Reflection Spectra of 5-Methoxyindole-3-acetic Acid. In order to confirm the assignment of spectra of 5-hydroxyindole derivatives, the polarized reflection spectra were measured with a single crystal of 5-methoxyindole-3-acetic acid on its (100) plane. The crystalline structure was determined by Sakaki, Wakahara, Fujiwara, and Tomita.[21] Projection of the molecule on (100) plane is shown in Fig. 6. It is noted that the short molecular axis is nearly parallel to the crystalline c-axis while the long axis lies nearly perpendicular to this plane. The crystals used for spectral measurement were 0.8×2 mm×*ca.* 0.3 mm. The devel-

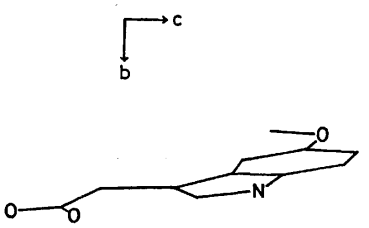

Fig. 6. Projection of 5-methoxyindole-3-acetic acid molecule onto the (100) plane of the crystal.

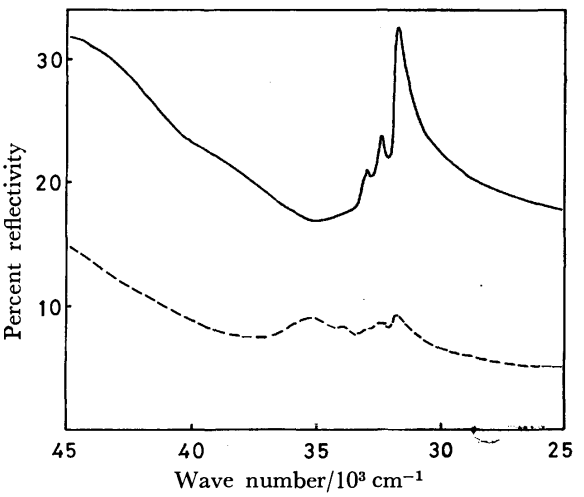

Fig. 7. Reflectivity of 5-methoxyindole-3-acetic acid crystal. Polarization of the light parallel to the b-axis (---) and the c-axis (——).

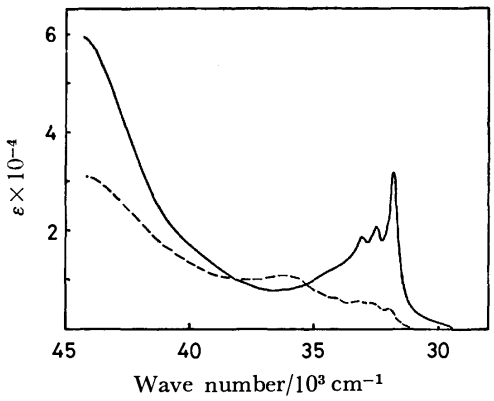

Fig. 8. Absorption spectra of 5-methoxyindole-3-acetic acid crystal obtained from Kramers-Kronig transformation. --- b-axis, —— c-axis.

oped plane was confirmed by X-ray photographs. The reflection spectra calibrated with SiC standard are shown in Fig. 7. The Kramers-Kronig transformation of reflectivity gives the absorption coefficient (Fig. 8).

The first band shows a vibronic structure at 31800, 32500, and 33100 cm^{-1}. Appearance of this structure peculiar to the first ^1L_b band has also been observed in the spectra of indole in the gaseous states.[22,23] The first absorption band shows a strong dichroism, strong along the c-axis. The direction of the transition moment obtained from the dichroic ratio confirms the calculated one shown in Fig. 4 and the band is thus assigned to the ^1L_b state. The second band observed at 36000 cm^{-1} is weak on this crystalline face, its dichroic ratio being $f_b/f_c=2$. The band is assigned to the ^1L_a band at 36000 cm^{-1} in solution spectra, its direction being consistent with that of the ^1L_a band deduced from theoretical calculation.

In their paper on indole derivatives, Yamamoto and Tanaka[24] estimated the directions of the transition moments of indole for ^1L_b and ^1L_a bands to make angles of 54 and −38°, respectively, to the long molecular axis. The present result confirms these assignments, *viz.*, although the present molecules have a hydroxyl or methoxyl substituent at C_5, the spectral features are very close to those of indole. Actually the calculated result on 5-hydroxyindole differs only by 9° rotation into anti-clockwise way from the result on indole by Yamamoto and Tanaka. Song and Kurtin[9] indicated that the transition moments of ^1L_b and ^1L_a states of indole are on the first and third quadrant and the second and fourth quadrant, respectively (Fig. 4). This is qualitatively in line with our result, but the directions are not in quantitative agreement with our assignment of indole and serotonin ^1L_b and ^1L_a bands.

As regards the oscillator strengths of ^1L_b and ^1L_a bands, whose relative intensity was discussed by Andrews and Forster,[11] the two bands overlap strongly but the whole band can be divided into two parts, *f*-values being estimated as 0.098 and 0.054 for ^1L_a and ^1L_b bands, respectively. From the crystalline spectra, the *f*-values for the ^1L_b band is estimated to be greater than 0.27, which is much greater than the value expected from the solution spectra (0.16), thus giving rise to a batho-chromic effect. The intensity ratio for $^1L_a/^1L_b$ bands is 1.8, whereas Andrews and Forster[11] estimated it to be 3—4 on indole and Yamamoto and Tanaka as 11. The effect of hydroxyl substituent is significant in enhancing the ^1L_b band.

The authors thank Mr. Tsutomu Kouyama, Physics Department, for his help in the fluorescence lifetime measurement and Dr. Tsuguhiro Kaneda of this laboratory for taking the X-ray photographs.

A Shock Tube Study of the Decomposition Mechanism of Chloroform in the Presence of Deuterium or Methane

Takayuki YANO

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received November 10, 1976)

Chloroform was pyrolyzed in the absence and in the presence of one of three additives—D_2, CH_4, and CD_4, over the temperature range of 1000—1200 K in a single-pulse shock tube. The main products of the decomposition of chloroform by itself were tetrachloroethylene and hydrogen chloride. On the other hand, tetrachloroethylene, trichloroethylene, dichloromethane, and hydrogen chloride were the major products in the presence of D_2, while in the chloroform–methane systems they were tetrachloroethylene, trichloroethylene, 1,1-dichloroethylene, vinyl chloride, ethane, and hydrogen chloride. From the deuterium distribution of the products, as determined by mass spectrometry, it is found that the hydrogen atoms of trichloroethylene and 1,1-dichloroethylene mainly came from chloroform and methane respectively, while the hydrogen atoms of vinyl chloride came from both chloroform and methane. The change in the product distribution resulting from the addition of deuterium or methane and the hydrogen isotopic distribution suggest that the mechanism is composed of Cl atom elimination in the initiation step and successive reactions involving "hot" molecule reactions. The hydrogen isotopic distribution of vinyl chloride may indicate that the three-centered hydrogen elimination ($\alpha\alpha$) process competes with the four-centered ($\alpha\beta$) process in the decomposition of "hot" 1,1-dichloroethane.

The decomposition of chloroform has been investigated by several authors. Among them, the studies of Semeluk and Bernstein[1] and Shilov and Sabirova[2] have been detailed. However, they came to different conclusions about the initiation process.

Semeluk and Bernstein[1] investigated the decomposition of chloroform at about 800 K by the flow method; they found that hydrogen chloride and tetrachloroethylene (C_2Cl_4) were the main products and that the decomposition rate was first-order with respect to chloroform. They proposed the radical chain mechanism to explain the main product distribution and the kinetics;

$$CHCl_3 \longrightarrow CHCl_2\cdot + Cl\cdot, \quad (1)$$

$$Cl\cdot + CHCl_3 \longrightarrow CCl_3\cdot + HCl, \quad (2)$$

$$CCl_3\cdot \longrightarrow CCl_2{:} + Cl\cdot, \quad (3)$$

$$CCl_3\cdot + Cl\cdot \longrightarrow CCl_4, \quad (4)$$

$$CCl_2{:} + CHCl_3 \longrightarrow C_2Cl_4 + HCl. \quad (5)$$

On the other hand, Shilov and Sabirova[2] studied the decomposition in a toluene carrier and found no bibenzyl. From their results, they proposed another mechanism;

$$CHCl_3 \longrightarrow CCl_2{:} + HCl, \quad (6)$$

$$CCl_2{:} + CHCl_3 \longrightarrow C_2Cl_4 + HCl. \quad (5)$$

It is desirable to investigate further the initiation step of the chloroform decomposition by the shock-tube technique, which enables us to neglect the surface reaction. Although the two mechanisms mentioned above produce the same main products and give similar kinetics of the first order, they produce different radicals in the initiation step. This provides a possible way to check both mechanisms. In order to detect the radicals formed in the initiation step, we pyrolyze chloroform in the presence of a relatively large amount of methane or hydrogen, whose decomposition itself can be neglected at the reaction temperatures. We found the change in the product distribution to result from the interaction between the radicals and the added gas molecule. Further, by the use of deuterated chloroform or deuterated additives, we also found the hydrogen isotopic distribution to be dependent upon the characteristics of the interaction.

Experimental

Apparatus. The decomposition was studied in a 4-cm-i.d. single-pulse shock tube. The design and operation of the shock tube were fully described previously.[3]

Materials and Procedure. Chloroform of a research grade was purified as follows. In order to purge the trace of ethanol involved as a stabilizer, we first shook unpurified chloroform with concd H_2SO_4 in a separatory funnel, washed it with water, dehydrated it, and distilled it. Finally, we distilled chloroform three times under a vacuum. Deuterated chloroform obtained from E. Merck Co. was also distilled three times under a vacuum. Methane (99.5% purity) and deuterium of a research grade (99.5 D atom %) and argon of an ultra-high purity (99.999% purity) were used without further purification. A considerable amount of oxygen was present in the methane-d_4 (99.5 D atom %) of the Matheson Co.; it was removed by passing it through a reduced copper column.[4] Experiments were carried out with the gas mixtures listed in Table 1.

TABLE 1. THE REACTANT MIXTURES AND THEIR COMPOSITIONS

Series No.	Components	Composition in mol%
I	$CHCl_3/Ar$	1.5/98.5
II	$CHCl_3/D_2/Ar$	1.5/4.8/93.7
IIIa	$CHCl_3/CH_4/Ar$	2.4/4.6/93.0, 1.1/4.4/94.5
IIIb	$CHCl_3/CD_4/Ar$	1.8/3.7/94.5, 2.0/4.0/94.0
IIIc	$CDCl_3/CH_4/Ar$	1.0/7.8/91.2, 1.0/3.1/95.9
		1.9/5.8/92.3, 1.0/2.2/96.8

The hydrocarbons and chlorinated hydrocarbons were separated and analyzed on a Yanaco G-80 gas chromatograph equipped with a temperature programer. The gas sample was separated on a 2-m-long Porapak Q column, with He as the carrier gas; the separated components were detected by means of thermal-conductivity and flame-ionization detectors. As occasion demanded, we determined each eluted component by mass spectrometry in order to confirm the identification of each peak of the gas chromatography.

After the separation of the product gas mixture into com-

ponents on a gas chromatograph, we analyzed the separated elutant by mass spectrometry in order to determine the hydrogen isotopic distribution. For the simplification of the mass spectrum, a low ionization voltage was employed. At an ionization voltage of about 10 eV, only the parent peak remained except for chloroform. In the case of chloroform, $CHCl_3$, the peak intensity of $CHCl_2^+$ was much stronger than that of $CHCl_3^+$, even at a low ionization voltage.

Results

The dwell time was practically constant (1 ms), and the total density behind the reflected shock waves was about $(2.4—3.9)\times10^{-5}$ mol/cm^3. The reaction temperature range was about 1000—1200 K. It was true in all the series that chlorinated ethylene and hydrogen chloride were the main products and that the chlorinated ethane was not present or, occasionally, present in a very small amount.[5] When one of the reactants was deuterated, the hydrogen isotopic isomers of chloroform were analyzed by mass spectrometry after the shock heating. It was thus confirmed that the isomer of chloroform converted by H/D exchange reaction was negligibly small. The experimental results for each series are described below.

Series I. Tetrachloroethylene and hydrogen chloride were produced predominantly. The hydrogen chloride was not quantitatively analyzed, since an exact determination of the yield is difficult because of the surface reactions. As the minor products, four species were found; trichloroethylene, dichloromethane, 1,1,2,2-tetrachloroethane, and an unidentified species. The characteristics of the product distribution were consistent with those reported of Semeluk and Bernstein.[1] Table 2 shows the yields of C_2Cl_4 and C_2HCl_3, together with the conversion of chloroform.

Series II. When deuterium was added, much more species were produced than those obtained from the decomposition of chloroform alone. Fifteen species involving unidentified peaks were detected. Trichloroethylene, which has been a minor product in Series I, here appeared as the main product. Tetrachloroethylene, dichloromethane, 1,1-dichloroethylene, vinyl chloride, and chloroacetylene were identified, while as trace species methane, ethylene, ethyl chloride, and 1,1,-2,2-tetrachloroethane were detected. The yields of the principal products are plotted against the chloroform conversion in Fig. 1.

As is shown in Fig. 1, trichloroethylene, C_2Cl_4, and dichloromethane increase linearly with the increase in the conversion at relatively low conversions, but they show their maximum at higher conversions. On the other hand, 1,1-dichloroethylene, vinyl chloride, and chloroacetylene were hardly detected at all at low conversions; they increased remarkably at high conversions.

The deuterium content of trichloroethylene is shown in Table 3. It should be noted that the yield of C_2HCl_3 is much greater than that of C_2DCl_3 over a wide conversion range.

Series III. Many species (13 species) were observed, as in the case of Series II. The principal products of the Series IIIa were 1,1-$C_2H_2Cl_2$, C_2H_3Cl, C_2H_6, C_2H_4, C_2HCl_3, and C_2Cl_4. Their yields, except for that of C_2Cl_4, are plotted against the chloroform conversion in Fig. 2 (C_2Cl_4 was not determined by gas

Table 3. Hydrogen isotopic distribution of trichloroethylene for series II

C_2HCl_3[a]	C_2DCl_3[a]	Chloroform conversion[a]
91.8	8.2	23.0
87.8	12.2	43.6
78.0	22.0	67.7
72.2	27.8	72.6

a) These values are expressed in percentages.

chromatography, but the mass spectra showed the yield of C_2Cl_4 was comparable with that of C_2HCl_3). The product distributions of Series IIIb and IIIc were similar to that of Series IIIa.

The main hydrogen isotopic isomers of each product for Series IIIb and IIIc are shown in Table 4. When the conversion of chloroform is smaller than 50%, 1,1-dichloroethylene and trichloroethylene almost always consist of only one hydrogen isotopic isomer; the other isomers form less than one tenth of the main isomer. Vinyl chloride consists of two hydrogen isotopic isomers of comparable amounts.

In Table 4, if we replace the H and D atoms of Series IIIc by D and H atoms respectively, we obtain the distributions of the isotopic isomers of Series IIIb. The hydrogen of trichloroethylene came mainly from the reactant chloroform. On the contrary, the hydrogens of 1,1-dichloroethylene came from the reactant methane. The hydrogens of vinyl chloride, like 1,1-dichloroethylene, were supplied mainly by the methane, but partly by the chloroform.

Figure 3 shows the hydrogen isotopic distribution of vinyl chloride, which is dependent upon the temperature for Series IIIb and IIIc. The ratios of $[CHCl=CD_2]/[CDCl=CD_2]$ and $[CDCl=CH_2]/[CHCl=CH_2]$ for Series IIIb and IIIc respectively are plotted against the temperature. In the following discussion, it will be shown that they are equal to the ratio of the rate of the $\alpha\beta$ process to that of the $\alpha\alpha$ process in the decomposition of "hot" 1,1-dichloroethane. The $R_{\alpha\beta}/R_{\alpha\alpha}$ ratio decreases with an increase in both the temperature and the [methane]/[chloroform] ratio. There is no detectable isotope effect in the IIIb and IIIc series.

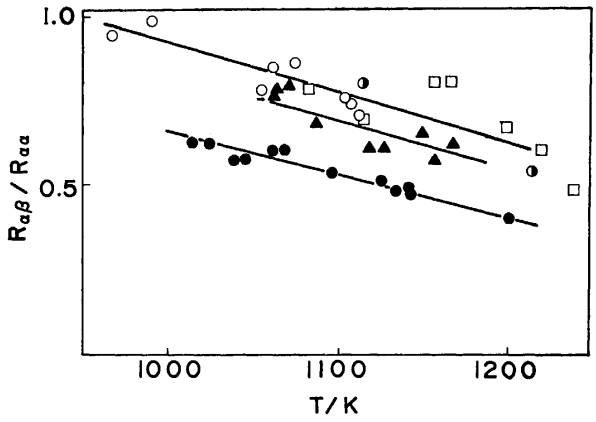

Fig. 3. Dependence of $R_{\alpha\beta}/R_{\alpha\alpha}$ on temperature and concentration ratio of r=[methane]/[chloroform] for series IIIb and IIIc. The ratio of $R_{\alpha\beta}/R_{\alpha\alpha}$ is equal to $[CHCl=CD_2]/[CDCl=CD_2]$ and $[CDCl=CH_2]/[CHCl=CH_2]$ for IIIb and IIIc, respectively.

TABLE 4. MAIN HYDROGEN ISOTOPIC ISOMERS OF CHLORINATED ETHYLENE FOR SERIES III

Species	Series IIIb	Series IIIc
Dichloroethylene	$C_2D_2Cl_2$	$C_2H_2Cl_2$
Vinyl chloride	C_2D_3Cl, C_2HD_2Cl	C_2H_3Cl, C_2H_2DCl
Trichloroethylene	a)	C_2DCl_3

a) This was not determined by mass spectrometry, but it may be C_2HCl_3 in view of the results of Series II and IIIc.

Discussion

The product distribution was changed drastically by the addition of methane or hydrogen. One of the characteristic changes is the decrease in C_2Cl_4; another is the increase in trichloroethylene.

In the case of D_2 addition, trichloroethylene, C_2Cl_4, and dichloromethane are supposed to be the primary products, because, in Fig. 1, their yields are linear to the conversion[6] at a low conversion. In the case of methane addition, ethane, vinyl chloride, 1,1-dichloroethylene, trichloroethylene, and C_2Cl_4 are probably the primary products, while ethylene is a secondary product, as may be seen from Fig. 2, although their plots are somewhat scattered.

The change in the product distribution can be readily explained by the Cl atom elimination, proposed by Semeluk and Bernstein,[1] from the chloroform molecule in the initiation step. In the case of D_2 addition, the Cl atom formed by Step 1 may abstract the D atom from the D_2 present in a large amount; then DCl and the D atom are produced;

$$Cl\cdot + D_2 \longrightarrow DCl + D\cdot \quad (7)$$

The D atom produced in Reaction 7 then further reacts with chloroform;

$$D\cdot + CHCl_3 \longrightarrow CHCl_2\cdot + DCl \quad (8)$$

Since there is a competitive relation between Reactions

7 and 2, Reaction 7 retards the radical-chain reaction to yield C_2Cl_4. On the other hand, because of the participation of Reaction 8, the formation rate of the $CHCl_2$ radical is increased. The "hot" molecule of 1,1,2,2-tetrachloroethane may be produced *via* the combination reaction of the $CHCl_2$ radical;

$$2CHCl_2\cdot \longrightarrow CHCl_2CHCl_2^* . \quad (9)$$

The "hot" molecule is stabilized by collisions or decomposes to an ethylene-type molecule and hydrogen chloride *via* a unimolecular reaction;

$$CHCl_2CHCl_2^* \xrightarrow{+M} CHCl_2CHCl_2, \quad (10)$$

$$\longrightarrow C_2HCl_3 + HCl. \quad (11)$$

The fact that hardly no 1,1,2,2-tetrachloroethane is found may show that the "hot" molecule prefers the decomposition to the stabilization under our experimental conditions. Dichloromethane as a primary product may be formed *via* a hydrogen-abstraction reaction of the $CHCl_2$ radical;

$$CHCl_2\cdot + D_2 \longrightarrow CHDCl_2 + D\cdot. \quad (12)$$

The production of C_2Cl_4 can be explained by the partly surviving chain reaction proposed by Semeluk and Bernstein.[1] It is apparent that the trichloroethylene produced through Reactions 9 and 11 has the same hydrogen isomer as the reactant chloroform.

On the other hand, the assumption by Shilov and Sabirova[2] that the CCl_2 radical is formed in the initiation step is not reasonable. In explaining the formation of trichloroethylene, the following plausible reactions are assumed on the basis of analogy with the CH_2 radical;

$$CCl_2: + D_2 \longrightarrow CDCl_2\cdot + D\cdot, \quad (13)$$

$$D\cdot + CHCl_3 \longrightarrow CHCl_2\cdot + DCl . \quad (8)$$

The decrease in the formation rate of C_2Cl_4 can be explained by the competition between Reactions 5 and 13. However, the yields of C_2HCl_3 and C_2DCl_3 which are produced from "hot" tetrachloroethanes would then be equal, since the formation rates of the $CHCl_2$ and $CDCl_2$ radicals are supposed to be equal. This expectation is not consistent with the experimental result; that is ,the formation of the CCl_2 radical in the primary step is doubtful. The increase in the composition of C_2DCl_3 with the increase in the conversion (Table 3) may be the result of some secondary reactions.[7]

In the case of the methane addition, in the IIIc series for example, the Cl atom elimination reaction also agrees with the experimental results. The following reactions may give C_1 radicals;

$$CDCl_3 \longrightarrow CDCl_2\cdot + Cl\cdot, \quad (1)$$

$$Cl\cdot + CH_4 \longrightarrow CH_3\cdot + HCl , \quad (14)$$

$$Cl\cdot + CDCl_3 \longrightarrow CCl_3\cdot + DCl. \quad (2)$$

The "hot" ethane-type molecules are formed *via* the association of these C_1 radicals. These "hot" chlorinated ethanes decompose to ethylene-type molecules and hydrogen chloride. Ethane and C_2Cl_6 are only be stabilized by collisions;

$$2CDCl_2\cdot \longrightarrow CDCl_2CDCl_2^* \longrightarrow C_2DCl_3 + DCl, \quad (11)$$

$$CDCl_2\cdot + CH_3\cdot \longrightarrow CDCl_2CH_3^* ,$$

$$\xrightarrow{\alpha\beta} CDCl{=}CH_2 + HCl , \quad (15)$$

$$\xrightarrow{\alpha\alpha} CHCl{=}CH_2 + DCl , \quad (16)$$

$$CDCl_2\cdot + CCl_3\cdot \longrightarrow$$

$$CDCl_2CCl_3^* \longrightarrow C_2Cl_4 + DCl , \quad (17)$$

$$CH_3\cdot + CCl_3\cdot \longrightarrow$$

$$CH_3CCl_3^* \longrightarrow CH_2{=}CCl_2 + HCl , \quad (18)$$

$$2CH_3\cdot \longrightarrow C_2H_6^* \xrightarrow{+M} C_2H_6 , \quad (19)$$

$$2CCl_3\cdot \longrightarrow C_2Cl_6^* \xrightarrow{+M} C_2Cl_6 , \quad (20)$$

All the products formed by Reactions 11 and 15—20 except C_2Cl_6 were identified as the primary products. The partly surviving chain mechanism as well as Reaction 17 may be responsible for the formation of C_2Cl_4, as in the case of D_2 addition.

The hydrogen isotopic distributions of trichloroethylene and 1,1-dichloroethylene through Reactions 11 and 18 are in good agreement with the experimental results. The assumption that the "hot" $CDCl_2CH_3$ molecule decomposes not only through the $\alpha\beta$ process but also through the $\alpha\alpha$ process can well explain the isotope distribution of vinyl chloride. It is well known that the haloethane eliminates hydrogen chloride *via* the $\alpha\beta$ process. Recently, however, Perona *et al.*[8] found the $\alpha\alpha$ process in the chemical activation study of the "hot" CHF_2CD_3, and its occurrence has lately been confirmed by Kim *et al.*[9] Moreover, Perona *et al.*[8] suggested that the $\alpha\alpha$ process was competitive with the $\alpha\beta$ process only when two halogen atoms are attached to the same carbon atom. It was also found from the studies of "hot" 1,1,2-trichloroethane-1-d_1[10] that the $\alpha\alpha$ process competed with the $\alpha\beta$ process. Therefore, the fact that the vinyl chloride consists of two hydrogen isotopic isomers may be evidence in support of the proposal by Perona *et al.*[8] Figure 3 indicates that the rate ratio of $R_{\alpha\beta}/R_{\alpha\alpha}$ decreases with the increase in the temperature; behavior like this has already been described by Perona *et al.*[8] and Kim *et al.*[9] This temperature dependence can be qualitatively explained by the RRK theory.[8,11] The $R_{\alpha\beta}/R_{\alpha\alpha}$ ratio is expressed by the following equation;

$$R_{\alpha\beta}/R_{\alpha\alpha} = A_{\alpha\beta}(1-E^*_{\alpha\beta}/E)^{n-1}\{A_{\alpha\alpha}(1-E^*_{\alpha\alpha}/E)^{n-1}\}^{-1}.$$

The number of effective oscillators, n, is assumed to be the same for both eliminations, and a value of $n=12$ has been adopted.[11] The internal energy, E, was taken to vary between 85.4 kcal/mol at 298 K and 109.6 kcal/mol[12] at 1200 K. The temperature dependence is ascertained by the choice of $E^*_{\alpha\beta}=52$ kcal/mol[13] and $E^*_{\alpha\alpha}=62$ kcal/mol. The difference in the critical energies ($E^*_{\alpha\alpha}-E^*_{\alpha\beta}$) is similar to that obtained by Perona *et al.*,[8] but is somewhat larger than that for "hot" 1,1,2-trichloroethane-1-d_1.[10] A more exact study will be necessary for a quantitative discussion.

In conclusion, in the case of methane addition, the product distribution and hydrogen isotopic distributions support the Cl atom elimination in the initiation step. On the contrary, the assumption that the CCl_2 radical is formed in the initiation step does not agree

with the experimental results. If the following reactions were possible;

$$CCl_2: + CH_4 \longrightarrow CHCl_2\cdot + CH_3\cdot, \quad (21)$$

$$CCl_2: + CDCl_3 \longrightarrow CDCl_2\cdot + CCl_3\cdot, \quad (22)$$

the formation rate of C_2HCl_3 would be larger than that of C_2DCl_3, because Reaction 21 must be predominant over the Reaction 22 in the presence of excess methane. Vinyl chloride would be produced by the following reactions;

$$CHCl_2\cdot + CH_3\cdot \longrightarrow CHCl_2CH_3^* \longrightarrow CHCl{=}CH_2 + HCl, \quad (15')$$

$$CDCl_2\cdot + CH_3\cdot \longrightarrow CDCl_2CH_3^* \xrightarrow{\alpha\beta} CDCl{=}CH_2 + HCl, \quad (15)$$

$$\xrightarrow{\alpha\alpha} CHCl{=}CH_2 + DCl. \quad (16)$$

Reaction 15′ might be predominant over the others, and the yield of $CDCl{=}CH_2$ would be considerably small. These expectations are actually not in agreement with the experimental results. Further, the possibility of the insertion reaction of CCl_2 into C–H or a C–Cl bond and the successive elimination of hydrogen chloride may be considered. However, these reactions can not satisfactorily explain the variety of the products and the hydrogen isotopic distributions.

The reaction scheme based on the Cl atom elimination in the initiation step can well account for the variety of the products and their isotopic distributions. The scheme can not, however, explain the relative yields of the products without any modification. For the case of methane addition, 1,1-dichloroethylene was the main product, as is shown in Fig. 2. This can not be derived from the scheme. Under the experimental conditions, the formation rates of the C_1 radicals of $CDCl_2$, CH_3, and CCl_3 decrease in that order.[14] Therefore, the [vinyl chloride]>[1,1-dichloroethylene] relation might be expected. Perhaps this apparent contradiction can be solved by the assumption that there is another path to produced 1,1-dichloroethylene in addition to Reaction 18.

In the study of the chemical activation of CHF_2CD_3, Perona *et al.*[8] found the yield of $CF_2{=}CD_2$ to be about 1/2—1/10 of that of vinyl fluoride. They supposed a third unimolecular reaction path of "hot" CHF_2CD_3;

$$CHF_2CD_3^* \longrightarrow CF_2{=}CD_2 + HD. \quad (23)$$

Kim *et al.*[9] also found $CF_2{=}CD_2$ in a similar reaction system and confirmed the unimolecular pressure dependence of the yield. Although they did not agree with the third unimolecular path because of its unusual nature, they could not find out any evidence denying it. Perona *et al.*[8] thought that Process 23 had a larger critical energy than those of the $\alpha\beta$ and $\alpha\alpha$ processes. The importance of the third path may, then, become greater at higher temperatures. The following reaction is assumed by analogy with Reaction 23;

$$CDCl_2CH_3^* \longrightarrow CCl_2{=}CH_2 + HD. \quad (24)$$

Since Reaction 24 competes with the $\alpha\beta$ and the $\alpha\alpha$ processes, the formation rate of vinyl chloride decreases and that of 1,1-dichloroethylene increases.

Let us examine other possible paths yielding 1,1-dichloroethylene. Tschuikow-Roux *et al.*[15] found $CF_2{=}CH_2$ besides the main product $CHF{=}CH_2$ in their shock tube study of CHF_2CH_3. They suggested the following reactions for the formation of $CF_2{=}CH_2$;

$$CH_3\cdot + CH_3CHF_2 \longrightarrow CH_3CF_2\cdot + CH_4, \quad (25)$$

$$2CH_3CF_2\cdot \longrightarrow CF_2{=}CH_2 + CH_3CHF_2. \quad (26)$$

In the present case, 1,1-dichloroethylene may be produced by the following reactions analogous to Reactions 25 and 26;

$$CDCl_2\cdot \text{ (or } CH_3\cdot) + CH_3CDCl_2 \longrightarrow CH_3CCl_2\cdot + CD_2Cl_2 \text{ (or } CH_3D), \quad (27)$$

$$2CH_3CCl_2\cdot \longrightarrow CH_2{=}CCl_2 + CH_3CHCl_2. \quad (28)$$

In the present experiment, however, neither dichloroethane nor dichloromethane was found in the products. This indicates that Reactions 27 and 28 are not important for the formation of dichloroethylene. Next, let us consider the disproportionation of the $CDCl_2$ radical;

$$2CDCl_2\cdot \longrightarrow CD_2Cl_2 + CCl_2:, \quad (29)$$

$$CCl_2: + CH_3\cdot \longrightarrow CH_3CCl_2\cdot^* \longrightarrow CH_2{=}CCl_2 + H\cdot. \quad (30)$$

These reactions would produce a considerable amount of dichloromethane, which also is not compatible with the above observation. Therefore, it may be concluded that Reaction 24 is the most probable process for yielding dichloroethylene.

The author would like to express his grateful acknowledgments to Professor Kenji Kuratani, the University of Tokyo, for his encouragement and kind discussion throughout the work.

5) All the chlorinated ethanes except the penta- and hexa-substituted ones were analyzed; only 1,1,2,2-tetrachloroethane was found in Series I, while 1,1,2,2-tetrachloroethane and ethyl chloride were found in Series II.

6) As can be seen from Figs. 1 and 2, the ratios among the main-product yields show little change in the range of conversion below 50%. This suggests that the same reaction mechanism is operative. When the conversions are reduced to the reaction temperatures, a wide conversion range corresponds to a very narrow temperature range, for example, a 20% conversion to less than 50 K. A change in mechanism is not likely to occur in this narrow temperature range. Therefore, the conversion may be regarded as the extent of the reaction in such a narrow temperature range.

7) In the case of the II series, dichloromethane is produced, but it seems to disappear at higher temperatures (Fig. 1). Therefore, the following secondary reactions may be supposed;

$$CHDCl_2 + \text{radical}(R\cdot) \text{ or } \text{atom}(X\cdot) \longrightarrow CDCl_2\cdot + RH \text{ or } XH,$$

$$CDCl_2\cdot + CHCl_2\cdot \longrightarrow CDCl_2CHCl_2^* \longrightarrow C_2DCl_3 + HCl.$$

11) S. W. Benson and G. Haugen, *J. Phys. Chem.*, **69**, 3898 (1965).

12) The change in the internal energy with the temperature was calculated from $C_v^{vib}(T-298)=3R(T-298)+[C_v^{vib}, CDCl_2(T)+C_v^{vib}, CH_3(T)]T-[C_v^{vib}, CDCl_2(298)+C_v^{vib}, CH_3(298)]298$. The same value of C_v^{vib} was assumed for $CDCl_2$ and $CHCl_2$. The vibrational contributions to the heat capacities of $CHCl_2$ and CH_3 were estimated from the heat capacities of CH_2Cl_2 and CH_3 respectively.

13) J. C. Hassler and D. W. Setser, *J. Chem. Phys.*, **45**, 3246 (1966).

14) In order to explain the greatest yield of 1,1-dichloroethylene, the change in the C_1 radical distribution due to the following hydrogen metathesis reactions are considered;

$$CDCl_2\cdot + CH_4 \longrightarrow CH_3\cdot + CHDCl_2,$$

$$CDCl_2\cdot + CDCl_3 \longrightarrow CCl_3\cdot + CD_2Cl_2.$$

However, the contributions of these reactions can be neglected for two reasons. The first is that there is no detectable amount of dichloromethane. The second is the kinetic one. Assuming the steady-state and the same recombination rate constants of the C_1 radicals, the steady-state rate is concluded to be considerably faster than that of the transformation among C_1 radicals. Thus, the disturbance of the C_1 radical distribution due to the above reactions is insignificant.

The Application of the Spin Trap, Phenyl *t*-Butyl Nitrone, to the Study of the γ-Radiolysis of Cyclohexane

Haruo IWAHASHI, Yo-ichi ISHIKAWA, Shin SATO, and Kinko KOYANO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

**Institute of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153*

(Received November 11, 1976)

It was shown that cyclohexyl radicals formed by the γ-radiolysis of cyclohexane were trapped by phenyl *t*-butyl nitrone (PBN) to give a nitroxide with a well defined ESR spectrum. We measured the yield of this nitroxide. In order to establish the radical and electron scavenging properties of PBN, we measured the effect of this compound on the yields of hydrogen and nitrogen by adding dinitrogen oxide in cyclohexane together with PBN. The results suggested that PBN is able to scavenge not only free radicals but also electrons. The following relative rates were obtained: $k(e^- + PBN \rightarrow PBN^-)/k(e^- + N_2O \rightarrow N_2O^-) = 0.7$ and $k(H + PBN \rightarrow HPBN)/k(H + C_6H_{12} \rightarrow H_2 + C_6H_{11}) \approx 200$ at room temperature. The *G*-value of the scavengeable hydrogen atoms from cyclohexane was estimated to be 3.4 ± 0.4.

The spin trapping technique has been applied to detect the short-lived free-radicals produced in various chemical reactions.[1] Since Eiben and Fessenden[2] used this technique in the study of the three primary species (e^-_{aq}, H, OH) produced in the radiolysis of water, this technique has been used in radiation chemistry, especially for the radiolysis of aqueous solutions,[3] water,[4] and alcohols.[5,6] So far, there seems to have been only one report about liquid alkanes.[7] Here, we wish to report the results obtained in the γ-radiolysis of cyclohexane using phenyl *t*-butyl nitrone (PBN) as a spin trap.

The radiolysis of cyclohexane has been studied extensively in many laboratories and it is now well known that the main radicals produced in the primary reaction are cyclohexyl radicals and hydrogen atoms. PBN as a spin trap reacts easily with free-radicals to produce relatively stable nitroxide and this nitroxide has a characteristic ESR spectrum.

$$\underset{\underset{\text{O}}{\downarrow}}{\text{PhCH=N-C(CH}_3)_3} + \text{R} \rightarrow \underset{\underset{\text{R}}{|}\ \ \underset{\text{O}}{|}}{\text{PhCH-N-C(CH}_3)_3} \qquad (1)$$

When we apply this technique to the study of the mechanism of the γ-radiolysis of liquid alkane, it is necessary to check the reactivity of PBN with free-radicals and electrons.

Experimental

PBN was prepared by the method of Emmons.[8] Cyclohexane (pure grade, Tokyo Kasei Kogyo Co.) was purified by being passed through an activated silica gel column.

For the ESR measurement, a constant volume (0.25 ml) of cyclohexane containing a certain concentration of PBN was sealed in a 4 mm i.d. Suprasil quartz tube in a mercury-free vacuum system. These samples were γ-irradiated with ^{60}Co γ-rays at a dose rate of 3.4×10^{17}—5.5×10^{18} eV g^{-1} h^{-1} at room temperature to a total dose 5×10^{15}—5×10^{17} eV g^{-1}. These samples were measured with a JEP-1 X-band ESR spectrometer with a field modulation of 100 kHz. The spin concentration was estimated by comparing integrated area of the spectrum with that of DPPH.

For the product analysis, 1 ml of cyclohexane-PBN solution was γ-irradiated. The yields of hydrogen and nitrogen were measured with a Toepler-McLeod gauge which was attached to a cuprous oxide furnace. The columns used for the gas chromatographic analysis were PEG-600: 2 m long for bicyclohexyl and dimethylsulfolane: 6 m long for cyclohexene.

Results

The γ-radiolysis of 0.1 M PBN solution in cyclohexane at room temperature gave the spectrum shown in Fig. 1. The spin adduct was quite stable at room temperature; no appreciable decay could be observed over one day. The spectrum was a triplet of doublets with $a^N \approx 14.5 \pm 0.2$ G and $a^H_\beta \approx 2.2 \pm 0.2$ G, which are characteristic to a cyclohexyl radical spin adduct. However, no hydrogen atom and electron spin adducts were detected.

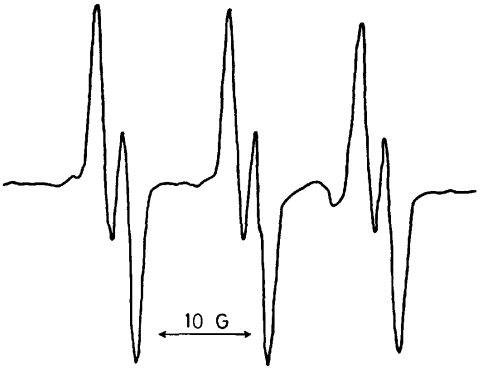

Fig. 1. A typical ESR spectrum of 0.1M PBN solution in cyclohexane after γ-radiolysis at room temperature.

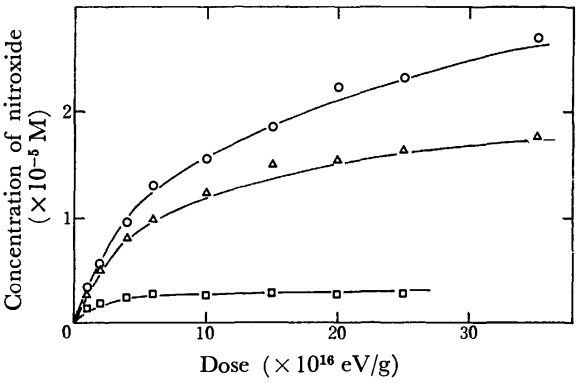

Fig. 2. The yield of nitroxide I as a function of radiation dose. PBN concentration; ○: 0.1 M, △: 0.05 M, □: 0.01 M.

Figure 2 shows the yields of the spin adduct as functions of the irradiation dose for 0.1, 0.05, and 0.01 M PBN solutions in cyclohexane. The yields are not linear with dose. This suggests that secondary reactions which destroy the spin adduct are occurring during the radiolysis. As the dose increases, the increasing rate of the yield decreases and the yield has a tendency to saturate. The saturating values are dependent on the PBN concentration.

Figure 3 shows the relation between the yield of the spin adduct and the dose rate for 0.1 M PBN solution. The yields show little dependence on the dose rate. This suggests that the reaction between two cyclohexyl radicals is not important compared with the reaction of cyclohexyl radicals with PBN to produce spin adducts.

Figure 4 shows the reciprocal of the G-value of spin adduct *vs.* the irradiation dose. Extrapolation to zero dose gives the results for the primary G-values of 3.1 ± 0.5, 2.9 ± 0.5, and 2.8 ± 0.5 respectively for 0.1, 0.05, and 0.01 M solutions.

In order to study the reaction of PBN in the radiolysis of cyclohexane, we measured the yields of several products from the γ-irradiated solutions. Figure 5 shows the yield of hydrogen. Figures 6 and 7 compare the yields of nitrogen and hydrogen respectively *vs.* the concentration of dinitrogen oxide in cyclohexane without PBN and with 0.1 M PBN. Solid lines are theoret-

Table 1. The effects of the radical scavengers on the G-values of products in the γ-radiolysis of cyclohexane

Radical scavenger	Total dose (eV g^{-1})	Products	
		$(c\text{-}C_6H_{11})_2$	$c\text{-}C_6H_{10}$
$C_3H_7SSC_3H_7$[17]	1.0×10^{19}	0.15	1.10
C_3H_7SH[18]	1.5×10^{19}	0.26	1.57
O_2[15]	$\geq2.5\times10^{19}$	0.29	1.49
p-Benzoquinone[15]	12.8×10^{19}	0.29	1.54
PBN (This work)	5.4×10^{19}	0.34	1.52

ical fits (see Discussion). Table 1 summarizes the yields of bicyclohexyl and cyclohexene in a γ-irradiated cyclohexane containing 0.1 M PBN together with the yields obtained by using different radical scavengers.

Discussion

The transient radicals produced in the radiolysis of cyclohexane are cyclohexane ion, electron, hydrogen atom, and cyclohexyl radical.[9] In the present experiment, the cyclohexyl radicals were identified as the nitroxide I:

$$C_6H_{11} + PBN \rightarrow (PBN)\text{-}C_6H_{11}. \qquad I \quad (2)$$

However, no other nitroxides could be observed, even though they were thought to be formed by the trapping of $C_6H_{12}^+$, e^-, and H by PBN. This does not necessarily mean that PBN does not react with them. In the study of the radiolysis of water in the presence of PBN, Sargent and Gardy suggested the existence of $(PBN)^-$.[4] On the other hand, the formation of (PBN)–H has been actually observed by ESR in the γ-radiolysis of methanol at low temperature[6] and during the radiolysis of water.[4] In the γ-radiolysis of hydrocarbon at room temperature, however, the formation of (PBN)–H has not been reported, except for the paper by Mao and Kevan.[7] Consequently, we think that nitroxides II and III are unstable and decay before the ESR measurement at room temperature:

$$e^- + PBN \rightarrow (PBN)^- \qquad II \quad (3)$$

$$H + PBN \rightarrow (PBN)\text{-}H. \qquad III \quad (4)$$

The curves shown in Fig. 2 have the same tendency as that obtained by Mao and Kevan in the γ-irradiated methanol containing PBN.[6] The nitroxide I may be attacked by cyclohexyl radicals or hydrogen atoms during the γ-irradiation:

$$(PBN)\text{-}C_6H_{11} + C_6H_{11} \rightarrow X, \qquad (5)$$

$$(PBN)\text{-}C_6H_{11} + H \rightarrow Y. \qquad (6)$$

As the concentration of PBN can be thought to change little during the γ-irradiation, the rate of formation of nitroxide I may be constant (Reaction 2). If this nitroxide I is consumed by the secondary reactions 5 and 6, we can derive the following relation for the steady-state treatment:

$$[(PBN)\text{-}C_6H_{11}] = A[PBN](1-\exp(-Bt)). \qquad (I)$$

Here, A stands for $k_2[C_6H_{11}]/(k_5[C_6H_{11}]+k_6[H])$ and B for $k_5[C_6H_{11}]+k_6[H]$. This relation can explain qualitatively the experimental result that saturating values are proportional to the concentration of PBN.

The hydrogen producing process in the γ-radiolysis of cyclohexane may be described as follows:

$$C_6H_{12} \sim\!\!\!\!\rightarrow C_6H_{12}^+ + e^- \rightarrow C_6H_{11} + H, \qquad (7)$$

$$\rightarrow C_6H_{10} + H_2, \qquad (8)$$

$$\rightarrow (C_6H_{11})_2 + H_2, \qquad (9)$$

$$\sim\!\!\!\!\rightarrow C_6H_{12}^* \rightarrow C_6H_{11} + H, \qquad (10)$$

$$\rightarrow C_6H_{10} + H_2, \qquad (11)$$

$$\rightarrow (C_6H_{11})_2 + H_2, \qquad (12)$$

$$H + C_6H_{12} \rightarrow H_2 + C_6H_{11}. \qquad (13)$$

Reactions 9 and 12 explain the formation of bicyclohexyl which is not suppressed by the presence of radical scavenger (Table 1). There are two processes in which PBN disturbs the formation of hydrogen: one is the capture of electrons produced in Reaction 7 and the other is the capture of hydrogen atoms produced in Reactions 7 and 10.

In order to determine the ability of PBN to capture electrons, we measured the yield of nitrogen from the 0.1 M PBN solution in the presence of dinitrogen oxide, which is a well known electron scavenger:[10]

$$e^- + N_2O \rightarrow N_2O^- \rightarrow \delta N_2. \qquad (14)$$

$$(1\leq\delta\leq2)$$

Figure 6 shows the results. Obviously, the yield of nitrogen was decreased by the presence of PBN. Schuler *et al.*[11,12] proposed an analytical treatment for the radiolysis system in which two electron scavengers are present. Using their technique, we estimated that $k_3=1.7\times10^{12}$ M^{-1} s^{-1}. Here, we assumed $k_{14}=2.4\times10^{12}$ M^{-1} s^{-1}.[13]

With k_3 estimated, we can calculate the G-value of hydrogen in the presence of PBN, if PBN does not scavenge hydrogen atoms. The calculated result is shown in Fig. 5 as the solid line. The difference between the solid line and the experimental plots must be due to the hydrogen-atom-scavenging by PBN.

The decrease in the G-value of hydrogen, $\Delta G(H_2)$, can easily be derived from the steady-state treatment of Reactions 4 and 7—13:

$$\Delta G(H_2) = \Delta G(H_2)_r + \Delta G(H_2)_i,$$

$$= G_0(H) - \frac{k_{13}[C_6H_{12}]}{k_4[PBN]}\Delta G(H_2)_r. \qquad (II)$$

Here, $G_0(H)$ stands for the G-value of hydrogen atoms in the γ-radiolysis of pure cyclohexane, $\Delta G(H_2)_i$ for the decrease of hydrogen due to the electron scavenging by PBN, and $\Delta G(H_2)_r$ for the decrease due to the hydrogen-atom-scavenging by PBN. $\Delta G(H_2)_i$ can be calculated with the value of k_3, while $\Delta G(H_2)_r$ can be estimated from the experimental data. Figure 8 shows the plots between $\Delta G(H_2)$ and $\Delta G(H_2)_r/[PBN]$. From this linear relationship, we can estimate the following values: $G_0(H)=3.4\pm0.4$ and $k_{13}/k_4=(6.0\pm0.6)\times10^{-3}$.

The decrease in the G-value of hydrogen in the presence of dinitrogen oxide together with PBN is shown in Fig. 7. The difference between the G-value with PBN and without PBN must be due to the hydrogen-atom-scavenging by PBN.

The effect of PBN on the yields of bicyclohexyl and cyclohexene is shown in Table 1, together with some

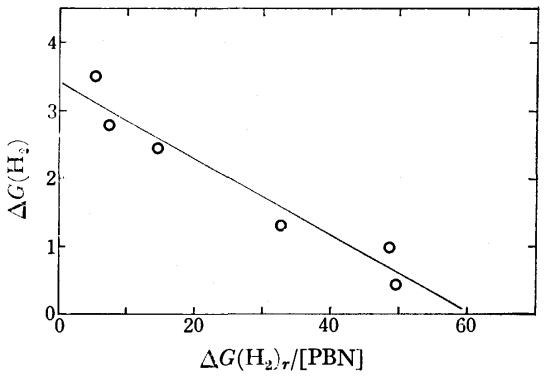

Fig. 8. The decrease in the G-value of hydrogen molecule as a function of $\Delta G(H_2)_r$/[PBN]. (Relation (II))

past data of radical scavengers. There is little difference between them, except in the case of di-*n*-propyl disulfide. It can thus be understood that PBN is one of the good radical scavengers.

Cyclohexane is probably the most popular hydrocarbon for the study of radiolysis. In spite of a large number of investigations, however, the quantitative assessment of the yields of the products from the radiolysis of cyclohexane such as the G-values of electrons, hydrogen atoms, and cyclohexyl radicals have not been settled yet. Only the G-value of hydrogen molecules seems to have reached a final assessment: $G(H_2)=5.7\pm0.2$.[14,15] For the G-value of electrons two values are proposed: One is about 4.0,[11] the other is around 5.2.[16] Both values were estimated by extrapolation to the infinite concentration of radical scavenger on the assumption of a certain reaction mechanism. The discrepancy between the two values is obviously beyond the experimental error. This difference is strongly connected to the fundamental interpretation of the radiolysis of hydrocarbons.

In the present study, we have estimated the G-value of hydrogen atoms. So far, this value has been estimated from the effect of the radical scavenger on the G-value of the hydrogen molecules produced; however, as is well known, the reaction of each radical scavenger is not clear cut. As has been stated above, the reaction of the spin trap, PBN, is also not clear cut; moreover, the spin adducts produced are not stable for reactive species. This fact complicates the analysis. Consequently, we regretfully have to say that the utilization of the spin trap for the quantitative estimation of the products in the radiolysis of hydrocarbons is not a very good technique.

Dichroism and Configuration Analysis of 2-Ethylthio-1,3-Diazaazulene

Hiroshi HIRATSUKA, Yoshie TANIZAKI, and Toshihiko HOSHI*

Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

**Department of Chemistry, Aoyama Gakuin University, Setagaya-ku, Tokyo 157*

(Received November 19, 1976)

Electronic absorption spectrum of 2-ethylthio-1,3-diazaazulene (ESDA) is investigated by means of dichroism analysis using the stretched PVA film. Seven π-π^* bands and an allowed n-π^* band are assigned. The experimental assignment of π-π^* bands is in good agreement with the theoretical result using the PPP calculation. The effect of substituent groups on 1,3-diazaazulene (DA) is discussed by making use of a correlation diagram of SCF MO's of ESDA, 2-ethoxy-1,3-diazaazulene (EODA), DA, and the substituent groups. Configuration analysis of wave functions for ESDA and EODA is carried out, and the substituent effects of the ethylthio and ethoxyl groups are compared. The result shows that the ethylthio group perturbs the electronic structure of DA more strongly than the ethoxyl group.

To date we have investigated the electronic spectra, including n-π^* transition bands, of 1,3-diazaazulene (abbreviation, DA) and its derivatives, such as 2-ethoxy-1,3-diazaazulene (EODA).[1-3] We have determined that they have five π-π^* transition bands above 220 nm, which are correspondent to each other concerning the transition direction, the position, and the relative intensity. These bands also correspond in nature to the respective ones of azulene. The only difference is that all bands of DA (and EODA) are at shorter wavelengths than the corresponding bands of azulene.

In this series of study on the 1,3-diazaazulenes, we expected that 2-ethylthio-1,3-diazaazulene (ESDA) would also reveal a spectrum similar to EODA, but found that the ESDA spectrum does not always correspond to those of EODA and DA. This fact has already been noticed by Nozoe *et al.*;[4] they have pointed out that the absorption spectrum of 2-methylthio-1,3-diazaazulene as well as that of the 2-dimethylamino derivative does not resemble that of DA. The only difference in the chemical structure between EODA and ESDA is in the substituent group: ethoxyl and ethylthio. For that reason, their spectral characteristics must be attributed to the difference of the substituent effect between the ethoxyl and the ethylthio groups.

We will first analyze the absorption spectrum of ESDA theoretically and experimentally. Then, in order to clarify the distinction between the ethylthio and the ethoxyl groups for the substituent effect on the MO levels of DA, we will examine the correlation diagram of their MO levels, and also analyze the state wave functions of ESDA and EODA by means of the configuration analysis proposed by Baba *et al.*[5]

Experimental and Calculation

2-Ethylthio-1,3-diazaazulene (ESDA) was provided by the Sankyo Company Ltd. It was recrystallized from cyclohexane solution. The analytical values in percent were as follows:

Found: C, 63.28; H, 5.50; N, 14.80; S, 17.00%. Calcd for $C_{10}H_{10}N_2S$: C, 63.15; H, 5.30; N, 14.73; S, 16.72%.

The measurement of the solution spectrum was carried out by using a Shimadzu MPS-50L recording spectrophotometer. The details of measurement and analysis of the dichroic spectra are given in the previous paper.[1,3] In the figure of the dichroic spectra, $D_{/\!/}$ and $D_{\perp}$ indicate the absorbance for the plane polarized light whose electric vector is respectively parallel (//) and perpendicular ($\perp$) to the stretched direction of the film. The dichroic ratio R_d is defined as $D_{/\!/}/D_{\perp}$. R_s is the stretching ratio of the film.

We followed the Pariser-Parr-Pople method modified by the Nishimoto-Mataga approximation[6] including CI. The CI caluculation was limited to all the singly excited configurations. The one-center Coulomb repulsion integral was set equal to the valence state ionization potential (I_p) minus the valence state electron affinity (E_a) after Pariser and Parr.[7] The two-center repulsion was estimated by the Nishimoto-Mataga formula.[6] The core resonance integral ($\beta_{\mu\nu}$) was constant. Parameters used are listed in Table 1.

TABLE 1. PARAMETER VALUES USED

	C	S	N	O
Ionization potential (eV)	11.16	22.2	14.12	33.00
Electron affinity (eV)	0.03	9.15	1.78	11.47
	C-C	C-S	C-N	C-O
Core resonance integral (eV)	−2.32	−1.16	−2.38	−2.30

The molecular geometry of the diazaazulene skeleton used was the same as before.[2] The bond lengths of carbon-carbon and carbon-nitrogen were taken as 1.40Å, and those of carbon-oxygen and carbon-sulfur as 1.37Å and 1.70Å, respectively.

Assignment

The calculated result for ESDA is given in Table 2 and is compared with the absorption spectrum determined in cyclohexane solution in Fig. 1. It has already been shown that both 1,3-diazaazulene (DA) and 2-ethoxy-1,3-diazaazulene (EODA) have five electronic transitions (bands) in the region below 50000 cm^{-1}.[1] In the case of ESDA, however, eight transitions are computed in the same region.

From the comparison of the calculated result and the observed spectrum shown in Fig. 1, the following assignment is obtained. The shoulder in the region of 23000—25000 cm^{-1} corresponds to the first π-π^* transition (Y-polarization), the intense band with the double peak in the region of 26000—30000 cm^{-1} to the second transition (X), and the two peaks in 30000—34000 cm^{-1} to the third transition (Y). The intense bands at about 37000 and 41000 cm^{-1} are respectively correspondent to the fourth (X) and the sixth (X) transitions. An absorp-

Table 2. Calculated results and assignment for 2-ethylthio-1,3-diazaazulene (ESDA)

Number of Transition	Transition energy		Oscillator strength		Polarization[d]	
	calcd	obsd[a]	calcd	obsd[c]	calcd	obsd[e]
1	22480 cm^{-1} (445 nm)	23800 cm^{-1} [b] (420 nm)	0.007	0.001	Y	Y
2	26660 (375)	26500 (378)	0.323	0.267	X	X

5	40090 (249)		0.002		Y	Y
6	40900 (245)	41320 (242)	1.187	0.387	X	X
7	47030 (213)		0.565		Y	Y
8	48760 (205)		0.004		X	

a) Observed in cyclohexane solution. b) Shoulder. c) Estimated by the following equation using the component spectra obtained in the dichroism analysis: $f=4.32\times10^{-9}\times\varepsilon_{max}\times(\Delta\nu)_{1/2}$, where $(\Delta\nu)_{1/2}$ is the half value width in cm^{-1} units and for the extinction coefficient, ε_{max}, the value in ethanol is used instead of that in PVA film. Band shapes of IV and VI are determined by the optional way. d) X and Y are molecular long and short axes, respectively. e) Results of dichroism analysis using a stretched PVA film.

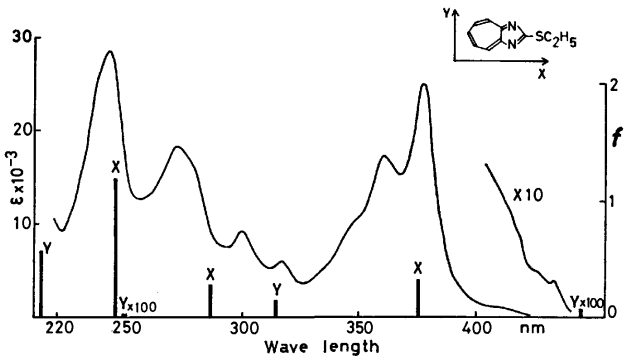

Fig. 1. Absorption spectrum of 2-ethylthio-1,3-diazaazulene (ESDA) in cyclohexane solution and the calculated result.

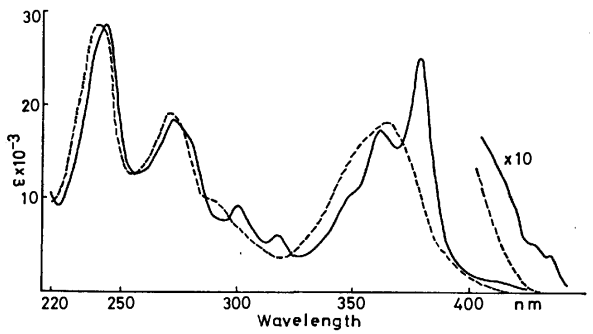

Fig. 2. Absorption spectra of 2-ethylthio-1,3-diazaazulene (ESDA) in cyclohexane (——) and ethanol solution (---).

tion band due to the fifth transition (Y) which is computed to be of very low intensity (see Table 2) should be hidden in the intense band which has been attributed to the sixth transition. The assignment thus deduced is tabulated in Table 2.

Figure 2 illustrates a solvent effect on the absorption spectrum of ESDA. The spectrum in ethanol solution loses its structure and undergoes a blue shift in comparison with that in cyclohexane solution. A similar situation is also observed for the spectrum in PVA film.

As above, we could characterize the absorption bands from the point of view of transition energy and intensity. However, in order to accomplish the assignment, it is desirable to examine the polarizations of the bands.

Dichroism Analysis

Since the symmetry of the π electron system of the ESDA molecule belongs to the point group C_{2v}, the possible π-π^* transitions must be along the long (X) or the short axis (Y) in the molecular plane. According to the dichroism-measurement using stretched PVA film, this is simply decided by the fact that the dichroic ratio ($R_d=D_{//}/D_{\perp}$) of a band polarized along the long axis of the molecule is larger than that along the short axis, because the orientation of the molecule by stretching is preferential in its longitudinal direction. Concerning the band polarizations in the quantitative sense, the dichroism analysis can provide the orientation angles of bands: the angles between an orientation axis of a molecule and the transition moments of bands. Since an orientation axis of a molecule must be a common axis to all the band polarizations which will determine orientation angles, the angle between any two band polarizations can be obtained by taking the sum or difference of the two experimental orientation angles, provided that the orientation axis and the two polarizations are in the same plane. In this case, when the two bands are both due to the transitions to the pure

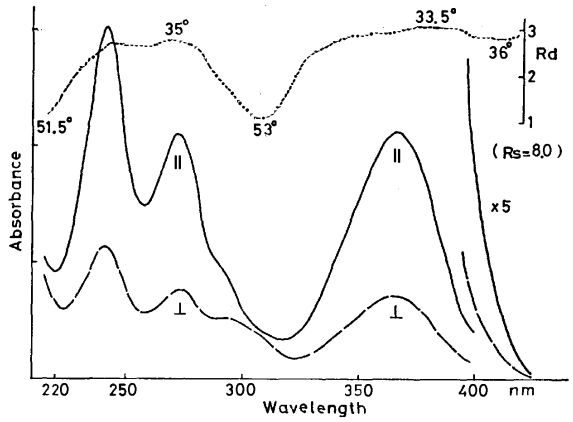

Fig. 3. Dichroic spectra and R_d curve of 2-ethylthio-1,3-diazaazulene (ESDA). R_s=8.0.

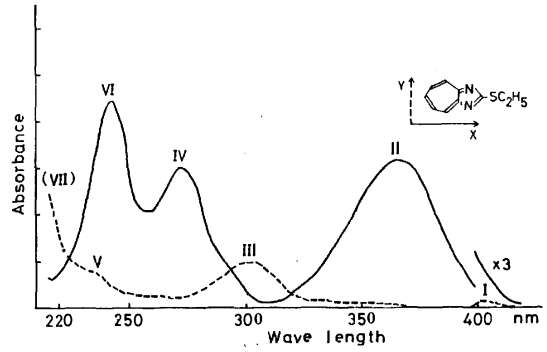

Fig. 4. Component spectra of 2-ethylthio-1,3-diazaazulene (ESDA). X(——) and Y(---) mean the components whose polarizations are along the molecular long and short axes, respectively.

electronic excited states, the sum of the orientation angles must be equal to 90° or the difference to 0° according to whether two band polarizations are orthogonal or parallel to each other, respectively. But it is rarely the case that the orthogonal-parallel relation is rigorously obtained under actual conditions, because there is often some mixing of other kinds of transitions and overlapping of other kinds of absorption bands with the band under consideration.

Figure 3 shows the dichroic spectra of ESDA in the stretched PVA film. The figures indicated along the R_d curve represent the orientation angles of the bands at the respective wavelengths. According to Fig. 3, the absorption band in the region 330—420 nm seems to be a single band. However, the R_d curve for the absorption above 400 nm falls slightly, indicating that a weak absorption is hidden. The presence of this weak absorption (the first band) is obvious from the absorption below 25000 cm^{-1} in Fig. 1.

The R_d value at 380 nm of the second band is the highest in the whole region observed (Fig. 3). It can be said, therefore, that the polarization of the second band is along the molecular long axis (X) and the first band which is hidden in the long wavelength tail of the second band must be polarized to the short axis (Y). The polarizations of other bands can be qualitatively discussed in the same way.

Incidentally, it should be noticed that the R_d curve is somewhat depressed (260 nm) between the strong fourth and sixth bands of X-polarization. This suggests the presence of a weak (fifth) band with Y-polarization.

In order to discuss in detail the polarization, in the next section, we will resolve the spectrum into the X- and Y-components.

Component Spectra of ESDA. The absorption spectrum of ESDA determined in a non-stretched PVA film could be decomposed into X- and Y-component spectra[1] using the R_d value in Fig. 3, assuming that the absorption at 380 nm, which shows the highest R_d value, has the pure X-polarization. The result is shown in Fig. 4.

From a comparison of the component spectra in Fig. 4 and the calculated results in Table 2, the absorption spectrum of ESDA in the PVA film is characterized in the following way. The second, fourth, and sixth bands which are polarized along the long axis (X) of the molecule can be attributed respecitvely to the second, fourth, and sixth transitions with X-polarizations. In addition, the observed bands and the calculated transitions correspond well to one another with respect to the relative intensities as well as the transition energies. Concerning the Y-component spectrum, the first, third, fifth, and seventh bands can be attributed to the first, third, fifth, and seventh transitions, respectively. In this assignment, however, the calculated oscillator strength of the fifth transition (Table 2) seems to be extremely small compared with the observed intensity of the fifth band (Fig. 4). Furthermore, the component spectra of Fig. 4 show that the shoulder due to the fifth band (Y) is at a shorter wavelength than the maximum of the sixth band (X). Therefore, the numbering of the order of the fifth (Y) and sixth (X) transitions by calculation must be reversed.

An extra weak absorption appears in the Y-component spectrum of Fig. 4, which extends from 320 to 365 nm. This is also suggested by the behavior of the R_d curve in Fig. 3, that is, the R_d curve shows some depression in that region. This extra band may be assigned to the forbidden character of the second π-π^* transition band and/or n-π^* transition band. However, since similar extra bands have been found in the Y-component spectrum of DA (1,3-diazaazulene) and EODA (2-ethoxy-1,3-diazaazulene) and have reasonably been assigned to allowed n-π^* transition bands polarized normal to the molecular plane (Z axis),[1] we may take the latter assignment here. (In the dichroism analysis, it must be noted that the Z- and Y-components cannot be distinguished from each other.[1,3])

Substituent Effect

Correlation Diagram of Molecular Orbitals. It has already been pointed out that the absorption spectrum of ESDA does not resemble that of DA, while that of EODA does.[4] That is to say, while all the bands observed for EODA keep the one-to-one correspondence to those of DA, in the case of ESDA, there appears an extra fourth and fifth band. The reason is to be

found in the difference of the substituent effect of the ethoxyl and ethylthio groups. In such a case, we can explain the substituent effect from the point of view of a one-electron molecular orbital. This is carried out by expanding the j-th SCF MO wave function ψ_j of EODA (or ESDA) into the SCF MO wave functions ψ°'s of DA and the ethoxyl (or ethylthio) group. Thus we have

$$\psi_j(\text{EODA}) = \sum_m C_m^j \psi_m^\circ(\text{DA}) + C_\circ^j \psi_\circ^\circ(\text{O}) . \quad (1)$$

Using the expansion coefficients, we can make a correlation among the SCF MO wave functions of EODA (or ESDA), DA, and the substituent. A correlation diagram of energy levels is shown in Fig. 5. The diagram consists of five sets of levels: from left to right, the energy levels for the MO's of substituent sulfur (S), ESDA, DA, EODA, and substituent oxygen (O). The levels are drawn by full and dotted lines which represent the symmetry species a_2 and b_1, respectively. For both ESDA and EODA, the occupied orbitals consist of four b_1 and two a_2 orbitals. DA has three b_1 and two a_2 occupied orbitals and three b_1 and two a_2 unoccupied ones. The substituents S and O have only one occupied orbital of b_1 symmetry, to which the substituents belong in the molecules.

Now, as is known from the symmetry consideration in the case of ESDA, for instance, the orbital of S cannot couple with a_2 type orbitals but only with b_1 type orbitals of DA. Actually, all four full lines (a_2) of ESDA or EODA keep nearly the same levels as the corresponding ones of DA. Furthermore, from the comparison of the unoccupied orbitals of ESDA (or EODA) and those of DA, it is recognized that even the b_1 orbitals are not perturbed by the substituent orbital. For that reason, in the correlation diagram, we can restrict the discussion to the relation between the substituent orbital and the occupied b_1 orbitals of DA.

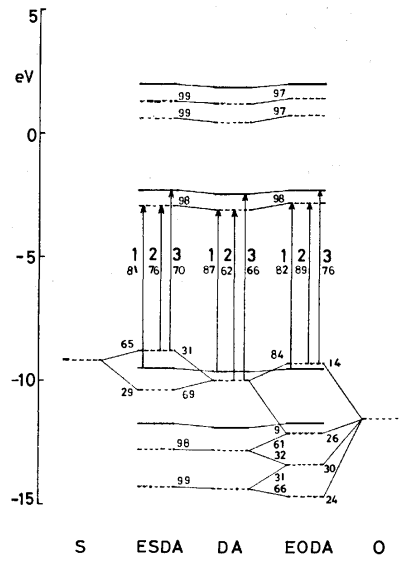

Fig. 5. Correlation diagram for SCF MO. From left to right, SCF MO's for sulfur, ESDA (2-ethylthio-1,3-diazaazulene), DA (1,3-diazaazulene), EODA (2-ethoxy-1,3-diazaazulene) and oxygen are arranged. a_2 and b_1 type SCF MO's are represented by the horizontal full and dotted lines, respectively. The figures along the joining fine lines are contribution weight from the MO's of sulfur, DA, oxygen to the MO's of ESDA and EODA. Each transition, being numbered by Roman numerals along the vertical arrow, is represented by the configuration which contains the two MO's connected with arrow and whose contribution weight is shown as the figure beneath the transition number.

The figures indicated on the correlation lines of Fig. 5 show the square values of the coefficients of Eq. 1 and represent the extent of the contribution from each of the wave functions. The highest occupied b_1 MO of ESDA, for instance, receives contributions of 65% and 31% from the MO of substituent S and the highest occupied b_1 MO of DA, respectively.

As the correlation diagram shows, the orbital of substituent S lies at around the highest occupied b_1 MO of DA, while the MO level of substituent O is much lower than that of the DA orbital. Consequently, the S MO couples strongly with the highest b_1 MO of DA to make two b_1 MO's of ESDA, while the O MO in EODA interacts more or less with all the occupied b_1 MO's of DA, but its interaction with the highest b_1 MO is especially weak (14%). This difference in the extent of interactions of the S and O orbitals with the DA orbitals could produce such differences in the spectra of ESDA and EODA as were described before; in comparison with the spectrum of DA, an extra band (either fourth or fifth band) is found in that of ESDA.

CA for Wave Functions of ESDA and EODA. The substituent effect can also be discussed from a point of view of CA (configuration analysis).[5] Making use of the CA method, any of the state wave functions of EODA or ESDA can be explained in terms of the wave functions of DA and the charge-transfer configurations which represent transitions from the π-orbital of the substituent to unoccupied molecular orbitals of DA. In short, we can write down the i-th state wavefunction Ψ_i (EODA) or Ψ_i (ESDA) by the reference configurations Ψ°'s as follows:

$$\Psi_i(\text{EODA}) = \sum_k C_k^i \Psi_k^\circ(\text{DA}) + \sum_l C_l^i \Psi_{\text{CT}l}^\circ , \quad (2)$$

where Ψ_k°(DA) stands for the k-th wave functions of DA and $\Psi_{\text{CT}l}^\circ$ stands for the l-th charge transfer configuration (electron excitation to the l-th molecular orbital of DA from the orbital of the subsituent).

By squaring the coefficients C_k^i and $C_{\text{CT}l}^i$, we can obtain the relative contribution of the respective configurations Ψ_k° and $\Psi_{\text{CT}l}^\circ$ to the state wave function Ψ_i (EODA) or Ψ_i (ESDA). The difference of the substituent effect of the ethoxyl and ethylthio groups can therefore be estimated by comparing the absolute values of $C_{\text{CT}l}^i$ of Ψ_i (EODA) and Ψ_i (ESDA).

Figure 6 shows the results of CA. The square values of the expansion coefficients are represented by circles which are drawn in such a way that their areas are proportional to the square values. Circles of values below 1% are omitted in Fig. 6. State wave functions (Ψ_i) are put on the tops of the columns and the reference configurations (Ψ_k°, $\Psi_{\text{CT}l}^\circ$) are arranged in the left column. Total weights are listed at the bottom of the columns.

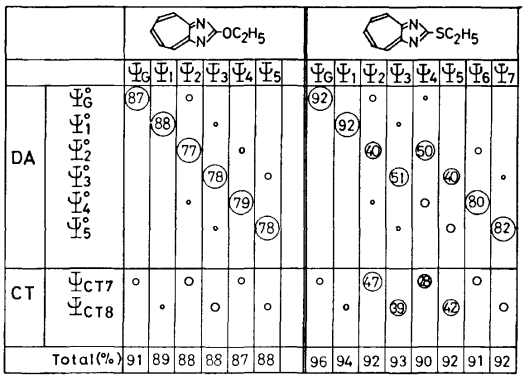

Fig. 6. The result of Configuration Analysis (CA). Top of each column is the state wave function of EODA and ESDA. Left hand side of each row is the reference configuration.

Since the total weight of the respective columns is nearly 90%, we may safely discuss the substituent effect without taking into account other wave functions such as doubly excited configurations. We can read any column in accordance with Eq. 2; for example, the ground (Ψ_G) and the first excited (Ψ_1) state wave functions of ESDA are as follows:

$$\Psi_G(\text{ESDA}) = (0.923)^{1/2}\Psi_G^\circ(\text{DA}) + \cdots + (0.033)^{1/2}\Psi_{CT7}^\circ , \quad (3)$$

$$\Psi_1(\text{ESDA}) = (0.917)^{1/2}\Psi_1^\circ(\text{DA}) + \cdots - (0.020)^{1/2}\Psi_{CT8}^\circ , \quad (4)$$

where Ψ_G° (DA) and Ψ_1° (DA) are the wave functions of the ground and first excited configurations of DA, respectively, and Ψ_{CT7}° and Ψ_{CT8}° mean respectively the transitions to the uncocupied DA orbitals 7th and 8th from the substituent orbital. In Eqs. 3 and 4, the absolute values of the coefficients of Ψ_G° (DA) and Ψ_1° (DA) are the largest and all the other coefficients are small enough to be neglected. In the first approximation, therefore, we can correlate Ψ_G (ESDA) and Ψ_1 (ESDA) to Ψ_G° (DA) and Ψ_1° (DA), respectively.

Any wave functions for ESDA and EODA in Fig. 6 can be read in the same manner as above. As shown in Fig. 6, all wave functions from Ψ_G to Ψ_5 of EODA are approximately equivalent to those from Ψ_G° to Ψ_5° of DA, respectively. As for ESDA, however, there is no one-to-one correspondence except for the pairs of Ψ_G–Ψ_G° and Ψ_1–Ψ_1°. In fact, all four wave functions, Ψ_2 to Ψ_5, of ESDA involve two kinds of predominant configurations: localized and charge transfer ones. Conversely, Ψ_2° of DA are distributed to Ψ_2 and Ψ_4 of ESDA, and Ψ_3° (DA) to Ψ_3 (ESDA) and Ψ_5 (ESDA). Therefore, the wave functions Ψ_2 to Ψ_5 of ESDA cannot be correlated by a one-to-one correspondence to Ψ_2° or Ψ_3° of DA. However, Ψ_6 and Ψ_7 of ESDA correspond well to Ψ_4° and Ψ_5° of DA.

From the above discussion, we can conclude as follows. The five transition bands of EODA correspond to each of the respective five bands of DA. Direct correspondence of the transition bands of ESDA and EODA exists between both of the first bands, between the sixth (ESDA) and fourth (EODA) bands and between the seventh (ESDA) and fifth (EODA) bands. But the second, third, fourth, and fifth bands of ESDA do not correspond directly to any single transition band of EODA.

The authors are greatly indebted to Dr. H. Negoro, Dr. G. Sunagawa, Dr. N. Soma, and Dr. H. Nakao of the Sankyo Company Ltd., for providing the sample.

Vibrational Spectra and Normal Coordinate Calculations for Trimethylarsine–Borane

Fumio WATARI

Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai 980

(Received November 19, 1976)

Studies were carried out on the infrared spectra (33—4000 cm^{-1}) of eight isotopic trimethylarsine–boranes, $(CH_3)_3AsBH_3$, $(CH_3)_3As^{10}BH_3$, $(CH_3)_3AsBD_3$, $(CH_3)_3As^{10}BD_3$, $(CD_3)_3AsBH_3$, $(CD_3)_3As^{10}BH_3$, $(CD_3)_3AsBD_3$, and $(CD_3)_3As^{10}BD_3$, in the solid state at low temperature, and on the Raman spectra (0—4000 cm^{-1}) in the solid state and in solution of dichloromethane at room temperature. The spectra were interpreted on the basis of C_{3v} molecular symmetry, complete assignments for all fundamentals except the internal torsion being made. Normal coordinate calculations were carried out utilizing a symmetry force field in order to confirm the assignments. One of the methyl rocks was found to be mixed with the borane rock, making the assignments of these frequencies complicated. The As–B and As–C force constants were found to have the values 1.849 and 3.087 mdyn/Å, respectively.

Group IIIb and Group Vb compounds form the so-called Lewis acid–base complexes. Reactions of diborane with several trialkyls of Group Vb elements and properties of the complexes were discussed by Hewitt and Holiday.[1] As regards phosphorus–boron and arsenic–boron bonding, Burg and Wagner,[2] and Stone and Burg[3] reported the preparation and properties of several phosphine–boranes and arsine–boranes. The arsine-borane compounds are less stable than the corresponding phosphine–boranes. Trimethylarsine–borane is slightly sensitive to water vapor, but stable at room temperature when kept in a vacuum or an inert gas atmosphere.

In studing these electron donor-acceptor complexes, the properties of the donor-acceptor bonds are of interest. Durig *et al.*[4] reported on microwave, vibrational, and NMR studies. During a course of vibrational studies on trimethylarsine oxide[5] and other trimethylarsine addition compounds, vibrational assignments obtained for trimethylarsine moiety were found to differ from the assignments of Durig *et al.* A detailed vibrational study was considered necessary for consistent assignments. A report is given herewith on infrared and Raman studies of trimethylarsine–borane for eight isotopic compounds prepared from $(CH_3)_3As$, $(CD_3)_3As$, B_2H_6, B_2D_6, $^{10}B_2H_6$, and $^{10}B_2D_6$ (the relative abundances of two isotopes in natural boron are 80.4% ^{11}B and 19.6% ^{10}B). The vibrational assignments were made by means of normal coordinate calculations.

Experimental

All the preparative work was carried out in a conventional vacuum-line. Spectral measurements were made in a vacuum. Trimethylarsine-d_0 and -d_9 were prepared by reactions of Grignard reagents, CH_3MgI and CD_3MgBr, with $AsCl_3$. B_2H_6 was prepared by the addition of BF_3–ether complex to $LiAlH_4$ suspension in ether.[6] B_2D_6 was prepared in a similar manner using $LiAlD_4$. In the preparation of ^{10}B isotopic diboranes, $^{10}BF_3$–ether complex was used, which was obtained by dissolving $^{10}BF_3$ gas in ether evolved by the thermal decomposition of $K^{10}BF_4$ at 750 °C.[7]

Trimethylarsine–borane complex was prepared by condensing trimethylarsine and diborane in a 2 : 1 mole ratio into a small reaction tube fitted with a stopcock at liquid nitrogen temperature. After closing the stopcock the tube was left to stand until it attained room temperature. It was then immersed in a −22 °C bath (carbon tetrachloride slush) and opened to the vacuum-line to remove volatile substances.

Infrared spectra were recorded on a Perkin-Elmer Model 337 in the region 400—4000 cm^{-1}. Frequencies were read on a Hitachi QPD-33 recorder by abscissa expansion with use of a Perkin-Elmer Expanded Scale Readout Kit. The instrument was calibrated in the ususal manner.[8] The spectra were obtained for the samples deposited onto a CsI plate cooled by liquid nitrogen. Before recording the spectra, the samples were annealed till there was a slight increase in intensity of absorption over that immediately after deposition.

Far infrared spectra were obtained between 33 and 400 cm^{-1} with a Hitachi FIS-III spectrophotometer which was evacuated in order to remove atmospheric water vapor. The instrument was calibrated with water vapor frequencies. The sample was sublimed onto a polyethylene window which was cooled by liquid nitrogen. The sample was annealed in a similar way to that for the mid-infrared study. The double chopping method was used to avoid the radiation effect resulting from the temperature difference between the sample and reference beam paths.

Raman spectra were recorded from 0 to 4000 cm^{-1} on a JEOL JRS-Sl laser Raman spectrophotometer equipped with a NEC GLG 108 He–Ne laser. The Raman spectrophotometer was calibrated with the emission lines of neon. The spectra were obtained at room temperature in the solid state and in CH_2Cl_2 solutions sealed into capillaries of about 1.5 mm o.d.

Results and Vibrational Assignments

The infrared spectra of ^{10}B complexes are shown in Fig. 1, and the Raman spectra of solid ^{10}B compounds in Fig. 2. In the far infrared spectra, only two absorptions were observed, one very weak and the other intense but broad. Since these frequencies are not sufficiently accurate because of high noise level and broadness, the spectra are not shown and no frequency data are used in this study.

If we assume a molecular symmetry of C_{3v}, we see from group theory that its 45 molecular vibrations are distributed as $10A_1+5A_2+15E$, in which A_1 and E vibrations are active in both infrared and Raman spectra, A_2 being inactive in both.

Nearly all the vibrations are observed in the region expected from trimethylarsine,[9] trimethylarsine addi-

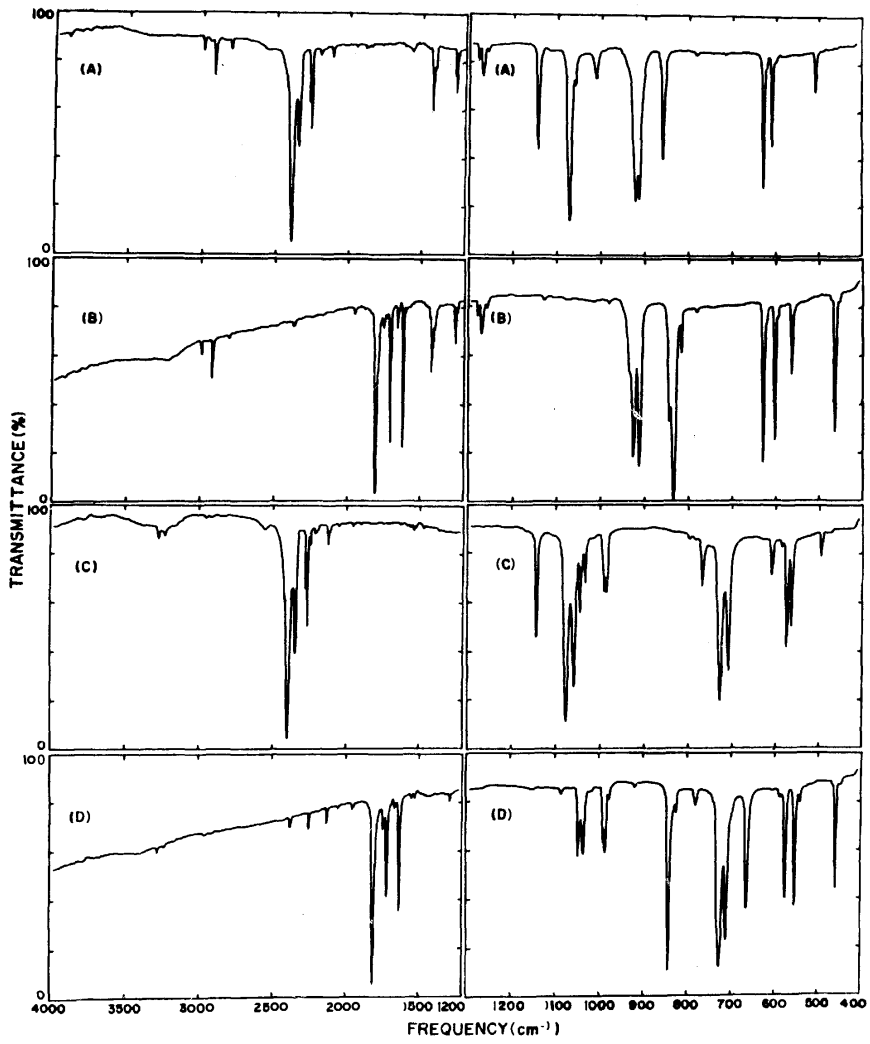

Fig. 1. Infrared spectra of (A) $(CH_3)_3As^{10}BH_3$, (B) $(CH_3)_3As^{10}BD_3$, (C) $(CD_3)_3As^{10}BH_3$, and (D) $(CD_3)_3As^{10}BD_3$ recorded at $-196°$.

tion compounds[10,11] and borane adducts.[12-17] For these vibrations, assignments are straightforward by comparison with the spectra for related compounds and taking into account of shifts upon deuteration. However, complexities are found in the region below 900 cm.$^{-1}$ The infrared spectra for all the eight isotopic compounds in this region are shown in Fig. 3. ^{10}B-^{11}B shifts are useful for assigning vibrational frequencies.

In the infrared spectrum of $(CH_3)_3As^{10}BH_3$ (Fig. 1), two absorptions are observed at 919 and 911 cm^{-1}, corresponding to 925 and 912 cm^{-1} absorptions of $(CH_3)_3As^{10}BD_3$. The E methyl rock is assigned to the higher frequency band and the A_1 rock, to the lower band. The two rocking frequencies shift on deuteration of the methyl groups to 728 and 710 cm^{-1} for $(CD_3)_3As^{10}BH_3$, and to 726 and 711 cm^{-1} for $(CD_3)_3As^{10}BD_3$.

The 857 cm^{-1} absorption in the infrared spectrum of $(CH_3)_3As^{10}BH_3$ was assigned to the BH_3 rock by Durig *et al.*[4] However, no absorption is found in the region 800—970 cm^{-1} in the spectrum of $(CD_3)_3As^{10}BH_3$. The corresponding absorption for $(CH_3)_3AsAuX$ (X=Cl, Br, I)[10] has been observed in the region 830—840 cm^{-1}. No absorption is expected from -AsAuX group in the region 830—840 cm^{-1}. It is very unlikely that the 857 cm^{-1} band of $(CH_3)_3As^{10}BH_3$ is due to the BH_3 rock as Durig *et al.* assigned it. Consequently this 857 cm^{-1} band is assigned to the CH_3 rock. The features of CD_3 rocking absorptions for $(CD_3)_3As^{10}BD_3$ are similar to those of $(CH_3)_3As^{10}BH_3$ except for the shifts toward lower frequencies. The 664 cm^{-1} band of $(CD_3)_3As^{10}BD_3$ is assigned to the CD_3 rock.

No absorption is found in the 850—900 cm^{-1} region in the spectrum of $(CH_3)_3As^{10}BD_3$. The CH_3 rock of this compound is assigned to the 844 cm^{-1} band. In the spectrum of $(CD_3)_3As^{10}BH_3$ also, no absorption is observed around 660 cm^{-1}, where the CD_3 rock of $(CD_3)_3As^{10}BD_3$ was assigned. The CD_3 rock of this compound is assigned to a low frequency band at 611 cm^{-1}.

The antisymmetric BH_3 and BD_3 deformations exhibit no resolvable ^{10}B-^{11}B isotopic shift. The symmetric deformation and the rocking of BH_3 and BD_3 groups have recognizable features of a ^{10}B-^{11}B isotopic shift in the infrared spctra (Fig. 3).

The symmetric BH_3 deformation indicates a clear

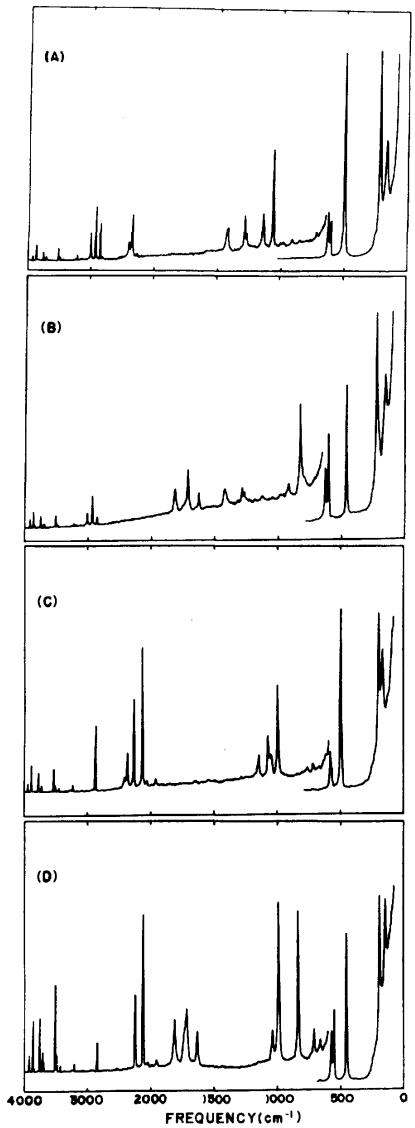

Fig. 2. Raman spectra of (A) $(CH_3)_3As^{10}BH_3$, (B) $(CH_3)_3As^{10}BD_3$, (C) $(CD_3)_3As^{10}BH_3$, and (D) $(CD_3)_3$-$As^{10}BD_3$ recorded in the solid state at room temperature.

^{10}B-^{11}B isotopic shift at 1070 and 1060 cm^{-1} for the $(CH_3)_3As$ adduct, and at 1076 and 1065 cm^{-1} for the $(CD_3)_3As$ adduct. The infrared spectrum of $(CD_3)_3$-$As^{10}BH_3$ represents curious features of a moderately strong absorption at 1059 cm^{-1}, which is lower by 6 cm^{-1} than the $^{11}BH_3$ symmetric deformation frequency (1065 cm^{-1}) and more intense than that expected from ^{11}B content (94% ^{10}B and 6% ^{11}B). The assignment of this absorption is still uncertain.

The symmetric BD_3 deformation for $(CD_3)_3As$ adducts are found at 842 cm^{-1} for $^{10}BD_3$ and at 827 cm^{-1} for $^{11}BD_3$. The antisymmetric BD_3 deformations are assigned to the bands at 842 cm^{-1} of the same frequency as that the symmetric $^{10}BD_3$ deformation. The symmetric BD_3 deformation for $(CH_3)_3As$ adducts is assigned to the absorption at 834 cm^{-1} for $^{10}BD_3$ and at 819 cm^{-1} for $^{11}BD_3$. Similarly the antisymmetric BD_3 deformation of $(CH_3)_3As$ adducts is assigned to the band at 834 cm^{-1} of the same frequency as the symmetric $^{10}BD_3$ deformation. We observe another

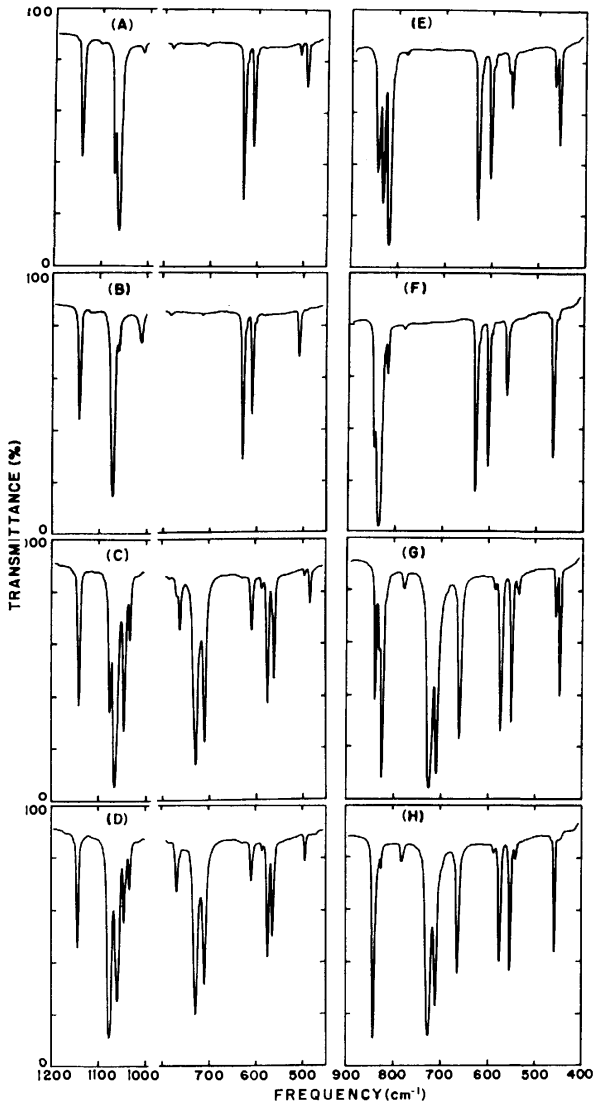

Fig. 3. Infrared spectra in the 1200—400 cm^{-1} region at −196 °. (A) $(CH_3)_3AsBH_3$, (B) $(CH_3)_3As^{10}BH_3$, (C) $(CD_3)_3AsBH_3$, (D) $(CD_3)_3As^{10}BH_3$, (E) $(CH_3)_3$-$AsBD_3$, (F) $(CH_3)_3As^{10}BD_3$, (G) $(CD_3)_3AsBD_3$, and (H) $(CD_3)_3As^{10}BD_3$.

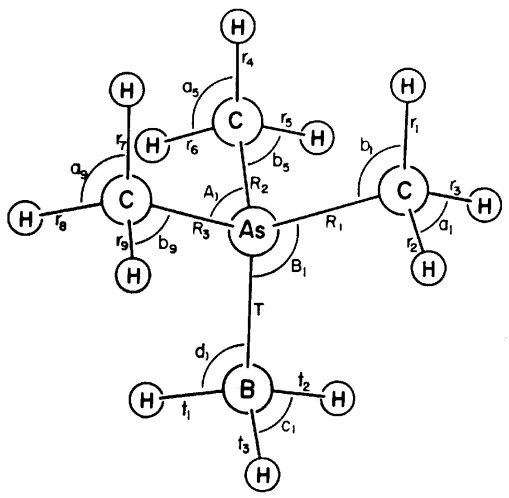

Fig. 4. Internal coordinates for trimethylarsine-borane.

absorption at 844 cm^{-1} in this region, which was previously assigned to the CH_3 rock.

A ^{10}B-^{11}B isotopic shift is also useful for the assignment of the BH_3 and BD_3 rocks. However, the rocks are rather weak and a coupling with the CH_3 or CD_3 rock makes the assignment more complicated. The $^{10}BH_3$ rock of $(CD_3)_3As^{10}BH_3$ is assigned to a band of weak intensity at 769 cm^{-1}. The $^{11}BH_3$ rocking frequency shifts by 6 cm^{-1} to 763 cm^{-1}. No absorptions assignable to the BH_3 rock are observed in the region 700—800 cm^{-1} in the infrared spectrum of $(CH_3)_3As^{10}BH_3$, but two very weak absorptions are found at 784 and 715 cm^{-1}. The latter band exhibits an isotopic shift, corresponding to the 710 cm^{-1} band for $(CH_3)_3AsBH_3$. Thus the 715 and 710 cm^{-1} bands are assigned to the $^{10}BH_3$ and $^{11}BH_3$ rocks, respectively for $(CH_3)_3AsBH_3$.

In the infrared spectrum of $(CH_3)_3As^{10}BD_3$, the 566 cm^{-1} band is assigned to the $^{10}BD_3$ rock, and the $^{11}BD_3$ rock is assigned to the 560 cm^{-1} absorption shifting by 6 cm^{-1}. For $(CD_3)_3AsBD_3$ adducts, the weak bands of low frequencies at 545 and 541 cm^{-1} are assigned to the $^{10}BD_3$ and $^{11}BD_3$ rocks, respectively.

Another absorption is observed in the region 450—500 cm^{-1} exhibiting a ^{10}B-^{11}B isotopic shift, which is assigned to the As–B stretching vibration. This vibration gives the most intense Raman band.

We should expect three skeletal deformations except the torsional modes in the region below 300 cm^{-1}. In the Raman spectra two strong Raman lines are observed. Durig *et al.*[4] resolved the higher frequency line into two at 232 and 217 cm^{-1} for $(CH_3)_3AsBH_3$, and at 232 and 216 cm^{-1} for $(CH_3)_3AsBD_3$, at liquid nitrogen temperature. We could not resolve the lines into two in either the infrared or Raman spectra under the experimental conditions. Consequently a higher frequency Raman line is assigned to the symmetric and the antisymmetric AsC_3 deformation. Finally a lower one is assigned to the AsC_3 rock which can be described as the CAsB bending mode.

One torsional mode should be observed, but no features ascribable to this mode were found in both the infrared and Raman spectra.

Normal Coordinate Analysis

Normal coordinate analysis was carried out in order to confirm the above assignments. The analysis was made by Wilson's *GF* matrix method on an ACOS 77/700 computer at the Computer Center, Tohoku

a 10 by 10, a 5 by 5, two 15 by 15 matrices and 5 redundancies, not including non-zero cross terms between any two symmetry blocks. The corresponding terms of two degenerate pairs are equal to each other. In constructing the symmetry coordinates of C_{3v} $(XY_3)_3Z$ group, those of Kuroda and Kimura[18)] were often used. Care should be taken so that the matrix is completely broken into the symmetry blocks, and for the degenerate symmetry species in particular, each element of a matrix must be equal to the corresponding one of another degenerate pair.

The G matrix was calculated by use of the structural parameters determined from the microwave study[4)] assuming tetrahedral angle around carbon atoms: r(C–H)=1.09 Å, r(B–H)=1.212 Å, r(As–C)=1.945 Å, r(As–B)=2.035 Å, $\angle$(HBH)=113.5°, and $\angle$(CAsC)=105°.

In the calculations the infrared frequencies were used except for the AsC_3 deformation for which the Raman frequencies were taken and the observed frequencies were weighted by $(1/\lambda)$. Initial force constants for the borane group were taken from the values by Durig *et al.*,[4)] and for trimethylarsine moiety, from those for trimethylarsine oxide.[5)]

The least-squares refinement was carried out in terms of symmetry force constants, which were fitted to the observed frequencies for four ^{10}B compounds simultaneously.

The observed and calculated frequencies are given

a) The stretching force constants are given in mdyn/Å, the deformation force constants in mdyn Å, the stretching-deformation interaction constants in mdyn.

Discussion

As seen in the potential energy distributions, the BH_3 and BD_3 rocks couple with the CH_3 and CD_3 rocks, making the rocking frequency region complicated.

The valence force constants obtained from the symmetry force constants are compared with those of other borane and related compounds (Table 9). The force constant f_{N-B} of H_3NBH_3 is greater than that of $(CH_3)_3NBH_3$, whereas the force constant f_{P-B} of H_3PBH_3 is smaller than that of $(CH_3)_3PBH_3$. Arsine, AsH_3, forms no addition compound with borane. If arsine could form a borane adduct, f_{As-B} of arsine–borane would be smaller than 1.849 mdyn/Å obtained for

$(CH_3)_3AsBH_3$. As expected the stability of trimethylarsine–borane is less than that of N and P analogs. The trend is reflected in the stretching force constants of the donor-acceptor bonds.

The CAsC angle becomes larger by adduct formation toward the tetrahedral angle and s character increases in rehybridization around the arsenic atom. This accounts for the increase in the As–C force constant and in the As–C stretching frequencies.

The As–B force constant is in good agreement with the value obtained by Durig *et al.*,[4] the f_{As-C} value being slightly larger than theirs, but in accord with that in $(CH_3)_3AsO$. The B–H force constant is larger than that in amine–boranes, but smaller than that in phosphine–boranes. Accurate examination for other boranes would be necessary in order to compare the B–H force constant with the value obtained in this study.

The author wishes to express his sincere gratitude to Prof. K. Aida for his continued encouragement during this work.

^{13}C Spin-Lattice Relaxation Times in Liquid Crystalline *p,p'*-Azoxyanisole

Kikuko HAYAMIZU and Osamu YAMAMOTO

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received November 24, 1976)

The ^{13}C spin-lattice relaxation time T_1 in the liquid crystalline compound *p,p'*-azoxyanisole; (PAA; 4,4'-dimethoxyazoxybenzene) was observed in the nematic and isotropic liquid phases. From the obtained T_1's of the ring and the methyl carbons, the anisotropic rotational diffusion constants were determined. It is concluded that the rotational reorientation around the molecular axis is faster by an order of 10^3 than the rotational motion around the axis perpendicular to the molecular axis in the nematic and isotropic liquid states.

Nuclear relaxation time in the liquid crystals is known to give important information about molecular motions and intermolecular interactions of some interesting compounds. The nematic liquid crystal *p,p-'* azoxyanisole (PAA); 4,4'-dimethoxyazoxybenzene) and its deuterated species have been studied by observing ^1H, ^2D, ^{13}C and/or ^{14}N relaxation times.[1-9] Most of the relaxation studies were made by the ^1H resonance, but the ^1H relaxation time is affected by both intra- and intermolecular interactions. The spins of the other nucleus, however, relax predominantly by the intramolecular processes. In particular, the relaxation of ^{13}C nuclei, which is bonded by one or more protons, mainly takes place through the dipole-diploe interaction with the attached protons modulated by the molecular reorientations.

PAA contains two different types of carbons bearing protons, *i. e.*, the ring carbons and the methyl carbons. Clearly the relaxation times of the ring carbons can be expected to be affected by the motion of the nematic director. Although the motion of the methyl carbons is averaged by the internal rotation, the relaxation time will be also affected by the anisotropic motion of the elongated molecule in the nematic state. Here we would like to present the temperature dependence of ^{13}C spin-lattice relaxation times for the ring and the methyl carbons observed in the nematic liquid crystalline and in the isotropic liquid states, and to discuss the anisotropic rotation of the nematic molecule.

Experimental

PAA was purified by the zone melting method, degassed, and then sealed into a 12-mm sample tube under vacuum. The ^{13}C relaxation times were obtained by the 180°—τ—90° pulse method using a Varian XL-100-15 spectrometer operating at 25.16 MHz in the external ^{19}F lock mode with proton decoupling. The temperature range of the nematic liquid crystalline phase is 117—135 °C for PAA, and T_1's were observed both in the nematic and in the isotropic liquid states by varying the temperature from 118 to 175 °C. In the nematic phase the measurement was made without sample spinning in order to prevent the disturbance of the allignment of the nematic director along the external magnetic field.

Results and Discussion

The ^{13}C spectrum of PAA in $CDCl_3$ solution at ambient temperature consists of ten peaks arising from the 10 chemically non-equivalent carbons.[10] In the isotropic state at higher temperature, the ^{13}C spectrum shows a similar pattern to that for the $CDCl_3$ sloution, but only 8 peaks are observed due to the overlapping of two sets of two peaks, *i. e.*, the signals from two methyl carbons and from four ring carbons meta to OCH_3 group. Here four peaks are obtained from the carbons bearing protons. In the isotropic state the ^{13}C chemical shifts relative to that of the methyl carbons are nearly constant throughout the temperature range studied, and agree with those in $CDCl_3$ solution within 0.8 ppm. This fact suggests that the molecular structure of PAA does not significantly change from ambient to sufficient high temperatures.

In the nematic state where the molecules are in an anisotropic condition, the ^{13}C spectral lines for PAA are rather broad, probably due to insufficient proton decoupling. The lines of the two quaternary aromatic carbons bonded to nitrogen disappear, as shown by Pines and Chang.[11] But the change in the spectrum from the isotropic to the nematic states in the ^{13}C resonance is much smaller than that in the ^1H or ^2D resonances, so that the measurement of ^{13}C relaxation times is still possible by the usual high resolution technique.

In this paper, since the molecular motion of PAA will be discussed assuming the dipole-dipole mechanism as the relaxation process, T_1's are observed for the carbons bonded by protons, *i. e.*, three aromatic carbon peaks and one methyl carbon peak. The temperature dependences of these T_1's are shown in Fig. 1, which

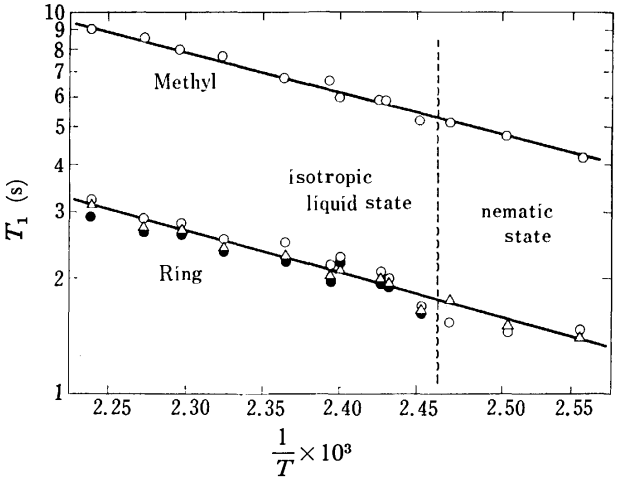

Fig. 1. The temperature dependences of ^{13}C relaxation times for PAA in the nematic and isotropic states. The ring carbons are expressed from a lower to a higher field by ○, ●, and △. In the nematic phase the two signals at the lower field collapses to a broad line which is shown by ○.

TABLE 1. NOE OF PAA IN THE ISOTROPIC LIQUID STATE

Temperature	Methyl	Ring		
137 °C	2.1	3.0	2.8	2.7
160 °C	2.3	2.6	2.7	2.6

have been observed both in the nematic and the isotropic liquid state. In order to estimate the contribution of the dipole-dipole relaxation mechanism to the observed ^{13}C relaxation times, NOE was determined in the isotropic state, as shown in Table 1. If we consider the experimental uncertainty, the observed NOE's are not very temperature dependent. Table 1 shows that the contribution of the dipole-dipole mechanism is a little larger in the ring carbons than in the methyl carbons, probably because the spin-rotation mechanism from the internal rotation may be effective in the ^{13}C relaxation of the methyl carbons. The dipole-diploe relaxation time T_{1d} can be calculated from the observed T_1 as follows[12]:

$$1/T_{1d} = \frac{\mathrm{NOE}-1}{1.988} \times 1/T_1.$$

A theoretical expression of nuclear magnetic relaxation in molecules with multiple internal rotations was first derived by Wallach.[13] In this derivation the molecular motion was treated as isotropic. It was shown that each internal rotation which is much faster than the overall molecular motion contributes a single factor $((3\cos^2\theta-1)/2)^2$ to the relaxation rate, where θ is the angle from the internal rotational axis of interest to the next internal rotational axis, or for the last internal rotational axis to the label axis of interset. Then Levine and his coworkers[14] have extended the theory to the dipolar relaxation for the case where the molecular motion is anisotropic, and presented the numerical results of the ^{13}C relaxation times in a hydrocarbon chain attached to an axially symmetric molecule.

The methyl groups of PAA are a dual rotation system which has internal rotations around the C–O bond and the three-fold axis. Possible mechanisms which are effective in the ^{13}C dipolar relaxation process for the methyl groups of PAA are molecular overall reorientation and the internal rotations. Since these dual internal rotations are reported to be activated in solid state,[19] it may be assumed that the methyl groups rotate freely around both bonds at higher temperatures in the nematic and isotropic states. We also assume that PAA is a symmetric rotor having two rotational diffusion constants, $D_{//}$ and $D_\perp$, where $D_{//}$ is the rotational diffusion constant for the motion about the molecular symmetry axis and $D_\perp$ is for the motion about an axis perpendicular to the molecular axis. According to the theory developed by Wallach and Levine *et al.*, and using the spectral density function for the internal rotation system attached to the molecule undergoing anisotropic molecular motion, the dipolar relaxation rate $1/T_{1d}$ for the methyl carbons of PAA can be derived as

$$\left(\frac{1}{T_{1d}}\right)_{Me} = \frac{3\gamma^2\gamma'^2\hbar^2}{2r^6} \times 3\left[\frac{1}{6D_\perp}\left(\frac{3\cos^2\theta-1}{2}\right)^2 + \frac{1}{2D_\perp+4D_{//}}\sin^4\theta\right] \times \left(\frac{3\cos^2\theta'-1}{2}\right)^2\left(\frac{3\cos^2\theta''-1}{2}\right)^2, \quad (1)$$

where θ is the angle between the molecular axis and the C–O axis, θ' is $\angle$COC, and θ'' is $\angle$OCH. The factor 3 corresponds to the three protons of the methyl groups. When $\theta=0°$, $D_{//}$ does not contribute to the relaxation rate of the methyl carbons. Even if θ is assumed to be 10°,[14] the contribution of $D_{//}$ will be negligibly small because of the term $\sin^4\theta$. In other words, the rotation around the molecular axis of PAA has little effect on the relaxation rate of the methyl carbons, and $(1/T_{1d})_{Me}$ may be assumed to be only a function of $D_\perp$. The angle $\angle$COC, θ' was determined to be 118° by the X-ray analysis.[16] Since the geometric factor $((3\cos^2\theta'-1)/2)^2$ is very sensitive to even small changes of this angle, the $D_\perp$ calculated using Eq. 1 contains some error due to the ambiguity of θ' in the nematic and isotropic states, in addition to the experimental error of $(1/T_{1d})_{Me}$.

On the other hand, since the ring carbons constitute the skeleton of the PAA molecule, the most important mechanism for the ^{13}C dipolar relaxation of the ring carbons bearing protons will be the molecular overall rotation. Huntress[17] has derived a theoretical expression for the relaxation rate of a nuclear spin in a molecule undergoing anisotropic diffusional rotation, which may be applied to the dipolar relaxation rate of the ring carbons of PAA. Then

$$\left(\frac{1}{T_{1d}}\right)_{Ring} = \frac{3}{2}\frac{\gamma^2\gamma'^2\hbar^2}{r^6}\frac{1}{6D_\perp}\left[1+\frac{3(D_\perp-D_{//})}{5D_\perp+D_{//}} \times \sin^2\alpha\left(1+\frac{3(D_\perp-D_{//})}{2(D_\perp+2D_{//})}\sin^2\alpha\right)\right], \quad (2)$$

where α is the angle between the molecular axis and the label axis of interest. For the dipole-dipole relaxation rate for the ring protons, $\alpha=58.7°$ (an average for two C–H bonds),[20] since the rotation around the molecular axis is expected. From Eq. 2, $D_{//}$ can be calculated using the $D_\perp$ value obtained from the relaxation time of the methyl carbons and Eq. 1. In Table 2 the calculated values of $D_{//}$ and $D_\perp$ are listed, together with those for D_{iso}, which are calculated from the assumption of isotropic motion.

TABLE 2. ROTATIONAL DIFFUSION CONSTANTS OF PAA

Temperature	$D_\perp$	$D_{//}$	D_{iso}	
			methyl	ring
137 °C	4.1×10^8	0.86×10^{11}	1.7×10^{11}	1.2×10^{10}
160 °C	4.8×10^8	1.7×10^{11}	2.0×10^{11}	1.8×10^{10}

Although Eqs. 1 and 2 are approximate equations for describing the internal and the anisotropic molecular rotations for an aligned molecule such as PAA in the nematic phase and in the isotropic phase near the transition point, where the short range order remains, they may be safely applied to the ^{13}C dipolar relaxation rate of PAA molecules at higher temperature in the isotropic state. The obtained rotational diffusion constants describe the molecular motion of PAA molecule in the isotropic state. The rotation around the

long molecular axis is much faster by an order of 10^3, than the rotation around the axis perpendicular to the molecular axis. Since the observed T_1 is continuous at the transition point from the nematic to the isotropic liquid states, as shown in Fig. 1, the same picture for the molecular motion of the PAA molecule will be almost true in the nematic state. The rotational motion expressed by the diffusion constant $D_\perp$ obtained from the ^{13}C relaxation time may be compared with the thermal fluctuation of the nematic director in the nematic state, which contributes to the ^1H relaxation rate as a frequency dependent phenomenon[1,2,9]. The order fluctuation of the director is shown to remain in the isotropic state,[5-7] and this is consistent with the fact that $D_\perp$ obtained in the isotropic state is still very small compared with the obtained $D_{//}$. Otherwise, in the usual isotropic liquid, $D_\perp$ and $D_{//}$ would have the values of the same order for a molecule about 18 Å in length and 6 Å in diameter, the approximate size of PAA.[16]

The measurement of ^2D relaxation time has been made by Orwoll *et al.*[8] for PAA-d_8 (ring positions are deuterated) in the nematic and isotropic liquid states. Although the relaxation mechanism is different for the ^{13}C and ^2D resonances, the direction of the interaction vector for the ^2D resonance in PAA-d_8 is the same as that for the ^{13}C resonance in the ring carbons of PAA. The correlation times calculated based on the assumption of the isotropic motion in the ^2D resonance are a little longer, by several percents, than thoes in the ^{13}C resonance at every temperature. Orwoll *et al.* also observed no frequency dependence of the ^2D relaxation time in the nematic and isotropic states. Since the correlation times and the observing frequencies are in a similar order for the ^{13}C and the ^2D resonances, it can be assumed that the ^{13}C relaxation time for the ring carbons is also frequency independent, and then the extreme narrowing condition will hold in the ^{13}C relaxation time when Eq. 2 is applied. From our measurement of ^2D relaxation times of PAA-d_6 (the methyl protons are deuterated) in the isotropic state[18], there is also the same trend in the correlation times of the methyl groups. The temperature dependences of the ^{13}C relaxation times in the ring and the methyl carbons shown in Fig. 1 are similar to those of the ^2D relaxation times in the ring position[8] and the methyl groups,[18] except that at the transition point there was observed the discontinuity in the T_1 of the ^2D resonance, while the T_1's of the ^{13}C resonance are continuous. Arrhenius plots of the ^{13}C relaxation times give the activation energies of 5.6 and 5.0 kcal/mol for the ring and the methyl carbons, respectively. The activation energy obtained for PAA-d_8 in the isotropic state is 5.5 kcal/mol,[8] and the agreement is good. Schwartz *et al.*[4] obtained the activation energy of 6.5 kcal/mol for the ^{13}C relaxation time for the ring carbons of PAA in a similar temperature region, and interpreted it by activation of the internal rotation about the C–N bond. But as discussed above and as also pointed out by Orwoll *et al.* from the results of the ^2D resonance, the main activation process which affects the temperature dependent ^{13}C and/or ^2D relaxation times from the nematic to the isotropic liquid phases may be concluded to be the anisotropic molecular rotational process.

Activity Coefficients of Glycylglycine and α-Aminobutyric Acid in Aqueous Sucrose Solutions

Hatsuho UEDAIRA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received November 24, 1976)

The activity coefficients of glycylglycine and α-aminobutyric acid in aqueous sucrose solutions have been measured by the isopiestic vapor pressure method at 25 °C. α-Aminobutyric acid is salted-out by sucrose, the effect increasing with an increase in the concentration of sucrose and a decrease in the concentration of amino acid. However, in the glycylglycine–sucrose–water system at lower concentrations of solutes salting-in of glycylglycine by sucrose takes place and then salting-out predominates at concentrations higher than 1 mol kg^{-1} glycylglycine and 2 mol kg^{-1} sucrose. The pairwise interactions and the free energy of the transfer of amino acids from water to various concentractions of sucrose solutions are calculated. The results account for the stabilizing effect of sucrose on the higher structure of globular proteins.

Although sugars have long been observed to affect the stability and activity of proteins, the mechanism of the effect remains unclear. Beilinson[1] found that sucrose and glycerol inhibit the heat coagulation of ovalbumin. Ball *et al.*[2] reported that various sugars prevent heat coagulation of serum albumin. Gersma and Stuur[3] found that polyvalent alcohols show protective effects on the reversible thermal denaturation of lysozyme, ribonuclease, and chymotrypsinogen A.

Shimpson and Kauzman[4] found that sucrose and glycerol inhibit the denaturation of ovalbumin by urea. According to Shikama,[5] the bovin serum albumin molecule denaturated by urea has different conformations after the renaturation in 1 mol kg^{-1} sucrose solutions. Metral and Yon[6] showed that the inhibition caused by sucrose on triptic hydrolysis of β-lactoglobulin A is due to the fixation of sucrose on this protein and to the existence of strong stabilizing interactions. Furthermore, at low concentration the sugars accelerate the rate of subunit dissociation of the olygomeric enzyme L-asparaginase with urea, and at higher concentrations, sugars decrease the rate at which the enzyme dissociates in the presence of urea.[7]

In order to clarify the fundemantal mechanisms involved in these phenomena, a thermodynamic study with model compounds is one of the best approaches. Lakshimi and Nandi[8] obtained the activity coefficients of aromatic amino acids and their *N*-acetyl ethyl esters in sucrose and glucose solutions by means of solubility measurements.

In the present work, the activity coefficients of glycylglycine (glygly) and α-aminobutyric acid (αABA) in sucrose solutions were determined by the isopiestic vapor pressure methods. These amino acids were selected as models of peptide unit and amino acids having alkyl side chains. The isopiestic method is superior to the solubility method in that the change in interactions with both concentrations of amino acid and sucrose can be obtained.

Experimental

Materials. Glygly (G. R.) was decolorized and recrystallized twice from a water–ethanol solution. Sucrose and αABA were recrystallized from a water ethanol solution. The samples were dried *in vacuo* over phosphorus pentaoxide at room temperature. Potassium chloride (analytical grade, Merck Co.) was dried *in vacuo* over phosphorus pentaoxide at 110 °C. Solutions were prepared with deionized water freed of air by boiling.

Measurements and Calculation of the Activity Coefficients. Osmotic and activity coefficients were determined with the same apparatus as previously reported.[9] Several ternary solutions of amino acid and sucrose with varing compositions and reference potassium chloride solutions were put in silver dishes. The dishes were placed on a flat copper block in a glass vacuum dessicator set in a thermostat bath at 25 °C.[9] The initial concentrations in the ternary solutions were adjusted to be sufficiently close to their equilibrium concentrations.[10] The time required for attainment of equilibrium was 4—14 days. Equilibrium concentration was measured by weighing, all the weights being corrected to those in vacuum.

In the analysis of the results we use the function Δ, defined by[11]

$$\Delta = 2m_R\phi_R - m_1\phi_1 - m_2\phi_2 , \quad (1)$$

where m_1 and m_2 are the molalities of solute 1 (glygly or αABA) and solute 2 (sucrose), respectively, in aqueous ternary solutions; ϕ_1 and ϕ_2 are the osmotic coefficients of binary aqueous solutions of solutes 1 and 2 at a molality of m_1 and m_2, respectively; m_R and ϕ_R are the molality and osmotic coefficient, respectively, of the reference potassium chloride solution which is in vapor pressure equilibrium with a ternary solution containing solutes 1 and 2 at molalities m_1 and m_2.

The value of Δ/m_1m_2 is given by the equations

$$\Delta/m_1m_2 = \sum_{i=0}^{n}\sum_{j=0}^{n} A_{ij}m_1^i m_2^j \qquad (n=i+j=2 \text{ or } 3) \quad (2)$$

From Eqs. 1 and 2, the activity coefficient for solute 1 in the ternary solution is given[11,12] by

$$\ln \gamma_1 = \ln \gamma_{10} + A_{00}m_2 + A_{10}m_1m_2 + \frac{1}{2}A_{01}m_2^2 + A_{20}m_1^2m_2 + \frac{2}{3}A_{11}m_1m_2^2 + \frac{1}{3}A_{02}m_2^3 + A_{30}m_1^3m_2 + \frac{3}{4}A_{21}m_1^2m_2^2 + \frac{1}{2}A_{12}m_1m_2^3 + \frac{1}{4}A_{03}m_2^4 , \quad (3)$$

and that of solute 2 by

$$\ln \gamma_2 = \ln \gamma_{20} + A_{00}m_1 + \frac{1}{2}A_{10}m_1^2 + A_{01}m_1m_2 + \frac{1}{3}A_{20}m_1^3 + \frac{2}{3}A_{11}m_1^2m_2 + A_{02}m_1m_2^2 + \frac{1}{4}A_{30}m_1^4 + \frac{1}{2}A_{21}m_1^3m_2 + \frac{3}{4}A_{12}m_1^2m_2^2 + A_{03}m_1m_2^3 , \quad (4)$$

where γ_1 and γ_2 are the molal activity coefficients of solutes

a) Calculated by the least-squares treatment of Eq. 20 and Table 2. b) Percentage error defined by Kelly *et al.*[16]

1 and 2 in a ternary solution containing solutes 1 and 2 with molalities m_1 and m_2, respectively; γ_{10} and γ_{20} are the molal activity coefficients, respectively, of binary solutions containing only solute 1 at molality m_1 or solute 2 at molality m_2. The values of osmotic and activity coefficients for reference potassium chloride solutions were taken from the values given by Robinson and Stokes.[13] The values of osmotic and activity coefficients for glygly and αABA solutions were taken from the data of Ellerton *et al.*,[14] and the values for sucrose solutions, from Robinson and Stokes.[15]

Results

The equilibrium molalities of solute 1 and 2 in ternary solutions and of potassium chloride in reference solutions for the systems, glygly–sucrose–water

and αABA–sucrose–water, are given in Table 1, together with the values of experimental quantities Δ/m_1m_2 defined by Eq. 1. In order to fit the experimental values of Δ/m_1m_2 to a power series in m_1 and m_2 with the form of Eq. 2, two polynomials involving terms up to squares or cubes in m_1 and m_2 were examined with a HITAC 8450 computer. In both systems, the better polynomials for representing the data are equations containing terms up to cubic. Their coefficients are given in Table 2.

From Eqs. 3 and 4 and Table 2, we obtain

$$\ln\gamma_1 = \ln\gamma_{10} - 0.077385m_2 + 0.034859m_1m_2 + 0.052662m_2^2 + 0.050339m_1^2m_2 - 0.021846m_1m_2^2 - 0.010044m_2^3 - 0.026230m_1^3m_2 + 0.000949m_1^2m_2^2 + 0.002549m_1m_2^3 + 0.000662m_2^4, \quad (5)$$

$$\ln\gamma_2 = \ln\gamma_{20} - 0.077385m_1 + 0.017429m_1^2 + 0.10532m_1m_2 + 0.016780m_1^3 - 0.021846m_1^2m_2 - 0.030133m_1m_2^2 - 0.006557m_1^4 + 0.000633m_1^3m_2 + 0.003824m_1^2m_2^2 + 0.002647m_1m_2^3, \quad (6)$$

for the system glygly–sucrose–water, and

$$\ln\gamma_1 = \ln\gamma_{10} + 0.13170m_2 - 0.20566m_1m_2 - 0.007944m_2^2 + 0.18176m_1^2m_2 + 0.014106m_1m_2^2 + 0.0016439m_2^3 - 0.046886m_1^3m_2 - 0.010024m_1^2m_2^2 + 0.000334m_1m_2^3 - 0.000253m_2^4, \quad (7)$$

$$\ln\gamma_2 = \ln\gamma_{20} + 0.13170m_1 - 0.10283m_1^2 - 0.015888m_1m_2 + 0.060588m_1^3 + 0.014106m_1^2m_2 + 0.004932m_1m_2^2 - 0.011721m_1^4 - 0.006683m_1^3m_2 + 0.000501m_1^2m_2^2 - 0.001012m_1m_2^3, \quad (8)$$

for the system αABA–sucrose–water.

The activity coefficients of glygly in binary solution and in ternary solutions containing several concentrations of sucrose are given in Fig. 1 and the activity coefficients of αABA in binary and in ternary solutions in Fig. 2. The activity coefficients of glygly and αABA increase with the concentration of sucrose. At lower concentrations, however, sucrose has a different effect on the activity coefficients of glygly and αABA. As shown in Fig. 1, when sucrose concentration is lower than 2 mol kg^{-1} glygly is salted-in by sucrose, but at higher concentrations of both glygly (>1 mol kg^{-1}) and sucrose (>2 mol kg^{-1}) sating-out predominates. The activity coefficient of αABA increases for all the concentrations studied, the increasing effect being greater at lower concentration of αABA.

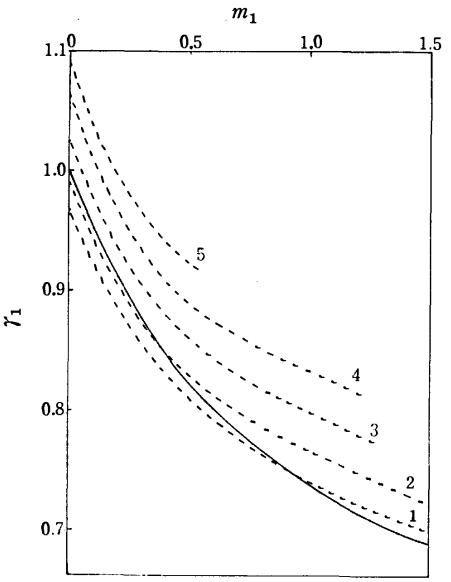

Fig. 1. Activity coefficients of glycylglycine in sucrose solutions: ——, in water; ----, in sucrose solutions at several concentrations of sucrose. The concentrations of sucrose (mol kg^{-1}): 1, 1.0; 2, 2.0; 3, 3.0; 4, 4.0; 5, 5.0.

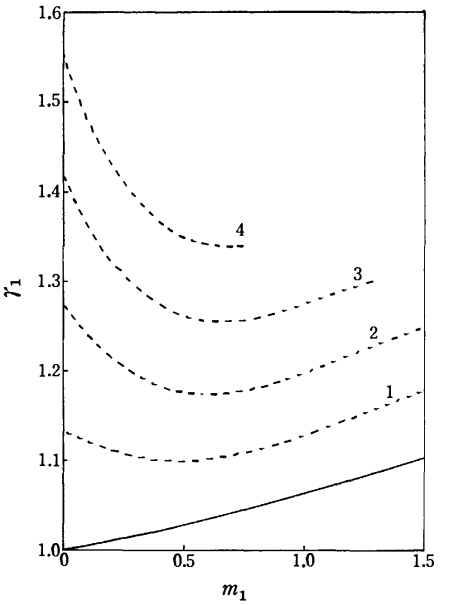

Fig. 2. Activity coefficients of α-aminobutyric acid in sucroes solutions: ——, in water; ----, in sucrose solutions at several concentrations of sucrose. The concentrations of sucrose (mol kg^{-1}): 1, 1.0; 2, 2.0; 3, 3.0; 4, 4.0.

Discussion

From the isopiestic data, the excess free energy of mixing per kilogram of solvent, $\Delta_m G_w^{ex}$, can be calculated. $\Delta_m G_w^{ex}$ for a mixture of two solutions of non-electrolytes A (concentration m_1) and B (m_2) is given

TABLE 3. FREE ENERGY EFFECTS OF PAIRWISE AND TRIPLET INTERACTIONS

A	B	$\{AB\}_g$[a] J mol^{-2} kg	$\{AAB\}_g$ J mol^{-3} kg^2	$\{ABB\}_g$ J mol^{-3} kg^2
α-Aminobutyric acid	Sucrose	160	−85	−6.6
Glycylglycine	Sucrose	−96	14	44
α-Aminobutyric acid	Urea	−54[b]	0.13	2.1
Glycylglycine	Urea	−123[b]	41	4.0
Sucrose	Urea	−155	7.5	6.2

a) $\{AB\}_g$ is $(2.303RT)$ times the "limiting interaction coefficients" which is defined by Schrier and Robinson[19] as a measure of the mutual interaction of the solutes (and the solvent) free of the contribution from concentration dependent terms. b) Lilley and Scott[20] obtained the values, −35 and −119 (J mol^{-2} kg), for αABA–urea and glygly–urea, respectively.

by Cassel and Wood[17] as follows:

$$\Delta_m G_w^{ex}/RT = (m_1+m_2)\phi_{mix} - m_1\phi_1 - m_2\phi_2 = [2\{AB\}_g m_1 m_2 + 6\{AAB\}_g m_1^2 m_2 + 6\{ABB\}_g m_1 m_2^2 + \cdots]/RT, \quad (9)$$

where ϕ_{mix} is the osmotic coefficient of a ternary solution, the species in brackets denoting the particles interacting, and subscript g the free energy of interaction. The values of the pairwise and triplet interactions calculated by Eq. 9 are given in Table 3, together with values for the systems αABA–urea–water,[18] glygly–urea–water,[9] and sucrose–urea–water.[12] Using an expression[17] similar to Eq. 9 and the data for binary solutions, the pairwise interactions for binary solutions of αABA,[14] glygly,[14] sucrose[15] and urea[12] are calculated to be 62, −660, 180 and −110 (J mol^{-2}kg), respectively.

Pairwise and triplet interactions formally depend only on the solute species, but they are affected by the interactions with the solvent water as Schrier and Robinson[19] pointed out.

It is interesting to classify the pairwise interactions by the effect of these solutes on water structure. Walrafen[21] showed from Raman spectral measurements that sucrose has a structure promoting effect on water. Taylor and Rowlinson[22] measured the heat of dilution of sucrose in water and concluded that strong hydrogen bonding exists between sucrose and surrounding water molecules. The self diffusion coefficients of water in aqueous solutions of glygly and αABA were measured at 25—50 °C by Altunina *et al.*[23] Glygly and αABA decrease the activation energy of self diffusion of water. On the other hand, the structure-making solutes cause the water near them to be more ice-like than normal; the melting of such a structure requires greater energy with the result that such solutes give rise to positive excess partial molal heat capacities.[24,25] Spink and Wadsö[26] measured the heat capacities of solid αABA and aqueous solution of the amino acid at 25 °C and also enthalpies of solution at several temperatures. By both direct and indirect measurements they determined the partial molal heat capacity, $\bar{C}^\circ_{p,2}$ and excess partial molal heat capacity, ΔC°_p, of αABA, 222—226 and 76—80 (J k^{-1}mol^{-1}), respectively. The corresponding values for glygly which are determined from the data of heat capacity of solid,[27] and of aqueous solutions[28] are 159 and −4.6 (J k^{-1}mol^{-1}) for $\bar{C}^\circ_{p,2}$, and ΔC°_p, respectively. The NMR and calorimetric data for αABA are not consistent as to the effect on the water structure, probably because αABA is near the borderline of the structure-making and structure-breaking solutes. We believe, however, that the precise calorimetric results by Spink and Wadsö are more reliable and thus, αABA is considered to be a weak structure maker. Many papers have appeared on the effect of urea on water structure, but it is generally accepted that urea behaves as a structure breaker.[29]

Thus, αABA and sucrose are ranked as structure makers (positive hydration) and glygly and urea as structure breakers (negative hydration). From Table 3, it is seen that the pairwise interactions between the two structure making solutes are positive (αABA+sucrose, sucrose+sucrose and αABA+αABA), and the interactions between the two structure breaking solutes are negative (glygly+urea, glygly+glygly and urea+urea). For the systems containing structure-making and structure-breaking solutes (sucrose+urea, glygly+sucrose and αABA+urea), the interactions are negative. The triplet interactions have signs opposite to the pairwise interactions between unlike solutes in the same systems.

The nature of the structure-making effect of hydrophylic sucrose on water structure differs from that of αABA having hydrophobic ethyl group, and the structure-breaking effects of glygly and urea are not the same. In spite of these differences, the signs of excess pairwise interactions entirely depend on the above classification by the effect on water structure.

In order to obtain the concentration dependency of the interaction quantitatively, the free energy of the transfer is calculated. The activity coefficients of the amino acids in sucrose solutions measured by the isopiestic method are referred to unity in the standard state in water, and not to the standard state in a water–sucrose solvent.[30] Thus the free energy of transfer at constant concentration of the solute is calculated from the change in activity coefficients. Consequently, the free energy of transfer, ΔG_t, of solute 1 from water to sucrose solution is given by[31]

$$\Delta G_t = RT \ln (f_1/f_{10}), \quad (10)$$

where f_{10} and f_1 are the activity coefficients in mole fraction scale of solute 1 in binary and ternary sucrose solutions, respectively, both at the same mole fraction; f_1 and f_{10} are defined as before.[31]

The values of ΔG_t of glygly and αABA from water to various concentrations of sucrose solutions are given

Table 4. Free energy of transfer (in J mol) of glycylglycine and α-aminobutyric acid from water to sucrose solutions

m_{10}[a]	m_2 0.5	1.0	2.0	3.0	4.0	5.0

1.0	13.5	54.4	178	318	462	
1.5	30.2	76.7	188	297		
			α-Aminobutyric acid			
0	181	354	686	992	1260	
0.2	140	275	536	791	1020	
0.5	106	210	418	632	837	
1.0	97.5	194	388	590		
1.5	111	215	402			

a) The molality of solute 1 in a binary solution. The molalities in ternary solutions are slightly greater than m_{10} as the transfer is made at constant mole fraction.[31]

in Table 4. At higher concentrations of sucrose (>2 m), ΔG_t of both glygly and αABA increases with increasing concentration of sucrose, the increasing effect on αABA being much larger than that on glygly. The values of ΔG_t depend differently on the concentration of the amino acids. ΔG_t increases with increasing concentration of glygly and with decreasing concentration of αABA. At lower concentrations ($m_{10}<1.0$ and $m_2<2.0$), the sucrose solution is a more favorable solvent than water for glygly. The results indicate that the sucrose solution environment is much more unforable than water for αABA having an alkyl side chain as compared with glygly which has no side chain. It would require much more work for alkyl groups in the interior of the protein to be exposed in the sucrose solution than in water, they would thus be caused by the sucrose solution to enter into the interior of protein, as Lakshimi and Nandi[8] reported for amino acids with aromatic side chain.

The denaturing process can be considered to involve a dilution process of local concentrations of amino acid residues in a protein. The dilution process of a solute is accompanied by the decrease of its chemical potential since the term $RT \ln \gamma_1 m_1$ decreases with dilution. While γ_1 of glygly in a sucrose sloution increases with decreasing concentration more solwly than in water, γ_1 of αABA increases with decreasing concentration at a concentration lower than 0.5 mol kg^{-1} even though γ_{10} decreases with decreasing concentration. (Fig. 1 and 2).

Klotz[32] obtained values for the average molar local concentrations of peptide and low apolar residues (Ala +Val+Ileu+Phe) whihin molecular volume of proteins (insurine, ribonuclease, ovalbumin and bovin serum albumin) to be 12—13 M and 3—4 M, respectively. Though the concentration range of the present work is lower than the values estimated by Klotz, and it is difficult to determine the real local concentration of amino acid residues at the surface of the protein molecules, the results suggest that the decrease in chemical potential with denaturing (dilution) process is less in sucrose solutions than in water for apolar residues. When denaturant molecules cause the loosening of the globular structure of the protein resulting in a contact of the interior hydrophobic side chains to solutions, the decrease in chemical potential with the subsequent extending process would become less in sucrose+denaturant solution than in denaturant solution. This would also result in more stability of a protein molecule in a sucrose solution and would reduce the extent of denaturation of protein molecule induced thermally or by denaturants.

The results with glygly suggest that the interaction of sucrose on peptide group is somewhat complicated. A sucrose solution is a favorable solvent for glygly at low concentration of sucrose, becoming unfavorable at higher concentration. Shifrin and Parrott[7] have demonstrated that low concentrations of polyhydric alcohols (including glucose and sucrose) accelerate the rate of dissociation of tetrameric L-asparaginase by urea, and higher concentrations of polyols protect the enzyme against the dissociating effect of urea. The change in the effect of polyols on the protein with concentration might be related to the switch from salting-in to salting-out of glygly by sucrose with increase in sucrose concentration.

The author wishes to thank Dr. Hisashi Uedaira for his valuable discussions.

Dynamic Structure of Water in Aqueous Solutions of Chloroacetate. I. Temperature Dependence of Limiting Mobilities of Mono-, Di-, and Tri-chloroacetate Ions

Satoshi EBINA and Hisashi UEDAIRA*

Central Research Laboratory, Fukushima Medical College, Sugitsuma-cho 65, Fukushima 960

**Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221*

(Received December 24, 1976)

Electric conductivities of the sodium salts of mono-, di-, and tri-chloroacetic acids were measured in water at 15, 25, and 35 °C. The molar conductivities were analyzed by the Fuoss-Onsager equation to obtain the limiting mobility. On the basis of the temperature dependence of the limiting mobilities, the dynamic structure of water around these anions was investigated by means of Samoilov's theory. Chloroacetate ions are structure maker and the degree of the positive hydration is in the order TCA^- > acetate ion > DCA^- > MCA^-. From the results, it is shown that a competition between the different orientation of water molecules in the surroundings of $-CH_2Cl$ and $-CHCl_2$ groups occurs, and consequently, shown that the water molecules around DCA^- and MCA^- ions more mobile than those around TCA^- and acetate ions.

There have been many investigations on the hydration of aqueous solutions of organic electrolytes. The particular interest in the hydration is related to the interactions between water and the hydrophobic or ionized groups of these electrolytes.

The study of aqueous solutions of halogenized organic compounds is important from both theoretical and biochemical point of view. For example, trifluoroacetic and trichloroacetic acids cause denaturation of proteins and nucleic acids. The systematic investigations, however, have been scarecely made.

Robinson and Jencks[1] determined the activity coefficient of acetyltetraglycine ethyl ester in the presence of various organic electrolytes. According to their results, trichloroacetate ion behaves as the structure breaker in contrast to acetate ion. On the other hand, Engel and Hertz[2] showed that the trichloroacetate ion is structure maker by means of the measurement of proton relaxation rates in aqueous solutions of the various electrolytes. Recently, we have measured the turbidity of several proteins in aqueous solutions by some aromatic sulfonic acids and trichloroacetic acid.[3] Only trichloroacetic acid gave a common profile for all of the proteins examined, *i. e.*, the turbidity of protein solutions increases abruptly with increasing the concentration of trichloroacetic acid, and above 0.5 mol dm^{-3} of trichloroacetic acid goes through a maximum. The values of maximum turbidity are similar for all of the protein solutions.

It is thought that the peculiar interaction between trichloroacetic acid and protein may be related to the nature of hydration of the precipitant. But on the hydration of trichloroacetate ion the above mentioned contradictory results are obtained. In a series of our studies of the effects of organic electrolytes on the dynamic structure of water, it was shown that the water structure around organic ions is affected by the individual interactions between water and the ionized, hydrophobic, or hydrophilic groups.[4-7] From this point of view, in order to examine the interaction between trichloroacetate ion and water, we present here the electric conductivities of the sodium salts of mono-, di-, and trichloroacetate in water at 15, 25, and 35 °C. The dynamic structure of water around these anions are discussed on the basis of Samoilov's theory.[8]

Experimental

Monochloroacetic and trichloroacetic acids (G. R., Wako Pure Chemicals) without further purification were neutralized with NaOH (G. R., Wako Pure Chemicals). Dichloroacetic acid (E. P., Wako Pure Chemicals) was once distilled before neutralization with NaOH. These sodium salts (NaMCA, NaDCA, and NaTCA) were recrystallized five times from ethanol for NaMCA, and from ethanol-water for NaDCA and NaTCA, and dried at 55 °C *in vacuo* over phosphorus pentoxide.

Water was deionized, glass-distilled, and the electrolytic conductivity of water was about $1 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ at 25 °C. All the solutions were prepared by weighing and all the weights were corrected to those in vacuum. The molar concentrations of these solutions were calculated from solution densities. Electric conductivities of all the solutions were measured at 15, 25, and 35±0.001 °C. The procedure of the measurements of the conductivity and density are described elesewhere.[9]

Results and Discussion

The molar conductivities of NaMCA, NaDCA, and NaTCA in water at 15, 25, and 35 °C are given in Tables 1, 2, and 3, respectively. The limiting molar conductivities of salts, Λ°, were determined by the Fuoss-Onsager equation,[10]

$$\Lambda = \Lambda^\circ - S\sqrt{c} + Ec\log c + Jc, \quad (1)$$

where c is a molar concentration and the other symbols are defined in Ref. 10. The plots of molar conductivities *vs.* $c^{1/2}$ at 25 °C are shown in Fig. 1, where the solid lines were calculated from Eq. 1.

The $\lambda_+^\circ(Na^+)$ used to calculate λ_-° from the Kohlraush rule were obtained from the literature.[11] The temperature dependence of λ_-° for MCA^-, DCA^-, and TCA^- ions are shown in Fig. 2.

According to Samoilov,[8,12] the dynamic structure of water around an ion is described by the quantities τ_1/τ_0 and ΔE_1, and the following relation approximately holds between these quantities:

$$\tau_1/\tau_0 = \exp(\Delta E_1/RT), \quad (2)$$

where τ_1 and τ_0 are the mean residence times of a water molecule in the immediate neighbourhood of the ion in an aqueous solution and in the immediate vicinity of a water molecule in pure water, respectively. ΔE_1 is the difference of the activation energies for the removal of a water molecule from the immediate neighbourhoods of the ion and the water molecule.

The value of ΔE_1 is obtained from the temperature dependence of the limiting mobility of the ion. One of the authors (H. U.) together with Uedaira[4] obtained the following equation for organic ions and molecules by extending the Samoilov's equation,[8] which holds

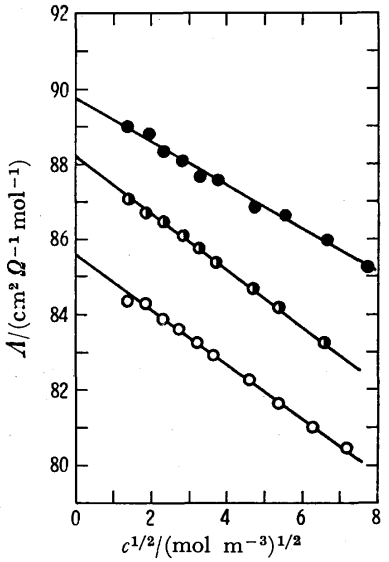

Fig. 1. Electric conductivities of NaMCA, NaDCA, and NaTCA in water at 25 °C.
—●— NaMCA, —◑— NaDCA, —○— NaTCA.

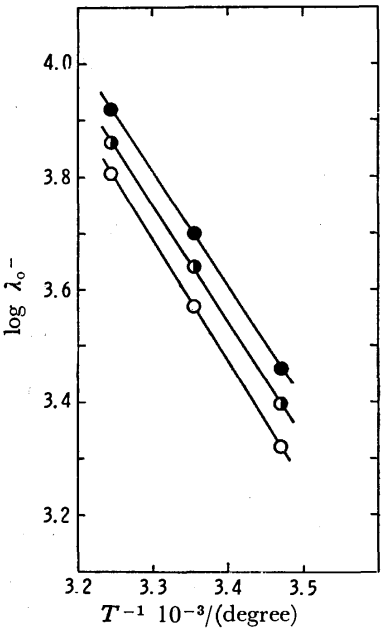

Fig. 2. Temperature dependence of limiting mobilities of MCA⁻, DCA⁻, and TCA⁻ ions.

for inorganic ions;

$$\frac{1}{\lambda_-^\circ}\frac{d\lambda_-^\circ}{dT}+\frac{1}{T}-\frac{1}{D_w}\frac{dD_w}{dT}=\frac{\Delta E_1}{RT^2}, \qquad (3)$$

where D_w is the self-diffusion coefficient of pure water. ΔE_1 consists of two terms,

$$\Delta E_1=\Delta E_1+\Delta E_2, \qquad (4)$$

where ΔE_1 and ΔE_2 represent the effects of the ionized and the hydrophobic groups on the thermal motion of water molecule around the organic ion, respectively. In general, ΔE_2 represents the effect of any group except the ionized group.

Table 4. The values of ΔE_1 and τ_1/τ_o for mono-, di-, and trichloroacetate ions at 25 °C

Ions	$r(10^{-10}\ m)$	$\Delta E_1(J/mol)$	τ_1/τ_o
MCA⁻	2.41	285	1.12
DCA⁻	2.54	582	1.26
TCA⁻	2.67	1247	1.65

From the results of Fig. 2 and the self-diffusion coefficient of water,[13] the values of ΔE_1 and τ_1/τ_o for MCA⁻, DCA⁻, and TCA⁻ ions at 25 °C were calculated by the Eqs. 2 and 3. The calculated results and the ionic radii estimated by the Pauling model[14] are presented in Table 4. The values of ΔE_1 and τ_1/τ_o for MCA⁻, DCA⁻, TCA⁻, and acetate ions[4] are shown in Fig. 3 as a function of the ionic radius.

It is seen from Table 4 that the residence times of a water molecule around MCA⁻, DCA⁻, and TCA⁻ ions are larger than that in pure water. That is to say, these anions are structure maker, and the structure making effect increases with an increase in the number of the chlorine atom.

As the result of the molecular motion, a water molecule change very rapidly its position and the momentary configurations between individual molecules. If the residence time of a water molecule in the hydration sphere of an ion is longer than that in pure water, also its reorientational time in the hydration sphere is longer than that in pure water. Hertz and Zeidler[15] showed that the residence time of the water molecule in the hydration sphere, τ_1, must be approximately equal to the reorientational correlation time. This concept was confirmed in the case of inorganic[16] and organic ions.[4] Engel and Hertz[2] obtained the value of 1.7, as the ratio of the reorientational correlation time in the hydration sphere to that in pure water

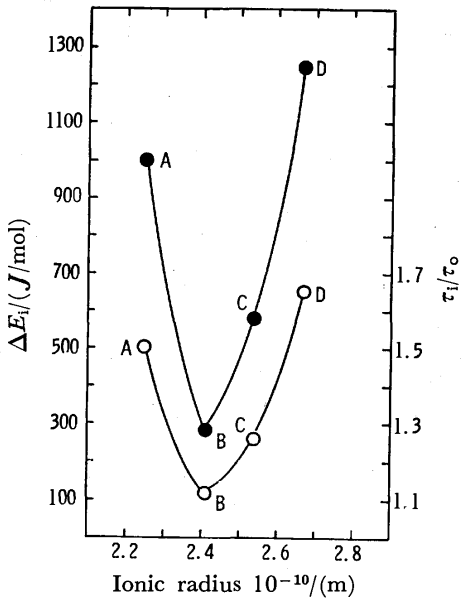

Fig. 3. The values of ΔE_1 and τ_1/τ_o of acetate, MCA⁻, DCA⁻, and TCA⁻ ions.

for TCA^- ion at 25 °C. Their result coincides very good with the result of Table 4.

From Fig. 3 one sees that ΔE_1 and τ_1/τ_0 for acetate ion are larger than those for MCA^- and DCA^- ions. Since ΔE_1 and τ_1/τ_0 are the characteristic quantities of the hydration at infinite dilution, the difference in ΔE_1 among acetate and chloroacetate ions is attributed to the difference in ΔE_2 in Eq. 4. Consequently, the thermal motion of the water molecule around $-CH_3$ group is slower than those around $-CH_2Cl$ and $-CHCl_2$ groups.

The possible explanation for this result is made as follows. At present, it is not yet clear what kind of water structure is formed around the alkyl groups in water. According to Wen,[17] there are two possibilities: ice-like and gashydrate-like types. The water molecule in the vicinity of the chlorine atom of MCA^-, DCA^-, and TCA^- ions may turn its proton preferentially towards the chlorine atom during the residence in the hydration sphere. This orientation is different from that of the water molecule around $-CH_3$ group. In the surroundings of $-CH_2Cl$ and $-CHCl_2$ groups, therefore, a competition between the different orientatins of water molecules occurs, and on account of this competitive action the water structure around these two groups may be in a state more disturbed than those around $-CH_3$ and $-CCl_3$ groups. As a result, the thermal motion of the water molecules around $-CH_2Cl$ and $-CHCl_2$ groups are faster than those around $-CH_3$ and $-CCl_3$ groups. Taking account of the fact that ΔE_1 of TCA^- ion is larger than that of acetate ion, the thermal motion of water molecule around $-CH_2Cl$ group is most vigorous (see Fig. 3).

If TCA^- ion and a compound with the hydrophobic group coexist in an aqueous solution, the water structure around the hydrophobic group may be disturbed by $-CCl_3$ group. That is, TCA^- ion behaves like a structure breaker and the hydrophobic compound is salted-in by TCA^- ion. The result of Robinson and Jencks[1] is accounted in this manner.

Both TCA^- and acetate ions are structure maker, but the water structure around them is very different from each other. Probably, the chlorine atom does not from the hydrogen bond with the water molecule, taking account of the values of τ_1/τ_0. Actually, Walrafen[18] found no evidence of the presence of the hydrogen bond between the water molecule and the chlorine atom by the measurement of Raman spectra of aqueous solution of NaTCA.

It is interesting to compare the dynamic structure of water around the chloro and methyl substituent groups of the protons in the methyl group of an acetate ion, since the van der Waals volume of the chlorine atom is equal to that of the methyl group. The limiting mobility is inversely proportional to both the ionic radius and the microviscosity of water around the ion, which depends on the water structure.[19] MCA^-, DCA^-, and TCA^- ions have the same volumes as propionate, isobutyrate, and trimethyl acetate ions, respectively. Therefore, the difference of the limiting mobilities of the ions can be ascribed in the difference in water structure around the ions. The limiting mobilities of propionate, isobutyrate, and trimethyl acetate ions at 25 °C are 35.82,[20] 24, and 23[4] Ω^{-1} cm^2 mol^{-1}, respectively.

From the values of the limiting mobilities, it is found that the microviscosities of water around MCA^-, DCA^-, and TCA^- ions are smaller than those around the corresponding methyl substituents of the acetate ion. Thus, the degree of the structure making effect of the chloroacetate ions is lower than that of the corresponding methyl substituents. Recently, we found that the degree of hydrophobic hydration of isobutyrate and trimethyl acetate ions is very strong.[4] These results support the existence of the competition between the different orientations of water molecules around $-CH_2Cl$ and $-CHCl_2$ groups.

The authors wish to acknowledge the helpful discussions and criticisms extended by Dr. Hatsuho Uedaira.

(Received January 21, 1977)

The rotational constants of 1-silabicyclo[2.2.1]heptane in the ground vibrational state were determined to be A_0=2744.775 (2) MHz, B_0=2662.017 (2) MHz, and C_0=2145.994 (2) MHz, with the standard deviations in parentheses. Because the spectrum was very rich, the Stark effects of two transitions were analyzed by a simulation technique. The dipole moments thus obtained are μ_b=0.5±0.1 D, μ_c=0.05±0.01 D, and μ_t=0.5±0.1 D. The observed spectra did not exhibit any anomalies which were due to deviations of the molecular symmetry from C_s. Three structural parameters, Si–C(7), ∠C(2)–Si–C(6), and ∠Si–C(2)–C(3), were adjusted so as to reproduce the rotational constants observed for the ground state. The Si–C(7) bond was found to be longer than Si–C(2) by 0.07 Å. Two vibrational satellites were detected and were assigned to the v=1 and the v=2 states of a torsional mode of the skeleton. A relative-intensity measurement resulted in the excitation energies of 70±25 cm^{-1} and 160±60 cm^{-1} for v=1 and v=2, respectively. The molecular structure and the internal motions were discussed in terms of intramolecular forces.

Bicyclic compounds are often characterized by highly strained structures of their skeletons, which involve three-, four-, and/or five-membered rings in most cases. Because two or more such rings are condensed to constitute the skeleton of a bicyclic molecule, new aspects are often introduced in the resultant structure. Bicyclo[2.2.2]octane, for example, has cyclohexane rings as constituents, and may thus be free from the strain of the valence angles. However the cyclohexane rings are forced to be of the boat form in the bicyclo[2.2.2]-octane molecule, rather than of the more stable chair form. The conformation about the three C–C bonds is thus eclipsed, provided that the molecular symmetry is D_{3h}. We might, however, expect additional lowering in energy by twisting slightly the skeleton about the symmetry axis. In fact, we have shown in our previons papers[3,4] that simple derivatives of bicyclo[2.2.2]-octane have a double-minimum potential function to the torsion of the skeleton and the height of the potential barrier which is sensitive to the substituents is explained by balance of two forces due to the valence-angle strain and to the internal-rotation potential.

Bicyclo[2.2.1]heptane or norbornane is obtained by replacing one of the three ethylene bridges by a methylene bridge. We have thus here two C–C bonds with unstable conformation. Furthermore, the methylene bridge which is introduced will cause considerable strain in the molecular skeleton. These two facts will thus favor the C_{2v} symmetry much higher than C_2 or the twisted form. In fact, electron-diffraction data on norbornane[5] are consistent with C_{2v}. Unfortunately this molecule has too small dipole moment to observe its microwave spectrum. In the present work we investigated the 1-silabicyclo[2.2.1]heptane molecule by microwave spectroscopy.

Experimental

A sample of 1-silabicyclo[2.2.1]heptane was prepared by a procedure described in Ref. 6. It is a white crystalline solid with mp of 75 °C. Because this compound sublimes easily, the sample was purified by sublimation before use. However, the vapor pressure permitted observation of the microwave spectrum only at room temperature or higher. The microwave spectrometer which was used was of conventional Stark-modulation type with a 110 kHz sine-wave or square-wave oscillator as a modulator.

Rotational Spectra

By transferring appropriate structure parameters from norbornane,[5] dimethylsilane,[7] and trimethylsilane[8] we calculated the rotational constants of 1-silabicyclo-[2.2.1]heptane on an assumption of C_s symmetry. Bond-moment consideration indicated that the b component of the dipole moment was much larger than the c component, while the a component was zero because of symmetry (see Fig. 1, where the heavy atoms are given numbers for identification).

We first searched the spectra in the 20—30 GHz region. We observed a number of lines with nearly first-order Stark effects, which we subsequently assigned to the b-type Q-branches of high J and high K_{+1}. Figure 2 shows a portion of the observed spectra, which are assigned to K_{+1}=20←21. Because the members of the series are weak in the limit of $J \cong K_{+1}$, it is difficult to determine the J numbers unambiguously. We therefore searched the b-type R branches in higher-frequency region, where the R branches

a) J', $K_{+1}'-J''$, K_{+1}'' for the degenerate transitions and J', K_{-1}' $K_{+1}'-J''$, K_{-1}'', K_{+1}'' for the non-degenerate transitions. b) Obsd−Calcd. The calculated frequencies are obtained using the constants listed in Table 2.

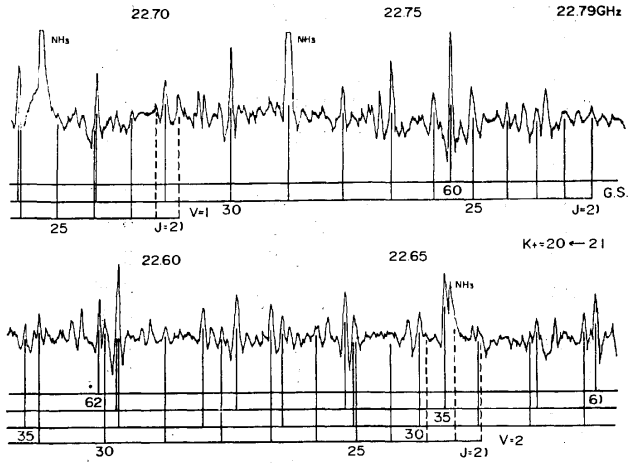

Fig. 2. A part of the *b*-type *Q*-branch spectra of 1-silabicyclo[2.2.1]heptane, recorded at room temperature with the AC modulation field of 20—40 V/cm superposed on the DC Stark field of 160—200 V/cm and with the time constant of 0.4 s.

were stronger than the *Q* branches. The *R* branches of $K_{+1}\cong J$ were degenerate and showed the first-order Stark effects. We observed peculiar lineshapes for transitions with small *K*-type splittings, that is, stronger Stark components between weaker zero-field doublets. This is due to Stark mixing of the *K* doublets, which induces forbidden transitions at finite Stark fields. Table 1 lists the observed frequencies of the assigned transitions, which we analyzed by a least-squares method taking into account the centrifugal distortion effects to the first order. In addition to those given in Table 1 we also observed the following transitions, but did not include them in a least-squares analysis; *Q* branches of $K_{+1}=19\leftarrow20$, $J=29$—44, of $K_{+1}=20\leftarrow21$, $J=42$—62, of $K_{+1}=21\leftarrow22$, $J=36$—67, of $K_{+1}=22\leftarrow23$, $J=36$—71, of $K_{+1}=23\leftarrow24$, $J=48$—75, of $K_{+1}=27\leftarrow28$, $J=29$—32, of $K_{+1}=52\leftarrow53$, $J=54$—83, of $K_{+1}=54\leftarrow55$, $J=66$—80, and of $K_{+1}=55\leftarrow56$, $J=57$—83, and four *R* branches, $5_{24}\leftarrow4_{13}$, $5_{14}\leftarrow4_{23}$, $5_{05}\leftarrow4_{14}$, and $5_{15}\leftarrow4_{04}$ (the latter two are degenerate). Table 2 lists the rotational constants and the centrifugal distortion constants which are thus derived. We set arbitrarily the τ_{aabb} constant to be zero. The transition frequencies which are calculated using the constants of Table 2 are compared with the observed frequencies in Table 1.

a) Values in parentheses denote the standard deviations and apply to the last digits of the constants. The τ_{aabb} constant is fixed to zero.

In addition to the ground-state spectra we observed two prominent sets of the vibrational satellites. Based on the frequency shifts from the ground-state spectra and on the relative intensities, which are observed, we assigned these two to the first and the second excited states of the lowest normal mode, probably the skeletal torsion. We listed the observed transitions in Table 3, and the rotational constants and the centrifugal distortion constants, which were derived by a least-

squares analysis, in Table 2. Although we included only the observed lines of $J\leqq48$ in a least-squares analysis, we measured additional lines which were mainly high J and K_{+1} transitions as in the case of the ground state. The intensities of the satellites were compared with those of the ground-state spectra at room temperature, as shown in Table 4. We thus determined the excitation energies to be 70±25 cm^{-1} and 160±60 cm^{-1} for $v=1$ and $v=2$, respectively. We did not observe any anomalies in the rotational spectra, even for the vibrational satellites, which were due to deviations of the molecular symmetry from C_s.

Dipole Moment

Because the spectrum is rich and weak, it is difficult to resolve the Stark components completely. We thus analyzed the Stark effects by a simulation technique similar to that described in our previous paper.[9] We made the following assumptions: (1) the linewidths of the Stark components are the same as that of the zero-field line, (2) the Stark components have the

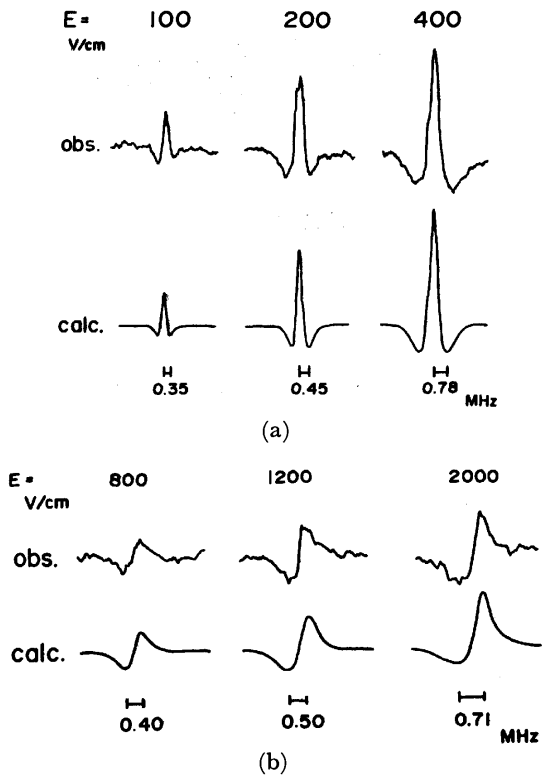

Fig. 3. Analysis of the Stark effects by a simulation method.
(a) J, $K_{+1}=13$, $13\leftarrow12$, 12. Calculated spectra are obtained using $\Delta\nu$(HWHM)=0.26 MHz and $\mu_c=0.05$ D.
(b) $J_{K_{-1},K_{+1}}=11_{11,1}\leftarrow10_{10,0}$. Calculated spectra are obtained using $\Delta\nu=0.25$ MHz, $\mu_b=0.5$ D, and $\mu_c=0.05$ D.

			∠Si-C(2)-C(3)	102.8°

a) See Fig. 1 for the atom numbers.

Lorentzian lineshape, and (3) the inhomogeneity of the Stark field may be neglected. We calibrated the Stark field using the $J=1\leftarrow0$ transition of OCS as a reference.

To determine the μ_c component we analyzed a K-degenerate transition J, $K_{+1}=13$, $13\leftarrow12$, 12. Its first-order Stark effect is determined by the μ_c component at low Stark fields. Overall fitting may be judged by two parameters, the intensity and the difference between the peak frequencies of the zero-field and of the Stark components. We obtained best fitting using the linewidth parameter $\Delta\nu$ (HWHM) of 0.26 MHz and μ_c of 0.05 D. The calculated spectrum thus obtained is compared with the observed in Fig. 3a. The error of μ_c is ±0.01 D. We determined the μ_b component from a similar analysis of the $11_{11,1}\leftarrow10_{10,0}$ transition. The two parameters which were derived are $\Delta\nu=0.25$ MHz and $\mu_b=0.5\pm0.1$ D. The total dipole moment is 0.5±0.1 D.

Molecular Structure

As stated above we did not observe any deviations of the molecular symmetry from C_s. An assumption of the C_s symmetry leaves nine parameters as independent to determine the heavy-atom skeleton. We adjusted three of the nine parameters, Si-C(7), ∠C(2)-Si-C(6), and ∠Si-C(2)-C(3), so as to reproduce the observed rotational constants, while others were fixed to the values of the related molecules.[5,7,8] Table 5 summarizes the fitted as well as the assumed parameters.

Discussion

We have recently shown[10] that the 1-silabicyclo[2.2.2]octane molecule has a double-minimum potential function to the skeletal torsion and the potential hump (212 cm^{-1}) is even higher than that (67 cm^{-1}) in 1-halogenobicyclo[2.2.2]octane.[3] The present work shows that replacement of one ethylene bridge by a methylene bridge removes the hump from the torsional potential function, and the 1-silabicyclo[2.2.1]heptane molecule actually belongs to C_s symmetry. This result is in accord with our expectation; the number of the C–C bonds with unstable *cis* conformation is decreased from three to two and the skeleton is more strained, and both factors favor the untwisted conformation. We have, however, still one silacyclohexane ring with unstable boat conformation. It may thus be easy to twist the molecular skeleton. In fact, we found that the frequency of the skeletal torsion was as low as 70 cm^{-1}. It may be interesting to compare this value with the torsional frequency of 132 cm^{-1} obtained for 7-thiabicyclo[2.2.1]heptane.[11]

We estimated only three structure parameters. The two angles, ∠C(2)-Si-C(6) and ∠Si-C(2)-C(3), may be compared with the corresponding angles, 103.5° and 104.3°, in norbornane.[5] It is interesting to note that Si–C(7) is considerably longer than Si–C(2) or the Si–C length (1.868 Å) in trimethylsilane.[8] The ∠Si-C(7)-C(4) angle is calculated to be 87.1° using the parameters of Table 5.

The dipole moment of 1-silabicyclo[2.2.1]heptane is close to that of trimethylsilane (0.525 D),[8] although methylsilane[12] and dimethylsilane[7] have the dipole moments of about 0.2 D larger.

The calculation in the present work is carried out at the Computation Center of Kyushu University.

Extraction of Nickel(II) in Aqueous Thiocyanate–Perchlorate Solutions with Trioctylphosphine Oxide in Hexane and with 4-Methyl-2-pentanone

Ryokichi MURAI, Shigehisa IWAHORI, and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received August 23, 1976)

The liquid-liquid partition of nickel(II) between hexane containing trioctylphosphine oxide or 4-methyl-2-pentanone and 1 mol dm^{-3} Na(SCN, ClO_4) solutions at 25 °C was measured. The absorption spectra of the organic and aqueous phases at equilibrium were also measured. From an analysis of these data, the extraction constant and absorption spectrum of each organic species were determined. By comparing the extraction and optical absorption of cobalt(II) complexes in the same systems with the above results for nickel(II), it was concluded that cobalt(II) thiocyanate complexes changed from octahedral to tetrahedral form upon extraction, but that nickel(II) thiocyanate complexes remained in octahedral form throughout.

It is known that cobalt(II) in thiocyanate solutions can be extracted with various oxygen-containing organic solvents. Since the extraction of cobalt(II) in these solutions is much better than that of nickel(II), this thiocyanate method has been recommended for the separation of trace amounts of cobalt(II) from large amounts of nickel(II).[1]

On the other hand, nickel(II) was found to form slightly more stable thiocyanate complexes in aqueous solutions than cobalt(II),[2] and the great difference in the extractability of these metal thiocyanates cannot be attributed to differences in the stabilities of the complexes in aqueous phase.

In order to learn further details of the thiocyanate extraction of these metal ions, solvent extraction and optical absorption measurements were made in aqueous phase for 1 mol dm^{-3} Na(SCN, ClO_4) and in organic phase for hexane containing trioctylphosphine oxide (TOPO) or for 4-metyl-2-pentanone at 25°C.

Experimental

All the reagents were of analytical grade. The TOPO was supplied by Dojindo & Co., Kumamoto. The sodium perchlorate was recrystallized three times from water.

All the distribution experiments and spectrophotometric measurements were performed in a thermostatically-controlled room at 25±0.3 °C. A portion of an aqueous 1 mol dm^{-3} Na(SCN, ClO_4) solution containing 10^{-5} to 10^{-2} mol dm^{-3} of nickel(II) or 10^{-4} to 10^{-2} mol dm^{-3} of cobalt(II) and the same volume of hexane containing TOPO or of 4-methyl-2-pentanone were placed in a stoppered glass tube and the tube was settled on a rotating frame (20 rpm). Since it was found that agitation for 2 h and for 24 h was sufficient to attain equilibrium distributions of cobalt(II) and nickel(II), respectively, agitation for the respective extractions were continued for these periods. The metal content in the organic phase was determined after back extraction into 0.1 mol dm^{-3} perchloric acid, while that in the aqueous phase was determined directly, in both cases, by the atomic absorption method. The optical absorption of the solutions was measured with a spectrophotometer (Hitachi type 139) using glass cells of 10-mm light paths.

Statistical

Throughout this paper, the subscript "org" denotes that in the organic phase while the lack of any subscript denotes that in the aqueous phase. The notation L^- represents the thiocyanate ion.

Since only the M^{2+}, ML^+, and ML_2 species are assumed to be present in the aqueous phase when extraction of higher complexes into the organic phase was possible, the following equation may be written for the distribution ratio:

$$D = ([M(ClO_4)_2]_{org} + [ML(ClO_4)]_{org} + [ML_2]_{org} + [ML_3Na]_{org} + [ML_4Na_2]_{org})([M^{2+}] + [ML^+] + [ML_2])^{-1},$$
$$= (\sum K_{ex,a}[L^-]^a[ClO_4^-]^b)(1+\beta_1[L^-]+\beta_2[L^-]^2)^{-1}, \quad (1)$$

where

$$\beta_n = [ML_n^{2-n}][M^{2+}]^{-1}[L^-]^{-n}, \quad (2)$$

$$K_{ex,a} = [ML_a(ClO_4)_bNa_c]_{org}[M^{2+}]^{-1}[L^-]^{-a}[ClO_4^-]^{-b}. \quad (3)$$

The sodium ion concentration was unity and thus the corresponding term was dropped. Here, $a+b-c=2$. Sodium ions were found in the extracted species only for $a>2$. Perchlorate ions were found only for $a<2$ and in such cases $a+b=2$.

The extraction data can be analyzed in a similar manner to that described in Ref. 3.

The optical absorption of the organic phase at a given wavelength can be written as;

$$E = \sum \varepsilon_a[ML_a(ClO_4)_bNa_c]_{org},$$
$$= \sum \varepsilon_a K_{ex,a}[M^{2+}][L^-]^a[ClO_4^-]^b, \quad (4)$$

where $0 \leq a \leq 4$. The total metal concentration in each phase was obtained by chemical analysis. The concentration of each species in each phase was calculated by Eq. 1 using these total metal concentrations and the stability and extraction constants which had been obtained from the distribution experiments. The molar extinction coefficient of the $M(ClO_4)_2$ species was obtained from an organic phase which was in contact with an aqueous solution containing no thiocyanate and those of the other metal species containing thiocyanate ions were obtained by analysis of the absorption curves of the organic phases which were in contact with aqueous thiocyanate solutions at various concentrations.

Results

Figure 1 gives the extraction curve of nickel(II) with 4-methyl-2-pentanone as a function of the thiocyanate concentration and also the curve for cobalt(II) extraction from a previous study.[4] As is seen in Fig. 1, the shape of the two curves is quite different

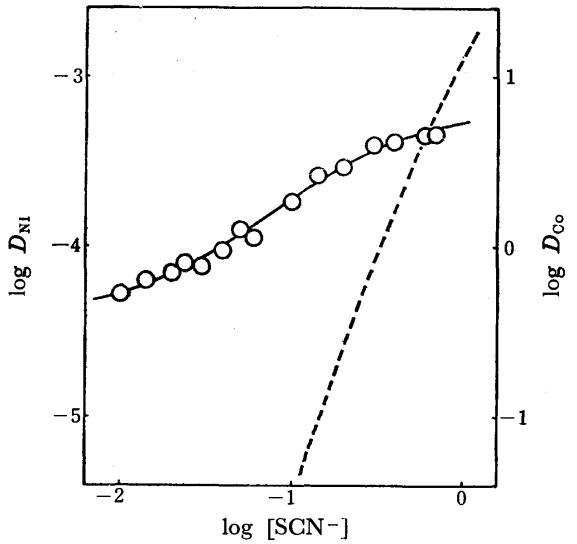

Fig. 1. Exrtaction curve of nickel(II) with 4-methyl-2-pentanone. The solid line was calculated by introducing the values in Table 1(a) and 1(b) into Eq. 1. The dotted curve is that of cobalt(II) in Ref. 4. The left ordinate is for the nickel(II) curve and the right ordinate is for the cobalt(II) curve.

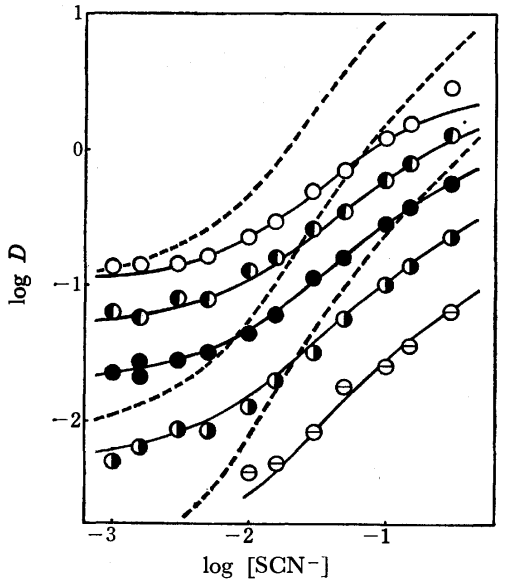

Fig. 2. Extraction curves of nickel(II) into hexane with 0.06 (○), 0.05 (◐), 0.04 (●), 0.03 (◑), and 0.02 (⊖) mol dm^{-3} of TOPO. The solid curves were calculated by introducing the values in Table 1(a) and 1(c) into Eq. 1. The dotted lines from the top to the bottom are curves of cobalt(II) into hexane with 0.04, 0.02, and 0.01 mol dm^{-3} of TOPO in Ref. 4.

and the extraction of nickel(II) is much poorer than that of cobalt(II). Figure 2 shows the extraction curves of nickel(II) with TOPO at various concentrations in hexane as a function of the thiocyanate concentration and also shows the curves for cobalt(II) from a previous study.[4] The shapes of the nickel(II) curves in this figure are similar to those of the curves of cobalt(II). However, the D values for nickel(II) are lower than those for cobalt(II), especially, in the higher thiocyanate concentration region. From an analysis of these distribution data, the extraction constants were obtained, as given in Table 1.

Table 1. Summary of equilibrium constants[a]

(a) Stability constants of aqueous thiocyanate complexes.

	$\log\beta_1$	$\log\beta_2$
Co(II)	1.00	1.32
Ni(II)	1.1	1.6

(b) Extraction constants with 4-methyl-2-pentanone.

	$\log K_{ex0}$	$\log K_{ex1}$	$\log K_{ex2}$	$\log K_{ex3}$	$\log K_{ex4}$
Co(II)	—	—	—	—	2.96
Ni(II)	−4.45	−2.66	−1.54	—	—

(c) Extraction constants with TOPO.

	$[TOPO]_{org}$	$\log K_{ex0}$	$\log K_{ex1}$	$\log K_{ex2}$	$\log K_{ex3}$
Co(II)	0.005	—	−1.00	1.10	0.49
	0.01	—	−0.43	1.80	1.48
	0.02	−2.06	−0.34	2.58	2.48
	0.04	−0.94	1.37	3.32	3.34
	0.08	0.00	2.18	4.00	—
Ni(II)	0.02	−2.62	0.63	0.66	—
	0.03	−2.36	1.10	1.24	—
	0.04	−1.72	1.30	1.64	—
	0.05	−1.18	1.43	1.90	—
	0.06	−0.84	1.58	2.20	—

a) The values in (a) were taken from Refs. 2 and 4, and the values for cobalt(II) in (b) and (c) from Ref. 4.

Table 2. Estimated solvation number of metal species for TOPO extracted into the hexane phase

	$M(ClO_4)_2$	$M(SCN)(ClO_4)$	$M(SCN)_2$	$M(SCN)_3Na$
Co(II)[a]	3	3	*ca.* 2	3
Ni(II)	4	4	3	not extracted

a) Taken from Ref. 4.

The extraction constant with TOPO for each metal species, $K_{ex,a}$, is dependent of the TOPO concentration. From the treatment described in Ref. 3, the solvation number of each species was obtained from the TOPO dependence of the constant, as listed in Table 2.

Figures 3a and 4a show the absorption curves for the organic phase obtained under the conditions described in the captions. Figures 3b and 4b show the absorbance per mole of complex for each extracted species calculated from the data in Figs. 3a and 4a using the procedures described in the statistical section. The absorption curve of cobalt(II) extracted into 4-methyl-2-pentanone has already been reported in Ref. 4(Fig. 7). This curve should be the absorption curve for the $Co(SCN)_4^{2-}$ species in 4-methyl-2-pentanone. The absorption of nickel(II) extracted into this solvent was too weak to be determined because of the low metal concentration due to poor extraction.

The absorption curves of the aqueous phases containing cobalt(II) or nickel(II) in 1 mol dm^{-3} Na(L, ClO_4) solutions were similar to those reported previously, for example (Ref. 6), the cobalt(II) solutions had an absorption peak at 510—520 nm, while the nickel(II) solutions had two peaks at 390—400 and 640—650 nm.

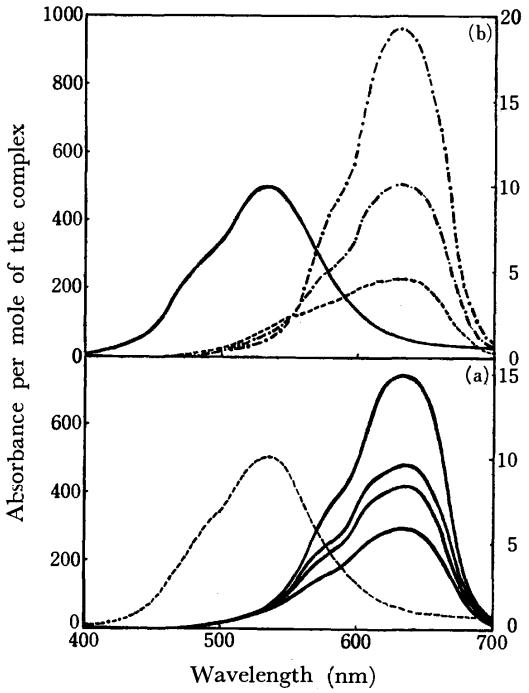

Fig. 3(a). Absorption curve of cobalt(II) extracted into hexane containing 0.04 mol dm^{-3} of TOPO from 1 mol dm^{-3} Na(SCN, ClO_4) aqueous solutions when [SCN^-] was 1, 0.1, 0.03, and 0.01 mol dm^{-3} from the top to the bottom (the absorbance per mole of the complex on the left ordinate). The dotted line is the curve when [SCN^-] was zero (the absorbance per mole of the complex on the right ordinate). Fig. 3(b). Absorption curve of $Co(ClO_4)_2$ ——, $Co(SCN)(ClO_4)$ ----, $Co(SCN)_2$ —·—·—, and $Co(SCN)_3^-$ —•—•— species combined with TOPO molecules in hexane obtained by analysis of the data in Fig. 3(a).

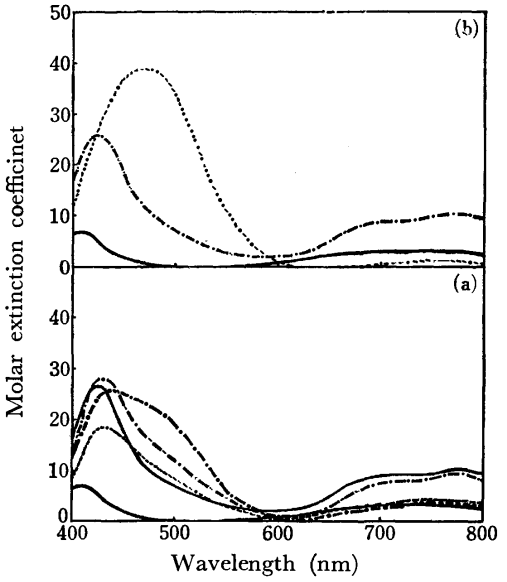

Fig. 4(a). Absorption curve of nickel(II) extracted into hexane containing 0.06 mol dm^{-3} of TOPO from 1 mol dm^{-3} Na(SCN, ClO_4) aqueous solutions when [SCN^-] was 1 ——, 0.3 —·—·—, 0.1 – – –, 0.03 —•—•—, and zero —— mol dm^{-3}. Fig. 4(b). Absorption curve of $Ni(ClO_4)_2$ ——, $Ni(SCN)(ClO_4)$ ----, and $Ni(SCN)_2$ —·—·— species combined with TOPO molecules in hexane obtained by analysis of the data in Fig. 4(a).

Discussion

It is known that cobalt(II) in aqueous solutions forms six-coordinated octahedral complexes which color the solution pink and four-coordinated tetrahedral ones which color the solution deep blue, while nickel(II) usually forms six-coordinated octahedral complexes in aqueous solutions except in some cases, such as those having chelating ligands (for example, see Ref. 6). The absorption for the aqueous phase in the present study ([L^-]<1 mol dm^{-3}), as described above, shows that both cobalt(II) and nickel(II) are present in six-coordinated octahedral form in the aqueous phase.

The absorption of the $Co(ClO_4)_2(TOPO)_3$ species in hexane, shown in Fig. 3, indicates that this cobalt(II) should also be in this form. However, it is notable that all the $CoL(ClO_4)(TOPO)_3$, $CoL_2(TOPO)_2$, $NaCoL_3(TOPO)_3$ species absorbed much more strongly and at higher wavelengths than the $Co(ClO_4)_2(TOPO)_3$ species and that all absorptions of these three thiocyanate species can usually assigned to a four-coordinated tetrahedral complex.[6] The absorption curve of the CoL_4^{2-} complex extracted into 4-methyl-2-pentanone together with two sodium ions in a previous study[4] also suggests the extraction of a four-coordinated tetrahedral species for this system.

The absorption curve of the organic phase which had extracted the $Ni(ClO_4)_2(TOPO)_4$, $NiL(ClO_4)(TOPO)_4$, and $NiL_2(TOPO)_3$ species are similar to that of the aqueous phase and thus these species in the organic phase should be of six-coordinated octahedral form.

The atom through which a thiocyanate ion coordinates with the metal ion has been discussed previously.[7] It is not possible to further discuss the position of the extractant in the coordination sphere or the details of the structure of the extracted species only on the basis of the present data. However, the extraction constants in Table 1 show that the extractabilities of the both perchlorates are similar, while the extractabilities of the other cobalt(II) thiocyanate complexes, which are assumed to be tetrahedral, are much higher than those of the other nickel(II) complexes, which are assumed to be octahedral.

An explanation for the higher extraction of the cobalt(II) tetrahedral species over that of the corresponding nickel(II) octahedral species may be that the latter accept water molecules more readily than the former and this stronger hydration hinders the extraction of the nickel(II) octahedral species more than that of the cobalt(II) tetrahedral species. However, much information appears to be necessary in order to explain this complicated phenomenon in more detail.

There have been some recent reports on the absorption spectra of cobalt(II) and nickel(II) perchlorates and thiocyanates in aqueous and nonaqueous solutions[8-10] and these as well as several previous reports[6,7] appear to support the conclusions of the present study.

Poor extraction of nickel(II) from thiocyanate solutions with various oxygen-containing solvents has been reported.[11–15] However, not much is known of the details of the nickel(II) distribution equilibria in these systems.

Dialkylpalladium(II) Complexes. Syntheses, Characterizations, and Reactions with CO, I_2, and CH_3I

Takashi Ito, Hirotaka Tsuchiya, and Akio Yamamoto

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 12, 1976)

The reaction of bis(acetylacetonato)palladium(II), [Pd(acac)$_2$] with $AlR_2(OEt)$ in the presence of tertiary phosphine, L, in diethyl ether yields a series of dialkylpalladium(II) complexes, [PdR_2L_2], where R=Me, Et, and Pr^n; L=PEt_3, PPh_2Me, and $\frac{1}{2}Ph_2PCH_2CH_2PPh_2$ (dpe). These complexes were characterized by means of elemental analysis, IR and ^{1}H-NMR spectra and of some decomposition reaction such as thermolysis and acidolysis. The *trans*- and *cis*-configurations of [$PdMe_2L_2$] (L=PEt_3 and PPh_2Me, respectively) in solution were established on the basis of the ^{1}H-NMR spectra. The examination of ^{1}H-NMR spectra in the presence of tertiary phosphine suggests the ligand exchange processes promoted by the added phosphine. [PdR_2L_2] (L=PEt_3 and PPh_2Me) reacted with CO in toluene to yield the quantitative amounts of the corresponding dialkyl ketones. The reactions of the complexes [PdR_2L_2] with iodine afforded [PdI_2L_2] and RI, and of [PdR_2(dpe)] with MeI gave CH_3H, CH_3CH_3, R(−H), RH, R·CH_3, R·R, and RI together with [PdI_2L_2], suggesting the presence of a quadrivalent, six-coordinate intermediate palladium species.

Among the transition elements, palladium and its compounds are known to show the most versatile catalytic activities, which include olefin oxidation (Hoechst-Wacker process), oligomerization, carbonylation, vinylation, acetoxylation, isomerization, and hydrogenation of olefins, dienes and acetylenes.[1] In most of these catalytic reactions, formation of the intermediate species possessing an unstable palladium-carbon σ-bond is thought to constitute one of the key steps.[1] In this respect, the systematic studies of the alkylpalladium complexes are expected to provide the useful information related to the mechanistic aspect of the catalytic reactions and to the exploitation of the new catalytic processes.

Since the first syntheses of the methylpalladium complexes by Calvin and Coates in 1960,[2] various kinds of methylpalladium complexes have been prepared:[3] the preparation method includes alkylation of halogenopalladium(II) complex with methyl Grignard reagent or methyllithium,[2] and with dimethyl(1,5-cyclooctadiene)platinum(II),[4] and oxidative addition of methyl halide to the palladium(0) complex.[5,6] The isolation of the ethylpalladium complex, on the other hand, has been limited to only one example: diethyl{1,2-bis(dicyclohexylphosphino)ethane}palladium(II) which was prepared by the reaction of [Pd(acac)$_2$] (acac=acetylacetonato) with diethylaluminum monoethoxide in the presence of a tertiaryphosphine ligand under the atmosphere of ethylene.[7] Following our systematic studies on the preparations of series of alkyl complexes of Cr,[8] Fe,[9] Co,[10] Ni,[11] and Cu[12] by the use of alkylaluminum compounds as the alkylating agent, we succeeded in the isolation of the series of dialkylpalladium complexes by the analogous method. Alkylation of bis(acetylacetonato)palladium by alkylaluminum compounds has the advantage over the conventional alkylation reaction using palladium halides and alkyllithium or Grignard reagent in that the product can be isolated simply by the filtration and washing with some organic solvents such as hexane. This merit enables the reaction product isolable even if it is susceptible to water and is stable only at the low temperature.

Here we report the preparation, characterization and some reactions of the series of dialkylpalladium complexes with tertiary phosphine ligands. Zerovalent complexes, such as [$Pd(PPh_3)_4$],[13] [$Pd(CO)(PPh_3)_3$],[14] [$Pd(CO)PPh_3]_n$,[14] [$Pd_3(CO)_3(PPh_3)_4$],[14] [$Pd(C_2H_4)(PPh_3)_2$],[7] and [$Pd\{P(C_6H_{11})_3\}_2$],[15] and diethyl and dihydrido complexes, [$PdEt_2\{(C_6H_{11})_2PCH_2CH_2P(C_6H_{11})_2\}$][7] and [$PdH_2\{P(C_6H_{11})_3\}_2$],[15] have been hitherto reported as reaction products between palladium acetylacetonate and alkylaluminum compounds.

Results and Discussion

Preparation of Dialkylpalladium Complexes. The reaction of [Pd(acac)$_2$], tertiary phosphine, L, and dialkylaluminum monoethoxide (molar ratio, 1 : 2 : 3—5) in diethyl ether under a nitrogen atmosphere afforded a series of dialkylpalladium complexes.

$$[Pd(acac)_2] + 2L + AlR_2(OEt) \rightarrow [PdR_2L_2]$$

L = PEt_3, R = Me, **1a**; Et, **2a**; and Pr^n, **3a**.

L = PPh_2Me, R = Me, **1b**; Et, **2b**; and Pr^n, **3b**.

L = $\frac{1}{2}$dpe, R = Me, **1c**; Et, **2c**; and Pr^n, **3c**.

(dpe=$Ph_2PCH_2CH_2PPh_2$)

The results of the elemental analysis for these complexes are listed in Table 1 together with their decomposition points measured *in vacuo*. Among the complexes, [$PdMe_2(PEt_3)_2$](**1a**)and [$PdMe_2$(dpe)](**1c**) have been already prepared by Calvin and Coates by the method employing methyllithium as an alkylating agent.[2] The complexes, white solid except for complex **2c**, which is yellow, are diamagnetic and mostly sensitive to air. When L=PEt_3, ethyl and propyl complexes, **2a** and **3a**, are thermally unstable and decompose at room temperature even under a nitrogen atmosphere. Thermal stability increases in the order of PEt_3<PPh_2Me<dpe for the complexes with the same alkyl groups, and of Pr^n(*n*-C_3H_7)<Et<Me for those with the same phosphine ligands. The latter series of stability suggests that the mechanism involving β-hydrogen abstraction[16] is operative in the thermal decomposition of these complexes *(vide infra)*. The solubility of the complexes depends mostly on the phosphine ligand. On the whole the complexes with PEt_3 are soluble in most organic

solvents while those with dpe are scarcely soluble. Thus, complex **1a** was recrystallized from hexane and **2a**, **3a**, **1b**, **3b**, and **1c** from acetone. The rest failed to be recrystallized.

Decomposition of the Complexes. Thermolysis of the dialkyl complexes released the corresponding alkene (R(−H)) and alkanes (RH and R·R) as are shown in Table 2. The formation of ethylene and methane in the thermolysis of dimethyl complexes, **1a** and **1c**, suggests the possibility of occurrence of the following α-elimination reaction as has been reported for $[FeMe_2(dpe)_2]$.[17]

$$2\rangle Pd\langle^{CH_3}_{CH_3} \rightarrow 2\rangle Pd(H)\langle^{CH_2}_{CH_3} \rightarrow CH_2{=}CH_2 + 2CH_4 \quad (1)$$

As the alternative source of ethylene, the alkyl groups in the tertiary phosphine ligand cannot be ruled out at present. In fact a high value of ΣR in the case of **1a** (130%) may be ascribed to the decomposition of triethylphosphine which might be catalyzed by Pd moiety.

Decomposition of the complexes with concd H_2SO_4 evolved mainly the corresponding alkane (R·H). The results are included in Table 2. The reason for evolution of smaller amounts of the gases as compared with the theoretical amount (except for methyl complex **1c**) may be ascribed to the dissolution of the product gases into sulfuric acid. The acidolysis of propyl complex **3c** evolved H_2 and propene, together with propane. The decomposition of **3c** with D_2SO_4 evolved hydrogen gas which was consisted mainly of HD (0.84) together

TABLE 3. IR[a] AND ^{1}H-NMR[b] SPECTRAL DATA OF $[PdR_2L_2]$

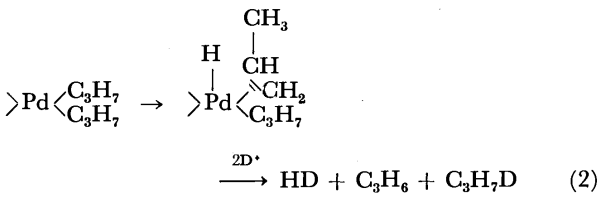
a) KBr disc, in cm^{-1}. b) 100 MHz, chemical shifts are in δ values (ppm) with respect to tetramethylsilane as an external standard (down field positive). Coupling constants, J, are in Hz. c) ν(C-H) of the coordinated alkyl group. d) The band due to the C-H deformation of the palladium-bonded methyl group and may contain contribution due to the other vibrations. e) The assignments are not certain, see text. f) ν(Pd-C) were not discernible from the complicated bands due to dpe. g) Multiplicity abbreviations are: s, singlet; t, triplet; q, quartet; qu, quintet, m, multiplet; br, broad singlet. h) An abnormal quartet, see Fig. 1 and text.

with minor amounts of H_2 (0.05) and D_2 (0.11) as analyzed by mass spectrometry. These results suggest the presence of such a β-elimination process as shown in Eq. 2, in addition to the normal protonation of propyl group with D_2SO_4 to yield propane-d_1.



$$\xrightarrow{2D^+} HD + C_3H_6 + C_3H_7D \qquad (2)$$

Infrared Spectra of the Complexes. [PdR_2L_2]. The representative absorption assignable to ν(C–H), δ(C–H) *etc.* of the coordinated alkyl group are listed in Table 3 together with Pd–C stretching vibrations. These assignments were made by comparing the spectra each other and with those of the corresponding dichloro complexes, [$PdCl_2L_2$].

Somewhat different frequencies from those observed for our complexes were reported by Calvin and Coates for the methyl complex **1a**,[2] *i. e.*, δ(C–H)=1164 and ν(Pd–C)=491 and 457 cm^{-1}. The difference in the configuration of the complex might have caused such differences (as for the discussion about the configurations of the complexes, see the following section). The palladium-carbon stretching frequencies of the dimethyl and diethyl complexes with L=PEt_3 and $P(Ph_2Me)_3$ are observed in the region of 455—475 cm^{-1} which is lower than those of the corresponding Pt complexes (495—525 cm^{-1}),[18] reflecting the weaker Pd–C bond than Pt–C.

The ^{1}H-NMR Spectra of the Complexes, [PdR_2L_2]. The results of the ^{1}H-NMR measurements of the dialkyl complexes are included in Table 3. Some complexes are unstable in the solution even at low temperatures making their assignments somewhat tentative. The spectra of [$PdEt_2(PPh_2Me)_2$] (**2b**) and [$PdPr^n_2L_2$] (L=PEt_3, **3a** and PPh_2Me, **3b**) accompanied the weak signals due to ethane and propane, respectively, which may be formed by partial decomposition of the original complexes in solution. For the dimethyl complexes, [$PdMe_2L_2$], well resolved spectra were obtained and are reproduced in Fig. 1 for L=PEt_3 (**1a**) and PPh_2Me (**1b**).

The apparent doublet of the phosphine–methyl signal in **1b** suggests that the complex is in *cis* configuration.[19,20] This is further supported by observation of the complicated pattern of Pd–C$\underline{H}_3$ signal centered at 0.10 ppm, the pattern of which is very close to those of Pt–C$\underline{H}_3$ signals reported for *cis*-[$PtMe_2L_2$].[21–25] In contrast to the *cis* configuration of [$PdMe_2(PPh_2Me)_2$], **1b**, the triethylphosphine complex, [$PdMe_2(PEt_3)_2$], **1a**, was found to possess trans configuration. As is shown in Table 3 and Fig. 1, palladium-bonded methyl protons in **1a** resonates at −0.61 ppm as a triplet due to the coupling with two equivalent phosphorus atoms present in mutually trans positions. The apparent quintet pattern of the methyl protons in the phosphine ligand is also characteristic of the *trans*-bis(triethylphosphine) complexes.[26]

The same dimethyl complex as **1a** has been prepared by Calvin and Coates *via* methylation of [$PdCl_2(PEt_3)_2$] with methyllithium.[2] Although no ^{1}H-NMR spectral data have been reported, they assumed *cis* configuration for the complex through the dipole moment measurement. Furthermore, a slow isomerization in the solution from *cis* to trans as monitored by a decrease in the dipole moment has been suggested. In fact, the ^{1}H-NMR spectrum taken in $(CD_3)_2CO$ by us for [$PdMe_2(PEt_3)_2$] prepared by Calvin and Coates' method[2] showed two sets of Pd–C$\underline{H}_3$ signals, one at 0.01 ppm as a deformed quartet characteristic of the *cis*-dimethyl complex *(vide supra)* and the other at −0.67 ppm as a triplet corresponding to the *trans*-dimethyl isomer. These findings indicate that the product contains both cis and trans isomers in accord with the observation by Calvin and Coates.[2]

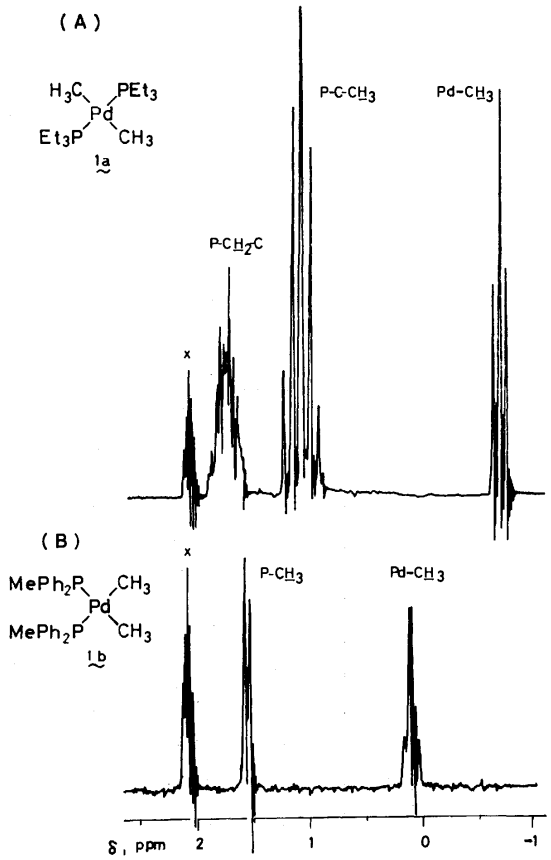


Fig. 1. ^{1}H–NMR spectra (100 MHz, methyl and methylene region) of the complexes, [$PdMe_2L_2$], L=PEt_3 **1a** (A) and PPh_2Me **1b** (B) in $(CD_3)_2CO$ at 25 °C. The sign x refers to the solvent impurities.

The ^{1}H-NMR spectra of the solutions of diethyl complexes, either after being heated at *ca.* 40 °C (for **2a**) or kept at room temperature for several days (for **2b**), indicated the formation of the ethylene-coordinated complex with the accompnaying evolution of ethane. As is shown in Fig. 2, the very small signals at 0.86 and 2.90 ppm observed in the spectrum of the freshly prepared acetone-d_6 solution of **2a** (Fig. 2A) grew considerably on heating the solution at the expense of the quartet at 0.33 ppm assigned to the palladium-attached methylene protons (Fig. 2B). A sharp singlet at 0.86 ppm in Fig. 2B can be assigned to ethane evolved

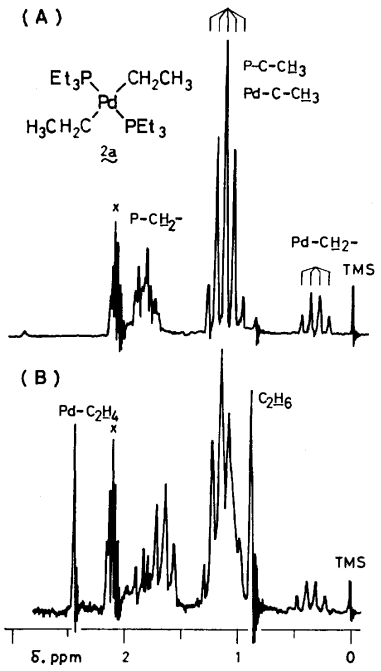

Fig. 2. ^{1}H-NMR spectra of $[PdEt_2(PEt_3)_2]$ **2a** in $(CD_3)_2CO$ at 25 °C. (A) Freshly prepared sample solution. (B) After being heated at 40 °C. The signals x refer to the solvent impurities.

whereas the one at 2.42 ppm (shifted upfield from the initial position of 2.90 ppm in Fig. 2A) to the coordinated ethylene protons. The similar values of the chemical shifts of the coordinated ethylene protons have been reported for $[Ni(C_2H_4)(PPh_3)_2]$ (2.55 ppm in toluene-d_8)[27] and $[Pt(C_2H_4)(PPh_3)_2]$ (2.41 ppm in toluene-d_8).[27] $[Pd(C_2H_4)(PPh_3)_2]$ prepared by the method reported by van der Linde and de Jongh[7] had the value of 2.88 ppm in acetone-d_6 at 25 °C. In the case of PPh_2Me complex **2b**, the proton resonance of the coordinated ethylene appeared at 3.64 ppm as a broad singlet, which is somewhat lower than the other coordinated ethylenes. The complete absence of the signal in the region of free ethylene (5.35 ppm in toluene-d_8)[27] suggests that ethylene, evolved by the decomposition of the diethyl complex according to the following equation, coordinates to palladium preferentially to form the zero-valuent ethylene complex.

$$L_2Pd(C_2H_5)_2 \rightarrow L_2Pd(H)(CH_2CH_2C_2H_5) \rightarrow L_2Pd(CH_2CH_2) + C_2H_6 \quad (3)$$

Attempted isolation of the ethylene complex by treatment of **2b** with excess ethylene in toluene failed.

Some evidence for the ligand exchange in the dimethyl complexes **1a** and **1b** was obtained by measuring the ^{1}H-NMR spectra in the presence of added phosphine ligand. Addition of PEt_3 to the solution of $[PdMe_2(PEt_3)_2]$ **1a** caused the ^{1}H-NMR spectral change from the triplet to a singlet for the Pd–C$\underline{H}_3$ signal, from the multiplet to a quartet for the P–C$\underline{H}_2$– signal and from the quintet to a triplet for the P–C–C$\underline{H}_3$ signal. The existence of a rapid exchange between the coordinated and dissociated PEt_3 has been demonstrated for $[CoMe_2(acac)(PEt_3)_2]$, where triplet, quintet and multiplet signals of the protons due to, respectively, Co–C$\underline{H}_3$, P–C–C$\underline{H}_3$, and P–C$\underline{H}_2$–, at −20 °C changes to singlet, triplet, and quartet, respectively, at 0 °C.[10c] The similar dissociation-exchange process has been observed for $[NiMe_2(PEt_3)_2]$ whose NMR at 25 °C consists of a siglet due to Ni–C$\underline{H}_3$, a triplet due to P–C–C$\underline{H}_3$, and a quartet assignable to P–C$\underline{H}_2$-protons.[28] The monomethyl complex $[PdMeCl(PEt_3)_2]$ also behaves quite similarly.

The ^{1}H-NMR spectrum of a mixture of $[PdMe_2(PPh_2Me)_2]$ and PPh_2Me at −40 °C in acetone-d_6 showed the resonances of the methyl protons of free $PPh_2\underline{Me}$ at 1.66 ppm as a singlet, of coordinated $PPh_2\underline{Me}$ at 1.49 ppm as a doublet (J=5 Hz) and of Pd–C$\underline{H}_3$ at 0.0 ppm, which appears as a distorted quartet as mentioned previously but is somewhat ill-resolved in the present spectrum. The reason for the absence of phosphorus coupling in the methyl proton signal of free PPh_2Me is uncertain. On raising the temperature to 25 °C, the methyl protons of the coordinated and uncoordinated PPh_2Me collapsed to a broad singlet at 1.6 ppm and the resonance due to Pd–C$\underline{H}_3$ also changed to a broad singlet at 0.04 ppm. The existence of the free phosphine ligand may be accelerating the exchange of the phosphine ligand and the exchange rate may be enhanced at the higher temperature. The similar ligand exchange process has been reproted for $[NiR(acac)(PPh_3)_{1\text{ or }2}]$.[29]

Reactions of Dialkylpalladium Complexes with Carbon Monoxide. Booth and Chatt have reported that the reaction of carbon monoxide with monomethyl complex, $[PdMeCl(PEt_3)_2]$, afforded the acyl complex $[Pd(COMe)Cl(PEt_3)_2]$, while the reactions with dimethyl complexes $[PdMe_2L_2]$ either gave uncharacterizable product (L=PEt_3) or led to decomposition (L=½ dpe).[30]

Introduction of carbon monoxide into the toluene solution of dialkyl complexes $[PdR_2L_2]$ (L=PEt_3 and PPh_2Me; R=Me, Et, and Pr^n) at *ca.* 1 atm afforded immediately a red clear solution, whose GLC analysis indicated the formation of a quantitative amount of the corresponding dialkyl ketone. None of alkanes, alkenes and α-diketones were detected in the system. The red solution was unstable in the absence of carbon monoxide and the removal of the solvent by evaporation *in vacuo* left a viscous yellow oil whose IR spectra showed the characteristic C≡O stretching band at 1800 and 1805 cm^{-1} for the PEt_3 and PPh_2Me complexes, respectively. This result suggests formation of carbonyl complexes, which may possibly be related to the reported palladium-carbonyl complexes, $[Pd(CO)(PPh_3)_3]$, $[Pd(CO)PPh_3]_n$ or $[Pd_3(CO)_3(PPh_3)_4]$[14]. However, purification and characterization of the complexes were not successful. Monitoring the reaction of $[PdEt_2(PPh_2Me)_2]$ with CO in toluene-d_8 by means of ^{1}H-NMR spectroscopy also supported the formation of a zero-valent palladium carbonyl complex as well as of diethyl ketone, since the spectrum consisted of the signals due to diethyl ketone (0.90 ppm, triplet, $J\approx7$ Hz, 4H, –C$\underline{H}_2$– and 1.87 ppm, quartet, $J\approx7$ Hz, 6H, –C$\underline{H}_3$) and the coordinated PPh_2Me (1.59 ppm, doublet, $J\approx7$ Hz, 6H, P–C$\underline{H}_3$).

$$[PdR_2L_2] + CO \rightarrow \{Pd(COR)RL_2\} \xrightarrow{CO} R_2CO + [Pd_x(CO)_yL_z]$$

Dialkylcobalt(III) complexes $[CoR_2(acac)(PR'_3)_2]$, have also been found to give the corresponding dialkyl ketones, $R_2C{=}O$, in a quantitative yield on the reaction with carbon monoxide,[10] while $[CuR(PR_3)_n]$ and $[NiR_2(bpy)]$ (bpy=2,2'-bipyridine) afforded ketones and/or diketones whose relative yield depended on the conditions employed.[12a,31] The formation of biacetyl by the reaction of CO with $[PtMe_2(PEt_3)_2]$ has been reported.[30] The acyl complexes which are considered to be the intermediates of the ketone or α-diketone formation have been isolated when $[NiR(acac)(PPh_3)_2]$,[32] $[CoMe(dpe)_2]$,[10a,33] and $[MRX(PEt_3)_2]$ (M=Pd and Pt, X=halogen, NCS, NO_2, and NO_3)[30] were allowed to react with carbon monoxide.

The reactions of $[PdR_2(dpe)]$ with carbon monoxide led to the decomposition of the complex evolving ethane (when R=Me) and ethylene and ethane (when R=Et). When R=Pr^n, dipropyl ketone was formed in 17% yield with concomitant evolution of propane.

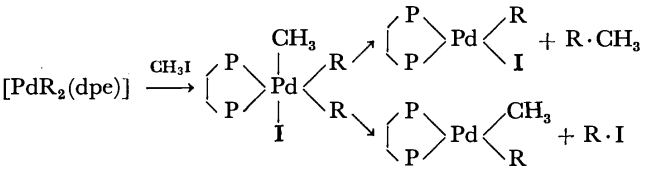
Reactions of Dialkyl Palladium Complexes with Iodine. Diethyl and dipropyl complexes of palladium $[PdR_2L_2]$ in benzene reacted with excess amounts of iodine at room temperature to yield di-iodo complex $[PdI_2L_2]$ (as analyzed by IR spectra and elemental analyses), the corresponding alkyl iodide, RI, and the gases such as ethylene and ethane when R=Et and propylene and propane when R=Pr^n (Table 4). The analogous reaction involving dimethyl(bipyridine)palladium and iodine to produce methyl iodide and $[PdI_2(bpy)]$ has been reported by Maitlis and Stone.[34]

Table 4. The reaction products of $[PdR_2L_2]$ and I_2

Compounds		Molar ratio R(−H)	Molar ratio R·H	ΣR[a] %	RI %
$[PdEt_2(PEt_3)_2]$	**2a**	0.42	0.58	30	trace
$[PdPr^n_2(PEt_3)_2]$	**3a**	0.06	0.94	3	54
$[PdPr^n_2(PPh_2Me)_2]$	**3b**	0.33	0.67	9	37
$[PdEt_2(dpe)]$	**2c**	0.40	0.60	10[b]	74
$[PdPr^n_2(dpe)]$	**3c**	c)	c)	c)	18

a) $\Sigma R = \{mol(R(-H)+R\cdot H)/2\ mol(complex)\} \times 100$ where R(−H) corresponds to C_2H_4 (R=Et) and C_3H_6 (R=Pr^n) and R·H to C_2H_6 (R=Et) and C_3H_8 (R=Pr^n). b) R contained a trace amount of C_4H_{10}. c) Not measured.

Reactions of $[PdR_2(dpe)]$ with Methyl Iodide. Addition of methyl iodide to $[PdR_2(dpe)]$(R=Me, **1c**; Et, **2c**; and Pr^n, **3c**) *in vacuo* yielded a clear red solution from which a yellow solid precipitated with the accompanying evolution of gases and alkyl iodides. The yellow powder thus obtained was identified as $[PdI_2(dpe)]$ by means of IR spectroscopy. When R is CH_3, the evolved gas was mainly ethane containing a trace of methane. The amount of the produced RI (CH_3I) could not be measured because of the presence of the unreacted CH_3I. As is shown in Table 5, the gases evolved by the reactions of diethyl and dipropyl complexes (**2c** and **3c**) with CH_3I contained C_1 to C_4 hydrocarbons. The formation of propane as well as ethyl iodide in the case of diethyl complex and of ethane, butane, and propyl iodide in the case of dipropyl complex by the reactions with CH_3I, suggest the formation of intermediate Pd(IV) species as shown below.



(5)

Beside the above equation, a number of processes may be postulated as the routes to yield the products listed in Table 5. Whichever process the reaction may follow, the six-coordinate palladium(IV) species seems to play an important role in these reactions. Although little has been known about the palladium(IV) compounds, quadrivalent platinum compounds have been amply reported including $[PtMe_2I_2(PEt_3)_2]$,[35] $[Pt(tolyl)RI_2(py)_2]$,[36] $[PtMeRX_2(PMe_2Ph)_2]$,[23,37] and $[PtMe_2RX(PMe_2Ph)_2]$[23,37,38] which were prepared by the oxidative addition of alkyl or aryl halide to the corresponding bivalent platinum-dialkyl or -alkyl halide complexes. Furthermore, the products of the thermal decomposition of series of platinum(IV) alkyl halide complexes have been studied[38,39] and the formation of ethane, methyl chloride and $[PtClMe(PMe_2Ph)_2]$ has

Table 5. The reaction products of $[PdR_2(dpe)]$ and excess CH_3I

Compounds		Products: CH_4 mol/mol·Pd	Molar ratio: C_2H_4	C_2H_6	C_3H_6	C_3H_8	C_4H_{10}	RI mol/mol·Pd
$[PdMe_2(dpe)]$	**1c**	trace	0	1.00 (R·R)	0	0	0	a)

a) Not measurable, see text.

been observed when $[PtClMe_3(PMe_2Ph)_2]$ was heated at 170 °C.[39] The attempted isolation of the intermediate Pd(IV) species in the reaction of $[PdEt_2(dpe)]$ **2c** with CH_3I by quenching the red clear solution by the addition of Et_2O was not successful, but the orange powder which may be a mixture of several kinds of Pd complexes including $[PdI_2(dpe)]$ was obtained. Evolution of CH_4 as well as C_2H_6 on decomposition of the orange powder with H_2SO_4 indicates the presence of Pd–CH_3 species in the mixture as the result of oxidative addition of CH_3I to **2c**.

In the metathesis reaction of $[PdMe_2(bpy)]$ with perfluoropropyl iodide to yield either $[PdMe(C_3F_7)(bpy)]$ (when equimolar amount of n-C_3F_7I was employed) or $[Pd(C_3F_7)_2(bpy)]$(excess C_3F_7I), Maitlis and Stone postulated the quadrivalent six-coordinate palladium intermediate, $[PdMe_2(C_3F_7)I(bpy)]$,[34] although the other possible by-products, MeI, $Me\cdot C_3F_7$, *etc.* have not been detected.

Experimental

All manipulations were carried out under an atmosphere of deoxygenated nitrogen or argon, or *in vacuo*. Solvents were dried in the usual manner, distilled, and stored under a nitrogen atmosphere.

Infrared spectra were recorded on Hitachi EPI-G3 and 295 spectrometers using KBr pellets prepared under an inert atmosphere. NMR spectra were measured on JEOL PS-100 spectrometer by Mr. Y. Nakamura of our reseach laboratory to whom we are indebted. ^{1}H-NMR signals are referred to tetramethylsilane as internal standard unless otherwise stated. Analysis of the gases evolved by the reaction or decomposition of the alkyl complexes was carried out by mass spectrometry and/or gas chromatography (Shimadzu GC-3BT) after collecting gases fractionally using a Toepler pump, by which the volumes of gases were also measured. Micro analyses (C, H, and halogens) were carried out by Mr. T. Saito of our laboratory using Yanagimoto CHN Autocorder Type MT-2 (for C and H analyses). Analysis of palladium content was performed by EDTA-back titration method using $Zn(NO_3)_2$ aqueous solution. The complete ionization of the palladium metal in the complex was achieved by treating the sample with a hot aqua regia.

Triethylphosphine (Strem) was used as purchased. Diphenylmethylphosphine[40] and 1,2-bis(diphenylphosphino)-ethane[41] were prepared by the literature method starting from PPh_2Cl (Strem) and PPh_3 (kindly donated by Ihara Chemical Industry Co. Ltd.), respectively. Dialkylmonoethoxyaluminums, $AlR_2(OEt)$ (R=Me, Et, and Pr^n), were prepared by the reactions of the corresponding trialkylaluminums and the equimolar amount of ethanol at a low temperature. $[PdCl_2L_2]$ (L=PEt_3 and PPh_2Me) were prepared by the analogous way as reported for $[PdCl_2\{tris(dimethylamino)phosphine\}_2]$.[42] $[PdCl_2(dpe)]$ was obtained from $PdCl_2$ and dpe according to the method described in the literature.[30] The monomethyl complex, $[PdMeCl(PEt_3)_2]$ was prepared by the methylation of $[PdCl_2(PEt_3)_2]$ with MeMgBr in Et_2O.[2]

Preparation of Dimethylbis(triethylphosphine)palladium(II), ***1a***. To a yellow heterogeneous mixture of $[Pd(acac)_2]$ (1.5 g, 5.0 mmol), PEt_3 (1.5 cm^3, 10 mmol) and 30 ml of diethyl ether cooled at −70 °C, $AlMe_2(OEt)$ (3.0 cm^3, 18 mmol) was added dropwise. On raising the temperature of the mixture gradually, it became homogeneous at −30 °C. The solution was stirred for several hours at 0 °C. Cooling the clear solution at −70 °C overnight yielded a white precipitate, which was filtered off, washed with a small amount of Et_2O at the same temperature and dried *in vacuo*. The product was recrystallized from cold hexane to yield colorless needles of $[PdMe_2(PEt_3)_2]$ **1a** (0.71 g, 40%). Similarly obtained were $[PdEt_2(PEt_3)_2]$ **2a** and $[PdPr^n{}_2(PEt_3)_2]$ **3a** by the use of, respectively, $AlEt_2(OEt)$ and $AlPr^n{}_2(OEt)$ in place of $AlMe_2(OEt)$. Complexes **2a** and **3a** were crystallized quickly from acetone at low temperatures. The low yields of crystallized complexes **2a** and **3a** (less than 15%) may be accounted for instability of the complexes in solution.

Preparation of Dimethylbis(diphenylmethylphosphine)palladium(II) ***1b***. To the heterogeneous yellow mixture of $[Pd(acac)_2]$ (1.5 g, 5 mmol), PPh_2Me (2.3 cm^3, 12 mmol) and diethyl ether (30 cm^3) cooled at −70 °C, was added 3 cm^3 (25 mmol) of $AlMe_2(OEt)$ dropwise. Gradual warming of the system to −20 °C with stirring afforded a clear red solution, and the solution was further stirred at 0 °C for several hours. Cooling the solution at −70 °C overnight yielded a white precipitate which was filtered off, washed with Et_2O and hexane at low temperature and dried *in vacuo*. The product was crystallized from cold acetone to give white crystals of $[PdMe_2(PPh_2Me)_2]$, **1b**, (0.23 g, 10%).

Similarly obtained were its ethyl and propyl analogs, **2b** and **3b**, using $AlEt_2(OEt)$ and $AlPr^n{}_2(OEt)$, respectively, in place of $AlMe_2(OEt)$. Crude complex **2b** (0.70 g, 25%) could not be crystallized due to its poor solubility. White crystals of **3b** (0.33 g, 10%) were obtained by the careful, low temperature crystallization from acetone.

Preparation of Dimethyl{1,2-bis(diphenylphosphino)ethane}palladium(II), ***1c***. Into the cooled (−70 °C) heterogeneous mixture of $[Pd(acac)_2]$ (1.5 g, 5 mmol), 1,2-bis(diphenylphosphino)ethane (dpe, 2.2 g, 5.5 mmol), and Et_2O (30 cm^3), was added dropwise 3 cm^3 (16 mmol) of $AlMe_2(OEt)$. Stirring the mixture at −20 to −30 °C yielded, at first, a sticky solid, and then finally a white precipitate, which was filtered off, washed with Et_2O and hexane, and dried *in vacuo*. Recrystallization of the product from acetone yielded white crystals of $[PdMe_2(dpe)]$ **1c** (1.6 g, 45%).

The analogous complexes, $[PdEt_2(dpe)]$ **2c** and $[PdPr^n{}_2(dpe)]$ **3c** were obtained by the similar method as above using $AlEt_2(OEt)$ and $AlPr^n{}_2(OEt)$, respectively, as alkylating agents in place of $AlMe_2(OEt)$. Complexes **2c** (2.1 g, 75%) and **3c** (2.5 g, 85%) could not be crystallized due to their poor solubility.

Reactions of Dialkylpalladium Complexes with Carbon Monoxide. To the pre-evacuated flask containing the mixture of $[PdMe_2(PEt_3)_2]$ **1a** (46.5 mg, 0.125 mmol) and toluene (1 cm^3) freezed at −198 °C, carbon monoxide was introduced. The system turned red instantly on melting by raising the temperature under carbon monoxide. At room temperature, a clear red solution resulted. No gas evolution was observed in the system. The formation of acetone (0.108 mmol, 90% on the basis of the amount of **1a** used) in the solution was confirmed by means of GLC.

The similar reactions of CO with complexes **2a**, **3a**, **1b**, **2b**, and **3b** yielded the corresponding ketones as shown in Table 6.

Reactions of Dialkylpalladium Complexes with Iodine. *$[PdEt_2(dpe)]$ (2c)*: Into the Schlenk flask fitted with a side arm, 74.1 mg (0.132 mmol) of $[PdEt_2(dpe)]$ was placed. The benzene (2 cm^3) solution of iodine (1.0 g) in a L-shaped tube was connected to the side arm of the flask. After being evacuated by freeze-thaw method, the contents were mixed together by rotating the L-shaped tube. The mixture was stirred at room temperature for several hours. The gases evolved by the reaction are listed in Table 4. From the solution, all volatile liquid was removed by a trap-to-trap distillation

Table 6. The amount of dialkylketones formed by the reactions of $[PdR_2L_2]$ with carbon monoxide

Complexes				Dialkylketones		
		mg	(mmol)		mmol	(%)
$[PdMe_2(PEt_3)_2]$	**1a**	46.5	(0.125)	Me_2CO,	0.108	(85)
$[PdEt_2(PEt_3)_2]$	**2a**	52.1	(0.130)	Et_2CO,	0.144	(110)
$[PdPr^n{}_2(PEt_3)_2]$	**3a**	21.1	(0.049)	$Pr^n{}_2CO$,	0.046	(95)
$[PdMe_2(PPh_2Me)_2]$	**1b**	77.0	(0.143)	Me_2CO,	0.129	(90)
$[PdEt_2(PPh_2Me)_2]$	**2b**	49.9	(0.088)	Et_2CO,	0.088	(100)
$[PdPr^n{}_2(PPh_2Me)_2]$	**3b**	25.2	(0.042)	$Pr^n{}_2CO$,	0.042	(100)

to leave a residual orange solid. The presence of methyl iodide (0.196 mmol, 74% on the basis of the amount of initially used complex) was confirmed by means of GLC. Recrystallization of the residue from acetone–hexane yielded orange crystals of $[PdI_2(dpe)]$ (Found: C, 41.6; H, 3.8; I, 33.0%. Calcd for $C_{26}H_{24}I_2P_2Pd$: C, 41.2; H, 3.2; I, 33.5%).

Similarly carried out were the reactions of $[PdEt_2(PEt_3)_2]$ and $[PdPr^n{}_2L_2]$ (L=PEt_3, PPh_2Me, and 1/2dpe) with iodine.

Reactions of $[PdR_2(dpe)]$ with methyl iodide. *$[PdMe_2(dpe)]$*: Methyl iodide (*ca.* 2 cm^3) was distilled over calcium hydride under a vacuum into a flask containing $[PdMe_2(dpe)]$ (69.6 mg, 0.13 mmol). On stirring the mixture at room temperature, the initial white suspension turned to a clear red solution and then finally to the suspension containing a yellow precipitate which was identified as $[PdI_2(dpe)]$ on the basis of the IR spectrum. The evolution of ethane containing a trace of methane was observed as analyzed by GLC. The amount of ethane can not be measured due to the coexistence of unreacted CH_3I. The reactions of diethyl and dipropyl complexes with methyl iodide were carried out similarly.

We thank the Kawakami Foundation for financial support.

Kinetics of the Proton-Transfer Reaction of 4-(2,4-Dihydroxyphenylazo)-nitrobenzene in Dioxane–Water Media*

Noboru Yoshida and Masatoshi Fujimoto

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 30, 1976)

Kinetics of proton-transfer reactions in 4 to 50%(v/v) dioxane–water media between hydroxide ion and 4-(2,4-dihydroxyphenylazo)nitrobenzene (Magneson; MAG) having a strong OH···N intramolecular hydrogen-bond are studied by means of the temperature-jump method. The forward and the backward rate constants k_f and $k_r[H_2O]$ for the reaction $OH^- + HA^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} H_2O + A^{2-}$ are evaluated to be in the range of 9.2×10^5—1.3×10^5 $mol^{-1}\,dm^3\,s^{-1}$ and 5.5×10^3—$1.8\times10^3\,s^{-1}$, respectively. The dependence of the k_f and the acid dissociation constant K_a^c on the dioxane contents of the medium is interpreted on the basis of solute-solvent interactions.

The kinetic studies of proton-transfer reactions in mixed solvents are of particular importance for the interpretation of fast proton-transfer reactions in aqueous solutions, especially from the point of view of solute-solvent interactions.

1,4-Dioxane, a typical water-miscible aprotic solvent, can cover the wide range of dielectric constant of the medium on mixing with water. This characteristic is favorable for evaluating the solvent effects such as electrostatic effect in the fast proton-transfer reactions. Many investigations on the structure of dioxane–water solutions have so far been reported in detail.[1] However, it is necessary to get further information on the liquid structure of dioxane–water system at the periphery of a *bulky* solute molecule such as 4-(2,4-dihydroxyphenylazo)nitrobenzene (Magneson; MAG).

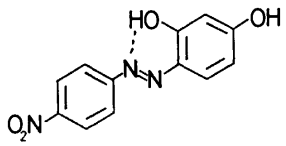
In a previous paper[2] we determined the overall rate constants k_f and k_r for the proton-transfer reactions between hydroxide ion and some *ortho*-hydroxy azo and azomethine compounds HA in 50%(v/v) dioxane–water medium and proposed the following reaction mechanism for this medium;

$$\underset{[1]}{\widehat{HA} + OH^-} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \underset{[2]}{HA^* + OH^-}$$

$$\overset{k_{23}}{\underset{k_{32}}{\rightleftharpoons}} \underset{[3]}{HA^* \cdots (H_2O)_n \cdots OH^-} \overset{k_{34}}{\underset{k_{43}}{\rightleftharpoons}} \underset{[4]}{A^- + H_2O}.$$

In the step [1]⇌[2], the hydrogen-bonded proton in $\widehat{HA}$ is set free from the azo-nitrogen atom and interacts with solvent *water* molecules to form HA*. Recently Jost and Liphard directly proved the existence of the first elementary step [1]⇌[2] from the activation volume of the overall reaction determined by the temperature-jump study under pressure.[3]

In the present study we found that for the uninegative acid HA^- of MAG the recombination rate constant k_f decreases with increasing dioxane contents in the medium. This dependence in the k_f was attributed to the change of the two terms, $K_{12}=k_{12}/k_{21}$ and k_{23}. From the dependence of $\log k_f$ on the value of the macroscopic dielectric constant of the medium, the number of intervening *water* molecules in the encounter complex, $HA^*\cdots(H_2O)_n\cdots OH^-$, was estimated to be $n=4$—5.



MAG: $\widehat{H_2A}$

Experimental

Reagents. The water used here was deionized and distilled. Guaranteed grade dioxane (Wako) was distilled and used without further purification.[2] 4-(2,4-Dihydroxyphenylazo)nitrobenzene was purified by repeated recrystallization from methanol. Dioxane solution of the dye (3×10^{-3} mol dm^{-3}) was stored in a well-stoppered bottle to avoid evaporation.

Measurements. *pH in the Mixed Solvent*: We used the following relationship[4] between pH-meter readings (pH*) and values of $-\log(C_H/\text{mol dm}^{-3}) = pC_H$

$$\log U_H = pC_H - pH^*,$$

where C_H denotes the analytical concentration of the solvated proton determined titrimetrically. The plot of pH* *vs.* pC_H shows a good linear relationship for any dioxane content in the medium. The values of $\log U_H$ were evaluated in the range of pH*=3—12 at 25 °C and I=0.1 mol dm^{-3} ($NaClO_4$) to be −0.07, −0.03, −0.06, −0.08, −0.11, and −0.14 for the mixed solvent containing 0, 10, 20, 30, 40, and 50%(v/v) dioxane, respectively. Hitachi-Horiba pH-meters Model P and Model M-7 were used throughout the study.

Equilibria and Kinetics: The acid dissociation constants of MAG were determined spectrophotometrically with a Hitachi recording spectrophotometer Model EPS-3T. The kinetic measurements were carried out with a Union Giken co-axial-cable temperature-jump apparatus Model RA-105. The temperature-jump cell was made of Teflon and equipped with gold electrodes. Temperature-rise was determined for discharge at 25 kV from the calibration curve between the light intensity and the temperature of the sample solution at I=0.1 mol dm^{-3} (KNO_3) to be 4.4 and 3.8 °C in the aqueous and the 50%(v/v) dioxane–water solution, respectively. The rise-time of the temperature in 50%(v/v) dioxane–water solution was *ca.* 5 μs.[5] To avoid partial decomposition of the dye after repeated discharges on the same sample solution, we often renewed the sample solution in the cell. As the

* Presented in part at the 26th Annual Meeting on Coordination Chemistry, Sapporo, August 30, 1976, Abstract p. 252.

noise-level in the signal was serious for dioxane-water system, the discharge voltage was carefully controlled below 25 kV. The reaction was followed on the screen of an oscilloscope Tektronix Type 545B at the absorption maximum of the conjugated base of the Brønsted acid. Temperature of the solution was kept constant by circulating the water thermostated with a regulator Lauda Type K2R or Coolnics Model CTR-1B.

Results

Equilibria of the Reaction. The apparent ionic product $K_w^c=[H][OH]$ of the water in dioxane–water mixture at 25 °C and $I=0.1$ mol dm^{-3} ($NaClO_4$) was calculated using the values of log U_H derived from the data of the potentiometric titrations as described in detail in a previous paper.[2] The values of K_w^c thus obtained were used for the evaluation of the acid dissociation constant K_a^c based on the kinetic data, according to the relation $K_a^c=[H][A]/[HA]=(k_f/k_r')[H][OH]=K_b^cK_w^c$, where K_b^c denotes the ratio k_f/k_r' and $k_r'=k_r\cdot[H_2O]$. Figure 1 shows the dependence of the pK_w^c ($=-\log(K_w^c/\text{mol}^2\,\text{dm}^{-6})$) on the mole fraction of dioxane in the medium, x_{dlox}, indicating the decrease in K_w^c with increasing dioxane content.

The absorption coefficient A of the solution at wavelength where the absorption of an acid form HA^- of MAG can be neglected is given by

$$A=\varepsilon_{HA}\bar{C}_{HA}+\varepsilon_A\bar{C}_A\simeq\varepsilon_A\bar{C}_A, \quad (1)$$

where ε and $\bar{C}$ denote the molar absorption coefficient and the equilibrium concentration, respectively. The acid dissociation constant $K_a^c=[H][A]/[HA]$ is derived from the following equation;

$$C/A_A=1/\varepsilon_A+\bar{C}_H/\varepsilon_AK_a^c, \quad (2)$$

where C denotes the total concentration, $C=C_{HA}+C_A$, and A_A the absorption coefficient of a basic form A^{2-}. The plot of C/A_A *vs.* $\bar{C}_H$ for each dioxane content of the medium gives a straight line as shown in Fig. 2. From the slope and the intercept of the straight line, the values of the K_a^c and ε_A are obtained, respectively. The acid dissociation constants K_a^c in the medium of varying dioxane content are summarized in Table 1.

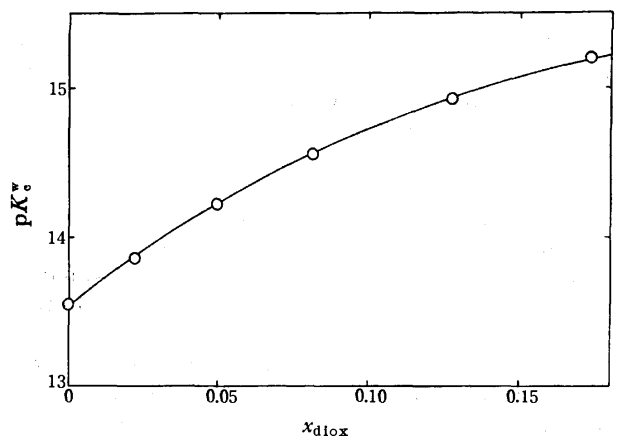


Fig. 1. Dependence of thep K_w^c on the mole fraction of dioxane, x_{dlox}. At 25 °C and $I=0.1$ mol dm^{-3} ($NaClO_4$).

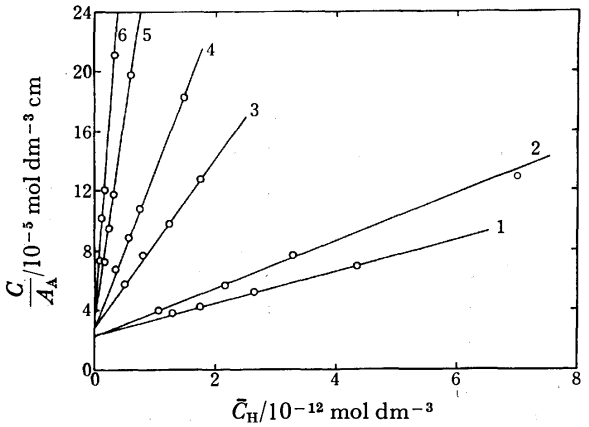

Fig. 2. Plots of C/A_A *vs.* $\bar{C}_H$ in dioxane-water media. Dioxane content: (1) 4, (2) 10, (3) 20, (4) 30, (5) 40, and (6) 50%(v/v). At 25 °C and $I=0.1$ mol dm^{-3} (KNO_3).

Table 1. Acid dissociation constants K_a^c of Magneson in dioxane-water medium at 25 °C determined from the spectrophotometric data

Dioxane/%(v/v)	pK_a^c ($=-\log(K_a^c/\text{mol dm}^{-3})$)[a]
4	11.66
10	11.88
20	12.26
30	12.60
40	12.98
50	13.23

a) $K_a^c=[A][H]/[HA]$, $I=0.1$ mol dm^{-3} (KNO_3).

In Fig. 4(a) the spectrophotometric acid dissociation constants are plotted against the mole fraction of dioxane, x_{dlox}. Increasing dioxane content in the medium would lead to a decrease in the acid dissociation constant of HA^-. A linear relationship between pK_a^c and x_{dlox} is observed in the range of x_{dlox} lower than 0.09, while for simple nonaromatic carboxylic acids such as acetic acid Van Uitert and Haas,[4] and Harned and Owen[6] reported the corresponding linear relationship in by far the wider range of the mole fraction of dioxane.

Kinetics. For the proton-transfer reactions of uninegative acid HA^- in the mixed solvent,

$$HA^- + OH^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} A^{2-} + H_2O$$

with the equilibrium constant $K_b^c=k_f/k_r'=\bar{C}_A/\bar{C}_{HA}\bar{C}_{OH}$, the relaxation time τ is expressed by

$$\tau^{-1}=k_f(\bar{C}_{OH}+\bar{C}_{HA})+k_r', \quad (3)$$

where k_r' involves the concentration of the water in the mixed solvent and equal to $k_r[H_2O]$. Figure 3 shows the plots of τ^{-1} *vs.* $\bar{C}_{HA}+\bar{C}_{OH}$, giving k_f and k_r' from the slope and the intercept, respectively. The values of k_f, k_r', and K_b^c are summarized in Table 2. In Fig. 4, pK_a^c evaluated as $K_a^c=K_b^cK_w^c$ from the kinetic data is plotted against x_{dlox} together with the spectrophotometric pK_a^c. Figure 5 shows a dependence of log k_f on x_{dlox}. At higher dioxane content, marked deviation from the linear dependence is observed.

Discussion

In Fig. 6 the kinetic and the spectrophotometric pK_a^c are plotted against the inverse macroscopic dielectric constant of the medium.[7] Both pK_a^c's increase with decreasing dielectric constant of the medium, though the linear dependence of pK_a^c on D^{-1} as interpreted by Gilkerson in terms of electrostatic interactions[8] is observed only for the lower dioxane contents. The free energy of the acid dissociation is a sum of the energies required to break the O–H bond, the energies required to break the intramolecular hydrogen-bond, and the hydration energies of various species involved.[9] The decrease of K_a^c with increasing dioxane content in the medium shown in Fig. 6 would partly be ascribed to the difference in the energies of hydration of the reactants.[10]

The recombination of hydroxide ion with a uninegative 4-(2-hydroxy-4-ethylphenylazo)benzenesulfonate ion having no *para*-OH group was found to be almost diffusion-controlled,[11] and the value of pK_a^c for the hydrogen-bonded proton is by two orders of magnitude lower than that of a uninegative ion of 4-(2,4-dihydroxyphenylazo)nitrobenzene having a dissociated *para*-OH group. These facts would lead to the following conclusions: 1. The thermodynamic stability of the intramolecular hydrogen-bond increases mainly due to the presence of a *para*-O^- group which contributes to a resonance quinoidal form and enhances the electron density on the azo-nitrogen. 2. Increased

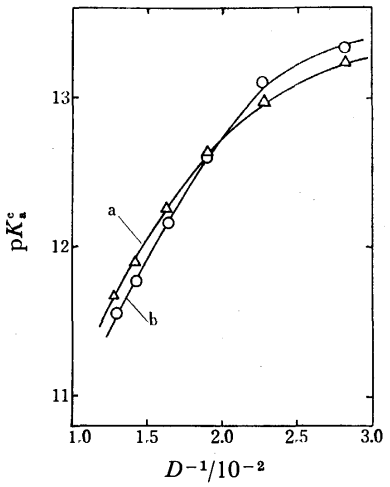

Fig. 6. Dependence of the acid dissociation constant K_a^c of MAG on the dielectric constant of the medium. At 25 °C and I=0.1 mol dm^{-3} (KNO_3). (a) The plot of the spectrophotometric pK_a^c *vs.* the dielectric constant of the medium. (b) The plot of the kinetic pK_a^c *vs.* the dielectric constant of the medium.

double-bond character of a C–N bond between an azo-nitrogen and the benzene ring owing to the resonance contribution from the *para*-O^- substituent may restrict the internal rotation about the C–N axis and further enhance the thermodynamic stability of the intramolecular hydrogen-bond. More recently, from the similar point of view Tōei[12] and Johnson and Florence[13] have also explained the stability of the complexes of *o*-hydroxyphenylazo multidentate ligands having a *para*-OH group in terms of a charge-quinone hypothesis.

For the proton-transfer reactions of a uninegative Brønsted acid ion $\widehat{HA}^- + OH^- \rightleftharpoons A^{2-} + H_2O$ in dioxane–water media, we propose the following mechanism which postulates the existence of the first pre-equilibrium between $\widehat{HA}^-$ and HA^{*-};

$$\underset{[1]}{\widehat{HA}^- + OH^-} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \underset{[2]}{HA^{*-} + OH^-}$$

$$\underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \underset{[3]}{HA^{*-}\cdots(H_2O)_n\cdots OH^-} \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} \underset{[4]}{A^{2-} + H_2O},$$

where $\widehat{HA}^-$ stands for the uninegative species having a *para*-O^- group and an intramolecular hydrogen-bond, and HA^{*-} an intermediate species without an intramolecular hydrogen-bond. The *ortho*-hydroxyl proton in $\widehat{HA}^-$ is set free from the intramolecular hydrogen-bond and associated with surrounding water molecules *via* hydrogen-bond to form HA^{*-}. If a proton-transfer reaction in dioxane-water media proceeds in accordance with the above mechanism, the relations between rate constants of the overall reaction and those for each elementary step are shown by Eqs. 4 and 5.

$$k_f = K_{12}k_{23}, \tag{4}$$

and

$$k_r = k_{32}/K_{34}, \tag{5}$$

where $K_{12}=k_{12}/k_{21}$ and $K_{34}=k_{34}/k_{43}$. The equilibrium constant K_{12} is characteristic of the structure of the Brønsted acid and may reflect the liquid structure of the water at the periphery of the reactant, namely, that in the vicinity of the hydroxyl proton. On the other hand, k_{23} is a function of the solvent composition and of the dielectric constant of the medium. Thus the value of K_{12} appears to be one of the measures of the differences in solute-solvent interactions for $\widehat{HA}^-$ and HA^{*-}. The values of k_f and k_r in dioxane–water media are found to be smaller than those in aqueous medium. As discussed above, this decrease in the recombination rate constant in the mixed solvent system is due to two terms K_{12} and k_{23}.

By neglecting the ionic-atmosphere term in Christiansen-Scatchard equation[14] we obtain

$$\ln (k_f/k_f^\circ) = -z_i z_j e^2/kTr^*D, \tag{6}$$

where z_i and z_j represent the charge of the reactants, D is the dielectric constant of the medium, k Boltzmann's constant, T the absolute temperature, r^* the reaction distance, e the elementary charge, and k_f° the rate constant at infinite dielectric constant. As shown in Fig. 7, the log k_f *vs.* D^{-1}-plot is linear in the region of higher dielectric constant (D=78—52). Since the decrease of log k_f in Fig. 7(a) is due to two terms K_{12} and k_{23}, and the term K_{12} is not constant[15] in this region, we obtain an unexpectedly small value of the reaction distance (2.9 Å) from the slope (a) in Fig. 7. In the region, where the term K_{12} is assumed to be nearly constant,[16] the slope in Fig. 7 is reduced to Eq. 7.

$$\mathrm{d}\log(k_f/\mathrm{mol}^{-1}\,\mathrm{dm}^3\,\mathrm{s}^{-1})/\mathrm{d}\,D^{-1} \simeq \mathrm{d}\log(k_{23}/\mathrm{mol}^{-1}\,\mathrm{dm}^3\,\mathrm{s}^{-1})/\mathrm{d}\,D^{-1}. \tag{7}$$

From the slope (b) of the log (k_f/mol^{-1} dm^3 s^{-1}) *vs.* D^{-1}-plot we obtain the value of r^*=18 Å as a phenomenological reaction distance. This value of the reaction distance would be reasonable in view of the charge and the size of the reactants, though further investigation is needed with respect to the phenomenological reaction distance derived from the assumption $K_{12}\simeq$constant. From the value 18 Å for r^*, the number of the inter-

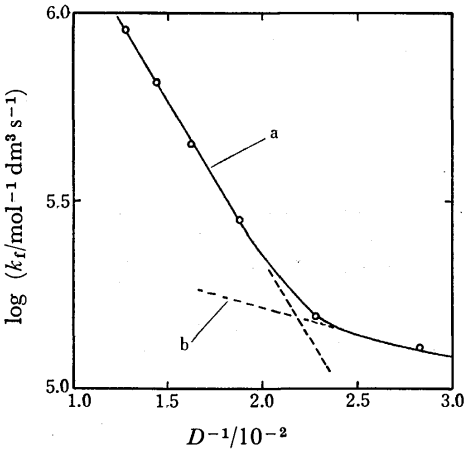

Fig. 7. Dependence of the log k_f on the dielectric constant of the medium. At 25 °C and I=0.1 mol dm^{-3} (KNO_3).

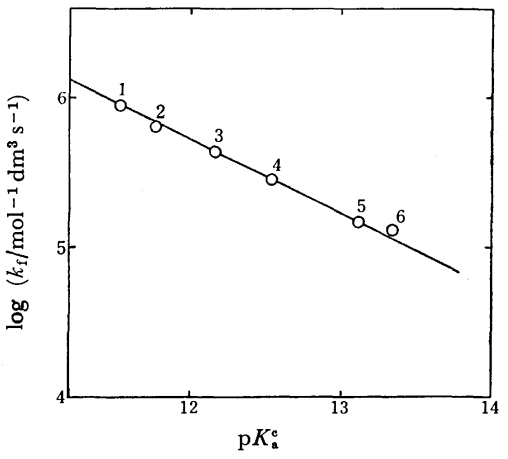

Fig. 8. Dependence of the recombination rate constants k_f on the acid dissociation constants K_a^c of MAG in dioxane-water media. Dioxane content: (1) 4, (2) 10, (3) 20, (4) 30, (5) 40, and (6) 50%(v/v). At 25 °C and I=0.1 mol dm^{-3} (KNO_3).

vening water molecules in the encounter complex, $HA^{*-}\cdots(H_2O)_n\cdots OH^-$ would be estimated to be n=4—5. The value is larger than that (n=2) for the neutralization reaction between the proton H_3O^+ and the hydroxide ion OH^- in aqueous solution.[17]

For a given solvent composition, it was found that the pK_a^c of the Brønsted acids of analogous structures shows a linear dependence on the value of log (k_f/mol^{-1} dm^3 s^{-1}).[2] Figure 8 shows the linear relationship between log (k_f/mol^{-1} dm^3 s^{-1}) and pK_a^c of MAG with respect to the medium effect. Since the variation of k_r' by varying solvent composition is small, the variation of $K_a^c=K_w^c(k_f/k_r')$ depends almost entirely on k_f and K_w^c. The plot of pK_w^c against pK_a^c for varying solvent composition shows a linear relationship, pK_w^c =0.8 pK_a^c+4.3. The plot in Fig. 8 gives a relationship, log (k_f/mol^{-1} dm^3 s^{-1}) = —0.5 pK_a^c + 11.5, or $k_f=G(K_a^c)^\alpha$, where G and α are constants. From Eq. 4 we have a simple relationship, $K_{12}k_{23}=G(K_a^c)^\alpha$. Considering the smaller variation in k_{23} than that in K_{12} we obtain

$$K_{12} = G'(K_a^c)^\alpha, \qquad (8)$$

where G' is a constant. Thus, the linear relationship between pK_a^c and log (k_f/mol^{-1} dm^3 s^{-1}) of MAG with respect to the medium effect could be explained by the linear relationship between pK_a^c and log K_{12}.

10) In general the solvent effect on the acid-base equilibrium is explained on the basis of the change in the dielectric constant and the acid-base property of the solvent. Furthermore in the case of a bulky organic solute such as Magneson in dioxane-water medium, the preferential solvation by dioxane or water of the various species involved would play a significant role in the acid-base equilibrium.

15) Since K_{12} is the equilibrium constant of the elementary process in which $\widehat{HA}^-$ interacts with surrounding water molecules *via* hydrogen-bond to form HA^{*-}, and since the unimolecular processes inherent to the properties of the reaction site itself, *viz.*, the rupture of the intramolecular hydrogen-bond and the rotation of OH-group around the C–O axis, are almost independent of the solvent composition, the increasing dioxane content of the medium would lead to the decrease in the value of K_{12}.

16) Since the process of dissolution of an ionic crystal is closely related to the process of solvation,[18] the large organic molecule ion $\widehat{HA}^-$ which dissolves readily in dioxane is strongly solvated by dioxane molecules in dioxane-water medium, namely, the preferential solvation of $\widehat{HA}^-$ by dioxane molecules is enhanced when the dioxane content in the medium is increased. The interaction of $\widehat{HA}^-$ with water molecules through hydrogen-bond is considerably restricted when the dioxane content in the medium is increased, and the change in the value of K_{12} due to the solvent composition[14] becomes smaller.

A Method for the Preparation of Potassium Hexafluorovanadate(III) and Its Polymorphic Transitions

Kōichirō Kōyama and Yasuhiko Hashimoto

Department of Materials Science, Himeji Institute of Technology, Shosya, Himeji 671-22

(Received December 13, 1976)

In order to determine the best conditions for the preparation of potassium hexafluorovanadate(III), the reaction of V_2O_3 with KHF_2 was studied by means of thermogravimetric analysis, differential thermal analysis, and X-ray diffraction analysis. The reaction begins at about 225 °C and terminates at about 300 °C, and the decomposition of excess KHF_2 terminates at from 300 to 450 °C, depending on the amount of the mixture of V_2O_3 and KHF_2. Potassium hexafluorovanadate(III) is stable in air up to about 300 °C and is oxidized at temperatures higher than 300 °C. Potassium hexafluorovanadate(III) has four polymorphic forms, and the transition points are 158, 200, and 218 °C. The transition from δ to γ or from γ to β on cooling is hindered by adding a small amount of sodium ion.

Previously we measured the freezing points of the KCl–VF_3, NaCl–VF_3, KCl–NaCl(equimolar)–VF_3, KCl–KF–K_3VF_6, NaCl–NaF–Na_3VF_6, KF–NaF–K_2NaVF_6, and KCl–NaCl–K_2NaVF_6 systems and pointed out that compositions in the vicinity of the minimum melting point of the KCl–NaCl–K_2NaVF_6 system are suitable as an electrolyte for the electrorefining or electroextraction of vanadium.[1,2] Most regions of the KCl–NaCl–K_2NaVF_6 system, shown by hatching in Fig. 1b, can be prepared by the use of K_3VF_6, which can be more easily prepared than K_2NaVF_6. Several methods for the preparation of K_3VF_6 have been reported by several groups of workers,[3–5] but none of these methods are practicable from the viewpoint of cost. In a previous paper,[6] we reported that $(NH_4)_3VF_6$ can be prepared by fusing a mixture of V_2O_3 and NH_4HF_2 in an inert atmosphere. By analogy with this preparation of $(NH_4)_3VF_6$, K_3VF_6 may be expected to be prepared by fusing a mixture of V_2O_3 and KHF_2. This work was undertaken to determine the conditions for the preparation of K_3VF_6 from V_2O_3 and KHF_2, and also to examine the polymorphic transition of K_3VF_6.

Experimental

The vanadium(III) oxide used was prepared by the hydrogen reduction of V_2O_5 of a special reagent grade at 800—900 °C for 3 h. The potassium hydrogenfluoride and lithium fluoride used were of a special reagent grade, while the sodium hydrogenfluoride was reagent-grade. X-Ray diffraction patterns at elevated temperatures were taken with an X-ray diffractometer, Rigaku Denki Model SG-7, equipped with a high-temperature attachment, with a Ni-filtered Cu$K\alpha$ radiation. The diffraction angles were corrected by using the diffraction angles of silicon. The differential thermal analysis curves were taken with an apparatus constructed in our laboratory by using 10 mg of a sample at a heating rate of 5 °C/min. The thermocouple used was calibrated by the transition temperatures of KNO_3(129 °C) and $KClO_4$(299 °C). The thermogravimetric analysis curves were taken with a microthermobalance, Shimadzu Model TG-20, by using 10 mg of a sample and at a heating rate of 5 °C/min.

Results and Discussion

X-Ray Diffraction Analysis. A mixture (2.5844 g) of V_2O_3 and KHF_2 in a molar ratio of 1 : 8 was placed in a platinum boat and heated at a given temperature for 30 min in a stream of argon (20 ml/min). Figure 2 shows a schematic diagram of the apparatus used for this experiment. The reaction product was identified by X-ray diffraction analysis at room temperature. Potassium hexafluorovanadate(III) was identified on the basis of the set of interplanar spacings for the low-temperature form of K_3VF_6 reported by Cretenet.[7] Table 1 shows the compounds identified in the product. The reaction of V_2O_3 with KHF_2 began at 225 °C and was completely terminated at 300 °C. The decomposition of the excess KHF_2 was almost terminated at 400 °C and completely terminated at 450 °C. As is shown in Table 1, $KF \cdot 2H_2O$ was detected in the products. The thermogravimetric study of $KF \cdot 2H_2O$ showed that $KF \cdot 2H_2O$ released the water of crystallization at 200—300 °C and that the residue was KF. Therefore, the $KF \cdot 2H_2O$ detected in the products is considered to have been formed while the substance

was standing at room temperature by the reaction of KF with the moisture in air.

Differential Thermal Analysis. The differential thermal analysis curve for the reaction of V_2O_3 with KHF_2 is shown in Fig. 3. For comparison, the differential thermal analysis curve for the decomposition of KHF_2 is also shown in Fig. 3. Peaks a and b correspond to the transition(194 °C) and melting (225 °C) of KHF_2. Peak c is judged to correspond to the begining of the reaction of V_2O_3 with KHF_2 on the basis of the fact that the reaction of V_2O_3 with KHF_2 was observed with the naked eye to begin immediately after the melting of KHF_2, and the fact that K_3VF_6 was identified in the product obtained at 225 °C, as is shown in Table 1.

Thermogravimetric Analysis. The thermogravimetric analysis curve for the reaction of V_2O_3 with KHF_2 is shown in Fig. 4. For comparison, the thermogravimetric analysis curve for the decomposition of KHF_2 is also shown in Fig. 4. In curve a, the weight loss began at about 200 °C and terminated at about 300 °C; in curve b, while the weight loss also began at about 200 °C, it terminated at about 340 °C. The temperature at which the decomposition of excess KHF_2 terminated differs in Table 1 and Fig. 4. This can be ascribed to the difference in the weight of the samples

used. The weight loss in the vicinity of 200 °C is considered to be due to the vaporization of HF from solid KHF_2, because the reaction of V_2O_3 with KHF_2 begins at about 225 °C.

From the results of the X-ray diffraction analysis, differential thermal analysis, and thermogravimetric analysis, it was found that the reaction of V_2O_3 with KHF_2 begins at about 225 °C and terminates at about 300 °C, and that the decomposition of excess KHF_2 terminates at 300—450 °C, depending on the weight of the mixture of V_2O_3 and KHF_2.

Molar Ratio of V_2O_3 to KHF_2. Since a part of the KHF_2 in a mixture decomposes without reacting with V_2O_3, an excess of KHF_2 is necessary for preparing

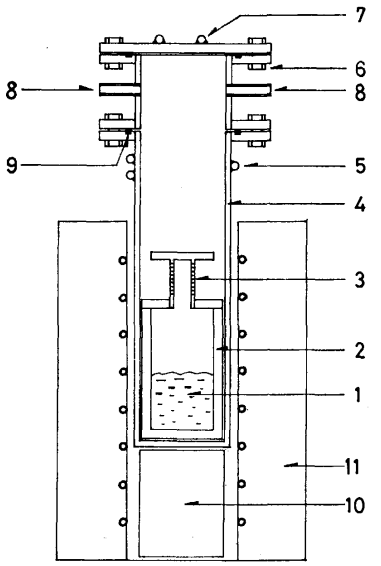

Fig. 5. Schematic diagram of the apparatus used for the preparation of K_3VF_6.
1: Mixture(about 300 g) of V_2O_3 and KHF_2, 2: graphite crucible(72 mm in inside diameter and 160 mm in height), 3: perforated lid, 4: stainless steel vessel, 5: copper cooling tube, 6: bolt and nut, 7: copper cooling tube, 8: inlet and outlet of argon, 9: O-ring.

K_3VF_6 free from V_2O_3. In order to determine the lower limit of the excess of KHF_2, a 300-gram portion each of mixtures in the molar ratios 1 : 6, 1 : 6.5, 1 : 7, 1 : 8, 1 : 9, 1 : 10, 1 : 11, and 1 : 12 was heated at 600 °C in a stream of argon(200 ml/min) with the apparatus shown in Fig. 5. After having been cooled, the reaction products were leached with water, and the residue was examined with the naked eye and also analysed by an X-ray diffraction technique. Vanadium-(III) oxide is black or brown, while the color of K_3VF_6 is bright green. When a reaction product was leached with water, the remaining V_2O_3 particles, if any, could be well discriminated from the K_3VF_6 in water with the naked eye. The mixtures in the molar ratios of 1 : 6 and 1 : 6.5 gave K_3VF_6 contaminated with V_2O_3, but those in the molar ratios of 1 : 7—1 : 12 gave K_3VF_6 free from V_2O_3. Figure 6 shows the scanning-electron micrographs of K_3VF_6 prepared from the mixtures of V_2O_3 and KHF_2 in the molar ratios of 1 : 7, 1 : 8, and 1 : 12. As is shown in Fig. 6, the crystals of K_3VF_6 were fine at the molar ratios of 1 : 6—1 : 7 and coarse at 1 : 8—1 : 12. The growth feature observed at 1 : 8—1 : 12 indicates that the grain of K_3VF_6 somewhat dissolves in the KHF_2 melt.

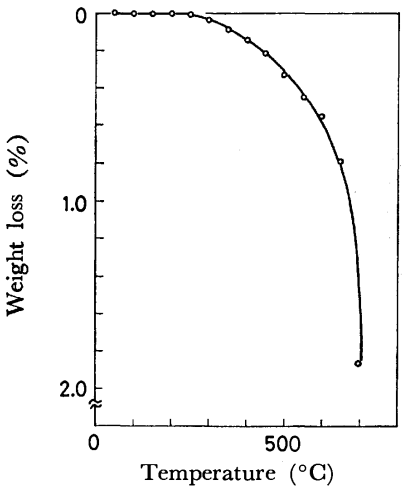

Fig. 7. Oxidation curve of K_3VF_6 in air.

Oxidation-resistance of K_3VF_6. A knowledge of the oxidation-resistance of K_3VF_6 is important for the synthesis of K_3VF_6 and also for the preparation of the electrolytic bath for the electroextraction of vanadium. One gram of K_3VF_6, the crystal sizes of which are shown in Fig. 6b, was heated at a given temperature for 30 min in air; then the product was weighed and analysed by means of an X-ray diffraction technique. The thermogravimetric analysis curve thus obtained is shown in Fig. 7. It may be seen that K_3VF_6 is

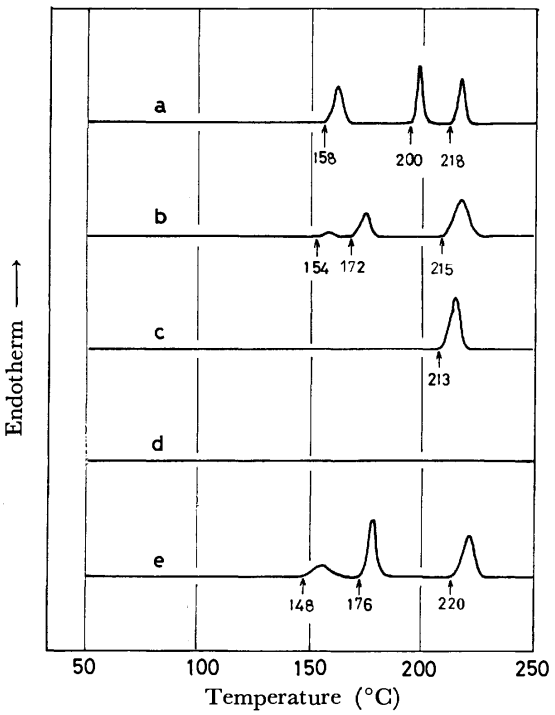

Fig. 8. DTA curves of K_3VF_6.
Curve a: K_3VF_6 prepared by using KHF_2 of a special reagent grade, curve b, c, d, e: K_3VF_6 prepared by using KHF_2 with the addition of a small amount of $NaHF_2$ or LiF.
b: $NaHF_2/KHF_2=1/999$, c: $NaHF_2/KHF_2=1/99$,

Heating rate: 5 °C/min.

stable in air up to about 300 °C and is oxidized at temperatures higher than 300 °C. Therefore, when a mixture of V_2O_3 and KHF_2 is heated at temperatures higher than 300 °C in order to decompose the excess KHF_2, heating must be done in a stream of an inert gas. The decomposition of excess KHF_2 to KF and HF makes the subsequent water-leaching easy. The product oxidized at 700 °C was yellowish green and was readily soluble in water. Its X-ray diffraction pattern was quite different from that of α-K_3VF_6, but was similar to that of γ-K_3VF_6, which will be shown below. This product is suspected to be tetrafluorodioxovanadate(V), $K_3VO_2F_4$.

Transition of K_3VF_6. The transition of K_3VF_6 was examined by differential thermal analysis and X-ray diffraction analysis. Curve a in Fig. 8. is the differential thermal analysis curve of the K_3VF_6 obtained by using KHF_2 of a special reagent grade. From curve a it may be seen that K_3VF_6 has four polymorphic forms and that the transition points are 158, 200, and 218 °C. These polymorphic forms will be called α, β, γ, and δ respectively as follows:

$$\alpha \overset{158}{\rightleftharpoons} \beta \overset{200}{\rightleftharpoons} \gamma \overset{218}{\rightleftharpoons} \delta$$

These transitions are all reversible. Figure 9 shows the X-ray diffraction patterns of α, β, γ, and δ. δ was found to be cubic with a lattice parameter of a=8.722Å at 235 °C. Cretenet[7] has found two polymorphic forms for K_3VF_6 and reported that the high-temperature form is cubic, with a lattice parameter of

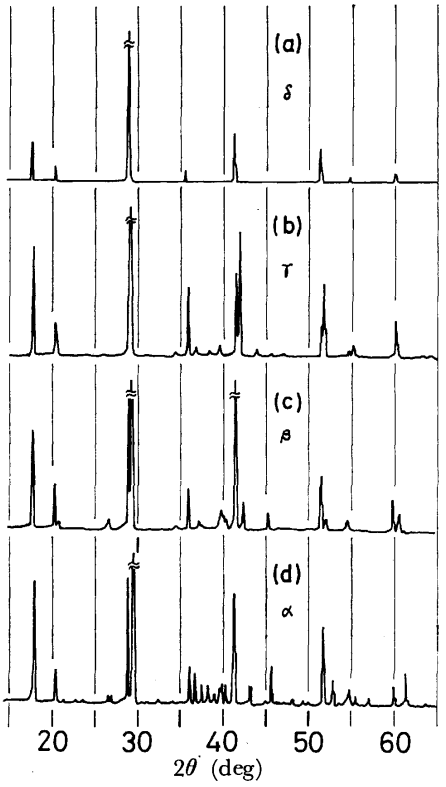

Fig. 9. X-Ray diffraction patterns of K_3VF_6(Cu$K\alpha$, Ni-filter). (a): 230 °C, (b): 210 °C, (c): 180 °C, (d): room temperature.

Table 2. The influence of sodium ion on the crystal transition of K_3VF_6

Molar ratio of $NaHF_2$ to KHF_2	1/999—3/997	8/992—20/980	30/970	50/950
Type of K_3VF_6	α γ	γ	γ δ K_2NaVF_6	δ K_2NaVF_6

K_3VF_6 was synthesized by heating a mixture of KHF_2 (with the addition of a small amount of $NaHF_2$) and V_2O_3 in a molar ratio 1 : 8 at 450 °C in a stream of argon.

a=8.7 Å at 250 °C.

When KHF_2 of a reagent grade was used in the synthesis of K_3VF_6, the X-ray diffraction pattern of the product showed some peaks of γ besides the peaks of α, or only the peaks of γ at room temperature. This was considered to be due to some impurity in the reagent used. Thus, $NaHF_2$ or LiF was deliberately added to KHF_2 of a special reagent grade in the synthesis of K_3VF_6. The K_3VF_6 thus obtained was examined by X-ray diffraction analysis and differential thermal analysis. Table 2 shows the relationship between the ratio of $NaHF_2$ to KHF_2 and the form of K_3VF_6. It may be seen that, on the addition of a small amount of Na^+, γ and δ remain stable, even at room temperature. Curve b, c, d, and e in Fig. 8 are the differential thermal analysis curves of the K_3VF_6 prepared by using the KHF_2 reagent with the addition of Na^+ or Li^+. With an increase in the amount of Na^+, first the β-γ transition temperature decreased, then the β-γ transition disappeared, and finally the γ-δ transition disappeared. These results show that a small amount of Na^+ stabilizes the high-temperature forms, γ and δ, at room temperature. This effect may be explained by the idea that Na^+, which has a smaller ionic radius than K^+, cancels the distortion of the lattice contraction caused by a lowering of the temperature. On the addition of a minute amount of Li^+, the β-γ transition temperature decreased, as in the case of Na^+. Lithium fluoride was almost insoluble in KHF_2, so the addition of more than 1/999 of LiF was not attempted.

The authors wish to express their thanks to Professor Tomoo Kirihara of Nagoya University for his helpful discussions.

Infrared Spectrum and Electronic State of *p*-Iodanil

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 9, 1976)

Synopsis. The infrared spectrum of *p*-iodanil was measured and the fundamental frequencies were assigned by using simple Urey-Bradley force field. The electronic state of *p*-iodanil was also discussed on the basis of those experimental results.

Halogen-substituted *p*-benzoquinones such as *p*-chloranil and *p*-bromanil (see Fig. 1) are known to be strong electron acceptor molecules, and much attention has been paid to the charge-transfer complexes with those acceptors.[1] However, only few attempts have been made to study the vibrational spectra of such acceptor molecules. In previous papers, we examined the infrared spectra of *p*-chloranil, *p*-bromanil, 2, 5-dibromo-3,6-dichloro-*p*-benzoquinone, and their anion radicals, and assigned their fundamental frequencies by using simple Urey-Bradley force fields (UBFF's).[2-4] This kind of investigation was found to be also very useful to study the electronic states of those π-conjugated *p*-benzoquinones, because the intramolecular force constants of those molecules are closely related to their electronic states. In the present paper, we examined the infrared spectrum and the electronic state of *p*-iodanil (see Fig. 1), which is one of the derivatives of iodo-substituted *p*-benzoquinones. It is interesting to compare the results of *p*-iodanil with those previously investigated for *p*-chloranil and *p*-bromanil.[2,3]

Fig. 1. Halogen-substituted *p*-benzoquinones; (a) *p*-chloranil, (b) *p*-bromanil, and (c) *p*-iodanil.

p-Iodanil was prepared by the reaction of *p*-bromanil with potassium iodide and sodium iodide and was crystallized from an ethyl acetate solution.[5] It was purified by sublimation *in vacuo*. The infrared spectrum of the solid *p*-iodanil was measured as Nujol mulls in the range from 400 to 4000 cm^{-1} using an IR-G infrared spectrophotometer (Japan Spectroscopic Co. Ltd.). The infrared spectrum in the regions where the absorption due to Nujol appears was measured using hexachlorobutadiene mulls. The observed absorptions are collected in Table 1.

Since only the intramolecular vibrations are expected to appear in the region from 400 to 4000 cm^{-1}, the vibrational spectrum of the solid compound can be approximately treated under the *p*-iodanil molecular point group D_{2h}. In order to understand the spectroscopic data, a normal coordinate treatment was made with *p*-iodanil molecule, and Wilson's ***GF*** matrix method was used for this purpose.[6] The structural data of *p*-iodanil were taken from those reported by Kobayashi *et al.*[7] Assuming that the *p*-iodanil molecule is planar, thirty normal modes of vibrations were reduced to the symmetry species:

$$\Gamma = 6A_g + 5B_{1g} + 5B_{2u} + 5B_{3u} + 1B_{2g} + 3B_{3g} + 2A_u + 3B_{1u}, \quad (1)$$

where the first four are the in-plane vibrations, and the rest, the out-of-plane vibrations. We calculated only the in-plane vibrations. A simple Urey-Bradley force field was employed as the potential function. The calculation process of the fundamentals of *p*-iodanil was very similar to the cases previously studied with *p*-chloranil and *p*-bromanil,[2,3] because the chloro-substituents or bromo-substituents were replaced by the iodo-substituents. Some of the force constants of *p*-iodanil could be transferred from those of *p*-chloranil or *p*-bromanil.[2,3] Refinements of the force constants were then carried out by the trial-and-error method making use of the Jacobian matrices. The calculated values of the *p*-iodanil fundamental vibrations with these force constants agreed well with the observed values. This is shown in Table 1 together with the assignments of the fundamental absorptions. In the following, we will only discuss the bond-stretching force constants, because the observed fundamentals arise mostly from the bond-stretching modes.

As for the C=O bond-stretching force constant, *K*-

a) s: strong, m: medium, w: weak, sh: shoulder.

(C=O) of *p*-iodanil was estimated to be 9.56 mdyn/Å, whose value is close to the 9.7 value of *p*-chloranil or the 9.62 value of *p*-bromanil.[2,3] The C=C bond-stretching force constant, K(C=C), of *p*-iodanil was calculated to be 6.32 mdyn/Å, which is found to be somewhat smaller than the 6.6 value of *p*-chloranil or the 6.67 value of *p*-bromanil.[2,3] On the other hand, the C–C bond-stretching force constant, K(C–C), of *p*-iodanil was estimated to be 2.43 mdyn/Å. This value was found to be almost the same magnitude as those of the force constants for C–C single bonds of aliphatic hydrocarbons.[8] The C–C bond of *p*-iodanil appears to have more single bond character than have those of *p*-chloranil and *p*-bromanil. In fact, the C–C bond-stretching force constants of *p*-chloranil and *p*-bromanil have been estimated to be 3.0 mdyn/Å and 2.96, respectively[2,3]; these values are appreciably larger than the 2.43 mdyn/Å value for *p*-iodanil. In order to see this situation more quantitatively, the bond-stretching force constant, $K(12)$, in a π-conjugated system was related to the bond order, $p(12)$, and self-polarizability, $\pi(1212)$, of a bond (12) according to the Coulson and Longuet-Higgins formula:[9]

$$K(12) = \{(1-p(12))K_s + p(12)K_d\} + \left\{\frac{K_sK_d(s-d)}{K_s(1-p(12))+K_dp(12)}\right\}^2 \frac{\pi(1212)}{2}, \quad (2)$$

where s, d, K_s, and K_d are the bond lengths and the force constants associated with pure single and double bonds, respectively.

In a homopolar carbon-carbon bond, the second term involving the self-polarizability may be small.[2] By the use of the empirical relationship between $K(12)$ and $p(12)$ given in the previous paper,[2] we estimated the bond orders in *p*-iodanil as p(C=C)=0.82 and p(C–C) $\leq$0.15, respectively. Thus, the C–C bond of *p*-iodanil corresponds almost to pure single bond, and there is a strong alternation of the bond order between the C=C and C–C bonds. *p*-Iodanil appears to have more quinoid structure than has *p*-chloranil or *p*-bromanil.[2,3] This strong quinoid character of *p*-iodanil is also evidenced by the crystal structure analysis made by Kobayashi *et al.*[7] They reported the C–C bond length of *p*-iodanil to be 1.50 Å, which is as long as that of C–C pure single bond.

As for the heteropolar C=O bond, if we take, in Eq. 2, the values of K_s=5.0 mdyn/Å and K_d=10.7 proposed by Bratoz and Besnainou,[10] and if we neglect the contribution of the self-polarizability to K(C=O), the K (C=O) force constant of *p*-iodanil gives the value for the bond order of p(C=O)=0.80, which should be compared with p(C=O)=0.82 of *p*-chloranil or 0.81 of *p*-bromanil.[2,3]

The C–I bond-stretching force constant, K(C–I), of *p*-iodanil was estimated to be 1.43 mdyn/Å. This value was somewhat close to the value for the C–I bond-stretching force constant of alkyl iodides.[8]

We observed a strong absorption at 695 cm^{-1} in *p*-iodanil, but could not assign it to any of the in-plane fundamental vibrations. However, *p*-chloranil and *p*-bromanil have analogous absorptions at 715 cm^{-1} and 705, respectively,[2,3] and these absorptions show no appreciable frequency shifts in going from *p*-chloranil, *p*-bromanil to *p*-iodanil. Girlando *et al.* assigned the 715 cm^{-1} band of *p*-chloranil to the B_{1u} out-of-plane vibration of C=O bending mode.[11] Therefore, the same assignment is applicable to the 695 cm^{-1} absorption of *p*-iodanil.

In view of these results, the application of the infrared spectrum of *p*-iodanil is very useful to study the electronic states of the molecule. Kobayashi *et al.* have reported on some solid-state properties characteristic of *p*-iodanil.[7] In connection with the electronic states of the molecule, there remains a possibility that such properties may be induced by the strong quinoid structure of *p*-iodanil molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (5), 1339—1340 (1977)

An MO-Theoretical Study of the Electronic Structures of Formyloxyl and Acetoxyl Radicals

Osamu KIKUCHI, Kayoko UTSUMI, and Keizo SUZUKI
Institute of Chemistry, The University of Tsukuba, Sakura-mura, Ibaraki 300-31

(Recived September 9, 1976)

Synopsis. A semi-empirical NDDO MO method was applied to formyloxyl(HCOO) and acetoxyl(CH_3COO) radicals in order to determine whether the ground-state electronic structure of the acyloxyl radical is of σ- or π-type. A σ-type state was found to be more stable than a π-type state over the entire range of values of the OCO angles of these radicals. This appears to be in agreement with the experimental facts which have been derived from the ESR spectra of several acyloxyl radicals.

Acyloxyl radicals are important intermediates in the thermal decomposition of acyl peroxides, although only a few acyloxyl radicals have directly been detected.[1-2] An important problem related to the acyloxyl radicals is to determine whether their ground-state electronic structures are of σ- or π-type. This problem is a key point in clarifying the role of acyloxyl radicals in the decomposition processes of acyl peroxides and has already been investigated both experimentally and theoretically. The observed principal values and directions of the g-tensors[1,2] appear to support a σ-type ground state for the acyloxyl radicals, while theoretical calculations performed up to now using INDO[3] and STO-3G[4] methods support a π-type state. This note presents theoretical results which were obtained using a semi-empirical NDDO MO method and which support a σ-type electronic structure for the ground-state of the acyloxyl radical.

The restricted SCF procedure for open-shell electronic systems proposed by Pople *et al.*[5] was applied to the simple acyloxyl radicals, the formyloxyl and acetoxyl radicals. In the SCF procedure, the MO of an open-shell system are divided into three parts, doubly-occupied, singly-occupied, and empty MO. A variational method was successively applied to two of the three groups, and the MO for a given electron configuration were determined by SCF iteration. The σ- and π-type electronic structrues for a given conformation of the acyloxyl radicals were obtained by assigning the singly-occupied MO to σ- and π-orbitals, respectively. In the evaluation of the matrix elements, the NDDO approximation,[6] which gives well-balanced molecular geometries and excitation energies, was employed.

The energetic dependence of σ- and π-states of the formyloxyl and acetoxyl radicals on their molecular geometries was calculated in detail. In the calculation of formyloxyl, a planar conformation was assumed. C_{2v} and C_s symmetries are possible geometries for the planar formyloxyl radical:

C_{2v} $\qquad$ C_s

The expected lower electronic states of C_{2v} symmetry are written as:

$$\cdots(b_2)^2(a_2)^2(a_1)^1;\ ^2A_1(\Sigma)$$
$$\cdots(a_2)^2(a_1)^2(b_2)^1;\ ^2B_2(\Sigma)$$
$$\cdots(a_1)^2(b_2)^2(a_2)^1;\ ^2A_2(\Pi)$$

and those of C_s symmetry as:

$$\cdots(a'')^2(a')^1;\ ^2A'\ (\Sigma)$$
$$\cdots(a')^2(a'')^1;\ ^2A''(\Pi)$$

The schematic shapes of the MO in the avove configurations are shown in Fig. 1. The energy variation of each electronic state on the OCO angle is shown in Fig. 2. The curves were obtained with CH and CO

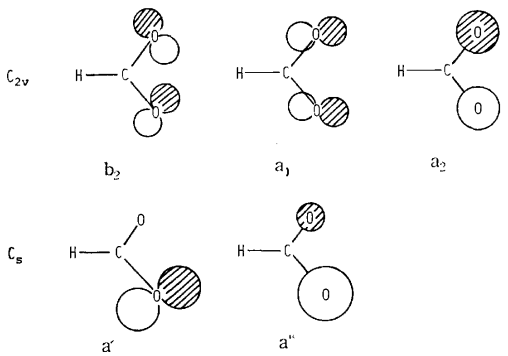

Fig. 1. Schematic representation of MO's which may be occupied by unpaired electron.

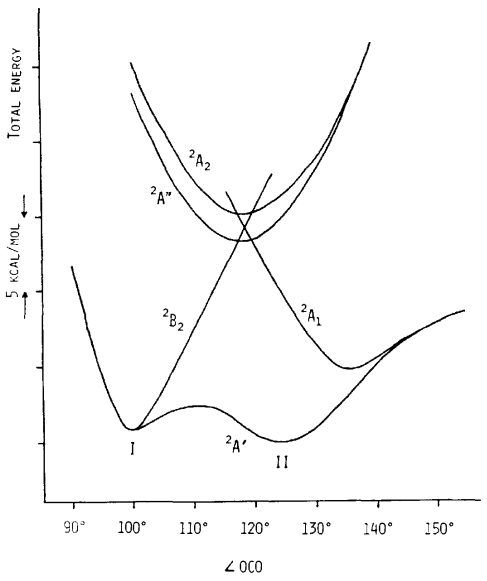

Fig. 2. Dependence of electronic states of formyloxyl radical upon the OCO angle. $^2B_2$, $^2A_1$, and $^2A'$ states correspond to the "σ-radical" and $^2A_2$ and $^2A''$ to the "π-radical".

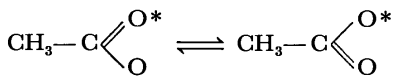
bond lengths which were optimized for each OCO angle and each state.

A σ-type electronic structure is more stable than a π-type structure over the entire range of OCO angles. The most stable π-type radical lies 13 kcal/mol above the most stable σ-radical. This is contrary to the theoretical results obtained up to the resent[2-4] and agrees with the experimental results which were derived from the g-tensors of several acyloxyl radicals.[1,2] Two stable conformations are expected for the ground state of formyloxyl: one is of C_{2v} symmetry (I: $^2B_2$ with $\angle OCO=100°$) and the other is of C_s symmetry (II: $^2A'$ with $\angle OCO=125°$). Although the energy difference between I and II is very small, their electronic structures differ greatly. In radical I, more than 98% of the unpaired electrons are equally shared on two equivalent oxygen atoms, while about 90% of the unpaired electrons localized on oxygen atom in radical II. The geometrical changes of formyloxyl along the lowest curve are listed in Table 1.

Table 1. Geometry of the $^2\Sigma$-type formyloxyl radical

Total energy	∠OCO	C-O(1)	C-O(2)	C-H
−772.04 eV	90°	1.315 Å	1.375 Å	1.065 Å
−772.51	100	1.250	1.250	1.075
−772.43	110	1.210	1.290	1.085
−772.52	120	1.245	1.300	1.075
−772.50	130	1.240	1.290	1.148
−772.31	140	1.230	1.255	1.225
−772.20	150	1.220	1.220	1.320
−772.15	160	1.190	1.190	1.420

The results for the acetoxyl radical were almost identical to those of the formyloxyl radical. In the acetoxyl radical, as for the formyloxyl radical, the energy difference between the two σ-radicals corresponding to I and II of formyloxyl is very small (<2 kcal/mol) and the barrier for the conversion between them is also very small (<2 kcal/mol). This indicates that the conversion



is very fast. In fact, the very fast scrambling between the two oxygen atoms, and the equivalence of the two oxygen atoms before the successive reactions involving the acetoxyl radical, have been confirmed experimentally.[7] A slight difference between formyloxyl and acetoxyl is the unpaired-electron distribution in radical II; 13% of the unpaired electrons delocalizes on the methyl-carbon atom in acetoxyl.

The question remains whether conventional MO methods can correctly predict the small energy difference between two closely adjacent electronic states. However, the present results are the first theoretical support for a σ-type ground state of the formyloxyl and acetoxyl radicals which appear to agree with the experimental facts derived from ESR spectra of several acyloxyl radicals.

ESR of F Center in $HgI_2 \cdot 2HgS$ Darkened with Sunlight

Kunio TAKEI, Hitoshi HAGIWARA, and Hiroshi TANAKA*

Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Miyazaki 880

**Minami Kyushu Coca Cola Bottling Co., Kumamoto 860*

(Received October 25, 1976)

Synopsis. When yellow powders of $HgI_2 \cdot 2HgS$ turn black in sunlight in a few seconds, the black powders show an ESR signal, whose intensity increases with the time of irradiation; its *g*-value is 2.0046 ± 0.00028. The result of analysis shows that this signal is due to F centers, consisting of electrons captured by positive holes prepared at sites of S^{2-} ions in the crystal.

Twenty five years ago one of the authors[1] observed by means of Gouy's method that initially diamagnetic yellow powders of $HgI_2 \cdot 2HgS$ become paramagnetic after a darkening with sunlight. A print-out of mercury atoms and evolution of SO_2 and I_2 from these crystals during irradiation with sunlight were confirmed by chemical analysis[2] and the darkening process was considered to occur as follows. When electrons belonging to S^{2-} or I^- ions in the crystals absorb wavelengths shorter than 510 nm and are excited to upper states, these electrons leave behind neutral S or I atoms, which diffuse toward the crystal surface, resulting in the formation of gases of SO_2 or I_2. Some parts of the excited electrons neutralize Hg^{2+} ions in the crystal, resulting in the formation of Hg atoms, which diffuse toward the crystal surface and aggregate there to form colloidal mercury. Other excited electrons are captured by positive holes, which were created at the sites of S^{2-} or I^- ions in the crystals after neutral S or I atoms escaped thermally out of the crystals. These trapped electrons, *i. e.*, F center electrons exhibit a paramagnetic behavior.

In recent years the authors[3] found by means of a radioactive tracer technique that when the yellow $HgI_2 \cdot 2Hg^{35}S$ or $Hg^{131}I_2 \cdot 2HgS$ is darkened in sunlight, gases of $^{35}SO_2$ or $^{131}I_2$ evolve and that the evolution velocity of the former gases is larger than that of the latter. It was found that the longer the time of irradiation, the larger the quantity of $^{35}SO_2$. This fact suggests that S^{2-} ions are more sensitive to sunlight than I^- ions and the paramagnetism of the darkened crystals is chiefly due to the F center electrons, consisting of positive holes and electrons belonging to S^{2-} ions. These trapped electrons must show an ESR signal, the details of which will be discussed in the present paper.

The ESR measurements were carried out at liquid nitrogen temperature by using a JEOL X-band spectrometer. Yellow powders of $HgI_2 \cdot 2HgS$ were made by the action of purified H_2S on a methanol solution of mercury(II) iodide, which was purified three times by sublimation. If crude powders of mercury(II) iodide were used as the material, the yellow powders showed an ESR signal in the dark. When the yellow powders prepared from the purified mercury(II) iodide, which gave no ESR signal, were darkened black as much as possible in sunlight with stirring by a glass rod for 1 or 2 h, an ESR signal appeared, as is shown in Fig. 1. The obtained signal is not sharp and the intensity is weak. This is due to the fact that the samples are powders, the particles of which are not completely darkened with sunlight. If the signal is due to a formation of a color center, the density of the color center of the darkened powders must be larger than 10^{16} cm^{-3}, because in general a color center can be recognized as an ESR line when the density reaches this value. The *g*-value of the observed signal, with a mean value from about 8 measurements for 8 different samples, was estimated to be 2.0046 ± 0.00028. This signal intensity increased with the time of irradiation with sunlight. This relation is shown in Fig. 2. When the darkened samples were heated at 95 °C for 30 and 60 min, the

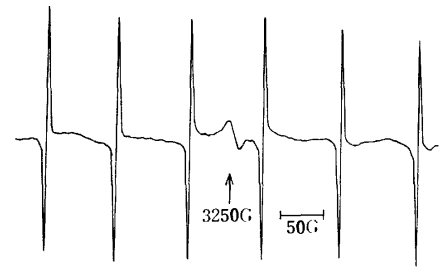

Fig. 1. ESR spectrum of $HgI_2 \cdot 2HgS$ irradiated by sunlight for 10 min.

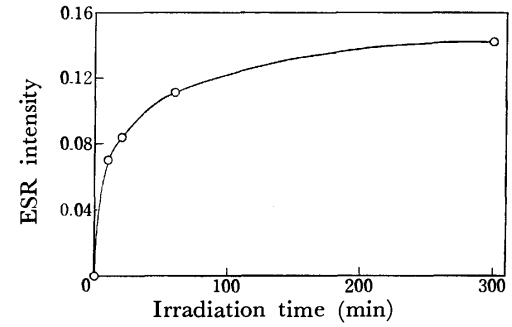

Fig. 2. ESR signal as a function of exposure time.

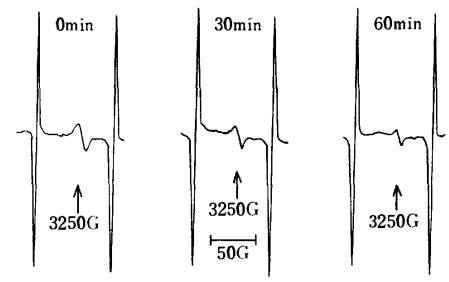

Fig. 3. ESR spectra of $(HgI_2 \cdot 2HgS)^*$ heated at 95 °C for some min.

intensity decreased with the time of heating and the sharpness increased, accompanied by a rapid recovery of the color. This relation is shown in Fig. 3. The *g*-value after thermal treatment, with a mean value of about 6 measurements for 6 different samples, was estimated to be 2.0026±0.00018.

The *g*-value obtained for the darkened $HgI_2 \cdot 2HgS$ is in agreement with the *g*-values of F centers presented by Alger[4] for different inorganic powder substances, and with the *g*-values of F centers for alkali halides given by Holton and Blum,[5] and with the *g*-value of the F center for MgO obtained by Wertz and his co-workers.[6] The F center ESR line often has some nuclear isotropic effects. Wertz and Auzins,[6] for example, found the F center ESR line for MgO with one or two ^{25}Mg ions around the negative ion vacancy, giving a six- or eleven-line hyperfine pattern centered upon the strong component. Similarly, Hausmann[7] found the F center ESR line for ZnO with one ^{67}Zn ion around the negative ion vacancy, giving a hyperfine pattern centered upon the strong component. In our sample, however, no effects of the nuclear spin of ^{199}Hg or ^{201}Hg on the pattern were observed, because of the complexity of the crystal structure of the sample. In 1972, Fujiwara and Isobe[8] showed that hot ions of the paramagnetic Hg(I) complex are formed by γ-irradiation of powders of $K_2[Hg(CN)_4]$ and that these ions are thermally very unstable at room temperature. All the spectra of the hot ions showed isotropic hyperfine splitting, which was recorded at K- or X-band frequency. The paramagnetism of the darkened $HgI_2 \cdot 2HgS$, however, is thermally very stable at room temperature and no isotropic hyperfine splitting appeared in spite of a sweep from 1000 to 10000 G. In 1966, Shields[9] reported that a reduction of silver ions in a pyrex glass by γ-rays induces an ESR spectra of Ag^0 accompanied with an isotropic hyperfine splitting. In our sample, the Hg^0 or Hg atom has nuclear spin, but no unpaired electrons. These discussions show that the ESR line in our sample cannot be explained by the mechanism of formation of Hg(I) or Hg^0.

Moran and his co-workers[10] reported that the bleaching of an F band produces a more rapid decrease in the density of magnetic centers than of the centers giving optical absorption in the F band; they suggested the presence of R, M, or N centers by a study of the temperature dependence of the relaxation time of F centers. Our complicated mercury complex exhibits a characteristic magnetic behavior, *i. e.*, a more rapid decrease in optical absorption centers than of the magnetic centers. This behavior is possible, because the results of thermal bleaching depend on the preparation methods of the F centers, as is reported by Alger.[11] If the signal in our sample is related to the existence of Hg^+ ions, or S or I neutral atoms in the crystal, the intensity of the signal should decrease rapidly when heated at 95 °C, because these ions or atoms are thermaly mobile in the crystal at 95 °C. It is conculded that the signal is not due to Hg^+ ions or S or I neutral atoms, but due to F centers, which are located at a deep energy level. When heated at 95 °C, the centers release slowly a small part of the trapped electrons, most of which are still captured, resulting in a formation of a new center, as is shown in Fig. 3. This new center has 2.0026±0.00018 as its *g*-value. The released electrons will be again captured by neutral atoms of S or I in the crystals to form S^{2-} or I^- ions, which react with Hg^{2+} ions to form HgS(black) or HgI_2, the existence of which was already chemically confirmed by the one of the authors.[2]

The authors with to thank Dr. S. Fujiwara, Dr. L. Shields, and Dr. A. Hausmann for many helpful discussions and suggestions during this work.

Luminescence of Aminopyridines and Related Molecules

Ko KIMURA, Hideko TAKAOKA, and Ryo NAGAI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received November 12, 1976)

Synopsis. Quantum yields and lifetimes of fluorescence and phosphorescence were measured for 2-, 3-, 4-aminopyridines, 2-, and 4-(dimethylamino)pyridines in ethanol–methanol, in an acidic ethanol–methanol mixture, and in a mixture of triethylamine and 2-methyltetrahydrofuran at 300 K and at 77 K. Quantum yields of fluorescence of 2- and 3-substituted pyridines are appreciable, while those of 4-substituted pyridines are as low as or less than 0.01 at 77 K. In view of the significant quantum yields of fluorescence for 2- and 3-substituted pyridines in the aprotic solvent, it may be concluded that the higher excited $^1(n\pi^*)$ or $^3(n\pi^*)$ states are not so close in energy to the lowest excited $^1(\pi\pi^*)$ states.

Quantum yields of fluorescence (Φ_f) of aminopyridines measured by Weisstuch and Testa[1] at room temperature suggest that the lowest excited singlet states (S_1) of 2- and 3-aminopyridines are assigned to $(\pi\pi^*)$, in contrast with that of 4-aminopyridine, which is assigned to $(n\pi^*)$ in nonpolar solvents or to the charge transfer type $(\pi\pi^*)$ in polar solvents. However, in view of the significant temperature dependence of Φ_f's for some nitrogen–heterocyclics,[2] measurements of Φ_f's and lifetimes of fluorescence (τ_f) at low temperature are desirable.

Φ_f's, τ_f's, quantum yields (Φ_p), and lifetimes (τ_p) of phosphorescence for 2-, 3-, 4-aminopyridines, 2-, and 4-(dimethylamino)pyridines are summarized in Tables 1 and 2. Solvents used were ethanol–methanol (A), an acidic (0.05 M H_2SO_4) ethanol–methanol mixture (H^+), and a mixture of triethylamine and 2-methyltetrahydrofuran (B). The first absorption bands of 2- and 3-substituted pyridines correspond fairly well to their fluorescence bands, as judged by the mirror symmetry relationship to each other. S_1's and the lowest excited triplet states (T_1) of 2- and 3-substituted pyridines are assigned unambiguously to $(\pi\pi^*)$ from Φ_f's and τ_p's in Table 1. The rate constants of the radiative transition (k_f) from S_1 are fairly independent of temperature and of protonation, while those of the radiationless deactivation (k_{nr}), which are composed of the rate constants of the internal conversion and the intersystem crossing from S_1, depend significantly on temperature and on protonation. If it is presumed that the k_f's are constant irrespective of the presence or absence of protons in solvents, then k_{nr}'s are estimated from Φ_f's without the observed τ_f's. k_{nr}'s at 77 K, designated in parentheses in Table 1, are calculated on this assumption, and those at 300 K on the assumption of the temperature-independent k_f's. As the Φ_p's of 2- and 3-substituted pyridinium cations used in this work are as low as or less than 0.01 at 77 K, their k_{nr}'s correspond

2AMP, 3AMP, and 2DMAMP represent 2-, 3-aminopyridines, and 2-(dimethylamino)pyridine, respectively.
k_f's and k_{nr}'s are deduced from the following equations: $k_f = \Phi_f/\tau_f$ and $k_{nr} = (1-\Phi_f)/\tau_f$.

approximately to the rate constants of the internal conversion from S_1. However, the estimated k_{nr}'s in an aprotic solvent at 77 K are fairly large, and suggest a significant contribution of the rate constants of the intersystem crossing from S_1, in view of decrease in Φ_f's and the corresponding increase in Φ_p's. An increase in k_{nr}'s for 2- and 3-aminopyridines in the aprotic solvent at 300 K may arise from the temperature dependence of the rate constants of the intersystem crossing[3] as well as those of the internal conversion, in marked contrast with the almost temperature-independent k_{nr} of 2-(dimethylamino)pyridine in the same solvent. However, the fairly large k_{nr} for a 2-(dimethylamino)pyridinium cation might be deduced from the scarcely observed Φ_f at 300 K, which is quite opposed to the change in Φ_f's found in 2- and 3-aminopyridinium cations. In view of the large Φ_f's even in the aprotic solvent at 77 K, the singlet or triplet ($n\pi^*$) states of 2- and 3-substituted pyridines are not so close in energy to the S_1's.

The Φ_f's of 4-substituted pyridines are smaller than 0.01 at 77 K, irrespective of the solvents used in this work. The phosphorescence spectra of 4-aminopyridine show vibrational structures, in which a characteristic vibration at 850 cm^{-1}, indicative of the C–H out-of-plane deformation mode of aromatic rings, may be found, while those of 4-(dimethylamino)pyridine are without vibrational structures.[4] As is summarized in Table 2, the large Φ_p's and the long τ_p's suggest that the T_1's of 4-substituted pyridines are ($\pi\pi^*$) irrespective of solvents used. The small Φ_f's of 4-substituted pyridines in the aprotic and the acidic solvents at 77 K are consistent with the assignment of S_1's proposed by Weisstuch and Testa.[1]

Experimental

2-, 3-, 4-Aminopyridines, and 4-(dimethylamino)pyridine were recrystallized three times from ethanol-ligroin, then purified through a basic alumina column, and finally sublimed *in vacuo*. 2-(Dimethylamino)pyridine was distilled through a spinning band column, then purified through a basic alumina column, and finally distilled twice *in vacuo*. Triethylamine and 2-methyltetrahydrofuran were stored over sodium-potassium alloy after distillation through a stainless steel helices packed column, and used without exposure to air. The methods of purification of other solvents and reagents were described elsewhere.[5]

Measurements of Φ_f's, Φ_p's, τ_f's, and τ_p's were the same as those described elsewhere.[5] The concentrations used in the measurements of Φ_f's and Φ_p's and those of τ_f's and τ_p's were 10^{-2}—10^{-3} M and 10^{-4}—10^{-5} M, respectively. In the former case, the correction of concentration quenching, if necessary, was made by the use of the Stern-Volmer equation. All the samples were evacuated by the repeated cycles of freezing, pumping, and thawing. Then, the sample cells were sealed off from the evacuation system.

A Note on the Rates of Complex Formation of Indium(III) with Murexide and the Decomposition of Murexide in the Presence of Indium(III)

Yoshimi OHTANI, Shin-ichi YAGIHASHI,* and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 11, 1976)

Synopsis. Kinetics of the complex formation between In(III) and murexide was studied by means of the temperature-jump method and the rate of decomposition of the ligand in acid nitrate media. The complex formation of $InOH^{2+}$ with murexide is about 10 times faster than that of In^{3+}. The stability constants indirectly obtained from the decomposition rate of murexide coincide with those from direct stopped-flow measurements.

Murexide, ammonium purpurate, is a useful metallochromic indicator except for the acid region where it decomposes to uramil and alloxan.[1] Kawai *et al.* studied the kinetics on the complex formation of murexide with In(III) and the decomposition of murexide in acid perchlorate media in the presence of In(III).[2] In this study no dependence of the rate of complex formation on hydrogen-ion concentration (0.001—0.5 M) could be observed. In addition a discrepancy in the stability constants was obtained from the two methods, the indirect calculation from the rate of decomposition of murexide giving a stability constant twice as large as that from the direct stopped-flow measurement. We have reexamined the questions with use of potassium nitrate instead of sodium perchlorate for adjusting the ionic strength in order to avoid the influence of the ion-pair formed between sodium ion and murexide anion.

Experimental

Materials. In order to prepare a stock solution of In(III) containing 1 M nitric acid, indium(III) oxide (Koso) was dissolved in excess of nitric acid by warming on a water bath. The concentration of In(III) was determined by titration with EDTA using Xylenol Orange as an indicator. The freshly prepared stock solution was used within a day in order to avoid undesired polymerization of In(III). Murexide was prepared and recrystallized.[3] A weighed amount of murexide was dissolved in water immediately before use. Acidity and ionic strength of the solution were adjusted with nitric acid and potassium nitrate.

Measurements. The rate of complex formation was measured with a Union Giken co-axial-cable temperature-jump apparatus Model RA-105. A Hitachi ESP-3T spectrophotometer equipped with a recorder was used to measure the rate of decomposition. Visible spectrum of unstable purpuric acid was obtained with a Union Giken rapid-scan spectrophotometer RA-1300, and the acid dissociation constant with a Yanagimoto SPS-1 stopped-flow apparatus.

Results and Discussion

Rate of Complex Formation. The rate of complex formation between In(III) and murexide was measured at the absorption peak of the complex, 460 nm, by means of the temperature-jump method at 20 °C and ionic strength 0.2 M (KNO_3). Acetic acid and potassium acetate were used to adjust pH. The results suggest the presence of a base-catalyzed path, the following mechanism being considered;

$$\begin{array}{ccc} In & + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} & InL \\ {\scriptstyle K_a}\downarrow\uparrow & & {\scriptstyle K_b}\downarrow\uparrow \\ In(OH) + H^+ & + L \underset{k_4}{\overset{k_3}{\rightleftharpoons}} & In(OH)L + H^+ \end{array}$$

$$\tau^{-1} = \frac{k_1[H]+k_3K_a}{[H]+K_a}\cdot C_{In} + \frac{k_2[H]+k_4K_b}{[H]+K_b},$$

where C_{In} is the total concentration of In(III) ($C_{In} \gg [L]$). The value of K_a in literature is adopted ($K_a = 10^{-4.42}$ M).[4] The values of rate constants are determined to be $k_1 = 6.0\times10^5$ M^{-1} s^{-1}, $k_2 = 50$ s^{-1}, $k_3 = 6.8\times10^6$ M^{-1} s^{-1}, and $k_4K_b = 2.3$ M s^{-1}. The hydrolyzed form, $InOH^{2+}$, reacts with the ligand about 10 times faster than the aquo form. This is in line with the tendency that the rate of complex formation of hydroxo metal ion is higher than that of the corresponding aquo metal ion.[5]

Acid Dissociation Constant of Purpuric Acid. Since murexide decomposes rapidly in an acid solution, the acid dissociation constant of protonated murexide or purpuric acid was measured by the stopped-flow method, giving $pK_1 = -0.24$. Rapid-scan spectroscopy gave $\lambda_{max} = 444$ nm, $\varepsilon = 2.2\times10^4$ l mol^{-1} cm^{-1} with an isosbestic point at 485 nm for purpuric acid.

Effect of [H] on the Decomposition Rate of Murexide. The decomposition of murexide is accelerated by acid. The reciprocal of the pseudo-first-order rate constant for the decomposition of murexide has a linear relationship with respect to $[H]^{-1}$, as shown in Fig. 1. The reaction mechanism is as follows;

$$MX + H \overset{K_H}{\rightleftharpoons} MXH \xrightarrow[+H_2O]{k} \text{Uramil} + \text{Alloxan},$$

$$k_{obsd}^{dec\,-1} = \frac{1}{k} + \frac{1}{kK_H}\cdot\frac{1}{[H]},$$

where MX and MXH denote purpurate anion and purpuric acid, respectively. Since the intercept of the straight line in Fig. 1 is too small for evaluation, the value obtained above is introduced into K_H ($K_H = K_1^{-1}$), giving the result $k = 0.13$ s^{-1}.

Rate of Decomposition of Murexide in the Presence of In(III). The rate of decomposition of murexide was measured at the absorption maximum of the complex. The rate decreases with increase in the concentration of In(III) (Fig. 2). The following reaction scheme is proposed:

* Present address: HOXAN Research Laboratories, Sapporo 060.

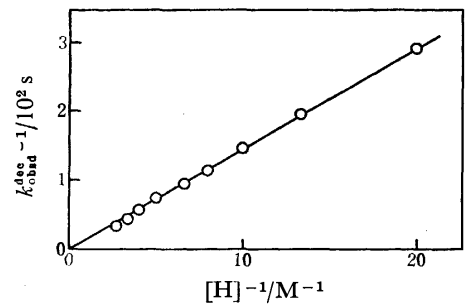

Fig. 1. Plot of $k_{obsd}^{dec\ -1}$ *vs.* inverse of hydrogen-ion concentration. At 520 nm, 10 °C, I=1.0 M (KNO_3), and $[MX]_0=5.0\times10^{-5}$ M.

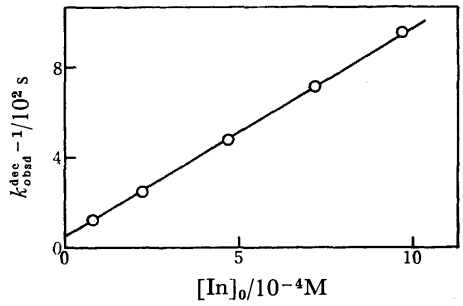

Fig. 2. Plot of $k_{obsd}^{dec\ -1}$ *vs.* total concentration of In(III). At 460 nm, 10 °C, [H]=0.25 M, I=1.0 M (KNO_3), and $[MX]_0=5.0\times10^{-5}$ M.

$$MX + In \overset{K_{In}}{\rightleftharpoons} InMX$$

$$MX + H \overset{K_H}{\rightleftharpoons} MXH \xrightarrow[+H_2O]{k} Uramil + Alloxan.$$

The rate of decomposition is given by

$$k_{obsd}^{dec\ -1} = \frac{[H]K_H + 1}{[H]kK_H} + \frac{K_{In}}{[H]kK_H}\cdot[In]_0.$$

Introduction of the above results into K_H and k leads to $K_{In}=1.5\times10^4\ M^{-1}$. The value coincides with the direct stopped-flow data, $K'_{In}=k_1/k_2=1.4\times10^4\ M^{-1}$, I=1 M (KNO_3) at 10 °C. Agreement of the two values indicates that the proposed mechanism is correct. The terdentate structure of the complex coordinated at the central nitrogen atom of the ligand stabilizes the ligand molecule against decomposition.[6]

The discrepancy in the two stability constants derived from the direct and the indirect measurements[2] would be clarified in terms of two effects of the sodium ion: (1) Sodium ion forms an ion-pair with purpurate anion, which is fairly stable against acid. (2) The ion-pair, $Na^+\cdots MX^-$, also forms a complex with In(III). Since the data on the ion-pair are very limited, no further discussion can be made.

The present work was supported by a grant-in-aid for Scientific Research from the Ministry of Education.

Polarographic Studies of Several Metal Ions in the Molten Salts of KNO_3–$LiNO_3$–$NaNO_3$

Makoto SAITO and Tamio MIURA

Department of Chemistry, College of Liberal Arts, Toyama University, Gofuku, Toyama 930

(Received December 10, 1976)

Synopsis. The polarographic waves of Pb(II), Cd (II), Zn(II), and Tl(I) ions in molten salts of KNO_3–$LiNO_3$–$NaNO_3$ were measured by means of d.c. polarography, using an $Ag/AgNO_3$ reference electrode. The half-wave potential of metal ions was shifted toward more negative values in comparison with those in a nitrate melt containing no Li(I) ion.

The formation constants of several metal halide complexes in an alkali nitrate melt have been determined by means of d.c. polarography.[1-3] On the other hand, there have been only a few studies about the effect of the alkali metal ion as a component of the solvent on the half-wave potential of the reducible species. Kawamura[4-6] studied, by means of voltammetry and chronopotentiometry, the change in the diffusion coefficient of the Ag(I) ion over a wide composition range of molten salts of KNO_3–$NaNO_3$, KNO_3–$LiNO_3$, and KNO_3–$CsNO_3$. Francini and Martini reported that the peak potentials(E_p) of the oscillopolarogram of some metal ions in molten salts of KNO_3–$NaNO_3$ were shifted toward more positive values by adding variable quantities of $LiNO_3$ to the melt.[3]

The present authors have studied the half-wave potential($E_{1/2}$) of the polarographic wave of several metal ions in the molten salts of KNO_3–$LiNO_3$–$NaNO_3$, using the $Ag/AgNO_3$ reference electrode, and compared the obtained half-wave potential with the data obtained by Swofford and Holified[7] and by Tridot *et al.*[8]

Experimental

Reagent-grade chemicals were used in these experiments. The solvent used was the KNO_3–$LiNO_3$–$NaNO_3$(53 : 30 : 17 mol%, mp 120 °C) eutectic system. The eutectic materials were separately dried in a vacuum-oven at 100 °C for several days, and these mixed and gently fused in an argon gas atmosphere.

The metal salts used were $Pb(NO_3)_2$, $TlNO_3$, $Cd(NO_3)_2 \cdot 4H_2O$, and $Zn(NO_3)_2 \cdot 6H_2O$. The polarographic waves of the metal ions were not disturbed by the crystal water in metal salts. The concentration of the metal ions in a melt was determined by means of EDTA titration. The capillary used as the dropping mercury electrode(DME) was made of Pyrex glass. The drop time of the DME was about 3—5 s per drop at a height of 60—80 cmHg. The $Ag/AgNO_3$(0.05 mol/kg) electrode was used as the reference electode. Asbestos was used as a diaphragm between the reference electrode and the test solution. The temperature used in the experiments was 180 °C. The rest of the experimental procedure has been described elsewhere.[9]

Results and Discussion

The polarographic waves of some metal ions at 180 °C are shown in Fig. 1, in which curve(a) is a typical residual current curve and in which the useful potential range available to obtain polarographic waves is from 0 to −1.4 V *vs.* the $Ag/AgNO_3$ reference electrode; the maximum current obtained in this range was about 2 μA at −1.4 V. However, the final ascendent potential in the residual current was shifted toward a positive potential and the useful potential range was diminished about 100 mV, when the solution stood for a day and night. Curves(b), (c), (d), and (e) in Fig. 1 are the polarographic waves of the Pb(II), Cd(II), Tl(I), and Zn(II) ions. The polarographic waves of these metal ions indicated S-shaped waves. The plots of E *vs.* $\log[i/(i_d-i)]$ for polarographic waves are shown in Fig. 2, in which the plots give a straight line and the slope of the line was Pb(II): 45 mV, Cd(II): 41 mV, Tl(I): 80 mV, and Zn(II): 41 mV

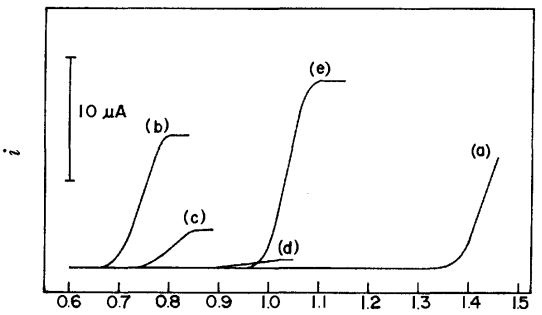

Fig. 1. Polarographic waves of some matel ions at 180 °C,
(a): Residual current curve of the molten salts of KNO_3–$LiNO_3$–$NaNO_3$, (b): Pb(II) ion, 2 mmol/kg, (c): Cd(II) ion, 1 mmol/kg, (d): Tl(I) ion, 0.2 mmol /kg, (e): Zn(II) ion, 3 mmol/kg.

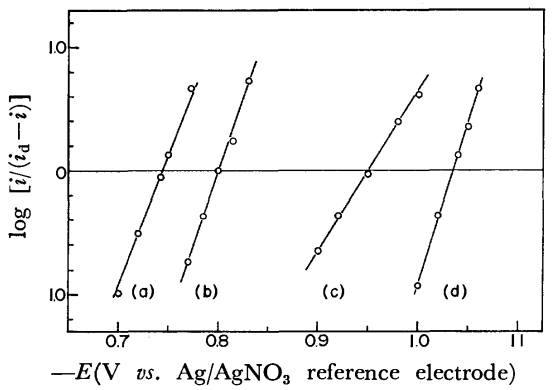

Fig. 2. Analyses of the polarographic waves of some metal ions at 180 °C. The slope of the line is 45, 41, 80, or 41 mV against $\log[i/(i_d-i)]$ for Pb(II), Cd(II), Tl(I), or Zn(II) ions.

TABLE 1. THE HALF-WAVE POTENTIALS OF SOME METAL IONS IN MOLTEN ALKALI NITRATES

	$-E_{1/2}$ (V *vs.* $Ag/AgNO_3$)				Ref.
	Pb(II)	Cd(II)	Tl(I)	Zn(II)	
Holifield and Swofford	—	0.665	0.828	—	(7)
Tridot *et al.*	0.560	0.565	0.730	0.820	(8)
Present authors	0.744	0.800	0.949	1.034	

($2.303RT/F$=90 mV at 180 °C). These polarographic waves are reversible, and the electrode reactions of metal ions are the transfer of two electrons(one electron in the case of the Tl(I) ion). The half-wave potentials of the metal ions were determined from the logarithm plots; they are tabulated in Table 1. As is evident from Table 1, the half-wave potentials of metal ions had more negative values than that obtained in the solvent containing the Li(I) ion and the useful potential range is diminished as compared with those obtained in the molten salts of KNO_3–$NaNO_3$ by Swofford *et al.* and by Tridot *et al.* The half-wave potentials of the metal ions obtained by Swofford *et al.* also differed from those obtained by Tridot *et al.* It is considered that the discrepancy in the half-wave potentials in their data reflects the difference in the concentration of $AgNO_3$ in the reference electrode.

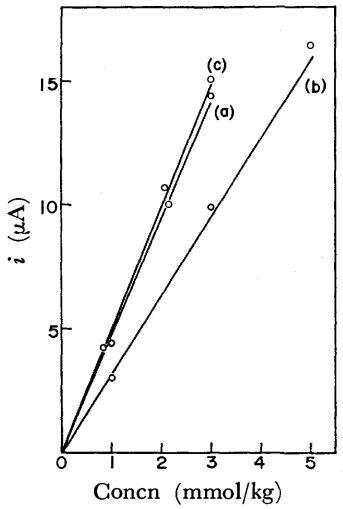

Fig. 3. Relationships between the limiting current and the concentrations of some metal ions at 180 °C.
(a): Pb(II) ion, (b): Cd(II) ion, (c): Zn(II) ion.

The linear dependence of the diffusion current on the metal ion concentration is shown in Fig. 3. The Ilkovic equation was applied in the ranges of 0.0—3.0 mmol/kg for Pb(II), 0.0—5.0 mmol/kg for Cd(II), and 0.0—3.0 mmol/kg for Zn(II). The diffusion current coefficients(I: $[\mu A]/[mg^{2/3}\,s^{-1/2}][mmol/kg]$) of the metal ions were Pb(II): 3.04, Cd(II): 3.11, Zn(II): 3.17. In the case of the Tl(I) ion, the maximum wave appeared in the concentration of the Tl(I) ion of more than 0.4 mmol/kg.

Photoreaction of Ferrocene with Some Acetylene Derivatives

Haruo WATANABE, Kazuo ITO, Fumio NAKANISHI, Takeo AKIYAMA, and Akira SUGIMORI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7, Chiyoda-ku, Tokyo 102

(Received March 17, 1976)

Synopsis. The UV-irradiation of ferrocene and dimethyl acetylenedicarboxylate in acetic acid–water solution afforded dimethyl ferrocenylmaleate and dimethyl ferrocenylfumarate in 40 and 5% yield, respectively. Methyl 3-carbamoylpropiolate, dicyanoacetylene, and methyl propiolate were also reactive and the corresponding substituted ferrocenes were obtained. The reaction can be considered to proceed *via* the excitation of the charge transfer complex between ferrocene and acetylene derivatives.

As reported,[1] UV-irradiation of the ferrocene-halogenated hydrocarbon-ethanol system gave substituted ferrocene *via* the excitation of the charge transfer complex between ferrocene and halogenated hydrocarbon. We found a similar photo-substitution of ferrocene with some electron defficient acetylene derivatives.

When an acetic acid–water solution of ferrocene (**1**) and dimethyl acetylenedicarboxylate (**2a**) in a quartz vessel was irradiated with 254 nm light for 24 h under nitrogen atmosphere, dimethyl ferrocenylmaleate (**3a**) and dimethyl ferrocenylfumarate (**4a**) were obtained in 40 and 5% yield, respectively. When methyl 3-carbamoylpropiolate (**2b**), dicyanoacetylene (**2c**), and methyl propiolate (**2d**) were used instead of **2a**, photo-products similar to **3a** and **4a** were obtained. However, the yields of the photo-products were lower than those of **3a** and **4a**, and the isomer ratio, **3**/**4**, was different from that obtained in the case of **2a**. The results of the photoreactions are listed in Table 1. Other acetylene derivatives, such as phenylacetylene, diphenylacetylene, methyl 3-phenylpropiolate, phenylpropiolaldehyde, and acetylenedicarboxamide, were unreactive for this photoreaction and gave no substituted ferrocene under the UV-irradiations. The effect of additives and the wavelength of light used were examined for the **1**–**2a**–acetic acid–water systems which showed the highest yields of the photo-products. The results showed that the radical scavenger, cyclohexene, retarded the photo-substitution of ferrocene very little [yield of **3a**: without additive, 21%; with cyclohexene, 14%]. This result indicates that this photo-substitution does not proceed *via* the coupling of free, separate radicals as reported for the reaction of furan with **2a**,[2] but proceed *via* the geminate coupling of the radical pair in the solvent cage.[3] Benzophenone, a triplet sensitizer, was not effective for the formation of **3a** and **4a**. This result indicates that the contribution of the triplet state of **1** or **2a** for the photo-substitution is very small. In the irradiation with light of wavelength longer than 300 nm(high pressure mercury lamp with a Pyrex filter), only a trace amount of **3a** was obtained and more than 60% of **1** and **2a** were recovered.

The formation of the charge transfer complex between **1** and **2a** in the ground state was supported by the

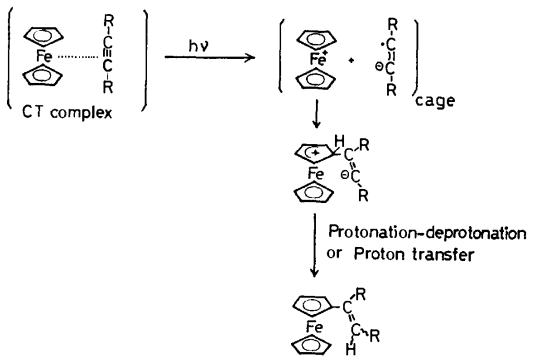
1) These photoreactions were carried out below 25 °C. 2) Yields based on consumed ferrocene. The yields in parentheses are the net yields based on ferrocene used. 3) LP denotes a low pressure mercury lamp. 4) This reaction was carried out above 35 °C.

spectral data. The UV-spectra of **1** and **2a** in acetic acid showed an increment of absorption in the 250—300 nm region and the NMR spectra (measured at 90 MHz) of the mixed solution of **1** and **2a** in acetic acid showed a small downfield shift of the proton signals of **1** and an upperfield shift of those of **2a**, as compared to the corresponding proton signals measured independently. Based on these spectral data and on the effect of additives, the following processes can be considered for the present photo-substitution of ferrocene: i) The excitation of the charge transfer complex of **1** and **2a** to its singlet state. ii) One electron transfer from **1** to **2a**, followed by the formation of ferrocenium cation and anion radical of **2a**. iii) Coupling of the radical anion of **2a** with ferrocenium cation in the solvent cage. iv) Deprotonation and protonation to the anionic center of olefin,[4] or proton transfer.



When acetone, acetonitrile, ethyl acetate, and methanol was used as the solvent, the yields of **3a** were much lower. This solvent effect indicates that the protic solvent with high polarity is necessary for this photo-substitution.

Experimental

Materials. Commercially available ferrocene (Wako Junyaku, GR-grade reagent) was used without further purification. Dimethyl acetylenedicarboxylate (Wako Junyaku, EP-grade reagent) was purified by column chromatography on silica gel (Merck, GF-254, Type 60) before use. Methyl 3-carbamoylpropiolate was prepared by mixing dimethyl acetylenedicarboxylate and ammonia–water for several hours. Dicyanoacetylene was prepared by the method described in the literature.[5] Commercial methyl propiolate (Wako Junyaku, EP-grade reagent) was used without further purification. Acetic acid and other solvents used in this reaction were all purified by distillation under nitrogen atmosphere and dried just before use.

Irradiation Procedure. The general execution of the photoreaction is represented by the procedure for the photo-substitution of ferrocene with dimethyl acetylenedicarboxylate.

Photoreaction of Ferrocene (1) with Dimethyl Acetylenedicarboxylate (2a). The acetic acid–water(3 : 1, v/v, 40 ml) solution of **1** (37 mg, 0.2 mmol) and **2a** (57 mg, 0.4 mmol) was degassed and then filled with nitrogen. This sample solution was irradiated in a quartz vessel with a low pressure lamp(Taika Kogyo, 16 W) for 24 h. After the irradiation, 100 ml of ethyl acetate was added to the reaction mixture and washed with water and then with aqueous sodium hydrogencarbonate solution. The ethyl acetate solution was dried and concentrated under reduced pressure. The residue was subjected to preparative TLC on silica gel (Merck, CF-254). **3a** and **4a** were obtained as a mixture. Further separation with TLC afforded 17.3 mg (40.6%) of **3a** as a red-purple oily solid. **3a**: IR(KBr) 1718, 1725 cm^{-1} (C=O), 1620 cm^{-1} (C=C), 1100, 1000 cm^{-1} (monosubstituted ferrocene); NMR(CCl_4), δ(ppm from TMS) 3.69 (s, 3H, $-CH_3$), 3.85 (s, 3H, $-CH_3$), 4.15 (s, 5H, C_5H_5), 4.32 (4H, C_5H_4), 5.86 (s, 1H, olefinic proton); MS(70 eV), *m/e*, 328(M^+). Found: C, 57.96; H, 5.00%. Calcd for $C_{16}H_{16}O_4Fe$: C, 58.57; H, 4.88%, M, 328. From another fraction, 2 mg (4.7%) of **4a** was obtained. **4a**: IR(direct) 1720, 1725 cm^{-1} (C=O), 1620 cm^{-1} (C=C), 1100, 1000 cm^{-1} (monosubstituted ferrocene); NMR(CCl_4), δ(ppm from TMS) 3.65 (s, 3H, $-CH_3$), 3.86 (s, 3H, $-CH_3$), 4.06 (s, 5H, C_5H_5), 4.30 (t, 2H, 3-, 4-position of C_5H_4–), 4.70 (t, 2H, 2-, 5-position of C_5H_4–), 6.37 (s, 1H, olefinic proton); MS(70 eV), *m/e*, 328(M^+). Found: C, 58.10; H, 4.95%. Calcd for $C_{16}H_{16}O_4Fe$: C, 58.57; H, 4.88%, M, 328.

3b and **4b** were obtained in the photoreaction of **1** with **2b**. **3b** and **4b** were obtained as a mixture and further separation was not possible. NMR(mixture in CCl_4), δ(ppm from TMS) 3.71(s, 3H, $-CH_3$ of ester **4b**), 3.87(s, 3H, $-CH_3$ of ester **3b**), 4.13(s, 5H, C_5H_5 of **4b**), 4.19(s, 5H, C_5H_5 of **3b**), 4.3—4.6(6H, C_5H_4– of **3b**, and H_2, and H_5 of C_5H_4– of **4b**), 4.74(t, 2H, H_3, H_4 of C_5H_4– of **4b**), 5.34 (s, 1H, olefinic proton of **3b**), 6.08(s, 1H, olefinic proton of **4b**); IR(mixture, KBr) 3490, 3390, 1630, 1550 cm^{-1} (NH_2 of primary amide), 1665 cm^{-1} (C=O of amide), 1715 cm^{-1} (C=O of ester), 3080, 1600, 780 cm^{-1} (C=C), 1100, 1000, 830 cm^{-1} (monosubstituted ferrocene).

3c and **4c** were obtained only when the acetic acid solution of **1** and **2c** was irradiated at 35—40 °C. As the isolation of **3c** and **4c** was not possible, the assignment and the quantitative analysis were done based on the NMR spectra of the mixture. NMR(mixture in CCl_4), δ(ppm from TMS) 4.24 (s, 5H, C_5H_5 of **4c**), 4.26(s, 5H, C_5H_5 of **3c**), 4.49 (t, 2H, H_2, H_5 of C_5H_4– of **4c**), 4.60(t, 2H, H_2, H_5 of C_5H_4– of **3c**), 4.94(t, 2H, H_3, H_4 of C_5H_4– of **4c**), 5.05(t, 2H, H_3, H_4 of C_5H_4– of **3c**), 5.72(s, 1H, olefinic proton of **3c**), 6.45(s, 1H, olefinic proton of **4c**); IR(direct) 3080, 1605, 770 cm^{-1} (C=C), 2210 cm^{-1} (–C≡N), 1105, 1030, 990(sh) cm^{-1} (monosubstituted ferrocene).

4d was obtained in the photoreaction of **1** with **2d** in acetic acid–water solution. As a main product, **4d** was obtained from TLC. NMR(CCl_4), δ(ppm from TMS) 2.12 (s, 3H, $-CH_3$), 3.81 (s, 3H, $-CH_3$ of ester), 4.10 (s, 5H, C_5H_5), 4.32 (s, 4H, C_5H_4–), 6.17 (s, 1H, olefinic proton). IR(KBr), 1725 cm^{-1} (C=O), 1580 cm^{-1} (C=C), 1100, 1000 cm^{-1} (ferrocene).

The Elimination Reaction of Chlorobutane over Some Molten Salts*

Shōichi KIKKAWA, Masakatsu NOMURA, and Takashi IKEUCHI
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received September 16, 1976)

Synopsis. The elimination reactions of hydrogen chloride from 1-chlorobutane and 2-chlorobutane over molten salts ($ZnCl_2$, $SnCl_2$, CuCl melts) have been studied by using both a microreactor and a conventional flow reactor. The preferential formation of *cis*-2-butene in the reaction of 2-chlorobutane can be explained in terms of the stereochemistry of the surface-adsorbed carbonium ion.

Some molten salts, such as $SnCl_2$–KCl and $ZnCl_2$-containing melts, are known to assist the dehydrohalogenation of alkyl halides.[1–4] However, little is known about the stereochemistry of dehydrohalogenation over molten-salt catalysts. The present investigation was undertaken in order to obtain stereochemical information about the dehydrochlorination of chlorobutanes over $ZnCl_2$–KCl–NaCl melts, $SnCl_2$–KCl melts, and CuCl–KCl melts from the butene isomer-distribution and in order to discover a convenient method of using the pulse technique[5] for such a dehydrochlorination.

Results and Discussion

Elimination by Microcatalytic Reaction. The contact time of reactants with molten-salt catalysts was arbitrarily defined to be the reciprocal of the flow rate of hydrogen (F^{-1} s/ml), where various flow velocities were attained by varying the flow rate of the hydrogen carrier gas. The conversion percentage of 2-chlorobutane is plotted as a function of F^{-1} at 250 °C and 280 °C in Fig. 1, where the ratio of % conv with the $ZnCl_2$ melts to that with the $SnCl_2$ melts is shown to be about 10 to 1 (at 250 °C), while this conversion ratio is about 2—3 to 1 in the case of the ratio of the $SnCl_2$ melts to the CuCl melts (280 °C). Therefore, the relative activities for dehydrochlorination are $ZnCl_2 \gg SnCl_2 >$ CuCl melts.

The distribution of butene isomers over three kinds of molten salts are shown in Table 1, where the values of the thermal reaction and the equilibrium values are also cited for comparison. Although the % conv varied markedly from melt to melt, the *cis*/*trans* ratios (cited in Table 1) of 2-butene produced are much the same (1.3—1.4) over the series of melts. To examine the possibility of the isomerization of the olefins after elimination, the pulses of 1-butene and 2-butene isomers were passed over the $ZnCl_2$ melts.[6] However, no isomerization among the 1-, *cis*-2-, and *trans*-2-butenes was observed. The *cis*/*trans* ratio of the 2-butene produced over these salts is larger than the equilibrium values; this preferable formation of *cis*-2-butene is considered to be characteristic of this reaction.

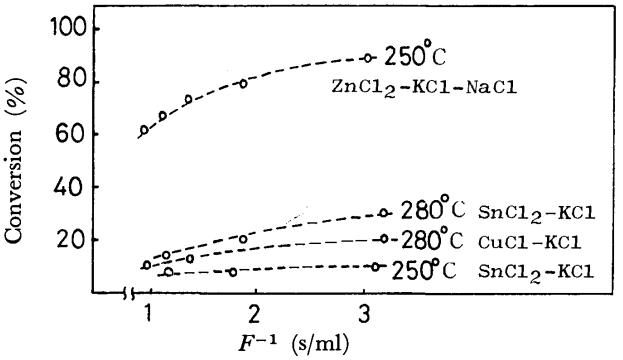

Fig. 1. Plots of % conv. of 2-chlorobutane *vs.* F^{-1}.

The reactivity of 1-chlorobutane over these molten salts becomes considerably lower than that of 2-chlorobutane. With $ZnCl_2$ melts, the % conv of 2-chlorobutane is 25 times as large as that of 1-chlorobutane, while the reactivity ratio of 2-chlorobutane/1-chlorobutane becomes about 9 in the case of the $SnCl_2$ melts. The relative catalytic activity of these melts for the de-

cis/trans		1.2	1.3	1.4

a) Flow rate of Ar: 0.056 mol/h. Feed rate of reactant: 0.12 mol/h.

hydrochlorination of 1-chlorobutane was found to be different from that for 2-chlorobutane; that is, the ratio of % conv with the $ZnCl_2$ melts to that with the $SnCl_2$ melts is 2.5 to 1 (at 310 °C).

Table 2 shows the distribution of butene isomers resulting from the reaction of 1-chlorobutane over molten salts. In the last row of Table 2, the *cis/trans* ratios of 2-butene are presented. The preferable formation of 2-butene from 1-chlorobutane indicates that this elimination proceeds *via* a carbonium-ion mechanism involving rearrangement.[3,4]

The finding that *cis*-2-butene is formed in preference to *trans*-2-butene in the reaction of 2-chlorobutane over a series of molten salts can be explained in terms of the stereochemistry of the surface-adsorbed carbonium ion proposed by Noller, with the elimination of chlorobutane over CaO solid catalysts.[7] The secondary carbonium ion is attached to the molten-salt surface, where its most favorable conformation is as is shown in Fig. 2. Accordingly, *cis*-2-butene is preferably formed by sharing a free-electron pair resulting from the removal of H_b(by the chloride ion), with the vacant p orbital at C_2 (preferred path of the lower-energy barrier).

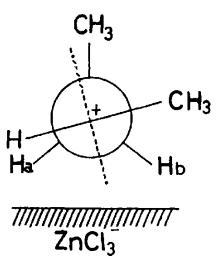

Fig. 2. Molten salts surface-adsorbed carbonium ion. Dotted line shows the vacant p orbital.

Elimination by Conventional Flow Method. Since the present elimination reaction is considered to be first-order, it was expected that the results from the pulse technique would be in agreement with those from the flow method. Table 3 shows the distribution of butene isomers obtained from both 1- and 2-chlorobutane, along with the values of % conv and the *cis/trans* ratios. As Table 3 clearly indicates, no notable differences were observed in the product distribution, the *cis/trans* ratio, or the % conv between the microcatalytic and the steady-state-flow reaction data. That is, in the study of such an elimination reaction over molten salts, the application of this microcatalytic method is of use experimentally. However, with the flow method, there was a tendency for the $ZnCl_2$ melts to have lower *cis/trans* ratios of the elimination of 2-chlorobutane compared with the results of the pulse method. This tendency may be explained by considering the small amount of the isomerization of products assisted by the considerable amounts of HCl dissolved in $ZnCl_2$ melts.

Experimental

Reagents. The 1-chlorobutane and 2-chlorobutane were obtained from Wako Pure Chemical Industries, Ltd. along with the three isomers of butene. The metal halides were guaranteed reagents from Nakarai Chemicals.

Apparatus and Procedure. A commercial gas chromatograph was arranged so as to record the amount of the pulse of the reactant (injected by means of a microsyringe, 1 μl) with a Silicone DC 550 column (75 cm) and to separate the products obtained after the reactant had passed over the melts in the reactor using a BMEE column (6 m) at 0 °C. A Pyrex-tube reactor containing the molten salts, immersed in a temperature-controlled salt bath, was connected to the gas chromatograph by means of a six-port valve which also served to dry the molten salt media by passing N_2 through before carrying out the pulse reaction.

For conventional flow experiments,[8] a vapor mixture of Ar and chlorobutane was bubbled up through dry molten salts for a period of 30 min. An Ar flow containing vaporized products was introduced, from the exit side, to the gas sampler once every 15 min. The gas-chromatographic separation of the products was done with a BMEE column (6 m).

(Received October 5, 1976)

Synopsis. Photolysis of diphenyltin polymer, $(Ph_2Sn)_m$, afforded diphenylstannylene, Ph_2Sn:, which was captured by alkyl halides, R'X, to give the insertion products, $Ph_2R'SnX$. The reactivity of Ph_2Sn: was found to be lower than that of dibutylstannylene, Bu_2Sn:.

In continuation of our investigations of diorganostannylenes,[1-3] the photolytic formation and some reactions of diphenylstannylene have been investigated. Diphenylstannylene, transiently formed, has been efficiently captured by several alkyl bromides and methyl iodide.

A solution of pale yellow diphenyltin, $(Ph_2Sn)_m$,[4] in a large excess of ethyl bromide was irradiated with a high pressure mercury lamp through a pyrex filter at 0 °C to give a mixture of distillable phenyltin bromides: *viz.*, $Ph_2EtSnBr$ (64%), Ph_2SnBr_2 (20%), $PhEtSnBr_2$ (3%), and Ph_3SnBr (2%), together with a trace of undistillable stannoxanes. The major product, $Ph_2EtSnBr$, should be produced by the insertion reaction of diphenyl stannylene, Ph_2Sn: (**2**), into the C–Br bond of ethyl bromide (Eq. 2). The minor disproportionation products, Ph_3SnBr and $PhEtSnBr_2$, could be formed by the photo-induced transposition[1] of the phenyl group and the scrambling of the phenyl and bromide groups, respectively.

$$(Ph_2Sn)_m \xrightarrow{h\nu} [Ph_2Sn:] + (Ph_2Sn)_{m-1} \quad (\mathbf{1} \rightarrow \mathbf{2} + \mathbf{1})$$

$$\text{or } \cdot Sn(Ph_2)-(Sn(Ph_2))_{m-3}-Sn(Ph_2)\cdot \quad (\mathbf{3}) \qquad (1)$$

$$[Ph_2Sn:] \xrightarrow{R'Br} Ph_2R'SnBr \quad (\mathbf{2}) \qquad (2)$$

It is important to note that a considerable amount (20%) of diphenyltin dibromide was obtained. In contrast, photochemical reactions of dibutyltin with alkyl bromides gave only a low yield of dibutyltin dibromide (4%).[1] There seem to be two possible pathways for the formation of diphenyltin dibromide. (i) A part of diphenylstannylene might possess a biradical character (*i. e.*, in a triplet state) and abstract two bromine atoms from ethyl bromide to give the dibromide. Although the spin state of the stannylene cannot be discussed from our present results, the idea of triplet diphenylstannylene could offer one explanation for the formation of diphenyltin dibromide. (ii) Diphenylbromostannyl radical (**5**) formed by the photochemical cleavage of the Sn–Sn bond of the compound (**4**) could

$$\cdot Sn(Ph_2)-(Sn(Ph_2))_{m-3}-Sn(Ph_2)\cdot \longrightarrow Br-Sn(Ph_2)-(Sn(Ph_2))_{m-3}-Sn(Ph_2)-Br \xrightarrow{h\nu}$$

(**3**) (**4**)

$$Br-Sn(Ph_2)-(Sn(Ph_2))_{m-3}\cdot + \cdot Sn(Ph)_2-Br \longrightarrow$$

(**5**)

$$Br-Sn(Ph_2)-(Sn(Ph_2))_{m-3}-Br + Br-Sn(Ph)_2-Br \qquad (3)$$

(**6**)

afford diphenyltin dibromide (Eq. 3). The possible intermediate, 1,2-dibromotetraphenylditin (**4**, $m=3$), could not be found in the reaction products. This compound could be completely consumed to give diphenyltin dibromide according to Eq. 3. This shows that the Sn–Sn bond of the tetraphenylditin compounds (**3**, **4**, $m=3$) could be cleaved by the UV irradiation in the case of diphenyltin derivatives. This is in sharp contrast to the case of dibutyltin, in which 1,2-dibromotetrabutylditin was formed in about 30% yield.[1]

Another noticeable observation in the photolytic reaction of diphenyltin is the lower reactivity of diphenylstannylene compared with that of dibutylstannylene. The lower reactivity of diphenylstannylene might be implied by the following facts: A longer irradiation time was needed to achieve a high conversion, and diphenyltin did not react with alkyl monochlorides. Even after the irradiation of diphenyltin in propyl chloride for 90 min, the insertion product, $Ph_2PrSnCl$, was not detected in the reaction mixture. A low yield (26

%) of the insertion product, $Ph_2(ClCH_2)SnCl$, was obtained in the reaction with dichloromethane.[5]

All the results of the photochemical reactions of diphenyltin with alkyl halides and the ^{13}C-NMR spectral data of the insertion products are listed in Tables 1 and 2, respectively.

Photolysis of diphenyltin has been proved to be a more effective and facile method for the formation of diphenylstannylene than a thermal reaction of diphenyltin.[3] In the thermal reaction, formation of diphenylstannylene was a minor reaction path and various disproportionation reactions predominated.

Experimental

The ^{13}C-NMR spectra were recorded in the pulse Fourier transform mode using a JEOL-FX 60 spectrometer operating at a resonance frequency of 15.03 MHz. The parameters used were: pulse width 8 μs, spectral width 2500 Hz for 8 K data points. Chemical shifts are given in ppm downfield from internal TMS.

The ^1H-NMR spectra were measured in deuteriochloroform with a Varian EM 360 spectrometer operating at 60 MHz.

Gas-liquid chromatography (GLC) was carried out at 230 °C using Apiezon grease L as a stationary phase.

Photolytic Reaction of Diphenyltin with Ethyl Bromide. Yellow crystalline diphenyltin[4] (0.362 g) was dissolved in a large excess of ethyl bromide (8 ml) in a sealed pyrex glass ampoule, and was irradiated with a high pressure mercury lamp (450 W) at 0 °C under nitrogen atmosphere for 80 min. After irradiation, the excess of ethyl bromide was evaporated off to give a viscous liquid. The product was distilled *in vacuo* using a Kugelrohr (bath temperature was up to 200 °C) to give a trace of residue and a colorless distillate (0.813 g) containing $PhEtSnBr_2$, Ph_2SnBr_2, $Ph_2EtSnBr$, and Ph_3SnBr. These bromides were identified by the IR, ^1H-NMR,[3] and ^{13}C-NMR spectra. A part of the distillate was treated with a large excess of methylmagnesium iodide in ether to convert the phenyltin bromides quantitatively into the phenylmethyltin derivatives. Distribution of the products was determined by GLC: $PhEtSnMe_2$: Ph_2SnMe_2 : $Ph_2EtSnMe$: Ph_3SnMe = 2.8 : 24.1 : 69.5 : 2.7. It was confirmed that vacuum distillation caused no noticeable change in the distribution of the products.

The reactions with methyl iodide, propyl bromide, dichloromethane, and dibromomethane were carried out under similar conditions. In the reaction with methyl iodide, the product was treated with ethylmagnesium bromide for the determination of the distribution. In the reaction with dibromomethane, the product was distilled under high vacuum (0.02 Torr) to avoid the thermal decomposition. The distribution was determined by the integral values in the ^1H-NMR spectrum, since the methylation of $Ph_2(BrCH_2)SnBr$ with methylmagnesium iodide gave undetectable compounds on GLC analysis.

The Effect of Crown Ethers on the Reaction of Alkali Metal Trichloroacetate with Cyclohexene under Decarboxylative Conditions

Kenjiro IDEMORI, Makoto TAKAGI, and Tsutomu MATSUDA
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received October 20, 1976)

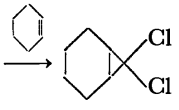
Synopsis. The reaction between alkali metal trichloroacetate and cyclohexene was studied in an aprotic medium in the presence and also in the absence of crown ethers. The crown ethers catalyzed decarboxylation but reduced the yield of the dichlorocarbene adduct.

Since the discovery of crown ethers and their metal complexes, numerous applications in organic chemistry have been worked out, in particular on the activation of anionic species as regards synthetic problems.[1] The anionic activation through complexation of alkali metal cations by crown ethers has been confirmed by the enhancement of nucleophilicity and basicity. However, recent studies show a variation of anionic activation, in which decarboxylation of certain alkali metal carboxylates is greatly accelerated. Hunter *et al.*[2] decarboxylated sodium 3-(9-fluorenylidene)-2-phenylacrylate in THF in the presence of dibenzo-18-crown-6 (I), and Smid *et al.*[3] described the decarboxylative rearrangement of potassium 6-nitrobenzisoxazole-3-carboxylate in aqueous media under the catalysis of a polymer crown, poly(vinylbenzo-18-crown-6). These works prompted us to examine the catalytic effect of crown ethers on the decarboxylation of alkali metal trichloroacetates, which has a synthetic utility to generate dichlorocarbene under neutral conditions.[4,5]

Results and Discussion

The reaction of alkali metal trichloroacetate with cyclohexene under decarboxylative conditions (Eq. 1) was studied in a suspension or solution in aprotic solvent using a thermostatted cell fitted with a small reflux condenser at 50—80 °C with and without added crown ether. The reaction was monitored by measuring

$$CCl_3COOM \xrightarrow[\Delta]{-CO_2} CCl_3M \xrightarrow{-MCl} :CCl_2$$



(M=Li, Na, K) (1)

the volume of evolved gas and analyzing the reaction mixture directly on GLC for 7,7-dichloronorcarane. In a typical run, 1.0 g of trichloroacetate salt, 2.6 g of cyclohexene (a large excess), 10 ml of appropriate solvent and 5—20 mol% (based on the salt) of crown ether (I, benzo-15-crown-5 (II) and dicyclohexyl-18-crown-6(III)) were utilized under anhydrous conditions. After the salt had been dried in the thermostatted cell under reduced pressure for 30 min, cyclohexene and the solvent were introduced into the cell, which was then connected to a gas burette, and the mixture was vigourously stirred magnetically. Crown ether dissolved in a solvent was used.

Reaction in the Absence of Crown Ether. The decarboxylation of potassium trichloroacetate at 80 °C was almost complete (>90% of the theoretical amount according to Eq. 1) within 30 min in acetonitrile and 1,2-dimethoxyethane (DME), while in benzene only 20% decarboxylation was observed after 5 h. As a solvent acetonitrile was at least four times more effective than DME when the reaction was carried out at 70 °C. Sulfolane behaved similarly to acetonitrile. The formation of dichloronorcarane paralleled the time course of the decarboxylation, but the yield remained at≈50% after 30 min (and for the rest of the reaction time) in acetonitrile and DME, and only at 2% (or 10% based on the salt decomposed) after 5 h in benzene. While the former yields are comparable to those originally reported by Wagner for the sodium salt in DME,[4] the extremely low yield in benzene is obviously caused by the insolubility of the salt, where decarboxylation took place in the suspended solid. The effect of cations (Li^+, Na^+, K^+) studied in acetonitrile (70 °C) and DME (80 °C)* showed that the initial rate of decarboxylation and the carbene adduct formation were in the increasing order of $K^+ > Na^+ > Li^+$ in line with previous results.[5] A difference of several times the magnitude of rates was observed between adjacent cations. Decomposition is accelerated when the anion is less tightly bound to cations of larger ionic radius. The enhanced reactivity in acetonitrile as compared with DME is also in line with the medium effect expected on the structure of ion pairs in aprotic medium.[2] However, it was noticeable that the final yield in the adduct was not proportional to the ease of decarboxylation. As an example, lithium salt in acetonitrile at 70 °C attained 80% decarboxylation and 60% yield of 7,7-dichloronorcarane in 5 h, and the reaction was still in progress. On the other hand, the reaction was complete for potassium and sodium salts well within a half hour, but the yields of the carbene adduct were 52 and 55% respectively.

Effect of Crown Ethers. The effect of added crown ethers in acetonitrile or DME was found to proceed in two ways, *i.e.*, a rate acceleration (both in decarboxylation and carbene adduct formation) and a decrease in the final yield of the carbene adduct. The rate increase in the initial phase of the reaction in the presence of 20 mol % of II ranged from two to

* Solubility of the salts in the solvents was in the order Li>Na>K. Lithium and sodium salts essentially gave uniform solutions.

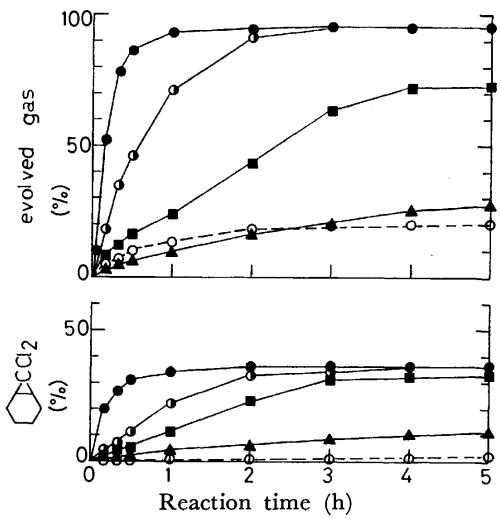


Fig. 1. Decarboxylation of potassium trichloroacetate in benzene (80 °C). Benzene, 10 ml; cyclohexene, 2.6 g; CCl_3CO_2K, 1.0 g(5.0 mmol). —▲— I(0.3 mmol); —■— II(1.0 mmol); —●— III(1.0 mmol); —◑— III(1.0 mmol), without benzene, cyclohexane 10 ml; --○-- without crown ether.

nine times of that in the case of its absence depending on the cation and the solvent. The rate increase was sufficient to lower the practical reaction temperature by 10—20 °C. However, the advantage was counterbalanced by the decrease in the yield of the adduct to two thirds of those in the case of the absence of crown ethers. The effect of crown ethers in benzene was much more pronounced. On addition of 20 mol % of III the reaction effectively approximated that in DME, as shown in Fig. 1. Even the reaction in cyclohexene (as both reactant and solvent) was successful. Obviously the crown ethers functioned as a solid-liquid phase-transfer catalyst.[1] In line with a similar observation on the effect of alkali metal ions, the trichloroacetate ion which is less tightly bound to the cation or freed from the cation by the intervention of crown ether decarboxylates more readily, but it introduces some unfavorable effects on the subsequent carbene formation and its reaction to form the adduct. The exact nature of these effects is not clear at present in view of the complexity of the side reactions involved in the carbene-generating system.[5,6] Decarboxylation on alkali metal trichloroacetate in aprotic medium was accelerated considerably by the cation complexation with crown ethers, but the extent was far less than the cases in which the resulting anions were strongly resonance-stabilized.[2,3,7,8] The acceleration of decarboxylation was counterbalanced by the reduced yield of dichlorocarbene adduct, thus diminishing the synthetic utility of crown ethers in the system.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (5), 1357—1358 (1977)

The Preparation of 3,5-Diacetoxy-1-cyclopentene[1)]

Seizi KUROZUMI, Takeshi TORU,* Toshio TANAKA, Shuji MIURA, Makiko KOBAYASHI, and Sachio ISHIMOTO

Institute for Biomedical Research, Teijin Ltd., Asahigaoka, Hino, Tokyo 191

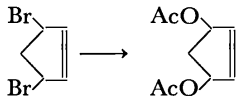
(Received November 8, 1976)

Synopsis. The phase-transfer reaction of 3,5-dibromo-1-cyclopentene with potassium acetate was studied using trialkylamines and a trialkylphosphine as catalysts. Various metal acetates were examined for their effects in this reaction.

We recently reported[2)] on the nucleophilic substitution reaction of alkyl bromides with potassium acetate employing a quaternary ammonium ion catalyst in a heterogeneous system. This phase-transfer reaction provided a convenient synthetic method for acetates from the corresponding bromides besides previously developed methods using silver acetate, tetraethylammonium acetate, or potassium acetate in glacial acetic acid and acetic anhydride.[2)] Thus, *cis*-3,5-diacetoxy-1-cyclopentene **2** was prepared from *cis*-3,5-dibromo-1-cyclopentene **1**, 4-acetoxy-2-cyclohexen-1-one from 4-bromo-2-cyclohexen-1-one, and octyl acetate from octyl bromide. In the course of the study of the synthesis of prostaglandins, we succeeded

$$RX \xrightarrow[KOAc]{\text{phase-transfer catalyst}} ROAc$$

in converting the diacetate **2** into chiral 4-hydroxy-2-cyclopenten-1-one,[3,4)] which is a key intermediate to prostaglandins[5)] and their mimics.[6)] Furthermore, it was reported that the diacetate **2** was effectively transformed into a useful lactone intermediate for the synthesis of prostaglandins.[7)] 4-Cyclopentene-1,3-diol, which is easily accessible from the diacetate **2** is also a useful precursor for the synthesis of prostaglandins[8)] and their intermediates.[9)] These results led us to study the phase-transfer reaction of 3,5-dibromo-1-cyclopentene **1** indetail and to extend the scope of the reaction using i) various catalysts and ii) various metal acetates.



1 **2**

Quaternary ammonium and phosphonium salts are well known to be good catalysts in phase-transfer reactions.[10)] Tertiary amines have also been reported to be effective for the dichlorocarbene generation.[11)] More recently, it has been reported that tertiary amines as well as primary and secondary amines catalyzed the nucleophilic conversion of alkyl bromides into alkyl cyanides.[12)] Tertiary amines also catalyzed the alkylation of the α-carbon attached to the carbonyl group with alkyl halides.[13)] We first carried out the nucleophilic substitution reaction of 3,5-dibromo-1-cyclopentene[14)] with potassium acetate in mixtures of water and carbon tetrachloride, using either trioctyl- or tridecylamines. These reactions resulted in the formation of the diacetate **2** in moderate yields (see Table 1).

TABLE 1. PHASE-TRANSFER REACTIONS OF 3,5-DIBROMO-1-CYCLOPENTENE WITH POTASSIUM ACETATE

Catalyst	Yield[a)] of 3,5-diacetoxy-1-cyclopentene
Trioctylphoshine	58%
Trioctylamine	49
Tridecylamine	55

a) Isolated yield.

To our knowledge, it has not been reported that trialkylphosphines catalyze the nucleophilic substitution reaction in a heterogeneous system. We were interested to examine the possibility of trialkylphosphines as phase-transfer catalysts, because trialkylphosphines are known[15)] to react with alkyl halides, *e.g.*, in refluxing benzene, to form tetraalkylphosphonium salts, which could be catalysts for our reaction. In fact, the phase-transfer reaction of the dibromide **1** with potassium acetate, using trioctylphosphine as a catalyst, proceeded to give the acetate **2** in a 58% yield (Table 1).

In order to examine the effect of metal acetate, phase-transfer reactions were studied using various metal acetates, such as the Group I, II, VII, and VIII metal acetates. Trioctylpropylammonium chloride was used as the catalyst. The results are summarized in Table 2. It is interesting that magnesium acetate and alkali metal acetates were among the most effective acetates. Since magnesium, lithium, and sodium acetates have a higher solubility in water than the other acetates[16)] listed in Table 2, our results suggest that the solubility of the metal acetate in the aqueous phase plays an important role this phase-transfer reaction.

Experimental

Using Trioctylphosphine. A mixture of 3,5-dibromo-1-cyclopentene **1** (45.2 g, 0.2 mol), potassium acetate (99 g, 1 mol), and trioctylphosphine (14.8 g, 0.04 mol) in carbon tetrachloride (120 ml) and water (45 ml) was vigorously stirred at 60 °C for 5 h. The reaction mixture was then extracted with carbon tetrachloride (3×30 ml), dried, and evaporated. The residue was distilled to give 3,5-diacetoxy-1-cyclopentene **2** (21.3 g; 58% yield): bp 70.5 °C/0.08 Torr.

Using Trioctylamine. A mixture of the dibromide **1** (151 g, 0.67 mol), potassium acetate (300 g, 3 mol), and trioctylamine (10 g, 0.029 mol) in carbon tetrachloride (400 ml) and water (150 ml) was vigorously stirred at 60 °C for 12 h. The mixture was then treated as above to give the diacetate **2** (68.7 g; 55% yield).

Table 2. Phase-transfer reactions of dibromide **1** with various metal acetates in the presence of $(C_8H_{17})_3C_3H_7N^+Cl^-$ [a]

Metal acetate, g (mmol)		Solvent		Reaction conditions		Yield[b] of diacetate **2**	Solubility[c]
		H_2O	CCl_4				
$LiOAc \cdot 2H_2O$	10.2 (100)	6 ml	15 ml	70°C	5 h	52%	300
$NaOAc \cdot 3H_2O$	4.1 (30)	2	6	60	4	37	76
$Mg(OAc)_2 \cdot 4H_2O$	6.4 (30)	4	8	60	18	35	120
$Ca(OAc)_2$	2.6 (30)	3.5	6	60	6	8	37
$Ba(OAc)_2$	7.6 (15)	4	7	60	6	14	59
$Cu(OAc)_2 \cdot H_2O$	6.0 (30)	6	15	60	3	15	**7**
$Zn(OAc)_2 \cdot 2H_2O$	6.6 (30)	10	25	60	3	13	31
$Mn(OAc)_2 \cdot 4H_2O$	7.4 (30)	10	25	70	5	17	—
$Co(OAc)_2 \cdot 4H_2O$	7.5 (30)	10	25	70	3	15	—
$Pb(OAc)_2 \cdot 3H_2O$	11.4 (30)	3	7	60	6	9	46

a) All the reactions were carried out using 2.26 g (10 mmol) of 3,5-dibromo-1-cyclopentene **1** and 0.86 g (2 mmol) of trioctylammonium chloride. The reaction conditions and yields are not optimized.
b) Isolated yield. c) Solubility in grams per 100 ml in cold water.[16]

Using Tridecylamine. The dibromide **1** (54 g, 0.139 mol), potassium acetate (90 g, 0.9 mol), tridecylamine (5.9 g, 0.014 mol), water (45 ml), and carbon tetrachloride (120 ml) were used. The yield of the acetate **2** was 21.6 g (49%).

Using Various Metal Acetates. The reactions were carried out substantially as has been described above under the conditions summarized in Table 2.

The authors are grateful to Drs. T. Noguchi and S. Tsunoda of Teijin, Ltd., for their encouragement throughout the course of this work.

Synthesis of Some Imidazo[1,2-*c*][1,2,3]triazolo[4,5-*e*]pyrimidines

Takashi SUGIMOTO and Sadao MATSUURA

College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 13, 1976)

Synopsis. The reaction of 7-amino[1,2,3]triazolo-[4,5-*d*]pyrimidine (**1a**) with chloroacetaldehyde gave imidazo-[1,2-*c*][1,2,3]triazolo[4,5-*e*]pyrimidine (**2a**) which underwent facile ring opening in dilute hydrochloric acid. The methyl derivatives (**2b,c,d**) were similarly made from the appropriate triazolopyrimidine (**1b,c,d**) and chloroacetaldehyde.

The isolation and structural elucidation of the fluorescent imidazo[1,2-*a*]purines from baker's yeast ^{Phe}t-RNA[1] and *T. utilis* ^{Phe}t-RNA[2] has aroused considerable interest in the chemistry and biology of fused tricyclic compounds derived from the common base residues of nucleic acids. At about the same time, Kost and his co-workers reported that the reaction of 9-methyladenine with chloroacetaldehyde gave fluorescent 3-methylimidazo[2,1-*i*]purine.[3] The ribonucleoside and ribonucleotides of imidazo[2,1-*i*]purine have been synthesized and their activities in several enzymatic systems reported.[4] It has also been shown that two fluorescent substances derived from N^6-(3-methyl-2-butenyl)adenosine, a clinically useful antileukemic agent, were members of the imidazo[2,1-*i*]purine series.[5] This finding prompted us to investigate the synthesis of analogous ring systems with a view to possible biological activities. In the present paper, we describe the synthesis of certain imidazo[1,2-*c*]-[1,2,3]triazolo[4,5-*e*]pyrimidines.

Treatment of 7-amino[1,2,3]triazolo[4,5-*d*]pyrimidine (**1a**)[6] with chloroacetaldehyde in aqueous ethanol in the presence of sodium acetate gave the fluorescent imidazo[1,2-*c*][1,2,3]triazolo[4,5-*e*]pyrimidine (**2a**) in moderate yield. The ^{1}H NMR spectrum of **2a** in TFA exhibited a pair of doublets at δ 8.25 and 8.62 (J= 2.0 Hz) representing protons at the 7- and 8-position, and a singlet at δ 9.77 for 5-H. Similarly, the condensation of 7-amino-5-methyl[1,2,3]triazolo[4,5-*d*]pyrimidine (**1b**)[7] with chloroacetaldehyde gave 5-methylimidazo[1,2-*c*][1,2,3]triazolo[4,5-*e*]pyrimidine (**2b**). This compound showed UV spectra very similar to those of **2a**; also a singlet at δ 3.82 and a pair of doublets at δ 8.28 and 8.42 (J=2.0 Hz) in its ^{1}H NMR spectrum.

When **2a** was treated with dilute hydrochloric acid, its fluorescence disappeared and a ring-opened product, 4-amino-5-(2-imidazolyl)-1,2,3-triazole (**3**) was obtained. The same compound was formed also, but more slowly, when **2a** was boiled in water. The structure of **3** was derived from elemental analysis, UV spectra, and a ^{1}H NMR spectrum exhibiting a sharp singlet at δ 7.48 for both 4- and 5-H of the imidazole ring. This ring opening took place most probably by nucleophilic addition of water at the 5,4-double bond. Therefore, a compound such as **2b**, with a blocking methyl group[8] at the site of potential addition, is expected to resist ring opening. In fact, no ring opening was detected when **2b** was treated with hydrochloric acid as above.

3-Methyl-(**2c**) and 3,5-dimethyl-imidazotriazolopyrimidines(**2d**) were made similarly from 3-methyl- and 3,5-dimethyl-7-aminotriazolopyrimidine(**2c** or **d**) respectively.

We also investigated the reaction of **1a** with bromoacetone. Under a variety of conditions, the reaction gave 7-acetonylamino[1,2,3]triazolo[4,5-*d*]pyrimidine(**4a**) as a main product; several minor products were formed, but no imidazotriazolopyrimidine was detected. The structure of **4a** was confirmed by elemental analysis and by UV spectra which were very similar to those of **1a**. Its ^{1}H NMR spectrum showed singlets at δ 2.63(CH_3), δ 5.93(CH_2), and δ 8.80 (the aromatic proton of the pyrimidine ring). The reaction of **1b** with bromoacetone took place in a similar manner to give the 5-methyl compound(**4b**) without any imidazotriazolopyrimidine.

Experimental

The elemental analyses were done by the Analytical Section, Meijo University, Nagoya. The pK_a values were determined by a spectroscopic method and the UV spectra on a JASCO UVIDEC-1 spectrophotometer. The ^{1}H NMR spectra were determined on a JEOL JNM-MH-60 NMR spectrometer in TFA with TMS as an internal standard.

Imidazo[1,2-c][1,2,3]triazolo[4,5-e]pyrimidine (2a). One gram of **1a**, chloroacetaldehyde (0.50 g,) and NaOAc (1.0 g) were heated in 50% aq EtOH (200 ml) under reflux for 2 h. The solution was evaporated to dryness and the residue was chromatographed on a Florisil column (4×40 cm) by gradient elution using 0—1% ammonia (1.0 l). The fluorescent fractions were combined, concentrated to *ca.* 50 ml under reducted pressure, treated with charcoal, and chilled to give colorless needles (1.10 g) of **3a**; mp>300 °C (Found: C,

38.67; H, 3.55; N, 44.87%. Calcd for $C_6H_4N_6$–1.5H_2O: C, 38.50; H, 3.74; N, 44.92%); ^{1}H NMR: δ 8.25(d, J=2.0 Hz, 1), 8.62(d, J=2.0 Hz, 1), and 9.77(s, 1); pK_a 2.46±0.03; λ_{max} (log ε) at pH 0.44: 214(4.35), 270(sh, 3.83), 282(3.88); at pH 5.0: 219(4.32), 235(sh, 4.19), 284(3.82).

*5-Methylimidazo[1,2-c][1,2,3]triazolo[4,5-e]pyrimidine (**2b**).* A solution of **1b**[7] (2.5 g), chloroacetaldehyde (2.0 g), and NaOAc (4 g) were refluxed in 50% aq EtOH (400 ml) for 4 h. Evaporation under reduced pressure and subsequent crystallization from water gave colorless needles (2.0 g) of **2b**; mp>300 °C (Found: C, 48.09; H, 3.27; N, 48.55%. Calcd for $C_7H_6N_6$: C, 48.27; H, 3.45; N. 48.26%); ^{1}HNMR: δ 3.82(s, 3), 8.28(d, J=2.0 Hz, 1), and 8.42(d, J=2.0 Hz, 1); pK_a 2.57±0.02; λ_{max} (log ε) at pH 0.44: 212(4.38), 270(sh, 3.85), 279(3.90); at pH 5.0: 217(4.31), 240(sh, 3.97), 285(3.87).

*4-Amino-5-(2-imidazolyl)-1,2,3-triazole (**3**).* A solution of **2a** (270 mg) in 1M-HCl (20 ml) was kept at 20 °C for 10 h. Evaporation to dryness under reduced pressure and crystallization from EtOH gave colorless needles (145 mg) of **3** as hydrochloride; mp>300 °C (Found: C, 32.45; H, 3.66; N, 44.99%. Calcd for $C_5H_6N_6$–HCl: C, 32.17; H, 3.75; N, 45.04%); ^{1}HNMR: δ 7.48(s); pK_a 8.30±0.03, 5.24±0.03, and −1.39±0.05; λ_{max} (log ε) at H_0 −3.0: 251 (4.05), 295(sh, 3.41); at pH 2.0: 243(3.86), 278(4.10); at pH 6.5: 243(3.87), 277(4.08); at pH 10.5: 215(3.81), 273(4.15).

*3-Methylimidazo[1,2-c][1,2,3]triazolo[4,5-e]pyrimidine (**2c**) and the 3,5-Dimethyl Derivative (**2d**).* 7-Amino-3-methyltriazolopyrimidine[9] (1.0 g), chloroacetaldehyde (2 g) and NaOAc (2 g) were heated in water (300 ml) at 60 °C for 5 h. Evaporation under reduced pressure to *ca.* 20 ml gave **a** solid which was crystallized from MeOH to give colorless needles (0.45 g) of **2c**. The analytical sample was prepared by sublimation at 160 °C/1 Torr; mp 282—283 °C(decomp) (Found: C, 48.57; H, 3.27; N, 47.82%. Calcd for $C_7H_6N_6$: C, 48.27; H, 3.47; N, 48.26%); ^{1}H NMR: δ 4.67(s, 3), 8.25(d, J=2.0 Hz, 1), 8.60(d, J=2.0 Hz, 1), and 9.70(s, 1); pK_a 2.47±0.01; λ_{max} (log ε) at pH 0.44: 219.5(4.38), 263(3.74), 281(3.73); at pH 5.0: 229(4.35), 260(3.60), 298(3.50).

4-Amino-6-chloro-2-methyl-5-nitropyrimidine[10] and 30% methanolic methylamine under reflux gave *the 6-methylamino analogue* in 90% yield; mp 242—243.5 °C (from MeOH) (Found: C, 39.29; H, 4.82; N, 38.23%. Calcd for $C_6H_9N_5O_2$: C, 39.34; H, 4.92; N, 38.25%). The nitropyrimidine (2.0 g) was hydrogenated over Pd/C in 0.5M-HCl (50 ml), and subsequently treated with $NaNO_2$ to give *7-amino-3,5-dimethyl[1,2,3]triazolo[4,5-d]pyrimidine* (**1d**) (1.35 g; colorless needles when recrystallized from water); mp>300 °C (Found: C, 44.13; H, 4.95; N, 51.46%. Calcd for $C_6H_8N_6$: C, 43.89; H, 4.29; N, 51.19%). This compound was treated with chloroacetaldehyde as in the foregoing reaction to give **2d** (95% yield); mp 221—222 °C (sublimed at 160 °C/1 Torr) (Found: C, 51.23; H, 3.91; N, 44.35%. Calcd for $C_8H_8N_6$: C, 51.04; H, 4.29; N, 44.66%); ^{1}H NMR: δ 3.27(s, 3), 4.58(s, 3), 8.20(d, J=2.0 Hz, 1). and 8.37(d, J=2,0 Hz, 1); pK_a 2.65±0.01; λ_{max} (log ε) at pH 0.44: 219(4.41), 268.5 (3.79), 281(3.81); at pH 5.0: 219(4.35), 266.5(3.60), 295.5 (3.65).

*7-Acetonylamino[1,2,3]triazolo[4,5-d]pyrimidine (**4a**) and Its 5-Methyl Derivative(**4b**).* A solution of **1a** (1.0 g) and bromoacetone (2.5 g) in 50% aq EtOH (300 ml) was refluxed for 2 h. Evaporation under reduced pressure and subsequent crystallization from water gave colorless needles (0.50 g) of **4a**; mp> 300 °C (Found: C, 43.63; H, 4.03; N, 43.87%. Calcd for $C_7H_8N_6O$: C, 43.74; H, 4.20; N, 43.73%); ^{1}H NMR: δ 2.63(s, 3), 5.93(s, 2), and 8.80(s, 1), pK_a 2.42±0.01; λ_{max} (log ε) at pH 0.44: 205(4.27), 264(4.09); at pH 4.5: 214 (4.07), 279(4.06).

The 5-methyl derivative (**4b**) was similarly obtained from **1b** in 56% yield; mp>300 °C (Found: C, 46.32; H, 4.85; N, 40.62%. Calcd for $C_8H_{10}N_6O$: C, 46.59; H, 4.90; N, 40.76%); pK_a 3.08±0.02; λ_{max} (log ε) at pH 0.83: 205(4.30), 264(4.10); at pH 5.5: 215(4.22), 277(4.06); ^{1}H NMR: δ 5.82(s, 3), 2.88(s, 3), and 5.87(s, 2).

We thank Miss Noriko Itoh for measuring the pK_a values and UV spectra, Miss Keiko Shibata for measuring the ^{1}H NMR spectra, and Dr. D. J. Brown of Australian National University for discussion.

Solid-state Reactions between CVD-TiO_2 and $BaCO_3$

Yoko SUYAMA and Akio KATO

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received July 17, 1976)

The solid-state reactions between CVD-TiO_2 powders of anatase- and rutile-forms with various particle sizes and $BaCO_3$ were investigated in O_2 and CO_2. The reactivity of the TiO_2 powders and the apparent activation energy for the reaction were independent of the crystal type of TiO_2. The reactivity of the TiO_2 powders increased remarkably as the particle sizes grew smaller than 0.15 μm. When such fine CVD-TiO_2 powders were used, the reaction proceeded to completion at temperatures below 1000 °C in both O_2 and CO_2 and gave fine $BaTiO_3$ powders. The particles of $BaTiO_3$ produced appeared single-crystalline and kept a shape similar to that of the starting TiO_2 particle. The sizes of the $BaTiO_3$ particles were controlled by those of the starting TiO_2 and were independent of those of $BaCO_3$.

On the solid-state reactions between TiO_2 and $BaCO_3$, there have been several investigations concerning the effects of the particle size and crystal type of the starting TiO_2 powders on the reactivity.[1,2] In these studies, anatase-TiO_2 powders were produced by wet methods and rutile-TiO_2 powders were prepared by the calcination of anatase-TiO_2 at temperatures above 900 °C. The primary TiO_2-particles aggregated in the powders, especially in calcined rutile-TiO_2 powders. Therefore, it is questionable whether or not the observed reactivities truly represent the effect of the size or crystal type of the primary TiO_2-particles.

On the other hand, both the anatase and rutile-TiO_2 powders produced by vapor-phase reactions (CVD-TiO_2) are characterized by high purity, a very closely controlled particle-size distribution, and easy dispersion, and consist of single-crystalline particles. Therefore, the effects of the size and crystal type of TiO_2-particles on the reactivity are expected to be caught more exactly by using CVD-TiO_2 powders. The present authors have reported that CVD-TiO_2 powders prepared from the $TiCl_4$-O_2 system show a high reactivity in the reaction with $BaCO_3$ and that the resulting $BaTiO_3$ powders consist of particles with the shape of the starting TiO_2 particles.[3]

In the present investigation, in order to elucidate the effects of the crystal type and particle size of TiO_2-particles on the reactivity and the properties of $BaTiO_3$ powders produced, the solid-state reaction between TiO_2 and $BaCO_3$ was carried out by using CVD-TiO_2 powders obtained from the reaction systems of $TiCl_4$-O_2, $TiCl_4$-H_2O, $TiCl_4$-H_2O-H_2, and $TiCl_4$-H_2-CO_2.

Experimental

Materials. The titanium dioxide powders were prepared by vapor-phase reactions, as has been described previously.[4,5] Their properties and electron micrographs are shown in Table 1 and Fig. 1, respectively. The TiO_2 powders obtained from the $TiCl_4$-H_2O-H_2 system consist of nealy spherical or cubic particles smaller than 0.1 μm in size (Figs. 1 (a) and (b)). The TiO_2 powders obtained from the $TiCl_4$-H_2-CO_2 system consist of plate-like particles grown preferentially in the plane perpendicular to the c-axis[5] (Figs. 1 (c) and (e)). The TiO_2 powders obtained from the $TiCl_4$-O_2 system consist of square and plate-like or square-bipyramidal particles grown in the plane perpendicular to the c-axis (Figs. 1 (d) and (f)).

TABLE 1. REACTION SYSTEMS AND THE CHARACTERISTICS OF TiO_2 POWDERS

No.	Reaction system	$D_{50}(D_{10}—D_{90})$ (μ)[a]	S_{BET} (m^2/g)[b]	W_A (%)[c]
a-20	$TiCl_4$-H_2O-H_2	0.05 (0.03—0.07)	—	0
a-15	$TiCl_4$-H_2O-H_2	0.06 (0.04—0.08)	21	5
a-13	$TiCl_4$-H_2O	0.09 (0.05—0.12)	—	52

a) D_{50}, D_{10}, and D_{90} are the particle sizes at which the weight of particles reaches 50, 10, and 90% respectively on the cumulative weight % distribution curve. b) Specific surface area obtained by the BET method. c) Content of the anatase form.

GR-grade $BaCO_3$ was obtained from Wako Pure Chemical Ind., Ltd. (purity>99.7%).[6] The particles of the $BaCO_3$ powder are needle-like and 0.5—10 μm long. They showed no weight loss when heated to 1000 °C at 5.4 °C/min in O_2.

Solid-state Reactions. Equimolar mixtures of TiO_2 and $BaCO_3$ were prepared by mixing with an ultrasonic wave in absolute ethanol. The mixture of 70—130 mg was heated in a platinum vessel up to 950—1100 °C at 5.4 °C/min in a flow of CO_2-free O_2 or CO_2. The flow rate was about 130—150 ml/min (the I.D. of the reactor was 17 mm). The weight loss caused by the reaction was followed by means of an electrobalance.[7] X-Ray diffraction [Co$K\alpha$] and electron-microscopic analyses of the products were done in the course of the reaction.

Results and Discussion

Thermogravimetric Analysis of Reactions between TiO_2 and $BaCO_3$. The TG curves of equimolar TiO_2-$BaCO_3$ mixtures are shown in Figs. 2 and 3. The reaction begins at about 530 °C, and the weight loss reaches 100% at 930—1010 °C in O_2. As the TiO_2 powders become finer, the reaction proceeds faster and the weight loss reaches 100% at a lower temperature; that is, the reactivity of the TiO_2 powders increases. The decrease in reactivity with the particle size of TiO_2, however, becomes smaller as the particles grow larger. In CO_2, the beginning and completion temperatures of the reaction are higher by 50 to 100 °C than those in

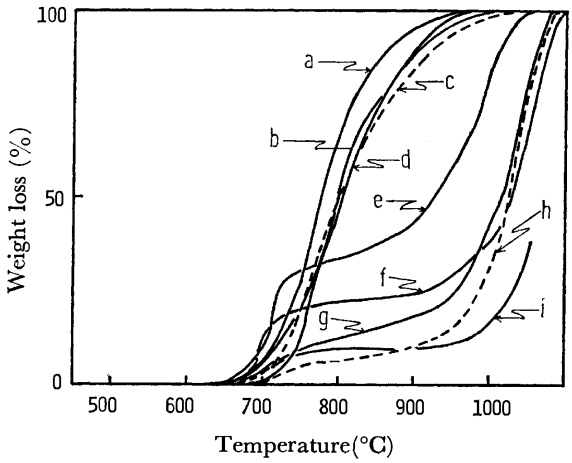

Fig. 3. TG curves of the reaction between TiO_2 and $BaCO_3$ in CO_2. Keys are the same as in Fig. 2.

O_2. The TG curves in CO_2 are classified into one- and two-step types. When the starting TiO_2 powders consist of particles smaller than 0.15 μm, the TG curves are of the first type and the reaction is completed below 1000 °C. When the TiO_2 powders contain particles larger than 0.15 μm, the TG curves are of the second type and the reaction is completed above 1000 °C. In the latter case, the rate of reaction in the first step is higher as the TiO_2 powders become richer in small particles. The difference in the TG curves between the reactions in O_2 and in CO_2 is due to the difference in the structure of the product layers.[3)]

In the reactions using other $BaCO_3$ powders which consisted of spherical particles finer than the present one,[3)] the TG curves changed with the particle size of TiO_2 in a manner similar to the present results, although the beginning and completion temperatures of the reaction were lower by 50—100 °C than in the present work. Therefore, the features of the TG curves in Figs. 2 and 3 may be considered to reflect the properties of the TiO_2 powders themselves.

The TG curves of a-15, a-13, and a-7, in which the

particle sizes of the TiO_2 powders are close, while the contents of the anatase-form differ, show little difference, indicating that the crystal form of TiO_2, whether anatase or rutile, does not affect the reactivity. It should be noted here that, in the course of the reaction of a-7, the unreacted TiO_2 consisted only of the anatase-form at 780 °C (the fraction reacted was 40%), although the anatase-rutile transition of the TiO_2 powders becomes appreciable above 900 °C when they are heated at 5.4 °C/min and the transition rate increases as the TiO_2 powders become finer.[3]

Reaction Products. The reaction products in O_2 are shown in Table 2, where the starting TiO_2 powders are classified into two groups according to the particle size: the TiO_2 powders consisting of particles smaller than 0.15 μm (S group) and the other TiO_2 powders (L group). In the S group, $BaTiO_3$ was the only product throughout the course of the reaction in both O_2 and CO_2. In the L group, $BaTiO_3$ was formed at first, and subsequently Ba_2TiO_4 was formed above 850 °C in O_2. The amount of Ba_2TiO_4 produced increased as the TiO_2 powders became coarser, in accord with the findings of a previous work.[1] In CO_2, the formation of Ba_2TiO_4 is suppressed thermodynamically up to 1145 °C.[8,9]

It is clear that the CVD–TiO_2 powders consisting of particles smaller than 0.15 μm show especially high reactivities and are converted into the $BaTiO_3$ powders at temperatures below 1000 °C.

Morphology of the Products. The electron micrographs of the products are shown in Figs. 4 and 5. Figure 4(a) shows the starting mixture of R-7. The particles of $BaCO_3$ are needle-like in shape. When a mixture is heated to 905 °C in O_2, products are formed on the surface of the TiO_2 particles consuming the neighboring $BaCO_3$ particles (Figs. 4(b) and (e)). The $BaCO_3$ particles become thinner with the progress of the reaction. When the mixture is finally heated to 1010 °C, all particles of the products maintain the outline of the starting TiO_2 particles (Figs. 4(d) and (f)). Figure 4(g) also shows the characteristic shape of the square and plate-like particles of the product in D-1 (compare with Fig. 1(f)). The change in the shape of particles in the course of the reaction of a-15 in O_2 is shown in Fig. 5. In this case, the change in the $BaCO_3$ particles is more significant. When the mixture is heated to 780 °C, large numbers of fine particles are attached to large particles of $BaCO_3$, as seen in Fig. 5(a). When the mixture is heated to 970 °C and wholly converted to $BaTiO_3$, the large particles disappear, as seen in Fig. 5(b). Although the particles are aggregated in part, they are cube-like and show the single-crystal pattern of $BaTiO_3$ in electron diffraction, the outline of the shape of the starting TiO_2 particles being held, too (Fig. 5(c)).

From the morphology mentioned above, it may be concluded that the $BaTiO_3$ is formed by a topotactical reaction of CVD–TiO_2 with $BaCO_3$. The manner of change in the shapes of the TiO_2 and $BaCO_3$ particles in the course of the reaction indicates that the reaction proceeds from the surface of the TiO_2-particle into the inside by the diffusion of the BaO component, forming a reaction-product layer on the surface of the TiO_2 particle.

When the reaction takes place by this model on a spherical TiO_2 particle with the radius of r_0, the fraction reacted α is given by:

$$\alpha = 1 - \left(\frac{r_0 - x}{r_0}\right)^3, \qquad (1)$$

where x is the thickness reacted. The values of α at 840 °C in Fig. 2, where $BaTiO_3$ is the only product, are compared in Fig. 6 with the ones calculated by means of Eq. 1. When the value of x at a given temperature is independent of r_0, the experimental and calculated values of α should agree. The agreement is not very good, but one can see that the present reaction model explains well the accelerated increase in the reactivity as the particle size of TiO_2 becomes smaller.

The particle-size distributions of the resulting $BaTiO_3$ and the starting TiO_2 are compared in Fig. 7. The average particle-size of the resulting $BaTiO_3$ is about 1.3 times that of the starting TiO_2. It is found that the TiO_2 powders with average particle-size of 1.3 μm were converted into the $BaTiO_3$ powders with that of

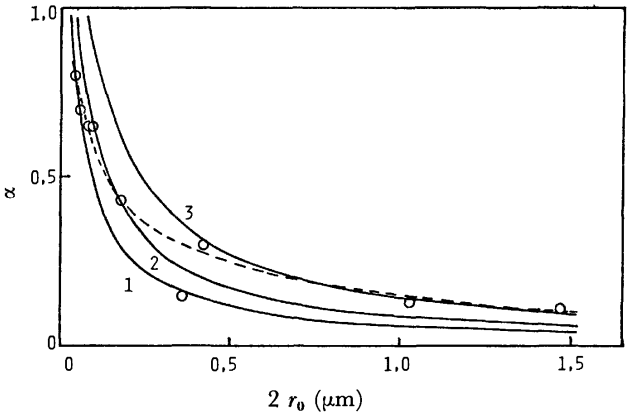

Fig. 6. Relation between the fraction reacted and particle size.
———, Calculated: 1, x=0.01 μm; 2, x=0.015 μm; 3, x=0.025 μm;
---○---, observed (at 840 °C).

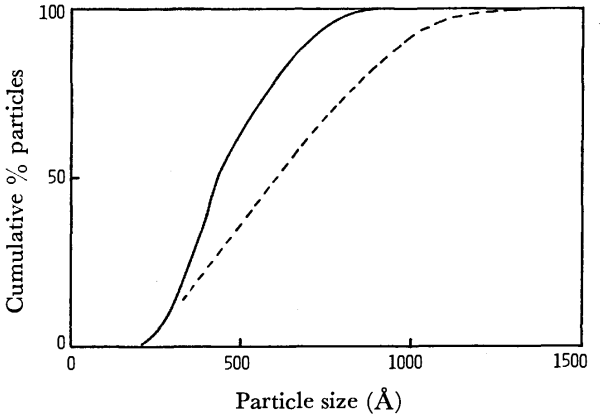

Fig. 7. Particle size distributions of the starting TiO_2 and the resulting $BaTiO_3$ powders of a-15.
——, TiO_2; ——, $BaTiO_3$.

$$(1-\sqrt[3]{1-\alpha})^2 = \frac{kt}{r_0^2} \quad (2)$$

where α is the fraction reacted at time t, k is the rate constant, and r_0 is the initial radius of the TiO_2 particle. We tried to analyze the TG curves in O_2 by the use of Jander's equation. To apply the equation to the TG data, it was modified as Eq. 3.[12-14]

$$K = \frac{2(1-\sqrt[3]{1-\alpha})}{3(1-\alpha)^{2/3}} \cdot \frac{\Delta\alpha}{\Delta T} = \frac{k_0}{ar_0^2} e^{-E/RT}, \quad (3)$$

where a is the heating rate. The values of K were calculated by taking ΔT=25 °C. Plots of log K *vs.* $1/T$ are shown in Fig. 8. Jander's equation holds well up to ≈770 °C for the S group and up to ≈840 °C for the L group. On the L group, the slope changes at ≈840 °C, suggesting that the reaction mechanism changes at this temperature. This may be caused by the appearance of Ba_2TiO_4 at ≈850 °C.

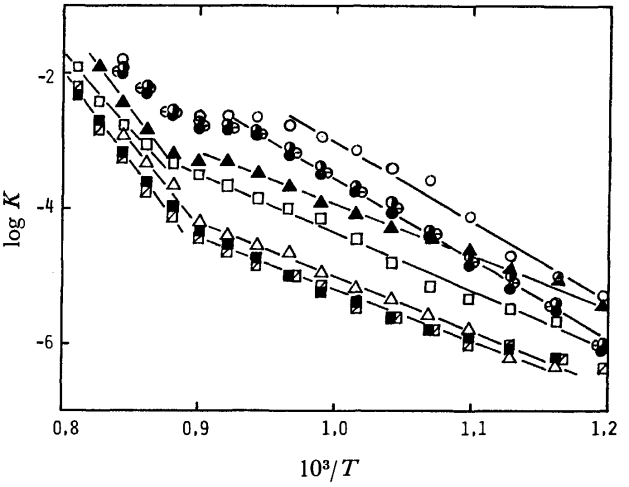

Fig. 8. Plots of log K *vs.* $10^3/T$ for the reactions in O_2.
○, a-20; ●, a-7; ◑, a-15; ⊖, a-13; △, A-1; ▲, A-11; □, R-22; ■, R-7; ⊠, D-1.

1.6 μm,[3] the ratio of the average particle sizes being 1.2. When a TiO_2 particle is converted into a $BaTiO_3$ particle, the particle size should increase by 1.26 times. The observed values are close to the calculated one. This supports also the reaction model mentioned above.

When reaction mixtures are heated up to 1100 °C, the resulting $BaTiO_3$ particles suffer sintering to a considerable extent. However, the reaction can be completed below 1000 °C by selecting appropriate reaction conditions such as the particle size of TiO_2 and $BaCO_3$, the heating rate, or the atmosphere. In this case, the particle sizes of the $BaTiO_3$ powders produced are controlled by those of the starting TiO_2 powders, and one can produce ultrafine $BaTiO_3$ powders, which have a fineness comparable with that obtained by the thermal decomposition of oxalate,[11] by a solid-state reaction.

Application of Jander's Equation. When the reaction between TiO_2 and $BaCO_3$ powders occurs in the manner mentioned above, the reaction rate may be controlled by the diffusion of the BaO component through the product layer and the kinetics may follow Jander's equation (2):

From the linear parts of the plots, the apparent activation energies are obtained (see Table 2). The activation energies for the former stage are different between the S and L groups. However, it should be noted that the activation energy is also independent of the crystal type of TiO_2 in each group. The activation energies reported hitherto are shown in Table 3. All of these activation energies are claimed for the diffusion process. When the diffusion of the BaO component in the $BaTiO_3$ layer is the rate-determining step, each experiment should give comparable activation energies independently of the crystal type of TiO_2. This is not the case, as may be seen in Table 3. However, it is interesting to note that, regardless of the crystal type of TiO_2, most of the values fall into two ranges: 34—36 and 54—60 kcal/mol; this is in good agreement with the results of the present work. The value of 99 kcal/mol is close to that of the L group in the higher-temperature range in the present work. This exceptionally high value, therefore, is considered to be due to the formation of Ba_2TiO_4 and not to the fact that TiO_2 has a rutile form.

Table 3. Activation energy for the formation of $BaTiO_3$

Workers	Crystal type of TiO_2	E_a kcal·mol^{-1}	Rate equation
Kubo and Shinriki[16]	Anatase	54	Jander
Kubo and Shinriki[15]	Rutile	99	modified
	Anatase	58	Jander
Kuno *et al.*[2]	Rutile	36	Tamman
	Anatase	34	
Arai *et al.*[14]	Anatase	60	Jander

The reason why the activation energies differ between the S and L groups, although both groups give the same reaction product, $BaTiO_3$, below 840 °C, is not clear at present. However, the following should be noted here.

It has been reported by Nakayama and Sasaki[10] that the activation energy of the diffusion of barium into the rutile-TiO_2 crystal is 59 kcal/mol for a direction perpendicular to the c-axis and 43 kcal/mol for a direction parallel to the c-axis. The activation energies obtained for the S and L groups in the lower-temperature range are of the same order of magnitude as the values of the former and the latter, respectively. The rutile-TiO_2 particles used in the present work are spherical or cubic in the S group and plate-like grown in the plane perpendicular to the c-axis in the L group. Accordingly, in the reaction of the L group, the diffusion of the BaO component may mainly occur along the direction of the c-axis of rutile-TiO_2 and give a lower activation energy. On the other hand, in the reaction of the S group, the diffusion may occur more isotropically and give a higher activation energy. On anatase-TiO_2 particles, the same interpretation may be applied in explaining the different behavior between the two groups.

Reactivity and Crystal Type of TiO_2. On the solid-state reaction of the TiO_2–$BaCO_3$ system, it has generally been accepted that anatase-TiO_2 shows a lower activation energy and a higher reactivity than rutile-TiO_2.[1] In the present study, however, there were no observable differences in the reactivity and activation energy between anatase- and rutile-forms. This is to be expected when the reaction is limited by a diffusion through the same reaction product. The particle size of TiO_2 governs the reactivity. In previous works, in which the differences in the reactivity and the activation energy between the two forms of TiO_2 were observed, the secondary properties of the TiO_2 powders such as the state of the agglomeration of primary particles, especially in the case of calcined rutile-TiO_2, would affect the reactivity and result in different reactivities between the two types of TiO_2.

This research was supported in part by the Science Foundation of the Ministry of Education (No. 885150).

Photoreduction of Quinones. I. One-electron Transfer to *p*-Benzoquinone in Ethanol Studied by ESR during Continuous Photolysis

Yoshihiko KAMBARA* and Hiroshi YOSHIDA

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received August 7, 1976; in revised form December 21, 1976)

Electron spin resonance was examined during the continuous photolysis of a flowing solution of *p*-benzoquinone in ethanol at room temperature. It was found that both semiquinone anions and semiquinone radicals were generated, but their relative yields changed depending on the experimental conditions. The semiquinone anion was generated in a comparatively high yield at low concentrations of *p*-benzoquinone and at high flowing rates. Its formation was, however, quenched by the addition of acetic acid without transformation to the semiquinone radical. The semiquinone radical was generated efficiently at high *p*-benzoquinone concentrations and at low flowing rates. Its formation was enhanced by the addition of hydroquinone. These results, as well as the previous results on the effect of the wavelength of light, indicate, in contrast with the currently accepted view, that there is effectively no equilibrium in ethanol between the semiquinone radical and the semiquinone anion under the present experimental conditions, and that the latter is formed by a photoinduced one-electron transfer from solvent to *p*-benzoquinone. The semiquinone radical seems to arise from the hydrogen abstraction of excited *p*-benzoquinone from the hydroquinone formed as a product during photolysis.

One of the main interests in photobiology is associated with the naturally occuring quinones mediating in the electron-transport mechanism in photosynthesis.[1] Such a biological function of quinones seems to have attracted the interest of chemists in studying the photochemistry of simple quinones, such as *p*-benzoquinone and duroquinone, by means of the flash photolysis-optical absorption technique[2-7] as well as the photolysis-electron spin resonance (ESR) technique.[8-14] The flash photolysis studies have stressed the hydrogen-abstraction reaction of simple photoexcited quinones since the pioneering works by Bridge and Porter.[2] The transient optical absorption due to the semiquinone radical and the semiquinone anion was observed in hydrogen-donating solvents such as ethanol or in the presence of hydrogen donors; the formation of the latter has generally been attributed to its equilibrium with the former, generated primarily by the hydrogen-abstraction reaction:

$$Q^* + CH_3CH_2OH \longrightarrow \dot{Q}H + CH_3\dot{C}HOH \quad (1)$$

$$\dot{Q}H \longrightarrow Q^- + H^+. \quad (2)$$

This seems to be the currently accepted reaction mechanism,[15] and it seems to have been supported also by ESR studies,[10-13] because only the ESR spectrum of semiquinone radicals, presumed to be generated primarily through Reaction 1, has been detected from solutions of quinones in alcohols.

However, our previous ESR study seems to conflict with the above mechanism, because the ESR spectra of both semiquinone radicals and semiquinone anions were observed from a solution of *p*-benzoquinone and its methyl derivatives in ethanol or methanol during continuous photolysis and the effective wavelength of the photolyzing light was found to be different between the semiquinone anions and the semiquinone radicals.[16] The results suggested that the semiquinone anions might be generated primarily from photoexcited quinones, but not by Reaction 2. However, this was not conclusively proven, because the observed ESR signals depended very much on the experimental conditions and we could not verify the factors controlling the yields of both the semiquinone anions and the semiquinone radicals.

The previous study of detecting semiquinone intermediates by ESR has now been extended to verify the factors controlling their yields and to give firm indications against Reactions 1 and 2. The advantage of such an ESR study is that semiquinone anions and semiquinone radicals are clearly distinguished from each other,[16] while the spectra of semiquinone anions, radicals, and triplet quinones overlap each other, and so it is not easy to study the kinetic behavior of the semiquinone intermediates separately in flash photolysis-optical absorption studies.

Experimental

Chemicals. The *p*-benzoquinone (BQ) was purified by sublimation three times. The purified BQ showed a melting point of 387—389 K, identical with that quoted in chemical handbooks. The hydroquinone (BQH_2) was sublimed twice under a vacuum, volatile impurities being removed by means of a liquid nitrogen trap. Ethanol with a claimed purity of 99.5% was generally used without further purification. Occasionally, however, it was purified further by distilling it after reflux with sodium hydroxide and zinc powder to remove the acetaldehyde, by refluxing it with magnesium ethoxide prepared from magnesium and absolute ethanol in the presence of ethyl bromide to remove the water, and by then distilling it again. However, such additional purification of the ethanol caused no difference in the results. The acetic acid was used as received. All the chemicals used were of an SG grade and were supplied by Wako Pure Chemical Ind., Ltd.

Photolysis and ESR Measurements. The experimental instrument has already been described elsewhere:[17] it is essentially the same as that developed first by Livingston and Zeldes.[18] Sample solutions were purged with helium gas for at least half an hour under dimmed room light. This procedure was essential to obtaining reproducible results. The solutions were allowed to flow at a rate of from 0.014 to 5.0 $cm^3 s^{-1}$, which gave a resident time of 3.6 s to 10 ms of the flowing solution within the effective volume of the ESR

* Present address: Mitsui-Toatsu Co., Ltd., Mobara, Chiba 297.

resonant cavity. Photolysis was carried out at room temperature with unfiltered light of a wavelength longer than 270 nm from a super-high-pressure mercury lamp (Philips, SP-500). The intensity of light gradually changed in the shorter-wavelength region, thus causing a scattering of the results. Therefore, each series of data shown in one figure was obtained at one time. The solution was warmed during photolysis, but its temperature immediately after photolysis was found to be 290±2 K except when the flow rate was extremely slow.

Results

The ESR signal observed from the ethanol solution of BQ generally consisted of a spectrum of benzosemiquinone radicals (triplet of double triplet, with hyperfine separations of 0.51, 0.19, and 0.03 mT) and one of benzosemiquinone anions (quintet, with a separation of 0.24 mT). These spectra are essentially the same as those reported previously.[8,16,19] The most prominent finding was that the relative intensities of both spectra changed depending on the experimental conditions. For instance, Fig. 1 shows the ESR signals recorded for two different concentrations of BQ, the other experimental conditions being unchanged. The dependence of the observed yield for both the benzosemiquinone radical ($BQH\cdot$) and the benzosemiquinone anion (BQ^-) on the BQ concentration is shown in Fig. 2 for two different resident times of the solutions. $BQH\cdot$ was generated only at high BQ concentrations, whereas BQ^- was observed to form in a high yield even if the concentration was lowered to 0.01 mmol dm^{-3}.

Fig. 1. ESR signal recorded during photolysis of *p*-benzoquinone in ethanol flowing at a resident time of 0.5 s at 293 K. Concentration of quinone, (A) 10 and (B) 1.0 mmol dm^{-3}.

The observed yields of $BQH\cdot$ and BQ^- are plotted as functions of the resident time in Fig. 3 for particular BQ concentrations. $BQH\cdot$ was observed only at long resident times for the higher BQ concentrations; its yield increased with the resident time up to about 1 s. On the other hand, the BQ^- yield showed no increase with the resident time. Rather, it remained constant for the lower BQ concentrations, or it decreased from the highest value observed at the shortest resident time examined for the higher BQ concentrations.[20] These observations agree qualitatively with the results obtained

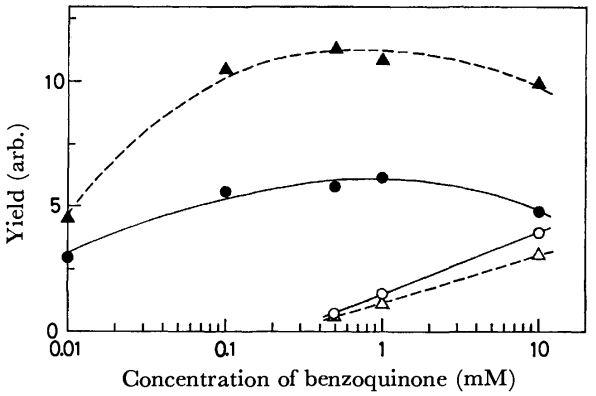

Fig. 2. Dependence of yield of benzosemiquinone anion and benzosemiquinone radical observed during photolysis of *p*-benzoquinone in ethanol on the benzoquinone concentration. Benzoquinone anion at resident time of (●) 1 s and (▲) 0.5 s, benzosemiquinone radical at resident time of (○) 1 s and (△) 0.5 s.

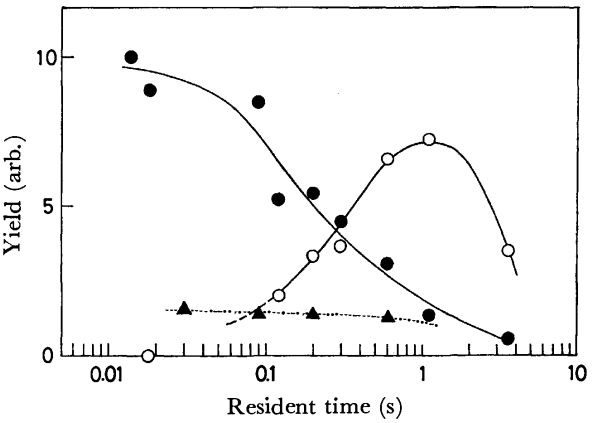

Fig. 3. Dependence of the yield of (●) benzosemiquinone anion and (○) benzosemiquinone radical observed during photolysis of flowing solution of 1.0 mmol dm^{-3} *p*-benzoquinone in ethanol, and (▲) that of the yield of benzosemiquinone anion from the solution of 0.01 mmol dm^{-3} *p*-benzoquinone on the resident time of the solutions within the effective volume of cell. No benzosemiquinone radical was detected from the diluted solution.

independently for the relationship between the yield and the BQ concentration, as is shown in Fig. 2.

Since $BQH\cdot$ is generated appreciably only at high BQ concentrations and at long photolysis times, it seems essential to study the effect of a photoproduct, BQH_2, on the formation of $BQH\cdot$ and on that of BQ^- as well. The yields of $BQH\cdot$ and BQ^- were examined by intentionally adding BQH_2 to a solution of 1 mmol dm^{-3} BQ under conditions where both $BQH\cdot$ and BQ^- were generated without added BQH_2. The yield of BQ^- remained unchanged, whereas that of $BQH\cdot$ increased with the concentration of the added BQH_2, as is shown in Fig. 4. Although both $BQH\cdot$ and BQ^- were found to form in the BQH_2 solution in ethanol, the increase in the $BQH\cdot$ yield shown in Fig. 4 cannot be attributed simply to the photodissociation of the added BQH_2 to $BQH\cdot$, because the effect of the added BQH_2 is prominent at its low concentrations. It should noted that the

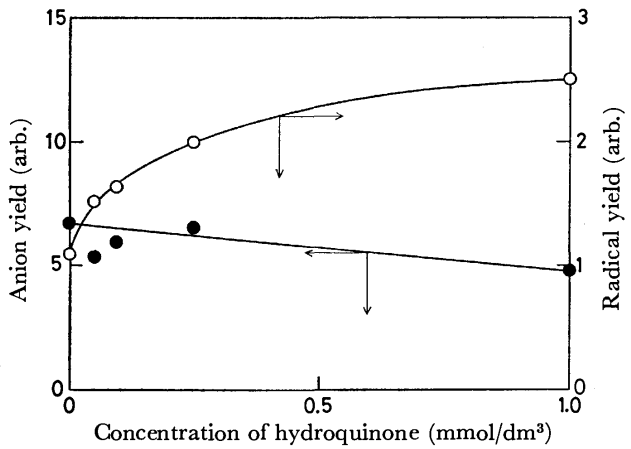

Fig. 4. Effect of the addition of hydroquinone into the solution of 1.0 mmol dm^{-3} *p*-benzoquinone in ethanol on the yield of (●) benzosemiquinone anion and (○) benzosemiquinone radical observed during photolysis at resident time of 1 s.

BQ^- formation from BQ is not affected by the addition of BQH_2.

Previously the addition of acids to the solution was found to eliminate the ESR spectrum of BQ^-. This was interpreted as being due to the protonation to BQ^-, resulting in the transformation of BQ^- into BQH·.[16] In the present study, however, it was found that the addition of acetic acid in increasing amounts up to 16 mmol dm^{-3} caused only a decrease in the BQ^- yield to zero, but no increase in the BQH· yield. When the BQ concentration was so low that only BQ^- was detected, the addition of acetic acid totally eliminated the ESR signal, indicating the absence of the transformation of BQ^- to BQH·.

Discussion

Although the ESR spectra of semiquinone anions have been recorded from halogenated benzoquinones[21,22] and anthraquinone,[9] the spectra recorded from BQ in fluid alcoholic solutions have been almost exclusively those of BQH·.[9,10,12,13,23,24] On the basis of the present results (Figs. 2 and 3), the absence of the BQ^- spectrum in the previous studies may be attributed to the effects of the BQ concentration and the photolysis time, since the solutions with comparatively high BQ concentrations were sealed in a sample tube and photolyzed for a long time or repeatedly by light pulses to overcome a poor signal-to-noise ratio. Pedersen *et al.* observed the coexistence of BQ^- and BQH· in an ethanol solution of BQ at a low concentration during photolysis by recycling a large volume of the solution.[14] This and our own previous studies[16] have been the only cases where evidence of the BQ^- formation was obtained by means of the ESR technique.

BQ^- was found to be generated at short resident times and/or at low BQ concentrations, while no BQH· at all was observed under the same experimental conditions. This strongly suggests that BQ^- is generated directly from BQ through a photoinduced one-electron transfer from the solvent ethanol. Although the above view of the BQ^- formation is not in accord with the currently accepted reaction mechanism for the photoreduction of quinones,[2,15] it is consistent with Tollin's interpretation of the observation of BQ^- by photolyzing BQ in a low-temperature ethanol matrix.[25] McLauchlan and Sealy applied the spin-trapping technique to the photochemical reaction of quinones including BQ in fluid alcoholic solutions and detected no 1-hydroxyethyl radical generated by Reaction 1, though they did detect alkoxyl radicals.[26] These radicals seem to have been generated through the deprotonation of the molecular cation of the alcohols primarily formed by the one-electron transfer between the quinones and the alcohols. The photoinduced electron transfer was demonstrated by Davis *et al.* by means of product analysis to occur from the alkoxide ion to amino anthraquinone derivatives.[27] They postulated that this reaction involves the charge-transfer lowest excited state.

One would anticipate that BQ^- might be generated from the primary intermediate, BQH·, by Reaction 2, which was so rapid that the primary intermediate could not be observed under the present experimental conditions. However, if the BQ^- formation is directly correlated to the BQH· formation by the rapid equilibration between these semiquinone intermediates, their relative yields should not depend on the BQ concentration. It can also be expected that the decrease in the BQ^- yield caused by the addition of acetic acid should be followed by an increase in the BQH· yield. Even if the equilibration was not rapid enough compared with the lifetime of the semiquinone intermediates, the primary intermediate should be observed comparatively more readily than the secondary one at short resident times. None of the present results, then, give any indication of a reaction mechanism comprising Reactions 1 and 2 for the BQ^- formation.

We found previously that BQH· was effectively generated with light of wavelengths of 260—300 nm, whereas BQ^- was generated with light of wavelengths around 460 nm.[16] The study of the wavelength effect on the formation of semiquinone intermediates is very undeveloped, but early in 1960 Bridge found, in his flash photolysis study, that the quantum yield of the durosemiquinone anion was the largest for the light of 350—400 nm, the longest wavelength examined.[28] This is consistent with our previous results.[16] The different wavelengths effective for the formation of BQ^- and BQH· support the view that the formation of the former is independent of that of the latter.

Some comments may be needed here on the BQH· formation, because it has thus far been believed to be the principal semiquinone intermediate in the photoreduction of BQ into BQH_2. The enhancement of the BQH· formation caused by the addition of a small amount of BQH_2 (see Fig. 4) seems to indicate that the hydrogen abstraction of photoexcited BQ from BQH_2 is one of the main sources of BQH·. This reaction reasonably interprets the observed dependence of the BQH· yield on the resident time and on the BQ concentration; the increase in the concentration of the photoproduct, BQH_2, during the photolysis of which the

rate is the higher for the higher BQ concentration, results in the observation of BQH· at long resident times from the solutions with higher BQ concentrations. It has been already observed in the flash photolysis study of duroquinone in ethanol[3,5,7] that the triplet excited quinone abstracts hydrogen from durohydroquinone with a diffusion-controlled rate, but from solvent ethanol only very slowly. However, we should reserve other possible sources for BQH·, especially for that observed at long resident times, because BQ is readily depleted under the present experimental conditions. In a separate experiment, for example, 1 mmol dm^{-3} BQ was found by optical absorption study to have been almost entirely transformed into BQH_2 and other unidentified stable products after the photolysis and ESR measurements at the resident time of 0.5 s. Therefore, the photodissociation of BQH_2 and the other products may be responsible for the BQH· formation in the later period of photolysis at a long resident time. Photolysis with light of selected wavelengths would give an insight into the detailed mechanism for the BQH· formation, but it could not be done mainly because of the limited sensitivity of the experimental method used.

In conclusion, the present ESR investigation revealed that the primary step in the photochemical reaction of BQ in ethanol is the one-electron transfer giving BQ^-:

$$BQ^* + CH_3CH_2OH \longrightarrow BQ^- + CH_3CH_2OH^+. \quad (3)$$

A question may arise as to the role of BQ^- in the photoreduction of BQ; is it really involved in the reduction process? In order to answer this question, we examined, though qualitatively, the optical absorption of the BQ solutions after the photolysis and ESR measurements under the conditions where BQ^- was exclusively formed, and found that a fraction of BQ had been transformed into BQH_2, giving an absorption band with its maximum at 295 nm. We are inclined to believe that BQ^- but not BQH· is involved in the photoreduction of BQ in ethanol, for which we propose the following reaction scheme based on the present results:

$$CH_3CH_2OH^+ + CH_3CH_2OH \longrightarrow CH_3CH_2\dot{O} + CH_3CH_2OH_2^+, \quad (4)$$

$$CH_3CH_2\dot{O} + CH_3CH_2OH \longrightarrow CH_3CH_2OH + CH_3\dot{C}HOH, \quad (5)$$

$$CH_3\dot{C}HOH + BQ \longrightarrow CH_3\overset{+}{C}HOH + BQ^-, \quad (6)$$

$$CH_3\overset{+}{C}HOH + CH_3CH_2OH \longrightarrow CH_3CHO + CH_3CH_2OH_2^+, \quad (7)$$

$$2BQ^- \longrightarrow BQ + BQ^{2-} \quad (8)$$

$$BQ^{2-} + 2CH_3CH_2OH_2^+ \longrightarrow BQH_2 + 2CH_3CH_2OH. \quad (9)$$

The above reaction scheme is only a matter of speculation. However, Reaction 4 is consistent with the detection of alkoxyl radicals by the spin-trapping technique applied to the photoreduction of quinones in alcohols.[26] Reaction 6 gives a reason why the hydroxyethyl radical was not observed in the present investigation, though it had been detected in a similar ESR study of the photoreduction of benzophenone in ethanol.[17] It was inferred in Willson's pulse radiolysis work[29] to occur as a route for the formation of the semiquinone anion. The disproportionation of semiquinone anion, Reaction 8, has been observed in the flash-photolysis study of duroquinone in an alkaline ethanol-water mixture.[2] This reaction, together with Reaction 9, explains the route without the participation of BQH· for the formation of BQH_2.

A part of this work was carried out at the Research Reactor Institute, Kyoto University, with the kind experimental assistance of Tetsuo Warashina, to whom we wish to express our sincere thanks.

Magnetic Properties and Low-Field ESR of Organic Free Radicals, Monochloroporphyrexide and Porphyrexide

Toshio YOSHIOKA*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received August 9, 1976)

The static magnetic susceptibility, and ESR and proton NMR spectra of powder samples of monochloroporphyrexide were measured above 1 K and compared with those of porphyrexide. A broad maximum in the static susceptibility of monochloroporphyrexide, indicating an antiferromagnetic interaction, appeared at 22.5 K. The relative susceptibilities of the two radicals obtained from the ESR signal intensities and the proton NMR shifts agree qualitatively with the static susceptibilities. In the low-field ESR spectra (135 MHz) of each radical, broadening of the $g=2$ absorption line and distinct appearance of the $g=4$ absorption line were found in the temperature region below T_m, the temperature at which the susceptibility is maximum. The anisotropy of the g-value was estimated from Q-band ESR spectra. Furthermore, the unpaired electron-spin distribution over the ring was estimated from the X-band ESR and the proton NMR spectra. The results are interpreted assuming that the magnetic behavior of the two radicals is due to alternating antiferromagnetic Heisenberg linear chains with alternating parameters, $a=0.4$ and $a=0.6$, respectively.

At low temperatures, the magnetic susceptibility of many stable neutral radicals deviates from the Curie-Weiss law and sometimes has a broad maximum which indicates the presence of an antiferromagnetic exchange interaction J between unpaired electrons of the radicals.[1-5] This anomalous magnetic behavior has been interpreted in terms of the one-dimensional Heisenberg model with an antiferromagnetic exchange interaction.[3] Such an interaction is considered to be due to the overlap of the $2P_z\pi$-orbitals, each of which is occupied by an unpaired electron, and the one-dimensionality may be caused by the uniaxial characteristic of the π-orbital. It has been reported in previous papers, however, that for the porphyrexide radical the magnetic behavior is different from that for 2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl(TANOL),which is a one-dimensional Heisenberg antiferromagnet typical of organic neutral radicals.[3,4] Its magnetic susceptibility is better interpreted using the Ising model rather than the linear Heisenberg model. The difference between the magnetic properties of TANOL and porphyrexide has been considered to be due to their different molecular structures; the former has a non-planar molecular framework and a localized spin distribution, while the latter is somewhat planar with the unpaired electron expected to be over the ring. In order to clarify the magnetic properties of porphyrexide radicals, a chloroderivative of porphyrexide has been chosen as an appropriate sample. In this paper, the results of the magnetic susceptibility and ESR and proton NMR measurements of monochloroporphyrexide (Cl-porphyrexide) are reported for temperatures above 1 K, and the exchange interaction, spin correlation, and unpaired electron-spin distribution in porphyrexide radicals are discussed by comparing the results with those of porphyrexide and TANOL. Cl-porphyrexide has been suggested to have the molecular structure shown in Fig. 1.[6]

* Present address: Fibers Research Laboratories, Toray Industries, Inc., Sonoyama, Otsu 520.

Experimental

The porphyrexide radical was obtained commercially and was used without further purification. The sample of monochloroporphyrexide was prepared according to the procedure of Piloty and Schwerin,[7] and was purified by recrystallization from methanol, mp 151—152 °C. The results of elemental analysis correspond closely to the calculated values. Found: C, 34.42; H, 4.61; N, 31.99; Cl, 20.10%. Calcd for $C_5H_8N_4OCl$: C, 34.18; H, 4.56; N, 31.91; Cl, 20.22%. TANOL was prepared by the oxidation of 2,2,6,6-tetramethyl-4-hydroxypiperidine according to the process of Rozantsev,[8] and was purified by recrystallization.

The magnetic susceptibilities were measured for powder samples of about 80 mg in a field of 8.8 kG from 1.7 to 300 K by means of a magnetic torsion balance described elsewhere.[9] The temperatures were measured with an AuCo–Cu thermocouple and a carbon resistor calibrated by measuring not only the magnetic susceptibility of Mn–Tutton salt, but also the vapor pressures of liquid helium, liquid hydrogen, and liquid nitrogen. The proton NMR measurements were carried out using a Robinson-type spectrometer operating at 35.0 MHz with an 80-Hz field modulation and with a field sweep. The magnetic field was calibrated by means of the proton absorption of H_2O. The low-field ESR (LF-ESR) spectra were observed using a Benedek-Kusida type spectrometer at 135 MHz.[10] Details of the apparatus for the low-field ESR measurements have been described elsewhere.[11] A conventional cryostat was used, and temperatures were determined using an Allen-Bradley carbon resistor calibrated against the vapor pressures of liquid helium, hydrogen, and nitrogen. The high-field ESR spectra in solution and in the crystalline state were obtained at room temperature, using JEOLCO X-band and Q-band spectrometers, respectively. The magnetic field was calibrated using the hyperfine splittings of Mn^{2+} doped in MgO.

Table 1. Results from susceptibility measurements

	χ_d (10^{-4} emu/mol)	θ (K)	T_m (K)	χ_m (10^{-4} emu/mol)	p	J/k(K)	a
Cl-porphyrexide	−1.08	−20	22.5	72	0.96	−18.2	0.4

Results

Susceptibility. The diamagnetic correction was made using Pascal's constant. The diamagnetic susceptibility, χ_d, is listed in Table 1. In the temperature range above 40 K, the paramagnetic susceptibility, χ_p, of Cl-porphyrexide follows the Curie-Weiss law, with a Weiss constant of $\theta=-20$ K and a spin concentration of 96.5%. As the temperature is lowered below 40 K, it deviates from the Curie-Weiss law and reaches a broad maximum at $T_m=22.5$ K, as is shown in Fig. 2. After passing through the maximum, it decreases gradually down to 3.5 K. However, below 3.5 K it increases again as the temperature is lowered. In the region from 1.7 to 2.3 K, the Curie-Weiss law was observed with a spin concentration of 0.5% and a Weiss constant of −0.4 K. When this low-temperature paramagnetic impurity curve is extrapolated to higher temperatures and subtracted from the experimental values, the corrected curve shown in Fig. 2 is obtained.

Proton NMR. In the proton NMR spectra of a powder sample of Cl-porphyrexide at 35.0 MHz, an assymetric single line was observed at a free proton position in the temperature range of 1.6—77 K. When the temperature was lowered below 77 K, the linewidth defined as the maximum slope width of signals obtained by 80-Hz field modulation increased and reached a maximum value of 8.0 G in the vicinity of $T_m=22.5$ K. Below T_m, it decreased as the temperature was lowered, and reached a value of 5.5 G at 4.2 K.

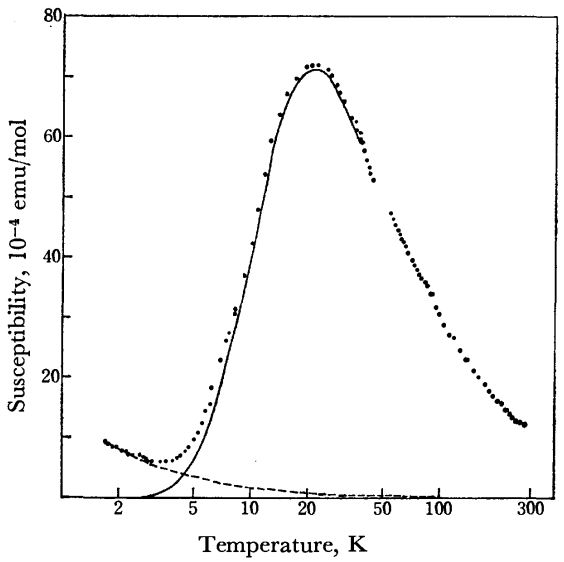

Fig. 2. Paramagnetic molar susceptibility of Cl-porphyrexide radical. The full circles represent the experimental values. The impurity curve indicated by the broken line is an extrapolation of the low temperature Curie-Weiss data. The solid line shows the difference between the experimental values and the impurity curve.

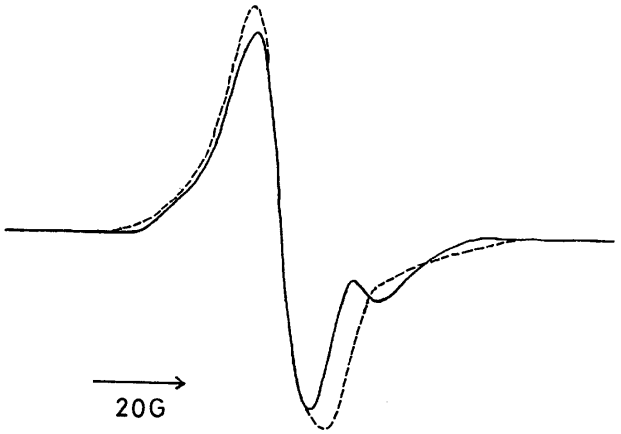

Fig. 3. Proton magnetic resonance spectra of porphyrexide, measured at 35 MHz. The solid line and the broken line represent the spectra at 20 K and 4.2 K, respectively.

The proton NMR spectra of a powder sample of porphyrexide at 35.0 MHz are shown in Fig. 3. In addition to the central unshifted line, one more absorption line shifted to higher magnetic field was observed in the temperature region 3.0—30 K. The magnitude of the shift was largest in the vicinity of $T_m=7.6$ K.[4] The resonance field of the unshifted line almost corresponded to the magnetic field of a free proton at that frequency.

X-Band ESR in Solution. The X-band ESR spectrum of Cl-porphyrexide in a chloroform solution is shown in Fig. 4. Triplet splitting ($a_N=8.5$ G), caused by the hyperfine interaction between an unpaired electron and a ^{14}N nucleus, and several subsplittings are observed. The g-value of Cl-porphyrexide in solution was determined to be 2.0060, which coincides with the values of other nitroxide radicals.

Fig. 4. The X-band ESR spectrum of Cl-porphyrexide in a chloroform solution.

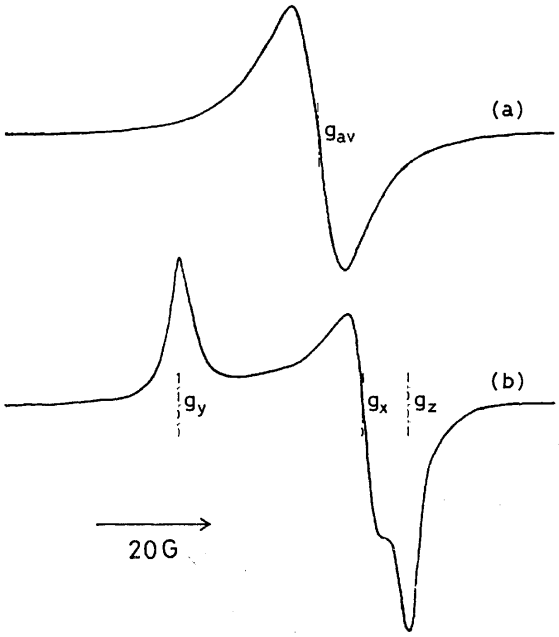

Fig. 5. The Q-band ESR spectra of porphyrexide (a) and Cl-porphyrexide (b) measured at room temperature.

Q-Band ESR. The *Q*-band ESR spectra for powder samples of porphyrexide and Cl-porphyrexide measured at room temperature are shown in Figs. 5(a) and (b), respectively. A relatively symmetrical single line was observed for porphyrexide. On the other hand, the spectrum of Cl-porphyrexide consists of three peaks. When single crystals of Cl-porphyrexide were used, a single line was obtained for any crystal orientation; the resonance field exhibited an angular dependence for an external magnetic field applied in a certain plane.

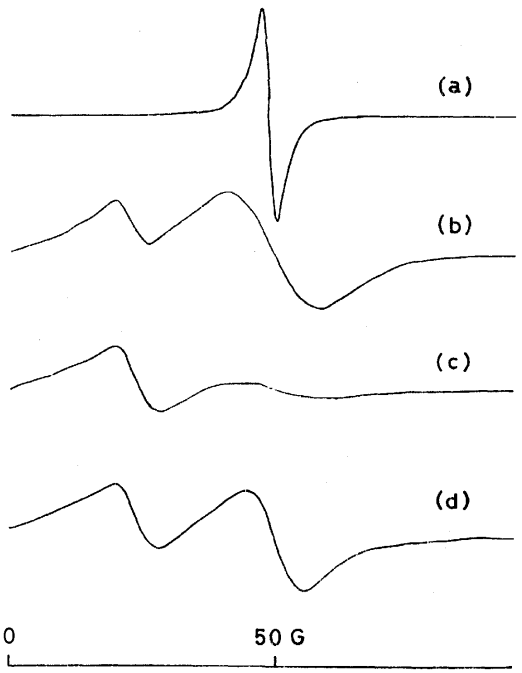

Fig. 6. The LF-ESR spectra of Cl-porphyrexide measured at 135 MHz.
(a) T=77 K, (b) T=6.3 K, (c) T=4.2 K, (d) T=2.0 K.

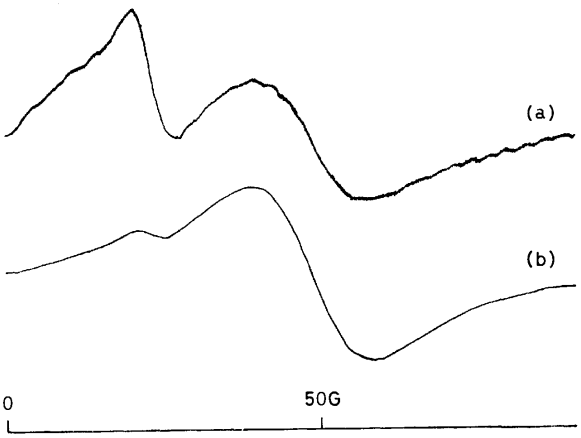

Fig. 7. The LF-ESR spectra of porphyrexide (a) and TANOL (b) measured at 135 MHz and at 1.4 K.

LF-ESR. The LF-ESR absorption spectra of powder samples of Cl-porphyrexide, porphyrexide, and TANOL all exhibit a single line which has an exchange-narrowed Lorentzian shape at room temperature. The temperature dependence of the LF-ESR spectrum for Cl-porphyrexide is shown in Fig. 6. Figures 7(a) and (b) show the LF-ESR spectra of porphyrexide and TANOL, respectively, measured at 1.4 K. When the temperature was lowered below room temperature, the linewidth of the g=2 absorption, defined as the peak-to-peak linewidth of the first derivative of the absorption spectrum, gradually decreased and exhibited a minimum in the vicinity of T_m. Then, it started to increase rapidly as the temperature was further decreased. Cl-porphyrexide and porphyrexide linewidths decreased again below given temperatures. The temperature dependence

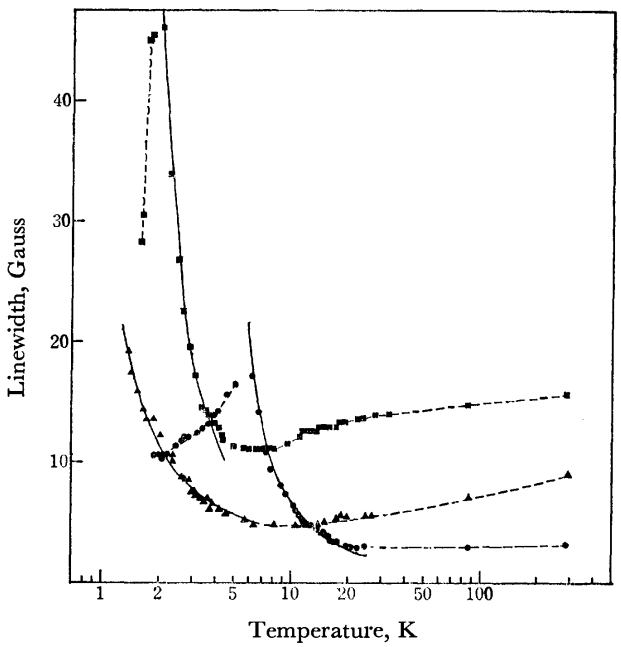

Fig. 8. The temperature dependence of the LF-ESR linewidth.
—●—, Cl-porphyrexide, —■— porphyrexide, —▲— TANOL.
The solid lines represent the curves calculated by Eq. 6.

of the linewidth for each sample is shown in Fig. 8. The relative susceptibility, obtained from the signal intensity, agreed qualitatively with the static susceptibility; it could not be treated quantitatively since the spectrometer sensitivity changed with temperature. The $g=4$ absorption could not be observed at room temperature or at liquid nitrogen temperature. Below the temperature at which the susceptibility deviated from the Curie-Weiss law, the $g=4$ ESR absorption was detected as the temperature was lowered. The linewidth of the $g=4$ ESR absorption was independent of the temperature within the experimental error. The ratio of the peak intensity of the $g=4$ resonance absorption to that of the $g=2$ absorption depended upon the angle between the direction of the radio-frequency field and that of the static magnetic field; it was the smallest when the radio-frequency field and the static magnetic field were perpendicular to each other.

Discussion

Susceptibility. The behavior of the magnetic susceptibility of Cl-porphyrexide is very similar to that of porphyrexide,[4] although the temperature T_m for the former is almost three times as high as that for the latter. The magnetic behavior cannot be explained quantitatively by the well-known pair model described by:

$$\chi_p = (Ng^2\beta^2S(S+1)/3kT)[1+(1/3)\exp(\Delta/kT)]^{-1}, \quad (1)$$

where Δ is the energy splitting between the ground singlet and the excited triplet states and is equal to $2J$. The maximum value of the observed susceptibility, χ_m, is about 15% smaller than the theoretical value calculated from Eq. 1. Moreover, the experimental values deviate from the theoretical χ_p-T curve as the temperature is decreased below T_m. These discrepancies can be reduced by introducing the alternating antiferromagnetic Heisenberg linear chain model[12] or the anisotropic regular chain model.[13] The susceptibility data of the nitroxide radical, TANOL, has been analyzed successfully on the basis of the regular Heisenberg model.[3] In the case of Cl-porphyrexide and porphyrexide, the g-values are nearly isotropic and are similar to those of nitroxide radicals, as is shown below, so that it is not appropriate to discuss their magnetic properties on the basis of the latter model. Therefore, the susceptibility data have been analyzed using the former model. The spin Hamiltonian for the former model is given by:

$$\mathcal{H} = -2J\sum_{i=1}^{N/2}(\boldsymbol{S}_{2i}\cdot\boldsymbol{S}_{2i-1}+a\boldsymbol{S}_{2i}\cdot\boldsymbol{S}_{2i+1}), \quad (2)$$

where J is the exchange integral coupling a certain spin with its nearest neighbor and aJ is the exchange integral of a spin with its next nearest neighbor. This model corresponds to the pair model when $a=0$ and to the regular Heisenberg model when $a=1$. The exact eigenvalue spectrum and thermodynamic properties of Eq. 2 have been calculated for short chains by Duffy and Barr.[12]

In Fig. 9, the (χ_p/p)-T data for Cl-porphyrexide and porphyrexide are given together with the "best fit"

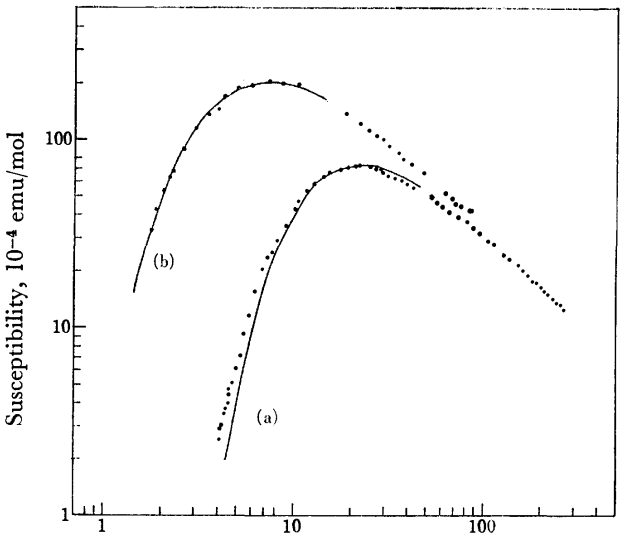

Fig. 9. Magnetic molar susceptibilities of Cl-porphyrexide (a) and porphyrexide (b). The full circles represent the experimental values of χ_p/p. The solid lines represent the theoretical χ_p-T curves with $a=0.4$ and $J/k=-18.2$ K (a), and $a=0.6$ and $J/k=-5.9$ K (b).

theoretical curves with $a=0.4$ and $J/k=-18.2$ K, and $a=0.6$ and $J/k=-5.9$ K, respectively. Here, p is the spin concentration which was found from the Curie-Weiss law observed at high temperature and is given in Table 1. The theoretical curves for $N=10$ were used, since it has been reported that the 10-spin chain values and ∞-spin chain estimates differ by less than 0.5% at $kT/|J|>0$, 0, 0.65, and 0.80 for $a=0.2$, 0.4, 0.6, and 0.8, respectively. The experimental results are in fairly good agreement with the theoretical curves. The interpretation based on this model may be tentative due to lack of a detailed crystal-structure determination. However, it may be concluded that the deviation of the susceptibility data from the pair-model curve is probably due to the existence of the second-strongest exchange interaction, since the curve for the pair model is described only by the strongest exchange interaction. The resulting parameters are summarized in Table 1, together with those for TANOL. The exchange parameter J for Cl-porphyrexide is relatively large in comparison with those of other neutral organic radicals and is the largest of the ring-iminoxyl radical exchange parameter investigated. The rise in the susceptibility of Cl-porphyrexide below 3.5 K is attributable to the impurity effect, as no abnormal behavior in the proton NMR spectra was found in this temperature range.

Recent specific heat and proton magnetic resonance measurements below 1 K, in the case of TANOL, revealed that the magnetic-phase transition occurs at about 0.4 K.[14,15] On the other hand, it may be impossible for Cl-porphyrexide and porphyrexide to change into a long-range ordered state even if the temperature is lowered below 1.4 K, since the magnitude of the susceptibilities is so small at 1.4 K that the exchange interaction leading to a long-range ordered state, such

as the interchain exchange interaction, is no longer effective.

Proton NMR. In the polycrystalline samples, the proton-resonance signal shift from the free-proton position in the direction of higher field can be approximately described by the following equation:[16,17]

$$\delta H = -a_H \chi H / g\beta g_N \beta_N. \quad (3)$$

The paramagnetic shift, δH, is proportional to the hyperfine coupling constant, a_H, and to the static magnetic susceptibility per molecule, χ. Taking the molecular framework of porphyrexide into account, the absorption line shifted to higher field can be roughly attributed to the three protons attached to the nitrogen atoms and the unshifted line to the six protons of the two methyl groups, since the spin density of the carbon atoms attached to the two methyl groups is expected to be very small. The hyperfine coupling constants of the three protons are evaluated to be −2.5 G using the susceptibility results.[4] From McConnell's relation, the unpaired electron-spin densities of the three nitrogen atoms are estimated to be +0.074 using $Q(\mathrm{NH}) = -33.7$ as obtained by Barton and Frenkel.[18] This assignment may be valid since the sign of the spin densities of the three nitrogen atoms is expected to be positive on the basis of electronic structure.

The resolved spectrum of Cl-porphyrexide could not be observed, since the static susceptibility is relatively small even at T_m. However, the asymmetric line shape may be due to the existence of a hyperfine interaction between the unpaired electron and the two protons attached to the nitrogen atoms. The temperature dependence of the linewidth may be explained by the hyperfine interaction which is related to the static susceptibility.[17] The susceptibility of TANOL obtained from the proton NMR shifts in single crystals agrees quantitatively with that of the one-dimensional Heisenberg model.[19]

X-Band ESR in Solution. The ^{14}N hyperfine constants, a_N, obtained in solution are shown in Table 2.[20,21] The hyperfine constants arising from the nitrogen nucleus of the NO group can be semiempirically described by the following equation:[22,23]

$$a_N = 134.8\rho_N - 35.8\rho_O, \quad (4)$$

where ρ_N and ρ_O are the unpaired π-electron spin densities at the nitrogen and oxygen atoms. In TANOL the values of $\rho_N+\rho_O$ is considered to be 1.0 since the unpaired electron is almost localized on the NO group masked by the four methyl groups. In porphyrexide the value of $\rho_N+\rho_O$ is estimated to be 0.78 using the NMR results neglecting the spin densities of the two carbon atoms attached to the nitrogen atoms which are expected to be negative and small on the basis of the electronic structure. Therefore, ρ_N and ρ_O were calculated from Eq. 4. In Cl-porphyrexide, they were calculated assuming that the value of ρ_N/ρ_O is equal to that of porphyrexide. The results are summarized in Table 2. The NMR and ESR results indicate that, in porphyrexide radicals, 20—30% of the unpaired electron from the NO group is distributed over the ring. Delocalization of the unpaired electron over the ring may play some role in the exchange interaction. Furthermore, it may be related to the high stabilization of these radicals, in addition to the steric hindrance of the two methyl groups.

Table 2. Hyperfine constants and spin densities

	a_N(G)	ρ_N	ρ_O
TANOL	15.5[a]	0.30	0.70
Porphyrexide	10.0[b]	0.22	0.56
Cl-porphyrexide	8.5	0.20	0.51

a) Ref. 20. b) Ref. 21.

Q-Band ESR. The Q-band ESR spectrum for powder samples of Cl-porphyrexide can be interpreted in terms of the g-factor anisotropy. The principal g-values obtained using the approximation of Kneübuhl[24] are shown in Table 3. Kikuchi has calculated the g-values of several nitroxide radicals using the CNDO/2 molecular-orbital calculation method.[25] The calculated principal g-values of H_2NO are cited in Table 3, along with the principal axes given by Kikuchi. The principal values are in fairly good agreement with those of Cl-porphyrexide. Furthermore, in the case of single crystals crystallized from methanol in rhombic plates, a single line was obtained for any crystalline orientation. These facts indicate that probably all the Cl-porphyrexide radicals are oriented with the N–O bond aligned along a unique direction in the crystalline state even if there is more than one site per unit cell. One-site ESR spectra were observed in the case of TANOL, as is expected from its crystal structure.[26] The principal velues are also given in Table 3.

On the other hand, a relatively symmetrical single line was observed for porphyrexide, with $g=2.0060$ which corresponds to the averaged g-value for the nitroxide radicals. The porphyrexide molecules have at least two different orientations in the crystalline state, so that the g-factor anisotropy may be averaged out by the exchange interaction between the unpaired electrons of two molecules oriented differently. The fact that Cl-porphyrexide has a large exchange interaction compared with that of porphyrexide can be ascribed to the difference in the crystal structure. The strongest exchange interaction of Cl-porphyrexide may arise from the overlap of the $P_z\pi$-orbitals between adjacent molecules

Table 3. Principle and averaged g-values

	g_x	g_y	g_z	g_{av}	Axis
Cl-porphyrexide	2.0048	2.0098	2.0034	2.0060	Porphyrexide	—	—	—	2.0061	
TANOL	2.0064	2.0096	2.0027	2.0062	
H_2NO[a]	2.0062	2.0091	2.0023	2.0059	

a) Calculated values (Ref. 25).

aligned in the z-direction. The decrease in the strongest exchange interaction of porphyrexide in comparison with that of Cl-porphyrexide is considered to be due to the increase in the distance between the two molecules or to the twisted overlap of the $P_z\pi$-obitals, which is caused by the existence of more than two molecular orientations.

LF-ESR. In the case of powder samples, the LF-ESR linewidths are more important since the contribution to the linewidth from the anisotropy of the g-values is excluded. The absorption lines observed at room temperature exhibit exchange-narrowed Lorentzian shapes. We can apply the usual three-dimensional Anderson-Weiss formula for a Lorentzian line:[27]

$$\Delta H = \Delta H_d^2/\sqrt{3}H_{ex}, \quad (5)$$

where ΔH is the peak-to-peak linewidth, ΔH_d^2 the second moment of the sum of the dipole-dipole interactions that would be observed in the absence of exchange, and H_{ex} the exchange field which is directly proportional to the exchange interaction J. In the low-field case, the so-called 10/3 effect is taken into account in Eq. 5. Since the crystal structures of Cl-porphyrexide and porphyrexide have not been determined, the second moment cannot be estimated from the Van Vleck formula. However, the second moment is the sum of the dipole-dipole interactions within the crystal, so that it is not as sensitive to changes in the crystal structure as is the exchange interaction. Therefore, the ratio of the exchange integrals J of Cl-porphyrexide and porphyrexide are evaluated from the ESR linewidths at 290 K and T_m to be 4.7 and 3.7, respectively, provided that the second moment of Cl-porphyrexide is approximately equal to that of porphyrexide. This ratio is consistent with the ratio 3.1 obtained from the magnetic susceptibility results (Table 1). This suggests that the ESR lines are narrowed predominantly by the strongest exchange interaction in the high-temperature range.

Table 4. Parameters for temperature dependent LF-ESR linewidth: $\Delta H=\alpha \exp(\beta J/kT)$

	α	β
Cl-porphyrexide	1.1	0.93
Porphyrexide	3.0	0.95
TANOL	3.6	0.48

The decrease in the linewidth from room temperature to T_m may be interpreted in terms of the contribution of spin-lattice relaxation to the linewidth since the spin-lattice relaxation time generally increases with decreasing temperature. The rapid broadening of the resonance is attributable to an increase in the correlation time for exchange motion because of spin ordering below the temperature of maximum susceptibility. As is shown in Fig. 7, the observed linewidth versus temperature below T_m can be fitted to the following empirical relation:

$$\Delta H = \alpha \exp(\beta J/kT). \quad (6)$$

The α and β values are summarized in Table 4. The β value is considered to be associated with the correlation mechanism of exchange motion which may be related to the magnetic behavior of the system. It is interesting that the β value for Cl-porphyrexide is roughly equal to that for porphyrexide and is almost twice as large as that for TANOL. These results indicate that the magnetic behavior of Cl-porphyrexide is similar to that of porphyrexide in spite of the difference in the crystal structures expected on the basis of the Q-band ESR spectra and is different from that of TANOL. Furthermore, they suggest that the exchange correlation time increases more rapidly in a pair-like system such as an alternating linear-chain system than in a regular linear-chain system. The narrowing of the resonance line below a certain temperature is probably due to paramagnetic impurities. Such behavior was also found in PAC and in Würster's blue perchlorate.[28]

The resonance line at $g=4$ is not due to the $\Delta M=2$ transition within the triplet levels caused by pairs of exchange coupling spins, since it has been found even for TANOL, in which no electron spin pairing occurs. It is probably caused by a forbidden transition due to dipolar interaction, as has been reported by Rhodes *et al.*[28] In the high-temperature region, the strong exchange interaction averages the dipolar coupling, so that the $g=4$ resonance cannot be detected.[29] The appearance of the $g=4$ resonance at low temperatures can be explained by an increase in the correlation time for exchange motion, as is expected from the linewidth of the $g=2$ resonance and the susceptibility data.

Summary

Because of the isotropic character of the g-factor, the susceptibility of Cl-porphyrexide was interpreted assuming that the magnetic behavior is due to alternating antiferromagnetic Heisenberg linear chains. The parameters derived from the susceptibility are $\theta=-20$ K, $T_m=22.5$ K, $\chi_m=72\times10^{-4}$ emu/mol, $J/k=-18.2$ K, and $a=0.4$. The fact that the strongest exchange interaction for Cl-porphyrexide is almost three times as large as that for porphyrexide is considered to be due to the difference of the crystal structures, as is expected from the Q-band ESR spectra. The LF-ESR lines are narrowed by the exchange interaction in the high-temperature region and the ratio of the strongest exchange integral J for Cl-porphyrexide to that for porphyrexide obtained from the linewidth is consistent with the ratio obtained from the susceptibility data. The rapid broadening of the $g=2$ absorption line and the distinct appearance of the $g=4$ absorption line are attributable to an increase in the correlation time for exchange motion resulting from spin ordering below the temperature of the susceptibility maximum. The susceptibility data and the temperature dependence of the LF-ESR linewidths indicate that the magnetic behavior of Cl-porphyrexide is similar to that of porphyrexide and is different from that of TANOL. In porphyrexide radicals, 20—30% of the unpaired electron is distributed over the ring from the NO group. More quantitative discussions concerning the magnetic interaction will be possible when detailed crystal-structure determinations are available in the future.

The author is deeply indebted to Professor Yasuo Deguchi for his continuous encouragement throughout this work, and also to Drs. Hiroaki Ohya-Nishiguchi, Jun Yamauchi, and Akira Nakajima for helpful advice and discussions. He also thanks Mr. Teruaki Fujito for supplying the susceptibility data of porphyrexide. Thanks are also due to Dr. Kohji Watanabe for his advice on the preparation of the samples.

Simple Relations between Scattering Cross Sections and Molecular Diameters

Yoshitsugu OONO and Yukio NISHIMURA

Research Institute of Industrial Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received August 12, 1976)

Empirical linear relations between the square roots of the electron-scattering cross sections for molecules and the cube roots of the van der Waals volumes for molecules due to Bondi are shown. The relations allow one to estimate, for example, the electron-impact ionization cross sections at 75 eV to within an error of ±15%. A dimensional analytic explanation of the relations is given.

It is a natural idea that the scattering cross section for a given collision process strongly depends on the size of the target. For example, in the case of electron collisions with molecules, Schmieder[1] has shown that there is a positive correlation between the molecular size and the collision probability P_c (*i.e.*, the number of collisions, per unit electron flux, per unit path length, per unit pressure at 0 °C). However, since the method for the evaluation of the size of the molecule was not systematic, it has not been possible to render this idea quantitative. Recently, Christophorou *et al.*[2] have shown that the cross section for the scattering of thermal electrons by normal alkanes is proportional to the mean square end-to-end distance, although the method for evaluating of the molecular size cannot be extended to molecules other than normal alkanes.

In this paper, it is shown that the following relation holds for several scattering processes involving molecules of molecular liquids:

$$\sigma^{1/2} = Av^{1/3} + B,$$

where σ is the scattering cross section, v the van der Waals volume of the molecule,[3] and A and B are numerical constants independent of the target molecule. Since the van der Waals volume is a good measure of the molecular size, this linear relation is a quantitative version of the natural idea mentioned above. There exist other measures of the molecular size, but the van der Waals volume is convenient for small molecules. For large molecules (or molecules with melting points higher than 150 K), the method of evaluation using the effective hard-core size of the molecule, proposed by one of the present authors,[4] can also be successfully used.

By using an empirical linear relation, rough estimations of the cross sections are possible. Such a relation reminds one of the Hammett rule, since the coefficients of the linear relation are independent of the target molecule and dependent only on the nature of process (or reaction).

A brief dimensional analytic account of the empirical relation will be given.

Empirical Relations

The van der Waals volumes for molecules, v, are calculated using the tables of Bondi.[3] Van der Waals volumes for rare gas atoms and hydrogen chloride are calculated from their critical volumes, V_c, using the crude relation, $v \simeq 0.18\ V_c$.

The relation between the ionization cross sections for 75-eV electrons σ_{ion}[5] and v is shown in Fig. 1. From Fig. 1 we get

$$\sigma_{ion}^{1/2} = 1.73v^{1/3} - 2.37, \quad (1)$$

where σ_{ion} is in Å^2 and v in cm^3/mol. Using Eq. 1, we can estimate σ_{ion}. The accuracy of the estimate is about ±15%, except for krypton, xenon, isobutane, and cyclohexane.

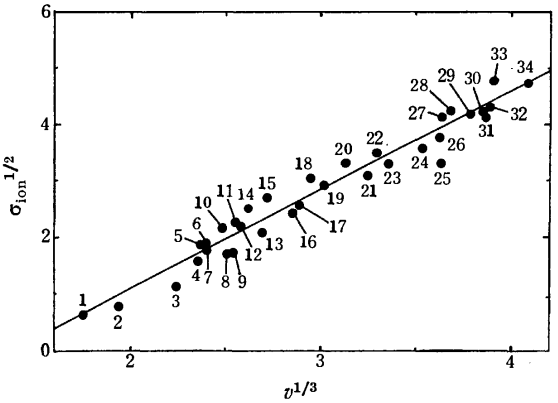

Fig. 1. The square root of the electron impact (75 eV) ionization cross section σ_{ion} (in Å^2)[5] *vs.* the cubic root of the van der Waals volume v (in cm^3/mol). The line denotes Eq. 1.
1: Helium, 2: neon, 3: hydrogen, 4: oxygen, 5: argon, 6: ammonia, 7: nitrogen oxide, 8: nitrogen, 9: carbon monoxide, 10: hydrogen chloride, 11: krypton, 12: methane, 13: carbon dioxide, 14: hydrogen sulfide, 15: xenon, 16: acetylene, 17: ethylene, 18: chloromethane, 19: ethane, 20: cyclopropane, 21: propene, 22: chloroethane, 23: propane, 24: isobutylene, 25: isobutane, 26: butane, 27: benzene, 28: cyclopentane, 29: isopentene (probably a mixture), 30: isopentene, 31: neopentane, 32: pentane, 33: cyclohexane, 34: hexane.

The linear relations between $P_c^{1/2}$ and $v^{1/3}$ for electron energies, E, of 49 and 25 eV are shown in Fig. 2. Even for E=4 eV this linear relation holds (Fig. 3). For 50 eV$\gtrsim E \gtrsim$15 eV these linear relations can be summarized as

$$P_c^{1/2} \simeq (5.56 - 0.22E^{1/2})(v^{1/3} - 1.0).$$

The linear relation between $P_c^{1/2}$ and $v^{1/3}$ also holds for much larger values of E, because the Born approximation is rather accurate for large E. However, the linear relation between $P_c^{1/2}$ and $E^{1/2}$ is crude and, for too large E, this linear relation ceases to hold.

For the case of monoatomic elements, it is known[6] that P_c is inversely proportional to the ionization

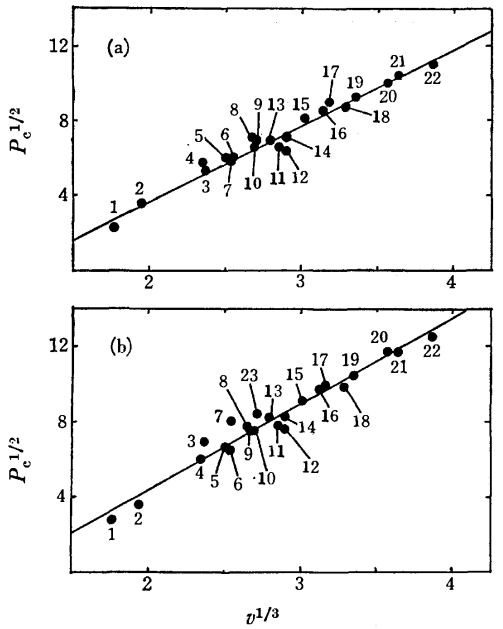

Fig. 2. The square root of the probability of collision P_c (in cm²/cm³ Torr)[1,6] *vs.* the cubic root of the van der Waals volume v (in cm³/mol). (a) is for the electron energy 49 eV, and (b) for 25 eV. The line in (a) denotes $P_c^{1/2}=4.02v^{1/3}-4.31$ and that in (b) $P_c^{1/2}=4.26v^{1/3}-4.49$.

potential, I. Although there is some correlation between the ionization potential and σ_{ion}^{-1} or P_c^{-1}, no clear relation similar to that shown above exists between them. According to Morrison (cited in Ref. 3) the van der Waals radii of atoms are proportional to $I^{-1/2}$, but this relation does not hold as accurately as the empirical relations proposed here. Lampe *et al.*[5] have shown that σ_{ion} is proportional to the polarizability, α. It is also

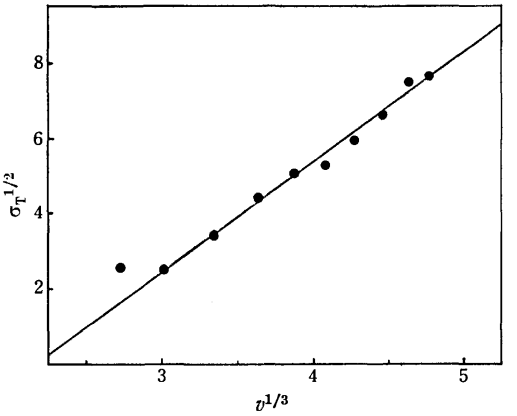

Fig. 4. The square root of the scattering cross section of thermal electrons with normal alkanes (methane to decane from left to right) σ_T (in Å²)[2] *vs.* the cubic root of the van der Waals volume v (in cm³/mol). The line denotes Eq. 2.

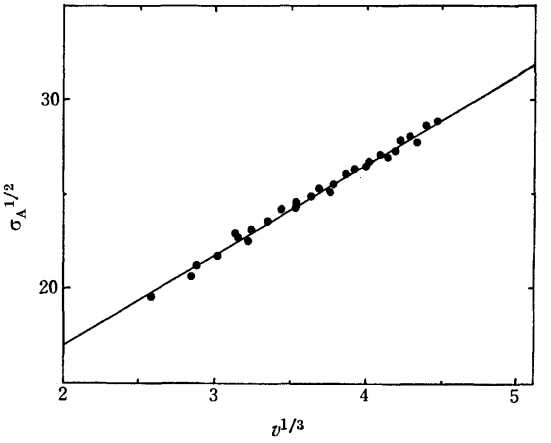

Fig. 5. The square root of the scattering cross section of thermal argon with hydrocarbons σ_A (in Å²)[8] *vs.* the cubic root of the van der Waals volume v (in cm³/mol). The line denotes Eq. 3.

known that P_c is proportional to α. However, it appears to be very difficult to explain these proportionalities. The explanation of Lampe *et al.* is based on the Born-approximation expression[7] of the cross sections, so that it is not conclusive.

The relation between the total cross section σ_T for the scattering of thermal electrons by normal alkanes[2] and v is shown in Fig. 4. The relation between the total cross section σ_A for the scattering of thermal argon atoms by hydrocarbons[8] and v is shown in Fig. 5. The empirical linear relations are as follows:

$$\sigma_T^{1/2} = 2.91v^{1/3} - 6.32 \quad (2)$$

and

$$\sigma_A^{1/2} = 4.79v^{1/3} + 7.38, \quad (3)$$

where σ_T and σ_A are in Å². For these very low-energy processes, the linear relations are valid only in a restricted group of compounds (*e.g.*, hydrocarbons), and hence are not very interesting, since we are interested in properties not strongly dependent on the electronic structure of the molecules.

Discussion

For higher-energy processes the Born approximation is valid, which suggests[7] that the cross sections are proportional to the geometrical cross sections of the target molecules. However, for lower-energy processes (for example, processes involving electrons having kinetic energy less than 100 eV), the Born approximation is not reliable. The theoretical calculation of the scattering cross sections for low-energy processes is very complicated. Thus, the derivation of the empirical relations above from scattering theory may be very difficult.

However, physical insight may be obtained from a dimensional analysis. All the relations obtained above are linear ones between $v^{1/3}+r_0$ and $\sigma^{1/2}$, where σ is the scattering cross section and r_0 is some constant. This suggests that the measure of the molecular diameter for collisional processes is not $v^{1/3}$, but $v^{1/3}+r_0$. The constant r_0 is considered, for example, to represent the Ramsauer-Townsend effect. Further considerations of r_0 are given below. Other relevant quantities with the dimension of length are σ, and the de Broglie wavelength of the projectile, λ. Hence we conclude that

$$\sigma^{1/2} = (v^{1/3}+r_0)f((v^{1/3}+r_0)/\lambda), \qquad (4)$$

where f is an appropriate function. In the high-energy limit, the scattering processes can be treated classically, so that $\lim_{\lambda\to 0} f((v^{1/3}+r_0)/\lambda)$ must be a finite constant. Therefore, for higher-energy scattering processes, f depends only slightly on $v^{1/3}+r_0$ and the empirical linear relation shown is obtained. As is seen in Figs. 1—5, r_0 is negative for σ_{ion}, P_c, and σ_T and is positive for σ_A. For the total cross sections for the scattering of positrons σ_P by rare gas atoms,[9] r_0 is also negative. Thus, we may concluded that r_0 is negative for charged particle scattering and positive for neutral particle scattering. For σ_T and σ_P, the negative r_0 can be explained by the Ramsauer-Townsend effect.[9] For impact ionization, an electron must strongly interact with the electron cloud of the target molecule, so that the length scale governing the cross section is not $v^{1/3}$ itself but the diameter of the electron cloud. Thus, the r_0 for σ_{ion} can be considered to represent the difference between the van der Waals diameter and the diameter of the electron cloud. For σ_{ion}, r_0 is *ca.* 1.8 Å and is about the twice the difference between the van der Waals radius and the covalent bond radius of Pauling. This may be a correct interpretation of r_0 for electron-impact ionization processes.

The square root of the (scattering) cross section *vs.* $v^{1/3}$ plot may be used to extract the specificity of molecules, since it has been implicitly assumed in deriving Eq. 4 that the electronic structure of the target molecules is relevant only through the van der Waals diameter. For example, the quenching cross sections of He (2^1S) by atoms and molecules[10] are shown in Fig. 6. From this, it may be concluded that ammonia, carbon dioxide, dinitrogen oxide, oxygen, and hydrogen have chemically specific properties in this reaction.

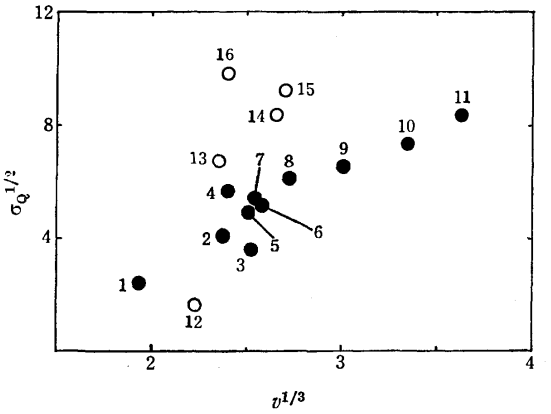

Fig. 6. The square root of the quenching cross section of He (2^1S) σ_Q (in Å^2)[10] *vs.* the cubic root of the van der Waals volume v (in cm^3/mol). ● Roughly satisfy a linear relation between $\sigma_Q^{1/2}$ and $v^{1/3}$, but ○ significantly deviate from this relation.

The Raman Spectra of Solid and Liquid Tetramethylsilane

Takako SHINODA

National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151

(Received September 16, 1976)

Laser Raman spectra of tetramethylsilane in its three crystalline forms and in the liquid state have been observed for the lattice and intramolecular vibrational regions. The bands due to lattice vibrations increase as the transitions from α to β and to γ occur. The spectra of the β and γ forms exhibit crystal-field splittings of intramolecular bands. The observed spectra suggest that the β and γ forms are isomorphous with each other and the α form has a higher symmetry.

Solid $Si(CH_3)_4$ has been shown by calorimetric studies[1] to have three crystalline forms designated by α, β, and γ, their triple point temperatures being 165.91, 170.98, and 174.05 K, respectively. The transitions α-to-β-to-γ seem to be irreversible. The infrared and Raman spectra of the liquid state were measured and band assignments made by several authors,[2] but the crystal structures of the three forms have not been studied.

In the present investigation, the Raman spectra of $Si(CH_3)_4$ in its three crystalline phases and liquid state have been measured for the entire spectral region including lattice and intramolecular vibrations in order to obtain information on the crystal structure and molecular motions of the three forms.

Experimental

The sample of $Si(CH_3)_4$ was the same as that used in a previous calorimetric measurement,[1] the purity of which was determined to be 99.995_4 mol% by the measurement of melting point. The Raman spectra were obtained with a Raman spectrometer, Kawaguchi Electric Works Ltd. model RL-62. The exciting light was 488.0 or 514.5 nm line of the Ar^+ laser, NEC model GLG2003. The cryostat, experimental techniques and temperature measurements have been reported.[3] The crystals were grown from the liquid by careful cooling. The result of total thermal analysis obtained by using the apparatus for laser Raman measurements is shown in Fig. 1. After each measurement, the crystalline form was checked by observing its melting point.

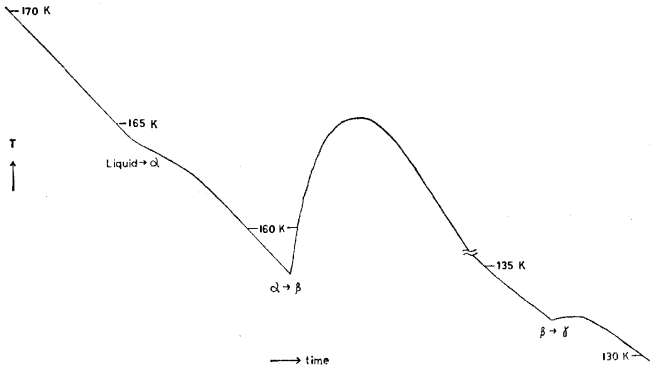

Fig. 1. Cooling curve (total thermal analysis) of $Si(CH_3)_4$.

Results and Discussion

Raman Spectrum in the Lattice Region. The observed spectrum in the lattice region consists of very weak and broad ghost bands. The lattice bands became very weak in the β and γ forms because a transparent crystal could not be obtained. The slitwidths of 3.1—3.6 cm^{-1} were used for reasonable intensities without too much background noise. The spectrum of the α-form in the lattice region is compared with corresponding spectrum of the γ-form in Fig. 2. The temperature measured was 163.9 K, which is about 2 K below the melting point of the α-form. The spectrum in the lattice vibrational region for the β-form at 152.7 K, about 18 K below its melting point, is shown in Fig. 3 together with the corresponding spectrum of the γ-form.

The Raman spectra of the β and γ forms have a pattern similar to each other with a large number of bands (Fig. 3). A similar spectral pattern suggests the two forms to be isomorphous with each other. Many bands in the lattice region suggest that the crystal contains many molecules of non-identical spatial position or orientation in a crystallographic unit cell with a low symmetry, as solid-CCl_4[4] and solid-CBr_4[5] in the low-temperature phases. In the Raman spectrum of the

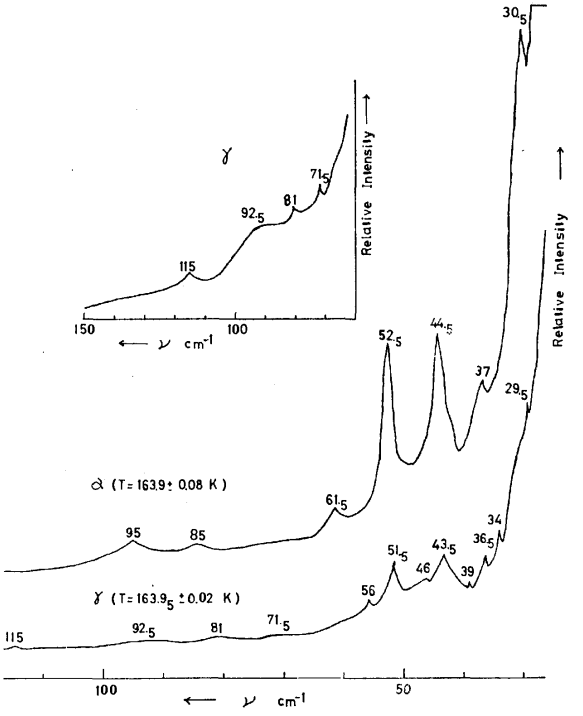

Fig. 2. Raman spectra in the lattice region of the α and γ forms at 163.9 K.

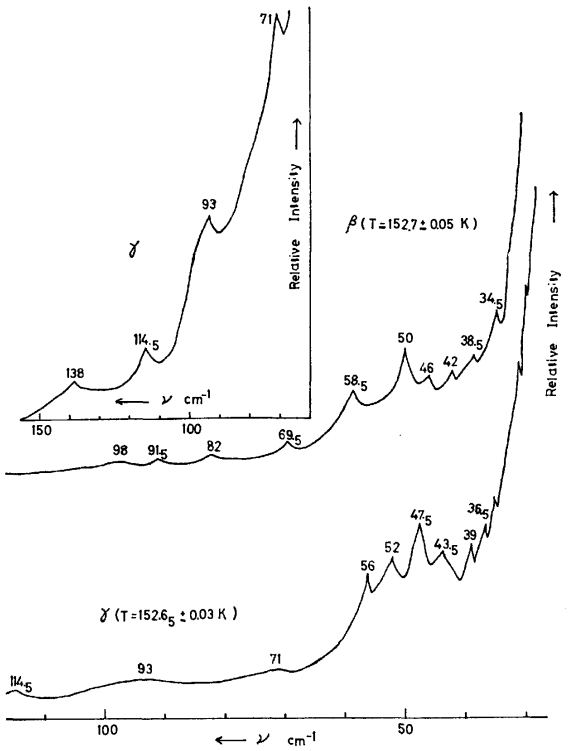

Fig. 3. Raman spectra in the lattice region of the β and γ forms at 152.7 K.

α-form the number of bands is smaller than that for the β and γ forms, probably owing to the high symmetry of the unit cell. We find no values in literature to compare with the ν values of lattice vibrations observed. The activation energies for the molecular reorientation or tumbling motion for γ-$Si(CH_3)_4$ were found to be 7.23 ± 0.40 and 8.7 ± 0.5 kcal mol^{-1} (above $\approx$140 K) by Smith[6] and Albert and Ripmeester[7] from their NMR studies. If molecules are assumed to be rigid rotators in a potential field of the type

$$V = (1/2)V_0(1-\cos n\theta), \quad (1)$$

the corresponding frequencies of librational lattice vibrations can be estimated from the above activation energies. The value of the moment of inertia of the molecule was calculated to be 27.20×10^{-39} g cm^2 by assuming the bond angle to be $\angle HCH=109°$ and interatomic distances $r_{CH}=1.10$ and $r_{CSi}=1.888$ Å.[8] The calculated results for $n=2$ and $n=3$ give values of frequencies of 32—35 and 48—53 cm^{-1}, respectively. Thus, the present values of lattice vibrations are reasonable.

Raman Spectrum of Intramolecular Vibrations. The Raman spectra of the liquid state and the three crystalline forms of $Si(CH_3)_4$ are shown in Fig. 4 for the intramolecular vibrational regions. The observed frequencies are given in Table 1 together with those reported.[2] The lines of the β and γ forms show a splitting of the degenerate fundamental of 7—26 cm^{-1}. In the crystal, the presence of some molecules of non-identical spatial position or orientation in the unit cell induces a splitting of the vibrational levels. In recent studies of other similar tetrahedral molecular crystals (CF_4[9] and CCl_4[10]) under high resolution, crystal splittings of the degenerate fundamentals were observed. The splittings observed for the degenerate fundamentals in the β and γ forms may be due to crystal effects.

The relative intensities of the lines obtained by integration are given in Table 1. We see that the relative intensities of the lines belonging to species e are large in α and those in β and γ are similar to each other. If only skeletal modes are taken into account, the vibrations $\nu_1(a_1)$, $\nu_2(e)$, $\nu_3(f_2)$, $\nu_4(f_2)$ are active in Raman scattering in the free molecule (T_d symmetry), The ratios of the intensity to that of the totally symmetric vibration, ν_1, for the liquid state, α, β and γ forms were estimated. The results are as follows, $I(\nu_2)/I(\nu_1)$: 1.3,

Table 1. Observed Raman active molecular vibrations of $Si(CH_3)_4$

a) Ref. 2. The relative intensities are integrated intensities referred to the maximum intensity of 100. Correction in sensitivity dependent upon the exciting light is made.

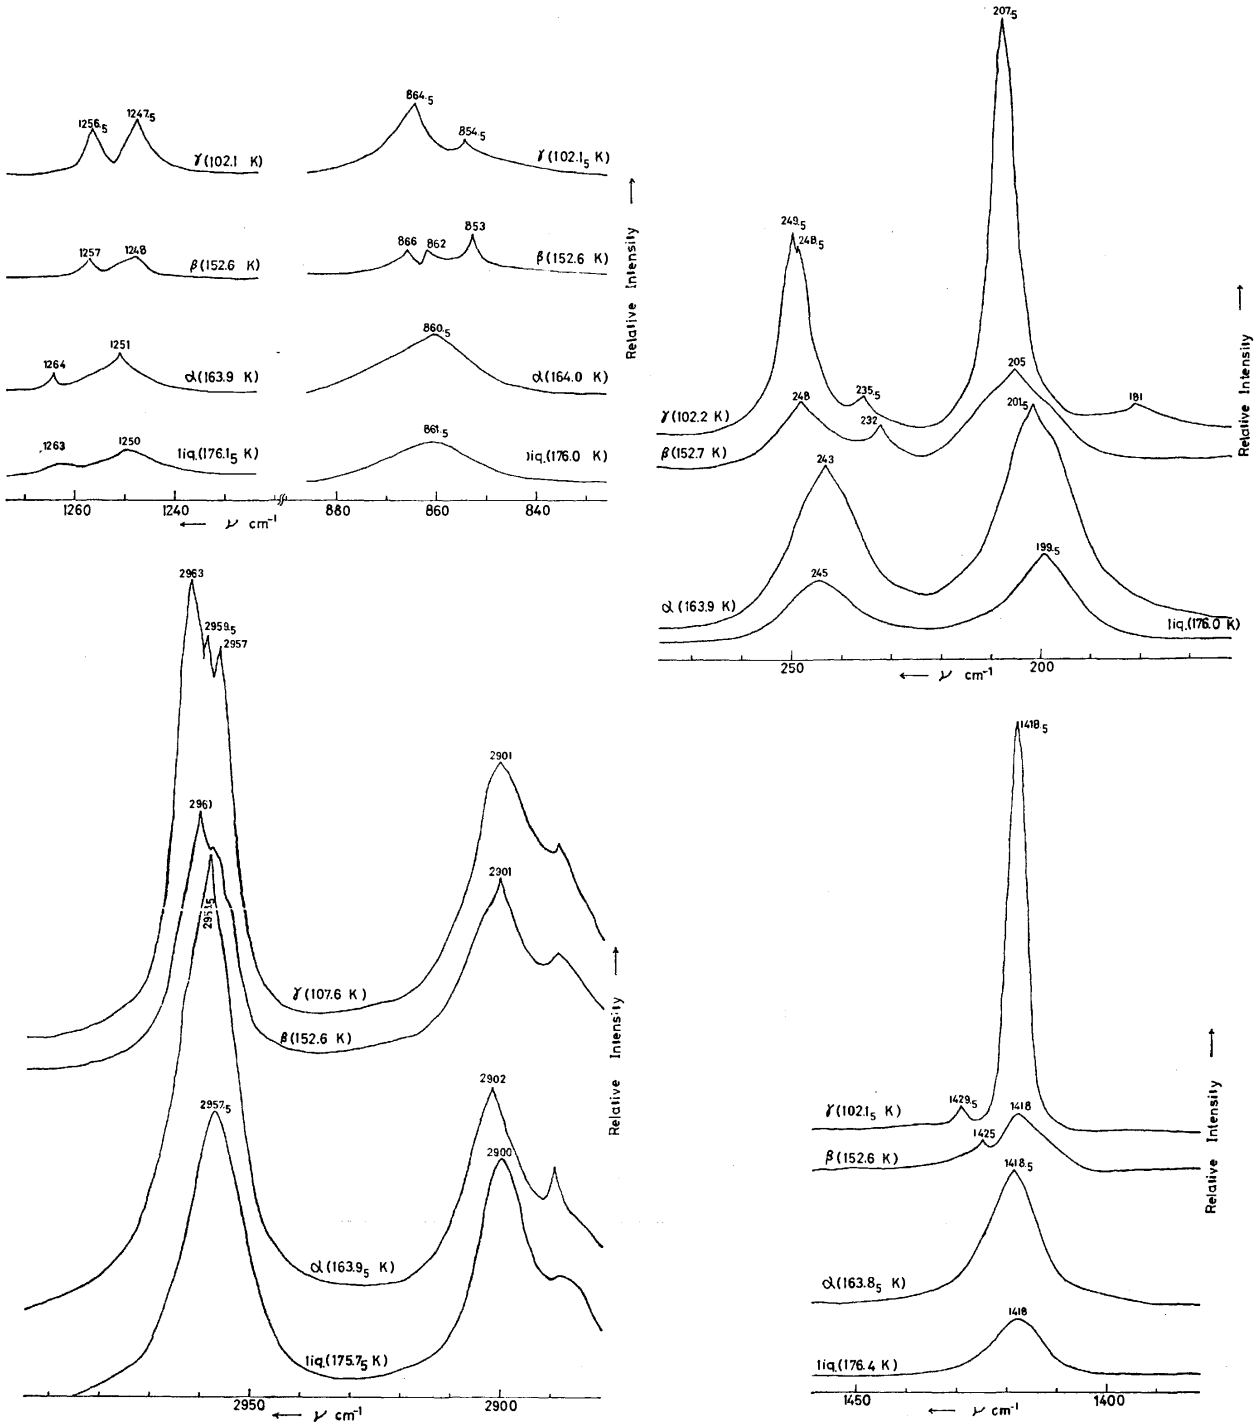

Fig. 4. Raman spectra in the intramolecular vibrational region of liquid and three crystalline forms. The temperatures observed are given in parentheses.

2.0, 0.67, 0.73; $I(\nu_3)/I(\nu_1)$: 0.87, 0.84, 0.35, 0.38; $I(\nu_4)/I(\nu_1)$: 0.81, 1.2, 0.44, 0.40, respectively.* The values for the β and γ forms are close to each other, the values for the α-form being nearer those for liquid than for the β and γ forms. On the assumption of the oriented gas model,[11] the derived polarizability tensor of the crystal related to the Raman intensity is obtained by the elements of the derived polarizability tensor of the free molecule and information on molecular orientation in crystal. It seems that the molecules of the α-form orientate in disorder favoring a high unit-cell symmetry, if we take into account the fact that the spectrum of the α-form exhibits on crystal-field splitting of intramolecular bands.

* The temperature dependence of the intensity is given by $I(T_1)/I(T_2)=[1-\exp(-h\nu/kT_2)]/[1-\exp(-h\nu/kT_1)]$. The present results are estimated at $T=102$ K.

Metal-ion Complexation of Noncyclic Poly(oxyethylene) Derivatives. I. Solvent Extraction of Alkali and Alkaline Earth Metal Thiocyanates and Iodides*

Shozo YANAGIDA, Kazutomo TAKAHASHI, and Mitsuo OKAHARA
Department of Applied Chemistry, Faculty of Engineering, Osaka University
Yamadakami, Suita, Osaka 565

(Received September 20, 1976)

The reaction of noncyclic poly(oxyethylene) derivatives with alkali and alkaline earth metal ions was investigated by means of the solvent extraction of their thiocyanates or iodides. Polyethylene glycols with more than 23 oxyethylene units showed a strong extracting power comparable to those of the crown ethers, and the power increased with the increasing number of oxyethylene units in them. Extraction studies using homogeneous poly(oxyethylene) monododecyl ethers revealed that more than 7 oxyethylene units were necessary to bind the potassium ion in the water phase and to transfer the complexed salt to the organic phase, and that the extracting ability of octa(oxyethylene) monododecyl ether was about one sixth of that of 18-crown-6. The monododecyl ether is fairly effective as a complexing agent for potassium picrate even below its critical micelle concentration; the stoichiometry of the extractable complex was found to be 0.8: 1 with respect to the ether and the picrate. There was no remarkable difference in the selectivity for alkali metal ions between noncyclic poly(oxyethylene) derivatives and 18-crown-6.

In comparison with cyclic polyethers, noncyclic polyethers seemed extraordinarily weak in ability of metal ion complexation,[1-3] while a search of the literature revealed that, before Pedersen's discovery of macrocyclic polyethers,[4] high-molecular-weight polyethylene glycols had been reported to form complexes with mercuric chloride[5] and with alkaline earth metal salts, especially in the presence of tetraphenylborate.[6-8]

Recently, in connection with the progress of the chemistry of macrocyclic polyethers, the interaction of open-chain poly(oxyethylene) derivatives with metal ions has attracted special interest; the unusual reaction of alkali metal in the presence of polyethylene glycol,[9] octopus molecules, and related compounds,[10,11] the isolation of the complexes with metal salts,[12,13] the crystalline structures of the complexes with mercuric and cadmium chlorides,[14-16] and solvent extraction using poly(oxyethylene) derivatives (POE) as extractants[17] are noteworthy.

The purpose of the present investigation is to clarify the effectiveness of noncyclic poly(oxyethylene) derivatives as complexing agents for metal ions. At first, solvent extraction was undertaken, because it is very convenient for the rapid screening of the complexing efficiency.

As regards the extraction of metal salts with cyclic polyethers, large hydrophobic anions such as picrate[18-21] and dipicrylaminate,[22] have been used as counter anions, since the ion-paired complexes formed are more extractable and can be easily determined colorimetrically. It has now been found, however, that thiocyanate and iodide salts form extractable salt–polyether complexes. Further, because they are stable and neutral in their aqueous solution, the thiocyanates and iodides were used in this extraction study.

Experimental

Materials. The following chemicals were obtained in the best available purity from the sources indicated: KSCN, $Ba(SCN)_2 \cdot 2H_2O$, $Ca(SCN)_2 \cdot 3H_2O$ (Pr. G. grade) NH_4SCN (G. R. grade), CsI (reagent grade) (Wako Pure Chemicals Industries, Ltd.); NaSCN, KI (G. R. grade), NH_4I, $Mg(SCN)_2 \cdot 4H_2O$ (E. P. Grade) (Nakarai Chemicals, Ltd.); LiI (G. R. grade) (Mitsuwa's Pure Chemicals), polyethylene glycols** 300 (n=7), 400 (n=9), 600 (n=14), 1000 (n=23), 4000 (n=90), 6000 (n=140), 20000 (n=450), polypropylene glycols** 1000; (diol type, n=17), 3000 (triol type, n=52), (Wako Pure Chemicals Industries, Ltd); penta(oxyethylene), hexa(oxyethylene), and octa(oxyethylene) monododecyl ethers (Tokyo Kasei Kogyo Co., Ltd.) (The purity was ascertained by NMR); and dicyclohexyl-18-crown-6 (Nakarai Chemicals, Ltd.). Block copolymers of propylene oxide (PO) and ethylene oxide (EO) (Pluronics), $PO_{34}EO_5$, $PO_{34}EO_{11}$, $PO_{34}EO_{45}$, and $PO_{34}EO_{232}$ were obtained from the Daiichi Kogyo Seiyaku Co., Ltd. The mole ratios of PO to EO were determined by means of both NMR and the molecular weight. Dibenzo-18-crown-6 and 18-crown-6 were prepared according to the methods of Pedersen[23] and Cram[24] respectively. Poly(oxyethylene) monododecyl ether with an average of 25 oxyethylene units was prepared by the reaction of dodecyl alcohol with ethylene oxide in the presence of sodium hydroxide. The average number of oxyethylene units was ascertained by NMR spectrometry.

Extraction Procedure. By preliminary experiments, halogenated solvents, such as dichloromethane, chloroform, and carbon tetrachloride, were found to be preferable, since other solvents, such as hexane and benzene, are readily emulsified in the presence of POE and are difficult to separate from the water phase. Considering the efficiency of dichloromethane for the extraction with cyclic polyethers,[19] we chose it as the solvent. An aqueous POE solution (0.02 M***, 25 cm^3), 25 cm^3 of a thiocyanate solution (1.0 M), and 50 cm^3

* A preliminary report of this work was presented at the 34th National Meeting of the Chemical Society of Japan, Hiratsuka, April, 1976.

** The figures indicate the nominal average molecular weight. The figures (n) in parentheses are the average numbers of oxyethylene units, calculated from the average molecular weight.

of dichloromethane saturated with water were transferred into 250-cm³ Erlenmeyer flask equipped with a well-grounded stopper. The mixture was placed in a thermostated water bath (25±0.5 °C) for ten minutes, and then shaken 200 times vigorously; this was found to be sufficient for equilibration. The stopper was replaced by the separation cock so as to use this Erlenmeyer flask as a separatory funnel in succession, and then the flask was turned upside down. With few exceptions, the phases separated clearly on standing. The dichloromethane layer was separated. After removing the dichloromethane by means of a rotary evaporator, the thiocyanate ion in the residue was determined by Volhard's method. In the extraction of potassium nitrate, the potassium ion in the residue was determined by means of Nippon Jarrell Ash Atomic Absorption Spectrometer AA-1. Duplicates agreed, usually to less than 5% from the mean, and were averaged for use in the calculation of the degree of extraction (Figs. 1, 2, 5, and 6.).

Percent Extraction of POE. According to the above-mentioned procedure, the extraction of the POE by dichloromethane was carried out in the absence of any salts. The residue of the dichloromethane layer was kept standing under a vacuum to a constant weight. The weight thus obtained was used in the calculation of the percentage of extraction (Table 1).

Extraction of Potassium Picrate. The extraction was worked out according to the procedure outlined by Frensdorf.[19] The picrate concentration in the water phase was measured by means of a Shimadzu Double-beam Spectrometer, UV-200, using as the extinction coefficient ($\lambda=357$ nm, $\varepsilon=1.46\times10^4$ in water).

Results and Discussion

The degree of extraction of potassium thiocyanate and the degree per oxyethylene unit are plotted against the number of oxyethylene units in each extractant in Figs. 1 and 2. Polyethylene glycols with more than about 23 oxyethylene units were found to have a strong power of extracting the potassium ion, one which was comparable to those of the macrocyclic polyethers. In addition, the extractability per oxyethylene unit was almost constant. The same is true of the poly(oxyethylene) monododecyl ethers with more than seven oxyethylene units (Fig. 2). While polypropylene glycols showed a low extracting power, a series of block copolymers of propylene oxide and ethylene oxide increased in their extracting power with the increase in the number of oxyethylene units (Fig. 1). The slope of the extraction curve was almost the same as that of polyethylene glycols, suggesting that the repeating oxyethylene is a factor governing the extraction. These facts indicate that even noncyclic poly(oxyethylene) derivatives have a remarkable complexing power for the potassium ion, even in an aqueous phase, if they have more than a definite number of oxyethylene units, and that the strength increases linearly with the number of repeating oxyethylenes.

POE concentration: 0.01 M. △, Polyethylene glycols; ▽, polypropylene glycols; ◇, the block copolymers of PO and EO (Pluronics); □, 18-crown-6; ▲, the degree of extraction per one oxyethylene unit by polyethylene glycols. ----: Average value.

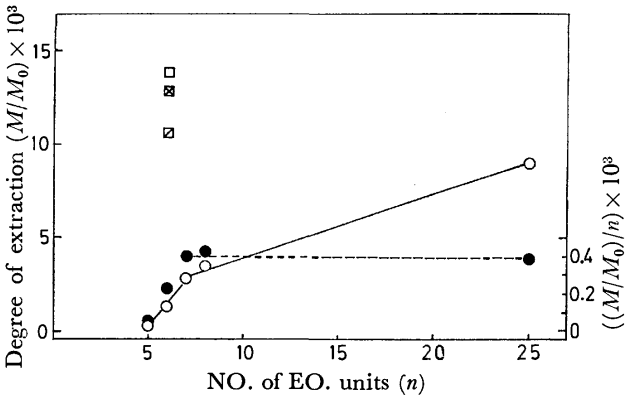

Fig. 2. Extraction of potassium thiocyanate into dichloromethane by homogeneous poly(oxyethylene) monododecyl ethers. Thiocyanate concentration $[M_0]=0.5$ M. Polyether concentration: 0.01 M. ○, homogeneous poly(oxyethylene) monododecyl ethers (The ether having 25 EO units is not homogeneous.); ●, the degree of extraction per one oxyethylene unit. ----: Average value; □, 18-crown-6; ▨, dicyclohexyl-18-crown-6; ⊠, dibenzo-18-crown-6.

As is shown in Table 1, the affinity of PEG to dichloromethane increased with the number of oxyethylene units. The rather hydrophobic property of the high-molecular-weight POE is worth noting.

Extraction properties are governed not only by the strenght of complex formation, but also by the solubility

Table 1. Percentage of extraction of poly(oxyethylene) derivatives by dichloromethane

Polyethylene glycols	Percentage of extraction	Pluronics of alkylated ether	Percentage of extraction
PEG 400 ($n=9$)[a]	6%	$PO_{34}EO_{11}$	91%
PEG 600 ($n=14$)[a]	14%	$PO_{34}EO_{45}$	95%
PEG 1000 ($n=23$)[a]	27%	$PO_{34}EO_{282}$	93%
PEG 4000 ($n=90$)[a]	*ca.* 100%	$C_{12}H_{25}EO_{25}$–H	93%

relation of the extractant and the formed complex.[19] The less efficient extraction of the short-chain polyethylene glycols is, thus, apparently due to their hydrophilic character.

The extraction using homogeneous poly(oxyethylene) monododecyl ethers as extractants has made it clear that seven repeating oxyethylenes are the minimum number to bind the potassium ion effectively in the water phase and to transfer the complexed salt to the dichloromethane phase (Fig. 2). This finding quite agreed with that of Liu,[25] who observed that the interaction of polyethylene glycols with potassium iodide in methanol became distinguished above heptaethylene glycol.[28]

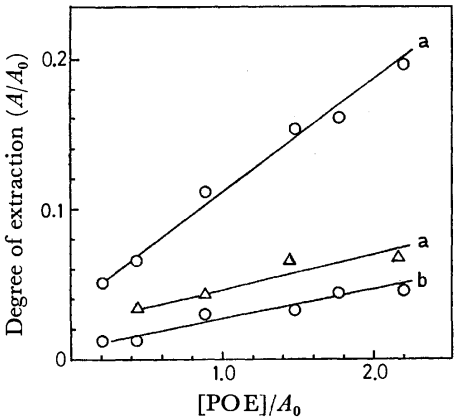

Fig. 3. Extraction of potassium picrate into dichloromehtane by homogeneous poly(oxyethylene) monododecyl ethers. Picrate concentration $[A_0]=7\times10^{-5}$ M. Potassium ion concentration $[M_0]=10^{-1}$ for a; 5×10^{-3} M for b.
○, Octa(oxyethylene) monododecyl ether;
△, hexa(oxyethylene) monododecyl ether.

However, the poly(oxyethylene) monododecyl ethers examined were all typical nonionic surfactants, and the effect of the micelle formation was conceivable under the conditions thus far discussed. To eliminate the influence of the micelle on the extracting properties as much as possible, the extraction of potassium picrate was undertaken when the extractants were diluted to around their critical micelle concentration.[26] Figure 3 shows that, even below the CMC, the extracting ability is fair for octa(oxyethylene) monododecyl ether, but very poor for the hexa(oxyethylene) ether. Compared with the results with dicyclohexyl-18-crown-6 under the same conditions,[19] the extracting ability of the octa(oxyethylene) ether was about one-sixth of that of the crown ether. This approximation is consistent with the results shown in Fig. 2. As expected, the extractability by the octa(oxyethylene) ether decreased much more drastically with a decrease in the potassium-ion concentration than by the crown ether.[19]

Assuming from the results shown in Table 1 that there is no complication due to the distribution of the ether between the two phases, the logarithm of the distribution ratio calculated from the degree of extraction by the octa(oxyethylene) ether was plotted against the logarithm of the total concentration of the ether (Fig. 4).

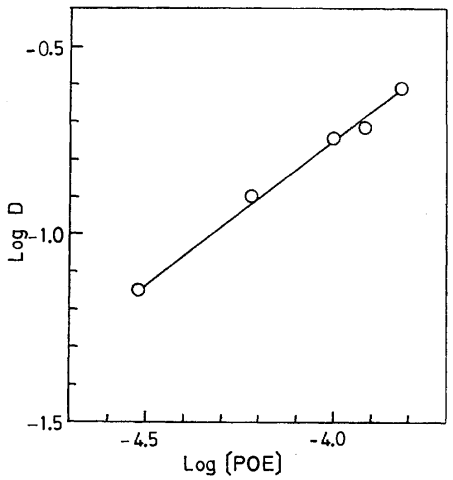

Fig. 4. Distribution ratio of potassium picrate *vs.* concentration of octa(oxyethylene) monododecyl ether. The conditions used are identical with those in Fig. 3. POE: Octa(oxyethylene) monododecyl ether.

This plot gave a straight line with a slope of about 0.8: 1 in respect to the ether and the picrate. The deviation from 1: 1 is probably due to a partial micelle formation, since the CMC's of these types of nonionic surfactants are generally lowered by the presence of an electrolyte.[27]

Calzolari *et al.*[12] recently reported the isolation of the complex formed by hexa(oxyethylene) diphenyl ether and sodium cobalt(II) thiocyanate. The composition of the complex indicates that the hexa(oxyethylene) coordinates with one sodium ion. Considering our result and this earlier finding, six to seven oxyethylene units seem critical for the complexation with alkali metal ions.[28] This conclusion contrasts with the 1: 2 and 1: 4 compositions needed in the $HgCl_2$–POE complexes.[14,15]

The extraction was also extended to other potassium salts. The iodide was found extractable to the same extent as the thiocyanate by both 18-crown-6 and noncyclic poly(oxyethylene) derivatives (Fig. 5). How-

ever, the nitrate, bromide, and chloride could not be extracted effectively by either of the extractants. The formation of extractable complexes with the thiocyanate and iodide may well be explained by the concept of water structure-enforced ion pairing.[29]

Figure 6 shows the extractions of other alkali and alkaline earth metal salts by polyethylene glycols (PEG) 1000 (n=23) and 18-crown-6. It is interesting to note that the selectivities for alkali metal ions are very similar to one another. On the other hand, ammonium iodide was found to be less extractable by PEG 1000.

As for barium thiocyanate, PEG 1000 was more effective than 18-crown-6. However, when dicyclohexyl-18-crown-6 was employed, the 1:1 complex[4] was precipitated during the extraction. The degree of extraction was found to be 7.2×10^{-3}, which corresponds to more than four times as much as that of 18-crown-6; it went up to 17.2×10^{-3} when the complex precipitated was included in the calculation of the degree of extraction. It should also be noted that 18-crown-6 extracted slightly more calcium thiocyanate than the barium salt; this is in contrast with their large differences in complexing stability constants reported by Izatt *et al.*[30] Recently, Rais *et al.* observed the synergistic effect of PEG in the extraction of alkaline earth metal ions by nitrobenzene.[31] In view of these findings, the solubility relation might exert much influence on the extraction of alkaline earth metal salts.

It was once concluded that the poly(oxyethylene) chain existed in a zigzag conformation at a low degree of polymerization and in a meander conformation at a high degree of polymerization.[32] Recently Tadokoro *et al.*[33] have established that the structure of poly(oxyethylene) in the crystalline state has a distorted helical structure containing seven oxyethylene units and two turns, and that it takes a planar zigzag structure only when it is elongated.[34] The molecular model (Corey-Pauling-Koltum model) based on this fact indicates that the helical structure is convenient for disposing the oxygen atoms of poly(oxyethylene) to the cationic species and can easily take a conformation very similar to 18-crown-6 by a slight rotation of each bonding. The hydrophobic property of high-molecular-weight poly(oxyethylene) derivatives, proved by the high-percent extraction by dichloromethane, implies that the helical conformation is energetically favorable in an organic solvent. In view of these points, noncyclic poly(oxyethylene) derivatives may take, on the average, a helical conformation even in the liquid state and may favorably complex with cations, or the cations may induce an energetically favorable helical structure and, as a result, show a fair extracting power for the cationic species. Polypropylene glycols were confirmed to have a nonplanar zigzag chain because of the steric effect of the methyl groups.[35] Their low extracting ability may be attributable to their nonplanar zigzag conformation.

A further investigation based on these results is now in progress.

The authors wish to express their thanks to Professor J. Shiokawa, Mr. Y. Hirashima, and Dr. M. Yokoyama (Department of Applied Chemistry of this Faculty) for their helpful discussions and kind advice. They also wish to acknowledge the generous gift of the Pluronics used in this work by Dr. H. Maki of the Daiichi Kogyo Seiyaku Co., Ltd.

A Theoretical Study on Biradicals. I. Theoretical Characteristics of Biradicals

Kenichi FUKUI and Kazuyoshi TANAKA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 28, 1976)

An interpretation is given on the characteristics of biradicaloids, such as the bonding, polar, and biradical characters of singlet biradicals. Systematization of the reactivity of singlet and triplet biradicals is based on the principle that 1) deformation takes place in the direction of bonding in singlet biradicals, and 2) deformation or bond formation occurs to separate unpaired-electrons from each other in triplet biradicals. Combination of the two principles is applied to the theory of orientation and stereoselection in excited-state reactions.

The word "biradical" in a chemical sense makes us think of a species having an odd electron on each of two sites of a molecule. This conforms to the interpretation of a biradical in the triplet state. However, problems may arise in the case of a singlet biradical.

The conversion of biradical species along the path of ground- and excited-state reactions has been treated theoretically.[1-4] Salem *et al.* discussed the nature of a singlet biradical by taking ionic states into account and explained a number of experimental results in regard to various reaction intermediates in photochemistry.[5-10] The present paper gives some new material.

Stabilization of Singlet Biradical by a Correlated Motion of Electrons

Consider a pair of two independent normalized one-electron space functions a and b whose overlap integral is s. In the case of biradical problems these two orbitals can be made to represent the two "unpaired"-electron orbitals essentially localized at each radical site. The following three configurations are here taken into consideration to treat the problem as a two-electron system:

a—o— —o—b $\Phi_1(1,2) = \frac{1}{\sqrt{2+2s^2}}\{a(1)b(2)+b(1)a(2)\}$

a-o-o- ——b $\Phi_2(1,2) = a(1)a(2)$ (1)

a—— -o-o-b $\Phi_3(1,2) = b(1)b(2)$

It is assumed that orbitals a and b are real and their signs are chosen in such a way that s becomes positive.

The electronic states of this two-electron system are then given by

$$\Psi = \frac{1}{\sqrt{N}}(C_1\Phi_1 + C_2\Phi_2 + C_3\Phi_3), \tag{2}$$

where C_1, C_2, and C_3 can be obtained by solving the eigenvalue problem of the Hamiltonian matrix, and $1/\sqrt{N}$ is the normalization factor. They are the usual energy-extremized wave functions in which the effect of correlation in electron motion is taken into account.

Direct consideration of the correlated motion of electrons might also be considered. The extent of correlation in orbital motion could roughly be represented by the averaged reciprocal interelectronic distance,

$$\overline{\frac{1}{r_{12}}} = \frac{2}{\nu(\nu-1)}\iint \rho(1,2|1,2)\frac{1}{r_{12}}\mathrm{d}v(1)\mathrm{d}v(2), \tag{3}$$

(ν: number of electrons)

where r_{12} is the distance of electrons 1 and 2, and

$$\rho(1',2'|1,2) = \frac{\nu(\nu-1)}{2}\int \Psi^*(r_1'\sigma_1, r_2'\sigma_2, r_3\sigma_3, \cdots) \times \Psi(r_1\sigma_1, r_2\sigma_2, r_3\sigma_3, \cdots)\mathrm{d}\sigma_1\mathrm{d}\sigma_2\mathrm{d}r_3\mathrm{d}\sigma_3\cdots \tag{4}$$

is the second-order spinless density matrix. For the present two-electron problem, we have

$$\gamma \equiv \overline{\frac{1}{r_{12}}} = \iint \Psi^*(1,2)\frac{1}{r_{12}}\Psi(1,2)\mathrm{d}v(1)\mathrm{d}v(2). \tag{5}$$

The extremization of $\overline{1/r_{12}}$ is achieved by obtaining the stationary values satisfying

$$\delta\gamma = 0. \tag{6}$$

The variation with respect to C_1, C_2, and C_3 leads to the secular equation

$$\begin{vmatrix} \gamma_{11}-\gamma & \gamma_{12}-S_{12}\gamma & \gamma_{13}-S_{13}\gamma \\ \gamma_{21}-S_{21}\gamma & \gamma_{22}-\gamma & \gamma_{23}-S_{23}\gamma \\ \gamma_{31}-S_{31}\gamma & \gamma_{32}-S_{32}\gamma & \gamma_{33}-\gamma \end{vmatrix} = 0, \tag{7}$$

where

$$\gamma_{jk} = \iint \Phi_j^*(1,2)\frac{1}{r_{12}}\Phi_k(1,2)\mathrm{d}v(1)\mathrm{d}v(2)$$

and

$$S_{jk} = \iint \Phi_j^*(1,2)\Phi_k(1,2)\mathrm{d}v(1)\mathrm{d}v(2)$$

($j, k = 1, 2$, and 3).

The coefficient of Φ_j in Eq. 2 can be obtained simultaneously, giving correlation-extremized wave functions $\{\Psi^{(i)}\}$ which are always mutually orthogonal. Both energy-extremization and correlation-extremization give wave functions with an essentially parallel trend in nonpolar species.[11] Thus in such favourable cases, we can use correlation-extremized wave functions as an approximate substitute of the usual energy-extremized functions. Such a consideration of the interaction of at least three configurations as mentioned above is essential in the theoretical interpretation of biradicals.

Bonding Character between Two Radical Sites

The bonding character between two radical sites each containing essentially one electron can be discussed by using Ψ of Eq. 2. A most reasonable scale of bonding

character[12] might be the magnitude of accumulation of electron population in the intermediate region between two radical sites.[13-15]

The distribution of electron density is given by

$$\rho(1) = 2\int \Psi^*(1,2)\Psi(1,2)\mathrm{d}v(2). \tag{8}$$

The density $\rho(1)$ is divided into three terms as

$$\rho(1) = A_{11}a(1)^2 + 2A_{12}a(1)b(1) + A_{22}b(1)^2. \tag{9}$$

The bonding strength can be determined by the second term of r.h.s. since the coefficient A_{12} of the cross term $a(1)b(1)$ contributes to the accumulation of electrons in the intermediate region.

It follows from Eq. 2 that

$$A_{12} = \frac{1}{N}\left\{\frac{s}{1+s^2}C_1^2 + \sqrt{\frac{2}{1+s^2}}C_1(C_2+C_3) + 2sC_2C_3\right\}, \tag{10}$$

where

$$N = C_1^2 + C_2^2 + C_3^2 + \frac{2\sqrt{2}s}{\sqrt{1+s^2}}C_1(C_2+C_3) + 2s^2C_2C_3.$$

In general, C_j may be complex. However, for the sake of simplicity, Eq. 9 is written for the real values of C_j. If we allow C_1, C_2, and C_3 of Eq. 2 to take *any* real values, the maximum and minimum values which A_{12} can take are $1/(1+s)$ and $-1/(1-s)$ corresponding to the wave functions

$$\left.\begin{aligned} \Psi^{(B)} &= \frac{1}{\sqrt{2}}\frac{1}{1+s}\left\{\sqrt{1+s^2}\Phi_1 + \frac{1}{\sqrt{2}}(\Phi_2+\Phi_3)\right\} \\ \text{and} \\ \Psi^{(AB)} &= \frac{1}{\sqrt{2}}\frac{1}{1-s}\left\{\sqrt{1+s^2}\Phi_1 - \frac{1}{\sqrt{2}}(\Phi_2+\Phi_3)\right\}, \end{aligned}\right\} \tag{11}$$

respectively. Thus, we see that the most bonding state ($\Psi^{(B)}$) or the most antibonding state ($\Psi^{(AB)}$) is obtained in the case of *moderate* mixing of three configurations Φ_1, Φ_2, and Φ_3. This implies that admixture of the ionic configuration Φ_2 or Φ_3 with the covalent configuration Φ_1, or the delocalization of each odd electron to the other radical site, serves as an effective origin of bonding character between two weakly interacting radical sites. The importance of such electron delocalization in the bond formation between molecules or radicals was early pointed out.[16-19] In particular, special importance of a cross term arising from two configurations, corresponding in the present case to the terms of C_1C_2 or C_1C_3 in A_{12}, was stressed.[20-22]

The bonding character of a singlet biradical is thus represented by sA_{12}. In the light of the relation

$$A_{11} + 2sA_{12} + A_{22} = 2,$$

we can also measure the less bonding character by the quantity $1/2(A_{11}+A_{22})$.

Polar Character of Two Radical Sites

The density $\rho(1)$ also provides information as to what extent the two radical sites are polar. Evidently, polarity parallels $|A_{11}-A_{22}|$. We tentatively define the polar character of a singlet biradical by means of

$$\Pi = \left|\frac{A_{11}-A_{22}}{A_{11}+A_{22}}\right|, \tag{12}$$

in which

$$\left.\begin{aligned} A_{11} &= \frac{1}{N}\left(\frac{1}{1+s^2}C_1^2 + \frac{2\sqrt{2}s}{\sqrt{1+s^2}}C_1C_2 + 2C_2^2\right), \\ A_{22} &= \frac{1}{N}\left(\frac{1}{1+s^2}C_1^2 + \frac{2\sqrt{2}s}{\sqrt{1+s^2}}C_1C_3 + 2C_3^2\right). \end{aligned}\right\} \tag{13}$$

These are the coefficients of the $a(1)^2$ and $b(1)^2$ terms in $\rho(1)$ of Eq. 9 which is derived from a wave function Ψ already *correlation-extremized* according to the procedure in previous section.

By this definition, we have

$$\Pi(\Phi_1) = 0, \quad \Pi(\Phi_2) = \Pi(\Phi_3) = 1,$$

provided that Φ_1, Φ_2, and Φ_3 are correlation-extremized states.

A change in electron distribution can be expected to arise causing bonding stabilization through a moderate mixing of ionic structures. In this connection the work of Wulfman and Kumei,[23] who first pointed out the high possibility of polarization in singlet excited states of alkenes, is of interest.

Biradical Character of Singlet Biradicals

Since the bonding character between two radical sites becomes maximum only in the case of moderate admixing of ionic configurations with a covalent configuration, the less ionic character can not be adopted for the measure of biradical character.

We must take into account the following requisites which qualify a biradical:

1) The bonding character between two radical ends should be small since a species with too large bonding character might be called a molecule, but not a biradical. The value $1/2(A_{11}+A_{22})$ should not be small.

2) The polar character should not be large since a species with a strong inequality in electron density at the radical ends should be called a zwitterion. Namely, $(1-\Pi)$ should not be small.

A conventional but reasonable definition of the biradical character $\mathfrak{B}$ may therefore be given by

$$\mathfrak{B} = \frac{1}{2}(A_{11}+A_{22})(1-\Pi) = \frac{1}{2}\{A_{11}+A_{22}-|A_{11}-A_{22}|\}$$
$$= (\text{the smaller of } A_{11} \text{ and } A_{22}). \tag{14}$$

Thus, the maximum possible biradical character in a *bonding* state is unity $(=1/(1+s))$, and the maximum biradical character in an *antibonding* state is larger than unity $(=1/(1-s))$. We also have

$$\mathfrak{B}(\Phi_1) = \frac{1}{1+s^2}, \quad \mathfrak{B}(\Phi_2) = 0, \quad \mathfrak{B}(\Phi_3) = 0,$$

in which Φ_1, Φ_2, and Φ_3 are the functions of Eq. 1, assuming that they are correlation-extremized ones.

The discussion can be easily extended to the case of complex wave functions.

Nonbonding Biradicals

It may happen that each odd electron occupies each of two orbitals orthogonal to each other so that the overlap integral s in Eq. 9 disappears. Hence, the

$\Psi^{(i)}$			γ	
$\frac{1}{\sqrt{2}}\{a(1)a(2)+b(1)b(2)\}$	$^1A_1$		$(aa\|aa)+(ab\|ab)$	≈ 0.89120(a.u.)
$\frac{1}{\sqrt{2}}\{a(1)a(2)-b(1)b(2)\}$	$^1B_2$		$(aa\|aa)-(ab\|ab)$	≈ 0.88969
$\frac{1}{\sqrt{2}}\{a(1)b(2)+b(1)a(2)\}$	$^1B_1$		$(aa\|bb)+(ab\|ab)$	≈ 0.39420
$\frac{1}{\sqrt{2}}\{a(1)b(2)-b(1)a(2)\}$	$^3A_2$		$(aa\|bb)-(ab\|ab)$	≈ 0.39268

maximal biradical character is unity.

An example is perpendicular ethylene in which two orthogonal radical orbitals a and b are $(2p_x)_A$ and $(2p_y)_B$, respectively, A and B denoting two carbon atoms. In this case, it follows from symmetry relations that

$$\gamma_{12}=\gamma_{13}=0,\quad S_{12}=S_{13}=0$$

in Eq. 7. Thus, $\Phi_1=1/\sqrt{2}\{a(1)b(2)+b(1)a(2)\}$ is already a correlation-extremized wave function with which Φ_2 or Φ_3 of different symmetry does not mix. From the definition of Eq. 14, the state $\Psi^{(1)}=\Phi_1$ has the $\mathfrak{B}$ value of unity and can be called "purely" biradical. The other two states ($\Psi^{(2)}=1/\sqrt{2}(\Phi_2+\Phi_3)$ and $\Psi^{(3)}=1/\sqrt{2}(\Phi_2-\Phi_3)$) also have the $\mathfrak{B}$ value of unity. Such a biradical species may be called a *nonbonding biradical.*

The level situation of three correlation-extremized states is given above, together with the value of γ. The result is qualitatively consistent with that of numerical calculations.[24]

It is to be noted that the level gap between $^1B_1$ and $^3A_2$ states is very small (*ca.* 1 kcal/mol) in this example. The small S–T separation is characteristic of nonbonding biradicals. From an energetic point of view, they are expected to interchange easily between singlet and triplet states.

Biradical with Cyclic Orbitals

Singlet Oxygen. Let two ($^1\pi_g$) orbitals of the oxygen molecule be

$$\phi_x=\frac{1}{\sqrt{2-2s}}\{(2p_x)_1-(2p_x)_2\},$$

$$\phi_y=\frac{1}{\sqrt{2-2s}}\{(2p_y)_1-(2p_y)_2\},$$

where O_1-O_2 axis is parallel to the z-axis and s is the overlap integral of $(2p_x)_1$ and $(2p_x)_2$ or that of $(2p_y)_1$ and $(2p_y)_2$. Three configurations are specified by

$$\Phi_1=\frac{1}{\sqrt{2}}\{\pi^+(1)\pi^-(2)+\pi^-(1)\pi^+(2)\},$$

$$\Phi_2=\pi^+(1)\pi^+(2),$$

$$\Phi_3=\pi^-(1)\pi^-(2),$$

where

$$\pi^+=\frac{1}{\sqrt{2}}(\phi_x+i\phi_y),$$

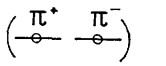
$$\pi^-=\frac{1}{\sqrt{2}}(\phi_x-i\phi_y).$$

Φ_1, Φ_2, and Φ_3 of different symmetries are correlation-extremized wave functions corresponding to the stationary values of γ.

$\Psi^{(i)}$		γ
$\Phi_1=\frac{1}{\sqrt{2}}\{\phi_x(1)\phi_x(2)+\phi_y(1)\phi_y(2)\}$	$^1\Sigma_g^+$	$(xx\|xx)+(xy\|xy)$,
$[\Phi_2,\Phi_3]=\left[\frac{1}{\sqrt{2}}\{\phi_x(1)\phi_x(2)-\phi_y(1)\phi_y(2)\},\ \frac{1}{\sqrt{2}}\{\phi_x(1)\phi_y(2)+\phi_y(1)\phi_x(2)\}\right]$	$^1\Delta_g$	$\frac{1}{2}(xx\|xx)+\frac{1}{2}(xx\|yy)$,
$\left(\frac{1}{\sqrt{2}}\{\phi_x(1)\phi_y(2)-\phi_y(1)\phi_x(2)\}\right.$	$^3\Sigma_g^-$	$\left.(xx\|yy)-(xy\|xy)\right)$

($(xy|xy)$, *etc.*, denote $(\phi_x\phi_y|\phi_x\phi_y)$, *etc.*).

The uppermost level corresponds to $^1\Sigma_g^+$ excited singlet state and the lower degenerate level to $^1\Delta_g$ state. The former stands for the configuration



with $\mathfrak{B}=1$. The species can thus be called purely biradical.

In the latter state, the correlation-extremized wave functions consist of purely doubly-occupied configurations

with $\mathfrak{B}=0$.

It should be noted that we have to employ the symmetry orbitals π^+ and π^- to construct wave functions with definite angular momenta.

Such cyclic orbitals, however, do not reflect the concept of radical site. The interpretation of $\mathfrak{B}$-values in this case should be made with certain reservation.

Cyclobutadiene (Planar Square). The orthogonal nonbonding orbitals can be taken as

$$\phi_1=\frac{1}{\sqrt{2-2s'}}\{(2p_z)_4-(2p_z)_2\},$$

$$\phi_2=\frac{1}{\sqrt{2-2s'}}\{(2p_z)_1-(2p_z)_3\},$$

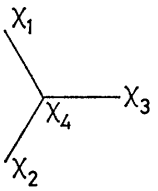
where $(2p_z)_j$ ($j=1$, 2, 3, and 4) are the four $2p_z$ orbitals and s' is the overlap integral of $(2p_z)_1$ and $(2p_z)_3$. The three states are as follows.

$\Psi^{(i)}$		γ
$\frac{1}{\sqrt{2}}\{\phi_1(1)\phi_1(2)+\phi_2(1)\phi_2(2)\}$	$^1A_{1g}$	$(11\|11)+(12\|12)$,
$\frac{1}{\sqrt{2}}\{\phi_1(1)\phi_1(2)-\phi_2(1)\phi_2(2)\}$	$^1B_{1g}$	$(11\|11)-(12\|12)$,
$\frac{1}{\sqrt{2}}\{\phi_1(1)\phi_2(2)+\phi_2(1)\phi_1(2)\}$	$^1B_{2g}$	$(11\|22)+(12\|12)$,
$\frac{1}{\sqrt{2}}\{\phi_1(1)\phi_2(2)-\phi_2(1)\phi_1(2)\}$	$^3A_{2g}$	$(11\|22)-(12\|12)$,

($(11|22)$, *etc.*, denote $(\phi_1\phi_1|\phi_2\phi_2)$, *etc.*).

The level situation is consistent with the results of more elaborate calculations.[25]

Singlet Planar Trimethylenemethane.[26] The two orthogonal orbitals containing nonbonding electrons are written as



$$\phi_1 = \sqrt{\frac{2}{3(1-s')}}\left\{\chi_1-\frac{1}{2}(\chi_2+\chi_3)\right\},$$

$$\phi_2 = \frac{1}{\sqrt{2(1-s')}}(\chi_2-\chi_3),$$

where χ_j ($j=1$, 2, 3, and 4) are the four $2p_z$ orbitals, and s' is the overlap integral of χ_1 and χ_2. The resulting three states are

$$^1A_1' \quad \frac{1}{\sqrt{2}}\{\phi_1(1)\phi_1(2)+\phi_2(1)\phi_2(2)\},$$

$$^1E' \quad \begin{cases} \frac{1}{\sqrt{2}}\{\phi_1(1)\phi_2(2)+\phi_2(1)\phi_1(2)\}, \\ \frac{1}{\sqrt{2}}\{\phi_1(1)\phi_1(2)-\phi_2(1)\phi_2(2)\}, \end{cases}$$

$$\left(\ ^3A_2' \quad \frac{1}{\sqrt{2}}\{\phi_1(1)\phi_2(2)-\phi_2(1)\phi_1(2)\}\ \right).$$

The density of $^1E'$ ground state becomes

$$\rho(1) = \frac{2}{3(1-s')}[\{\chi_1(1)^2+\chi_2(1)^2+\chi_3(1)^2\} - \{\chi_1(1)\chi_2(1)+\chi_1(1)\chi_3(1)+\chi_2(1)\chi_3(1)\}]$$

showing that this is an antibonding biradical with $\mathfrak{B}=1/(1-s')$. The antibonding character might primarily cause the nonpolar geometry of singlet ground-state trimethylenemethane.[27]

General Characterization of Biradicals

The correlation-extremization approach developed in previous section is convenient for grasping a qualitative feature, but it can not be used in polar species where the potential field is partial to either one of the two radical sites. In such cases, the usual energy-extremization procedure, *viz.*, the configuration interaction (CI) approach, must be taken.

We use a CI wave function of n electron system $\Psi(1, 2, \cdots n)$ to construct the density distribution $\rho(1)$, which is decomposed in such a way as

$$\rho(1) = A_{11}a(1)^2 + 2A_{12}a(1)b(1) + A_{22}b(1)^2 + 2\sum_j\{B_{aj}a(1)+B_{bj}b(1)\}\chi_j(1) + \sum_{j,k}B_{jk}\chi_j(1)\chi_k(1), \quad (15)$$

The set of orbitals, a, b, and χ_j, in principle atomic hybrids or usual atomic orbitals, is obtained by a relevant transformation of the set of valence-shell atomic orbitals in such a way that orbitals a and b are appropriately associated with essentially located radical sites.

The bonding character and polar character can be represented by sA_{12} and Π of Eq. 12, respectively. We define a new concept, the delocalized character of a biradical, $\mathfrak{D}$, by

$$\mathfrak{D} = 2 - (A_{11}+2sA_{12}+A_{22}). \quad (16)$$

The biradical character of Eq. 14 can then be modified as

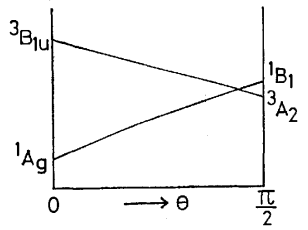
$$\mathfrak{B} = \frac{A_{11}+A_{22}}{2-\mathfrak{D}}(1-\Pi) = \frac{2}{2-\mathfrak{D}}(\text{the smaller of } A_{11} \text{ and } A_{22}). \quad (17)$$

Bonding Deformation of Singlet Biradicals

In the following examples, where the polar character Π can be put equal to zero, the biradical character $\mathfrak{B}$ depends only upon the overlapping between radical sites. Thus singlet biradicals stabilize with increasing overlapping between radical sites, which is in accordance with the direction of decreasing biradical character $\mathfrak{B}$. In contrast, the triplet species tend to decrease overlapping to stabilize.[29,30]

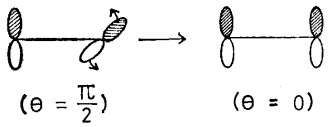
A molecular deformation in singlet biradicals to raise overlapping may even take place when stabilization overcomes destabilization, if it arises, due to the deformation. It may happen that a triplet biradical with minimal overlapping shifts to the singlet state through intersystem crossing to cause stabilization by bonding deformation. Let us discuss the bonding deformation in the direction of decreasing $\mathfrak{B}$ with regard to several examples of singlet biradicals.

The dependence of energy on the torsional angle θ in perpendicular ethylene discussed in previous section is shown below.[24] The lowest singlet has a deformation-instability in addition to the triplet-instability near $\theta=\pi/2$. The $^3A_2$ ground state of perpendicular geometry once formed may tend towards the planar form through the intersystem crossing to produce ^1A_g ground-state ethylene.

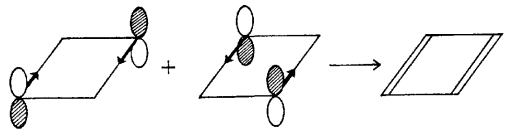


The direction of bonding deformation of perpendicular

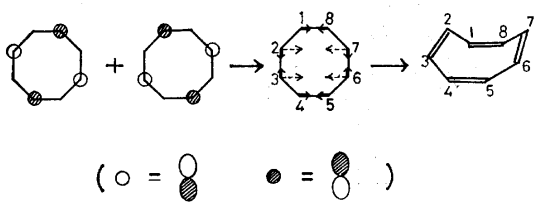
species is simply represented by the following orbital phase scheme.[28]



Similarly, the direction of deformation of square cyclobutadiene is given by the direction of in-phase overlapping of two odd-electron orbitals.

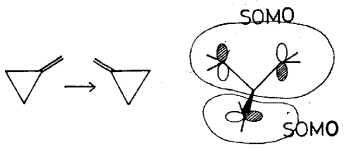


Also planar octagonal cyclooctatetraene will deform in the following way.



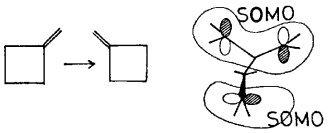
The bonding deformation consideration is employed to predict the geometry of stable intermediates in singlet radical reactions.

methylene-cyclopropane



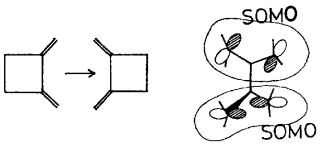
31)

methylene-cyclobutane



32)

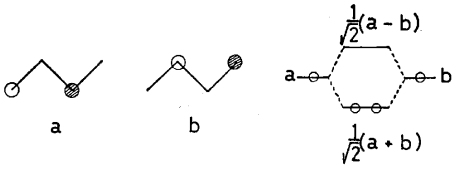
1,2-dimethylene-cyclobutane



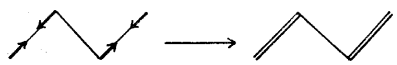
33)

SOMO denotes a singly occupied molecular orbital.

The bond alternation in carbon 2pπ chains can be explained by the following. The highest occupied (HO) and the lowest unoccupied (LU) MO's of a chain of equally distanced four p orbitals result approximately from the combination of the following two orbitals *a* and *b*.



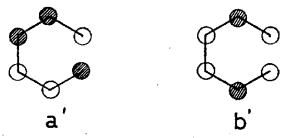
In this fictitious singlet biradical, the direction of deformation is also caused by the bonding overlapping of *a* and *b* to form a butadiene molecule, shown by



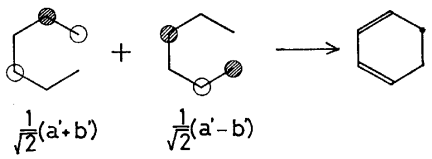
The lower occupied π orbital has hardly any connection with this deformation owing to its less nodal property.

Similarly, the difference in bond lengths in hexatriene, fulvene, naphthalene, *etc.*, is explained by considering the next HOMO's which contribute to the deformation less than HOMO because of their less nodal character.

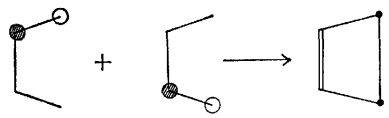
An interesting application of the bonding deformation approach may be the prediction of the reaction path in excited states. In the π-π^* excited singlet state of hexatriene, the highest half-occupied orbital (a') and the lowest unoccupied orbital (b') are represented by



In order to consider bonding stabilization of the electron in orbital a', let us construct in the place of a' and b' the following quasiorthogonal orbitals.



Combinations of these orbitals lead to orbitals a' and b', the former becoming occupied by a single electron to contribute to the bonding stabilization, and the direction of ring closure, if it occurs simultaneously, should be conrotatory. The conclusion is unchanged in the excited state with doubly occupied a'. In contrast, in the excited butadiene, the direction of hypothetical 1,4-bonding would be disrotatory.



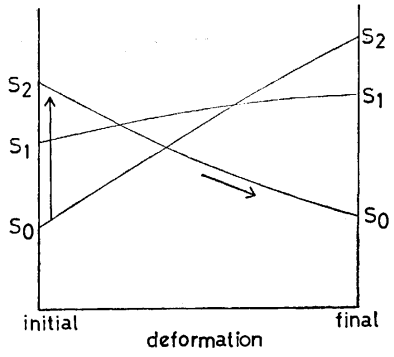
The lower singly occupied orbitals would contribute less by a similar discussion in terms of their less nodal property.

The simple approach is useful since it can be applied to a rough estimation of the direction of bonding in higher excited singlet states of a known electron configuration. The configuration might have several SOMO's. The general procedure is as follows:

i) By a linear combination of the HOMO (singly or doubly occupied) and the LUMO, say a' and b', we construct two MO's, *a* and *b*, which are mutually orthogonal and spatially separated from each other to construct a fictitious singlet biradical species.

ii) The direction of maximal overlapping of *a* and *b* to decrease the biradical character $\mathfrak{B}$, obtained by the usual procedure in the orbital interaction approach,[28] leads to a favourable reaction path.

In some cases, an excited state of the species before deformation may correlate to the ground state of the species after deformation, as in the following,

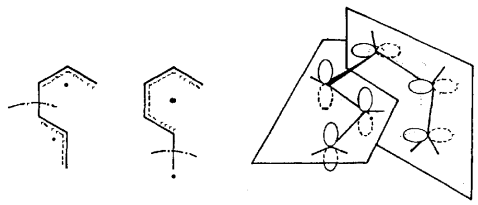


An example is the hypothetical disrotatory cyclization of S_2 excited butadiene to S_0 cyclobutene in the Longuet-Higgins-Abrahamson state correlation diagram.[34] The direction of such processes can be discussed by the method mentioned above.

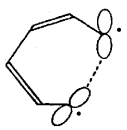
Unpaired-Electron Isolating Deformation or Bonding in Triplet Biradicals

Once a triplet state is formed photochemically or thermally, a deformation or bond formation may be liable to take place to acquire stabilization in such a way that each of the two unpaired-electrons enters each of two orthogonal orbitals, or they become separated from each other by the newly formed bond as far away as possible.[9,30] In this connection Michl's conception of "loose" and "tight" biradicaloids is useful.[30c] The following examples are given for illustration.

Consider a π-π^* triplet hexatriene molecule. Twisting of the carbon chain would certainly diminish the overlapping of the two unpaired-electron orbitals. Two possibilities exist in regard to the twisting.

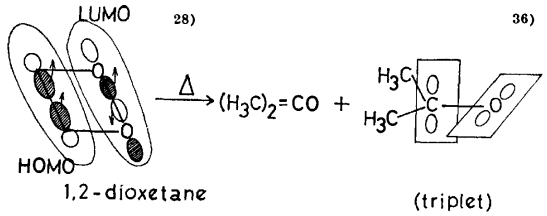


The sum of conjugation stabilization in the two separated parts in (I) is greater than in (II). The resulting geometry is shown in (III). Courtot and Salaün[35a] showed that sensitized photoreactions of hexatrienes preferentially cause the *cis-trans* isomerization of the *central* double bond, and that the singlet reaction causes isomerization of the terminal double bonds. The results are consistent with the theoretical prediction by Baird and West[35b] that the twisting of inner bonds should be preferred in the lowest triplet excited state of polyenes. In the singlet reaction a structure essentially like

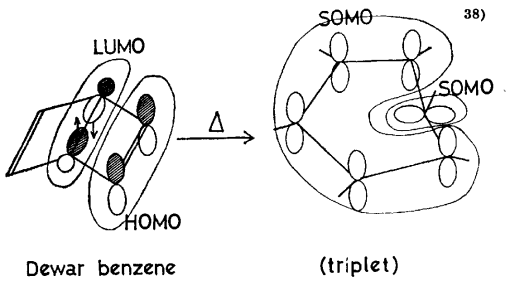


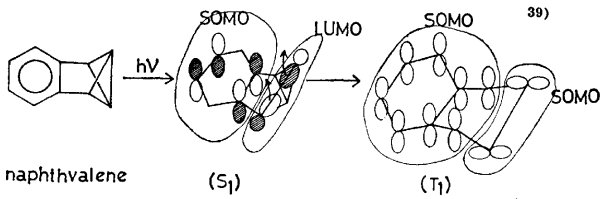
may be prevalent on account of the bonding nature of singlet biradicals, which will favour the terminal bond isomerization.

Geometries in which the planes associated with two unpaired-electron orbitals are perpendicular to each other might be expected more widely.[35c]

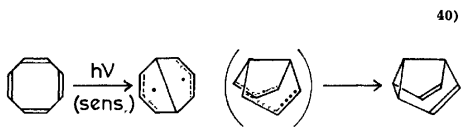


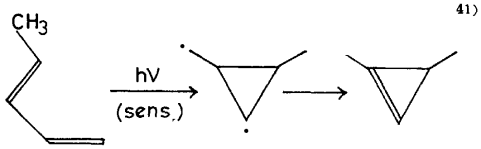
(Similar reactions are considered in chemiluminescent decomposition of 1,2-dioxetanone derivatives.[37])



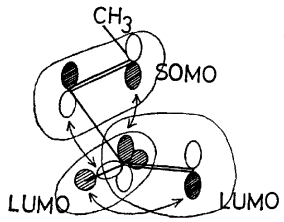


The above are examples of the separation of unpaired-electron orbitals by deformation. The isolation of unpaired-electrons also takes place by the formation of separating bonds.





In the singlet-state reaction, a similar reaction takes place. In this case a certain concertedness may be mixed in the mechanism.[28]



It appears that combination of the principle of unpaired-electron isolation in the triplet state with that of bonding deformation in the singlet state brings about a plausible mechanism occasionally prevalent in photochemical processes in which biradicaloid intermediates play an important role.

Suppose that the lowest triplet state (T_1) is produced, in some cases from higher excited singlet states (S_n) *via* S_1, through radiationless transitions (triplet biradical formation by a nonsensitized photoprocess). A possible deformation path might be composed of stages (I) and (II) as shown in Fig. 1.

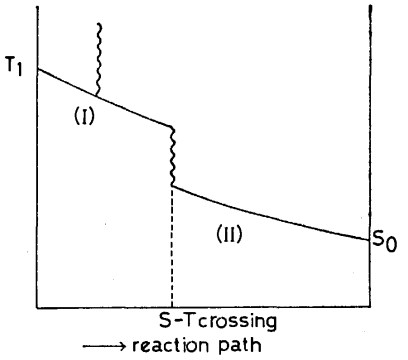


Fig. 1. A possible reaction path. (S_0: singlet ground state; T_1: first triplet state; ~~~~~: radiationless transition)

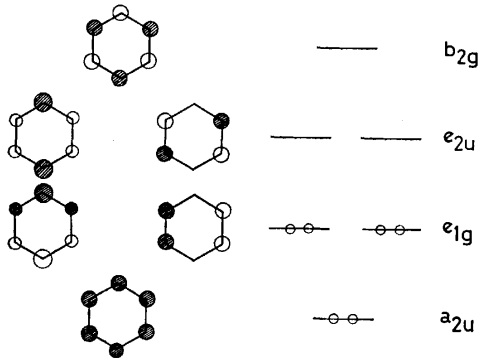
Stage (I) involves separation of unpaired-electron orbitals by orthogonally twisting deformation or bond formation, occuring in the first triplet state. Stage (II) is that of bonding deformation or bond formation in the singlet ground state, S_0.

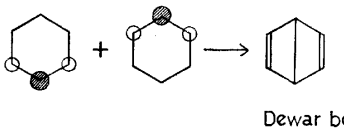
By considering intermediate T_1, stereoselective phenomena can be explained by the augmenting chance to undergo further conversion due to the long lifetime of the triplet state.

This mechanism of the intermediation of triplet state is supported by Kushick and Rice[42] as regards the effectuation of the S-T transition by dynamical coupling of the torsional motion around the C_1–C_2 bond in the *cis-trans* photoisomerization of butadiene.

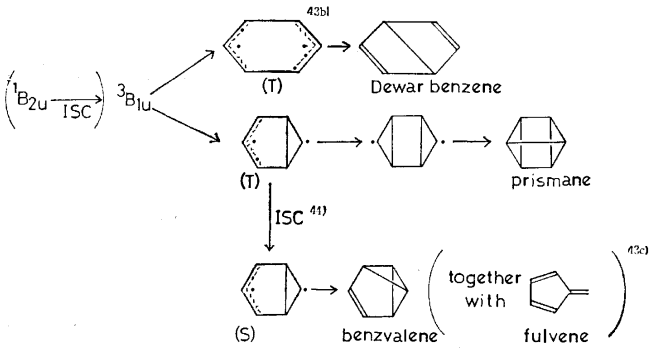
Let us consider excited-state reactions of benzene, six π MO's of which are given below.



Thus, Dewar benzene might be produced from $e_{1g} \rightarrow e_{2u}$ excited singlet ($^1B_{1u}$),[43a]



and the formation of benzvalene, prismane, and Dewar benzene would be favoured by triplet intermediation.



The mechanism involved might control the direction of reaction, giving a new principle of orientation or stereoselection in excited-state reactions.

This work was partly supported by Grants-in-Aid for Scientific Research from the Ministry of Education of Japan (No. 047068 and No. 139012). The authors express their appreciation to Prof. Hiroshi Kato, Nagoya University, for valuable discussions. One of the authors (K. F.) wished to thank Prof. P. Courtot for the interesting photochemical problem which stimulated him to carry out the present work.

44) The possibility of the triplet intermediation in non-sensitized photolysis should be further examined. The sudden polarization of singlet biradicals[23] could be combined with the intersystem crossing $T_1 \rightarrow S_1$. The molecular geometry having minimum energy in the excited state is one with which the state T_1 has minimum energy. Such T_1 geometry would play some role in excited-state reactions (*e.g.*, see K. Yamaguchi, T. Fueno, and H. Fukutome, *Chem. Phys. Lett.*, **22**, 466 (1973)).

Large-Area (600 mm^2) Bimolecular Film in Aqueous Solutions. The Effect of an Amine-Ni^{2+} Complex on the Stability of *cis*-9-Octadecenylamine Bimolecular Film

Tadayoshi Yoshida, Masataka Okuyama, and Takahiro Itoh

Department of Engineering Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received October 29, 1976)

A large, planar, bimolecular film (bilayer, 600 mm^2) of *cis*-9-octadecenylamine (oleylamine) was found to be formed in an $NiCl_2$ solution. From the effect of the added metal ions on the proton magnetic resonance spectrum of octadecenylamine, it appears that the complex between the octadecenylamine molecule and the metal ion increases the stability of the bilayer. The thickness of the bilayer depended strongly on the kind of solvent in the film-forming solution. When decane, a normal alkane solvent, was used, the thickness of the bilayer was greatest (4.6 nm), and the temperature effect was smallest. The experimental results are explained in terms of (i) the influence of the solvent on the conformation of the octadecenyl chain and (ii) the amount of solvent remaining in the film.

A previously reported bilayer of 1-tetradecanol in an aqueous solution was stable, but not large (1 mm^2).[1,2] An increase in the bilayer size is essential to the improvement of the accuracy of electrical and optical measurements. Using a dipping technique, Tien *et al.* have prepared the largest planar bilayers thus far produced (*ca.* 100 mm^2).[3] Spherical bilayer has also been produced with areas up to *ca.* 100 mm^2 using a bubble technique.[4] For most measurements, however, a spherical bilayer is not as appropriate as a planar bilayer.

In order to prepare a large bilayer, it is necessary to increase the layer stability. The bonds between the constituent molecules and their surroundings may have a stabilizing effect on the bilayer. For example, it is expected that complex formation between the hydrophilic group of molecules in the bilayer and multivalent ions in the aqueous solution increases the stability of the bilayer.

On the other hand, it has been found empirically that no stable bilayer can be prepared from a dilute film-forming solution (surface-active molecule/organic solvent).[2]

Therefore, the molecules of an unsaturated hydrocarbon chain are more suitable than those of a saturated chain in view of the solubility. As a system which satisfies the above factors governing stability, a *cis*-9-octadecenylamine bilayer was formed in an $NiCl_2$ solution.

Experimental

Materials. The distilled *cis*-9-octadecenylamine (purity>99%) used in this study was purchased from the Tokyo Kagaku Seiki Co., Ltd. The aqueous solution surrounding the bilayer were prepared from redistilled water and guaranteed reagents (Wako Pure Chemical Industries, Ltd.). All solvents were of reagent grade.

Preparation of Large Bilayer Films. Bilayers were prepared by two methods (I and II), using the dipping technique. Method I: (1) Two compartments (F_1 and F_2) of the same volume were separated by a Teflon plate A (thickness: 2 mm) having a unique hole (width: 13 mm, length: 60 mm) at its center (Fig. 1). A 30 mM* $NiCl_2$ solution was introduced into both compartments through tubes (T_1 and T_2) until the water levels were raised to a point just below the hole in the Teflon plate (Fig. 1a). A small volume D (*ca.* 0.1 cm^3) of an octadecenylamine/alkane solution [*i.e.*, the film-forming solution, 0.2/1 (v/v)] was then delivered onto the rim around

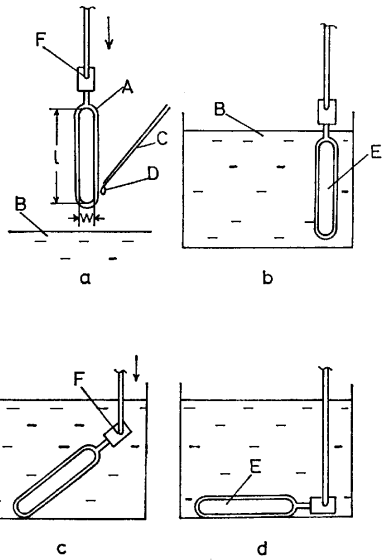

Fig. 2. Method (II) for the preparation of large bilayer. A: Frame of Teflon-coated wire (diameter: 2 mm), B, C, D, and E are the same as those of Method (I), F: joint.

* Throughout this paper, 1 M=1 mol/dm^3.

the hole with the help of a Teflon tube C (diameter: 1 mm) attached to a syringe. (2) The 30 mM $NiCl_2$ soultion was gradually added to both compartments. Two water levels were maintained at equal heights. The water levels were then raised until they reached *ca.* 5 mm above the hole (Fig. 1b). By this procedure, a colored film formed over the hole in the Teflon plate. After *ca.* 10 min, the colored film became black. Method II: A frame of Teflon-coated wire (diameter: 2 mm, Fig. 2a) was used in place of the Teflon plate. (1) A small volume D of the film-forming solution was delived onto the frame A in a manner similar to that described for Method I. (2) By lowering the frame into the aqueous solution (30 mM $NiCl_2$), a colored film formed on the frame (Fig. 2b). (3) After the frame had been further lowered, the major axis of the frame was rotated around the joint F through 90 ° (Figs. 2c and 2d). Thus, a longer film formed in the lateral direction, as well as in the vertical direction.

After *ca.* 10 min, these colored films became black. In order to improve the stability of the black film, care was taken to protect the film from vibration. The stability of the film was also increased by prepainting the frame with the sample solution.

Measurements. In order to estimate the thickness of the black film, the electrical capacitance of the film was measured by means of an AC bridge (Ando Electric Co., Ltd., Model TR-IC). Measurements were carried out in the frequency range from 30 Hz to 3MHz. The resistance of the black film was also obtained by the transient DC method. The potential across the film was measured using an electrometer of high-input impedance (Takeda Riken Industry Co., Ltd., Model TR-8651) by means of a pair of reversible Ag/AgCl electrodes. The area of the film was estimated from a photograph. The temperature of the film and its surrounding solution was maintained constant to within an accuracy of ± 0.5 °C by thermostatically-controlled water circulation. Proton magnetic resonance (PMR) spectra of metal octadecenylamine complexes were obtained at 60 MHz and 35 °C, using a Hitachi R-24 spectrometer. Monolayer characteristics of the octadecenylamine at the air–aqueous solution interface were obtained using the Wilhelmy method.

Results and Discussion

The black film formed by Method I is suitable for the measurement of electric properties, while that formed by Method II is suitable for the measurement of optical properties. The stability of the films was greatly influenced by the kind of solvent in the film-forming solution. When octane and dodecane were used as film-forming solution solvents, planar black films with areas up to 600 mm^2 were formed in the 30 mM $NiCl_2$ solution. In the case of decane as the solvent, the largest bilayer (5000 mm^2) was obtained. The films persisted over a period of one hour. When hexane, tetradecane, and hexadecane were used as solvents, however, the areas of the black films were less than 10 mm^2.

The stability of the bilayer was also influenced by the cation in the aqueous solution. The order of the stabilities of large black films was $Ni^{2+}>Co^{2+}>Mn^{2+}$. On the other hand, stable black films were not formed in NaCl, KCl, $CaCl_2$, and $MgCl_2$ solutions (30—100 mM). The addition of Ni^{2+} ions changed the PMR spectrum of the octadecenylamine (Fig. 3). The $-NH_2$ signal o octadecenylamine was no longer observable, as can be

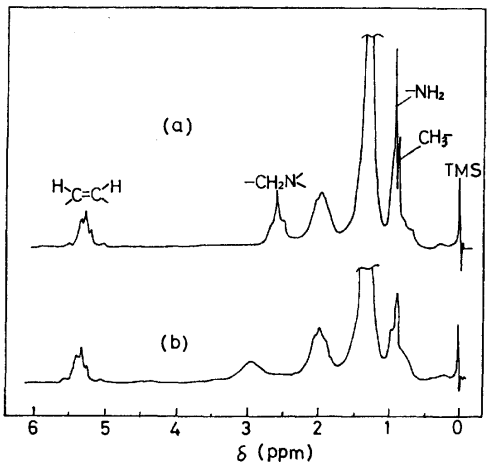

Fig. 3. Effect of added Ni^{2+} ion on the PMR spectrum of octadecenylamine; (a) octadecenylamine, (b) 1 dm^3 octadecenylamine plus 4 mM $NiCl_2 \cdot 6H_2O$. Internal reference: TMS.

seen in Fig. 3b. The $-CH_2N<$ signal is shifted downfield by 0.3 ppm and is also broadened. When ethyl glycinate was mixed in a 0.1 mM Cu^{2+} ion solution, the glycine–CH_2– signal changed in a manner similar to that for the $-CH_2N<$ signal.[5] The change in the glycine–CH_2– signal is accounted for by the proximity of the paramagnetic Cu^{2+} ion. Therefore, it appears that the proximity of the paramagnetic Ni^{2+} ion to the nitrogen atom of the octadecenylamine molecule is responsible for the change in the PMR spectrum (Fig. 3b). The magnitude of change in the $-CH_2N<$ signal was dependent on the kind of metal ion in the aqueous solution (Fig. 4). In particular, the addition of Ni^{2+} ions results in a remarkable change in the $-CH_2N<$ signal. The order of the change in magnitude of the $-CH_2N<$ signal was compatible with the Irving-Williams series ($Ni^{2+}>Co^{2+}>Mn^{2+}$), with respect to the stability of the complexation. The order of the stabilities of black films also agree with the Irving-Williams series.

From the above argument, it can be assumed that the interaction (complex formation) between the octadecenylamine molecule and metal ion (particularly,

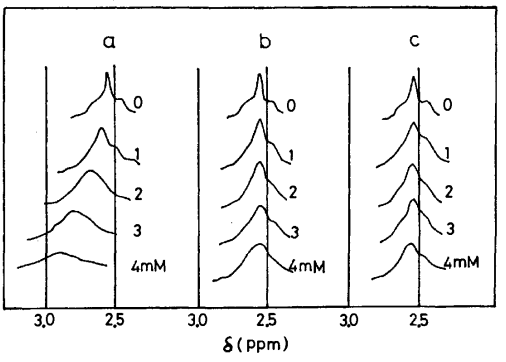

Fig. 4. Effect of the concentration of added metal ions on the $-CH_2N<$ signal of octadecenylamine; (a) $NiCl_2 \cdot 6H_2O$ plus octadecenylamine, (b) $CoCl_2 \cdot 6H_2O$ plus octadecenylamine, (c) $MnCl_2 \cdot 4H_2O$ plus octadecenylamine. Internal reference: TMS.

the Ni^{2+} ion) increases the stability of black film and that black films of large area are thus formed in aqueous solutions.

In accordance with the suggestion of Hanai *et al.*,[6] the static capacitance C_t (0 Hz) of the entire system (*i.e.*, the black film and its surrounding aqueous solution) is equal to the capacitance C_m of the black film itself, $C_t(0\text{ Hz})=C_m$. For several systems it was found that the static capacitance and the capacitance at 1 kHz agree with each other, $C_t(0\text{ Hz})=C_t(1\text{ kHz})$. Thus, the capacitance of the black film itself can be approximated by the observed capacitance of the entire system at 1 kHz. This approximation is the same as that which was used for 1-tetradecanol bilayers.[1] The capacitance of the black film itself depends strongly on the kind of hydrocarbon solvent used in its formation. In Fig. 5, it is seen that with decane as the film-forming solution solvent, the capacitance is smaller than that for any other alkane. In $CoCl_2$ solutions, as well as in $NiCl_2$ solutions, decane minimizes the capacitance.

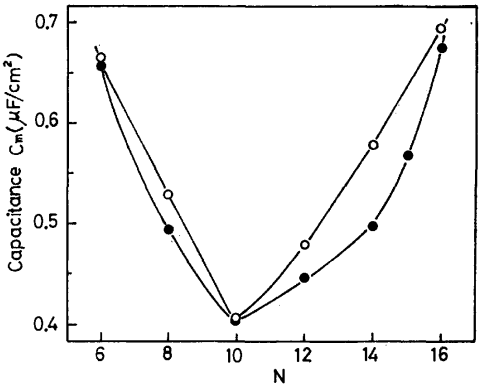

Fig. 5. Capacitance per unit area of black films of octadecenylamine dissolved in various alkanes. N is the number of carbon atoms of alkane used as solvent. ○: In 30 mM $NiCl_2$ solution, ●: in 30 mM $CoCl_2$ solution.

The capacitance of the black film is influenced both by the thickness and the dielectric constant of the hydrocarbon core of the film. Since the volume fraction of the solvent in core is not known, the dielectric constant of the core cannot be unequivocally estimated. Thus, the thickness of the black film cannot be accurately calculated from the capacitance measurement. Assuming, however, that the dielectric constant of the core has an intermediate value between that of the solvent of the sample solution and that of the octadecenyl chains, the thickness of the core may be estimated, as is shown in Fig. 6. The thickness of the film has a maximum value in the case of decane. The variation in thickness suggests that the hydrocarbon solvent greatly affects the conformation of the octadecenyl chains.

Fettiplace *et al.*[7] have reported the for hydrocarbon solvents of chain lengthgreater than decane, the thickness of black films (of glycerol monooleate or of lecithin) decrease with increasing solvent chain length. In addition, the following fact was observed. For solvents of chain length shorter than decane, the thickness of the octadecenylamine films decreases markedly with decreasing length of the hydrocarbon

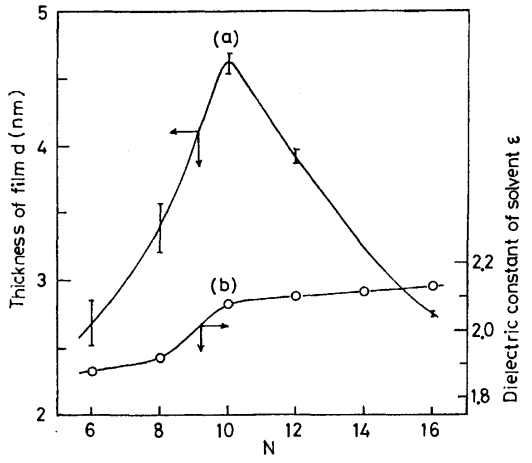

Fig. 6. Curve (a): calculated thickness of black film in the 30 mM $NiCl_2$ aqueous solution. N is the number of carbon atoms of alkane (solvent of the sample solution). The upper end of vertical line indicates the calculated value, assuming the dielectric constant of the core of black film to be equal to the value in curve (b) (*i.e.* the dielectric constant of normal alkane in the same solution). The lower end of vertical line indicates the calculated values, assuming the dielectric constant of the core to be that 1-octadecene, 2.15. The curve shows the mean value.

chain of the solvent (Fig. 6). This experimental, result can be accounted for both by (i) the influence of the solvent on the conformation of octadecenyl chain and (ii) that of the amount of solvent remaining in the film as described below. (i) The influence of the solvent on the conformation of the octadecenyl chain: The monolayer of octadecenylamine on the $NiCl_2$ solution (30 mM) is not condensed, but expanded. As a result, it appears that the molecular cavity (vacancy) between octadecenyl chains is larger than that between octadecyl chains, but that the octadecenyl chains are contiguous with each other due to the Van der Waals force which minimizes the molecular cavity. This property of octadecenylamine may appear also in black films of this molecule (note the properties of monolayers and bilayers of tetradecanoic acid[1]). Therefore, the effective length of a octadecenyl chain in a black film (*i.e.*, the thickness of the film) becomes shorter than the length of the fully extended form. Since the alkane molecules used as solvents occupy the molecular cavity of the octadecenyl chain, the conformation of the octadecenyl chain should be influenced by both the kind and the amount of solvent remaining in the film. In other words, the effective length of the octadecenyl chain (*i.e.*, the thickness of the black film) should be increased by the solvent remaining in the black film. (ii) The influence of the amount of solvent remaining in the film on the film thickness: Bewing and Zisman[8] have estimated the amount of normal alkanes in alkylamine–normal alkane mixed films adsorbed on platinum. Their conclusion is as follows. When both chains contain the same number of carbon atoms, the largest quantities of alkanes remain in the film. When the length of the alkane molecule is shorter or longer than that of the alkylamine molecule, the molar fraction of the alkane remaining in the films

decreases. Their conclusion was made on the basis of the alkane remaining in saturated hydrocarbons. On the other hand, Shah and Schulman[9] have suggested from the additivity of the surface areas of mixed lecithin–cholesterol monolayers that the stereochemical dimensions of cholesterol are appropriate for occupying the molecular cavities in lecithin monolayers. In the present case, it appears from curve (a) in Fig. 6 that decane rather than other normal alkanes tends to remain among the octadecenyl chains. The decrease in the molar fraction of alkane in the film increases the conformational change of the octadecenyl chains, and the film thus becomes thinner. Consequently, decane as a solvent results in maximum film thickness.

From the above argument, the change in the film thickness may be interpreted on the basis of the solvent in the film.

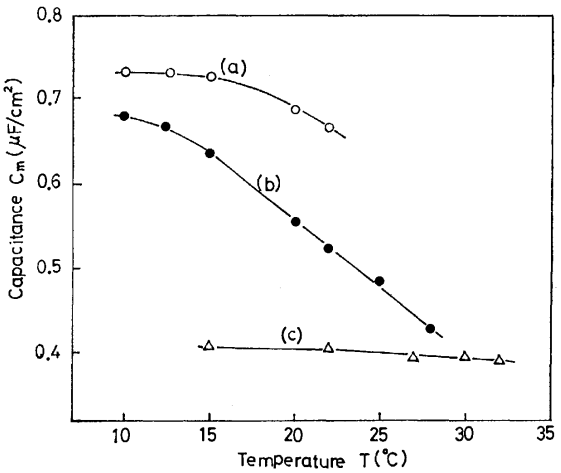

Fig. 7. Effect of temperature on the capacitance of black films in the 30 mM $CoCl_2$ solution.
(a): Film formed from octadecenylamine/hexane solution, (b): Film formed from octadecenylamine/tetradecane solution, (c): Film formed from octadecenylamine/decane solution.

Figure 7 shows the influence of temperature on the capacitance of the films. For films formed from an octadecenylamine/hexane or tetradecane solution, a marked effect of temperature on the capacitance of the film is found. It appears that the temperature dependence of the capacitance is associated with the molar fraction of the solvent in the films. That is to say, the molar fraction of the solvent in the films decreases with decreasing temperature, and then the octadecenyl chains in the film approach each other in order to reduce the molecular cavity from which the solvent molecules emerged. Consequently, the capacitance of the film increases with decreasing temperature. Since the capacitance of octadecenylamine and hexane films remains constant below 15 °C, it appears that hexane is almost completely excluded from the film. On the other hand, for black films produced in octadecenylamine/decane solutions, the capacitance also remains constant. However, the reason for the constancy of curve c in Fig. 6 differs from that for the flat part of curve a. As described above, it may be assumed from curve a that decane rather than other alkanes tends to remain in the octadecenyl chains. Therefore, since decane molecules in the film are hardly excluded, in spite of the decrease in temperature (from 32 to 15 °C), no temperature dependence of the capacitance is observed. The experimental results shown in Fig. 7 is, therefore, consistent with the assumption for curve a in Fig. 6.

For the film formed in an octadecenylamine/decane solution, the resistance of the $NiCl_2$ solution (30 mM) was in the range from 4 to $8\times10^6\,\Omega\,cm^2$. For films formed from octadecenylamine dissolved in other solvents, their resistances were from 1 to $5\times10^6\,\Omega\,cm^2$. In view of the uncertainties in the experimental results, it cannot be asserted that films formed with decane had higher resistances. The above result, however, suggests that a change in the film thickness has no significant effect on the film resistance. In other words, it appears that the rate-determining step for the permeation of ions across the black film is not the stage at which the ions move through the hydrocarbon core of the film, but the stage at which the ions enter from the aqueous solution into the hydrocarbon core of the film.

The authors wish to thank Dr. Hirofumi Okabayashi of this laboratory for valuable discussions. A part of this research was supported by a Scientific Research Grant from the Ministry of Education.

On the Gibbs Adsorption Equation for Electrolyte Solutions

Shoichi IKEDA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received January 21, 1977)

A general method is developed to derive the Gibbs adsorption equation in the form applicable to aqueous solutions of electrolytes, either strong or weak, composed of multi-components. Assuming that the solution is ideal, the chemical potentials of solute electrolytes are represented by their concentrations, and the lowering of surface tension is calculated as a function of variations of these concentrations. Explicit expressions for surface excesses of various species are obtained on aqueous solutions of two strong electrolytes having a common cation, such as sodium dodecyl sulfate and NaCl, and on solutions containing a weak acid adjusted its ionization by addition of alkali, such as fatty acid or soap, in the presence of an added salt. The convention for drawing the Gibbs dividing plane is discussed when the Gibbs adsorption equation is represented in terms of all the species in solution.

For the experimental verification of the Gibbs adsorption isotherm, aqueous solutions of surface-active substances are the most appropriate to be examined, but, owing to the electrolytic nature of most of the well-defined surfactants, the Gibbs adsorption equation has to be cast into a form applicable to such multi-component systems. Nevertheless, considerable controversy has been raised about it, since Brady[1] and Hutchinson[2] first gave an equation for a solution of strong electrolyte, in which each constituent ionic species contributes to the lowering of surface tension.[3–7] Later it was shown, however, that when an excess amount of salt is added, the electric double layer reduces the contribution of counter ion, and only the surfactant ion is responsible for surface activity.[8–11] Davies[12] derived an approximate form of the Gibbs adsorption equation for a solution of strong electrolyte, which gave the results cited above in both extreme cases, *i.e.*, in the absence and excess presence of added salt.[13,14] Recently, Tajima[15] succeeded to find an exact equation for aqueous solution of strong electrolytes.

In the present work, we will develop a general method to derive the Gibbs adsorption equation in the form applicable to aqueous solutions of electrolytes, either strong or weak, composed of multi-components. This method is first adapted to a solution of two strong electrolytes having a common cation, *i.e.*, NaD and NaCl, where D^- may be any anion other than Cl^-. Then it is extended to treat aqueous solutions containing a weak electrolyte, HD, such as a solution of HD, NaOH and NaCl, or solutions of NaD, HCl, and NaCl, or NaD, NaOH, and NaCl, in the latter two of which HD is generated by hydrolysis. The binary system containing HD or NaD alone will appear as a limiting case of ternary or quaternary systems cited above.

Our approach is general and purely thermodynamic. The Gibbs adsorption equation is expressed in terms of chemical potentials of added solute components. The method is applicable to any multi-component systems. The assumption is made that the solution is dilute and ideal, in spite of electrolytes involved, so that the activity coefficients of solute components are put equal to unity. The lowering of surface tension is then given as a function of variations of concentrations of added solute components.

Principles of the Method

Our starting equation is given by

$$-\mathrm{d}\gamma = \sum_{\mathrm{i}} \Gamma_{\mathrm{i}} \mathrm{d}\mu_{\mathrm{i}}, \tag{1}$$

where γ is the surface tension, Γ_{i} is the surface excess referred to a dividing plane set at an unspecified position of the interface between two phases (vapor and solution), and μ_{i} is the chemical potential or may be the electrochemical potential (in the solution phase). The suffix, i, represents the chemical species, either nonionic or ionic, and the summation extends over all species actually present in the system (solution).[16–18] In the three-component system concerned, i stands for H_2O, Na^+, D^-, and Cl^-, and in the case of hydrolysis occurring, it should include HD, H^+, and OH^-. In the four-component systems, all these species must be taken into account.

It should be noticed that values of Γ_{i} thus given are not definite unless the position of the dividing plane is specified. When n_{i} moles of species i are distributed between vapor and solution phases, in which its molar concentrations are C_{i}' and C_{i}, respectively, the surface excess, Γ_{i}, is given by

$$A\Gamma_{\mathrm{i}} = n_{\mathrm{i}} - V'C_{\mathrm{i}}' - VC_{\mathrm{i}}, \tag{1a}$$

where A is the area of the plane interface. Volumes of the vapor phase and the solution phase, V' and V, are not definite as far as the location of dividing plane is unspecified, while the system is closed and $V'+V$ is constant. Consequently, values of Γ_{i} remain indefinite at this stage.[16–18]

Let ν neutral components be added to make up the solution, where ν is 3 or 4. When HD is involved, two ionization equilibria are set up. The condition for equilibrium is determined by

$$\mu_\lambda = \mu_{\mathrm{H}^+} + \mu_{\mathrm{a}}, \tag{2}$$

where λ is H_2O or HD and a is OH^- or D^-. It should be noticed that μ_λ stands for the chemical potential of water component or the weak acid added as well as that of unionized H_2O or HD.[17] Furthermore, the chemical potential of a (uni-univalent) strong electrolyte can also be represented by the sum of the potentials of its constituent ions:

$$\mu_\lambda = \mu_{\mathrm{k}} + \mu_{\mathrm{a}}, \tag{3}$$

where λ is NaD, HCl, NaOH, or NaCl, and k and a are

the corresponding cation and anion, respectively.

By means of Eqs. 2 and 3 we eliminate all the chemical potentials of ionic species except for one, and then we can express the decrease in surface tension in terms of the variations of chemical potentials of added neutral components and that of the single ionic species. As the chemical potential of a single ion cannot be altered by itself, the relevant term should not appear, and it is actually found that the condition is satisfied by the electroneutrality among surface excesses of ionic species. Equation 1 is then written in a form

$$-\mathrm{d}\gamma = \sum_{\lambda=1}^{\nu} \Gamma_\lambda \mathrm{d}\mu_\lambda, \tag{4}$$

where λ runs over all ν neutral components actually added, including water as 1. Γ_λ is here expressed by an algebraic sum of Γ_i, when started from Eq. 1, but it represents the surface excess of added neutral component, λ.

In a ν-component system composed of two phases (vapor and solution), the number of degrees of freedom is $\nu-1$ at constant temperature. Consequently, a term of Eq. 4 must vanish, and for dilute solutions the solvent, water, term is chosen, so that the coefficient of $\mathrm{d}\mu_{H_2O}$, *i.e.*, Γ_1, is put equal to zero.[18] This procedure is equivalent to set the dividing plane of the interface at a definite position, which makes the surface excesses of solute components definite. In Appendix an alternative definition of surface excesses is given, which eventually agrees with the above.

The Gibbs adsorption equation is now given by

$$-\mathrm{d}\gamma = \sum_{\lambda=2}^{\nu} \Gamma_\lambda^{(1)} \mathrm{d}\mu_\lambda, \tag{5}$$

where the superfix, (1), for Γ_λ implies that the dividing plane is placed at such a position that the surface excess of water, 1, is zero. An algebraic sum of $\Gamma_i^{(1)}$ will replace for $\Gamma_\lambda^{(1)}$. In the following we will omit the superfix, (1), for the sake of brevity, which will not cause any confusion.

It remains to express the chemical potentials of added neutral solutes by their concentrations. In the present work we make an assumption that the solution is ideal so that the activity coefficients of the solute components are unity. Then the chemical potential of an unionized solute species (or a weak electrolyte), λ=HD, has a form

$$\mu_\lambda = \mu_\lambda^\circ + RT \ln C_\lambda, \tag{6}$$

where C_λ is the molar concentration of λ and the superfix, O, refers to the standard state. The chemical potential of a strong electrolyte has a form

$$\mu_\lambda = \mu_\lambda^\circ + RT \ln C_k C_a, \tag{7}$$

where C_k and C_a are the molar concentrations of cation and anion, respectively. The concentrations, C_λ, C_k, and C_a, can be expressed by the concentrations of added neutral solutes and the degree of ionization.

Ternary System: H_2O+NaD+NaCl

We consider an aqueous solution of NaD and NaCl, where NaD may be an anionic surfactant. Hydrolysis of NaD is not taken into account, and accordingly, the ionization of water is not involved either. Then we have four chemical species in solution, and Eq. 1 is written as

$$-\mathrm{d}\gamma = \Gamma_{H_2O}\mathrm{d}\mu_{H_2O} + \Gamma_{Na^+}\mathrm{d}\mu_{Na^+} + \Gamma_{D^-}\mathrm{d}\mu_{D^-} + \Gamma_{Cl^-}\mathrm{d}\mu_{Cl^-}. \tag{8}$$

Using Eqs. 3 for chemical potentials of NaD and NaCl, Eq. 8 is converted into

$$-\mathrm{d}\gamma = \Gamma_{H_2O}\mathrm{d}\mu_{H_2O} + \Gamma_{D^-}\mathrm{d}\mu_{NaD} + \Gamma_{Cl^-}\mathrm{d}\mu_{NaCl} + (\Gamma_{Na^+} - \Gamma_{D^-} - \Gamma_{Cl^-})\mathrm{d}\mu_{Na^+}. \tag{9}$$

As the chemical potential of Na^+ cannot be varied by itself, the last term should not appear, but its coefficient vanishes owing to the electroneutrality condition

$$\Gamma_{Na^+} = \Gamma_{D^-} + \Gamma_{Cl^-}. \tag{10}$$

According to the phase rule, the system must have two degrees of freedom at constant temperature, so that we may put

$$\Gamma_{H_2O} = 0, \tag{11}$$

which defines the position of dividing plane and the surface excesses of solutes. Eq. 9 then becomes

$$-\mathrm{d}\gamma = \Gamma_{D^-}\mathrm{d}\mu_{NaD} + \Gamma_{Cl^-}\mathrm{d}\mu_{NaCl}. \tag{12}$$

It is evident that Γ_{D^-} is identical with the surface excess of NaD and Γ_{Cl^-} is that of NaCl.

If the molar concentrations of added NaD and NaCl are represented by C and C_S, respectively, the concentrations of ions are

$$\begin{aligned} C_{Na^+} &= C + C_S, \\ C_{D^-} &= C, \\ C_{Cl^-} &= C_S. \end{aligned} \tag{13}$$

Substituting Eqs. 13 into Eqs. 7 for NaD and NaCl, and putting them into Eq. 12, we obtain

$$-\mathrm{d}\gamma = RT[\Gamma_2 \mathrm{d} \ln C + \Gamma_3 \mathrm{d} \ln C_S], \tag{14}$$

where

$$\Gamma_2 = \left(1 + \frac{C}{C+C_S}\right)\Gamma_{D^-} + \frac{C}{C+C_S}\Gamma_{Cl^-}, \tag{14a}$$

$$\Gamma_3 = \frac{C_S}{C+C_S}\Gamma_{D^-} + \left(1 + \frac{C_S}{C+C_S}\right)\Gamma_{Cl^-}. \tag{14b}$$

Solving Eqs. 14a and b, we have the surface excesses or the adsorbed amounts of ions of NaD and NaCl:

$$\Gamma_{D^-} = \left(1 - \frac{C}{2(C+C_S)}\right)\Gamma_2 - \frac{C}{2(C+C_S)}\Gamma_3, \tag{15a}$$

$$\Gamma_{Cl^-} = -\frac{C_S}{2(C+C_S)}\Gamma_2 + \left(1 - \frac{C_S}{2(C+C_S)}\right)\Gamma_3. \tag{15b}$$

The surface excess of Na^+ is given by

$$\Gamma_{Na^+} = \Gamma_{D^-} + \Gamma_{Cl^-} = \frac{1}{2}(\Gamma_2 + \Gamma_3). \tag{15c}$$

The equations derived by Tajima[15] reduce to Eqs. 15a and 15b, if the activity coefficients of solutes are substituted by unity, instead of being given by the Debye-Hückel limiting law. Eqs. 14 and 15 are applicable to solutions of sodium dodecyl sulfate in the presence or absence of NaCl, provided that no (surface) hydrolysis occurs. It is easy to show that no surface hydrolysis occurs unless HCl is added, as far as HD is a strong acid.[19]

When HD is generated by hydrolysis, as in solutions

of sodium carboxylate, three additional species, HD, H^+, and OH^-, must be taken into account. Such a system will be treated as a special case of the quaternary systems below.

Quaternary Systems

When we consider an aqueous solution of HD, NaOH, and NaCl, in which HD is a weak acid such as fatty acid, there are seven chemical species in it. Clearly these species are also produced in solutions of NaD and NaCl, either in the presence or absence of HCl or NaOH. Then the Gibbs adsorption equation, Eq. 1, for these quaternary systems is commonly written as

$$-d\gamma = \Gamma_{H_2O}d\mu_{H_2O} + \Gamma_{HD}d\mu_{HD} + \Gamma_{H^+}d\mu_{H^+} + \Gamma_{OH^-}d\mu_{OH^-} + \Gamma_{Na^+}d\mu_{Na^+} + \Gamma_{D^-}d\mu_{D^-} + \Gamma_{Cl^-}d\mu_{Cl^-}, \quad (16)$$

For these systems the electroneutrality of surface excesses of ionic species

$$\Gamma_{H^+} + \Gamma_{Na^+} = \Gamma_{D^-} + \Gamma_{OH^-} + \Gamma_{Cl^-}. \quad (17)$$

holds.

There exist ionization equilibria given by Eqs. 2 for water and the weak acid, and these equilibrium conditions can be substantially represented by the molar concentrations of added HD or NaD, C, and of added NaCl, C_S, if the activity coefficients of solutes are assumed to be unity.

When the apparent ionic product of water is defined by K_W, Eq. 2 may be put as

$$C_{H^+}C_{OH^-} = K_W. \quad (18)$$

Similarly, when the degree of ionization of the weak acid is α and its ionization constant is K, then the concentrations of unionized and ionized acid species are given by

$$C_{HD} = (1-\alpha)C,$$
$$C_{D^-} = \alpha C, \quad (19)$$

and Eq. 2 reduces to

$$C_{H^+}\frac{\alpha}{1-\alpha} = K. \quad (20)$$

By means of the electroneutrality condition of the solution

$$C_{H^+} + C_{Na^+} = C_{D^-} + C_{OH^-} + C_{Cl^-}, \quad (21)$$

we can obtain C_{H^+} and α as a function of C and C_A or C_B for the individual systems, where C_A and C_B are the molar concentrations of added HCl and NaOH, respectively. It is ready to substitute the variations of solute concentrations, C, C_A or C_B, and C_S, for the differentials of chemical potentials.

(I) H_2O+HD+NaOH+NaCl

For this system Eqs. 3 are used for NaOH and NaCl, and Eq. 16 is modified into a form composed of terms for added neutral components and a term of $d\mu_{OH^-}$. It is found that the coefficient of the last term is equal to zero owing to Eq. 17, and we have

$$-d\gamma = (\Gamma_{H_2O}+\Gamma_{H^+}-\Gamma_{D^-})d\mu_{H_2O} + (\Gamma_{HD}+\Gamma_{D^-})d\mu_{HD} + (\Gamma_{Na^+}-\Gamma_{Cl^-})d\mu_{NaOH} + \Gamma_{Cl^-}d\mu_{NaCl} \quad (23)$$

As the number of degrees of freedom of the system should be 3 at constant temperature, the solvent, water, term is put equal to zero.

$$\Gamma_{H_2O} + \Gamma_{H^+} - \Gamma_{D^-} = 0 \quad (24)$$

Equation 24 implies that the dividing plane of two phases be drawn at such a position as to make the surface excess of added water zero. The left-hand side of Eq. 24 is equal to the surface excess of water component, since either H^+ or H_2O is generated by the dissociation of HD or the reaction of HD with OH^-, the amount of which being equal to that of D^- formed. The water component should be considered to contain H^+ or OH^- as well as H_2O, when weak electrolytic solute is present, and its surface excess should be $\Gamma_{H_2O}+\Gamma_{H^+}=\Gamma_{H_2O}+\Gamma_{OH^-}$, when the solute is absent. Thus we obtain

$$-d\gamma = (\Gamma_{HD}+\Gamma_{D^-})d\mu_{HD} + (\Gamma_{Na^+}-\Gamma_{Cl^-})d\mu_{NaOH} + \Gamma_{Cl^-}d\mu_{NaCl}, \quad (25)$$

where $\Gamma_{HD}+\Gamma_{D^-}$ is the total surface excess of the weak acid added, $\Gamma_{Na^+}-\Gamma_{Cl^-}$ is clearly equal to the surface excess of NaOH, and Γ_{Cl^-} is totally assignable to that of NaCl.

For the ideal solution, the chemical potential of HD is given by Eq. 6, and those of NaOH and NaCl are given by Eqs. 7, in which

$$C_{Na^+} = C_B + C_S,$$
$$C_{Cl^-} = C_S. \quad (26)$$

Replacing Eqs. 18, 19, and 26 into Eq. 21, and combining it with Eq. 20, we have an equation for C_{H^+} or α, which can give dC_{H^+} or $d\alpha$ in terms of dC and dC_B explicitly.

The final form of the Gibbs equation is then written as

$$-d\gamma = RT\{\Gamma_2 d\ln C + \Gamma_B d\ln C_B + \Gamma_3 d\ln C_S\}, \quad (27)$$

where

$$\Gamma_2 = \left(1+\frac{\alpha^2 C}{Q_B}\right)(\Gamma_{HD}+\Gamma_{D^-}) - \frac{\alpha C}{Q_B}(\Gamma_{Na^+}-\Gamma_{Cl^-}), \quad (27a)$$

$$\Gamma_B = -\frac{\alpha C_B}{Q_B}(\Gamma_{HD}+\Gamma_{D^-}) + \left(\frac{C_B}{Q_B}+\frac{C_B}{C_B+C_S}\right)\Gamma_{Na^+} - \frac{C_B}{Q_B}\Gamma_{Cl^-}, \quad (27b)$$

$$\Gamma_3 = \frac{C_S}{C_B+C_S}\Gamma_{Na^+} + \Gamma_{Cl^-}, \quad (27c)$$

and

$$Q_B = \alpha(2-\alpha)C - C_B + 2C_{OH^-} = -\alpha^2 C + C_B + 2C_{H^+}. \quad (27d)$$

Solving Eqs. 27a, b, and c, the surface excesses or the adsorbed amounts of the weak acid, Na^+ and Cl^- are obtained as follows:

$$\Gamma_{HD} + \Gamma_{D^-} = \frac{C_B+C_S}{H_B}\left\{\left(1+\frac{Q_B+C_S}{C_B+C_S}\right)\Gamma_2 + \left(\frac{Q_B}{C_B}+\frac{C_S}{C_B+C_S}\right)\frac{\alpha C}{C_B}\Gamma_B - \frac{\alpha C}{C_B+C_S}\Gamma_3\right\}, \quad (28a)$$

$$\Gamma_{Na^+} = \frac{C_B+C_S}{H_B}\left\{\alpha\Gamma_2 + \frac{Q_B+\alpha^2 C}{C_B}\Gamma_B + \Gamma_3\right\}, \quad (28b)$$

$$\Gamma_{Cl^-} = \frac{C_B+C_S}{H_B}\left\{-\frac{\alpha C_S}{C_B+C_S}\left(\alpha\Gamma_2 + \frac{Q_B+\alpha^2 C}{C_B}\Gamma_B\right) + \left(1+\frac{Q_B+\alpha^2 C}{C_B+C_S}\right)\Gamma_3\right\}, \quad (28c)$$

and

$$H_B = 2\alpha C + 2C_S + 2C_{OH^-} = 2C_B + 2C_S + 2C_{H^+}. \quad (28d)$$

This kind of equations is applicable to the solutions of monolauryl phosphoric acid in the presence of NaOH, as studied recently by Nakagaki, Handa, and Shimabayashi,[20] when it is modified for a uni-divalent acid instead of HD.

In particular, in the absence of added NaOH, $\Gamma_B = \Gamma_B/C_B = 0$, and also in the absence of added NaCl, $\Gamma_3 = 0$. Then we have

$$\Gamma_{HD} + \Gamma_{D^-} = \left(1 - \frac{\alpha^2 C}{2\alpha C + 2C_{OH^-}}\right)\Gamma_2. \quad (29)$$

This case corresponds to that often cited for illustration of the Traube's rule and Langmuir's deduction of fatty acid solutions,[21] which has been treated as $\alpha = 0$.

(II) H_2O+NaD+HCl+NaCl

For this system Eq. 16 is rearranged, by using Eqs. 3 for NaD, HCl, and NaCl, into a form composed of terms of added neutral components and a term of $d\mu_{Cl^-}$. The coefficient of the last term is found to vanish owing to Eq. 17. Thus we have

$$\begin{aligned} -d\gamma = {} & (\Gamma_{H_2O} + \Gamma_{OH^-})d\mu_{H_2O} + (\Gamma_{HD} + \Gamma_{D^-})d\mu_{NaD} \\ & + (\Gamma_{Cl^-} - \Gamma_{Na^+} + \Gamma_{HD} + \Gamma_{D^-})d\mu_{HCl} \\ & + (\Gamma_{Na^+} - \Gamma_{HD} - \Gamma_{D^-})d\mu_{NaCl}. \end{aligned} \quad (30)$$

By the requirement of phase rule, the number of variables must be 3 at constant temperature, and accordingly, the dividing plane should be set in such a way that

$$\Gamma_{H_2O} + \Gamma_{OH^-} = 0. \quad (31)$$

This means that the surface excess of added water, $\Gamma_{H_2O} + \Gamma_{OH^-}$, is zero, as OH^- has arisen from water by self ionization or by the reaction with D^- but H^+ is generated from HCl as well as from water. Then Eq. 30 becomes

$$\begin{aligned} -d\gamma = {} & (\Gamma_{HD} + \Gamma_{D^-})d\mu_{NaD} \\ & + (\Gamma_{Cl^-} - \Gamma_{Na^+} + \Gamma_{HD} + \Gamma_{D^-})d\mu_{HCl} \\ & + (\Gamma_{Na^+} - \Gamma_{HD} - \Gamma_{D^-})d\mu_{NaCl}. \end{aligned} \quad (32)$$

The chemical potentials of the three neutral components are given by Eqs. 7 in which

$$\begin{aligned} C_{Na^+} &= C + C_S, \\ C_{Cl^-} &= C_A + C_S. \end{aligned} \quad (33)$$

After straightforward calculation we have

$$-d\gamma = RT\{\Gamma_2 d\ln C + \Gamma_A d\ln C_A + \Gamma_3 d\ln C_S\} \quad (34)$$

where

$$\Gamma_2 = \left(1 - \frac{\alpha(1-\alpha)C}{Q_A}\right)(\Gamma_{HD} + \Gamma_{D^-}) + \left(\frac{(1-\alpha)C}{Q_A} + \frac{C}{C + C_S}\right)\Gamma_{Na^+} - \frac{(1-\alpha)C}{Q_A}\Gamma_{Cl^-}, \quad (34a)$$

$$\Gamma_A = \frac{\alpha C_A}{Q_A}(\Gamma_{HD} + \Gamma_{D^-}) - \frac{C_A}{Q_A}\Gamma_{Na^+} + \left(\frac{C_A}{Q_A} + \frac{C_A}{C_A + C_S}\right)\Gamma_{Cl^-}, \quad (34b)$$

$$\Gamma_3 = \frac{C_S}{C + C_S}\Gamma_{Na^+} + \frac{C_S}{C_A + C_S}\Gamma_{Cl^-}, \quad (34c)$$

and

$$Q_A = (1-\alpha^2)C - C_A + 2C_{H^+} = -(1-\alpha)^2 C + C_A + 2C_{OH^-}. \quad (34d)$$

No such system as that formed by neutralization of NaD by addition of HCl seems to have been dealt with experimentally. In the case of fatty acid, the formation of acid soap[22-24] would complicate the situation. Accordingly, we will not pursue this line further.

However, in the absence of added HCl and NaCl, *i.e.*, for $C_A = C_S = 0$, Eq. 34a yields

$$\Gamma_2 = \left(2 + \frac{(1-\alpha)^2 C}{(1-\alpha^2)C + 2C_{H^+}}\right)(\Gamma_{HD} + \Gamma_{D^-}) \quad (35)$$

Aqueous solutions of sodium carboxylate such as sodium laurate correspond to this system. Surface tension of such solutions has been measured by Powney.[25]

(III) H_2O+NaD+NaOH+NaCl

Equation 16 is now converted into a form of terms of neutral components, by the use of Eqs. 3 for NaD, NaOH, and NaCl, in such a way to leave the term of $d\mu_{Na^+}$ as a term of a single ion, which eventually vanishes by means of Eq. 17. As a result, we obtain

$$\begin{aligned} -d\gamma = {} & (\Gamma_{H_2O} + \Gamma_{H^+} + \Gamma_{HD})d\mu_{H_2O} + (\Gamma_{HD} + \Gamma_{D^-})d\mu_{NaD} \\ & + (\Gamma_{Na^+} - \Gamma_{Cl^-} - \Gamma_{HD} - \Gamma_{D^-})d\mu_{NaOH} \\ & + \Gamma_{Cl^-}d\mu_{NaCl}. \end{aligned} \quad (36)$$

Because of the condition imposed for the dividing plane, the coefficient of the first term must be zero:

$$\Gamma_{H_2O} + \Gamma_{H^+} + \Gamma_{HD} = 0. \quad (37)$$

The left-hand side of Eq. 37 comes from the fact that H_2O is consumed by reaction with D^- by the amount equal to that of HD formed, while H^+ remaining unaltered. Then Eq. 36 becomes

$$\begin{aligned} -d\gamma = {} & (\Gamma_{HD} + \Gamma_{D^-})d\mu_{NaD} \\ & + (\Gamma_{Na^+} - \Gamma_{Cl^-} - \Gamma_{HD} - \Gamma_{D^-})d\mu_{NaOH} \\ & + \Gamma_{Cl^-}d\mu_{NaCl}, \end{aligned} \quad (38)$$

where $\Gamma_{HD} + \Gamma_{D^-}$ is the surface excess of NaD, $\Gamma_{Na^+} - \Gamma_{Cl^-} - \Gamma_{HD^-} - \Gamma_{D^-} = \Gamma_{OH^-} - \Gamma_{H^+} - \Gamma_{HD}$ is that of NaOH, and Γ_{Cl^-} is that of NaCl.

The chemical potentials of the three solutes are given by Eqs. 3, for which

$$\begin{aligned} C_{Na^+} &= C + C_B + C_S, \\ C_{Cl^-} &= C_S. \end{aligned} \quad (39)$$

After direct calculations we reach the equation in a form

$$-d\gamma = RT\{\Gamma_2 d\ln C + \Gamma_B d\ln C_B + \Gamma_3 d\ln C_S\}, \quad (40)$$

where

$$\Gamma_2 = \left(1 - \frac{\alpha(1-\alpha)C}{P_B}\right)(\Gamma_{HD} + \Gamma_{D^-}) + \left(\frac{(1-\alpha)C}{P_B} + \frac{C}{C + C_B + C_S}\right)\Gamma_{Na^+} - \frac{(1-\alpha)C}{P_B}\Gamma_{Cl^-}, \quad (40a)$$

$$\Gamma_B = -\frac{\alpha C_B}{P_B}(\Gamma_{HD} + \Gamma_{D^-}) + \left(\frac{C_B}{P_B} + \frac{C_B}{C + C_B + C_S}\right)\Gamma_{Na^+} - \frac{C_B}{P_B}\Gamma_{Cl^-}, \quad (40b)$$

$$\Gamma_3 = \frac{C_S}{C+C_B+C_S}\Gamma_{Na^+} + \Gamma_{Cl^-}, \quad (40c)$$

and

$$P_B = (1-\alpha^2)C + C_B + 2C_{H^+}. \quad (40d)$$

Solving Eqs. 40a, b, c, the surface excesses or the adsorbed amounts of the salt, either ionic or hydrolyzed, and Na^+ and Cl^- are found to be

$$\Gamma_{HD} + \Gamma_{D^-} = \frac{1}{Z_B}\left\{(C+C_B+P_B+2C_S)\Gamma_2 - \frac{C}{C_B}[(1-\alpha)(C+C_B+2C_S)+P_B]\Gamma_B - \alpha C\Gamma_3\right\}, \quad (41a)$$

$$\Gamma_{Na^+} = \frac{C+C_B+C_S}{Z_B}\left\{\alpha\Gamma_2 - \frac{1}{C_B}[\alpha(1-\alpha)C-P_B]\Gamma_B + \Gamma_3\right\}, \quad (41b)$$

$$\Gamma_{Cl^-} = \frac{1}{Z_B}\left\{-\alpha C_S\Gamma_2 + \frac{C_S}{C_B}[\alpha(1-\alpha)C-P_B]\Gamma_B + [(1+\alpha^2)C+C_B+P_B+C_S]\Gamma_3\right\}, \quad (41c)$$

and

$$Z_B = 2C + 2C_B + 2C_S + 2C_{H^+}. \quad (41d)$$

These equations are applicable to the solutions of sodium carboxylate in the presence of NaOH, such as studied by Powney and Addison.[25] The effect of added K_2CO_3 on the surface tension of aqueous solutions of potassium laurate[26] may also be treated along the same line of consideration.[27]

In the absence of added NaOH and NaCl, *i.e.*, for $C_B=C_S=0$, again we can arrive at Eq. 35 from Eq. 40a.

Discussion

It was shown that the Gibbs adsorption equation for a plane surface of electrolyte solution can be represented either in terms of all species, both ionic and nonionic, present in the solution, as given by Eq. 1, or in terms of added neutral components, as shown by Eq. 4. The equivalence of both representations has not been well recognized so far, and the former representation has been preferred by most workers,[8–15,19,28] although the latter representation is more favorable and convenient for thermodynamic treatments. We have also followed the former.

To make the values of surface excess definite, a dividing plane has to be drawn at a definite position between two phases. The usual convention for dilute solutions is to set the plane in such a way as to extinguish the surface excess of added water component. As far as the solution of nonelectrolytes or strong electrolytes is concerned, this convention usually does not cause any confusion, irrespective of which kind of representation has been employed, because neither H^+ and OH^- nor the ionization of water need be taken into account. However, once a weak electrolyte is involved, the choice of the representation comes to have a serious effect on the formal expression of convention. While the representation in terms of the neutral components does not require any novel expression for the surface excess of water, the representaion in terms of all species in the solution distinguishes unionized water, H_2O, from total added water, because the ionization of water itself must be taken into account. Consequently, the surface excess of added water component, which should be put to be zero, is expressed by the sum of the surface excesses of unionized water, H_2O, and of H^+ or OH^- formed by the dissociation, in the absence of solutes. However, the significance of the setting of the dividing plane is nothing new but remains as usual, although the formal expression differs.

It is also noted that the measurements of surface tension on solutions containing a weak acid does not permit to estimate Γ_{HD} or Γ_{D^-} separately but only gives the values of $\Gamma_{HD}+\Gamma_{D^-}$. They are also limited in the evaluation of Γ_{H^+}, Γ_{OH^-} or even $\Gamma_{H^+}-\Gamma_{OH^-}$ and can give only the value of $\Gamma_{H^+}+\Gamma_{HD}-\Gamma_{OH^-}$.

For the rigorous treatment of experimental results, the postulate of ideal solution should be removed, but the introduction of the limiting expressions of the Debye-Hückel theory for activity coefficients of ions leads to explicit results with great difficulty, in general.

Appendix

For simplicity, we assume the concentrations of all species in the vapor phase to be negligible. In the solution phase the Gibbs-Duhem equation holds among chemical potentials of all species, and it can be written as

$$\sum_i C_i d\mu_i = 0. \quad (A1)$$

By means of Eqs. 2 and 3 and the condition of electroneutrality among concentrations of ionic species, Eq. A1 can be rewritten

$$\sum_{\lambda=1}^{\nu} C_\lambda d\mu_\lambda = 0. \quad (A2)$$

Equation A2 is the Gibbs-Duhem equation given in terms of all the neutral components added, and C_λ is actually expressed by an algebraic sum of C_i.

From Eq. A2 the variation of chemical potential of water component, 1, is represented by

$$d\mu_1 \equiv d\mu_{H_2O} = -\frac{1}{C_1}\sum_{\lambda=2}^{\nu} C_\lambda d\mu_\lambda. \quad (A3)$$

Substituting Eq. A3 into Eq. 4, we have Eq. 5, in which

$$\Gamma_\lambda^{(1)} = \Gamma_\lambda - \frac{C_\lambda}{C_1}\Gamma_1. \quad (A4)$$

Equation A4 gives $\Gamma_1^{(1)}=0$, which is equivalent to set the dividing plane at the definite position.

The Theoretical Estimation of the *G*-Values for the Ionization and Excitation of Thirty-eight Gaseous Compounds Irradiated by 100 keV Electrons

Kiyoshi OKAZAKI, Masaki YAMABE, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 15, 1976)

The *G*-values for the ionization and excitation of thirty-eight gaseous compounds irradiated by 100 keV electrons have been calculated by combining the binary-encounter-collision theory with the theory of the degradation spectrum, which is based on the continuous-slowing-down approximation (CSDA). The thirty-eight compounds include C_2—C_6 alkanes, cycloalkanes, C_2—C_4 olefins, acetylene, 1,3-butadiene, benzene, toluene, phenol, pyrrole, furan, several alcohols, ethers, ketones, acetaldehyde, carbon dioxide, and hydrogen cyanide. Most of the calculated *G*-values of the electrons were in fair agreement with the experimental values. In the cases of several hydrocarbons, the dissociation from the superexcited state into the neutral fragments was taken into account, since the data for the fragmentation ratios were available. In the case of acetylene, the discrepancy in the *G*-values of electrons obtained experimentally and theoretically suggests that excited acetylene gives rise to a chemi-ionization reaction. In order to check the CSDA, the Fowler equation for helium has been calculated and the results compared with those obtained under the CSDA. The discrepancy in the *G*-values obtained by the two methods did not exceed 7%.

Three years ago we started the theoretical calculation of the *G*-values for the ionization and excitation of gaseous compounds irradiated by 100 keV electrons. Previously we have reported the results obtained with 5 rare gases (He, Ne, Ar, Kr, and Xe),[1,2] 5 diatomic molecules (H_2, N_2, CO, NO, and O_2),[3] and 3 ten-electron-containing molecules (H_2O, NH_3, and CH_4).[4,5] All of the *G*-values estimated were in fair agreement with the experimental ones. This agreement encouraged us to extend the calculation to other compounds. In this paper, we wish to report the results obtained with 38 gaseous compounds, which include most of the compounds whose *W*-values have been reported in the literature.

Method of Calculation

The details of the method of calculation have been reported in previous papers;[1—5] therefore, we will not repeat them here. In the present calculation, we do not take the double collision into account, since we know that the contribution of this process to the final *G*-values does not exceed 5% if the molecules consist of atoms with low atomic numbers.[5]

In the following calculation, all of the molecules excited to above their ionization potentials are assumed to ionize. Strictly speaking, this is not correct, for some of the superexcited states are known to dissociate into neutral fragments, as was mentioned by Platzman.[6] The correction for this process will be discussed in a later section.

Constants Used for Calculation

In order to perform the calculation, we need the constants belonging to each electron in the molecules; the binding energy (I_i), the average kinetic energy (E_i), and the energies of the lowest excited singlet and triplet states of the molecules (E_s and E_t).

The binding energy of an electron in the outermost shell is the ionization potential of the molecule. This value has been measured accurately by means of photoelectron spectroscopy.[7] For the binding energies

TABLE 1. THE ENERGIES OF THE LOWEST SINGLET AND TRIPLET STATES (eV)

	Compound	E_s	E_t
1.	Ethane	7.7[a]	6.3
2.	Propane	7.6	6.2
3.	Butane	7.5	6.1
4.	Isobutane	7.5	6.1
5.	Pentane	7.5	6.1
6.	Isopentane	7.5	6.1
7.	Neopentane	7.5	6.1
8.	Hexane	7.5	6.1
9.	Cyclopropane	7.8	6.4
10.	Cyclopentane	8.7	7.3
11.	Cyclopentene	6.2	4.2
12.	Cyclopentadiene	4.8[a]	3.4
13.	Cyclohexane	8.7[b]	7.3
14.	Spiro[2.2]pentane	7.8	6.4
15.	Ethylene	5.0[a]	3.6[a]
16.	Propylene	6.5[a]	5.1
17.	1-Butene	6.2	4.8
18.	*cis*-2-Butene	6.2	4.8
19.	*trans*-2-Butene	6.2	4.8
20.	2-Methyl-1-propene	6.2	4.8
21.	Acetylene	5.2[a]	4.0
22.	*s-trans*-1,3-Butadiene	6.0[a]	3.9
23.	Benzene	4.7[a]	3.6[a]
24.	Toluene	4.7	3.6
25.	Phenol	4.6	3.5
26.	Pyrrole	5.7[a]	4.5[a]
27.	Furan	5.9[a]	4.7
28.	Methanol	4.0	3.0
29.	Ethanol	4.0	3.0
30.	1-Propanol	4.0	3.0
31.	2-Propanol	4.0	3.0
32.	Dimethyl ether	3.8	2.8
33.	Diethyl ether	3.8	2.8
34.	Acetone	3.8[a]	2.8
35.	2-Butanone	3.8	2.8
36.	Acetaldehyde	3.6[a]	2.6
37.	Carbon dioxide	5.7[a]	4.5
38.	Hydrogen cyanide	6.5[a]	5.0

a) Ref. 10. b) Ref. 11.

Table 2. The G-value of ionization from each orbital

The binding energy of the electron in the orbital is I_i. The number in parentheses behind the value of I_i is the number of electrons in the orbital. The number in parentheses behind the value of G_i is the number of electrons ejected because of the Auger effect.

	Compound		I_i (eV) and G_i
1.	Ethane	I_i	11.51(2), 11.92(4), 14.15(4), 20.96(2), 28.84(2), 307(4)
		G_i	0.90, 1.67, 1.22, 0.33, 0.21, 0.020(6)
2.	Propane	I_i	11.06(4), 11.35(2), 12.67(2), 12.84(2), 13.91(2), 14.87(2), 19.71(2), 23.95(2), 30.63(2), 307(6)
		G_i	1.28, 0.61, 0.50, 0.49, 0.42, 0.38, 0.24, 0.18, 0.13, 0.021(6)

of the other electrons in several molecules, the experimental data obtained by ESCA are available;[8] however, most of the binding energies of electrons in large molecules are not known. In this case, we use the values calculated by Dewar and Worley.[9] They obtained these values by using the MINDO approximation.

We previously calculated the average kinetic energies by using the SCF functions reported in the literature. In the present paper, we use the following relation to estimate them, since the SCF functions are not available for most of the molecules:

$$E_i = 2.34 I_i^{0.93}. \quad (1)$$

Equation 1 roughly satisfies the relation between the I_i and E_i values for rare gases, diatomic molecules, and ten-electron-containing molecules.

For the E_s and E_t values, we use the values reported by Herzberg[10] and Lassettre and Francis.[11] When no data are available, these values are tentatively assumed from those of similar compounds. The E_s and E_t values used in the present calculation are summarized in Table 1.

Results

The calculated results are summarized in Tables 2 and 3. Table 2 shows the G-values of ionization from each orbital in the molecules. This table can be used when discussing the initial process of energy absorption from high-energy electrons and also the properties of the ions initially produced. So far, such a discussion has been made for an only limited number of molecules.[3-5]

In Table 3, the total G-values of ionization and excitations are summarized; the experimental values are listed in the last column. Except for a few compounds, the calculated G-values of electrons are roughly equal to, or a little larger than, the observed ones.

Discussion

Neutral Fragmentation of the Superexcited State. In the present calculation, all compounds excited to above their ionization potentials are assumed to ionize; therefore, if the neutral fragmentation of the superexcited state is an important process, the G-values of the electrons listed in Table 3 may be overestimated. Since the amount of the neutral fragmentation is dependent upon the form and energy of the superexcited state, the estimation is not easy. However, we have a procedure to estimate them, although it is very rough—the optical approximation proposed by Platzman.[12]

According to the Bethe theory, the total cross section for ionization may be expressed as follows:

$$Q_i(T) = \frac{4\pi a_0^2 R}{T} M_i^2 \ln \frac{4c_i T}{R} \quad (2)$$

Here, a_0 is the Bohr radius, R is the Rydberg energy, c_i is a constant, and M_i^2 is the dipole matrix-element squared for ionization:

$$M_i^2 = \int_I^\infty \eta(E) \frac{R}{E} \frac{df}{dE} dE \quad (4)$$

where E is the excitation energy, I is the ionization potential, df/dE is the differential oscillator strength, and $\eta(E)$ is the probability of ionization upon excitation at E. On the other hand, the total cross section of dissociation into the neutral fragments may be expressed as follows:

$$Q_d(T) = \frac{4\pi a_0^2 R}{T} M_d^2 \ln \frac{4c_i T}{R}. \quad (4)$$

Here, M_d^2 is the dipole matrix-element squared for dissociation:

$$M_d^2 = \int_I^\infty [1-\eta(E)] \frac{R}{E} \frac{df}{dE} dE. \quad (5)$$

Therefore, if we can assume that these two total cross sections are applicable throughout the energy range of the incident electron, the ratio of neutral fragmentation/ionization may be expressed in this form:

$$F = M_d^2/M_i^2 = G_d'/G_e'. \quad (6)$$

Here, G_d' and G_e' are the G-values of neutral fragmentation and of ionization from the superexcited state respectively. In the present calculation, the sum of G_d' and G_e' should be equal to G_e.

Using the oscillator strengths reported in the literature,[13-15] Hatano estimated the F ratios for several hydrocarbons.[16] We can use these values for the calculation of G_d' and G_e'. The calculated results are included in Table 3. Except for a few compounds, the corrected G-values of the electrons, G_e', are in good agreement with those obtained experimentally. Most of the differences between calculation and experiment in the G-value of electrons, G_e and G_e^{exp}, seem to be explainable in terms of this fragmentation of the superexcited state. If this is true, Table 3 suggests that the neutral fragmentation from the superexcited state of oxygen-containing compounds is small compared with that of hydrocarbons.

Chemi-ionization. In the cases of a few compounds (C_2H_2, CH_3OH, and CO_2), the calculated G-values of electrons are smaller than the observed ones. In the case of acetylene especially, the difference in G-value amounts to 1.0.

It is well known that some of the excited states of rare gases give rise to the Hornbeck-Molnar process, which induces an extra ionization:[17]

$$M^* + M \longrightarrow M_2^+ + e^-$$

If a similar reaction should occur in acetylene, the difference in the G-value of electrons may be explainable. According to the mass-spectrometric study by Koyano *et al.*, acetylene excited by ultraviolet light at 121.6 nm gives rise to the following chemi-ionization:[18]

$$C_2H_2^* + C_2H_2 \longrightarrow C_4H_3^+ + H + e^-$$
$$\searrow\ C_4H_2^+ + H_2 + e^-$$

This process might be the cause of the difference in the G-value of electrons between calculation and experiment. Such processes, however, have not been reported with methanol and carbon dioxide.

G-value of Excitation. The calculated G-values for singlet and triplet excitations are summarized in Table 3; however, there are no available experimental data which they can be directly compared with. In Fig. 1,

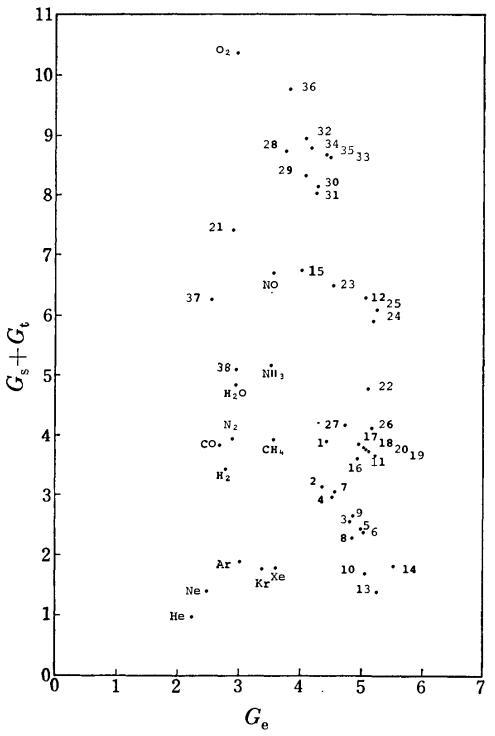

Fig. 1. Correlation between the Calculated G-values of Electrons (G_e) and Excited States (G_t+G_s). The number corresponds to the compounds listed in Table 3.

we plot all of the calculated G-values, including the results obtained in the previous papers.[1-5] The G-values of the electrons range from 2 to 6, while those of the excitations range from 1 to 11. Although the plots are widely scattered, there are some tendencies: the ratios of $G(\text{excitation})/G_e$ are smaller than unity for rare gases and saturated hydrocarbons, while those for oxygen-containing compounds and unsaturated hydrocarbons range from 1 to 4. This figure may provide useful information when the details of the radiolysis are discussed.

Appendix

In order to calculate the degradation spectrum, we have thus far used the CSDA. However, this approximation has not been justified quantitatively.[19] Before the concept of the degradation spectrum was developed, the W-values ($W=100/G_e$) had been calculated by using a more direct method.[20,21] The equation used for such calculations is called the Fowler equation. The actual calculation using the Fowler equation, however, is very tedious, even if an electronic computer is used. Consequently, only a few compounds have been subjected to the calculation.[22,23]

In the following, we will show the calculation for helium using the Fowler equation and compare its result with that obtained under the CSDA. Since both calculations use exactly the same cross sections for various inelastic collisions, the results may clarify the limits of the applicability of the CSDA in the calculation of the W-value.

The Fowler equation to be calculated may be written as follows:

$$N_m(T) = \sum_k \{N_m(T-E_k)+\delta_{km}\}p_k(T) + \sum_i \int_{I_i}^{T} \{N_m(T-E)+N_m(E-I_i)+\delta_{im}\}\frac{dp_i(T)}{dE}dE \quad (7)$$

Here, $N_m(T)$ is the number of atoms in the excited or ionized state, m, produced by the impinging of an electron with the energy, T, into a helium gas; I_i is the binding energy; E_k is the energy of the k-th excited state, and E is the energy loss. The suffixes i and k indicate the ionized and excited states respectively. $p_k(T)$ is the probability that an electron with the energy, T, loses its energy, E_k, in the first collision with the medium and excites the atom to the k-th state. When the medium absorbs the residual energy, $T-E_k$, of the electron, the number of the m-th excited state produced is $N_m(T-E_k)$. The $\{dp_i(T)/dE\}dE$ is the probability that an electron with the energy, T, loses its energy, $E\approx E+dE$, in collision with an atom and ionizes the atom to the i-th state. As a result of this collision, the energies of the scattered and ejected electrons are $T-E$ and $E-I_i$ respectively. Therefore, the numbers of the m-th excited states produced by absorbing the energies of $T-E$ and $E-I_i$ are $N_m(T-E)$ and $N_m(E-I_i)$. The δ_{km} and δ_{im} are Kronecker deltas. When m is equal to k, $\delta_{km}=1$; *i.e.*, an atom is excited to the m=k state in the first collision with the electron of energy, T. The formulation of $p_k(T)$ and $\{dp_i(T)/dE\}dE$ can easily be made as the ratios of the total cross section for ionization and excitations previously formulated.[1]

Equation 1 is a Volterra second-kind integral equation. In order actually to solve this equation, we must first calculate $N_m(T)$ numerically at an energy near the threshold energy. Then, using the obtained $N_m(T)$, we calculate $N_m(T)$ at a hi her energy. This calculating method is opposite to that used in the calculation of the degradation spectrum under CSDA, where the calculation is carried out from the higher energy to the lower energy.

For the estimation of the yields of ionization and excitations, we have to set up a Fowler equation for each process, one for ionization and two for the excitations, singlet and triplet. Since $N_m(T)$ at lower energies ($T<100$ eV) depends strongly upon T, the mesh of the calculation must be taken to be as small as possible. In the present calculations, we took 0.2 eV for the mesh. Consequently, the calculation time for the Fowler equation was about sixty times that of the method of the degradation spectrum under CSDA. These calculations were carried out by means of two computers, HITAC 8700 at the Tokyo Institute of Technology and HITAC 8800 at the University of Tokyo.

The $N_m(T)$ values for the ionization and singlet and triplet excitations in helium are shown in Fig. 2 as functions of the

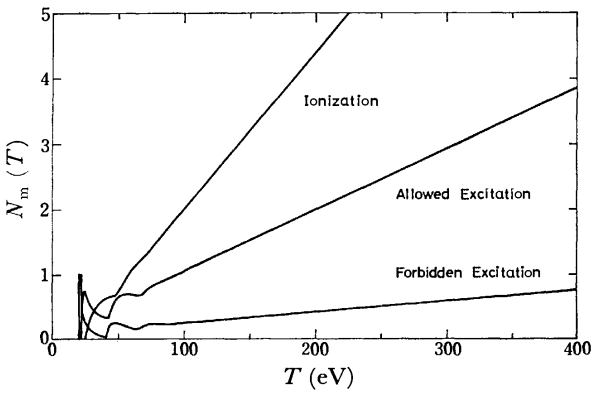

Fig. 2. The yields of ionization and excitations in helium as functions of the incident electron energy.

Table 4. Comparison of the G-values estimated by using the Fowler equation with those obtained by the method of the degradation spectrum under CSDA

Method of calculation	Incident electron energy (keV)	G_e	G_s	G_t
Fowler equation	1	2.35	0.94	0.18
	100	2.38	0.91	0.17
Degradation spectrum	1	2.23	0.88	0.17
	100	2.27	0.85	0.17

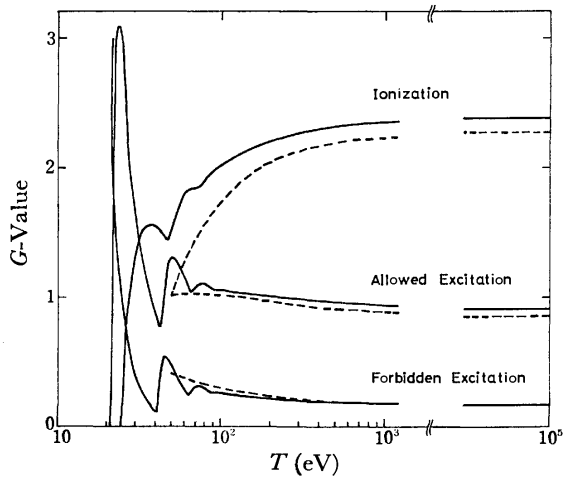

Fig. 3. The G-values for ionization and excitations as functions of ln T.
——: Estimated by using the Fowler equation,
----: estimated by the method of the degradation spectrum under CSDA.

Table 5. Comparison of the W-values obtained experimentally and theoretically

Theoretical:		
Method of calculation		W
Fowler equation	Present	42.0
	Miller[21]	46.5
	Alkhazov[22]	46.45±1.0
Degradation spectrum Douthat[24]		47.9
Degradation spectrum under CSDA		44.05
Experimental:		
Exciting source		W
Po-α		42.7 a)
Po-α		46.0 b)
Tritium-β		42.3 c)
Proton (3.6 MeV)		45.2 d)

a) W.P. Jesse and J. Sadauskis, *Phys. Rev.*, **90**, 1120 (1953). b) J. C. Bortner and G. S. Hurst, *Phys. Rev.*, **93**, 1236 (1954). c) W. P. Jesse and J. Sadauskis, *Phys. Rev.*, **107**, 766 (1957). d) J. E. Parks, G. S. Hurst, T. E. Stewart, and H. L. Weidner, *J. Chem. Phys.*, **57**, 5467 (1972).

electron energy, T. All the yields at the lower energies ($T<500$ eV) are strongly dependent on the energy of the incident electron. However, the yields at the higher energies ($T>1000$ eV) are nearly linear with T. Actually we have calculated the $N_m(T)$ from the threshold energy to 1200 eV, and then extrapolated it to 100 keV by using the linear relation between $N_m(T)$ and T.

Table 4 shows the G-values for ionization and two excitations estimated by the Fowler equation, together with those estimated by the degradation spectrum under CSDA. The values estimated by the two methods agree with each other within 7%. Figure 3 shows the incident electron-energy dependence of the G-values.

For comparison, the experimental and other theoretical W-values of helium are listed in Table 5. The W-value obtained in the present calculation (42.0 eV) seems to coincide with the experimental value (42.3 eV) reported by Jesse and Sadauskis, who used β-rays as the exciting source, while other experiments used heavier particles. This coincidence, however, should be taken as accidental, because the cross sections of ionization and excitations used in the present calculation cannot be more accurate than those used by Miller[21] and Alkhazov.[22] This point has already been discussed.[1]

The Structure of the Cyclodextrin Complex. V. Crystal Structures of α-Cyclodextrin Complexes with *p*-Nitrophenol and *p*-Hydroxybenzoic Acid

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received November 30, 1976)

α-Cyclodextrin (α-CDx) forms a 1: 1 complex with *p*-nitrophenol (*p*-NP) and *p*-hydroxybenzoic acid (*p*-HB). The crystal structures were determined by the X-ray method. The crystals of both complexes are orthorhombic, and the space group is $P2_12_12_1$ with $Z=4$. The cell dimensions are $a=13.455(1)$, $b=15.296(1)$, and $c=24.740(3)$ Å for the *p*-NP complex, and $a=13.356(1)$, $b=15.342(1)$, and $c=24.896(2)$ Å for the *p*-HB complex. The crystal structures were determined on the basis of the isomorphous structure of the *p*-iodophenol complex by using 4811 reflections for the *p*-NP complex and 4692 reflections for the *p*-HB complex, and refined by the block-diagonal least-squares method to the final *R*-values of 0.066 and 0.067 respectively. In both complexes, the guest molecule is included in the α-CDx cavity, and the α-CDx ring is deformed from the regular hexagonal symmetry as a result of the inclusion of the planar molecule. The nitrophenyl or carboxyphenyl group is located in the cavity, while the phenolic hydroxyl group protrudes from the secondary hydroxyl side of the cavity. Several intermolecular hydrogen-hydrogen contacts shorter than the ideal van der Waals contact are observed between α-CDx and guest molecules, indicating that the guest molecule is rigidly fixed in the cavity. The nitro or carboxyl group is situated on the O(6) side and is hydrogen-bonded to water or a hydroxyl group of the adjacent α-CDx molecule. The geometry of the complex gives a reasonable model for the α-CDx-substrate complex in the hydrolysis of *p*-nitrophenyl acetate and *p*-carboxyphenyl acetate catalyzed by α-CDx.

α-Cyclodextrin (α-CDx) forms a number of inclusion complexes with a variety of molecules and ions,[1] and the inclusion process affects the reactivity of the guest molecule.[2] A remarkable stereospecific acceleration is caused by α-CDx in the hydrolysis of substituted phenyl esters.[3] The rate of phenol-release from *meta*-substituted phenyl esters is greatly enhanced, whereas the rate of phenol-release from the corresponding *para*-isomers is only slightly enhanced. It has been emphasized that the magnitude of the rate acceleration does not parallel the stabilities of the α-CDx-ester complex, but depends on the geometry of the complex. Moreover, the stereospecificity of the rate accerelation has been interpreted on the basis of the interaction of the secondary hydroxyl groups of α-CDx with the carbonyl carbon of the substrate in the α-CDx cavity.

The crystal structures of many α-CDx complexes have been determined by the X-ray method.[4-16] In the complexes with *p*-iodoaniline (*p*-IA)[14,15] and *p*-iodophenol (*p*-IP),[16] the hydrophobic iodophenyl group is located in the α-CDx cavity, while the amino or hydroxyl group protrudes from the secondary hydroxyl side. *p*-Nitrophenol (*p*-NP) and *p*-hydroxybenzoic acid (*p*-HB) forms a 1: 1 complex with α-CDx. In this case, the nitro or carboxyl group has been expected, from the kinetic study of the α-CDx-catalyzed hydrolysis of *p*-nitrophenyl acetate and *p*-carboxyphenyl acetate,[3] to be situated on the O(6) side of the cavity. The X-ray analysis of α-CDx complexes with *p*-NP and *p*-HB was carried out in order to investigate the geometry of the complexes in relation to the catalytic property of α-CDx.

Experimental

A yellowish and plate-like crystal of the α-CDx–*p*-NP complex was prepared by cooling an aqueous solution containing α-CDx and *p*-NP in a 1: 1 molar ratio. The crystals of the α-CDx–*p*-HB complex, which were obtained by the same procedure, are colorless needles. The determination of the lattice parameters and the intensity measurements were carried out on a Rigaku automatic four-circle diffractometer with graphite-monochromated Cu$K\alpha$ radiation. Intensity data were collected up to 150° in 2θ by using the 2θ-ω scan technique. 5765 independent reflections for the *p*-NP complex and 5410 for the *p*-HB complex were obtained, but reflections with $|F_o|<3\sigma(F)$, 954 for the *p*-NP complex and 718 for the *p*-HB complex, were treated as unobserved. No correction was made for absorption and extinction. The crystal data are shown in Table 1.

Table 1. Crystal data

	α-Cyclodextrin–*p*-nitrophenol $C_{36}H_{60}O_{30}\cdot C_6H_5NO_3\cdot 3H_2O$	α-Cyclodextrin–*p*-hydroxybenzoic acid $C_{36}H_{60}O_{30}\cdot C_7H_6O_3\cdot 3H_2O$

	Z 4	4
Density	D_m 1.53 g cm^{-3}	1.53 g cm^{-3}
	D_x 1.52	1.52

Determination and Refinement of the Structure

The crystals of the α-CDx–*p*-NP complex and the α-CDx–*p*-HB complex are isomorphous with the crystals of the α-CDx–*p*-IA complex[14,15] and the α-CDx–*p*-IP complex.[16] A set of coordinates of α-CDx found in the α-CDx–*p*-IP complex was used to calculate the initial phases for the *p*-NP complex and the *p*-HB complex. The phases were refined by the block-diagonal least-squares method. Then, an electron-density map was

Table 2. Final atomic parameters ($\times 10^4$) for the non-hydrogen atoms
The anisotropic thermal factors are of the form: $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{23}kl+B_{31}lh)]$.
OC indicates the occupancy factor of the disordered atom.

calculated. The guest molecule and water molecules were found on the map. The hydrogen atoms were found on a difference-Fourier map. In both complexes, O(6,G4), O(W2), and O(W3) were revealed to be statistically disordered. The occupancy was estimated on the electron-density map, but they were not refined. The refinement of the crystal structures was carried out by the block-diagonal least-squares method. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$, with $w=1.0$ for the all reflections used. The thermal factors of the hydrogen atoms were not refined, but they were fixed as equal to the isotropic ones of the carbon or oxygen atoms to which the hydrogen atoms are bonded. The final R-values were 0.066 for the *p*-NP complex and 0.067 for the *p*-HB complex. The atomic scattering factors were taken from "International Tables for X-ray Crystallography."[17] The atomic parameters are listed in Tables 2 and 3. The observed and calculated structure factors are given in Table 4.*

Description of the Structure and Discussion

The structure and numbering schemes of the complexes are shown in Figs. 1 and 2. The atom numbering for α-CDx is the same as that used in the *p*-IA complex[14] and the *p*-IP complex.[16] The bond distances, angles, and conformation angles are shown in Figs. 3—6 and Tables 5* and 6. The geometrical data for the complex are shown in Tables 7 and 8. The crystal structure and hydrogen-bonding schemes are given in Figs. 7—9 and Table 9.

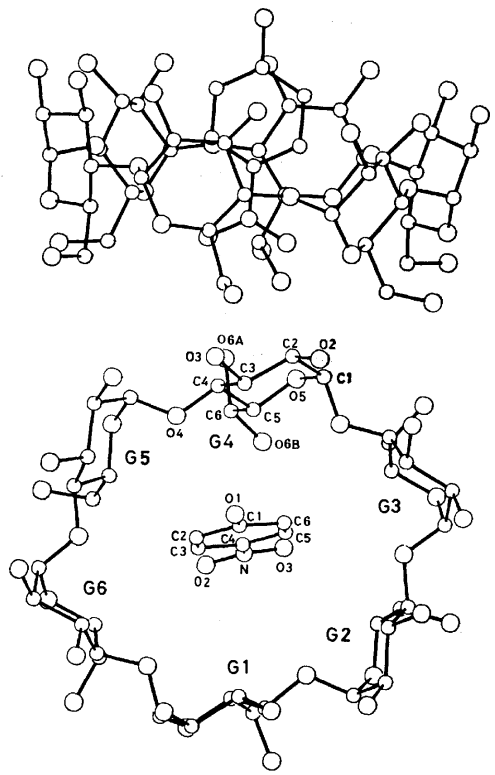

Fig. 1. The structure and numbering scheme of the α-cyclodextrin–*p*-nitrophenol complex.

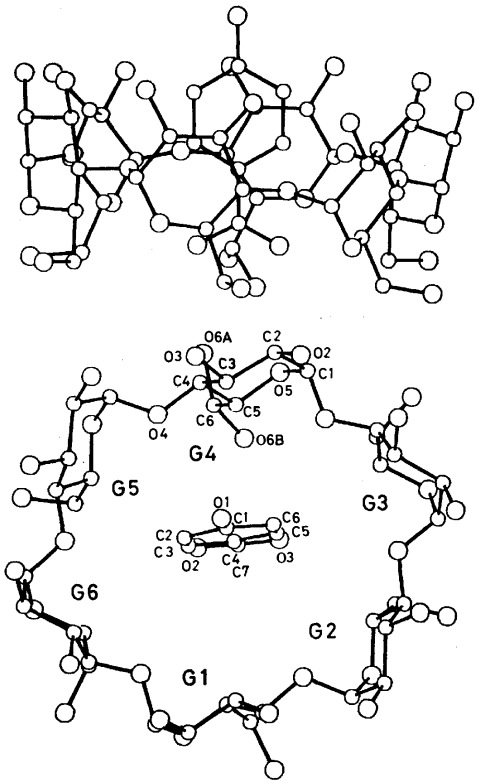

Fig. 2. The structure and numbering scheme of the α-cyclodextrin–*p*-hydroxybenzoic acid complex.

Structure of α-CDx. In both the α-CDx–*p*-NP complex and the α-CDx–*p*-HB complex, the conformation of α-CDx is nearly identical with the conformation found in the complexes with *p*-IA and *p*-IP. The distances of the C(1)–C(2) and C(4)–C(5) bonds are slightly longer than the C(2)–C(3) and C(3)–C(4) distances, while the contrary tendancy is observed in α-D-glucose monohydrate.[18] The C(4)–O(4) bond of the glycosidic linkage is longer than the C(1)–O(4) bond. In the pyranose ring, the C(5)–O(5) bond is longer than the C(1)–O(5) bond; a similar effect is observed in α-D-glucose monohydrate. The C(1)–O(5)–C(5) angles are in good agreement with the values found in the α-D-glucose derivatives[18,19] and in the maltose derivatives.[20-22] The α-1,4-linking oxygen angles of C(4)–O(4)–C(1′) are a little larger than those found in the maltose derivatives, but such large values are commonly observed in other α-CDx complexes.

A small conformational difference is observed among the glucose residues. One of the indices which represent the conformational change of glucose residues is the O(4)···O(4′) distance.[23] The O(4)···O(4′) distance in the *p*-NP complex and the *p*-HB complex (Table 7) are quite small compared with that found in α-D-glucose monohydrate. This may be due to the cyclic structure of α-CDx. The distance of the C(4) atom from the plane through C(2), C(3), C(5), and O(5) also indicates the conformational change in the pyranose ring (Table 8). The C(4) atom approaches to the plane slightly when the O(4)···O(4′) distance is shortened.

* Tables 4 and 5 are kept in the office of The Chemical Society of Japan (Document No. 7707).

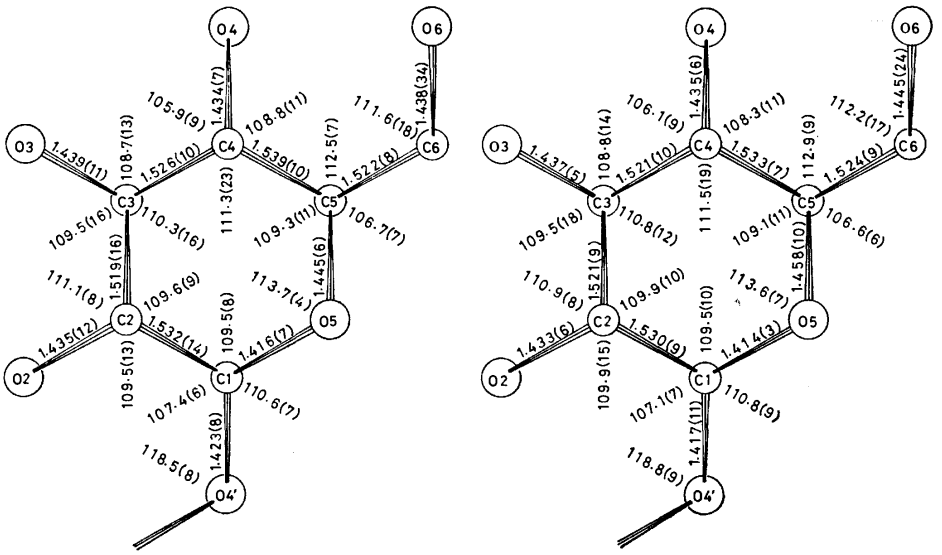

Fig. 3. Average bond distances and angles for the glucose residue in the α-cyclodextrin–*p*-nitrophenol complex (left) and the α-cyclodextrin–*p*-hydroxybenzoic acid complex (right). Standard deviations given in parentheses were estimated according to $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x})^2/5]^{1/2}$, where x_i is the bond distance or angle in the i-th glucose residue and $\bar{x}$ is the average value.

Table 6. Conformation angles (ϕ/°) in α-cyclodextrin

O(4, G5)–O(4, G6)	4.049	4.103
Average value	4.235	4.239
O(4, G1)–O(4, G4)	7.984	8.055
O(4, G2)–O(4, G5)	8.902	8.923
O(4, G3)–O(4, G6)	8.457	8.418
Average value	8.457	8.465

II. Torsion-angle index[a] (ϕ/°) in the *p*-NP complex (A) and in the *p*-HB complex (B).

Residue	Index A	Index B	Residue	Index A	Index B
G1	125.7	127.1	G4	111.4	108.9
G2	125.8	128.6	G5	131.5	133.6
G3	148.1	145.9	G6	142.5	135.5
			Average value	130.8	129.9

a) The torsion-angle index is defined as follows: $|\phi(C(1)-C(2))|+|\phi(C(2)-C(3))|+|\phi(C(5)-O(5))|+|\phi(O(5)-C(1))|-|\phi(C(3)-C(4))|-|\phi(C(4)-C(5))|$, if the conformation angle of C(1)–C(2)–C(3)–C(4) is expressed as $\phi(C(2)-C(3))$.

The conformation angles in the G4 residue, which gives the largest O(4)···O(4′) distance are in agreement with those of α-D-glucose monohydrate within 3.0° in the *p*-NP complex and within 4.0° in the *p*-HB complex. A small difference in the pyranose-ring conformation is observed between the G3 residue and the G4 residue. The C(3)–C(4)–C(5)–O(5) conformation angle of the G3 residue is greater by 15.8° in the *p*-NP complex and by 14.0° in the *p*-HB complex than the values found in the G4 residue. The change in the pyranose-ring conformation is also clearly shown by means of the torsion-angle index defined by French and Murphy.[23] The torsion-angle indices in the *p*-NP complex and the *p*-HB complex, except for that in the G4 residue, are

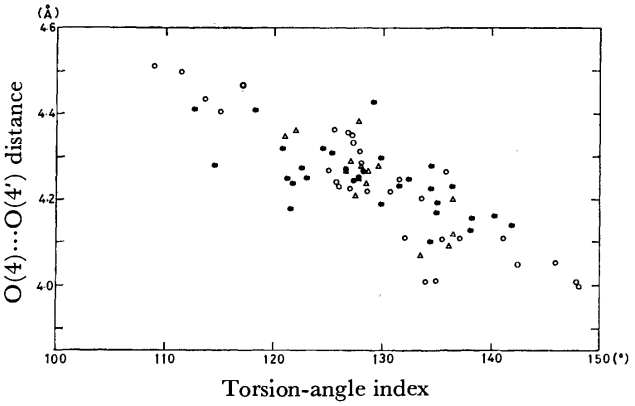

Fig. 4. Plot of the O(4)···O(4′) distance against the torsion-angle index in the α-cyclodextrin complexes with *para*-disubstituted benzenes (○), the complexes with the cage-type structure (●), and the complexes with the channel-type structure (△).

greater than that found in α-D-glucose monohydrate. The glucose residue, which has a small O(4)—O(4′) distance, gives a large torsion-angle index, and *vice versa*. The value found in the G3 residue is considerably larger than the values of 112.6—134.6° found in the α-CDx–water complex. This suggests that the pyranose ring changes its conformation when α-CDx includes the planar molecule.

The O(4)···O(4′) distance is plotted against the torsion-angle index for the three types of crystal structures in Fig. 4. In the complexes with *para*-disubstituted benzenes, a correlation similar to that found in mono-, di-, and trisaccharides[23] is found between the two variables, while in the complexes with the cage-type structure[4-8] or the channel-type structure[9-12] the correlation is not clear. In the channel-type structure, the O(4)···O(4′) distance and the torsion-angle index are found in a relatively small region, although the dimension and shape of the guest molecule are quite flexible. This indicates that the geometrical freedom of the pyranose ring is restricted not only by the guest molecule, but also by the crystal structure.

The α-CDx ring shows a distorted hexagon. The diagonal distances measured between the glycosidic oxygen atoms vary from 7.984 to 8.902 Å in the *p*-NP complex and from 8.055 to 8.923 Å in the *p*-HB complex (Table 7). On the other hand, the PSNa complex[12] gives 8.40—8.59 Å, showing a nearly regular hexagon. A distorted hexagon was also observed in the other α-CDx complexes with phenyl derivatives. The planarity of the six O(4) atoms is quite good (Table 8).

The intramolecular O(2)···O(3) hydrogen bonds are observed between the adjacent glucose residues (Table 9). Not all of these hydrogen bonds are oriented in the same direction, but both O(2)→O(3) and O(3)→O(2) hydrogen bonds are found. In the G4 and G6 residues, both of the secondary hydroxyl groups act as donors, but in the G1 residue, they are acceptors. The O(2) hydroxyl group in the G2 and G3 residues donates the hydrogen atom. O(2,G4)···O(3,G3) in the *p*-NP complex and O(2,G6)···O(3,G5) in the *p*-HB complex are rather doubtful hydrogen bonds since the O–H···O angles are too small.

Structures of p-*NP and* p-*HB.* The bond distances and angles in *p*-NP (Fig. 5) are in good agreement with those found in the crystal structure of *p*-NP.[24,25] The inequality in the C(2)–C(1)–O(1) and C(6)–C(1)–O(1) angles which is found in *p*-NP is not found in *p*-HB (Fig. 6). The bond distances of C(7)–O(2) and C(7)–O(3) in *p*-HB agree with those found in *p*-chlorobenzoic acid.[26] In both *p*-NP and *p*-HB, the benzene ring shows a good planarity (Table 8).

α-CDx-Guest Interaction. The nitrophenyl or carboxyphenyl group is located in the α-CDx cavity, while the phenolic hydroxyl group protrudes from the O(2),

O(3) side. The relative orientation of the guest molecule in the cavity is similar to that found in the *p*-IA complex and the *p*-IP complex. In the channel-type structure and the cage-type structure, the hydroxyl group or sulfonato group of the guest molecule is hydrogen-bonded to the primary hydroxyl group with the *gauche-trans* conformation. However, in the complexes with *p*-NP and *p*-HB, the nitro or carboxyl group does not form the hydrogen bond with O(6B,G4), although the C(6,G4)–O(6B,G4) bond shows the *gauche-trans* conformation. It is noteworthy that the location of the benzene ring is the same as in the other α-CDx complexes with the aromatic guest molecule, such as *p*-IA,[14,15] *p*-IP,[16] Methyl Orange,[10] and BSNa.[11] This may be due to the fact that this position is sterically most favorable for the benzene ring. The plane of the guest molecule is nearly parallel to the longest diagonal line which passes through O(4,G2) and O(4,G5). The benzene ring makes angles of 80.6 and 83.6° against the plane through the six O(4) atoms in the *p*-NP complex and the *p*-HB complex respectively, while in the BSNa complex the benzene plane is perpendicular to the O(4) plane. The distances of O(4,G2)···C(5,NP), O(4,G5)···C(3,NP), O(4,G2)···C(5,HB), and O(4,G5)···C(3,HB) are in good agreement with the corresponding distances found in the *p*-IA complex, the *p*-IP complex, and the BSNa complex. Several hydrogen-hydrogen contacts shorter than the ideal van der Waals contact[27] are found between α-CDx and the benzene ring, as is shown in Figs. 5 and 6. This indicates that the guest molecule is tightly packed in the α-CDx ring. The hydrogen atoms attached to C(3) and C(5) of α-CDx are located inside the cavity, and are in contact with the guest molecule. The six hydrogen atoms bonded to C(5) form a neck of the cavity. The C(4)–C(7) bond of *p*-HB and C(4)–N bond of *p*-NP are located at the neck, showing a good fit of the guest molecule to the cavity. A similar geometrical fitness is observed in the complexes with *p*-IA, *p*-IP, Methyl Orange, and iodine.[4]

In the *p*-IA complex and the *p*-IP complex, the iodine atom is found at the position where the nitro or carboxyl group is located. In this case, the inclusion of the iodophenyl group has been interpreted as being mainly due to the hydrophobic interaction, since the interior of the cavity is relatively hydrophobic. It has also been shown by the theoretical calculation of the complex formation energy[11] that the inclusion of the hydrophobic group gives a more stable complex than the inclusion of the hydrophilic group when the guest molecule consists of hydrophobic and hydrophilic groups. In the complexes with *p*-NP and *p*-HB, the nitro or carboxyl groups are hydrophilic, and they form hydrogen bonds with water and the hydroxyl group of the adjacent α-CDx molecule (Table 9). It is geometrically possible that the *p*-NP and *p*-HB molecules are situated upside down in the cavity, that is, the nitro or carboxyl group protrudes from the secondary hydroxyl side of the cavity, and the phenolic hydroxyl group is situated at the primary hydroxyl side in the cavity. However, this structure may be unfavorable in view of the fit of the guest molecule to the α-CDx cavity. The guest molecule seems to be more loosely packed in the cavity. Moreover, the phenolic hydroxyl group can not be in contact with water or hydroxyl groups outside the cavity, since it is buried in the cavity. Thus, the geometry of inclusion may be determined by the fit of the guest molecule and the hydrogen bonds.

Crystal Structure and Hydrogen Bonds. The α-CDx molecules are arranged nearly parallel to the ac plane, forming a molecular layer (Fig. 7). The least-squares plane through the six O(4) atoms makes an angle of 6.2° in the *p*-NP complex and one of 5.7° in the *p*-HB complex against the ac plane. This type of the crystal structure is different from the cage-type structure,[4–8] since both ends of the cavity are open to the space between the layers. The α-CDx molecule, which lies in the next layer, is slipped so that the overlap of the annular aperture is quite small. Therefore, this arrange-

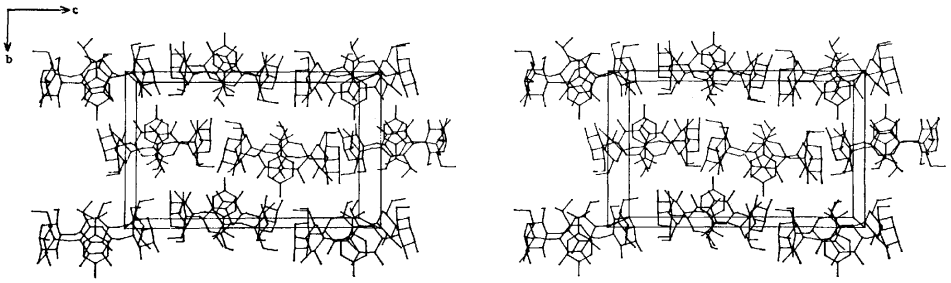

Fig. 7. A stereo drawing of the packing of the complex, viewed down along the a axis.

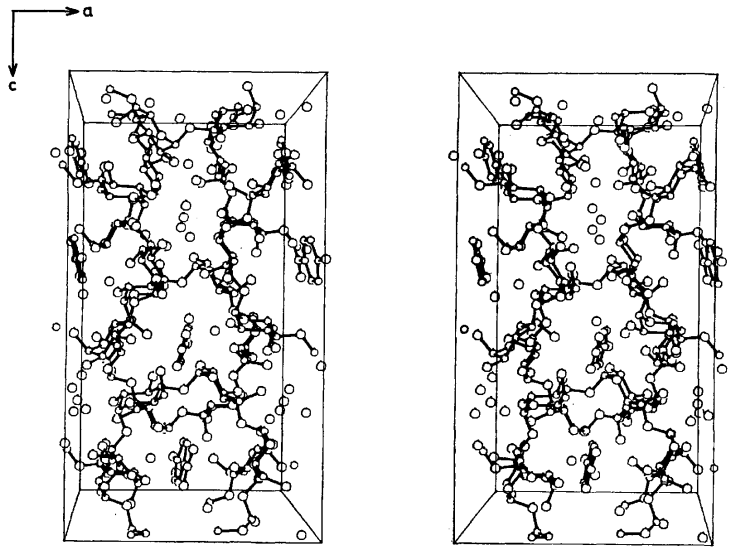

Fig. 8. A stereo drawing of the crystal structure of the α-cyclodextrin–*p*-nitrophenol complex, viewed down along the b axis.

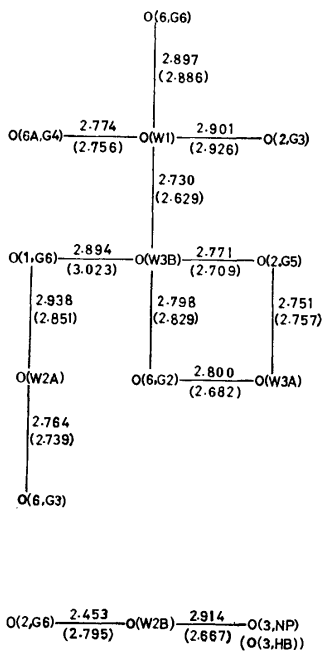

Fig. 9. A hydrogen-bonding scheme involving water molecules in the α-cyclodextrin complexes with *p*-nitrophenol and *p*-hydroxybenzoic acid. Hydrogen bond distances (*l*/Å) in the *p*-hydroxybenzoic acid complex are shown in parentheses.

ment of α-CDx molecules does not form a continuous channel such as is found in the channel-type structure.[9–12] The guest molecules are situated nearly parallel to the bc plane. The empty space between the α-CDx molecules is filled with three water molecules, two of which are statistically disordered.

A complete explanation of the hydrogen-bonding scheme is impossible since not all of the hydrogen atoms have been determined, but intermolecular oxygen-oxygen contacts less than 3.0 Å were considered as hydrogen bonds. All of the primary or secondary hydroxyl groups except for O(2,G4) and O(3,G6) are involved in the intermolecular hydrogen bonds in both the *p*-NP complex and the *p*-HB complex (Table 9). The phenolic hydroxyl groups of *p*-NP and *p*-HB donate the hydrogen atom to the O(2,G2) of α-CDx in the next layer, and accept it from O(6,G5) of the symmetry-related α-CDx by the two-fold screw axis parallel to the b axis. The hydrogen bonds of the same type are also found in the *p*-IA complex,[14,15] and the *p*-IP complex.[16] However, different hydrogen bonds are observed between the α-CDx and guest molecules. The carboxyl group of *p*-HB forms the two hydrogen bonds with O(W2B) and O(2,G6) in the next layer, while the nitro group is hydrogen-bonded to only O(W2B). In the *p*-IA complex and the *p*-IP complex, O(W2) is not disordered, but occupies the same position as O(W2A). Therefore, the hydrogen bonds involving

O(W2B) are not found in these complexes. O(W1) forms the four hydrogen bonds with O(2,G3), O(6A,G4), O(6,G6), and O(W3A), as is shown in Fig. 9. Both O(W3A) and O(W3B) are hydrogen-bonded to O(2,G5) and O(6,G2).

Structure and Catalytic Ability of α-CDx. α-CDx catalyzes the hydrolysis of *p*-nitrophenyl acetate and *p*-carboxyphenyl acetate.[3] The reaction mechanism has been interpreted on the basis of the α-CDx-substrate inclusion complex and the nucleophilic attack of the secondary hydroxyl group on the carbonyl carbon atom of the substrate. The structures of the *p*-NP complex and the *p*-HB complex support this reaction mechanism. If the *p*-nitrophenyl group or *p*-carboxyphenyl group is included in the same manner as in the crystal, the carbonyl group of the ester will be situated near the secondary hydroxyl side of α-CDx. However, the carbonyl carbon atom is expected for geometrical considerations to be more than 5 Å apart from the secondary hydroxyl groups. The phenyl group is rigidly fixed in the cavity so that the severe restriction is imposed on the translational and rotational freedom of the included substrate. Therefore, a considerable strain energy may be required to the α-CDx molecule to bring the carbonyl group in close contact with the secondary hydroxyl groups. As has been suggested by VanEtten *et al.*,[3] this seems to be the reason why the catalytic ability of α-CDx is low in the hydrolysis of *para*-substituted phenyl acetates.

The author wishes to thank Dr. Hisashi Uedaira for supporting this study and for his helpful discussions. The computation was carried out on a HITAC 8450 computer in our laboratory.

Conductance of Some High Valence Type Electrolytes in Mixed Solvents. II. Conductance of Pentaamminenitrocobalt(III) and Tris(1,10-phenanthroline)iron(II) Sulfates in Water-Ethylene Glycol Mixtures at 25 °C*

Eiji KUBOTA and Masatoki YOKOI

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received December 3, 1976)

Conductance data are reported for dilute solutions of pentaamminenitrocobalt(III) sulfate, $[Co(NO_2)(NH_3)_5]SO_4$, and tris(1,10-phenanthroline)iron(II) sulfate, $[Fe(phen)_3]SO_4$ in water–ethylene glycol mixed solvents at 25 °C. The conductance data were analyzed in terms of the 1957 Fuoss-Onsager and Fuoss-Hsia equations. While the application of the 1957 Fuoss-Onsager equation to $[Fe(phen)_3]SO_4$ data suggested a complete dissociation of the salt over the entire range of solvent compositions, the Fuoss-Hsia equation fitted the data better and yielded K_A values which are in accord with the ion association theories. $[Co(NO_2)(NH_3)_5]SO_4$ had a higher association constant in the range of solvent composition studied (0 to 40% ethylene glycol) than the predictions of the ion association theories.

In a previous paper[1] we reported the conductance data of $[Fe(phen)_3]SO_4$ in a water–methanol mixed solvent at 25 °C. The association constant of the salt was estimated to be 40 in water by the analysis of the data with the Fuoss-Hsia equation[2] in the form developed by Fernandez-Prini.[3]

Masterton and Biery[4] reported that $[Co(NO_2)(NH_3)_5]SO_4$ is much more ion-paired than has been calculated from the ion association theory, the association constants being 400 in water at 25 °C. Since the values of the association constants of bivalent metal sulfates are 150—250 in water and those of the *m*-benzenedisufonates of bivalent metals are much lower than the constants of the corresponding sulfate, the complex salt seems to be the most highly associated 2:2-type sulfate in water.[5]

It seemed interesting to study the association equilibiria of the complex salts in water–organic solvent systems. Thus, the conductance of $[Co(NO_2)(NH_3)_5]SO_4$ and $[Fe(phen)_3]SO_4$ in water–ethylene glycol mixtures was measured at 25 °C, and the association constants thus derived were compared with the predictions of the ion association theories.

Experimental

Materials. The $[Co(NO_2)(NH_3)_5]SO_4$ was synthesized as has been described in the literature.[6] The $[Co(NO_2)(NH_3)_5]Cl_2$ was prepared by reaction between $[CoCl(NH_3)_5]Cl_2$ and sodium nitrate; it was then converted to $[Co(NO_2)(NH_3)_5]SO_4$. The raw crystals were recrystallized repeatedly from a hot aqueous solution by adding ethanol and then dried at 105 °C. The procedure was carried out in the dark as far as possible to avoid nitrito-form contamination. The purity of the sample was checked by means of its UV and IR spectra, by elementary analysis (Found: N, 29.25; H, 5.32%. Calcd: N, 29.37; H, 5.28%), and by a total-cation determination untilizing cation-exchange resin.

The $[Fe(phen)_3]SO_4$ was prepared and purified as has been described in the previous paper.[1]

The ethylene glycol was dried with anhydrous sodium sulfate and fractionally distilled at 5 Torr. The specific conductivity was less than 7×10^{-8} ohm^{-1} cm^{-1}.

Apparatus and Measurement. The conductance measurement was performed by a transformer bridge (with a reproducibility of 0.005%) and a 3—10 kHz audio oscillator. Two flask-type cells with constants of 0.11631 and 0.09695 cm^{-1} were used. The temperature of the liquid paraffin bath was controlled at 25.000±0.005 °C.

The dilution method of a stock solution was not suitable for the preparation of $[Co(NO_2)(NH_3)_5]SO_4$ solutions because of the low solubility of the salt. The samples (10—20 mg) were weighed in small polyethylene dishes 10 mm in diameter, and the dishes were thrown into the cell. The conductivity was measured after each dissolution of samples.

$[Fe(phen)_3]SO_4$ had enough solubility for preparin the stock solution over the complete range of solvent compositions.

Results and Discussion

The conductance data of $[Co(NO_2)(NH_3)_5]SO_4$ and $[Fe(phen)_3]SO_4$ in water–ethylene glycol are given in Tables 1 and 2 respectively.

The data were analyzed by means of the Fuoss-Onsager (1957) equation:[7]

$$\Lambda = \Lambda_0 - Sc^{1/2}\gamma^{1/2} + Ec\gamma\log c\gamma + Jc\gamma - K_A c\gamma\Lambda f_\pm^2, \quad (1)$$

where the symbols have their usual meanings.[1] The f's were calculated from the extended Debye-Hückel theory, including the ion-size parameter, $\mathring{a}$. The coefficient, J, is also a function of $\mathring{a}$; the adjustable parameters are thus Λ_0, K_A, and $\mathring{a}$. The results of the computer analysis of the $[Co(NO_2)(NH_3)_5]SO_4$ data are summarized in Table 3.

The application of Eq. 1 to the $[Fe(phen)_3]SO_4$ data gave negative K_A values, as in the data for the salt in a water–methanol mixture.[1] Thus, the data were fitted by means of Eq. 2 for unassociated electrolytes:[7]

$$\Lambda = \Lambda_0 - Sc^{1/2} + Ec\log c + Jc. \quad (2)$$

Here, the adjustable parameters are Λ_0 and $\mathring{a}$. The results are given in Table 4.

For the $[Fe(phen)_3]SO_4$ data in water–methanol, the Fuoss-Hsia[2] equation was applied in the form of Eq. 3 developed by Fernandez-Prini:[3]

$$\Lambda = \Lambda_0 - Sc^{1/2}\gamma^{1/2} + Ec\gamma\log c\gamma + J_1c\gamma - J_2c^{3/2}\gamma^{3/2} - K_A c\gamma\Lambda f_\pm^2. \quad (3)$$

* Presented in part at the 29th National Meeting of the Chemical Society of Japan, Nagoya, October 1974.

a) Table 1, a) and b).

The application improved $\sigma\Lambda$ and gave reasonable K_A values. Therefore, the fitting of the present data to Eq. 3 was examined.

The best-fit values of Λ_0, K_A, and $\mathring{a}$ were calculated by a successive approximation for the series of initial values of the ion-size parameter, $\mathring{a}_i$, between 1—28 Å with 0.05 Å intervals. $\sigma\Lambda$ is defined as:

$$\sigma\Lambda = \left[\frac{\sum(\Lambda_{expti}-\Lambda_{calcd})^2}{N-3}\right]^{1/2}, \quad (4)$$

where N is the number of experimental points.

An example of the results is shown graphically in Fig. 1 for the $[Co(NO_2)(NH_3)_5]SO_4$ data in water. The solid lines of Fig. 1 indicate the variation in Λ_0, K_A, $\sigma\Lambda$,

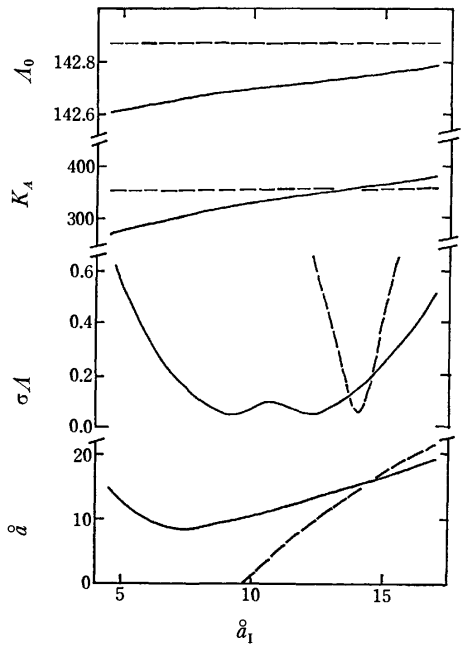

Fig. 1-A. Values of parameters and standard deviations as a function of $\mathring{a}_I$ for $[Co(NO_2)(NH_3)_5]SO_4$ in water. The units of Λ_0 and $\sigma\Lambda$ are ohm^{-1} cm^2 equiv^{-1} and those of K_A are dm^3 mol^{-1}. The broken lines are calculated by fixing $\mathring{a}=q$ in the J_1 and $f_\pm$ terms.

and $\mathring{a}$ with the change in $\mathring{a}_I$. While the K_A and Λ_0 values increase with the $\mathring{a}_I$, $\sigma\Lambda$ has two similar minima corresponding to the $\mathring{a}$ values of 9.0 and 12.0 Å. In Fig. 2, the $\sigma\Lambda$ values are shown as contour lines with the

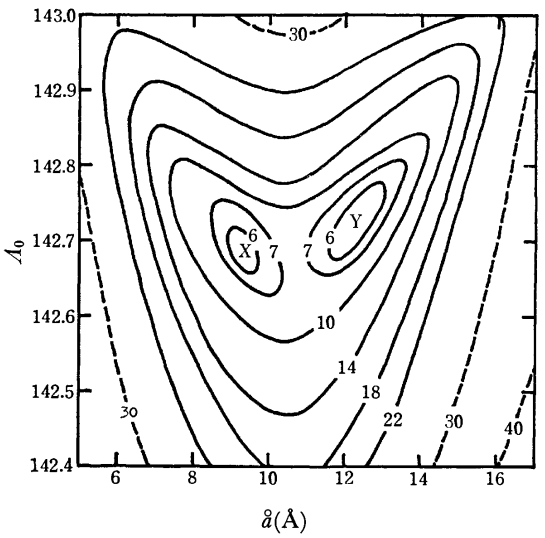

Fig. 1-B. Contour diagram for the $[Co(NO_2)(NH_3)_5]SO_4$ in water. The contour lines illustrate how $\sigma\Lambda$ depends on different conbinations of the Λ_0 and $\mathring{a}$. The figures on the contours represent the values of $10^2\sigma\Lambda$. The minimum at point X, $\sigma\Lambda=0.06$, corresponds to the parameters, $\Lambda_0=142.68$, $K_A=316$, $\mathring{a}=9.2$Å, while the minimum at point Y, $\sigma\Lambda=0.06$, corresponds to $\Lambda_0=142.72$, $K_A=343$, $\mathring{a}=12.4$Å.

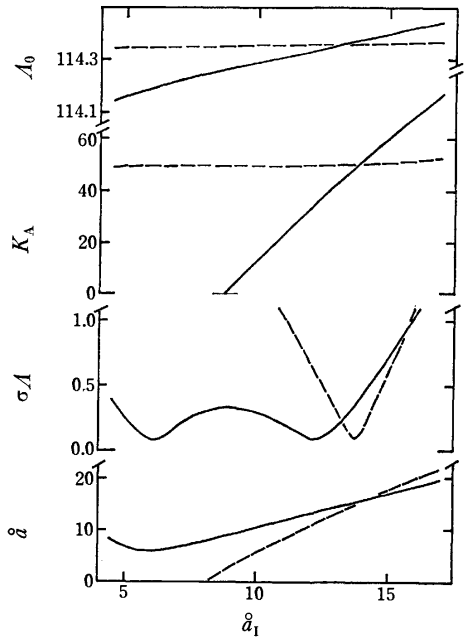

Fig. 2. Values of parameters and $\sigma\Lambda$ as a function of $\mathring{a}_I$ for $[Fe(phen)_3]SO_4$ in water. The broken lines are calculated by fixing $\mathring{a}=q$ in the J_1 and $f_\pm$ terms.

variation in the $\mathring{a}_I$ and Λ_0 values. It is apparent that two sets of parameter values were obtained by the above computation method. For the $[Co(NO_2)(NH_3)_5]SO_4$ data in other water–ethylene glycol solvent systems, two sets of parameter values of the minimum $\sigma\Lambda$ with different $\mathring{a}$ values are obtained. The appearance of the two minima in fitting the conductance data to the Fuoss-Hsia equation were observed for some 1 : 1-type electrolytes.[8)] It is rather difficult to decide which

a) q, Bjerrum's distance (Å); $\mathring{a}_{J_2}$, ion-size parameter (Å); Table 1, a).

minimum is preferable. Thus, both sets of parameters are given in Table 5-A, which summarizes the results for $[Co(NO_2)(NH_3)_5]SO_4$.

For the $[Fe(phen)_3]SO_4$ data also, two minima with the lowest $\sigma\Lambda$ value are obtained, but the one corresponding to the lower $\mathring{a}$ has a negative K_A value. The results obtained for the data in water are shown as solid lines in Fig. 3. Similar results were obtained for the data in water–ethylene glycol solvents and for the data[1)] of the $[Fe(phen)_3]SO_4$ in water–methanol. In this case, the minimum $\sigma\Lambda$ values with a negative K_A are disregarded; the results are summarized in Table 6-A.

As another method of fitting the data to Eq. 4, the ion-size parameters appearing in the J_1 and $f_\pm$ terms were fixed as equal to the Bjerrum q values,[9)] and the best-fit $\mathring{a}$ values for the J_2 term were calculated. The results of the calculation are shown as broken lines in Figs. 1 and 3. In this case, a single minimum of $\sigma\Lambda$ was obtained; the corresponding $\mathring{a}_{J_2}$ was close to the q values. Tables 5-B and 6-B summarize the results for $[Co(NO_2)(NH_3)_5]SO_4$ and $[Fe(phen)_3]SO_4$ respectively.

Tables 5-A and 5-B show that, in comparison with the parameters listed in Table 3, the Fuoss-Hsia equation gives the same values of Λ_0 within the limits of error, but the values of K_A and $\mathring{a}$ are a little larger than those obtained by means of the Fuoss-Onsager equation. On the other hand, Tables 6-A and 6-B show that the application of the Fuoss-Hsia equation to the

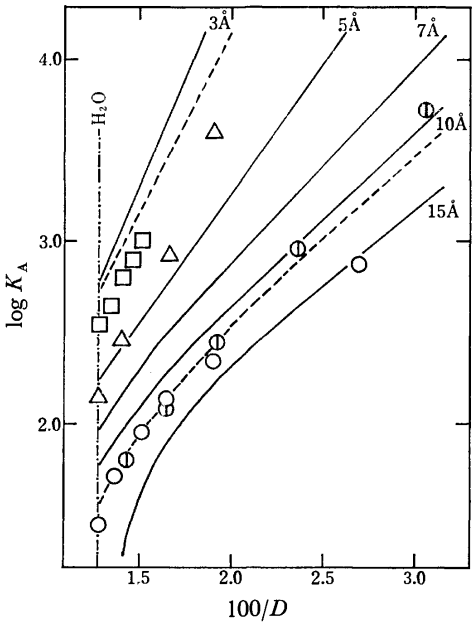

Fig. 3. Plot of log K_A *vs.* $1/D$.
□, $[Co(NO_2)(NH_3)_5]SO_4$ and ○, $[Fe(phen)_3]SO_4$, the present work at 25 °C. △, $MnSO_4$ in water–ethylene glycol and ⓘ, $[Fe(phen)_3]SO_4$ in water–methanol at 25 °C. Curves are theoretical curves due to Bjerrum's (——) and Yokoyama-Yamatera's (----) theories[9,16)] with each ion sizes.

$[Fe(phen)_3]SO_4$ data gives apparently better data, just fitting the results on the data of the salts in water–methanol. The association constant is estimated to increase with a decrease in the solvent dielectric constant. A conductance equation which contains higher terms than c seems to be required as the reference function in the analysis of the conductance data of slightly associated 2:2 electrolytes.

Fuoss has revised his conductance equation recently;[7)] also, an extended conductance equation[10)] including the $c^{3/2}$ term has been proposed by Pitts.[11,12)] These equations will have to be examined for the conductance data of a slightly associated 2:2 electrolyte. At present, the discussion is based on the results obtained by means of the Fuoss-Hsia equation.

Λ_0 value of $[Co(NO_2)(NH_3)_5]SO_4$ obtained here in water, 144.9, is about 2 units lower than that reported by Masterton and Bierly; the association constant obtained is also a little lower than their value. The ionic conductances of $[Co(NO_2)(NH_3)_5]^{2+}$ and $[Fe(phen)_3]^{2+}$ ions in water are obtained as 63.1 and 34.6 by subtracting the $\lambda_0^-=80.0$[13)] of the SO_4^{2-} ion from the Λ_0 values. The latter values are in accord with values, 34.8—34.9, reported by Yamamoto *et al.* in their conductance measurements of the chloride and the bromide in water.[14)] The ionic conductance of the aquo Co^{2+} ion has been reported as 52.8,[15)] while those of the $[Ni(en)_3]^{2+}$ and aquo Ni^{2+} ions were estimated as 58.9 and 49.4[16)] respectively. The substitution of the first hydration-sphere by a ligand gives the ion higher mobility. A large ligand like phenanthroline, which may cover more than the second hydration sphere, will decrease the mobility of the ion.

a) q, Bjerrum's distance (Å); $\mathring{a}_{J_1}$, ion-size parameter (Å); Table 1, a). b) Ref. 1.

In Fig. 3 the log K_A's of $[Co(NO_2)(NH_3)_5]SO_4$ and $[Fe(phen)_3]SO_4$ in water–ethylene glycol are plotted against the reciprocal of the dielectric constants of the solvents. The predictions of the ion association theories of Bjerrum[9] and Yokoyama-Yamatera[17] are shown as solid and dotted lines respectively for the specific contact distances. The data of $[Co(NO_2)(NH_3)_5]SO_4$ are on a straight line, which is located on Bjerrum's prediction corresponding to about 3.7 Å.

The size of the $[Co(NO_2)(NH_3)_5]^{2+}$ ion could be estimated from the X-ray crystal analysis data of $[CoCl(NH_3)_5]Cl_2$.[18] The minimum distance of the approach of the cobalt atom and chloride in the crystal is 4.2 Å. The crystal analysis data[19] of anhydrous sulfates of alkaline earth and first-transition metals gave effective radii of the sulfate ions ranging 2.3 to 2.5 Å. If the effective radius of $[Co(NO_2)(NH_3)_5]^{2+}$ is close to that of $[CoCl(NH_3)_5]^{2+}$, the closest distance of approach in the sulfate would be about 4.8 Å. This is larger than the distance found from the location of the log K_A-1/D plot in Fig. 3. The plot of the $MnSO_4$ data in the same solvent system[20] corresponds to a contact distance of 4.6 Å, judging from a comparison with Bjerrum's theory. The minimum distance of Mn^{2+} and SO_4^{2-} separation in the anhydrous $MnSO_4$ crystal is 3.3 Å.[19]

The above results suggest that the main species of association in the $MnSO_4$ solution might be a solvent-separated ion pair. The Mn–SO_4 distance separated by one water molecule would be about 4.8 Å, which is found as the closest distance between metal and sulfur in the $[Ni(OH_2)_6]SO_4$ crystal. On the other hand, in the $[Co(NO_2)(NH_3)_5]SO_4$ solution, the main species of association would be a contact-ion pair, as was suggested by Osugi *et al.* in their interpretation of the pressure dependence of the ion association constant.[12] Interaction between opposite-charged ions other than the coulombic attraction of opposite charges stabilizes the contact-ion pair. Masterton *et al.* suggested that the extra stability of the associated species comes from a dispersion interaction. D'Aproano and Fuoss[22] interpreted the high association constant of TlCl in water–dioxane mixture by calculating the energies due to the interaction between the charges and the induced dipoles. In a 1:1 cobalt complex salt solution, an extra stability of associated species sometimes promotes the K_A value to an order higher.[4] In a 2:2 electrolyte, however, the effect of extrastabilization is not so remarkable as in the 1:1 salt solution, since the charge-charge interaction energy is larger; yet it is clear that the effect is maintained independently of the macroscopic dielectric constant of the solvent.

The data of the log K_A of $[Fe(phen)_3]SO_4$ in water–methanol are plotted in Fig. 3 for purposes of comparison. The plots for the two solvent systems coincide with each other in the water-rich solvent range, but deviate in a high organic solvent content medium. This suggests that solvent-separated association species may contribute by some extent. The overall data points are located close the Yokoyama-Yamatera theory of 10 Å.

In this case, the cation is large enough and is not easily polarizable, and the specific interaction with the sulfate ion contributes little to the extra stability of the contact-ion pair.

All the calculations were performed on HITAC 10-II remote-batch system, FACOM 230-60, and HITAC 8800/8700 computers using the program of FORTRAN IV. The authors wish to thank the staffs of the Shinshu University Remote Batch Computation Center, Nagoya University Computation Center, and Tokyo University Computation Center for the use of the computers.

Department of Materials Science and Technology, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812

(Received December 6, 1976)

The catalytic NO reduction with NH_3 over Cu(II) ion-exchanged zeolite was studied with special attention to the temperature dependence of catalytic activity which reaches maximum at *ca.* 120 °C. ESR study showed that in the catalytic system all the exchanged copper ions exist as Cu(II) up to *ca.* 120 °C, above which Cu(II) ions decrease with a rise in temperature. The reaction rates measured at 110 and 140 °C were found to show similar dependence on both NO and NH_3 partial pressures, indicating that the reaction mechanism does not differ much. By lowering temperature the Cu(I) ions formed at higher temperatures were reoxidized to Cu(II), accompanied by N_2O formation due to the disproportionation of NO. From the results and the IR spectroscopic data a reaction mechanism was proposed. It includes a step in which NO reacts with NH_3 adsorbed to Cu(II) ions to give rise to the evolution of N_2 and the reduction of Cu(II) ions, and steps in which Cu(II) ions are regenerated accompanying the evolution of N_2+N_2O.

The catalytic reduction of nitrogen oxide with ammonia is important from the standpoint of removal of air pollutants. For the reduction we found that Cu(II) ion-exchanged zeolite exhibits pronounced unique catalytic activity.[1,2] In addition to the significant catalytic activity shown at temperatures below 100 °C, a characteristic bell-shaped temperature dependence with a maximum appearing at *ca.* 120 °C was observed. This catalytic reaction is not only of practical importance with its low temperature performance, but it also gives a case in which complex formation and redox change of the exchanged metal ions within the zeolite framework take place reversibly. These are in marked contrast to the case of Co(II) ion-exchanged zeolites, first reported by Windhorst and Lunsford,[3] in which Co(II) ions are reactive to the mixture of NO and NH_3 in a similar temperature region but are irreversibly oxidized to unreactive Co(III).

The catalytic NO reduction with NH_3 over Cu(II) ion-exchanged zeolite, however, remains unclarified as regards the path and mechanism of the reaction and the role of copper ions. We have investigated the problems by means of ESR spectroscopy, IR spectroscopy, and reaction kinetics. Efforts were made to elucidate the bell-shaped correlation between the catalytic activity and temperature. A kind of temperature jump method was applied to pursue the transient phenomena observed when the catalytic system was forced to shift from one stationary state to another, especially in relation to the regeneration step of Cu(II) ions from Cu(I).

Experimental

Partly Cu(II) ion-exchanged zeolites, Cu(II)NaY and Cu(II)NaX, were prepared by treating Linde Y and X zeolites with aqueous $CuSO_4$ solutions. The ion-exchanged samples were thoroughly washed with deionized water and dried at 100 °C. The ion-exchange levels of Cu(II) were determined by X-ray fluorometry.

The ESR spectra of Cu(II) ions were recorded in the X-band region at room temperature with a Hitachi 771 spectrometer, by using 2,2-diphenyl-1-picrylhydrazyl (DPPH) standard ($g=2.0036$).

IR spectra were recorded with a JASCO-IR-G spectrophotometer in the double beam absorbance mode. The infrared cell consists of a Pyrex glass fitted with potassium bromide windows. The cell allowed heating of the sample wafer at elevated temperatures measured with a thermocouple in contact with the wafer. The sample wafer, 20 mm diameter, was prepared by pressing the exchanged zeolite powder (*ca.* 10 mg) at 100 kg/cm^2.

Stationary as well as non-stationary reactions between NO and NH_3 were carried out in a fixed bed flow reactor under an atmospheric pressure. The gas composition was analyzed by gas chromatography.

Results

Oxidation State of Copper Ions. For the catalytic NO reduction with NH_3, Cu(II) ion-exchanged zeolite exhibits catalytic activity with unique temperature dependence.[1,2] A typical activity *vs.* temperature profile of a convex bell-shape is exemplified by curve (a) in Fig. 1 where activity is given in terms of the conversion of NO. The reaction products are N_2, N_2O, and H_2O.

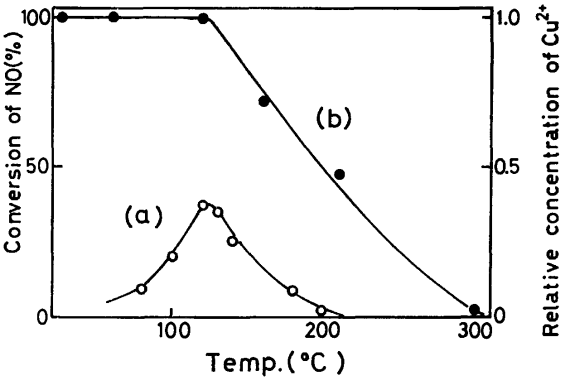

Fig. 1. Changes in catalytic activity (a) and in Cu(II) concentration (b) with temperature in the catalytic NO–NH_3 reaction over copper ion-exchanged Y zeolites.
Feed; NO (3%)+NH_3 (2%)+He,
Contact time; 1.0 g·s/mol.

The selectivity for N_2O ($N_2O/(N_2+N_2O)$) is little influenced by the reaction temperature. It seems that such an activity profile is correlated with the change in oxidation state of the copper ions present in the zeolite framework, as observed by the change in the coloration of catalysts. The correlation was first examined by ESR study as follows.

Cu(II)NaY zeolite with 60% cation exchange (150 mg) was loaded as a catalyst bed in a Pyrex glass tube of o.d. 3.5 mm, which was thereafter connected to a gas flow system. After heating the catalyst bed to the desired temperature, a stream (10 cm^3/min) of gas mixture of NO (3%), NH_3 (2%), and He (95%) was introduced. The same composition and contact time as those used to obtain curve (a) in Fig. 1 were selected. After treatment for 4 h, which was found to be sufficient for the catalytic system to reach a stationary state, the catalyst was purged of the gaseous compounds at the same temperature for 15 min by He stream. The Pyrex glass tube containing the catalyst was then removed from the flow system, and the catalyst was subjected to ESR measurement at room temperature. Figure 2

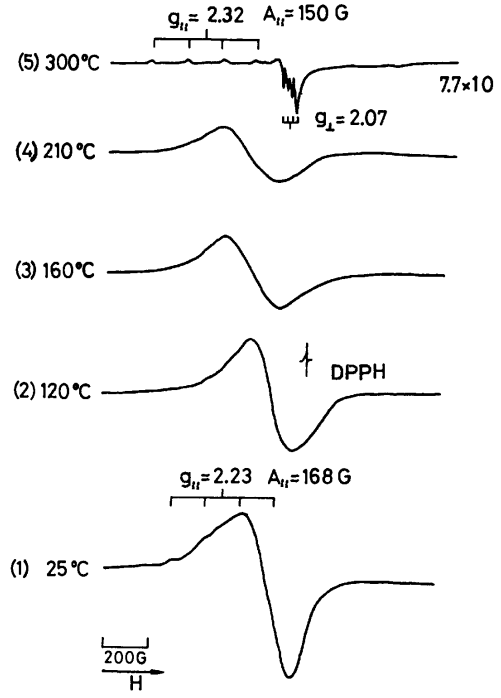

Fig. 2. ESR spectra of Cu(II) ions for a 60% copper ion-exchanged Y zeolites treated by NO (3%)+NH_3 (2%) at various temperatures.

shows ESR spectra of Cu(II) ions recorded after the treatment at various temperatures. All the spectra were taken for one and the same sample by subjecting it to repeated treatment. The signals except (5) turned or nearly turned in to symmetric ones due to high Cu(II) concentrations. Spectra (1) and (2) can be ascribed to square planer Cu(II)$(NH_3)_4$ ($g_{//}$=2.23, $A_{//}$=1.68 G),[4] while (3) and (4) agree with the spectra recorded for partially dehydrated Cu(II)NaY. The decrease in Cu(II) concentration at elevated temperatures made the hyperfine structure of the signal to appear in spectrum (5); g values ($g_\perp$=2.07, $g_{//}$=2.32, $A_{//}$=150 G) show that the Cu(II) center is dehydrated and probably located at site I or I'.[5] It is evident that the Cu(II) ions exchanged in the zeolite exist mostly as tetraammine complexes below 120 °C, above which the complexes are replaced by partially or entirely dehydrated Cu(II) ions. No particular evidence was obtained for the formation of distorted tetrahedral Cu(II)–NH_3 complexes reported by Vansant and Lunsford.[5]

By double integration of the ESR signals the concentrations of Cu(II) ions were determined relative to that obtained after the treatment at 25 °C. They are plotted against temperatures (curve (b), Fig. 1). The Cu(II) concentration remains up to 120 °C, but decreases monotonously at higher temperatures. The decrease in Cu(II) concentration is related to that in catalytic activity shown by curve (a). However, agreement of the two curves is not satisfactory in detail. With rise in temperature, the activity falls more rapidly than Cu(II) concentration. At 200 °C, the activity is almost completely lost but the Cu(II) concentration remains near 50% level. The discrepancy seems to be correlated to the distribution of Cu(II) ions over several sites in the zeolite framework; the Cu(II) ions present above 200 °C are mostly located at inactive "locked-in" sites within the sodalite cage or hexagonal prism.

In dehydrated Cu(II)NaY zeolite, Cu(II) ions show rather strong preference to the "locked-in" sites.[6,7] In the presence of water or ammonia, however, the the Cu(II) ions are pulled toward the supercage by complex formation as reported by Huang and Vansant.[8] Under the present reaction conditions, the catalytic activity of Cu(II)NaY catalyst at 120 °C has been found to be proportional to the Cu(II) ion-exchanged level.[2] This indicates that at temperatures below 120 °C the Cu(II) ions are dominantly present in the supercage and act as active catalytic sites. Above 120 °C, however, the present ESR study shows that complex formation of Cu(II) with NH_3 or water molecules becomes increasingly difficult. This might be the reason for the Cu(II) ions returning to the "locked-in" sites at higher temperatures. The decrease in catalytic activity above 120 °C (curve (a)) results from a decrease in Cu(II) concentration within the supercage, which is caused partly by the reduction of Cu(II) ions to Cu(I) and partly by the migration of Cu(II) ions towards the "locked-in" site.

Reaction Kinetics. The reaction kinetics of the NO reduction with NH_3 over Cu(II)NaY catalysts was studied at 110 and 140 °C in a flow system. The temperatures were so chosen as to include the temperature for maximum activity (120 °C). As a result, the reaction rates at both temperatures were found to be expressed by empirical equations of the following form;

$$r = -\frac{dP_{NO}}{dt} = k_1 P_{NO}^n P_{NH_3}^m, \quad (1)$$

where P_{NO} and P_{NH_3} denote the partial pressures of nitrogen oxide and ammonia, respectively, and k_1 is a rate constant. P_{NO} and P_{NH_3} were varied in the range 0.01—0.08 atm. The reaction orders, n and m, obtained at 110 and 140 °C are given in Table 1. The difference in reaction temperature affects both n and m only slightly.

Table 1. Reaction orders on NO and NH_3 (Eq. 1) in the NO and NH_3 reaction over a Cu(II)NaY catalyst (Contact time; 1.0 g · s/cm³)

Temp (°C)	n	m	k[a]
110	1.0	0.63	2.45×10^{-4}
140	0.92	0.53	0.79×10^{-4}

a) Mols NO/s · (atm)$^{n+m}$ · g.

The rate data were found to satisfy the following expression within experimental errors at both temperatures.

$$r = \frac{k_2 P_{NO} P_{NH_3}}{(1+K_{NH_3}P_{NH_3})^2}. \quad (2)$$

This was derived by assuming a Langmuir-Hinshelwood type of reaction between weakly adsorbed NO and strongly adsorbed NH_3. Here, K_{NH_3} is the adsorption equilibrium constant and k_2 is a constant. It turned out subsequently, however, that the rate data also satisfy the equation

$$r = \frac{k_3 P_{NO} P_{NH_3}}{(1+K_{NH_3}P_{NH_3})}, \quad (3)$$

which implies that NO weakly adsorbs on sites different from those for NH_3 or that a Redeal type of reaction takes place between NO and adsorbed NH_3. Differentiation between (2) and (3) was difficult on the basis of kinetic data only. However, the results of IR study suggest that (3) appears to be more appropriate. The kinetic scheme does not change much for the two temperatures. Kinetic study also revealed that selectivity of the N_2O formation is slightly dependent upon the contact time as shown in Fig. 3. The selectivity ratio N_2/N_2O was extrapolated to exactly 2: 1 at contact time 0. The increase of the ratio at longer contact times indicates a consecutive reduction of N_2O to N_2.

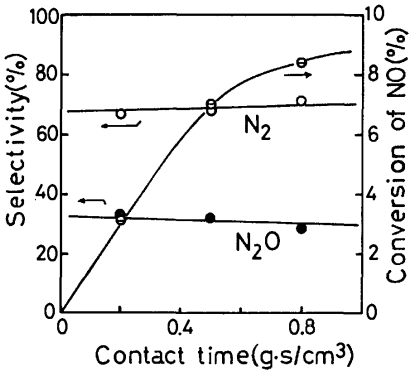

Fig. 3. Effect of the contact time on the conversion and selectivity of the NO-NH_3 reaction.

IR Study on NO-NH_3 Reaction. IR study was carried out to pursue *in situ* the reaction between NO and NH_3 over Cu(II)NaY catalysts. NH_3 undergoes adsorption on both the zeolite skeleton and the Cu(II) ions exchanged. The latter amounts to 3—4 NH_3 molecules per Cu(II) ion at room temperature in agreement with the result of Lunsford *et al.* who reported the formation of tetraammine complexes of Cu(II) ions in the zeolite cavity.[4] As for the NO adsorption, *ca.* one NO molecule is adsorbed per Cu(II) ion at room temperature with no detectable adsorption on the zeolite skeleton.

The results of IR spectroscopic study of the reaction at room temperature are shown in Figs. 4 and 5. A 32% Cu(II) ion-exchanged zeolite was used. The zeolite wafers were evacuated for 4 h at 400 °C in the IR cell before experiments. Introduction of NO over Cu(II)NaY gave curve 2 in Fig. 4. A strong absorption band at 1910 cm^{-1} is attributable to the stretching of the

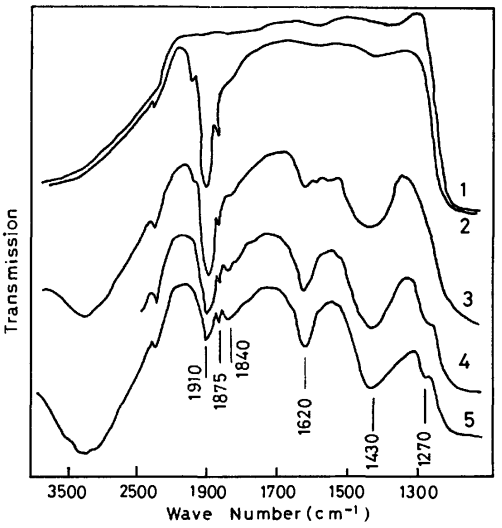

Fig. 4. Infrared spectra produced on introduction of NH_3 over a Cu(II)NaY preadsorbing NO (recorded at 25 °C). (1) Cu(II)NaY after evacuation at 400 °C for 4 h. (2) 30 min after the exposure to NO (49.5 Torr) at 25 °C. (3), (4), and (5) 30, 60, 180 min after the introduction of NH_3 (8 Torr) to (2), respectively.

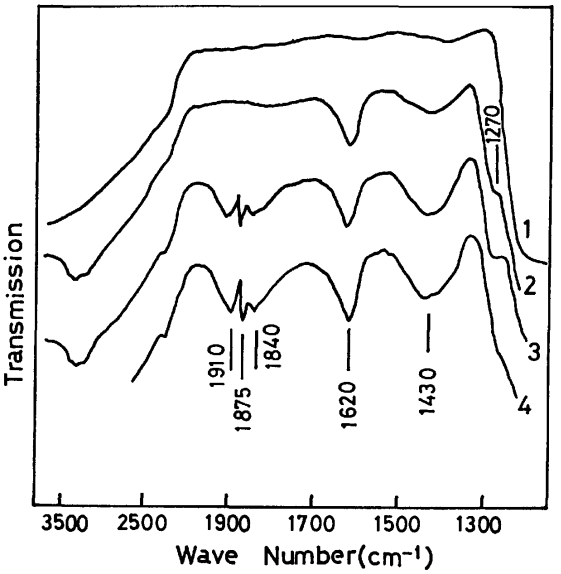

Fig. 5. Infrared spectra produced on introduction of NO over a Cu(II)NaY preadsorbing NH_3.
(1) Cu(II)NaY after evacuation at 400 °C for 4 h. (recorded at 25 °C). (2) Cu(II)NaY evacuated for 30 min after the adsorption of NH_3 (0.75 Torr) at 25 °C. (3) 60 min after the introduction of NO (64 Torr) to (2) at 25 °C. (4) After heating of (3) to 80 °C.

adsorbed NO, as first reported by Tarrit *et al.*[9] Bands at 1875 cm^{-1} are ascribable to gaseous NO. Gaseous NO shows a typical rotation-vibration spectrum with its Q branch centered at 1875 cm^{-1}, as exemplified by curve 2 or 3 in Fig. 5. A band at 2240 cm^{-1} is due to gaseous N_2O, mainly brought about as an impurity contained in NO gas. Curves 3, 4, and 5 in Fig. 4 were recorded 30, 60, and 180 min respectively after the addition of NH_3 (8 Torr). The band at 1910 cm^{-1} became weaker with the elapse of time while the intensities of the band at 1620 cm^{-1} and a broad one at 1430 cm^{-1} increased. A shoulder at 1270 cm^{-1} is a characteristic band due to the symmetric deformation vibration of NH_3 contained in $Cu(II)(NH_3)_4$.

NH_3 was adsorbed prior to the introduction of NO (Fig. 5). In curve 1, bands at 1270 and 1620 cm^{-1} and a broad band around 3300 cm^{-1} are ascribable to adsorbed NH_3, while a broad band around 1430 cm^{-1} is due to the deformation vibration of NH_4^+ formed. Major changes in the spectra caused by the introduction of gaseous NO (64 Torr) were the increase of the broad band centered at 1430 cm^{-1} and the slight increase of the band at 1620 cm^{-1}. Bands in 1910—1840 cm^{-1} of curves 2 and 3 are attributed to gaseous NO. Throughout Figs. 4 and 5, there is no evidence for the formation of nitrosyl ammine complex of Cu(II) ions. The NO adsorption is much weaker as compared with NH_3 adsorption. The adsorbed NO is easily replaced by NH_3. This makes the Langmuir-Hinshelwood type of reaction between adsorbed NO and adsorbed NH_3 (Eq. 2) less plausible. The reaction between NO and NH_3 gives rise to a remarkable increase in intensity of the broad band around 1430 cm^{-1}. It is probable that this band is in fact a composite of bands responsible for NH_4^+ and some other adsorbates. It seems that in this case the absorption of NO_2^- overlaps that for NH_4^+. NO_2^- shows absorption at 1430 and 1330 cm^{-1} in $[Co(NH_3)_nNO_2]^{2+}$, and at 1630, 1420, 1332, and 1260 cm^{-1} in $K_2Ba[Cu(NO_2)_6]$.[10,11]

Regeneration of Cu(II) from Cu(I). The bell-shaped dependence of the catalytic activity of Cu(II)-NaY catalysts implies that a reversible redox change occurs between Cu(II) and Cu(I) with the change in reaction temperature. Elucidation of the redox step is considered to contribute to the understanding of the catalytic reaction. A study was made on how the Cu(I) ions produced in the catalytic reaction at high temperature were reoxidized by lowering temperature in the same system. The experiments were performed in a flow system as well as in a pulse reactor. In the flow experiments, either a gas of NO (3%), NH_3 (2%), and He (95%) or a purge gas of He was allowed to flow (60 cm^3/min) over the catalyst bed. Cu(II)NaY with 60% cation exchange were first treated in a stream of the gas mixture at 300 °C for 4 h and then purged by He stream for 15 min. Almost all the Cu(II) ions were reduced to Cu(I) as revealed by ESR. The reduced sample was then cooled to the desired temperature and brough again into contact with the flow of the gas mixture. This caused a transient reaction to occur until a stationary catalytic reaction between NO and NH_3 was reached. The stationary state was reached

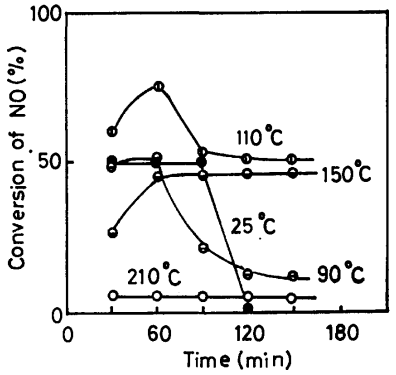

Fig. 6. Time course of NO conversion observed when gas mixture NO (3%)+NH_3 (2%) was contacted to reduced copper ion-exchanged Y zeolites at various temperatures.

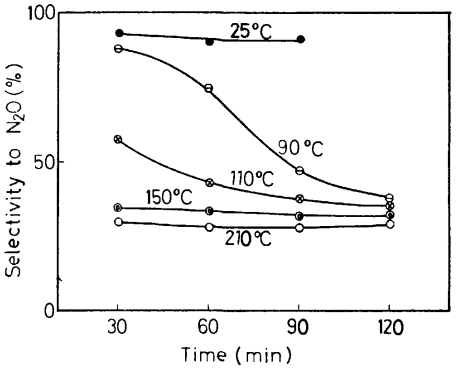

Fig. 7. Time course of the slectivity to N_2O, corresponding to Fig. 6.

within 60 min at 150 °C and above, while a period longer than 2 h was required at 90 °C and below.

The transients in conversion of NO and in selectivity for N_2O formation are shown in Figs. 6 and 7, respectively. The former transients are complicated. Selectivity for N_2O formation, on the contrary, showed monotonous decreases with time from the initial values to the stationary ones near 1/3 except for the case at 25 °C, where no stationary reaction proceeded at a

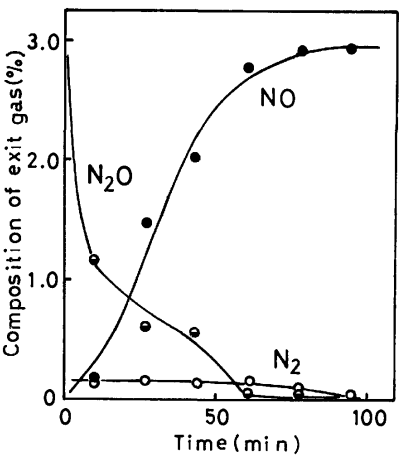

Fig. 8. Time course of N_2O and NO formation observed when NO (3%)+NH_3 (2%) was contacted to a reduced copper ion-exchanged 13X zeolites at 15 °C. Contact time; 1.0 g·s/cm^3.

significant rate. The high N_2O selectivity at the initial period, especially at lower temperatures, suggests that the transient reaction is connected to the reoxidation of Cu(I) to Cu(II). The transients at 15 °C are described in more detail in Fig. 8. In this case, Cu(II)Na 13X with 66% Cu(II) ion-exchanged was used after the reduction. The consumption of NO decreased rapidly with time until it ceased within *ca.* 1 h. A corresponding change took place in the evolution of N_2O, while N_2 formation in small quantities decreased more gradually over a longer reaction period. The color of the catalyst turned rapidly into pale greyish blue on contact with the gas mixture, and then gradually into blue developing from an upstream end of the catalyst bed to another. When the catalyst became entirely blue, N_2O formation stopped. The greyish blue might be due to the complex formation of a trace amount of unreduced Cu(II) ions with NH_3. The blue coloration is ascribable to the ammine complex of the Cu(II) ions regenerated.

The transient reaction at 15 °C was examined by a pulse reaction technique in order to obtain quantitative information. It was found that 2.7 mol of NO and 0.8 mol of N_2O are consumed and formed, respectively, to regenerate 1.0 mol of Cu(II). This strongly indicates the following disproportionation reaction.

$$Cu(I)(NH_3)_m \xrightarrow{+3NO} Cu(II)(NH_3)_mNO_2^- + N_2O \quad (4)$$

The reaction was found to proceed only in the presence of NH_3. After the completion of reaction, the catalyst, when heated at 150 °C in the same atmosphere, evolved a large amount of N_2 presumably by the following reaction.

$$Cu(II)(NH_3)_mNO_2^- + NH_4^+{}_{ad} \longrightarrow Cu(II)(NH_3)_m + N_2 + 2H_2O \quad (5)$$

Nitrite ion NO_2^- is known to react with NH_4^+ to produce N_2. Reaction (5) is considered to be slow at 25 °C, judging from the prolonged evolution of a small amount of N_2 (Fig. 8).

Discussion

From the results, we propose the following reaction path for the steady reaction between NO and NH_3 over Cu(II)NaY catalysts.

$$Cu(II)(NH_3)_n + NO \longrightarrow Cu(I)(NH_3)_m + N_2 + H_2O + (n-m-1)NH_3 + H^+{}_{ad} \quad (6)$$

$$H^+{}_{ad} + NH_3 \longrightarrow NH_4^+{}_{ad} \quad (7)$$

$$Cu(I)(NH_3)_m + 3NO \longrightarrow Cu(II)(NH_3)_mNO_2^- + N_2O \quad (8)$$

$$Cu(II)(NH_3)_mNO_2^- + NH_4^+{}_{ad} \longrightarrow Cu(II)(NH_3)_m + N_2 + 2H_2O \quad (9)$$

$$Cu(II)(NH_3)_m + (n-m)NH_3 \longrightarrow Cu(II)(NH_3)_n \quad (10)$$

$$4NO + 2NH_3 \longrightarrow 2N_2 + N_2O + 3H_2O \quad (11)$$

Here, n and m are the numbers of NH_3 molecules coordinating to a Cu(II) ion, probably 4 and 2, respectively, because of the complexes $Cu(II)(NH_3)_4$ and $Cu(I)(NH_3)_2$. Reaction (6), initiated between NO and coordinated NH_3, produces N_2, H_2O, and an atomic hydrogen, the last species of which reduces a Cu(II) ion to Cu(I) through a electron transfer. The H^+ produced is adsorbed on the framework oxygen of zeolite, being ammoniated to form NH_4^+ according to Reaction (7). Reactions (6) and (7) are supported by the result of IR study which shows that the band intensity of NH_4^+ at 1430 cm^{-1} for NH_3-preadsorbed Cu(II)-NaY increases on contact with NO. Reaction (8), which is identical with Reaction (4), is applied to regenerate Cu(II) ions. The NO_2^- produced then reacts with NH_4^+ by Reaction (9) to evolve N_2. The overall reaction is reduced to Reaction (11) which explains the observed N_2O selectivity at zero contact time.

The bell-shaped temperature dependence of catalytic activity is explained as follows. At temperatures lower than 120 °C, Reaction (6) is slow and rate-determining. Above 120 °C, on the other hand, it is presumed that Reaction (8) becomes less and less favored with an increase in temperature, causing the stationary Cu(II) concentration and therefore the steady reaction rate also to decrease with increasing temperature.

Reaction (8) can formally be separated into the following two reactions.

$$3NO \longrightarrow NO_2 + N_2O \quad (12)$$

$$Cu(I)(NH_3)_m + NO_2 \longrightarrow Cu(II)(NH_3)_mNO_2^- \quad (13)$$

The disproportionation reaction of NO on zeolites was first reported by Addison and Barrer.[12] They found that over unexchanged zeolites the reaction is fast at dry ice temperature or at 0 °C but very slow at 25 °C. Regarding Reaction(13), Kasai and Bishop reported that addition of NO_2 to Cu(I)NaY at room temperature restores the ESR signal of Cu(II) instantaneously.[13] The important result in the present study is that Reaction (8) proceeds only in the presence of NH_3. This implies that Reaction(8) can not be separated into Reactions(12) and (13). The crucial role of NH_3 for Reaction (8) may come from two possible effects.

(1) The redox potential between Cu(I) and Cu(II) is lowered by the formation of ammine complexes; it is 0.153 eV for $Cu(I) \rightarrow Cu(II) + e$, whereas −0.01 eV for $Cu(I)(NH_3)_2 + 2NH_3 \rightarrow Cu(II)(NH_3)_4 + e$.

(2) The location of copper ions in the zeolite framework is affected by the presence of NH_3. As a result of coordination, NH_3 pulls out copper ions from the sodalite cage or hexagonal prism toward the supercage in which the copper ion becomes more easily accessible for reactants.

Which of the two effects is more dominant can not be distinguished at present. However, the same effects can be operative for the depression of the reaction rate above 120 °C. The dissociation pressure of NH_3 for $CuSO_4 \cdot 4NH_3 \rightarrow CuSO_4 \cdot 2NH_3 + 2NH_3$ is 0.08 atm at 120 °C.[14]

It is of interest to compare the present reaction with the oxidation of ammonia with oxygen over Cu(II)NaY catalyst reported by Williamson *et al.*[15] In the latter reaction, the rate was found to show first and zero orders with respect to NH_3 and O_2, respectively, and was concluded to be solely determined by a step in which Cu(II) ions are reduced to Cu(I) by NH_3. There are several marked contrasts between the reactions of

NH_3–NO and NH_3–O_2.

(1) The dependence of the rate on the NH_3 partial pressure differs entirely for the two reaction. This reflects that, unlike the NH_3–O_2 reaction, the NH_3–NO reaction does not follow a simple redox mechanism.

(2) The NH_3–NO reaction is characterized by the bell-shaped temperature dependence, whereas the rate of the NH_3–O_2 reaction shows a normal increase with increasing temperature. This indicates that, at higher temperatures, the reoxidation of Cu(I) to Cu(II) is much slower in the former case. This would be important when the NH_3–NO reaction is carried out in the presence of oxygen.

ESR of Hot Ions: Low Spin Pt(III) Complex Ions Produced by γ-Irradiation

Chikara AMANO* and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 9, 1976)

Tervalent platinum complex ions have been observed by the electron spin resonance method upon γ-irradiation of both bivalent and quadrivalent complexes. From their g-values, the tervalent complex ions can be classified into two types, one axially symmetric and the other rhombic, the former having typical g-values of 2 ($g_{//}$) and 2.4($g_{\perp}$), and the latter a g_1-value slightly lower than the free electron value of 2.0023. It has been shown by means of ligand field theory that both types have $5d^7$ low spin electron configuration. The hyperfine interaction due to ^{195}Pt is one order of magnitude larger than that in cobalt complexes with $3d^7$ low spin configuration, indicating that the configuration interaction involving 6s-orbital is more important than that for 3d transition metal complexes involving 4s-orbital, and that 5d electrons penetrate deeply into inner shells, resulting in core polarizarion.

γ-Irradiation produces metal complex ions with unusual valence states, Co^{2+}, Ni^{+}, Pd^{+}, Zn^{+}, Cd^{+} *etc.*[1-4] All these hot ions are produced through reduction of original complexes having the usual valence. Thus univalent platinum complexes which seem to have $5d^9$ electron configuration are expected to be produced by γ-irradiation of bivalent complexes. The electronic states of transition metal ions belonging to the 5d group remain unclarified. Neither visible nor ultraviolet absorption spectra have been assigned to any transitions between multiplet states, and the order of one-electron energy levels has not been established. Almost all the complexes with d^9 electron configuration studied thus far show the same type of g-value: $g_{//}>g_{\perp}>2$. It has not been clarified whether univalent platinum complexes show this type of g-value.

In the present work eleven bivalent platinum complexes and three quadrivalent ones were γ-irradiated at 77 K and their ESR spectra were recorded. The present paper reports on a new valence state of tervalent platinum complex ions along with a discussion on their electronic state.

Experimental

Both platinum metal and hydrogen hexachloroplatinate(VI) ($H_2PtCl_6 \cdot 6H_2O$) were used to synthesize bivalent and quadrivalent platinum complexes. Copper(II) ions contained in commercial $H_2PtCl_6 \cdot 6H_2O$ were removed in synthetic processes; they were not found in potassium tetrachloroplatinate(II). The complexes subjected to γ-irradiation are summarized in Table 1. Each complex of polycrystalline state was put into a radiation-protected sample tube for ESR measurement, in 50—100 mg amount. The sample tubes were immersed in liquid nitrogen and subjected to γ-irradiation at 77 K. They were inverted on γ-irradiation, the upper half of the tubes shielded with lead blocks to prevent production of paramagnetic centers. The tubes were again inverted before ESR measurement. The total dose was 10^6 R with a 5×10^4 R/h dose rate at 77 K, and 10^7 R with a 5×10^5 R/h dose rate at room temperature. ESR spectra were recorded with a JEOL 3BSX spectrometer.

Results and Discussion

$[Pt(py)_4]Cl_2 \cdot 3H_2O$. The ESR absorption shown in Fig. 1 was obtained on γ-irradiation of a polycrystalline sample. The strong absorption at about 2800 G shows a large g-shift ($\Delta g=g-2.0023$), which suggests that the paramagnetic center is due to a platinum complex; the large g-shift is caused mainly by the strong spin-orbit interaction. Platinum has a large spin-orbit coupling constant, *e.g.* 3368 cm^{-1} for Pt^+ ion.[5] The strong singlet line is accompanied by weak doublet satellite lines at 2300 and 3100 G. The doublet

D	d^7	$^2B_{1g}$	$2+(4+8a_1b_1)\zeta/E(^2B_{2g})^a)$ $+(4+8a_2b_2)\zeta/E(^2B_{2g}{}^b)$[b]	$2+(1+2a_1b_1)\zeta/E(^2E_g{}^a)$ $+(1+2a_2b_2)\zeta/E(^2E_g{}^b)$	$g_{//}>g_{\perp}>2$

a) Energy value of multiplet when that of the ground multiplet is set to zero. b) $a_1=-10B/\{(4B+C+A)^2+100B^2\}^{1/2}$, $b_1=(4B+C+A)/\{(4B+C+A)^2+100B^2\}^{1/2}$, $a_2=-10B/\{(4B+C-A)^2+100B^2\}^{1/2}$, $b_2=(4B+C-A)/\{(4B+C-A)^2+100B^2\}^{1/2}$, $A=(116B^2+8BC+C^2)^{1/2}$. A, B, and C are Racah's parameters.

has a large splitting of *ca.* 800 G, presumably due to the hyperfine interaction with ^{195}Pt, only one stable isotope with nonzero nuclear spin 1/2. Since the natural abundance of ^{195}Pt is 33.8%, the relative absorption strength of one of the doublets to the main singlet should be 1/4 (Fig. 1). The shift of the singlet from the center of the doublet toward upper field is due to the large hyperfine interaction with ^{195}Pt nucleus.[6] The spectral feature shows that the paramagnetic platinum complex ion produced takes axial symmetry and the absorption at 2800 G is a perpendicular component. The parallel component should be much weaker than the perpendicular one. It would be observed near 3300 G, where the strong absorption of unidentified radicals obscures the observation of the parallel component. Careful investigation shows that no parallel component was found at any other magnetic field strength.

The value of $g_{\perp}$ was found to be 2.377 ± 0.002, which can be directly calculated from the main singlet line, that of $g_{//}$ being probably 2. The principal value of the hyperfine splitting tensor due to ^{195}Pt, $A_{\perp}$, also obtained by use of the usual second order perturbation formula, is 877×10^{-4} cm^{-1}.[6]

As regards the valence state of paramagnetic platinum complexes, two possibilities should be considered, univalent complexes with $5d^9$ electron configuration and tervalent complexes with $5d^7$ electron configuration. The g-values for possible ground states for these two valences have been calculated by means of ligand field theory (Table 2).[2] The experimental g-values are consistent in cases B and C. However, B corresponds to the structure of uniaxially compressed D_{4h}, found to be very rare for d^9 configuration, while C corresponds to the uniaxially elongated structure, which seems reasonable in consideration of the tetragonaly four-coordinated structure of the original complex. The complexes having d^7 low spin configuration have been shown to take this multiplet in several cases.[7,8] Thus, the paramagnetic center observed can be assigned to a tervalent platinum complex ion which takes $^2A_{1g}$ as the ground multiplet, having one unpaired electron in $5d_{z^2}$ orbital.

In contrast to the transition metal complexes of the 3d group, no systematic studies have been made on the electronic state of the 5d group. Optical absorption spectra of some Pt(II) complexes were studied by Chatt, Gamlen, and Orgel.[9] The order of the one electron energy level for $[PtCl_4]^{2-}$ was determined: $5d_{x^2-y^2}>5d_{xy}>5d_{yz,zx}>5d_{z^2}$, though the position of $5d_{z^2}$ was uncertain. However, it seems difficult to assign an absorption band to a certain transition between multiplets because of the presence of strong spin-orbit coupling. Krigas and Rogers studied γ-irradiation of $K_2[PtCl_4]$ by the ESR method and found the formation of $[PtCl_5]^{2-}$ with $5d^7$ electron configuration.[10] Since the original $[PtCl_4]^{2-}$ takes a tetragonally four-coordinated structure, one chlorine ion appears to be attached to the axial position in the course of oxidation. It is concluded that one electron energy level of $[PtCl_5]^{2-}$ has the order: $5d_{x^2-y^2}>5d_{z^2}>5d_{xy}>5d_{yz,zx}$. The unusually high energy of $5d_{z^2}$ was explained to be caused by the presence of the axial chloride ion. The present g-values of $[Pt(py)_4]^{3+}$ are also in line with this order. However, there can be no chloride ion at the axial position, since the absorption of the perpendicular part (Fig. 1) has a very narrow width of about 20 G, showing neither hyperfine splitting by chlorine nucleus nor line broadening due to unresolved structure by chlorine.

Let us compare the hyperfine splitting of $[Pt(py)_4]^{3+}$ with that of bivalent cobalt complexes having $3d^7$ low spin configuration. A comparison between tervalent nickel and tervalent palladium and tervalent platinum complexes would have been preferable, but we could not obtain the A-values of either tervalent nickel or tervalent palladium of low spin type. We chose β-cobaltphthalocyanine as an example, since this is one of the few bivalent cobalt complexes taking low spin configuration. A-values of β-cobaltphthalocyanine have been reported to be 160×10^{-4} cm^{-1} ($A_{//}$) and 280×10^{-4} cm^{-1} ($A_{\perp}$).[7] In order to see the effect of electron orbitals, we compared the values which can be obtained by dividing the experimental A-values by nuclear moment of each isotope. They are 60.3 for the cobalt complex and 1480 for the platinum complex on a ceartin scale, which shows that the latter is about twenty times greater than the former. In 5d transition metal complexes the valence electrons mainly in metal 5d orbitals could penetrate deeply near the metal nucleus because of the incomplete shielding of the nuclear potential by the other inner closed shell electrons, resulting in large core polarization.

$K_2[Pt(NO_2)_4]\cdot2H_2O$. There is a strong absorption at 2500 G with a weak satellite at 1900 G (Fig. 2). This should be due to platinum complexes because of the large g-shift and the large hyperfine splitting. From the line shape this can be ascribed to the perpendicular component, which splits slightly to form g_2 and g_3 component. A parallel component is also observed at

Table 3. ESR parameters of low spin Pt^{3+} complexes

A) Axial symmetry

Complexes	$g_{//}$	$g_{\perp}$	$A_{//}$	$A_{\perp}$ (10^{-4} cm^{-1})
$[Pt(py)_4]^{3+}$	(≈2)	2.377	—	877
$[Pt(NH_3)_4]^{3+}$	(≈2)	2.395	—	940
cis-$[Pt(py)_2Cl_2]^{+}$	(≈2)	2.544	—	768
$[PtCl_6]^{3-}$	(≈2)	2.659	—	591

B) Rhombic symmetry

Complexes	g_1	g_2	g_3	A_1	A_2	A_3 (10^{-4} cm^{-1})
$[Pt(gly)_2]^{+}$	1.939	2.338	2.674	1025	—	1210
$[Pt(NO_2)_4]^{-}$	1.910	2.572	2.622	1690	—	—

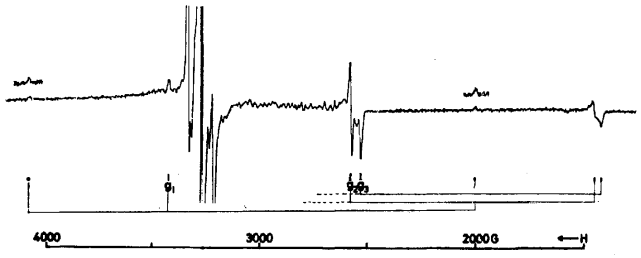

Fig. 2. The ESR spectrum of $[Pt(NO_2)_4]^{-}$ produced by γ-irradiation. The splitting of $g_{\perp}$ part shows the small distortion of ligand configuration.

slightly upper field than that of strong absorptions due to unidentified radicals with *g*-value of 2. Very weak satellites are observed at both 2000 and 1400 G. The ESR parameters obtained are given in Table 3.

Since original $[Pt(NO_2)_4]^{2-}$ has square-planar configuration of ligand ions, the tervalent platinum complex produced through oxidation should show a line with axial symmetry, if the original configuration is maintained. However, the line shape (Fig. 2) indicates that the tervalent platinum has a slightly deformed ligand configuration. Some of the complexes having d^7 low spin configuration have been shown to have smaller $g_{//}$- or g_1-value like this. As an example, β-cobaltphthalocyanine has $g_{//}$ of 1.91.[7] Griffith tried to explain this by means of ligand field theory.[11] He assumed several ground multiplets which arise from different orders of one electron energy levels, and concluded that the ground state is $|d_{zx}\bar{d}_{zx}d_{yz}\bar{d}_{yz}d_{xy}\bar{d}_{xy}d_{z^2}|$ and that the smaller $g_{//}$ than 2 is due to the third order terms of spin-orbit interaction. It is uncertain, however, whether the sum of many spin-orbit terms can result in $g_{//}$ smaller than 2. On the other hand, we presume that g_1 smaller than 2 is caused by the lowering of symmetry from D_{4h}. In D_{2h} symmetry, $5d_{z^2}$ orbital mixes with $5d_{x^2-z^2}$ to form new one-electron eigenfunctions. It can be assumed from the small splitting of $g_{\perp}$ component observed that the distortion from D_{4h} to D_{2h} is small. We obtained one-electron eigenfuctions in D_{2h} ligand field $5d_{xy}$, $5d_{yz}$, $5d_{zx}$, $5d_{z^2}'=(1+a^2)^{-1/2}(5d_{z^2}+a5d_{x^2-y^2})$ and $5d_{x^2-y^2}'=(1+a^2)^{-1/2}(5d_{x^2-y^2}-a5d_{z^2})$, where *a* is a small mixing coefficient. Considering electron-electron repulsion, the ground multiplet becomes $|^2A_{1g}1/2>=|5d_{yz}\bar{5}d_{yz}5d_{zx}\bar{5}d_{zx}5d_{xy}\bar{5}d_{xy}5d_{z^2}'|$. Applying the usual perturbation formula to calculate *g*-values, we have $g_1=2+8a^2(1+a^2)^{-1}/E(^2B_{1g}-{}^2A_{1g})$. This predicts that g_1 is slightly greater than 2, a disappointing result. The simple model presented here gives no reasonable explanation of the observed *g*-value.

cis-*[Pt(py)$_2$Cl$_2$]*. Although this complex does not have a fourfold axis, the electronic state can be explained approximately in terms of D_{4h}. The ligand field of *cis*-type complexes has D_{4h} symmetry contrary to their geometrical symmetry.[12] The ESR spectrum which can be assigned to $[Pt(py)_2Cl_2]^{+}$ from its large *g*-shift showed that the complex has D_{4h} or C_{4v} symmetry in spite of the lack of a fourfold axis in geometrical structure. This suggests that the tervalent platinum complex ion does not suffer from distortion through oxidation. $g_{//}$ is probably 2, though it was not observable in the superposition of the strong absorption of unidentified radicals. *trans*-$[Pt(py)_2Cl_2]$ was also examined, but it gave no ESR absorption other than that of radicals at 3300 G. This indicates that the tervalent complex of the *cis*-type is produced in a greater amount than the *trans*-type by a factor of at least 100.

trans-*[Pt(gly)$_2$]*. This complex has a asymmetry between the axis of N–Pt–N and that of O–Pt–O in the plane formed by ligand and a central platinum ion. Thus, the ESR spectrum of the tervalent platinum complex produced by oxidation should show asymmetric shape with three different principal values of *g*-tensor (Fig. 3). The g_1-value less than 2, 1.939 also obtained in this case, suggests that a g_1-value smaller than 2 may be due to the lack of a fourfold axis.

K_2[PtCl$_6$]. A tervalent platinum complex was produced on γ-irradiation at room temperature. This tervalent platinum has different ESR parameters from

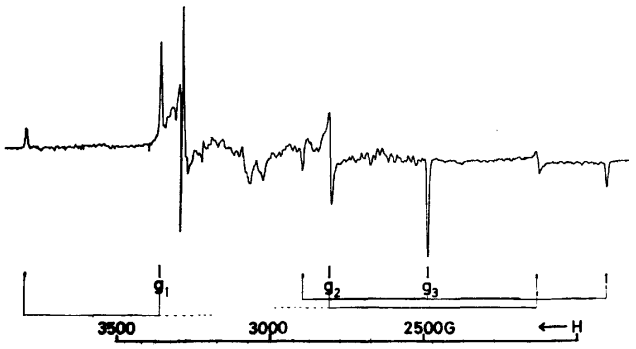

Fig. 3. The typical rhombic ESR spectrum of $[Pt(gly)_2]^{+}$ produced by γ-irradiation.

the paramagnetic chlorine-coordinated platinum complexes reported by Krigas and Rogers.[10] $g_{//}$ was not observable, but it is probably 2, considering that ESR absorption was not observed at any other position than near 3300 G where unidentified absorption of complex structure was observed. On the other hand, γ-irradiation at 77 K gave ESR absorption, which may come from platinum complexes by considering its large g-shift, +0.379. However, the hyperfine splitting due to ^{195}Pt was not clearly observed. The $g_{\perp}$-value is similar to that of the $[PtCl_5]^{2-}$ reported by the above authors.

In contrast to the formation of univalent complexes upon γ-irradiation of bivalent nickel and bivalent palladium complexes, γ-irradiation of bivalent platinum complexes gives tervalent complexes but not univalent ones. Since ionization probability is proportional to electronic density, it seems reasonable that the tervalent platinum complexes are produced in a greater amount than tervalent nickel or palladium complexes. The tervalent platinum complexes usually take $5d^7$ low spin electron configuration and show typical g-values like those of 3d complexes: $g_{\perp} > g_{//} \approx 2$. The $g_{\perp}$-value smaller than 2 observed in rhombic complexes seems to come from the lack of a fourfold axis, but no simple explanation can be given. The A-values of the tervalent platinum complexes are usually one order greater than those of the cobalt complexes, suggesting that 5d electrons penetrate deeply into the closed shell and result in the large core polarization. The yield of the tervalent platinum complexes varies from complex to complex, as shown typical between *cis*- and *trans*-$[Pt(py)_2Cl_2]$. It is interesting to see whether univalent platinum complexes would show the typical g-values of $3d^9$ and $4d^9$ complexes: $g_{//} > g_{\perp} > 2$.

We wish to thank Dr. Yoji Arata for reading this manuscript.

The Effect of NCS^- on the Radiation-induced Decoloration of Azo and Anthraquinone Dyes in N_2O-saturated Aqueous Solutions

Nobutake SUZUKI and Hiroshi HOTTA

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma 370-12

(Received December 13, 1976)

The radiation-induced decoloration of azo and anthraquinone dyes was studied in N_2O-saturated aqueous solutions containing NCS^-. In the N_2O-saturated solutions, the decoloration yield, $G(-\text{Dye})$, increased markedly upon the addition of NCS^-, which is an efficient scavenger of the OH radical—that is, from 1.46 up to 2.10 for Acid Red 265 and from 0.51 up to 1.51 for Acid Blue 40 upon the addition of 1 mM NCS^-. In the nitrogen-saturated solutions, however, the $G(-\text{Dye})$ decreased upon the addition of NCS^-. It is concluded that the increase in the $G(-\text{Dye})$ upon the addition of NCS^- in the N_2O-saturated solutions is mainly attributable to the attack of the radical anion $(NCS)_2^-$ on the ring structure of the dyes. This radical anion is formed through the following path: $NCS^- + OH \rightarrow NCS + OH^-$ and $NCS + NCS^- \rightleftarrows (NCS)_2^-$. At low NCS^- concentrations, the $G(-\text{Dye})$ decreased for Acid Red 265 and increased for Acid Blue 40. This may be attributable to the larger reactivity of $(NCS)_2^-$ on Acid Blue 40 than on Acid Red 265.

As has been described in preceding papers,[1,2] the radiation-induced decoloration of Acid Red 265 (azo dye) in aqueous solutions is mainly attributable to the attack of the OH radicals on the aromatic rings connected directly to the azo group, while that of Acid Blue 40 (anthraquinone dye) is attributable to the attack of the hydrated electrons on the carbonyl group in the anthraquinone ring, in addition to the attack of the OH radicals on the anthraquinone ring. In both cases, the decoloration is promoted in the N_2O-saturated solutions; that is, this increase in the $G(-\text{Dye})$ is due to the conversion of the hydrated electrons into the OH radicals by means of the following reaction;[3]

$$N_2O + e_{aq}^- \longrightarrow OH + OH^- + N_2. \qquad (1)$$

The yield of the OH radical in the N_2O-saturated aqueous solution $(G(OH) + G(e_{aq}^-) = 5.5)$[4] becomes about twice as large as that in the nitrogen-saturated aqueous solution $(G(OH) = 2.74)$.[4]

In such systems, the rate constants of the reactions of the hydrated electron with N_2O and Acid Blue 40 are 8.7×10^9 M^{-1} s^{-1} at pH 7[5] and 1.5×10^{10} M^{-1} s^{-1} at pH 6.3—5.1[2] respectively. In the N_2O-saturated 0.1 mM Acid Blue 40 solution, since the N_2O concentration (about 3×10^{-2} M) is about 300 times larger than the dye concentration, a large portion of the hydrated electrons are converted into OH radicals because $(8.7 \times 10^9\ M^{-1}\ s^{-1}) \times (3 \times 10^{-2}\ M) \gg (1.5 \times 10^{10}\ M^{-1}\ s^{-1}) \times (1 \times 10^{-4}\ M)$. Therefore, in the N_2O-saturated solution, the OH radical is considered to be the only active species. In the present study, the effect of NCS^-, which is an efficient scavenger of the OH radical, on the radiation-induced decoloration of azo and anthraquinone dyes was investigated in order to demonstrate the above scheme more clearly.

Experimental

The experimental procedures were the same as in the preceding works.[1,2] The dye solutions were prepared by dissolving recrystallized Acid Red 265[1] or Acid Blue 40[2] in triply distilled water. The solutions were bubbled with N_2O for 20 min prior to irradiation and were then irradiated with cobalt-60 gamma rays at room temperature.

The absorption spectra were measured with a Shimadzu UV-200 spectrophotometer. The decoloration yield was determined by measuring the optical density at 542 nm for Acid Red 265 and at 610 nm for Acid Blue 40. The NCS^- concentration was determined by the iron-thiocyanate method.[6]

Results and Discussion

N_2O-saturated NCS^- Solutions without Dye. In order to study the effect of NCS^- on the radiation-induced decoloration of the dyes in N_2O-saturated solutions, it is necessary first to elucidate the behavior of the consumption of NCS^- in a solution without the dye. Thus, the NCS^- concentration in N_2O- and nitrogen-saturated solutions without the dye was measured after irradiation.

The reduction of NCS^-, $G(-NCS^-)$, for the N_2O- and nitrogen-saturated solutions without the dye (initial pH 7.2) is shown as a function of the NCS^- concentration in Fig. 1. The $G(-NCS^-)$ for the N_2O-saturated solution increased steeply with an increase in the NCS^- concentration up to about 0.4 mM, and then it increased gradually above about 0.4 mM. The $G(-NCS^-)$ increased up to 1.72 from 0.96 in the NCS^- concentration

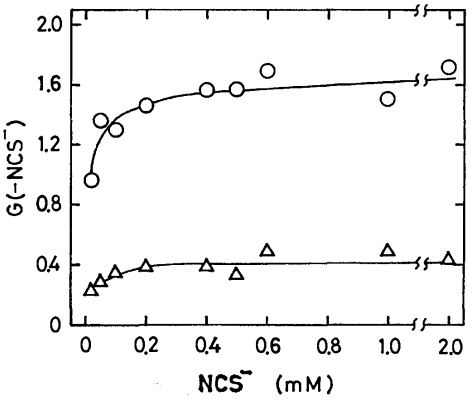

Fig. 1. $G(-NCS^-)$ as a function of NCS^- concentration in the N_2O- and nitrogen-saturated NCS^- solutions without the dye.
Dose: 1.8×10^4 rad. N_2O saturation (○) and N_2 saturation (△).

range from 0.02 to 2 mM. On the other hand, the $G(-NCS^-)$ for the nitrogen-saturated solution increased with an increase in the NCS^- concentration up to about 0.2 mM, and then it was kept nearly constant above about 0.2 mM. The $G(-NCS^-)$ increased up to 0.43 from 0.22 in the NCS^- concentration range from 0.02 to 2 mM. The ratio of $G(-NCS^-)_{N_2O}/G(-NCS^-)_{N_2}$ is about 4 ± 1 in this NCS^- concentration range.

In the irradiated N_2O-saturated solution, the hydrated electrons are converted into the OH radicals as Reaction 1. The OH radical reacts rapidly with NCS^- to form the NCS radical, following the formation of the radical anion $(NCS)_2^-$;[7,8]

$$NCS^- + OH \xrightarrow{k_2} NCS + OH^-, \quad (2)$$

$$NCS + NCS^- \underset{k_{3b}}{\overset{k_{3a}}{\rightleftharpoons}} (NCS)_2^-. \quad (3)$$

Then;[7,9]

$$2(NCS)_2^- \longrightarrow (NCS)_2 + 2NCS^-, \quad (4)$$

$$NCS + NCS \longrightarrow (NCS)_2. \quad (5)$$

Baxendale *et al.* determined the value of k_2 (2.8×10^{10} $M^{-1}s^{-1}$) from a kinetic study of the equilibrium of Reaction 3 at pH 7 by pulse radiolysis ($k_{3a}=7.0\times10^9$ $M^{-1}s^{-1}$ and $k_{3b}=3.4\times10^4$ s^{-1}).[7] On the other hand, Willson *et al.* concluded that the most reasonable value of k_2 was 1.03×10^{10} $M^{-1}s^{-1}$, since the above value was significantly higher than the values obtained by other methods.[10]

Since the ratio of $G(OH)_{N_2O}/G(OH)_{N_2}$ equals about 2, as has been described already, the ratio of $G(-NCS^-)_{N_2O}/G(-NCS^-)_{N_2}$ should equal about 2. However, the ratio of $G(-NCS^-)_{N_2O}/G(-NCS^-)_{N_2}$ (about 4 ± 1) obtained from Fig. 1 is larger than the above ratio. This may be mainly attributable to the consumption of the NCS radical by the hydrated electron in the nitrogen-saturated solution as Reaction 6:[9]

$$NCS + e^-_{aq} \longrightarrow NCS^- \quad (6)$$

N_2O-saturated Acid Blue 40 Solutions. The $G(-Dye)$ for the N_2O-saturated 0.1 mM Acid Blue 40 solutions containing NCS^- (initial pH 6.3) is shown as a function of the NCS^- concentration in Fig. 2. The $G(-Dye)$ increased steeply with an increase in the NCS^- concentration up to about 0.4 mM, and then it increased gradually above about 0.4 mM. The $G(-Dye)$ increased up to 1.51 upon the addition of 1 mM NCS^- from 0.51 for the N_2O-saturated solution without NCS^-. It is noteworthy that the tendency of the $G(-Dye)$-NCS^- concentration curve is similar to that of the $G(-NCS^-)$-NCS^- concentration curve for the N_2O-saturated NCS^- solution without the dye in Fig. 1. In the case of an unirradiated N_2O-saturated solution, the absorption spectrum was not changed upon the addition of NCS^-. On the other hand, in a nitrogen-saturated solution, the $G(-Dye)$ decreased to 0.06 upon the addition of 1 mM NCS^- from 0.18 for the solution without NCS^-.[2]

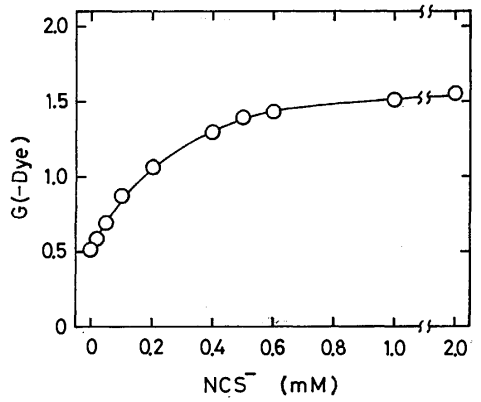

Fig. 2. Effect of NCS^- on $G(-Dye)$ in the N_2O-saturated Acid Blue 40 solutions.
Dye concentration: 0.1 mM. Dose: 1.8×10^4 rad.

The radiation-induced decoloration scheme of Acid Blue 40 in the nitrogen-saturated solution has been represented in a preceding paper[2] as follows:

$$AB + OH \xrightarrow{k_7} ABOH \text{ (decolored product)}, \quad (7)$$

$$AB + OH \longrightarrow ABOH' \text{ (colored product)}, \quad (8)$$

$$AB + e^-_{aq} \longrightarrow AB_{red} \text{ (decolored product)}, \quad (9)$$

$$AB + e^-_{aq} \longrightarrow AB_{red}' \text{ (colored product)}, \quad (10)$$

where AB, ABOH, and AB_{red} are Acid Blue 40, its OH adduct, and its reduction product by the attack of the hydrated electron respectively. In the N_2O-saturated solution, however, since the hydrated electrons are converted into the OH radicals as Reaction 1, Acid Blue 40 is decolored only by Reaction 7.

According to the earlier studies of the radiation-induced inactivation of lysozyme in the N_2O-saturated solution containing NCS^-,[8,11] the inactivation was caused by a reaction between lysozyme and $(NCS)_2^-$:

$$\text{lysozyme} + (NCS)_2^- \longrightarrow \text{inactive product} \quad (11)$$

The site of the $(NCS)_2^-$ attack is the ring structure of tryptophan in lysozyme; that is, the reaction with $(NCS)_2^-$ is a direct addition to the ring structure of tryptophan (T);

$$T + (NCS)_2^- \longrightarrow (T(NCS)_2)^-. \quad (12)$$

In the Acid Blue 40 solution containing NCS^-, most of the OH radicals react rapidly with NCS^- to form the NCS radical at NCS^- concentrations above about 0.2 mM, because k_2 is larger than k_7 (6.6×10^9 $M^{-1}s^{-1}$ at pH 6.3—5.1).[2] Therefore, it may be concluded from these facts that the increase in the $G(-Dye)$ upon the addition of NCS^- in the N_2O-saturated solution is mainly attributable to the attack of the radical anion $(NCS)_2^-$ formed through Reactions 2 and 3 on the Acid Blue 40 molecule as follows:

$$AB + (NCS)_2^- \longrightarrow (AB(NCS)_2)^- \text{ (decolored product)}, \quad (13)$$

$$AB + (NCS)_2^- \longrightarrow (AB(NCS)_2)^{-\prime} \text{ (colored product)}. \quad (14)$$

The Acid Blue 40 molecule has two kinds of reaction sites for Reactions 13 and 14; (a) the anthraquinone ring and (b) the substituted benzene ring, not conjugated to the carbonyl group in the anthraquinone ring. The attack of the radical anion $(NCS)_2^-$ on Site b is independent of the decoloration reaction. The increase in the $G(-Dye)$ in Fig. 2 indicates that the radical anion

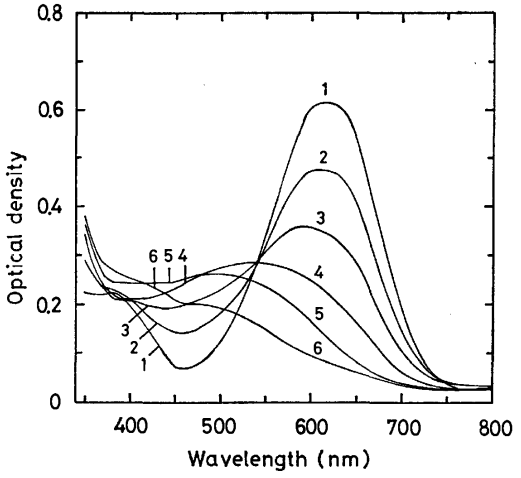

Fig. 3. Absorption spectra of unirradiated and irradiated N_2O-saturated Acid Blue 40 solutions containing 1 mM NCS^-.
Dye concentration: 0.1 mM. Doses (rad): 0 (Curve 1), 1.8×10^4 (Curve 2), 3.7×10^4 (Curve 3), 5.5×10^4 (Curve 4), 1.1×10^5 (Curve 5), and 3.9×10^5 (Curve 6).

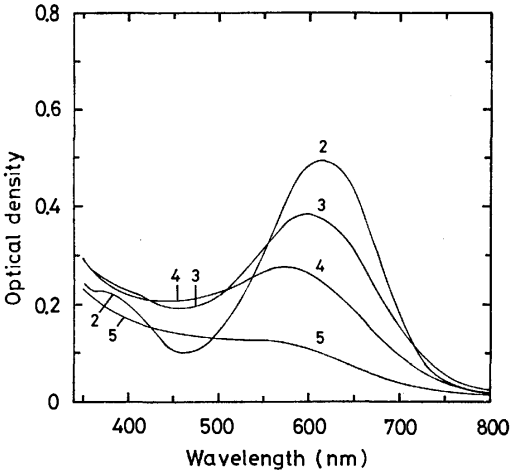

Fig. 4. Absorption spectra of irradiated N_2O-saturated Acid Blue 40 solutions without NCS^-.
Dye concentration: 0.1 mM. Doses (rad): 3.7×10^4 (Curve 2), 1.7×10^5 (Curve 3), 3.9×10^5 (Curve 4), and 5.5×10^5 (Curve 5).

$(NCS)_2^-$ destroys the dye chromophore more efficiently than the OH radical does.

The absorption spectra for the unirradiated and irradiated N_2O-saturated solution containing 1 mM NCS^- are shown in Fig. 3. The absorption band at 610 nm disappeared with an increase in the dose, and at the same time, the new absorption band near 460—490 nm seems to appear at a slightly higher dose (Curves 5 and 6 in Fig. 3). This new absorption band hardly appeared at all in the N_2O-saturated solution without NCS^-, as is shown in Fig. 4. The absorption band near 460—490 nm coincides approximately with that for the reduction products of Acid Blue 40 formed by the attacks of the hydrated electron and the alcohol radical on the carbonyl group in the anthraquinone ring.[2] It is known that quinones are easily reduced by such reducing species as alcohol radicals.[12,13] Therefore, it is assumed that a part of the Acid Blue 40 is reduced by the attack of the radical anion $(NCS)_2^-$ on the carbonyl group in the anthraquinone ring, thus forming the reduction product as follows:

$$AB + (NCS)_2^- \longrightarrow AB_{red}\text{ (decolored product)} + (NCS)_2 \quad (15)$$

On the other hand, the G(–Dye) for the nitrogen-saturated solution decreased upon the addition of NCS^-,[2] in contrast to that for the N_2O-saturated solution. The decrease in the G(–Dye) upon the addition of NCS^- in the nitrogen-saturated solution may be mainly attributable to the consumption of the NCS radical by Reaction 6, without forming $(NCS)_2^-$.

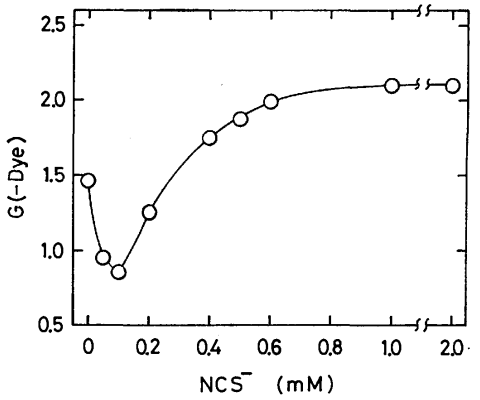

Fig. 5. Effect of NCS^- on G(–Dye) in the N_2O-saturated Acid Red 265 solutions.
Dye concentration: 0.1 mM. Dose: 1.8×10^4 rad.

N_2O-saturated Acid Red 265 Solutions. The G(–Dye) for the N_2O-saturated 0.1 mM Acid Red 265 solutions containing NCS^- (initial pH 6.4) is shown as a function of the NCS^- concentration in Fig. 5. The G(–Dye) decreased at first to 0.85 upon the addition of 0.1 mM NCS^-, and then it increased steeply with an increase in the NCS^- concentration up to about 0.6 mM NCS^-, in contrast to the result for the Acid Blue 40 solution in Fig. 2. The G(–Dye) increased up to 2.10 upon the addition of 1 mM NCS^- from 1.46 for the N_2O-saturated solution without NCS^-. In the case of the unirradiated N_2O-saturated solution, the absorption spectrum was also unchanged upon the addition of NCS^-. On the other hand, in the nitrogen-saturated solution the G(–Dye) decreased to 0.22 upon the addition of 1 mM NCS^- from 1.00 for the solution without NCS^-.[1]

The radiation-induced decoloration scheme of Acid Red 265 in the nitrogen-saturated solution has been represented in a preceding paper[1] as follows:

$$AR + OH \longrightarrow AROH\text{ (decolored product)} \quad (16)$$

$$AR + OH \longrightarrow AROH'\text{ (colored product)} \quad (17)$$

where AR and AROH are Acid Red 265 and its OH adduct respectively.

In the N_2O-saturated solution containing NCS^-, the increase in the G(–Dye) is also mainly attributable to the attack of the radical anion $(NCS)_2^-$ formed through Reactions 2 and 3 on the Acid Red 265 molecule as follows:

$$AR + (NCS)_2^- \longrightarrow (AR(NCS)_2)^- \text{ (decolored product)}, \quad (18)$$

$$AR + (NCS)_2^- \longrightarrow (AR(NCS)_2)^{-\prime} \text{ (colored product)}. \quad (19)$$

The Acid Red 265 molecule has two kinds of reaction sites for Reactions 18 and 19; (a) the aromatic rings connected directly to the azo group, and (b) the substituted benzene ring, not conjugated to the azo group. The attack of the radical anion $(NCS)_2^-$ on Site b is independent of the decoloration reaction. It is difficult for the direct attack of the radical anion $(NCS)_2^-$ on the azo group to take place because the azo group is stabilized by the hydrogen bonding with an adjacent OH group in a naphthalene ring.[1] Furthermore, the masking of the azo group can be expected because of the steric effect of the adjacent SO_3Na and CH_3 groups.[1]

The decrease in the G(–Dye) upon the addition of NCS^- up to 0.1 mM in Fig. 5 may be explained as follows. At low NCS^- concentrations, since the equilibrium of Reaction 3 may be rather shifted to the left side, a part of the NCS radical is consumed by Reaction 5, thus decreasing the G(–Dye). As the NCS^- concentration increases, the OH radicals are scavenged efficiently by NCS^- and the equilibrium of Reaction 3 is shifted to the right side. Therefore, the G(–Dye) increases at high NCS^- concentrations, as has previously been described.

The decrease in the G(–Dye) upon the addition of NCS^- was not observed in the N_2O-saturated Acid Blue 40 solution. This may be attributable to the larger reactivity of the radical anion $(NCS)_2^-$ on Acid Blue 40 than on Acid Red 265, because the increase in the G(–Dye) upon the addition of NCS^- is larger for Acid Blue 40 than for Acid Red 265 in spite of the smaller G(–Dye) value for the Acid Blue 40 solution without NCS^- than for the Acid Red 265 one.

The authors wish to thank Mr. Masamitsu Washino of JAERI for his encouragement and support.

Charge-Transfer Absorption of Solid Ion Radical Salts. Application of One-Dimensional Hubbard Model

Yôichi IIDA

Departmebt of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 24, 1976)

The electronic spectrum of solid ion radical salt is known to be different from the monomer spectrum of the radical ion and to show an intermolecular charge-transfer band in the low-energy region. In order to understand the character of this charge-transfer absorption, one-dimensional Hubbard model was applied to such solid ion radical salt. The transition energy and the theoretical line shape of the charge-transfer absorption were derived and were compared with those of certain TCNQ anion radical salts.

The prominent magnetic, electrical, and optical properties of a number of solid ion radical salts have been the subject of many theoretical and experimental investigations over the past fifteen years.[1-5] In such ion radical salts, the planar ion radical molecules are known to form, in themselves, a plane-to-plane stacking into infinite one-dimensional columns so as to make a large overlap between their half-filled molecular orbitals.[6,7] In this case, since any individual radical molecule interacts through charge-transfer most strongly with two other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution but shows a charge-transfer transition between ion radicals in the low-energy region.[3-5]

In the present paper, we applied one-dimensional Hubbard model to the columns of ion radical molecules, and investigated the optical properties of solid ion radical salts. We attempted to explain the character of such charge-transfer absorptions on the basis of Green's function method. The transition energy and the theoretical absorption shape were compared with those observed for K^+ $TCNQ^-$ anion radical salt, where TCNQ is 7,7,8,8-tetracyanoquinodimethane.

Theoretical

In a narrow energy band with strong electron correlation, an electron transfers from one site to another site, but a strong repulsive force will take place when an electron happens to come onto a site which is already occupied by another electron with opposite spin. Let us denote the intra-site Coulomb repulsive energy as I, and consider a system of electrons described by the following Hamiltonian, which is often called the Hubbard Hamiltonian;[8,9]

$$\mathcal{H} = \sum_{i,j,\sigma} t_{ij} C_{i\sigma}^{+} C_{j\sigma} + I \sum_{i} n_{i\downarrow} n_{i\uparrow}, \tag{1}$$

where $n_{i\sigma}=C_{i\sigma}^{+}C_{i\sigma}$, and $C_{i\sigma}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where t_{ij} is the transfer matrix element between the i-th and j-th sites, and the repulsive potential, I, appears only when two electrons are at the same site. We put $t_{ii}=0$ without loss of generality. The unperturbed band energy, ε_k, of the system is related to t_{ij} by

$$\varepsilon_k = \sum_j t_{ij} e^{ik\cdot(R_i-R_j)}. \tag{2}$$

Hubbard studied, in his first paper (it is often referred to as Hubbard I),[8] the one-particle Green's function of this system by using decoupling method of equation of motion. The Green function is given by

$$G_{k\sigma}(E) = \frac{1}{2\pi}\left\{\frac{E_{k\sigma}^{U}-I(1-n_{-\sigma})}{E_{k\sigma}^{U}-E_{k\sigma}^{L}}\frac{1}{E-E_{k\sigma}^{U}} + \frac{I(1-n_{-\sigma})-E_{k\sigma}^{L}}{E_{k\sigma}^{U}-E_{k\sigma}^{L}}\frac{1}{E-E_{k\sigma}^{L}}\right\}, \tag{3}$$

where

$$n_\sigma = \langle n_{i\sigma}\rangle,$$

$$E_{k\sigma}^{U} = \frac{1}{2}(\varepsilon_k + I + \sqrt{\varepsilon_k^2 + 2(2n_{-\sigma}-1)\varepsilon_k I + I^2}),$$

$$E_{k\sigma}^{L} = \frac{1}{2}(\varepsilon_k + I - \sqrt{\varepsilon_k^2 + 2(2n_{-\sigma}-1)\varepsilon_k I + I^2}).$$

Here $E_{k\sigma}{}^{L}$ is the energy of an electron with σ-spin which moves about avoiding other electrons with $-\sigma$-spin, while $E_{k\sigma}{}^{U}$ is the energy of an electron which propagates mainly among sites already occupied with electrons with $-\sigma$-spin.

On the other hand, starting from Kubo's formula,[10] Kubo expressed the conductivity tensor of the Hubbard Hamiltonian in terms of two-time Green's function.[11] The spectrum of optical absorption from $E_{k\sigma}{}^{L}$ to $E_{k\sigma}{}^{U}$ (*i.e.*, the intermolecular charge-transfer absorption) is given by the real part of the diagonal element of the frequency-dependent conductivity tensor, $\mathrm{Re}\sigma_{xx}(\omega)$, that is,

$$\mathrm{Re}\sigma_{xx}(\omega) = \frac{e^2}{\pi V}\frac{1}{\omega}\sum_{k,\sigma}\delta(\omega - E_{k\sigma}^{U} + E_{k\sigma}^{L}) \times \frac{\delta E_{k\sigma}^{U}}{\delta k_x}\frac{\delta E_{k\sigma}^{L}}{\delta k_x}\{f(E_{k\sigma}^{U}) - f(E_{k\sigma}^{L})\}, \tag{4}$$

where V is the volume of the system, and $f(E)$ is the Fermi distribution function.

In order to apply this theory to one-dimensional stacks of ion radical molecules, we consider non-alternant linear chain of sites for which the transfer matrix elements are assumed to exist only between nearest neighbor sites. In this case, the unperturbed band energy is given by

$$\varepsilon_k = 2T\cos ka, \quad \left(-\frac{\pi}{a}\leq k\leq\frac{\pi}{a}\right), \tag{5}$$

where $T(<0)$ is the transfer matrix element between nearest neighbors and a is the lattice separation. Re $\sigma_{xx}(\omega)$ in Eq. 4 is composed of two contributions from the transitions of electrons with up and down spins. In the following, we only consider the contribution of electrons with up spin, but the optical absorption by

electrons with up spin depends strongly upon $n_\downarrow$ through correlation effect. From the δ-function of Eq. 4, an electron with a wave vector $\boldsymbol{k}$ absorbs the electromagnetic wave with the frequency ω;

$$\omega^2 = \varepsilon_k{}^2 + 2(2n_\downarrow - 1)I\varepsilon_k + I^2. \quad (6)$$

This leads to

$$\varepsilon_k = \varepsilon^{\pm}(\omega) = -I(2n_\downarrow - 1) \pm \sqrt{\omega^2 - 4I^2 n_\downarrow (1-n_\downarrow)}. \quad (7)$$

The optical transition from $E_{k\sigma}{}^L$ to $E_{k\sigma}{}^U$ with the wave vector $\boldsymbol{k}$, which satisfies $\varepsilon_k = \varepsilon^+(\omega)$, gives the absorption

$$\mathrm{Re}\sigma^+(\omega) = \frac{e^2}{2} \frac{I^2 n_\downarrow (1-n_\downarrow)}{\omega^2 \sqrt{\omega^2 - 4I^2 n_\downarrow (1-n_\downarrow)}}$$
$$\times \sqrt{4T^2 - \{-(2n_\downarrow - 1)I + \sqrt{\omega^2 - 4I^2 n_\downarrow (1-n_\downarrow)}\}^2}\, \theta_+(\omega), \quad (8)$$

where

$$\theta_\pm(\omega) = f(E_\pm{}^L) - f(E_\pm{}^U),$$

$$E_\pm{}^L = \frac{1}{2}\{\varepsilon^\pm(\omega) + I - \sqrt{(\varepsilon^\pm(\omega) + I)^2 - 4I(1-n_\downarrow)\varepsilon^\pm(\omega)}\},$$

$$E_\pm{}^U = \frac{1}{2}\{\varepsilon^\pm(\omega) + I + \sqrt{(\varepsilon^\pm(\omega) + I)^2 - 4I(1-n_\downarrow)\varepsilon^\pm(\omega)}\}.$$

In a similar way, the transition between the two states with the wave vector $\boldsymbol{k}$, which satisfies $\varepsilon_k = \varepsilon^-(\omega)$, gives the absorption

$$\mathrm{Re}\sigma^-(\omega) = \frac{e^2}{2} \frac{I^2 n_\downarrow (1-n_\downarrow)}{\omega^2 \sqrt{\omega^2 - 4I^2 n_\downarrow (1-n_\downarrow)}}$$
$$\times \sqrt{4T^2 - \{-(2n_\downarrow - 1)I - \sqrt{\omega^2 - 4I^2 n_\downarrow (1-n_\downarrow)}\}^2}\, \theta_-(\omega). \quad (9)$$

Therefore, the total contribution to the optical absorption, $\mathrm{Re}\sigma_{xx}(\omega)$, due to the electrons with up spin is given by $\mathrm{Re}\sigma^+(\omega) + \mathrm{Re}\sigma^-(\omega)$.

Discussion

In this section, we shall apply this theory to the optical properties of certain crystalline TCNQ anion radical salts. Let us consider, for example, a system of simple anion radical salt of K^+TCNQ^-. According to Anderson and Fritchie's X-ray analysis data,[6] the crystal structure of K^+TCNQ^- belongs to the monoclinic system with space group $P2_1/n$. The structure consists of one-dimensional columns of $TCNQ^-$ ions parallel to the a (needle) axis with a plane-to-plane stacking; the molecular normal vectors nearly coincide with the column axes. Each column is surrounded by four columns in which the $TCNQ^-$ ions are rotated by 90° from those in the central column. The potassium ions occupy sites between $TCNQ^-$ columns in such a manner that each K^+ ion is surrounded by eight nitrogen atoms at the corners of a distorted cube.

On the other hand, each TCNQ anion radical molecule is almost planar, and has sixteen molecular orbitals for seventeen $2p\pi$ electrons.[12] Therefore, in the ground state, the molecular orbitals from the lowest to the 8 th are fully occupied, while an unpaired electron is in the 9 th molecular orbital. The other molecular orbitals are vacant orbitals.

In order to apply Hubbard model of Eq. 1 to the crystalline K^+ $TCNQ^-$ anion radical salt, we consider the column of TCNQ anion radicals. We take only the 9 th molecular orbital of the unpaired electron for one site of TCNQ anion radical, and assume a model of non-alternant one-dimensional column composed of infinite number of such sites. From the crystallographic data,[6] the intermolecular distance between nearest neighbor sites, a in Eq. 5, is of the order of 3.4 Å. Therefore, in this model, each TCNQ anion radical site has one identical molecular orbital with equal energy level, and there is one electron per each site. Then, we have $n_\downarrow = 0.5$ if we assume a paramagnetic state for our system. Under these situations, we consider the optical absorption (charge-transfer absorption) of the crystalline K^+TCNQ^- anion radical salt as expressed by Eqs. 8 and 9. By using $n_\downarrow = 0.5$, we can easily obtain

$$\mathrm{Re}\sigma^+(\omega) = \frac{e^2}{8} \frac{I^2}{\omega^2 \sqrt{\omega^2 - I^2}} \sqrt{4T^2 - \omega^2 + I^2}\, \theta_+(\omega), \quad (10)$$

$$\mathrm{Re}\sigma^-(\omega) = \frac{e^2}{8} \frac{I^2}{\omega^2 \sqrt{\omega^2 - I^2}} \sqrt{4T^2 - \omega^2 + I^2}\, \theta_-(\omega). \quad (11)$$

Here we assume, for the sake of simplicity, that the Coulomb repulsion potential is much greater than the band width, or we consider the absorption spectrum at very low temperature. In this case, $\theta_\pm(\omega) = 1$ so that both $\mathrm{Re}\sigma^+(\omega)$ and $\mathrm{Re}\sigma^-(\omega)$ in Eqs. 10 and 11 have the same absorption spectrum. Fig. 1 shows a schematic description of $\mathrm{Re}\sigma^+(\omega)$ or $\mathrm{Re}\sigma^-(\omega)$ *versus* ω for this case, as is shown by the (a) line. Therefore, the total contribution to the absorption spectrum, $\mathrm{Re}\sigma^+(\omega) + \mathrm{Re}\sigma^-(\omega)$, is given by the (b) line of Fig. 1.

As is shown in Fig. 1, the theoretical optical absorption due to the charge-transfer transition between TCNQ anion radical sites has a sharp divergent peak at the energy $\omega = I$, where the spectrum has a van Hove singularity in the lower energy side.[11] The spectrum has no absorption in the energy region $\omega < I$, but has an absorption intensity in the region $\omega > I$. The absorption intensity is the greatest at $\omega = I$, and decreases progressively with the increase of ω. The highest energy of the absorption takes place at $\omega = \sqrt{I^2 + 4T^2}$,

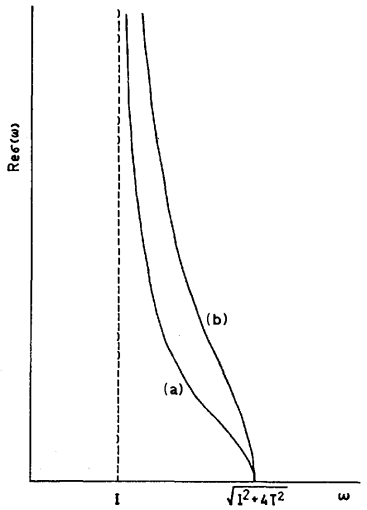

Fig. 1. The theoretical absorption line shape due to the charge-transfer transition between ion radical molecules in one-dimensional Hubbard model. Curve (a) indicates the spectrum of $\mathrm{Re}\sigma^+(w)$ of Eq. 10 or $\mathrm{Re}\,\sigma^-(w)$ of Eq. 11 with $\theta_\pm(w) = 1$, while curve (b), that of $\mathrm{Re}\sigma^+(w) + \mathrm{Re}\sigma^-(w)$. See text.

where the intensity falls down to zero. The spectrum has a shoulder in the region $I<\omega<\sqrt{I^2+4T^2}$. Therefore, the charge-transfer absorption has a width of $\sqrt{I^2+4T^2}-I$. This width is caused by the existence of non-zero transfer matrix element of T in the unperturbed energy band of Eq. 5. In fact, if we assume $T=0$, that is, if we assume an independent site model in the unperturbed energy band, the absorption spectrum, $\mathrm{Re}\sigma^+(\omega)+\mathrm{Re}\sigma^-(\omega)$, is only a δ-function at $\omega=I$ with no width, as this model requires.

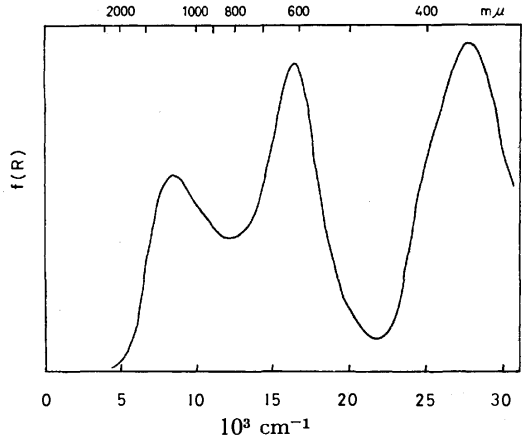

Fig. 2. The experimental result on the diffuse reflection spectrum of solid K^+ $TCNQ^-$ anion radical salt, where the value of Kubelka-Munk function, $f(R)=(1-R)^2/2R$, was plotted *versus* wave number (10^3 cm^{-1} unit). See Ref. 3.

Let us compare these theoretical predictions with the experimental electronic spectrum of crystalline K^+ $TCNQ^-$ anion radical salt. In a previous paper,[3] we measured the electronic spectrum of this salt by means of diffuse reflection method. The observed spectrum is reproduced in Fig. 2. The Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance and $f(R)$ is proportional to the absorbance, was plotted against the wave number (10^3 cm^{-1} unit). In the energy region from 5000 to 30000 cm^{-1} the solid-state spectrum of K^+ $TCNQ^-$ anion radical salt has three absorptions. The absorptions at 16400 and 27800 cm^{-1} are the shifted bands of the monomer spectrum of the TCNQ anion radical at 11900 and 25300 cm^{-1}, respectively, while the low-energy band at 8500 cm^{-1} characteristic of the solid salt has been assigned to the charge-transfer transition between TCNQ anion radicals in one-dimensional column.[3] If the theoretical absorption of Fig. 1 is applied to this characteristic low-energy band, the observed absorption peak value, 8500 cm^{-1}, should correspond to $\omega=I$, so that the intra-site Coulomb repulsive energy for the system of TCNQ anion radicals is estimated to be $I=8500$ cm^{-1}. As for the line shape and the line width, the theoretical spectrum has no absorption in the region $\omega<I$, while the observed charge-transfer absorption has a considerable width even in the energy region lower than its peak position. Moreover, the theoretical spectrum has absorption only in the region $I\leq\omega\leq\sqrt{I^2+4T^2}$ so that the line shape should be asymmetrical with respect to $\omega=I$. However, this asymmetric character is not obvious in the observed charge-transfer absorption, although the charge-transfer band overlaps with the higher-energy band of 16400 cm^{-1}. There may be several reasons for these discrepancies:

(1) An important one is that in our theory we assumed, as is shown in Eq. 4, a δ-function for the elementary transition from $E_{k\sigma}{}^L$ to $E_{k\sigma}{}^U$ at each wave vector, while the actual elementary transition is not a δ-function but involves finite width. In fact, the individual site in our Hubbard model is the TCNQ anion radical molecule composed of 20 atoms. Then, the elementary absorption may involve a width of vibrational structures due to the vibronic effect of the molecule.

(2) Another reason for the broadening of elementary transition at each wave vector comes from two electronic effects in the scattering process of an electron by those with opposite spin.[9] One is the effect of the randomness in the spacial distribution of electrons with opposite spin; Hubbard called it as the scattering correction. Another is the effect of the motion of electrons with opposite spin; he called it as the resonance broadening correction. These two electronic effects will also influence significantly the shape of charge-transfer absorption spectrum. We can make these corrections if we use the method proposed by Hubbard in his third paper.[9] There has been a relevant work made by Sadakata and Hanamura,[13] who examined the optical properties of three-dimensional half-filled band system for certain transition metal compounds.

(3) In the theoretical absorption spectrum of Fig. 1, we neglected the temperature effect and only considered the extreme case of $\theta_\pm(\omega)=1$. However, the experimental spectrum of Fig. 2 was observed at room temperature. Therefore, if we consider the effect of Fermi distribution term, $\theta_\pm(\omega)$, at finite temperature, the theoretical spectrum of Fig. 1 will become more smoothed.

At any rate, in the charge-transfer absorption of K^+ $TCNQ^-$ system, the observed line shape is almost symmetrical with respect to $\omega=I$. In this respect, the absorption line width due to the transfer matrix element, $\sqrt{I^2+4T^2}-I$, seems to be very narrow compared to the width due to the elementary transition, 3500 cm^{-1}, so that the $|T|$ value may be much less than 4200 cm^{-1}. As this $|T|$ value appears much less than the I value, we can well see that a narrow band system with strong electron correlation takes place in such one-dimensional column of TCNQ anion radicals. On the other hand, however, it is very important to find certain crystalline ion radical salts where transfer matrix element is comparable to or larger than the width of elementary transition, because they will show asymmetric charge-transfer absorption with a shoulder in the high-energy region. Then we can estimate the magnitude of T directly by analyzing such asymmetric line shape with our theoretical model, as long as the approximation for the Green function of Eq. 3 is applicable to our system.

So far, in order to apply simple one-dimensional Hubbard Hamiltonian of Eq. 1 to the crystalline K^+ $TCNQ^-$ salt, we have only considered the 9 th molecular

orbital of the unpaired electron as one site of TCNQ anion radical, and neglected the other occupied and vacant molecular orbitals. This simple model solely leads to the optical properties of the charge-transfer transition between TCNQ anion radicals, but cannot explain the character of other higher-energy electronic transitions which arise mostly from local excitations of TCNQ anion radical molecules. Therefore, further theoretical treatment including all of the molecular orbitals is required to explain those higher-energy transitions as well as the low-energy charge-transfer transition in such crystalline ion radical salts.

In the present paper, we have only discussed the one-dimensional system of simple TCNQ anion radical salts, where each TCNQ anion radical has one unpaired electron so that each TCNQ site is equivalent. However, there are a number of complex TCNQ anion radical salts,[1,2] which include not only TCNQ anion radicals but also formally neutral TCNQ molecules so that each TCNQ site is no longer equivalent. In order to take into account this inequivalence, Soos and Klein modified the Hubbard Hamiltonian of Eq. 1 and studied the electronic states of less than half-filled band system for those complex TCNQ anion radical salts.[14] Therefore, we will also attempt to investigate, by extending our present method, the optical properties of such complex TCNQ anion radical salts.

The author wishes to express his thanks to Dr. Kenn Kubo of Tokyo Kyoiku University for his valuable discussion regarding this work.

Formation of CN($B^2\Sigma^+$) in the Reaction of Acetonitrile with Metastable Ar($^3P_{2,0}$) Atoms

Kaoru SUZUKI and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received January 7, 1977)

A flowing-afterglow method was applied to the formation of CN($B^2\Sigma^+$) from CH_3CN by impact of metastable argon atoms, Ar($^3P_{2,0}$). Emission spectra of CN $B^2\Sigma^+$-$X^2\Sigma^+$ (violet band) were analyzed to estimate the energies distributed to the vibrational and rotational motions of CN($B^2\Sigma^+$). In comparison with the CN($B^2\Sigma^+$) produced from HCN under similar experimental conditions, relative populations in excited vibrational states are smaller. The effective rotational temperatures range from 5000±1000 K (v=0—2) to 2000±1500 K (v=5—10). An intensity anomaly caused by the rotational perturbation with $A^2\Pi$ is used for estimating the ratio of the formation rates of CN $B^2\Sigma^+$ and $A^2\Pi$, F_B/F_A, to be 0.19±0.05.

Metastable argon atoms, Ar($^3P_{2,0}$), are known to react with cyanides (XCN, X=H, Cl, Br, I, CN, and CH_3) and produce CN radicals in electronically excited states. Studies on light emission from the CN radicals thus formed have been reported.[1-6] The vibrational and rotational distributions of the CN($A^2\Pi$) and CN($B^2\Sigma^+$) radicals produced by photodissociation[7,8] and electron impact[9,10] have also been studied in detail. A comparison of the results shows that the distributions resulting from the metastable reactions extend more broadly among different internal states and that the production of CN($A^2\Pi$) is more favored than that in the other reactions.

The emission from CN($B^2\Sigma^+$) formed in the reaction of metastable argon atoms with CH_3CN has previously been studied; spectra were reported in Refs. 1 and 5, and an analysis of a vibrational distribution was made on a spectrum taken with medium resolution,[3] where no rotational structure was observed. In the present paper a detailed analysis of the CN violet emission from acetonitrile based on a spectrum taken with higher resolution is presented. Rotational and vibrational distributions are obtained by a band envelope analysis for $\Delta v=0$ and -1 sequences. In addition, quantitative information on the formation rate to the CN $A^2\Pi$ and $B^2\Sigma^+$ states is obtained by an analysis of anomalies in the rotational distribution caused by the rotational perturbation between the two states.

Experimental

A flowing afterglow apparatus[1] was used. The flow tube was evacuated by a mechanical booster pump (500 l/s). Argon gas (99.99% nominal purity) was admitted into the flow tube after passing through a liquid nitrogen trap and is subjected to microwave discharge (2450 MHz, 500 W). Ionic species generated in the discharge section were collected on grids, and neutral atoms were led into the reaction zone. Acetonitrile (extra pure) was introduced into the flow about 15 cm downstream from the discharge section. The time of flight of argon atoms from the discharge section to the reaction zone was estimated to be of the order of 1 ms. The flame in the reaction region was observed through a quartz window and focused by a lens on a Spex 1704 monochromator. A photomultiplier (HTV R585) and a photon counting unit were used. The CN violet system ($B^2\Sigma^+$-$X^2\Sigma^+$) was observed for $\Delta v=+1$, 0, and -1 sequences.

The pressures of argon and the sample were monitored at the reaction zone by a Pirani gauge, which was calibrated against a McLeod gauge. Typical pressures were 0.3 and 0.01 Torr for argon and acetonitrile, respectively.

The effect of the light generated in the discharge section was checked by a time-of-flight experiment[13] and was found to be negligible.

Vibrational and Rotational Distributions

Provided the CN($B^2\Sigma^+$) formed has thermal velocity, the effect of collisional relaxation on the rotational distribution can be ignored, since the mean time between effective collisions (200 ns, as estimated from the cross section of rotationally inelastic collision, 85 Å^2)[4] is appreciably longer than the radiative lifetime of CN($B^2\Sigma^+$) (60 ns[14]). It is not known, however, whether the CN($B^2\Sigma^+$) produced is thermal. Therefore, the effect of collisional relaxation was tested by taking spectra at different argon pressures (Fig. 1). Since the spectra were essentially pressure-independent, the effect of rotational relaxation was ignored in the present analysis of relative intensities.

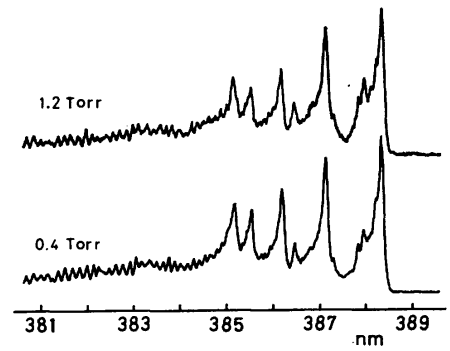

Fig. 1. Check of dependence of the spectra on argon pressure, CN $B^2\Sigma^+$-$X^2\Sigma^+$ 0-0 sequence. No appreciable collisional relaxation with argon is observed.

The CN $B^2\Sigma^+$-$X^2\Sigma^+$ $\Delta v=0$ and -1 sequences were used for analysis. Since transitions from different vibrational states, especially from higher vibrational states, were heavily overlapped by one another in these sequences, their band envelopes were analyzed by simulation. Relative vibrational populations and effective rotational temperatures were taken as parameters. The intensity of a transition is given by

$$I_{v'N'}^{v''N''} \propto P_{v'N'} q_{v'v''} \nu^3 S_{N'N''} R_{v'N'} / Q_{v'}, \quad (1)$$

where $P_{v'N'}$ is the population in the level v' and N', ν is the transition frequency, $q_{v'v''}$ is the Franck-Condon factor, $S_{N'N''}$ is the rotational line-strength, $Q_{v'}$ is the rotational state sum, and $R_{v'N'}$ is the rotational distribution, which is assumed to follow the Boltzmann statistics. The intensities were superposed to obtain a band envelope. Molecular constants[15,16] and the Franck-Condon factors[17] were taken from the literature. Rotational line-strengths were calculated according to Mulliken's formulas.[18]

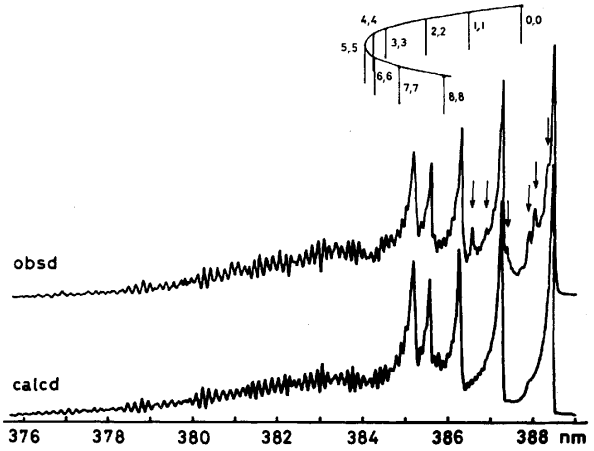

Fig. 2. Observed and simulated spectra of the CN $B^2\Sigma^+$-$X^2\Sigma^+$ 0-0 sequence. Those lines in the observed spectrum for which rotational perturbations with the $A^2\Pi$ state are known (indicated by arrows) are enhanced.

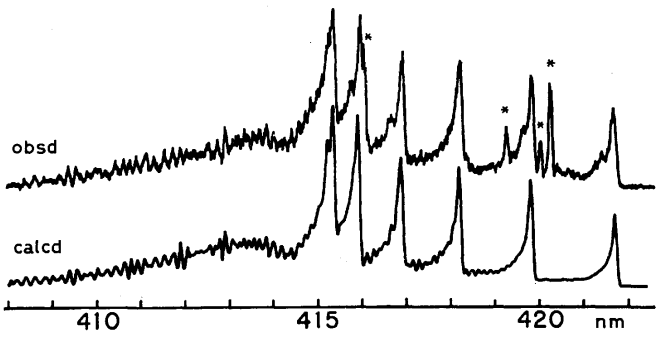

Fig. 3. Observed and simulated spectra of the CN $B^2\Sigma^+$-$X^2\Sigma^+$ 0-1 sequence. Asterisks indicate argon stray lines.

Simulated spectra are shown in Figs. 2 and 3 for the $\Delta v=0$ and -1 sequences, respectively. The observed and simulated spectra agree well except in the region where the intensities of the observed spectra are enhanced by the rotational perturbation with the $A^2\Pi$ state. The parameters used are listed in Table 1. The available energy, which is calculated from the argon metastable energies (11.55 and 11.72 eV[19]) and the C–C bond dissociation energy (5.2[20] or 5.32 eV[21]), is such that CN radicals can be excited up to $v'=14$ in the $B^2\Sigma^+$ state. Nevertheless, levels higher than $v'=11$, which are expected to appear as tail bands, were not observed.

Excess energy is defined as $E_{\text{excess}}=E_{\text{Ar}(^3P_{2,0})}-D_0-E_{\text{CN(B)}}$, where $E_{\text{Ar}(^3P_{2,0})}$ is the excitation energies of $\text{Ar}(^3P_{2,0})$, D_0 is the dissociation energies for H–CN and CH_3–CN, and $E_{\text{CN(B)}}$ is the electronic excitation energy of the $CN(B^2\Sigma^+)$. Then, excess energies for HCN and CH_3CN are nearly equal, since the dissociation energies, D_0, for H–CN (5.2[22] or 5.5 eV[20]) and CH_3CN (5.2[20] or 5.32 eV[21]) are nearly equal. The excess energy is distributed to vibration and rotation of $CN(B^2\Sigma^+)$ and the translational motions of the fragments. For CH_3CN, energy is also consumed in the internal degrees of freedom of the methyl radical.

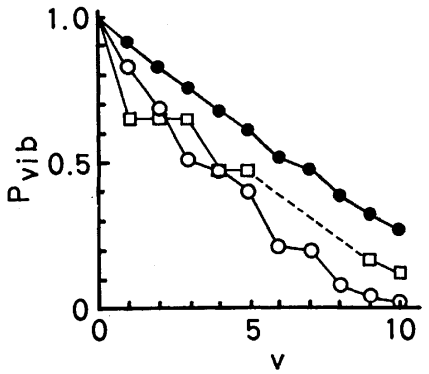

Fig. 4. Relative vibrational populations of the CN ($B^2\Sigma^+$) formed by impact of argon metastable atoms from CH_3CN (○, this work), HCN (●, Ref. 2), and HCN (□, Ref. 5).

Relative vibrational populations for the $CN(B^2\Sigma^+)$ from CH_3CN are compared with those from HCN[2,3,5] in Fig. 4. In spite of a slight discrepancy existing in the published populations for HCN, a clear difference is observed in the CH_3CN and HCN cases; populations in higher vibrational states are lower in the former case. The rotational excitation in the $CN(B^2\Sigma^+)$ from CH_3CN is higher than that from HCN (Table 1) in the $v'=0$—3 states.

Table 1. Relative vibrational populations, P_{vib}, and effective rotational temperatures, T_{rot}, of $CN(B^2\Sigma^+)$ formed in $Ar(^3P_{2,0})$ reactions

v	from CH_3CN[a]		from HCN[b]	
	P_{vib}	T_{rot}/K	P_{vib}	T_{rot}/K
0	0.23	5000	0.137	2400
1	0.19	5000	0.126	
2	0.15	5000	0.114	
3	0.12	4000	0.105	1900
4	0.11	3000	0.094	
5	0.09	2000	0.084	
6	0.05	2000	0.073	
7	0.04	2000	0.066	
8	0.02	2000	0.054	
9	0.01	2000	0.045	
10	$\lesssim$0.01	2000	0.038	

a) Errors in P_{vib} are about 0.02 for $v<5$ and about 0.01 for $v\gtrsim 5$. Errors in T_{rot} are estimated to be about 1000 K for $v<4$ and about 1500 K for $v\gtrsim 4$. b) Ref. 2.

Average energies distributed to vibration and rotation are 0.79 ± 0.10 and 0.35 ± 0.09 eV, respectively, for the CN($B^2\Sigma^+$) from CH_3CN, to be contrasted with those for HCN,[2] 1.2 and 0.2 eV, respectively. Accordingly, the CN($B^2\Sigma^+$) produced from CH_3CN is vibrationally less populated than that produced from HCN. This trend may be explained as that the methyl radical acts as an energy absorber,[3] *i.e.*, the residual energy may be used to excite the internal motions of the methyl radical. A similar trend was observed in the reaction of active nitrogen with organic compounds.[23]

Rotational Perturbation

The CN $A^2\Pi$ and $B^2\Sigma^+$ states are coupled through rotational perturbation,[24] and extra lines and anomalies in emission intensities have been observed. In order to estimate the ratio of the formation rates to the $A^2\Pi$ and $B^2\Sigma^+$ states, relative intensities for rotationally perturbed lines were analyzed. The analysis followed the scheme used in the analyses of the CN radicals formed in the reaction of active nitrogen with organic compounds,[25] in the electron impact on XCN (X=H, Br, and CN),[11] in the metastable-Ar impact on HCN and BrCN,[5] and in the photodissociation of ICN.[12]

Enhancement of intensities of the transitions from $N'=4$, 7, 11, and 15 in the $v'=0$ state were observed in a low resolution spectrum (Fig. 2). These states are known to be rotationally perturbed by the corresponding rotational levels in the $v=10$ level of the $A^2\Pi$ state. The R(14) transition was used for the analysis as the most suitable case.

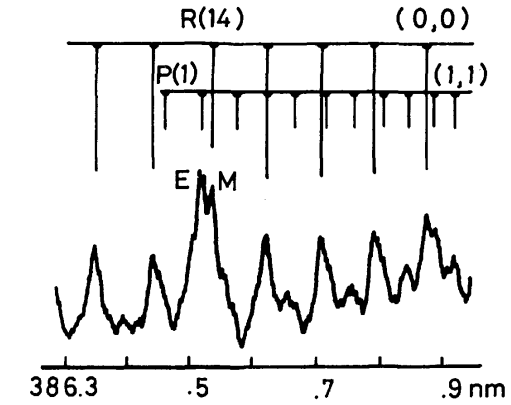

Fig. 5. A portion of the CN violet 0-0 band showing the rotationally perturbed R(14) lines (indicated as E and M).

A typical observed spectrum showing a rotationally perturbed line is given in Fig. 5. The spectrum was taken with a slit width of 10 μm. An extra line and a main line, which is overlapped by an unperturbed line, were observed. The relative intensities of the extra and main lines were essentially independent of the argon pressure between 0.3 and 0.8 Torr. Therefore, the effect of collisional relaxation is ignored in the following analysis.

The energy-level relations relevant to the rotational perturbation at the $B^2\Sigma^+$, $v=0$, $N=15$ level are shown in Fig. 6. The rate equations for the states shown in Fig. 6 lead to

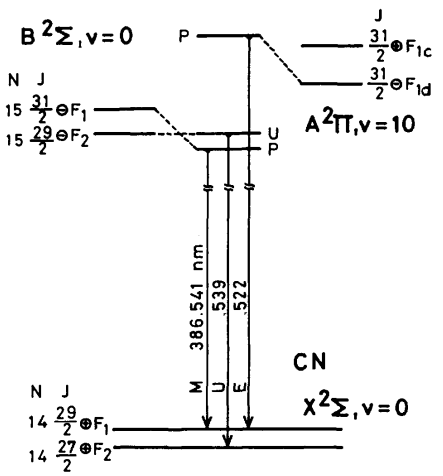

Fig. 6. Energy level diagram (schematic) for the rotational perturbation at the $B^2\Sigma^+$, $v=0$, $N=15$ level, drawn after Refs. 11, 24, and 26.

$$\frac{I_E}{I_M+I_U} = \frac{1+\beta\rho^2/(1-\rho^2)}{1+\beta(1-\rho^2)/\rho^2} \times \frac{1-\rho^2+\alpha\rho^2}{\rho^2+\alpha\{2-\rho^2+\beta\rho^2/(1-\rho^2)\}}, \quad (2)$$

where α is the ratio of formation rates to the $B^2\Sigma^+$ and $A^2\Pi$ states, F_B/F_A, β is the ratio of the radiative lifetimes of the states, τ_B/τ_A, and ρ^2 is a parameter representing the degree of mixing of the states. The values for β and ρ^2 are characteristic of the states and reported to be 0.14 and 0.22 respectively. Thus, the relative formation rate, α, is a function of the observable value, $I_E/(I_M+I_U)$. In deriving Eq. 2 the following assumptions are made: 1) Collisional transitions to and from the states shown in Fig. 6 are negligible. This implies that Eq. 2 is an exact expression for the low pressure limit. 2) The rates of formation of the different spin sublevels are equal. 3) A steady state is established. 4) The transition moment for the $A^2\Pi$ to $X^2\Sigma^+$ states is negligible in comparison with that for the $B^2\Sigma^+$-$X^2\Sigma^+$ transition. In addition, the difference in the transition frequencies between the extra and main lines is disregarded.

Since the rotational temperatures of the CN($B^2\Sigma^+$) levels obtained by a band envelope analysis are several thousand kelvins, the R(14) line is overlapped by the P-branches of $v'=0$ and 1. The intensities, I_E and I_M+I_U, are estimated by subtracting the overlapping band intensities estimated from the rotational temperatures.

The α value is then estimated from I_E and I_M+I_U to range between 0.14 and 0.23. In other words, the $A^2\Pi$ state is formed 4—7 times faster than the $B^2\Sigma^+$ state. This value is consistent with those produced from BrCN ($\alpha\simeq0.08$ obtained by extrapolating the values in Ref. 5 to zero pressure) and from HCN ($\alpha<0.18$).[5] Accordingly, a typical value of α in metastable argon reactions seems to be of the order of 0.1. This is in striking contrast with the corresponding values in electron-impact dissociative excitations of HCN, BrCN, and C_2N_2 ($0.5\lesssim\alpha\lesssim1.3$)[11] and in photodissociation of HCN

and BrCN ($\alpha \gg 1$)[7] by rare-gas (Xe, Kr), Hg (184.9 nm), and Br (145—170 nm) lamps. (Note, however, that a recent photodissociation experiment with the hydrogen Lyman-α line (10.2 eV) on ICN gave $\alpha=0.3$—0.5.[12]) The difference in α by different methods of excitation indicates a difference in the excited states of the parent molecules from which CN $A^2\Pi$ and $B^2\Sigma^+$ are produced.

Note added in proof. According to a recent report by Ashfold and Simons (*Chem. Phys. Lett.*, **47**, 65 (1977)), CN-($A^2\Pi$) as well as CN($B^2\Sigma^+$) was formed in the vacuum UV photodissociation of BrCN. See also Luk and Bersohn, *J. Chem. Phys.*, **58**, 2153 (1973).

Kinetic Study of Oxidative Addition and Replacement Reactions of Chlorotris(triphenylphosphine)rhodium(I) in Benzene

Yoshimi OHTANI, Masatoshi FUJIMOTO, and Akihiko YAMAGISHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 7, 1976)

Chlorotris(triphenylphosphine)rhodium(I) exists in benzene as $RhCl(PPh_3)_3$, a dimeric species $[RhCl(PPh_3)_2]_2$ and a reaction intermediate $RhCl(PPh_3)_2$. The rates of oxidative addition and replacement reactions were examined in benzene. For the oxidative addition reaction, $RhCl(PPh_3)_3$, $RhCl(PPh_3)_2$, or $[RhCl(PPh_3)_2]_2$+ $X_1 \overset{k_{add}}{\rightleftarrows}$Products ($X_1=H_2$, O_2, C_2H_4, $CHCl=CCl_2$, CH_3I), it was found that the reaction intermediate $RhCl(PPh_3)_2$ is most reactive, the degree of its reactivity depending largely on the reactants (X_1). A significant enhancement of the rate ($k_{sub}>k_{add}$) was observed for the ligand substitution reaction, $RhClX_1(PPh_3)_m+X_2 \overset{k_{sub}}{\rightleftarrows} RhClX_2(PPh_3)_n+X_1$ (m, $n=3$ or 2), where $X_1=H_2$ and $X_2=$olefin and *vice versa*. The results are discussed in relation to the mechanism of hydrogenation.

In recent years homogeneous reactions catalyzed by metal complexes have attracted attention and have been studied extensively.[1] Wilkinson's complex, chlorotris(triphenylphosphine)rhodium(I), is well known owing to its high reactivity in hydrogenation reactions.[2-6] A number of works have appeared on the mechanisms of the hydrogenation reactions catalyzed by this complex. In most works the overall rate of the reactions was determined by following the rate of H_2 gas absorption[3,4] or the change in concentration of the reactant and the product by gas-liquid chromatography.[7,8] The mechanisms of the hydrogenation of olefins were assumed by the dependence of the overall rate on the reactant concentrations. However, this sometimes leads to erroneous conclusions. There is another method in which the concentration change of the identified species of metal complexes or metal-reactant complexes is followed in solution. From the transient change of the species, it would be possible to establish the sequence of the reaction steps leading to the final hydrogenation products. Halpern and Wong studied the H_2 addition on Wilkinson's complex in benzene with a stopped-flow apparatus.[9] They determined the rate constant for several elementary steps with little ambiguity. We applied a similar method to study monomer$\rightleftarrows$dimer reactions of Wilkinson's complex, $2RhCl(PPh_3)_3 \rightleftarrows [RhCl(PPh_3)_2]_2+2PPh_3$, in benzene,[10] and identified the total mechanisms of the above reaction taking the intermediate species $RhCl(PPh_3)_2$ into consideration.

As an extension of the above work we report on the results of kinetic studies on the reactivities of the three species for the addition and the replacement reactions,

$$\underset{\text{Products}}{RhCl(PPh_3)_3,\ RhCl(PPh_3)_2,\ [RhCl(PPh_3)_2]_2} + X_1 \underset{\text{(addition)}}{\rightleftarrows}$$

$$RhClX_1(PPh_3)_m + X_2 \underset{\text{(replacement)},}{\rightleftarrows} RhClX_2(PPh_3)_n + X_1,$$

where X denotes a substrate and m, $n=3$ or 2. The intermediate structure of Wilkinson's complex during the course of hydrogenation is also discussed.

Experimental

Chlorotris(triphenylphosphine)rhodium(I) was prepared by the method described by Osborn *et al.*[3] Di-μ-chloro-tetrakis(triphenylphosphine)dirhodium(I) $[RhCl(PPh_3)_2]_2$ was obtained by dissolving Wilkinson's complex in benzene *in vacuo* and heating at *ca.* 60 °C. The precipitate was rapidly filtered and stored *in vacuo*. For the kinetic measurements it was solubilized in benzene by warming at 60 °C *in vacuo*. Triphenylphosphine was recrystallized from ethanol. Benzene, trichloroethylene, and acrylonitrile were distilled. Hydrogen, oxygen, ethylene, and methyl iodide were used without purification. The concentrations of H_2, O_2, and C_2H_4 at 1 atm were calculated from the solubility data.[11] The concentrations of H_2 and C_2H_4 were obtained by the gas-chromatography with a Molecular sieve 5A.

All the reactions were studied at 20 °C in oxygen-free benzene. The addition reactions of $CHCl=CCl_2$ and CH_3I were slow enough to measure with a Hitachi recording spectrophotometer model EPS-3T *in vacuo*. The progress of the reaction was followed by the absorbance change at 400 nm for $CHCl=CCl_2$ and 430 nm for CH_3I. The experiments of the addition and the replacement reactions involving C_2H_4, $CH_2=CHCN$, H_2, and O_2 were carried out with a Union Giken RA-1300 stopped-flow apparatus. The addition and the replacement reactions of C_2H_4 and $CH_2=CHCN$ were followed by the absorbance change at 422 nm and 400 nm, respectively. The addition reaction of O_2 was followed at 400 nm or 440 nm. The replacement reactions, $RhClX_1(PPh_3)_m+X_2 \rightleftarrows RhClX_2(PPh_3)_n+X_1$ (m, $n=3$ or 2), were observed by mixing an X_2 solution with an $RhClX_1(PPh_3)_m$ solution, where $X_1=H_2$ and $X_2=$olefin and *vice versa*. Above reactions were followed either by the decrease of $RhClX_1(PPh_3)_m$ or by the increase of $RhClX_2(PPh_3)_n$.

Results and Discussion

Oxidative Addition Reactions. Figure 1 shows the visible spectra of the addition products between $RhCl(PPh_3)_3$ (5.0×10^{-4} M) and H_2 (1.4×10^{-3} M), O_2(4.6×10^{-3} M), C_2H_4 (7.5×10^{-2} M), $CH_2=CHCN$(1.5×10^{-1} M), $CHCl=CCl_2$ (0.56 M), and CH_3I (2.5×10^{-2} M). The values in parentheses are the initial concentrations of the reactants.

Addition of Ethylene: Ethylene reacts reversibly with Wilkinson's complex to produce $RhCl(C_2H_4)L_2$, where $L=PPh_3$.[3,12] The stoichiometry of the reaction is

$$RhClL_3 + C_2H_4 \rightleftarrows RhCl(C_2H_4)L_2 + L. \quad (1)$$

The equilibrium constant of Eq. 1 is calculated to be $K=0.4$, which agrees with the value obtained by Tolman and co-workers.[12] The pseudo-first-order rate constant

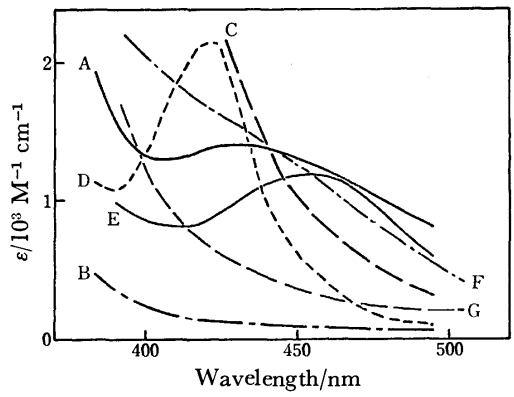

Fig. 1. Visible spectra of the equilibrium addition products on $RhClL_3$. $[RhClL_3]=5.0\times10^{-4}$ M, and $[PPh_3]=3\times10^{-3}$ M was added to exclude dimer formation. (A) none, (B) H_2 (1.4×10^{-3} M), (C) O_2 (4.6×10^{-3} M), (D) C_2H_4 (7.5×10^{-2} M), (E) CH_2=CHCN (1.5×10^{-1} M), (F) CHCl=CCl_2 (5.6×10^{-1} M), (G) CH_3I (2.5×10^{-2} M). The values in the parentheses are the initial concentrations of the reactants.

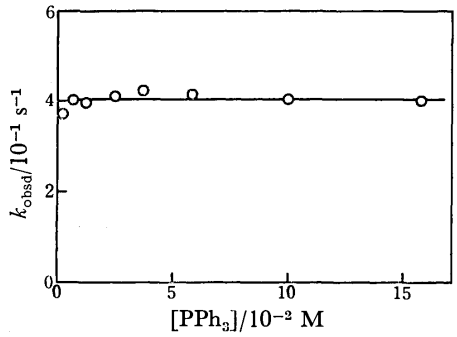

Fig. 2. Dependence of the observed rate constant of the ethylene addition reaction on the concentration of PPh_3. $[RhCl(PPh_3)_3]_0=5.0\times10^{-4}$ M, $[C_2H_4]=7.5\times10^{-2}$ M, and at 422 nm.

of the ethylene addition, k_{obsd}, is dependent neither on the concentration of L (0.002—0.16 M) (Fig. 2) nor on that of ethylene (0.025—0.075 M) added. The rate of the dissociation of ethylene from $RhCl(C_2H_4)L_2$ was measured by mixing the solution of L with the solution of the ethylene complex, $RhCl(C_2H_4)L_2$. The dissociation rate constant is also independent of the concentrations of L (0.012—0.081 M) (Fig. 3a) and ethylene (0.012—0.075 M) (Fig. 3b). The results are consistent with the following mechanism:

$$RhClL_3 + C_2H_4 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} RhClL_2 + L + C_2H_4$$

$$\underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} RhCl(C_2H_4)L_2 + L. \quad (2)$$

The value of k_{obsd} is expressed in terms of k_1, k_{-1}, k_2, and k_{-2} as

$$k_{obsd} = \frac{k_1k_2[C_2H_4]+k_{-1}k_{-2}[L]}{k_2[C_2H_4]+k_{-1}[L]}. \quad (3)$$

Since the rate of addition and dissociation show no dependence on the concentration of either C_2H_4 or L,

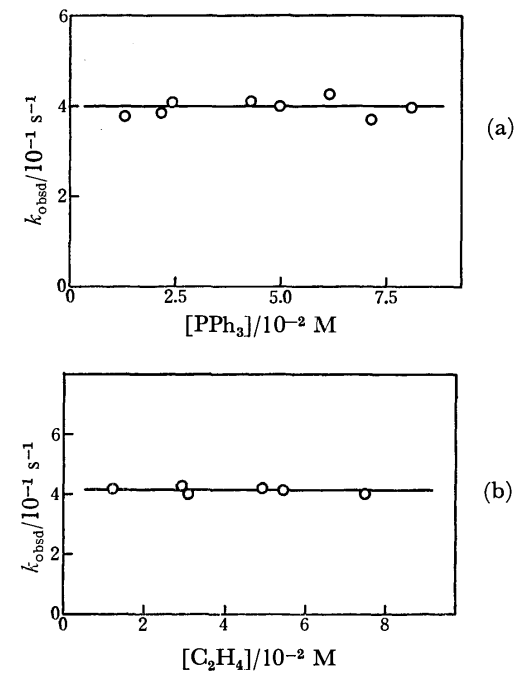

Fig. 3. Dissociation rate of ethylene from $RhCl(C_2H_4)(PPh_3)_2$. (a) Plot of k_{obsd} *vs.* $[PPh_3]$. $[RhCl(C_2H_4)(PPh_3)_2]_0=5\times10^{-4}$ M, $[C_2H_4]=7.5\times10^{-2}$ M, and at 422 nm. (b) Plot of k_{obsd} *vs.* $[C_2H_4]$. $[RhCl(C_2H_4)(PPh_3)_2]_0=5\times10^{-4}$ M, $[PPh_3]=5.2\times10^{-2}$ M, and at 422 nm.

we have $k_1=k_{-2}$; that is, $k_{obsd}=k_1=k_{-2}=0.4$ s^{-1} from Figs. 2 and 3. The value of the ratio $k_1k_2/k_{-1}=0.16$ s^{-1} since $K=k_1k_2/k_{-1}k_{-2}=0.4$. It is found that C_2H_4 reacts with only $RhClL_2$, whereas $RhClL_3$ is inactive for C_2H_4 addition.

Addition of Oxygen. Molecular oxygen adds to the Wilkinson's complex,[3,13] followed by the oxidation of the ligand PPh_3 in the Wilkinson's complex with coordinated active oxygen. In the present work, the fast addition reactions were studied:

$$RhClL_{3,2} + O_2 \longrightarrow RhCl(O_2)L_n \quad (n=3 \text{ or } 2)$$
$$(RhClL_2)_2 + O_2 \longrightarrow \text{Product}. \quad (4)$$

When a solution of Wilkinson's complex (5.0×10^{-4} M) was mixed with a solution of O_2 (9.1×10^{-3} M) under the conditions where the concentration of L is lower than 3×10^{-3} M, a two-step increase in absorbance was observed at 400 nm, the faster process terminating within 2 s and the slower one within 20 s. At 440 nm, the isosbestic point for $RhClL_3$ and $RhCl(O_2)L_n$ in equilibrium,[14] only the faster increase of the absorbance was observed. When the concentration of L exceeded 3×10^{-3} M, the faster process disappeared. This indicates that the slower step consists of the reaction between monomeric species $RhClL_3$ ($RhClL_2$ partly participates) and molecular oxygen. The faster one consists of the reaction between the dimer $(RhClL_2)_2$ and O_2. This was confirmed by a study of the solution containing only di-μ-chloro-terakis(triphenylphosphine)dirhodium (I) and oxygen.

The rate of the slower step is proportional to the concentration of O_2 ($(0.9—4.1)\times10^{-3}$ M). Figure 4

shows the dependence of the observed rate constant, k_{obsd}, on the concentration of L added. The value of k_{obsd} decreases until the concentration of L becomes *ca.* 1×10^{-2} M, attaining a constant value beyond this value. This trend is similar to that of the addition reaction of H_2 to the same complex reported by Halpern and Wong.[9] As in the case of the H_2 addition, the decrease of k_{obsd} with the addition of L may arise from the decrease of an active intermediate, $RhClL_2$, which is produced from $RhClL_3$ according to

$$RhClL_3 \rightleftharpoons RhClL_2 + L. \quad (5)$$

The mechanism for the O_2 addition to the monomeric species $RhClL_3$ is thus expressed by

$$\begin{array}{ccc} RhClL_3 + O_2 & \xrightarrow{k_M} & RhCl(O_2)L \\ k_1 \uparrow\downarrow k_{-1} & & \uparrow\downarrow \text{fast} \\ RhClL_2 + O_2 & \xrightarrow{k_I} & RhCl(O_2)L \\ + & & + \\ L & & L \end{array} \quad (6)$$

Application of the steady state approximation to $RhClL_2$ gives the following rate law:

$$-\frac{d[RhClL_3]}{dt} = \left\{k_M + \frac{k_1k_I}{k_{-1}[L]+k_I[O_2]}\right\}[O_2][RhClL_3]. \quad (7)$$

The ratio k_1/k_{-1} is less than 1×10^{-5} M.[9] k_1 was found to be 0.4 s^{-1} from the experiments of ethylene.[15] Thus $k_{-1}>4\times10^4$ M^{-1} s^{-1}. The value of k_M is found to be 26 M^{-1} s^{-1} by means of Eq. 7 from the constant value in Fig. 4. Introducing the above values of k_{-1} and k_M into Eq. 7 and applying the curve-fitting method to the results given in Fig. 4, we get the following rate constants: $k_1k_I/k_{-1}=1.7\times10^{-2}$ s^{-1}, $k_I>1.7\times10^3$ M^{-1} s^{-1}.

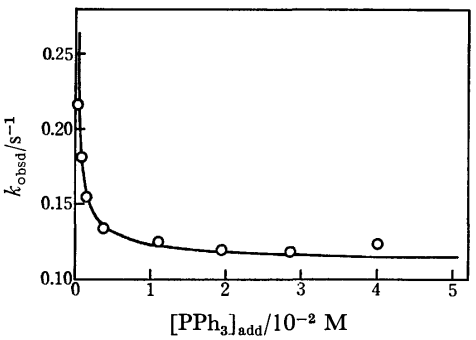

Fig. 4. Plot of the observed rate constant of the addition of O_2 *vs.* $[PPh_3]$. A solid curve is calculated from Eq. 7. $[RhCl(PPh_3)_3]_0=2.5\times10^{-4}$ M, $[O_2]=4.6\times10^{-3}$ M, and at 400 nm.

The rate of the following dimerization is negligibly small as compared to the rates of the O_2 addition (4).[10]

$$2RhClL_3 \rightleftharpoons (RhClL_2)_2 + 2L \quad (8)$$

The rate constant of the O_2 addition on the dimer which initially exists in Eq. 8 can thus be obtained by observing the decrease of the initial concentration of the dimer estimated from Eq. 8. The result is given in Fig. 5: $k_D=7.5\times10^2$ M^{-1} s^{-1}, where k_D is the addition rate constant on the dimer. The figure also contains the result involving only the dimer and O_2. It is seen

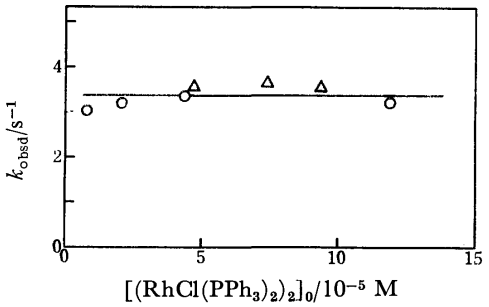

Fig. 5. Addition rate constant of O_2 on the dimer. ○; using Wilkinson's complex, △: using a pure dimer solution. $[O_2]=4.6\times10^{-3}$ M, at 440 nm.

that the faster process mentioned above corresponds to the O_2 addition on the dimer. Ethylene does not react with the monomer, while oxygen reacts with the monomer. The order of the rate constants is $k_I>k_D>k_M$ for the O_2 addition. The order corresponds to that for the H_2 addition reported by Halpern and Wong.[9]

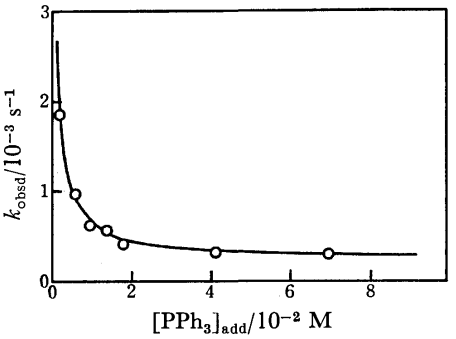

Fig. 6. Addition rate of $CHCl=CCl_2$. Plot of k_{obsd} *vs.* $[PPh_3]$. $[RhCl(PPh_3)_3]_0=5.0\times10^{-4}$ M, $[CHCl=CCl_2]=5.4\times10^{-2}$ M, and at 400 nm.

Addition of Trichloroethylene. The observed rate constant for the addition of $CHCl=CCl_2$ on Wilkinson's complex depends on the concentration of L as shown in Fig. 6. The trends of k_{obsd} are similar to those for the O_2 addition (Fig. 4), analysis thus being carried out in a similar way to that for oxygen. The results $k_M=4.6\times10^{-3}$ M^{-1} s^{-1}, $k_1k_I/k_{-1}=6.5\times10^{-5}$ s^{-1} and $k_I>6.5$ $M^{-1}\cdot s^{-1}$ were obtained.

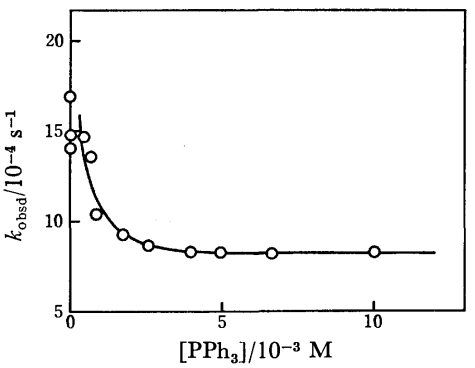

Fig. 7. Addition rate of CH_3I. Plot of k_{obsd} *vs.* concentration of PPh_3. The curve is calculated from Eq. 9. $[RhCl(PPh_3)_3]_0=5.1\times10^{-4}$ M, $[CH_3I]=2.5\times10^{-2}$ M, anda at 400 nm.

Addition of Methyl Iodide. Figure 7 shows the dependence of k_{obsd} for the addition of CH_3I on the concentration of L. When $[L]>1\times10^{-2}$ M, phosphonium salt precipitates during the course of measurement. However the CH_3I addition rate is not affected.[16] The value of k_{obsd} decreases with the addition of L as in the case of O_2 and $CHCl{=}CCl_2$.

By assuming the following mechanism involving the fast monomer-dimer equilibrium we obtained the curve given in Fig. 7.

$$\begin{array}{ccc} RhClL_3 + RhClL_3 & \overset{K}{\rightleftharpoons} & (RhClL_2)_2 + 2L \\ + & & + \\ CH_3I & & CH_3I \\ \downarrow k_M & & \downarrow k_D \\ \text{Product A} & & \text{Product B} \end{array} \quad (9)$$

$$-\frac{d[RhClL_3]}{dt} = k_M[RhClL_3][CH_3I] + k_D[(RhClL_2)_2][CH_3I], \quad (10)$$

$$= k_M[RhClL_3][CH_3I] + k_DK\frac{[RhClL_3]^2}{[L]^2}[CH_3I], \quad (10')$$

$$k_{obsd} = \left\{k_M + k_DK\frac{[RhClL_3]}{[L]^2}\right\}[CH_3I], \quad (11)$$

where k_M is the rate constant under the higher L concentration ($>3\times10^{-3}$ M) and k_D the rate constant obtained for the solution of di-μ-chloro-tetrakis(triphenylphosphine)dirhodium(I) and CH_3I. The curve shows that the decrease of k_{obsd} is interpreted by the monomer-dimer equilibrium species alone. No contribution of the reaction intermediate, $RhClL_2$, is observed. This is confirmed by the dependence of k_{obsd} on the concentration of $RhClL_3$ ($(2—15)\times10^{-4}$ M) observed without L added ($[CH_3I]=0.025$ M=const.) (Fig. 8). The fact that k_{obsd} increases with the increase in the total concentration of Rh complex even under the conditions of $[CH_3I]\gg$[Rh complex] indicates that the aggregated form of Rh complex (dimer) is more active than a monomer for the addition of CH_3I.

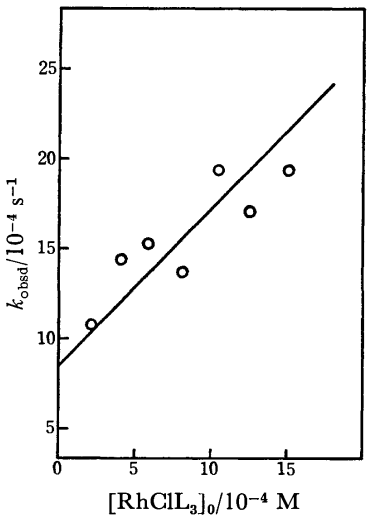

Fig. 8. Addition rate of CH_3I. Plot of k_{obsd} *vs.* $[RhCl(PPh_3)_3]_0$. $[CH_3I]=2.5\times10^{-2}$ M, $[PPh_3]_{add}=0$ M, and at 400 nm.

If the dimerization process is rate-determining in the reaction path of product B, Eq. 10 is modified as Eq. 13:

$$\begin{array}{ccc} RhClL_3 + RhClL_3 & \overset{K_1}{\rightleftharpoons} & RhClL_3 + RhClL_2 + L \\ + & & \overset{k_2}{\longrightarrow} (RhClL_2)_2 + 2L \\ CH_3I & & + \\ \downarrow k_M & & CH_3I \\ \text{Product A} & & \downarrow k_D \\ & & \text{Product B} \end{array} \quad (12)$$

$$-\frac{d[RhClL_3]}{dt} = k_M[RhClL_3][CH_3I] + K_1k_2\frac{[RhClL_3]^2}{[L]}, \quad (13)$$

$$k_{obsd} = k_M[CH_3I] + K_1k_2\frac{[RhClL_3]}{[L]},$$

where $K_1k_2=1.1\times10^{-3}$ s^{-1}.[10] The intercept of the curve in Fig. 8 gives 8×10^{-4} s^{-1} which is equal to the value in the higher concentration of L in Fig. 7. Thus the value 8×10^{-4} s^{-1} corresponds to the observed rate constant of the reaction of CH_3I with the monomer.

Conclusion of the Addition Reactions: The results are summarized in Table 1. The main findings are as follows.

(i) Except for CH_3I, an intermediate complex ($RhClL_2$) is the most reactive among the three species, $RhClL_3$, $RhClL_2$, and $(RhClL_2)_2$.

(ii) The values of k_M and k_D increase in the sequence of $CHCl{=}CCl_2<CH_3I<H_2<O_2$ and k_I in the sequence of $CHCl{=}CCl_2<O_2<C_2H_4<H_2$.

$RhClL_2$ might be a solvated species obtained by replacing one L of $RhClL_3$ with a solvent molecule. Thus the first finding implies that the main factor in determining the reactivity of the metal complex for oxidative addition is the presence of the labile site occupied by a solvent molecule. If the addition rate were determined by the dissociation of L from $RhClL_3$ (Eq. 5), k_I would be constant irrespective of the kind of substrate. However, as stated in (ii), k_I varies over several orders of magnitude for the substrates studied. k_I is remarkably large for C_2H_4 and H_2 but not for O_2. Therefore the addition reaction on $RhClL_2$ may be of an

Table 1. Rate constants of oxidative addition

a) From Ref. 9, at 25 °C. b) The exact values could not be estimated.

associative character proceeding through a five coordinated complex, $RhClL_2SYZ$, where S and YZ are the solvent molecule and the reactant, respectively.

The kinetic nature of Wilkinson's complex becomes more evident when the present results are compared with those for Vaska's complex, $IrCl(CO)L_2$. Vaska's complex undergoes the oxidative addition reaction as follows.

$$IrCl(CO)L_2 + X \rightleftarrows IrClX(CO)L_2.$$

For Vaska's complex, the rates of the addition of various substrates follow the order $C_2H_4 < O_2 < H_2$ in chlorobenzene at 30 °C.[17] Probably because of the presence of a labile site in Wilkinson's complex, the magnitude of k_1 is generally much higher than for Vaska's complex.[18] Comparing the reactivities with C_2H_4 and O_2 of Wilkinson's complex with those of Vaska's complex we find that their reactivities are reversed. The difference in the reactivities for both complexes may also be related to the bond nature of metal-substrate, but not entirely to the electronic property intrinsic to the substrate such as electron affinity.

Chock and Halpern[18] suggested that for the addition reaction of CH_3I to the $IrCl(CO)L_2$ complex the transition-state configuration would be

$$L_2(CO)ClIr^{\delta+}\cdots CH_3\cdots I^{\delta-}.$$

The present reaction for CH_3I may proceed through a similar transition-state configuration. Thus the change in the polarity both in a central metal and CH_3I plays a more important role than the substitution lability in $RhClL_2$. The labile site is not highly effective also in the case of the addition reaction of CH_3I on Pt complex. The rate constants are reported to be 3.5×10^{-3} $M^{-1}s^{-1}$ and 2.0×10^{-2} $M^{-1}s^{-1}$ for $Pt(PPh_3)_3$ and $Pt(PPh_3)_2$, respectively.[16]

Replacement Reactions. $RhCl(C_2H_4)L_2+H_2+L$ and $RhClH_2L_3+C_2H_4$: When a solution of $RhCl(C_2H_4)L_2$ ($[C_2H_4]=7.5\times10^{-2}$ M) is mixed with a solution of H_2 ($[H_2]=1.4\times10^{-3}$ M), a rapid decrease of $RhCl(C_2H_4)L_2$ occurs. No hydrogenation of C_2H_4 takes place within the time range[3] studied. There is no free Rh complex present under the given H_2 and C_2H_4 concentrations. The reaction of $RhCl(C_2H_4)L_2$ and H_2 thus seems to proceed as follows:

$$RhCl(C_2H_4)L_2 + H_2 + L \rightleftarrows RhClH_2L_3 + C_2H_4. \quad (14)$$

The equilibration is confirmed by the same spectra of $RhCl(C_2H_4)L_2+H_2+L$ and of $RhClH_2L_3+C_2H_4$, irrespective of the mode of mixing. Figures 9(a) and (b) give the dependence of k_{obsd} on [L] for the reaction of $RhCl(C_2H_4)L_2+H_2+L$ and $RhClH_2L_3+C_2H_4$, respectively. Increase of k_{obsd} with decreasing [L] suggests that in the replacement reaction $RhClH_2L_3$ is activated by dissociation of an L molecule. Thus the mechanism of the replacement reaction is

$$RhCl(C_2H_4)L_2 + H_2 + L \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} RhClH_2L_2 + C_2H_4 + L \underset{K}{\rightleftarrows} RhClH_2L_3 + C_2H_4, \quad (15)$$

$$k_{obsd} = k_1[H_2] + k_{-1}\frac{[C_2H_4]}{1+[L]/K}, \quad (16)$$

where K is the equilibrium constant for the dissociation of L from $RhClH_2L_3$. It is assumed in the derivation of the equation that the dissociation of L from $RhClH_2L_3$ is much faster than the replacement reaction of $RhCl(C_2H_4)L_2$ with H_2.[19] Equation 16 shows that the value of k_{obsd} in the plateau region of Figs. 9 (a) and (b) ($20\ s^{-1}$) corresponds to the forward reaction rate of Eq. 14 (when $[L]>5\times10^{-3}$ M, $k_{obsd}=k_1[H_2]$). Figures 10(a) and (b) show the dependence of k_{obsd} on the concentration of H_2 and C_2H_4 for the reactions $RhCl(C_2H_4)L_2+H_2+L$ and $RhClH_2L_3+C_2H_4$, respectively ($[L]=7.0\times10^{-3}$ M). The fact that k_{obsd} is independent of $[C_2H_4]$ is in line with the conclusion that k_{obsd} corresponds to the forward reaction rate. It will be expected from Eq. 16 that k_{obsd} is proportional to $[H_2]$. The dependence of k_{obsd} on the H_2 concentration, however, does not follow the relation $k_{obsd}=k_1[H_2]$. The results in Fig. 10(a) imply that the forward rate consists of at least two terms, one independent of $[H_2]$ and the other proportional to $[H_2]$. Thus we assume two parallel paths for the replacement of $RhCl(C_2H_4)L_2$ with H_2.

$$RhCl(C_2H_4)L_2 + H_2 \xrightarrow[A]{L} RhClH_2L_3 + C_2H_4 \text{ (path 1)}$$
$$\xrightarrow[B]{} Rh^*Cl(C_2H_4)L_2 + H_2 \xrightarrow{L} RhClH_2L_3 + C_2H_4 \text{ (path 2)} \quad (17)$$

Path 1 is the direct exchange between H_2 and the coordinated C_2H_4 ($k=7.8\times10^3$ M^{-1} s^{-1}). Path 2 involves the uni-molecular step (B) in which $RhCl(C_2H_4)L_2$ is

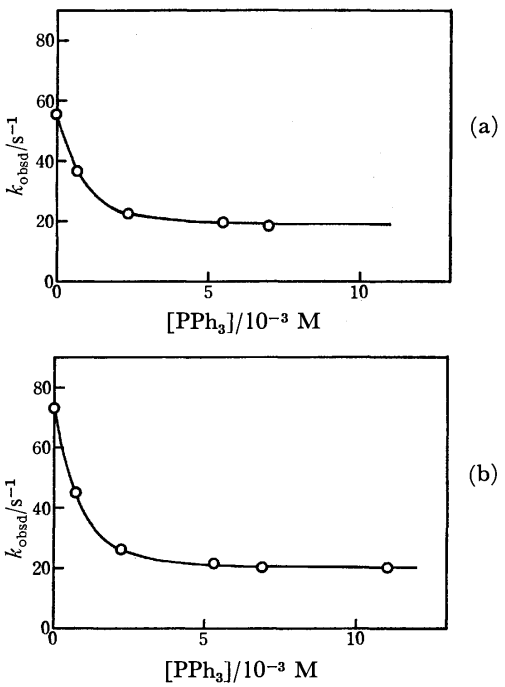

Fig. 9. Replacement reactions. Plot of k_{obsd} *vs.* $[PPh_3]$. (a) $RhCl(C_2H_4)(PPh_3)_2+H_2+PPh_3$; $[RhCl(C_2H_4)(PPh_3)_2]=2.5\times10^{-4}$ M, $[C_2H_4]=7.5\times10^{-2}$ M, $[H_2]=1.4\times10^{-3}$ M, and at 422 nm. (b) $RhClH_2(PPh_3)_3+C_2H_4$; $[RhClH_2(PPh_3)_3]_0=2.5\times10^{-4}$ M, $[H_2]=1.4\times10^{-3}$ M, $[C_2H_4]=7.5\times10^{-2}$ M, and at 422 nm.

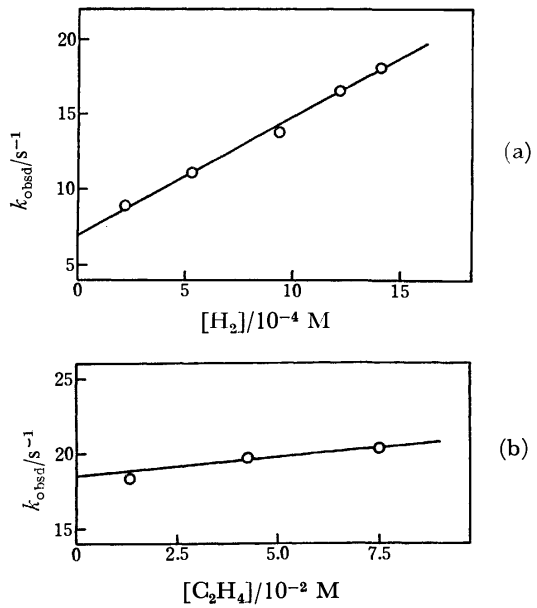

Fig. 10. Replacement reactions. Plots of k_{obsd} *vs.* concentration of the reactants. (a) $RhCl(C_2H_4)(PPh_3)_2+H_2+PPh_3$; dependence of k_{obsd} on the concentration of H_2. $[RhCl(C_2H_4)(PPh_3)_2]_0=1.6\times10^{-4}$ M, $[C_2H_4]=7.5\times10^{-2}$ M, $[PPh_3]=7.0\times10^{-3}$ M, and at 422 nm. (b) $RhClH_2(PPh_3)_3+C_2H_4$; dependence of k_{obsd} on the concentration of C_2H_4. $[RhClH_2(PPh_3)_3]_0=2.5\times10^{-4}$ M, $[H_2]_0=1.4\times10^{-3}$ M, $[PPh_3]=7.0\times10^{-3}$ M, and at 422 nm.

activated ($k=7\ s^{-1}$). Process B does not involve the dissociation of C_2H_4. The rate constant of the dissociation of C_2H_4, k_{diss}, is $0.4\ s^{-1}$ as determined previously. On the other hand the intercept in Fig. 10(a) gives $7\ s^{-1}$ to the rate constant of the uni-molecular process in path 2, which is much greater than k_{diss}. The uni-molecular process seems to be the dissociation process of a solvent molecule which is loosely coordinated to the central metal above or below the plane of $RhCl(C_2H_4)L_2$ complex.

$RhCl(CH_2=CHCN)L_2+H_2+L$ and $RhClH_2L_3+CH_2=CHCN$: The results of kinetic studies on this system are very similar to those obtained for $RhCl(C_2H_4)L_2+H_2+L$ and $RhClH_2L_3+C_2H_4$. The results are summarized in Table 2.

TABLE 2. OBSERVED RATE CONSTANTS OF THE REPLACEMENT REACTIONS ($RhClX_1L_m+X_2\rightleftarrows RhClX_2L_n+X_1$; $m, n=3$ or 2)

k_{obsd}/s^{-1}

$RhClX_1L_m$	X_2		
	H_2	C_2H_4	$CH_2=CHCN$

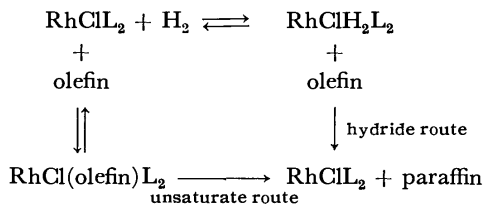
C_2H_4	18	—	310
$CH_2=CHCN$	20	250	—
None[a]	0.071	0.4	0.5

a) Observed rate constants of the addition reactions under comparable conditions. $[RhCl(PPh_3)_3]_0=2.5\times10^{-4}$ M, $[PPh_3]=7\times10^{-3}$ M, $[H_2]_0=1.4\times10^{-3}$ M, and $[C_2H_4]=[CH_2=CHCN]=7.5\times10^{-2}$ M.

Conclusion on the Replacement Reactions: In the replacement reaction the rate of replacement of the coordinated olefin by H_2 is greater by about two orders of magnitude than the rate of the oxidative addition of H_2 on Rh complex under comparable conditions. The acceleration effect observed implies that the approach of H_2 to Rh(olefin) complex makes the coordinated olefin labile. In other words, a strong interaction exists through the central metal between H_2 and the coordinated olefin. It strongly supports the presence of an associative intermediate $RhClH_2(olefin)L_2$. The hydrogenation of the olefins proceeds much more slowly than the replacement reaction.[3] However, it is probable that on hydrogenation of the olefins the same associative intermediate exists, on which 2H migrate on olefin to produce paraffin. If that is the case the complex formation step is considered to be a pre-equilibrium in the hydrogenation of olefins. If this conclusion is correct, there is no question as to whether H_2 or olefin adds first on the Rh complex during the course of hydrogenation, that is the hydride route or the unsaturate route.[3,4,6,7]



We consider that the high activity of Wilkinson's complex may arise from the existence of both the intermediates $RhClL_2$ and $RhClH_2(olefin)L_2$ through which hydrogenation of the olefin proceeds.

We wish to express our thanks to Dr. Tokio Iizuka of this department for the supply of ethylene. The present work was supported by the Grant-in-Aid for Scientific Research from the Ministry of Education.

The Fluorometric Determination of Indium with 8-Quinolinethiol[1)]

Kunihiro WATANABE, Akio FUJIWARA, and Kyōzō KAWAGAKI
Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda-shi, Chiba 278
(Received October 7, 1976)

8-Quinolinethiol reacts with indium in the presence of acetic acid to give a yellow ternary complex. The complex, which has a greenish-yellow fluorescence with an emission maximum at 515 nm, can be extracted into chloroform at pH 2—4. In the ternary complex, the fluorescence intensity was about two times as large as that of the indium 8-quinolinethiolato complex containing no acetate ion. The fluorescence was stable for at least 1 h. By the use of a 0.2 μg/ml uranine solution as the setting reagent, 0—25 μg of indium in 10 ml of chloroform was determined. The coefficient of the variation was 3% for 12 μg of indium. The extractability of the ternary complex from 50 ml of an aqueous solution into 10 ml of chloroform was 99%. Iron, mercury, and silver, which interfere with the determination of indium, were masked with ascorbic acid, potassium iodide, and thiourea. Other interfering elements, including zinc, cadmium, gallium, nickel, palladium, cobalt, antimony, gold, copper, bismuth, and vanadium, must be removed before any analysis.

8-Quinolinethiol reacts with metal ions to form water-insoluble chelates, and they are extracted into some organic solvents. The indium 8-quinolinethiolato chelate extracted into chloroform or benzene has been used in spectrophotometric[2)] and fluorometric[3,4)] determination methods. The spectra and the composition of the indium chelate have also been obtained by Davis.[3)] Suprunovich *et al.*[5)] found that the indium 8-quinolinethiolato chelate reacts with acetic acid to form a ternary complex. However, the determination of indium in terms of the ternary-complex formation has not yet been studied. Recently, the present authors have found the ternary complex of indium–8-quinolinethiol–acetic acid to have a stronger fluorescence than the indium 8-quinolinethiolato chelate containing no acetate ion.

The present paper will report on the fundamental conditions for the fluorometric determination of indium with 8-quinolinethiol in the presence of acetic acid. Chloroform and methyl isobutyl ketone (MIBK) were used as the extraction solvents.

Experimental

Reagents. Standard solution of indium: 0.2502 g of 99.99% indium metal (Mitsubishi Kinzoku) was dissolved in 25 ml of hydrochloric acid, and then the solution was diluted to 250 ml with water. The solution was diluted further as a more diluted solution was required.

0.2% 8-Quinolinethiol Solutiol: In 50 ml of 6 M (M=mol dm^{-3}) hydrochloric acid, 0.1 g of 8-quinolinethiol hydrochloride (Dojin Yakukagaku) was dissolved.

Buffer Solution: A 2% ammonium acetate solution was prepared. The pH of the buffer solution was adjusted with hydrochloric acid or ammonia.

Acetic Acid: Glacial acetic acid of an analytical grade (Wako Chemicals Co.) was used.

A 0.2 μg/ml Uranine Solution: 0.1 g of uranine was dissolved in water, and the solution was diluted to 100 ml. The solution was then further diluted with water to obtain a solution containing 0.20 μg uranine per ml.

Other Reagents: The chloroform and MIBK used as extraction solvents and the other chemicals used were all of an analytical reagent grade.

Apparatus. The fluorometric measurements were carried out using a Hitachi fluorescence spectrophotometer, Model 203, with a mercury lamp. A 120-W Xenon lamp was used as the exciting source for the measurements of the fluorescence and excitation spectra. A 1 cm × 1 cm quartz cell was used. The pH was measured with a Toa Denpa Model HM-5 pH meter. An Iwaki KM shaker was used.

Procedure. To a sample solution containing 0.5—25 μg of indium, we added 10 ml of glacial acetic acid and 0.2 ml of a 0.2% 8-quinolinethiol solution. After the solution had then been diluted to 50 ml with water, the pH of the solution was adjusted to 2.5 with diluted hydrochloric acid or ammonia. The resultant aqueous solution was then transferred into a separatory funnel. The indium complex was extracted with 10 ml of chloroform or MIBK by shaking it vigorously for 2 min. After the separation of the mixture into two phases, the organic phase was transferred into a quartz cell and the fluorescence intensity of the extract was measured using a 0.2 μg-per-ml uranine solution as the reference standard. The excitation and fluorescence wavelengths used were 365 and 515 nm respectively. The content of indium was calculated using the calibration curve.

Results and Discussion

Excitation and Fluorescence Spectra. The apparent excitation and fluorescence spectra of the ternary complex and the indium 8-quinolinethiolato chelate extracted into chloroform and MIBK are given in Fig. 1. The ternary complex had an excitation maximum at 395 nm and a fluorescence maximum at 515 nm, while the indium 8-quinolinethiolato chelate had an excitation maximum at 395 nm and a fluorescence maximum at 505 nm. No shift of these maximum wavelengths due to extraction solvents was observed. The ternary complex, however, had a fluorescence intensity about two times as large as that of the indium 8-quinolinethiolato chelate. The fluorescence intensity of the complex extracted into chloroform was greater than that of the complex extracted into MIBK.

Effect of the pH. The effect of the pH of the aqueous phase on the fluorescence intensity is shown in Fig. 2. The optimum pH for the extraction of the indium 8-quinolinethiolato chelate was 1.6. The maximum extractability of the ternary complex into chloroform was, however, obtained at pH values from 2 to 4 and the fluorescence intensity of the complex in MIBK gave a maximum at pH 1.8—2.2. Therefore, the extractions of the ternary complex were carried out at pH 2.5 in chloroform and at pH 2.0 in MIBK.

Emission spectra (II): Excited at 395 nm, a: acetic acid 10 ml, chloroform extraction, pH: 2.5, b: acetic acid 10 ml, MIBK extraction, pH: 2.0, c: acetic acid 0 ml, chloroform extraction, pH: 1.6, In 12 μg.

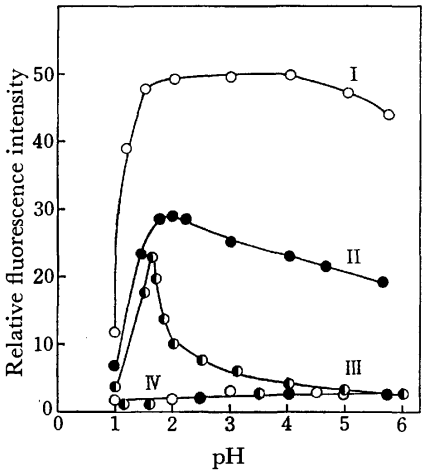

Fig. 2. Effect of pH on fluorescence intensity. In: 12 μg, I: acetic acid 10 ml, chloroform extraction, II: acetic acid 10 ml, MIBK extraction, III: acetic acid 0 ml, chloroform extraction, IV: reagent blanks.

Effect of the Acetic Acid Concentration. The effect of the acetic acid concentration in the aqueous phase on the extraction of ternary complex was examined by varying the acetic acid concentration. As the concentration of the acetic acid increased, the fluorescence intensity of the extract increased remarkably. However, above 3.4 M (10 ml acetic acid/50 ml) the fluorescence intensity increased gradually with the amount of acetic acid, as is shown in Fig. 3. On the other hand, since acetic acid in concentrations higher than 6.8 M gave difficulties in the pH adjustment and in the separation of the aqueous and MIBK phases, the concentration of acetic acid was kept at 3.4 M.

Effect of the Concentration of 8-Quinolinethiol. The effect of the 8-quinolinethiol concentration in the aqueous phase on the extractability of the ternary

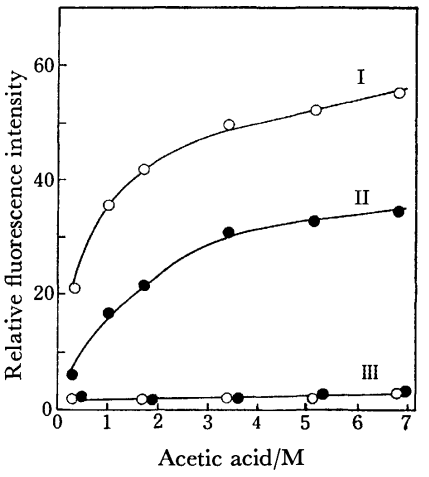

Fig. 3. Effect of the concentration of acetic acid on fluorescence intensity. In: 12 μg, I: chloroform extraction, II: MIBK extraction, III: reagent blanks.

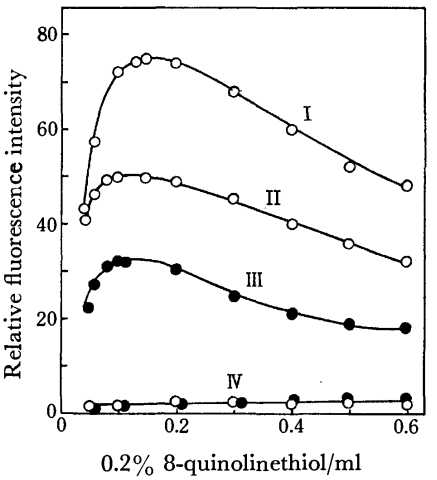

Fig. 4. Effect of amount of 8-quinolinethiol on fluorescence intensity. I: chloroform extraction, In: 18 μg, II: chloroform extraction, In: 12 μg, III: MIBK extraction, In: 12 μg, IV: reagent blanks, Acetic acid: 10 ml.

complex was examined by varying the amount of the 0.2% 8-quinolinethiol solution added, while the other variables were held constant. The results shown in Fig. 4 indicate that the optimum amount of the reagent was 0.1 ml of the 0.2% solution for 12 μg of indium, and from 0.1 to 0.2 ml for 18 μg of indium. The fluorescence intensity of the extracts decreased gradually with the increase in the reagent. The reagent blank was constant. Therefore, the amount of the 0.2% 8-quinolinethiol solution was kept at 0.2 ml.

Effect of the Volume of the Aqueous Solution. For the investigation of the effect, the volume of the organic phase was kept at 10 ml, while that of the aqueous phase was varied from 30 to 150 ml. When the concentration of acetic acid added was kept at 3.4 M, the fluorescence intensity in chloroform was nearly constant regardless of the increase in the volume of the aqueous phase. On the other hand, when MIBK was used for the extraction of the complex, a small amount of MIBK dissolved in the aqueous phase, so that the fluorescence

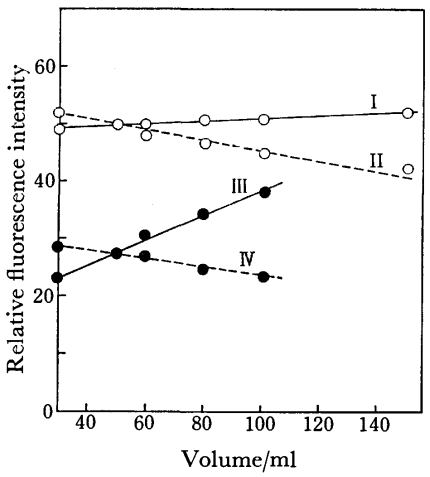

Fig. 5. Effect of volume of aqueous solution on fluorescence intensity. I, III: Concentration of acetic acid was kept at 3.4 M, II, IV: amount of acetic acid added was kept at 10 ml, I, II: chloroform extraction, III, IV: MIBK extraction.

intensity gradually increased with the volume of the aqueous phase. However, when the amount of acetic acid added was kept at 10 ml, the fluorescence intensities in organic solvents decreased with a decrease in the concentration of acetic acid. The results are shown in Fig. 5.

Effect of the Shaking Time, and the Stability of the Ternary Complex. The shaking time was varied from 0.25 to 30 min. It was found that shaking for 1 min was, in most cases, long enough for the extraction. A shaking time of 2 min was chosen, however, taking into consideration the possibility of accidental failure in extractability.

The fluorescence intensity of the ternary complex in a closed quartz cell was measured at 5 min intervals. The fluorescence intensity was constant until 10 min, past which point it increased gradually with the decrease in the amount of the solvent because of evaporation. However, after the ternary complex had been extracted, the fluorescence was stable at least for 60 min in a separatory funnel. It is recommended, therefore, to measure the fluorescence intensity of the complex within 10 min after it is transferred into a quartz cell.

TABLE 1. RELATIVE FLUORESCENCE INTENSITIES OF THE INDIUM–8-QUINOLINETHIOL–ACETIC ACID COMPLEX IN VARIOUS ORGANIC SOLVENTS

Solvent (10 ml)	Relative fluorescence intensity		
	Complex	Reagent blank	Difference
Chloroform	49.1	2.0	47.1
Benzene	31.8	1.2	30.6
MIBK	30.7	2.2	28.5
Toluene	27.0	1.8	25.2
Carbon tetrachloride	24.8	1.2	23.6
Xylene	26.1	2.9	23.2
Diisopropyl ether	23.0	1.2	21.8
Cyclohexane	4.0	1.2	2.8

In: 12 μg.

Extractability. A 50 ml portion of the aqueous phase containing the indium complex was shaken with 10 ml of chloroform, and the fluorescence intensity of the extract was measured. Then the indium remaining in the aqueous phase was extracted twice with chloroform. Extractability was calculated from the sum of the fluorescence intensities of the extracts and that of the first extract. It was found that 99% of indium was extracted by a single extraction.

Choice of Solvent. Chloroform was used as the extraction solvent of indium 8-quinolinethiolato chelate by Davis,[3] while benzene was used by Korenman *et al.*[4] The ternary complex of indium–8-quinolinethiol–acetic acid can also be extracted into many organic solvents. Therefore, the relative fluorescence intensities of the ternary complex extracted into several organic solvents were examined. The experimental results showed that chloroform and benzene, as well as MIBK, were excellent solvents, as is shown in Table 1. Chloro-

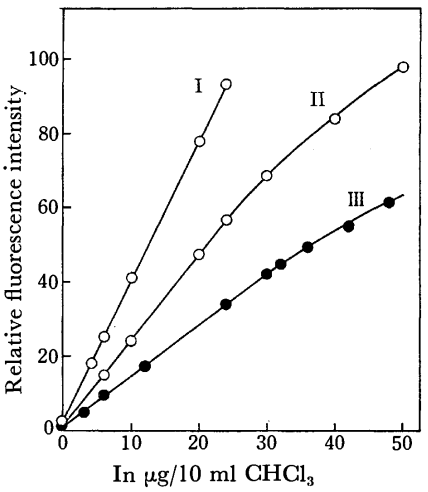

Fig. 6. Calibration curves for indium. Fluorometer reading was set at 50 div. (curve I) or 30 div. (curves II, III) with the uranine reference solution (0.2 μg/ml). I, II: chloroform extraction, III: MIBK extraction.

form and MIBK have been chosen as the solvents.

Calibration Curves. Figure 6 shows the calibration curves for indium, which were obtained by the described procedure above, based on the experimental results. However, the pH's of extraction were 2.5 in the chloroform extraction and 2.0 in the MIBK extraction. The sensitivity of the fluorometer was adjusted by setting the fluorescence of the standard uranine solution (0.2 μg/ml) at 30 or 50 on the fluorometer scale.

A good linear relationship was obtained over the concentration ranges from 0 to 25 μg per 10 ml of chloroform, and from 0 to 32 μg per 10 ml of MIBK. The coefficient of the variation obtained in 25 measurements was 3% for 12 μg of indium.

Effects of Diverse Ions and of Masking. The effects of 29 cations on the determination of indium were studied under optimum conditions. The results are shown in Table 2. Gallium, zinc, and cadmium gave positive errors in the determination of indium, and copper, cobalt, iron, nickel, palladium, mercury, bismuth, antimony, gold, vanadium, and silver ions reduced the fluorescence, but the other ions presented in Table 2 did not interfere.

The interference of ions such as iron (up to 1 mg), mercury (up to 100 μg), and silver (up to 1 mg) can be masked by using ascorbic acid, a mixture of ascorbic acid and potassium iodide, and thiourea respectively.

Composition of the Ternary Complex. By using the variation method fluorometrically, the molar ratio of indium to 8-quinolinethiol was found to be 1 : 2. However, the molar ratio of indium to acetic acid was not determined.

The Effect of Steric Condition on the Structure of Cobalt(II), Nickel(II), and Copper(II) Complexes with Schiff Bases Obtained from Salicylaldehyde Derivatives and 9-Aminofluorene

Shoichiro YAMADA, Hideaki TANAKA, and Kuniko YAMANOUCHI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received November 1, 1976)

Cobalt(II), nickel(II), and copper(II) complexes with *N*-(9-fluorenyl)salicylideneaminates (abbreviated as X-sal-fl) have been examined in relation to the effect of steric condition on the structure of the metal complexes. Compounds of the type $M(X\text{-sal-fl})_2$ and their pyridine adducts were isolated as crystals. Complexes of the type Cu(X-sal-fl)Cl were also obtained. Both in the solid state and in non-donor solvents, the complexes $Co(X\text{-sal-fl})_2$ have a tetrahedral configuration, and $Ni(X\text{-sal-fl})_2$ and $Cu(X\text{-sal-fl})_2$ have a square-planar configuration. Possible structures of the pyridine adducts are discussed. The results indicate that the steric hindrance caused by fluorenyl is greater than that by diphenylmethyl.

Transition metal complexes with *N*-substituted salicylideneaminates (abbreviated as X-sal-R, a) vary widely in structure, depending upon the steric conditions arising from the substituent R.[1-3] Many 3d metal complexes with *N*-isopropyl- and *N*-diphenylmethylsalicylideneaminates (b, c)[4] were synthesized and the steric effect of the substituents on the structure of the metal complexes was discussed. The present work deals with cobalt(II), nickel(II), and copper(II) complexes with *N*-(9-fluorenyl)salicylideneaminates (d), whose steric condition is expected to differ slightly from that of the *N*-diphenylmethyl-derivatives.

Experimental

Materials. Analytical data of the new complexes are given in Tables 1 and 2.

Bis[N-*(9-fluorenyl)salicylideneaminato]metal(II) Complexes, M-(X-sal-fl)*$_2$ *(M=Co, Ni, Cu).* These complexes were obtained as crystals by methods similar to those reported previously.[1,2,4] Two methods were used. (A) To a suspension of bis(salicylaldehydato)metal(II) (0.01 mol) in ethanol (20 ml) was added 9-aminofluorene (0.02 mol) at 60 °C under stirring. (B) To a solution of X-salicyldehyde (0.01 mol) in ethanol (25 ml) was added 9-aminofluorene (0.01 mol) at 60 °C and the mixture was stirred for 30 min. A solution of the appropriate metal(II) salt (0.005 mol) in ethanol (15 ml) was added to the resulting solution and stirred for 15 min, followed by addition of an aqueous solution of sodium carbonate (0.01 mol).

In both cases the reaction mixture was heated on a water-bath at 60 °C for about 2h. The resulting precipitate was recrystallized from chloroform.

The cobalt(II), nickel(II), and copper(II) complexes obtained are orange, olive-green and olive-green, respectively. They are moderately soluble in chloroform and benzene with the exception of bis[*N*-(9-fluorenyl)-2-hydroxy-1-naphthylmethyleneaminato]nickel(II), abbreviated as Ni(5,6-benzo-sal-fl)$_2$, which is less soluble than the others. They are almost insoluble in methanol, ethanol and acetone. The cobalt(II) and nickel(II) complexes are almost insoluble in cold pyridine but soluble in hot pyridine, accompanied by colour change. The copper(II) complexes are soluble in pyridine at room temperature, the colour of the solution changing gradually with time.

Bis[N-*(9-fluorenyl)salicylideneaminato]metal(II) Monopyridine Adducts, M(X-sal-fl)*$_2$*·py (M=Co, Ni, Cu).* These adducts were obtained as crystals when a hot saturated solution of the parent complex was allowed to stand overnight in a

a) 1/3 $CHCl_3$. b) 1/2H_2O.

refrigerator. The cobalt(II) and nickel (II) complexes are reddish brown, and the copper(II) complex is dark green. They are soluble in cold pyridine, chloroform and acetone and almost insoluble in methanol and ethanol. They do not lose a pyridine molecule in the atmosphere at room temperature.

Cu(X-sal-fl)Cl (X=H, 5-Br, 5-Cl). Salicylaldehyde (0.01 mol) was added to a solution of copper(II) chloride hydrate (0.01 mol) in ethanol (20 ml) under stirring at 70 °C. After 10 min a solution of sodium carbonate (0.005 mol) in water (5 ml) was added to the resulting solution; a yellowish green precipitate appeared in the solution. To this mixture was added 9-aminofluorene (0.01 mol), and stirred for 1 h at 70 °C. Brown microcrystals were filtered off and washed with ethanol. Recrystallization was unsuccessful.

They are insoluble in benzene, methanol, ethanol and water but are soluble in chloroform, undergoing decomposition.

Measurements. Electronic absorption spectra of the complexes were measured on a Shimadzu MPS 50L spectrophotometer. Solubility of some complexes in appropriate solvents was too low for spectral measurements. Infrared spectra of the complexes were recorded as Nujol mulls using a Hitachi EPI-S2 infrared spectrophotometer and a Hitachi 215 infrared spectrophotometer.

Magnetic measurements were carried out at room temperature by the Gouy method. Powder diffraction patterns were obtained with a Rigakudenki 4001-A2 diffractometer using Co$K\alpha$ radiation and an iron filter.

Results and Discussion

Nickel(II) and Cobalt(II) Complexes. Complexes of the type Ni(X-sal-fl)$_2$ are diamagnetic in the solid state, indicating that they have a four-coordinate, square-planar structure. They show electronic absorption spectra typical of the square-planar nickel(II) complexes in non-donor solvents or in the solid state (Table 3). A d-d band with a maximum at about 16000 cm^{-1}, which may be ascribed to a $d_{x^2-y^2} \leftarrow d_{xy}$ transition, is slightly lower than that of the *N*-diphenylmethyl analogue,[4] implying that the ligand field produced by X-sal-fl is weaker than that by X-sal-dpm (dpm, diphenylmethyl).

In spite of the steric hindrance, the tetrahedral species has neither been isolated as crystals nor detected in solution at room temperature for the nickel(II) complexes of the type Ni(X-sal-fl)$_2$. This finding is similar to that for Ni(X-sal-dpm)$_2$ but contrary to that for Ni(X-sal-*i*-C_3H_7)$_2$.[4]

ν: 10^3 cm^{-1}. a) With the solution obtained by heating at 70 °C for a few hours.

It has not been possible to isolate tris(Schiff base)-cobalt(III) complexes so far, probably owing to the steric condition. The cobalt(II) complexes Co(X-sal-fl)$_2$ are paramagnetic with magnetic moments of 4.0—4.3 BM, which lie in the range expected for the tetrahedral cobalt(II) complex. They also show electronic absorption spectra typical of the tetrahedral cobalt(II) complex (Table 3). The d-d band at 7500—8000 cm^{-1} with a shoulder at 10300—10600 cm^{-1} may be assigned to a transition $^4T_1(F) \leftarrow {}^4A_2$.

Monopyridine adducts of the type M(X-sal-fl)$_2$·py were isolated as crystals. Six-coordinate bis(pyridine)-adducts have neither been isolated in crystals nor detected in solution, in contrast to the *N*-diphenylmethyl analogues.[4] The steric hindrance due to the ligands X-sal-fl is thus greater than that due to X-sal-dmp.

The pyridine molecule in M(X-sal-fl)$_2$·py is not readily lost. No weight loss was observed when the adducts were heated at 100 °C for several hours. It is likely that the pyridine molecule is bound with the metal(II) ion in the adducts. This presumption seems to be borne out by the observation that the parent complexes are not soluble in pyridine at room temperature, and that the adducts M(X-sal-fl)$_2$·py isolated from hot pyridine are readily soluble in cold pyridine. Since the pyridine adducts show infrared ν(C–O)

(1520—1530 cm^{-1}) and ν(C=N) bands (1600—1610 cm^{-1}) at almost the same frequencies as those of the parent complexes, it is presumed that the ligands X-sal-fl in the pyridine adducts function as bidentates, as in the parent complexes. All these findings indicate that the pyridine adducts with cobalt(II) and nickel(II) complexes have a five-coordinate structure.

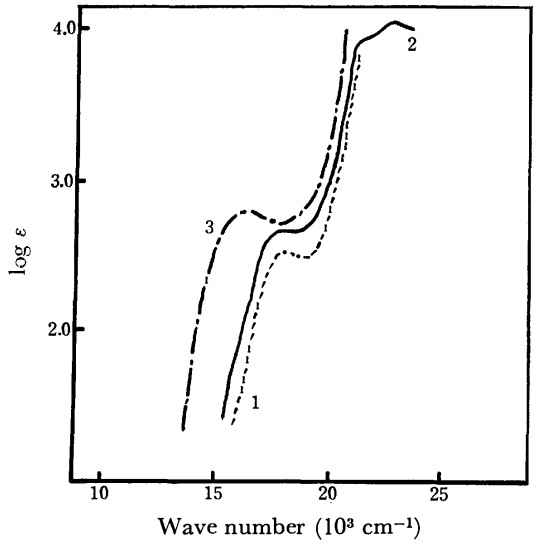

Fig. 1. Electronic absorption spectra of nickel(II) complexes: 1. Ni(5,6-benzo-sal-fl)$_2$·py, in Nujol, scale arbitrary; 2. Ni(5,6-benzo-sal-fl)$_2$·py, in pyridine; 3. Ni(5,6-benzo-sal-fl)$_2$, in Nujol, scale arbitrary.

Since the nickel(II) complexes Ni(X-sal-fl)$_2$·py are diamagnetic, they are considered to be spin-paired, five-coordinate complexes. As shown in Fig. 1, the solid state spectra of Ni(X-sal-fl)$_2$·py, which are essentially similar to the spectra of their pyridine solutions, have a main d-d band at 17400—17800 cm^{-1}. The band maxima are much higher than those (15700—16000 cm^{-1}) of the parent complexes, which have a diamagnetic square-planar structure, and the intensity of the d-d bands for the pyridine adducts is significantly higher than of the parent complexes. These findings are also in agreement with the five-coordinate structure for the pyridine adducts. The principal spectral data are summarized in Table 4.

Table 4. Main d-d absorption maxima of M(X-sal-fl)$_2$·py, M^{II} being Co and Ni

Compound	Solvent	ν (log ε)
Ni(5-Br-sal-fl)$_2$·py	Nujol	17.6
	pyridine	17.5(2.38)

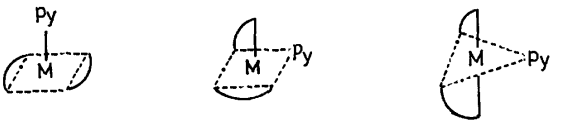
	pyridine	6.7(1.38), 11.5(1.14)
	$CHCl_3$	5.3(1.20), 8.1(1.33)
Co(5,6-benzo-sal-fl)$_2$·py	Nujol	5.3, 8.3
	pyridine	5.5(1.42), 8.1(1.28)
	$CHCl_3$	5.5(1.50), 8.2(1.47)

ν: 10^3 cm^{-1}.

Two types of structure may be considered for the five-coordinate complexes, trigonal-bipyramidal and square-pyramidal. Spin-paired, five-coordinate, trigonal-bipyramidal nickel(II) complexes having NP_3Cl, NP_3Br, and NAs_3Br donors sets[6] were reported to show a d-d band at a much lower frequency than the pyridine adducts (N_3O_2 set) obtained in the present work (about 18000 cm^{-1}). Even the trigonal bipyramidal complex with the P_4Cl donor set shows the band at 17500 cm^{-1}, although the P_4Cl donor set is expected to produce considerably stronger ligand field than the N_3O_2 set. The trigonal-bipyramidal structure, therefore, seems to be unlikely. On the contrary, the spectra of Ni(X-sal-fl)$_2$·py may reasonably be interpreted on the basis of the model of spin-paired, five-coordinate, square-pyramidal stereochemistry.[5] For the square-pyramidal structure II rather than structure I (Fig. 2)



(I) (II) (III)

Fig. 2. Some possible structures for M(5,6-benzo-sal-fl)$_2$·py (M=Co, Ni, and Cu).

is considered to be more likely, judging from their formation reaction; the pyridine adducts are obtained only on heating the parent complexes in pyridine. Simple axial addition of a pyridine molecule to the square-planar complex would readily produce structure I, for instance, without heating, if this species were stable enough at all. This, however, is not the case. The very high frequencies of the d-d band maxima for Ni(X-sal-fl)$_2$·py also favor structure II, suggesting that the bond between the nickel(II) ion and the axial fifth donor atom is weak.

The d-d band maxima in the spectra of the pyridine adducts in chloroform are almost the same as those of the pyridine adducts in pyridine or in the solid state, indicating that the structure of the adducts in the solid state is retained in the chloroform solution.

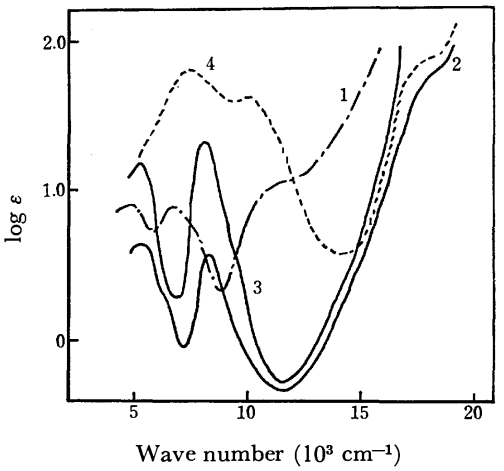

Fig. 4. Electronic absorption spectra of cobalt(II) complexes: 1. Co(5-Cl-sal-fl)$_2$·py, in Nujol, scale arbitrary; 2. Co(5-Cl-sal-fl)$_2$·py, in Nujol; 3. Co-(5-Cl-sal-fl)$_2$·py, in chloroform; 4. Co(5-Cl-sal-fl)$_2$, in chloroform.

Two types of cobalt(II) pyridine adducts were isolated as a solid, one being spin-paired and the other spin-free. One of them, Co(5,6-benzo-sal-fl)$_2$·py, is paramagnetic with a moment of 2.53 BM and is thus regarded to be a spin-paired, five-coordinate complex. Its X-ray powder diffraction pattern (Table 5) is almost the same as that of Ni(5,6-benzo-sal-fl)$_2$·py, which was presumed to consist of a spin-paired, five-coordinate complex. This is also borne out by the infrared spectrum in the whole 250—4000 cm^{-1} region of the cobalt(II) complex, which is slmost the same as that of the nickel-(II) analogue. It is thus presumed that Co(5,6-benzo-sal-fl)$_2$·py has the same structure as that of Ni(5,6-benzo-sal-fl)$_2$·py, possibly a spin-paired, square-pyramidal structure. The solid state spectrum of this cobalt(II) compound is essentially similar to the spectrum of its pyridine solution having a rather narrow band at 8400 cm^{-1}, in addition to a band at about 5300 cm^{-1} (Fig. 3). The spectrum is found to be correlated with that of a spin-paired, five-coordinate, square-planar cobalt(II) complex.[7] A remarkable similarity of its solid spectrum to that of the spin-paired, square-planar cobalt(II) complex indicates that the bond between the cobalt(II) ion and the axial fifth donor atom is weak, as in the corresponding nickel(II) analogue.

In contrast to Co(5,6-benzo-sal-fl)$_2$·py, Co(5-Cl-sal-fl)$_2$·py is paramagnetic with a moment of 4.25 BM, indicating that the latter is a spin-free, five-coordinate cobalt(II) complex. The solid state spectrum of Co(5-Cl-sal-fl)$_2$·py, which is very similar to the spectrum of its pyridine solution, differs a great deal from that of the tetrahedral cobalt(II) complex as well as from that of the six-coordinate, octahedral compex. lIn contrast, the solid spectrum is similar to the spectra of the spin-free, five-coordinate cobalt(II) complexes.[8]

The spectrum of Co(5-Cl-sal-fl)$_2$·py in chloroform differs considerably from its solid state spectrum, but is remarkably similar to the solid spectrum of Co(5,6-benzo-sal-fl)$_2$·py, which was presumed to have a spin-paired, five-coordinate structure (Fig. 4). It is interesting to note that the conversion of the spin state, probably accompanied by configurational change, occurs in this pyridine adduct on going from the solid state to the chloroform solution. If the pyridine molecule were lost from Co(5-Cl-sal-fl)$_2$·py on dissolution in chloroform, remaining complex Co(5-Cl-sal-fl)$_2$ would assume a tetrahedral configuration.

The pyridine solutions of Co(H-sal-fl)$_2$ and Co(5-Br-sal-fl)$_2$, obtained by heating the complexes in pyridine, show electronic absorption spectra similar to the solid spectrum of Co(5-Cl-sal-fl)$_2$·py, which was presumed to have a spin-free, five-coordinate complex.

Copper(II) Complexes. Electronic absorption spectra of copper(II) complexes of the type Cu(X-sal-fl)$_2$ in non-donor solvents have a d-d band at about 16000 cm^{-1}. From the frequency of the band, it may be reasonable to assume that these copper(II) complexes in non-donor solvents have an essentially square-planar configuration.

The complexes Cu(X-sal-fl)$_2$ are soluble in pyridine at room temperature, but the colour of the solution changes with time. The complexes, which are originally olive-green, turn bluish green immediately upon dissolution in pyridine, becoming greenish brown by reflected light (orangish brown by transmitted light) after more than 24 h. Absorption spectra of Cu(5-Cl-sal-fl)$_2$ in pyridine are shown as representative data in Fig. 5.

The spectrum obtained within 8 min after dissolution in pyridine (curve 2) has a broad d-d band, which shifts toward significantly lower frequencies than the d-d band of the original complex. It is recognized that curve 2 is similar to the spectrum expected for the five-coordinate species formed by axial addition of a pyridine molecule to the square-planar copper(II) complexes.[9] When dissolved in pyridine the first d-d band of the copper(II) complex shifts toward considerably lower frequencies, becoming also much broader than that of the complexes in non-donor solvents. In fact, curve 2

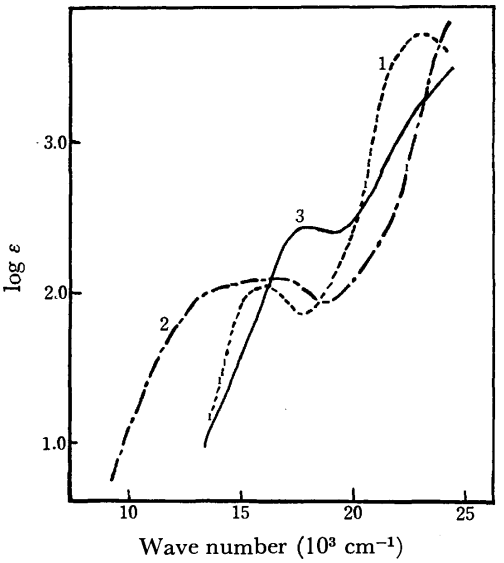

Fig. 5. Electronic absorption spectra of Cu(5-Cl-sal-fl)$_2$: 1. in chloroform; 2. in pyridine (measured within 8 min after dissolution); 3. in pyridine (measured after 24 h).

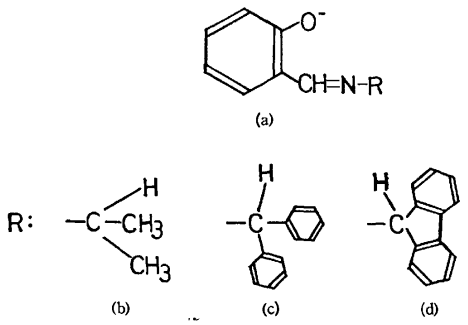
is very similar to the spectra of Cu(X-sal-dpm)$_2$ in pyridine.[4] The species corresponding to curve 2, therefore, may be assumed to have structure I in Fig. 2, or a structure slightly distorted from it.

The spectrum recorded after more than 24 h (curve 3), which differs entirely from curves 1 and 2, has a d-d band with a distinct maximum at about 18000 cm^{-1}. The pyridine adduct Cu(5,6-benzo-sal-fl)$_2$·py also shows a similar solid state spectrum having a d-d band at nearly the same frequency as that of curve 3. It is most likely that the main species existing after 24 h in pyridine may have the same structure as that of Cu(5,6-benzo-sal-fl)$_2$·py in the solid state. The pyridine adduct shows infrared ν(C–O) (1530 cm^{-1}) and ν(C=N) (1610 cm^{-1}), which are almost the same frequencies as those of the parent complexes. It is thus very likely that the ligand functions as a bidentate, as in the parent complexes.

It seems that one of the most probable structures of the species corresponding to curve 3 is structure II in Fig. 2. The considerably high frequency of the d-d band maximum seems to exclude a trigonal-bipyramidal structure,[10] which would show the corresponding band at a much lower frequency. The bond between the copper(II) and the axial fifth donor atom would not be strong.



Complexes of the type Cu(X-sal-fl)Cl (X=H, 5-Br, 5-Cl) at room temperature have subnormal magnetic moments of 1.35, 1.34 and 1.39 BM, respectively, which are much lower than the normal magnetic moments expected for the d^9 system. A sort of interaction, therefore, may be expected to exist between two copper(II) ions, as in complexes of a similar type.[11–13] Their infrared ν(C–O) bands appear at 1550 (X=H), 1535 (X=5-Br) and 1540 cm^{-1} (X=5-Cl), respectively. They are significantly higher than those of Cu(X-sal-fl)$_2$, which appear at 1525 cm^{-1} for X=H, 5-Br and 5-Cl. Based upon the criteria proposed previously,[11–13] the present finding on the infrared spectra seems to indicate that these complexes have a binuclear structure with the phenolic oxygen atom bridging two copper(II) ions.

Their solid state electronic spectra, which are similar to each other, show the first d-d band as a shoulder at about 11500 cm^{-1} and the next shoulder at 15600 cm^{-1}, more intense absorption rising up in the higher frequency region. Kato *et al.*[12] classified the spectra of the Cu(X-sal-alkyl)Cl type complexes into two groups, designating them as B- and Y-type. The spectra of Cu(X-sal-fl)Cl are similar to those of B-type, their magnetic moments also being in the range expected for B-type complexes.

The authors are grateful to Professor Shoichi Kume and Dr. Yoshinari Miyamoto, Institute of Geology, Osaka University, for X-ray powder diffraction patterns. Thanks are also due to Mr. Hiro Kuma for valuable discussions.

Secondary Ion Mass Spectrometry for Diffusion Studies in Glass

Atsushi MIZUIKE and Akira IINO
Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464
(Received December 24, 1976)

A procedure has been established for obtaining quantitative diffusion profiles by means of an ion microanalyzer in the narrow region within 1 μm of the glass surface. The interdiffusion of silver and sodium ions in Pyrex glass immersed in molten silver nitrate was studied as an example.

Diffusion kinetics during ion exchange in various glasses has been studied by many workers[1] from purely physicochemical points of view (*e.g.*, to get a better understanding of the basic mechanism of ionic transport in glass and the structure of glass) and in connection with industrial problems (*e.g.*, the strengthening of glass). The radioactive tracer technique and electron microprobe X-ray analysis have been employed extensively in these studies to obtain diffusion profiles (concentration *vs.* depth curves).

Secondary ion mass spectrometry (SIMS) offers a new means for obtaining profiles in the near-surface region (within 1 μm of the surface). In this technique, the sample surface is bombarded with a beam of high-energy primary ions, and the resulting ions from the sample are analyzed by means of a mass spectrometer. The successive removal by sputtering of the surface layers enables one to obtain the profiles by monitoring the ion intensity at the appropriate mass *vs.* sputtering time. This technique, however, is still semiquantitative,[2] because there remain three unresolved problems. First is the quantification of the SIMS intensities, *i.e.*, the conversion of the ion intensity at the appropriate mass into the concentration of the corresponding element. The large variations in the secondary ion yields and the matrix effects complicate the quantification. Although a theoretical correction procedure based on the local thermal equilibrium model has been proposed by Andersen and Hinthorne,[3] standard samples are still generally required for an accurate quantification. These standards have to shape both the chemical and physical nature of the sample as much as possible; therefore, their preparation is often very difficult. Second is the depth assignment, *i.e.*, the conversion of the sputtering time into depth. The rate of material removal depends on the sample matrix as well as the primary ion characteristics. Third, ion migration induced by ion bombardment may distort the diffusion profiles.[4]

The present work has been undertaken in order to resolve these problems and to establish a procedure for obtaining quantitative diffusion profiles in the near-surface region by SIMS. Experiments have been carried out on the interdiffusion of silver and sodium ions in Pyrex glass immersed in molten silver nitrate.

Experimental

Apparatus. A Hitachi IMA-2 ion microanalyzer was operated under the following conditions unless otherwise stated: primary ion-source gas, 99.99% argon; primary ion-accelerating voltage, 15 kV; primary beam current, 0.1 μA; spot diameter, 250 μm; sample chamber pressure, 3×10^{-5} Pa; secondary ion-accelerating voltage, 3 kV; electron-multiplier voltage, 2 kV. The electric charges accumulated on the glass surfaces were eliminated by means of the electron-spray method. The SIMS peak ratios—$^{109}Ag^+/^{30}Si^+$, $^{23}Na^+/^{28}Si^+$, and $^{39}K^+/^{28}Si^+$—were measured after rastering the primary beam (total number of scanning lines, 500; line frequency, 100 Hz) over an area 0.8 mm square around the spot to be measured. A Mizojiri Kogaku model II multiple-beam interferometer (Hg 546.1 nm, magnification 40X) was used to measure the depth of craters formed on glass surfaces by ion etching (ion sputtering) and the thickness of the chemically etched glass-surface layers. A Nippon Jarrell-Ash AA-1 MK II atomic-absorption flame-emission spectrophotometer with an SA-61 slit burner (acetylene 2 l/min, air 7 l/min) and a Hitachi model QPD53 recorder was employed for the atomic-absorption spectrophotometric determination of silver at 328.1 nm and the flame-photometric determination of sodium at 589.3 nm.

Material. Pyrex glass sheets (81% SiO_2, 13% B_2O_3, 4% Na_2O, 2% Al_2O_3, 0.5% or 0.04% K_2O; density, 2.2 g/cm^3) were annealed at 550 °C for 30 min and then cooled to room temperature at a rate of 1—2 °C/min. They were then washed with a detergent solution, followed by water, at room temperature, and subsequently dried.

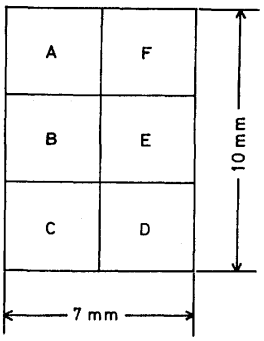

Fig. 1. Standard sample.

Preparation of Standard Sample. A 30-mm-square glass piece was immersed in molten silver nitrate at 335 °C for 90 min to effect the interdiffusion of silver and sodium ions into the glass. The piece was then withdrawn, cooled, washed in water, and dried. A 10×7 mm piece was cut from the above piece, and after covering Part A of the piece (see Fig. 1) with paraffin wax, we immersed it in 5% hydrofluoric acid at 19 °C for 15 min, withdrew it, washed it in water, and dried it. Parts B to E of the piece were successively covered with paraffin wax, and the above chemical etching was repeated. Finally, all the paraffin was removed with benzene. The piece thereafter served as a standard sample with 6 different surface concentrations of silver and sodium.

The surface concentrations were determined as follows. Another 10×7 mm piece was cut from the 30-mm-square

piece, and after its edges had been covered with paraffin wax, immersed in 5% hydrofluoric acid at 19 °C for 15 min, withdrawn, washed in water, and dried. The hydrofluoric acid and the washings were analyzed for silver and sodium by atomic absorption spectrometry and flame photometry. The above procedure was then repeated. The means of the concentrations of silver (or sodium) in two adjacent etched layers correspond to the surface concentrations of the standard sample.

Results and Discussion

Construction of Concentration Calibration Curves. A standard sample was prepared by the interdiffusion of silver and sodium ions in Pyrex glass, followed by chemical etching as has been described above. The corresponding diffusion profiles, obtained by chemical etching and chemical analysis, are shown in Fig. 2. The potassium profile was measured by SIMS, the details of which will be published elsewhere. The sum of the atomic concentrations of silver and sodium, as well as the potassium concentration, remained nearly constant over the whole range. Figure 3 illustrates the concentration calibration curves constructed by the use of the standard sample. Before each SIMS measurement, the surface layer (about 30 nm) of the standard sample was removed by ion etching (0.1 μA, 7-min rastering). The SIMS peak ratios were proportional to the atomic concentrations of the corresponding ions, with maximum deviations of about ±10%. There was no day-to-day variation in the calibration curves.

Depth Resolution and Depth Scale Assignment. When the primary beam was continuously focused on a spot on the glass surface, a conical crater was produced by ion sputtering and the signal from the crater walls deteriorated the depth resolution. To overcome this difficulty, the primary beam (0.3 μA) was rastered over an area 0.8 mm square in order to produce a flat-bottomed crater; then the beam (0.1 μA) was focused for 1 min on the center of the area for SIMS measurements. A fresh spot on the glass surface was used for each measurement. Thus, a depth resolution of the order of 10 nm was achieved.

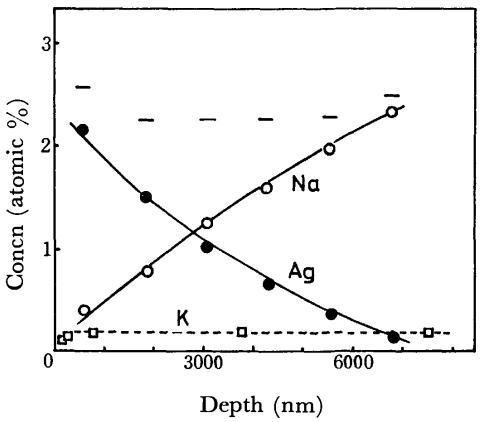

Fig. 2. Diffusion profiles. Pyrex (0.5% K_2O). 335 °C, 90 min. —: Sum of Ag and Na.

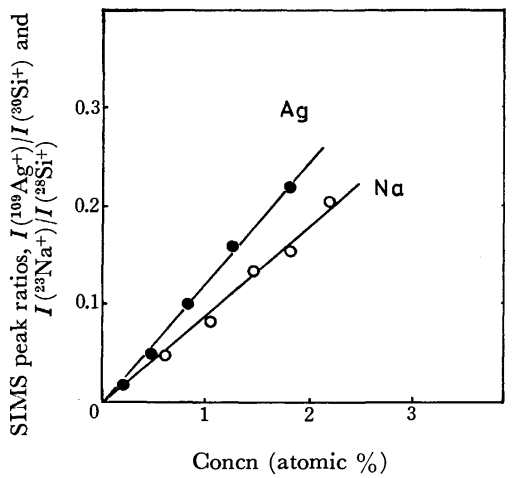

Fig. 3. Concentration calibration curves. Pyrex (0.5% K_2O).

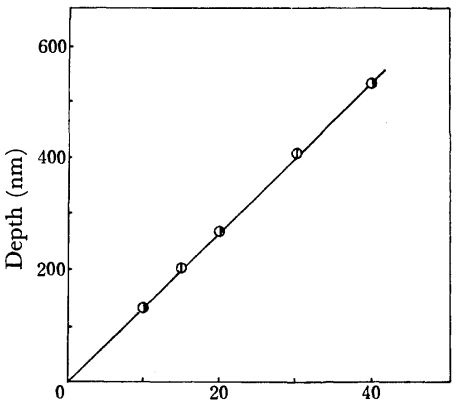

Fig. 4. Plots of crater depth *vs.* sputtering time. ⓘ: Pyrex (0.5% K_2O), ◑: Pyrex (0.5% K_2O) in which Na is nearly completely replaced by Ag.

The rate of material removal by ion sputtering under the above conditions was independent of the possible variation in composition of the glass under study, as is shown in Fig. 4. In addition, the day-to-day instrumental fluctuation was negligible. Therefore, the sputtering time can be readily converted to the depth.

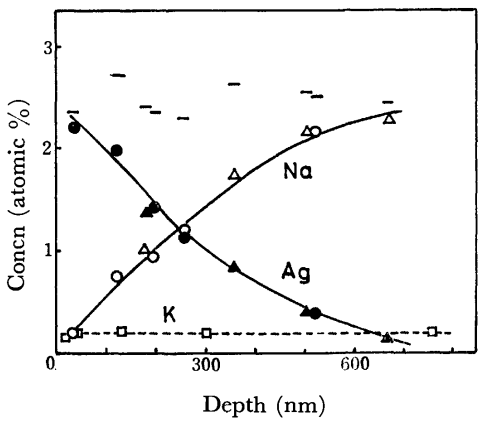

Fig. 5. Diffusion profiles. Pyrex (0.5% K_2O). 335 °C, 1 min. ●○: Ion etching, ▲△: chemical etching. —: Sum of Ag and Na.

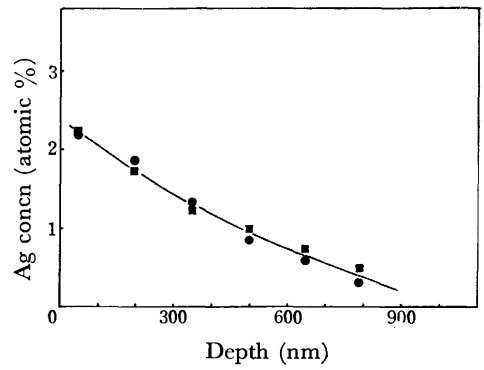

Fig. 6. Diffusion profile. Pyrex (0.04% K_2O). 335 °C, 1 min. ●■: Data on two separately prepared samples.

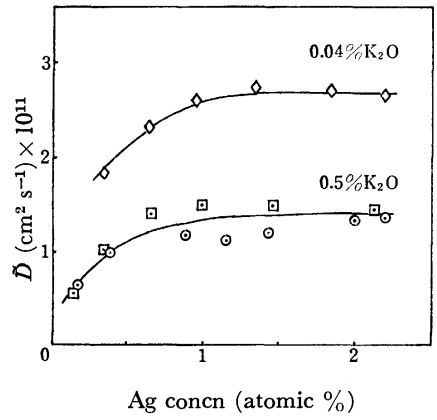

Fig. 7. Interdiffusion coefficients $\tilde{D}$ *vs.* silver concentration. Data from Fig. 2 (⊡), Fig. 5 (⊙), and Fig. 6 (◇).

Diffusion Profiles in the Near-Surface Region. The interdiffusion of silver and sodium ions was effected at 335 °C for 1 min, after which the diffusion profiles were obtained by SIMS. The results are shown in Figs. 5 and 6. The distortion of the diffusion profiles due to ion migration during the ion etching is negligible, because there is no appreciable difference from the profiles obtained by chemical etching with 0.8% hydrofluoric acid instead of ion etching prior to SIMS measurements.

Interdiffusion Coefficients. The interdiffusion coefficients at 335 °C were obtained from the profiles shown in Figs. 2, 5, and 6 by the Boltzmann-Matano method.[5] The results are illustrated in Fig. 7. The interdiffusion coefficients (between 1 and 2.4 atomic% Ag) are 1.4×10^{-11} cm^2 s^{-1} for Pyrex glass containing 0.5% K_2O and 2.7×10^{-11} cm^2 s^{-1} for Pyrex glass containing 0.04% K_2O, showing the mixed alkali effect.[6] The latter value is in reasonable agreement with the values obtained for Pyrex glass containing a negligible amount of potassium by Sjöblom and Andersson (2.6×10^{-11} cm^2 s^{-1})[7] and by Doremus (3.0×10^{-11} cm^2 s^{-1}).[8]

(Received December 25, 1976)

The hydrolytic reactions of cadmium(II) ions were studied at 25 °C in dioxane–water and methanol–water mixtures with varying compositions of the organic solvents, each mixture containing 3 mol dm^{-3} (Li)ClO_4 as an ionic medium. Emf measurements were carried out over the range of the total cadmium(II) concentrations of 0.2 to 0.8 mol dm^{-3} in all the systems. Two complexes Cd_2OH^{3+} and $CdOH^+$ were found in the dioxane–water mixtures, but the latter complex was not detected in the methanol–water system. The formation constant of the $Cd_2OH_4^{3+}$ complex was slightly larger in the methanol–water mixtures than in the dioxane–water mixtures at the same mole-fraction concentration of the organic solvents.

The formation of the mononuclear complex $CdOH^+$ was reported by many authors[1–6] in the hydrolytic reactions of cadmium(II) ion in aqueous solutions. The formation of the dinuclear Cd_2OH^{3+} complex, which has been first reported by Biedermann and Ciavatta,[7] was confirmed by us in a previous work.[8] However, the existence of the tetranuclear $Cd_4(OH)_4^{4+}$ complex was doubtful as an equilibrium species of hydrolyzed cadmium ions.[8]

The solvent effects on the hydrolytic reactions of various metal ions such as beryllium,[9–11] copper,[12,13] nickel,[14] and aluminium[15] have so far been studied in various aqueous–organic mixtures and the results can be summarized as follows: 1) The formation constants of the complexes, most of which were large polynuclear complexes, were little affected by the solvent composition even though the dioxane concentration changed widely, *e.g.*, 0—83% w/w, in contrast with the dissociation constants of carboxylic acids[16] and phenols,[17] which markedly changed with the solvent composition. 2) Similar results were found in other solvent systems, water–methanol, water–ethanol, and water–acetone mixtures. 3) The solvent effects on the hydrolytic reactions of metal ions were qualitatively explained by Kawai[18] in terms of the changes in the activity coefficients of the ions in solutions.

However, Wada and his coworkers[19,20] have shown that the formation constant $*\beta_{1,1}$ of the mononuclear hydroxo complex of Fe^{3+} monotonously increased with the increase of the concentration of methanol in which 0.5 mol dm^{-3} (Na,H)ClO_4 was contained as an ionic medium, as well as the formation constant of the $FeCl^{2+}$ complex in the same ionic medium, containing methanol up to 0.52 mole fraction (about 66% w/w).

In order to find if the formation constant of a mononuclear hydroxo complex would be affected by the solvent composition of aqueous mixed solvents in a different manner from that of a polynuclear complex, we have examined the hydrolysis of cadmium(II) ions in dioxane–water and methanol–water mixtures, because both mononuclear and polynuclear complexes are formed in this system and their formation constants can be determined with reasonable accuracies in various mixed media.

Experimental

Reagents. *Cadmium(II) Perchlorate*: Cadmium oxide (99.99%, Mitsuwa Pure Chemicals Co., Osaka) was dissolved in 1:1 $HClO_4$ (Super special grade, Wako Pure Chemical Ind., Osaka) and cadmium perchlorate thus prepared was recrystallized three times from water. The purity of the cadmium oxide had been checked by emission spectroscopy.

Lithium perchlorate and *lithium hydroxide* were prepared by the same procedures as described in the previous paper.[8] *Dioxane* purified by the ordinary method[13] was stored in a refrigerator and melted just before preparation of a test solution. *Methanol* of reagent grade was distilled twice.

Apparatus. Beckman (No. 40498) glass electrodes were used in combination with an Orion Digital pH Meter Model 801. A cadmium-ion selective electrode Model 94-48A (Orion Research Inc., Mass., USA) was used, and the potentials were measured by use of Takeda Riken Digital Multimeter 6854. The potentials were reproducible within ± 0.1 mV in the mixed solvents used. A Metrohm E211 type Coulometer was employed as a current source for generation of hydrogen ions in a solution during the course of titrations. Silver–silver chloride electrodes set in the Kawai type[11] of the half-cell were prepared according to Brown.[21]

Preparation of the Test Solutions. A slightly acid cadmium(II) perchlorate solution in a mixed solvent was placed in a glass vessel and bubbled with nitrogen gas to remove carbon dioxide, and then a small amount of CdO powder was added to the solution. White precipitates appeared in the solution while agitating for several hours. The agitation was continued for a day passing nitrogen gas through the mixture and then the glass vessel was tightly sealed. The mixture was still continuously agitated for about 20 days in a thermostated room at 25 ± 1.5 °C. Then the solution was filtered through G-3 and G-4 glass filters and the filtrate was left to stand for one day at 25 °C in a liquid paraffin thermostat. This solution was filtered again through a G-4 glass filter to a measuring vessel. The volume of the test solution was determined from the weight and density of the test solution in the vessel. The total concentration of cadmium ion in the test solution was determined gravimetrically as $Cd_2P_2O_7$.

The method of emf measurements was essentially the same as that used in the previous works of this series.

All the measurements were carried out at 25.00 ± 0.02 °C in a liquid paraffin bath set in a room thermostated at 25.0 ± 1.5 °C.

Results and Discussion

When cadmium(II) ions hydrolyze in a solution, the reaction equilibrium may be written as follows:

$$qCd^{2+} + pH_2O = Cd_q(OH)_p^{(2q-p)+} + pH^+. \quad (1)$$

The average number of hydrogen ion set free per metal ion Z is given as follows:

$$Z = \sum_q \sum_p p{*\beta}_{p,q} b^q h^{-p}/B, \quad (2)$$

where ${*\beta}_{p,q}$ is the formation constant of a species defined by Eq. 3

$${*\beta}_{p,q} = [Cd_q(OH)_p^{(2q-p)+}]h^p/b^q, \quad (3)$$

and B stands for the total concentration of cadmium ion, $b=[Cd^{2+}]$ and $h=[H^+]$ at equilibrium.

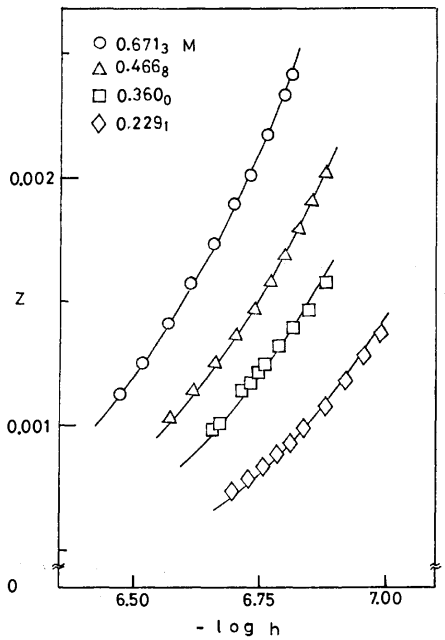

Fig. 1. Values of Z *vs.* $-\log h$ in the 0.10 mole fraction dioxane–water mixture. Solid lines show calculated curves of Z with the formation constants listed in Table 1.

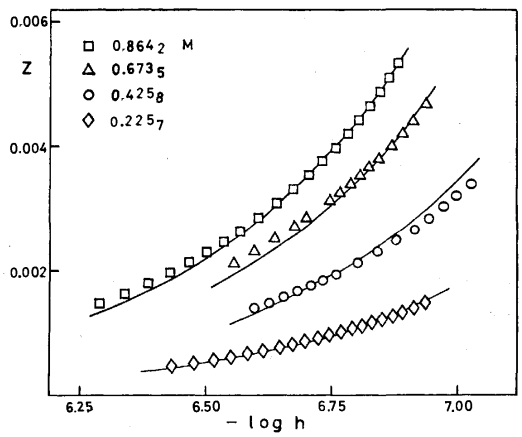

Fig. 2. Values of Z *vs.* $-\log h$ in the 0.10 mole fraction methanol–water mixture. Solid lines show calculated curves of Z with the formation constant listed in Table 1.

Typical results represented by Z plotted against $-\log h$ are graphically shown in Figs. 1 and 2 for the 0.1 mole fraction dioxane–water and methanol–water systems, respectively. According to the same procedure described in the previous paper,[8] we obtained a set of horizontal lines of Zh *vs.* h^{-1} and the intercepts which were dependent on B in each solvent. Thus we concluded that homoligandic complexes, $p=1$, were formed and the equilibrium species were Cd_2OH^{3+} and $CdOH^+$.

Table 1. Formation constants ($\log {*\beta}_{p,q}$) of the $Cd_q(OH)_p^{(2q-p)+}$ complex in dioxane–water and methanol–water mixtures at 25 °C

Solvent	Dioxane–Water		Methanol–Water
	Cd_2OH^{3+}	$CdOH^+$	Cd_2OH^{3+}
Aqueous	−9.13±0.01	−10.3±0.1	−9.13±0.01
0.05 mole fraction	−9.23±0.02	−9.9±0.1	−9.07±0.02
0.10 mole fraction	−9.28±0.02	−10.7±0.1	−9.08±0.02
0.15 mole fraction	−9.37±0.02	−11.0±0.1	—
0.20 mole fraction	−9.3±0.2	−10.7±0.5	−9.3 ±0.2

Table 1 lists the values of $\log {*\beta}_{p,q}$ determined by the least squares method[18] with a help of an electronic computer HITAC 8700 situated at the Tokyo Institute of Technology. The solid lines in Figs. 1 and 2 show calculated Z values with the constants which are inserted into Eq. 4.

$$Z = ({*\beta}_{1,1} bh^{-1} + {*\beta}_{1,2} b^2 h^{-1})/B \quad (4)$$

In the methanol–water mixtures, the values of ${*\beta}_{1,1}$ were so small in all the solvents that the values were not evaluated with reasonable accuracies.

The solvent effect of the organic solvents on the formation constants of cadmium(II) hydroxo complexes is rather small as is expected from the results obtained previously of this series.

The formation constant of the Cd_2OH^{3+} complex monotonously decreases with the increase of the dioxane concentration. In the methanol–water mixtures ${*\beta}_{1,2}$ is slightly larger than that in aqueous solution, but the change in ${*\beta}_{1,2}$ is not systematic. The formation constant of the $CdOH^+$ complex in the dioxane–water mixtures first increases with increasing concentration of dioxane up to 0.05 mole fraction and then decreases. The similar change in the formation constants, *i.e.*, ${*\beta}_{p,q}$ increases with the dioxane concentration and then decreases after passing through a broad maximum at around 0.1 mole fraction dioxane, has been observed in ${*\beta}_{3,3}$ of beryllium,[10] ${*\beta}_{1,1}$ of copper,[13] ${*\beta}_{4,4}$ of nickel,[14] and ${*\beta}_{4,4}$ and ${*\beta}_{8,6}$ of lead hydroxo complexes.[18] The values of ${*\beta}_{1,1}$ of the mononuclear $CdOH^+$ complex changed in a different manner from that of ${*\beta}_{1,1}$ of Fe^{3+} observed by Wada and his coworkers.[19,20]

Since the changes in ${*\beta}_{p,q}$ in a constant ionic medium with the solvent composition are caused by the changes of the ratios of activity coefficients of relevant ions in Eq. 1 and the concentration of water, the changes of the activity coefficients of the metal and hydrogen ions

were measured with varying solvent compositions by means of emf measurements of the cells,

Cd(selective electrode)|test solution|Ref (5)

and GE|test solution|Ref. (6)

The potentials of the cells may be written as follows: for cell (5)

$$E_{Cd} = E^{\circ}_{Cd} + 29.58 \log b + 29.58 \log y_{Cd} + E_j \quad (7)$$

and for cell (6)

$$E_H = E^{\circ}_H + 59.15 \log h + 59.15 \log y_H + E_j \quad (8)$$

where y denotes the activity coefficient of a species in the solution. In an acid solution where no hydrolysis of cadmium ion occurs, $B=b$. At low and constant b and h, the potential changes of cells 5 and 6 with the solvent composition are proportional to the values of log $\{y_{Cd(mix)}/y_{Cd(aq)}\}$ and log $\{y_{H(mix)}/y_{H(aq)}\}$, respectively, and the change of the liquid junction potentials is negligible in a high ionic medium.[22] Thus, the changes of the activity coefficients of cadmium and hydrogen ions in a 3 mol dm^{-3} $LiClO_4$ can be described with a good approximation as follows:

$$\log \{y_{Cd(mix)}/y_{Cd(aq)}\} = \Delta E_{Cd}/29.58, \quad (9)$$

and

$$\log \{y_{H(mix)}/y_{H(aq)}\} = \Delta E_H/59.15, \quad (10)$$

where ΔE_{Cd} and ΔE_H represent the potential changes of cells (5) and (6), respectively, with the solvent composition.

If the standard state of any reacting species is so chosen that the activity coefficient of the species approaches unity when the solution approaches 3 mol dm^{-3} $LiClO_4$ aqueous solution, the activity coefficient of the reacting species y in the aqueous medium is regarded as unity. Therefore, Eqs. 9 and 10 may be simplified as Eqs. 11 and 12, respectively.

$$\log y_{Cd} = \Delta E_{Cd}/29.58 \quad (11)$$

and

$$\log y_H = \Delta E_H/59.15 \quad (12)$$

The values of log y_{Cd} and log y_H thus evaluated in dioxane–water and methanol–water mixtures are plotted against the concentration of the organic solvents in Figs. 3 and 4, respectively.

The formation constant of the $Cd_q(OH)_p^{(2q-p)+}$ complex is given in terms of activities as follows:

$$*\beta^{\circ}_{p,q} = \frac{a_{Cd_q(OH)_p} \cdot a_H^p}{a_{Cd}^q \cdot a_{H_2O}^p} = \frac{[Cd_q(OH)_p^{(2q-p)+}] \cdot h^p}{b^q} \cdot \frac{1}{[H_2O]^p} \cdot \frac{y_{Cd_q(OH)_p} \cdot y_H^p}{y_{Cd}^q \cdot f_{H_2O}^p} \quad (13)$$

$*\beta^{\circ}_{p,q}$ is the formation constant thermodynamically defined, which is independent of the solvent composition at a given temperature. The activity coefficient y is defined in terms of molarity and is independent of the concentration of the relevant species in a constant ionic medium, but is dependent on the solvent composition. f_{H_2O} is the activity coefficient of water in a mixed solvent expressed by the mole fraction scale of the solvent component. Since the value $[Cd_q(OH)_p^{(2q-p)+}]h^p/b^q = *\beta_{p,q}$ is experimentally determinable for the complex $Cd_q(OH)_p^{(2q-p)+}$ in a given solvent and $*\beta^{\circ}_{p,q}$ is the formation constant of the complex in the aqueous medium according to definition stated above, the difference between the formation constants obtained in a mixed solvent and in the aqueous solution may be given as follows:

$$\Delta \log *\beta_{p,q} = \log *\beta_{p,q}(mix) - \log *\beta_{p,q}(aq) = \log [H_2O]^p + \log \{y_{Cd}^q/y_H^p\} - \log \{y_{Cd_q(OH)_p}/f_{H_2O}^p\}. \quad (14)$$

The first two terms of the right hand side of Eq. 14 can be determined experimentally and log $\{y_{Cd_q(OH)_p}/f_{H_2O}^p\}$ is thus determined. The values of log $\{y_{Cd_q(OH)_p}/f_{H_2O}^p\}$ are plotted for the Cd_2OH^{3+} complex against the mole

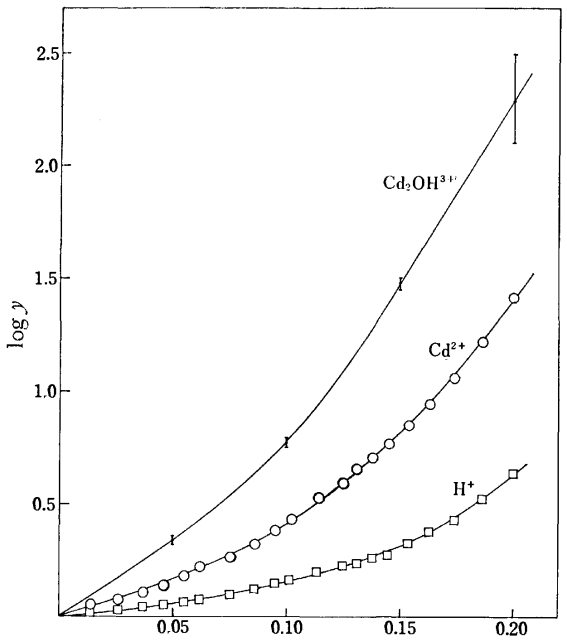

Fig. 3. Variations of log y for H^+, Cd^{2+}, and Cd_2OH^{3+} ions with the concentration of dioxane–water mixtures. The error bar shown for the Cd_2OH^{3+} curve represents an estimated error in log y_{Cd_2OH} from the uncertainty of the log $*\beta_{1,2}$ value.

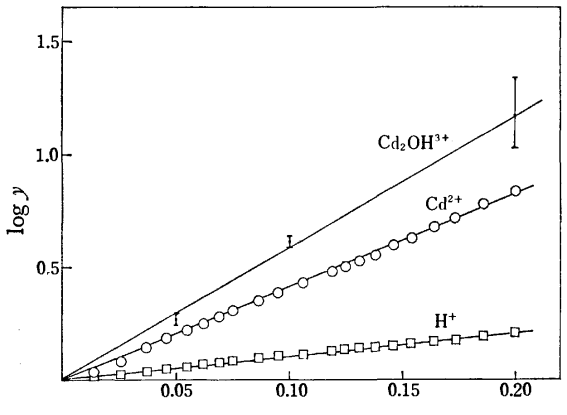

Fig. 4. Variations of log y for H^+, Cd^{2+}, and Cd_2OH^{3+} ions with the concentration of methanol in methanol–water mixtures. The error bar shown for the Cd_2OH^{3+} curve represents an estimated error in log y_{Cd_2OH} from the uncertainty of the log $*\beta_{1,2}$ value.

fractions of dioxane and methanol at $[H_2O]=0.95$, 0.90, 0.85, and 0.80 in Figs. 3 and 4, respectively. If we can assume that $f_{H_2O}=1$ as a first approach over the range of the solvent composition examined here, the curves thus drawn may represent the variations of the activity coefficients of the Cd_2OH^{3+} complex in the dioxane–water and methanol–water mixtures containing 3 mol dm^{-3} $LiClO_4$ at 25 °C. It seems reasonable that the activity coefficient of the Cd_2OH^{3+} ion, as well as those of Cd^{2+} and H^+ ions, was more sensitive to the solvent composition in the dioxane–water mixtures than that in the methanol–water mixtures, because it is expected that the dielectric constants of the former solvent may be lower than that of the latter at the same mole-fraction composition. The change in the activity coefficient of the Cd_2OH^{3+} ion was much larger than those of Cd^{2+} and H^+ ions in the both solvents as is expected from the larger charge of the complex ion.

The authors wish to thank Dr. T. Kawai for his technical assistance during the work. The work is financially supported by the Ministry of Education and, in part, by the Ministry of International Trade and Industry.

Enhancement of the Pfeiffer Effect Arising from the Cation-Cation Interaction*

Katsuhiko MIYOSHI, Yasushige KURODA, Hiroshi OKAZAKI, and Hayami YONEDA

Department of Chemistry, Faculty of Science, Hiroshima University Higashi-senda-machi, Hiroshima 730

(Received January 5, 1977)

The influence of added sodium and potassium chloride, bromide, and sulfate was examined on the Pfeiffer effect of the $[Co(phen)_3]^{2+}$– and $[Ni(phen)_3]^{2+}$–*d*-cinchoH$^+$ systems in water (phen=1,10-phenanthroline, and *d*-cinchoH$^+$=*dextro*-cinchoninium ion). It was found that the added anions enhance the circular dichroism (CD) induced in the d-d transition region of $[Co(phen)_3]^{2+}$ and $[Ni(phen)_3]^{2+}$ ions, and that the CD-enhancing order is $Br^- > Cl^- > SO_4^{2-}/2$. These findings were well interpreted in terms of reduced electrostatic repulsion between $[Co(phen)_3]^{2+}$ or $[Ni(phen)_3]^{2+}$ and *d*-cinchoH$^+$ by the added anions, and of the resulting enhanced enantiomerization of these cationic complexes in favor of Δ-isomers in the presence of *d*-cinchoH$^+$. Logarithm of the magnitude of the induced CD was found to be a linear function of logarithm of the total anion concentration in all the systems examined. This fact gives a strong support to the above interpretation, and suggests a close resemblance of these Pfeiffer-active systems to aqueous cationic surfactant solutions.

When a racemic mixture of a labile metal complex is added to a solution containing a certain chiral molecule called an environment compound, additional optical activity is sometimes developed. This phenomenon is known as the Pfeiffer effect,[1] and several possible mechanisms have been proposed, *e.g.*, configurational activity,[2] differential association,[1c,3] equilibrium shift (enantiomerization),[4] hydrogen bonding,[5] and hydrophobic bonding.[1c,6] The fact that partial resolution of some metal complexes is performed by exploiting this phenomenon,[4a,4b,7] provides decisive evidence for the equilibrium shift mechanism by which metal complexes enantiomerize in favor of either *d*- or *l*-isomer, depending on the spacial demand of the chiral environment compound present. As a result, the Pfeiffer effect is successfully applied to assign the absolute configuration of metal complexes,[5,7-9] in particular for those which are so labile that conventional resolution techniques fail to isolate them as antipodes.[10,11]

It seems convenient to classify the Pfeiffer-active systems into three groups according to their charge type as far as tris-phen or tris-bpy complexes are concerned; i) systems of the same charge, *e.g.*, $[M(phen)_3]^{2+}$–*l*-stryH$^+$ and –*d*-cinchoH$^+$ in water, ii) systems of opposite charge, *e.g.*, $[M(phen)_3]^{2+}$–*d*-BCS$^-$ in water, and iii) systems containing nonelectrolytes, *e.g.*, $[M(phen)_3]^{2+}$–*l*-malic acid and –*d*-tartaric acid in water, and $[Ni(phen)_3]^{2+}$ in *l*-2,3-butanediol[4b] (M(II)=Co(II) or Ni(II), phen=1,10-phenanthroline, bpy=2,2′-bipyridine, *l*-stryH$^+$ = *levo*-strychninium ion, *d*-cinchoH$^+$ = *dextro*-cinchoninium ion, and *d*-BCS$^-$ = *dextro*-3-bromocamphor-9-sulfonate ion). Among these groups, the first group is seemingly unusual in the sense that the Pfeiffer effect is well observed despite the inevitable electrostatic repulsion between cationic complexes and cationic environment compounds even at a low concentration in water. Thus, some mechanisms must operate which force these cations to attract each other against their mutual repulsion. In this paper, we present some experimental results suggesting a close resemblance of these Pfeiffer systems to aqueous ionic surfactant solutions in which hydrophobic ions of the same charge associate to form aggregates called micelles.

Experimental

Sample solutions containing both $[Co(phen)_3]Cl_2$ and *d*-cinchoHCl were prepared by diluting respective stock solutions with water in volumetric flasks. To prevent the decomposition of the complex, a small amount of free phen was added.[4b] To these solutions were added varying amounts of NaCl or KCl. Completely the same operation was employed to prepare the corresponding bromide and sulfate solutions, and NaBr or KBr, and Na_2SO_4 or K_2SO_4 were added respectively in place of NaCl or KCl. Tetraalkylammonium bromides R_4NBr (R=methyl to butyl) were also added to the bromide solution in place of NaBr or KBr. A similar procedure was applied to the $[Ni(phen)_3]^{2+}$–*d*-cinchoH$^+$ system, but the sample solutions thus prepared were allowed to stand for two weeks at room temperature to attain an enantiomerization equilibrium.[4a] Absorption (AB) and circular dichroism (CD) spectra were recorded on a Shimadzu UV-200 and a Jasco J-40CS spectrometer at ambient temperature, and optical rotations were measured with a Union-Giken PM-71 polarimeter in a 5 cm cell. All chemicals used were of reagent grade.

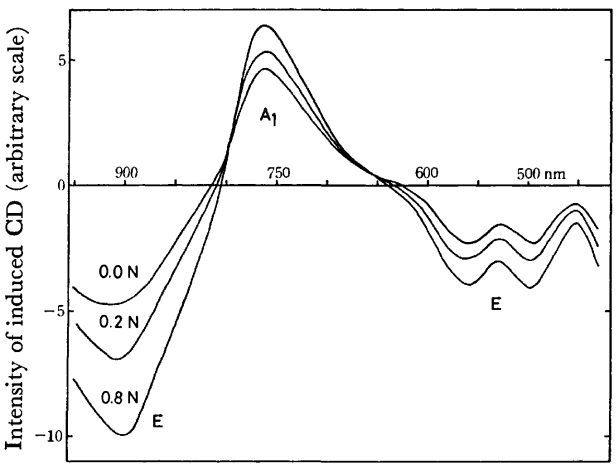

Fig. 1. CD spectra induced in the $[Ni(phen)_3]SO_4$ (0.03 M)–*d*-cinchoH1/2SO_4(0.03 M) systems containing various amounts of Na_2SO_4.

* Preliminary results of this work were reported in, H. Yoneda, K. Miyoshi, and S. Suzuki, *Chem. Lett.*, **1974**, 349; K. Miyoshi, K. Sakata, and H. Yoneda, *ibid.*, **1974**, 1087.

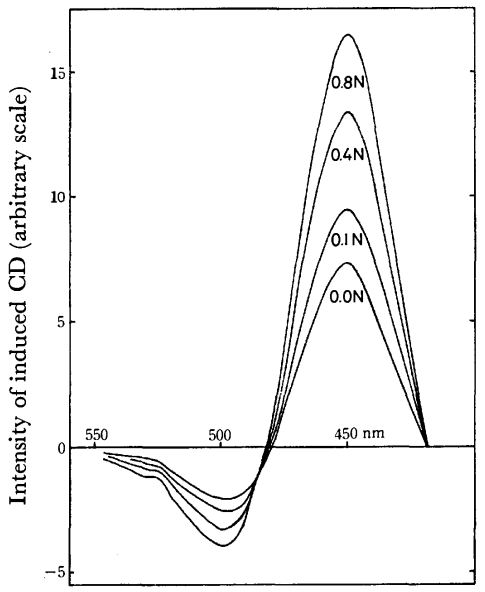

Fig. 2. CD spectra induced in the $[Co(phen)_3]Cl_2$(0.015 M)-*d*-cinchoHCl (0.03 M) systems containing various amounts of NaCl.

Results and Discussion

Figures 1 and 2 show the CD induced in the d-d transition region for the $[Ni(phen)_3]SO_4$-*d*-cinchoHl/$2SO_4$ and the $[Co(phen)_3]Cl_2$-*d*-cinchoHCl systems in water, where varying amounts of Na_2SO_4 and NaCl are added respectively. It is seen that the CD spectrum for the former system is almost the same in shape as that of *levo*-$[Ni(phen)_3]^{2+}$ ion,[4b,12] and that its intensity is enhanced uniformly throughout the spectrum upon the addition of Na_2SO_4. These facts mean that an enantiomerization of $[Ni(phen)_3]^{2+}$ ion actually takes place in favor of its *levo*- or Λ-isomer[13] in the presence of *d*-cinchoH$^+$ and is enhanced by added Na_2SO_4, and that the same will be true for the $[Co(phen)_3]Cl_2$-*d*-cinchoHCl system. Similar results obtained in other systems are summarized in Table 1, which clearly indicates that the intensities of the induced CD are dependent on the kind of the added anions, but not of cations when they are compared at a fixed concentration of added salts. Therefore, it is concluded that the added anions are responsible for the enhancement of the Pfeiffer effect shown in Figs. 1 and 2 and Table 1.

The influence of added inert counter-ions on the optical activity of metal complexes has been extensively studied[14] and has been usually attributed to outer-sphere association of the complexes with added counter-ions. However, the anion effect shown in Figs. 1 and 2 and Table 1 is not ascribed to usual ion association, because each component of the induced CD in $[Ni(phen)_3]^{2+}$ and $[Co(phen)_3]^{2+}$ ions is affected uniformly but not differently by the added anions.[12c,14] Instead, it is attributed to reduced electrostatic repulsion between these cationic complexes and *d*-cinchoH$^+$ by the added anions and to the resulting enhanced enantiomerization of $[Ni(phen)_3]^{2+}$ or $[Co(phen)_3]^{2+}$ ion in the presence of *d*-cinchoH$^+$.

In order to confirm the above interpretation, an

0.2N	Na_2SO_4	2.2%(497 nm)	2.0%(562 nm)
0.8N	Na_2SO_4	3.0%(497 nm)	2.9%(562 nm)
$[Co(phen)_3]Cl_2$(0.015M)–*d*-cinchoHCl(0.03M)[b]			
0.2N	NaCl	1.1%(492 nm)	
0.4N	NaCl	1.4%(492 nm)	

a) $\Delta\varepsilon_{497}=-4.57\times10^{-2}$ and $\Delta\varepsilon_{562}=-5.12\times10^{-2}$ for optically-pure Λ-$[Ni(phen)_3]^{2+}$ in an acetone–water mixture. Racemization of $[Ni(phen)_3]^{2+}$ in this mixed solvent is not taken into account. See, N. R. Davies and F. P. Dwyer, *Trans. Faraday Soc.*, **50**, 1325 (1954). b) $\Delta\varepsilon_{492}=-1.29$ for optically-pure Λ-$[Co(phen)_3]^{3+}$ in water. See, Ref. 18. Oxidation of $[Co(phen)_3]^{2+}$ with H_2O_2 to $[Co(phen)_3]^{3+}$ is not necessarily quantitative.

excess amount of $NaClO_4$ was added to the $[Ni(phen)_3]$-SO_4–*d*-cinchoHl/$2SO_4$ system and resulting precipitates containing both $[Ni(phen)_3](ClO_4)_2$ and *d*-cinchoHClO_4 were re-dissolved in acetone–water mixtures (1 : 1 volume ratio). In Fig. 3 are shown their CD spectra, which are completely the same in shape as that of Λ-$[Ni(phen)_3]^{2+}$ ion in an acetone–water mixture.[12c] Since the Pfeiffer effect is not exhibited in this mixed solvent, our interpretation is verified, and the degree of optical resolution estimated is given in Table 2. However, a detailed examination of Fig. 1 reveals that the CD induced in the $[Ni(phen)_3]SO_4$–*d*-cinchoHl/$2SO_4$ system is somewhat different in shape from that of Λ-$[Ni(phen)_3]^{2+}$ ion resolved by a usual method,[12c] in particular at a long wavelength region, *e.g.*, the $^3A_{2g}\rightarrow{}^3T_{2g}$ transition in an Oh approximation. That is, the E($^3T_{2g}$) component is greater in magnitude than the $A_1(^3T_{2g})$ component in the Pfeiffer system,[15] while the corresponding E component of resolved $[Ni(phen)_3]^{2+}$ ion is not detected in water unless acetone or some polyoxyanions are added.[12c] This difference is attributed to marked association of $[Ni(phen)_3]^{2+}$ ion with *d*-cinchoH$^+$, because the Pfeiffer effect is not exhibited unless the complex comes into direct contact with chiral environment compounds.[16]

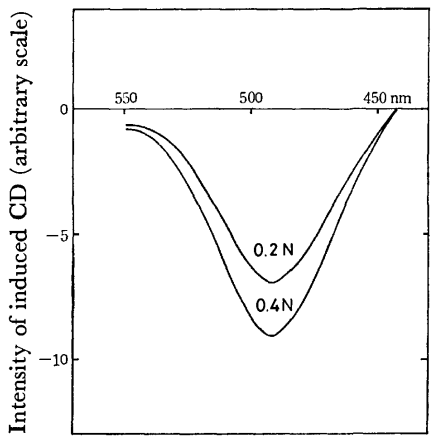

Fig. 4. CD spectra of the $[Co(phen)_3]Cl_2$ (0.015 M)–*d*-cinchoHCl (0.03 M) systems containing various amounts of NaCl after oxidation with H_2O_2.

Figure 4 shows the CD spectra of the $[Co(phen)_3]Cl_2$–*d*-cinchoHCl systems containing varying amounts of NaCl after they are oxidized with H_2O_2 in the presence of MnO_2. It is seen that their CD spectra are the same in shape as that of resolved *levo*- or Λ-$[Co(phen)_3]^{3+}$ ion,[12b,17,18] and that their intensity is increased as the amount of NaCl added to these systems is increased. Since $[Co(phen)_3]^{3+}$ ion does not exhibit the Pfeiffer effect with *d*-cinchoH$^+$, it is confirmed that $[Co(phen)_3]^{2+}$ ion also enantiomerizes[7] in favor of its Λ-isomer in the presence of *d*-cinchoH$^+$ like $[Ni(phen)_3]^{2+}$ ion does. By comparing the CD intensities, the degree of optical resolution is estimated as before for the $[Co(phen)_3]Cl_2$–*d*-cinchoHCl systems and is included in Table 2.

It is now well known that ionic surfactants associate to form aggregates called micelles at relatively low concentrations against their mutual electrostatic repulsion in water. In the process of micellization, two opposing factors[19] are usually taken into account, *i.e.*, electrostatic repulsion between surfactant ions of the same charge, and the hydrophobic interaction[20] which is regarded as a main driving force for the aggregation of surfactants in water. If anions (or cations) are added to cationic (or anionic) surfactant solutions, the resulting reduced electrostatic repulsion leads to increased micelle

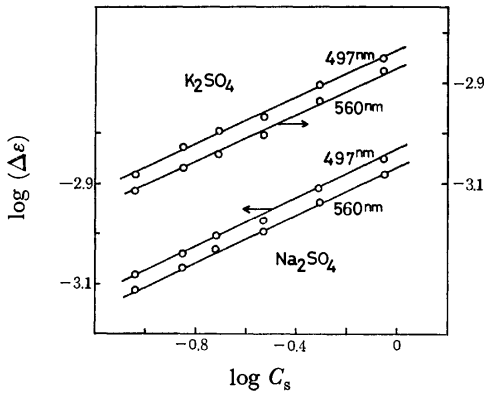

Fig. 5. Plots of log ($\Delta\varepsilon$) at 497 and 560 nm *vs.* log C_s for the $[Ni(phen)_3]SO_4$(0.03 M)–*d*-cinchoHl/$2SO_4$(0.03 M) system.

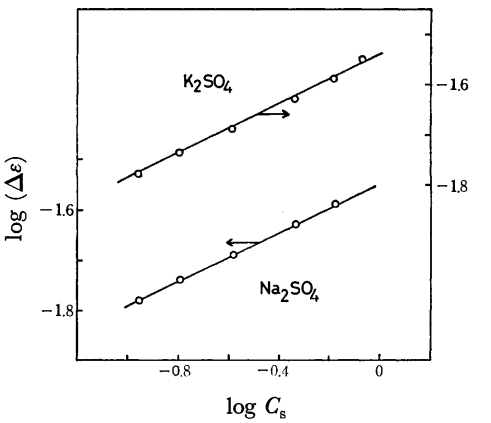

Fig. 6. Plots of log ($\Delta\varepsilon$) at 450 nm *vs.* log C_s for the $[Co(phen)_3]SO_4$ (0.015 M)–*d*-cinchoHl/$2SO_4$ (0.03 M) system.

Plots of the Pfeiffer rotation α_p *vs.* time (h) for the $[Ni(phen)_3]Cl_2$ (0.016 M)-*d*-cinchoHCl (0.016 M) systems containing various amounts of NaCl, measured at 436 nm in a 5 cm cell. 0.0 N NaCl; α_p (0)= −0.122°, α_p (∞)= −0.505°, 0.1 N NaCl; α_p (0)= −0.138°, α_p (∞)= −0.661°, 0.2 N NaCl; α_p (0)= −0.135°, α_p (∞)= −0.759°.

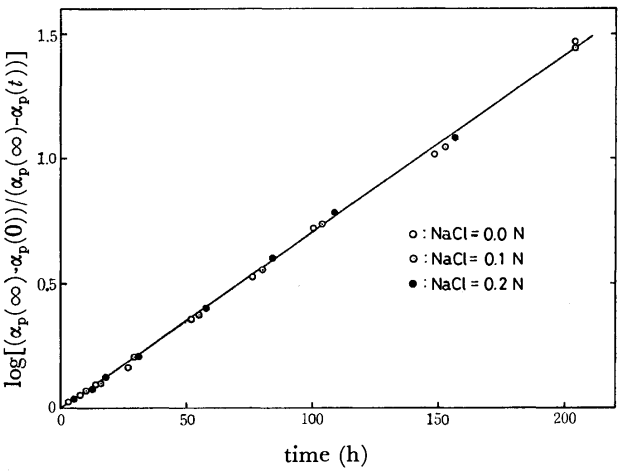

Fig. 9. Plots of $\log[(\alpha_p(\infty)-\alpha_p(0))/(\alpha_p(\infty)-\alpha_p(t))]$ *vs.* time (h) for the $[Ni(phen)_3]Cl_2$(0.016M)-*d*-cinchoHCl (0.016M) systems containing various amounts of NaCl.

stability.[21] That is, the CMC (critical micelle concentration) is greatly lowered by added ions possessing charges opposite in sign to those of surfactant ions. According to the theory of micellization for ionic surfactants,[21] the CMC is expressed as a function of the total equivalent counter-ion concentration C_s by

$$\log (CMC) = -K_g \log C_s + \text{constant},$$

where K_g is a measure of the degree of charge neutralization on the micelle surface. Since *d*-cinchoH$^+$ is a bulky organic ion with its positive charge localized on its nitrogen atom like usual cationic surfactant molecules, and since tris-phen complexes are surrounded by bulky organic ligands, they are all regarded as hydrophobic. In fact, the hydrophobic nature of $[Fe(phen)_3]^{2+}$ ion[22,23] and some compounds[24] like *d*-cinchoH$^+$ or *l*-stryH$^+$ has been recently examined by some workers. Consequently, it is fairly plausible for these hydrophobic cations to attract each other through the hydrophobic interaction to form aggregates in water like cationic surfactants. Though the structure and the aggregation number of the aggregates are not known, highly aggregated species are improbable, judging from the molecular structures of $[M(phen)_3]^{2+}$ and *d*-cinchoH$^+$. Then, by analogy with aqueous ionic surfactant solutions, log (Δε) is plotted against log C_s for both the $[Co(phen)_3]^{2+}$- and $[Ni(phen)_3]^{2+}$-*d*-cinchoH$^+$ systems in Figs. 5—7. Good linear relationships are observed in these plots, derived slopes of which are listed in Table 1. It should be noted here that these plots have an almost constant slope for a given system irrespective of the kind of added cations and of the wavelength chosen for the CD measurement, and that the slope is constant for sulfate systems whether the central metal ion is Co(II) or Ni(II). These findings are completely consistent with the above interpretation for the anion effect shown in Figs. 1 and 2 and Table 1. Furthermore, the increasing order of the degree of charge neutralization, *i.e.*, the increasing order of the induced CD is $Br^- > Cl^- > SO_4^{2-}$/2,[25] which is in agreement with the decreasing order of the CMC of usual cationic surfactants in water (Hofmeister or lyotropic series).[26] This order is also consistent with the influence of the added anions on the chemical potential of cationic tris-phen complexes in aqueous solutions.[27] That is, hydrophobic cations like these complexes are more stable when their counter-ions are structure-breaking anions like Br^- than when they are structure-making anions like SO_4^{2-}.[28]

In order to elucidate the anion effect more clearly, we examined the influence of the added NaCl on the time-dependence[4a,11] of the Pfeiffer rotation α_p.[1] Figure 8 shows the plots of α_p *vs.* time after mixing $[Ni(phen)_3]Cl_2$ with *d*-cinchoHCl in water, where varying amounts of NaCl are added. It is seen that α_p increases exponentially with time,[1,4a] and is enhanced by the added NaCl. In Fig. 9 is plotted $\log[(\alpha_p(\infty)-\alpha_p(0))/(\alpha_p(\infty)-\alpha_p(t))]$ against time t, $\alpha_p(0)$ and $\alpha_p(t)$ being the Pfeiffer rotation immediately after mixing and at a time t after mixing, respectively, and $\alpha_p(\infty)$ the Pfeiffer rotation at enantiomerization equilibrium. It is seen that the value of $\log[(\alpha_p(\infty)-\alpha_p(0))/(\alpha_p(\infty)-\alpha_p(t))]$ is almost constant at a given time after mixing whether NaCl is added or not. This suggests that added NaCl has no effect at all on the rate constant of the

enantiomerization of $[Ni(phen)_3]^{2+}$ in the presence of *d*-cinchoH$^+$, but increases the number of $[Ni(phen)_3]^{2+}$ ion interacting with *d*-cinchoH$^+$, thereby enhancing the Pfeiffer effect. The same will be true for the sulfate system as well as for the $[Co(phen)_3]^{2+}$–*d*-cinchoH$^+$ systems, though the enantiomerization is too rapid[7] to be measured for the latter systems under our experimental conditions.

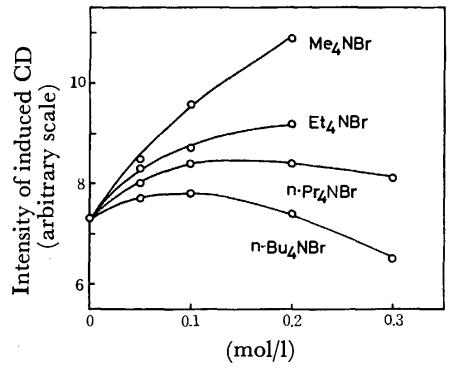

Fig. 10. Plots of the intensity of induced CD at 450 nm *vs.* molar concentration of added R_4NBr (R=methyl to butyl) for the $[Co(phen)_3]Br_2$(0.0075M)–*d*-cinchoHBr (0.03M) system.

In Fig. 10 is plotted the intensity of the induced CD at 450 nm as a function of molar concentration of added tetraalkylammonium bromides R_4NBr (R=methyl to butyl) for the $[Co(phen)_3]Br_2$–*d*-cinchoHBr system. It is seen that the intensity of the induced CD ceases to increase and finally decreases as the alkyl group of added R_4N^+ ion becomes bulky, in other words, as the R_4N^+ ion bears hydrophobic character.[29] This may be interpreted to mean that, when the added R_4N^+ ion is hydrophobic, the hydrophobic bond is formed between R_4N^+[23,30] and $[Co(phen)_3]^{2+}$ or *d*-cinchoH$^+$, and that as a result, the hydrophobic bonding between the complex and *d*-cinchoH$^+$ giving rise to the Pfeiffer effect, is thereby prohibited. Interestingly enough, Steigman *et al.*[31] have found the addition of hydrophobic R_4NBr to raise the CMC of a cationic surfactant, hexadecyltrimethylammonium bromide in aqueous solutions despite the accompanying increase in the counter-ion (Br^-) concentration. They attributed this anomalous cation effect to highly organized water-structure brought about by the added R_4N^+ ion. However, it is still difficult at this stage to decide which explanation is more probable.[26d,32]

Finally, Kirschner and Ahmad,[1b] and Kan and Brewer[33] have reported that *Λ*-isomer[13,34,35] is enriched in both the $[Co(ox)_3]^{3-}$– and $[Cr(ox)_3]^{3-}$–*d*-cinchoH$^+$ systems in water (ox=oxalate anion). On the other hand, *Λ*-isomer is enriched in the present $[Co(phen)_3]^{2+}$– and $[Ni(phen)_3]^{2+}$–*d*-cinchoH$^+$ systems, though the same environment compound as above is used. Consequently, the Pfeiffer effect does not work as an absolute tool for the determination of the absolute configuration of labile metal complexes.[9]

In conclusion, $[Co(phen)_3]^{2+}$ or $[Ni(phen)_3]^{2+}$ ion comes into contact with *d*-cinchoH$^+$ to enantiomerize in favor of its *Λ*-isomer, and added anions reduce the electrostatic repulsion between the cationic complexes and *d*-cinchoH$^+$, thereby enhancing the enantiomerization of these complexes. This situation is similar to that encountered in aqueous cationic surfactant solutions in which ions of the same charge associate to form aggregates against their mutual electrostatic repulsion and added anions facilitate their aggregation greatly. Therefore, so-called long-range interaction is not important to the chiral discrimination even in the Pfeiffer-active systems of the same charge, contrary to the speculation of Schipper.[1d]

Reactions of Aminoalkanols with Some Copper(II) Complexes of the Mixed and Non-mixed Bis(Schiff base) Ligands

V. B. MOHANKUMAR, B. T. THAKER, Rakesh K. KOHLI, and P. K. BHATTACHARYA
Chemistry Department, Faculty of Science, M. S. Universiry of Baroda, Baroda 390-002, India
(Received March 22, 1976; in revised form January 18, 1977)

Reactions of aminoalkanols have been carried out with mixed and non-mixed bis(Schiff base) complexes of copper(II). In these reactions one of the ligands combines with the aminoalcohol forming a tridentate ligand, wheras another ligand is removed. From the resulting complexes the tendency to form the Schiff base is found to be in the order 2-hydroxybenzophenone≈2-hydroxy-1-naphthaldehyde>salicylaldehyde>2-hydroxyacetophenone. The complexes formed have been characterized by analytical, spectral, and magnetic studies.

Tridentate Schiff bases of amino acids with salicylaldehyde, and other similar tridentate Schiff base ligands form 1 : 1 complexes with copper(II),[1-6] the fourth site being occupied by a water molecule[2,3]. Aminoalkanols are also known to form tridentate Schiff base with aromatic aldehydes or ketones.[7] It has been shown by X-ray studies that the tridentate ligand occupies three positions around the metal ion.[2] Chakravorty and co-workers[8] have recently observed that mixed-ligand complexes of copper(II) containing salicylaldehyde, and the Schiff base of *N,N*-diethylethylenediamine with salicylaldehyde react with acids to lose the salicylaldehyde part, and that a complex of tridentate Schiff base is formed with water at the forth position. These facts suggest that the tridentate Schiff bases have a great tendency to form stable copper(II) complexes. An attempt was, therefore, made to study the reactions of aminoalkanols with bis(bidentate Schiff base)complexes of copper(II), and to confirm the formation of copper(II) complexes with tridentate Schiff bases through an amine-exchange reaction.[9] The reactions were also carried out on the mixed Schiff base complexes of copper(II) reported by us earlier[10-12] to compare the relative reactivity among the tridentate ligands. The structures of the resulting tridentate Schiff base complexes have been discussed, and the machanism of the formation of the 1 : 1 complex has been suggested.

Experimental

All the complexes used for the reactions with aminoalkanols were prepared according to the published procedures.[10-16] Aminoalkanols used were 2-aminoethanol(mea) and 1-amino-2-propanol(ipa) of A. R. quality.

Reactions with Bis(imine) Complexes of Copper(II). The following bis-complexes have been used:

(a) Bis(salicylideneaminato)copper(II),
(b) bis(2-hydroxy-1-naphthylmethyleneaminato)copper(II),
(c) bis[1-(*o*-hydroxyphenyl)ethyleneaminato]copper(II),
(d) bis[α-(*o*-hydroxyphenyl)benzylideneaminato]copper(II).

The complexes (a), (b), (c), or (d) (1 g) was taken in suspension in ethanol (30 ml), and to this was added mea (2 ml) or ipa (2 ml), and the mixture was refluxed for 3 h. The reaction mixture was stirred well, and water was added when a solid separated out. It was filtered, washed and dried.

Reactions with the Mixed Schiff Base Complexes of Copper(II). The reactions were carried out with the following mixed complexes:

(a′) (Salicylideneaminato)(2-hydroxy-1-naphthylmethyleneaminato)copper(II),
(b′) (salicylideneaminato)[1-(*o*-hydroxyphenyl)ethylideneaminato]copper(II),
(c′) (salicylideneaminato)[α-(*o*-hydroxyphenyl)benzylideneaminato]copper(II),
(d′) (2-hydroxy-1-naphthylmethyleneaminato)[α-(*o*-hydroxyphenyl)benzylideneaminato]copper(II).

An ethanolic (30 ml) suspension of the complex (a′), (b′), (c′), or (d′) (1 g) was refluxed for 3 h with 2-aminoethanol (2 ml) or 1-amino-2-propanol (2 ml). The reaction mixture was stirred well and water was added to obtain the compound. The complex was filtered, washed, and dried.

The complexes have been analysed for metal, N, C, and H (in some cases). The results have been tabulated in Table 1. Conductivity measurements were carried out in chloroform using a Toshniwal conductivity bridge Type CLOI/OIA. The magnetic susceptibilities of the complexes were determined at room temperature by the Gouy method using $Hg[Co(NCS)_4]$ as the calibrant. Infrared spectra of the complexes were recorded on a Perkin Elmer 427 infrared grating spectrophotometer in the form of KBr pellets. The electronic spectra of the complexes in chloroform solutions were taken on a Beckman DU-2 spectrophotometer at room temperature using 1 cm quartz cells in the range of 400—1000 nm. The reflectance spectra in the LiF medium have been obtained for some of the complexes.

The molar conductances of all the copper(II) complexes in chloroform show them to be non-electrolytes. The magnetic and spectral data have been presented in Table 1. The important IR bands of some of the complexes are listed in Table 2.

Results and Discussion

The reactions of 2-aminoethanol with the complexes (a), (b), (c), and (d) gave the products (A), (B), (C), and (D), respectively. Similar reactions take place with 1-amino-2-propanol and, the products obtained are (E), (F), (G), and (H). The reaction schemes proposed are as follows:

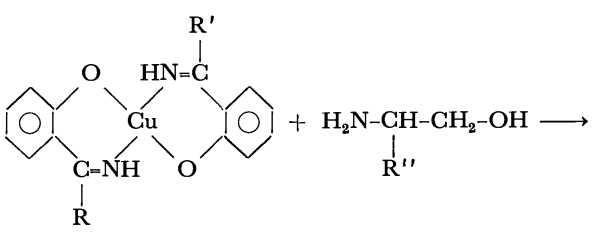

TABLE 1. ANALYTICAL DATA

R=R′=H, CH_3, or C_6H_5
R″=H or CH_3

Thus it is observed that the aminoalkanols replace ammonia from of the Schiff base molecule, and the resulting tridentate Schiff base occupies three positions around the metal ion, the other Schiff base molecule being removed. The fourth position may be occupied by a water molecule.

The reaction can be explained by analogy with the Schiff base copper(II) complex of *N*,*N*-diethylethylene-

diamine.[8] It can be considered that the OH of the aminoalkanol liberates on coordination the H^+ ion which attacks the phenolic-O of the other Schiff base molecule reforming OH, and that a Schiff base molecule is detached.

The reactions of 2-aminoethanol with the mixed complexes (a'), (b'), and (c') gave the products (A'), (B'), and (C'), respectively, salicylideneamine or 1-(*o*-hydroxyphenyl)ethylideneamine being removed. Similar reactions take place with 1-amino-2-propanol. Reactions of 1-amino-2-propanol with (c') gave no definite compound. The reactions can be shown by the same scheme as above where R is H and R' is CH_3.

Thus it is observed that for the mixed ligand complexes also aminoalkanol replaces ammonia from one of the ligands forming a tridentate Schiff base and another ligand molecule is removed.

The above reaction is a confirmation of the fact that the mixed Schiff base complex (CuLL') is really a mixed ligand complex. If it were a mixture of the two bis-compounds, CuL_2 and CuL_2', a mixture of complexes of tridentate Schiff base from both the ligands (L and L') would have been obtained. In the cases of reactions of mea and ipa on mixed Schiff base complexes, it is also interesting to observe which ligand forms the tridentate Schiff base, and which one is displaced. For the copper(II) complexes (b'), salicylaldehyde is retained, and 1-(*o*-hydroxyphenyl)ethylideneamine is removed. This shows that salicylaldehyde has a stronger tendency to form the Schiff base. For the complex (c'), 2-hydroxybenzophenone is retained, and salicylideneamine is removed. It is indicated that 2-hydroxybenzophenone has a stronger tendency to form the Schiff base than salicylaldehyde. Thus the order found is as follows:

2-hydroxybenzophenone>salicylaldehyde>
2-hydroxyacetophenone.

Similarly with complex (a'), 2-hydroxy-1-naphthaldehyde is retained, salicylideneamine being removed. For the complex (d'), no definite compound was obtained on reaction with 2-aminoethanol. The composition of the compound obtained is very close to the complex in which both 2-hydroxy-1-naphthaldehyde and 2-hydroxybenzophenone form Schiff bases and remain with copper(II). This shows that 2-hydroxy-1-naphthaldehyde and hydroxybenzophenone have similar tendencies to form a Schiff base. Thus the order of forming Schiff base is 2-hydroxybenzophenone ≈2-hydroxy-1-naphthaldehyde>salicylaldehyde> 2-hydroxyacetophenone

This is expected from theoretical considerations also. Schiff base formation or amine exchange is due to the nucleophilic attack of an amine on the positively charged carbonyl carbon atom.[17] Attachment of a methyl group with the +I effect lowers the positive charge on the carbon atom, reducing the nucleophilic attack. Thus 2-hydroxyacetophenone is less susceptible to Schiff base formation. The attachment of a phenyl group with the −I effect to C=O group increases the possibility of the nucleophilic attack of 2-hydroxybenzophenone. Similarly the naphthalene ring in 2-hydroxy-1-naphthaldehyde makes the carbonyl carbon atom more positive.

Above reactions with mixed and non-mixed Schiff base complexes show that copper(II) prefers to form a 1 : 1 complex with the tridentate Schiff base. All the copper(II) complexes formed are paramagnetic, corresponding to the nearly spin-only value of one unpaired electron. This shows that a water molecule is in the coordination sphere, and it is a monomeric complex. In some copper(II) complexes the magnetic moment is slightly lower than the spin-only value of one unpaired electron. This may be due to the fact that the complexes are anhydrous and dimeric, leading to the Cu–Cu interaction and the lowering of paramagnetism.[18] The electronic spectra of all the copper (II) complexes are similar and show a peak at ≈620 nm expected for the $Cu(N)(O)_3$ type complexes[19]. This broad band is a combination of three bands corresponding to

$$^2B_{1g} \longrightarrow 2A_{1g},\ ^2B_{1g} \longrightarrow {}^2B_{2g} \text{ and } {}^2B_{1g} \longrightarrow {}^2E_g \text{ transitions.}^{20}$$

The IR spectra of copper(II) complexes exhibit a broad band at 3400 cm^{-1} showing the presence of water. Since there is a band at 900 cm^{-1} corresponding to the O–H out-of-plane deformation mode, this suggests the coordinated water molecule[21]. The absence of the N–H stretching frequency at about 3300 cm^{-1} is also in keeping with the structure of the complexes.

Authors' thanks are due to Prof. S. M. Sethna, former Head, Department of Chemistry, for providing all the laboratory facilities. Two of the authors (V.B.M) and (R.K.K) are also grateful to M. S. University, Baroda, and U.G.C. New-Delhi for providing fellowships.

Lead(II) Butanedioate–Pentanedioate Mixed Complexes

S. C. BAGHEL, K. K. CHOUDHARY, and J. N. GAUR
Department of Chemistry, University of Rajasthan, Jaipur 302004, India
(Received June 21, 1976)

Butanedioate and pentanedioate form 1 : 3 highest complexes separately with lead(II) in aqueous medium, three mixed complexes of these two ligands with the metal ion expected in solution being observed. The formation constants of mixed complexes have been evaluated on the basis of polarographic measurements by the method of Schaap and McMasters. The formation constants of the mixed complexes $[Pb(X)(Y)]^{2-}$, $[Pb(X)(Y)_2]^{4-}$, and $[Pb(X)_2(Y)]^{4-}$ are 3.57, 4.22, and 4.49 respectively in their logarithmic form at 303 K, where X^{2-} and Y^{2-} stand for butanedioate and pentanedioate ion, respectively. The statistically calculated values of logarithm of formation constants are 3.43, 4.43, and 4.49 in the above order. The small differences in the observed and calculated values may be due to electrostatic, steric *etc.* factors. The relative probability of the existence of these mixed complexes and also simple complexes has been explained.

When two or more complexing species are added to a solution containing a metal ion, it has been observed that metal ion forms complex with all the ligand molecules simultaneously. The complexes so formed in the solution are called mixed complexes. Such species have been found as components in natural waters and biological fluids.

Many workers have reported the existence of mixed complexes.[1-4] Polarographic measurements have also shown the formation of mixed complexes in solution.[5-8]

Discussion of the Schaap and McMasters method has been given in detail in our previous publication.[5]

Experimental

All the chemicals used were of reagent grade purity. The sodium salts of butanedioic and pentanedioic acids were used as complexing species at pH 6.8±0.1. The capillary of DME had the following characteristics, $m=2.14$ mg s^{-1} and $t=4.65$ s, where m is the mass of mercury in milligram falling from capillary per second and t is the drop life in seconds. Ionic base strength was kept constant at 2.0 mol dm^{-3} using KNO_3 as electrolyte. At 5×10^{-4} mol dm^{-3} metal ion concentration no maximum suppressor was required. Potentials were measured with reference to SCE. All solutions were prepared in twice distilled water. The temperature was maintained constant at 303±0.1 K using a U_3 Ger. Nr. 8954 type thermostat.

Results

Polarographic Behavior. *Simple Systems*: In each case a single well defined reversible and diffusion controlled reduction wave was obtained. Reversibility and the diffusion controlled nature of reduction were revealed from the slope (31±1) mV of the E_{de} *vs.* $\log(i/(i_d-i))$ plots and the i *vs.* $h^{1/2}$ straight line plots, respectively, where E_{de} is applied potential, i_d is diffusion current, i is current at any potential and h, is effective height of mercury head of DME. The method of DeFord and Hume[10] was used to calculate the overall formation constants (β's) of complexes formed by butanedioate and pentanedioate ions individually with lead(II). The results are as follows:

Equilibria with Butanedioate:

$[Pb(H_2O)_6]^{2+} + X^{2-} \rightleftharpoons [Pb(H_2O)_4X]$; β_{10} (230)

$[Pb(H_2O)_6]^{2+} + 2X^{2-} \rightleftharpoons [Pb(H_2O)_2(X)_2]^{2-}$; β_{20} (3250)

$[Pb(H_2O)_6]^{2+} + 3X^{2-} \rightleftharpoons [Pb(X)_3]^{4-}$; β_{30} (11700)

Equilibria with Pentanedioate:

$[Pb(H_2O)_6]^{2+} + Y^{2-} \rightleftharpoons [Pb(H_2O)_4Y]$; β_{01} (200)

$[Pb(H_2O)_6]^{2+} + 2Y^{2-} \rightleftharpoons [Pb(H_2O)_2(Y)_2]^{2-}$; β_{02} (2950)

$[Pb(H_2O)_6]^{2+} + 3Y^{2-} \rightleftharpoons [Pb(Y)_3]^{4-}$; β_{03} (7850)

where the numerals in parentheses are the overall formation constant at 303 K.

Mixed Systems: The lead(II) butanedioate–pentanedioate mixed complexes were found to reduce reversibly at DME with the involvement of two electrons. The ions reaching the electrode were solely due to diffusion. The above conclusions were drawn from the slopes of the log plots (30—32) mV and the constancy of the ratio of diffusion current and square root of the effective height of mercury column.

In the first set of observations the fixed concentration of pentanedioate ion was 0.075 mol dm^{-3} in all the solutions. The varying quantities of butanedioate were added to the solutions. A cathodic shift in the half wave potential was observed as a function of butanedioate concentration. The shift was greater in the presence of pentanedioate than the one obtained for the simple lead(II) butanedioate system. This indicates the mixed ligand complex formation of butanedioate and pentanedioate with lead(II). In the second set of observations the pentanedioate ion concentration was fixed at 0.2 mol dm^{-3}.

The Schaap and McMasters functions F_{10} given in the theory were computed. The graphical extrapolation of the plots of F_{10} *vs.* C_X gave the values of A, B, C, and D; A, B, C, and D are constants and are the intercepts of the plots of F_{00}, F_{10}, F_{20}, and F_{30} *vs.* C_X on the F_{10} axis, respectively. C_X is the butanedioate concentration which is varied. The functions F_{10} and the constants A, B, C, and D have been defined in our previous publication.[5] The values of A, B, C, and D for the two fixed concentrations of pentanedioate are recorded below:

[Pentanedioate] in mol dm^{-3}	Temperature 303 K			
	A	B	C	D_{av}
0.075	35	600	5550	12200
0.20	200	1850	9400	14100

The values of β_{11} and β_{12} were calculated using values of B at two fixed concentrations of pentanedioate by means of the equation

$$B = \beta_{10} + \beta_{11}[Y] + \beta_{12}[Y]^2,$$

from which we get β_{11} and β_{12} to be 3.57 and 4.22, respectively, in their logarithmic form. The β's are overall formation constants of the corresponding simple and mixed complexes.

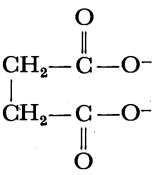
The two values of C gave two values of log β_{21}, both of which are 4.49. The relation between β_{21} and C is given by

$$C = \beta_{20} + \beta_{21}[Y].$$

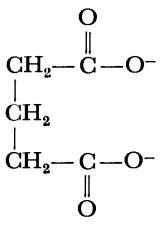
The polarographic measurements and the values of F_{10} functions values are given in Tables 1 and 2 at pentanedioate concentrations 0.075 and 0.20 mol dm^{-3}, respectively.

Discussion

The structures of butanedioate and pentanedioate are as follows:

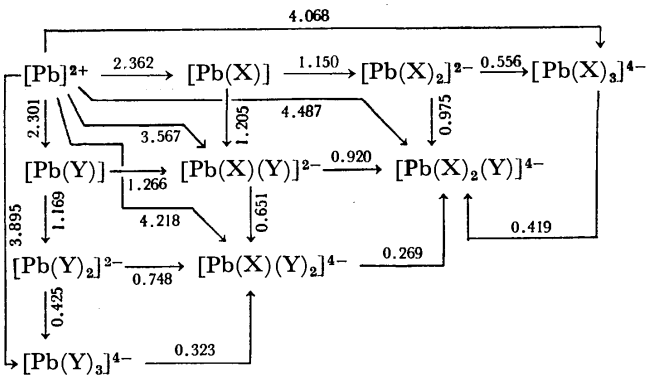


Butanedioate



Pentanedioate

As is evident from their structures the butanedioate complexes are more stable than the pentanedioate complexes (see results of the simple complexes). The highest complex formed with lead(II) is 1 : 3 with each ligand which shows the formation of three mixed complexes, *viz.* $[Pb(X)(Y)]^{2-}$, $[Pb(X)_2(Y)]^{4-}$, and $[Pb(X)(Y)_2]^{4-}$, where X^{2-} and Y^{2-} stand for butanedioate and pentanedioate ion, respectively. The schematic representation of all the complexes (simple as well as mixed) present in the system and the equlibria between them are:



The numerical values in the scheme above are log K values for the step indicated where K is the equilibrium constant for that step.

Statistical calculations[9)] suggest that

$$\beta_{11} = 2.\ 3.\ \beta_{30}^{1/3}.\ \beta_{03}^{1/3},$$
$$\beta_{12} = 3.\ \beta_{30}^{1/3}.\ \beta_{03}^{2/3},$$
and $$\beta_{21} = 3.\ \beta_{30}^{2/3}.\ \beta_{03}^{1/3}.$$

The statistically calculated values of log β_{11}, log β_{12} and log β_{21} are 3.43, 4.43, and 4.49, respectively. The observed and calculated values of log β_{21} agree well, while those of log β_{11} and log β_{12} slightly differ. The deviations in the values of β_{11} and β_{12} may be due to steric or electrostatic factors and also to different approaches for getting these values. From the theory it is seen that log D equals log β_{30} as was observed in our results.

we can compare the tendency of various unsaturated complex species to add another ligand with that of saturated complex species to substitute another ligand. The complexes [Pb(X)] and [Pb(Y)] have a tendency to add Y^{2-} and X^{2-}, respectively. The equilibrium constants in the logarithmic form for these addition reactions are 1.205 and 1.266, respectively. These values show greater probability of the formation of the mixed complex $[Pb(X)(Y)]^{2-}$ from [Pb(Y)] than from [Pb(X)] and hence a slightly greater complexing tendency of X^{2-} than of Y^{2-}. The tendency of [Pb(X)] to add X^{2-} and Y^{2-} shows that there is a greater probability of a mixed ligand complex formation than a

simple complex formation. The same is also concluded from the relative tendency of $[Pb(Y)]$ to add X^{2-} and Y^{2-}. The equilibrium constants for all the above addition reactions are nearly equal, showing a nearly equal complexing tendency of the two ligands, as seen from their nearly equal size.

The tendency of $[Pb(X)_2]^{2-}$ to add X^{2-} and Y^{2-} favor the formation of mixed complexes. Similarly X^{2-} is more easily added to $[Pb(Y_2)]^{2-}$ than Y^{2-}. It is also seen that $[Pb(X)_3]^{4-}$ has a tendency to substitute Y^{2-} and $[Pb(Y)_3]^{4-}$ to substitute X^{2-}. These substitution reactions prove that formation of mixed complexes is favored.

The unsaturated mixed complex $[Pb(X)(Y)]^{2-}$ has a greater tendency to add X^{2-} than Y^{2-}, which shows that the approach of Y^{2-} to $[Pb(X)(Y)]^{2-}$ is hindered to a greater extent. The saturated mixed complex $[Pb(X)(Y)_2]^{4-}$ can substitute X^{2-} but not Y^{2-}. The saturated mixed complex $[Pb(X)_2(Y)]^{4-}$ can substitute neither X^{2-} nor Y^{2-}.

Metal Complexes of Sulfur–Nitrogen Chelating Agents. IV. Complexes of Ni(II), Pd(II), Pt(II), and Rh(III) with Methyl Ester of 2-Amino-1-cyclopentene-1-carbodithioic Acid

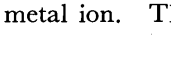
D. S. JOARDAR, S. K. MONDAL, and K. NAG*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received August 23, 1976)

The methyl ester of 2-amino-1-cyclopentene-1-carbodithioic acid (HE) acts both as an unidentate and a bidentate ligand. With Ni(II) and Pd(II) the deprotonated chelates of the ME_2 type are obtained readily, the corresponding Pt(II) complex being obtained on the addition of an equivalent amount of alkali. In these compounds, bond formation takes place from the nitrogen and the sulfur atoms and there is strong delocalization in the chelate ring. Unidentate bonding behavior of the ligand is observed in the complexes $Pt(HE)_2Cl_2$ and $Rh(HE)_3Cl_3$, where the bonding takes place through the nitrogen atom only.

Coordination compounds with ligands showing linkage isomerism are a topic of interest. We have shown[1–4] that in the complexes of 2-amino-1-cyclopentene-1-carbodithioic acid (ACDA) and its *N*-ethyl derivative the metal-ligand bonding takes place either from the amino nitrogen and the deprotonated thiol sulfur or from the dithiocarboxylic moiety depending on the type of a metal ion. The methyl ester of ACDA



which contains the skeletal unit $H_2N–CH=CH–C(SCH_3)=S$ is also capable of forming linkage isomers with metal ions. There are several possibilities for the ligand to bind a metal ion, *e. g.* (i) through NH_2 and C=S, (ii) through NH_2 and the deprotonated thiol sulfur or through the deprotonated amino nitrogen and C=S, (iii) through NH_2 only, (iv) through C=S only, and (v) interaction of SCH_3 in combination with the other donor atoms.

We wish to report here the preparation and characterization of Ni(II), Pd(II), Pt(II), and Rh(III) complexes with the methyl ester of 2-amino-1-cyclopentene-1-carbodithioic acid (hereafter abbreviated as HE).

Experimental

The ligand was prepared by the method of Bordăs *et al.*[5] and recrystallized from (1 : 1) ethanol–water mixture (mp 75 °C, lit,[5] 77—79 °C). Satisfactory results in the elemental analysis of the compound were obtained (Table 1). Other chemicals used were of reagent grade.

Preparation of the Complexes. *NiE_2*: To an ethanolic solution of the ligand (4 mmol) was slowly added an ethanolic solution of hydrated nickel chloride (2 mmol) with stirring. The complex began to separate almost immediately, but to ensure the completion of reaction the mixture was stirred for 30 min. The olive green crystals were collected by filtration, washed with ethanol, and recrystallized from chloroform; yield 90%.

PdE_2: On slow addition of an ethanolic solution of the ligand (4 mmol) to an ethanolic solution of sodium tetrachloropalladate(II) (2 mmol), a brownish yellow compound was formed. This was filtered and washed first with ethanol and then with water till the filtrate showed negative test for chloride ion. The compound was recrystallized from chloroform; yield 80%.

$Pt(HE)_2Cl_2$: A mixture of potassium tetrachloroplatinite (II) (2 mmol) and HE (4 mmol) in acetone was stirred for 2 h. The brownish red product was filtered, washed with ethanol and warm water, and finally recrystallized from chloroform; yield 70%.

$PtE_2 \cdot H_2O$: To a solution of potassium tetrachloroplatinite (2 mmol) in acetone was added dropwise a mixture of 4 mmol of the ligand and 5 mmol of sodium hydroxide in ethanol. The brick red product was filtered and washed successively with petroleum ether, 1 : 1 aqueous ethanol, and warm water. The compound was recrystallized from chloroform; yield 70%.

$Rh(HE)_3Cl_3 \cdot 2H_2O$: A mixture of hydrated rhodium chloride (2 mmol) and the ligand (6.5 mmol) in acetone was stirred for 4 h. A brown compound precipitated slowly was collected on a glass frit, and washed with acetone and water. The compound was dried over fused calcium chloride but could not be recrystallized due to the lack of solvent; yield 50%.

Physical Measurements. Infrared spectra were recorded in nujol mulls on a Perkin-Elmer 457 spectrophotometer in the frequency range 4000—250 cm^{-1}. The NMR spectrum of the ligand in carbon tetrachloride was recorded on a Varian T 60 spectrometer using TMS as a reference. Electronic spectral measurements were made on a Hilger UV-spek spectrophotometer. Conductivity measurements were carried out using a Philips PR 9500 conductivity bridge. Magnetic measurements were performed on a Guoy balance. Thermal analysis was carried out in a Derivatograph (MOM). Molecular weight determination was made with a Mechrolab vapor phase osmometer.

Analyses. C and H were determined by micro combustion analysis, nitrogen by semimicro combustion analysis, and sulfur and metal ions as described earlier.[1]

Results and Discussion

The analytical data (Table 1) indicate that with HE two types of compounds are obtained, *viz.* (a) type ME_2(Ni, Pd, Pt) in which the ligand is in the deprotonated form, and (b) type $M(HE)_mX_n$(Pt, Rh) in which the ligand is in the uncharged form. With Ni(II) and Pd(II), compounds of the type $M(HE)_2Cl_2$ could not be prepared; NiE_2 is formed even in slightly acidic solution (pH≈2). Of the compounds, NiE_2 is soluble in chloroform, acetone, and DMF; PdE_2 in chloroform, nitrobenzene, and DMSO, $PtE_2 \cdot H_2O$ in chloroform and DMF, $Pt(HE)_2Cl_2$ in acetone, chloroform, and nitrobenzene, and $Rh(HE)_3Cl_3 \cdot 2H_2O$ in DMF. The diamagnetic nature of the compounds under investigation indicates the square planar configuration of Ni(II), Pd(II), and Pt(II) complexes and the octahedral configuration of the Rh(III) complex. Both $Pt(HE)_2Cl_2$ and $Rh(HE)_3Cl_3$ act as non-electrolytes (in nitro-

benzene) which indicate the unidentate behavior of the ligand in these compounds.

In order to confirm the coordination sites involved in bond formation, the structure of the ligand itself requires prior consideration. The PMR spectrum of the ligand has the following characteristics: 4-CH_2 (δ 1.78 ppm; quintet), SCH_3 (δ 2.50 ppm; singlet), 3,5-CH_2 (δ 2.33—2.93; multiplet), NH (δ 5.66 ppm; broad, slowly exchanged with D_2O). The above assignments are compatible with structures I and II, excluding other structures which could be envisaged. The hydrogen bonded structures are also supported by the IR spectra of the ligand (in the solid state and in chloroform) which show the presence of a weak broad band due to ν(N-H) at 3240 cm^{-1}, and the absence of a band due to ν(S-H). It appears that both the tautomeric forms coexist in solution.

In the ME_2 type chelates bond formation may take place as in III or IV. If the bond type is III, bands due to C=C and C=S stretching should be expected in the IR spectra. In the bond type IV both ν(C=C) and ν(C=N) vibrations will be observed but no band due to ν(C=S). For substituted cyclopentenes ν(C=C) is observed in the range 1670—1620 cm^{-1}, and for non-conjugated systems ν(C=N) is usually observed in the range 1690—1640 cm^{-1}. For a series of esters of carbodithioic acid Bellamy and Rogasch[6] reported ν(C=S) in the range 1200—1170 cm^{-1}. Thus, a band around 1650 cm^{-1} is expected in both III and IV. However, if a delocalized chelate ring (V) results from the conjugation of 1,3-double bonds present in III and IV, bond orders of C=C, C=N, and C=S will decrease to a great extent. As a result, the stretching vibrations will be observed at lower frequencies. This was actually the case as shown in Table 2. It can be seen that the ν(N-H) band of the ligand at 3240 cm^{-1} remains almost in the same position as in the chelates. The lowering of ν(N-H) frequency in the ligand is shown to be due to hydrogen bonding and in the chelates the lowering of this band to a similar extent is also justified with the bond type (V). Two new bands appearing at 500 cm^{-1} and in the 380—350 cm^{-1} range are assigned to ν(M-N) and ν(M-S) respectively. In Table 2 assignments, based on observations made in several other related systems,[1-4,6-9] have been made to several other vibrations which are structurally important.

Bond formation may take place either as VI or VII in $Pt(HE)_2Cl_2$ and in $Rh(HE)_3Cl_3$ where the unidentate nature of the ligand has been indicated. If bond formation takes place through the thione sulfur atom, ν(N-H) should be expected to occur in the 3500—3300 cm^{-1} range (the usual range for primary amines), whereas bond formation through the amino nitrogen atom would result in its displacement to lower frequency. In the Pt(II) complex two weak bands appear at 3220 and 3150 cm^{-1}, and in the Rh(III) complex these two bands are observed at 3240 and 3140 cm^{-1}. The presence of two bands and their shift to lower frequency indicates bond formation through the nitrogen atom. The band due to (N-H) deformation ap-

pears as a shoulder in the Pt(II) complex and as a band of medium intensity in the Rh(III) complex at 1580 cm^{-1}. In these two compounds a new band observed at 1630 cm^{-1} is absent in the ligand as well as in the deprotonated chelates. On the basis of the preceding arguments we assign this band due to ν(C=C). Moreover, a band due to ν(C=S) as required in VI is observed in the expected range, *viz.* at 1200 cm^{-1} in the Pt(II) complex and at 1215 cm^{-1} in the Rh(III) complex. Although ν(M–N) appears in both compounds at 500 cm^{-1}, ν(M–Cl) which is usually observed at 350—300 cm^{-1} probably gets merged with the ligand band at 320 cm^{-1}. Except for these bands no other significant variation in the spectral features of these compounds from the deprotonated chelates could be observed.

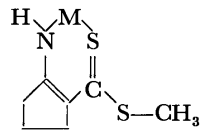
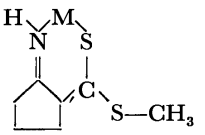
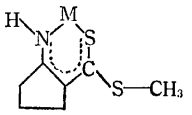
II



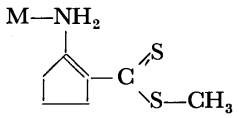
III



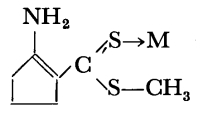
IV



V



VI



VII

The electronic spectra of the compounds proved to be less useful in confirming the bond types because of the presence of high intensity ligand bands in the UV region. In methanol, the ligand shows the presence of two bands at 25840 and 32050 cm^{-1} with the extinctions (log ε) 4.38 and 4.10, respectively (in chloroform these bands are shifted slightly to lower energy). The spectra of the complexes were measured in chloroform solution except for the Rh(III) compound for which a dimethylformamide solution was used. In the nickel complex the lowest energy band at 15870 cm^{-1} (log ε=1.98) is the ν_1 band ($^1A_{1g} \rightarrow {}^1A_{2g}$) of the square planar complexes. The next higher energy band observed at 22730 cm^{-1} (log ε=3.72) appears to be the ν_2 band ($^1A_{1g} \rightarrow {}^1B_{1g}$), but the high extinction indicates that it is mixed with the ligand band in this region. A third band at 33560 cm^{-1} (log ε=4.68) arises due to internal ligand transition. It is interesting to note that in complexes containing the chromophore [NiS_4], the ν_1 band is observed in the range 14500—16000 cm^{-1},[10] whereas for[NiN_2S_2] chromophore, it is usually observed at 18000 cm^{-1}.[11,12] The energy of the ν_1 band in our complex (15870 cm^{-1}) on this basis would indicate disulfur chelated species. However, molceular weight determination in chloroform established the monomeric nature of the complex and the infrared data showed that chelation takes place from the nitrogen and the sulfur atoms. There are increasing evidences[13,14] to show that in [NiN_2S_2] chromophores having strong delocalization in the chelate ring the energy range for the ν_1 band is 15500—16500 cm^{-1}.

No band due to d-d transition could be noted in the Pd(II), Pt(II), and Rh(III) complexes. This is not unexpected since the energy range at which such transitions occur is masked by the ligand band. The Pd(II) complex shows two bands at 24510 cm^{-1} (log ε=3.93) and 32680 cm^{-1} (log ε=4.38) due to the ligand, however a band at 41150 cm^{-1} (log ε=4.55) appears to be due to charge transfer transition. Similar is the case with $PtE_2 \cdot H_2O$ whose bands are located at 26320 cm^{-1} (log ε=3.87), 31250 cm^{-1} (log ε=4.25) and 41150 cm^{-1} (log ε=4.24). $Pt(HE)_2Cl_2$ shows only two bands at 30770 cm^{-1} (log ε=4.33) and 41490 cm^{-1} (log ε=4.34). In the Rh(III) complex also only the ligand bands at 25840 cm^{-1} (log ε=4.28) and 36360 cm^{-1} (log ε=4.59) are observed.

Thanks are due to Dr. T. Seshadri, Institut für anorganische Chemie, Technische Hochschule, Karlsruhe for some of the infrared spectra and to Prof. G. B. Singh of Beneras Hindu University, India for molecular weight measurement. One of us (DSJ) is indebted to CSIR, India, for awarding a PDF.

The Correlation between Photo-electrochemical Cell Reactions and Photocatalytic Reactions on Illuminated Rutile

Mikio MIYAKE, Hiroshi YONEYAMA, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received October 29, 1976)

Photocatalytic reductions of MnO_4^-, $Cr_2O_7^{2-}$, and Fe^{3+} on illuminated rutile were demonstrated. The suitability of a method to analyze the reduction process of the photocatalytic reaction was discussed. It was concluded that a high utilization of light energy could not be expected for photocatalytic reactions because both bands of the semiconductor participated in the reaction. In such a case, the development of the photocatalytic process into a photoelectrochemical cell has a great advantage from the point of view of energy utilization.

Recently, electrochemical reactions on semiconductor electrodes have been investigated extensively.[1-3] The "Photo-sensitized electrolytic reaction" on an illuminated semiconductor electrode is one of the most interesting features of semiconductor electrochemistry.[4] Fujishima and Honda reported a photo-electrochemical cell with a decomposition of water,[5,6] and the cells of this type have been investigated intensively.[7-9] On the other hand, photocatalytic reactions on illuminated semiconductor catalysts seem to be another feature of the "photo-sensitized electrolytic reaction."[10,11] Some attempts have been made to analyze a photocatalytic reaction on an illuminated semiconductor catalyst by electrochemical methods.[11]

It has been reported that electrochemical measurements based on the local cell process are useful for analyses of the reaction rates and mechanisms of the reduction of Methylene Blue[12] and quinones[13] dissolved in methanol on illuminated rutile catalysts. The local cells of these reactions were found to be composed of the "photo-sensitized electrolytic oxidation" and the cathode process of a reaction which obeys usual thermodynamics.[10]

When the local cell is established on an illuminated semiconductor catalyst, a photo-electrochemical cell can be constructed in which the cell reaction is composed of the two individual reactions. This idea was successfuly demonstrated in a previous paper.[10]

It is well known that water is oxidized to oxygen on an illuminated rutile anode in the following way:[4-7]

$$2H_2O + 4p^+ \longrightarrow O_2 + 4H^+, \qquad (1)$$

where p^+ denotes a positive hole in the valence band of rutile. If one chooses an oxidizing agent whose redox-potential is more noble than the potential at which the oxidation of water commences on an illuminated rutile electrode, then one can easily construct a photo-electrochemical cell by using a rutile anode and a Pt cathode. The performance of the cell will be different depending on the redox-potentials of the oxidizing agents chosen so long as the anode process is not heavily disturbed by the existence of the oxidizing agent, which may cause a partial cathodic current.

If the Pt cathode is taken out from the cell, and the rutile electrode is illuminated at the open-circuit condition, then a local cell must be established on the illuminated rutile surface with the same reaction as that in the photo-electrochemical cell. The reaction in this case may be termed a photocatalytic reaction, as in the cases of the reduction of Methylene Blue[12] and quinones[13] on illuminated rutile in methanol solutions. It is quite natural to expect, however, that the reaction behavior will be different between the photo-electrochemical cell and the photocatalytic process.

The purpose of this paper is to present the difference in the behavior between the two kind of reactions by using several kinds of oxidizing agents.

Experimental

A commercial single crystal of rutile ($1 \times 1 \times 0.2$ cm) was used as the electrode material. It was reduced in an argon atmosphere at 800 °C for 2 h. Before being mounted in a glass tube with epoxy resin, the rutile was etched in a concd H_2SO_4 solution containing the same weight of $(NH_4)_2SO_4$ at 240 °C for 0.5 h. The (100) face was chosen as the electrode surface. Its carrier concentration (N_D), as estimated from Mott-Shottky plots in the dark, was about $10^{19}/cm^3$. Before measurements, the rutile electrode was dipped in a concd HNO_3 solution for 2 min, washed with de-ionized water for about 0.5 h, and then dried by hot air. A Pt electrode (1×1 cm) as the cathode of a photo-electrochemical cell and rutile powder as the catalyst were prepared in a manner described previously.[13]

The solution used in this study was 0.5 mol dm^{-3} H_2SO_4 containing an oxidizing agent. The oixdizing agents chosen were $KMnO_4$, $K_2Cr_2O_7$, and $Fe_2(SO_4)_3$. The water used as the solvent was distilled twice, and the H_2SO_4 solution was pre-electrolyzed for 48 h. All the chemicals were of a guaranteed reagent grade. Nitrogen gas was bubbled into the solution during all the electrochemical and chemical experiments.

A 500 W ultra-high pressure Hg arc lamp (Ushio Electric, Inc.; model UI-501) was used as the light source. The light of wavelengths shorter than 350 nm was cut off by setting a convex glass lens in front of the quartz window of the measurement cell. In the case of the experiment using the $KMnO_4$ solution, a $CoSO_4$-solution filter was set in front of the cell to prevent the photo-excitation of MnO_4^-.[14]

Polarization curves were obtained in a steady-state condition by means of a potentiostat (Hokuto Denko Co.; model ps-500B). The potentials were measured against the SCE. The concentration of chemical species in the solution was determined by means of absorptiometry. A Hitachi 124 spectrophotometer was used for this purpose.

The other details such as the purification of the gas, the construction of the measurement cell, and the procedure for the chemical analysis, have been described before.[13]

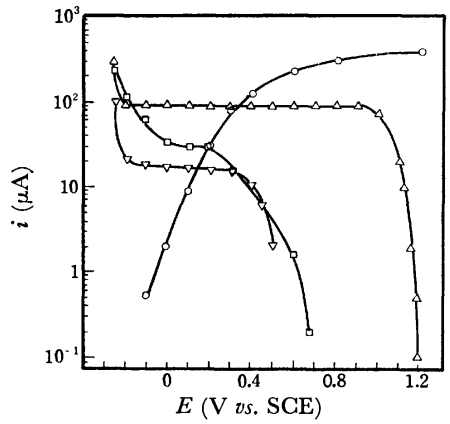

Fig. 1. Polarization curves of the illuminated rutile and the Pt electrodes in 0.5 mol dm^{-3} H_2SO_4 solution with and without 5×10^{-4} mol dm^{-3} of the oxidizing agent. (○) Anodic curve at rutile without the oxidizing agent, and cathodic curves at Pt with (△) $KMnO_4$, (□) $K_2Cr_2O_7$, and (▽) $Fe_2(SO_4)_3$.

Results and Discussion

Photo-electrochemical Cells. Figure 1 shows the polarization curves of the photo-electrochemical cells of

rutile|0.5 mol dm^{-3} H_2SO_4|Ox, 0.5 mol dm^{-3} H_2SO_4|Pt,

where Ox denotes the oxidizing agent. This figure suggests that if the cell of

rutile|Ox, 0.5 mol dm^{-3} H_2SO_4|Pt

works ideally, the cell reaction is composed of the oxidation of water and the reduction of the oxidizing agent. The term "ideally" means that the partial cathodic reduction of Ox and the oxidation of the product formed at the Pt cathode are negligible at the rutile electrode. The establishment of this ideal condition was confirmed, at least in the cases of the reduction of MnO_4^- to MnO_2 and of $Cr_2O_7^{2-}$ to Cr^{3+}, by analyzing the concentration of the oxidizing agent in the cell as a function of the quantity of electricity drawn under short-circuited conditions.

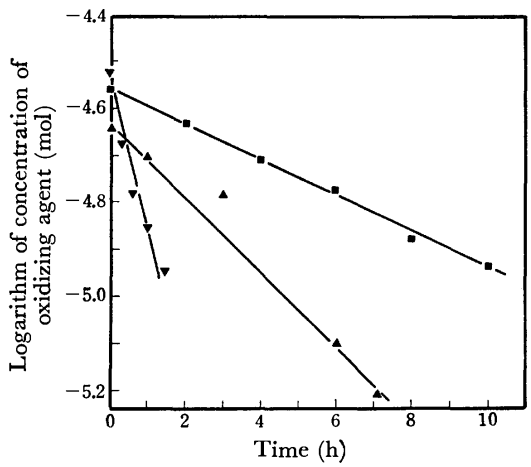

Fig. 2. Change of the concentration of oxidizing agents in 0.5 mol dm^{-3} H_2SO_4 with the reaction time on the illuminated rutile powder catalyst. The solutions containing (▼) Fe^{3+}, (■) $1/2Cr_2O_7^{2-}$, and (▲) MnO_4^-, respectively.

Chemical Analysis of Photocatalytic Reactions. When a rutile powder catalyst was suspended in a 0.5 mol dm^{-3} H_2SO_4 solution (50 cm^3) containing an oxidizing agent, the concentration of the oxidizing agent was decreased by illumination. The results are shown in Fig. 2.

The solutions retained their original absorbance when they were illuminated without the rutile catalyst for 20 h. By the reaction, the solution containing $KMnO_4$ produced a brown precipitate and the purple solution turned light yellow. The other solutions became transparent, and no deposit was detected on the catalyst. Accordingly, the cathode processes of the photocatalytic reactions are the reductions of MnO_4^-, $Cr_2O_7^{2-}$, and Fe^{3+} to MnO_2, Cr^{3+}, and Fe^{2+} respectively. On the other hand, the anodic process is the oxidation of water.[4-7] These results suggest that illuminated rutile worked effectively as a catalyst, causing the same reaction as in the photo-electrochemical cell.

The reaction in Fig. 2 seems to be first-order with respect to the oxidizing agent chosen, since linear relations were established between the logarithm of the concentration of the oxidizing agent and the reaction time. The rate constant calculated from the slopes of the lines are summarized in Table 1.

Table 1. Reaction rates determined by electrochemical analysis and reaction rate constants determined by chemical analysis

Solution	$K_2Cr_2O_7$	$KMnO_4$	$Fe_2(SO_4)_3$
Electrochemical analysis (μA)	0.26	0.73	2.2
Chemical analysis ($\times10^{-4}$, 1/s)	1.1	1.5	6.0

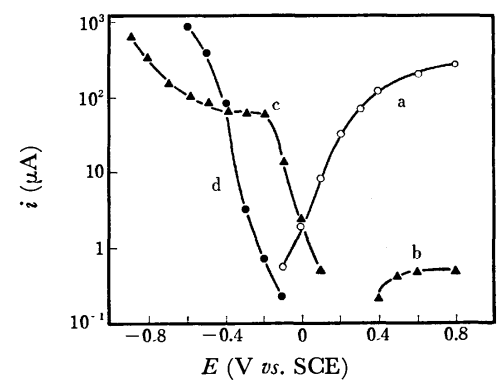

Fig. 3. Polarization curves of the rutile electrode in 0.5 mol dm^{-3} H_2SO_4 solution with and without 5×10^{-4} mol dm^{-3} $KMnO_4$. (a): Anodic curve without $KMnO_4$ under illumination, (b): anodic curve with $KMnO_4$ in the dark, (c): cathodic curve with $KMnO_4$ in the dark, (d): cathodic curve without $KMnO_4$ in the dark.

Electrochemical Analysis of Photocatalytic Reactions. Figure 3 shows the polarization curves of the rutile electrode in 0.5 mol dm^{-3} H_2SO_4 solutions with and without 5×10^{-4} mol dm^{-3} $KMnO_4$. The anodic curve (a), obtained under illumination in a solution without $KMnO_4$, is the same as the curve at the rutile anode in

Fig. 1, and indicates the anodic oxidation of water by positive holes.[4-7] This curve was little affected by the presence of $KMnO_4$ in the solution. On the other hand, it can be noticed, from a comparison of the two cathodic curves (c) and (d), that the cathodic current was distinctly increased by addition of $KMnO_4$ to the solution. This increase in the cathodic current may be ascribed to the participation of the reduction of $KMnO_4$ to MnO_2. The magnitude of the current in the presence of the oxidizing agent was by far larger than that in the absence of it. This means that the polarization curve of the oxidizing agent was eventually the same as curve (c). The stagnation of the cathodic current in curve (c) under a relatively high cathodic polarization is attributable to the deposition of MnO_2 onto the rutile surface. The cathodic process is based on the conduction-band electrons, since the cathodic current increased exponentially with an increase in the cathodic polarization.[1-3]

Similar results were obtained for the solutions with the other oxidizing agents. The reduction curves of these oxidizing agents are summarized in Fig. 4, together with the oxidation curve of water.

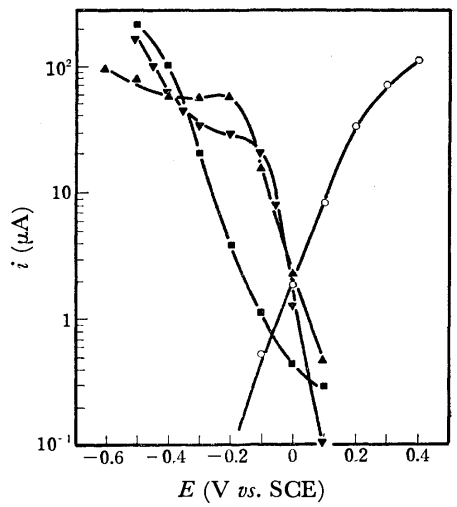

Fig. 4. Polarization curves of the rutile electrode in 0.5 mol dm^{-3} H_2SO_4 solution with and without the oxidizing agent. (○) Anodic curve without the oxidizing agent under illumination. Cathodic curves with 5×10^{-4} mol dm^{-3} (▲) $KMnO_4$, and 2.5×10^{-4} mol dm^{-3} (▼) $Fe_2(SO_4)_3$ and (■) $K_2Cr_2O_7$ in the dark.

When the cathodic polarization curves obtained in the dark are not changed by the illumination, the rate of the catalytic reaction on illuminated rutile can be estimated as the current value at the intersection point of the anodic and the cathodic curves in Fig. 4; this procedure is widely adopted in the estimation of the corrosion rates of metals.[15] The illumination has a negligible influence on the cathodic polarization curves when the electron concentration at the rutile surface is almost unchanged by the illumination. Therefore, it is necessary to discuss whether or not such a condition is fulfilled in the present study.

The electron concentration at equilibrium in the rutile electrode at room temperature (n_0) was about $10^{19}/cm^3$, as stated in the experimental section. The concentration of excited electrons by the illumination (n^*) is given as a function of the distance x from the illuminated surface by[16]

$$dn^*(x)/dt = \alpha f' \exp(-\alpha x) - di/dx - n^*(x)/\tau,$$
$$i = -Ddn^*(x)/dx \qquad (2)$$

where α, f', τ, and D denote the absorption coefficient of rutile, the numbers of incident photons per cm^2 per second on the crystal, the lifetime of the carrier in rutile, and the diffusion constant of the carrier in rutile respectively. In a steady state, Eq. 2 becomes

$$\alpha f' \exp(-\alpha x) + Dd^2n^*(x)/dx^2 - n^*(x)/\tau = 0 \qquad (3)$$

since $dn^*(x)/dt=0$.[16] By applying the conditions that $n^*(x)$ becomes 0 when x is infinitely large, and that carriers which diffuse to the surface can escape from the crystal to cause the current to flow, that is, $i=-D\{dn^*(x)/dx\}_{x\to0}=n^*(x\to0)$, Eq. 3 gives the following equation:

$$n^*(x) = \alpha f'\tau\{\exp(-\alpha x)\}/(1-D\tau\alpha^2) + K\exp\{-x/(D\tau)^{1/2}\}$$
$$K = \alpha f'\tau^{3/2}(D\alpha-1)/\{(D\alpha^2\tau-1)(D^{1/2}-\tau^{1/2})\} \qquad (4)$$

α is judged to be $10^3/cm$ for the light of 400 nm,[17,18] which gives the maximum photo-response at the rutile electrode.[19,20] τ has been reported to be 5×10^{-6} s and almost independent of the applied electric field and temperature.[21] If a value of 1 cm^2/V s is chosen as the electron mobility,[22,23] then we can obtain 3×10^{-2} cm^2/s for D from the well-known Einstein relation.[24]

The quantum yield of the "photo-sensitized electrolytic oxidation" of water is dependent on the wavelength and N_D, and is around 0.3 ± 0.2 in an rutile anode having 10^{19} carriers/cm^3 at 2 V *vs.* SCE for the light of 400 nm.[19] If it is assumed that the numbers of holes reached at the electrode surface per second are a 0.1 fraction of that of the incident photons, we can get a rough measure of f' from a knowledge of the saturated photo-current. We use here the smallest value of the quantum yield, 0.1, because we have to estimate the upper limit of n^*. In the present study, the saturated hole current at 2 V *vs.* SCE in a 0.5 mol dm^{-3} H_2SO_4 solution was 875 $\mu A/cm^2$. Accordingly, f' was estimated to be less than $10^{17}/cm^2$ s.

In order to get information on the concentration of photo-generated electrons at the surface, Eq. 4 was simplified with the condition of $x\to0$:

$$n^*(x\to0) = \alpha f'\tau/(1-D\tau\alpha^2) + K. \qquad (4')$$

By substituting the just-estimated values into Eq. 4', $n^*(x\to0)$ was determined to be smaller than $10^{15}/cm^3$.

Now it is possible to get information on the relative measure of the numbers of photo-generated electrons at the surface of rutile to those of electrons at equilibrium in the dark. The electron concentration at the surface of the electrode n_s in the dark is given by Eq. 5:[25]

$$n_s = n_o \exp\{-e(E-E_{fb})/kT\} \qquad (5)$$

where E and E_{fb} are the electrode potential and the flat-band potential of rutile respectively. The E_{fb} of rutile in a 0.5 mol dm^{-3} H_2SO_4 solution was reported to be −0.1 V *vs.* SCE.[26] A similar argument can also be applied to $n^*(x\to0)$ when the effect of the band

bending is taken into consideration for $n^*(x\rightarrow 0)$. Anyway, comparing the value of n_s with that of $n^*(x\rightarrow 0)$, $n^*(x\rightarrow 0)$ is too small to give a distinct change in the numbers of electrons at the rutile surface.

It may also be valuable to discuss the effect of the photovoltage on cathodic polarization curves obtained in the dark. A depletion layer is formed when an *n*-type semiconductor electrode such as rutile is placed in contact with a solution containing a chemical species which has a more noble redox-potential than E_{fb}. By illumination, the degree of the band bending is reduced, and this effect causes the so-called photovoltage.[27] According to Gerischer, the electron-energy level in the semiconductor is changed by illumination by the magnitude of the photovoltage, and the change is equal to $e(E_F^*-E_F)$ eV, where E_F^* and E_F denote the Fermi levels of the semiconductor under illumination and in the dark respectively. By the illumination, the electrode potential is shifted toward a cathodic direction by the magnitude of the change in the band bending. If the illuminated electrode is polarized anodically by $|E_F^*-E_F|$, the electrode potential is brought back to the same value as before illumination, and simultaneously the band bending also returns to the same situation as before illumination. It is concluded from this discussion that the same band situation is realized at rutile electrodes both with and without illumination if the electrodes are polarized at the same potential.

It is, therefore, believed that the reduction curves obtained in the dark in Fig. 4 represent the behavior of the reduction of the oxidizing agents on the illuminated rutile catalyst.

It is, then, possible to determine the rates of the photocatalytic reactions as the current values of the intersection points in Fig. 4.[12,13] In the cases of MnO_4^- and $Cr_2O_7^{2-}$, three and six Faradays are needed to produce 1 mol of MnO_2 and 2 mol of Cr^{3+} respectively. One-third of the current values at the intersection points in Fig. 4 thus correspond to the reaction rates for these systems. The reaction rates estimated from the electrochemical measurements are summarized in Table 1, together with the reaction rate constants determined by the chemical analysis described above.

The rutile powder catalyst used in the chemical analysis had an unidentified N_D and various crystal planes exposed to the solution. On the other hand, the electrochemical analysis was performed on the single crystal which had a fixed N_D and crystal plane. Nevertheless, the results in Table 1 show that the reaction rates determined by the two kinds of methods had a similar tendency in their relative magnitudes. The important influence of N_D on the rate of the photoelectrochemical reaction was theoretically predicted[27] and was also experimentally found on the photoelectrolytic decomposition of water at rutile anodes and GaP cathodes.[19] However, the ambiguity of N_D does not cause any serious problem in the qualitative comparison of the reaction rates determined by the two kinds of methods, because the dimensions of the reaction rates are completely different between the two kinds of methods, and the same powder catalyst was used in the series of the experiments, by which the effect of N_D was fixed in various systems of the photocatalytic reactions.

The value of the reaction rates on the illuminated rutile catalyst is determined by the feasibility of electron exchange between the semiconductor and the species in the solution, as has been discussed in a previous paper in the case of quinones dissolved in methanol.[13] The feasibility is determined by the positions of the energy levels of the band edges of semiconductor relative to the electron-energy levels of the chemical species, which are distributed with a specified rearrangement energy.[2,3] Accordingly, the difference in the reaction rates of the oxidizing agents in Table 1 seems to be due to this factor. No detailed discussion of the difference in the reactivity could be done, however, since we have no data on the rearrangement energy of MnO_4^- and $Cr_2O_7^{2-}$, which are reduced by three-step processes.

Difference in the Behavior of the Cathodic Polarization Curves between Photo-electrochemical Cells and Photocatalytic Reactions. It can be noticed by comparing Figs. 1 and 4 that the main difference lies in the cathodic polarization behavior of the oxidizing agents.

The cathodic curves on the rutile electrode given in Fig. 4 commenced at almost the same potential of 0.1 V *vs.* SCE. This means that the overpotential was different depending on the kind of oxidizing agent. In the case of a semiconductor electrode, an externally applied potential causes a change in the band bending in the semiconductor.[1-3] When the semiconductor electrode is polarized at potentials anodic to E_{fb}, the bands bend up toward the surface.[1-3] Consequently, the cathodic current should be controlled by this energy barrier, and it shoud eventually be independent of the redox-potentials of the oxidizing agents used as long as the cathodic process is affected only by the electron density at the semiconductor surface. The validity of this view has already been reported in connection with ZnO.[25] In that case, the potential barrier to bringing the cathodic current flow of an order of 0.1 $\mu A/cm^2$ was 0.6 eV at most.[25] Therefore, the cathodic polarization curves in Fig. 4 are judged to be reasonable, since the E_{fb} values of rutile in 0.5 mol dm^{-3} H_2SO_4 has been reported to be -0.1 V *vs.* SCE.[26]

On the other hand, the polarization of the rutile electrode at a potential cathodic to E_{fb} causes an energy barrier for the positive holes reaching the electrode surface in the same manner as electrons for the anodic process.[1-3]

When both electrons and positive holes transfer from the electrode to the chemical species in the solution, as is the case in the present photocatalytic reaction, the flat-band condition will be feasible for the transfer of both carriers. The potential where the reaction proceeds reflects this situation and is located around E_{fb}, as Fig. 4 shows. Under these conditions, the quantum yield of the reaction should be quite low, since electron-hole recombination predominates,[19,27,28] and the reaction rate is low, as is shown in Fig. 4. Therefore, it can be confirmed in the present study that a good utilization of light energy can not be expected for a photocatalyst where both bands participate in the reaction.

In the case of photo-electrochemical cells using the

illuminated rutile anode and metal cathode, it is necessary to take the energy barrier into consideration only for positive holes in the anode. When the energy bands bend up enough to accelerate positive holes effectively to the semiconductor surface, a larger reaction rate can be expected than that of the photocatalytic reaction.

Studies on the Thermal Separation Column. V. Thermal Separation Column Having Horizontal Barriers

Kazuo SASAKI, Seiji TAO, and Yoshio HIRANO

Department of Applied Chemistry, Hiroshima University, Sendamachi, Hiroshima 730

(Received November 29, 1976)

The performance of a hot wire type thermal separation column in which many horizontal barriers of Teflon or copper plates are installed has been examined. At the optimum spacing of barrier plates, the quality factor defined by $(2AL)_{barrier}/(2AL)_{open}$ exceeds 3. This means that a barrier column constructed properly has a performance equivalent to that of an open column of three times taller in height. Visualization of a stream line in the barrier assembly indicates that a helical transverse motion takes place in the space partitioned by two adjacent barrier plates.

We have studied the effect of installing flow barriers inside the gas chamber of a thermal separation column.[1-3] It was concluded that the presence of a flow barrier retards the convectional velocity of separating gas mixture and the largest separation is attainable when convectional velocity is minimized. A similar conclusion was also obtained from the study of a tilted column.[4]

Although the use of a vertical barrier has been proved effective to improve the performance of thermal separation, there are some difficulties as regards the construction of the vertical barrier system.

This paper deals with the effect caused by the use of horizontal barriers in place of vertical ones. The structural difficulty in the vertical system can mostly be eliminated by use of the horizontal barrier system for which there is no difficulty in selecting the standard of comparison.[3] Utilization of horizontal barriers was first studied by Treacy and Rich[5] who claimed the merit of the barriers. However, the procedure of the experiment and the data do not seem convincing.

Experimental

Apparatus. An outline of the column is shown in Fig. 1. A straight column employing an iron tube for the outer wall of the gas chamber is fixed vertically as accurately as possible. Inclination of a column seriously affects the degree of equilibrium separation.[4] The upper end of the center wire (diam. 0.23 mm, nichrome) (9) is tightly fixed to the column top which is electrically insulated from the column body. A micalex rod (1) was used for this part. At the lower end of the heater wire, a copper rod (10), 99 g, is connected to assure the verticality and tautness of the heater wire. A mercury pool (11) is provided in contact with the tail end of the weight to make allowance for the thermal elongation of heating wire. The elongation is measured with a travelling microscope in order to estimate the heater temperature. The length of the column as measured by the distance between two sampling ports (5) at top and bottom is 54 cm.

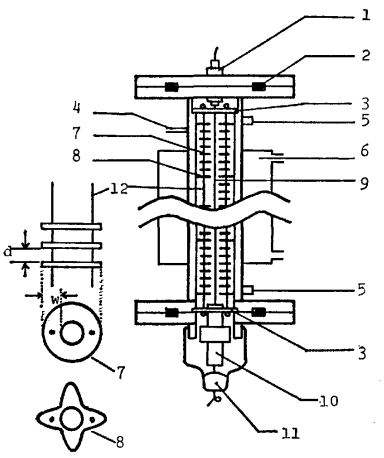

Fig. 1. Illustration of barrier-column.
1: Micalex rod, 2: O-ring seal, 3: terminal plates, 4: gas inlet, 5: sampling port, 6: water jacket, 7: flat doughnut barrier, 8: cruciform barrier, 9: nichrome heater, 10: weight, 11: mercury pool, 12: fine wire.

Barriers. The horizontal barrier assembly consists of many plane parallel plates made from Teflon (0.8 mm thick) or copper sheets (0.55 mm thick). Each barrier plate is in the form of a flat doughnut (7) having outer and inner diameter of 12.0 and 4.7 mm, respectively. The desired number of barrier plates are assembled into one unit by keeping the plates plane parallel with a regular distance. This was done by sewing the plates with two pieces of fine wire (12). At least 89 and at most 260 plates were fitted over the whole length of the barrier assembly (52 cm). Regardless of the number of barrier plates fitted, twelve cruciform barriers (8), slightly larger than the doughnut barriers, were placed every 4.7 cm in place of the doughnut barrier. This was necessary for assuring the installation of the barrier assembly in the proper position inside the column space. When copper was used as barrier material, the contact point between the plate and sewing wire was cemented by epoxy resin, while no cement was necessary for Teflon plates. The barrier assembly built up outside the column was carefully transferred into the column space and fixed to the terminal plates (3) located at the top and bottom of the gas chamber.

Operation of the Column. Operation of the column was more or less the same as described previously.[2] A d.c. power source with stabilized voltage was used for heating the nichrome wire. The column was filled with test gas before heating current was supplied. After steady temperature difference had been set up the column was evacuated and filled with fresh gas in order to start the measurement. The gas pressure was kept at 785±4 Torr throughout the experiment. The test gas was an equimolar mixture of argon and nitrogen.

Results and Discussion

Theoretical Value of q_e for the Open Column. So far we have no reliable means to predict a theoretical value of q_e attainable in a column having a horizontal barrier

Table 1. Calculated values of transport coefficients and equilibrium separation factor

ΔT (°C)	$h\times10^3$	$k_c\times10^2$	k_d	$H\times10^4$ (g/s)	$K_c\times10^2$ (g cm/s)	$K_d\times10^4$ (g cm/s)	$A^{a)}\times10^3$ (cm^{-1})	$q_e^{b)}$
221	4.10	1.74	0.52	1.60	1.97	6.17	3.93	1.53

a) $A=\dfrac{H}{2(K_c+K_d)}$. b) $q_e=\exp(2AL)$.

assembly. A theoretical value can be obtained only for the open column.

The basic equation derived by Jones and Furry[6] was used for calculation. The following values were used for basic parameters;

$$\alpha = 0.127-13.6/T,^{7)}\quad (D_{12})_1 = 0.20\ \mathrm{cm^2\ s^{-1}},$$

$$(\bar{\rho})_1 = 1.53\times10^{-3}\ \mathrm{g\ cm^{-3}},\quad (\bar{\eta})_1 = 1.97\times10^{-4}\ \mathrm{pois}.$$

Subscript 1 outside the parentheses refers to the temperature of the cold wall taken to be 289 K. The numerical tables by Saxena and Raman[8] were used for the corrections as regards the cylindricity of the column. This is equivalent to assuming both argon and nitrogen molecules to be rigid spheres. The calculated values of equilibrium separation factor, q_e, as well as the transport coefficients are given in Table 1.

Experimental Results. Measurements were carried out (1) with an open column in which no barrier was installed, (2) with a column having Teflon barriers, and (3) with a column having copper barriers. In the measurements with barrier-columns the effect of barrier distance, *i.e.* vertical distance between two adjacent plates, was also studied. Altogether, seven series of experiments were made, the results of which are summarized in Table 2.

The progress of separation with time for the initial 15 min of each measurement is shown in Fig. 2. The curves are numbered according to the series of experiments and correspond to those in Table 2.

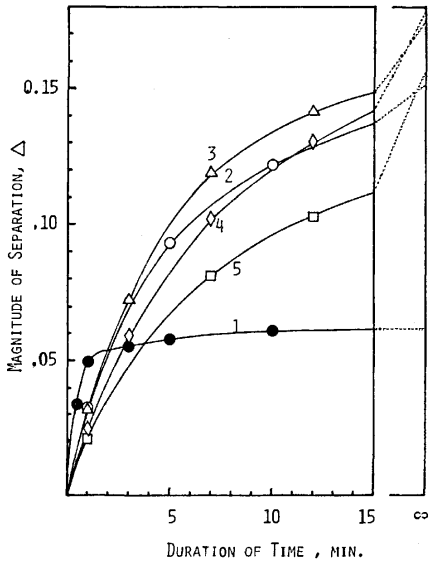

Fig. 2. Progress of separation with time.
The magnitude of separation is the difference in mole fractions of component 1 between top and bottom of the column.

Variations of equilibrium separation, q_e, with temperature difference, ΔT, are shown in Fig. 3. We see that in each series of experiments with the barrier-column, q_e increases linearly with increasing ΔT.

The dotted line connects theoretical values calculated for the open column. The experimental values for q_e for the open column are much lower than those of theoretical prediction. In contrast, the q_e values

observed with barrier-columns are always larger than those with the open column even in comparison with theoretical prediction. The quality factor, f,[2] defined by

$$f = (\ln q_e)_{\text{barrier}}/(\ln q_e)_{\text{open}}$$

takes values greater than two (Table 2). In this equation, q_e is defined by

$$\ln q_e = 2AL,$$

where A is the characteristic constant of each individual column and L the column length. The two fold increase in the quality factor is equivalent to using an open column of two times taller in height. The quality factor seems to be affected largely by spacer distance. This is shown in Fig. 4, where the solid curve stands for Teflon barriers and the dotted curve for copper barriers. An optimum appears at about 2.8 mm.

Effect of Barrier Material. The barrier material affects the equilibrium separation, copper being superior

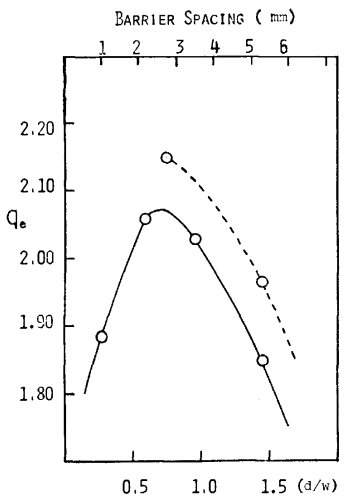

Fig. 4. Change in q_e against the barrier spacing, d, as well as the ratio of d to the barrier width, w. Full line; Teflon plates, Dotted line; copper plates.

to Teflon. Prior to the experiment we surmised that q_e would be reduced by the local disturbance of uniform temperature gradient caused by the metallic heat conductor. The result was contrary to expectation but it is understandable if we take the temperature gradient in a field of forced convection into consideration. The temperature is thought to fall steeply at the surface region of the central heater, never changing linearly. It seems that, in the column studied, most part of the temperature gradient is set up in a restricted region near the heater surface and the space in which barrier plates are located is almost isothermal. If this is the case, the barrier material would have no effect. Actually, however, copper enhances the equilibrium separation. The enhancing effect of metallic barriers can be attributed to the enhancement of net heat conduction through the column. The primary driving force of thermal diffusion is undoubtedly the heat flux. The presence of a heat conductor inside the gas chamber, even in the isothermal region, would increase the net heat flux giving rise to an enhanced separation. This is in accordance with the fact that when the barrier assembly of copper plates was used approximately 10% larger power dissipation was necessary for maintaining a given temperature difference as compared to the case in which Teflon plates were used. Teflon plate is also a better heat conductor when compared with separating gas. As a result, power dissipation always increases when barriers are used.

Effect of Barrier on the Rate of Separation. Use of horizontal barriers resulted in an appreciable increase in q_e (Table 2). This is reflected in the retardation of the rate of separation. If we assume that the separation proceeds by the exponential function[10]

$$\Delta = \Delta_e(1-e^{-t/t_r}),$$

we can estimate the relaxation time, t_r, experimentally. The values of t_r thus determined are given in Table 2. We see that the use of barriers increases the transition time a great deal; the denser the barrier spacing, the greater the transition time (Fig. 5). This is in line with what we found in the case of vartical barrier, that the retardation of convectional velocity is the primary factor for the enhancement of equilibrium separation.[1] In the present case, however, it should be emphasized that too dense installation of barrier plates reduces q_e and an optimum appears in the relation between q_e and barrier spacing (Fig. 4). This suggests that the enhancement in equilibrium separation can not be entirely attributed to the retardation of convectional velocity (Fig. 2). The rate of separation (tangential slope of each curve at $t=0$) varies with curve. However, the slopes have no simple correlation with the relaxation time. It seems that the greater the equilibrium separation the faster the intial rate of separation.

Visualization of Stream Line. Let us consider the question of why the use of the barrier assembly increases the magnitude of q_e. Each barrier plate serves to disturb the stream line of flowing gas making the flow turbulent. A turbulent flow would act to mix rather than to separate the mixed components. Actually, this was not the case and the use of barrier was unexpectedly effective for

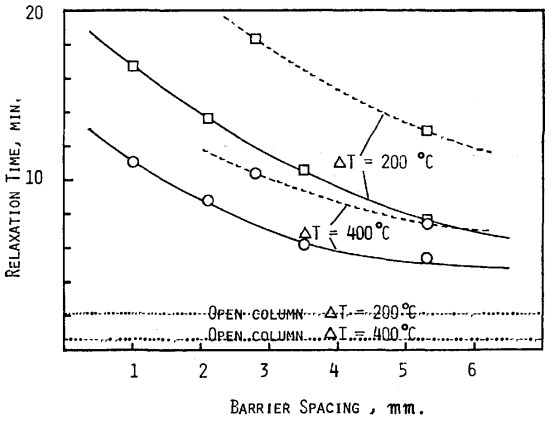

Fig. 5. Relaxation time against the barrier spacing. Full line, Teflon plates, Broken line, copper plates, Dotted straight line, open column.

attaining a larger separation. We thus attempted to visualize the flow pattern inside the barrier-column. Attempts in a gas sample using several kinds of aerosols were unsuccessful. We then carried out the experiment with use of a solid suspension in a liquid. Fine powder of polyethylene suspended in a water–isopropyl alcohol mixture was employed. A model column of a glass tube, in which a barrier assembly and a central heater wire were installed, was filled with the indicator solution. The whole apparatus was immersed vertically in a thermostatted water bath (25 °C). The temperature of the heater wire was not measured but the heating current was so controlled as to make the flow pattern visible.

A typical example of stream line is shown in the photograph attached. It is evident that the flow of fluid occurs in a regular manner. The path of particle movement as observed in a vertical cross section is a circle. It is unlikely that indicator particles move only in a fixed vertical plane. The path of each particle must be continuous in the transverse direction. It is highly probable that the path of stream line forms a doughnut-shaped circular helical coil surrounding the central heater wire. Although the picture was taken in a dummy column with a liquid sample which might differ from gaseous sample in many respects, a rough concept on the nature of flow pattern can be attained.

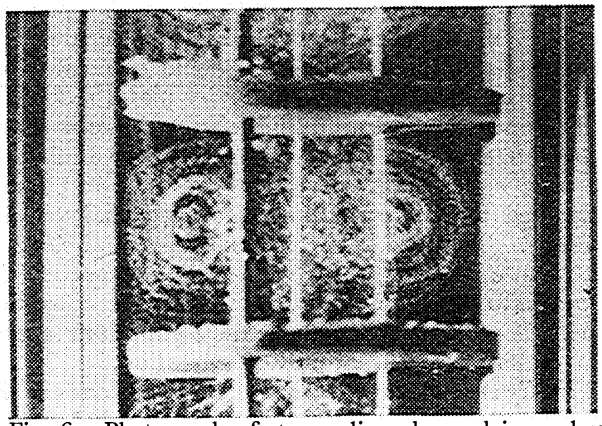

Fig. 6. Photograph of stream line observed in a glass column. Moving particles are polyethylene powder suspended in a water–isopropyl alcohol mixture. Inner diameter of glass tude; 18 mm, Outer and Inner diameters of barrier; 14 and 5 mm, Barrier spacing; 8 mm.

The flight length of a particle in upward convection stream should be L, the length of column, in the open column. The flight length should be elongated in the barrier column by involvement in the helical transverse motion. Involvement in the helical transverse motion might be rationalized from the view that the value of the quality factor, f, can be considered as an effective elongation of column length.

Optimum Spacing of Barriers. We see in Fig. 4 that an optimum barrier distance exists for the largest separation. The scale of abscissa is also expressed tentatively in terms of the ratio of spacer distance, d, against the width of barrier plate, w. The optimum lies at about 0.75 of this scale. The optimum distance should be a function of the relative dimension of inner and outer diameters of barrier plate relative to those of column and heater wire.

Conclusion

1. Installation of a horizontal barrier assembly, consisting of many plates with the form of a flat doughnut, remarkably increases the equilibrium separation as compared with the open column. The spacing between two adjacent barrier plates has an appreciable effect on the eqilibrium separation. There is an optimum spacing for the largest separation. Almost three times greater separation can be obtained by suitable choice of horizontal barriers.

2. As the barrier material, copper was found to be superior to Teflon. The presence of the barrier assembly, which is a better heat conductor as compared with gaseous material, increases the effective heat conductivity of the whole apparatus and the increase in heat flux enhances the separation. The enhanced separation would be partly due to this effect. The power dissipation per unit time increases by using barriers.

3. Installation of a barrier assembly reduces the rate of separation and elongates the relaxation time for separation. The relaxation time is a simple function of the barrier spacing, increasing monotonously with decreasing barrier spacing (increasing number of barrier plates). However, the actual rate of separation determined from the tangential slope of separation-time curve has no simple correlation with the relaxation time. The rate so determined varies in line with the statement "the greater the separation, the greater the rate."

4. Attempts were made to visualize the flow pattern in the barrier column with use of a dummy column. The movement of polyethylene powder suspended in a water–isopropyl alcohol mixture in the field of forced convection was recorded in order to show that the stream line forms a helical coil at each space partitioned by barrier plates. It is suggested that the use of horizontal barriers is equivalent to lengthening the open column. The situation is similar to that observed in

a tilted column.[4]

5. In contrast to the vertical barrier, the enhancement of separation in a horizontal barrier system can not be attributed solely to the retardation of convectional velocity. The regular helical motion of molecules would have an important effect.

Nanosecond Fluorescence Anisotropy of the DNA-Acridine Complexes

Yukio KUBOTA* and Robert F. STEINER

Department of Chemistry, University of Maryland, Baltimore County, Baltimore, Maryland 21228, U.S.A.

(Received November 30, 1976)

The rotational motions of various acridine dyes bound to DNA were investigated by the measurements of nanosecond fluorescence anisotropy. It was found that the total decay of fluorescence is a single exponential, whereas the decay of fluorescence anisotropy is a sum of an exponential function and a constant. The apparent values of the rotational relaxation time of the complexes calculated from anisotropy data range from 21 to 31 ns. The results are discussed by comparing with those obtained from the measurements of steady-state fluorescence depolarization.

Since Lerman[1,2] proposed the intercalation model in which the dye molecule is sandwiched between the adjacent base pairs of DNA by extension and local unwinding of the helix, the general features of the model have been widely accepted.[3,4] However, the exact location of the intercalated dye is not yet definitely known. One of the approaches to elucidate the possible location of the dye is a systematic investigation of the dependence of the binding nature on the dye structure.[5-7]

In a previous paper,[6] it was found that the mean rotational relaxation times of the DNA-acridine complexes obtained from the measurements of steady-state fluorescence depolarization depend on the dye structure. In this paper, nanosecond fluorescence anisotropy and viscosity studies have been undertaken to obtain further information on the rotational motions of the dye bound to DNA, using various acridine dyes.

Experimental

Materials. Calf thymus DNA was purchased from Worthington Biochemical Corporation. The concentration of DNA was determined spectrophotometrically at 260 nm with the extinction coefficient per mol of DNA phosphate ($\varepsilon_p = 6600\ M^{-1}\ cm^{-1}$).[8] Acridine Orange (AO), Proflavine (PF), 3,6-bis(methylamino)acridine (Ac[NHMe]$_2$), 3,6-bis(ethylamino)acridine (Ac[NHEt]$_2$), 3,6-bis(diethylamino)acridine (Ac[NEt$_2$]$_2$), 3,6-bis(dimethylamino)-10-propylacridinium chloride (AO-propyl) and 3,6-bis(dimethylamino)-10-isopropylacridinium chloride (AO-isopropyl) were the same as previously reported.[6,7]

Nanosecond Fluorescence Anisotropy. Fluorescence decay curves were measured with an Ortec 9200 single photon counting nanosecond fluorometer.[9] In the measurements of fluorescence anisotropy, the exciting light was vertically polarized. A polarizer was also placed in the emission beam, which could be rotated by 90 ° to permit the measurements of the intensities of the vertically and horizontally polarized components. The time-dependent anisotropy $r(t)$ is defined as:

$$r(t) = \frac{I_{//}(t) - I_{\perp}(t)}{I_{//}(t) + 2I_{\perp}(t)} = \frac{d(t)}{s(t)}, \tag{1}$$

where $I_{//}(t)$ and $I_{\perp}(t)$ are the fluorescence intensities observed with the analyzer parallel and perpendicular to the direction of polarization of the exciting light. Unequal response of the detector system to the polarized light was corrected using an aqueous dilute solution of 9-aminoacridine.[9] The total decay of fluorescence $s(t)$ was determined independently. This was achieved by orienting the polarization axis of the analyzer at 35.3 ° from the vertical direction and using unpolarized exciting light.[10] In the measurements of the fluorescence decay curves, there was a small contribution of the scattered light; this was subtracted from the decay curves prior to analysis.

In agreement with previous observations,[6,11] the polarization of fluorescence was constant above *ca.* 400 nm and showed a minimum around 320—340 nm. Therefore, the complexes were excited at 430 nm for the measurements of nanosecond anisotropy.

All the measurements were carried out in 5 mM phosphate buffer (pH 6.9, ionic strength of 0.01) at room temperature (23±1 °C). The molar ratio of DNA phosphate to dye (P/D) was about 200, and the dye concentration ranged from 5×10^{-6} to 10^{-5} M. In such conditions, the concentration of free dye and energy transfer between bound dye molecules were negligible.[7,11]

Analysis of Nanosecond Anisotropy Decay Curves. The fluorescence decay functions $S(t)$ and $D(t)$ are related to the observed decay curves $s(t)$ and $d(t)$ by the following convolution integrals;

$$s(t) = \int_0^t S(t-u)E(u)\mathrm{d}u, \tag{2}$$

$$d(t) = \int_0^t D(t-u)E(u)\mathrm{d}u, \tag{3}$$

where $E(t)$ is the response function of the apparatus to the exciting pulse. First, $S(t)$ was determined by deconvolution of Eq. 2. In every case, $S(t)$ was found to be a single exponetial;

$$S(t) = S_0 e^{-t/\tau}, \tag{4}$$

where τ is the fluorescence lifetime. Next, the result was checked by a synthetic method.[12] The anisotropy decay function is given by

$$R(t) = \frac{D(t)}{S(t)}, \tag{5}$$

where $S(t)$ is the function given by Eq. 4. Several $R(t)$ functions were tested so that the numerically computed convolution of $D(t)$ with $E(t)$ may fit the experimental decay curve. The computed curve, $f^{\circ}(k)$, was then visually compared with the experimental curve, $f(k)$, and the weighed residue (χ^2) was calculated according to the method of Knight and Selinger.[13] Here, k denotes channel number.

$$\chi^2 = \frac{1}{n}\sum_{k=1}^{n}\frac{1}{f(k)}[f(k) - f^{\circ}(k)]^2. \tag{6}$$

The best fit between the computed and experimental decay curves was achieved by minimizing the χ^2 value.

* Present address: Department of Chemistry, Yamaguchi University, Yamaguchi 753.

Deconvolution was made with the aid of the methods of moments[14,15] and Laplace transformation.[16] Both methods yielded very similar results. Copies of the computer programs for these methods were kindly supplied to us by Dr. D. R. Dyson and Dr. L. Brand. All the analyses were carried out with a Univac 1108 computer.

Viscosity Measurements. Viscosity measurements of the sonicated DNA-acridine complexes were performed at 25± 0.05 °C by means of a Ubbelohde viscometer. The flow time of the solvent (5 mM phosphate buffer) was 270 s. We limited our study to r values smaller than 0.12 to avoid the errors due to the possible presence of the weakly bound dye molecules; r represents the number of moles of dye bound per DNA phosphate. The r value was determined by using data of equilibrium dialysis reported previously.[7]

Sonication of DNA was carried out with a Kubota ultrasonicator (200 W, 9 kHz). Immediately prior to irradiation, the sample solution was flushed with nitrogen gas, and during irradiation, ice-cold water was circulated through the jacket sorrounding the steel cup of a sonic oscillator. The molecular weight of sonicated DNA was determined to be 5.2×10^5 from the viscosity measurements; this value means that the sonicated DNA behaves almost like a rigid rod.[17]

Results and Discussion

A typical set of anisotropy data is shown in Fig. 1 for the DNA–AO complex, where the observed $s(t)$, $d(t)$, and $E(t)$ values are plotted every five channels. After deconvolution using the methods of moments[14,15] and Laplace transformation,[16] the function $S(t)$ was found to be a single exponential. On the other hand, the function $D(t)$ was found to be a sum of two exponential functions whose decay constants are very close. Figure 1 shows that, at large channel numbers, $s(t)$ and $d(t)$ are superposable on each other upon translation. As can be seen in Figs. 1 and 2, the anisotropy curves $r(t)=d(t)/s(t)$ obtained by point by point division exhibit non-exponential decays. They tend to decay exponentially at the initial stage and then to become constant, although the calculated points are somewhat scattered after channel 200. In view of these findings, it seems reasonable to assume that $R(t)$ and $D(t)$ are expressed by the following equations:[12,18]

$$R(t) = R_0(\alpha e^{-t/\phi} + 1-\alpha), \quad (7)$$

$$D(t) = R(t)S(t) = S_0R_0\alpha e^{-t/\tau'} + S_0R_0(1-\alpha)e^{-t/\tau}, \quad (8)$$

where

$$\tau' = \frac{\phi\tau}{\phi+\tau}, \quad (9)$$

and where ϕ corresponds to the rotational correlation time of the dye. This is a rather general result for the dye–macromolecule and dye–membrane systems in which the motion of the dye is locally limited.[12,18,19] Since two decay constants are very close in our case ($\tau/\tau'\simeq1.5$), we can not accurately deconvolute the observed $d(t)$ curves.[16,20] Therefore, using the deconvoluted $S(t)$ function which is a single exponential like Eq. 4 and assuming appropriate α and ϕ in Eq. 7, several $R(t)$ functions were tested so that the numerically computed convolution of $D(t)$ with $E(t)$ may fit the experimental curve. The solid line for $d(t)$ in Fig. 1 shows the calculated best-fit curves.

Table 1 summarizes the results of nanosecond anisotropy. The two different methods were used for deconvolution of the observed $s(t)$ curves. Both methods give almost the same lifetimes, which are in fairly good agreement with the lifetimes obtained by phase-shift method.[6] All anisotropy decay curves for the complexes are expressed by a function like Eq. 7. It should be noted that acridine dyes bound to DNA behave similarly to ethidium bromide (another intercalative dye) with respect to the anisotropy decay.[18] The values of limiting anisotropy ($R_0=0.31$—0.36) are comparable to those obtained from the measurements of steady-state depolarization.[6,21] The apparent values of the rotational relaxation time ($\rho_a=3\phi$) were calculated using decon-

voluted $R(t)$ functions; the results are listed in Table 1. The ρ_a values are much smaller when compared to the values obtained by a steady-state study (Table 1).[6]

A continuous light source may be considered as a sum of an infinite number of pulses. Therefore, the observed static anisotropy is the mean value of $R(t)$.

$$\langle R\rangle = \frac{\int_0^\infty D(t)\mathrm{d}t}{\int_0^\infty S(t)\mathrm{d}t}. \tag{10}$$

If $S(t)$ is a single exponential like Eq. 4, Eq. 10 gives

$$\langle R\rangle = \frac{1}{\tau}\int_0^\infty R(t)\mathrm{e}^{-t/\tau}\mathrm{d}t. \tag{11}$$

Put the case that $R(t)$ is an exponential function like $R(t)=R_0\mathrm{e}^{-t/\phi}$, Eq. 11 leads to

$$\langle R\rangle = \frac{R_0}{1+\tau/\phi}. \tag{12}$$

Equation 12 is equivalent to Perrin's well-known formula.[22] When $R(t)$ is a function like Eq. 7, which is the present case, one obtains

$$\langle R\rangle = \frac{R_0\{\phi+(1-\alpha)\tau\}}{\phi+\tau} = \frac{R_0}{1+\tau/\phi'}, \tag{13}$$

where

$$\phi' = \frac{1}{\alpha}\{\phi+(1-\alpha)\tau\}. \tag{14}$$

According to Eq. 13, Perrin's plot in the steady-state study gives us ϕ' instead of ϕ. If Eq. 14 is applied to the deconvoluted $R(t)$ functions for the DNA–acridine complexes, the ρ_a values ($\rho_a=3\phi'$) listed in Table 1 are obtained. These values are in agreement with those obtained from the steady-state measurements (Table 1).[6] Thus, the discrepancy between steady-state and nanosecond anisotropy results can be understood.

It should be noted that the ρ_a values reported here are comparable to the rotational correlation times for the DNA–ethidium bromide[18] and *Cl. perfringens* DNA–PF[23] complexes which were obtained by nanosecond fluorometry. However, the ρ_a values are too much small to correspond to the rotation of the whole DNA molecule.[24] The most probable origin for the observed depolarization appears to be a local deformation motion of DNA base pairs.[18,21]

As is seen in Table 1, the ρ_a values for acridine dyes with bulky substituents ($Ac[NEt_2]_2$ and AO-isopropyl) are a little smaller than those obtained with the other dyes. Further, fluorescence quenching[5] and equilibrium dialysis[7] studies showed that the binding constant and the maximum number of binding sites per DNA phosphate are much smaller for acridine dyes with bulky substituents. This implies that the bulky groups attached to the acridine ring (*e.g.*, diethylamino and isopropyl) produce some steric hindrance to the binding.

Due to the presence of bulky substituents on the acridine ring, some changes in hydrodynamic properties of DNA may arise when acridine dyes are bound to it. Cohen and Eisenberg[25] showed that for short, almost rodlike fragments of DNA, the ratio of the contour length at the binding ratio r to that in the absence of dye (L/L_0) can be calculated from the viscosity data:

$$\frac{L}{L_0} = \left\{\frac{[\eta]f(p)_0}{[\eta]_0 f(p)}\right\}^{1/3}. \tag{15}$$

where $f(p)$, a function of the axial ratio p of the DNA rod, is insensitive to variations in p for large p, and $[\eta]$ and $[\eta]_0$ are intrinsic viscosities, respectively, in the

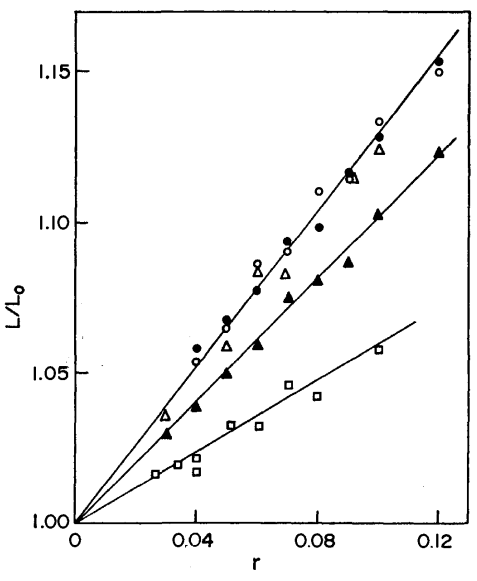

Fig. 3. Variation of L/L_0 as a function of r for sonicated DNA–acridine complexes. The molar concentration of DNA phosphate: 3.7×10^{-4} M. Acridine dyes: ○PF, ● AO, △ $Ac[NHMe]_2$, ▲ $Ac[NHEt]_2$, □ $Ac[NEt_2]_2$.

presence and absence of dye. The results obtained with various acridines are plotted in Fig. 3. In all cases, L/L_0 varies linearly with the binding ratio r.

$$\frac{L}{L_0} = 1 + \beta r. \tag{16}$$

The values of the slope β are listed in Table 1. The result obtained with PF is in good agreement with that previously reported.[25] As is clearly seen in Fig. 3 and Table 1, β is dependent on the dye structure; the β values for $Ac[NEt_2]_2$ and AO-isopropyl are much smaller than those for the other dyes.

Lerman's intercalation model[1,2] predicts that the DNA molecule is lengthened by 3.35 Å per intercalated dye molecule. If all bound molecules are completely intercalated, the slope of the L/L_0 *vs.* r plot should be 2.[1,25] From temperature jump relaxation studies of the DNA–PF complex, Crothers *et al.*[26,27] showed that most of bound PF molecules are intercalated, but some of those are bound outside of the DNA helix even at low binding ratios. On the other hand, Müller *et al.*[28] and Bontemps *et al.*[29] showed that a derivative of PF with bulky side chains, 3,6-diamino-2,7-di-*t*-butylacridine, binds to DNA but not by intercalation; they concluded that an outside bound complex is formed. In view of these, our viscosity results can be interpreted as follows: (1) the β values smaller than 2 result from the existence of the outside bound complex which would not contribute to an increase in the length of DNA[25–27] and (2) there exists a higher fraction of the outside bound complex in the case of $Ac[NEt_2]_2$ and AO-isopropyl because of the presence of bulky substituents.

Hydrodynamic and thermodynamic properties of outside bound dye are different from those of intercalated dye, while their optical properties are very similar.[26,27] In practice, the fluorescence decay of the complex could be characterized by a single exponential function (Fig. 1; Table 1). However, the structure of the outside bound complex is not yet well-defined.[26,27] In conclusion, the interpretation of the anisotropy results may be complicated by the heterogeneity of binding sites (intercalating and outside binding sites). If we assume that the local movement of the outside bound dye is more rapid compared to that of the intercalated dye which is restricted between adjacent base pairs, the smaller ρ_a values obtained with $Ac[NEt_2]_2$ and AO-isopropyl may be qualitatively understood. Further study would be necessary to clarify the origin for depolarization of the DNA–acridine complexes.

The authors are indebted to Dr. Ming S. Tung and Dr. Lih-Heng Tang for valuable advice and helpful discussions. We also thank Mr. Masaaki Wakita for viscosity measurements.

The Crystal and Molecular Structure of *dl*-2-*cis*-4-*trans*-Abscisic Acid

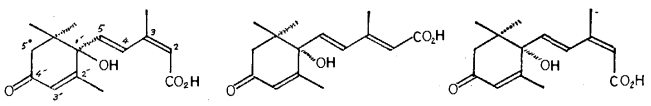
Hideo UEDA* and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received December 22, 1976)

The crystal and molecular structure of *dl*-2-*cis*-4-*trans*-abscisic acid has been determined by the X-ray method. The crystal is monoclinic, $P2_1/c$, with lattice parameters $a=6.316(1)$, $b=33.575(3)$, $c=7.607(1)$ Å, and $\beta=118.42(1)°$. The molecule has two independent conjugated systems forming respective planes which are orthogonal to each other. The molecules form a dimer by the hydrogen bonding and are connected by the other hydrogen bonding along the c-axis.

Abscisic acid is an important plant hormone which promotes abscission of leaves and dormancy in buds and seeds. Ohkuma, Lyon, and Adicott[1] isolated abscisic acid and determined its chemical structure. Cornforth and his co-workers[2,3] synthesized and determined the absolute configuration of natural (+) abscisic acid as (I) by applying Mill's empirical rule to the diols obtained through the reduction of optically active abscisic acid.



I II III

Burden and Taylor[4] reported that $(+)_{589}$-2-*trans*-4-*trans*-abscisic acid(II) obtained from violaxanthine shows a positive Cotton effect, which is in contradiction with the result of Cornforth and his co-workers. Oritani and Yamashita,[5–7] Ryback,[8] Mori,[9] and Weiss, Koreda, and Nakanishi[10] showed that the natural $(+)_{589}$-abscisic acid has *S*-configuration(III) at C_1'.

The crystal structure of *dl*-2-*trans*-4-*trans*-abscisic acid has been determined recently by Swaminathan, Vijayalakshmi, and Srinivasan;[11] the acid has only 1% activity as compared to the natural (*S*)-2-*cis*-4-*trans*-abscisic acid.[2,12]

In this paper we report on the crystal and molecular structure of *dl*-2-*cis*-4-*trans*-abscisic acid, which has the most efficient hormonal activity.

Experimental

The crystals were obtained as transparent thin plates from ethanol solution in the dark in a refrigerator.

The space group was determined as $P2_1/c$ from the oscillation and Weissenberg photographs. The density was measured by the floatation method in KI aqueous solution. The unit-cell parameters were determined by the least-squares method, using twelve reflections carefully measured on Hilger & Watts four circle diffractometer with Ni-filtered Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). The intensity data were collected on the diffractometer with the 2θ-ω scanning mode ($2\theta\leqq 57°$). The size of the crystal used was $0.2\times0.1\times0.3$ mm. The crystal used for the X-ray measurement was mounted in a glass capillary. In order to confirm the stability of the crystal and the counting system, the intensities of three standard reflections were measured every 50 reflections. The fluctuation and decay of standard reflections were within 5%. No absorption nor extinction correction was made. The crystal data are given in Table 1.

Table 1. Crystal data

$C_{15}H_{20}O_4$
Mol wt: 264.32
Crystal system: $P2_1/c$; $Z=4$
$a=6.316(1)$, $b=33.575(3)$, $c=7.607(1)$ Å;
$\beta=118.42(1)°$
$D_m=1.232$, $D_c=1.237$ g cm^{-3}
$\mu=7.37$ cm^{-1} (for Cu$K\alpha$ radiation)

Determination and Refinement of the Structure

The structure was determined by the direct method with the program MULTAN[13] using 162 reflections with $|E|\geqq1.70$. An E map computed from the phase set with the highest figures of merit ($FOM=1.16$) revealed the positons of 16 atoms. Other atoms were found by the successive Fourier synthesis. Refinement of the structure was performed by the block-diagonal least-squares method with 1315 independent reflections of $|F°|\geqq3\sigma$. The final refinement was carried out with anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal factors for hydrogen atoms. The R-index converged to 0.071 with an equal weight for each reflection. The atomic scattering factors were

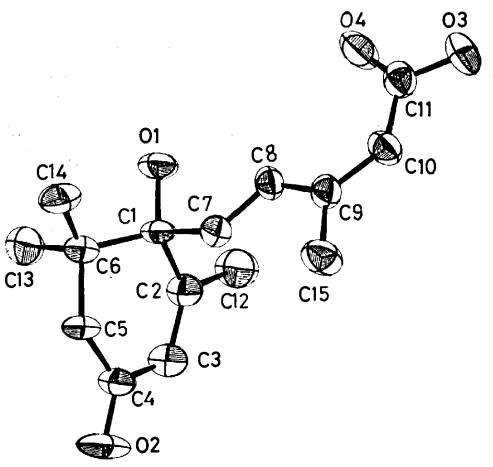


Fig. 1. The atomic labelings of abscisic acid. Carbon and oxygen atoms are represented as thermal ellipsoids of a size such that the vibrating atoms have a 50% probability of being found within them.

* Present address: Central Research Laboratory, Ube Industries Ltd., Nishihon-machi, Ube, Yamaguchi 755.

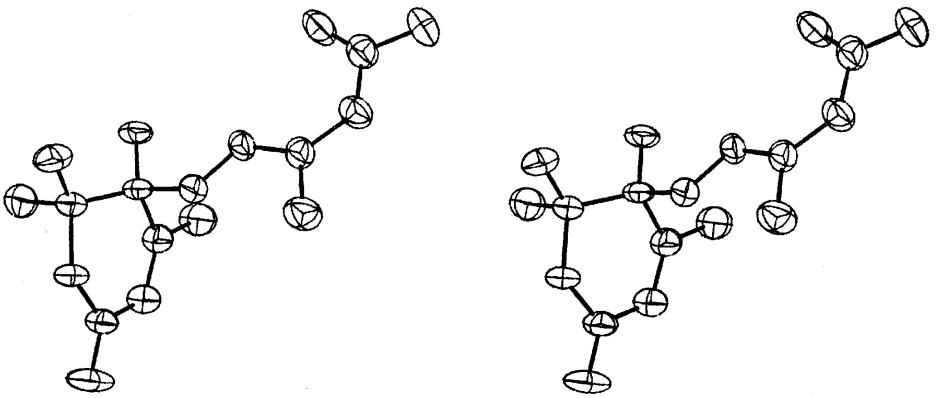

Fig. 2. A stereoscopic view of abscisic acid. The criterion to the themal ellipsoids of carbon and oxygen atoms are the same as in Fig. 1.

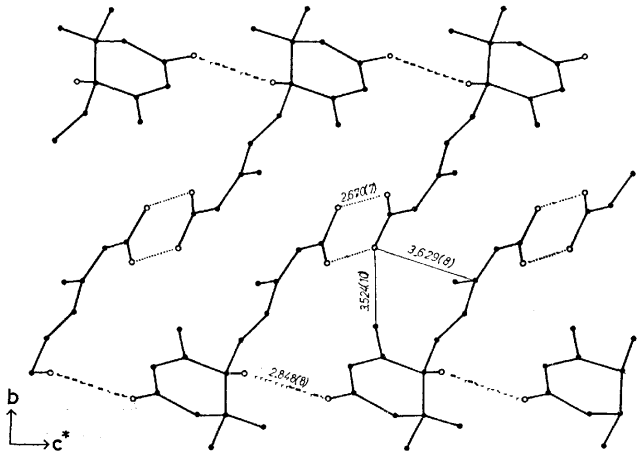

Fig. 3. Hydrogen bond network viewed along the a-axis. Carbon atoms are depicted as filled circles and oxygen atoms as open circles. Hydrogen bonds are represented with both dotted and broken lines.

taken from the International Tables for X-Ray Crystallography.[14] The program HBLS-IV coded by Ashida in UNICS was utilized for the refinement. The program ORTEP coded by Johnson was used for drawing of Figs. 1 and 3. A part of the computation was performed at the Nagoya University Computation Center. The observed and calculated structure factors are given in Table 2.[20]

Results and Discussion

The molecular structure, atomic labelings, and thermal ellipsoids are shown in Fig. 1. It can be seen that the conformation around C–C double bonds is *cis-trans*. The positional and thermal parameters of non-hydrogen atoms with their standard deviations are given in Tables 3 and 4, respectively. The coordinates and isotropic thermal parameters of hydrogen atoms are given in Table 5.

Molecular Structure. The bond lengths and bond angles with their standard deviations are given in Tables 6 and 7, respectively. The bond distances are normal. The C=O bond of the carboxylic group takes the *cis*-conformation with respect to the diene group. The angles, C(1)C(7)C(8), C(7)C(8)C(9), C(8)C(9)-C(10), and C(9)C(10)C(11), are larger than 120°, having values 128, 123, 126, and 128°, respectively. The conjugated double bond of the diene group forms plane A. Deviations of atoms from the plane and equations of the planes are given in Table 8. The carboxylic group forms plane B, at 9° to plane A.

The six-membered ring is puckered, C(1) and C(6) being out of plane C formed by the remaining atoms, C(2), C(3), C(4), C(5), C(12), and O(2). The planarity of plane C is fairly good, the largest deviation being 0.016 Å of C(3).

Planes A and C are orthogonal; the dihedral angle is 91°. A stereoscopic projection of the (*S*)-isomer is shown in Fig. 2. Two independent chromophores take a chiral configuration, the strong optical rotatory power of the $(+)_{589}$-abscisic acid thus being explained.

Crystal Structure. The crystal structure projected along the a-axis is shown in Fig. 3. The molecule is connected with neighboring ones by the hydrogen bonds; two molecules related by a center of symmetry form a dimer through the hydrogen bonds of carboxylic groups.

Short van der Waals contacts

O(2)–C(14)^{III}	3.360(11)Å	O(3)–C(9)^{IV}	3.629(8)Å
O(3)–C(10)^{V}	3.296(9)	O(3)–C(11)^{II}	3.482(9)
O(3)–C(12)^{IV}	3.524(10)	O(4)–C(11)^{II}	3.421(9)
O(4)–C(12)^{VI}	3.534(10)	O(4)–C(15)^{VII}	3.459(9)
C(9)–C(11)^{IV}	3.664(9)	C(10)–C(10)^{IIx}	3.608(9)
C(12)–C(15)^{VII}	3.632(11)		

Symmetry code

Superscript	Symmetry operator		
i)	x	y	$1+z$
ii)	$1-x$	$-y$	$-1-z$
iii)	x	y	$-1+z$
iv)	$1-x$	$-y$	$-z$
v)	$-x$	$-y$	$-1-z$
vi)	$1+x$	y	$1+z$
vii)	$-1+x$	y	z
iix)	$-1-x$	$-y$	$-z$

The O(3)–H···O(4) distance is 2.67 Å, the angle O(3)–H···O(4) is 171°, and the H atom is nearly on the line O(3)···O(4). Another hydrogen bond exists between the hydroxyl group attached to the cyclohexenone ring and the carbonyl group of the ring of the adjacent molecule. The O(1)–H···O(2) distance is 2.85 Å and the angle O(1)–H···O(2) is 147°. The hydrogen bond is not linear, but the distance is within the range of the O–H···O hydrogen bond.[15]

Other short contacts are given in Table 9. Most of them are in the range of van der Waals contact, but O(3)···C(10) 3.30 Å is slightly shorter than the sum of van der Waals radii (3.40 Å). Close C···O contacts have been reported and several types of molecular interaction have been recognized.[16–19] In one type the C–H group is attached to the electronegative oxygen atom. In another type the C=O group interacts with aromatic rings or C=C groups. In the present crystal the oxygen atom of the carboxylic group is close to the carbon atom of the diene group and situated antiparallel.

The authors are grateful to Dr. Takayuki Oritani, Tohoku University, for the supply of the sample. They also thank Mr. Chuji Katayama for his help in collection of the data.

N-Alkylation of Nitrogen Heterocyclic Compounds with Dialkyl Phosphites

Masahiro HAYASHI, Kiyoshi YAMAUCHI, and Masayoshi KINOSHITA

Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received August 26, 1976)

Dialkyl phosphites were found to be efficient alkylating agents for various nitrogen heterocyclic compounds, especially for imidazole analogs and pyridones, producing the corresponding *N*-alkyl derivatives.

Generally, *N*-alkylation of nitrogen heterocyclic compounds has been attempted with dialkyl sulfates or alkyl halides. Recently, trialkyl phosphate, dialkyl phosphonate, and alkyl phosphinate were found to alkylate nitrogen heterocyclic compounds to give the corresponding *N*-alkyl derivatives in good yields.[1-4]

On the other hand, there are a few reports which show the addition of a dialkyl phosphite to the carbonyl groups of various heterocyclic compounds[5,6] and to etherify cholesterols.[7] However, there has been no report on the use of a dialkyl phosphite as an alkylating agent. The present paper shows a new method for the alkylation of imidazoles, 2,4-pyrimidinediols, and pyridones by means of a dialkyl phosphite.

Results and Discussion

Reactions were carried out by heating a mixture of a heterocyclic compound and a dimethyl, diethyl, diisopropyl, or dibutyl ester of phosphorus acid. The products were isolated by distillation or extraction after neutralization of the reaction mixtures. In the reaction

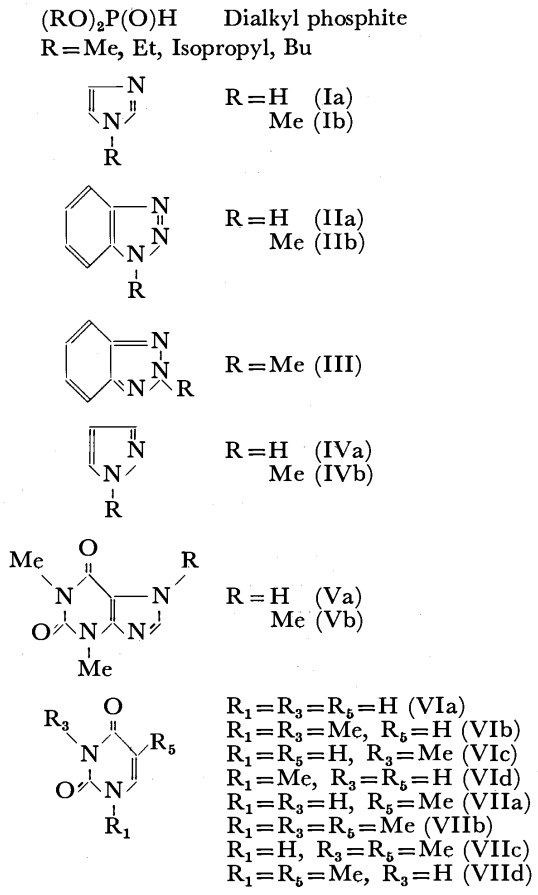
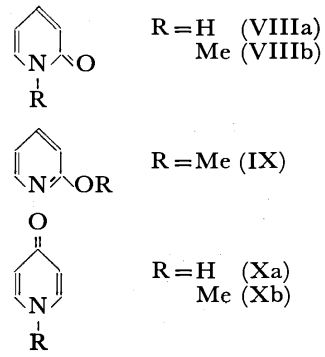
a) Tributylamine was added.

of uracil and thymine, the yields of products were obtained spectrometrically. The results are summarized in Table 1.

The reaction of imidazole (Ia) with dimethyl phosphite proceeded smoothly at 155 °C to give 1-methylimidazole (Ib) as a liquid with the coformation of monomethyl phosphite or phosphorus acid. Facile alkylations were also observed in theophylline (Va) and pyrazole (VIa) giving 7-alkyl and 1-alkyl derivatives, respectively. Selective alkylation took place in benzotriazole (IIa) in which alkylation occurred at the N-1 position preferentially to the N-2 position producing 1-methylbenzotriazole (IIb) and 2-methylbenzotriazole (III) at an approximately 11 to 1 molar ratio. Other alkylating agents, such as dialkyl sulfates, alkyl halides, and diazomethane, are known to give N-1 and N-2 derivatives at less selective ratios (2: 1, 5: 3, and 3: 10, respectively).[8-14]

In 2,4-pyrimidinediols, the yields of *N*-alkyl derivatives was rather low, *e.g.*, in the reaction with uracil (VIa) at 170 °C, 1,3-dimethyluracil (VIb), 3-methyluracil (VIc), and 1-methyluracil (VId) were obtained in 12, 29, and 11% yields, respectively. But when a large amount of a tertiary amine was used in the reaction, the conversion of uracil to methylated derivatives increased even at low reaction temperature (140 °C), *e.g.*, for tributylamine, 1,3-dimethyluracil (VIb), 3-methyluracil (VIc), and 1-methyluracil (VId) were obtained in 19, 13, and 26% yields, respectively, with no other product. The employment of solvents, such as *N*,*N*-dimethylformamide, ethanol, and diglyme,





lowered the yield of the *N*-alkyl derivatives by about one-third, but tended to increase the relative yield of the 1-alkyl derivatives produced. In the reaction of thymine (VIIa), alkylation occurred mainly at the N-1 position giving 1-alkyl derivatives along with small amounts of 3-alkyl and 1,3-dialkyl derivatives. In this case, the reaction was not appreciably affected by the addition of a tertiary amine. The yield of the 1,3-dialkyl derivative increased with the reaction temperature and no *O*-alkylation was observed for these 2,4-pyrimidinediols (VIa, VIIa). At higher temperature (about 200 °C), the yields of alkylated products from VIa and VIIa decreased and relatively large amounts of unknown products were obtained, which appeared to be derived from decomposition of the pyrimidine ring, since no absorption was observed in the aromatic region of complex NMR spectra.

However, for 2-pyridone (VIIIa), alkylation occurred very smoothly giving the corresponding *N*-alkyl derivative. Here, the *O*-alkyl derivative was isolated only when the reaction was carried out at low temperature and was found to undergo rapid thermal rearrangement to the corresponding *N*-alkyl derivative upon heating at high temperature. Similar facile alkylation was observed in 4-pyridone (Xa) although the *O*-alkyl derivative was neither isolated nor detected even at low temperature (97 °C).

For the above reactions, the reactivities of the dialkyl phosphites were found to be in the following general order; methyl>ethyl>butyl>isopropyl as shown in Table 1. The present results suggest that dialkyl phosphites may be utilized as covenient alkylating agents, especially for imidazole analogs and pyridones.

Experimental

UV and IR spectra were measured with Hitachi 3-T and Jasco IR-G spectrometers, respectively. NMR spectra were recorded on a Hitachi-Perkin Elmer R-20 spectrometer with a dilute solution in deuterochloroform and deuterium oxide using tetramethylsilane as an internal and external standard.

Preparative thin-layer chromatography (aluminium oxide, Merck Art 1064) was used to analyze the reaction products.

All materials are commercially available and were used without further purification. The reaction conditions are given in Table 1. The following experiments are typical. Other compounds in the table were prepared similarly and their physical constants agreed with the literature values.

Methylation of Imidazole (Ia). A mixture of Ia (1.00 g, 0.015 mol) and dimethyl phosphite (0.81 g, 0.70 mol) was

heated at 155 °C with stirring for 1 h. After the reaction mixture had been neutralized by aqueous sodium hydrogencarbonate, it was extracted with tetrahydrofuran. Upon concentration of the organic extract, 1-methylimidazole (Ib) was obtained as a liquid; (0.70 g, 58%). bp 76—77 °C/11 Torr (lit,[11] 94—95 °C/13 Torr). IR and NMR spectra of the product are identical with those of an authentic sample.

Methylation of Theophylline (Va). 1.01 g (0.0056 mol) of Va and 1.20 g (0.0109 mol) of dimethyl phosphite were heated at 130 °C for 4.5 h with stirring. The reaction mixture was neutralized and extracted with chloroform. The organic layer gave 7-methyltheophylline (Vb, caffeine, 0.775 g, 71%). IR, NMR, UV, and mp measurements were consistent with those of an authentic sample.

Methylation of Pyrazole (IVa). A mixture of IVa (1.00 g, 0.0147 mol) and dimethyl phosphite (0.81 g, 0.0073 mol) was heated at 130 °C for one hour with stirring. 1-Methylpyrazole (IVb) was distilled at 127 °C during the reaction through a distillation column; (0.85 g, 69%). bp 127 °C (lit,[15] 127 °C); NMR: τ($CDCl_3$): 2.60 (d, J=3 Hz, 2H, ring), 3.81 (t, J=3 Hz, 1H, ring), and 6.20 (s, 3H, $-CH_3$).

Methylation of Benzotriazole (IIa). A mixture of IIa (2.00 g, 0.0168 mol) and dimethyl phosphite (0.93 g, 0.0084 mol) was heated at 165 °C with stirring for one hour. The reaction mixture was neutralized with aqueous sodium hydrogencarbonate and extracted with chloroform. The organic layer was concentrated to give the residue (1.44 g), the NMR spectrum of which showed only peaks attributable to 1-methylbenzotriazole (IIb), 2-methylbenzotriazole (III), and benzotriazole (IIa). From the area ratio (34: 3: 4) of the singlet peaks of the CH_3 groups of both isomers (τ=5.83 for IIb and τ=5.60 for III), and the NH group of IIa (τ=−5.50), the yields of IIb, III, and IIa were calculated to be 46, 4, and 16%, respectively. Isolation of these products was carried out in a manner similar to that mentioned in a previous paper.[4] The values of the physical constants agree with those of authentic samples.

Methylation of Uracil (VIa). A mixture of VIa (3.01 g, 0.0268 mol), dimethyl phosphite (6.00 g, 0.0545 mol), and tributylamine (10.0 g) was heated at 140 °C for 11 h with stirring. After one hour of heating, VIa was a thoroughly mixed solution. The reaction mixture was diluted with water to 50 ml, then separated using preparative aluminium oxide thin-layer chromatography (eluted with $CHCl_3$: MeOH=10: 1). This gave four ultraviolet absorbing spots [R_f and λ_{max} (mμ): **a**= 0.97, 267.5, **b**=0.57, 260.0, **c**=0.38, 268.0, and **d**=0.10, 259.5], which were identified to be **a**=1,3-dimethyluracil (VIb), **b**=3-methyluracil (VIc), **c**=1-methyluracil (VId), and **d**=uracil (VIa), from a comparison of the physical constants (from IR, UV, NMR, and mp determinations) with literature values[7,16,17] and authentic samples. The yields for the reaction products were calculated to be VIb=19, VIc=26, and VId=30%.

Methylation of Thymine (VIIa). A mixture of VIIa (0.50 g, 0.0039 mol) and dimethyl phosphite (2.40 g, 0.0218 mol) was heated at 172 °C for 4 h with stirring. The reaction mixture was neutralized with sodium hydrogencarbonate and diluted to 80 ml and then separated in a manner similar to that described above. The following products were obtained (their physical constants are consistent with those of authentic samples and literature values): *N*-Alkyl derivatives, yield, R_f ($CHCl_3$: MeOH=10: 1), and λ_{max}(H_2O): 1,3-dimethylthymine (VIIb), 10, 0.98, 272, 3-methylthymine (VIIc), 4, 0.72, 265, and 1-methylthymine (VIId), 35%, 0.47, 273 mμ, respectively; (lit,[18] VIIb, 272, VIIc, 264.5, and VIId, 273 mμ).

Methylation of 2-Pyridone (VIIIa). A mixture of VIIIa (3.00 g, 0.0316 mol) and dimethyl phosphite (3.60 g, 0.0327 mol) was heated at 100 °C for 11.5 h. Then the mixture was made alkaline with aqueous sodium hydroxide and then extracted with chloroform. Thin-layer chromatography (eluted with $CHCl_3$: MeOH=10: 1) showed three spots (R_f, **e**=0.77, **f**=0.44, **g**=0.33). The spots **e** and **g** were identified from authentic samples to be *N*-methyl-2-pyridone (VIIIb) and 2-pyridone (VIIIa), respectively. The residue (1.97 g) from the organic layer dissolved with deuterochloroform in order to obtaine the NMR spectrum. From the area ratio (20: 2.1) of the singlet peaks of the CH_3 groups of both isomers [τ=6.62 for VIIIb and τ=6.27 for 2-methoxypyridine (IX)], the yield of *N*-methyl and *O*-methyl derivatives were calculated to be 52 and 5%, respectively. Distillation of this mixture gave IX (trace) and VIIIb (1.44 g, 42%): 2-methoxypyridine (IX); bp 60 °C/50 Torr (lit,[20] 142.4 °C), picrate (acetone–H_2O); mp 141—143 °C (lit,[20] 145—146 °C): *N*-methyl-2-pyridone (VIIIb); bp 92 °C/4 Torr (lit,[19] 250 °C).

Methylation of 4-Pyridone (Xa). 1.74 g (0.0183 mol) of Xa and 2.04 g (0.0185 mol) of dimethyl phosphite reacted at 169 °C for 5.5 h. The reaction mixture produced only one thin-layer chromatographic product; R_f=0.72 (Xb) and R_f= 0.41 (Xa) (eluted with $CHCl_3$: MeOH=10: 1). Making the solution alkaline with aqueous sodium hydroxide and extracting with chloroform gave *N*-methyl-4-pyridone (Xb, 1.95 g, 98%); picrate (acetone–H_2O), mp 183.5—184.5 °C, NMR; τ ($CDCl_3$) 2.49 (d, J=7 Hz, 2H, ring), 3.77 (d, J= 7 Hz, 2H, ring), and 6.36 (s, 3H, $-CH_3$).

Isolation of Enammonium Salt and Its Rearrangement to the Corresponding Iminium Salt

Hajime MATSUSHITA, Yasuko TSUJINO, Masao NOGUCHI, and Sadao YOSHIKAWA*

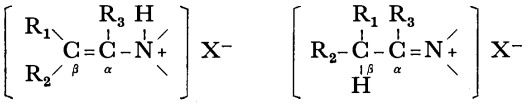
Central Research Institute, The Japan Tobacco and Salt Public Corporation, 6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227

**Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received October 14, 1976)

Enammonium salt of 2-methyl-1-(β-methylstyryl)piperidine (**1**) was isolated for the first time and characterized. The enammonium salt, 2-methyl-1-(β-methylstyryl)piperidinium chloride (**2**), was found to change easily to the corresponding iminium salt, 2-methyl-1-(2-phenylpropylidene)piperidinium chloride (**3**), at room temperature. The structure of the salts derived from 1-(β-methylstyryl)piperidine (**4**), 2-methyl-1-(β-methylstyryl)pyrrolidine (**5**), 1-(β-methylstyryl)pyrrolidine (**6**), 1-(2-methyl-1-propenyl)pyrrolidine (**7**), and 2-methyl-1-(2-methyl-1-propenyl)piperidine (**8**) were also examined.

Enamines are useful as a starting material for various organic syntheses, and their reactivities have been investigated by many workers.[1] One of the reactions is the formation of salts with acids. Protonation on the nitrogen or the β-carbon of the enamine to give the salt (I) or (II) is possible.



Enammonium salt (I) Iminium salt (II)

It has been shown that the protonation takes place rapidly on nitrogen and is followed by a transfer of the proton to the carbon. The evidence for *N*-protonation has been based on the reaction of ozone, diazomethane or lithium aluminum hydride with *N*-protonated salts under cooling.[2] Existence of the enammonium salt and its rearrangement to the corresponding iminium salt were also suggested kinetically.[3] However, the enamine salts so far isolated have the iminium salt structure (II).[4] This paper deals with the isolation and identification of *N*-protonated salt derived from 2-methyl-1-(β-methylstyryl)piperidine (**1**), 2-methyl-1-(β-methylstyryl)piperidinium chloride (**2**), and its rearrangement to the corresponding iminium salt (**3**). Structures of the salts derived from 1-(β-methylstyryl)piperidine (**4**),[5] 2-methyl-1-(β-methylstyryl)pyrrolidine (**5**),[6] 1-(β-methylstyryl)pyrrolidine (**6**),[5] 1-(2-methyl-1-propenyl)-pyrrolidine (**7**)[3] and 2-methyl-1-(2-methyl-1-propenyl)piperidine (**8**) were also examined.

Experimental

Proton magnetic resonance spectra were obtained with a JNM-PS-100 Spectrometer. Chemical shifts are indicated in δ value using TMS as an internal standard. The IR spectra were recorded with a JASCO IR-S Spectrometer. Gas chromatographic analyses were carried out on a 2 m column of 20% Carbowax 20 M on Cromosorb W with a Hitachi Gas Chromatograph, Model K 53.

Materials. Enamines, **1**, **4**, **5**, **6**, **7**, and **8** were prepared by the usual azeotropic procedures with benzene as a solvent. **8**; bp 66.5—67 °C (17 Torr).

Preparation of the Salts. The preparation of the salts was carried out as follows. Dry hydrogen chloride gas was bubbled into a benzene solution (60 ml) of each enamine (0.1 mol) under cooling in an ice-salt bath. White very fine needles precipitated out gradually. The needles were separated from the solution by filtration, washed with benzene completely in a dry box, and dried under vacuum. The data of PMR spectra and IR spectra are summarized in Tables 1 and 2, respectively.

PMR Spectra of Enamines and Their Salts. The solutions for PMR spectral measurements were prepared by dissolving about 30 mg of the enamines or their salts in 0.5 ml CD_3OD or $CDCl_3$ in a dry box. They are easily soluble in both solvents. The spectra of the salts were obtained immediately after preparation of the samples.

Results and Discussion

The salts derived from **1**, **4**, **5**, and **6** are highly hydroscopic and decompose into 2-phenylpropanal and the amine hydrochlorides on exposure to air. No elemental analyses of these salts could be carried out. The salts were hydrolyzed and the resulting 2-phenylpropanal was estimated gas-chromatographically. (The 2-phenylpropanal obtained from the hydrolyzates of the salts: 0.93 mol/1 mol salt of **1**, 0.91 mol/1 mol salt of **4**, 0.97 mol/1 mol salt of **5**, 0.95 mol/1 mol salt of **6**). The results show that one mol of 2-phenylpropanal is obtained from one mol of each salt within experimental error.

PMR spectra of **1**, **2**, and **3** in CD_3OD and those of **2** and **3** in $CDCl_3$ are shown in Fig. 1. The spectrum of **1** in $CDCl_3$ was essentially the same as that of **1** in CD_3OD.

Two olefin proton signals (5.75 and 5.99 ppm) and

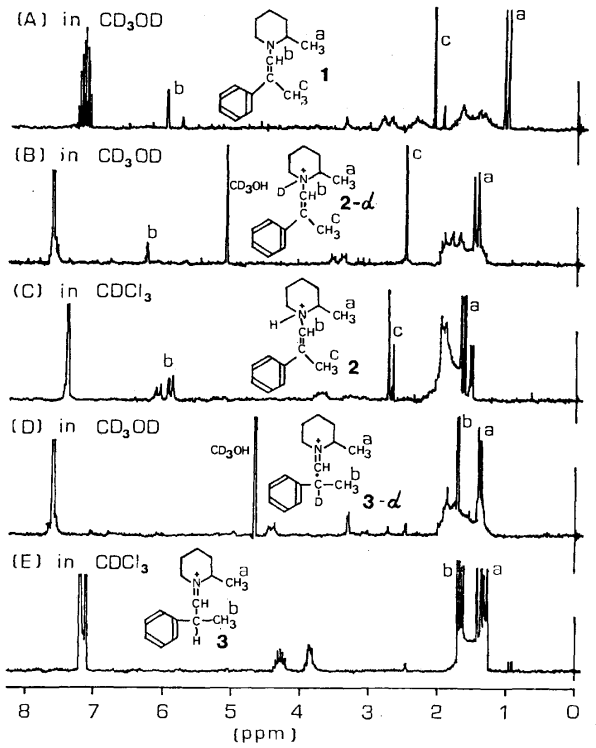

Fig. 1. 100 MHz PMR spectra of **1**, **2**, and **3** in CD_3OD or $CDCl_3$.

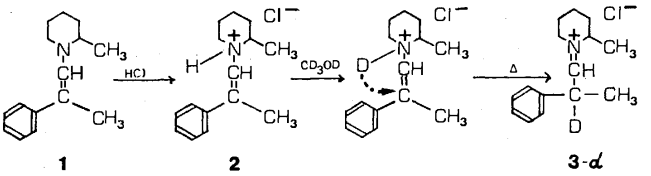
two propenyl methyl proton signals (1.95 and 2.10 ppm) were observed (Fig. 1-(A)). The area ratio of the former signals 5.75 ppm: 5.99 ppm is 8: 92, coinciding with that of the latter 1.95 ppm: 2.10 ppm (10: 90). This shows that **1** is a mixture of two geometrical isomers, one of which predominantes over the other. The existence ratio of the isomers in $CDCl_3$ is essentially the same as that in CD_3OD. The predominant one seems to have a structure where the phenyl and the 2-methylpiperidino groups are situated in trans position to each other judging from the steric models of the two geometrical isomers. Allyl couplings (1.5 Hz) are observed between the corresponding olefin and methyl protons. The allyl coupling constant, 1.5 Hz, was also observed between the olefin proton (6.27 ppm) and the propenyl methyl protons (2.48 ppm) (Fig. 1-(B)). This shows that **2** has the same partial structure, N–CH=C–CH_3, as enamine, **1**. The propenyl methyl signals at 2.10 ppm in spectrum (A) shift toward lower field, 2.48 ppm, in spectrum (B). This also supports the partial structure of the enammonium salt, N^+H–CH=C–CH_3. The occurrence of the proton exchange between CD_3OD and N^+H–CH=C–CH_3 or HCl is shown by the appearance of the signal at 5.10 ppm assignable to CD_3OH in spectrum (B). The hydrochloric acid might be derived from that of crystallization. The PMR signals of the two geometrical isomers in CD_3OD are considered to completely overlap each other, because of the existence of the isomers as shown in Fig. 1-(C). The existence ratio of the geometrical isomers was determined as 2: 3 based on the area ratio of the respective signals. This suggests that the formation of the enammonium salt is accompanied by geometrical isomerization. The isomerization was also observed in the case of **4**.[5] The signal of the olefin proton seems to be the A part of a nearly pure first-order AMX_3 pattern; major isomer (J=8.0, 1.2 Hz), minor isomer (J=9.1, 1.5 Hz). The coupling constant, 1.2 or 1.5 Hz, is due to the allyl coupling between the olefin proton and the propenyl methyl protons. The coupling constant, 8.0 or 9.1 Hz, may be due to the coupling between this olefin proton and the proton attached to the nitrogen atom. The major one seems to have a structure in which the phenyl and the 2-methylpiperidino groups are situated in trans position to each other. The smaller allyl coupling constant of the major isomer (1.2 Hz) suggests that the propenyl methyl group is situated in trans position of the olefin proton, because J_{cisoid} is usually larger than $J_{transoid}$.[7]

When the CD_3OD solution of **2** was heated up to 50 °C, the signals of the PMR spectrum of **2** (spectrum B) changed to those of **3** in a CD_3OD solution (Fig. 1-(D)). The methyl proton signal at 2.48 ppm in spectrum B is shifted to the higher field (at 1.70 ppm) in spectrum D. This suggests that the enammonium structure, CH_3–C=C–N^+–, was converted in solution into the iminium structure, CH_3–C–C=N^+. The signal at 1.70 ppm was singlet, and no allyl coupling could be observed, indicating that **3** in CD_3OD had been deuterated at the β-carbon. This shows that **2** is easily deuterated in CD_3OD to the N-deuterated salt which is subsequently rearranged to the corresponding iminium salt. The sequence of the reactions (Scheme 1) is in line with the generally accepted mechanism of the iminium salt formation.



Scheme 1.

In the case of a $CDCl_3$ solution, the signals of the PMR spectrum of **2** (Fig. 1-(C)) also changed to those of **3** (Fig. 1-(E)).[8] Addition of CD_3OD to the $CDCl_3$ solution of **2** is recognized to accelerate the rearrangement, giving **3-d** (Fig. 1-(D)). Possibility of the existence of two geometrical isomers of **3** can be neglected by consideration of the steric interaction using models (Corey-Pauling-Kaltum type and Dreiding type).[6] PMR spectra of the salts derived from **4** and **5** were also obtained. As shown in Table 1, the produced salts have the iminium salt structures. Bubbling of dry hydrogen chloride gas into the solution of **4** or **5** under cooling also gave the corresponding enammonium salts although their amounts were much smaller in comparison with those of the iminium salts.

From the PMR spectral data of the enamines and their salts, **1**—**8** (Table 1), we see that the salts except for **2** have an iminium salt structure.

The complex bands observed in 2350—2600 cm^{-1} in the IR spectrum of **2** were assignable to the ammonium

structure, N^+–H. In the case of nicotine hydrochloride, it was reported that the band attributable to the ammonium structure was observed in the region of 2350—2440 cm^{-1}.[9] The IR spectrum of **3** was obtained after concentration of its $CDCl_3$ solution. The absorption band, 1637 cm^{-1}, due to the double bond stretching of the enamine shifts by 21 and 34 cm^{-1} toward higher frequencies in those of **2** and **3**, respectively. Leonard and Gash reported a shift of 20—50 cm^{-1} toward higher frequencies when an enamine was converted into its iminium salt.[4] The salts derived from enamines except for **2** have an iminium salt structure, since the band due to ν_{NH} connot be observed in the spectra of these salts (Table 2).

It seems that the enammonium salt is too labile to be isolated. Salt **2** seems to be the first case of the isolation of the enammonium salt. Preparation of the salts of **4**, **5**, and **6** under cooling also gave the enammonium salts although their contents were low. This shows that **4**, **5**, and **6** as well as **1** have a possibility of giving their corresponding enammonium salt. No enammonium salts could be detected in the salts derived from **7** and **8**. The stability of the enammonium salt can be attributed to the conjugation of the C=C double bond with benzene ring. The salt isolated as crystals derived from **1** was enammonium salt **2**, and iminium salt **3** could be obtained as the product of the rearrangement of **2**. On the other hand, the salts of **4**, **5**, and **6** isolated as crystals were iminium salts. It seems that enammonium salt of **1** is sparingly soluble in benzene, but those of **4**—**5** are readily soluble and subsequently converted into the corresponding less soluble iminium salts. Thus, it is concluded that in the case of the salt of **1**, rearrangement from **2** to **3** would be interfered by the immediate precipitation of **2** out of the solution. This may be the reason why the salt derived from **1** has the enammonium salt structure.

Photolysis of Ethyl Azidoformate in Ethers and in Alcohols

Noboru TORIMOTO, Tadao SHINGAKI,* and Toshikazu NAGAI*

Science Education Institute of Osaka Prefecture, Karita-cho, Sumiyoshi-ku, Osaka 558

**College of General Education, Osaka University, Toyonaka, Osaka 560*

(Received October 18, 1976)

Ethoxycarbonyl nitrene, generated by the photolysis of ethyl azidoformate (I), was inserted preferentially into the α C–H bonds of acyclic ethers. Each of the reactions with acyclic ethers gave *N*-alkoxyurethane *via* a cleavage of the C–O bond, indicating that an O–N ylide is an intermediate of the nitrene reaction. Comparing sensitized photolysis with direct photolysis of I in ethers and in alcohols, it was found that the nitrene insertion into the α C–H bonds of ethers proceeds for both singlet and triplet and that the insertion into the β and γ C–H bonds of ethers and the O–H bonds of alcohols proceeds only for the singlet.

In a previous paper,[1] the photolysis of ethyl azidoformate (I) in cyclic ethers was reported. The ethoxycarbonyl nitrene, generated by the photolysis of I, was inserted preferentially into the α C–H bonds of cyclic ethers. The reactions with cyclic ethers bearing an alkyl group at the α-position gave unsaturated alkoxyurethane *via* a cleavage of the ring C–O bond. In addition, the nitrene insertion into the α C–H bonds of *cis*- and *trans*-2,5-dimethyltetrahydrofurans proceeded non-stereospecifically. From these results, a mechanism which included an O–N ylide intermediate for the insertion reaction was proposed, although the hydrogen abstraction-recombination mechanism was not ruled out.

The present paper reports further information about the mechanism based on a study of the photolyses of I carried out in acyclic ethers and in alcohols. Furthermore, the sensitized photolysis of I was examined and compared with direct photolysis in the ethers and alcohols.

Results and Discussion

Direct Photolysis of Ethyl Azidoformate in Acyclic Ethers. Ethyl azidoformate (I) in acyclic ether (III) was irradiated by the light (mainly of 2537 Å) from a low-pressure mercury arc at 0 °C with stirring in an atmosphere of nitrogen. Insertion products (IV) of ethoxycarbonyl nitrene (II) into the C–H bonds of the acyclic ethers were obtained, accompanied by the hydrogen abstraction product, urethane (VI), and small amounts (0.3—1.3%) of diethyl hydrazodiformate (VII). In addition, *N*-alkoxyurethanes (V) were obtained for each reaction.

TABLE 1. DIRECT PHOTOLYSIS OF ETHYL AZIDOFORMATE IN ACYCLIC ETHERS

Ether (III)	Product (%)[a]				
	Insertion (IV)		C–O Cleavage (V)		Abstraction (VI)
(a) Diethyl	(a) $CH_3CHOC_2H_5$ (NHR)	31.2	(a) CH_3CH_2ONHR[b]	3.9	17.6

$$R\text{-}O\text{-}C_nH_{2n}NHCOOEt + R\text{-}ONHCOOEt$$

(IV) (V)

$$+ NH_2COOEt + \begin{matrix} NHCOOEt \\ | \\ NHCOOEt \end{matrix}$$

(VI) (VII)

The yields of the products mentioned above are listed in Table 1.

The insertion occurred preferentially at the C–H bonds of the α-position. In the reaction with an unsymmetrical ether, isobutyl methyl ether, insertion into the secondary α C–H bond predominated over insertion into the primary α C–H bond. In the reaction with 2-methoxyethanol (methylcellosolve), however, the product of O–H insertion was isolated instead of that of C–H insertion. The formation of *N*-alkoxyurethane (V) shows that cleavage of the C–O bonds occurs during the reactions. Olefins, although not detected, might be formed concomittantly by V, in analogy to the formation of an unsaturated product of the cleavage of the ring C–O bonds of cyclic ethers.[1,2]

Relative Reactivities. As mentioned above, the α C–H bonds of the acyclic ethers were more reactive for nitrene insertion than the other C–H bonds. In order to compare the insertion reactivities of the α C–H bonds with those of the cyclohexane C–H bonds, direct photolysis of I was carried out in a mixture of equimolar amounts of an acyclic ether and cyclohexane. The yields of the products and the reactivities are summarized in Table 2, with the reactivities of primary (1°), secondary (2°), and tertiary (3°) C–H bonds in 2-methylbutane.[3]

Table 2. Direct photolysis of I in a mixture of an acyclic ether and cyclohexane

	Product (%)[a]		Type of C–H bond	Relative reactivity[b]	2-Methylbutane		
	Insertion (IV)	Cyclohexylurethane			1°	2°	3°
(c_1)	17.8	12.0	2°(α)	4.5			
(c_2)	2.8		2°(β)	0.7			
(c_3)	3.0		2°(γ)	0.8			
(d_1)	13.2	9.2	2°(α)	4.4			
(d_2)	4.5		3°(γ)	2.9			
					0.09	0.8	3.0

a) Calculated on the basis of the azide used.
b) Relative reactivity: per C–H bond of cyclohexane.

The secondary C–H bonds at the α-position of the acyclic ethers were much more reactive for nitrene insertion than the corresponding C–H bonds of hydrocarbons. Such unusually high reactivities and the formation of *N*-alkoxyurethanes (V) are very similar to reactions with cyclic ether.[1] Thus the reaction of nitrene with acyclic ethers may involve the O–N ylide, which has been proposed for the reaction with cyclic ethers.[1]

Sensitized Photolysis in Ethers. As has been pointed out in a previous paper,[1] the abstraction-recombination mechanism due to the triplet nitrene was not ruled out for insertion into the α C–H bonds of the ethers. Thus, the decomposition of I was carried out under conditions involving no singlet nitrene. Ethyl azidoformate (I) in ether was irradiated with the light from a high-pressure mercury lamp in the presence of a sensitizer, acetophenone, in an atmosphere of nitrogen. A 1.5 M-$CuSO_4$ aqueous solution was circulated as a filter. The filter completely inhibited the direct excitation of I. The yields of the products are listed in Table 3, in which they are compared with those for reactions using a low-pressure mercury lamp (direct photolysis).

Table 3. Sensitized photolysis of I in ethers

Ether	Product (%)[a]		
	Insertion into α C–H bond (IV)	Abstraction (VI)	Ratio VI/IV
	27.0(32.8)	44.6(22.2)	1.7(0.7)
	27.8(25.0)[b]	72.5(16.0)	2.6(0.6)
	16.5[c] (12.0)[b,c]	65.2(34.0)	4.0(2.8)
$(CH_3CH_2CH_2\text{-}CH_2)_2O$	8.4(25.0)	50.5(17.4)	6.0(0.7)

( ) Indicates the values for direct photolysis.
a) Calculated on the basis of the azide used.
b) From Ref. 1.
c) Insertion into the tertiary C–H bond.

The nitrene species involved in these sensitized photolysis reactions must be in the triplet state.[4] The molar ratios of VI/IV for sensitized photolysis are larger than those for direct photolysis. The findings for dioxane are similar to those reported by Nozaki *et al.*[5] In the sensitized photolysis with dibutyl ether, neither the products of insertion into the β and γ C–H bonds nor *N*-butoxyurethane were detected in contrast to direct photolysis, as is shown in Table 1. Furthermore, neither the product of insertion into the β C–H bonds of tetrahydropyran nor the C–O cleavage product in 2-methyltetrahydropyran was detected, although both were isolated for direct photolysis.[1] It is noteworthy that both singlet and triplet ethoxycarbonyl nitrenes are inserted into the C–H bonds adjacent to the oxygen atom, in contrast to insertion by only the singlet into the C–H bonds of hydrocarbons.[6-8]

The insertion of the triplet nitrene is initiated by hydrogen abstraction from the etheral α-position, followed by the radical recombination, as shown in Scheme 1.

$$R\text{-}\dot{N}\cdot \xrightarrow{-\underline{O}\text{-}\underset{H}{\underset{|}{C}}\text{-}CH_2-} -\underline{O}\text{-}\underset{\cdot}{\underset{|}{C}}\text{-}CH_2- + H\dot{N}R$$

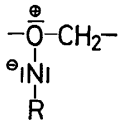
(II)
triplet nitrene

$$\longrightarrow -\underline{O}\text{-}\underset{HNR}{\underset{|}{C}}\text{-}CH_2-$$

Scheme 1.

Concerning hydrocarbons, such a radical recombination mechanism has been ruled out because of no insertion by the triplet.[6-8] For ethers, however, the α-carbon radical is stabilized by the adjacent oxygen atom, permitting recombination with the HNR radical. As is seen in Table 3, the molar ratios of VI/IV for direct photolysis are much smaller than those for sensitized photolysis. This means that the singlet nitrene participates in the insertion into the α C–H bonds. Judging from the view point of non-stereospecific insertion,[1] the singlet nitrene is not inserted into the α C–H bonds by a one-step mechanism.

The insertion of the singlet nitrene, which results only from direct photolysis, is initiated by the formation of an O–N ylide (VIII) with the ethereal oxygen. The ylide VIII abstracts a proton from the α C–H bond, followed by homolytic cleavage of the O–N bond giving



(VIII)

the radical species, the α-carbon radical, and HNR. The recombination of these two radicals results in the α-insertion product as has been reported in a preceding paper.[1] On the other hand, VIII leads to V *via* hydrogen abstraction and cleavage of the C–O bond.[1]

Insertion into the β and γ- C–H bonds, however, may proceed by the one-step mechanism proposed for the reaction with hydrocarbons,[6-8] since the β- and γ-carbon radicals, whose resonances with the oxygen lone pair are insulated by the methylenes, are not as stable as the α-carbon radical. These two distinct mechanisms can explain the difference in reactivity between the α C–H bond and the β or γ C–H bond shown in Table 2.

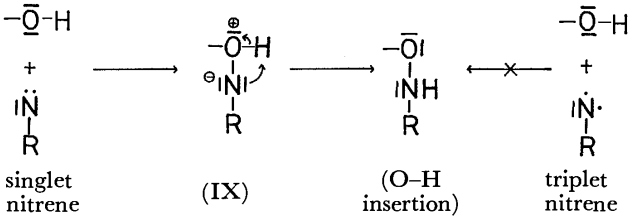
In the reaction with isobutyl methyl ether, as shown in Table 1, preferential insertion into the α-methylene group may be due to the difference between the radical stabilities of $-\dot{C}HOCH_3$ and $-CH_2O\dot{C}H_2$.

Direct and Sensitized Photolysis in Alcohols. To obtain further information about the behavior of the nitrene for other oxygen compounds, direct and sensitized photolysis of I were carried out in alcohols. The results are shown in Table 4. Direct photolysis gave products for nitrene insertion into the O–H bonds, while sensitized photolysis gave no such insertion products. Therefore, it is concluded that the O–H insertion products are formed only by the singlet nitrene as shown in Scheme 2.[9] The O–H insertion can be considered to proceed by a one-step of the singlet nitrene.

Table 4. Photolysis of I in alcohols

Alcohol	Product (%)[a,b] Insertion into O–H bond		Abstraction (VI)	
	Direct	Sensitized	Direct	Sensitized
CH_3CH_2OH	11.0	ND[c]	71.0	64.6
$CH_3CH_2CH_2OH$	15.0	ND	46.0	80.5
$CH_3CH_2CH_2CH_2OH$	27.0	ND	47.0	74.9

a) Calculated on the basis of the azide used.
b) Photolysis gave the corresponding aldehydes in addition to the insertion and abstraction products.
c) ND: not detected.



Scheme 2.

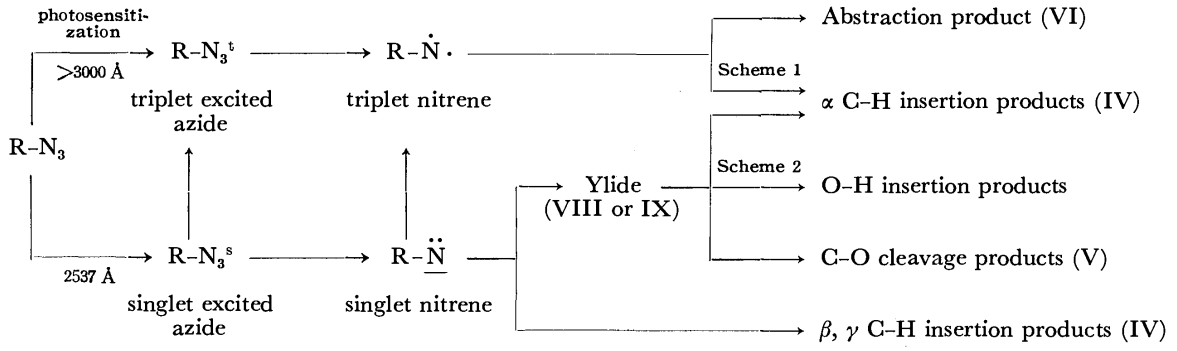
However, it is more reasonable that O–H inserion proceeds *via* an O–N ylide intermediate (IX), in analogy to reactions of ethers with the singlet nitrene, as mentioned above.

Reaction Course. The facts observed for the reactions of nitrene with ethers and alcohols can be accommodated into Scheme 3.

Experimental

Most of the equipment and techniques have been described in preceding papers.[1,10] In addition, a Nippon Bunko (JASCO) Model A-3 photometer was used for the IR measurements and a 20% mixture Apiezone Grease L on Neosorb NC (60—80 mesh) was employed as the absorbent for VPC.

Materials. Ethyl azidoformate (I) was prepared by the method of Lwowski and Mattingly.[4] Cyclohexane, dioxane, alcohols, and most of the ethers were used after the



Scheme 3.

commercial reagents had been purified according to published directions.[11] All the acyclic ethers were purified by boiling with sodium and by distillation. The absence of alcohols in the ethers was confirmed by VPC. Isobutyl methyl ether was prepared from sodium isopropoxide and methyl iodide using the Williamson procedure; bp 58.5 °C (lit,[12] 59 °C); yield, 73%. Diisobutyl ether was prepared from isobutyl alcohol and concentrated sulfuric acid. A mixture of 100 ml of concentrated sulfuric acid and 400 ml of isobutyl alcohol was refluxed in a flask equipped with a distillation column. A fraction, bp 82—91 °C, was collected and dried over anhydrous calcium chloride. After the solid part had been removed by filtration, the filtrate was washed with water, dried over anhydrous calcium chloride, and distilled; bp 120—123 °C (lit, 122—124 °C). To prepare the authentic IVc_2, amino ether was prepared from 2-amino-1-butanol and butyl iodide using the Williamson procedure; bp 96 °C/25 Torr; yield, 76%. A solution of 10 g of the amino ether in diethyl ether was cooled and 7 g of ethyl chloroformate was added dropwise to the solution. The solution was washed with 10% sodium carbonate and with water. The ether layer was dried over anhydrous sodium sulfate, the solvent was evaporated, and the residue was distilled; bp 124 °C/3 Torr; yield, 56%.

Direct Photolysis of I in Acylic Ethers. A solution of 5.0 g (0.043 mol) of ethyl azidoformate in 0.5 mol of acyclic ether was irradiated using a low-pressure mercury lamp, with stirring and cooling at 0 °C, until the evolution of nitrogen was no longer observed. The nitrogen evolved then gave almost the theoretical amount based on the azide used. The excess substrate was removed by distillation at 25—85 °C and 20—30 Torr. The residue was analyzed by VPC on columns. The IR and NMR spectra and VPC retention time of urethane (VI) were identical to those of an authentic sample, and a mixed melting point test with the authentic sample was undepressed. Diethyl hydrazodiformate (VII) was obtained in yields of 0.01—0.05 g for each experiment. The IR and NMR spectral, and elemental analysis data of VII have been described previously.[1] The insertion products (IV) and *N*-alkoxyurethanes (V) displayed strong absorptions in the 3260—3360 and 1700—1730 cm^{-1} regions due to the NH groups and the ester C=O groups, respectively. The NMR spectra of IV and V were measured in carbon tetrachloride and the chemical shifts were given in τ values. The IR and NMR spectral data, and the VPC retention times of V are identical to those of the products obtained by nitrene insertion into the O–H bonds when I was photolyzed in alcohols.[13]

(a) In Diethyl Ether (IIIa): *N*-(1-ethoxyethyl)urethane (IVa, 2.16 g) and *N*-ethoxyurethane (Va, 0.22 g) were isolated. IVa: NMR: 4.25 (NH, 1H, bs), 5.00 (CH, 1H, m), 5.94 (ester-CH_2, 2H, q), 6.50 (OCH_2, 2H, m), 8.70 (CH_3, 3H, d), 8.76 (ester-CH_3, 3H, t), 8.86 (CH_3, 3H, t). Found: C, 52.58; H, 9.51; N, 8.46%. Calcd for $C_7H_{15}O_3N$: C, 52.15; H, 9.38; N, 8.69%. Va: NMR: 1.97 (NH, 1H, bs), 5.85 (ester-CH_2, 2H, q), 6.14 (CH_2, 2H, q), 8.70 (CH_3, 3H, t), 8.73 (ester-CH_3, 3H, t). Found: C, 45.62; H, 8.08; N, 10.91%. Calcd for $C_5H_{11}O_3N$: C, 45.10; H, 8.33; N, 10.52%.

(b) In Dipropyl Ether (IIIb): *N*-(1-propoxypropyl)urethane (IVb_1, 2.62 g), *N*-[1-(propoxymethyl)ethyl]urethane (IVb_2, 0.25 g), and *N*-propoxyurethane (Vb, 0.35 g) were isolated. IVb_1: NMR: 4.65 (NH, 1H, bs), 5.25 (CH, 1H, m), 5.93 (ester-CH_2, 2H, q), 6.57 (OCH_2, 2H, m), 8.40 (CH_2, 4H, m), 8.76 (ester-CH_3, 3H, t), 9.08 (CH_3, 6H, t). Found: C, 56.98; H, 10.01; N, 7.62%. Calcd for $C_9H_{19}O_3N$: C, 57.11; H, 10.12; N, 7.40%. IVb_2: NMR: 5.29 (NH, 1H, bs), 5.97 (ester-CH_2, 2H, q), 6.06 (CH, 1H, m), 6.64 (OCH_2, 2H, bt), 6.68 (CH_2, 2H, d), 8.40 (CH_2, 2H, m), 8.84 (CH_3, 3H, d), 8.78 (ester-CH_3, 3H, t), 9.07 (CH_3, 3H, t). Found: C, 57.37; H, 10.28; N, 7.15%. Calcd for $C_9H_{19}O_3N$: C, 57.11; H, 10.12; N, 7.40%. Vb: NMR: 2.00 (NH, 1H, bs), 5.86 (ester-CH_2, 2H, q), 6.25 (OCH_2, 2H, t), 8.37 (CH_2, 2H, six), 8.71 (ester-CH_3, 3H, t), 9.03 (CH_3, 3H, t). Found: C, 49.15; H, 9.12; N, 9.81%. Calcd for $C_6H_{13}O_3N$: C, 48.96; H, 8.90; N, 9.52%.

(c) In Dibutyl Ether (IVc): *N*-(1-butoxybutyl)urethane (IVc_1, 2.33 g), *N*-[1-(butoxymethyl)propyl]urethane (IVc_2, 0.35 g), *N*-(3-butoxy-1-methylpropyl)urethane (IVc_3, 0.36 g), and *N*-butoxyurethane (Vc, 0.28 g) were isolated. IVc_1: NMR: 5.15 (NH, 1H, bs), 5.16 (CH, 1H, m), 5.94 (ester-CH_2, 2H, q), 6.56 (OCH_2, 2H, t), 8.53 (CH_2, 8H, m), 8.74 (ester-CH_3, 3H, t), 9.05 (CH_3, 6H, t). Found: C, 61.08; H, 10.35; N, 6.18%. Calcd for $C_{11}H_{23}O_3N$: C, 60.80; H, 10.67; N, 6.45%. IVc_2: NMR: 5.30 (NH, 1H, bs), 5.96 (ester-CH_2, 2H, q), 6.40 (CH, 1H, m), 6.62 (OCH_2, 4H, bt), 8.25 ($CHCH_2$, 2H, m), 8.52 (CH_2, 4H, m), 8.77 (ester-CH_3, 3H, t), 9.06 (CH_3, 6H, t). Found: C, 61.18; H, 10.42; N, 6.08%. Calcd for $C_{11}H_{23}O_3N$: C, 60.80; H, 10.67; N, 6.45%. IVc_3: NMR: 4.85 (NH, 1H, bs), 5.98 (ester-CH_2, 2H, q), 6.33 (CH, 1H, m), 6.56 and 6.65 (OCH_2, 4H, t), 8.50 (CH_2, 6H, m), 8.58 (CH_3, 3H, d), 8.79 (ester-CH_3, 3H, t), 9.07 (CH_3, 3H, t). Found: C, 60.98; H, 10.38; N, 6.11%. Calcd for $C_{11}H_{23}O_3N$: C, 60.80; H, 10.67; N, 6.45%. Vc: NMR: 1.97 (NH, 1H, bs), 5.86 (ester-CH_2, 2H, q), 6.22 (OCH_2, 2H, t), 8.2—8.9 (CH_2, 4H, m), 8.71 (ester-CH_3, 3H, t), 9.05 (CH_3, 3H, t). Found: C, 52.51; H, 9.19; N, 8.44%. Calcd for $C_7H_{15}O_3N$: C, 52.15; H, 9.38; N, 8.69%. The insertion product, IVc_2, exhibited IR and NMR spectra and a VPC retention time identical with those of an authentic sample.

(d) In Diisopentyl Ether (IIId): *N*-(3-methyl-1-isopentyloxybutyl)urethane (IVd_1, 1.80 g), *N*-(1,1-dimethyl-3-isopentyloxypropyl)urethane (IVd_2, 0.60 g), and *N*-isopentyloxy urethane (Vd, 0.18 g) were isolated. IVd_1: NMR: 5.14 (NH, 1H, bs), 5.14 (OCH, 1H, t), 5.94 (ester-CH_2, 2H, q), 6.57 (OCH_2, 2H, t), 8.15 and 8.30 (CH, 2H, m), 8.70 (CH_2, 4H, m), 8.75 (ester-CH_3, 3H, t), 9.06 and 9.10 (CH_3, 12H, d). Found: C, 63.69; H, 10.92; N, 5.58%. Calcd for $C_{13}H_{27}O_3N$: C, 63.64; H, 11.09; N, 5.71%. IVd_2: NMR: 4.55 (NH, 1H, bs), 6.04 (ester-CH_2, 2H, q), 6.50 and 6.60 (OCH_2, 4H, t), 8.39 (two CH_2 and CH, 5H, m), 8.66 (CH_3, 6H, s), 8.80 (ester-CH_3, 3H, t), 9.08 (CH_3, 6H, d). Found: C, 63.23; H, 10.98; N, 5.95%. Calcd for $C_{13}H_{27}O_3N$: C, 63.64; H, 11.09; N, 5.71%. Vd: NMR: 2.08 (NH, 1H, bs), 5.85 (ester-CH_2, 2H, q), 6.18 (OCH_2, 2H, t), 8.1—8.6 (CH_2 and CH, 3H, m), 8.71 (ester-CH_3, 3H, t), 9.06 (CH_3, 6H, d). Found: C, 54.52; H, 9.54; N, 8.27%. Calcd for $C_8H_{17}O_3N$: C, 54.83; H, 9.78; N, 7.99%.

(e) In Isobutyl Methyl Ether (IIIe): *N*-(1-methoxy-2-methylpropyl)urethane (IVe_1, 1.24 g), *N*-(isobutoxymethyl)-urethane (IVe_2, 0.43 g), and *N*-isobutoxyurethane (Ve_1, 0.18 g) were isolated. IVe_1: NMR: 4.68 (NH, 1H, bs), 5.45 (OCH, 1H, m), 5.90 (ester-CH_2, 2H, q), 6.71 (OCH_3, 3H, s), 8.26 (CH, 1H, m), 8.75 (ester-CH_3, 3H, t), 9.08 (CH_3, 6H, d). Found: C, 55.12; H, 9.92; N, 7.69%. Calcd for $C_8H_{17}O_3N$: C, 54.83; H, 9.78; N, 7.99%. IVe_2: NMR: 4.19 (NH, 1H, bs), 5.14 (NCH_2, 2H, d), 5.87 (ester-CH_2, 2H, q), 6.77 (OCH_2, 2H, d), 8.10 (CH, 1H, m), 8.74 (ester-CH_3, 3H, t), 9.10 (CH_3, 6H, d). Found: C, 55.05; H, 9.98; N, 7.70%. Calcd for $C_8H_{17}O_3N$: C, 54.83; H, 9.78; N, 7.99%. Ve_1: NMR: 2.04 (NH, 1H, bs), 5.85 (ester-CH_2, 2H, q), 6.42 (OCH_2, 2H, d), 7.63—8.57 (CH, 1H, m), 8.71 (ester-CH_3, 3H, t), 9.05 (CH_3, 6H, d). Found: C, 52.51; H, 9.12; N, 8.81%. Calcd for $C_7H_{15}O_3N$: C, 52.15; H, 9.38; N, 8.69%.

The VPC retention time for methoxyurethane (Ve_2) was identical with that of an authentic sample.

(f) In 2-Methoxyethanol (IIIf): *N*-(2-methoxyethoxy)-urethane (Vf, 2.39 g) was isolated. Vf: NMR: 1.37 (NH, 1H, bs), 5.84 (ester-CH_2, 2H, q), 5.81—6.21 (CH_2ON, 2H, m), 6.26—6.58 (CH_2, 2H, m), 6.62 (CH_3, 3H, s), 8.72 (ester-CH_3, 3H, t). Found: C, 49.25; H, 9.12; N, 9.28%. Calcd for $C_6H_{13}O_3N$: C, 48.96; H, 8.90; N, 9.52%.

Direct Photolysis of I in Dioxane and Alcohols. In dioxane, ethyl 1,4-dioxan-2-ylcarbamate was obtained in yield of 2.47 g. NMR: 4.37 (NH, 1H, bs), 4.87—5.27 (CH, 1H, m), 5.82 (ester-CH_2, 2H, q), 5.97—6.77 (CH_2, 6H, m), 8.74 (ester-CH_3, 3H, t). Found: C, 47.46; H, 7.62; N, 8.21%. Calcd for $C_7H_{13}O_4N$: C, 47.99; H, 7.48; N, 8.00%. The NMR spectrum was in good agreement with that reported in Ref. 8. In the alcohols, Va, Vb, and Vc were obtained in yields of 0.63, 0.95, and 1.87 g, respectively.

Sensitized Photolysis of I in Ethers and Alcohols. A solution of 2.3 g (0.02 mol) of ethyl azidoformate (I) and 3.12 g (0.026 mol) of acetophenone in 0.5 mol of a substrate was irradiated, with stirring at 25 °C, using a high-pressure mercury lamp until the evolution of nitrogen was no longer observed. The reaction mixture was treated as in the case of direct photolysis. In addition, for each of the reactions with alcohols, the excess substrate and a volatile product, aldehyde, were trapped in a flask immersed in a Dry Ice–methanol bath under reduced pressure. The trapped solution was added to a 2,4-dinitrophenylhydrazine solution and the aldehyde was converted to hydrazone. For ethanol, 1-propanol, and 1-butanol, acetaldehyde, propionaldehyde, and butyraldehyde were isolated as hydrazones in yields of 0.43, 0.58, and 0.53 g, respectively. For the reactions with IIIc, dioxane, tetrahydropyran, and 2-methyltetrahydrofuran, IVc_1, ethyl 1,4-dioxan-2-ylcarbamate, ethyl 2-tetrahydropyranylcarbamate, and ethyl 2-methyl-2-tetrahydrofurylcarbamate were isolated in yields of 0.36, 0.95, 0.96, and 0.57 g, respectively. The identification procedure for the third and fourth products has been reported elsewhere.[1)]

Direct Photolyses of I in a Mixture of Acyclic Ether and Cyclohexane. A solution of I (5.0 g, 0.043 mol) in III (0.25 mol) and cyclohexane (21 g, 0.25 mol) was irradiated internally as described above. The excess substrate was removed by distillation, and the residue was analyzed by VPC. The *N*-cyclohexylurethane was identified by comparison with an authentic sample. The yields of the insertion products and urethane are displayed in Table 2.

The authors are particulary indebted to Dr. Hisao Arakawa of the Science Education Institute of Osaka Prefecture for help in the preparation of this paper and for many useful suggestions.

The Benzannelated Annulenones. Syntheses and Properties of 10-Methylbenzo[*d*]- and Dibenzo[*d,j*]-6,8-bisdehydro[13]annulenone

Jūro Ojima,* Yōji Yokoyama, and Michiko Enkaku

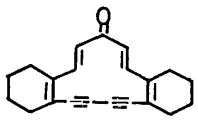
Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received October 21, 1976)

In order to examine the paratropic nature expected for a thirteen-membered ring system arising from polarization of the carbonyl group, the two benzannelated bisdehydro[13]annulenones, VI and IX, were prepared respectively by the aldol condensation of an appropriate aldehyde and an appropriate ketone followed by the oxidative coupling of the resulting acyclic ketone containing terminal acetylene groups. The NMR spectra indicate that both of VI and IX, as well as the respective protonated species, VII and X, are paratropic and paratropicities decrease in the sequence of VI>IX with the increasing number of fused benzene ring. The dibenzannelated annulenone (IX) and its precursor (VIII) were converted into the corresponding alcohols or ethers (XIIa, XIIb and XIa, XIb), respectively, to test the presence of the paratropic nature of IX. The NMR spectra of XIa, XIb and XIIa, XIIb, in addition to those of VIII and IX, suggested that IX seemed to be weakly paratropic. An attempt made to prepare the dibenzannelated bisdehydro[13]annulenyl anion (XIII) was unsuccessful.

A series of fully conjugated monocyclic monoketones (annulenones) are expected to be diatropic or paratropic owing to polarization of a carbonyl group provided they contain a $(4n+3)$-membered ring or $(4n+1)$-membered ring, respectively.[1]

In connection with the studies to confirm this prediction Howes *et al.* have reported a simple general approach to bisdehydro[13]- (I), [15]-, and [17]-annulenones in which the carbonyl group is flanked by ethylenic bonds on both sides.[2] The method consists in employing an aldol condensation of an appropriate aldehyde and ketone, containing terminal acetylene group, followed an intramolecular oxidative coupling of the resulting acyclic ketone.



I

We have now applied with advantage the method to the synthesis of benzannelated bisdehydro[13]annulenones (VI and IX) by using *o*-ethynylbenzaldehyde (II) as the starting material and essentially by the same approach as that of Howes *et al.* It is now established[3] that the annelated benzenoid nuclei such as benzene or naphthalene reduce the diatropic nature of a $(4n+2)$-membered annulene. However, when this work was commenced, little reports had yet appeared concerning the effect of annelation of benzene nuclei on annulenones.[4] Some aspect of this work have appeared in the preliminary form.[5] In this paper, we present a full account of our investigation on the synthesis and properties of monobenzo and dibenzo analogues of I, *i.e.*, 10-methylbenzo[*d*]- (VI) and dibenzo[*d,j*]-6,8-bisdehydro[13]annulenone (IX).

The preparation of VI and IX was carried out as follows. The ketone (III) was obtained by treatment of *o*-ethynylbenzaldehyde (II) with excess acetone in the presence of aqueous sodium hydroxide as previously

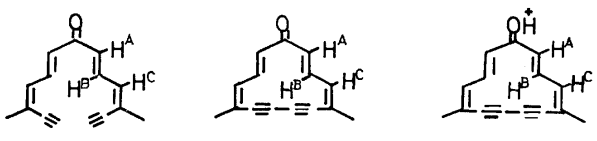
a) In addition, a singlet at 6.87 (–C≡CH). b) In addition, a singlet at 6.54 (–C≡CH). c) This shows the chemical shift differences. d), e) These assignments may be reversed in each group. However, most probable values are given in Table 1 by referring to the chemical shifts of the related compounds.[9]

reported.[6] Aldol coupling of III and *cis*-3-methyl-2-penten-4-ynal (IV)[7] by methanolic potassium hydroxide gave the acyclic ketone (V) in a 10% yield, upon chromatographic purification of the product over alumina, as an unstable orange liquid. Both of the aldehyde (IV) and the ketone (V) were unstable at room temperature. Oxidative coupling of V, under Eglinton's conditions using copper(II) acetate in pyridine,[8] gave the cyclic ketone, the desired annulenone (VI), in a 20% yield as relatively stable crystals. While, condensation of 2 molar equivalents of II with 1 molar equivalent of acetone, under the same conditions as indicated for the reaction of III and IV, afforded a 44% yield of the acyclic ketone (VIII). Oxidation of VIII with copper(II) acetate as before, gave the dibenzannelated annulenone (IX) in a 61% yield. The assigned conformations were given to the annulenones (VI) and (IX) in analogy with the compound (I) which was shown to have the conformation based on NMR spectroscopy of dideutrio compound of I.[2] Treatment of VI or IX with trifluoroacetic acid gave the corresponding carbonyl protonated species, VII (dark red; λ_{max} 277 sh, 292, 350 sh, with absorption>700 nm) or X (yellow brown; λ_{max} 285 sh, 301, 348, 413 sh, with absorption>700 nm), respectively.



XIV XV XVI

The ^{1}H-NMR parameters of the obtained compounds, V and VI, are listed in Table 1, as well as the chemical shift differences for various resonances on passing from V to VI, indicating the magnitude of the upfield shift of the outer proton signals and the downfield shift of the inner proton signals.

The comparison of the NMR spectra of V and VI (Table 1) reveals the compound VI to be paratropic, as expected for a potential 12π-electron system by the polarization of the carbonyl group, since the inner proton (H^B, $H^{B'}$) resonances of VI have moved to a lower field, the outer (H^A, $H^{A'}$, $H^{C'}$) and methyl proton resonances to a higher field, as compared with those of the corresponding proton of V.

In order to obtain an approximate measure regarding the effect of benzannelation on thirteen-membered ring system, the NMR spectral data of VIII and IX, and the chemical shift differences are also given in Table 1, together with those of XIV and XV which were prepared by Ojima and Sondheimer.[9] The data (Table 1) suggests that IX is also paratropic as VI, because the inner proton (H^B) signal has moved to a lower field, and the outer proton (H^A) signal to a higher field as compared with that of the respective proton of VIII.

As indicated in Table 1, an examination of the NMR spectra demonstrated that the thirteen-membered ring system in dimethyl compound XV is paratropic, in monobenzo-fused compound VI, it is less paratropic, in dibenzo-fused compound IX, it is at most weakly paratropic. This can be seen in particular by the downfield shifts, as compared with the respective models (XV, VI, IX), of the inner proton (H^B, $H^{B'}$) bands [−1.71, (−0.53 and −0.87), −0.29 ppm, respectively],

Table 2. ^{1}H-NMR parameters of XVI, VII, and X in CF_3COOD at 60 MHz (τ-values; Internal standard, TMS; J values in Hz in parentheses)

and the chemical shifts [0.61, (1.45 and 1.26), 1.53 τ, respectively].

Furthermore, the result analogous to the above is also obtained by the comparison of the NMR spectra in CF_3COOD (Table 2); the same trend is observed in the downfield shifts and the chemical shifts of the inner proton (H^B, $H^{B'}$) bands [−3.11, (−1.94 and −1.33), −0.84 ppm], [−0.79, (0.65 and 0.19), 0.98 τ] of the respective models (XVI, VII, X).[9,10]

As described above, it was concluded that the dibenzannelated [13]annulenone (IX) is paratropic. This conclusion was derived by comparing the chemical shifts of H^A and H^B protons of IX with those of the acyclic ketone (VIII) which is an atropic compound. However, the chemical shift differences between VIII and IX are so small that we attempted to examine these differences in the corresponding atropic models.[11] Along this line we undertook to prepare the alcohols (XIa, XIIa) and the methyl ethers (XIb, XIIb) which are the corresponding atropic models of VIII and IX.

Reduction of the acyclic ketone (VIII) in ether with sodium borohydride gave a 57% yield of the alcohol (XIa) as a pale yellow liquid. The methylation of XIa with methyl iodide and silver oxide gave fruitless results. However, methylation of XIa could be effected with methy iodide and sodium hydride[12] to afford a 51% yield of the ether (XIb) as a pale yellow liquid. The cyclic ketone (IX) was reduced more readily than the acyclic ketone (VIII) by sodium borohydride to afford alcohol (XIIa) in a 91% yield. Methylation of XIIa with methyl iodide and silver oxide in ether gave a 67% yield of the ether (XIIb) as crystals.

The ^{1}H-NMR data of the compounds thus obtained are given in Table 3, as well as the chemical shift differences. As illustrated in Table 3, we can see the chemical shift differences between XIa and XIIa, or between XIb and XIIb, which are definitely atropic. The chemical shift differences of H^A proton between XIa and XIIa, and that between XIb and XIIb, respectively, (+0.23 and +0.38) are smaller than that of H^A between VIII and IX (+0.40). Whereas, as for H^B proton the reverse is observed (+0.20 and +0.23, −0.29).

This result seems to suggest that the compound IX is weakly paratropic although the differences in chemical shifts of both H^A and H^B are small.

We have also attempted without success to prepare the dibenzannelated [13]annulenyl anion (XIII) by abstraction of ^{1}H from XIIb with dimsyl sodium in DMSO,[13] as reported by LeGoff and Sondheimer.[14] Under conditions performed, XIIb afforded a deep green solution, however all attempts to obtain a satisfactory NMR spectrum were failed owing to the unstability of the product.

Experimental

Freshly deoxygenated ether, methanol, and acetone were used to minimize an oxidation of the compounds used for aldol condensation. The ether was freed from a peroxide by passing through a short column of basic alumina (Act. I) followed by flushing with nitrogen. The methanol and acetone were flushed by nitrogen. All 20% methanolic potassium hydroxide solutions were prepared by dissolving 10 g of potassium hydroxide in 50 ml of methanol and by flushing the solution with nitrogen immediately prior to use. All the melting points are uncorrected. Brockmann alumina (Act. II—III) was used for column chromatography. The ^{1}H-NMR, IR, UV, and mass spectra were taken using the instruments JEOL-JNM-MH-60 or Varian XL-100, Hitachi EPI-S2, Hitachi-124, and JEOL-MS-OI-SG-2, respectively. Shoulders in UV spectra are denoted by sh.

o-Ethynylbenzaldehyde (II) and 4-(o-Ethynylphenyl)-1-buten-2-one (III). The aldehyde (II) and the ketone (III) were prepared as reported previously.[6]

cis-3-Methyl-2-penten-4-ynal (IV). The aldehyde (IV) was obtained by the reported method.[7]

9-(o-Ethynylphenyl)-3-methyl-3,5,8-nonatrien-1-yn-7-one (V). A mixture of the ketone (III, 3.6 g, 21.2 mmol) and the aldehyde (IV, 2.0 g, 21.3 mmol) in deoxygenated ether (85 ml) was treated with a 20% methanolic potassium hydroxide (3.1 ml). The mixture was further stirred at room temp for 2 h. Neutralization with acetic acid (4.0 ml) followed by addition of water (100 ml), and extraction with ether, and work up in the usual manner gave a dark red liquid. Chromatography of the liquid over alumina (80 g) with light petroleum–ether (8:2) as eluent gave the desired ketone (V, 0.5 g, 10%) as an unstable organge liquid: MS: *m/e* 246 (M^+, 40), 149 (100); mol wt, 246.29; IR (neat): 3250 (–C≡CH), 2100 (–C≡C–), 1660, 1615, 1600 (C=O, C=C), 980 cm^{-1}

(*trans* C=C); UV: λ_{max}^{EtOH} 226 (11000), 248 (9230), 321 nm (8830); NMR: see Table 1.

10-Methylbenzo[d]-*6,8-bisdehydro*[*13*]*annulenone (VI).* A soln of V (0.5 g, 2.0 mmol) in pyridine (11 ml) was added dropwise to a stirred soln of copper(II) acetate monohydrate (5.5 g) in pyridine (19 ml) for 10 min at 50—55 °C, and the reaction mixture was stirred for further 2 h at 55—65 °C. The ppt formed on cooling and diluting with benzene (100 ml) was washed with benzene (50 ml×2). Then the filtrate was washed with 6% hydrochloric acid until it was slightly acidic, saturated aq sodium hydrogencarbonate, and sodium chloride solutions successively, and dried over sodium sulfate. The residual dark red liquid obtained after evaporation of the solvent was chromatographed on alumina (80 g) with light petroleum–ether (7: 3) to afford VI (0.1 g, 20%) as relatively stable solid. Recrystallization from hexane gave pure VI as orange needles: mp *ca.* 160 °C (dec); IR (KBr disk): 2150 (–C≡C–), 1630, 1610, 1590 (C=O, C=C), 980 cm^{-1} (*trans* C=C); UV: λ_{max}^{EtOH} 236 (9880), 258 (15800), 388 nm (2100); MS: *m/e* 244 (M^+, 20), 215 (100); mol wt, 244.28; NMR: see Table 1.

1,5-Bis(o-ethynylphenyl)-1,4-pentadien-3-one (VIII). To a stirred soln of *o*-ethynylbenzaldehyde (II, 4.0 g, 0.031 mol) and acetone (0.94 g, 0.016 mol) in deoxygenated ether (48 ml) was added a 20% methanolic potassium hydroxide soln (1.5 ml) at 15—16 °C. After stirring for 3 h at the same temp, the reaction was quenched with acetic acid (1.5 ml). A dark red liquid obtained by usual work up of the ethereal extracts was purified by chromatography over alumina (150 g) using light petroleum–ether (95: 5—90: 10) as eluent. The fractions containing VIII were collected and evaporated, yielding the ketone (1.9 g, 44%) as a partly crystalline oil. Crystallization from light petroleum–benzene formed yellow cubes: mp 101.3—101.7 °C; MS: *m/e* 282 (M^+, 20), 155 (100); mol wt, 282.32; IR (KBr disk): 3250 (–C≡CH), 2100 (–C≡C–), 1660 (C=O), 1595 (C=C), 985, 965 cm^{-1} (*trans* C=C); UV: λ_{max}^{EtOH} 250 (24400), 332 nm (24500); NMR: see Table 1.

Found: C, 89.18; H, 4.76%. Calcd for $C_{21}H_{14}O$: C, 89.33; H, 5.00%.

Dibenzo[d,j]-*6,8-bisdehydro*[*13*]*annulenone (IX).* A soln of the ketone (VIII, 1.15 g, 4.07 mmol) dissolved in pyridine (25 ml) was added dropwise to a stirred soln of copper(II) acetate monohydrate (12.0 g) in pyridine (40 ml) for 10 min at 50 °C, and the reaction mixture was stirred for further 3 h at 60—65 °C. The mixture was cooled, diluted with benzene (300 ml), and the resulting mixture was filtered through Hyflo Super-Cel and washed with benzene (100 ml×2). Work up of the filtrate, as described for the isolation of VI, gave a dark red solid. The solid was chromatographed on alumina (70 g) and the ketone (IX, 0.7 g, 61%) was eluted with light petroleum–ether (9: 1—8: 2). Recrystallization from benzene gave pure IX as yellow cubes: mp 194 °C (dec); MS: *m/e* 280 (M^+, 100); mol wt, 280.31; IR (KBr disk): 2150 (–C≡C–), 1640, 1620, 1590 (C=O, C=C), 975 cm^{-1} (*trans* C=C); UV: λ_{max}^{EtOH} 284 (39000), 298 (46000), 379 sh (3820), 468 sh (1380), NMR: see Table 1.

Found: C, 90.03; H, 4.59%. Calcd for $C_{21}H_{12}O$: C, 89.98; H, 4.32%.

1,5-Bis(o-ethynylphenyl)-1,4-pentadien-3-ol (IXa). To a stirred soln of the ketone (VIII, 3.5 g, 0.012 mol) in dry ether (300 ml) was added a soln of sodium borohydride (8.5 g, 0.22 mol) in absolute ethanol (400 ml). After stirring at 20—23 °C for 20 h the reaction mixture was poured into water (900 ml) containing acetic acid (6 ml). The organic layer combined with the ethereal extracts was washed with dilute acetic acid, water, saturated aq sodium hydrogencarbonate, and sodium chloride successively, and dried over sodium sulfate. The residual yellow liquid obtained after evaporation of the solvent was chromatographed on alumina (100 g) and the fractions eluted with light petroleum–ether (4: 6—2: 8) gave the desired alcohol (XIa, 2.0 g, 56%) as a pale yellow liquid: MS: *m/e* 284 (M^+, 10), 129 (100); mol wt, 284.34; IR (neat): 3300 (–OH), 3250 (–C≡CH), 2100 (–C≡C–) 1700, 1640, 1595 (C=C), 965 cm^{-1} (*trans* C=C); UV: λ_{max}^{EtOH} 226 sh (12100), 233 (15000), 239 (12800), 249 (8550), 264 (8430), 276 nm (6350); NMR: see Table 3.

4,5 : 10,11-Dibenzocyclotrideca-2,12-diene-6,8-diyn-1-ol (XIIa). To a stirred soln of the ketone (IX, 0.60 g, 2.14 mmol) in dry ether (600 ml) was added a soln of sodium borohydride (900 mg, 0.024 mol) in absolute ethanol (120 ml) at room temp, and the reaction mixture was allowed to stir at the same temp for 2 h. Then the mixture was poured into water (450 ml) containing acetic acid (3 ml) and worked up as described for the isolation of XIa. The residual, partly crystallized, pale yellow liquid was chromatographed on alumina (100 g) with benzene–chloroform (1: 1) to give the alcohol (XIIa, 0.55 , 91%). Recrystallization from benzene formed white needles: mp *ca.* 150 °C (dec); MS: *m/e* 282 (M^+, 25), 253 (100); mol wt, 282.32; IR (KBr disk): 3350, 3250 (–OH), 2150 (–C≡C–), 1640 (C=C), 975, 965 cm^{-1} (*trans* C=C); UV: λ_{max}^{EtOH} 257 (20700), 268 (20000), 297 (13200), 322 (16500), 343 (17500), 368 sh nm (3310); NMR: see Table 3.

1,5-Bis(o-ethynylphenyl)-3-methoxy-1,4-pentadiene (XIb). To a slurry of sodium hydride (derived from washing 0.065 g of 53% NaH in oil) was added a soln of the alcohol (XIa, 0.24 g, 0.85 mmol) in dry tetrahydrofuran (20 ml) and methyl iodide (5 ml) at room temp under a nitrogen atmosphere. The reaction mixture was stirred at the same temp and the reaction was monitored at appropriate intervals by TLC. After stirring for 20 h additional methyl iodide (2 ml) and sodium hydride (30 mg) was added. After stirring for a total 26 h, the mixture was poured into water (200 ml) and extracted with ether. The extracts were washed with saturated aq sodium chloride soln and dried over sodium sulfate. The residue obtained after the evaporation of the solvent was chromatographed on alumina (130 g) with light petroleum to give the ether (XIb, 0.13 g, 51%) as a pale yellow liquid: IR (neat): 3300 (–C≡CH), 2100 (–C≡C–), 1145, 1110, 1080 (C–O–C), 970 cm^{-1} (*trans* C=C); UV: λ_{max}^{EtOH} 231 (59900), 238 (47900), 256 (33900), 265 (35300), 274 nm (23100); NMR: see Table 3.

1-Methoxy-4,5: 10,11-dibenzocyclotrideca-2,12-diene-6,8-diyne (XIIb). To a stirred soln of the alcohol (XIa, 0.25 g, 0.90 mmol) in dry ether (40 ml) was added methyl iodide (10 ml) and silver oxide (2 g), and the mixture was allowed to stir for 7 h at the same temp. A second silver oxide (2 g) was added and stirring was continued for another 8 h at the same temp. Then the mixture was filtered and the filtrate was concentrated under reduced pressure to give a pale yellow liquid. Chromatography of the liquid on alumina (100 g) with light petroleum–ether (95: 5—90: 10) afforded the ether (XIIb, 0.15 g, 57%) as yellow liquid which gave white crystals (mp 79—82 °C) on strong cooling. Attempts to recrystallize this material were failed. MS: *m/e* 296 (M^+, 40), 266 (100); mol wt, 296.35; IR (KBr disk): 2200 (–C≡C–), 1105, 1080 (C–O–C), 970 cm^{-1} (*trans* C=C); UV: λ_{max}^{EtOH} 231 (40200), 257 (19000), 268 (17900), 300 (8730), 320 (13100), 342 nm (13400); NMR: see Table 3.

Attempts to Prepare the Anion XIII. To a soln of the ether (XIIb, 252 mg) in dimethyl-d_6 sulfoxide (4 ml) was added a dimsyl anion (0.6 ml, prepared from dimethyl-d_6 sulfoxide and sodium hydride)[13] with stirring at room temp. A deep green color developed. However, no satisfactory

NMR spectrum could be obtained although we performed several runs under similar conditions for various elapse of time.

We wish to thank Professor Franz Sondheimer, University College, London, for useful suggestions, and Dr. Shuzo Akiyama and Professor Masazumi Nakagawa, Osaka University, for measurement of NMR spectra at 100 MHz. This research was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (054103, 1975), which is gratefully acknowledged.

(Received November 4, 1976)

By an analytical method using oxidation-reduction potential measurements of the formose reaction, which were previously shown to be useful for separately analyzing the induction and the formose-forming steps, the influence of various factors on each step and on the sugar yield were examined. It was found for the batch-system formose reaction that the rate of both steps and the sugar yield are affected by the concentration of formaldehyde, the amount of calcium hydroxide, and also by the ratio of the two. The dissolved calcium ion is believed to be an essential catalyst for either the induction or the formose-forming step, with the hydroxy anion playing significant role as the catalyst for the latter step. The optimum conditions necessary for obtaining the sugars in high yields are discussed.

Since Butlerow[1] found in 1861 that various saccharides are formed from an aqueous formaldehyde solution in the presence of $Ca(OH)_2$, many investigations concerning the formose reaction have been undertaken concerning many aspects,[2] such as the catalytic effect of organic and inorganic bases,[3-5] the function of a co-catalyst having enediol-forming ability,[6] and analytical techniques for the products.[7] The formose reaction is considered to proceed *via* the following two steps.[2] The first step is an induction period involving most probably formaldehyde condensation forming glycolaldehyde, and this induction period can be reduced by the addition of substances capable of forming an enediol, *e.g.*, various monosaccharides and benzoins.[8] In the subsequent step, rapid aldol condensation, a Cannizzaro reaction, and a cross-Cannizzaro reaction take place simultaneously resulting in formaldehyde condensation to saccharides. Some other reactions such as the interconversion of intermediates (the Lobry de Bruyn-Alberda van Eckenstein rearrangement) and the decomposition of various products also accompany the above reactions.

There are two important unsolved problems concerning the formose reaction which has rather complex features. One is to provide a convenient method for separately analyzing the induction step and the formose-forming step, and the other is to separately examine the roles of the dissolved and undissolved amounts of the $Ca(OH)_2$ catalyst. Although many approaches have been made to understanding the mechanism of the formose reaction and a number of workers have proposed the mechanism of $Ca(OH)_2$ catalytic action,[4,9,10] there are still ambiguities to be clarified with respect to these two points. Weiss *et al.* have reported important aspects of the kinetics of the formose reaction using a continuously stirred tank reactor (CSTR) which was desinged to maintain the reaction in steady-state conditions. They observed inevitable instabilities caused by varying the formaldehyde concentration, the calcium hydroxide concentration,** or the reaction pH.[9,11,12] However, as far as their method is concerned, no discussion of the induction-step mechanism is possible because they allowed the reaction to start by adding an endiol initiator, in which case the formose-forming step occurred instantly without any induction period.

In an approach to the investigation of the formose reaction, the measurement of the oxidation-reduction potential (ORP) during the $Ca(OH)_2$-catalyzed reaction in the batch system has proven useful for the separate analysis of each reaction step.[13,14] This showed that whenever the formose reaction occurs, the ORP curve invariably shows a minimum at the beginning of the formose-forming step and a maximum near the end point of the reaction (the so-called yellowing point[5,15]), at which the highest sugar yield is usually obtained. In a continuation of this study using the ORP method, this paper reports detailed examinations of various factors affecting the induction step, the sugar-forming step, and the sugar yield. Particular attention is placed on the following factors; the formaldehyde concentration, the $Ca(OH)_2$ quantity and particle size, the dissolved $Ca(OH)_2$, and the initial pH.

Experimental

A formaldehyde solution was prepared as follows: 200 g of paraformaldehyde (Merck) was suspended in 400 ml of distilled water, refluxed for 4 h, and filtered through a sintered glass disk. The filtrate containing *ca.* 30 wt-% of formaldehyde was stored in a brown bottle at the dark and was used for experiments within a few days, in order that no substances accelerating the formose reaction be produced. Commercial grade $Ca(OH)_2$ was used as a catalyst and the ground powder was passed through a 200 mesh sieve. When other $Ca(OH)_2$ particle sizes were required, the $Ca(OH)_2$ was prepared by a method similar to that described by Huttig and Arbes[16] and fractionated into the desired sizes by sieving.

The formose reaction was started without adding any initiator but by adding $Ca(OH)_2$ to a formaldehyde solution pre-heated to 60±1 °C. The procedure and apparatus used in the present experiments, the methods for determining the formaldehyde consumption and sugar yield, and the manner of measuring the ORP were essentially the same as those

** The term "concentration," which was used by Weiss *et al.* for $Ca(OH)_2$, is not relevant, because their reaction system (CSTR) was not initially homogeneous, but can accurately be called heterogeneous, in view of the coexistence of dissolved and undissolved calcium hydroxide in the system.

described in a previous paper.[14] The dissolved calcium ion concentration was determined by the EDTA method with an NN-reagent as the indictator.[17]

The sugar composition of the formose product for several runs was determined by GLC after trimethylsilylation.[18] The chromatographic patterns obtained were virtually identical in all cases.

Results and Discussion

Throughout the present paper, the following terms are adopted: [HCHO] is the formaldehyde concentration, $[Ca(OH)_2]$ the quantity of calcium hydroxide added as catalyst, T_{min} the length of the induction period, which is the time from the start of the formose reaction to the ORP minimum,[14] T_{max} the time from the start to the ORP maximum,[14] and $T_{max}-T_{min}$ the length of the formose-forming period. T_{min} and $T_{max}-T_{min}$ can be used for evaluating the rate of each step.

Effects of [HCHO] and $[Ca(OH)_2]$. As has been observed by Weiss *et al.*, the formose reaction is sensitive to [HCHO] and $[Ca(OH)_2]$. In the present work, this sensitivity to concentration is shown to occur in both the induction and formose-forming steps and to affect the sugar yield.

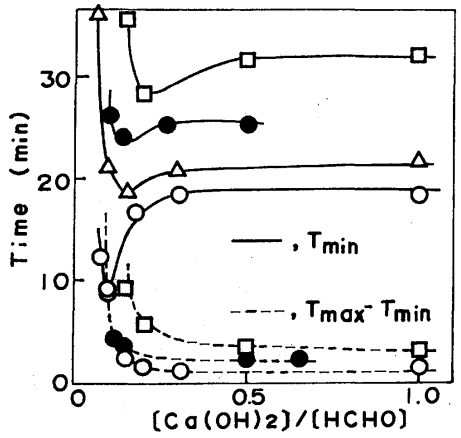

Fig. 1. Effect of $[Ca(OH)_2]$ on T_{min} and $T_{max}-T_{min}$. [HCHO]: □, 0.1 M; ●, 0.5 M; △, 1.0 M; ○, 2.2 M; $Ca(OH)_2$: 200 mesh.

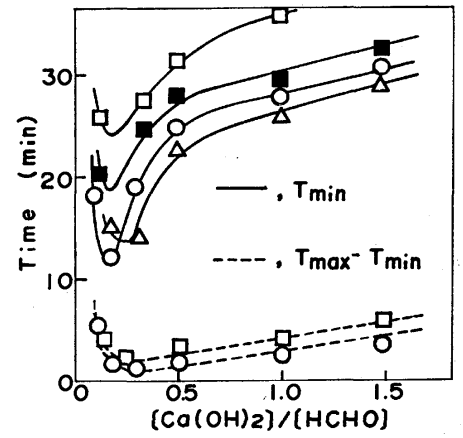

Fig. 2. Effect of [HCHO] on T_{min} and $T_{max}-T_{min}$. $Ca(OH)_2$: 200 mesh; □, 0.05 M; ■, 0.13 M; ○, 0.25 M; △, 0.33 M.

The Effect on the Induction Period: These are shown in Figs. 1 and 2. Figure 1 shows that, for increased $[Ca(OH)_2]$ at constant [HCHO], T_{min} decreases, passes through a minimum and then at about $[Ca(OH)_2]/[HCHO]=0.1—0.2$ becomes constant. Similar behavior is observed for decreased [HCHO] at constant $[Ca(OH)_2]$, however, T_{min} tends to be prolonged (Fig. 2). In both cases, the formose reaction did not occur when the $[Ca(OH)_2]/[HCHO]$ ratio was set to less than 0.05. As is seen in Table 1, which shows the effects of $[Ca(OH)_2]/[HCHO]$ on the initial pH, the $Ca(OH)_2$ solubility and the amount of HCHO adsorbed on solid $Ca(OH)_2$, the pH decreases at lower $[Ca(OH)_2]/[HCHO]$ ratios; for example, it is as low as 10.5 at $[Ca(OH)_2]/[HCHO]=0.05$. It is known that the formose reaction does not occur such a low pH value.[9]

TABLE 1. THE EFFECTS OF [HCHO] AND $[Ca(OH)_2]$ ON pH AND $Ca(OH)_2$ SOLUBILITY AT 60 °C

[HCHO] (M)	$[Ca(OH)_2]$ (M)	$[Ca(OH)_2]/[HCHO]$	pH	Dissolved $Ca(OH)_2$	HCHO adsorbed on solid $Ca(OH)_2$ (mg/ml)
1.90	0.60	0.32	11.3	0.11	10.9
1.90	0.40	0.21	11.2	0.12	6.8
1.90	0.20	0.11	11.0	0.12	3.3
1.90	0.16	0.08	11.0	0.12	1.4
1.53	0.30	0.20	11.4	0.09	1.0
2.99	0.30	0.10	11.0	0.14	4.2
5.94	0.30	0.05	10.5	0.21	8.4

In spite of the fact that Weiss *et al.* have observed in their CSTR experiments that the reaction does not occur when the $[Ca(OH)_2]/[HCHO]$ ratio is more than 2, it was demonstrated that the reaction did occur for the appearance of the ORP minimum and maximum even at $[Ca(OH)_2]/[HCHO]=5$. Furthermore, experiments at extremely low or high [HCHO] showed that such conditions are not appropriate for the formose reaction. Thus, when the [HCHO] is set to less than 0.01 M, neither did the ORP minimum appear nor did the reaction occur even for an extension of the reaction time up to 90 min. At high [HCHO] (*ca.* 10 M), the reaction occurred whenever an adequate amount of $Ca(OH)_2$ was used. However, because of a highly exothermic reaction, the mixture became too viscous to control properly.

The Effect on the Formose Forming Step. These effects were examined at constant [HCHO] and $[Ca(OH)_2]$ and are shown as dotted curves in Figs. 1 and 2, respectively. At constant [HCHO], $T_{max}-T_{min}$ is sharply reduced with increased $[Ca(OH)_2]$ in the range of $[Ca(OH)_2]/[HCHO]$ ratios between 0.1 and 0.3, and remains constant at higher ratios. For constant $[Ca(OH)_2]$, it also decreases with decreasing [HCHO] for lower $[Ca(OH)_2]/[HCHO]$ ratios but increases with decreasing [HCHO] for higher ratios.

In comparison with the effects on the induction period (Figs. 1 and 2), the kinetics for the formose-

forming step apparently differ from those for the induction step. However, when a comparison is made in the region of $[Ca(OH)_2]/[HCHO]$ ratios greater than 0.3, for both steps the rate increases with increasing [HCHO] at constant $[Ca(OH)_2]$ (Fig. 2), but the rate remains unchanged with increasing $[Ca(OH)_2]$ at constant [HCHO] (Fig. 1). These results suggest that, under certain conditions ($[Ca(OH)_2]/[HCHO] \geq 0.3$), the reactions for both the induction and formose-forming steps are of zeroth order for $Ca(OH)_2$ and probably of first order for formaldehyde. This is contrary to the concept of Weiss and Lapierre[12] that, at intermediate conversion levels, the formose reaction is of first order for $Ca(OH)_2$ and of zeroth order for the organics. Although there are some difficulties in accounting for the discrepancy between their and the present results, it is reasonable to assume that this is due to a difference between the CSTR kinetics and those of the present study.

The Effect on Sugar Yield: As shown in Figs. 3 and 4, the sugar yield is considerably altered by varying the [HCHO] and $[Ca(OH)_2]$. In summarizing the results, it can generally be said that the sugar yield increases with a decrease in either the [HCHO] or $[Ca(OH)_2]$. This may be partly explained in terms of the Cannizzaro reaction for formaldehyde. The consumption of formaldehyde in the induction period is known to be largely caused by the Cannizzaro reaction,[11] the rate of which is expressed by $-d[HCHO]/dt = k[OH^-]^{1-2}[HCHO]^{1-2}$.[2,19-21] Therefore, a higher [HCHO] or $[Ca(OH)_2]$ is not recommended for obtaining sugar products in a high yield. As discussed below, a higher $[Ca(OH)_2]$ also causes facile decomposition of the sugars formed.

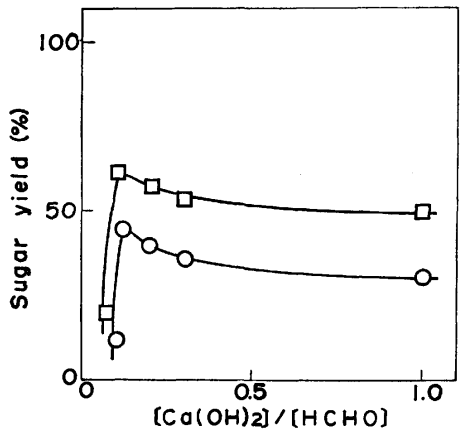

Fig. 3. Effect of $[Ca(OH)_2]$ on the sugar yield.
[HCHO]: □, 1.0 M; ○, 2.2 M; $Ca(OH)_2$: 200 mesh.
The sugar yield is based on the used formaldehyde.

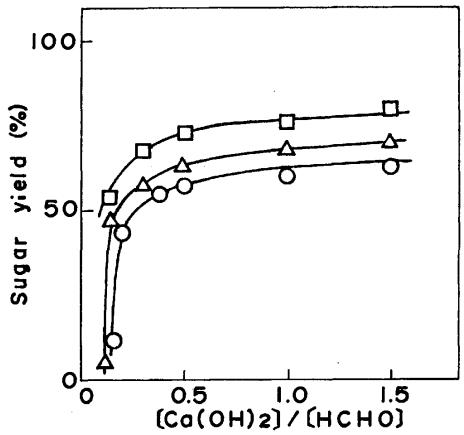

Fig. 4. Effect of [HCHO] on the sugar yield.
$Ca(OH)_2$: 200 mesh; □, 0.13 M; △, 0.25 M; ○, 0.33 M. The sugar yield is based on the used formaldehyde.

Effect of $Ca(OH)_2$ Particle Size. As a probe of the catalytic action of $Ca(OH)_2$, which exists in several forms, *e.g.*, dissolved, undissolved, or free and bound to organic materials, the influence of $Ca(OH)_2$ particle size was examined. The results are shown in Table 2. For a constant $[Ca(OH)_2]$ (0.22 or 0.33 M), an increase in particle size led to an increase of both T_{min} and $T_{max} - T_{min}$.

Since, in general, the particle size of a solid is inversely proportional to the specific surface area, the increase in the $Ca(OH)_2$ particle size causes a lowering of the dissolved rate. Thus, as shown in Table 3 (Runs 2, 5, and 6), the dissolved calcium ions at the beginning (T_s) decrease with increasing $Ca(OH)_2$ particle size. The delay in the induction period caused by the increase in $Ca(OH)_2$ size suggests that the dissolved calcium species plays an important role in the catalysis of this step. Conversely, undissolved $Ca(OH)_2$ may not be an essential catalyst but may play the role of either continuously supplying the dissolved calcium species or maintaining the pH range required for the induction period.

The delay effect on the rate of the formose-forming step for the larger $Ca(OH)_2$ particles can also be explained in terms of the slow dissolution rate. The particle size did not have any appreciable influence on the sugar yield, even when the formose reaction proceed-

Table 2. The influence of $Ca(OH)_2$ particle-size on the formose reaction[a]

$[Ca(OH)_2]$ (M)	Particle size (mesh)	T_{min} (min)	T_{max} (min)	$T_{max} - T_{min}$ (min)	Sugar yield at T_{max} (%)	Sugar yield 3 min after T_{max}

ed slowly (see Table 2, for a 0.33 M [$Ca(OH)_2$]). However, the decomposition of sugar products after T_{max} was found to be suppressed with increased $Ca(OH)_2$ size, although the $T_{max}-T_{min}$ was prolonged. This may also be due to the slow dissolution rate of $Ca(OH)_2$ which is considered to accelerate the decomposition of sugar in dissolved form.

Effects of the pH and the Dissolved Calcium Ions. The above results led us to the preliminary conclusion that the pH and the dissolved calcium species may be important factors in the formose reaction, in addition to the effect of the [HCHO] and [$Ca(OH)_2$]. The importance of the pH effect has already been pointed out.[9,22,23)] Weiss and John have shown that the consumption rate of formaldehyde using CSTR is highly pH-dependent at constant [HCHO] and [$Ca(OH)_2$]: for example, the highest rate is observed for a pH of *ca.* 11.0 for 1.3 M [HCHO] and 0.45 M [$Ca(OH)_2$] and for a pH of *ca.* 11.5 for 1.3 M [HCHO] and 0.35 M [$Ca(OH)_2$].[9)]

In order to gain more insight into the nature of the formose reaction, the effects of the initial conditions were examined while measuring the initial pH and dissolved calcium ion and the T_{min} and T_{max} points, as well as the formaldehyde consumption and the sugar yield. The results are summarized in Table 3. The most typical standard conditions that give good sugar yields are Runs 2, 8, and 11, which will be compared with other Runs in the following discussion.

The Effect of [$Ca(OH)_2$] (Runs 1—4). At the same [HCHO] and $Ca(OH)_2$ particle size, the initial pH (at T_S) increases with increasing [$Ca(OH)_2$], in accord with the results shown in Table 1, however, the initial concentration of the dissolved calcium ion is virtually independent of the [$Ca(OH)_2$] which has a significant effect on the yield and the sugar decomposition rate.

The Effect of the $Ca(OH)_2$ Particle Size (Runs 2, 5, and 6). Delayed effects similar to those described above were observed for T_{min} and $T_{max}-T_{min}$ (Table 2). It should be noted that the initial concentration of the dissolved calcium ion decreases significantly with increased particle size despite the fact that the initial pH is practically the same in all cases.

The Effect of [HCHO] (Runs 7—10). For the same [$Ca(OH)_2$] and $Ca(OH)_2$ particle size, the initial pH showed a tendency to decrease with increasing [HCHO], while the initial dissolved calcium ion increased.

The Effect of the Initial pH (Runs 11—14). For constant [HCHO] and [$Ca(OH)_2$], the effect of the initial pH was examined, as adjusted to the desired value by the addition of potassium hydroxide. For increased pH, the initial concentration of dissolved calcium ions decreased and, in proportion to this decrease, T_{min} increased while $T_{max}-T_{min}$ decreased.

Other Significant Observations. T_{min} is increased with decreasing initial concentration of the dissolved calcium ion. Also, $T_{max}-T_{min}$ is prolonged with decreasing pH at T_{min}. A lowering of the pH was observed throughout the induction and formose-forming steps; this was more significant in the latter step. The pH lowering near the end of the formose-forming step has previously been reported.[5,6)] This may be largely due to the facile complex formation between sugars and $Ca(OH)_2$.[5,9)] In fact, when an aqueous $Ca(OH)_2$ solution was titrated with a solution of several sugars, an appreciable fall in the pH was observed, as is shown in Fig. 5. However, for titration with 0.1 M glucose, the pH of a $Ca(OH)_2$ solution showed no tendency to decrease. It should be noted that the formation of organic acids by the Cannizzaro reaction may also contribute to the pH lowering either in the induction or the formose-forming step, and it has been shown that the rate of organic-acid formation in the induction period is similar to that for the formose-

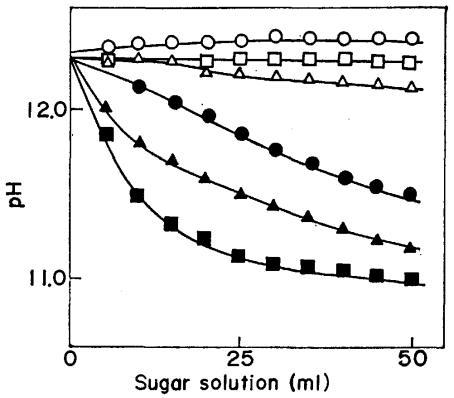

Fig. 5. pH change of 0.1 M $Ca(OH)_2$ solution (50 ml) by titration with an aqueous sugar solution. Temp, 26°C; Sugar solution: □, Blank; ○, 0.1 M glucose; △, 0.1 M xylose; ●, 1.0 M glucose; ▲, 1.0 M xylose; ■, 1.0 M fructose.

forming step.[3,14]

Conclusion. From these observations, one can draw the following conclusions. First, the formose reaction does not occur for low $[Ca(OH)_2]/[HCHO]$ ratios (<0.05). Under such conditions, the induction step is not initiated because of the low pH (<10.5). Second, the dissolved calcium ion may act as an active catalyst in the induction step when the pH is maintained at the appropriate range (approximately 10.8—11.7) and when the $[Ca(OH)_2]/[HCHO]$ ratio is not extremely low (<0.1). The undissolved $Ca(OH)_2$ may not play a significant role in the catalysis during the induction period, but may serve as a supplier of dissolved calcium ions, which are consumed by the Cannizzaro reaction for formaldehyde, and for maintaining the neccessary pH. Third, the dissolved calcium ion is considered to be essential for catalyzing the formose-forming step. However, due to the fact that the rate of this step is accelerated with increasing initial pH (T_{min}), it is suggested that the OH^- ion plays a significant role in the catalysis of the formose-forming step.

There are some discrepancies between the results of Weiss *et al.*[9,11,12] and those presented here regarding the kinetic behavior of the formose reaction. However, the above conclusions are not inconsistent with those of Weiss *et al.* such as the suggestion that $CaOH^+$ might be the true catalyst in the overall formose reaction, in view of the pH dependence and the sensitivities to the $[Ca(OH)_2]$ and [HCHO]. More details on the nature of the catalyst will be reported in a subsequent paper.

Finally, the present investigation provides the following guide-lines for obtaining high sugar yield in batch-reaction systems. The amount of formaldehyde consumed by the Cannizzaro reaction must be minimized. This may be done at low formaldehyde concentrations ($[HCHO]<1$ M), at relatively low pH values, such as *ca.* 11.2 (Table 3, Runs 7 and 11) and at high $[Ca(OH)_2]/[HCHO]$ ratios with low $[Ca(OH)_2]$ (Fig. 4). In order to prevent sugar decomposition, it is strongly recommended to stop the reaction exactly at T_{max} and to set the pH as low as possible. For example, under the conditions described here, when the $[Ca(OH)_2]/[HCHO]$ ratio was set in the range from 0.11 to 0.15, the sugar yields were 45 and 58% at 2.2 and 1.0 M [HCHO], respectively (Fig. 3). When the $[Ca(OH)_2]/[HCHO]$ ratio was set to 1.5, the sugar yields were 60 and 77% at 0.33 and 0.13 M $[Ca(OH)_2]$, respectively (Fig. 4). However, when the [HCHO] was less than 0.01 M for any $[Ca(OH)_2]/[HCHO]$ ratio, the formose reaction could not occur.

Asymmetric Reactions. II. Asymmetric Synthesis of Methyl α-Phenylpropionate by Means of Chiral Polymers

Tetsushi YAMASHITA, Hiroshi YASUEDA, Yasushi MIYAUCHI, and Nobuo NAKAMURA

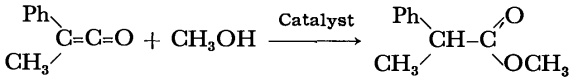
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received November 8, 1976)

The asymmetric addition of methanol to phenylmethylketene was carried out in the presence of propionylcinchonine and poly(acryloylcinchonine). The use of poly(acryloylcinchonine) produced additional products with higher optical yields than that of propionylcinchonine. The highest optical yield (35%) was obtained with the above polymeric catalyst at −78 °C. An insoluble, cross-linked polymer obtained by the co-polymerization of acryloylcinchonine with *N,N'*-diacryloylhexamethylenediamine, was also used as a catalyst. The products obtained for the cross-linked polymer showed a linear correlation between log k_R/k_S and $1/T$ while those with non-cross-linked poly(acryloylcinchonine) exhibited a relationship deviating somewhat from linearity. A linear relationship was also observed using insoluble, cross-linked poly(acryloylquinine).

The use of chiral synthetic polymers for asymmetric synthesis has been attempted by several workers[1-8] because of the interest in the study of asymmetric reactions, new catalysts, enzyme models, and polymer effects.

In a previous paper,[1] the asymmetric addition of methanol to phenylmethylketene (PMK) was examined in the presence of optically-active polymers and their corresponding monomeric model compounds.



A distinct polymer effect with regard to stereoselectivity was observed with poly(*N*-benzyl-2-pyrrolidinylmethyl acrylate) (**P-1**) and poly(acryloylquinine) (**P-2**).

Figure 1 indicates the result of the addition reaction obtained with **P-1** and *N*-benzyl-2-pyrrolidinylmethyl propionate in plots of log k_R/k_S against $1/T$ [$k_R(k_S)$: the rate constant for the *R*(*S*)-isomer]. The addition products with **P-1** showed a linear relationship between log k_R/k_S and $1/T$.

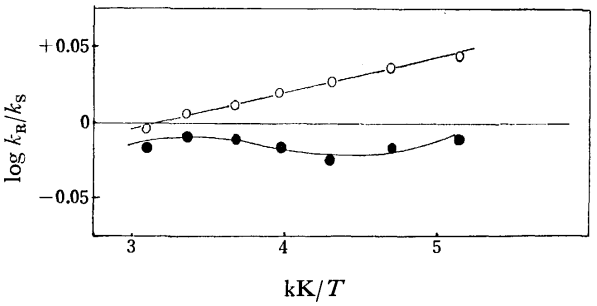


Fig. 1. Plots of log k_R/k_S against $1/T$ in case of **P-1** (—○) and *N*-benzyl-2-pyrrolidinylmethyl propionate (—●).

Pracejus and his co-workers[9] have previously reported that a linear correlation between log k_R/k_S and $1/T$ was observed with α-isocinchonine[9c] (**B**) (a cyclic ether derived from cinchonine) rather than with acetylcinchonine[9b] (**A-1**) (see Fig. 2).

Pracejus *et al.* explained their results using the effect of molecular immobility. Rotation about the carbon-carbon bond (C_8–C_9) of **B** is strongly restricted, and the conformation of **B** is more rigid than that of **A-1**.

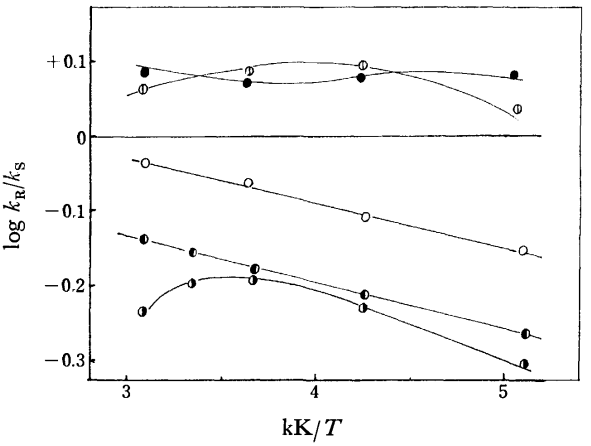

Fig. 2. Plots of log k_R/k_S against $1/T$ in case of cinchonine catalysts
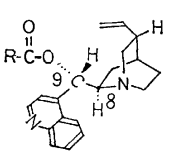
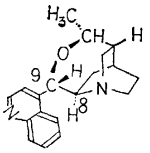
A-1 —●, **A-2** —◐, **B** —○, **P-3** —◑, **P-4** —◐.



Acylcinchonine (**A**)
A-1, CH_3
A-2, CH_2CH_3
A-3, $CH{=}CH_2$



α-Isocinchonine (**B**)

The results obtained with **P-1** are interpreted on the basis of the concept of Pracejus *et al.* The steric bulkiness of the back-bone of the polymer restricts the mobility of the side chain and increases the degree of conformational rigidity of the molecules in the side chain.

In the present work, this sort of polymer effect was examined in detail with cinchonine and quinine derivatives as catalysts. The reactions of cinchonine with acetic anhydride, propionic anhydride and acryloyl chloride was carried out in the presence of triethylamine producing **A-1**, **A-2**, and **A-3**, respectively.

Acryloylcinchonine (**A-3**) was polymerized using azobisisobutyronitrile as an initiator in dry benzene under reflux giving a polymer (**P-3**) soluble in common organic solvents.

An insoluble, cross-linked polymer (**P-4**) was obtained

by the co-polymerization of **A-3** with *N,N'*-diacryloylhexamethylenediamine.[10] Acryloylquinine[1] was similarly co-polymerized with *N,N'*-diacryloylhexamethylenediamine and *N,N'*-diacryloyldodecamethylenediamine to give **P-5** and **P-6**, respectively. These insoluble, polymeric catalysts were easily separated from the reaction mixture by filtration.

The asymmetric addition of methanol to PMK was carried out with the above catalysts in a manner similar to that reported earlier.[1] To one equivalent amount of PMK and a small excess of methanol was added a 0.01 molar equivalent of the catalyst.

The molar equivalent amount of the polymeric catalyst was calculated on the basis of that of the monomer used in the polymerization (*e.g.*, 10 mg of **P-3** corresponds to 10 mg of **A-3**).

Table 1. The specific rotations, optical yields and configurations of the addition products

Catalyst	T (°C) −78 $[\alpha]_D$	−78 O.Y.[a]	0 $[\alpha]_D$	0 O.Y.	+50 $[\alpha]_D$	+50 O.Y.	Conf[b]
A-2	−4.8	4.4	−10.5	9.6	−8.9	8.2	*R*
P-3	+38.1	35.0	+23.6	21.7	+29.6	27.2	*S*
P-4	+33.1	30.4	+23.3	21.4	+17.5	16.1	*S*
P-5	−16.2	14.9	−11.4	10.5	−8.4	7.7	*R*
P-6	−12.9	11.8	−11.3	10.4	−10.1	9.3	*R*

a) The O.Y. (optical yield, %) was calculated from the specific rotation of the product and that of optically pure methyl α-phenylpropionate[9a] (*S*-form, $[\alpha]_D^{22}=+109°$, *c* 6.2, toluene). b) Configuration of the predominant isomer.

Table 1 gives the specific rotations, optical yields and configurations of the addition products obtained with cinchonine and quinine catalysts at −78, 0 and +50 °C.

Figure 2 shows the log (k_R/k_S) *vs.* $1/T$ relation of the addition products obtained for the cinchonine catalysts (**A-2**, **P-3**, and **P-4**).

The products for **P-4** (cross-linked) showed a linear relationship between log k_R/k_S and $1/T$ while those with **P-3** (non-cross-linked) showed a relation deviating from linearity.

In Figure 3 are shown plots of log k_R/k_S against $1/T$ in the case of the quinine catalysts (**P-2**, **P-5**, and **P-6**).

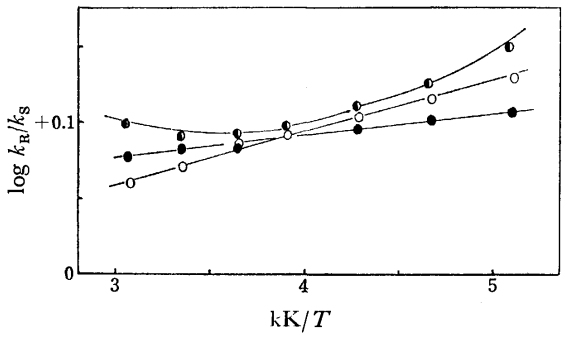


Fig. 3. Plots of log k_R/k_S against $1/T$ in case of **P-2** (—◐), **P-5** (—○), **P-6** (—●).

The products for the cross-linked polymer (**P-5** and **P-6**) showed a linear correlation between log k_R/k_S and $1/T$.

Figures 2 and 3 suggest that the cross-linking of polymers, which further restricts the mobility of the side chain, resulted in the linear relationship for the addition products of the cinchonine and quinine catalysts.

Experimental

Propionylcinchonine (A-2). A solution of cinchonine (1.5 g), propionic anhydride (0.7 g) and triethylamine (0.8 g) in dry benzene (100 ml) was stirred under refluxing. After 4 h, the solution was cooled to room temperature, and poured into water (100 ml). The organic layer separated out was washed with saturated sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was recrystallized from ether. Yield, 90%. Mp 46 °C. $[\alpha]_D^{20}=+101°$ (*c* 2, chloroform). Found: C, 75.60; H, 7.50; N, 8.15%. Calcd for $C_{22}H_{26}O_2N_2$: C, 75.42; H, 7.42; N, 8.00%. IR (cm^{-1}): 1720, 1180: NMR (ppm): 1.1, 2.4 (propionyl group proton), 5.5—6.5 (olefinic proton), 7.5, 8.1, 8.8 (quinoline ring proton).

Acryloylcinchonine (A-3). To a solution of cinchonine (3 g) and triethylamine (1.5 g) in dichloromethane (100 ml) a solution of freshly distilled acryloyl chloride (1.3 g) in dichloromethane (50 ml) at −20 °C was dropwise added with stirring. After standing overnight, the reaction mixture was poured into water (200 ml). The organic layer separated out was washed with saturated sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate.

The solution was concentrated, and subjected to chromatography on alumina (2×30 cm, 200 mesh, neutral). Elution with ethyl acetate gave **A-3** as a clear oil in a 94% yield. $[\alpha]_D^{20}=+80°$ (*c* 2, chloroform). TLC of **A-3** gave only one spot for several solvent systems. IR (cm^{-1}): 1720, 1180, 990. NMR (ppm): 5.6—6.5 (olefinic proton), 7.5, 8.1, 8.8 (quinoline ring proton).

Poly(acryloylcinchonine) (P-3). A solution of **A-3** (1 g) and azobisisobutyronitrile (10 mg) in dry benzene (10 ml) was refluxed with stirring in an argon atmosphere. After 20 h, the solution was cooled to room temperature and poured into ether. A precipitate (**P-3**) was filtered off and washed thoroughly with ether. Yield, 74%. $[\alpha]_D^{20}=+50°$ (*c* 1, chloroform). Mol wt 13000 (dichloromethane).

Acryloylquinine[1] was similarly polymerized to give **P-2**.[1] Yield, 56%. $[\alpha]_D^{20}=-14°$ (*c* 1, chloroform). Mol wt 14000 (dichloromethane).

Cross-linking Agents. 1) *N,N'*-diacryloylhexamethylenediamaine (**CA-1**) was prepared by the reaction of hexamethylenediamine with acryloyl chloride according to the method reported previously.[10] Mp 147 °C. Found: C, 64.45; H, 9.00; N, 12.11%. Calcd for $C_{12}H_{20}N_2O_2$: C, 64.28; H, 8.92; N, 12.50%. IR (cm^{-1}): 3300, 1660, 1610. NMR (ppm): 5.5—6.5 (olefinic proton). 2) *N,N'*-Diacryloyldodecamethylenediamine (**CA-2**) was obtained similarly by the reaction of dodecamethylenediamine with acryloyl chloride. Mp 123—125 °C. Found: C, 69.90; H, 10.50; N, 8.70%. Calcd for $C_{18}H_{32}N_2O_2$: C, 70.12; H, 10.38; N, 9.09%. IR (cm^{-1}): 3300, 1665. NMR (ppm): 5.6—6.6 (olefinic proton).

Co-polymers. A solution of **A-3** (700 mg), **CA-1** (224 mg) and azobisisobutyronitrile (10 mg) in dry benzene (10 ml) was refluxed with stirring in an argon atmosphere. After 40 h, a white precipitate was filtered off and washed thoroughly with acetone, benzene, chloroform, ethanol and ethyl acetate, successively. An insoluble polymer (**P-4**) was

obtained in an 80% yield. Acryloylquinine was similarly co-polymerized with **CA-1** (**CA-2**) to give **P-5** (**P-6**) in an 80—90% yield.

Poly(N-benzyl-2-pyrrolidinylmethyl acrylate) (P-1).

N-Benzyl-2-pyrrolidinylmethyl acrylate[1] (2.1 g) containing azobisisobutylronitrile (21 mg) was polymerized without solvents in a sealed tube at 80 °C for 70 h and cooled to room temperature. The product was dissolved in benzene and the solution was poured into methanol. A yellow precipitate was filtered off and washed with methanol. Yield, 50%. $[\alpha]_D^{15} = -43°$ (*c* 1.6, benzene). Mol wt 5300 (dichloromethane).

The polymerization of *N*-benzyl-2-pyrrolidinylmethyl acrylate was not successful under the conditions described for the cases of **P-2** and **P-3**.

The co-polymerization of *N*-benzyl-2-pyrrolidinylmethyl acrylate with **CA-1** and **CA-2** was also unsuccessful and gave only polymers of **CA-1** and **CA-2**. The *N*-benzyl-2-pyrrolidinylmethyl acrylate was largely recovered. The shapes of the ORD and CD curves for **P-1** were similar to those of *N*-benzyl-2-pyrrolidinylmethyl propionate. The hydrolyzed **P-1** showed no optical activity.

These facts suggest that there was no occurrence of asymmetric induction to the main chain configuration of **P-1**.

Similar results[11] were also observed for **P-2**[11a] and **P-3**.

The Addition Reaction of Methanol with PMK. (A)Freshly distilled PMK (330 mg) and **P-5** (11 mg) were added to 25 ml of dry toluene at −78 °C in an argon atmosphere. After addition of methanol (82 mg), the mixture was stirred at the same temperature for 20 h. The end point of the reaction was confirmed by the absence of the yellow color of PMK. After the removsl of **P-5** by filtration, the toluene solution was washed with saturated sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. The solution was evaporated to dryness under reduced pressure. The residue was distilled to give a colorless oil in a 70% yield. Bp 69—71 °C at 2 mmHg. $[\alpha]_D^{20} = -16.2°$ (*c* 10, toluene).

TLC and GLC of the product showed it to be a single material. The IR and NMR spectra of the product were completely in agreement with those of authentic methyl α-phenylpropionate. The addition of methanol to PMK was carried out similarly in the presence of other insoluble catalysts (**P-4** and **P-6**) at various reaction temperatures.

(B) Freshly distilled PMK (330 mg) and **A-2** (8 mg) were added to 25 ml of dry toluene at −78 °C in an argon atmosphere. After the addition of methanol (82 mg), the mixture was stirred at the same temperature for 10 h. The toluene solution was poured into dilute hydrochloric acid. The organic layer separated out was washed with saturated sodium hydrogencarbonate, water, and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled to give an oil in a 72% yield. $[\alpha]_D^{20} = -4.8°$ (*c* 10, toluene).

The structure of this oil was confirmed in the manner described in (A).

The use of other soluble catalysts was similarly attempted at various reaction temperatures.

For the measurement of the samples, a Jasco IRA-1 (IR), a Jeol-60 MC (NMR), a Varian M920 (GLC), a Jasco J-20(ORD,CD), a Rex-automatic polarimeter (specific rotation, length of sample: 10 cm) and a Knauer vapor-pressure osmometer (molecular weight) were used in this experiment.

(Received November 18, 1976)

The driving force for the catalytic activity of metal ions on the reduction of α-keto esters with an NAD(P)H-model compound has been discussed. The scope of the reaction and spectroscopic investigations as well as molecular orbital consideration have revealed that the transition state of the reaction consists of a ternary complex in analogy with a coenzyme-enzye-substrate complex in an enzymic system. It is concluded that, at the transition state, one electron migrates from a model compound to a substrate through a metal ion, which is followed by the transfer of a proton.

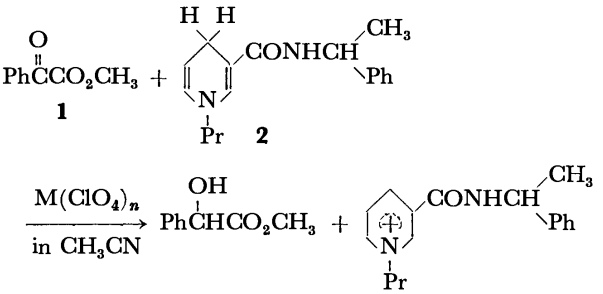
Dihydropyridine nucleotides, NADH and NADPH, are coenzymes which are widely co-operating with dehydrogenases. It has been acepted that the reaction with NAD(P)H proceeds with a one-step hydride transfer from the coenzyme to a substrate.[1,2] On the other hand, recent model reactions revealed that the reduction involves at least one intermediate,[3,4] and that there appear ion-radicals during the reduction.[5,6] ESR signals were also observed with enzymic systems.[7] Yet, the mechanism or the driving force of the reduction with NAD(P)H or its model compounds has not been understood.

In a series of investigations, we found that 1-benzyl-1,4-dihydronicotinamide (BNAH) or its analogs reduces α-keto esters in acetonitrile in the presence of a bivalent metal ion such as magnesium or zinc perchlorate.[8] When the amide-nitrogen is substituted by a chiral group, asymmetric reduction takes place.[8] The ratio of the concentration of metal perchlorate to that of the model compound, but not the absolute concentration of metal perchlorate, influences the optical yield of the product.[9]

The metal ion in the present model reaction may be regarded as a mimetic enzyme in the sense that it catalyzes the reaction as does an enzyme in biological reactions, and the information for the mechanism of the model reaction may provide an insight into the mechanism of enzymic reactions. The purpose of the present paper is focused to elucidate the role of metal-ion catalysts.

Results

Reaction. As was reported, the reaction of methyl benzoylformate (**1**) with *R*-(−)- or *S*-(+)-*N*-(α-methylbenzyl)-1-propyl-1,4-dihydronicotinamide (**2**) afforded *R*-(−)- or *S*-(+)-methyl mandelate, respectively, in quantitative chemical yield with about 15% enantiomeric excess, in the presence of equimolar amount of magnesium perchlorate.[10] When magnesium perchlorate was substituted by lithium perchlorate, the catalytic efficiency decreased remarkably and 6 to 8 molar excess of the lithium salt resulted in the formation



of methyl mandelate in only 60—70% yield. Moreover, it is surprising that the reaction with lithium perchlorate is non-stereospecific. Although less than 1% of enantiomeric excess was observed with the lithium salt, the value was well within the experimental error of ±2%. Tetraethylammonium perchlorate was ineffective to promote the reaction. The reaction was not catalyzed by acetylacetonate magnesium or tris(3-trifluoroacetyl-*d*-camphor)europium, Eu(TFAC)$_3$, effectively; 10 and 12% reductions were observed with these catalysts, respectively.

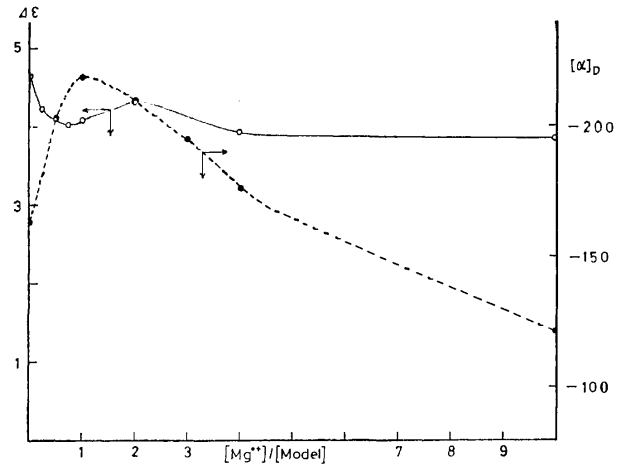

Fig. 1. Variations of $[\alpha]_D$ (----) and maximum intensity in CD spectrum (——) of *N*-(α-methylbenzyl)-1-propyl-1,4-dihydronicotinamide (**2**) as a function of $[Mg^{2+}]/[2]$ (in CH_3CN).

spectrum even at its saturated concentration. The dependencies of the intensity of the CD spectrum, observed at around 350 nm, and $[\alpha]_D$ of **2** on the molar ratio are illustrated in Fig. 1. Chemical shifts of protons in NMR spectrum of **2** were not altered significantly by the addition of magnesium perchlorate.[11] Remarkable shift was observed, however, with the addition of chiral shift reagents, $Eu(TFAC)_3$ and its ytterbium analog. Nevertheless, the protons at the chiral and prochiral centers in *R*- and *S*-**2** behaved similarly (Fig. 2). No appreciable difference was detected from IR spectra of **2** with and without magnesium perchlorate.

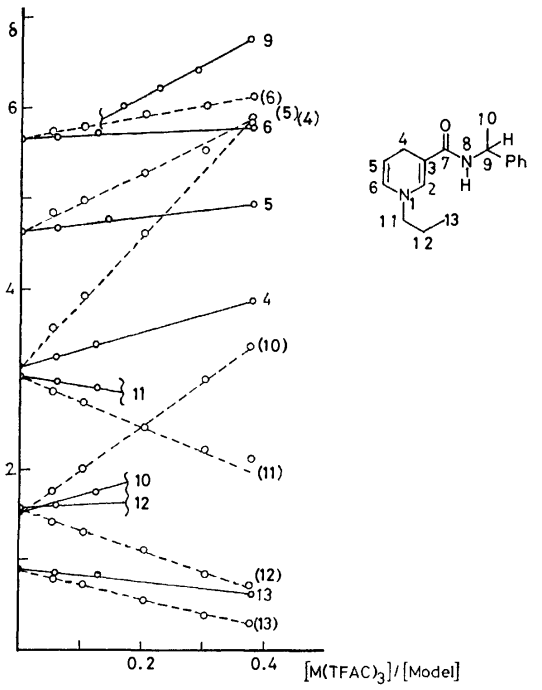

Fig. 2. Variations of chemical shift of protons in *N*-(α-methylbenzyl)-1-propyl-1,4-dihydronicotinamide (**2**) as functions of $[Eu(TFAC)_3]/[2]$ (——) and $[Yb(TFAC)_3]/[2]$ (----) (in $CDCl_3$).

All spectra were recorded with acetonitrile solutions and were not affected by the addition of **1**. The electronic and vibrational spectra of **1** remained unchanged in the presence of magnesium ion.

Discussion

The absorption at around 350 nm is attributed to the π,π^* transition of the dihydropyridine moiety.[12,13] It should be noted that only closed (ring) enamine-structure can account for the absorption at such a long wavelength as 350 nm.[12] All spectral data are in accord with the concept that the metal ion coordinates onto the dihydropyridine moiety instead of the amide-carbonyl; the absorption at 350 nm was affected by the addition of magnesium ion; but not by the addition of tetraethylammonium ion; only slight difference was observed in the CD spectrum; the chiral NMR shift reagent did not discriminate the chiral protons; no shift was observed for the stretching frequencies of the amide–C–O, C=N, and N–H groups; the fact that the band at 350 nm is the longest-wavelength absorption indicates that the π-orbital of the dihydropyridine ring is the highest-occupied molecular orbital (HOMO) of **2**. Coordination of metal ions onto the pyridine ring of nicotinamide has also been witnessed.[14,15] The meaning of minimum and maxima in curves shown in Fig. 1 is equivocal because the absorption spectra did not show an isosbestic point to calculate the dissociation constant of the complex. A complex containing four moelcules of BNAH coordinated onto a magnesium ion has been isolated from an acetonitrile solution.[11] It is also reported that the rate *vs.* molar ratio, $[Mg^{2+}]/[BNAH]$, profile for the reaction of BNAH with 2-benzoylpyridine has a maximum at the ratio of 0.4.[11]

Since the prochiral C_4-protons were shifted in the same extent by the chiral NMR shift reagent, it is apparent that the coordination does not introduce the chirality at the C_4-position, or the C_4-protons still remain to be prochiral in the coordination complex.

The red-shift of the absorption maximum at 350 nm indicates that the decrease of the energy level of the lowest-unoccupied molecular orbital (LUMO) of **2**, by the influence of magnesium ion, is larger than that of the HOMO.[17] Consequently, the hyperconjugative participation of the C_4–H σ-bond to the π-orbital of the dihydropyridine moiety (or, more precisely, the contribution of the C_4–H σ-bond to the molecular orbital which is mainly constituted by π-orbitals of dihydropyridine moiety) becomes larger when magnesium ion coordinates onto the ring. The importance of the C_4-moiety was emphasized at the beginning of this discussion. Under such a circumstance, it is highly unlikely to expect that a hydride ion dissociates from the C_4-position, whereas a proton may easily dissociate because of the developing positive charge on the dihydropyridine ring in the complex. The localization of large positive-charge density on the C_4-protons is also proved by the large down-field shift of the corresponding NMR signal on complexation of **2** with $Yb(TFAC)_3$.[16]

On the other hand, molecular orbital theories have proposed that a positive charge operates to decrease

the energy level of the LUMO of a carbonyl group so that the carbonyl group is activated to accept an electron.[17-19] Since magnesium ion is a bivalent cation, a one-to-one complex of **2** and magnesium ion remains one more positive charge on the magnesium ion formally, which, in the present reaction, may play to activate the substrate, **1**.[20] In other words, an electron migrates from **2** to **1** in the transition-state ternary-complex, **2**-Mg^{2+}-**1**, which is followed by the migration of a proton from the cation-radical of **2** to the anion-radical of **1**.[21,22] The transfer of an electron may or may not precede the migration of a proton. What is the most important here is that an electron and proton move separately and the movement of an electron triggers the migration of a proton. Catalytic activity of alkali and alkaline earth metal ions in an electron-transfer process has been reported and discussed in relation to the polarizabilities of metal ions and ligands.[23] The same kinetic deuterium isotope effect for an electron-transfer process[25] and for the reduction of an organic substrate ($\approx$1.7)[4] as well as large and similar isotope partitioning ratios in products from various reductions ($\approx$4)[1,3,4] also suggest the existence of two distinguishable processes for electron- and proton-migrations.[25] The migration of a second electron seems to take place almost spontaneously, because the pyridinyl radical can gain large stabilization energy by converting into the pyridinium ion.[26] Thus, the chirality in **2** is recognized by **1** in a complex, or with intramolecular fashion. When magnesium ion is substituted by univalent lithium ion, on the other hand, the corresponding binary complex, **2**-Li^+, remains no positive charge on the metal ion and another lithium ion (or ions) has to be used to activate the substrate. In this case, therefore, the reaction takes place bimolecularly and the transition state is so loose that the chirarity in **2** cannot be recognized by **1**. The idea of a positive-charge-promoted reaction discussed above is supported by the inability of tetraethylammonium and chelated metal ions to catalyze the reaction.[20] The dependency of the optical yield on the molar ratio of $[Mg^{2+}]/[\mathbf{2}]$[9] can also be interpreted with the present proposal: under the condition of $[Mg^{2+}]/[\mathbf{2}]<1$, is favored the formation of complexes composed of a magnesium ion and more than two molecules of **2**. The positive charge in such a complex is so diffused that it has no facility to activate the substrate and the situation becomes similar to that with lithium perchlorate.

The scheme for the stereospecific reaction may be represented as follows:

$$MgX_2 \rightleftharpoons MgX^+ + X^-,$$

$$NH + MgX^+ \rightleftharpoons (NH\cdot MgX)^+,$$

$$(NH\cdot MgX)^+ + S \longrightarrow [(NH\cdot Mg\cdot S)^{2+}]^{2+} + X^-$$

$$\downarrow$$

$$N^+ + HSMg^+$$

$$2HSMg^+ + 2X^- \rightleftharpoons Mg(SH)_2 + MgX_2$$

where X, NH, N^+, S, and SH are perchlorate ion, reduced form of a coenzyme-model, oxidized form of a coenzyme-model, α-keto ester, and the anion of α-hydroxy ester, respectively. The double dagger stands for the transition state, which may be depicted as shown in Fig. 3. It seems better, as a minor effect, to take into account the interaction between the amide-carbonyl group and magnesium ion, because the stereospecificity of the reaction depends on the basisity of the carbonyl-oxygen.[27]

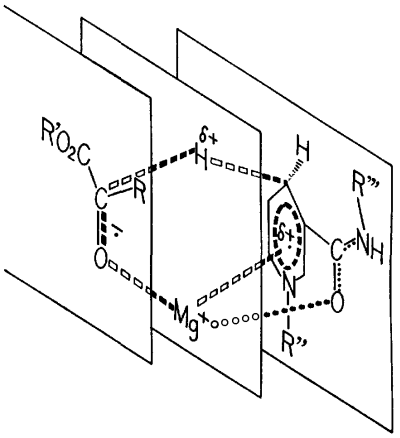

Fig. 3. Schematic representation of the transition state of the reaction.

Mechanistic studies so far reported have had no facility to discriminate the one-step hydride transfer and three-step electron-proton-electron transfer mechanisms and the present paper is the first one to deal with the detailed interaction of molecules at the transition state of the reaction in favor of the latter process. Kinetic studies will provide further support for the discussed concept and the research in our laboratories is in progress toward this end.

Experimental

Preparation and purification of materials and general procedure of the reduction were described previously.[10] Tris(3-trifluoroacetyl-*d*-camphor)-europium and -ytterbium were prepared according to the literature.[28]

UV, IR, NMR, and CD spectra were recorded on Union Giken SM-401, Hitachi EPI-S2, Varian T-60, and Union Giken CD-1000 spectrometers, respectively. Optical rotations were observed with a JASCO DIP-180 automatic polarimeter.

Support for a part of this research by the Ministry of Education, Japanese Government, with a Scientific Research Grant is acknowledged. The authors also wish to thank Dr. S. Inagaki of Gifu University for fruitful discussions on molecular orbital theory.

Direct Synthesis of Methyl Isobutyl Ketone by Reductive Aldol Condensation. III. Kinetics

Yoshiaki WATANABE, Masato OKADA, Yusuke IZUMI, and Yukio MIZUTANI
Tokuyama Soda Co., Ltd., Mikage-cho, Tokuyama, Yamaguchi 745
(Received November 19, 1976)

The kinetics of the direct catalytic conversion of acetone and hydrogen into methyl isobutyl ketone (MIBK) were investigated in the liquid phase using palladium-zirconium phosphate as a catalyst. Kinetic studies on the conversion of acetone into mesityl oxide (4-methyl-3-pentene-2-one) and its hydrogenation were separately carried out using the same catalyst. It was found that the direct reaction proceeded *via* a sequence of processes: mesityl oxide was first formed by condensation of acetone on acid sites of the catalyst and MIBK was then produced by hydrogenation of the mesityl oxide on palladium metal in the catalyst. Moreover, the experimental results were well interpreted by assuming that the condensation of acetone was controlled by a surface reaction between the acetone molecules adsorbed on the catalyst surface and that the rate of hydrogenation of mesityl oxide was determined by a surface reaction between dissociated hydrogen atoms and adsorbed mesityl oxide molecules.

Recently, several processes have been developed for the production of methyl isobutyl ketone (MIBK) by the direct catalytic reaction of acetone with hydrogen on palladium metal supported on solid acids such as cation-exchange resins,[1-5] alumina,[6-8] and zeolite.[9-10]

Some kinetic studies on the catalytic conversion of acetone into mesityl oxide[11] and on the hydrogenation of mesityl oxide[12] have been reported independently, but little work has been done on the kinetics of the direct catalytic reaction of acetone with hydrogen to form MIBK.

In a previous paper,[13] zirconium phosphate containing dispersed metallic palladium was shown to be a highly-active bifuctional catalyst for direct MIBK synthesis.

The present paper deals with the kinetics of the direct reaction using a palladium-zirconium phosphate catalyst (Pd-ZrP Cat). The direct reaction may involve the reversible condensation of acetone to mesityl oxide on the acid sites of zirconium phosphate and consecutive hydrogenation of mesityl oxide to MIBK on the palladium metal:

$$2CH_3COCH_3 \rightleftharpoons (CH_3)_2C{=}CHCOCH_3 + H_2O \quad (1)$$

$$(CH_3)_2C{=}CHCOCH_3 + H_2 \longrightarrow (CH_3)_2CHCH_2COCH_3 \quad (2)$$

The above mechanism was investigated in detail by comparing the rate constants for the direct reaction with those for acetone condensation and hydrogenation of mesityl oxide measured independently.

Experimental

Catalyst and Reagents. Pd-ZrP cat was prepared according to the method described in a previous paper.[13] After being treated with hydrogen, the catalyst was ground to fine powder in order to pass through a 100 mesh sieve. Before use, the catalyst was dried in a stream of nitrogen at 400 °C for 3 h. Acetone and hexane were purified by distillation after the dehydration with P_2O_5 and a molecular sieve 5A, respectively. Commercial mesityl oxide (reagent grade) was used without further purification.

Apparatus and Procedure. Figure 1-A shows the apparatus for the condensation of acetone. The reaction vessel was equipped with a Dry Ice-methanol condenser and a sampling tube with a rubber stopper. The upper part of the reactor

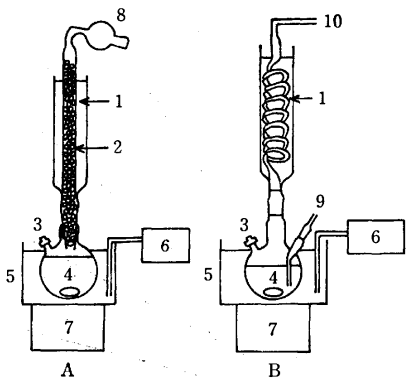

Fig. 1. Apparatus. 1: Dry Ice-methanol condenser, 2: Glass beads, 3: sampling tube, 4: rotator, 5: water bath, 6: water heater and circulator, 7: magnetic stirrer, 8: $CaCl_2$ tube, 9: hydrogen delivery tube, 10: hydrogen gas outlet.

was filled with glass beads to prevent gasification of the reactant, as is shown in Fig. 1-A. The direct conversion of acetone as well as the hydrogenation of mesityl oxide was carried out using the apparatus shown in Fig. 1-B. The reaction vessel was fitted with a hydrogen-delivery tube, a Dry Ice-methanol condenser and a sampling tube. The reaction vessel containing the catalyst (0.1—2.0 g) was filled with hexane, and immersed in a water bath maintained at a given temperature (±0.5 °C). The reaction was initiated by injecting the reactant through the rubber stopper into the reaction vessel with a syringe. The total volume of the reactant and the solvent was maintained constant (50 ml). The reactants were vigorously stirred in order to reduce physical effects to a negligible level. All of the experiments were carried out at a temperature between 30 and 50 °C at atmospheric pressure. Except during the condensation of acetone, hydrogen was continuously introduced into the vessel at a rate of 20 ml/min through the delivery tube, and the vapor of the reactants contained in the exhaust hydrogen gas completely condensed in the Dry Ice-methanol condenser. The product was sampled using a syringe and analyzed by gas chromatography on a column of PEG-1000; the operating conditions were identical to those described previously.[13] In all experiments in the present study, no by-products, such as 4-hydroxy-4-methyl-2-pentanone, 4-methyl-2-pentanol and other high-boiling point products, were detected.

Results and Discussion

Condensation of Acetone to Mesityl Oxide. In order to determine the rate-determining step of the condensation of acetone, the changes in conversion with reaction time at constant volume were measured for different initial concentrations of acetone in hexane (Fig. 2). The conversion rate was approximately proportional to the reaction time. Accordingly, the initial reaction rates for mesityl oxide formation can be determined from the slopes of the straight lines in Fig. 2 and are given in Table 1.

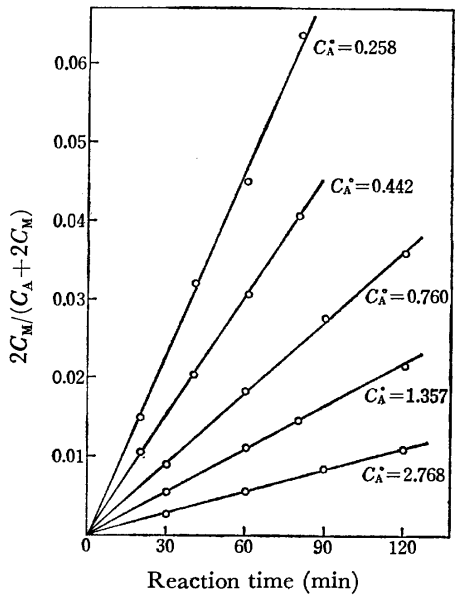

Fig. 2. Effect of the initial concentration of acetone in hexane on the charge in conversion with reaction time. Conditions: temp; 45 °C, catalyst; 1.000 g.

TABLE 1. THE EFFECT OF THE INITIAL CONCENTRATION ON THE INITIAL RATE

Initial concentration of acetone (C_A°) (mol/l)	Initial rate (r_0) (mol/l h g-cat)	$1/C_A^\circ$	$1/\sqrt{r_0}$
0.258	0.01225	3.876	9.03
0.442	0.01358	2.262	8.58
0.760	0.0144	1.316	8.33
1.357	0.0148	0.737	8.22
2.768	0.0153	0.361	8.08

Temp: 45 °C, catalyst: 1000 g.

The over-all reaction is shown by reaction 1. If the reaction between acetone molecules adsorbed on the catalyst surface is rate-determining, the rate equation should be:

$$r = \frac{k_c(C_A^2 - C_M C_W/K)}{(1+K_A C_A + K_M C_M + K_W C_W + K_S C_S)^2}, \quad (3)$$

where k_C denotes the rate constant for acetone condensation, K_A, K_M, K_W, K_S are the adsorption equilibrium constants for acetone, mesityl oxide, water and hexane, respectively, K is the equilibrium constant and C_A, C_M, C_W, and C_S are the concentrations of acetone, mesityl oxide, water and hexane, respectively.

For lower conversion rates, the reverse reaction of acetone condensation and the adsorption terms for mesityl oxide and water in the rate equation are negligible. Assuming that the hexane used as a solvent is not appreciably adsorbed on the catalyst, the adsorption term may be also omitted from the rate equation.[14] Consequently, the initial rate can be expressed in terms of the initial concentration of acetone:

$$r_0 = \frac{k_c C_A^2}{(1+K_A C_A)^2} \quad (4)$$

If the assumptions described above are a reasonable interpretation of the results given in Table 1, the plot of $1/C_A$ *vs.* $1/\sqrt{r_0}$ should be a straight line. In reality, Fig. 3 shows a linear relationship between $1/C_A$ and $1/\sqrt{r_0}$, which suggests that the surface reaction between adsorbed acetone molecules is rate-controlling.

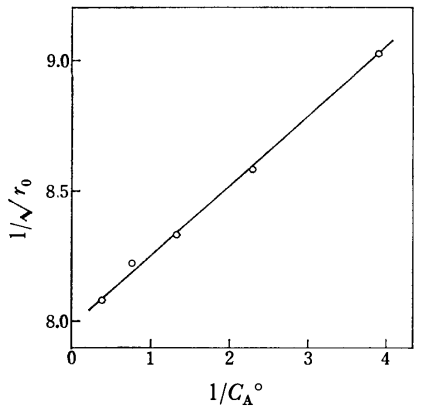

Fig. 3. $1/r_0^{1/2}$ *vs.* $1/C_A^\circ$.

The rate constant and the adsorption equilibrium constant for acetone at unit catalyst concentration calculated from Fig. 3 are shown in Table 2.

TABLE 2. VALUE OF THE RATE PARAMETERS OBTAINED BY FITTING Eq. 3 TO THE DATA SHOWN IN Fig. 2 AT 45 °C

Rate parameter	Value
k_C	17.8 mol/l h g-cat
K_A	33.9 l/mol

Another possible mechanism that the rate-determining step might be the adsorption of acetone, the desorption of mesityl oxide or the desorption of water is unsatisfactory in interpreting the results.

The effect of temperature on the initial reaction rate was examined at an acetone concentration of 2.768 mol/l in the temperature range of between 35 and 50 °C. The relation between the logarithm of r_0 and the reciprocal of the absolute temperature is shown in Fig. 4. The apparent activation energy was calculated to be 18.4 kcal/mol. This value indicates that probably diffusion of the reactants does not control the reaction rate. The activation energy for the formation of 4-hydroxy-4-methyl-2-pentanone from acetone with a base catalyst has been reported to be 17.3 kcal/mol by

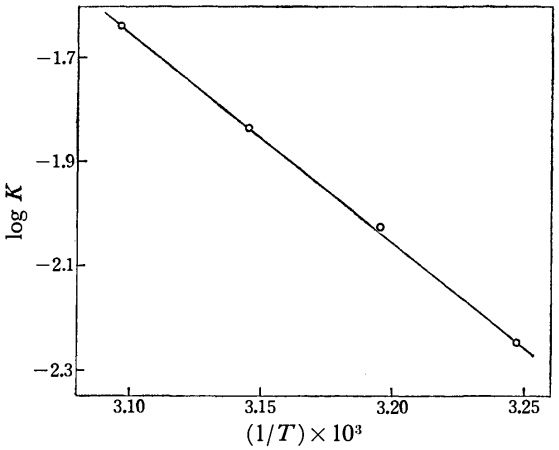

Fig. 4. Arrhenius plot.

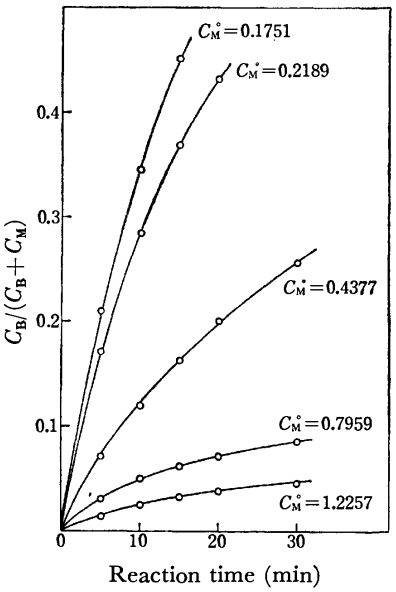

Fig. 5. Effect of the initial concentration of mesityl oxide in hexane on the charge in conversion with reaction time. Conditions: temp; 45 °C, catalyst; 0.500 g.

Lemcoff *et al.*[15]

Hydrogenation of Mesityl Oxide. The changes in the conversion rate with reaction time at constant volume were measured with different initial concentrations of mesityl oxide in hexane, as is shown in Fig. 5. The rate of hydrogenation of mesityl oxide decreases gradually with reaction time.

In order to estimate the initial rates with accuracy, the time-conversion curve shown in Fig. 5 can be empirically represented by the following third-order equation:

$$B = Xt^3 + Yt^2 + Zt, \tag{5}$$

where B denotes $C_B/(C_B+C_M)$ after reaction time t and X, Y, and Z are constants. The rate after reaction time t is derived from Eq. 5 and is found to be:

$$\frac{dB}{dt} = 3Xt^2 + 2Yt + Z \tag{6}$$

Thus, the initial rate is given by

$$\left(\frac{dB}{dt}\right)_{t=0} = Z. \tag{7}$$

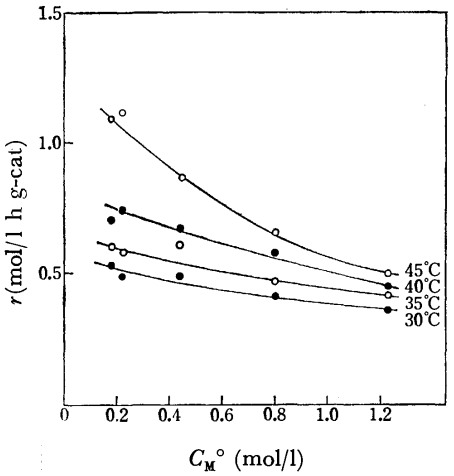

Fig. 6. Effect of the initial concentration of mesityl oxide on the initial rate at various reaction temperatures.

The initial rates for hydrogenation of mesityl oxide are plotted against the initial concentration of mesityl oxide in Fig. 6. The results suggest that the reaction proceeds according to the Langmuir-Hinshelwood mechanism, in which hydrogen and mesityl oxide are absorbed competitively. The rate equation corresponding to the mechanism is

$$r = k_H \cdot \theta_H \cdot \theta_M, \tag{8}$$

where k_H denotes the rate constant of the surface reaction, θ_H the fractional surface coverage of hydrogen, and θ_M that of mesityl oxide. From Eq. 8 Teranishi *et al.*[14] and Kubomatsu *et al.*[16] have obtained

$$r_0 = \frac{k_H \cdot b \cdot C_M}{(1+bC_M)^2}, \tag{9}$$

where C_M denotes the concentration of mesityl oxide, and b is a function of the hydrogen concentration.

When the rate of hydrogenation is measured at constant hydrogen pressure, and the solubility of hydrogen is considered to be independent of the composition of the reaction mixture, b has a constant value at a given temperature. The adsorption of hexane is negligible.

Equation 9 can be rearranged to

$$\left(\frac{C_M}{r_0}\right)^{1/2} = \left(\frac{1}{k_H \cdot b}\right)^{1/2} + \left(\frac{b}{k_H}\right)^{1/2} C_M. \tag{10}$$

Plots of $(C_M/r_0)^{1/2}$ *vs.* C_M at various reaction temperatures are straight lines, as is shown in Fig. 7.

Assuming that hydrogenation occurs between the dissociated hydrogen atoms and the molecules of mesityl oxide adsorbed on the catalyst surface, the plot of $(C_M/r_0)^{1/3}$ *vs.* C_M should be a straight line. However, such plots actually deviate from straight lines, as is shown in Fig. 8.

The adsorption of mesityl oxide, the adsorption of hydrogen with or without dissociation, or the desorption of MIBK might be considered as the rate-controlling step, although they do not reasonably explain the data.

On the other hand, the fact that the rate of formation of MIBK decreases gradually with reaction time, as is shown in Fig. 5, suggests that the rate is retarded by the

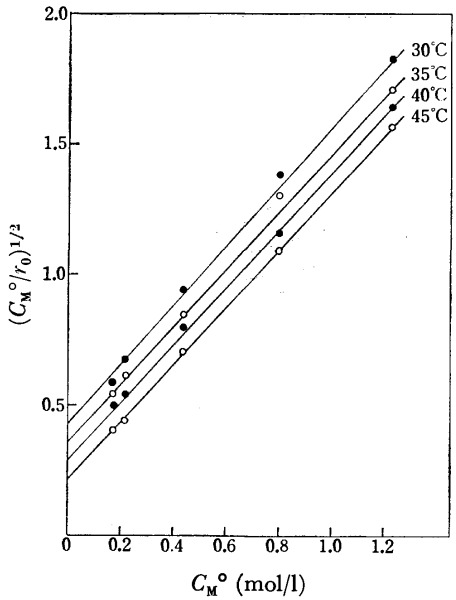

Fig. 7. $(C_M°/r_0)^{1/2}$ *vs.* $C_M°$.

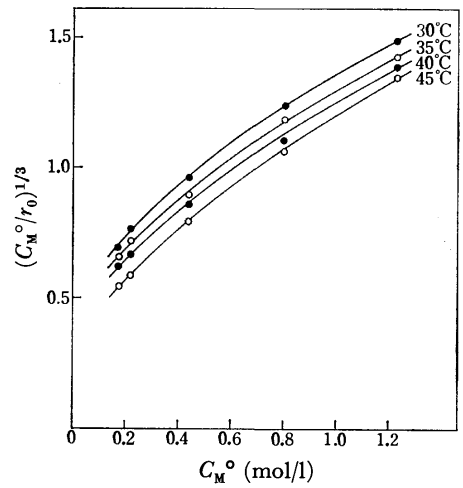

Fig. 8. $(C_M°/r_0)^{1/3}$ *vs.* $C_M°$.

adsorption of MIBK onto the catalyst. By introducing the MIBK adsorption term into Eq. 9, we obtain

$$r = \frac{k_H \cdot b \cdot C_M}{(1+bC_M+K_BC_B)^2} \tag{11}$$

Using Eq. 11, the values of k_H, b, and K_B obtained from the data shown in Fig. 5 are given in Table 3.

TABLE 3. VALUES OF THE RATE PARAMETERS OBTAINED BY FITTING Eq. 11 TO THE DATA SHOWN IN Fig. 5 AT 45 °C

Rate parameter	Value
k_H	3.70 mol/l h g-cat
b	4.75 l/mol
K_B	19.65 l/mol

The relation between the logarithm of k_H calculated from the plots in Fig. 7 and the reciprocal of the absolute temperature is shown in Fig. 9. The apparent activation energy for the hydrogenation of mesityl oxide is 8.1 kcal/mol. This value is considered to be reasonable

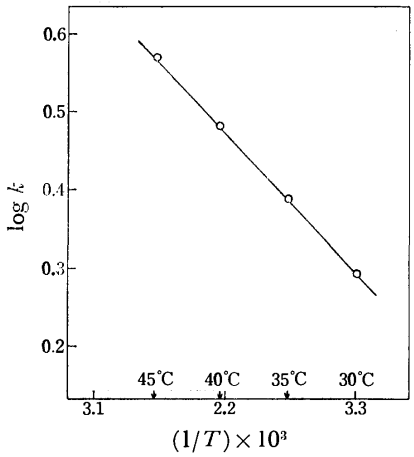

Fig. 9. Arrhenius plot.

compared with those reported by other authors.[14,16]

Direct conversion of Acetone and Hydrogen to MIBK.

In the direct conversion of acetone and hydrogen to MIBK using a bifuctional catalyst, it appears probable that the condensation of acetone on the acid sites of the catalyst and hydrogenation of the resultant mesityl oxide on palladium metal occur in succession.

The rate equations for the consecutive reactions are obtained by combining the individual rate equations obtained from studies of acetone condensation and of the hydrogenation of mesityl oxide. Considering that the direct synthesis of MIBK was carried out in an acetone medium and that the hydrogenation was separately investigated in a medium of mesityl oxide–hexane, the rate equation for hydrogenation of mesityl oxide by direct synthesis may include an adsorption term for acetone:

$$-\frac{dC_A}{dt} = 2\frac{dC_M}{dt} = 2\frac{dC_W}{dt} = \frac{K_1C_A^2}{(1+33.9C_A)^2}, \tag{12}$$

$$\frac{dC_B}{dt} = \frac{17.8C_M}{(1+4.75C_M+K_A'C_A+19.65C_B)^2} \tag{13}$$

where k_1 denotes the apparent rate constant for acetone condensation.

The above differential equations were integrated using the Runge-Kutta-Gill method. The minimum value of the sum of the square of the difference between the experimental and the calculated concentration distributions was chosen as the parameter using Hill-Climbing, as is given in Table 4.

The apparent rate constant for acetone condensation and the adsorption equilibrium constant for acetone at unit catalyst concentration were calculated from the data in Table 4 as given in Table 5.

The molar fractions of mesityl oxide and MIBK for various reaction times were calculated from Eqs. 12 and 13 by substituting the numerical values for k_1 and K_A'. The solid curves shown in Fig. 10 are in good agreement with the data.

The value of k_1 is about 1.6 times larger than that of the rate constant K_C obtained independently from the study of acetone condensation. The reason for this is not obvious at the present time. However, the difference appears to be due to experimental error.

Table 4. Data for the direct conversion of acetone and hydrogen to MIBK

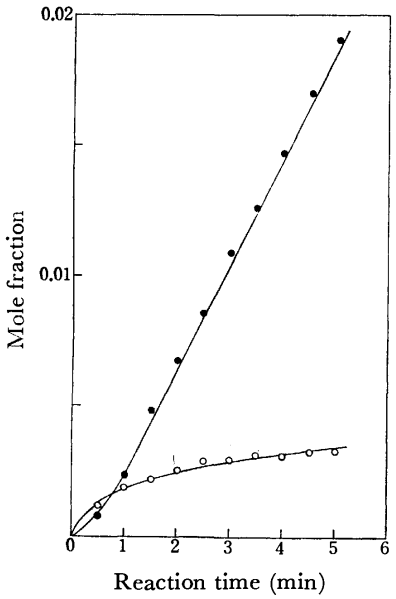

Fig. 10. Comparison of calculated curves with experimental data.
●: y_B, ○: $y_{M'}$, ——: calculated curve.

When the condensation reaction of acetone to mesityl oxide and the direct reaction of acetone and hydrogen to MIBK are carried out in acetone alone using the apparatus shown in Fig. 1-B, both rate constants are approximately equal. On the other hand, when the condensation of acetone to mesityl oxide is carried out using the apparatus shown in Fig. 1-B or when direct conversion of acetone to MIBK is carried out in a mixture of acetone and hexane, reproducible data cannot always be obtained.

In conclusion, the direct reaction by reductive aldol condensation over a Pd–ZrP catalyst involves the condensation of acetone to mesityl oxide on the acid sites of the catalyst and subsequent hydrogenation of the mesityl oxide to MIBK on the palladium metal dispersed over the catalyst.

The authors express their sincere thanks to Prof. Yoshinobu Takegami of Kyoto University and to Dr. Yasuharu Onoue, Director of the Tokuyama Soda Co. for valuable discussion and advise.

Nomenclature

k	Reaction rate constant (mol/l h g-cat).
K	Equilibrium constant (1/mol).
K_1	Adsorption equilibrium constant of component i (1/mol).
r	Reaction rate (mol/l h g-cat).
t	Time.
C_i	Concentration of component i (mol/l).
C_t	Total concentration of reactants.
θ_i	Fractional surface coverages of component i.
y_i	Molar fraction of component i.
T	Temperature (K).
b, X, Y, Z	Constant.
Suffixes	
A	Acetone.
M	Mesityl oxide.
W	Water.
B	MIBK.
H	Hydrogen.
i	General component.
o	Initial rate of reaction.
t	Total.
c	Condensation.
h	Hydrogenation.

A One-step Synthesis of 2,7-Dimethyl-5-silaspiro[4.4]nona-2,7-diene and the Synthesis of Its Derivatives

Daiyo TERUNUMA, Satoshi HATTA, Tsunao ARAKI,* Tadashi UEKI, Tsutomu OKAZAKI, and Yasutaka SUZUKI

Department of Applied Chemistry, Faculty of Engineering, Saitama University, Urawa, Saitama 338

(Received November 27, 1976)

The *in situ* reaction of dialkoxydichlorosilanes, such as dimethoxy-, diethoxy-, dipropoxy-, dibutoxy-, and diisobutoxydichlorosilane, with isoprene and magnesium in tetrahydrofuran (THF) was investigated. It was found that the double annelation product, *i.e.*, 2,7-dimethyl-5-silaspiro[4.4]nona-2,7-diene (**1**), was obtained from diethoxy-, dipropoxy-, and dibutoxydichlorosilane in 87.0, 65.2, and 66.5% yields respectively. On the other hand, the reaction of dimethoxy- and diethoxydichlorosilane with butadiene and magnesium in THF gave 5-silaspiro[4.4]nona-2,7-diene (**7**) in 20.7 and 35.4% yields respectively. Several silaspirononane derivatives were synthesized from **1**.

Recently, Salomon reported on the synthesis of 5-silaspiro[4.4]nona-2,7-diene by a one-step reaction[1] from silicon tetrachloride and the butadiene-magnesium complex prepared from active-magnesium[2] and butadiene. Takase *et al.* reported independently on the preparation of silaspiro compounds by treating silicon tetrachloride with diene-magnesium compound in a step-by-step manner.[3] In a preliminary communication,[4] we have reported on a convenient method for the preparation of 2,7-dimethyl-5-silaspiro[4.4]nona-2,7-diene (**1**). The double annelation product was obtained in a high yield when a mixture of diethoxydichlorosilane and isoprene in a molar ratio of 1/2 was refluxed in the presence of magnesium in THF. In this paper we wish to describe further details of the double annelation reaction and the synthesis of the derivatives of **1**.

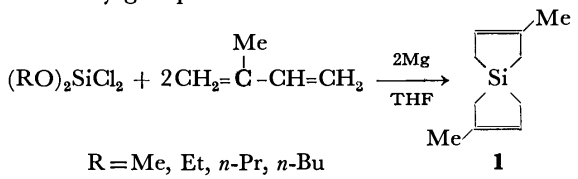
Results and Discussion

Reaction of Dialkoxydichlorosilanes with Isoprene and Magnesium. Dialkoxydichlorosilanes, such as dimethoxy-(**2**), diethoxy-(**3**), dipropoxy-(**4**), dibutoxy-(**5**), and diisobutoxydichlorosilane(**6**), were obtained by means of disproportionation reactions between the appropriate tetraalkoxysilane and silicon tetrachloride in a manner described by Kumada[5] [Table 1].

$$Si(OR)_4 + SiCl_4 \xrightarrow[30\,h]{160^\circ C} ROSiCl_3 + (RO)_2SiCl_2 + (RO)_3SiCl$$

R=Me, Et, *n*-Pr, *n*-Bu, *i*-Bu

To investigate the effect of the varieties of alkoxyl groups of dialkoxydichlorosilanes in the preparation of **1**, the reactions of dialkoxydichlorosilanes (R=Me, Et, Pr, Bu) with two mole equivalents of isoprene and magnesium were carried out in THF [Table 2]. It was observed that the magnesium dichloride precipitated at the beginning of the exthothermic reaction dissolved gradually as the reaction proceeded. The reaction mixture became homogenous at the end of the reaction. These observations presumably indicate that the isoprene-magnesium complex reacts with dialkoxydichlorosilanes in 2 steps, *i.e.*, a first reaction with chloride groups, and a second reaction with alkoxide groups. In this reaction it was found that **3** was the best agent for the preparation of the double annelation product(**1**). In contrast, **2**, like silicon tetrachloride, was found to be less effective for the preparation of **1**. The predominance of the yield of **1** in the reaction using **3** as the starting material may be considered to be because **3** contains Si–Cl and Si–OR bonds which have a suitable reactivity difference from the isoprene-magnesium complex without decreasing the reactivity of the alkoxy group itself.



R=Me, Et, *n*-Pr, *n*-Bu **1**

The reactions of the dialkoxydichlorosilanes with equimolar amounts of isoprene and magnesium were then carried out. When such dialkoxydichlorosilanes as **3**, **4**, **5**, and **6** were employed in the reaction, it was found, by GLC analysis of the reaction mixture, that not only the mono annelation product, *i.e.*, 1,1-dialkoxy-

3-methyl-1-sila-3-cyclopentene(**7**), but also the double annelation product(**1**) and tetraalkoxysilanes were formed [Table 3]. These results may support the above consideration that the 2-mole-equivalent reaction of isoprene-magnesium complex with unimolar dialkoxydichlorosilanes proceeds in 2 steps:

$$(RO)_2SiCl_2 + CH_2{=}\overset{\overset{Me}{|}}{C}{-}CH{=}CH_2 \xrightarrow[THF]{Mg} \mathbf{7} + \mathbf{1} + Si(OR)_4$$

R=Et, *n*-Pr, *n*-Bu, *i*-Bu

Table 3. Reaction of dialkoxydichlorosilanes with equimolar amounts of isoprene and magnesium

$(RO)_2SiCl_2$ R=	Yield[a] (%)		
	7	**1**	$Si(OR)_4$
Me	5	5	5
Et	32.5	23.2	23.1
n-Pr	40.0	20.1	25.0
n-Bu	49.4	18.9	18.4
i-Bu	36.5	10.1	15.4

a) The yields were estimated by GLC.

It may be considered that the tetraalkoxysilanes found in the above experiment resulted from the reaction of magnesium dialkoxides with dialkoxydichlorosilanes as follows:

$$\mathbf{7} \xrightarrow[\text{isoprene}]{Mg} \mathbf{1} + Mg(OR)_2$$

$$Mg(OR)_2 + (RO)_2SiCl_2 \longrightarrow Si(OR)_4 + MgCl_2$$

When butadiene was used as an annelating agent, **2** and **3** gave 5-silaspiro[4.4]nona-2,7-diene(**8**) in 20.7 and 35.4% yields respectively.

$$(RO)_2SiCl_2 + CH_2{=}CH{-}CH{=}CH_2 \xrightarrow[THF]{Mg} \underset{\mathbf{8}}{Si} + Si(OR)_4$$

R=Me, Et

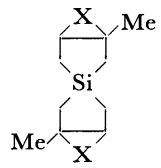
On the other hand, when the reaction of **3** and the Grignard reagent prepared from 1,4-dibromobutane in a molar ratio of 1/2 was carried out, 5-silaspiro[4.4]nonane(**9**) was obtained in a 61.6% yield.

$$2Br(CH_2)_4Br + (EtO)_2SiCl_2 \xrightarrow[Et_2O]{Mg} \underset{\mathbf{9}}{Si}$$

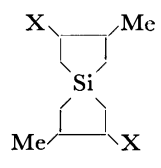
West[6] obtained **9** in a 26.5% yield by the treatment of silicon tetrachloride with the same Grignard reagent, followed by treatment with the organolithium reagent prepared from 1,4-dibromobutane. These results indicate that **3** is also useful for the one-step synthesis of **9**.

Preparation of the Derivatives of **1**. The new derivatives of silaspirononane synthesized in the present work are 2,7-dimethyl-2,3: 7,8-dimethylene-5-silaspiro-[4.4]nonane(**10**), 2,7-dimethyl-2,3: 7,8-diepoxy-5-silaspiro[4.4]nonane(**11**), 2,7-dimethyl-5-silaspiro[4.4]-nonane(**12**), 2,7-dimethyl-5-silaspiro[4.4]nonane-3,8-diol(**13**), and 2,7-dimethyl-5-silaspiro[4.4]nonane-3,8-diamine (**14**). The silaspirononane **10** was obtained in a 54.9% yield by using the Simmons-Smith agent.[7] The silaspirononane **11** was obtained in a 65.4% yield by the treatment of **1** with perbenzoic acid in chloroform.[8] The structural assignment was done by the analysis of the IR and NMR spectra. (**10**, IR spectrum; -CH- in the cyclopropane ring, 3030 cm^{-1}; skeletal vibration, 1030, 1010 cm^{-1}: **11**, IR spectrum; skeletal vibration, 1040, 1005 cm^{-1}; NMR spectrum; (δ) 3.0—3.1 $\diagup O \diagdown H$).

The hydrogenation of **1** by using Pd-C catalyst in hexane gave **12** in a 78.8% yield. Although the hydrogenation of 1,1,3-trimethyl-1-sila-3-cyclopentene(**15**) using Pd-C catalyst in methanol afforded only a ring-opening product, *i.e.*, dimethylmethoxyisopentylsilane,[7b] that of **1** in the presence of methanol gave **12** in a 64.4% yield. The hydroboration of **1**, followed by treatment with hydrogen peroxide in the presence of sodium hydroxide[8b,9] or with hydroxylamine-*O*-sulfonic acid,[10] gave **13** and **14** in 46.0 and 46.8% yields respectively. A large excess of diborane was required to attain the complete hydroboration of the bifunctional compound (**1**). The diol **13** and the diamine **14** were identified by the analysis of the IR and NMR spectra. (**13**, IR spectrum; skeletal vibration, 1075, 1040, 1030 cm^{-1}; NMR spectrum; (δ) 3.6 (CH-O): **14**, IR spectrum; skeletal vibration, 1075, 1040, 1030 cm^{-1}; NMR spectrum; (δ) 2.7 (CH-N)).

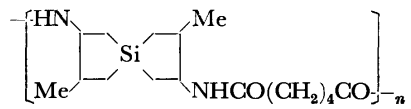


10: X=CH_2
11: X=O



12: X=H
13: X=OH
14: X=NH_2

The interfacial polycondensation reaction[11] of the diamine(**14**) with adipoyl dichloride was carried out, and a white solid polymer (**16**) ([η]=1.07) was thus obtained in a 69.8% yield. The polymer was soluble in methanol and ethanol, but insoluble in such solvents as ether, benzene, and acetone.



16

Experimental

All the boiling and melting points are uncorrected. The IR and mass spectra were recorded on a JASCO IR-2A spectrometer and on a JEOL-01SG instrument respectively. The NMR spectra were recorded on a Varian A-60 spectrometer in CCl_4 using TMS as the internal standard. The analytical GLC was carried out with a Shimadzu GC-3A chromatograph [1.5 m, 15% SE-30 on Chromosorb W (60—80 mesh)].

Preparation of Dialkoxydichlorosilanes. A mixture consisting of the appropriate tetraalkoxysilane and silicon tetrachloride was placed into a sealed glass tube. The reaction tube was then maintained at 160 °C (at 150 °C for tetramethoxysilane) for 30 h. The fractional distillation of the reaction mixture by using a 1×60 cm column packed with Fenske ring gave the dialkoxydichlorosilanes in about a 60% yield. The results are shown in Table 1.

*Reaction of **3** with Two Mole Equivalents of Isoprene and Mg.* A mixture of **3** (75.5 g, 0.4 mol), isoprene (68.0 g, 1.0 mol), and Mg (21.4 g, 0.88 mol) in dry THF (300 ml) was refluxed with stirring for 30 h under a nitrogen atmosphere. During the reaction, the internal temperature gradually rose from 60 to 69 °C. After the removal of the solvent from the reaction mixture, dry hexane (150 ml) was added to the residue, and then the deposited magnesium salts was separated by filtration. The distillation of the mixture gave **1** in a 87.0% (57.2 g) yield. NMR: (δ) 1.1—1.4 (m, 8H, Si-CH_2) 1.5—1.7 (m, 6H, C-CH_3) 4.9—5.2 (m, 2H, =CH). IR (neat): 2900, 1640, 1450, 1430, 1400, 1220, 1160, 1100, 1030, 1010, 760 cm^{-1}. Mass, *m/e* 164 (M^+). Bp 140 °C/105 Torr, n_D^{20} 1.5062, d_4^{25} 0.9897. Found: Si, 17.1%. Calcd for $C_{10}H_{16}Si$: Si, 17.2%.

The reaction of **4** and **5** with isoprene and Mg was carried out in THF under the reaction conditions described above. These results are shown in Table 2.

*Reaction of **3** with Equimolar Amounts of Isoprene and Mg.* A mixture of **3** (25 g, 0.13 mol), isoprene (16.5 g, 0.24 mol), and Mg (3.2 g, 0.13 mol) in dry THF (160 ml) was refluxed with stirring for 30 h under a nitrogen atmosphere. After the removal of the solvent, dry hexane (150 ml) was added to the residue, and the deposited magnesium salts were filtered off. The resulting solution was evaporated to give 1,1-diethoxy-3-methyl-1-sila-3-cyclopentene (**17**), **1**, and tetraethoxysilane in 32.5, 23.2, and 23.1% yields respectively, as determined by GLC analysis. **17**, NMR: (δ) 1.1 (t, 6H, CH_3), 0.9—1.2 (m, 1H, Si-CH_2), 1.5—1.6 (m, 3H, =C-CH_3), 3.4 (q, 4H, O-CH_2), 5.0 (m, 1H, =CH). IR (neat): 2900, 1640, 1440, 1400, 1160, 1080, 1030, 1010, 780 cm^{-1}. Mass, *m/e* 172 (M^+). Bp 190 °C, n_D^{25}1.4389.

The reaction of **4**, **5**, and **6** with isoprene and Mg was carried out in THF under the reaction conditions described above, and the yields of the products were estimated by GLC. These results are shown in Table 3.

*Reaction of **3** with Butadiene and Mg.* A mixture of **3** (18.9 g, 0.1 mol), Mg (8.2 g, 0.3 mol), and dry THF (150 ml) was placed in a flask equipped with a magnetic stirrer and a Dry Ice trap. Butadiene was then introduced into the mixture at room temperature under a nitrogen atmosphere. After stirring for 30 h, saturated aq NH_4Cl (100 ml) was added to the mixture. The organic layer was separated and then treated with 4M NaOH at room temperature for 24 h in order to hydrolyze the side reaction product, *i.e.*, tetraethoxysilane. Then the mixture was washed with two 50 ml portions of water, and dried over Na_2SO_4. Evaporation and distillation gave **8** in a 35.4% (4.8 g) yield. Bp 102 °C/72 Torr (lit, 65—68 °C/13 Torr).[1] In a similar manner, when **2** was employed in place of **3**, **8** was obtained in a 20% yield.

*Preparation of **9**.* A mixture of **3** (23.2 g, 0.12 mol) and 1,4-dibromobutane (53.0 g, 0.25 mol) in diethyl ether (100 ml) was added, over a 3-h period to magnesium (14.2 g, 0.58 mol) in diethyl ether (400 ml). After stirring had been continued for an additional 8 h, 150 ml of water was added to the mixture. The organic layer was separated, washed with water, and then dried over $CaCl_2$. Evaporation and distillation gave **9** in a 61.6% (10.6 g) yield. Bp 103 °C/90 Torr (lit, 178.5 °C).[6]

*Preparation of **10**.* A mixture of **1** (3.3 g, 0.02 mol) and diiodomethane (26.8 g, 0.1 mol) in dry ether was refluxed in the presence of a Zinc-Copper couple (6.5 g) with stirring for 30 h. The ether slution was decanted from the unreacted couple, washed with two 30 ml portions of saturated aq NH_4Cl, and then dried over Na_2SO_4. Fractional distillation gave **10** in a 54.9% (2.1 g) yield. NMR: (δ) −0.2, 0.5 (m, 4H, $\angle CH_2 \rangle$), 0.7—1.2 (m, 8H, Si-CH_2), 1.2—1.5 (m, 6H, C-CH_3). IR (neat): 3030, 2900, 1440, 1400, 1250, 1180, 1160, 1120, 1060, 1030, 1010, 930, 850, 750 cm^{-1}. Bp 110—112 °C/34 Torr, n_D^{20} 1.5033, d_4^{25} 0.9802. Found: Si, 14.6%. Calcd for $C_{12}H_{20}Si$: Si, 14.9%.

*Preparation of **11**.* To a solution of perbenzoic acid (0.09 mol) in chloroform (157 ml), **1** (4.9 g, 0.03 mol) was added at 5 °C over 1 h. After the mixture had been maintained at 5 °C for two days, benzoic acid and excess perbenzoic acid were extracted with 1M NaOH (200 ml). The chloroform solution was washed with two 60 ml portions of water, and then dried. The removal of the solvent under reduced pressure at room temperature, followed by distillation, gave **11** in a 65.3% (3.8 g) yield. NMR: (δ) 0.7—1.3 (m, 8H, Si-CH_2), 1.2—1.5 (m, 6H, C-CH_3), 3.0—3.1 (m, 2H, $\overline{O}\wedge H$); IR (neat): 2950, 1450, 1390, 1260, 1180, 1040, 1005, 950, 900, 830, 780, 760 cm^{-1}. Bp 80 °C/0.45 Torr, n_D^{20} 1.4969, d_4^{25} 0.9974. Found: Si, 14.3%. Calcd for $C_{10}H_{16}O_2Si$: Si, 14.9%.

*Preparation of **12**.* Compound **1** (6.6 g, 0.04 mol) was hydrogenated in a catalytic hydrogenating apparatus in hexane, using palladium charcoal (0.3 g) as the catalyst, at room temperature. The hydrogen up-take was almost theoretical. After the removal of the solvent, distillation gave **12** in a 78.7% (5.3 g) yield. NMR: (δ) 0.2—1.0 (m, 8H, Si-CH_2), 1.0 (d, 6H, -CH_3), 1.1—2.0 (m, 6H, -CH_2-CH-). IR (neat): 2940, 1450, 1405, 1370, 1180, 1080, 1040, 1030, 970, 840, 780, 750, 720 cm^{-1}. Bp 105—107 °C/45 Torr, n_D^{20} 1.4079, d_4^{20} 0.8682. Found: Si, 16.9%. Calcd for $C_{10}H_{20}$-Si: Si, 16.7%.

*Preparation of **13**.* Gaseous diborance generated from $NaBH_4$ (2.8 g) in diglyme and BF_3OEt_2 was added to a solution of **1** (8.2 g, 0.05 mol) in THF (125 ml) at 0 °C over a period of 2 h. After the mixture had then been stood for 2 h at room temperature, small chips of ice were added to hydrolyze the excess diborane. The solution was then immersed in an ice bath, and 3M NaOH (11 ml) was added, followed by 30% H_2O_2 (11 ml) over a period of 1 h. One hour later the organic layer was extracted with ether. The combined organic layer was dried and distilled to yield 4.6 g (46.0%) of **13**. NMR: (δ) 0.25—0.6 (m, 4H, Si-CH_2), 0.95 (d, 6H, C-CH_3), 0.7—1.3 (m, 4H, Si-CH_2-C-O), 1.5—2.1 (m, 2H, CH), 2.4 (s, 2H, OH), 3.6 (q, 2H, CH-O). IR (neat): 3300, 2900, 1450, 1400, 1330, 1250, 1190, 1130, 1075, 1040, 1030, 1000, 900, 840, 800, 780 cm^{-1}. Bp 122 °C/0.1 Torr. Found: Si, 14.9%. Calcd for $C_{10}H_{20}Si$: Si, 14.0%.

*Preparation of **14**.* Gaseous diborane generated from $NaBH_4$ (4.5 g, 0.12 mol) in diglyme and BF_3OEt_2 was added

to a solution of **1** (6.6 g, 0.04 mol) in diglyme (100 ml) at 0 °C over a period of 3 h. After the mixture was stood for 2 h at room temperature, a solution of NH_2OSO_3H (18.1 g, 0.16 mol) in diglyme (30 ml) was added. The solution was then refluxed for 4 h. The mixture was cooled, treated with concd HCl (32 ml), and poured into water (200 ml). The acidic solution was then made strongly alkaline with a concd NaOH solution, and the liberated amine was extracted with ether. The extracts was dried over KOH, and the solvent was evaporated. The residual solid product was distilled to yield 3.7 g (46.8%) of **14**. NMR: (δ) 0.25—0.7 (m, 4H, Si-CH_2), 0.95 (d, 6H, C-CH_3), 0.8—1.3 (m, 4H, Si-CH_2-CN), 1.0 (s, 4H, NH_2), 1.3—1.9 (m, 2H, CH), 2.7 (q, 2H, CH-N). IR (neat): 3350, 2900, 1560, 1450, 1360, 1100, 1075, 1040, 1030, 800, 760 cm^{-1}. Mass: *m/e* 198 (M^+). Mp 53 °C, Bp 79 °C/0.5 Torr. Found: N, 13.90, Si, 13.9%. Calcd for $C_{10}H_{22}N_2Si$: N, 14.11, Si, 14.2%.

*Polycondensation of **14** with Adipoyl Dichloride.* A solution of adipoyl dichloride (0.17 g, 0.93 mmol) in CCl_4 (7 ml) was placed in beaker. A solution of **14** (0.5 g, 2.5 mmol) in 3.3 ml of water was then carefully poured over the acid chloride solution. The polymeric film which formed at the interface of the two solutions was grasped with tweezers and raised from the beaker. Yield 0.2 g (69.8%). IR(KBr): 3250, 2950, 1640, 1540, 1460, 1400, 1280, 1160, 1075, 1010, 770 cm^{-1}. $[\eta]=1.07$ (MeOH). Found: N, 8.73%. Calcd for $C_{16}H_{28}N_2O_2Si$: N, 9.80%.

The authors wish to thank Professor Nohira for his many helpful discussions and the Nihon Gosei-Gomu Co. for providing the isoprene.

Chemistry of 1,3-Glycol Derivatives. II. Lithium Aluminium Hydride and Meerwein-Ponndorf-Verly Reductions of 6,6-Dimethylspiro[2.5]octane-4,8-dione

Osamu Itoh, Tsutomu Okita, Makoto Umezu, Masashi Inoue, and Katsuhiko Ichikawa*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received December 6, 1976)

Lithium aluminium hydride reduction of 6,6-dimethylspiro[2.5]octane-4,8-dione in tetrahydrofuran gave *cis*- and *trans*-6,6-dimethylspiro[2.5]octane-4,8-diols. Almost the same ratio of *cis*: *trans*=1: 2 was obtained with various substrate-reagent ratios. In the case of Meerwein-Ponndorf-Verly reduction, however, *cis*-diol was obtained almost exclusively. It is clear that the former reduction gave kinetically-controlled products and that the latter gave thermodynamically-stable products. Unusual results were obtained by changing the hydrolysis conditions for the lithium aluminium hydride reduction products and these are explained assuming that the intermediate aluminium alkoxide is oxidized by acid.

The reduction of 6,6-dimethylspiro[2.5]octane-4,8-dione (**1**) produces *cis*- and *trans*-6,6-dimethylspiro[2.5]-octane-4,8-diols (*cis*- and *trans*-**2**). Because of the special structure of **1**, a study of the steric course will provide a convenient tool for examining the mechanism for various reducing reagents and the spectral data of the resulting diol will be useful in stereochemistry. In this article, the results of lithium aluminium hydride and Meerwein-Ponndorf-Verly reductions of **1** are reported.

Lithium aluminium hydride reduction of **1** in tetrahydrofuran at 0 °C gave two kinds of diols, A and B, which were separated by fractional recrystallization from chloroform. As mentioned below, it was concluded that A (mp 166—168 °C) is *cis*-**2** and B (mp 119—121 °C) is *trans*-**2**.

The melting points of the *cis*- and *trans*-isomers of 1,3-cyclohexanediols appear to be related to the conformations. The melting points of the *cis*-isomers which can form intramolecular hydrogen bonds are higher than those of the *trans*-isomers, but this relation is reversed in cases where the intramolecular hydrogen bond is difficult to form due to steric repulsion. Related data are shown in Table 1. Applying this conclusion to the present case, it appears likely that A and B are *cis*- and *trans*-**2** respectively.

Finegold and Kwart have discussed the conformation of the 1,3-cyclohexanediol system and concluded that the hydroxyl groups of the *cis*-isomer are diaxial forming an intramolecular hydrogen bond when C-5 has no substituent, and are diequatorial when C-5 is substituted with two methyl groups because of the 1,3-diaxial repulsion between the hydroxyl and methyl groups.[1] Therefore, two hydroxyl groups of the present *cis*-**2** should also be diequatorial.

The NMR spectra can be explained reasonably well in terms of the above conformations. Protons of the two methyl groups at the C-6 position of *trans*-**2** gave only one singlet at δ=1.09, since rapid ring-inversion renders the two methyl groups equivalent. In the case of *cis*-**2**, two singlets were observed at δ=1.00 (axial) and at δ=1.13 (equatorial), since ring inversion is restricted. Cyclopropane ring protons of *trans*-**2** gave a multiplet of A_2B_2 type centered at δ=0.52. The same protons of *cis*-**2** gave a singlet at δ=0.54, since the cyclopropane ring is perpendicular and symmetrical to the plane of C-1, C-4, and C-8 which includes the two C–OH bonds. Assignments of the signals due to the cyclohexane ring protons are as follows. In the case of *cis*-**2**, a doublet (J=12.0 Hz) of doublets (J=8 Hz) centered at δ=1.45 can be assigned to the signals of the two axial

Table 1. Melting points and IR absorptions due to the hydroxyl group of 1,3-diols

Diol			Mp, °C	IR absorption, cm^{-1}
	a)	*cis*	166—168	3610 (free)
		trans	119—121	3610 (free)

hydrogens at C-5 and C-7, a doublet (J=12 Hz) of doublets (J=4 Hz) centered at δ=1.65 to those of the two equatorial hydrogens, and a doublet (J=8 Hz) of doublets (J=4 Hz) centered at δ=3.67 to the two methine protons at C-4 and C-8, respectively. In the case of *trans*-**2**, a doublet (J=13 Hz) of doublets (J=7 Hz) centered at δ=1.45 can be assigned to the two axial protons at C-5 and C-7, a doublet (J=13 Hz) of doublets (J=4 Hz) centered at δ=1.16 to those of the two equatorial protons, and a doublet (J=7 Hz) of doublets (J=4 Hz) centered at δ=3.77 to the two methine protons, respectively. The protons of the hydroxyl groups gave a rather sharp singlet at δ=1.54 in the case of *cis*-**2**, and a rather broad singlet at δ=1.61 which overlapped with the signals of the axial protons in the case of *trans*-**2**.

Lithium aluminium hydride reduction of **1** in tetrahydrofuran at 0 °C followed by hydrolysis gave *cis*- and *trans*-**2** in a ratio of 37: 63. In contrast, aluminium isopropoxide reduction in 2-propanol under reflux followed by hydrolysis gave *cis*-**2** almost exclusively (the *cis*- to *trans*-**2** ratio was 99: 1). These results are in accordance with the conclusions of Dauben *et al.* that the Meerwein-Ponndorf-Verly reduction gives thermodynamically more stable products (product development-control) and that lithium aluminium hydride reduction gives sterically approach-controlled products.[2]

Attacks by aluminium isopropoxide on **1** appear to occur to form the less hindered diequatorial intermediate leading to *cis*-**2**. Because the reduction is reversible, thermodynamic stabilities of the products determine the product distribution. The possibility that one aluminium isopropoxide molecule reacts with two carbonyl groups of the same molecule leading to *cis*-**2** appears to be unlikely because of the steric repulsion with cyclopropyl group.

In the case of lithium aluminium hydride, the reduction process is not reversible. In the intermediate of the attack on the first carbonyl, the $-OAlH_3^-$ group will take the equatorial position, prohibit ring inversion, and fix the conformation. The less hindered reaction path for second carbonyl group reduction appears to proceed from the opposite side of the axial methyl group at C-5 and results in *trans*-**2** preferentially.

Unusual results were obtained during the course of the attempts to obtain the hydroxy ketone by the half reduction of dione **1**. In tetrahydrofuran at 0 °C, **1** was treated with a 1/3 mole equivalent of lithium aluminium hydride. After one hour, 2 M-HCl was added. In one experiment, the reaction mixture was heated to 40—50 °C to remove the solvent using a rotary evaporator immediately after the addition of hydrochloric acid. In another experiment, the solvent was evaporated after standing at room temperature for two days. The former experiment gave 2-(2-chloroethyl)-3-hydroxy-5,5-dimethyl-2-cyclohexanone (**3**), which is the enol form of 2-(2-chloroethyl)-5,5-dimethyl-1,3-cyclohexanedione (**4**) and is the cleaved product of the cyclopropane ring of **1** with hydrochloric acid. The latter gave diol **2**. Related results are shown in Table 2. Since the experiments were carried out on a small scale because of the limited amount of **1** available and the product separations were performed by column chromatography, the data are not quantitative.

These results show that the reduction intermediate, aluminium alkoxide, decomposes to give **3** at a higher temperature, 40—50 °C, and hydrolyzes slowly to give **2** at room temperature. The addition of hydrochloric acid to the intermediate alkoxide results in the rapid hydrolysis of the hydrides bonded to aluminium. The hydrolysis of the Al–O bond, however, appears to be not always fast. For example, it is well known that the B–O bond in the borohydride reduction intermediate is sometimes hydrolyzed only slowly with acid. Rickborn and Quartucci have suggested the possibility that the intermediate of lithium aluminium hydride reduction of epoxide could be oxidized to ketone by a hydride acceptor (AlH_3).[3] In the present case, oxidation back to ketone **1** and its subsequent decomposition by hydrochloric acid cannot explain the results, because **1** does not react with hydrochloric acid under the same conditions, but does react giving 6,6-dimethyl-2,3,4,5,-6,7-hexahydrofuran-4-one (**5**) instead of **3** under tetrahydrofuran refluxing. The formation of **3**, therefore, follows some other reaction path. The most probable scheme is depicted in Fig. 1 together with those of related reactions. The oxidation step with hydrochloric acid might be intramolecular, if both or either of the H^+ and Cl^- ions come from the ligands of aluminium. However, further detailed experiments are required to examine this interesting possibility.

The unusual results were obtained only in runs with smaller lithium aluminium hydride to **1** ratios (1 : 2—1 : 3), and no formation of the expected hydroxy ketone was observed. These results appear to show that the oxdation of alkoxide with acid occurs only in the case of an $RO–AlH_2–OR$ type alkoxide where the hydrolysis of Al–O bond is strongly hindered by two bulky R groups.

Some of the chemical properties of **3** were investigated. The reaction with equimolar sodium carbonate in 75% ethanol at 40 °C for 24 h gave **1**. The changes of **3** in pyridine were followed by NMR at 40 °C (NMR-probe temperature). Into 0.5 ml of pyridine were dissolved 30 mg of **3** and the spectra were determined immediately

Table 2. The effects of hydrolysis condition on the product distribution[a]

Run No.	$1/LiAlH_4$ mole ratio	Duration time of hydrolysis	Product
1	0.6/1	10 min	**2**
2	3.0/1	48 h	**2**
3	3.0/1	40 min	**3** and a trace of **2**
4	3.0/1	10 min	**3**
5[b]	2.3/1	1 h	**3**

a) **1** (3 mmol in runs 1 and 5 and 5 mmol in runs 2, 3, and 4, respectively) was reduced with lithium aluminium hydride in 30 ml of tetrahydrofuran at 0 °C for 1 h. The reaction mixtures were treated with 4 ml of 2M-HCl to hydrolyze the products at room temperature for the duration times given in the table. b) Diethyl ether (30 ml) was used in place of tetrahydrofuran.

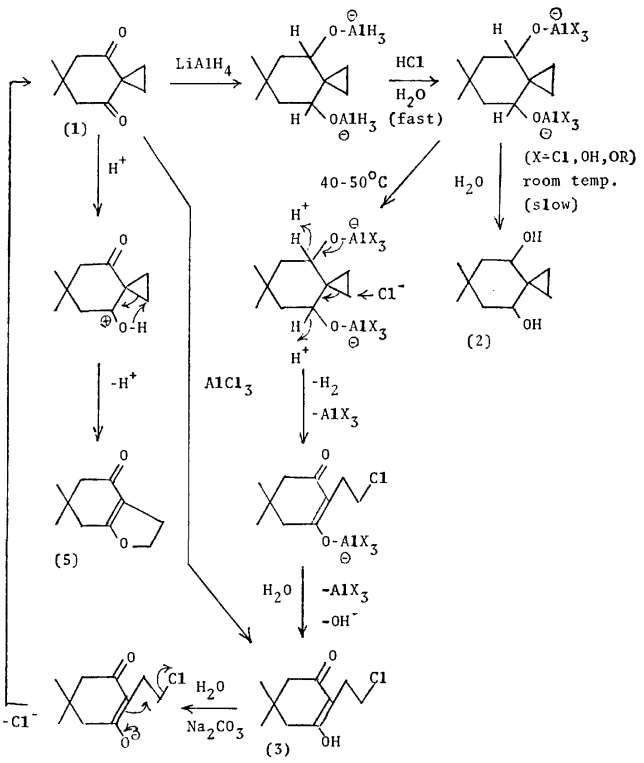

Fig. 1. Reaction of **1** and related reaction scheme.

after preparation of the solution, and at 24 and 48 h after preparation. When one drop of D_2O was added to the sample, the spectra showed that **3** was transformed to **1** after 24 h and further to **5** after another 24 h. When no D_2O was added, the changes were much slower. The reaction of **1** with a half mol of aluminium chloride in chloroform at room temperature gave **3**.

Experimental

Materials. The preparation of **1** has been reported previously.[4] Aluminium isopropoxide was prepared by a method reported in the literature.[5] Commercial tetrahydrofuran and 2-propanol were dried over calcium hydride and distilled before use. Other reagents were commercial ones of analytical grade.

*Reduction of **1** with Lithium Aluminium Hydride.* The following examples show typical experimental procedures. Into a tetrahydrofuran (20 ml) solution of lithium aluminium hydride (0.379 g, 10 mmol) was added a tetrahydrofuran (10 ml) solution of **1** (1.68 g, 10 mmol) over a period of 5 min at 0 °C. After 2 h, 2 M-HCl (5 ml) was added. After standing for 24 h, the solvent was evaporated with a rotary evaporator (bath temperature, 40—50 °C) and the residue was dissolved in ethyl ether, washed with a saturated aqueous sodium chloride solution, and dried over anhydrous sodium sulfate. After evaporation of the ether, a colorless solid of **2** (1.58 g) was obtained. The *cis-* to *trans-* **2** ratio in the crude **2** was determined to be about 1: 2 by measuring the proton ratio of the NMR spectra in pyridine. The solid was dissolved in ether and passed through Wakogel C-200, $2\phi \times 3$ cm, to remove inorganic salts. After evaporating the solvent the product was recrystallized from chloroform (20 ml) to give fraction A, mp 166—168 °C (Found: C, 70.54; H, 10.54%. Calcd for $C_{10}H_{18}O_2$: C, 69.93; H, 10.54%) and fraction B, mp 119—121 °C (Found: C, 69.85; H, 10.56%).

1 (0.83 g, 5 mmol) was reduced with lithium aluminium hydride (0.062 g, 1.63 mmol) by the same procedure as described above, except that tetrahydrofuran was removed from the reaction mixture just after the addition of 2 M-HCl using a rotary evaporator at 45—50 °C. The evaporation required about 10 min. A work-up gave crystals of **3**, mp 144—145 °C (0.524 g, 52% yield). Found: C, 58.83; H, 7.21; Cl, 17.21%. Calcd for $C_{10}H_{15}ClO_2$: C, 59.26; H, 7.46; Cl, 17.59%. NMR in dimethyl-d_6 sulfoxide δ: 0.95 (s, 6H, methyl), 2.23 (s, 4H, cyclohexane ring methylene), 2.62 (t, J=7.0 Hz, 2H, branched α-methylene), 3.49 (*t*, J=7.0 Hz, 2H, branched β-methylene), and 4.10 (s, broad, 1H, hydroxyl). IR (KBr disc): 3350 (ν_{O-H}), 2470 ($\nu_{C=O\cdots H-O}$), 1635 ($\nu_{C=O}$), and 1558 cm^{-1} ($\nu_{C=C}$).

*Meerwein-Ponndorf-Verly Reduction of **1**.* According to the reported method,[5] **1** (1.0 g, 6 mmol) was reduced with aluminium isopropoxide (4.08 g, 20 mmol) in dry 2-propanol (9.0 g, 150 mmol). **2** was obtained in a yield of 98% (0.98 g). Gas-chromatographic analysis could not be applied to **2**. However, application of the trimethylsilylation method[6] gave satisfactory results, although the detector was damaged after repeated analyses. The ratio of *cis-* to *trans-***2** was found to be 99: 1.

The NMR spectra were recorded on a Varian Associates HR-220 spectrometer at 220 MHz at room temperature or on a Jeol PMX-60 spectrometer. The IR spectra were recorded on a Hitachi EPI-G2 spectrometer. The gas-chromatographic analyses were carried out by Yanaco GC-550 TPH chromatograph with a 1.5 m OV-17 column.

This work was partially supported by a Grant-in-Aid for Scientific Research (No. 911503) from the Ministry of Education, Japan.

(Received December 10, 1976)

3β,4β-Epoxyshionane (**15**) was treated with boron trifluoride etherate in ether at −30 °C to give dihydrobaccharis oxide (**4**; yield 17%), 4α-fluoroshionan-3β-ol (**17**; 10%), D: B-friedo-bacchar-5-en-3β-ol (**18**; 18%), D: B-friedo-bacchar-5(10)-en-3β-ol (**20**; 15%), and D: C-friedo-bacchar-7-en-3β-ol (**21**; 15%). The reaction in benzene, toluene, cyclohexane, or in hexane at −5 °C or at room temperature yielded bacchar-12-en-3β-ol (**5**), D: C-friedo-bacchar-8-en-3β-ol (**25**), **18**, **20**, and **21**. The reaction product ratios in the same reaction in various solvents are listed in Table 1.

Baccharis oxide (**1**)[2] is a triterpene oxide isolated from *Baccharis halimifolia* L. and shionone (**2**)[3] is a tetracyclic triterpene ketone contained in *Aster tataricus* L. These two triterpenes are biogenetically considered to be derived from a common intermediate (**3**) (or its equivalent species) and closely related to each other.[2,3] Baccharis oxide (**1**) may be formed from **3** by an attack of an oxygen atom on C-3 to the cationic center at C-10.

It has been reported that a boron trifluoride etherate-catalyzed rearrangement of dihydrobaccharis oxide (**4**) gives bacchar-12-en-3β-ol (**5**).[2b,4] In view of a correlation between compounds with shionane (D: A-friedobaccharane) and baccharane skeletons, we previously investigated[5] a backbone rearrangement of 3α,4α-epoxyshionane (**6**)[5] to afford bacchar-12-en-3α-ol (**7**) and D: B-friedo-bacchar-5(10)-en-3α-ol (**8**). We also reported[6] a transformation of friedelin (**9**) into dendropanoxide (**10**).[7] 3β,4β-Epoxyfriedelane (**11**) prepared from **9** was treated, according to Halsall's procedures,[8] with boron trifluoride etherate to give **10** together with D: B-friedo-olean-5(10)-en-3β-ol (**12**), D: B-friedo-olean-5-en-3β-ol (**13**), and β-amyrin (**14**).[6]

Backbone rearrangements in the steroid and terpenoid fields are well documented.[9] Intracyclic tension in the rigid polycyclic ring provokes of backbone rearrangements to give the products less constrained. Electronic effects resulting from the presence of functional groups and kinetic effects due to the nature of reagents can modify the development of rearrangement.[10] The shionane skeleton is considered to be 3α-(4-methylpentyl)-3β,5α,8β,17aβ-tetramethyl-D-homoandrostane, in which there exists an intracyclic tension due to 1,3-diaxial interactions among the alkyl substituents. The backbone rearrangements in **6** were shown to proceed from ring A towards ring D;[5] a 1,3-diaxial interaction between the side chain and the 13α-methyl group is released in **7**. The present paper deals with a reaction of 3β,4β-epoxyshionane (**15**) with boron trifluoride etherate and a preparation of dihydrobaccharis oxide (**4**).[2] Solvent effects on this reaction were also examined.

Shionone (**2**) was converted *via* shionan-3-one (**16**),[3b,c] shionan-3β-ol,[3b,c] and shion-3-ene,[3c] into 3β,4β-epoxyshionane (**15**)[5] by known procedures. Treatment of the β-epoxide (**15**) with boron trifluoride etherate in anhydrous ether at −30 °C for 1 h gave a complex mixture which was separated by column chromatography over silica gel, recrystallization, preparative thin-layer chromatography (TLC), column chromatography on silica gel impregnated with silver nitrate, and by high performance liquid chromatography (HPLC) (*cf.* Experimental).

The reaction mixture was separated into five components (**a**—**e**; designated in an order of the elution) by column chromatography (Column I). The least polar component **a** (yield: *ca.* 17%) was shown to be identical with dihydrobaccharis oxide (**4**),[2] mp 127—128.5 °C, by direct comparison with an authentic specimen, which was prepared by hydrogenation of baccharis oxide (**1**) over palladium charcoal.[2b] The second component **b** (y: *ca.* 1%) was found to be the starting β-epoxide (**15**).

The third component **c** (**17**; y: *ca.* 10%), $C_{30}H_{53}OF$, mp 174—175 °C, was suggested to be a fluoro alcohol based on the spectral data and elemental analysis. The IR spectrum showed a band attributable to a hydroxyl group and the PMR spectrum showed a quintet centered at δ 3.70 due to a proton on a carbon atom ($C_{(3)}$) bearing the hydroxyl group. In the PMR

measurement using Eu(fod)$_3$-d_{27} as a shift reagent, signals due to a methyl group on a carbon atom bearing a fluorine atom ($C\underline{H}_3$–C(–F)) suffered a considerable downfield shift and were observed as a doublet (J=23 Hz). The fluoro alcohol (**17**) was treated with potassium hydroxide in methanol under reflux to generate the starting 3β,4β-epoxide (**15**). The reaction of an epoxide with boron trifluoride etherate to give a fluorohydrin is often encountered.[11] These observations together with the mechanistic consideration[11] led to the conclusion that the fluoro alcohol should be formulated as 4α-fluoroshionan-3β-ol (**17**).

The presence of a secondary hydroxyl group [IR 3450 cm^{-1}; PMR δ 3.47 (1H, t-like; $C_{(3)}$–H)] and a trisubstituted double bond [IR 820 cm^{-1}; PMR δ 5.62 (1H, m; $C_{(6)}$–H)] was shown for the fourth component **d** (**18**; y: *ca.* 18%), $C_{30}H_{52}O$, mp 124—125 °C, by its IR and PMR spectra. The appearance of peaks at *m/e* 276 and *m/e* 152 due to a retro-Diels-Alder fragmentation[12] in the mass spectrum showed the presence of the double bond between C-5 and C-6. Thus the structure of D: B-friedo-bacchar-5-en-3β-ol (**18**) was proposed for the fourth component **d**. This was substantiated by the following transformation. The unsaturated alcohol (**18**) was converted by a usual procedure into a corresponding acetate. Oxidation of the acetate with selenium dioxide in acetic acid under reflux gave a diene identical with a known D: B-friedo-bacchara-1(10),5-dien-3β-yl acetate (**19**).[5]

The fifth component **e** was found to be a mixture of two compounds (**20** and **21**) containing a small amount of **17** and **18** by HPLC examination. The component **e** was chromatographed on silica gel impregnated with silver nitrate (Column II) to give a mixture of two compounds (**20** and **21**). This mixture could not be separated into pure compounds by repeated column and thin layer chromatography and by recrystallization. Application of HPLC however gave a satisfactory separation: D: B-friedo-bacchar-5(10)-en-3β-ol (**20**; y: 15%) and D: C-friedo-bacchar-7-en-3β-ol (**21**; y: 15%) were obtained. Their structures were characterized as follows.

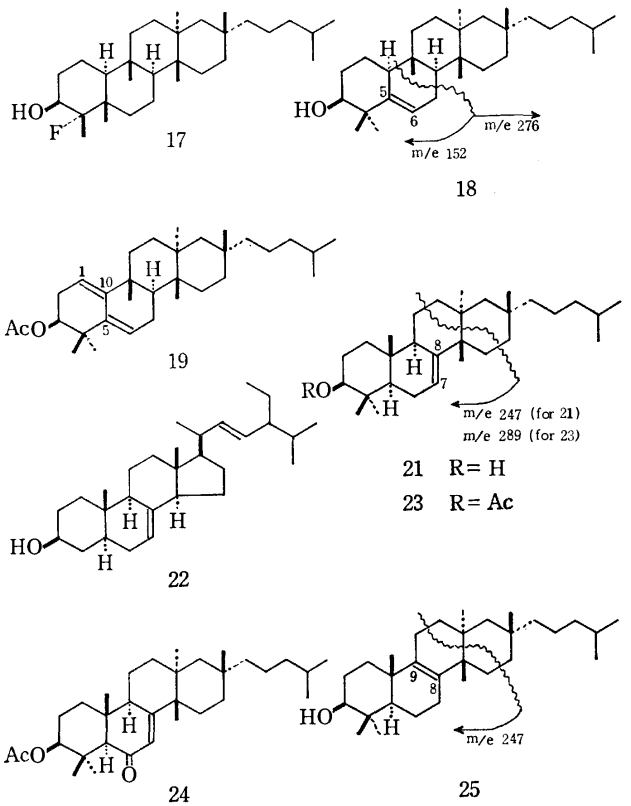
The former compound (**20**), mp 142—143 °C, showed the same spectral data and melting point (and mixed mp) as those of an authentic D: B-friedo-bacchar-5(10)-en-3β-ol (**20**)[13] prepared from shionanone (**16**) *via* D: B-friedo-bacchara-1,5(10)-dien-3-one.[13]

The latter compound was inferred to be **21** by the following evidence. The compound (**21**) had mp 136.5—137.5 °C and a molecular formula $C_{30}H_{52}O$. The presence of a secondary hydroxyl group [IR 3350 cm^{-1}; PMR δ 3.26 (1H, dd, $J_{2\beta,3\alpha}$=8 and $J_{2\alpha,3\alpha}$=5 Hz; $C_{(3\alpha)}$–H)] and a trisubstituted double bond [IR 820 cm^{-1}; PMR δ 5.39 (1H, quartet, $J_{6\beta,7}$=3, $J_{6\alpha,7}$=3, and $J_{7,9\alpha}$=3 Hz; $C_{(7)}$–H)] was indicated by the IR and PMR spectra. In the PMR spectrum using Eu(fod)$_3$-d_{27} as a shift reagent, signals due to the olefinic and allylic protons and the methyl protons at C-10 shifted to downfield and were easily assignable (Fig. 1). The magnitude and tendency of the shift of these protons were found to be similar to those (Fig. 2) of α-spinasterol (**22**).[14] The position of the trisubstituted double bond between C-7 and C-8 was supported by fragment ion peaks at *m/e* 247 and *m/e* 229. The peak at *m/e* 247 is characteristic for Δ^7- and Δ^8-triterpenoids[15] and the latter peak at *m/e* 229 is corresponding to the dehydration peak of the former ion. It is therefore concluded that the compound (**21**) should be formulated as D: C-friedo-bacchar-7-en-3β-ol. The proposed structure was further supported by the following transformations (a and b).

a) The compound (**21**) was acetylated in a usual manner to give an acetate (**23**), $C_{32}H_{54}O_2$, which also showed a characteristic fragment ion peak at *m/e* 289 due to a retro-Diels-Alder fragmentation of Δ^7- and Δ^8-triterpenoids[15] accompanied with a peak at *m/e* 229 due to loss of acetic acid from the ion at *m/e* 289. In the PMR and IR spectra, the presence of an acetoxyl group and an olefinic proton [PMR δ 5.39 (1H, quartet, $J_{6\beta,7}$=3, $J_{6\alpha,7}$=3, and $J_{7,9\alpha}$=3 Hz; $C_{(7)}$–H)] was observed. On allylic oxidation with *t*-butyl chromate,[16] the acetate (**23**) afforded an enone acetate (**24**), $C_{32}H_{52}O_3$, as an oil. Its IR, UV [λ_{max} 248 nm (ε 12000)], and PMR [δ 2.17 (s, $C_{(5)}$–H) and 5.81 (d, $J_{7,9\alpha}$=2.4 Hz; $C_{(7)}$–H)] spectral data may best be interpreted by a structure of D: C-friedo-bacchar-7-en-6-on-3β-yl acetate (**24**).[17]

b) Treatment of the acetate (**23**) with hydrogen chloride in chloroform, followed by alkaline hydrolysis and purification by HPLC, gave an isomerized product (**25**), $C_{30}H_{52}O$, as an oil. The presence of a hydroxyl group and the absence of olefinic proton in **25** were shown by the IR and PMR spectra. Prominent peaks at *m/e* 247 and 229 characteristic for Δ^7- and Δ^8-triterpenoids[15] were observed in the mass spectrum. When **23** was treated with hydrochloric acid in acetic acid at

60 °C and then subjected to alkaline hydrolysis, the 12-ene (**5**)[2b,4] was formed together with **25**. These observations suggest the structure of D: C-friedo-bacchar-8-en-3β-ol for the isomerized alcohol (**25**) and



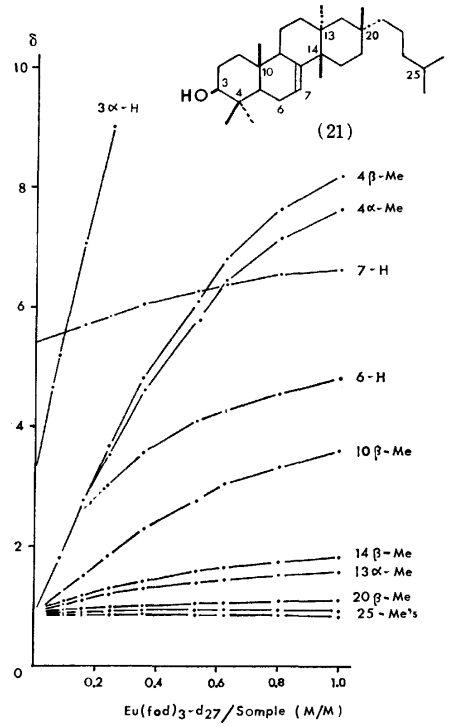


Fig. 1. Induced paramagnetic shifts for D: C-friedo-bacchar-7-en-3β-ol (**21**) in a 3% (w/v) solution in $CDCl_3$.

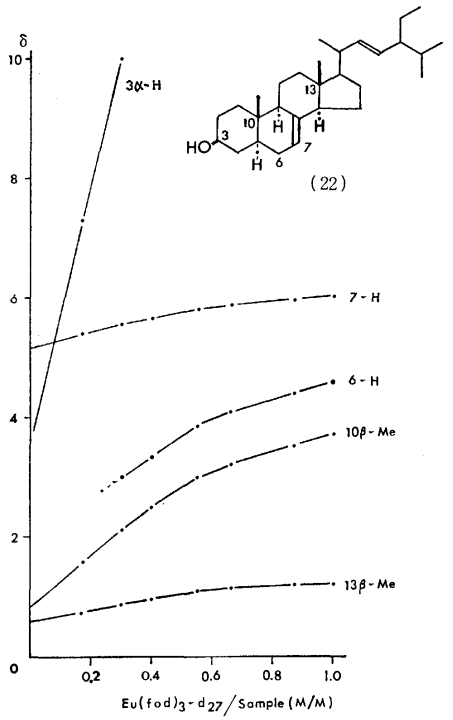

Fig. 2. Induced paramagnetic shifts for α-spinasterol (**22**) in a 3% (w/v) solution in $CDCl_3$.

that of D: C-friedo-bacchar-7-en-3β-ol for the alcohol (**21**).

Solvent effects on the formation of these reaction products were then investigated. The small scale reaction using 1—3 mg of the 3β,4β-epoxide (**15**) and boron trifluoride etherate (2 drops) in a solvent (2—10 ml) was carried out at room temperature or at —5 °C. The reaction mixture, after the usual treatment, was extracted with ether to give a residue. This residue was dissolved in 10% ether–hexane and the identification of each component and the determination of its relative amount were carried out by HPLC (Table 1).

In the reaction conditions listed in Table 1, five alcohols were detected besides dihydrobaccharis oxide (**4**) and the fluorohydrin (**17**), and four of the alcohols were identified to be **18**, **20**, **21**, and **25** by HPLC. The fifth alcohol was found to be bacchar-12-en-3β-ol (**5**) by direct comparison (IR, mass spectrum, TLC, and HPLC) with an authentic specimen[2b] prepared by the acid-catalyzed rearrangement of dihydrobaccharis oxide (**4**).

In the rearrangement of the 3β,4β-epoxide (**15**), the cationic center at C-4 was initially formed by boron trifluoride etherate-attack to an oxygen atom of the epoxide. A sequence of 1,2-shifts of methyl group(s) and hydrogen atom(s) were then followed. From the derived cations in various rearranged stages, the rearranged alcohols (**5**, **18**, **20**, **21**, and **25**) would be produced after deprotonation in the last step.[18]

It is obvious that the rearrangement in solvents with low nucleophilicity *e.g.* such as nitromethane, proceeds up to C/D rings because the cationic centers survive longer in these solvents and spread over the whole skeleton; therefore the formation of bacchar-12-en-3β-ol

a) Relative yields were determined by HPLC. Measurements were carried out at room temperature using a Liquid Chromatograph Model ALC/GPC 202/401 (Waters Assoc.) with an RI detector; column: μ-PORASIL 1/8 (inch)×1 (foot); solvent system: 1 or 10% ether–hexane; flow rate: 1.0 or 1.2 ml/min; pressure: *ca.* 500 psi. Under the conditions (1% ether–hexane; 1.0 ml/min), retention time for **17**, **4**, **18**, **20**, and **21** was shown to be 54.7, 8.3, 51.7, 69.7, and 81.7 min, respectively. Under the other conditions (10% ether–hexane; 1.2 ml/min), retention time for **18**, **20**, **25**, **21**, and **5** was found to be 11.0, 14.6, 17.0, 15.6, and 18.3 min, respectively. b) Room temperature (r.t.) refers to a temperature range between 20 and 28 °C. c) The epoxide (**15**) was recovered in about 80% yield. d) Yields in this line are expressed as isolated yields (in %). e) A small quantity (*ca.* 1%) of the starting material (**15**) was recovered.

(**5**), derived from a species with a cationic center at C-13, was observed. On the contrary, in a solvent apt to coordinate with a cation such as dimethoxyethane (DME), tetrahydrofuran, or ether, the rearrangement reaction was interrupted in early stages; *e.g.* the D: B-friedo-type alcohols (**18** and **20**) were formed preferentially in the rearrangement in the former two solvents (DME and THF) (*vide infra* for the reaction in ether).

In the reaction of the 3β,4β-epoxide (**15**) in ether or in dimethoxyethane, dihydrobaccharis oxide (**4**) was formed together with the other reaction products, while no **4** was produced in the reaction in nitromethane, dichloromethane, benzene, toluene, cyclohexane, hexane, acetonitrile, and in tetrahydrofuran.

Dihydrobaccharis oxide (**4**) was then treated with boron trifluoride etherate in ether at various temperatures. No reaction occurred at a temperature range between −40 and 0 °C; this shows that the intermediacy of the oxide (**4**) for the formation of the rearranged alcohols (**18**, **20**, and **21**) from 3β,4β-epoxyshionane (**15**) under the similar conditions (at −30 and at −5 °C) is improbable. The reaction of **4** in ether at room temperature for 1 h gave **18** (relative yield determined by HPLC: 10%), **20** (8%), and **21** (2%), besides the starting material (**4**; 80%).

According to Anthonsen's procedure,[2b)] dihydrobaccharis oxide (**4**) was treated with boron trifluoride etherate in benzene at room temperature for 10 min. An examination of the reaction mixture by HPLC showed that bacchar-12-en-3β-ol (**5**; 50%) was the main product and that minor products were **18** (10%), **20** (10%), **21** (10%), and **25** (20%).

The conversion of shionone (**2**) into dihydrobaccharis oxide (**4**) *via* the 3β,4β-epoxide (**15**) was thus shown. As the total synthesis of shionone (**2**) was recently achieved,[19)] the present report constitutes formally the total synthesis of dihydrobaccharis oxide (**4**).

Experimental

Melting points were measured on a Mel-temp capillary melting point apparatus (Laboratory Devices) and were uncorrected. IR and UV spectra were determined on a Hitachi EPI-G2 and EPS-2 spectrometer, respectively. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer and high resolution mass spectra on a Hitachi RMH-2 mass spectrometer operating at 70 eV with a direct inlet system. PMR spectra were measured using a JEOL JNM PS-100 (100 MHz), a Hitachi R-20B (60 MHz), or a JEOL JNM FX-60 (Fourier Transform) spectrometer in deuteriochloroform. Measurements of optical rotations were carried out using a JASCO polarimeter DIP-SL. Thin layer chromatography (TLC) was carried out on Kieselgel PF_{254} (E. Merck) in 0.25 or 0.5 mm thickness or Wako Alumina B-10F (Wako). Wakogel C-200 (Wako) was used for column chromatography.

*Reaction of 3β,4β-Epoxyshionane (**15**) with Boron Trifluoride Etherate in Ether.* To a solution of 3β,4β-epoxyshionane (**15**; 384 mg)[5)] in ether (30 ml, distilled from sodium wire) at −30 °C was added boron trifluoride etherate (1.0 ml) with stirring. After 1 h the starting material mostly disappeared and several spots were observed on TLC. The reaction was stopped by addition of 5% methanolic potassium hydroxide (10 ml) kept at the same temperature. The reaction products were extracted with ether twice (each 50 ml) and the organic layer was washed with water (50 ml) and brine, dried over magnesium sulfate, and evaporated to give a colorless oil (384 mg).

The resulting oil was dissolved in petroleum ether–ether (10: 1), absorbed on silica gel (200 g), and eluted with the following solvent system (each fraction 100 ml; Column I): frs. 1—6, petroleum ether–ether (10: 1); frs. 7—12, (5: 1); frs. 13—35, (10: 3).

From frs. 5—8 was obtained dihydrobaccharis oxide (**4**; 42 mg)[2)] after purification by preparative TLC and crystallization from ethyl acetate–methanol, mp 127—128.5 °C (lit, 127—128 °C)[2b)]; IR (KBr) 1000 and 910 cm^{-1}; PMR δ 3.73 (1H, d, $J_{2\beta,3\alpha}$=5 Hz; $C_{(3\alpha)}$–H); mass spectrum *m/e* (relative intensity %) 428 (23; M^+), 413 (73), and 137 (base peak); $[\alpha]_D$ +45 ° (*c* 1.7, chloroform) [lit, +44 ° (*c* 2.30)][2b)]; Found: C, 84.00; H, 12.31%. Calcd for $C_{30}H_{52}O$: C, 84.02; H, 12.23%.

Fr. 9 gave the starting material (**15**; 4 mg).

From frs. 10—12 was obtained a mixture of dihydrobaccharis oxide (**4**) and 4α-fluoroshionan-3β-ol (**17**), which was further separated by preparative TLC to give **17** (35 mg), mp 174—175 °C (crystallized from methanol); IR (KBr) 3450 cm^{-1}; PMR δ 3.70 (1H, quintet, $J_{2\beta,3\alpha}=3$, $J_{2\alpha,3\alpha}=3$, and $J_{3\alpha,F}=6$ Hz; $C_{(3\alpha)}$-H); mass spectrum *m/e* 448 (11; M^+), 433 (8), 428 [18; $(M-HF)^+$], 413 (11), 343 (46), 275 (33), 247 (33), 229 (28), 220 (31), and 95 (base peak); Found: C, 80.29; H, 11.87%. Calcd for $C_{30}H_{53}OF$: C, 80.30; H, 11.90%.

From frs. 13—15 was obtained a mixture of 4α-fluoroshionan-3β-ol (**17**) and D: B-friedo-bacchar-5-en-3β-ol (**18**), which was passed through a short column of silica gel (4 g) impregnated with silver nitrate (20%, 1 g) and eluted with benzene to afford **17** (0.5 mg) and **18** (63 mg), mp 124—125 °C (crystallized from acetone); IR (KBr) 3450, 1630, 1100, 830, and 820 cm^{-1}; PMR δ 3.47 (1H, t-like, $W_{1/2}$ 6 Hz; $C_{(3\alpha)}$-H and 5.62 (1H, m, $C_{(6)}$-H); mass spectrum *m/e* 428 (8; M^+), 413 (10), 410 (5), 395 (8), 276 (39), 261 (base peak), 152 (21), and 134 (79); Found: C, 84.07; H, 12.62%. Calcd for $C_{30}H_{52}O$: C, 84.04; H, 12.23%.

Fractions 16—22 gave a mixture (194 mg) of D: B-friedo-bacchar-5(10)-on-3β-ol (**20**) and D: C-friedo-bacchar-7-en-3β-ol (**21**) containing a small amount of **17** and **18**. This mixture was dissolved in benzene, absorbed on silica gel (34 g) impregnated with silver nitrate (20%, 8 g), and eluted with the same solvent (Column II, each 100 ml). Frs. 1 and 2 gave **17** (4 mg), while **18** (6 mg) was obtained from frs. 13—18. Since frs. 3—12 afforded a mixture of **20** and **21** in a various ratio, these fractions were combined and subjected to separation by HPLC (*vide infra*).

Frs. 23—35 afforded a mixture of **20** and **21**, which was also subjected to HPLC separation (*vide infra*).

Separation of D: B-Friedo-bacchar-5(10)-en-3β-ol (20) and D: C-Friedo-bacchar-7-en-3β-ol (21) by High Performance Liquid Chromatography (HPLC). The above fractions (Column I, frs. 23—35 and Column II, frs. 3—12) were subjected to separation by HPLC to give D: B-friedo-bacchar-5(10)-en-3β-ol (**20**) and D: C-friedo-bacchar-7-en-3β-ol (**21**). Each compound was collected by repeating the procedure to afford **20** (59 mg), mp 142—143 °C (crystallized from acetone) (lit, 141.5—142 °C)[13]; IR (KBr) 3350 cm^{-1}: PMR δ 3.48 (1H, dd, $J_{2\beta,3\alpha}=10$ and $J_{2\alpha,3\alpha}=4$ Hz, $C_{(3\alpha)}$-H); mass spectrum *m/e* 428 (17; M^+) and 135 (base peak), and **21** (59 mg), mp 136.5—137.5 °C (crystallized from petroleum ether); IR (liquid) 3350, 1630, 1035, and 820 cm^{-1}; PMR δ 3.26 (1H, dd, $J_{2\beta,3\alpha}=8$ and $J_{2\alpha,3\alpha}=5$ Hz, $C_{(3\alpha)}$-H) and 5.39 (1H, quartet, $J_{6\beta,7}=3$, $J_{6\alpha,7}=3$, and $J_{7,9\alpha}=3$ Hz, $C_{(7)}$-H); mass spectrum *m/e* 428 (25, M^+), 413 (base peak), 395 (51), 247 (14), 229 (28), and 135 (46); high resolution mass spectrum, Found: 428.4000. Calcd for $C_{30}H_{52}O$: 428.4015. Found: 247.2045. Calcd for $C_{17}H_{27}O$: 247.2060. Found: 229.1928. Calcd for $C_{17}H_{25}$: 229.1954.

Base Treatment of 4α-Fluoroshionan-3β-ol (17). 4α-Fluoroshionan-3β-ol (**17**; 64 mg) was treated with 5% methanolic potassium hydroxide (15 ml) for 21 h under reflux temperature. The reaction mixture was extracted with chloroform followed by the usual work-up to give a residue (62 mg), which was crystallized from acetone to afford 3β,4β-epoxyshionane (**15**; 34 mg) as white needles, mp 152.5—153.5 °C (lit, 154—155 °C)[5]; IR, PMR, and mass spectrum were superimposable with those of an authentic specimen.

D: B-Friedo-bacchara-1(10),5-dien-3β-yl Acetate (19). D: B-Friedo-bacchar-5-en-3β-ol (**18**; 23 mg) was treated with acetic anhydride (1.5 ml) in pyridine (2 ml) at room temperature and was allowed to stand overnight. After usual work-up, the corresponding acetate (24 mg) was obtained. A mixture of this acetate (11 mg) in acetic acid (3 ml) and selenium dioxide (11 mg) in water (0.5 ml) was heated under reflux for 5 h. After the similar work-up according to Ref. 5b, an oil was obtained. The dehydrogenation reaction of the acetate (5 mg) was repeated once more and the resulting oil was combined and passed through a short column of silica gel to afford a residue (16 mg). Purification by preparative TLC and crystallization from methanol gave white crystalline D: B-friedo-bacchara-1(10),5-dien-3β-yl acetate (**19**; 7 mg), mp 123—124 °C (lit, 123—123.5 °C).[5]

Acetylation of D: C-Friedo-bacchar-7-en-3β-ol (21). A solution of D: C-friedo-bacchar-7-en-3β-ol (**21**; 32 mg) in pyridine (2 ml) and acetic anhydride (1 ml) was allowed to stand overnight at room temperature. Methanol was added and the reaction mixture was poured into water and extracted with ether three times. On usual work-up, a colorless gum (**23**; 31 mg) was obtained. IR (liquid) 1730, 1240, 1030, 820, and 760 cm^{-1}; PMR δ 2.04 (3H, s, $-OCOCH_3$), 4.51 (1H, dd, $J_{2\beta,3\alpha}=9$ and $J_{2\alpha,3\alpha}=5$ Hz; $C_{(3\alpha)}$-H), and 5.39 (1H, quartet, $J_{6\beta,7}=3$, $J_{6\alpha,7}=3$, and $J_{7,9\alpha}=3$ Hz; $C_{(7)}$-H); mass spectrum *m/e* 470 (36; M^+), 455 (base peak), 395 (57), 289 (7), and 229 (28); molecular weight (by high resolution mass spectrometry), Found: 470.4121. Calcd for $C_{32}H_{54}O_2$: 470.4121.

Allylic Oxidation of D: C-Friedo-bacchar-7-en-3β-yl Acetate (23). A solution of D: C-friedo-bacchar-7-en-3β-yl acetate (**23**; 19 mg) in benzene (1 ml) was treated with *t*-butyl chromate in benzene [0.1 ml; prepared from *t*-butyl alcohol (24.6 g), chromium trioxide (11.1 g), and benzene (50 ml)] and was allowed to stand overnight at room temperature. Saturated aqueous formic acid solution was added and the reaction mixture was poured into water and extracted with ether three times. On usual work-up, a pale yellow oil was obtained, which was separated by TLC to give D: C-friedo-bacchar-7-en-6-on-3β-yl acetate (**24**; 0.5 mg) and the starting material (**23**; 14 mg). This procedure was repeated twice and the enone-acetate fractions were combined (1.8 mg), and purified by silica gel TLC, alumina TLC, and then by HPLC. D: C-Friedo-bacchar-7-en-6-on-3β-yl acetate (**24**; *ca.* 1.5 mg) was obtained as an oil, IR (liquid) 1730, 1660, 1610, and 1245 cm^{-1}; UV λ_{max}^{EtOH} 248 nm (ε 12000); PMR δ 2.17 (s, $C_{(5\alpha)}$-H) and 5.81 (d, $J_{7,9\alpha}=2.4$ Hz, $C_{(7)}$-H); mass spectrum *m/e* 484 (13; M^+), 469 (4), 424 (23), 409 (17), 302 (43), 277 (9), 243 (9), 217 (25), 196 (50), and 121 (base peak); molecular weight (by high resolution mass spectrometry), Found: 484.3902. Calcd for $C_{32}H_{52}O_3$: 484.3913.

Isomerization of D: C-Friedo-bacchar-7-en-3β-yl Acetate (23). a) Hydrogen chloride was bubbled for 5 min through a solution of D: C-friedo-bacchar-7-en-3β-yl acetate (**23**; 7 mg) in chloroform (3 ml) at 0 °C. The solution was kept for 10 min at the same temperature, poured into water, extracted with chloroform, washed with 10% aqueous sodium carbonate, and brine, and then evaporated. A resulting residue was treated with 5% methanolic potassium hydroxide (10 ml) at 60 °C for 2 h. The reaction mixture was diluted with water and extracted with ether. After usual work-up and purification by preparative TLC, D: C-friedo-bacchar-8-en-3β-ol (**25**; 1.8 mg) was obtained as an oil, which was subjected to examination by HPLC and proved to be pure. IR (liquid) 3400 cm^{-1}; PMR δ 3.28 (1H, m, $C_{(3\alpha)}$-H), no olefinic proton was observed; mass spectrum *m/e* 428 (29; M^+), 413 (base peak), 395 (50), 247 (13), and 229 (40); high resolution mass spectrum, Found: 428.4018. Calcd for $C_{30}H_{52}O$: 428.4015, Found: 247.2056. Calcd for $C_{17}H_{27}O$: 247.2059. Found: 229.1929. Calcd for $C_{17}H_{25}$: 229.1954.

b) To a solution of D: C-friedo-bacchar-7-en-3β-yl acetate (**23**; 1.5 mg) in acetic acid (2 ml) was added concd hydro-

chloric acid (0.2 ml) and the mixture was heated at 60 °C for 19 h. The reaction mixture, after usual treatment, was extracted with ether to give a residue, which was treated with 5% methanolic potassium hydroxide (2 ml) at room temperature overnight. The usual work-up gave an oil, which was subjected to examination by HPLC and was found to be a mixture of the 7-ene (**21**), the 8-ene (**25**), and the 12-ene (**5**)[2b,4] in a ratio of 6: 9: 5.

Reaction of Dihydrobaccharis Oxide (4) with Boron Trifluoride Etherate in Ether and in Benzene. Boron trifluoride etherate (4 drops) was added to a solution of dihydrobaccharis oxide (**4**; 5 mg)[2] in ether (1 ml), and the solution was kept at room temperature for 1 h. The reaction mixture was treated as usual to give a residue. An examination of this residue by HPLC showed that it consisted of the 5-ene (**18**; relative amount ratio 10%), the 5(10)-ene (**20**; 8%), the 7-ene (**21**; 2%), and of the oxide (**4**; 80%).

The small scale reaction of **4** (9 mg) with boron trifluoride etherate (5 drops) in benzene[2b] (2 ml) was effected at room temperature for 10 min. The product was found to be a mixture of the 12-ene (**5**; relative amount ratio 10%), **18** (10%), **20** (10%), **21** (10%), and the 8-ene (**25**; 20%), by HPLC examination.

The authors wish to thank Dr. Torger Bruun, Norges Teckniske Hφgskole, Trondheim, Norway, for a generous gift of an authentic sample of baccharis oxide. The authors also wish to thank Dr. Nobuo Nakamura, Dr. Hidehiro Ishizuka, and Dr. Kazuyuki Aizawa for the measurements of PMR (FT), PMR (100 MHz), and high resolution mass spectra, respectively.

Reactions of a Variety of Diazoalkanes with *o*-Sulfobenzoic Anhydride

Takumi OSHIMA and Toshikazu NAGAI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received December 13, 1976)

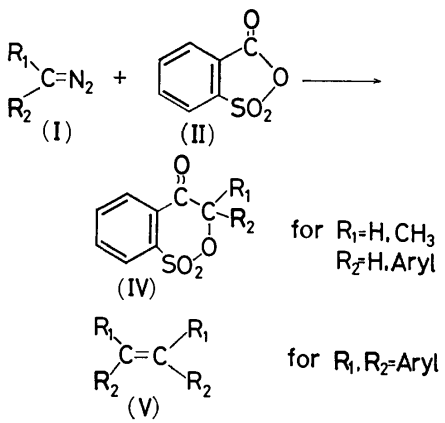
It was found that a number of diazoalkanes (I) bearing a relatively small substituent reacted with *o*-sulfobenzoic anhydride (II) in acetonitrile at an ordinary temperature to give the *o*-(substituted glycoloyl)benzenesulfonic acid sultones (IV), which correspond formally to the products from the insertion into the C–O bond of II by the carbenes, while diaryldiazomethanes underwent decomposition under the same conditions to produce the corresponding tetraarylethylenes (V) instead of the inserted products (IV). The olefin formation reaction was very fast compared to the sultone formation and was considered to be the result of the acid-catalyzed decomposition caused by the contaminant *o*-sulfobenzoic acid (III) which was derived from II. The kinetics and the mechanism of these reactions were discussed on the basis of the nature of diazoalkanes.

It is well known that diazoalkanes(I) undergo decomposition in the presence of protic acids,[1] a variety of metalic halides,[2] or other Lewis acids[3]—*e.g.*, $ZnCl_2$, Hg_2Cl_2, and BF_3—involving intermediate diazonium ions or carbenoids. However, the decomposition of I under the influence of an organic Lewis acid has not been widely investigated.[4] During our recent study of a mixed sulfonic carboxylic anhydride such as *o*-sulfobenzoic anhydride(II), we found that II can act as an electron acceptor toward tertiary amines, thus giving rise to their radical cations.[5] This Lewis acid behavior of II led us to investigate the decomposition of diazoalkanes using it. We now wish to report that *o*-sulfobenzoic anhydride(II) reacts under ordinary conditions with a variety of diazoalkanes(I) to afford the keto sultones(IV), and that, in the case of diaryldiazomethanes, a trace amount of contaminant *o*-sulfobenzoic acid(III) rather than II preferentially causes the acid-catalyzed decomposition to yield the olefins(V).

Results and Discussion

The reactions of a variety of diazoalkanes(I) with II in dry acetonitrile gave the keto sultones(IV) or the tetraarylethylenes(V) depending on the nature of I (Scheme 1 and Table 1).

As may be seen in Table 1, the diazoalkanes (I-1—5) which bear a relatively small substituent, R_1, such as H or CH_3, gave the keto sultones(IV), while when the R_1 and R_2 substituents were both aryl rings (I-6—9), the olefins(V) were isolated instead of the keto sultones



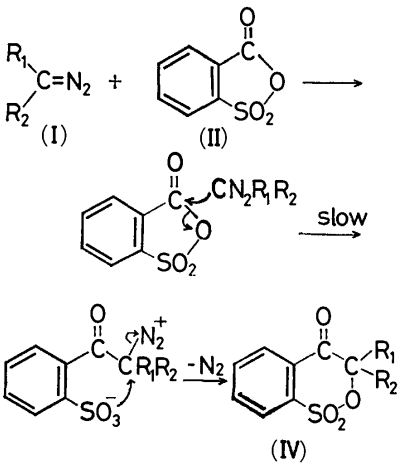
Scheme 1.

Table 1. Product distributions from the reactions of a number of diazoalkanes(I) with *o*-sulfobenzoic anhydride(II) in acetonitrile at room temperature[a]

	R_1	R_2	Products (Yield[b])	
I-1	H	H	IV-1 (74)	—
I-2	H	C_6H_5	IV-2 (71)	—
I-3	H	*p*-$C_6H_4CH_3$	IV-3 (81)	—
I-4	H	*p*-C_6H_4Cl	IV-4 (95)	—
I-5	CH_3	C_6H_5	IV-5 (67)	—
I-6	C_6H_5	C_6H_5	—	V-6 (96)
I-7	C_6H_5	*p*-$C_6H_4CH_3$	—	V-7 (97)
I-8	*p*-$C_6H_4OCH_3$	*p*-$C_6H_4OCH_3$	—	V-8 (≈100)
I-9			—	V-9 (75)

a) Reaction time: 1 h. b) The yield is in mol% based on the I used.

In the course of these reactions it was noticed that the disappearance of diazo-color and the evolution of nitrogen gas occurred very much more rapidly and vigorously in the case of the diaryldiazomethanes (I-6—9) than in the case of the monoaryldiazomethanes (I-2—5). The marked difference in the product distributions and the reaction velocities suggests that these reactions proceed by way of a different mechanism between the monoaryldiazomethanes and the diaryldiazomethanes.



Scheme 2.

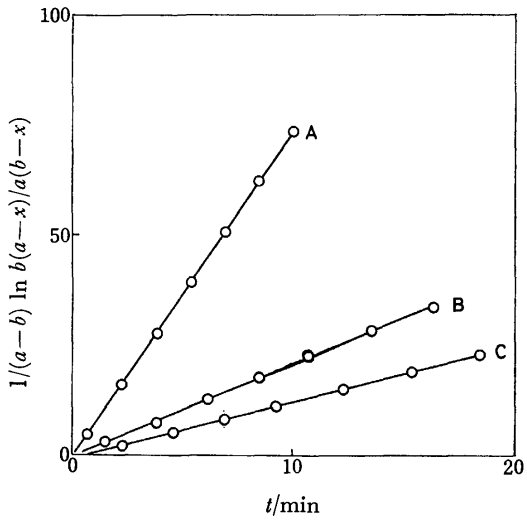


Fig. 1. Second-order kinetic behavior in the reactions of aryldiazomethanes with *o*-sulfobenzoic anhydride (II) in acetonitrile at 23 °C; a plot of the integrated form $[1/(a-b)\ \ln b(a-x)/a(b-x)]$ against time, where a and b are the initial concentrations of II and I respectively, x being the concentration of product IV.
A: *p*-Tolyldiazomethane (I-3); 2.71×10^{-2} M, II; 8.43×10^{-2} M, B: phenyldiazomethane (I-2); 2.54×10^{-2} M, II; 9.50×10^{-2} M, C: *p*-chlorophenyldiazomethane (I-4); 2.21×10^{-2} M, II; 9.00×10^{-2} M.

* *o*-Sulfobenzoic anhydride solution used here is identical to that used in the case of marked ○ but has been stood for 1 day in glass stoppered flask.

The kinetic measurements of these reactions provided some information about the mechanism. Keto sultone formation reactions obeyed a clean second order, as is shown in Fig. 1, suggesting a rate-determining nucleophilic attack of diazoalkanes at the carbonyl position of II (Scheme 2). This is also supported by the tendency for the rate constants to increase with the electron-donating ability of the aryl substituents of these monoaryldiazomethanes: $k=1.25$ (1 mol^{-1} min^{-1}) (*p*-Cl), $k=2.48$ (*p*-H), and $k=6.85$ (*p*-CH_3). Taking into account the fact that II is a good acylating reagent,[6] it is reasonable to account for this insertion reaction in terms of the nucleophilic attack of the diazo-carbon at the carbonyl position of II.

On the other hand, as Fig. 2 shows, the olefin-formation reactions progressed quickly even in the presence of a catalytic amount of II. Here, it is noteworthy that I-7, bearing an electron-donating *p*-substituent (CH_3), decomposes much faster than I-6. In addition, the IR spectra of equimolar I and II in acetonitrile showed no change in the two characteristic carbonyl absorptions at 1818 and 1836 cm^{-1} of II after the reactions. These facts imply that the decomposition of diaryldiazomethanes does not consume II and that it proceeds through a catalytic mechanism.

Considering that II invariably contains a trace amount of free acid,[7,8] *o*-sulfobenzoic acid (III), it seems possible that this free acid induces the decomposition of diazoalkanes. The quantitative formation of the tetraarylethylenes in our present reaction is well consistent with that in the acid-catalyzed decompositions of diaryldiazomethanes in aprotic solvents with such strong acids as *p*-toluenesulfonic acid.[1b,9,10,11] Keeping this in mind, we examined the decompositions of I by III, which had been prepared independently, and compared the decompositions with those by II (Fig. 2).

As for the reaction leading to V, the kinetic order by authentic III was very similar to that by II: the kinetic order was close to zero up to the final stage of the reaction, in analogy with that of the *p*-toluenesulfonic acid-catalyzed decomposition of diaryldiazomethanes in dry acetonitrile.[12] Furthermore, a rate acceleration was observed when we employed a solution of II which had been stored for one day (Fig. 2). This phenomenon is due to the partial transformation of II to III by the action of atmospheric moisture, as was confirmed by the UV spectra of II, as may be seen in Fig. 3. When the measurement was done one day later, the intensity in the UV spectrum of II (Curve b) decreased at $\lambda_{max}=286.5$ nm and had new absorption maxima at 237 and 278.5 nm instead of at 239 and 279 nm, with two isosbestic points at 254 and 284 nm. Therefore, it is apparent that the decomposition of diaryldiazomethanes was induced by the trace amount of III instead of by II.

As is well known, the acid-catalyzed reaction of diaryldiazomethanes, involving a rate-determining proton transfer and obeying a pseudo-first order, proceeds by way of intermediate diazonium ions[1b,9,10,11] (or carbonium ions derived from them). Bethell and Callister[11] studied the decomposition of diphenyl-

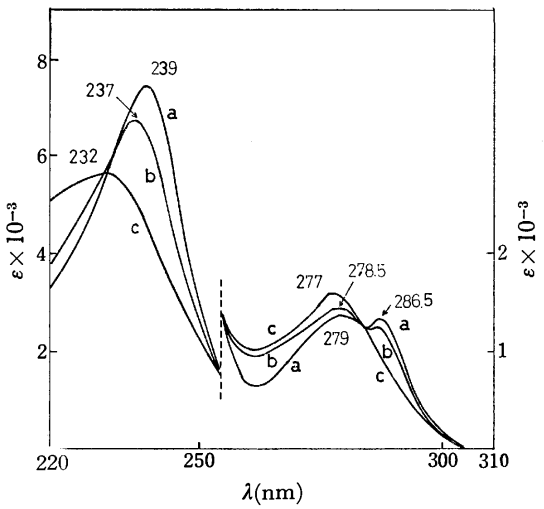

Fig. 3. UV spectra of II under the various conditions. a: Measured immediately after preparation, b: measured after 1 day, c: measured after hydrolysis.

diazomethane in dry acetonitrile with perchloric acid, which is fully ionized in this solvent,[13] and found the kinetic order to be pseudo-first, as is formulated in Scheme 3:

$$Ph_2CN_2 \xrightarrow[k_1]{H^+ \text{ slow}} Ph_2CHN_2^+ \xrightarrow{-N_2}$$

$$Ph_2CH^+ \xrightarrow[k_2]{Ph_2CN_2} Ph_2C{=}CPh_2 + N_2 + H^+$$

Kinetic equation:

$$\frac{-d[Ph_2CN_2]}{dt} = 2k_1[H^+][Ph_2CN_2] = k_1'[Ph_2CN_2]$$

Scheme 3.

However, at the same time they found that the kinetic order changes to zero when perchloric acid is replaced by *p*-toluenesulfonic acid, which reacts in an undissociated form in dry acetonitrile.[12] As to this zero order decomposition, they thought that the diphenyldiazomethane reacts first to form the benzhydryltoluenesulfonate intermediate, which subsequently undergoes a slow solvolysis to form tetraphenylethylene, as is formulated in Scheme 4:

$$Ph_2CN_2 + HOTs \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} [Ph_2CHN_2^+ \ ^-OTs \longrightarrow$$

$$Ph_2CHOTs] \xrightarrow[k_4 \text{ slow}]{} Ph_2CH^+ + {}^-OTs \xrightarrow{Ph_2CN_2}$$

$$Ph_2C{=}CPh_2 + HOTs + N_2$$

Kinetic equation:

$$\text{if } (k_3/k_{-3})[Ph_2CN_2] \gg 1, \quad \frac{-d[Ph_2CN_2]}{dt} = k_4[HOTs]_{st}$$

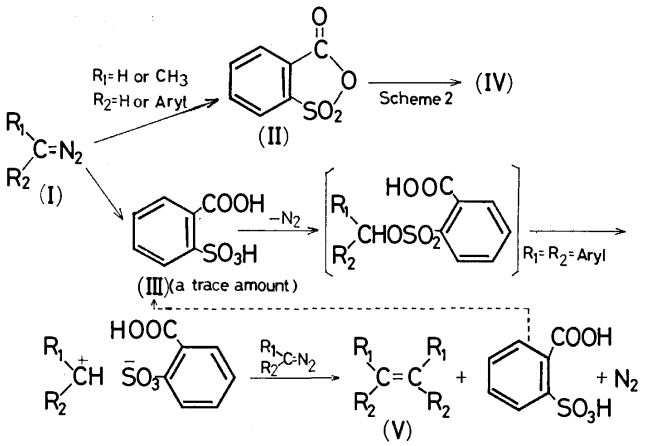
$[HOTs]_{st}$: the stoicheiometric acid concentration

Scheme 4.

In the present system, *o*-sulfobenzoic acid (III) has both carboxyl and sulfo groups, and its behavior toward diazoalkanes can be regarded as being comparable to *p*-toluenesulfonic acid because the two acids similarly bring about a quantitative olefin formation under zero order kinetics.

The decompositions of monoaryldiazomethanes by the action of III were quite slow compared with those of diaryldiazomethanes, even in the presence of about a ten-fold concentration of III (Fig. 2). This marked change in the decomposition rate between the monoaryldiazomethanes and the diaryl ones may be attributed to the differences in the stabilities of the intermediate sulfonates. The sulfonates derived from diaryldiazomethanes seem to be much more subject to solvolysis than the corresponding sulfonates from monoaryldiazomethanes.

Consequently, it is concluded that, in the cases of diazomethane and monoaryldiazomethanes, the insertion reaction is preferential because these diazoalkanes have an effective nucleophilicity toward II; even if the reaction could occur with a trace amount of III, it would essentially stop at the stage of the sulfonate formation because of its stability against solvolysis. On the other hand, in the cases of diaryldiazomethanes, the lesser nucleophilicity of the diazo-carbon atom toward II resulting from the conjugation with the two aromatic rings as well as the steric effects and the readier solvolysis of the sulfonates make the acid-catalyzed decomposition predominant. From these observations, the present decomposition reactions are formulated as follows (Scheme 5):



Scheme 5.

Experimental

The NMR spectra were obtained with a Varian EM-360 (60 MHz) instrument, with tetramethylsilane as the internal standard. The IR spectra were recorded on a Hitachi 215 Grating Infrared Spectrophotometer; a 0.1 mm NaCl cell was used for the measurement in solution. The UV spectra were taken with a Union SM-401 spectrophotometer.

Materials. The acetonitrile was purified by careful distillation from phosphorus pentoxide through a 10-in helix-packed column. The middle fractions were collected and stored in a glass-stoppered flask. The *o*-sulfobenzoic anhydride (II) was prepared by the method of Clarke and Dreger,[14] and recrystd from benzene; mp 126—127 °C, (lit,[14] 126—127 °C); IR (in CH_3CN): 1836 and 1818 (C=O), 1206, 996, 810 cm^{-1}. The anhyd *o*-sulfobenzoic acid (III) was given on the hydrolysis of II and was dried *in vacuo* above 105 °C; mp 140—141 °C; IR (Nujol): 3500—2500 (COOH

and SO_3H), 1720 (C=O), 1160 and 1020 cm^{-1} (SO_2). Because of moisture-sensitive substances, the anhydride and the acid, placed in a bottle fitted with a sealing cap, were stored in a desiccator, with silica gel as the desiccant. The diazomethane was prepared by the procedure in the literature,[15] and its ethereal solution was dried over potassium hydroxide. The monoaryldiazomethanes and diaryldiazomethanes were synthesized by the methods of Closs and Moss[16] and Smith and Howard[17] respectively. $\lambda_{max}(\varepsilon)$ in CH_3CN: 488 nm (25) for phenyldiazomethane (I-2), 495 (25) for *p*-tolyldiazomethane (I-3), 484 (32) for *p*-chlorophenyldiazomethane (I-4), 525 (95) for diphenyldiazomethane (I-6); these values are essentially identical with those in the literature.[11,16]

p-Tolylphenyldiazomethane (I-7); mp 51—53 °C, reddish purple needles (from petroleum ether), (lit,[18] 53—55 °C), $\lambda_{max}(\varepsilon)$ in CH_3CN: 530 nm (98). Bis(*p*-methoxyphenyl)-diazomethane (I-8); mp 99 °C (dec), purple needles (from ether), (lit,[11] 99—100 °C (dec)). 9-Diazofluorene (I-9); mp 94—95 °C (from EtOH), (lit,[19] 94—95 °C). Because of the unstability of the diazo compounds, they were prepared just before use for the aryldiazomethanes and were purified before use by recrystallization for the diaryldiazomethanes.

Kinetic Measurements. The temperature during the measurements was not especially controlled, but its change was within ±0.5 °C. As a rule, solutions of I, II, and III were made up separately just before use. The change in the optical density at the wavelength of the absorption maximum of I in the visible region was followed spectrophotometrically. The second order rate constants, k, were determined graphically from the plots of $1/(a-b)\ln b(a-x)/a(b-x)$ against the time.

General Procedure. To a three-necked flask (100 ml) equipped with a dropping funnel, a thermometer, and a drying tube of calcium chloride, we added II (5 m mol) in dry acetonitrile (25 ml), and then I (5 m mol) in dry acetonitrile (25 ml) was stirred in over a 10-min period. Stirring was then continued for 50 min. In the case of diazomethane, its excess in an ether solution dried over potassium hydroxide was dropped in. The addition of I caused the evolution of nitrogen gas. The removal of the solvent *in vacuo* gave oily reaction mixtures in the cases of I-1—5 or solid ones in the cases of I-6—9. The same procedure was used for the *o*-sulfobenzoic acid-catalyzed decomposition of diaryldiazomethanes (I-6—8) by employing a catalytic amount of III instead of II. These catalytic decompositions also gave almost quantitative olefins for I-6—8. These reaction mixtures were submitted to chromatography, using silica gel as the adsorbent. Elution with a petroleum ether–ether gave the olefins (V), while elution with chloroform gave the keto sultones (IV). The olefins, V-6, 8, were identified by comparison with authentic specimens,[11] while the V-7 and V-9 were confirmed by elemental analyses: V-7; Found: C, 93.11; H, 6.79%. Calcd for $C_{28}H_{24}$: C, 93.29; H, 6.71%. V-9; Found: C, 94.74; H, 5.11%. Calcd for $C_{26}H_{16}$: C, 95.09; H, 4.91%. 1,2-Di-*p*-tolyl-1,2-diphenylethylene (V-7) showed two kinds of methyl signals to the same extent, centered at δ 2.2 and due to the *cis* and *trans* isomers. The structures of the keto sultones (IV-1—5) were determined by means of elemental analyses and by measurements of the IR, NMR, and Mass spectra.

o-*Glycoloylbenzenesulfonic Acid Sultone (IV-1)*: Mp 93—94 °C, colorless needles (from CH_3OH), (lit,[20] 93—94 °C). IR (Nujol): 1700 (C=O), 1367 and 1195 cm^{-1} (SO_2). MS: m/e=198 (M^+). NMR (δ, $CDCl_3$): 7.7—8.2 (m, 4H), 5.25 (s, 2H). Found: C, 48.27; H, 3.17%. Calcd for $C_8H_6O_4S$: C, 48.49; H, 3.05%.

o-*(Phenylglycoloyl)benzenesulfonic Acid Sultone (IV-2)*: Mp 54—55 °C, colorless needles (from CH_3OH). IR (Nujol): 1703 (C=O), 1370 and 1195 cm^{-1} (SO_2). MS: m/e=274 (M^+). NMR (δ, $CDCl_3$): 7.67—8.17 (m, 4H), 7.40 (s, 5H), 6.38 (s, 1H). Found: C, 61.22; H, 3.77%. Calcd for $C_{14}H_{10}O_4S$: C, 61.32; H, 3.68%.

o-*(Tolylglycoloyl)benzenesulfonic Acid Sultone (IV-3)*: Mp 123—124 °C, pale yellow needles (from CH_3OH). IR (Nujol): 1700 (C=O), 1365 and 1195 cm^{-1} (SO_2). MS: m/e=288 (M^+). NMR (δ, $CDCl_3$): 7.67—8.17 (m, 4H), 7.25 (s, 4H), 6.37 (s, 1H), 2.37 (s, 3H). Found: C, 62.52; H, 4.23%. Calcd for $C_{15}H_{12}O_4S$: C, 62.50; H, 4.20%.

o-*(p-Chlorophenylglycoloyl)benzenesulfonic Acid Sultone (IV-4)*: Mp 89—90 °C, colorless needles (from CH_3OH). IR (Nujol): 1705 (C=O), 1360 and 1195 cm^{-1} (SO_2). MS: m/e=308, 310 (3:1) (M^+). NMR (δ, $CDCl_3$): 7.73—8.33 (m, 4H), 7.40 (s, 4H), 6.40 (s, 1H). Found: C, 54.21; H, 3.35%. Calcd for $C_{14}H_9O_4SCl$: C, 54.40; H, 3.01%.

o-*(Methylphenylglycoloyl)benzenesulfonic Acid Sultone (IV-5)*: Mp 80—81 °C. Colorless needles (from CH_3OH). IR (Nujol): 1700 (C=O), 1365 and 1194 cm^{-1} (SO_2). MS: m/e=288 (M^+). NMR (δ, $CDCl_3$): 7.67—8.07 (m, 4H), 7.27—7.57 (m, 5H), 2.28 (s, 3H). Found: C, 62.41; H, 4.59%. Calcd for $C_{15}H_{12}O_4S$: C, 62.50; H, 4.20%.

(Received December 14, 1976)

Irradiation of 1,2-diphenylcyclobutene (**1**) in methanol affords the methyl ethers, 1,2-diphenyl-1-methoxycyclobutane (**2a**) and 1-(α-methoxybenzyl)-1-phenylcyclopropane (**3a**). In acetic acid and in a mixture of water and dioxane, the corresponding esters (**2b** and **3b**) and alcohols (**2c** and **3c**) are formed, respectively. Evidence supporting the involvement of a singlet species was obtained upon finding that the fluorescence of **1** is substantially quenched upon the addition of methanol or acetic acid to a solution of **1** in hexane.

One of the simplest organic chromophores is the carbon-carbon double bond. However, its photochemical behavior is not at all simple. This chromophore undergoes, on direct or sensitized irradiation, *cis-trans* isomerization, cycloaddition, reduction, and the addition of protic solvents depending on the nature of the double bond, the solvent, and the sensitizer.[1] Even for the photochemical behavior of cyclic olefins in protic solvents, no consistent explanation has been given. The behavior of six- and seven-membered cycloalkenes are the best documented and most studied.[2] Direct or sensitized irradiation of cyclohexenes and cycloheptenes in an (acidic) alcoholic solution affords ethers arising from the addition of the alcohol to the double bond.[2] In these cases, the orthogonal excited triplet olefin or a highly-strained ground state of *trans*-olefin is considered to be the reactive species.[2]

Eight-membered cycloalkenes, which easily isomerize through the triplet state upon irradiation, also undergo this polar addition, but less efficiently.[2b,2d,2j,3] Polar addition disappears on going to smaller ring sizes. Cyclopentenes undergo reduction of the double bond, but do not undergo the addition of protic solvents.[2d,2e,2j] However, bicyclic olefins containing a five-membered ring, such as 2-phenylbicyclo[2.2.1]hept-2-ene and its 1,7,7-trimethyl derivative, have been reported to undergo polar addition of methanol under illumination.[4] The reaction products are apparently similar to those from cyclohexenes, cycloheptenes, and cyclooctenes, but the reaction course is unequivocally different because the bicyclic olefins fail to transform to the orthogonal triplet states or to the *trans*-configurations. The polar addition of the bicyclic olefins as well as styrene derivatives has been interpreted in terms of a reactive singlet excited state displaying a charge-transfer character.[4]

In a previous communication,[5] the first example of the photochemical ionic addition to the rigid cyclobutene system was reported and evidence supporting the involvement of a singlet excited species in the addition was presented by showing that the irradiation of 1,2-diphenylcyclobutene (**1**) in methanol and acetic acid affords polar addition products, methyl ethers and acetates and that the fluorescence of **1** is quenched substantially by methanol. In the present paper, the details of these results will be described.

Results and Discussion

A solution of 1,2-diphenylcyclobutene (**1**, 5×10^{-5} M) in methanol, ethanol, acetic acid, or in a mixture of water and dioxane was irradiated with 330 nm light. The bands of **1** at 227 and 297 nm decreased in intensity during the irradiation. A typical example is shown for methanol in Fig. 1. Three isosbestic points maintained

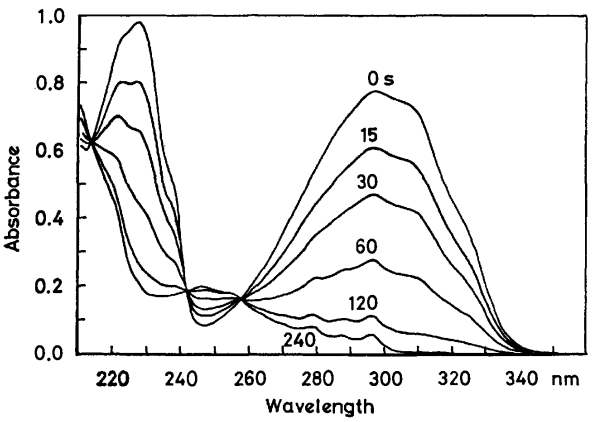

Fig. 1. Spectral change of a solution of 1,2-diphenylcyclobutene (**1**) in methanol (4×10^{-5} M) during irradiation with 330 nm light.

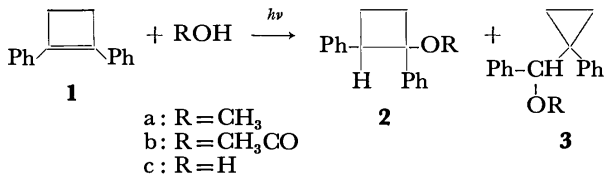
their positions during the reaction, suggesting that this reaction is straightforward. In order to obtain the reaction products, **1** in methanol (7×10^{-3} M) was irradiated by a 500 W xenon lamp through a filter (Corning glass filter 0—54, nominally wavelengths longer than 300 nm). The reaction mixture was separated by column chromatography on silica gel into two components in addition to the recovered starting material. One component was a colorless liquid which was identified as 1-(α-methoxybenzyl)-1-phenylcyclopropane (**3a**) by the presence in the NMR spectrum of a four-proton multiplet at δ 0.65—1.15 which is characteristic of methylene protons attached to a cyclopropane ring and by elemental analysis (*cf.* Experimental). The other component was a white crystalline solid which was characterized as 1,2-diphenyl-1-methoxycyclobutane (**2a**) from the spectral data and elemental analysis (*cf.* Experimental). Gas chromatographic analysis and the NMR spectrum show that **2a** consists of only one isomer.



Similar irradiation of **1** in acetic acid afforded 1,2-diphenylcyclobutyl acetate (**2b**) and α-(1-phenylcyclopropyl)benzyl acetate (**3b**). Their structures were established from spectral data and elemental analysis (*cf.* Experimental). Compound **2b** was also found to consist of one isomer from gas chromatographic analysis and NMR data. The addition products, **2a** and **2b**, as well as *N,N*-disubstituted 1,2-diphenylcyclobutanamines, the adducts of **1** with *s*-amines, displayed a multiplet due to a methine proton at the same region (δ 3.7—4.2) as did *cis*-1,2-diphenylcyclobutane, while *trans*-1,2-diphenylcyclobutane exhibited a multiplet at a somewhat higher field (δ 3.2—3.6).[6] Taking into account the small effect of the β-substituents on the chemical shift of a methine proton,[7] **2a** and **2b** can safely be assigned to the *cis*-configuration. The results are summarized in Table 1.

Table 1. Products from the irradiation of 1,2-diphenylcyclobutene (**1**) in polar solvents

Solvent	Irradiation time (h)	Product yield (%)[a]	
		2	**3**
MeOH	18	25	43
AcOH	100	50	17
H_2O[b]	80	12	44
D_2O[b]	90	16	34

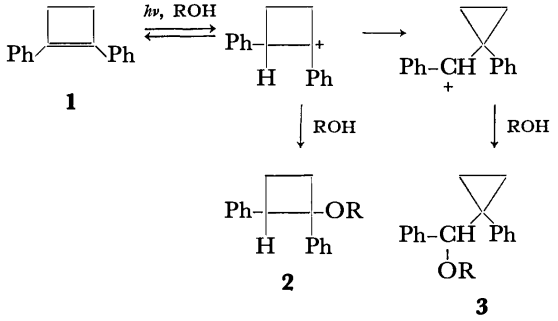
a) The yield based on the amount of **1** reacting.
b) In dioxane.

α,1-Diphenylcyclopropanemethanol (**3c**) and 1,2-diphenylcyclobutanol (**2c**)[8] were similarly obtained upon irradiation of **1** in a mixture of water and dioxane (1 : 4 by volume), as is summarized in Table 1. These products, **2c** and **3c**, were characterized by their spectral data and by comparing the spectral data of their acetates with those of **2b** and **3b**.

The possibility that **2** and **3** could have arisen non-photochemically from **1** was eliminated by leaving solutions of **1** in methanol, acetic acid, and water–dioxane in the dark for 3 days.

The formation of **3**, as well as **2**, from **1** suggests that these products arise from an initial photoprotonation of **1** with the formation of a cyclobutyl cation, which in turn undergoes three competing reactions: a) nucleophilic capture by the solvent to afford **2**, b) skeletal rearrangement to a cyclopropylmethyl cation, with subsequent capture by the solvent affording **3**, and c) deprotonation which regenerates the starting olefin **1**.

Although a protonated bicyclobutane has been proposed as an intermediate in the deamination of cyclobutanamine and cyclopropylmethanamine producing the same mixture of cyclobutanol and cyclopropanemethanol in each case,[9] there is no need to postulate a nonclassical cation in this photochemical process, and the product ratio is attributable to kinetic control in the nucleophilic capture by the solvent. This assumption



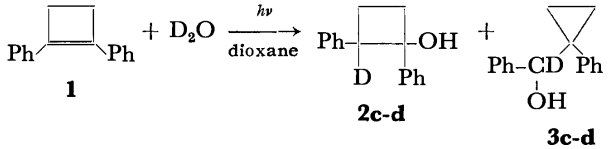
is consistent with the sole formation of the *cis*-cyclobutane derivatives since the nucleophile would preferentially attack the 1,2-diphenylcyclobutyl cation from the less hindered side. The behavior of the diphenylcyclobutyl cation upon rearrangement to the cyclopropylmethyl cation is in remarkable contrast to that of the 1-phenylcyclobutyl cation, which shows no tendency to rearrange in superacid solutions.[10] For the photoreaction of 2,3-diphenyl-1,3-butadiene in methanol, Baldry[11] has isolated **2a** and **3a** together with **1** and other products, and postulated a mechanism for the ether formation involving a bicyclobutane intermediate.[12] However, the possibility that **2a** and **3a** arise from the photoprotonation of primarily formed **1** can not be ruled out completely in view of the photolability of **1**.

Table 2. Kinetic data for the photoprotonation of 1,2-diphenylcyclobutene (**1**) in hexane[a]

Quencher	$k_q\tau_0$ (M^{-1})		k_d/k_r
	From fluorescence quenching experiment	From quantum-yield measurement	
EtOH	0.36	0.41	12
AcOH	0.38	0.40	9

a) Conducted under aerated conditions.

In order to gain more insight into the mechanism for the polar addition, a labeling study using deuterated water as the additive was undertaken. 1,2-Diphenylcyclobutene (**1**) was irradiated in a mixture of deuterated water and dioxane (1 : 4 by volume), and the products were isolated in a manner similar to that described above. The deuteration position for each product was determined by comparing its NMR spectrum with that of the non-deuterated product; 1,2-diphenylcyclobutanol (**2c-d**) undergoes deuteration at the 2-position and α,1-diphenylcyclopropanemethanol (**3c-d**) at the α-position. These results confirm the assumption that the addition proceeds from the initial photoprotonation of the cyclobutene (**1**).



Since the quantum yield for fluorescence of **1** is

reported to be almost as high as unity in a diluted solution,[13] photoprotonation is assumed to proceed from the excited singlet state of **1**. Evidence supporting the involvement of a singlet species was obtained from the finding that the fluorescence of **1** is substantially quenched upon the addition of methanol, ethanol, and acetic acid to the solution of **1** in hexane. Plots of the reciprocals of the relative fluorescence intensities against the quencher concentrations are linear and can be fitted to the Stern-Volmer equation,

$$I_0/I = 1 + k_q\tau_0[Q],$$

where I_0 and I denote the intensities of the fluorescence of **1** in the absence of and in the presence of the quencher, respectively, in the concentration [Q], k_q is the rate constant of the bimolecular quenching process, and τ_0 denotes the average lifetime of the excited singlet state of **1** in the absence of the quencher. The quenching constants, $k_q\tau_0$, obtained from the slopes of these plots are 0.42, 0.36, and 0.38 M^{-1} for methanol, ethanol, and acetic acid, respectively. The singlet lifetime of **1** (τ_0) has been reported to be shorter than 5 ns,[13] and thus the k_q values are estimated to be larger than 8×10^7 M^{-1} s^{-1}, and are probably about 10^8 M^{-1} s^{-1}, suggesting that the excited singlet state of **1** interacts with the ground state of the alcohols and acetic acid.

The quantum yield of the photochemical polar addition of ethanol and acetic acid to **1** was determined under aerated conditions in hexane by monitoring the decrease of **1** upon irradiation with 330 ± 7 nm light. A linear relationship is found between the reciprocal of the quantum yield (Φ) for the decrease of **1** and the reciprocal of the concentration of the additive. The intercepts and the slopes were estimated to be 13 and 32 for ethanol, and 10 and 25 for acetic acid, respectively.

The simplest mechanism which accounts for all the above results can be written as follows,

$$\mathbf{1} + h\nu \longrightarrow \mathbf{1}^*$$

$$\mathbf{1}^* \xrightarrow{k_f} \mathbf{1} + h\nu'$$

$$\mathbf{1}^* + O_2 \xrightarrow{k_0} \mathbf{1} + O_2$$

$$\mathbf{1}^* + HOR \xrightarrow{k_q} [\mathbf{1}\cdots HOR]^*$$

$$[\mathbf{1}\cdots HOR]^* \xrightarrow{k_d} \mathbf{1} + HOR$$

$$[\mathbf{1}\cdots HOR]^* \xrightarrow{k_r} [\mathbf{1}\text{–}H^+ + {}^-OR] \longrightarrow \text{products},$$

where **1*** denotes the excited singlet state of **1**. At infinite dilution under degassed conditions, the quantum yield for the fluorescence of **1** is unity,[13] and therefore, intersystem crossing to the triplet state can be neglected. By making the usual steady-state assumption, the quantum yield for the decrease of **1** is written as follows;

$$1/\Phi = (1+k_d/k_r)(1+1/k_q\tau_0[Q]).$$

The k_d/k_r values, *i.e.*, the ratio of rates for the decay process and the protonation in the interaction of excited **1** and the polar solvent, can be estimated to be 12 for ethanol and 9 for acetic acid, and the $k_q\tau_0$ values were found to be 0.41 M^{-1} for ethanol and 0.40 M^{-1} for acetic acid. These values are in good agreement with those obtained in the fluorescence quenching experiments: 0.36 M^{-1} for ethanol and 0.38 M^{-1} for acetic acid. These results substantiate the above mechanism.

When 1-phenylcyclobutene was irradiated in methanol no addition products resulted. This, combined with the results for 1,2-diphenylcyclobutene, suggests that substituents on the cyclobutene ring play important roles in the reactivity of cyclobutenes. These substituent effects upon the reactivity will be discussed in a future publication. 1,2-Diphenylcyclopentene was also irradiated in methanol giving no polar addition products but a phenanthrene derivative, the formation of which was so efficient that it was observed in the course of the fluorescence measurement.

The only previously observed ring system for photoprotonation from the excited singlet state is the case of 2-phenylbicyclo[2.2.1]hept-2-ene derivatives,[4] and thus 1,2-diphenylcyclobutene is the first example for a four-membered cycloalkene. For three-membered cycloalkenes, 1,2-diphenyl-3,3-dimethylcyclopropene has been reported to give open-ring products, 1,2-diphenyl-1-methoxy-3-methyl-2-butene and *cis*-1,2-diphenyl-3-methoxy-3-methyl-2-butene, upon irradiation in methanol, through a carbene intermediate arising from the excited singlet state with subsequent capture by methanol.[14] It is interesting that the cyclobutene system has almost the same strain energy as the bicyclo[2.2.1]hept-2-ene system, the cyclopropene system having a much higher energy.[15]

Recently, the reactive intermediate in the photoprotonation of 1-phenylcyclohexene was shown to be *trans*-phenylcyclohexene, which must be very twisted, by more than 90°.[16] This is assumed to be the case for the phenylcycloheptene photoprotonation. These *trans*-cycloalkenes are singlet in nature and possess a partial singlet diradical character if the twist is not completed to 180°.[16] This may be common to the excited singlet states of highly-strained cycloalkenes, such as the phenylbicyclo[2.2.1]heptenes and diphenylcyclobutene. Thus, protonation in the highly-strained *cis*-cycloalkenes, as well as in the highly-twisted *trans*-cycloalkenes, would be effected by the simultaneous release of strain in those intermediates.

Experimental

The IR and UV spectra were recorded on a Hitachi EPI-G3 grating infrared spectrophotometer and a Hitachi EPS-3 recording spectrophotometer, respectively. The NMR spectra were recorded on a JEOL C-60HL spectrometer. GLPC analysis was performed on a Hitachi 163 gas chromatograph equipped with a flame ionization detector.

Materials. 1,2-Diphenylcyclobutene,[17] 1-phenylcyclobutene,[18] and 1,2-diphenylcyclopentene[19] were prepared according to reported methods. Solvents were purified by distillation.

Irradiation of 1,2-Diphenylcyclobutene (1) in Methanol. A solution of **1** (300 mg) in methanol (200 ml) was irradiated in a nitrogen atmosphere for 18 h using a 500-W xenon lamp and a Corning 0—54 filter. This procedure was repeated six times. The reaction mixtures were combined, and the solvent was removed by rotary evaporation. The residue was subjected to chromatography on silica gel using hexane–benzene eluants affording a colorless liquid (540 mg), a white crystalline solid (310 mg), and the starting olefin (720 mg).

The colorless liquid was identified to be 1-(α-methoxybenzyl)-1-phenylcyclopropane (**3a**) from the spectral data and elemental analysis. Bp *ca.* 270 °C. IR (liquid film) 1090 cm^{-1}. NMR δ 0.65—1.15 (m, 4H, cyclopropyl CH_2-CH_2), 3.22 (s, 3H, OCH_3), 4.02 (s, 1H, methine H), 6.8—7.4 (m, 10H, aromatic H). Found: C, 85.47; H, 7.44%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

The white solid was deduced to be 1,2-diphenyl-1-methoxycyclobutane (**2a**) from the spectral data and elemental analysis. The GLPC analysis and NMR data showed that **2a** consists of only one isomer. Mp 91.5—92.0 °C (from petroleum ether). IR (KBr) 1080 cm^{-1}. NMR ($CDCl_3$) δ 1.7—2.3 (m, 4H, CH_2CH_2), 2.93 (s, 3H, OCH_3), 3.7—4.1 (m, 1H, methine H), 6.6—7.3 (m, 10H, aromatic H). Found: C, 86.09; H, 7.54%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

Irradiation of 1,2-Diphenylcyclobutene (1) in Acetic Acid. A solution of **1** (2.0 g) in acetic acid (200 ml) was similarly irradiated for 100 h using a 500-W xenon lamp. The solvent was removed by rotary evaporation, and the residue was subjected to chromatography on silica gel with hexane-benzene eluants resulting in three components: the first white solid (640 mg) was found to be the starting olefin, and the second colorless liquid (300 mg) was identified as α-(1-phenylcyclopropyl)benzyl acetate (**3b**) from spectral data and elemental analysis. Bp *ca.* 300 °C. IR (liquid film) 1740, 1240 cm^{-1}. NMR (CCl_4) δ 0.6—1.4 (m, 4H, cyclopropyl CH_2CH_2), 1.95 (s, 3H, $OCOCH_3$), 5.40 (s, 1H, methine H), 6.6—7.2 (m, 10H, aromatic H). Found: C, 81.17; H, 6.74%. Calcd for $C_{18}H_{18}O$: C, 81.17; H, 6.81%.

The third colorless liquid (870 mg) was characterized as 1,2-diphenylcyclobutyl acetate (**2b**) from spectral data and elemental analysis. The GLPC analysis and NMR data showed that **2b** consists of only one isomer. Bp *ca.* 235 °C. IR (liquid film) 1745, 1240 cm^{-1}. NMR (CCl_4) δ 1.90 (s, 3H, $OCOCH_3$), 1.7—3.35 (m, 4H, CH_2CH_2), 3.7—4.1 (m, 1H, methine H), 6.4—7.2 (m, 10H, aromatic H). Found: C, 81.01; H, 6.90%. Calcd for $C_{18}H_{18}O$: C, 81.17; H, 6.81%.

Irradiation of 1,2-Diphenylcyclobutene (1) in a Mixture of Water and Dioxane. A solution of **1** (300 mg) in a mixture of water (40 ml) and dioxane (160 ml) was similarly irradiated by a 500-W xenon lamp for 80 h. This procedure was repeated twice. The reaction mixtures were combined, and the solvent was removed by rotary evaporation. The residue was subjected to chromatography on silica gel. The products obtained were diphenylacetylene[20] (20 mg), α,1-diphenylcyclopropanemethanol (**3c**, 235 mg), 1,2-diphenylcyclobutanol (**2c**, 65 mg), and 1,2-dibenzoylethane[21] (40 mg). The starting olefin (10 mg) was recovered. **3c** and **2c** were identified upon esterification with acetic anhydride to the corresponding acetates, **3b** and **2b**, respectively.

α,1-Diphenylcyclopropanemethanol (**3c**). NMR (CD_3COCD_3) δ 0.6—1.4 (m, 4H, cyclopropyl CH_2CH_2), 4.45 (s, 1H, OH, exchanged with D_2O), 4.75 (s, 1H, methine H), 7.2—7.7 (m, 10H, aromatic H).

1,2-Diphenylcyclobutanol (**2c**).[8] NMR (CD_3COCD_3) δ 2.0—3.0 (m, 4H, CH_2CH_2), 3.9—4.4 (m, 1H, methine H), 5.15 (s, 1H, OH, exchanged with D_2O), 6.9—7.9 (m, 10H, aromatic H).

Irradiation of 1,2-Diphenylcyclobutene (1) in a Mixture of Deuterated Water and Dioxane. The irradiation of **1** (500 mg) in a mixture of deuterated water (40 ml) and dioxane (160 ml) was performed under otherwise similar conditions. Deuterated products, α,1-diphenylcyclopropanemethanol-α-*d* (**3c-d**, 140 mg) and 1,2-diphenylcyclobutanol-2-*d* (**2c-d**, 70 mg), were isolated in a similar manner together with 1,2,5,6-tetraphenyltricyclo[4.2.0.$0^{2,5}$]octane[13,20] (35 mg), 1,2,5,6-tetraphenylcycloocta-1,5-diene[13,20] (10 mg), and the recovered starting olefin (120 mg). The position of deuteration in the products, **2c-d** and **3c-d**, was determined by comparing their NMR spectra with those for non-deuterated products, **2c** and **3c**, respectively.

Quenching of the Fluorescence of 1,2-Diphenylcyclobutene (1). The fluorescence of **1** (4×10^{-4} M) in hexane containing various concentrations of alcohols or acetic acid (0—0.8 M) was determined using a Hitachi MPF-2A fluorescence spectrophotometer.

Quantum-yield Measurements. The exciting light for the quantum-yield measurements was furnished by a JASCO CRM-FA spectroirradiator. Hexane solutions of **1** (10^{-3} M) and ethanol or acetic acid (0—1 M) were irradiarted with 330 ± 7 nm light for 3 min. The reaction mixture was diluted twenty times with the same solvent and its UV spectrum was measured. The light intensity was measured by potassium ferrioxalate actinometry.

The Highly Selective Sulfonylation of Cycloheptaamylose and Syntheses of Its Pure Amino Derivatives

Kenji TSUJIHARA, Hironori KURITA, and Mitsutaka KAWAZU

Organic Chemistry Research Laboratory, Tanabe Seiyaku Co., Ltd., Toda Saitama 335

(Received December 14, 1976)

Mesitylenesulfonyl chloride reacted selectively with primary hydroxyl groups of cycloheptaamylose to give hexakis(6-*O*-mesitylsulfonyl)cycloheptaamylose (II) and heptakis(mesitylsulfonyl)cycloheptaamylose (I). The selectivity of mesitylenesulfonyl chloride in the preferential sulfonylation is 24 times larger than that of tosyl chloride. Pure hexakis(6-azido-6-deoxy)cycloheptaamylose (III) and hexakis(6-amino-6-deoxy)cycloheptaamylose (IV) were synthesized from II. Pure heptakis(6-amino-6-deoxy)cycloheptaamylose (VII) and mixture of positional isomers of hexakis(6-amino-6-deoxy)mesitylsulfonylcycloheptaamylose (VIII)* were obtained by the catalytic hydrogenation of the corresponding azido compounds V and VI,* which were themselves given by the reaction of I with sodium azide. These amino derivatives, IV, VII, and VIII,* showed significant antimicrobial activities against such gram-negative bacteria as Escherichia, Shigella, and Pseudomonas. These compounds also exhibited hypocholesterolemic effects in the chick when added in the diet for two weeks, probably through sequestration of intestinal bile acids.

Cycloamyloses have attracted increased interest in recent years[1] because of their ability to include a compound into their cavity utilizing hydrophobic interaction in an aqueous solution. In this respect, a variety of cycloamylose derivatives have been prepared as models of enzymes.[2] Therefore, the pure sulfonylesters of cycloamylose have been required as important key intermediates.

Lautsch and his co-workers[3] were the first to attempt the selective modification of one position in each D-glucose residue. They attempted to prepare heptakis(6-*O*-tosyl) and heptakis(6-*O*-mesyl)cycloheptaamyloses by using one molar equivalent of the corresponding sulfonyl chlorides per D-glucose residue.

Recently, Cramer and his co-workers[4] studied in detail the specific modification of each D-glucose residue of cycloamyloses at a primary carbon atom and claimed that hexakis- and heptakis(6-*O*-tosyl)cyclohexa and cycloheptaamyloses were obtained by the reaction of a 50% excess of tosyl chloride and the corresponding cycloamyloses.

Using this method with a 50% excess of tosyl cloride, Umezawa and Tatsuta[5] reported that the product was a mixture of tosylated cyclohexaamyloses and that pure hexakis(6-*O*-tosyl)cyclohexaamylose was obtained after purification on a silica gel column.

However, it is still uncertain whether tosylation occurred exclusively at the primary hydroxyl groups in all the residues as claimed by these workers, because the tosylation of monosaccharides, such as α-D-glucose[6] and methyl α-D-glucopyranoside,[7] and polysaccharides, such as amylose[8] and cellulose,[9] under similar conditions has been reported to cause further tosylation at some secondary hydroxyl groups. The tosyl esters in which all the tosyloxyl groups are attached to primary carbon atoms are obtained only by purification in the case of monosaccharides, while such tosyl esters can not be obtained in the case of polysaccharides. Thus, a functional modification of cycloamyloses has been prevented by difficulties in purifying the products and it has been practically impossible to obtain the pure products by the usual methods.

Pure sulfonylesters of cycloamyloses must have definitive numbers and established positions of sulfonyloxyl groups such as all at the C-2, C-3, or C-6 positions.

Both the number and the position of sulfonyloxyl groups are equivocal in Cramer's work, in which the term "hexakis" or "heptakis" represents only the average number of the tosyl groups of a complex mixture of the products. In Umezawa's work the number is evident upon the separation of the products, but the position has not been established. It seems most likely that they obtained a mixture of the positional isomers of hexakis(tosyl)cyclohexaamyloses, as we have clarified in the present work that the heptasulfonyl ester of cycloheptaamylose with a single spot in its thin-layer chromatography was found to be still a mixture of the positional isomers.

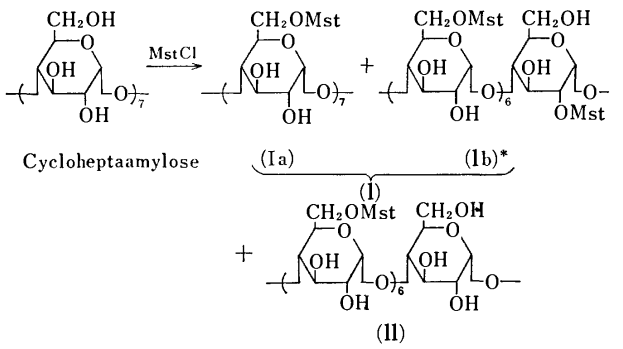
It seems almost impossible to obtain the pure sulfonyl esters without utilizing more highly selective sulfonylating agents than tosyl chloride or mesyl chloride.

Meanwhile, the use of mesitylenesulfonyl chloride (MstCl) as a selective sulfonylating agent has been reported. Palmer and his co-workers[10] reported that MstCl was a preferable sulfonylating agent in the case of secondary and tertiary hydroxyl groups of a steroid system. Furthermore, Creasey and Guthrie[11] found that MstCl reacted more selectively with one hydroxyl group of a vicinal secondary diol of α-D-glucopyranoside than did tosyl chloride, though Johnson *et al.*[12] showed in their aldosterone synthesis that the use of MstCl offered no significant advantage over the use of tosyl chloride for the selective esterification of a primary hydroxyl group in the presence of a secondary one.

In this paper we wish to report a highly selective sulfonylation of the primary hydroxyl groups of cycloheptaamylose using MstCl and describe the synthesis of some pure derivatives of cycloheptaamylose.

Results and Discussion

The selective esterification was carried out by adding a 20% excess of MstCl to a solution of cycloheptaamylose in dry pyridine at 0—5 °C and by then allowing the mixture to stand at room temperature for 3 days. The product was obtained as a white powder, and its

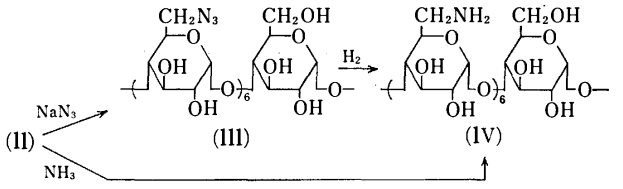


I: A mixture of Ia and Ib*.
Mst: 2,4,6-trimethylbenzenesulfonyl.
* This represents one of many kinds of possible positional isomers with regard to one secondary sulfonyl group.

thin-layer chromatography (TLC) gave only three spots (R_f; 0.79, 0.41, 0.02).

Compound Ib*, with an R_f value of 0.79, was separated on silica gel column and was established to be heptakis(mesitylsulfonyl)cycloheptaamylose by analyzing the sulfur content, while the one(II) with an R_f value of 0.41 was determined to be hexakis(mesitylsulfonyl)cycloheptaamylose in the same manner. A small amount of the compound with an R_f value of 0.02 may be pentakis(mesitylsulfonyl)cycloheptaamylose, though it was not further examined. The reaction of compound II with sodium azide in DMF at 80—85 °C, instead of at the 135 °C previously reported,[5] for 7 h led to the complete replacement of all the mesitylsulfonyloxyl groups by the azido groups.

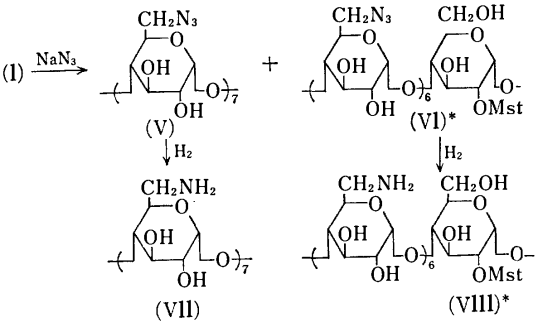
The IR absorption bands at 1600, 1350, 1190, and 1170 cm^{-1} due to the mesitylsulfonyloxyl group disappeared completely, while the one at 2100 cm^{-1} due to the azido group appeared. The azido compound obtained in this way was determined to be pure hexakis(6-azido-6-deoxy)cycloheptaamylose (III) with satisfactory physical properties. This indicates that II contains sulfonyloxyl groups only at the primary carbon atoms and none at the secondary ones, since a sulfonyloxyl group attached to a secondary carbon atom can hardly be replaced by an azido group under these reaction conditions.[13] Therefore, II must be pure hexakis(6-*O*-mesitylsulfonyl)-cycloheptaamylose.



The catalytic hydrogenation of III gave pure hexakis-(6-amino-6-deoxy)cycloheptaamylose (IV) as a hexahydrochloride with satisfactory physical properties. IV was also obtained directly by the reaction of II with ammonia in methanol.

On the other hand, Ib* gave an azido compound (VI)* upon heating with sodium azide in DMF at 85—90 °C for 7 h. The product VI*, whose TLC gave almost a single spot (R_f=0.37), had the IR absorption bands due to the mesitylsulfonyloxyl group together with the band due to the azido group and gave a satisfactory analysis for a mixture of the positional isomers of hexakis(6-azido-6-deoxy)mesitylsulfonylcycloheptaamylose, in which the mesitylsulfonyl group is considered to bind with one among the fourteen secondary hydroxyl groups. Thus, Ib* was determined to be the positional isomers of hexakis(6-*O*-mesitylsulfonyl)-mesitylsulfonylcycloheptaamylose, in which six sulfonyl groups are attached to six primary hydroxyl groups, while one is attached to one among the fourteen secondary hydroxyl groups.

Meanwhile, Compound I, with the same R_f value as that of Ib*, was also obtained by washing the crude sulfonylation product with an appropriate solvent (see Experimental section). The azido compound obtained from I in the manner described above gave two spots in its TLC (R_f=0.01, 0.37); each component was separated on treatment with an appropriate solvent. The compound with an R_f value of 0.37 proved to be identical with the VI* previously obtained from Ib*. On the contrary, Compound V, with an R_f value of 0.01, had the IR absorption bands at 2100 cm^{-1} due to the azido group, with no sulfonate band, and had seven azido groups, as evidenced by its elemental analysis. Therefore, V was determined to be pure heptakis(6-azido-6-deoxy)cycloheptaamylose. Thus, from these results, I, with the same R_f value as that of Ib*, was found to be a mixture of heptakis(6-*O*-mesitylsulfonyl)cycloheptaamylose (Ia) and Ib*. The latter had previously been obtained by the separation of the crude sulfonylation product by column chromatography. These results suggest that Ia, with its highly crowded and strained structure, may be easily hydrolyzed to the more stable II during separation on a silica gel column. Actually, the sulfonyl esters of cycloheptaamylose were not stable, and their TLC figures were changed almost completely when methanol solutions of the esters were allowed to stand at room temperature for two weeks.



The catalytic hydrogenation of V and VI* gave hydrochlorides of heptakis(6-amino-6-deoxy)cycloheptaamylose (VII) and positional isomers of hexakis (6-amino-6-deoxy) mesitylsulfonylcycloheptaamylose (VIII)* respectively.

The more highly selective sulfonylation of cycloheptaamylose with MstCl than with TsCl was clearly revealed by plotting the average number of the sulfonyloxyl groups against the reaction time. In dry pyridine,

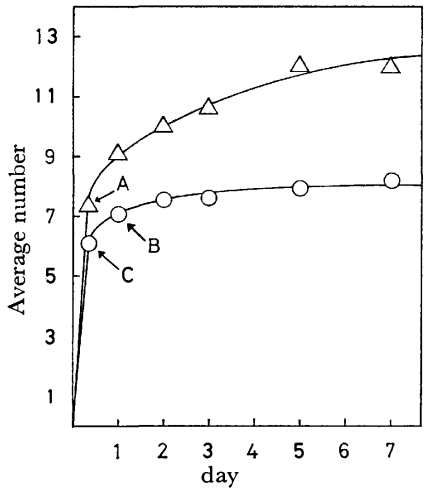


Fig. 1. Relation between average numbers of entered sulfonyloxyl groups and reaction time.
○: MstCl, △: TsCl.
[Numbers of primary, and secondary RSO_3; A: 6.2, 1.1; B: 6.6, 0.5; C: 6.1, 0].

cycloheptaamylose was esterified by the use of 4 eq-moles of the corresponding sulfonyl chlorides for the D-glucose residue at 15 °C.

The average number of the sulfonyloxyl groups introduced was determined by analyzing the sulfur content of the products which has been obtained from an aliquot of the reaction mixture. Furthermore, the positions of the sulfonyloxyl groups were determined by the transformation of the samples (A, B, and C) to azido compounds by the usual method. The number of the sulfonyloxyl groups remaining after this treatment should correspond to the number of the secondary sulfonyloxyl groups. The results are shown in Fig. 1. These data indicate that the preparation of pure heptakis(6-*O*-tosyl)cycloheptaamylose is almost impossible, while that of Ia or II is possible. As can be seen from the figure, both the sulfonylating reagents react with the six hydroxyl groups of cycloheptaamylose at a similar rate. After the six primary hydroxyl groups are esterified, however, subsequent sulfonylation becomes very slow in the case of MstCl, while TsCl reacts rapidly until eight hydroxyl groups are esterified. After 7 days, MstCl had reacted with eight hydroxyl groups, probably corresponding to seven primary and one secondary groups, while TsCl esterifies twelve hydroxyl groups, which may consist of seven primary and five secondary groups. This result indicates that bulky MstCl reacts less readily with a secondary hydroxyl group than does TsCl. It takes 5 h for TsCl and 120 h for MstCl to increase the sulfonylation number from six to eight; the latter process may involve one or two secondary hydroxyl groups. In conclusion, the selectivity of MstCl in the preferential sulfonylation of the primary hydroxyl groups is 24 times larger than that of TsCl. The surprisingly large selectivity may be due to the doughnut-shaped structure[14] of cycloheptaamylose, where the primary hydroxyl groups are located apart from the side of the torus, while the secondary hydroxyls are located directly on the other side of the torus.

Preliminary Biological Tests

It has been found that the amino compounds, IV, VII, and VIII*, showed significant antimicrobial activities, as tested by the two-fold dilution method in a heart-infusion agar medium, though it was earlier reported[5] that hexakis(6-amino-6-deoxy)cyclohexaamylose inhibited the growth of Bacillus subtilis PCI 219 at the concentration of 2000 μg/ml. These amino derivatives inhibited the growth of Staphylococcus aureus at concentrations of 25—100 μg/ml, of Escherichia coli at 12.5—50 μg/ml, of Shigella flexneri and sonnei at 1.56—100 μg/ml, and of Pseudomonas aeruginosa at 6.25—50 μg/ml.

It is also noteworthy that some of these compounds exhibited hypocholesterolemic activities, which were tested by feeding groups of 10 male one-day old chicks with a diet containing 0.2% cholesterol and a 1% test compound for two weeks, and by then determining the serum cholesterol using the method of Zak *et al.*,[15] with blood samples obtained through heart puncture. In this method, a mixture of IV and VII depressed the cholesterol level by 10—15% in comparison with the control groups. The details of the results will be reported elsewhere.

Experimental

All the melting points are uncorrected. The solutions were concentrated under reduced pressure at a bath temperature not exceeding 50 °C. The IR spectra were taken in Nujol mull on a Hitachi 215 spectrometer. The optical rotations were measured in a 0.5-dm tube with a Jasco DIP-180 polarimeter and were corrected as an anhydrous form if a compound had several molecules of adherent water. The TLC was performed on Merck TLC plate silica gel 60 F_{254}. Concentrated sulfuric acid was used as the spray reagent. The column chromatography was carried out by the use of Merck silica gel 60. The paper chromatography was conducted by using Merck Pre-Coated TLC Plates cellulose as a substitute for paper, and the substances were detected by the use of ninhydrin spray. The following solvent systems were used: for TLC, methanol–chloroform (3: 7) (Solvent A); for column chromatography, methanol–chloroform (1: 5) (Solvent B); for paper chromatography, 1-butanol–pyridine–acetic acid–water (1: 5: 2: 4) (Solvent C) and 1-propanol–pyridine–acetic acid–water (6: 4: 1: 3) (Solvent D).

Selective Sulfonylation of Cycloheptaamylose; Heptakis(mesitylsulfonyl)cycloheptaamylose (I and Ib); Hexakis(6-O-mesitylsulfonyl)cycloheptaamylose (II).* Into a solution of cycloheptaamylose (32.7 g, containing 0.8% water) in dry pyridine (320 ml), we stirred MstCl (55.6 g, 1.2 eq-moles for the D-glucose residue) at 0—5 °C. After 3 h, the mixture was allowed to stand for 3 days at room temp. To the mixture 20 ml of cold water was stirred in, drop by drop, under cooling after which the new mixture was allowed to stand for 1 h at room temp. The mixture was then poured into a large volume of a dil-HCl solution under cooling to obtained a white precipitate which was collected and washed with water; yield, 66.0 g (S, 9.07%). TLC with Solvent A proved the product to be composed of three components with R_f values of 0.79, 0.41, and 0.02. These products (33.0 g) were chromatographed on a silica gel column (60×700 mm) with Solvent B. The substance with an R_f value of 0.79 was obtained as a white powder and

was determined to be Ib*; yield, 5.0 g; mp 187.0 °C (decomp), $[\alpha]_D^{20}$ +70.8 ° (*c* 1.0, chloroform), IR spectrum: 1600 (phenyl), 1350, 1185, 1170 (sulfonate) cm^{-1}. Found: C, 52.20; H, 5.89; S, 9.40%. Calcd for $C_{105}H_{140}O_{49}S_7$: C, 52.33; H, 5.81; S, 9.30%.

The substance with an R_f value of 0.41 was also obtained as a white powder and was determined to be II; yield, 12.5 g; mp 189.5 °C (decomp), $[\alpha]_D^{20}$ +76.2 ° (*c* 1.0, chloroform), IR spectrum; 1600 (phenyl), 1355, 1185, 1180 (sulfonate) cm^{-1}. Found: C, 51.64; H, 5.91; S, 8.76%. Calcd for $C_{96}H_{130}O_{47}S_6$: C, 51.75; H, 5.84; S, 8.63%.

The powdered mixture of the crude sulfonyl esters (33.0 g) described above was suspended in a mixture of ethyl acetate (800 ml) and ethanol (200 ml) at 50 °C for 1 h. To the mixture, ethyl acetate (500 ml) was then added, and the mixture was stirred for 10 h at room temperature and subsequently filtered. The remaining powder was suspended in a mixture of the same solvent; to the mixture we then added ethyl acetate, and then we stirred and filtered the solution. This treatment was repeated two more times. The filtrate (about 5 l) was then concentrated, and the residue was suspended in a hot ethyl acetate (2 l) for 30 min, stirred at room temperature overnight, and filtered. To the filtrate ether was added, drop by drop, until the clear solution became slightly cloudy after which it was allowed to stand overnight. After the precipitate had then been filtered off, the filtrate was concentrated, the residue was dissolved in hot ethyl acetate (1.5 l), and ether was added. These procedures were repeated two further times, after which the white precipitate I was obtained by adding ether to the last residue. This was practically pure heptakis(mesitylsulfonyl)cycloheptaamylose, as determined by TLC (R_f=0.79), though a trace of II (R_f=0.41) was still present; yield, 1.4 g; mp 177—181 °C (decomp), $[\alpha]_D^{20}$ +69.8 ° (*c* 1.0 chloroform). Found: C, 52.66; H, 6.06; S, 9.38%. The substance with an R_f value of 0.02 was not further examined.

Hexakis(6-azido-6-deoxy)cycloheptaamylose (III). To a solution of II (3.0 g) in dry *N,N*-dimethylformamide (30 ml), sodium azide (3.0 g) was added after which the mixture was heated with stirring at 80—85 °C for 7 h. The reaction mixture was then poured into a large volume of cold water the white precipitate thus obtained was collected and washed with water; yield, 1.60 g (92.5%); mp above 230 °C (decomposed slowly); IR spectrum: 2100 (azido) cm^{-1}, no sulfonate band. Found: C, 39.07; H, 5.26; N, 19.24%. Calcd for $C_{42}H_{64}N_{18}O_{29}$: C, 39.25; H, 4.98; N, 19.63%.

Heating of I and Ib with Sodium Azide: Heptakis(6-azido-6-deoxy)cycloheptaamylose (V) and Hexakis(6-azido-6-deoxy)mesitylsulfonylcycloheptaamylose (VI)*.* To a solution of I (1.2 g) in dry *N,N*-dimethylformamide (20 ml) sodium azide (1.2 g) was added; there after the mixture was heated with stirring at 85—90 °C for 7 h and then poured into a large volume of cold water. A white precipitate (0.60 g) was collected, washed with water, and dried; it showed two spots in its TLC with Solvent A (R_f 0.37 and 0.01). The precipitate was dissolved in a mixture of methanol (20 ml) and *N,N*-dimethylformamide (20 ml), and then diisopropyl ether was added slowly. The white precipitate which separated was collected. This treatment was repeated twice more. A white powder (0.20 g) thus obtained was determined to be V; mp above 220 °C (decomposed slowly); IR spectrum: 2100 (azido) cm^{-1}, no sulfonate band. Found: C, 38.24; H, 5.04; N, 21.54%. Calcd for $C_{42}H_{63}N_{21}O_{28}$: C, 38.50; H, 4.81; N, 22.46%.

The filtrate was concentrated, the residue was dissolved in ethyl acetate, and the solution was treated with active charcoal and filtered. To the filtrate, diisopropyl ether was added, and the white precipitate VI*, whose TLC gave only one spot (R_f=0.37), was collected; yield, 0.3 g; mp 211—216 °C (decomp). IR spectrum; 2100 (azido), 1600 (phenyl), 1185, 1175 (shoulder) (sulfonate) cm^{-1}. Found: C, 41.41; H, 5.16; N, 17.74; S, 2.23%. Calcd for $C_{51}H_{74}O_{31}N_{18}S$: C, 41.75; H, 5.05; N, 17.19; S, 2.18%. Compound VI* was also obtained by heating Ib* with sodium azide in *N,N*-dimethylformamide at 85—90 °C for 7 h.

Hexakis(6-amino-6-deoxy)cycloheptaamylose (IV). A sample (1.20 g) of III was suspended in methanol (200 ml) containing 5%-HCl aq (20 ml), and the mixture was hydrogenated with platinum dioxide (300 mg) under 3 atm of hydrogen pressure at 10—20 °C for 2 days. After the removal of the catalyst, the filtrate was concentrated. To the residue ethanol was added, and the precipitate which was thus separated was collected and dissolved in a small amount of water. The solution was lyophilized, and the hexahydrochloride of IV was obtained as a white powder; yield, 1.15 g (91%); mp 190.5—191.5 °C (decomp). $[\alpha]_D^{20}$ +136.4 ° (*c* 1.0, H_2O), R_f=0.37 with Solvent C. IR spectrum; 3300 (*ν* OH, NH, broad), 1600 (*δ* as NH_3^+), 1550 (*δ* s NH_3^+) cm^{-1}. Found: C, 34.05; H, 6.13; N, 5.64; Cl, 14.23%. Calcd for $C_{42}H_{82}O_{29}N_6Cl_6 \cdot 7H_2O$: C, 34.22; H, 6.52; N, 5.70; Cl, 14.46%.

A small quantity of IV was hydrolyzed with 3M hydrochloric acid in a sealed tube for 4 h at 100 °C, and the mixture was concentrated. The hydrolyzate was then paper-chromatographed with Solvent D and detected by ninhydrin. The chromatogram was completely identical (R_f=0.27, violet; R_f=0.63, yellow) with that obtained from the hydrolysis of 6-amino-6-deoxy-α-methylglucoside (mp 200—201 °C, lit,[16] mp 195—200 °C, R_f=0.41 with Solvent D).

Heptakis(6-amino-6-deoxy)cycloheptaamylose (VII). A sample (200 mg) of V was subjected to catalytic hydrogenation with platinum dioxide (100 mg) in a mixture of methanol (200 ml) and 3%-HCl aq (5 ml) and then treated in a manner similar to that described above. The heptahydrochloride of VII was obtained as a white powder; yield, 150 mg (70%); mp 182—185 °C (decomp). $[\alpha]_D^{20}$ +131 °C (*c* 1.0, H_2O). R_f=0.30 with Solvent C. IR spectrum: 3300 (*ν* OH, NH, broad), 1600 (*δ* as NH_3^+), 1500 (*δ* s NH_3^+) cm^{-1}. Found: C, 33.41; H, 6.32; N, 6.21; Cl, 16.03%. Calcd for $C_{42}H_{84}O_{28}N_7Cl_7 \cdot 8H_2O$: C, 33.02; H, 6.55; N, 6.42; Cl, 16.28%.

Positional Isomers of Hexakis(6-amino-6-deoxy)mesitylsulfonylcycloheptaamylose (VIII). A sample (600 mg) of VI* was hydrogenated with platinum dioxide (150 mg) in methanol (50 ml) containing 5%-HCl aq (10 ml) in a manner similar to that described above; the hexahydrochloride of VIII* was thus obtained as a white powder; yield, 550 mg (88%); mp 187—188 °C (decomp). $[\alpha]_D^{20}$ +112 ° (*c* 1.0, H_2O). R_f=0.69 with Solvent C. IR spectrum: 3300 (broad, *ν* OH, NH), 1605 (*δ* as NH_3^+), 1505 (*δ* s NH_3^+), 1195, 1175 (shoulder) (sulfonate) cm^{-1}. Found: C, 36.20; H, 5.91; N, 5.24; Cl, 13.51; S, 1.94%. Calcd for $C_{51}H_{92}O_{31}N_6Cl_6S \cdot 7H_2O$: C, 36.98; H, 6.40; N, 5.08; Cl, 12.87; S, 1.93%.

Reaction of II with Ammonia in a Methanol Solution. A sample (6.0 g) of II was dissolved in a 10%-NH_3–methanol solution (100 ml), and the mixture was heated at 70—75 °C in a sealed tube for 3 days. After the reaction mixture had then been cooled to 0—10 °C, the slightly yellow crystals which were thus separated were collected and washed with methanol. The crystals were dissolved in water (30 ml), treated with active charcoal, and lyophilized. The free base of IV was thus obtained as a white powder; yield, 2.7 g (89%); mp above 230 °C. IR spectrum; 3300, 3350 (*ν* OH, NH), 1600 (*δ* NH_2) cm^{-1}. Found: C, 42.75; H, 6.52; N, 6.79%. Calcd for $C_{42}H_{76}O_{29}N_6 \cdot 3H_2O$: C, 42.64; H, 6.94; N, 7.11%.

The aqueous solution of the base was neutralized with hydrochloric acid to pH 2 and then concentrated. The white precipitate of the hexahydrochloride was obtained by adding ethanol to the residue. The physical properties of the hexahydrochloride thus obtained were identical with those of the hexahydrochloride which was obtained by the hydrogenation of III.

More Highly Selective Sulfonylation of Cycloheptaamylose with MstCl than with TsCl. Into a solution of cycloheptaamylose (9.97 g, containing 2.5% water) in dry pyridine (200 ml) we quickly stirred a solution of the corresponding sulfonylating agent (MstCl, 55.47 g, TsCl 48.36 g; 4.0 eq-moles respectively) in dry pyridine (100 ml) at 15.0 °C; the mixture was then kept at 15.0±0.5 °C during experiments. An aliquot portion (10—15 ml) of the reaction mixture was taken up from time to time and was quenched with 1 ml of cold water. After 3 h the aliquot was poured into a large volume of water to give a white precipitate, which was collected. The average number of entering sulfonyloxyl groups was determined by analyzing the sulfur content of the precipitate. The results are shown in Fig. 1. The samples (A, B, and C) were all heated with sodium azide in DMF at 80 °C for 7 h, and the average numbers of the sulfonyloxy groups remaining and of the azido group replacing them were analyzed. The average number of the azido groups introduced corresponds to the number of the primary sulfonyloxyl groups, while that of the sulfonyloxy groups remaining represents the number of secondary sulfonyloxy groups in the samples (A, B, and C).

The authors wish to express their thanks to Mr. Michio Yamazaki, Director of this Laboratory, for his encouragement and to Dr. Tomishige Mizoguchi for his kind advice. Thanks are also due to Dr. Shigeyuki Takeyama for the hypocholesterolemic activity tests and to Dr. Totaro Yamaguchi for the antimicrobial activity tests.

Nucleoside Analogs. 4. Synthesis of 3′-Amino-3′-deoxyadenosine Analogs

Kin-ichi TADANO, Yasufumi EMORI, Mitsukuni AYABE, and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

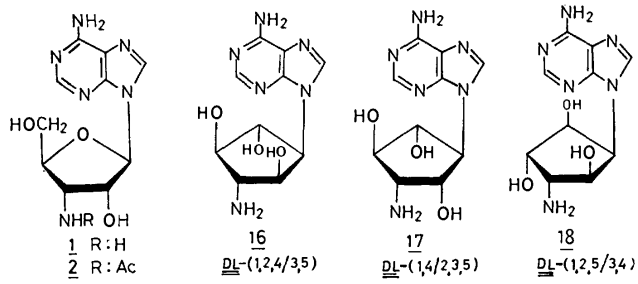
(Received December 15, 1976)

Three 9-(3-amino-2,4,5-trihydroxycyclopentyl)adenines and their *N*-acyl derivatives were prepared as carbocyclic analogs of 3′-amino and 3′-acetamido-3′-deoxyadenosine from the three diastereomers of diaminocyclopentanetriol and 4-amino-6-chloro-5-nitropyrimidine.

We have been working on a synthesis of nucleoside analogs, in which the ribofuranosyl moiety of adenosine is replaced by a cyclopentane ring stable against hydrolysis and enzymic action. In connection with the preceding paper,[1] we wish to report a synthesis of carbocyclic analogs of 3′-amino-3′-deoxyadenosine.

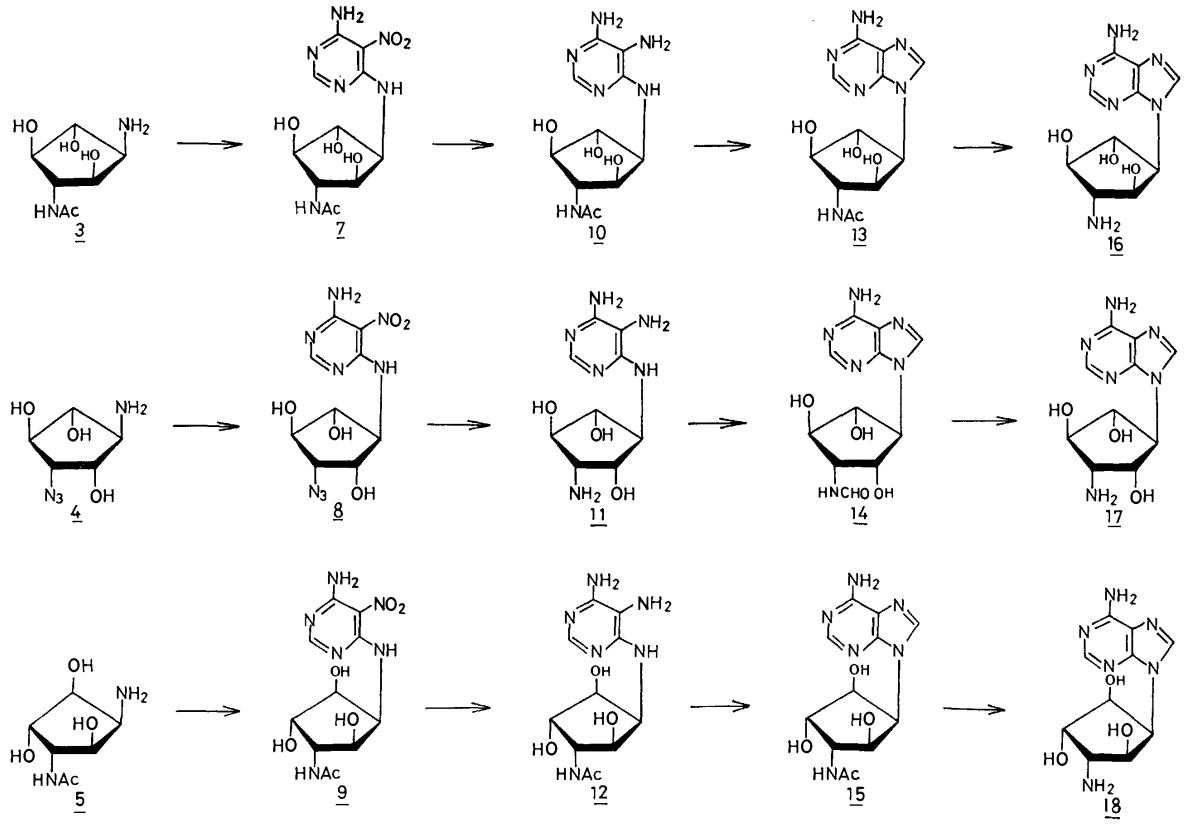
3′-Amino-3′-deoxyadenosine (**1**) has been found in a fermentation broth of *Helminthosporium*,[2] *Cordyceps militaris*,[3] and *Aspergillus nidulans*.[4] The compound has antitumor and antimitotic activity, inhibiting growth of *Cryptococcus neoformans* 4806 and *Candida albicans*.[4] 3′-Acetamido-3′-deoxyadenosine (**2**)[5] was found in a culture filtrate of *Helminthosporium* together with **1**, but inhibited growth of neither Ehrlich carcinoma nor of bacteria.[5]

The structural requirements in puromycin analogs for inhibition of protein synthesis were demonstrated by Daluge and Vince[6] in a synthesis of carbocyclic analogs of puromycin. They suggested that the ribofuranosyl ring can be replaced by the cyclopentyl ring without loss of activity, and that removal of the hydroxymethyl group is not detrimental to the activity, its removal being desirable for reducing toxicity.



Scheme 1.*

We were prompted to attempt the synthesis of a carbocyclic analog retaining the structural features suggested so far. We have prepared 9-(3-amino-2,4,5-trihydroxycyclopentyl)adenines (**16**, **17**, and **18**) and their *N*-acyl derivatives (**13**, **14**, and **15**) by the following reaction routes (Scheme 2).



Scheme 2.*

* Structures in Schemes 1 and 2 dipict only one enantiomer of the racemic form actually obtained in the present experiment.

Tri-*O*-acetyl-DL-(1,2,4/3,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol[7] was selectively *O*-deacetylated, and subsequently hydrogenated to give DL-(1,3,5/2,4)-2-acetamido-5-amino-1,3,4-cyclopentanetriol (**3**).

Hydrolysis of the starting material in 3 M hydrochloric acid, followed by removal of the chloride ion, gave 5-amino-2-azido-1,3,4-cyclopentanetriol (**4**). Another diastereomer: tri-*O*-acetyl-DL-(1,2,3/4,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol[7] was *O*-deacetylated, and subsequently hydrogenated catalytically to give DL-(1,4,5/2,3)-2-acetamido-5-amino-1,3,4-cyclopentanetriol (**5**).

Compounds **3**, **4**, and **5** were condensed with 4-amino-6-chloro-5-nitropyrimidine[8] (**6**) to give the corresponding pyrimidine derivatives (**7**), (**8**), and (**9**), respectively. Reduction of the nitro group, followed by ring closure of the respective pyrimidine derivatives (**10**), (**11**), and (**12**) with formamide, gave the corresponding 3′-*N*-acyl adenine derivatives (**13**), (**14**), and (**15**), respectively. Hydrolysis of **13**, **14**, and **15** in barium hydroxide solution yielded the corresponding adenine analogs (**16**), (**17**), and (**18**), respectively. These compounds showed no biological activity against HeLa S3 cell.

Experimental

Melting points were determined in capillary tubes in a liquid bath and are uncorrected. Solutions were evaporated under reduced pressure at 40—50 °C. TLC was performed on a silica gel plate (Wakogel B-10, Wako Pure Chemical Industries Ltd.). Elemental analyses were performed by Mr. Saburo Nakada to whom our thanks are due.

DL-(1,3,5/2,4)-2-Acetamido-5-amino-1,3,4-cyclopentanetriol (3). A 4.94 g portion of DL-1,3,4-tri-*O*-acetyl-(1,2,4/3,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol[7] was *O*-deacetylated in methanolic ammonia. The product was catalytically hydrogenated in 50% aqueous ethanol in the presence of Raney nickel to give 2.48 g of crude **3**, which was recrystallized from aqueous ethanol to give 0.98 g (36%) of pure **3**, mp 199—200 °C.

Found: C, 44.16; H, 7.39; N, 14.72%. Calcd for $C_7H_{14}N_2O_4$: C, 44.20; H, 7.42; N, 14.73%.

DL-(1,2,4/3,5)-5-Amino-2-azido-1,3,4-cyclopentanetriol (4). DL-1,3,4-tri-*O*-acetyl-(1,2,4/3,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol[7] (5.39 g) was hydrolyzed in 3 M hydrochloric acid (100 ml) at 100 °C for 3 h, and the solution was evaporated. The residue was dissolved in water and the solution was treated with Amberlite IRA-400 (OH^-) resin in a column. The effluent was evaporated and the residue was recrystallized from isopropyl alcohol to give 2.40 g (88%) of **4**, mp 115—116 °C.

Found: C, 34.73; H, 5.78: N, 32.02%. Calcd for $C_5H_{10}N_4O_3$: C, 34.48; H, 5.79; N, 32.17%.

DL-(1,4,5/2,3)-2-Acetamido-5-amino-1,3,4-cyclopentanetriol (5). DL-1,3,4-Tri-*O*-acetyl-(1,2,3/4,5)-5-acetamido-2-azido-1,3,4-cyclopentanetriol[7] (3.35 g) was *O*-deacetylated in methanolic ammonia to give 2.45 g of crude product. The product was triturated in ethanol to give 1.97 g (93%) of *O*-deacetylated derivative, mp 168—169 °C.

Found: C, 38.77; H, 5.74; N, 25.60%. Calcd for $C_7H_{12}N_4O_4$: C, 38.89; H, 5.60; N, 25.92%.

The above product (1.38 g) was catalytically hydrogenated in water (32 ml) overnight to give 1.17 g (97%) of crude **5**, which was recrystallized from ethanol to give an analytical sample, mp 175—176 °C (dec).

Found: C, 43.90; H, 7.36; N, 14.56%. Calcd for $C_7H_{14}N_2O_4$: C, 44.20; H, 7.42; N, 14.73%.

The hydrochloride melted at 194—195 °C.

Found: C, 37.29; H, 6.61; N, 12.13; Cl, 15.72%. Calcd for $C_7H_{15}N_2O_4Cl$: C, 37.09; H, 6.67; N, 12.36; Cl, 15.64%.

6-[DL-(1,2,4/3,5)-3-Acetamido-2,4,5-trihydroxycyclopentyl]-amino-4-amino-5-nitropyrimidine (7). A mixture of **3** (1.00 g), 4-amino-6-chloro-5-nitropyrimidine[8] (**6**) (1.10 g) and triethylamine (1 ml) was heated in 2-methoxyethanol (50 ml) at 90—95 °C for 1.5 h. After being cooled to ambient temperature, the resulting crystalline product was collected by filtration. The product was recrystallized from hot water and subsequently washed with warm ethanol to give 1.58 g (92%) of **7**, 275—285 °C (dec).

Found: C, 40.34; H 4.89; N, 25.72%. Calcd for $C_{11}H_{16}N_6O_6$; C, 40.25; H, 4.91; N, 25.60%.

4-Amino-6-[DL-(1,4/2,3,5)-3-azido-2,4,5-trihydroxycyclopentyl]-amino-5-nitropyrimidine (8). A mixture of **4** (1.00 g), 4-amino-6-chloro-5-nitropyrimidine[8] (1.10 g) and triethylamine (1 ml) was heated at 80 °C in 2-methoxyethanol (30 ml) for 1 h. The reaction mixture was evaporated and the residue was triturated with warm benzene. The residual solid was recrystallized from hot water to give 1.70 g (95%) of **8** as yellow crystals, mp 206—207 °C (dec).

Found: C, 34.68; H, 3.88; N, 35.66%. Calcd for $C_9H_{12}N_8O_5$: C, 34.62; H, 3.88; N, 35.89%.

6-[DL-(1,2,5/3,4)-3-Acetamido-2,4,5-trihydroxycyclopentyl]amino-4-amino-5-nitropyrimidine (9). A mixture of **5** (1.17 g), 4-amino-6-chloro-5-nitropyrimidine[8] (1.29 g) and triethylamine (2.4 ml) was heated in 2-methoxyethanol (59 ml) at 85 °C for 3 h. The reaction mixture was evaporated and the residue was triturated with warm ethanol to give 1.43 g (71%) of **9** as yellow crystals, mp 237—238 °C (dec).

Found: C, 40.31; H, 4.93; N, 25.28%. Calcd for $C_{11}H_{16}N_6O_6$: C, 40.25; H, 4.91; N, 25.60%.

6-[DL-(1,2,4/3,5)-3-Acetamido-2,4,5-trihydroxycyclopentyl]amino-4,5-diaminopyrimidine (10). Compound **7** was dissolved in hot water (80 ml) and to the resulting solution zinc powder (15 g) was added. The mixture was heated under reflux for 7.5 h, and filtered. The filtrate was evaporated and the residue was washed with ethanol to give 455 mg (100%) of **10**, which was acetylated in the usual way to give a hexa-*N*,*O*-acetyl derivative. The product was recrystallized from ethyl acetate–ethanol (1:1 v/v%) to give an analytical sample, mp 232—233 °C (dec).

Found: C, 49.69; H, 5.73; N, 16.68%. Calcd for $C_{21}H_{28}N_6O_9$: C, 49.60; H, 5.55; N, 16.53%.

6-[DL-(1,2,5/3,4)-3-Acetamido-2,4,5-trihydroxycyclopentyl]amino-4,5-diaminopyrimidine (12). Compound **9** (504 mg) was reduced with zinc powder in boiling water as in the preparation of **10**. The crude product was recrystallized from ethanol to give 402 mg (88%) of **12**. An analytically pure sample was obtained by further recrystallization from water as pale yellow crystals, mp 237—238 °C (dec).

Found: C, 44.40; H, 6.17; N, 27.84%. Calcd for $C_{11}H_{18}N_6O_4$: C, 44.29; H, 6.08; N, 28.17%.

9-[DL-(1,2,4/3,5)-3-Acetamido-2,4,5-trihydroxycyclopentyl]-adenine (13). Compound **10** was heated at 175—180 °C in formamide (10 ml) for 1.5 h, and evaporated. The residue was recrystallized from hot water (3 ml) to give 131 mg (37%) of **13** as colorless needles, mp 290—300 °C (dec).

UV: $\lambda_{max}^{0.1\ M\ HCl}$ 259 nm (ε=12400), $\lambda_{max}^{H_2O}$ 261 nm (ε=12900), $\lambda_{max}^{0.1\ M\ NaOH}$ 259 nm (ε=6450).

Acetylation of **13** in the usual way gave 9-[DL-(1,2,4/3,5)-3-acetamido-2,4,5-triacetoxycyclopentyl]-6-diacetylaminopurine, mp 201—203 °C.

Found: C, 50.90; H, 5.10; N, 16.13%. Calcd for $C_{22}H_{26}$-

N_6O_9: C, 50.96; H, 5.06; N, 16.21%.

9-[DL-(1,4/2,3,5)-3-Formamido-2,4,5-trihydroxycyclopentyl]-adenine (14). Compound **8** (600 mg) was hydrogenated in the presence of Raney nickel under hydrogen atmosphere (3.4 kg/cm²) for 18 h in a Parr apparatus. After the catalyst had been filtered off, the filtrate was evaporated. The residue (484 mg) was heated at 170 °C for 1 h in formamide (20 ml) and subsequently evaporated. The residue was dissolved in hot water and decolorized with active charcoal. The solution was evaporated, and the residue was recrystallized from hot water to give 235 mg (42%) of **14**, mp 277—278 °C (dec).

Found: C, 44.64; H, 5.07; N, 28.77%. Calcd for $C_{11}H_{14}N_6O_4$: C, 44.90; H, 4.79; N, 28.56%.

9-[DL-(1,2,5/3,4)-3-Acetamido-2,4,5-trihydroxycyclopentyl]-adenine (15). Compound **12** was heated at 175 °C for 2 h in formamide (30 ml), and evaporated. The residue was decolorized with active charcoal in boiling water to give 381 mg (42%) of crude product. Recrystallization from hot water gave 318 mg (34%) of **15**, mp 278—280 °C (dec). **15** was acetylated in the usual way to give penta-*N,O*-acetyl derivative. The product was recrystallized from ethyl acetate to give an analytical pure sample, mp 219—220 °C (dec).

Found: C, 50.15; H, 4.99; N, 17.72%. Calcd for $C_{20}H_{24}N_6O_8$: C, 50.42; H, 5.08; N, 17.64%.

9-[DL-(1,2,4/3,5)-3-Amino-2,4,5-trihydroxycyclopentyl]adenine (16). Compound **13** (150 mg) was heated at 85 °C for 3 h in a barium hydroxide [$Ba(OH)_2 \cdot 8H_2O$, 300 mg] solution (water, 23 ml). Carbon dioxide was bubbled into the solution and the resulting precipitate was filtered off. The filtrate was evaporated to a small volume and the residue was allowed to stand in a refrigerator to give 114 mg (88%) of crystals. The product was recrystallized from hot water to give an analytical sample of **16**, mp 280—290 °C (dec).

Found: C, 45.09; H, 5.34; N, 31.19%. Calcd for $C_{10}H_{14}N_6O_3$: C, 45.11; H, 5.30; N, 31.56%.

UV: $\lambda_{max}^{0.1\,M\ HCl}$ 259 nm (ε=14200), $\lambda_{max}^{H_2O}$ 260 nm (ε=12400), $\lambda_{max}^{0.1\,M\ NaOH}$ 261 nm (ε=6700).

9-[DL-(1,4/2,3,5)-3-Amino-2,4,5-trihydroxycyclopentyl]adenine (17). Compound **14** (230 mg) was treated with Dowex IX-2 (OH^-) (5 ml) in water (180 ml) at 50 °C for 3 h with agitation. After the resin had been filtered off, the solution was evaporated. The residue was recrystallized from hot water to give 176 mg (85%) of **17**, mp 255—256 °C (dec).

Found: C, 44.81; H, 5.25; N, 30.99%. Calcd for $C_{10}H_{14}N_6O_3$: C, 45.11; H, 5.30; N, 31.56%.

UV: $\lambda_{max}^{0.1\,M\ HCl}$ 258 nm (δ=15000), $\lambda_{max}^{H_2O}$ 260 nm (ε=16000), $\lambda_{max}^{0.1\,M\ NaOH}$ 261 nm (ε=16000).

The hydrochloride melts at 250 °C (dec).

Found: C, 39.49; H, 4.97; N, 27.49; Cl, 11.75%. Calcd for $C_{10}H_{15}N_6O_3Cl$: C, 39.68; H, 4.99; N, 27.76; Cl, 11.71%.

9-[DL-(1,2,5/3,4)-3-Amino-2,4,5-trihydroxycyclopentyl]adenine (18). Compound **15** (200 mg) was hydrolyzed by treating in the barium hydroxide solution for 6 h as in the preparation of **16** to give 105 mg (61%) of **18**, mp 264—266 °C (dec).

Found: C, 44.69; H, 5.25; N, 30.69%. Calcd for $C_{10}H_{14}N_6O_3 \cdot 1/4\ H_2O$: C, 44.36; H, 5.40; N, 31.04%.

UV: $\lambda_{max}^{0.1\,M\ HCl}$ 258 nm (ε=14300), $\lambda_{max}^{H_2O}$ 259 nm (ε=14600), $\lambda_{max}^{0.1\,M\ NaOH}$ 259 nm (ε=14500).

A Convenient Synthesis of (±)-Taxodione, (±)-Ferruginol, and (±)-Sugiol

Takashi MATSUMOTO, Shuji USUI, and Toshitaka MORIMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 24, 1976)

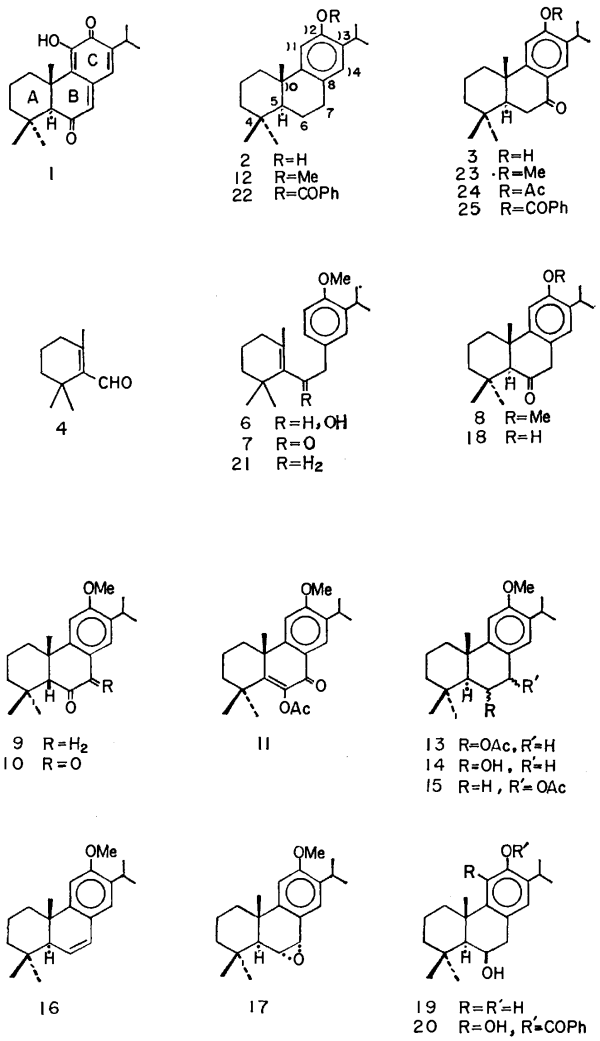
The condensation of β-cyclocitral (**4**) with 3-isopropyl-4-methoxybenzyl chloride (**5**) in the presence of lithium naphthalenide gave an alcohol (**6**), which was then oxidized to the corresponding α,β-unsaturated ketone (**7**). The Intramolecular cyclization of **7** with polyphosphoric acid yielded (±)-12-methoxyabieta-8,11,13-trien-6-one (**8**) and its *cis*-isomer (**9**), which was then successfully converted into **8** *via* an enol acetate (**11**). The **8** ketone was demethylated with boron tribromide to give a phenol (**18**), and this was then reduced with lithium aluminium hydride to yield the corresponding alcohol (**19**). The oxidation of the C-11 position in **19** with benzoyl peroxide gave (±)-12-benzoyloxyabieta-8,11,13-trien-6β,11-diol (**20**), which, on reduction with lithium aluminium hydride and subsequent oxidation with Jones reagent, afforded (±)-taxodione (**1**). The reductive cleavage of the hydroxyl group in **6** with dichloroaluminium hydride, followed by cyclization, gave (±)-ferruginyl methyl ether (**12**), which was then demethylated with boron tribromide to produce (±)-ferruginol (**2**). Further, the oxidation of **12** with chromium trioxide, followed by demethylation, gave (±)-sugiol (**3**).

Taxodione (**1**), a tumor-inhibitory diterpene quinone methide, was isolated from Taxodium distichum Rich by Kupchan *et al.*[1] In a previous paper, Matsumoto *et al.*[2] reported the total synthesis of (±)-**1** by the route of C→B→A ring construction. However, this synthetic route involves eighteen reaction steps and affords a low over-all yield (*ca.* 0.3%). Very recently, Matsumoto and Harada[3] also reported the syntheses of highly-oxygenated tricyclic diterpenes, taxoquinone, 7α-acetoxyroyleanone, dehydroroyleanone, horminone, 7-oxoroyleanone, and inuroyleanol, all starting from ferruginol (**2**). In conjunction with these previous works, we studied a general synthetic route for the naturally-occurring tricyclic diterpenes (C_{20} unit). This paper[4] will describe the simple and short-step syntheses of (±)-**1**, (±)-**2**, and (±)-sugiol (**3**) starting from two C_{10} units, β-cyclocitral (**4**)[5] and 3-isopropyl-4-methoxybenzyl chloride (**5**).

The condensation of **4** with **5** in the presence of lithium naphthalenide in tetrahydrofuran in a stream of nitrogen afforded the desired alcohol (**6**), which was then oxidized with the chromium trioxide–pyridine complex to yield an α,β-unsaturated ketone (**7**). The intramolecular cyclization of **7** with polyphosphoric acid afforded (±)-12-methoxyabieta-8,11,13-trien-6-one (**8**) as the minor product and its *cis*-isomer (**9**) as the major one, along with a small amount of (±)-xanthoperyl methyl ether (**10**),[6] which must have been produced by the air-oxidation of **9** during chromatographic purification. The *cis*-configuration of an A/B ring junction in **9** and **10** was supported by their NMR spectra, which showed signals due to the $C_{4\alpha}$ methyl group[7] at δ 0.32 and 0.44 ppm respectively. Since all natural compounds (**1**, **2**, and **3**) possess a *trans* A/B ring junction, the **9** *cis*-isomer was then converted into the **8** *trans*-isomer in the following manner. The oxidation of **9** with the Jones reagent readily produced **10**, which, on being refluxed with acetic anhydride in the presence of sodium acetate, gave the corresponding enol acetate (**11**) in a good yield. The **11** acetate in ethyl acetate was then submitted to catalytic hydrogenation over Pd–C in the presence of perchloric acid to afford a mixture of (±)-ferruginyl methyl ether (**12**, 33%), **8** (2%), (±)-6α- and (±)-6β-acetoxy-12-methoxyabieta-8,11,13-triene (**13**) (*ca.* 3:2, 42%), and (±)-12-methoxyabieta-8,11,13-trien-6α-ol (**14**, 5%). The treatment of **13** with lithium aluminium hydride in refluxing ether, followed by the oxidation of the resulting alcohols with the Jones reagent, afforded **8**. Further, the oxidation of **12** with lead tetraacetate in acetic acid afforded a mixture of 7α- and 7β-acetoxy compounds (**15**), which were then refluxed with dilute hydrochloric acid to yield (±)-12-methoxyabieta-6,8,11,13-tetraene (**16**). The **16** tetraene was then oxidized with *m*-chloroperoxybenzoic acid and the epoxide (**17**) was treated with dilute hydrochloric acid to give **8**. Subsequently, the **8** *trans*-ketone was demethylated with boron tribromide in dichloromethane, giving the corresponding phenol (**18**). The reduction of the carbonyl group in **18** was carried out with lithium aluminium hydride; (±)-abieta-8,11,13-trien-6β,12-diol (**19**) was thus obtained. The oxidation of the C-11 position in **19** with benzoyl peroxide in chloroform yielded (±)-12-benzoyloxyabieta-8,11,13-trien-6β,11-diol (**20**), which responded positively to the Gibbs test,[8] suggesting the presence of an aromatic proton para to a phenolic hydroxyl group. The reductive cleavage of the benzoyl group in **20** with lithium aluminium hydride and the subsequent oxidation of the crude product with the Jones reagent afforded (±)-**1**. The IR and NMR spectra of the synthetic **1** were identical with those of natural taxodione. Thus, (±)-**1** was synthesized starting from β-cyclocitral (**4**) in eight steps, giving an over-all yield of *ca.* 7%.

As has been described above, ferruginol (**2**) is an important intermediate for the syntheses of the highly-oxygenated tricyclic diterpenes.[3] Therefore, it is worthwhile to synthesize **2** by a simple and short-step procedure, although several synthetic routes have already been reported by other workers.[9–13] For this purpose, the hydroxyl group in **6** was reductively removed with dichloroaluminium hydride in ether, and the resulting phenethyl derivative (**21**) was cyclized with anhydrous aluminium chloride in refluxing benzene, thus producing **12**. The demethylation of **12** with boron tribromide in dichloromethane gave (±)-ferruginol (**2**), which was characterized as its benzoate (**22**).[9,10,13] Subsequently, **12** was oxidized with chromium trioxide in acetic acid to afford the corresponding 7-oxo com-

pound (**23**).[6] The demethylation of **23** with boron tribromide yielded (±)-sugiol (**3**),[11] which was also characterized as its acetate (**24**) and benzoate (**25**).



Experimental

All melting points are uncorrected. The IR spectra were taken in chloroform, and the NMR spectra in carbon tetrachloride at 60 MHz, with tetramethylsilane as the internal standard, unless otherwise stated. The chemical shifts are presented in terms of δ values. Column chromatography was performed using Merck silica gel (0.063 mm).

3-Isopropyl-4-methoxybenzyl Chloride (5). A solution of methyl 3-isopropyl-4-methoxybenzoate (2.48 g)[14] in dry ether (7 ml) was added, drop by drop, to a suspension of lithium aluminium hydride (500 mg) in dry ether (20 ml) over a 20-min period. The mixture was then refluxed for 1 h, poured into an iced aqueous ammonium chloride solution, and extracted with ether. The extract was washed with brine. The dried extract was evaporated *in vacuo* to give 3-isopropyl-4-methoxybenzyl alcohol as an oil; NMR: 1.18 (d, 6, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.72 (s, 1, -OH), 3.28 (m, 1, $-C\underline{H}(CH_3)_2$), 3.78 (s, 3, $-OCH_3$), 4.42 (s, 2, $-CH_2-$), 6.65 (d, 1, J=8 Hz), 7.00 (dd, 1, J=8 and 2 Hz), and 7.07 (bs, 1) (aromatic protons).

A solution of the above alcohol in thionyl chloride (2.0 ml) was stirred at 0 °C for 30 min and then at room temperature for 1 h, decomposed with ice water, and extracted with ether. The dried extract was evaporated *in vacuo* to give **5** as an oil (1.82 g: 77%); NMR: 1.20 (d. 6, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.28 (m, 1, $-C\underline{H}(CH_3)_2$), 3.80 (s, 3, $-OCH_3$), 4.48 (s, 2, $-CH_2-$), 6.67 (d, 1, J=9 Hz), 7.08 (dd, 1, J=9 and 2 Hz), and 7.10 (d, 1, J=2 Hz) (aromatic protons).

In another experiment, the above benzyl alcohol derivative was prepared from 3-isopropyl-4-methoxybenzaldehyde[15] by a similar reduction.

Condensation of β-Cyclocitarl (4) and 3-Isopropyl-4-methoxybenzyl Chloride (5). A mixture of naphthalene (1.92 g) and small pieces of lithium (103 mg) in dry tetrahydrofuran (15 ml) was stirred for 1.5 h at room temperature under an atmosphere of nitrogen. Into the above solution we then stirred, drop by drop, a solution of β-cyclocitral (610 mg) and 3-isopropyl-4-methoxybenzyl chloride (890 mg) in dry tetrahydrofuran (3.0 ml) at 0—10 °C over a 15-min period. The mixture was then stirred at room temperature for 2.5 h in a stream of nitrogen, diluted with ether and then with aqueous ammonium chloride, and extracted with ether, and the extract was washed with brine. The dried extract was evaporated *in vacuo* to give a crude product which was subsequently purified by column chromatography on silica gel, using benzene–ether (98: 2) as the eluent, to afford an oily alcohol (**6**) (1.10 g: 87%); IR: 3580 cm^{-1}, NMR: 0.94 and 1.08 (each s, 6, $-C(CH_3)_2$), 1.20 (d, 6, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.88 (s, 3, $=CCH_3$), 3.15 (m, 1, $-C\underline{H}(CH_3)_2$), 3.77 (s, 3, $-OCH_3$), 4.27 (dd, 1, J=4 and 9 Hz, $-C\underline{H}OH$), 6.63 (d, 1, J=9 Hz), 6.90 (dd, 1, J=9 and 2 Hz), and 6.92 (d, 1, J=2 Hz), (aromatic protons). Found: C, 79.93; H, 10.32%. Calcd for $C_{21}H_{32}O_2$: C, 79.70; H, 10.19%.

2,6,6-Trimethyl-1-cyclohexenyl 3-Isopropyl-4-methoxybenzyl Ketone (7). A solution of the **6** alcohol (5.424 g) in pyridine (10 ml) was added, drop by drop at 7—10 °C, to a chromium trioxide–pyridine complex prepared from chromium trioxide (5.0 g) and pyridine (50 ml). The mixture was stirred at 10—20 °C for 3.5 h, poured into ice–dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried, and then evaporated. The crude product was purified by column chromatography on silica gel (500 g), using benzene–ether (99: 1) as the eluent, to give an α,β-unsaturated ketone **7** as an oil (3.507 g: 65%); IR: 1690 cm^{-1}, NMR: 1.02 (s, 6, $-C(CH_3)_2$), 1.19 (d, 6, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.52 (s, 3, $=CCH_3$), 3.29 (m, 1, $-C\underline{H}(CH_3)_2$), 3.65 (s, 2, $-COCH_2-$), 3.80 (s, 3, $-OCH_3$), 6.65 (d, 1, J=8.5 Hz), 6.91 (dd, 1, J=8.5 and 2 Hz), and 6.93 (d, 1, J=2 Hz) (aromatic protons). Found: C, 79.98; H, 9.43%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

Intramolecular Cyclization of 7. A mixture of **7** (879 mg) and polyphosphoric acid prepared, from 85% phosphoric acid (9 ml) and phosphorus pentaoxide (13 g) at 100 °C for 1 h, was heated at 100 °C for 1.5 h. After cooling, the mixture was diluted with water and extracted with ether, and the dried extract was evaporated to dryness. The crude product was purified by column chromatography on silica gel (90 g) using benzene–ether (99: 1 and then 97: 3) as the eluent, to give three ketones (**8**—**10**).

a) (±)-12-Methoxyabieta-8,11,13-trien-6-one (**8**) as an oil (182 mg: 21%); IR: 1708 cm^{-1}, NMR: 1.06 and 1.13 (each s, 6, $-C(CH_3)_2$), 1.14 and 1.16 (each d and J=7 Hz, 6, $-CH(C\underline{H}_3)_2$), 1.28 (s, 3, $C_{10}-CH_3$), 2.29 (s, 1, C_5–H), 3.22 (m, 1, $-C\underline{H}(CH_3)_2$), 3.43 (s, 2, $-COCH_2-$), 3.78 (s, 3, $-OCH_3$) 6.67 and 6.75 (each s, 2, C_{11}–H and C_{14}–H). Found: C, 80.09; H, 9.32%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%

b) (±)-12-Methoxy-5βH-abieta-8,11,13-trien-6-one (**9**).

(341 mg: 39%); mp 94—95 °C (from methanol), IR: 1692 cm^{-1}, NMR: 0.33 (s, 3, $C_{4\alpha}$-CH_3), 0.92 (s, 3, $C_{4\beta}$-CH_3), 1.07 (s, 3, C_{10}-CH_3), 1.18 (d, 6, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 1.99 (s, 1, C_5-H), 3.10 (m, 1, -C$\underline{H}$(CH_3)$_2$), 3.42 (s, 2, -$COCH_2$-), 3.83 (s, 3, -OCH_3), 6.70 and 6.78 (each s, 2, C_{11}-H and C_{14}-H). Found: C, 80.11; H, 9.54%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

c) (±)-Xanthoperyl methyl ether (**10**) (13 mg: 1%), which has been obtained from benzene–ether (97: 3) fraction; mp 204—207 °C (from methanol) (lit,[6] mp 205 °C), IR: 1715, 1668 cm^{-1}, NMR ($CDCl_3$): 0.44 (s, 3, $C_{4\alpha}$-CH_3), 0.98 (s, 3, $C_{4\beta}$-CH_3), 1.23 (s, 3, C_{10}-CH_3), 1.24 (d, 6, J= 7 Hz, -CH($C\underline{H}_3$)$_2$), 2.66 (s, 1, C_5-H), 3.28 (m, 1, -C$\underline{H}$(CH_3)$_2$), 3.98 (s, 3, -OCH_3), 6.82 (s, 1, C_{11}-H), 7.96 (s, 1, C_{14}-H). Found: C, 76.73; H, 8.69%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%.

The **10** diketone was also obtained in a 92% yield by the oxidation of **9** in acetone with the Jones reagent at room temperature for 30 min.

(±)-6-Acetoxy-12-methoxyabieta-5,8,11,13-tetraen-7-one (11). A mixture of **10** (511 mg) and anhydrous sodium acetate (2.0 g) in acetic anhydride (20 ml) was refluxed for 33 h, and then filtered. After the filtrate had been evaporated to dryness, the residue was extracted with ether and the extract was washed with aqueous sodium hydrogencarbonate and water. The dried extract was evaporated to yield a crude product which was subsequently purified by column chromatography on silica gel (70 g), using benzene–ether (97: 3) as the eluent, to give **11** (556 mg: 96%), which was then recrystallized from methanol; mp 126—126.5 °C, IR: 1755, 1648 cm^{-1}, NMR: 1.22 and 1.26 (each d and J=7 Hz, 6, -CH($C\underline{H}_3$)$_2$), 1.31 and 1.36 (each s, 6, -C(CH_3)$_2$), 1.57 (s, 3, C_{10}-CH_3), 2.27 (s, 3, -$OCOCH_3$), 3.23 (m, 1, -C$\underline{H}$-(CH_3)$_2$), 3.88 (s, 3, -OCH_3), 6.78 (s, 1, C_{11}-H), 7.79 (s, 1, C_{14}-H). Found: C, 74.70; H, 8.19%. Calcd for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16%.

Catalytic Hydrogenation of the Enol Acetate (11). A mixture of **11** (283 mg), 5% Pd-C (250 mg), and 70% perchloric acid (10 drops) in ethyl acetate (10 ml) was subjected to catalytic hydrogenation at room temperature. After the usual work-up, the crude product was purified by column chromatography on silica gel (25 g), using hexane–benzene (1: 1) and benzene–ether (97: 3) as eluents, to yield **12**, **8**, **13**, and **14** (in the order of elution).

a) (±)-12-Methoxyabieta-8,11,13-triene (ferruginyl methyl ether) (**12**) as an oil (76 mg: 33%); NMR: 0.94 (s, 6, -C(CH_3)$_2$), 1.14 (d, 6, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 1.18 (s, 3, C_{10}-CH_3), 3.15 (m, 1, -C$\underline{H}$(CH_3)$_2$), 3.72 (s, 3, -OCH_3), 6.53 and 6.67 (each s, 2, C_{11}-H and C_{14}-H). Found: C, 84.17; H, 10.76%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

b) **8** (4.3 mg: 2%), whose IR and NMR spectra were identical with those of (±)-12-methoxyabieta-8,11,13-trien-6-one.

c) (±)-6α- and 6β-Acetoxy-12-methoxyabieta-8,11,13-triene (**13**) as an oil (115 mg: 42%); IR: 1721 cm^{-1}. The ratio of 6α- and 6β-acetoxy compounds was found to be *ca.* 3: 2 by NMR analysis of the mixture, using signals due to C_6-H at δ 5.35 (m, $W_{1/2}$=19 Hz) and 5.65 (m, $W_{1/2}$=10 Hz) ppm.

d) (±)-12-Methoxyabieta-8,11,13-trien-6α-ol (**14**) as an oil (13 mg: 5%); IR: 3600 cm^{-1}, NMR: 1.10, 1.10, and 1.15 (each s, 9, -C(CH_3)$_2$ and C_{10}-CH_3), 1.16 (d, 6, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 4.20 (m, 1, $W_{1/2}$=16 Hz, C_6-H), 3.77 (s, 3, -OCH_3), 6.58 and 6.78 (each s, 2, C_{11}-H and C_{14}-H).

(±)-12-Methoxyabieta-8,11,13-trien-6-one (8). *a*) A mixture of **13** (177 mg) and lithium aluminium hydride (20 mg) in dry ether (10 ml) was refluxed for 1 h. After the usual work-up, the crude alcohol was immediately oxidized at 0 °C for 5 min with the Jones reagent (8N, 12 drops) in acetone (3.0 ml). The mixture was diluted with water, and the ether extract was washed with brine, dried, and evaporated. The product was then chromatographed on silica gel (15 g), using benzene as the eluent, to give a ketone (127 mg: 82%), whose IR and NMR spectra were identical with those of the *trans*-ketone **8**.

b) A solution of **12** (110 mg) and 85% lead tetraacetate (290 mg) in acetic acid (1.0 ml) was heated at 42—47 °C for 1 h in a stream of nitrogen. The solution was then diluted with water and extracted with ether, and the extract was washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried extract was evaporated to give a crude acetate (**15**) (129 mg); IR: 1720 cm^{-1}, NMR: 1.97 and 2.06 (each s, C_7-$OCOCH_3$).

The above crude acetate (129 mg) was dissolved in ethanol (5.0 ml) containing 10% hydrochloric acid (1.0 ml) and refluxed for 2 h. After the solution had been diluted with ether, the ether solution was washed with brine, dried, and then evaporated to give (±)-12-methoxyabieta-6,8,11,13-tetraene (**16**) as an oil (109 mg); NMR: 0.97, 1.01, and 1.04 (each s, 9, -C(CH_3)$_2$ and C_{10}-CH_3), 1.15 and 1.19 (each d and J=7 Hz, 6, -CH($C\underline{H}_3$)$_2$), 3.21 (m, 1, -C$\underline{H}$(CH_3)$_2$, 3.79 (s, 3, -OCH_3), 5.78 (dd, 1, J=3 and 10 Hz, C_6-H), 6.42 (dd, 1, J=3 and 10 Hz, C_7-H), 6.57 and 6.77 (each s, 2, C_{11}-H and C_{14}-H).

A solution of **16** and 85% *m*-chloroperoxybenzoic acid (90 mg) in chloroform (3.0 ml) was allowed to stand at room temperature for 6 h and then diluted with ether. The solution was washed successively with aqueous potassium iodide, aqueous sodium hydrogencarbonate, and brine. After the removal of the solvent, the crude epoxide (**17**) was refluxed with dilute hydrochloric acid in ethanol (5.0 ml) for 1 h and then diluted with ether. The ether solution was washed with brine, dried, and evaporated. The chromatographic purification of the crude product afforded **8** (39 mg: 34% from **12**).

(±)-12-Hydroxyabieta-8,11,13-trien-6-one (18). A solution of **8** (143 mg) and boron tribromide (0.2 ml) in dichloromethane (2.0 ml) was stirred at 0 °C for 30 min, diluted with ether, and then poured into ice water. The mixture was extracted with ether, and the extract was washed successively with aqueous sodium thiosulfate and brine. The dried ether solution was then evaporated to dryness and purified by column chromatography on silica gel (15 g), using benzene–ether (97: 3) as the eluent, to produce **18** (117 mg: 85%), which was subsequently recrystallized from hexane–acetone; mp 134—135 °C, IR: 3605, 3360, 1707 cm^{-1}, NMR: 1.08 and 1.10 (each s, 6, -C(CH_3)$_2$), 1.20 (d, 6, J=7 Hz, -CH-($C\underline{H}_3$)$_2$), 1.29 (s, 3, C_{10}-CH_3), 2.33 (s, 1, C_5-H), 3.51 (s, 2, -$COCH_2$-), 6.15 (bs, 1, -OH), 6.67 and 6.73 (each s, 2, C_{11}-H and C_{14}-H). Found: C, 80.08; H, 9.34%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

(±)-Abieta-8,11,13-trien-6β,12-diol (19). A mixture of **18** (117 mg) and lithium aluminium hydride (20 mg) in dry ether (10 ml) was refluxed for 1 h. The mixture was then poured into ice–aqueous ammonium chloride and extracted with ether. The extract was washed with brine. The dried extract was evaporated to give **19** (108 mg: 92%), which was subsequently recrystallized from hexane–acetone; mp 174—176 °C, IR: 3610, 3350 cm^{-1}, NMR ($CDCl_3$): 1.03 and 1.28 (each s, 6, -C(CH_3)$_2$), 1.22 (d, 6, J=7 Hz, -CH($C\underline{H}_3$)$_2$), 1.53 (s, 3, C_{10}-CH_3), 4.5—4.9 (m, 2, -OH and C_6-H), 6.67 and 6.82 (each s, 2, C_{11}-H and C_{14}-H). Found: C, 79.24; H, 9.94%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

(±)-12-Benzoyloxyabieta-8,11,13-trien-6β,11-diol (20).

A solution of **19** (185 mg) and benzoyl peroxide (160 mg) in chloroform (10 ml) was allowed to stand at room temperature for 5 h, diluted with ether containing a small amount of acetic acid, and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and water. After drying over sodium sulfate, the solvent was removed and the residue was chromatographed on silica gel (35 g), using benzene–ether (98: 2) as the eluent, to yield **20** (152 mg: 59%), which responded positively to the Gibbs test;[8] mp 201—201.5 °C (from hexane–acetone), IR: 3580, 3400, 1743 cm^{-1}, NMR ($CDCl_3$): 1.04 and 1.23 (each s, 6, $-\dot{C}(CH_3)_2$), 1.20 (d, 6, $J=7$ Hz, $-CH(C\underline{H}_3)_2$), 1.70 (s, 3, $C_{10}-CH_3$), 4.64 (m, 1, $W_{1/2}=9$ Hz, C_6-H), 6.62 (s, 1, $C_{14}-H$), 7.4—8.3 (m, 5, $-C_6H_5$). Found: C, 76.96; H, 8.20%. Calcd for $C_{27}H_{34}O_4$: C, 76.74; H, 8.11%.

(±)-Taxodione (1). A mixture of **20** (70.0 mg) and lithium aluminium hydride (30 mg) in dry tetrahydrofuran (10 ml) was refluxed for 1.5 h and then treated by **a** method similar to that used for **19**. The crude product was immediately oxidized with the Jones reagent (3 drops) in acetone (2.0 ml) at 0 °C for 2 min. After the usual work-up, the product was purified by column chromatography on silica gel (10 g), using hexane–benzene (1: 4) as the eluent, to yield an oil (**1**) (19.6 mg: 38%); IR: 3344, 1670, 1641, 1625, 1616, 1598 cm^{-1}, NMR: 1.10, 1.26, and 1.26 (each s, 9, $-\dot{C}(CH_3)_2$ and $C_{10}-CH_3$), 1.18 (d, 6, $J=7$ Hz, $-CH(C\underline{H}_3)_2$), 2.50 (s, 1, C_5-H), 6.13 (s, 1, C_7-H), 6.85 (s, 1, $C_{14}-H$), 7.50 (s, 1, -OH). The IR and NMR spectra of (±)-**1** were identical with those of natural taxodione.

2-(2,6,6-Trimethyl-1-cyclohexenyl)-1-(3-isopropyl-4-methoxypheny)ethane (21). Lithium aluminium hydride (110 mg) was added to a solution of anhydrous aluminium chloride (1.2 g) in dry ether (18 ml), and then the mixture was stirred at room temperature for 100 min. To the above solution we then added, drop by drop, a solution of **6** (315 mg) in dry ether (4.0 ml) at 5—6 °C over an 8-min period. The mixture was further stirred at this temperature for 30 min, poured into ice–dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated to give an oil which was purified by column chromatography on silica gel (30 g), using hexane as the eluent, to yield **21** (142 mg: 47%); NMR: 1.04 (s, 6, $-\dot{C}(CH_3)_2$), 1.20 (d, 6, $J=7$ Hz, $-CH(CH_3)_2$), 1.65 (s, 3, $=\dot{C}CH_3$), 3.23 (m, 1, $-C\underline{H}(CH_3)_2$), 3.74 (s, 3, $-OCH_3$), 6.58 (d, 1, $J=9$ Hz), 6.86 (dd, 1, $J=9$ and 3 Hz), and 6.9 (d, 1, $J=3$ Hz) (aromatic protons). Found: C, 84.14; H, 10.43%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

(±)-12-Methoxyabieta-8,11,13-triene (12). A mixture of **21** (298 mg), anhydrous aluminium chloride (140 mg), and dry benzene (10 ml) was refluxed for 3 h. The mixture was then poured into water and extracted with ether. The extract was washed with water, dried, and then evaporated. The chromatographic purification on silica gel (30 g) yielded **12** (155 mg: 52%), whose IR and NMR spectra were identical with those of an authentic sample.

(±)-Ferruginol (2). A solution of **12** (138 mg) and boron tribromide (0.2 ml) in dichloromethane (2.0 ml) was allowed to stand at room temperature for 2 h. The solution was then poured into water and extracted with ether. The extract was washed with brine, dried, and then evaporated to dryness. The crude product was purified by column chromatography on silica gel (15 g), using hexane–benzene (6: 4) as the eluent, to give **2** as an oil (127 mg: 96%); IR: 3605, 3355 cm^{-1}, NMR: 0.93 (s, 6, $-\dot{C}(CH_3)_2$), 1.11 (s, 3, $C_{10}-CH_3$), 1.19 (d, 6, $J=7$ Hz, $-CH(C\underline{H}_3)_2$), 3.08 (m, 1, $-C\underline{H}(CH_3)_2$), 4.70 (s, 1, -OH), 6.42 and 6.67 (each s, 2, $C_{11}-H$ and $C_{14}-H$). The IR and NMR spectra of the synthetic **2** were identical with those of authentic ferruginol.

(±)-Ferruginyl Benzoate (22). A mixture of **2** (127 mg) and benzoyl chloride (0.1 ml) in pyridine (1.0 ml) was heated at 50 °C for 1 h. After the usual work-up, the crude product was chromatographed on silica gel (20 g), using benzene as the eluent, to yield **22** (146 mg: 85%), which was subsequently recrystallized from methanol; mp 125—126 °C (lit,[13] mp 127—130 °C), IR: 1728 cm^{-1}, NMR: 0.95 (s, 6, $-\dot{C}(CH_3)_2$), 1.19 (d, 6, $J=7$ Hz, $-CH(C\underline{H}_3)_2$), 1.21 (s, 3, $C_{10}-CH_3$), 6.82 and 6.86 (each s, 2, $C_{11}-H$ and $C_{14}-H$), 7.3—8.2 (m, 5, $-C_6H_5$). Found: C, 83.01; H, 8.75%. Calcd for $C_{27}H_{34}O_2$: C, 83.03; H, 8.78%.

(±)-12-Methoxyabieta-8,11,13-trien-7-one (23). A mixture of **12** (161 mg) and chromium trioxide (160 mg) in acetic acid (5.0 ml) was stirred at room temperature for 11 h. After the usual work-up, the product was purified by column chromatography on silica gel (15 g), using benzene as the eluent, to yield **23** (110 mg: 65%), which was subsequently recrystallized from methanol; mp 125—126 °C (lit,[6] mp 125—126 °C), IR: 1660 cm^{-1}, NMR 0.95 and 1.00 (each s, 6, $-\dot{C}(CH_3)_2$), 1.21 (d, 6, $J=7$ Hz, $-C\underline{H}(CH_3)_2$), 1.24 (s, 3, $C_{10}-CH_3$), 3.21 (m, 1, $-C\underline{H}(CH_3)_2$), 3.87 (s, 3, $-OCH_3$), 6.66 (s, 1, $C_{11}-H$), 7.69 (s, 1, $C_{14}-H$). Found: 80.01; H, 9.48%. Calcd for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

(±)-Sugiol (3). A solution of **23** (110 mg) and boron tribromide (0.3 ml) in dichloromethane (2.0 ml) was allowed to stand at room temperature for 4 h and then treated as has been described for **2**. The crude product was chromatographed on silica gel (15 g) and eluted with benzene–ether (99: 1) to give **3** (84 mg: 80%), which was then recrystallized from methanol; mp 246.5—247 °C, IR (KBr): 3120, 1643 cm^{-1}, NMR (pyridine-d_5): 0.83 and 0.87 (each s, 6, $-\dot{C}(CH_3)_2$), 1.14 (s, 3, $C_{10}-CH_3$), 1.35 (d, 6, $J=7$ Hz, $-CH(C\underline{H}_3)_2$), 3.60 (m, 1, $-C\underline{H}(CH_3)_2$), 7.05 (s, 1, $C_{11}-H$), 8.30 (s, 1, $C_{14}-H$). Found: C, 79.73; H, 9.25%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

(±)-Sugiyl Acetate (24). A solution of **3** (49 mg) and acetic anhydride (0.2 ml) in pyridine (2.0 ml) was heated at 50—55 °C for 3 h. The crude product was then chromatographed on silica gel (10 g) and eluted with benzene to afford **24** as an oil (47 mg: 85%); IR: 1753, 1675 cm^{-1}, NMR ($CDCl_3$): 0.93 and 1.01 (each s, 6, $-\dot{C}(CH_3)_2$), 1.22 (d, 6, $J=7$ Hz, $-CH(C\underline{H}_3)_2$), 1.25 (s, 3, $C_{10}-CH_3$), 2.32 (s, 3, $-OCOCH_3$), 2.99 (m, 1, $-C\underline{H}(CH_3)_2$), 6.96 (s, 1, $C_{11}-H$), 7.94 (s, 1, $C_{14}-H$). Found: C, 77.44; H, 8.88%. Calcd for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83%. The NMR spectrum was identical with that published[7] for (+)-sugiyl acetate.

(±)-Sugiyl Benzoate (25). A solution of **3** (48 mg), benzoyl chloride (0.1 ml), and pyridine (1.0 ml) was heated at 50—55 °C for 1 h. The crude product was then chromatographed on silica gel (15 g) and eluted with benzene–ether (99: 1) to give **25** (57 mg: 88%), which was subsequently recrystallized from methanol; mp 164—166 °C, IR: 1734, 1673 cm^{-1}, NMR: 0.97 and 1.02 (each s, 6, $-\dot{C}(CH_3)_2$), 1.25 and 1.27 (each d and $J=7$ Hz, 6, $-CH(C\underline{H}_3)_2$), 1.28 (s, 3, $C_{10}-CH_3$), 3.06 (m, 1, $-C\underline{H}(CH_3)_2$), 7.02 (s, 1, $C_{11}-H$), 7.89 (s, 1, $C_{14}-H$). Found: C, 80.05; H, 8.11%. Calcd for $C_{27}H_{32}O_3$: C, 80.16; H, 7.97%.

A Synthesis of 3′,4′-Dideoxykanamycin B

Tomo NISHIMURA, Tsutomu TSUCHIYA, Sumio UMEZAWA, and Hamao UMEZAWA*

Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

**Institute of Microbial Chemistry, Kamiosaki, Shinagawa-ku, Tokyo 141*

(Received December 25, 1976)

3′,4′-Dideoxykanamycin B was prepared from kanamycin B *via* 4″,6″-*O*-cyclohexylidenation, *N*-benzyloxycarbonylation, 3′,4′,2″-tri-*O*-benzylsulfonylation, double bond formation at C-3′,4′, removal of the cyclohexylidene group, simultaneous removal of the *N*,*O*-protecting groups with sodium metal in liquid ammonia and hydrogenation of the resulting 3′,4′-dideoxy-3′-eno-kanamycin B.

3′,4′-Dideoxykanamycin B[1] (Dibekacin) (**10**) has strong antibacterial activities against usual and resistant bacteria including *Pseudomonas aeruginosa*. The first[1] and an improved synthesis[2] have been reported. This paper describes another synthesis of **10**.

In this synthesis, various protecting groups used in transformation of aminoglycoside antibiotics were first studied to increase the yield of **10**.

In order to prepare kanamycin derivatives, protection of the amino groups is generally the requisite step which comes first, but we tried, in this paper, to protect the 4″- and 6″-hydroxyl groups in advance to the protection of the amino groups. In this attempt, kanamycin B (KMB) was converted to its penta-*p*-toluenesulfonate (**1**) in order to raise the solubility of kanamycin B in organic solvents. The pentasulfonate was treated with 1,1-dimethoxycyclohexane in *N*,*N*-dimethylformamide (DMF) in the presence of *p*-toluenesulfonic acid in a manner as described in a previous paper[2] to give 4″,6″-*O*-cyclohexylidene-kanamycin B (**2**) in 85% yield. Similar treatment of the pentasulfonate (**1**) with 2,2-dimethoxypropane gave the corresponding 4″,6″-*O*-isopropylidene derivative (**3**). The low yield (48%) of the latter compound will be due to[3] the low boiling point of the ketal reagent. It was surprising that **2** and **3** (especially **3**) retained antibacterial activity as shown in Table 1. As already reported, even minor modifications of 6-amino-6-deoxyglucose and 2,6-diamino-2,6-dideoxyglucose moieties of kanamycin (3′-*O*-methylkanamycin[4]) and neamine (3′- and 4′-*O*-methylneamines[5]) gave derivatives almost devoid of antibacterial activity. However, it seems that the antibacterial activity is not strongly reduced by minor modifications of the 3-amino-3-deoxyglucose moiety of kanamycins or other related antibiotics.

The amino groups of **2** were protected with benzyl chloroformate in a usual manner to give **4** in 94% yield. To carry out 3′,4′-di-*O*-sulfonylation, which is the requisite step for making 3′,4′-unsaturation bond, benzylsulfonylation was adopted from the following reason. In *N*-tosyl derivatives[2] of kanamycin B, 3′,4′-dibenzylsulfonylation can smoothly be carried out and the 2″-*O*-benzylsulfonyl group, which is simultaneously formed, can readily be removed in addition to the *N*-tosyl groups in a later step without formation of 2″,3″-epimine. On the other hand, 3′,4′-di-*O*-tosylation was shown to be difficult to attain on account of steric hindrance caused by the first tosyl group introduced at C-3′ or C-4′ of the *N*-ethoxycarbonyl derivative[6] of kanamycin B. Instead of tosylation, 3′,4′-di-*O*-

a) Agar dilution streak method (nutrient agar, 37 °C, 18 h). b) A strain of clinical origin having the ability of phosphorylating the 3′-hydroxyl group of kanamycin B. c) 48 h.

mesylation is also possible, however, 2″-*O*-mesyl group, which is simultaneously formed, resists[7] sometimes to elimination in treatment with sodium metal in liquid ammonia in comparison to the 2″-*O*-benzylsulfonyl group. In view of these results benzylsulfonylation was selected. When **4** was treated with benzylsulfonyl chloride in pyridine–collidine (1: 1), 3′,4′,2″-tri-*O*- (**5**) and 5,3′,4′,2″-tetra-*O*-benzylsulfonyl (**6**) derivatives were formed. The formation of the 5-*O*-sulfonate was unexpected, because 5-*O*-acylation of kanamycins in pyridine occurs scarcely, in general. Since **6** gave, in the next unsaturation step, an unidentified product, **5** was selected for the precursor for unsaturation and an effort was made to increase the yield of **5**. When **4** was treated with four equivalents of benzylsulfonyl chloride for **4** at −20 °C for 4.5 h, **5** was obtained in 98% yield.

3′,4′-Unsaturation of **5** was tried firstly with sodium iodide in DMF in a similar fashion as described[2] for 3′,4′-di-*O*-benzylsulfonyl-penta-*N*-tosylkanamycin B derivative, however, no unsaturated compound was obtained as previously[2] experienced. Raising the reaction temperature or prolongation of the reaction period also failed to give the desired product. Addition of zinc dust, however, readily gave the 3′,4′-unsaturated derivative (**7**) in 86% yield. The presence of the 3′,4′-unsaturation bond was supported by the optical rotation[1,2,8] and also by the PMR spectrum, in which a 2-proton AB quartet ($J \approx 11$ Hz) assignable to protons of *cis* double bond[8] was observed. In this reaction, no 2″,3″-aziridine as experienced in the above-described *N*-tosyl derivative[2] of kanamycin B was formed. These features of reactions may be due to the nature of the *N*-protecting groups, *i.e.* the benzyloxycarbonyl and tosyl groups.

Acidic hydrolysis of **7** gave the decyclohexylidenated product (**8**). Treatment of **8**, which has been carefully purified to remove inorganic impurities,[9] with sodium metal in liquid ammonia at −50 °C for 1 h gave the desired 3′,4′-unsaturated derivative (**9**), both the *N*-benzyloxycarbonyl[10] and *O*-benzylsulfonyl groups being readily removed. Catalytic hydrogenation of **9** gave 3′,4′-dideoxykanamycin B (**10**) in 95% yield. The physical constants, IR and PMR spectra, and antibacterial activity were identical with those of specimen previously prepared.[1,2] Overall yield of **10** from kanamycin B was over than 50% of the theoretical.

Antibacterial activities of the synthesized products and related antibiotics are ahown in Table 1. The antibacterial activity of **9** was found to be fairly weaker than that of 3′,4′-dideoxykanamycin B (**10**), although **9** inhibited growth of resistant bacteria and *pseudomonas*

Experimental

PMR spectra were recorded at 60, 90, and 100 MHz with Hitachi R-24A, Varian EM-390, and Varian XL-100 spectrometers, respectively. Thin-layer chromatography (TLC) was performed on Wakogel B-5 with sulfuric acid spray for detection. Paper chromatography (PPC) was carried out on Toyo-Roshi No. 50 descending with 1-butanol–pyridine–water–acetic acid=6: 4: 3: 1 and detected by 0.5% ninhydrin in pyridine. For column chromatography, silica gel (Wakogel C-200) was used. For experiments at lower than 0 °C, cooling assembly of Haake constant temperature circulator KS60W was used.

*Kanamycin B Penta-*p*-toluenesulfonate (**1**).* To an aqueous solution (5 ml) of kanamycin B monocarbonate (4.1 g), *p*-toluenesulfonic acid monohydrate (8.5 g) was added and to the acidic solution (pH≈1), acetone (300 ml) was added. Precipitates were collected, washed thoroughly with acetone and dried *in vacuo* in a desiccator to give kanamycin B penta-*p*-toluenesulfonate as tetrahydrate, 10.17 g (96%), $[\alpha]_D^{25}$ +55° (*c* 1, water).

Found: C, 45.15; H, 5.65; N, 4.83; S, 11.29%. Calcd for $C_{18}H_{37}N_5O_{10}\cdot 5C_7H_8O_3S\cdot 4H_2O$: C, 44.94; H, 6.05; N, 4.94; S, 11.32%.

*4″,6″-O-Cyclohexylidenekanamycin B (**2**).* Compound **1** tetrahydrate (5.16 g) was dried at 60 °C *in vacuo* in the presence of CaH_2 for 2.5 h and the dried **1** was dissolved in dry DMF (26 ml). To the solution, anhydrous *p*-toluenesulfonic acid (1.85 g) and 1,1-dimethoxycyclohexane (4.2 ml) were added and the solution was kept at room temperature overnight, further at 50 °C for 30 min and at 65 °C for 15 min *in vacuo* (both at 20 Torr). The solution contained two components, **2** (major, TLC, R_f 0.38 with 1-BuOH–EtOH–$CHCl_3$–17% NH_4OH=4: 4: 2: 3, doubly developed; *cf.* **1**, R_f 0.05) and dicyclohexylidene derivative (R_f 0.52). Water (0.015 ml) was added and the solution was kept at room temperature overnight. Dicyclohexylidene derivative almost disappeared. The solution was poured into 8 M ammonia solution (20 ml) with vigorous stirring and concentrated *in vacuo*. The residue

was dissolved in water and the solution was passed through a column of Amberlite IRA 900 (OH form, 50 ml) with water. The ninhydrin-positive fractions were concentrated to give a solid (2.8 g), which was further chromatographed over CM-Sephadex C-25 (NH_4 form, 300 ml) with 0.03→0.15 M ammonia (gradually changed). After minor product was eluted (≈0.2 g), **2** was eluted, 1.93 g (85% as monocarbonate), $[\alpha]_D^{25}$ +114° (*c* 1, water); PMR (D_2O) δ: 1.0—2.2 (12H, H-2,2 and cyclohexylidene), 4.98 and 5.32 (each 1H d, $J\approx$ 3 Hz, anomeric).

Found: C, 48.31; H, 7.77; N, 11.31%. Calcd for $C_{24}H_{45}N_5O_{10}\cdot H_2CO_3$: C, 47.97; H, 7.57; N, 11.20%.

4'',6''-O-Isopropylidenekanamycin B (3). Compound **1** tetrahydrate (100 mg) was treated with 2,2-dimethoxypropane (0.1 ml) similarly as described for **2** to give **3** as a solid of monocarbonate, 20.0 mg (48%). Recovered **2** was 13 mg.

Compound **3**: $[\alpha]_D^{25}$ +110° (*c* 0.5, water); PMR (D_2O) δ: 1.94 and 2.07 (each 3H s, $(CH_3)_2C$).

Found: C, 45.10; H, 7.47; N, 11.74%. Calcd for $C_{21}H_{41}N_5O_{10}\cdot H_2CO_3$: C, 45.12; H, 7.40; N, 11.96%.

Penta-N-benzyloxycarbonyl-4'',6''-O-cyclohexylidenekanamycin B (4). To a stirred mixture of **2** (1.60 g) and anhydrous sodium carbonate (1.57 g) in acetone (16 ml)–water (16 ml)–methanol (1.6 ml), benzyl chloroformate (2.05 ml) was added and the mixture was stirred at room temperature for 2 h. After concentration, the residue was washed successively with ether and water and dried, 2.97 g (94%), $[\alpha]_D^{25}$ +47° (*c* 1, pyridine); IR (KBr): 1700, 1520 cm^{-1}.

Found: C, 62.06; H, 6.11; N, 5.61%. Calcd for $C_{64}H_{75}N_5O_{20}$: C, 62.28; H, 6.12; N, 5.67%.

Penta-N-benzyloxycarbonyl-3',4',2''-tri-O- and 5,3',4',2''-tetra-O-benzylsulfonyl-4'',6''-O-cyclohexylidenekanamycin B (6 and 5). Reaction 1. To a cold solution (−20 °C) of **4** (1.00 g) in dry pyridine–collidine (1: 1, 20 ml), benzylsulfonyl chloride (925 mg, 6 equivalents for **4**) was added and the solution was kept at −20 °C for 20 h. The solution was gradually warmed to 3 °C in 20 min and further kept at the temperature for 2 h. Water (0.1 ml) was added to stop the reaction and the solution was allowed to stand at 3 °C for 1 h. The solution was poured into aqueous 0.05% sodium carbonate solution. Slightly yellow precipitates were collected, washed with water, and dissolved in chloroform. The solution was washed with water, dried (Na_2SO_4), and concentrated to give a solid (1.67 g). The solid was chromatographed over silica gel with chloroform–acetone=12: 1 to give **5** (847 mg, 62%, R_f 0.5 with benzene–ethyl acetate=2: 1) and **6** (327 mg, 22%, R_f 0.77).

5: mp 198—205 °C (dec), $[\alpha]_D^{25}$ +59° (*c* 0.8, dioxane).

Found: C, 59.90; H, 5.45; N, 4.03; S, 5.67%. Calcd for $C_{85}H_{93}N_5O_{26}S_3$: C, 60.17; H, 5.52; N, 4.13; S, 5.67%.

6: mp 110—114 °C, $[\alpha]_D^{25}$ +52° (*c* 0.8, dioxane).

Found: C, 59.68; H, 5.40; N, 3.69; S, 6.79%. Calcd for $C_{92}H_{99}N_5O_{28}S_4$: C, 59.70; H, 5.39; N, 3.78; S, 6.93%.

Reaction 2. To a cold solution (−20 °C) of **4** (200 mg) in dry pyridine (4 ml), benzylsulfonyl chloride (123 mg, 4 equivalents for **4**) was added and the solution was kept at −20 °C for 4.5 h. After addition of water (0.02 ml), the solution was further kept at the temperature for 1 h. The solution contained, on checked by TLC, **5** accompanied by only a slight amont of **6**. The solution was poured into aqueous 0.05% sodium carbonate solution. Colorless solid precipitated was then treated similarly as described in Reaction 1 (but without column chromatography) to give a solid, which was purified by reprecipitation with chloroform–hexane to give **5**, 270 mg (98%).

Penta-N-benzyloxycarbonyl-2''-O-benzylsulfonyl-4'',6''-O-cyclohexylidene-3',4'-dideoxy-3'-eno-kanamycin B (7). A mixture of **5** (169 mg), sodium iodide (1.7 g), and zinc dust (840 mg) in dry DMF (3.4 ml) was stirred at 95 °C for 35 min. The solution, which soon solidified on cooling, was extracted with chloroform (7 ml×6). The solution was washed with water, dried (Na_2SO_4), and concentrated. The resulting syrup was dissolved in a mixture of hot chloroform (16 ml) and hexane (6 ml) and gradually cooled to give precipitates. After filtration, hexane was added to the filtrate to give additional precipitates. The process was further repeated three times. Precipitates combined were chromatographically homogeneous colorless solid, 115 mg (86%), $[\alpha]_D^{25}$ +12.5° (*c* 0.8, dioxane); PMR ($CDCl_3$): δ 1.1—1.9 (12H, H-2,2 and cyclohexylidene), $\delta\approx$5.5 (12H, CH_2Ph), a deformed AB quartet (2H, $J\approx$11 Hz) centered at δ 5.6 (H-3',4').

Found: C, 62.73; H, 5.96; N, 5.04; S, 2.32%. Calcd for $C_{71}H_{79}N_5O_{20}S$: C, 62.96; H, 5.88; N, 5.17; S, 2.32%.

Penta-N-benzyloxycarbonyl-2''-O-benzylsulfonyl-3',4'-dideoxy-3'-eno-kanamycin B (8). A suspension of **7** (115 mg) in a mixture of dioxane (0.25 ml)–water (0.15 ml)–acetic acid (1.6 ml) was heated at 80 °C for 2.5 h. The solution showed, on TLC with chloroform–acetone=2: 1, a spot at R_f 0.15 (**8**), and the spot of R_f 0.85 (**7**) disappeared. The solution was concentrated with several additions of toluene to give a residue, which was dissolved in dioxane. Addition of water gave precipitates, which were washed with hexane and with water to give a solid, 104 mg (96%), $[\alpha]_D^{25}$ +10° (*c* 0.2, dioxane).

Found: C, 61.43; H, 5.71; N, 5.70; S, 2.78%. Calcd for $C_{65}H_{71}N_5O_{20}S$: C, 61.26; H, 5.62; N, 5.50; S, 2.52%.

3',4'-Dideoxy-3'-eno-kanamycin B (9). A hot solution of **8** (61 mg) in dioxane (4 ml) was filtered with aid of absorbent cotton in close distance of a bar magnet, and to the filtrate, Dowex 50W X2 resin (H form, 1 ml) pretreated with dioxane was added. After agitation for a while, the mixture was filtered and the filtrate was concentrated. The residual solid was dried at 65 °C *in vacuo* for 2 h. An air-proof vessel containing the above solid was cooled to −60 °C and to it, ammonia was introduced. To the resulting solution (≈18 ml), a piece of sodium metal (≈120 mg) was added and the solution was warmed to −50 °C with stirring within 15 min. The deep-blue solution was kept at the temperature for 1 h. After addition of methanol, ammonia was evaporated with gradual warming to room temperature. To an aqueous solution of the residue, Dowex 50W X2 resin (H form, 4 ml) was added and after agitation for a while, the mixture was poured into a column containing the same resin (3.5 ml). The column was washed thoroughly with water and the product was eluted with 1 M aqueous ammonia. The ninhydrin-positive fractions were collected and concentrated to give a solid, which was thoroughly dried *in vacuo* to give **9** as monocarbonate, 23.8 mg (97%), $[\alpha]_D^{25}$ +44° (*c* 0.4, water); **9** has slightly slower mobility than that of **10** on PPC, and **9** gives bluish brown coloration (*cf.* **10**, blue) with ninhydrin in pyridine. PMR (D_2O+slight DCl) δ: 1.3 (1H q, $J\approx$12 Hz, H-2_{ax}), 2.0 (1H double t, J=3—4, 3—4, and 12 Hz, H-2_{eq}), 5.0 (1H m, H-1'), 5.4 (1H, d, J=3 Hz, H-1''), 5.82 (2H, slightly broadened s, H-3',4').

Found: C, 44.76; H, 7.51; N, 13.75%. Calcd for $C_{18}H_{35}N_5O_8\cdot H_2CO_3$: C, 44.61; H, 7.29; N, 13.69%.

3',4'-Dideoxykanamycin B (10). To an aqueous solution (0.3 ml) of **9** monocarbonate (12.1 mg), platinum oxide (≈3 mg) was added and the mixture was hydrogenated with hydrogen under pressure (3.5 kg/cm^2) at room temperature for 1.5 h. Filtration followed by concentration gave a solid, which was dried thoroughly to give **10** as monocarbonate, 11.5 mg (95%), $[\alpha]_D^{25}$ +109° (*c* 1, water) (lit,[1] +132° as free base).

Found: C, 44.91; H, 7.96; N, 13.63%. Calcd for $C_{18}H_{37}N_5O_8 \cdot H_2CO_3$: C, 44.44; H, 7.65; N, 13.64%.

The Benzannelated Annulenones. Syntheses and Properties of 12-Methylbenzo[*f*]- and Dibenzo[*f,l*]-8,10-bisdehydro[17]annulenone

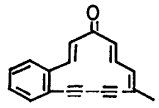
Jūro Ojima,* Miyako Ishiyama, and Akihiko Kimura

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

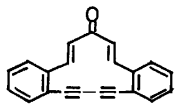
(Received December 27, 1976)

The benzannelated annulenones VII and XI have been synthesized to establish the effect of annelation of benzene ring on the seventeen-membered ring system. An examination of the NMR spectra suggested that both of VII and XI are paratropic and the paratropicities decrease in the order of VII>XI with the number of benzene ring fused to seventeen-membered ring system.

As reported in the previous papers,[1] the monobenzo- (I) and dibenzobisdehydro[13]annulenone (II) were prepared by an aldol condensation of an appropriate aldehyde and ketone containing terminal acetylene group, followed by an oxidative coupling of the resulting acyclic ketone. The same approach has been now extended to synthesis of a next higher $(4n+1)$-membered ring system. The present paper deals with the synthesis and properties of the respective vinylogues of I and II, *i.e.*, 12-methylbenzo[*f*]- (VII) and dibenzo[*f,l*]-8,10-bisdehydro[17]annulenone (XI).[2]



I



II

As outlined in Scheme, the methylbenzo[17]-annulenone (VII) was synthesized as follows. The starting material was the available *cis*-3-methyl-2-penten-4-ynal (III).[3] This substance was converted to the vinylogue (IV) in an 88% overall yield by transformation to the diethyl acetal of III followed by condensation with ethyl vinyl ether in the presence of zinc chloride and treatment of the ethoxy acetal of the resulting vinylogue with sodium acetate in acetic acid according to the method of Isler *et al.*[4,5] *o*-Ethynylcinnamaldehyde (IX), prepared from *o*-ethynylbenzaldehyde (VIII) as has been reported previously,[6] was condensed with acetone in the presence of aqueous sodium hydroxide to afford the ketone (V) in a high yield. Aldol condensation of the dienyne aldehyde (IV) and the ketone (V) by means of methanolic potassium

Table 1. ^{1}H-NMR parameters of VI and VII in $CDCl_3$ at 100 MHz (τ-values; internal standard, TMS; J in Hz in parentheses)

b) The resonances of H^C and H^D protons are submerged by those of benzenoid protons.

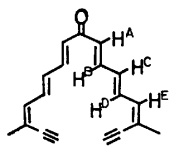
hydroxide gave the acyclic ketone (VI) in a 38% yield. Oxidation of VI with copper(II) acetate in pyridine[7] afforded the monobenzannelated annulenone (VII) as yellow crystals in a low yield.

While, a condensation of 2 molar equivalents of IX with 1 molar equivalent of acetone, under the same conditions as indicated for the reaction of IV and V, afforded the acyclic ketone (X) in a 28% yield as orange crystals. Oxidation of X as before yielded the dibenzannelated annulenone (XI) as yellow crystals.

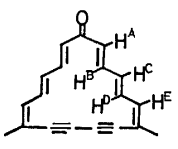
An inspection of the Dreiding molecular model reveals that the title compounds VII and XI should have the assigned conformations corresponding to those for I and II, respectively.

The ^{1}H-NMR parameters of the compounds thus obtained are shown in Tables 1 and 2. The comparison of VI and VII (Table 1) suggests that the compound VII is paratropic, as expected for a potential 16π-electron system due to the polarization of the carbonyl group, since the inner proton (H^B, $H^{B'}$, H^D, $H^{D'}$) resonances have moved to a lower field, and the outer (H^A, $H^{A'}$, H^C, $H^{C'}$, $H^{E'}$) and methyl ones to a higher field, as compared with those of the corresponding protons of the acyclic analogue (VI), respectively.

The similar result as above is obtained for the comparison of the parameters between X and XI (Table 2),[8] although the chemical shift differences are smaller than those between VI and VII. Furthermore, the chemical shifts of the olefinic protons of XI in CF_3-COOD (the carbonyl protonated species) also suggest that XI is paratropic, if we consider the small downfield shift of all protons may be caused by introduction of the positive charge.



XII



XIII

In order to obtain an approximate measure of the effect of benzannelation on seventeen-membered ring system, the ^{1}H-NMR parameters of the model compounds (XII and XIII) synthesized by Ojima and Sondheimer,[9] are listed in Table 3.

As shown in Tables (1, 2, 3), an examination of the NMR spectra demonstrated that the seventeen-membered ring system in dimethyl compound XIII is paratropic, in monobenzo-fused compound VII, it is less paratropic, and in dibenzo-fused compound XI, it is at most weakly paratropic. The sequence can be seen in particular by the downfield shifts, as compared with the respective models (XIII, VII, XI), of the inner proton (H^B, $H^{B'}$, H^D, $H^{D'}$) bands [(−1.24——1.55), (−0.43——0.60), (−0.22——0.77) ppm, respectively], and the chemical shifts [(1.37—1.40), (1.85—),[10] (2.08—2.28) τ, respectively].

Table 3. ^{1}H-NMR parameters of XII and XIII at 60 MHz (τ-values; internal standard, TMS; J in Hz inparentheses)

Proton	XII[a]	XIII	ΔXIII−XII
H^A	3.57d(16)	4.20d(16)	+0.63
H^B	2.64dd(16,11) or 2.92dd(16,11)	1.37dd(16,11) or 1.40dd(16,11)	−1.24——1.55
H^C	3.61dd(16,11)	3.98dd(16,11)	+0.37
H^D	2.64dd(16,11) or 2.92dd(16,11)	1.37dd(16,11) or 1.40dd(16,11)	−1.24——1.55
H^E	3.60d(11)	3.67d(11)	+0.07
CH_3	8.01s	8.23s	+0.22

a) In addition, a singlet at 6.59 (-C≡CH).

The result obtained in the above is accord with that on thirteen-membered ring system obtained by us.[1]

Experimental

The deoxygenated ether, methanol, and acetone were used to minimize an oxidation of the compounds used for aldol condensation and prepared immediately before use. The ether was freed from a peroxide by passing through a short column of basic alumina (Woelm, Act. I) followed by flushing with nitrogen. The methanol and acetone were flushed by nitrogen immediately prior to use. All 20% methanolic potassium hydroxide solutions were prepared before each use by dissolving 10g of potassium hydroxide in 50 ml of methanol and flushing the solution with nitrogen. All the melting points are uncorrected. Brockmann alumina (Act. II—III) was used for column chromatography unless otherwise indicated. The IR, UV, and mass spectra were taken on a Hitachi EPI-S2 or a Unicam SP-200, a Hitachi 124 or a Unicam SP-800, and a JEOL-JMS-SG-2 or an AEI MS-12 spectrometers, respectively. Shoulders in UV spectra are denoted by sh, and wavelength of absorption maximum is recorded in nm and ε-values are given in parentheses. NMR

spectra were taken on a Varian XL-100, a Varian EM-930, a JEOL-JNM-MH-60 or a Varian T-60 spectrometer. Chemical shifts are given in τ-values with respect to TMS as an internal standard, while the coupling constants (J) are given in Hz.

5-Methyl-2,4-heptadien-6-ynal (IV)[5] A 1% solution of *p*-toluenesulfonic acid monohydrate in absolute ethanol (9 drops) was added to a solution of the aldehyde (III, 3.0 g, 0.032 mol) and ethyl orthoformate (6.0 g, 0.04 mol) in absolute ethanol (5 ml). After being stirred at room temperature for 24 h, the mixture was treated with pyridine (0.5 ml) and poured into 2% aqueous sodium hydrogencarbonate (50 ml). Extraction with ether, drying over magnesium sulfate, and evaporation of the solvent yielded the crude diethyl acetal of III as a red liquid. The liquid was dissolved in ethyl acetate (5 ml) and warmed to 35 °C in a flask equipped with two dropping funnels, a condenser, and a magnetic stirrer. A 10% solution of zinc chloride in ethyl acetate (10 drops) was added, and then simultaneously this solution (5 ml) and ethyl vinyl ether (20 ml) during 15 min with stirring at 35 °C. The mixture was stirred for 2 h at room temperature, stoppered, and allowed to stand for 17 h. A solution of sodium acetate (10 g) in water (7 ml) and acetic acid (100 ml) was then added, and the mixture was heated to 90 °C for 2 h. Dilution with water (500 ml), extraction with ether, drying over magnesium sulfate, and evaporation gave a residue, which was chromatographed on alumina (100 g, Woelm, Act. III). Elution with pentane–ether (96: 4—94: 6) and evaporation of the solvents gave the aldehyde (IV, 3.4 g, 88%) as pale yellow liquid, IR (neat): 3250 (–C≡CH), 2100 (–C≡C–), 1675, 1615 (C=O, C=C), 980 cm^{-1} (*trans* C=C), UV: λ_{max}^{ether} 290 (24100), 300 sh nm (23100), NMR ($CDCl_3$, 60 MHz): 0.33 (d, J=8, 1H, –CHO), 2.47 (dd, J=15, 11, 1H, H^B), 3.47 (d, J=11, 1H, H^C), 3.83 (dd, J=15, 8, 1H, H^A), 6.32 (s, 1H, –C≡CH), 7.95 (s, 3H, $-CH_3$), MS: *m/e* 120 (M^+), 119 (M^+–1), 105 (M^+–15), 91 (M^+–29); mol wt, 120.14.

6-(o-Ethynylphenyl)-3,5-hexadien-2-one (V). To a stirred solution of *o*-ethynylcinnamaldehyde (IX, 4.7 g, 0.031 mol) in acetone (250 ml) was added under a nitrogen atmosphere a 5% aqueous sodium hydroxide solution (135 ml) over a period of 15 min at room temperature and stirring was continued for further 2 h at the same temperature. Neutralization with acetic acid and addition of water (250 ml) was followed by extraction with ether. The extracts were washed successively with saturated aqueous sodium hydrogencarbonate and sodium chloride solutions, dried over sodium sulfate and evaporated. The residue was chromatographed on alumina (130 g), eluting with 30% ether in light petroleum to give the ketone (V, 4.8 g, 81%) as crystals. Recrystallization from hexane–benzene afforded pure V as yellow cubes, mp 75.0—76.5 °C, IR (KBr disk): 3250 (–C≡CH), 2100 (–C≡C–), 1655, 1620, 1595 (C=O, C=C), 1000, 970 cm^{-1} (*trans* C=C), MS: *m/e* 196 (M^+, 55), 153 (100); mol wt, 196.24, UV: λ_{max}^{THF} 246 (11000), 254 (15000), 320 nm (29500), NMR ($CDCl_3$, 60 MHz): 2.47—3.05 (m, 6H, phenyl and olefinic H), 3.25 (dd, J=16, 10, 1H, H^B), 3.85 (d, J=16, 1H, H^A), 6.55 (s, 1H, –C≡CH), 7.82 (s, 3H, Me).

Found: C, 85.42; H, 6.09%. Calcd for $C_{14}H_{12}O$: C, 85.68; H, 6.16%.

1-(o-Ethynylphenyl)-11-methyl-1,3,6,8,10-tridecapentaen-12-yn-5-one (VI). To a mixture of the dienyne aldehyde (IV, 1.5 g, 0.0125 mol) and the ketone (V, 1.2 g, 0.0061 mol) in deoxygenated ether (80 ml) was added a 20% methanolic potassium hydroxide solution (4.5 ml) with stirring on ice-bath. The mixture was then stirred at room temperature for 90 min. Neutralization with acetic acid (5 ml) followed by pouring into water (1000 ml) and extraction with benzene gave an organic extract which was washed successively with saturated sodium hydrogencarbonate and sodium chloride solutions, and dried over sodium sulfate. The residue obtained by evaporation of the solvent was chromatographed on alumina (100 g) with light petroleum–ether (7: 3) to give the ketone (VI, 0.7 g, 38%) as unstable solids. Recrystallization from hexane–benzene formed yellow-brown needles, mp 121.5—122.5 °C, MS: *m/e* 298 (M^+, 80), 154 (100); mol wt, 198.36, IR (KBr disk): 3300, 3250 (–C≡CH), 2100 (–C≡C–), 1660, 1605, 1600 (C=O, C=C), 1010 cm^{-1} (*trans* C=C), UV: λ_{max}^{THF} 258 (20200), 267 (21800), 288 sh (18500), 378 nm ((40700), NMR: see Table 1.

12-Methylbenzo[f]-8,10-bisdehydro[17]annulenone (VII). A solution of VI (0.6 g, 0.002 mol) in pyridine (26 ml) was added, drop by drop, with stirring over a period of 10 min into a solution of copper(II) acetate monohydrate (9.0 g) in pyridine (19 ml) kept at 55 °C; the mixture was stirred for further 2 h at 60—65 °C. Then the mixture was chilled, diluted with benzene (200 ml), and poured into 6% hydrochloric acid (1000 ml). The layers were separated, and the aqueous layer was extracted with benzene. The combined benzene layer was washed successively with aqueous sodium hydrogencarbonate and saturated sodium chloride solutions, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on alumina (100 g) with light petroleum–ether (1: 1) to give VII (0.07 g, 12%) as relatively stable solids. Recrystallization from hexane–benzene afforded pure VII as yellow cubes, mp *ca.* 180 °C (dec), MS: *m/e* 296 (M^+, 45), 252 (100); mol wt, 296.35, IR (KBr disk): 2200 (–C≡C–), 1630 (C=O), 1595 (C=C), 995 cm^{-1} (*trans* C=C), UV: λ_{max}^{THF} 285 sh (28500), 299 (35500), 317 (30400), 400 nm (2760), NMR: see Table 1.

1,10-Bis(o-ethynylphenyl)-1,3,6,8-decatetraen-5-one (X). A 20% methanolic potassium hydroxide solution (2 ml) was added dropwise to a stirred solution of *o*-ethynylcinnamaldehyde (IX, 5.0 g, 32.0 mmol) and acetone (1.14 g, 19.6 mmol) in deoxygenated ether (103 ml) at room temperature over a period of 15 min. After had been stirred for 2 h at the same temperature, the reaction mixture was neutralized with acetic acid (2 ml) and mixed with water (300 ml). The mixture was extracted with benzene. After work up of the extracts in the standard way, a dark red liquid obtained was chromatographed on alumina (150 g) with light petroleum–ether (75: 25—55: 45) to give X (1.49 g, 28%) as solids. Recrystallization from light petroleum–benzene gave pure X as orange needles, mp 149.0—149.8 °C,[11] MS: *m/e* 334 (M^+, 85), 154 (100); mol wt, 334.39, IR (KBr disk): 3250 (–C≡CH), 2100 (–C≡C–), 1660, 1620, 1595 (C=O, C=C), 995 cm^{-1} (*trans* C=C), UV: λ_{max}^{THF} 236 (42200), 259 (29500), 267 (29800), 369 nm (57400), NMR: see Table 2.

Found: C, 89.59; H, 5.18%. Calcd for $C_{25}H_{18}O$: C, 89.79; H, 5.43%.

Dibenzo[f,l]-8,10-bisdehydro[17]annulenone (XI). A solution of the ketone (X, 2.08 g, 6.22 mmol) in pyridine (35 ml) was added to a stirred solution of copper(II) acetate monohydrate (17.0 g) in pyridine (56 ml) at 50 °C over a period of 30 min, and the reaction mixture was stirred for further 3 h at 60—65 °C. The precipitate formed on cooling and diluted with benzene (300 ml) was washed with benzene (50 ml × 3). Then the filtrate was washed with 6% hydrochloric acid until it was slightly acidic, and saturated aqueous sodium hydrogencarbonate and sodium chloride solutions successively, and dried over sodium sulfate. The residual dark red liquid obtained after evaporation of the solvent was chromatographed on alumina (130 g) with light petroleum–ether (1: 1) to give the ketone (XI, 348 mg, 17%) as crystals.

Recrystallization from benzene gave pure XI as yellow cubes, mp 209—210.5 °C (dec),[11] MS: *m/e* 332 (M^+, 60), 313 (100); mol wt, 332.38, IR (KBr disk): 2200 (–C≡C–), 1640, 1606, 1594 (C=O, C=C), 1000, 960 cm^{-1} (*trans* C=C), UV: λ_{max}^{THF} 224 (63300), 297 (63300), 313 nm (70000); λ_{max} (CF_3-COOH): 275 sh, 292, 309, 328, 355 sh, 395 sh, 572 nm, NMR: see Table 2.

Found: C, 90.33; H, 4.79%. Calcd for $C_{25}H_{16}O$: C, 90.33; H, 4.85%.

The authors wish to thank Professor F. Sondheimer, University College London, for kindly providing unpublished result. We also thank Dr. S. Akiyama and Prof. M. Nakagawa, Osaka University, for measuring NMR spectra at 100 MHz, and Mr. M. Ikeguchi for his experimental help. This research was financially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (974151, 1974), which is gratefully acknowledged.

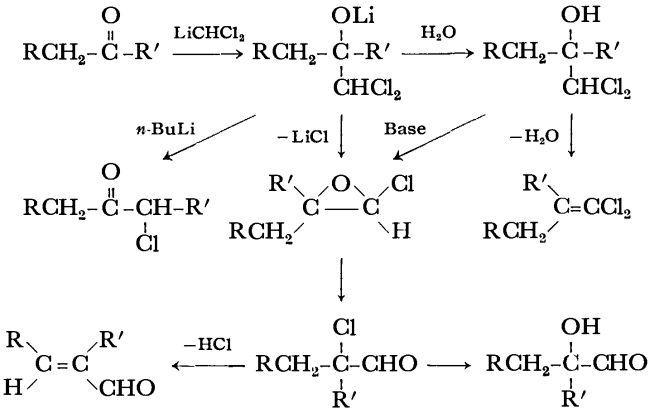
A Practical Synthesis of Polyhalomethyllithium-Carbonyl Adducts[1)]

Hiroaki TAGUCHI, Hisashi YAMAMOTO, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received January 5, 1977)

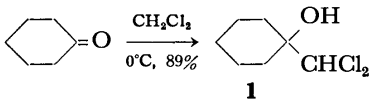
The title adducts are produced upon treatment of a mixture of polyhalomethane and a carbonyl compound with a hindered lithium amide. The kinetically controlled, selective lithiation of the halide enables us to avoid a troublesome procedure involving preformed lithium carbenoid. The halide components examined are dichloromethane, dibromomethane, diiodomethane, chloroform, and bromoform, while the carbonyl ones are ubiquitous ketones and nonanal. A *gem*-dichloroallyllithium is generated similarly from 3,3-dichloropropene and, furthermore, the procedure is successfully extended to the Darzens-type reaction of α-halo esters.

Polyhalomethyllithiums have proved to be extremely useful in organic synthesis as shown in the accompanying scheme.[2,3,4)] For example, nucleophilic addition of dichloromethyllithium to ketones, followed by α-chloro aldehyde formation and dehydrochlorination, gives one carbon homologated α,β-unsaturated aldehydes.[4b)]



Difficulties arise from the extreme thermolability of the carbenoids[2,3)] in generating them on a large scale. Slow and constant addition of butyllithium under vigorous stirring of the halide solution is essential even at −78 °C in order to prevent the local heating, which causes the rapid decomposition of the resulting lithium reagent. The optimum reaction temperature, which is normally between −70 and −120 °C (internal temperature), is limited at the lower end of the range by the rate of formation, and the upper end by the tendency of the carbenoids to decompose.

We have disclosed that the *in situ* reaction of a polyhalomethyllithium with carbonyl compounds offers a simple and direct solution to this problem. Treatment of a mixture of polyhalomethane and carbonyl component with an *N,N*-disubstituted lithium amide[5)] results in the preferential formation of polyhalomethyllithium instead of the expected enolate. The carbenoid attacks instantaneously the carbonyl group prior to its thermal decomposition. With this new technique in hand, we can prepare dichloromethyllithium–cyclohexanone adduct even at the reaction temperature of 0 °C in an 89% isolation yield. Table 1 summarizes the fairly extensive scope of this technique.

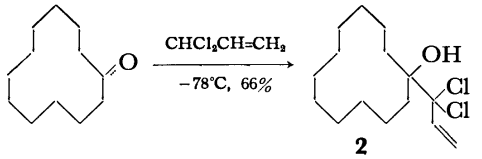


1

Obvious side reaction is the formation of 2-halooxirane, whose rearrangement produces α-halo aldehyde. The extent of such consecutive reactions was not significant upon treatment of simple ketones or aldehydes with dichloro- or dibromomethyllithium. However, the rate of ring closure was found to be greatly enhanced in the reaction of dibromomethyllithium with carbonyl componenents having bulky group directly attached to C=O moiety, probably owing to the steric acceleration. Minimizing this pathway has been attained by performing the reaction in less polar solvents and at lower temperatures. Ether was found to be a favorable solvent for the isolation of hydroxylic adducts, while tetrahydrofuran (THF) gave poor yields. Although the safe upper limit of the reaction temperature was found to be −78 °C, the reaction of crowded carbonyl components should preferably be performed at −95 °C.

Both diiodomethyllithium and tribromomethyllithium are extremely unstable even at −110 °C.[6)] The carbonyl adducts of these carbenoids could, however, be prepared in good to excellent yields by means of the present *in situ* technique at −78 °C (external cooling). Although cyclopentanone is known as one of the readily enolizable ketones, the generation of polyhalomethyllithium proceeded in preference of the enolate formation to afford the desired adducts in good yields. With respect to the basic reagent, lithium diisopropylamide, lithium dicyclohexylamide, and lithium 2,2,6,6-tetramethylpiperidine all gave satisfactory results.

Seyferth and co-workers previously prepared *gem*-dichloroallyllithium from $Ph_3PbCH_2CH{=}CCl_2$ by the action of butyllithium.[7)] In extention of the present method, the carbenoid-carbonyl adduct was synthesized directly from 3,3-dichloropropene in a single step. Addition of lithium diisopropylamide to a mixture of cyclododecanone and the dichloride furnished 1-(3,3-dichloropropenyl)cyclododecanol **2** in 66% yield.



2

Attempts to obtain a carbonyl adduct of monohalomethyllithium derived from allyl bromide or methyl iodide failed to success. The halides containing –COOR moiety on the α-carbon afforded the desired adducts almost quantitatively. Treatment of a mixture of methyl bromoacetate and cyclohexanone with lithium

Table 1. Preparations of polyhalomethyllithium-carbonyl adducts

Polyhalomethane	Carbonyl	Method[c]	Temp, °C	% Yield[b]
CH_2Cl_2	Cyclohexanone	A	−78	quant.
CH_2Cl_2	Cyclohexanone	B	0	89

$CHCl_3$	Cyclohexanone	F	−78	94
$CHBr_3$	Cyclohexanone	C	−78	91

a) For details, see experimental part. b) Yields are based on material isolated by column or thin layer chromatography. c) *Method A*: Lithium dicyclohexylamide (2 equiv) was added to a polyhalomethane solution of carbonyl compound over a period of 1 h; *Method B*: Lithium dicyclohexylamide (2 equiv) was added to a polyhalomethane solution of carbonyl compound over a period of 10 min; *Method C*: Lithium dicyclohexylamide (2 equiv) was added to a THF solution of carbonyl compound and polyhalomethane (24 equiv) over 1 h; *Method D*: Lithium 2,2,6,6-tetramethylpiperidine (2.2 equiv) was added to a THF solution of carbonyl compound and polyhalomethane (2.2 equiv) over a period of 1 h; *Method E*: Lithium 2,2,6,6-tetramethylpiperidine (2.2 equiv) was added to an ether solution of carbonyl compound and polyhalomethane (2.2 equiv) over a period of 1 h; *Method F*: Lithium dicyclohexylamide (2 equiv) was added to a THF solution of carbonyl compound and polyhalomethane (2 equiv) over a period of 1 h.

dicyclohexylamide afforded a Darzens-type product, methyl α,β-epoxycyclohexylacetate **3**, in 93% yield.[8] In contrast, ethyl dichloroacetate gave an aldol, ethyl dichloro(1-hydroxycyclohexyl)acetate **4**, in 91% yield. This variation provides a simple and efficient means of preparing two carbon homologated esters.

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra, on a Hitachi RMU-6L mass spectrometer; and the NMR spectra, on a JEOL C-60-H or a Varian EM-360 spectrometer. The chemical shifts are given in δ, with TMS as the internal standard. The analyses were carried out by the staff at the Elemental Analyses Center of Kyoto University. All the experiments were carried out under an atmosphere of dry nitrogen, by preparative thin-layer chromatography (PLC) on silica gel PF-254 plates (Merck) with benzene as an eluent, and by preparative column chromatography on silica gel Wakogel C-100 (Wako).

Preparation of Polyhalomethylcarbinols. Method A: Lithium dicyclohexylamide (50 mmol) was prepared from dicyclohexylamine (9.05 g, 50 mmol) in dry THF (50 ml) with butyllithium (50 mmol, 33 ml of 1.5 M hexane solution) at 0 °C. This solution was added dropwise into a well-stirred polyhalomethane (50 ml) solution of carbonyl compound (25 mmol) under a nitrogen atmosphere over a period of 1 h at the low temperature described in Table 1. The mixture was then allowed to stand for 1 h at the same low temperature. After hydrolysis at that temperature, the resulting organic layer was extracted with ether, and the extract was washed with water and dried over anhydrous Na_2SO_4. The solution was condensed under reduced pressure, and the residue was purified by column chromatography using benzene as an eluent.

Method B: A well-stirred solution of carbonyl compound (1.0 mmol) in polyhalomethane (2.0 ml) was cooled to the temperature listed in Table 1. To the mixture was added a THF solution of lithium dicyclohexylamide (2.0 mmol) dropwise over a period of 10 min, and the resulting solution was stirred for 5 min at the same temperature. After extractive work up, polyhalomethylcarbinol was obtained by PLC using benzene as an eluent.

Method C: A well-stirred solution of polyhalomethane (50 mmol) and carbonyl compound (25 mmol) in dry THF (50 ml) was cooled to the temperature described in Table 1. To the mixture was added a THF solution of lithium dicyclohexylamide (50 mmol) dropwise over a period of 1 h. The mixture was stirred for 1 h at that temperature. After extractive work up, polyhalomethylcarbinol was obtained by column chromatography using benzene as an eluent.

Method D: A THF solution of lithium 2,2,6,6-tetramethylpiperidide (2.2 mmol) was added to a stirred solution of polyhalomethane (2.2 mmol) and carbonyl compound (1.0 mmol) in dry THF over a period of 1 h at low temperature. Polyhalomethylcarbinol was obtained according to the similar procedure.

Method E: To an ether solution of polyhalomethane (2.2 mmol) and carbonyl compound (1.0 mmol) was added a THF solution of lithium 2,2,6,6-tetramethylpiperidine (2.2 mmol) mmol) over a period of 1 h at low temperature, and the solution was stirred for 1 h at the same temperature. Polyhalomethylcarbinol was obtained according to the similar procedure.

Method F: A well-stirred solution of polyhalomethane (24 mmol) and carbonyl compound (1 mmol) in dry THF was cooled to low temperature. To the mixture was added a THF solution of lithium dicyclohexylamide (2 mmol) over a period of 1 h and the resulting solution was stirred for 1 h at

the same temperature. After extractive work up, polyhalomethylcarbinol was obtained by PLC using benzene as an eluent.

1-Dibromomethylcyclohexanol: Bp 74 °C (2 Torr); IR (neat) 3570, 974, 745 cm^{-1}; NMR (CCl_4) δ 1.30—2.20 (m, 10H), 1.98 (s, 1H), 5.59 (s, 1H); mass *m/e* (%) 231 (trace), 229 (trace), 227 (trace), 99 (100). Found: C, 31.0; H, 4.5%. Calcd for $C_7H_{12}Br_2O$: C, 30.9; H, 4.5%.

1-Dibromomethylcycloheptanol: Bp 152 °C (bath temp 2 Torr); IR (neat) 3460, 800, 720 cm^{-1}; NMR (CCl_4) δ 1.30—2.27 (m, 12H), 2.31 (s, 1H), 5.62 (s, 1H); mass *m/e* (%) 288 (trace), 286 (trace), 284 (trace), 113 (100). Found: C, 33.8; H, 4.9%. Calcd for $C_8H_{14}Br_2O$: C, 33.6; H, 4.9%.

1-Dibromomethylcyclooctanol: Bp 150 °C (bath temp 1 Torr); IR (neat) 3460, 787, 688 cm^{-1}; NMR (CCl_4) δ 1.10—2.23 (m, 14H), 2.33 (s, 1H), 5.68 (s, 1H); mass *m/e* (%) 302 (1), 300 (2), 298 (1), 127 (100). Found: C, 36.3; H, 5.4%. Calcd for $C_9H_{16}Br_2O$: C, 36.0; H, 5.4%.

1-Dibromomethylcyclododecanol: Mp 61 °C; IR (Nujol) 3450, 693 cm^{-1}; NMR ($CDCl_3$) δ 0.77—2.00 (m, 22H), 2.08 (s, 1H), 5.73 (s, 1H); mass *m/e* (%) 279 (3), 277 (3), 183 (100). Found: C, 43.9; H, 6.8%. Calcd for $C_{13}H_{24}Br_2O$: C, 43.8. H, 6.8%.

1-Dibromomethyl-2-methylcyclohexanol: Bp 156 °C (bath temp 15 Torr); IR (neat) 3560, 737, 684 cm^{-1}; NMR (CCl_4) δ 0.90 (d, J=6, 3H), 1.07—2.36 (m, 9H), 2.47 (s, 1H), 5.70 (s, 1H); mass *m/e* (%) 288 (1), 286 (2), 284 (1), 95 (100); Found: C, 33.8; H, 5.0%. Calcd for $C_8H_{14}Br_2O$: C, 33.6; H, 4.9%.

1-Dibromomethyl-2-methylcyclododecanol: Mp 61 °C; IR (Nujol) 3500, 958, 700 cm^{-1}; NMR ($CDCl_3$) δ 5.73 (s, C<u>H</u>Br_2 of major isomer), 5.81 (s, C<u>H</u>Br_2 of minor isomer); mass *m/e* (%) 380 (2), 197 (100). Found: C, 45.6; H, 7.3%. Calcd for $C_{14}H_{26}Br_2O$: C, 45.4; H, 7.1%.

1-Dibromomethyl-2-methylcyclotetradecanol: Bp 190 °C (bath temp 2 Torr); IR (neat) 3580, 978, 702 cm^{-1}; NMR (CCl_4) δ 5.78 (s, C<u>H</u>Br_2 of major isomer), 5.86 (s, C<u>H</u>Br_2 of minor isomer); mass *m/e* (%) 398 (trace), 225 (51), 55 (100). Found: C, 48.1; H, 7.6%. Calcd for $C_{16}H_{30}Br_2O$: C, 48.3; H, 7.6%.

1-Dibromomethyl-2-cyclohexenol: Bp 110 °C (bath temp 2 Torr); IR (neat) 3450, 850, 736 cm^{-1}; NMR (CCl_4) δ 1.52—2.30 (m, 6H), 2.38 (m, 1H), 5.63 (s, 1H), 5.70—6.16 (m, 2H); mass *m/e* (%) 272 (1), 270 (2), 268 (1), 97 (100). Found: C, 31.1; H, 3.9%. Calcd for $C_7H_{10}Br_2O$: C, 31.1; H, 3.7%.

1-Dibromomethyl-2-cycloheptenol: Bp 125 °C (bath temp 1 Torr); IR (neat) 3450, 861, 757 cm^{-1}: NMR (CCl_4) δ 1.30—2.50 (m, 8H), 1.62 (s, 1H), 5.69 (s, 1H), 5.60—6.20 (m, 2H); mass *m/e* (%) 286 (trace), 284 (trace), 282 (trace), 111 (100). Found: C, 33.9; H, 4.4%. Calcd for $C_8H_{12}Br_2O$: C, 33.8; H, 4.3%.

1,1-Dibromo-2-decanol: Bp 165 °C (bath temp 4 Torr); IR (neat), 3450, 708 cm^{-1}; NMR (CCl_4) δ 0.66—1.06 (m, 3H), 1.06—1.97 (m, 14H), 2.77 (m, 1H), 3.75 (m, 1H), 5.64 (d, J=4, 1H); mass *m/e* (%) 205 (trace), 203 (1), 201 (trace), 143 (40), 69 (100). Found: C, 38.2; H, 6.6%. Calcd for $C_{10}H_{20}Br_2O$: C, 38.0; H, 6.4%.

1,1-Diiodo-2-decanol: Bp 180 °C (bath temp 0.1 Torr); IR (neat) 3440, 758, 677 cm^{-1}; NMR (CCl_4) δ 0.65—1.05 (m, 3H), 1.05—2.00 (m, 14H), 2.96 (m, 1H), 3.05 (m, 1H), 5.22 (d, J=4, 1H); mass *m/e* (%) 410 (M^+, 1), 283 (10), 268 (15), 170 (15).

1-Trichloromethylcyclopentanol: Bp 135 °C (bath temp 14 Torr); IR (neat) 3470, 886, 830, 786 cm^{-1}; NMR (CCl_4) δ (1.50—2.80 (m, 8H), 2.58 (s, 1H); mass *m/e* (%) 186 (1), 85 (100). Found: C, 35.6; H, 4.7%. Calcd for $C_6H_9Cl_3O$: C, 35.4; H, 4.5%.

1-Trichloromethylcyclohexanol: Mp 56 °C; IR (Nujol) 3480, 812, 780 cm^{-1}; NMR (CCl_4) δ 1.30—2.50 (m, 10H), 2.06 (s, 1H); mass *m/e* (%) 198 (3), 99 (46).

1-Tribromomethylcyclohexanol: Mp 74 °C; IR (Nujol) 3450, 760, 696 cm^{-1}; NMR (CCl_4) δ 1.40—2.80 (m, 10H), 2.13 (s, 1H); mass *m/e* (%) 273 (1), 271 (3), 269 (1). 99 (100). Found: C, 24.0; H, 3.2%. Calcd for $C_7H_{11}Br_3O$: C, 23.9; H, 3.0%.

Preparation of Methyl α,β-Epoxycyclohexylideneacetate. To a solution of methyl bromoacetate (168 mg, 1.1 mmol) and cyclohexanone (98 mg, 1.0 mmol) in dry THF (2 ml) was added dropwise a solution of lithium dicyclohexylamide (2.0 mmol) in THF over a period of 30 min at −78 °C. The reaction mixture was then stirred for 1 h at the same temperature, and for 3 h at room temperature. After extractive work-up 158 mg (93%) of methyl α,β-epoxycyclohexylacetate was obtained by preparative TLC using benzene as an eluent.

Preparation of Ethyl Dichloro(1-hydroxycyclohexyl)acetate. To a stirred solution of cyclohexanone (98 mg, 1.0 mmol) and ethyl dichloroacetate (0.246 ml, 2.0 mmol) was added dropwise lithium dicyclohexylamide (2.0 mmol) over a period of 30 min at −78 °C, and the reaction mixture was stirred for 30 min at the same temperature. According to the usual procedure 234 mg (92%) of ethyl dichloro(1-hydroxycyclohexyl)acetate was obtained by PLC using benzene as an eluent: Bp 165 °C (bath temp 5 Torr); IR (neat) 3475, 872, 694, 666 cm^{-1}; NMR (CCl_4) δ 1.36 (t, J=8, 3H), 1.20—2.20 (m, 10H), 3.71 (s, 1H), 4.03 (q, J=8, 2H); mass *m/e* (%) 218 (10), 98 (100). Found: C, 47.4; H, 6.6%. Calcd for $C_{10}H_{16}Cl_2O_3$: C, 47.1; H, 6.3%.

Preparation of 1-(3,3-Dichloropropenyl)cyclododecanol. To a solution of cyclododecanone (3.64 g, 20 mmol) and 3,3-dichloropropene (2.42 g, 22 mmol) in dry THF (40 ml) was added dropwise lithium diisopropylamide (30 mmol) at −78 °C over a period of 30 min, and stirred for 30 min at the same temperature. After extractive work-up 3.83 g (66%) of 1-(3,3-dichloropropenyl)cyclododecanol was obtained by column chromatography using benzene as an eluent: Mp

89 °C; IR (Nujol) 3480, 840, 794 cm^{-1}; NMR (CCl_4) δ 1.20—2.00 (m, 22H), 2.08 (s, 1H), 5.26 (d, $J=10$, d, $J=1$, 1H), 5.76 (d, $J=16$, d, $J=1$, 1H), 6.30 (d, $J=16$, d, $J=10$, 1H); mass *m/e* (%) 292 (4), 243 (32). Found: C, 61.7; H, 9.2%. Calcd for $C_{15}H_{26}Cl_2O$: C, 61.4; H, 8.9%.

The authors wish to thank the Ministry of Education Japan, for a Grant-in-Aid (No. 911506).

A Facile Ring Enlargement Reaction *via* β-Oxido Carbenoid[1)]

Hiroaki TAGUCHI, Hisashi YAMAMOTO, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received Jannuary, 5, 1977)

A general method of transforming a cyclic ketone to the next higher ring homolog chlorinated at the α-carbon or alternatively to its parent ketone is described. Treatment of a dichloromethyllithium-carbonyl adduct **2** with butyllithium affords a β-oxido carbenoid **3** at low temperature. Upon warming, **3** decomposes to a lithium enolate **4**, which is quenched with diluted hydrochloric acid to give the α-chloro ketone **5**. Cycloalkanone is converted to a one-carbon ring enlarged halogenated ketone. Meanwhile, dibromomethylcarbinol **7** is transformed to the halogen-free ketone **8** *via* monobromo β-oxido carbenoid upon treatment with butyllithium. α-Methyl substituted ketone is exclusively converted to the β-methyl substituted homolog and therefore *dl*-muscone is synthesized from cyclotetradecanone according to this new method.

The construction of the desired medium or large ring structure can be performed easily by ring enlargement of readily available cyclic compounds.[2)] The one-carbon ring expansion is most important and has been attained by either (a) diazomethane reaction[3)] or (b) the Tiffeneau-Demjanov rearrangement.[4)] However, preparative disadvantages arise from either the complex mixture being formed in the method (a) or from the number of steps required in the method (b).[5)] In addition, regioselectivity can hardly be expected when these methods are applied to an α-substituted or an α,β-unsaturated cyclic ketone. In this report we describe a new method, which is not only simple and convenient, but is highly regioselective. The method is based on smooth decomposition of a β-oxido carbenoid to a lithium enolate.

Synthesis of α-Chloro Ketones.[1a,6)] Nucleophilic addition of dichloromethyllithium to a carbonyl component **1** proceeds smoothly at low temperature to afford a lithium (dichloromethyl)alkoxide **2**. Treatment of the solution with butyllithium at −95 °C, gradual warming to 0 °C, and quenching with diluted hydrochloric acid yielded a one-carbon homologated α-chloro ketone **5**. The reaction obviously involves initial formation of the dilithiated intermediate, β-oxido carbenoid **3**, followed by decomposition to the enolate **4** as shown in Scheme 1.

From benzaldehyde (**1a**), phenacyl chloride (**5a**) was obtained in 72% yield. The possible phenyl migration

Scheme 1.

producing PhCHClCHO was anticipated, but the NMR assay of the reaction product indicated the absence of any isomer other than **5a** before and after purification.

The reaction of PhCDO (98% D content)[7)] gave PhCOCHDCl (97% D content) after recrystallization from the crude product. This is a token indicating the intermediacy of the enolate **4a** resulting from intramolecular carbene insertion to the adjacent C–H bond of β-oxido carbenoid.

The conversion of cyclic ketones to the one-carbon ring enlarged chloro ketones was performed under similar conditions. Sequential treatment of cyclododecanone (**1e**) with dichloromethyllithium at −78 °C and then with butyllithium at −30 °C afforded 46% of 2-chlorocyclotridecanone (**5e**).

Similarly, nonanal (**1b**), furfural (**1c**), citral (**1d**), and cyclopentanone (**1f**) gave the one-carbon homologated chloro ketones in the yield as shown in Table 1.

TABLE 1. PREPARATION OF α-CHLORO KETONE

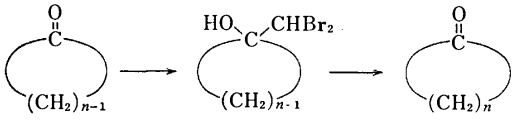
Carbonyl compd	α-Chloro ketone	Yield, %
PhCHO **1a**	$PhCOCH_2Cl$ **5a**	72
$CH_3(CH_2)_7CHO$ **1b**	$CH_3(CH_2)_7COCH_2Cl$ **5b**	62
 **1c**	 **5c**	62
 **1d**	 **5d**	51
 **1e**	 **5e**	46
 **1f**	 **5f**	64

One-Carbon Ring Enlargement of Cyclic Ketones. The next problem was the synthesis of halogen-free ketones under one-carbon homologation, which required generation of monohalo β-oxido carbenoids. This was attained by the lithium-halogen exchange proceeding upon treatment of lithium (dibromomethyl)alkoxide with

butyllithium.

The dibromides **7** were readily prepared from cyclic ketones **6** by the previous method.[8] Treatment with butyllithium in tetrahydrofuran (THF) gave the homologous ketones **8** as shown in Table 2. Thus a two step, facile transformation of a cyclic ketone to a next higher ring homolog has been established.

Table 2. Preparation of cycloalkanones from 1-dibromomethylcycloalkanols



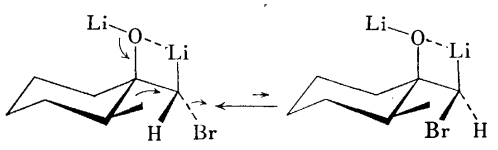
6 **7** **8**

Dibromide	n	Product	Yield, %
7a	12	**8a**	89
7b	8	**8b**	87
7c	7	**8c**	80
7d	6	**8d**	70
7e	5	**8e**	92

Regioselectivity in the Ring Enlargement Reaction. 2-Methylcyclohexanone gives the dibromide **9b**, whose treatment with butyllithium afforded methylcycloheptanone. Yields and isomer ratios under various reaction conditions are listed in Table 3. Thus, the regioselectivity is highly dependent upon the nature of solvent and the reaction temperature. When the reaction was conducted at −95 °C in ether, 3-methylcycloheptanone (**10b**) was obtained with high selectvity (97: 3). At −45 °C a significant amount of 2-methylcycloheptanone was produced. THF as a solvent was characterized by higher selectivity giving 3-methyl ketone **10b** almost exclusively. In ether, **10b** still dominated, but significant amount of 2-methyl ketone **11b** was produced at −78 °C. In hexane solvent the regioselectivity was scarcely observed, and the yield was poor. The low yield in THF was ascribed to the thermal lability of dibromide **9b** even at −78 °C.

The high selectivity was observed as well in the larger ring system. Under similar procedure the dibromide **9c** (n=12) afforded 96% isolated yield of 3-methylcyclotridecanone (**10c**) in 99% selectivity.

The regioselectivity is rationalized by assuming the contribution of β-oxido carbenoid **12** and **13** (from the dibromide **9b**) to be in equilibrium. The absence of repulsion between bulky bromine and methyl group should favor **12** thermodynamically over **13**. Curved arrows indicate that simultaneous elimination of Br^- and selective migration of methyl substituted carbon should afford the observed 3-methylcycloheptanone (**10b**) in preference.



12 **13**

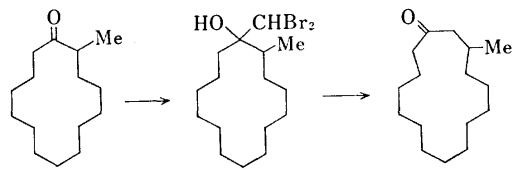
9d[i]	14	−78	THF	97:3[j]	(79)

a) Prepared according to the previously reported procedure.[8] b) Cooling bath temperature. c) Determined by GLPC assay on analytical samples before bulk purification. d) The yields were determined by analytical GLPC using an internal standard: isolated yields in parentheses. e) Reaction of cyclopentanone with dibromomethyllithium afforded **9a** in a ratio of *trans*: *cis*=7: 3. The isomers were separated by preparative TLC. The stereochemical course of the reaction was estimated by the analogy in similar systems. See, for example, E.C. Ashby and J. T. Laemmle, *Chem. Rev.*, **75**, 521 (1975). f) Only one isomer was detected from the reaction of dibromomethyllithium and 2-methylcyclohexanone. 2-Methylcyclohexanone is known to be attacked from the equatrial side to a large extent. It has been suggested that the 2-methyl group introduces a pseudo-axial hydrogen into the molecule which increases hindrance of attack from the axial side; see G. Chauviere, Z. Welvart, D. Eugene, and J. Richer, *Can. J. Chem.*, **47**, 3285 (1969). g) Low yield of this reaction was due to the thermal lability of dibromide **9b** even at −78 °C. h) Mixture of stereoisomers (≈4:1 by NMR assay). i) Mixture of stereoisomers (≈8: 1 by NMR assay). j) Estimated by NMR analysis.

The effectiveness of THF may be attributed to the increased stability of the β-oxido carbenoid because of the solvation of THF for lithium atom.[5] Since the β-oxido carbenoid is stabilized more in THF than in less polar solvent such as ether or hexane, the species is supposed to have enough time for establishment of the equilibrium **12**⇄**13**, which should result in the observed high regioselectivity.

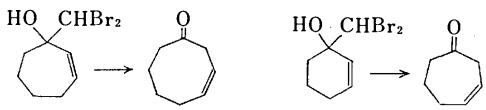
The novel reaction of remarkable regioselectivity has a wide applicability as exemplified by the following *dl*-muscone synthesis.[9] Addition of dibromomethyllithium to 2-methylcyclotetradecanone (**14**) afforded 1-

dibromomethyl-2-methylcyclotetradecanol (**9d**) in 78% yield. The dibromide **9d** was transformed into *dl*-muscone (**10d**) exclusively (≈97% of selectivity) in 79% yield by the reaction with butyllithium.



14 **9d** **10d**

The present method is successfully applied also to the regioselective ring enlargement of α,β-unsaturated cyclic ketone affording β,γ-unsaturated ketone. Treatment of the dibromide **15a** and **15b** with butyllithium gave 3-cyclooctenone (**16a**) (85% yield, 98% of selectivity) and 3-cycloheptenone (**16b**) (76% yield, 95% of selectivity) respectively.



15a **16a** **15b** **16b**

Experimental

The IR spectra were determined on a Shimadzu IR-27-G spectrometer; the mass spectra on a Hitachi RMU-6L mass spectrometer; the GLPC analyses on a Yanagimoto GCG-550F; and NMR spectra on a Varian EM-360 spectrometer. The chemical shifts are given in δ with TMS as the internal standard. The analyses were carried out by the staff at the the Elemental Analyses Center of Kyoto University. All the experiments were carried out under an atmosphere of dry nitrogen, preparative thin layer chromatography (PLC) on silica gel PF-254 plates (Merck) with benzene as an eluent, and preparative column chromatography on silica gel Wakogel C-100 (Wako). THF was purified by distillation from $LiAlH_4$. Ether and hexane were dried over Na metal.

Preparation of Dichloromethyllithium. To a stirred solution of dichloromethane (0.18 ml, 2.8 mmol) in dry THF (5 ml) butyllithium (2.4 mmol) was added drop by drop at −95°C. The resulting solution was stirred for 0.5 h at the same temperature and used immediately.

Preparation of Phenacyl Chloride. Benzaldehyde (212 mg, 2.0 mmol) was added slowly to a stirred solution of dichloromethyllithium (2.4 mmol) at −95 °C. The reaction mixture was stirred for 2 h at the same temperature. To the solution, butyllithium (3.6 mmol) was added dropwise at −95 °C. The resulting mixture was warmed gradually to 0 °C for 20 min, and then quenched with 1M hydrochloric acid. The aqueous layer was separated and extracted with ether 3 times. All organic layers were combined, washed with brine, dried over Na_2SO_4, and concentrated *in vacuo*. Preparative TLC of the residue gave 223 mg (72%) of phenacyl chloride: IR (KBr) 1699, 1600 cm^{-1}; NMR (CCl_4) δ 4.52 (s, 2H), 7.30—8.05 (m, 5H); mass *m/e* (%) 156 (1), 105 (100).

PhCDO was obtained from benzil by the method of Burgstahler.[7]

PhCOCHDCl: NMR (CCl_4) δ 4.52 (s, 1H); mass *m/e* (%) 157 (1), 105 (100).

The reactions of aldehydes, such as furfural, nonanal, and citral, were carried out according to the above procedure, and the yields of the corresponding chloromethyl ketones are summarized in Table 1. The spectral and analytical data of the products are listed below.

1-Chloro-2-decanone: IR (neat) 1719 cm^{-1}; NMR (CCl_4) δ 3.89 (s, 2H); mass *m/e* (%) 190 (1), 141 (59), 57 (100).

2-(Chloroacetyl)furan: IR (neat) 1682 cm^{-1}; NMR (CCl_4) δ 4.46 (s, 2H), 7.23—7.72 (m, 3H); mass *m/e* (%) 146 (8), 95 (100); Found: C, 50.0; H, 3.6%. Calcd for $C_6H_5ClO_2$: C, 49.9; H, 3.5%.

1-Chloro-4,8-dimethyl-3,7-nonadien-2-one: IR (neat) 1710 cm^{-1}; NMR (CCl_4) δ 3.84 (s, 2H); mass *m/e* (%) 202 (1), 69 (100); Found: C, 65.5; H, 8.7%. Calcd for $C_{11}H_{17}ClO$: C, 65.8; H, 8.5%.

Preparation of 2-Chlorocyclotridecanone. To a stirred solution of dichloromethyllithium (2.4 mmol), a solution of cyclododecanone (364 mg, 2.0 mmol) in dry THF (2 ml) was added slowly at −78 °C. The resulting solution was stirred for 1.5 h at the same temperature, and for 0.5 h at −26 °C. To the solution butyllithium (6.0 mmol) was added at the same temperature. The resulting mixture was warmed gradually to 0 °C for 20 min, and then quenched with 1M hydrochloric acid. After extraction with ether, the combined organic layers were washed, dried, and then concentrated under reduced pressure. The residue was purified by preparative TLC affording 212 mg (46%) of 2-chlorocyclotridecanone: IR (neat) 1715 cm^{-1}; NMR (CCl_4) δ 4.20 (m, 1H); mass *m/e* (%) 232 (3), 98 (74), 55 (100). The preparation of 2-chlorocyclohexanone was carried out under the same procedure, and the yield is given in Table 1.

2-Chlorocyclohexanone: IR (neat) 1720 cm^{-1}; NMR (CCl_4) δ 4.32 (m, 1H); mass *m/e* (%) 134 (10), 117 (50), 55 (100).

Preparation of Cyclotridecanone. 1-Dibromomethylcyclododecanol (365 mg, 1.0 mmol) was dissolved in dry THF (3 ml) under nitrogen and cooled to −78 °C. To the stirred solution butyllithium (1.3 ml of a 1.6M hexane solution, 2.1 mmol) was added dropwise over a period of 30 min. The resulting pale yellow solution was stirred for 30 min at −78 °C and 5 min at 0 °C, quenched by pouring into ice cold 1 M hydrochloric acid, and extracted with ether 3 times. The ethereal layers were washed with brine, dried over Na_2SO_4, and concentrated *in vacuo* to afford cyclotridecanone in 89% yield after preparative TLC on silica gel using benzene as an eluent: IR (neat) 1715 cm^{-1}; mass *m/e* (%) 196 (26), 55 (100).

The preparations of cycloalkanones, such as cyclohexanone, cycloheptanone, cyclooctanone, and cyclononanone were carried out according to the above procedure, and the yields of cycloalkanones are listed in Table 2. The product was identified by the comparison of its spectral data or mp of 2,4-dinitrophenylhydrazone derivative with those of the authentic specimen.

Reaction of 1-Dibromomethyl-2-methylcyclopentanol with Butyllithium. To a THF (5 ml) solution of 1-dibromomethyl-2-methylcyclopentanol (272 mg, 1.0 mmol), butyllithium (2.2 mmol) was added dropwise over a period of 10 min at −78°C. The resulting pale yellow solution was stirred for 1 h at −78 °C and 5 min at 0 °C, quenched by pouring into ice cold 1M hydrochloric acid, and extracted with ether. The GLPC analysis of the ethereal layers was performed using cycloheptanone as an internal standard. The yields and isomer ratios are given in Table 3.

Reaction of 1-Dibromomethyl-2-methylcyclohexanol with Butyllithium. The reactions under various conditions were carried out similarly as described above. The GLPC analyses of the ethereal layers were performed using cyclooctanone as an internal standard, and the results are summarized in Table 3.

Preparation of 3-Methylcyclotridecanone. To a solution of 1-dibromomethyl-2-methylcyclododecanol (370 mg, 1.0 mmol) butyllithium (2.2 mmol) was added dropwise over a period of 10 min at −95 °C. The resulting solution was stirred for 1 h at the same temperature and 5 min at 0 °C. Usual work up afforded a colorless oil after preparative TLC on silica gel using benzene as an eluent. Before and after purification, GLPC analyses showed that the oil contains 99% of 3-methylcyclotridecanone (yield 96%): IR (neat) 1710, 1370, 1124, 780 cm^{-1}; NMR (CCl_4) δ 0.95 (d, J=6, 3H), 1.06—1.88 (m, 18H), 2.00—2.60 (m, 5H); mass *m/e* (1) 210 (22), 125 (23), 110 (42), 55 (100).

Preparation of 2-Methylcyclotetradecanone. To a solution of diisopropylamine (0.77 ml, 5.5 mmol) in dry THF (5 ml) butyllithium (5.5 mmol) was added at 0°C and the resulting solution was stirred for 10 min. A solution of cyclotetradecanone (1.05 g, 5.0 mmol) in dry THF (3 ml) was added to the solution, and the reaction mixture was stirred for 30 min at 0°C. To the solution, hexamethylphosphoric triamide (HMPA) (1 ml) and methyl iodide (0.62 ml, 10 mmol) was added at −78 °C. The mixture was stirred for 30 min at the same temperature, and 2 h at room temperature. After extraction with ether, the ethereal layer was concentrated to afford 2-methylcyclotetradecanone (820 mg, 73%) after preparative TLC using benzene as an eluent: IR (neat) 1710, 1020, 720 cm^{-1}; NMR (CCl_4) δ 1.01—2.86 (m, 25H); mass *m/e* (%) 224 (22), 166 (15), 98 (30), 55 (100).

Preparation of 1-Dibromomethyl-2-methylcyclotetradecanol. A well-stirred solution of dibromomethane (0.73 ml) and 2-methylcyclotetradecanone (819 mg, 3.7 mmol) dissolved in dry ether (18 ml) cyclotetradecanone (819 mg, 3.7 mmol), dissolved in dry ether (18 ml) and dry THF (2 ml) was cooled to −78 °C. To the mixture, lithium 2,2,6,6-tetramethylpiperidide (prepared from 2,2,6,6-tetramethylpiperidine (1.14 g, 8.1 mmol) and butyllithium (3.3 ml of 2.4 M hexane solution at 0 °C) was added dropwise over a period of 2 h. The mixture was stirred for 30 min at that temperature. After hydrolysis at −78 °C, the resulting organic layer was extracted with ether, and the extract was washed with 1M hydrochloric acid 3 times and water. The mixture was dried over anhydrous Na_2SO_4, and condensed under reduced pressure to afford 1-dibromomethyl-2-methylcyclotetradecanol (1.14 g, 78%) after preparative TLC using hexane and ether mixture (15: 2) as an eluent: bp 190 °C (bath temp 2 Torr); IR (neat) 3580, 1460, 1154, 978, 708 cm^{-1}; NMR (CCl_4) δ 0.93 (d, J=6, $C\underline{H}_3$ of major isomer), 1.02 (d, J=6, $C\underline{H}_3$ of minor isomer), 5.78 (s, $C\underline{H}Br_2$ of major isomer), 5.86 (s, $C\underline{H}Br_2$ of minor isomer); mass *m/e* (%) 398 (trace), 225 (51), 55 (100). Found: C, 48.1; H, 7.6%. Calcd for $C_{16}H_{30}Br_2O$: C, 48.3; H, 7.6%.

Preparation of dl-*Muscone.* 1-Dibromomethyl-2-methylcyclotetradecanol (183 mg, 0.46 mmol) was dissolved in dry THF (2.5 ml) and cooled to −78 °C. The stirred solution, butyllithium (0.65 ml of a 1.6 M solution, 1.0 mmol) was added dropwise over a period of 10 min. The resulting solution was stirred for 1 h at −78 °C and 5 min at 0 °C, quenched by pouring into ice cold 1M hydrochloric acid, and extracted with ether. The ethereal layer was concentrated to afford *dl*-muscone (86 mg, 79%) after preparative TLC. Before purification, the product was shown by NMR analysis to contain 97% of 3-methylcyclopentadecanone (*dl*-muscone): bp 140 °C (bath temp 2 Torr); IR (neat) 1710, 1370, 1280, 1125, 1055, 790 cm^{-1}; NMR (CCl_4) δ 0.92 (d, J=6.5, 3H), 1.01—1.85 (m, 22H), 1.90—2.50 (m, 5H); mass *m/e* (%) 238 (21), 223 (9), 55 (100). Found: C, 80.4; H, 12.4%. Calcd for $C_{16}H_{30}O$: C, 80.6; H, 12.7%.

Preparations of 3-Cyclooctenone and 3-Cycloheptenone. These β,γ-unsaturated ketones were prepared from 1-dibromomethyl-2-cycloheptenol and 1-dibromomethyl-2-cyclohexenol respectively by the method similar to the preparation of 3-methylcyclotridecanone.

The authors wish to thank the Ministry of Education, Japan, for a Grant-in Aid (No. 911506).

Synthesis of Mesoionic Triazolopyridine. I. *N*-Alkylation of 1,2,4-Triazolo[4,3-*a*]pyridin-3(2*H*)-one

Akio SAITO and Bunji SHIMIZU

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received January 6, 1977)

Mesoionic *anhydro*-1-alkyl-3-hydroxy-1,2,4-triazolo[4,3-*a*]pyridinium hydroxide (**6**) was synthesized by selective alkylation at the N^1-position of 1,2,4-triazolo[4,3-*a*]pyridin-3(2*H*)-one (**8**). The selectively depends on the use of a mercuric salt catalyst in combination with the trimethylsilyl derivative of **8**, and its mechanistic features were also studied with reference to the benzylation of **8**.

During the course of an investigation on nucleoside and nucleotide synthesis we found that the mercuric salt catalyzed silyl procedure* is an excellent method for the glycosylation of purine and pyrimidine bases.[1] In this procedure, the reaction proceeds under mild conditions, the yield being satisfactory. The procedure has been widely applied[4] to the glycosylation of a variety of *N*-heterocycles.

In a series of studies on the application, we attempted the glycosylation of 2-trimethylsilyl-1,2,4-triazolo[4,3-*a*]-pyridin-3(2*H*)-one (**1**) with *O*-acyl-glycosyl halide (**2**) expecting to obtain N^2-glycosyltriazolopyridine (**4**). However, an unusual glycoside which showed strong fluorescence in an aprotic solvent in day light, exhibiting polar behavior as compared with **4** on TLC, was obtained as the main product along with a small amount of **4**. By comparison of its IR, UV, and NMR spectra with those of authentic samples of *anhydro*-1-benzyl-3-hydroxy-1,2,4-triazolo[4,3-*a*]pyridinium hydroxide (**6**, R=benzyl), the glycoside was found to have mesoionic structure (**3**), which was the first example of a mesoionic triazole glycoside.

Mesoionic 1,2,4-triazoles were prepared by cyclization of appropriate hydrazidine derivatives.[5] Mesoionic triazolopyridines (**6**, R=alkyl) have also been obtained[6] in this way from 1-alkyl-1-(2-pyridyl)hydrazine (**7**). It may be possible to obtain the mesoionic compound (**6**) if the reaction occurs exclusively at the N^1-position in the alkylation of 1,2,4-triazolo[4,3-*a*]pyridin-3(2*H*)-one (**8**). In the alkylation of **8** an N^2-alkylated product (**9**) was known[7] to be obtained predominantly. Our findings in the glycosylation of **1** suggested the possibility of this approach. By applying the "mercuric salt catalyzed silyl procedure" to the alkylation, we found it possible to obtain the mesoionic compounds (**6**) from **8**.

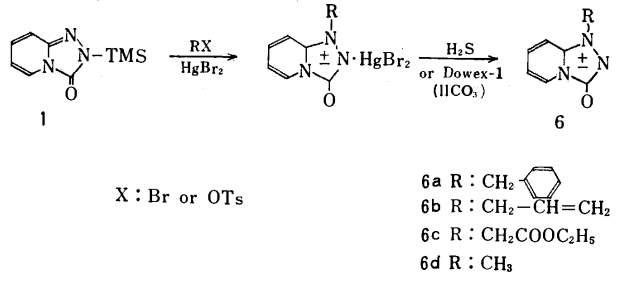
7 6 8 9 10

This report deals with a novel synthesis of mesoionic triazolopyridines (**6**). A detailed study of benzylation of **8** or **1** was also carried out under various conditions in order to clarify the procedure.

Result and Discussion

The synthesis of mesoionic compound (**6**) by an alkylation of **8** was conducted as follows.

The reaction of the trimethylsilyl derivative of **8** with an equimolar amount of alkyl halide or alkyl tosylate in the presence of mercury(II) bromide in nitrobenzene at 60—90 °C gave **6** as the $HgBr_2$-complex in moderate yield. The other alkylated products, **9** and **10**, were obtained in a negligible amount.



1 6

* The term "silyl solvent method" was proposed in a previous paper.[1b] It refers to an improved silyl procedure in which the glycosylation of trimethylsilylated purine or pyrimidine bases with *O*-acyl-glycosyl halide is conducted in the presence of a mercuric salt, *e.g.* mercury(II) chloride or mercury(II) bromide, in a solvent. An analogous procedure, in which the mercuric salt was used in combination with mercury(II) oxide, was reported independently by Wittenburg.[2] Several Lewis acids have been surveyed[3] as an alternative to the mercuric salt in this procedure, tin(IV) chloride being most widely employed.

Table 1. Yields and physical data of mesoionic triazolopyridines (**6**)

Compound	Mp °C	Yield[a] %	Found % C	Found % H	Found % N	Calcd % C	Calcd % H	Calcd % N	UV: λ_{max}^{MeOH} (nm)

a) Based on the products isolated.

The physical properties of the free mesoionic compounds (**6**) obtained by treating the complex with hydrogen sulfide or ion exchange resin (Dowex-1, HCO_3^-) are given in Table 1.

Detailed studies on the benzylation of **8** were carried out in order to elucidate the factor inducing the remarkable selectivity on alkylation.

Since **8** includes three active sites for alkylation N^1,N^2, and O), a number of products would be expected. In fact, three monoalkylated products, **6a**, **9a** (R=benzyl), and **10a** (R=benzyl) were obtained by the reaction of Ag-salt of **8** with benzyl bromide under mild conditions (80 °C, in nitrobenzene). The reaction of **8** with benzyl bromide at relatively high temperature gave **9a** predominantly with a small amount of **6a**. The reaction was accelerated by the addition of mercury(II) bromide, the main product being **6a**. Trimethylsilyl substitution at the N^2-position of **8** afforded a result similar to that obtained by the use of **8** itself on benzylation with regard to the distribution of the products. Sufficient selectivity to give **6a** on the benzylation was obtained by the use of **1** in combination with mercury(II) bromide. The results on the benzylation of **1** or **8** are given in Table 2.

Table 2. Benzylation[a] of **1** or **8**: reaction conditions and products

a) Carried out using 1-eq. of benzyl bromide in nitrobenzene. b) Based on the product isolated.

The results indicate that products can be selected by varying the reaction conditions appropriately. Previous studies[8] on the alkylation of purine bases revealed that alkyl migration plays an important role in determination of the reaction product. The following experiments suggest that the benzyl moiety attached to the triazolopyridine ring easily migrates under the same reaction conditions as described above, the migration proceeding successively in the order $O \rightarrow N^1 \rightarrow N^2$.

Heating of **10a** in nitrobenzene (100—110 °C, 23 h) gave **6a** exclusively. The conversion was accelerated by the addition of a mercuric salt catalyst, *e.g.* $HgBr_2$ or $Hg(CN)_2$. Conversion of **6a** into **9a** was observed in the presence of mercury(II) bromide, but not in the absence of the catalyst even at high temperature (150 °C).

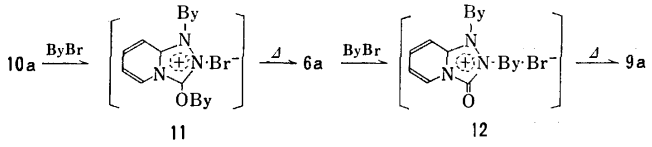
a) Conducted in nitrobenzene. b) Based on the product isolated. c) $HgBr_2$-complex.

80 °C for 5 h gave **6a** almost quantitatively. Conversion of **6a** into **9a** took place by a similar treatment of **6a** with benzyl bromide at 120 °C

Quaternary salts (**11**) and (**12**), assumed to be the intermediates of these conversions, could be isolated as $HgBr_2$-complexes. Detailed results are given in Table 3.



Demercuration of the complex of **12** gave a free quaternary salt which decomposed easily to give **9a** in nitrobenzene at 80 °C. On treatment with hydrogen sulfide, the $HgBr_2$-complex of **11** gave **6a** as a result of the instability of the free quaternary salt.

The results suggest that the primary factor determining the products of benzylation is the benzyl migration under the reaction conditions employed. Presumably, the initial product is either **6a** or **10a**. However, the formation of the latter is uncertain in the reaction of **8** with benzyl bromide since conversion of **10a** into **6a** is very rapid. When the reaction is carried out at high temperature, these compounds are transformed easily into thermodynamically more stable **9a** by benzyl migration. The migration seems to proceed mainly through intermediates **11** and **12**. In order to obtain the mesoionic compound (**6a**) by the benzylation of **8**, it is apparent that further benzylation of **6a** should be suppressed. The use of trimethylsilyl substituent with mercury(II) bromide for the benzylation makes the formation of **6a** under mild conditions possible, **6a** not undergoing further benzylation. The metal probably not only acts as a Friedel-Crafts catalyst but also suppresses the nucleophilic capability of the N^2-atom by the complex formation with **6a**.

By applying the mercuric salt catalyzed silyl procedure to the alkylation of **8**, the reaction was controlled sufficiently to give the mesoionic compound as a product. An analogous controlled acylation of **8** was found to give a new mesoionic *N*-acyltriazolopyridine (**6**, R= acyl).

Experimental

Melting points were determined on a Yazawa hot-stage apparatus and are uncorrected. Infrared, UV and NMR spectra were recorded on Hitachi EPI-S2, Hitachi-124 and Varian T-60 spectrometers respectively.

Triazolopyridine (**8**) was prepared by the method of Potts and Burton.[9] An authentic sample of **6a** was prepared by ring closure of 1-benzyl-1-(2-pyridyl)hydrazine with urea and that of **10a** by the reaction of 3-bromo-1,2,4-triazolo[4,3-*a*]-pyridine with sodium benzyl alcoholate.

2-Trimethylsilyl-1,2,4-triazolo[4,3-a]pyridin-3(2H)-one (**1**). To a mixture of **8** (13.6 g), trimethylchlorosilane (13.0 g) in dry benzene (200 ml) under stirring was added dropwise a solution of triethylamine (12.1 g) in dry benzene (50 ml). After being stirred at room temperature for 2 h, the reaction mixture was filtered, and the cake was washed with a small amount of dry benzene. The combined filtrate and washings were evaporated to give a solid product: yield 20.65 g (99.7%). UV: $\lambda_{max}^{Dioxane}$ 252, 268, 279, 345 nm. Found: C, 51.95; H, 6.45; N, 20.03%. Calcd for $C_{19}H_{13}N_3OSi$: C, 52.10; H, 6.31; N, 20.05%. (Owing to the instability of the product toward water, all the operation had to be performed under the conditions protected from atmospheric moisture.)

Anhydro-*1-(β-D-ribofranos-1-yl)-3-hydroxy-1,2,4-triazolo[4,3-a]pyridinium Hydroxide* (**5**) *and Its* N^2-*Isomer*. Acetic anhydride (0.05 ml) and acetic acid (5 ml) saturated with hydrogen bromide were added to a solution of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-*D*-ribofranoside (2.52 g) in dry chloroform (5 ml). The resulting solution was allowed to stand at room temperature for 45 min, and then evaporated *in vacuo* to give a thick sirup at a temperature below 40 °C. Co-evaporation with dry toluene was repeated three times. The residual sirup was dissolved in dry benzene (10 ml), and mercury(II) bromide (1.80 g) and **1** (1.04 g) were added. The mixture was stirred at room temperature for 2 h, then evaporated *in vacuo*, and the residue was extracted with chloroform. The extract was washed successively with 25% potassium iodide (2 times) and with water, dried over anhydrous sodium sulfate, and evaporated to give an amorphous solid (3.169 g). The protected glycoside thus obtained was heated in methanol (70 ml) containing sodium methoxide (216 mg) under reflux for 60 min. The reaction solution was cooled, then evaporated *in vacuo* to dryness, and the residue was dissolved in water (10 ml). The aqueous solution was washed with ether, rendered neutral with 1M HCl, and applied to a column of 50 ml of Dowex-1×4 (OH^-, 100—200 mesh) anion exchange resin. The column was washed with water (200 ml) and eluted with 40% methanol. The eluate could be separated into two fractions. Evaporation of the first fraction gave **5**, which was recrystallized from aqueous ethanol. Yield 989 mg (74%); fine needles, mp 204—206 °C. UV λ_{max}^{MeOH} 236, 283, 339 nm. IR (Nujol): 1660 cm^{-1} (C=O). NMR (D_2O); δ: 8.18 (d, J=7 Hz, 1, H-5), 7.7—8.0 (m, 2, H-7 and H-8), 7.1—7.4 (m, 1, H-6), 6.12 (d, J=5 Hz, 1, H-1′), 3.8—4.9 ppm (m, 5, ribose ring protons). Found: C, 49.60; H, 5.07; N, 15.85%. Calcd for $C_{11}H_{13}N_3O_5$: C, 49.47; H, 4.91; N, 15.73%. On evaporation, the second fraction yielded 2-(β-*D*-ribofranos-1-yl)-1,2,4-triazolo[4,3-*a*]-pyridin-3(2*H*)-one; 57 mg (4.3%) mp 172—173 °C. UV: λ_{max}^{MeOH} 220, 259(sh), 275, 328 nm. IR (Nujol); 1710 cm^{-1} (C=O). Found: C, 49.70; H, 4.92; N, 15.65%. Calcd for $C_{11}H_{13}N_3O_5$: C, 49.47; H, 4.91; N, 15.73%.

Anhydro-*1-benzyl-3-hydroxy-1,2,4-triazolo[4,3-a]pyridinium Hydroxide* (**6a**). A mixture of **1** (2.08 g), benzyl bromide (1.75 g) and mercury(II) bromide (3.60 g) in nitrobenzene (10 ml) was stirred at 85 °C for 20 h. 2-Propanol was then added. The crystals deposited were collected by filtration to give $HgBr_2$-complex of **6a**: yield 4.878 g (83.5%); mp 116—117 °C. The complex was suspended in methanol (300 ml), and then treated with hydrogen sulfide stream until the starting white crystals disappeared. The resulting precipitate of mercury sulfide was filtered off. The filtrate was evaporated to give a yellow powder, which was crystallized from 2-propanol. Yield 1.79 g (79.5%, based on **1**); yellow needles; mp 163—164 °C. UV; λ_{max}^{MeOH} 236, 285, 348 nm. IR (Nujol); 1660 cm^{-1} (C=O). NMR (DMSO-d_6); δ: 8.21 (m, 1, H-5), 7.5—7.9 (m, 2, H-7 and H-8), 7.02 (m, 1, H-6), 5.41 ppm (s, 2, CH_2-Ph). Found: C, 69.36; H, 4.92; N, 18.59%. Calcd for $C_{13}H_{11}N_3O$: C, 69.31; H, 4.93; N, 18.66%.

General Procedure for the Preparation of **6**. A mixture of **1** (10 mmol), alkyl halide (or alkyl tosylate) (10—11 mmol) and mercury(II) bromide in nitrobenzene (10 ml) was stirred at 60—90 °C under monitoring with TLC until the starting material disappeared, and then evaporated *in vacuo*. The residue was dissolved in methanol. The resulting solution

was neutralized with Dowex-1 (HCO_3^-), and the resin was filtered off. The filtrate was evaporated *in vacuo* to give a yellow powder, which was crystallized from appropriate solvent. Yields and physical constants of the products are given in Table 2.

Reaction of the Ag-salt of 8 with Benzyl Bromide. A suspension of the Ag-salt of **8** (121 mg) in nitrobenzene (1 ml) containing benzyl bromide (81 mg) was stirred at 80 °C for 3 h, and then evaporated *in vacuo* to give sirupy residue which was extracted with chloroform. Chromatographic separation of the extract on a silica gel plate yielded three isolated products: **9a** (31.1 mg), **10a** (20.3 mg) and **6a** (40.5 mg). Physical constants of **9a**: mp 114—115 °C. UV λ_{max}^{MeOH} 222, 260 (sh), 268, 278, 331 nm. IR (Nujol); 1720 cm^{-1} (C=O). NMR (DMSO-d_6); δ: 7.89 (m, 1, H-5), 7.36 (s, 5, C_6H_5), 7.15—7.3 (m, 2, H-7 and H-8), 6.63 (m, 1, H-6), 5.15 ppm (s, 2, $C\underline{H}_2$-Ph). Found: C, 69.22; H, 5.02; N, 18.69%. Calcd for $C_{13}H_{11}N_3O$: C, 69.31; H, 4.93; N, 18.66%. Physical constant of **10a**: oil. UV λ_{max}^{MeOH} 227, 256 (sh), 260, 271, 301 nm. NMR (DMSO-d_6); δ: 8.08 (m, 1, H-5), 7.2—7.7 (m, 2, H-7 and H-8), 7.43 (s, 5, C_6H_5), 6.85 (m, 1, H-6), 5.70 ppm (s, 2, $C\underline{H}_2$-Ph).

Reaction of 8 with Benzyl Bromide. a) A mixture of **8** (1.35 g) and benzyl bromide (1.80 g) in nitrobenzene (10 ml) was stirred at 125 °C for 12 h, and then evaporated *in vacuo*. The residue was dissolved in methanol, neutralized with Dowex-1 (HCO_3^-), and the resin was filtered off. The filtrate was concentrated *in vacuo* giving a crystalline mass, which was recrystallized from 2-propanol to give pure **9a**: yield 1.482 g (66%); mp 114—115 °C. A further crop of **9a** (280 mg, 12.4%) and **6a** were isolated from the mother liquor by column chromatography on silica gel.

b) In the Presence of $HgBr_2$. A mixture of **8** (1.35 g), benzyl bromide (1.80 g) and mercury(II) bromide (3.60 g) in nitrobenzene (10 ml) was stirred at 125 °C for 3 h, then evaporated *in vacuo*, and the residue was dissolved in methanol. The solution was neutralized with Dowex-1 (HCO_3^-), filtered, and the filtrate was evaporated to give a sirupy residue. Chromatographic separation of the residue on silica gel (40 g, 1% methanol in chloroform was used as eluent) yielded two isolated product: **6a** (1.537 g, 68.3%) and **9a** (450 mg, 20%).

1-Benzyl-3-benzyloxy-1,2,4-triazolo[4,3-a]pyridinium Bromide (11). A solution of **10a** (678 mg), benzyl bromide (513 mg) and mercury(II) bromide (1.08 g) in nitrobenzene (3 ml) was stirred at room temperature for 20 h, and then poured into a large amount of ethanol. The precipitate formed was crystallized from methanol to give $HgBr_2$-complex of **11**: yield 1.175 g (51.7%); mp 78—80 °C. UV λ_{max}^{MeOH} 218, 260 (sh), 299 nm. NMR (DMSO-d_6); δ: 7.4—8.8 (m, 14, pyridine and phenyl ring H), 5.83 and 5.74 ppm (two s, 4, $C\underline{H}_2$-Ph). Found: C, 31.75; H, 2.40; N, 5.55; Br, 10.56%. Calcd for $C_{20}H_{18}N_3OBr \cdot HgBr_2$: C, 31.90; H, 2.70; N, 5.49; Br, 10.72%.

1,2-Di-benzyl-3-oxo-1,2,4-triazolo[4,3-a]pyridinium Bromide (12). A solution of **6a** (1.13 g), benzyl bromide (90 mg) and mercury(II) bromide (1.80 g) in nitrobenzene (5 ml) was stirred at 125 °C for 3 h. Methanol was added to the reaction solution giving a crystalline solid. On filtration, the pure $HgBr_2$-complex of **12** was obtained: yield 1.39 g (36.8%); mp 157—158 °C. Found: C, 41.77; H, 3.31; N, 7.16; Br, 14.08%. Calcd for $C_{20}H_{18}N_3OBr \cdot 1/2HgBr_2$: C, 41.73; H, 3.49; N, 7.77; Br, 13.82%.

The complex (577 mg) was dissolved in methanol. Hydrogen sulfide was bubbled through the solution until the precipitation of mercury sulfide was complete. The precipitate was then filtered off. Evaporation of the filtrate gave white powder which was crystallized from ethanol–ether to give pure **12**: yield 376 mg (95%); mp 157—158 °C. UV λ_{max}^{MeOH} 212, 230 (sh), 260 (sh), 328 nm. IR (Nujol); 1770 cm^{-1} (C=O). NMR (DMSO-d_6); δ: 8.79 (m, 1, H-5), 8.2—8.5 (m, 2, H-7 and H-8), 7.56 (m, 1, H-6), 5.85 and 5.41 ppm (two s, 4, $C\underline{H}_2$-Ph). Found: C, 60.41; H, 4.60; N, 10.55; Br, 20.05%. Calcd for $C_{20}H_{18}N_3OBr$: C, 61.60; H, 4.58; N, 10.60; Br, 20.16%.

Benzyl Migration. A solution of the starting material (**10a** or **6a**, 10 mmol) in nitrobenzene (10 ml) was heated with (or without) a catalyst ($HgBr_2$ or benzyl bromide) in the desired temperature range. The reaction mixture was worked up in the manner described above.

The author thank Dr. Y. Baba of these Laboratories for helpful discussions.

Stereoselective One-pot Dialkylation of *gem*-Dihalocyclopropanes by Means of Dialkylcopperlithiums

Katuzi KITATANI, Tamejiro HIYAMA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received January, 17, 1977)

The transformation of *gem*-dihalocyclopropanes (**1**) into 1-alkyl-1-butylcyclopropanes (**2** and **3**) is established by successive treatment with dibutylcopperlithium and several electrophiles. This sequence is found to be stereochemically controllable and is successfully applied to *dl*-sirenin synthesis. In contrast to the reaction of dibutylcopperlithium, dimethyl- and divinylcopperlithiums convert 1,1-dibromo-2-phenylcyclopropane (**1a**) into 1-bromo-1-methyl- and 1-bromo-1-vinyl-2-phenylcyclopropanes (**15a**, **16a** and **15b**, **16b**) respectively.

It is remarkable that a class of natural products commonly possess a substituted cyclopropane ring[1] in spite of the large strain energy therein involved. One of the most facile routes to the smallest carbocyclic ring is dihalocyclopropanation of olefins[2] by phase-transfer technique, but unfortunately efficient methodology has never been recorded for replacing each halogen atom of the dihalocarbene-adducts with two different alkyl groups successively. Although monoalkylation of *gem*-dihalocyclopropanes proceeds effectively and stereoselectively,[3] the second alkylation of the resulting α-alkylcyclopropyl halides has turned out extremely arduous. Remarkably, it is known that the reaction of *gem*-dihalides with dimethylcopperlithium results in *gem*-dimethylation.[4,5] Being interested in this particular observation we have carefully investigated the interaction of *gem*-dihalocyclopropanes with dibutylcopperlithium to find that α-butylcyclopropylcopper compounds thus initially produced react with methyl iodide giving stereoselectively the desired dialkylated products which have the methyl group always on the more hindered (*cis* or *endo*) site. On the basis of this finding a novel approach to sirenin synthesis has been exploited.[6]

Reaction of gem-*Dihalocyclopropanes with Dibutylcopperlithium.* Upon treatment with 5 mol of dibutylcopperlithium the dibromocyclopropane **1a**, for example, produced a stereoisomeric mixture of organometallic species, which after workup with excess methyl

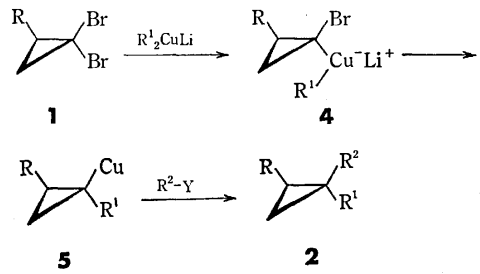
iodide afforded a 4: 1 mixture of **2a** and **3a** in a quantitative yield. Various *gem*-dihalocyclopropanes were allowed to react first with some dibutylcopperlithiums and then with a variety of electrophiles including methyl iodide. The results are summarized in Table 1. Preliminary experiments revealed, however, that the yields were very much influenced by the reaction conditions. Among solvent systems examined (hexane, hexane–ether, ether, tetrahydrofuran (THF), THF–hexamethylphosphoric triamide (HMPA)) hexane–ether gave the best results. The strict absence of unchanged butyllithium should be assured and therefore a slight excess of cuprous iodide was used for the preparation of the cuprate. Finally, the reaction temperature should be controlled carefully: the temperature during the reaction of the cuprate with dihalocyclopropanes being adjusted at −40 to −78 °C and the second alkylation at −20 °C.

Of importance in the alkylation is the stereochemical consequence. The reaction of **1a** under the condition cited above resulted in the preferred formation of *cis*-methyl isomer (entry 1). The ratio was better at low temperatures, while the use of more polar solvent systems (THF or THF–HMPA) or the presence of *n*-Bu_3P as a ligand gave no improvement. Reaction of **1a** with di-*s*-butylcopperlithium or di-*t*-butylcopperlithium followed by methylation afforded predominantly *cis*-methylated **2b** and **2c** albeit in lower yields (entry 3, 4). Noteworthy is the reaction of 7,7-dibromonorcarane (**1e**) and its derivative **1f**, in which *endo*-methyl isomers (**2j** and **2k**) were formed exclusively (entry 12 and 13).



Scheme 1.

These stereochemical results are explained by Scheme 1 which involves halogen-copper exchange *at the less hindered halogen*, the consecutive S_N2 type alkyl migration (*inversion on the cyclopropane carbon*), and the second alkylation by R^2–Y with *retention of configuration*. The steric hindrance of large substituent(s) and/or the bulkiness of the copper reagent would strongly direct the dialkylcuprate to attack the less hindered halogen.

The configurational stability of α-alkylcyclopropylcopper reagent of type 5 was verified as follows. At −78 °C the dibromocyclopropane **1a** was treated with 5 mol of dibutylcopperlithium which had been prepared at −48 °C, and then the reaction mixture was gradually warmed up finally to −10 °C in *ca.* 3 h. Aliquots of the sample at various temperatures were withdrawn, quenched with methanol and the products, 1-butyl-2-phenylcyclopropanes (**2f** and **3f**), were analyzed by GLC to give a nearly invariable ratio of 4: 1 of **2f**/**3f** throughout the period of experiment. This indicates that the species **5** is configurationally stable at the temperature range examined.

Application to dl-*Sirenin Synthesis.*[7] With these observations in hand we extended the reaction to the preparation of a key intermediate of *dl*-sesquicarene and *dl*-sirenin syntheses. As attempted preparation of the dibromocarbene adduct of cyclohexenone ethylene acetal failed to success, we were compelled to start with the dichlorocarbene adduct **1f** which was obtained by the phase-transfer technique.[2] Treatment of **1f** with bis-(4-methyl-3-pentenyl)copperlithium and then with excess methyl iodide, followed by deacetalization, afforded **6** in 44% yield. The GLC and PMR analyses showed no contamination of the stereoisomer. The configuration was established by the methoxycarbonyla-

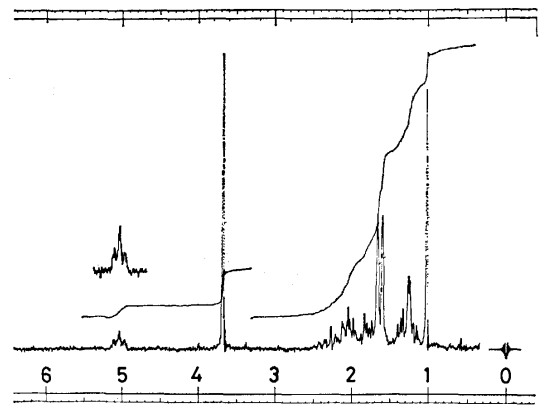

Fig. 1. The PMR spectrum of the keto ester **7** (CCl_4, 100 MHz).

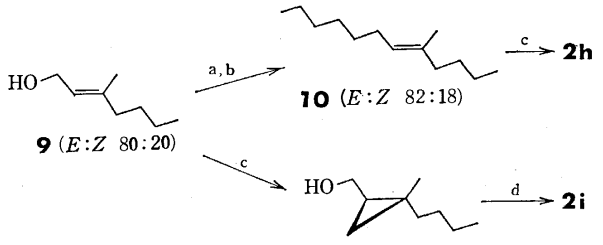
tion of **6**. The methyl chemical shift (δ 1.02) of the product **7** (Fig. 1) was strictly the same as that of the 7-*endo*-methyl keto ester and clearly different from that of 7-*exo*-methyl isomer (δ 1.14).[7a] Further transformation of **7** to *dl*-sesquicarene (**8a**) and *dl*-sirenin (**8b**) has been already established.[7a]

Stereochemistry of Dialkylated Cyclopropanes. The configuration of each phenyl substituted cyclopropane (**2a—g**, **3a—g**) was identified by the comparison of PMR spectra. In general, the methyl signal *cis* to phenyl group appeared at higher field than that of *trans* isomer (see Experimental).[3] For example, the methyl signal of **2a** appeared at δ 0.73, whereas that of its stereoisomer **3a** appeared at δ 1.18. Similarly, *cis*-acetylated cyclopropane **2e** showed acetyl signal at δ 1.61 and its *trans* isomer **3e** at δ 2.12. The peak shape analysis of butyl signal also afforded a basis for the stereochemical determination of **2d** and **2f**. The α-methylene proton peak of butyl group *cis* to phenyl group appeared at slightly higher field than that of the *trans* isomer due to the shielding effect of the benzene ring. The stereochemical assignment is also possible from the fact that proton(s) *cis* to butyl group on the three membered ring generally appeared at higher field than the *trans* proton(s) probably due to the deshielding effect by σ bond(s).[8] This criterion was applied to the determination of the iodinated cyclopropanes: benzylic proton of **2g** at δ 2.16 and that of **3g** at δ 2.78.



a: PBr_3; b: *n*-AmMgBr; c:CH_2I_2/Zn–Cu; d: NaH/$PhCH_2Cl$.

Scheme 2.

Stereochemistry of **2h** and **2i** was unambiguously determined by the independent syntheses as shown in Scheme 2. An allyl alcohol **9**[9] was converted into a trisubstituted olefin **10**, which was subjected to the Simmons-Smith reaction[10] to give **2h** and **3h** (84: 16). The authentic samples of **2i** and **3i** were obtained by cyclopropanation on **9** and the successive benzylation. Scheme 3 shows the syntheses of the authentic specimens of **2j** and **2k**. The route involves a well-established diazoketone cyclization.[11] Copper catalyzed thermal decomposition of **14** afforded **2k** and its stereoisomer (71: 29). The Wolff-Kishner reduction[12] of **2k** gave the hydrocarbon **2j**.

Scheme 3.

Further Extention and Possible Reaction Mcehanism. In sharp contrast to the above reaction of dibutylcuprates, dimethylcopperlithium reacted with **1a** in THF at —78 °C to afford dimethylated product **17a** (48%). Remarkably, the same procedure at —38 °C in ether gave a mixture (43: 57) of mono-methylated products **15a** and **16a** (49% yield) along with **17a** (17%). More drastic change of the reaction path was achieved only by temperature control in the reaction of divinylcopperlithium. Whereas at —48 °C in ether divinylcyclopropane **17b** was obtained in 47% yield, the reaction at —78 °C afforded 1-bromo-1-vinylcyclopropanes **15b** and **16b** (26: 74) in 80% yield. It should be noted that the reaction of **1a** with dibutylcopperlithium gave no **17c**.

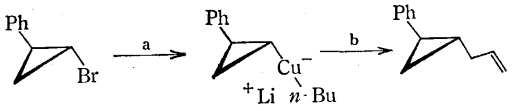
R=Me or vinyl **18** **15** or **16**

Scheme 4.

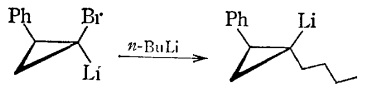
We do not believe that all these three cuprates react with **1a** by a single mechanism. The initial step in the reaction of dibutylcopperlithium shown in Scheme 1 is copper-halogen exchange (two-electron transfer process)[5a] to afford a mixed cuprate **4** which easily rearranges to an α-alkylated cyclopropylcopper **5** under S_N2 type alkyl migration. Another possibility is shown in Scheme 4 in which a trivalent copper species is assumed in the initial step. Reductive elimination of this unstable transient affords an α-alkylated cyclopro pyl bromide. The reaction of dimethyl- ;or divinylcopperlithium should be explained by this scheme, which is quite similar to the one proposed for the coupling of dialkylcuprates with alkyl halides and tosylates.[13]

The Scheme 1 is supported by the related observations as follows. When *trans*-1-bromo-2-phenylcyclopropane (**19**) was treated with 4 mol of dibutylcopperlithium in THF and successively with allyl bromide, *trans*-1-allyl-2-phenylcyclopropane (**20**) was obtained in 97% yield. No butylated product was detected and, therefore, the copper intermediate is probably the one as shown below. It should be noted that **19** was more susceptible to the reaction than its *cis* isomer.[14]



19 **20**

a: *n*-Bu_2CuLi/THF; b: CH_2=$CHCH_2Br$.



The second step in Scheme 1 is the intramolecular S_N2 type alkyl migration which is exemplified by the following experiment. A solution of **1a** in THF was added to a solution of butyllithium (3.3 mol) in THF at −95 °C. Aqueous workup afforded *trans*-1-butyl-2-phenylcyclopropane.[15] Introduction of butyl group is attributed to nucleophilic attack of butyl anion as illustrated below.[16]

Experimental

All the temperatures are uncorrected. The IR spectra were obtained on a Shimadzu spectrometer 27-G, MS on a Hitachi RMU-6L, and PMR on JEOL JNM-PMX 60, Varian EM-360, or Varian HA-100D spectrometers. Butyllithium and *t*-butyllithium were purchased from Aldrich Co. Ltd. Vinyllithium in ether,[17] methyllithium in ether,[18] and *s*-butyllithium in pentane[19] were prepared according to the literature. Commercial cuprous iodide was purified according to the literature.[20] Ether and hexane were distilled and dried on sodium metal. THF was dried on benzophenone ketyl and distilled. All the reactions were performed under a nitrogen atmosphere. The cold bath of −48 °C was prepared by mixing Dry Ice and *m*-xylene.

gem-*Dihalocyclopropanes.* These were prepared by the reaction of the corresponding olefins with bromoform/*t*-BuOK. *gem*-Dichlorocyclopropanes were prepared by the phase transfer method. A typical procedure is illustrated in the synthesis of **1f**.

*7,7-Dichloronorcaran-2-one Ethylene Acetal (**1f**).* A solution of cyclohexenone ethylene acetal (11.2 g, 80 mmol) in benzene (10 ml) was mixed with 120 ml of 50% aqueous sodium hydroxide. The mixture was warmed to 40 °C and under vigorous stirring 80 ml of chloroform was added during 4 h. After the addition was completed, the reaction mixture was stirred at 40 °C for 2 h. Extraction with hexane and subsequent fractionation through a 15 cm Vigreux column gave **1f** (88—90 °C/1 Torr, 11.6 g, 71% based on the consumed starting olefin). IR (neat): 1107, 1020, 948, 784 cm^{-1}; MS: *m/e* (%), 226 (M^++4, 0.5), 224 (M^+ +2, 2), 222 (M^+, 3.4), 187 (32), 99 (100), 86 (37); PMR (CCl_4): δ 1.0—2.3 (m, 8H), 3.7—4.2 (m, 4H). Found: C, 48.7; H, 5.7%. Calcd for $C_9H_{12}Cl_2O_2$: C, 48.5; H, 5.4%.

*1-Butyl-1-methyl-2-phenylcyclopropane (**2a** and **3a**).* Dibutylcopperlithium was prepared by the treatment of butyllithium (5.7 ml of 1.75 M hexane solution) with cuprous iodide (0.96 g, 5.0 mmol) suspended in ether (10 ml) at −48 °C. A solution of **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was added dropwise to this solution. The reaction mixture was gradually warmed up to −20 °C in 1 h, treated with excess methyl iodide (1 ml), and further warmed to room temperature during 15 h. Workup followed by short path distillation at 82—92 °C/26 Torr gave a mixture of **2a** and **3a** (0.19 g, quantitative yield). Each isomer was separated by preparative GLC (20% Silicone HV grease on Celite 545, 1 m, 160 °C, He, 1.2 kg/cm^2).

r-*1-Butyl-1-methyl*-t-*2-phenylcyclopropane (**2a**)*: R_t 25 min; bp 84—89 °C (bath temp)/2 Torr; IR (neat): 3070, 3040, 1605, 1580, 1498, 1450, 1385, 1070, 1030, 780, 735, 700 cm^{-1}; MS: *m/e* (%), 188 (M^+, 16), 173 (2), 131 (100), 117 (15), 104 (32), 91 (34); PMR (CCl_4): δ 0.6—1.7 (m, 11H), 0.73 (s, 3H, Me), 1.83 (t, J=7 Hz, 1H, PhCH), 6.8—7.4 (m, 5H, Ph). Found: C, 89.3; H, 10.9%. Calcd for $C_{14}H_{20}$: C, 89.3; H, 10.7%.

r-*1-Butyl-1-methyl*-c-*2-phenylcyclopropane (**3a**)*: R_t 20 min; bp 85—95 °C (bath temp)/1 Torr; IR (neat): 3070, 3040, 1605, 1497, 1460, 1380, 1025, 777, 699 cm^{-1}: MS: *m/e* (%), 188 (M^+, 14), 173 (2), 131 (100), 117 (18), 104 (39), 91 (37); PMR (CCl_4): δ 0.5—1.6 (m, 11H), 1.18 (s, 3H, Me), 1.83 (dd, J=6, 8 Hz, 1H, PhC*H*), 6.9—7.4 (m, 5H, Ph). Found: C, 89.5; H, 10.7%. Calcd for $C_{14}H_{20}$: C, 89.3; H, 10.7%.

r-*1*-s-*Butyl-1-methyl*-t-*2-phenylcyclopropane (**2b**).* A cooled solution of *s*-butyllithium (16 ml of 0.62 M pentane solution, 10 mmol) was added to a suspension of cuprous iodide (0.95 g, 5.0 mmol) in ether (10 ml) at −78 °C. The suspension immediately turned to black, and after 5 min a solution of **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was added. The reaction mixture was gradually warmed to −20 °C in 3 h, treated with methyl iodide (1 ml) and further warmed to room temp during the period of 5 h. Aqueous workup and subsequent preparative TLC (silica gel, hexane, R_f 0.7—0.8) afforded 83 mg of **2b** (93% pure on GLC assay). Analytical sample was obtained by preparative GLC. Bp 84—92 °C (bath temp)/23 Torr; IR (neat): 3060, 3040, 1603, 1575, 1498, 1450, 1370, 1075, 1020, 775, 733, 700 cm^{-1}: MS: *m/e* (%), 188 (M^+, 4), 131 (100), 117 (11), 104 (45); PMR (CCl_4): δ 0.3—1.7 (m, 11H), 0.61 (s, 3H, Me), 1.83 (dd, J=6, 8 Hz, 1H, PhC*H*), 6.7—7.3 (m, 5H, Ph). Found: C, 89.0; H, 10.6%. Calcd for $C_{14}H_{20}$: C, 89.3; H, 10.7%. GLC separation of minor components gave **3b** which was identified by MS: *m/e* 188 (M^+).

r-*1*-t-*Butyl-1-methyl*-t-*2-phenylcyclopropane (**2c**).* To di-*t*-butylcopperlithium, prepared from *t*-butyllithium (3.1 ml of 1.6 M pentane solution, 5.0 mmol) and cuprous iodide (0.48 g, 2.5 mmol) in ether (5 ml) at −55 °C, **1a** (0.14 g, 0.5 mmol) in ether (1 ml) was added, and the reaction mixture was gradually warmed up to −20 °C in 3 h, then treated with methyl iodide (1 ml) and further warmed up to room temp during the period of 15 h. Workup followed by preparative TLC (silica gel, hexane, R_f 0.7—0.8) gave **2c** (19 mg, 20% yield). Any isomer was not detected by GLC or PMR assay. Bp 95—100 °C (bath temp)/24 Torr; IR (neat): 3090, 3050, 1605, 1580, 1500, 1383, 1363, 1172, 1080, 1028, 773, 734, 699 cm^{-1}; MS: *m/e* (%), 188 (M^+, 3), 131 (78), 84 (100), 69 (73), 57 (46), 41 (38); PMR (CCl_4): δ 0.66 (s, 3H, Me), 0.7—1.3 (m, 2H), 0.93 (s, 9H, *t*-Bu), 2.10 (dd, J=5, 9 Hz, 1H, PhC*H*), 6.8—7.3 (m, 5H, Ph). Found: C, 89.6; H, 11.0%. Calcd for $C_{14}H_{20}$: C, 89.3; H, 10.7%.

*1-Butyl-1-ethyl-2-phenylcyclopropanes (**2d** and **3d**).* A solution of **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was added to *n*-Bu_2CuLi (5.0 mmol) prepared at −48 °C. Stirring was continued for 1 h and ethyl iodide (1 ml) was added. Then the mixture was gradually warmed to room temp during 15 h. Workup and preparative TLC (silica gel, hexane, R_f 0.8—0.9) afforded an isomeric mixture of **2d** and **3d** (0.14 g, 65%). Each isomer was separated by GLC (Silicone HV grease, 150 °C He, 1.7 kg/cm^2).

r-*1-Butyl-1-ethyl*-t-*2-phenylcyclopropane (**2d**)*: R_f 16 min; bp 87—95 °C (bath temp)/27 Torr; IR (neat): 3060; 3040, 1605, 1580, 1497, 1453, 1378, 1070, 1029, 774, 730, 699 cm^{-1}; MS: *m/e* (%), 202 (M^+, 18), 173 (28), 145 (100), 117 (78), 104 (52), 91 (76); PMR (CCl_4): δ 0.5—1.6 (m, 16H), 1.87 (dd, J=6, 8 Hz, 1H, PhC*H*), 6.9—7.4 (m, 5H, Ph). Found: C, 88.8; H, 10.9%. Calcd for $C_{15}H_{22}$: C, 89.0; H, 11.0%.

r-*1-Butyl-1-ethyl*-c-*2-phenylcyclopropane (**3d**)*: R_t 13 min; bp 82—89 °C (bath temp)/20 Torr; IR (neat): 3070, 3040, 1605, 1580, 1499, 1450, 1380, 1070, 1029, 778, 730 cm^{-1}; MS: *m/e* (%), 202 (M^+, 19), 173 (28), 145 (100), 117 (76),

104 (57), 91 (61); PMR (CCl_4): δ 0.5—1.6 (m, 16H), 1.82 (dd, J=6, 8 Hz, 1H, PhCH), 6.8—7.4 (m, 5H, Ph). Found: C, 88.8; H, 11.0%. Calcd for $C_{15}H_{22}$: C, 89.0; H, 11.0%.

*1-Acetyl-1-butyl-2-phenylcyclopropanes (**2e** and **3e**).* A solution of **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C. The reaction mixture was warmed to −20 °C during 1 h and then cooled again to −78 °C. Acetyl bromide (1.0 ml) was added and the reaction mixture was gradually warmed to room temp during 15 h. Workup and preparative TLC (silica gel, hexane–ether (4: 1) gave **2e** and **3e**.

r-*1-Acetyl-1-butyl*-c-*2-phenylcyclopropane (**2e**)*: R_f 0.4—0.5; bp 70—75 °C (bath temp)/0.07 Torr; IR (neat): 1690, 1600, 1580, 1498, 1450, 1355, 1196, 1134, 1025, 958, 768, 730, 695 cm^{-1}: MS: *m/e* (%), 216 (M^+, 18), 173 (26), 129 (17), 117 (19), 91 (20), 43 (100); PMR (CCl_4): δ 0.7—2.5 (m, 12H), 1.61 (s, 3H, Ac), 6.9—7.4 (m, 5H, Ph). Found: C, 83.2; H, 9.4%. Calcd for $C_{15}H_{20}O$: C, 83.3; H, 9.3%.

r-*1-Acetyl-1-butyl*-t-*2-phenylcyclopropane (**3e**)*: R_f 0.3—0.4; bp 66—70 °C (bath temp)/0.06 Torr; IR (neat): 1688, 1605, 1580, 1500, 1450, 1380, 1356, 1200, 1142, 778, 732, 700 cm^{-1}; MS: *m/e* (%), 216 (M^+, 16), 173 (24), 129 (13), 117 (27), 91 (19), 43 (100); PMR (CCl_4): δ 0.5—1.9 (m, 11H), 2.12 (s, 3H, Ac), 2.57 (dd, J=7, 9 Hz, 1H, PhCH), 6.9—7.3 (m, 5H, Ph). Found: C, 83.0; H, 9.5%. Calcd for $C_{15}H_{20}O$: C 83.3; H, 9.3%.

*1-Butyl-2-phenylcyclopropanes (**2f** and **3f**).* A solution of **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C. The reaction mixture was warmed up tp −20 °C during 1 h, and ethanol (2 ml) was added. Workup and subsequent preparative TLC purification gave a mixture of **2f** and **3f** (0.17 g, 96% yield). Each isomer was separated by preparative GLC (Silicone HV grease, 150 °C, 0.7 kg/cm^2).

trans-*1-Butyl-2-phenylcyclopropane (**2f**)*: R_t 12 min; bp 82—83 °C/21 Torr; IR (neat): 1605, 1500, 1465, 1084, 1020, 750, 695 cm^{-1}; MS: *m/e* (%), 174 (M^+, 22), 117 (77), 104 (100), 91 (33); PMR (CCl_4): δ 0.5—1.7 (m, 13H), 6.7—7.3 (m, 5H, Ph). Found: C, 89.5; H, 10.3%. Calcd for $C_{13}H_{18}$: C, 89.6; H, 10.4%.

cis-*1-Butyl-2-phenylcyclopropane (**3f**)*: R_t 11 min; bp 70—74 °C (bath temp)/4 Torr; IR (neat): 1600, 1495, 1025, 770, 723, 700 cm^{-1}; MS: *m/e* (%), 174 (M^+, 17), 117 (72), 104 (100), 91 (32); PMR (CCl_4) δ 0.4—1.7 (m, 12H), 1.7—2.3 (m, 1H), 7.0—7.2 (m, 5H, Ph). Found: C, 89.5; H, 10.7%. Calcd for $C_{13}H_{18}$: C, 89.6; H, 10.4%.

*Reaction of 1,1-Dichloro-2-phenylcyclopropane (**1b**) with Dibutylcopperlithium.* A solution of **1b** (0.19 g, 1.0 mmol) in ether (1 ml) was added to a solution of *n*-Bu_2CuLi (5.0 mmol) prepared at −48 °C, and the reaction mixture was warmed to 0 °C in 3.5 h, treated with methyl iodide (1 ml), and allowed to warm to room temp (15 h). Workup and preparative TLC afforded a mixture of **2a** and **3a** (97 mg, 71% yield) besides a recovered starting material (49 mg).

*1-Iodo-1-butyl-2-phenylcyclopropane (**2g** and **3g**).* A solution of **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C. The reaction mixture was warmed to −30 °C in 1 h and then treated with iodine (2.5 g, 10 mmol) dissolved in THF (4 ml), and further warmed up to room temp. Usual workup involving reduction of the excess iodine with aq. sodium thiosulfate, followed by preparative TLC (silica gel, hexane), gave **2g** (R_f 0.5—0.6, 0.16 g, 52%) and **3g** (R_f 0.6—0.7, 81 mg, 27%) along with **17c** (R_f 0.7—0.8, 22 mg, 10%).

r-*1-Iodo-1-butyl*-c-*2-phenylcyclopropane (**2g**)*: Bp 123—128 °C (bath temp)/3 Torr; IR (neat): 3090, 3060, 3040, 1602, 1580, 1497, 1450, 1370, 1150, 1022, 780, 756, 722, 690 cm^{-1}; MS: *m/e* (%), 300 (M^+, 2), 217 (5), 173 (38), 131 (22), 117 (100) 91 (68); PMR (CCl_4): δ 0.6—2.2 (m, 12H), 6.8—7.4 (m, 5H, Ph). Found: C, 52.3; H, 5.8%. Calcd for $C_{13}H_{17}I$: C, 52.0; H, 5.7%.

r-*1-Iodo-1-butyl*-t-*2-phenylcyclopropane (**3g**)*: Bp 118—124 °C (bath temp)/3 Torr; IR (neat): 3090, 3070, 3040, 1600, 1580, 1499, 1450, 1370, 1195, 1142, 770, 725, 695 cm^{-1}; MS: *m/e* (%), 300 (M^+, 2), 217 (1), 173 (37), 131 (23), 117 (100), 91 (68); PMR (CCl_4): δ 0.5—1.8 (m, 11H), 2.78 (dd, J=7, 10 Hz, 1H, PhC*H*), 7.0—7.4 (m, 5H, Ph). Found: C, 52.3; H, 5.8%. Calcd for $C_{13}H_{17}I$: C, 52.0; H, 5.7%.

*1,1-Dibutyl-2-phenylcyclopropane (**17c**)*: Bp 80—86 °C (bath temp)/2 Torr; IR (neat): 3040, 1600, 1495, 1460, 1027, 780, 727, 700 cm^{-1}; MS: *m/e* (%), 230, (M^+, 17), 173 (66), 117 (100), 104 (55), 91 (68); PMR (CCl_4): δ 0.5—1.7 (m, 20H), 1.83 (dd, J=7, 10 Hz, 1H, PhC*H*), 6.8—7.3 (m, 5H, Ph). Found: C, 88.4; H, 11.4%. Calcd for $C_{17}H_{26}$: C, 88.6; H, 11.4%.

*Air Oxidation of the Cyclopropylcopper Reagent Prepared from **1a** and Dibutylcopperlithium.* A solution of **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C. After 1 h dry air (passed through $CaCl_2$ and silica gel) was introduced into the reaction mixture which was subsequently allowed to warm to 0 °C in 3 h. Workup and subsequent TLC purification (silica gel, hexane) gave **17c** (R_f 0.7—0.8, 80 mg, 34%), **3g** (R_f 0.6—0.7, 38 mg, 12%), and **2g** (R_f 0.5—0.6, 54 mg, 18%).

*1-Butyl-1-methyl-2-hexylcyclopropane (**2h** and **3h**).* Dibromocyclopropane **1c** (0.30 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C to −20 °C for 1 h. Addition of methyl iodide (1 ml) at −20 °C, followed by usual workup and preparative TLC (silica gel, hexane, R_f 0.8—0.9), gave a mixture of **2h** and **3h** (0.10 g, 50% yield). Each product was separated by GLC (Silicone HV grease, 150 °C, 0.8 kg/cm^2).

r-*1-Butyl-1-methyl*-t-*2-hexylcyclopropane (**2h**)*: R_t 58 min; bp 75—80 °C (bath temp)/4 Torr; IR (neat): 3050, 2930 2860, 1465, 1375, 1020, 730 cm^{-1}; MS: *m/e* (%), 196 (M^+, 4) 154 (6), 139 (11), 126 (4), 111 (8), 97 (24), 83 (55), 69 (98), 55 (100); PMR (CCl_4): δ −0.3—0.5 (m, 3H), 0.97 (s, 3H, Me), 0.7—1.9 (m, 22H). Found: C, 85.8; H, 14.5%. Calcd for $C_{14}H_{28}$: C, 85.6; H, 14.4%.

r-*1-Butyl-1-methyl*-c-*2-hexylcyclopropane (**3h**)*: R_t 38 min; bp 60—65 °C (bath temp)/3 Torr; IR (neat): 3050, 2930, 1460, 1370, 1255, 1015 cm^{-1}; MS: *m/e* (%), 196 (M^+, 3), 154 (5), 139 (8), 126 (3), 111 (11), 97 (17), 83 (41), 69 (79), 55 (78), 44 (100); PMR (CCl_4): δ −0.3—0.6 (m, 3H), 0.99 (s, 3H, Me), 0.6—1.7 (m, 22H). Found: C, 85.6; H, 14.4%. Calcd for $C_{14}H_{28}$: C, 85.6; H, 14.4%.

*1-Butyl-1-methyl-2-benzyloxymethylcyclopropanes (**2i** and **3i**).* A solution of **1d** (0.32 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C. The reaction mixture was gradually warmed up to −20 °C during 1 h and treated with methyl iodide (1 ml), and then further warmed to room temp in 15 h. Workup and preparative TLC (silica gel, hexane–ether 1: 1) gave a mixture of **2i** and **3i** (0.12 g, 50% yield). Each product was separated by preparative GLC (Apiezon L (30%) and KOH (10%) on Chromosorb W, 2 m, 150 °C, 1.0 kg/cm^2 of He gas).

r-*1-Butyl-1-methyl*-t-*2-benzyloxymethylcyclopropane (**2i**)*: R_t 35 min; bp 73—80 °C (bath temp)/0.06 Torr; IR (neat): 1492, 1450, 1374, 1254, 1090, 1025, 790, 734, 700 cm^{-1}; MS: *m/e* (%), 232 (M^+, 0.2), 217 (0.1), 191 (2), 188 (1), 175 (2), 91 (100); PMR (CCl_4): δ 0.3—0.6 (m, 1H), 0.7—1.7 (m, 11H), 1.03 (s, 3H, Me), 3.17 (dd, J=8, 10 Hz, 1H, OCH_aH_b), 3.53 (dd, J=6, 10 Hz, 1H, OCH_aH_b), 4.43 (s, 2H, $PhCH_2$), 7.2—7.3 (m, 5H, Ph). Found: C, 82.9; H, 10.6%. Calcd

for $C_{16}H_{24}O$: C, 82.7; H, 10.4%.

r-*1-Butyl-1-methyl*-c-*2-benzyloxymethylcyclopropane (3i)*: R_t 30 min; bp 75—83 °C (bath temp)/0.06 Torr; IR (neat): 1494, 1451, 1375, 1255, 1090, 1027, 805, 736, 700 cm^{-1}; MS: *m/e* (%), 232 (M^+, 0.05), 217 (0.1), 191 (0.5), 188 (0.5), 175 (0.5), 91 (100); PMR (CCl_4): δ 0.3—0.5 (m, 1H), 0.7—1.7 (m, 11H), 1.03 (s, 3H, Me), 3.22 (dd, J=8, 10 Hz, 1H, OCH_aH_b), 3.50 (dd, J=6, 10 Hz, 1H, OCH_aH_b), 4.41 (s, 2H, $PhCH_2$), 7.2—7.4 (m, 5H, Ph). Found: C, 82.6; H, 10.5%. Calcd for $C_{16}H_{24}O$: C, 82.7; H, 10.4%.

7-exo-*Butyl*-*7*-endo-*methylnorcarane (2j)*. A solution of 7,7-dibromonorcarane (**1e**) (0.26 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C. After 1 h methyl iodide (1.0 ml) was added and the reaction mixture was gradually warmed up to room temp in 3 h. Workup and subsequent preparative TLC (silica gel, hexane, R_f 0.8—0.9) afforded **2j** (0.14 g, 82% yield). Bp 100—106 °C (bath temp)/15 Torr; IR (neat): 3000, 1465, 1449, 1380, 785 cm^{-1}; MS: *m/e* (%), 166 (M^+, 5), 152 (3), 151 (3), 123 (9), 110 (54), 109 (100), 95 (26); PMR (CCl_4): δ 0.4—0.6 (m, 2H), 0.93 (s, 3H, Me), 0.6—2.6 (m, 17H). Found: C, 86.6; H, 13.6%. Calcd for $C_{12}H_{22}$: C, 86.7; H, 13.3%.

exo-*7-Butyl*-endo-*7-methylnorcaran-2-one (2k)*. Dichlorocarbene adduct **1f** (0.22 g, 1.0 mmol) in ether (1 ml) was treated with *n*-Bu_2CuLi (5.0 mmol) in ether (10 ml) at −48 °C to 0 °C for 3 h and at 0 °C for 1 h. After the addition of methyl iodide (1 ml) the reaction mixture was gradually warmed to room temp (3 h). Workup and concentration *in vacuo* afforded an oil which was subsequently treated with a mixture of THF (1 ml) and 1.5 M aq H_2SO_4 at room temp for 1 h. Workup and subsequent TLC (silica gel, hexane–ether 3: 1, R_f 0.3—0.4) afforded **2k** (0.14 g, 78% yield). Bp 90—97 °C (bath temp)/15 Torr; IR (neat): 1690, 1470, 1320, 1240, 1180, 1110, 890 cm^{-1}; MS: *m/e* (%), 180 (M^+, 8), 124 (42), 95 (100), 82 (84); PMR (CCl_4): δ 0.6—2.6 (m, 17H), 1.09 (s, 3H, Me). Found: C, 80.0; H, 11.3%. Calcd for $C_{12}H_{20}O$: C, 79.9; H, 11.2%.

exo-*7-(4-Methyl-3-pentenyl)*-endo-*7-methylnorcaran-2-one (6)*. An ethereal solution of 4-methyl-3-pentenyllithium (14 ml of 0.86 M solution, 12 mmol) was added to cuprous iodide (1.1 g, 6.0 mmol) suspended in a mixture of hexane (15 ml) and ether (5 ml) at −78 °C. During the period of 40 min the reaction mixture was warmed to −70 °C and then a solution of **1f** (0.27 g, 1.2 mmol) in ether (1 ml) was added to the resulting dark gray slurry. The reaction mixture was gradually warmed to −20 °C in 1 h, treated with methyl iodide (2 ml) and allowed to warm to room temp (16 h). Usual workup gave an oil which was subsequently treated with a mixture of THF (1 ml) and 1.5 M aq H_2SO_4 (1 ml) at room temp for 40 min. Workup and preparative TLC purification (silica gel, CH_2Cl_2, R_f 0.3—0.4) gave **6** (0.11 g, 44%). Bp 95—105 °C (bath temp)/0.1 Torr; IR (neat): 1685, 1445, 1380, 1349, 1330, 1245, 895, 790 cm^{-1}; MS: *m/e* (%), 206 (M^+, 5), 137 (22), 69 (87), 41 (100); PMR (CCl_4): δ 1.115 (s, 3H, Me), 1.59 (s, 3H, Me), 1.67 (s, 3H, Me), 1.2—2.3 (m, 12H), 4.9—5.2 (m, 1H). The product **6** was converted into 3-carbomethoxy-*exo*-7-(4-methyl-3-pentenyl)-*endo*-7-methylnorcaran-2-one (**7**) according to the literature.[7a] Bp 110—120 °C (bath temp)/0.3 Torr; IR (neat): 1744, 1689, 1644, 1610 cm^{-1}; MS: *m/e* (%), 264 (M^+, 3), 69 (82), 55 (48), 41 (100); PMR: Fig. 1.

Authentic Samples of 2h and 3h. A solution of 3-methylhept-2-en-1-ol (**9**) (0.74 g, 5.7 mmol, *E*: *Z* 80: 20) in ether (5 ml) was treated with phosphorous tribromide (0.52 g, 1.9 mmol) at −78 °C. The solution was stirred at room temp for 3 h and worked up. Distillation (80—90 °C/18 Torr) of the crude product gave 1-bromo-3-methylhept-2-ene (0.78 g, 71%). The bromide was directly treated with amylmagnesium bromide (5.0 mmol) in ether (4 ml) at room temp for 2 h. Workup and GLC separation (Silicone HV grease, 150 °C, 0.8 kg/cm^2, R_t 30 min) gave an isomeric mixture of 5-methyl-5-dodecene (**10**) (15 mg, *E*: *Z* 82: 18), which was converted to a mixture of **2h** and **3h** (ratio 84: 16) upon heating with methylene iodide (85 mg, 0.32 mmol), zinc powder (42 mg, 0.64 mmol), and cuprous chloride (10 mg, 0.10 mmol) for 15 h.[10] GLC separation of the products gave the authentic samples of **2h** and **3h**, both of which showed the identical GLC retention times (5% Apiezon L grease and 1% KOH on Chromosorb W, 2 m, 104 °C, 0.6 kg/cm^2; R_t of **2h**, 27 min; R_t of **3h**, 25 min) and MS spectra with the samples prepared by the cuprate reaction.

Authentic Samples of 2i and 3i. The allyl alcohol **9** (0.13 g, 1.0 mmol, *E*: *Z* 80: 20) was transformed, upon heating with methylene iodide (0.41 g, 1.5 mmol), zinc powder (0.20 g, 3.0 mmol) and cuprous chloride (30 mg, 0.30 mmol) in ether (2 ml) for 15 h,[10] to the cyclopropyl carbinol **11**: bp 85—95 °C (bath temp)/56 Torr; IR (neat): 3340, 1020 cm^{-1}: MS: *m/e* 124 (M^+-H_2O); PMR (CCl_4): δ 1.05 (s, 3H, Me), 3.1—3.8 (m, 2H, CH_2O). The crude cyclopropyl carbinol **11** in *N*,*N*-dimethylformamide (DMF) (0.5 ml) was mixed with sodium hydride (50 mg) in DMF (1 ml) and the whole was stirred at room temp for 1 h, treated with benzyl chloride (0.15 ml) and worked up after 30 min. Preparative TLC of the crude product (silica gel, ether–hexane 1: 3, R_f 0.8) gave a mixture of **2i** and **3i** (92 mg, 40% overall yield from **9**, 76: 28 ratio). GLC separation afforded each isomer which was identical with the samples prepared by cuprate reaction.

Authentic Samples of 2k. A solution of **12** (0.76 g, 3.7 mmol, *E*: *Z* 77: 23) in ethanol (1 ml) was treated with diethyl sodiomalonate (prepared from 1.2 g of diethyl malonate, 7.4 mmol) according to the literature.[7d] Workup and short path distillation at 124—134 °C/6 Torr gave crude diethyl 4-methyl-3-octenylmalonate (0.49 g) which was directly hydrolyzed (KOH, ethanol reflux) and decarboxylated (acetic acid, reflux for 2 days).[7d] Short path distillation at 106—116 °C/4 Torr gave 6-methyl-5-decenoic acid (**13**) (0.24 g); IR (neat): 3600—3200, 1710, 1410, 1240, 930 cm^{-1}; PMR (CCl_4): δ 1.60 and 1.68 (s, 3H, vinylic methyl of *E* and *Z* isomers), 5.06 (t, J=6 Hz, 1H); *E*: *Z* 70: 30. The acid **13** (0.24 g, 1.3 mmol) was heated with $SOCl_2$ (0.18 g, 1.5 mmol) in dry benzene (5 ml) to reflux for 1 h and the mixture was concentrated. The residue was distilled at 90—100 °C/0.2 Torr and the distillate was treated with excess diazomethane in ether at 0 °C and left over night. The solvent and the excess diazomethane were removed by passing a nitrogen stream over the surface. The concentrated crude diazoketone **14** was dissolved in cyclohexane (1 ml) and added dropwise to a suspension of cupric sulfate (0.30 g, 1.9 mmol) in refluxing cyclohexane (110 ml). After 2 h reflux the reaction mixture was filtered and concentrated *in vacuo*. Short path distillation of the residue at 100—115 °C/5 Torr afforded an oil (0.18 g, 78% overall yield from **13**). Although the product showed identical IR and MS spectra with that of **2k** prepared by cuprate reaction, GLC (3% Apiezol L grease and 10% KOH on Neosorb NC, 154 °C, 1.0 kg/cm^2 of He) and PMR revealed that it was a mixture (71: 29) of **2k** (R_t 6.9 min, methyl signal at δ 1.09) and its stereoisomer (R_t 5.6 min, methyl signal at δ 1.11).

Authentic Samples of 2j. A mixture of **2k** (0.14 g, 0.78 mmol), 80% hydrazine hydrate (3.2 g, 51 mmol) and hydrazine dihydrochloride (0.65 g, 6.2 mmol) in triethylene glycol (15 ml) was heated at 130 °C. After 3 h potassium hydroxide

(0.96 g, 17 mmol) was added and the mixture was heated at 210 °C for 3 h during which volatile products were distilled off. Preparative TLC (silica gel, hexane) of the distillate gave an oil (R_f 0.9, 24 mg) which was further purified by preparative GLC (Silicone HV grease, 130 °C, He, 0.8 kg/cm^2) giving an authentic sample of **2j**.

*Reaction of **1a** with Dimethylcopperlithium in Ether.* Methyllithium (20 ml of 0.5 M ether solution, 10 mmol) was added to cuprous iodide (0.95 g, 5.0 mmol) suspended in ether (5 ml) and hexane (15 ml) at 0 °C. After cooling to −38 °C **1a** (0.28 g, 1.0 mmol) in ether (1 ml) was added and the reaction mixture was gradually warmed to 0 °C in 3 h. Workup and preparative TLC (silica gel, hexane) afforded 1,1-dimethyl-2-phenylcyclopropane (**17a**) (R_f 0.6—0.7, 26 mg, 17%) and a mixture of **15a** (R_f 0.4—0.5, 46 mg, 21%) and **16a** (R_f 0.5—0.6, 60 mg, 28%). Physical properties of **17a**: bp 69—76 °C (bath temp)/20 Torr; IR (neat): 1609, 1580, 1499, 1451, 1375, 1028, 779, 730, 700 cm^{-1}; MS: *m/e* (%), 146, (M$^+$, 38), 131 (100), 117 (20), 91 (50); PMR (CCl_4): δ 0.5—2.0 (m, 3H), 0.78 (s, 3H, Me), 1.22 (s, 3H, Me), 6.7—7.3 (m, 5H, Ph). Found: C, 90.6; H, 9.4%. Calcd for $C_{11}H_{14}$: C, 90.4; H, 9.7%.

*Conversion of **1a** to **17a**.* A solution of methyllithium (3.2 ml of 1.9 M ether solution, 6.0 mmol) was added to a suspension of cuprous iodide (0.58 g, 3.0 mmol) in THF (10 ml) at 0 °C. The reaction mixture was cooled at −78 °C, treated with **1a** (0.28 g, 1.0 mmol) in THF (1 ml) and warmed to room temp in 15 h. Workup and preparative TLC (silica gel, hexane, R_f 0.7—0.8) afforded **17a** (69 mg, 48% yield).

*Reaction of **1a** with Divinylcopperlithium.* A solution of vinyllithium (35 ml of 0.85 M ether solution, 30 mmol) was added to a suspension of cuprous iodide (2.9 g, 15 mmol) in hexane (18 ml) at −48 °C. After 5 min the cuprate solution was cooled to −78 °C and a solution of **1a** (1.4 g, 5.0 mmol) in hexane (2 ml) was added. After 2 h the reaction mixture was quenched with ethanol (1 ml) and allowed to warm to room temp. Workup and subsequent preparative TLC (silica gel, hexane) afforded **15b** and **16b**.

r-*1-Bromo-c-2-phenyl-1-vinylcyclopropane (**15b**)*: R_f 0.7—0.8, 0.23 g, 20% yield; bp 80—87 °C (bath temp)/3 Torr; IR (neat): 1630, 1604, 1500, 1450, 1120, 1020, 970, 903, 698 cm^{-1}; MS: *m/e* (%), 222 (M$^+$, 1), 195 (1), 143 (89), 141 (24), 128 (100), 115 (35), 91 (24), 65 (15); PMR (CCl_4): δ 1.5—1.9 (m, 2H), 2.23 (dd, J=8, 10 Hz, 1H, PhCH), 4.9—6.1 (m, 3H), 7.0—7.4 (m, 5H, Ph). Found: C, 59.2; H, 4.9%. Calcd for $C_{11}H_{11}Br$: C, 59.2; H, 5.0%.

r-*1-Bromo-t-2-phenyl-1-vinylcyclopropane (**16**)*: R_f 0.8—0.9, 0.66 g, 59%; bp 75—82 °C (bath temp)/2 Torr; IR (neat): 1630, 1602, 1496, 1450, 1160, 970, 903, 697 cm^{-1}; MS: *m/e* (%), 222 (M$^+$, 1), 195 (1), 143 (86), 141 (26), 128 (100), 115 (45), 91 (21), 65 (16); PMR (CCl_4): δ 1.4—2.0 (m, 2H), 2.91 (dd, J=8, 9 Hz, 1H, PhC*H*), 4.9—5.5 (m, 3H), 7.0—7.3 (m, 5H, Ph). Found: C, 59.3; H, 5.0%. Calcd for $C_{11}H_{11}Br$: C, 59.2; H, 5.0%.

*1-Phenyl-2,2-divinylcyclopropane (**17b**).* A solution of **1a** (0.14 g, 0.50 mmol) in ether (0.5 ml) was added to a solution of divinylcopperlithium (2.5 mmol) in a mixture of ether (6 ml) and hexane (4 ml) at −48 °C. The reaction mixture was gradually warmed to 0 °C during the period of 3 h. Workup followed by preparative TLC (silica gel, hexane, R_f 0.3—0.4) gave **17b** (40 mg, 47%). Bp 61—66 °C (bath temp)/3 Torr; IR (neat): 1634, 1623, 1600, 1492, 985, 895, 773, 733, 695 cm^{-1}; MS: *m/e* (%), 170 (M$^+$, 58), 155 (82), 141 (46), 128 (85), 115 (80), 91 (100); PMR (CCl_4): δ 0.8—1.7 (m, 2H), 2.35 (dd, J=6, 9 Hz, 1H, PhC*H*), 4.7—6.3 (m, 6H), 6.9—7.3 (m, 5H, Ph). Found: C, 91.9; H, 8.4%. Calcd for $C_{13}H_{14}$: C, 91.7; H, 8.3%.

trans-*1-Allyl-2-phenylcyclopropane (**20**).* A solution of *n*-BuLi (7.2 ml of 1.7 M hexane solution, 12 mmol) was added slowly to a stirred suspension of cuprous iodide (1.1 g, 6.0 mmol) in THF (20 ml) at −48 °C. After 10 min a solution of *trans*-1-bromo-2-phenylcyclopropane (**19**) (0.29 g, 1.5 mmol) in THF (2 ml) was added and stirring was continued further 49 min at this temp. Allyl bromide (1.5 ml) in HMPA (1 ml) was then added and after 30 min the reaction mixture was worked up as usual. Preparative TLC (silica gel, hexane, R_f 0.3—0.4) of the crude oil gave **20** (0.22 g, 97%). Bp 55—60 °C (bath temp)/15 Torr; IR (neat): 1639, 1605, 1497, 1460, 1030, 995, 913, 790, 756, 700 cm^{-1}; MS: *m/e* (%), 158 (M$^+$, 6), 143 (4), 129 (9), 117 (100), 104 (36), 91 (35); PMR (CCl_4): δ 0.6—1.5 (m, 3H), 1.5—1.9 (m, 1H, PhCH), 2.0—2.4 (m, 2H, allylic H), 4.9—6.3 (m, 3H), 6.8—7.4 (m, 5H). Found: C, 90.8; H, 9.0%. Calcd for $C_{12}H_{14}$: C, 91.1; H, 8.9%.

(Received January 26, 1977)

The ^{13}C NMR spectra of thirteen acyclic and cyclohexenyl π-allyl palladium chloride dimers are examined and their chemical shifts are compared with those of the corresponding olefins. The signals for the central carbons of the π-allyl palladium moiety were displaced upfield by 8.0—25.5 ppm and those for the terminal carbons by 34.9—55.9 ppm compared to the corresponding carbons of the corresponding olefins.

In recent years, considerable effort has been directed towards the elucidation of the molecular structures of organic compounds using ^{13}C NMR spectroscopy. However, its application to organometallic compounds has so far been limited. Although there have been a number of ^{1}H NMR studies on π-allyl palladium chloride dimers, the ^{13}C NMR spectra of only a few simple chain compounds are to be found in the literature.[1] Here ^{13}C NMR spectra of π-allyl palladium chloride dimers of simple acyclic olefins and substituted cyclohexenes are reported. The carbon chemical shifts are compared with those of the corresponding olefins.

Results and Discussion

The π-allyl palladium chloride complexes of acyclic olefins were prepared from the corresponding allylic chlorides[2] and those of cyclic olefins from the corresponding olefins.[3] Natural abundance 25.15-MHz ^{13}C FT-NMR spectra were obtained using the ^{1}H noise-decoupling technique. The spectra were obtained in $CDCl_3$ as a primary solvent. Since 2- (**4**) and 1-phenyl-π-allyl palladium chloride (**5**) were not sufficiently soluble in this solvent, DMSO-d_6 was also used. The signals were assigned by comparing the signal shifts due to the structural differences between closely-related compounds and by using the ^{1}H off-resonance decoupling technique. The carbon chemical shifts obtained are listed in the table together with those of the corresponding olefins. The butenyl palladium chloride complex (**3**) and **5** are assumed to be composed predominantly of *syn*-isomers.[4] Although each of the cyclohexenyl palladium chloride complexes, **9**, **10**, and **12**, can exist as two stereoisomers, it was impossible to determine the stereochemistry of the complexes obtained here.

For the carbon chemical shifts of the π-allyl palladium moiety, the resonances for the tertiary central carbons of the *endo*-cyclic complexes appeared at fields slightly higher than those of the *exo*-cyclic complexes, while the resonances for the secondary terminal carbons of the *endo*-cyclic complexes appeared at fields lower than those of the *exo*-cyclic isomers. The carbon resonances for the acyclic compounds appeared at fields lower than those of the corresponding cyclic complexes.

The ^{13}C chemical shift of π-allyl palladium complexes were compared with those of the corresponding olefins. The chemical shifts of **3** and **5** were compared with those of the corresponding internal olefins and only the chemical shifts for the primary terminal carbons were compared with those of the terminal olefins. For cyclic π-allyl palladium complexes, the ^{13}C chemical shifts were compared with those of the corresponding cyclohexenes. Only the primary terminal carbons were compared with those of the corresponding methylenecyclohexanes. In order to evaluate the solvent shifts by DMSO, the ^{13}C spectra of the π-allyl (**1**), 2-methylallyl (**2**), **3** and cyclohexenyl palladium chloride complexes (**6**) were also measured in the DMSO-d_6 solvent. The carbon resonances for the central carbons moved downfield by 6.4—7.6 ppm and those of the terminal carbons by 4.1—4.7 ppm. It has been reported that the bridged π-allyl palladium chloride dimers in DMSO are converted to form solvent adducts[5] and that the ^{1}H resonances of the allyl part of the adducts moved downfield compared to the parent bridged dimers.[6] A similar trend was observed for the ^{13}C NMR spectra. If the averaged values of such solvent shifts are applied to the ^{13}C chemical shifts of **4** and **5**, the values for $CDCl_3$ can be estimated. These values are tabulated in the table.

The signals for the secondary central carbons revealed upfield shifts of 14.4—25.5 ppm, while those of the tertiary carbons shifts of 8.0—19.3 ppm. For the terminal carbons, the signals for the primary position moved upfield by 47.1—55.9 ppm, for the secondary ones by 42.7—52.5 ppm and for the tertiary one by 34.9 ppm. Such upfield shifts of the carbon resonances of these π-allylic ligands are generally observed in the ^{13}C NMR spectra of π-allylic-type transition metal complexes.[7] The bonding of the π-allyl metal complexes involves two components: forward donation from the φ_1 orbital to an empty metal d orbital, which causes the electron density to decrease around all three carbon atoms, and interaction of the φ_2 and φ_3 orbitals, which increases the electron density only for the terminal carbon atoms of the π-allylic ligand.[8] This results in larger upfield shifts for the terminal carbons in the π-allyl palladium moiety than for the central carbon atoms.

The ^{13}C NMR spectra of 1-phenylcyclohexene revealed that the resonances corresponding to the carbons of the phenyl group, excepting that of the substituted carbons moved downfield for the π-allylic complex **13**, especially those corresponding to the para- and ortho-related carbons. This implies that the electrons, as a whole, are shifted by the complex formation from the ligand to the metal.

For the carbons of the remaining π-cyclohexenyl ligands, the C-3 and C-5 signals of the *endo*-cyclic

Phys.*, **49**, 2395 (1968). c) The value for the complex minus that for the olefin. Positive values represent shifts toward lower field. d) These values are taken from J. B. Stothers, "Carbon-13 NMR Speetroscopy," Academic Press, New York (1972), p. 70. The solvent used was not indicated. e) These values are taken from Ref. 1e. f) Substituted. g) The values in brackets are estimated. See text. h) The values in parenthesis may be interchanged.

complexes are usually shifted downfield, while the C-4 signal is shifted upfield relative to the corresponding carbons of the corresponding olefins. Such a downfield shift of the C-3 and C-5 signals implies that these carbons are closer to the palladium atom than C-4 and the nonbonding paramagnetic shielding effect of a palladium atom which is a function of $(r_{M-C})^{-3}$,[9] plays a major role in the shift to lower field for complex formation. The exception is the case of C-4 for complex **9**. The deformation of the six-membered ring due to the replacement of the hydrogen at the C-4 position with the methyl group may result in a net decrease in the shielding of this carbon. In the *exo*-cyclic complexes, it was impossible to assign the carbon signals other than that for the π-allyl palladium moiety to specific carbon atoms. The resonances for the substituted methyl groups revealed no appreciable shift due to complex formation.

Experimental

NMR Spectra. ^{13}C FT-NMR spectra were obtained at 25.15 MHz using a JEOL JNM-MH-100 instrument equipped with a JNM-MFT-100 Fourier transform accessory; the instrument was controlled by a JEC-6 spectrum computer. The samples were in 5-mm spining tubes in $20\pm10\%$ solutions of $CDCl_3$ or DMSO-d_6 at 26 °C. The solvents provided the internal lock signal. Measurement conditions were as follows: pulse width, 27.5 μs (*ca.* 45°); reptition time, 4 s; spectral width, 6250 Hz; data points, 8192; and acquisition time, 0.65 s. Noise-modulated proton decoupling was carried out at a nominal power of 20 W. All chemical shifts are expressed in δ (ppm downfield from internal Me_4Si). Each observed chemical shift is estimated to be accurate to within ±0.06 ppm.

Materials. π-Allylic palladium complexes, **1**—**5** were prepared by the method of Dent *et al.*[2a] or Hüttel *et al.*[2b] The complexes, **6**—**13** were prepared by the method of Trost and Strege.[3] For the synthesis of the new compounds (**9**—**13**), the following general procedure was used; sodium acetate (6.0 g, 0.073 mol), sodium chloride (4.2 g, 0.072 mol), cupric chloride (4.6 g, 0.034 mol) and palladium chloride (1.0 g, 0.006 mol) were stirred for 2 h at 95 °C in 62 ml of glacial acetic acid and 1.3 ml of acetic anhydride. The solution was cooled and 0.013 mol of the corresponding cyclohexene in 4 ml of acetic acid was added. The solution was heated for several hours. The reaction temperature and time were as follows: **9** from 1,4-dimethylcyclohexene, 60 °C, 4 h; **10** from 1,4-dimethylcyclohexene, 60 °C, 27 h; **11** from 1,2-dimethylcyclohexene, 55 °C, 5 h; **12** from 2,3-dimethylcyclohexene, 60 °C, 44 h; and **13** from 1-phenylcyclohexene, 55 °C, 24 h. The solution was cooled to room temperature and filtered. After an aqueous work-up and extraction with benzene, the crude yellow oil was purified by chromatography on SiO_2 with chloroform as the eluting solvent. The addition of pentane to the purified yellow oil and refrigeration (at 5 °C) for 2 days induced crystallization giving pure yellow crystals. Since compounds **10** and **11** were obtained in a mixture with **9** and **12**, respectively, separation was performed using SiO_2 chromatography with benzene. Compound **10** was only partially separated (80% purity). Compound **9**; yield, 0.36 g (26%); mp 82—86 °C (dec) (Found: C, 38.01; H, 5.02 %. Calcd for $C_{16}H_{26}Pd_2Cl_2$: C, 38.26; H, 5.18%); ^1H NMR ($CDCl_3$); δ 4.86 (bs, 2H), δ 2.07 (s, 3H), δ 0.91 (d, J=6.8 Hz, 3H), δ 1.5—2.3 (5H): compound **10**; yield, 0.22 g (16%); mp 114—118 °C (dec) (Found: C, 38.19; H, 5.15%. Synthesis of Mono-*O*-tritylraffinoses and Deca-*O*-acetylraffinoses

Tetsuo SUAMI,* Toshiki OTAKE, Toshihide IKEDA, and Ryoichi ADACHI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received February 8, 1977)

Starting from raffinose (**1**), its 6″-*O*-trityl (**2**) and 6′-*O*-trityl derivative (**6**) have been prepared. Acetylation of **2** and **6** gave deca-*O*-acetyl-6″-*O*-tritylraffinose (**3**) and deca-*O*-acetyl-6′-*O*-tritylraffinose (**7**) respectively. Detritrylation of **3** gave two products: 1′,2,2″,3,3′,3″,4,4′,4″,6′-deca-*O*-acetylraffinose (**4**) as a main product and 1′,2,2″,3,-3′,3″,4,4′,6′,6″-deca-*O*-acetylraffinose (**5**) as a minor product, which were successfully separated by a column chromatography. On the other hand, detritylation of **7** gave 1′,2,2″,3,3′,3″,4,4′,4″,6″-deca-*O*-acetylraffinose (**8**) as a sole product. Their structures were established by NMR spectra, together with a chemical evidence.

Tri-*O*-tritylraffinose has been described by Josephson[1] in 1929, but mono-*O*-tritylraffinose has never been described in a literature. In connection with our previous studies on sucrochemistry,[2-6] mono-*O*-trityl derivatives of raffinose have been prepared in our laboratory. By acetylation and subsequent detritylation, mono-*O*-tritylraffinose was readily converted to deca-*O*-acetylraffinose, which is an attractive key compound for a synthesis of a tetrasaccharide. For instance, a naturally occurring tetrasaccharide: stachyose will be prepared from 1′,2,2″,3,3′,3″,4,4′,4″,6′-deca-*O*-acetylraffinose (**4**), since α-D-galactopyranosyl group is linked to the 6″-*OH* of raffinose in this tetrasaccharide.

Results and Discussion

A reaction between raffinose (**1**) and trityl chloride in pyridine afforded a mixture of mono-, di-, and tri-*O*-tritylraffinoses. The di- and tri-*O*-tritylraffinoses are considerably less soluble in cold water, compared to the mono-*O*-tritylraffinoses. The mono-*O*-tritylraffinoses were able to be separated from the others by means of this solubility difference in an aqueous solution. The mono-*O*-tritylraffinoses thus obtained consisted of two components of 6″-*O*-trityl (**2**) and 6′-*O*-tritylraffinose (**6**). After acetylating, the intact mixture of **2** and **6** revealed two peaks in a ratio of 4: 1 on a high performance liquid chromatogram. The major component was assumed to be deca-*O*-acetyl-6″-*O*-tritylraffinose (**3**) and the minor component was assumed to be deca-*O*-acetyl-6′-*O*-tritylraffinose (**7**), since in the case of sucrose,[7] the hydroxyl group on C-6 of the D-glucopyranosyl moiety is most reactive and the hydroxyl group on C-1′ of the D-fructofuranosyl moiety is least reactive among the three primary hydroxyl groups against tritylation.

Compounds **2** and **6** were successfully separated by a column chromatography, and subsequently acetylated to give **3** and **7** respectively.

The assumed structure of **3** was confirmed by the following evidence. The ^{1}H NMR spectrum of **3** revealed the signals of the two methylene groups (4 protons) in a region between δ 2.9 and 3.9. These signals were regarded as two AB parts of ABM-systems, and each of them consisted of eight-line-signals. The signal pattern in a lower field was almost superposable on the signal pattern of the bridge methylene protons (C-6) of raffinose undecaacetate (**9**). The signal pattern in a higher field was coincident in the chemical shifts and coupling constants with that of the methylene protons of methyl 2,3,4-tri-*O*-acetyl-6-*O*-trityl-α-D-galactopyranoside (**10**). Therefore, the signal pattern was attributable to the methylene protons on C-6″ of **3**, on which the trityloxyl group was attached (Fig. 1).

The structure of **7** was deduced from carbon-13 nuclear magnetic resonance (^{13}C NMR) spectrum of its detritylation product. That is, detritylation of **7** with

* To whom correspondence should be addressed.

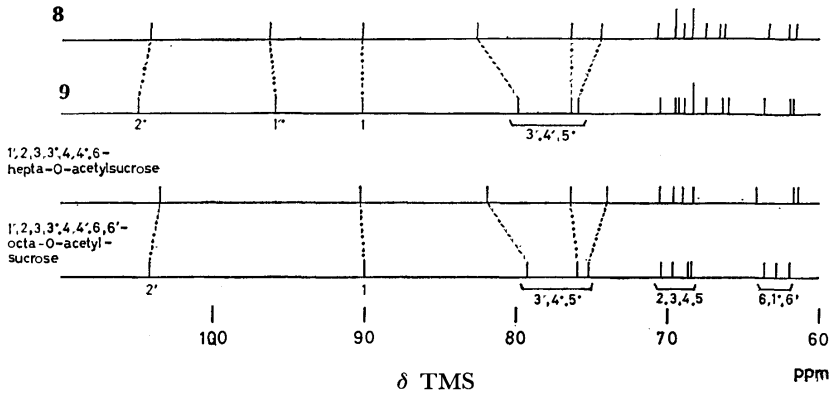

Fig. 2. Correlation map of ^{13}C NMR spectra of **8**, **9**, 1,2,3,3',4,4',6-hepta-*O*-acetylsucrose,[8] and 1',2,3,4,4',6,6'-octa-*O*-acetylsucrose.[12]

hydrogen bromide in glacial acetic acid gave 1',2,2'',3,-3',3'',4,4',4'',6''-deca-*O*-acetylraffinose (**8**) as a sole product. ^{13}C NMR spectrum of **8** revealed the signals of the three methine carbons of C-3', 4' and 5' in the D-fructofuranosyl moiety in a region between 74 and 82 ppm, which were shifted remarkably from the signals of the corresponding three methine carbons of **9** and were almost the same as those revealed by these carbons of 1',2,3,3',4,4',6-hepta-*O*-acetylsucrose[8] (Fig. 2).

On the other hand, detritylation of **3** with hydrogen bromide in glacial acetic acid under ice cooling gave a mixture of two products. These products were separated by a column chromatography, and the major component was assumed to be 1',2,2'',3,3',3'',4,4',4'',6'-deca-*O*-acetylraffinose (**4**). The minor component was assumed to be 1',2,2'',3,3',3'',4,4',6',6''-deca-*O*-acetylraffinose (**5**).

To establish the structure of **4**, a deuteration technique for an individual acetyl group[9] was applied. When ^1H NMR spectrum of a deuterioacetyl derivative of **4** was compared with the spectrum of **9**, it was readily observed that an intensity of the signal (6 protons) at δ 2.05 in the spectrum of **9** was reduced to one half (3 protons) in the spectrum of the deuterioacetyl derivative. The missing half of the signal was attributed to the acetoxyl group on C-6'' of **9**, since the acetoxyl group on C-6 of methyl 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside[11] (**12**) revealed its signal at δ 2.04. Furthermore, this assignment of the signal of **12** was achieved by comparing the ^1H NMR spectrum of methyl 2,3,4-tri-*O*-acetyl-6-*O*-trideuterioacetyl-α-D-galactopyranoside (**11**) with that of **12**. Therefore, the structure of **4** was reasonably established.

Scheme 2.

Meanwhile, **5** might be formed from **4** by an acetyl group migration from 4''-*OH* to 6''-*OH* during a course of the reaction, and this has been verified by the fact that detritylation of **3** in an aqueous acetic acid solution at elevated temperature yielded **5** as a main product.

Experimental

General Methods. Raffinose was purchased from a commercial source. Melting points were determined in capillary tubes and are uncorrected. Solutions were evaporated under diminished pressure below 40 °C. Optical rotations were measured on a Japan Spectroscopic DIP-SL polarimeter. ^1H NMR spectra were recorded on a Varian A-60D spectrometer at 60 MHz or a Varian XL-100 spectrometer at 100 MHz. ^{13}C NMR spectra were recorded by the Fourier transform technique on a Varian CFT-20 spectrometer at 20 MHz. In both spectra, deuteriochloroform was used as a solvent and tetramethylsilane was used as an internal standard, and the peak positions are given in δ values. A high performance liquid chromatogram was obtained on a Varian Model 8520 liquid chromatograph equipped with a MicroPak Si-10 column using dichloromethane as an eluting solvent. Acetylation was carried out with acetic anhydride in pyridine in the usual manner. TLC was performed on Wakogel B-10 (Wako Pure Chemical Co., Ltd.) plates, and silica gel (Wakogel C-300) was employed for a column chromatography. Elemental analyses were performed by Mr. Saburo Nakada.

6''-O-Tritylraffinose (2) and 6'-O-Tritylraffinose (6). After drying over phosphorous pentoxide at 50 °C for several days, raffinose (**1**, 7.45 g, 14.8 mmol) was treated with trityl chloride (7.00 g, 25.1 mmol) in dry pyridine (60 ml) for 64 h under mild stirring at ambient temperature. The reaction mixture was poured into ice cold water (1 l), and an insoluble matter was filtered off. The filtrate was evaporated to one tenth of the original volume to give 2.74 g of amorphous precipitates which were collected by filtration. The product consisted mainly of mono-*O*-tritylraffinoses. The product was fractionated on a column using 4:9:4:1 (v/v) acetone–chloroform–methanol–water as an eluant, and each fraction was monitored on TLC in the same solvent system.

The fractions which showed a single spot at R_f 0.40 were combined and evaporated. The residue was recrystallized from ethanol to give 1.04 g (9.4%) of **2**, mp 221—222 °C, $[\alpha]_D^{21}$ +70.9° (*c* 1.03, pyridine).

Found: C, 59.66; H, 6.17%. Calcd for $C_{37}H_{46}O_{16}$: C, 59.51; H, 6.21%.

The fractions having a single spot at R_f 0.31 were combined

and evaporated to give 0.19 g (1.7%) of **6** as a glassy solid, $[\alpha]_D^{21}$ +88° (*c* 0.5, pyridine).

*1′2,2″3′,3″,4′,4″,6′,-Deca-*O*-acetyl-6″-*O*-tritylraffinose (3).* Compound **2** (1.04 g) was acetylated, and the product was recrystallized from isopropyl alcohol to give 1.07 g (66%) of **3**, mp 96—98 °C, $[\alpha]_D^{22}$ +73.8° (*c* 0.84, chloroform). ^{1}H NMR: δ 1.87 (s, OAc), 1.95 (s, 3, OAc), 2.04 (s, 12, 4OAc), 2.09 (s, 6, 2OAc), 2.12 (s, 3, OAc), 2.15 (s, 3, OAc), 4.77 (dd, 1, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 10.5 Hz, H-2), 5.72 (d, 1, H-1).

Found: C, 58.64; H, 5.80%. Calcd for $C_{57}H_{66}O_{26}$: C, 58.66; H, 5.70%.

*1′,2,2″,3,3′,3″,4,4′,4″,6″,-Deca-*O*-acetyl-6′-*O*-tritylraffinose (7).* Compound **6** (186 mg) was acetylated, and the product was recrystallized from isopropyl alcohol to give 187 mg (64%) of **7**, mp 96—97.5 °C, $[\alpha]_D^{23}$ +98.1° (*c* 1.05, chloroform). ^{1}H NMR: δ 1.78 (s, 3, OAc), 1.88 (s, 3, OAc), 1.96 (s, 3, OAc), 2.02 (s, 6, 2OAc), 2.04 (s, 3, OAc), 2.09 (s, 9, 3OAc), 2.14 (s, 3, OAc), 4.70 (dd, 1, $J_{1,2}$ 3.7 Hz, $J_{2,3}$ 10.5 Hz, H-2), 5.04 (dd, 1, $J_{3,4}$ 9.5 Hz, $J_{4,5}$ 9.5 Hz, H-4), 4.65 (d, 1, H-1).

Found: C, 58.43; H, 5.75%. Calcd for $C_{57}H_{66}O_{26}$: C, 58.66; H, 5.70%.

Detritylation of 3. To a solution of **3** (1.12 g) in glacial acetic acid (10 ml), a 0.5 ml portion of glacial acetic acid saturated with hydrogen bromide was added under ice cooling with agitation. After two min, the mixture was quenched into ice cold water, and the solution was extracted with chloroform repeatedly. The chloroform solution was washed with sodium hydrogencarbonate solution and water. After drying over sodium sulfate, the solution was evaporated to give 1.05 g of a crude product, which showed two spots on TLC at R_f 0.54 (major component) and 0.50 (minor component) in 20: 1 (v/v) chloroform–ethanol with a ratio of approximately 4: 1.

The major component: 1′,2,2″,3,3′,3″,4,4′,4″,6′-deca-*O*-acetylraffinose (**4**, 110 mg, 12%) was obtained from the mixture by a column chromatography with 1: 5 (v/v) acetone–benzene as an eluant. The amorphous product of **4** had $[\alpha]_D^{23}$ +101.8° (*c* 0.56, chloroform). ^{1}H NMR: δ 1.97 (s, 3, OAc), 2.00 (s, 3, OAc), 2.05 (s, 3, OAc), 2.08 (s, 3, OAc), 2.10 (s, 6, 2OAc), 2.12 (s, 3, OAc), 4.80 (dd, 1, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 10.5 Hz, H-2), 5.06 (dd, 1, $J_{1'',2''}$ 5.0 Hz, $J_{2'',3''}$ 10.5 Hz, H-2″), 5.10 (dd, 1, $J_{3,4}$ 10.0 Hz, $J_{4,5}$ 10.0 Hz, H-4), 5.24 (d, 1, H-1″), 5.26 (dd, 1, $J_{3'',4''}$ 4.5 or 3.5 Hz, $J_{4'',5''}$ 3.5 or 4.5 Hz, H-4″), 5.66 (d, 1, H-1).

Found: C, 49.31; H, 5.69%. Calcd for $C_{38}H_{52}O_{26}$: C, 49.35; H, 5.67%.

Compound **4** (45 mg) was acylated with acetic anhydride-d_6 in pyridine to give 46 mg of 1′,2,2″,3,3′,3″,4,,4′,4″,6′-deca-*O*-acetyl-6″-*O*-trideuterioacetylraffinose as a glassy solid, $[\alpha]_D^{20}$ +88.9° (*c* 2.07, chloroform). ^{1}H NMR: δ 1.955 (s, 3, OAc), 2.015 (s, 3, OAc), 2.055 (s, 3, OAc), 2.10 (s, 6, 2OAc), 2.105 (s, 3, OAc), 2.11 (s, 3, OAc), 2.12 (s, 3, OAc), 2.135 (s, 3, OAc), 2.175 (s, 3, OAc).

The minor component: 1′,2,2″,3,3′,3″,4,4′,6′,6″-deca-*O*-acetylraffinose (**5**, 100 mg, 11%) was obtained by the column chromatography as described above. The amorphous product of **5** had $[\alpha]_D^{21}$ +101.0° (c 1.00, chloroform). ^{1}H NMR: δ 2.02 (s, 3, OAc), 2.06 (s, 3, OAc), 2.075 (s, 3, OAc), 2.095 (s, 6, 2OAc), 2.12 (s, 9, 3OAc), 2.15 (s, 3, OAc), 2.18 (s, 3, OAc), 3.50 (dd, 1, $J_{6''a,6''b}$ 10.0 Hz, $J_{6''a,5''}$ 1.3 Hz, H-6″a), 3.75 (dd, 1, $J_{6''b,5''}$ 5.0 Hz, H-6″b), 4.78 (dd, 1, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 10 Hz, H-2), 5.66 (d, 1, H-1).

Found: C, 49.08; H, 5.50%. Calcd for $C_{38}H_{52}O_{26}$: C, 49.35; H, 5.67%.

Besides **4** and **5**, a mixture of **4** and **5** (340 mg, 38%) was recovered from the column.

Detritylation of 3 in 98% Acetic Acid. Compound **3** (120 mg) was heated in 98% acetic acid (5 ml) on a boiling water bath. After 70 min, the solution was evaporated, and the residue was purified by a column chromatography with 1: 5 (v/v) acetone–benzene as an eluant to give 48 mg (51%) of **5** as a main product.

Detritylation of 7. Compound **7** (166 mg) was detritylated with hydrogen bromide in glacial acetic acid under ice cooling as described in the case of **5**, to give 159 mg of a crude product. The product was purified by a column chromatography with 1: 5 (v/v) acetone–benzene as an eluant. The fractions that showed a single spot at R_f 0.53 on TLC in 20: 1 (v/v) chloroform–ethanol were combined and evaporated to give 107 mg (81%) of 1′,2,2″,3,3′,3″,4,4′,-4″,6″-deca-*O*-acetylraffinose (**8**) as a glassy solid, $[\alpha]_D^{21}$ +101.0° (*c* 1.00, chloroform). ^{1}H NMR: δ 1.97 (s, 3, OAc), 2.02 (s, 3, OAc), 2.08 (s, 6, 2OAc), 2.13 (s, 15, 5OAc), 2.20 (s, 3, OAc), 4.79 (dd, 1, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 10.5 Hz, H-2), 5.70 (d, 1, $J_{1,2}$ 3.5 Hz, H-1).

Found: C, 48.84; H, 5.49%. Calcd for $C_{38}H_{52}O_{26}$: C, 49.35; H, 5.67%.

*Methyl 2,3,4-Tri-*O*-acetyl-6-*O*-trityl-α-*D*-galactopyranoside (10).* Methyl α-D-galactopyranoside[10] (1.6 g) was treated with trityl chloride (6.5 g) in pyridine for 47 h, and subsequently acetylated in the conventional method. The product was purified by a column chromatography with 1: 40 (v/v) acetone–benzene to give 3.6 g of a crude product. Recrystallization from ethanol gave 2.9 g (63%) of **10**, mp 179—180 °C, $[\alpha]_D^{25}$ +69.2° (*c* 1.71, chloroform).

Found: C, 68.39; H, 6.09%. Calcd for $C_{32}H_{34}O_9$: C, 68.31; H, 6.09%.

*Methyl 2,3,4-Tri-*O*-acetyl-6-*O*-trideuterioacetyl-α-*D*-galactopyranoside (11).* Compound **10** (0.5 g) was detritylated with hydrogen bromide in glacial acetic acid under ice cooling analogously as described above and the product was purified by a column chromatography with 1: 5 (v/v) acetone–benzene to give 0.24 g (86%) of methyl 2,3,4-tri-*O*-acetyl-α-D-galactopyranoside as a glassy solid, $[\alpha]_D^{20}$ +56.8 °C (*c* 0.67, chloroform).

The product (60 mg) was acylated with acetic anhydride-d_6 in pyridine, and the product was purified by a column chromatography to give 62 mg (91%) of **11** as a glassy solid, $[\alpha]_D^{20}$ +130 °C (*c* 1.6 chloroform).

^{1}H NMR: δ 1.97 (s, 3, OAc), 2.07 (s, 3, OAc), 2.13 (s, 3, OAc), 3.40 (s, 3, OCH_3).

^{1}H NMR spectrum of methyl 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranoside (**12**) was determined by Rathbone and his coworkers[11] [δ 1.97 (s, 3, OAc), 2.035 (s, 3, OAc), 2.07 (s, 3, OAc), 2.13 (s, 3, OAc), 3.40 (s, 3, OCH_3)].

Kinetics and Mechanism of the Oxidation of Substituted Benzyl Alcohols by Chloramine-T in Acid Solution

Kalyan K. BANERJI

Department of Chemistry, University of Jodhpur, Jodhpur 342001, India

(Received August 16, 1976)

The oxidation of benzyl alcohol and eight monosubstituted benzyl alcohols by chloramine-T in acid solution has been studied. The reaction is of first order with respect to the concentration of alcohol and oxidant. The rate constant is proportional to the square of hydrogen ion concentration. The kinetic isotope effect (k_H/k_D) is 4.13 at 303 K. The solvent isotope effect ($k(D_2O)/k(H_2O)$) is 5.93 at 303 K. The activation enthalpies and entropies are linearly related. The reaction exhibited a reaction constant $\rho^+ = -2.08 \pm 0.08$ at 303 K. The active oxidizing species is considered to be $(H_2OCl)^+$. A mechanism involving transfer of a hydride ion to the oxidant is suggested.

Chloramine-T (CAT) acts as an oxidizing agent in both acid and alkaline solutions. The kinetics of the oxidation by alkaline CAT has received much attention.[1,2] The reports on the oxidation by CAT in acid solutions are rather scanty. Mushran *et al.*[3] studied the oxidation of some primary alcohols in the pH range 4.0—5.2. Mahadevappa and Naidu[4] reported the oxidation of allyl alcohol by CAT in aqueous HCl medium.

This paper deals with the oxidation of monosubstituted benzyl alcohols by CAT in acid solution and the evaluation of the reaction constant. During the course of this investigation the oxidation of 2-propanol in acid solutions was reported by Natarajan and Thiagarajan.[5] Their results are also discussed.

Results

The oxidation of benzyl alcohol by CAT in acetic acid–water (1 : 1 (v/v)), in the presence of perchloric acid, results in the formation of benzaldehyde as the main product.

Stoichiometry. Excess of CAT was allowed to react with 0.02 M benzyl alcohol at various acidities. For some runs the carbonyl product was determined using an excess of benzyl alcohol. Values of $\Delta[CAT]/\Delta[alcohol]$ and $\Delta[CAT]/\Delta[benzaldehyde]$ in Table 1 show that the overall reaction corresponds to

$$PhCH_2OH + MeC_6H_4SO_2NCl^- \rightarrow PhCHO + MeC_6H_4SO_2NH_2 + Cl^- \quad (1)$$

Rate Laws. The rate laws were determined for the oxidation of benzyl alcohol and the eight monosubstituted benzyl alcohols. Since the results are similar, only those of benzyl alcohol are reproduced.

When the alcohol is in excess, the rate of disappearence of CAT follows the first-order rate laws. The rate constant is independent of the initial concentration of CAT (Table 2), confirming that the order with respect to CAT is one. The reaction is of first order with respect to the alcohol concentration also (Table 3). The rate constant is proportional to the square of hydrogen ion concentration (Table 4). The rate law for the oxidation is therefore given as follows:

$$\text{Rate} = k[CAT][Alcohol][H^+]^2. \quad (2)$$

The rate law differs from those reported for the oxidation of primary alcohols and allyl alcohol in aqueous solutions.[3,4] However, it agrees with the results of Natarajan and Thiagarajan[5] obtained in the oxidation of 2-propanol in acetic acid–water (1 : 4 (v/v)).

The rate constants for the oxidation of benzyl alcohol and α,α-dideuteriobenzyl alcohol in acetic acid–water (1 : 1 (v/v)) at 303 K, are $10^6 k = 6.32$ and $1.53\ l^3 m^{-3} s^{-1}$, respectively. The kinetic isotope effect (k_H/k_D) is 4.13 at 303 K.

Benzyl alcohol was oxidized in 95% deuterium oxide and the rate constant was $16.7 \times 10^{-6}\ l^3 m^{-3} s^{-1}$ at 303 K. The rate constant under similar conditions in water is $2.81 \times 10^{-6}\ l^3 m^{-3} s^{-1}$. The solvent isotope effect ($k(D_2O)/k(H_2O)$) is 5.93 at 303 K. In this set of experiments no acetic acid was present.

The oxidation of benzyl alcohol in an atmosphere of nitrogen failed to induce polymerisation of acrylo-

Substiutent	*p*-Cl	*m*-Br	*p*-NO_2	*m*-NO_2	
ΔH^* kJ mol^{-1}	59.6	66.4	77.7	75.6	
$-\Delta S^*$ J mol^{-1} K^{-1}	158	145	123	124	

nitrile. Thus a hydrogen abstraction giving rise to free radicals is unlikely.

The oxidation of benzyl methyl ether also follows similar rate laws, the ease of its oxidation being comparable to that of benzyl alcohol (Table 5).

The oxidation of benzyl alcohol and the monosubstituted benzyl alcohols was determined at various temperatures (Table 6) and the activation parameters were evaluated (Table 7). The average errors in the values of ΔH^* and ΔS^* are ± 4 kJ mol^{-1} and ± 11 J mol^{-1}K^{-1}, respectively.

Discussion

Chloramine-T is a strong electrolyte dissociating into ions in aqueous solution;[6]

$$RNClNa \rightleftharpoons RNCl^- + Na^+, \quad (3)$$

where R=*p*-$MeC_6H_4SO_2$. The anion is protonated in acid solution to give the acid. No free acid could be isolated since it undergoes hydrolysis;[4]

$$RNCl^- + H_3O^+ \rightleftharpoons RNHCl + H_2O, \quad (4)$$

$$RNHCl + H_2O \rightleftharpoons RNH_2 + HOCl. \quad (5)$$

However, the second order dependence on acidity and the magnitude of the solvent isotope effect suggest that a protonated species is involved in the rate-determining step. Thus Eq. 5 is followed by a protonation

$$HOCl + H_3O^+ \rightleftharpoons H_2OCl^+ + H_2O. \quad (6)$$

This accords well with the suggestion of earlier workers[4,5] that in the oxidation by CAT in acid solution, the active oxidizing species is $(H_2OCl)^+$. Natarajan and Thiagarajan[5] have suggested an alternate oxidizing species $(RNH_2Cl)^+$ in the oxidation of 2-propanol. Some earlier workers[7] however, have preferred HOCl as the oxidizing species in a weak acid solution. The sulfonamide group is not likely to be sufficiently basic to accept another proton.

The kinetic isotope effect, $k_H/k_D=4.13$, is very close to the value obtained in the oxidation of benzyl alcohol by bromine.[8] The mechanistic conclusion is that the rate-determining step involves a C–H bond rupture from the carbinol carbon.

The difference in the rate laws of the oxidation of allyl alcohol[4] and benzyl alcohol can be explained on the basis of different reactivities of the two alcohols towards the oxidant. In the case of allyl alcohol, the oxidation is a fast step following the slow formation of HOCl or H_2OCl^+ (depending upon the reaction conditions), wheras the oxidation of benzyl alcohol is solwer than the formation of the oxidizing species. Thus the oxidation of benzyl alcohol should be slower than that of allyl alcohol. This is actually the case. The oxidation of allyl alcohol is so fast that it has been studied at 273 K.

The activation enthalpies and entropies of the nine compounds are linearly related ($r=0.991$). The correlation was tested and found genuine by applying Exner's criterion.[9] The isokinetic temperature computed from the plot is 540 ± 35 K. Current views do not attach much physical significance to isokinetic temperature,[10] though a linear relation is usually a necessary condition for the validity of the Hammett equation.

No systematic study of the effect of substituents on the oxidation of alcohols by CAT is available. The rates of the oxidation of monosubstituted benzyl alcohols correlate well with σ^+ values ($r=0.996$). The reaction constant was $\rho^+ = -2.08 \pm 0.08$ at 303 K. The negative value of the reaction constant indicates an electron-deficient carbon center in the transition state.

Natarajan and Thiagarajan[5] have suggested an initial formation of a hypochlorite in the oxidation of 2-propanol. However, the ester formation is unlikely in view of the almost equal ease of the oxidation of benzyl alcohol and its methyl ether. The large negative reaction constant thus arises only out of the differential effects of the substituents in the rate-determining step. The correlation with σ^+, together with the substantial deuterium isotope effect suggest a considerable carbonium ion character in the transition state.

From the results, a mechanism involving transfer of a hydride ion from the alcohol to the oxidant is suggested. Simultaneous release of hydroxylic proton is

unlikely in view of the observed solvent isotope effect and the magnitude of the reaction constant. The polar requirement on the alcohol carbon for hydride release from C–H is opposite to that for proton release from O–H, the reaction constant being likely to be nearly zero in a concerted process:

$$PhCH_2OH + (H_2OCl)^+ \xrightarrow{slow} \overset{+}{P}HCHOH + H_3O^+ + Cl^- \quad (7)$$

$$\overset{+}{P}hCHOH \xrightarrow{fast} PhCHO + H^+. \quad (8)$$

It is of interest to recall here that in the oxidation of substituted benzyl alcohols by bromine[8] and acid permanganate,[11] which involve rate-determining transfer of a hydride ion, the reported values of ρ are -2.3 and -1.76 respectively.

Experimental

Materials. The preparation and specification of the alcohols used have been described earlier.[11] Isotopic purity of α,α-dideuteriobenzyl alcohol, as determined by NMR, was 92±5%. Commercial benzyl methyl ether was purified by distillation from all glass apparatus. Aqueous solution of chloramine-T (E. Merck, pro analysi) was stored in dark bottles. Acetic acid was purified by the usual methods.[12] Perchloric acid was used as a source of hydrogen ions.

Product Analysis. Benzaldehyde was characterized and estimated by the isolation of its 2,4-dinitrophenylhydrazone.

Kinetic Measurements. The reactions were carried out under pseudo-first-order conditions by keeping a large excess of the alcohol over CAT. The temperature was kept constant to ±0.1 K. The solvent used was acetic acid–water (1 : 1 (v/v)), unless otherwise stated. The reactions were followed iodometrically up to nearly three half-lives, the reactions being found smooth. The rate constants were evaluated from the plots of log [oxidant] against time and were reproducible within ±3%. Preliminary experiments showed that the oxidation is not sensitive to ionic strength, hence no attempt was made to keep it constant. The rate for the deuterated alcohol was corrected for the ordinary alcohol present. The usual concentration of the reactants in the reaction mixture was: the alcohol 0.05—1.0 M, CAT 0.01—0.08 M, and perchloric acid 0.1—1.5 M.

Branched-Chain Deoxy Nitro and Amino Sugar Derivatives from Ketose

M. M. A. ABDEL-RAHMAN

Department of Chemistry, Faculty of Science, Alexandria University, Alexandria, Egypt

(Received September 22, 1976)

The nitromethane addition to 1,2-*O*-isopropylidene-5-*O*-trityl-α-D-*erythro*-pentofuranos-3-ulose (**1**) proceeded smoothly to give the corresponding branched-chain sugar (**2**), which on acetylation afforded (**3**) followed by elimination of acetic acid in presence of a base catalyst, resulted in the formation of the corresponding nitro olefin (**4**). The nitro olefin when subjected to borohydride reduction gave 5-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-3-(nitromethyl)-α-D-ribofuranose (**5**), which on catalytic hydrogenation followed by acetylation yielded the 3-(acetamidomethyl)-5-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (**6**). By the study of the NMR spectra of 3-deoxy derivatives (**5**) and (**6**), their D-ribo configurations were established.

The synthesis of various branched-chain carbohydrates was the aim of several investigators in recent years.[1,2] These syntheses usually utilise the required oxo sugars as intermediates, which then condense with diazomethane,[3] organolithium compounds,[1,4] Grignard reagents,[1,4,5] sulfur ylides,[6] and phosphorane.[7,8]

The synthesis of amino sugars by the method of nitromethane-sugar dialdehyde[9] has been modified,[10] by using nitroethane to afford branched-chain amino deoxy sugars, in which branching is on the carbon atom having the amino group.

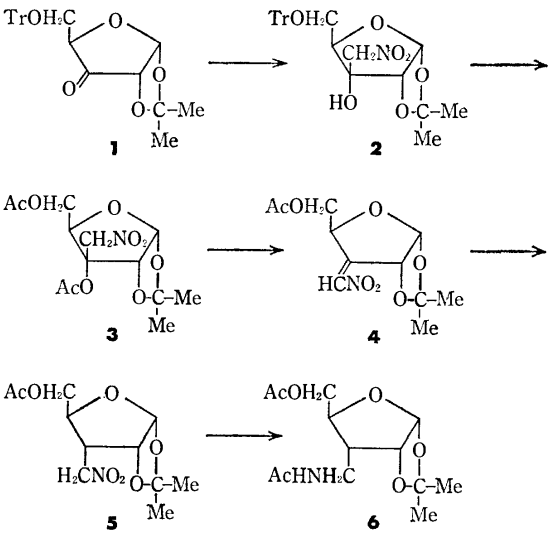
A recent method[8] described the synthesis of deoxy sugars having a nitrile or an amino group on the branched-chain. The synthesis of branched-chain nitro sugars[11] was carried out by the addition of nitryl iodide to a branched-chain unsaturated sugars, whereas Michael addition of nitro-alkanes to unsaturated nitro sugars produced branched-chain dinitro sugar derivatives.[12] The nitromethane method[9] has now been applied to oxo sugar to produce sugar derivatives with a nitro group on the branch, which could be readily converted into deoxy sugars having a nitro or an amino group on the branched-chain. This mehtod and others[13] led to the direct introduction of a functionalized one-carbon branch into carbohydrates.

Results and Discussion

The reaction of 1,2-*O*-isopropylidene-5-*O*-trityl-α-D-*erythro*-pentofuranos-3-ulose[14] (**1**) with a suspension of the sodium salt of nitromethane (prepared by careful addition of sodium hydride to nitromethane)in nitromethane afforded 1,2-*O*-isopropylidene-3-(nitromethyl)--5-*O*-trityl-α-D-ribofuranose (**2**) in 76% yield.
Its NMR spectrum showed the existence of an exchangeable proton (3-OH) and an AB quartet of the two methylene protons of the branch. The IR spectrum showed the presence of a nitro group.

Acetylation of **2** with acetic anhydride in the presence of *p*-toluenesulfonic acid resulted in acetolysis of the 5-trityl ether in addition to acetylation of the 3-hydroxyl group, to produce 3,5-di-*O*-acetyl-1,2-*O*-isopropylidene-3(nitromethyl)-α-D-ribofuranose (**3**).

β-Acetoxynitroalkanes are useful precursors for α-nitroalkene synthesis, since they easily undergo base-catalyzed elimination of acetic acid.[15] Thus, treatment of **3** with anhydrous sodium carbonate in dry benzene readily gave the nitro olefin (**4**), which was then reduced



using sodium borohydride in aqueous acetonitrile,[16] to give the corresponding branched-chain deoxy nitro sugar (**5**) in a good overall yield. The 1,2-*O*-isopropylidene group, as expected, controlled the reaction sterically. From the NMR data of **5**, the configuration at C-3 was deduced. It showed a doublet at τ 4.14 (H-1) and a triplet at 5.19 (H-2), indicating that it was also coupled to H-3 . Since there was no coupling between H-2 and H-3 in 1,2-*O*-isopropylidene -α-D-xylo-furanose,[17] the product should have the deoxy-D-ribo configuration.

Catalytic reduction of **5** followed by acetylation afforded 3-(acetamidomethyl)-5-*O*-acetyl-3-doxy-1,2-*O*-isopropylidene-α-D-ribofuranose (**6**). Its NMR spectral data also confirmed the deoxy-D-ribo configuration.

This series of reactions describes the synthesis of functionalized branched-chain deoxy sugars from a branched-chain sugar with inversion of configuration at the center of branching, which is achieved by the steric influence of the 1,2-*O*-isopropylidene group.

Experimental

Melting points were determined with a Fischer-Jones apparatus and were uncorrected. NMR spectra were observed on a Varian HA-100 spectrometer using TMS as an internal standard. IR spectra were recorded with a Unican SP 200 spectrometer. Optical rotations were determined with a Perkin-Elmer 141 recording polarimeter. Solutions were concentrated on a rotary evaporator at below 20 °C under

reduced pressure.

1,2-O-Isopropylidene-3-(nitromethyl)-5-O-trityl-α-D-ribofuranose (2). A suspension of sodium hydride (0.15 g) in nitromethane (10 ml) was added dropwise to a cooled (Dry Ice bath below −20 °C) and stirred solution of 1,2-*O*-isopropylidene-5-*O*-trityl-α-D-*erythro*-pentofuranos-3-ulose[14] (1.1 g) in nitromethane (10 ml). The reaction mixture was stirred for one additional hour at room temperature and neutralized with glacial acetic acid, and the solvent was evaporated. The residue was dissolved in water (60 ml) and extracted with chloroform (3×50 ml), washed with water and dried. The syrup obtained on evaporation of the extract was crystallised from acetone–hexane to give the title compound **2** (0.9 g, *Y*= 76%); mp 120—122 °C, $[\alpha]_D^{20}$ +29° (*c* 1, $CHCl_3$), IR ν_{max}^{KBr} 3450 (OH), 1560 cm^{-1} (NO_2); NMR ($CHCl_3$): τ 3.98 (1H, d, $J_{1,2}$ 4.0 Hz); 5.13 (2H, d), 5.88 (4H, t, $J_{4,5}$ 5 Hz); 6.68 (5H, m); 5.59 (CH_2NO_2, q, $J_{a,b}$ 12.5 Hz); 8.40, 8.60 (CMe_2, s); 6.83 (OH, s, disappeared on deuteration with D_2O).

Found: C, 68.5; H, 5.7; N, 3.0%. Calcd for $C_{28}H_{29}NO_7$: C, 68.4; H, 5.9; N, 2.8%.

3,5-Di-O-acetyl-1,2-O-isopropylidene-3-(nitromethyl)-α-D-ribofuranose (3). A solution of **2** (0.6 g) in acetic anhydride (6 ml) was stirred overnight at room temperature in the presence of anhydrous *p*-toluenesulfonic acid (0.1 g). The reaction mixture was then slowly poured onto an aqueous solution of sodium hydrogencarbonate and the gummy product was decanted, washed several times with cold water and dissolved in chloroform, which was washed with water and dried (Na_2SO_4). On evaporation of the dried chloroform, compound **3** was obtained as a pale yellow syrup (0.4 g); IR ν_{max} 1760 (OAc); 1510 cm^{-1} (NO_2).

Found: C, 45.1; H, 4.8; N, 4.6%. Calcd for $C_{12}H_{16}NO_9$: C, 45.3; H, 5.0; N, 4.4%.

5-O-Acetyl-3-deoxy-1,2-O-isopropylidene-3-(nitromethyl)-α-D-ribofuranose (5). Powdered potassium carbonate (0.5 g) was added to a solution of **3** (1.8 g) in dry benzene (25 ml) and the suspension was stirred magnetically for 6 h at room temperature. The mixture was filtered using Celite pad and the filtrate was evaporated to give **4** as yellow viscous syrup. It was dissolved in acetonitrile (25 m), cooled in an ice bath, stirred. To this was added a solution of sodium borohydride (0.2 g) in water (2 ml). After one hour stirring, the reaction mixture was diluted with water (100 ml) and extracted with chloroform (4×25 ml). The extracts were washed with water and dried (Na_2SO_4). On evaporation, the residue obtained (0.8 g, *Y*=58%) was crystallised from acetone–hexane, mp 127—129 °C; $[\alpha]_D^{20}$ +62° (*c* 1, $CHCl_3$), IR ν_{max}^{KBr} 1750 (OAc), 1565 cm^{-1} (NO_2), NMR ($CDCl_3$): τ 4.14 (1H, d, $J_{1.2}$ 4.0 Hz); 5.14 (2H, t); 7.32 (3H, m); 5.70—6.07 (3-proton, m, 4H, 5H); 5.39 (CH_2NO_2, q); 8.52, 8.72 (CMe_2, 2 s); 7.96 (Ac, s).

Found: C, 48.2; H, 6.3; N, 4.9%. Calcd for $C_{11}H_{17}NO_7$: C, 48.0; H, 6.2; N, 5.1%.

3-(Acetamidomethyl)-5-O-acetyl-3-deoxy-1,2-O-isopropylidene-α-D-ribofuranose (6). A solution of **5** (0.14 g) in ethanol (20 ml) was reduced with hydrogen in the presence of platinum oxide (0.1 g) at room temperature under atmospheric pressure for 2 h, during which the calculated amount of hydrogen was consumed. The reaction mixture was filtered and evaporated to give the corresponding amine as a syrup. It was dissolved in dry pyridine (2 ml) and acetic anhydride (2 ml) was added, and the solution was stirred for 2 h. The reaction mixture was then poured onto ice, and extracted with chloroform (4× 20 ml). The extracts were then washed with cold dilute hydrochloric acid, aqueous sodium hydrogencarbonate and water, and dried (Na_2SO_4). On evaporation of the dried extract compound **6** was obtained as a syrup, (0.11 g, *Y*= 82%) $[\alpha]_D^{20}$+57° (*c* 1, $CHCl_3$); IR ν_{max} 3450 (NH), 1750 (OAc), 1680, 1525 cm^{-1} (NHAc); NMR ($CDCl_3$): τ 4.20 (1H, *d*, $J_{1,2}$ 4.0 Hz); 5.34 (2H, t); 3.74 (NH, broad);7.93, 8.04 (Ac, two s); 8.50, 8.70 (CMe_2, two s).

Found: C, 54.4; H, 7.6; N, 4.7%. Calcd for $C_{13}H_{21}NO_6$: C, 54.3; H, 7.4; N, 4.9%.

Accordionlike Skeletal Motions of $CH_3NHCONH(CH_2)_nCH_3$ (n=1—15)

Yoshiyuki MIDO, Fumiko FUJITA, and Teizo KITAGAWA*

Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657
**Institute for Protein Research, Osaka University, Yamadakami, Suita, Osaka 565*

(Received December 6, 1976)

Synopsis. Solid $CH_3NHCONH(CH_2)_nCH_3$ (n=1—15) gave two intense Raman lines in the 100—500 cm^{-1} region. The frequency of one of them varied with n, but that of the other was unvarying. The n-dependent frequencies fit the theoretical ν-δ curve of C–C–C deformation of polyethylene and were, therefore, assigned to the accordion modes.

In early Raman studies of normal paraffin crystals, Mizushima and Shimanouchi[1] found sharp Raman lines which appeared at frequencies inversely proportional to the number of carbon atoms; they assigned them to the accordion-like motion of the totally symmetric skeletal deformation. Schaufele and Shimanouchi[2] elucidated the frequencies (ν) of the accordion modes of C_nH_{2n+2} molecules in terms of the phase difference (δ) of the vibrational displacements between two adjacent methylene groups.

We ourselves have previously studied the vibrational spectra of alkylureas[3-5] and pointed out that the C–N–C–N–C skeleton of the $CH_3NHCONHCH_2$– group is of a planar zigzag structure.[3] In the present study we examined the accordion modes of dialkylureas of $CH_3NHCONH(CH_2)_nCH_3$ (n=1—15). These compounds were prepared by a standard method[4] and were purified through repeated crystallization. The laser Raman spectra were excited by the 514.5 nm line and recorded on a JEOL-400D Raman spectrometer.

Two prominent Raman lines were found in the region between 100 and 500 cm^{-1}. One of them appeared around 230 cm^{-1} irrespective of n, but the other was located at a frequency which varied sensitively with n, although it became a shoulder of the libration band at about 100 cm^{-1} when $n \geqq 6$. The frequencies of the latter group of the Raman lines were approximately inversely-proportional to $n+5$ and were thus assigned to the accordion mode.

The n-dependent frequencies observed for solid $CH_3NHCONH(CH_2)_nCH_3$ are plotted against the phase difference in Fig. 1, where $\delta = 2\pi/(n+5)$ (instead of $\pi/n+5$) is used to refer to the theoretical ν-δ curve of the polyethylene crystal. The observed frequencies fit closely the theoretical curve (solid line) calculated for the ν_5 branch of the polyethylene crystal by Kitagawa and Miyazawa.[6] The ν-δ curve used has also been applied satisfactorily to the analysis of the skeletal modes of $CH_3(CH_2)_nCONH_2$.[7] Furthermore, the corresponding ν-δ plots observed for various polyethers of the $[-(CH_2)_m-O-]_n$ type have been reported to fit the theoretical ν-δ curve of the infinite polymethylene chain.[8]

Upon the determination of δ for the skeletal deformation vibrations of chain molecules with a *trans* zigzag structure, the number of constituent atoms is taken, in general, as the denominator.[2] In the present case, if the plane of the C–N–C–N–C of $CH_3NHCONHCH_2$– coincides with the *trans* zigzag plane of $-(CH_2)_nCH_3$, there will be $n+5$ atoms as the constituents of the *trans* zigzag chain of $CH_3NHCONH(CH_2)_nCH_3$ molecule; therefore $n+5$ was adopted for the denominator in the plot of Fig. 1.

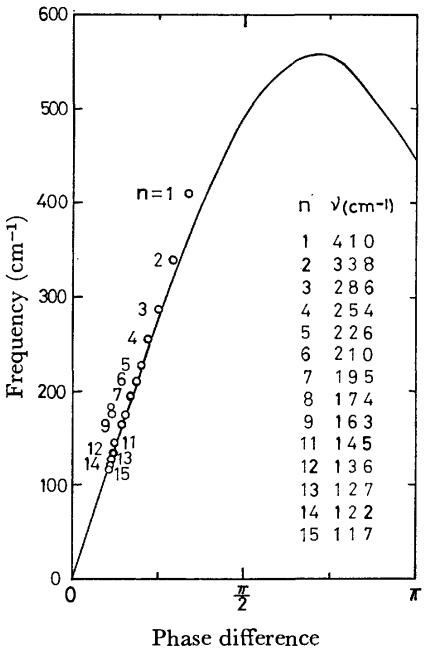

Fig. 1. The ν-δ plots for the accordionlike motion of $CH_3NHCONH(CH_2)_nCH_3$.

Usually, when n is small, the experimental ν-δ plots deviate considerably from the theoretical ν-δ curve and a correction for the effect of the end group is required.[7] Nevertheless, it is surprising that the present data for small n values fall closely on the theoretical curve without any correction for the end group. This fact may imply that all the skeletal atoms constitute a *trans* zigzag plane, and also that the deformations of NH–CO–NH and CO–NH–CH_2 (or CH_3) are effectively coupled with other skeletal deformations of the molecule just as where those parts are replaced with CH_2–CH_2–CH_2. If this consideration is correct, then it is not unexpected that the present data for n=2 fall on the theoretical ν-δ curve, because it corresponds to the case of the n=7 of C_nH_{2n+2}, for which the observed frequency fits the theoretical curve fairly well.

The authors wish to express their gratitude to Mr. Shuuichi Muraishi of Japan Electric Co., Ltd., for his measurements of the Raman spectra.

X-Ray Diffraction Studies of the Metal Soaps of Fatty Acids of Odd Carbon Numbers

Keizo OGINO and Toshio SAITO

Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received September 20, 1976)

Synopsis. X-Ray diffraction patterns have been observed for metal soaps of fatty acids with odd carbon numbers. The soaps of Pb, Cd, Ba, and Zn were prepared from the fatty acids of hexanoic, heptanoic, nonanoic, decanoic, undecanoic, dodecanoic, tridecanoic, tetradecanoic, pentadecanoic, hexadecanoic, heptadecanoic, and octadecanoic, the long spacings of which were studied in comparison with those of sodium soaps. The most prominent characteristic of these soaps is the presence of a definite order of long spacing which is directly proportional to the number of carbon atoms in the hydrocarbon chains, this is in contrast to the sodium soaps, which show a zigzag relation.

Although many reports have been presented on X-Ray diffraction studies on metal soaps, they have been concerned with the fatty acid salts of even carbon numbers originating from natural fatty oils.[1-6]

Recently, though the advance of organic synthesis has made the fatty acids of odd carbon numbers readily available for technical uses. It is important to investigate the properties of metal soaps of fatty acids with odd carbon numbers to facilitate the present industrial activity. With this in view, X-Ray diffraction patterns have been obtained for the metal soaps of fatty acids of odd carbon numbers in this study.

Experimental

Materials. *Fatty Acids*: The fatty acids, from hexanoic acid (C_6) to octadecanoic acid (C_{18}), used in this investigation were supplied from the Ajinomoto Co., Ltd. The purities of the fatty acids were confirmed to be over 98.5 per cent by gas chromatography.

Metal Salts: The inorganic chemicals used in the preparation of metal soaps were a reagent grade: lead acetate $Pb(CH_3COO)_2$, cadmium sulfate $CdSO_4$, barium nitrate $Ba(NO_3)_2$, and zinc acetate $Zn(CH_3COO)_2$.

Preparation of Metal Soaps. The soaps of Pb, Cd, Ba, and Zn were prepared by the addition of aqueous solutions of sodium soaps to a large excess of solutions of the metal salts. The precipitates were washed with water and then with ethanol, and successively extracted with boiling acetone. The purified metal soaps were dried *in vacuo* and then stored in a desiccator at room temperature for two months.

Apparatus. The X-ray diffraction measurements were performed with a Rigaku Denki Geiger Spectrometer D-9C instrument, using copper K_α radiation through a nickel filter, under the following conditions: voltage, 30 kV; 10 mA; count full scale, 1000 c/s; scanning speed, 2/min; time constant, 2 cm/min.

Results and Discussion

X-Ray diffraction patterns were obtained for a series of metal soaps made from straight-chain fatty acids containing 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, and 18 carbon atoms. Figure 1 shows the X-Ray diffraction patterns of the metal soaps of tridecanoic acid in comparison with the sodium soap.

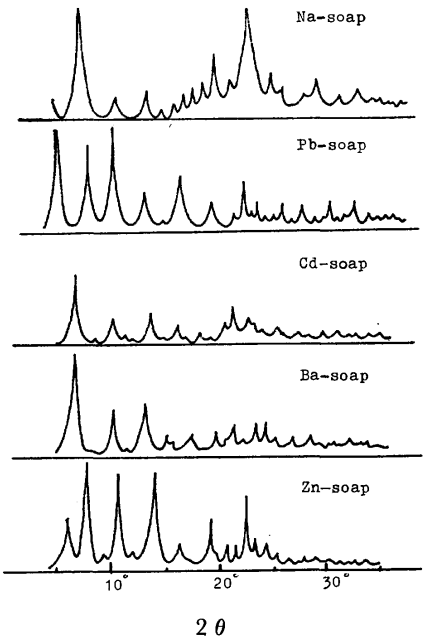

Fig. 1. X-Ray diffraction pattern of metal soaps of tridecanoic acid.

All of the metal soaps showed several strong diffraction patterns corresponding to the spacings. It is noticed that sodium soap diffracts strongly, showing the higher crystallinity of sodium soaps than those of the other metal soaps. Similar results were also obtained for the metal soaps of the other fatty acids.

In Table 1, the long spacings for the metal soaps of

Zn-soap	4.55(s)	4.33(m)	4.04(m)	3.85(ss)	—
	(ii) C_{13}-soaps				
Na-soap	4.91(s)	4.19(m)	3.87(ss)	3.56(m)	—
Pb-soap	4.21(m)	4.08(ss)	3.85(m)	3.79(w)	3.65(m)
Cd-soap	4.12(m)	3.78(m)	3.53(w)	—	—
Ba-soap	4.60(m)	4.42(m)	4.35(m)	4.01(m)	3.80(m)
Zn-soap	4.62(ss)	4.27(m)	4.15(m)	4.10(ss)	3.80(m)

fatty acids with even and odd carbon numbers from C_6 to C_{18} are shown. The short spacings for metal soaps of hexadecanoic and tridecanoic acid are shown in Table 2. The short spacings permit the identification of the soaps.

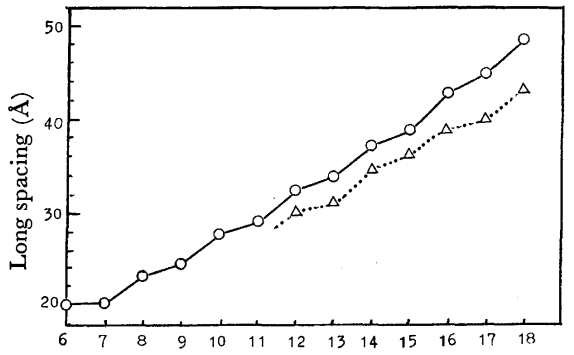

Fig. 2. Long spacing of sodium soaps in reference with those of fatty acids.
○; Sodium soap, △; fatty acid.

Figure 2 shows the long spacings of the sodium soaps and the fatty acids. The data for the fatty acids are taken from the literature.[7,8] Here, the crystalline forms of the acids are denoted as the B-form for even-carbon-number acids and as the B'-form for odd-carbon-number acids.

When the long spacings of the sodium soaps of saturated fatty acids are plotted against the number of carbon atoms, as in Fig. 2, one obtains a zigzag curve (high at even carbon numbers and low at odd). It is also well known that the long spacings of fatty acids are related to the carbon numbers of the fatty acids in a zigzag curve.

On the other hand, the melting points of saturated fatty acids with even and odd numbers of carbon atoms are known to be related to the carbon number in a zigzag curve with higher melting points for the even fatty acids than those for the odd ones. This is because fatty acids with odd carbon numbers have structures of the *cis*-form, by analogy with other organic compounds showing long and short terminal distances between two adjacent molecules when the molecules are declined, while the fatty acids with even carbon numbers have structures of the *trans*-form showing a short terminal distance only. Therefore, the packings of fatty acids with odd carbon numbers are more loose than those of even ones.

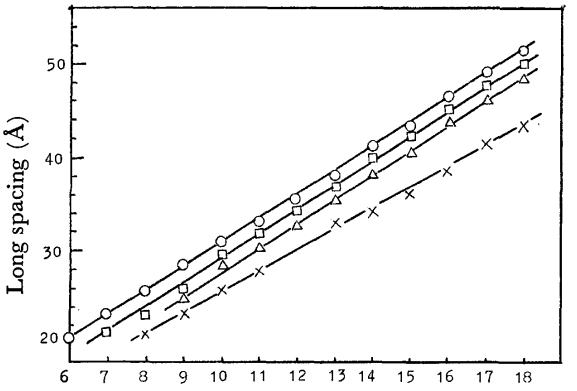

Fig. 3. Long spacing of metal soaps.
○; Pb-soap, □; Cd-soap,
△; Ba-soap, ×; Zn-soap.

Figure 3 shows plots of the long spacings of the metal soaps against the carbon numbers of the fatty acids. It may be noted in the figure that the long spacings of these metal soaps increase linearly with the number of carbon atoms in the fatty acids.

Vold *et al.*[4] have reported that the long spacings of heavy metal soaps are correlated with their structures, in which the cations are separated in parallel planes at a distance somewhat less than the length of two fatty acid radicals. In this work, it was found that the regular increase in spacing (about 2.5 Å per additional carbon atom) corresponds to twice the size of the CH_2 unit.

However, the slope of the linear relation for Zn-soap differs from those of the other metal soaps. Matuura[6] found that the long spacings for the soaps of fatty acids with most of the light metals in the periodic table appear to be peculiar. The peculiarity of Zn-soaps seems to be related to Matuura's result. The theoretical approaches to the details of this evidence will be here after studied.

The Channeling of Hot H Atoms in the Radiolysis and Photolysis of Crystalline Alkane

Tetsuo MIYAZAKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 16, 1976)

Synopsis. The possibility of a long migration of hot H atoms through crystalline alkane is discussed in terms of a simple channeling theory. The potential energy surface for an H atom in crystalline neopentane shows that the channeling directions are perpendicular to the [110] and [100] planes. The energy dependence of the channeling of hot H atoms is discussed.

Recently Miyazaki *et al.* found that H atoms, which are produced by the radiolysis of solvent neopentane or by the photolysis of hydrogen halide, react selectively with a small amount of solute alkane in a neopentane matrix at 77 K.[1] A similar phenomenon has also been observed in isobutane, 2,2,3,3-tetramethylbutane and cyclopropane matrices at 77 K.[1] At present, we cannot give a clear answer to the question whether the reactive H atoms are thermal or hot.

The following observations, however, favor the hypothesis of the hot H atoms: (1) The competitive reaction between *c*-C_6H_{12} and HI for H atoms was studied in the radiolysis and photolysis of a *neo*-C_5H_{12}–*c*-C_6H_{12}–HI mixture at 77 K. The rate constants of these reactions in the neopentane matrix are quite different from those of the thermal H atom reaction.[1] (2) When a H atom is produced by the photolysis of HBr with a 185 nm light, the hot H atom has initially a kinetic energy of 67 kcal/mol. When C_3H_8 is present in the *i*-C_4H_{10} matrix, the hot H atom reacts selectively with solute C_3H_8 to form the C_3H_7 radical.[1] (3) The selective hydrogen atom abstraction by H atoms occurs even at 4 K in *neo*-C_5H_{12} matrix and the H atoms cannot be detected at all by ESR spectroscopy.[2]

There is, however, a dogmatic conception that a long migration of a hot H atom through solid alkane is quite improbable. In this report the author will discuss the possibility of a long migration of the hot H atom by means of the channeling phenomenon.[3]

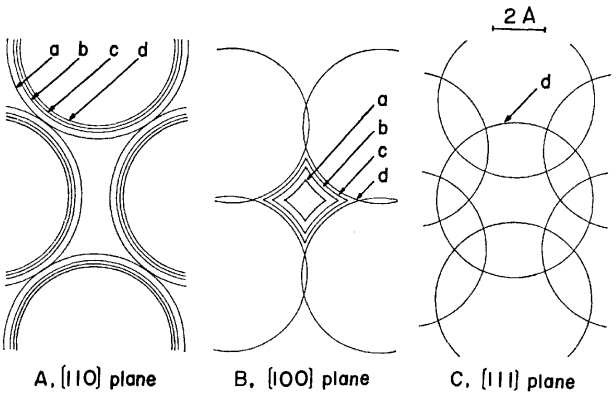

Fig. 1. Projections of potential energy distribution in neopentane crystal.
Contour lines are : a, 1.0 kcal/mol; b, 3.0 kcal/mol; c, 5.0 kcal/mol; d, 9.3 kcal/mol. Position of the contour map represents the position of mass center of H atom.

Potential Energy Surface for H Atoms in Crystalline Neopentane. The occurrence of the channeling in the crystal depends on the existence of the channeling region, which is decided by the potential energy distribution in the crystal. Since the calculation of the potential energy between *neo*-C_5H_{12} and an H atom is quite difficult, the potential energy between an H atom and CH_4, which is a very similar compound to *neo*-C_5H_{12}, is applied here to the neopentane crystal as an approximation. Recently Raff has calculated the potential energy surface between CH_4 and a T atom.[4] He considered the energy for an angular displacement of C–H bonds in addition to the energy calculated by London-Eyring-Polanyi-Sato's method. The potential energy, $V(R_i, \theta_i)$, is given by:

$$V(R_i, \theta_i) = T(R_1, R_5, R_6) + T(R_2, R_5, R_7) + T(R_3, R_5, R_8) + T(R_4, R_5, R_7) + \frac{1}{2}\sum_{j=1}^{6} k_j(\theta_j - \theta_j^0)^2 \quad (1)$$

where R_i represents the interparticle distance between C, H, and T atoms. The θ_i are the six H–C–H angles of CH_4. The bending-force constant for the θ_j angle is k_j, with θ_j^0 representing the equilibrium angle. The four terms $(T(R_i, R_j, R_k))$ in Eq. 1 represent the energies of three-body interaction among C, H, and T atoms.

Raff calculated the potential energy surface of the CH_4–T system by means of the above procedure. Here the potential energy surface calculated by him is applied to the crystalline *neo*-C_5H_{12}–H atom system. The crystalline structure of neopentane at 77 K consists of face-centered cubic unit cells with a lattice constant of 11.4 A.[5] Since the chemical structure of neopentane is symmetrical, the structure is depicted as a sphere. Since an overall rotation of the neopentane molecule occurs even at 77 K,[6] the positions of the H atoms of the methyl group are not fixed in the lattice. Therefore, the depiction of the neopentane molecule as a sphere is reasonable. The energy of the abstraction saddle point on the potential energy surface is normalized to 9.3 kcal/mol,[7] which is the observed activation energy for an H atom-abstraction reaction from neopentane by an H atom. Projections of the potential energy distributions of the three principal planes of the f.c.c. lattice of neopentane are shown in Fig. 1. The potential energy surface in Fig. 1 is based on the energy of the H and CH_4 pair, and the distance between the reactive H atom and the H atom of the methyl group is 1.08 Å at the saddle point of the potential energy surface. The distances between the reactive H atom and the nearest H atoms

of the other methyl groups are 1.9 Å for the other methyl group of the same neopentane molecule and 2.9 Å for the methyl group of the neighboring neopentane molecule. Therefore, the interaction energies of the reactive H atom and these nearest H atoms may be negligible as compared with the energy at the saddle point.

It is clear that the layers of the [110] and [100] orientations exhibit low potential regions to the incident H atoms, which are produced by the radiolysis of neopentane or by the photolysis of hydrogen halide. If the energy in the transverse motion of a hot H atom is larger than the 9.3 kcal/mol shown in Fig. 1A and B, the H atom reacts with neopentane. If, on the other hand, the energy in the transverse motion is smaller than 9.3 kcal/mol, the hot H atom travels a long distance by a succession of glancing collisions with the channel walls of neopentane molecules and then reacts with a solute alkane, which may exist as a defect in the neopentane crystal. When hot H atoms are incident upon the [111] plane, however, they react with neopentane molecules in the first collision (Fig. 1C).

The selective hydrogen atom abstraction reaction by H atoms in neopentane-alkane mixtures is not observed in the liquid phase.[1] This phenomenon can be explained by the channeling hypothesis. Since a random arrangement of molecules in the liquid phase does not contain channels, the hot H atom collides head-on with a solvent molecule in the liquid phase and loses its energy by chemical reaction or deactivation.

Energy Dependence of the Channeling of Hot H Atoms. When the channeling of H atoms takes place, the intervals of glancing collisions of H atoms with the channel wall are much longer than in the lattice period. It is a good approximation[3] to assume that the potential distribution of Fig. 1A or B continues in a direction perpendicular to the [110] or [100] plane. The collision in the channeling is depicted in Fig. 2A, where E is the kinetic energy of an H atom. If the energy of an H atom in its x-direction motion is smaller than 9.3 kcal/mol, then:

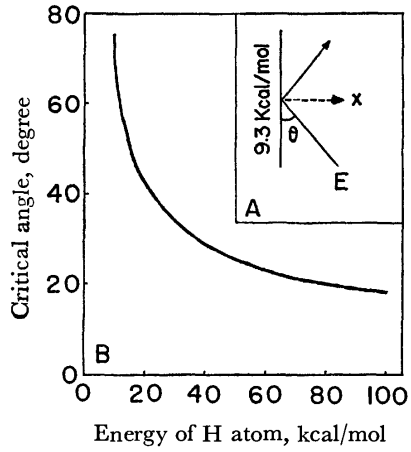

Fig. 2. Critical angle of channeling of hot H atom. A, Glancing collision of hot H atom with channel wall of 9.3 kcal/mol. B, Dependence of critical angle of channeling upon kinetic energy of H atom.

$$E \sin^2\theta < 9.3 \text{ kcal/mol} \quad (2)$$

where θ is the angle between the H-atom motion and the channel direction.

Though the thermalization process of the hot H atom may be important, only the hydrogen-atom-abstraction reaction is considered in this model for the following two reasons: (1) The cross section of the H atom abstraction reaction by hot H atoms in the 3-methylpentane matrix at 77 K is three times as large as that of the thermalization.[8] (2) Though the H atom abstraction reaction by hot H atoms takes place in the neopentane matrix at 4 K, trapped H atoms are not observed at 4 K by ESR spectroscopy.[2]

The substitution reaction of hot H atoms is neglected also in this treatment for the following reasons. The activation energy for the substitution reaction is about 35 kcal/mol,[9] which is much higher than that for the H-atom-abstraction reaction. The cross section for the abstraction from methane by a 65 kcal/mol tritium atom is 3.7 times as large as that for the substitution reaction.[9]

The critical angle for the channeling of the hot H atoms can be calculated by means of Eq. 2; it is shown in Fig. 2B. The H atoms easily undergo a channeling with a decrease in the kinetic energies, when they converse upon the crystal from all directions.

When hot H atoms are produced by the photolysis of hydrogen halide or by the radiolysis of the solvent alkane, the direction of the initial motion of the H atoms is also important. If hydrogen halide is dissolved in a void space of the lattice, as is shown in Fig. 1A, the H atoms easily converse upon the channeling region.

It can be concluded that the channeling phenomenon of hot H atoms can take place in the organic crystal if the conditions are optimum. We cannot reject *a priori* the possibility of long migrations of hot H atoms in the organic crystal.

The author wishes to express his appreciation to Professor Noriaki Ito, Professor Kenji Fueki, and Dr. Kenji Morita of Nagoya University for their fruitful discussions.

The Reactions of the Nitrogen Atom with Ethylene and Ethylene-d_4

Saku TAKAHASHI and Shozo MIYAZAKI

Department of Chemistry, Defense Academy, Hashirimizu, Yokosuka-shi, Kanagawa 239

(Received December 24, 1976)

Synopsis. In the N–C_2H_4 system, the main final product was HCN, and the stoichiometry (ΔN/HCN) of the reaction was about 1.3. In the N–C_2D_4 system, CD_2 and CD_2N were found as the reactive intermediates. We suggested a mechanism different from that proposed by Herron.

On the reaction of N with C_2H_4, the following reaction mechanism was postulated by Herron:[1]

$$N + C_2H_4 \longrightarrow HCN + CH_3 \quad (1)$$

$$N + CH_3 \longrightarrow HCN + 2H \quad (2)$$

$$H + C_2H_4 \longrightarrow C_2H_5 \quad (3)$$

$$H + C_2H_5 \longrightarrow 2CH_3 \quad (4)$$

$$N + C_2H_5 \longrightarrow NH + C_2H_4 \quad (5)$$

$$N + NH \longrightarrow N_2 + H \quad (6)$$

The features of this mechanism are that the amount of CH_3 produced through the reaction depends on the competition between H and N for C_2H_5 and that the formation of HCN is mainly due to the reaction of N with CH_3. This list of reactions is not meant to be inclusive. For instance, it does not account for the recombination of CH_3 which proceeds with a rate constant of 3.6×10^{-11} ml/molecure·s.[2] This rate is so fast that, in order to produce HCN in Reaction 2, the rate constant, k_{N-CH_3}, between N and CH_3 needs to have a value greater than 10^{-11} ml/molecule·s. The value of k_{N-CH_3} has not been evaluated experimentally; however, 10^{-11} ml/molecule·s for k_{N-CH_3} seems to be too large.

In order to define the intermediate compounds and to determine the reaction mechanism, the reactions of N with C_2H_4 and C_2D_4 were reinvestigated.

Experimental

The apparatus and procedure were almost the same as those used by Herron and Klein.[3] N was generated by a 2450 MHz electrodeless discharge in N_2. A reaction tube of Pyrex glass, 20 mm i.d. and 100 cm long, formed a part of the fast-flow system. C_2H_4 and C_2D_4 diluted with Ar were added through a movable central inlet tube in the reaction tube. At the end of the reaction tube, the sampling orifice of a mass spectrometer was located. The mass spectra were recorded on a quadrupole mass spectrometer. The pressure in the reaction tube was about 4 Torr and the linear velocity of the gas was 200 cm/s. The materials used in this experiment were research-grade. The observation was carried out at room temperature. The initial concentration of N was measured by means of a gas-phase titration with NO.[4] The HCN was determined by titration with $AgNO_3$. The reaction time was calculated from the linear velocity of the gas and from the distance between the tip of the inlet of the hydrocarbon reactants and the sampling orifice.

The quantities of reactants and products were followed by the ion current with ionization by 23 eV. As to the intermediate products, assuming that they had the same mass spectrometric sensitivity as N, the quantities were determined. The measurements were done in both the N–C_2H_4 and N–C_2D_4 systems.

Results and Discussion

Substracting the background ion current from the observed value in the reaction, the detectable species and their concentrations are determined. The atoms and free radicals investigated in these observations are as follows:

m/e	14	15	16	27	29	30	34
Species	N,CH_2	CH_3	CD_2	HCN	C_2H_5	CD_2N,C_2H_6	C_2D_5

In the N–C_2H_4 system, the quantities of species of *m/e* 14, 15 and 27 are plotted as functions of the reaction time. They are shown in Fig. 1. In this figure, the quantity of species of *m/e* 14 shows a maximum at the beginning of the reaction, and the maximum moves in the direction of the increase in the reaction time with the decrease in the initial concentration of C_2H_4. This fact suggests that CH_2 is formed in the course of the reaction. The quantities of species of *m/e* 15 and 29 produced through the reactions are small and about equal in amount. The species of *m/e* 30 is not found as a product. The stoichiometry of the reaction (ΔN/HCN) is evaluated to be about 1.3.

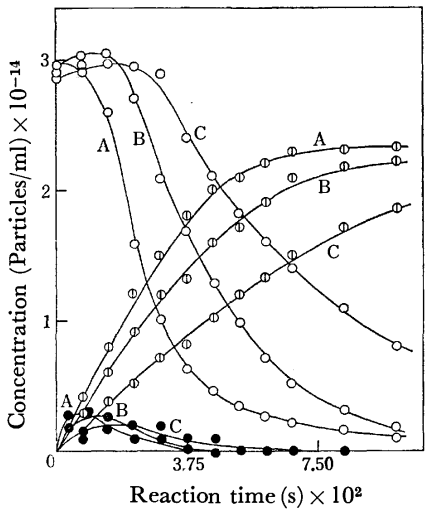

Fig. 1. Kinetics of the reaction of N with C_2H_4.
○: *m/e* 14, ◑: *m/e* 27, ●: *m/e* 15.

Initial concentration

	$[N]_0\times10^{-14}$ atoms ml^{-1}	$[C_2H_4]_0\times10^{-14}$ molecules ml^{-1}
A	2.90	3.25
B	2.90	2.66
C	2·90	1.42

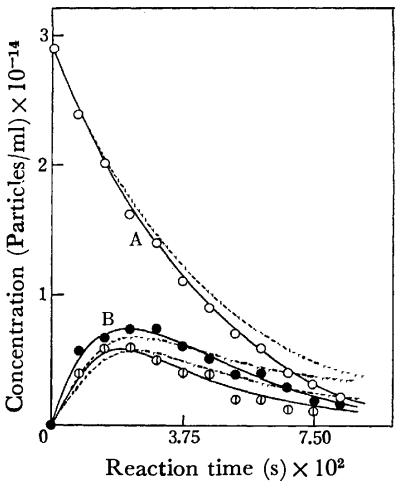

Fig. 2. Kinetics of the reaction of N with C_2D_4.
○: *m/e* 14, ●: *m/e* 16, ◑: *m/e* 30.
Initial concentration
$[N]_0$: 2.90×10^{14} atoms ml^{-1},
$[C_2D_4]_0$: 2.66×10^{14} molecules ml^{-1}.
——: Experimental results, ·····: calculated results.

As a supplementary method to determine the formation of CH_2, the reaction was studied in the N–C_2D_4 system. The results are shown in Fig. 2 in the same manner as in Fig. 1. In this case, the decrease in the quantity of the species of *m/e* 14 with the reaction time is shown by a monotonous curve, Curve A, and the concentrations of species of *m/e* 16 and 30 are varied with the time, having these maximum values in the course of the reaction, shown as Curve B. No species of *m/e* 34 was found.

At the same initial concentrations of reactions in the N–C_2H_4 and N–C_2D_4 systems, assuming that the quantity of N (*m/e* 14) in the N–C_2H_4 system represented as a function of the reaction time is equal to that in the N–C_2D_4 system, we can estimate the quantity of CH_2 produced in the N–C_2H_4 system. It is shown in Fig. 3. It is impossible, though, to measure the quantity of CH_2N produced in the reaction, because CH_2N has the same *m/e* value as N_2.

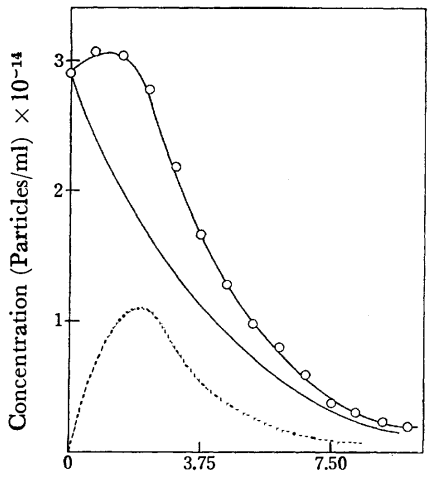

Fig. 3. Kinetics of the reaction of N with C_2H_4.
–○–: *m/e* 14, ——: *m/e* 14 (N),
----: *m/e* 14 (estimated value of CH_2).
Initial concentration
$[N]_0$: 2.90×10^{14} atoms ml^{-1},
$[C_2H_4]_0$: 2.66×10^{14} molecules ml^{-1}.

Comparing these results obtained in the N–C_2H_4 system with those in the N–C_2D_4 system, we can suggest that CH_2 and CH_2N are produced as intermediate compounds in the course of reactions in the N–C_2H_4 system.

In the N–C_2H_4 system, it seems possible that CH_2 and CH_2N might be formed at the beginning of the reaction:

$$N + C_2H_4 \longrightarrow CH_2 + CH_2N \quad (1)$$
$$N + CH_2 \longrightarrow CH_2N \quad (2)$$
$$CH_2N \longrightarrow HCN + H \quad (3)$$
$$N + CH_2N \longrightarrow N_2 + CH_2 \quad (4)$$
$$H + CH_2N \longrightarrow H_2 + HCN \quad (5)$$
$$CH_2 + CH_2 \longrightarrow C_2H_4 \quad (6)$$
$$N + N + M \longrightarrow N_2 + M \quad (7)$$
$$H + H + M \longrightarrow H_2 + M \quad (8)$$
$$CH_2 + \text{wall} \longrightarrow \frac{1}{2}C_2H_4 \quad (9)$$

In the N–C_2D_4 system, the reaction mechanism is almost the same as that considered in the N–C_2H_4 system. The main feature of the mechanism is the competition reaction between N and H for CH_2N in Steps 4 and 5. This competition roughly determines whether N will be detected as HCN or will remain undetected as N_2. An increase in the concentration of H would favor Reaction 5 relative to Reaction 4 and, hence, bring about a decrease in the ΔN/HCN ratio. It is known that the ΔN/HCN ratio approaches unity[1] with the introduction of H into the reactor.

Table 1. Evaluated rate constants in the N–C_2D_4 system (at room temperature)

Step	k ml molecule^{-1} s^{-1}	Step	k ml molecule^{-1} s^{-1}
1	1.0×10^{-13}	6	2.0×10^{-12}
2	5.0×10^{-14}	7	5.0×10^{-16}
3	6.0×10	8	5.0×10^{-16}
4	5.0×10^{-14}	9	3.0×10
5	1.0×10^{-14}		

In the N–C_2D_4 system, the rate constants are evaluated by a computer simulation of the experimental data. The rate constants for the reactions are listed in Table 1. With these values, the quantities of N, CD_2, and CD_2N are calculated as function of the reaction time. The results are shown by dotted lines in Fig. 2. The curves are seen to be identical within the limits of experimental uncertainty.

Self-Consistent Renormalized RPA: The Electronic Excited States of Benzene in the INDO/S Method

Hirotoshi Ito and Yasumasa J. I'Haya

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182

(Received January 24, 1977)

Synopsis. A self-consistent renormalized RPA and its approximated analogues are compared in the calculation of the electronic excited states of benzene by using the INDO/S method.

In previous papers,[1,2] we have presented an approximate self-consistent renormalized random-phase approximation (SCrRPA) with the CNDO/S method and shown that making use of a well-correlated ground state charge density the rRPA equation can be self-consistently solved though approximately. In this note, we like to present the result of the complete SCrRPA calculation for benzene and compare it with those of the approximate SCrRPA ones. We use the INDO/S basis, since the CNDO method has a deficiency that energy separations between the singlet and triplet levels of both $\sigma\pi^*$ and $\pi\sigma^*$ states are calculated to be zero in high-symmetry molecules like benzene.

For the real basis, the rRPA equation is given by[3,4]

$$\begin{pmatrix} \tilde{A}(S) & -\tilde{B}(S) \\ -\tilde{B}^*(S) & -\tilde{A}^*(S) \end{pmatrix} \begin{pmatrix} \tilde{Y}(\lambda S) \\ \tilde{Z}(\lambda S) \end{pmatrix} = \omega_\lambda \begin{pmatrix} (\tilde{Y}\lambda S) \\ \tilde{Z}(\lambda S) \end{pmatrix}, \quad (1)$$

where

$$\tilde{A}_{\mathrm{ph,vf}}(S) = \delta_{\mathrm{pv}}\delta_{\mathrm{hf}}(E_{\mathrm{p}}-E_{\mathrm{h}}) + (1/2)(\rho_{\mathrm{h}}-\rho_{\mathrm{p}})^{1/2}(\rho_{\mathrm{f}}-\rho_{\mathrm{v}})^{1/2} \times (A^0_{\mathrm{ph,vf}}(S)-\delta_{\mathrm{pv}}\delta_{\mathrm{hf}}(E_{\mathrm{h}}-E_{\mathrm{p}})),$$

$$\tilde{B}_{\mathrm{ph,vf}}(S) = (1/2)(\rho_{\mathrm{h}}-\rho_{\mathrm{p}})^{1/2}(\rho_{\mathrm{f}}-\rho_{\mathrm{v}})^{1/2}B^0_{\mathrm{ph,vf}}(S).$$

A^0 and B^0 are the well-known normal RPA(nRPA) matrices for the HF ground state, E_i the ith HF orbital energy, ρ_i the charge density (non-integral occupation number) of the ith MO in the correlated RPA ground state. Subscripts *ph* and *vf* are used for the particle-hole and vacant-filled MO pair states, respectively. We are interested in the cases except $\rho_{\mathrm{h}}=\rho_{\mathrm{f}}=2$ and $\rho_{\mathrm{p}}=\rho_{\mathrm{v}}=0$ (nRPA), which correspond to a higher RPA and are referred to merely as RPA in the following. The renormalized transition amplitudes matrices $\tilde{\boldsymbol{Y}}$ and $\tilde{\boldsymbol{Z}}$ are given by the unrenormalized ones $\boldsymbol{Y}$ and $\boldsymbol{Z}$.[5] The λth excited state creation operator $O^+_{\lambda SM}$ which satisfies $O^+_{\lambda SM}|0\rangle=|\lambda SM\rangle$ is expanded in terms of the singly excited unrenormalized amplitudes $Y_{\mathrm{ph}}(\lambda S)$ and $Z_{\mathrm{ph}}(\lambda S)$ and the particle-hole pair creation and annihilation operators $C^+_{\mathrm{ph}}(SM)$ and $C_{\mathrm{ph}}(\overline{SM})$. The correlated RPA ground state is unknown before solving Eq. 1 and is assumed to take the form

$$|0\rangle = N_0 e^U|\mathrm{HF}\rangle \quad (2)$$

with

$$U = (1/2)\sum_{S=0,1}\sum_{i}\sum_{\mathrm{ph}\in\Gamma_i}\sum_{\mathrm{vf}\in\Gamma_i} C_{\mathrm{ph,vf}}(S)C^+_{\mathrm{ph}}(S0)C^+_{\mathrm{vf}}(\overline{S0}), \quad (3)$$

$$\Gamma_i \times \Gamma_i \in \Gamma_{\mathrm{HF}},$$

Γ being denote the irreducible representation of a certain set of the excited states under consideration, and N_0 the normalization constant. $C_{\mathrm{ph,vf}}(S)$ in Eq. 3 is then given by a solution of the equation

$$O_{\lambda SM}|0\rangle = 0 \quad (\text{all } \lambda SM), \quad (4)$$

leading to the equation $\boldsymbol{Z}=\boldsymbol{CY}$ and/or $\tilde{\boldsymbol{Z}}=\boldsymbol{C}\tilde{\boldsymbol{Y}}$. Assuming the starting value of $C_{\mathrm{ph,vf}}(S)$ under this constraint, we can determine by an iterative prodecure the occupation number of the ith MO averaged with respect to a trial ground state. Invoking the identity, operator $\times e^U$, we can derive the correlated charge densities of the uth particle and oth hole states averaged according to the correlated RPA ground state as follows;

$$\rho_{\mathrm{u}} = 2^{1/2}\langle 0|C^+_{\mathrm{uu}}(00)|0\rangle = (1/2)\sum_{s}\sum_{\mathrm{h}}\sum_{\mathrm{vf}}|C_{\mathrm{uh,vf}}(S)|^2, \quad (\text{for all } \Gamma_i) \quad (5)$$

and

$$\rho_{\mathrm{o}} = 2^{1/2}\langle 0|C^+_{\mathrm{oo}}(00)|0\rangle = 2-(1/2)\sum_{s}\sum_{\mathrm{p}}\sum_{\mathrm{vf}}|C_{\mathrm{po,vf}}(S)|^2. \quad (\text{for all } \Gamma_i) \quad (6)$$

In order to circumbent the triplet instability at an initial stage, we start a computation by making use of the following trial correlated coefficients of a ground state wavefunction,[6] so as to satisfy the equation $\tilde{\boldsymbol{Z}}=\boldsymbol{C}\tilde{\boldsymbol{Y}}$;

$$C^{\mathrm{trial}}_{\mathrm{ph,vf}}(S) = (E_{\mathrm{p}}+E_{\mathrm{v}}-E_{\mathrm{h}}-E_{\mathrm{f}})^{-1}B^0_{\mathrm{ph,vf}}(S). \quad (7)$$

We can then iteratively determine new renormalized coefficients as[7,8]

$$\boldsymbol{C}^{\mathrm{new}}(S) \approx (\tilde{\boldsymbol{Y}}^{-1}(S)\tilde{\boldsymbol{Z}}(S))^{\mathrm{trial}}. \quad (8)$$

The convergence criterion used is $|\rho_i(\mathrm{new})-\rho_i(\mathrm{old})|\leqq 10^{-5}$ (i for all the MO's).

The summation over i of Γ_i indicates that the excited states of different symmetry groups affect the correlated ground state. Therefore, if possible, it is better to solve such an rRPA equation that all the possible particle-hole pair configurations are involved in a one matrix, without paying attention to a special symmetry representation. At least for the RPA equation of limited particle-hole pairs this may play a considerable role in the computation of ρ's.

In our previous SCF calculation of benzene by the INDO/S method,[9] the ground-state electronic configuration was given by

$$(1a_{1g})^2(2,3e_{1u})^4(4,5e_{2g})^4(6a_{1g})^2(7b_{1u})^2(8b_{2u})^2(9,10e_{1u})^4 (11\pi a_{2u})^2(12,13e_{2g})^4(14\pi,15\pi e_{1g})^4(16\pi,17\pi e_{2u})^0 (18b_{2u})^0(19\pi b_{2g})^0(20,21e_{2g})^0(22a_{1g})^0(23,24e_{1u})^0 (25b_{1u})^0(26,27e_{1u})^0(28,29e_{2g})^0(30a_{1g})^0.$$

From this, we take *thirty* particle-hole pair configuration, in which we promote an electron from *five* MO's below the highest occupied orbital to *six* MO's above the lowest unoccupied orbital. Then, we solve a 60×60 matrix of the rRPA equation involving $\sigma\pi^*$, $\pi\sigma^*$, $\sigma\sigma^*$, and $\pi\pi^*$ particle-hole pairs, iteratively. For comparison,

a) See the footnotes of Table 1.

we calculate pure $\pi\pi^*$ excitations taking nine $\pi\pi^*$ particle-hole pair configurations.

Without solving Eq. 1 iteratively, the coefficients $C_{\mathrm{ph,vf}}(S)$ can be approximately determined either (i) by using the perturbation theory in the CI language to include doubly excited configurations which mix with the HF ground state (referred to as rRPA/CI), or (ii) by relating $C_{\mathrm{ph.vf}}(S)$ with $B^0_{\mathrm{ph.vf}}(S)$ matrix in the basis of Rayleigh-Schrödinger perturbation theory (Eq. 7) (as rRPA/RS). With the trial RPA ground state to be obtained in such ways, we can bypass the problem of solving Eq. 4, in case when the trial coefficients satisfy Eq. 4 approximately. These methods have been called an approximate SCrRPA in our previous paper.[5]

The numerical results are summarized in Tables 1 and 2. The SCrRPA results satisfactorily agree with the experimental values except for the lowest $^3B_{1u}$ state. The self-consistency has been attained after nine iterations. It should be mentioned that we have fixed the correlated charge densities as $\rho(\mathrm{new}')=(1/2)\times\{\rho(\mathrm{new})+\rho(\mathrm{old})\}$ at every iterative step in order to get a quick convergence. It is observed that the following relationship holds for most cases:

$$\omega(\mathrm{rRPA}) > \omega(\mathrm{TDA}) > \omega(\mathrm{nRPA}) \quad (9)$$

or in more detail

$$\omega(\mathrm{SCrRPA}) > \omega(\mathrm{rRPA/CI}) > \omega(\mathrm{rRPA/RS}) > \omega(\mathrm{TDA}) > \omega(\mathrm{nRPA}). \quad (10)$$

The $^1E_{1u}$ and $^3B_{1u}$ transition energies fall out of this sequence, for which $\omega(\mathrm{TDA})>\omega(\mathrm{SCrRPA})$. It has been numerically ascertained that this sequence also holds for the electronic excited states of DNA bases in the CNDO/S method.[5] The treatment including σ electrons (Table 1) gives rise to the considerable lowering of the transition energy and oscillator strength of the dipole-allowed $^1E_{1u}$ transition, compared with that of the π electrons only (Table 2). This can be ascribed to the sigma-pi coupling; *i.e.*, the so-called dynamical screening effect of the $\pi\pi^*$ transition by σ electrons which has been pointed out previously by several authors.[10,11]

The sequence of Eq. 10 and Table 1 indicates that rRPA/CI promises to give a good approximation to SCrRPA, and that the correlated ground-state wavefunction (HF+doubly excited CI's) takes in the triplet correlation effect through $B^0_{\mathrm{ph.vf}}(S)$ matrix elements in a somewhat skillful way. It might also be concluded that to solve the nRPA equation with a partinent choice of parameters in the semiempirical MO methods rivals a higher RPA, fully accounting the correlation effect in large conjugated systems. This can also be visualized in a Green's function language; *i.e.*, the use of the CNDO/S and/or INDO/S parametrization together with nRPA has a drastic effect upon the self-energy part, leaving the zero-order polarization propagator unaffected.[12]

Comparison of the present semiempirical results with the *ab initio* ones computed by Rose *et al.*[10] suggests that if the present restricted configurational space is extended the lowest $^3B_{1u}$ state will be refined. This possibility can be observed from the inspection of Tables 1 and 2, where the sigma-pi coupling effect puts the lowest $^3B_{1u}$ state a little bit up. Extensive calculation including a larger particle-hole pair space is now in progress.

The Behavior of Aerosol OT in Organic Solvents

Masaharu UENO and Hiroshi KISHIMOTO

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received January 28, 1977)

Synopsis. The parameters concerning the micelle formation of Aerosol OT in organic solvents were determined. In order to determine CMC, an apparatus was constructed for the measurement of the interfacial tension between mercury and organic media. The association numbers were estimated by vapor pressure depression measurements.

The behavior of oil-soluble surfactants in organic solvents has been studied from the stand-point of micelle formation,[1,2] but more data are needed for its elucidation as compared with the behavior of surfactants in water. We have carried out the following experiments on Aerosol OT (sodium 1,2-bis(2-ethylhexyloxycarbonyl)ethane-1-sulfonate, American Cyanamid Co., Ltd.) in benzene, cyclohexane, and carbon tetrachloride. In order to determine CMC, a new method and apparatus based on interfacial tension measurement between mercury and organic media were devised. The number average association numbers were estimated by vapor pressure depression measurements.

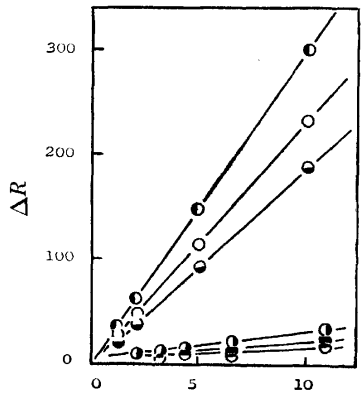

Fig. 1. Thermister bridge reading (ΔR) *vs.* solute concentration in benzene.

●: Aerosol OT as solute at 37 °C.
◓: Aerosol OT as solute at 45 °C.
◐: Triphehylmethane as solute at 25 °C.
○: Triphenylmethane as solute at 37 °C.
◒: Triphenylmethane as solute at 45 °C.

(1) Vapor Pressure Depression Measurement: For this a molecular weight apparatus (Hitachi-Perkin-Elmer, Type 115) was used. The thermister bridge reading, ΔR, which depends only on the vapor pressure, is plotted against the solute concentration in benzene in Fig. 1. The results for other solvents are similar to those shown in Fig. 1. In each measurement, triphenylmethane was used as a standard substance for calibration. The relationship of thermister bridge reading, ΔR, *vs.* solute concentration in benzene was linear above 1×10^{-3} mol kg^{-1}. As the ratio of the slope for Aerosol OT to that for reference, the number average association number was estimated to be 13. The values in other solvents are summarized in Table 1. The temperatue dependence of association numbers was small.

Table 1. CMC and association number (N) of Aerosol OT in organic solvents

		CMC (mol kg^{-1})	N

	45 °C		17

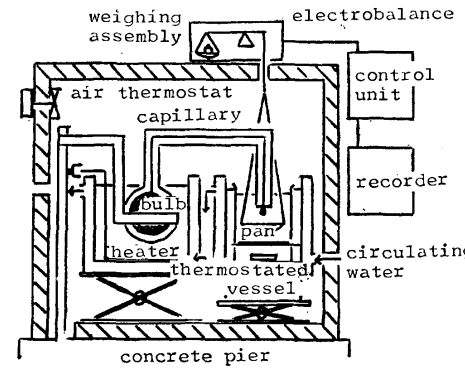

Fig. 2. The apparatus for the interfacial tension measurement between mercury and organic media.

(2) Interfacial Tension Measurements between Mercury and Organic Media: The measurements were carried out by the drop weight method. The apparatus is shown in Fig. 2. In order to drop mercury without vibration, the thermal expansion of mercury was employed according to the method of Sonntag and Strenge.[3] The bulb is heated just a little for the mercury to expand and fall into the platinum pan after a long interval. The weight of falling mercury drop in the organic media containing various amounts of Aerosol OT was measured *in situ* with the accuracy of $\pm 10^{-5}$ g by means of the load added to the electrobalance (Cahn RG Electrobalance, Cahn Instrument Co., Ltd.) holding the pan. The interfacial tension was calculated according to the method of Harkins and Brown.[4] The radius of the tip (0.045 cm) was obtained by calculation using the data[5] between mercury and

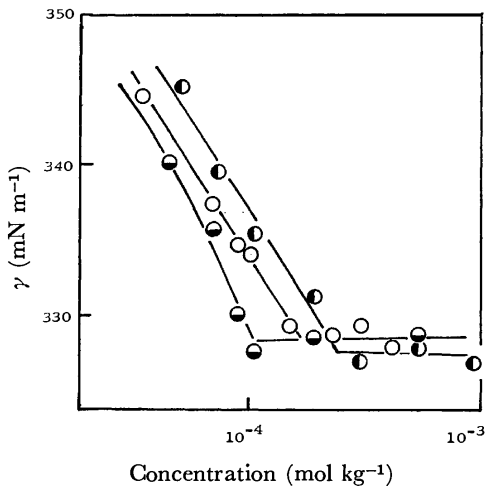

Fig. 3. Interfacial tension between mercury and carbon tetrachloride *vs.* solute concentration in logarithmic scale.
◒: at 25°C. ○: at 30°C. ◐: at 37°C.

benzene. As shown in Fig. 3, the plots of interfacial tension between mercury and carbon tetrachloride solution show a behavior similar to that of the surface or interfacial tension of aqueous solution of surfactant near CMC. From the equation of adsorption isotherm (Eq. 1), surface (or interfacial) tension against solute concentration in logarithmic scale breaks when the relationship between activity and concentration of surface active solute has a breaking point or CMC.

$$-d\gamma = RT\Gamma d \ln a_1 \quad (1)$$

Since the depression (Fig. 3) indicates the surface activity of solute to mercury/organic medium interface and relatively large association numbers were obtained (Table 1), we identified the breaking points in Fig. 3 as the CMC of Aerosol OT in carbon tetrachloride, also given in Table 1 with those in benzene and cyclohexane.

The Microwave Spectra, Molecular Structures, and Quadrupole Coupling Constants of Methyltrichlorosilane and Trichlorosilane

Harutoshi TAKEO and Chi MATSUMURA

National Chemical Laboratory for Industry, Honmachi-1, Shibuya-ku, Tokyo 151

(Received January 31, 1977)

Synopsis. The microwave spectrum of methyltrichlorosilane has been re-examined in order to determine the precise molecular structure by observing the spectra due to the isotopic species. The previously reported value of the nuclear quadrupole coupling constant of trichlorosilane has been corrected by the reinvestigation of the hyperfine structure.

The microwave spectra of methyltrichlorosilane and its isotopic species have been investigated first by Mockler *et al.*[1] and recently by Mitzlaff *et al.*[2] In both cases, the spectrum arising from the silicon isotopic species has not been observed, and therefore the precise molecular structure has not been determined. We reinvestigated the microwave spectrum of this molecule in order to obtain the spectrum of the silicon isotopic species, and succeeded in observing it. Furthermore, we found the spectrum of the ^{13}C species at frequencies different from the previously reported values. In their paper[2] Mitzlaff *et al.* have also reported the quadrupole coupling constant of trichlorosilane. Their value, however, seemed too small compared with that of chlorosilane. We reinvestigated the spectrum of this molecule and corrected their value. In this paper we report the newly determined molecular constants and the precise molecular structures of methyltrichlorosilane and trichlorosilane.

Methyltrichlorosilane. The spectra were examined with a conventional 100 kHz Stark-modulation spectrometer, with a 3-m X-band waveguide cell. Both ^{29}Si and ^{13}C species were measured in natural abundances. To obtain the spectrum due to the ^{29}Si species, the regions near the high-J transitions of normal species were searched, because the low-J transitions have fairly broad linewidths and low intensities. Very low modulation voltages (*ca.* 10 V/cm) were used to prevent disturbances by the Stark lobes of the normal species and its strong excited states. The transitions of the ^{29}Si species were assigned on the basis of the intensity ratio to the lines of normal species, and the assignment was confirmed by the measurement of the intensity change between room and Dry Ice temperatures. Unfortunately, the line due to the ^{30}Si species could not be obtained, since the predicted positions were overlapped by the strong vibrational satellites. The observed transition frequencies are listed in Table 1. For the precise determination of the rotational constants, several transitions of normal species including low-J transitions were also measured. Since the observed peak positions differ from the hypothetical unsplit values because of the hyperfine structure due to the chlorine nuclei, the observed peak values were corrected to unsplit values[3] using the calculated frequency differences on the assumptions of $eqQ=-40$ MHz and $\angle ClSiCl=108.6°$. The rotational constant and the centrifugal distortion constant, D_J, were obtained by a least-squares fit of all the corrected transition frequencies in Table 1. The rotational constant of the ^{29}Si species listed in the table was determined from the high-J transitions, assuming the same D_J value.

The obtained rotational constants lead to the C–Si bond distance of 1.865 Å by the use of Kraitchman's equation, if the previously reported rotational constant of ^{13}C species[2] is included. This C–Si distance, which is close to that of methylsilane (1.867 Å), seemed too long considering that the substitution of the hydrogen atoms by the halogen atoms should cause a fairly large bong shortening;[4] in fact the C–Si distance in CH_3SiF_3 is 1.812 Å. Therefore, a reinvestigation of the spectrum of the ^{13}C species was undertaken. We tried to observe a few high-J transitions of the ^{13}C species, but we could not find them at the frequencies calculated from the B value reported in Ref. 2 except for the $J=9\leftarrow8$ transition, which is the only transition observed by Mitzlaff *et al.* Furthermore, the intensity measurements at room and Dry Ice temperatures showed that it was impossible that this transition belongs to the ground state line. Presumably it is to be ascribed to one of the excited vibrational states of the $^{35}Cl_2{}^{37}Cl$ species, since this region is near to its ground state transitions. We found several lines which should be ascribed to the spectrum of the ^{13}C species at slightly lower frequencies, as calculated from the reported value. The assignment was confirmed by a comparison of the intensities with those of the ^{29}Si species and by the change in the intensities between room and Dry Ice temperatures. The molecular structure, except for the methyl group, was determined by the substitution method, as Table 1 shows. The coordinates of the chlorine atoms were obtained by combining the A and B rotational constants of $^{35}Cl_2{}^{37}Cl$ species and the B rotational constants of the $^{35}Cl_3$ and $^{37}Cl_3$ species with a modification of Kraitchman's equation.[5] The obtained Si–C bond distance shows a clear bond shortening upon the substitution of chlorine atoms for hydrogen atoms attached to the silicon. The amount of the shortening is about a half of that by fluorine substitution, as has been estimated from the results for other molecules.[6]

Trichlorosilane. Mitzlaff *et al.* have also investigated the microwave spectrum of trichlorosilane. They have reported the eQV_{zz} to be +12.8 MHz, which was obtained from the measurement of the two strong lines in the $J=2\leftarrow1$ transition on the basis of the theory presented by Wolfe.[7] This theory, however, was found to be incorrect and was amended by Wolf *et al.* recently.[3] If we analyze the reported frequencies by means of the new theory, the eQV_{zz} of trichlorosilane becomes 8

MHz; this leads to −25 MHz of eQV_{aa}, by assuming ∠ClSiCl = 109.6°. This eQV_{aa} seemed too small compared with the eQq of −40 MHz in SiH_3Cl. Therefore, we reinvestigated the hyperfine structure of trichlorosilane.

The $J=2\leftarrow1$ transition was measured carefully and repeatedly, and two strong components were found at the values calculated from the high-J transitions and a reasonable eQV_{aa} value. We did not find strong lines at the frequencies reported by Mitzlaff *et al.* From these two components, the eQV_{zz} is determined to be 12 MHz, which leads to an eQV_{aa} value of −37 MHz. This value is quite reasonable as the quadrupole coupling constant of the chlorine atom attached to silicon. The rotational constants obtained by Mitzlaff *et al.* were also refined using the quadrupole coupling constant newly determined by the method used for the analysis of methyltrichlorosilane; they were determined to be as listed in the table. The molecular structure was also recalculated with these rotational constants by means of the substitution method. However, the change in the molecular structure is small, since the changes in the rotational constants are very small.

The Coercive Force of γ-Fe_2O_3 Prepared from γ-FeOOH

Shuichi HAMADA and Kenshi KUMA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received October 22, 1976)

Synopsis. The γ-Fe_2O_3 with a high coercive force was prepared by reducing the acicular γ-FeOOH at 300 °C and by then reoxidizing it at 250 °C. A conversion from γ-FeOOH to γ-Fe_2O_3 at lower temperatures was effective in obtaining acicular particles without pores because of the large mobilities of ions in the crystal.

The γ-Fe_2O_3 with a high coercive force has usually been prepared from the acicular α-FeOOH through complex processes: dehydration, reduction, and reoxidation, especially by the heat treatment of the α-Fe_2O_3 before the reduction.[1] These three processes were also effective in obtaining the γ-Fe_2O_3 with a high coercive force when the γ-FeOOH was used as the starting material, while the γ-Fe_2O_3 obtained by only the dehydration of the γ-FeOOH exhibited a very low coercive force. In this work, the effect of this heat treatment on the coercive force was examined for the γ-FeOOH.

Experimental

Two kinds of γ-FeOOH were prepared as the starting materials by the method described in a previous paper.[2] Three kinds of α-FeOOH were also prepared by the method reported by Nakajima *et al.*[1] in order to compare them with the γ-FeOOH as follows: a solution of iron(II) chloride or sulfate was made alkaline (pH 13.1—13.7) after the dissolved oxygen had been removed, and then the iron(II) ions were oxidized at 45 °C by bubbling air at the flow rate of 2.5 l/min, while the pH value of the reaction mixture was not controlled. The preparative conditions are shown as follows:

Sample No.	Product	Initial concn mol/l	pH	Temp °C
L-1	γ-FeOOH	0.064 ($FeCl_2$)	6.5	25
L-2	γ-FeOOH	0.096 ($FeCl_2$)	6.5	25
G-1	α-FeOOH	0.064 ($FeCl_2$)	13.7→12.8	45
G-2	α-FeOOH	0.064 ($FeSO_4$)	13.5→12.5	45
G-3	α-FeOOH	0.257 ($FeCl_2$)	13.1→12.2	45

These iron(III) hydroxide oxides were then converted to γ-Fe_2O_3 in the following manners:

Process 1.

$$\left.\begin{matrix}\gamma\text{-FeOOH}\\ \alpha\text{-FeOOH}\end{matrix}\right\} \xrightarrow[440\text{—}800\text{°C (60 min)}]{\text{Heat treatment, in air}} \alpha\text{-}Fe_2O_3$$

$$\xrightarrow[360\text{°C (30 min)}]{\text{Reduction in } H_2} Fe_3O_4 \xrightarrow[250\text{°C (30 min)}]{\text{Reoxidation in air}} \gamma\text{-}Fe_2O_3$$

Process 2.

$$\left.\begin{matrix}\gamma\text{-FeOOH}\\ \alpha\text{-FeOOH}\end{matrix}\right\} \xrightarrow[300\text{—}340\text{°C (30 min)}]{\text{Dehydration and reduction in } H_2}$$

$$Fe_3O_4 \xrightarrow[250\text{°C (30 min)}]{\text{Reoxidation in air}} \gamma\text{-}Fe_2O_3$$

The coercive force, ${}_BH_C$ (maximum applied field; H_m= 2 KOe), of the γ-Fe_2O_3 was measured at 25 °C at the packing density of 0.1 with an automatic B-H curve tracer, model BHH-5, from the Riken Denshi Co.; the packing density, p, was expressed as follows: $p=d/d_0$, where d is the apparent density of a cylindrical specimen, and d_0, the intrinsic density of γ-Fe_2O_3 (5.24 g/cm³).[3]

The particles were observed at magnifications of from 24000 to 36000 times with an electron microscope, model HU-200F, from Hitachi Seisakusho.

The crystallite sizes of the heat-treated α-Fe_2O_3 were estimated by the Scherrer method[4] at the directions of [012], [104], [110], and [113] by using Fe$K\alpha$ radiation.

Results and Discussion

Figure 1 shows the relationships between the coercive force of the γ-Fe_2O_3 and the reduction temperature in Process 2 or the heat-treatment temperature in Process 1. The γ-Fe_2O_3 was found to exhibit sufficiently high coercive forces when the samples were prepared from the γ-FeOOH by Process 2 at the reduction temperature of 300 °C. The γ-FeOOH was not reduced completely into the Fe_3O_4 below 300 °C. The coercive force, however, was lowered abruptly with the rise in the reduction temperature in Process 2 and in the heat-treatment temperature in Process 1. On the contrary, a remarkable effect on the coercive force was observed by heat treatment at 600 or 700 °C in Process 1 when the α-FeOOH was used as the starting material. This effect has previously been reported by Nakajima *et al.*[1]

The DTA pattern of the γ-FeOOH showed an endothermic peak near 270 °C based on the dehydration of structural water and an exothermic peak near 440 °C based on the transformation to α-Fe_2O_3 from γ-Fe_2O_3.

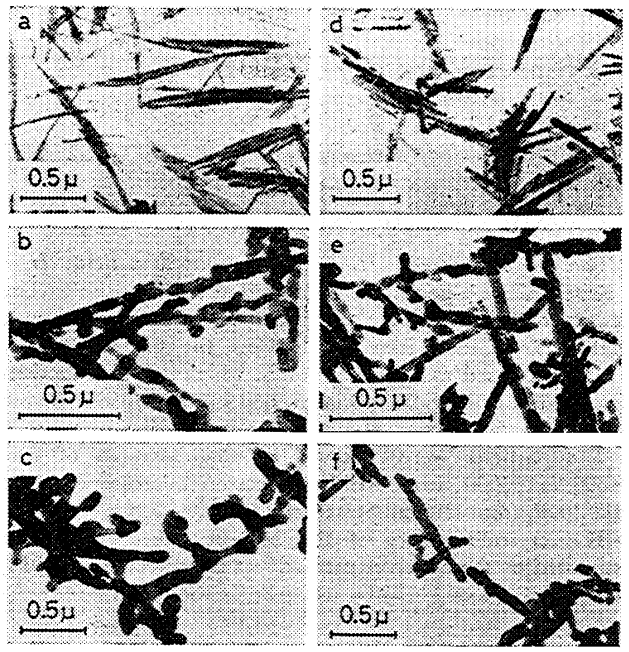

Fig. 2. Particles of γ-, α-FeOOH and γ-Fe_2O_3.
a: γ-FeOOH(L-1), b: γ-Fe_2O_3, reduced L-1 at 300°C in Process 2, c: γ-Fe_2O_3, heat-treated L-1 at 600°C in Process 1, d: α-FeOOH(G-1), e: γ-Fe_2O_3 reduced G-1 at 300°C in Process 2, f: γ-Fe_2O_3, heat-treated G-1 at 600°C in Process 1.

Figures 2a and 2d show the original γ- and α-FeOOH particles with acicular shapes. When the γ-Fe_2O_3 was obtained only by the dehydration at 300 °C, countless number of fine pores were observed, while the particles kept the original shapes of the γ-FeOOH. This γ-Fe_2O_3 exhibited very low values of the coercive force, 126 and 129 Oe.

Figure 2b shows the γ-Fe_2O_3 particles obtained from the γ-FeOOH by Process 2. Few pores were observed in the particles thus prepared, while the shapes were deformed in some degree compared with the original ones. Much deformation and sintering were, however, observed among the particles prepared by the heat treatment at 600 °C in Process 1, as is shown in Fig. 2c. On the contrary, several pores were observed in the particles, though there was less deformation, when the γ-Fe_2O_3 was prepared from the α-FeOOH by Process 2, as is shown in Fig. 2e. The pores, however, were scarcely detectable by heat treatment, especially at 600 or 700 °C, in Process 1, as is shown in Fig. 2f. Remarkable deformation and sintering among the particles were observed by heat treatment at 800 °C, even when the α-FeOOH was used as the starting material as well as the γ-FeOOH.

In the acicular particles of γ-Fe_2O_3 with a single domain size,[5] the shape anisotropy is well known to dominate their coercive force; $H_c=(1/2)\Delta N \cdot M_s$ in random-oriented powders,[6] where ΔN is the difference between the demagnetizing factors along the minor and major axes of the acicular particles, which can take 2π as the maximum value in the CGS-Gauss unit system,

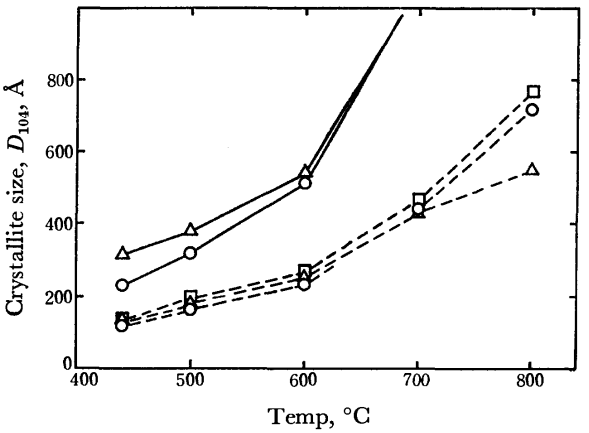

Fig. 3. Plots of crystallite size, D_{104}, of α-Fe_2O_3 against heat-treatment temperature.
—○—: L-1, —△—: L-2, ---○---: G-1, ---△---: G-2, ---□---: G-3.

and M_s, the saturation magnetization. Therefore, the coercive force depends mainly on the acicularity of the particles. On the other hand, the existence of pores in the particles lowers the coercive force.[5] The coercive force of the γ-Fe_2O_3 varies reasonably according to the degree of deformation and the existence of the pores, as Figs. 1 and 2 show.

The crystallite size, D_{104}, for [104] of the α-Fe_2O_3, the intermediate in Process 1, grew as the heat-treatment temperature increased, as is shown in Fig. 3. The crystallite of the α-Fe_2O_3 obtained from the γ-FeOOH grew much extensively than that obtained from the α-FeOOH. Similar tendencies were confirmed for the other directions of the α-Fe_2O_3 lattice. Such a clear difference between them is considered to be due not to the absorbed Cl^- ions, but to the difference in the structural arrays of ions in the iron(III) hydroxide oxides, judging from the corresponding results between the G-1 and G-2 samples. This fact indicates that the ions in the lattice moved easily when the α-Fe_2O_3 was obtained from the γ-FeOOH. It can be considered that the large mobilities of ions in the lattice carry a positive effect which serves to abolish the pores, but also a negative effect which serves to keep the acicularity of the particles, when the γ-FeOOH is converted into the γ-Fe_2O_3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (6), 1637—1638 (1977)

Preparation and the Acid Hydrolysis of *N*-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetate Complex of Di-μ-oxo-bis(oxomolybdenum(V))

Yoichi SASAKI and Tomoji S. MORITA

Chemistry Department, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received October 30, 1976)

Synopsis. A hedta (H_3hedta = *N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′-triacetic acid) complex of molybdenum(V), Mo_2O_4(hedta)$(H_2O)^-$, has been prepared and characterized. The rate of acid hydrolysis of this complex in an aqueous perchloric acid solution ($[H^+]=0.5$—2.0 mol dm^{-3}; $I=2.0$) is of similar magnitude to that of $Mo_2O_4(edta)^{2-}$ (H_4edta = ethylenediaminetetraacetic acid), increasing with increase in $[H^+]$.

A dimeric unit, $Mo_2O_4^{2+}$, di-μ-oxo-bis(oxomolybdenum(V)) is common in molybdenum(V) chemistry in aqueous media. The ligand substitution reactions on the $Mo_2O_4^{2+}$ center have been studied with various ligands such as $edta^{4-}$,[1] ida^{2-} (H_2ida = iminodiacetic acid),[2] $C_2O_4^{2-}$,[2] and NCS^-.[3] The results show that the rate of substitution reactions on the $Mo_2O_4^{2+}$ center varies remarkably with ligand, spanning six orders of magnitude. The number of ligating atoms of a ligand, and/or the location on the oxo metal moiety at which substitution occurs (*cis* or *trans* to oxo ligand) would be important factors controlling the substitution rate. In order to obtain further information on the substitution reactions on the $Mo_2O_4^{2+}$ center, we used $hedta^{3-}$ as a ligand, the structure of which is similar to that of $edta^{4-}$.

Experimental

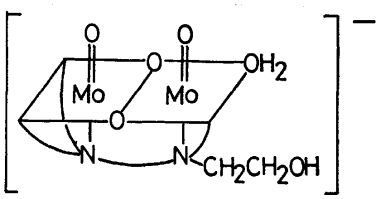
Material. *Sodium Salt of Aqua*[N-*(2-hydroxyethyl)ethylenediamine*-N,N′,N′-*triacetato*]-*di*-μ-*oxo*-*bis*(*oxomolybdate(V)*) *Complex*, *Na*[Mo_2O_4(*hedta*)(H_2O)]·$2H_2O$: Nine grams of dipyridinium pentachlorooxomolybdate(V), $(pyH)_2[MoOCl_5]$,[4] and 2.8 g of H_3hedta were dissolved in 100 cm^3 of water. The solution was warmed at 90 °C for about 3 h with constant stirring, and then cooled to room temperature. To this solution were added 5 g of $NaClO_4$ and then 100 cm^3 of ethanol, and the solution was kept in a refrigerator for a day. Orange crystals were filtered off, washed with ethanol, and dried in air. They were recrystallized from water. Found: C, 19.53; H, 3.62; N, 4.74; Mo, 31.15%. Calcd for $C_{10}H_{21}N_2O_{11}NaMo_2$: C, 19.75; H, 3.48; N, 4.61; Mo, 31.55%.

Measurements. Ultraviolet and visible absorption spectra were recorded with a Hitachi 323 spectrophotometer. For kinetic studies, a Hitachi 124 spectrophotometer with a Hitachi recorder QPD-34 was used. The acid dissociation constant of the complex was determined by pH titration with a pH-meter E300B of Metrohm Herisau. The meter was standardized against perchloric acid solutions in 2 M $LiClO_4$ (M = mol dm^{-3}) so that H^+ concentration rather than activity was measured. Thermal decomposition curves of the complexes were obtained with a Shinku Riko TGD-3000 differential thermal microbalance with a heating rate of 10 K/min.

Kinetic Runs. All the solutions used for kinetic runs were prethermostatted at a given temperature for at least 20 min. A solution of the complex was mixed with a perchloric acid solution for starting the kinetic run. The solutions contained appropriate amounts of lithium perchlorate to adjust ionic strength. The change of absorbance was followed at a fixed wavelength (mostly at 295 nm). Rate constants were evaluated from the first-order plots of absorbance changes. Since the aqua ion of molybdenum(V), $Mo_2O_4(aq)^{2+}$,[5] undergoes slow oxidation by oxygen,[1] some runs were carried out under a nitrogen atmosphere.

Results and Discussion

It was suggested that the two peaks at *ca.* 300 nm ($\varepsilon = 3000$—10000 l mol^{-1} cm^{-1} per dimer) and at *ca.* 390 nm (100—400) are characteristic of complexes containing the dimeric unit, $Mo_2O_4^{2+}$.[2,6] The present complex has two peaks in these two regions, indicating the presence of $Mo_2O_4^{2+}$ group. The complex liberates two water molecules at 20—90 °C and one at 100—140 °C. We assigned the former to the water of crystallization and the latter to the coordinated water. This was supported by the patterns of thermal decomposition of other molybdenum(V) complexes, $Ba[Mo_2O_4(C_2O_4)_2(H_2O)_2]\cdot 3H_2O$ (liberate three water molecules at 20—100 °C and two at 140—180 °C)[7] and $Na[Mo_2O_4(edta)]$ (no weight loss up to 370 °C). On the basis of these findings, the structure of the present complex is considered as follows.



The pH of an aqueous solution of the hedta complex (*ca.* 5×10^{-3} mol dm^{-3}) is *ca.* 2. The solution was titrate with 0.1 M sodium hydroxide. There was one sharp break for one equivalent sodium hydroxide to the complex, no further inflection being observed up to pH = 11. The sharp break would be associated with the deprotonation of the coordinated water as follows.

$$\underset{\text{(aqua form)}}{Mo_2O_4(hedta)(H_2O)^-} \overset{K_a}{\rightleftharpoons} \underset{\text{(hydroxo form)}}{Mo_2O_4(hedta)(OH)^{2-}} + H^+ \qquad (1)$$

The pK_a value for this process was estimated from the pH titration curve; 3.02 ± 0.03 at 25 °C and $I=2.0$ M. The absorption spectrum of the aqua complex was measured in 0.1 M perchloric acid in the presence of the ligand added in order to avoid dissociation of the ligand from the complex. The spectrum of the hydroxo

complex was measured in an acetate buffer at pH 5. Peak positions (and intensities) are 383 nm (ε=300) and 295 nm (9200) for the aqua complex, and 393 nm (300) and 305 nm (9500) for the hydroxo complex.

In acidic aqueous solution, the complex decomposed to give $Mo_2O_4(aq)^{2+}$ and the protonated forms of the free ligand.

$$Mo_2O_4(hedta)(H_2O)^- + nH^+ \xrightarrow{k_f} Mo_2O_4(aq)^{2+} + H_nhedta^{(3-n)-} \quad (2)$$

The rate of this reaction was measured at $[H^+]$=0.5—2.0 M, I=2.0 M and at 20—35 °C. (The k_f was not obtained accurately at $[H^+]<0.5$ M since reaction (2) did not proceed completely.) The observed first-order rate constant (k_f) was of similar magnitude to that of the acid hydrolysis of $Mo_2O_4(edta)^{2-}$,[1] and much smaller than that of other complexes of $Mo_2O_4^{2+}$.[2,3] The dependence of k_f on $[H^+]$ is not simple (Fig. 1).

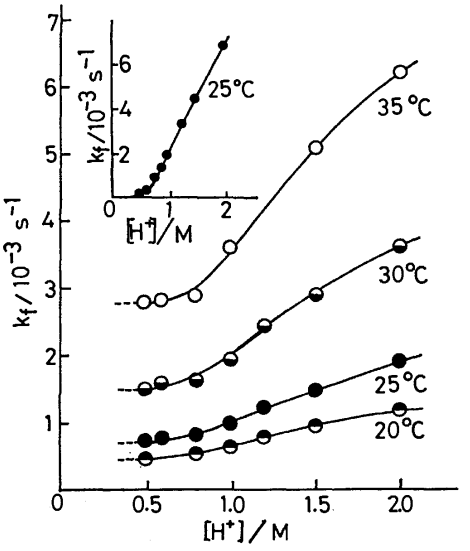


Fig. 1. $[H^+]$-Dependence of k_f for the acid hydrolysis of $Mo_2O_4(hedta)(H_2O)^-$ in aqueous perchloric acid solutions. Each point represents the average of at least 3 runs. The inset is a similar plot for $Mo_2O_4(edta)^{2-}$.[2]

As in the case of the edta complex, k_f increases when $[H^+]$ exceeds 1.0 M. There is a slight tendency for the k_f value to saturate when $[H^+]$ increases. For the edta complex, it was suggested from the analysis of $[H^+]$ dependence that the cleavage of the last acetate group, *viz.* the dissociation of H_3edta^- (uni- or bidentate), is rate-determining, its rate being of similar magnitude to that of the overall rate.[1] A similar rate-determining process would be possible for the hedta complex at least in a higher $[H^+]$ region. It should be noted that the multi-step preequilibria would not be necessarily responsible for the slow rate of acid hydrolysis of these complexes.

In a lower $[H^+]$ region ($[H^+]<1.0$ M), unlike the edta complex, k_f does not approach zero. The difference can be explained by considering equilibrium (1) of the hedta complex. If both aqua and hydroxo forms of the complex contribute to the dissociation reaction (rate constants are expressed as k_{H_2O} and k_{OH}, respectively), k_f is written as follows under the conditions $K_a \ll [H^+]$.

$$k_f = K_a k_{OH}[H^+]^{-1} + k_{H_2O} \quad (3)$$

Here both k_{H_2O} and k_{OH} may change with $[H^+]$. No path corresponding to k_{OH} is expected for the edta complex in which no coordinated water exists. No discussion will be given on the mechanism as for the edta complex,[1] since we cannot estimate each term of (3) accurately.

The sequence of the apparent rate of acid hydrolysis of various ligands from the $Mo_2O_4^{2+}$ center is given in the following, with order of rate (s^{-1}) at 25 °C and at $[H^+]$=1.0 M in parentheses.[1-3]

$$edta^{4-} \approx hedta^{3-} < ida^{2-} < C_2O_4^{2-} < NCS^-$$
$$(10^{-3}) \quad (10^{-3}) \quad (10^{-2} \text{ at } 0°C) \quad (10^0) \quad (10^2)$$

The rate decreases remarkably as the dentate number of the ligand increases.

We are grateful to Professor K. Saito for his helpful discussion and to Dr. K. Nagase for the measurement of thermal decomposition of the complexes and his helpful discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (6), 1639—1640 (1977)

A Palladium-catalyzed Alkoxycarbonylation of Ethynylmercury Compounds

Akira KASAHARA, Taeko IZUMI, and Akio SUZUKI

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received November 15, 1976)

Synopsis. Bis(phenylethynyl)mercury reacts with carbon monoxide and alcohol at room temperature in the presence of palladium(II) salt to form dialkyl phenylmaleate, accompanied by small amounts of alkyl phenylpropiolate and dialkyl phenylfumarate. An alkoxycarbonylation at 100 °C afforded a trialkoxycarbonylation product, accompanied by dialkoxycarbonylation products. The alkoxycarbonylation of bis(ethylethynyl)mercury proceeds similarly.

The palladium-promoted alkoxycarbonylation of alkyl,[1] aryl,[2] and vinyl-mercury compounds[3] has been described. Heck[4] has also reported the palladium-catalyzed carbonylation of olefins and acetylenes with methoxycarbonylmercuric chloride. In this paper, we wish to report the palladium-catalyzed alkoxycarbonylation of bis(phenylethynyl)mercury (**1**) and bis(ethylethynyl)mercury (**2**).

The methoxycarbonylation of **1** was carried out at room temperature under a carbon monoxide pressure of 20 atm in the presence of lithium tetrachloropalladate(II) in methanol to give dimethyl phenylmaleate (**3a**) as the main product. Small amounts of methyl phenylpropiolate (**4a**) and dimethyl phenylfumarate (**5a**) were also produced. The methoxycarbonylation of **1** at 100 °C resulted in the formation of **3a**, **4a**, **5a**, and trimethyl 2-phenyl-1,1,2-ethanetricarboxylate (**6a**). In ethanol, the corresponding ethyl esters were obtained. Similarly, the alkoxycarbonylation of **2** at room temperature afforded dialkoxycarbonylated products, and the reaction at 100 °C led to the formation of trialkoxycarbonylation products. These results are presented in Table 1.

The palladium-catalyzed alkoxycarbonylation of **1** and **2** undoubtedly proceeds by means of an initial mercury-palladium exchange reaction, carbon monoxide insertion into the resultant ethynyl palladium compounds, and subsequent alcoholysis to give **4** and [HPdCl]. The formation of **3** and **5** could be explained by considering the re-addition of [HPdCl] to **4**. A proposed reaction mechanism is shown in Scheme 1. That the elimination and addition of [HPdCl] on unsaturated carbon-carbon bond proceed *via* a *cis* stereochemistry is well-known.[5] Consequently, the

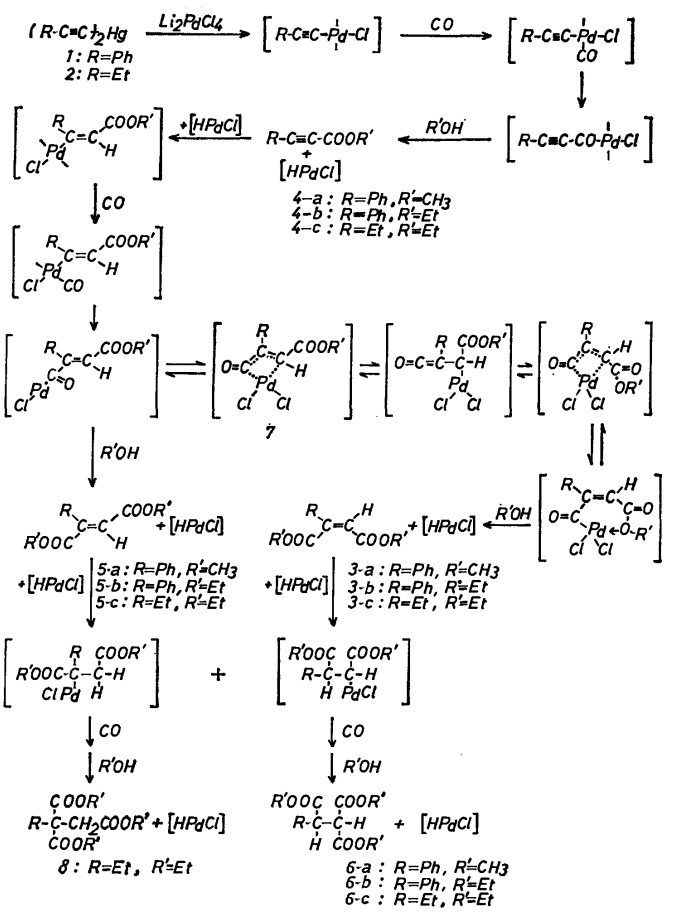
a) Yields are based on the mercurial used.



Scheme 1.

reaction pathway of the formation of **5** may very probably include a *cis* addition of [HPdCl] to **4**, but the *cis-trans* isomerization (**5**→**3**) can not be explained only in terms of a palladium-hydride addition-elimination mechanism in the present case. Furthermore, the product, **5**, did not isomerize to **3** under the present reaction conditions.

Schoenberg *et al.*[6] reported that the palladium-catalyzed butoxycarbonylation of (*Z*)-β-bromostyrene gave a mixture of (*E*)- and (*Z*)-butyl cinnamate, and, with reference to the formation of the (*E*)-isomer, they suggested that the *cis-trans* isomerization proceeds probably *via* a ionic carbene-type intermediate or a π-acryloylpalladium-type intermediate. As they have pointed out, the mechanism of the formation of **3** probably involves a π-acryloylpalladium-type intermediate (**7**), and the overwhelming formation of **3** compared with **5** is consistent with this process, because a coordination of the palladium atom to the alkoxycarbonyl group occurs. In the alkoxycarbonylation of **1** and **2** at 100 °C, the formation of **6** and/or **8** proceeds *via* a re-addition of [HPdCl] to **3** and/or **5**. **8a** and **8b** could not be detected because of their poor yields.

Experimental

Materials. The bis(phenylethynyl)mercury (**1**) and bis(ethylethynyl)mercury (**2**) were prepared according to the method described by Johnson and McEwen.[7]

General Procedure for the Alkoxycarbonylation of 1 and 2.

A lithium tetrachloropalladate(II) solution was prepared by stirring 0.82 g (20 mmol) of lithium chloride with 1.77 g (10 mmol) of palladium(II) chloride overnight at room temperature in 80 ml of methanol or ethanol. In this solution, 5 mmol of mercurial (**1** or **2**) was then carbonylated under a carbon monoxide pressure of 20 atm for 6 h with shaking. The reaction mixture was then filtered to remove a precipitated palladium and distilled under reduced pressure to remove the solvent. The products were isolated by preparative gas chromatography or column chromatography (Al_2O_3–hexane), analysed by gas chromatography on 1-m SE 30 (5% on celite) column with a Hitachi K-53 gas-chromatograph, and identified by comparing their retention time and IR and NMR spectra with those of an authentic sample. The reactions carried out are listed in Table 1.

Additions of Dibenzyl Selenoxides and Selenonium Ylides to an Electron-Deficient Ethylene and Acetylene

Seizo TAMAGAKI, Ryuji AKATSUKA, and Seizi KOZUKA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received November 19, 1976)

Synopsis. Dibenzyl selenoxides reacted with dimethyl acetylenedicarboxylate and tetracyanoethylene to give new ylides, while the reaction of selenonium ylides produced new ylides or cyclopropane derivatives.

Although the reactions of selenoxides and selenomium ylides have attracted attention over the last few years,[1] no systematic study seems to have appeared on their reactions with unsaturated C–C bonds. We wish to report on the reactions obtained by use of dimethyl acetylenedicarboxylate and tetracyanoethylene (TCNE) representing an electron-deficient olefin and acetylene, respectively.

Results and Discussion

A number of addition reactions to dimethyl acetylenedicarboxylate affording ylides, known as the reverse Wittig reactions, were reported with regard to various oxides such as amine and arsine oxides,[2,3] and sulfoxides.[4] We have observed new examples of such reaction type, giving new ylides.

The reaction of dibenzyl selenoxide (**1**) with the carboxylate ester was found to produce the corresponding stable ylide (**2**) in a good yield.[5] The structure of the product was easily assigned on the basis of

$$(PhCH_2)_2Se{=}O + (MeOOCC{\equiv})_2 \xrightarrow[2\,h,\ quant.]{r.t.,\ CHCl_3} (PhCH_2)_2Se{=}C(COOMe)(CCOOMe)(=O)$$

(**1**) (**2**)

some spectral evidence and by the independent synthesis from the correspoding selenoxide and the active methylene compound.[6]

$$(PhCH_2)_2Se{=}O + MeOOCCH_2COCOOMe \xrightarrow[5\,min]{r.t.,\ CHCl_3} \mathbf{2}$$

Similarly, dibenzylselenonium cyano(methoxycarbonyl)methylides, **3a** and **3b**, were allowed to react with the carboxylate at room temperature in $CHCl_3$ to afford the unstable oily ylides, **4a** and **4b**, respectively. The NMR spectrum of **4a** in $CDCl_3$ shows a multiplet between 3 and 4 ppm due to the three methoxycarbonyl methyl groups and a quartet centered at 4.2 ppm due to the benzyl protons characteristic of the dibenzylselenonium ylide, its IR spectrum displaying moderately intense bands at 2200, 1655, and 1720 cm^{-1} due to the C=N and C=O's, respectively.

$$R_2Se{=}C(CN)(COOMe) + (MeOOCC{\equiv})_2$$

3a: R = $PhCH_2$
3b: R = $MeC_6H_4CH_2$

$$\xrightarrow[24\,h]{r.t.,\ CHCl_3} R_2Se{=}C(COOMe)(CCOOMe)(C(=O)CCN)$$

4a: 78%
4b: 90%

A suspension of TCNE in a $CHCl_3$ solution of **3a** at room temperature immediately afforded a violet-colored solution. On being stirred vigorously for 1 h, the cyclopropane derivative (**5**) was obtained as a precipitate in an excellent yield.

$$R_2Se{=}C(CN)(COOMe) + TCNE$$

3a (**3b**)

$$\xrightarrow[2\,h]{r.t.,\ CHCl_3} R_2Se + (NC)_2C(COOMe)C(CN)_2$$

82% (90%) **5**: 98% (82%)

Trost reported on a similar decomposition reaction of dimethylsulfonium ylides in the presence of olefins to yield cyclopropane derivatives.[7] The results can thus be explained in terms of initial addition of the starting ylide to the olefinic carbon atom to form the zwitter-ion intermediate, with subsequent three-membered ring closure on the ylide carbon to give the products.

The treatment of dibenzyl selenoxide with an equivalent of TCNE at room temperature in polar aprotic solvents such as CH_3CN and THF afforded the precipitation of dibenzylselenonium dicyanomethylide (**6**). Yields greater than 14% were not attained.
(*Reaction A*)

$$R_2Se{=}O + TCNE \xrightarrow[30\,min]{r.t.,}$$

1a: $PhCH_2$
1b: $MeC_6H_4CH_2$

$$R_2Se{=}C(CN)_2 + RSeCN + R_2Se$$

(**6**) (**7**)

From the reaction mixture two additional products were isolated and identified as selenocyanates (**7**) and selenides. The results are summarized in Table 1 together with those for reaction B of the selenides with TCNE oxide (Table 2).[8]

(*Reaction B*)

$$R_2Se + (NC)_2C\overset{O}{\diagdown\diagup}C(CN)_2 \longrightarrow R_2Se{=}C(CN)_2 + RSeCN$$

Several pathways to these products are possible. One of them is the formation of a selenide and TCNE oxide at the initial stage.

$$R_2Se{=}O + TCNE \longrightarrow R_2\overset{\oplus}{S}e{-}O{-}C(CN)_2\,{}^{\ominus}\!\overset{|}{C}(CN)_2$$

$$\longrightarrow Re_2Se + (NC)_2C\overset{O}{\diagdown\diagup}C(CN)_2$$

The mechanism bringing about such a cyclization has been found in the reaction of ylides affording cyclopropane derivatives, referred to above. However, this pathway is highly unlikely and, even if operative, would be a minor one. The two related reactions A, and B, give the same products having markedly different ratios in the distribution of ylides and selenocyanates especially in non-polar solvents such as benzene and $CHCl_3$. The ylide formation is nil in the reaction of a selenoxide with TCNE, while it exceeds 50% in that of selenides with TCNE oxide, the yields of the selenocyanates being far higher in the latter in all solvents employed.

The results can only be rationalized by the assumption that the reaction proceeds *via* at least two common intermediates which are not so rapidly equilibrated as to give an identical product distribution for the two reactions.

Table 1. Reaction (A) of dibenzyl selenoxides with TCNE at room temperature

(Received December 8, 1976)

Synopsis. A number of 3-(alkoxycarbonylmethylthio)-coumarins (**3**) were prepared by reactions of thiocyanatoacetic esters (**1**) with salicylaldehydes in the presence of potassium carbonate.

In previous papers,[1-5] it has been shown that thiocyanatoacetic ester (**1**) is available for the synthesis of sulfur-containing heterocycles. Here, the direct synthesis of the hitherto unknown coumarin derivatives from **1** and salicylaldehydes are reported. The reaction of **1b** with salicylaldehyde was carried out in the presence of potassium carbonate at room temperature giving 3-(methoxycarbonylmethylthio)coumarin (**3b**) as the major product and 3,3′-thiodicoumarin (**4**) as a minor product. The structural elucidation of the products are based on elemental analysis and spectral studies. Further confirmation of the structure (**3b**) was made by a comparison with an authentic sample prepared from 2-mercapto-3-(*o*-hydroxyphenyl)acrylic acid (**5**) and **1b** or ethyl chloroacetate (**6**). On the other hand, **4** was also obtained by the reaction of **3** with **2** in the presence of potassium carbonate. In this reaction, **1** and substituted salicylaldehydes also gave similar coumarin derivatives (**3**), but the product corresponding to **4** could not be found.

Although an investigation of the reaction mechanism was not undertaken, the reaction is considered to proceed

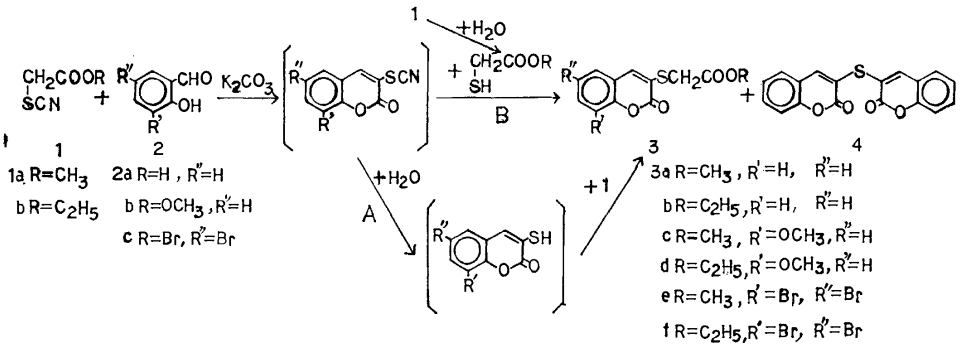
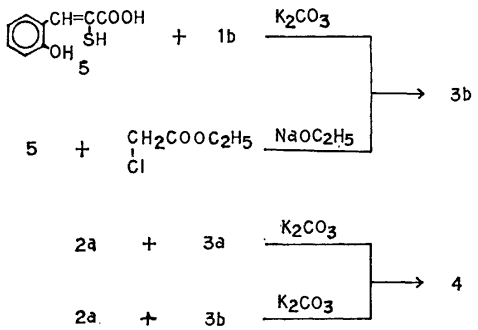


Scheme 1.



Scheme 2.

via route A or B. Product **4** may form upon further condensation of **3** with **2** as depicted above.

Experimental

*Preparation of **3** and **4**.* A mixture of **1** (0.02 mol), salicylaldehyde (0.01 mol) and potassium carbonate (0.01 mol) was stirred in 10 ml of acetone at room temperature for 6—7 h. Upon cooling to room temperature, crystals precipitated; the precipitate was washed with water, dried, and then washed with hot ethanol. The residue was recrystallized from dioxane to give **4**. To the ethanolic washing was added a small amount of water, and then the solution, when allowed to stand overnight at room temperature, gave pale yellow crystals (**3**) which were recrystallized from alcohol. Substituted coumarines (**3c—f**) are also obtained similarly, but no compound of type **4** could be found.

Preparation of 2-Mercapto-3-(o-hydroxyphenyl)acrylic Acid (5). The title acid was prepared by a modification of the reported method.[6] 5-(*o*-Hydroxybenzylidene)-2-thioxothiazolidin-4-one (0.01 mol) was hydrolyzed with 8% sodium hydroxide (20 ml) by heating to 50—60 °C. The mixture was well stirred until a clear solution was obtained. After cooling with an ice-salt mixture, the solution was acidified with 3M-hydrochloric acid, and the stirring was continued for 30 min. The resulting acid was washed with water, dried in air, and recrystallized from dichloromethane.

Preparation of an Authentic Sample from 2-Mercapto-3-(o-hydroxyphenyl)acrylic Acid (5) and Ethyl Chloroacetate. To a solution of sodium 2-mercapto-3-(*o*-hydroxyphenyl)acrylate (0.005 mol) in absolute ethanol (10 ml) was added ethyl chloroacetate (0.005 mol). The solution was stirred for 4 h and then allowed to stand overnight in a refrigerator. The resulting crystals were collected on a filter, washed with water, and dried. Recrystallization from ethanol gave **3b**; yield: 0.6 g (45%); mp 113—114 °C.

*Preparation of an Authentic Sample from 2-Mercapto-3-(o-hydroxyphenyl)acrylic Acid and **1b**.* A mixture of 2-mercapto-3-(*o*-hydroxyphenyl)acrylic acid (0.005 mol), **1b** (0.005 mol) and potassium carbonate (0.005 mol) in acetone (10 ml) was stirred at room temperature for 5 h. After the mixture was allowed to stand overnight in a refrigerator, crystalline matter separated out. Recrystallization from ethanol gave **3b**; yield: 0.5 g (38%); mp 113—114 °C.

*Preparation of **4** from **3** and Salicylaldehyde.* A mixture of **3** (0.005 mol), salicylaldehyde (0.005 mol), and potassium carbonate (0.005 mol) in acetone (10 ml) was stirred for 1 h. Crystalline matter precipitated out during the reaction; this was recrystallized from dioxane affording **4**; yield 0.9 g (56%) from **3a** and salicylaldehyde; 1.1 g (69%) from **3b** and salicylaldehyde: mp 271—272 °C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (6), 1645—1646 (1977)

A New Synthetic Approach to Esters of β-Keto Thiocarboxylic *S*-Acids

Toshimitsu WAKUI, Haruzo YAMAGUCHI, and Shinichi MOTOKI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received December 23, 1976)

Synopsis. Esters of β-keto thiocarboxylic *S*-acids (**5**) were synthesized from *S*-ethyl bromothioacetate (**1**), through a reaction sequence involving the reduction of sulfonium ylides (**4**) with zinc in acetic acid.

S-Ethyl acetothioacetate (**5a**) reacts with mercury(II) oxide to afford diacetylacetone and mercury(II) ethanethiolate, along with carbon dioxide.[1] Since the corresponding oxygen ester dose not react with mercury(II) oxide in a similar way, we thought it of interest to develop a general method of preparing esters of β-keto thiocarboxylic *S*-acids.

Esters of acetothioacetic *S*-acid, representative esters of β-keto thiocarboxylic *S*-acid, are readily prepared by the Claisen ester condensation[2] or by the reaction of alkanethiols with diketene.[1,3] However, no other esters of β-keto thiocarboxylic *S*-acids can be obtained. In this paper, we wish to report a new general route for the preparation of esters of β-keto thiocarboxylic *S*-acids (**5**) starting from *S*-ethyl bromothioacetate (**1**).

S-Ethyl bromothioacetate **1**, obtained from bromoacetyl bromide and ethanethiol in the presence of triethylamine, was treated with dimethyl sulfide at room temperature for 24 h to afford [(ethylthio)carbonylmethyl]dimethylsulfonium bromide (**2**, 70%), which was deprotonated with sodium hydride in a tetrahydrofuran solution affording [(ethylthio)carbonylmethylene]dimethylsulfurane (**3**, 85%). **3** was obtained as a yellow solid (mp 50—52 °C) after evaporation of the solvent, while sulfonium ylide of the corresponding oxygen ester was obtained as a yellowish oily substance.[4] Acylation of **3** with a half-equivalent amount of acid chlorides gave new ylides, [[(ethylthio)carbonyl]acyl(or benzoyl)methylene]dimethylsulfuranes (**4**, Table 1). Ylides **4** were readily reduced with zinc in acetic acid as in the case of sulfoxonium ylides,[5] affording esters of β-keto thiocarboxylic *S*-acids (**5**, R=alkyl, Table 2)

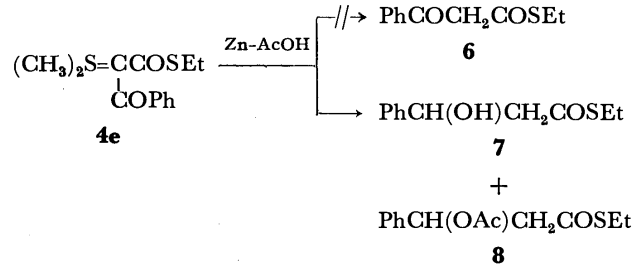
a) Based on sulfonium ylides **4** used. b) In liquid film. c) Estimated from integration of the NMR signal. d) Lit,[2] 30.8%.

in moderate yields.

On the other hand, reduction of ylide **4e** (R=Ph) did not give the expected compound *S*-ethyl benzoylthioacetate (**6**), but afforded *S*-ethyl 3-hydroxy-3-phenylpropanethioate (**7**, 15%) and *S*-ethyl 3-acetoxy-3-phenylpropanethioate (**8**, 38%).



Experimental

All the melting points and boiling points are uncorrected. The IR spectra were obtained on a Hitachi EPI-G2 spectrometer and the NMR spectra on a Varian A-60 spectrometer, using tetramethylsilane as an internal standard. Mass spectra were taken with a Hitachi RMU-7M mass spectrometer at 70 eV by a direct insertion technique.

S-Ethyl Bromothioacetate (1). Bromoacetyl bromide (101 g, 0.5 mol) was added dropwise over a 1 h-period at 0—5 °C with stirring to a solution of ethanethiol (37.3 g, 0.6 mol) and triethylamine (50.5 g, 0.5 mol) in ether (200 ml). The reaction mixture was stirred at the same temperature for 5 h and then poured into water (200 ml). The organic layer was separated and the aqueous layer was extracted with ether. The combined ether solution was dried over anhydrous sodium sulfate and evaporated under reduced pressure. Distillation of the residue gave 65.9 g (72%) of **1**. Bp 60 °C/5 Torr; IR (liquid film): 1685 cm^{-1} (COS). Found: S, 17.63%. Calcd for C_4H_7OSBr: S, 17.51%.

Sulfonium Bromide 2. Treatment of *S*-ethyl ester **1** (54.9 g, 0.3 mol) with dimethyl sulfide (27.9 g, 0.45 mol) at room temperature for 24 h afforded 51.5 g (70%) of **2**. Recrystallization from ether-ethanol gave a pure sample. Mp 117—118 °C; IR (Nujol): 1670 cm^{-1} (COS); NMR (trifluoroacetic acid): δ 1.36 (t, 3H), 3.15 (s, 6H), 3.16 (q, 2H), 4.75 (s, 2H). Found: C, 26.15%. Calcd for $C_6H_{13}OS_2Br$: S, 25.97%.

Sulfonium Ylide 3. Sodium hydride (5.76 g, 0.2 mol), free of mineral oil, was added portionwise with stirring to a suspension of sulfonium bromide **2** (49 g, 0.2 mol) in tetrahydrofuran (150 ml). After stirring for 10 h at room temperature, the precipitate was filtered off and the filtrate was concentrated to afford 27.9 g (85%) of crude ylide **3**. Mp 50—52 °C; IR (Nujol): 1600 cm^{-1} (COS); NMR ($CDCl_3$): δ 1.24 (t, 3H), 2.83 (q, 2H), 2.88 (s, 6H), 3.58 (s, 1H).

General Procedure for Acylation of 3. An acid chloride (0.1 mol) was added dropwise to a solution of *S*-ethyl ester ylide **3** (0.2 mol) in benzene (250 ml), the temperature being kept below 30 °C by occasional cooling. After being stirred at room temperature for 24 h, the precipitate ([(ethylthio)-carbonylmethyl] dimethylsulfonium chloride, mp 150—151 °C) was filtered off. Addition of hexane to the filtrate resulted in the precipitation of a new ylide **4** (Table 1).

General Procedure for Reduction of 4. Zinc powder (0.25 mol) was added in many portions to a solution of a ylide **4** (0.05 mol) in acetic acid (50 ml), the temperature being kept below 20 °C with external cooling. The reaction mixture was stirred at 15—20 °C for 30 h. The insoluble material was filtered and washed with ether. Concentration of the filtrate afforded a crude product, which was purified by distillation. Yields and physical properties of **5** thus obtained are shown in Table 2. The NMR data (in CCl_4, δ) of **5** are as follows: **5a**: 1.25 (t), 1.92 (s), 2.19 (s), 2.90 (q), 3.63 (s), 5.43 (s), 12.66 (s). **5b**: 1.02 (t), 1.27 (t), 2.20 (q), 2.54 (q), 2.90 (q), 3.59 (s), 5.38 (s), 12.70 (s). **5c**:[6] 1.08 (d), 1.14 (d), 1.28 (t), 2.89 (q), 3.60 (s), 5.32 (s), 12.73 (s). **5d**: 1.15 (s), 1.28 (t), 2.89 (q), 3.65 (s), 5.37 (s), 12.94 (s).

Reduction of 4e. Zinc powder (4.9 g, 75 mmol) was added portionwise at 15—20 °C with stirring to a solution of **4e** (1.34 g, 5 mmol) in acetic acid (20 ml). The reaction mixture was stirred at the same temperature for 24 h and the insoluble material was filtered off. Concentration of the filtrate gave a colorless liquid which was subjected to column chromatography on silica gel (Wakogel C-200) to afford 158 mg (15%) of **7** and 475 mg (38%) of **8** by eluting with benzene. **7**: IR (liquid film): 1685 cm^{-1} (COS); NMR (CCl_4): δ 1.22 (t, 3H), 2.83 (d, 2H), 2.84 (q, 2H), 3.31 (s, 1H), 5.06 (t, 1H), 7.22 (s, 5H); MS *m/e*, 210 (M^+). **8**: IR (liqid film): 1745 (COO) and 1685 cm^{-1} (COS); NMR (CCl_4): δ 1.18 (t, 3H), 1.98 (s, 3H), 2.81 (m, 4H), 6.20 (m, 1H), 7.28 (s, 5H); MS *m/e* 252 (M^+).

Tungsten Hexachloride-catalyzed Decomposition of Diazo Compounds. A Novel Oxazole Synthesis

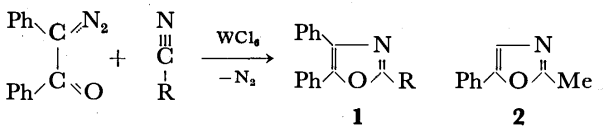
Katuzi KITATANI, Tamejiro HIYAMA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received January 28, 1977)

Synopsis. Benzoylphenyldiazomethane and diazoacetophenone react with several nitriles in the presence of WCl_6 catalyst to produce 2-substituted 4,5-diphenyloxazoles (**1a—d**) and 2-methyl-5-phenyloxazole (**2**) in good yields. The remarkable catalysis is ascribed to the good affinity of tungsten with carbenes. The catalytic decomposition of diphenyldiazomethane yields diphenylcarbenium ion, which is transformed into triarylmethanes in aromatic solvents.

Lewis acid-catalyzed decomposition of diazo compounds gives intermediary carbene complexes, which are often too much reactive for synthetic applications.[1] The requisite selectivity should be attained by proper choice of the metal salt catalyst in which the central metal atom has good affinity with carbenes and therefore stabilizing the intermediate carbene complex. Among them tungsten salt seems to be a candidate since low valent tungstens give very stable carbene complexes.[2] On this account we have investigated the catalytic activity of tungsten hexachloride in the thermal decomposition of diazo compounds.

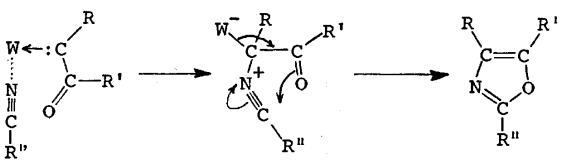
Decomposition of Diazo Ketones in Nitriles. When benzoylphenyldiazomethane was treated with tungsten hexachloride suspended in benzonitrile at room temperature, immediate decomposition occurred. Work-up gave 2,4,5-triphenyloxazole (**1a**). Similarly upon the catalytic decomposition in several nitriles the diazo ketone afforded oxazoles **1b—d** in good to moderate yields. Diazoacetophenone was also converted into 2-methyl-5-phenyloxazole (**2**).



1 **2**

a: R=Ph; **d**: R=Me
c; R=Et; **d**: R=CH_2=CH

The results are in sharp contrast to the thermal, photochemical or copper(II)-catalyzed decomposition which give only negligible yields of oxazoles.[3] The remarkable catalysis by WCl_6 can be attributed to the Lewis acidity of the salt[4] coupled with its good affinity with carbenes.[2,5] The dual character would probably account for the assumption that both α-keto carbenes and nitriles are assembled together within the ligand sphere of W(VI) and are cyclocoupled effectively. Another noteworthy facet is the formation of 2-vinyl-4,5-diphenyloxazole (**1d**) in the reaction of benzoylphenyldiazomethane with acrylonitrile, where none of the cyclopropanation product has been detected. This suggests the electrophilic nature of carbenic center.[6] These observations are in accord with the following mechanistic postulation.[7]



Decomposition of Diphenyldiazomethane. Tungsten hexachloride catalyzes the decomposition of diphenyldiazomethane (**3**) in another way. *N*-Benzhydrylacetamide was produced in the reaction with acetonitrile. When **3** was treated with WCl_6 dissolved in *N,N*-dimethylformamide (DMF), immediate decomposition was again observed and a light green solution was obtained which upon hydrolysis gave benzhydrol and upon methanolysis benzhydryl methyl ether (see Experimental). Deuterium oxide quenching of this solution resulted in no deuterated benzhydrol. Obviously the aliphatic proton of diphenylcarbenium ion intermediate originates from the catalyst, but the proton source could not be eliminated in spite of repeated sublimations.[8] The catalytic decomposition of **3** in aromatic solvents (benzene, toluene, and anisole) gave Friedel-Crafts type products, triarylmethanes (Ph_3CH, 58%; $Ph_2CHC_6H_4Me$, 47%; $Ph_2CHC_6H_4$-*p*-OMe, 76% respectively).

Experimental

All the temperatures were uncorrected. The IR spectra were obtained on a Shimadzu spectrometer 27-G, mass spectra on a Hitachi RMU-6L, and PMR spectra on JEOL JNM-PMX 60, JEOL C-60-H, or Varian EM-360 spectrometer. Unless otherwise stated, commercial tungsten hexachloride was sublimed once (160 °C/0.2 Torr). All the experiments were performed under a nitrogen atmosphere and at room temperature.

*Triphenyloxazole (**1a**).* A solution of benzoylphenyldiazomethane (0.11 g, 0.50 mmol) in benzonitrile (3 ml) was added to a suspension of WCl_6 (0.20 g, 0.49 mmol) in the same solvent (2 ml). Nitrogen evolution immediately occurred and after 5 min the solution turned to light brown, then to dark blue after 2 h. After the addition of water the reaction mixture was extracted (AcOEt), dried (Na_2SO_4), and concentrated *in vacuo*. Preparative TLC (alumina, benzene, R_f 0.6—0.8) afforded **2a** (80 mg, 66%). Mp 113—115 °C (lit,[9] 114—115 °C); IR (Nujol): 3050; 1602, 1595, 1555, 1490, 1450, 968, 770, 694, cm^{-1}; MS: *m/e* 297 (M^+); PMR (CCl_4): δ 7.2—8.1 (m, Ph). Byproducts were diphenylethanedione (**4**) (13 mg, 12%) and 2-chloro-1,2-diphenylethanone (**5**) (21 mg, 18%).

*2-Methyl-4,5-diphenyloxazole (**1b**):*[9] 65% yield; bp 80—90 °C (bath temp)/0.1 Torr; IR (neat): 3060, 2940, 1602, 1585, 1500, 1443, 1270, 1226, 1051, 1020, 967, 767, 699 cm^{-1}; MS: *m/e* 235 (M^+); PMR (CCl_4): δ 2.50 (s, 3H, Me), 7.1—7.6 (m, 10H, Ph).

*2-Ethyl-4,5-diphenyloxazole (**1a**)*:[9] 45% yield; bp 110—125 °C (bath temp)/0.3 Torr; IR (neat): 3060, 1603, 1570, 1500, 1450, 1211, 1060, 1024, 965, 761, 692 cm^{-1}; MS: *m/e* 249 (M^+); PMR (CCl_4): δ 1.43 (t, J=9 Hz, 3H, Me), 2.85 (q, J=9 Hz, 2H, CH_2), 7.0—8.1 (m, 10H, Ph). **4** was a by-product (7%).

*4,5-Diphenyl-2-vinyloxazole (**1d**)*:[10] 50% yield; bp 150—168 °C (bath temp)/0.2 Torr; IR (neat): 1600, 1530, 1180, 1070, 1029, 980, 760, 695 cm^{-1}; MS: *m/e* 247 (M^+); PMR (CCl_4): δ 5.3—6.9 (m, 3H, $CH{=}CH_2$), 7.0—8.2 (m, 10H, Ph). By-products were **4** (19%), **5** (13%) and 2-hydroxy-1,2-diphenylethanone (15%).

*2-Methyl-5-phenyloxazole (**2**)*: 66% yield; mp 56—58 °C (lit,[11] 58 °C); IR (Nujol): 1580, 1560, 1215, 1132, 1060, 940, 839, 830, 764, 698, 676 cm^{-1}; MS: *m/e* 159 (M^+); PMR (CCl_4): δ 2.48 (s, 3H, Me), 7.1—7.8 (m, 6H, aromatic protons). 2-Chloro-1-phenylethanone (41%) was also obtained.

*Decomposition of **3** in Acetonitrile.* A solution of **3** (97 mg, 0.50 mmol) in acetonitrile (1 ml) was added to a suspension of WCl_6 (0.20 g, 1.5 mmol) in the same solvent (5 ml). After 10 h the reaction mixture was worked up. Preparative TLC (silica gel, benzene) afforded *N*-benzhydrylacetamide[12] (R_f 0.3—0.4, 38 mg, 32%) along with 9,10-diphenylphenanthrene[13] (R_f 0.9—0.95, 57 mg, 64%).

*Decomposition of **3** in DMF.* A solution of **3** (97 mg, 0.50 mmol) in DMF (1 ml) was added to a solution of WCl_6 (0.20 g, 0.50 mmol) in DMF (5 ml). After 1 h the reaction mixture was quenched (H_2O) and extracted (ether). Preparative TLC (silica gel, benzene, R_f 0.2—0.3) of the crude product afforded benzhydrol (63 mg, 77%) along with tetraphenylethylene (R_f 0.8—0.9, 13 mg, 9%). Quenching with methanol afforded benzhydryl methyl ether in 60% yield.[14]

*Decomposition of **3** in Anisole.* A solution of **3** (0.10 g, 0.53 mmol) in anisole (1 ml) was added to a brown solution of WCl_6 (0.20 g, 0.51 mmol) in anisole (5 ml). After 5 h the reaction mixture was quenched with water and extracted with ether. The organic layer was dried (Na_2SO_4), concentrated *in vacuo*, and the residue was purified by preparative TLC (silica gel, benzene, R_f 0.8—0.9, 0.10 g, 76%). Mp 61—62 °C (lit,[15] 61 °C); IR (Nujol): 1610, 1510, 1250, 1030, 700 cm^{-1}; MS: *m/e* 274 (M^+); PMR (CCl_4): δ 3.73 (s, 3H, OMe), 5.47 (s, 1H, CH), 6.6—7.1 (ABq, 4H, C_6H_4-OMe), 7.0—7.5 (m, 10H, Ph).

3) In these reactions Wolff rearrangement predominates over the dipolar cycloaddition. R. Huisgen, G. Binsch, and L. Ghosez, *Chem. Ber.*, **97**, 2628 (1964). A preliminary results of the present note have been published in K. Kitatani, T. Hiyama, and H. Nozaki, *Tetrahedron Lett.*, **1974**, 1531.

4) In order to check the contribution of Lewis acidity to the catalysis, benzoylphenyldiazomethane was treated with such halides as $ZnCl_2$, $SnCl_4$, $TiCl_4$, and $AlCl_3$ in acetonitrile. The major product was 2-chloro-1,2-diphenylethanone (**5**) in each case ($ZnCl_2$, 33%; $SnCl_4$, 22%; $TiCl_4$, 48%; $AlCl_3$, 41%), although the desired product **1b** was obtained as follows: $ZnCl_2$, 12%; $SnCl_4$, 6%; $TiCl_4$, 16%; $AlCl_3$, 8%.

5) T.-L. Ho, *Chem. Rev.*, **75**, 1 (1975).

6) In contrast, thermal reaction of electron-deficient diazo compounds (*e.g.* 10-diazoanthrone) with acrylonitrile affords cyanocyclopropanes. N. Filipescu and J. W. Pavlik, *J. Chem. Soc., C*, **1970**, 1851.

7) The intermediacy of **5** is readily excluded because it does not react with acetonitrile even in the presence of WCl_6 at room temperature.

8) The addition of deuterium oxide prior to the reaction resulted in the formation of the products derived from diphenyldeuteriomethyl cation. In the reaction of benzoylphenyldiazomethane with acetonitrile, however, the presence of water in the reaction mixture strongly depressed the oxazole formation (17% yield).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 50 (6), 1649—1650 (1977)

Synthesis of 2-Alkoxy-3,4,6-trihydroxyacetophenones

Kiyotaka HATAKEDA, Norio SAITO, Shota ITO, and Takashi ASANO

Government Industrial Research Institute, Tohoku, Nigatake, Harano-machi, Sendai 983

(Received November 12, 1976)

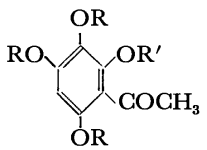
Synopsis. 2-Alkoxy-3,4,6-trihydroxyacetophenones have been prepared from 2,3,4,6-tetrakis(benzyloxy)acetophenone (II) in good yields by the following reactions: hydrolysis of II to 2-hydroxy-3,4,6-tris(benzyloxy)acetophenone (IIIa), alkylation of IIIa to 2-isopropoxy and 2-ethoxy-3,4,6-tris(benzyloxy)acetophenones (IVa and VIb), and hydrogenolysis of IVa and IVb to the corresponding 2-alkoxy-3,4,6-trihydroxyacetophenones (Va and Vb).

Synthsis of two kinds of monomethyl ether of 2,3,4,6-tetrahydroxyacetophenone (I) (3 and 4 position) was reported by Phadke[1] and Krishna.[2] However, 2-alkoxy-3,4,6-trihydroxyacetophenones have not been reported in literature.

In the synthetic course of flavonoid compounds, we found a new synthetic method of 2-alkoxy-3,4,6-trihydroxyacetophenones from 2-hydroxy-3,4,6-tris(benzyloxy)acetophenone (IIIa) which was obtained by the selective hydrolysis of 2,3,4,6-tetrakis(benzyloxy)acetophenone (II). Recently, several polyhydroxy flavonoids (and/or their ether derivatives) have been found in nature.[3,4] Therefore our method offers a good starting material for these flavonoid synthesis.

IIIa was obtained when II was hydrolyzed by 90% acetic acid. The signal of hydrogen bonding OH (13.98 ppm) with ketone in its NMR spectrum and hydrogen bonded ketone (1620 cm^{-1}) in its IR spectrum are observed. IIIa gave isopropoxy-tris(benzyloxy)acetophenone (IVa) by isopropylation. Hydrogenolysis of IVa gave isopropoxy-trihydroxyacetophenone (Va). The compound Va was transformed to the corresponding trimethyl ether (VI) which was also obtained from the known compound, 2-hydroxy-3,4,6-trimethoxyacetophenone (IIIb).[5]

IIIa is an useful compound as a starting material in the synthesis of 2-alkoxy-3,4,6-trihydroxyacetophenones. For example, 2-ethoxy-3,4,6-trihydroxyacetophenone (Vb) was synthesized from IIIa in the same manner as described above.



I, R=R'=H
II, R=R'=CH_2Ph

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi Model 285 infrared spectrophotometer. The mass spectra were recorded with a JEOL Model JMS-OMS mass spectrometer. The NMR spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as the internal standard. 2,3,4,6-Tetrahydroxyacetophenone (I)[6] was prepared from 1,2,3,5-benzenetetrol which was obtained by hydrogenolysis of 1,3-bis(benzyloxy)-2,5-benzenediol.[7]

2,3,4,6-Tetrakis(benzyloxy)acetophenone (II). A mixture of 2,3,4,6-tetrahydroxyacetophenone (I)[6] (0.68 g, 3.7 mmol), benzyl chloride (3.14 g, 22 mmol) and potassium carbonate (anhyd 22 g) in *N,N*-dimethylformamide (DMF) (30 ml) was heated for 1 h at 190 °C. The reaction mixture was poured into ice–water, and then extracted with benzene. The benzene layer was chromatographed over silica gel and eluted with benzene to give 0.81 g of crystals of II, mp 81 °C. IR (KBr): 1680 cm^{-1} (C=O); MS *m/e*: 544 (M^+); NMR δ ($CDCl_3$): 2.35 (3H, s, acetyl methyl), 4.98—5.08 (8H, benzyl methylene), 6.36 (1H, s, phenyl) and 7.15—7.45 (20H, phenyl). Found: C, 79.37; H, 5.99%. Calcd for $C_{36}H_{32}O_5$: C, 79.41; H, 5.88%.

2-Hydroxy-3,4,6-tris(benzyloxy)acetophenone (IIIa). A solution of II (1 g, 2 mmol) in 90% acetic acid (65 ml) was refluxed for 17 h. The reaction mixture was poured into ice–water, and then extracted with 300 ml of benzene. The benzene layer was washed with aqueous sodium hydrogencarbonate and water, dried and then evaporated to give IIIa as yellow crystals. Recrystallization from ethanol gave pale yellow needles of IIIa (0.65 g, 78%); mp 141—142 °C. IR (KBr): 1620 cm^{-1} (C=O, hydrogen bonded); NMR δ ($CDCl_3$): 2.50 (3H, s, acetyl methyl), 4.93—5.02 (6H, benzyl methylene), 5.98 (1H, s, phenyl), 7.20—7.50 (15H, phenyl) and 13.98 (1H, s, hydrogen bonding OH). Found: C, 76.41; H, 5.72%. Calcd for $C_{29}H_{26}O_5$: C, 76.65; H, 5.73%.

2-Isopropoxy-3,4,6-tris(benzyloxy)acetophenone (IVa). A mixture of IIIa (0.33 g, 0.7 mmol), isopropyl bromide (0.17 g, 1.4 mmol) and potassium carbonate (anhyd 20 g) in DMF (30 ml) was heated for 1 h at 150 °C. The reaction mixture was poured into ice–water, and then extracted with benzene. The benzene layer was washed with water, dried, and then evaporated. Recrystallization of the residue from hexane gave 0.29 g (80%) of IVa as colorless needles; mp 114 °C. IR (KBr): 1685 cm^{-1}; MS *m/e*: 496 (M^+); NMR δ ($CDCl_3$): 1.16 (6H, d, isopropyl methyl, J=7 Hz), 2.41 (3H, s, acetyl methyl), 4.65 (1H, septet, isopropyl methine, J=7 Hz), 4.93—4.99 (6H, benzyl methylene), 6.32 (1H, s, phenyl) and 7.10—7.45 (15H, phenyl). Found: C, 77.55; H, 6.61%. Calcd for $C_{32}H_{32}O_5$: C, 77.42; H, 6.45%.

2-Ethoxy-3,4,6-tris(benzyloxy)acetophenone (IVb). IVb was prepared according to the procedure described above. In place of isopropyl bromide, ethyl iodide (0.22 g, 1.4 mmol) was used to give 0.3 g (86%) of IVb; mp 87 °C (from hexane). IR (KBr): 1695 cm^{-1}; MS *m/e*: 482 (M^+): NMR δ ($CDCl_3$): 1.28 (3H, t, ethoxyl methyl, J=7.5 Hz), 2.40 (3H, s, acetyl methyl), 4.09 (2H, quartet, ethoxyl methylene, J=7,5 Hz), 4.93—4.99 (6H, benzyl methylene), 6.29 (1H, s, phenyl), 7.20—7.48 (15H, phenyl). Found: C, 77.26; H, 6.26%. Calcd for $C_{31}H_{30}O_5$: C, 77.18; 6.22%.

2-Isopropoxy-3,4,6-trihydroxyacetophenone (Va). A mixture of IVa (0.2 g, 0.4 mmol), 5% palladium–charcoal (3 g), and ethanol (50 ml) was shaken under hydrogen atmosphere for 5 h at room temp. After the removal of the catalyst, ethanol was evaporated to give Va. Recrystallization from

water gave yellow plates of Va (86 mg, 94%); mp 137 °C. IR (KBr): 3450 (OH) and 1630 cm^{-1} (C=O, hydrogen bonded); MS *m/e*: 226 (M^+); NMR δ (CD_3COCD_3): 1.32 (6H, d, isopropyl methyl, J=7 Hz), 2.61 (3H, s, acetyl methine, J=7 Hz), 6.17 (1H, s, phenyl), and 12.87 (1H, s, hydrogen bonding OH). Found: C, 58.69; H, 6.37%. Calcd for $C_{11}H_{14}O_5$: C, 58.40; H, 6.19%

2-Ethoxy-3,4,6-trihydroxyacetophenone (Vb). Vb was prepared according to the procedure described above. Recrystallization from 30% ethanol gave yellow plates of Vb (96%); mp 169 °C. IR (KBr): 3350 (OH) and 1610 cm^{-1} (C=O, hydrogen bonded); NMR δ (DMSO-d_6): 1.45 (3H, t, ethoxy methyl, J=7.5 Hz), 4.21 (2H, quartet, ethoxyl methylene, J=7.5 Hz) 6.18 (1H, s, phenyl), 9.80 (2H, broad, s, OH), and 13.42 (1H, s, hydrogen bonding OH). Found: C, 56.76; 5.81%. Calcd for $C_{10}H_{12}O_5$: C, 56.60; H, 5.66%.

2-Isopropoxy-3,4,6-trimethoxyacetophenone (VI). A solution of 2,4-dihydroxy-3,6-dimethoxyacetophenone[8] (1 g, 4.7 mmol) in ether (10 ml) was treated with excess of etheral diazomethane for 1 h. Evaporation of ether gave a residue which was recrystallized from diisopropyl ether. 2-Hydroxy-3,4,6-trimethoxyacetophenone (IIIb) thereby separated as yellow needles, mp 110—111 °C (lit,[5] mp 112—113 °C). IR (KBr): 1630 cm^{-1} (C=O, hydrogen bonded); NMR δ ($CDCl_3$): 3.64, 3.78 and 3.80 (methoxyl methyl), and 13.60 (1H, s, hydrogen bonding OH). A mixture of IIIb (0.2 g, 0.88 mmol), potassium carbonate (anhyd 5 g) and isopropyl bromide (0.2 g, 1.6 mmol) in DMF (20 ml) was heated for 1 h at 150 °C. The product VI was recrystallized from hexane as colorless needles (0.19 g, 80%); mp 60 °C. IR (KBr): 1710 cm^{-1} (C=O); MS *m/e*: 268 (M^+); NMR δ ($CDCl_3$); 1.26 (6H, d, isopropyl methyl, J=7 Hz), 2.44 (3H, s, acetyl methyl), 3.79—3.88 (9H, methoxyl methyl), 4.56 (1H, septet, isopropyl methine, J=7 Hz), and 6.22 (1H, s, phenyl). Found: C, 62.29; H, 7.78%. Calcd for $C_{14}H_{20}O_5$: C, 62.69; H, 7.46%.

An MO Calculation of the Reaction Path of a Symmetry-Disfavored 1,3-Sigmatropic Rearrangement

Tsutomu MINATO, Satoshi INAGAKI, Hiroshi FUJIMOTO, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 8, 1976)

The path of suprafacial 1,3-sigmatropic rearrangement is studied with the INDO-CI and INDO LMO methods. The methyl migration has been found to be represented by successive 1,2-shifts with a biradicaloid transition state. The interaction between the singly occupied MO's of allyl and methyl fragments is suggested to be responsible for the determination of the path. A subsidiary orbital also plays a part. On the other hand, the chlorine migration has been shown to be a direct 1,3-shift. The interaction between the lowest unoccupied MO of the allyl cationic part and the highest occupied MO of the remaining part, chloride anion, has been found to govern the path of chlorine migration. The lone pair electrons of the migrating fragment makes the successive 1,2-shifts quite unlikely in the 1,3-suprafacial chlorine rearrangements.

The frontier orbital theory[1] and Woodward-Hoffmann rule[2] have been demonstrated to be useful in disclosing the electronic control of chemical reaction paths. On the other hand, some interesting suggestions[3] have been presented on the mechanism of the reactions which do not obey the prediction obtained from the usual orbital symmetry considerations. In this paper, the mechanistic difference between the suprafacial 1,3-sigmatropic migrations of a methyl group and a chlorine atom over the allylic framework will be studied on the basis of a semiempirical all-valence electron MO calculation.

Recently, there have been several notable developments in the study of 1,3-sigmatropic rearrangements. According to the Woodward-Hoffmann rule, 1,3-sigmatropic rearrangements should occur in a suprafacial fashion over the allylic framework with the inversion of the configuration of the migrating group, or in an antarafacial fashion with the retention of the configuration of the migrating species. Experiments do show, however, that some thermal suprafacial 1,3-sigmatropic reactions take place with retention.[4] On the other hand, intramolecular chlorine migration was observed in allyl chloride.[5] If the single chlorine p orbital participates in the rearrangement, the 1,3-migration would be a symmetry-disfavored process. There have been some MO calculations[6] on the mechanisms of the 1,3-migrations. However, the reaction paths have not been discussed in detail as yet. Accordingly it may be worthwhile to study the mechanism of the 1,3-sigmatropic rearrangements based on the detailed information on the possible course of the migration.

We studied first the paths of the 1,3-methyl and chlorine migrations over the allylic framework by the use of the INDO MO method. Then, the bond interchange along the reaction path was examined in terms of the localized molecular orbital (LMO) to get a clearer insight into the formation and breaking of chemical bonds which are characteristic of the migrations.

Method

The INDO approximation[7] is employed in the present MO calculation. The reaction system consists of an allyl and a methyl fragment and of an allyl and a chlorine fragment. The geometrical parameters of allyl and methyl fragment were taken after the standard values proposed by Pople.[7a] Three typical pathways of a suprafacial 1,3-sigmatropic reaction, depicted in Fig. 1, have been examined tentatively. In the first model, Route 1, the migration occurs along the line connecting C_1 and C_3 of the allylic framework. The second is Route 2 in which the migrating group (M) approaches first to C_2, and then moves on to C_3. In Route 3, M transfers from C_1 to C_3 far away from C_2. The energies of the two reaction steps, Step 1 and Step 2, for each of the models, Route 1—3, were compared. Figure 1 illustrates the variables representing the reaction systems. Two independent parameters, R_1 and R_2 were selected. R_1 represents the height of M above the plane of the allylic framework. R_2 stands for the vertical distance between the point of the projection of M onto the allylic plane and the line connecting the two terminal carbons (C_1 and C_3) of the allylic framework. The origin of the coordinate system is taken at the midpoint of C_1 and C_3. The minus sign of R_2 means that M moves away from the origin in the opposite direction to C_2. Step 1 corresponds to the initial stage of the reaction. Namely, M is above the

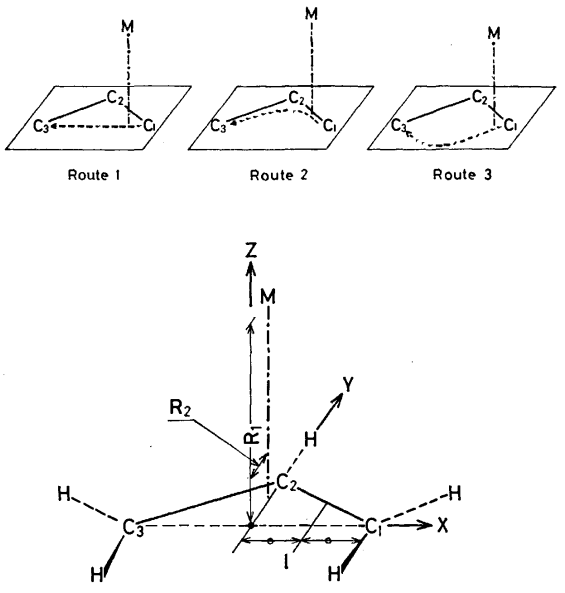

Fig. 1. Assumed reaction models. The origin of the coordinate system is on the center of C_1–C_3 line.

TABLE 1. TOTAL ENERGY OF METHYL MIGRATION

line (l) which is perpendicular to the line connecting C_1 and C_3 with X= one-fourth of C_1–C_3 length. Step 2 represents the transition state, and M is placed above the Y-axis. Total energies of the system are listed in Tables 1 and 2.

The Reudenberg-Edmiston LMO's[8] used in Steps 1 and 2 were calculated to investigate the change in the chemical bonds during the reaction. The bond orbitals obtained visualize the appearance and disappearance of specific bonds along the reaction process, as will be seen in the next section.[9]

Results

From the results of the INDO calculation without configuration interaction (CI) given in Table 1 it is seen that Route 2 is adequate for representing the methyl migration at the initial stage but is not suitable for describing the transition state. However, the result with CI suggests that the reaction path would be close to Route 2 throughout the migration. These results indicate that the inclusion of the CI is of essential significance in obtaining reasonable results in regard to the loosely bound transition state. The gross atomic charges given in Table 3 show that the methyl and allyl fragments tend to be neutral at the transition state (R_1=1.50 Å, R_2=0.35 Å).

The most stable geometry for the chlorine migration was found to be R_1=1.80 Å and R_2=−0.175 Å in Step 1, and R_1=1.80 Å, R_2=−0.525 Å in Step 2, as shown in Table 2: that is, the reaction path is close to Route 3. It should be noted that the path is very

The methyl migration. The chlorine migration.

different from that of the methyl migration mentioned above. The chlorine migrates along the pathway as to minimize the interaction with C_2 of the allylic framework. In the chlorine migration the inclusion of the CI did not show any serious change in our conclusion, so the CI result was omitted in Table 2. The electron populations given in Table 3 show that the transition state of the chlorine migration is likely to be an ion-pair.

The LMO's of the methyl migration are illustrated in Fig. 2. It is found that the LMO's localized in C–H bonds do not change markedly throughout the migration. The methyl carbon (C_M)–C_1 bond which disappears in the reaction is transformed into a three-centered bond, C_1–C_M–C_2, and the double bond (C_2=C_3) is represented by two bent bonds in Step 1. In Step 2 one of the bent bonds of C_2=C_3 is transformed into the three-centered bond (C_2–C_M–C_3), and the other bent bond is converted to a σ-bond (C_2–C_3). Accordingly, two three-centered bonds appear in Step 2. The LMO's of the doubly-excited configuration were also calculated. The doubly-excited configuration in which a pair of electrons are promoted from the highest occupied (HO) MO to the lowest unoccupied (LU) MO of the whole system was found to be the most important one from the CI calculation. Figure 3 illustrates several LMO's of the doubly-excited configuration in Step 2. One of the two three-centered bond orbitals is converted to the C_M–C_2 bond and the other is transformed to the orbital which localizes at C_1 and C_3. This localized orbital at C_1 and C_3 seems to represent the biradical nature of the system. The transition state has been found from the CI calculation to be described sufficiently well by the linear combination of the ground configuration and the doubly-excited configuration mentioned above. It is concluded, therefore, that the transition state of the methyl migration possesses a biradical character to a certain extent.

The LMO's for the chlorine migration are illustrated in Figs. 4 and 5. It is seen that the LMO's localized in the C–H bonds are not changed markedly throughout the migration. Figure 4 demonstrates that the mode

of bond interchange in the chlorine migration is different from that in the methyl migration. In the case of the chlorine migration, one of the bent LMO's representing C_2–C_3 bond is transformed into the LMO composed of three $2p_z$ atomic orbitals (AO's) of allyl carbons. The chlorine atom is bonded to C_1 and C_3 of the allylic framework by the LMO corresponding to the chlorine lone pair at the transition state. However, the LMO representing C_1–Cl–C_3 three-centered bond is almost exclusively localized at the chlorine $3p_x$ AO and, hence, the migrating chlorine is bound to the allylic framework very weak in the neighborhood of the transition state. The gross charges on the composed atoms and groups shown in Table 3 indicate that the transition state should be described as an ion-pair between the allyl cation and chloride ion, in agreement with the result of the LMO calculation.

We may conclude here from our INDO-CI and LMO calculations that the suprafacial migration of methyl with retention of the configuration of the migrating center, takes place *via* successive 1,2-shifts. However, the migration possesses a single symmetrical transition state and, hence, it should be classified as a one-step process. On the contrary, the chlorine migration is concluded to occur by way of a direct 1,3-shift with an ion-pair transition state.

Discussion

Let us interpret here the reaction mechanisms of the methyl and chlorine migrations by means of the orbital interaction in order to disclose the reason why the paths of the migrations are different from each other.

Methyl Migration. The principal orbital interactions involve the three π orbitals (π_1, π_2, and π_3) of the allyl group, and a σ-type (ϕ_σ) and a π-type (ϕ_π) orbitals of the methyl group as shown in Fig. 6. The interaction of ϕ_σ with π_1 and π_3 gives ϕ_1, ϕ_4, and ϕ_5, and that between π_2 and ϕ_π gives ϕ_2 and ϕ_3. The CI coefficients of the lowest closed-shell configuration and the $\phi_3\rightarrow\phi_4$ doubly-excited configuration are listed in Table 4, as well as the orbital energies of ϕ_3 and ϕ_4. The contributions of the other excited configurations are found to be negligibly small. The MO ϕ_4 has a bonding nature between C_2 and C_M, but the MO ϕ_3 is antibonding. Accordingly, the mixing in of the $\phi_3\rightarrow\phi_4$ doubly-excited configuration gives rise to the strengthening of both the σ and π type bondings in the reaction system. Table 4 clearly indicates that the effect of the CI becomes more significant as the separation between the methyl carbon and C_2 gets smaller.

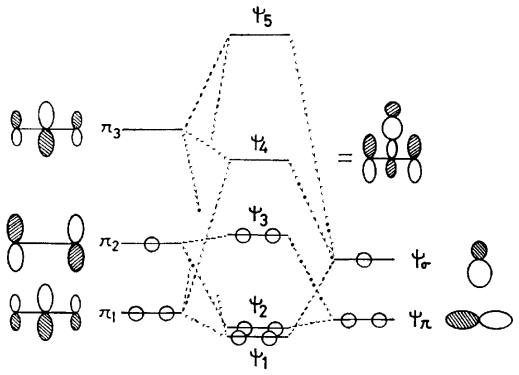

Fig. 6. The MO interaction diagram at the transition state of the methyl migration.

TABLE 4. THE CI BOEFFICIENTS AND ORBITAL ENERGY AT THE TRANSITION STATE OF THE METHYL MIGRATION

R_1	R_2	C_0	$C_{3\rightarrow4}$	ϕ_3	ϕ_4
1.50 Å	0.70 Å	0.934	0.352	−6.99 eV	2.39 eV
1.50	0.35	0.950	0.309	−6.72	3.31
1.50	0.0	0.979	0.192	−6.31	4.14

The enhancement of mixing in of the diexcited configuration is attributable to the decrease in the energy gap between ϕ_3 and ϕ_4. The interaction between ϕ_σ and π_1 stabilizes the system.[3a] On the other hand, the interaction between ϕ_σ and π_3 leads to the lowering of the ϕ_4 orbital. It is obvious that the dominant component of ϕ_4 is π_3. The interaction between ϕ_σ and π_3 contributes to the stabilization of the transition state, as well as the interaction between ϕ_σ and π_1, through the lowering of the composite MO ϕ_1.

Berson and Salem introduced the subjacent orbital effect in order to explain the occurrence of the formally symmetry-disfavored 1,3-migrations. They claimed that this resulted not from an effect on the HOMO but instead from the interaction of the carbon p orbital with a subjacent, bonding allyl orbital.[3a] We feel, however, that the interaction of the carbon p orbital with a subjacent orbital (π_1) was over-emphasized in their discussion. Since the carbon p orbital can interact both with π_1 and π_3, the role of π_3 orbital should be clearly recognized.[10] Our INDO-CI calculation disclosed not only the importance of the depression of ϕ_1 as the major stabilization through the direct overlap interaction between ϕ_σ and π_1 but also that of ϕ_4 for lifting the destabilization due to ϕ_3 through the mixing in of the $\phi_3\rightarrow\phi_4$ doubly-excited configuration to facilitate the occurrence of the migration.

The mechanism of 1,3-sigmatropic shift was rationalized above as a successive 1,2-shift. The interaction between the singly occupied (SO) MO of the allyl and the SOMO of the methyl is considered to have a key importance in stabilizing the reaction system at the

initial stage of the migration. As the migration proceeds, however, the stabilization decreases because of the out-of-phase overlapping of ψ_σ with the C_3 lobe of the antisymmetric π_2 becomes large. Accordingly, the reaction would proceed along the pathway in which the C_3 lobe and ψ_σ tend to overlap as little as possible. That is, the migration seems to take the pathway in which the destabilization due to the weakening of the SOMO-SOMO interaction is as small as possible. Furthermore, the reaction should take place in a way as to give a large overlapping between ψ_σ and π_1. At the transition state the interaction of ψ_σ with π_1 and π_3 orbitals is important. Since the π_1 and π_3 MO's possess the largest amplitudes at the central carbon, the methyl group comes closer to C_2 to create larger overlaps of ψ_σ with π_1 and with π_3. The reason why Route 2 is the most favorable pathway is thus clarified.

The preference of the 1,2-shift to the direct 1,3-shift is explained in another way by considering the orbital interaction between the π bond (C_2–C_3) and the σ-bond (C_1–C_M) to be broken.[11] The reaction may be initiated by the charge-transfer interaction from the former to the latter and *vice versa*. The mode of the orbital interaction between the HOMO and the LUMO of the two localized bonding regions is depicted in Fig. 7. It

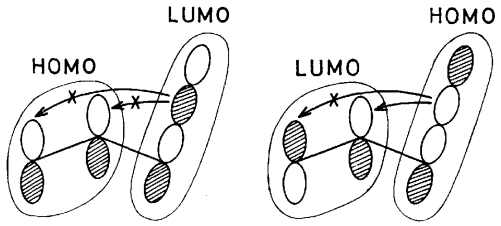

Fig. 7. The mode of the orbital interaction between the two bonding region.

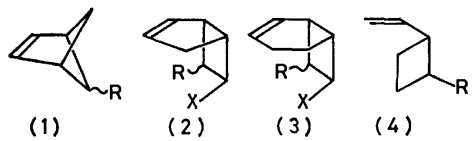
is seen that the overlapping of the HOMO of the C_2–C_3 π bond with the LUMO of the C_1–C_M σ bond is ineffective, while the overlapping of the LUMO of the former with the HOMO of the latter is effective. It is now obvious that the overlap interaction between the HOMO of the C_1–C_M bond and the LUMO of the C_2–C_3 π bond in this migration makes a successive 1,2-shift more likely than a direct 1,3-shift. This explanation leads to an important prediction that the 1,3-sigmatropic rearrangement with retention will occur easily when the migrating group has an electron donating group.[12]

The mechanism presented here (a successive 1,2-shift) agrees with the experimental results in regard to the stereoselectivity of the migrating center.[4c] The rate ratio of the 1,3-suprafacial rearrangement with retention to the rearrangement with inversion increases in the order bicyclo[2.1.1]hexene series (1)<bicyclo[3.2.0]-heptene series (2)<bicyclo[4.2.0]octene series (3)< monocyclic series (4).[13]



Berson and Holder[4c] proposed that this rate ratio might depend on the reactant structures. Namely, they suggested that the overlap between the front lobe of the migrating carbon and the suprafacial lobe of the central carbon of the allylic framework would stabilize the transition state of the symmetry-disfavored reactions. The Berson's interpretation is consistent with our conclusion derived here, *i.e.*, the suprafacial 1,3-shift with retention of the configuration can be interpreted in terms of a successive 1,2-shift, because the facility of a 1,2-shift is also dependent upon the reactant structure.

Chlorine Migration. The orbital interaction of Step 2 was examined in a similar way as that of the methyl migration. The principal orbital interaction seems to include the three π orbitals of the allylic framework and chlorine $3p_x$ and $3p_z$ AO's. From the gross charges in Table 3, it is appropriate to consider here the orbital interaction between an allyl cation and a chloride anion. The MO interaction diagram is presented in Fig. 8. It is noted that the ψ_3 and ψ_4 MO's are interchanged in chlorine migration in comparison with the case of methyl migration. This is a reason why the inclusion of the CI does not change seriously the conclusion derived from the results of calculation without CI. The MO ψ_3 of the chlorine migration was found to have antibonding character between Cl and C_2 in the transition state. This means that the interaction between $3p_z$ AO and π_1 is greater than that between $3p_z$ AO and π_3. The difference in the ordering of the ψ_3 and ψ_4 levels between methyl and chlorine migrations is attributed to the lower energy of the chlorine $3p_z$ AO than that of the ψ_σ MO of the methyl group. Figure 8 shows that the interaction between the HOMO ($3p_x$ AO) of the chloride anion and the LUMO (π_2) of the allyl cation stabilizes the transition state effectively.

The path of the 1,3-migration of chlorine is rationalized in the following manner. The interaction between the π_2 MO and the $3p_z$ AO has a key importance in stabilizing the reaction system at the initial stage of the migration. As the migration proceeds, however, the stabilization decreases because the out-of-phase overlapping of $3p_z$ AO with the C_3 lobe of the antisymmetric π_2 becomes large. However, throughout the chlorine migration reaction, unlike the methyl migration, the interaction between π_2 and $3p_x$ AO is bonding in character to stabilize the system efficiently. The interaction between π_1 and $3p_z$ AO is larger than that be-

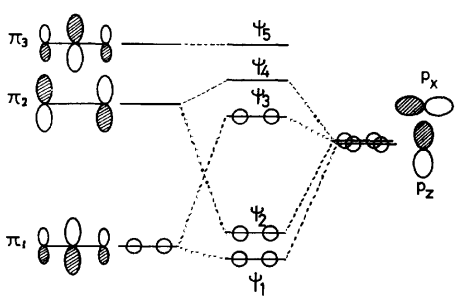


Fig. 8. The MO interaction diagram at the transition state of the chlorine migration.

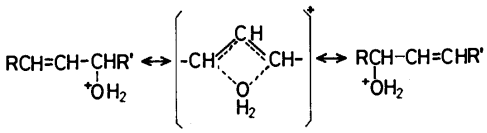
tween π_3 and $3p_z$ AO as mentioned above. Consequently, the interaction of $3p_z$ with π_1 and π_3 leads to the destabilization of the reaction system. The destabilization makes the chloride anion migrate in such a way as to minimize the overlap with C_2. The reason why Route 3 is the most favorable pathway is clarified. The difference between the mechanism of the methyl migration and that of the chlorine migration can be ascribed to the presence of a low-lying pair of electrons in the migrating species in the latter case.

It is interesting to examine the intramolecular acid-catalyzed isomerization of allyl alcohols[14] in relation to the chlorine migration described above.



In this case, the transfer of the double-bond and the migration of the hydroxyl group as a neutral water molecule are supposed to take place simultaneously.[14b] It is considered that the path of isomerization may be similar to the chlorine migration, water molecule being bonded to two terminal carbons of the allylic framework at the transition state, because the migrating species has a lone pair orbital relevant to the orbital interaction with the π_1 and π_3 MO's and another lone pair orbital to the interaction with π_2 MO of the allyl fragment.

Conclusion

It is concluded here that 1,3-sigmatropic rearrangement may occur suprafacially on the allylic framework with retention of the configuration of the migrating center as the result of a successive 1,2-shift with a radical nature. This is interpreted by the SOMO-SOMO interaction between the allyl radical and the methyl radical in the initial stage and the subsidiary orbital effect near the transition state. In the chlorine migration the HOMO-LUMO interaction between the allyl cation and the chloride anion provides the dominant stabilization to the reaction system. From the present calculation, it is clarified that the mechanism of 1,3-migration in allylic framework depends on the property of the migrating species.

We would like to express our gratitude to the Data Processing Center, Kyoto University, for its generous permission to use the FACOM 230-75 computer. Our MO calculation was carried out under the financial support of the Ministry of Education (Grant-in-Aid 047068).

10) We shall examine the interaction of the carbon p orbital having one electron with the occupied π_1 orbital and the unoccupied π_3 orbital. This interaction gives three orbitals. The lowest energy level orbital given by the interaction is depressed relative to the π_1 by the interaction between the p and π_1. The new radical orbital energy level is not remarkably affected, because the interaction between the p and π_1 raises the new radical orbital but that between the p and π_3 depresses the radical orbital. Thus the transition state is considered to be stabilized. Similar discussion is implicitly included in Ref. 3a.

12) The rate ratio of the suprafacial 1,3-sigmatropic rearrangement with retention to that with inversion was observed to be greater on *endo*-7-*exo*-methylbicyclo[3.2.0]heptenyl acetate than on *endo*-7-*exo*-D-bicyclo[3.2.0]heptenyl acetate.[4c] This observation seems to show that the migrating group with an electron donating group would make the 1,3-rearrangement occur easily since the methyl group is considered to be an electron donating one.

13) The high stereospecificity was observed in the case of bisallyl system.[4d,4e,4f] In this case there is another factor, a multi-cyclic interaction. *C.f.*, S. Inagaki, T. Minato, H. Fujimoto, and K. Fukui, *Chem. Lett.*, **1976**, 89.

Determination of the $6^3P_1 \rightarrow 6^3P_0$ Transition Rate of Hg in CO and NO by a Modulation Technique

Hiroyuki HORIGUCHI and Soji TSUCHIYA

Department of Pure and Applied Sciences, College of General Education, University of Tokyo, Meguro-ku, Tokyo 153

(Received November 1, 1976)

In order to determine the branching ratio for $Hg(6^3P_1)$ deactivation to the 6^3P_0 and 6^1S_0 states in CO or NO, a modulation technique was utilized. The intensity of 253.7-nm radiation was modulated at a frequency in the range from 0.1 to 20 kHz, and the resulting a.c. component of the $Hg(6^3P_1$ or $6^3P_0)$ concentration was measured by monitoring the absorption of the 435.8- or the 404.7-nm emission line from an Hg discharge lamp. The lower detection limit of excited Hg atoms was 10^7 cm^{-3} in this experimental method. On the basis of the $Hg(6^3P_0)$ concentration relative to that of $Hg(6^3P_1)$ in an Ar+CO or NO mixture including information on the phase delay, the $6^3P_1 \rightarrow 6^3P_0$ transition rate could be determined; the $6^3P_1 \rightarrow 6^3P_0$ cross section was found to be 22.4 Å^2 for CO and 7.1 Å^2 for NO and the $6^3P_0 \rightarrow 6^1S_0$ cross section to be 1.80 Å^2 for CO and 37 Å^2 for NO at room temperature.

A number of studies[1] have been reported on the lifetime measurement of $Hg(6^3P_1)$ atoms, which gives the sum of the rate constants for the collisional processes, $6^3P_1 \rightarrow 6^3P_0$ and $\rightarrow 6^1S_0$. In order to separate these two processes, it is necessary to monitor a transient or stationary concentration of $Hg(6^3P_0)$ atoms through an energy transfer process. (Hereafter, $Hg(6^3P_1)$, Hg (6^3P_0) and $Hg(6^1S_0)$ will be denoted by Hg_1*, Hg_0* and Hg, respectively.) Three reports have appeared on the determination of the $Hg_1^* \rightarrow Hg_0^*$ spin-orbit relaxation rate. The method employed by Callear and McGurk[2] is based on the fact that the Hg_0* concentration in a quenching gas relative to that in N_2 just after the flash excitation of Hg results in the quantum yield of Hg_0* (=the spin-orbit relaxation rate divided by the Hg_1* deactivation rate), since N_2 deactivates Hg_1* only to Hg_0*. In a previous experiment by Horiguchi and Tsuchiya,[3] a stationary concentration of Hg_0* atoms yields the spin-orbit relaxation rate if the Hg_0* deactivation rate is known. Vikis *et al.*[4] have also determined this rate by detecting the Hg_0* atoms through the amount of H_2 formed by the reaction of ethylene with Hg_0*. In these experiments, however, if the collisional transition from the 6^3P_1 state is mostly to the 6^1S_0 state or if the deactivation rate of Hg_0* is of the same order of magnitude as that of Hg_1*, the Hg_0* concentration becomes very small, and it is difficult to determine it to high accuracy. In this paper, a modulation technique is introduced in order to improve the detectivity of the Hg_0* atoms as well as to obtain information on the kinetics of excited Hg atoms.

Experimental

The apparatus was essentially the same as that described in a previous paper.[5] A quartz cell (3 cm in diameter and 24 cm in length) containing a gaseous mixture of Ar+a quenching gas containing Hg vapor at 1.9×10^{-4} Torr was illuminated by six low-pressure Hg discharge lamps (Toshiba 10-W germicidal lamps). A 200-W oscillator (Elger, 251) with a frequency variable in the range from 0.01 to 10 kHz supplied the power for the lamps through ballast resistors. Then, the intensity of 253.7-nm radiation was modulated at twice the frequency of the power source with a waveform that was approximately triangular rather than sinusoidal. An example of the waveform is shown in Fig. 1. The waveform is composed mainly of the fundamental component, the harmonic contribution being less than 10% of the fundamentals. For the present experiment, only the fundamental component is considered. This is justified if the rate equation for Hg* deactivation is of first order with respect to [Hg*], since the harmonic components may be separated from the fundamentals.

For detection of the Hg* atoms, the 404.7- or 435.8-nm emission line from a d.c.-operated Hg discharge lamp was passed through the cell, and then into a monochromator (Spex, 1700III) equipped with a photomultiplier. The output was analyzed by a lock-in amplifier (P. A. R. 186), the reference signal of which was supplied from a photo-tube that monitored 253.7-nm radiation. A quadrature output from the lock-in amplifier divided by an in-phase output gave the tangent of the phase-shift angle for the a.c. component of the Hg* concentration. Since the absorption intensity is not proportional to the Hg* concentration at higher densities, a condition of a low Hg* concentration was chosen in order to meet the requirement that the optical density for absorption be less than 0.02. The signal-to-noise ratio was greatly improved by using a lock-in amplifier, so that absorptions with optical densities as small as 10^{-4} could be detected. This absorption corresponds to 10^7 cm^{-3} of Hg_0* or Hg_1* atoms under the present conditions. In a previous experiment,[3] the lower detection limit of [Hg_0*] was *ca.* 10^9 cm^{-3}. This can be expected from the atomic absorption spectrometry for analyses of atoms having *f*-numbers similar to Hg_0*. Thus, the sensitivity is improved by a factor of 10^2 in the present modulation technique.

The nominal purities of the sample gases, Ar, N_2, CO, and NO, were 99.999, 99.995, 99.5, and 98.5%, respectively. The first two gases were used without further treatment.

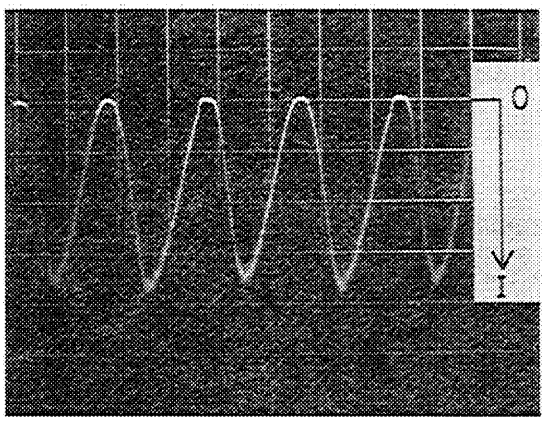

Fig. 1. Waveform of the 253.7-nm radiation intensity from an Hg discharge lamp powered by an oscillator whose frequency is 500 Hz (0.5 ms/div.).

CO was purified by repeated adsorption and desorption on molecular sieve 5A at liquid N_2 temperature, and NO was first passed through a column containing molecular sieve 5A and solidified several times for further purification. The fraction of Ar or CO in an Ar+CO mixture was determined by pressure measurement in a mixing vessel of calibrated volume. Hg vapor in the gas mixture was once removed by passing the gas through a spiral trap at 77 K, and later, the gas was fed into the cell through an Hg saturator at 0 °C. Since Hg-sensitized decomposition of NO was expected, a flow technique was adopted for measurements in an Ar+NO mixture. A capacitance manometer (M.K.S. 210) was employed for the pressure measurements; the fraction of NO in the mixture was determined from the pressure increase which was measured differentially.

Principle of the Modulation Technique

The application of the modulation technique to studies on chemical kinetics has been reviwed by Phillips.[6] Here, the modulation spectroscopy to elucidate the initial stage of Hg-photosensitized reactions will be discussed. If excited Hg atoms are formed in an Ar+CO mixture, the following energy transfer processes should be taken into account:

$$\mathrm{Hg} + h\nu(253.7\text{-nm}) \rightleftharpoons \mathrm{Hg_1}^*, \quad (1)$$

$$\mathrm{Hg_1}^* + \mathrm{CO}(v=0) \rightleftharpoons \mathrm{Hg_0}^* + \mathrm{CO}(v=1), \quad (2)$$

$$\mathrm{Hg_1}^* + \mathrm{CO}(v=0) \longrightarrow \mathrm{Hg} + \mathrm{CO}(v\geq 0), \quad (3)$$

$$\mathrm{Hg_0}^* + \mathrm{CO}(v=0) \longrightarrow \mathrm{Hg} + \mathrm{CO}(v\geq 0), \quad (4)$$

$$\mathrm{Hg_0}^* \longrightarrow \mathrm{Hg}, \quad (5)$$

$$\mathrm{CO}(v=1) \longrightarrow \mathrm{CO}(v=0), \quad (6)$$

of which Reaction 5 is the sum of all deactivation processes including wall collisions and those with impurity molecules, and Reaction 6 represents similar processes for the deactivation of $CO(v=1)$. Vibrational excitation of CO in Reactions 3 and 4 has been demonstrated by the infrared emission measurements of Polanyi and coworkers.[7] However, direct experimental evidence for vibrational excitation in Reaction 2 has not yet appeared. However, since the spin-orbit relaxation in N_2 accompanies vibrational excitation of N_2,[5] it is reasonable to suppose a similar reaction for Hg_1*-CO collisions.

The modulated intensity of 253.7-nm radiation may be represented as

$$I = \bar{I} + I_0 e^{i\omega t}, \quad (7)$$

where ω is the angular frequency of modulation. Corresponding to the above equation, the excited species formed make a cycle of appearance and dissipation, *i.e.*,

$$x_0 = [\mathrm{Hg}] = \bar{x},$$
$$x_1 = [\mathrm{Hg_1}^*] = \bar{x}_1 + \boldsymbol{x}_1 e^{i\omega t},$$
$$x_2 = [\mathrm{Hg_0}^*] = \bar{x}_2 + \boldsymbol{x}_2 e^{i\omega t},$$
$$y_0 = [\mathrm{CO}(v=0)] = \bar{y}_0,$$
$$y_1 = [\mathrm{CO}(v=1)] = \bar{y}_1 + \boldsymbol{y}_1 e^{i\omega t},$$

where the first term of the right-hand side in each case represents the d.c. component of the respective concentration and the second term the a.c. component, except for ground-state atoms or molecules whose a.c. components are disregarded since they are much more abundant than the excited species. The amplitude of the a.c. component must be a complex number since a phase delay is expected.

On the basis of the mechanism involving Reactions 1—6, the rate equations can be written as

$$dx_1/dt = k_1 I_0 x_0 - k_{-1}x_1 - k_2 y_0 x_1 - k_3 y_0 x_1 + k_{-2}x_2 y_1, \quad (8)$$

and

$$dx_2/dt = k_2 x_1 y_0 - k_{-2}x_2 y_1 - k_4 x_2 y_0 - k_5 x_2, \quad (9)$$

where the rate constant for Reaction j is denoted by k_j and the reverse reaction rate by k_{-j}. If the a.c. parts of these equations are separated, the following equations can be derived:

$$i\omega \boldsymbol{x}_1 = k_1 I_0 \bar{x}_0 - (k_{-1} + k_2\bar{y}_0 + k_3\bar{y}_0)\boldsymbol{x}_1 + k_{-2}\bar{y}_1 \boldsymbol{x}_2, \quad (10)$$

and

$$i\omega \boldsymbol{x}_2 = k_2 \bar{y}_0 \boldsymbol{x}_1 - (k_{-2}\bar{y}_1 + k_4\bar{y}_0 + k_5)\boldsymbol{x}_2. \quad (11)$$

In these equations, it is assumed that $\bar{y}_1 \gg |\boldsymbol{y}_1|$, since the lifetime of $CO(v=1)$ is much longer than ω^{-1}, which is less than 1.3 ms. The imaginary part of Eq. 10 results in the equation,

$$-\boldsymbol{x}_1^i/\boldsymbol{x}_1^r = \tan\phi_1 = [1/(k_{-1} + k_2\bar{y}_0 + k_3\bar{y}_0)][\omega + k_{-2}\bar{y}_1(-\boldsymbol{x}_2^i/\boldsymbol{x}_1^r)]. \quad (12)$$

The corresponding equation derived from Eq. 11 is

$$-\boldsymbol{x}_2^i/\boldsymbol{x}_2^r = \tan\phi_2 = [1/(k_{-2}\bar{y}_1 + k_4\bar{y}_0 + k_5)][\omega + k_2\bar{y}_0(-\boldsymbol{x}_1^i/\boldsymbol{x}_2^r)]. \quad (13)$$

Here, ϕ_1 and ϕ_2 are defined as phase delay angles for the a.c. components of $[Hg_1^*]$ and $[Hg_0^*]$, respectively, and $\boldsymbol{x}_j^r$ and $\boldsymbol{x}_j^i$ are the real and imaginary parts, respectively, of $\boldsymbol{x}_j$. The real part may be obtained from the in-phase signal of the absorption and the imaginary from the quadrature.

The reciprocal radiative lifetime of Hg_1* is estimated to be 3.5×10^6 s^{-1} which is calculated according to the Milne-Samson equation[8] for the correction of radiation imprisonment effect. This value is much larger than the angular frequency of modulation in this experiment. Therefore, the phase delay for the Hg_1* concentration may not be of detectable magnitude, *i.e.*, $\tan\phi_1 \fallingdotseq 0$. Hence, Eq. 13 can be approximated by

$$\tan\phi_2 = \omega/(k_{-2}\bar{y}_1 + k_4\bar{y}_0 + k_5). \quad (13')$$

In addition, the real part of Eq. 11 results in the relation,

$$k_2 y_0 = \omega(\boldsymbol{x}_2^r/\boldsymbol{x}_1^r)(\tan\phi_2 + \cot\phi_2). \quad (14)$$

Thus, the spin-orbit relaxation rate of $Hg_1^* \rightarrow Hg_0^*$ can be determined if the phase-delay angle and the a.c. component of the Hg_0* concentration relative to that of Hg_1* are measured.

Results and Discussion

In Fig. 2, the observed phase-delay angle, ϕ_2, for the a.c. component of the Hg_0* concentration in an Ar+CO mixture is plotted as a function of the modulation frequency. The results are in good agreement with the relation

$$\tan\phi_2 = \omega\tau, \quad (15)$$

where τ is the lifetime of Hg_0* and is defined by Eq. 13′ as

$$\tau = (k_{-2}\bar{y}_1 + k_4\bar{y}_0 + k_5)^{-1}. \quad (16)$$

This equation shows that the lifetime is dependent on the concentration of vibrationally excited CO as well as on that of ground-state CO. If the spin-orbit relaxation accompanies the vibrational excitation, an excess amount of $CO(v=1)$ is formed. Hence, it is expected that strong 253.7-nm radiation causes an ac-

cumulation of vibrationally excited CO which shortens the Hg_0^* lifetime through Reaction 2 in the reverse direction. This has been confirmed in the lifetime measurements of Hg_0^* in Ar+N_2 mixtures.[5] However, in an Ar+CO mixture, the lifetime of Hg_0^* does not depend on the intensity of 253.7-nm radiation, as is shown in Table 1, which lists the observed lifetimes as a function of the 253.7-nm photon intensity entering the cell. The latter quantity was varied by changing the number of illuminating lamps and their distance from the cell; the intensity was estimated from the observed value of Hg_1^* concentration in pure Ar, since Ar does not deactivate Hg_1^* and its concentration is given by $x_1=k_1I_0x_0/k_{-1}$. The results in Table 1 leads to the conclusion that there is no accumulation of CO (v=1) in the present system, which is probably due to the relatively short lifetime of CO(v=1). Thus, the vibrational temperature of CO must be room temperature and the reverse of Reaction 2 may be disregarded. This estimate should be valid for other quenching gases, since these gases have relaxation times shorter than those of CO and N_2.

The reciprocal lifetime determined from the data in Fig. 2 is proportional to the CO partial pressure and, thus, gives the rate constant for Hg_0^* deactivation, k_4, which is $(8.89\pm0.27)\times10^{-12}\ cm^3\ s^{-1}$. The spin-orbit relaxation rate, k_2, was determined to be $(1.13\pm0.04)\times10^{-10}\ cm^3\ s^{-1}$ using Eq. 14 and the data listed in Table 2. The rates thus determined may be converted to

collision cross sections as summarized in Table 3 together with the results for NO and literature values. The total deactivation cross section of Hg_1* by a collision with CO (Reactions 2 and 3) has been measured accurately by Deech *et al.*[9] and found to be 21.7 Å² at room temperature. This value was determined from a measurement of the 253.7-nm fluorescence decay after pulsed excitation of Hg to Hg_1*. The value agrees well with the present measurement of 22.4 Å² for Reaction 2 within the error limits. This means that the deactivation of Hg_1* by collisions with CO leads mainly to formation of Hg_0* and not to ground-state Hg; the latter process may occur with a probability of less than 2% of the Hg_1* deactivation. Clear evidence for vibrat onal excitation of CO by the spin-orbit relaxation was not obtained in the present experiment. However, since CO is isoelectronic with N_2 and the resonance is improved ($\Delta E = -373$ cm^{-1} for CO compared with -563 cm^{-1} for N_2) in Reaction 2, vibrational excitation is expected to be accompanied by the spin-orbit relaxation.[5]

Formerly, it was difficult to detect Hg_0* atoms produced in Hg_1*-NO collisions, and, thus, the rate constant, k_2, could not be determined. However, the present modulation technique makes it possible to detect the a.c. component of [Hg_0*] which has been so small that rate constants, k_2 and k_4, cannot be determined accurately. A more reliable value for k_4 was obtained from phase-shift measurements of Hg_0* in a mixture of N_2+NO; the cross section is given in Table 3. Contrary to the case of Hg_1*-CO collisions, NO deactivates Hg_1* mainly to the ground state, with only 10% of the Hg_1* deactivation proceeding *via* spin-orbit relaxation.

The energy transfer mechanism for Hg*-CO collisions can be understood if the non-adiabatic coupling between spin-orbit states is complete in the course of the collisional interaction *via* the simultaneous vibrational excitation of CO, while adiabaticity is preserved between the 6^3P and 6^1S states of Hg. Contrary to this, in Hg*-NO collisions, a large probability for crossing from the 6^3P surface to the 6^1S surface significantly reduces the relative importance of the transition from the 6^3P_1 state to the 6^3P_0 state.

Appendix

For the readers' convenience, the equivalence of the sine or cosine formulation to the vector notation in the complex plane is explained. According to the radiation intensity expressed as

$$I = \bar{I} + I_0 \sin \omega t, \tag{A1}$$

the Hg_1* and Hg_0* concentrations are described as

$$x_1 = \bar{x}_1 + \tilde{x}_1 \sin(\omega t - \phi_1) \tag{A2}$$

and

$$x_2 = \bar{x}_2 + \tilde{x}_2 \sin(\omega t - \phi_2). \tag{A3}$$

If these equations are substituted into Eqs. 8 and 9, and the coefficients of $\cos \omega t$ are taken, the following two equations can be derived:

$$\tan \phi_1 = [1/(k_{-1} + k_2\bar{y}_0 + k_3\bar{y}_0)] \times [\omega + k_{-2}\bar{y}_1(\tilde{x}_2 \sin \phi_2/\tilde{x}_1 \cos \phi_1)] \tag{A4}$$

and

$$\tan \phi_2 = [1/(k_{-2}\bar{y}_1 + k_4\bar{y}_0 + k_5)] \times [\omega + k_2\bar{y}_0(\tilde{x}_1 \sin \phi_1/\tilde{x}_2 \cos \phi_2)]. \tag{A5}$$

These equations are equivalent to Eqs. 12 and 13 assuming that

$$x^r = \tilde{x} \cos \phi \quad \text{and} \quad x^i = \tilde{x} \sin(-\phi).$$

The Detection of Hg(6^3P_1 and 6^3P_0) Atoms by an Atomic Absorption Method and Their Quenching Cross Sections

Hiroyuki HORIGUCHI and Soji TSUCHIYA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Meguro-ku, Tokyo 153

(Received November 1, 1976)

The absorption intensities of the 435.8- and 404.7-nm lines by Hg(6^3P_1 and 6^3P_0) atoms were calculated taking into account the hyperfine structure under the assumption of a Doppler spectral line shape. The calculated values were tested by comparison with experimental absorption of the line in an Ar+N_2+Hg mixture illuminated by 253.7-nm radiation. This procedure led to the conclusion that the ratio of the spectral half-width of the 404.7-nm line from a low-pressure Hg lamp to that of the Hg(6^3P_0) absorption line should be 2.25±0.25 instead of the value of 5 determined in the previous experiment. On the basis of this value, the quenching cross sections of the excited Hg atoms reported in the previous paper were revised. The corrections are generally less than 20%, so that it is not necessary to change the previous conclusions.

In a previous paper,[1] a method was described to determine the quenching rate of excited Hg atoms for the processes $6^3P_1 \rightarrow 6^3P_0$ and $\rightarrow 6^1S_0$ from the observation of a stationary concentration of Hg(6^3P_0) atoms in a gaseous mixture of quencher +Hg vapor illuminated by 253.7-nm radiation. (Hereafter, Hg_1*, Hg_0*, and Hg stand for Hg atoms in the 6^3P_1, 6^3P_0, and 6^1S_0 states, respectively.) The Hg_0* concentration [Hg_0*], was estimated by the absorption measurement of the 404.7-nm line emitted from a low-pressure Hg discharge lamp. In this procedure, care was paid to verify that the absorption intensity was a function of [Hg_0*] as well as of the ratio of the spectral line half-width from the light source to that of the absorption line. In order to determine this ratio (denoted here by α), it was assumed that the [Hg_0*] in the mixture of Ar+N_2 is proportional to the intensity of the 253.7-nm radiation and that the 404.7-nm line is composed of a single spectral line. However, according to recent results,[2] the [Hg_0*] in the Ar+N_2 mixture is proportional to the square root of the 253.7-nm radiation intensity. Moreover, the 404.7-nm line has 9 hyperfine components resulting from the isotope shift and the nuclear-spin coupling. Therefore, the value of α reported previously must be corrected. In addition, the quenching cross sections[3] of the excited Hg atoms determined from the observed decay of the absorption at 404.7-nm must also be revised.

Experimental

The apparatus is essentially the same as that described in Ref. 1. In a quartz cell (3 cm in diameter and 24 cm in length) containing an Ar+N_2 mixture with an Hg pressure of 1.9×10^{-4} Torr, excited Hg atoms were formed by illumination with 253.7-nm radiation from 6 low-pressure Hg discharge lamps (Toshiba, 10-W germicidal lamp) surrounding the cell. The cell has an outer jacket filled with a 0.6 M $NiSO_4$ aq solution to avoid excitation of the Hg atoms to levels higher than the 6^3P_1 state. Another low-pressure Hg discharge lamp was employed as a light source for the 404.7- and 435.8-nm lines which were modulated by a chopper at 125 Hz before entering the cell. A d.c. source supplied the power for the Hg discharge lamps. A monochromator (Spex, 1700) and a lock-in amplifier (P. A. R. 186) were used to monitor the line intensity. The absorption due to [Hg_1*] was very weak, so that the 253.7-nm radiation intensity was modulated at a frequency of 0.12—3 kHz and the resulting a.c. component of the absorption at 435.8-nm was measured without the chopper; the signal obtained divided by the d.c. intensity of the 435.8-nm line from the source gives the absorbance. This procedure makes it possible to detect optical densities for absorption as small as 10^{-4}.

The rotational (=translational) temperature of the sample gas in the cell under the irradiation of 253.7-nm radiation was 292±15 K. This was estimated from the observed rotational temperature of CO, added as a tracer to the mixture.[4]

The nominal purities of the sample gases, Ar and N_2, were 99.999% and 99.99%, respectively. The method of gas handling is the same as that described previously.

Results and Discussion

Calculation of the Absorption Intensities of Excited Atoms. Taking the hyperfine splitting of 404.7- and 435.8-nm lines into account, the intensities for absorption by Hg_0* and Hg_1* atoms were calculated. For the calculation, the fine structure of the Hg lines observed by Schüler and Keyston[5] were adopted; the 404.7- and 435.8-nm lines are composed of 9 and 15 hyperfine components, respectively. It can be assumed that the line profile of each component of the 404.7- and 435.8-nm absorption lines is Doppler broadened with a common F. W. H. M. denoted by $\Delta\nu_D$. Though the line profile for radiation from a discharge lamp is dependent on many factors such as Doppler and collisional broadening, the Stark effect, *etc.*, it can be approximated by a Doppler-broadened line with a F. W. H. M. of α times that of the absorption line, *i.e.*, $\alpha\Delta\nu_D$. Thus, the spectral profile of the i-th component of the line from an Hg discharge lamp is given by

$$E^{(i)}(\nu) = E_0{}^{(i)}\exp\{-(\ln 2)[2(\nu-\nu_0{}^{(i)})/\alpha\Delta\nu_D]^2\}, \quad (1)$$

where $\nu_0{}^{(i)}$ is the frequency at the line center of the i-th component and $E_0{}^{(i)}$ is the peak intensity at $\nu_0{}^{(i)}$. Similarly, the absorption coefficient of the i-th component is

$$k^{(i)}(\nu) = k_0{}^{(i)}\exp\{-(\ln 2)[2(\nu-\nu_0{}^{(i)})/\Delta\nu_D]^2\}. \quad (2)$$

Since the absorbance A is defined as 1−(transmitted radiation, I)/(incident radiation, I_0), the observed absorption which should be the sum of those for the individual hyperfine components is described as

$$A = \int\sum_i E^{(i)}(\nu)[1-\exp(-k^{(i)}(\nu)l)]\mathrm{d}\nu \Big/ \int\sum_i E^{(i)}(\nu)\mathrm{d}\nu, \quad (3)$$

where l is the absorption length. The Hg discharge

lamp emits spectral lines under optically-thin conditions, so that the relative intensity of each hyperfine component is equal to that for the absorption coefficient;

$$k_0^{(i)}/k_0 = E_0^{(i)}/E_0,$$

where $E_0=\sum_i E_0^{(i)}$ and $k_0=\sum_i k_0^{(i)}$. This last quantity is described as

$$k_0 = (2/\Delta\nu_D)(\ln 2/\pi)^{1/2}(\pi e^2/mc)fN,$$

where e and m are the charge and mass of electron, respectively, and c is the velocity of light, f the f-number, and N the number density of excited atoms; $k_0=5.905\times10^{-12}N\,\mathrm{cm}^{-1}$ for Hg_0^* and $6.207\times10^{-12}N\,\mathrm{cm}^{-1}$ for Hg_1^* atoms.

Numerical integration of Eq. 3 was carried out for various α and k_0l values. In Figs. 1 and 2, the calculated values of $\log(1-A)^{-1}$ which is equal to $\log(I_0/I)$ are plotted as a function of k_0l. It is obvious that the optical density calculated with the hyperfine splittings is smaller than that calculated assuming a single line. In the region of small optical densities (<0.1) the calculation assuming a single line for the 404.7-nm line gives 4.6 times the value with the hyperfine splittings for $\alpha=1$ and decreases to 3.4 for $\alpha=2$ and 2.7 for $\alpha=3$. This may be interpreted to a very rough approximation as a 404.7-nm line having 3 to 4 lines with equal intensities; a large α causes a dense overlapping of hyperfine lines resulting in a reduction in the effective number of lines.

Determination of the Ratio of the Emission Line Width to the Absorption Line Width. Previously, it was assumed that the $[Hg_0^*]$ in an $Ar+N_2$ mixture is proportional to the intensity of 253.7-nm radiation. This is based on the processes for the Hg_0^* production:

$$Hg + h\nu \rightarrow Hg_1^*, \quad \text{(i)}$$

$$Hg_1^* \rightarrow Hg + h\nu, \quad \text{(ii)}$$

$$Hg_1^* + N_2 \rightarrow Hg_0^* + N_2, \quad \text{(iii)}$$

$$Hg_0^* \rightarrow Hg. \quad \text{(iv)}$$

However, the recent measurement[2] of the Hg_0^* lifetime indicates that the above processes cannot explain the formation and deactivation of Hg_0^*, and that reaction (iii) must be replaced by

$$Hg_1^* + N_2(v=0) \rightarrow Hg_0^* + N_2(v=1), \quad \text{(v)}$$

where $N_2(v=1)$ is vibrationally-excited N_2. Moreover, the inverse of this reaction and the deactivation of N_2 $(v=1)$ must be added:

$$Hg_0^* + N_2(v=1) \rightarrow Hg_1^* + N_2(v=0), \quad \text{(vi)}$$

and

$$N_2(v=1) \rightarrow N_2(v=0). \quad \text{(vii)}$$

A steady-state analysis of reactions (i)—(vii), excepting (iii), leads to the relation

$$[Hg_0^*] = \frac{k_7}{2k_6}\left\{\left[\left(\frac{k_5}{k_2}[N_2]+1\right)^2+4\frac{k_1k_5k_6}{k_2k_4k_7}I[Hg][N_2]\right]^{1/2} - \left(\frac{k_5}{k_2}[N_2]+1\right)\right\}, \quad (4)$$

where I is the intensity of the 253.7-nm radiation and k_1 is the rate constant for reaction (i). Equation 4 may be simplified to a good approximation as

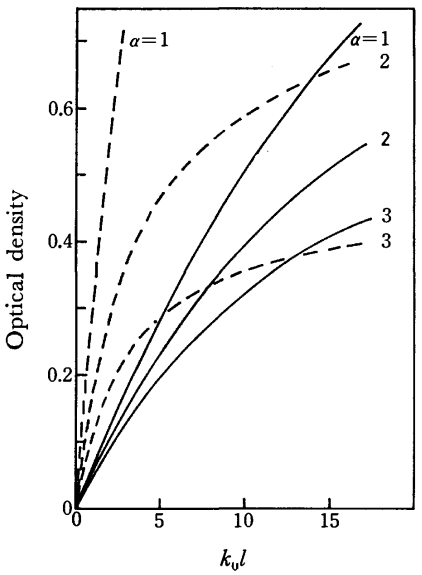

Fig. 1. Absorption intensity of the 404.7-nm line by $Hg(6^3P_0)$ atoms as a function of α; solid line: calculation with the hyperfine line structure, broken line: calculation assuming a single line.

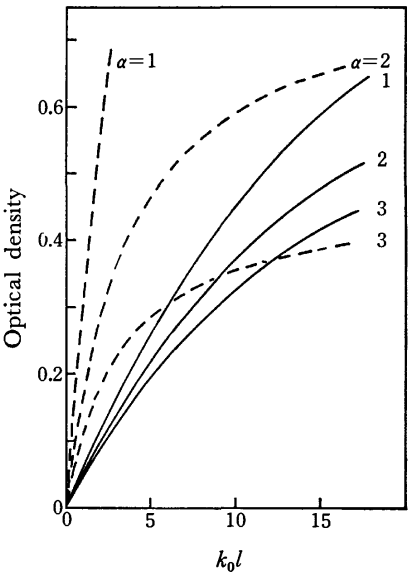

Fig. 2. Absorption intensity of the 435.8-nm line by $Hg(6^3P_1)$ atoms as a function of α; solid line: calculation with the hyperfine line structure, broken line: calculation assuming a single line.

$$[Hg_0^*] = (k_1k_5k_7[Hg][N_2]/k_2k_4k_6)^{1/2} \quad (5)$$

under the condition that $k_2>k_5[N_2]\gg k_4$. This condition is satisfied if the N_2 pressure is in the range from 1 to 30 Torr.

In order to determine α, the optical density of the 404.7-nm absorption was measured as a function of the relative intensity of the 253.7-nm radiation, as well as of the N_2 partial pressure. The intensity was estimated from the absorption of the 435.8-nm line caused by the formation of Hg_1^* in pure Ar, *i.e.*,

$$[Hg_1^*]_0 = k_1I[Hg]/k_2. \quad (6)$$

Substituting this equation into Eq. 5, the relation

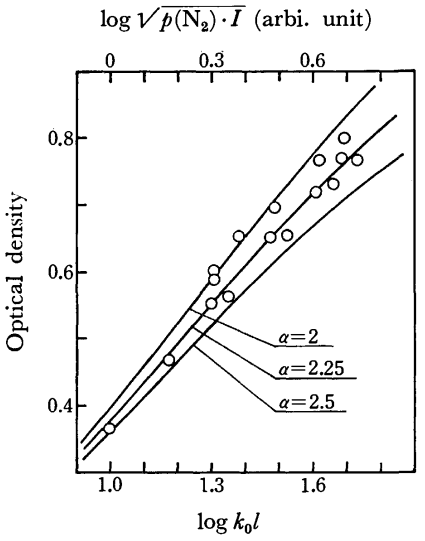

Fig. 3. Comparison of the calculated absorption intensities (solid line) of the 404.7-nm line with the experimental ones(circle) as a function of the N_2 partial pressure and the 253.7-nm radiation intensity.

$$[Hg_0^*] = [(k_5[N_2]/k_4)[Hg_1^*]_0(k_7/k_6)]^{1/2} \quad (5')$$

is obtained. Here, the absorption at 435.8-nm is so weak that the optical density can be assumed to be proportional to $[Hg_1^*]$ for any value of α. In Fig. 3, the optical density of the 404.7-nm absoption is plotted against $\log([N_2]I)^{1/2}$, together with the theoretical optical density, as a function of $\log k_0l$. The best fit to the experimental points is obtained for

$$\alpha = 2.25 \pm 0.25.$$

With this value of α, the optical density of the absorption at 404.7-nm gives the absolute magnitude of k_0l or $[Hg_0^*]$. The same value of α is assumed for the 435.8-nm line in the absence of experimental evidence. However, only a very weak absorption appears at 435.8-nm in the Hg* quenching experiment, so that the error caused by this assumption is rather small as can be understood from Fig. 2, in which the optical density is seen to be almost proportional to k_0l.

Quenching Cross Sections of Hg(6^3P_1 and 6^3P_0). The decay of the 404.7-nm absorption after a short pulse of 253.7-nm radiation was measured to estimate the Hg_0* quenching cross section as well as the spin-orbit relaxation rate of $Hg_1^* \rightarrow Hg_0^*$.[3] The new value of α, which is 2.25 instead of 5, as found previously, changes the conversion from the optical density to the $[Hg_0^*]$. Thus, the reported quenching cross sections are revised to new values as summarized in Table 1, in which the data for collision partners of CO and NO are given from the new measurement employing a phase-shift method.[6] There are minor changes in the cross sections: most of the Hg_0* deactivation cross sections are smaller by 10—20% than the previous values. This is due to the fact that the deactivation rate is deduced from the normalized quantity, $[Hg_0^*]/[Hg_1^*]_0$, which is not very sensitive to the value of α, especially for cases of weak absorption intensity. Thus, it is not necessary to change the conclusion derived in Ref. 3.

(Received November 22, 1976)

Semiempirical SCF-MO-CI caluculation was carried out for the 1,4-dicyanobenzene (DCB) and naphthalene system which is known to form exciplex (DA)* and triple exciplex (D_2A)*. Potential energy curves of the electronic interactions between excimer and electron acceptor molecule, and between exciplex and electron donor molecule were constructed. The results show that the array of component molecules in the triple exciplex is DDA, and the stabilization energy of triple exciplex is $\approx$0.4 eV from the excimer and $\approx$0.2 eV from the exciplex. They are in line with results reported on the experiment of exciplex and triple exciplex formation.

The system of 1,4-dicyanobenzene (DCB) and naphthalene exhibits exciplex fluorescence and also triple exciplex fluorescence as reported by Beens and Weller. They suggested from the solvent effect of the fluorescence spectra that the array of component molecules in the triple exciplex is not DAD but DDA.[1] Mimura and Itoh also reported the triple exciplex formation in 1,4-dicyanobenzene and dinaphthylpropane(DNP) where an array of the triple exciplex was proposed to be DDA from a steric factor of the trimethylene chain in DNP.[2] They reported on the mechanism of triple exciplex formation in the DCB and several alkylnaphthalene systems. In high concentration of electron donor ($>10^{-2}$ M), the triple exciplex was formed from excimer of alkylnaphthalene and DCB as well as from exciplex and alkylnaphthalene, while the triple exciplex formation from exciplex and electron donor in the concentration below $\approx 10^{-2}$ M is predominant in another process.[3] The dissociation process from the triple exciplex to the exciplex is so fast that the fluorescence rise of the triple exciplex and double exponential decay of the exciplex fluorescence are observed. The fluorescence rise as well as two-component decay of the exciplex was observed in the system of DCB and alkylnaphthalene which exhibits no triple exciplex fluorescence. This was explained by the exciplex formation through triple exciplex *via* the excimer in high concentration of electron donor.[3] A similar investigation was reported by Grellman and and Suckow in connection with the formation of triplet state of anthracene in the diethylaniline and anthracene system.[4]

Most molecular orbital calculations of the electron-donor-acceptor (EDA) complex as well as the exciplex are based on the configuration interaction between the ground and locally excited states of each component molecule, including the charge transfer interaction (CT) which is called the method of "composite molecules." On the other hand, some attempts have been made to calculate the electronic structure of the EDA complex as a single conjugate system of π-electrons.[5-7] The method of calculation of molecular orbital is almost the same as reported, namely the Pariser-Parr-Pople type semiempirical LCAO-SCF-MO method including CI.[7] We have calculated the trimolecular system as well as bimolecular system as a single molecule.

In this paper we discuss the electronic structure of triple complex in both the ground state and the excited state. The potential energy curves obtained revealed the correlation between four excited species, excited monomer, exciplex, excimer and triple exciplex.

Method of Calculation

The method of calculation and the parameters used are the same as in the previous paper.[7] It was also assumed that π-electron approximation is applicable to the triple complex. Two center resonance integrals were evaluated for the two molecules neighboring each other in the triple complex, but neglected for the two molecules far from each other. Two center resonance integrals were evaluated by following the Katagiri-Sandorfy formula:[8]

$$H_{\mu\nu} = \frac{1}{4}(C_\mu + C_\nu + \gamma_{\mu\mu} + \gamma_{\nu\nu} - 2_{\mu\nu})S_{\mu\nu}, \quad (1)$$

where C_μ is one center penetration integral and $S_{\mu\nu}$ is the overlap integral between atomic orbitals and evaluated from single Slater atomic orbitals. When two atomic orbitals are associated with different molecules, we use SCF-atomic orbitals.[9] Two center repulsion integrals $\gamma_{\mu\mu}$ were evaluated by the Nishimoto-Mataga formula,[10] and $\gamma_{\mu\mu}$ were estimated according to the Pariser-Parr method.[11] Core energy, $H_{\mu\mu}$ is assumed to be the negative of the ionization potential, given by Hinze and Jaffé.[12] Intermolecular core-core repulsion integrals $\gamma^c_{\mu\nu}$ were estimated by following the Dewar-Klopman formula[13] modified by Ohta *et al.*[6]

$$\gamma^c_{\mu\nu} = \gamma_{\mu\nu} + \left(\frac{1}{R_{\mu\nu}} - \gamma_{\mu\mu}\right)\exp\left[\alpha(R_{\mu\nu} - D_\mu - D_\nu)\right]. \quad (2)$$

Parameters used in this calculation (Table 1) are the same as those previously reported. The nature of electronic transition was estimated by the following equations which are almost the same as reported.[7]

$$\mathrm{LE}(\mathrm{M_1{}^*M_2M_3}) = \sum_{ij} b^{s_2}_{ij} m^1_i m^1_j, \quad (3)$$

$$\mathrm{CT}(\mathrm{M_1^+M_2^-M_3}) = \sum_{ij} b^{s_3}_{ij} m^1_i m^3_j, \quad (4)$$

where M_i is i-th molecule in the complex and b^s_{ij}, m^1_i are given by Eqs. 5 and 6, respectively.

$$m^1_i = \sum_{\mu=1}^{n_1} c^2_{i\mu} \quad (5)$$

$$\Phi_a = \sum_{ij} b^a_{ij} \Psi_{ij} \quad (6)$$

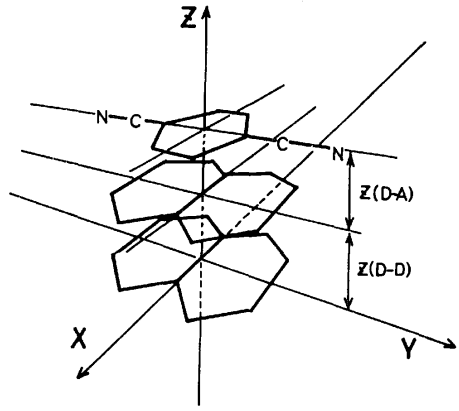

Fig. 1. The conformation and the geometrical parameters used for these calculations where Z(D–D) and Z(D–A) are distances between the molecular planes (parallel) of these component molecules.

		$\alpha=-1.75$			

where n_1 indicates the number of atoms in molecule 1, Φ_a the wave function of a-th electronic excited state, and Ψ_{ij} a configuration promoting an electron from i-th MO to j-th MO.

In the actual calculation of the electronic structures, molecular planes of each component molecule in the complex were assumed to be both parallel to each other and also to the long axes of each component molecule as shown in Fig. 1. The geometrical change from the standard conformation, such as component molecules being twisted together around an axis perpendicular to the molecular planes, did not affect so much the energy of the excited state of molecular complex. The iteration of SCF-MO calculation was repeated until the deviation in the total electronic energy became less than 10^{-4}%. For evaluation of the electronic transition energy and the oscillator strength of each transition, forty lowest singly excited configurations were taken into account. The calculation was carried out by the HITAC 8700/8800 operating system of the University of Tokyo.

Results and Discussion

Potential energy curves of the ground state and the excited state of complex (DA) are shown in Fig. 2. The abscissa indicates the distance between electron donor D and electron acceptor A. The complex in the ground state is unstable between D and A. With decreasing distance of each component molecule (D and A), a charge transfer state (CT-state) is stabilized in the potential energy surface, crossing a potential energy curve of locally excited state (LE-state) of the electron donor at 6.2 Å. This indicates that an electron transfer state mixes with the LE state at 6.2 Å in association with the excited electron donor D and the electron acceptor A to form the exciplex (DA)*. A prominent feature of (DA)* is that the CT character of the first excited state amounts to 98—100% at any distance below ≈6 Å of Z(D–A).

The potential energy curves of the naphthalene dimer, (DD), both in the ground and excited states are shown in Fig. 3. The abscissa indicate the distance between two naphthalene molecules. The dimer (DD) is unstable in the ground state, while it is stabilized by the exciton interaction mixed with the charge resonance interaction. The mixing ratio of the molecular exciton interaction with the charge resonance interaction is 1 : 1 for all the excited states. The first excited state of the dimer stabilized from the monomer is the state including ^1L_a exciton interaction (not ^1L_b exciton interaction) in a D_{2h} symmetry.[14]

The potential energy curves of the ground state and the excited state are shown in Fig. 4 for the case of an interaction of the exciplex and the donor molecule to form the array of DDA of the triple exciplex. The intermolecular distance between a centered electron

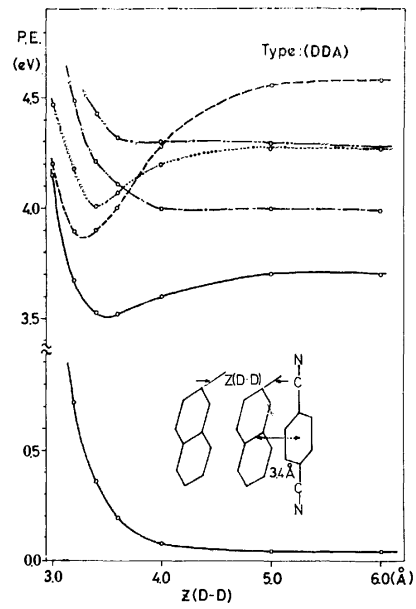

Fig. 4. Potential curves of complex (DDA). Variable parameter is Z(D–D) and Z(D–A) is constant (3.4 Å). In the excited state, ——, ———, – – –, and ····· indicate mainly (D···D$^+$A$^-$), (D···DA*), excimer (^1L_a) and excimer (^1L_b) levels, respectively.

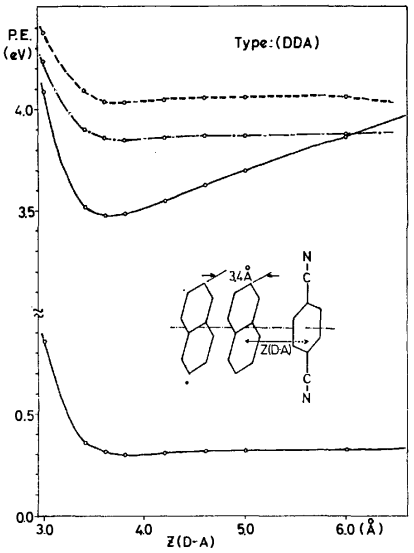

Fig. 5. Potential curves of complex (DDA). Variable parameter is Z(D–A) and Z(D–D) is constant (3.4 Å). In the excited state, ——, ———, and – – – – indicate mainly (D$^+$D···A$^-$)↔(DD$^+$···A$^-$), excimer (^1L_a), and excimer (^1L_b) levels, respectively.

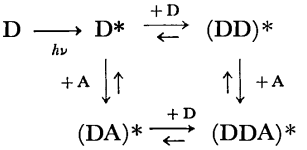
donor and a terminal electron acceptor is set to be constant (3.4 Å), and the intermolecular distance between two electron donors as is variable (Z(D–D) as abscissa). The triple complex is repulsive in the ground state. However, there is a shallow minimum in the first excited state of DDA which implies the triple exciplex formation in the excited state.

Figure 5 shows the potential energy curves of the ground state and the excited state of electronic interaction between the excimer and the electron acceptor to also form the array of DDA, where the intermolecular distance between electron donors in the dimer is constant (3.4 Å) and the intermolecular distance between centered electron donor and terminal electron acceptor changes (Z(D–A) as abscissa). The first excited singlet state (S_1 state) of this triple complex at the distance between D and A of 7.0 Å is almost first LE state of naphthalene dimer, namely excimer state. The charge transfer from the excimer to the electron acceptor occurs at the D–A distance ≈6 Å, then the CT state is stabilized by coulomb interaction between (DD)$^+$ and A$^-$. The energy gap of the triple exciplex from the excimer state of naphthalene was found to be *ca.* 0.4 eV.

It was suggested in the nano-second time resolved fluorescence investigation on the triple exciplex formation in the intermolecular system of DCB-alkylnaphthalene that the triple exciplex is formed *via* exciplex in a dilute solution of the electron donor ($<10^{-2}$ M), and the triple exciplex is also formed *via* excimer in a high concentration of the electron donor ($>10^{-1}$ M) (see Scheme 1).



Scheme 1.

It was also verified that the dissociation process from the triple exciplex, (DDA)*, to the exciplex, (DA)*, is significant at room temperature. These results are clarified by the MO calculations described above. Since the energy gap of the stable triple exciplex, (DDA)*, from the exciplex, (DA)*, is 0.2 eV (≈4.6 kcal/mol), the triple exciplex (DDA)* and the exciplex (DA)* might coexist at room temperature, and the stable triple exciplex (Type: DDA) would be formed from the exciplex even in the considerably dilute solution of electron donor. On the other hand, the energy gap between the excimer state of naphthalene and the more stable triple exciplex (Type: DDA) in the excited state is 0.4 eV (≈9.2 kcal/mol) as shown in Fig. 5. The energy gap calculated is so great that the naphthalene excimer can not coexist thermodynamically with the triple exciplex of the array of DDA at room temperature. The triple exciplex formation *via* the excimer as well as *via* the exciplex with increasing concentration of electron donor greater than 10^{-1} M was mentioned. Subsequently, the triple exciplex *via* the excimer may dissociate easily to the exciplex at room temperature due to the small stabilization energy (≈0.2 eV) of the triple exciplex.

The potential energy curves of the ground state and the excited states for the array of component molecules, DAD, are given in Fig. 6. The intermolecular distance between a centered electron acceptor and one of two electron donors is constant (3.4 Å), while that between A and D varies (Z(A–D) as abscissa). The triple complex in the array of DAD is stable neither in the ground state nor in the first excited state. The exciplex (DA)* seems to be unperturbed by the approach of another

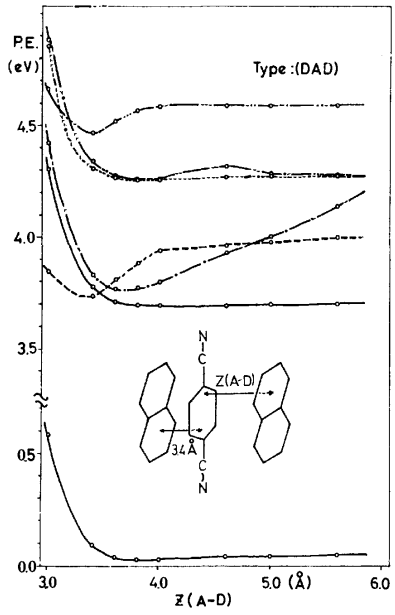


Fig. 6. Potential curves of complex (DAD). Variable parameter is Z(A–D), and Z(D–A) is constant (3.4 Å). In the excited state, ——, ——, ----, ——, and —·—·— indicate mainly ($D^+A^-\cdots D$), ($DA^-\cdots D^+$), ($DA^*\cdots D$), ($D^*A\cdots D$)↔($DA\cdots D^*$) (^1L_b) and ($D^*A\cdots D$) (^1L_a), respectively.

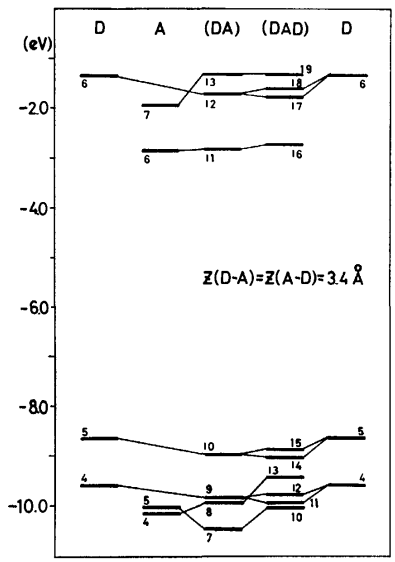

Fig. 7. Origins of SCF-MOs of complexes (DA) and (DAD) from SCF-MOs of component molecules.

D molecule leading to the formation of DAD. The calculated results concerning with the array of the triple exciplex are in line with the experimental results of the intramolecular triple exciplex formation in 1,3-dinaphthylpropane (DNP) and DCB system and also with the suggestion by Beens and Weller.[1] In the intramolecular system, it is impossible that triple exciplex takes an array of DAD because of trimethylene chain of DNP.[2]

The first electronic transition energies calculated in D, (DD), (DA) and (DDA) are summarized in Table 2 in comparison with the results from their fluorescence

Table 2. The first electronic transition energies (eV)

	D[a]	(DA)[a]	(DD)	(DDA)

spectra, where the molecular distance of component molecules are all 3.4 Å. The calculated transition energies are compared with those of fluorescence maxima, transition energy obtained in this kind of MO calculation being usually compared with that of electronic absorption spectra. Decrease in the transition energy in the order D>(DA)>(DD)>(DDA) is in line with that of transition energy from their fluorescence spectra, though all the energies were calculated to be *ca.* 0.5—0.6 eV greater than those of the corresponding fluorescence maxima, and the observed energy of (DD) is a little greater than that of (DA). Characters of the electronic transition of the lowest excitation in several D–D distance of the triple complex of DDA are given in Table 3. When donor molecule approaches the exciplex which has great CT-character (D^+A^-), the electronic configuration ($D^+\cdots DA^-$) gradually mixes with ($D\cdots$

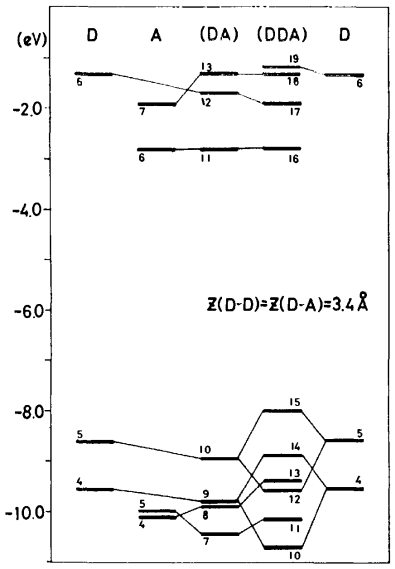

Fig. 8. Origins of SCF-MOs of complexes (DA) and (DDA) from SCF-MOs of component molecules.

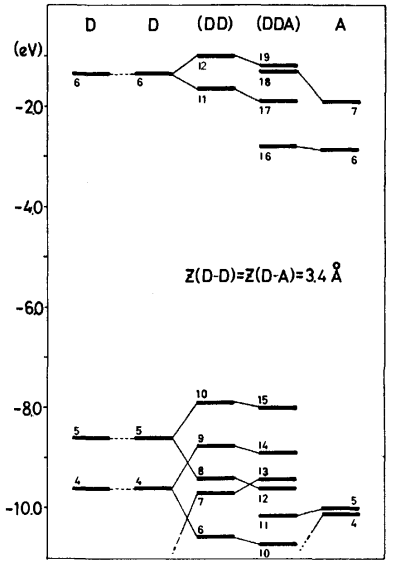

Fig. 9. Origins of SCF-MOs of dimer (DD) and complex (DDA) from SCF-MOs of component molecules.

D^+A^-). The dipole moment of the exciplex was calculated to be 16.16 D, while that of the triple exciplex was 18.13 D at the most stable molecular distance shown in Figs. 2 and 4. If the donor molecule approaches the exciplex to form (DDA)*, the donor molecule shares a positive charge with the another D molecule in the (D^+A^-) of the exciplex leading to form ($(DD)^+A^-$). It is necessary to stabilize the triple exciplex that two electron donors interact with each other effectively when the exciplex associates with another electron donor. In the symmetric triple exciplex (DAD)* formation (Fig. 6), however, the CT state of ($DA^-\cdots D^+$) does not mix with ($D^+A^-\cdots D$), the electronic structure of which is almost the same as that of the initial exciplex (D^+A^-) (Table 4). The first excited state of triple complex ($DA\cdots D$) maintains the CT character of the exciplex (DA)* in approaching another D molecule. Figures 7—9 show the molecular orbitals and their correlations obtained in each conformation. Higher occupied orbitals of triple complexes (DDA) and (DAD) and the complex (DA) are supplied from electron donor molecule. In (DAD) alignment, the interaction between the highest occupied molecular orbital (HOMO, 5th MO) of electron donor and HOMO (10th MO) of the complex (DA) which consists of mostly HOMO (5th MO) of electron donor is not so great. They form 14 and 15th MO's (Fig. 7). However, the great interaction occurs between 5th MO of D molecule and 10th MO of the complex (DA) which is supplied from the electron donor (Fig. 8) in DDA alignment. In the electronic interaction between (DD) and A, the electronic attribution of MO's of component molecules to MO's of the triple complex in DDA alignment is obvious (Fig. 9). The 14 and 15th MO's of the triple complex are supplied from the dimer. Since there is no chance for the two electron donors interacting with each other in DAD alignment, the symmetric exciplex of (DAD) would be unstable.

The Electron Capture by Bromobenzene in the γ-Radiolyses of Cyclohexane and 2,2,4-Trimethylpentane

Hidetoshi KARASAWA, Eung-Ryul KIM, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 22, 1976)

The γ-radiolyses of cyclohexane and 2,2,4-trimethylpentane have been reinvestigated. Bromobenzene was used as the electron scavenger. The analysis of the *G*-values of benzene obtained at high concentrations of bromobenzene showed that the empirical formula proposed by Hummel for the electron scavenging

$$G = G_{fi} + G_{gi}\{1-\exp(-\sqrt{\alpha S})\}$$

is better than that proposed by Warman *et al.* The values of $G_{fi}+G_{gi}$ thus obtained were 3.7±0.3 for cyclohexane and 3.5±0.2 for 2,2,4-trimethylpentane. The bromobenzene-concentration dependence of the *G*-values of hydrogen and methane from 2,2,4-trimethylpentane was well explained by the hypothesis that the lifetimes of the 2,2,4-trimethylpentane ion for the decomposition are in the same order as the time needed for the geminate recombination.

Bromobenzene is an efficient electron scavenger in the radiolysis of hydrocarbon. As the product of the electron scavenging reaction, benzene is formed, in amounts which can easily be estimated by gas chromatography.[1] In this paper we wish to report the *G*-values of benzene, hydrogen, and methane from cyclohexane and 2,2,4-trimethylpentane solutions as functions of the concentration of bromobenzene.

Such studies have been carried out by many radiation chemists in order to clarify the initial process of the radiation chemistry of hydrocarbons. Although many aspects of the initial process have been clarified by this method, one of the most interesting values has not yet been finally assessed—the total *G*-value of electrons. In the gas phase, the *G*-value of electrons can easily be measured by the current-saturation-method. However, in the liquid phase, this method cannot easily be applied. Moreover, the definition of the ionization in the liquid phase itself is somewhat obscure; *i.e.*, the ionized state and the highly excited state are not clearly distinguishable in the liquid phase.

When we use the electron-scavenging method, the value we can determine is the *G*-value of scavengeable electrons, which might not equal the total *G*-value of the electrons. For example, a certain highly excited state might be quenched by the electron transfer to the scavenger.[2,3] Moreover, when we use the electron-scavenging method, we have to face the problem of extrapolation. If there are two different equations which fit the data at low concentrations of the scavenger, the extrapolation to an infinite concentration would give two different values of the total *G*-value of the scavengeable electrons. From this point of view, bromobenzene is one of the most useful electron scavengers, because we can make experiments with pure bromobenzene and, therefore, can apply the extrapolation technique from both sides, from lower concentrations and from higher concentrations, when the direct radiolysis of bromobenzene becomes important. In this paper, we wish to show that, in order to obtain a self-consistent value, the empirical formula proposed by Hummel[4] for the electron scavenging is better than that proposed by Warman *et al.*[5]

Experimental

The cyclohexane (Wako Pure Chemical Co. and Tokyo Kagaku Seiki Co.) and 2,2,4-trimethylpentane (Koso Chemical Co. and Tokyo Kagaku Seiki Co.) were used after being passed through 1-m-long silica gel columns. The bromobenzene (Wako Pure Chemical Co.) was purified by fractional distillation before use.

The 2-ml solutions *in vacuo* were irradiated by ^{60}Co γ-rays. The dose rate was $3—9\times10^{19}$ eV/g h, and the total dose ranged from 1 to 15×10^{19} eV.

The products noncondensable at the temperature of liquid nitrogen, hydrogen and methane, were collected in a Toepler-McLeod apparatus and the amount measured by means of a gas buret. The gas was circulated through a cuprous oxide furnace maintained at 260 °C and a liquid nitrogen trap to convert the hydrogen into water. The residual gas, methane, was then collected again, and its amount was measured.

The condensable products were measured gas-chromatographically. The following columns were used: the 4-m tricresyl phosphate column at 60 °C for benzene, the 5-m dimethylsulfolane column at room temperature for cyclohexene, and the 2-m polyethylene glycol column at 80 °C for bicyclohexyl. As the standard compound, toluene or hexane was used.

Results

Figures 1 and 2 show the *G*-values of benzene, hydrogen, and methane from the bromobenzene solutions in cyclohexane and 2,2,4-trimethylpentane as functions of the concentration of bromobenzene, where the concentration of bromobenzene is lower than 1 mol l^{-1}.

In order to subtract the contribution of the direct

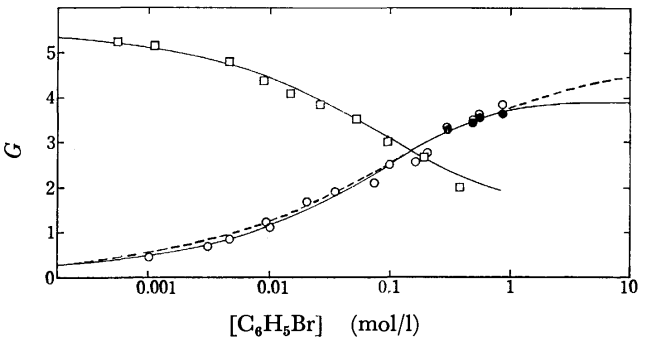

Fig. 1. The *G*-values of benzene (○) and hydrogen (□) from the bromobenzene solution in cyclohexane. For the filled circles and the curves, see the text.

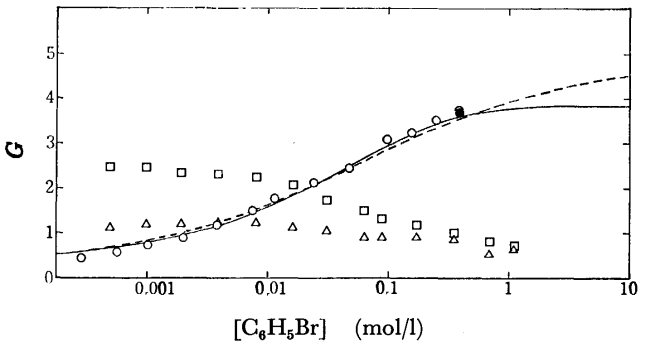

Fig. 2. The G-values of benzene (○), hydrogen (□), and methane (△) from the bromobenzene solution in 2,2,4-trimethylpentane. For the filled circle and the curves, see the text.

radiolysis of bromobenzene, we assumed that the G-value of benzene from pure bromobenzene is 1.2 (see below) and that the energy absorption occurs proportionally to the electron fraction. The filled signs in Figs. 1 and 2 represent the corrected values.

The two kinds of curves for the G-values of benzene, solid and dashed, shown in Figs. 1 and 2, were drawn by using the following two empirical equations; for the solid curves,

$$G(C_6H_6) = G_{fi} + G_{gi}\{1-\exp(-\sqrt{\alpha S})\} \quad (1)$$

and for the dashed curves,

$$G(C_6H_6) = G_{fi} + G_{gi}\frac{\sqrt{\alpha S}}{1+\sqrt{\alpha S}}. \quad (2)$$

Here, S is the concentration of bromobenzene. G_{fi}, G_{gi}, and α are empirical constants, whose values are summarized in Table 1. Since the two equations coincide with each other at the low-concentration limit, the G_{fi}'s in both equations should be the same.

Figures 3 and 4 show the G-values of benzene observed at the concentrations higher than 1 mol l^{-1}. The abscissa is the electron fraction of bromobenzene. Obviously, the G-value of benzene has its maximum value at about 1 mol l^{-1} of bromobenzene. The solid lines correspond to the equation

$$G(C_6H_6) = g_B(C_6H_6)\varepsilon_B + g_H(C_6H_6)\varepsilon_H, \quad (3)$$

where ε_B and ε_H are the electron fractions of bromobenzene and the hydrocarbon used. The g_B and g_H values thus obtained may be summarized as follows; $g_B=1.2\pm0.3$, $g_H=3.7\pm0.3$ for cyclohexane and $g_B=1.0\pm0.2$, $g_H=3.5\pm0.2$ for 2,2,4-trimethylpentane. Since g_H corresponds to the total G-value of benzene when ideal electron scavenging occurs in a pure hydrocarbon, the g_H should be equal to the sum of G_{fi} and G_{gi}.

Table 1. Empirical constants obtained by fitting the data to Eq. 1 and to Eq. 2.

Equation	Cyclohexane			2,2,4-Trimethylpentane		
	G_{fi}[a]	G_{gi}	α[b]	G_{fi}[a]	G_{gi}	α[b]
(1)	0.15	3.8	10	0.33	3.5	18
(2)	0.15	4.8	10	0.33	4.5	16

a) Determined by the conductivity method.[10]
b) 1 mol^{-1}.

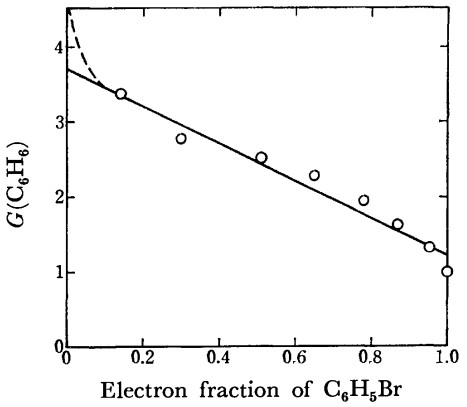

Fig. 3. The G-values of benzene from the bromobenzene solution in cyclohexane at the high concentrations of bromobenzene. For the solid and dashed lines, see the text.

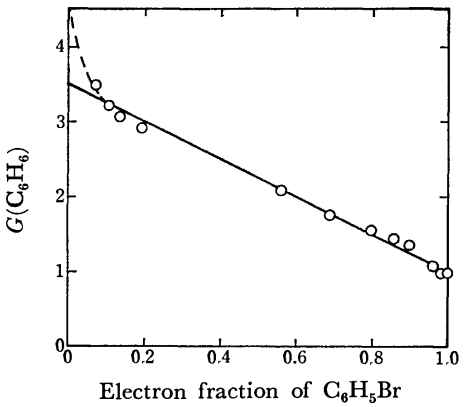

Fig. 4. The G-values of benzene from the bromobenzene solution in 2,2,4-trimethylpentane at the high concentrations of bromobenzene. For the solid and dashed lines, see the text.

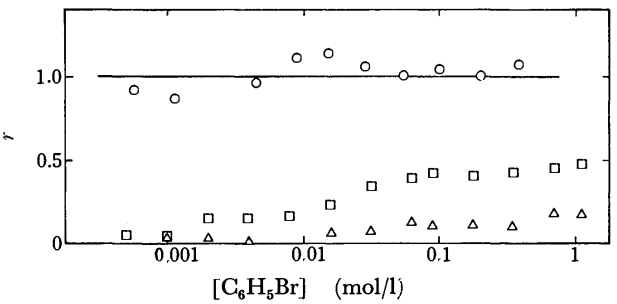

Fig. 5. Compensation between the G-value of benzene and the G-value of noncondensable products. ○: r_{H_2} from cyclohexane solution, □: r_{H_2} from 2,2,4-trimethylpentane solution, and △: r_{CH_4} from 2,2,4-trimethylpentane solution.

Comparing the g_H's shown above with the values in Table 1, we can conclude that Eq. 1 gives more self-consistent values than does Eq. 2.

Figure 5 shows the following ratios;

$$r_{H_2} = \{G_0(H_2) - G(H_2)\}/G(C_6H_6), \quad (4)$$

and

$$r_{CH_4} = \{G_0(CH_4) - G(CH_4)\}/G(C_6H_6). \quad (5)$$

TABLE 2. G-VALUES OF CYCLOHEXENE, BICYCLOHEXYL, AND CYCLOHEXYL BROMIDE FROM THE BROMOBENZENE SOLUTION IN CYCLOHEXANE

Bromobenzene (mol l^{-1})	$G(C_6H_{10})$	$G(C_{12}H_{22})$	$G(C_6H_{11}Br)$
0	3.01	1.95	
0.00045	0	0.49	
0.42	0	0.31	0.75
1.06	0	0.23	0.72

Here, G_0 stands for the G-value from a pure hydrocarbon. Obviously, in the case of cyclohexane, the $G(H_2)$ are compensated by the $G(C_6H_6)$. The G-values of hydrogen and methane from 2,2,4-trimethylpentane solution will be discussed later.

A few experiments were made in the measurement of the G-values of cyclohexene, bicyclohexyl, and cyclohexyl bromide in the presence of bromobenzene. The results obtained are summarized in Table 2.

Discussion

When Warman *et al.* proposed Eq. 2 for expressing the G-values of the methyl radicals formed by the electron scavenging of methyl bromide in cyclohexane, they compared Eq. 2 with Eq. 1,[6] which had been proposed by Hummel. Since their data beautifully fit Eq. 2, they abandoned Eq. 1. However, the highest concentration they used was 0.5 mol l^{-1}, and the G-value obtained at this concentration was 2.8, which corresponds to 72% of the value of G_{gi} they estimated by applying Eq. 2 to their data. In other words, the G_{gi} value they determined is based on a long extrapolation. Consequently, it is doubtful that the sum of G_{fi} and G_{gi} thus obtained is the true total G-value of scavengeable electrons.

As is shown in Figs. 1 and 2, the present data obtained at lower concentrations of bromobenzene are not reproducible enough to discriminate Eq. 1 from Eq. 2. However, as has been shown above, the extrapolation from the high-scavenger-concentration side seems to be more consistent with Eq. 1 than with Eq. 2.

Theoretically we cannot discuss the merits of the two empirical equations. All we can say at present is that the sum of G_{fi} and G_{gi} obtained by the use of Eq. 1 is closer to the total G-value of scavengeable electrons estimated by the extrapolation from the high-concentration side than that estimated by the use of Eq. 2. Of course, Eq. 3 is also an empirical equation. Therefore, $G(C_6H_6)$ might deviate from Eq. 3 at the low-electron fraction of bromobenzene, as is shown by dashed lines in Figs. 3 and 4. However, we do not think this is plausible.

As Fig. 5 shows, the $G(H_2)$ from the cyclohexane solution are compensated by $G(C_6H_6)$. This seems to substantiate the idea that one neutralization reaction between the cyclohexane ion and electron leads to the formation of one hydrogen molecule. The curve for $G(H_2)$ in Fig. 3 was drawn by the use of the equation

$$G(H_2) = 5.6 - [G_{fi} + G_{gi}\{1-\exp(-\sqrt{\alpha S})\}]. \quad (6)$$

Here, the value of 5.6 is the G-value of hydrogen from pure cyclohexane.

On the other hand, in the case of 2,2,4-trimethylpentane, the situation is much more complex. The ratios, r, for hydrogen and methane depend on the concentration of bromobenzene. In order to explain this dependence, we propose the following reaction mechanism.

According to the mass-spectrometric analysis, the parent ion of 2,2,4-trimethylpentane is not stable, but easily decomposes into a butyl ion and a butyl radical. If this type of decomposition competes with the geminate recombination between the parent ion and an electron, and if the neutralization reaction between a butyl ion and an electron does not lead to the formation of hydrogen or methane, then we can derive the concentration-dependences of $G(H_2)$ and $G(CH_4)$.

The probability of the electron scavenging by bromobenzene by the time t may be expressed as follows:

$$\int_0^t kSe^{-kSt'}dt' = 1 - e^{-kSt}. \quad (7)$$

Here, k is the rate constant of the electron scavenging by bromobenzene. Then, the fraction of electrons which react with the electron scavenger should be expressed by the equation

$$F(\phi) = \int_0^\infty f(t)(1-e^{-kSt})dt = 1 - \int_0^\infty f(t)e^{-kSt}dt. \quad (8)$$

Here, $f(t)$ is the time distribution function of the geminate electrons. If Hummel's empirical equation can be used for expressing the electron scavenging in the present system, the $f(t)$ function should satisfy the following equation:

$$\int_0^\infty f(t)e^{-kSt}dt = \exp(-\sqrt{\alpha S}). \quad (9)$$

The $F(\phi)$ fraction corresponds to the yield of benzene produced by the reaction between bromobenzene and geminate electrons.

When the electron scavenger is absent, the formation of hydrogen depends on the decomposition lifetime of the parent ion ($\tau = 1/k_0$) and on the efficiency of the hydrogen formation from the neutralization reaction (γ):

$$F(H_2) = \gamma\int_0^\infty e^{-k_0t}f(t)dt. \quad (10)$$

In the presence of bromobenzene, this fraction should be modified as follows:

$$F(H_2)_S = \gamma\int_0^\infty e^{-k_0t}f(t)e^{-kSt}dt. \quad (11)$$

Therefore, we can easily derive the following equations:

$$r'_{H_2} = \frac{G(H_2)_0 - G(H_2)}{G(\phi) - G_{fi}} = \gamma\frac{\int_0^\infty f(t)\{e^{-k_0t} - e^{-(k_0+kS)t}\}dt}{1-\int_0^\infty f(t)e^{-kSt}dt} = \gamma\frac{\exp(-\sqrt{\beta}) - \exp(-\sqrt{\beta+\alpha S})}{1-\exp(-\sqrt{\alpha S})}. \quad (12)$$

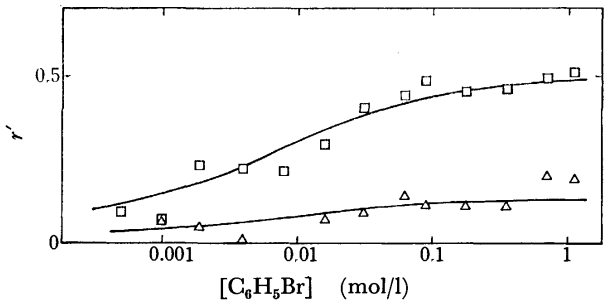

Fig. 6. The interpretation of the formation of hydrogen and methane from 2,2,4-trimethylpentane solution. □: r'_{H_2} and △: r'_{CH_4}.

Here, $\beta=k_0\alpha/k$. The curve for r'_{H_2} in Fig. 6 was drawn by using the following values; $\alpha=18$ l mol^{-1}, $\beta=0.052$, and $\gamma=0.61$. A similar treatment can be applied to r'_{CH_4} ratio. The value of γ used for drawing the curve for methane was 0.16.

In order to estimate the decomposition lifetime of the 2,2,4-trimethylpentane ion, let us assume that $k=10^{13}$ l mol^{-1} s^{-1}.[7] Then, the lifetime can be estimated to be 2×10^{-11} s.

Freeman and Sambrook commented that, when one uses a bromide compound as an electron scavenger, one has to pay attention to the effect of the product, especially hydrogen bromide, on the electron scavenging process.[8] According to the radiolysis study of pure bromobenzene, the G-value of hydrogen bromide is not small, but ranges from 1.0 to 2.0.[9]

When we measured the G-value of benzene from the bromobenzene solution in cyclohexane, we observed the formation of cyclohexyl bromide as is shown in Table 2. Upon the addition of bromobenzene, the formation of cyclohexene was completely suppressed. This is probably due to the reaction of cyclohexene with the hydrogen bromide eventually produced.

Although we could not clarify the fate of all of the bromine atoms, the final form of bromine atoms may be alkyl bromide. If such products as alkyl bromide should seriously affect the electron scavenging process of bromobenzene, some changes would be needed in the present treatment, especially for the absolute value of G_{gl}. However, since the absolute amount of any product is much smaller than that of bromobenzene added to the solution, we do not think that the effect of a product such as alkyl bromide on the electron-scavenging process of bromobenzene is serious.

Cation Distribution in Mixed Formates. I. Change in Lattice Constants and in Infrared Spectra with the Chemical Constitution of $(Cu,M^{II})(HCOO)_2 \cdot 2H_2O$

Toshiko OGATA,* Tooru TAGA, and Kenji OSAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 22, 1976)

Mixed crystals of formates, with the general formula of $(Cu,M^{II})(HCOO)_2 \cdot 2H_2O$, were found to show non-uniform changes in lattice constants with the change in the chemical constitution. The reason for this unusual change was sought in relation to a possible non-uniform distribution of the cations over the two non-equivalent sites for metal ions. A simple model based merely on the difference in the radii of metallic ions did not agree with the results of IR measurements nor with those of an ESR study by Wagner *et al.* Another model, incorporating the change in the direction of the longest axis of the octahedron coordinating to the Cu^{2+} ion at the M1-site, as suggested from the results of a related work (Part II), was found not only to explain the changes in lattice constants, but also to conform with other evidences; it seems to be an essentially correct interpretation.

It has been reported that formates of divalent transitional metals, such as Mn, Fe, Co, Ni, Cu, Zn, and Cd, form isomorphous crystals with the general formula of $M^{II}(HCOO)_2 \cdot 2H_2O$.[1-7] Figure 1 shows the crystal structure of the copper salt as an example. The crystals are monoclinic, with a space group of $P2_1/c$, and the metal ions occupy two sets of non-equivalent centers of symmetry: the M1-site at 0,0,0, *etc.* and the M2-site at 1/2, 1/2, 1/2, *etc.* The metal ion at the M1-site is coordinated by an octahedron of six oxygen atoms, all from formate ions, while that at the M2-site is coordinated by a second octahedron of four water molecules and two oxygen atoms from formate ions.

The existence of the two sets of metal sites with different surroundings suggested the possibility that, when mixed crystals were prepared among the members of this series, cations of different chemical species might occupy different sites with different occupancy. Such a phenomenon would be interesting not only because it has been observed frequently in minerals, but also because it reminds us of the selectivity of biologically important substances to metal ions.[8]

From a series of preliminary experiments made in this laboratory,[9] it has been found that mixed crystals containing copper ions as one of the components exhibit an unusual behavior in the change of lattice constants with the change in the molar ratio of cations. A systematic study was thus undertaken of copper-containing mixed crystals of dihydrated formates.

Description of the Results

Preparation and Chemical Constitution. Mixed crystals with various molar ratios were prepared for the Cu–Zn, Cu–Ni, and Cu–Mn systems by the slow evaporation of the corresponding mixed solution at 55±2 °C. Only a small portion from a large quantity of each solution was crystallized out so as not to cause a substantial change in the composition of the solutions during crystallization. The relative amount of metallic ions in mixed crystals and in the mother liquor, both before and after the crystallization, were determined by absorptiometric methods. Figure 2 shows the relations between the compositions of the solution and the mixed crystals obtained in this way.

Powder X-Ray Pattern and Lattice Constants. The mixed crystals obtained were studied by X-ray powder diffractometry; the results are shown diagrammatically in Fig. 3. It may be noted that the 2θ values of some of the reflections do not change uniformly, indicating that the change in the lattice constants with the chemical constitution is not uniform; this can be seen more clearly in Fig. 4. The results obtained here seem to indicate a non-uniform distribution of the metal ions over the two possible sites, but a detailed interpretation will be given later.

Study by Infrared Absorption. IR measurements were made in order to get some additional clue as to the possibility that either one of the two sites, M1 or M2, might be preferentially occupied by Cu^{2+} ions. The spectra that were found to be most useful for this purpose are those assigned to the wagging vibrations of the water molecules, as is shown in Table 1, where the assignment was obtained by studying the IR spectra

reproduced in Fig. 5 with reference to some reports on related substances.[10,11]

Figure 6 shows how the spectra in this region change with the molar ratio of the cations. The relative amounts of the two kinds of metal ions occupying the M2-sites were determined from these spectra by comparing the optical densities at appropriate wavelengths (600, 555, 550, and 568 cm^{-1} for Cu, Zn, Ni, and Mn, respectively), assuming a 100% transmission at about 430 cm^{-1} and making use of the calibration curves prepared by mixing known amounts of the two kinds of pure substances corresponding to Fig. 5.

The results are shown in Fig. 7, in which the dotted lines, A, B, and C, correspond to the simple models described in the next section. Although there is some scattering of the observed points, it may be concluded that there is a definite tendency for the Cu^{2+} ions to occupy the M1-site rather than the M2-site.

Discussion

As has already been stated, the observed characteristic change of the lattice constants shown in Fig. 3 can not be explained by the uniform replacement of the metal ions in both M1- and M2-sites; some kind of structural change must be taken into account in order to explain the results obtained.

Model calculations were attempted of the lattice constants, a and c, of the Cu–Ni and Cu–Mn systems, for which the two extreme structures are shown in Fig. 8 in superposed projections. We assumed that the change in the lattice constants is mainly the result of the dif-

ference in metal-oxygen distances observed in Fig. 8. In the first place, calculations were made for the three simplest models:

(Model A) The two kinds of ions occupy the two sites without any preference;

(Model B) The Cu^{2+} ions occupy the M2-sites, and the other ions occupy the M1-sites, both with a 100% preference;

(Model C) The same as in model B, except that the M1- and M2-sites are interchanged.

In all three cases, it was assumed that the orientations of the Cu-octahedra at the M1- and M2-sites are the same as those found in the crystal structure of the pure Cu salt.[6]

The results of these model calculations are shown in Fig. 9. Of the three models given above, Model B appears to be in better agreement with the observed points than does A or C. However, this is just the opposite of the results of the IR measurements given above, and also contradicts the results of the ESR study by Wagner *et al.*[12] Moreover, it is noticed that the change in *a* in Fig. 9 (a) is too big to be explained even with Model B.

As a matter of fact, it has been shown, from the single crystal study described in Part II,[13] that, in the 1 : 1 mixed crystal of Cu and Zn salts, most of the Cu-octahedra occupying the M1-site have their longest axis pointing normal to the $[Cu(HCOO)_2]$ sheet, unlike those in the pure Cu salt. This is a possibility that has not been taken into account thus far, so model calculations were also tried for the following two models:

(Model D) Similar to Model C, except that the orientation of the Cu-octahedron at the M1-site is varied according to the Zn/Cu ratio; the longest axis of the Cu octahedron mostly lies along the bc-plane, while the Zn/Cu ratio is low, but as the Zn/Cu ratio increases the proportion of the longest axis pointing normal to the bc-plane becomes larger, attaining to a 70 to 80% orientation at Zn/Cu=1 : 1 (Part II);

(Model E) Both ions occupy both M1- and M2-sites without any preference, as in Model A, but the longest axis of the Cu-octahedron at the M1-site changes its direction, just as in Model D.

In both cases, the longest axis of the Cu-octahedron at the M2-site always corresponds to M2–O3′. The results for these models, also shown in Fig. 9, seem to indicate that the best model lies somewhere between D and E. This result is also in accord with that of the IR measurements and seems to be the most reasonable interpretation of the mixed crystal formation in the $(Cu,M^{II})(HCOO)_2 \cdot 2H_2O$ system.

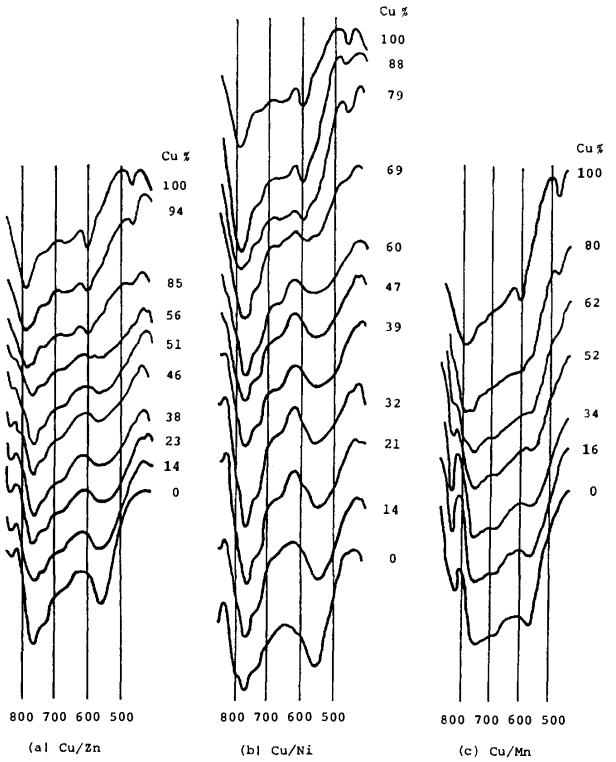

Fig. 6. Changes of the IR spectra assigned to wagging vibrations of water molecules, caused by the change in the molar ratio of metal ions. The abscissa are the wavelengths ($\nu \times$ cm).

Experimental and Calculational Details

Preparation of Mixed Crystals. A mixture of calculated amounts of the starting substances, carbonates for Zn and Mn or basic carbonates for Cu and Ni, was decomposed in water with a slight excess of formic acid. The solution thus obtained (pH 3—4) was then evaporated in a constant-temperature box at 55±2 °C.

Chemical Analysis. Mixed crystals from each batch were dissolved in water and analyzed by absorptiometric methods,

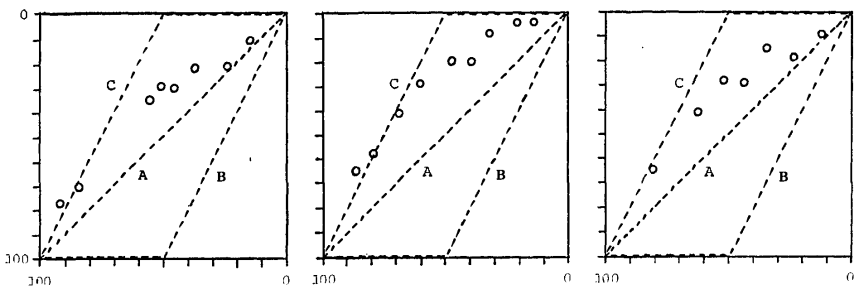

Fig. 7. Relative amount of metal ions coordinated by water molecules (in M2-sites) against the total amount contained in the mixed crystals.

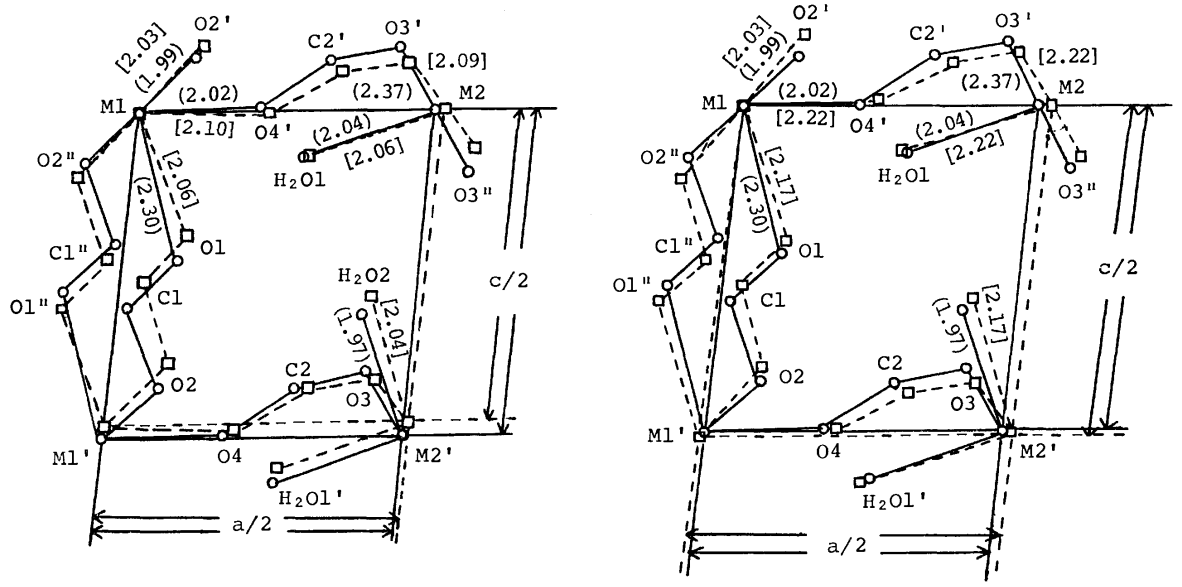

Fig. 8. Crystal structures of $Cu(HCOO)_2 \cdot 2H_2O$ and of $M^{II}(HCOO)_2 \cdot 2H_2O$, shown superposed in b-axis projections. Figures in ( ) and in [ ] are those for the Cu salt and for the salt of the other metals, respectively.

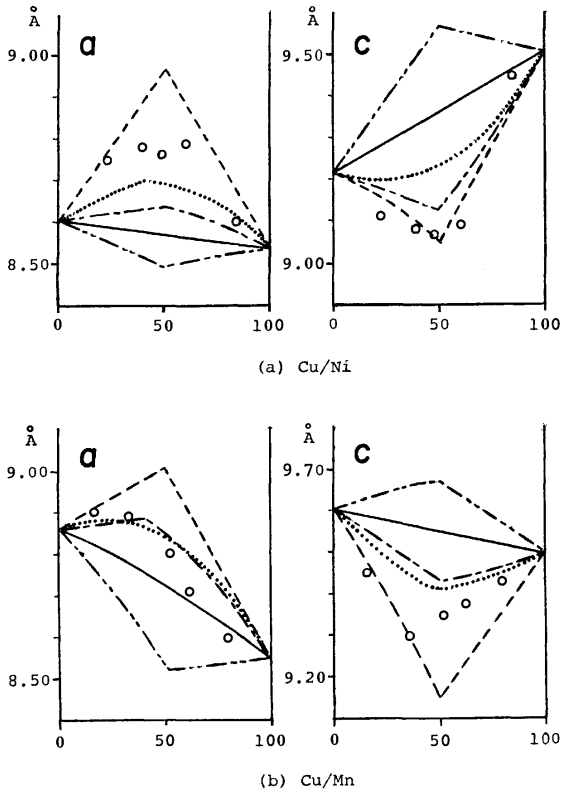

Fig. 9. Model calculations on the lattice constants a and c.
——— model A, ------ model D,
—— — model B, ····· model E.
—— — model C,

as will be described below. The same method was used also for the analysis of the mother liquor.

For the case of Cu–Zn, the zincon method[14,15] was used. For the case of Cu–Ni, the absorbance of the solutions colored by EDTA (pH≈6) was measured at two suitable wavelengths selected from 740, 590, and 385 mμ according to the concentration adopted (from 10^{-3} to 4×10^{-2} mol/l). For the case of Cu–Mn, Mn was measured using the permanganic-acid method[16], while Cu was measured as in the case of Cu–Ni.

X-Ray Powder Diffractometry. The conditions of powder diffractometry were, for the Cu–Zn and Cu–Ni systems: Rigaku Geigerflex; Ni-filtered CuK radiation; 30 kV; 15 mA; receiving slit, 0.15 mm; scanning speed, 1°/min; time constant, 4 s; for the Cu–Mn system: Norelco Diffractometer; Mn-filtered FeK radiation, 35 kV; 10 mA; receiving slit, 0.006 inch; scanning speed, 1°/min; time constant, 8 s.

No signs of unusual line broadening were detected in the powder diagrams of mixed crystals; this suggests that the compositions of the powdered crystal grains in the same batch were fairly uniform and that local fluctuations in the lattice constants were not appreciable.

Indices were given at first only to lower-order, non-overlapping reflections, making use of the similarity in the powder patterns of the mixed crystals and of individual pure substances. The lattice constants calculated by the least-squares method from the observed spacings of these reflections made possible the indexing of additional reflections. This process was repeated until it became difficult to add new reflections.

Infrared Absorption Measurements. The IR spectra shown in Fig. 5 were obtained with a Perkin-Elmer Model 521, and those in Fig. 6, with a Koken DS-301, both using the nujol mull method. In Fig. 5, the spectra shown by dotted lines are those of the anhydrous salt in the case of $Cu(HCOO)_2 \cdot 2H_2O$ and those of the deuterates in the case of $Ni(HCOO)_2 \cdot 2H_2O$.

Model Calculations of the Lattice Constants. The following assumptions were also made:

1) The change in β can be ignored;

2) The change in the axial length, a, is mainly determined by the a-axis component of the variations in the M1–O4′ bond distances, though some additional corrections were also applied taking into consideration the differences in the M2–

O4′ distances which were actually observed in the Cu, Ni, and Mn salts;

3) The change in the axial length, c, is mainly determined by the c-axis component of the difference in the M1–O1 bond distances, though corrections similar to those above were also made for the change in the M1′–O1 distance.

The authors are indebted to Professor Emeritus Eiji Suito, Institute for Chemical Research, Kyoto University, and to Professor Katsunosuke Machida of this Faculty for their helpful advice in doing the IR measurements. The preliminary part of this work has been participated in by Miss Yoko Kokado (Mrs. Taga), Miss Miyako Yasuda (Mrs. Hoshiai), Miss Ouko Hamada (Mrs. Umemura), Miss Noriko Okudaira, Miss Yuriko Tanaka (Mrs. Ohno), Miss Yasuko Matsuo and Miss Yumiko Sumida, to all of whom the authors' thanks are also due.

One of the authors (K. O.) is also especially indebted to Professor Emeritus Isamu Nitta and Professor Emeritus Tokunosuké Watanabé, in the atmosphere of whose laboratories in the Faculty of Science, Osaka University, the idea of this work has emerged.

Most of the computations were performed on the HITAC 5020 at the Kyoto University Computation Center or on the FACOM 230-60 at the Data Process ing Center, Kyoto University, using UNICS programs and those written by the authors.

Cation Distribution in Mixed Formates. II. The Structure of the Mixed Crystal $Cu_{0.5}Zn_{0.5}(HCOO)_2 \cdot 2H_2O$

Toshiko OGATA,* Tooru TAGA, and Kenji OSAKI
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received November 22, 1976)

The structure of the 1 : 1 mixed crystal between $Cu(HCOO)_2 \cdot 2H_2O$ and $Zn(HCOO)_2 \cdot 2H_2O$ has been determined on the basis of 878 visual intensity data. The space group is $P2_1/c$, with $a=8.77$, $b=7.25$, $c=9.17$ Å, $\beta=98.0°$, and $Z=4$. The structure is similar to that of $Cu(HCOO)_2 \cdot 2H_2O$, except that the two metal ions are distributed over two metal ion sites, the Cu^{2+} ions being mostly localized in the $[Cu(HCOO)_2]$ sheet, and except that the longest axis of the coordination octahedron around the Cu^{2+} ion in this sheet is nearly perpendicular to it. It is suggested that the type of sheet found in the mixed crystal as well as in $Cu(HCOO)_2 \cdot 4H_2O$ is more favorable than that in $Cu(HCOO)_2 \cdot 2H_2O$ for an independent $[Cu(HCOO)_2]$ sheet.

In Part I of this series,[1] it has been shown that the lattice constants of the mixed crystals with the general formula of $(Cu,M^{II})(HCOO)_2 \cdot 2H_2O$ do not change uniformly with the change in the chemical constitution, and that simple models based merely on the preferential occupation of the two non-equivalent sites by different metal ions were unsatisfactory in explaining the observed results. It was, therefore, hoped that a detailed structure study of a 1 : 1 mixed crystal of this series would provide some evidence which might help elucidate the problem.

Structure Determination

Apparently single crystals containing approximately equal amounts of Cu^{2+} and Zn^{2+} ions were obtained by the slow evaporation of a mixed solution with an appropriate molar ratio, as determined from Fig. 2 of Part I.

The lattice constants obtained from Weissenberg photographs are $a=8.77\pm0.03$, $b=7.25\pm0.02$, $c=9.17\pm0.02$ Å, and $\beta=98.0\pm0.5°$. There are four formula units in this unit cell with the space group of $P2_1/c$, just as in $Cu(HCOO)_2 \cdot 2H_2O$.[2] The intensity data, visually estimated on Weissenberg photographs and put on a common scale after necessary corrections, amounted to 878, excluding non-observed reflections.

An approximate structure was easily obtained with reference to those of related formates,[2,3] assuming averaged atoms at both metal sites. Refinements were performed with full-matrix least-squares for the two cases: one with Zn^{2+} at the M1-site and Cu^{2+} at the M2-site (case 1), and the other in which they are interchanged (case 2), in the hope that the slight difference in the number of electrons in the metal ions might give evidence as to which of these two cases corresponds to the true structure. The results are given in Table 1. The R value was 0.110 for both cases. No significant difference was found in the positions of the lighter atoms. From the smaller difference in the thermal parameters for the two metal sites, it might seem that Case 1 could be the correct structure. As a matter of fact, it turned out that the final model adopted after a detailed examination of the structure (to be described later) was closer to Case 2, though the localization of the metal ions was found to be incomplete. A reasonable interpretation of the above contradiction is that the large difference in the thermal parameters has upset the effect of the small difference in electron density.

The atomic scattering factors used were taken from the International Tables for X-ray Crystallography (Vol. 3), and dispersion corrections were applied to the real parts of the scattering factors for Cu^{2+} and Zn^{2+}. The

Description and Interpretation of the Structure

The crystal structure of $Cu_{0.5}Zn_{0.5}(HCOO)_2 \cdot 2H_2O$ is similar to that of $Cu(HCOO)_2 \cdot 2H_2O$,[2)] as is shown in Fig. 1 in superposed projections along the b-axis. They both contain parallel sheets with the composition of $[M^{II}(HCOO)_2]$, interleaved with another kind of sheet with the composition of $[M^{II}(H_2O)_4]$ and linked together by a second formate ion. However, closer study shows that, in the mixed crystal, both the M1–O4′ and M2–O3′ listed in Table 3 are definitely longer than those to be expected for a Zn–O bond (0.74+1.40=2.14 Å), and that the longest axis (M1–O4′) of the coordination octahedron at the M1-site points almost normal to the $[M^{II}(HCOO)_2]$ sheet, which is quite different from that found in $Cu(HCOO)_2 \cdot 2H_2O$, where the longest axis M1–O1 lies along the sheet. The latter observation suggests that the longest axis of the Cu-octahedron at the M1-site changes its direction in relation with the relative concentration of the Cu atom and opens the possibility of some new models for the relation between lattice constants and chemical constitution which has been discussed in Part I.

Table 4. Observed and calculated M–O distances

Bond	Observed	Calcd[a)]		
		70%	80%	100%
M1-O4′	2.22 Å	2.20 Å	2.23 Å	2.27 Å
M1-O1	2.10	2.10	2.08	2.03
M1-O2′	2.02	2.03	2.03	2.03
M2-O3′	2.19	2.18	2.18	2.18
M2-W1	2.10	2.07	2.07	2.07
M2′-W2	2.04	2.07	2.07	2.07

a) The percentages given for the calculated values are the proportions of the longest axis orientated along M1–O4′.

The observed length of M1–O4′ and M2–O3′ can only be explained if it is assumed that both M1 and M2 sites are occupied by Cu^{2+} ions to some extent and that the two bond lengths mentioned above are the average values including the contributions from the longest axis of the Cu octahedron. If we adopt the findings of our IR study described in Part I, that in a 1 : 1 mixed crystal between the Cu and Zn salts about 70% of the M1-site is occupied by Cu^{2+} ions, and make the further assumption that from about 70 to 100% of the Cu-octahedra occupying the M1-site are orientated with their longest axis along M1–O4′, we obtain the calculated M–O distances given in Table 4.

It will be seen that a satisfactory agreement between observed and calculated M–O lengths is obtained with

** Table 2 is kept at the office of the Chemical Society of Japan, 1-5 Kanda-Surugadai, Chiyoda-ku, Tokyo 113 (Document No. 7708).

a 70 to 80% orientation. In this calculation, it was further assumed that all the Zn–O bond is 2.10 Å, while for Cu–O, the longest axis is 2.35 Å and the shorter ones are 2.00 Å.

The conclusions obtained here, that in the 1 : 1 mixed crystals between Cu and Zn salts, the M1-site is preferentially occupied by Cu^{2+} ions and that most of the longest axes of the Cu-octahedra at the M1-site point to M1–O4′, while those at the M2-site point to M2–O3′, not only explain the observed changes in the lattice constants with respect to the chemical constitution (Part I), but are in agreement with the results of an ESR study of the Cu-doped $Zn(HCOO)_2 \cdot 2H_2O$ by Wagner *et al.*[4] if the principal axis of the magnetic field at the Cu^{2+} ion found by ESR coincides with the longest axis of the Cu-octahedron.

The structure of the 1 : 1 mixed crystal between Cu and Zn salts has now been elucidated including the distribution of the cations, but questions still remain as to why the Cu^{2+} ion occupies the M1-site preferentially and why the longest axis of the Cu-octahedron at the M1-site points to M1–O4′ and not to M1–O1, as in the pure Cu salt.

A sheet with the composition of $[M^{II}(HCOO)_2]$, similar to that found in the mixed crystal, is also found in $Cu(HCOO)_2 \cdot 4H_2O$;[5] it resembles the one in the mixed crystal also with respect to the orientation of the longest axis of the Cu-octahedron. The sheet in the tetrahydrate has been the subject of many investigations because of its remarkable anti-ferromagnetic nature,[6–15] and it seems generally accepted that the superexchange interaction by way of the delocalized π-electron cloud of the formate ion is responsible for the magnetic interaction between the neighboring Cu^{2+} ions in the sheet.[4,16,17] Since the Cu^{2+} ion is coordinated with an elongated octahedron, an arrangement with the long axis almost normal to the sheet will be most favorable for a better overlapping between the copper d-orbitals and oxygen π-orbitals of the formate ion. The very large exchange integrals observed for the tetrahydrate ($-54\ cm^{-1}$)[12] and for the Cu^{2+} ions in $Zn(HCOO)_2 \cdot 2H_2O$ ($-33\ cm^{-1}$)[4], as compared with the corresponding values for $Cu(HCOO)_2 \cdot 2H_2O$ (1.5 K),[18] seem to support this view.

A comparison among the $[Cu(HCOO)_2]$ sheets found in the three compounds discussed shows that the sheet in the mixed crystal is, in a sense, intermediate between those in $Cu(HCOO)_2 \cdot 4H_2O$ and in $Cu(HCOO)_2 \cdot 2H_2O$ (Fig. 2). Perhaps it may be said that the sheets found in $Cu(HCOO)_2 \cdot 4H_2O$ and in the mixed crystal represent the most stable structure for a single $[Cu(HCOO)_2]$ sheet, while that of the other type, found in $Cu(HCOO)_2 \cdot 2H_2O$, is probably a result of some additional interaction through the second formate linkages.

Most of the computations were made on the HITAC 5020 at the Kyoto University Computation Center, using programs written by the present authors.

Radiative Lifetimes of $NH_2(^2A_1)$ Produced by Photodissociation of NH_3 on Irradiation with Vacuum Ultraviolet Light

Seiichiro KODA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received December 1, 1976)

$NH_2(\tilde{A}^2A_1)$ was produced by photolysis of NH_3 on irradiation with vacuum ultraviolet light. The zero pressure lifetimes were evaluated to be *ca.* 15 μs from the phase lag of the emission excited by modulated Xe and Kr resonance lamps. The quenching rate coefficient of $NH_2(^2A_1)$ for NH_3 was determined to be *ca.* $(1.6\pm0.3)\times10^{-10}$ cm³/molecule·s.

Emission from NH_2* (* denotes $^2A_1$) in the visible region was observed from various sources in discharges and flames.[1] Steady state fluorescence was measured following the production of the excited state radical by photodissociation of NH_3 on irradiation with vacuum ultraviolet light from a hydrogen discharge lamp.[2] Rare gas resonance lamps have been rarely used as an exciting light source.

The radiative lifetimes and the quenching rate of the fluorescence for NH_3 was studied by Lenzi *et al.*[3] by a static method. No absolute values could be determined. Only the product value $\tau_0 k_q$ could be obtained, where τ_0 is the zero pressure lifetime and k_q the quenching rate coefficient for NH_3. Halpern *et al.*[4] observed the time resolved fluorescence from NH_2* following the excitation of the radical in its ground state by means of a pulsed tunable dye laser, and measured zero pressure lifetimes and collisional de-excitation rate constants for several rovibronic levels of NH_2*. The calculated values of $\tau_0 k_q$ from their data disagreed with the values in the UV photolysis experiment.[3]

This work was undertaken with the object of measuring τ_0 and k_q, separately, for NH_2* produced in the UV photolysis by using modulated resonance lamps. Through this work deals only with the lifetime measurement of NH_2*, it has a wide applicability. Recently, the pulse method seems to be much more popular than the modulation method for measuring emission lifetimes. This seems to be mainly due to the usefulness of pulsed lasers with a very short pulse width. It is not easy to find a good pulsed light source in the vacuum UV region. Thus the method using modulated resonance lamps and digital lock-in detection of feeble emission light should be utilized for the lifetime measurement of various excited species produced by vacuum UV photolysis.

Experimental

The apparatus is shown in Fig. 1. The fluorescence cell with several appropriate light horns is made of glass, the outside being blackened; the total volume is *ca.* 600 cm³.

The sample gas, NH_3, is illuminated with light from a 2450 MHz microwave discharge lamp inserted directly into the fluorescence cell. The Xe (CaF_2 window) and Kr(LiF window) lamps were of the type described by Loewenstein *et al.*[5] The microwave power was modulated by a circuit similar to that described by Phillips.[6] The light from the discharge lamp could be modulated as nearly a sine-wave form, judging from its oscilloscope trace. Observation was restricted to the UV-visible light from the lamp.

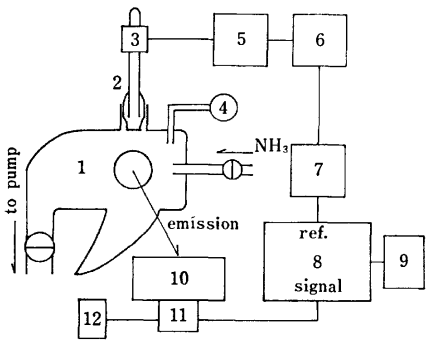

Fig. 1. Reaction apparatus.
1: Fluorescence cell, 2: vuv resonance lamp, 3: microwave cavity, 4: oil manometer, 5: microwave generator, 6: modulation circuit, 7: sine wave generator, 8: photon-counter with a synchronous sampler, 9: chart recorder, 10: monochromator, 11: photomultiplier, 12: high voltage power supply.

Emission from NH_2* was observed at right angles to the exciting beam with a *f*/4.5 monochromator (Nikon P-250). The emission light was then converted into electron pulses by H.T.V. R464 and/or R456 photomultipliers and fed to a Brookdeal 5 Cl photon counter. For lifetime measurements, the reference signal in each cycle from the modulation circuit was fed to the synchronous sampler 5C21. The data of "*A*"−"*B*" were recorded, where "*A*" is the photon count number during a small sampling interval lagging from the reference signal by an arbitrary degree ϕ and "*B*" is that by $\phi+180$ degree. The percent duty, 2×(sampling interval)/(time for one cycle), was set to be 5%.

Ammonia (Matheson Co., 99.99%) was purified by freeze-thaw cycles. The pressure of NH_3 in the cell was measured with an oil manometer.

Results and Discussion

When NH_3 was irradiated by a Xe lamp with a CaF_2 window (147 nm), a weak emission was observed in the range 380—650 nm. The cut-off wavelength at the longer wavelength side could not be determined accurately because of the poorer response of the detector system at longer wavelengths. The Xe lamp with a LiF window (147, 129.6 nm) and a Kr lamp (123.6 nm) eventually gave the same emission besides a much stronger NH (c→a) emission at 327 nm. Because of the weakness of emission, it could only be detected under relatively poor resolution of the monochromator (a band path width above 1.2 nm was adopted) and we could not determine whether the emission was of continuous or many-line type. However, it was evident

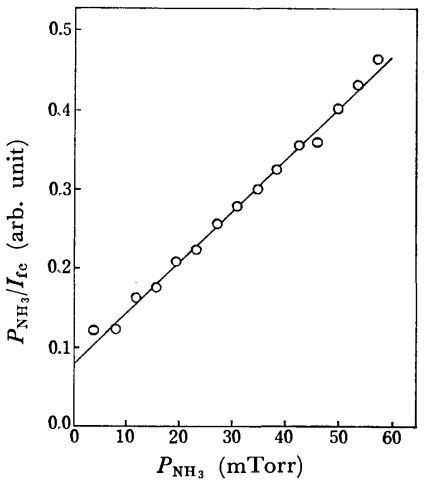

Fig. 2. A typical relationship between P_{NH_3}/I_{fc} and P_{NH_3}.
Excitation by Xe lamp, observation at 520±6 nm. $k_q/k_B=(2.6\pm0.4)\times10^{-15}$ cm^3/molecule is obtained.

from its behavior and the quenching experiments that the emission was from the electronically excited NH_2. Becker and Welge[7] failed to observe this emission with similar resonance lamps. This might be due to the fact that the emission lines were buried in the background under their relatively higher resolution, as suggested by Okabe and Lenzi.[2]

A typical plot is given in Fig. 2 which shows the quenching of NH_2* due to NH_3. The data for the quenching was treated according to the usual mechanism.

$$NH_3 + h\nu \longrightarrow NH_2^* + H$$
$$NH_2^* \longrightarrow NH_2(X) + \text{fluorescence} \quad k_B = \tau_0^{-1}$$
$$NH_2^* + NH_3 \longrightarrow NH_2(X) + NH_3 \quad k_q$$

The fluorescence intensity, I_{fc}, is related to NH_3 pressure, P_{NH_3}, by the equation

$$P_{NH_3}/I_{fc} \propto k_B + k_q P_{NH_3}. \quad (1)$$

Under higher NH_3 pressures, the effect of NH_3 pressure on the light absorption should be considered. Necessary corrections were made on the basis of the geometry of the cell and the extinction coefficient of NH_3 against the exciting lines.[8] The maximum correction was *ca.* 4%.

TABLE 1. THE RATIO k_q/k_B

Exciting light (nm)	Observation wavelength (nm)	k_q/k_B (10^{-15} cm^3/molecule)	Lit

	530±9	2.9±0.4	this work

a) Band path width.

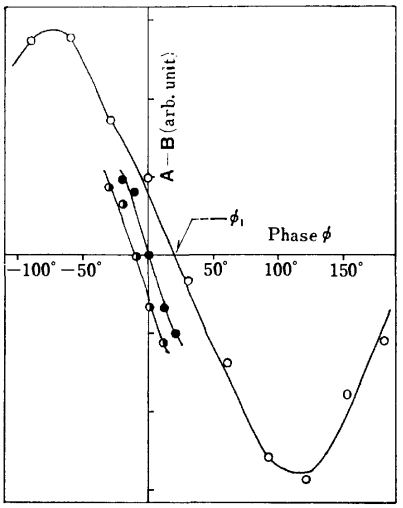

Fig. 3. The data of "A"—"B" at various phases in a modulation experiment.
Excitation by modulated Kr lamp (50 kHz), observation at 520±12 nm. P_{NH_3}=450 mTorr (○), 110 mTorr (●), 50 mTorr (◑). As for ϕ_1, see text.

The fluorescence was observed at several wavelengths. k_p/k_B were evaluated from similar plots to those in Fig. 2 and are given in Table 1. The values are almost independent of the observation wavelength, though allowance should be made for the fact that the fluorescence was observed under relatively low resolution. These values seem to be in good agreement with those of Lenzi *et al.*[3]

Direct lifetime measurements were carried out by means of a modulation technique. The exciting light was modulated as $I_0=\bar{I}_0+\tilde{I}_0\sin(2\pi ft)$, where $\bar{I}_0$ is the d.c. part and $\tilde{I}_0$ is the amplitude of the a.c. part. The possible phase lag of the fluorescence is related to the kinetic process by the equation

$$\theta = \tan^{-1}[2\pi f(k_B+k_qP_{NH_3})^{-1}]. \quad (2)$$

The value "A"—"B" could be measured against any desired phase of degree ϕ (Fig. 3). If we find the degree ϕ_1 at which "A"—"B" is zero, ϕ_1 is equal to $\theta+\phi_0$, where ϕ_0 is the common, though unknown, phase lag of the exciting light from the reference signal of the modulation circuit. ϕ_0 was not measured directly. However, it was so selected that it might give the best linearity as indicated in Eq. 2 between $\theta(=\phi_1-\phi_0)$ and P_{NH_3} at various NH_3 pressures.

The experiments were carried out with several modulation frequencies. Figures 4 and 5 show the results in the case of Xe and Kr lamp excitation, respectively. Because of the weakness of emission, the slightly different wave form of the a.c. part of the exciting light from a precise sine wave, and the relatively large duty factor in measuring "A"—"B", the precision in the measurements of the phase lag was only within ±5 degree. The data do not lie exactly on the straight line, the error limit at the zero pressure limit not being small. In order to confirm the reliability of this technique, measurement was made of the zero pressure lifetime of the c state of NH produced by the Kr lamp excitation. The lifetime of 530 ns ($k_B=1.9\times10^6$/s) was

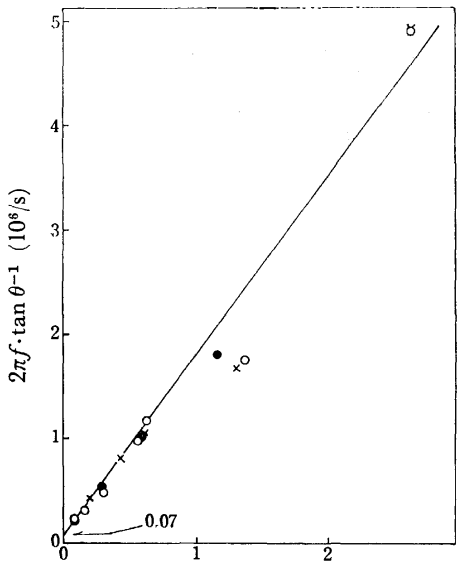

Fig. 4. Emission lifetimes of NH_2* produced by modulated Xe lamp at various pressures of NH_3.
Excitation by Xe lamp, observation at 530±12 nm. Modulation frequency, 54.3 kHz (○), 87.7 kHz (●), 96.2 kHz (×). $k_B=(0.7\pm0.3)\times10^5$/s, $k_q=(1.7\pm0.3)\times10^{-10}$ cm^3/molecule·s are obtained.

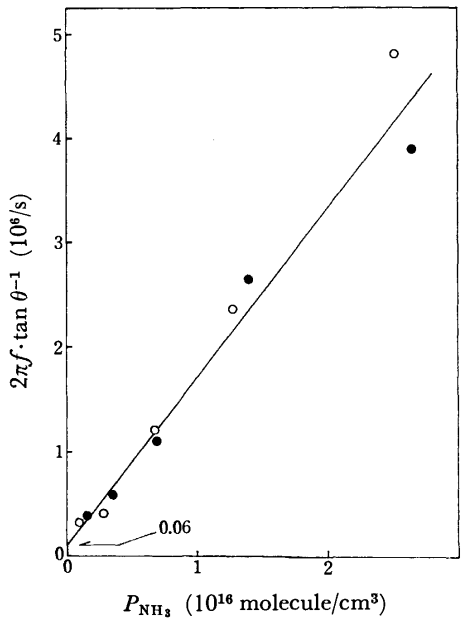

Fig. 5. Emission lifetimes of NH_2* produced by modulated Kr lamp at various pressures of NH_3.
Excitation by Kr lamp, observation at 520±12 nm. Modulation frequency, 54.1 kHz (●), 87.7 kHz (○). $k_B=(0.6\pm0.3)\times10^5$/s, $k_q=(1.6\pm0.3)\times10^{-10}$ cm^3/molecule·s are obtained.

obtained by the same procedure (Fig. 6). The result agrees with the reported value 480±90 ns.[9]

The zero pressure lifetime 14 μs [$k_B=(0.7\pm0.3)\times10^5$ /s] for Xe lamp and 16 μs [$k_B=(0.6\pm0.3)\times10^5$/s] for Kr lamp excitation are near the lifetime 10 μs for the (0,9,0) state obtained by laser light excitation.[4]

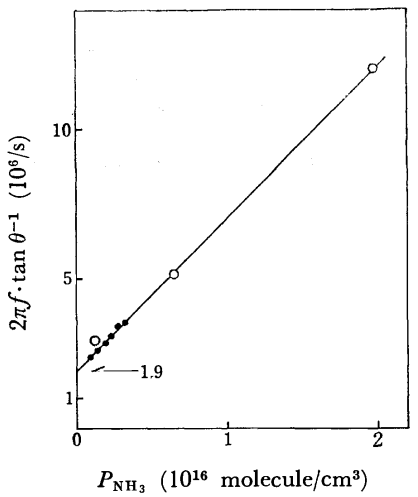

Fig. 6. Emission lifetimes of NH (c) produced by Kr lamp at various pressures of NH_3.
○: $2\pi f \cdot \tan\theta^{-1}$ *vs.* P_{NH_3}, excitation by modulated Kr lamp, observation at 327±3 nm, modulation frequency, 87.7 kHz.
●: P_{NH_3}/I_{fc} *vs.* P_{NH_3}, obtained by steady illumination of Kr lamp, observation at 327±3 nm. In this case, the unknown k_B value (for NH) is assumed to be 1.9×10^6/s in order to plot the value of P_{NH_3}/I_{fc} in the same scale as the data of $2\pi f \cdot \tan\theta^{-1}$.

The k_q values were $(1.7\pm0.3)\times10^{-10}$ (Xe lamp) and $(1.6\pm0.3)\times10^{-10}$ cm^3/molecule·s (Kr lamp). The product values $\tau_0 k_q$ of 2.4×10^{-15} (Xe lamp) and 2.7×10^{-15} cm^3/molecule are in good agreement with the values given in Table 1.

The k_q values are much smaller than the value 10×10^{-10} cm^3/molecule·s for the (0,9,0) state. Thus the discrepancy between the $\tau_0 k_q$ value given by Halpern *et al.*[4] and by Lenzi *et al.*[3] seems to be mainly due to the large difference in the k_q value. The present values as well as those of Lenzi *et al.*[3] are the average of the quenching coefficients for various different vibronic levels of NH_2* produced by the dissociation of NH_3. Fluorescence under low resolution was observed. It should thus consist of the primary emission from the excited NH_2* before any relaxation plus a secondary emission from the relaxed but still electronically excited NH_2. The relatively small k_q values in our case as compared with those of Halpern *et al.*[4] indicates an appreciably efficient vibrational relaxation within the upper electronic state of NH_2 against electronic relaxation to the ground state NH_2.

The author is grateful to Professors S. Tsuchiya and K. Akita, Tokyo University, for their encouragement and valuable suggestions. Thanks are due to Dr. S. Tsunashima, Tokyo Institute of Technology, for his valuable comments as regards the construction of the modulation circuit.

Heat Capacities of Aqueous Solutions of Glutaric and Malonic Acids*

Fumio KAWAIZUMI, Tuneyuki NOGUCHI, and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 6, 1976)

Using a calorimeter composed of a Dewar vessel and a Beckmann thermometer, the specific heat capacities of aqueous solutions of glutaric and malonic acids were measured at 30 °C. Techniques for establishing the temperature gadient between the solution in the Dewar and the outer air bath were adopted. The partial molar heat capacities at infinite dilution were estimated assuming a relation of the form $m\phi_{Cp}=bm+cm^2$. The contributions of the $-CH_2-$ and $-COOH$ groups to the partial molar heat capacities in aqueous solution are roughly additive: for $-CH_2-$ a positive contribution and for $-COOH$ a negative one. The $\Delta(=\overline{Cp}_2^\circ-Cp_2(\text{pure state}))$ were also calculated and positive and negative values were obtained for $\Delta(-CH_2-)$ and $\Delta(-COOH)$, respectively.

It is widely recognized that the heat capacity of a solution is one of the essential quantities which characterizes the solute in solution, especially for solutes containing both hydrophobic and hydrophilic groups.[1-4] From this point of view, the determination of the heat capacities of an aqueous solution of 1,2-ethanediol, 1,2-propanediol, and 1,3-butanediol at 30 °C has been reported.[5]

The present study deals with similar work on aqueous solutions of glutaric and malonic acids using a laboratory-constructed calorimeter composed of a Dewar vessel and a Beckmann thermometer. The heat capacities of aqueous solutions of monocarboxylic acids and their sodium salts have been reported many years ago with sufficient precision,[6] but the situation is completely different for the dicarboxylic series.

Experimental

The calorimeter vessel used is shown in Fig. 1. Although the experimental procedures for determining the heat capacities of solutions are essentially the same as reported previously,[5] the following should be mentioned regarding the calorimeter and the manipulations in the present study. 1) The entire Dewar, except for the upper part of the stirrer and the Beckmann thermometer, is placed in a constant-temperature air bath, while in a previous work,[5] the Dewar was immersed up to the neck in a water bath. 2) In order to obtain more favorable adiabatic conditions, a magnetic stirring system was used in the Dewar. The rotational speed of the stirrer is slow but no heat conduction delay due to the viscosity of the solution was observed. 3) The temperature of the air bath was maintained at a temperature lower than that of the solution in the Dewar. This latter temperature was set near 30 °C and thus the temperature gradient between the solution in the Dewar and the air bath was established. Preliminary experiments showed that with the air bath maintained at 28 °C the most satisfactory results, *i.e.* the temperature variations as a function of time for the solution in the calorimeter before and after the heating are nearly "parallel" to each other (see Fig. 2), are obtained.

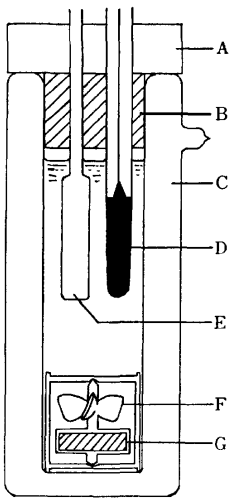

Fig. 1. Calorimeter.
A: Wood plate, B: cork cap,
C: Dewar vessel, D: Beckmann thermometer,
E: glass tube containing heater(manganin wire),
F: glass stirrer,
G: stirring magnet driven externally.

The contact between the cork cap and the Dewar was not so tight as to prevent the passage of vapor from the solution. Other parts of the experimental equipment, such as the electric heating circuit, the circuit for the measurement of the supplied electric power, and the details of the manipulations for determining the heat capacities of the solutions are the same as reported previously.[5]

The heat capacities of the Dewar determined using 100 ml of water are 24.8 cal/K (1 cal=4.184 J) and the reproducibility relative to this value was within ±2.5%. Therefore, the errors due to this uncertainty are *ca.* 0.5% for measurements of 100 g solutions. The precision of the experiments using this calorimeter was checked with the aid of an aqueous solution of Na_2CO_3 at 30 °C, the results being as shown in

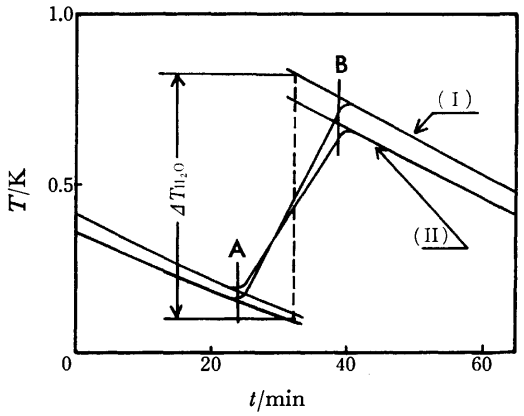

Fig. 2. Temperature variations of the calorimeter with time.

14.86	0.874	0.8855	0.987
9.48	0.900	0.9138	0.985
5.64	0.932	0.9445	0.987
5.46	0.941	0.9462	0.994
3.14	0.967	0.9685	0.998

a) Estimated from the data in "Kagaku Binran," Maruzen, Tokyo (1966), p. 775.

Table 1. There was no special reason for choosing Na_2CO_3 as a standard sample, except that it is easy to handle. As shown in Table 1, the values obtained are always smaller than those found in the literature and the differences increase with concentration. These differences might arise from differences in the degree of vaporization in pure water and that in the aqueous solution.

On taking account of the uncertainty of the heat capacity relative to the Dewar, and the deviations shown in Table 1, in order to determine the specific heat capacity within a precision of 1%, the use of the present calorimeter should be limited to solutions whose specific heat capacities exceed *ca.* 0.9 cal/g K.

Guaranteed pure-grade reagents were used without further purification.

Results and Discussion

The values of the specific heat capacities of the solutions Cp are listed in Tables 2 and 3. The quantity which is of greatest importance in the discussion of the solute-solvent interaction in solution is the partial molar heat capacity, which is defined as

$$\phi_{Cp} = \frac{1}{m}\{(1000+mM_2)Cp-1000Cp_1\}, \qquad (1)$$

where M_2 is the molar mass of the dissolved solute, m the molality, and the subscript 1 refers to the solvent. The limiting partial molar heat capacities, $\phi^\circ_{Cp}=\overline{Cp}^\circ_2$, can be estimated by extrapolating the relationship between ϕ_{Cp} and m. Carboxylic acids are electrolytes but the variation of the ϕ_{Cp} for the carboxylic acids with concentration is linear.[6] Hence $\overline{Cp}^\circ_2$ was obtained from least-squares calculation of the relation

$$m\phi_{Cp} = bm+cm^2, \qquad (2)$$

on taking account of the uncertainties of the Cp data which increase as the concentration becomes more dilute. The relation between $m\phi_{Cp}$ and m is shown in Fig. 3. The coefficients b and c obtained are, for glutaric acid, $b=37.2\pm4.6$ and $c=17.8\pm4.0$, and for malonic acid, $b=0.2\pm3.4$ and $c=18.8\pm2.4$. In Table 4 are summarized the values of $\overline{Cp}^\circ_2(=b)$ thus obtained, along with the results reported by Ackermann *et al.*[6,7] Table 4 also includes the values of $\Delta=\overline{Cp}^\circ_2-Cp_2$(pure state), which are considered to represent the degree of structural change caused by the dissolution of the solutes.

From the data shown in Table 4, the contribution of the $-CH_2-$ and $-COOH$ groups to the $\overline{Cp}^\circ_2$ values can be evaluated;

for $-CH_2-$,

$$1/2\{(CH_2)_3(COOH)_2-CH_2(COOH)_2\} = 18.5$$

monocarboxylc acids: 16.7—20.5

and for $-COOH$,

$$(CH_2)_3(COOH)_2-n\text{-}C_3H_7COOH = -38.3$$

$$CH_2(COOH)_2-CH_3COOH = -41.8.$$

Table 4. Partial molar heat capacities of aqueous solutions of mono- and dicarboxylic acids

Molecule	Cp_2- (pure state) (cal/mol K)	$\overline{Cp}_2^\circ$ (cal/mol K)	Δ (cal/mol K)
$(CH_2)_3(COOH)_2$	39.5[a]	37.2±4.6	−2.3
$CH_2(COOH)_2$	28.6[a]	0.2±3.4	−28.4
HCOOH	23.7[b]	21.5[b]	−2.2
CH_3COOH	29.5[b]	42.0[b]	12.5
C_2H_5COOH	38.1[b]	58.8[b]	20.7
n-C_3H_7COOH	45.3[b]	75.5[b]	30.2

a) "International Critical Tables," Vol. 5, McGraw-Hill, New York (1928), p. 102. b) Cited in Ref. 7.

The values of $\overline{Cp}_2^\circ(-CH_2-)$ for an aqueous system obtained in the present work are compatible with those reported previously,[5] (14.9—20.9 cal/mol K) from diols. The $\overline{Cp}_2^\circ(-CH_2-)$ values have been determined for carboxylic acids by Ackermann *et al.*[6,7] and Konicek and Wadsö[8] (20.1), for amines[8] (21.5), for *N*-substituted amines[8] (20.6), for alcohols[9] (22.7), for *n*-alkylamine hydrobromide[3] (21.1), for bolaform electrolytes[10] (19.4—23.7), and for alkyl-substituted ammonium chlorides[4] (12—18).

Similar calculations for Δ result in the following values:

for $-CH_2-$,

$$1/2\{(CH_2)_3(COOH)_2-CH_2(COOH)_2\} = 13.1$$

monocarboxylic acids: 8.2—14.4

and for $-COOH$,

$$(CH_2)_3(COOH)_2-n\text{-}C_3H_7COOH = -32.5$$

$$CH_2(COOH)_2-CH_3COOH = -40.9.$$

In Ref. 5, 8.1 and −1.6 cal/mol K were reported for $\Delta(-CH_2-)$ and $\Delta(-OH)$, respectively. As mentioned above, Δ is a measure of the structural change accompanying the dissolution of a solute and positive values of $\Delta(-CH_2-)$ have been ascribed to the hydrophobic interaction between water and the $-CH_2-$ group, or iceberg formation.

While the values of ϕ_V°, the apparent molar volume, appear to be precise to within ±0.05 cm^3/mol or better at all temperatures, the situation is quite unfavorable for ϕ_{Cp}°. For instance, Ackermann *et al.*[7] have given, for $MeNH_3Cl$ and $EtNH_3Cl$, −2.0 and 14.6 cal/mol K, respectively, at 25 °C, while Desnoyers *et al.*[10] have reported, for the corresponding bromides, 1.9 and 24.3 cal/mol K, respectively. These differences are too large even after taking account of the difference between $\phi_{Cp}^\circ(Cl^-)$ and $\phi_{Cp}^\circ(Br^-)$. It is highly questionable, at least at the present stage of experimental accuracy inherent in the determination of $\overline{Cp}_2^\circ$, whether the small differences in the $\overline{Cp}_2^\circ(-CH_2-)$ and $\Delta(-CH_2-)$ observed for different homologs, and also for the same homolog, can be related to the neighboring organic groups.

The Effect of Added Inorganic Salts on the Micelle Formation of Nonionic Surfactants in Aqueous Solutions

Nagamune NISHIKIDO and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received December 20, 1976)

In order to divide the inorganic salt effect on the micelle formation of nonionic surfactants into the effects on the hydrocarbon and on the hydrophilic moieties of the surfactant, the critical micelle concentrations(CMC) of nonionic surfactant homologs (8,10,12 methylene and 6 oxyethylene groups) were determined in aqueous salt solutions. The salt-effect parameters of methylene and hexa(oxyethylene) groups were calculated from the CMC data. The orders of both the parameters with respect to the anion obeyed the Hofmeister series. The variation in the extent of the parameters with respect to the cation was much less than that with respect to the anion. These phenomena were discussed in terms of the direct and indirect effects of ions on the water structure around the hydrocarbon and hydrophilic moieties of the surfactants. In addition, the salt effect on the cloud point (CP) and the amount of solubilization toward the Yellow OB dyestuff in aqueous solutions were discussed in connection with the salt effect on the hydrophilic moiety.

The critical micelle concentrations (CMC) of nonionic surfactants in aqueous solutions are lowered by the addition of most inorganic salts.[1-5] In explaining this phenomenon, it has been suggested that salts bring about the dehydration of the hydrophilic moiety of the surfactant "monomer," causing the enhancement of the tendency toward micelle formation, *i.e.*, CMC lowering.[2,3] This mechanism has thus far been the standard view, although others have been suggested.[6,7] However, the micelle formation, *i.e.*, the CMC, is determined by the balance of surfactant stability between that in the monomer and that in the micelle state. Salts have influence not only on the dissolved state of monomers, but also on that of micelles in the solution, and so the dehydration mechanism is questionable. Recently, Mukerjee proposed a salting-out mechanism of the hydrocarbon moiety of surfactant, in which the salt effects on the hydrophilic moieties of the monomer and micelle were assumed to be almost equal in magnitude and to cancel each other out in determining the CMC.[7,8] More recently, Ray and Nemethy[9] and Kresheck[10] examined Mukerjee's suggestion. However, their discussion is insufficient because Mukerjee's assumption of the cancellation of the salt effect on the hydrophilic moiety was not fully taken into consideration. In order to get rid of this ambiguity, it is necessary to estimate separately the salt effects on hydrocarbon and hydrophilic moieties.

In this study, the salt-effect parameter of each moiety during micellization was estimated. Also, we discussed qualitatively the salt effect on the dissolved state of nonionic surfactants in an aqueous solution, since there have been no theories concerning the quantitative clarification of the salt effect on aqueous polar or nonpolar substances.[11-17] In this connection, the cloud points (CP) and the amount of solubilization toward Yellow OB in aqueous salt-nonionic surfactant mixed solutions were determined and discussed.

Experimental

Materials. The nonionic surfactants, poly(oxyethylene) alkyl ethers (abbreviated as C_mE_n; m: the number of methylene groups; n: the number of ethylene oxide groups), were the same materials as those used in a previous paper.[18] All the inorganic salts were of a reagent grade (min 99.0 or 99.5% pure), supplied by the Wako Pure Chemical Co., and were used without further purification. The purification of the Yellow OB dyestuff (1-(o-tolylazo)-2-naphthylamine) as a solubilizate was described in the previous paper.[18]

Method. The CMC values of C_8E_6, $C_{10}E_6$ and $C_{12}E_6$ in aqueous salt solutions at 20 °C were determined by plotting the surface tension against the logarithm of the concentration. The surface tensions were measured with the Dû Noüy tensiometer. In Table 1 are tabulated the CMC values of C_8E_6, $C_{10}E_6$ and $C_{12}E_6$ in a pure aqueous solution. The cloud points were determined as the temperatures at which a sudden turbidity appeared or disappeared in the 1 wt% $C_{12}E_6$ aqueous solutions containing salts, when the solutions were heated or cooled at a constant rate of 0.5 °C/min under stirring. The change in the transparency of the solutions was observed with the naked eye. The procedure for determining the amount of solubilized Yellow OB in the aqueous $C_{12}E_{10}$-salt solutions at 30 °C has been described elsewhere.[18]

TABLE 1. THE VALUES OF THE CMC OF NONIONIC SURFACTANTS USED IN THIS STUDY IN AN AQUEOUS SOLUTION AT 20 °C

Surfactant	CMC (10^{-3} mol/dm^3)
C_8E_6	8.3
$C_{10}E_6$	0.86
$C_{12}E_6$	0.074

Results and Discussion

Salt-effect Estimation from CMC Measurements. By considering the equilibrium between N' surfactant monomers and a micelle in an aqueous salt solution, it is shown that the molar standard free energy for micelle formation, $\Delta G_m^{(c)0}$, is expressed by the following equation:

$$\Delta G_m^{(c)0} = \frac{1}{N'}(\mu_m^{(c)0} - N'\mu_2^{(c)0})$$

$$= kT \ln c_2' f_2' - \frac{kT}{N'} \ln c_m' f_m', \qquad (1)$$

where $\mu^{(c)0}$ denotes a molar standard chemical potential; the subscripts m and 2 refer to the micelle and the monomer respectively, and where c' and f' denote a molar-concentration and a molar-activity coefficients

respectively. The molar activity coefficients of the monomer and the micelle are expressed by the well-known Setschnow equation:

$$\log f'_1 = k_2 C_s, \qquad \log f'_m = k_m C_s, \tag{2}$$

where k is a salt-effect parameter and C_s is the molar concentration of salts. Here, it may be assumed that the concentrations of the monomer and the micelle are low enough and, therefore, that ideality holds near the CMC in the aqueous solution free of salts.[15] By introducing Eq. 2 into Eq. 1, and by using Phillips' definition for CMC in the mass-action model,[19] the following equation is derived:

$$\Delta G_m^{(c)0} \simeq kT \ln C' + 2.303 kTk_2 C_s - \frac{2.303kT}{N'} k_m C_s, \tag{3}$$

where C' is the CMC in the aqueous salt solution. In the aqueous solution free of salts, the molar standard free energy, $\Delta G_m^{(c)0}$, is expressed as follows:

$$\Delta G_m^{(c)0} \simeq kT \ln C, \tag{4}$$

where C is the CMC in the aqueous solution. From the standpoint of the pseudo-phase separation model,[20] the following CMC equation holds:[21]

$$kT \ln C = -m\omega + \Delta + K(T, P), \tag{5}$$

where ω and Δ denote the free energy difference of methylene and poly(oxyethylene) groups between in the monomer state and in the micelle state respectively; K is a constant at constant temperature and pressure, and m is the number of methylene groups in the hydrocarbon chain of the surfactant. We assume the additivity for the salt-effect parameters to be as follows:

$$k_2 = mk_{CH_2} + k_{p,2}, \qquad k_m = N'k_{p,m}, \tag{6}$$

where k_{CH_2} and $k_{p,2}$ are the salt-effect parameters of the methylene and poly(oxyethylene) groups in the monomer respectively and where $k_{p,m}$ is that of the poly(oxyethylene) group in the micelle, because the hydrocarbon moieties form the micelle core and are shielded from the aqueous environment containing salts if we neglect the exposure of some of the hydrocarbon tails to the solvent near the micelle surface.[22] Then, the following equation is derived formally from Eqs. 3—6:

$$kT \ln C' = -m\omega' + \Delta' + K, \tag{7}$$

where

$$\omega' = \omega + 2.303 kTk_{CH_2} C_s, \tag{7a}$$

and

$$\Delta' = \Delta + 2.303 kT(k_{p,m} - k_{p,2}) C_s. \tag{7b}$$

The values of the salt-effect parameters, k_{CH_2} and $k_{p,m} - k_{p,2}$, can be determined by the use of Eqs. 7, 7a, and 7b as follows. The value of ω' can be determined from the slope in the log C' *vs.* m plots at a constant salt concentration C_s; a representative example is shown in Fig. 1 for the case of the sodium chloride additive. These plots form a straight line and then give a well-defined ω' value. The value of ω' thus determined is plotted in Fig. 2 against C_s. These plots also form a straight line, and the value of k_{CH_2} can be determined from the slope of the line. The value of Δ' at a constant C_s can be calculated by introducing the value of ω' and the experimental C' into Eq. 7. Figure 3 shows the plots of Δ' *vs.* C_s, whose slope gives the value of $k_{p,m} - k_{p,2}$. The calculated respective salt-effect param-

eters are tabulated in Table 2. As may be seen from Table 2, the salt effect on the hydrophilic moiety during micellization is found not to cancel out; *i.e.*, $k_{p,m}-k_{p,2}\neq 0$. The positive value of $k_{p,m}-k_{p,2}$ means that $k_{p,m}>k_{p,2}>0$. That is, a salting-out effect occurs on the hydrophilic moieties in the monomer and micelle states, and the extent of the effect on the micelle is greater than that on the monomer state. This salting-out effect, $k_{p,m}-k_{p,2}>0$, contributes to raising the CMC, as can be seen from Eqs. 7 and 7b. Therefore, in this case, the CMC lowering is caused by the salting-out effect on the hydrocarbon moiety, $k_{CH_2}>0$, which overcomes the $k_{p,m}-k_{p,2}>0$ effect from Eqs. 7 and 7a. On the contrary, the negative $k_{p,m}-k_{p,2}$ means that $k_{p,m}<k_{p,2}<0$; *i. e.* it is a salting-in effect, which contributes to lowering the CMC. Especially in the solution containing sodium thiocyanate, the CMC lowering is attributable to the salting-in effect on hydrophilic moieties, because the value of k_{CH_2} is nearly zero. As has been mentioned above, the various modes for the salt effect on the micelle formation are shown according to the kind of salts.

In addition, two features are found in Table 2; (1) the salt effects on the hydrocarbon and hydrophilic moieties give the same order with respect to the relative efficiency, and (2) the variation in the extent of the salt effect with respect to the anion is larger than that with respect to the cation. By considering the above two features, the salt effect can be explained qualitatively as follows. In the case of sodium salts, the order of the salt effect follows the Hofmeister series or the order of the water-structure-making or -breaking capacity of salts.[23-26] That is, the more strongly water-structure-making salt gives the greater, positive k-value, whereas the more strongly water-structure-breaking salt gives the smaller, negative k-value. Water molecules are oriented around the water-structure-making ions, which leads to the reduction of the hydrophobic or hydrophilic hydration of the surfactants as a salting-out effect. On the contrary, the water-structure-breaking ions increase the ratio of monomeric water molecules in the bulk and promote the hydration of the surfactants as a salting-in effect. However, the second feature suggests another source for the salt effect. The following fact is suggestive in considering the second tendency; an air– or hydrocarbon–water interfacial tension is increased by the kind of anion to a greater extent than in the case of cations.[12,27-30] This fact shows that cations are almost completely excluded from an air– or hydrocarbon–water interface because of their requirement for hydration, whereas the less hydrated anions exhibit a large variation in the degree of their exclusion, and may even be concentrated at the interface. This situation may be applied to the exclusion of ions from the water region around the hydrocarbon moiety of a surfactant. That is, the more weakly hydrated anions are excluded to a less extent and then directly disturb the hydrophobic hydration around hydrocarbon moieties to a greater extent, which leads to salting-out. On the contrary, the more strongly hydrated anions are excluded to a greater extent and so exhibit a less direct effect on hydration. Cations also exhibit a less direct effect. As a result of the two factors inferred from the above two features, (1) and (2), the more strongly water-structure-making (more strongly hydrated) anions and cations have, for the most part, an indirect salting-out effect. The more strongly water-structure-breaking (more weakly hydrated) anions have an indirect salting-in and a direct salting-out effect, which cancel each other out for the most part in the overall salt effect, *e.g.*, $k_{CH_2}\simeq 0$ for sodium thiocyanate. As for the water region near the polar poly(oxyethylene) moiety of a surfactant, ions will be less excluded from this region than in the case of the water region near the hydrocarbon moiety. The weakly hydrated anions, *e.g.*, thiocyanate and iodide anions, may even be concentrated in this region; especially, the magnesium cation forms an oxonium compound with the lone-pair electrons of ether oxygen atoms in the poly(oxyethylene) moiety[31] to cause salting-in. It may be because of these factors that we find the experimental $k_{p,m}-k_{p,2}<0$ for sodium thiocyanate and iodide, and the large difference between the value of $k_{p,m}-k_{p,2}$ for magnesium chloride and that for sodium sulfate, in which the two salts have nearly equal water-structure-making capacities. As we have mentioned, the salt effect includes two types of effects on the hydrophobic and hydrophilic hydration of surfactants: the direct effect by the accessibility of ions to the water region near the monomers and the micelles, and the indirect effect.

Salt Effect on Cloud Points and Solubilization. The cloud points of 1 wt% $C_{12}E_6$ in aqueous salt solutions were measured; results similar to those reported in the literature were obtained.[2,31-34] Cloud points can be regarded as a measure of the affinity of the oxyethylene groups in a nonionic surfactant for the water environment.[35] Then, the limiting slope in the plots of the cloud point *vs.* the salt concentration, $\lim_{C_s\to 0}(d\,CP/dC_s)$, may be regarded as the variation of this affinity by salt. These slopes are plotted in Fig. 4 against the values of $k_{p,m}-k_{p,2}$ for various salts. The plots give

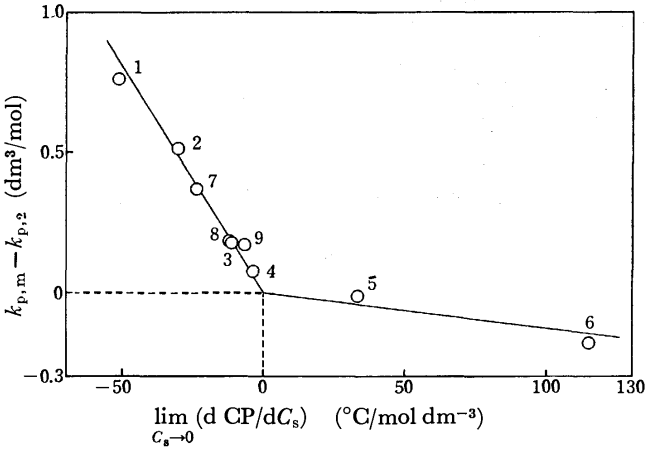

Fig. 4. $k_{p,m}-k_{p,2}$ *vs.* $\lim_{C_s\to 0}$(d CP/dC_s) plots for various salts.

two straight lines, which cross at the point that $\lim_{C_s\to 0}$(d CP/d C_s)$=k_{p,m}-k_{p,2}=0$ and which divide the salts into the two groups, salting-out and -in. From the discussion in the previous section, this correlation shows that the strengthening or weakening of the affinity of oxyethylene groups for the water environment by salts is brought about through the promotion or reduction of the hydration of oxyethylene groups respectively. The strengthening of the affinity is also caused by the ion concentration in the water region near oxyethylene groups.

Next, the amount of solubilization toward Yellow OB was determined at 30 °C in the aqueous $C_{12}E_{10}$ solutions containing sodium chloride, sulfate, and thiocyanate; it was found to increase linearly with the concentration of $C_{12}E_{10}$. The slopes of the lines, referred to as the solubilizing power,[36] are plotted in Fig. 5 against the concentrations of three representative salts. It may be found from Fig. 5 that the salts exhibiting a salting-out or -in effect on oxyethylene groups give an increased or decreased solubilizing power respectively with the salt concentration as compared with that in the salt-free solution. The solubilizing power depends sensitively on the compactness of the poly(oxyethylene) shell of the micelle,[18,36] and so the following explanation is possible. The oxyethylene groups on the micelle cohere as a result of the weakening of the hydration of these groups, and then this increased compactness brings about the increased solubilizing power. On the contrary, the enhancement of the hydration of the oxyethylene groups on the micelle leads to a decreased compactness, which causes a decrease in the solubilizing power.

We wish to express our hearty thanks to the Kaō Soap Co., Ltd., and to Dr. Noboru Moriyama for supplying the nonionic surfactants used in the present study.

The Nuclear Quadrupole Resonance of Dibromoiodate Ions

Tsutomu OKUDA, Isamu TOMOYASU, Koji YAMADA, and Hisao NEGITA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received January 10, 1977)

The NQR sepctra due to ^{81}Br and ^{127}I in potassium dibromoiodate and its monohydrate were observed, and the Zeeman effect of ^{81}Br NQR in the monohydrate was examined. The resonance lines indicate that both compounds have two kinds of dibromoiodate ions and that these ions in the anhydride are slightly asymmetric, while those in the monohydrate are symmetric. The difference in frequency between the two resonance lines due to each resonant nucleus in the monohydrate is explained in terms of the I···Br intermolecular interaction. The charge distributions in both compounds were evaluated to be about $-0.6e$ and $0.2e$ on the terminal and central atoms respectively.

In general, trihalide ions are almost linear and the iodine atom occupies the center of the ion.[1] The reported halogen-halogen length is considerably larger than the sum of the covalent bond radii. The bonding in these ions is considered to result from the overlap of the valence np_σ orbitals of the constituting atoms. Trihalide compounds have been studied so far by means of the nuclear quadrupole resonance,[2-9] since they can give more useful information about the bond character and the charge distribution.

According to the crystal structure of $KIBr_2 \cdot H_2O$ as determined by X-ray analysis,[10] the space group is Pnnm and all atoms lie on the mirror planes at $z=0$ $z=1/2$. The structure consists of nearly linear chains of halogen atoms extending infinitely along the b axis, as is shown in Fig. 1. The two independent IBr_2^- anions are linear and symmetric. The closest O···Br and I···Br distances are 3.60 Å and 3.87 Å respectively, indicative of weak hydrogen bonding and intermolecular interaction. Therefore, it is interesting to examine not only the charge distribution on halogen atoms but also the influence of the intermolecular interaction on the electric field gradient of the halogen atom.

Experimental

The potassium dibromoiodate monohydrate was prepared by heating an aqueous solution of potassium bromide, bromine, and iodine. Its anhydride was obtained by dehydrating the monohydrate. The single crystal of the monohydrate was obtained by slowly lowering an ampoul filled with a saturated aqueous solution of potassium dibromoiodate through an electric furnace. The single crystal of the anhydride could not be obtained.

A super-regenerative oscillator was used for the detection of the NQR line. The absorption lines were displayed on an oscilloscope. The resonance frequencies were determined by the use of a universal counter, TR-5578, of the Takeda Riken Industry Co. Ltd. The Zeeman effect was measured by means of the zero-splitting cone method. The magnetic field was provided by a Helmholtz coil with a field strength of about 200 G.

Results and Discussion

Table 1 shows ^{81}Br and ^{127}I NQR frequencies of $KIBr_2 \cdot H_2O$ and $KIBr_2$. Since ^{127}I has a nuclear spin equal to 5/2, it shows two NQR lines. However, we could not observe the resonance line due to the transition between the $\pm 3/2$ and $\pm 5/2$ levels, because the resonance frequency was too high to be detected with a conventional NQR spectrometer. Two resonance lines each were observed for ^{81}Br and ^{127}I nuclei in the monohydrate. On the other hand, four and two resonance lines were observed for ^{81}Br and ^{127}I respectively in the anhydride. These findings indicate that both compounds have two kinds of IBr_2^- ions in the crystals, and that the IBr_2^- ions are symmetric in the monohydrate, while those in the anhydride are slightly asymmetric. In general, it is accepted that the trihalide ions are symmetric only when the cation in a trihalide compound is as large as a tetralkylammonium ion.[8] In the present case, the IBr_2^- ions seem to become symmetric in spite of having a small cation because the crystal includes a water of crystallization. The two resonance frequencies of ^{81}Br in the mono-
