental section, are *N*-benzyloxycarbonyl-L-serine[32] (87.8%), *N*-(*p*-methoxybenzyloxycarbonyl)-L-phenylalanine[33] (64.6%), *N*-(2,2,2-trichloroethoxycarbonyl)-D-phenylglycine (mp 141—143 °C, 92.1%),[34] and *N*-(1-cyclopropylethoxycarbonyl)-D-phenylglycine (mp 94—96 °C, 88.5%).[34] The 1-cyclopropylethoxycarbonyl group was easily removed under the conditions required for the Boc group.

Experimental

The capillary melting points were observed on a Hoover "Uni-Melt" apparatus and are uncorrected. Precoated silica gel 60 F_{254} plates (Merck) were used for thin layer chromatography (TLC).

Materials. Trichloromethyl chloroformate was obtained from Hodogaya Chemical Co., Ltd., Tokyo. Diethyl (hydroxyimino)malonate (**2a**),[22] ethyl 2-(hydroxyimino)acetoacetate (**2b**),[23] 2-(hydroxyimino)-2-(*p*-chlorophenyl)acetonitrile (**2d**),[24] benzophenone oxime (**2f**),[25] 1-cyclopropylethanol,[29] and *p*-methoxybenzyl chloroformate[30] were prepared according to the literature.

2-(Hydroxyimino)-2-phenylacetonitrile (2c). Into an ice-cooled solution of benzyl cyanide (117 g, 1 mol) and sodium hydroxide (40 g, 1 mol) in methanol (300 ml) was introduced gaseous methyl nitrite[26] which was generated from a suspension of sodium nitrite (83 g) in a mixture of methanol (53 ml) and water (50 ml) by dropwise addition of a mixture of concentrated sulfuric acid (32 ml) and water (65 ml). The mixture was stirred for 2 h at room temperature and concentrated to dryness. The residue was dissolved in water and washed with toluene twice. The aqueous layer was acidified with concentrated hydrochloric acid to precipitate **2c**: 120 g (82%); mp 119—124 °C (lit,[27] mp 126—128 °C); TLC, R_f=0.50 (chloroform–methanol (9: 1)). This was used in the next step without further purification.

2-(Hydroxyimino)-2-(1-naphthyl)acetonitrile (2e). This was prepared from 2-(1-naphthyl)acetonitrile by the procedure described above. The syrupy product obtained in 36.2 % yield was used in the next step without purification.

Diethyl (t-Butoxycarbonyloxyimino)malonate (3a). To a well-stirred solution of phosgene (151 g, 1.53 mol) in benzene (800 ml) was added dropwise a solution of **2a** (289 g, 1.53 mol) and *N*,*N*-dimethylaniline (DMA) (186 g, 1.53 mol) in benzene(800 ml) at 5—6 °C over the period of 2.5 h under nitrogen atmosphere. The mixture was stirred for 2 h at 5—6 °C, and for 18 h at room temperature. To the resultant mixture was added dropwise a mixture of *t*-butyl alcohol (225 g, 3.06 mol) and pyridine (Pyr) (486 ml, 6.12 mol) at 5—6 °C over the period of 1.5 h under nitrogen. Stirring was continued for 18 h at room temperature. After filtration of precipitates the filtrate was washed with cold 1M hydrochloric acid (1 l×6) and cold water (1 l×3), and stirred with sodium hydrogencarbonate solution (70 g in 1 l) for 3 h at room temperature. The organic phase was washed with 5% sodium carbonate solution (100 ml×2), water (200 ml×2) and saturated sodium chloride solution (100 ml), and dried over magnesium sulfate with 15 g of charcoal. Evaporation gave 341 g (77.2%) of **3a**. IR (neat, cm^{-1}) 1800, 1750; nuclear magnetic resonance (NMR) (in CCl_4, δ(ppm)) 1.39 (3H, triplet, J=6.5 Hz), 1.41 (3H, triplet, J=6.5 Hz), 1.59 (9H, singlet), 4.34 (4H, quartet, J=6.5 Hz).

Ethyl 2-(t-Butoxycarbonyloxyimino)acetoacetate (3b). This was prepared from **2b** by a procedure similar to that described in the preparation of **3a**, except for the use of Pyr in the place of DMA. IR (neat, cm^{-1}) 1780, 1730, 1690; NMR (in CCl_4, δ(ppm)) 1.37 (3H, triplet, J=7 Hz), 1.57 (9H, singlet), 2.48 (3H, singlet), 4.34 (2H, quartet, J=7 Hz).

2-t-Butoxycarbonyloxyimino-2-phenylacetonitrile (3c). To a stirred solution of trichloromethyl chloroformate (6.7 ml, 0.055 mol) or an equivalent of phosgene (0.11 mol) in benzene (30 ml) was added dropwise a solution of **2c** (14.6 g, 0.1 mol), DMA (12.0 g), and dioxane (5 ml) in benzene (100 ml) at 3—5 °C. The mixture was stirred for 6 h at room temperature and allowed to stand overnight. To the resultant mixture was added a solution of *t*-butyl alcohol (11.1 g) and Pyr (16.0 ml) in benzene (20 ml) at 5—10 °C. The mixture was allowed to react for 3 h at the same temperature, then for 4 h at room temperature, and to stand overnight. The mixture was then washed with water, 1 M hydrochloric acid, water, 5% sodium hydrogencarbonate solution, and water again, and dried over magnesium sulfate. After evaporation of the solvent, the residue was triturated with 20 ml of 90% aqueous methanol, filtered, washed with 30 ml of the same solvent, and dried to give 17.0 g of **3c**: mp 84—86 °C; TLC, R_f=0.74 (chloroform–methanol (9: 1)).

Found: C, 63.69; H, 5.71; N, 11.20%. Calcd for $C_{13}H_{14}O_3N_2$: C, 63.40; H, 5.73; N, 11.38%. IR (Nujol, cm^{-1}) 1785; NMR (in $CDCl_3$, δ(ppm)) 1.62 (9H, singlet), 7.2—8.2 (5H, multiplet).

2-(t-Butoxycarbonyloxyimino)-2-(p-chlorophenyl)acetonitrile (3d). This was prepared from **2d** (37.5 mmol) by a procedure similar to that described above except that chloroformylation was done by the use of DMA in a mixture of dioxane (10 ml), tetrahydrofuran (10 ml), and dichloromethane (70 ml). (See Table 1).

Found: C, 55.80; H, 4.65; N, 10.07; Cl, 12.62%. Calcd for $C_{13}H_{13}O_3N_2Cl$: C, 55.62; H, 4.67; N, 9.98; Cl, 12.63%. IR (Nujol, cm^{-1}) 1790; NMR (in $CDCl_3$, δ(ppm)), 1.63 (9H, (singlet), 7.50 and 7.90 (2H, each, AB Quartet, J=4.5 Hz).

2-(t-Butoxycarbonyloxyimino)-2-(1-naphthyl)acetonitrile (3e). A similar procedure to that described above was followed in toluene. IR (Nujol, cm^{-1}) 1790.

Found: C, 68.85; H, 5.38; N, 9.40%. Calcd for $C_{17}H_{16}O_3N_2$: C, 68.90; H, 5.44; H, 9.46%.

(t-Butoxycarbonyloxyimino)diphenylmethane (3f). A similar procedure to that described above was employed. IR (Nujol, cm^{-1}) 1770; NMR (in $CDCl_3$, δ(ppm)), 1.48 (9H, singlet), 7.17—7.65 (10H, multiplet).

General Procedures for the Introduction of t-Butoxycarbonyl Group. a) By the Use of 3a: To a solution of L-alanine (0.89 g, 10 mmol) and triethylamine (TEA) (1.68 ml, 1.2 mmol) in a mixture of water (5 ml) and *t*-butyl alcohol (5 ml) was added

3a (3.2 g, 11 mmol). The mixture was stirred for 1 h at room temperature. After evaporation of *t*-butyl alcohol and addition of ether and 5% sodium hydrogencarbonate solution, the mixture was adjusted to pH 7.0 precisely with a citric acid solution. The aqueous layer was separated, overlaid with ether, and adjusted to pH 7.0 again. The aqueous layer separated was acidified with citric acid solution and extracted with ethyl acetate (EtOAc). The extract was treated in the usual manner to give *N*-*t*-butoxycarbonyl-L-alanine: 1.59 g (84.1%); mp 82—84 °C. Conditions employed in the other examples are presented in Table 2.

b) By the Use of ***3c***: To a solution of L-tryptophan (2.05 g, 10 mmol) and TEA (2.10 ml, 15 mmol) in water (6 ml) was added dioxane (6 ml) and crystalline **3c** (2.71 g, 11 mmol) at room temperature. The mixture became homogeneous within 1 h and stirring was continued for two more hours. After addition of water (15 ml) and EtOAc (20 ml), the aqueous layer was separated, washed with EtOAc (20 ml), acidified with 5% citric acid solution, and extracted with EtOAc. The extract was treated in the usual manner to give *N*-*t*-butoxycarbonyl-L-tryptophan: 3.00 g (98.6%); mp 137—138 °C (decomp). Other amino acids were allowed to react by the same procedure, unless stated otherwise in Table 2. Dicyclohexylammonium salts were crystallized by the addition of dicyclohexylamine (1.8 g per 10 mmol amino acid) to an ether solution of *t*-butoxycarbonylamino acids.

The Reactions of Carbonimidoyl Dichlorides with Metal Thioacetates, Acetates, Thiocyanates, and Selenocyanate

Sakuya TANAKA, Sakae UEMURA, and Masaya OKANO*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received August 6, 1976)

The reactions of carbonimidoyl dichlorides with potassium thioacetate and thiocyanate in tetrahydrofuran afford the corresponding isothiocyanates. Similarly, the reaction with potassium selenocyanate gives isoselenocyanates. Thallium(I) acetate reacts with phenylcarbonimidoyl dichloride with greater facility than potassium acetate to give a mixture of phenyl isocyanate and acetanilide in which the latter is predominant. A displacement of one chlorine atom in the carbonimidoyl dichlorides by a SAc, OAc, SCN, or SeCN group, followed by elimination of AcCl or CNCl, has been proposed as a reasonable reaction path.

The carbonimidoyl dichlorides can be used as starting materials for the preparation of many types of organic substances.[1] As one of a series of studies on carbonimidoyl dichlorides[2] and isocyanides,[3] we now report the results of the reactions of phenyl- and cyclohexylcarbonimidoyl dichlorides (hereinafter abbreviated as PCD and CCD respectively) with various metal thioacetates, acetates, and thiocyanates, as well as with potassium selenocyanate. Although the substitution reactions of imidoyl chlorides and their derivatives with metal acetates,[4] thioacetates,[4] and thiocyanates[5] have been reported, information about similar reactions on carbonimidoyl dichlorides is rare.

Results and Discussion

Reactions with Metal Thioacetates and Acetates (Table 1). The heterogeneous reaction of PCD or CCD with two equivalents of KSAc in tetrahydrofuran (THF) proceeded smoothly at room temperature to give the corresponding isothiocyanate in a fair yield without affoding any other organic products except for acetic thioanhydride (runs 3 and 4). In the case of 1 : 1 molar ratio, nearly 50% of the dichloride (PCD) or more was recovered, though the yield based on the consumed dichloride was nearly quantitative (runs 1 and 2). Thus the reaction appeared to occur in accord with the stoichiometry shown in Scheme 1 (Z=S):

$$\underset{\text{PCD (R=Ph)}\quad \text{CCD (R=}\textit{cyclo}\text{-}C_6H_{11})}{R\text{-}N{=}CCl_2} + 2CH_3COZM \longrightarrow R\text{-}N{=}C{=}Z + (CH_3CO)_2Z + 2MCl \quad (1)$$
(Z=S or O)

With TlSAc, probably less ionized than KSAc, the reaction was sluggish and was brought to completion by heating (run 5).

In a similar way, PCD reacted with two equivalents of metal acetates in boiling THF to give a mixture of phenyl isocyanate and acetanilide in which the latter was predominant; the combined yield was nearly quantitative (based on the consumed dichloride), but no acetic anhydride could be found in the reaction products. In order to examine whether acetanilide is formed by the reaction of phenyl isocyanate with acetic anhydride under the reaction conditions, some controlled

TABLE 1. REACTIONS OF $RN{=}CCl_2$ WITH METAL THIOACETATES AND ACETATES[a]

a) $RN{=}CCl_2$ (5 mmol; R=Ph) and THF (10 ml) were used unless otherwise stated. b) Determined by GLC; Based on $RN{=}CCl_2$. c) Z=S. d) R=*cyclo*-C_6H_{11}. e) Z=O. f) Other products; two unidentified compounds (*ca.* 3% each). g) $PhN{=}CCl_2$ 1 mmol; dicyclohexyl-18-crown-6 (2 mmol) was added.

* To whom correspondence should be addressed.

experiments were carried out. When either phenyl isocyanate or acetic anhydride was heated in THF (at 68 °C for 3 h), no appreciable change (including their hydrolysis) occurred in either case. However, when an equimolar mixture of these two compounds (5 mmol each) was similarly treated in the same solvent (10 ml), 14% of acetoanilide was produced; this was probably formed by the participation of external moisture (originated from the solvent, the acetate, and/or the atmosphere) in the reaction between two components. In this case considerable amounts of phenyl isocyanate and acetic anhydride remained unreacted, as opposed to the case of the dichloride-acetate reaction in which only 4% of the isocyanate and no acetic anhydride were found (see run 9). Though the reason for this disagreement is not clear at present, it may be possible that some acidic impurities formed during the course of the reaction accelerate the above acetanilide formation.

Further, it was found unexpectedly that in the reaction with metal acetates TlOAc (less ionized[6]) reacts more easily than KOAc (more ionized) (runs 9 *vs.* 6). In the case of other monovalent heavy-metal acetates such as Ag(I) and Hg(I), however, no such striking results were observed (runs 11 and 13). Since crown ethers have been known to increase the concentrations of "naked" anions by complexing with counter-cations, we also examined the reaction with metal acetates in the coexistence of dicyclohexyl-18-crown-6.[7] Considerable improvements in the yields were achieved in all cases, but it was insufficient in the case of AgOAc (runs 7, 10, and 12).

Next, we will briefly consider a probable reaction path for the above two reactions. It is known that the 1 : 1 molar reactions of carbonimidoyl dichlorides with alkoxide ions and amines afford the corresponding monosubstituted products in good yields.[1] In the present reactions, however, no detectable amounts of such products (**1**) were found in the reaction mixtures. This may suggest their rapid disappearance owing to some subsequent reaction. In connection with the present reactions, it has been reported that PCD reacts with acetic acid to afford phenyl isocyanate and acetyl chloride with generation of HCl.[8] It has also been reported that the reaction of PCD with ethanol affords *N*-phenylethylurethane with the liberation of HCl and ethyl chloride, suggesting the intermediacy of ethyl *N*-phenylchloroformimidate.[9] Based on these facts and the stoichiometry of the reactions, the following pathway would be highly probable:

$$R\text{-}N{=}CCl_2 \xrightarrow[-Cl^-]{CH_3COZ^-} \underset{\mathbf{1}}{\left[R\text{-}N{=}C\begin{matrix}\diagup Cl\\ \diagdown ZCOCH_3\end{matrix}\right]} \xrightarrow[-CH_3COCl]{} R\text{-}N{=}C{=}Z \quad (2)$$

$$CH_3COCl + CH_3COZ^- \longrightarrow (CH_3CO)_2Z + Cl^- \quad (Z{=}S \text{ or } O)$$

There may be another route for RNCZ which involes further displacement of the intermediate **1** by CH_3COZ^- to give $R\text{-}N{=}C(ZCOCH_3)_2$ (**2**), followed by elimination of $(CH_3CO)_2Z$, especially in the thioacetate reaction, since AcS^- is known to be a stronger nucleophile than AcO^-.

We must add a short comment on the facile reaction with TlOAc in the absence of crown ether. We roughly compared the solubility of this salt in boiling THF with those of other acetates, but it appeared that no significant differences were present (*i.e.*, 0.012 mol/l for TlOAc, 0.016 mol/l for AgOAc, and 0.002 mol/l for KOAc). Besides, no variations in the yields were observed within the experimental error by changing the amount of the solvent by half or five times in the reactions with TlOAc or KOAc respectively. Thus it is clear that the rate of dissolution of metal acetates is not the dominant factor in affecting the reaction rate. Since the considerably covalent character of the Tl-O bonds of similar compounds has been recognized,[6] most of the dissolved TlOAc is expected to exist in un-ionized form. Thus, the contribution of a four-center-type reaction between un-ionized TlOAc and carbonimidoyl dichlorides affording **1** may be possible, though no direct evidence is available at present. Needless to say, when the crown ether is added to the reaction system, the attack of the "naked" OAc^- which is in equilibrium with the un-ionized species becomes predominant.

Reactions with Potassium Thiocyanate, Selenocyanate, and Cyanate (Table 2). When PCD was treated with two equivalents of KSCN in boiling THF, phenyl isothiocyanate was obtained (run 15). The yield was rather poor, and the reaction was accompanied with the formation of an unidentified yellow solid of which the

a) Determined by GLC; based on $RN\text{-}CCl_2$. b) An unidentified yellow solid was also obtained.

IR spectrum did not show any absorptions due to -N=C=S or -S-C≡N groups.[10] Neither the improvement of the yield and the depression of the by-product formation could be achieved by changing molar ratios or solvents (*e.g.*, diglyme, acetone, ethanol, and *N,N*-dimethylformamide). In the case of ethanol solvent, phenyl isothiocyanate was obtained in a similar yield, but a larger amount of yellow solid was formed (runs 16 and 17, see also Experimental section). Since the displacement of one Cl atom in carbonimidoyl dichlorides by CN is known to be achieved by using CuCN, we examined the reaction between PCD and CuSCN in diglyme (at 162 °C for 1 h). The reaction with the Ag(I) or Hg(I) salts was also examined under similar conditions. However, the yield of phenyl isothiocyanate was quite poor (17—28%) in all cases.

The reaction of PCD or CCD with KSeCN, in which $SeCN^-$ is isoelectronic to SCN^-, gave the corresponding isoselenocyanate in a good yield, together with small amounts of an unidentified by-product (runs 19 and 21). The reaction with KOCN did not occur to any extent under similar conditions.

In view of the facts that the stoichiometry of the reaction with KSCN (runs 14 and 15) or KSeCN (runs 18 and 19) was the same as that of the reaction with KSAc or KOAc, a reaction path quite similar to Scheme 2 may be postulated in this case:

$$R\text{-}N{=}CCl_2 \xrightarrow[-Cl^-]{ZCN^-} \underset{\mathbf{3}}{\left[R\text{-}N{=}C(Cl)(ZCN)\right]} \xrightarrow{-ClCN} R\text{-}N{=}C{=}Z \qquad (3)$$

$$ClCN + ZCN^- \longrightarrow (CN)_2Z + Cl^- \quad (Z{=}S \text{ or } Se)$$

In connection with this, the following result is worth noting. In an attempt to prepare the compound **3** (Z=S) by the reaction of phenyl isocyanide with ClSCN (formed *in situ* from a mixture of $Pb(SCN)_2$ and $SbCl_5$[11]), phenyl isothiocyanate rather than **3** was obtained in 8.5% yield, in addition to a slight amount of PCD (1.4%) and considerable amounts of a tarry compound (mostly a polymer of the isocyanide). Here, it was confirmed that the isothiocyanate was not formed by the reaction of PCD or the isocyanide with $Pb(SCN)_2$.

Experimental

The IR and NMR spectra were recorded with a Hitachi EPI-S2 and a Varian EM-360 apparatus respectively. GLC analyses were carried out on a Shimadzu 5APTF apparatus, using Apiezon-L (30%)-Celite (1m) and EGSS-X (30%)-Chromosorb-W (1m) columns (N_2 as the carrier gas, iodobenzene as an internal standard).

Materials. Two carbonimidoyl dichlorides ($R\text{-}N{=}CCl_2$) were prepared by the method of Kühle *et al.*:[12] R=*cyclo*-C_6H_{11} (CCD), bp 88—91 °C/23 Torr (lit,[12] bp 79—82 °C/13 Torr); R=Ph (PCD), bp 79—80 °C/8 Torr (lit,[12] bp 83—85 °C/11 Torr). KSAc was prepared by the method of Barnish *et al.*[13] TlSAc was prepared from thioacetic S-acid and $Tl(OAc)_3$.[14] Other organic materials and solvents were purified before use by distillation. Commercial inorganic materials, except KSCN, were used without further purification. KSCN was used after drying at *ca.* 70 °C under reduced pressure.

Reaction of PCD with KSAc. To a stirred suspension of KSAc (1.14 g, 10 mmol) in THF (10 ml) was slowly added PCD (0.87 g, 5 mmol) at room temperature. The mixture was stirred for 3 h at 20 °C and then the precipitated inorganic salt was filtered off. GLC analysis of the filtrate showed the presence of 4.58 mmol (92% yield based on PCD) of phenyl isothiocyanate as a product. The distillation gave 0.52 g of phenyl isothiocyanate: the IR spectrum [2120 cm^{-1} ($\nu_{N=C=S}$)] and the retention time in GLC were identical with those of an authentic sample. The formation of acetic thioanhydride was also confirmed by the IR spectrum of the distillate.

Reaction of PCD with TlSAc. To a stirred suspension of TlSAc (2.79 g, 10 mmol) in THF (10 ml) was slowly added PCD (0.87 g, 5 mmol) at room temperature. The mixture was stirred for 3 h under reflux. After being cooled down to room temperature the precipitated inorganic salt was filtered off. GLC analysis of the filtrate showed the presence of 3.50 mmol (70% yield based on PCD) of phenyl isothiocyanate and unreacted PCD (1.36 mmol, 27%).

Reaction of CCD with KSAc. A mixture of CCD (0.90 g, 5 mmol) and KSAc (1.14 g, 10 mmol) was stirred in THF (10 ml) at 20°C for 24 h. GLC analysis of the filtrate showed the presence of cyclohexyl isothiocyanate (3.23 mmol, 65%) and unreacted CCD (1.47 mmol, 29%).

Reaction of PCD with KOAc. A mixture of PCD (0.87 g, 5 mmol) and KOAc (0.98 g, 10 mmol) was stirred in THF (10 ml) under reflux for 3 h. GLC analysis of the filtrate showed the presence of acetanilide(0.64 mmol, 13%), unreacted PCD (3.63 mmol, 73%), and small amounts of two unidentified compounds (*ca.* 3% each, as calculated from peak area in GLC).

Reaction of PCD with KOAc in the Presence of Crown Ether. A mixture of PCD (0.174 g, 1 mmol), KOAc (0.196 g, 2 mmol) and dicyclohexyl-18-crown-6 (0.745 g, 2 mmol) was stirred in THF (10 ml) under reflux for 3 h. GLC analysis of the filtrate showed the presence of phenyl isocyanate (0.09 mmol, 9%) and acetanilide (0.75 mmol, 75%).

Reaction of PCD with TlOAc. A mixture of PCD (0.87g, 5 mmol) and TlOAc (2.63 g, 10 mmol) in THF (10 ml) was stirred under reflux for 3 h. GLC analysis of the filtrate showed the presence of phenyl isocyanate (0.21 mmol, 4.2%), acetanilide (3.74 mmol, 75%), and unreacted PCD (0.9 mmol, 18%). The presence of phenyl isocyanate was also confirmed by the IR spectrum ($\nu_{N=C=O}$, 2250 cm^{-1}) of the residue after evaporation of the solvent from the filtrate. The distillation of the residue gave 0.32 g of crude acetanilide, which was recrystallized from aqueous ethanol: the IR and NMR spectra were identical with those of an authentic sample.

Reaction of PCD with KSCN. A mixture of PCD (0.87 g, 5 mmol) and KSCN (0.97 g, 10 mmol) in THF (10 ml) was stirred under reflux for 3 h. GLC analysis of the filtrate showed the presence of phenyl isothiocyanate (1.85 mmol, 37%) and unreacted PCD (0.15 mmol, 3%). Similar treatment of PCD (10 mmol) with KSCN (10 mmol) in EtOH (20 ml) at 0—5 °C for 5 h, followed by extraction with $CHCl_3$, evaporation of the solvent, and addition of hexane to the residue, gave 0.84 g of yellow solid besides 17% yield of phenyl isothiocyanate. The solid was purified by repeated reprecipitation from DMF (DMF dissolves this solid) and water: mp 215—243 °C; IR, broad absorptions, with distinct ones due to phenyl group, and no absorptions due to -S-C≡N or -N=C=S groups; Found: C, 47.98; H, 3.36; N, 18.54; S, 18.08; Cl, 1.81%.

Reaction of PCD with KSeCN. A mixture of PCD (0.87 g, 5 mmol) and KSeCN (1.44 g, 10 mmol) in THF (10 ml) was stirred under reflux for 3 h. GLC analysis of the filtrate showed the presence of phenyl isoselenocyanate (2.91 mmol, 58%) and unreacted PCD (0.38 mmol, 8%). The distillation gave 0.38 g of phenyl isoselenocyanate: bp 81—83 °C/5 Torr (lit,[15] bp 82 °C/7 Torr); IR, 2130 and 2060 cm^{-1} ($\nu_{N=C=Se}$).

The IR and NMR spectra and the retention time in GLC were identical with those of an authentic sample.[15]

Reaction of Phenyl Isocyanide with ClSCN. A mixture of $SbCl_5$ (2.99 g, 10 mmol) and $Pb(SCN)_2$ (3.23 g, 10 mmol) in CCl_4 (10 ml) was heated to 60 °C under stirring. To this mixture was slowly added a CCl_4 (10 ml) solution of phenyl isocyanide (1.03 g, 10 mmol), keeping the temperature at 60—70 °C. The resulting mixture was then stirred for 1 h. After being cooled down to room temperature the precipitated inorganic salt and tarry compounds were filtered off. The organic layer was washed with water and dried over Na_2SO_4. GLC analysis of the organic layer showed the presence of phenyl isothiocyanate (0.85 mmol, 8.5%), PCD (0.14 mmol, 1.4%), unreacted phenyl isocyanide (*ca.* 20%), and two unidentified compounds (*ca.* 8—10% each, as calculated from peak area in GLC) which did not show any absorptions due to –S–C≡N in the IR spectrum.

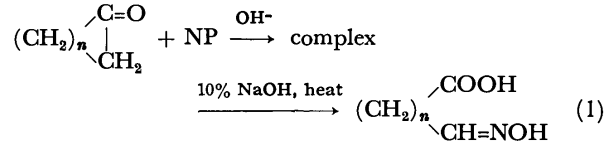
(Received August 30, 1976)

Cycloalkanones reacted with sodium pentacyanonitrosylferrate(II) (NP) to give red-brown or red-violet colored complexes under an alkaline condition. The solvolysis of the complexes gave ω-(hydroxyimino)alkanoic acids under a hot alkaline condition and gave ω-cyanoalkanoic acids or their esters in an acidic condition in good yields. These Products correspond to nitrosolysis products of cycloalkanones. The reaction mechanism was invesigated by use of ^{15}N labeled NP. The complex was formed initially by an electrophilic attack of the nitrosyl ligand of NP to the active methylene of the cycloalkanone. Then a C-C bond cleavage of the resulting ligand, 2-(hydroxyimino)cycloalkanone, occurred by an action of the solvent species under the influence of the central ferrate ion. The solvolysis of the ligand occurred through Beckmann fission by an action of the acid in the coordination sphere.

There have been a number of investigations of the nitrosation of aliphatic and alicyclic ketones by use of alkyl nitrite. While the nitrosation of aliphatic open chain ketones gave mononitrosation products,[1] cyclopentanone, cyclohexanone, and cycloheptanone gave the corresponding α,α′-bis(hydroxyimino) cyclic ketones.[1,2] A reaction of another type, the nitrosolysis reaction: a carbon–carbon bond cleavage through solvolytic nitrosation, was reported for the nitrosation of cycloalkanones by use of nitrosyl chloride.

Kataoka and Ohno[3] found that the nitrosolysis of cyclohexanone under the following conditions gave 5-cyanovaleric acid in 60% yield. The reaction was carried out by use of an ethereal solution of nitrosyl chloride in the presence of sulfuric acid and *N,N*-dimethylformamide under a chilled condition (−30 °C). Recently, Rogic *et al.*[4] reported a novel single step nitrosolysis of cyclopentanone, cyclohexanone, alkylcyclohexanone, cyclododecanone, and cyclotridecanone. The reaction was carried out in liquid sulfur dioxide by use of nitrosyl chloride in the presence of an alcohol. The nitrosolysis of the cycloalkanones under the above conditions gave corresponding ω-(hydroxyimino)alkanoic esters in max 95% yield.

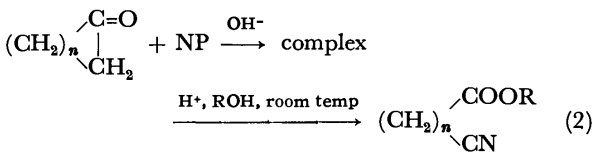
We have been investigating the nitrosation of ketones by using sodium pentacyanonitrosylferrate(II), (sodium nitroprusside) NP, as a nitrosation reagent. In an earlier work[5] prior to these reports, we reported a similar nitrosolysis reaction which occurred in the alkaline hydrolysis of cycloalkanone–NP complexes.



(1)

The complexes reacted in a hot alkaline medium to give ω-(hydroxyimino)alkanoic acids in good yield (Eq. 1).

The present paper deals with the other nitrosolysis reaction of the cycloalkanone–NP complexes under acid-catalyzed conditions: the complexes reacted with solvent species to give ω-cyanoalkanoic acids and their esters also in good yields (Eq. 2).



(2)

The role of nitrosyl ligand of NP in the reaction is discussed in the following section, based on the experimental results using ^{15}N labeled NP. The structure of the intermediate complex is also discussed, based on the information about the structural investigation of an isolated cyclododecanone–NP complex.

Results and Discussion

The Alkaline Hydrolysis Products of the Cycloalkanone–NP Complex. The red-violet or brown colored complexes prepared from NP and cycloalkanones were treated with aqueous alkali at the boiling point. The alkaline hydrolysis products of the cycloalkanone–NP complexes are shown in Table 1. These products were ω-(hydroxyimino)alkanoic acids; however, no 2-(hydroxyimino)-cycloalkanones were found in the hydrolysates. The detailed experimental results have already been described in the previous paper.[5]

The Acid Hydrolysis Products of Cycloalkanone–NP Complex. After the aqueous methanolic solutions of cycloalkanone–NP complexes had been allowed to stand under an acidic condition, other products were found in the solution. These products were ω-cyanoalkanoic acid and their methyl esters (Table 2), which revealed an IR absorption band characteristic of aliphatic nitriles at 2245 cm^{-1}. The NMR data and C, H, N, contents of *p*-bromophenacyl esters derived

† Preliminary reports of this work were presented at the 32nd and 33rd Annual Meetings of the Chemical Society of Japan, 1975.

11-Cyanoundecanoate	68.2	$C_{20}H_{26}NBrO_3$	58.20	6.49	3.12	58.85	6.42	3.43

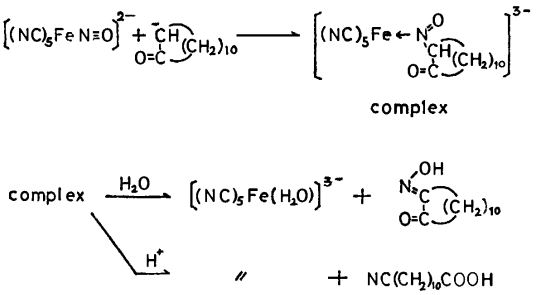

Fig. 1. A possible structure of the cyclododecanone-NP complex and reaction products from it.

from the acids are shown in Tables 3 and 4. No components other than these products were found, except for the products from cyclopentanone-NP complex: this complex gave a by-product, glutarimide.

Structural Investigation on the Cyclododecanone-NP Complex. Hydrolysis of cyclododecanone-NP complex normally gave 12-(hydroxyimino)dodecanoic acid under the alkaline conditions, and gave 11-cyanoundecanoic acid under the acidic conditions. However, after the aqueous solution of the complex had been allowed to stand under a weakly alkaline condition, another crystalline product, 2-(hydroxyimino)cyclododecanone,

was formed. These facts suggest the possible reaction routes which are illustrated in Fig. 1.

To investigate the structure of the intermediate complex shown in Fig. 1, we tried to isolate the cyclododecanone–NP complex in a pure form. The spectral data of the isolated complex supported the predicted structure of the complex illustrated in Fig. 1. As we would expect, hydrolysis of the isolated complex gave under the weakly alkaline conditions 2-(hydroxyimino)-cyclododecanone, and also gave 11-cyanoundecanoic acid under the acidic conditions.

*Investigation of the Reaction Products Prepared from Cyclohexanone and ^{15}N Labeled NP(N*P).* In the hydrolysis of the cycloalkanone–NP complexes, we assumed that the nitrogen atom in the hydroxyimino or cyano group of the reaction products must be introduced from the nitrosyl ligand of NP. To confirm the assumption we have investigated the reaction products prepared from cyclohexanone and N*P, which contained ^{15}N labeled nitrosyl ligands.

Three kinds of N*P (N*P-0, N*P-5 and N*P-30) were prepared from sodium hexacyanoferrate(II) and ^{15}N labeled sodium nitrites. These sodium nitrites contained ^{15}N of natural abundance, 5%, and 30%. The IR spectra of the prepared N*P revealed the characteristic bands at 2150 cm^{-1} (ν CN), 1945 cm^{-1} (ν ^{14}NO), and 1915 cm^{-1} (ν ^{15}NO, calcd 1911 cm^{-1}). The intensity of the last band increased with an increase in the ^{15}N content of N*P, as shown in Fig. 2.

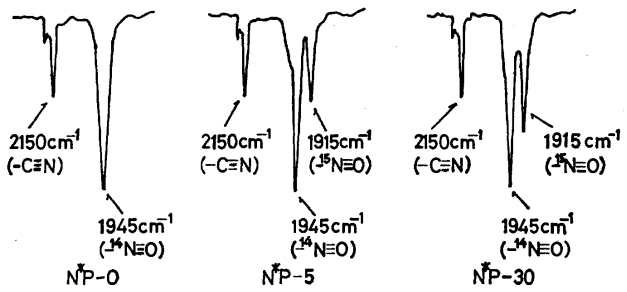

Fig. 2. IR spectra of N*P.

After having been prepared from cyclohexanone and N*P under the hot alkaline condition (Eq. 1), 6-(hydroxyimino)valeric acid was checked for the presence of the hydroxyimino-^{15}N group. Although the hydroxyimino-^{15}N group was difficult to characterize by IR spectral analysis, the presence of ^{15}N labeled fragment ion peaks (*m/e* 73, 128, and other values) in the mass spectra indicated the presence of the hydroxyimino-^{15}N group, as shown in Eq. 3. The relative abundance of the labeled ion peaks increased with an increase in the ^{15}N content of N*P, as shown in Table 5.

$$\begin{array}{l}[HO\text{-}^{15}N{=}CH(CH_2)_4COOH]^{\ddagger} \longrightarrow M^{\ddagger}\text{-}H_2O \quad m/e\ 128 \\ \quad M^+\ m/e\ 146 \qquad\qquad \searrow\ CH_2\text{-}CH_2 \\ \qquad\qquad\qquad\qquad\quad HO\text{-}{}^{15}\overset{|}{N}{}^{+}{=}\overset{|}{C}H \quad m/e\ 73\end{array} \tag{3}$$

A more reliable method for detecting the hydroxyimino-^{15}N group was performed by means of the following procedure. Methyl 5-cyanovalerate prepared from the 6-(hydroxyimino)valeric-^{15}N acid by an ordinary method (Eq. 4) was checked for the presence of the cyano-^{15}N group.

Table 5. Ratios of relative abundance of the fragment ions(I)

N*P	*m/e*73/*m/e*72	*m/e*128/*m/e*127
N*P-0	47%	25%
N*P-5	49	27
N*P-30	78	65

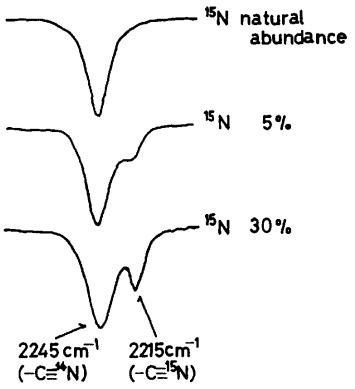

Fig. 3. IR spectra of the methyl 5-cyanovalerates-^{15}N prepared from cyclohexanone and N*P.

$$HO\text{-}{}^{15}N{=}CH(CH_2)_4COOH \xrightarrow{Ac_2O} {}^{15}NC(CH_2)_4COOH \xrightarrow{CH_3OH,\ H^+} {}^{15}NC(CH_2)_4COOCH_3 \tag{4}$$

The IR spectrum of the methyl 5-cyanovalerate-^{15}N revealed the characteristic bands at 2245 cm^{-1} (ν ^{14}NC) and 2215 cm^{-1} ($\nu^{15}NC$, calcd 2210 cm^{-1}). The intensity of the latter absorption band definitely increased with an increase in the ^{15}N content of N*P used for the preparation of 6-(hydroxyimino)valeric-^{15}N acid, as shown in Fig. 3.

The mass spectrum of the methyl 5-cyanovalerate-^{15}N of course revealed ^{15}N labeled fragment ion peaks at *m/e* 83, 111, and other values.

$$\begin{array}{l}[{}^{15}NC(CH_2)_4COOCH_3]^{\ddagger} \longrightarrow {}^{15}NC(CH_2)_4C{=}O^+ \quad m/e\ 111 \\ \quad m/e\ 142 \qquad\qquad \downarrow \\ \qquad\qquad\qquad\qquad {}^{15}NC(CH_2)_4{}^+ \quad m/e\ 83\end{array} \tag{5}$$

The relative abundance of the labeled ion peaks also increased with an increase in the ^{15}N content of N*P used. The ratios of the relative abundance of the labeled and the corresponding unlabeled ion peaks were in fair agreement with the calculated values, as shown in Table 6.

The methyl 5-cyanovalerate-^{15}N were directly prepar-

Table 6. Ratios of relative abundance of the fragment ions(II)

N*P	*m/e* 83/*m/e* 82		*m/e* 111/*m/e* 110	
	Found	Calcd[a)]	Found	Calcd[a)]
N*P-0	8.8%	5.9%	8.3%	7.0%
N*P-5	14.1	10.8	16.1	11.9
N*P-30	51.6	48.8	52.4	49.9

a) Calculated on the assumption that the ratios of ^{15}N and ^{14}N in the nitriles are nearly equal to the corresponding N*P.

ed from the cyclohexanone-N*P complexes according to the procedure described above (Eq. 2). The IR and mass spectra of these products were in fair agreement with those of the products which had been derived from the 6-(hydroxyimino)valeric-^{15}N acid (Eq. 4).

These facts indicate that the nitrogen atom in the functional group, *i.e.*, hydroxyimino or cyano group, is definitely introduced from the nitrosyl ligand of NP through the nitrosolysis of cyclohexanone under either the alkaline or the acidic condition.

Discussion on the Nitrosolysis of Cycloalkanones by Use of NP. There were a number of compounds which form colored complexes with NP. Ketones and aldehydes containing active methylene group showed a red, orange or violet color in an alkaline medium. These colors turned to bluish when the solution was made acidic.[6] For example, a deep coloration occurred when aqueous alkaline solution containing acetone or acetophenone was mixed with aqueous NP solution. The color gradually faded untill the final solution was yellow, producing pentacyanoaquoferrate(II) ion and α-hydroxyimino derivatives of the corresponding ketones, as shown in Eq. 6.[7-9] The colored complex should be formed by an electrophilic attack of the nitrosyl ligand to the active methylene. Therefore, NP acted like a nitrosation reagent, such as alkyl nitrites, in the reaction.

$$CH_3CO\text{-}Y \xrightarrow{NP,\ OH^-} \text{colored complex} \longrightarrow [Fe(CN)_5H_2O]^{4-} + HON{=}CHCO\text{-}Y \quad (6)$$
$$(Y = CH_3\text{-},\ C_6H_5\text{-})$$

For example, when an aqueous solution of the colored acetophenone-NP complex was made acidic, very soon a flocculent precipitate of α-(hydroxyimino)-acetophenone separated out, but no nitrosolysis products were formed under this condition. However, cycloalkanone-NP complexes reacted in a similar manner to give ω-cyanoalkanoic acids under the acidic conditions, in general. The ω-cyanoalkanoic acid could result from fission of a carbon-carbon bond of the corresponding 2-(hydroxyimino)cycloalkanone present as a ligand of the colored cycloalkanone-NP complex, a prusso complex, as shown in Fig. 4.

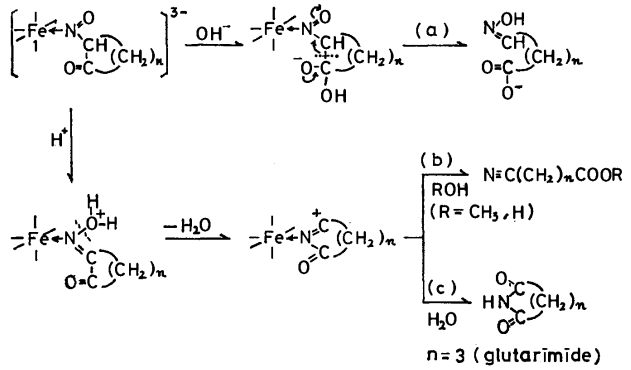

Fig. 4. A possible nitrosolysis reaction route of cycloalkanones using NP.

These facts indicate that the 2-(hydroxyimino)-cycloalkanone present as the ligand of the prusso complex should be in a labile state. The lability would be caused by a ring tension or an electron deficiency of the nitrogen atom under the influence of the electron-withdrawing effect of the central metal ion. In this way the carbon-carbon bond cleavage of the ligand occurred by hydrolysis even under the alkaline condition and gave ω-(hydroxyimino)alkanoic acids in a good yield (see Fig. 4a). Under the acidic condition another solvolytic carbon-carbon bond cleavage of the ligand occurred by Beckmann fission, a Beckmann rearrangement of an abnormal type[10] in the coordination sphere, and gave ω-cyanoalkanoic acids and their esters (see Fig. 4b). The Beckmann rearrangement of the normal type also occurred in a special case by use of cyclopentanone-NP complex. The ligand of this complex, 2-(hydroxyimino)cyclopentanone, was rearranged by acid into the more stable six-membered cyclic imide, *i.e.*, glutarimide (see Fig. 4c).

Experimental

All melting points were uncorrected. The IR spectra were obtained on a Hitatchi EPI S-2 infracord. The NMR spectra were obtained on a Nippon Denshi JNM-PS-100. The mass spectra were obtained on a Hitatchi RMU-6E spectrometer.

Reagent grade sodium pentacyanonitrosylferrate(II) hydrate (NP) and cycloalkanones were used without purification, while cyclohexanone was purified just before use by distillation under reduced pressure. Sodium nitrites-^{15}N (^{15}N contents: 5% and 30%) were obtained from The British Oxygen Co.,

Preparation of Cycloalkanone-NP Complexes. Cycloalkanone (0.05 mol) and sodium hydroxide(0.10 mol) were dissolved in 100 ml methanol. After having been cooled in an ice bath, the solution was poured into a solution of NP (0.05 mol) in 300 ml methanol and then the mixture was stirred for one hour at 0°C. The red-violet or red-brown colored complex was produced during the reaction. After the reaction had been completed, the solvent was removed under vacuum at room temperature to obtain a wet residue: crude cycloalkanone-NP complex.

The Alkaline Hydrolysis of the Cycloalkanone-NP Complex. The alkaline hydrolysis (Eq. 1) was performed by means of the following procedure. After the crude complex had been treated with 10% aqueous sodium hydroxide solution for one hour under reflux, the hydrolysate was filtered. After the filtrate had been extracted with ether to remove the unchanged ketone, the aqueous layer made acidic and was extracted with ether to separate the reaction product: ω-(hydroxyimino)-alkanoic acid was precipitated as colorless needles upon recrystallization from methyl acetate.

The Acid Hydrolysis of the Cycloalkanone-NP Complex. The acid hydrolysis (Eq. 2) was performed by means of the following procedure. After having been made acidic to pH 3 with an appropriate acid, such as phosphoric acid or others, the aqueous solution of the crude complex stood for 24 h at room temperature, and was then extracted with ether. The reaction products and the unchanged ketone were separated from the ethereal extract by fractional distillation under reduced pressure. The products, ω-cyanoalkanoic acid and its methyl ester, were derived into the corresponding crystalline *p*-bromophenacyl ester and were identified.

The by-product, glutarimide, produced from cyclopentanone-NP complex was confirmed by direct comparison with an authentic sample prepared from glutaric anhydride.

Preparation of 2-(Hydroxyimino)cyclododecanone from the Complex. After the crude cyclododecanone-NP complex, which was

prepared by the method described above, had been dissolved in water, the solution(pH 12) was extracted with ether. 2-(Hydroxyimino)cyclododecanone was separated from the ethereal extract; yield 0.2 g (from 0.05 mol cyclododecanone), mp 71—72 °C. Found: C, 68.15; H, 10.39; N, 6.65%. The IR, NMR, and mass spectral data corresponded to the authentic sample prepared by the other method by use of nitrosyl chloride.[3] After having been made acid to pH 3.5 with 6 M hydrochloric acid, the residual aqueous layer was extracted with ether. 11-Cyanoundecanoic acid was separated from the extract; yield 0.4 g, mp 52—54 °C.

Isolation of the Cyclododecanone–NP Complex. Three grams of cyclododecanone was dissolved in a sodium methylate solution prepared from sodium(0.5 g) and anhydrous methanol (35 ml). To the solution 5.0 g of NP in 65 ml of anhydrous methanol was added slowly and stirred for one hour. After the reaction had been completed, the mixture was concentrated to 35 ml under reduced pressure and was poured into 200 ml of anhydrous ethanol to precipitate the complex. The precipitate was separated by means of centrifugation, washed, and dried under reduced pressure. The pure complex was a reddish violet powder; IR: 3400(broad, νOH), 2850 and 2920 (νCH), 2040(sharp, νC≡N, bonded to Fe), 1660(weak, νC=O), 1610 and 1560 cm^{-1}; NMR: δ 1.35, 2.2(q) and 7.24(t) ppm (DMSO-d_6).

Hydrolysis of the Cyclododecanone–NP Complex. The purified cyclododecanone–NP complex(7.2 g, 14 mmol) was dissolved in 100 ml of water, and the solution was extracted with ether. 2-(Hydroxyimino)cyclododecanone was separated from the ethereal extract; yield 1.7 g(8 mmol). After having been made acid to pH 3.0 with 3M sulfuric acid, the residual aqueous layer was extracted with ether. 11-Cyanoundecanoic acid was separated from the extract; yield 1.0 g(4 mmol).

*Preparation of ^{15}N Labeled NP (N*P).* The general method of preparation of the N*P is as follows. Sodium nitrite containing an appropriate amount of ^{15}N was dissolved in an aqueous solution of sodium hexacyanoferrate(II). After an aqueous solution of barium chloride had been added to the solution, carbon dioxide was bubbed into the solution with stirring at 100 °C, and then the solution was filtered to remove barium carbonate. The appropriate amount of ethanol was added to the filtrate to precipitate sodium chloride. The red crystalline N*P was separated from the supernatant liquor by concentration.

The present work was partially supported by a Grant-in-Aid for Developmental Scientific Research from the Ministry of Education.

Odor and Volatile Compounds in Liquid Swine Manure. I. Carboxylic Acids and Phenols

Akio YASUHARA and Kei-ichiro FUWA

Division of Chemistry and Physics, National Institute for Environmental Studies, Yatabe, Tsukuba-gun, Ibaraki 300-21

(Received October 16, 1976)

Seventeen carboxylic acids and four phenol compounds were isolated from liquid swine manure by steam distillation and identified by gas chromatography-mass spectrometry. The major components are butyric, isovaleric, benzoic, phenylacetic acids, and *p*-cresol. The only carboxylic acid fraction has the same odor as liquid acidic swine manure. The odor of the phenols is rather pleasant and sweetish. The butyric, isovaleric, and phenylacetic acids have a very strong malodor, while the odor of phenylacetic acid is identical with that of liquid acidic swine manure.

The large quantities of manure produced by modern confinement swine buildings evolve a very strong and offensive odor by means of anaerobical microbial decomposition. The odor which is discharged into the atmosphere of the adjacent residential area is nuisance and polluting.

Little is known about the chemical nature of the odor of swine manure. Information on the nature of the odor would, however, be valuable for odor control and deodorization in confinement swine buildings.

The identification of some components in swine manure has been carried out by several research workers. Amines,[1] alcohols,[2] aldehydes,[2] acids,[2] ketones,[3] and other substances[4] which contain hydrogen sulfide, methane, *etc.* have been detected in the atmosphere of confinement swine buildings. However, in those studies only highly volatile components were caught because of the use of the head-space method. There is a possibility, therefore, that swine manure contains some other odorous components, because odor does not always result from major components. Another method is, then, required in order to isolate minor components possessing malodors.[5] Steam distillation is another useful method for isolating odorous compounds.[6,7]

An intolerable odor results from the acidification of swine manure. The acidic volatile compounds reported in poultry liquid manure[8] are acetic, propionic, isobutyric, butyric, isovaleric, and valeric acids, while in swine manure formic, acetic, propionic, and butyric acids have been reported.[2] However, none of these compounds explains the odor of acidic swine manure.

This paper will deal with the separation of odorous components by steam distillation and with the results of the application of gas chromatography-mass spectrometric and organoleptic techniques to the determination of the important compounds responsible for the malodor of liquid swine manure.

Experimental

Gas Chromatography. A Model Shimadzu GC-5A gas chromatograph was equipped with dual-flame ionization detectors, dual-thermoconductivity detectors, a matrix temperature programmer, a dual-pen recorder, and a Takeda Riken -*tr*-2215A degital integrator. The flame detectors were operated using a hydrogen-flow rate of 50 ml/min and an air-flow rate of 0.5 l/min. Thermoconductivity detectors were used for the organoleptic tests.

The gas-chromatographic conditions were as follows on the carboxylic acid fraction: injector and detector temperatures, 250 °C; column temperatures, 50 °C for 3 min, followed by an increase to 180 °C at a rate of 8 °C/min, and then held at 180 °C until the completion of the analysis; carrier-gas (nitrogen) flow rate, 20 ml/min at 6 kg/cm^2.

On the phenol fraction the gas-chromatographic conditions were as follows: injector and detector temperatures, 200 °C; column temperature, 160 °C; carrier-gas (nitrogen) flow rate, 20 ml/min at 6 kg/cm^2.

A 3m×3mm i.d. glass column packed with 2% DEGS+0.5% H_3PO_4 on 60- to 80-mesh, acid-washed, DMCS-treated Chromosorb-W was used for the analysis of the carboxylic acids and phenols.

Mass Spectrometry. A Model JEOL JMS-D 100 mass spectrometer was connected with a JEOL JGC-20K gas chromatograph. The gas-chromatographic conditions were the same as above. The mass-spectrometric conditions were as follows on both carboxylic acid and phenol fractions: ion-source temperature, 140°C; ionizing current, 3×10^{-4} A; ionizing voltage, 75 eV; accelerating voltage, 3 kV; scan speed, 5 sec from *m/e* 0 to 800.

Sampling Procedure and Fractionation. The experiments reported here were performed using accumulating liquid swine manure collected from pits under confinement swine buildings. Liquid manure (36 l) was acidified with concd hydrochloric acid in order to move its pH below 1.0 and was then shaken two times with dichloromethane (4.8 l). The resultive slurry was separated and steam-distilled. The distillate was saturated with sodium chloride and extracted two times with dichloromethane. The extract was evaporated by means of a Kvrderna-Danish concentrator under atmospheric pressure. The concentrated residue was dissolved in ether (50 ml) and fractionated as will be described below.

(a) Phenol Fraction. The ether solution was washed several times with a potassium hydroxide aquous solution. The organic layer was used for the neutral fraction. Sodium hydrogencarbonate was added to the aquous layer until saturation, and then carbon dioxide gas was passed into it. Then, the separate phenol compounds were extracted with ether (50 ml). The extract was washed, dried, and concentrated.

(b) Carboxylic Acid Fraction. After the extraction of the phenol compounds, the aquous layer was acidified with concd hydrochloric acid until it showed a pH below 1.0; then it was extracted with ether (50 ml). After washing and drying, the extract was evaporated to a small volume and then injected into the gas chromatgraph and the gas chromatograph-mass spectrometer without any protection of the carboxyl group.

(c) Neutral Fraction. The organic layer obtained in

Operation *(a)* was washed, dried, and concentrated.

Organoleptic Test for Odor. This test was carried out by means of smelling the odor of compounds progressively eluted from the outlet of the gas chromatograph.

Results and Discussion

The steam distillate has the same odor as acidic swine manure. In this case, steam distillation has been proved to be a useful method of obtaining odorous compounds.

Separation and Identification of Volatile Carboxylic Acids. From several microlitres of the prepared sample solution injected into the gas chromatograph, seventeen peaks were obtained on the DEGS+H_3PO_4 column. Figure 1 shows the gas chromatogram, while the table shows the results of the identification, which was performed by a comparison of the measured mass spectra with the standard mass spectral data and by a comparison of the retention times with those of authentic samples.

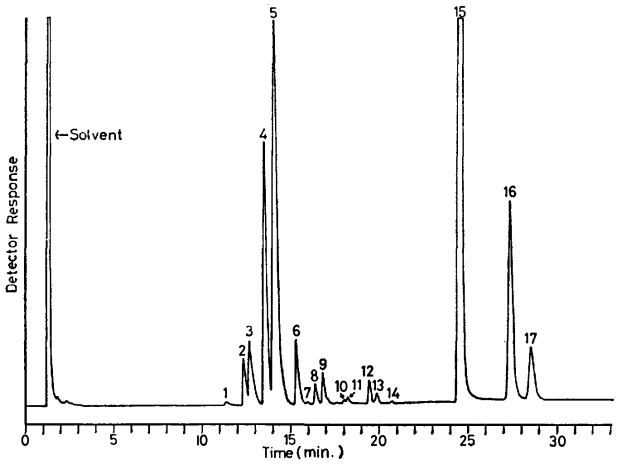

Fig. 1. Gas chromatogram of volatile carboxylic acids in swine manure.

TABLE 1. RESULTS OF IDENTIFICATION OF VOLATILE CARBOXYLIC ACIDS

Peak number	Name of compound	Content ratio (%)
1	Acetic acid	0.2
2	Propionic acid	1.6
3	Isobutyric acid	2.8
4	Butyric acid	10.1
5	Isovaleric acid	20.6
6	Valeric acid	2.2
7	2-Methylbutyric acid	0.1
8	2,2-Dimethylpropionic acid	0.6
9	Hexanoic acid	1.1
10	4-Methylhexanoic acid	0.1
11	Heptanoic acid	0.2
12	Octanoic acid	0.7
13	$C_8H_{16}O_2$	0.4
14	Nonanoic acid	0.1
15	Benzoic acid	45.8
16	Phenylacetic acid	9.9
17	3-Phenylpropionic acid	3.1

The main components are butyric, isovaleric, benzoic, and phenylacetic acids. The compound with the peak number of 13 was not identified, but it was confirmed to have the molecular formula of $C_8H_{16}O_2$, according to its mass spectrum, which is as follows: *m/e* (rel. intensity), 144 (2), 128 (35), 110 (15), 101 (17), 99 (29), 83 (44), 73 (100), 68 (32), 55 (54), 43 (29), 41 (34).

The organoleptic test shows that butyric, isovaleric, and phenylacetic acids have very strong malodors. The odor of phenylacetic acid is the most offensive among them; it is the same as that of acidic swine manure. Although butyric and isovaleric acids are recently considered as malodorous air pollutants, phenylacetic acid must be taken into consideration. Phenylacetic acid plays a very significant role in the malodor of liquid swine manure, although neutral or alkaline swine manure has a different order.

The origin of the carboxylic acids is considered to be proteinaceous material.[2)]

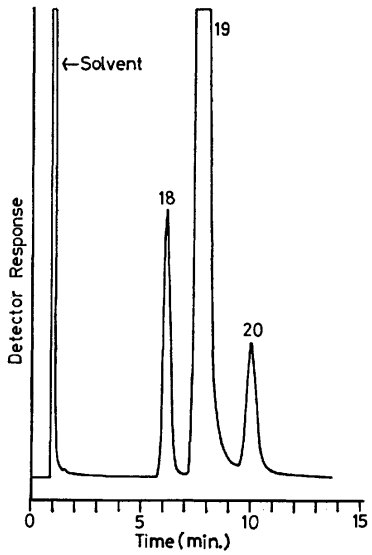

Fig. 2. Gas chromatogram of volatile phenols in phenol fraction of swine manure. (18): Phenol, (19): *m*- and *p*-cresols, (20): *p*-ethylphenol.

Separation and Identification of Volatile Phenols. Three peaks were obtained from the phenol fraction by gas chromatography using a DEGS+H_3PO_4 column. Identification was carried out by gas chromatograph-mass spectrometry. Figure 2 shows the gas chromatogram. It was confirmed by the use of a Golay R column (45 m×0.25 mm i.d.) that *p*-cresol was the major component, *m*-cresol was the minor component, and *o*-cresol was not present. Furthermore, another phenol compound was observed in the neutral fraction. It is 2,6-di-*t*-butyl-*p*-cresol, which is a well-known synthetic antioxidant. 2,6-Di-*t*-butyl-*p*-cresol is absent in the phenol fraction because of an obstruction of the dissociation of the hydroxyl group by the steric hindrance of the two tertiary butyl groups and the hydroxyl group.

Most of the phenols come from the disinfectant used in the confined swine buildings.

Organoleptically, phenols have a rather pleasant and sweetish odor. Although they evidently do not contribute

any offensive notes to the odor of swine manure, they most certainly contribute to the total odor.

Thermochemistry of Bis(tropolonato)copper(II)

Manuel A. V. RIBEIRO DA SILVA and Roger J. IRVING*

Chemistry Department, Faculty of Sciences, University of Oporto, Portugal

**Thermochemistry Laboratory, Chemistry Department, University of Surrey, Guildford GU2 5XH, England*

(Received May 10, 1976)

The standard enthalpy of formation of crystalline bis(tropolonato)copper(II) has been determined at 298.15 K by solution calorimetry: $\Delta H_f^\circ[Cu(trop)_2]\ (c) = -102.47 \pm 0.42$ kcal mol^{-1}. Enthalpy changes at 298.15 K for the following hypothetical gaseous reactions have been subsequently derived:

$$Cu(g) + 2\,trop^{\cdot}(g) = [Cu(trop)_2](c) \qquad \Delta H = -150.4 \pm 14.1 \text{ kcal mol}^{-1}$$

$$Cu^{2+}(g) + 2\,trop^{-}(g) = [Cu(trop)_2](c) \qquad \Delta H = -731.4 \pm 11.4 \text{ kcal mol}^{-1}$$

The corresponding homolytic (E) and heterolytic(E') copper(II)-oxygen bond energy parameters were calculated as

$$E_{Cu-O} = 38 \pm 4 \text{ kcal mol}^{-1} \text{ and } E'_{Cu-O} = 183 \pm 3 \text{ kcal mol}^{-1}$$

respectively.

The emphasis on the study of metal-complex compounds has been largely on questions of stereochemistry and reactivity, but much work has also been done on the stability of particular species in aqueous solutions. In marked contrast, however, direct information on the strength of metal-ligand bonds is scarce. The determination of the heat of formation of a coordination compound is not particulary difficult, but, using this result to calculate the metal-ligand bond strength, often needs auxiliary data which are inaccurate, and difficult, or even impossidle to determine at the present stage of the development of chemical knowledge.

In this paper we report the heat of formation of the copper(II) complex of tropolone and consider the problem of deriving the copper(II)-oxygen bond energies from it. Tropolone** forms complexes with metal ions analogous to β-diketones.[1] Many of the metal-tropolonates are crystalline, non-ionic solids, and volatile enough to sublime under reduced pressure. Stability constant studies[2] and the general behaviour of the tropolonates suggest that they are more stable than the corresponding acetylacetonates. Both complexes decompose into the metal cation and the protonated ligand in the presence of acid. We make use of this reaction to determine the enthalpy of formation of the crystalline complex bis-(tropolonato) copper(II) and the corresponding Cu–O bond energies.

Experimental

The Solution Calorimeter. The LKB 8700 reaction and solution precision calorimeter was used for all the reactions. This particular calorimeter has an 18 carat gold stirrer plated with pure gold, which was not attacked by acids, and a calibrating resistance (R_h) of 50.183 Ω measured at the leads midway between the calorimeter and its jacket; thermistor resistance at 25 °C is 2000 Ω.

The molar enthalpy of reaction was calculated from the relation $\Delta H = \varepsilon \Delta R_r / n R_{mr}$, where $\Delta R_r = R_i - R_f$, $R_{mr} = (R_i + R_f)/2$, n=number of moles of reactant, and R_i and R_f are the initial and final thermistor resistances in ohms as determined by the Dickinson treatment.[3] The energy constant, ε, of the calorimetric system is given by $\varepsilon = Q_c R_{mc} / \Delta R_c$, where Q_c is an accurately defined quantity of heat supplied electrically *via* the built-in heater, $Q_c = R_h I^2 t / 4.1840$ cal (R_h is the resistance of the calibrating heater in ohms, I the calibration current in amps, and t the heating time in seconds), and R_{mc} and ΔR_c have the same significance in a calibration experiment as R_{mr} and ΔR_r have in a reaction. The ratio $\Delta R_r / R_{mr}$ is directly proportional to the temperature change.

Thermochemical functions are expressed in terms of "the thermochemical calorie" (1 thermochemical calorie=4.184 J) and refer to the isothermal process at 298.15 K and the true mass, calculated with the atomic weights of 1966 based on the isotope ^{12}C. The uncertainty interval is twice the standard deviation of the mean. A check on the accuracy of the colorimeter was carried out by determining the heat of dissolution of *N,N',N''*-tris(hydroxymethyl)methane triamine (tham) in dilute hydrochloric acid. The result, -7.118 ± 0.006 kcal mol^{-1} is in agreement with previous results[4] (-7.120 ± 0.007 kcal mol^{-1}).

Materials. *Tropolone*, Htrop, was prepared by a modification of the method of Stevens *et al.*,[5] recrystallised from light petroleum (40—60 °C), sublimed, and recrystallised again from light petroleum, mp=51—52 °C (lit, 50—51 °C).

Found: C, 68.7; H, 4.95%. Calcd for $C_7H_6O_2$: C, 68.8; H, 4.95%.

Bis(tropolonato)copper(II). [Cu(trop)$_2$]—A solution of "AnalaR" copper(II) sulfate pentahydrate (2.0 g) in water (30 cm^3) was slowly added to a solution of tropolone (2.5 g) in ethanol (100 cm^3). The complex was filtered off, washed with cold ethanol, dried and recrystallised from benzene. Mp=298 °C (dec) (lit, 300 °C[6]).

Found: C, 54.93; H, 3.30; Cu, 20.78%. Calcd for $C_{14}H_{10}O_4Cu$: C, 54.99; H, 3.30; Cu, 20.78%.

Copper(II) Sulfate Pentahydrate: "AnalaR" grade copper(II) sulfate pentahydrate was powdered and dried in a desiccator, over sillica gel, for 48 h. Its composition was determined by means of copper analyses and was found to be $CuSO_4 \cdot 5H_2O$.

Sulfuric Acid. Concentrated "AnalaR" grade sulfuric acid was diluted with distilled water, and its concentration was determined by acid-base titration against $Na_2B_4O_7 \cdot 10H_2O$, after convenient dilution, and found to be 2.1567 ± 0.0003 M〈〉$H_2SO_4 \cdot 23.69\,H_2O$.[7]

Calorimetric Solvent. A molar solution of "AnalaR" grade sulfuric acid was made up, by using a "B. D. H." concentrated volumetric solution. The concentration of the prepared solution was checked by acid-base titration against $Na_2B_4O_7 \cdot 10H_2O$. A series of six determinations gave the

** Tropolone(Htrop) = 2-hydroxy-2,4,6-cycloheptatrien-1-one.

result 1.0000±0.0005 M, which corresponds to the composition $H_2SO_4 \cdot 53.5391 H_2O$.[7]

Analyses. All carbon and hydrogen analyses were carried out in the Microanalytical Service, University of Surrey; copper was analysed by a complexometric titration with ethylenediaminetetraacetic acid (H_4edta) and Pyrocatechol Violet as indicator.[8] Since bis(tropolonato)copper(II) is insoluble in water, it was necessary to decompose the complex by treating samples with successive small amounts of concentrated nitric acid, followed by gentle evaporation to dryness. The residures were dissolved in the minimum possible amount of 1 M sulfuric acid, transferred to volumetric flasks and diluted with distilled water.

Calculation. The standard enthalpy of formation of the bis(tropolonato)copper(II) complex can be determined from known standard enthalpies of formation and the enthalpy change for the reaction:

$$2\text{Htrop(c)} + CuSO_4 \cdot 5H_2O \xrightarrow{\Delta H_R} H_2SO_4 \cdot 5H_2O\text{(aq)} + [Cu(trop)_2]\text{(c)} \quad (1)$$

The difference between the enthalpies of solution of the products and reactants in the same stoichiometric ratio gives the required enthalpy of formation, provided equilibrium is reached from either side within the period of the experiment.

To 100.0 cm^3 of calorimetric solvent, ampoules of bis(tropolonato)copper(II) were added consecutively, and ΔH_2 was measured. To a second portion of the same solvent (100.0 cm^3) were added consecutively ampoules of tropolone and copper(II) sulfate pentahydrate, and ΔH_4 and ΔH_5 were measured. The thermochemical cycle and the general procedure used are given in the following scheme. The values of ΔH_1 and ΔH_3 were calculated from literature data,[9] and they were found to be $\Delta H_1 = +0.001 \pm 0.001$ kcal mol^{-1} and $\Delta H_3 = 0.000 \pm 0.001$ kcal mol^{-1}. In order to maintain the necessary stoichiometry of the reaction, the appropriate amounts of sulfuric acid and water were added to the calorimetric solvents by means of a calibrated microsyringe.

$$CuSO_4 \cdot 5.00\,H_2O\text{(c)} + 2\text{Htrop(c)} + 18.69\,H_2O(l) \xrightarrow{\Delta H_R}$$

Solvent + $H_2O \xrightarrow{\Delta H_3}$ Solution A_1

Solution A_1 + Htrop $\xrightarrow{\Delta H_4}$ Solution A_2

Solution A_2 + $CuSO_4 \cdot 5.00\,H_2O \xrightarrow{\Delta H_5}$ Solution A_3

$$\Delta H_R = 18.69\Delta H_3 + 2\Delta H_4 + \Delta H_5 - \Delta H_1 - \Delta H_2 + \Delta H_6$$

Scheme.

The quantities of reactants in a particular series of experiments were determined by the amount of bis(tropolonato)copper(II) in the particular ampoule; strict control of stoicheiometry was maintained throughout each series.

When this procedure is used, the value calculated for ΔH_R refers to the reaction indicated in the first line of the scheme, provided that solutions A_3 and B_2 are identical, and that the value of ΔH_6 is zero. As a check on the validity of this assumption, ampoules of solution B_2 were broken into A_3 in the calorimeter; no detectable heat change occured.

Results and Discussion

The experimental data are given in Table 1, leading to the value $\Delta H_R = +6.88 \pm 0.06$ kcal mol^{-1}.

The following values were taken from the literature: $\Delta H_f^\circ[CuSO_4 \cdot 5.00\ H_2O\ (c)] = -544.85$ kcal mol^{-1},[10] $\Delta H_f^\circ[\text{Htrop(c)}] = -57.18 \pm 0.21$ kcal mol^{-1} [11,12] and $\Delta H_f^\circ[H_2SO_4 \cdot 5.00\ H_2O\ (aq)] = -549.863 \pm 0.001$ kcal mol^{-1}.[9] The standard enthalpy of formation of crystalline bis(tropolonato)copper(II), at 25 °C, was calculated from relationship (1) to be $\Delta H_f^\circ[Cu(trop)_2]\text{(c)} = -102.47 \pm 0.42$ kcal mol^{-1}.

Enthalpies of sublimation of few coordination compounds have been accurately measured, but from con-

4.9938	1.0237	2593.1	+5.316

Mean: $\Delta H_5 = +5.30 \pm 0.03$ kcal mol^{-1}

sideration of the existing data it is possible to make a reasonable estimate for the bis(tropolonato)copper(II) complex;[13] the uncertainty must be of the order of 10 kcal mol^{-1}, but this only produces an uncertainty of *ca.* 2.5 kcal in the bond energy. Accordingy, if we take $\Delta H^{\circ}_{sub}[Cu(trop)_2](c) = +35.0 \pm 10.0$ kcal mol^{-1}, the standard heat of formation of the geseous complex is $\Delta H^{\circ}_f[Cu(trop)_2](g) = -67.5 \pm 10.0$ kcal mol^{-1}.

The metal-oxygen bond strengh can be related to the energy needed to break the molecule into metal and ligands, and all referred to the gaseous state (Eq. 2), in order to remove the condensed state effects

$$[Cu(trop)_2](g) \xrightarrow{\Delta H_f(r)} Cu(g) + 2\,trop^{\cdot}(g) \qquad (2)$$

Since the oxygens in β-diketonates are known to be equivalent,[14] which is supported by the crystal structure of this particular complex,[15] the copper(II)-oxygen homolytic bond strengh E(Cu-O), is $\Delta H^{\circ}_f(r)/4$.

Calculating the heat of formation of the tropolone radical itself presupposes a knowledge of the dissociation energy of the tropolone, that is, the heat of reaction of process (3)

$$Htrop(g) \longrightarrow H^{\cdot}(g) + trop^{\cdot}(g) \qquad (3)$$

For acetylacetone (2,4-pentanedione),[16] trifluoroacetylacetone (1,1,1-trifluoro-2,4-pentanedione)[17] and dipivaloylmethane (2,2,6,6-tetramethyl-2,4-pentanedione)[17] we assumed a value of 100 ± 5 kcal mol^{-1}, but, because of the resonating tropolone ring, there is reason to suggest that a value closer to phenol (85 kcal mol^{-1} [18]) is more appropriate,[19] Accordingly we take 90 ± 5 kcal mol^{-1} [20] for the dissociation eneregy of Htrop. In this way, from the literature values of ΔH°_f[H trop] (c) $= -57.18 \pm 0.21$ kcal mol^{-1} [11,12] and ΔH°_{sub}[H trop](c) $= +20.1 \pm 0.1$ kcal mol^{-1},[21] we calculate ΔH°_f[H trop](g) $= -37.08 \pm 0.23$ kcal mol^{-1} and, using the value ΔH°_f H$^{\cdot}$(g) $= 52.095$ kcal mol^{-1},[9] we calculate $\Delta H^{\circ}_f[trop^{\cdot}](g) = 1 \pm 5$ kcal mol^{-1},[20]

As ΔH°_f[Cu(g)] $= 80.86$ kcal mol^{-1},[10] the value of $\Delta H_f(r) = 150.4 \pm 14.1$ kcal mol^{-1} and, hence, the copper(II)-oxygen homolytic bond energy E(Cu-O) $= 38 \pm 4$ kcal mol^{-1} was calculated.

It is sometimes convenient to consider the bond energy in terms of the ions, as defined by equation(4)

$$[Cu(trop)_2](g) \xrightarrow{\Delta H_f(i)} Cu^{2+}(g) + 2trop^{-}(g) \qquad (4)$$

Estimating the electron affinity of the ligands to be approximately equal to that of the oxygen atom, $E_L = 33.8$ kcal mol^{-1},[22] the enthalpy of formation of the gaseous tropolone ion was calculated to be -33 ± 5 kcal mol^{-1} [20] and using the literature value of $\Delta H^{\circ}_f[Cu^{2+}](g) = 729.93$ kcal mol^{-1} [10] the value of ΔH_f(i) for the ionic gas reaction (4) was calculated to be $\Delta H_f(i) = 731.4 \pm 11.2$ kcal mol^{-1} and, thence, the so-called heterolytic copper(II)-oxygen bond energy E'(Cu-O) $= \Delta H_f(i)/4$ is calculated as E'(Cu-O) $= 183 \pm 3$ kcal mol^{-1}.

In the present work, careful and precise measurements of molar enthalpies of solution led to a new value of the standard enthalpy of formation of the crystalline complex of bis(tropolonato)copper(II), with an accuracy better than 0.4%.

In attempting a rigorous determination of bond energies of complexes of tropolone, estimations of some enthalpies of sublimation have had to be made and, in addition, it has also been necessary to estimate the dissociation energy of the enolic hydrogen from tropolone. The resulting bond energies, therefore, have a large uncertainty attached to them.

Table 2. (all values in kcal mol^{-1})

Complex	ΔH_f(r)	E(M-O)	ΔH_f(i)	E'(M-O)
$[Be(trop)_2]$[23]	263 ± 11	66 ± 3	833 ± 11	208 ± 3
$[Al(trop)_3]$[20]	368 ± 15	61 ± 3	1468 ± 15	250 ± 3
$[Al(4\text{-}Metrop)_3]$[20]	357 ± 15	60 ± 3	1487 ± 15	248 ± 3
$[Cu(trop)_2]$	150 ± 14	38 ± 4	731 ± 11	183 ± 3

However, as is summarized in Table 2, the beryllium-oxygen bond is stronger than the aluminium-oxygen bond as one would expect from a simple electrostatic model. The copper(II) complex has been studied because it contains the metal in a planar environment of ligands. In spite of all the assumptions that were required to obtain the metal-oxygen bond parameters, it seems to provide a clear evidence that the copper(II) complex has considerably weaker bonds than the aluminium and beryllium complexes.

The value we obtained for the copper(II)-oxygen bond energy of the tropolonato complex (38 ± 4 kcal mol^{-1}) is very close to the value found by Jones and co-workers[24] for the copper complex of acetylacetone (2,4-pentanedione): 42 kcal mol^{-1}. One would expect to find a higher value for the tropolonato complex as a direct result of the interaction of the bulky seven membered ring of the ligand and the chelate rings. However, it must be pointed out that the value of Jones *et al.* has been derived from the measured heat of combustion of the metal complex. This method has two major disadvantages for coordination compounds with organic ligands: (a) a very large heat of combustion of the organic ligand, which tends to swamp the metal-ligand bond energy; (b) the difficulty of deciding the exact thermodynamic state of the combustion products at the reference temperature. Neither of these is encountered in solution calorimetry where the formation reaction $M + mL \rightarrow ML_m$ is directly involved.

As the conclusion of the above discussion we might think that a further investigation with other copper(II) complexes will be needed before more reliable information about this bond energy can be obtained.

We thank the Calouste Gulbenkian Foundation, Lisbon, for the award of a research scholarship (to M. A.V.R.S.) and the Chemistry Department of the Faculty of Sciences, Oporto University, and "Instituto de Alta Cultura," Portugal, for leave of absence (to M.A.V.R.S.).

Extractive Spectrophotometric Determination of Mercury with Thiobenzoylacetone; Analysis of Waste Water

M. V. R. Murti and S. M. Khopkar

Department of Chemistry, Indian Institute of Technology, Bombay 400076, India

(Received June 14, 1976)

Thiobenzoylacetone was used for the extraction and spectrophotometric determination of mercury(II). The complex quantitatively extracted at pH 4.0 with 10 ml of 0.001 M reagent in benzene. After removing the excess of the reagent with the buffer solution of pH 12.0, the complex was measured at 345 nm against reagent blank prepared similarly. The system adhered to Beer's law in the concentration range of 0.6 to 12.1 μg of mercury per ml. The molar extinction coefficient was 1.7×10^4 and the sensitivity was 0.011 μg/cm². The complex was stable for 48 h. The extraction was quantitative within 10 min of equilibbrium. It was possible to determine mercury in the presence of a large number of ions (1 : 1000). The method was found to be applicable to the analysis of waste water from chloro-alkali industries.

Many investigations have been made on the extractive photometric determination of mercury(II) with chelating ligands. 1-(2-Pyridylazo)-2-naphthol[1] was used for such purpose but the pH range of extraction was very narrow. The extraction involving dithizone[2] has been considered unsatisfactory because of its extreme sensitivity to variations in the laboratory conditions, while Bindschedler's Green[3] was used with some advantage but the dissolved chlorine in water showed a strong interference in such determinations. Brilliant Green[4] is not a good extractant as gold, and thallium interfered seriously. The extraction with Crystal Violet[5] was feasible within a narrow pH range of 1.3—1.6. In the Rhodamine-B[6] extraction, heavy metals showed strong interferences, and the colour has to be stabilised by the addition of potassium bromide.

Amongst β-diketones, extraction with acetylacetone and benzoylacetone[7] were not quantitative. The extractions with dibenzoylmethane[7] needed a long period of equilibration. Although thiothenoyltrifluoroacetone[8–10] was a good extractant, it was necessary to remove the excess of the reagent in order to improve sensitivity. With di(thiobenzoyl)methane[11] (II) as an extractant the absorbance was measured in the ultraviolet region. In this paper a simple, selective and sensitive method is described for solvent extraction and spectrophotometric determination of mercury(II) with thiobenzoylacetone. The method has been further extended to the determination of mercury from waste water.

Experimental

Apparatus and Reagent. A Spektromom 204 spectrophotometer with matched 10 mm quartz cuvettes, and a Cambridge pH meter with glass and calomel electrodes were used.

Thiobenzoylacetone (SBA) was synthesised from benzoylacetone (Fluka, A. G.) by the procedure described earlier.[12] About 0.001 M reagent was used in benzene. The reagent was preferably preserved in a refrigerator.

A stock solution of mercury was prepared by dissolving 1.356 g of mercury(II) chloride (B. D. H. AnalaR) in 1 litre of distilled water. The solution was standardised gravimetrically as thionalide.[13] It contained 3.872 mg of mercury per ml. The solutions of lower concentrations were prepared by volumetric dilution of the stock solution.

Buffer solution of pH 4.0 was prepared by dissolving 14.0 g of sodium acetate in 500 ml of distilled water and acidified with 0.2 M acetic acid.

Buffer solution of pH 12.0 was prepared by mixing 100 ml of 0.05 M Borax and 126.5 ml of a 0.1 M sodium hydroxide solution.

General Procedure. An aliquot of mercury(II) chloride solution containing about 48.4 μg of mercury was taken. Then 10 ml of buffer solution of pH 4.0 was added, and the total volume of the aqueous phase was made to 25 ml. The solution was then introduced into a separatory funnel, and shaken with 10 ml of 0.001 M SBA in benzene for 10 min. The layers were allowed to settle and separate. After separating out the aqueous phase, the organic phase was washed twice to remove excess of the free reagent with the buffer solution of pH 12.0. The organic phase was carefully withdrawn into a 10 ml volumetric flask. It was measured spectrophotometrically at 345 nm against a reagent blank prepared similarly. The amount of mercury was then calculated from the calibration curve.

Results and Discussion

Absorption Spectra. The absorption spectrum of the Hg(II)-SBA complex extracted at pH 4.0 against the reagent blank as a reference solution is shown

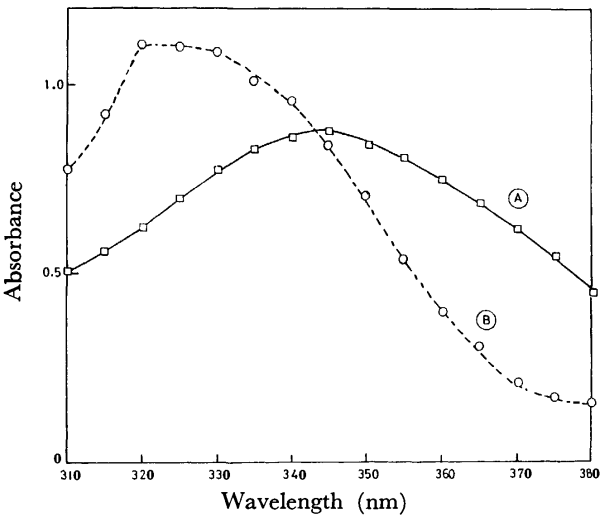

Fig. 1. Absorption of (A) mercury(II)-thiobenzoylacetone complex *vs.* reagent blank, and (B) reagent blank, and (B) reagent blank *vs.* benzene.
[Hg] = 4.84×10^{-5} M, SBA = 1.0×10^{-3} M, pH 4.0.

in Fig. 1. The spectrum of the reagent blank *vs.* benzene is also given. The difference in absorbance between the Hg(II)-SBA complex and the reagent blank appears to be maximum around 345 nm ; All absorbance measurements were therefore carried out at 345 nm. The molar extinction coefficient of the complex at 345 nm was 1.7×10^4 when the concentration of mercury was 48.4 μg/10 ml and the effective cell width was 10 mm. The sensitivity as per Sandell's definition was 0.011 μg/cm^2.

Extraction as the Function of pH. The exraction of mercury was studied as a function of pH(Fig. 2) from 1.0 to 11.0. Figure 2 shows that the extraction was quantitative between pH 0.2 to 9.0 ; the extraction started decreasing at pH 9.5 and at 11.0, it was 60.9%. Hence for all practical purposes pH 4.0 was employed for the purpose of extractions.

Adherence to Beer's Law. Different amounts of mercury(II) were taken and extracted at pH 4.0 and measured at various wavelengths, such as 335, 345 and 355 nm (Fig. 3). The Hg-SBA system conformed to Beer's law over the concentration range of 0.6 to 12.1 of mercury per ml at 345 nm only. Furthermore, at this wavelength there is a maximum slope for the absorbance-concentration plot. Hence all absorbance measurements were carried out at 345 nm.

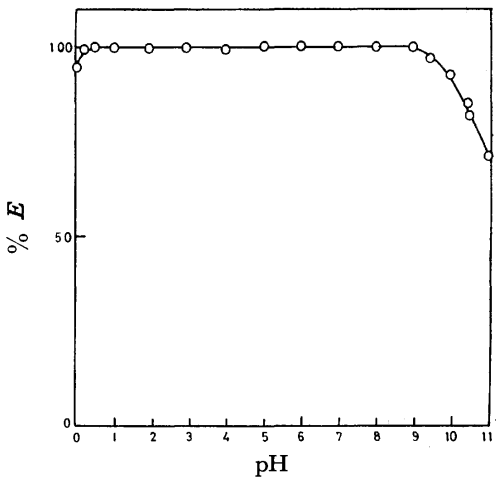

Fig. 2. Extraction of mercury as a function of pH.

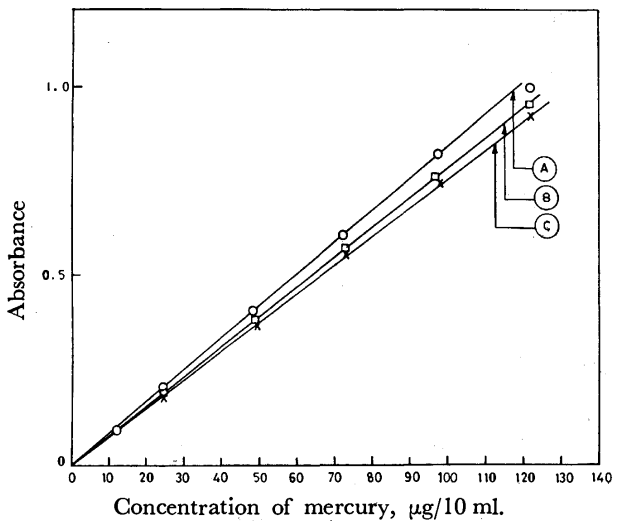

Fig. 3. Calibration curve at (A) 345 nm, (B) 335 nm, and (C) 355 nm.

Stability of the Colour of the Complex. As per the general procedure, the absorbance of the Hg(II) complex was measured at elapsed intervals of 0, 8, 16, 24, 48, 72, and 118 h. The absorbance of the complex was constant for 48 h. Hence the complex should be measured within 48 h of complexation.

Effect of Reagent Concentration. The extraction of mercury was carried out with varying concentration and varying volume of the reagent (Table 1). The result showed that a single extraction with 10 ml of 0.001 M reagent was adequate for quantitative extraction. There was insignificant enhancement in the extraction of mercury with greater concentration of reagent, and with dilute solutions the extraction was incomplete.

Table 1. Effect of reagent concentration
48.4 μg of Hg(II); 0.001 M SBA in benzene

SBA concentration $M\times10^{-4}$	SBA added, ml	Absorbance at 345 nm
2.0	10	0.165
4.0	10	0.280
5.0	10	0.380
6.0	10	0.410
8.0	10	0.410
10.0	10	0.410
	2.5[a)]	0.210
	5.0[a)]	0.380
	7.5[a)]	0.410
	15.0	0.290
15.0	10	0.410
20.0	10	0.415

a) Volume is made to 10 ml.

Effect of Salting-Out Agents. The chlorides of ammonium, lithium, sodium and calcium (1 to 3 M) were used as salting-out agents to study their effects on the extraction of mercury with 0.001 M SBA at pH 4.0 and 340 nm. The results showed that none of them had significant effects on extraction.

Period of Equilibration. The period of equilibration was varied from 2—30 min. It was observed that the extraction was quantitative after 7 min of equilibration. Hence for all purposes, 10 min equilibration period was employed.

Effect of Diverse Ions. The results in Table 2 show the effect of various ions the process of extraction. The tolerance limit was set at the amount of foreign ions required to cause a ±2% error in the mercury recovery. Alkali and alkaline earth metals, chloride, nitrite, nitrate, sulphate, acetate, perrhenate are tolerated in the ratio of 1 to 1000, whereas ions such as thallium(I), cadmium, antimony(V), bismuth(III), osmium(VI), platinum(IV), aluminium, thorium, cerium(IV), manganese(II), beryllium, sulphte, phosphate, fluoride and anions of organic dicarboxylic acids were tolerated in the ratio of 1 to 500. Other ions were tolerated in lesser ratios. Silver, lead, copper, pal-

Table 3. Determination of mercury from waste water with thiobenzoylacetone (SBA) and Bindschedler's Green (BG)[3]

Volume taken (in ml)	Absorbance		Amount found		Total amount of mercury present in 150 ml of waste water	
	SBA	BG	SBA	BG	SBA method in μg	BG method
2	0.065	0.240	8.24	8.24	1020.0	1031.0
4	0.135	0.470	16.30	16.40	1018.7	1025.0
6	0.205	0.700	24.30	24.50	1012.5	1020.0
10	0.340	—	40.4	—	1010.0	—

ladium and cyanide ions showed strong interference, but the interference of some of the ions was eliminated by selective extraction with 2-thenoyltrifluoroacetone[2] for copper and lead, and dimethylglyoxime[2] for palladium.

Analysis of Mercury in Waste Water. The method was applied on waste water containing ethyl mercury which was collected from chloro-alkali industry. About 150 ml of waste water was treated with 10 ml of concentrated sulfuric acid and 30 ml of 30% hydrogen peroxide. It was gently heated over a waterbath until the foaming ceased. The solution was allowed to cool and it was diluted to 250 ml.

A known volume of an aliquot of the solution was taken. Then 10 ml of buffer solution of pH 4.0 was added to it. The solution was extracted with 10 ml

of 0.001 M SBA in benzene. The absorbance of mercury–thiobenzoylacetone complex was measured spectrophotometrically at 345 nm. For the purpose of comparison and testing the reproducibility the mercury in waste water was also determined by the extraction with Bindschedler's Green.[3] The results obtained are summarised in Table 3. It was seen that the proposed method compares favourably with existing methods for the separation and determination of mercury.

From ten determinations with 48.4 μg of Hg, the absorbance was found to be 0.410±0.010. The total operation requires about 45 min. The standard deviation was ±1.54%.

(Received July 27, 1976)

A compound of the type $Ni(Bz\text{-}\beta\text{-}ala)_2\cdot 2H_2O$ (Bz-β-ala=benzoyl-β-alaninate anion) and its amine adducts of the type $Ni(Bz\text{-}\beta\text{-}ala)_2B_n\cdot xH_2O$ ($n=1$; B=piperazine (pipz), 1,10-phenanthroline (*o*-phen) and $x=2$; $n=1$, B=2,2′-bipyridine (2,2′-bpy) and 4,4′-bipyridine (4,4′-bpy) and $x=4$; $n=2$, B=*N*-methylpiperazine (CH_3-pipz), morpholine (morph), pyridine (py), 3-methylpyridine (3-pic) and 4-methylpyridine (4-pic) and $x=2$; $n=3$, B=en, and $x=0$) were prepared. Each complex was characterized by elemental analysis, solid spectroscopy and magnetic moment. All the complexes are six-coordinated and the presence of NiO_6 and NiN_6 chromophores for $Ni(Bz\text{-}\beta\text{-}ala)_2\cdot 2H_2O$ and $Ni(en)_3(Bz\text{-}\beta\text{-}ala)_2$ complexes respectively and of NiO_4N_2 chromophores for the amine adducts is suggested. In all the complexes the amino acid appears to act as a bidentate ligand toward the carboxyl group. A ligand field strength in the aromatic heterocyclic amine adducts was found greater than in the aliphatic heterocyclic amine adducts. The amine adducts complexes appear to dissociate in solution with a change of the donor site, without changing in the stereochemistry, around the nickel ion.

In the framework of a systematic investigation we have examined the interaction of small peptides, as *N*-acetyl-[1-3] and *N*-benzoylglycine[4,5] with some transition metal ions. A recent study deals with the interaction of the copper ion with the benzoyl-β-alanine and the effect of the amines on the coordination properties of the amino acid and on the geometry around the copper ion.[6]

This work treats the nickel complexes of the benzoyl-β-alanine and their amine adducts. The nickel(II) peptide complexes may be of great help in understanding the reactions and stereochemistries of the peptide complexes of other metals, and thus the coordination behavior of peptides in general. Further interest may be derived by the fact that nickel may also have a biological role in animals, as it is recently suggested.[7]

Experimental

Preparation of the Compounds. The $Ni(Bz\text{-}\beta\text{-}ala)_2\cdot 2H_2O$ complex was prepared by mixing a potassium benzoyl-β-alaninate (2×10^{-2} mmol) solution in methanol with a nickel(II) perchlorate hexahydrate (1×10^{-2} mmol) in ethanol at room temperature. After cooling at 5 °C for one hour and filtering the potassium perchlorate precipitated, the solution was slowly evaporated until an oil was obtained. The oil was dissolved in acetone, treated with diethyl ether and cooled at 5 °C. After some days a microcrystalline pale-green compound separated from the solution. This nickel(II) salt was used as starting materials for the adduct preparation.

$Ni(Bz\text{-}\beta\text{-}ala)_2B_2\cdot 2H_2O$ (B=py and morph). The compounds were obtained by dissolving the nickel salt (1 mmol) in 3—4 cm^3 of the amines, adding acetone (5 cm^3) and diethyl ether (5 cm^3) and cooling at 5 °C.

$Ni(Bz\text{-}\beta\text{-}ala)_2B_2\cdot 2H_2O$ (B=3-pic, 4-pic and CH_3-pipz). The salts were prepared by dissolving the nickel salt (1 mmol) in the amines (5 cm^3), adding diethyl ether until an incipient precipitation was obtained and by cooling at 5 °C.

$Ni(Bz\text{-}\beta\text{-}ala)_2B\cdot xH_2O$ (B=pipz and o-phen and x=2; B=4,4′-bpy and x=4). The complexes were prepared by treating an ethanolic solution (5 cm^3) of the nickel salt (1 mmol) with an ethanolic solution (5 cm^3) of the amines (1.5 mmol), adding diethyl ether and cooling at 5 °C.

$Ni(en)_3(Bz\text{-}\beta\text{-}ala)_2$. Complex was prepared by suspending the nickel salt in ethanol (5 cm^3), adding en (1 cm^3) and warming the solution at 50—60 °C until a clear solution was obtained. By adding diethyl ether and cooling at 5 °C a crystalline compound precipitated.

Physical Measurments. Infrared spectra were recorded with a Perkin-Elmer 521 spectrophotometer in KBr pellets (4000—250 cm^{-1}) and in Nujol mull (600—250 cm^{-1}). The electronic spectra of the compounds were recorded with a Beckman DK 1A spectrophotometeter. Solid samples were prepared by grinding the complexes on a filter paper as support. The room-temperature magnetic moments were measured with Gouy method by using $Ni(en)_3S_2O_3$ as calibrant and correcting for diamagnetism with the appropriate Pascal constants.

Analyses. Nitrogen, carbon and hydrogen were analyzed by Mr. Giuseppe Pistoni using a Perkin-Elmer 240 Elemental Analyser.

Results and Discussion

The prepared compounds and their colors, analyses and magnetic moments are reported in Table 1. All the complexes are stable in air and soluble in chloroform or methanol. From these solvents the compounds cannot be recrystallized, as the ligand precipitated by evaporation of the solutions.

Electronic and Magnetic Properties of the Complexes in the Solid State. The coordination geometry of the complexes reported in this paper is studied and discussed in the light of their electronic and magnetic properties.

The magnetic moments (Table 1) of all the complexes, which do not show significant change, passing from the (benzoyl-β-alaninato) nickel(II) dihydrate to its adducts with bases, indicate a high spin configuration, corresponding to a possible cubic or tetragonal symmetry.[8]

The electronic spectra of all the nickel complexes (Table 2) are typical of hexacoordinated nickel(II). The three absorption peaks in each spectrum indicate a rather symmetric octahedral field.[9] The low energy band is broad, but all the others are quite symmetrical.

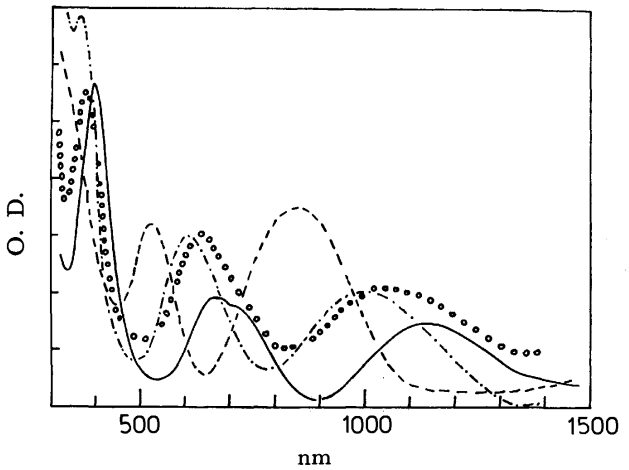

Fig. 1. Electronic spectra of the solid $Ni(Bz\text{-}\beta\text{-}ala)_2\cdot 2H_2O$ (——); $Ni(Bz\text{-}\beta\text{-}ala)_2(morph)_2\cdot 2H_2O$ (∘∘∘∘); $Ni(Bz\text{-}\beta\text{-}ala)_2(py)_2\cdot 2H_2O$ (-·-·-) and $Ni(en)_3(Bz\text{-}\beta\text{-}ala)_2$ (- - -) complexes.

The band maxima of the absorption spectra in Table 2 are listed in order of increasing energy. The energy represents the eletronic transition from the $^3A_{2g}$ ground state to the successively higher excited states, $^3T_{2g}(\nu_1)$, $^1E_g(\nu_2)$, $^3T_{1g}(F)(\nu_3)$, and $^3T_{1g}(P)(\nu_4)$.

The dihydrate bis(benzoyl-β-alaninato)nickel(II) complex shows an electronic spectrum similar to that of the hexaaqua nickel(II) cation[10,11] indicating no difference in ligand field strength between the oxygens of the water and of the benzoyl-β-alanine.

On the other hand the tris(ethylenediamine)nickel-(II) dibenzoyl-β-alaninato complex shows the typical spectrum of the tris(ethylenediamine)nickel(II) cation[11,12] suggesting the presence of the amino acids in the ionic form.

When the effect of additional binding of amine ligands on the electronic spectrum of the bis(benzoyl-β-alaninato)nickel(II) dihydrate (NiO_6 chromophore) was investigated, it was found that the d-d bands shift linearly to a shorter wavelength toward the position of the d-d bands found for the tris(ethylenediamine)-nickel(II) di-benzoyl-β-alaninato complex (NiN_6 chromophore). This may indicate that the adduct complexes have chromophore groups containing both the oxygen and nitrogen atoms, confirming the amine coordination. Spectra exemplifying this situation are reported in Fig. 1.

As the energy of the first band represents the average ligand field strength,[9] we found a greater ligand field effect in the aromatic heterocyclic amine adducts than in the aliphatic heterocyclic amine adducts.

Table 3 gives the wave numbers of the first band maximum of a series of nickel(II) and copper(II) complexes. The ratio between the observed wave numbers ν_{Cu}/ν_{Ni} gives a relative measure for the tetragonality of the copper complex and it was found that ν_{Cu}/ν_{Ni} varies from 1.1, in cases where the copper complexes approximate to cubic symmetry, to 1.7 in the cases of strong tetragonality.[13] The ν_{Cu}/ν_{Ni} values found for our adducts confirm that the copper adducts possess a strongly tetragonal distorted or square planar coordination as previously suggested.[6]

Infrared Spectra of the Complexes in the Solid State (Table 2). The assignment of the antisymmetric and symmetric carboxy stretching frequencies and of the CO ketonic and NH stretching frequencies of the benzoyl-β-alanine, which are considered very important in the assignment of the coordination sites on the amino acid, are made, as previously described,[6] by comparing the amino acid, its potassium salt and their deuterated analogues.

The peptide group is uncoordinated in all the complexes reported in this work, as in the case of the copper complexes,[6] as the shift to higher energies of the NH and CO ketonic stretching bands with respect to the free ligands suggests. These groups are however differently involved in some inter or intramolecular hydrogen bondings varying their position from 1640—1642 cm^{-1} $\nu(CO)_{ket}$ and 3400 cm^{-1} $\nu(NH)$ in the py, 3-pic and 4-pic adducts to 1618—1632 cm^{-1} $\nu(CO)_{ket}$ and 3400 cm^{-1} $\nu(NH)$ in the other complexes. This indicates lower hydrogen bonding interactions in the former complexes than in the latter.

IR-active $\nu(OCO)$ vibrations, associated with carboxylate ligands, RCO_2^-, give rise to bands in the region 1300—1700 cm^{-1}. Values of $\nu(OCO)_{asym}$ and $\nu(OCO)_{sym}$ for uni- or bi-dentate carboxylate ligands, RCO_2^-, are dependent upon the eletronic nature of the group R, the properties of the central metal ion, and

a) The solution electronic and infrared spectra have identical concentration: $(2.10—3.20)\times 10^{-2}$ M.

possibly the identity of the *trans*-ligands present.[14]

The values of $\nu(OCO)_{asym}$ and the $\Delta\nu$ separation ($\nu(OCO)_{asym}-\nu(OCO)_{sym}$) afford the most sensitive indication of the mode of carboxylate coordination. Bidentate carboxylate has values of $\nu(OCO)_{asym}$ and $\nu(OCO)_{sym}$ close to those found in the corresponding free ion whereas unidentate carboxylate has $\nu(OCO)_{asym}$ at substantially higher frequencies and thus give larger values of $\Delta\nu$.[14,15] Our assignment of uni- or bi-dentate carboxylate group is based on these criteria.

The reported values of $\Delta\nu$ for the $Ni(en)_3(Bz\text{-}\beta\text{-}ala)_2$ complex of 168 cm^{-1} are assumed to typify ionic benzoyl-β-alaninate spectra, for which the values of $\Delta\nu$, found in all the complexes lower than 168 cm^{-1}, may indicate the presence of bidentate carboxyl groups. In the py, 3-pic and 4-pic and CH_3-pipz adducts in which the $\Delta\nu$(119—125 cm^{-1}) is strongly reduced compared with the ionic values, it may suggest that both benzoyl-β-alaninato ions act as symmetrical chelates.[16]

The highest values of $\Delta\nu$ are found for the pipz (160 cm^{-1}) and 4,4′-bpy (186 cm^{-1}) adducts. These ligands which cannot be bidentate, but have two donor sites, must therefore bind with different nickel ions giving rise to polymeric complexes. This is supported by their insolubility, by the similar behavior exhibited in other amino acid adducts.[6] The coordination of the amines is confirmed by the shift to lower frequencies of the $\nu(NH)^B$ (Table 2) in the aliphatic heterocyclic amine adducts and by the shift of the bands in the 800—500 cm^{-1} region in the aromatic heterocyclic amine adducts by respect to the free amines.[6] In the en complex the position of the $\nu(NH)^B$ bands is consistent with a bidentate coordination of the ethylenediamine.[17]

Since the amino acid acts as chelating agent and the amines turn out to be clearly coordinated to the metal ion, we may exclude the presence of coordinated water in all the amine adducts.

These results and the position of the d-d bands in all the amine adducts are consistent with the presence of N_2O_4 donor sets.

Electronic and Infrared Spectra of the Complexes in Solution (Table 4). The electronic spectra of all the complexes in solution moreover suggest the presence of hexacoordinated nickel(II). While the solution eletronic spectra of the $Ni(Bz\text{-}\beta\text{-}ala)_2\cdot 2H_2O$ and $Ni(en)_3(Bz\text{-}\beta\text{-}ala)_2$ complexes in methanol resemble those of the solid complexes, those of the other adducts show a red shift of the d-d bands compared with those of the corresponding solid compounds greater in chloroform in presence of an amine excess. The band at 3310 and 3300 cm^{-1} in the $Ni(Bz\text{-}\beta\text{-}ala)_2\cdot B_2\cdot 2H_2O$ (B=CH_3-pipz and morph), respectively, which is enhanced in intensity in presence of amine excess, may indicate the presence of uncoordinated amine. The $\nu(OCO)_{asym}$ position (1630—38 cm^{-1}) and the $\Delta\nu$ separation (220—228 cm^{-1}) in these complexes are similar to those found for the benzoyl-β-alaninato copper complexes and other copper complexes having dimeric carboxylate structure.[6] This may suggest that the carboxylate group acts as dimeric bidentate or bridging unidentate ligand. The hypothesis of a copper acetate monohydrate type coordination cannot be supported by magnetic measurements in solution, these complexes being insufficiently soluble.

Instead, an essentially unidentate coordination of the amino acid may be proposed for the aromatic heterocyclic amine adducts in chloroform solution from the $\nu(OCO)_{asym}$ position (1588—1600 cm^{-1}) and from the $\Delta\nu$ separation (177—191 cm^{-1}). Their electronic spectra are still consistent with a NiO_4N_2 chromophore, suggesting that the two coordination positions lost from the carboxylate groups may be replaced by water molecules.

The authors are grateful to Prof. Giorgio Peyronel of the Istituto di Chimica Generale ed Inorganica of the University of Modena for making the instruments available to us.

Photochemical Study of the Alkylammonium Molybdates. III. Preparation and Properties

Toshihiro YAMASE and Tsuneo IKAWA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received April 30, 1976)

Six alkylammonium molybdates which we have prepared were examined for photochemical and photochromic properties in a solid and in an aqueous solution. The white crystals were reddish brown or violet when irradiated with UV light. Five compounds of the six were photochromic under aerobic conditions. The thermal return to the white color was slow, taking several hours at room temperature. The irradiation of the aqueous solution (pH 4.3—6.5) by UV light caused a blue coloration; the quantum yield increased with an increase in the molybdate concentration. A UV-induced coloration in both solid and solution was ascribable to the photoreduction of Mo(VI) to Mo(V). The blue form in the aqueous solution possesses several unique characteristics, including: (1) $g=1.926$ and $a=52$ G in its ESR spectrum; (2) the oxidation of Mo(V) to Mo(VI) upon exposure to oxygen, with an accompanying bleaching, and (3) thermochromism (blue form$\leftrightarrows$greenish yellow form) with $\Delta H_r \approx 15$ kcal/mol.

In previous papers we reported the photochromism of bis(dimethylammonium) trimolybdate monohydrate and bis(isopropylammonium) dimolybdate dihydrate.[1,2] When the polycrystalline material was irradiated with UV light, the white crystals became reddish brown or violet because of the formation of Mo(V). A return to the original white color was observed in the dark in the presence of oxygen. This color change could be repeated many times. Recently, Arnaud-Neu and Schwing-Weill reported, on the basis of photochromism tests of the various molybdates of different amines, that only secondary amines yield photochromic molybdates.[3] However, their conclusion is doubtful, since some of the primary aliphatic amines yield photochromic molybdates. This report will present several generalizations regarding the photochemical behavior of the 6 alkylammonium molybdates in a solid and an aqueous solution; these generalizations should provide a better understanding of this behavior.

Experimental

Preparation of Alkylammonium Molybdates. All the chemicals were of a G. R. or reagent grade of the Tokyo Kasei Co. and were used without further purification.

Bis(isopropylammonium) dimolybdate dihydrate (IPAM),—Isopropylamine (52 ml) was added to a solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (80 g) in water (50 ml). After stirring about 6 h, the solution was concentrated under reduced pressure to form a white solid, which was then filtered off and dried. One recrystallization of the crude product from water yielded colorless solids. Found: C, 13.96; H, 4.78; N, 5.96; Mo, 40.0%. Calcd for $(C_3H_{10}N)_2\ Mo_2O_7\cdot 2H_2O$: C, 15.65; H, 5.22; N, 6.09; Mo, 41.7%.

Hexakis(isopropylammonium) Octamolybdate Dihydrate (6IPA8M2),[4]—This compound was crystallized from an aqueous solution (10 ml) containing 5 g of bis(isopropylammonium) dimolybdate dihydrate at room temperature when the solution was kept in the dark for two weeks. Found: C, 13.09; H, 4.21; N, 5.40; Mo, 47.2%. Calcd for $(C_3H_{10}N)_6H_2Mo_8O_{28}\cdot 2H_2O$: C, 13.39; H, 4.09; N, 5.21; Mo, 47.6%.

Bis(dimethylammonium) Trimolybdate Monohydrate (DMAM),—$(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (300 g) was added to a solution of dimethylamine (40%) in 500 ml of water. After stirring about 4 h, the solution was concentrated under reduced pressure, and the resultant white solid was allowed to crystallize. The white solid then dissolved in 1500 ml of water. This solution was warmed 50—60 °C while stirred for 2—3 h to form white precipitates. The precipitated product was filtered off, washed with cold water, and dried under a vacuum. Found: C, 8.68; H, 3.25; N, 5.12; Mo, 53.4%. Calcd for $(C_2H_8N)_2Mo_3O_{10}\cdot H_2O$: C, 8.59; H, 3.26; N, 5.01; Mo, 51.6%. DMAN could be otained by another method, too: The dioxobis(dimethyldithiocarbamato) molybdenum (VI) complex, $MoO_2[(CH_3)_2NCS_2]_2$, was made by Moore and Larson's method[5] and a nearly saturated solution of 1 g of $MoO_2[(CH_3)_2NCS_2]_2$ in 1000 ml of chloroform was refluxed for 1—2 h. After cooling, a white product was allowed to crystallize.

Bis(diethylammonium) Trimolybdate Monohydrate (DEAM),—DEAM was obtained by a modification of the above DMAM-preparation procedure using an aqueous solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (10 g) in 20 ml of diethylamine (40%). Found: C, 15.11; H, 4.24; N, 4.45; Mo, 47.1%. Calcd for $(C_4H_{12}N)_2Mo_3O_{10}\cdot H_2O$: C, 15.64; H, 4.23; N, 4.56; Mo, 46.9%.

Bis(propylammonium) Dimolybdate Dihydrate (PAM),—PAM was obtained by a modification of the above IPAM-preparation procedure using an aqueous solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (50 g) in 100 ml of propylamine (30%). Found: C, 14.24; H, 4.68; N, 5.81; Mo, 42.1%. Calcd for $(C_3H_{10}N)_2Mo_2O_7\cdot 2H_2O$: C, 15.65; H, 5.22; N, 6.09; Mo, 41.7%.

Bis(methylammonium) Dimolybdate Dihydrate (MAM),—MAM was obtained by a modification of the above IPAM-preparation procedure using an aqueous solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (350 g) in 450 ml of methylamine (30%). Found: C, 6.12; H, 3.93; N, 7.35; Mo, 46.2%. Calcd for $(CH_6N)_2Mo_2O_7\cdot 2H_2O$: C, 5.94; H, 3.96; N, 6.93; Mo, 47.5%.

Procedures. The sample was irradiated using a 500-W super-high-pressure Hg lamp. The following filters were used for the different wavelength regions: $\geq$313 nm, a liquid filter (1 cm thick) consisting of an aqueous solution of 0.5 g of potassium hydrogen phthalate/100 ml; 313 nm, conjunction with a liquid filter (3 cm thick) consisting of an aqueous solution of 46 g of $NiSO_4\cdot 6H_2O$ + 14 g of $CoSO_4\cdot 7H_2O$/100 ml and a filter (1 cm thick) of a potassium hydrogen phthalate solution; 365 nm, Toshiba UV-DI + UV-35 filters. The light intensities were measured by means of potassium ferrioxalate actinometry. The UV-induced coloration of the aerobic solution to blue was followed by the conjuction with a He-Ne laser and a photodiode.[6] The oxygen concentration was measured with a kyusuikagaku Kenkyusho D.O. Meter-TP. Thermochromism studies were done in a homemade Dewar vessel. The tempera-

ture was measured by means of a copper-constantan thermocouple kept in contact with the sample cell (1 cm internal pathlength). The evacuation of solutions was carried out by several freeze-pump-thaw cycles on 10^{-4} Torr. Molybdenum analyses were done by means of a Varian Techtron Model 1000 atomic absorption spectrophotometer. Differential scanning calorimetry showed that each of the alkylammonium molybdates was stable below 100 °C. The IR (KBr discs) and Raman spectra were recorded on Shimadzu-IR-27G and JEOL laser Raman spectrophotometers respectively. The UV and visible absorption or reflectance spectra were taken with a Hitachi 624 spectrophotometer. The ESR spectra were obtained with a Varian E-12 spectrometer.

Photometry of Mo(V) in the Aqueous Solution. On the basis of the fact that the colored IPAM powder gave a blue color when dissolved in deaerated water, the photometric determination of Mo(V) in deaerated water was carried out, assuming that all of the Mo(V) in the colored powder was converted into the blue species in water. The number of spins due to Mo(V) in the UV-irradiated IPAM powder was obtained by comparing the sum of the intensities of the Mo(V) ESR signals with the intesity of a DPPH standard (1.44×10^{15} spin in the sample powder of 230 mg). When the sample powder was dissolved in the deaerated water, DPPH had no observable effect on the blue coloration, at least not during the experimental procedure. The numerical double integration of the Mo(V) signals showed that the Mo(V) exhibiting the blue color obeys Beer's law below 4×10^{-4} M ($\varepsilon_{730}=2.3\times10^{3}$ M^{-1} cm^{-1} at 20 °C).

Results and Discussion

Photosensitive Properties in the Solid. In Fig. 1 alkylammonium molybdates are divided into two categories according to the similarity among the IR spectra of the compounds in the Mo-O vibrational region (400—1000 cm^{-1}). The IR spectra of Group (1) compounds (IPAM, 6IPA8M2, PAM, and MAM) were very similar to those of $(NH_4)_6Mo_7O_{24}\cdot4H_2O$. The IR spectra of Group (2) compounds (DMAM and DEAM) showed characteristic strong bands at ≈500 and ≈640 cm^{-1}. Table 1 lists the solubility in water, the absorption maximum (λ_{max}) which is observed after irradiation with UV light, and the approximate speeds of the coloration and return reactions. Under irradiation with UV (313 or 365 nm) light, the white crystals were

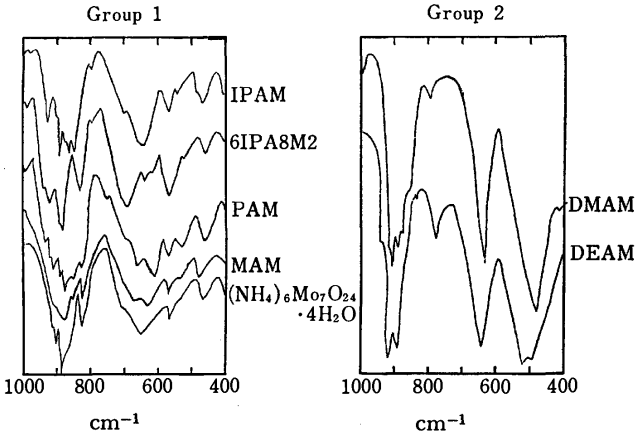

Fig. 1. IR spectra (KBr discs) of alkylammonium molybdates.

Table 1. Photosensitive alkylammonium molybdates

Group	Alkylammonium molybdate		λ_{max}, nm	Approx. coloration time, min[b]	Approx. return time, h[c]
(1)	IPAM	(108)[a]	510	5—7	7—10
	6IAP8M2	(11)	480	≈3	15—20
	PAM	(90)	490	5—7	4—5
	MAM	(330)	480	1—2	—
(2)	DMAM	(1.4)	470	<1	2—3
	DEAM	(1.0)	475	<1	2—3

a) Numbers in parentheses are solubilities in water (100 ml) at 20 °C. b) Numbers indicate the irradiation time required to obtain the reflectance of ≈50% at λ_{max} when the white briquetted powder is exposed to UV (≥313 nm) light at a distance of 30 cm from the light source. c) Numbers indicate the half-life period of the colored species at room temperature under aerobic conditions.

reddish brown or violet. No significant changes in the IR spectra and X-ray diffraction powder patterns after irradiation were observed. The effect of oxygen on the coloration seemed to be negligible. The apparent coloration decreased in this order: DMAM, DEAM> MAM>6IPA8M2>IPAM, PAM. For DMAM, DEAM, 6IPA8M2, IPAM, and PAM, a return to the original white color was observed in the dark under aerobic conditions. Although the entire bleaching did not obey the simple first-order law, the half-life period of the colored species was several hours at room temperature and increased in this order: DMAM, DEAM< PAM<IPAM<6IPA8M2. The return reaction was the thermal process which was catalyzed by oxygen, since irradiation with visible light or the deaerated system brought about no observable bleaching. Therefore, the stronger bleaching effect was obtained by thermal treatment in oxygen. For example, ≈1 atm of oxygen at 50 °C changed the return half-life of DMAM from 2—3 h under aerobic conditions at room temperature to less than 10 min. MAM was UV-sensitive, but did not return to the white color in the dark. It should be noted that Group (2) compounds exhibit lower solubilities in water, higher UV sensitivities, and faster return rates than Group (1) compounds. All of the colored polycrystallines exhibited an ESR signal due to Mo(V), while the white crystallines exhibited no significant ESR signal of Mo(V).[1,2] The colored samples in Group (1) turned blue (λ_{max} 730 nm, λ_{sh} 620 nm), when dissolved in deaerated water. The resulting solution gave rise to a single intense line ($g=$ 1.926), with six weak satelite lines, three on each side and equally spaced ($a=52$ G), in its ESR spectrum, as was previously reported for IPAM.[2] This equal spacing of the six weak lines indicated a hyperfine structure (hfs) due to isotopes with a nuclear spin of 5/2. The line-width was too great to allow the resolution of separate lines from ^{95}Mo and ^{97}Mo. This is not surprising, since the nuclear magnetic moments differ by only 2%.[7] The exposure of the blue solution to oxygen brought about the oxidation of Mo(V) to Mo(VI), with an accompanying bleaching, resulting in no observable ESR signal of Mo(V). The colored samples in Group (2) gave no detectable amount of Mo(V) in their

homogeneous deaerated solution, although the solution obtained was slightly blue. This seemed to be ascribable to the fact that each compound in Group (2) was much less soluble in water than these in Group (1). The difference in photosensitivity, reversibility, or the return rate among the 6 molybdates in the solid state may be strongly connected with their crystal structures. However, we have not made a crystal structure determination of any compounds except for 6IPA8M2.

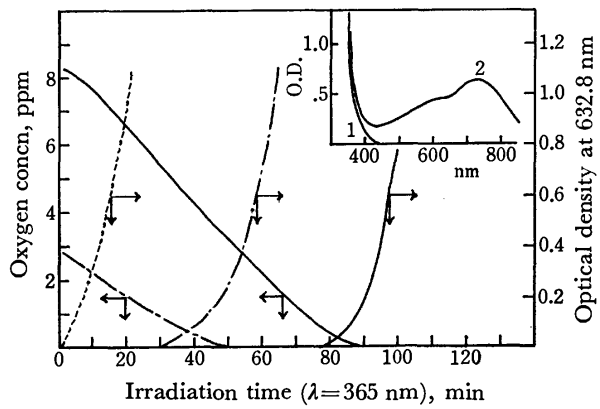

Fig. 2. Effect of oxygen on the UV-induced coloration of the aqueous solution containing 4% IPAM at 20 °C: $[O_2]_{ini}$=8.3 ppm (———), $[O_2]_{ini}$=3.0 ppm (—·—), N_2-bubbled (·····). Incident light intensity is 3.0×10^{-5} E/l min. Optical path length of the solution is 45 mm. Small figure shows spectral changes of a deaerated solution with 1 cm of its thickness: (1) before irradiation, (2) after 5 min of 365 nm irradiation with incident intensity of 2.4×10^{-4} E/l min.

Photosensitive Properties in the Aqueous Solution. Each of the fresh aqueous solutions exhibited pH levels of 4.3—6.5. Under the irradiation of a deaerated solution with UV light, the color changed from colorless to blue, as is shown in Fig. 2. Oxygen inhibited the UV-induced blue coloration of the solution: For the 4% solution of IPAM with initial oxygen levels of 8.3 3.0, and ≈0 ppm, UV irradiation caused the consumption of oxygen in the course of the induction period, and coloration at the steady state was observed when the oxygen level reached about 1 ppm (Fig. 2). The inhibiting effect of oxygen on the coloration may be explained in terms of the rapid oxidation process of Mo(V) to Mo(VI), judging from the fact that the blue form was oxidized by oxygen to yield the colorless form. The blue form was considered to be essentially the same as the blue form on the dissolution (in water) of a colored polycrystalline sample, judging from the similarity between their ESR spectra, giving g=1.926 and a=52 G. The blue forms in the deaerated solution exhibited thermochromism (blue⇄greenish yellow) over the temperature range from 0 to 70 °C.[8] Analysis of the temperature-dependent spectral changes in the IPAM solution revealed a single isosbestic point at 480 nm between the blue and greenish yellow forms, as is shown in Fig. 3(a). With OD_h and OD_l referring to the optical densities at 730 nm at the highest and the lowest temperatures respectively, a plot of (ODh—OD)

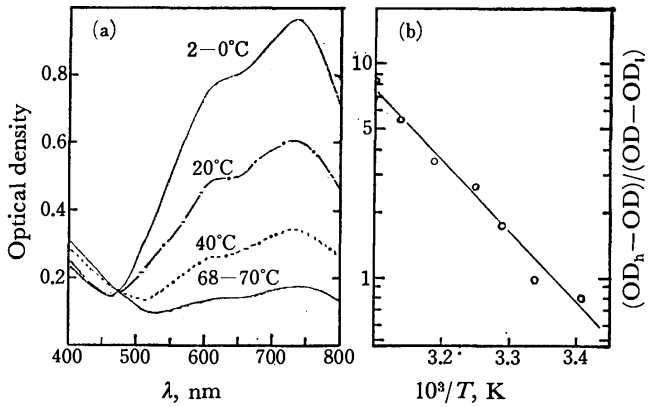

Fig. 3. Thermochromism of the blue form in the deaerated aqueous solution containing 4.3% IPAM: Mo(V)=2.6×10^{-4} M.

/(OD–OD_l) corresponding to the ratio of the concentration of the blue form to that of the greenish yellow form against the reciprocal absolute temperature was approximately linear, giving≈15 kcal as the value of the heat of reaction (ΔH_r) on the equilibrium of the blue form⇄ the greenish yellow form, as is shown in Fig. 3(b). The same value of ΔH_r was obtained for the MAM solution, supporting the idea that the chemical structure of the blue form is independent of the molybdates. The Mo(V) formation quantum yields (η) of the deaerated solution at 20 °C are summarized in Table 2. A comparison of these data shows that the blue form is photochemically produced at pH=4.3—6.5 without any significant difference in η between irradiations with 313 nm and 365 nm light and that η increases with an increase in the molybdate concentration. There have been no reports of the formation of blue species in an aqueous solution containing molybdates at pH 4.3—6.5. In aqueous solutions containing Na_2MoO_4 or $(NH_4)_6Mo_7O_{24}$, $Mo_7O_{24}^{6-}$, which is the predominant species at pH 4.8—6.8, is not reducible, although more acidic solutions (pH≤1.2) are easily reduced to a blue species, which is written as $H_2Mo_2^{V}Mo_4^{VI}O_{19}^{2-}$.[9,10] These

Table 2. Quantum yield of the deaerated aqueous solutions for the Mo(V) formation

Alkylammonium molybdate	Initial concn, wt%	Fresh solution pH	Quantum yield[a] η_{313}	Quantum yield[a] η_{365}
IPAM	4.3	5.3	0.48	0.48
	2.8		0.32	—
	1.2		0.30	—
	0.4		0.03	—
6IPA8M2	2.8	6.2—6.5	0.38	0.30
MAM	4.8	5.6	0.05	0.04
DMAM	1.4	4.3	0.04	—
$(NH_4)_6Mo_7O_{24}\cdot4H_2O$	4.0	5.3	0	—

a) η_{313} and η_{365} indicate the quantum yields obtained by using the exciting light of 313 nm and 365 nm respectively. The incident light intensities at 313 nm and 365 nm are $4—5\times10^{-5}$ E/l min and 2.3—2.4×10^{-4} E/l min respectively.

conclusions are also supported by these of our experimental results: bands in the Raman spectra of the molybdate solution appeared at 925, 890, 350, and 220 cm^{-1} and were close to those of the solid $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$. Furthermore, the solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ at pH 5.3 gave no blue species photochemically (Table 2). The tendency for η to increase with an increase in the molybdate concentration suggests that the primarily-formed photoproduct reacts with the ground-state molybdate to yield the mixed-valence blues containing molybdenum cluster groups. The possibility of a molybdenum cluster containing more than two atoms of Mo(V) (for example, $H_2Mo_2^{V}Mo_4^{VI}O_{19}^{2-}$ which may be produced when $pH \leq 1.2$), may be excluded, since Mo(V) should not obey Beer's law if this possibility is operative. In order to understand the reaction mechanism of the blue coloration, the structure of the blue form must be revealed at least. However, further speculation is inappropriate, since the true formula of the blue species is not known at present.

(Received June 23, 1976)

Synopsis. Phenols (phenol, hydroquinone, resorcinol, and *o*-cresol) reacted with prenyl halides (3-methyl-2-buteny chloride and geranyl chloride) in the presence of an alkali metal (Na) in ether. In these reactions, phenols with the corresponding prenyl group at the ortho position were obtained selectively.

Claisen *et al.* have reported that, in general, the amount of C-alkylation can be greatly increased by the alkylation of sodium phenolates in benzene.[2] In a previous paper, we ourselves reported that phenol reacted with 3-methyl-2-butenyl chloride in the presence of metallic sodium in ether and that *o*-(3-methyl-2-butenyl)phenol (**1**) was thus isolated selectively (98%). In this paper, the studies of this reaction will be reported in detail.

In the reaction of phenol with geranyl chloride, *o*-geranylphenol (**2**) was also obtained in a high yield (90%) in a reaction similar to that in the case of 3-methyl-2-butenyl chloride. *o*-Cresol reacted with 3-methyl-2-butenyl chloride in the same manner, and 2-methyl-6-(3-methyl-2-butenyl)phenol (**3**) was obtained in a 76% yield. A similar reaction of hydroquinone with 3-methyl-2-butenyl chloride afforded 4-hydroxy-2-(3-methyl-2-butenyl)phenol (**4**) in a 66% yield. In the case of resorcinol, 3-hydroxy-4-(3-methyl-2-butenyl)-phenol (**5**) and 3-hydroxy-2-(3-methyl-2-butenyl)phenol (**6**) were obtained in 16 and 27% yields respectively. In this case, though the structures were not determined, the di- and tri-isoprenylated compounds were confirmed by GC-MS (GLC peaks showing molecular ion peaks at *m/e* 246 and 414 were observed).

From these results, metallic sodium in an aprotic solvent was found to be useful in obtaining selectively phenols with an acyclic isoprenyl group at the ortho position, while the Friedel-Crafts alkylation did not give such phenols mainly.[3]

Experimental

The Reaction of Phenols with Allylic Chloride. To an ethereal solution (50 ml) of phenol (0.05 mol), metallic sodium (0.2 mol) was added. After the mixture had been stirred for 0.5—1.5 h, an allylic chloride (0.05 mol) was added slowly; then the mixture was refluxed for 10 h. After the unreacted metallic sodium had been taken out, the solution was acidified with 0.1M aq HCl (20 ml) and extracted with ether. The ethereal solution was treated with 5% aq NaOH to remove the unreacted phenol, and then washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent by distillation under reduced pressure, the products were obtained. The structures of the products were identified by means of the IR, NMR, and mass spectra. These IR and NMR spectral data agreed with the previously reported data.

2-Geranylphenol (2).[4] IR (cm^{-1}): 3400, 1925, 1890, 1780, 1210, 840, 750. NMR (δ, CCl_4): 1.57(s, 3,-CH_3), 1.65 (s, 3, -CH_3), 1.69 (s, 3, -CH_3), 2.00 (m, 4), 3.25 (d, 2, J=7.0 Hz, -CH_2-), 5.10 (s, 1, -OH), 5.25 (t, 2, J=7.0 Hz, =CH-), 6.50—7.10 (m, 4, aromatic protons). Mass (*m/e*): 230 (M^+).

2-Methyl-6-(3-methyl-2-butenyl)phenol (3.[5]*)* IR (cm^{-1}): 3500, 1910, 1780, 845, 760, 740. NMR (δ,CCl_4): 1.72 (s, 6, =C(CH_3)$_2$), 2.10 (s, 3, -CH_3), 2.00 (m, 4), 3.25 (d, 2, J= 7.0 Hz, -CH_2-), 5.10 (s, 1, -OH), 5.25 (t, 2, J=7.0 Hz, =CH-), 6.50—7.10 (m, 4, aromatic protons). Mass (*m/e*): 176 (M^+), 161 (M^+—15), 121 (M^+—55).

4-Hydroxy-2-(3-methyl-2-butenyl)phenol (4). mp 99—100 °C (colorless plates, lit,[6] mp 102°C). IR (cm^{-1}): 3500, 1895, 1815 1780, 840, 810. NMR (δ, CD_3OD): 1.67 (s, 6, =C(CH_3)$_2$), 3.15 (d, 2, J=7.0 Hz, -CH_2-), 5.10 (t, 1, J=7.0 Hz, =CH-), 6.25—6.70 (m, 3, aromatic protons). MS (*m/e*): 178 (M^+), 123 (M^+), 123 (M^+ —55).

3-Hydroxy-2-(3-methyl-2-butenyl)phenol (5).[7] IR (cm^{-1}): 3500, 1655, 1200, 840, 800. NMR (δ, CCl_4): 1.74 (s, 3, -CH_3), 1.79 (s, 3, -CH_3), 3.32 (d, 2, J=7.0 Hz, -CH_2-), 5.20(m, 3), 6.10—6.60 (m, 3, aromatic protons). MS (*m/e*): 178 (M^+), 163 (M^+ —15), 123 (M^+ —55).

3-Hydroxy-2-(3-methyl-2-butenyl)phenol (6).[7] IR (cm^{-1}): 3400, 1645, 1220, 835, 785, 775. NMR (δ, CCl_4): 1.66 (s, 3, -CH_3), 1.72 (s, 3, -CH_3), 3.09 (d, 2, J=7.0 Hz, -CH_2-), 4.85 (s, 2, -OH), 5.13 (t, 1, J=7.0 Hz, =CH-), 6.15—6.80 (m, 3, aromatic protons). MS (*m/e*): 178 (M^+), 163 (M^+—15), 123 (M^+—55).

(Received September 30, 1976)

Synopsis. The effect of urea on the 1st and 2nd CMC's of aqueous solutions of sodium and lithium dodecyl sulfates was investigated by the measuments of electric conductivity. The results were discussed in terms of the breaking effect of urea on the water structure not only around the hydrocarbon chains, but also around the counter ions of these surfactants.

In our previous papers, the micelle structure in the aqueous solutions of sodium dodecyl sulfate (NaDS) was investigated mainly in the concentration region above the 1st critical micelle concentration (CMC) through systematic studies including measurements of the electric conductivity,[1] density, viscosity,[2] light-scattering,[3] and depolarization of fluorescence.[4] It was revealed by these studies that there exists a 2nd CMC, where a change in the micelle structure takes place. Furthermore, in order to investigate the effect of the counter ions on the 2nd CMC, conductivity measurements were carried out in solutions of potassium (KDS) and lithium (LiDS) dodecyl sulfates in addition to NaDS.[5] It was revealed that, at the 2nd CMC, there occurs an increased counter-ion binding with the micelle.

It is well known that urea disrupts the water structure.[6] Several workers have used dissolved urea as a probe for investigating the contribution of structural changes in water to micelle formation.[7-9] In this study, conductivity measurements were carried out over a wide concentration range of NaDS and LiDS solutions in the presence of urea. The results were discussed by taking into account the effect of urea on the water structure, not only around the hydrocarbon chains, but also around the counter ions of these surfactants.

Experimental

The NaDS and LiDS used in this study were the same as those described in our previous paper.[5] Urea obtained from the Wako Pure Chemical Co. was recrystallized from 65 vol% aqueous etanol below 40°C.[10] The conductivity was measured in the manner described in a previous work.[1]

Results and Discussion

The results of the conductivity measurements in the neighborhood of the 1st CMC are shown in Fig. 1, where the specific conductivity (κ) is plotted againt the concentration of NaDS solutions containing various amounts of urea. The 1st CMC of a NaDS solution rises with an increase in the concentration of urea, as has been observed by other workers.[7-9] In recent investigations, the micelle formation has been discussed in terms of a change in the water structure according to Frank and Evan's theory;[11] the formation of the so-called iceberg structure around the hydrocarbon chains of surfactant molecules brings about a loss of entropy at their dissolution. The increase in CMC values in the presence of urea may be ascribed to a drop in the standard chemical potential of the surfactant in the monomeric state due to the breaking effect of urea on the iceberg structure, without any corresponding large change in the micellar state.

The ratio of the CMC in the presence of urea to the CMC in the absence of urea, CMC/CMC(0), is plotted against the concentration of urea in Fig. 2, where the results for the NaDS solution are compared with those for the LiDS solution. These results agree fairly well with those obtained by Schick,[9] who gives no explanation for the difference in CMC/CMC(0) between the NaDS solution and the LiDS solution. The effect of urea on the two hydrated counter ions, Li^+ and Na^+, needs to be discussed.

Bower and Robinson[12] revealed, by means of the isopiestic vapor pressure method, that the activity coefficient of NaCl is decreased by the addition of urea. The Na^+ ion is a structure-former, as is well known, and has a structural-orienting influence on neighboring water molecules.[11,13] The decrease in the activity coefficient of NaCl by urea may result from an increased electrostatic interaction between Na^+ and Cl^- due to a diminished hydration of Na^+. That is, urea disrupts the water structure in the vicinity of Na^+. This effect of urea may facilitate the adsorption of Na^+ as a counter ion on the micelle surface. The results shown in Fig. 2 may include the effect of urea on the counter ion, which lowers the 1st CMC, in addition to that on the hydrocarbon chain, which raises the 1st CMC. The Li^+ ion, which is more strongly hydrated in the absence of urea (than Na^+), may be more effective on the lowering of the 1st CMC in the presence of urea than Na^+. Thus, the increment in CMC/CMC(0) for LiDS solutions is less than that for NaDS solutions, as is shown in Fig. 2.

The conductivity measurements over a wide concentration range of NaDS solutions are shown in Fig. 3, where the results in the presence of urea are compared with those in the absence of urea. There occurs a break point corresponding to the 2nd CMC, in addition to that at the 1st CMC, as revealed by the conductivity measurements in our previous papers.[1,5] Moreover, the specific conductivity *vs.* concentration curve bends toward the concentration axis at the 2nd CMC in the presence of urea, while it breaks upward in the absence of urea, as was also observed in our previous work.[1,5] The conductivity behavior of the NaDS solutions at the 2nd CMC can be made clear in Fig. 4(a),which shows the deviation of the specific conductivity from the extrapolation of the linear plot of the specific conduc-

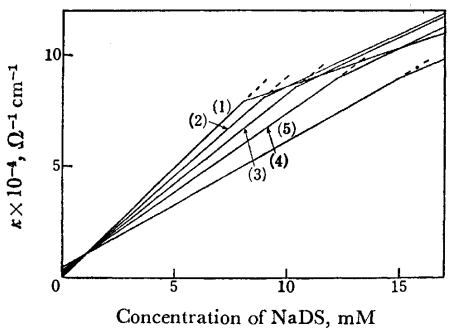

Fig. 1. Specific conductivities of NaDS solutions in the presence of urea in the neighborhood of the 1st CMC; concentration of urea: (1) 0 M, (2) 2 M, (3) 4 M, (4) 6 M, (5) 8 M.

tivity *vs.* concentration below the 2nd CMC in Fig. 3 to a higher concentration, $\Delta\kappa$; $\Delta\kappa$ is negative, at least in the concentration range of urea studied. Furthermore, $\Delta\kappa$ increases and, at the same time, the 2nd CMC as well as the 1st CMC rises, with an increase in the concentration of urea. The effect of urea on the conductivity behavior above the 2nd CMC of LiDS solutions is similar to that in NaDS solutions, as is shown in Fig. 4(b).

It was suggested in our previous studies[1-5] that a change in the micelle structure at the 2nd CMC leads to an increase in the counter-ion binding with the micelle to compensate for the increment in the electrostatic energy resulting from the closer aggregation of hydrophilic parts of the amphipathic ions, of which the micelle is composed, above the 2nd CMC than below the 2nd CMC. As has been mentioned above, the disruption of the water structure by urea brings about a diminished hydration of the alkali metal counter ions of dodecyl sulfate. Under these circumstances, some counter ions in the bulk may be adsorbed additionally on the micelle surface at the 2nd CMC. As can be seen in Figs. 4 (a) and 4 (b), the lowering of the slopes of the straight lines above the 2nd CMC may be ascribed at least partly to a decrease in the counter-ion concentration in the bulk. Furthermore, the increase in the 2nd CMC with the concentration of urea (see Figs. 4 (a) and 4 (b)) may be caused primarily by the change in the standard chemical potentials of the surfactant in the monomeric state, as well as in the micellar state between 1st and 2nd CMC, relative to the corresponding change in the micellar state above the 2nd CMC.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (3), 753—754 (1977)

An Effect of Heat-treatment on the Activity of Titanium Dioxide Film Electrodes for Photo-sensitized Oxidation of Water

Hideo TAMURA, Hiroshi YONEYAMA, Chiaki IWAKURA, and Takaaki MURAI

Department of Applied Chemistry, Faculty of Enginnering, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 21, 1976)

Synopsis. When an anodic oxide film of titanium and a pyrolytically prepared TiO_2 film were subjected to a heat-treatment in an argon atmosphere, their activities for photo-sensitized oxidation of water were improved.

The photo-sensitized oxidation of water on an illuminated rutile electrode[1] has been studied recently by many investigators with a special interest in photo-emf cells.[2,3] The electrochemical properties of TiO_2 film electrodes prepared by a variety of methods, such as chemical vapor deposition,[4,5] anodic oxidation,[5-7] thermal oxidation,[6,8,9] pyrolysis of titanium salts,[10] and spraying by a plasma jet,[8] as well as of single crystal rutile, have been investigated in connection with the photo-sensitized oxidation. The following points can be noticed in these investigations: (1) the anodic oxide film shows far less activity than that of single crystal rutile; (2) the films prepared by the thermal oxidation do not always have the same properties, but have some possibility of giving the same activity as that of single crystal rutile if a suitable preparation condition is chosen; and (3) the activities of the pyrolytically prepared film for oxygen adsorption and for photo-sensitized oxidation of chloride ions are influenced by the preparation temperature of the film.

It is suggested by the above information that the heat-treatment has a great influence on the activity of a TiO_2 film electrode for the photo-sensitized oxidation of water. The present study was conducted, therefore, to elucidate the effect of the heat-treatment on the activity of TiO_2 films. Anodically formed and pyrolytically prepared films were chosen for the TiO_2 films.

Experimental

A rectangular titanium sheet ($20 \times 10 \times 0.5$ mm) was anodically oxidized in ethylene glycol containing 100 g/l sodium borate.[11] Sodium borate was purified by recrystallization from distilled water twice, and ethylene glycol was distilled twice. When the titanium electrode was oxidized with a constant current of 0.5 mA/cm^2, its potenial increased with the oxidation time until it reached around 20 V *vs.* S.C.E., after which no further potential rise occurred. After the polarization under this condition for 20 min, the current density was changed to 1 mA/cm^2 and maintained at that value until the potential reached a desired value. The heat-treatment was conducted under an argon atmosphere at a desired temperature for 1 h. Pyrolytic TiO_2 films were prepared by the same procedure as that described previously,[12] except that a solution of 0.1 mol·dm^{-3} $TiCl_3$–20% HCl containing a few drops of 30% H_2O_2 was subjected to the pyrolysis. A 500 W xenon arc lamp was used as a light source and monochromatic light was obtained by using the grating of a spectrophotometer (Shimadzu, QB-50).

Results and Discussion

The activity of an anodically formed oxide film for the photo-sensitized oxidation of water was poor, as expected. When the film was heat-treated at 700 °C, however, it became almost as active as single crystal rutile. Figure 1 shows the polarization curves of an electrode formed at 50 V. In the measurement of each polarization curve, the photo-intensity was maintained at the same value. Trials of the heat-treatment at 800 °C were failures due to the fact that the film flaked off in some patches from the substrate. The polarization curves in 0.5 mol·dm^{-3} Na_2SO_4 and 1 mol·dm^{-3} NaOH were almost the same as those in Fig. 1, except that they shifted cathodically depending on the pH values of the electrolytes.

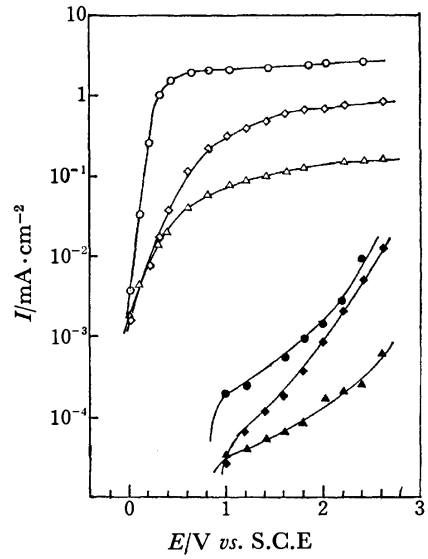

Fig. 1. Influence of heat-treatment on current-potential curves of anodic oxide films on titanium. Temperature of heat-treatment; -○-, -●-: 700°C, -◇-, -◆-: 600 °C, -△-, -▲-: non-heat-treatment, open symbol: under illumination, closed symbol: in the dark.

X-Ray diffraction patterns of the oxide film showed that the initial film formed by the anodization was amorphous and changed into rutile modification by the heat-treatment, as expected from the transformation of anatase to rutile by the heat-treatment.[13,14] It was also observed that the crystallization of the film was promoted with an increase of the temperature of the heat-treatment. Hence, one of the reasons for the increase of the activity is this crystallization. Another effect of the heat-treatment is to bring about an increase of the electrical conductivity of the film, as is usually

observed in single crystal rutile, although the determination of the carrier concentration of the film by Mott-Schottky plots before and after the heat-treatment was unsuccessuful, because the film thickness was so thin that the length of the space charge layer exceeded the film thickness by anodic polarization beyond a fairly low anodic potential.[4] As for the film thickness, it increases at a rate of 20—30 Å/V in the anodization.[11,15] Thus, the oxide film thickness formed at 50 V amounts only to 1000—1500 Å. By the heat-treatment, there is a possibility that the titanium substrate extracts oxygen from the oxide film,[16] by which a decrease in the film thickness would be expected. It was theoretically predicted that there is an optimum carrier concentration for a semiconductor electrode to attain a high quantum yield of a photo-sensitized reaction,[17] and the experimentally found optimum concentration was in the order of as high as 10^{18} carriers/cm^3.[18]

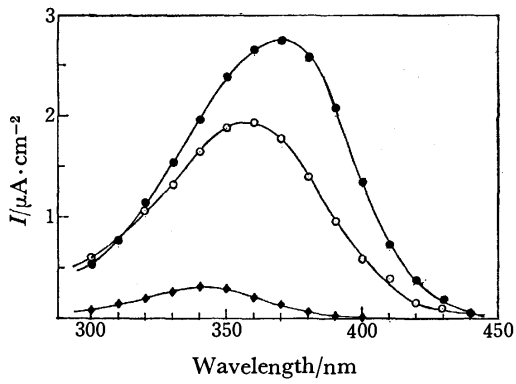

Fig. 2. Photo-current spectra of anodic oxide films on titanium.
-●- Heat-treated at 700 °C, -○- heat-treated at 600 °C, -◆- non-heat-treated.

Figure 2 gives the anodic current spectra of the film with and without the heat-treatment. By the heat-treatment, the photo-current at 2.0 V distinctly increased and its maximum occurred at a longer wavelength. Since the electrode was illuminated through the electrolyte, excitation of hole-electron pairs must be most predominant in a layer near the film/electrolyte interface. The results shown in Fig. 2, therefore, suggest that the probability of carrier recombination in the process in which electrons move from the excited sites to the substrate was decreased by the heat-treatment.

The above mentioned effects of the heat-treatment were also observed on a pyrolytic oxide film. The pyrolytic oxide film had a history of high temperature (450 °C) preparation. Nevertheless, the as-prepared film showed a poor activity.

When the activated TiO_2 film electrode was used as the electrode for the photo-sensitized oxidation of water in 0.5 mol·dm^{-3} H_2SO_4, a gradual deterioration of the activity was noticeable due to the oxidation of the electrode surface, as was already reported for a single crystal electrode.[3,19] From the above results, however, it is suggested that a TiO_2 film will be as effective as single crystal rutile as a semiconductor electrode if the film consists of highly crystalline TiO_2 with an appropriate conductivity.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (3), 755—756 (1977)

Flux Growth of Rare-earth Niobates with Fergusonite Structure

Yoshinori SUGITANI

Department of Chemistry, The University of Tsukuba, Sakuramura, Niihari-gun, Ibaraki 300-31

(Received November 1, 1976)

Synopsis. Single crystals of rare-earth niobates $RNbO_4$ (R denotes a rare-earth element) were grown from a melt of PbF_2–PbO flux. They are monoclinic and isostructural with natural and synthetic fergusonites. These crystals, except those containing Pr, Nd, Sm, and Ho were found to emit luminescent colors under UV irradiation.

Yttrium niobate $YNbO_4$, a member of mineral fergusonite (Y, Er, U) (Nb, Ta, Ti,···)O_4, belongs to a monoclinic system having a pseudo-sheelite type structure.[1] Natural fergusonite occurs mostly in metamict form due to the inclusion of radioactive elements such as uranium and thorium, so that its original structure had long been believed to be tetragonal from studies on samples recrystallized by heating to over 400 °C.[2] Studies of refractory materials such as $YNbO_4$ have been made mainly on powder samples prepared by the sintering or arc fusion method.[3]

Recently, Sugitani and Nagashima have grown crystals of $YNbO_4$ of macroscopic size by the flux method,[4] and have found that the monoclinic form of $YNbO_4$ is also supported by optical observations in addition to X-ray studies. In this note, the preparation of rare-earth niobate crystals which have monoclinic forms are reported. It was found that most of these crystals produce luminescent emission of various colors which is considered to be rare for "pure type" oxide phosphors.

As a typical case, the method of growing yttrium niobate is given here. Other rare-earth niobates can be grown, in general, in a manner similar to that for $YNbO_4$, with some minor changes in the growing conditions, such as the cooling rate, solute-flux ratio, *etc.* Equimolar Nb_2O_5 (purity 3N) and Y_2O_3 (purity 4N) were mixed in a platinum crucible together with the flux material PbF_2–PbO (purity 3N, the flux ratio PbF_2: PbO=80: 20) of an amount several times the molar ratio. All of the rare-earth oxides used as starting materials were sesquioxides R_2O_3, except for Pr_6O_{11} and Tb_4O_7. The crucible was tightly covered by a lid and was placed in an alumina-box filled with alumina powder. This system was placed in an electric furnace maintained at 1300 °C. After about two hours at that temperature, it was cooled down to 1100 °C at the rate of 1.2 °C/h by a programmed controller. At the final temperature the system was removed from the furnace and was allowed to cool down to room temperature. The products in the crucible were removed and washed with hot 6M–HNO_3 for several hours. The crystals thus obtained were confirmed to have the desired $RNbO_4$ composition by chemical analysis and/or by X-ray analysis. They are mostly in the shape of slightly elongated octahedra, and their sizes range from 0.2 to 3 mm for their largest dimension.

Table 1 shows a list of the rare-earth niobates prepared, together with their colors, cell parameters, and luminescent colors under UV irradiation. The values of the cell parameters were calculated from the $\bar{1}21$, 031, 121, 040, 200, 002, 112, and 240 reflections.

It was found that Bi_2O_3–V_2O_5 flux (the flux ratio

s: strong, m: medium, w: weak. —: not observed. a) Bi_2O_3–V_2O_5 flux.

Bi_2O_3: V_2O_5=120: 8) was also useful in growing these niobates, though the sizes of the crystals obtained were usually smaller than those obtained using PbF_2–PbO flux, for the same growing conditions. The color of $YNbO_4$ grown in PbF_2–PbO flux is pale yellow with a tint of brown, while that grown in Bi_2O_3–V_2O_5 flux is yellow (Table 1). This is considered to be due to contamination by the flux material, but details remain unknown.

Crystals which were obtained as by-products during the growing runs are CeO_2, $Pb_2Nb_2O_7$, $Pb_3Nb_2O_8$, PbO and other unidentified crystals.

Brixner[5] has reported the emission colors of sintered pellets of several niobates of $RNbO_4$ composition. His results are considered to agree with the present results within a small discrepancy in color description. Suemune[6] has reported coloring and bleaching of several $RNbO_4$ materials which had been exposed to UV light for 5 min at 25 °C and maintained at 100 °C for 24 h after the exposure. From the present experiments, it is apparent that the coloring for UV irradiation does not remain but the samples immediately return to their original colors when the irradiation ceases.

Spectroscopic studies as well as other studies, are needed to understand the luminescence and photochromism of fergusonite-type niobates. Such studies are now in progress.

The author is grateful to Professor Kozo Nagashima for his kind support of this work, and to the late Mr. Toshio Nakamura for his help in the early stages of this work.

Transfer-free Energy Aspect on the Keto-enol Tautomerization Rate of Benzoylacetone in Water-Dimethyl Sulfoxide Mixtures

Hitoshi WATARAI and Nobuo SUZUKI*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received September 24, 1976)

Synopsis. The transfer-free energies of the keto form, the enol form, and the transition state of benzoylacetone from water to water–dimethyl sulfoxide (DMSO) mixtures have been evaluated on the basis of kinetic and partition experiments at 25 °C. The results were compared with those of acetylacetone, and the substituent effects of methyl and phenyl groups on the transfer-free energies have been discussed in terms of the group transfer-free energy.

The study of solvent effect on the kinetic behavior of β-diketone is necessary in order to elucidate the formation reaction of metal chelates with β-diketone and the solvent extraction mechanisms of these compounds. In the course of our study of the solvent effect on the keto-enol tautomerization rate of acetylacetone, we pointed out the usefulness of the partition coefficient in interpreting the kinetic solvent effect.[1] When the extent of solvent effect on a reactant is measured as a function of the change in the partition coefficient, the solvent effect on a transition state can be conveniently evaluated by simultaneous knowledge of the rate constant and the partition coefficient of the reactant. In this study, the solvent effect on the keto-enol tautomerization rate of benzoylacetone (BA) in a water–DMSO mixture will be described in terms of the transfer-free energy and the estimated free energies will be compared with those of acetylacetone (AA) in order to examine the substituent effects of methyl and phenyl groups.

Experimental

Chemicals. Benzoylacetone (Wako Junyaku Co., G. R.) was purified by recrystallization from diethyl ether. Heptane and DMSO were purified by a method described previously.[1] All the mixed solvents were prepared from the purified DMSO and the doubly distilled water by weight.

Kinetic Measurements. The tautomerization reaction was initiated by injecting a minute amount of a dioxane solution of BA into the mixed solvent in an optical cell thermostated at 25±0.1 °C. Since BA exists solely as the enol form in dioxane, the decreasing absorbance of the enol form is observed at 310 nm immediately after the injection. From the decrease in the absorbance recorded on a spectrophotometer, a first-order rate constant (k_{obsd}) was obtained. The concentration of BA was below 10^{-4} M in all measurements.

Equilibrium Measurements. The enol fractions (f) of BA in the mixed solvents were estimated from the apparent molar absorptivity at 310 nm. The molar absorptivity of the enol form of BA in water has been determined to be 1.62×10^4 at 310 nm by means of a stopped-flow technique.[2] The apparent partition coefficients (P_{obsd}) of BA between heptane and the mixed solvents were determined photometrically at 25±0.05 °C by the same method as was used for AA.[1] All the photometric measurements were carried out by means of a Hitachi 356 spectrophotometer.

Results and Discussion

The kinetic and equilibrium results are shown in Fig. 1. Both k_{obsd} and P_{obsd} decrease rapidly with an increase in the DMSO, while the enol fraction f increases moderately.

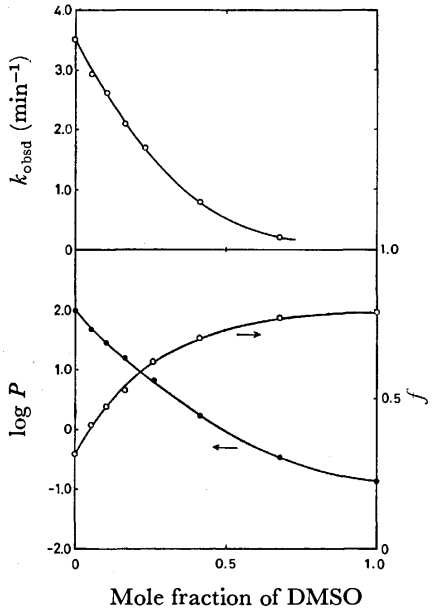

Fig. 1. Observed rate constant (k_{obsd}), enol fraction (f) and partition coefficient (P) of BA as a function of the mole fraction of DMSO.

From the equilibrium data, the transfer-free energies of the keto form ($\delta\Delta G_{s,K}$) and the enol form ($\delta\Delta G_{s,E}$) from water to the mixed solvents can be evaluated by means of Eqs. 1 and 2 respectively:

$$\delta\Delta G_{s,K} = RT\ln\frac{(1-f^\circ)}{(1-f)}\cdot\frac{P}{P^\circ} \quad (1)$$

$$\delta\Delta G_{s,E} = RT\ln\frac{f^\circ}{f}\cdot\frac{P}{P^\circ} \quad (2)$$

where the superscript $^\circ$ denotes the values in water, chosen as the reference solvent. Moreover, the transfer-free energies of the transition state can be estimated by means of the following equation:

$$\delta\Delta G^{\ddagger} = RT\ln\left(\frac{P}{P^\circ}\cdot\frac{1-f^\circ}{1-f}\cdot\frac{f^\circ}{f}\cdot\frac{k^\circ_{obsd}}{k_{obsd}}\right) \quad (3)$$

By using the partition coefficient on the mole fraction scale which is calculated from P_{obsd} and the density data of the mixed solvent in the literature,[3] we can obtain the transfer-free energies, $\delta\Delta G_{s,K}$, $\delta\Delta G_{s,E}$, and

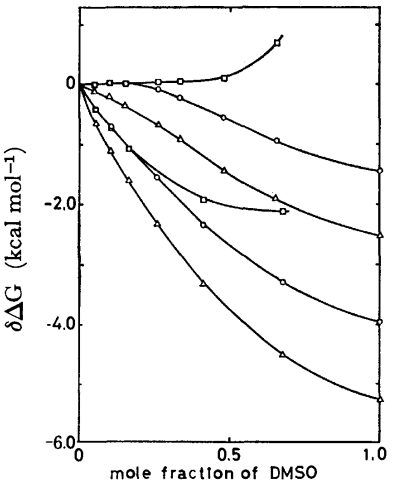

Fig. 2. Estimated transfer-free energies of AA (the upper three plots) and BA (the lower three plots) as a function of the mole fraction of DMSO. □: $\delta\Delta G^t$, ○: $\delta\Delta G_{s,K}$, △: $\delta\Delta G_{s,E}$.

$\delta\Delta G^t$, expressed as on the mole fraction scale. The estimated values, together with those for AA, are shown in Fig. 2 as a function of the DMSO mole fraction.

Figure 2 points to the following: (i) all the transfer-energy values of BA are smaller than those of AA; (ii) the $\delta\Delta G_{s,K}$ of AA is nearly zero in the composition region of $X_S<0.2$, whereas that of BA decreases with the increase in DMSO in the same region; (iii) the $\delta\Delta G^t$ of AA is zero or a positive value, whereas that of BA is negative. These differences are considered to be mainly due to the destabilization of BA in water, which is caused by the substitution of the phenyl group for one methyl group of AA.

The substituent effect on the transfer-free energy should be discussed in terms of the group transfer-free energy. The $\delta\Delta G_{s,K}$ values, for example, of AA and BA may be divided into the corresponding free energies of the groups as follows:

$$\delta\Delta G^A_{s,K} = \delta\Delta G^A_s(\text{-COCH}_2\text{CO-}) + 2\delta\Delta G^A_s(\text{CH}_3\text{-}) \quad (4)$$

$$\delta\Delta G^B_{s,K} = \delta\Delta G^B_s(\text{-COCH}_2\text{CO-}) + \delta\Delta G^B_s(\text{CH}_3\text{-}) + \delta\Delta G^B_s(\text{C}_6\text{H}_5\text{-}) \quad (5)$$

where the superscripts A and B denote AA and BA respectively. If the next assumption is valid:

$$\delta\Delta G^A_s(\text{-COCH}_2\text{CO-}) = \delta\Delta G^B_s(\text{-COCH}_2\text{CO-})$$
$$\delta\Delta G^A_s(\text{CH}_3\text{-}) = \delta\Delta G^B_s(\text{CH}_3\text{-}) \quad (6)$$

the difference between Eqs. 4 and 5 becomes:

$$\delta\Delta G^A_{s,K} - \delta\Delta G^B_{s,K} = \delta\Delta G^B_s(\text{CH}_3\text{-}) - \delta\Delta G^B_s(\text{C}_6\text{H}_5\text{-}) \quad (7)$$

Similar treatments of $\delta\Delta G_{s,E}$ and $\delta\Delta G^t$ lead to Eq. 8:

$$\delta\Delta G^A_{s,K} - \delta\Delta G^B_{s,K} = \delta\Delta G^{tA} - \delta\Delta G^{tB} = \delta\Delta G^A_{s,E} - \delta\Delta G^B_{s,E} . \quad (8)$$

This equation shows that the transfer-free energy differences between the corresponding states of the two diketones are independent of the solvent composition and equal each other. However, the experimentally estimated values of the differences do not show an equality as in Eq. 8. The estimated values are as follows:

$$\delta\Delta G^A_{s,K} - \delta\Delta G^B_{s,K} : \delta\Delta G^{tA} - \delta\Delta G^{tB} : \delta\Delta G^A_{s,E} - \delta\Delta G^B_{s,E} = 1 : 1.6 : 1.7 \quad (9)$$

The discrepancy between these data and the prediction in Eq. 8 may be due to a difference in the charge delocalization of the keto forms, the enol forms, and the transition states of the two diketones, which is caused by substituting the phenyl group for one methyl group of AA. The result of Eq. 9 suggest that the charge distribution in the transition state is closer to that for the enol form than to that for the keto form.

The reaction indices for the enolization and the ketonization, α_e and α_k,[1] which are defined as:

$$\alpha_e = \frac{\delta\Delta G^t}{\delta\Delta G_{s,K}}, \quad \alpha_k = \frac{\delta\Delta G^t}{\delta\Delta G_{s,E}} \quad (10)$$

respectively, were estimated in the low-mole-fraction region of DMSO as follows: $\alpha_e=-0.17$ and $\alpha_k=-0.05$ in AA and $\alpha_e=1.07$ and $\alpha_k=0.69$ in BA. The signs of α in the two diketones are opposite, according to the sign of $\delta\Delta G^t$.

From the above results, it seems that the effect of the mixed solvent on the transfer-free energies is more striking in AA than in BA. Recently, Symons[4] has investigated the hydrogen-gas solubility in the water–DMSO mixed solvent at 25 °C and has observed a distinct minimum of the solubility expressed on the molar scale in the region of 25—35 mol % DMSO. In a previous study of the liquid-liquid partition of AA between heptane and the mixed solvent, a distinct maximum in the partition coefficient of the keto form has been observed at $X_S=0.2$.[1] However in the case of BA no such phenomenon is observed at all. Although the hydrogen-gas solubility has been interpreted in terms of a changing entropy and energy of "hole" formation in the solvent with the composition,[4] the transfer-free energy of β-diketone is not likely to be solely interpreted by this factor. In the case of β-diketone, a solute-solvent interaction energy including a size contribution of solute and solvent[5] seems to be a possible factor governing the transfer-free energy, in addition to the "hole" formation energy which may be related to such a property as an internal pressure of the solvent.[6,7]

ESR and Optical Spectra of Low-spin Square Planar Cobalt(II) Complexes with Some Quadridentate Schiff Bases of the N_2S_2 Type[1)]

Yuzo NISHIDA, Akira SUMITA, and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received October 29, 1976)

Synopsis. ESR and electronic spectra of low-spin cobalt(II) complexes with some quadridentate Schiff bases of the N_2S_2 type were measured. Analysis of ESR parameters led to the conclusion that an unpaired electron is in the d_{yz} orbital of the cobalt atom. On this basis the absorption at 10×10^3 cm^{-1} was attributed to the $d_{x'-y'}\rightarrow d_{yz}$ transition.

The relative energies of d-orbitals in low-spin square-planar cobalt(II) complexes have been subjects of many investigations and still in controversies. Recently, we have reinvestigated the electronic structures of square planar cobalt(II) complexes with the quadridentate Schiff bases, **1-a**, **1-b**, and **1-c**, as shown in Fig. 1.[2)] As the results, it was concluded that an unpaired electron lies in the d_{yz} orbital and the separations among d_{yz}, $d_{x'-y'}$, d_{xz}, and $d_{z'}$ orbitals are small in these complexes.[2)] In this study the ESR and electronic spectra of cobalt(II) complexes with some quadridentate Schiff bases, **1-d**, were investigated in order to compare the ligand field effect of **1-d** with those of other quadridentate Schiff bases such as **1-a**, **1-b**, and **1-c**.

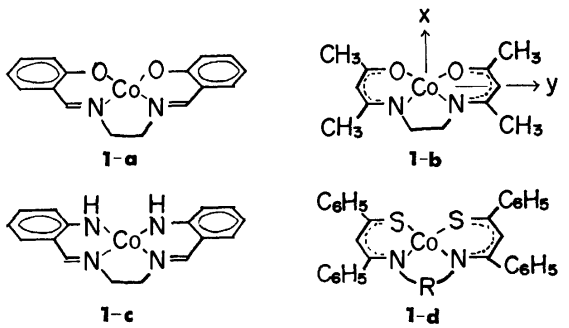

Fig. 1. Some quadridentate ligands cited in this paper. In **1-d**, R represents $-CH_2CH_2-$, $-CH_2CH_2CH_2-$, and $-CH(CH_3)CH_2-$ for H_2(nsen), H_2(nstn) and H_2(nspn), respectively. x and y axes are shown in **1-b**, z axis being perpendicular to the plane.

Experimental

The ligands, *N,N'*-bis(1-phenyl-2-thiobenzoylvinyl)ethylenediamine, *N,N'*-bis(1-phenyl-2-thiobenzoylvinyl)trimethylenediamine and *N,N'*-bis(1-phenyl-2-thiobenzoylvinyl)propylene diamine, abbreviated as H_2(nsen), H_2(nstn) and H_2(nspn), respectively, were prepared according to the modified methods of Uhlemann[3)] and Tang *et al.*[4)] The cobalt(II) complexes were obtained by mixing a methanol solution of cobalt(II) acetate tetrahydrate and a chloroform solution of the ligand under a nitrogen atmosphere. The nickel(II) complexes were also obtained according to the same method as described for cobalt(II) complexes.

ESR spectra were obtained with a JEOL ESR-apparatus model JES-ME-3X using an X-band. DPPH was used as a standad marker. Magnetic susceptibilities were measured by the Faraday method at room temperature, Pascal's constants being used for diamagnetic correction. $HgCo(NCS)_4$ was employed as a standard for magnetic susceptibility. Reflectance spectra were measured with a Shimadzu Multipurpose Spectrophotometer, MPS-5000 at room temperature.

Results and Discussion

The magnetic moments of cobalt(II) complexes with H_2(nsen), H_2(nstn) and H_2(nspn) were found to be in the range 2.2—2.3 BM at room temperature, indicating that all the complexes are of the low-spin type. Figure 2 shows the ESR spectrum of [Co(nstn)], diluted in [Ni(nstn)]. From the spectrum, it was found that $g_1=3.29$, $|A_1|=164\times10^{-4}$ cm^{-1}, and g_2, $g_3\approx2.0$. The other complexes, [Co(nsen)] and [Co(nspn)], showed ESR patterns similar to that of [Co(nstn)]. It should be noted that the ESR patterns of *cis*-[CoN_2S_2] type complexes obtained here are very similar to those of *cis*-[CoN_2O_2] type complexes with Schiff bases such as **1-a** and **1-b**,[5,6)] for which the $(yz)^1$ ground state* was assumed in our recent investigation.**,[2)] Therefore, it is reasonable to assume that an unpaired electron is localized in the d_{yz} orbital of the cobalt atom in the complexes with quadridentate Schiff bases of the *cis*-[CoN_2S_2] type.

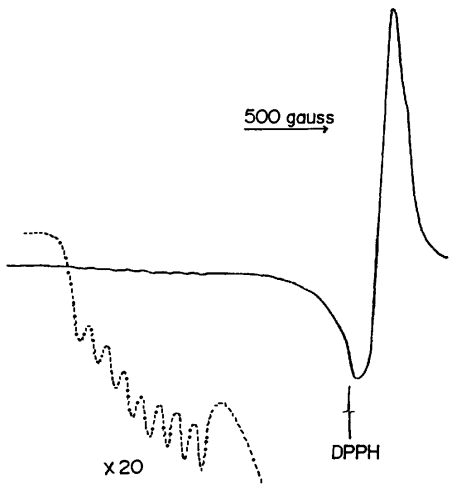

Fig. 2. ESR spectrum of [Co(nstn)] diluted in [Ni(nstn)] obtained at 123 K by an X-band.

* $(yz)^1$ represents electronic configuration $(d_{x'-y'})^2(d_{xz})^2(d_{z'})^2(d_{yz})^1$.

** Throughout this paper, x, y, and z axes were adopted as shown in Fig. 1.

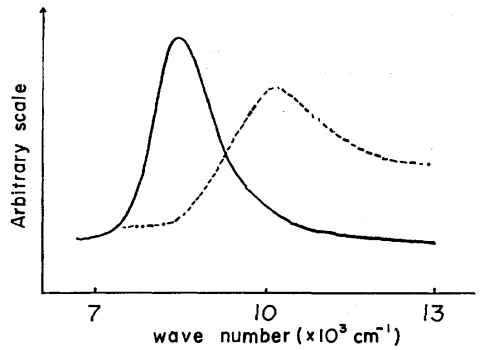

Fig. 3. Reflectance spectra of [Co(nspn)] (------) and [Co(sals)] (——).

The reflectance spectrum of [Co(nspn)] is shown in Fig. 3, together with that of [Co(sals)], which is one of the *cis*-$[CoN_2O_2]$ type complexes, and where H_2(sals) represents *N*,*N*′-disalicylidene-1,2-diphenylethylenediamine. A broad band was observed at 10×10^3 cm^{-1} for [Co(nspn)], whereas a similar band was observed at 8.4×10^3 cm^{-1} for the *cis*-$[CoN_2O_2]$ type complexes with quadridentate Schiff bases.[7] It is reasonable to assume that both bands are attributed to the same origin, to which the $d_{x^2-y^2} \rightarrow d_{yz}$ transition was assigned for the *cis*-$[CoN_2O_2]$ type complexes with Schiff bases.[2] The blue shift of the band upon substitution of the N_2S_2 ligand for the N_2O_2 ligand suggests that the energy separation between $d_{x^2-y^2}$ and d_{yz} orbitals is larger in the $[CoN_2S_2]$ complexes than those in the $[CoN_2O_2]$ complexes. From the above discussion, it can be concluded that the order of the d-orbitals in the cobalt(II) complexes with Schiff bases, **1-d** is the same as those in the complexes with **1-b** and **1-c**.

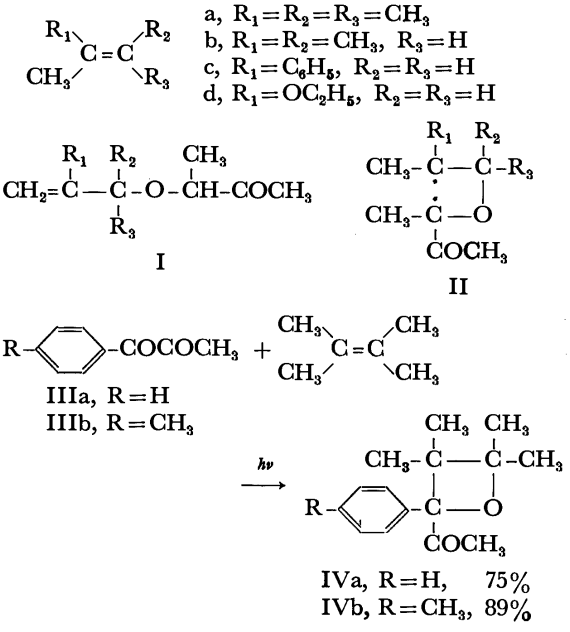
Organic Photochemical Reactions. XXV. The Photoaddition of 1-Phenyl-1,2-propanedione to Olefins[1]

Kensuke SHIMA, Shigeki TAKEO, Ken-ichi YOKOYAMA, and Hideaki YAMAGUCHI
Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Miyazaki 880

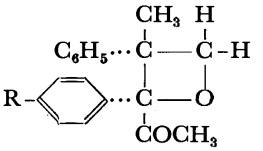
(Received September 1, 1976)

Synopsis. The irradiation of 1-phenyl-1,2-propanedione and olefins, such as 2,3-dimethyl-2-butene and α-methylstyrene, in benzene gives mainly oxetanes, in sharp contrast to the results obtained from the photoaddition of biacetyl to these olefins. The differences between these results are discussed in terms of the reactivity of the 1,4-biradical intermediates.

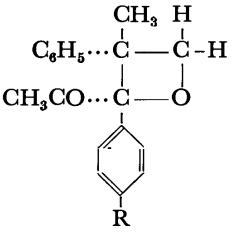
In a previous publication,[2] it was suggested that biacetyl adds to methyl-substituted olefins, such as 2,3-dimethyl-2-butene, 2-methyl-2-butene, α-methylstyrene and 2-ethoxypropene, to give unsaturated ethers (I),[3] which are the products expected from the disproportionation of 1,4-biradical intermediates (II). In order to investigate the scope and limitations of these photoaddition reactions, the photoaddition of 1-phenyl-1,2-propanedione (IIIa) and 1-(*p*-tolyl)-1,2-propanedione (IIIb) to 2,3-dimethyl-2-butene and α-methylstyrene was studied.



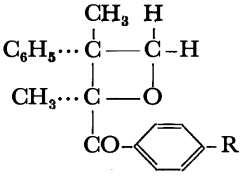
The irradiation of a benzene solution of IIIa and 2,3-dimethyl-2-butene using a 300-W high-pressure mercury lamp through a filter solution of naphthalene in hexane gave an oxetane (IVa) as the main product (75%).[4] IVa was isolated by column chromatography on silica gel and characterized by spectroscopic methods. The IR spectra of IVa showed absorption by an acetyl carbonyl at 1715 cm^{-1} and its NMR spectra showed an acetyl proton at δ 2.09. From these results, the structure of the oxetane was assigned to 1,1,2,2-tetramethyl-3-acetyl-3-phenyloxetane (IVa). Similarly, the addition of IIIb to 2,3-dimethyl-2-butene gave 1,1,2,2-tetramethyl-3-acetyl-3-(*p*-tolyl)oxetane (IVb) in an 89% yield. On the other hand, the photoaddition of IIIa (or IIIb) to α-methylstyrene gave three isolated products: Va, Vb, and Vc (or VIa, VIb, and VIc).[5] In these cases, addition products for acetyl carbonyl to α-methylstyrene were also observed. The stereochemistry of Vb and Vc can be deduced from a comparison of the NMR spectra of their methyl protons: the *trans* isomer (Vc) shows methyl absorption at a field higher than that of the *cis* isomer (Vb) due to the ring current of the phenyl group. The stereochemistry of Va was deduced using the same reasoning.



Vb (R=H), 40%
VIb (R=CH_3), 55.3%

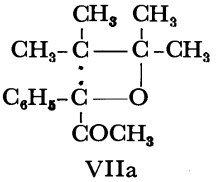


Vc (R=H), 36%
VIc (R=CH_3), 11.1%

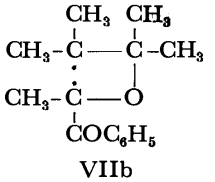


Va (R=H), 24%
VIa (R=CH_3), 33.4%

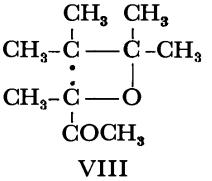
In the present experiment, unsaturated ethers, whose formation was a predominant process in the case of biacetyl and 2,3-dimethyl-2-butene, could not be detected. This sharp contrast can be explained by the



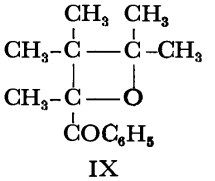
VIIa



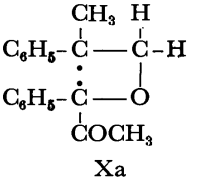
VIIb



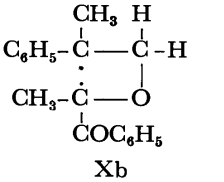
VIII



IX



Xa



Xb

smaller hydrogen abstraction ability of 1,4-biradical VIIa compared with VIII. In addition, the absence of product IX could be a reflection of a difference in

the stability of 1,4-biradicals VIIa and VIIb. In the case of the reaction of IIIa with α-methylstyrene, the product expected from the addition of an acetyl carbonyl in IIIa to α-methylstyrene was obtained, though as a minor product. Probably the difference in the stability of 1,4-biradicals Xa and Xb is not as large as that of VIIa and VIIb. Finally, the absence of the stereoisomer of Va (or VIa) may be a reflection of a steric requirement in 1,4-biradicals: bulkier phenyl and aroyl groups may be far apart.

Experimental

General. NMR spectra were obtained with a JEOL JNM-MH 100 instrument for solutions in CCl_4 containing tetramethylsilane as the internal standard, IR spectra with a JASCO IRA-1 spectrophotometer, mass spectra with a Hitachi Perkin-Elmer RMU-60 spectrometer, and VPC with a Shimadzu GC-3BF apparatus using a column of Ucon Oil LB-550X (20% on Celite 545, 2 m) at 200 °C.

The following materials were prepared by previously reported procedures: 1-phenyl-1,2-propanedione (IIIa),[6,7] 1-(*p*-tolyl)-1,2-propanedione (IIIb),[6-8] and 2,3-dimethyl-2-butene.[9]

Irradiation of 1-Phenyl-1,2-propanedione (IIIa) and 2,3-Dimethyl-2-butene. A solution of IIIa (22.2 g, 0.15 mol) and 2,3-dimethyl-2-butene (17.7 g, 0.21 mol) in benzene (60 ml) was irradiated for 5 days using a 300-W high-pressure mercury arc filtered through a hexane solution of naphthalene in nitrogen at room temperature. After the removal of the low-boiling materials, the remaining liquid was distilled under reduced pressure to give a liquid (11 g, bp 82—107 °C/3 mmHg), leaving a viscous liquid (1 g). VPC of the distillate showed an oxetane (IVa, 75%), benzoic acid (14%), and a small amount of an unidentified product (11%). IVa was isolated by chromatography on silica gel: bp 59 °C/5.5 mmHg;[10] *m/e* 189(M^+-COCH_3), 105(base, $C_6H_5CO^+$), and 77($C_6H_5^+$); IR 1715 and 970 cm^{-1}; NMR δ 0.80(3H, s), 1.25 (3H, s), 1.26(3H, s), 1.37(3H, s), 2.09(3H, s), 7.27(3H, m), and 7.53(2H, m). Found: C, 77.43; H, 8.59%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

Irradiation of 1-(p-Tolyl)-1,2-propanedione (IIIb) and 2,3-Dimethyl-2-butene. A mixture of IIIb (8.1 g, 0.05 mol) and 2,3-dimethyl-2-butene (5.9 g, 0.07 mol) in benzene (20 ml) was irradiated for 5 days. After the removal of the unreacted materials, a fraction boiling at 92—119 °C/5 mmHg (4.7 g) was collected; residues, 1 g. VPC analysis showed three products with a relative ratio of peak areas of 89: 9.7: 1.3. The major product (IVb) was isolated by chromatography on silica gel: bp 94 °C/2 mmHg;[11] *m/e* 203, 119(base), and 91; IR 1715 and 980 cm^{-1}; NMR δ 0.78(3H, s), 1.23(3H, s), 1.26(3H, s), 1.37(3H, s), 2.07(3H, s), 2.35(3H, s), 7.12(2H, m), and 7.41(2H, m). Found: C, 78.26; H, 9.02%. Calcd for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00%.

Irradiation of 1-Phenyl-1,2-propanedione (IIIa) and α-Methylstyrene. A solution of IIIa (10.4 g, 0.07 mol) and α-methylstyrene (11.8 g, 0.1 mol) in benzene (60 ml) was irradiated for 10 days. After the removal of the unreacted materials, a fraction boiling at 80—140 °C/3 mmHg(3.9 g)[12] was collected; residues, 4.8 g. The distillate was chromatographed on silica gel in hexane using 4% acetone as the eluent, giving three isolated products. The first eluted product was 1,*t*-2-dimethyl-1-benzoyl-2-phenyloxetane (Va, 24%): mp 85 °C; *m/e* 266(M^+), 118(base), 105, and 77; IR 1680 and 995 cm^{-1}; NMR δ 1.41(3H, s), 1.52(3H, s), 4.09(1H, d, J=5.7 Hz), 4.94(1H, d, J=5.7 Hz), 7.09(8H, m), and 7.95(2H, M). Found: C, 81.12; H, 6.67%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%. The second eluted product was 1,*c*-2-diphenyl-1-acetyl-2-methyloxetane (Vb, 40%): bp 145 °C/5 mmHg; *m/e* 266, 118, 105, and 77; IR 1715 and 990 cm^{-1}; NMR δ 1.77 (3H, s), 2.12(3H, s), 4.19(1H, d, J=5.7 Hz), 5.10(1H, d, J=5.7 Hz), 6.99(8H, m), and 7.23(2H, m). Found: C, 81.42; H, 6.84%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%. The third eluted product was 1,*t*-2-diphenyl-1-acetyl-2-methyloxetane (Vc, 36%): mp 71 °C; *m/e* 266, 118, 105, and 77; IR 1720 and 990 cm^{-1}; NMR δ 1.21(3H, s), 1.90(3H, s), 4.30(1H, d, J=5.7 Hz), 4.92(1H, d, J=5.7 Hz), 7.13(8H, m), and 7.47 (2H, m). Found: C, 81.21; H, 6.77%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

Irradiation of 1-(p-Tolyl)-1,2-propanedione (IIIb) and α-Methylstyrene. After 10 days of irradiation of a mixture of IIIb (8.1 g, 0.05 mol) and α-methylstyrene (8.4 g, 0.07 mol) in benzene (20 ml), a fraction boiling at 105—130 °C/4 mmHg (1.8 g)[13] was obtained; residues, 2 g. The distillate was chromatographed on silica gel. The first eluted product was VIa (33.4%): *m/e* 280(M^+), 119(base), 118, 91, and 43; IR 1675 and 990 cm^{-1}; NMR δ 1.42(3H, s), 1.53(3H, s), 2.41(3H, s), 4.16(1H, d, J=5.7 Hz), 5.06(1H, d, J=5.7 Hz), 7.24(7H, m), and 8.01(2H, m). The second eluted product was VIb(55.5%): *m/e* 280, 119(base), 118, and 91; IR 1715 and 990 cm^{-1}; NMR δ 1.74(3H, s), 2.07(3H, s), 2.12(3H, s), 4.14(1H, d, J=5.7 Hz), 5.07(1H, d, J=5.7 Hz), and 6.95(9H, m). The third eluted product was VIc(11.1%): *m/e* 119, 118, and 91; IR 1720 and 995 cm^{-1}; NMR δ 1.23(3H, s), 1.95(3H, s), 2.35(3H, s), 4.44 (1H, d, J=5.7 Hz), 5.05(1H, d, J=5.7 Hz), and 7.40(9H, m).

The authors wish to thank Dr. C. Pac of Osaka University, for helpful discussions. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 747020).

Hydrogen-Deuterium Exchange Reaction *via* β-Sulfinyl Carbanion. Neighboring Sulfur Participation in Carbanion Formation

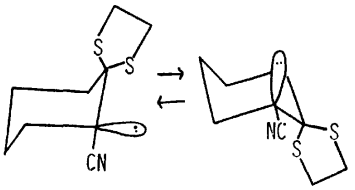
Tohru KOYANAGI, Jun-ichi HAYAMI, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received September 8, 1976)

Synopsis. The rate of base-catalyzed H-D exchange reaction of substituted cyclopropanes and cyclohexanes containing sulfur atom at the β-position of reaction center was investigated. Neighboring sulfur participation in stabilization of the carbanion was suggested in the case of ethyl *trans*-2-(phenylthio)cyclopropanecarboxylate.

Participation of neighboring sulfur, and sulfur located at a remote site has widely been known in reactions where carbenium ion takes part as an intermediate.[1] However, no similar participation has been reported for carbanions having sulfur-containing substituents at the β or more remote positions.[2] This is quite a contrast with the fact that the considerable experimental evidence has accumulated which indicates that carbanions are stabilized by the adjacent sulfur atom.[3]

We tried to reveal the effect of the participation of sulfur atom located at the β-position to carbanion. The reactions studied were base-catalyzed hydrogen-deuterium exchange of alicyclic compounds.



[A] [B]

Fig. 1. [A] Both of the sulfur atoms can participate in the carbanion lobe. [B] One of the sulfur atoms can participate in the carbanion lobe.

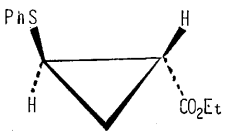
TABLE 1. SECOND-ORDER RATE CONSTANTS AND PARAMETERS OF ACTIVATION FOR THE H-D EXCHANGE REACTION OF CYCLOHEXANE CARBONITRILES

Substrate	$10^6\ k^{a,b)}$ ($M^{-1}\ s^{-1}$)	Rel. k	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq\ a)}$ (e.u.)
1	5.35	1.97	19.3±0.5	−27.0±2
2	2.72	1	21.9±0.5	−24.0±2

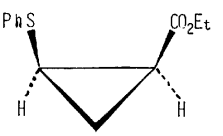
a) At 72 °C. b) [pyridine]$=9.90\times10^{-1}$ M.

The initial investigation was carried out with 1,1-ethylenedithio-2-cyanocyclohexane (**1**). In our study with cyclohexyl derivatives, though the ring inversion may be operative in **1**, at least one of the sulfur atoms should be able to interact with the carbanion lobe (Fig. 1). In Table 1, second-order rate constants and parameters of activation on pyridine-catalyzed deuterium exchange reaction of **1** are shown with those of cyclohexanecarbonitrile (**2**). Thus, in ethanol-*d*, **1** underwent the H-D exchange reaction about twice as fast as **2**, and **1** showed smaller enthalpy of activation than that of **2**. But it is too imprudent to discuss the presence of neighboring sulfur participation, since the separation of the potential effect of participation and inductive effect, both played by dithiacyclopentyl group, cannot be performed with certainty.

In the next trial, to make a clear distinction between these two effects, stereoisomers of cyclopropyl compounds were selected for the model compounds. Compounds used were ethyl *trans*-2-(phenylthio)cyclopropanecarboxylate (*trans*-**3**) and ethyl *cis*-2-(phenylthio)cyclopropanecarboxylate (*cis*-**3**), with ethyl *trans*-2-phenylcyclopropanecarboxylate (**4**) as the reference compound.



(*trans*-**3**)



(*cis*-**3**)

Cyclopropyl derivatives should be suitable for our study, since they have acidic hydrogens, and in many cases the rate of the racemization of carbanion is much smaller than that of deuterium exchange owing to the strain of cyclopropane ring.[4] In fact no isomerization between *trans*-**3** and *cis*-**3** was observed during the deuterium exchange in the present study. Second-order rate constants and relative rate ratios of these compounds are listed in Table 2. More pronounced electron-withdrawing ability of phenylthio group than that of phenyl group makes *trans*-**3** and *cis*-**3** more reactive than **4**.[5] *Trans*-**3** exchanges faster than *cis*-**3**, thus in *trans*-ester the operation of neighboring sulfur participation may be suggested.

TABLE 2. SECOND-ORDER RATE CONSTANTS FOR THE H-D EXCHANGE REACTION OF CYCLOPROPANE CARBOXYLATE ESTERS

Substrate	$10^6\ k^{a,b)}$ ($M^{-1}\ s^{-1}$)	Rel. k
trans-**3**	45.7	18.4
cis-**3**	20.0	8.0
4	2.49	1.0

a) At 70 °C. b) [pyridine]$=2.48\times10^{-1}$ M.

TABLE 3. PARAMETERS OF ACTIVATION FOR THE H-D EXCHANGE OF *trans*-**3** AND *cis*-**3**

Substrate	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq\ a)}$ (e.u.)
trans-**3**	16.0±0.5	−34.0±2
cis-**3**	19.7±0.5	−27.7±2

a) At 70 °C.

Parameters of activation were evaluated for *trans*-**3** and *cis*-**3**, and are shown in Table 3. Large negative values of entropy of activation (ΔS^*) indicate that the rate-determining step of this reaction is the removal of the acidic proton by the base (pyridine) to form a hydrogen-bonded carbanion.[4] In *trans*-**3** the attack of pyridine is sterically more hindered than in *cis*-**3**, since both the phenylthio group and the hydrogen being attacked reside on the same side of the cyclopropane ring. Although the contribution of this steric hindrance can hardly be evaluated, such a hindrance can cause an increase in enthalpy of activation (ΔH^*) for *trans*-**3**, partly compensating a decrease in ΔH^* that results from the presence of the sulfur participation.

Thus the difference in ΔH^* between *trans*-**3** and *cis*-**3** should be appreciated to show apparently the neighboring sulfur participation for the former compound in stabilizing the transition state and the resulting carbanion.

Table 4. IR and UV absorptions of *trans*-**3** and *cis*-**3**

Substrate	cm^{-1} a)	λ_{max} b) (MeOH)	($\log \varepsilon$)
trans-**3**	1040	250.0	(4.1)
cis-**3**	1028	252.5	(4.1)

a) Skeletal vibration of cyclopropane ring in IR spectrum.
b) N→V transition of the three-membered ring.

Furthermore, IR and UV spectroscopic data, summarized in Table 4, suggest that *cis*-**3** is less stable than *trans*-**3** at the ground state due to the steric strain. In IR spectrum, frequencies of skeletal vibration for cyclopropane ring is lower in *cis*-**3**, which indicates the increase of molecular strain in *cis*-**3**.[6] In UV spectrum, the absorption maximum of *cis*-**3** appears at 252.5 nm (N→V transition of the three-membered ring), 2.5 nm longer than that of *trans*-**3**, reflecting the difference in the ground state strain perturbation.[7] Thus one can estimate that *cis*-**3** exists at about 1 kcal/mol higher in energy than *trans*-**3** does at the ground state.[8]

Therefore, taking into account the increase of ΔH^* by steric hindrance for the approach of base, and the difference in ground state energy, the stabilization should be more pronounced for *trans*-**3** than that inferred from the difference in observed ΔH^*.[8] Consequently it is quite probable that a neighboring sulfur atom participates in stabilizing the carbanion of *trans*-**3**.

Experimental

The IR spectra were obtained using a Perkin-Elmer 521 spectrophotometer. The NMR spectra were recorded on a JEOL PS-100 spectrometer. The UV spectra were measured with a Hitachi 200-10 spectrophotometer. All compounds gave satisfactory results on spectroscopic analysis (IR, NMR), and on elemental analysis.

Materials. *1,1-Ethylenedithio-2-cyanocyclohexane* (***1***): Dry HCl gas was bubbled into a benzene solution (30 ml) of 2-cyanocyclohexanone[9] (7.5 g) and 1,2-ethanedithiol (15 g) for 1 h at room temperature. After usual work-up and recrystallization from benzene, 2.0 g (13 %) of **1** was obtained; white needles, mp 61 °C.

Cyclohexanecarbonitrile (***2***): A benzene solution (10 ml) of cyclohexanecarboxamide (8.7 g) and thionyl chloride (17.8 g) was heated under reflux for 6 h. After cooling, the solution was poured in ice–water, and the organic layer was extracted with ether. After usual work-up, distillation of the residual oil gave 5.8 g (78 %) of **2**; bp 75 °C/18 mmHg.

Ethyl trans- *and* cis-*2-(Phenylthio)cyclopropanecarboxylate* (trans-***3***), (cis-***3***): Ethyl diazoacetate (12 g) was added dropwise to the refluxing xylene solution (50 ml) of phenyl vinyl sulfide (10 g) in 1 h. The solution was heated under reflux for additional 1 h, and then xylene was distilled off, leaving brown residual oil (18 g), which was fractionated by preparative GLC (Shimadzu GC-5A) to give *trans*-**3** and *cis*-**3**.

Ethyl trans-*2-phenylcyclopropanecarboxylate* (***4***): Ethyl diazoacetate (12 g) was added dropwise to refluxing xylene solution (30 ml) of styrene (20 g) and hydroquinone (0.5 g) in 1 h. After the same procedure for *trans*-**3** and *cis*-**3**, **4** was obtained.

Kinetics. The stock solutions were prepared in volumetric flask by adding the stock base solutions (pyridine in ethanol-*d*) to a weighed amount of the substrate. With a syringe each 0.5 ml portion was transferred to glass ampoules, which were then flame sealed. The tubes were placed in a thermostat at an appropriate temperature. After predetermined time, tubes were withdrawn and were quenched in a Dry Ice–acetone bath. After removing ethanol and pyridine *in vacuo*, the remaining substrate was transferred with CCl_4 to an NMR tube. Rate constants were evaluated by comparing the intensity of the specified peak with that of standard one in their NMR spectra.

The Action of Malononitrile and Ethyl Cyanoacetate on Diphenylcyclopropenone

Israel AGRANAT, Gerhard V. BOYD,* and Mark A. WIRT*

Department of Organic Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

** Department of Chemistry, Chelsea College, London SW3 6LX, England*

(Received May 4, 1976)

Synopsis. Diphenylcyclopropenone reacts with malononitrile in the presence of ethanolic sodium methoxide to yield, after acidification, (*E*)-1,1-dicyano-2-hydroxy-3,4-diphenyl-1,3-butadiene (**1a**); an analogous product, ethyl (2*Z*, 4*E*)-2-cyano-3-hydroxy-4,5-diphenyl-2,4-pentadienoate (**1b**), is formed from ethyl cyanoacetate.

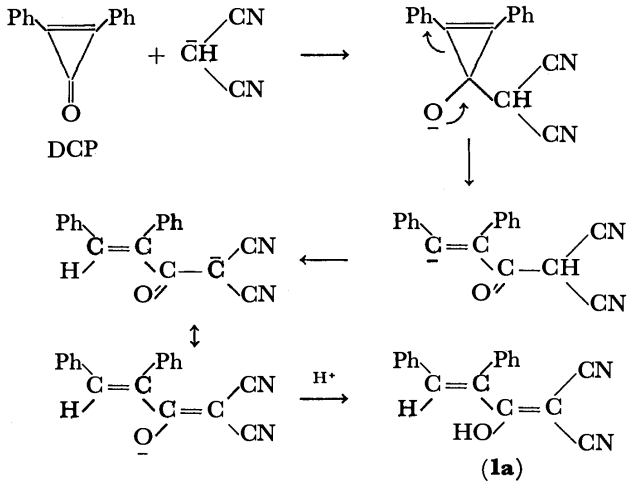
In the young chemistry of cyclopropenones, a leading role has been played by diphenylcyclopropenone (DCP).[1] The synthesis of DCP is considered 'a milestone in theoretical organic chemistry'[2] The 'state of the art' of the cyclopropenones has recently been reviewed.[3,4] The general picture that emerges is the *erratic* behaviour of these microcyclic ketones, particularly in addition reactions.[3] This trend, in which the unpredictable predominates, may be illustrated by the action of malononitrile and ethyl cyanoacetate on DCP.

The reactions of cyclopropenones with malononitrile have previously been employed as a synthetic route to triafulvenes. DCP reacted with malononitrile in boiling acetate anhydride solution to give 4,4-dicyano-1,2-diphenyltriafulvene;[5] aliphatic cyclopropenones condensed analogously.[6-8] The use of β-alanine[9] or boron trifluoride[10] as a catalyst resulted in increased yields.

Likewise, condensation of DCP and ethyl cyanoacetate gave the corresponding triafulvene.[9] In general, basic condensation agents which could cleave the three-membered ring were avoided. An improved procedure employed an active form of DCP. Thus, treatment of 3-ethoxy-1,2-diphenylcyclopropenium tetrafluoroborate and malononitrile with one mole of *N,N*-diethylisopropylamine in dichloromethane solution afforded the dicyanotriafulvene in 85% yield.[11] 3,3-Dichloro-1,2-diphenylcyclopropene reacted directly with malononitrile at 100—120° C without solvent to give the triafulvene in 10% yield.[12] It has been claimed that in the reaction of DCP with malononitrile in pyridine solution seven products were obtained, one of which was tentatively assingned the structure of 3-amino-2-cyano-4,4-diphenyl-2,4-cyclopentadien-1-one (or its 2-amino-3-cyano isomer).[13]

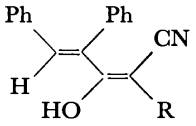
In the present investigation, the reactions of DCP with malononitrile and with ethyl cyanoacetate were studied under basic conditions in protic solutions. We had thought that a Michael addition of the nucleophile (*e.g.*, $\bar{C}H(CN)_2$) to the activated carbon-carbon double bond of the cyclopropenone ring might occur, followed perhaps by a ring enlargement process, leading eventually to a pyridinone derivative. Various nucleophilic addition reactions at the carbon-carbon double bond of cyclopropenones have been effected.[3,4] However, in this case the reactions followed a different course. Treatment of DCP with an ethanolic solution of malononitrile in the presence of sodium methoxide, followed by acidification, gave a high yield of a pale yellow acidic solid, whose analysis and mass spectrum corresponded to that of a 1:1 adduct. The NMR spectrum showed only a multiplet in the aromatic region, but the IR spectrum was more revealing, containing broad OH absorption and strong bands at 2214 and 2209 cm^{-1}, indicative of two α,β-unsaturated cyanide groups. We therefore considered that the product was the enolic dinitrile (**1a**) and this structure, together with the *cis*-configuration of the phenyl groups, was readily confirmed by an unambiguous synthesis of the compound from the sodium salt of malonoitrile and (*E*)-2,3-dipheylpropenoyl chloride.[14] The reaction of DCP with ethyl cyanoacetate under the same conditions yielded a colourless adduct, which was insoluble in aqueous alkali; however, the virtual identity of its UV spectrum with that of the previous compound, a positive $FeCl_3$ reaction, and the appearance of intense CN absorption and a sigle carbonyl band at 1655 cm^{-1} (chelated ester) in its IR spectrum suggested that it was the analogue (**1b**), and, indeed, it was also formed by condensation of ethyl sodio-cyanoacetate with the foregoing acid chloride.

The formation of **1a** and **1b** closely resembles the hydrolyses of cyclopropenones with sodium or potassium hydroxide, in which salts of α,β-unsaturated acids are produced.[3] The present reaction presumably involves the addition of the anion of malononitrile (and of ethyl cyanoacetate) to the carbonyl group of DCP, followed by collapse of the intermediate open chain carbanion species (Scheme 1). Protonation



Scheme 1.

would then complete the process. It is interesting to note that the *cis*-configuration of phenyl groups in the substrate (DCP) is retained in the product, in analogy with various basic hydrolyses of cyclopropenones. It may be an indication of the high rate of protonation of the carbanion intermediate. The course of the nucleophilic addition to DCP contrasts with the reaction of malononitrile and 3-ethoxy-1,2-diphenylcyclopropenium tetrafluoroborate in the presence of *two* moles of *N,N*-diisopropylethylamine.[15] In the latter reaction, an addition of the nucleophile to the carbon-carbon doble bond is preferred, and the product is 1,3-diphenyl-3-ethoxy-4,4-dicyano-1,3-butadiene. The reduced cyclopropenium contribution in DCP might have been the determining factor which directed the addition of the nucleophile to the carbonyl rather than to the carbon-carbon double bond. Thermodynamic effects are probably responsible for the ultimate transformation to the conjugated dienols **1a** and **1b**.



1 **a**; R=CN, **b**; R=CO_2Et

Experimental

Melting points were taken on a "Unimelt" Thomas-Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were recorded on Perkin-Elmer 457 and 257 spectrophotometers for Nujol mulls. Ultraviolet spectra were determined with Unicam Model SP 800 and Perkin-Elmer 402 spectrophotometers and NMR spectra with a Perkin-Elmer R 32 instrument at 90 MHz and are reported in ppm relative to Me_4Si as internal standard. The mass spectra of the new compounds, obtained with a Varian Mat-311 spectrometer, contained the appropriate signals representing the molecular ions.

*(E)-1,1-Dicyano-2-hydroxy-3,4-diphenyl-1,3-butadiene (**1a**).* *(a)*: A magnetically stirred solution of sodium methoxide (0.60 g, 11 mmol) in absolute ethanol (100 ml) was treated under anhydrous conditions at room temperature first with malononitrile (0.86 g, 13 mmol) and then with DCP[16] (2.27 g, 11 mmol), whereupon the solution became yellow. After 12 h at room temperature most of the solvent was removed under reduced pressure, concentrated hydrochloric acid and water were added successively to the residue, and the remainder of the ethanol was distilled off. The resulting yellow solid was collected, washed with water, and recrystallised from aqueous ethanol or xylene to give **1a** (2.70 g, 90%) as pale yellow needles, mp 182 °C (decomp); IR 3170 (broad), 2214, 2209, and 1608 cm^{-1}; UV_{max} (CH_3CN) 259 (log ε 4.12) and 325 nm (4.06); UV_{max} (cyclohexane) 234, 258, and 338 nm; NMR (DMSO) δ=7.08—7.42 (m).

Found: C, 79.58; H, 4.22; N, 10.57%. Calcd for $C_{18}H_{12}N_2O$: C, 79.40; H, 4.44; N, 10.29%.

(b): A stirred solution of malononitrile (0.61 g, 9.2 mmol) in ethanolic sodium ethoxide, prepared from sodium (0.14 g, 6.1 mmol) and ethanol (50 ml), was slowly treated with (*E*)-2,3-diphenylpropenoyl chloride[14] (1.5 g, 6.1 mmol). After 12 h the solvent was removed under reduced pressure and the residue was stirred with 1 M hydrochloric acid (54 ml); the resulting oil was separated by decantation, washed with water, and dissolved in a small amount of aqueous 5% sodium carbonate. The solution was washed with ether (2×50 ml) and then acidified with 2 M hydrochloric acid; the resulting precipitate was recrystallised from xylene, giving **1a** (0.81 g, 48%), identical (IR spectrum, mp and mixed mp) with the previous product.

*Ethyl (2Z, 4E)-2-Cyano-3-hydroxy-4,5-diphenyl-2,4-pentadienoate (**1b**).* *(a)*: This compound was prepared analogously from ethyl cyanoacetate (1.774 g, 15.7 mmol), DCP (2.55 g, 12.4 mmol), sodium methoxide (0.756 g, 14 mmol), and ethanol (60 ml). After most of the solvent had been removed, dilute hydrochloric acid was added and the resulting oil was separated and crystallised from ethanol or cyclohexane to give **1b** (2.88 g, 73%) as colourless needless, mp 130 °C. IR 2210, 1655, and 1585 cm^{-1}; UV_{max} (CH_3CN) 265 (log ε 4.00) and 331 nm (4.18); UV_{max} (cyclohexane) 234 (4.07), 258 (3.96), and 338 nm (4.19); NMR ($CDCl_3$) δ=1.37 (t, *J*=7 Hz, 3H), 4.36 (q, *J*=7 Hz, 2H), 7.04—7.27 (m, 6H), 7.30—7.45 (m, 5H), and 7.57 (s, 1H).

Found: C, 75.28; H, 5.33; N, 4.64; OEt, 13.7%. Calcd for $C_{20}H_{17}NO_3$: C, 75.22; H, 5.37; N, 4.39; OEt, 14.1%.

(b): Diphenylpropenoyl chloride (1.5 g, 6.1 mmol) was condensed with ethyl cyanoacetate (1.5 g, 13.2 mmol), as described in (*b*) above, and the solvent was removed after 12 h. The residue was treated with 1 M hydrochloric acid and the resulting oil was washed with water (3×30 ml) and crystallised from ethanol to yield **1b** (0.55 g, 27%), identified by its IR spectrum, mp, and mixed mp.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (3), 767—768 (1977)

Further Studies on the Decarboxylation of Cinnamylidenemalonic Acid in Resorcinol and Catechol

M. A. HALEEM and M. A. HAKEEM
College of Engineering, University of Riyadh, Riyadh, Saudi Arabia

(Received March 17, 1976)

Synopsis. Kinetic data are reported for the decarboxylation of cinnamylidenemalonic acid in resorcinol and catechol. The activation parameters are culculated and compared with those previously reported for the decarboxylation of unsubstituted and substituted malonic acids.

The kinetics for decarboxylation of the derivatives of malonic acid[1] have been reported in our earlier investigations in resorcinol and catechol solvents. Bernoulli and Jakubowicz[2] studied the decarboxylation of malonic acid derivatives in aqueous solution in the range of 76—110 °C, including disubstituted malonic acids. Muus[3] reported the kinetic data of dibromomalonic acid in water at 45 °C. Clark[4] studied the decarboxylation of cinnamylidenemalonic and malonic acids in phenol, *m*-cresol, *p*-cresol and several aromatic amines. In the transition state of decarboxylation, it is considered that the carbonyl carbon atom of the reactant coordinates with a pair of unshared electrons on the nucleophilic atom of the solvent molecule and that these interactions between the reagents lower the enthalpy of activation ($\Delta H^{\neq}$) of the reaction. This principle has been tested on a number of compounds and it was thought to be worth-while to carry out the decarboxylation of cinnamylidenemalonic acid to see whether or not any exception could be found. For this purpose a kinetics study of the decarboxylation of cinnamylidenemalonic acid was carried out in resorcinol and catechol.

Experimental

Reagents. The cinnamylidenemalonic acid was prepared by Riaz Ahmed and Das Gupta in Sirohi College by condensation of cinnamaldehyde with malonic acid and purified several times with ethanol, mp 201 °C. Resorcinol and catechol were of analar reagent grade.

Apparatus and Technique. The reaction was usually followed by measuring the volume of carbon dioxide evolved. The apparatus and technique are similar to those described in previous articles.[5-7] About 20 g of resorcinol were separately taken in each run and 0.394 g of cinnamylidenemalonic acid weighed in a sample tube was placed on the movable probe inside the reactor. The set-up was then placed in a constant temperature oil-bath (±0.05 °C) and, when thermal equilibrium was established, the reaction was started by dropping the acid in the solvent. The evolved CO_2 was determined with a measuring burette filled with water saturated with carbon dioxide.

Results and Discussion

Plots of $\log(V_\infty - V_t)$ *vs.* t (where V_∞ is the volume of CO_2 after completion of the reaction and V_t is the volume at time t) showed straight lines, indicating a first order reaction. The rate constant at each temperature was calculated from the slope of the line and these values are tabulated in Table 1. The activation parameters calculated are tabulated in Table 2, along with the results of Clark in other solvents.

TABLE 1. APPARENT FIRST-ORDER RATE CONSTANTS FOR THE DECARBOXYLATION OF CINNAMYLIDENEMALONIC ACID IN RESORCINOL AND CATECHOL

Temp (°C)	No. of data pairs	$k_1 \times 10^5$ (s^{-1}) Catechol	Av. dev.	$k_1 \times 10^5$ (s^{-1}) Resorcinol	Av. dev.
140	5	3.63	±0.02	5.13	±0.01
145	3	5.37	±0.03	8.13	±0.02
150	2	7.76	±0.04	10.96	±0.02
155	3	12.02	±0.02	15.85	±0.02
160	4	16.60	±0.03	21.88	±0.03

In the same solvent, the $\Delta H^{\neq}$ was less for the decarboxylation of cinnamylidenemalonic acid that for malonic acid (see Table 2). Hall[8] found that the mono-anion and the free acid of malonic acid have different rates of decarboxylation in aqueous solution. In non-aqueous solvents the mono-ions may be few and a change is not expected to increase the rate of the process. However, carbon isotope effect studies on hydrogen malonate ions suggest that CO_2 originates from the COOH group and not from the COO^- group, in the decarboxylation in quinoline[9] or dioxane.[10]

As seen in Table 2 (lines 4 and 5) the entropy of activation ($\Delta S^{\neq}$) for the decarboxylation of cinnamylidenemalonic acid in catechol is more negative than in resorcinol, indicating that the activated complex is more stable in catechol than in resorcinol; this result is similar to that in 2,4-dihydroxybenzoic acid, xalic acid,[12] benzoic acid,[13] substituted benzoic acids,[14] oxanilic acid,[15] picolinic acid,[16] and hexylmalinic acid.[1] This proves that the adjacent hydroxyl groups of catechol are mainly responsible for forming the hydrogen bonding and for stabilizing the complex. The methyl and hydroxyl groups in *o*-cresol are adjacent and the entropy of activation is expected to be somewhat more negetive than in *p* and *m*-cresols. Unfortunately, no data is available. However, the comparative entropy of activation of malonic acid and butylmalonic acid[17] (Table 2, line 1) is in support of our conclusion. The decrease in entropy of activation in catechol is an indication of greater interaction towards the acid that in resorcinol. On the contrary, the malonic acid has almost the same enthalpy of activation, probaly due to a super-molecule cluster as proposed by Clark.[18] Substituted malonic acids gave less enthalpy of activation than malonic acid in most of the solvents.

Table 2. Comparative thermodynamic parameters

Solvents	Malonic acid		Cinnamylidenemalonic acid		Butylmalonic acid	
	$\Delta H^{\neq}$ a)	$\Delta S^{\neq}$ b)	$\Delta H^{\neq}$ a)	$\Delta S^{\neq}$ b)	$\Delta H^{\neq}$ a)	$\Delta S^{\neq}$ b)
o-Cresol[17]	24.2	−16.5	—	—	21.3	−22.8
m-Cresol[17]	32.3	+ 3.2	22.0	−25.2	29.7	− 2.3
p-Cresol[17]	29.8	− 2.4	27.1	−14.2	24.0	−15.8
Resorcinol	32.3	+ 1.95	27.08	−11.4	—	—
Catechol	32.2	+ 1.82	22.09	24.2	—	—

a) kcal/mol. b) kcal/mol K.

A plot of $\Delta H^{\neq}$ *vs.* $\Delta S^{\neq}$ for cinnamylidenemalonic acid is approximately linear. Such a linear relationship is evidence that the reaction mechanism in different phenolic solvents is almost the same.

The authors thank Dr. H. Siddiqui for helpful discussions and Dr. C. Balasubramanium for his valuable suggestions. We further thank Mr. Khalid Sayyid for reading this manuscript. Financial support from the Ministry of Education is acknowledged with gratitude.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (3), 769—770 (1977)

A Study of the Asymmetric Reaction of Methyloxirane with Acetic Acid Catalyzed by an Optically-Active Cobalt Complex

Michihiro ISHIMORI, Haruhiko AOI, Yasuyuki TEZUKA, and Teiji TSURUTA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received July 14, 1976)

Synopsis. A novel asymmetric reaction of methyloxirane with acetic acid catalyzed by an optically-active Co(salen)-type complex was explored. The products were identified to be propylene diacetate, 2-hydroxypropyl acetate, and 2-hydroxy-1-methylethyl acetate. The mechanistic features of this resolution-type reaction were characterized by the optical activities of the products and of the unchanged methyloxirane.

It has been reported that *N,N'*-disalicylidene-(1*R*,-2*R*)- 1,2-cyclohexanediaminatocobalt(II), $Co^{II}(sal)_2$(*R*-CHXDA), is a low-spin square-planar complex with a λ-conformation of the central chelate ring. Highly asymmetric selectivity was observed in a kinetic resolution of DL-methyloxirane using the $Co^{II}(sal)_2$(*R*-CHXDA)/$LiAlH_4$ system,[1] however, the isomerization of the selected methyloxirane to acetone was observed to occur by hydride shift involving electron transfer from the oxygen to the cobalt atom.[2]

It would be of interest and preparatively useful to explore a reaction in which an asymmetric center is maintained throughout the reaction. In the present series of our studies, the $Co^{II}(sal)_2$(*R*-CHXDA)/butyllithium/methyloxirane/acetic acid system has been found to give optically-active products. In this paper we would like to report the identification of the products and the mechanistic features of the reaction system.

Results and Discussion

Optically-active products I, II, and III, were found to be formed when a reaction was carried out at a mole ratio for Co^{II}: BuLi: methyloxirane: CH_3COOH of 1: 1: 150: 40 at 20 °C (the reaction conditions were as described in Table 1). The optical purity of the reacted methyloxirane calculated from the optical rotation of the unchanged methyloxirane, (L—D/L+D)rm, was 31% (conv. 11.8%). When $MgEt_2$, $ZnEt_2$, $LiAlH_4$, and $AlEt_3$ were used instead of BuLi, the (L—D/L+D)rm values were observed to be 18 (conv. 27.6%), 14 (2.9%), 8 (6.8%), and 0% (27.6%), respectively.

Products I, II, and III were isolated and respectively determined to be propylene diacetate, 2-hydroxypropyl acetate, and 2-hydroxy-1-methylethyl acetate, by mass spectral, elemental, and NMR analyses. Further confirmation of the products was obtained by comparison with authentic samples (see Experimental).

In order to clarify the features of the Co^{II}/BuLi/methyloxirane/CH_3COOH system, was carried out a series of experiments given in Tables 1 and 2. The ratio of the amount of product II $CH_3COOCH_2CH(CH_3)CH_2OH$ to the amounts of products II and III $CH_3COOCH(CH_3)CH_2OH$ was found to be 68—78% in the systems in Tables 1 and 2, indicating that the ring openings take place by acid-catalyzed reactions.[3] In accord with this observation, the systems involving little or no free acetic acid (Nos. 6 and 7 in Table 1) exhibit little or low reactivity for the ring opening reactions. The reaction of acetic acid with methyloxirane was catalyzed by the Co-complex, and presumably also by lithium acetate (formed by a rapid reaction of the Li moiety with CH_3COOH) as shown in Nos. 4, 5, and 9.

In Table 2, products I, II, and III were combined and hydrolyzed to 1,2-propanediol, their optical purities (L—D/L+D)mp* being about 11%. Assuming that III was formed by a complete inversion mechanism (CH–O opening),[3,5] the expected optical purity of 1,2-propanediol (L—D/L+D)cp was calculated from that of reacted methyloxirane (L—D/L+D)rm and the product ratio of III to II (see Table 2). Concerning the data at 25 °C (No. 2-1), the measured optical purity (L—D/L+D)mp is higher than the calculated value (L—D/L+D)cp, suggesting that another type of reaction such as oligomerization involving non-asymmetric selection [see the equations in d) of Table 1 and in e) of Table 2] may take place in parallel with the product(I/II/III)-forming reaction, a suggestion of which is supported by low material balance, (I+II+III)/reacted methyloxirane=78%. On the other hand, in Exp No. 2-2 of high material balance (98%) at 18 °C, the measured value (L—D/L+D)mp is lower than the calculated value; racemization is considered to take place to some extent during hydrolyzing of the products to 1,2-propanediol. The optical activity of pure D(+)-methyloxirane(neat) was assumed to be 15°, which, however, may be a higher value estimated to be 18.3°, using the highest $[\alpha]_{589}^{25}$ value (in $CHCl_3$) so far reported [14.05 (neat)×8.9 ($CHCl_3$)/7.0 ($CHCl_3$)];[6,7] the value of (L—D/L+D) cp (No. 2-2) would be 12.6% if this [α] value were used for [α_0].

It would be of interest to discuss some plausible mechanism for this asymmetric reaction, the mechanism of which is much different from the Co^{I}-catalyzed process observed for the systems $Co^{II}/LiAlH_4$/methyloxirane (L-selectivity, max. ee. 90%)[1] and Co^{II}/BuLi/methyloxirane (D-selectivity, 10%)[8] in dioxane/benzene solvents, where CH_2–O opening predominantly takes place, giving acetone by isomerization.

Comparing the data of No. 5 in Table 1 with those of Nos. 1, 2, 3, and 2-1, the chiral structure of the active species is suggested to be established by the Co^{II} species and acetic acid. In the reaction systems of Nos. 1, 2, 2-1, and 2-2 (addition order: Co^{II}/BuLi/methyloxirane/CH_3COOH), and of No. 3 (Co^{II}/BuLi/CH_3COOH/methyloxirane), there should be Co^{II} species produced

* (L—D/L+D)mp, (L—D/L+D)cp and (L—D/L+D)rm: optical purities measured for 1,2-propanediol, calculated for 1,2-propanediol, and measured for the reacted methyloxirane.

2—2	18	9.5	+0.451	28.7	5	73	22	+1.61	10.8	15.4

a) Co^{II}/BuLi/AcOH=1/1/100 (mole ratio). Co^{II} 0.70 mmol, MO 140 mmol, benzene (20 ml)/dioxane (10 ml), 7 days. b) Described as in Table 1. c) [α] (neat) for 1,2-propanediol obtained by hydrolysis of I, II, and III. d) Measured optical purity. $[\alpha_0]_{mp}^{25}=15.9°$ for pure (*S*)-(*L*)-(+)-1,2-propanediol (Ref. 4). e) Expected optical purity calcd from $(L-D/L+D)rm\times[(II-III)/(II+III)]$.

by radical decompositions of the CH_3COOCo^{III}-[8,9] and HCo^{I}-complexes formed,[10] respectively. However, the (L−D/L+D)rm value of run No. 5, in spite of the low conversion, is similar to those of Nos. 1, 2, and 2—1, which suggests that a Li compound may also play an important role in this asymmetric reaction, since (L−D/L+D)rm usually decreases with conversion in kinetic resolution.

As to the reaction of cobalt complexes with acetic acid, Clifford and Waters have reported the following equilibrium:[9,11]

$$RCOOH + Co^{III}(H_2O)_6 \rightleftharpoons RCOO\text{-}Co^{III}(OH_2)_5 + H_3O^+$$

It seems reasonable to consider the enhancement of acidity of the acetic acid interacting with the $Co^{II}(sal)_2$-(*R*-CHXDA) complex in the present study using an aprotic solvent, $[Co^{II}\cdots RCOO\overset{\delta-}{-}\overset{\delta+}{H}]$. The selective ring opening of L(−)-methyloxirane with the acetic acid interacting with the chiral Co^{II}-complex leads to the resolution of DL-methyloxirane and formation of the optically-active products in this Co^{II}/BuLi/methyloxirane/acetic acid system.

Experimental

Measurements. The NMR spectra were taken on a JEOL PS-100 spectrometer. The mass spectra were measured by electron impact method using a Hitachi RMU-6E instrument and by the chemical ionization method with a Jasco/Finnigan 3100 instrument. Optical rotations were observed by means of a Perkin-Elmer model 241 polarimeter.

Reagents. The Co^{II}-complex, BuLi, and other reagents were prepared and/or purified by the usual methods described elsewhere.[1,8]

Procedure. To a benzene/dioxane solution of Co^{II}-$(sal)_2$(*R*-CHXDA) and BuLi, methyloxirane and acetic acid were added. The mixture was sealed in an ampule under dry nitrogen and reacted with stirring at an appropriate temperature. After a given reaction time, the non-reacted methyloxirane and products were analyzed by GLC. The methyloxirane was recovered by distillation and the products were isolated using the preparative GLC technique. The NMR analyses for the products were satisfactory; $-CH(CH_3)CH_2-$ parts: $ABMX_3$(I), A_2BX_3(II), and A_2MX_3(III) spin systems.

Authentic Samples. Propylene diacetate(I) was prepared by the reaction between 1,2-propanediol (60 ml) and acetic anhydride (300 ml) with a few drops of sulfuric acid at 170—180 °C for 4.5 h,[12] bp 81 °C/14 mmHg; n_D^{20} 1.4110; MW 160 (mass). Found: C, 52.41; H, 7.47%. Calcd for $C_7H_{12}O_4$: C, 52.49; H, 7.55%. 2-Hydroxypropyl acetate(II) and 2-hydroxy-1-methylethyl acetate(III) were prepared by the reaction of methyloxirane (8 ml) with acetic acid (80 ml) at 35 °C for 8 days.[13] The products (II and III) were isolated as a mixture from the distillate at 86—88 °C/16 mmHg, by preparative GLC. MW 118 (mass). Found: C, 50.85; H, 8.55%. Calcd for $C_5H_{10}O_3$: C, 50.84; H, 8.53%.

Hydrolysis. Products I, II, and III (in Table 2) were combined and hydrolyzed with a 5-M KOH aq solution to give 1,2-propanediol, which was extracted with ethyl acetate.

The authors are grateful to Prof. M. Tsuchiya of the University of Tokyo for the mass spectral measurements and analysis and to Dr. N. Akimori of Hitachi Ltd. (Naka) for his technical advice on GLC analysis. We also thank Mr. T. Takeichi for performing some of the experiments and other assistance.

On the Lowest Triplet State of the Pyridazine Crystal

Charles J. MARZZACCO

Department of Physical Science, Rhode Island College, Providence, R. I. 02908, U. S. A.

(Received June 22, 1976)

Synopsis. The lowest singlet-triplet transition recently observed at 440 nm by Yamamoto, Takemura, and Baba for pyridazine in EPA is shown to correlate with the 410 nm transition observed by Hochstrasser and Marzzacco. This correlation is contrary to that of Yamamoto *et al.*

In a recent article in this journal, Yamamoto, Takemura, and Baba[1] reported on the singlet-triplet absorption of pyridazine measured by means of sensitized-phosphorescence excitation in EPA rigid-glass solution at 77 K. They observed weak broad intensity in the 370—440 nm spectral region and assigned it to two singlet-triplet absorption transitions. The main basis for the two transition assignment is that there are two absorption regions, a weaker one at 440—410 nm and a stronger one at 410—370 nm. These authors correlate the long wavelength system with the 445 nm singlet-triplet absorption observed by Innes *et al.*[2] for pyridazine vapor and the short wavelength system to the 410 nm singlet-triplet absorption observed by Hochstrasser and Marzzacco[3] in the pyridazine neat crystal. This assignment of the 410 nm crystal absorption to the $S_0 \rightarrow T_2$ transition is contrary to Hochstrasser and Marzzacco's analysis and would imply that they missed the observation of a lower energy singlet-triplet system, $S_0 \rightarrow T_1$. In correlating their spectral data for pyradazine in EPA with spectral data of pyridazine in two different phases, Yamamoto, Takemura, and Baba do not take into account the large blue shifts in the $n \rightarrow \pi^*$ transitions upon going from the vapor to the solid phase of pyridazine. In the pyridazine vapor, the origin of the $S_0 \rightarrow S_1$ ($^1B_1(n\pi^*)$) transition lies at 26649 cm^{-1} [2] whereas it is found at 28351 cm^{-1} in the crystal.[3,4] This huge blue shift of 1702 cm^{-1} may be due in part to the large dipole moment change accompanying the transition. The origin of the triplet system observed by Innes *et al.*[2] appears at 22487 cm^{-1} in the vapor and that in the crystal appears at 24251 cm^{-1}.[3] The similarity of this 1764 cm^{-1} shift observed in the triplet system to the 1702 cm^{-1} shift in the singlet system is strong evidence that the 440 nm vapor and the 410 nm crystal absorptions are both due to the same singlet-triplet transition namely $S_0 \rightarrow T_1$. This transition correlates with the 440 nm absorption observed by Yamamoto *et al.* In the phosphorescence excitation of pyridazine in EPA. It should also be noted that the singlet-triplet gap is about 4000 cm^{-1} in all three environments consistent with the lowest triplet being of the same character as the lowest singlet excited state namely $B_1(n\pi^*)$.

These comments are in no way meant to refute the suggestion of Yamamoto *et al.* that a second singlet-triplet transition occurs at 410 nm for pyridazine in EPA. Since transitions to other than the lowest excited state of a given multiplicity are often very broad,[5] such a transition would not have been observed under the high resolution spectrographs used by Innes *et al.* for the vapor work or by Hochstrasser and Marzzacco for the low temperature crystal work.

Polarography of α-Keto Acids in Aqueous and Nonaqueous Solutions

Mitsuaki OHMORI* and Masanosuke TAKAGI

Laboratory of Biophysical Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai 591
**Osaka City Institute of Public Health and Environmental Sciences, Tennoji-ku, Osaka 543*

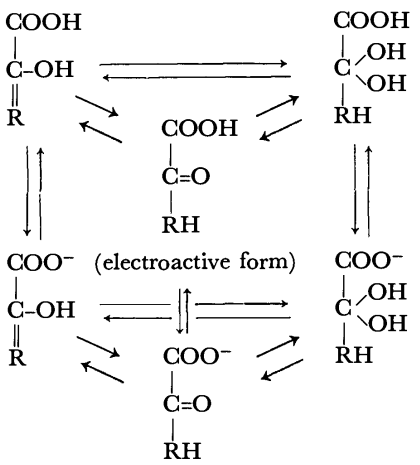
(Received March 22, 1976)

Phenylglyoxylic acid (I), phenylpyruvic acid (II), and pyruvic acid (III) were polarographically studied in buffer solutions and in DMF. Their reduction waves were reinvestigated in a wider pH range. Cyclic voltammetry showed that most electrode reactions of these acids in acidic pH are irreversible. pH-Dependence of $E_{1/2}$ and limiting current was studied. The observed decrease of the limiting currents of II and III in the strongly alkaline region was attributed to the dissociation of their corresponding enol forms. The *i-E* curves of these acids in DMF showed successive poorly-defined reduction waves, while those of the corresponding tetraethylammonium salts (TEA salts) were found to be much simpler in shape. A small oxidation wave was also observed with TEA salts of II and III, suggesting the presence of the enol form in DMF. The reduction products of I and its salt in DMF were studied by means of controlled potential electrolysis and NMR-spectroscopy. The electrode reaction mechanism of α-keto acids in nonaqueous solution is discussed, emphasizing the role of the free acid form as a proton-donor and the formation of a radical anion followed by a disproportionation reaction.

In polarographic investigations of biologically important α-keto acids, the first systematic study on the reduction of pyruvic acid was reported by Müller and Baumberger in 1939.[1] They found that the limiting currents of the two successive reduction waves change with pH, taking the form of an acid dissociation curve, the total current of the two waves being constant in the pH range studied. They attributed this phenomenon to the keto and enol forms of the acid in equilibrium in the buffer solutions.

It was pointed out by Brdička and Wiesner[2,3] that the two waves of pyruvic acid should be ascribed to the free acid and anion of the keto form and not to the enol form of the compound. The rate constants of the dissociation and recombination reactions of α-keto acids were determined by the polarographic method on the basis of the theory of kinetic current.[2-4] Because of this successful application of polarography, pyruvic acid has been considered to be representative of organic compounds whose rates of reaction in acid dissociation and recombination can thus be readily determined.

Later, participation of the hydrate form of α-keto acids in their polarographic behavior was suggested.[5-8] In 1961, Ono, Takagi, and Wasa[8] showed that the pH dependence of the limiting current of various α-keto acids could not be interpreted unless hydration and even enolization of the keto form when possible, in addition to the dissociation and recombination of the acid, were considered as factors in their equilibria in solution. The presented equilibria between an electroactive free keto form and various electroinactive ones should be considered in most cases even for the first reduction wave of α-keto acid.



We took up the polarography of α-keto acids from our interest in electro-reduction of biologically-important conjugated carbonyl compounds such as dehydro-L-ascorbic acid.[9-11] We chose three α-keto acids: phenylglyoxylic acid (I), with no possibility of enolization; phenylpyruvic acid (II), which definitely includes enol forms in aqueous equilibria; pyruvic acid (III), in which enolization is possible but occurs in aqueous solution in a restricted concentration range (<2%).[12]

Experimental

Chemicals. Phenylglyoxylic acid (I) was prepared according to the method previously described.[13] For phenylpyruvic acid (II), since the instability of the free acid even as crystal is undesirable for quantitative experiments, α-acetoamidocinnamic acid was prepared and stored.[14] It was converted into α-hydroxycinnamic acid (the enol form of II) before each experiment, by hydrolysis in a dilute hydrochloric acid solution.[15] The specimen recrystallized from distilled water was dissolved in 0.1 M (mol dm^{-3}) HCl containing 10% ethanol. This was used as the stock solution for polarography in aqueous solutions. Pyruvic acid (III) (analytical grade, Wako Pure Chemicals Co., Ltd., Osaka) was used without further purification.

Tetraethylammonium hydroxide for neutralizing α-keto acids to the corresponding tetraethylammonium salts was of reagent grade (10% aqueous solution, Wako Pure Chemicals Co.)

Tetraethylammonium perchlorate (TEAP) was prepared according to Fujinaga *et al.*[16]

Nonaqueous Solvents. *N,N*-Dimethylformamide (DMF) and acetonitrile (AN) were purified and dried as prescribed by Mann.[17]

As buffer solutions, McIlvaine buffer and other buffers were employed. The ionic strength of the aqueous electrolytic solutions was not always controlled to a definite value. For the sake of confirmation, it was adjusted to 0.5 by adding the requisite amount of KCl in certain experiments.

Apparatus. A Yanagimoto Polarograph Type PA-202

combined with a Yanagimoto *iR*-drop compensator was used for most polarographic measurements. An aqueous saturated calomel electrode (SCE) was used as a reference electrode. The characteristics of the capillaries used were $m=2.40$ mg/s, $t=3.75$ s in pH 6.12 McIlvaine buffer when the Hg level was 60 cm and -1.0 V was applied, and $m=1.16$ mg/s, $t=3.77$ s in DMF at -1.5 V and 50 cm mercury head. All the polarographic experiments were carried out at (25 ± 0.1)°C.

For controlled potential electrolysis, a Yanagimoto Controlled Potential Electrolyzer was employed. NMR Spectra of the electro-reduction products were recorded on a JEOL MH-60 Spectrometer.

For cyclic voltammetry, a Yanagimoto Polarovision PA-20 was combined with a function generator of NF Circuit Design Block Co., Ltd., Osaka, Model FG-121A. The working electrode was a hanging mercury drop of appropriate size.

Experimental Procedures. Polarographic measurements in aqueous solutions were carried out by conventional methods. However, when the α-keto acids were not stable in the given pH, the buffer solution in an electrolytic cell was previously deoxygenated by bubbling nitrogen gas. To this oxygen-free buffer solution, the required volume of the stock solution was added and the polarogram was taken immediately.

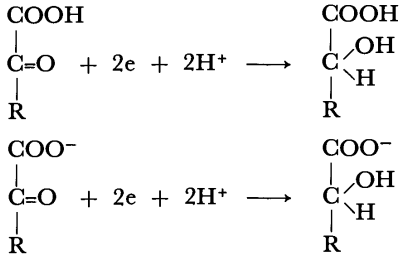
For nonaqueous solvents, a salt bridge to connect with the SCE was constructed of three gel layers, modifying the bridge devised by Takaoka.[18] The layers were 3% aqueous agar gel saturated with KCl, 3% agar gel containing 70% DMF, 30% H_2O, and 0.5 M TEAP, and 3% methylcellulose gel in DMF or in a DMF–AN mixture containing 0.5 M TEAP.

For the experiments with tetraethylammonium salts of α-keto acids, aqueous solutions of each α-keto acid were carefully neutralized to pH 7 by adding 10% aqueous solution of tetraethylammonium hydroxide. The neutralized solution was lyophyllized and stored in a refrigerator as a tetraethylammonium salt of the given α-keto acid.

Results and Discussion

Behavior of α-Keto Acids in Aqueous Buffer Solutions. In previous papers[8,19] the pH range was restricted to 0—8. Since additional data for enol forms of α-keto acids were expected in the alkaline range, this range was examined most carefully.

Change of Limiting Currents with pH. As shown in Figs. 1 and 2, each of the α-keto acids showed two reduction waves whose limiting currents change with pH.



We see that the first wave corresponds to the reduction of the free α-keto acid and the second to that of its anion form, involving the kinetic current due to the recombination of the anion form with hydrogen ion.[2-8]

In the reduction of I, with no possibility of enolization, the small decrease of the limiting current of the

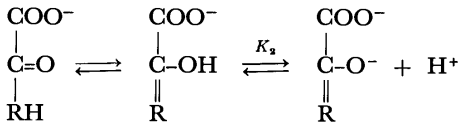
○: Phenylglyoxylic acid, ●: phenylpyruvic acid, ◒: pyruvic acid. I_0: the largest limiting current of each keto acid in acidic pH range was taken as I_0 for the corresponding acid.

first wave with decreasing pH in the acidic range may be attributed to the effect of hydration of the free acid.[8,19] The changes of the limiting current in the pH range above 4 can be interpreted by the kinetics of acid dissociation.[2-4]

However, for II, in which enolization was observed by UV spectroscopy,[8] a pronounced minimum in the limiting current-pH curve of the first wave near pH 1 was observed. A decrease of the limiting current of the second wave with pH could be seen in the pH range above 12. The decrease in the acidic range is due to the inactivation of the keto form by hydration and enolization, but that in the alkaline range may be explained by the inactivation of the anion by dissociation of the enol form and the increase of the enolate form with pH:



For III, decrease of the limiting current similar to that of II could be observed in both acidic and alkaline regions. The apparent pK_2 value of II and III is estimated to be *ca.* 13, provided that no kinetic current due to acid recombination is involved in such a high pH region. It is interesting that this pK_2 value is in good accordance with pK_3 value obtained by Bamann and Sethi for oxalacetic acid.[20]

Even in strongly alkaline pH, no decrease of the limiting current such as those of II and III was observed in I, in which enolization is not possible.

However, it is not clear whether the enolization of the free acid form would participate in the decrease of the limiting current of III in acidic region.

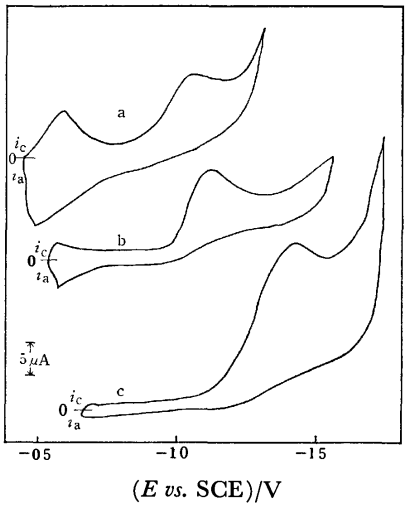

Fig. 5. Cyclic voltammetry of phenylglyoxylic acid in buffer solutions.
a: pH 1.13, b: pH 1.87, c: pH 4.95. Potential sweep: 2 V/s.

Relation between Half-wave Potentials of α-Keto Acids and pH. We see from Fig. 3 that each first wave of I, II, and III shows a linear relation of the $E_{1/2}$ with pH, the slopes being 84, 100, and 112 mV/pH, respectively, whereas the half-wave potentials of the second wave are almost unchanged with pH.

Reversibility of the Electrode Reaction. Since the presence of acid dissociation, enolization and hydration equilibria for three acids in the wide pH range makes analysis of the electrode reaction difficult, an acidic pH range was chosen in which the effects of acid recombination kinetics and dehydration kinetics, at least, can be minimized (pH near 1.1). In pH range below 1.1, increase of the limiting current with decreasing pH observed for II and III may be explained by the acid-catalyzed dehydration reaction of the hydrated free acid form.[8] The conventional logarithmic analysis

of the current-potential curve was applied. Each acid exhibited a linear relation with a slope of 31, 89, and 140 mV for I, II, and III, respectively (Fig. 4), suggesting the largest reversibility of the electrode reaction for I and the smallest for III. However, the results of cyclic voltammetry indicate no ideally reversible character of the electrode reaction, even for I, as seen in Fig. 5.

Behavior of α-Keto Acid in Nonaqueous Solvents. Polarograms of the Free α-Keto Acids: Polarograms of each α-keto acid examined, given in Fig. 6, show two or three poorly-defined reduction waves in DMF containing 0.1 M TEAP (curve a). Almost the same of results were obtained in AN. Of the three α-keto acids, the total wave height of I greatly exceeds that of II and III. The phenomena may be partly due to the presence of intramolecular proton donors, probably those of carboxylic groups. In order to eliminate the proton-donating effect of the carboxylic group, the acids were neutralized with tetraethylammonium hydroxide having the same cation as that of the supporting electrolyte. The results obtained with these tetraethylammonium salts of α-keto acids show much simpler reduction waves (curve b, Fig. 6). The limiting currents indicate a certain intermedial number of transferred electrons between 1 and 2 as compared with the 2-electron transferred current in aqueous solution, considering effects of viscosity on the limiting current in nonaqueous solvents.[21]

A small oxidation wave was observed for II and III, when the polarogram was taken with tetraethylammonium salt. The wave, which is absent in I, may be attributed to the oxidation of the enol form, but no further discussion is possible on this.

In order to examine the mechanism of electrode reactions of α-keto acids in nonaqueous solvents, electro-reduction products were studied with free acid and tetraethylammonium salt by applying controlled potential electrolysis. In preliminary experiments carried out with the three keto acids, only I gave reproducible results. This might be due to the instability of the reduction products. The experiment carried out with I is given in the following.

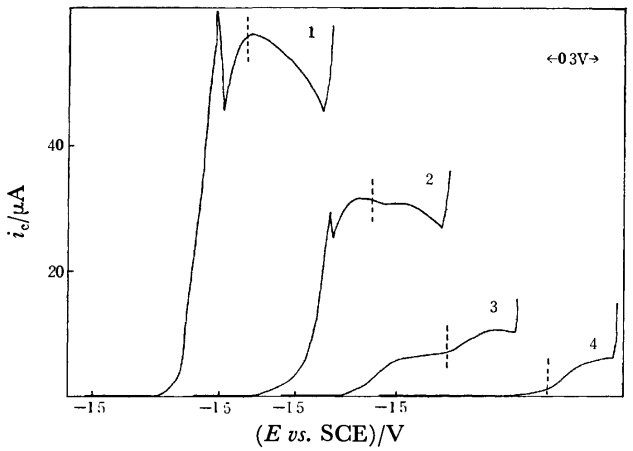

Fig. 7. Change of polarograms of phenylglyoxylic acid TEA salt by the controlled potential electrolysis in DMF.
Concn of the depolarizer *ca.* 1×10^{-2}M. Applied potential −2.4 V *vs.* SCE, 1: Before electrolysis, 2: 1 h, 3: 3 h, 4: 5 h.

Controlled potential electrolysis was carried out with the salt of I exhibiting a relatively simple current-potential curve. When started with a relatively high concentration of the depolarizer, the polarogram of the initial stage showed a pronounced maximum which had not been seen with dilute solutions of the same specimen (Fig. 7). The electrolysis was carried out at −2.4 V, using a mercury pool as the working electrode. After completion of the electrolysis at the applied potential, a small reduction wave appeared at a more negative potential, for which we have no explanation.

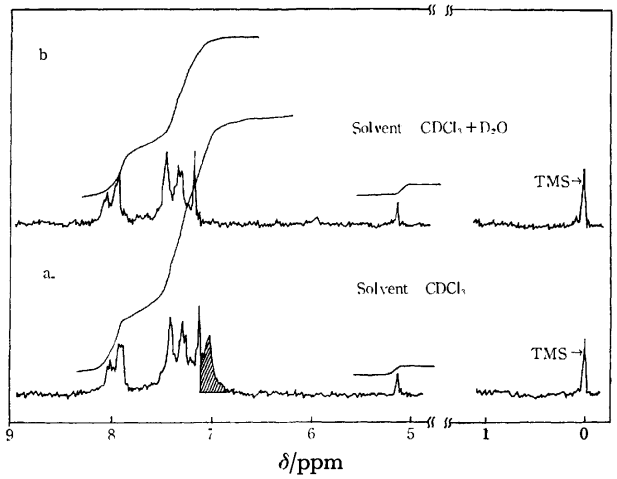

Fig. 8. NMR Spectra of the reduction products of phenylglyoxylic acid TEA salt in DMF at 60 MHz in $CDCl_3$.

The electrolyte solution after electrolysis was evaporated under reduced pressure, and the residue was acidified by addition of excess 0.5 M H_2SO_4 solution. The acid solution was then extracted with ethyl ether. The residue from the ether extract after evaporation was used for NMR measurement. The results are given in Fig. 8. In comparison with the spectrum of DL-mandelic acid,[22] a small signal at 5.13 ppm (a) can be attributed to the proton bound directly to the α-carbon of mandelic acid, while the proton of the alcoholic OH at the α-position seems to exhibit a signal near 7 ppm. It is not, however, a well-defined singlet, but a somewhat broad signal indicating the overlap with that of the carboxylic proton. The addition of D_2O to the electro-reduction product (Fig. 8-b) causes the disappearance of the hatched portion of Fig. 8-a. The change in the integrated absorption intensity caused by the addition of D_2O seems to correspond roughly to two protons, *i.e.*, carboxylic and hydroxyl, if we assume that the unchanged part is the total contribution of 5 phenyl protons. Consequently, the small signal at 5.13 ppm may indicate the formation of mandelic acid after the electrolysis, the yield of which may be 1/4 mol per 1 mol of the starting I. The remainder of the electrolytic product can therefore be attributed to the formation of the dimer.

The results suggest that the electrolytic product of I under these conditions is a mixture of DL-mandelic acid

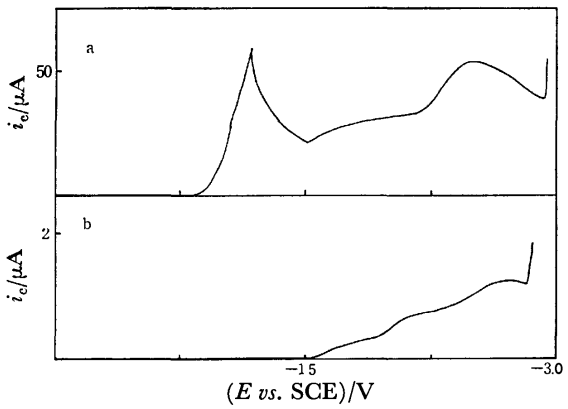

Fig. 9. Change of polarograms of phenyglyoxylic acid by controlled potential electrolysis in DMF.
Applied potential −1.2 V *vs.* SCE, a: before electrolysis (Concn of the depolarizer *ca.* 1.7×10^{-2}M), b: after the completion of the electrolysis (Concn of the depolarizer 6.6×10^{-4}M).

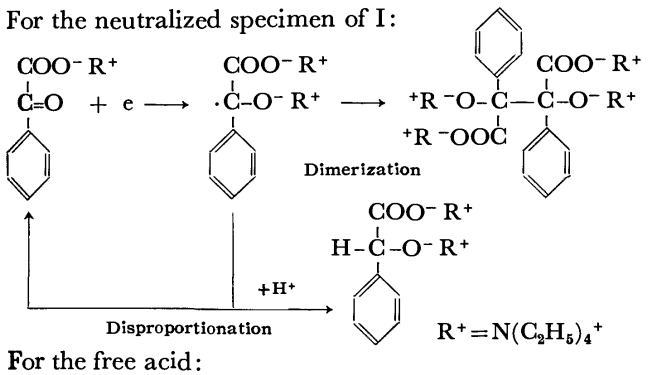
and the dimer due to the binding of two radicals from I

Electrolytic reduction was applied to the free acid form of I. The behavior of I in free acid form in relatively high concentrations differs a great deal from that in dilute concentrations (Fig. 9-a). −1. 2 V was chosen for the applied potential. The polarogram after electrolysis still shows poorly-defined reduction waves (Fig. 9-b).

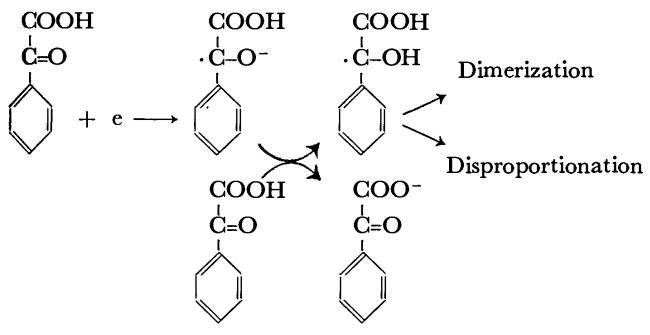
The electro-reduction product was extracted in the same manner as in the treatment of the neutralized I. The products were confirmed to be a mixture of DL-mandelic acid and the dimer but in a different ratio from that in the above case, more mandelic acid formation being detected with the free acid form than with the neutralized specimen of I.

Proposed Scheme of the Electrode Reaction. From the results, the following schemes are proposed for the principal process of the electrolytic reduction of I in DMF.

For the neutralized specimen of I:



For the free acid:



For the salt of I, one-electron reduction can produce the radical, most of which may be converted into the dimer. The remainder then exhibits a disproportionation reaction yielding the salts of I and mandelic acid, as is sometimes seen in the polarography of carbonyl groups in nonaqueous solvents,[23] provided that protons can be supplied from either DMF or TEAP.

The possibility of the involvement of two-electron reduction to form dianions is not completely excluded. However, since no well-defined stepwise reduction waves were observed, it is preferable to represent the simplified schemes using disproportionation only in the production of mandelic acid.

Electrolysis of the free acid would be more complicated than that of the salt. The effect of proton-donors should be considered. The radical anion formed in the first step of one-electron reduction might react with an unreacted molecule, and the protonated radical might perform the same kind of dimerization and disproportionation as in the case of the salt. The anion produced by the reaction of a radical with an unreacted free acid molecule would be reduced at a more negative potential than in the case of the original free acid.

Besides the electro-reduction of the carbonyl group, the discharge of protons liberated from carboxylic groups might be considered in the polarograms of the free acid. Since various chemical species having carboxylic groups can be produced as a result of the first electrode reaction, these acids with slightly different pK values may cause successive and poorly-defined, more negative waves.[24]

The Correlation of Steric Effects and Equilibrium Constants Evaluated from Lanthanoid-induced ^{1}H Shifts in Aniline Derivative-Eu(fod)$_3$ Systems

Masatoshi HIRAYAMA and Norio ISHIDA

Department of Chemistry, Ibaraki University, Bunkyo, Mito 310

(Received June 7, 1976)

The equilibrium constants, K_1 and K_2, between a series of *o*- and *N*-substituted anilines and Eu(fod)$_3$ in CCl_4 were evaluated using a four-parameter analysis of lanthanoid-induced shifts. It was found that the order of magnitudes of the values of K corrected for the effect of the pK_a-value well corresponds to the accessibility of the nitrogen lone-pair to the Eu ion on the complexation.

Ernst *et al.*[1] have found that in a series of *p*-substituted anilines, the Eu(dpm)$_3$-induced ^{1}H-NMR shifts (the so-called *S*-values) can be linearly correlated to its basicity, and furthermore, that no such relation exists in comparisons of amines with a different steric accessibility of the N-lone pair. However, one may consider that the use of pure intrinsic shifts[2-5] should lead to a more precise discussion of the correlation between shift and basicity. The intrinsic shifts should be related to the tightness of the interaction between the N-lone pair and the Eu ion, while the equilibrium between an Eu-chelate and amine depends on the frequency of occurrence of the interaction between these in solution. Therefore, it may be reasonable to consider that the magnitudes of the equilibrium constants should be dependent on both the basicity of amine and the steric accessibility of the N-lone pair to the Eu ion, as would be expected from the amounts of the lanthanoid-induced intrinsic shifts.

The present paper describes the correspondence between the equilibrium constants obtained from a least-squares analysis of the experimental Eu(fod)$_3$-induced shifts for a series of *o*- and *N*-substituted anilines and the predicted steric hindrance on complexing to Eu(fod)$_3$.

Experimental

All the liquid aniline derivatives used were distilled *in vacuo* and dried over molecular sieves, and 2-aminobiphenyl, recrystallized from ethanol. CCl_4 (spectro grade) dried over molecular sieves was used as the solvent without further purification. Eu(fod)$_3$ obtained commercially was used after drying over P_2O_5 in a vacuum desiccator.[6] In order to prepare the observed lanthanoid-induced shifts (LIS) *vs.* [Eu(fod)$_3$]/[Aniline] (ρ) plots, an original complex solution with the largest value of ρ was first prepared in a ^{1}H-NMR tube. This solution was then diluted step by step with an amine solution of concentration [S_0], while the NMR spectrum was measured. The total amine concentration [S_0] was 0.19 to 0.25 M, the largest ρ value 2.1 to 3.4, and the number of data points 19 to 22.

The NMR spectra were recorded on a Hitachi R-20A spectrometer at a probe temperature of 34 °C at 60 MHz in the frequency-swept mode using TMS as an internal standard.

All computations for the fitting analysis were carried out on HITAC-8800/8700 computers at the Computer Center of the University of Tokyo, except for some of which were performed on the HITAC-8250 computer at the Computer Center of Ibaraki University. The program used was LISA2 which was prepared by Shapiro *et al.* and partially modified in this laboratory.

Results and Discussion

Several *o*- and *N*-substituted anilines were chosen, because various degrees of steric hindrance may be expected with these amines upon complexing to Eu(fod)$_3$ in solution, and moreover, because the basicities (given in terms of pK_a-values) of these amines do not vary widely in magnitude.

The fitting analysis of the LIS *vs.* ρ plot was made by postulating an equilibrium system in which a self-association effect of Eu(fod)$_3$ was added to the two-step mechanism for the complexation of amine to Eu(fod)$_3$, that is, L+S$\leftrightarrows$LS (K_1), LS+S$\leftrightarrows$LS$_2$ (K_2) and L+L$\leftrightarrows$L$_2$ (K_L).[2,7] These examinations using K_L-values up to 100 led to a monotonic increase or decrease in the standard deviation (σ) with increasing K_L-value for most proton resonances, although in a few cases a minimum value of σ was reached within this range of K_L. Therefore, the inclusion of this effect may be unfavorable. All the systems studied were therefore analyzed assuming K_L to be zero. Table 1 shows the intrinsic shifts (δ_1 and δ_2) and the σ-values obtained by the least-squares analysis. It can be said that these σ-values are adequately small. Representative examples are shown in Figs. 1 and 2. Table 2 shows the pK_a-values[8] and the averages of the K-values, for which the K-values were weighted according to the δ_1-value of each resonance in the molecule. The variation of K-values obtained from the various resonance lines in the molecule was fairly large (with a standard deviation of 18 to 50%). However, the averaged K-value changed considerably with the kind, position and number of substituents on aniline, as seen from Table 2. Therefore, these values may be useful for a qualitative discussion of the steric effect.

Table 2 shows that the large variation of K-values does not correspond to the small change in pK_a-values. This clearly indicates that the pK_a-value does not play a major role in the equilibria and suggests that steric hindrance may predominantly affect the complexation. *o*-Toluidine, *o*-ethylaniline and 2,3- and 2,4-, and 2,5-xylidines have much smaller equilibrium constants (both K_1 and K_2) than does aniline, in spite of the fact that their pK_a-values are similar in magnitude to that of aniline. Of these five compounds, *o*-ethylaniline has extraordinarily small values of K_1 and K_2. Consequently, the four remaining derivatives may be regarded as a

a) Measured in ppm. b) Values for methyl protons. c) Values for *N*-methyl protons. d) Values for *N*-ethyl protons. e) Only four curves were thoroughly analyzed. f) This resonance line was assigned to the 2′ proton in the neighboring ring. This assignment is probably correct from the amount of shift and the coupling pattern of this line. g) It cannot be determined whether this signal should be assigned to 4H or 5H. h) $\left[\sum_{i=1}^{N}(\delta_{\mathrm{obsd},i}-\delta_{\mathrm{calcd},i})^2/(N-1)\right]^{1/2}$ measured in ppm, where δ_{obsd} and δ_{calcd} are the observed and calculated LIS, respectively and N is the number of data points.

group having K-values larger than those of *o*-ethylaniline, in view of the accuracy of the present estimates for the K. *N*-Methyl, *N*-ethyl, and *N,N*-dimethyl derivatives have particularly small values of K_1 and K_2, in contrast to their relatively large pK_a-values, especially those which are much smaller for the latter derivative. However, it cannot be clearly decided which K-values, those for the *N*-methyl or *N*-ethyl derivatives, are the larger. Thus, the order of magnitudes of K_1 and K_2, after correction for the effect of basicity, is as follows:

aniline > *o*-methyl > *o*-ethyl > *N*-methyl, *N*-ethyl > *N,N*-dimethyl.

2,6-Xylidine and 2-aminobiphenyl have comparatively small pK_a-values. It may be said that the K_1 for 2,6-xylidine is located between those for *o*-ethylaniline and the *N*-monoalkyl-derivatives, but that the K_2 is similar in magnitude to that for the *N*-monoalkyl-derivatives, and that the K_1 and K_2 for 2-aminobiphenyl are similar in magnitude to those for the *N*-monoalkyl-derivatives having larger pK_a-values. Thus, the order, corrected for the effect of the pK_a-values, is

o,o-dimethyl > *o*-phenyl > *N*-methyl, *N*-ethyl,

which holds for both K_1 and K_2. From the trend in the variation of K_1 relative to that of pK_a for the four *o*-methyl derivatives, it is difficult to consider that the equilibrium constant for *o*-ethylaniline, which is about six times that for 2,6-xylidine (for both K_1 and K_2), can be ascribed to the difference in the pK_a-values, which is about 0.5 (see Table 2). Consequently, the overall order of the K-values corrected for the effect of the pK_a-values, is[9]

aniline > *o*-methyl > *o*-ethyl > *o,o*-dimethyl > *o*-phenyl > *N*-methyl, *N*-ethyl > *N,N*-dimethyl.

On the other hand, one may assume that the aniline adduct of $Eu(fod)_3$ has a geometry similar to those of $Eu(dpm)_3Py_2$[10] and $Ho(dpm)_3(4\text{-picoline})_2$,[11] although correct information about the present adduct is not known. Then, on the basis of this assumption, the degrees of steric hindrance for these aniline derivatives

Table 2. The equilibrium constants, K_1 and K_2,[a] and pK_a[b]

Compound	K_1	K_2	pK_a
o-Toluidine	1188	109	4.39
o-Ethylaniline	282	65	4.37

N,*N*-dimethylaniline[e]	<0.1	—	5.07
N,*N*-Diethylaniline[f]	—	—	5.11
Aniline[g]	5230	582	4.62

a) These are average values in which the values of K are weighted according to the value of δ_1 for each resonance. When convergence of a K-value was unobtainable in the fitting analysis or one K-value was extremely different in magnitude from the other K-values for the resonances of the molecule, this value was excluded from the estimate of the averages. b) These values were taken from Ref. 8. c) Since the pK_a-value of *N*-ethyl-*m*-toluidine could not be found in the literature, that of *N*-ethylaniline is listed. This value is situated between 4.96 (*N*-ethyl-*o*-toluidine) and 5.72 (*N*-ethyl-*p*-toluidine) and appears to be plausible in analogy with the pK_a-values of aniline and toluidines: 4.62 (aniline), 4.39 (*o*-toluidine), 4.69 (*m*-toluidine), and 5.12 (*p*-toluidine). d) The averages of the K-values for only three resonances. e) All the values of K_2, δ_1 and δ_2 are very unreliable because the observed shifts are too small. However, the K_1-value is consistently less than 0.1 for all the protons. f)Analysis is almost impossible due to further small shift values. g) Listed for comparison with the present compounds, as a representative which may be considered to have no particular effect due to the steric hindrance.

have been discussed using the Eu-N distance, 2.65 Å,[10,12] and the angle (θ) between the Eu-N and N-C bonds, 120—140°.[12] Such a comparison of steric hindrance was made qualitatively based mainly on the access of substituent groups to several oxygen atoms of the β-diketonato ligands in both the 1:1 and 1:2 adducts. One may recognize that the order is unaffected by a slight variation of the geometry, and thus

$$\text{aniline} < o\text{-methyl} < o\text{-ethyl} < o\text{-phenyl}$$

holds for steric hindrance. For *o*-derivatives, in order to decrease the steric effect, the N-C bond can be slightly twisted so as to increase the distances between the *o*-substituent group and several oxygen atoms, at a small expense of the π-overlap in the N-C bond. However, no such possibility can be expected for the complexation of 2,6-xylidine.[13] Thus, it seems reasonable to consider that the steric effect for 2,6-xylidine is more rigorous than that for *o*-ethylaniline, because the methyl group in the ethyl group can be oriented in the direction away from the oxygen atoms. In *o*-aminobiphenyl, the two rings are considerably twisted with respect to each other and the neighboring ring may be fairly close to the *t*-butyl or heptafluoropropyl group. These must cause a fairly large hindrance, although whether 2,6-xylidine

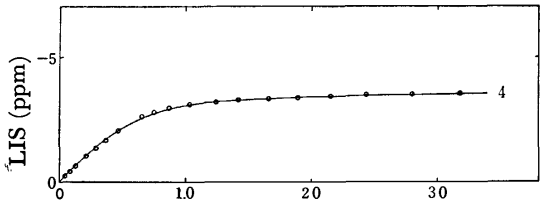

Fig. 1 (a)

Fig. 1. Results of theoretical fits of the two step mechanism, L+S⇄LS, LS+S⇄LS$_2$, to the observed Eu(fod)$_3$-induced data for (a) 2,5-xylidine at $[S_0]=0.25$ M and (b) *N*-methyl-*m*-toluidine at $[S_0]=0.19$ M. The numbers indicate the positions.
○, ●: The observed data.

or *o*-aminobiphenyl has the larger steric effect cannot be determined. In *N*-methyl, *N*-ethyl, and *N,N*-dimethyl derivatives, the *N*-methyl and *N*-methylene groups generally become much closer to some of the oxygen atoms than the ring-substituents in the other compounds, even though the degree of proximity is appreciably sensitive to a slight variation of θ. Such a situation allows us to consider that these *N*-derivatives are expected to have a steric effect that is considerably larger than those for the other amines mentioned above. *N,N*-Dimethylaniline should be less accessible to the Eu ion than the *N*-methyl or *N*-ethyl aniline, for the same reason as in the case of 2,6-xylidine.

Thus, it was found that the K_1- and K_2-values obtained from the present investigation in the aniline derivative–$Eu(fod)_3$ systems correspond well to the predicted steric accessibility of the *N*-lone pair to $Eu(fod)_3$, without any large discrepancy.

A quantitative correlation of the intrinsic shifts with the steric hindrance in the present systems is difficult to elucidate for the following reasons: (1) the steric effect possibly alters the geometry of the adduct, and consequently, the intramolecular distribution of the dipolar shifts may be changed, and (2) the variation of the extent of the steric effect may lead to a change in the cs-contribution to the LIS.

The authors would like to express their grateful appreciation to Professor B. L. Shapiro for providing them with the LISA2 program.

Photoelectrochemical Behavior of n-Type TiO_2 and Other Semiconductor Electrodes in Acetonitrile Solutions Containing Various Aromatic Amines

Kenji NAKATANI and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received November 18, 1976)

The electrode behavior of n-type TiO_2 in acetonitrile solutions containing one of a variety of aromatic amines under illumination has been investigated. The onset potential of the anodic photocurrent leading to the oxidation of the amines changed from the most negative −0.51 V *vs.* SCE for *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine to the least negative −0.27 V for aniline. These values parallel the change of the flat band potential by the amine and become more negative as the ionization potential of the amine decreases. The influence of the amine on the flat band potentials of ZnO, CdS, and GaP was also studied and found to be much less than in the case of TiO_2. From these results, the reason for the change of the flat band potential in the case of TiO_2 is attributed to a specific charge transfer interaction between the semiconductor and the amine.

The electro-photochemical behavior of semiconductor electrodes in aqueous solutions has been extensively studied for various semiconductors such as GaP,[2] ZnO,[3,4] CdS,[5,6] TiO_2,[7-9] and others.[13] The photocurrents observed for the n-type semiconductors such as GaP, ZnO and CdS under illumination are attributed to the anodic dissolution of the electrodes. Honda and Fujishima found that the n-type TiO_2 electrode is electrochemically stable and the electrode reaction under illumination is the decomposition of water.[7,8] A similar photoeffect may also play a role in organic electrosynthesis using sunlight as an energy source. However, very few studies have been made on the electrode behavior of semiconductors in non-aqueous solutions,[14] although it seems important for the elucidation of semiconductor properties as well as for use in organic synthesis.

We have now carried out studies in this relatively unexplored area and, in this paper, report the results on the n-type TiO_2 electrodes under illumination in acetonitrile solutions.

Experimental

Single crystals of TiO_2 in the form of a wafer with optically flat (001) surfaces were obtained from Nakazumi Crystals Corp. The electrodes were constructed in a way similar to those used in our previous work.[9] Figure 1 shows the experimental setup. High purity nitrogen gas was bubbled through the solution in order to remove oxygen. A saturated calomel electrode (SCE) was used as the reference electrode. Acetonitrile was purified according to the literature.[10] In order to prevent contamination by water, the SCE was placed in a vessel connected with a tube to the electrochemical cell. Both the vessel and the tube were filled with the same solution as that in the cell. Lithium perchlorate, dried at 180 °C for 6 h *in vacuo*, was used as a supporting electrolyte at the concentration of 0.1 M (mol dm^{-3}). Aromatic amines were purified from reagent grade materials by recrystallization or sublimation *in vacuo*. A 250 W super high pressure mercury lamp was used as the light source. The light was passed through a Toshiba UV-35 filter. A Hokutodenko HA 101 potentiostat and a Shimadzu VM 101 voltammeter were used for measurements of the voltage and current of the photo-cells. Differential capacitance measurements were made by use of a Yokogawa Hewlet-Packard 4265B Universal Bridge.

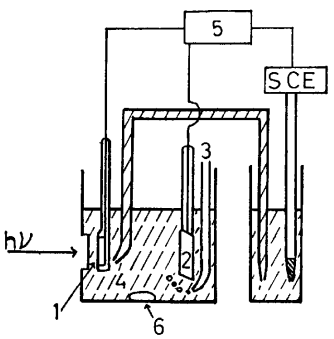

Fig. 1. Schematic diagram of the electrochemical cell. 1: TiO_2 electrode, 2: Pt electrode, 3: N_2 gas inlet, 4: CH_3CN solution containing 0.1 M $LiClO_4$, 5: potentiostat, 6: magnetic stirrer.

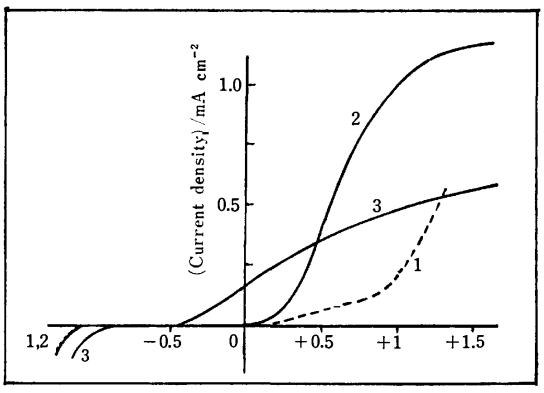
Results

Figure 2 shows typical current-voltage curves. In the dark, no anodic current was observed. From curves 1 and 2, we can see that the photocurrent for the acetonitrile solution shows no change in the onset potential, but an increase in the saturation current by addition of 0.8 M water. This result shows that the anodic photocurrent observed in the range 0 to +1 V, in the



(Potential)/V *vs.* SCE

absence of amine, is not due to the oxidation of the solvent but to the decomposition of water dissolved in a trace amount. On the other hand, the anodic photocurrent of the solution containing 10^{-3} M *p*-phenylenediamine (*p*-PD) appeared at around −0.4 V, showing that the onset potential of the photocurrent shifted to the cathodic side by *ca.* 0.4 V by the addition of the amine. The onset potentials of the photocurrents for the other amines, *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD), *N,N*-dimethyl-*p*-phenylenediamine (DMPD), *N,N*-dimethylaniline (DMA), *p*-toluidine (PTD) and aniline (AN), differed from each other as shown in Fig. 3.

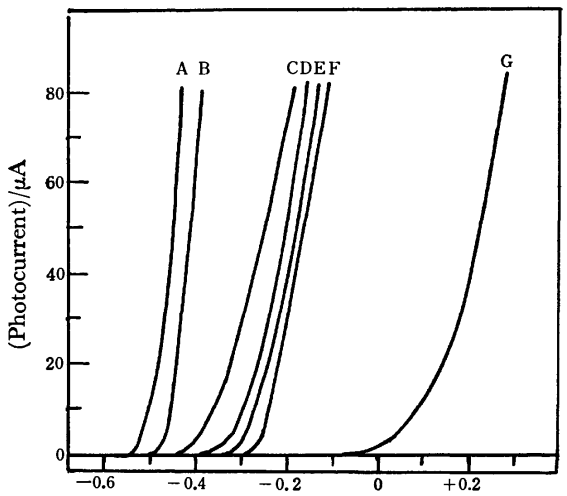

Fig. 3. Photocurrent-potential curves for the TiO_2 electrode in acetonitrile solutions containing 10^{-3} M amines.
A: TMPD, B: DMPD, C: *p*-PD, D: DMA, E: *p*-TD, F: AN, G: 0.8 M H_2O.

Although the onset potential is usually regarded to be approximatly equal to the flat-band potential (V_{fb}), more exact information about V_{fb} can be obtained from the differential capacitance measurements. A plot of $1/C^2$ against the electrode potential, V, according to the Schottky-Mott equation[1]

$$1/C^2 = (2/\varepsilon\varepsilon_0 eN_D)(V - V_{fb} - kT/e) \quad (1)$$

gives the flat band potential and the donor density (N_D), where C represents the space charge capacitance, e the electronic charge, ε the dielectric constant of the TiO_2, and ε_0 the permittivity of vacuum. Some typical results of the measurements are shown in Fig. 4. The

donor concentration determined from these plots by assuming ε for TiO_2 to be 120[12] is about 8×10^{18} cm^{-3}. Though the V_{fb} for the TiO_2 in acetonitrile obtained from the Schottky-Mott plot varied with specimen between −0.64 V and −1.1 V (the value most frequently obtained being *ca.* −1.0 V), a constant shift of V_{fb} to the cathodic direction was obtained by adding an amine into the solution as shown by ΔV_{fb} in Table 1. An almost constant value was obtained for the V_{fb} for the aqueous solution of 0.1 M $LiClO_4$ to be −0.80 V. The onset potentials of the photocurrents, V_0, given in Table 1 are more positive than the V_{fb} in each of the

corresponding solutions. However, the onset potentials for various amines parallel the corresponding ΔV_{fb} values. This change in V_{fb} by the addition of the amine does not occur in water but only in the acetonitrile solutions. The sequence of the V_{fb}'s for various amines did not change even when the supporting electrolyte concentration was increased from 0.1 to 0.4 M or the donor concentration of the TiO_2 was altered. Table 2 gives the V_{fb} values for other semiconductors, CdS, GaP, and ZnO in acetonitrile solutions with and without 2×10^{-3} M *p*-PD.

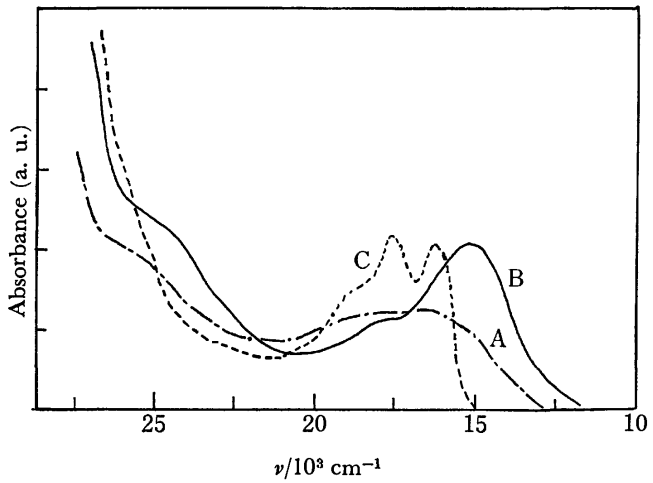

Fig. 5. The absorption spectra of acetonitrile solutions of 0.1 M $LiClO_4$ and 10^{-3} M amine after photo-anodic reactions A: *p*-PD, B: DMPD, C: TMPD.

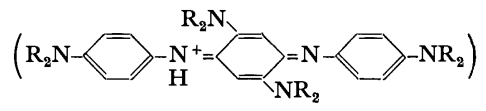
The absorption spectra of the acetonitrile solutions were measured after letting the anodic photocurrent flow in the cell in order to identify the reaction products formed from the amines (Fig. 5). The spectra for the case of *p*-PD and DMPD resemble those of the Bandrowski's bases



formed by the oxidation of the respective amine.[16] As it has been established that these Bandrowski's bases are formed by the reactions between the radical cations *p*-PD$^+$ or TMPD$^+$ and the neutral amines, the detection of the Bandrowski's bases shows that the primary products of the photo-anodic reactions at the electrodes are the cation radicals of the amines. The absorption spectrum, in the case of TMPD, resembles that of TMPD$^+$.[17] On the other hand, for aniline and dimethylaniline, the solutions remained colorless, a black solid substance being formed on the Pt surface, presumably the condensation reaction products formed from oxidized amines.

Discussion

On excitation of the TiO_2 electrode at the wavelength corresponding to the band gap (3.0 eV),[7] electrons are promoted from the valence band to the conduction band and driven inward by the electric field existing in the space charge layer, while the holes created in the valence band move onto the surface and presumably oxidize the molecules having oxidation potentials lower than the higher limit of the valence band (E_v) at the surface. The ionization potentials in acetonitrile, I_p(sol), of the amines used in this experiment are calculated to be 5.8 eV for TMPD and 6.3 eV for AN by the use of Born's equation,

$$I_p(\text{sol}) = I_p(\text{g}) - (e^2/2r)(1-1/n^2)$$

where I_p(g) represents the gas phase ionization potential of the amine, r the radius of the amine molecule, and n the refractive index of acetonitrile.[20]

The lower limit of the conduction band of TiO_2 (E_c) is calculated to be 3.7 eV by use of the flat band potential −1.0 V (*vs.* SCE) and the absolute energy level of SCE, *ca.* 4.7 eV.[21] Then, the higher limit of the valence band of the TiO_2 (E_v) is obtained to be *ca.* 6.7 eV using the band gap energy 3.0 eV of TiO_2.[7] Therefore, it is reasonable to assume that the amines are oxidized by the photoexcited TiO_2 electrode. The oxidation of the amine was experimentally verified from the absorption spectra of the solutions after illumination at the closed circuit condition, which showed the spectra of the oxidation products.

As described earlier, the onset potentials of the photocurrents and the flat band potentials are changed by adding amines to the solution. The magnitudes of the changes of these two types of potentials are parallel to each other and both become more negative, as the ionization potential of the amine is lowered. The flat band potential, V_{fb}, of the TiO_2 electrode has been reported to shift to the more negative direction with increasing pH of the electrolyte solution.[11] This shift of V_{fb} is explained by taking account of the increase of the negative charge at the surface of the TiO_2, which is produced by the following proton dissociation equilibrium.

It was also reported that the V_{fb}'s of ZnO[15] and GaP[19] have the similar pH dependence as that of the TiO_2, while CdS does not.[11]

It might be concluded therefore that the shift of V_{fb} of TiO_2 is caused by the enhanced proton dissociation by the amine. In order to verify this, we studied the V_{fb} of TiO_2 by changing the concentration of *p*-toluidine, whose basicity is relatively weak, from 10^{-6} to 5×10^{-2} M in the acetonitrile solution. The V_{fb} changed from −0.64 to −0.9 V as the amine concentration increased from 10^{-6} to 10^{-5} M and then remained almost constant up to the amine concentration of 5×10^{-2} M. This result shows that if the proton dissociation were to occur by the addition of the amine, it comes to equilibrium at a very small concentration

of amine. Therefore, it is clear that the difference of the ΔV_{fb} given in Table 1, which are for solutions containing 2×10^{-3} M amine, is not explained by the proton dissociation equilibrium.

As shown in Table 2, the change of V_{fb} for TiO_2 by the addition of *p*-PD is indeed large. But the change for GaP is much less and there is hardly any change for ZnO and for CdS. These results for GaP and especially for ZnO show also that the change in V_{fb} for these semiconductors cannot be explained by the proton dissociation equilibrium.

It seems, therefore, that there is a specific interaction, which affects the V_{fb}, between the semiconductor and the amine on the interface. One possibility is a charge transfer interaction. If one assumes that the TiO_2 electrode has unoccupied intrinsic surface states, the charge transfer interaction (S···D) between the amine (D) and the surface state (S) might bring about a surface dipole on the semiconductor, and cause a potential drop at the interface. Consequently, the V_{fb} of the TiO_2 electrode will shift towards the negative direction. The degree of the shift at a given concentration of amine depends on the degree of charge transfer between the amine and the surface state. The stronger the charge transfer force is, the greater is the negative shift of V_{fb}. The degree of charge transfer, X, is expressed approximately as $\sqrt{X}=\beta/(I_p-W_s)$,[18] where $-W_s$ is the energy of the surface state, I_p the ionization potential of the amine, and β the interaction energy between the ground state (S···D) and the ionized state ($S^-\cdots D^+$). It can then be expected that the change of the onset potential for the anodic photocurrent and that of V_{fb} will be proportional to $\sqrt{X}$. As shown in Fig. 6,

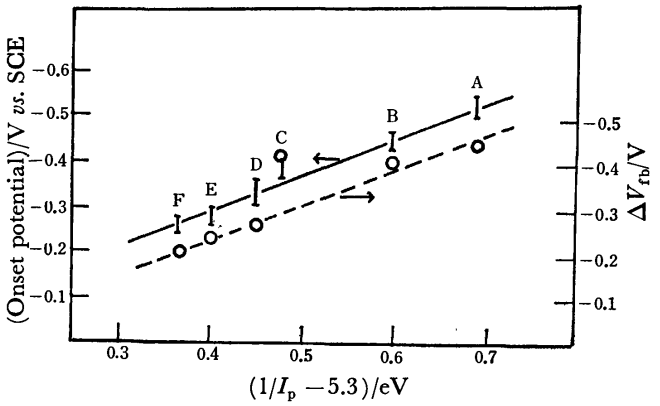


Fig. 6. Dependence of the onset potential of the photocurrent and that of V_{fb} on the ionization potential of amines.
A: TMPD, B: DMPD, C: *p*-PD, D: DMA, E: *p*-TD, F: AN.

straight lines are obtained for the plots of V_0 and ΔV_{fb} *vs.* $\sqrt{X}$ by assuming W_s to be 5.3 eV, which seems to be of a fairly reasonable magnitude (Fig. 6). These results seem to support our present interpretation by use of the specific charge transfer interaction of the surface state with the amine.

As stated in the Results, the V_{fb} of the TiO_2 electrode in aqueous solution does not change by addition of the amine. This is explained by taking account of the

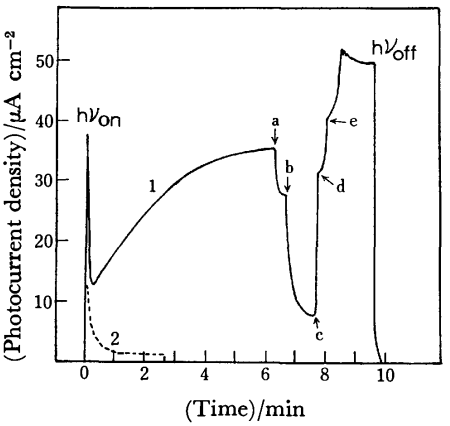

Fig. 7. Change of the photocurrent density of acetonitrile solution containing TMPD with time.
1: 0.1 M CH_3CN solution of $LiClO_4$, 2: the same solution containing 10^{-3} M TMPD.

hydrogen bonding of water, or protonation, with amine, which decreases or prevents the charge transfer interaction of the amine with TiO_2.

Performance of the Photoelectric Cell. The performance of the system $<TiO_2|CH_3CN-amine|\ Pt>$ as a photocell has been examined with TMPD used as the amine. The photocurrent for 10^{-3} M acetonitrile solution of TMPD changes with time as shown in Fig. 7. It shows a spike just after illumination, which might be attributable to the charging on the surface of the Pt electrode because there is initially no cathode active species in the solution. With continued illumination, the generation of $TMPD^+$ is observed by the development of blue color in the solution, and the photocurrent increases gradually until saturation. When the nitrogen gas bubbling was stopped, the photocurrent decreased immediately, reappearing on stirring. These results suggest that the photocurrent depends on the diffusion rate of the charge carrier, the amine cation, in the solution. The photocurrent for the acetonitrile solution containing 5×10^{-4} M TMPD became constant after 6 min, began to decrease gradually after 20 min, and became one half

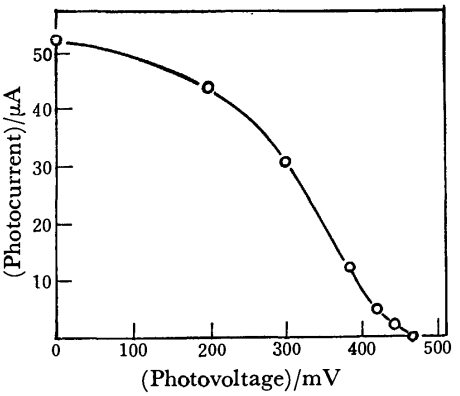

Fig. 8. The photocurrent-photovoltage curve for a cell $<TiO_2\ |CH_3CN(TMPD)|\ Pt>$. Illumination intensity was 4×10^{-3} W/cm².
The concentration of TMPD is 10^{-3} M.

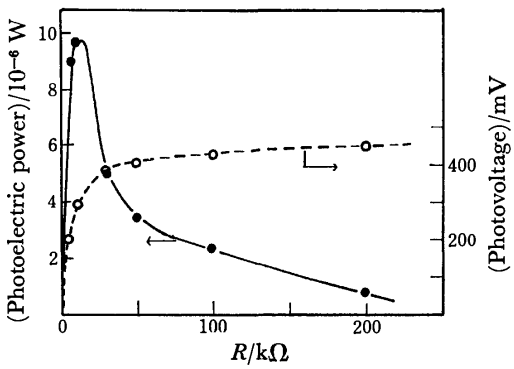

Fig. 9. The photoelectric power and photovoltages *vs.* outer resistance for same cell at the same working conditions as that of Fig. 8.

after about 3 h. This decrease of the photocurrent was proportional to the decrease of the absorbance of $TMPD^+$. These results indicate that $TMPD^+$ undergoes further reaction to form an electrochemically inactive colorless product.

Figure 8 shows a photocurrent-photovoltage curve obtained by illuminating the TiO_2 electrode in the cell $<TiO_2|CH_3CN\text{–}TMPD|Pt>$ with the electrodes connected by a variable resistance (R). Figure 9 shows the corresponding relation between photogenerated power output ($i \times V$) and the resistance, R. The maximum power was obtained to be 9.6×10^{-6} W/cm^2 at $R=10$ kΩ. The power efficiency with respect to the light intensity (4×10^{-3} W/cm^2) was 2.4×10^{-3}.

It was found that the CdS electrode which has a smaller band gap (2.4 eV) than TiO_2 can also be used in a similar photocell. In this case, the oxidation reaction of TMPD occured in competition with the dissolution reaction of the CdS electrode.

Performance of Thermal Separation Column with Vertical Barriers

Kazuo SASAKI, Yoshio HIRANO, and Seiji TAO
Department of Applied Chemistry, Hiroshima University, Hiroshima 730
(Received August 6, 1976)

The relative performance of a new type thermal separation column has been reinvestigated. It was concluded that a column having a couple of vertical barriers is superior to an ordinary open column working under the same temperature gradient.

In previous papers[1,2] reports were given on the performance of a new type thermal separation column in which a couple of vertical screens are installed as flow barriers. The discussion given therewith was found to contain some defects.[3] The column consisted of a couple of cylindrical screens suspended coaxially between double cylinders each of which served as a hot and cold plate. Two different views can be considered in evaluating the performance of this type of column.

(1) The screens are merely inserted in a column space of width $2w$.

(2) Two additional spaces are produced outside the pair of screens.

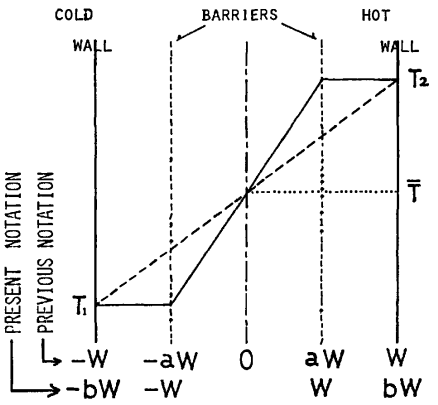

Fig. 1. Basic model of the column with vertical barriers. T_1; Temperature at cold wall, T_2; temperature at hot wall, T; mean temperature.

The reason for the confusing concept is closely related to the assumption as regards mathematical treatment, the underlying assumption being that the temperature gradient is located only over the space between the two screens and the spaces outside the screens are isothermal (Fig. 1). If the mathematical model is realized in an actual column, a larger temperature gradient will be obtained (solid line, Fig. 1) in the space between the two screens as compared with the case in which the same temperature difference is applied over the whole apparatus (dotted line). This will lead to an enhanced separation. The question arises: Is the better performance observed with the barrier-column simply caused by the enhanced temperature gradient? Comparison should be made under the same temperature gradient but not the temperature difference.

If the temperature gradient developed in the column is not much influenced by the installation of vertical barriers view (1) should be adopted. We thus need to use two reference columns for discussing the relative performance of the barrier-column. In order to fulfill the requirement of the same temperature gradient, one of the references should be an open column having two walls located at positions where screens are located in the barrier-column (narrower reference column). The other is an open column having the same geometry as that of the barrier-column (wider reference column). The previous discussion was developed only with the latter reference for the reason that the actual temperature gradient in the barrier-column might differ from that of the mathematical model, and that the externally applied temperature difference might be divided over each sub-column. It is also difficult to compare the performance when we take the narrower reference column with a different geometry as a standard.

Experimental

In order to confirm the reliability of the theory we have constructed an open column (narrower reference). Dimensions and characteristic constants of the two reference columns together with those for the barrier-columns are given in Table 1, and a schematic diagram of the reference columns in Fig. 2. The structure of the barrier-column and details of the experiments were reported.[2]

a) Corrected for cylindricity. b) Relaxation time.

Results and Discussion

If we take view (2) the narrower reference column should be taken as the standard. A slight modification of the theory is advantageous. It is convenient to use the reciprocal $b(=1/a)$ of design parameter a, which indicates the relative location of barriers against the hot and cold walls.

The basic coefficients of transport are then expressed as follows in terms of b:

$$H' = \{2(b-1)^3+1\}H \quad (1)$$

$$K_c' = \{4(b+1)(b-1)^6+4(b-1)^3+1\}K_c \quad (2)$$

$$K_d' = b\cdot K_d \quad (3)$$

where symbols with primes are for the barriered column and those without ones are for the reference column. The quality factor (Eq. 24, Ref. 1) thus becomes

$$\frac{A'}{A} = \frac{H'/2K_c'}{H/2K_c} = \frac{2(b-1)^3+1}{4(b+1)(b-1)^6+4(b-1)^3+1}, \quad (4)$$

A(or A') defined, respectively, by

$$A = H/2(K_c+K_d) \quad (5)$$

is a parameter appearing in the definition of equilibrium separation factor

$$q_e = e^{2AL}. \quad (6)$$

In the derivation of Eq. 4, the contribution of K_d (and K_d') was ignored. Equation 4 is graphically represented in Fig. 3 against parameter b. Experimental value of A'/A referred to the narrower reference was found to be 0.242, *ca.* 40% greater than the theoretical one, 0.175, at $b=2.0$ (*i.e.*, $a=1/2$). A 40% deviation is acceptable if local inhomogeneity in both the column structure and temperature distribution is taken into consideration. The result is in line with the theory. We see that the quality factor A'/A decreases with increasing b. This was expected, since gases in the additional spaces will have a diluting effect to reduce the separation.

Monotonous decrease in A'/A with increasing b (Fig. 3) does not mean that the performance of the barrier-column is inferior. The performance of a given column should be evaluated by taking into account the factors such as product yield per unit time, per unit volume of

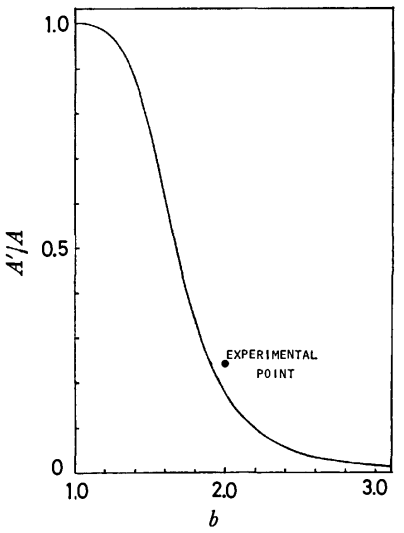

Fig. 3. Change in quality factor A'/A with b according to Eq. 4.
Experimental point is the ratio of columns C and B.

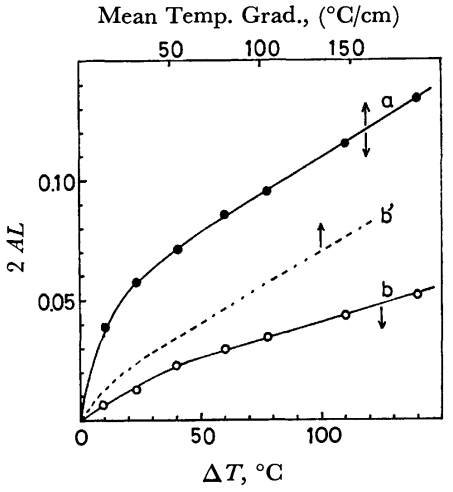

Fig. 4. Comparison of performance of barriered column (curve a) with that of the wider reference (b and b'). Curves b and b' are drawn on the base of applied temperature difference and temperature gradient, respectively.[3] Curve a can refer to both the two scales at upper and lower marginals.

apparatus, per unit energy consumed, *etc.* besides the degree of equilibrium separation. A comparison of any given two columns is complicated. We have no reliable means to compare the overall performances of two columns of different size. If, however, we take the wider reference as the standard, both total capacity of the column and energy consumed per unit time can be assumed almost to be common. This is clearly an advantage.

There still remains a question concerning the temperature gradient, which should be higher in the barrier-column than in the wider reference under the same temperature difference applied. The barrier-column was constructed to fulfill the design parameter a to be 0.5 ($b=2$). Thus the temperature gradient should be twice as high as the wider reference if applied temperature difference is equal. The performance for the barrier-column observed at a given ΔT should be compared with that for the wider reference column observed at a twice greater value of the given ΔT.

In Fig. 4, a part of which was reproduced from Ref. 2, the scale of abscissa is expressed as applied temperature difference and also as mean temperature gradient. Curve a, which stands for the barrier-column, refers to both the two scales, while b is drawn on the base of applied ΔT. Curve b′ was drawn by shifting[4] curve b in order to compare the performances at the same temperature gradient. It is clearly indicated that the performance of the barrier-column is much better than that of the wider reference column operating under a twice greater temperature difference.

(Received August 23, 1976)

Enthalpies of mixing of some α,ω-alkanediol monoalkyl ether(ADAE)+heptane systems were measured at 298 K, and limiting partial molar excess enthalpies of ADAE at infinite dilution, $\lim_{x\to 0} H^E/x(1-x)$, were estimated. The ADAE used were $CH_3O(CH_2)_nOH$ (n=2, 3, 4), $C_2H_5O(CH_2)_nOH$ (n=2, 3), $C_3H_7O(CH_2)_nOH$ (n=2, 3), and $C_4H_9O(CH_2)_2OH$. The values of $\lim_{x\to 0} H^E/x(1-x)$ obtained were compared with those of normal alcohols, and discussed in the light of the intramolecular hydrogen bond contained in ADAE. The enthalpic contribution due to the intramolecular hydrogen bond in ADAE is estimated to be about 10 kJ mol^{-1}.

The solution behavior of α,ω-alkanediol monoalkyl ethers (ADAE), $C_mH_{2m+1}O(CH_2)_nOH$, in various solvents is of interest since the ADAE molecule contains both an etheric oxygen and a hydroxyl group, and hence can form hydrogen bonds in several different ways. Not only are intramolecular hydrogen bonds possible between the hydroxyl hydrogen and the etheric oxygen on the same molecule, but also intermolecular hydrogen bonds between the hydroxyl hydrogen on one molecule and either the etheric oxygen or the hydroxyl oxygen on another molecule can be formed. While, in general, investigations for the intramolecular hydrogen bond have been carried out by the use of infrared spectra,[1-5] NMR[6] or dielectric constant measurements,[7,8] it is worthwhile to obtain thermodynamic information about ADAE solutions, because few thermodynamic properties of these solutions have been investigated. In this paper, measurements of enthalpies of mixing for ADAE+heptane at 298 K are described and the results are discussed in view of the several kinds of hydrogen bonds forming in ADAE solutions.

Experimental

The α,ω-alkanediol monoalkyl ethers used were prepared by alkylation of the corresponding α,ω-alkanediols, and purified by fractional distillation in a nitrogen atmosphere. The middle fraction from each distillation was collected and analyzed by an analytical gas-liquid chromatograph (Shimadzu, Model GC-3BT) with a column packed 15% PEG6000 on Teflon; their purities were more than 99.5% for $C_mH_{2m+1}O(CH_2)_2OH$(m=1,2,3,4). As for $C_mH_{2m+1}(CH_2)_nOH$(n=3,4), peaks which seemed to show the existence of isomers were observed; their contents were estimated to be at the greatest 1 and 3% respectively. The heptane from Wako Pure Chemicals Co., Ltd. was purified using the conventional method. The purified heptane was also checked with the gas-liquid chromatograph. The result showed no impurity peaks.

Enthalpies of mixing for ADAE+heptane systems were determined by a successive dilution technique at 298 K using the isothermal displacement calorimeter described previously.[9] The precision is estimated to be ±0.5 per cent in a molar excess enthalpy of 100 J mol^{-1} for a equimolar mixture. In order to determine the limiting partial molar excess enthalpies of ADAE at infinite dilution, precise measurements of H^E at very low mole fractions of ADAE were especially needed. The concentration range covered by our calorimeter, where considerable precision can be expected, is within about 1/60–60/1 as volume fraction of components. So, the enthalpies of mixing in the dilute region were determined as follows. A previously prepared solution of a known mole fraction x_0 was diluted by the solvent, *i.e.* heptane, successively, and the enthalpy of dilution H_d^E per one mole of solution was measured at each step. The enthalpy of mixing H_0^E of the solution at a given concentration x_0 was estimated from the separately determined H^E *vs.* x curve for the pure component system with the least squares method, using the following polynomial:

$$H^E/x(1-x) = \sum_{i=0}^{n} h_i(x)^{i/2}$$

where x indicates the mole fraction of ADAE in the mixture. In this case, the enthalpies of mixing at each step in the dilute region are obtained as

$$H^E = (H_0^E/x_0)x + H_d^E$$

For each system measured, the process described above was repeated twice to evaluate H^E values in the dilute region. For the $CH_3O(CH_2)_2OH$ system, H^E changes linearly with composition from about 0.15 to 0.9 mole fraction of ADAE, because phase separation occurs in this region.[10] Hence, the enthalpy of mixing for this system was measured below the mole fraction of about 0.15.

Results and Discussion

Limiting Partial Molar Excess Enthalpy. For each system, the results were fitted by the method of least squares to the polynomial

$$H^E = x(1-x)\sum_{i=0}^{n} h_i(x)^{i/2} \quad (1)$$

Values of the coefficients h_i and the standard deviations σ for each system are collected in Table 1. In the dilute region of these systems, the remarkably unsymmetrical character of the excess enthalpies, such as seen in alcohol+nonpolar solvent systems, was observed.[11] Because of this asymmetrical dependence of H^E on x, the experimental results could not be fit by either polynomial (1) or $H^E = x(1-x)\sum_{i=0}^{n} h_i'(1-2x)^i$ in the dilute region of ADAE. So, the coefficients in Table 1 were obtained from the experimental H^E values in range of x=0.05 to 1.0. Hence, limiting partial molar excess enthalpies, $\lim_{x\to 0} H^E/x(1-x)$, could not be obtained by the use of the coefficients listed in Table 1. Even though, in order to obtain limiting partial molar excess enthalpies, several kinds of polynomials which represent the $H^E/x(1-x)$ *vs.* x relation were adopted to

$C_3H_7O(CH_2)_3OH$+heptane	17.5	−10

our results, these curves were too steep in the dilute region of ADAE; an adequate form has not yet been found. So, the reciprocals of $H^E/x(1-x)$ were plotted against x, and the limiting partial molar excess enthalpies for all systems were estimated by extrapolation to infinite dilution "by eye." For an example, the observed points for the $C_3H_7O(CH_2)_3OH$ system are shown in Fig. 1. Values of limiting partial molar excess enthalpies determined by extrapolation to infinite dilution are listed in Table 2. The errors included in these values were estimated to be less than 5%.

Intramolecular Hydrogen Bond in ADAE. When liquids forming hydrogen bonds in the pure liquid state, such as alcohols, are diluted with nonpolar solvents, the hydrogen bonds are broken by the addition of the solvent molecules, and hence this process corresponds to an extremely large positive value of H^E. In general, the shapes of the $H^E/x(1-x)$ *vs.* x curves of such systems become very steep in the dilute region of solute. Although in the present systems the $H^E/x(1-x)$ *vs.* x curves show an appreciable rise in the dilute region, the slope is not so steep as that of normal alcohol+nonpolar solvent systems, and the difference of the limiting partial molar excess enthalpies between the two series is about several kJ mol^{-1}. This seems to mean that, in the dilute region ADAE molecules become free through the destruction of the intermolecular hydrogen bonds by the addition of solvent molecules, and each ADAE molecule forms an intramolecular hydrogen bond between the hydroxyl hydrogen and the etheric oxygen on the same molecule, and thus stabilizes itself.

To discuss the intramolecular hydrogen bond in the ADAE molecule, it will be useful to compare ADAE with normal alcohol. In a normal alcohol+nonpolar solvent system, alcohol molecules form intermolecular hydrogen bonds between hydroxyl groups in the pure

alcohol state. On the other hand, at infinite dilution of alcohol in a nonpolar solvent, the intermolecular hydrogen bonds are broken and each alcohol molecule is surrounded by solvent molecules. Therefore, the value of the limiting partial molar excess enthalpy of alcohol at infinite dilution is assumed to represent the energy sufficient to break the intermolecular hydrogen bond in pure alcohol.

While many investigations have been carried out for excess enthalpies of alcohol+nonpolar solvent systems so far,[12-15] available data for limiting partial molar excess enthalpies have not been provided because of the steep rise of $H^E/x(1-x)$ *vs.* x curves in the dilute region. However, values of limiting partial molar excess enthalpies reported so far are distributed in the neighborhood of 23 to 24 kJ mol^{-1} for normal alcohol systems.[12] This figure seems to be independent of nonpolar solvents, and constant within the experimental error.[11] Brown *et al.* suggest that, for normal alcohols larger than ethanol, the strength of the intermolecular hydrogen bond hardly depends on the carbon chain length in the molecule.[16] Further, for 1,3-butanediol which has two terminal hydroxyl groups in its molecule, it was suggested previously by Murakami *et al.* that almost all the molecules form intermolecular hydrogen bonds between the hydroxyl hydrogen on one molecule and the hydroxyl oxygen on another molecule in the pure liquid state, and the amount of the intramolecular form is negligibly small.[17] It can hence be presumed that ADAE molecules also hardly form intramolecular hydrogen bonds in the pure liquid state, and it will be reasonable to assume that the relation between the strength of the hydrogen bond and the carbon chain length of ADAE is also similar to that of normal alcohols. Therefore, the difference in the values of limiting partial molar excess enthalpies for various ADAE seems to be attributed mainly to the difference in the enthalpic contribution due to formation of the intramolecular hydrogen bond between the hydroxyl hydrogen and the etheric oxygen on the same molecule.

Evaluation of the Enthalpic Contribution due to the Intramolecular Hydrogen Bond in ADAE. On the basis of the consideration in the previous section, the enthalpic contribution due to the intramolecular hydrogen bond in the ADAE molecule, H_i, can be estimated. In this

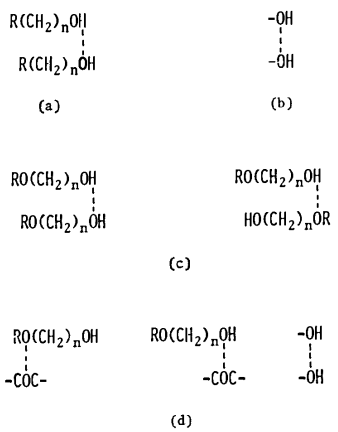

Fig. 2. Schematic diagram of main intermolecular interactions in pure liquid state of alcohol and ADAE.

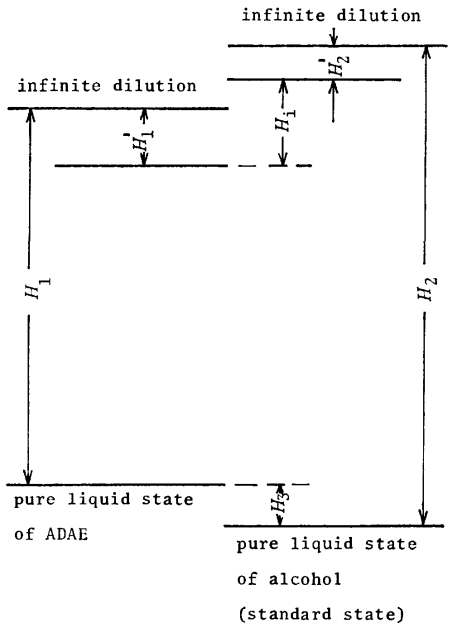

Fig. 3. Energy level diagram of ADAE and alcohol.

estimation, the pure liquid state of normal alcohol is taken as a standard state. As the main intermolecular interactions in this state, those shown in Fig. 2(a) and (b) are considered: (a) contribution due to the intermolecular hydrogen bond and (b) contribution due to the van der Waals force including the dipolar interaction. On the other hand, in the pure liquid state of ADAE, the intermolecular interactions shown in Fig. 2(c) and (d) are also considered: (c) contribution due to two types of intermolecular hydrogen bonds and (d) contribution due to three types of van der Waals forces. The process used to evaluate H_i is given in a form of an energy level diagram in Fig. 3. In this figure, H_2 represents the limiting partial molar excess enthalpy of normal alcohol in a nonpolar solvent. H_2 includes an enthalpic contribution arising from the interruption of the van der Waals interaction among alcohol molecules shown in Fig. 2(b) through dilution with the nonpolar solvent. This contribution is represented by H_2' in Fig. 3, and then the net contribution due to the hydrogen bond becomes H_2-H_2'. H_1 represents the limiting partial molar excess enthalpy of ADAE in a nonpolar solvent. H_1 also includes an enthalpic contribution arising from the interruption of the van der Waals interactions among ADAE molecules shown in Fig. 2(d) through dilution with the nonpolar solvent. H_1' represents this contribution; then the net contribution due to hydrogen bonds (including the intramolecular hydrogen bond) becomes H_1-H_1'. As shown in Fig. 2(c), two types of intermolecular hydrogen bonds may exist in the pure liquid state of ADAE, and the energy level of this state is considered to be different from that of the pure liquid state of alcohol which is taken as the standard state. This difference between the levels is designated as H_3. With these notations, the enthalpic contribution due to the intramolecular hydrogen bond in the ADAE molecule, H_i, can be evaluated as

$$H_i = (H_1-H_1'+H_3) - (H_2-H_2') \qquad (2)$$

Values of H_1', H_2', and H_3 are evaluated as follows. If the difference in nature of the oxygen atoms contained in the ADAE molecule and the alcohol molecule is assumed to be negligible, H_1' and H_2' can be replaced by limiting partial molar excess enthalpies of ethers, $RO(CH_2)_nOR$ and ROR, where R represents an alkyl group, in nonpolar solvent, which are unable to form hydrogen bonds. One mole of ADAE is assumed to consist of one mole of alcoholic hydroxyl groups and one mole of etheric oxygen atoms, and then the pure liquid state of ADAE will be approximated by one mole of alcohol plus one mole of ether. Hence, $H_3/2$ is replaced by the enthalpy of mixing of the alcohol+ether system at equimolar fraction, $H^E(x=0.5)$. According to these assumptions, H_1', H_2', and H_3 are estimated to be 5.8 kJ mol^{-1},[18] 0.4 kJ mol^{-1},[19] and 1.5 kJ mol^{-1},[19] respectively. As for H_2, the latest value of 23.2 kJ mol^{-1} for the ethanol+hexane system[11] is used, which was measured in a sufficiently dilute region. For H_1, the values listed in Table 2 are used. Using these values and Eq. 2, H_i values for various ADAE are found and are also listed in Table 2. These results are distributed in the neighborhood of 10 kJ mol^{-1}, and it seems that the values of H_i for ADAE depend on the length of the internal methylene group in the ADAE molecule, but hardly depend on the chain length of the terminal alkyl group in the ADAE molecule. The values of H_i for ADAE having the same terminal alkyl group are in the order of $RO(CH_2)_2OH>RO(CH_2)_3OH>RO(CH_2)_4OH$. On the other hand, the values of H_i for α,ω-alkanediols ($HO(CH_2)_nOH$, $n=3$, 4) were estimated from the infrared spectra[20] and dielectric measurements,[21] and are comparable with those in the present systems. However, the dependence of H_i values on the length of the internal methylene group seems to be the reverse of that of ADAE. At present, we have no satisfactory explanation of this fact.

In conclusion, the present results suggest that the enthalpic contribution due to the intramolecular hydrogen bond contained in the ADAE molecule is smaller than that due to the normal intermolecular hydrogen bond between hydroxyl groups, and in general can be estimated to be about 10 kJ mol^{-1}.

The present work was partially supported by a grant from the Ministry of Education.

The Dimerization of 2-Methylpropene Induced by γ-Radiation at High Temperatures and Pressures

Teruyuki NAITO

National Chemical Laboratory for Industry, Meguro Division, Mita, Meguro-ku, Tokyo 153

(Received August 26, 1976)

The dimerization of 2-methylpropene by γ-irradiation occurred at a temperature of 300 °C and a 2-methylpropene density of 0.1 g/cm^3, giving rise to the formation of 1,1,3-trimethylcyclopentane. The G value of this dimer was 50 at an absorbed dose rate of 4.3×10^{18} eV/g h and a total absorbed dose of 2.2×10^{19} eV/g. The G value of this dimer was inversely proportional to about 0.47 the power of the absorbed dose rate and was proportional to the 2-methylpropene density. The formation of this dimer was suppressed by the addition of oxygen or nitrogen monoxide. These facts led to the conclusion that the dimer was formed *via* chain reactions with the participation of the 2-methylallyl radical.

The radiation chemistry of 2-methylpropene has been studied by several investigators. Collin and Herman[1] examined the products of the radiolysis of gaseous 2-methylpropene, and they proposed some mechanisms leading to the formation of several low boiling-point products.

Many studies of the low-temperature radiation-induced polymerization of 2-methylpropene, both in the gas phase and in the liquid phase, have shown that the chain propagation was not the free-radical mode but the ionic one and that the most likely initiating species was the *t*-butyl cation, *t*-$C_4H_9^+$. For instance, Okamoto *et al.*[2] studied the gas-phase radiation-induced polymerization of 2-methylpropene and established the *t*-butyl cation mechanism. This cation was considered to be produced from the 2-methylpropene parent ion, *i*-$C_4H_8^+$, *via* an ion-molecule reaction:

$$i\text{-}C_4H_8 \rightsquigarrow i\text{-}C_4H_8^+ + e$$
$$i\text{-}C_4H_8^+ + i\text{-}C_4H_8 \longrightarrow t\text{-}C_4H_9^+ + C_4H_7\cdot \qquad (1)$$

From their mass spectrometric observations, Tal'rose and Lyubimova[3] showed that Reaction 1 did indeed occur, and Koyano[4] showed that this reaction had a very large cross section.

Collinson *et al.*[5] suggested that Reaction 1 also occurred in the radiolysis of liquid 2-methylpropene and that the $C_4H_7\cdot$ produced together with the *t*-butyl cation was most likely a methyl allyl radical.

On the other hand, McKinley *et al.*[6] studied the thermal polymerization of 2-methylpropene at 370—460 °C, at maximum pressures of from 37 to 370 atm, and at times of from one half hour to four hours. Under these conditions a cyclic dimer, 1,1,3-trimethylcyclopentane (**1**), was the main reaction product.

The present work showed that dimer **1** is not formed at 300 °C and a 2-methylpropene density of 0.1 g/cm^3 for five hours, but by γ-irradiation under the same conditions **1** is formed as a major dimer product, while, 2,4,4-trimethyl-2-pentene (**2**) is formed as a minor one. It will then be concluded that the dimerization of 2-methylpropene induced by γ-radiation proceeds mainly by means of a radical chain reaction whose chain carrier is $C_4H_7\cdot$ and that the contribution of the *t*-butyl cation to the dimerization is not greater than that of $C_4H_7\cdot$.

Experimental

Research-grade 2-methylpropene and all the other gaseous meterials except oxygen were degassed by repeating the freezing-pumping-thawing cycle several times.

The reaction vessel was a stainless steel autoclave (2 cm in inner diameter and with a volume of about 20 cm^3) which was surrounded by a mantle heater. The temperature was controlled at 300±3 °C.

The samples were irradiated with γ-rays from ^{60}Co, and in most cases, the absorbed dose rate was 4.3×10^{18} eV/g h and the total absorbed dose was 2.2×10^{19} eV/g. The G values were calculated from the energy absorbed by the sample, where it was assumed that the absorbed energy was proportional to the electron density of the sample. The absolute energy absorption was determined by means of Fricke dosimetry, taking $G(Fe^{+3})=15.5$.

All the irradiations were carried out at a temperature of 300 °C and a 2-methylpropene density of 0.1 g/cm^3 except where otherwise specified.

After irradiation, the liquid products in the reaction vessel were collected in a trap immersed in liquid nitrogen by vaporizing and pumping them. In order to differentiate between the saturated compounds and the unsaturated compounds in the collected products, the products were hydrogenated in ethanol over Raney's nickel. Gas-liquid-phase chromatography and gas chromatograph-mass spectrography were applied to both the original and hydrogenated products for the identification and determination of the two dimers, **1** and **2**.

Results and Discussion

The yields of the liquid product from γ-irradiated 2-methylpropene were determined at temperatures between 30 and 300 °C. In the lower-temperature range, many kinds of products were formed, but their yields were poor. However, the yields increased with an increase in the temperature; moreover, the proportion of the **1** dimer in the product increased. It was expected that the dimerization proceeded by means of some chain mechanisms above 200 °C.

At 300 °C and a 2-methylpropene density of 0.1 g/cm^3, various scavengers were used in order to see whether the dimerization takes place by means of an ionic or radical mechanism. The experimental results are shown in Table 1.

The addition of ammonia, whose concentration range

TABLE 1. EFFECT OF SCAVENGERS ON THE γ-RADIATION-INDUCED DIMERIZATION OF 2-METHYLPROPENE AT A TEMPERATURE OF 300 °C AND A 2-METHYLPROPENE DENSITY OF 0.1 g/cm^3

Scavenger	Concn (mol %)	G value of dimer	
		1	**2**
None		50	5
NH_3	1.0	48	2
	3.0	51	1
	5.0	52	1
O_2	0.05	30	4
	0.15	14	4
NO	0.5	41	5
	1.0	30	4
	5.0	15	5

The absorbed dose rate is 4.3×10^{18} eV/g h, and the total absorbed dose is 2.2×10^{19} eV/g.

was 0.5—5.0% in the molar fraction, suppressed the formation of **2**, but had little influence on the formation of **1**. This implied at least that the precursor of **1** was not a cation, while **2** was formed by the participation of some cations.

Oxygen and nitrogen monoxides of various concentrations were used as the radical scavengers. It was observed that the addition of small amounts of them sup ressed the formation of **1**. On the other hand, the yield of **2** did not change upon the addition of the radical scavengers. Consequently, these observations were in marked contrast to those of ammonia addition.

It is well-known that the intermediary species formed during the γ-irradiation of 2-methylpropene are varieties of ions, radicals, and excited molecules. Among these species, the *t*-butyl cation and the $C_4H_7\cdot$ formed through Reaction 1 seem to be the most reasonable precursors of the 2-methylpropene dimers. Assuming this, it may be considered that, after the formation of the *t*-butyl cation and $C_4H_7\cdot$, they can bring about the subsequent reactions in the following ways:

$$t\text{-}C_4H_9^+ + i\text{-}C_4H_8 \longrightarrow C_8H_{17}^+ \longrightarrow \text{dimer} \longrightarrow \text{polymer} \quad (2)$$

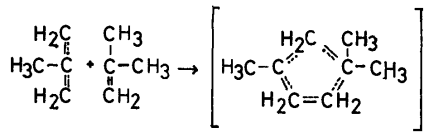
$$C_4H_7\cdot + i\text{-}C_4H_8 \longrightarrow C_8H_{15}\cdot \quad (3)$$

$$C_8H_{15}\cdot + i\text{-}C_4H_8 \longrightarrow C_8H_{16} + C_4H_7\cdot \quad (4)$$

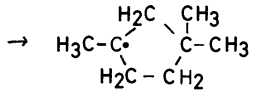
It has been found that the *t*-butyl cation reacts predominantly with the terminal carbon in 2-methylpropene both in the gas phase[7] and in the liquid phase[8] to give $C_8H_{17}^+$, the 2,2,4-trimethylpentyl cation, and that this cation then produces mainly **2** by means of a proton-transfer reaction with 2-methylpropene. In the present work also, **2** is probably formed by means of the ionic reaction mentioned above. This speculation seems reasonable because of the observation that the formation of **2** was suppressed by the addition of ammonia. Ammonia is a well-known scavenger of the *t*-butyl cation[9]:

$$t\text{-}C_4H_9^+ + NH_3 \longrightarrow i\text{-}C_4H_8 + NH_4^+ \quad (5)$$

On the other hand, it may be considered that $C_4H_7\cdot$ is a 2-methylallyl radical (structural formula (**3**)).[5] If so, **3** will readily react with 2-methylpropene to form a 1,3,3-trimethylcyclopentyl radical, (**5**), *via* an intermediary adduct, (**4**), and the radical **5** will subsequently abstract a hydrogen atom from 2-methylpropene; then, as a result of the abstraction, **1** and $C_4H_7\cdot$ (probably, the 2-methylallyl radical) will be formed. That is to say, the reformed $C_4H_7\cdot$ will serve as a chain carrier to repeat the above cyclic reaction and to cause a chain reaction:



3 4



5

In this case, it is assumed that the primary $C_4H_7\cdot$ is formed only by way of Reaction 1, not by other ways such as the decomposition of the excited 2-methylpropene molecule:

$$i\text{-}C_4H_8 \rightsquigarrow i\text{-}C_4H_8^* \longrightarrow C_4H_7\cdot + H\cdot \quad (6)$$

No hydrogen or compounds formed by the participation of the hydrogen atom could be detected.

It is assumed that the termination reaction can be expressed as follows:

$$C_4H_7\cdot(\text{or } C_8H_{15}\cdot) + R \longrightarrow \text{Products} \quad (7)$$

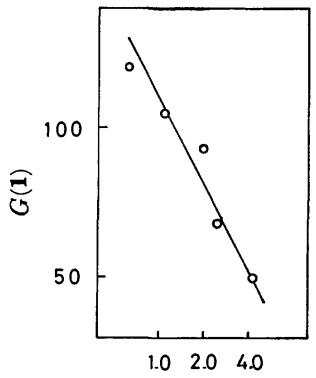
where R denotes the $C_4H_7\cdot$ radical, the $C_8H_{15}\cdot$ radical, or other radicals in this system, for instance, the fragment radicals such as $CH_3\cdot$ or $C_3H_5\cdot$ from the radiolysis of 2-methylpropene. Unfortunately, in this work, the termination reactions could not be defined because it was not possible to determine accurately each product derived from the respective termination reactions because of the uncertainty of the gas-chromatographic analysis. However, it may be considered that $C_4H_7\cdot$ and $C_8H_{15}\cdot$ are the most important radicals and that the other radicals are negligible. Therefore, it is assumed that the overall velocity of the termination reaction is $k_t[C_4H_7\cdot][C_8H_{15}\cdot]$, where k_t is the rate constant.

In the reaction sequence mentioned above, provided a stationary state holds for the radicals of both $C_4H_7\cdot$ and $C_8H_{15}\cdot$, **1** can form only *via* Reactions 3 and 4; further, the rate of the formation of primary $C_4H_7\cdot$ (Reaction 1) is proportional to the absorbed dose rate, and the G value of **1** is inversely proportional to one-half the power of the absorbed dose rate and is proportional to the 2-methylpropene density:

$$G(\mathbf{1}) = k_4(k/k_t)^{1/2}I^{-1/2}[i\text{-}C_4H_8]$$

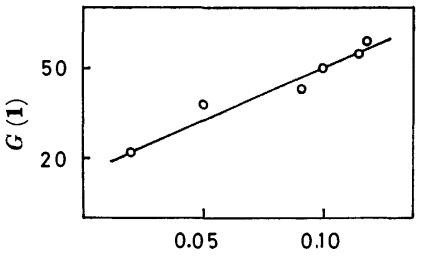
where k and k_4 are the rate constants of Reactions 1 and 4 respectively, and where I is the absorbed dose rate.

The variations in the G value of **1** with the absorbed dose rate and the 2-methylpropene density are shown in Figs. 1 and 2 respectively. The G value of **1** was



Absorbed dose rate (10^{18} eV/g h)

Fig. 1. A plot of G value of **1** *vs.* absorbed dose rate. The absorbed dose, about 2.2×10^{19} eV/g.



2-Methylpropene density (g/cm^3)

Fig. 2. A plot of G value of **1** *vs.* 2-methylpropene density. The absorbed dose rate, 4.3×10^{18} eV/g h and the total absorbed dose, 2.2×10^{19} eV/g

inversely proportional to about the 0.47 power of the absorbed dose rate and was proportional to the 2-methylpropene density. These experimental results were consistent with the schematic consideration. Therefore, it seems reasonable to conclude that, on γ-irradiation, 2-methylpropene dimerizes to form the cyclic dimer, **1**, by means of a radical chain mechanism where the chain carriers are both $C_4H_7\cdot$ and $C_8H_{15}\cdot$.

Lampe[10] showed a $G(C_4H_7\cdot)$ of 4.2 and $G(t\text{-}C_4H_9^+)=G(C_4H_7\cdot)$ in the liquid-phase polymerization of 2-methylpropene, where the *t*-butyl cation formed *via* Reaction 1 was a polymerization initiator. If it can be assumed that a $G(C_4H_7\cdot)$ of 4.2 is little affected by the phase of 2-methylpropene and the irradiation conditions, this value is equal to the initial G values of Reaction 1, that is, to the initial G values of $C_4H_7\cdot$ or the *t*-butyl cation under the conditions of this work. Therefore, the chain dimerizations concerned in the formation of **1** have chain-lengths of about 12, as evaluated by $G(\mathbf{1})/G(C_4H_7\cdot)=50/4.2$.

The Electronic States of $(SN)_x$ and $(SCH)_x$ Polymers

Tokio YAMABE, Kazuyoshi TANAKA, Akira IMAMURA,* Hiroshi KATO**, and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

**Shiga University of Medical Science, Seta, Otsu 520-21*

(Received October 12, 1976)

One-dimensional $(SN)_x$ and its isoelectronic system $(SCH)_x$ polymers are treated on the basis of the SCF-tight-binding MO theory. The Pennsylvania structure of $(SN)_x$ has been shown energetically favorable comparing the Lyon structure. Judging from the state density at the Fermi level of $(SCH)_x$, it may be expected to be a metallic conductor under some favorable condition.

There have been considerable experimental and theoretical interests in low-dimensional metallic conductors such as tetracyanoquinodimethane (TCNQ) charge-transfer salts and $K_2[Pt(CN)_4]Br_{0.3}\cdot 3H_2O$ mixed valence complex.[1] Recently, the third member, polymeric sulfur nitride, $(SN)_x$, has been revealed as a low-dimensional metallic polymer,[2] which does not show the Peierls transition like the above two, and even becomes a superconductor at $\approx$0.3 K.[3]

The theoretical band structure calculations of $(SN)_x$ have been performed with the OPW method[4] and several non SCF-tight-binding techniques such as the extended Hückel method.[5] In these tight-binding MO calculations, however, the electron-electron interaction potential is not taken into account explicitly, and hence these methods would be only reliable on the non-polar polymers such as polyethylene.[6] Since the sulfur-nitrogen bond in $(SN)_x$ has been estimated experimentally to be of rather polar character,[7] it would be suitable to calculate the MO including the electron repulsion integrals for this polymer. The SCF-tight-binding MO calculation including these repulsion integrals has been carried out only by Zunger and by Merkel and Ladik[8] for the one-dimensional structure of $(SN)_x$ in the crystal structure proposed by Boudeulle and Michel (Lyon structure)[9] based on the electron-diffraction analysis as shown in Fig. 1(A). The band structures obtained by them clearly show the metallic nature of $(SN)_x$, and the possibility of the occurrence of the Peierls transition has been denied by the former.

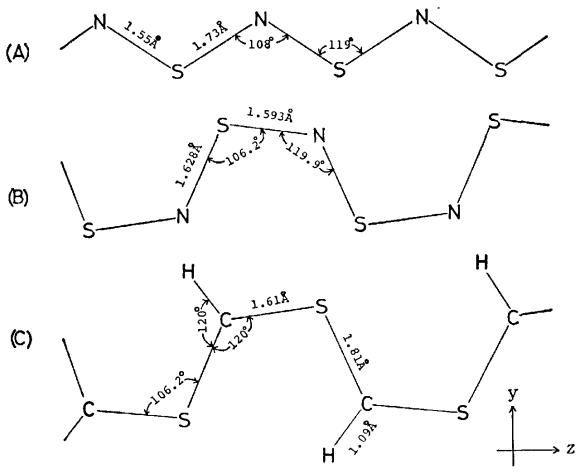

Fig. 1. The structures of $(SN)_x$ and $(SCH)_x$; (A) the Lyon structure (Ref. 9), (B) the Pennsylvania structure (Ref. 10), and (C) an assumed structure for the calculation here (see text).

More recently, however, the more reliable structure of $(SN)_x$ has been proposed by MacDiarmid *et al.* (Pennsylvania structure)[10] based on the X-ray diffraction analysis as shown in Fig. 1(B). In this paper, we present the result of electronic states of the one-dimensional Pennsylvania structure of $(SN)_x$ by the SCF-tight-binding MO calculation including the electron repulsion, and, furthermore, the calculation for an assumed structure of $(SCH)_x$ polymer has been made so as to study an isoelectronic system with the $(SN)_x$ polymer.

Method of Calculation

In order to avoid the complicated calculations of the all matrix elements by *ab initio* methods, we employ the CNDO/2 approximation by Pople and Segal[11] as Zunger did. The SCF iteration process is accelerated by the density matrix method previously introduced by Imamura and Fujita to calculate biopolymers.[12] The formalism of the calculation has been described thoroughly in their article, so we will not mention the details here again. All valence AOs and 3d orbitals for sulfur atoms were considered since it has been pointed out that the contribution from 3d orbitals is not negligible for $(SN)_x$.[8] For the parametrizations were adopted those of spd set by Santry and Segal,[13] and the number of representative wave vector K was chosen as 21 at regular intervals ($\pi/10a$; a is the length of the unit cell) in the Brillouin zone.

We assumed the structure of $(SCH)_x$ to be analogous to that of the Pennsylvania structure of $(SN)_x$, as shown in Fig. 1(C). The angle at sulfur was chosen as 106.2° after that in $(SN)_x$, and that at carbon as 120° after ordinary sp^2 hybridization. The two kinds of S–C bond distance, 1.81 and 1.61 Å, are employed from the data for dimethyl disulfide[14] and thioformaldehyde,[15] respectively. The C–H bond distance, 1.09 Å, also from the latter. Each of SN and SCH units consists of 11 valence electrons and, hence, an open-shell structure. Since the $(SN)_x$ crystal, however, does not show paramagnetism,[10] the system could be treated as a closed-shell system. We employed $(SN)_2$ as a unit cell in the MO calculation of the $(SN)_x$ polymer. We also assumed $(SCH)_2$ as a unit cell in the $(SCH)_x$ polymer. Since the polymer chains possess a two-fold screw rotation as a symmetry operation, all pairs of bands stick together at the edges of the Brillouin zone,[16] and in this case, the HOMO(π) and the LUMO(π^*) bands

also degenerate there. At such points, it is in principle unreasonable to describe the system with a single Slater determinant. Thus we extrapolated the density matrix elements at $K=\pm 9\pi/10a$ and $\pm\pi/10a$ to obtain those at $K=\pm\pi/a$ and 0, respectively. The values of overlap integrals between the central unit cell and the N-th nearest neighboring cell rapidly decrease to 0 where $N=3$—4 (9—13.5 Å from the central unit cell). But as those of electron repulsion (Coulomb) integrals slowly decrease, we consider them as far as the 7-th nearest neighbors (≈31 Å from the central unit cell).

Results and Discussion

The calculated results of AO densities, atomic net charges and the total energies per unit cell are shown in Table 1 along those of the Lyon structure of $(SN)_x$. As we set the direction of the polymer chain along the z-axis and the polymer plane perpendicular to the x-axis, the π orbitals are of $2p_x$, $3p_x$, $3d_{xy}$, and $3d_{xz}$ AOs. Both of $(SN)_2$ and $(SCH)_2$ units have six π electrons, supplied two π electrons from the sulfur atom and one from the nitrogen or the carbon atom. In $(SN)_x$ calculated here, the densities of $3p_x$ and $2p_x$ AOs on S and N are 1.407 and 1.218, respectively, and the contribution from $3d_{xy}$ and $3d_{xz}$ AOs is totally 0.375, the magnitude of which is not negligible. The atomic net charge on S is +0.231, and it is somewhat larger than that estimated for the Lyon structure, +0.186,[8] but somewhat less than that estimated by XPS method, +0.30—0.42.[7] In $(SCH)_x$, although the π electron densities on S and C are not so different from those on S and N in $(SN)_x$, the atomic net charge on S is +0.087 which is by far less than that in $(SN)_x$. This would be direct reflection of the electronegativity of each atom, namely S<C<N in order. It is also interesting that the atomic net charge on H is very close to that on S. It is clearly shown, from the difference in the total energies of a unit cell and isolated $(SN)_2$ molecules, that the polymeric state is more stable than the isolated molecules. Moreover, the comparison of the total energies per unit cell of the two structures of $(SN)_x$ definitely shows that the Pennsylvania structure is favorable. For $(SCH)_x$, it is similarly predicted that the polymeric state is stable in comparison with the isolated $(SCH)_2$ molecule.

The energy bands and the state densities of the polymers are shown in Figs. 2(A) and (B). The curves of the state densities are obtained with the Brust's method[17] summing over 300 points sampled in the Brillouin zone for each energy band. The valence bands consist of three π bands and eight σ bands, and the HOMO and the LUMO bands are of π MOs mainly composed of the sulfur $3p_x$ AO in both $(SN)_x$ and $(SCH)_x$. These energy bands of $(SN)_x$ and $(SCH)_x$ are seen to be of rather similar shape and the Fermi energies (E_F) are obtained as −4.996 and −4.340 eV, respectively. E_F of the Lyon structure of $(SN)_x$ has been reported to be −5.714 eV.[8] The shape of the state density of $(SN)_x$ agrees qualitatively with those obtained previously by ESCA spectroscopy.[7,18] The state density at E_F ($D(E_F)$) is small but finite for $(SN)_x$, namely, 0.04 states/eV spin-molecule, which shows the metallic nature of $(SN)_x$. Experimental value of $D(E_F)$ is 0.12—0.18 states/eV spin-molecule[18,19] which agrees quantitatively with our result but is somewhat larger, showing perhaps the reflection of the actual three-dimensional structure of $(SN)_x$ crystal. For $(SCH)_x$, the shape of the state density again resembles that of $(SN)_x$ but the peaks are more sharpened than in $(SN)_x$, and $D(E_F)$ is 0.06 states/eV spin-molecule. This value encourages us that $(SCH)_x$ may become also a metallic conductor if it should be successfully synthesized, and unless any interference such as Peierls transition

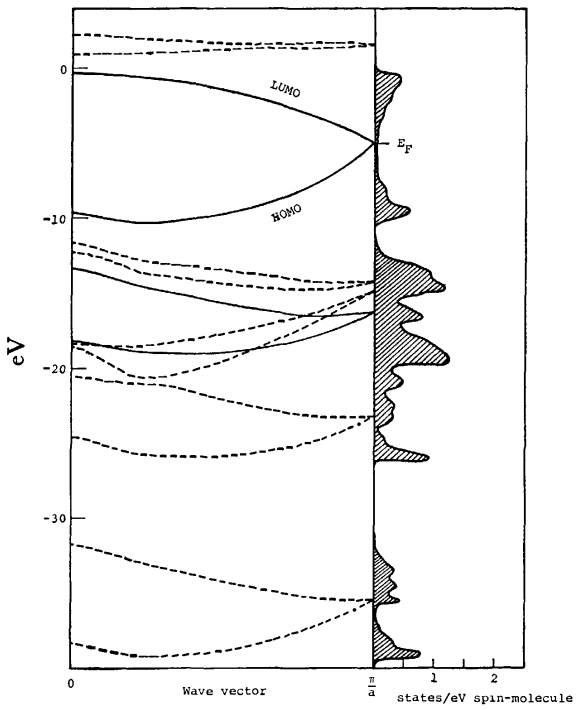

Fig. 2. The band structures and the state densities of (A) $(SN)_x$ and (B) $(SCH)_x$. Dotted lines and solid ones indicate σ bands and π bands, respectively. The upper several vacant MO bands and the state densities of those which are upper than the LUMO bands are not essential and omitted here.

should occur to break down the metallic state of $(SCH)_x$.

The E_{AB} analyses in the scheme of the CNDO/2 method are shown in Fig. 3 for $(SN)_x$ and $(SCH)_x$. It is shown that N_1–S_4 in $(SN)_x$ and S_1–C_6 in $(SCH)_x$

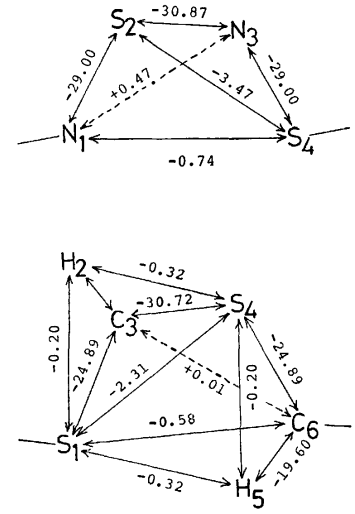

Fig. 3. The E_{AB} analyses for the representative unit cells of $(SN)_x$ and $(SCH)_x$. The energies are shown in eV. Dotted lines and solid ones indicate the repulsive and attractive interactions, respectively.

are both attractive. Moreover, it should be noticed that, both in $(SN)_x$ and in $(SCH)_x$, S_2–S_4 and S_1–S_4 are considerably attractive, while N_1–N_3 and C_3–C_6 are weakly repulsive, and hence the skeleton of each unit cell is held rather tightly. This would cause interesting effects to the force constant of the lattice displacement and to the Debye frequency of the system.

It is also noticed that much attention should be paid to the description of the system at $K=\pm\pi/a$, since there occurs a degeneracy of the HOMO and the LUMO bands. In order to overcome such a situation, some appropriate linear combination of the Slater determinants (Configuration Interaction) should be adopted.

The possibility of the interaction between two $(SN)_x$ chains or the highly anisotropic two- or three-dimensionality of $(SN)_x$ crystal has also been pointed out from some experimental aspects.[10,20] The SCF-tight-binding calculation including two chains is desirable.

We are grateful to the Data Processing Center of Kyoto University for its generous permission to use the FACOM 230-75 Computer. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education of Japan (No. 065101).

Calorimetric Study of the Glassy State. XI. Plural Glass Transition Phenomena of Cyclohexene

Osamu HAIDA, Hiroshi SUGA, and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received October 14, 1976)

Two kinds of glassy crystalline phases (I and III) of cyclohexene were realized by different thermal treatments. The heat capacities of the glassy and the supercooled crystal-I and -III, as well as the stable crystalline phases were measured by an adiabatic calorimeter in the temperature range 12—300 K. The glass transition temperature T_g, the heat capacity jump at T_g and the residual entropy were found to be 81 K, 11.4 JK^{-1} mol^{-1} and 11.7 JK^{-1} mol^{-1} for crystal-I and 83 K, 3.6 JK^{-1} mol^{-1} and 2.6 JK^{-1} mol^{-1} for crystal-III, respectively. The glassy liquid state of cyclohexene was realized by vapor condensation technique, its T_g being 78 K as determined by DTA method. The results provide the first example of plural glass transition phenomena in one and the same low-molecular-weight compound.

The heat capacity of liquid contains a contribution from a potential energy variation caused by structural change with temperature. This degree of freedom is usually known as "configurational freedom" and has been used in many theoretical works for describing the thermal behavior of glass-forming liquid in a transfigured fashion such as free volume,[1] trans-gauche conformation[2] and bond-lattice model.[3] These treatments have been successful to a certain extent to explain thermodynamic and kinetic aspects of the glass transition in spite of their simplified models.

Discovery of glassy crystals[4] brought about an extension of the concept of glass from the originally defined non-equilibrium frozen state of liquid to that of a system including some kind of disorder. In addition it offers a new possibility for studying the glassy state. The site randomness will be eliminated from the configurational freedom in the case of glassy crystals since they have three-dimensional positional periodicity. Even in this favorable situation, however, the "configuration" is of a complex mixture of orientational and internal freedom of molecule, as pointed out by Adachi *et al.*[4] The realization of more than one kind of glassy state of a compound is therefore expected to give a clue in resolving the entanglement between these freedoms.

The calorimetric study by Huffman *et al.*[5] revealed the fact that cyclohexene has two crystalline phases, I and II. Adachi *et al.*[6] realized the glassy state of high temperature crystalline phase I based on the results of DTA experiment. We have found a new crystalline phase (crystal-III) and its glassy crystalline state. The glassy liquid state of cyclohexene was also realized by the vapor condensation method. A brief account of these findings was reported in a short communication.[7]

Experimental

Material. Commercial "Standard Material" of cyclohexene (Tokyo Kagaku Seiki Co., Ltd.) was deaerated and then distilled twice in a vacuun. The final purity of the sample was determined to be 99.98% by gas chromatography (Shimadzu Gas Chromatogram G.C./C. column; Apiezon grease on serite, column temperature; 70 °C) and 99.96% by calorimetric study.

Apparatus. The heat capacity was measured with an adiabatic calorimeter.[8] The purified sample was introduced into the calorimeter cell by vacuum distillation through a copper tubing attached to the top of the cell. When the procedure was over, the cell was pinched off at the copper tubing and sealed with a soft solder. The weight of the sample used for the heat capacity measurement was 23.154 g.

The DTA apparatus used in the preparation of the glassy liquid has also been reported.[9]

Experimental Results

DTA. The thermal behavior of cyclohexene at low temperature was examined by use of DTA, the results being given in Fig. 1. Run 1 shows the cooling curve with a rate of −2 K min^{-1}, and Run 2 the subsequent heating curve. Run 3 shows the heating curve of rapidly cooled sample at a rate greater than 7 K min^{-1} from high temperature crystal-I or liquid. The result of Run 3 coincides with that reported previously[6] except for a difference in anomalies at 120 and 140 K. The endothermic peaks at 140 K in Run 3 and 170 K in Runs 2 and 3 correspond to the processes crystal-I→crystal-II and crystal-II→liquid, respectively. When the liquid is cooled slowly as in Run 1, it crystallizes into crystal-I at around 130 K with successive two exothermic effects, and then the crystal-I transforms into a newly found crystal-III reversibly at about 115 K. The successive peaks at 130 K in Run 1 were separated

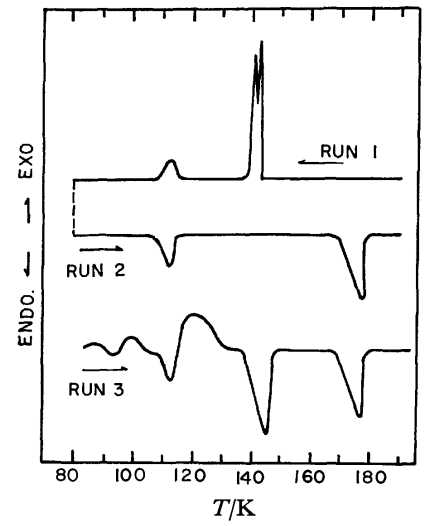

Fig. 1. DTA curves of cyclohexene.

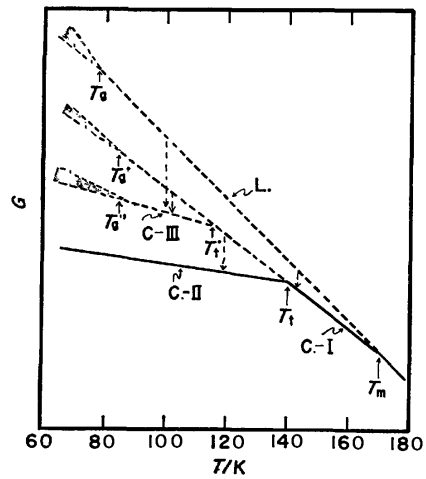

Fig. 2. Schematic diagram for Gibbs energy relationship of cyclohexene.

by chance and might be attributed to the appearance of a metastable phase on the way from liquid into crystal-I.

The thermogram Run 3 is interpreted as follows. When crystal-I is chilled through the transition temperature (115 K) at a rate greater than -7 K min^{-1}, the glassy crystal-I can be prepared. During the course of subsequent heating, the glassy crystal-I recrystallizes into crystal-III at *ca.* 100 K after the glass transition at 92 K is over, and then successive transformations of crystal-III→crystal-I→crystal-II→crystal-I→liquid take place at 115, 120, 140, and 160 K, respectively. This interpretation was confirmed by calorimetric studies. Among the transitions in Run 3 the rate of irreversible transition from crystal-I to crystal-II at 120 K was found to be sensitive to the purity and thermal history of the specimen. Thus a different thermal behavior in the temperature range 120—140 K is seen in the results of Runs 2 and 3 (Fig. 1), Runs 2, 3, and 4 (Fig. 6) and those reported by Adachi *et al.*[6] The phase relations represented by Gibbs energy are schematically illustrated in Fig. 2. Glassy state of liquid (glassy liquid) was obtained by vapor condensation method, but not by rapid cooling method. This can be seen from the fact that the samples quenched from liquid and crystal-I gave the same thermogram Run 3.

Measurement of Heat Capacity. Glassy crystal-I was prepared by rapid chilling of the liquid sample by introducing liquid nitrogen directly into the calorimeter can. The average cooling rate in the temperature interval 220—80 K was *ca.* -40 K min^{-1}, which is much greater than the limit -7 K min^{-1} to obtain the thermogram Run 3 (Fig. 1). Concerning the crystal-III, series of measurement were performed with different samples. Thermal treatments adopted to obtain these samples were as follows. For series-I, crystal-III was prepared by cooling crystal-I at the cooling rate of *ca.* -1 K min^{-1}; for series-2 crystal-III (obtained by the same procedure as series-I) was annealed at 78 K for *ca.* 36 h; for series-3, it was made through the phase transformation from crystal-I (on which the heat capacity measurement up to 100 K was carried out) and subsequent annealing at 80—100 K for about 2 days. Crystal-II was prepared by cooling the crystal-I to 78 K and subsequent annealing at *ca.* 120 K. Complete transformation of crystal-I into crystal-II was confirmed by observing the cessation of the heat evolution accompanied by irreversible phase transition.

The molar heat capacities are given in Table 1 and plotted in Fig. 3. Besides the big heat capacity jump due to the glass transition phenomenon of crystal-I, a small heat capacity jump for crystal-III at *ca.* 80 K can also be seen. In the measurement for crystal-I and -III, heat evolution was observed in the temperature range

53—78 K. The effect of this heat evolution due to stabilization was removed from heat capacity values by correcting the temperature drift. At temperatures near 80 K, the temperature drift was followed for half an hour after the energy input was over. The last temperature observed was used as the final temperature for the calculation of heat capacity. Thus, these values correspond to the heat capacities for the time scale of 1/2 h. The heat capacity we obtained was compared with the data of Huffman *et al.*[5] Their data are 0.3—0.5% greater for liquid and 0.2—0.8% greater for crystal-I. For crystal-II, they are about 0.5% greater at temperatures near the melting point.

Studies on Phase Transitions. *a) Crystal-II→Crystal-I Phase Transition*: This phase transition is of a sluggish nature.[5] In order to determine the transition temperature, the electric energy for the completion of transition was added to the sample in eight separate stages, the temperature drift being followed each time for 2 h or more after the energy input was over. The temperature drift did not cease even after 2 h. The temperature after 2 h was observed to decrease in the first three stages. The temperature drift for 3rd and 4th energy inputs was analyzed by means of exponential function and the equilibrium temperature was estimated. Since the value coincides within 25/10000 K, we adopt it as the transition temperature. Heat of transition was measured twice, the results being given in Table 2 together with those of Huffman *et al.*

b) Fusion: The equilibrium temperature during the course of fusion was measured as a function of fraction melted. Assuming no solid solution formation, the

Huffman *et al.*	
$T_{t.p.}=169.67\pm0.05$ K	$\Delta_m H=3.293\pm0.002$ kJ mol^{-1}

purity of the specimen was determined to be 99.96%. The heat of fusion was measured twice (Table 3).

c) Crystal-III→Crystal-I Phase Transition: Since a rather long time (an hour or more) was necessary to obtain one heat capacity data, an irreversible phase transition from the newly formed crystal-I into crystal-II inevitably began during the measurement of crystal-III →crystal-I transition. The transition temperature and the molar heat of transition ($\Delta_{III-I}H$) were determined as follows: Crystal-III was heated by electric energy from T_i to a temperature at which the crystal-III was transformed almost completely into crystal-I. The spontaneous temperature rise due to the irreversible phase transition from crystal-I to crystal-II was then followed. When the transition was almost completed, the electric energy was further supplied to the sample in order to bring it into crystal-I, the final temperature being T_f. This last procedure was necessary because the final stage of the transition (metastable crystal-I→ crystal-II) was so sluggish that it caused a large error due to the heat leak during the time consuming observation for detecting the end point of transition. The value $\Delta_{III-I}H$ can be calculated by means of the following relations.

$$\Delta_{III-I}H = H^{I}_{T_t} - H^{III}_{T_t} \quad (1)$$

$$H^{I}_{T_t} = H^{I}_{T_m} - \int_{T_t}^{T_m} C_p^{I} dT \quad (2)$$

$$H^{III}_{T_t} = H^{I}_{T_i} + \int_{T_i}^{T_t} C_p^{III} dT - E \quad (3)$$

where T_t is the transition point of crystal-III→crystal-I, T_m the melting point, C_p^{I}, C_p^{III} the extrapolated values of heat capacity of crystals I and III, respectively, and E the total energy input. In Eqs. 1, 2 and 3 the terms for the empty cell are omitted for the sake of simplicity. The approximation that the whole of $\Delta_{I-III}H$ is absorbed at $T=T_t$ is also involved implicity. The data and equations used for calculating $\Delta_{III-I}H$ are summarized in Table 4. Because of the spontaneous recrystallization, the heat capacity measurement for crystal-I was intervened between 85 and 139 K. The heat capacities in this range were estimated by means of the equation given in Table 4, calculated by extrapolating the measured heat capacities between 140 and 152 K and bringing the result to fit smoothly the data around 85 K.

Table 4. Transition (Crystal-III→Crystal-I) data summary

$T_t=112.3\pm0.1$ K
$\Delta_t H=1.483\pm0.054$ kJ mol^{-1}
$\Delta_m S=13.72\pm0.45$ JK^{-1} mol^{-1}
$C_p^{I}=32.19+0.4437\ T$
$C_p^{III}=3.60+0.6650\ T$
$T_i=99.9117$ K
$T_f=141.5663$ K
$E=1830.84$ J

On the other hand, the transition temperature was determined by the dynamical method. Electric energy was put into the crystal-III at a constant rate and the time variation of temperature was followed. Transition temperature was determined to be the temperature where dT/dt (T; temperature, t; time) attained minimum value. The temperature difference between temperature during the energy input and that corresponding to the equilibrium state was corrected by measuring the difference at lower temperatures at which no phase transition effect takes place.

Residual Entropy of Glassy Crystalline States. Beckett *et al.*[10] calculated the entropy and heat capacity of ideal gas state of cyclohexene on the basis of spectroscopic data. Although spectroscopic entropy coincided with the experimental one within their error limits, there was a significant difference between the calculated and the observed heat capacity data. They explained the difference by assuming the existence of an energy-rich conformer having a larger strain energy (11.3 kJ mol^{-1}) than that of the ordinary half-chair conformer. Since the discrepancy for entropy (0.16 JK^{-1} mol^{-1}) is within experimental error, it might be that the crystal-II has

no residual entropy at 0 K. Taking this into consideration, the residual entropies of glassy crystal-I and glassy crystal-III were calculated. Contribution below 14 K was calculated by means of extrapolated heat capacities with a Debye model. The contribution from 85—140 K for crystal-I was calculated by the equations given in

Table 4. Details of the calculation are given in Table 5. The residual entropies of glassy crystal-I and glassy crystal-III were found to be (11.67±0.70) and (2.61±0.37) JK^{-1} mol^{-1}, respectively.

Thermodynamic Functions. Smoothed values of heat capacity at rounded temperatures along with values of other derived thermodynamic functions are given in Table 6. For all the phases, $H_0°$ refers to the zero point enthalpy of crystal-II. The entropy values for all phases are also referred to the entropy of crystal-II at 0 K, which is considered to be zero.

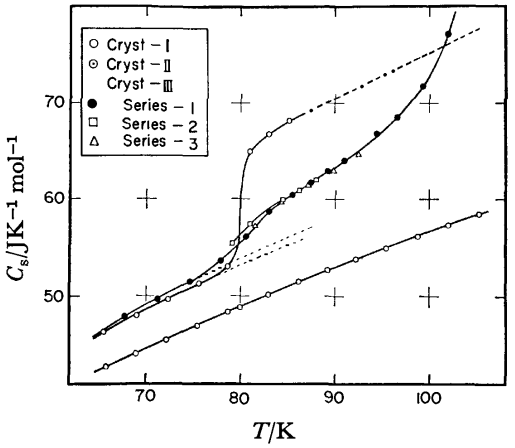

Fig. 4. Heat capacities of glassy crystal-I, -III and crystal-II around glass transition temperature.

Purity of the Crystal-III Phase. Heat capacity curves for crystal-I, -II, and -III around glass transition region are shown in Fig. 4. The temperatures at which the heat capacity jump occurs are very close for crystal-I and -III. Thus the possibility that the heat capacity jump for crystal-III is caused by crystal-I contained in crystal-III as an impurity might be considered. However, this possibility was discarded for the following reasons. (1) The results for series-1 and -3 agree in spite of the difference in the method of preparation of crystal-III. It is very improbable that different samples contain almost the same amount of impurity. (2) The ratios $S_0°$ (III)/$S_0°$ (I) (=0.22) and ΔC_p (III)/ΔC_p (I) (=0.32) differ from each other beyond the estimated error (ΔC_p is the heat capacity jump at around 80 K). (3) The activation enthalpies of the relaxation phenomena around glass transition region differ for crystal-I and crystal-III. (4) The heat capacity of crystal-III is greater in the temperature region 62—80 K. Our view that the heat capacity jump of crystal-III at around 80 K is an intrinsic property of this phase is thus supported.

Relaxation Around Glass Transition Region For both the glassy crystal-I and -III, heat evolution due to the enthalpy relaxation was observed to start at *ca.* 50 K, the temperature rising linearly with time (Fig. 5). If we assume an exponential type for the enthalpy relaxation, the following equation holds.

$$\frac{d\Delta H(t)}{dt} = -\frac{1}{\tau}\Delta H(t), \qquad (4)$$

where $\Delta H(t)$ is the enthalpy difference of the glassy state at time t and equilibrium state and τ the relaxation time. For small t ($t \ll \tau$), $\Delta H(t)$ is nearly equal to $\Delta H(0)$.

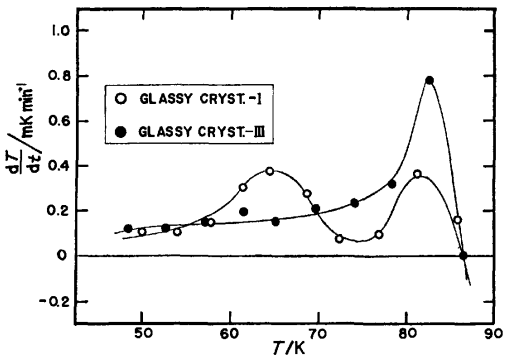

Fig. 5. Rate of the temperature rise at temperatures below T_g.

Thus, $d\Delta H(t)/dt$ is nearly constant, or the temperature of the sample rises linearly with time, the slope being proportional to $\Delta H(0)/\tau$. If a simple relaxation mechanism of the type of Eq. 4 is assumed, the behavior of the glassy crystal-III, in which one peak appears in dT/dt *vs.* T curve, seems to be normal. No interpretation can be given for the origin of the second peak in the dT/dt *vs.* T curve for glassy crystal-I. At temperatures above 78 K, the sign of the $\Delta H(0)$ changed, a negative temperature drift being observed. Relaxation times at various temperatures were determined by analysis of the drift by means of Eq. 4. From the Arrhenius plot of the relaxation time, the activation enthalpy of the relaxation was found to be 18 and 7 kJ mol^{-1} for glassy crystals -I and -III, respectively. The temperature at which the relaxation time for glassy crystal-I becomes one minute is found to be 92 K from this plot. The difference in the T_g values determined by the DTA method and heat capacity measurement might be explained by the difference in the time scale of the observation.

Preparation of Glassy Liquid by Vapor Condensation Method. DTA curves obtained with a vapor condensation type DTA apparatus are reproduced in Fig. 6. Run 1 is the heating curve of the sample condensed from vapor directly onto the sample holder maintained at 68 K. Runs 2 and 3 show the heating curves after the tempera-

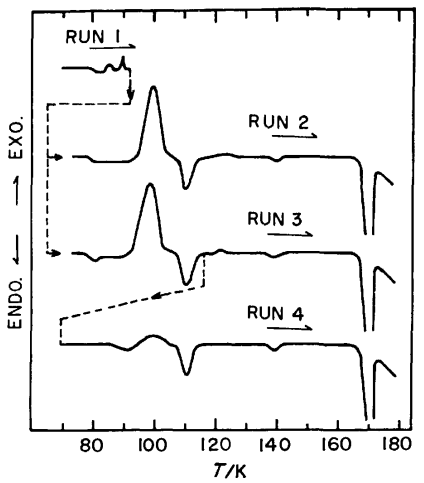

Fig. 6. DTA curves for the samples condensed from vapor.

ture cycling between 68 and 92 K. For Run 3 the sample was annealed for an hour at 77 K prior to the measurement. Run 4 shows the heating curve after the temperature cycling between 68 and 118 K and corresponds to Run 3 in Fig. 1. Although some exothermic anomalies in Run 1 cannot be assigned yet, there are evidences for concluding that each baseline shift to endothermic direction in these runs (Runs 1, 2, and 3) at 78 K is the manifestation of glass transition of liquid: (1) Annealing effect characteristic of the glass transition in Run 3. (2) Rough agreement of the liquid→crystal-III crystallization enthalpy (=4.3 kJ mol^{-1}) estimated from its peak area referring to the peak areas of crystal-III→crystal-I and melting of crystal-I with its value (4.8 kJ mol^{-1}) calculated from calorimetric data. It is tacitly assumed that the peaks in Run 1 do not represent the inherent property of a large part of the vapor condensed phase but that of the unstable crystalline phase formed as complex phase during the course of vapor condensation. Another interpretation that the peaks were caused by the transition occurring in all parts of the sample is also possible. If this is the case, the base line shift to endothermic direction in Run 1 corresponds to the glass transition of liquid but that in Runs 2 or 3 correspond to the glass transition of unstable new crystalline phase. We can conclude that the glassy liquid was prepared by the vapor condensation method, its glass transition temperature being 78 K.

Discussion

Molecular motions in crystalline state of cyclohexene were studied by Saffar *et al.*[11] by means of NMR. In their study on the temperature dependence of the second moment as well as of the spin lattice relaxation time, they found a phase transition at 128.5 K where we found no thermal anomaly. The lack of detailed description of the thermal treatment of their sample and the inconsistency between their assignment on the crystalline phases and ours make it difficult for us to discuss our results in reference to their work. A tentative interpretation is as follows.

Cyclohexene molecule has two half-chair conformations. The existence of another conformation (boat conformation) can be neglected in the low temperature region because of its high strain energy (11.3 kJ mol^{-1} by Beckett *et al.*[10] and 18.0 kJ mol^{-1} by Anet[12]). Saffar *et al.*[11] reported that the ring inversion motion appears at 115 K in crystal-I (our nomenclature). Above this temperature the Arrhenius plot of the correlation time obtained from their T_1 experiment gave 10 kJ mol^{-1} for the activation energy which we obtained from the plot in Fig. 4 of their paper. Similarity of the value with the activation enthalpy of the relaxation phenomenon in crystal-III (7 kJ mol^{-1}) suggests that the ring inversion mode dominates the relaxation phenomenon of crystal-III near the glass transition region. It is plausible that this mode will survive down to a lower temperature than the life of molecular rotation because the energy difference giving rise to the ordering of the mode of such a ring inversion will be created with the settling down of the rotational motion. The energy difference between the two conformers also depends upon the packing density and symmetry of the crystal; higher density or the lower symmetry will give larger energy difference. It is likely that the energy difference in crystal-II, which seems to have higher density and lower symmetry, is so large that the order is attained at the transition temperature. On the other hand, the energy difference for crystal-III may be of the order of thermal energy, so the relaxation phenomenon of the ring inversion was observed calorimetrically. Complete disorder of the ring inversion mode should contribute to the entropy by $R\ln 2$ (=5.8 JK^{-1} mol^{-1}). Thus the partial order is already attained at T_g in crystal-III since the residual entropy of the glassy crystal-III (2.7 JK^{-1} mol^{-1}) is less than the value for complete disorder.

Since the residual entropy of glassy crystal-I is larger than $R\ln 2$, there must be some other type of disorder such as orientational randomness around the axis (z axis) normal to the molecular plane. The rotation about the axis was suggested by Saffar for crystal-I. The energy difference between the two conformers in crystal-I at T_g may be smaller than that of crystal-III at T_g' because of the more disordered orientational freedom, lower density, and presumably of the higher crystal symmetry of crystal-I. Mode of ring inversion in crystal-I seems to contribute to the residual entropy by the amount corresponding to nearly complete disorder.

Glassy crystals of cyclohexene seem to provide an interesting example for the simplification of the configurational mode. It is likely that the configurational freedom may be the rotation about z axis+ring inversion and simply ring inversion in crystal-I and crystal-III, respectively. If this is the case, the glass transition of crystal-III corresponds simply to the mode of ring inversion and successive simplification of the configurational freedom is achieved in the order of glassy liquid→glassy crystal-I→glassy crystal-III.

Heat Capacity of Potassium *p*-Chloranil Anion Radical Salt between 13 and 330 K*

Akio Kosaki,† Michio Sorai, Hiroshi Suga, and Syûzô Seki
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received October 18, 1976)

The heat capacity measurement for an organic free-radical salt, potassium *p*-chloranil, revealed a first-order phase transition at T_c=260.01 K. In spite of a first-order nature, the pre- and the post-transitional effects are remarkable. The enthalpy and the entropy of transition were determined to be ΔH=2796 J mol^{-1} and ΔS=11.06 JK^{-1} mol^{-1}, respectively. The magnetic contribution to ΔS is only 2.23 JK^{-1} mol^{-1} when a dimeric configuration with a singlet-triplet spin equilibrium is assumed in the low temperature phase and a monomeric behavior of radicals with spin doublet is assumed above T_c. The present phase transition bears a close resemblance to a spin-Peierls transition in a linear chain system. The infrared spectrum at 120 K indicates a possible formation of dimers in the low temperature phase of this salt. A phenomenological model for the present phase transition is presented.

Among a number of stable organic free radicals, the compounds which exhibit a cooperative phase transition due to unpaired electrons are very scarce. Moreover, these phase transitions are quite unique in that the spin and electronic state and the structural change are inseparably related to one another and that the mechanism of phase transition is different from radical to radical.

In this paper we report the heat capacity of potassium *p*-chloranil crystal [abbreviated hereafter as K$^+$(*p*-chloranil)$^-$ or more simply as K$^+$(CA)$^-$]. This is one of the typical anion radical salts together with the TCNQ salts. The magnetic susceptibility and the electron paramagnetic resonance (EPR) measured by Andre *et al.*[1] revealed a first-order phase transition at T_c=260 K on raising and at T_c=210 K on lowering temperature. The magnetic susceptibility above T_c follows well the Curie-Weiss law while the magnetic behavior below T_c is described by the energy scheme of a singlet-triplet equilibrium. This result suggests that the *p*-chloranil anion radicals exist as monomers in the K$^+$-(CA)$^-$ salt above T_c and as dimers below T_c. EPR,[1,2] electronic absorption spectra,[3-6] and X-ray diffraction analysis[7] of this salt support the monomeric behavior of the *p*-chloranil anion radicals in the high temperature phase. On the other hand, Hiroma and Kuroda[8] investigated the temperature dependence of the electronic absorption spectra of the K$^+$(CA)$^-$ salt and found that an abrupt increase of intensity occurs in the charge-transfer band at the phase transition point when the specimen is cooled. This fact suggests that the low temperature phase has a crystal structure of a dimeric arrangement of the *p*-chloranil anions. Although an X-ray diffraction analysis of the low temperature phase has not been made, this suggestion seems to be quite reasonable in comparison with the electronic absorption spectra of K$^+$(CA)$^-$ in solution,[5,6,9,10] where the monomer-dimer equilibrium is established.

In spite of a useful method which provides important information concerning the energetic aspects, the number of works in which heat capacity measurements are applied to organic free-radical salts are scarce.[11-21] The present paper clearly reveals a first-order phase transition at 260.01 K. As is in the case of other radicals, the magnetic contribution to the transition entropy is not dominant. Although a quantitative explanation for the phase transition is not given, a phenomenological model is described here.

Infrared spectroscopy also serves as a useful tool to elucidate the local symmetry of the constituent entity. But the infrared spectra hitherto reported are room temperature data.[22-24] We also report here the infrared spectra of the K$^+$(CA)$^-$ salt between 4000 and 30 cm^{-1} in both the high and the low temperature phases.

Experimental

Material. The starting materials, potassium iodide and *p*-chloranil, were recrystallized twice from water and benzene, respectively. The solvent, acetone, was purified by the method of Scheibe *et al.*[25] The K$^+$(CA)$^-$ salt was prepared according to the method of Torrey and Hunter.[26] The reaction temperature was 263±2 K. The product was washed with chilled acetone and dried *in vacuo* for three days. Found: C, 25.26; Cl, 49.37%. Calcd for $C_6Cl_4O_2K$: C, 25.29; Cl, 49.76%.

It has been reported[7,8,10] that the preparation method by Torrey and Hunter does not yield one and the same modification of the K$^+$(CA)$^-$ crystal. We prepared the K$^+$(CA)$^-$ salt at two different temperatures (263 and 273 K) and examined their thermal properties by using a differential scanning calorimeter (DSC). The salt prepared at 263 K exhibited a sharp endothermic peak due to the phase transition at 260 K while the salt precipitated above 273 K gave a broad peak. This fact implies the contamination of some impurities in the salt prepared above 273 K. On the other hand, it is possible that the salt prepared at 263 K would be a mixture of the high and the low temperature modifications as the synthesis temperature is close to the phase transition point (T_c=260.01 K) and thus the free energies of both phases are virtually the same magnitude in this temperature region. In fact the DSC curve showed the trace of a small amount of the low temperature modification. Therefore, whenever the infrared and the Raman spectra were recorded at roon temperature, the specimen was once cooled down to about 100 K and warmed up to a room temperature.

Heat Capacity Measurement. The heat capacity was measured with an adiabatic calorimeter[27] in the temperature

* Presented before the Symposium on the Magnetochemistry, Nagoya (1970).

† Deceased on July 16, 1974.

region from 13 to 330 K. The sample of 8.0239 g (=0.028156 mol) was sealed into the calorimeter cell together with a small amount of helium gas as the heat exchanger.

Infrared and Raman Spectra. The infrared spectra at a room temperature and 120 K were recorded on a Grating-type Infrared Spectrophotometer Model DS-402G (Japan Spectroscopic Co., Ltd.) in the wave number region from 4000 to 400 cm^{-1} and on a Spectrophotometer Model FIS-001 (Hitachi Ltd.) in the range from 400 to 30 cm^{-1}. Nujol mull method was employed for the preparation of samples.

The Raman spectra of $K^+(CA)^-$ salt were recorded on a laser Raman Spectrophotometer Model R-750 with the argon laser (514.5 nm) in the range from 0 to 4000 cm^{-1} at a room temperature. It was difficult to obtain a good Raman spectrum of this salt because of its continuous absorption band in the corresponding wave number region and the instability of this radical salt against the strong argon laser exposure.

Results

Heat Capacity of $K^+(CA)^-$ Salt. Prior to the heat capacity measurement, we performed the DSC measurement for the $K^+(CA)^-$ salt. An exothermic peak was observed at 220 K on cooling and an endothermic peak appeared at 260 K in a heating run. A large hysteresis effect with a temperature interval of 40 K indicates a typical first-order nature of the phase transition.

The measured values for the heat capacity are plotted in Fig. 1 and the numerical values are given in Table 1. The standard thermodynamic functions for the $K^+(CA)^-$ salt are shown in Table 2. A sharp heat capacity anomaly is found around 260 K. The phase transition

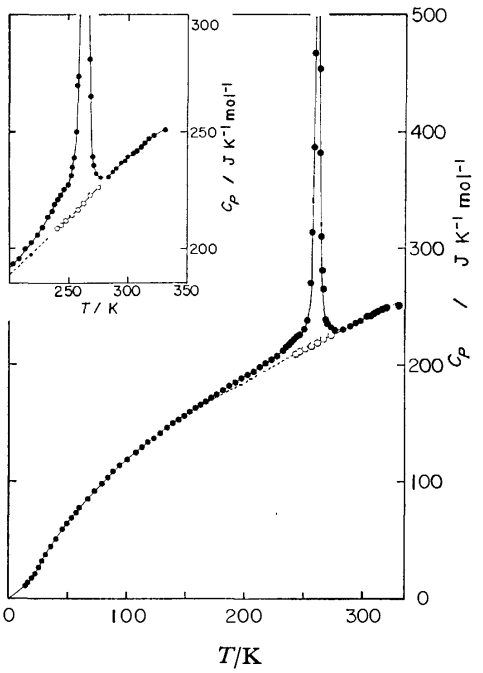

Fig. 1. The molar heat capacity of the $K^+(p$-chloranil)$^-$ anion radical salt. Open circles indicate the heat capacities of the supercooled high temperature phase. Broken line is the extrapolated curve of the supercooled high temperature phase and serves as a "normal" heat capacity for the estimation of the transition enthalpy and entropy.

temperature T_c is determined to be 260.01 K. We succeeded in measuring the heat capacities for the supercooled high temperature phase between 240 and 270 K. These values are represented in Fig. 1 by open circles.

In order to determine the enthalpy and the entropy associated with the phase transition, it is necessary to separate the "excess" heat capacity from the total one by estimating a plausible "normal" heat capacity. In the present case, the normal heat capacity is rather easily determined by extrapolating the experimental values for the supercooled high temperature phase to the low temperature side. The broken line shown in Fig. 1 represents the normal heat capacity. In spite of the first-order nature of the present phase transition the excess heat capacity has its long tail down to about 150 K. This fact suggests a higher-order nature of the initial stage of the present phase transition. The enthalpy and the entropy of transition are determined to be $\Delta H=2796$ J mol^{-1} and $\Delta S=11.06$ J K^{-1} mol^{-1}, respectively. The transition entropy corresponds to R ln 3.78 and this value is too large to be accounted for solely in terms of the magnetic contribution.

According to the structural analysis by Konno *et al.*,[7] the $K^+(CA)^-$ salt has several polymorphs and two dominant modifications are denoted as the α-form (orthorhombic, space group $P2_12_12_1$ and molar volume $V_m=139.3$ cm^3 mol^{-1}) and the β-form (orthorhombic, $P22_12$ and $V_m=136.9$ cm^3 mol^{-1}). Hiroma and Kuroda[8] found that the amount ratio of the α- to the β-form is about 10: 1. As was described in the previous section, we found that when the synthesis temperature is higher than 273 K, the salt contains some impurities and when the salt is prepared at 263 K, the contamination of impurities is considerably reduced but a small amount of the crystals having the low temperature modification is mixed. In addition to this observation, the fact that the β-form has the slightly smaller molar volume than that of the α-form suggests that the β-form is the low temperature modification of the $K^+(CA)^-$ salt.

Temperature Dependence of Infrared Spectra. Figure 2 shows the infrared spectra of the $K^+(CA)^-$ salt at 295 and 120 K in the wave number region from 1800 to

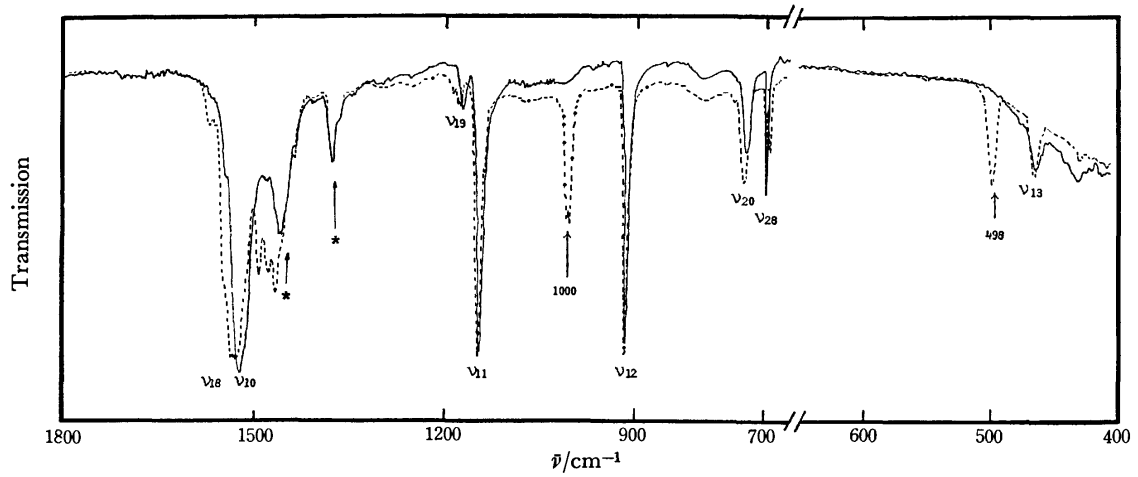

Fig. 2. Infrared spectra of the $K^+(CA)^-$ salt at 295 K (——) and at 120 K (——). The bands marked with an asterisk are the absorption bands due to Nujol. In this and in Fig. 3, the fundamentals already assigned by Girlando *et al.*[24] are indicated by their symmetry species.

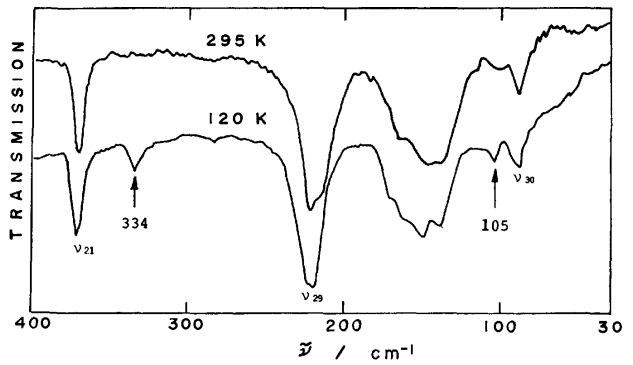

Fig. 3. Far infrared spectra of the $K^+(CA)^-$ salt at 295 and 120 K.

400 cm^{-1}. The far infrared spectra between 400 and 30 cm^{-1} are reproduced in Fig. 3. The spectra recorded at 295 K coincide well with the data previously reported.[23,24] The infrared spectra are markedly influenced by the effect of the phase transition. In the low temperature phase at 120 K, new absorption bands appear at 105, 334, 498, 1000 (doublet) and around 1450 cm^{-1} (doublet). Furthermore the band assigned as $b_{3u}\nu_{28}$ splits into a doublet.

Since the *p*-chloranil anion radical belongs to D_{2h} point group at least in the high temperature phase, it has a center of symmetry and a twofold axis. Under this symmetry the rule of mutual exclusion can be applied to the spectroscopic data. The gerade normal modes for the symmetry operation are infrared inactive and Raman active while the ungerade normal modes are infrared active and Raman inactive. The new bands at 1000, 498, and 334 cm^{-1} appeared in the low temperature phase seem to belong to the gerade normal modes in the high temperature phase because the Raman spectrum of this salt recorded at 295 K has the bands corresponding to the same wave numbers. Therefore, it is concluded that the D_{2h} symmetry of the *p*-chloranil anion radical in the high temperature phase is lowered in the low temperature phase through the intermolecular interaction characterized by the dimerization and/or by the variation of the crystalline field due to a possible structural change at the phase transition temperature. In this situation, some of the infrared inactive gerade modes are changed into the infrared active modes below the phase transition temperature.

Owing to the lower symmetry than D_{2h} of *p*-chloranil anion radical in the low temperature phase, there exist in general no multi-degenerate normal modes. Accordingly, the appearance of the doublets at 1000 and 698 cm^{-1} (the ν_{28} mode) should be attributed to two inequivalent anion radicals in the crystal lattice of the low temperature phase. Unfortunately the structural data on the low temperature phase of the $K^+(CA)^-$ radical salt, which confirms the present prediction, has not been reported. The *p*-chloranil anion radicals are known to behave as monomer in the high temperature phase and as dimer in the low temperature phase characterized by a siglet-triplet spin equilibrium.[8] This suggests a strong intermolecular interaction between adjacent radicals below the transition temperature. The selection rule of the infrared spectra in the low temperature phase is governed by the total symmetry of the dimeric entity. Two identical normal modes, which originally belong to two individual radicals forming a dimer, couple with each other and the absorption occurs at slightly different wave numbers. The origin of the seeming doublets at 1000 and 698 cm^{-1} can be interpreted in this way.

Hiroma and Kuroda[10] reported that the $K^+(CA)^-$ radical salt has a tendency to take water molecules into the crystal lattice when the crystal is exposed to a humid air. The hydrate is characterized by three infrared absorption bands at 3400 cm^{-1} (the O-H stretching), 1630 cm^{-1} (the H-O-H bending vibration) and 1000 cm^{-1} (the librational motion of water molecule). The present infrared spectra at 295 K show no bands at these wave number region, which indicates that the present salt is anhydrous.

Relationship between Magnetic Behavior and Phase Transition

Andre *et al.*[1] measured the magnetic susceptibility, χ, of the $K^+(CA)^-$ anion radical salt and concluded that the magnetic spins behave as in the singlet-triplet equilibrium below T_c while the magnetic behavior above T_c is accounted for in terms of spin doublet due to the monomeric radical. This prediction has been supported by various kinds of experiments such as EPR[1,2] electronic absorption spectra,[3-6,8] and the structural analysis.[7] However, the logic of Andre *et al.* leading to their conclusion is not correct in the meaning that they have drawn their conclusion based on their incorrect estimation of the asymptotic value of χT at infinite temperature for the singlet-triplet energy scheme. They obtained the value of $(\chi T)_\infty$ to be 1/4 and 3/8 for the singlet-triplet scheme (abbreviated as the ST-scheme) and the doublet scheme (the D-scheme), respectively. But in the present case, the value of $(\chi T)_\infty$ should be identical to each other.

The magnetic susceptibility for the ST-scheme is represented by

$$\chi = \left(\frac{N_A}{2}\right)\frac{S(S+1)g^2m_B^2}{3kT}\left\{1+\frac{1}{3}\exp(J/kT)\right\}^{-1} \quad (S=1), \quad (1)$$

where N_A is the Avogadro constant, g the electron g-factor (=2.0), m_B the Bohr magneton, S the spin quantum number, and J the triplet excitation energy corresponding to the energy separation between the singlet and the triplet states. If the triplet density is defined by

$$\rho_T \equiv \left\{1+\frac{1}{3}\exp(J/kT)\right\}^{-1}, \quad (2)$$

we obtain the following relation:

$$\chi T = \frac{1}{2}\rho_T. \quad (3)$$

Because of $0 \leqq \rho_T \leqq 3/4$, the range of χT becomes

$$0\,(T=0) \leqq \chi T \leqq \frac{3}{8}\,(T=\infty). \quad (4)$$

On the other hand, the susceptibility for the D-scheme is given by the Curie law,

$$\chi = \frac{Ng^2m_B^2}{3kT}S(S+1) \quad \left(S=\frac{1}{2}\right), \tag{5}$$

where N is the number of spins having $S=1/2$. Since the doublet density is defined by

$$\rho_D \equiv \frac{N_A}{N} \quad (0 \leqq \rho_D \leqq 1), \tag{6}$$

we obtain the following relations:

$$\chi T = \frac{3}{8}\rho_D \tag{7}$$

and

$$0(T=0) \leqq \chi T \leqq \frac{3}{8}(T=\infty). \tag{8}$$

We estimated the triplet excitation energy J and the doublet density ρ_D by applying respectively the ST- and the D-schemes to the magnetic susceptibility data obtained by Andre *et al.*[1] The results are shown in Fig. 4 in terms of J/k and ρ_D against T. It should be remarked here that the triplet excitation energy shows a constant value ($J/k=660$ K) below T_c. This fact supports the validity of the ST-scheme below T_c.

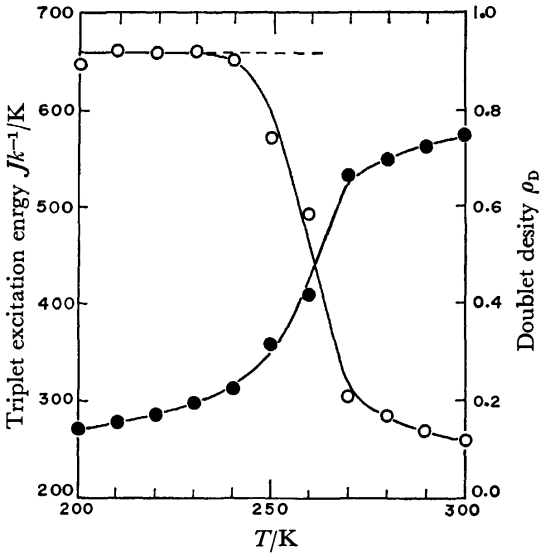

Fig. 4. The triplet excitation energy J/k(○) and the doublet density ρ_D(●) against temperature($T_c=260.01$ K) for the $K^+(CA)^-$ salt. These quantities are estimated from the magnetic susceptibility obtained by Andre *et al.*[1]

On the other hand, in the high temperature phase the magnetic feature is more complicated. If the doublet scheme is applied to the present system, the doublet density amounts to 0.75 at 300 K and shows a tendency to approach 1.00 with further increasing temperature. In case of the singlet-triplet scheme, the triplet excitation energy is considerably reduced to $J/k=250$ K at a room temperature. Although solely from the present result we cannot explicitly give an answer to the question of which scheme is established in the high temperature phase of the $K^+(CA)^-$ salt, it is very likely that most of the *p*-chloranil radicals behave as monomers with $S=1/2$ but the remaining minor fraction exists in the singlet-triplet equilibrium. With increasing temperature, the ST-scheme is transferred into the D-scheme. At any rate, the present phase transition is essentially characterized by the transition between dimer and monomer in a magnetic linear chain. This situation bears a close resemblance to a spin-Peierls transition in a Heisenberg linear chain system,[28] where an instability of magnetic linear chain at low temperatures is overcome by a structural phase transition coupled with the spin system.[29]

The entropy of the magnetic system with the triplet density ρ_T is represented by

$$S = \frac{1}{2}R\{\rho_T \ln 3 - \rho_T \ln \rho_T - (1-\rho_T)\ln(1-\rho_T)\}, \tag{9}$$

while the magnetic entropy due to the doublet density ρ_D is given by

$$S = R\rho_D \ln 2, \tag{10}$$

where R is the gas constant. We estimated the magnetic contribution to the transition entropy for the following three cases: (i) the ST-scheme below T_c and the D-scheme above T_c, (ii) the ST-scheme below and above T_c, and (iii) the D-scheme below and above T_c. As the pre- and the post-transitional effects are rather large in the heat capacity curve shown in Fig. 1, the estimation of the magnetic entropy has been made for the temperature interval between 200 and 285 K. In the case of (i), the change in spin state from the ST-scheme ($J/k=660$ K, $\rho_T=0.10$) to the D-scheme ($\rho_D=0.70$) yields the magnetic entropy of $\Delta S_{mag}=2.23$ J K^{-1} mol^{-1}. As to the case (ii), $\Delta S_{mag}=S(J/k=280\text{ K}, \rho_T=0.53)-S(J/k=660\text{ K}, \rho_T=0.10)=3.49$ J K^{-1} mol^{-1}. The case (iii) gives the magnetic entropy of $\Delta S_{mag}=S(\rho_D=0.70)-S(\rho_D=0.14)=3.23$ J K^{-1} mol^{-1}. Since the total entropy arising from the phase transition is $\Delta S=11.06$ J K^{-1} mol^{-1}, the magnetic contribution corresponds merely to 20% for the case (i) and 30% for (ii) and (iii). The remaining entropy results from the phonon system. On the other hand, the total magnetic entropy for the $K^+(CA)^-$ salt is at most $R\ln 2$ (=5.76 J K^{-1} mol^{-1}) independently of the spin scheme (see Eqs. 9 and 10), and the cooperative fraction of the magnetic entropy is 39, 61, and 56% for the cases (i), (ii), and (iii), respectively.

Phenomenological Model for Phase Transition

The phase transition found for the $K^+(CA)^-$ salt is of a first order in nature but the pre- and the post-transitional effects spread over a wide temperature region suggest easy fluctuations of the heterophases in this temperature region. We apply here a phenomenological model, which is virtually the same with the Frenkel theory of heterophase fluctuation in liquid,[30] to the present phase transition.

We shall assume that one phase contains "embryos" of a second phase in the transition region and that each embryo consists of a uniform size. We consider a system consisting of N cells each of which contains n molecules. The product of N and n is equated to Avogadro's constant N_A. The interaction energy between the adjacent cells belonging to the low and the high temperature phases is denoted by J_{LH}. As the surface area

of a cell changes with its dimension, the interaction energy is multiplied by $N^{1/3}$. The Gibbs energy of the system can be written as

$$G = G_L x + G_H(1-x) + N^{1/3}J_{LH}x(1-x) + NkT\{x\ln x + (1-x)\ln(1-x)\}, \quad (11)$$

where G_L and G_H are the Gibbs energies of the low and the high temperature phases, respectively, and x is the fraction of the cells belonging to the low temperature phase. The equilibrium value of x may be found by minimizing G with respect to x: $\partial G/\partial x=0$. The solution to this is given by those values of x which satisfy

$$\frac{1}{x} = 1 + \exp[\{G_L - G_H + N^{1/3}J_{LH}(1-2x)\}/NkT]. \quad (12)$$

The heat capacity of the system, C_p, is represented as follows:

$$C_p = xC_{pL} + (1-x)C_{pH} + \left(\frac{\partial x}{\partial T}\right)\{H_L - H_H + N^{1/3}J_{LH}(1-2x)\}, \quad (13)$$

here

$$\left(\frac{\partial x}{\partial T}\right)\frac{N^{2/3}x(1-x)}{N^{2/3}kT - 2J_{LH}x(1-x)}\left(\frac{S_H - S_L}{N} + k\ln\frac{x}{1-x}\right) \quad (14)$$

where H and S mean the enthalpy and the entropy of the system. When the denominator of Eq. 14 becomes zero, the heat capacity (Eq. 13) diverges infinitely at T_c. According to its definition, the J_{LH} is positive. Therefore, the condition under which a phase transition occurs is given by

$$J_{LH}/N^{2/3} \geqq 2kT_c. \quad (15)$$

When $(J_{LH}/N^{2/3})$ is equal to $2kT_c$, the phase transition is of a second order while in case of $(J_{LH}/N^{2/3})>2kT_c$ a first-order phase transition takes place. If we define f as a fraction of the transition enthalpy corresponding to the first-order phase transition, namely the latent heat, the following relationship is obtained:

$$f^2 = 1 - 2kT_cN^{2/3}/J_{LH}. \quad (16)$$

The fraction of the latent heat increases with increasing the value of $(J_{LH}/N^{2/3})$. On the other hand, when J_{LH} is constant, the anomalous heat capacity due to the phase transition becomes broad with increasing N.

In order to apply this model to the actual system, the hypothetical Gibbs energies of both the low and the high temperature phases are necessary. We estimated these energies by extrapolating the heat capacity curve of the K+(CA)$^{\tau}$ salt above and below T_c. Figure 5 demonstrates temperature dependences of the fraction of the low temperature phase, x, for four different values of N_A/N under a condition of $(J_{LH}/N^{2/3})=2.2\,kT_c$. A discontinuity of x at T_c is apparent.

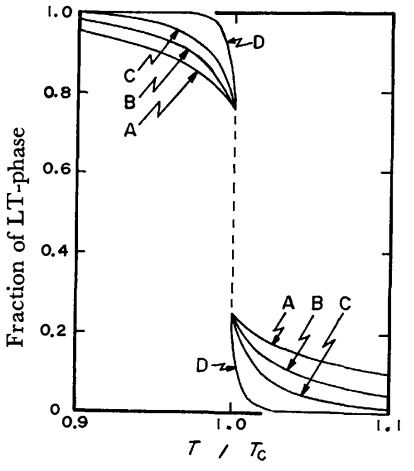

Fig. 5. Temperature dependence of the fraction of the low temperature phase, x, under a condition of $(J_{LH}/N^{2/3})=2.2kT_c$. $N_A/N=5$(A), 10(B), 20(C), and 100 (D).

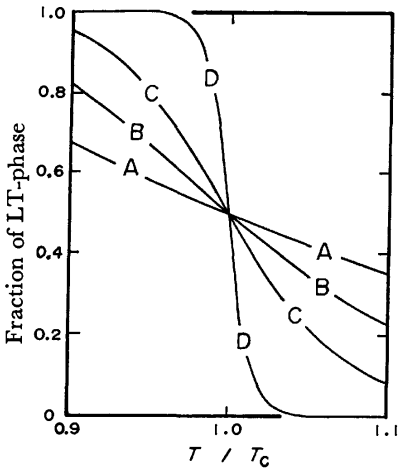

Fig. 6. Temperature dependence of the fraction of the low temperature phase, x, under a condition of $(J_{LH}/N^{2/3})=0$.
$N_A/N=5$(A), 10(B), 20(C), and 100(D).

When $(J_{LH}/N^{2/3})$ is smaller than $2kT_c$, the present model gives rise to neither a first- nor a second-order phase transition. This situation is illustrated in Fig. 6. The gradient of x at T_c increases with decreasing N.

The "best" fit of the calculated values to the experimental one is shown in Fig. 7. Here, the experimental value of x has been determined as $x=\Delta H(T)/\Delta H$. Although the phase transition of the K+(CA)$^{\tau}$ salt is of a typical first order, the "best" fit between the

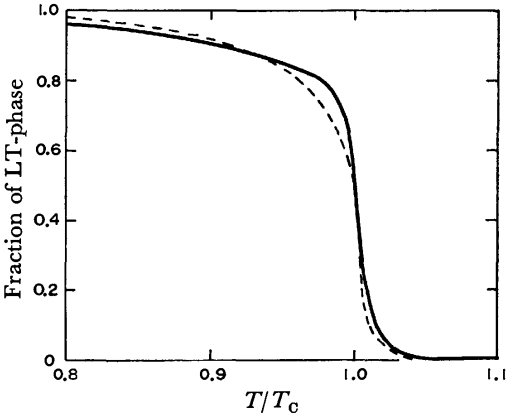

Fig. 7. Comparison of the fraction of the low temperature phase, x, between the experiment and the theory.
Solid line: the experimental curve.
Broken line: $(J_{LH}/N^{2/3})=1.8kT_c$, $N_A/N=5(T<T_c)$ and $200(T>T_c)$.

experiment and the present model is obtained under a condition of $(J_{LH}/N^{2/3})=1.8\,kT_c$. This fact indicates a complexity of the phase transition found for organic free radical salts as well as an incompleteness of the present model. However, it is interesting to note that the number of radicals included in a cell varies from $N_A/N=5$ in the low temperature phase to 200 in the high temperature phase. This suggests a considerably different correlation between radicals below and above T_c.

Thermodynamic Properties and Phase Transitions of Methyltriphenylphosphonium and Methyltriphenylarsonium Bis(7,7,8,8-tetracyanoquinodimethanide)s and Their Solid Solutions*

Akio KOSAKI,† Michio SORAI, Hiroshi SUGA, and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received October 18, 1976)

The heat capacities of stable organic free-radical salts $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$ (x=0, 0.159, 0.250, 0.449, and 1, and TCNQ=7,7,8,8-tetracyanoquinodimethane) have been measured with an adiabatic calorimeter in the temperature range between 12 and 370 K. The phase transitions are found for the former four cases at 315.65, 325.80, 333.05, and 357.92 K, respectively. The enthalpy and the entropy due to the phase transitions are determined. The transition temperature is raised by diluting the phosphonium salt with the arsonium one. This tendency is quite contrary to that found for usual solid solutions. The magnitude and the composition dependence of the transition entropy indicate that the phase transition of the solid solutions may be attributable to the changes in both the crystal structure and the magnetic spin state at the transition point. A plausible explanation for the present unusual tendency for the composition dependence is presented.

Organic anion radical salts based on 7,7,8,8-tetracyanoquinodimethane(TCNQ) have been found to exhibit very high electric conductivity and unusual magnetic properties.[1] The unpaired electron of a TCNQ anion radical is not necessarily lacalized on a particular atom but distributed over a whole TCNQ radical to a considerable extent.[2] The rather easy flip-flop motion of the unpaired electrons between adjacent radicals forming a column in a crystal brings about high electric conductivity. Because of the unique interaction of the spins associated with the unpaired electrons, the ground spin manifold is not a doublet but a singlet with a thermally accessible triplet state. Owing to these situations neither the localized spin model nor the continuous band model due to the collective motion of conduction electrons can describe satisfactorily the magnetic properties of anion radical salts. These peculiar behavior is of course expected to be reflected on their thermal properties.

In a previous publication[3] we reported briefly the heat capacity of methyltriphenylphosphonium bis(7,7,-8,8-tetracyanoquinodimethanide)[abbreviated hereafter as $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ or more simply as the P-salt] and pointed out that the phase transition observed at T_c=315.65 K cannot be described solely by the spin contribution. Based on the analysis of the transition entropy, it was predicted that the phase transition may be accompanied by a crystallographic change. The precise structural analyses by X-ray diffraction[4,5] demonstrated really the existence of a structural change at T_c. In the present paper we report thermodynamic properties and phase transitions of the P-salt and the methyltriphenylarsonium homolog[abbreviated as $[(C_6H_5)_3AsCH_3]^+(TCNQ)_2^-$ or more simply as the As-salt] as well as their solid solutions $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$ (x=0.159, 0.250 and 0.449).

Since the first synthesis of these radical salts,[6] extensive studies have been made by means of electron paramagnetic resonance (EPR),[7–13] electric conductivity,[14–18] magnetic susceptibility[19] and of high-pressure experiment[20,21] and also by theoretical treatment.[22–25] As to the mechanism of phase transition, two simple phenomenological models have been reported.[20,23] On the one hand, Chesnut[23] tried to interpret the transition mechanism of the P-salt by assuming that the spin state exists in a singlet-triplet equilibrium with the attractive interaction between triplets. His model accounts for the occurrence of phase transition when adequate values be assigned to the triplet excitation energy and to the exciton-exciton interaction energy. On the other hand, Merkl *et al.*[20] observed the pressure-induced phase transition for the P- and the As-salts and explained the p-T phase diagram for the As-salt in terms of an elementary theory of non-interacting triplet excitons. These two models succeeded in accounting for the gross aspects of the phase transition but failed to explain the transition entropy.

Kepler[19] measured the magnetic susceptibilities of the solid solutions $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$ with seven different values of x in the range from 100 to 450 K and found a discontinuity at each transition point for all the materials except for the pure As-salt. The interesting feature is that the transition temperature T_c was raised with increasing x. Iida[26] examined also this relationship between x and T_c by use of a differential scanning calorimeter (DSC). He confirmed the same result and found that the entropy of transition decreases in proportion to x. As will be seen below, the present investigation leads to a quite different conclusion as to the x-dependence of the transition entropy.

Experimental

Materials. The P-salt was prepared according to the method of Melby *et al.*[27] The purified starting materials, methyltriphenylphosphonium iodide and TCNQ, were dissolved respectively into purified acetonitrile. Then these two solutions were mixed at about 70 °C with vigorous stirring under nitrogen atmosphere. After the reaction was over, the solution was kept quietly standing for 24 hours at a cool and dark place to give blackish prism crystals. The As-salt was

* Presented before the 5th Annual Meeting of the Society of Calorimetry and Thermal Analysis, Japan, Osaka (1969) and the 26th Annual Meeting of the Chemical Society of Japan, Tokyo (1972).

† Deceased on July 16, 1974.

prepared from purified methyltriphenylarsonium iodide and TCNQ by the same method with that of the P-salt. Three kinds of solid solutions $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$ (x=0.159, 0.250, and 0.449) were obtained by the following procedures: Methyltriphenylphosphonium and methyltriphenylarsonium iodides were dissolved into pure acetonitrile in the ratio of $(1-x)$ to x. To this solution the acetonitrile solution containing the stoichiometric amount of TCNQ was added with vigorous stirring under nitrogen atmosphere at 70 °C.

Table 1. Weight of the sample used for heat capacity measurements and the results of elementary analyses[a] for $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$

a) The figures in parentheses are the values expected from the initial composition of the starting materials.

The results of elementary analyses for the five kinds of specimens are given in Table 1. The arsonium concentration x in each specimen was simply estimated from the amounts of the starting materials. The estimated values seem to approximate well to the true ones because Table 1 indicates that the composition of each specimen is simply proportional to the initial composition of the starting materials.

Measurements of Heat Capacities and Infrared Spectra. Heat capacity measurements of these radical salts were made with adiabatic calorimeters[28,29] in the temperature region from 12 to 370 K. The sample was sealed into the calorimeter cell with a small quantity of helium gas as a heat exchanger. The amounts of the samples used for the measurements are given in Table 1.

Infrared absorption spectra were recorded on a Grating-type Infrared Spectrophotometer Model DS-402G(Japan Spectroscopic Co., Ltd.) in the wave number region from 400 to 4000 cm^{-1}. Nujol mull and KBr-disk methods were employed for the preparation of samples. Far infrared absorption spectra of these radical salts were obtained by using a Spectrophotometer Model FIS-001 (Hitachi Ltd.) in the range from 30 to 400 cm^{-1}. Nujol mull method could not be used at high temperatures, so the sample was mixed with a small amount of polyethylene having low melting point.

Results

Heat Capacities. Heat capacity measurements were made for five kinds of solid solutions $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$($x$=0, 0.159, 0.250, 0.449, and 1) in the temperature range from 12 to 370 K. The observed heat capacities for the salts with x=0.159, 0.250, 0.449, and 1 are plotted in Fig. 1, while the heat capacity of the pure P-salt (x=0) has been given in a previous paper.[3] The numerical values of the heat capacities for the P- and the As-salts are summarized in Table 2 and their standard thermodynamic quantities are given in Table 3.

The P-salt and the solid solutions exhibited the phase transition phenomenon at T_c=315.65 K (x=0), 325.80 K (x=0.159), 333.05 K (x=0.250), and 357.92 K (x=0.449). In the case of the pure As-salt, however, any heat capacity anomaly due to a phase transition was not observed in the temperature region investigated. The phase transition temperature T_c was regularly raised with increasing x and the heat capacity anomaly concerning the phase transition of the solid solution was very sharp as that of the pure P-salt. From these two facts we can imagine that random mixing of the phosphonium and the arsonium cations is established and that the present specimens can be regarded as complete solid solutions.

The enthalpy and the entropy of transition were estimated by subtracting plausible normal heat capacities from the overall ones. In each case the normal heat capacity extrapolated from the high temperature phase was smaller than that of the low temperature phase at the transition point. The values of transition enthalpy ΔH and entropy ΔS thus obtained and also the jump of normal heat capacity ΔC_p detected at T_c are given in Table 4.

The heat capacities in the temperature region far below the transition points have a tendency to increase with increasing fraction x of the As-salt.

Infrared Absorption Spectra. In order to examine the influence of the phase transition we measured the infrared spectra of the P-salt both of the low and the high temperature phases. The spectra of both phases resembled closely each other except for minor changes in position and intensity of the absorption peaks. Figure 2 illustrates the far infrared spectra for the P-salt at 15 °C ($=T_c-27.5$ K), 40 °C ($=T_c-2.5$ K), and 80 °C ($=T_c+37.5$ K). In this wave number region only appreciable changes were observed at 320, 220, and 40 cm^{-1}. The band at 320 cm^{-1} vanished above T_c while a new band appeared at 40 cm^{-1}. The intensity of the band at 220 cm^{-1} was diminished above T_c. As a whole, it may be concluded that the phase transition phenomenon scarcely affected the infrared active modes of normal vibrations. This fact coincides well with the X-ray structural analyses,[4,5] which demonstrate that crystal structures of both the low and the high temperature modifications of the P-salt are triclinic system with the space group $P\bar{1}$.

Figure 3 represents the composition dependence of the infrared spectra for five kinds of materials in the wave number region from 1100 to 600 cm^{-1} at room temperature. The absorption bands at 710 and 900 cm^{-1} can safely be assigned to the phosphonium species since the intensities are proportional to the phosphonium concentration $(1-x)$. The band at 884 cm^{-1} is characteristic of the arsonium species because its intensity changes in proportion to the arsonium concentration x. Similar band arising from the arsonium species was observed in the far infrared region at 347 cm^{-1}. On the other hand, a new absorption peak was observed at

860 cm^{-1} only when the specimen formed the solid solution. As the crystal structures of the P- and the As-salts are isomorphous at room temperature,[4] this new band may correspond to the boundary mode between the phosphonium and the arsonium cations.

Phase Transition of the P-salt

As was described in a previous section, the normal heat capacity of the high temperature phase was 15.75

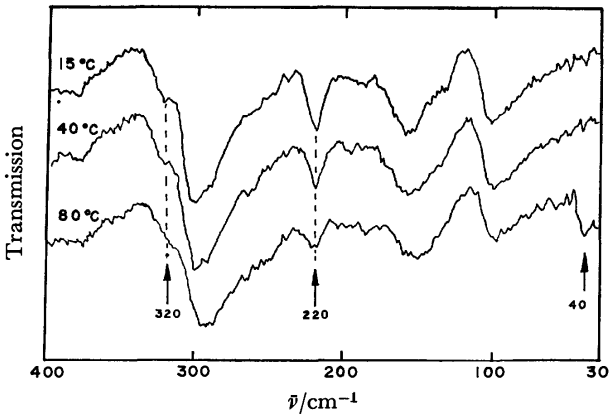

Fig. 2. Far infrared spectra of $[(C_6H_5)_3PCH_3]^+$-$(TCNQ)_2^-$ in the wave number region from 400 to 30 cm^{-1} at three different temperatures (T_C=42.50 °C).

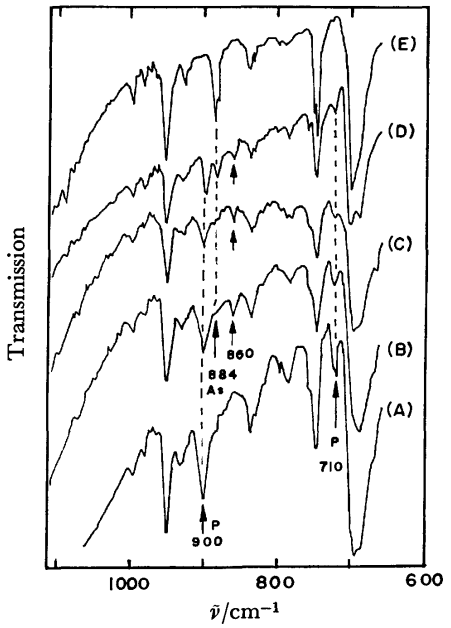

Fig. 3. Infrared spectra of $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3$-$AsCH_3]_x^+(TCNQ)_2^-$ in the wave number region from 1100 to 600 cm^{-1} at a room temperature. (A) x=0.000, (B) x=0.159, (C) x=0.250, (D) x=0.449, and (E) x=1.000.

J K^{-1} mol^{-1} smaller than that of the low temperature phase at T_c. This fact implies that the excitation of phonons is easier in the low- than in the high-temperature phase at least in the vicinity of T_c. This situation seems to be related with the contraction of crystal volume[5,20] at T_c.

The enthalpy and the entropy of transition were determined to be 2030 J mol^{-1} and 6.431 J K^{-1} mol^{-1}, respectively. The entropy corresponds to R ln 2.12. This value cannot be explained solely by the contribution from the elctronic spin freedom. We discuss below a problem what kinds of freedoms contribute to the phenomenon of the phase transition.

(1) Contribution of Magnetic Spin Freedom. The magnetic spin in this radical salt is known to behave just like being in the singlet-triplet equilibrium.[7,8,22] The contribution of the magnetic spin system to the entropy of transition can be estimated from the triplet density defined by

$$\rho \equiv \left\{1+\frac{1}{3}\exp(J/kT)\right\}^{-1}, \quad (1)$$

where J is the energy difference between a singlet ground state and an excited triplet state. The temperature dependence of ρ is obtained from the magnetic susceptibility measurements[19] as the paramagnetic contribution to the susceptibility can be fitted approximately to the expression

$$\chi = \frac{NS(S+1)g^2m_B^2}{3kT}\left\{1+\frac{1}{3}\exp(J/kT)\right\}^{-1}, \quad (2)$$

where g is the electronic g-factor, m_B the Bohr magneton, S the spin quantum number and N the number of quasimolecules. By assuming g=2.0, S=1 and $N=N_A/2$ (N_A is the Avogadro constant), we obtain the relation

$$\chi T = 0.5002\rho. \quad (3)$$

The entropy arising from the spin system corresponds to

$$S = \frac{1}{2}R\{\rho \ln 3 - \rho \ln \rho - (1-\rho)\ln(1-\rho)\}. \quad (4)$$

Since the triplet density is zero at 0 K and 3/4 at infinite temperature, the total spin entropy amounts to R ln 2(=5.763 J K^{-1} mol^{-1}). However, the observable magnetic entropy as the transition entropy is limited to only a small part of R ln 2 and the remaining part is smeared over a wide temperature region as the Schottky-type anomaly, because the present phase transition is characterized by a small jump of the magnetic susceptibility[19] and thus a small change in ρ. By using Kepler's data,[19] the contribution of the spin entropy to the phase transition was estimated to be 1.93 J K^{-1} mol^{-1}. Since the anomalous heat capacity has its skirt below T_c, the calculation is made based on the change in ρ over the temperature range corresponding to the heat capacity anomaly.[30] At any rate, the estimated magnetic entropy merely corresponds to thirty percent of the total entropy of transition. Therefore, the remaining entropy of transition due to other origins amounts to 4.50 J K^{-1} mol^{-1}. On the other hand, if the system be allowed to include a considerable fraction of doublet as well as the singlet-triplet equilibrium, the transition entropy due to the magnetic origin would become larger than 1.93 J K^{-1} mol^{-1}. The experimental evidence,[19] however, is not favorable to the existence of such a large amount of doublet in the temperature region investigated here.

(2) Contribution of Conduction Electrons. The electric conductivity of this radical salt[10] is abruptly increased at T_c. Increase in the number of conduction electrons will cause an increase in the entropy of the system. The energy gap between the conduction and the filled bands has been estimated to be 0.4 eV below T_c and 0.3 eV above it.[26] This difference leads to an increase in the excitation of conduction electrons in the high temperature phase. The energy gap, however, is about ten times larger than the thermal energy kT in the neighborhood of T_c. Accordingly the number of electrons which can be excited to the conduction band by the thermal energy is negligibly small and the

entropy gain due to such electrons is the order of magnitude of the present experimental error. Thus the freedom of conduction electrons cannot practically contribute to the entropy of transition.[31]

(3) Contribution of the Change in Lattice Structure. According to the recent structural analyses by Konno and Saito,[5] the conformations of the phosphonium cations are quite different each other in both the low- and the high-temperature phases, whereas the crystal structure and the space group are not changed by the phase transition. In the high temperature phase two of the three phenyl groups belonging to a phosphonium cation are rotated drastically by about 56 and 45° from the positions observed in the low temperature forms, and the interplanar distances in the TCNQ column are altered. These changes in the conformation and the packing geometry modify the distribution function of the lattice vibration to some extent. Accordingly, a part of the excess transition entropy other than the magnetic contribution may be attributable to this origin. The quantitative estimation of this effect is, however, not easy.

The interesting but peculiar feature concerning the high temperature phase is the existence of about ten percent of the phosphonium cations having the different configuration.[5] If it were the case, the entropy due to their mixing amounts to 2.70 J K^{-1} mol^{-1}. This corresponds to sixty percent of the remaining entropy other than the spin contribution.

Phase Transitions of Solid Solutions

In order to demonstrate clearly the composition dependence of heat capacities of the solid solutions, the heat capacity curves around T_c of the five samples are shown in Fig. 4. One of the interesting features is that the transition temperature was shifted toward the high temperature side with increasing fraction of the As-salt. If the solid solution is simply regarded as the P-salt being diluted with the As-salt, the composition dependence of the transition temperature seems to be quite curious. In general the effect of dilution would make the existing interaction weaker and thus would lead to a system having a lower transition temperature. In view of the fact, however, that it is not the cations but the $(TCNQ)_2^-$ anion radicals which are responsible for the magnetic spin system, the existence of the P-salt fraction should be regarded only as a trigger for the phase transition.

The transition enthalpy ΔH and the entropy ΔS

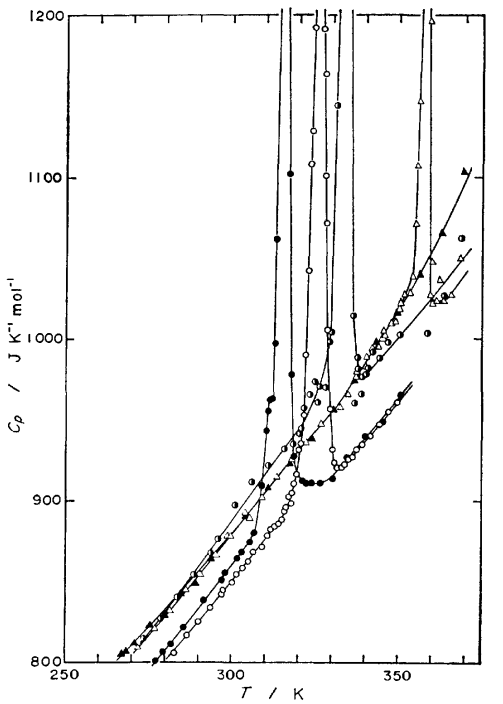

Fig. 4. Heat capacities of $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$ in the vicinity of T_C. (●) x=0.000, (○) x=0.159, (◑) x=0.250, (△) x=0.449, and (▲) x=1.000.

determined from the heat capacity anomalies are plotted in Figs. 5 and 6, respectively, as a function of the As-salt fraction. Also shown in Fig. 5 is the composition dependence of the transition temperature. A remarkable feature is that the enthalpy and the entropy of transition do not seem to converge to zero when the As-salt fraction x approaches to unity. These results are quite different from the previous ones by Iida[26] obtained with a differential scanning calorimeter(DSC). His results indicate that the ΔH and the ΔS are decreased linearly with x and finally vanished at $x=1$. The heat capacity anomaly due to the present phase transition becomes broader with increasing fraction of the As-salt and the contribution from the skirt of the heat capacity anomaly was increased. A shortcoming inherent in a thermal analysis by use of DSC is to fail in detecting a moderate thermal change and to truncate a heat capacity peak. Therefore, a simple thermal analysis has a risk to underestimate the enthalpy and the entropy of transition. The discrepancy between his results and ours may be due to these situations.

The entropy due to the magnetic contribution was estimated in a scheme of the singlet-triplet equilibrium. For this purpose, the magnetic susceptibilities of the solid solutions measured by Kepler[19] were used to obtain the value of triplet density below and above the transition point. The results are shown in Fig. 6. As is in the case of the P-salt, the contribution from the magnetic spin system amounts to only twenty or thirty percent of the total entropy of transition. A remarkable feature found here is that the entropy other than the magnetic contribution is nearly independent of the composition of the solid solution. This fact suggests that the solid solution may undergo almost the same structural or geometrical change with that of the pure P-salt independently of the arsonium fraction. A favorable evidence for the structural change is the discontinuity of the normal heat capacity found at T_c (see Table 4).

According to the high-pressure experiment by Merkl *et al.*[20] the transition temperatures of both the P- and the As-salts are lowered with increasing the external pressure although the As-salt does not show the corresponding phase transition at an atmospheric pressure because of its thermal decomposition. If the p-T diagram for the P-salt is extrapolated into the negative pressure region, the occurrence of a hypothetical phase transition would be possible at a temperature higher than 315.65 K where the P-salt undergoes the phase transition at 1 atm. The volume of the unit cell at negative pressure is considered to be slightly larger than that at 1 atm. According to the X-ray analyses for the P- and the As-salts at room temperature[4,5] the lattice volume of the As-salt is slightly larger than that of the P-salt. Therefore it is plausible that the increase of the As-salt fraction in the solid solution will bring about the increase in the lattice volume. This effect just corresponds to the lattice expansion of the P-salt or in other words the negative pressure in the p-T diagram. This is one of the most probable reasons why the transition temperature is raised with the increase of the arsonium salt fraction.

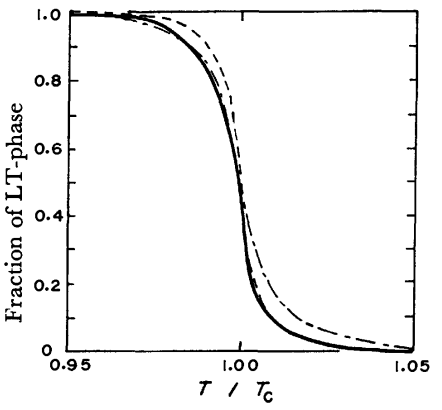

Fig. 7. Comparison of the low temperature fraction of the P-salt between the experiment and the theory (T_C= 315.65 K).
(——): The experimental value, (- - -): the calculated value for $(J_{LH}/N^{2/3}) = 1.5\,kT_C$ and $(N_A/N) = 100$, (----): the calculated value for $(J_{LH}/N^{2/3}) = 1.5\,kT_C$ and $(N_A/N) = 167$.

Table 5. The parameters determined by the "best" fit of the present model to the experimental values for $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$

x	0.000	0.159	0.250	0.449
$J_{LH}/(N^{2/3}kT_C)$	1.5	1.1	1.0	0.5
$N_A/N\,(T<T_C)$	100	125	200	100
$N_A/N\,(T>T_C)$	167	217	500	1430

In a previous paper,[33] we presented a phenomenological model for the phase transition of potassium p-chloranil anion radical salt. The principle is virtually the same with the Frenkel theory of heterophase fluctuation in liquid.[34] The parameters characteristic of this model are the number of cells or embryos, N, and the interaction energy between adjacent cells belonging to the low and the high temperature phases, J_{LH}. If the Avogadro constant is denoted as N_A, the ratio, (N_A/N), corresponds to the number of molecules included in a cell. The phase transition becomes a first order when $(J_{LH}/N^{2/3})>2kT_c$, while the phase transition is of a higher order when $(J_{LH}/N^{2/3})$ is equal to $2kT_c$. Figure 7 illustrates the "best" fit of this model to the experimental value for the P-salt. The "best" fit below T_c is obtained under the condition of $(J_{LH}/N^{2/3})=1.5\,kT_c$ and $(N_A/N)=100$ but above T_c it is necessary to adopt a large value of $(N_A/N)=167$ for the "best" fit. This tendency is found for all the phase transitions observed for the solid solutions (see Table 5). This suggests that the intermolecular correlation is different below and above T_c. It should be remarked here that as shown in Table 5, the "best" fit value of $J_{LH}/(N^{2/3}kT_c)$ becomes small with increasing the arsonium fraction x while the value of (N_A/N) increases with x. These results indicate that the cooperativeness of the phase transition becomes weak with increasing x and that the more the P-salt is diluted with the As-salt, the larger number of molecules is included in a correlation region in which the

transition from the low to the high temperature modification takes place simultaneously.

Calorimetric Study of the Glassy State. XIII.* Thermodynamic Properties of Normal and Deuterated Orthoboric Acid Crystals

Masaharu OGUNI, Takasuke MATSUO, Hiroshi SUGA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received November 18, 1976)

Thermal properties of normal and deuterated orthoboric acids were studied through the measurements of heat capacity in the temperature range from 13 to 370 K by using an adiabatic calorimeter and differential thermal analysis curves above room temperature. For both crystals, the heat capacity anomaly was found around 290 K in the heat capacity values dependent upon the thermal history of the specimen; *i.e.*, the endothermic or exothermic enthalpy relaxation was observed in this temperature range. This behavior is of characteristic to the glass transition and is considered to be ascribed to the freezing-in phenomenon of the motion of rearrangement of the protons in hydrogen bondings. The enthalpy relaxation curves were analyzed with the exponential law and the characteristic time constant toward the equilibrium state was longer for enthalpy-excessive side than for enthalpy-deficient side. The glass transition temperature at which the endothermic relaxation time becomes 1 ks is 296.6 K for normal orthoboric acid and 298.2 K for deuterated orthoboric acid, respectively. The activation enthalpies were estimated to be 88 ± 5 and 91 ± 5 kJ mol^{-1} for the endothermic processes of normal and deuterated orthoboric acid, respectively. The melting points of normal and deuterated orthoboric acids were determined from the differential thermal analysis curves to be 169.9 and 167.4 °C, respectively.

Orthoboric acid crystal is a typical example of the hydrogen-bonded systems with two-dimensional structure being essentially a molecular arrangement of planar $B(OH)_3$ (see Fig. 10). Each hydroxyl group is linked by hydrogen bonds to two others belonging to different molecules and forms a six-membered hydrogen bonded ring. The hydrogen atom is situated on the O–O line, occupying the ordered position at room temperature.[1] The ring is arranged in a pattern of triangular lattice in two dimension and the crystal is built up by the superposition of these layers. There have been discussions about the position of the hydrogen atoms since the first determination of B and O positions by Zachariasen[2] in an early X-ray study. Electron diffraction study of the thin crystal by Cowley[3] showed that the hydrogen was displaced off the O–O bonds and that the hydrogen positions are disordered. The nonlinear O–H···O hydrogen model was also favored by Kume and Kakiuchi[4] in their NMR study, which was criticized in a subsequent recalculation by Ibers and Holm.[5] In the reinvestigation of the structure by X-ray method, Zachariasen[6] found the hydrogen atom situated on the O–O line. The neutron diffraction experiment,[1] designed specifically for the determination of the hydrogen position, seemed to have settled the discussion conclusively. In both X-ray and neutron diffraction studies it was also found that the layers are not strictly planar, but some tilts occur between the individually coplanar molecules.

However, two questions remain still open about the behavior of the hydrogen atom in the crystal. First, is the hydrogen position completely ordered at room temperature? The hydrogen bond length in orthoric acid is comparable with that in ice I_h for which existence of the hydrogen-positional disorder is well-established. Therefore, one may expect *partial* disordering of the hydrogen position in a double minimum potential of the hydrogen bonding in the present crystal, although complete disordering is ruled out by the neutron diffraction study.[1] If such a disorder was actually observed, one would find a very typical order-disorder transition in two dimensional system. Another question is how rapid would be the change of the hydrogen position in such an order-disorder system. Our experience with ice I_h,[7] heavy ice I_h,[8] $SnCl_2\cdot2H_2O$[9] and $SnCl_2\cdot2D_2O$[9] showed that the positional change of hydrogen atoms can be extremely slow in spite of the small mass of the atom at low temperature. Its relaxation time can be of the order of one minute or one hour, or for that matter, may be one year or one century. In such cases, we can observe the relaxation process calorimetrically as a glass transition phenomenon at some appropriate temperature.

In view of the current interest in the molecular relaxational phenomena in relatively simple substances, we have investigated orthoboric acid and its deuterated analog by low temperature heat capacity measurements, and in fact found heat capacity anomalies that possess every characteristic of a glass transition. Based on this observation of a glass transition, which implied the existence of partial disordering of hydrogen position, we performed differential thermal analysis (DTA) of the substance in the temperature region higher than the glass transition, for the purpose of investigating the behavior due to development of the hydrogen atom disordering with increasing temperature. This paper reports the experimental facts and their interpretation briefly.

Experimental

Preparation of the Material and the Heat Capacity Measurement. The heat capacity of normal (undeuterated) orthoboric acid crystal was measured for two different samples. The first sample, "Suprapur" reagent from Merck Co., was vacuum-dried for an hour at 20 °C in order to remove excess water if

* A part of this paper was presented on The Fourth International Conference of Chemical Thermodynamics, Montpéllier, 1975.

For part XII, see O. Haida, H. Suga, and S. Seki, *J. Chem. Thermodyn.*, in press.

any, and its heat capacity was measured in the temperature region between 13 and 315 K. The second was obtained by recrystallizing the extrapure grade reagent, purchased from Wako Pure Chemical Co., from the aqueous solution, and was investigated in the temperature region from 250 to 370 K. The deuterated orthoboric acid sample was obtained by recrystallization of B_2O_3 from heavy water solution (99.75%). The B_2O_3 crystals were prepared by complete dehydration of the normal orthoboric acid (purchased from Yamanaka Chemical Co.) by heating *in vacuo* to 200 °C for three days. The deuterium exchange ratio of the obtained crystals was analysed to be 99.5% by NMR method. The sample weight was 40.472, 48.586, and 53.495 g for the first and second samples of normal orthoboric acid and the deuterated orthoboric acid sample, respectively.

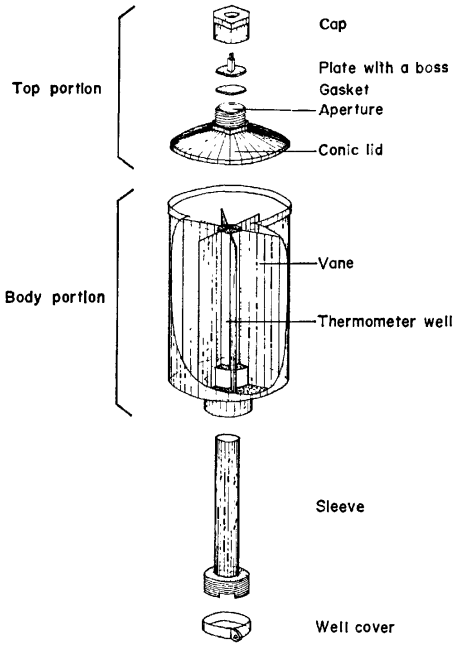

Fig. 1. A sectional drawing of the new calorimeter cell.

Calorimetric Apparatus. The calorimetric apparatus which was described before,[10] was so modified as to be capable of measurement up to 140 °C. Namely, the bronze adiabatic shields were replaced by those made of copper. This improved the temperature uniformity of the shields and hence the adiabatic regulation. The calorimeter cell, formerly sealed with low-melting solder, was replaced by a new cell of the Trowbridge and Westrum-type (marked with W-22) construction.[11] A sectional drawing of the cell pieces is given in Fig. 1. The body portion with a well and six vanes and the sleeve for a platinum thermometer were made of copper for achievement of rapid thermal equilibration, while the top portion, consisting of the cap, plate, and conic lid with an aperture, of stainless steel. The sleeve was settled on the body by being screwed in the well. High-melting solder was used for the seal between the lid and the body. The vacuum-tight closure was achieved by an annealed gold gasket forced against a circular knife edge of aperture. Plate with a boss served for preventing the gasket from turning in the closure by holding the boss. The typical equilibration time of the cell after turning off the calorimeter heater was around 13 min at room temperature. The second sample of the normal orthoboric acid and the deuterated orthoboric acid sample were measured with the improved apparatus. The inaccuracy of the measurement is estimated to be 1% at liquid hydrogen temperature and smaller than 0.2% above 40 K.

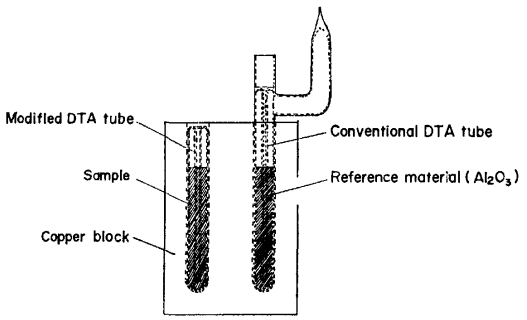

Fig. 2. Conventional and modified DTA tubes.

Differential Thermal Analysis. DTA studies of normal and deuterated orthoboric acids were carried out in the temperature region above the glass transition point. DTA apparatus previously reported[12] was modified for coping with the decomposition of the sample to metaboric acid and water vapor. For this purpose the sample tube as shown in Fig. 2 was used. The modified sample tube is smaller than the previous one. This modification decreased the dead volume in the tube and enabled the whole body of the sealed tube to be entirely embedded in the well of the copper block of the DTA apparatus. Thus any cold spot that might have caused trouble with the original sample tube was successfully avoided.

Results and Discussion

Melting. Melting of normal orthoboric acid has been reported by several authors. Carnelley[13] reported the melting at 184—186 °C from the heat capacity measurement and visual observation, and Stackelberg *et al.*[14] at 170 °C by visual observation under 4 atm pressure. Kracek *et al.*[15] obtained 170.9±0.2 °C from the solubility measurement. Benrath,[16] on the other hand, obtained 181 °C using the similar method. We performed the first observation for the melting of deuterated orthoboric acid, in addition to that of normal orthoboric acid. Figures 3 and 4 show melting curves in DTA for the normal and deuterated samples, respectively, obtained in the present study. The melting points were 169.9 and 167.4 °C for the respective substances, and the crystallization took place practically at the same temperature as the melting. These curves were reproduced repeatedly without significant changes.

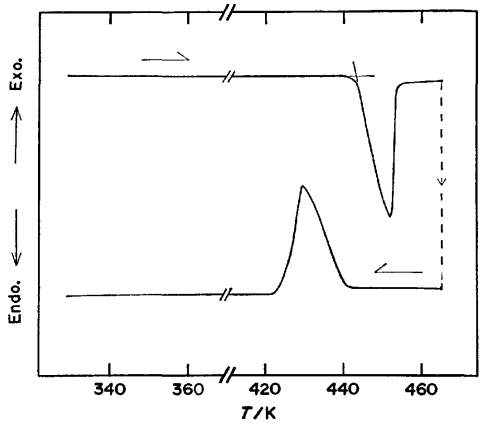

Fig. 3. DTA curves of normal orthoboric acid.

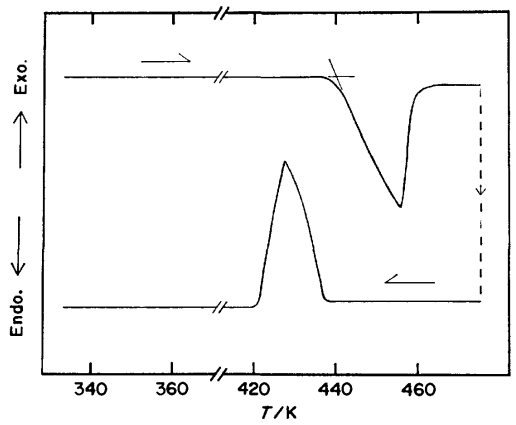

Fig. 4. DTA curves of deuterated orthoboric acid.

The melting points for normal orthoboric acid determined by Stackelberg *et al.* and Kracek *et al.* are in fairly good agreement with the present data, though their determination was performed through visual observation. The melting point of deuterated orthoboric acid is lower by 2.5 K than that of normal acid.

Heat Capacity. The heat capacity values are tabulated in Tables 1 and 2 for normal and deuterated orthoboric acid crystals, respectively. They are also shown in Fig. 5 as a function of temperature together with data (△) of Johnston and Kerr.[17] Johnston and Kerr's values are smaller than ours, the discrepancy increasing with the increasing temperature. This tendency may be attributed to a partial dehydration of their sample which might have happened during drying over a period of three days at 70 °C *in vacuo* in their

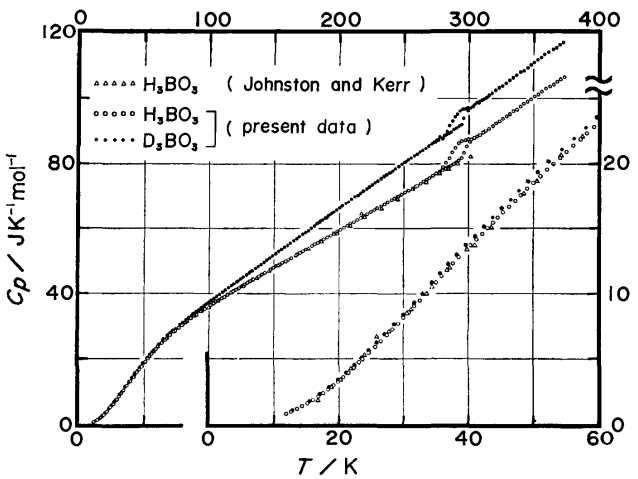

Fig. 5. Heat capacity of normal and deuterated orthoboric acids.

sample preparation. Johnston and Kerr stated that the heat capacity curve exhibits a double inflection at about 40 K. The anomaly is, however, scattering of their data. The present data, being more precise, preclude presence of any anomaly in this temperature region. Johnston and Kerr also mentioned the appearance of a spread-out hump, from about 20 to 150 K, which they interpreted as an indication of development of the hydrogen position disorder. However, this interpretation is not supported by recent evidence because the hydrogen atoms occupy almost completely their ordered positions even at room temperature, as was evidenced in a neutron diffraction study. It is likely that an unusual temperature dependence of the curve, resembling a spread-out hump, has the lattice-vibrational origin indicative of the two-dimensional feature of the crystal structure. Temperature dependence of the heat capacity of the deuterated orthoboric acid is similar to that of the normal acid, except that the deuterated compound has the larger heat capacity in the whole temperature range studied. Such an isotope effect is expected in terms of the increased mass by deuteration.

In contrast to the tolerably good agreement between the present data and those by Johnston and Kerr at the lower temperatures, there is a remarkable difference around 290 K. The present data exhibit occurrence of a step-like anomaly amounting to 3—4% of the total heat capacity. A similar anomaly is observed for the deuterat-

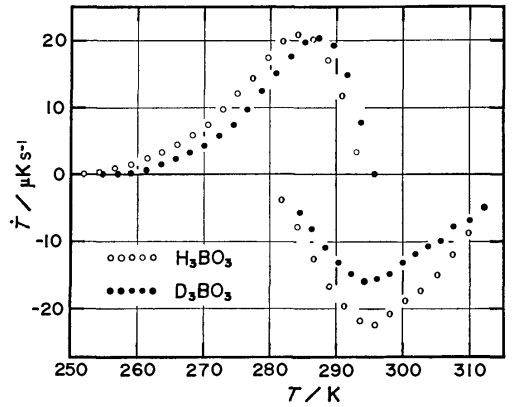

Fig. 6. Spontaneous temperature drift rate of the calorimeter cell for two different thermal treatments.

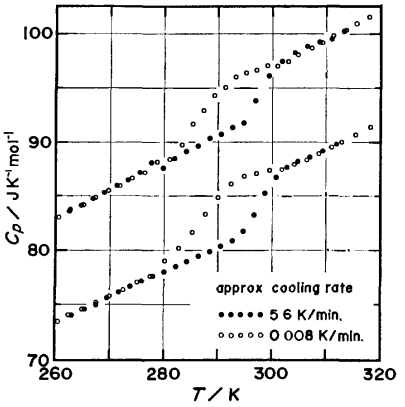

Fig. 7. Dependence of the heat capacity on the cooling rate around 290 K.

ed compound. A hysteretic behavior was also noted for both compounds at the same temperature. Thermal equilibration of the calorimeter was very sluggish in the temperature region between 260 and 310 K and an exothermic or endothermic effect was observed depending on the cooling rate and the thermal history of the sample. The heat capacity measurement was therefore performed in the following procedure. Prior to each measurement, the sample was first equilibrated at 315 K (at which temperature the thermal equilibrium was attained rapidly) and then cooled below 250 K at a respective cooling rate indicated in Fig. 7. A series of measurements was started at 250 K at which the temperature drift of the cell was normal within our experimental error. The temperature drift was then followed step by step up to 320 K. Each step of the measurement consisted of first heating the calorimeter by 2 K and then following its temperature drift. The energy input took 15 min and the drift measurement 40—60 min. Figure 6 illustrates the temperature drift rate of the calorimeter at 25 min after the calorimeter heater was switched off. If cooled rapidly the sample gave out heat in earlier stage of the subsequent warming, and then tended to absorb heat as indicated by the negative temperature drift at the higher temperature, whereas, if cooled slowly, it exhibited only negative temperature drift in the subsequent heat capacity measurement. The temperature drift approached normal behavior gradually above 300 K. This thermal behavior means that the anomaly in this region may be ascribed to a glass transition.[18] The heat capacity value was determined by employing the same method as used for $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$.[9] The operational definition of the heat capacity involves an arbitrariness as to how the contribution from the strongly temperature-dependent relaxational degree of freedom is taken into account. The initial or final temperatures taken in the case of the exothermic drifts were calculated by extrapolating them to the mid-point of the heating period and consequently the contribution is excluded from the heat capacity, while in the endothermic case the temperatures at 40 min after the heating-off were employed as the temperatures for the heat capacity determination and therefore the heat capacities calculated involve the contribution deficiently or excessively compared with those in the equilibrium states. The heat capacity curve is illustrated in Fig. 7 in the temperature region from 260 to 320 K. The curve exhibits a clearly different behavior in the region depending on the cooling rate of the sample, *i.e.* the heat capacity is larger for the annealed sample than for the quenched one. This behavior can be also regarded as a general characteristic of a glass transition. The step-like increase around the transition point discloses the amount of configurational contribution to the heat capacity. The jump, ΔC_p, at 290 K was estimated by extrapolation to be 3.58 J K^{-1} mol^{-1} and 2.96 J K^{-1} mol^{-1} for the normal and deuterated orthoboric acids, respectively. It should be added that the behavior in the transition region was the same for the first and the second samples of normal orthoboric acid. This confirms that the glass transition is an intrinsic property of the substance.

Tables 3 and 4 give the thermodynamic functions derived from the smoothed heat capacity on the assumption that it jumps stepwise at 290 K. The heat capacity between 290 and 310 K where the annealing effect is prominent was estimated by extrapolation from above 310 K.

Kinetic Property of the Glass Transition. The exothermic and endothermic temperature drifts described above were analysed on the assumption that the

These thermodynamic functions were derived by assuming that the heat capacity jumps stepwise at 290 K. a) $S_0°$ is estimated to be 0.41 J K^{-1} mol^{-1} from molecular field approximation using heat capacity jump at 290 K.

enthalpy relaxation toward the equilibrium state follows an exponential law with a single relaxation time τ and they (*i.e.* exothermic and endothermic effects) were treated separately. The characteristic time for the former (*i.e.* exothermic) case was obtained by employing the evaluation method already explained in detail in the case of $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$.[9] For the latter (*i.e.* endothermic) drift curves the exponential function fitted the experimental data within the imprecision of the temperature measurement, suggesting the validity of above assumption. The exothermic and endothermic effects resulted in two different straight lines as shown in Fig. 8, where the solid and dotted lines represent respectively the least square fits of the relaxation times derived from the exothermic and endothermic drifts. The difference means that the approach to the thermal equilibrium is governed by different characteristic times depending upon whether the equilibrium state is approached from the enthalpy-excessive side or from the enthalpy-deficient side. A similar behavior of the relaxation time was observed in $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$. The Arrhenius plot of the relaxation

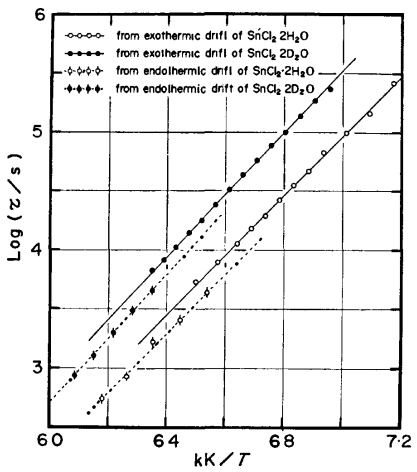

Fig. 9. Arrhenius plots of the characteristic times of exothermic and endothermic enthalpy relaxation drifts for $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$.

time is shown in Fig. 9 for these compounds, where the relaxation times for the heat-absorption and heat-evolution processes follow different straight lines.

It should be noted that the characteristic time at a fixed temperature is longer for the exothermic process (*i.e.* on the enthalpy-excessive side) than for the endothermic process (*i.e.* on the enthalpy-deficient side) in these hydrogen-bonded systems. It should be added that the relaxation time was derived under the adiabatic condition. Thus, the temperature of the crystal changed as the relaxation proceeded. This means that the run of the adiabatic drift measurement corresponds to a small but finite temperature interval on the Arrhenius plot. This also means that the apparent final temperature to which the proton configuration tends is not constant but depends on the extent to which the relaxation has proceeded. These two aspects of the non-isothermal character of the drift measurement were not considered in the analysis of the relaxation effects in $SnCl_2 \cdot 2H_2O$ and $SnCl_2 \cdot 2D_2O$. Correction for these effects was found to decrease and increase the derived relaxation time typically by 0.5% for the exothermic and endothermic runs, respectively, and thus safely neglected. A relevant observation was reported by Davies and Jones[19] for glass transition in super-cooled liquids. They followed both the isothermal volume-relaxational change of glucose and the enthalpy-relaxational change of glycerol in the respective transition regions. According to their report, the characteristic time was longer on the volume-deficient (or enthalpy-deficient) side than on the volume-excessive (or enthalpy-excessive) side of the equilibrium state, and there occurred significant departure from the exponential form of the relaxation curve when the displacement from the equilibrium state was large. Thus the relaxational property of the present substance deviates from the idealized behavior, *i.e.* recovery of the equilibrium with a constant relaxation time independent of the sense and amount of the departure from the equilibrium. Furthermore, the deviation from the ideal relaxational behavior is in the direction opposite to Davies and Jones' observation on the super-cooled liquids. They explained their observation by arguing that the structure of the substance is looser in the volume-excessive state than in the volume-deficient state. Consequently the molecules are expected to be more mobile in the former non-equilibrium state, resulting in a smaller relaxation time. This is certainly a plausible explanation for the glassy liquids. In contrast, our present observation is difficult to understand in this intuitively agreeable argument. There exists, however, a peculiar character of the present hydrogen-boned system that might explain the difference qualitatively. In the glassy state of boric acid the hydrogen position has the long-range order, which means that if one particular site is occupied by a hydrogen atom an equivalent site in a distant unit cell has also non-zero probability of occupation by another hydrogen atom. When a disordered hydrogen atom tries to settle into a low energy site in the exothermic relaxation, it has a very limited choice as to the site it can occupy because the low energy site is dictated by the long-range order. In contrast, a molecule in a super-cooled liquid can find a local low energy conformation determined by its neighboring molecules. Thus, there is a formal probabilistic difference in addition to the structural and chemical differences between the long-ranged glassy state (glassy crystals) and the ordinary glassy state (glassy liquid). At present, however, we cannot find a convincing argument that relates the above mentioned peculiar features of the orthoboric acid with its observed relaxational property.

Table 5. Calorimetric quantities characterising the glass transition in H_3BO_3 and D_3BO_3 crystals

	T_g [a] / K	ΔC_p [b] / J K^{-1} mol^{-1}	σ [c]	$(H_a)_{exo}$ / kJ mol^{-1}	$(H_a)_{endo}$ / kJ mol^{-1}
H_3BO_3	296.6	3.58	0.94	89±5	88±5
D_3BO_3	298.2	2.96	0.96	97±5	91±5

a) The temperature at which the endothermic relaxation time becomes 1 ks. b) The heat capacity jump at 290 K in the transition region. c) The order parameter at 290 K estimated from the molecular field approximation.

The activation enthalpies estimated from the respective Arrhenius plots (Fig. 8) are given in Table 5 together with the glass transition points, the heat capacity jumps at 290 K, and the order parameters at 290 K calculated by a mean field approximation method. The values seem to be slighly larger for deuterated orthoboric acid than that for normal acid.

Interpretation of the Frozen-in Freedom. The glass transition in the present substance can be interpreted as the phenomenon originated from the disordered-frozen-in configuration of hydrogen-bonded system. Craven and Sabine[1] assigned uniquely all the atomic positions at room temperature. However the ordering of the atoms, in particular the hydrogen or deuterium atoms, is *not* completely attained in our interpretation. The six-membered oxygen ring, which is assumed to be the individual ordering unit of the hydrogen-bond network, has two permissible arrangements, *i.e.* clockwise and counterclockwise under the extended Bernal-Fowler condition, as is shown in Fig. 10. The interaction

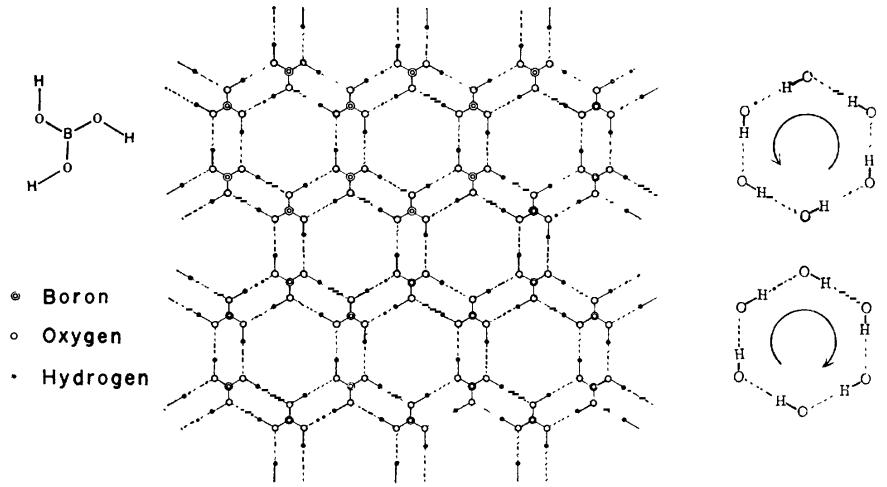

Fig. 10. The schematic atomic arrangement of a single layer in crystalline orthoboric acid and the two arrangements of the hydrogen atoms satisfying the local electric neutrality in the six-membered oxygen ring.

energy among the hydrogen-bonded hexagonal rings stabilizes the ferro-state where all of the hexagonal ring is the same (either all in the clockwise or all in the counterclockwise) arrangement. The entropy of this model is $(R/2)$ ln 2 at the completely disordered state. A mean field approximation can be applied, to a fairly good approximation, at the glass transition in such a system, since the hydrogen position is *almost* completely ordered at room temperature in the transition region. Then the order parameter σ is determined by the following equation at 290 K at which the configurational contribution to heat capacity is estimated:

$$C = \frac{\sigma R\left\{\ln\left(\frac{1+\sigma}{1-\sigma}\right)\right\}^2}{2\left\{\frac{2\sigma}{1-\sigma^2}-\ln\left(\frac{1+\sigma}{1-\sigma}\right)\right\}},$$

where the order parameter σ is given by $\sigma=(2n-N)/N$, n, the number of rearrangement units in the preferred arrangement, N, the number of total arrangement unit. The order parameter estimated at 290 K was *ca.* 0.94 and *ca.* 0.96 for normal and deuterated orthoboric acids, respectively. This degree of estimated ordering is consistent with Craven and Sabine's result[1] on account of the R factor in the neutron diffraction study. This interpretation of the "transition" as a relaxational effect of the hydrogen redistribution process in the crystal is also supported by comparison between the obtained activation energy and the hydrogen bond energy. The activation enthalpy of *ca.* 90 kJ mol^{-1} corresponds to the energy required for simultaneous activation of six hydrogen atoms, and therefore the activation enthalpy per atom amounts to *ca.* 15 kJ mol^{-1}, while the hydrogen bond energy between O-O in medium to long hydrogen bond systems such as ice is known to be 15—25 kJ mol^{-1}. These two values are in good agreement with each other, and thus the above interpretation of the transition would be reasonable provided that the activation process corresponds to the breaking of hydrogen bond.

There are alternative possibilities for the actual motion of the hydrogen atoms in the rearrangement. It is either an O-H librational mode around B-O axis or an O-H stretching-vibrational mode on an O-O bond. Recent NMR studies of inorganic hydrates have shown that a 180° flipping is a typical motion of water in the crystals.[20] If we adopted the former as the relevant mode, the activation enthalpy obtained above should be compared with the potential barrier (of the O-H librational mode) estimated by Durig *et al.*[21] They reported that the infrared absorption band at 808 cm^{-1} was assigned to this mode of vibration and estimated the potential barrier to be 96 kJ mol^{-1}. There is a large difference between this barrier height and the activation enthaply per hydrogen atom. The estimation of the hindering barrier rests entirely upon the assumption of a cosine-type potential function, which is not always a good approximation. In view of the hydrogen bond breaking of the mode discussed above, we may have to consider that the potential curve around the top of the barrier may be flatter than that given by the simple trigonometric function due to the interaction with the adjacent layer. A more reliable and direct estimation would be obtained by proton magnetic relaxation measurements. The relation between these two values will be a subject in the future work.

Deuterium Isotope Effect on a Glass Transition Temperature. In Table 6, the glass transition temperatures are collected for three hydrogen-bonded glassy crystals

Table 6. Glass transition temperature and its deuterium isotope effect for three hydrogen-bonded glassy crystals

	T_g (H) / K	T_g (D) / K	T_g (D) − T_g (H) / K
$H_2(D_2)O$	107.6	126.1	18.5
$SnCl_2 \cdot 2H_2(D_2)O$	159.1	163.7	4.6
$H_3(D_3)BO_3$	296.6	298.2	1.6

The glass transition temperature is defined for ice as temperature at which the exothermic relaxation time becomes an hour, and for $SnCl_2 \cdot 2H_2O$ and H_3BO_3 as the temperature at which the endothermic relaxation time becomes 1 ks.

together with the corresponding data for the respective deuterium compounds. Here the glass transition temperature is defined as the temperature described below the table. Evidently, the isotope effect is larger in the substance with the lower glass transition temperature.

Further Discussion on the Absence of the Phase Transition. The hydrogen-bonding model illustrated in Fig. 10, and the interpretation of the glass transition deduced thereby, have a definite implication on the thermodynamics of the order-disorder system; the molar configurational entropy at infinite temperature is $(R/2)\ln 2$ and the heat capacity is equal to the jump in the observed heat capacity at the glass transition. These two quantities enable us to determine exactly the hypothetical transition temperature of the present hydrogen-bonded system by a statistical triangular Ising model;[22] 378 K for H_3BO_3 and 404 K for D_3BO_3. No phase transition is observed at these temperatures. The estimated transition temperature should be a lower limit because the lattice statistics involved is solved in two-dimensions. On the other hand, the upper limit is given by the molecular field approximation. The transition temperatures predicted by this approximation are 536 K and 587 K for the ordinary and the deuterated orthoboric acids, respectively. These temperatures are higher than the respective melting temperatures. We may conclude that we should have observed the transition if it was not interrupted by the melting. This may also imply that the interaction among the hexagonal rings is three-dimensional in spite of the structural two-dimensionality, because the absence of the phase transition below the fusion means that the hypothesized transition temperature lies much higher than the two-dimensional limit.

The Microwave Spectrum of *anti*-Acetaldehyde Oxime-*d*

Osamu Ohashi, Hisao Hara, Keiko Noji, Takeshi Sakaizumi,
Masao Onda, and Ichiro Yamaguchi

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received October 22, 1976)

The microwave spectrum of *anti*-acetaldehyde oxime-*d* was investigated in the frequency region from 9 to 36 GHz. The rotational transition lines widely split into the A and E species due to the tunneling of the methyl group through the low potential barrier hindering the internal rotation. The transition lines belonging to the A species were fitted to the rigid rotor Hamiltonian, and the following effective rotational constants in MHz were obtained: $A_A=17250$, $B_A=6284.33$, and $C_A=4704.96$. All the observed transition frequencies were fitted to the Hamiltonian containing perturbation terms to the fourth order in order to obtain the internal-rotation parameters using the principal axis method. The potential barrier, V_3, hindering the internal rotation was determined to be 373 cal mol^{-1}. The dipole moment was determined to be 0.828 D from the Stark effect of the transitions belonging to the A species.

Rogowski and Schwendeman[1] studied the microwave spectrum of acetaldehyde oxime and revealed that the potential barrier hindering the internal rotation of the methyl group in the *anti* form is much lower than that in the *syn* form. The microwave spectrum of the deuterated species (CH_3CH=NOD) of *syn*-acetaldehyde oxime was investigated, and the orientation of the OH bond in the molecule was determined to be at the *trans* position to the CN bond.[2]

We have examined the microwave spectrum of *anti*-acetaldehyde oxime-*d* and determined the effective rotational constants, internal-rotation parameters, dipole moment, and r_s coordinates of the hydroxyl hydrogen atom.

Experimental

The sample of acetaldehyde oxime was commercially obtained from the Tokyo Kasei Kogyo Co., Ltd., and purified by trap-to-trap distillation *in vacuo*.

Acetaldehyde oxime in the *anti* form is solid at room temperature (melting point 46.5 °C).[3] We obtained the white solid sample of the *anti* form by gradual cooling in the course of distillation.

The deuterated species was prepared by the method used for *syn*-acetaldehyde oxime-*d*.[2]

The spectrometer used was a conventional 100 kHz sinusoial and square-wave Stark-modulation type with a phase-sensitive detector. The rotational spectrum was observed at 0— −10 °C in order to prevent the decomposition of the sample. The sample gas was renewed about every half hour.

Results and Discussion

Observed Spectrum and Assignment. There are two possible orientations of the OH bond in *anti*-acetaldehyde oxime when the molecule is assumed to have a plane of symmetry. Figure 1 shows the projections of the molecule on its plane of symmetry. In the present analysis, we assumed that the molecule is in the *trans* form (Fig. 1(a)) and predicted the transition frequencies from the structural parameters in Table 1.

From the results for *anti*-acetaldehyde oxime,[1] the following predictions were made: The transition lines of the deuterated species split widely into the A and E

C_1=methyl carbon.

members due to the internal rotation of methyl group; the transitions belonging to the A member have little effect on the internal rotation and show the usual second-order Stark effect.

In the first place, according to the predictions, the transition lines belonging to the A member were identified and were fitted to the rigid rotor Hamiltonian in order to obtain the effective rotational constants. The results, given in Table 2, show large differences between the observed and calculated frequencies of the 2_{02}-3_{03}, 2_{11}-3_{12}, 2_{21}-3_{22}, and 3_{13}-3_{12} transitions.

If the molecule has a plane of symmetry, only two hydrogen atoms of the methyl group are out of the symmetry plane. Consequently, the inertia defect, $\Delta(=I_\alpha+I_c-I_a-I_b)$, should be zero for the rigid-rotor model, where I_α is the moment of inertia of the methyl top about its rotational axis and where I_a, I_b, and I_c are the moments of inertia about the principal axes. The value of Δ was calculated to be 0.798 amu Å^2 from the effective rotational constants in Table 2, using the assumed value of $I_\alpha=3.1$ amu Å^2. This Δ value deviates greatly from zero. The facts mentioned above indicate

that the rotational transitions of *anti*-acetaldehyde oxime-*d* are affected by some kind of rotation-vibration interaction.

Using the method described by Rogowski and Schwendeman,[1] we estimated the barrier height, V_3, hindering the internal rotation of the methyl group, and then predicted the transition frequencies belonging to the E symmetry species. In the vicinity of the predicted transition frequencies, we observed lines which could be attributed to the E member. The lines belonging to the E member exhibited a characteristic first-order Stark effect. The assignment of the transitions was made by observing the Stark effect.

The hyperfine structure of the absorption lines due to the ^{14}N nuclear quadrupole moment could not be observed.

Barrier to Internal Rotation. All the observed transition frequencies are listed in Table 3. These frequencies were fitted to the internal-rotation parameters, by using the Hamiltonian described by Rogowski *et al.*[1] except for the denominator correction term, whose matrix elements were given by Stelman.[4] The internal-rotation parameters obtained are listed in Table 4. The parameters are defined as follows: A_0, B_0, and C_0 are the rotational constants in the absence of internal rotation; λ_g is the cosine of the angle between the axis of the internal top and the principal g axis; s is the dimensionless parameter, the reduced barrier height, and the $s=(4/9)(V_3/F)$ relation holds for a threefold barrier; F is defined by the expression $\hbar^2/(2rI_\alpha)$, where r is equal to the quantity of $1-\sum_g\lambda^2{}_g(I_\alpha/I_g)$.

In Table 4, Set I is obtained assuming I_α=3.1 amu·Å^2, while Set II is obtained with I_α as the fitting parameter. The value of 2.804 amu Å^2 for I_α in Set II is far from the value of 3.0—3.2 amu Å^2 usually found for the methyl top in various molecules. Therefore, the I_α parameter was fixed at 3.1 amu Å^2 in another fitting (Set I). The results of the two fittings are compared in Table 3. The deviations of the calculated frequencies from the observed ones, and the small value of I_α obtained by the least-squares fit in the present work, are comparable with those reported for normal species.[1] These deviations and the small value of I_α may be ascribed to the facts that the perturbation terms higher than the fourth order for the internal rotation were neglected and that no other rotation-vibration interaction except the methyl torsion was considered.

Although the uncertainty to the value of I_α remains, there is not much difference in the values of V_3 between Set I and Set II, as Table 4 shows. Therefore, it is likely that the value of V_3 for deuterated species is not much different from the values in Table 4. Consequently, the value of V_3 for deuterated species may safely be concluded to be 373±30 cal mol^{-1}. This value is comparable to that of 375 cal mol^{-1} for normal species.[1]

Dipole Moment. The A species transitions exhibited the usual second-order Stark effect. The dipole moment

was determined from measurements of the Stark shifts of the transitions, $J=0\rightarrow1$, $1\rightarrow2$, and $2\rightarrow3$, belonging to the A species. The electric field inside the absorption cell was calibrated by measurements of the Stark shifts of the $J=0\rightarrow1$ and $1\rightarrow2$ transitions of OCS with the dipole moment of 0.71521 D.[5]

Table 5. Stark effect of *anti*-acetaldehyde oxime-*d*

		μ_{total}	0.828±0.011 D	0.828±0.013 D

a) Based on μ(OCS)=0.71521 D.

The results obtained by the least-squares fit given in Table 5 show good agreements between the observed and calculated Stark coefficients. The fifth column of Table 5 shows the results obtained with the assumed value of $\mu_c=0$. The results given in the fourth column were obtained by the least-squares fit, using all three components, μ_a, μ_b, and μ_c, as parameters. The value of 0.02 D obtained for μ_c is comparable to the uncertainty in this work. Consequently, the value of μ_c is thought to be nearly equal to zero. The values of μ_a and μ_b determined in the fitting (Calcd I) are consistent with those obtained in the other fitting (Calcd II). From the above results, the molecule may reasonably be concluded to have a plane of symmetry.

Orientation of the OH Bond. The rotational constants, A_0, B_0, and C_0, in Table 4 are what the effective rotational constants A_A, B_A, and C_A, would be in the absence of internal rotation.[1] Consequently, from these rotational constants and the corresponding ones for the normal species,[1] the r_s coordinates of the hydroxyl hydrogen atom can be calculated using Kraitchman's expressions.[6] In Table 6, the first column

Table 6. Coordinates of the hydrogen atom of the hydroxyl group

	Obsd-I[a]	Obsd-II[b]	Calcd-I[c]	Calcd-II[d]
a	2.128± 0.031Å	2.129± 0.009Å	2.132Å	0.354Å
b	0.49± 0.13	0.48± 0.04	0.507	1.152
c	—	0.14± 0.19	0 (assumed)	0 (assumed)

a) Using the rotational constants with $I_\alpha=3.1$ amu·Å². b) Using the rotational constants with $I_\alpha=2.80$ amu Å. c) Obtained from the assumed structure shown in Fig. 1(a). d) Obtained from the assumed structure shown in Fig. 1(b).

shows the coordinates calculated from the rotational constants with $I_\alpha=3.1$ amu Å², while the second column refers to those obtained from the constants with $I_\alpha=2.80$ amu Å². The above two sets of results are consistent within the limits of accuracy of the present work. The third and fourth columns show the coordinates of the hydroxyl hydrogen atom calculated from the assumed structures given in Fig. 1(a) and Fig. 1(b) respectively. The coordinates determined experimentally are in good agreement with those calculated from the structure shown in Fig. 1(a). Consequently, it may clearly be concluded that the orientation of the OH bond in the *anti*-acetaldehyde oxime molecule is at the position *trans* to the C–N bond, as is shown in Fig. 1(a). This result is consistent with the orientation of the OH bond in formaldehyde oxime[7] and *syn*-acetaldehyde oxime.[2]

Electrical Properties and Constitution of the Phenothiazine–Iodine and Related Complexes[1)]

Susumu Doi,* Tamotsu Inabe, and Yoshio Matsunaga**
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received November 4, 1976)

The electrical properties of the phenothiazine–iodine complex were examined in detail as a function of the composition. A shoulder in the resistivity-composition isotherm, a decrease in the activation energy for semiconduction by a factor of two, and a change in the sign of the Seebeck coefficient from negative to positive were observed at a composition of two molecules of phenothiazine to five atoms of iodine. These observations and the spectral behavior reported earlier indicate the formation of a complex cation radical salt, $(\text{phenothiazine})_2^+I_5^-$, which exhibits a resistivity of about 800 ohm cm at room temperature. By the incorporation of a half mole of iodine into this salt, the resistivity reaches a minimum of about 20 ohm cm at room temperature. Similar singularities in the resistivity-composition isotherms were observed with the complexes of the benzo[*a*]-, benzo[*c*]-, and *N*-methyl-derivatives.

Since Akamatu, Inokuchi, and Matsunaga reported anomalously low electrical resistivities exhibited by some polycyclic aromatic hydrocarbon–halogen complexes,[2,3)] a large number of halogen complexes, mostly iodine complexes, have been studied by various workers. For example, the organic component compounds so far examined include such hydrocarbons as pyrene,[4)] perylene,[2,4,5)] and violanthrene,[3,6)] such diamines as *p*-phenylenediamine,[7)] benzidine,[8)] and their derivatives,[9,10)] carotene,[11)] pyridazine,[12)] phenothiazine,[13–16)] its *N*-methyl derivative,[13,17–19)] and phenoselenazine.[16)] However, only relatively few works have been published on the nature of low-resistivity halogen complexes.

The vibrational spectrum of the phenothiazine–iodine complex of a mole ratio of 2: 3 has been shown to be clearly different from that of the parent organic compound, but nearly identical with that of the cation radical bromide.[13)] Later, we found two patterns rather similar to each other for the latter,[20)] and demonstrated that one of them can be ascribed to the simple cation radical bromide, and the other, to the complex cation radical bromide of the 2: 1 type.[21)] The spectrum identical to that of the iodine complex is the latter. Thus, this iodine complex appears to be a kind of the complex cation radical salt; however, six atoms of iodine per two molecules of phenothiazine do not fit to the composition of any polyiodide. Labes *et al.* have found that the vibrational spectrum of the perylene–bromine complex with a mole ratio of 2: 7 is quite different from that of either the parent hydrocarbon or the reaction product, 3,9-dibromoperylene, indicating a significant decrease in symmetry.[22)] They have suggested the formation of a σ-type complex.

Undoubtedly, the analysis of the crystal and molecular structure is a powerful tool in solving the problem. However, the task becomes more and more difficult with an increase in the heavy halogen content. There are only a few works on low-resistivity complexes with relatively low iodine contents. Both of the following compounds have been reported to contain cation radicals: [4,4′-bis(dimethylamino)diphenylamine] I and [*N*,*N*′-diphenyl-*p*-phenylenediamine]$_5$I$_{12}$. The former salt, with a resistivity of the order of 10^5 ohm cm, is a simple iodide.[23)] The halogen atoms in the latter are arranged in columns in the form of triiodide ions.[24)] As the number of the diamine molecules exceeds that of the triiodide ions, the salt contains both the cations and formally neutral molecules. This complex cation radical salt is known to exhibit a resistivity of about 3 ohm cm.[10)] More recently, the structure of highly conducting tetrathiafulvalene (TTF) halides with a deviation from the 1: 1 composition has been clarified.[25–27)] The halogen atoms are in the form of simple halide ions, and the stack of organic molecules consists of neutral and fully charged molecules or fractionally charged molecules. All the available results agree on the points that the low-resistivity halogen complexes are actually cation radical salts and that the resistivities are particularly low when the compositions are complex.

Until now, resistivity-composition isotherms have been prepared for the following systems: violanthrene–iodine,[3)] phenothiazine–iodine,[14)] and phenothiazine bromide–iodine.[20)] In these works, the resistivity minimum has been assumed to correspond to the composition of a distinct compound. This simple assumption is, however, good only for the systems in which two coexisting phases are stoichiometric and mechanically mixed without interaction. If the incorporation of a marked stoichiometric imbalance is conceivable, the electrical behavior should depend quite differently upon the composition. As conduction electrons or holes are introduced by incorporating an excess of one of the components to a pure, accurately stoichiometric compound, the composition must be indicated by a maximum or a shoulder in the resistivity-composition isotherm. On the other hand, the minimum, if any, may be indicative of the limit of the deviation from stoichiometry. Furthermore, we may expect a change in the sign of the Seebeck coefficient at the composition of this stoichiometric compound. No such singularity has been noted in the published isotherms; however, the Seebeck coefficient in the phenothiazine–iodine complex has been reported to change its sign somewhere between two and six iodine atoms per thiazine molecule.[15)] Thus, the careful examination of

* Present address: Central Research Laboratory, Showa Denko K. K., Tamagawa, Tokyo.
** To whom inquiries may be addressed.

the electrical properties as functions of the composition seemed to be a tool more powerful than has been supposed for elucidating the constitution of semiconducting organic compound-iodine complexes. Accordingly, we decided to initiate the present series of works with the four thiazine-iodine complexes.

Experimental

Materials. Samples were prepared by the following three methods, and the iodine contents were determined by microanalysis.

a) Thiazine-iodine complexes with a mole ratio of 2: 3 were precipitated by mixing the organic component and iodine separately dissolved in hot benzene or ether.[13,16,17] The preparation of samples of other mole ratios was carried out by the careful grinding of the weighed complex and the thiazine or iodine in the presence of a small amount of the solvent.

b) An equimolar mixture of the thiazine and its *S*-oxide was thoroughly ground in an agate mortar. The fine powder was spread in a beaker and moistened with concentrated hydroiodic acid. The reaction mixture was then dried in a vacuum desiccator containing potassium hydroxide pellets.[28] The "iodide" thus prepared was mixed with the thiazine or iodine in order to adjust the composition.

c) The weighed thiazine and iodine were directly ground in an agate mortar in the presence of a small amount of benzene or ether.

Measurements. The electrical resistivities and Seebeck coefficients of compactions were recorded as functions of the temperature by the procedures described in the paper by Kan and Matsunaga.[17]

Results and Discussion

Phenothiazine–Iodine In Fig. 1, the electrical resistivity values at 20 °C are plotted against the number of iodine atoms per phenothiazine molecule, *n*. The samples made by Method a are indicated by shaded circles, while those made by Method b are indicated by open circles. The "iodide" gave the following analytical results: C, 38.61; H, 2.77; I, 46.09%. Calcd for $C_{12}H_9NSI_{1.35}$: C, 38.81; H, 2.43; I, 46.33%. A shoulder appears at $n=2.5$ in the resistivity-composition isotherm, the value at this composition being about 800 ohm cm. Then the resistivity reaches a minimum of about 20 ohm cm at $n=3$. The latter is the composition of the iodine complex deposited from the solution. The temperature dependence of the resistivity, ρ, follows the typical semiconductor behavior: $\rho=\rho_0\exp(E/kT)$. As is shown in Fig. 2, the activation energy for semiconduction, E, is about 0.3 eV up to $n=2.5$; it then suddenly decreases to about 0.15 eV. For the above-mentioned reason, one may postulate that a distinct compound is formed at a composition of $n=2.5$. In conjunction with our earlier observation that the vibrational spectrum of the complex agrees well with that of the complex cation radical bromide of the 2: 1 type,[21] the compound may be identified as $(C_{12}H_9NS)_2^+I_5^-$. The two thiazine molecules are equivalent in the time scale of infrared spectroscopy. A deviation of as much as a half mole of iodine is allowed in this formula. This iodine plays a crucial role in the significant decrease in the activation energy. Thus, the very sharp decrease in the electrical resistivity arises undoubtedly from a drastic increase in the charge-carrier concentration. Above $n=3$, the resistivity increases as the iodine content becomes higher. As the vibrational spectrum of phenothiazine mixed with a large amount of iodine resembles that of the simple cation radical bromide, the increase may be attributed to the coexistence of a high-resistivity simple salt rather than free iodine. The rapid increase in the activation energy in this composition range appears to be consistent with the observed high resistivity. Although a resistivity minimum is located at $n=3$ in the isotherm reported by Gutmann and Keyzer, their value, 350 ohm cm, is considerably higher than ours.[14] Moreover, the change observed by them in the composition range from $n=1$ to 4 is merely about one order of magnitude.

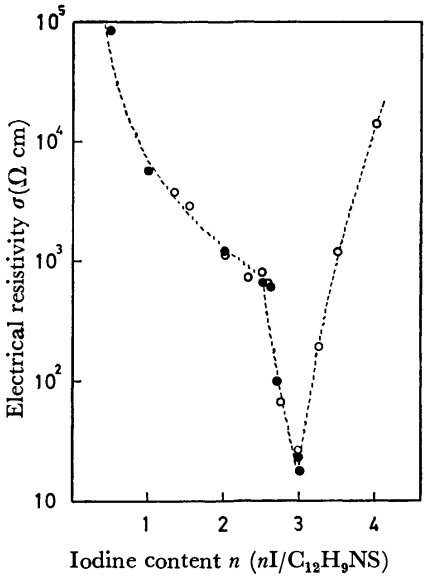

Fig. 1. Electrical resistivity at 20 °C plotted against the iodine content (*n* iodine atoms/thiazine molecule) in the phenothiazine–iodine system.

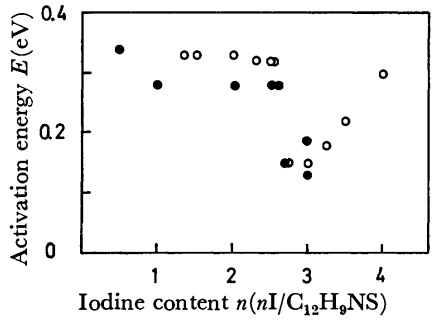

Fig. 2. Activation energy for semiconduction plotted against the iodine content in the phenothiazine–iodine system.

In Fig. 3, the variation in the Seebeck coefficient with the temperature for some representative samples made by Method b is presented. The coefficient depends remarkably upon the composition. Up to $n=2.5$, a linear relationship with the reciprocal temperature is observed near room temperature. Such a range is wider when the composition becomes closer to $n=2.5$. This behavior implies that the compound expressed by the

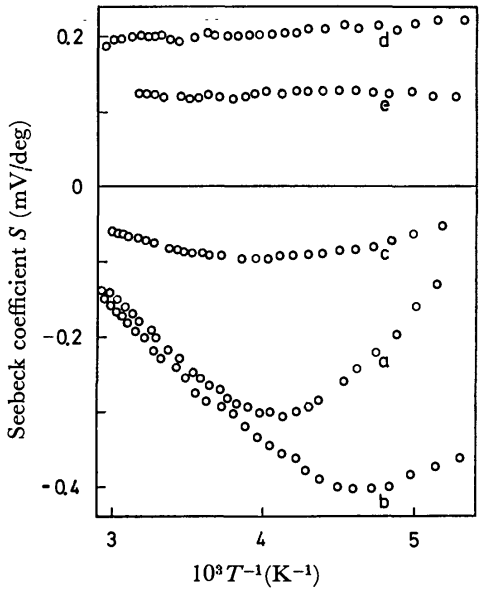

Fig. 3. Seebeck coefficient of the phenothiazine-iodine complexes; a) $n=1.35$, b) 2.50, c) 2.55, d) 2.75, and e) 4.00.

$(C_{12}H_9NS)_2^+I_5^-$ formula exists in these samples. In other words, the solubility of phenothiazine into the compound is rather small and the samples examined in this composition range are not homogeneous. The shape of the resistivity-composition isotherm does seem to be in accord with this view. The linear part appears to fit in with the expression for the thermoelectric motive force of an intrinsic semiconductor; therefore, we attempted to estimate the ratio of the electron mobility, μ_e, to the hole mobility, μ_h, tentatively assuming the applicability of the band model to the present compound. It is given by:

$$b = \mu_e/\mu_h = \left[\frac{E_G}{2} - \frac{\Delta S}{\Delta(10^3/T)}\right]\left[\frac{E_G}{2} + \frac{\Delta S}{\Delta(10^3/T)}\right]^{-1},$$

provided that S is measured in mV/deg.[29] E_G is the width of the forbidden band and is assumed to be twice the observed activation energy for semiconduction. With samples of $n=2.00$, 2.30, and 2.50, the above ratio is found within 4 and 6. Then, the conductivity, σ, is given by:

$$\sigma = \frac{1}{\rho} = e\mu_e\left(\frac{b+1}{b}\right)N\exp(-E/kT),$$

where N is taken to be equal to the number of phenothiazine molecules per cm³ of the compaction; that is, $(2.6—2.9)\times10^{21}$. Employing the resistivity and the activation energy presented in Figs. 1 and 2, the electron mobility is estimated to be 0.6—0.9 cm²/Vs. This value is a little smaller than those estimated similarly for the *N*-methylphenothiazine complex, 2.3 cm²/Vs,[17] and for the phenoselenazine complex, 2.6 cm²/Vs.[16,30]

Above $n=2.5$, the Seebeck coefficient becomes less negative (see Curve c), and finally it changes its sign (see Curve d). A maximum value of about 0.2 mV/deg is observed near $n=3$. In Fig. 4, the coefficient at 20 °C is plotted against the iodine content. This physical quantity is apparently more sensitive to the preparation methods than the electrical resistivity. The values

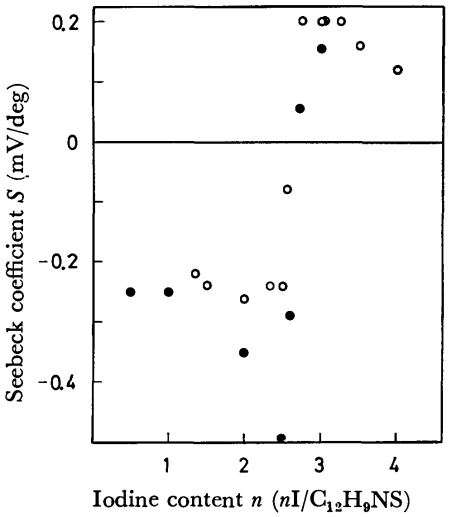

Fig. 4. Seebeck coefficient at 20°C plotted against the iodine content in the phenothiazine–iodine system.

observed with samples made by Method a are appreciably more negative than those made by Method b in the composition range from $n=2$ to 2.5. Regardless of such disagreement, though, the formation of the $(C_{12}H_9NS)_2^+I_5^-$ compound is strongly supported by the sudden change in the sign near this composition. The behavior above $n=2.5$ suggests that the electrical conduction is extrinsic and that the major charge carriers are holes.

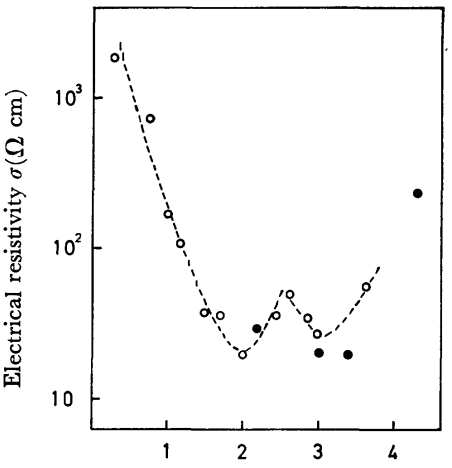

Fig. 5. Electrical resistivity at 20°C plotted against the iodine content in the benzo[*a*]phenothiazine–iodine system.

Benzo[a]*phenothiazine-Iodine.* The complex deposited from a benzene solution has a mole ratio of 2: 3 and exhibits a resistivity of about 20 ohm cm at room temperature.[13,16] For the present work, the samples were prepared by Methods a and c. The resistivity-composition isotherm at 20 °C is presented in Fig. 5. The shaded circles denote samples prepared from the 2: 3 complex, and the open circles those prepared by mixing the components. The maximum of about 50 ohm cm clearly observed near $n=2.5$ and the minima near $n=2$ and 3 make the formation of a complex cation radical salt, $(C_{16}H_{11}NS)_2^+I_5^-$, very plausible. The

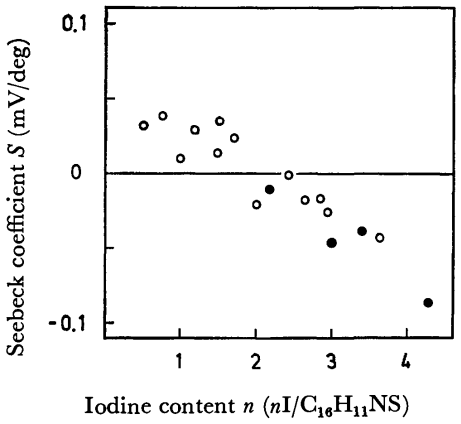

Fig. 6. Seebeck coefficient at 20 °C plotted against the iodine content in the benzo[*a*]phenothiazine–iodine system.

presence of two resistivity minima suggests that the solubilities of both iodine and the thiazine into this salt are appreciable. In other words, the salt is highly nonstoichiometric. It must be noted that the resistivity of this salt is lowered by only a factor of two by the deviation. The values of the activation energy for semiconduction near room temperature are mostly in the range from 0.11 to 0.15 eV. Higher values, 0.18—0.20 eV, were obtained at $n=0.27$, 3.63, and 4.29. Contrary to the phenothiazine–iodine system, no abrupt change could be detected at the composition of the resistivity maximum. The Seebeck coefficient of this system depends only slightly upon the temperature and seems to be dominated by some impurities. The values are rather small and scattered (see Fig. 6). Nevertheless, they are consistently positive at low iodine contents and negative at high iodine contents. The composition at which $S=0$ appears to be $n\simeq 2.2$. Although the values at higher temperatures are more positive or less negative in all the samples, the shift of this composition by the temperature is inconsiderable. The impurities mentioned above may be the components present in excess; however, the change in the sign here is in the direction opposite to that found with unsubstituted phenothiazine. We earlier noted the similarity in the vibrational patterns of the 2:3 iodine complex and the cation radical bromide.[16] Now this observation suggests the difficulty in drawing a distinction on the basis of the vibrational spectrum between the simple benzophenothiazine cation radical salt and the complex one. Furthermore, the electronic spectrum of the "iodide" was found to be quite different from those of the other simple cation radical salts, but to resemble that of the low-resistivity iodine complex.[28] In view of the present work, the "iodide" prepared earlier is probably a kind of complex cation radical salt. Even in the case of the bromide, the simple salt was found to convert easily into the complex salt at room temperature.[21] As iodine is less electronegative than bromine, the simple thiazine cation radical "monoiodide" may be unstable or may not exist at all.

Benzo[c]*phenothiazine–Iodine.* A shoulder with a resistivity of about 20 ohm cm is observed at $n=2.5$ and a minimum is located near $n=2$ in the isotherm presented in Fig. 7. Here, the samples prepared by Method a are indicated by shaded circles. The rest were prepared starting from the "iodide" which had the following composition: C, 46.36; H, 2.74; N, 3.07; I 38.63%. Calcd for $C_{16}H_{11}NSI_{1.27}$: C, 46.82; H, 2.68; N, 3.41; I, 39.27%. No singularity is seen at $n=3$, which is the composition of the complex deposited from a benzene solution.[13,16] Thus, the effect of excess thiazine is much larger than that of excess iodine on the electrical resistivity in this system. The activation energy for semiconduction increases gradually up to $n=2.5$ and sharply above this composition. The values at $n=0.5$, 2.5, and 4.0 are 0.09, 0.12, and 0.21 eV respectively. The thermoelectric behavior is similar to that of the isomeric thiazine–iodine system. As is illustrated in Fig. 8, the Seebeck coefficient at room temperature decreases nearly linearly with n and changes its sign near $n=2.3$. Even though the evidence is not so complete as in the case of the phenothiazine complex, one may conclude that the stoichiometric compound formed in this system has a composition of $(C_{16}H_{11}NS)_2{}^+I_5{}^-$.

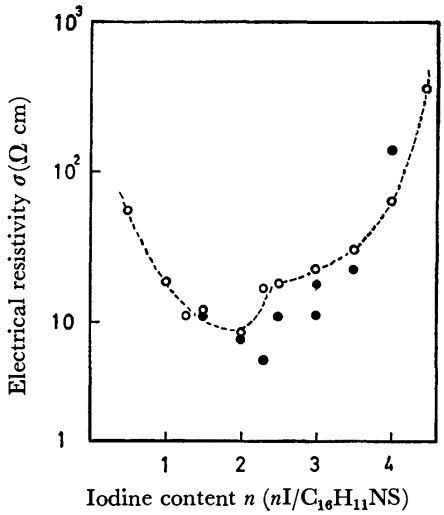

Fig. 7. Electrical resistivity at 20 °C plotted against the iodine content in the benzo[*c*]phenothiazine–iodine system.

N-*Methylphenothiazine–Iodine.* The complex deposited from ether has a mole ratio of 2:3 and is

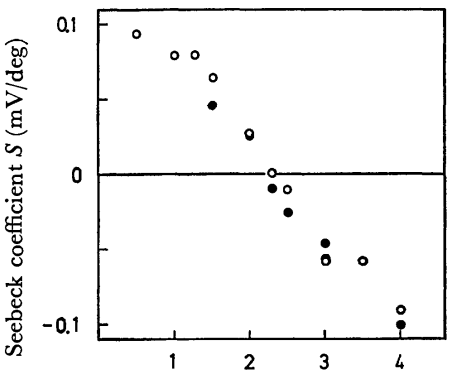

Fig. 8. Seebeck coefficient at 20 °C plotted against the iodine content in the benzo[*c*]phenothiazine–iodine system.

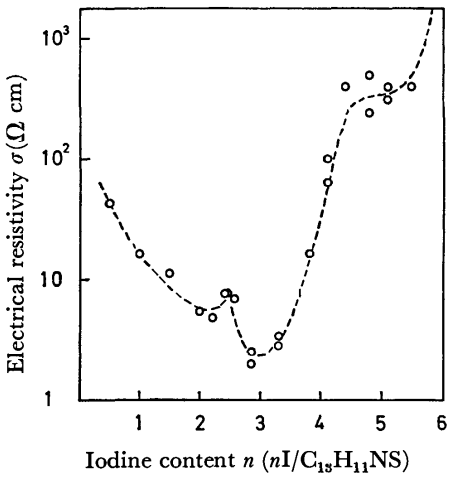

Fig. 9. Electrical resistivity at 20 °C plotted against the iodine content in the *N*-methylphenothiazine-iodine system.

more conductive by an order of magnitude than the unsubstituted phenothiazine complex.[13,17] The single crystal is known to be highly anisotropic. The principal conductivities at 23 °C, as measured by Dix, are as follows: 95, 0.96, and 0.022 ohm^{-1} cm^{-1}.[19] In addition to this complex, Dix has isolated two more, the 2: 5 and 2: 7 complexes. The resistivity-composition isotherm reported in Fig. 9 was derived from measurements of samples prepared by Method c. Clearly, the isotherm possesses a maximum of about 8 ohm cm at $n=2.5$, minima near $n=2$ and 3, and a shoulder around $n=4.5$. By analogy to the phenothiazine-iodine system, one may suggest the formation of the complex cation radical salt, $(C_{13}H_{11}NS)_2^+I_5^-$. The 2: 3 complex corresponds to a minimum at $n=3$. The low resistivity is, to some extent, due to the incorporation of a half mole of iodine into the above-mentioned salt. Because of the instability, the temperature-dependence is rather complicated and no obvious manifestation of the formation of the salt is apparent in the activation energy. The Seebeck coefficient of the 2: 3 complex depends markedly upon the temperature, as has been reported by Sano *et al.* and also by Kan and Matsunaga.[17,31] It is surprising to see that this feature is hardly modified by the composition change over the entire range examined here. The vibrational spectra of the samples with $n>4.5$ consist of sharp bands and are very different from both that of the parent compound and that of the 2: 3 complex. Therefore, the formation of a simple cation radical salt, $(C_{13}H_{11}NS)^+I_5^-$, seems to be likely. This composition agrees with the 2: 5 complex reported by Dix.

In conclusion, all the 2: 3 thiazine-iodine complexes studied may be expressed by $(thiazine)_2^+I_5^- + 1/2I_2$. Their low electrical resistivities are more or less attributable to the charge carriers generated by the incorporation of extra iodine into the complex cation radical pentaiodide. Some years ago, Wakayama determined the lattice constants of the *N*-methylphenothiazine complex.[32] This complex is orthorhombic with $a=11.4$, $b=21.4$, and $c=21.1$ Å. The unit cell is so large that six formally neutral thiazine molecules, six positively charged thiazine radicals, six pentaiodide anions, and three iodine molecules are accommodated. The exact form of the last constituent remains to be clarified, however. It may exist as the molecule, the triiodide ion, or a part of polyiodide ion(s). No matter which is the exact form, all the species derived from iodine are diamagnetic.

Catalytic Activity of Silver and Gold Metals Doped with Alkali Metals

Shigenobu HAYASHI, Mitsuyuki SOMA, Tamotsu KONDOW, Takaharu ONISHI, and Kenzi TAMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 4, 1976)

When alkali metals are brought into contact with silver or gold, catalytic activity for hydrogen activation reactions results which is higher than that for each of the constituent metals. The order of the activity per mole of alkali metal for the H_2-D_2 exchange reaction is Ag–Cs>Ag–K>Au–Cs>Ag–Na. The Ag–Cs and Ag–K systems absorb considerable amounts of hydrogen. The nature of the active sites and the contact effect of the IB metal with the alkali metal are discussed.

It has been reported that the addition of alkali metals to various materials results in marked changes in their catalytic properties.[1-3] The compounds formed between alkali metals and various aromatic compounds or graphite are of special interest because they exhibit marked catalytic activity for the activation of hydrogen molecules, although individually both constituents are of low activity in activating hydrogen molecules. Ichikawa *et al.* reported in a preliminary communication[4] that considerable catalytic activity was created when alkali metals were brought into contact with silver film, while the effect was not so large in the case of gold film. Since both silver and gold are regarded as inactive with respect to hydrogen activation, the study of the effect of the addition of alkali metals on the catalytic activity and selectivity may give clues to understanding the nature of catalysis for hydrogen activation. In this study the activation of molecular hydrogen on silver- and gold-alkali metal catalysts, as well as on each of the constituent elements, was examined in detail.

Experimental

Preparation of Catalysts. *Ag–Alkali Metal*: Silver powder was obtained by reducing silver oxide (Wako Pure Chemical Industries, 99.0%) with hydrogen at *ca.* 100 °C. Sodium (Merck) and potassium (Wako) metals were purified by repeated distillation under vacuum. Cesium metal was prepared *in vacuo* by a reaction between cesium chloride and calcium metal at 600 °C[5] and purified by repeated distillation. The alkali metals thus obtained were evaporated onto the silver powder in an evacuated glass vessel, and the resulting catalysts were subjected to heat treatments at various temperatures between 100 and 200 °C under vacuum. The surface areas of the catalysts were 0.1—0.5 m^2/g, which were determined by the BET method. The composition of the catalysts was determined by titration of the alkali metals. The sodium-doped silver catalyst (Ag–Na) weighed 9.39 g, which consisted of 9.38 g of Ag and 0.01 g of Na (0.10 wt%, 5×10^{-4} mol), (Ag–K) 9.8 g (Ag 9.1 g, K 0.7 g (7 wt%, 2×10^{-2} mol)) and (Ag–Cs) 9.5 g (Ag 8.7 g, Cs 0.8 g (8.3 wt%, 6×10^{-3} mol)).

Au–Cs: Gold powder was obtained by reducing chloroauric acid (Wako) with hydroquinone.[6] Cesium was introduced onto the gold powder sealed in a Pyrex glass tube, as shown in Fig. 1, by the "dual furnace" method[7] under vacuum. The gold powder was charged in A of the figure, and the cesium metal in B. A and B were heated

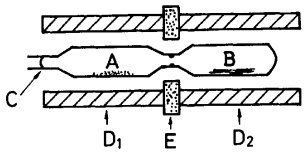

Fig. 1. Schematic diagram of "Dual Furnace" method. A: IB metal, B: alkali metal, C: breakable seal, D_1, D_2: furnaces; each furnace can be operated independently. E: insulating ring.

for 35 days at 146 and 140 °C, respectively. The catalyst weighed 1.1 g (Au 0.9 g, Cs 0.2 g (19 wt%, 2×10^{-3} mol)) and was dark-blue-violet.

Alkali Metals: The alkali metals, purified as above, were evaporated *in vacuo* onto the inside wall of a Pyrex glass tube which had been baked out beforehand at temperatures between 200 and 300 °C. The sodium film (Na) weighed 1.2×10^{-4} g, the potassium film 1 g, and the cesium film 1.2 g and the total geometrical surface areas were 50—90 cm^2.

Reactants. Commercial reactant gases were purified as follows. Hydrogen was passed through a DEOXO catalyst (Engelhard Industries, Ltd.) at room temperature and then through a 5A molecular-sieve column cooled to 77 K. Deuterium was passed through a 5A molecular-sieve column and then an activated charcoal column at 77 K. Ethylene was frozen at 77 K, evacuated, and then was passed through a dry ice–methanol trap. Propylene was purified by repeated freeze, evacuation and thaw cycles.

Apparatus and Procedures. The apparatus employed for the reactions was a closed circulating system whose dead volume was about 300 cm^3. The total pressures of the reactant gases were ordinarily between 13 and 27 kPa. The pressure change during the course of the reaction was followed using a mercury manometer. The reacting gas mixtures were analyzed by gas chromatography,[8] infrared spectroscopy, mass spectrometry, and microwave spectroscopy. The activity of the catalysts remained unchanged upon repeated runs and each run was normally carried out without pretreatment.

Results

Absorption of Hydrogen and the H_2-D_2 Exchange Reaction. When hydrogen was introduced into various catalyst systems, the absorption of hydrogen took place at various extents, as given in Table 1. The absorption of hydrogen by Ag–Cs, for example, is shown in Fig. 2. A negligible amount of thermal desorption of the

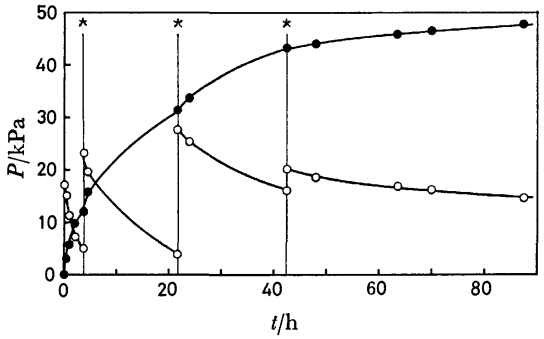

Fig. 2. Absorption of hydrogen on Ag–Cs at 23 °C. ○: pressure of hydrogen gas, ●: total decrease in pressure, *i.e.*, amount of absorbed hydrogen (The pressure decrease of 1 kPa corresponds to the absorption of 0.35 cm³ STP/g-catalyst.). At the point denoted by * hydrogen was added into gas phase.

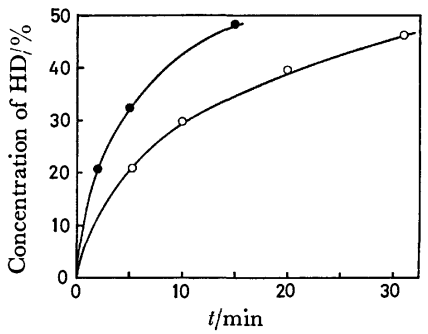

Fig. 3. The H_2-D_2 exchange reaction over Ag–Cs. The total pressure of reacting gas was 8 kPa. The equimolar mixture of H_2 and D_2 was introduced over the catalyst with preabsorbed hydrogen of 170 cm³ STP per 9.5 g catalyst. Reaction temperature; ○: 0 °C, ●: 23 °C.

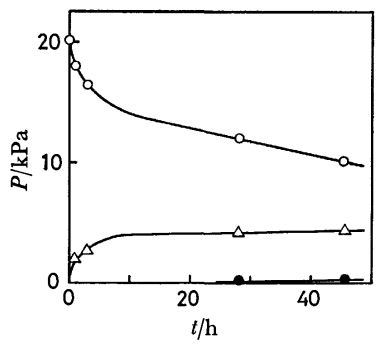

Fig. 4. The exchange reaction between gaseous deuterium and the absorbed hydrogen on Ag–Cs at 23 °C. The total amount of hydrogen preabsorbed at 23 °C was 150 cm³ STP per 9.5 g catalyst. ○: D_2, ●: H_2, △: HD.

absorbed hydrogen took place *in vacuo* below 170 °C, the amounts of saturated absorption remaining unchanged. No appreciable hydrogen absorption was detected on the alkali metals in the absence of silver under the same conditions. At higher temperatures, however, alkali metals reacted with hydrogen, forming hydrides.

When an equimolar mixture of H_2 and D_2 was introduced over Ag–K and Ag–Cs systems, the H_2-D_2 exchange reaction took place at a rather high rate at room temperature, as shown in Fig. 3. When deuterium was introduced over the Ag–K and Ag–Cs catalysts, which contained preabsorbed hydrogen, at a temperature above 100 °C and at room temperature, respectively, at first HD quickly appeared in the gas phase but soon slowed down, as shown in Fig. 4. The rate of HD formation after the initial surge was 10^2 or 10^3 times slower than that in the H_2-D_2 exchange reaction under similar reaction conditions. The deuterium preabsorbed over Ag–Cs participated in the hydrogenation of ethylene and propylene at 100 °C, whereas the deuterium in the alkali metal hydrides, in the absence of silver, did not.

The H_2-D_2 exchange reaction was of first order with respect to the total pressure. The dependence of the reaction rate with pressure for Ag–K at 0 °C is shown

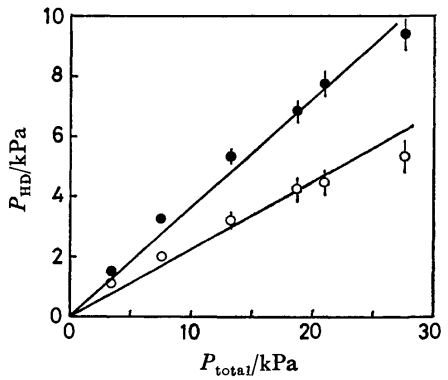

Fig. 5. Pressure dependence of the rate of the H_2-D_2 exchange reaction over Ag-K at 0 °C, with the initial amount of H_2 equal to that of D_2. Reaction time; ○: 2 min, ●: 6 min.

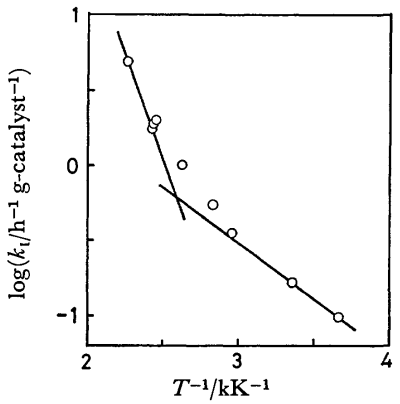

Fig. 6. Temperature dependence of the rate constants of the H_2-D_2 exchange reaction over Au-Cs.

in Fig. 5. The rate constant k_1 was calculated using the equation,

$$k_1 = -\frac{1}{t} \ln \frac{[HD_\infty]-[HD_t]}{[HD_\infty]},$$

where $[HD_t]$ and $[HD_\infty]$ are the concentrations of HD at time t and that at equilibrium, respectively. The temperature dependence of k_1 over Au-Cs is shown in Fig. 6. The apparent activation energies for the reaction over various catalysts are listed in Table 1. The activation energies were not affected by the heat treatments, although the rate of the exchange reaction was changed. The catalytic activity of each of the Ag-alkali metal catalysts was increased by repeated heat treatments and approached a saturated value at a given temperature between 100 and 200 °C under vacuum. The activity decreased, however, when the temperature of the heat treatment was higher than 200 °C. In the case of Au-Cs, the catalytic activity remained constant for heat treatments up to a temperature of 260 °C *in vacuo*. In the case of Ag-K and Ag-Cs catalysts, the rate of the H_2-D_2 exchange reaction was neither affected by the preabsorbed hydrogen nor by the presence of ethylene. The activity of Au-Cs was markedly enhanced (more than ten times) when fresh cesium metal was additionally evaporated onto the catalyst, but decreased and finally reached the original value after repeated heat treatments. The first order rate constants for the exchange reaction on each catalyst are listed in Table 1. In some systems, the measurements were carried out at temperatures above 0 °C, and the values of the rate constant k_1 at 0 °C were then estimated from their temperature dependences. The results given in Table 1 lead to the following conclusions.

(1) The catalytic activity of silver for the H_2-D_2 exchange reaction is increased by contact with alkali metals as follows:
3×10 for Ag-Na/Ag, 5×10^5 for Ag-K/Ag, and 6×10^5 for Ag-Cs/Ag.

(2) The increase in the activity per mole of the alkali metals by contact with IB metals are as follows: 5×10^3 for Ag-Na/Na, 1×10^5 for Ag-K/K, 7×10^2 for Ag-Cs/Cs and 2×10 for Au-Cs/Cs.

(3) The activity per mole of the alkali metal was in the following increasing orders:
Na<K<Cs and Ag-Na<Au-Cs<Ag-K<Ag-Cs.

The frequency factors for the exchange reaction are listed in Table 1.

Hydrogenation of Ethylene and Propylene. When ethylene or propylene was brought into contact with Ag-Cs which contained preabsorbed hydrogen (or deuterium) at 100 °C, olefin adsorption took place and simultaneously ethane or propane (with deuterium) appeared in the gas phase. Cs metal adsorbed the olefins at 100 °C and the alkanes were formed concurrently through self-hydrogenation of the olefins. When hydrogen was introduced after ethylene had been preadsorbed on Ag-Cs and Cs, 10—20% of the preadsorbed ethylene reacted to form ethane with a small amount of 2-butenes. On the other hand, most of the propylene adsorbed on Ag-Cs was desorbed into the gas phase upon the introduction of hydrogen with only a small amount of propane, followed by slow hydrogenation. Ag-K containing preabsorbed hydrogen adsorbed little ethylene at 20—50 °C, as hydrogen is adsorbed more strongly than ethylene.

The hydrogenation of ethylene with molecular hydrogen to form ethane took place on Ag-Cs, Ag-K, Au-Cs, and Cs, and the pressure dependence of this process was first order with respect to the amount of ethylene and zeroth order with respect to the amount of hydrogen, as shown in Fig. 7. The reaction rate can accordingly be expressed by the equation,

$$\text{rate} = k_1'[C_2H_4],$$

where k_1' is the rate constant and $[C_2H_4]$ is the partial pressure of ethylene. The k_1' for each catalyst is given in Table 1.

The initial rate of ethylene hydrogenation over Ag-Cs between hydrogen gas and ethylene was more than fifty times as fast as that between ethylene and preabsorbed hydrogen in the absence of gaseous hydrogen at 100 °C.

It was also demonstrated that hydrogen in the gas phase at higher pressures inhibits the production of propane over Ag-Cs and Cs at 100 °C, as is shown in Fig. 8.

The hydrogen exchange reaction between propylene and deuterium was approximately 100 times faster than the hydrogenation of propylene on Au-Cs at 215 °C. The isotopic distribution of the deuterated propylenes

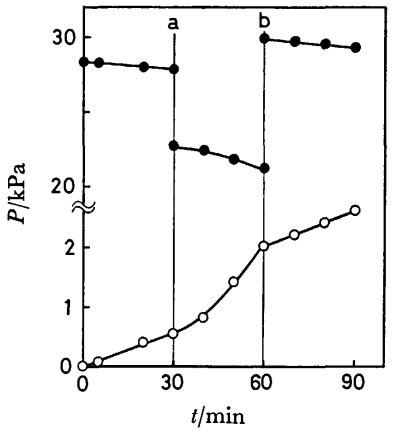

Fig. 8. The hydrogenation of propylene over Ag–Cs with preabsorbed hydrogen at 104 °C. The total amount of absorbed hydrogen was 170 cm³ STP per 9.5 g catalyst. The initial gas was composed of 15.0 kPa of propylene and 13.3 kPa of hydrogen. a) Hydrogen gas was partially removed. b) Hydrogen gas was added. ●: Total pressure of gas phase. ○: Propane pressure. Hydrogen absorption was saturated and the partial pressure of C_3 species in the gas phase was not changed in the course of reaction, and, consequently, the decrease in pressure during the reaction corresponds to the production of propane.

determined by their microwave spectra[9] indicated that no hydrogen exchange takes place at the 2-carbon positions and only the hydrogen at both end carbons participates in the exchange.

Discussion

It is, thus, demonstrated that alkali metal-doped IB metal catalysts have higher catalytic activities for hydrogen activation reactions per mole of each constituent than each of the IB metals or alkali metals, as given in Table 1. The activation energies for the H_2-D_2 exchange reaction were also changed by the doping. This behavior is similar to that of other alkali metal-doped catalysts, such as potassium-condensed aromatic hydrocarbons.[2] Thus, when they are brought into contact, the electron donor (alkali metals) and acceptor (IB metals) exhibit new catalytic activity, higher than each of the constituents.

The H_2-D_2 exchange reaction was of first order with respect to the total pressure, and the hydrogenation of ethylene was of first order with respect to the amount of ethylene and of zeroth order with respect to that of hydrogen. In addition to the kinetic expression, the H_2-D_2 exchange reaction was not retarded by the presence of ethylene, which strongly suggests that hydrogen is more strongly adsorbed than olefins.

It has been reported that the Ag–Na and the Au–alkali metal systems form metallic compounds, whereas no such compounds are formed in the Ag–K and Ag–Cs systems.[10] The latter group is more active in activating molecular hydrogen. The activity of these doped catalysts also depends upon the electropositivity of the alkali metals, which is in the following increasing order, Na<K<Cs. A higher electropositivity generally results in a higher catalytic activity.

The behavior of the IB metal–alkali metal catalysts suggests the following scheme for the active sites relevant to hydrogen activation. The IB metal–alkali metal catalysts appear to possess at least two kinds of active sites for hydrogen activation and absorption, site (A) and site (B). The H_2-D_2 exchange reaction proceeds mainly *via* adsorbed hydrogen (or deuterium) on site (A), while the absorption of hydrogen takes place on site (B), most of the hydrogen thus absorbed hardly participating in the exchange reaction.

Site (A) is apparently much more active when no metallic compounds are formed between the constituents or if the alkali metals are more electropositive. The heat treatment under vacuum changes only the number of sites, the apparent activation energy remaining unchanged. Site (A) may be considered to be located at the doped alkali metal which is in contact with the IB metal because of the similarity in the reaction kinetics over site (A) with those over alkali metals; *i.e.*, the similarity of the pressure dependences in the H_2-D_2 exchange reaction and in ethylene hydrogenation. The contact with IB metals reduces the activation energies for the reaction on the alkali metal.

In the case of Au–Cs, further addition of cesium by evaporation produced higher activity, but subsequent heat treatments reduced the enhanced activity to its original magnitude. Two different activation energies for the H_2-D_2 exchange reaction were observed over the reaction-temperature range, as shown in Fig. 6.

Hydrogen is strongly absorbed on site (B) such that the absorbed hydrogen is not desorbed by mild heat treatments *in vacuo*. Site (B) is less active than site (A) for the H_2-D_2 exchange reaction and the hydrogenation of ethylene. In the case of hydrogenation of propylene, higher hydrogen pressures even retard the rate of hydrogenation, as shown in Fig. 8.

Since the atomic ratio of the total amount of absorbed hydrogen to cesium was more than two on Ag–Cs, as

given in Table 1, the formation of alkali metal hydride cannot account for all of the absorbed hydrogen, while silver metal alone absorbs no hydrogen. It is thus revealed that the contact of cesium with silver exhibits new activity not only for hydrogen activation reactions, such as the H_2-D_2 exchange and hydrogenation reactions, but also for hydrogen uptake. Although the reason why such new activity appears is a matter of conjecture, electron donation from the alkali metal to the IB metal is most probably associated with this phenomenon.

Conclusion

High catalytic activity for hydrogen activation reactions was produced by the contact of alkali metals with IB metals. The addition of alkali metals activates the silver surface for the chemisorption of hydrogen. The enhanced activity of alkali metals upon contact with IB metals is due to the decrease in the activation energy.

The new catalytic activity is considered to be caused by electron donation from the alkali metal to the IB metal and not by the formation of metallic compounds.

The authors thank Dr. T. Kondo of the Sagami Chemical Research Center for undertaking the mass and microwave spectroscopic analyses.

The Absorption Spectra of Disubstituted Benzenes. Interpretation by Means of Configuration Analysis

Tsuneo Fujii, Satoshi Suzuki, and Michiyuki Fujishima*

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received November 4, 1976)

The method of configuration analysis has been applied to the interpretation of the ground and the excited states of disubstituted benzenes with two electron-donating groups, *o*-, *m*-, and *p*-benzenediols and *o*-, *m*-, and *p*-phenylenediamines, with particular attention paid to the dependence of the spectra on the positions of substitution and on the molecular symmetry. The wave functions calculated by the Pariser-Parr-Pople method are analyzed in terms of locally-excited states and intramolecular charge-transfer states. The characteristic changes in the location of the L_b, L_a, and B_b bands caused by substitution are adequately explained by the analysis. The intensification of the L_b band caused by the introduction of the substituents is interpreted as due to the mixing between the L_b, B_b, and B_a bands for the *o*- and *m*-substituted benzenes and between the L_b and B_b bands for the *p*-disubstituted benzenes. It was found empirically that the magnitudes of the spectral shift from benzene to the derivatives are determined primarily by the extent of charge-transfer contributions.

Although the effects of substitution on the electronic spectra have been extensively investigated for monosubstituted benzenes,[1-7] the electronic spectra of disubstituted benzenes have received little attention.[8-14] Kiss and Szöke have calculated many disubstituted benzenes, including fluoro, chloro, hydroxyl, amino, formyl, carboxyl, and nitro groups, and have discussed the singlet transition energies as well as the ground-state charge densities and bond orders.

The present paper will report on the results of the configuration analysis (CA) of six disubstituted benzenes: *o*-, *m*-, and *p*-benzenediols (*o*-, *m*-, and *p*-$(OH)_2$) and *o*-, *m*-, and *p*-phenylenediamines (*o*-, *m*-, and *p*-$(NH_2)_2$). The *o*- and *m*-disubstituted benzenes both have the C_{2v} symmetry, but the former have the symmetry axis along the b-axis of the benzene ring, while the latter have the symmetry axis along the a-axis of the benzene ring. The *p*-disubstituted benzenes have the D_{2h} symmetry and have the symmetry axis along the b-axis of the benzene ring.

Calculation

The method of calculation, the procedure, the parameters, and the molecular geometry are the same as have previously been described except for one added substitution.[6,7] The geometry of the compounds studied in this paper are shown in Fig. 1. The SCF MO's are numbered in the order of increasing energy. In the CI calculation of all the compounds, the following 10 singly-excited configurations are included: 5→6, 7, 8; 4→6, 7, 8; 3→6, 7; 2→6, 7.

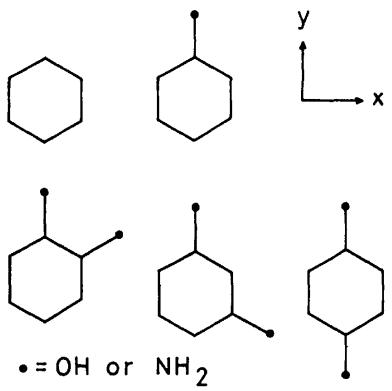

Fig. 1. The molecular geometry of the compounds.

Experimental

o-Benzenediol and phenylenediamines were purified by repeated crystallizations and subsequent sublimation *in vacuo* prior to use. Isooctane (2,2,4-trimethylpentane) was fractionally distilled and then passed through a column of silica gel. The absorption spectra were recorded on a Hitachi EPS-3 recording spectrophotometer.

Results

The calculated energies, the oscillator strengths, and the directions of the transition moments, which are the angles from the x-axis, for the lower singlet states of the six compounds are presented in Table 1, together with the available experimental data. The symbols used in the present paper for denoting the electronic states and absorption bands have the same meaning as the corresponding symbols in previous papers,[6,7] unless otherwise noted.

The results of the CA of the six compounds are given in Tables 3—8. The reference MO's employed in the analysis are the SCF MO's of benzene $\phi_1^\circ, \cdots, \phi_6^\circ$, and the 2 MO's of the substituents, ϕ_{X+}° and ϕ_{X-}°, which are the linear combination of the AO's, χ_1 and χ_2, of the substituents:

$$\phi_{X+}^\circ = \frac{1}{\sqrt{2}}(\chi_1+\chi_2),$$

$$\phi_{X-}^\circ = \frac{1}{\sqrt{2}}(\chi_1-\chi_2).$$

The reference states taken into account in the analysis are as follows: the ground and 4 locally-excited states of benzene, Ψ_G°, $\Psi_1^\circ, \cdots, \Psi_4^\circ$: 4 intramolecular charge-transfer reference states, Ψ_{CT4+}°, Ψ_{CT4-}°, Ψ_{CT5+}°, and Ψ_{CT5-}°. The Ψ_{CT4+}° corresponds to a one-electron excitation from ϕ_{X+}° to ϕ_4°, *etc.* The total weight means the sum of the weights of all 9 reference states described above.

a) Ref. 8.

The band assignments are given in Tables 3—8. When a single reference state has a weight higher than 50%, the state notation of the state is indicated in the column of the band assignments.

Discussion

The calculated band shifts in the transition energies caused by the introduction of hydroxyl and amino groups are compared with the observed band shifts including phenol and aniline in Table 2. There are 4 electronic absorption bands in the ultraviolet region. Although the same parameters are used irrespective of the positions of substitution, the calculated and observed band shifts agree very well except for Band II of the *o*-disubstituted benzenes. The effect of *o*-substitution may perhaps appear in Band II of *o*-disubstituted benzenes. The order of the observed band shifts, ΔE, of the individual absorption band are: $\Delta E(p\text{-}) > \Delta E(m\text{-}) \approx \Delta E(o\text{-})$ for Band I; $\Delta E(p\text{-}) > \Delta E(m\text{-}) > \Delta E(o\text{-})$ for

Band Assignment. Tables 3—5 show the results of the CA of the benzenediols. The first and the second bands of *o*-, *m*-, and *p*-$(OH)_2$ can reasonably be assigned to the L_b and L_a respectively. Since a strong mixing is found to occur between the B_b and B_a reference states in the Ψ_3 and Ψ_4 excited states, one can hardly identify the B_b and B_a bands in the cases of *o*- and *m*-$(OH)_2$. On the other hand, Band III and IV, which may be found in the higher energy side of Band II, of *p*-$(OH)_2$ are assigned to the B_b and B_a respectively. The main charge-transfer reference states to each state are as follows: Ψ°_{CT4-} (Band I), Ψ°_{CT5+} (Band II), Ψ°_{CT4+} (Band III), and Ψ°_{CT4-} (Band IV) in *o*-$(OH)_2$, Ψ°_{CT4+} (Band I), Ψ°_{CT5-} (Band II), Ψ°_{CT4-} (Band III), and Ψ°_{CT5+} (Band IV) in *m*-$(OH)_2$, and Ψ°_{CT4+} (Band I), Ψ°_{CT5-} (Band II), Ψ°_{CT4+} (Band III), and Ψ°_{CT5-} (Band IV) in *p*-$(OH)_2$.

Since the amino group is known to be a strong electron donor, charge-transfer configurations are mixed effectively with locally-excited states of benzene of a lower energy, as is seen in Tables 6—8. Accordingly, the amino-substitution has a greater influence on the electronic structure of benzene than does the hydroxy-substitution.

The most important reference states in the excited states of phenylenediamines are the charge-transfer reference states. Indeed, Ψ°_{CT4+} in the Ψ_3 of *o*-$(NH_2)_2$ and in the Ψ_1 of *p*-$(NH_2)_2$, Ψ°_{CT4-} in the Ψ_3 of *m*-$(NH_2)_2$, Ψ°_{CT5+} in the Ψ_2 of *o*-$(NH_2)_2$ and in the Ψ_4 of *m*-$(NH_2)_2$, and Ψ°_{CT5-} in the Ψ_2 of *p*-$(NH_2)_2$ are the most important reference states in the states of phenylenediamines.

The L_b reference state does not interact with the L_a reference state, but interacts with the B_b and B_a for the *o*- and *m*-$(OH)_2$ and the B_b for the *p*-$(OH)_2$, from which the intensity of Band I is derived.

Band Shift. The contributions of charge-transfer configurations to the individual excited states of substituted benzenes are expected to be the principal source of the spectral changes.[15] In order to ascertain the dependence of the spectral shifts on the contribution of charge-transfer states of substituted benzenes, the calculated state energies, E_{calcd}, for Bands I, II, III, and IV are plotted against the total charge-transfer weights, W_{CT}, including the corresponding values of phenol and aniline. The calculated state energies of benzene are also plotted on the axis of the ordinate in Fig. 2.

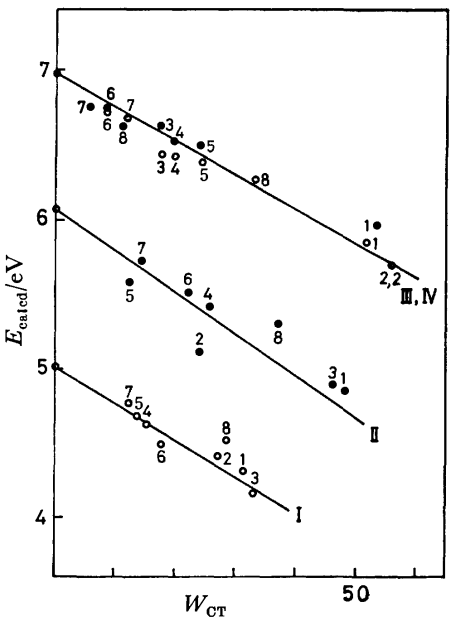

Fig. 2. The plots of E_{calcd} against W_{CT}. 1: *o*-Diaminobenzene, 2: *m*-diaminobenzene, 3: *p*-diaminobenzene, 4: *o*-dihydroxybenzene, 5: *m*-dihydroxybenzene, 6: *p*-dihydroxybenzene, 7: phenol, 8: aniline. The calculated state energies of benzene are plotted on the axis of ordinate. Band I: ○; Band II: ●; Band III: ○; Band IV: ●. Band III and IV lie on the same line.

It may be seen from Fig. 2 that approximately linear relationships exist between E_{calcd} and W_{CT} for individual bands of benzene derivatives including phenol and aniline. The plots of E_{calcd} against W_{CT} for Band I intersect the ordinate axis at the point corresponding to the L_b-state energy of benzene. The plot for Band II may be approximated by a straight line, and the point of intersection of the ordinate for Band II is the point representing the L_a-state energy of benzene. The plots for Bands III and IV also have an approximately linear relation and lie on the same straight line. It is to be noted that the gradients for the individual bands have approximately the same values. It is concluded that the plots of E_{calcd} against W_{CT} are approximately linear and that the extrapolations of the plots for each band to zero total weight give the corresponding state energies of benzene.

The plots for the observed state energies, E_{obsd}, against the total charge-transfer weights, W_{CT}, are presented in Fig. 3. Although the observed data are

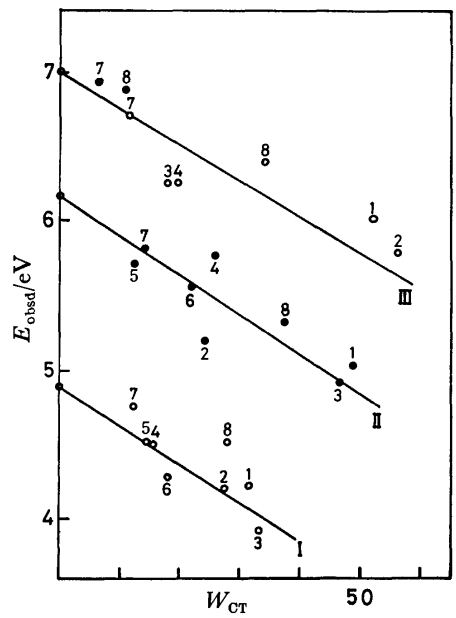

Fig. 3. The plots of E_{obsd} against W_{CT}. The numberings are the same as in Fig. 2. The observed state energies of benzene are plotted on the axis of ordinate.

not so many, approximately linear relationships also exist between E_{obsd} and W_{CT}. As is the case of E_{calcd} *vs.* W_{CT}, the gradients of the individual bands have nearly the same values.

Although the contribution of the charge-transfer configurations to individual bands is expected to increase with the decrease in molecular size, the total weight of the charge-transfer configurations is closely correlated with the spectral shifts on going from benzene to its derivatives, as in the case of naphthalene derivatives.[15] This shows that the total charge-transfer contributions determine the spectral shifts on going from parent compounds to their derivatives.

Relaxation Studies of the Adsorption-Desorption Equilibrium of Surfactants on the Gas-Liquid Interface. I. Theoretical Studies

Minoru SASAKI, Tatsuya YASUNAGA, and Nobuhide TATSUMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received November 9, 1976)

A general theory for the propagation characteristics of the capillary wave on the gas-liquid interface, where the physicochemical equilibrium exists, is proposed. The theory is developed on the basis of the two-dimensional relaxation theory and the surface thermodynamics. The relaxation parameters in the equations are closely related to the dynamic behavior of the equilibrium. As an example, the theory was applied to the surfactant solution, taking account of the adsorption-desorption and diffusion processes of the surfactant. The derived equations revealed that the adsorption-desorption process plays an important role in the surfactant transfer between the surface and the bulk phase in a concentrated surfactant solution, while the diffusion process plays such a role in a dilute solution.

The measurements of the propagation characteristics of the capillary wave, *e.g.*, the propagation velocity and the damping coefficient, are effective for the study of the dynamic properties of materials existing on the gas-liquid interface. The theoretical studies for the insoluble monolayers have been performed by Dorrestein,[1] Mayer and Eliassen,[2] and Mann and Du,[3] while those for the soluble monolayer have been performed by van den Tempel and van de Riet,[4] Hansen and Mann,[5] and Lucassen and Hansen.[6] The former has developed their theories taking account of the surface rheologies, and the latter with the assumption that the rate-determining step of surfactant transfer between the surface and the bulk phase is the diffusion process.

Provided that the physicochemical equilibrium on the interface, *e.g.*, the conformational change and the monomer-dimer reaction, is perturbed by the propagation of the wave, the relaxation effect concerned with the equilibrium may be expected. Though studies of such phenomena are valuable for the clarification of the dynamic properties of the equilibrium, theoretical studies have never been performed, while experimentally Davies and Vose[7] have observed the relaxation effect on the surfactant solution.

In the present investigation, a general theory on a surface involving the physicochemical equilibrium is developed on the basis of the relaxation theory[11] and the surface thermodynamics.[12,13]

General Equation

Let us consider a plane wave moving on a liquid surface in the x direction. Here, the motion of an incompressible liquid must satisfy the Navier-Stokes equations:[8]

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \nu\Delta u,$$

$$\frac{\partial v}{\partial t} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \nu\Delta v - g, \qquad (1)$$

with

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0,$$

where u and v are the velocity components in the x and y directions respectively; p is the hydrostatic pressure; ν, the kinematic viscosity, and g, the gravitational acceleration. u and v can be written by means of the stream function, Φ, and the potential function, Ψ:

$$u = -\frac{\partial \Phi}{\partial x} - \frac{\partial \Psi}{\partial y},$$

$$v = -\frac{\partial \Phi}{\partial y} + \frac{\partial \Psi}{\partial x}. \qquad (2)$$

In order to solve Eq. 1, one must impose a boundary condition that the liquid motion becomes zero as $y \to -\infty$. Under the condition that the liquid motion satisfies the requirement of simple periodic movement, Φ and Ψ are given by the following equations:

$$\Phi = E_1 \exp(ky) \exp\{i(rt+kx)\},$$

$$\Psi = E_2 \exp(my) \exp\{i(rt+kx)\}, \qquad (3)$$

with

$$m^2 = k^2 + \frac{ir}{\nu},$$

where E_1 and E_2 are the complex constants associated with the amplitudes of Φ and Ψ respectively; k is the wave number; m, the complex constant associated with the decay of liquid motion, and r, the complex angular frequency. From Eqs. 1—3, the equations for the velocities are obtained:

$$u = \{-ikE_1 \exp(ky) - mE_2 \exp(my)\} \exp\{i(rt+kx)\},$$

$$v = \{-kE_1 \exp(ky) + ikE_2 \exp(my)\} \exp\{i(rt+kx)\}. \qquad (4)$$

The liquid motion at the surface is described by the elevation of the surface, ϕ:

$$\frac{\partial \phi}{\partial t} = v_s, \qquad (5)$$

where the subscript s indicates the surface.

The boundary conditions for the normal and tangential stresses[4,6] are given as follows:

$$p - 2\eta\frac{\partial v}{\partial y} + \gamma\frac{\partial^2 \phi}{\partial x^2} = 0,$$

$$\eta\left(\frac{\partial v_s}{\partial x} + \frac{\partial u_s}{\partial y}\right) - \frac{\partial \gamma}{\partial x} - \eta_s\frac{\partial^2 u_s}{\partial x^2} = 0. \qquad (6)$$

The $\left(\frac{\partial \gamma}{\partial x}\right)$ term is expressed as

$$\frac{\partial}{\partial t}\left(\frac{\partial \gamma}{\partial x}\right) = C_s^{-1}\frac{\partial^2 u_s}{\partial x^2}, \qquad (7)$$

with

$$C_s^{-1} = \left(\frac{\partial\gamma}{\partial s}\right), \tag{8}$$

where C_S is the surface compressibility, and s, the surface area per unit area. As C_S reflects the dynamic behavior of the physicochemical equilibrium on the surface, the dynamic surface compressibility has to be introduced. It is derived by applying the relaxation theory to the perturbed equilibrium system.

The following one-step equilibrium existing on a surface is considered:

$$\nu_i R_1 + \cdots + \nu_i R_i \rightleftarrows \nu_1' P_1 + \cdots + \nu_j' P_j,$$

where ν_i and ν_j' are the stoichiometric coefficients, and R_i and P_j, the species. When the wave propagates on the surface, the accompanying liquid motion causes the periodic variation in the surface area, which acts as the external driving force for the disturbance of the equilibrium. Consenquently, the extensive variables such as the concentration or ordering parameter of species, are perturbed periodically, and so behind the external driving force. The relaxation process of the perturbed system is described by the ordering coefficient, ξ, as follows:[11]

$$\xi = LA, \tag{9}$$

with

$$\xi = \bar{\xi} + \Delta\xi \exp(i\omega' t),$$

$$d\xi = \Delta\xi \exp(i\omega' t) = \frac{dN_i}{\nu_i} = \frac{dN_j'}{\nu_j'},$$

where A denotes the chemical affinity; L, the constant; the bar, the equilibrium state; $\omega'(=2\omega)$, the angular frequency associated with the perturbation of the surface area (see Appendix I), and N_i and N_j', the numbers of moles of the R_i and P_j species respectively. A and γ are expanded in terms of the changes in s and ξ in the vicinity of the surface:[12,13]

$$A(\xi, s, S) = \left(\frac{\partial A}{\partial \xi}\right)_{s,S} d\xi + \left(\frac{\partial A}{\partial s}\right)_{\xi,S} ds,$$

$$d\gamma = \left(\frac{\partial \gamma}{\partial \xi}\right)_{s,S} d\xi + \left(\frac{\partial \gamma}{\partial s}\right)_{\xi,S} ds, \tag{10}$$

where S is the entropy. Here, the adiabatic approximation is reasonably applied (see Appendix II). If ds is zero, Eq. 10 becomes:

$$\dot{\xi} = L\left(\frac{\partial A}{\partial \xi}\right)_{s,S} d\xi = -\frac{d\xi}{\tau_{s,S}}. \tag{11}$$

$\tau_{s,S}$ denotes the relaxation time of the local fluctuation of equilibrium. The similarly obtained $\tau_{r,S}$ is related to $\tau_{s,S}$ by the ollowing relation

$$\frac{\tau_{r,S}}{\tau_{s,S}} = \frac{(C_S^{-1})_{\xi,S}}{(C_S^{-1})_{A,S}}. \tag{12}$$

The combination of Eqs. 9 and 10 gives the relationship between $d\gamma$ and ds:

$$d\gamma = \frac{\left(\frac{\partial\gamma}{\partial s}\right)_{A,S} + i\omega'\tau_{s,S}\left(\frac{\partial\gamma}{\partial s}\right)_{\xi,S}}{1+i\omega'\tau_{s,S}} ds. \tag{13}$$

From Eqs. 8 and 13, we obtain the dynamic surface compressibility, C_S^*:

$$(C_S^*)_S^{-1} = (C_S^{-1})_{A,S}\frac{1+i\omega'\tau(\delta+1)}{1+i\omega'\tau}, \tag{14}$$

with

$$\tau_{s,S} = \tau, \quad \delta = \frac{(C_S^{-1})_{\xi,S}}{(C_S^{-1})_{A,S}} - 1,$$

were δ is the relaxation strength.

The combination of Eqs. 2—7 and 14 gives two homogeneous equations for E_1 and E_2:

$$\{E_1(ir^2 - i\sigma^2 + 2\nu k^2 r) - E_2(\sigma^2 + 2i\nu k m r)\} \times \exp\{i(\omega t + kx)\} = 0,$$

$$\{E_1(2i\nu k^2 r + \chi^*\sigma^2) + E_2(ir^2 + 2\nu k^2 r - i\chi^*\sigma^2 m k^{-1})\} \times \exp\{i(\omega t + kx)\} = 0, \tag{15}$$

with

$$\sigma^2 = gk + \frac{\gamma k^3}{\rho}, \tag{16}$$

$$\chi^* = \frac{k^3}{\rho\sigma^2}\left\{(C_S^{-1})_{A,S} + i\eta_S r + (C_S^{-1})_{A,S}\frac{i\omega\tau\delta}{1+i\omega'\tau}\right\}, \tag{17}$$

χ^* consisting of two terms, χ_{ela} and χ_r. The former is attributed to the surface viscoelasticity, and the latter, to the relaxation:

$$\chi_{ela} = \frac{k^3}{\rho\sigma^2}\{(C_S^{-1})_{A,S} + i\eta_S r\}, \tag{18}$$

$$\chi_r = \frac{k^3}{\rho\sigma^2}(C_S^{-1})_{A,S}\left(\frac{\omega'^2\tau^2\delta}{1+\omega'^2\tau^2} + \frac{i\omega'\tau\delta}{1+\omega'^2\tau^2}\right).$$

The available solution of Eq. 15 is given by the following determinant:

$$\begin{vmatrix} ir^2 - i\sigma^2 + 2\nu k^2 r & -\sigma^2 - 2i\nu k m r \\ 2i\nu k^2 r + \chi^*\sigma^2 & ir^2 + 2\nu k^2 r - i\chi^*\sigma^2 m k^{-1} \end{vmatrix} = 0. \tag{19}$$

The propagation velocity, c, and the damping coefficient, α, are defined by the following equations:

$$c = \frac{r_{re}}{k}, \tag{20}$$

$$\alpha = \frac{r_{im}}{V}, \tag{21}$$

where the re and im subscripts indicate the real and imaginary parts respectively, and where $V(=3c/2)$ is the group velocity. In the case of $\chi^* \neq 0$, the complex angular frequency, r, exhibits the frequency dispersion. Then, the dispersion terms, ε_{ela} and ε_r, are introduced as follows.

$$r = \sigma(1 + \varepsilon_{ela} + \varepsilon_r). \tag{22}$$

ε_{ela} and ε_r are concerned with the surface viscoelasticity and the relaxation respectively. From Eqs. 18, 19 and 22, ε_{ela} and ε_r are obtained as:

$$\varepsilon_{ela} = \frac{\frac{2\nu k^2}{\sigma} i + \frac{1}{2}\chi_{ela}}{1 - (1+i)\chi_{ela}\left(\frac{2\nu k^2}{\sigma}\right)^{1/2}}. \tag{23}$$

and

$$\varepsilon_r = \frac{\chi_r}{2}.$$

Therefore, c and α are given by Eqs. 16 and 20—23:

$$c^2 = \left(\frac{g}{k} + \frac{\gamma k}{\rho}\right)(1 + 2\varepsilon_{ela,re} + 2\varepsilon_{r,re}), \tag{24}$$

$$\alpha = \frac{\sigma}{V}(\varepsilon_{ela,im} + \varepsilon_{r,im}). \tag{25}$$

These are the general equations for the propagation

characteristics of the capillary wave, taking account of the relaxation process.

Propagation Characteristics of Wave on the Surface of a Surfactant Solution

The surfactant transfer between the surface and the bulk phase is expressed by the following scheme, taking account of two processes; the adsorption-desorption process between the surface and the subsurface, and the diffusion process between the subsurface and the bulk phase, as is shown schematically in Fig. 1:

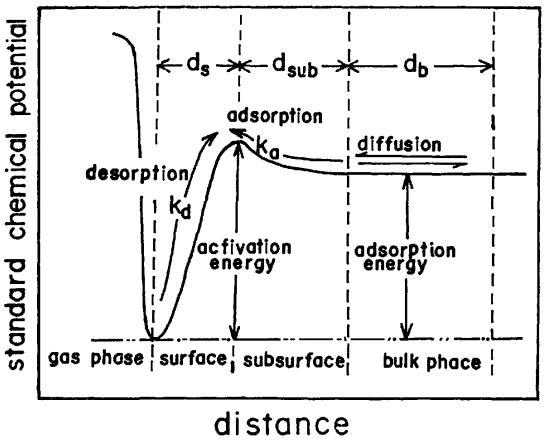

Fig. 1. Diagrammatic representation of the surfactants in the vicinity of surface. k_a and k_d are the adsorption and desorption rate constants, and d_s, d_{sub}, and d_b the thicknesses of the surface, subsurface, and bulk phase layers, respectively.

$$S_s \underset{\text{(adsorption)}}{\overset{k_d\ \text{(desorption)}}{\rightleftharpoons}} S_{sub} \rightleftharpoons S_b, \quad \text{(diffusion)}$$

where S_b, S_{sub}, and S_s are the surfactants in the bulk phase, the subsurface, and the surface, and where k_a and k_d are the adsorption and desorption rate constants, respectively. The adsorption-desorption process is governed by the activation energy of the adsorption and desorption processes and is represented by a Langmuir-type rate equation.[10,14] On the other hand, the diffusion process is expressed by the diffusion theory. Thus, the following equations are given for the adsorption-desorption mechanism:

$$\frac{dc_s}{dt} = k_a(1-\theta)c_{sub} - k_d c_s \quad (-d_{sub} \leq y \leq 0), \tag{26}$$

$$\frac{dc_b}{dt} = D\left(\frac{\partial^2 c_b}{\partial x^2} + \frac{\partial^2 c_b}{\partial y^2}\right) \quad (y < -d_{sub}), \tag{27}$$

where c_s, c_{sub}, and c_b are the molar concentrations of S_s, S_{sub}, and S_b respectively; θ is the fraction of sites occupied by S_s; d_{sub}, the thickness of the subsurface layer, and D, the diffusion coefficient. c_s and θ in Eq. 26 are related by

$$c_s = \frac{10^3 \Gamma_{max}\theta}{d_s}, \tag{28}$$

where Γ_{max} is the maximum value of the surface excess, and d_s, the thickness of the surface layer. When the equilibrium is perturbed, θ, c_{sub}, and c_b are expressed in these forms:

$$\begin{aligned} \theta &= \bar{\theta} + \Delta\theta \exp\{i(\omega' t + \kappa x)\}, \\ c_{sub} &= \bar{c}_{sub} + \Delta c_{sub} \exp\{i(\omega' t + \kappa x)\}, \\ c_b &= \bar{c}_b + \Delta c_b \exp\{i(\omega' t + \kappa x)\}, \end{aligned} \tag{29}$$

where $\kappa(=2k)$ is the wave number of perturbed variables (see Appendix I). Using Eqs. 28 and 29, Eq. 26 is rewritten as

$$i\omega'\Delta\theta = -(k_{a,\theta}\bar{c}_{sub} + k_d)\Delta\theta + k_{a,\theta}(1-\bar{\theta})\Delta c_{sub}, \tag{30}$$

with

$$k_{a,\theta} = \frac{d_s}{10^3 \Gamma_{max}} k_a.$$

The solution of Eq. 27 is

$$\Delta c_b = E_b \exp(ny), \tag{31}$$

with

$$n = d_b^{-1}, \quad n^2 = \kappa^2 + \frac{i\omega'}{D},$$

where E_b is the constant, and d_b, the thickness of the bulk phase concerned with the diffusion process. From Eq. 31, Δc_{sub} becomes (see Appendix III):

$$\Delta c_{sub} = -n d_s \Delta c_s. \tag{32}$$

c_{sub} is expressed by the theory of an electric double layer[8] with the electric potential, ψ_{sub}, at $y=-d_{sub}$:

$$c_{sub} = c_0 \exp\left(-\frac{Ze\psi_{sub}}{k_B T}\right), \tag{33}$$

where c_0 is the initial concentration; Z, the valency; e, the elementary charge; k_B, the Boltzmann constant, and T, the temperature. Combining Eqs. 30, 32 and 33, the relaxation time is derived:

$$\tau^{-1} = \frac{k_{a,\theta}c_0 \exp\left(-\frac{Ze\psi_{sub}}{k_B T}\right) + k_d + k_a n_{re} d_s (1-\bar{\theta})}{1 + k_a n_{im} d_s (1-\bar{\theta})}, \tag{34}$$

with

$$n = n_{re} + i\omega' n_{im}.$$

The relaxation strength δ is derived from Eq. 10 as (see Appendix IV)

$$\delta = -\frac{\left(\frac{\partial\gamma}{\partial\xi}\right)_{s,S}\left(\frac{\partial A}{\partial s}\right)_{\xi,S}}{\left(\frac{\partial\gamma}{\partial s}\right)_{A,S}\left(\frac{\partial A}{\partial\xi}\right)_{s,S}}. \tag{35}$$

This equation is then rewritten by means of the Maxwell relationship:[11]

$$\delta = -\frac{(\Delta\gamma)^2}{(C_s^{-1})_{A,S}\left(\frac{\partial A}{\partial\xi}\right)_{s,S}}, \tag{36}$$

with

$$\Delta\gamma = \left(\frac{\partial\gamma}{\partial\xi}\right)_{s,S},$$

where $\Delta\gamma$ denotes the standard surface tension change. Meanwhile, the chemical affinity, A, is expressed by the chemical potential as follows:

$$A = -\mu_{sub} + \mu_s, \tag{37}$$

with

$$\begin{aligned} \mu_{sub} &= \mu_{sub}^{\ominus} + RT\ln c_{sub}, \\ \mu_s &= \mu_s^{\ominus} + RT\ln\Gamma, \end{aligned}$$

where μ_{sub} and μ_s are the chemical potentials of S_{sub} and S_s respectively; primsol indicates the standard

state, and Γ, the surface excess. The $(\partial A/\partial\xi)_{s,S}$ term in Eq. 35 is rewritten as follows:

$$\left(\frac{\partial A}{\partial \xi}\right)_{s,S}=\left(\frac{\partial A}{\partial \mu_s}\right)_{s,S}\left(\frac{\partial \mu_s}{\partial \Gamma}\right)_{s,S}\left(\frac{\partial \Gamma}{\partial \xi}\right)_{s,S} + \left(\frac{\partial A}{\partial \mu_{sub}}\right)_{s,S}\left(\frac{\partial \mu_{sub}}{\partial c_{sub}}\right)_{s,S}\left(\frac{\partial c_{sub}}{\partial \xi}\right)_{s,S}, \quad (38)$$

$d\xi$ being

$$d\xi = dn_{sub} = -d\Gamma, \quad (39)$$

where n_{sub} is the number of moles of S_{sub} per unit area. Meanwhile, c_{sub} and n_{sub} are related by the following relation:

$$Nn_{sub} = \left(\frac{c_{sub}N}{10^3}\right)^{2/3}, \quad (40)$$

The combination of Eq. 36—40 gives

$$\delta = \frac{(\Delta\gamma)^2}{RT(C_s^{-1})_{A,S}}\left\{\frac{3}{2}\times 10^2 N^{1/3}c_0^{-2/3}\exp\left(\frac{2Ze\psi_{sub}}{3k_BT}\right)+\Gamma^{-1}\right\}^{-1}. \quad (41)$$

$(C_s^{-1})_{A,S}$ in Eqs. 18 and 41 is obtained on the assumption that the adsorption-desorption process is in equilibrium; this is the same as the assumption that the molecular transfer between the surface and the bulk phase is governed by only the diffusion process.[4-6] Thus, the following equation is obtained:

$$(C_s^{-1})_{A,S} = \left(-\frac{\partial\gamma}{\partial \ln\Gamma}\right)\frac{1}{1-\frac{inD}{\omega'}\left(\frac{\partial c_0}{\partial\Gamma}\right)}. \quad (42)$$

According to this equation, Eq. 41 becomes

$$\delta = \frac{(\Delta\gamma)^2}{RT\left(-\frac{\partial\gamma}{\partial\ln\Gamma}\right)}\left\{\frac{3}{2}\times 10^2 N^{1/3}c_0^{-2/3} \times \exp\left(\frac{2Ze\psi_{sub}}{3k_BT}\right)+\Gamma^{-1}\right\}^{-1}. \quad (43)$$

On combining Eqs. 34, 43, and 18, ε_{ela} and ε_r are obtained. Therefore, the equations for the propagation characteristics of the wave for surfactant solutions are finally given as follows:

$$c^2 = \left(\frac{g}{k}+\frac{\gamma k}{\rho}\right)(1+2\varepsilon_{ela,re}+2\varepsilon_{r,re}), \quad (24)$$

$$\alpha = \frac{\sigma}{V}(\varepsilon_{ela,im}+\varepsilon_{r,im}), \quad (25)$$

with

$$\varepsilon_{ela} = \frac{\frac{2\nu k^2}{\rho}i+\frac{k^3}{2\rho\sigma^2}\left[\left(-\frac{\partial\gamma}{\partial\ln\Gamma}\right)\left\{1-\frac{inD}{\omega'}\left(\frac{\partial c_0}{\partial\Gamma}\right)\right\}^{-1}+i\eta_s\sigma\right]}{1-\frac{k^3(1+i)}{\rho\sigma^2}\left[\left(-\frac{\partial\gamma}{\partial\ln\Gamma}\right)\left\{1-\frac{inD}{\omega'}\left(\frac{\partial c_0}{\partial\Gamma}\right)\right\}^{-1}+i\eta_s\sigma\right]\left(\frac{2\nu k^2}{\sigma}\right)^{1/2}}, \quad (44)$$

and

$$\varepsilon_r = \frac{k^3}{2\rho\sigma^2}\left(-\frac{\partial\gamma}{\partial\ln\Gamma}\right)\left\{1-\frac{inD}{\omega'}\left(\frac{\partial c_0}{\partial\Gamma}\right)\right\}^{-1}\left(\frac{\omega'^2\tau^2\delta}{1+\omega'^2\tau^2}+\frac{i\omega'\tau\delta}{1+\omega'^2\tau^2}\right). \quad (45)$$

The relaxation parameters in these equations are given by Eqs. 34 and 43.

Discussion

This theory is applicable to the two-dimensional relaxation phenomena on the surface of a surfactant solution and the monolayer. The derived equations can be simplified easily by evaluating the magnitudes of the parameters.

For the surfactant solutions, the two cases of approximations are given as follows.

Relaxation Effect (or χ_r) is Negligibly Small. This is satisfied at $\omega'\tau\ll 1$. Equations 24 and 25 are simplified to

$$c^2 = \left(\frac{g}{k}+\frac{\gamma k}{\rho}\right)(1+2\varepsilon_{ela,re}), \quad (46)$$

$$\alpha = \frac{\sigma\varepsilon_{ela,im}}{V} \equiv \alpha_d. \quad (47)$$

ε_{ela} in these equations is given by Eq. 44. These equations result in those based on only the diffusion process.[4,6]

Relaxation Effect (or χ_r) is Relatively Large. In a dilute solution, c and α are given by Eqs. 24, 25, 34, 43, and 45. Since the relaxation time depends on the frequency, however, the application of the equations is troublesome. In case of the concentrated solution, the following equations are obtained (see Appendix V):

$$c^2 = \left(\frac{g}{k}+\frac{\gamma k}{\rho}\right)\left(1+2\varepsilon_{ela,re}+\frac{\gamma k}{\rho c^2}\frac{\omega'^2\tau^2\delta'}{1+\omega'^2\tau^2}\right), \quad (48)$$

$$\alpha = \alpha_d + \frac{\gamma k}{2V\rho c}\cdot\frac{\omega'\tau\delta'}{1+\omega'^2\tau^2}, \quad (49)$$

with

$$\tau^{-1} = k_{a,\theta}c_0\exp\left(-\frac{Ze\psi_{sub}}{k_BT}\right)+k_d,$$

and

$$\delta' = \frac{(C_s^{-1})_{A,S}}{\gamma}\delta = \frac{3(\Delta\gamma)^2c_0\exp\left(-\frac{2Ze\psi_{sub}}{3k_BT}\right)}{2\times 10^2 RT\gamma N^{1/3}},$$

where δ' is the apparent relaxation strength.

For an insoluble monolayer, the following two kinds of approximations are given.

Relaxation Effect (or χ_r) is Negligibly Small. Since the solubility of molecules is negligibly small, Eq. 44 is simplified:

$$\varepsilon_{ela} = \frac{\frac{2\nu k^2}{\sigma}i+\frac{k^3}{2\rho\sigma^2}\{(C_s^{-1})_{mo}+i\eta_s\sigma\}}{1-\frac{k^3(1+i)}{\rho\sigma^2}\{(C_s^{-1})_{mo}+i\eta_s\sigma\}\left(\frac{2\nu k^2}{\sigma}\right)^{1/2}}, \quad (50)$$

where $(C_s^{-1})_{mo}$ is obtained from the (surface pressure)-(molecular surface area) curve. Inserting Eq. 50 into Eqs. 46 and 47, Dorrestein's equations[1] can be obtained.

Relaxation Effect (or χ_r) is Relatively Large. The relaxation time in χ_r is derived by solving the rate equation related to the equilibrium on monolayer. The relaxation strength is also derived in the same manner as in the treatment for a surfactant solution. Then, ε_r is expressed by the concentration of species and the kinetic parameters connected with the equilibrium. Consequently, from Eq. 50 and the equation for ε_r, Eqs. 24 and 25 are represented in a concrete form.

In conclusion, the derived equations can be extensively applied, particularly to concentrated surfactant solutions, and can be expected to give kinetic parameters associated with the adsorption-desorption process of the surfactant. The experimental results of the propagation

characteristics of the wave on the surface of various surfactant solutions and the applicability of the equations obtained in the present study will be reported in a subsequent paper.

Appendix

I. The relative change in the surface area, β, is expressed by the following equation, in which the wave is represented by $a=a_0\sin(\omega t+kx)$:

$$\beta = \left(\frac{a_0 k}{2}\right)^2[1+\cos\{2(\omega t+kx)\}]$$
$$= \left(\frac{a_0 k}{2}\right)^2\{1+\cos(\omega' t+\kappa x)\},$$

where a_0 is the amplitude, and ω, the frequency of the wave. As is seen from this equation, the surface tends to expand at the nodes.

II. The thermal diffusion coefficient, D_T, in water is 1.4×10^{-3} cm^2 s^{-1}, while that in gas is of the order of 10^{-4} cm^2 s^{-1}. Under the present experimental conditions, the wavelength is about 9.8 mm at the lowest frequency (25 Hz) and 0.4 mm at the highest frequency (2 kHz).[9] Therefore, the $2\pi/kD_T \gg k/\omega$ condition is always satisfied; *i. e.*, the adiabatic approximation can be applied.

III. The thickness of the subsurface layer, d_{sub}, is much thinner than $d_b(=n^{-1})$. From Eq, 29, therefore, Δc_{sub} is approximated as

$$\Delta c_{sub} = E_b \exp(-nd_{sub}) \simeq E_b.$$

Moreover, the law of mass conservation is given as

$$d_s\Delta c_s = \int_{-d_{sub}}^{-\infty} E_b \exp(ny)\,dy \simeq -\frac{E_b}{n}.$$

The above equations lead to the relation between Δc_{sub} and Δc_s:

$$\Delta c_{sub} = -nd_s\Delta c_s.$$

IV. By eliminating $d\xi$ from Eqs. 9 and 10, $d\gamma$ becomes:

$$d\gamma = \left\{\left(\frac{\partial\gamma}{\partial s}\right)_{\xi,S} - \left(\frac{\partial\gamma}{\partial\xi}\right)_{s,S}\left(\frac{\partial A}{\partial s}\right)_{\xi,S}\left(\frac{\partial A}{\partial\xi}\right)_{s,S}^{-1}\right\}ds + \left(\frac{\partial\gamma}{\partial\xi}\right)_{s,S}\left(\frac{\partial A}{\partial\xi}\right)_{s,S}^{-1} dA.$$

Therefore

$$\left(\frac{\partial\gamma}{\partial s}\right)_{A,S} = \left(\frac{\partial\gamma}{\partial s}\right)_{\xi,S} - \left(\frac{\partial\gamma}{\partial\xi}\right)_{s,S}\left(\frac{\partial A}{\partial s}\right)_{\xi,S}\left(\frac{\partial A}{\partial\xi}\right)_{s,S}^{-1}.$$

δ is obtained from the above equation and Eq. 14:

$$\delta = -\frac{\left(\frac{\partial\gamma}{\partial\xi}\right)_{s,S}\left(\frac{\partial A}{\partial s}\right)_{\xi,S}}{\left(\frac{\partial\gamma}{\partial s}\right)_{A,S}\left(\frac{\partial A}{\partial s}\right)_{s,S}}.$$

V. If $c_0 > 10^{-3}$ mol dm^{-3}, $k_a < 10^6$ s^{-1}, $\theta > 0.95$, and $\phi_{sub} \approx 0$, Eq. 34 is simplified, with $\omega' \approx 10^3$ s^{-1}, $D \approx 10^{-6}$ cm^2 s^{-1}, $d_s \approx 10^{-7}$ cm and $\Gamma_{max} \approx 5\times 10^{-10}$ mol cm^{-2}:

$$\tau^{-1} = k_{a,\theta}c_0 \exp\left(-\frac{Ze\phi_{sub}}{k_B T}\right) + k_d.$$

The second term in the bracket in Eq. 43 is neglected compared with the first term:

$$\delta = \frac{3(\Delta\gamma)^2 c_0 \exp\left(-\frac{2Ze\phi_{sub}}{3k_B T}\right)}{2\times 10^2 RT(C_s^{-1})_{A,S}N^{1/3}}.$$

Notations

A;	chemical affinity.
a, a_0;	displacement and amplitude of wave respectively.
C_s;	surface compressibility (10^{-5} N/cm).
C_s*;	dynamic surface compressibility.
$(C_s^{-1})_{mo}$;	reciprocal surface compressibility for an insoluble monolayer.
c;	propagation velocity of the capillary wave.
c_b;	concentration of the surfactant solution in the bulk phase.
c_0;	initial concentration.
c_s, c_{sub};	concentrations of S_s and S_{sub} respectively.
D;	diffusion coefficient.
D_T;	thermal diffusion coefficient.
d_b;	thickness of the bulk phase concerned with the diffusion process.
d_s, d_{sub};	thicknesses of the surface and the subsurface layers respectively.
E_1, E_2;	complex constants associated with the amplitudes of Φ and Ψ respectively.
E_b;	amplitude of perturbed concentration in the bulk phase.
e;	elementary charge.
g;	gravitational acceleration.
k;	wave number.
k_a, k_d;	adsorption rate constant (s^{-1}) and desorption rate constant (s^{-1}) respectively.
$k_{a,\theta}$;	converted adsorption rate constant (mol^{-1} dm^3 s^{-1}).
k_B;	Boltzmann constant.
L;	proportional constant in the relaxation equation.
m;	complex constant.
N;	Avogadro number.
N_i, N_j';	numbers of moles of R_i and P_j species respectively.
n;	reciprocal of the thickness of the bulk phase concerned with the diffusion process.
n_{sub};	number of moles of S_{sub} per unit surface area.
p;	hydrostatic pressure.
P_j, R_i;	species in equilibrium.
R;	gas constant.
r;	complex angular frequency.
S;	surface entropy.
S_s, S_{sub}, S_b;	surfactants on surface, subsurface, and bulk phase respectively.
s;	surface area per unit area.
T;	temperature.
t;	time.
u, v;	horizontal and vertical components of liquid velocity respectively.
V;	$(3/2)c$, group velocity.
x, y;	Cartesian coordinate.
Z;	valency of surfactant.
α;	damping coefficient (cm^{-1}).
β;	relative change in the surface area.
Γ;	surface excess.
γ;	sulface tension (10^{-5} N cm^{-1}).
$\Delta\gamma$;	standard surface tension change.
δ;	relaxation strength.
ε_{ela}, ε_r;	dispersion terms of the angular frequency.
η;	viscosity (10^{-5} N s cm^{-2}).
η_s;	surface viscosity (10^{-5} N s cm^{-1}).
θ;	fraction of sites occupied by S_s.
κ;	$2k$, wave number.

μ_s, μ_{sub}; chemical potentials of S_s and S_{sub} respectively.
ν; η/ρ kinematic viscosity.
ν_i, ν_j' stoichiometric coefficients of R_i and R_j respectively.
ξ; ordering coefficient.
ρ; density.
σ; $(g/k+\gamma k^3/\rho)^{1/2}$, angular frequency of the wave.
$\tau_{s,s}$, $\tau_{r,s}$; relaxation times.
Φ, Ψ; stream and potential functions respectively.
ϕ; elevation of the surface.
χ^*; dimensionless parameter associated with the dynamic surface compressibility and the surface viscosity.
ψ_{sub}; electric potential at $y=-d_{sub}$.
ω, $\omega'(=2\omega)$; angular frequencies of the wave and the external driving force respectively.

Relaxation Studies of the Adsorption-Desorption Equilibrium of Surfactants on the Gas-Liquid Interface. II. Experimental Studies

Minoru SASAKI, Tatsuya YASUNAGA, and Nobuhide TATSUMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received November 9, 1976)

The propagation characteristics of the capillary wave were studied in aqueous solutions of sodium dodecyl sulfate, octylamine hydrochloride, and dodecylamine hydrochloride. In most of the solutions, relaxation was observed both in the propagation velocity and the damping coefficient; it could be well interpreted by means of the theory for the propagation characteristics derived in Part I.[1] The obtained relaxation parameters reveal the dynamic behavior of the adsorption-desorption of surfactants on the gas-liquid interface.

The dynamic physicochemical properties of the gas-liquid interface have been studied by many investigators[2-5] by means of the capillary wave method. Davies and Vose[2] have found relaxation on the surface of the surfactant solutions and have attributed it to the adsorption-desorption process of surfactants on the surface. However, questions still remain concerning the definition of the relaxation frequency and the rate equation.[6]

The purpose of the present investigation is to explore the validity of the theory[1] which supports to solve the above problems. Since the experimental values of the damping coefficient reported by Davies and Vose[2] were not precise enough to apply the theoretical equations, the experimental studies were newly carried out in the surfactant solutions.

Experimental

The apparatus used was a modification of that described by Davies and Vose;[2] the schematic diagram is shown in Fig. 1. The capillary wave was generated by a vibrator attached to a drive-unit of the trumpet speaker. The vibrator was made of Teflon, which has a weak affinity to all solutions. The flash of the stroboscope was synchronized with the signal of the oscillator, and the stationary image of focus was observed with a microscope. The propagation velocity and the damping coefficient were obtained as has been described in Brown's paper.[7] The frequency range of the apparatus was from 25 Hz to 4 kHz.

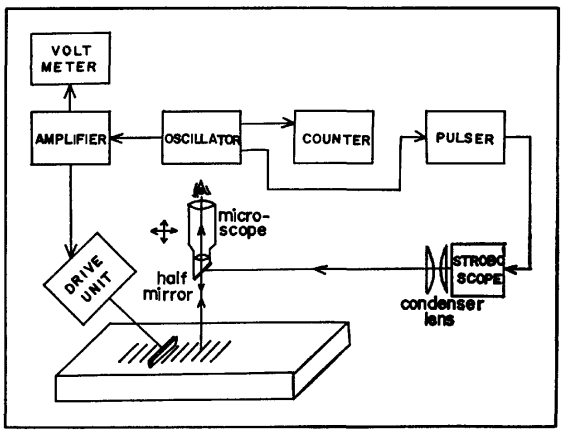

Fig. 1. Schematic diagram of the apparatus for measurements of the propagation characteristics of the capillary wave.

Sodium dodecyl sulfate (SDS) was prepared from Tokyo Kasei reagent-grade dodecyl alcohol (purity; 99.5%) according to the procedure of Dreger *et al.*[8] Octylamine hydrochloride (OAC) and dodecylamine hydrochloride (DAC) were prepared as follows. Octylamine and dodecylamine (Tokyo Kasei reagent-grade; Purities; 97.7 and 99.7% respectively) were neutralized by HCl in benzene solutions and were then recrystallized three times from benzene solutions and finally washed with petroleum ether. The values of the CMC were determined to be 8.3, 15.8, and 175 mM* for the SDS, DAC, and OAC solutions respectively by the electric conductivity method at 25 °C.

Results and Discussion

The propagation velocity, c, and the damping coefficient, α, of water were measured at various frequencies; they are shown in Figs. 2 and 3. The theoretical values

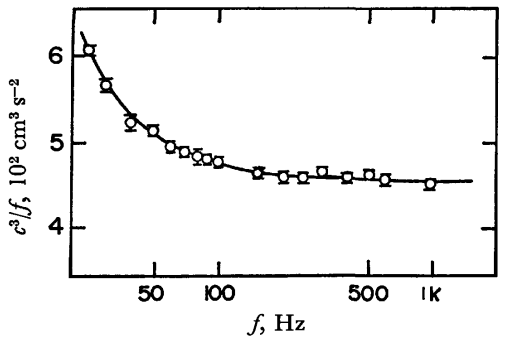

Fig. 2. The plots of c^3/f *vs.* f in water. The solid line shows the theoretical curve of c^3/f calculated by Eq. 1.

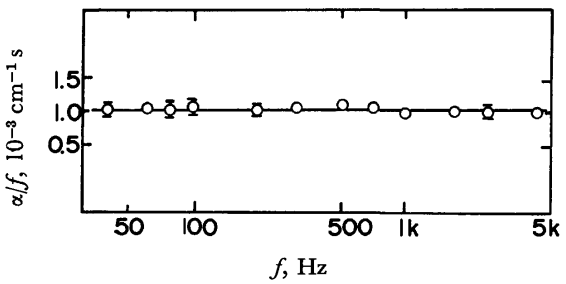

Fig. 3. The plots of α/f *vs.* f in water. The solid line shows the theoretical curve of α/f calculated by Eq. 2.

* Throughout this paper 1 M = 1 mol dm^{-3}.

of c and α were calculated by means of the following equations for a clean (fully mobile) surface,[2] using the literature values of ρ, ν, and γ:[9]

$$\frac{c^3}{f} = \frac{g\lambda^2}{2\pi} + \frac{2\pi\gamma}{\rho}, \tag{1}$$

$$\frac{\alpha}{f} = \frac{8\pi\rho\nu}{3\gamma}, \tag{2}$$

where f is the frequency, and λ, the wavenumber. The observed values of c^3/f and α/f fell on those curves within ± 0.7 and $\pm 4\%$ respectively in the frequency range studied. These facts confirm that the present apparatus can be applied to the measurements of c and α in the frequency range from 25 Hz to 4 kHz.

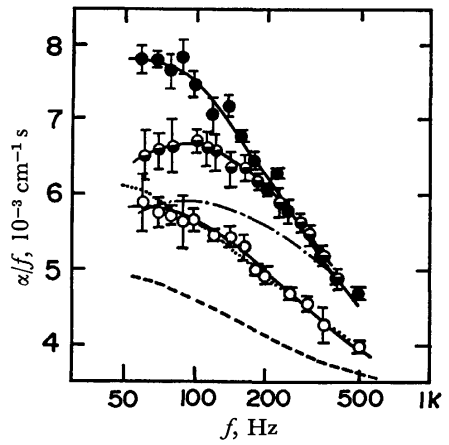

Fig. 4. The plots of α/f *vs.* f in SDS, DAC, and OAC solutions.
The theoretical curves of α_d/f are shown; ----: 8 mM SDS, ·····: 15 mM DAC, —·—: 121 mM OAC.
○: 8 mM SDS, ●: 15 mM DAC, ◒: 121 mM OAC.

The measurements were carried out on the surfaces of the SDS, DAC, and OAC solutions; the frequency depences of α/f are shown in Fig. 4. As seen from this figure, the experimental values of α/f are greater than the theoretical ones of α_d/f, where α_d refers to the damping coefficient based on only the diffusion process between the surface and the bulk phase. According to the theory presented in the previous paper,[1] the equations for the frequency dependences of c and α on the surface of relatively concentrated surfactant solutions are given by

$$c^2 = \left(\frac{g}{k} + \frac{\gamma k}{\rho}\right)\left(1 + 2\varepsilon_{\text{ela.re}} + \frac{\gamma k}{\rho c^2}\,\frac{\omega'^2\tau^2\delta'}{1+\omega'^2\tau^2}\right), \tag{3}$$

$$\frac{\alpha}{f} = \frac{\alpha_d}{f} + \frac{2\pi\gamma k}{3\rho c^3}\,\frac{\omega'\tau\delta'}{1+\omega'^2\tau^2}. \tag{4}$$

Equation 4 is, then, rearranged as follows:

$$\frac{3\rho c^3}{2\pi\gamma k}\left(\frac{\alpha}{f} - \frac{\alpha_d}{f}\right) = \frac{\omega'\tau\delta'}{1+\omega'^2\tau^2}. \tag{5}$$

The frequency dependences of the l. h. s. of this equation are shown in Fig. 5. This figure shows that the excess damping can be expressed by a single relaxation equation. The relaxation phenomena were also observed in all the other solutions except the 60 mM OAC solution, where the apparent relaxation strength was

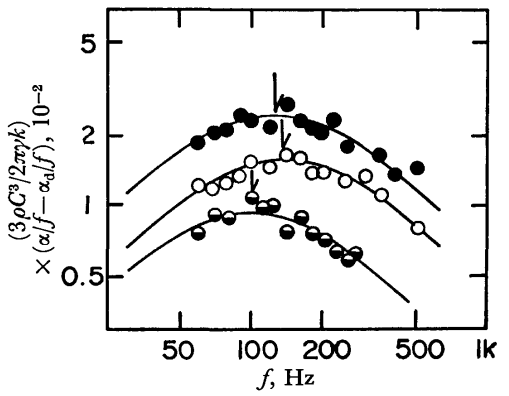

Fig. 5. The plots of $(3\rho c^3/2\pi\gamma k)\cdot(\alpha/f - \alpha_d/f)$ *vs.* f in SDS, DAC, and OAC solutions. The solid lines show the theoretical curves calculated by r. h. s. of Eq. 5 with the relaxation parameters listed in Table 1. The arrows show the relaxation frequency $f_r = (4\pi\tau)^{-1}$.

negligibly small. Nonlinear least-squares routines employing a computer were used to calculate the relaxation parameters; the values of τ and δ' obtained are listed in Table 1.

Table 1. Relaxation parameters in SDS, DAC, and OAC solutions at 25 °C

	CMC (mM)	c_0 (mM)	τ^{-1} (10^3 s^{-1})	δ' (10^{-2})
SDS	8.3	4	1.3±0.2	2.2±0.5
		6	1.6±0.2	2.7±0.3
		8	1.7±0.2	3.0±0.4
		10	1.8±0.2	2.2±0.3
DAC	15.8	5	1.0±0.2	1.0±0.6
		8	1.4±0.4	1.2±0.3
		10	1.6±0.3	2.2±0.2
		12	1.4±0.2	3.4±0.3
		15	1.6±0.3	5.0±0.4
		20	1.9±0.2	4.3±0.3
OAC	175	60	—	0
		80	0.8±0.2	1.5±0.4
		100	1.0±0.3	1.4±0.4
		121	1.3±0.1	1.8±0.5

The relaxation parameters can also be obtained from the frequency dispersion of c, which was expressed by the following equation with the assumption that $\gamma k/\rho \gg g/k$:

$$\frac{c^3}{f} - \frac{g\lambda^2}{2\pi} = \frac{2\pi\gamma}{\rho}\left(1 + 2\varepsilon_{\text{ela.re}} + \frac{\gamma k}{\rho c^2}\,\frac{\omega'^2\tau^2\delta'}{1+\omega'^2\tau^2}\right). \tag{6}$$

The theoretical curves in Fig. 6 were calculated by means of this equation, using the values of the relaxation parameters in Table 1. Unfortunately, the apparent relaxation strength was so small that the experimental results of the propagation velocity were not precise enough to give the relaxation parameters, only to refine the validity of those obtained from the damping coefficient.

If the observed relaxation phenomena are based on the adsorption-desorption process of the surfactants, the concentration dependence of the relaxation time is

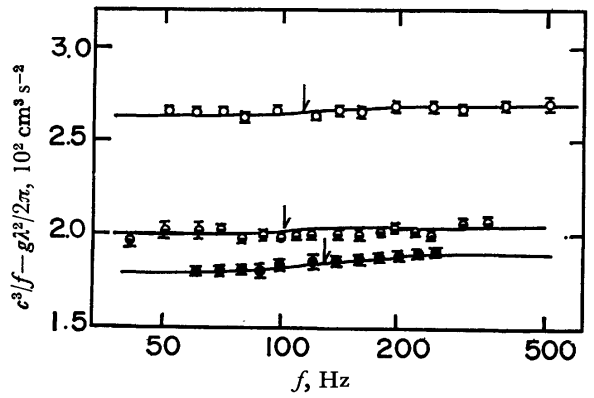

Fig. 6. The frequency dispersion of $(c^3/f-g\lambda^2/2\pi)$ in SDS, DAC, and OAC solutions. The solid lines show the theoretical curves calculated by Eq. 6 with the relaxation parameters listed in Table 1. The arrows show the relaxation frequency obtained from the experimental results of the damping coefficient.

expressed by[1]

$$\tau^{-1} = \frac{d_s k_a c_m \exp\left(-\frac{Ze\psi_{sub}}{k_B T}\right)}{10^3 \Gamma_{max}} + k_d, \qquad (7)$$

where c_m is the monomer concentration of the surfactants. In the concentrated surface concentration of ionic surfactants, most of the adsorbed surfactants are neutralized by the counter ions and the Stern layer is formed at the surface. Then, ψ_{sub} may be much smaller than k_BT/e. Under this condition, Eq. 7 is simplified to

$$\tau^{-1} = \frac{d_s k_a}{10^3 \Gamma_{max}} c_m + k_d = k_{a,\theta} c_m + k_d. \qquad (8)$$

The plots of τ^{-1} *vs.* c_m are on the straight lines, as is shown in Fig. 7. The linearity of these plots suggests that the relaxation phenomena are based on the adsorption-desorption process of the surfactants. The values of $k_{a,\theta}$ and k_d were calculated from the straight lines in Fig. 7; they are listed in Table 2. The values of k_a were calculated from $k_{a,\theta}$ with the literature values of d_s[10] and Γ_{max};[11] they are also listed in Table 2.

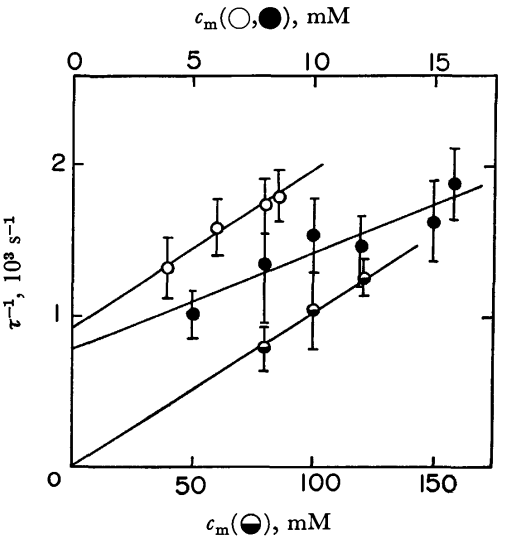

Fig. 7. The plots of τ^{-1} *vs.* c_m in SDS (○), DAC (●), and OAC (◒) solutions.

Table 2. KINETIC PARAMETERS IN SDS, DAC, AND OAC SOLUTIONS AT 25 °C

	$k_{a,\theta}$ (10^5 M^{-1} s^{-1})	k_a (10^5 s^{-1})	k_d (10^2 s^{-1})	ΔG ($-RT$)		$\Delta\gamma$ (10^{10} dyn·cm mol^{-1})[c]	
SDS	1.1±0.5	4±2	9±1	6.1[a]	6.8	10[b]	6
DAC	0.6±0.3	3±1	8±2	5.9[a]	6.3	8[b]	7
OAC	0.1±0.03	0.6±0.2	—	—		3[b]	7

a) The values were calculated by means of Szyszkowski's equation. b) The values were calculated by means of $\Delta\gamma \approx (\gamma_{water}-\gamma_{CMC})/\Gamma_{max}$. c) 1 dyn=$10^{-5}$ N.

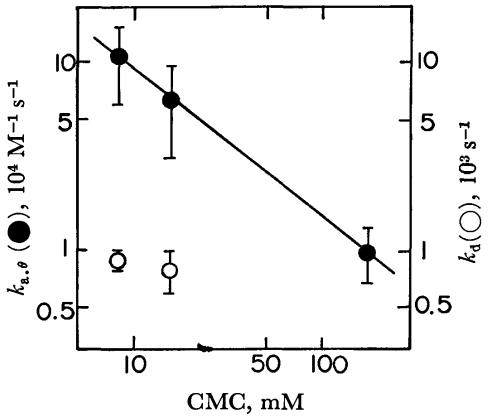

Fig. 8. The plots of $k_{a,\theta}$ (closed circles) and k_d (open circles) *vs.* CMC.

Among the values in Table 2, $k_{a,\theta}$ is fairly dependent on the CMC, but k_d is appreciably independent of the CMC, as is seen from Fig. 8. As a result, the following relation was obtained:

$$\log k_{a,\theta} = (3.4\pm0.3) - (0.8\pm0.3)\log \mathrm{CMC}. \qquad (9)$$

On the other hand, the values of k_d were evaluated as follows. Since the state of surfactants on an adsorbed layer is similar to that in a micelle in a surfactant solution, the desorption rate constant can be reasonably compared with the dissociation rate constant of the monomer from the micelle. In an SDS solution, the value of the former falls in the same order of magnitude as that of the latter, 7.5×10^2 s^{-1}, obtained by means of the pressure-jump method.[12] These facts support the idea that the adsorption-desorption mechanism proposed is reasonable.

The adsorption-desorption energies, ΔG, were calculated by means of k_a and k_d; $\Delta G=-RT\ln(k_a/k_d)$. They are listed in Table 2. The obtained values, however, cannot be referred to the literature ones by the static methods,[6] since the surface excess near the CMC increases appreciably with c_m. Then, the effective adsorption-desorption energy near the CMC was computed by means of Szyszkowski's equation; it is listed in Table 2. The values of ΔG obtained are in good agreement with the calculated ones. This also suggests that the proposed mechanism is reasonable.

The concentration dependences of the apparent relaxation strength obtained must also be interpreted by means of the following equation:[1]

$$\delta' = \frac{2(\Delta\gamma)^2 N^{-1/3} c_m^{2/3}}{3\times10^2 RT\gamma}. \qquad (10)$$

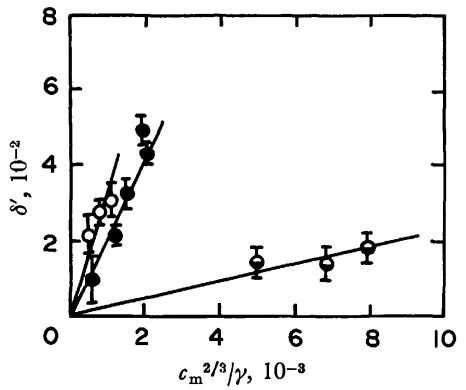

Fig. 9. The plots of δ' *vs.* $c_m^{2/3}/\gamma$ in SDS (○), DAC (●). and OAC (◒) solutions.

The plots of δ' *vs.* $c_m^{2/3}/\gamma$ are on the straight lines, as is shown in Fig. 9. The values of $\Delta\gamma$ calculated from the slopes of these straight lines are in good agreement with those of $\delta\gamma/\delta\Gamma \approx (\gamma_{water}-\gamma_{CMC})/\Gamma_{max}$ listed in Table 2, where γ_{water} and γ_{CMC} are the surface tensions in water and the surfactant solution at the CMC respectively.

A preliminary kinetic investigation of the adsorption-desorption on the surfaces of other surfactant solutions by means of the capillary-wave method has shown that similar relaxation phenomena exist in these systems. Further studies of these systems will lead to a quantitative clarification of the adsorption-desorption phenomena.

Crystal Field Levels of Neodymium and Erbium Ethylsulfate Nonahydrates

Yoshifumi KATO, Toshiyuki NAGAI, and Apollo SAIKA*

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

**Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606*

(Received December 8, 1976)

The energy levels of the Nd^{3+} ion in $Nd(C_2H_5SO_4)_3 \cdot 9H_2O$ and of the Er^{3+} ion in $Er(C_2H_5SO_4)_3 \cdot 9H_2O$ are calculated within the $4f^N$ configuration by the tensor operator method. The Hamiltonian containing a configuration interaction is diagonalized for the free ion levels and complete J-mixing is performed for the crystal field levels. The experimental "free-ion" energy levels of Nd^{3+} and Er^{3+} are fitted with a mean deviation of 70.8 cm^{-1} for 19 terms and 78.2 cm^{-1} for 22 terms, respectively. The crystal field parameters obtained for $Nd(C_2H_5SO_4)_3 \cdot 9H_2O$ and $Er(C_2H_5SO_4)_3 \cdot 9H_2O$ yield a mean deviation of 3.6 cm^{-1} for 43 levels and 3.6 cm^{-1} for 50 levels, respectively. The calculated Zeeman splitting factors (g values) in the direction along the crystal principal axis are in fair agreement with the experimental values.

It is well known that the crystal field theory provides a powerful tool for the energy level calculation of crystals containing rare earths, because the spin-orbit interaction of rare earths is not negligible as compared with the Coulomb or other interactions and f electrons in a crystal are generally well localized in an electrostatic field of the proper symmetry. On the reduction of the matrix elements of the Hamiltonian for rare earth crystals, the tensor operator method has been widely used instead of the early operator equivalent method, since the mathematical quantities necessary to apply the former method are now readily accessible in the form tabulated by Nielson and Koster.[1] Furthermore, the configuration interaction (CI) has a sizable effect on the energy levels of rare earths, and Rajnak[2] showed in the energy level calculation of trivalent neodymium and erbium ions that a least-squares fit by use of 4 or 5 parameters for CI reproduces the experimental "free-ion" levels with a deviation of about 50 cm^{-1}, which is less than half the deviation without CI.

Recently Crosswhite and Crosswhite[3] have carried out a crystal field calculation of Nd^{3+} doped in $LaCl_3$ by using as fully developed a Hamiltonian as appears feasible at the present time and by simultaneously diagonalizing the ion and crystal field parts of the Hamiltonian matrix. In their calculation, the experimental 101 crystal field levels have been fitted with a mean error of 8.1 cm^{-1} by using 24 adjustable parameters. Successively Carnall *et al.*[4] have made an energy level calculation of Pm^{3+} in the $LaCl_3$ host with similar accuracy to that by Crosswhite and Crosswhite.[3] In order to make such an extensive calculation, unambiguous experimental data must be available and the rare earths doped in $LaCl_3$ are probably the most adequate crystals among all the known salts. For these crystals, the absorption bands are sharp, there is very little evidence of superimposed crystal vibrations and furthermore strong fluorescences are observed in contrast with hydrated crystals.

For rare earth crystals which have been widely investigated, CI is expected to play a very important role in their electronic properties. However, previous energy level calculations for rare earth ethylsulfate crystals employ only partial J-mixing and no CI. In this paper crystal field level calculations of the neodymium and erbium ethylsulfate nonahydrates (Nd(ES) and Er(ES)) are carried out by simultaneously diagonalizing both the ion and crystal field parts of the Hamiltonian matrix with CI for the ion levels and complete J-mixing for the crystal field levels. Furthermore, the spectroscopic splitting factors (g factors) are evaluated from the wavefunctions obtained, and compared with the experimental values.

Calculational Procedure

Theoretical. The theoretical treatment for $4f^N$ configurations by use of the tensor operator method first introduced by Racah[5] and extended by Judd[6] is given in detail elsewhere.[7,8] Here the general procedure of calculations will be briefly outlined.

The $4f^N$ electronic states can be described satisfactorily in terms of intermediate coupling. Thus we may expand the wavefunction of a rare earth ion in crystals according to the Russell-Saunders coupling scheme to give

$$|\Psi\rangle = \sum_i a_i \psi_i |f^N, q, S, L, J, M\rangle, \quad (1)$$

where q is an additional quantum number introduced to distinguish the electronic states. The Hamiltonian for an ion placed in a crystal field may be written as

$$H = H_{coul} + H_{so} + H_{cry} + H', \quad (2)$$

where H_{coul}, H_{so}, and H_{cry} denote the Coulomb interaction between a pair of 4f electrons, the spin-orbit interaction and the potential due to the crystal field, respectively. The energy shift that gives the same contribution to all the levels belonging to a given configuration is neglected in the following treatment, because it does not affect the electronic structure of the configuration. The last term H' in Eq. 2 stands for an additional CI and may be taken as

$$\langle \Psi | H' | \Psi' \rangle = \delta(\Psi, \Psi')[\alpha L(L+1) + \beta G(G_2) + \gamma G(R_7)], \quad (3)$$

where α, β, and γ are linear combinations of radial integrals discussed by other authors[9,10] and are treated as parameters. Further minor CI parameters are not included in Eq. 3.

The matrix elements of the Hamiltonian in Eq. 2 can be reduced by the tensor operator method. Then the matrix element of the electrostatic interactions within the $4f^N$ configuration can be written as a linear combina-

tion of the Slater radial integrals F_n,

$$\langle f^N qSLJM|\sum_{i>j} e^2/r_{ij}|f^N q'SLJM\rangle = \sum_n p_n F_n(4f, 4f),$$
$$(n=2,\ 4,\ \text{and}\ 6), \quad (4)$$

where the coefficient p_n represents the angular part of the interaction. Similarly the matrix element of the spin-orbit interactions can be reduced to

$$\langle f^N qSLJM|\zeta_{4f}\sum_i (s_i\cdot l_i)|f^N q'S'L'J'M'\rangle$$
$$= \delta(J,J')\delta(M,M')2\sqrt{21}\zeta_{4f}(-1)^{J+L+S'} \times \begin{Bmatrix} L & L' & 1 \\ S' & S & J \end{Bmatrix} \langle f^N qSL\|V^{(11)}\|f^N q'S'L'\rangle, \quad (5)$$

where ζ_{4f} is the spin-orbit radial integral with respect to a 4f electron and $V^{(11)}$ is the double tensor defined by Racah.[5] The matrix elements of electrostatic interactions and those of spin-orbit interactions of the $4f^3$ configuration are already tabulated by Nielson and Koster,[1] and Judd and Loudon,[11] respectively. We need only to evaluate the matrix elements of the crystal field potential. This may also be expanded by the irreducible tensor operator $C_q^{(k)}$ as

$$H_{cry} = \sum_i \sum_{k,q} B_q^k (C_q^{(k)})_i, \quad (6)$$

in which the summation over i is for all the electrons and the coefficient B_q^k is the crystal field parameter. Then the matrix element of H_{cry} will be reduced to

$$\langle f^N qSLJM|H_{cry}|f^N q'S'L'J'M'\rangle$$
$$= \delta(S,S')\sum_{k,q} 7B_q^k(-1)^{2J+S+L'+k-M-1} \times [(2J+1)(2J'+1)]^{1/2} \begin{pmatrix} 3 & k & 3 \\ 0 & 0 & 0 \end{pmatrix} \times \begin{pmatrix} J & k & J' \\ -M & q & M' \end{pmatrix} \begin{Bmatrix} J & J' & k \\ L' & L & S \end{Bmatrix} \times \langle f^N qSL\|U^{(k)}\|f^N q'SL'\rangle, \quad (7)$$

in which the doubly reduced matrix elements of the unit tensor operator $U^{(k)}$ are given in the table of Nielson and Koster.[1]

Once the eigenvectors are determined by diagonalizing the Hamiltonian, we can obtain the z component of the g value as

$$g_z = \langle \Psi|\mu_z|\Psi\rangle = \sum_i a_i^2 M g_i(qSLJ), \quad (8)$$

where μ_z is the component of the magnetic dipole operator along the principal axis of a crystal and $g_i(qSLJ)$ denotes the Lande g factor for an ion level.

Application. The Nd^{3+} and Er^{3+} ions in ethylsulfates have $4f^3$ and $4f^{11}$ configurations, respectively. Since these two configurations are complementary to one another, the Er^{3+} ion has the same number and kind of states as the Nd^{3+} ion, for which there are 41 different $|JM\rangle$ states. According to the crystal structure of rare earth ethylsulfates determined by X-ray diffraction,[12] the space group is $P6_3/m$ (C_{6h}^2) and the local symmetry about a rare earth ion is D_{3h} as far as only the nearest-neighbor oxygen atoms of 9 crystalline waters are concerned.[13] The crystal field of the D_{3h} symmetry is expanded as

$$H_{cry} = B_0^2 C_0^{(2)} + B_0^4 C_0^{(4)} + B_0^6 C_0^{(6)} + B_6^6(C_6^{(6)} + C_{-6}^{(6)}). \quad (9)$$

Following Hellwege,[14] each ion level under this symmetry may be classified in three irreducible representations specified by the crystal quantum number η. As a result, the secular determinant for crystal levels can be reduced to two 60×60 matrices for $\eta=\pm 1/2$ and $\pm 5/2$ and one 62×62 matrix for $\eta=\pm 3/2$ by the usual group-theoretical procedure. Each crystal level has, of course, a twofold degenerate Kramers' pair.

After the subprograms for the 3-j and 6-j symbols were checked to agree with the tables already published,[15] the eigenvalue problem was solved by machine. With the parameters determined by Eisenstein[16] for the energy calculation of Nd^{3+} in $LaCl_3$ as a test run, our results reproduced those of Eisenstein with an accuracy of five significant figures. The actual determination of the parameters was made in the following manner. First, the Hamiltonian without H_{cry} in Eq. 2 was diagonalized to determine the intermediate coupling parameters (F_2, F_4, F_6, and ζ_{4f}) and the CI parameters (α, β, and γ) by fitting the calculated values to the centers of gravity of the experimental levels by an iterative procedure. Secondly, the diagonalization of the entire Hamiltonian with all the J-mixing was performed iteratively by adjusting the crystal field parameters (B_0^2, B_0^4, B_0^6, and B_6^6). Finally, a minor adjustment of all the parameters was made by a least-squares method. All the calculations were performed by the use of a FACOM 230-75 computer at Kyoto University.

Results and Discussion

The parameters used in the final calculation and the standard deviations are given in Tables 1 and 2 for Nd(ES) and Er(ES), respectively together with those obtained by others. Here, the root mean square (rms) deviation is defined as

$$\sigma = [\sum_i \Delta_i^2/N]^{1/2}, \quad (10)$$

in which Δ_i is the difference between the observed and

calculated values of the ith level and N is the number of levels. The calculated numerical results are presented in Tables 3 and 4 for Nd(ES) and Er(ES), respectively.

Nd(ES). Among the experimental energy levels of Nd(ES) reported by several authors,[17–19] we use the 19 electronic terms proposed by Gruber and Satten.[19] For the definitely assigned 9 electronic terms, the centers of gravity by Gruber and Satten differ within 6 cm^{-1} from those proposed by others. The discrepancy is smaller than the final rms deviation and should not have any significant effect on the final results. Since the calculated terms are not so sensitive to the variation of CI parameters, both α and β contain a considerable amount of error; especially γ is not determined because the electronic term (100)(10) ^2F affected strongly by γ has not been observed in Nd(ES). As can be seen in Table 1, while there exist only small differences between the intermediate coupling parameters by ours and those by Gruber and Satten, the rms deviation is considerably improved by the inclusion of the CI parameters α and β. A further improvement should be expected by introducing other higher-order interactions for CI and the increasing the number of levels available. For several crystal levels, both the assignments and splittings by Gruber and Satten[19] differ slightly from those by Dieke.[20] In the present calculation the 28 reliable crystal field levels for 9 electronic terms by Dieke[20] could be fitted with an rms deviation of 2.9 cm^{-1}, and the 43 levels containing ambiguous ones fitted with 3.6 cm^{-1}. The calculation by Gruber and Satten yielded an rms deviation of 7.7 cm^{-1} for 37 levels by first-order perturbation treatment with only partial J-mixing for the ground multiplet.[21] The crystal field parameters thus obtained are somewhat different from those of Gruber and Satten; especially for the B_0^2 parameter the difference exceeds 20 percent. This is due to their use of only the ground state multiplet levels for fitting.

From the eigenfunctions obtained, it became clear that through spin-orbit interactions $^2P_{3/2}$, $^2G_{7/2}$, and $^2G_{9/2}$ couple strongly with $^2D_{3/2}$, $^4G_{7/2}$, and $^4G_{9/2}$, respectively, whereas the strong coupling through J-mixing, in particular, occurs between the terms with $\Delta J=1$ and 6. Comparison of the calculated g values with the
