The behavior of the 2′- and 3′-ethoxy derivatives of 2,4-dinitro- and 2,4,6-trinitro-diphenylamines resemble that of the corresponding methoxy derivatives. Because of the presence of the bulky ethoxy group, each curve observed with the trinitro compound is located at a temperature about 10 °C lower than that of the methoxy derivative. The melt of 2,4-dinitro-3′-ethoxydiphenylamine could be supercooled to 85 °C, but that of the 2′-ethoxy derivative could not. The curve obtained with the former compound lies at slightly lower temperatures than that obtained with 2,4-dinitro-3′-methoxydiphenylamine. It is clear that the non-ideal viscosity-against-temperature characteristics displayed by these compounds are sensitive to small changes in the molecular shape.

Flash Photolysis Study on the Addition Reaction of Alkylthiyl Radical to Olefins

Osamu Ito and Minoru Matsuda

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received July 18, 1977)

The transient absorption band appearing at 370 nm by flash photolysis of di-*t*-butyl dusilfide was assigned to the *t*-butylthiyl radical. Photolyses of the disulfide solutions containing olefins such as 1,1-diphenylethylene and styrene gave new transient bands in a wavelength region similar to that of the diphenylmethyl radical and benzyl radical, respectively. These new bands can be attributed to the radicals produced by the addition of the thiyl radical to olefins; $(Ph)_2\dot{C}-CH_2-SR$ and $H(Ph)\dot{C}-CH_2-SR$. Kinetic studies including the addition of the thiyl radical to olefins were performed.

A number of studies have been carried out on the reactivity of free radicals in solution by means of flash photolysis, attention being focused mainly on the recombination and hydrogen abstraction reactions of the radicals.[1-3] Flash kinetic spectroscopy was applied to the triplet anthracene[4] and the diarylcarbenes[5] for the addition reaction to olefins. Addition of the thiyl radical to olefin was followed indirectly in the competition reaction between thiolate anion and olefin.[6] However, no study seems to have been carried out on the detection of the radical produced from the addition of the primary formed radical by flash exposure to olefin. The thiyl radicals are known to react very rapidly with olefins by means of the rotating sector in the mode of anti-Markownikoff addition.[7,8] If this is the case, the absorption spectrum of the radical formed from the addition reaction having the structure $R'(R'')\dot{C}-CH_2-SR$ might be detected.

Experimental

Di-*t*-butyl disulfide, styrene, and 1,1-diphenylethylene were purified by distillation under reduced pressure. Ferrocene was purified by sublimation after recrystallization. All the solvents were of spectrophotometric grade. The solutions were degassed up to 10^{-5} Torr. The flash photolysis apparatus of standard design[9] delivered a flash with an energy of up to 100 J from xenon-filled flash lamps with a half-peak duration of 20 μs. A band pass filter (Toshiba UV-D25) transmitting light between 240 nm and 400 nm was used. The quartz irradiation vessel, length 10 cm and diameter 1 cm, had optically flat quartz window at both ends. The photolysis was carried out at 23 °C.

Results and Discussion

Thiyl radicals are formed by the photolysis of disulfides. The derivatives of diphenyl disulfide give only thiyl radicals which exhibit absorption at around 500 nm.[2,10] Although dialkyl disulfides give the dithio radicals (RSS·) besides a large amount of the thiyl radical under the irradiation of light of a short wavelength such as 195 nm,[11] photolysis with light of a longer wavelength (>240 nm) has not been studied by means of the flash photolysis. Before studying the addition reaction of the alkylthiyl radical to olefin, the absorption spectra of the alkylthiyl radical should be examined.

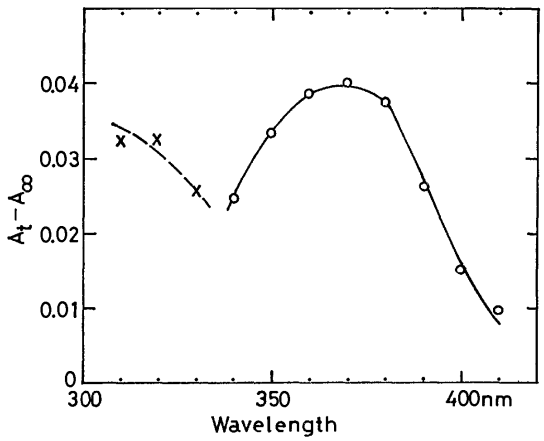

Fig. 1. Transient absorption spectra produced by the flash photolysis of the degassed hexane solution of di-*t*-butyl disulfide (5.0 mM). (a); Immediately after flash (-○-). (b); 500 μs after flash (-×-). A_t-A_∞ is difference of the absorbance at time t and time ∞ after flash.

Flash photolysis of the degassed solution of di-*t*-butyl disulfide gave the transient absorption spectra as shown in Fig. 1. The main band at 370 nm reaches maximum immediately after flash (*ca.* 40 μs) and decays rapidly with a half-life (τ) of 150 μs, a large decrease in the initial intensity being observed in the aerated solution. Another band can be seen in a shorter wavelength region than 330 nm. The band reaches maximum at *ca.* 500 μs after flash, decaying slowly with τ=*ca.* 3 ms, and is insensitive to oxygen. It thus can not be attributed to the free radical formed directly by the flash photolysis of disulfide. The band at 370 nm can not be assigned to the triplet←triplet absorption of disulfide, since its initial intensity and decay rate were not affected by addition of ferrocene which is known to be efficient triplet quencher,[12] and thus, it could be attributed to the *t*-butylthiyl radical. With another disulfide such as dibutyl disulfide, a weak absorption band, observed at 370 nm, is slightly longer as compared with that of HS· in gas phase reported by Norrish and Zeelenberg[13] and that of the thiyl radicals having amino acid group reported by Hoffman and Hayon.[14] $2k_r/\varepsilon$, in which ε is molar extinction coefficient and k_r the second order rate constant, was obtained from the slope of the second order plot at 370 nm. Assuming that ε of the

thiyl radical at absorption maximum is similar to that of the thiyl radical having amino acid group (ε= 300—600 M^{-1} cm^{-1}),[14] 2 k_r was given as 2—4$\times 10^9$ M^{-1} s^{-1} in hexane at 23 °C, suggesting that the thiyl radical decays predominantly with the recombination. Since these values are 4 times greater than those in liquid paraffin (5—10$\times 10^8$ M^{-1} s^{-1}), the rate of recombination is thought to be a diffusion-controlled reaction.

When a mixed solution of 1,1-diphenylethylene and di-*t*-butyl disulfide was subjected to irradiation of flash light a new intense band was observed at 332 nm having a shoulder at 315 nm (Fig. 2). The absorbance at 332 nm was 30 times stronger than that of transient band observed without olefin. The transient spectrum shown in Fig. 2 is very similar to that of the diphenylmethyl radical.[15] Thus, the band could be assigned to the radical having diphenylmethyl radical moiety, which might be formed by the anti-Markownikoff addition of the thiyl radical to 1,1-diphenylethylene, $(Ph)_2\dot{C}$–CH_2–SR, to form a more stable intermediate radical. The mixed solution of disulfide and styrene gave a new sharp band at 322.5 nm (Fig. 3), the absorbance at this region being twice as strong as that of the transient band observed without styrene. A band at 370 nm, assigned to the thiyl radical, was also observed decaying more rapidly than the new band at 322.5 nm. Since the new band at 322.5 nm is very similar to that of the benzyl radical,[15] it can be attributed to the radical having benzyl radical moiety, which might be formed by the anti-Markownikoff addition of the thiyl radical to styrene, $H(Ph)\dot{C}$–CH_2–SR.

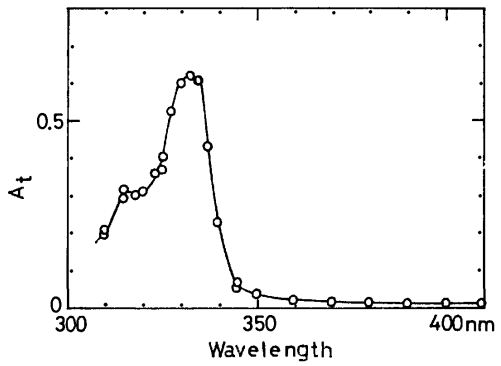

Fig. 2. Transient absorption spectrum produced by the flash photolysis (200 μs after flash) of the degassed hexane solution containing 1,1-diphenylethylene (2.3 mM) and di-*t*-butyl disulfide (2.0 mM).

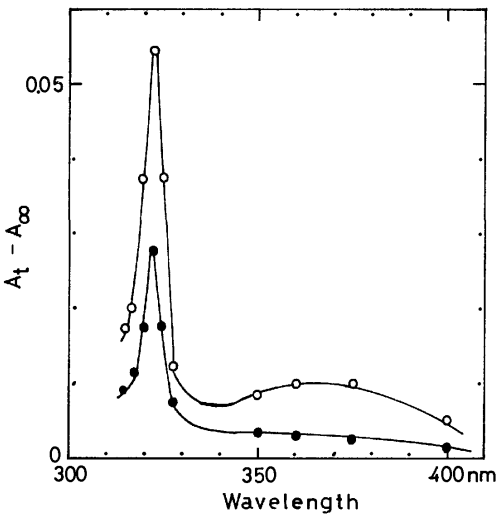

Fig. 3. Transient absorption spectra produced by the flash photolysis of the degassed solution containing styrene (140 mM) and di-*t*-butyl disulfide (4.9 mM). (a); 200 μs after flash (-○-). (b); 500 μs after flash (-●-).

It is most unlikely that these new bands are attributed to the radical ion formation, since no absorption bands due to the radical anions and cations of disulfide[16] and olefins[17] were observed for a mixed solution of disulfide and olefin even in the polar solvent such as dichloromethane. Possibility of the triplet←triplet absorption of olefins also should be examined. Even when 0.9 mM of ferrocene, an efficient triplet quencher, was added to the solution of disulfide and 1,1-diphenylethylene, no difference was observed either in the initial intensity or decay rate. Thus, any process involving the triplet states can not be included.

The new bands reached maximum intensity at 150 μs after flash, indicating that the absorption band related to the addition is attributed to the band at 370 nm rather than the shorter wavelength band than 330 nm band which is observed with flash light irradiation on the di-*t*-butyl disulfide solution without olefin. This is also supported by the effect of oxygen added. The band at 370 nm observed in the absence of olefin was very reactive to oxygen and scarcely observed in aerated solution, while the band at shorter wavelength was insensitive to oxygen. In the system containing olefins, no transient band due to the radicals formed from the addition reaction was observed in the presence of oxygen. The benzyl and diphenylmethyl radicals were reactive to oxygen as indicated by Porter and Windsor,[15] but this might mainly result from the reactivity of the primarily formed thiyl radical assigned to the band at 370 nm. It has been reported that small portion of dithio radical was formed [11,18] by photolysis of disulfide with the short wavelength light. Although no evidence for the formation of the dithio radical was obtained in our flash experiment, the dithio radical is known to be not reactive to olefin.[19] Furthermore, the alkyl radical, which may be formed as a pair of the dithio radical, is also known to add to olefin considerably more slowly (10^2—10^3 M^{-1} s^{-1}) as compared with the thiyl radical.[7,20]

The observed reactions above can be accounted for by the following scheme:

$$RSSR \xrightarrow{h\nu} RSSR^* \quad (1)$$

$$RSSR^* \longrightarrow 2RS\cdot \quad (2)$$

$$2RS\cdot \xrightarrow{k_r} RSSR \quad (3)$$

$$RS\cdot + R'(R'')C{=}CH_2 \xrightarrow{k_a} R'(R'')\dot{C}{-}CH_2{-}SR \quad (4)$$

I

RSSR* may not be the triplet state since the initial yield and decay rate of the thiyl radical was not affected by mixing with ferrocene. Decrease in thiyl radical formation by oxygen should be due to the reactivity of the thiyl radical to oxygen. In Reaction 4, k_a can be estimated from the decay of the thiyl radical. In the case of 1,1-diphenylethylene, however, the tail of the larger absorption band at 332 nm of radical **I** masked the band of the thiyl radical. For styrene, although the initial yield of the thiyl radical decreased with increase in the concentration of styrene, the increase in the decay rate of the band at 370 nm was observed. The decay kinetics fit the first order plottings up to 70% consumption in the styrene concentration range 1—11 mM. Further addition of styrene interfered in the analysis of the decay kinetics because of decrease in the initial yield. Pseudo-first order rate constants were proportional to the concentration of styrene as shown in Fig. 4. From the slope, a value 3.8×10^5 $M^{-1}\,s^{-1}$ ($\pm15\%$) was obtained, which might correspond to the addition rate, if the observed decrease in the initial yield was simply due to the decrease in the light intensity of a flash by the absorption of styrene. The rate constant is 10^2—10^3 times smaller than the value obtained by the rotating sector method.[7,8] We have no criterion more reliable. As regards our flash experiment, there is one disadvantage; we can not completely neglect the possibility that the decrease in the initial yield of the band at 370 nm in the presence of styrene is related to the faster reaction of thiyl radical with styrene. Even if the value estimated by the flash technique may be a lower limit for the addition reaction, this is larger than that of the alkyl radical,[19] and comparable to that of the diarylcarbenes (10^5 $M^{-1}\,s^{-1}$).[5]

The ralative rate of addition reaction can be given, since the initial yield of the band at 332 nm decreased by the addition of styrene to the solution of diphenylethylene and disulfide. The reduction of the absorbance with the system containing an equimolar amount (1.5 mM) of styrene and diphenylethylene was 40% as compared with the absorbance of 3.0 mM of diphenylethylene. Assuming that this decrease was caused by the competitive addition reaction of the thiyl radical to both olefins, the rate of addition to diphenylethylene is 1.3 times greater than that of styrene. The ratio might be comparable to that of methyl radical (ratio=2.0)[21] and diphenylcarbene (ratio=1.0).[5]

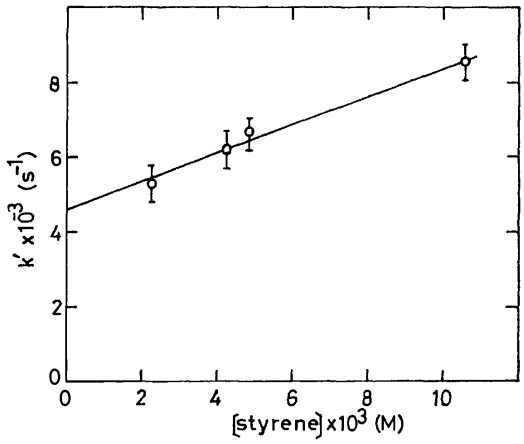

Fig. 4. Pseudo-first order rate constant (k') for the disappearance of the band at 370 nm as a function of styrene concentration.

Concerning the cause of the large absorbance observed for diphenylethylene compared with the case of styrene, the following factors might be mentioned: Large ε value, high addition rate, high efficient selectivity of anti-Markownikoff addition, and /or stability of radical **I** formed. In the absence of oxygen, decay of radical **I** formed can be caused by the recombination of the radicals, hydrogen abstraction from solvent, and addition to the remaining excess olefins. Half-lives of these radicals were 1 ms for diphenylethylene and 500 μs for styrene. In the case of diphenylethylene, a mixed order decay was observed. The decay kinetics of the styrene system at 322.5 nm band obeys the second order plot, giving $k/\varepsilon=5\times10^5$. In this case, ε of radical **I** may be similar to that of the benzyl radical. Choosing $\varepsilon=5500$ of the benzyl radical at absorption maximum as obtained by the pulse radiolysis technique,[22] the rate of the recombination of radical **I** was given to be 2.8×10^9 $M^{-1}\,s^{-1}$. The value is slightly smaller than that of the benzyl radical (3.1×10^9 $M^{-1}\,s^{-1}$).[22] The decay rate of radical **I** was not affected by the addition of styrene, since the rate constant of the propagating step is known to be very small for the polystyryl radical (100 $M^{-1}\,s^{-1}$ at room temperature).[23]

The authors wish to thank Professor H. Kokubun and Dr. K. Kikuchi, Tohoku University, for introduction of the flash photolysis technique and for their useful discussions.

Temperature Effects on the Raman Intensity of Liquid Samples and an Averaged Molecular Field

Haruo HATAKEYAMA and Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received July 23, 1977)

The relative Raman intensities of the ν_1 line of carbon tetrachloride, the ν_8 line of acetonitrile, and the ν_3 line of chloroform were observed in the liquid phase and at various temperatures. The apparent intensity change due to the temperature were explained in terms of the local field effect, the density change, the statistical distribution effect, and the contribution of transition hyperpolarizability in the presence of a non-zero averaged molecular field.

Raman intensity measurements have a great advantage, in principle, over the intensity measurements of absorption spectra. They are free from the effects of a slit-function,[1] the effects related to anomalous dispersion,[2-6] the effects of multi-reflections inside sample layers,[7-10] the so-called baseline effects,[1,11] and so on, all of which are notorious difficulties in the intensity measurements of liquid samples by infrared absorption methods. Therefore, careful measurements of Raman intensities will afford useful information about intermolecular interactions in the liquid phase.

In our preceding report, the intermolecular interaction of a dipole-dipole type has been shown to be most important in explaining the concentration dependence of the Raman intensities in various binary solutions.[12] If the component molecules in solutions have dipole moments, there exists a non-zero averaged molecular field at a given molecule, and the contribution of the transition hyperpolarizability cannot be neglected in comparison with that of the transition polarizability. As the concentration dependence of the averaged molecular field results from the change in an intermolecular distance due to different concentrations,[13] the averaged molecular field and, therefore, the Raman intensity may be expected to be dependent on the temperature, also.

In the present report, the temperature effects on the Raman intensities were measured for three different liquid systems in order to study the role of the averaged molecular field which was produced by the dipole-dipole interaction. Carbon tetrachloride, acetonitrile, and chloroform were chosen because they were typical examples of a non-polar molecule, a molecule with a large dipole moment, and a molecule with a rather small dipole moment respectively.

Experimental

The spectrometer used for the present work was designed and constructed in our laboratory. The instrument was composed of a He-Ne gas laser source (NEC GLG 105, 15 mW), a grating monochromator (JEOL JSG 125B), a photomultiplier (HTV R374, S-20 response), a lock-in amplifier (NF LI-573), and a recorder.

The temperature of a sample cell ($10\times20\times40$ mm^3) was regulated by means of a thermostating box whose temperature was controlled by changing the electrical current supplied to nichrome heaters. The temperatures of the thermostating box and the sample cell were observed by means of a mercury thermometer and a thermocouple respectively. The temperature drift of the sample was less than ±1 K within the temperature range of 300—370 K.

The stability of the laser out-put during the individual spectral measurements was observed by monitoring the light energy which penetrated through the 100% reflectance mirror of the laser cavity. When the power of the laser source drifted more than 1% during the measurements, the data observed were completely discarded.

All the chemicals used in the present study were commercial products. The carbon tetrachloride and acetonitrile were purified by fractional distillations repeated three times. The chloroform was purified by column chromatography on alumina.

The Raman spectra were observed for the ν_1 line of carbon tetrachloride, the ν_8 line of acetonitrile, and the ν_3 line of chloroform. The Raman intensity was determined from the observed band area by means of the weight method. The observations were repeated four times for each temperature; their averaged values were then taken as the observed intensities. The deviations of the observed band areas from the averaged values were less than 2%.

Results and Discussion

ν_1 Line of Carbon Tetrachloride. The Raman intensities of the ν_1 line of liquid carbon tetrachloride were observed in the temperature range from 291 to 333 K. The observed relative intensity ratios are summarized in Table 1, where the relative intensity at 291 K serves as the standard. The relative intensity decreases about 8% as the temperature changes from 291 to 333 K.

Table 1. ν_1 Line of carbon tetrachloride

T/K	d/d_{291}	s/s_{291}	L/L_{291}	Lsd/Lsd_{291}	I/I_{291}
291	1.000	1.000	1.000	1.000	1.000
315	0.972	1.021	0.961	0.954	0.948
326	0.957	1.033	0.943	0.932	0.929
330	0.952	1.038	0.936	0.925	0.917

The apparent intensity change due to the temperature has been discussed in detail in a previous report,[14] where the effects of the density, the local field, and the statistical distribution of molecules in relation to a vibrational state have been emphasized. These factors are all temperature-dependent and should be taken into account in interpreting the present results.

The density, d, as a function of the temperature may be found in the International Critical Tables.[15] The relative values of the density at various temperatures,

d/d_{291}, are summarized in Table 1, where the density at 291 K is chosen as the standard.

The statistical factors, s, may be expressed as

$$s = \frac{1}{1-\exp(-hc\nu/kT)}, \quad (1)$$

where ν is the frequency displacement of a Raman line from that of the radiating wave; T, the absolute temperature; h, the Planck constant; k, the Boltzmann constant, and c, the velocity of light. The calculated relative values, s/s_{291}, are summarized in Table 1, where the s value at 291 K is taken as the standard.

The local-field correction in the Raman scattering, L, of the Eckhardt type may be expressed as[16]

$$L = \left(\frac{n^2+2}{3}\right)^4, \quad (2)$$

where n is the refractive index at the Stokes frequency. The calculated relative values of the local-field correction factors, L/L_{291}, are summarized in Table 1, where L at 291 K is taken as the standard. In the calculation, the refractive indices for the different temperatures were estimated from the density values found in the International Critical Tables and the empirical Eykman equation:

$$\frac{n^2-1}{n+0.4} = \frac{d}{M} \times C, \quad (3)$$

where C is a constant characteristic for a molecule, M, the molecular weight, and d, the density.[17]

Finally, the products of L, s, and d were calculated. They are summarized in Table 1 (designated as (Lsd)). The relative values, $(Lsd)/(Lsd)_{291}$, are expected to agree with those of the relative intensity, I/I_{291}, if the factors considered here contribute mainly to the apparent intensity change resulting from the change in the temperature. Actually, the agreement between these two sets of values is excellent.

Table 2. ν_8 Line of acetonitrile

T/K	d/d_{290}	s/s_{290}	L/L_{290}	Lsd/Lsd_{290}	I/I_{290}
290	1.000	1.000	1.000	1.000	1.000
301	0.981	1.016	0.980	0.977	0.950
305	0.974	1.022	0.974	0.969	0.929
314	0.963	1.031	0.962	0.955	0.900

ν_8 Line of Acetonitrile. The same procedure was applied to the ν_8 line of liquid acetonitrile in the temperature range from 290 to 314 K. The results are summarized in Table 2. It may be seen from the table that the apparent intensity ratio, I/I_{290}, of this line decreases about 10% as the temperature changes from 290 to 314 K, where the relative intensity at 290 K is chosen as the standard. On the other hand, the calculated correction factor, $(Lsd)/(Lsd)_{290}$, decreases only 5% within the same temperature range. The disagreement between these two sets of values is in good contrast with the excellent agreement found for the ν_1 line of carbon tetrachloride and can be ascribed mostly to the physical property of acetonitrile. Therefore, we will focus our attention on the role of the large dipole moment of acetonitrile in a consideration of the temperature dependence of the apparent intensities.

It has been shown in our previous report[12] that the apparent Raman intensity can be affected by the transition hyperpolarizability in the presence of an averaged molecular field produced by the dipole moments of the surrounding molecules. According to the theory, the Raman scattering cross section corresponding to the ν_8 line of acetonitrile, $\Omega(CH_3CN; \nu_8)$, is expressed as

$$\Omega(CH_3CN; \nu_8) \propto \frac{14}{15}(B + A\langle F_{oz}\rangle_{av}), \quad (4)$$

where

$$A = 2\{{}^{Q_8}(\alpha_1^\circ)_{xy}\,{}^{Q_8}(\beta_1^\circ)_{xyz} + {}^{Q_8}(\alpha_1^\circ)_{yz}\,{}^{Q_8}(\beta_1^\circ)_{yzz}\},$$
$$B = {}^{Q_8}(\alpha_1^\circ)_{xy}^2 + {}^{Q_8}(\alpha_1^\circ)_{yz}^2.$$

In the above equations, ${}^{Q_8}(\alpha_1^\circ)_{ij}$ and ${}^{Q_8}(\beta_1^\circ)_{ijk}$ are the i,j-element of the transition polarizability and the i,j,k-element of the transition hyperpolarizability tensor related with the normal coordinate, Q_8, respectively, and the i, j, and k refer to the molecular fixed Cartesian coordinates, with the molecular axis being chosen as the z-axis. In the case of the ν_8 line of acetonitrile, the A and B of Eq. 4 have been determined experimentally as

$$A = 15.308 \times 10^{-10}\ (\text{Å}^6\,\text{dyn}^{-1}\,\text{esu}),$$
$$B = 1.66 \times 10^{-3}\ (\text{Å}^6),$$

from the observation of the concentration dependence of the Raman intensity. $\langle F_{0z}\rangle_{av}$ is the averaged electric field produced at the position of a molecule by the influence of the surrounding molecules.

There are various types of intermolecular interactions which produce electric fields at the position of a given molecule in a liquid. The simplest and most important of these is the interaction of a dipole-dipole type. A molecule with a dipole moment affects the orientational distribution of surrounding molecules through dipole-dipole interactions. This results in the appearance of a non-zero averaged electric field at the position of the central dipole. For a pure liquid, this averaged electric field has been calculated to be[13]

$$\langle F_{0z}\rangle_{av} = \frac{4\pi^2}{27} N_a^2 \frac{\mu_0^3}{kT} \frac{\rho^2}{W_m^2} + \frac{2\pi^2}{25\times 243} N_a^2 \frac{\mu_0^7}{(kT)^3} \frac{\rho^4}{W_m^4}, \quad (5)$$

where μ_0 is a permanent dipole moment; ρ, the density; W_m, the molecular weight; k, the Boltzmann constant; T, the absolute temperature, and N_a the Avogadro number. Using the permanent dipole moment value of 3.92 D observed for acetonitrile,[18] the $\langle F_{0z}\rangle_{av}$ value is calculated to be of the order of 10^5 dyn esu^{-1}; the detailed results are shown in Table 3. Obviously, the $\langle F_{0z}\rangle_{av}$ value is temperature-dependent. By inserting the numerical values of A, B, and $\langle F_{0z}\rangle_{av}$ into Eq. 4, the relative magnitudes of the scattering cross sections were calculated for the various temperatures. Obviously, the calculated relative scattering cross sections, Ω/Ω_{290}, are temperature-dependent. The products of the calculated relative scattering cross sections, Ω/Ω_{290}, and the relative correction factors, Lsd/Lsd_{290}, are in good agreement with the observed

Table 3. Averaged molecular field and Raman intensity for ν_8 line of acetonitrile

T/K	$\langle F_{0z}\rangle_{av}$ (dyn esu^{-1})	Ω/Ω_{290}	$\frac{\Omega \cdot Lsd}{\Omega_{290} \cdot Lsd_{290}}$	I/I_{290}
290	4.31×10^5	1.000	1.000	1.000
301	3.81×10^5	0.967	0.944	0.950
305	3.66×10^5	0.957	0.927	0.929
314	3.40×10^5	0.940	0.900	0.900

relative intensities, I/I_{290}. This result shows that the transition hyperpolarizability derivative plays an important role in producing the apparent temperature dependence of the Raman intensity under the existence of a considerable magnitude of $\langle F_{0z}\rangle_{av}$.

ν_3 Line of Chloroform. Exactly the same procedures were applied to the ν_3 line of liquid chloroform. The results are summarized in Table 4. It can be seen from the table that the relative intensity of this line decreases about 8% as the temperature changes from 292 to 320 K, while the calculated correction factor, $(Lsd)/(Lsd)_{292}$, decreases about 3%. It is clear that the discrepancy between the observed and the calculated intensity ratios can hardly be explained by the effect of the averaged molecular field, $\langle F_{0z}\rangle_{av}$.

Table 4. ν_3 Line of choroform

T/K	d/d_{292}	s/s_{292}	L/L_{292}	Lsd/Lsd_{292}	I/I_{292}
292	1.000	1.000	1.000	1.000	1.000
305	0.983	1.013	0.977	0.973	0.974
312	0.975	1.022	0.966	0.963	0.950
320	0.964	1.032	0.954	0.950	0.923

The scattering cross section of this line, including the effect of the averaged molecular field, can be expressed as[12]

$$\Omega(CHCl_3;\nu_3) \propto \frac{1}{15}(B+A\langle F_{0z}\rangle_{av}),$$

where

$$\begin{aligned} A &= 18^{Q_3}(\alpha_1^0)_{xx}{}^{Q_3}(\beta_1^0)_{xxz} + 8^{Q_3}(\alpha_1^0)_{zz}{}^{Q_3}(\beta_1^0)_{zzz} \\ &\quad + 2^{Q_3}(\alpha_1^0)_{xx}{}^{Q_3}(\beta_1^0)_{zzz} + 2^{Q_3}(\alpha_1^0)_{zz}{}^{Q_3}(\beta_1^0)_{xxz}, \qquad (6) \\ B &= 9^{Q_3}(\alpha_1^0)_{xx}^2 + 2^{Q_3}(\alpha_1^0)_{xx}{}^{Q_3}(\alpha_1^0)_{zz} + 4^{Q_3}(\alpha_1^0)_{zz}^2. \end{aligned}$$

The magnitude of $\langle F_{0z}\rangle_{av}$ can be calculated from Eq. 5 using the dipole moment value of 1.05 D for chloroform.[19] The $\langle F_{0z}\rangle_{av}$ value of chloroform is of the order of 10^3 dyn esu^{-1}, which is about hundredth of that for acetonitrile. As the magnitude of A for chloroform may be expected to be as large as that for acetonitrile, the effect of $\langle F_{0z}\rangle_{av}$ on the Raman intensity is negligibly small. Therefore, the discrepancy between the observed and the calculated intensity ratios corresponds to the real change in the transition polarizability of this line on passing from 292 to 320 K; this can be explained with respect to the direct intermolecular interactions, such as the break-down of hydrogen bonding between chloroform molecules in the liquid phase on the elevating of the temperature. It is important to add that the relative intensity changes its magnitude about 20% as the temperature changes from 297 to 313 K in the case of the ν_2 line of liquid chloroform, while the correction factor, $(Lsd)/(Lsd)_{297}$ decreases only 6%.[14] This discrepancy may originate from the same type of intermolecular interaction.

Averaged Molecular Field and Conclusions. A few important conclusions can be drawn from the present results. In most cases, the effects of the L, s, and d factors make the observed Raman intensities temperature-dependent. When a component molecule has a large dipole moment, the Raman intensity is temperature-dependent because of the existence of a non-zero averaged molecular field, $\langle F_{0z}\rangle_{av}$, in the liquid phase. If the magnitude of $\langle F_{0z}\rangle_{av}$ is of the order of 10^5 dyn esu^{-1} or more, the Raman intensity is determined not only by the transition polarizabilities (the first term of Eq. 4 or 6) but also by the transition hyperpolarizabilities (the second term of Eq. 4 or 6).

Charge-transfer Absorption of Complex TCNQ Anion Radical Salts: $(Cs^+)_2(TCNQ)_3^{\cdot -}$ and $(Morpholinium^+)_2(TCNQ)_3^{\cdot -}$

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 29, 1977)

The charge-transfer transition between ion radical molecules is known to take place in solid ion radical salts. The present paper describes some spectroscopic features of the charge-transfer absorptions observed in complex anion radical salts of $(Cs^+)_2(TCNQ)_3^{\cdot -}$ and $(Morpholinium^+)_2(TCNQ)_3^{\cdot -}$. A one-dimensional Hubbard model consisting of equivalent sites with less than half-occupied orbitals was applied to those systems in order to explain the transition energy and the line shape of the charge-transfer absorptions.

In a number of solid ion radical salts, the planar ion-radical molecules are known to form, in themselves, a face-to-face stacking into infinite one-dimensional columns so as to make a large overlap between their half-occupied molecular orbitals.[1–11] In this case, since any individual radical molecule interacts through charge-transfer most strongly with two other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution but shows a charge-transfer transition between ion radicals in the low-energy region.[8–11]

It is well known that 7,7,8,8-tetracyanoquinodimethane (TCNQ) forms chemically-stable crystalline anion radical salts with various diamagnetic counter cations.[1–9] We can obtain two kinds of TCNQ anion radical salts depending on their chemical composition.[6–9] One belongs to simple anion radical salts where each TCNQ has one unpaired electron. Another is called complex anion radical salts, which include not only TCNQ anion radicals but also formally neutral TCNQ molecules. In a previous paper,[12] we studied the optical properties of the charge-transfer absorption of simple TCNQ anion radical salts. We applied the one-dimensional Hubbard model to the columns of TCNQ anion radicals by assuming equivalent sites with half-occupied orbitals, and investigated the character of the intermolecular charge-transfer absorption by using a Green's function method. On the other hand, in complex TCNQ anion radical salts, each TCNQ species no longer has one unpaired electron because of the existence of formally neutral TCNQ molecules. In the present paper, by the use of an approach similar to our previous work,[12] we examined the spectroscopic features of charge-transfer transition between TCNQ anion radicals for one-dimensional system of sites with less than half-occupied orbitals. The transition energy and the theoretical line shape of the charge-transfer absorption were derived and were compared with those observed in such complex salts as $(Cs^+)_2(TCNQ)_3^{\cdot -}$ and $(Morpholinium^+)_2(TCNQ)_3^{\cdot -}$.[9]

Results

In order to describe a narrow energy band with strong electron correlation in crystalline ion radical salts, we consider a system of electrons expressed by the Hubbard Hamiltonian;[13–15]

$$\mathcal{H} = \sum_{i,j,\sigma} t_{ij} C_{i\sigma}^{+} C_{j\sigma} + I \sum_{i} n_{i\downarrow} n_{i\uparrow}, \qquad (1)$$

where $n_{i\sigma}=C_{i\sigma}^{+}C_{i\sigma}$, and $C_{i\sigma}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, and where t_{ij} is the transfer matrix element between the i-th and j-th sites, and the intra-site Coulomb repulsive potential, I, appears only when two electrons with up and down spins are on the same site. Hereafter, we confine our system within the framework of the one-particle Green's function given by Hubbard in his first paper (it is often referred to as Hubbard I),[13] and consider one-dimensional stacks of ion radical molecules in the solid state. For the sake of simplicity, we assume a non-alternant linear chain of equivalent sites for which the transfer matrix element is taken only between nearest neighbor sites and is denoted by $T(<0)$, and we only consider the charge-transfer transition between ion radicals. According to the previous paper,[12] the charge-transfer absorption due to the transition of electrons with up spin in such one-dimensional column is given by $\mathrm{Re}\,\sigma_{xx}(\omega) \propto \mathrm{Re}\,\sigma^{+}(\omega) + \mathrm{Re}\,\sigma^{-}(\omega)$;

$$\mathrm{Re}\,\sigma^{\pm}(\omega) = \frac{e^2}{2} \frac{I^2 n_{\downarrow}(1-n_{\downarrow})}{\omega^2 \sqrt{\omega^2 - 4I^2 n_{\downarrow}(1-n_{\downarrow})}} \times \sqrt{4T^2 - \{-(2n_{\downarrow}-1)I \pm \sqrt{\omega^2 - 4I^2 n_{\downarrow}(1-n_{\downarrow})}\}^2}\,\theta_{\pm}(\omega), \qquad (2)$$

where ω is the frequency of electromagnetic wave absorbed by electrons with up spin and $n_{\downarrow}=\langle n_{i\downarrow}\rangle$ is the mean number of electrons with down spin per site, and where $\theta_{\pm}(\omega)$ is the term related to Fermi distribution function. When the intra-site Coulomb repulsion energy is much greater than the observed temperature, we can well put $\theta_{\pm}(\omega)=1$. If we assume paramagnetic state (*i.e.*, $n_{\downarrow}=n_{\uparrow}$) for our system, an expression of the absorption analogous to Eq. 2 is obtained for electrons with down spin. Therefore, we only consider the absorption due to electrons with up spin, as given in Eq. 2.

Let us examine how the optical absorption of Re $\sigma^{+}(\omega)$ and Re $\sigma^{-}(\omega)$ depends on $n_{\downarrow}$. From Eq. 2, if $2|T| \geq (2n_{\downarrow}-1)I$, that is, if $-T/I+1/2 \geq n_{\downarrow} \geq T/I+1/2$, both Re $\sigma^{+}(\omega)$ and Re $\sigma^{-}(\omega)$ make contribution to the charge-transfer absorption of Re $\sigma_{xx}(\omega)$. We can see that both Re $\sigma^{+}(\omega)$ and Re $\sigma^{-}(\omega)$ have a sharp divergent peak at the energy $\omega_0=2I\sqrt{n_{\downarrow}(1-n_{\downarrow})}$, where the spectra have a van Hove singularity in the lower energy side. They have no absorption in the energy region below ω_0, but have absorption in the energy region above ω_0. The absorption intensities of Re $\sigma^{+}(\omega)$ and Re $\sigma^{-}(\omega)$ are the greatest at $\omega=\omega_0$, and decrease

progressively with increasing ω. For Re $\sigma^+(\omega)$, the maximum frequency at which absorption can occur is at $\omega_-=\sqrt{4T^2-4IT(2n_\downarrow-1)+I^2}$ where the intensity becomes zero, and the spectrum has a shoulder in the energy region between ω_0 and ω_-. On the other band, for Re $\sigma^-(\omega)$, the maximum frequency takes place at $\omega_+=\sqrt{4T^2+4IT(2n_\downarrow-1)+I^2}$ where the intensity drops to zero, and the spectrum has a shoulder in the energy region between ω_0 and ω_+. Since Re $\sigma_{xx}(\omega)$ consists of the superposition of Re $\sigma^+(\omega)$ and Re $\sigma^-(\omega)$, the charge-transfer absorption spectrum of our system does not have a simple line shape, but has a structure due to the different line shapes of Re $\sigma^+(\omega)$ and Re $\sigma^-(\omega)$. In the case of $n_\downarrow=1/2$, however, as we can see from Eq. 2, Re $\sigma^+(\omega)$ coincides with Re $\sigma^-(\omega)$, so that the charge-transfer absorption of Re $\sigma_{xx}(\omega)$ can be described by a simple line shape of 2Re $\sigma^+(\omega)$ or 2Re $\sigma^-(\omega)$.

Next, we consider the case of $2|T|<(2n_\downarrow-1)I$, that is, $n_\downarrow>-T/I+1/2$ or $n_\downarrow<T/I+1/2$. In the case of $n_\downarrow>-T/I+1/2$, the charge-transfer absorption of Re $\sigma_{xx}(\omega)$ comes solely from Re $\sigma^+(\omega)$, and there is no contribution of Re $\sigma^-(\omega)$ to Re $\sigma_{xx}(\omega)$. We can easily see from Eq. 2 that, for Re $\sigma^+(\omega)$, the minimum value of ω takes place at $\omega_+=\sqrt{4T^2+4IT(2n_\downarrow-1)+I^2}$, where Re $\sigma^+(\omega)=0$ and no discontinuity exists. As ω increases slightly, Re $\sigma^+(\omega)$ rises very steeply and takes the greatest value of Re $\sigma^+(\omega)$ at the energy just above ω_+. As ω further increases, Re $\sigma^+(\omega)$ decreases progressively and has a shoulder, falling down to zero at $\omega_-=\sqrt{4T^2-4IT(2n_\downarrow-1)+I^2}$. Then, the charge-transfer absorption of Re $\sigma_{xx}(\omega)$ ranges from ω_+ to ω_- with no discontinuity. On the other hand, in the case of $n_\downarrow<T/I+1/2$, the situation is reversed, and the charge-transfer absorption of Re $\sigma_{xx}(\omega)$ comes solely from Re $\sigma^-(\omega)$. The spectrum ranges from $\omega_-=\sqrt{4T^2-4IT(2n_\downarrow-1)+I^2}$ to $\omega_+=\sqrt{4T^2+4IT(2n_\downarrow-1)+I^2}$ with no discontinuity. Re $\sigma^-(\omega)$ has the greatest value at the frequency just above ω_-, and has a shoulder in the region between ω_- and ω_+. It is interesting to note from Eq. 2 that, except for Fermi distribution term, Re $\sigma^-(\omega)$ for $n_\downarrow$ has properties symmetrical to those of Re $\sigma^+(\omega)$ for $1-n_\downarrow$.

In the previous paper,[12] we have already examined the charge-transfer absorption for the system of $n_\downarrow=1/2$. Therefore, in the present paper, we will discuss, as a case of $n_\downarrow\neq1/2$ system, the optical properties of complex TCNQ anion radical salts with composition ratio of (2: 3) such as $(Cs^+)_2(TCNQ)_3^{-}$ or (Morpholinium$^+$)$_2$(TCNQ)$_3^{-}$. In these systems, three TCNQ molecules share two unpaired electrons. According to X-ray analysis data reported by Arthur *et al.*,[2,3] the crystal structure of $(Cs^+)_2(TCNQ)_3^{-}$ belongs to the monoclinic system with space group $P2_1/c$. The crystal structure reported by them is shown in Fig. 1. The structure consists of one-dimensional columns of TCNQ molecules parallel to the b axis with a plane-to-plane stacking. The caesium cations occupy sites between TCNQ columns in such a manner that each Cs^+ ion is surrounded by eight nitrogen atoms at the corners of a distorted cube. In one-dimensional stacking of TCNQ molecules, however, the sites are crystallographically no longer equivalent and TCNQ molecules form a triad; in a unit cell two rather ionic TCNQ anions are at non-centric positions and one rather neutral TCNQ molecule is at centric position.[3] On the other hand, the crystal structure of (Morpholinium$^+$)$_2$(TCNQ)$_3^{-}$ was determined by Sundaresan and Wallwork.[5] The arrangements of TCNQ molecules were found to be very similar to those of the caesium salt. In both of these anion radical salts, the charge distribution of unpaired electrons depends on the sites, but our present model for the charge-transfer absorption given in Re $\sigma_{xx}(\omega)$ and Eq. 2 is based on homogeneous charge distribution of the electrons along one-dimensional column. This point will be further discussed in the following section. In order to examine the applicability of our model and to explain the character of the charge-transfer absorptions observed in those solid salts, we proceed to consider the system of $(Cs^+)_2(TCNQ)_3^{-}$ or (Morpholinium$^+$)$_2$(TCNQ)$_3^{-}$ in terms of one-dimensional column consisting of equivalent TCNQ sites where each TCNQ species carries a formal charge of $-2/3$.

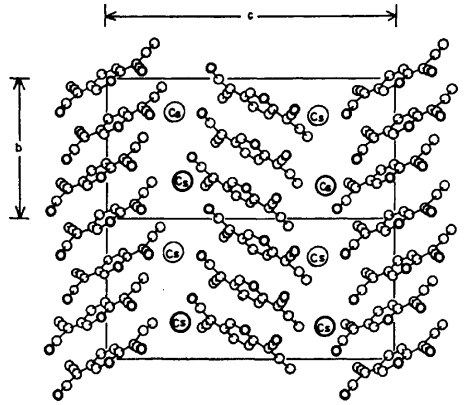

Fig. 1. View of the crystal structure of $(Cs^+)_2(TCNQ)_3^{-}$ reported by Chesnut and Arthur and by Fritchie and Arthur. See Refs. 2 and 3.

On the other hand, neutral TCNQ molecule is almost planar, and has sixteen molecular orbitals for sixteen $2p\pi$ electrons.[16] Then, in the ground state of $TCNQ^{-2/3}$, the molecular orbitals from the lowest to the 8 th are fully occupied, while 2/3 unpaired electron is in the 9 th molecular orbital. The other molecular orbitals are vacant orbitals. In the column of TCNQ molecules, we take only the 9 th molecular orbital with the 2/3 unpaired electron for one site of TCNQ molecule, and assume a model of non-alternant one-dimensional column composed of infinite number of such sites. In this model, each TCNQ molecular site is composed of one identical molecular orbital with equal energy level, and there is 2/3 electron per each site. Then, we have $n_\downarrow=1/3$ if we assume paramagnetic state for our system. Under these situations, we consider the optical absorption (intermolecular charge-transfer absorption) of crystalline $(Cs^+)_2(TCNQ)_3^{-}$ and (Morpholinium$^+$)$_2$(TCNQ)$_3^{-}$ as expressed by Re $\sigma_{xx}(\omega)$ and Eq. 2. At this time, we have two possibilities for the system of $n_\downarrow=1/3$, depending on the magnitudes of I and T. If $|T|\geq(1/6)I$, the charge-transfer absorption will come from the case of $-T/I+1/2\geq n_\downarrow\geq T/I+1/2$. In this case, as has been mentioned, Re $\sigma_{xx}(\omega)$ has two contributions of Re

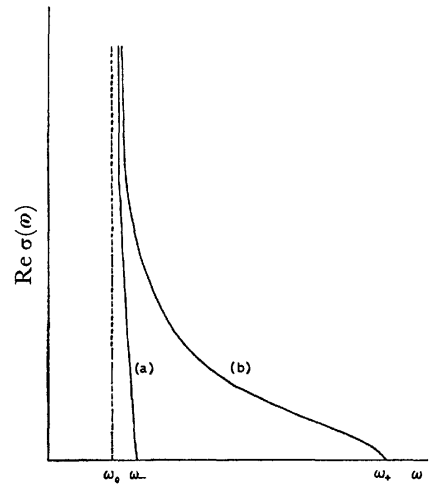

Fig. 2. The intermolecular charge-transfer absorption spectrum Re $\sigma_{xx}(\omega) \propto$ Re $\sigma^+(\omega)$+Re $\sigma^-(\omega)$, as given by Eq. 2 for the $n_\downarrow = 1/3$ system with $|T| \geq (1/6)I$, where (a) Re $\sigma^+(\omega)$, (b) Re $\sigma^-(\omega)$, $\omega_0 = (2/3)\sqrt{2}\,I$, and $\omega_\pm = \sqrt{4T^2 \mp 4IT/3 + I^2}$. See text.

$\sigma^+(\omega)$ and Re $\sigma^-(\omega)$; both of them have a divergent peak at $\omega_0 = 2\sqrt{2}\,I/3$. The Re $\sigma^+(\omega)$ component converges to zero at $\omega_- = \sqrt{4T^2+4IT/3+I^2}$, while the Re $\sigma^-(\omega)$ component, at $\omega_+ = \sqrt{4T^2-4IT/3+I^2}$. Since $T<0$ and $\omega_- < \omega_+$, the band width is determined by $\omega_+ - \omega_0$. Then, the spectrum of the charge-transfer absorption, Re $\sigma_{xx}(\omega)$, is given by the superposition of Re $\sigma^+(\omega)$ and Re $\sigma^-(\omega)$; both of them are shown in Fig. 2. On the other hand, if $|T| < (1/6)I$, the charge-transfer absorption corresponds to the case of $n_\downarrow < T/I + 1/2$. In this case, Re $\sigma_{xx}(\omega)$ comes solely from Re $\sigma^-(\omega)$, which ranges from $\omega_- = \sqrt{4T^2+4IT/3+I^2}$ to $\omega_+ = \sqrt{4T^2-4IT/3+I^2}$ with no discontinuity, and has absorption maximum at the energy just above ω_-. Then, the spectrum of the charge-transfer absorption, Re $\sigma_{xx}(\omega)$, is schematically given in Fig. 3.

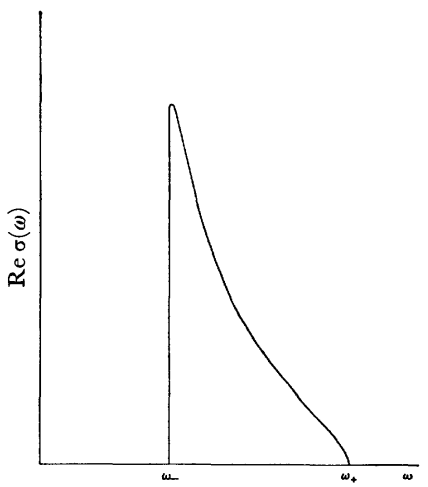

Fig. 3. The intermolecular charge-transfer absorption spectrum Re $\sigma_{xx}(\omega) \propto$ Re $\sigma^-(\omega)$, as given by Eq. 2 for the $n_\downarrow = 1/3$ system with $|T| < (1/6)\,I$, where $\omega_\pm = \sqrt{4T^2 \mp 4IT/3 + I^2}$. See text.

Discussion

Let us compare these theoretical predictions with the experimental electronic spectra of crystalline $(Cs^+)_2(TCNQ)_3^{--}$ and $(Morpholinium^+)_2(TCNQ)_3^{--}$. In a previous paper,[9] we measured those electronic spectra by means of diffuse reflection method. The observed spectra are reproduced in Fig. 4. The Kubelka-Munk function, $f(R) = (1-R)^2/2R$, where R is the reflectance and $f(R)$ is proportional to the absorbance, was plotted *versus* wave number (10^3 cm^{-1} unit).

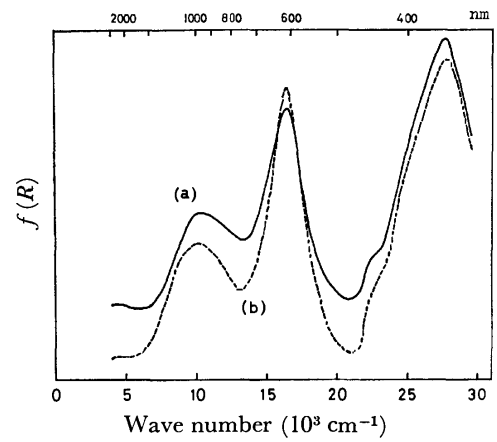

Fig. 4. The experimental results on the diffuse reflection spectra of the solid salts of (a) $(Cs^+)_2(TCNQ)_3^{--}$ and (b) $(Morpholinium^+)_2(TCNQ)_3^{--}$, where the value of Kubelka-Munk function, $f(R) = (1-R)^2/2R$, was plotted *versus* wave number. See Ref. 9.

In the case of $(Cs^+)_2(TCNQ)_3^{--}$, the solid-state spectrum has four absorptions in the energy region from 5000 to 30000 cm^{-1}. The absorptions at 27500 and 16200 cm^{-1} are the shifted bands of the monomer spectrum of the TCNQ anion radical at 22800 and 11900 cm^{-1}, respectively, while the low-energy band at 10100 cm^{-1} characteristic of the solid salt has been assigned to the charge-transfer transition between TCNQ anion radicals in the one-dimensional column.[9] Moreover, the complex salt shows additional weak and broad absorption around the energy region of 4000—6000 cm^{-1}; this band has been assigned to the charge-transfer transition from TCNQ anion radical to the neutral TCNQ.[9] The spectroscopic features of the former three absorptions are very similar to those of simple TCNQ anion radical salts such as K^+TCNQ^-,[8,12] while the absorption around 4000—6000 cm^{-1} is characteristic of the complex salt.

The theoretical approach in the preceding section can solely explain the charge-transfer absorption due to the transition between TCNQ anion radicals, but cannot explain the other electronic transitions. Therefore, the absorption at 10100 cm^{-1} of $(Cs^+)_2(TCNQ)_3^{--}$ is of our main interest. If Re $\sigma_{xx}(\omega)$ with $|T| \geq (1/6)I$ and $-T/I+1/2 \geq n_\downarrow \geq T/I+1/2$ corresponds to this charge-transfer band, the observed peak value of 10100 cm^{-1} should be $\omega_0 = 2\sqrt{2}\,I/3$ thus giving $I = 10700$ cm^{-1}. The absorption band width is related to the $|T|$ value,

which should be larger than $(1/6)I$. If we assume $|T| \approx 0.2\,I$ for example, the theoretical band width is $\omega_+ - \omega_0 \approx 2700\ \mathrm{cm^{-1}}$. This width should only take place in the energy region higher than the absorption peak, and the charge-transfer band shape will have strong asymmetric character with respect to $\omega=\omega_0$. However, as is shown in Fig. 4, the observed charge-transfer absorption at $10100\ \mathrm{cm^{-1}}$ has almost symmetrical line shape with respect to the peak energy axis, although this band overlaps appreciably, in the higher energy region, with the $16200\ \mathrm{cm^{-1}}$ band. Therefore, the case of $|T| \geq (1/6)I$ will not be applicable to the observed charge-transfer absorption.

Next, we examine the case of $|T| < (1/6)I$ and $n_\downarrow < T/I+1/2$. If the $|T|$ value is assumed to be of the order of 0.1 I, the theoretical peak value of the absorption is very close to $\omega_- = 0.954\ I$, which will correspond to the observed peak value of $10100\ \mathrm{cm^{-1}}$. Therefore, $I = 10600\ \mathrm{cm^{-1}}$ and $|T| \approx 1100\ \mathrm{cm^{-1}}$ is estimated for this case. The I and $|T|$ values thus estimated are of quite reasonable magnitudes because of the following explanation. By the use of those I and $|T|$ values, the absorption width, $\omega_+ - \omega_-$, is estimated to be $1300\ \mathrm{cm^{-1}}$, and the absorption line shape is then given by Fig. 3 with $\omega_- = 10100\ \mathrm{cm^{-1}}$ and $\omega_+ = 11400\ \mathrm{cm^{-1}}$. As has been discussed in the previous paper,[12] for many reasons, the actual charge-transfer absorption involves certain width other than the width due to non-zero transfer matrix element, and the actual absorption has a width even in the energy region lower than ω_-. It appears that such a width is of the order of 3500—4000 $\mathrm{cm^{-1}}$ and is much larger than the width of $1300\ \mathrm{cm^{-1}}$ due to transfer matrix element. Then, with respect to the axis of peak energy, the charge-transfer absorption will have a width of 3500—4000 $\mathrm{cm^{-1}}$ in the lower-energy side and a width of 4800—5300 $\mathrm{cm^{-1}}$ in the higher-energy side. The asymmetric character of the line shape of this absorption is so weak that we can well expect almost symmetrical line shape of the charge-transfer absorption with respect to the peak energy axis. This consideration seems to agree well with the observed charge-transfer absorption of $(Cs^+)_2(TCNQ)_3^{--}$ at 10100 $\mathrm{cm^{-1}}$.

The solid-state spectrum (see Fig. 4) of (Morpholinium$^+$)$_2$(TCNQ)$_3^{--}$ has three strong absorptions at 27600, 16300, and 10000 $\mathrm{cm^{-1}}$ and a broad and weak low-energy absorption around 4000—6000 $\mathrm{cm^{-1}}$.[9] These spectroscopic features are very similar to those of the caesium salt. From the peak energy and the line shape of the charge-transfer absorption at $10000\ \mathrm{cm^{-1}}$, the magnitudes of I and $|T|$ of the morpholinium salt were found to be almost the same as the corresponding magnitudes of the caesium salt.

Our theoretical treatment for the charge-transfer absorptions of $(Cs^+)_2(TCNQ)_3^{--}$ and (Morpholinium$^+$)$_2$(TCNQ)$_3^{--}$ assumed a narrow energy band and uniform 2/3-charge distribution in equivalent site systems. This simple model only led to a single charge-transfer transition around $10000\ \mathrm{cm^{-1}}$, which may be interpreted as the transition between $TCNQ^{-2/3}$ molecules. However, another electronic transition from rather ionic TCNQ to rather neutral TCNQ is actually taking place around 4000—6000 $\mathrm{cm^{-1}}$ (see again Fig. 4). This transition thus gives strong evidence for the existence of both rather ionic and neutral TCNQ molecular species in those crystalline complex salts. It is to be noted that one cannot explain such kind of transition as long as one uses uniform charge distribution model. One way of taking those inequivalent TCNQ molecular species into consideration was made by Soos and Klein,[17] who used the modified Hubbard model to include three crystallographic sites per unit cell in one-dimensional column. Their treatment led to three bands of $N/3$ levels, and the two lower-energy bands accomodate the $2N/3$ electrons of the 1/3-filled Hubbard model. The charge-transfer transition between ionic and neutral sites was interpreted as the transition from the occupied band to the unoccupied band. Our problem will then be to find an appropriate theoretical treatment by the Green's function method for one-dimensional system consisting of inequivalent sites and to explain more quantitatively the charge-transfer transitions between ionic and neutral sites as well as those between ionic sites in $(Cs^+)_2(TCNQ)_3^{--}$ and (Morpholinium$^+$)$_2$(TCNQ)$_3^{--}$.

Some Remarks

Finally, we compare some spectroscopic features of the charge-transfer absorption of $n_\downarrow \neq 1/2$ system (complex ion radical salts) with those of $n_\downarrow = 1/2$ system (simple ion radical salts) on the basis of Re $\sigma_{xx}(\omega)$ and Eq. 2. As for the peak energy, the $n_\downarrow = 1/2$ system, where each site has one unpaired electron with paramagnetic state, has a divergent peak at $\omega_0 = I$.[12] On the other hand, the $n_\downarrow \neq 1/2$ system with $-T/I+1/2 \geq n_\downarrow \geq T/I+1/2$ has a divergent absorption peak at $\omega_0 = 2I\sqrt{n_\downarrow(1-n_\downarrow)}$, which is definitely less than the ω_0 value of the $n_\downarrow = 1/2$ system. The $n_\downarrow > -T/I+1/2$ system has absorption peak at the energy close to $\omega_+ = \sqrt{4T^2+4IT(2n_\downarrow-1)+I^2}$, while the $n_\downarrow < T/I+1/2$ system, at the energy close to $\omega_- = \sqrt{4T^2-4IT(2n_\downarrow-1)+I^2}$. For these cases, since $T<0$ and $\omega_\pm < I$, the peak energy is again smaller than the I value. Therefore, the peak energy of the charge-transfer absorption of less than half-occupied or more than half-occupied orbital system is definitely smaller than that of half-occupied orbital system.

Next, we consider the band width, which is related to the magnitudes of $|T|$ and I. Therefore, by using the constant values of $|T|$ and I, we examine how the band width of the charge-transfer absorption depends on $n_\downarrow$. For the $n_\downarrow = 1/2$ system, the band width is given by $\sqrt{I^2+4T^2} - I$.[12] In the system of $n_\downarrow \neq 1/2$, however, the band widths are $|\omega_+ - \omega_-|$ for the case of $n_\downarrow > -T/I+1/2$ or $n_\downarrow < T/I+1/2$, $\omega_- - \omega_0$ for the case of $-T/I+1/2 \geq n_\downarrow > 1/2$, and $\omega_+ - \omega_0$ for the case of $1/2 > n_\downarrow \geq T/I+1/2$. In all cases, the band width for the $n_\downarrow \neq 1/2$ system becomes much broader than the width for the $n_\downarrow = 1/2$ system. The reason is as follows. As has been discussed in the previous paper,[12] in the Hubbard Hamiltonian of Eq. 1, the unperturbed band energy, ε_k, of unpaired electron system splits into two subbands, $E_{k\sigma}^L$ and $E_{k\sigma}^U$, through correlation effect. Here, $E_{k\sigma}^L$

is the energy of an electron with σ-spin which moves about avoiding other electrons with $-\sigma$-spin, while $E_{k\sigma}{}^{U}$ is the energy of an electron which propagates mainly among sites already occupied with electrons with $-\sigma$-spin. The charge-transfer absorption is then composed of elementary transitions from $E_{k\sigma}{}^{L}$ to $E_{k\sigma}{}^{U}$ in the first Brillouin zone by conserving $\boldsymbol{k}$ and σ (*i.e.*, vertical transition). In the $n_{\downarrow}=1/2$ system, however, since the sites occupied by electrons with $-\sigma$-spin and those unoccupied exist with equal probability, the energy spectra of the two subbands have nearly the same shape. Therefore, the charge-transfer absorption of the $n_{\downarrow}=1/2$ system becomes narrow and has a steep peak at the energy $\omega=I$. On the other hand, in the case of $n_{\downarrow}>1/2$, the $E_{k\sigma}{}^{L}$ subband becomes flat but the $E_{k\sigma}{}^{U}$ subband has strong $\boldsymbol{k}$ dependence with considerable width, while in the case of $n_{\downarrow}<1/2$, the situation is reversed. Therefore, in both cases, the charge-transfer absorption spectra become much broader than that of the $n_{\downarrow}=1/2$ system.

The author wishes to express his thanks to Dr. Kenn Kubo of Tokyo Kyoiku University for his valuable discussion regarding this work.

Studies of the Adsorbing Particle Flotation of Fe^{3+} and Cu^{2+}

Koichi KOBAYASHI,* Kenichi NATORI,** Masamizu KAMAYA,† and Tsunetaka SASAKI††

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received July 29, 1977)

The adsorbing particle flotation of Fe^{2+} or Fe^{3+} and Cu^{2+} ions was studied by the combined use of bentonite (Bt) and a cationic surfactant, benzylhexadecyldimethylammonium chloride (BHDAC). Fe^{3+} ions were effectively floated from an aqueous solution by the use of Bt and cationic surfactant in a manner similar to the flotation by the use of sodium silicate and cationic surfactant. Most Fe^{2+} ions were found to be floated as Fe^{3+} ions, when the pH was increased by the addition of sodium hydroxide. The maximum floatability of 98% was obtained for Fe^{3+} under optimum conditions. The pH corresponding to the beginning of flotation of Fe^{3+} was influenced by the manner in which the pH of the solution was controlled. Cu^{2+} ions could also be floated, but less effectively than Fe^{3+} ions. Selective flotation of Fe^{3+} from the mixed solution of Fe^{3+} and Cu^{2+} was attempted and effectively achieved.

A limited number of studies have been reported for Fe^{3+} and Cu^{2+} ion flotation. Rubin and Johnson studied the effect of pH on the precipitation flotation of Fe^{3+} ion using an anionic surfactant, sodium dodecyl sulfate; the results were compared with a calculated precipitation flotation curve.[1] Rubin *et al.* found that Fe^{3+} ions were effectively removed from an aqueous solution by the use of sodium dodecyl sulfate.[1] They also studied the removal of Fe^{3+} and Cu^{2+} ions by octadecylamine as a function of pH.[1] Floatability of Cu^{2+} ions as $Cu_2[Fe(CN)_6]$ or the 8-quinolinol complex has also been reported.[2]

In a previous paper, it was reported that Fe^{3+} ions were effectively removed from an aqueous solution by the ion flotation using sodium silicate and a cationic surfactant, and that the floatability is greatly influenced by the order of addition of these reagents.[3] We have also reported that various kinds of heavy metal ions were more effectively floated by the combined use of bentonite and cationic surfactant than by the use of an anionic surfactant alone.[4]

In this study, therefore, the adsorbing particle flotation of Fe^{2+}, Fe^{3+}, and Cu^{2+} ions has been attempted and the effects of pH, gas-flow time, and the amount of bentonite on the floatability are reported.

Experimental

Materials. Extra-pure grade ammonium iron(II) sulfate and ammonium iron(III) sulfate, obtained from the Wako Pure Chemical Industries, Ltd. were used without further purification. The copper(II) sulfate used was an extra-pure grade $CuSO_4 \cdot 5H_2O$; it was recrystallized from distilled water. The bentonite powder (Bt) used as an ion exchanger was obtained from the Wako Pure Chemical Industries, Ltd.; the fraction passing through a 350-mesh sieve was collected and dried under reduced pressure. The benzylhexadecyldimethylammonium chloride, a product of the Kao Soap Co., Ltd., was recrystallized from acetone and was dried under reduced pressure. All other chemicals used for colorimetric determination were of analytical reagent-grade, except that the carbon tetrachloride and ammonia used were of special grade.

Apparatus and Procedure. The apparatus and method used for flotation measurements were the same as have been described previously.[5] The concentrations of Fe^{2+} and Cu^{2+} ions were determined by colorimetric methods as follows.

Iron:[6] Five cm^3 of the solution after flotation was transferred into a 25 cm^3 flask, 0.2 to 0.5 cm^3 of 0.5 mol/dm^3 H_2SO_4 was added to dissolve iron hydroxide, and 2 cm^3 of acetate buffer solution and 1 cm^3 of a 10% solution of hydroxylammonium chloride were added to insure the complete reduction of Fe^{3+} to Fe^{2+} ions. Further, 1 cm^3 of a 0.2% aqueous solution of 1, 10-phenanthroline solution was added to develop the color. After 30 min, the total volume was increased with water to 25 cm^3. The concentration of Fe^{2+} ions was then determined by the colorimeter, Bausch & Lomb, Spectronic 20, at 510 nm. The errors in the colorimetric method due to the scattering of light by Bt are of the order of $\pm 2\%$; this was taken into account by the blank experiment.

Copper:[7] 2 to 3 cm^3 of sample solution were transferred into a separatory funnel together with a little water. To this solution were added 5 cm^3 of 20% aqueous solution of ammonium citrate and 2—3 drops of Tymol Blue solution. The mixed solution was adjusted to pH 9.0—9.2 with ammonia, and the total volume was then made 50 cm^3 with water. To this solution was added 1 cm^3 of 1% aqueous solution of sodium diethyldithiocarbamate. The concentration of Cu^{2+} ions extracted in carbon tetrachloride solution was determined by using the colorimeter at 440 nm.

A humidified nitrogen gas was bubbled through a sintered glass plate (No. 4) at the gas-flow rate of 10 cm^3/min. The measurements were conducted at the room temperature of about 25 °C. Floatability was expressed as the percentage of the sublate floated.

Results and Discussion

Ion Flotation of Fe. Floatability and Gas-flow Time: Figure 1 shows the effects of gas-flow time on floatability for the solution containing 1.8×10^{-4} mol/dm^3 Fe^{2+} (which floated as Fe^{3+} ions, as will be mentioned later), 5.0×10^{-5} mol/dm^3 BHDAC, and 1.0×10^{-2}% Bt at the optimum floatability of pH=10.7. It can be seen that the floatability attains a steady value after 1.5 min. Accordingly, all subsequent experiments were made at a gas-flow rate of 10 cm^3/min and a gas-flow time of 2 min

unless stated otherwise.

Floatability and pH: In order to study the effect of pH on floatability, the flotation was carried out under the conditions of 1.8×10^{-4} mol/dm^3 Fe^{2+}, 5.0×10^{-5} mol/dm^3 BHDAC and 1.0×10^{-2}% Bt. This composition of flotation agents is modeled on the optimum composition of Co^{2+} ion flotation mentioned in a preceding paper.[8] The results are shown in Fig. 2. In Fig. 2, the circles (system I) show the floatability of Fe^{2+} ions from aqueous solutions of varying pH, which were obtained by dissolving ammonium iron(II) sulfate in an aqueous sulfuric acid at pH 2.3 and then increasing the pH by adding sodium hydroxide. The squares (system II) show the floatability of Fe^{2+} ions from an aqueous solution prepared by dissolving ammonium iron(II) sulfate in distilled water of pH 5.7 and adjusting the pH by sodium hydroxide for higher pH and sulfuric acid for lower pH. The triangles (system III) show the floatability of Fe^{2+} ions from an aqueous solution prepared by dissolving ammonium iron(II) sulfate in distilled water of pH 5.7, followed by decreasing the pH to 2 by sulfuric acid and then increasing the pH by the addition of sodium hydroxide.

In the case of systems I and III, the floatabilities increase sharply at pH 3, and reach 95% at pH 6 and above; in the case of system II, the floatability increases sharply by the slight addition of sodium hydroxide only from pH 6 and reaches 95% at pH 8 and above. Generally, metal ions are known to be floated effectively from a solution whose pH value corresponds to the beginning of metal hydroxide formation.[1] However, the present results show that the pH corresponding to the beginning of flotation is influenced by the reagent to be used for the pH control.

In order to clarify the state of the iron ions floated, the amount of Fe^{3+} ions in the sample solution was determined by the chelate titration method using EDTA.[9] The results show that the aqueous solution(I) contains 11% Fe^{3+} ions at pH 2.3, but that the aqueous solution(III), whose pH was decreased below 3 by H_2SO_4 and then increased above 3 by the addition of sodium hydroxide solution, contains 98% Fe^{3+} ions. It was also observed that the precipitate became reddish-brown at pH 3 and above by the addition of sodium hydroxide in the case of systems I and III and above pH 5.7 in the case of system II. In the case of Fe^{3+} solution using ammonium iron(III) sulfate, the floatability curve was the same as that of the systems I and III. Therefore, in the case of systems I and III, Fe^{2+} ions in ammonium iron(II) sulfate solution are considered to be oxidized almost completely to Fe^{3+} ions, as is mentioned in the literature.[10] In the case of system II, the flotation does not occur and the color of the solution does not change to reddish-brown in the pH region of 5.7 and 3. In this pH range for the conditions II, the solution is considered to be in a state of Fe^{2+} ions. Thus the beginning of the flotation and probably the formation of iron(III) hydroxide seems to

Bt: 1.0×10^{-2}%.

be influenced at least by the addition of sodium hydroxide, the reagent used for controlling pH. The reason is not clear at present.

Effect of Bentonite: In order to study the effect of Bt on Fe^{3+} ion flotation, the flotation was carried out at various pH values with and without Bt addition. The results are shown in Fig. 3. As may be seen in Fig. 3, in the system without Bt addition the floatability for the case of gas-flow time of 2 min shows a plateau of 14% in the pH region of 3 to 8, above which it sharply increases. But in the case of the system with Bt addition, as has been shown, the floatability increases sharply at about pH 3; this is shown by the squares in the figure. A marked effect of Bt addition is evident from these curves. Here the Bt acts as a bridge between positively charged iron(III) hydroxide and BHDAC, especially in the relatively low pH region. The rather rapid increase of floatability in a strongly alkaline region in the case of the system without the Bt addition in Fig. 3 may be explained by the interaction between negatively charged iron(III) hydroxide and positive BHDAC ions, as has been reported.[11] It should be mentioned, however, that when the gas-flow time is increased to 7 min, the floatability of the above system without the Bt addition is found to increase and the floatability curve coincides with that of the system I of Fig. 2, as shown by the circles in Fig. 3. The reason for this is not certain, but it is perhaps due to the flotation caused by the weak interaction between similarly charged iron(III) hydroxide and BHDAC, aided by the prolonged gas-flow time.

We have also studied in detail the flotation behavior in the relatively high pH region, and obtained the floatability of Fe^{3+} in a solution of fixed BHDAC concentration at pH 11 as a function of Bt amount added. The results are shown in Fig. 4. In Fig. 4, the floatability decreases for system I with increasing Bt concentration. The decrease of floatability is due to the uptake of BHDAC by Bt, resulting in the decomposition of the Fe hydroxide–BHDAC complex which is effective in

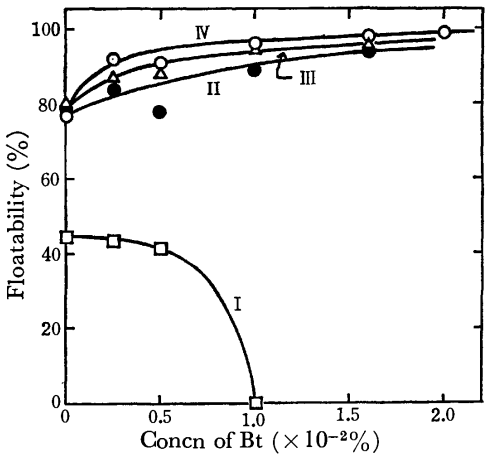

Fig. 4. Effect of Bt on Fe^{3+} floatability.
Fe^{3+}: 1.8×10^{-4} mol/dm^3, gas-flow time: 2 min,

the flotation process. In the case of systems II, III, and IV, the floatability increases with increasing addition of BHDAC. In these systems, the presence of a sufficient amount of BHDAC ensures the flotation of negatively charged Fe-hydroxide in the presence of Bt by a mechanism similar to the flotation of permanganate anions reported in an earlier paper.[3]

Ion Flotation of Cu. Floatability and pH: The effect of pH on the floatability of Cu^{2+} ions was also measured under conditions of 2.0×10^{-4} mol/dm^3 Cu^{2+}, 5.0×10^{-5} mol/dm^3 BHDAC, and 1.0 or 0.5×10^{-2}% Bt. The results are shown in Fig. 5. It can be seen in this figure that the floatability sharply increases from zero above pH 6; this corresponds to the beginning of $Cu(OH)_2$ precipitation. The increase of the amount of Bt added has little effect, as seen by the comparison of the systems of circles and triangles in the figure. The maximum flotation obtained is not so large as that for the Fe^{3+} ions.

Effect of Bentonite: In order to study the effect of Bt, the flotation was carried out for the system without the addition of Bt and a comparison was made. The results are shown in Fig. 6, together with the system with Bt

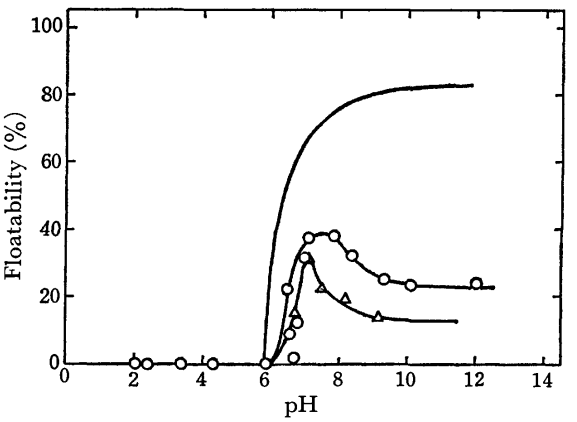

Fig. 6. Effect of pH on Cu^{2+} floatability.

Solid line II: simple system of Cu^{2+} ions.

(Fig. 5). It is seen in this figure that the lack of Bt remarkably decreases the floatability of Cu^{2+}, and the increase of gas-flow time from 2 min through 5 to 7 min increases the floatability in a slightly different way from the case of Fe^{3+} flotation. The increase of BHDAC concentration shows no effect. Thus, the addition of Bt is found effective in both the reduction of gas-flow time and the increase of floatability.

Selective Ion Flotation from a Mixed System. The flotation of Cu^{2+} and Fe^{3+} ions from a solution containing 2.0×10^{-4} mol/dm^3 Cu^{2+}, 2.0×10^{-4} mol/dm^3 Fe^{3+}, 1.0×10^{-2}% Bt, and 5.0×10^{-5} mol/dm^3 BHDAC was carried out by controlling pH with NaOH. The results are shown in Fig. 7, as open circles and triangles respectively, together with the results obtained for the separate systems of Cu^{2+} and Fe^{3+} ions, shown as solid lines. In the mixed systems, Fe^{3+} and Cu^{2+} ions are floated above pH 3 and 6 respectively, as in the flotations of the separate systems. Thus, even in the mixed system the flotation begins at the point of the formation of insoluble iron and copper hydroxides. Accordingly, the selective flotation of Fe^{3+} ions was achieved between pH 3 and 6, enabling the separation of Fe^{3+} ions from Cu^{2+} ions. However, in the above system, because of a relatively limited amount of Bt and BHDAC, the floatability of Fe^{3+} ions decreases as soon as the Cu^{2+} ion flotation begins and they both attain a steady value of about 40% at pH values higher than 8. In the case of a sufficient addition of Bt and BHDAC, as shown by the solid curves and triangles in Fig. 7, the flotation of Fe^{3+} and Cu^{2+} ions increases; beyond pH 10, the flotation of both Fe^{3+} and Cu^{2+} attains their steady maximum of about 80%. These conditions are applicable for the non-selective removal of both Fe^{3+} and Cu^{2+}.

Thermal Decomposition of CF_3CN in Shock Waves

Kazuo OKADA, Okitsugu KAJIMOTO, and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 4, 1977)

The thermal decomposition of CF_3CN diluted to 0.2 and 0.5 mol% in argon was studied behind incident shock waves over the temperature range 2450—3610 K. Mass spectrometry of the reaction mixture revealed that the decomposition products are C_2F_6, C_2N_2, C_2F_4, and a trace of FCN. The course of the primary process of decomposition, $CF_3CN+Ar \rightarrow CF_3+CN+Ar$, was followed by monitoring the CN(0—1) violet absorption centered at 421.5 nm. It was confirmed that the reaction is still in the low-pressure limit under our experimental conditions. The initial slope of absorption gave the bimolecular rate constant, $k=(7.9\pm3.1)\times10^{15}\exp[-(94.0\pm2.8)$ kcal mol$^{-1}/RT]$ cm^3 mol^{-1} s^{-1}. The rate constants obtained are best fitted by the classical collision-theory expression $k=\lambda(Z/n!)(E/RT)^n\exp(-E/RT)$ with $\lambda=0.44$, $n=2$, and $E=D_0(CF_3\text{–}CN)=102.7$ kcal/mol. The mechanism of the overall decomposition was suggested and checked by numerical integrations of the relevant rate equations.

The shock-tube decomposition of simple cyano compounds such as C_2N_2,[1,2] ClCN,[3] BrCN,[4,5] and HCN[6,7] in argon has already been a subject of intensive studies by several groups of workers. It is generally agreed that the primary step of the decomposition is the bimolecular process:

$$XCN + Ar \longrightarrow X + CN + Ar. \quad (1)$$

The present work is an extension of our previous studies on C_2N_2,[2] BrCN,[5] and HCN[7] to the case of trifluoroacetonitrile CF_3CN. Despite the larger number of atoms involved, the primary decomposition step proved to be still in the low-pressure limit under the shock-wave conditions adopted. The bimolecular rate constants for the primary step (1) were obtained from the initial slopes of the CN absorption records.

Product analysis showed that small amounts of C_2F_4 and FCN were formed in addition to the major decomposition products C_2F_6 and C_2N_2. The overall decomposition mechanism is thus somewhat more complex than that already established for simpler cyano compounds.[3–5,7] Presumably, the sources of these minor products are CF_2 and F which have been generated by a further decomposition of CF_3. A possible overall mechanism was inferred on this basis. Adequacy of the assumed mechanism was examined by numerical integrations of the overall kinetic equations. The time-concentration profiles calculated for CN radicals showed an excellent agreement with the observed CN absorption traces.

Experimental

Material. Trifluoroacetonitrile was prepared by heating a mixture of trifluoroacetamide and diphosphorus pentaoxide at 145—150 °C for 2 h,[8] and purified by trap-to-trap distillations. Commercial argon having a purity of 99.999% was used without further purification. Sample gases of 0.2 and 0.5 mol% CF_3CN in Ar were prepared at a total pressure of *ca.* 600 Torr [1 Torr=(101325/760) Pa].

Kinetic Measurements. Decomposition experiments were conducted in a stainless-steel shock tube having an internal diameter of 10.4 cm. The initial total pressure P_1 of gas samples ranged from 8.3 to 34 Torr. Hydrogen was used as driver gas. The diaphragms used were Myler sheets of 0.10 and 0.25 mm in thickness, which gave the driver bursting pressures of 3 and 9 atm (1 atm=101325 Pa), respectively. The temperatures T calculated for the shock-heated gas samples were in the range from 2450 to 3610 K. No temperature correction was made for the reaction heat, inasmuch as the gas samples used were sufficiently dilute to ignore it.

The course of decomposition was followed by monitoring the CN $B^2\Sigma^+$—$X^2\Sigma^+$ (0—1) absorption at 421.50±0.21 nm. To isolate the spectral bandwidth, a Rikotsusho grating monochromator MC-50 was used at the entrance and exit slit width of 0.30 mm. The band selected encompasses the overlapping rotational lines $J=9$—36 of the ground-state CN($X^2\Sigma^+$, $v=1$). The detection devices and procedure used were entirely the same as those described previously.[2] The response time of the optics and its associated electronic circuit was no greater than 2 μs.

Product Analysis. A gas sample, 4 mol% CF_3CN in Ar, was shock-heated for an unspecified time interval at *ca.* 3400 K by using helium as driver gas. The gaseous reaction mixture, which was cooled down to room temperature by the rarefaction, was let pass through a trap immersed in liquid nitrogen. After having been degassed in the trap, the liquefied material was allowed to evaporate at room temperature.

The reactant-product mixture gas thus prepared was subjected to mass-spectrometric analysis. The mass-spectrum obtained had the intensity peaks ascribable to CF_3CN, C_2N_2, C_2F_6, C_2F_4, and FCN. Attempts were made to determine the relative concentrations of these species from the intensity ratios between relevant mass peaks. The standard intensity ratios between such peaks were calibrated beforehand with various equimolar binary mixtures (CF_3CN–C_2N_2, C_2F_6–C_2N_2, C_2F_6–C_2F_4, and C_2F_6–FCN) as references. The results of determination (in mol%) were as follows:

$$CF_3CN : C_2N_2 : C_2F_6 : C_2F_4 : FCN = 85.15 : 5.16 : 8.01 : 1.50 : 0.16.$$

Results

Equilibrium. As has been confirmed by mass-spectrometry, the main products of the CF_3CN decomposition are C_2N_2 and C_2F_6. By the analogy to the mechanism already established for the decompositions of ClCN,[3] BrCN,[4,5] and HCN,[7] the main body of the present decomposition is considered to consist of the following elementary reactions:

$$CF_3CN + Ar \overset{1}{\rightleftarrows} CF_3 + CN + Ar,$$

$$C_2N_4 + Ar \overset{2}{\rightleftarrows} 2CN + Ar,$$

$$C_2F_6 + (Ar) \overset{3}{\rightleftarrows} 2CF_3 + (Ar),$$

$$CN + CF_3CN \overset{4}{\rightleftarrows} C_2N_2 + CF_3,$$

$$CF_3 + CF_3CN \overset{5}{\rightleftarrows} C_2F_6 + CN.$$

The formations of C_2F_4 and FCN as minor products strongly suggest the intermediacies of CF_2 and F. The elementary reactions of importance which involve these transient species are conceivably as follows:

$$CF_3 + Ar \overset{6}{\rightleftarrows} CF_2 + F + Ar,$$

$$C_2F_4 + Ar \overset{7}{\rightleftarrows} 2CF_2 + Ar,$$

$$F_2 + Ar \overset{8}{\rightleftarrows} 2F + Ar,$$

$$FCN + Ar \overset{9}{\rightleftarrows} F + CN + Ar,$$

$$CF_4 + Ar \overset{10}{\rightleftarrows} F + CF_3 + Ar,$$

$$F + CF_3CN \overset{11}{\rightleftarrows} CF_4 + CN.$$

Presumably, both CF_2 and F are generated directly from CF_3 by Reaction 6. Reactions 7 and 8 are the dissociation-homorecombination processes associated with these species. Reactions 9 and 10 concern the associations of F with the primary radicals CN and CF_3, respectively. Reaction 11 is a bimolecular reaction between F and CF_3CN, which is equivalent in type to Reaction 5.

Oscillographic records of the CN absorption showed, in all cases, an initial rapid rise in intensity, followed by a gradual increase up to a steady level. The constancy in absorbance may be taken as an indication that the overall process, Reactions 1 through 11, is in a complete equilibration.

Of the eleven species (except for Ar) present, only nine can take on independent concentrations at any given instance, since the total numbers of CN and F should be conserved all the time. At complete equilibrium, however, the local equilibria 4 and 5 cannot be independent ones either; $K_4=K_1/K_2$ and $K_5=K_1/K_3$. In addition, one may assume complete dissociations of C_2F_6, C_2F_4, and F_2 (*i.e.*, $K_3=K_7=K_8=\infty$) in the temperature range studied.[9] The overall equilibrium problem could thus be solved for six independent concentrations [CF_3CN], [CF_3], [CN], [CF_2], [F], and [FCN] by use of the six equilibrium constants for Reactions 1, 2, 6, 9, 10, and 11. The standard free energy changes ΔG_T° for the various elementary reactions have been taken from the JANAF tables[10] and are listed in Table 1.

The equilibrium concentrations $[CN]_e$ calculated in the above-described manner should be related to the observed absorbance at equilibrium through[1,2,5]

$$\ln (I_0/I)_e = \beta_{01} l F_{ab}(T) [CN]_e \qquad (2)$$

Here, β_{01} is the effective absorption coefficient for the CN radicals in the absorbing levels, l is the optical path length (l=10.4 cm), and $F_{ab}(T)$ is the fractional population of the absorbing $CN(X^2\Sigma^+)$ radicals (v=1, J=9—36). The $F_{ab}(T)$ for the present case is given by

$$F_{ab}(T) = \frac{\sum_{J=9}^{36}(2J+1)\exp\left(-\frac{J(J+1)\varepsilon_r+\varepsilon_v}{kT}\right)}{Q_r Q_v}, \qquad (3)$$

where ε_r and ε_v respectively denote the rotational and vibrational quanta of CN radicals and where Q_r and Q_v are the corresponding partition functions.

The β_{01} values to be obtained for different runs should be least temperature-dependent.[2,5] This was

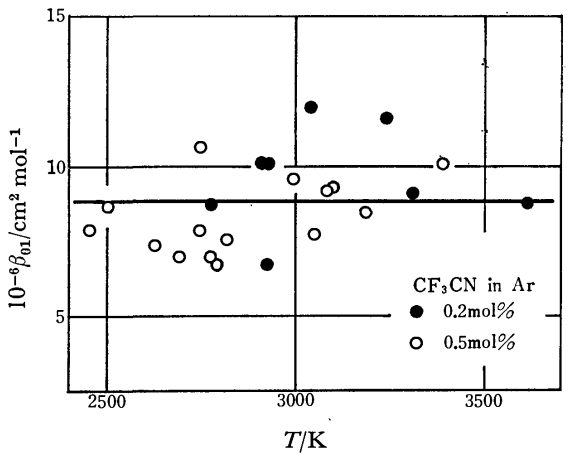

Fig. 1. Constancy of the CN absorption coefficient β_{01} over the temperature range studied.

substantiated as is shown in Fig. 1. The average value of β_{01} was found to be $(8.85\pm0.95)\times10^6$ cm^2 mol^{-1}, in good agreement with the value $(9.16\pm0.76)\times10^6$ cm^2 mol^{-1} observed previously in the study of the dissociation equilibrium: $C_2N_2\rightleftharpoons2CN$.[2]

Dissociation Rates of CF_3CN. With the β_{01} value at hand, we have determined the bimolecular rate constants k_1 from the initial slope of absorbance

$$r_0 = \{d \ln (I_0/I)/dt\}_0, \quad (4)$$

where t is the particle time. k_1 is obtained as

$$k_1 = r_0/\beta_{01}lF_{ab}(T)[CF_3CN]_0[Ar]_0, \quad (5)$$

where $[CF_3CN]_0$ and $[Ar]_0$ are the concentrations at zero time, *i.e.*, immediately behind the shock front. The values of k_1 obtained for some representative runs are given in Table 2, together with pertinent experimental data.

Figure 2 shows the Arrhenius plots of k_1 obtained for a total of 25 runs. A single straight line is seen to fit the plots, irrespective of the $[CF_3CN]_0/[Ar]_0$ ratio. Although the total gas pressure was not changed independently

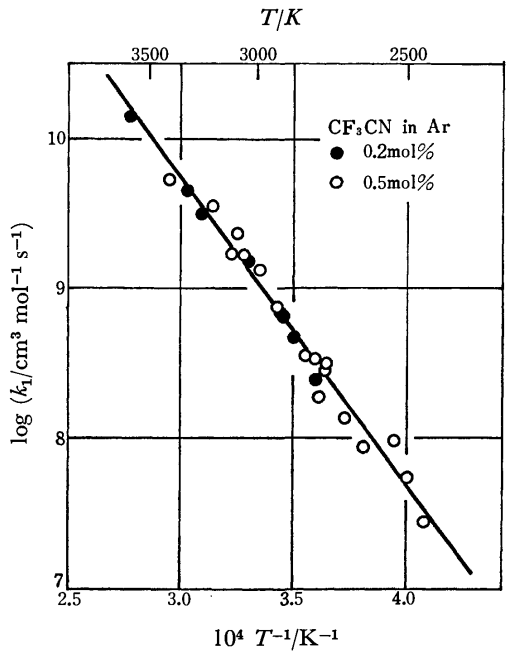

Fig. 2. Arrhenius plots of k_1.
$k_1=7.9\times10^{15}\exp(-94.0$ kcal mol$^{-1}/RT)$ cm^3 mol^{-1} s^{-1}.

of the reaction temperature, it is evident that the dissociation rate is proportional to $[Ar]_0$. Thus the reaction is indeed bimolecular under the experimental conditions adopted in this work. Least-squares treatment of the linearity has led to the Arrhenius expression

$$k_1 = (7.9\pm3.1)\times10^{15} \times \exp[-(94.0\pm2.8) \text{ kcal mol}^{-1}/RT] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}. \quad (6)$$

Overall Decomposition Kinetics. The rate equations for the entire mechanism comprising Reactions 1—11 were subjected to numerical (Runge-Kutta-Gill) integration on a computer. The rate constants used for computation are listed in Table 1. The forward rate constants for Reactions 1, 2, 6, 8, and 10 were those determined experimentally.[2,11,12] The constant k_3, when multiplied by $[Ar]_0$, was assumed to be equal to the first-order rate constant for the ethane decomposition in the high-pressure limit.[13] The preexponential factors for k_7 and k_9 were estimated from those observed for the dissociations of N_2F_4[14] and BrCN.[5] Entirely indeterminate at this stage are k_4, k_5, and k_{11}. Most likely, the preexponential factor for k_5 would be about the same as that for k_4, and the activation parameter in k_5 would be nearly equal to the endothermicity of Reaction 5. It was decided to estimate k_4 and k_{11} by requiring the best overall fit of the calculated time-concentration profiles of CN radicals to the observed absorption curves. The rate constants for the reverse reactions were all calculated from those for the forward reactions and the equilibrium constants. The time step used for integration was 0.5 μs.

Preliminary calculations showed that the rate constants k_3, k_5, k_7, and k_8 exert virtually no effect on the CN concentration profiles. In what follows, therefore, we will ignore Reactions 3, 5, 7, and 8 throughout. The simplification is in line with the assumption of complete dissociations of C_2F_6, C_2F_4, and F_2 which has been invoked in the equilibrium considerations.

The time histories of the CN radical concentrations calculated for the cases of T=3385 and 2920 K are shown in Fig. 3. The full lines indicate the CN concentrations calculated for the entire mechanism (excluding Reactions 3, 5, 7, and 8), while the dashed lines show the concentrations which CN radicals would have if Reaction 1 were the only reaction to be considered.

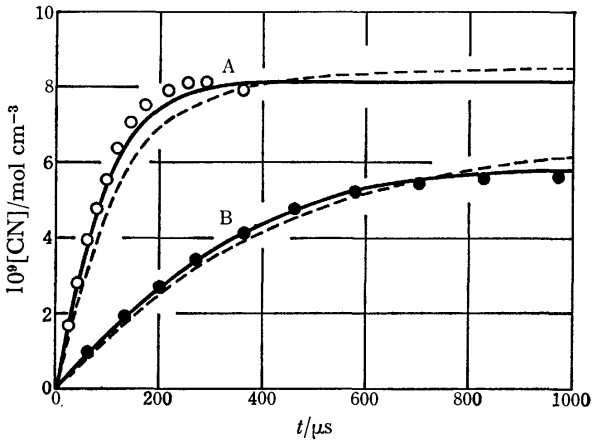

Fig. 3. Comparisons of the computed CN concentration profiles with the observed.
A: T=3385 K, m=0.5 mol%, $[Ar]_0=1.65\times10^{-6}$ mol/cm^3;
B: T=2920 K, m=0.2 mol%, $[Ar]_0=3.29\times10^{-6}$ mol/cm^3.
—: Computed with the rate constants given in Table 1; ---: Reaction 1 alone; ○, ●: experimental; t: particle time.

The experimental values of [CN] read from the absorption records are indicated with circles.

As a whole, the assumed mechanism with the rate constants given in Table 1 seems to be detailed enough to account for the observed time-concentration profiles of CN radicals. It has also been verified that the various reactions following the primary step 1 exert little influence on the initial slope. These results corroborate not only the adequacy of the assumed overall mechanism but also the legitimacy of the initial slope technique used to determine the k_1 values.

Discussion

In the computer tracing of the CN concentration profiles, the rate constants for the abstraction Reactions 4 and 11 were treated as the only adjustable parameters. The values for the Arrhenius A factors obtained for k_4 and k_{11} both appear to be reasonable; the A factors for abstractions by a radical are generally of the order of 10^{12} cm^3 mol^{-1} s^{-1} while those for similar reactions of an atom are usually *ca.* 10^{14} cm^3 mol^{-1} s^{-1}.[15] Not much can be said, however, about the activation energies obtained.

The experimental activation energy E_a=94.0 kcal/mol found for the CF_3CN dissociation is apparently smaller than the bond dissociation energy D_0=102.7 kcal/mol. This can readily be accounted for in terms of the participation of the internal energy of CF_3CN to its dissociation.

The classical collision theory due to Fowler and Guggenhiem[16] provides a semi-quantitative clue for understanding the above-stated situation. According to the theory, the rate constant for a bimolecular reaction is expressed as

$$k_1 = \lambda(Z/n!)(D_0/RT)^n \exp(-D_0/RT), \quad (7)$$

where n is the effective number of the internal degrees of freedom contributing to the activation process and where λ is a correction factor termed the "steric" factor. The temperature variation of the present experimental results, Eq. 6, is best fitted to that of Eq. 7, when n is assigned a value of 2. The least-squares fit of Eq. 7 with n=2 to the experimental k_1 values has led to the expression

$$k_1 = [4.30\times10^{12}/2]T^{1/2}(D_0/RT)^2 \exp(-D_0/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}. \quad (8)$$

Assuming the CF_3CN-Ar collision diameter to be 0.42 nm, we get λ=0.44, a value which does not appear unreasonable.

The Fowler-Guggenheim expression, Eq. 7 is formally equivalent to the low-pressure-limit form of the RRK theory for unimolecular reactions.[17] The theory permits a rough estimation of the "fall-off pressure"

$$P_{1/2} \simeq \frac{\bar{\nu}}{\lambda Z}\left\{1+\frac{D_0}{(n+1)RT}\right\}^{-n} RT, \quad (9)$$

where $\bar{\nu}$ is a mean frequency of the vibrations participating in the activation process. Taking $\bar{\nu}=10^{13}$ s^{-1}, $P_{1/2}$ for the CF_3CN dissociation was calculated to be 210 and 140 atm at 3000 and 2500 K, respectively. The dissociation in question is thus considered to be in the low-pressure limit under our experimental conditions.

It was not *a priori* obvious that the thermal dissociation of CF_3CN, a six-atom molecule, would exhibit the bimolecular behavior. Perhaps, the C–F bondings are rigid enough for the CF_3 group to be regarded as a pseudoatom. The value n=2 agrees closely with n=1.5 found for the case of BrCN,[5] a triatomic molecule.

The conclusion that the CF_3CN dissociation is bimolecular in the ordinary pressure region is interesting in connection with the results reported by Perettie and Janz.[18] They investigated the thermal decomposition of pure CF_3CN by the flow method in the temperature range 684—809 K. The reaction obeyed a kinetics of second order in CF_3CN

$$2CF_3CN \longrightarrow C_2F_6 + (CN)_2, \quad (10)$$

with the bimolecular rate constant

$$k = 10^{14.7}\exp[-(64.7\pm3.0) \text{ kcal mol}^{-1}/RT] \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}. \quad (11)$$

Although the conclusion that Reaction 10 is a concerted (one-step) process involving a four-centered cyclic activated complex may perhaps be still debatable, the observed kinetics certainly negates a dominance of the unimolecular decomposition of CF_3CN. Even if the concerted Process 10 is involved in our shock-wave kinetics, it is least significant in our reaction system in which CF_3CN was used in an extremely high dilution in argon as environment gas. At 2455 K, the lowest temperature studied, the rate of Reaction 10 should be only one-sixth that of Reaction 1.

This work was supported in part by a Scientific Research Grant from the Ministry of Education, Japan (No. 110301).

Ring Transformation of γ-Butyrolactone into γ-Thiobutyrolactone over Alkaline Cation Exchanged Zeolites

Kou HATADA,* Yoichi TAKEYAMA, and Yosho ONO

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

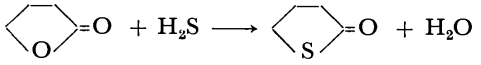
(Received August 6, 1977)

The reaction of γ-butyrolactone and hydrogen sulfide to give γ-thiobutyrolactone over zeolites was studied. Alkaline cation exchanged zeolites have high catalytic activity for the ring conversion, acidic zeolites very low activity. γ-Thiobutyrolactone was obtained in 99% yield with CsY at 330 °C. There is no decay of catalytic activity with time. The reaction kinetics over LiY, NaY, and CsY are expressed by

$$r = \frac{k(a_L P_L)(a_H P_H)}{(1+a_L P_L+a_H P_L)^2},$$

where r is the rate of reaction, P_L and P_H are the partial pressure of γ-butyrolactone and hydrogen sulfide, respectively, and k, a_L, a_H are constants. The activation energies for k are 39, 31, and 26 kcal mol^{-1} with LiY, NaY, and CsY, respectively. Catalytic activity is enhanced by addition of pyridine but almost completely depressed by addition of hydrogen chloride. It is concluded that basic sites play an important role in the ring transformation.

Synthetic zeolites usually act as acidic catalysts, having very high activity for major carbonium ion hydrocarbon transformations such as cracking, alkylation and isomerization. For these reactions, hydrogen-, rare-earth-, and alkaline earth-exchanged zeolites are the most active catalysts. However, the parent Na^+ and K^+-exchanged zeolites are inactive.[1] There are, however, some reactions in which NaY has a catalytic activity comparable with HY, *e.g.* the reactions of γ-butyrolactone with primary amines to form 1-alkyl-2-pyrrolidinone.[2] The mechanism proposed for this reaction involves the activation of primary amines on basic sites.[2] A related reaction, the conversion of γ-butyrolactone in the presence of hydrogen sulfide has been studied by Venuto and Landis.[3]



A notable feature of the reaction is that NaX was found to be the most active catalyst among the zeolites studied, HY and ReX having only a meager catalytic activity.[3] The catalytic activity for this reaction does not seem to be associated with Brönsted centers.

The kinetic behavior of the ring transformation of γ-butyrolactone into γ-thiobutyrolactone (tetrahydro-2-thiophenone) was examined over a series of alkaline Y-zeolites in order to find the mechanistic grounds of high activity of alkaline zeolites for the ring conversion reaction.

Experimental

Materials. γ-Butyrolactone (purity>99%) was distilled prior to each run. Commercial hydrogen sulfides, NaX and NaY (Linde Division of Union Carbide Corp.) were used. Various cation forms of Y-zeolites were prepared by means of the conventional cation exchange using salt solution. The cation exchanged zeolites were pelleted without a binder and crushed and made into 9—16 mesh. They were stored in a desiccator containing a saturated aqueous ammonium chloride.

* Present address: Faculty of Education, Saitama University, Urawa, Saitama 338.

Apparatus and Procedure. A continuous flow reactor was used under atmospheric pressure. The reactor was silica tubing (13 mm i.d.) placed in a vertical furnace. Prior to the reaction, the catalyst in the reactor was heated up to the reaction temperature in a nitrogen stream. Hydrogen sulfide was then fed. After 15 min, γ-butyrolactone was pumped into the preheating zone of the reactor containing 10 ml quartz powder. Nitrogen was used as diluent for regulating the initial pressure of reactants. The gaseous materials were fed through flowmeters. Reaction products collected in the receiver were withdrawn at certain intervals during the run and analyzed by gas chromatography.

Result and Discussion

Catalytic Activity of Various Forms of Zeolites. The catalytic activities of various cation forms of zeolites for the reaction of γ-butyrolactone and hydrogen sulfide were compared at 330 °C. The activities and selectivities to γ-thiobutyrolactone production on various zeolites are given in Table 1. We can see the following features of the reaction.

Table 1. Catalytic activity of various zeolites

Catalyst	Exchanged (%)	Conversion (%)	Yield (%)
LiY	58	27	26
NaY	—	52	51
KY	97	45	45
RbY	64	51	51
CsY	64	79	78
NaX	—	99	86
KL	—	23	22
HY	66	4	1
MgY	56	2	2

Reaction conditions; 330 °C, H_2S/lactone=6, W/F=6.26 g h mol^{-1}.

(1) Alkaline forms of zeolites are much more active than acidic zeolites (HY, MgY).

(2) The catalytic activity of alkaline forms of Y-zeolites increases in the following order.

$$LiY < NaY \simeq KY \simeq RbY < CsY$$

(3) NaX is a more active catalyst than NaY, but shows less selectivity.

(4) The selectivity to γ-thiobutyrolactone is essentially 100% over alkaline Y-zeolites.

It should be noted that no decay of activity with time is observed except for the case of MgY.

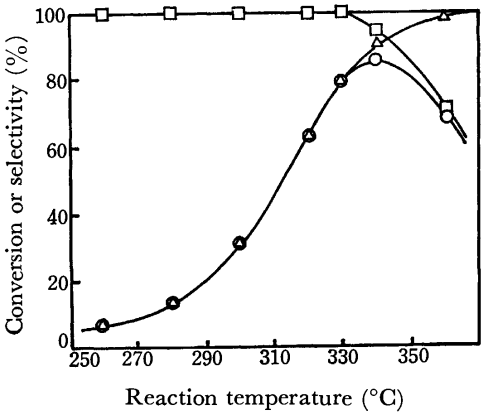


Fig. 1. Variation of the conversion (△), the yield (○) and the selectivity (□) with reaction temperature.
CsY 1.0 g, W/F=6.26 g h mol^{-1}, H_2S/lactone=6.

Influence of Reaction Temperature. The effect of reaction temperature on the yield and the selectivity to γ-thiobutyrolactone was examined with CsY as a catalyst. As shown in Fig. 1, the yield of γ-thiobutyrolactone sharply increases with temperature below 340 °C. Maximum yield is reached at 340 °C. The yield falls at higher temperatures. The selectivity to γ-thiobutyrolactone is 100% up to 330 °C, decreasing at higher temperatures.

Effect of Contact Time. The effect of contact time (W/F) on the yield of γ-thiobutyrolactone was examined at 330 °C. W/F is defined as follows:

$$W/F = \frac{\text{Weight of catalyst (g)}}{\text{Total feed } (H_2S+\text{lactone}+N_2)\ (\text{mol h}^{-1})}.$$

The results are illustrated in Fig. 2. The yield increases with contact time. At W/F=18.8 g h mol^{-1}, a 99% yield can be attained. The selectivity for γ-thiobutyrolactone is always 100% at this temperature.

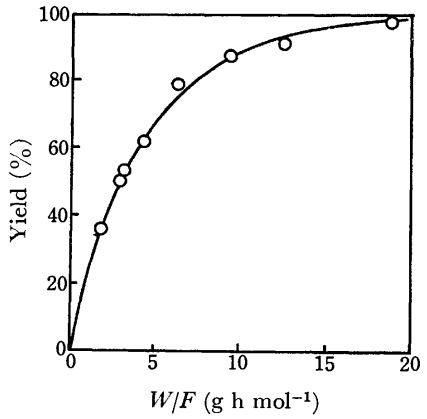

Fig. 2. Effect of contact time on γ-thiobutyrolactone yield.
CsY, 330 °C, H_2S/lactone=6.

Reaction Kinetics. The kinetics of the reaction was studied in a short contact time with LiY, NaY, and CsY as catalyst. The effect of partial pressure of γ-butyrolactone on the reaction rate was examined by keeping the partial pressure of hydrogen sulfide at 0.5 atm. The partial pressure of nitrogen was adjusted to keep the contact time constant. The results for CsY are given in Fig. 3. The rate decreases with increase in lactone partial pressure.

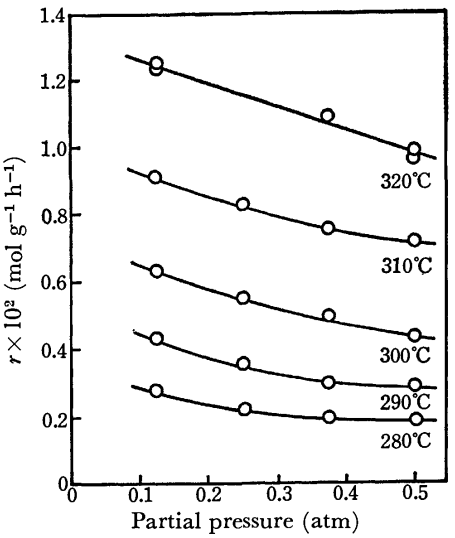

Fig. 3. Dependence of the reaction rate over CsY on the partial pressure of γ-butyrolactone.
CsY 0.5 g, W/F=2.74 g h mol^{-1}, P_H=0.5 atm.

The dependence of reaction rate on the partial pressure of hydrogen sulfide was examined by keeping the lactone partial pressure at 0.125 atm. The results for CsY are given in Fig. 4.

The presence of the reaction products (water and γ-thiobutyrolactone) does not affect the reaction rate, since addition of these substances to the reactant feed does not change the yield of γ-thiobutyrolactone.

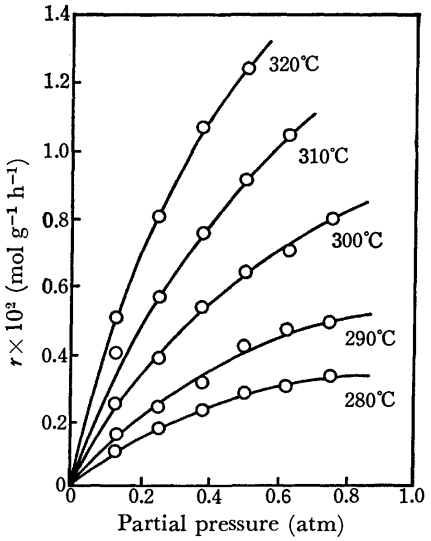

Fig. 4. Dependence of the reaction rate over CsY on the partial pressure of hydrogen sulfide.

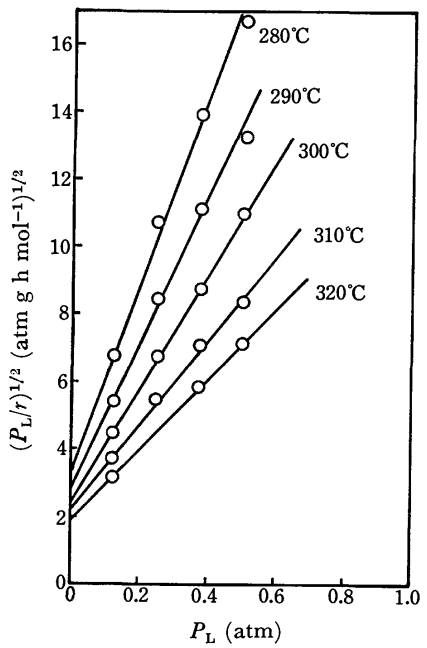

Fig. 5. $(P_L/r)^{1/2}$ *vs.* P_L plot for CsY.

It was found that the rate of the reaction can be expressed by

$$r = \frac{k(a_L P_L)(a_H P_H)}{(1+a_L P_L+a_H P_H)^2}, \quad (1)$$

where r is the rate of reaction, P_L and P_H are the partial pressures of γ-butyrolactone and hydrogen sulfide, respectively, and k, a_L, a_H are constants.

By rearranging Eq. 1, we have

$$\left(\frac{P_L}{r}\right)^{1/2} = \frac{1+a_H P_H}{(k a_L a_H P_H)^{1/2}} + \frac{a_L}{(k a_L a_H P_H)^{1/2}} \cdot P_L, \quad (2)$$

or

$$\left(\frac{P_H}{r}\right)^{1/2} = \frac{1+a_L P_L}{(k a_H a_L P_L)^{1/2}} + \frac{a_H}{(k a_L a_H P_L)^{1/2}} \cdot P_H. \quad (3)$$

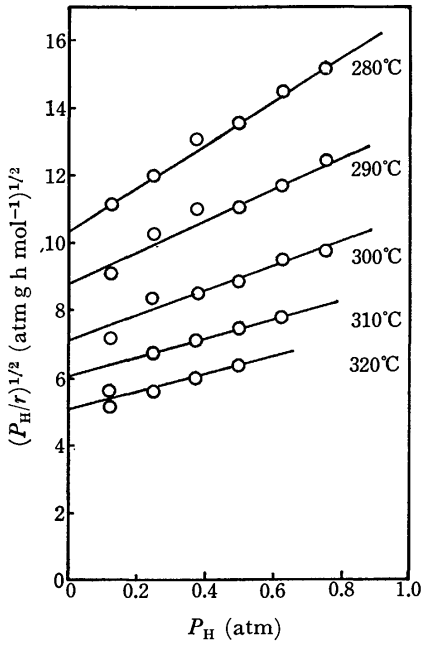

Fig. 6. $(P_H/r)^{1/2}$ *vs.* P_H plot for CsY.

Table 2. Kinetic parameters for the conversion of γ-butyrolactone into γ-thiobutyrolactone over CsY

Temperature (°C)	k (mol g^{-1} h^{-1})	a_L (atm^{-1})	a_H (atm^{-1})
280	2.3×10^{-2}	14	1.8
290	4.1×10^{-2}	13	1.3
300	6.0×10^{-2}	12	1.5
310	8.0×10^{-2}	11	1.8
320	11.7×10^{-2}	10	1.6

Table 3. Kinetic parameters for the conversion of γ-butyrolactone into γ-thiobutyrolactone at 320 °C

Catalyst	k (mol g^{-1} h^{-1})	a_L (atm^{-1})	a_H (atm^{-1})	E_a (kcal mol^{-1})
LiY	4.0×10^{-2}	8	0.5	39
NaY	6.1×10^{-2}	7	0.9	31
CsY	11.7×10^{-2}	10	1.6	26

Straight lines are obtained (Fig. 5) when $(P_L/r)^{1/2}$ is plotted against P_L by using the data given in Fig. 3. Straight lines are obtained (Fig. 6) also when $(P_H/r)^{1/2}$ is plotted against P_H by using the data given in Fig. 4. From the slopes and intercepts of the plots of Figs. 5 and 6, the constants, k, a_L, a_H are determined as given in Table 2. In a similar way, the rate constants and the constants (a_L, a_H) for LiY and NaY were determined. The values at 320 °C are given in Table 3. The rate constant, k, changes with the increasing order LiY$<$NaY$<$CsY. The constant a_H also changes with the increasing order LiY$<$NaY$<$CsY, while the constant a_L does not depend much on the catalyst used. From the temperature dependence of the rate constant, the activation energy for k is determined to be 39, 31, and 26 kcal mol^{-1} for LiY, NaY, and CsY, respectively.

Nature of Active Centers. Acidic zeolites (HY and MgY) have only a limited activity for this ring transformation reaction (Table 1). However, alkaline zeolites are very effective. This clearly indicates that the active centers are not acidic sites.

Yashima *et al.*[4] found that in the alkylation of toluene with methanol or formaldehyde, xylenes were selectively formed over Li zeolite, styrene and ethylbenzene being produced over the other alkaline zeolites. They concluded that the formation of xylenes depends on the solid acidity, the formation of styrene and ethylbenzene depending on the solid basicity. The side-chain alkylation is promoted by added aniline, while the nuclear alkylation is promoted by hydrogen chloride.[4] The presence of basic sites has been further confirmed by the conversion of 2-propanol over alkaline zeolites,[5] since the dehydration and dehydrogenation of alcohols are catalyzed by the acidic and the basic sites, respectively.[6] The order of catalytic activity of alkaline Y-zeolites is as follows.[5]

For dehydration LiY$>$NaY$>$KY$>$RbY$>$CsY,

For dehydrogenation LiY$<$NaY$<$KY$<$RbY$<$CsY.

The order of catalytic activity among alkaline zeolites

for the reaction of γ-butyrolactone and hydrogen sulfide suggests that the active centers for this ring conversion is basic in nature. In order to gain further insight into the active centers, the effects of addition of hydrogen chloride and of pyridine on the catalytic activity were examined.

Effect of Hydrogen Chloride. Matsumoto *et al.*[7] reported that the cracking of cumene over NaY is greatly enhanced by addition of hydrogen chloride to the system. The enhancement of the catalytic activity is ascribed to the formation of Brönsted acid sites by the interaction of hydrogen chloride with NaY.

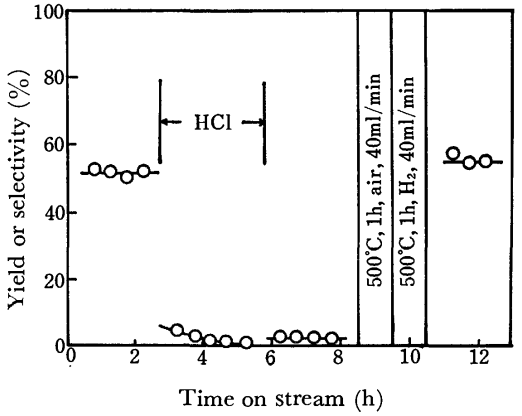

Fig. 7. Effect of hydrogen chloride on the reaction rate.
CsY, 330 °C, W/F=3.13 g h mol^{-1}, H_2S/lactone=6.

Addition of hydrogen chloride was carried out by passing a hydrogen sulfide stream over the concentrated hydrogen chloride aqueous solution. The results are given in Fig. 7. Hydrogen chloride almost completely inhibits the catalytic activity. The effect is irreversible, since the activity does not recover when feeding of hydrogen chloride is interrupted. The activity can be recovered by consecutive treatment of the catalyst with air and hydrogen at 500 °C. This eliminates the possibility of deactivation being caused by the destruction of the zeolite framework. The presence of water vapor does not affect the catalytic activity. Thus, it can be assumed that the deactivation is associated with the poisoning of the active centers, presumably the basic sites, by hydrogen chloride.

Effect of Pyridine. Pyridine is often used to poison acidic center. The effect of addition of pyridine on the ring conversion was examined. The dependence of the rate of γ-thiobutyrolactone on the pyridine partial pressure is given in Fig. 8. We see that pyridine does not poison the catalysis. However, it enhances the catalytic activity; the activity increases 35 and 250% for CsY and LiY, respectively, with pyridine partial pressure$>$0.01 atm.

The effect of hydrogen chloride and pyridine indicates that the acidic sites are not responsible for the catalysis, but the active centers are associated with basic sites. The enhancement of activity by pyridine may be caused by enrichment of the electron density of the oxygen anions in $(AlO_4)^-$ unit by the induced effect of pyridine absorbed close to the basic center. A similar mechanism of the enhancement by adsorbed pyridine

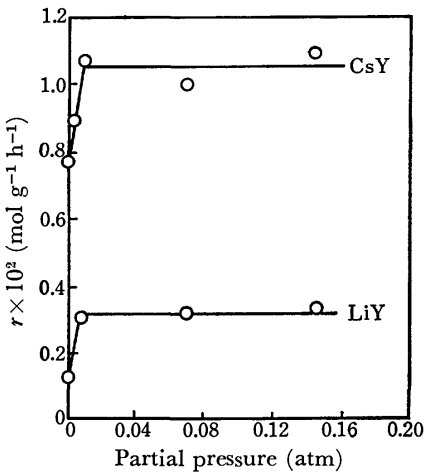

Fig. 8. Effect of pyridine partial pressure on the reaction rate.
CsY, 300 °C, W/F=3.14 g h mol^{-1}, P_H=0.714 atm, P_L=0.143 atm.

has been postulated for the base catalyzed butadiene formation from ethanol over SiO–MgO (75:25) catalyst.[8] Flockhart *et al.* found that the striking increase in reducing power of the decationated zeolites is caused by the addition of electron donors and suggested the existence of a strong interaction between electropositive and electronegative $(AlO_4)^-$ sites.[9]

Catalysis by Silica-Magnesia. Niyama *et al.*[8,10] determined the acidity and basicity of SiO_2–MgO catalysts of various compositions, and found that the basicity per unit area increases with increase in MgO content, the acidity per unit area having maximum at MgO/SiO_2=1. The ring transformation of γ-butyrolactone into γ-thiobutyrolactone was carried out with SiO_2–MgO catalysts. The results are summarized in Table 4. The rate per unit area increases with increasing MgO content. This indicates also that the basic sites, rather than acid sites, are responsible for the ring conversion.

Table 4. Ring conversion of γ-butyrolactone to γ-thiobutyrolactone over SiO_2–MgO catalysts

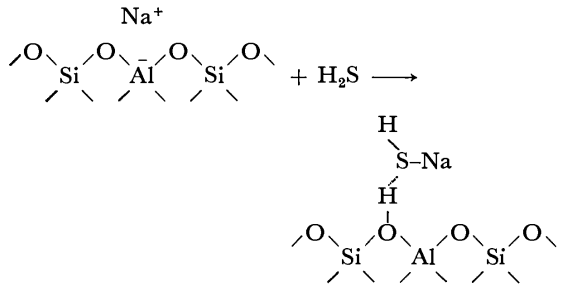
Catalyst	Yield (%)	Surface area (m^2 g^{-1})	Rate (mol m^{-2} h^{-1})
SiO_2	1	180	1.3
SiO_2–MgO (3:1)	5	170	6.7
SiO_2–MgO (1:1)	7	150	11
SiO_2–MgO (1:3)	10	130	18
MgO	3	23	30

Reaction conditions; 330 °C, H_2S/lactone=6, W/F= 6.16 g h mol^{-1}.

Nature of Basic Sites. All the results suggest that the active centers are basic in nature. A possible candidate for the basic sites in zeolites are oxygen anions bound to aluminum cations $(AlO_4)^-$. A negative charge at the site is neutralized and shielded by an alkaline cation. However, our results suggest that the reactant molecules are accessible to and are adsorbed on the basic oxygen anions at reaction conditions. A recent infrared study by Karge and Raskò[11] has shown

that hydrogen sulfide is dissociatively adsorbed on Na form of faujasite-like zeolites. They suggest that the adsorption sites are cationic sites of low coordination, where the Na^+ cations are weakly bound. The higher the Si/Al ratio, the smaller the population of such sites. This explains why hydrogen sulfide dissociates quite easily over NaX, but not over NaY.[11] Our result showing that NaX has higher catalytic activity for the ring transformation than NaY appears to support the idea. The order of reactivity among Y-zeolites (LiY< NaY<KY<RbY<CsY) may be associated with the ionic radius of the cations. The larger cations are bound more weakly to the basic sites, which, in turn, are more readily attacked by foreign molecules. The observed activation energy values can be understood on this basis. Thus, the activation energy for CsY is much smaller than that for NaY and LiY, which implies that the reactant molecules are more easily activated by the former catalyst.

Mechanism of the Reaction. The above discussion indicates that the active center involves the basic $(AlO_4)^-$ tetrahedron. Thus, hydrogen sulfide may be activated by the following scheme.



Karge and Raskò[11] showed that hydrogen sulfide dissociates on NaX. They found no evidence of the dissociation of hydrogen sulfide on NaY. It is very plausible, however, that H_2S molecules dissociate at reaction conditions (≈300 °C) on NaY.

γ-Butyrolactone molecules have an easily polarizable carbonyl group and can be activated by the electrostatic field exerted by a Na^+ cation and/or a $(AlO_4)^-$ unit. The reaction may proceed through the reaction between adsorbed hydrogen sulfide and adsorbed γ-butyrolactone, which may compete for the adsorption sites made up of the combination of Na^+-$(AlO_4)^-$ unit.[12] This explains the observed Langmuir-Hinshelwood type kinetics where the adsorption of γ-butyrolactone is much easier than that of hydrogen sulfide ($a_L<a_H$).

The authors are very grateful to Prof. Tominaga Keii for many fruitful discussions.

Conductivities of the Methyl Orange-Dodecyltrimethylammonium Complex in Dioxane-Water Mixtures

Masaru MITSUISHI, Yuzoh YAMAGUCHI, and Naoko ISHII

Faculty of Textile Science and Technology, Shinshu University, Tokida, Ueda 386

(Received August 16, 1977)

The ionic-association reaction of the complex between the Methyl Organic anion and the dodecyltrimethylammonium cation in dioxane–water mixtures has been studied by analyzing the conductivity data. The equivalent conductivities at an infinite dilution and the ionic association constants (K_A) have been determined by means of Shedlovsky's treatment, and they have been compared with those of Methyl Orange (sodium salt). The K_A values have been seen to increase with a rise in the temperature and with an increase in the dioxane content. The Walden products have been essentially constant, and they have been found to be comparable to those of Methyl Orange (sodium salt). The data have been analyzed further by the use of the Denison-Ramsey equation, and the ion-ion distance in an associate has been obtained. The ionic-association reaction have been found to increase the heat content and also the entropy.

In a previous paper,[1] we have concluded, on the basis of the conductivity data, that the sodium salt of an anionic dye such as the sodium salt of 1,5-dihydroxy-4,8-diaminoanthraquinone-2-sulfonic acid exists in the form of an ionic associate in dioxane–water mixtures.

Recently, the formation of a complex between large organic ions of opposite charges in water has been found to be explainable in terms of a twofold interaction mechanism, *i.e.*, Coulombic and hydrophobic interactions.[2,3]

Since there have been few reports on the ionic-association reaction of large organic anions with large organic cations in organic solvent–water mixtures with low dielectric constants, it seems that it would be valuable to examine the conductivity behavior of complexes between large organic ions of opposite charges, such as the Methyl Orange–dodecyltrimethylammonium complex in dioxane–water mixtures, and to compare the ionic-association reaction of the complex with that of Methyl Orange (sodium salt).

In this paper, the conductivity data on this kind of ionic complex were used to determine the equivalent conductivity at an infinite dilution and the ionic association constant by means of Shedlovsky's treatment[4] based on Onsager's theory,[5] and the behavior of the complex in the mixtures was considered.

Experimental

Materials. The Methyl Orange (sodium salt) was prepared by coupling diazotized sulfanilic acid with *N,N*-dimethylaniline in a weakly acetic acid solution, after which the product was recrystallized three times from water.

The dodecyltrimethylammonium bromide was prepared by boiling a mixture of trimethylamine and dodecyl bromide in ethanol for several hours. The product was recrystallized from acetone and benzene after the ethanol has been removed by distillation.

The Methyl Orange–dodecyltrimethylammonium complex (M–D complex) was prepared as follows: 1 dm^3 of 10^{-3} mol/dm^3 Methyl Orange (sodium salt) was added to the same volume of a 10^{-3} mol/dm^3 dodecyltrimethylammonium bromide aqueous solution. The finely dispersed M–D complex was then separated by centrifugation from the solution. The M–D complex was purified by recrystallizing from ethanol. Microelemental analysis gave the following results. Found: C, 64.87; H, 8.93; N, 10.61%. Calcd for $C_{29}H_{48}N_4SO_3$ (1:1 M–D complex): C, 65.41; H, 9.02; N, 10.53%.

The dioxane used in this experiment was purified by the method described in a previous work.[1]

Conductivity Measurements. These measurements were carried out at 15, 25, 35, and 45±0.01 °C using the same apparatus and the same procedures as those described in a previous work.[1]

Results and Discussion

The equivalent conductivities, Λ, of the M–D complex in dioxane–water mixtures at 25 °C are plotted against the square root of the concentration, $C^{1/2}$, as shown in Fig. 1.[6] The Λ values in 45 and 70% dioxane are seen to become larger almost linearly with an increase in the dilution. In 82% dioxane, the Λ value decreases monotonically with an increase in the complex concentration. The dotted lines in Fig. 1 give the limiting slopes of the Onsager equation.[5] The slopes of the experimental curves of the Λ-$C^{1/2}$ plot are seen to be larger than those of the corresponding theoretical

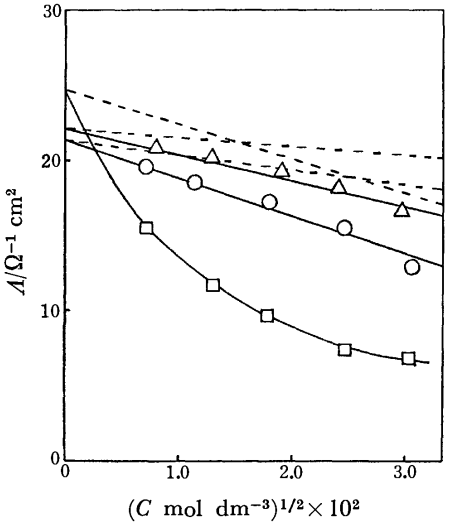

Fig. 1. Equivalent conductivities of Methyl Orange–dodecyltrimethylammonium complex in dioxane–water mixtures at 25 °C.
△: 45% dioxane, ○: 70% dioxane, □: 82% dioxane.

Table 1. Constants for sodium Methyl Orange and Methyl Orange–dodecyltrimethylammonium complexes in dioxane–water mixtures

Solutes	Solvents	t/°C	Λ_0	$\Lambda_0\eta$	K_A
Sodium Methyl Orange	82% dioxane	15	19.97	0.420	6.98×10^3
		25	25.92	0.433	8.97
		35	30.13	0.409	1.05×10^4
M–D Complex	45% dioxane	15	16.21	0.398	3.15×10^2
		25	22.10	0.406	3.64
		35	28.58	0.409	4.90
		45	37.18	0.425	6.31
	70% dioxane	15	15.84	0.393	8.32×10^2
		25	21.47	0.412	9.72
		35	27.30	0.416	1.05×10^3
		45	34.40	0.426	1.19
	82% dioxane	15	18.36	0.387	1.70×10^4
		25	24.72	0.413	1.91
		35	30.73	0.417	2.01
		45	36.14	0.404	2.51

lines. These results suggest that the ionic-association reaction between the Methyl Orange anion and the dodecyltrimethylammonium cation takes place in the mixtures. Similar plots were also obtained at 15, 35, and 45 °C.

From the results of the conductivity measurements, the equivalent conductivities at an infinite dilution, Λ_0, and the ionic-association constants, K_A, were obtained by means of Shedlovsky's treatment,[4] based on Onsager's limiting equation,[5] in a manner similar to that described in the previous work[1] and the results are shown in Table 1. From Table 1 the K_A values of Methyl Orange (sodium salt) and the M–D complex are seen to increase with a rise in the temperature of the solvents at a constant solvent composition, and they also increase with the dioxane content, *i.e.*, with a lowering in the dielectric constant of the solvents. The K_A values of the M–D complex are much larger than those of Methyl Orange (sodium salt) in 82% dioxane. This suggests that the dodecyltrimethylammonium ion contributes strongly to the formation of the ionic associate with the Methyl Orange.

The Walden products,[7] $\Lambda_0\eta$, of the Methyl Orange (sodium salt) and the M–D complex are also shown in Table 1. Their $\Lambda_0\eta$ values are essentially constant. This can be explained most simply by assuming that the ions in the mixtures are selectively hydrated over the entire solvent composition range studied, *i.e.*, the dioxane molecules are excluded from the first coordination sphere of the ions.[8,9] The evidence that the Walden products of the Methyl Orange (sodium salt) in 82% dioxane are almost equal to those of the M–D complex may suggest also that the Stokes's radii of the sodium and dodecyltrimethylammonium ions are equal to each other.

In an attempt to analyze the data further, the relation of K_A to $1/DT$[10] was examined by means of the Denison-Ramsey equation[11] as a first approximation,

$$K_A = \exp(e^2/aDkT). \quad (1)$$

Here, e is the electron charge, a is the center-to-center distance of the ions in an associate, and k is the Boltzmann constant.

According to Eq. 1, the plot of K_A *vs.* $1/DT$ must be linear. As an example, the plot of log K_A *vs.* $1/DT$ for the M–D complex in 82% dioxane is shown in Fig. 2. This plot gives a straight line. From the slope, the a value is obtained. The a values of Methyl Orange (sodium salt) and the M–D complex in the mixtures are shown in Table 2. All the a values are seen to be reasonable except for the one in 45% dioxane, and they are comparable to those of some of the organic and inorganic electrolytes in organic solvent–water mixtures.[1,12–15]

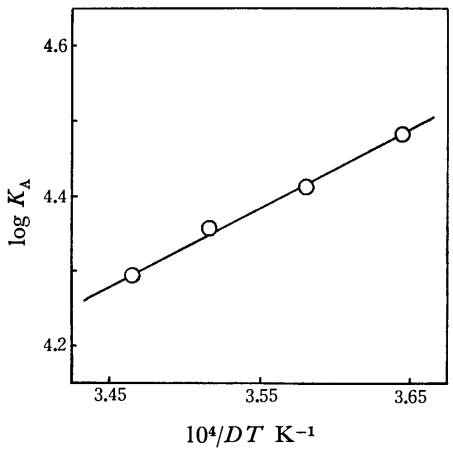

Fig. 2. The relation betweem log K_A and $1/DT$ in 82% dioxane.

The enthalpy changes ($\Delta H°$) and entropy changes ($\Delta S°$) in the ionic-association reactions can be obtained in the usual way; they are also shown in Table 2. Since the $\Delta H°$ values are positive, the reactions are endothermic. The $\Delta H°$ values are comparable to those for the ionic-association reactions of several organic

Table 2. Thermodynamic parameters of ionic-association reactions at 25 °C and center-to-center distance of ions in an associate

Solute	Solvents	K_A	$\Delta H°$ kcal[a] mol^{-1}	$\Delta G°$ kcal mol^{-1}	$\Delta S°$ cal K^{-1} mol	a Å[b]
Sodium Methyl Orange	82% dioxane	8.94×10^3	0.17	−5.39	19	5.0
M–D Complex	45% dioxane	3.64×10^2	6.10	−3.50	32	1.4
	70% dioxane	9.72×10^2	2.05	−4.08	21	6.8

salts in water and some of the anionic dyes in dioxane–water mixtures.[1)]

The $\Delta S°$ values for the reactions are also positive. The results can be considered to reflect the fact that the degree of freedom of the system increases, since the solvent molecules are removed from the solvation sphere of the ions when the ionic-association reaction takes place. The $\Delta S°$ values are comparable to those for the reaction of the sodium salt of an acid dye in dioxane–water mixtures, and those for some of the thallium and the calcium salts in water.[16,17)]

Adsorption of 1,2-Propanediol and Methyl Cellosolve at Mercury–0.10 m KCl aq Interface at 25 °C

M. V. RAMANAMURTI and B. V. APPARAO

Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi 221005, India

(Received April 30, 1977)

Adsorption of 1,2-propanediol and methyl cellosolve (isomeric compounds) at Hg–0.10 m KCl (aq) solution interface evaluated through equilibrium double layer capacity measurements indicated congruency of adsorption isotherms with respect to both potential (E) and charge density (σ^M); applicability of Langmuir's adsorption isotherm; quadratic dependence of $\Delta\bar{G}^\circ$ on E and single stable orientation with the hydrocarbon chain facing the electrode and functional group in solution throughout the coverage region, for both the compounds. Surface excess, standard free energy of adsorption and the anodic shift of E_{pzc}, are greater while the charge corresponding to maximum adsorption is more negative, for methyl cellosolve than for the diol.

The differences in the adsorption behaviour of some aromatic isomeric compounds[1] at the mercury-solution interface were attributed to differences in dipole moment and intramolecular hydrogen bonding. However, such studies are scanty in the literature.

Diols have been shown to behave in a different way[2,3] from monohydric alcohols at the mercury-aq solution interface. Adsorption of glycol has been thoroughly studied by electrocapillary[3] and differential capacity measurements.[4] 1,2-Propanediol (methyl glycol) and 2-methoxy ethanol (glycol monomethyl ether also known as methyl cellosolve) are two isomeric compounds with dipole moments 2.25 and 2.04 respectively, the hydrogen bonding of the former with water molecules being relatively higher. The present communication describes their adsorption behaviour at Hg–0.10 m KCl (aq) solution interface through equilibrium double layer capacity measurements.

Experimental

Differential capacities were measured by Grahame's a.c. bridge method[5,6] using a dropping mercury electrode. A variable signal generator (Marconi TF 1370) facilitated variation of a.c. frequency from 200 to 10000 Hz. Observed frequency independent capacity data with Hg–0.10 m KCl aq agreed with Grahame's data.[6] In the presence of the adsorbates, the capacity was frequency dependent and the data reported in this paper are equilibrium double layer capacities (extrapolated zero frequency values). Mercury drops knocked off periodically at a prefixed interval by a locally made electromagnetic drop detacher were perfectly spherical at the instant of bridge balance. Interval of two successive knocks of the detacher was measured accurate to 0.005 s. The bridge was balanced at the instant of the detachment of the drop from the capillary tip. The bridge output signal amplified by a multistage transistor preamplifier (Marconi TM 6591A) was displayed on a Dumont oscillograph (type 274). A large mercury pool electrode and 1 M KCl calomel electrode (NCE) were used as the auxiliary and reference electrodes respectively. The potential between the test electrode and the reference electrode was measured on a portable potentiometer (Pye-Cambridge; accuracy one mV). Differential capacities were measured in the potential range -0.10 to -1.80 V *vs.* NCE. The measurements were carried out in an air thermostat controlled at 25 ± 0.1 °C.

Mercury was purified following Trasatti's method.[3] KCl (BDH-AnalaR) twice recrystallized from conductivity water was used. Methyl cellosolve (Riedel) was treated with lithium hydride until the evolution of hydrogen gas ceased and then distilled twice. 1,2-Propanediol (BDH-AnalaR) was twice distilled under reduced pressure and the middle cut was collected. Solutions at required molalities of the adsorbates in 0.10 m KCl (aq) were deoxygenated with purified and presaturated nitrogen before carrying out the experiments.

The differential capacitance measured was independent of the drop time even at the desorption peaks indicating universal attainment of adsorption equilibrium.

Results and Discussion

The differential capacity-potential curves for both 1,2-propanediol (Fig. 1) and methyl cellosolve (Fig. 2) follow the same shape typical for an aliphatic organic compound. The capacity curves for methyl cellosolve exhibit small cathodic and anodic desorption peaks whereas these peaks are totally absent in the curves for 1,2-propanediol; there is only a characteristic cross-over of the curves at extreme cathodic and anodic polarizations. With the increase in concentration of

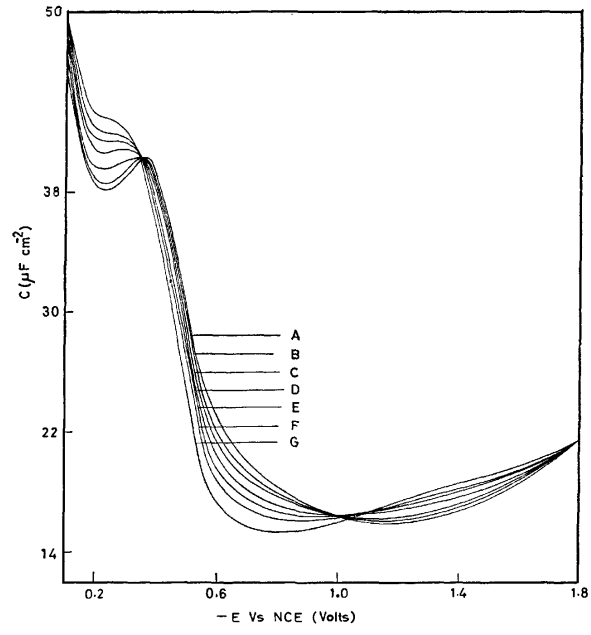

Fig. 1. Differential capacity-potential curves for Hg in 0.10 m KCl solution containing 1,2-propanediol at concentrations: (A) 0, (B) 0.05, (C) 0.10, (D) 0.20, (E) 0.30, (F) 0.40, (G) 0.60 m.

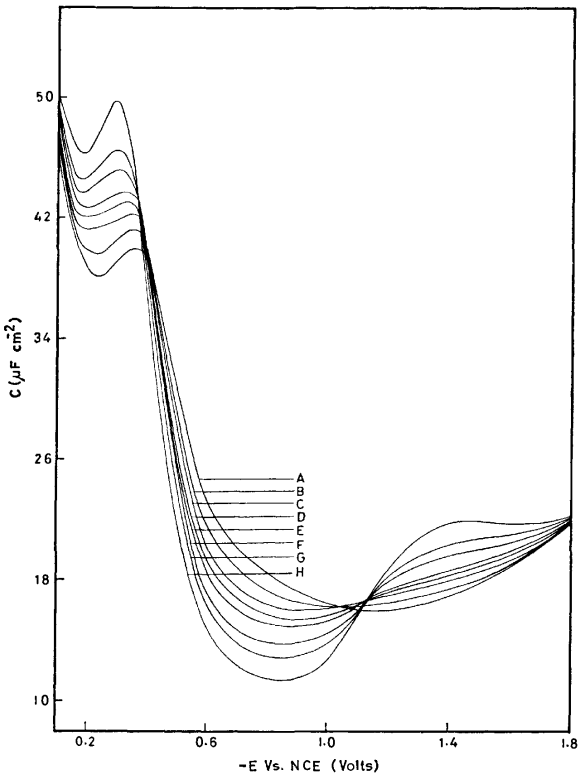

Fig. 2. Differential capacity-potential curves for Hg in 0.10 m KCl solution containing methyl cellosolve at concentrations: (A) 0, (B) 0.05, (C) 0.10, (D) 0.15, (E) 0.20, (F) 0.30, (G) 0.40, (H) 0.60 m.

methyl cellosolve, the cathodic desorption peak shifts towards more cathodic potentials and the anodic peak, towards more anodic potentials.

Evaluation of σ^M *and* Γ_A. Charge density on the electrode surface (σ^M) has been computed according to the equation:

$$\sigma^M = \int C dE + K_1, \qquad (1)$$

and surface excess of the organic adsorbate (Γ_A), with the help of the equation:

$$\Gamma_A = \frac{1}{2.303RT}\left(\frac{\partial \sigma^M}{\partial \log c}\right)_E dE + K_2, \qquad (2)$$

where R and T have their usual thermodynamic meaning.

Both the integrations have been performed numerically at the intervals of 10 mV starting at extreme cathodic potential *viz.*, −1.8 V *vs.* NCE at which the capacity curves at all concentrations of the adsorbates coincided with the corresponding one of the base electrolyte. K_1 was the charge density on the electrode in pure base electrolyte solution (K_2 being equal to zero) at −1.8 V. The differential term in Eq. 2 is obtained from σ^M *vs.* log c plots; these adsorbates are knwon to behave ideally especially in the concentration range studied and hence the activity is replaced by concentration.

Surface Excess of the Organic Adsorbates. The surface excess-potential curves (*cf.* Fig. 3) show complete desorption of both the compounds at extreme cathodic polarizations; desorption is, however, incomplete at

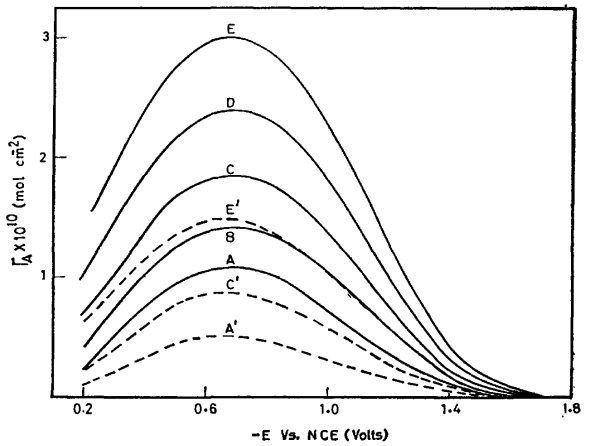

Fig. 3. Surface excess of the adsorbate as a function of electrode potential. (A) 0.10, (B) 0.15, (C) 0.20, (D) 0.30, (E) 0.40 m methyl cellosolve. (A′) 0.10, (C′) 0.20, (E′) 0.40 m 1,2-propanediol.

anodic polarizations in the potential range studied. At a given bulk concentration and potential, the surface excess of methyl cellosolve is found to be more than that of 1,2-propanediol.

Linear plots observed in the variation of (i) electrode charge *vs.* surface excess at constant potential and (ii) electrode potential *vs.* surface excess at constant charge suggest that the adsorption isotherms for both the compounds are congruent with respect to both electrode potential and charge.[7,8] Such plots for methyl cellosolve are shown in Figs. 4a and 4b.

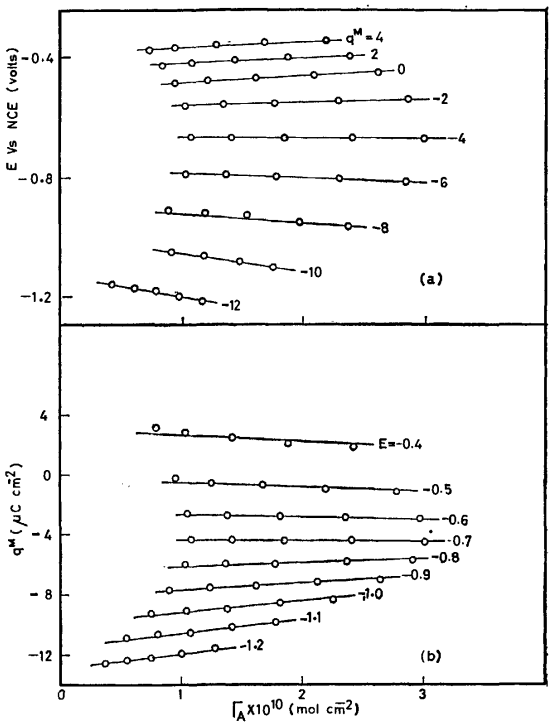

Fig. 4. (a) Electrode potential as a function of surface excess of methyl cellosolve at constant charge. Charge (μC cm^{-2}) indicated on each line.
(b) Electrode charge as a function of surface excess of methyl cellosolve at constant potential. Potential (V *vs.* NCE) indicated on each line.

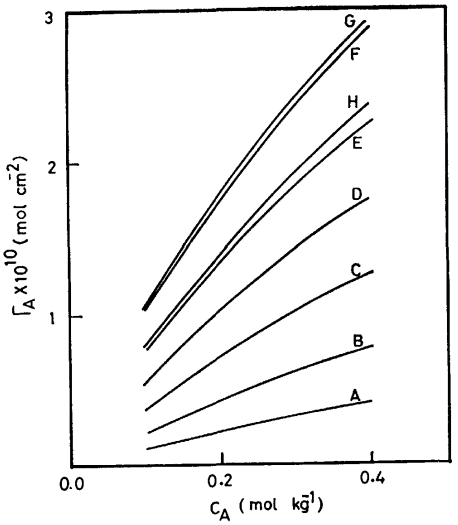

Fig. 5. Surface excess as a function of bulk concentration of methyl cellosolve at constant potential. (A) $E=-1.4$, (B) -1.3, (C) -1.2, (D) -1.1, (E) -1.0, (F) -0.8, (G) -0.6, (H) -0.4 V *vs.* NCE.

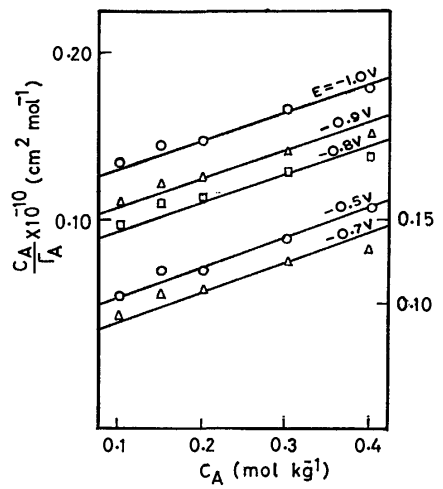

Fig. 6. Test for Langmuir's isotherm for methyl cellosolve at various potentials. Potential (V *vs.* NCE) indicated on each line.

The plots of surface excess *vs.* bulk concentration at constant electrode potential for both the compounds do not yield saturation value of surface excess (Γ_S) within the concentration range studied (*cf.* Fig. 5 for methyl cellosolve). The value of Γ_S is therefore obtained by an indirect method as given below. The plots of c_A/Γ_S *vs.* c_A at constant E are linear and parallel for both the compounds showing thereby that their adsorption behaviour obeys Langmuir's adsorption isotherm with a slope equivalent to $1/\Gamma_S$. These plots for methyl cellosolve are shown in Fig. 6. The values of Γ_S thus obtained are 5.00 and 5.26 for 1,2-propanediol and methyl cellosolve respectively.

Standard Free Energy of Adsorption. The standard free energy of adsorption ($\Delta\bar{G}^\circ$) has been calculated according to the equation given by Conway and Barradas[9] when the adsorption isotherm is of Langmuir's type.

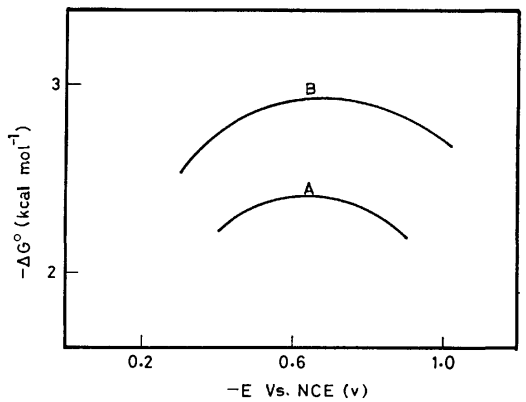

Fig. 7. Standard free energy of adsorption ($\Delta\bar{G}^\circ$) as a function of electrode potential (E). (A) 1,2-propanediol, (B) methyl cellosolve.

$$\ln\left(\frac{55.5}{c_A}\cdot\frac{\theta}{1-\theta}\right)=\frac{-\Delta\bar{G}^\circ}{RT}. \qquad (3)$$

The values of $\Delta\bar{G}^\circ$ have been obtained at constant coverage, $\theta=0.3$ ($\theta=\Gamma_A/\Gamma_S$) and at various electrode potentials. The dependence of $\Delta\bar{G}^\circ$ on E (*cf.* Fig. 7) is found to be quadratic for both the compounds as expected for simple neutral organic substances. The magnitude of $\Delta\bar{G}^\circ$ at any potential is higher for cellosolve than for diol. This can be attributed to the relatively weaker hydrogen bonding of cellosolve molecules with water molecules than that of diol.

E_{pzc} vs. log c_A and θ. Anodic shift of E_{pzc} with the increase in concentration of both the adsorbates

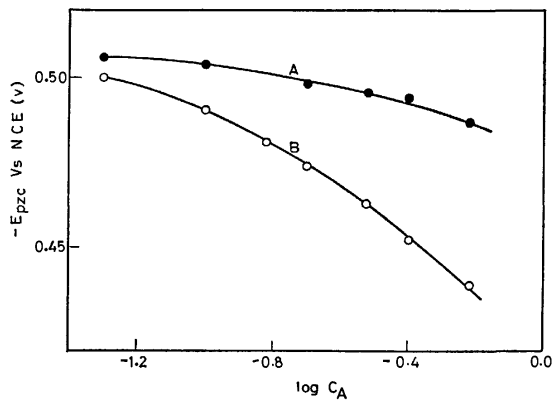

Fig. 8. E_{pzc} as a function of log c_A of the adsorbates. (A) 1,2-propanediol, (B) methyl cellosolve.

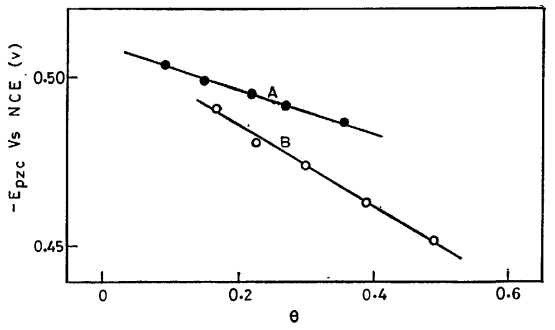

Fig. 9. E_{pzc} as a function of surface coverage of the adsorbates. (A) 1,2-propanediol, (B) methyl cellosolve.

indicates their orientation with the positive end towards the electrode and functional group in solution (*cf.* Fig. 8). Linear shift of E_{pzc} with surface coverage (θ) of the adsorbates (*cf.* Fig. 9) suggests single and stable orientation[10] throughout the coverage region. The magnitude of $(\partial E_{pzc}/\partial\theta)_{\theta\to 0}$ which accounts for the contribution due to normal components of the permanent organic dipoles[11] is greater for methyl cellosolve than for 1,2-propanediol. For equivalent concentrations, the magnitude of ΔE_{pzc} is more for cellosolve than for diol. This can be explained on the basis of (i) the normal component of the cellosolve dipoles being higher than that of diol dipoles and (ii) more number of negatively oriented water dipoles being replaced, due to relatively stronger adsorption of cellosolve dipoles than diol dipoles.

The electrode charge corresponding to maximum adsorption (σ^{M}_{max}) is $-3.2\ \mu C\ cm^{-2}$ for 1,2-propanediol and $-4.2\ \mu C\ cm^{-2}$ for methyl cellosolve. Damaskin and Frumkin[12] have expressed σ^{M}_{max} as

$$\sigma^{M}_{max} = -\left(\frac{\partial E_{pzc}}{\partial\theta}\right)_{\theta\to 0}\left(\frac{C_0^2}{C_0-C_1}\right). \quad (4)$$

The first term on the right hand side accounts for the contribution due to permanent dipoles and the second term, due to induced dipoles where C_0 and C_1 are the capacities at $\theta=0$ and $\theta=1$ respectively. It appears that the contribution due to permanent dipoles (Methyl cellosolve>1,2-propanediol) controls the value of σ^{M}_{max} in these two compounds and hence more negative σ^{M}_{max} for methyl cellosolve.

The authors are grateful to the Head of the Department of Chemistry, Banaras Hindu University for providing the necessary facilities and to the UGC, New Delhi, for the financial assistance to one of them (BVA).

Oxidation of Azide by Peroxodisulfate in Aqueous Medium

V. PONNURAJ, M. S. RAMACHANDRAN, T. S. VIVEKANANDAM, and U. CHANDRA SINGH
School of Chemistry, Madurai University, Madurai 652021, India

(Received May 11, 1977)

Results on the oxidation of N_3^- by peroxodisulfate in neutral and acid media are presented. The rate of the reaction is found to be proportional to $[N_3^-]$ and $[S_2O_8^{2-}]$directly. The product of oxidation is found to be pure nitrogen. The stoichiometry of the reaction is

$$S_2O_8^{2-} + 2N_3^- = 2SO_4^{2-} + 3N_2.$$

The reaction shows positive salt effect. Thermodynamic activation parameters ΔH^* and ΔS^* have been calculated for this reaction. It is observed that H^+ ion inhibits the reaction. The mechanism is discussed in terms of the kinetic results.

Peroxodisulfate ion is a powerful two-electron oxidizing agent with a redox potential of −2.01 eV. Oxidations of both inorganic and organic substrates were reviewed by House,[1] by Wilmarth and Haim[2] and recently by Wilson[3] and by Buist.[4] The oxidations of hydroxylamine[5] and hydrazine[6] were studied by Gupta *et al.* and they reported a multi-electron-transfer from the substrate to $S_2O_8^{2-}$. The chemistry of azide has gained impetus in recent years[7,8] because of the powerful complexing properties of this ion. From a survey of the literature it appears that the oxidation of this ion by $S_2O_8^{2-}$ has not been reported so far. The reactions of this ion with triiodide ion[9,10] and carbon disulfide[11] have been studied. The present paper reports the kinetic study of the oxidation of this ion with peroxodisulfate in neutral and acid medium.

The oxidation-reduction stoichiometry of the azide-peroxodisulfate reaction in neutral medium was determined by mixing various non-stoichiometric amounts of the reactants and measuring the amount of the reactant in excess at the completion of the reaction. The results show that the redox stoichiometry of the reaction is accurately represented by

$$S_2O_8^{2-} + 2N_3^- = 2SO_4^{2-} + 3N_2. \quad (1)$$

The product of oxidation was found to be pure nitrogen by gas chromatographic analysis in accordance with the above equation.

Experimental

Potassium peroxodisulfate (E. Merck, GR) was used without further purification. The stock solution was prepared daily and was analyzed quantitatively by cerimetry. Sodium azide (E. Merck, Germany) solution was prepared daily and was estimated by iodometry.[12] Water, deionized by passing through ion exchange resin (Permutit Mark-8) was distilled twice from alkaline permanganate in Corning glass apparatus and was stored in a stoppered polythene bottle. All solutions were prepared using this water.

Because of the high reactivity of azide ion, chemical method was not used to follow the reaction. The rate was followed by measureing the amount of gases produced from the system. The apparatus consisted of a 100 ml flask with ground glass joints. The flask was connected to a horizontal capillary tube of uniform bore of about 120 cm length, with inner diameter of ≈1.5 mm, having a mercury thread. A meter scale was attached to the tube and from the movements of the mercury thread the rate was measured.

The solution containing requisite amount of sodium perchlorate, peroxodisulfate was thermostated in the reaction vessel and was saturated with pure N_2 gas. The azide solution was thermostated separately and after the attainment of thermal equilibrium requisite amount of N_3^- solution was pipetted into the reaction vessel. The total volume of the reaction mixture was 50 ml. Powdered glass were added to avoid supersaturation. When the evolution of gas became steady, the rate was measured. It was observed that the steady state was attained within 5—10 minutes. The method was quite sensitive and the rate constant could be reproduced within 2—3%.

Results and Discussion

The plot of time *vs.* scale reading was perfectly linear (Fig. 1) and from the slope the rate dv/dt ($cm^3\ s^{-1}\ l^{-1}$) was calculated by taking the volume of the tube per cm.

N_3^- Dependence. The effect of N_3^- on rate was studied over a tenfold range of initial N_3^- concentration. The plot of log (dv/dt) *vs.* log $[N_3^-]$ shows that the rate is first order in N_3^- concentration in this range (Fig. 2).

$S_2O_8^{2-}$ Dependence. The concentration of peroxodisulfate was varied from 0.02 to 0.16 M. The plot of log (dv/dt) *vs.* log $[S_2O_8^{2-}]$ yields a slope of ≈1.0

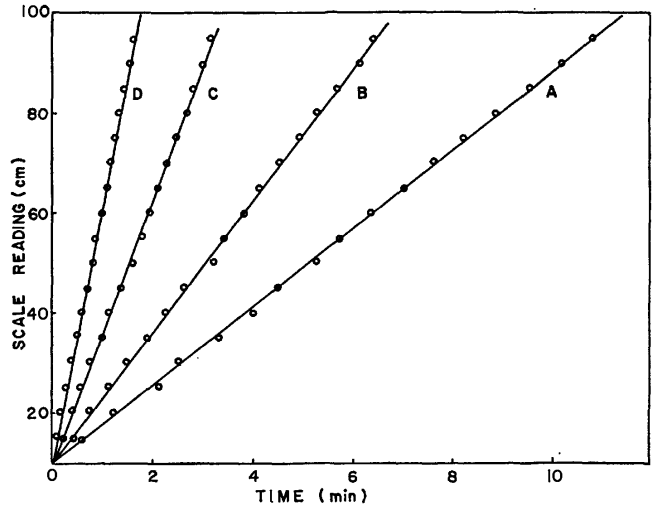

Fig. 1. The scale reading as a function of time under various initial $[N_3^-]$.
$[S_2O_8^{2-}]_0 = 0.04$ M; $\mu = 0.92$ $t = 45.0$ °C; A: 0.06 M, B: 0.10 M, C: 0.20 M, D: 0.40 M.

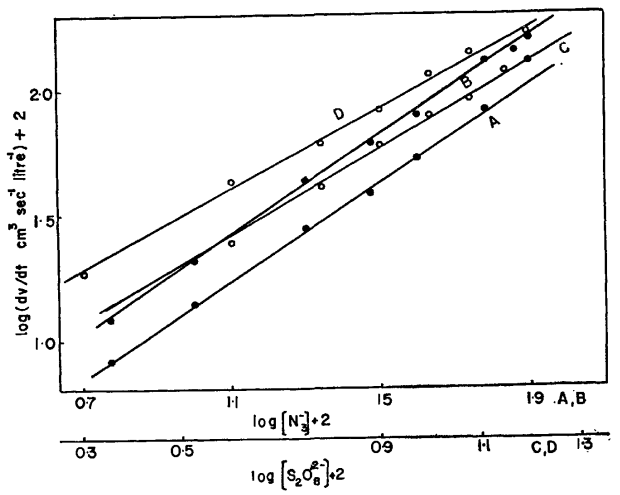

Fig. 2. Dependence of $[N_3^-]$ and $[S_2O_8^{2-}]$ on rate of the reaction.
A, B: N_3^- dependence, A: $[S_2O_8^{2-}]_0=0.04$ M; $\mu=0.92$; $t=45.0$ °C; Slope=1.0. B: $[S_2O_8^{2-}]_0=0.04$ M; $\mu=0.92$, $t=50.0$ °C; Slope=1.0. C, D: $[S_2O_8^{2-}]$ dependence. C: $[N_3^-]_0=0.20$ M; $\mu=0.72$; $t=45.0$ °C, Slope=1.15. D: $[N_3^-]_0=0.20$ M $\mu=0.92$, $t=50$ °C, Slope=1.08.

showing the first order dependence of $S_2O_8^{2-}$ (Fig. 2).

Hydrogen ion Dependence. The rate was found to decrease linearly with the addition of H^+ and almost reached to zero when the concentration of H^+ added was equal to $[N_3^-]_0$ (Fig. 3).

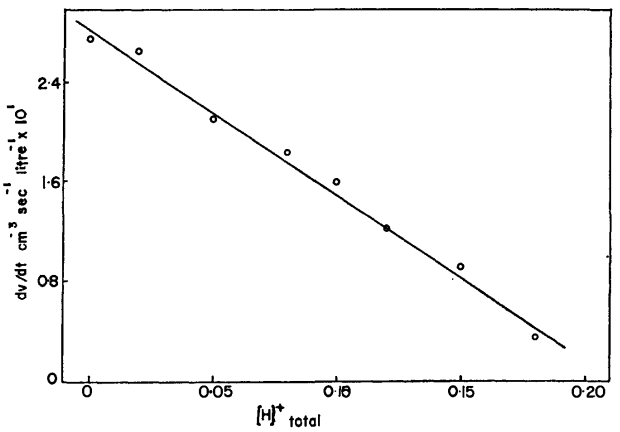

Fig. 3. Effect of H^+ on rate of the reaction. $[S_2O_8^{2-}]_0=0.04$ M; $[N_3^-]_0=0.20$ M. $\mu=0.92$; $t=45.0$ °C.

Evaluation of the Rate Constant. From the first order dependence of N_3^- and $S_2O_8^{2-}$ on rate and the stoichiometry of the reaction, the rate law could be written as

$$\frac{d[N_2]}{dt} = 3k_1[N_3^-][S_2O_8^{2-}]. \quad (2)$$

Applying the gas law Eq. 2 is modified as

$$(dv/dt)\times P/3RT = k_1[N_3^-][S_2O_8^{2-}]. \quad (3)$$

Taking $P\approx 1$ atm, $T=(300\pm0.5)$ K and the initial concentrations of N_3^- and $S_2O_8^{2-}$ the absolute rate constant k_1 was calculated.

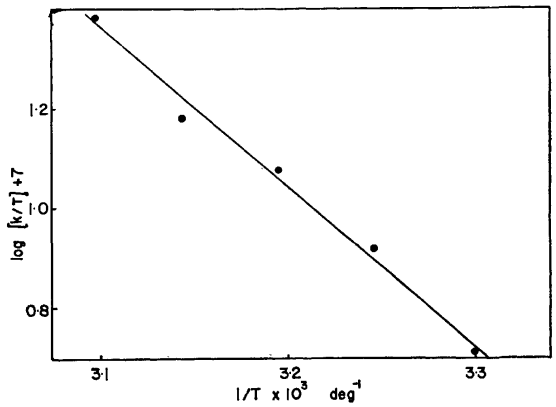

Fig. 4. Temperature dependence of k_1 between 30 and 50 °C.

Temperature Dependence. The kinetic study was made at the temperature range of 30—50°C. The plot of $\log(k/T)$ *vs.* $1/T$ was linear from which thermodynamic activation parameters were computed (Fig. 4). The values are $\Delta H^*=15.0$ kcal M^{-1} and $\Delta S^*=-25$ e.u.

Other Dependence. The rate increased with the increase in the ionic strength of the medium (Table 1). The reaction was not affected by the presence of Cu(II), Co(II), Mn(II), and Fe(III) (Table 1).

We suggest the following mechanism for the reaction in the light of the experimental results.

$$S_2O_8^{2-} + N_3^- \xrightarrow{k_1} N_3 + SO_4^{2-} + SO_4^{\cdot-} \quad (4)$$

Table 1. Rate constant of reaction of peroxodisulfate and azide ions under various conditions

a) $[Mn^{2+}]\times10^3$M. b) $[Fe^{3+}]\times10^5$M.

$$SO_4^{\cdot-} + N_3^- \longrightarrow N_3 + SO_4^{2-} \quad (5)$$

$$N_3 + N_3 \longrightarrow 3N_2 \quad (6)$$

The rate determining step is the one-electron transfer from N_3^- to $S_2O_8^{2-}$ followed by the fast consumption of SO_4^{2-} by N_3^- to form the transient species N_3 which subsequently decompose into molecular nitrogen. The reaction (6) is indeed shown[13] to be very fast ($k = 1.3\times10^{10}\ M^{-1}\ s^{-1}$). The positive salt effect and the highly negative values of ΔS^* lend support for the above mechanism. It can be shown[14] that for a bimolecular reaction between two charged species with charges Z_A and Z_B, ΔS^* would be approximately equal to $-10Z_AZ_B$. The agreement between the calculated value ($\Delta S^* \approx -20$ e.u.) and the experimental value in this investigation is reasonably good. Further, during the course of the reaction the change in the acid concentration is negligible in accordance with the above mechanism (Table 2).

TABLE 2. PRODUCTION OF ACID DURING THE REACTION
$\mu=0.72$, $t=45.0$ °C.

$[S_2O_8^{2-}]_0$	$[N_3^-]_0$	pH	
		Initial	Final
0.04	0.10	7.90	8.20
0.04	0.20	8.00	8.35
0.08	0.20	7.25	7.70
0.08	0.30	6.95	8.00
0.12	0.20	6.80	7.90

In acid medium the following steps may be included along with (3)—(6).

$$N_3^- + H^+ \overset{K_a}{\rightleftharpoons} HN_3 \quad (7)$$

$$HN_3 + S_2O_8^{2-} \overset{k_2}{\longrightarrow} N_3 + HSO_4^- + SO_4^{\cdot-} \quad (8)$$

$$SO_4^{\cdot-} + HN_3 \longrightarrow N_3 + HSO_4^- \quad (9)$$

Surprisingly H^+ acts as an anti-catalyst for the reaction. Hydrazoic acid is a very weak acid[15] ($K_a = 2.1\times10^{-5}$ at 20°C) with high thermal stability.[16] Assuming the complete formation of HN_3 with the addition of H^+ ($[HN_3] \approx [H^+]_t$) the rate equation is given by

$$\frac{d[N_2]}{dt} = 3(k_1[N_3^-]_0 + (k_2-k_1)[H^+]_t)[S_2O_8^{2-}], \quad (10)$$

where $[N_3^-]_0$ represents the total concentration of azide in the solution. The value of k_2 is found to be $\approx 3.0\times10^{-5}\ M^{-1}\ s^{-1}$ which may be compared with k_1 ($45.8\times10^{-5}\ M^{-1}\ s^{-1}$). The result clearly shows that H^+ stabilizes azide ion towards $S_2O_8^{2-}$.

It is a pleasure to acknowledge the kind help and encouragement of Prof. N. R. Subbaratnam, and Dr. K. Venkata Rao, School of Chemistry, Madurai University, India. One of us (M.S.R.) wishes to acknowledge C.S.I.R., India for their financial support as Junior Research Fellowship.

The Use of Solvent E_T-values in High Pressure Kinetics

Jörn von JOUANNE, Donald A. PALMER, and Hartwig KELM
Institute for Physical Chemistry, University of Frankfurt, Robert-Mayer-Strasse 11, D-6000 Frankfurt am Main, West Germany

(Received August 1, 1977)

The solvatochromic shift and its pressure dependence of the charge transfer band of 2,4,6-triphenyl-pyridinium-*N*-(3,5-diphenyl-)phenol betaine (E_T-values) have been measured together with partial molar volumes of the betaine in a number of solvents.

Despite the relative success of the Kirkwood theory, considerable effort[1] has been made to replace it by a more general description of the influence of various solvents on chemical equilibria and rate constants. Since the physical forces that govern solute-solvent interactions differ widely in strength and range it seems most unlikely that a comparatively simple theory will exceed the Kirkwood theory. An alternative is to try and replace the theoretical description by an empirical approach. Among the latter, the scale of E_T values, which was originally derived by Dimroth and coworkers[2,3] from the solvatochromic effect on the charge transfer band of 2,4,6-triphenyl-pyridinium-*N*-(3,5-diphenyl-)phenol betaine, has deserved the most interest.[4]

The present study was undertaken in order to investigate whether: 1. the effect of pressure on E_T might be a useful parameter to describe the overall variation of solvent properties with applied pressure; 2. the zwitterionic ground state of the betaine could prove to be a good model for ionic transition states as may be demonstrated by studying the solvent dependence of the partial molar volume of the betaine itself. In view of some recent publications[5–8] the limitations and the reliability of the parameters E_T, dE_T/dp and $\bar{V}$ will be critically discussed.

Experimental

The synthesis of the 2,4,6-triphenyl-pyridinium-*N*-(3,5-diphenyl-)phenol betaine was conducted according to literature procedures[2] and yielded a product with one mole of water of crystallization (formula $C_{41}H_{24}NO \cdot H_2O$, mol wt 563.71). A determination of its molecular weight in solution by the vapor pressure depression method indicated that, even at the highest concentrations (*ca.* 10^{-2} M in CH_2Cl_2), no detectable dimerization takes place. All solvents were purified according to standard procedures.

Precision density measurements of the betaine solutions were carried out using a DMA 02C instrument (Anton Paar K.G.) at 25 °C. The temperature was controlled to within ±0.001 °C and monitored by a Hewlett-Packard 280 A quartz thermometer. Spectrophotometric studies were made with a Zeiss DMR 10 instrument equipped with a high pressure attachment which is described elsewhere.[9]

Results and Discussion

Solvatochromic Shifts. The band maximum, λ_{max}, of the intramolecular charge transfer transition of the betaine shows the most remarkable solvatochromic shift so far known. The values of λ_{max} given in Table 1 agree with the results of a number of previous investigations.[2–4] As has been already discussed by Dimroth[2] and Reichardt,[4] generally the more polar the solvent, the more λ_{max} is blue-shifted. Two distinct classes of solvents have emerged: protic and aprotic.

There are many examples[7,10] in which linear free energy relationships satisfactorily hold for the solvent dependence of rate constants of reactions with polar routes and the E_T values of the pure solvents. The concept to use the E_T values of the betaine as a microprobe monitoring local polarities within a solvent might be of even more interest in mixed solvents than in pure ones. The rate constants of the Menschutkin reaction: 3,5-lutidine+ethyl iodide, have been shown to perfectly follow a $\ln k$ *vs.* E_T relationship in benzene–nitrobenzene mixtures.[7] The E_T values of two mixed systems with widely differing dielectric constants have been measured during this study: water–dioxane and methanol–dichloromethane (Fig. 1). For the system water–dioxane the shape of the $E_T(x)$ (x=mole fraction) function is very different from that of the $q(x) = (D(x)-1)/(2D(x)+1)$ parameter. Kinetic data on the hydrolysis of the 1-chloro-2-nitroethane, chlorodiphenyl-

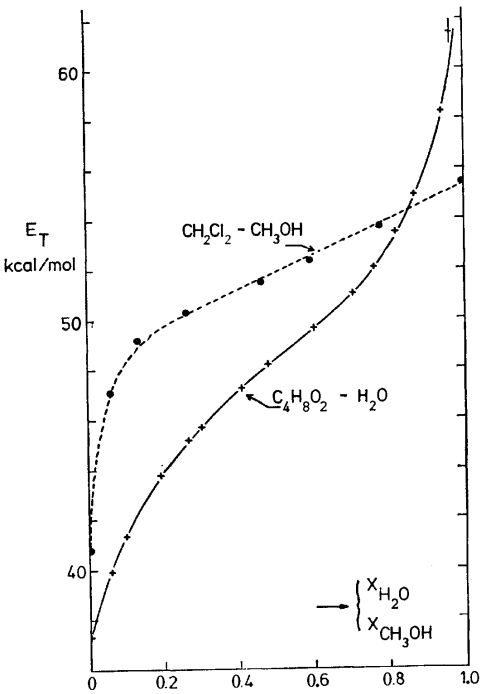

Fig. 1. Variation of solvent E_T parameters in mixed solvents.
——: Dioxane–water, ------: dichloromethane–methanol.

methane, and benzoylchloride[11] show that in water–dioxane mixtures (excluding very high and very low mole fractions) a linear dependence $\ln k \approx E_T$ is found only in the latter case. For the former reactions no preference of E_T above q can be established. In the inorganic field, data of Burgess *et al.*[12,13] show that in water–dioxane either E_T, or Y (Winstein-Grunwald parameter) or q correlate with $\ln k$. The rate constants for the isomerization of *trans*-diaquobis(oxalato)-chromate(III) anions in water–dioxane mixtures[14] closely obey a linear free energy relationship with E_T. Thus the choice of the proper parameter depends crucially on the reacting system in question.

A close inspection of the E_T values in water–dioxane mixtures reveals that E_T is influenced by several effects. The sharp decline of E_T when small amounts of dioxane are added in the water rich region ($1 > x_{H_2O} > 0.8$) is similar to the decline of the dielectric constant, but *not* of q. Thus E_T seems to be sensitive to the rupture of the water structure. The hydrophobic interactions between the phenyl substituents of the betaine and the solvent obviously play a major part in determining E_T. In the dioxane rich region ($x_{dioxane} \geqq 0.8$) the functions $q(x)$ and $E_T(x)$ are very similar. Thus lowering the ground state of the betaine by dipolar interactions is dominant when the dielectric constant of the mixture is increased by adding water. How far specific solvation interactions between the positions of very high charge density within the betaine molecule and the polar water molecules are reflected in E_T is not known. The existance of such a type of interaction can be concluded from the fact that the betaine contains water of crystallization, but is insoluble in pure water. An attempt to gain further insight into these interactions failed because the betaine has no triplet ESR spectrum which could give information about the distribution of electron density within the molecule. Furthermore, the experimental dipole moment of 12 Debye[3] does not agree with a simple $N^+—O^-$ dipole. However, the existence of some preferential solvation by the polar component of a mixture is also evident from the E_T values in dichloromethane–methanol mixtures. Minor amounts of methanol in dichloromethane drastically increase E_T as is shown in Fig. 1.

TABLE 1. ABSORPTION MAXIMUM OF CHARGE TRANSFER BAND, λ_{max}, BLUE-SHIFT OF λ_{max} UNDER PRESSURE AND PARTIAL MOLAR VOLUMES, $\bar{V}$, OF 2,4,6-TRIPHENYLPYRIDINIUM-*N*-(3,5-DI-PHENYL)PHENOL BETAINE IN DIFFERENT SOLVENTS

a) Ref. 4 and the references quoted therein.

Piezo-Solvatochromic Shifts. Generally, when hydrostatic pressure is applied on a solution of the betaine the charge transfer band is blue-shifted. The total effect at 1000 bar, however, reaches only 4 to 8 nm (Table 1). Considering that the charge transfer band is very broad (width at $\varepsilon_{max}/2$ *ca.* 170 nm in $CHCl_3$ at 25 °C) and unsymmetrical, the accuracy in determining λ_{max} may be expected to be *ca.* ±1 nm at best. Thus within our experimental conditions no definite trend between $\Delta\lambda_{max}/\Delta P$ and the nature of the various solvents could be established. This is despite the varied nature of the solvents employed. Therefore we are convinced that the effect of pressure on the betaine charge transfer band is not a suitable indicator of the sum of all the pressure dependent solvent-solute interactions. In particular, no useful empirical parameter could be derived from $\Delta\lambda_{max}/\Delta P$ of the betaine describing the rearrangement of solvent structure in the vicinity of a dipolar species under various external pressures. The linear dependence of $\ln k(P)$ *vs.* $\Delta\lambda_{max}/\Delta P$ reported for two Menschutkin reactions in two solvents[5,8] seems to be more or less accidental in view of the limited range and accuracy of the $\Delta\lambda_{max}/\Delta P$ parameter. On the contrary, the values of $\Delta\lambda_{max}/\Delta P$ can be explained satisfactorily on the basis of the simple Kirkwood theory taking into account the pressure dependence of the macroscopic dielectric constant (q_p-parameter). Therefore we conclude that under pressure mainly the ground state of the betaine is lowered by dipolar solvent-solute interactions. How far the less polar excited state of the betaine, which according to the Franck Condon principle is not in thermodynamic equilibrium with its solvation shell, is influenced by pressure is not known. An attempt to determine the effect of pressure on the excited state failed because no fluorescence spectrum of the betaine could be found. It is most probable that the solvent structure around an excited nonpolar betaine molecule is very similar to that around the very polar ground state.[8] Only the induced dipole moments of the solvent molecules can follow the optical transition of the betaine. However, interaction with induced dipole moments is known to be comparatively small.

Partial Molar Volumes. The apparent molar volumes, φ_i, were determined according to the equation

$$\varphi_i = M/d_0 - (d_i - d_0) \cdot 1000/c_i \cdot d_0,$$

where M is the molecular weight of the betaine and c_i is its molar concentration, while d_i and d_0 are the densities of the solution and the pure solvent, respectively. Within experimental errors, no concentration dependence of φ_i was observed, which may be expected considering the relatively low concentration range studied, *i.e.*, $c \leqq 0.02$ M. Thus the partial molar volumes $\bar{V}$, of the betaine were merely taken from the average values of φ_i over the entire concentration range.

These values, which are listed in Table 1, certainly show no distinctive trend with solvent polarity parameters such as D, q, or E_T. Thus the effects that govern the solvent dependence of $\bar{V}$ are not solely of a dipolar origin (electrostriction). Therefore, we conclude that with respect to partial molar volumes the dipolar ground

state of the betaine is not a suitable model for ionic transition states in chemical kinetics, *e.g.* in Menschutkin reactions. Of all possible solvent parameters the $\bar{V}$ values of the betaine correlate best with the compressibilities and internal pressures of the different solvents. Following Dack's arguments,[15] such a behaviour is caused by the sum of all solvent-solute interactions as well as "the ability of the solvent to create cavities absorbing the intrinsic volume" of the betaine. Unfortunately, the individual contributions to $\bar{V}$ such as: electrostriction due to charge-dipole and dipole-dipole interactions; hydrogen bonding; hydrophobic and van der Waals interactions, *etc.* cannot be separated. Despite the severe limitations of the Kirkwood theory, so far the $q_p=\frac{\partial}{\partial P}\left(\frac{D-1}{2D+1}\right)$-parameter seems to best describe the large electrostriction effects found when the solvent dependence of activation volumes in polar reactions is studied.

It is obvious from the above arguments that a lot of questions on solute-solvent interactions, which were hoped to be "solved" by introducing empirical parameters, are still open. In view of the many exceptions that exist, both when the Kirkwood theory or the scale of E_T values is used, the choice of a proper description of solvent effects depends on the system studied and perhaps on personal judgement as to whether one prefers an oversimplified but theoretically based physicochemical treatment, or a more overall empirical approach.

The authors wish to thank Drs. M. Geiss and F. K. Fleischmann of their preliminary investigations. The financial assistance of the Deutsche Forschungsgemeinschaft is gratefully appreciated.

(Received June 7, 1977)

The following four chromium(III) and cobalt(III) double complexes were prepared and the thermal reactions were investigated both isothermally and non-isothermally in the solid-phase: [(Cr or Co)(H_2O)(NH_3)$_5$][(Cr or Co)(sida)$_2$] where sida denotes *N*-(2-sulfoethyl)iminodiacetate ion. The double complexes were found to be thermally deaquated to form the homo- and hetero-metal binuclear complexes [(NH_3)$_5$(Cr or Co)(sida)(Cr or Co)-(sida)] in which one of *N*-(2-sulfoethyl)iminodiacetate ions functions as the bridging ligand between two metal ions. The complexes thus obtained were purified from a 50% $HClO_4$ or a 1 M $NaClO_4$ solution in the forms of the hydrogen salts [(NH_3)$_5$(Cr or Co)(sida)(Cr or Co)(sidaH)]ClO_4 or the sodium salts [(NH_3)$_5$(Cr or Co)(sida)-(Cr or Co)(sidaNa)]ClO_4.

Only a few complexes are known in which natural or artificial amino acids function as the bridging ligand: the homo-metal binuclear complexes[2] such as [en_2Co(L-asp)Co(H_2O)en_2](ClO_4)$_4$·H_2O[3] and [(NH_3)$_5$Co(edta)-Co(H_2O)](ClO_4)$_2$[4] were recently isolated by means of column chromatography. When the solid-phase bridging[5–7] and ligand-transfer[8] reactions reported previously were applied to the preparation of the amino acid-bridging binuclear complexes, they were obtained easily.

The present study was therefore undertaken to prepare the amino acid-bridging homo- and hetero-metal binuclear complexes[2] by the use of solid-phase thermal reactions. The preparative procedures of the present study are based on the following thermal reactions:

$$[(\text{Cr or Co})(H_2O)(NH_3)_5][(\text{Cr or Co})(\text{sida})_2] \xrightarrow[\Delta]{-H_2O} [(NH_3)_5(\text{Cr or Co})(\text{sida})(\text{Cr or Co})(\text{sida})],$$

where sida denotes *N*-(2-sulfoethyl)iminodiacetate ion.

The thermal syntheses according to the above reaction have the following characteristics: firstly, the hetero-metal binuclear complexes can conveniently be synthesized by selecting the combination of metal ions in the starting double complexes. Secondly, amino acid-bridging binuclear complexes can be obtained with simpler processes. Thirdly, the complexes in which the $-SO_3$ group in sida is coordinated to a metal ion can be isolated, although they have not been isolated previously because of the weak coordination ability of a $-SO_3$ group.[9,10]

Experimental

Preparation of the Starting Complexes for Obtaining Double Complexes. The starting complexes [Cr(H_2O)(NH_3)$_5$](NO_3)$_3$,[11] [Co(H_2O)(NH_3)$_5$](NO_3)$_3$,[12] *trans*(*N*)-K_3[Cr(sida)$_2$]·4H_2O[9] and *trans*(*N*)-K_3[Co(sida)$_2$]·4H_2O[13] were prepared by the same method as that reported in each literature, and they were identified by means of elemental analyses and spectrophotometric measurements.

Preparation of Double Complexes. Aquapentaamminechromium(III) Bis(N-(2-sulfoethyl)iminodiacetato)chromate(III) Dihydrate, [Cr(H_2O)(NH_3)$_5$][Cr(sida)$_2$]·2H_2O (Red) (I). Ten and seven tenth grams (3.2×10^{-2} mol) of [Cr(H_2O)(NH_3)$_5$](NO_3)$_3$ and 15.0 g (3.2×10^{-2} mol) of *trans*(*N*)-K_3[Cr(sida)$_2$]·4H_2O were dissolved separately in about 50 ml of water and then they were mixed together. The mixture was stirred with a glass rod for a few minutes and allowed to stand in a refrigerator overnight, red crystals being obtained. They were collected by filtration, washed with small amounts of water, ethanol and ether, and air-dried. Yield about 16 g.

Found: C, 19.98; H, 5.02; N, 13.27%. Calcd for $C_{12}H_{37}O_{17}N_7S_2Cr_2$: C, 20.03; H, 5.19; N, 13.63%.

Aquapentaamminechromium(III) Bis(N-(2-sulfoethyl)iminodiacetato)cobaltate (III) Dihydrate, [Cr(H_2O)(NH_3)$_5$][Co(sida)$_2$]·2H_2O (Pink) (II). This was prepared in a manner similar to that of complex I except that a solution of 15.3 g (3.2×10^{-2} mol) of *trans*(*N*)-K_3[Co(sida)$_2$]·4H_2O in 50 ml of water was used in place of the solution of *trans*(*N*)-K_3[Cr(sida)$_2$]·4H_2O.

Found: C, 19.78; H, 5.03; N, 13.55%. Calcd for $C_{12}H_{37}O_{17}N_7S_2CrCo$: C, 19.83; H, 5.14; N, 13.50%.

Aquapentaamminecobalt(III) Bis(N-(2-sulfoethyl)iminodiacetato)-chromate(III) Dihydrate, [Co(H_2O)(NH_3)$_5$][Cr(sida)$_2$]·2H_2O (Orange) (III). The complex was also obtained by a method similar to that of complex I except that a solution of 10.9 g (3.2×10^{-2} mol) of [Co(H_2O)(NH_3)$_5$](NO_3)$_3$ in 150 ml of water was used instead of the solution of [Cr(H_2O)(NH_3)$_5$]-(NO_3)$_3$. Yield about 15 g.

Found: C, 19.49; H, 5.07; N, 13.12%. Calcd for $C_{12}H_{37}O_{17}N_7S_2CrCo$: C, 19.83, H, 5.14; N, 13.50%.

Aquapentaamminecobalt(III) Bis(N-(2-sulfoethyl)iminodiacetato)-cobaltate(III) Dihydrate, [Co(H_2O)(NH_3)$_5$][Co(sida)$_2$]·2H_2O (Pale Red) (IV). This was synthesized according to a procedure similar to that of complex I from 10.9 g (3.2×10^{-2} mol) of [Co(H_2O)(NH_3)$_5$](NO_3)$_3$ and 15.3 g (3.2×10^{-2} mol) of *trans*(*N*)-K_3[Co(sida)$_2$]·4H_2O in 150 ml and 50 ml of water, respectively.

Found: C, 19.66; H, 5.06; N, 13.48%. Calcd for $C_{12}H_{37}O_{17}N_7S_2Co_2$: C, 19.65; H, 5.09; N, 13.37%.

Preparation of Binuclear Complexes. μ-N-*(2-Sulfoethyl)iminodiacetatopentaamminechromium(III)(or cobalt(III))hydrogen(or sodium)*-N-*(2-sulfoethyl)iminodiacetatochromium(III)(or cobalt(III)) Perchlorates, [(NH_3)$_5$(Cr or Co)(sida)(Cr or Co)(sidaH or sida-Na)]ClO_4 (Reddish Violet) (V through XII).* For simplification, the procedures for preparing the binuclear complexes are schematically outlined in Fig. 1.

First of all the corresponding double complexes were triturated thoroughly in an agate mortar and were heated at given temperatures for a given period of time. The products [(NH_3)$_5$(Cr or Co)(sida)(Cr or Co)(sida)] were purified in

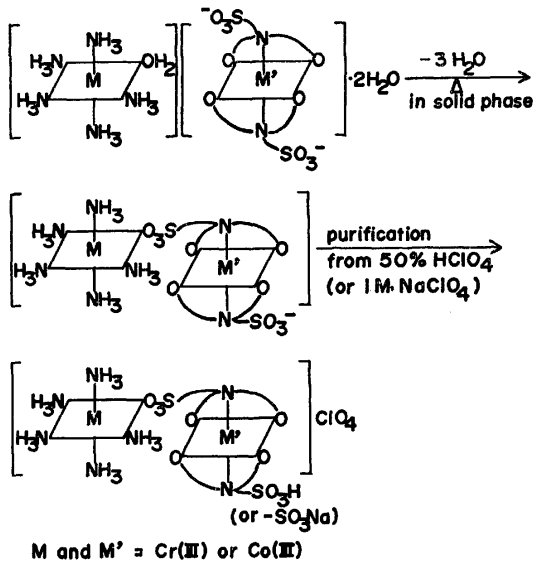

Fig. 1. Procedures for obtaining the binuclear complexes.

the forms of the hydrogen salts $[(NH_3)_5$(Cr or Co)(sida)(Cr or Co)(sidaH)$]ClO_4$ and the sodium salts $[(NH_3)_5$(Cr or Co)-(sida)(Cr or Co)(sidaNa)$]ClO_4$ from a 50% $HClO_4$ solution and a 1 M $NaClO_4$ solution, respectively. The yields of the hydrogen salts and the sodium salts were about 40% and 30% based on the amounts of the double complexes used, respectively.

Table 1 summarizes the binuclear complexes obtained, their analytical data, the starting double complexes, and the heating conditions determined non-isothermally (derivatographically) and/or isothermally.

Derivatographic Measurements. The derivatograms of the samples were recorded on a MOM Derivatograph Typ-OD-102. All the measurements were carried out in a nitrogen stream at the heating rate of 1 °C min^{-1}, 0.4 g of the samples being used in each run.

Isothermal Measurements. For the determination of the heating conditions for obtaining the desired binuclear complexes, isothermal measurements were carried out by using a Shimadzu TM-1A Thermanobalance in a static air at various temperatures.

Spectral Measurements. Visible and ultra-violet, and IR absorption spectra of the samples were measured in aqueous solutions and in KBr disks with Union High-sens. Spectrophotometer SM-401 and with a JASCO A-3 Infrared Spectrophotometer, respectively.

Magnetic Susceptibilities. The magnetic susceptibilities of the samples were measured by Gouy method at room temperatures. The effective magnetic moments were evaluated from the magnetic susceptibilities measured above and corrected by the use of Pascal's constants for each component in the complexes.

Molar Conductivities. Molar conductivities were measured to determine the charges of the binuclear complexes with a YEW Universal Bridge TYPE BU-Z-13A.

Behaviors toward Ion Exchangers. The behaviors of the binuclear complexes toward ion exchangers were examined to find whether they were cationic complex species or not. Dowex 1-X8 (100—200 mesh) and Dowex 50W-X8 (50—100 mesh) were used as anion and cation exchangers, respectively.

Results and Discussion

For convenience, in the following discussion, the double complexes ([Cr or Co)$(H_2O)(NH_3)_5$][(Cr or Co)-$(sida)_2$]) and binuclear complexes ($[NH_3)_5$(Cr or Co)-(sida)(Cr or Co)(sida)]) will be abbreviated as [Cr or Co][Cr or Co] and [(Cr or Co)–(Cr or Co)], and the hydrogen salts ($[(NH_3)_5$(Cr or Co)(sida)(Cr or Co)-(sidaH)$]ClO_4$) and the sodium salts ($[(NH_3)_5$(Cr or Co)-(sida)(Cr or Co)–(sidaNa)$]ClO_4$) will be designated similarly as [(Cr or Co)–(Cr or Co)H] and [(Cr or Co)–(Cr or Co)Na], respectively.

(1) Determination of the Conditions for Thermal Syntheses of Binuclear Complexes. For the determination of preparative conditions (temperature and duration of heating) of the binuclear complexes, the thermal reactions of the corresponding double complexes were observed both derivatographically and isothermally.

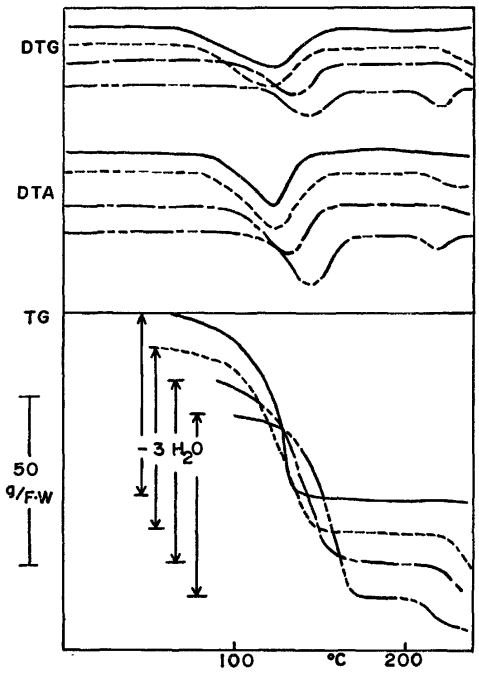

Fig. 2. Derivatograms of $[Cr(H_2O)(NH_3)_5][Cr(sida)_2]\cdot 2H_2O$ (——), $[Cr(H_2O)(NH_3)_5][Co(sida)_2]\cdot 2H_2O$ (·····), $[Co(H_2O)(NH_3)_5][Cr(sida)_2]\cdot 2H_2O$ (·—·), and $[Co(H_2O)(NH_3)_5][Co(sida)_2]\cdot 2H_2O$ (··—··).

Derivatography. The derivatograms of the double complexes are depicted in Fig. 2. The TG curves show that all the double complexes evolve smoothly three moles of water (two moles of lattice water and one mole of coordinated water) in the temperature range of 60—135 °C ([Cr][Cr]), 50—150 °C ([Cr][Co]), 90—160 °C ([Co][Cr]), and 100—170 °C ([Co][Co]), remaining unchanged in weight losses up to 200—220 °C. The [Cr][Cr] complex was stable even at about 220 °C, but the other three ([Cr][Co], [Co][Cr] and [Co][Co]) were decomposed gradually in a complicated way above 200—210 °C with the reduction of Co(III) to Co(II) ions. These double complexes were initially orange or pink in color, but changed to reddish violet at the end of the evolution of three moles of water. The

TABLE 1. BINUCLEAR COMPLEXES OBTAINED, ANALYTICAL DATA, STARTING DOUBLE COMPLEXES, AND HEATING CONDITIONS

Binuclear complex	Analytical data %[a] C	H	N	Starting double complex	Heating conditions[b] Temp (°C)	Time (min)

$[(NH_3)_5CosidaCrsidaNa]ClO_4$ (X)	18.25 (18.13)	4.01 (3.94)	12.27 (12.34)			
$[(NH_3)_5CosidaCosidaH]ClO_4$ (XI)	18.80 (18.49)	4.19 (4.14)	12.32 (12.57)	$[CoH_2O(NH_3)_5]\cdot[Co(sida)_2]\cdot 2H_2O$	142	210
$[(NH_3)_5CosidaCosidaNa]ClO_4$ (XII)	18.33 (17.97)	4.07 (3.90)	12.11 (12.23)			

a) The figures in parentheses are calculated values. b) The heating conditions were determined derivatographically and/or isothermally.

color changes are, as will be mentioned later, due to the liberation of the coordinated water in the complex cation ($[(Cr \text{ or } Co)(H_2O)(NH_3)_5]^{3+}$) and the subsequent coordination of the $-SO_3^-$ group in the complex anion ($[Cr \text{ or } Co)(sida)_2]^{3+}$).

The information obtained here implies that all the complexes are highly stable even after the liberation of water and hence the desired binuclear complexes are obtained by the use of the thermal reaction in the solid-phase without controlling conditions.

Isothermal Measurements. On the basis of the above results, preliminary experiments were carried out to determine the effective heating conditions for the thermal syntheses. Figure 3 shows the change in the weight losses of the double complexes with time at the given temperatures.

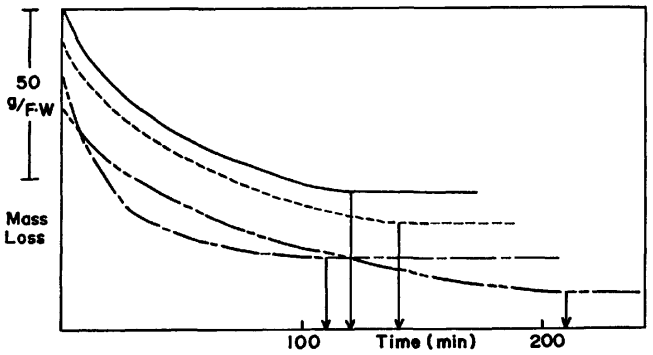

Fig. 3. Changes in weight losses with time of $[Cr(H_2O)(NH_3)_5][Cr(sida)_2]\cdot 2H_2O$ at 122 °C (——), $[Cr(H_2O)(NH_3)_5][Co(sida)_2]\cdot 2H_2O$ at 122 °C (·····), $[Co(H_2O)(NH_3)_5][Cr(sida)_2]\cdot 2H_2O$ at 130 °C (·—·), and $[Co(H_2O)(NH_3)_5][Co(sida)_2]\cdot 2H_2O$ at 142 °C (··—··).

The [Cr][Cr] double complex gradually and monotonously loses the weight of 54 g/*F.W.* (*F.W.*=Formula Weight) which corresponds to 3 mol of water, no further weight change being found even after prolonged heating. From this result, 122 °C and 120 min were selected as the optimal heating temperature and the time duration for the thermal synthesis of the [Cr–Cr] binuclear complex. Similarly, the heating conditions for the other three complexes were determined as specified in Table 1.

(2) Properties of the Binuclear Complexes. Magnetic Susceptibilities: The [Cr][Cr] double complex gave the value of 3.9 B.M. (290 K) per one chromium ion. The values 3.9 B.M. (291 K) and 3.8 B.M. (291 K) were observed for the [Cr][Co] and [Co][Cr] double complexes, respectively. The [Co][Co] double complexes were found to be diamagnetic (291 K).

On the other hand, the values for the binuclear complexes are, in general, slightly smaller as compared with those for the corresponding double complexes: 3.6 B.M. (291 K) for [Cr–CrH], 3.7 B.M. (291 K) for [Cr–CoH] and 3.5 B.M. (291.5 K) for [Co–CrH]. The [Co–CoH] binuclear complex was diamagnetic (292 K). These results suggest that the cobalt and chromium ions are all tervalent in both the double and binuclear complexes.

Molar Conductivities: Table 2 lists the molar conductivities. The binuclear complexes of the hydrogen and

TABLE 2. MOLAR CONDUCTIVITIES (25 °C) OF THE BINUCLEAR COMPLEXES

Complex			Molar Conductivities (mho cm^{-1})[a]
Hydrogen salts	[Cr–CrH]	(V)	432
	[Cr–CoH]	(VII)	321
	[Co–CrH]	(IX)	406
	[Co–CoH]	(XI)	359
Sodium salts	[Cr–CrNa]	(VI)	145
	[Cr–CoNa]	(VIII)	137
	[Co–CrNa]	(X)	142
	[Co–CoNa]	(XII)	133

a) 1.0×10^{-3} mol/l of aqueous solution was used.

Table 3. IR data for the starting double complexes and the hydrogen salts of binuclear complexes obtained (cm^{-1})

Complex			H_2O ν(O–H)	ClO_4^- ν(Cl–O)	R–SO_3^- $\nu(SO_3^-)$
Double complexes	[Cr][Cr]	(I)	3450	—	642, 1035, 1053, 1190
	[Cr][Co]	(II)	3460	—	648, 1040, 1058, 1210
	[Co][Cr]	(III)	3450	—	641, 1035, 1054, 1194
	[Co][Co]	(IV)	3480	—	653, 1042, 1059, 1208
Binuclear complexes	[Cr–CrH]	(V)	—	1095	638, 1030, 1047, 1180
	[Cr–CoH]	(VII)	—	1100	643, 1032, 1049, 1185
	[Co–CrH]	(IX)	—	1095	638, 1032, 1047, 1182
	[Co–CoH]	(XI)	—	1085	648, 1037, 1052, 1189

the sodium salts exhibited 320—430 mho cm^{-1} and 130—145 mho cm^{-1}, respectively. These values may correspond to the conductivities of $HClO_4$ (hydrogen salts) and $NaClO_4$ (sodium salts) in solutions.

Both the hydrogen and sodium salts were adsorbed on neither cation nor anion exchangers at pH 7, but were adsorbed on cation exchanger at pH 3. These results indicate that at pH 7 the complexes are dissociated into $[(NH_3)_5$(Cr or Co)(sida)(Cr or Co)(sida)$]^0+Na^+ + ClO_4^-$, and at pH 3, $[(NH_3)_5$(Cr or Co)(sida)(Cr or Co)-(sidaH)$]^+ + ClO_4^-$.

IR Data. The IR data of the double and binuclear complexes are summarized in Table 3. The characteristic band due to H_2O (3450—3480 cm^{-1}) is seen in the double complexes, but not in the binuclear complexes. The band due to ClO_4^- (1085—1100 cm^{-1}) is detected in the binuclear complexes. The characteristic bands due to the $-SO_3^-$ group of the binuclear complexes appear in the lower wavenumber region as compared with those of the double complexes. The shifts probably result from the coordination of a $-SO_3^-$ group in the cationic moiety of the double complexes.

Table 4. Visible and UV spectral data for the starting double complexes and the hydrogen salts of binuclear complexes obtained

Complex			$\bar{\nu}_1$ 10^{-3} cm^{-1} (log ε_1)	$\bar{\nu}_2$ 10^{-3} cm^{-1} (log ε_2)
Double complexes	[Cr][Cr]	(I)	19.53(2.13)	26.95(2.09)
	[Cr][Co]	(II)	19.34(2.17)	26.60(2.13)
	[Co][Cr]	(III)	19.38(2.15)	26.67(2.11)
	[Co][Co]	(IV)	19.19(2.19)	26.32(2.15)
Binuclear complexes	[Cr–CrH]	(V)	18.02(2.15)	25.38(2.10)
	[Cr–CoH]	(VII)	17.86(2.18)	25.06(2.15)
	[Co–CrH]	(IX)	17.89(2.17)	25.13(2.12)
	[Co–CoH]	(XI)	17.73(2.20)	24.81(2.16)

Electronic Spectra. Table 4 summarizes the absorption maxima in the region of d-d transitions. The absorption bands of the binuclear complexes appear at lower wavenumber regions than those of the corresponding double complexes. The shifts may be due to the fact that the coordinated water in the complex cation ($[$(Cr or Co)$(H_2O)(NH_3)_5]^{3+}$) is expelled and replaced by the $-SO_3^-$ group in the complex anion ($[$(Cr or Co)$(sida)_2]^{3-}$).

When the aqueous solutions of the binuclear complexes were allowed to stand at room temperature overnight, their absorption maxima were shifted to those of the corresponding double complexes. Thus the binuclear complexes are hydrolyzed gradually in aqueous media changing from $[(NH_3)_5$(Cr or Co)(sida)(Cr or Co)-(sida)] into $[$(Cr or Co)$(H_2O)(NH_3)_5]^{3+} + [$(Cr or Co)-$(sida)_2]^{3-}$.

2.5 th Order Differential Electroanalysis

Masashi GOTO, Takafumi HIRANO, and Daido ISHII

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 8, 1977)

The theory which describes the properties of the 2.5th order derivative of current, e'', *vs.* the electrode potential, E, curves is presented in response to an imposed ramp signal on a stationary electrode. The 2.5th order differential, $e''(t)$, of the current, $i(t)$, is defined by

$$e''(t) \equiv \frac{d^{2.5}}{dt^{2.5}} i(t) = \frac{d^3}{dt^3}\left[\frac{1}{\sqrt{\pi}}\int_0^t \frac{i(\lambda)}{\sqrt{t-\lambda}} d\lambda\right].$$

The predicted dependences of peak height, peak potential, and peak width on concentration, electron number, and scan rate, *etc.* have been confirmed experimentally, using the analogue circuit to monitor the electroreductions of Cd^{2+}, Pb^{2+}, Tl^+, Zn^{2+}, and Ni^{2+} on a hanging mercury electrode. It was proved that the proposed technique adds the advantages of further higher resolution and higher sensitivity to those of semidifferential electroanalysis. At the scan rate of 100 mV/s, the signals observed in this technique were about 50 and 8 times larger than those in linear sweep voltammetry for the reductions of Cd^{2+} and Ni^{2+}, respectively. Sufficient resolution was obtained for the qualitative analyses between Pb^{2+} and Tl^+, between Ni^{2+} and Zn^{2+}, and between Ni^{2+} and H^+ at pH 1.4 in this technique.

Oscillographic polarography with applied voltage or, in other words, linear sweep voltammetry was first introduced by Matheson and Nichols[1] and developed by Randles[2] and Sevcik,[3] and many others[4] in order to reduce the time necessary for a polarographic analysis. In the linear sweep voltammetry, the electrolytic current increases up to a certain maximum value and then decreases rather gradually with increasing applied voltage. The maximum current, measured from the base line, is proportional to the bulk concentration of depolarizer, but it depends upon the potential scan rate and its constancy. The shape of the observed curve renders the determination of two or more depolarizers present very difficult. In 1972 Oldham[5-7] first introduced a new electroanalytical method "semiintegral electroanalysis" that has the merit of being independent of the details of the applied potential signal. The semiintegral, $m(t)$, of the current, $i(t)$, is defined by

$$m(t) \equiv \frac{d^{-0.5}}{dt^{-0.5}} i(t) = \frac{1}{\sqrt{\pi}}\int_0^t \frac{i(\lambda)}{\sqrt{t-\lambda}} d\lambda.$$

The method measures the semiintegral of the current as a function of electrode potential. When a ramp signal is applied, the shape of the observed curve is similar to that of a classical d.c. polarogram. Imbeux and Saveant,[8] and Senda and Ikeda[9] have also proposed, under the heading "convolutive potential sweep voltammetry," and "a new method for recording polarographic curves in oscillographic polarography with applied voltage, in which the surface concentration *vs.* potential curve is recorded," a similar transformation of the current *vs.* potential curve with reference to kinetic analysis of mechanisms and to analytical application, respectively.

By analogy with the relationship between d.c. polarography and a.c. polarography (or between normal pulse polarography and differential pulse polarography), a companion method "semidifferential electroanalysis" for semiintegral electroanalysis was recently announced by the present authors *et al.*[10-12] In this method, the semiderivative of current or the derivative of $m(t)$ is measured as a function of electrode potential, and the method appends the features of higher sensitivity and higher resolution to those of semiintegral electroanalysis as expected. For further higher resolution and higher sensitivity, the present article has proposed a new technique in which the 2.5th order derivative of current is recorded as a function of electrode potential.

Theory

Consider the case of a working electrode immersed in a solution containing, in addition to excess supporting electrolyte, a concentration C of the electroreducible species Ox. This species undergoes the n-electron reduction

$$Ox + ne^- \longrightarrow Rd \qquad (1)$$

to the initially-absent species Rd. A potential ramp,

$$E = E_0 - vt, \qquad (2)$$

is applied to the working electrode, where E is the electrode potential, E_0 is the initial potential, v is the scan rate of potential, and t is the time. E_0 is adjusted at a value at which Ox is virtually not reduced. It will be assumed throughout this article that the transport of Ox to, and of Rd in the reversible case from, the electrode is solely by semiinfinite diffusion.

We use the symbol e to denote the semiderivative[13] (0.5th order derivative) of the current i with respect to t

$$e \equiv \frac{d^{0.5}}{dt^{0.5}} i = \frac{d}{dt}\left[\frac{1}{\sqrt{\pi}}\int_0^t \frac{i(\lambda)}{\sqrt{t-\lambda}} d\lambda\right]. \qquad (3)$$

If Reaction 1 is reversible, the following equations[10]

$$e = \frac{nFv}{4RT} m_d \operatorname{sech}^2(x), \qquad (4)$$

where

$$m_d = nAF\sqrt{DC}\,, \qquad (5)$$

$$x = \frac{nF}{2RT}(E_{1/2} - E), \qquad (6)$$

relate the semiderivative of current to the electrode potential. In these equations, F is the Faraday constant, R is the gas constant, T is the absolute temperature, A is

the electrode area, D is the diffusion coefficient of Ox. and $E_{1/2}$ is the half-wave potential of the d.c. polarogram.

Differentiation of Eq. 4 with respect to t is aided by the chain rule in the form

$$e' \equiv \frac{de}{dt} = \frac{de}{dx} \cdot \frac{dx}{dt}, \tag{7}$$

and yields

$$e' \equiv \frac{d^{1.5}}{dt^{1.5}} i = -\left(\frac{nFv}{2RT}\right)^2 m_d \operatorname{sech}^2(x) \tanh(x), \tag{8}$$

as the expression for the shape of the 1.5th order derivative of current e' *vs.* E curve. On differentiation of Eq. 8, the 2.5th order derivative of current e'' is derived and presented by

$$e'' \equiv \frac{d^{2.5}}{dt^{2.5}} i = -\left(\frac{nFv}{2RT}\right)^3 m_d \{\operatorname{sech}^2(x) - 3\operatorname{sech}^2(x) \tanh^2(x)\}. \tag{9}$$

This equation represents the shape of a reversible e'' *vs.* E curve observed in the proposed method, to which the name "2.5th order differential electroanalysis" is suggested. The curve is symmetrical consisting of a minimum and two maxima as shown by the solid line in Fig. 1. The negative peak height is

$$e''_p = -m_d\left(\frac{nFv}{2RT}\right)^3, \tag{10}$$

and the potential corresponding to the negative peak is simply

$$E_p = E_{1/2}, \tag{11}$$

the polarographic half-wave potential. The width of the negative peak at an ordinate value equal to one-half of the peak height or, in short, the peak width is

$$W_p = \frac{1.56RT}{nF}. \tag{12}$$

Notice that the above peak width is much narrower than that of e *vs.* E curve which is 3.53 RT/nF.[11]

If Reaction 1 is totally irreversible, the following relation applies:[14]

$$e = -\frac{n\alpha Fv}{RT} m_d \sum_{j=1}^{\infty} \frac{(-1)^j j \exp(jz)}{\sqrt{j!}}, \tag{13}$$

where z is defined by

$$z = \frac{n\alpha F}{RT}(E_s - E) + \frac{1}{2}\ln\left(\frac{RTk_s^2}{n\alpha FvD}\right) \equiv \frac{n\alpha F}{RT}(E_* - E). \tag{14}$$

Here α is the transfer coefficient, E_s is the standard potential, k_s is the standard, heterogeneous rate constant, and E_* is a characteristic potential for an irreversible species being defined by Eq. 14. Differentiations of Eq. 13 with respect to t yield

$$e' = -\left(\frac{n\alpha Fv}{RT}\right)^2 m_d \sum_{j=1}^{\infty} \frac{(-1)^j j^2 \exp(jz)}{\sqrt{j!}}, \tag{15}$$

and

$$e'' = -\left(\frac{n\alpha Fv}{RT}\right)^3 m_d \sum_{j=1}^{\infty} \frac{(-1)^j j^3 \exp(jz)}{\sqrt{j!}}, \tag{16}$$

in the same way as for the reversible case. Equation 16 is the expression for the shape of a totally irreversible e'' *vs.* E curve observed in the proposed technique.

Values of the summation term in Eq. 16 for an assortment of small z values are listed in Table 1 together with the values of the hyperboric function term in Eq. 9 for x values. For large z values, sufficient precison of computation could not be retained. These data are also plotted as the dashed line in Fig. 1 for comparison with the corresponding shape of a reversible e'' *vs.* E curve. As expected, the irreversible peak is broader, and is somewhat asymmetric. From Table 1, the minimum value of the summation term is −0.2194, whence it follows that the negative peak height is

Table 1. Values of the function that describes the shapes of e'' *vs.* E curves

The entries marked (a) and (b) correspond to the negative and positive peaks of e'' *vs.* E curves, respectively, while those marked (c) and (d) correspond to the negative half-peak potentials of reversible and irreversible curves, respectively.

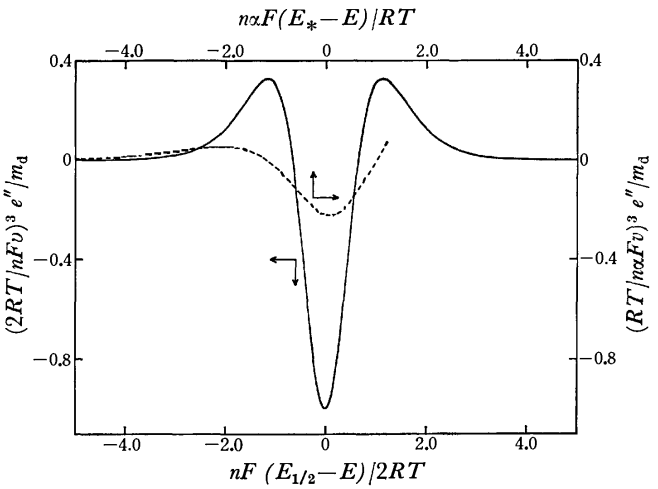

Fig. 1. Shapes of reversible (full line) and irreversible (dashed line) e'' *vs.* E curves.

$$e''_p = -0.219 m_d \left(\frac{n\alpha Fv}{RT}\right)^3. \quad (17)$$

From the fact that the minimum value of the summation occurs when z equals 0.07, if follows that the negative peak potential is

$$E_p = E_* - \frac{0.07RT}{n\alpha F}. \quad (18)$$

Likewise the tabulated data indicate the peak width to be

$$W_p = \frac{1.29RT}{n\alpha F}. \quad (19)$$

Information from Eqs. 10—12, 17—19 has been assembled into Table 2 which for 20 °C, summarizes the features of reversible and irreversible curves observed in the proposed technique.

Table 2. Features of e'' *vs.* E curves at 20 °C

	Reversible	Irreversible
Peak potential, E_p	$E_{1/2}$	$E_* - \frac{(1.77\text{ mV})}{n\alpha}$
Peak height, e''_p	$-\frac{n^4 A\sqrt{D}Cv^3}{(1.33n\ \text{V}^3\ \text{mol/C})}$	$-\frac{n^4\alpha A\sqrt{D}Cv^3}{(0.76n\ \text{V}^3\ \text{mol/C})}$
Peak width, W_p	$\frac{(39.4\text{ mV})}{n}$	$\frac{(32.5\text{ mV})}{n\alpha}$

The peak currents observed in linear sweep polarography[15] are given by

$$i_p = 0.447 m_d \left(\frac{nFv}{RT}\right)^{0.5}, \quad (20)$$

for reversible electrode processes, and

$$i_p = 0.496 m_d \left(\frac{n\alpha Fv}{RT}\right)^{0.5}, \quad (21)$$

for totally irreversible processes. Therefore the ratios of e''_p to i_p for reversible and irreversible processes are represented respectively by the following equations:

$$\frac{e''_p}{i_p} = -0.280 \left(\frac{nFv}{RT}\right)^{2.5}, \quad (22)$$

and

$$\frac{e''_p}{i_p} = -0.442 \left(\frac{n\alpha Fv}{RT}\right)^{2.5}. \quad (23)$$

The actual values of the ratios are listed in Table 3 for different potential scan rates, n and $n\alpha$ values at 20 °C. It is expected from Table 3 that the signals observed in this proposed method are further larger than those in linear sweep voltammetry at higher scan rates in both reversible and irreversible cases.

Experimental

Apparatus. The instrument for 2.5th order differential electroanalysis was constructed from a function generator (NF Co., model FG-121B) as the applied potential sweeper, an analogue circuit for 2.5th order differential, and a recorder (Toa Electronics Ltd., model EPR-2TC). The 2.5th order differential circuit is shown in Fig. 2 with the circuit for correction of electrode sphericity effect. The current flowing through an indicator electrode is converted to voltage signal by means of a current follower (A1). The output of the current follower is fed to both a semidifferentiator (A2) and a potentiometer (PT). The potentiometer is adjusted to feed the voltage equivalent to $(\sqrt{D}/r)\ s^{1/2}$ portion of the output of the current follower to an adder (A3), where r is the radius of electrode sphere. The attenuated output of the current follower is subtracted from the output of the semidifferentiator by the adder. The output of the adder is fed to two differentiators (A4 and A5) in turn. When i, e', and e'' are to be recorded, the terminals of T1, T2, and T3 are connected directly to the recorder, respectively. Oldham's paralleling geometric ladder was used with a little modification as shown in Fig. 2 of the literature[16] as the semidifferential element (SE) in Fig. 2.

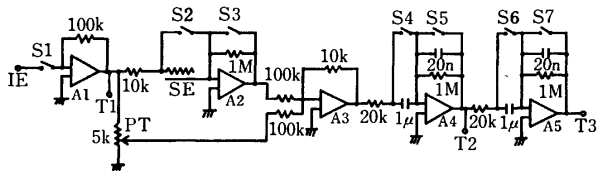

Fig. 2. 2.5th order differential circuit with the circuit for correction of electrode sphericity effect. IE: Indicator electrode, SE: semidifferential element, PT: potentiometer for the correction of electrode sphericity effect, S1: switch for electrolysis, S2—S7: switches for circuit reset, A1—A5: operational amplifiers (Analog Devices Co., model 118A), T1, T2, and T3: terminals for i, e', and e'' measurments, respectively.

A hanging mercury drop (Beckman Instruments Inc., model 39016) was used as a working electrode. A saturated calomel electrode with large surface area was served for both a counter and a reference electrode. A potential ramp signal was applied to the working electrode against the saturated calomel electrode.

Reagents etc. The salts $Cd(NO_3)_2 \cdot 4H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $ZnSO_4 \cdot 7H_2O$, $TlNO_3$, and $Pb(NO_3)_2$ were used as solutes in 100 mmol/l KNO_3 plus HNO_3 at various concentrations. Solutions were prepared by direct weighing of the appropriate quantities of reagent grade chemicals, and deoxygenated by passage of N_2 gas. Measurments were made at room temperature (about 20 °C).

Results and Discussion

Figures 3 and 4 show typical e'' *vs.* E curves for Cd^{2+} as an example of reversibly reduced species and for Ni^{2+} as an example of irreversibly reduced ones, respectively, and also show the corresponding i *vs.* E and e' *vs.* E curves. As expected from the theory, a symmetric,

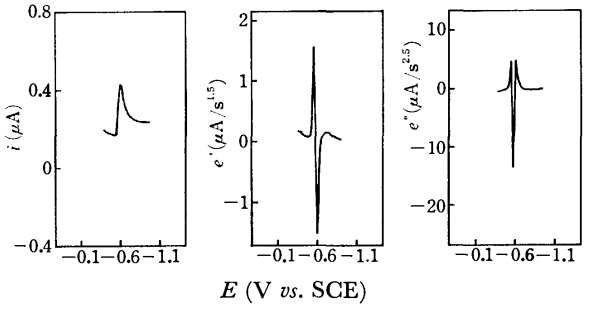

Fig. 3. Comparison of i *vs.* E, e' *vs.* E, and e'' *vs.* E curves of 10.5 μmol/l Cd^{2+} in 100 mmol/l KNO_3. Scan rate: 100 mV/s, electrode area: 4.69 mm^2.

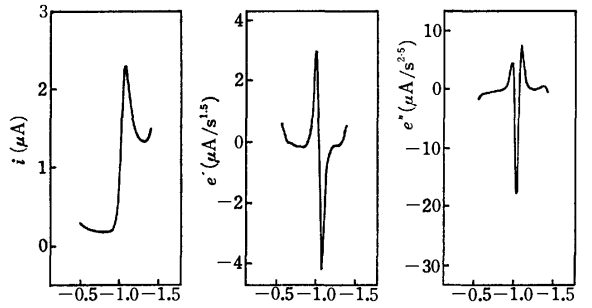

Fig. 4. Comparison of i *vs.* E, e' *vs.* E, and e'' *vs.* E curves of 104 μmol/l Ni^{2+} in 100 mmol/l KNO_3 plus 0.101 mmol/l HNO_3 (pH 4.1). Scan rate and electrode area: as Fig. 3.

sharp peak was observed in the e'' *vs.* E curve of Cd^{2+}, while a somewhat asymmetric, broad peak was observed in that of Ni^{2+}. It is evident from these diagrams that e'' *vs.* E and e' *vs.* E curves have attractive and promising features for both qualitative and quantitative analyses over ordinary i *vs.* E curve.

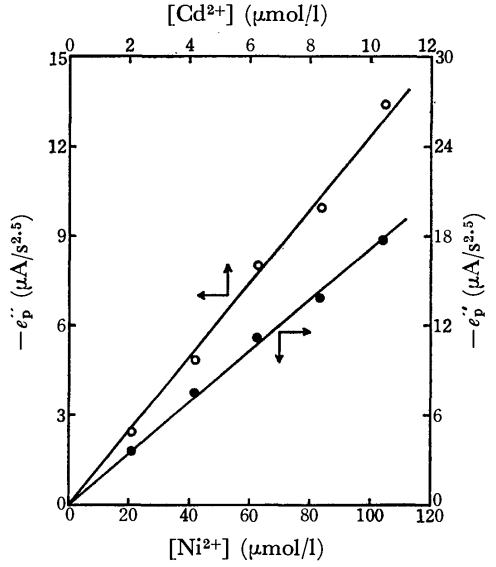

Fig. 5. Relationship between negative peak height of e'' *vs.* E curve and concentration of electroactive solutes. ○: Cd^{2+} in 100 mmol/l KNO_3, ●: Ni^{2+} in 100 mmol/l KNO_3 plus 0.101 mmol/l HNO_3, scan rate and electrode area: as Fig. 3.

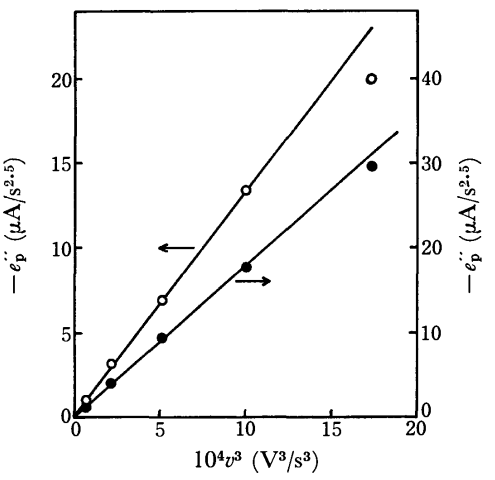

Fig. 6. Relationship between negative peak height of e'' *vs.* E curve and scan rate. ○: 10.5 μmol/l Cd^{2+} in 100 mmol/l KNO_3, ●: 104 μmol/l Ni^{2+} in 100 mmol/l KNO_3 plus 0.101 mmol/l HNO_3, electrode area: 4.69 mm^2.

Equations 5, 10, and 17 predict a linear dependence of negative peak height of e'' *vs.* E curve on the concentration of electroactive species and the cubic power of potential scan rate. These proportionalities are tested in Figs. 5 and 6 for Cd^{2+} and Ni^{2+} reductions, examples comprising both a reversible and an irreversible electrode reaction. In both cases, linearity was satisfactory and the lines passed through the origin. The slope de''_p/dC for Cd^{2+} in Fig. 5 has an experimental value of -1.24 A $s^{-2.5}$ mol^{-1} l, compared with a theoretical value, $-nAF\sqrt{D}(nFv/2RT)^3$, of -1.48 A $s^{-2.5}$ mol^{-1} l, calculated on the basis of a diffusion coefficient[17] of 6.9×10^{-6} cm^2 s^{-1}. Similarly for the Ni^{2+} line, the experimental slope $de''_p/dC=-0.170$ A $s^{-2.5}$ mol^{-1} l compares well with the theoretical value $-0.219nAF\sqrt{D}(n\alpha Fv/RT)^3=-0.166$ A $s^{-2.5}$ mol^{-1} l, based on $D=6.9\times10^{-6}$ cm^2 s^{-1} [18] and $\alpha=0.4$.[19] The slopes of the lines in Fig. 6 also agree approximately with the values predicted by Eqs. 10 and 17.

In Table 4 the experimental peak heights of e'' *vs.* E curves are compared with those of i *vs.* E curves at different concentrations for the Cd^{2+} and Ni^{2+} reductions. Table 4 also shows the corresponding, theoretical

Table 4. Comparison of experimental peak heights between e'' *vs.* E and i *vs.* E curves at the scan rate of 100 mV/s

Species	C (μmol/l)	i_p (μA)	e''_p (μA/$s^{2.5}$)	$-e''_p/i_p$($s^{-2.5}$) Exptl.	Theor.
Cd^{2+}	6.30	0.150	−8.09	53	49
Cd^{2+}	8.40	0.192	−9.96	52	49
Cd^{2+}	10.5	0.260	−13.4	52	49
Ni^{2+}	62.4	1.37	−11.2	8.2	7.9
Ni^{2+}	83.2	1.75	−13.8	7.9	7.9
Ni^{2+}	104	2.09	−17.7	8.5	7.9

Supporting electrolyte: 100 mmol/l KNO_3 for Cd^{2+}, 100 mmol/l KNO_3 plus 0.101 mmol/l HNO_3 for Ni^{2+}, electrode area: 4.69 mm^2.

Table 5. Peak potentials of e'' *vs.* E curves for Cd^{2+} and Ni^{2+} at different concentrations

$[Cd^{2+}]$ (μmol/l)	E_p for Cd^{2+} (mV *vs.* SCE)	$[Ni^{2+}]$ (μmol/l)	E_p for Ni^{2+} (mV *vs.* SCE)
2.10	−575	20.8	−1044
4.20	−586	41.6	−1048
6.30	−583	62.4	−1040
8.40	−587	83.2	−1046
10.5	−575	104	−1037
	Theor. −578[17]		Theor. −1034[18]

Supporting electrolyte, scan rate, and electrode area: as Table 4.

peak ratios of both curves for reference. It is evident from Table 4 that at the scan rate of 100 mV/s, the proposed technique provides about 50 and 8 times larger signals for Cd^{2+} and Ni^{2+} reductions, respectively, than linear sweep voltammetry does.

The peak potentials of e'' *vs.* E curves for the reductions of Cd^{2+} and Ni^{2+} were found to be independent of concentration, as shown in Table 5, and to average respectively −581 and −1043 mV *vs.* SCE (the latter value refers to $v=100$ mV/s). The experimental peak potential for Cd^{2+} is to be compared with the polarographic half-wave potential in the literature[17] of −578 mV *vs.* SCE. That for Ni^{2+} may likewise be compared with the −1034 mV *vs.* SCE value calculated from the half-wave potential of −980 mV *vs.* SCE at the mercury drop time τ of 4.48 s in classical polarography[18] by application of Eq. 18 and the relation[11]

$$E_{1/2} = E_* + \frac{0.30RT}{n\alpha F} + \frac{RT}{2n\alpha F}\ln\left(\frac{n\alpha Fv\tau}{RT}\right). \quad (24)$$

For Ni^{2+} reduction, the peak potential should vary with scan rate in accordance with the relation:

$$E_p = E_s + \frac{RT}{2n\alpha F}\ln\left(\frac{0.869RTk_s^2}{n\alpha FD}\right) - \frac{RT}{2n\alpha F}\ln(v)$$

predicted by Eqs. 14 and 18, while it should be independent of scan rate for Cd^{2+} reduction. Table 6 resorts the experimental data and lists the theoretical values of peak potentials. Agreement is within a few millivolts in all the cases.

Table 7 assesses how well the observed peak widths in the proposed technique agree with theoretical predictions. The data refer to the reduction of Cd^{2+} and Ni^{2+}

Table 6. Scan rate dependence of peak potentials of e'' *vs.* E curves for Cd^{2+} and Ni^{2+}

as an example of reversible and irreversible processes, respectively. The theoretical predictions are based on Eqs. 12 and 19.

All theoretical predictions concerning 2.5th order differential electroanalysis have been confirmed. Though this entire article is couched in terms of cathodic processes, it is evident that the conclusions are easily widened to embrace electrooxidations.

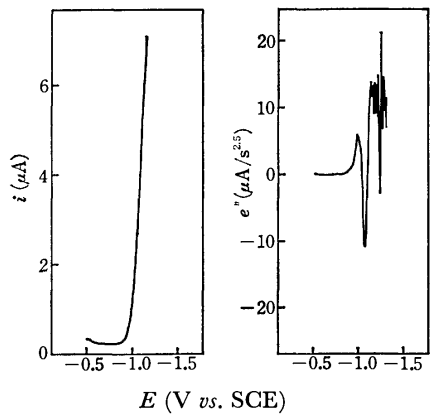

Fig. 7. Comparison of resolution between i *vs.* E and e'' *vs.* E curves for 104 μmol/l Ni^{2+} plus 50.5 mmol/l H^+ in 100 mmol/l KNO_3. Scan rate and electrode area: as Fig. 3.

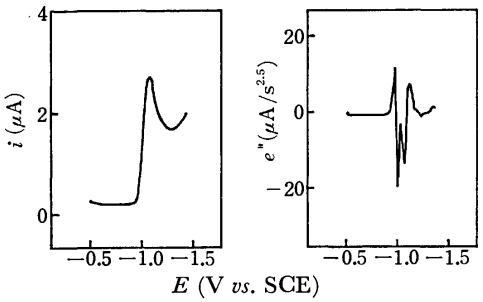

Fig. 8. Comparison of resolution between i *vs.* E and e'' *vs.* E curves for 25.0 μmol/l Zn^{2+} plus 104 μmol/l Ni^{2+} in 100 mmol/l KNO_3 plus 0.101 mmol/l HNO_3. Scan rate and electrode area: as Fig. 3.

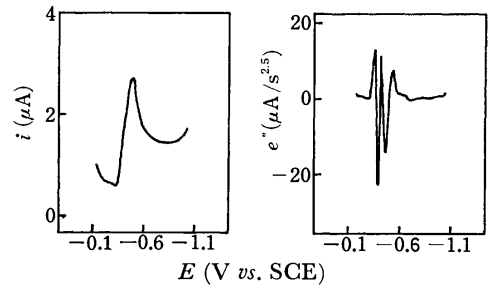

Fig. 9. Comparison of resolution between i *vs.* E and e'' *vs.* E curves for 20.0 μmol/l Pb^{2+} plus 100 μmol/l Tl^{+} in 100 mmol/l KNO_3 plus 10.1 mmol/l HNO_3. Scan rate and electrode area: as Fig. 3.

Figures 7, 8, and 9 demonstrate how clear resolution the proposed technique provides by comparison with ordinary linear sweep voltammetry. It is evident from these diagrams that Ni^{2+} in 100 mmol/l KNO_3 at pH 1.4 can be detected separately from hydrogen wave and simultaneous detections between Zn^{2+} and Ni^{2+}, and between Pb^{2+} and Tl^{+}, whose reduction potentials close together, are possible in the proposed technique.

In conclusion, 2.5th order differential electroanalysis is an attractive, fast method for the identification of many electroactive species coexistent in solution, and may provide quite high sensitivity for the detection of electroactive species at higher scan rates of potential as expected from Table 3. The study of detection limit for various species in this technique is continuing in our laboratory.

The authors are grateful to Dr. T. Matsuzaki and Mr. K. Kitagawa, Nagoya University, for computational assistance.

The Preparation and Some Properties of 3-Substituted 2,4-Pentanedionato Metal(II, III) Complexes

Kuninobu KASUGA, Masao ANAMI, and Yasuo YAMAMOTO

Department of Chemistry, Faculty of Literature and Science, Shimane University, Nishikawatsucho, Matsue 690

(Received June 25, 1977)

In the substitution reactions of phenol, benzenethiol, and their sodium salts on the chelate ring of 3-bromo-2,4-pentanedionato metal complexes (metal=iron(III), aluminium(III), and beryllium(II)), benzenethiol was found to be substituted for bromine, while phenol was not substituted under the same conditions. In the case of sodium salts, both sodium phenoxide and benzenethiolate gave substituted products. The UV and PMR data of tris(3-substituted 2,4-pentanedionato)aluminium(III) complexes gave some information on the substituted groups.

The electrophilic substitution on the chelate ring of acetylacetonato complexes is known to be brought about by various reagents, such as bromine,[1,2] iodine,[1] *N*-halosuccinimides,[1,5] and nitro derivatives,[3,4] while only a few reports have appeared on the further conversion of the substituted chelates.[6,7] It was found by Yoshida *et al.* that the bromine atom on the chelate ring of 3-bromo-2,4-pentanedionatocobalt(III), -chromium(III), or -aluminium(III) is replaced by benzenethiol or its derivatives.[7] On the other hand, we ourselves have previously reported that the bromine atom on the chelate ring of 3-bromo-2,4-pentanedionatoiron(III) is replaced by succinimide or phthalimide in the presence of sodium methoxide.[8] In this paper another nucleophilic substitution reaction will be presented for the bromine atom on the chelate ring of iron(III), aluminium(III), cobalt(III), or beryllium(II) complex by phenol, benzenethiol, or their sodium salts.

Experimental

The 3-position carbons of 2,4-pentanedionato metal(II, III) complexes were halogenated according to the procedure of Collman *et al.*[1]

The Syntheses of 3-Phenoxy-2,4-pentanedionato Metal(II, III) Complexes. From Phenol: A 20-ml dichloromethane solution of phenol (0.02 mol) was added to a solution of 3-bromo-2,4-pentanedionatoiron(III), -aluminium(III), -cobalt(III), -chromium(III), -beryllium(II), or their chloro compounds (0.005 mol) in 50 ml of dichloromethane, after which the mixture was left standing for 5—6 days at room temperature. However, phenol was found not to react with these complexes, and the starting material was recovered in each case.

From Sodium Phenoxide: A mixture of sodium phenoxide (0.02 mol) and tris(3-bromo-2,4-pentanedionato)iron(III) (0.005 mol) in 50 ml of dichloromethane was left to stand, with stirring, for three days at room temperature, after which the precipitates formed were filtered off. The filtrate was washed twice with aqueous sodium hydrogencarbonate and then with water. After the solution had been dried with anhydrous sodium sulfate, the dichloromethane was evaporated under a reduced pressure. The resulting solid was recrystallized from ethanol, yielding the red powder of tris(3-phenoxy-2,4-pentanedionato)iron(III) (abbreviated as Fe(acacOph)$_3$). Yield, 36% (based on Fe(acacBr)$_3$). Found: C, 62.79; H, 5.16%. Calcd for $C_{33}H_{33}O_9Fe$: C, 62.97; H, 5.28%. The other substituted products were also prepared according to the same procedure; their analytical results were as follows: Al(acacOph)$_3$. Yield, 31% (based on Al(acacBr)$_3$). Found: C, 66.18; H, 5.38%. Calcd for $C_{33}H_{33}O_9Al$: C, 66.00; H, 5.54%. Be(acacOph)$_2$. Yield, 22% (based on Be(acacBr)$_2$). Found: C, 67.62; H, 5.18%. Calcd for $C_{22}H_{22}O_6Be$: C, 67.52; H, 5.67%. Also from 3-chloro-2,4-pentanedionato metal(II, III) complexes, the same substituted products were obtained, but the yields were less than those from the bromo compounds. In the case of the chromium(III) complex, sodium phenoxide was not substituted by the same method or by reflux for three days; neither its bromo and chloro complexes gave a substituted product. As to the cobalt(III), both the bromo and chloro complexes were immediately decomposed by the same reaction.

The Syntheses of 3-Phenylthio-2,4-pentanedionato Metal(II, III) Complexes. From Benzenethiol: A solution of benzenethiol (0.03 mol) in 20 ml of dichloromethane was slowly stirred, into a solution of tris(3-bromo-2,4-pentanedionato)iron(III) (0.005 mol) in 50 ml of dichloromethane. After standing for 2 h at room temperature, the solution was washed with aqueous sodium hydrogencarbonate and water, and then dried with anhydrous sodium sulfate. The dichloromethane was removed and the resulting tarry solid was recrystallized from ethanol–water. Yield, 18%(based on Fe(acacBr)$_3$). Found: C, 58.25; H, 5.29%. Calcd for $C_{33}H_{33}O_6S_3Fe$: C, 58.49; H, 4.91%. The other substituted products were also synthesized by the same procedure; the analytical results were as follows: Be(acacSph)$_2$. Yield, 55%(based on Be(acacBr)$_2$). Found: C, 61.98; H, 5.49%. Calcd for $C_{22}H_{22}O_4S_2Be$: C, 62.39; H, 5.24%. The substituted products were not obtained from 3-chloro-2,4-pentanedionatoiron(III) or -beryllium(II) under the same conditions.

From Sodium Benzenethiolate: The substituted products were obtained according to the procedure used for the preparations of 3-phenoxy-2,4-pentanedionato metal(II, III) complexes. The analytical results were as follows: Fe(acacSph)$_3$. Yield, 24%(based on Fe(acacBr)$_3$). Found: C, 57.94; H, 4.93%. Calcd for $C_{33}H_{33}O_6S_3Fe$: C, 58.49; H, 4.91%. Al(acacSph)$_3$. Yield, 43%(based on Al(acacBr)$_3$). Found: C, 61.01; H, 5.30%. Calcd for $C_{33}H_{33}O_6S_3Al$: C, 61.10; H, 5.13%. Be(acacSph)$_2$. Yield, 37%(based on Be(acacBr)$_2$). Found: C, 62.21; H, 5.42%. Calcd for $C_{22}H_{22}O_4S_2Be$: C, 62.39; H, 5.24%.

Measurements. The electronic spectra in solution and the infrared spectra using KBr pellets were measured on a Hitachi 124-type spectrophotometer and a Hitachi 215-type spectrophotometer respectively. The PMR spectra were recorded with a JEOL-MH 100 spectrophotometer at a frequency of 100 MHz. The chemical shifts were determined in ppm, using TMS as the internal standard. The elemental analyses were carried out by means of a Yanagimoto MT 2 CHN Corder.

Results and Discussion

Electronic, Infrared, and PMR Spectra. From the data given in Table 1, we see that the 3-phenoxy derivatives of these metal complexes and phenylthio compounds show the band of the phenoxyl or phenylthio group at around 270 or 253 nm respectively. In the infrared spectra, these substituted compounds show the bands characteristic of a skeletal stretching and a CH-out-of-plane bending of the phenyl group at around 1490 and 820 cm^{-1} respectively.[7] In the PMR spectra, the methyl proton of acetylacetone shows a singlet signal in the range of 1.4—2.4 ppm, while the phenyl proton shows multiplet signals in the range of 6.8—7.4 ppm. The PMR spectrum of the iron(III) complex was not measured because of its paramagnetism.

The UV and PMR Spectral Data of the Tris(3-substituted 2,4-pentanedionato)aluminium(III) Complexes. From the UV data given in Table 2, we can see that the chloro, bromo, and phenoxy complexes show the absorption band due to a π-π^* transition of an acetylacetone ring at around 310 nm, while the acetylacetonato complex and its benzenethiol, succinimide, and phthalimide derivatives show the absorption bands at around 290 nm. It has been known that the absorption band of the π-π^* transition of benzene is shifted to longer wavelengths when the hydrogen of benzene is replaced by such a group as chlorine, bromine, or amine, which has lone-pair electrons taking part in the π system of benzene.[9] Therefore, the oxygen atom of the phenoxyl group in this compound has hybridized sp or sp^2 orbitals and the electrons of the nonhybridized p orbital must participate in the π system of the acetylacetone ring. The sulfur atom of the phenylthio group may have hybridized sp^3 orbitals and no electrons which take part in the π system of an acetylacetone ring; thus, the absorption band of the phenylthio compound shows no shift to longer wavelengths. The succinimido or phthalimido group of this compound is perpendicular to an acetylacetone ring because of the steric hindrance between the carbonyl group of these imides and the methyl group of the acetylacetone ring. Therefore, the absorption band arising from the π-π^* transition of the acetylacetone ring is not shifted. The PMR signals of the methyl protons of the chelated acetylacetone of the 2,4-pentanedionatoaluminium(III) complex, and its 3-bromo and 3-chloro compounds are shifted to lower magnetic fields in the order of their electronegativities. The PMR signal of the phenylthio compound is shifted to a lower magnetic field than that of the phenoxy compound. It can be said that this is caused by the ring-current effect of benzene. From the UV spectra and the fact that the PMR signal of the methyl group is a singlet in these compounds, the oxygen atom of the phenoxyl group can be said to have sp hybridized orbitals, while the sulfur atom of the phenylthio group has sp^3 hybridized orbitals. That is, the benzene ring of phenylthio group is situated nearer to the methyl group than that of the phenoxyl group. Thus, the methyl protons of phenoxy compounds are affected by the ring current of benzene more strongly than that of phenylthio compounds, and the PMR signal of the phenylthio compound is shifted to a lower magnetic field than that of the phenoxy compound. The PMR spectra of the 3-succinimido and 3-phthalimido compounds have also been compared. In spite of the strong electron attraction of a carbonyl group of these imides, the signal of the methyl protons of these compounds appears at nearly the same position as that of

the 2,4-pentanedionato compound. This may arise from the magnetic anisotropy. The protons of methyl groups of the acetylacetone ring are situated over the π system of O–C–N–C–O, because the plane of cyclic imides and the acetylacetone ring are perpendicular to each other. Thus, the anisotropic effects can shift the PMR signal to a higher magnetic field.

Studies of the Hydrous Titanium Oxide Ion Exchanger. III. Distribution Coefficients and Some Applications*

Yasushi INOUE and Masamichi TSUJI**

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received July 16, 1977)

In order to understand the cation-exchange behavior of hydrous titanium oxide, the distribution coefficients of various cations were measured as a function of the pH and the ionic strength. The order of selectivity for alkali metal ions is $Cs^+ > Rb^+ > K^+ > Na^+$, for alkaline earth metal ions, $Ba^{2+} > Sr^{2+} > Ca^{2+}$, and for bivalent transition metal ions, $Zn^{2+} > Cu^{2+} > Co^{2+}$. From the dependency of the distribution coefficients on the pH, it is concluded that the apparent dissociation constants of the exchanger reported previously are not constant, but gradually decrease with the pH of the medium. By using ammonium chloride and ammonium nitrate solutions as eluents, nearly quantitative separations of ^{137}Cs—^{133}Ba and ^{137}Cs—^{89}Sr were achieved with a relatively small column.

The method of synthesizing hydrous titanium oxide as an ion exchanger proposed by the present authors has the merits of good reproducibility and the large ion-exchange capacity of the product. The adsorption of cations on this material was confirmed, through the measurement of the amount of hydrogen ion released by the uptake of a definite amount of sodium or strontium ions, to occur by cation-exchange reaction. Other important properties of the exchanger, such as its composition, stability against various chemicals, and its ion-exchange properties including ion-exchange capacity and acidity, have also been investigated, as has been described in the foregoing reports.[1,2] The studies of the application of hydrous titanium oxide have been concentrated on the recovery of uranium from seawater,[3] scarcely have been devoted to the chromatographic separations of cations except in a few cases—the separation of ^{134}Cs—^{90}Sr, ^{134}Cs—^{142}Pr,[4] and chromate and phosphate ions.[5]

The purpose of the present investigation is to understand the cation-exchange reaction of the exchanger through the examination of the distribution coefficients of various cations as a function of the pH, and to show the applicability of the exchanger to the chromatographic separation. As examples, the separations of ^{137}Cs—^{133}Ba and ^{137}Cs—^{89}Sr were performed by using ammonium nitrate and ammonium chloride solutions as eluents.

Experimental

Reagents and Apparatus. Hydrous titanium oxide was prepared by a method described previously.[2] The radioactive purity of the radioisotopes employed was confirmed in advance; all the reagents, of the highest grade of purity, were obtained from Wako Pure Chemical Industries, Ltd.

The equipment for the β- and γ-counting was the same as has been described previously.[1,2]

Distribution Coefficients. The distribution coefficients were determined in the following way, except as otherwise noted.

A half gramme of the exchanger of a desired ionic form was placed in contact, in a thermostat at 25 °C, with 50 cm³ of a suitable solution containing 2.0×10^{-4} M (1 M = 1 mol/dm³) of the cation in question until the concentration of the cation in the supernatant solution became constant (about 2 d). After filtration, the pH and the concentration of cations in the solution were measured. The amount of cation employed was less than 1% of the total ion-exchange capacity of the exchanger. The analysis of Na, K, Rb, Cs, Ca, Sr, Ba, Fe, Co, Cu, Zn, Ga, and Y was carried out radiometrically using ^{22}Na, ^{42}K, ^{86}Rb, ^{137}Cs, ^{45}Ca, ^{89}Sr, ^{133}Ba, ^{59}Fe, ^{60}Co, ^{64}Cu, ^{65}Zn, ^{72}Ga, and ^{90}Y respectively as tracers.

The distribution coefficients, K_d, were calculated by means of the following equation:

$$K_d = \frac{I-F}{F} \cdot \frac{V}{m} \quad (\mathrm{cm^3/g}),$$

where I and F are the initial and the final radioactivity concentrations in the solution respectively; V, the volume of the solution in cm³, and m, the weight of the exchanger in g. The distribution coefficients thus obtained were not equilibrium values, as will be described later.

The total concentration of alkali metal ions was determined in the following way. To a 10-cm³ aliquot of the sample solution, an excess amount of a 6 M HCl solution was added. This was then heated to dryness and dissolved in water. Finally the alkali metal ion was indirectly determined by titrating the chloride ion with Fajans' method.

Column Operation. Two grammes of the exchanger in H^+ form (100—200 mesh) were packed in a glass column, 7 mm in inside diameter, and completely converted into the NH_4^+ form by passing through a 3% NH_4OH solution. The flow rate of the effluent was kept nearly constant, 0.08—0.13 cm³/min, throughout a series of elutions. The radioisotopes used were carrier-free except for ^{133}Ba, the specific activity of which was about 2 mCi/mg.

Results and Discussion

Distribution Coeffcients. Figures 1 and 2 show the dependency of the distribution coefficients of the alkali metal and alkaline earth metal ions on the pH. Table 1 presents the distribution coefficients of the other metal ions. The order of selectivity is $Cs^+ > Rb^+ > K^+ > Na^+$ for alkali metal ions and $Ba^{2+} > Sr^{2+} > Ca^{2+}$ for alkaline earth metal ions. These series follow the same pattern as those shown by strongly acidic cation-exchange resin. For bivalent transition metal ions, the series is $Zn^{2+} > Cu^{2+} > Co^{2+}$, assuming that the dependency of the distribution coefficients on the pH is about the same as that for alkaline earth metal ions.

	3.68	$(1.56\pm0.05)\times10^2$
	3.83	$(3.8\pm0.3)\times10^2$

The selectivity series for alkali metal ions is the same as that found by Heitner-Wirguin *et al.*,[6] but the order for Co^{2+} and Cu^{2+} is reversed. The possible reasons for this conflicting result are as follows: (1) The concentration of the cations adopted by them is 0.01 M, which is considerably higher than that used in the present experiment; (2) Their ion exchanger contains about 4% of oxalate as an impurity; (3) The properties of the exchangers themselves differ from each other as a result of the difference in the synthetic methods. If the oxalate groups contained in their ion exchanger are considered to act as exchanging sites, the improvement in the selectivity for an ion will increase its prominence with the stability of the oxalato-complex. Since the stability constant of oxalato-complex of Cu^{2+} is not larger than that of Co^{2+},[7] the second possibility seems unlikely. As the inversion of the selectivity cannot be considered to occur in such a low concentration as this, the third possibility appears most promising.

Figure 1 also shows that the distribution coefficients of the sodium ion did not depend on the particle size of the ion exchanger. This observation suggests that the exchanging sites are distributed uniformly within the body of the exchanger, which corresponds to the fact that the ion-exchange capacity is independent of the particle size of the ion exchanger, as has been pointed out previously.[1] The distribution coefficients of the sodium ion were affected by the ratio between the volume of the liquid phase and the weight of the exchanger. This means that the curves in Fig. 1 do not show true equilibrium values, although two phases have been in contact with each other until the adsorbed amount of the sodium ion becomes constant.

Figure 3 indicates that a linear relationship held between the logarithms of the distribution coefficients of the cesium ion on the ion exchanger in the Na^+ form and the concentration of the sodium ion at a constant pH. The slope of the line increased with the pH until it reached unity at pH 7. When the solution became more basic than this, essentially the same relation was obtained at any pH. Figure 4 shows the relation at

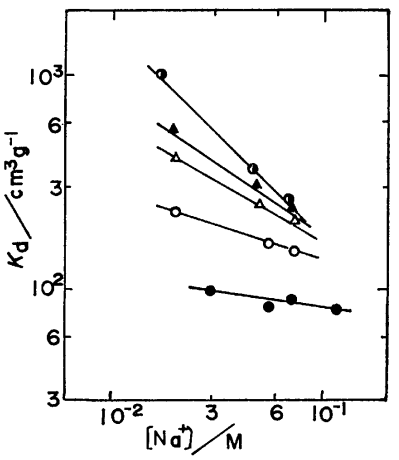

Fig. 3. Dependency of distribution coefficients of Cs^+ on the concentration of Na^+ ($RNa+Cs^+ \rightarrow RCs+Na^+$). Exchanger; Na^+ form, 100—200 mesh, 500 mg. pH; ●: 3, ○: 4, △: 5, ▲: 6, ◑: 7.

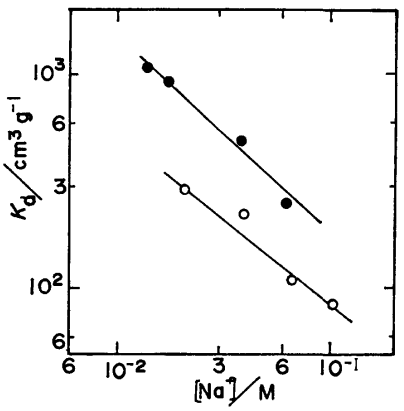

Fig. 4. Dependency of distribution coefficients of Cs^+ on the concentration of Na^+ at pH 8. Exchanger; Na^+ form, 100—200 mesh, 500 mg.
○: Forward reaction ($RNa+Cs^+ \rightarrow RCs+Na^+$),
●: reverse reaction ($RCs+Na^+ \rightarrow RNa+Cs^+$).

pH 8 as an example. The distribution coefficients obtained from the forward- and the reverse reactions did not agree with each other. Therefore, the reaction never reached equilibrium, as in the H^+–Na^+ exchange reaction mentioned above. This introduces the problem that it is difficult to discuss the relation in terms of the theory of chemical equilibrium. However, if the curves determined from the forward- and the reverse reactions run parallel with each other, it is natural to assume that the curve in true equilibrium may be somewhere between, and parallel with, them. Therefore, one can discuss the dependency of the apparent distribution coefficients on various factors from the viewpoint of the chemical equilibrium theory with due regard to the limitation imposed by the assumption.

The ion-exchange reaction between the monovalent cation, M^+, and the n-valent cation, N^{n+}, and the equilibrium constant can be expressed by the following equations:

$$nMR + N^{n+} = NR_n + nM^+, \tag{1}$$

$$K = \frac{a_{NR_n}(a_M)^n}{(a_{MR})^n a_N} = \frac{f_N[NR_n](a_M)^n}{\gamma_N[N^{n+}](a_{MR})^n}, \tag{2}$$

where a denotes the activity, R^-, the matrix anion of the exchanger, [ ], the concentration, f_N, the activity coefficient of the N^{n+} ion in the exchanger, and γ_N, the activity coefficient of the N^{n+} ion in the solution.

The distribution coefficient, K_d, of the N^{n+} ion is expressed by this equation:

$$K_d = \frac{[NR_n]}{[N^{n+}]} \quad (cm^3/g). \tag{3}$$

By combining Eqs. 2 and 3, we obtain

$$K = K_d \frac{f_N(a_M)^n}{\gamma_N(a_{MR})^n}. \tag{4}$$

When the amount of N^{n+} is negligible as compared with that of M^+, a_{MR} and f_N are regarded as constant. Moreover, γ_N is also constant if the ionic strength of the solution is kept constant. Under such conditions, the following equation holds, by taking the logarithm of Eq. 4:

$$\log K_d = \text{const} - n \log a_M. \tag{5}$$

That is, if the logarithm of the distribution coefficients of N^{n+} is plotted against pH, a straight line possessing the slope of n should be obtained.

The results in Figs. 1 and 2 cannot be explained by this argument because the slopes are about a half of the valency of the exchanging cation, N^{n+}. Since the experimental condition satisfies the assumption for deducing Eq. 5, this contradiction compels us to consider that K must depend on the pH.

If the solution is acidic enough to permit the participation of only ion-exchange sites with the lowest apparent pK_a value[2] in the ion-exchange reaction, and if the cations to be exchanged are present as hydrated ions, it can be regarded that the reaction of Eq. 1 on the H^+-form exchanger is a combination of the following two reactions:

$$HR = H^+ + R^-, \qquad K_H = \frac{a_H a_R}{a_{HR}}, \tag{6}$$

$$nR^- + N^{n+} = NR_n, \qquad K_N = \frac{a_{NR_n}}{(a_R)^n a_N}. \tag{7}$$

Accordingly,

$$K = K_H{}^n \cdot K_N. \tag{8}$$

Equation 6 represents the acid dissociation of the exchanger, and Eq. 7, the reaction of the anionic form of the exchanger with the exchanging cation, N^{n+}. As a similar conflict between Eq. 5 and the experimental results was observed for every kind of ion examined, it was considered that the contradiction was attributable to the gradual decrease in the acid dissociation constant, K_H, of the ion exchanger with the pH. Accordingly, it is considered that the pK_i described in the previous paper[2] is not constant, but a certain average value.

If this discussion holds true, the relation of Eq. 5 should hold in the ion-exchange reaction between alkali metal ions in an alkaline medium, where the acid dissociation can be ignored. In the ion-exchange reaction between Na^+ and Cs^+ in a basic medium, the results obeyed Eq. 5 as was expected (Fig. 4).

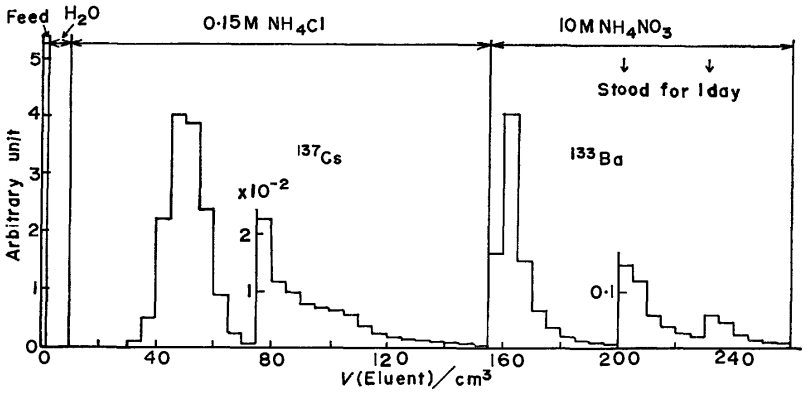

Fig. 6. Separation of ^{137}Cs and ^{133}Ba.
Column: 0.7 cm $\phi \times 3.8$ cm (NH_4^+ form, 100—200 mesh, 2 g).
Flow rate: 0.10—0.13 cm³/min.

The relationship between the distribution coefficient of the cesium ion on the exchanger in the Na^+ form and the pH is compatible with the argument presented above, as is shown in Fig. 5.

Gallium behaved differently; that is, the distribution coefficient decreased with the pH. This unusual behavior is attributable to the hydrolysis of the ion, because the gallium ion hydrolyzes at a pH value above 2.

Separations of ^{137}Cs—^{89}Sr and ^{137}Cs—^{133}Ba. In order to confirm that the hydrous titanium oxide ion exchanger could be used for the chromatographic separation, an attempt was made to separate the long-lived fission products, Cs, Sr, and Ba ions.

The results for the ^{137}Cs—^{133}Ba separation are represented in Fig. 6. Cs^+ and Ba^{2+} were eluted with 0.15 M ammonium chloride and 10 M ammonium nitrate solutions respectively. The sharp elution peaks were followed by slight tailings. ^{137}Cs could be quantitatively recovered by the use of 150 cm³ of the eluent, but the recovery of ^{133}Ba was only 94% even after passing through 160 cm³ of the eluent.

Figure 7 shows the separation of ^{137}Cs—^{89}Sr. After the ^{137}Cs had been eluted by a 0.15 M ammonium chloride solution in a manner similar to that shown in Fig. 6, a 0.3 M ammonium chloride–0.1 M hydrogen chloride solution was passed through. In this case, also, some tailings appeared after the sharp elution peaks. ^{89}Sr, however, could be recovered nearly quantitatively by letting 125 cm³ of this eluent flow through.

Therefore, we can conclude that the complete separation of ^{137}Cs from ^{89}Sr is possible.

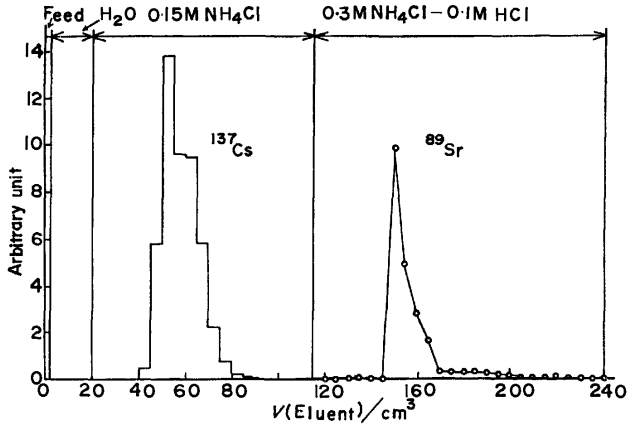

Fig. 7. Separation of ^{137}Cs and ^{89}Sr.
Column: 0.7 cm $\phi \times 3.8$ cm (NH_4^+ form, 100—200 mesh, 2 g). Flow rate: 0.08 cm³/min.

A Kinetic Study of the Ligand Exchange between Bis(acetylacetonato)-oxovanadium(IV) and Acetylacetone[^{14}C] in Organic Solvents

Masato NISHIZAWA and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received July 19, 1977)

Square pyramidal [VO(acac)$_2$] (acac, acetylacetonate) undergoes ligand exchange with Hacac[^{14}C] in 1,2-dichloroethane (DCE) without side reactions. The rate is expressed by $R=k_2$[complex][Hacac], where [Hacac] stands for the concentration of free acetylacetone in enol form. The second order rate constant and activation parameters are 0.071 M^{-1} s^{-1} (M=mol dm^{-3}) at −33 °C, $\Delta H^{\ddagger}=(46.7\pm1.7)$ kJ mol^{-1} and $\Delta S^{\ddagger}=(-61.9\pm8.4)$ J·mol^{-1} K^{-1}. The deuterium isotope effect is $k_H/k_D=1.3\pm0.2$. It appears as if the free Hacac first interacts with the complex as unidentate and the chelation of the unidentate accompanied by proton transfer to the leaving $acac^-$ is the rate determining step. On addition of a donor solvent the exchange rate decreases, and the extent is correlated with Gutmann's donor number. The k_2, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ in 0.06 M dimethyl sulfoxide (DMSO) in DCE are 0.0038 M^{-1} s^{-1} at −33 °C, (71.9±10.0) kJ mol^{-1}, and (−4±40) J mol^{-1} K^{-1}, respectively. The DMSO molecule seems to interact with the intermediate species with a unidentate Hacac and inhibits the associative rate determining step.

Vanadium(IV) gives characteristic square pyramidal complexes with an oxo-anion on the apical position. Interaction of various species including the solvent molecules with the complex has been studied by visible and ultraviolet (UV) absorption spectrometry[1] and correlated with various parameters of the interacting molecule such as donor number.[2] ESR studies in organic solvents disclosed that the interaction at the apical site was a very rapid phenomenon and the rate was mostly diffusion controlled.[3] Reuben and Fiat, and Wüthrich and Connick found two rates for the exchange of water between $[VO(H_2O)_5]^{2+}$ and the solvent by NMR spectroscopy with ^{17}O, and assigned them to the exchanges at the apical ($\approx10^{11}$ s^{-1}) and the basal site (5.2×10^2 s^{-1}).[4] Substitution reactions at the basal site have been studied by absorption and PMR spectrometry by use of bidentate ligands such as glycinate[5] and malonate,[6] and found to be much slower than those at the apical site.

As an extension of our studies of isotopic exchange of various acetylacetonato complexes of main group and transition elements,[7] we have found that the exchange between bis(acetylacetonato)oxovanadium(IV), [VO(acac)$_2$], and acetylacetone[^{14}C] is measurable in 1,2-dichloroethane at a temperature below −20 °C, and the rate decreases on addition of donor solvents. This paper deals with the kinetic studies, and presents a plausible reaction mechanism.

Experimental

Materials. VO(acac)$_2$ was prepared by Rowe and Jones' method[8] and recrystallized from benzene. The purity was examined by elemental analysis of carbon and hydrogen, and visible and ultraviolet absorption spectra. Acetylacetone[^{14}C] was synthesized by the known method.[9]

1,2-Dichloroethane (DCE) was washed with potassium hydroxide solution and water, dried with calcium chloride, fractionally distilled through an effective column, and the distillate dried with Molecular Sieve 4A. Acetonitrile (AN) was dried with calcium chloride and distilled over phosphorus pentoxide. Nitromethane (NM) was distilled, frozen at −40 °C and distilled over Molecular Sieve 4A under a reduced pressure. Dimethyl sulfoxide (DMSO) was dried with activated alumina and distilled under a reduced pressure. *N,N*-Dimethylformamide (DMF) was dried with anhydrous copper(II) sulfate and distilled under a reduced pressure. Methanol was distilled and dried with Molecular Sieve 3A. 1,1,2,2-Tetrachloroethane (TCE) was shaken with several portions of concentrated sulfuric acid until the acid layer remained colorless, washed with water and distilled under a reduced pressure. The purity of the purified solvents was examined by gas chromatography, and the water content determined by Karl-Fischer titration.

Kinetic Runs. The complex solution (≈0.02 M, M=mol dm^{-3}; 5 to 8 cm^3) and acetylacetone (Hacac) labelled with ^{14}C (*ca.* 0.2 μCi) in DCE (10^{-2}—10^{-1} M, 2 to 5 cm^3) were introduced into each of the two bottoms of a co-necked flask with a glass stopper. It was placed in a thermostat, and both solutions were mixed. One cubic centimeter portions were pipetted out at appropriate time intervals, and poured into hexane (10 cm^3) in a test tube chilled at −55 to −58 °C within 8 s. The tubes were shaken and placed in a mixture of dry ice and methanol (−77 °C) to freeze DCE. The curd was filtered with filter paper at room temperature to leave crystalline VO(acac)$_2$, which was washed with hexane and dried *in vacuo*. For kinetic runs at −39.8 °C, 10% TCE (v/v) was added to the DCE solvent to prevent the freezing of DCE. Donor solvents (NM, AN, DMF, and DMSO) were added to DCE prior to the dissolution of the complex. When the reaction mixture contained NM and AN, 10% diethyl ether (v/v) was added to hexane.

The purified DCE contained *ca.* 3×10^{-3} M water, which floated mostly as ice on the surface of the reaction mixture in the thermostat. Hence the water content of the reaction mixture should be much less than 0.03 M but remained unknown.

The separated VO(acac)$_2$ was dissolved in AN (3 cm^3) and the absorption coefficient measured at 394 nm ($\varepsilon_{max}=77$ cm^{-1} M^{-1}). A 1 cm^3 portion was dissolved in toluene containing 0.01% (w/v) 1,4-bis(5-phenyl-2-oxazolyl)benzene (POPOP) and 0.4% (w/v) *p*-terphenyl (14 cm^3) and the counting rate measured by liquid scintillation counting.

Apparatus. The visible and UV absorption spectra were recorded with a Hitachi 323 Spectrometer. The counting rate due to ^{14}C was recorded with a Nuclear Chicago Unilux IIA Counter. A Haake KT 33 Thermostat was used for keeping the temperature the range from −40 to −20 °C (±0.3 °C).

Calculation of the Exchange Rate. The specific counting

rate of the recovered $[VO(acac)_2]$ was known from the recorded counting rate and the weight of $[VO(acac)_2]$, which was calculated from the extinction coefficient of the AN solution. McKay's formula was used to find the rate of exchange.

$$R = -2.3[2ab/(2a+b)][\log(1-F)]/t. \quad (1)$$

Where a and b stand for the concentrations of the complex and the free ligand, respectively. The t is the lapse of time and F is the fraction of reaction expressed by $(x_t-x_0)/(x_\infty-x_0)$. The x's are the specific counting rates at time 0, i, and infinity, respectively. The x_∞ is known by both calculation and experiment. Acetylacetone is in tautomeric equilibrium between keto and enol form, and the interchange rate (*ca.* 10^{-5} s^{-1} at 25 °C[10]) is smaller than the present ligand exchange. The percentages of enol form are 81.4[11] and 80 in itself and in DCE, respectively at 25 °C. Since the Hacac was kept at room temperature for a long time before use, dissolved and cooled immediately before mixing, 0.80 time of the concentration of Hacac was taken as b. (Preferential participation of the enol form in the exchange was also reported for the system $[Ti(acac)_3]^+$ *vs.* Hacac in AN.[12]) The calculated x_∞ value on this basis coincided with the experimental value. Hence the participation of the keto-form in the ligand exchange reaction was not taken into consideration.

Results

Absorption Spectrum. Selbin measured the visible absorption spectrum of $[VO(acac)_2]$ in various solvents, and found that the difference in wave numbers ($\Delta\nu$) between the two absorption peaks in 600—800 nm region was characteristic of the solvents.[1] Gutmann found a good correlation[13] between $\Delta\nu$ and the donor number[2] of the solvent. We have measured the visible absorption spectrum of $VO(acac)_2$ in Hacac and found two peaks at 13980 and 17120 cm^{-1} with ε values 39 and 33 cm^{-1} M^{-1}, respectively. From the difference in wave numbers of these peaks the donor number of Hacac can be calculated to be 20 at room temperature.

Gutmann measured the absorption spectra of $VO(acac)_2$ in dichloromethane containing varying amounts of organic solvents and calculated the formation constants of one to one adducts between $VO(acac)_2$ and the solvent molecules.[14] We have applied this method to the present system and obtained the formation constants of $[VO(acac)_2 \cdot Hacac]$ to be 0.14 and 0.19 M^{-1} at 25 and −33 °C, respectively, the corresponding $\Delta G°$ values being 4.8 and 3.3 kJ mol^{-1}.

In the reaction mixtures additivity law in the UV absorption spectrum was obeyed between $[VO(acac)_2]$ and Hacac. Since the concentrations of both the complex and Hacac were very low, the concentration of the adduct should be too small to be reflected in the absorption spectrum.

Kinetic Data. The visible and UV absorption spectra of the reaction mixture in DCE remained unchanged during the course of the kinetic runs. McKay plots of the runs gave straight lines with very small intercepts, which seemed to be separation-induced. Hence it was verified that the ligand exchange reaction took place exclusively throughout the reaction time. The gradients were determined by the least square method, and the experimental errors in R values calculated on 70% confidence level to be *ca.* 10%. McKay plots were linear in the presence of donor solvents, too.

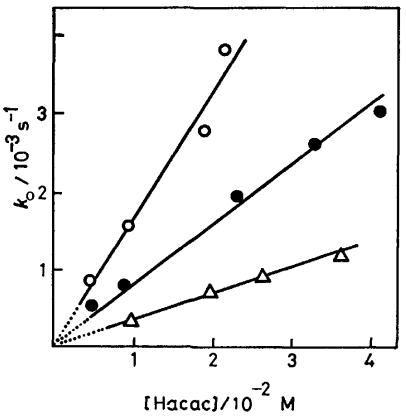

Fig. 1. Dependence of the observed first-order rate constants upon the concentration of free Hacac in enol form in DCE.
-○-: −25.0, -●-: −33.0, -△-: −39.8 °C.

The R was linearly dependent on a in the range between 0.0127 and 0.030 M and the first order rate constant k_0 ($=R/a$) can be the measure of rate of the present ligand exchange. Figure 1 indicates that k_0 increases linearly with increase in b, and the intercept is zero within experimental error. Hence Eq. 2 holds for the range of b from 0.0046 to 0.041 M.

$$R = k_0 a = k_2 ab. \quad (2)$$

The activation parameters obtained from k_2 values at −39.8, −33.0, and −25 °C are listed in Table 1.

Table 1. Rate constants and activation parameters for the substitution reaction of oxovanadium(IV) complexes

(chelation)	Stopped flow	25	35	—	—
$[VO(acac)_2]$—Hacac* in DCE[e]	Label	−33	0.071 M^{-1}	47.6±1.7	−61.9±8.4
$[VO(acac)_2]$ in DCE+DMSO[f]	Label	−33	0.0038 M^{-1}	71.9±10	−4±40

a) Substitution at the basal site. b) At the apical site; both Ref. 4. c) Ref. 5. d) Ref. 18. e) Present study f) Present study in 0.0643 M DMSO.

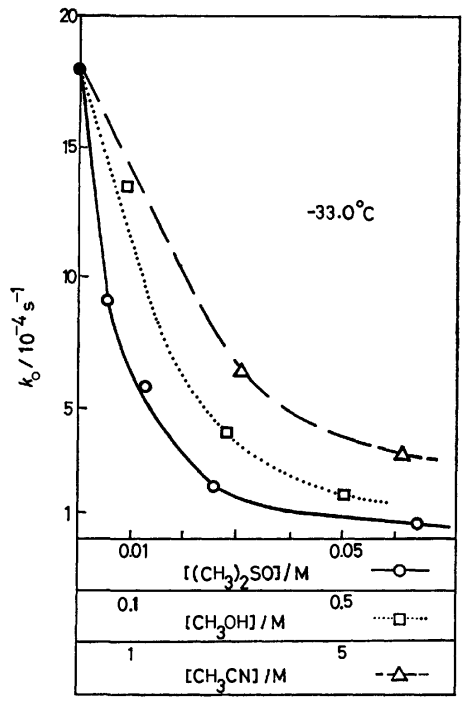

Fig. 2. Decrease in rate of the isotopic exchange on addition of donor solvents to the DCE solution.
—○—: DMSO, ···□···: methanol, ---△—: AN, at −33.0 °C, [Hacac]=0.0222 (—○—, ···□···), 0.0218 M (---△---).

The ligand exchange becomes slower on addition of donor solvents to the DCE solution (Fig. 2). The extent of retardation increases in the following sequence (Eq. 3). (Gutmann's donor numbers are shown in the parentheses).

$$\underset{\text{NM}}{CH_3NO_2} < \underset{\text{AN}}{CH_3CN} < \underset{\text{MeOH}}{CH_3OH} < \underset{\text{DMF}}{HCON(CH_3)_2} < \underset{\text{DMSO}}{(CH_3)_2SO} \qquad (3)$$

$$\underset{(2.7)}{\text{NM}} \quad \underset{(14.1)}{\text{AN}} \quad \underset{(19)}{\text{MeOH}} \quad \underset{(26.6)}{\text{DMF}} \quad \underset{(29.8)}{\text{DMSO}}$$

NM gave only a negligible effect. The extent of retardation by all the other donor solvents increased with increase in their concentrations in DCE. The dependence of k_0 upon b was similar to Eq. 2 in DCE containing DMSO as indicated in Fig. 3. The k_2 and activation parameters in 0.0643 M DMSO in DCE are shown in Table 1.

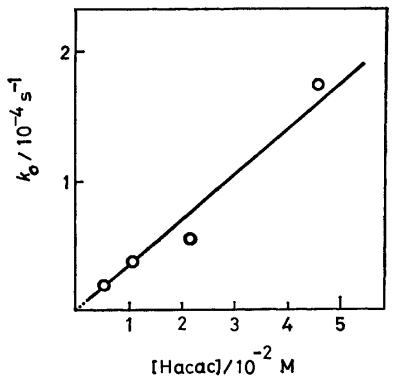

Fig. 3. Dependence of the first-order rate constant upon the concentration of free Hacac in enol form in DCE containing DMSO. At −33.0 °C, [DMSO]=0.0643 M.

Acid and base catalysis were not examined, because trichloroacetic and *m*-toluic acid caused rapid decomposition of [VO(acac)$_2$], and pyridine hindered the separation of the complex in the reaction mixture.

The deuterium isotope effect was measured in a system [VO(acac[^{14}C])$_2$] *vs.* Hacac[^2H] to find the ratio $k_H/k_D=1.3\pm0.2$ at −33 °C in DCE.

Discussion

The basal and the apical site of a square pyramidal structure are not equivalent to each other, and the known rates of substitution at these two sites are different from each other. All the known data support that the substitutions at the apical and the basal site take place with rate constants $>$ *ca.* 10^7,[3,4,15] and 10^2—10^3 s^{-1},[4-6,15,16] respectively.

Since the absorption spectra of the reaction mixtures remained unchanged, no other reactions than isotopic exchange have taken place. The influence of donor solvents is characteristic, and the reaction mechanism is discussed separately in their absence and presence.

In Dichloroethane. We have considered that the interaction between [VO(acac)$_2$] and Hacac reflected in the visible absorption spectra must be due to the addition of the free ligand at the basal position of [VO(acac)$_2$] to give *cis*-[VO(acac)$_2$(Hacac)].[17] The interaction at the basal site can involve either a direct addition or an intramolecular rearrangement, in which the free ligand first associated at the apical site rearranges to the basal site. In either case substitutions at the basal site must proceed much faster than the present isotopic exchange. Hence we consider that the exchange would proceed through the adduct, as shown in Eq. 4.

$$[VO(acac)_2] + Hacac^* \overset{K_L}{\rightleftharpoons} cis[VO(acac)_2(Hacac^*)] \qquad (4)$$

$$cis[VO(acac)_2(Hacac^*)] \overset{k_{ex}}{\longrightarrow} cis[VO(acac^*)_2(Hacac)]. \qquad (5)$$

Thus the observed rate constant k_0 should be expressed by

$$k_0 = R/a = k_2 b = k_{ex}K_L b, \qquad (6)$$

and the k_{ex} values are calculated to be 0.37 and 63 s^{-1} at −33 and 25 °C, respectively.

For the exchange of acac$^-$ to be completed, the reaction of Eq. 5 should involve two steps, *i.e.* transfer of a proton from the incoming Hacac to the coordinated acac$^-$, and the following chelation of the deprotonated unidentate ligand. The calculated k_{ex} (63 s^{-1}) at 25 °C is similar to that of the rate of chelation of unidentate glycinate in water[18] (Table 1). If the proton transfer itself were the rate determining step, isotope effect should be significant between Hacac and Dacac. Experiments gave a ratio $k_H/k_D=1.3\pm0.2$. Decisive conclusion is difficult because of the large experimental error, but the proton transfer does not seem to be an

independent rate determining step. Chelation associated with the proton transfer would be responsible in determining the k_{ex}.

The ΔH^* value for the overall k_2 in DCE is rather small, and the ΔS^* is large in minus. These suggest an associative mechanism at the rate determining step. When the incoming Hacac at the basal site undergoes chelation to eliminate the old ligand, associative attack by the free end upon the old V–O bond, which is in consonance with the proton transfer, would be responsible in determining the rate (Fig. 4).

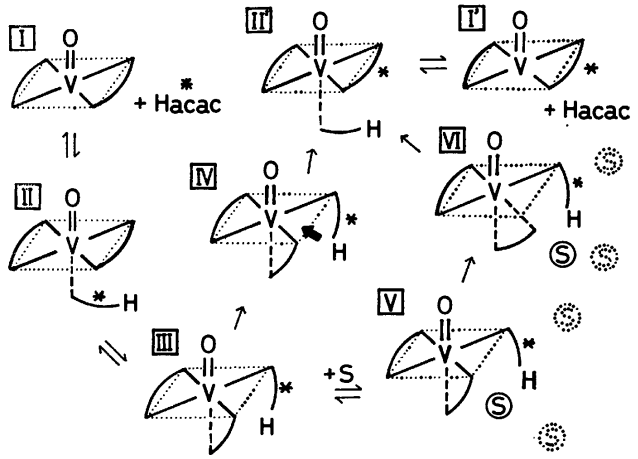

Fig. 4. Plausible reaction mechanism of the ligand exchange in DCE in the absence and the presence of donor solvents. S, donor solvent molecule; arc-like curves, acac$^-$; *, ^{14}C-labelled ligands; thick broken line, weak interaction.

Solvent Effect. In the presence of donor solvents the rate of exchange decreases. The extent is better correlated with Gutmann's donor number than with other parameters such as dielectric constant and dipole moment. Hence a direct interaction between the complex and the donor solvent should be taken into consideration. The kinetics were closely studied with DMSO as a model. The interaction can be understood in two ways: one is to reckon the competition between DMSO and free Hacac towards the coordination site of the complex as responsible, and presumes no difference in the actual route of isotopic exchange; the other is to anticipate a different mechanism in the presence of DMSO.

If the exchange proceeded through the same route as Eqs. 4 and 5, and DMSO molecule behaved as merely a rival of Hacac for the coordination site, the kinetic formula should be modified as Eq. 7, where K_S stands for the formation constant of the adduct [VO(acac)$_2$(DMSO)],

$$k_0 = k_2 b = k_{ex} K_L b/(1+K_S[S]), \qquad (7)$$

where [S] stands for the concentration of donor solvent. If this were valid, the plot of $1/k_2$ *vs.* [S] should give a straight line. However, the diagram is concave upwards. The activation parameters in the presence and the absence of DMSO differ significantly as shown in Table 1. Hence we have to consider that the contribution of competition should be small, not necessarily be ignored, and a different mechanism should be operating in the presence of donor solvent.

The large ΔH^* and almost zero ΔS^* in the presence of DMSO suggest that the exchange would proceed *via* a dissociative mechanism. If DMSO molecules interact with intermediate III in Fig. 4 to give an outer-sphere coordination (V), the nucleophilic attack of the free end of unidentate Hacac upon the V–O bond of the leaving acac$^-$ would be disturbed, so that the associative mechanism would not function any more. Hence a dissociative cleavage of the V–O bond of the leaving acac$^-$, which is accompanied by the proton transfer from the incoming Hacac, would become responsible for the exchange (VI in Fig. 4). (A dissociative mechanism could operate on the adduct [VO(acac)$_2$(DMSO)], but such a route would operate independently of the free Hacac concentration to bring about an intercept on Fig. 3. Absence of intercept on Fig. 3 excludes such a route.) Thus we can conclude that the main role of a donor solvent molecule should be an outer sphere coordination to the intermediate, which hinders the progress of associative rate-determining step of the exchange. Formation of an inactive adduct as [VO(acac)$_2$(DMSO)] would give only a minor contribution, if not necessarily nothing.

Haake and Pfeiffer introduced a new parameter, number of solvent participation, n.[19] This figure indicates the number of solvent molecules which interact with the substrate complex to inhibit the attack of a nucleophilic reagent upon the substrate. The n values were measured in the present system to be 1.6, 0.6, and 1 to 2 (depending on the concentration of methanol), for DMSO, AN and methanol in DCE, respectively. The non-integral figures reflect the complexicity with which the donor solvent molecules interact with the substrate. They may compete with Hacac in the formation of II (Fig. 4), and more than one molecule can interact with III to give V. Hence the n values do not seem to contradict our reaction mechanism.

The Analogs of Hofmann Type Clathrate Formed between Diammine- or Diaminemetal(II) Tetracyanometallate(II) Host and Aromatic Guest Molecule

Toschitake IWAMOTO, Mamoru KIYOKI, Yutaka OHTSU, and Yasuko TAKESHIGE-KATO

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo 153

(Received July 29, 1977)

A novel series of clathrates $Cd(tn)M'(CN)_4 \cdot 2G$ ($M'=Cd$ or Hg; $G=C_4H_4S$, C_4H_5N, C_6H_6, or $C_6H_5NH_2$) were prepared as an analogous series of Hofmann type clathrate. Including the novel series, Hofmann type and the analogous clathrates with a general formulation $M(diam)M'(CN)_4 \cdot 2G$ were classified into five groups according to the combination of the host constituents and the resulting host framework structures as follows: Hofmann type $M(NH_3)_2M'(CN)_4 \cdot 2G$ with square-planar $M'(CN)_4$, Hofmann-en type $Cd(en)NM'(CN)_4 \cdot 2G$ with ambident en and square-planar $M'(CN)_4$, Hofmann-Td type $Cd(NH_3)_2M'(CN)_4 \cdot 2G$ with tetrahedral $M'(CN)_4$, en-Td type $Cd(en)M'(CN)_4 \cdot 2G$ with ambident en and tetrahedral $M'(CN)_4$, and tn-Td type $Cd(tn)M'(CN)_4 \cdot 2G$ with ambident tn and tetrahedral $M'(CN)_4$. Their structural features were discussed based on the flexibility of the framework whether it can enclathrate aniline as the largest guest or not.

Among the clathrates formed between metal complex host and aromatic guest molecules, a family can be grouped with a general formulation $M(diam)M'(CN)_4 \cdot 2G$ where M refers to a bivalent metal ion, diam to diammine or diamine ligand, $M'(CN)_4$ to a square-planar or tetrahedral tetracyanometallate(II), and G to an aromatic guest species. This family of the clathrates originates from Hofmann's benzene clathrate $Ni(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$ first prepared in 1897.[1] The naming "Hofmann type clathrate" was proposed to the clathrates with a general formulation $M(NH_3)_2M'(CN)_4 \cdot 2G$ (M=Mn, Fe, Co, Ni, Cu, Zn, or Cd; M'=Ni, Pd, or Pt; $G=C_4H_4S$, C_4H_5N, C_6H_6, $C_6H_5NH_2$, or $C_{12}H_{10}$),[2-6] in which the host is isostructural to that of the original Hofmann's clathrate.[7-10] Several analogous clathrates have been prepared by replacing $(NH_3)_2$ in Hofmann type by an ambident en ligand,[11-13] or by replacing the square-planar $M'(CN)_4$ by tetrahedral $M'(CN)_4$ (M'=Cd or Hg).[14-16] In this paper, a novel series of $Cd(tn)M'(CN)_4 \cdot 2G$ clathrates will be reported for M'=Cd or Hg and $G=C_4H_4S$, C_4H_5N, C_6H_6, or $C_6H_5NH_2$. Some novel members of the known series will also be described. Their structural features will be discussed on the basis of the flexibility of host framework whether the host can enclathrate aniline as the largest guest or not. According to these features the family of Hofmann type and the analogous clathrates including the present novel one can be classified into five groups.

Experimental

Preparation. *$Cd(tn)M'(CN)_4 \cdot 2G$ ($M'=Cd$ or Hg; $G=C_4H_4S$, C_4H_5N, C_6H_6, or $C_6H_5NH_2$)*: Fifteen millimoles of tn (trimethylenediamine) was added to an aqueous solution of $CdCl_2$ (5 mmol in 50 cm³). A white precipitate once formed did not completely dissolve away by adding the excessive amounts of tn. After the small amounts of undissolved precipitate were filtered off, $K_2[M'(CN)_4]$ (5 mmol in 50 cm³ aq solution) was added to the filtrate in a conical flask. The aqueous phase was kept in contact with the organic phase of the relevant guest species mixed with xylene (1:1) in the flask covered by a stopper for a few weeks in a refrigerator. Colorless crystals grown up on the interface between the aqueous and the organic phases were picked out, washed successively with small amounts of water and ethanol, and dried on a sintered clay plate in a desiccator charged with silica gel desiccator and saturated vapor of neat liquid of the guest species.

$Cd(en)M'(CN)_4 \cdot 2G$ ($M'=Cd$ or Hg; $G=C_4H_4S$ or C_4H_5N): These clathrates were prepared by the methods analogous to those for $Cd(en)Ni(CN)_4 \cdot 2G$[13] and $Cd(en)M'(CN)_4 \cdot 2C_6H_6$[14] using the relevant combination of the potassium tetracyanometallate(II) and the guest species diluted with xylene.

$Cd(NH_3)_2M'(CN)_4 \cdot 2C_6H_5NH_2$ ($M'=Cd$ or Hg): After aniline–xylene mixture (1:1) was shaken with an aqueous solution (*ca.* 100 cm³) containing 5 mmol each of $CdCl_2$ and $K_2[M'(CN)_4]$, and 15 cm³ of concd ammoniacal water at 0 °C, the whole mixture was kept standing in a refrigerator for a few weeks. Colorless crystals were grown up on the interface between the organic and the aqueous phases separated spontaneously. The crystals were treated with the procedure similar to that for $Cd(tn)M'(CN)_4.2C_6H_5NH_2$.

$Cd(NH_3)_2Hg(CN)_4 \cdot 2C_6H_6$:[17] A benzene–xylene (1:1) mixture was placed over an aqueous solution (*ca.* 100 cm³) containing 5 mmol each of $CdCl_2$ and $K_2[Hg(CN)_4]$ and 15 cm³ of concd ammoniacal water in a conical flask. The flask covered with a stopper was kept standing in a refrigerator for a few weeks. Colorless crystals grown up on the interface between the aqueous and the organic phases were treated similarly to the above-mentioned method.

Measurements. The powder X-ray diffraction patterns were recorded on a JEOL diffractometer with Ni-filtered Cu$K\alpha$ radiation and a GM counter. Preliminary single crystal diffraction data were collected with Weissenberg photographs. The infrared spectra were recorded on a JASCO DS403G spectrometer in the 4000—400 cm^{-1} region for the Nujol and the hexachlorobutadiene mulls.

Results and Discussion

Formation and Classification of the Clathrates. The analytical results of the clathrates prepared in the present study are listed in Table 1. It was rather difficult to obtain stoichiometric results for the thiophene clathrates because of the high dissociation pressure and the small dimensions of thiophene molecule. All the clathrates presently prepared as well as those previously reported are generally not stable enough to retain guest species stoichiometrically in an open atmosphere at

room temperature. There is a tendency that the guest species with lower boiling point of its neat liquid is more easily released from the clathrate. Even in the case of Hofmann type biphenyl clathrate, the decomposition occurs gradually.[6] Therefore, analytical results were often poor for finely crystallized samples owing to the partial decomposition of the products. However, it is again difficult to evacuate the guest completely from the host for those clathrates with ambident diamine ligands and tetrahedral M'(CN)$_4$ in the host framework. For example, it took longer than 24 h to evacuate benzene completely from Cd(tn)Hg(CN)$_4$·2C$_6$H$_6$ under a reduced pressure at 80 °C.

The formation of clathrate is feasibly diagnosed on the infrared spectrum of the product. The characteristic bands are those of the out-of-plane CH bending modes for the aromatic guest, and additionally those of the NH or NH$_2$ vibration modes for pyrrole or aniline guest. Some of the typical results are given in Table 2.

Those clathrates which so far have been prepared with the general formulation M(diam)M'(CN)$_4$·2G are seen in Table 3 with the classification and the tentative namings. The M metal was limited to cadmium(II) for those clathrates other than Hofmann type. Zinc(II) did not give any stable clathrates, and mercury(II) precipitates its cyanide or diaminedicyanomercury(II) complexes under the preparation procedures described in Experimental section. The bivalent metal cations of Mn, Fe, Co, Ni, and Cu which give the host complex of Hofmann type[5] never gave the clathrates with the diamine ligands presumably because of the high stabilities of their en or tn chelated species in solution.

The classification is defined on the combination of host constituents diam and M'(CN)$_4$, the geometrical features of which rule the size and shape of the cavities for guest molecule. The host framework with square-planar M'(CN)$_4$ gives a tetragonal[10,12] or rhombic[18] rectangular box to a guest molecule. There are two

kinds of cavities in the host framework with tetrahedral M'(CN)$_4$. One is similar to the rectangular box in the square-planar framework, and the other is a biprismatic box as has been demonstrated for Cd(en)Cd(CN)$_4$·2C$_6$H$_6$[15] and Cd(NH$_3$)$_2$Hg(CN)$_4$·2C$_6$H$_6$.[16] When diam is $(NH_3)_2$ there is no bridge between two six-coordinate M metals. On the other hand, ambident en or tn bridges two Cd atoms to make the host framework less flexible.

Structural Features of the Classified Clathrates. The host of Hofmann type M(NH$_3$)$_2$M'(CN)$_4$·2G is built of two-dimensional sheets of square-planar M(NC)$_4$ and M'(CN)$_4$ arrays in which the ambident CN ligand bridges adjacent M and M' atoms; the two NH$_3$ ligands coordinate to an M metal up and down from the sheet.[6-10] Among the stacked sheets guest molecules are enclathrated. The larger the dimensions of guest are, the longer becomes the distance between the sheets.[5] The observed distance ranges from 7.97 Å for a pyrrole clathrate to 9.33 Å for an aniline clathrate. An exceptionally long distance 12.65 Å has been observed for a biphenyl clathrate Ni(NH$_3$)$_2$Ni(CN)$_4$·2C$_{12}$H$_{10}$.[6]

Hofmann-en type Cd(en)M'(CN)$_4$·2G (M'=Ni or Pd) is obtained by replacing two NH$_3$ ligands of Hofmann type structure between the adjacent square-planar sheets by an ambident en ligand bridging two Cd atoms in the respective sheets. The resulting three-dimensional host framework gives a limit to the dimensions of guest molecule within the distance between the sheets. Therefore, aniline molecule can no longer be enclathrated in Hofmann-en type host. The longest distance between the sheets has been observed for a benzene clathrate Cd(en)Ni(CN)$_4$·2C$_6$H$_6$ to be 8.06 Å,[12] and the distance decreases to 7.86 Å in the pyrrole clathrate Cd(en)Ni(CN)$_4$·2C$_4$H$_5$N.[18]

Hofmann-Td and en-Td types are derived from Hofmann and Hofmann-en types by replacing the square-planar M'(CN)$_4$ by tetrahedral M'(CN)$_4$. In Hofmann-Td type host Cd(NH$_3$)$_2$M'(CN)$_4$ (M'=Cd or Hg), three-dimensional host framework is built of *catena*-tetra-μ-cyanometallate(II) bridging M' and Cd(NH$_3$)$_2$. This structure resembles PdO structure when the square-planar Pd and tetrahedral O sites are occupied by Cd(NH$_3$)$_2$ and M'(CN)$_4$, respectively, and the PdO linkage is replaced by the Cd–NC–M' linkage.[16] In en-Td type, the six-coordinate Cd atoms are additionally bridged by an ambident en ligand instead of two protrusions of ammine ligands.[15] This additional Cd–en–Cd bridge makes the en-Td host framework less flexible than Hofmann-Td host framework. The former cannot enclathrate aniline molecule but the latter can.

Among the powder diffraction patterns of the novel members of en-Td type clathrates, that of Cd(en)Cd(CN)$_4$·2C$_4$H$_4$S can be interpreted in terms of a tetragonal system as likely to those of Cd(en)Cd(CN)$_4$·2C$_6$H$_6$ and Cd(en)Hg(CN)$_4$·2C$_6$H$_6$.[14,15] The unit cell dimensions a=8.16 Å and c=15.62 Å are shorter in a by 0.1 Å and longer in c by 0.1 Å than those of Cd(en)Cd(CN)$_4$·2C$_6$H$_6$ (a=8.26 Å and c=15.50 Å).[15] Since the a dimension of the latter corresponds to the Cd–en–Cd bridge length in its host framework, the length decreases to 8.16 Å in the thiophene clathrate by assuming that the both framework structures are isostructural to each other. The decrement in a appears to be cancelled by the increment in c to keep the host framework tetragonal. Those diffraction patterns of Cd(en)Cd(CN)$_4$·2C$_4$H$_5$N, Cd(en)Hg(CN)$_4$·2C$_4$H$_4$S, and Cd(en)Hg(CN)$_4$·2C$_4$H$_5$N could not be assigned to any tetragonal system or those systems with higher symmetries. Monoclinic or triclinic distortion may occur in these host frameworks to hold the smaller guest molecules with optimal fitness.

a) The eleven strong lines are listed.

When the ambident en in Cd–en–Cd bridge in en-Td type is replaced by an ambident tn, the novel host tn-Td type is derived. In tn-Td type, the powder diffraction pattern of Cd(tn)Hg(CN)$_4$·2C$_6$H$_6$ was assigned to a tetragonal system with a=8.67 Å and c=14.81 Å as listed in Table 4. Assuming that the tn-Td benzene clathrate has the structure similar to that of the en-Td type Cd(en)Cd(CN)$_4$·2C$_6$H$_6$ except that the en is replaced by the tn, the a dimension 8.67 Å corre-

sponds to the Cd–tn–Cd bridge length. The 0.4 Å increment in a appears to be cancelled by the 0.7 Å decrement in c from those for Cd(en)Cd(CN)$_4$·2C$_6$H$_6$ so that the volumes per a benzene molecule in the both structures are 278 and 284 Å^3, respectively.

Another fact to be noted is that tn-Td host can enclathrate aniline molecule which is rejected by en-Td host. The Cd–tn–Cd bridge length appears to be 8.80 Å in Cd(tn)Cd(CN)$_4$·2C$_6$H$_5$NH$_2$ structure preliminarily refined using the single crystal diffraction data. The refinement has not been advanced from the present stage with R=0.18 because of disorders in the conformation of tn molecules and in the orientation of aniline molecules in the monoclinic unit cell with dimensions a=11.86 Å, b=13.01 Å, c=15.14 Å, and β=89.01° (Z=4). However, the distance between two Cd atoms linked with a tn molecule can be read on the Fourier projection at the present stage.

Since Baur and Schwarzenbach examined to develop "Hofmann type clathrate" from Hofmann's Ni(NH$_3$)$_2$-Ni(CN)$_4$·2C$_6$H$_6$ by replacing the octahedral Ni by Cu, Zn, and Cd,[19] the present authors and coworkers have developed several types of M(diam)M'(CN)$_4$·2G clathrates. The purpose of these investigations was to materialize an idea to design a host framework of metal complex with an appropriate combination of host constituents in order to enclathrate desired guest molecule. A successful example may be seen in the case of tn-Td type host enclathrating aniline molecule. However, tn-Td host appears not to have a capability to enclathrate styrene molecule.

The authors wish to express their thanks to Professors Niro Matsuura and Yukichi Yoshino for their kind supports and encouragement throughout this work. This work was partially supported by Grants-in-Aid for Scientific Research from the Ministry of Education, Nos. 054070 and 047027.

The Crystal Structure of Guanidinium Hexamolybdobis(phenylarsonate) Tetrahydrate, $(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2]\cdot 4H_2O$

Kazuko Y. MATSUMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 17, 1977)

Two heteropoly anions, $[C_6H_5AsMo_6O_{21}(H_2O)_6]^{2-}$ and $[(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}$, have been synthesized by the reaction of phenylarsonic acid with molybdenum trioxide in an aqueous solution of pH *ca.* 2. The latter anion has been subjected to crystal-structure analysis as a guanidinium salt, $(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2]\cdot 4H_2O$, and a heteropoly anion with a new type of structure has been established. The crystal is monoclinic with the space group of $P2_1$ and cell dimensions of $a=13.754(5)$, $b=15.752(7)$, $c=11.900(5)$ Å, $\beta=115.59(2)°$, $V=2325.3$ Å^3, $D_m=2.25$, $D_x=2.28$ g cm^{-3}, and $Z=2$. The formula of the anion has been proved to be $[(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}$, which is different from the expected formula, $[(C_6H_5As)_2Mo_6O_{24}]^{4-}$, though the latter had previously been proposed on the basis of a ^{17}O NMR study and an independent X-ray investigation of the methyl derivative had confirmed the existence of the $[(CH_3As)_2Mo_6O_{24}]^{4-}$ anion. The present anion, $[(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}$, consists of six MoO_6 octahedra, which form a ring with one face-, two corner- and three edge-sharings, the two $C_6H_5AsO_3$ tetrahedra are attached to the ring from above and below, with their three oxygens shared with molybdenums. The two phenyl groups are oriented upwards and downwards from the ring respectively.

In a previous paper[1] the present author reported the structure of two heteropoly molybdates derived from methylarsonic acid and dimethylarsinic acid. That study suggested the possibility that many other such acids with metal-organic group bonds may act as hetero elements to enter poly anions. Thus, the author has continued this preparative and structural study, extending the hetero parts from methyl derivatives to a phenyl derivative of arsenic acid. In this paper the author will report on the crystal structure of $(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2]\cdot 4H_2O$; a preparative description of this appeared as early as in 1913,[2] but the analytical results seem unsatisfactory and no further study has been undertaken since.

Experimental

Preparation. Two g (0.01 mol) of $C_6H_5AsO_3H_2$ and 0.8 g of NaOH were dissolved in 500 ml of water and then 8.6 g (0.06 mol) of MoO_3 was gradually added while the solution was heated to boiling. After the solution had then been filtered to remove the small amount of unreacted MoO_3, the filtrate was condensed to 75 ml on a water bath and 2 g of CN_3H_6Cl was added. A colorless precipitate which appeared instantly was filtered out. The reaction of the formation of the heteropoly anion may be described as follows:

$$2C_6H_5AsO_3^{2-} + 6MoO_3 + H_2O \longrightarrow [(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}.$$

The results of elemental analyses are: Found: C, 11.99; H, 2.72; N, 10.38%. Calcd for $(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2]\cdot 4H_2O$: C, 12.05; H, 2.79; N, 10.55%.

After the filtrate had stood at room temperature for about a week, colorless, bush-like crystals appeared. Their composition was formulated as $(CN_3H_6)_2[C_6H_5AsMo_6O_{21}(H_2O)_6]\cdot 3H_2O$, and from the IR spectrum the anion was concluded to be analogous to the corresponding methyl derivative reported in a previous paper.[1] The formation reaction may be described as follows:

$$C_6H_5AsO_3^{2-} + 6MoO_3 + 6H_2O \longrightarrow [C_6H_5AsMo_6O_{21}(H_2O)_6]^{2-}.$$

The results of elemental analyses are: Found: C, 7.32; H, 2.65; N, 6.28%. Calcd for $(CN_3H_6)_2[C_6H_5AsMo_6O_{21}(H_2O)_6]\cdot 3H_2O$: C, 7.13; H, 2.63; N, 6.24%.

Crystal Data. The single crystal of $(CN_3H_6)_4[(C_6H_5As)_4Mo_6O_{25}H_2]\cdot 4H_2O$ was obtained by the diffusion method, its approximate dimensions were $0.1\times0.15\times1.0$ mm. Preliminary Weissenberg photographs exhibited a monoclinic symmetry, and the observed systematic absence indicated the space group to be $P2_1/m$ or $P2_1$. However, a satisfactory solution for the Patterson map was achieved only when $P2_1$ was assumed, hence, the space group was determined to be $P2_1$. The crystal data are as follows:

$(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2]\cdot 4H_2O$
monoclinic $P2_1$
$a = 13.754(5)$
$b = 15.752(7)$
$c = 11.900(5)$ Å
$\beta = 115.59(2)°$
$V = 2325.3$ Å^3
$M.W. = 1594.2$
$Z = 2$
$D_m = 2.25$
$D_x = 2.28$ g cm^{-3}
$\mu = 16.6$ cm^{-1} (for Mo $K\alpha$ radiation)

Data Collection. All the intensities were measured on a Philips automatic four-circle diffractometer. Graphite-monochromated Mo $K\alpha$ radiation was used, and the scan mode was ω-2θ, with a scan rate of 2θ 1° min^{-1}. The scan range was calculated for each reflection according to this formula: $\omega=1.4+0.6\tan\theta$, and stationary-crystal, stationary-counter background counts of 20 s were taken at the end of each scan. In order to check the crystal deterioration, three standard reflections were monitored every three hours, but no significant intensity loss was observed throughout the data collection. The data were corrected for the Lorentz and polarization effects. No absorption or extinction corrections were applied. The intensities were collected up to $2\theta=60°$, and 4720 independent reflections with $|F_o|\geq3\sigma(|F_o|)$ were used for further computation.

Solution and Refinement of the Structure. The coordinates of the molybdenum atoms were determined from the Patterson map, while all the remining non-hydrogen atoms were located from the successive Fourier syntheses. After the structure had been refined with isotropic temperature factors by the block-diagonal least-squares method, anisotropic temperature factors were applied to all the atoms. After the refinement had been

continiued several more cycles, the final R value was 0.066 ($R=\sum||F_o|-|F_c||/\sum|F_o|$).

The final atomic coordinates and temperature factors are listed in Tables 1 and 2 respectively. The F_o-F_c table is kept at the office of this Bulletin (Document No. 7801). The atomic scattering factors were based on Ref. 3, and the effects of the anomalous dispersion for molybdenum and arsenic were corrected according to Ref. 4. All the calculations were performed on a HITAC 8700/8800 computer at the Computer Center of the University of Tokyo.

Description of the Structure and Discussion

The structure of the anion is depicted in Fig. 1, while the interatomic distances and angles within the anion and guanidinium cations are listed in Tables 3 and 4.

Each molybdenum is octahedrally coordinated by six oxygen atoms, and the anion is constituted of six MoO_6 octahedra and two $C_6H_5AsO_3$ tetrahedra. These octahedra are connected with one face-sharing (the shared face is O(13)–O(14)–O(15)), two corner-sharings (the shared corners are O(9) and O(18)), and three edge-sharings (the shared edges are O(4)–O(5), O(1)–O(6), and O(22)–O(23)) to form a ring. The six molybdenum atoms are not coplanar. Each of the two arsenics is tetrahedrally coordinated by three oxygen atoms and a phenyl group, and each joins the ring through sharing the three oxygens with molybdenums, one arsenic atom from above and the other from below the ring. These two arsenics are not, however, equivalent in their bonding manner. As(1) is bonded to O(5), O(14), and O(23), each of which is shared with two molybdenums besides As(1), whereas As(2) is coordinated by O(6), O(8), and O(21), of which each of O(8) and O(21) is bonded to one molybdenum and O(6) is shared with two molybdenums. There is no significant difference observed between the bond lengths and angles in the two $C_6H_5AsO_3$ tetrahedra of the present anion and those of free arsonic acid.[5]

Just before the present structural analysis had been completed, the ^{17}O NMR spectra of a heteropoly molybdate containing phenylarsonic acid was reported.[6] Based on the similarity of its spectral pattern to that of $[TeMo_6O_{24}]^{6-}$, the formula of the anion was concluded to be $[(C_6H_5As)_2Mo_6O_{24}]^{4-}$, which has one less oxygen than the present anion. Then the problem arose of whether these anions are really different anions or whether they are the same but have been considered to be different merely because of an erroneous interpretation of the experimental results. However, subsequent X-ray structural analysis of the analogous methyl derivative, $[(CH_3As)_2Mo_6O_{24}]^{4-}$, confirmed its formula and structure,[7] which is depicted in Fig. 2, and it was concluded that there are two kinds of heteropoly molybdate anions, both of which have a hetero part to the molybdenum atoms in the ratio 2:6, but which are different in the number of their oxygens. The $[(CH_3As)_2Mo_6O_{24}]^{4-}$ anion is synthesized at pH 4—5 and consists of six MoO_6 octahedra, all of which share

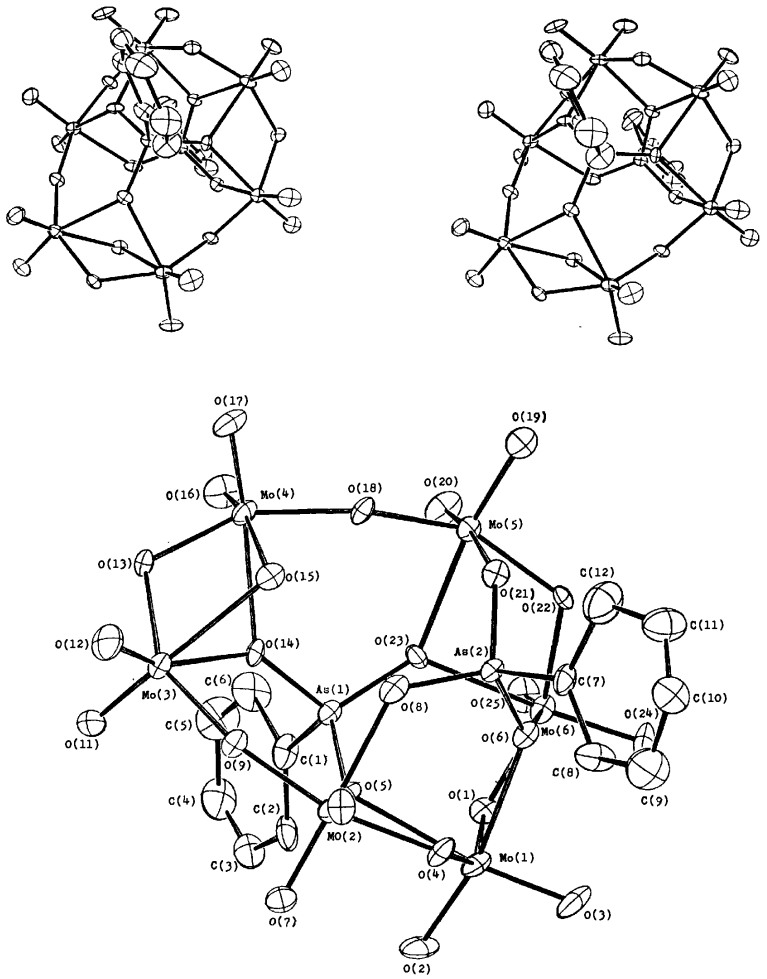

Fig. 1. Stereoscopic view of the $[(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}$ anion, with the vibrational ellipsoids drawn at the 50% probability level (ORTEP, Johnson, 1971).

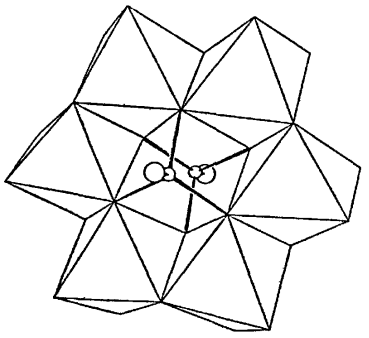

Fig. 2. The structure of the $[(CH_3As)_2Mo_6O_{24}]^{4-}$ anion. All the MoO_6 groups are expressed as octahedra.

edges to form a coplanar ring.

The crystal structure viewed along the b axis is shown in Fig. 3, while the interionic distances are listed in Table 5.

Parallel to the present work, Pope *et al.* have independently studied the same system, consisting of MoO_4^{2-} and $RAsO_3^{2-}$. However, the anions they obtained were $[(RAs)_2Mo_6O_{24}]^{4-}$ and $[(RAs)_4Mo_{12}O_{46}]^{4-}$ (R=CH_3, C_6H_5, and *p*-$NH_2C_6H_4$ for the former and R=CH_3, C_2H_4OH, C_6H_5, and *p*-$NH_2C_6H_4$ for the latter), whose structures have been clarified by the X-ray diffraction technique.[7,8] This system thus exhibits a complicated aspect, giving various heteropolyanions with different ratios of molybdenum to hetero parts depending on the pH of the solution. All these reactions are summarized below, including both the present work and that of Pope *et al.*:

(I) $RAsO_3^{2-} + 6MoO_3 + 6H_2O \xrightarrow{\text{pH 2}} [RAsMo_6O_{21}(H_2O)_6]^{2-}$ [1]

(II) $2RAsO_3^{2-} + 6MoO_3 + H_2O \xrightarrow{\text{pH 2}} [(RAs)_2Mo_6O_{25}H_2]^{4-}$

(III) $4RAsO_3^{2-} + 12MoO_3 + 4H^+ \xrightarrow{\text{pH 2}} [(RAs)_4Mo_{12}O_{46}]^{4-} + 2H_2O$ [8]

(IV) $2RAsO_3^{2-} + 6MoO_3 \xrightarrow{\text{pH 4.5}} [(RAs)_2Mo_6O_{24}]^{4-}$ [8]

Symmetry code

i	$-x$,	$0.5+y$,	$1.0-z$
ii	$-x$,	$0.5+y$,	$-z$
iii	x,	y,	$-1.0+z$
iv	$1.0+x$,	y,	z
v	$-1.0-x$,	$0.5+y$,	$-1.0-z$
vi	$-1.0-x$,	$-0.5+y$,	$-z$

The (III) anion is of the same structural type as $[As_4Mo_{12}O_{50}H_4]^{4-}$, in which R groups are replaced

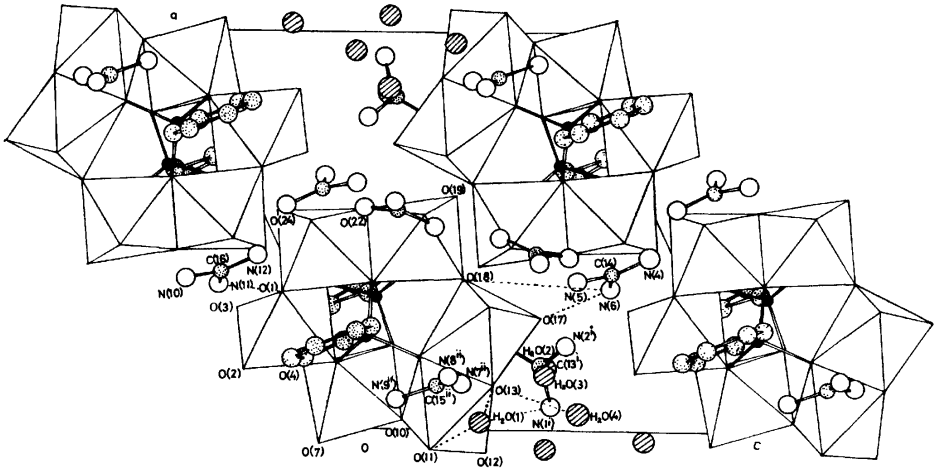

Fig. 3. The crystal structure of $(CN_3H_6)_4[(C_6H_5As)_2Mo_6O_{25}H_2]\cdot 4H_2O$ viewed along b axis.

by hydroxyl groups.[9] The (IV) anion is probably structurally analogous to $[As_2Mo_6O_{26}]^{6-}$.[10]

In such a system where two or more anions may be expected to exist in equilibrium with one another, it is of interest and important to know what species is formed and stable in which pH region and what equilibrium relations exist among them in the solution. Although the study attempting to clarify these points is still in progress and has not been completed, an interesting interconversion through dehydration and rehydration has been proved, with the aid of the Raman, IR, and 90 MHz ^{1}H FT-NMR spectra, to occur between the $[(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}$ and $[(C_6H_5As)_2Mo_6O_{24}]^{4-}$ anions when the CD_3CN solution of $(n\text{-}Bu_4N)_4[(C_6H_5As)_2Mo_6O_{25}H_2]$ is kept at 90 °C and then cooled to room temperature, as is expressed in the following:[11]

$$[(C_6H_5As)_2Mo_6O_{25}H_2]^{4-} \xrightarrow[90^\circ C]{-H_2O} [(C_6H_5As)_2Mo_6O_{24}]^{4-}$$

$$\xrightarrow[r.t.]{H_2O} [(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}$$

It can not said decisively what the two hydrogen atoms in the $[(C_6H_5As)_2Mo_6O_{25}H_2]^{4-}$ anion are bonded to. However, the above-mentioned interconversion caused by hydration and dehydration and the two anomalously long Mo–O bonds to O(15) (Mo(3)–O(15) is 2.393 Å and Mo(4)–O(15) is 2.478 Å; see Fig. 1 and Table 3) suggest that O(15) is a water molecule and is bridging Mo(3) and Mo(4).

The author wishes to express her thanks to Professor M. T. Pope of Georgetown University, who kindly sent her the IR data and some other helpful information on compounds related to those in the present work. The author is also indebted to Professor Yukiyoshi Sasaki of the University of Tokyo for his continual interest in the present work. Thanks are also due to Prefessor Hisao Kuroya and Dr. K. Matsumoto of Osaka City University for the use of a Philips automatic diffractometer.

1-Allylpyrazole as a Ligand. V.*) Preparation and Characterization of Some Iron(0) and Group VI Metal(0) Carbonyls

Kazuo FUKUSHIMA, Takeshi MIYAMOTO, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 25, 1977)

The 1-allylpyrazole complexes of the general formula $Fe(CO)_3L$ (L=substituted 1-allylpyrazoles) have been prepared by the photochemical reaction of $Fe(CO)_5$ in the presence of 1-allylpyrazoles, and characterized by the IR, ^1H-, and ^{13}C-NMR spectroscopies. These complexes show a large decrease of ν(C=C) frequency and ^1H- and ^{13}C-NMR upfield shifts of the olefinic nuclei compared with free ligands. The upfield shifts of olefinic ^1H-NMR spectra are not influenced by the substituent groups on the pyrazole ring, but, so far as the terminal olefinic protons are concerned, the shifts are distinctively decreased on replacement of the allyl by the 2-methylallyl group. The upfield shifts of ^{13}C-NMR spectra substantially parallel those of ^1H-NMR spectra in these complexes. On refluxing $Fe(CO)_3L$ in a hexane solution containing PPh_3, the complex liberates 1-allylpyrazole to give *trans*-$Fe(CO)_3(PPh_3)_2$ in a small yield. Some new complexes of general formula $M(CO)_4L$ (M=Cr, Mo, or W, L= 1-allylpyrazole) have also been prepared for comparison.

In order to rationalize the metal-olefin bond, Dewar, Chatt and Duncanson had postulated a model,[1] which emphasized the dual bonding nature, that is, olefin→metal σ-donation and metal→olefin π-back donation. The properties of some metal–olefin complexes have been well explicated by this model. However, many types of the olefin complexes are now accumulating, and in order to elucidate the particular bonding nature in each type of the complexes, it is important to study systematically closely related complexes.

In previous reports,[2–5] we have already prepared and characterized a large number of the 1-allylpyrazole–transition metal complexes. Thus successful preparation of these chelating-olefin complexes has so far enabled us to obtain much information concerning the particular bonding nature in each metal complex. We have now extended our study to a series of iron(0) complexes $Fe(CO)_3L$ (L=substituted 1-allylpyrazole), and spectroscopically characterized these complexes. Spectroscopic data on the isolated iron complexes are compared with those of other olefin–transition metal complexes. The effects of pyrazole substituents upon the metal–olefin and metal–carbonyl bonds are also discussed on the basis of IR and NMR data.

Experimental

All manipulations were carried out under a nitrogen atmosphere. The solvents were dried over sodium wire or lithium aluminium hydride and were distilled just before use. Metal carbonyls (Strem Chemicals or Pressure Chemicals Co.,) were used without further purification.

The IR and ^1H-NMR spectra were recorded as described previously.[5] The ^{13}C-NMR spectra were recorded on a JEOL-PET-100 Fourier Transform Spectrometer operating at 25.2 MHz with proton noise decoupling. In order to make the assignment clear, some ^{13}C-NMR spectra were obtained without decoupling. Chemical shifts were referred to the internal standard of TMS. Samples were dissolved in $CDCl_3$ as much as possible (about 20 wt%) and sealed up under an argon atmosphere.

Ligands. The ligands were synthesized from the reaction of pyrazole derivatives with allyl halide or 2-methylallyl halide. The vigorous stirring throughout the reaction generally gave a high yield of product. The boiling points and yields of ligands are summarized in Table 1.

Table 1. List of the 1-allylpyrazoles

Abbreviation[a)]	Bp (°C/mmHg)	Yield (%)
ap	90—100/100	66
admp	90—100/30	35
amdmp	55—62 /0.2	35
atmp	85—86 /12	48
amtmp	99—103/12—14	43
admpBr	106—107/14	57
amdmpBr	118—125/14	70
admpNO_2	150—151/12	63

a) ap=1-allylpyrazole, admp=1-allyl-3,5-dimethylpyrazole, amdmp=1-(2-methylallyl)-3,5-dimethylpyrazole, atmp=1-allyl-3,4,5-trimethylpyrazole, amtmp=1-(2-methylallyl)-3,4,5-trimethylpyrazole, admpBr=1-allyl-4-bromo-3,5-dimethylpyrazole, amdmBr=1-(2-methylallyl)-4-bromo-3,5-dimethylpyrazole, amdmpNO_2=1-allyl-3,5-dimethyl-4-nitropyrazole.

Group VI Metal Complexes, $M(CO)_4(ap)$ (M=Cr, Mo, or W, ap=1-allylpyrazole). The group VI metal complexes $M(CO)_4$(ap) were prepared as described already.[5] They were sparingly soluble in hexane and were recrystallized from diethyl ether–hexane.

Tricarbonyl-1-allylpyrazoleiron(0), $Fe(CO)_3(C_6H_8N_2)$. The iron complexes were obtained in a similar manner to the group VI metal complexes. A tetrahydrofuran solution (300 ml) containing both pentacarbonyliron(0) (2.0 g, 0.01 mol) and allylpyrazole (1.1 g. 0.01 mol) was irradiated with a mercury lamp (400 W). The flask(Riko, UVL-400 HA) was equipped with a gas buret to follow the course of the reaction. In 3—4 h, the reaction was completed showing the stoichiometric evolution of CO. The amber-colored solution was evacuated to dryness and the resulting residue was completely extracted with hexane(100 ml) at room temperature. The hexane solution was filtered and condensed to half a volume *in vacuo*. On cooling the solution at −78 °C, yellow fine crystals were deposited in a yield of 80%(2.0 g). The product was purified by the repeated recrystallization from hexane.

Similarly the iron(0) complexes containing substituted 1-allylpyrazole were prepared as listed in Table 2. The complexes are soluble in most organic solvents usually used. In

* Part IV, see Ref. 5.

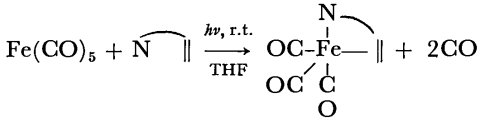
a crystalline form, they are fairly air-stable, but in a solution they are rapidly decomposed by contact with air.

No solid product was obtained in the reaction of $Fe(CO)_5$ with 1-allyl-3,5-dimethyl-4-nitropyrazole, in spite of the excessive generation of CO gas.

Reaction of $Fe(CO)_3$(ap) with PPh_3. A hexane solution containing $Fe(CO)_3$(ap)(0.3 g, 1.2 mmol) and triphenylphosphine (1.2 g, 4.6 mmol) was refluxed for 5 h. On standing, yellow crystals are formed to give a yield of 0.3 g. The product was identified to be *trans*-$Fe(CO)_3(PPh_3)_2$ by IR and elemental analysis. IR data in $CHCl_3$: 1886(s) [lit,[6] 1887 (s)] cm^{-1}.

Results and Discussion

King and coworkers[7] isolated the complexes $Fe(CO)_3$(ap) and $Fe(CO)_3$(admp) (ap=1-allylpyrazole, admp=1-allyl-3,5-dimethylpyrazole), firstly as by-product of the reaction of (π-allyl)$Fe(CO)_3I$ with potassium monohydridotris(1-pyrazolyl)borate or potassium monohydridotris(3,5-dimethylpyrazolyl)borate, and subsequently as main products of the thermal reaction of $Fe_2(CO)_9$ with the ligands (ap or admp). However, those iron complexes were not fully characterized. In our experiment, the iron complexes have been synthesized quite smoothly by the photochemical reactions of $Fe(CO)_5$ with the 1-allylpyrazole ligands, in the same way as the group VI metal carbonyl complexes.[5]



^{1}H-NMR and IR Spectra. Although a great number of iron-olefin complexes have so far been prepared,[8] the infrared spectrum, which is one of the most important criteria of the metal–olefin bond, have been curiously ignored in literatures. The IR band ν(C=C) for the iron complexes $Fe(CO)_3L$ (L=1-allylpyrazole) was tentatively assignable in comparison with the spectra of the chromium(0) analogues $Cr(CO)_4L$ in the region of 1400—1600 cm^{-1}. The lowered shifts $\Delta\nu$(C=C) for the iron complexes were determined to be *ca.* 180 cm^{-1}. This abnormally large shift of ν(C=C) well agreed with the large NMR upfield shifts of the olefinic

Table 2. Elemental analyses and (CO) frequencies

protons. The observed value $\Delta\nu$(C=C) of about 180 cm^{-1}, as well as the value of the upfield shifts $\Delta\delta$H of 2.2—3.8 ppm were much larger than those of the chromium(0) complexes ($\Delta\nu$(C=C): 120 cm^{-1}, $\Delta\delta$H: 1.0—2.4 ppm). Tolman and coworkers[9] tabulated the spectroscopic data on the many ethylene–transition metal complexes. According to the table, it can be clearly shown that the iron(0)-olefin interaction is classified as the largest, and the chromium(0)-olefin one as the medium.

Through a series of the iron complexes, $Fe(CO)_3L$, the increase of the methyl sibstituents on the pyrazole ring caused a substantial decrease of the ν(C=O) frequencies as shown in Table 2, but did not give significant changes in the final chemical shifts for the olefinic protons (Table 3), regardless of the fairly different chemical shifts of the free ligands. These results indicate that the metal-olefin bond in these iron complexes has a lower sensitivity towards the methyl substitution on the pyrazole ring, compared with the metal-carbonyl bond. The increase in the σ-donor ability of the *N*-coordinating site owing to the methyl substituents seems to promote the π-delocalization to the carbonyl moiety, but not to the olefinic group.

^{13}C-NMR Spectra. The ^{13}C-NMR spectral data for the four 1-allylpyrazole (ap) complexes are listed in Table 4 together with the shift data of the stretching frequencies of ν(C=C). The shift difference between the two olefinic carbons decreased as a result of coordination of the olefinic part in ap, compared with free ap; such a case had already been reported by Brown.[10] The ^{13}C-NMR spectra due to the olefinic carbons as a whole shifted towards a higher magnetic field from the position of the free ligands as described in the case of ^{1}H-NMR spectra. Though ^{13}C-NMR spectral data of other group VI metal–olefin complexes are not available, the observation that the ^{13}C-NMR chemical shift of the $M(CO)_4L$, where M=Cr, W, and L=ap move upfield when chromium is replaced by tungsten may be consistent with the stronger olefin–metal bond present in the tungsten complex.

While each group VI metal carbonyl complexes showed the four carbonyl carbon resonances, only one signal was found for three unequivalent carbonyls of the iron complex. As has been reported in detail by several workers,[11] it indicates the high fluctionality of the iron carbonyl complexes. The carbonyl carbon resonance for the group VI metal complexes have the following order of deshielding as: Cr>Mo>W. This is the same order as that observed in the parent hexacarbonyls $M(CO)_6$ and a series of pentacarbonyl complexes, $M(CO)_5L$ (M=Cr, Mo, or W, L=a unidentate ligand).[12]

Displacement Reaction of the Coordinated Ligand. The great tendency to the displacement of the coordinated *N*-allylpyrazole by the strong donor ligands has been the most remarkable feature for the Pt(II), Cr(0), and Mo(0) complexes.[3,5] The iron(0) complex $Fe(CO)_3L$, however, did not react with PPh_3 under mild conditions. Only after refluxing both reagents in a hexane solution for several hours, the complex, *trans*-$Fe(CO)_3(PPh_3)_2$ was obtained in a low yield. The lability of the coordinated ap ligand in the iron complex is obviously lower than that in the chromium complex $Cr(CO)_4$(ap).

Metal–Olefin Bond Strength. The correlation between the NMR upfield shifts and the metal-olefin bond nature has not been confirmed yet.[13] One research group attributed it to the paramagnetic shielding effect induced by the non-bonding partially filled d-orbitals,[14] while the other group to the magnitude of the π-bond order due to the π-back donation.[15] Our results support the latter one, since so far as iron(0) and the group VI metals(0) concerned, the large NMR upfield shifts were always accompanied by the larger decrease in the ν(C=C) frequencies and the lower activity of the displacement of the coordinated olefinic ligand, *i.e.*, in the order of Fe>W>Cr>Mo. This result that iron(0) is more strongly bonded to the olefin than chromium(0) by the larger π-back bonding will support Hoffmann's MO calculations of the metal carbonyl fragments.[16]

The authors gratefully acknowledge Dr. Hideomi Koinuma, the University of Tokyo for ^{13}C-NMR measurements.

Stereoselective Substitution of *trans*-2-Butene for the *S,S*-2-Butene in Trichloro-*S,S*-2-buteneplatinate(II) in Acetone

Yoshiro TERAI and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received September 1, 1977)

A new complex salt $[Ph_4P][PtCl_3(S,S\text{-tbn}[1,3\text{-}^3H])]$ (tbn, *trans*-2-butene) undergoes racemization and ligand isotopic exchange in acetone containing a large excess of tbn without side reactions. Both rates are expressed by the second order rate equations, $R_{(CD)}=k_{2(CD)}[Pt][tbn]$ and $R_{(IE)}=k_{2(IE)}[Pt][tbn]$, the k_2 values being 17.6 and $70.6\times10^{-3}M^{-1}s^{-1}$ at 8.0 °C, respectively (M=mol dm^{-3}). Individual k_2 values for the substitutions without and with inversion of configuration of coordinated tbn are calculated to be 62.0 and $8.7\times10^{-3}M^{-1}s^{-1}$, respectively, the corresponding $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values being 36.3 ± 3.1 and 37.6 ± 2.7 kJ mol^{-1}, and -138 ± 12 and -149 ± 10 J·mol^{-1} K^{-1}. Source of the stereoselectivity appears to consist in the difference in ease of formation of square pyramidal transition state on the nucleophilic attack of tbn upon the complex.

In a previous paper we have reported the kinetics of ligand isotopic exchange and epimerization of *trans*(*N*, olefin)[PtCl(L-pro)(*S,S*-2-butene)] in acetone in the presence of an excess of *trans*-2-butene (tbn), and found that the coordinated *S,S*-2-butene is replaced by tbn faster with retention than with inversion of configuration by *ca.* 10 times.[1] The substrate complex has two asymmetric sources, the L-prolinate (with two asymmetric centers, the carbon and the coordinated nitrogen) and the *S,S*-2-butene. In order to find the origin of the stereoselectivity, complexes having only one source of asymmetry should be needed. We have found that *trans*(*N*,olefin)[PtCl(L-pro)(*S,S*-2-butene[1,3-^3H])] gives $[PtCl_3(S,S\text{-2-butene}[1,3\text{-}^3H])]^-$ in 6 M hydrochloric acid and crystallizs as tetraphenylphosphonium salt with retention of configuration. This salt enabled us to carry out kinetic studies of the isotopic exchange and racemization in acetone.

Experimental

Materials. Tetraphenylphosphonium trichloro-*S,S*-2-butene[1,3-^3H]platinate(II) was prepared by treating optically active [PtCl(L-pro)(*S,S*-2-butene[1,3-^3H])] (0.2 g, $\Delta\varepsilon$ at 27000 cm^{-1} 1.05) with 6 M hydrochloroic acid (4 cm^3) and tetraphenylphosphonium chloride (0.23 g) for 1 h at room temperature, and cooling in a refrigerator. The precipitated product was filtered off, air dried, and recrystallized from acetone by adding petroleum ether. Yield 0.3 g (85% on platinum). The specific activity was *ca.* 2×10^4 d.p.m. per mg, and $\Delta\varepsilon$ at 23800 cm^{-1} *ca.* 0.7. The purity was examined by the ultraviolet (UV) absorption spectrum. The elemental analysis of carbon and hydrogen was carried out by use of a similarly prepared non-radioactive sample. Found: C, 48.22; H, 4.04%, Calcd C, 48.25; H, 4.05%.

trans-2-Butene of research grade (>99.3%) from Nippon Tokushu Gas Co. was used without further purification. Acetone and acetonitrile were purified by the usual method.

Kinetic Runs. *trans*-2-Butene boils at 0.88 °C under atmosphere and the solutions for kinetic studies should be prepared carefully as follows. *trans*-2-Butene chilled in a mixture of Dry Ice and acetone (0.1 to 2 g) was swiftly added into a stoppered Erlenmeyer flask containing a known amount (30 to 40 cm^3) of acetone, weighed, and preserved in a mixture of Dry Ice and acetone. The complex solution (to produce *ca.* 5 cm^3 of 10^{-4} to 10^{-3} M) was added to 6 to 10 small test tubes kept in a mixture of Dry Ice and acetone, and the tbn solution was added to each tube by use of a pipette wrapped with powdered Dry Ice. The tubes were stoppered and kept in a thermostat at −30 to +8 °C. They were withdrawn at appropriate intervals, placed in a liquid nitrogen bath, and tbn and the solvent evaporated off in a vacuum line at Dry Ice and room temperature, respectively. The residue consisting of pure complex was dissolved in acetonitrile (5 ml), and the UV absorption and CD spectra were recorded. A 1 ml portion of the AN solution was mixed with the liquid scintillation medium (0.108 mg of *p*-bis(5-phenyl-2-oxazolyl)benzene and 4.29 g of terphenyl per 1 dm^3; 14 cm^3) and submitted to the counting of the β-rays. The density of tbn solution in acetone differs significantly at reaction and Dry Ice–acetone temperatures, and due correction was made.

The experimental results of racemization and isotopic exchange were calculated in accordance with the first order kinetic law and the McKay formula, respectively.

Measurements. The UV absorption and CD spectra were recorded with a Hitachi 323 Spectrophotometer, and JASCO J-40 Spectrometer, respectively. The radioactivity was recorded with a Liquid Scintillation Spectrometer from Nuclear Chicago. The electrolytic conductivity was measured with a Conductoscope from Metrohm Co.

Results and Discussion

Synthesis and Spectra. The UV absorption curve (Fig. 1) is very similar to that of Zeise's salt,[2] and remains unchanged for many hours both in the absence and the presence of an excess of tbn in many kinds of solvent. Konya *et al.* gave the CD spectrum of $(+)^{\Delta\varepsilon}_{330}$-*trans*(*N*,olefin)[PtCl(L-pro)(*S,S*-2-butene)] in concentrated hydrochloric acid, and considered that the pattern represented the CD of $[PtCl_3(S,S\text{-butene})]^-$.[3] The CD curve in Fig. 1 is very similar to theirs, and the small difference may be due to the difference in solvent, and to the presence of free L-proline in their solution, which can give outer-sphere perturbation. Since the tetraphenylphosphonium salt of this complex is sparingly soluble in hydrochloric acid, the pure salt must have been precipitated as shown in the Experimental part.

This salt is insoluble in water and methanol, rather readily soluble (to give 0.1 M solution) in acetone, acetonitrile (AN), *N,N*-dimethylformamide (DMF), and dichloromethane, and dissolves in dimethyl sulfoxide with gradual decomposition. The CD pattern changes very slowly in acetone, AN, and DMF. The apparent first order rate constant of the spontaneous racemization

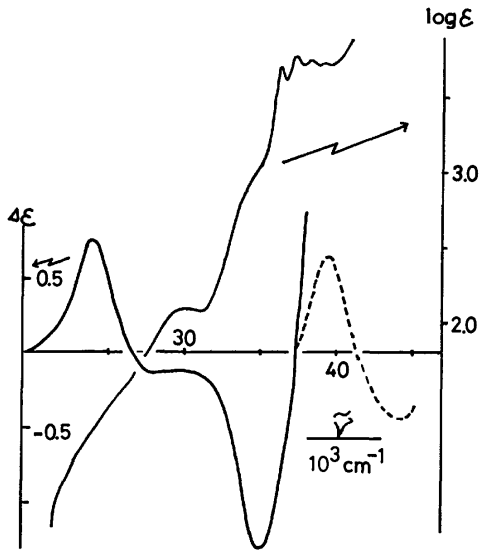

Fig. 1. Ultraviolet (UV) absorption and circular dichroism (CD) spectra of $[(C_6H_5)_4P][PtCl_3(S,S\text{-2-butene})]$ in acetonitrile (AN) at room temperature.

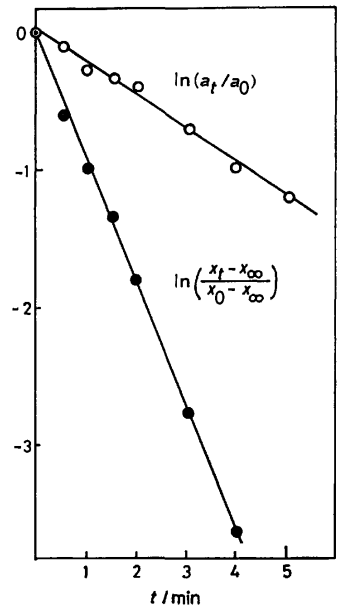

Fig. 2. The first order kinetic plots of the racemization (○) and isotopic exchange (●) of $[PtCl_3(S,S\text{-2-butene-}[^3H])]^-$ in acetone at 8.0 °C. [Complex], 8.61×10^{-4} M, [tbn], 0.218 M

is $<3\times10^{-6}$ s^{-1} at 15 °C in acetone. Addition of water, acetic acid and alcohols enhanced whilst that of chloride retarded the spontaneous racemization. However, under the present experimental conditions, such a CD change can be ignored. Molar conductivity measurement in acetone gave a straight line on the plot *vs.* square root of concentration of this salt for $<1\times10^{-3}$ M. The degree of electrolytic dissociation of a 0.9×10^{-3} M solution (almost equal to the concentration at which the kinetic studies were made) was 0.91 at 8.0 °C.

Kinetic Data. The absorption spectrum of the reaction mixtures was equal to that of the complex and remained unchanged during the course of the kinetic runs. The kinetic measurements were made in the concentration ranges, [complex]=0.0005 to 0.003 M and [*trans*-2-butene]=0.02 to 1.15 M (40 to 1500 times excess to the complex). The CD strength at 23800 cm^{-1} decreased with time to reach zero at infinite time, and the diagram $\ln(a_t/a_0)$ *vs.* t was straight as shown in Fig. 2. (a_t and a_0 stand for the CD strengths at time t and zero, respectively). The observed first order rate constant $k_{o(CD)}$ increased linearly with increase in free tbn concentration, and it did not change on addition of tetraphenylphosphonium chloride (Fig. 3). The decrease in specific β-activity of the recovered complex also decreased in accordance with first order rate law as shown in Fig. 2, where x's denote the specific counting rate at the times indicated by the subscripts. McKay's R was proportional to the concentration of the complex, and the observed first order rate constant $k_{o(IE)}$ increased linearly with increase in concentration of the free tbn as shown in Fig. 3.

Thus the rate constants obtained by both CD and β-activity measurement can be written as Eqs. 1 and 2.

$$k_{o(CD)} = k_{2(CD)}[tbn] \quad (1)$$

$$k_{o(IE)} = k_{2(IE)}[tbn] \quad (2)$$

The k_2 values are shown in Table 1.

The linear diagrams in Fig. 3 give no intercept. The spontaneous racemization was very slow, and the racemization must proceed exclusively *via* a bimolecular mechanism. When the individual second order rate constants of the substitution reaction with retention and inversion of configuration are written as $k_{2[SS]}$ and $k_{2[SR]}$, they are related to the observed k_2's by Eqs. 3 and 4.

$$k_{2(CD)} = 2k_{2[SR]} \quad (3)$$

$$k_{2(IE)} = k_{2[SR]} + k_{2[SS]} \quad (4)$$

TABLE 1. SECOND ORDER RATE CONSTANTS AND ACTIVATION PARAMETERS FOR THE SUBSTITUTION OF *trans*-2-BUTENE FOR $[PtCl_3(S,S\text{-}trans\text{-2-BUTENE}[1,3\text{-}^3H])]^-$ IN ACETONE

Temp / °C	$k_{2(CD)}$ / 10^{-3} M^{-1} s^{-1}	$k_{2(IE)}$ / 10^{-3} M^{-1} s^{-1}	$k_{2[SS]}$ / 10^{-3} M^{-1} s^{-1}	$k_{2[SR]}$ / 10^{-3} M^{-1} s^{-1}	$k_{2[SS]}/k_{2[SR]}$
8.0	17.3	70.6	62.0	8.7	7.2

−20.0	2.65	11.4	10.1	1.3	7.8
ΔH^* / kJ mol^{-1}			36.3±3.1	37.6±2.7	
ΔS^* / J mol^{-1} K^{-1}			−138±12	−149±10	

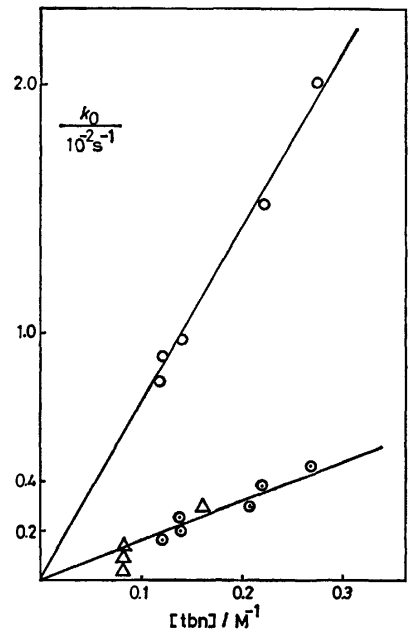

Fig. 3. Dependence of the observed first order rate constants of the racemization (○) and isotopic exchange (●) of $[PtCl_3(S,S\text{-2-butene}[^3H])]^-$ upon the concentration of free tbn in acetone at 8 °C. (△0.0034 M Ph_4PCl added.)

On the basis of the observed k_2's, $k_{2[SR]}$, and $k_{2[SS]}$ were calculated as shown in Table 1. The activation parameters are also included in the same table.

Dynamic Stereoselectivity. The ratio $k_{2[SS]}/k_{2[SR]}$ is *ca.* 8 in the present temperature range. The activation parameters involve rather large experimental errors, but the difference in k_2's must consist in the ΔS^* term. It is generally believed that the substitution of such square planar complexes proceed *via* S_N2 mechanism, and the ease of nucleophilic attack by the incoming ligand is the rate-determining step. The two kinds of substitution with retention and inversion of configuration should have very similar transition states and the approach of tbn resulting in retention of configuration must be slightly easier than that resulting in inversion. Such a difference must be of a steric origin, and very naturally reflected in the ΔS^* rather than in the ΔH^* value.

So far as the substitution reaction proceeds *via* an associative mechanism, the transition state should be either a trigonal bipyramid or a square pyramid. Some

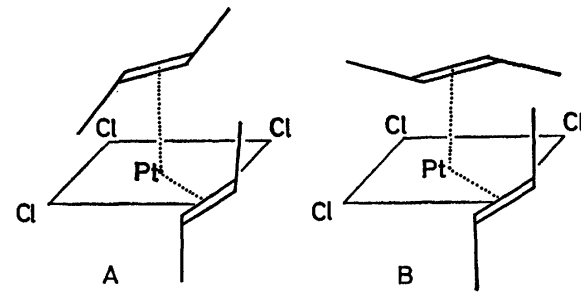

Fig. 4. Plausible transition state on the nucleophilic attack of tbn upon $[PtCl_3(S,S\text{-2-butene})]^-$.

trigonal bipyramidal complexes have been isolated as crystals (*e.g.* $[PtCl_2(C_2H_4)(phen)]$[4] and $[Ir^ICl(C_2H_4)_4]$[5]), and π-accepting ligands are claimed to stabilize trigonal bipyramidal structure.[6] Hence the present substitution reaction may have a square pyramidal transition state (Fig. 4), which undergoes internal rearrangement to give a trigonal bipyramidal intermediate. Even a simple molecular model study discloses that the approach of tbn as shown in Fig. 4A involves less steric hindrance than that as shown in Fig. 4B. The stereoselctivity of the present substitution is slightly smaller than that in the substitution of tbn for *trans*(*N*, olefin)[PtCl(L-pro)(*S,S*-2-butene)], but very near to it. Similar difference to that shown in Fig. 4 may be encountered in the substitution of the L-prolinato complex, and we can conclude that the main source of selectivity in this complex should be in the asymmetrically coordinated *trans*-2-butene.

The authors thank the finantial support given by Takeda Science Foundation.

Non-isothermal Studies of the Dehydration of Double Salt Hydrates and Their Deuterium Oxide Analogues. I

N. RAY CHAUDHURI, M. K. DASGUPTA, S. MITRA, and G. K. PATHAK

Inorganic Chemistry Laboratory, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received December 10, 1976)

Non-isothermal studies of the dehydration of double salt hydrates of the type $(NH_4)_2AB_4 \cdot M(II)SO_4 \cdot 6H_2O$ and their D_2O analogues in solid state were carried out with a derivatograph, where $AB_4 = BeF_4^{2-}$ or SeO_4^{2-}, M(II)=Mg(II), Mn(II), Co(II), Ni(II), Cu(II), or Zn(II). These salt hydrate molecules lost water/heavy water in single or multiple steps upon heating. Intermediate hydrates were isolated and characterised by elemental analysis and IR spectral measurements. The activation energy for each step of dehydration of the salt hydrate was evaluated from the analysis of TG, DTG, and DTA curves of the respective derivatograms. Enthalpy change was evaluated from the DTA peak area and the order of reaction was found to be unity for each step of dehydration. The nature of dehydration was little affected by deuteration. Thermal parameters for the $(NH_4)_2AB_4 \cdot M(II)SO_4 \cdot 6H_2O$ and their D_2O analogues were compared with the salt hydrates, $K_2AB_4 \cdot M(II)SO_4 \cdot 6H_2O$, $(NH_4)_2SO_4 \cdot M(II)SO_4 \cdot 6H_2O$ and their D_2O analogues.

Non-isothermal studies on the dehydration of double salt hydrates of the type $M(I)_2SO_4 \cdot M(II)SO_4 \cdot 6H_2O$ where M(I)=NH_4(I),[1] K(I),[2] Rb(I),[3] Cs(I),[4] or Tl(I)[5] and M(II)=Mg(II), Mn(II), Co(II), Ni(II), Cu(II), Zn(II), or Cd(II) and their D_2O analogues were carried out. Thermal studies on the dehydration of double salt hydrates of the type $K_2AB_4 \cdot M(II)SO_4 \cdot 6H_2O$, where $AB_4 = BeF_4^{2-}$ or SeO_4^{2-} and their D_2O analogues[6] were also reported. These studies showed that the thermal properties are affected by changes of univalent cation and/or anion contained in the double salt hydrates. The present paper deals with the dehydration of double salt hydrates of the type $(NH_4)_2AB_4 \cdot M(II)SO_4 \cdot 6H_2O$ where $AB_4 = BeF_4^{2-}$ or SeO_4^{2-}, M(II) =Mg(II), Mn(II), Co(II), Ni(II), Cu(II), or Zn(II) and their D_2O analogues, which was carried out in order to see the cation effect with change of K(I) by NH_4 (I) and the anion effect with change of SO_4^{2-} by BeF_4^{2-} or SeO_4^{2-} attached to the univalent cation. The values of activation energies of dehydration processes were evaluated from TG, DTG and DTA curves simultaneously, the order of reaction from TG, enthalpy changes from DTA peak area and the thermal stability from first DTG peak temperature. The effect of deuteration on the thermal properties is described. The role of divalent cation on the thermal properties of dehydration is also discussed.

Experimental

Preparation of $(NH_4)_2BeF_4 \cdot M(II)SO_4 \cdot 6H_2O$ where M(II) =Mg(II), Mn(II), Co(II), Ni(II), Cu(II), or Zn(II). These salts were prepared by the standard procedure.[7-9]

Preparation of $(NH_4)_2SeO_4 \cdot M(II)SO_4 \cdot 6H_2O$, where M(II)=Mg(II), Mn(II), Co(II), Ni(II), Cu(II), or Zn(II). These salts were prepared by crystallization from a mixture of equimolecular proportions of the corresponding single salts in water. D_2O analogues of the salt hydrates were prepared by dissolving the anhydrous single salts required in D_2O (99.5%) and subsequent crystallization. Elemental analysis of all the salt hydrates and their D_2O analogues was carried out before thermal analysis.

A Paulik-Paulik-Erdey type MOM derivatograph was used for the thermal analysis. The particle size of the sample was 150—200 mesh. A platinum crucible was used, the heating rate being maintained at 1.5 °C min^{-1}. The volume of the sample was nearly the same in each case.

The following abbreviations were used for the double salt hydrates of the present two series and also other series given in Results and Discussion.

A: $(NH_4)_2SO_4 \cdot M(II)SO_4 \cdot 6H_2O$
B: $(NH_4)_2BeF_4 \cdot M(II)SO_4 \cdot 6H_2O$
C: $(NH_4)_2SeO_4 \cdot M(II)SO_4 \cdot 6H_2O$
A(K): $K_2SO_4 \cdot M(II)SO_4 \cdot 6H_2O$
B(K): $K_2BeF_4 \cdot M(II)SO_4 \cdot 6H_2O$
C(K): $K_2SeO_4 \cdot M(II)SO_4 \cdot 6H_2O$

The following abbreviations were used for representation of a particular salt of any series.

A-Mg(II): $(NH_4)_2SO_4 \cdot MgSO_4 \cdot 6H_2O$
B-Mn(II): $(NH_4)_2BeF_4 \cdot MnSO_4 \cdot 6H_2O$
C-Co(II): $(NH_4)_2SeO_4 \cdot CoSO_4 \cdot 6H_2O$ *etc.*

Results

The derivatograms of B-Mg(II), B-Mn(II), and B-Co(II) are shown in Fig. 1. B-Mg(II) and B-Co(II) lose water molecules in a single step. The TG curve for the dehydration of B-Mn(II) shows dehydration taking place in a single step. However, the two DTA peaks partially overlap each other and two DTG peaks also partially overlap each other, indicating the existence of a thermally unstable intermediate product. The derivatograms of B-Ni(II), B-Cu(II), and B-Zn(II) are shown in Fig. 2. B-Ni(II) and B-Zn(II) show single step dehydration, whereas B-Cu(II) undergoes dehydration as follows: $(NH_4)_2BeF_4 \cdot CuSO_4 \cdot 6H_2O \rightarrow (NH_4)_2BeF_4 \cdot CuSO_4 \cdot H_2O \rightarrow (NH_4)_2BeF_4 \cdot CuSO_4$. The intermediate hydrate is not stable enough to be isolated. B-Mg(II) and B-Ni(II) start decomposition as soon as the dehydration ceases. The derivatograms C-Mg(II), C-Mn(II), and C-Co(II) are shown in Fig. 3. C-Mg(II) loses water molecules in a single step. C-Mn(II) becomes anhydrous passing through an unstable intermediate *i.e.*, dihydrate. The two DTA peaks and also the two DTG peaks overlap each other. C-Co(II) becomes anhydrous passing through an unstable hemihydrate. The derivatograms of C-Ni(II), C-Cu(II), and C-Zn(II) are shown in Fig. 4. C-Ni(II) and C-Zn(II) show dehydration in a single step, but the latter shows a shoulder in its DTA and DTG curves,

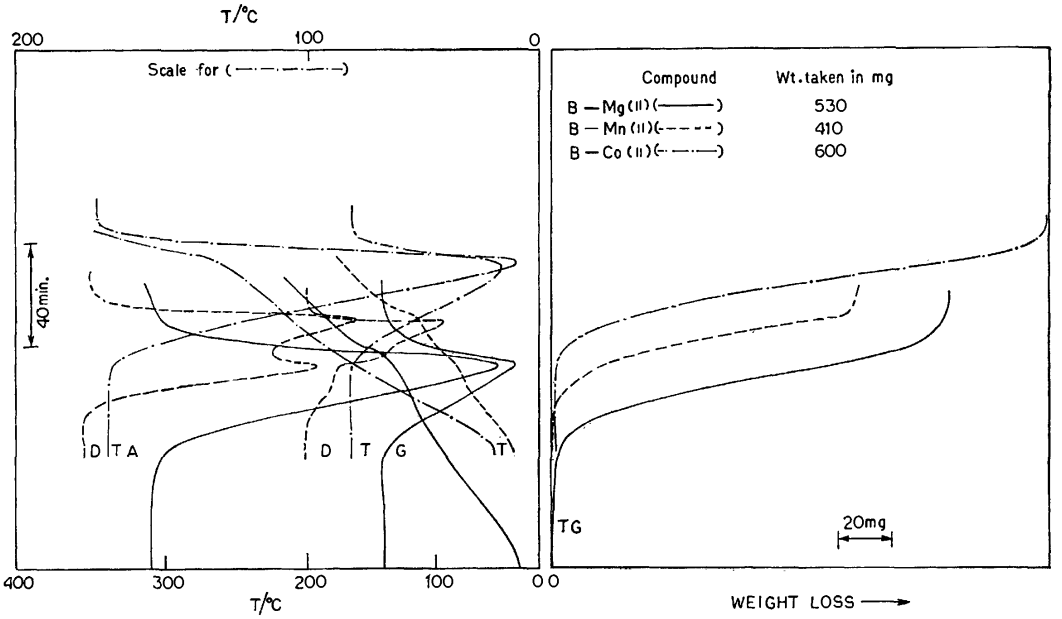

Fig. 1. Derivatograms for $(NH_4)_2BeF_4 \cdot MgSO_4 \cdot 6H_2O$[B-Mg(II) (——)], $(NH_4)_2BeF_4 \cdot MnSO_4 \cdot 6H_2O$[B-Mn(II) (— — —)], and $(NH_4)_2BeF_4 \cdot CoSO_4 \cdot 6H_2O$[B-Co(II) (—·—·—)].

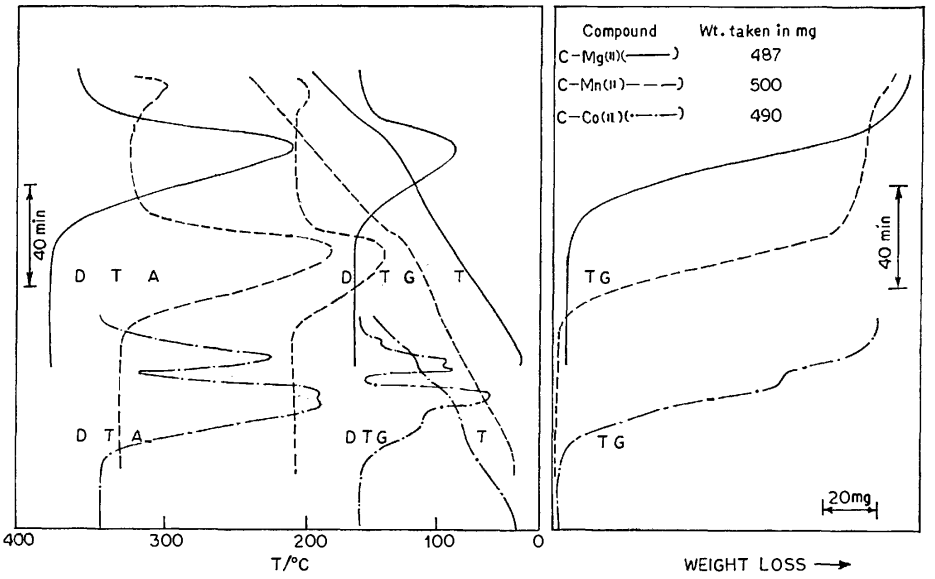

Fig. 3. Derivatograms for $(NH_4)_2SeO_4 \cdot MgSO_4 \cdot 6H_2O$[C-Mg(II) (——)], $(NH_4)_2SeO_4 \cdot MnSO_4 \cdot 6H_2O$[C-Mn(II) (—·—·—)], and $(NH_4)_2SeO_4 \cdot CoSO_4 \cdot 6H_2O$[C-Co(II) (———)].

indicating a very unstable intermediate hydrate. C-Cu(II) dehydrates through an unstable dihydrate. The derivatograms of the deuterated salt hydrates are not given since the nature of dehydration remains unaltered.

DTG peak temperatures and the temperature ranges of dehydration of the double salt hydrates of "B" and "C" and their D_2O analogues are given in Tables 1 and 2, respectively. Enthalpy changes for each step of dehydration of the double salt hydrates and their D_2O analogues were evaluated by the method used by Tsuchiya *et al.*[10] using copper sulfate pentahydrate as a standard. When the peaks are too much overlapped, the values are evaluated from the overall area of the DTA curves. Activation energies for each step of dehydration of the salt hydrates and their D_2O analogues are evaluated from the analysis of TG curves using Freeman and Carroll's equation.[11] The activation energies for each step of dehydration were evaluated from the analysis of DTG curves using the method of Dave and Chopra[12] and also from that of DTA curves using the equation of Brochardt and Daniels[13] for first order reactions. In a few cases the values of activation energy obtained from TG curves appear high in comparison with those determined from the corresponding DTA and DTG curves (Table 2). As a result, we evaluated the activation energy also from TG curves

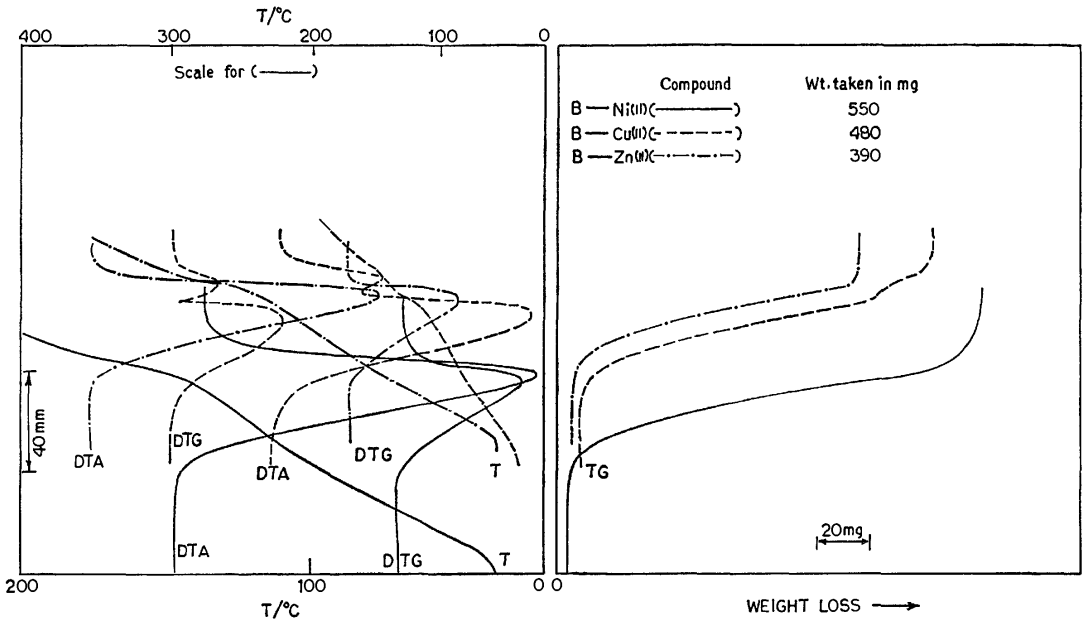

Fig. 2. Derivatograms for $(NH_4)_2BeF_4 \cdot NiSO_4 \cdot 6H_2O$[B-Ni(II) (——)], $(NH_4)_2BeF_4 \cdot CuSO_4 \cdot 6H_2O$ [B-Cu(II) (— — —)], and $(NH_4)_2BeF_4 \cdot ZnSO_4 \cdot 6H_2O$[B-Zn(II) (—·—·—)].

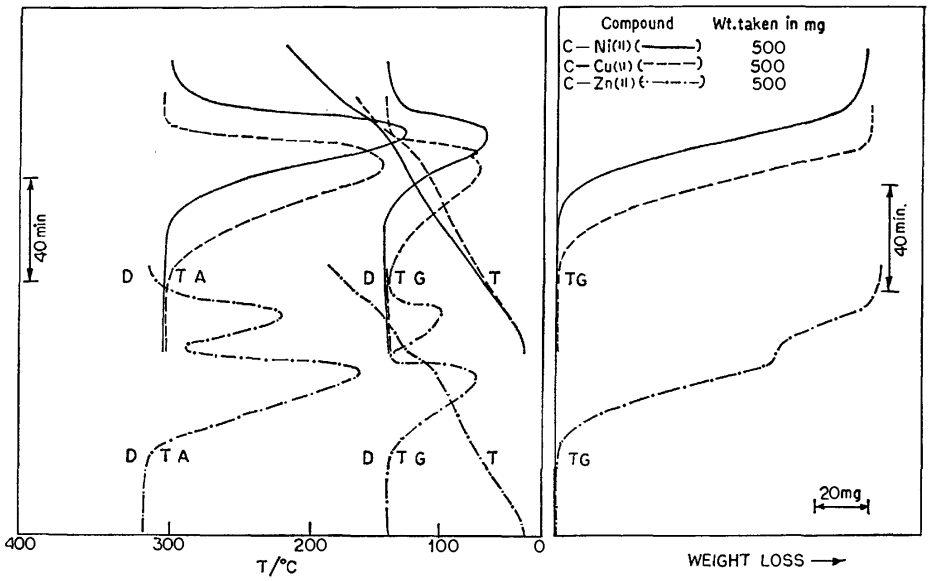

Fig. 4. Derivatograms for $(NH_4)_2SeO_4 \cdot NiSO_4 \cdot 6H_2O$[C-Ni(II) (——)], $(NH_4)_2SeO_4 \cdot CuSO_4 \cdot 6H_2O$[C-Cu(II) (—·—·—)], and $(NH_4)_2SeO_4 \cdot ZnSO_4 \cdot 6H_2O$[C-Zn(II) (———)].

using Horowitz and Metzger's equation[14] and a modified Dharwadkar and Phandnis equation.[15] The results are given in Table 2 within parentheses. The order of reaction is found to be unity for the dehydration of all the double salt hydrates and their D_2O analogues. The IR spectra of the salt hydrates and their D_2O analogues were taken to confirm the fact that the deuteration of the hydrates takes place to the desired extent.

Discussion

The patterns of elimination of water molecules of B-Mg(II) and C-Mg(II) are similar to each other, but differ from that of A-Mg(II). The mode of dehydration of B-Mg(II) does not differ from that of B(K)-Mg(II), but that of C-Mg(II) differs from that of C(K)-Mg(II) where dehydration takes place in double steps. B-Mn(II) differs from C-Mn(II), but shows similarity to A-Mn(II) with respect to the pattern of elimination of water molecules. B-Co(II) shows similarity to A-Co(II), but differs from C-Co(II) with respect to the elimination of water molecules. Our earlier work shows that the patterns of elimination of water molecules for both B-Co(II) and C-Co(II) differ from those of B(K)-Co(II) and C(K)-Co(II). The modes of elimination

a) In some cases thermal parameters could not be calculated due to very poor resolution of the curve. b) Activation energy for the first step of dehydration of B(K). c) Overall enthalpy change where DTA curves overlap too much.

of water molecules of B-Ni(II) and C-Ni(II) are similar to each other and are also similar to A-Ni(II). B-Ni-(II) shows no change in the elimination of water molecules due to the change of cation K by NH_4, but in C-Ni(II) a difference is observed from C(K)-Ni(II) where dehydration takes place in double steps. The patterns of elimination of water molecules of B-Cu(II) and C-Cu(II) differ from each other, and also from A-Cu(II) where dehydration takes place in three steps. Both B-Cu(II) and C-Cu(II) differ in the nature of dehydration from B(K)-Cu(II) and C(K)-Cu(II), respectively. Apparently A-Zn(II), B-Zn(II), and C-Zn-(II) show no difference in the nature of dehydration, but in C-Zn(II) a slight difference is observed. B-Zn-(II) shows similarity to B(K)-Zn(II). C-Zn(II) difffers from C(K)-Zn(II) with respect to the elimination of water molecules.

Salt hydrates of "B" show no dihydrate, whereas our earlier work on the dehydration of the salt hydrates of "B(K)" shows thermally stable dihydrates in the cases of Co(II) and Cu(II). On the other hand, salt hydrates of "C" show the existence of thermally unstable dihydrates in the cases of Mn(II) and Cu(II), and the salt hydrates of "C(K)" show thermally stable dihydrates in the cases of Mg(II), Co(II), Ni(II), and Zn(II).

No noticeable change in the nature of dehydration due to deuteration is observed in the salt hydrates of "A", "B", and "C". In the salt hydrates of "B(K)" a slight deuteration effect was observed in the case of Cu(II) only, whereas appreciable deuteration effect was observed in C(K)-Ni(II) and C(K)-Cu(II).

The first DTG peak temperature of the salt hydrates of "B" shows thermal stability to be in the order: Ni(II)>Co(II)>Mg(II)>Zn(II)>Mn(II)>Cu(II) and that of "C" in the order: Ni(II)>Mg(II)>Co(II)>Zn-(II)>Cu(II)>Mn(II). In both series thermal stability of Ni(II) is appreciably high. This phenomenon is observed in "A" and also in "B(K)" and "C(K)" we reported.

In our works on non-isothermal studies on the dehydration of salt hydrates we evaluated the value of activation energy and order of reaction (n) from TG using Freeman and Carroll's equation,[11] reaction order always being found to be unity. It was observed that the specific rate constant of the reaction at different temperatures can be ascertained from the equation of Dave and Chopra[12] as follows:

$$k = \frac{\left(\frac{A}{N_0}\right)^{n-1}\left(-\frac{dx}{dt}\right)}{(A-a)^n},$$

where k=specific rate constant,
N_0=number of molecules of the sample at the time when DTG peak appears,
A and a=the total peak area and the area swept up till time t,
dx/dt=the displacement of DTG curve from the base line at time t,
and n=the order of reaction.

The values of log k are plotted against the reciprocal of the absolute temperature assuming different values of n, the correct one resulting in a straight line. The slope of the line gives the value of activation energy for the order of reaction. The value of n evaluated by this method is in good agreement with the value determined from Freeman and Carroll's equation. When the value of n becomes greater or less than unity, evaluation of the specific rate constant by means of Brochardt and Daniel's equation becomes very difficult. We did not face this difficulty as we observe unit value of n evaluated from the plot of Freeman and Carroll's equation. As a result we chose Freeman and Carroll's equation instead of other kinetic equations, *e.g.*,

a) In some cases thermal parameters could not be calculated due to very poor resolution of the curve. b) Activation energy for the first step of dehydration of C(K). c) Evaluated by method of Horowitz and Metzger. d) Evaluated by modified method of Dharwadkar and Phadnis. e) Overall ethalpy change.

Horowitz and Metzger,[14] modified Dharwadkar and Phadnis[15] *etc.* for TG curves where the value of n is based on assumption. The value of n obtained by using Freeman and Carroll's equation appears greater or less than one besides the unit value in number of cases observed by different workers.[16–18] However, in our works on salt hydrates[1–6] and the adduct molecules of metallic halides[19–23] with oxo compounds we did not find the order of reaction other than unity, and found a closeness of values of activation energy evaluated using Freeman and Carroll's equation for TG, Dave and Chopra's equation for DTG and Brochardt and Daniel's equation for DTA. This is also observed in most of the cases of the present two series. In a few cases (see Table 2) Freeman and Carroll's equation shows values appreciably high in comparison with the values evaluated from DTA and DTG curves. In such cases on application of two other standard equations, Horowitz and Metzger's equation and modified Dharwadkar and Phadnis equation, to the TG curve, the value of activation energy becomes closer to those obtained from DTA and DTG curve. However, when the value of activation energy obtained by using Freeman and Carroll's equation does not differ much from that evaluated from DTA and DTG curves, application of other two methods to the TG curve gives comparable values. Under such context we have emphasised Freeman and Carroll's equation because of its advantage over the other kinetic equation for TG curve.

The activation energy for the first step of dehydration of salt hydrates of "A" increased with increase in atomic number in the order Mg(II)<Mn(II)<Co(II)<Ni(II), reaching a maximum in Cu(II) and decreasing as Zn(II)>Cd(II). This trend is not observed in both of the present series. The values of activation energy for the first step of dehydration of B-Mg(II), B-Mn(II) and B-Cu(II) are very close and the values of B-Co(II), B-Ni(II), and B-Zn(II) are close to each

other respectively, but the former values are appreciably high (Table 1). The highest value of activation energy is observed in C-Mn(II). The values of activation energies of C-Mg(II), C-Ni(II), and C-Cu(II) are close to each other. Those of C-Co(II) and C-Zn(II) are also close, but the former values are higher than those of latter such as the salt hydrates of "B" (Table 2). B-Ni(II) shows considerably low value of activation energy due to change of K by NH_4, though the pattern of dehydration hardly differs. The difference in the value of activation energy between the salt hydrates of "B" and "C" is not so prominent as was observed for the salt hydrates of "B(K)" and "C(K)" (Tables 1 and 2).

No deuteration effect is observed on the value of activation energy in both the salt hydrates of "B" and "C". It was observed in the salt hydrates of "B(K)" and more clearly in the salt hydrates of "C(K)".

The values of enthalpy changes of dehydration of the salt hydrates of "B" and "C" are $\approx$10—$\approx$16 kcal mol^{-1}. Deuteration causes no marked effect on the value of ΔH.

In the salt hydrates of "A", "B", and "C" for particular divalent cation except Mg(II) and Cu(II) we observed pronounced anion effect with respect to elimination of water molecules, whereas this effect was observed for each divalent cation amongs the salt hydrates of "A(K)", "B(K)", and "C(K)".

Kinetics and Mechanism of Thermal Isomerisation of Aryl Alkanehydrazonates into *N'*,*N'*-Diarylhydrazides. Extension of a Recent Free Radical Analogue of the Chapman Rearrangement

Ahmad Sami SHAWALI, Hamdi Mahmoud HASSANEEN, and Saleh ALMOUSAWI
Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

(Received December 18, 1977)

A series of twelve aryl *N*-(*p*-nitrophenyl)alkanehydrazonates (I) have been prepared and their thermal rearrangement into *N*-acyl-*N'*,*N'*-diarylhydrazines (II) was investigated. The structures of I and II were derived from their elemental analyses and spectral properties. Hydrolysis of II afforded the corresponding *N'*,*N'*-diarylhydrazines. Kinetic experiments have shown that electron withdrawing substituents decrease the rate of the rearrangement whereas electron donating groups increase it. The rate of conversion of I into II was also increased by addition of benzoyl peroxide. A free radical mechanism was proposed to account for the results.

We have been exploring the synthesis and thermal isomerization of several hydrazonates of type I (R= aryl, H_5C_2OOC- or C_6H_5NHCO-).[1-4] In continuation of these studies, we have investigated the synthesis of a number of aryl alkanehydrazonates (I, R=alkyl) and examined the kinetics of their rearrangement into the hydrazides (II, R=alkyl).

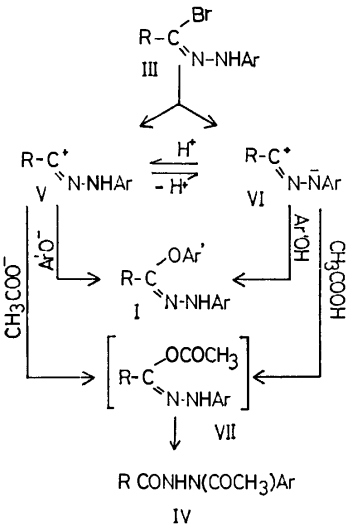
Results and Discussion

Treatment of *N*-(*p*-nitrophenyl)ethanehydrazonoyl bromide (IIIa) with sodium phenoxide in ethanol results in the formation of phenyl *N*-(*p*-nitrophenyl)ethanehydrazonate (Ia). The latter ester was also prepared by treating IIIa with phenol in ethanol in presence of triethylamine at room temperature. These two procedures were found to be general and good yields of the hydrazonate esters, Ib to Il were obtained when other alkanehydrazonoyl bromides and phenols were used. In an attempt to prepare Ia, Ie, and Ii by the reaction of the respective hydrazonoyl bromides with phenol in presence of sodium acetate in ethanol, *N*,*N'*-diacyl-*N*-*p*-nitrophenyl)hydrazines (IVa, IVe, and IVi) were obtained and no hydrazonate was formed (Scheme 1). These results indicate that the formation of I involves the carbonium ion, (V)[5] or the nitrilimine, VI[6] as intermediate. The former ion can be attacked by nucleophilic reagents, namely the phenoxide and acetate



Scheme 1.

ions to form I and the acetate ester VII, respectively. Alternatively, the nitrilimine can add phenol and acetic acid to give I and VII respectively. The acetate ester VII seems to be unstable; it undergoes OAc→NAc rearrangement to form IV as it is formed[7] (Scheme 1).

The structures of the hydrazonates Ia to Il were derived from their elemental analyses and spectral data. Thus, the IR spectra showed, in each case, two characteristic bands at 1264 and 1080 cm^{-1} assignable to an aryl ether linkage. The UV absorption pattern was of typical hydrazones. The data are summarized in Table 1.

On heating the hydrazonates Ia to Il at 125 °C for 60 min in the absence of solvent, rearrangement occurred and the corresponding *N*-acyl-*N'*,*N'*-diarylhydrazines (IIa to IIl) were obtained. The latter products were characterized by strong absorption band near 1680 cm^{-1} assignable to the CONH grouping. The assigned hydrazide structure for the rearranged products was also indicated by the fact that *N*-phenyl-*N*-(*p*-nitrophenyl)hydrazine (VIII) was obtained upon acid hydrolysis of the rearranged products IIa and IIi. Acetylation of VIII with acetic anhydride gave back IIa.

The thermal isomerization of I was also effected by refluxing the esters in xylene for 1—3 h. The hydrazide

obtained from a given ester by this method was identical in all respects with that obtained by the above procedure. The compounds prepared and their physical constants are listed in Table 2.

To shed more light on the mechanism of the rearrangement of I, the kinetics of the rearrangement of the esters Ia to Il were studied in p-xylene spectrophotometrically. In this solvent both the ester and the respective hydrazide have absorption maxima in the region 350—390 nm. However, the molar absorptivity of the ester, at a given wavelength, is higher than that of the hydrazide at the same wavelength. The data are summarized in Table 3. Therefore the absorbance in the region 350—390 nm decreases with the progress of the rearrangement. Accordingly, the rates of the isomerization of I were followed spectrophotometrically at the wavelength where maximum absorbance difference was observed. In case of the p-nitrophenyl esters (Id, Ih, and Il) a tight isosbestic point in the UV spectra was observed. This indicates that the rearrangement occurred without the formation of intermediates which absorb in the same region.

For the rearrangement of all esters, the following first order rate equation was obtained;

$$-\log(A_t - A_\infty) = k_1 t/2.3 - \log(A_0 - A_\infty),$$

where A_0, A_t, and A_∞ are the absorbance values of the reaction mixture at time 0, t, and ∞, respectively. The rate constant was calculated from the slope of the plot

Table 3. UV data of aryl alkanehyrazonates (I) and N',N'-diarylhydrazides (II) in p-xylene and rate constants for conversion of I into II at 110 °C

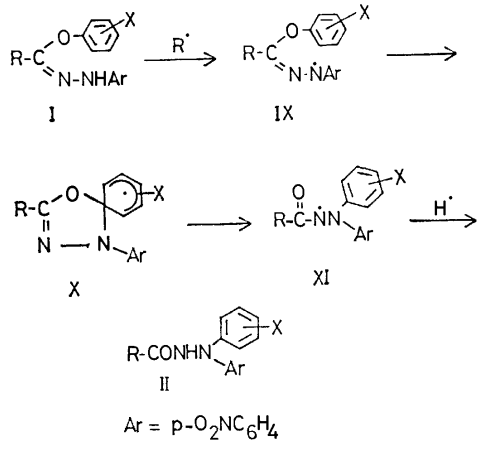
of log $(A_t - A_\infty)$ *versus* time using the least squares method. In Table 3 are listed the first-order rate constants obtained for the esters investigated. The values reported are the average of those obtained in duplicate or triplicate experiments. The data indicate that the rate of the rearrangement is influenced by the nature of both the substituent on the phenolic moiety and the C-alkyl group. In a given series of esters, electron withdrawing substituents decrease the reactivity, whereas electron donating ones increase it. The esters having the same OAR group, and different R's, their rates follow the sequence: $CH_3 > CH_3CH_2 > (CH_3)_2CH$.

TABLE 4. RESULTS OF STATISTICAL TREATMENT OF THE KINETIC DATA[a)]

Series	$-\rho \pm s$	$-\log k_H \pm s$	r	n
Ia—d	0.396±0.012	3.79±0.005	0.999	4
Ie—h	0.522±0.009	4.02±0.004	0.994	4
Ii—l	0.497±0.013	4.29±0.053	0.939	4

a) ρ, reaction constant; log k_H, intercept of the Hammett plot; r, correlation coefficient; s, standard deviation; n, number of points.

The values of log k_1 for each series of esters were then correlated with the Hammett substituent constant, σ, as taken from the compilation of Ritchie and Sager.[8)] The results of statistical analysis of the rate data by the least squares method are summarized in Table 4. The rho values obtained are in agreement with a free radical pathway because their absolute value is small, and with an electron deficient transition state because they are negative.



Scheme 2.

The sequence that probably accounts for the foregoing results is presented in Scheme 2. It is assumed that a radical initiator, R·, removes the amino hydrogen atom to give the hydrazonate radical, IX; this then undergoes intramolecular rearrangement possibly *via* the cyclic radical species X to give the more stable hydrazide radical XI. Hydrogen abstraction from the solvent or from another hydrazonate ester then gives the hydrazide II. The intermediacy of hydrazyl radicals has been postulated for several reactions of hydrazones,[9)] and their stability has been examined by Goldschmidt *et al.*[10)]. Under the conditions which we have used to investigate the kinetics of the conversion of I into II, the radical initiator is probably the trace of oxygen[11)] which might be present. This was substantiated by the observation that the rate of the rearrangement was increased by addition of the free radical initiator namely benzoyl peroxide. For example, the rate constant of the isomerization of the ester Ie in xylene at 110 °C in presence of 4.95×10^{-5} M benzoyl peroxide has a value of 2.08×10^{-4} s^{-1}; whereas in the absence of the peroxide the value of the rate constant was 0.93×10^{-4} s^{-1}. The suggested mechanism (Scheme 2) is also consistent with the recent observation by Hegarty *et al.*[9)] that the rate of the rearrangement of the related aryl arenecarbohydrazonates in dioxane–water mixture is accelerated by the addition of oxidizing agents such as manganese dioxide.

Experimental

All melting points are uncorrected and were measured on a Gallenkamp Electrothermal melting point apparatus, model 1A6301. Elemental analysis was performed by Alfred Bernhardt Mikroanalytisches Chemie Laboratorium, West Germany. Infrared and ultraviolet spectra were measured with Unicam SP1000 and SP8000 spectrophotometers respectively. The solvent *p*-xylene was Analar grade and redistilled twice before use in kinetic study.

The alkanehydrazonoyl bromides (III, R=CH_3, CH_3CH_2, and $(CH_3)_2CH$) used in synthesis of I were prepared by literature method, and their constants (mp' s) corresponded to liserature data.[12)]

Aryl Alkanehydrazonates, Ia to Il. Method-A. To an ethanolic sodium ethoxide solution (prepared from sodium (0.11 g, 0.005 g atom) and ethanol (20 ml) was added the appropriate phenol (0.005 mol) followed by the hydrazonoyl bromide (0.005 mol). The mixture was stirred for 5 min and left overnight at room temperature. The crude ester that precipitated was collected, washed with water and finally crystallized from methanol. The results are summarized in Table 1.

Method-B. Equivalent amounts (0.005 mol each) of hydrazonoyl bromide and phenol were stirred in ethanol or acetonitrile (30 ml) containing triethylamine (0.01 mol) at room temperature for 2 h. The product was collected by filtration, washed with water and dried. Crystallization from methanol gave the hydrazonates Ia to Il in 50 to 75% yield. The results are given in Table 1.

Reaction of III with Phenol in Presence of Sodium Acetate. To a suspension of III (R=CH_3) (0.003 mol) in ethanol (20 ml) was added a solution of sodium acetate and phenol (0.003 mol each) in water (5 ml). The reaction mixture was stirred for 5 min and left overnight at room temperature. The solid was collected and crystallization from ethanol gave IVa, mp 184—185 °C, Found: C, 50.60; H, 5.07; N, 18.02%. Calcd for $C_{10}H_{11}N_3O_4$: C, 50.63; H, 4.67; N, 17.70%.

Similar treatment of III (R=CH_3CH_2) and III (R=$(CH_3)_2CH$) with phenol and sodium acetate afforded IVe and IVi respectively. Compound IVe, mp 133.5—134 °C; Found: C, 52.98; H, 5.12; N, 16.50%. Calcd for $C_{11}H_{13}N_3O_4$: C, 52.58; H, 5.21; N, 16.72%. Compound IVi, mp 192 °C, Found: C, 54.10; H, 5.66; N, 15.62%. Calcd for $C_{12}H_{15}N_3O_4$: C, 54.32; H, 5.69; N, 15.84%.

Thermal Rearrangement of Aryl Alkanehydrazonates. Method-A: The hydrazonate (0.5 g) was heated in a test tube

in an oil bath at 120 °C for 1 h. The crude product was extracted with acetone. The solvent was then evaporated and the residue was boiled with benzene (20 ml), cooled, then filtered. Crystallization from methanol–water mixture gave II in 60—70% yield.

Method-B: The hydrazonate (0.5 g) was refluxed in xylene for 3 h. The pale yellow solid that precipitated on cooling was collected (0.45 g). Crystallization from methanol–water mixture gave II (*ca.* 0.4 g). The hydrazides prepared are listed in Table 2 together with their physical constants.

Hydrolysis of IIa and IIi. The hydrazide IIa (0.5 g) was refluxed in 95% ethanol (20 ml) and concentrated hydrochloric acid (20 ml) for 10 h. The reaction mixture was then concentrated to its 1/4 volume and cooled. The solid formed was collected, and washed with dilute solution of sodium acetate. Crystallization from dilute methanol gave *N*-phenyl-*N*-(*p*-nitrophenyl)hydrazine, VIII, yellow needles, mp 100—102 °C, Found: C, 62.42; H, 4.85; N, 17.73%. Calcd for $C_{12}H_{11}N_3O_2$: C, 62.86; H, 4.84; N, 18.33%.

Following the same procedure the hydrazide IIi yielded the hydrazine VIII in 55% yield.

Kinetic Experiments. A stock solution 10^{-4} to 10^{-5} M (suitable for UV analysis) in hydrazonate was prepared in xylene at room temperature. The resulting solution was distributed among ampules (15 at minimum). The ampules were placed in an oil bath at 110 ± 1 °C. At suitable time intervals, the ampule was taken out of the bath, quenched in ice and the UV spectrum of its contents was recorded. The first spectrum was usually taken after 10 min to allow temperature equilibration. Complete spectra taken at the end of each kinetic run corresponded to the spectra of hydrazide solution in xylene of the same concentration. Under these conditions reasonable first order plots of log (A_t-A_∞) *vs.* time, *t*, min were obtained. Each kinetic run was repeated at least twice and the average rate constants are reported. The average deviation was $<\pm8\%$.

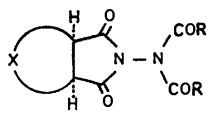
Structural Assignment by NMR Analyses of *N*-(Diacylamino)imide Derivatives. Diels-Alder Adducts of 2,3-Dimethylnaphthalene and 6,6-Diphenylfulvene with Maleic Anhydride

Shiva Mohan VERMA and Ashok Kumar SINGH
Department of Chemistry, Banaras Hindu University, Varanasi 221005, India
(Received October 22, 1976)

The configurations of the Diels-Alder adducts of maleic anhydride with 2,3-dimethylnaphthalene and 6,6-diphenylfulvene have been investigated by NMR spectroscopy. Restricted rotation and non-planar conformations about the N–N bond in the corresponding *N*-aminoimide derivatives of the adducts have been employed in solving the structural problem. While the *N'*,*N'*-diacetyl system has been shown to be a suitable probe for configurational assignment, *N'*-acetyl-*N'*-aroyl-*N*-aminoimide derivatives have been found to be a more diagnostic probe even to simple adducts.

Preferred conformations about N–N bond in the system of type I have been reported with the help of a cage-moiety which is asymmetric about the plane of the succinimydyl ring.[1–3] Hindered rotation and non-planar conformations about N–N bond in *N'*,*N'*-diacylaminoimides of Diels-Alder adducts have been used for their configurational (*endo*/*exo*) assignments. The utility of this NMR technique was first explored with naphthalene maleic anhydride adducts and their reduction products as model compounds. It is shown that *N'*-acetyl-*N'*-aroyl-*N*-aminoimide system can be a versatile probe for direct determination of the configurations of such adducts.[4,5] It is evident that this system enables the assignment of correct configuration to either *endo* or *exo*-adduct without a comparison with the pattern of the corresponding isomer, and therefore, this method offers a distinct advantage over the earlier methods especially when one of the isomers is not formed.



X= Chain of four Carbons

I

In this communication we have demonstrated the configurational assignment of 2,3-dimethylnaphthalene–maleic anhydride and 6,6-diphenylfulvene–maleic anhydride Diels-Alder adduct with the help of NMR spectral studies of their *N*-aminoimide derivatives (IIa—IId, IIIa—IIIf, IVa—IVd, and Va—Vd).

The Diels-Alder reaction of 2,3-dimethylnaphthalene with maleic anhydride was reported by Kloetzel and Herzog[6] to give adducts having the benzobicyclo-[2.2.2]octene system. The configuration of anhydride group of the adduct was studied by these workers with the help of UV absorption and also by chemical methods but the problem remained unsettled. This Diels-Alder reaction has also been carried out in the presence of aluminium chloride and the product was assigned the *exo*-configuration[7] which was later shown to have the *endo*-configuration. The configuration of these adducts has been proposed with the help of their NMR spectra: the one which has deshielded C-2 and C-3 methine protons (δ 3.41) was assigned the *endo*-configuration

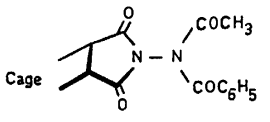
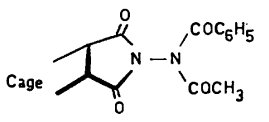
while the other having shielded C-2 and C-3 methine protons (δ 3.28), the *exo*-configuration.[8,9] The *exo*- and *endo*-adducts were also confirmed by lactonization studies: the adduct which formed an iodolactone was assigned an *exo*-configuration, while the other isomer which did not undergo lactone formation but yielded

* The prefixes *endo* and *exo* are used in the sense that substituents on the same side of the bicyclo[2.2.2]octene ring as benzene ring are *endo*, those on the other side are *exo*.

** The prefixes *endo* and *exo* are used in the sense that the isomer with the succinimidyl ring towards the cage olefinic system is *endo* and that with the succinimidyl ring away from the olefinic system is *exo*.



VI



VII

its carboxylic acid was given *endo*-configuration.[9] Based on aromatic solvent induced shift studies in rigid cyclic ketones,[10] the configurations of these adducts have also been reported.[9] These adducts showed a small shift difference for the methyl protons and the configuration of either *exo*- or *endo* can be assigned only when the spectrum of the other corresponding isomer is available.

The configuration of 6,6-diphenylfulvene and maleic anhydride adduct was first studied by the ozonization method and was assigned the *exo*-configuration, no *endo*-isomer being produced.[11] The work was reinvestigated and the *endo* and *exo* configurations were established by chemical methods. The *endo*-adduct on treatment with hypobromous acid formed bromolactone acid which subsequently yielded a dilactone. The *exo*-adduct formed a lactone acid with hypobromous acid.[12]

Results and Discussion

N-(Diacylamino)imide Derivatives (IIb—IId and IIIb—IIIf) The NMR spectra of the isomeric *N*-(diacylamino) imide derivatives (IIb and IIIb) are in accordance with the restricted rotation about N–N bond showing two singlets each for the *N'*-acetyl protons with an internal chemical shift of 10 Hz and 97 Hz, respectively (Table 1). On shielding considerations on one of the *N'*-acetyl groups, IIIb could be assigned the *endo*-configuration and IIb the *exo*-configuration.[5]

The spectra of *N'*-acetyl-*N'*-benzoyl derivatives (IIc and IIIc) exhibit two conformations VI and VII resulting from the restricted rotation about N–N bond. Splitting in the cage-methyl resonances by the *N'*-benzoyl group in the compound IIc confirms the *exo*-configuration of the adduct (Table 1). In the other isomeric product IIIc, the cage-methyl resonances remain unaffected and the splitting in the *N'*-acetyls ($\Delta\nu$=60 Hz) demonstrates the *endo*-configuration of the adduct.

A careful study of the spectra shows the preference for conformation (VII) in both the *endo* and *exo*-isomers, where the *N'*-benzoyl group lies *anti* to the cage-moiety. While the conformational preference (VI) has been reported in the *exo*-derivatives of naphthalene-maleic anhydride adduct,[5] sterically the same conformer is not favoured in the case of IIc. The other *N'*-acetyl-*N'*-aroyl compounds (IId and IIId—IIIf) also support the configurational assignment.

N',N'-Diacetyl Derivatives (IVb and Vb). The NMR spectra of *N',N'*-diacetyl-*N*-amino [2.2.1] bicyclo-5-heptene-7-diphenylmethylene-2,3-*endo/exo*-dicarboximide (IVb) and (Vb) in $CDCl_3$ exhibit a similar pattern (Table 2). These isomeric compounds show two singlets, one each for *N'*-acetyl protons, with an internal chemical shift of 16 and 20 Hz, respectively, along with other proton resonances. These observations suggest that the C-5 and C-6 olefinic protons and 7-diphenylmethylene group exert a similar shielding effect on the *N'*-acetyl protons. In such a system where *N'*-acetyls do not appear to be a diagnostic probe for the configurational study, introduction of a group at the *exo*-cyclic nitrogen, which can strongly influence the resonance of the cage protons, would give useful information. *N'*-Acetyl-*N'*-benzoyl-*N*-amino-

imide system has been found to be suitable for the purpose.

N'-Acetyl-N'-benzoyl Derivatives (IVd and Vd) The NMR spectrum of IVd shows multiplicity for C-5 and C-6 olefinic proton resonances ($\Delta\nu$=57 Hz) as well as for the *N'*-acetyl protons (intensity ratio 2: 1, $\Delta\nu$=4 Hz) with other proton resonance (Table 2) caused by restricted rotation about the N–N bond. The spectral features of the compound IVd are very similar to those of *N'*-acetyl-*N'*-benzoyl derivative of *N*-amino[2.2.1]-bicyclo-5-heptene-2,3-*endo*-dicarboximide. The compound also shows preference for the conformation (VI) where the benzoyl group lies *syn* to the cage-olefinic protons. The multiplicity in the cage-olefinic protons indicates the *endo*-configuration of the adduct. The spectrum of the isomeric compound Vd shows two singlets for *N'*-acetyl protons (intensity ratio 2: 3, $\Delta\nu$= 29 Hz) and a triplet for C-5 and C-6 olefinic protons along with other proton resonance (Table 2). The spectral pattern is in conformity with the restricted rotation about N–N bond, showing the presence of two conformations. The appearance of *N'*-acetyl resonance at the shielded position (δ 1.96) indicates that the conformation (VII), in which the acetyl group lies *syn* to 7-diphenylmethylene, is preferred. Since no multiplicity in the cage-olefinic resonance has been observed, the spectrum indicates it to be an *exo*-adduct. Shielding of the *N'*-acetyl protons by the 7-diphenylmethylene further supports the *exo*-configuration.

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer equipped with a variable temperature controller (Model No. V-6040). IR spectra were recorded for Nujol mulls on Perkin-Elmer-720 spectrophotometer. NMR spectral data are given in Tables 1 and 2, and IR spectral data, melting points and elemental analyses of all the compounds (IIa—IId, IIIa—IIIf, IVa—IVd, and Va—Vd) in Table 3.

*1,2,3,4-Tetrahydro-9,10-dimethyl-1,4-ethenonaphthalene-2,3-*exo/endo-*dicarboxylic Anhydride.* The *exo* and *endo*-adducts of 2,3-dimethylnaphthalene and maleic anhydride were obtained by the method of Kloetzel and Herzog.[6] A mixture of 2,3-dimethylnaphthalene (1 g) and maleic anhydride (19 g) was heated on an oil bath at 99—100 °C for about 24 h. The hot reaction mixture was poured into water; unreacted maleic anhydride went into the solution leaving behind adduct (*exo/endo*) diacids and 2,3-dimethylnaphthalene. The product was subsequently washed with water and the unreacted 2,3-dimethylnaphthalene was eliminated by converting the *exo/endo*-diacids into water soluble potassium salts by treating the mixture with KOH solution (5%). These acids were liberated by acidification with hydrochloric acid, filtered and then converted into their anhydrides by heating with acetic anhydride on a water bath for about 2 h. A fractional crystallization procedure from carbontetrachloride was developed for the isolation of *exo* (mp 193—195 °C) and *endo* (mp 175—176 °C) adducts. The *exo*-isomer crystallized out first.

[*2.2.1*]*Bicyclo-5-heptane-7-diphenylmethylene-2,3-*endo/exo*dicarboxylic Anhydride.* These isomeric adducts were obtained according to the method of Alder *et al.*[12] The *endo*-isomer was obtained from 6,6-diphenylfulvene and maleic anhydride in benzene solution at room temperature which on recrystallisation from ethylacetate melted at 174 °C. However, the more predominant *exo*-adduct was obtained on boiling the reactants in xylene. The *exo*-adduct was more soluble in ethylacetate (mp 147 °C).

N-*Aminoimide Derivatives (IIa, IIIa, IVa, and Va).* *N*-Aminoimide derivatives of these isomeric adducts were prepared by adding hydrazine hydrate dropwise while stirring, to the equimolar quantities of adducts in ethanol at room temperature. These *N*-amino-imides were characterised by IR, NMR and chemical analyses.

N′,N′-*Diacetyl Derivatives (IIb, IIIb, IVb, and Vb).* *N′,N′*-Diacetyl derivatives were prepared by heating the corresponding *N*-aminoimides with an excess of acetic anhydride. The product was washed with water, dried and recrystallized from ethanol.

N′-*Acetyl*-N′-*aroyl Derivatives (IIc, IId, IIIc—IIIf, IVd, and Vd).* The *N′*-acetyl-*N′*-benzoyl derivatives were prepared in two steps: *N′*-mono benzoyl derivatives were obtained by refluxing equimolar amounts of *N*-aminoimides and benzoyl chloride with a few drops of pyridine in dry benzene for 4 h. After removal of the solvent, the product was washed with water and recrystallized. The mono-benzoyl derivatives thus obtained were acetylated with an excess of acetic anhydride and a few drops of pyridine on a water bath for 3—4 h. The product was washed with water, dried and recrystallized from ethanol. The other aroyl derivatives were obtained in the same way.

We thank the C.S.I.R., India, for the award of a research fellowship (to A. K. Singh).

Structural Assignment by NMR Spectroscopy: Restricted Rotation about Aryl C–N Bond and Configurations of Diels-Alder Adducts

Shiva Mohan VERMA and Nripendra B. SINGH

Department of Chemistry, Banaras Hindu University, Varanasi 221005, India

(Received February 28, 1977)

Restricted rotation and non-planar conformations about the aryl C–N bond in *ortho* substituted arylimides have been studied in order to assign the *endo* and *exo* configurations of Diels-Alder adducts, employing the adducts of maleic anhydride with naphthalene and cyclopentadiene as model compounds. The adducts are readily transformed into their *o*-tolylimide derivatives and the *N*-*o*-tolyl probes satisfactorily into the magnetic environment of the cage moiety. In 1-naphthylimide derivatives, the *naphthyl* group causes splitting in the cage-proton resonances and is found to be more diagnostic for structural assignment.

Recently we reported restricted rotation and non-planar ground state conformations about the aryl C–N bond in a system of type (I).[1] The high energy barrier (ΔG^* 22 kcal/mol) was attributed purely to the steric interaction of the *o*-substituent, the carbonyl groups of the succinimidyl ring which is of similar order as that of the N–N bond in tetracylhydrazines (II) having lone pair electronic interactions at the two nitrogens.[2] With the help of conformational studies about the N–N bond through their *N*-aminoimide derivatives the *endo*/*exo* configuration of Diels-Alder adducts of maleic anhydride with cyclic dienes such as cyclopentadiene,[3] β-naphthol,[4] naphthalene,[5,6] and substituted anthracenes[7] was demonstrated. In this communication the applicability of the N–C bond conformations in the structural assignment of the Diels-Alder adducts is discussed. *o*-Substituted phenylimide(I) is quite diagnostic and effective in the structural elucidation which can easily be obtained from the DA adducts in one step under ordinary experimental conditions. Earlier studies revealed that *o*-CH_3 or 2,3-*benzo* substituents in the *N*-phenyl(I) can be more diagnostic than *o*-OCH_3, *o*-Cl, and *o*-Br substituents in the structural assignments.[1] *o*-Substituted anilides of cyclopentadiene–maleic anhydride and naphthaline–maleic anhydride and their reduced products (III to X) have been prepared and their NMR spectra are discussed in the light of their configurational assignment.

Results and Discussion

Naphthalene–Maleic Anhydride Adducts (endo/exo) *1) o-Toluidide Derivatives (IIIa, IVa)*: The NMR spectrum of the compound IIIa shows two singlets for the *o*-tolyl methyl protons at δ 1.0 and 2.0 and a multiplet of 0.58 H intensity at δ 5.45 along with the other normal proton resonances (Table 1). In the other isomeric derivative (IVa), the *o*-tolyl protons also appear as two singlets at δ 2.10, and 2.13 along with other normal resonances (Table 1). These spectral multiplicities are due to the hindered rotation about aryl C–N bond[1] and the existence of the two conformations XI and XII is indicated.

On the basis of shielding effect on the syn-*o*-tolyl protons by the cage-moiety (XII) a reasonable assignment of the configuration of the adduct is possible. A high degree of shielding on the *o*-methyl protons ($\Delta\nu$= 60 Hz) suggests the *endo* configuration for IIIa while

TABLE 1. 60 MHz NMR SPECTRAL DATA[a] (δ ppm) OF THE COMPOUNDS IIIa, IIIb, IVa, IVb, Va, Vb, VIa, VIb

Compound	R	Ortho (*N*-phenyl)	2+3	1+4	9+10	5—8+*N*-phenyl (m & p)
IIIa	1.0, 2.0 (ds, 2: 3, 3H)	5.45, 7.16 (dm, 3: 2, 1H)	3.23 (t, 2H)	4.5 (m, 2H)	6.65 (q, 2H)	7.16 (m, 7H)
IIIb	7.33 (m, 4H)	5.33, 7.33 (dm, 2: 1, 1H)	3.33 (t, 2H)	4.53 (m, 2H)	6.5 (q, 2H)	7.33 (m, 6H)
IVa	2.10, 2.13 (ds, 6: 7, 3H)	7.18 (m, 1H)	3.13 (t, 2H)	4.48 (m, 2H)	6.65 (q, 2H)	7.18 (m, 7H)
IVb	7.5 (m, 4H)	7.5 (m, 1H)	3.15 (m, 2H)	4.51 (m, 2H)	6.66, 6.83 (dq, 1: 1, 2H)	7.5 (m, 6H)
Va	0.9, 2 (ds, 2: 3, 2H)	5.45, 7.25 (dm, 3: 2, 1H)	3.27 (t, 2H)	4.51 (m, 2H)	1.53 (q, 4H)	7.25 (m, 7H)
Vb	7.43 (m, 4H)	5.3, 7.43 (dm, 2: 1, 1H)	3.33 (t, 2H)	3.73 (m, 2H)	1.66 (q, 4H)	7.43 (m, 6H)
VIa	2.15, 2.31 (ds, 5: 7, 3H)	7.25 (m, 1H)	3.01 (m, 2H)	3.61 (m, 2H)	1.66 (bq, 4H)	7.25 (m, 7H)
VIb	7.43 (m, 4H)	7.43 (m, 1H)	3.12 (m, 2H)	3.81 (m, 2H)	1.68 (m, 4H)	7.43 (m, 6H)

a) The NMR spectra of all the compounds were recorded in $CDCl_3$. The total number of protons and the multiplicity of the bands are indicated in brakets. In the case of multiplicity due to slow rotation, the ratio of the intensity of the upfield to down field signales are indicated. Signals are abbreviated as: s=singlet; t=triplet; ds=double singlet; dt=double triplet; q=quartet; dq=double quartet; bq=broad quartet; dm=double multiplet.

the small shielding value ($\Delta\nu$=2 Hz) suggests the *exo*-configuration for IVa.

The *endo* configuration for IIIa is further demonstrated by the observation of a multiplet at δ 5.45 (0.58 H) which could arise from the shielding of the *ortho*-hydrogen of the *N*-phenyl by the cage benzo ring in the conformer XI.

2) 1-Naphthylimide Derivatives (IIIb, IVb): The spectra of 1-naphthylimide derivatives of the isomeric adducts (*endo*/*exo*) are diagnostic in the configurational assignment of the adducts as the 2,3-benzo group of the 1-naphthylimide strongly influences the resonances of the cage protons providing fruitful results.

The NMR spectrum of VIb shows a double quartet for the C9 and C10 olefinic protons at δ 6.66 and 6.83 ($\Delta\nu$=10 Hz) with other normal proton resonances, while the spectrum of the other isomeric adduct IIIb shows a single quartet for the C9 and C10 olefinic protons at δ 6.5 and a multiplet at δ 5.33 (0.68 H) for the *ortho* proton of the naphthylimide. The appearance of the olefinic protons as a double quartet in IVb indicates the *exo* configuration of the adduct, whereas no multiplicity in the olefinic proton resonances as well as the appearance of the *ortho* naphthyl proton at a shielded postion in IIIb suggest the *endo* configuration.

3) o-Toluidides of Reduced Products (Va, VIa): The NMR spectra of both the isomeric adducts (Va, VIa) show a double singlet each for the tolyl methyl protons with internal chemical shifts of 66 Hz and 10 Hz respectively. The spectrum of Va also shows a multiplet for the *ortho N*-phenyl proton at an upfield position and a quartet for the C9 and C10 methylene protons at δ 1.53, while the spectrum of VIa shows a broad quartet at δ 1.66 for the C9 and C10 methylene protons (Table 1). These observations further support the assignment of the *endo* (Va) and *exo* configurations (VIa).

4) 1-Naphthylimide Derivatives of the Reduced Products (Vb, VIb): The NMR spectra exhibit similar features to those of the unreduced derivatives (IIIb, IVb). The spectrum of Vb shows a quartet for the C9 and C10 protons at δ 1.66, while (VIb) shows a broad multiplet at δ 1.68 for C9 and C10 protons (Table 1). The appearance of the broad multiplet for the C9 and C10 protons is caused by the shielding of the 2,3-*benzo* group and the adduct could be assigned as *exo*, while a quartet in the spectrum of Vb for C9 and C10 indicates the *endo* configuration.

Cyclopentadiene–Maleic Anhydride Adducts.

1) o-Toluidide Derivatives (VIIa, VIIIa): The configuration of the adducts (*endo*/*exo*) could be assigned by comparing the spectra of their *o*-toluidide derivatives. The NMR spectrum of VIIa shows two singlets for the *o*-tolyl methyl protons at δ 2.06 and 2.09 with an internal chemical shift of 2 Hz and an AB quartet for C7 methylene protons at δ 1.53 and δ 1.78, while the other isomer (VIIIa) shows a singlet of 3H intensity at δ 2.16 for the *o*-tolyl protons and a multiplet at δ 1.58 for the C7 methylene proton (Table 2).

The spectral pattern is in conformity with the restricted rotation about N–C bond and the existence of two conformations XI and XII is indicated. The multiplicity in methyl resonances of the *o*-tolyl group indicates the *endo* configuration (VIIa) whereas its appearance as a singlet suggests the *exo* configuration (VIIIa) resulting from the less magnetic interaction of methylene bridge.

2) 1-Naphthylimide Derivatives (VIIb, VIIIb): Compound VIIb shows a double triplet for the C5 and C6 olefinic protons at δ 6.4 and 6.58 ($\Delta\nu$=11 Hz) and an AB quartet for the C7 methylene protons with other normal proton resonances (Table 2). The spectrum of the other isomeric compounds (VIIIb) shows a triplet at δ 6.3 for the olefinic protons along with duplication in the resonances of C7, C2+C3, and C1+C4 protons (Table 2). The multiplicity in the olefinic protons suggests the *endo* configuration for (VIIb), while a single triplet for the olefinic protons as well as the multiplicity in methylene proton resonances indicate the *exo* configuration (VIIIb).

3) o-Toluidide of Reduced Products (IXa, Xa): The spectra of the reduced products (IXa and Xa) also exhibit similar features to those of their unreduced de-

Table 2. 60 MHz NMR spectral[a] data (δ ppm) of the compounds VIIa, VIIb, VIIIa, VIIIb, IXa, IXb, Xa, Xb

IXb	7.5 (m, 4H)	2.93 (m, 2H)	3.71 (m, 2H)	1.7 (m, 2H)	1.7 (m, 4H)	7.5 (m, 3H)
Xa	2.15 (s, 3H)	2.83 (m, 2H)	2.83 (m, 2H)	1.58 (m, 2H)	1.53 (q, 4H)	7.08 (m, 4H)
Xb	7.55 (m, 4H)	2.81 (ds, 2H)	3.4 (bm, 2H)	1.55 (bm, 2H)	1.55 (bm, 4H)	7.55 (m, 3H)

a) The NMR spectra of all the compounds were recorded in $CDCl_3$. The total number of protons and the multiplicity of the bands are indicated in brackets. In the case of multiplicity due to slow rotation the ratio of the intensity of the upfield to down field signals are indicated. Signals are abbreviated as: s=singlet; t=triplet; m=multiplet; ds=double singlet; dt=double triplet; dm=double multiplet; bm=broad multiplet; dbm=double broad multiplet.

rivatives (VIIa and VIIIa). In IXa, the tolyl methyl protons appear as two singlets at δ 2.11 and 2.23 with an internal chemical shift of 7 Hz and C5 and C6 protons appear as a quartet at δ 1.66, whereas the *o*-methyl protons in Xa appear as a singlet at δ 2.15 and C5 and C6 protons as a multiplet (Table 2). The *endo* configuration can thus be assigned to IXa and *exo* configuration to Xa.

4) 1-Naphthylimide Derivatives of Reduced Products (IXb, Xb): The spectra of these derivatives also provide valuable information regarding the structural elucidation of the adducts. The naphthyl group influences the C5 and C6 cage methylene protons in IXb, indicating the *endo* configuration, while C5 and C6 methylene protons remain unaffected in Xb suggesting the *exo* configuration (Table 2).

Experimental

NMR spectra were recorded on a Varian A60D spectrometer at 45 °C. Spectral data of the compounds are given in Tables 1 and 2. Infrared spectra were recorded in Nujol mull on a Perkin Elmer-720 spectrometer. Melting points, chemical analyses and IR bands of the compounds are given in Table 3.

*Naphthalene-Maleic Anhydride Adducts (*endo/exo*) and Their Derivatives (IIIa, IVa, IIIb, IVb, Va, VIa, Vb, VIb).* The *endo* and *exo* adducts of maleic anhydride with naphthalene were obtained according to the method of Takeda *et al.*[8] and separated from ethanol by fractional crystallisation. Adducts were transformed into their toluidide (IIIa and IVa) and naphthylimide derivatives (IIIb and IVb) by heating carefully with equimolar amounts of *o*-toluidine and, 1-naphthylamine respectively in a round bottomed flask fitted with an air condenser at 80 °C for *ca.* 2 h. The products obtained were crystallised from ethanol. The toluidide and naphthylimide derivatives on further refluxing with hydrazinehydrate (slightly excess than 2 mol) in ethanol in the presence of animal charcoal gave the reduced products[9] (Va, VIa, Vb, VIb). These compounds were recrystallised from ethanol.

Cyclopentadiene-Maleic Anhydride Adducts and Their Derivatives (VIIa, VIIIa, VIIb, VIIIb, IXa, Xa, IXb, Xb). [2.2.1] Bycyclo-5-heptene 2,3 *endo/exo* dicarboxalic anhydride were prepared according to the method of Craig.[10]

Toluidide (VIIa and VIIIa) and naphthylimide (VIIb and VIIIb) derivatives were obtained on heating the isomeric adducts with equimolar amounts of *o*-toluidine and 1-naphthylamine, respectively, in a round bottomed flask attached to an air condenser at 100—120 °C for 3 h. The products obtained were crystallised from ethanol. These compounds on further refluxing with hydrazinehydrate (slightly excess than 2 mol) in ethanol in the presence of animal charcoal gave the reduced products[9] (IXa, Xa, IXb, Xb) which were recrystallised from ethanol.

Synthesis and Reactions of Some New 1,3-Dioxa-2-bora Heterocycles Derived from *o*-Hydroxybenzyl Alcohol

G. SRIVASTAVA and P. N. BHARDWAJ

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(Received March 22, 1977)

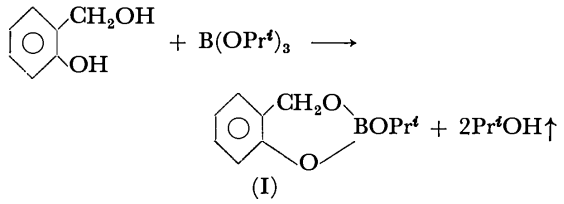
2-Isopropoxy-4*H*-1,3,2-benzodioxaborin(I), obtained from isopropyl borate and *o*-hydroxybenzyl alcohol, reacts with a variety of hydroxy compounds (*viz.*, *t*-butyl alcohol, phenol, ethane-1,2-diol, 2-aminoethanol, *o*-amino phenol) and acetic anhydride to give the corresponding 2-substituted heterocycles. Reactions of (I) as well as other 1,3-dioxa-2-bora heterocycles with bases (*viz.*, ammonia, triethylamine, pyridine, dimethylformamide) show that the electrophilicity of boron decreases in the order: 2-alkoxy-1,3,2-benzodioxaborole>2-phenoxy-4*H*-1,3,2-benzodioxaborin>(I)>2-alkoxy-1,3,2-dioxaborinane.

Codisproportionation reaction between bis(4*H*-1,3,2-benzodioxaborin-2-yl)oxide (obtained directly from boric acid and *o*-hydroxybenzyl alcohol) and triorganotin hydroxide or oxide yields 2-triorganostannoxy-4*H*-1,3,2-benzodioxyborin. Cleavage and insertion reactions of these compounds have been studied.

Boron heterocycles containing two oxygen atoms, *e.g.*, 1,3,2-dioxaborolanes,[1] -borinanes[2] and 1,3,2-benzodioxaboroles[3] have been extensively studied. The effect of ring size on the stability[4] as well as the electrophilic nature of boron[5] in such derivatives have also been investigated. The higher reactivity of benzodioxaborole derivatives in comparison to dioxaborinanes and dioxaborolanes can be easily understood in terms of greater electron deficient character of boron in the former class of compounds. Boron heterocycles derived from *o*-hydroxybenzyl alcohol form a mixed system and have been synthesized only recently by the reactions of this ligand with tris(dimethylamino)borane, tris(ethanethiolato)borane and phenylboric acid.[6] Azeotropic removal of water from a mixture of *o*-hydroxybenzyl alcohol, boric acid and an alcohol leads to the formation of the corresponding 2-alkoxy-4*H*-1,3,2-benzodioxaborin. In the present paper we report a detailed study of the synthesis and reactions of various 2-substituted-4*H*-1,3,2-benzodioxaborins. Attempts have also been made to compare the electrophilic nature of boron in these and in other types of 1,3-dioxa-2-bora heterocycles.

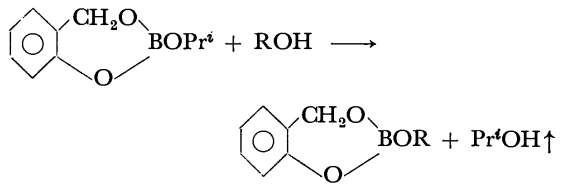
Results and Discussion

2-Isopropoxy-4*H*-1,3,2-benzodioxaborin (I) is obtained as a colourless volatile liquid by the interaction of isopropyl borate with *o*-hydroxybenzyl alcohol in refluxing benzene, with azeotropic removal of the liberated isopropanol.



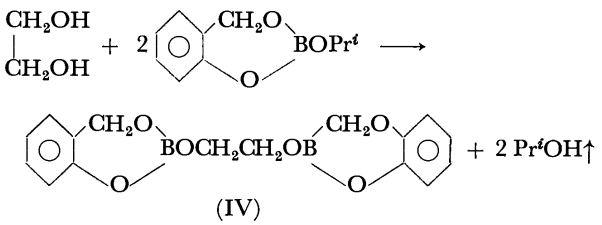
(I)

The isopropoxy group of the boron heterocycle (I) could be easily replaced by other alkoxy and phenoxy groups by simple alcohol interchange technique in benzene. The progress of the reaction could be followed by estimating the amount of isopropanol in azeotrope. It has been observed qualitatively that these reactions are comparatively slower than those of 2-isopropoxy-1,3,2-benzodioxaborole.



(II), R=Bu^t; (III), R=Ph

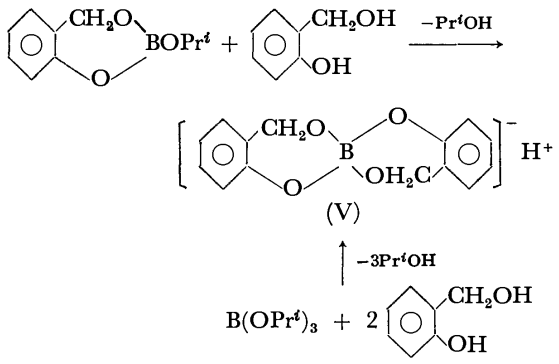
Reaction of I with ethylene glycol affords 2,2′-ethylenedioxybis(4*H*-1,3,2-benzodioxaborin) (IV) as a white solid.



(IV)

It is noteworthy that the reaction of I with *o*-hydroxybenzyl alcohol in 2: 1 molar ratio does not proceed to completion and only half of the calculated amount of isopropanol is obtained in the azeotrope. The resulting semisolid on distillation yields, some unreacted 2-isopropoxyborin (I) and decomposed residue. Similar results are obtained when reaction of isopropyl borate with *o*-hydroxybenzyl alcohol in 2: 3 molar ratio is carried out. It appears that the product in these reactions is an equimolar mixture of I and bis(*o*-benzomethylenedioxy)borate (V). 2,2′-(*o*-Benzomethylenedioxy)bis(4*H*-1,3,2-benzodioxaborin) is not obtained in these reactions even under forcing conditions. This may be due to steric reasons. Molecular models show that two 4*H*-1,3,2-benzodioxaborin-2-yl moieties present on the two oxygen atoms of *o*-benzomethylenedioxy moiety cannot rotate freely.

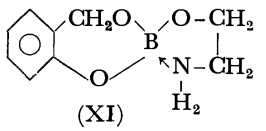
Compound V is obtained in quantitative yields as a viscous semisolid by the following routes:



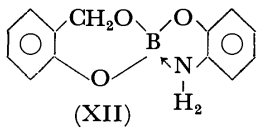
Attempts to synthesize the sodium salt of V by crystallisation from an aqueous solution of boric acid, *o*-hydroxybenzyl alcohol and sodium hydroxide were unsuccessful. The ammonium salt $[(C_7H_6O_2)_2B]^-[NH_4]^+$ (VI), however, is immediately precipitated on passin gammonia to a benzene solution of V.

Reactions of 2-phenoxy- and 2-isopropoxy-4*H*-1,3,2-benzodioxaborin with nitrogen donors have been studied. The phenoxy derivative (III) forms stable 1:1 complexes with triethylamine and pyridine (VII and VIII respectively) exothermally whereas with dimethylformamide, no reaction appears to take place. I also does not give an adduct with dimethylformamide but on mixing with pyridine, heat is evolved and liquid complex (IX) is formed which loses pyridine slowly under high vacuum, leaving behind a highly viscous semisolid, insoluble in benzene and carbon tetrachloride. This semisolid yielded I on distillation under reduced pressure. The structure of the semisolid could not be studied further. Unlike pyridine, ammonia forms a stable 1:1 complex (X) with I. Attempts to prepare a salt of the type $[C_6H_4\langle{}^{O}_{CH_2O}\rangle B(OPr^i)_2]^-[NH_4]^+$ by passing ammonia to an equimolar mixture of I and isopropanol in benzene were unsuccessful. The addition complex (X) was precipitated in these cases also. It may be pointed out in this context that 2-isopropoxy-1,3,2-benzodioxaborole forms addition complexes with various donors including dimethylformamide whereas 2-isopropoxy-4,4,6-trimethyl-1,3,2-dioxaborinane does not show any tendency of complex formation.[7] Thus, the electrophilicity of boron in 1,3-dioxa-2-bora heterocycles appears to decrease in the order: 2-isopropoxy-1,3,2-benzodioxaborole>III>I>2-isopropoxy-4,4,6-trimethyl-1,3,2-dioxaborinane.

Reactions of I with 2-aminoethanol and *o*-aminophenol in refluxing benzene give insoluble solid products XI and XII in which there is internal coordination from nitrogen to boron. In contrast to I and III, the derivatives XI and XII do not show any tendency to form complexes with nitrogen donors.

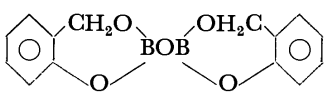


(XI)

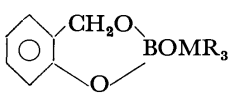


(XII)

Azeotropic removal of water with benzene from an equimolar mixture of boric acid and *o*-hydroxybenzyl alcohol yields bis(4*H*-1,3,2-benzodioxaborin-2-yl)oxide (XIII) which reacts further with bis(tributyltin)oxide and triphenyltin hydroxide giving 2-tributylstannoxy- and 2-triphenylstannoxy-4*H*-1,3,2-benzodioxaborin, XIV and XV, respectively. These are new examples of stannoboroxanes.[8] The facile cleavage of Sn–O–B bond in XV by trimethylchlorogermane and -silane affords the corresponding trimethylgermoxy (XVI) and trimethylsiloxy (XVII) derivatives which are easily separated from triphenyltin chloride by fractional distillation.

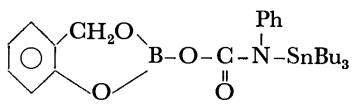


(XIII)

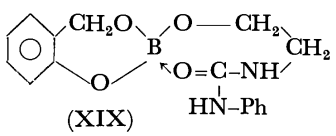


(XIV) $MR_3=SnBu_3$
(XV) $MR_3=SnPh_3$
(XVI) $MR_3=GeMe_3$
(XVII) $MR_3=SiMe_3$

The higher reactivity of Sn–O bond in comparison to B–O bond in stannoboroxanes has been demonstrated previously by the study of their cleavage and insertion reactions.[9] Insertions of unsaturated substrates across Sn–O bond are very facile. On the other hand, the only reported example of insertion across B–O bond appears to be the extremely slow reaction (24% yield in 30 days at room temperature) of 2-butoxy-1,3,2-benzodioxaborole with phenyl isocyanate.[10] The present studies show that whereas I, as expected, does not show any tendency to react with phenyl isocyanate, the corresponding 2-tributylstannoxy derivative (XIV) reacts immediately and exothermally to give the insertion product (XVIII). Aminoethoxy derivative (XI) also reacts with phenyl isocyanate presumably at the amino group and based on earlier studies,[11] the addition compound has been tentatively assigned structure XIX, in which the carbonyl group of the substituted urea moiety coordinates with boron.



(XVIII)



(XIX)

IR and PMR Spectra. The common peaks present in the IR spectra of all the derivatives (I—XIX) are; (i) a sharp and strong peak at 755 cm^{-1} (out of plane aromatic C–H bending); (ii) peaks of medium intensity at 1030, 1115 and 1160 cm^{-1} (inplane C–H bending), (iii) strong intensity peaks at 1080 and 1255 ± 5 cm^{-1} (due to aliphatic and aromatic C–O stretching vibrations respectively) and (iv) a weak intensity band at 3050 ± 10 cm^{-1} (due to aromatic C–H stretching). The region 1300—1500 cm^{-1} shows four to five strong peaks and an attempt to assign ν_{B-O}

a) In $CDCl_3$. b) Insoluble in CCl_4 and $CDCl_3$.

with any amount of certainty is rather difficult. $\nu_{B-OC(aliphatic)}$ and $\nu_{B-OC(aromatic)}$ will absorb at different positions, the latter being at higher wave number and the two peaks present in 1350—1420 cm^{-1} region may tentatively be assigned to these vibrations.

In the derivative XIV, the presence of tributylstannoxy group[12] is shown by the appearance of $\nu_{as\ SnC_3}$ at 670 and 600 cm^{-1}, $\nu_{s\ SnC_3}$ at 515 cm^{-1} and ν_{B-O-Sn}[9] at 1280 cm^{-1}. Similarly compound (XVII) shows the characteristic peaks[13,14] of B–OSiMe$_3$ group at 840 cm^{-1} ($\rho_{as\ CH_3}$), 660 cm^{-1} ($\nu_{as\ SiC_3}$), 620 cm^{-1} ($\nu_{s\ SiC_3}$) and 1325 cm^{-1} ($\nu_{as\ B-O-Si}$). The corresponding peak positions for BOGeMe$_3$ group in derivative XVI are 830 cm^{-1} ($\rho_{as\ CH_3}$), 615 cm^{-1} ($\nu_{as\ GeC_3}$), 575 cm^{-1} ($\nu_{s\ GeC_3}$) and 1300 cm^{-1} ($\nu_{as\ B-O-Ge}$).[15] The symmetric deformation of Si–CH_3 and Ge–CH_3 groups, generally appearing at 1240—1260 cm^{-1} are masked by the strong ν_{C-O} band.

ν_{N-H} appears as a sharp weak peak at 3180 cm^{-1} in the *o*-aminophenoxy derivative (XII) but in the 2-aminoethoxy derivative (XI) it is present as a broad shoulder at 3100—3200 cm^{-1}. In the insertion product XIX of the latter compound with phenyl isocyanate, the ν_{NH} peak moves to a higher frequency at 3300 cm^{-1} and the $\nu_{C=O}$ peak is present at 1630 cm^{-1}. The $\nu_{C=O}$ peak in the ureido compound (XVIII) appears at 1610 cm^{-1}.

The purity of most of the new heterocycles (I—XIX) was checked by their PMR spectra in CCl_4. The specific peak positions are reported in the experimental section. The common peaks due to *o*-O–C_6H_4–CH_2–O-moiety, present in all the PMR spectra are a complex multiplet at 2.5—3.7 τ due to aromatic protons and a sharp singlet near 5.0 τ due to CH_2 protons. The position of the latter peak appears to be influenced by the coordination number of boron. Thus, the methylene singlet is present at 4.97 and 4.96 τ in 2-isopropoxy and 2-phenoxy-4*H*-1,3,2-benzodioxaborins respectively. In the corresponding 1 : 1 pyridine complexes, this peak shifts to 5.2 and 5.4 τ respectively. This increased shielding of the methylene protons probably reflects decreased p→pπ bonding from oxygen to born when the latter goes from three-coordinate to four-coordinate state.

Experimental

o-Hydroxybenzyl alcohol (Fluka) was used as supplied. Benzene (B.D.H., L.R.) was kept overnight on sodium wire and distilled, and was finally dried azeotropically with ethanol. Molecular weights were determined ebulliometrically in benzene using thermistor sensing.

Boron was estimated by Thomas' method.[16] Isopropanol in the azeotrope was estimated by oxidation method.[17] Infrared spectra were recorded on Perkin-Elmer model 337-grating spectrometer. PMR spectra were recorded on Perkin-Elmer R12B spectrometer.

2-Isopropoxy-4H-1,3,2-benzodioxaborin. Fractionation of a mixture of isopropyl borate (3.55 g, 18.8 mmol) and *o*-hydroxybenzyl alcohol (2.27 g, 18.3 mmol) in benzene (≈60 ml) yielded isopropanol (2.06 g, calcd 2.26 g) in the azeotrope and the desired product (I) (3.03 g, 88%) at 72 °C/0.01 mmHg as a colourless liquid. (Found: B, 5.63; M, 185. Calcd for $C_{10}H_{13}BO_3$: B, 5.73%; M, 192).

PMR (CCl_4): τ 2.7—3.3 (m, 4H, aromatic), 4.97 (S, 2H, CH_2). 5.5 (Septet, 1H, J=6 Hz), 8.83 (d, 6H, CH_3, J=6 Hz).

Bis(o-benzomethylenedioxy)borate and Its Ammonium Salt.

(a) On refluxing isopropyl borate (2.77 g, 14.7 mmol) with *o*-hydroxybenzyl alcohol (3.65 g, 29.4 mmol) in benzene (≈60 ml) for one hour followed by fractionation, isopropanol (2.66 g, calcd 2.71 g) was obtained in the azeotrope. On removing excess of solvent under reduced pressure, the desired product (V) (3.68 g, 99.2%) was obtained as viscous semisolid. (Found: B, 4.18. Calcd for $C_{14}H_{13}BO_4$: B, 4.24%).

PMR (CCl_4): τ 2.9—3.45 (m, 8H, aromatic), 5.2 (s, 4H, CH_2).

(b) A mixture of 2-isopropoxy-4*H*-1,3,2-benzodioxaborin (1.92 g, 10.0 mmol) and *o*-hydroxybenzyl alcohol (1.24 g, 10.0 mmol) in benzene (≈40 ml), on fractionation, gave isopropanol (0.50 g, calcd 0.60 g) in the azeotrope. After removal of excess benzene *in vacuo*, the product (V) (2.55 g,

100%) was obtained as a viscous semisolid (Found: B, 4.15. Calcd for $C_{14}H_{13}BO_4$: B, 4.24%).

By passing ammonia to a solution of V (3.38 g) in benzene (≈60 ml), the ammonium salt was immediately precipitated (VI) (3.48 g, 96.7%) mp 210—213 °C (Found: B, 3.82; N, 4.46. Calcd for $C_{14}H_{16}BNO_4$: B, 3.96; N, 4.83%).

Attempted Preparation of 2,2'-(o-Benzomethylenedioxy)bis(4H-1,3,2-benzodioxaborin). *(a)*: A mixture of isopropyl borate (2.89 g, 15.3 mmol) and *o*-hydroxybenzyl alcohol(2.78 g, 22.4 mmol) in benzene (≈60 ml) was refluxed for 3 h and fractionated (Found: isopropanol 2.20 g, calcd for 46 mmol 2.76 g) Removal of excess benzene under vacuum, yielded a semisolid (3.36 g) which on distillation under reduced pressure gave 2-isopropoxy-4*H*-1,3,2-benzodioxaborin(1.07 g) at 62 °C/0.05 mmHg (authentic IR and PMR spectra) and a light yellow solid (1.36 g) as undistilled residue (Found: B, 5.40%).

(b): Reaction of compound I (2.04 g, 12.5 mmol) and *o*-hydroxybenzyl alcohol (0.66 g, 5.3 mmol) in benzene (≈60 ml) yielded isopropanol (0.30 g, calcd 0.64 g) and a viscous product (2.35 g, calcd 2.06 g) (Found: B, 4.88%).

Reactions of 2-Isopropoxy-4H-1,3,2-benzodioxaborin with Hydroxy Compounds. A mixture of I and the hydroxy compound in benzene was refluxed and fractionated. After complete removal of the liberated isopropanol azeotropically, the solvent was distilled. The product was finally freed of solvent *in vacuo*. The details of these reactions are summarised in Table 1.

Addition Complexes of 2-Isopropoxy-4H-1,3,2-benzodioxaborin.

(a): Heat was evolved on adding pyridine (1.08 g) to 2-isopropoxy-4*H*-1,3,2-benzodioxaborin (1.92 g). Excess of pyridine was removed *in vacuo* leaving 1: 1 complex (2.70 g) as a viscous product. PMR (CCl_4): τ 1,3—3.1 (m, 5H, pyridine), 3.1—3.6 (m, 4H, aromatic), 5.2 (s, 2H, CH_2), 5.75 (Septet, 1H, C*H*Me_2), 8.95 (d, 6H, CH*Me*$_2$). This complex lost pyridine very slowly (20 h/0.01 mmHg) giving a highly viscous semisolid (2.16 g, Found: B, 5.05%). This on distillation gives I (0.78 g) at 82 °C/0.01 mmHg leaving an undistilled residue (1.14 g).

(b): A solid product X (1.44 g, 100%) mp 205—208 °C, was precipitated immediately on passing ammonia to a solution of compound I (1.32 g) in benzene(≈40 ml) (Found: B, 5.25; N, 6.69. Calcd for $C_{10}H_{16}BNO_3$: B, 5.27; N, 6.70%).

The above complex X (0.92 g, mp 205—208 °C) was also precipitated on passing ammonia to a mixture of compound I (0.86 g) and isopropanol (0.42 g) in benzene (≈50 ml). Unreacted isopropanol (0.4 g) was obtained from the filtrate by azeotropic distillation.

Addition Complexes of 2-Phenoxy-4H-1,3,2-benzodioxaborin.

(a): A solid 1: 1 complex (VII) (0.58 g, 90%) mp 135—138 °C was precipitated on adding triethylamine (0.34 g) to a benzene solution of 2-phenoxy-4*H*-1,3,2-benzodioxaborin (0.44 g)(Found: B, 3.36. Calcd for $C_{19}H_{26}BNO_3$: B, 3.46%).

(b): Heat was evolved on adding pyridine (0.20 g) to 2-phenoxy-4*H*-1,3,2-benzodioxaborin (0.40 g). Excess of pyridine was removed *in vacuo*, leaving 1: 1 complex (VIII) (0.54 g, 100%) as a solid, mp 120 °C (Found: B, 3.53. Calcd for $C_{18}H_{16}BNO_3$: B, 3.55%). PMR(CCl_4): τ 1.3—3.1 (m, 5H, pyridine), 3.1—3.7 (m, 9H, aromatic), 5.4 (s, 2H, CH_2).

(c): No reaction appeared to take place on adding dimethylformamide (0.40 g) to the 2-phenoxy derivative (III) (1.12 g); unchanged (III) was obtained on removing dimethylformamide *in vacuo*.

2-Acetoxy-4H-1,3,2-benzodioxaborin. A mixture of acetic anhydride (0.59 g, 5.8 mmol) and 2-isopropoxy-4*H*-1,3,2-benzodioxaborin (0.97 g, 5.1 mmol) was kept at room temperature for several days. The liberated ester was removed *in vacuo* yielding the product (0.97 g, 100%) as viscous semisold (Found: B, 5.81; $OCOCH_3$, 27.53. Calcd for $C_9H_9BO_4$: B, 5.73; $OCOCH_3$, 28.63%).

Bis(4H-1,3,2-benzodioxaborin-2-yl)oxide. On removal of water azeotropically from a mixture of boric acid (1.17 g, 18.9 mmol) and *o*-hydroxybenzyl alcohol (2.34 g, 18.9 mmol) in benzene (≈60 ml), followed by drying the product under reduced pressure, bis(4*H*-1,3,2-benzodioxaborin-2-yl)oxide (XIII) (2.66 g, 100%) was obtained as a viscous semisolid which solidified slowly on keeping at low temperature, (mp 160—164 °C)(Found: B, 7.80. Calcd for $C_{14}H_{12}B_2O_5$: B, 7.64%).

2-Tributylstannoxy-4H-1,3,2-benzodioxaborin. A mixture of bis(4*H*-1,3,2-benzodioxaborin-2-yl)oxide (3.98 g, 14.1 mmol) and bis(tributyltin)oxide (8.41 g, 14.9 mmol) in benzene was refluxed for 2 h. The product was freed from solvent *in vacuo* to yield the desired product (XIV) (11.77 g, 95.3%) as a colourless liquid, bp 178—180 °C/0.9 mmHg. (Found: B, 34; Sn, 26.94; M, 430. Calcd for $C_{19}H_{33}BO_3Sn$; B, 2.37; Sn, 27.06%; M, 439).

PMR (CCl_4): τ 2.65—3.35 (m, 4H, aromatic), 5.0 (s, 2H, CH_2), 7.7—9.5 (m, 27H, Bu_3Sn).

2-Triphenylstannoxy-4H-1,3,2-benzodioxaborin. Water was removed azeotropically from a mixture of bis(4*H*-1,3,2-benzodioxaborin-2-yl)oxide (2.14 g, 7.6 mmol) and triphenyltin hydroxide (5.51 g, 15.0 mmol) in benzene. Removal of excess benzene gave the product (7.49 g, 100%) as a viscous semisolid (XV) (Found: B, 2.18; Sn, 23.60. Calcd for $C_{25}H_{21}BO_3Sn$: B, 2.20; Sn, 23.68%).

2-Trimethylsiloxy-4H-1,3,2-benzodioxaborin. Trimethylchlorosilane (1.53 g, 14.4 mmol) reacted exothermally with 2-triphenylstannoxy-4*H*-1,3,2-benzodioxaborin (7.49 g, 15.0 mmol). Distillation under reduced pressure yielded 2-trimethylsiloxy-4*H*-1,3,2-benzodioxaborin (XVII) (2.50 g, 85.1 %) as a colourless liquid, bp 80 °C/0.8 mmHg. leaving triphenyltinchloride (6.90 g) as an undistilled residue (Found: B, 4.91; Si, 12.40; M, 214. Calcd for $C_{10}H_{15}BO_3Si$: B, 4.95; Si, 12.47%; M, 222).

PMR (CCl_4): τ 2.6—3.45 (m, 4H, aromatic), 5.06 (s, 2H, CH_2), 8.85 (s, 9H, Me_3Si).

2-Trimethylbermoxy-4H-1,3,2-benzodioxaborin. On adding trimethylchlorogermane (2.40 g, 15.7 mmol) to 2-triphenylstannoxy-4*H*-1,3,2-benzodioxaborin (7.49 g, 15.0 mmol) heat was evolved. Distillation yielded the desired compound (XVI) (3.52 g, 88.2%), bp 125 °C/1.0 mmHg as a colourless liquid (Found: B, 4.11%; M, 261. Calcd for $C_{10}H_{15}BGeO_3$: B, 4.12%; M, 267).

PMR (CCl_4): τ 2.9—3.35 (m, 4H, aromatic), 5.0 (s, 2H, CH_2), 9.52 (s, 9H, Me_3Ge).

Reaction between 2-Tributylstannoxy-4H-1,3,2-benzodioxaborin and Phenyl Isocyanate in 1: 1 Molar Ratio. Phenyl isocyanate (0.31 g, 2.6 mmol) reacted exothermally with 2-tributylstannoxy-4*H*-1,3,2-benzodioxaborin (1.14 g, 2.6 mmol) in benzene (≈5 ml) giving the adduct as a light brown viscous liquid (XVIII) (1.45 g, 100%) which showed no free isocyanate peak in the IR spectrum (Found: B, 1.93; Sn, 20.77. Calcd for $C_{26}H_{38}BNO_4Sn$: B, 1.94; Sn, 20.91%). The compound distils with slight decomposition at 210 °C/1.0 mmHg.

PMR (CCl_4): τ 2.5—3.5 (m, 9H, aromatic), 5.0 (s, 2H, CH_2), 7.9—8.5 (m, 27H, Bu_3Sn).

Reaction between 2-(2-Aminoethoxy)-4H-1,3,2-benzodioxaborin and Phenyl Isocyanate in 1: 1 Molar Ratio. To a suspension of 2-aminoethoxy-4*H*-1,3,2-benzodioxaborin (1.52 g, 7.9 mmol) in benzene (≈10 ml), phenyl isocyanate (0.95 g, 7.9 mmol) was added. The mixture was refluxed for 2 h giving a white crystalline solid (XIX) (2.46 g, 100%) (mp 160—165 °C) which was filtered and dried at 30 °C/0.01 mmHg (Found: B, 3.51; N, 7.20%. Calcd for $C_{16}H_{17}BN_2O_4$: B, 3.53; N,

7.26%).

(Received May 13, 1977)

Solvolysis of 7β-methylbicyclo[3.3.1]non-3β-yl tosylate (**1**) was carried out in a series of carboxamides, *N*-methylformamide (NMF), *N*-methylacetamide (NMA), *N,N*-dimethylformamide (DMF), and *N,N*-dimethylacetamide (DMA), as solvents. The rate (k_1, first-order rate constant) of **1** decreases in the order NMF>NMA>DMF>DMA, a linear free-energy relationship being found between the rates of **1** and those of 1-adamantyl tosylate in acetic acid and 80% ethanol as well as the carboxamides. The products consist of olefin (≥96%) (*exo*-7-methylbicyclo[3.3.1]non-2-ene (**4**) and 3-methylbicyclo[3.3.1]non-2-ene (**5**)) and small amounts of esters (acetates or formates, ≤4%). The content of rearranged olefin **5** is considerably less than that of acetolysis (55%) and ethanolysis (55%), decreasing in the order NMF (34%)>NMA(22%)>DMF(13%)>DMA(9%). A linear reactivity-selectivity relationship holds between log k_1 and log (%**5**/%**4**) for the four carboxamide solvents. The observed kinetic isotope effect ($k_H/k_D=1.01\pm0.03$) for 7α-deuterium-tagged derivative (**1**-7α-*d*) in NMF indicates that the σ(C(7)–H)-assisted ionization process for the solvolysis of **1** in the amides is absent. The results are in line with the stepwise mechanism which involves the formation of an intimate ion-pair intermediate followed by competitive processes such as 1,5-hydride shift, *syn*-E1 reaction, and nucleophilic substitution by the amide molecules. Substitution by the amide molecule leads to the formation of a cationic imidate, the hydrolysis of which affords the carboxylic esters. It is proposed that the *syn*-E1 process *via* an intimate ion-pair intermediate is affected by the tosylate anion reactivity in each amide solvent and suppressed by the hydrogen bonding of the each amide with the tosylate anion.

The occurrence of intramolecular hydride shift in S_N1 solvolysis has been demonstrated in various secondary alkyl or cycloalkyl systems.[1] As regards 7β-methylbicyclo[3.3.1]non-3β-yl tosylate (**1**), Eakin *et al.*[2] observed that acetolysis of **1** is accompanied by significant 1,5-transannular hydride shift (55%). They reported that the hydrogen migration occurs after the rate-determining step, on the basis of the absence of a detectable kinetic isotope effect with regard to 7α-deuterium-tagged substrate (**1**-7α-*d*).

Stéhelin *et al.*[3] observed by use of Taft-Hammett treatment that solvolysis of 7β-substituted (CH_3OCH_2–, CH_3OCO–, and NC–) derivatives and **1** is accelerated when it is accompanied by hydride migration from C(7) to C(3), concluding that there is σ(C(7)–H) participation in the rate-determining step of the ethanolysis. Thus, both the stepwise mechanism, involving the formation of an ion-pair intermediate followed by subsequent processes, and the partially or fully concerted mechanism have been proposed.

In the course of our study on the characteristics of carboxamides as an S_N1 solvolysis solvent, it was shown[4] that the solvolysis of *trans*-4-*t*-butylcyclohexyl tosylate in *N*-methylacetamide (NMA) proceeds with markedly suppressed 1,2-hydride shift as compared with acetolysis[5] and phenolysis,[6] giving exclusively unrearranged olefin. From this finding it has been suggested that intramolecular elimination by the leaving tosylate anion in the intimate ion-pair intermediate is markedly accelerated in NMA solvent.

In the present system **1**, the tosyloxy group is oriented in an equatorial position as in the case of *trans*-4-*t*-butylcyclohexyl system. Thus, it is of interest to examine whether solvolysis of **1** in carboxamide solvents proceeds with suppression of 1,5-hydride shift as compared with acetolysis[2] and ethanolysis.[3] It is also interesting to see whether the solvolysis proceeds with σ(C(7)–H) participation or not. We have studied the solvolysis of **1** in carboxamides, *N*-methylformamide (NMF), *N,N*-dimethylformamide (DMF), and *N,N*-dimethylacetamide (DMA), in addition to NMA.

Results and Discussion

Solvolytic Elimination Rates of 7β-Methylbicyclo[3.3.1]non-3β-yl Tosylate **1**. Solvolysis rates of **1** were determined in four carboxamides (NMF, NMA, DMF, and DMA) at two or three temperatures by the usual titrimetric method. Good first-order behavior was observed for all the kinetic runs over two to three half-lives both in the absence and the presence of pyridine added as a neutralizing agent for the liberated *p*-toluenesulfonic acid. Absence of the effect of added pyridine on the rate indicates that the solvolysis proceeds by the typical S_N1-type mechanism. The rate constants and thermodynamic parameters are given in Table 1. The solvolysis rates for **1** decrease in the sequence NMF>NMA>DMF>DMA in line with the trend observed for 1-adamantyl tosylate.[7]

A good linear relation has been observed in a plot of log k_1 (25 °C) for **1** *vs.* log k_1 (25 °C) for 1-adamantyl tosylate, when the solvolysis rates are compared for a series of solvents, such as 80% ethanol,[3,8] acetic acid,[2,8] NMF,[7] NMA,[7] DMF,[7] and DMA[7] (Fig. 1). The magnitude of the Grunwald-Winstein *m* value[9] (0.53) is comparable to those (0.4—0.7) known for the solvolysis of the usual secondary substrates.[10]

Deuterium Isotope Effects in the Solvolysis of 7α-Deuterium-Tagged Substrate **1**-7α-d *in NMF*. If transannular

Table 1. Kinetic data for the solvolysis of 7β-methylbicyclo[3.3.1]non-3β-yl tosylate (**1**) in various carboxamides

Amide	$k_1/(10^{-5}\ s^{-1})$[b]			$\Delta H^{\neq}$[c]	$\Delta S^{\neq}$[c]
	25 °C	35 °C	50 °C	4.184 KJ/mol	4.184 J/(K mol)
DMA	0.114	0.515	3.77	26.2±0.3	2.2±0.8
DMF	0.218	0.949	5.83	24.5±0.7	−2.0±1.7
NMA	1.08	4.24	—	24.4±0.7	0.6±1.7
NMF	3.20	12.4	—	24.1±0.8	1.8±1.9

a) $[ROTs]_0=0.05$ mol/dm³. The rate constants obtained in the presence of equimolar amount of pyridine were essentially the same as those in its absence. b) Mean deviation for k_1 is ±3.6%. c) Probable errors are quoted.

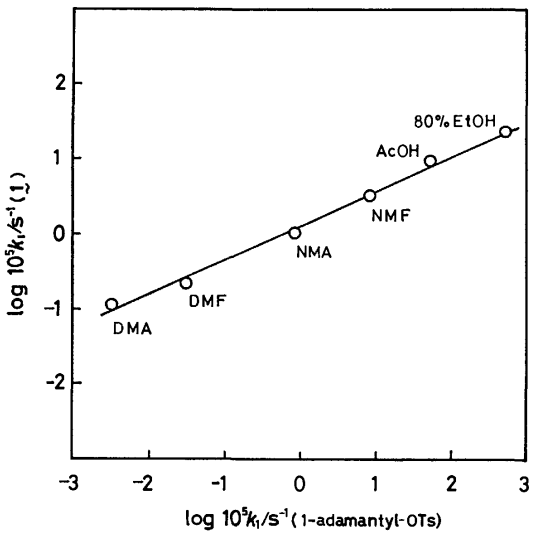

Fig. 1. A linear free-energy relationship between log k_1 (**1**) and log k_1(1-adamantyl tosylate) at 25 °C.

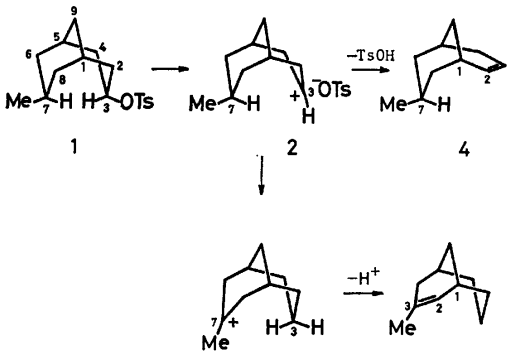
C–H bond breaking (σ-participation) is involved in the rate-determining step, a positive kinetic isotope effect ($k_H/k_D>1$) should be observed upon replacement of the migrating hydrogen atom by a deuterium atom. Thus, the rate of solvolysis of 7α-deuterium-tagged substrate **1**-7α-*d* was determined, using NMF as a solvent. NMF was selected for the reason that a maximal yield of the rearranged olefin (3-methylbicyclo[3.3.1]non-2-ene (**5**)) was observed in the case of NMF as a solvent (*vide infra*). The observed value $k_H/k_D=1.01\pm0.03$, indicates that the solvolysis of **1** proceeds without σ(C(7)–H) participation in NMF.

Elimination Products of the Solvolysis of ***1*** *in the Carboxamides.* In acetic acid[2] and 80% aqueous ethanol[3] the solvolysis product is exclusively a mixture of *exo*-7-methylbicyclo[3.3.1]non-2-ene (**4**) and **5** (**4**: **5**=45: 55). The latter is supposed to be derived from a carbenium ion intermediate (**3**) produced by a transannular C(7)–C(3) hydride shift from the intimate ion-pair intermediate (**2**) of solvolysis (Scheme 1).

It has been accepted that the tosylate **1** has predominantly a twin chair conformation.[11] In this conformation the intermolecular *anti*-elimination is sterically less favored because of the equatorial position of the tosyloxy group, the proton abstraction in this elimination thus being intramolecularly caused by the tosylate anion.

The results of GLC analysis of the solvolysis products



Scheme 1.

indicate that the major product in a series of carboxamide solvolysis is an olefin mixture of **4** and **5**. However, in contrast to the results of acetolysis[2] and ethanolysis,[3] the yield of **5** is much lower and decreases in the order NMF>NMA>DMF>DMA (Table 2). In other words, the hydride shift is suppressed in the carboxamide solvents in the sequence DMA>DMF>NMA>NMF.

Thus, the suppression of hydride shift seems to be a general feature of the carboxamide solvent, since such

Table 2. Products for the solvolysis of 7β-methylbicyclo[3.3.1]non-3β-yl tosylate (**1**) in various carboxamides

a) $[\mathbf{1}]_0=0.05$ mol/dm³. [pyridine]=0.0535 mol/dm³. b) Average of two independent experiments. c) Water contents for carboxamides are ≤0.03 mol/dm³. d) Inverted acetate for DMA and NMA, and formate for DMF and NMF. e) Retained acetate for DMA and NMA, and formate for DMF and NMF. f) 7-Methylbicyclo[3.3.1]-nonan-3-ol; isomer compositions were not determined. g) Trace amount of these compounds were detected on GLC. h) Ref. 2. i) Ref. 3.

phenomenon has also been observed in the solvolysis of 4-*t*-butylcyclohexyl tosylate in NMA.[4] Possible causes for such a suppression might be a) specific solvation from the rear side of the carbenium ion **2** by the nucleophilic carboxamide molecule (negative end of dipole) and/or b) the enhancement of the rate of deprotonation in the intimate ion-pair intermediate **2** due to an increase in the basicity of the leaving tosylate anion in such a solvent as carboxamides. However, judging from the steric disadvantage for the carboxamide molecule to achieve such a solvation toward the U-shaped cationic intermediate **2**, cause a) seems less likely.

The basicity of the leaving tosylate anion in the carboxamide solvents would be the reverse of the hydrogen bonding order (NMF>NMA>DMF>DMA),[12] being in line with the observed solvent sequence for the suppression of rearrangement.

The acceleration of intramolecular *syn*-elimination in E1 reaction has been observed in the elimination of 1-methylpropyl-2-*d* tosylate in a dipolar aprotic solvent, *i.e.* nitrobenzene.[13] Kim and Brown[14] proposed that the leaving group anion can in principle attack β-hydrogen in the stage of tight ion-pair formation to give elimination products. The process leading to the unrearranged olefin **4** (**2**→**4** in Scheme 1) in the present study appears to be close to the one they proposed.

A reactivity-selectivity linear relation[15] has been observed between the rates and the composition of olefin **4** and **5**, when log k_1 values in NMF, NMA, DMF, and DMA are plotted against the logarithms of the ratio %**5**: %**4** (Fig. 2), indicating that both elimination products stem from a single intermediate **2** as depicted in Scheme 1.[16]

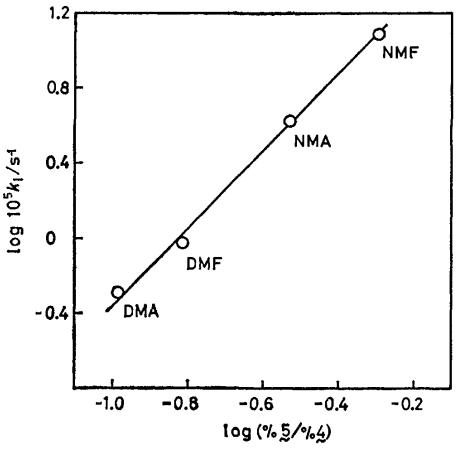

Fig. 2. Linear reactivity-selectivity relationship between log k_1 and log(%**5**/%**4**) for the carboxamide solvent.

Substitution Products of the Solvolysis of ***1*** *in the Carboxamides.* Besides the elimination products, formation of small amounts (≤3%) of ester (acetate or formate) was observed (Table 2). Since the carboxamide solvent used for the solvolysis study is usually contaminated with water (*ca.* 0.003 mol/dm³ or less) even after rigorous purification, the esters seem to be produced by the hydrolysis of an *N*-protonated (as to NMF or NMA) or *N*-methylated (as to DMF or DMA) imidate ester (**6**)[17] which might be derived from the ion-pair intermediate **2** (Scheme 2, *vide infra*). In fact, an examination of the ester yield in DMF with various water contents indicates (Fig. 3, *vide infra*) that no formate is obtained in a completely dried DMF. It is known that a protonated or methylated imidate ester similar to **6** can be rapidly hydrolyzed.[18]

Small amounts of bicyclic alcohol (≤0.7%) are also produced by the hydrolysis of **1** with water contained in the carboxamide solvent.

Effects of Added Water on the Product Distribution in the Solvolysis of ***1*** *in DMF.* GLC product analysis were carried out on the solvolysis of **1** in DMF in the presence of various amounts of water (0.003—0.519 mol/dm³). With an increase in the water content, the yield of the formate increases from zero and reaches a maximum value (7.3%), accompanied by a decrease in the yield of unrearranged olefin **4** from 85.8 to 79.5% (Table 3), whereas the yield of rearranged olefin **5** remains unchanged throughout the whole range of water concentration.

Table 3. Effects of added water on the product distribution for the solvolysis of 7β-methylbicyclo[3.3.1]non-3β-yl tosylate (**1**) in DMF at 35 °C[a]

$[H_2O]$[b] mol/dm³	Yield/% Olefin **4**	Olefin **5**	Ester 3α[c]	Ester 3β[d]	ROH[e]
0.003	85.8	12.8	0.2	0.7	0.5
0.019	84.6	12.5	1.6	1.3	0.0
0.036	83.4	12.9	2.4	1.3	0.0
0.068	82.3	12.6	3.8	1.2	0.0
0.126	80.4	12.7	5.6	1.1	0.2
0.519	79.5	12.7	6.7	0.6	0.5

a) $[ROTs]_0=0.08$ mol/dm³. [pyridine]=0.084 mol/dm³. b) Desired amount of water was added except for the first run, in which the $[H_2O]$ was determined by means of the Karl-Fischer titration. c) Inverted formate. d) Retained formate. e) 3-ol; isomer compositions were not determined.

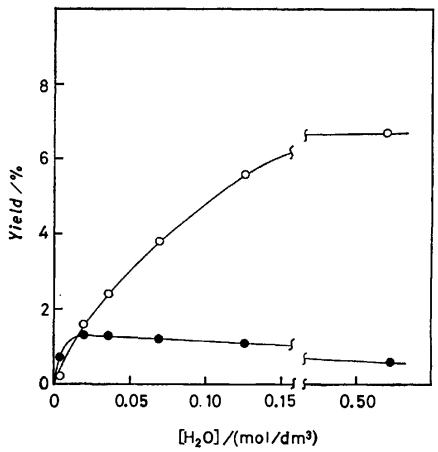

Fig. 3. Effect of added water content in DMF on the formation of 3α- (○) and 3β-formates (●).

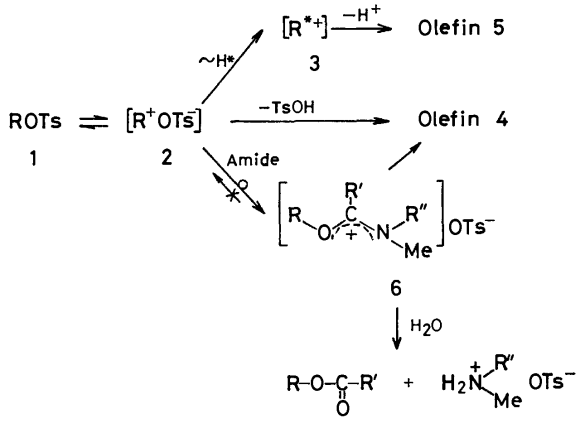
The fact that the change in water content affects the yield of unrearranged olefin **4** as well as the yield of the formate suggests that cationic imidate **6** is produced even in the absence of water to form olefin **4**, not returning to the intimate ion-pair intermediate **2**. If such a return course is probable, a decrease in the yield of the olefin **5** would be observed with an increase in the water content. However, this is not the case (Table 3). The probable reaction pathways are shown in Scheme 2.



Scheme 2. (R′=H or Me; R″=H or Me)

The yields of the 3β-formate are less than 1.3%, while the yields of 3α-formate continuously increase with an increase in the water content up to 6.7% (Table 3 and Fig. 3). The latter is most probably formed through the usual inversion course in the reaction sequence as shown in Scheme 2. The course of the formation of 3β-formate remains open for further examination, though it is in low yields and might not represent a major feature of the solvolysis.

In conclusion, the solvolysis of **1** in the carboxamide solvents proceeds *via* the initially-formed intimate ion-pair intermediate **2** upon which the transannular 1,5-hydride shift, *syn*-E1 reaction, and nucleophilic displacement by the carboxamide molecule occur competitively (Scheme 2). The mechanism is essentially in line with Graham's conclusion.[2]

Experimental

All the melting points are uncorrected. NMR spectra were measured with a Hitachi R-24 instrument, tetramethylsilane being used as an internal standard, IR spectra with a Hitachi 215 or EPI-S2 spectrometer, only the major absorption being cited, and mass spectra with a Hitachi RMS-4 mass spectrometer at 70 eV, the molecular ion being cited. For GLC analysis, a Hitachi K-53 gas chromatograph fitted with a flame ionization detector was used with a 3 m column (i.d. =3 mm) packed with Carbowax 20M or PEG 6000 on Chromosorb W.

Purification of Carboxamides. All the carboxamides used in this study were purified as follows. A reagent grade material was dried for three days over molecular sieves (Type 4A). It was distilled under reduced pressure in the presence of concd H_2SO_4 and the distillate was allowed to stand over CaO or CaH_2 (except for NMF) for several hours. The liquid was transferred to a distillation flask using a large-bore, double ended needle under a positive pressure of nitrogen and distilled under reduced pressure in a dry nitrogen system. The purified carboxamide was stored in an amber bottle with a septum closure under dry nitrogen. In use, a syringe needle is pushed through the septum to gain access to the carboxamides. Titration with Karl Fischer reagent indicates that the water content of the carboxamide is less than 0.003 mol/dm³.

Synthesis of the Substrate ***1***. The synthesis of **1** was reported by Eakin *et al.*[2,19] without any details of the preparation or properties of the substances.

1-Hydroxy-7β-methylbicyclo[3.3.1]nonan-3-one ***(7)***: The procedure is essentially the same as that of Macrosson *et al.*[20] To a stirred solution of NaOMe in MeOH (Na; 0.4 g, MeOH; 30 cm³) was added a mixture of 5-methyl-2-cyclohexen-1-one[21] (1.9 g) and ethyl acetoacetate (2.7 g). After the solution had been heated under reflux for 72 h, a solution of KOH (2.6 g) in water (7.6 cm³) was added, heating under reflux being continued for 12 h. The methanolic solution was concentrated by rotoevaporation. The organic layer was taken up in CH_2Cl_2 and the organic extracts were washed with 5% aq HCl, saturated aq $NaHCO_3$, and saturated aq NaCl. The CH_2Cl_2 solution was dried (Na_2SO_4), concentrated, and recrystallized from CCl_4–hexane, giving 1.95 g (68%) of the hydroxy ketone **7**: mp 79—80 °C; IR (KBr) 3300 (OH) and 1702 cm⁻¹ (C=O); NMR ($CDCl_3$) δ=0.86 (d, 3H, J=4.4 Hz, CH_3), 1.03—2.23 (m, 12H), and 2.59 ppm (s, 1H, exchangeable with D_2O); MS, *m/e* 168. (Found: C, 71.15; H, 9.41%).

1-Bromo-7β-methylbicyclo[3.3.1]nonan-3-one ***(8)***: To a stirred solution of **7** (1.96 g) in dry ether (15 cm³) was added freshly distilled PBr_3 (1.11 g) and the resulting solution was heated under reflux for 30 min. The ether solution was washed with cold water, dried (Na_2SO_4), concentrated, and recrystallized from hexane, giving 2.38 g (88%) of bromo ketone **8**: mp 64.5—65.4 °C; IR (CCl_4) 1718 cm⁻¹ (C=O); NMR ($CDCl_3$) δ=0.86 (d, 3H, J=3.6 Hz, CH_3), 1.0—2.8 (m, 10H), and 3.06 ppm (s, 2H, C(Br)–CH_2–CO).

7β-Methylbicyclo[3.3.1]nonan-3-one ***(9)***: A mixture of **8** (2.1 g), (*n*-Bu)$_3$SnH (5.48 g), AIBN (2.07 g), and dry toluene (60 cm³) was heated at 60—65 °C for 4 h. After removal of toluene by rotoevaporation, the residue was treated with hexane and filtered. The filtrate was concentrated and distilled (100 °C/67 Pa) to give crude ketone, from which 1.2 g (87%) of ketone **9** was isolated by means of preparative TLC (alumina PF_{254}, Merck) using hexane–CH_2Cl_2 (19: 1, v/v) as a developing agent: mp 54—54.5 °C (lit,[22] mp 57—58 °C); IR (CCl_4) 1710 cm⁻¹ (C=O); NMR ($CDCl_3$) δ=0.83 (d, 3H, J=5 Hz, CH_3) and 1.1—2.7 ppm (m, 13H).

7β-Methylbicyclo[3.3.1]nonan-3β-ol ***(10)***: Lithium (0.334 g) was dissolved in NH_3 (l) (80 cm³) and to this solution was added a solution of **9** (1.5 g) in dry THF (30 cm³). After being stirred for 30 min, dry EtOH (6.8 cm³) was added and the mixture was stirred until the blue color disappeared. The usual work-up afforded 1.27 g (84%) of the alcohol: mp 69—76 °C. It was found convenient to convert the alcohol into the corresponding formate for separation of the 3α- and 3β-epimers. This was done by treatment of the alcohol with large excess of acetic formic anhydride in pyridine (12 h at room temp). The formate was isolated after the usual work-up as a pale yellow oil (1.45 g) which was recrystallized from ether at −78 °C to give 1.38 g (94%) of 3β-formate (**11**): mp 37—38 °C; IR (neat) 1728 (C=O) and 1185 cm⁻¹ (C–O–C); NMR ($CDCl_3$) δ=0.85 (d, 3H, J=5.8 Hz, CH_3), 1.0—2.3 (m, 13H), 5.56 (nine-line m, 1H, C<u>H</u>(OCHO)), and 7.99 ppm (s, 1H, CHO).

Found: C, 72.77; H, 9.73%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

Pure 3β-alcohol **10** was obtained by the hydrogenolysis of

11 with $LiAlH_4$ in 98% yield: mp 76—78.5 °C (lit,[22] mp 72—75 °C); IR (CCl_4) 3620 (OH), 3300 (OH), and 988 cm^{-1} (C–O); NMR ($CDCl_3$) δ=0.84 (d, 3H, J=5 Hz, CH_3), 1.0—2.5 (m, 14H), and 4.34 ppm (nine-line m, 1H, C<u>H</u>(OH)); MS, *m/e* 154.

7β-Methylbicyclo[3.3.1]non-3β-yl Tosylate ***1***: The compound was prepared from **10** following the method of Stéhelin *et al.*[22] Spectroscopic data for **1** were identical with those reported:[3,22] mp 63.5 °C (dec) (lit,[3,22] mp 64 °C (dec)).

7β-Methylbicyclo[3.3.1]nonan-3α-ol (12).[2] To s atirred solution of $NaBH_4$ (1.5 g) in MeOH (20 cm^3) was added a solution of **9** (1.35 g) in MeOH (60 cm^3) and the resulting mixture was stirred for 15 h at room temp. After the usual work-up, sublimation of the residue *in vacuo* afforded 1.2 g (88%) of an alcohol. GLC assay for the corresponding acetate showed that the alcohol consists of **10** and **12** in the ratio 13: 87. 3α-Alcohol **12** was isolated conventionally from the mixture by fractional crystallization from hexane in 26% yield (based on **9**): mp 66.5—68.5 °C; IR (CCl_4) 3620 (OH), 3300 (OH), and 983 cm^{-1} (C–O): NMR ($CDCl_3$) δ=0.85 (d, 3H, J=6.6 Hz, CH_3), 0.6—2.5 (m, 14H), and 3.92 ppm (distorted m, 1H, C<u>H</u>(OH)); MS, *m/e* 154. (Found: C, 77.53; H, 11.54%).

exo-*7-Methylbicyclo[3.3.1]non-2-ene* ***4***.[2,3] Dehydration of **12** with $POCl_3$ and pyridine afforded olefin **4** in 72% yield: bp 80 °C (bath temp)/427 Pa; IR (neat) 3005 (=C–H) and 1650 cm^{-1} (C=C); NMR ($CDCl_3$) δ=0.83 (d, 3H, J=6 Hz, CH_3), 0.9—2.7 (m, 11H), and 5.70 ppm (m, 2H, CH=CH).

3-Methylbicyclo[3.3.1]non-2-ene ***5***.[2,3] The olefin was separated from a mixture of **4** and **5**, obtained by treating **4** with boiling formic acid,[23] by means of preparative GLC, and used as an authentic sample for GLC assay.

*7β-Methylbicyclo[3.3.1]non-3β-yl-7α-*d *Tosylate* ***1-7α-d***.[2] The compound was prepared according to the reported methods.[2,22] 7-Methylenebicyclo[3.3.1]nonan-3-one obtained by fragmentation of 1,3-dibromoadamantane[24] was reduced with $LiAlD_4$ in ether.[25] By chromatography over neutral alumina (Merck Al_2O_3, 90), pure 7-methylenebicyclo[3.3.1]nonan-3β-ol-3α-*d* was obtained as a minor reduced product (15%). The alcohol was treated with concd H_2SO_4 in MeOH (1: 1, v/v) at room temp for 3 min[2] to furnish the ketone (**9**-7α-*d*), from which **1**-7α-*d* was derived by the method described for the preparation of **1** (*vide supra*): mp 63.5 °C (dec); NMR ($CDCl_3$) δ=0.83 (s, 3H, CH_3–C(7)), 1.0—2.3 (m, 12H), 2.43 (s, 3H, aryl CH_3), 5.20 (nine-line m, 1H, CH(OTs)), and 7.53 ppm (m, 4H, aryl H).

The Acetates of ***10*** *and* ***12****, and the Formate of* ***12***. The acetates were prepared by the usual method (acetic anhydride–pyridine) and the formate was prepared by the same method as described above. They were used as authentic sample for GLC assay.

Spectral Data for 3β-Acetate: IR (CCl_4) 1730 (C=O) and 1022 cm^{-1} (C–O); NMR ($CDCl_3$) δ=0.85 (d, 3H, J=5.2 Hz, CH_3–C(7)), 1.0—2.3 (m, 13H), 2.0 (s, 3H, CH_3CO), and 5.43 ppm (nine-line m, 1H, C<u>H</u>(OAc)).

Spectral Data for the 3α-Acetate: IR (CCl_4) 1730 (C=O) and 1029 cm^{-1} (C–O); NMR ($CDCl_3$) δ=0.86 (d, 3H, J=6 Hz, CH_3–C(7)), 0.7—2.5 (m, 13H), 1.98 (s, 3H, CH_3CO), and 4.98 ppm (distorted m, 1H, C<u>H</u>(OAc)).

Spectral Data for the 3α-Formate: IR (CCl_4) 1728 (C=O) and 1180 cm^{-1} (C–O); NMR ($CDCl_3$) δ=0.87 (d, 3H. J=6 Hz, CH_3), 0.7—2.6 (m, 13H), 5.12 (distorted m, 1H, C<u>H</u>(OCHO)), and 8.01 ppm (s, 1H, CHO).

Found: C, 72.48; H, 9.73%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

Kinetic Measurement. Rates in carboxamides for **1** were determined titrimetrically by the usual sealed-ampoule technique. In a typical experiment, 13 ampoules each containing *ca.* 1.1 cm^3 of the solution were prepared. They were sealed after being flashed with nitrogen. An aliquot (1 cm^3) of the reaction mixture was pipetted from each ampoule after quenching thermally and titrated with standardized (n-Bu)$_4$NOH (in 2-propanol–MeOH; 3: 1, v/v) or with KOH (in EtOH) solution, using Thymol Blue or Thymol Blue–phenolphthalein mixed indicator, respectively. The rate constants were calculated by means of a linear least-squares fit of the integrated form of the first-order rate equation. All the rate constants are the average values of at least two independent determinations.

Product Analysis. Tosylate **1** (100 mg) was weighed into an ampoule which was repeatedly evacuated and filled with dry nitrogen. A septum is placed over the opening, and a solvent (*ca.* 6.5 cm^3) was introduced with a dried syringe, followed by addition of pyridine (0.028 cm^3) with a dried micro syringe through the septum. The ampoule was then sealed under nitrogen and kept at the desired temperature for ten half-lives. The mixture was poured into water (50 cm^3) and extracted with ether (15 cm^3, three times). The combined ether solution was washed with water, 5% aq HCl, saturated aq $NaHCO_3$, and saturated aq NaCl. After being dried (Na_2SO_4), the ether solution was carefully concentrated by use of a 30-cm column packed with glass helix to *ca.* 1—2 cm^3. The condensed ether solution was subjected to GLC assay.

The products from the solvolysis of **1** in the carboxamides were identified by their retention times on GLC. Separation was achieved at 70 °C for olefins (**4** and **5**) and at 140 °C for esters (3α- and 3β-acetates or formates).

The authers wish to express their thanks to Mr. Masami Inaba for measurement of the mass spectra, and to Messrs. Eiichiro Amano and Tadashi Hanafusa for the microanalysis.

Chemistry of Nitrosoimines. XVI.[1] A New Method for Facile Preparation of Azamonomethinecyanines *via* Nitrosoimines

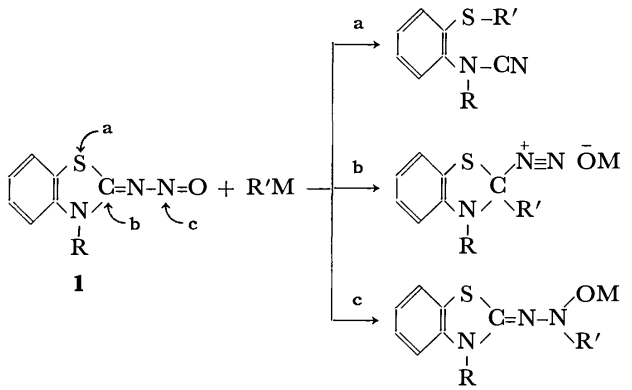
Kin-ya AKIBA, Kiyofumi ISHIKAWA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 10, 1977)

The reaction of 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) with Grignard-type reagents of 3-substituted 2-imino-2,3-dihydrobenzothiazoles (**2**) gave azamonomethinecyanines (**3**) in high yields (71—96%). This is a new type of reaction for the preparation of **3**. Hydrolysis of **3** afforded ring-opened disulfides, bis[*o*-{*N*-methyl-*N*-(3-methyl-2,3-dihydrobenzothiazol-2-ylidenecarbamoyl)amino}phenyl] disulfides, in high yields (78—85%). Formation of by-products is explained by the presence of transnitrosation between **1** and **2** and ring-opening equilibrium of Grignard-type reagent of 2-imino-3-phenyl-2,3-dihydrobenzothiazole.

A series of investigations on the reactivity of nitrosoimines has revealed that there are three paths of attack on 3-substituted 2-nitrosoimino-2,3-dihydrobenzothiazoles (**1**) by organometalloids depending on the structure of the latter, *i.e.*, paths a and b by organolithiums[2] and paths b and c by Grignard regents[3] (Scheme 1). The reactivities are recognized by the large contribution of charge separated structures to the ground state of **1** shown by spectroscopic measurements, especially by ESCA.[4]

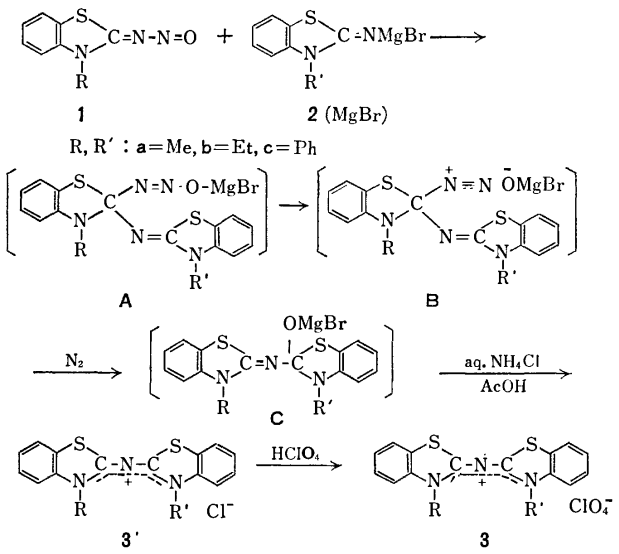


Scheme 1.

In continuation of the research directed to find out conditions under which each path is observed specifically, we report the reaction of **1** with Grignard-type reagents of 3-substituted 2-imino-2,3-dihydrobenzothiazoles (**2**) which followed path b almost exclusively to give the corresponding azamonomethinecyanines (**3**).[5] Concerning the preparation of azamonomethinecyanines, the reaction of 3-methyl-2-phenylsulfonylazobenzothiazolium tetrafluoroborate with sodium azide,[6] that of 2-amino-3-methylbenzothiazolium iodide with 3-methyl-2-methylthiobenzothiazolium iodie,[7] and base-catalyzed decomposition of triazatrimethinecyanine[8] are known.

3-Methyl-2-nitrosoimino-2,3-dihydrobenzothiazole (**1a**) reacted with Grignard-type reagent of 2-imino-3-methyl-2,3-dihydrobenzothiazole (**2a**) in THF at room temperature under nitrogen to give azamonomethinecyanine chloride (**3'a, a**) almost quantitatively, which gave the perchlorate (**3a, a**) in 84.5% yield by treatment with excess perchloric acid.

Evolution of nitrogen was followed for the reaction of **1a** with Grignard-type reagent of **2a** by measuring the increase of the gas volume of the reaction vessel set up as a closed system. Gas was evolved continuously during the course of reaction to yield 87% of the calculated amount (3.5 h, at 27.5 °C). No additional gas evolution was observed by injection of excess acetic acid. The cyanine perchlorate (**3a, a**) was obtained in 83% yield by the usual work-up.



Scheme 2.

Table 1. Yields and melting points of azamonomethinecyanine perchlorates (**3**)

1	2	3	Yield (%)[a]	Mp (°C)	Recovery of **2** (%)[b]
R=Me	R'=Me	a, a	84.5	319.0—320.0 (dec)	29.3
Me	Et	a, b	89.8	276.8—278.0	29.8
Et	Me	b, a	95.8	276.8—278.0	34.7
Et	Et	b, b	89.3	275.0—276.5	28.6
Ph	Me	c, a	70.9	312.0—314.0 (dec)	36.7
Ph	Et	c, b	78.0	253.5—255.0	28.2
Ph	Ph	c, c	80.0[c]	316.0—317.3 (dec)	28.2

a) After recrystallization from ethanol once. b) Based on **2** initially charged. c) The reaction was carried out at 0 °C.

Formation of **3** can be explained as shown in Scheme 2. The Grignard-type reagent of **2** attacks the *C*-2 of benzothiazoline ring of **1** (path b). The resulting diazotate (**A**) is not stable under the reaction conditions releasing nitrogen to give the alcohol (**C**), where contribution of diazonium character (**B**) to the transition state may be significant. The intermediate alcohol (**C**) is converted into a stabilized cation, *i.e.*, azamonomethinecyanine (**3**).

The results are given in Table 1.

Similar reactions of 2-nitrosoimino-3,4-diphenyl-2,3-dihydrothiazole (**4**) with Grignard-type reagents of **2** also gave the corresponding azamonomethinecyanine perchlorate (**5**) in high yields (Table 2).

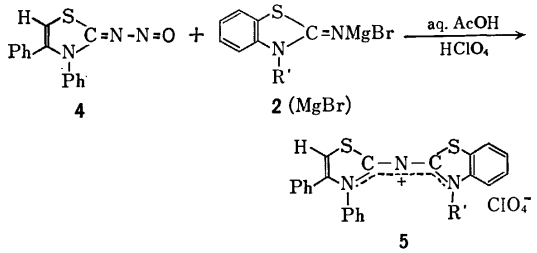


Table 2. Yields and melting points of azamonomethinecyanine perchlorates (**5**)

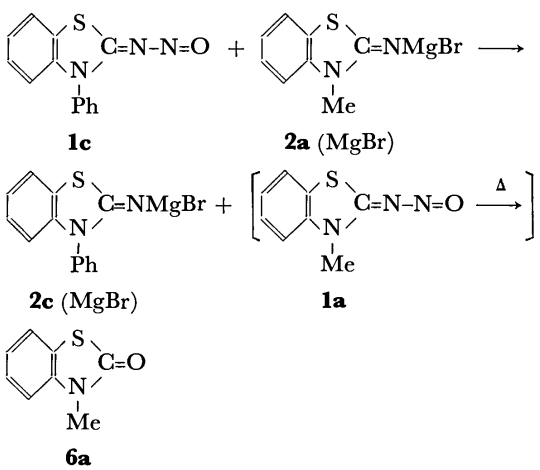
5	Yield[a] (%)	Mp (°C)	Recovery of 2 (%)[b]
a) R′=Me	80.5	236.8—238.2	33.6
b) R′=Et	74.6	274.2—276.0(dec)	27.7

a) After recrystallization once from ethanol. b) Based on **2** initially charged.

The yield of **3c**, **a** (70.9%) was relatively low. **2c** (18.4%) and 3-methyl-2,3-dihydrobenzothiazol-2-one (**6a**, 13.6%) were obtained from the benzene extract of the reaction mixture along with the recovered **2a** (36.7 %) as shown in Table 1. This can be explained by the attack of Grignard-type reagent on the nitroso group (path c), where the nitroso group is transferred to the imine of stronger basicity.



For the preparation of **3c**, **c**, the reaction was carried out at 0 °C instead of at room temperature. When the reaction was carried out at room temperature, **3c**, **c** was obtained in lower yield. Thus the same reaction was carried out at higher temperature (60—80 °C) in order to examine the nature of side reactions. The following products were isolated.

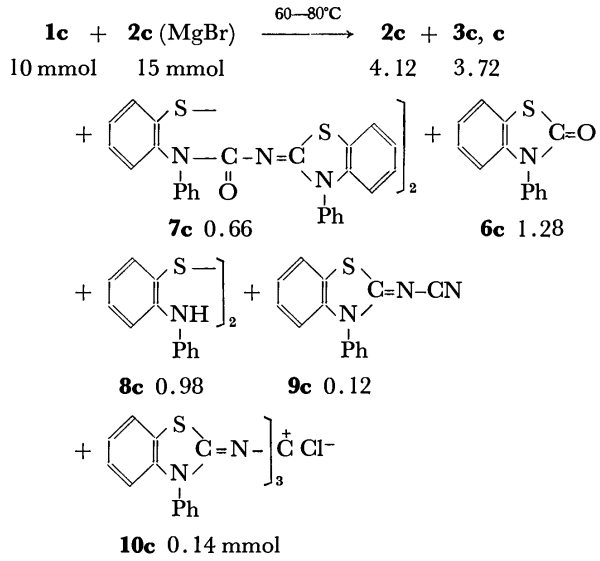


Table 3. Yields and melting points of the disulfides (**7**)

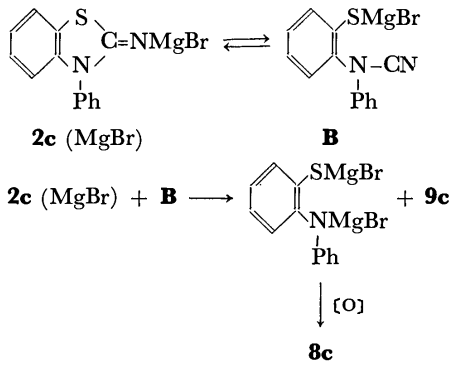
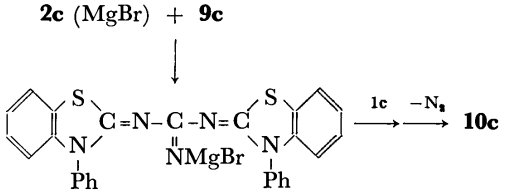
7	Yield (%)	Mp (°C)
a) R=Me	84.0	253.0—253.5
b) R=Et	84.5	119.5—120.5
c) R=Ph	78.0	230.0—231.0

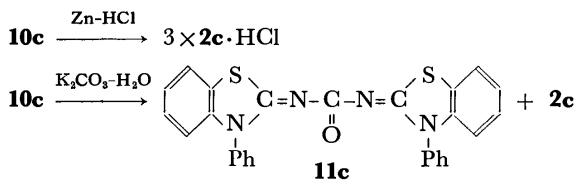
The formation of **8c** and **9c** can be rationalized by assuming the presence of ring-opening equilibrium in Grignard-type reagent of **2c**.[9]



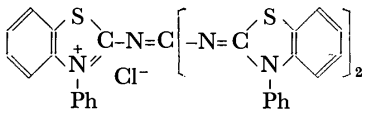
The formation of **10c** can be explained by the following sequence of reactions.



The structure of **10c** is supported by the following reactions where products were obtained almost quantitatively.



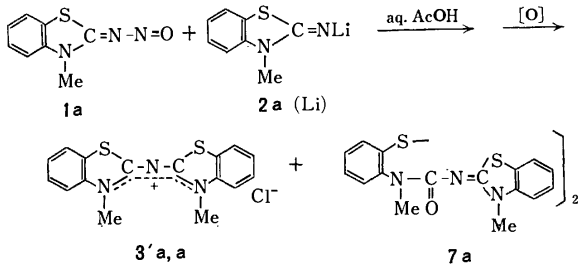
Compound (**10c**) seems to be less stable for alkaline hydrolysis than **3c**, **c**, in spite of the presence of a larger conjugation system for the carbonium ion.



10c

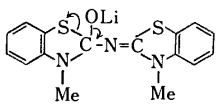
The formation of **7c** is due to the thermal decomposition of the intermediate alcohol (*C*) of **3c**, **c**.

Lithium reagent of **2a** reacted with **1a** in THF at 0 °C under nitrogen to give bis [*o*-{*N*-methyl-*N*-(3-methyl-2,3-dihydrobenzothiazol-2-ylidenecarbamoyl)-amino}phenyl] disulfide (**7a**, 78.3%) as a major product and cyanine chloride (**3'a**, **a**, 10.9%) as a minor product.



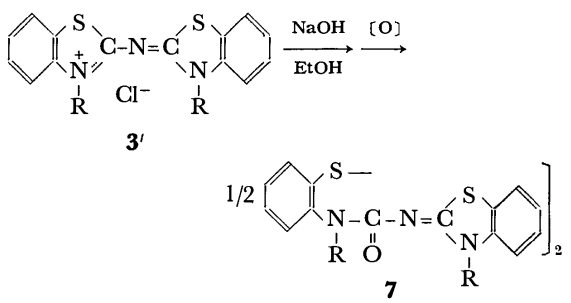
1a **2a** (Li) **3'a, a** **7a**

Formation of **7a** during the course of reaction is understandable by simultaneous ring-opening of lithium alkoxide (*C*) which might be produced after extrusion of nitrogen.



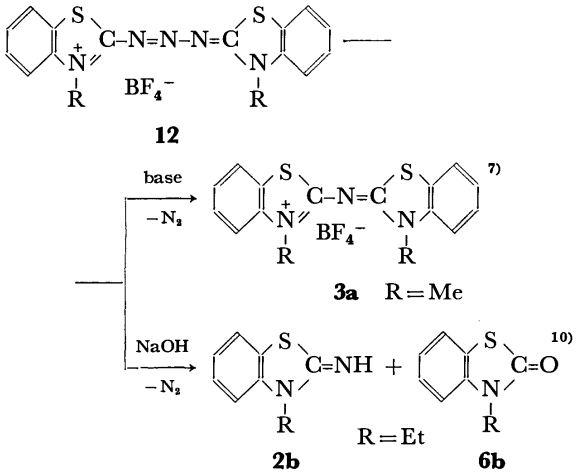
C

For the sake of clarification, symmetrical cyanine chlorides (**3'**) were treated with sodium hydroxide in ethanol which gave the disulfides (**7**) in high yields.



3' **7**

Ring-opening reaction of azamonomethinecyanine (**3'**) by sodium hydroxide is in contrast to the decomposition of triazatrimethinecyanine (**12**).



12 **3a** R=Me **2b** **6b** R=Et

Experimental

NMR spectra were recorded with Hitachi R-20 B and R-24 spectrometers (60 MHz) using TMS as an internal standard, IR spectra with a Hitachi EPI-G2 spectrometer and MS with a Hitachi RMU-6L mass spectrometer at 70 eV. All the melting points are uncorrected.

Materials. 2-Imino-3-methyl- (**2a**, mp 122—123 °C),[11] 3-ethyl-2-imino- (**2b**, mp 86—87 °C),[12] and 2-imino-3-phenyl-2,3-dihydrobenzothiazoles (**2c**, mp 73—74 °C)[11,13] were pre pared by reported methods. 3-Methyl-2-nitrosoimino-(**1a**, mp 146—147 °C (dec)),[11] 3-ethyl-2-nitrosoimino(**1b**, mp 147—148 °C (dec))[12] and 2-nitrosoimino-3-phenyl-2,3-dihydrobenzothiazoles (**1c**, mp 139—140 °C (dec))[11,13] were also prepared by reported methods. 2-Imino-3,4-diphenyl-2,3-dihydrothiazole (mp 108—109.5 °C)[14] was nitrosated in acetic acid with an aqueous solution of sodium nitrite to give 2-nitrosoimino-3,4-diphenyl-2,3-dihydrothiazole (**4**), mp 154—155 °C (dec).[15]

All the reactions were carried out under nitrogen except for the alkaline hydrolysis reactions of **3'**.

General Procedure for the Reaction of 3-Substituted 2-Nitrosoimino-2,3-dihydrobenzothiazole (1) with Grignard-type Reagent of 3-Substituted 2-Imino-2,3-dihydrobenzothiazole (2). A THF (50 ml) solution of **2** (7.5 mmol) was added dropwise at room temperature to a stirred solution of Grignard reagent prepared from magnesium (0.18 g, 7.5 mmol) and ethyl bromide (0.82 g, 7.5 mmol) in THF (25 ml) and the resulting solution was stirred for 30 min. **1** (5.0 mmol) was then added portionwise. The reaction took place immediately and precipitation appeared meanwhile. The mixture was stirred for 2 h and the solvent was evaporated under reduced pressure. To the residue were added a saturated aqueous solution of ammonium chloride (50 ml), glacial acetic acid (0.5 ml) and benzene (25 ml), and the mixture was stirred vigorously. After separation of the benzene layer, the remaining precipitates were collected by filtration and washed with 10% aqueous acetic acid (10 ml) and with water (25 ml) and then recrystallized from ethanol to give azamonomethinecyanine chloride (**3'**). The chloride was dissolved in ethanol and an excess of 70% aqueous perchloric acid was added to the solution. The resulting precipitates were collected by filtration after cooling in an ice bath and recrystallized from ethanol to give azamonomethinecyanine perchlorate (**3**).

By evaporation of benzene from the benzene layer under reduced pressure, the resulting residue was recrystallized from benzene–hexane (1: 5) to give recovered **2**.

NMR spectra were recorded for cyanine chlorides (**3'**),

since the solubility of cyanine perchlorates (**3**) in methanol was too small for measurement.

Measurement of Evolved Gas Volume. To a THF (25 ml) solution of Grignard reagent prepared from magnesium (182 mg, 7.5 mmol) and ethyl bromide (0.82 g, 7.5 mmol) was added **2a** (1.230 g, 7.5 mmol) in THF (50 ml) at 0 °C under nitrogen. This was carried out in a three-necked 100 ml round bottomed flask equipped with a rubber septum, a gas outlet tube and a Liebig condenser. A small flask containing **1a** (965 mg, 5.0 mmol) was connected to the top with a rubber tube. After the solution had been stirred at 0 °C for 30 min, **1a** was added in small portions from the top and stirring was continued at 0 °C during the course of reaction. Gas was evolved continuously during 3.5 h up to 108 ml measured at 27.5 °C (r.t.) (87.6% based on added **1a**, 5.0 mmol). No additional gas was evolved by addition of excess acetic acid (0.5 ml).

Reaction of 2-Nitrosoimino-3,4-diphenyl-2,3-dihydrothiazole (4) with Grignard-type Reagent of 2b. **4** (1.41 g, 5 mmol) was added portionwise at room temperature to a stirred solution of Grignard-type reagent of the imine prepared from ethylmagnesium bromide (7.5 mmol) and **2b** (1.36 g, 7.5 mmol) in THF (75 ml) and the resulting mixture was stirred for 2 h. A similar work-up to that above gave cyanine chloride (**5'b**, mp 298.2—299.5 °C (dec), (7.46 mmol, 74.6%). Treatment of the chloride with 70% aqueous perchloric acid gave cyanine perchlorate (**5**).

Residual **2b** (mp 86—87 °C, 368 mg, 27.7%) was recovered from the benzene layer.

Reaction of 1c with Grignard-type Reagent of 2c at Higher Temperature (60—80 °C). **2c** (3.30 g, 15 mmol) in THF (100 ml) was added at room temperature to a stirred solution of ethylmagnesium bromide (15.0 mmol) in THF (50 ml). The solution became turbid because of low solubility of Grignard-type reagent of **2c**. **1c** (2.56 g, 10.0 mmol) was then added to the solution portionwise. The mixture was stirred for 10 min at room temperature, and then refluxed for 17 h. The residue obtained by evaporation of the solvent under reduced pressure was extracted with dichloromethane (50 ml × 5) after addition of saturated aq ammonium chloride (100 ml).

By condensation of the extract, greenish yellow ppt were collected to give **3c,c** (0.84 g, 1.86 mmol) after recrystallization from ethanol. The filtrate was chromatographed on silica gel.

The following products were eluted from silica gel chromatography in the described order with the solvents shown in parentheses: bis(*o*-anilinophenyl) disulfide (**8c**, 0.39 g, 0.98 mmol, benzene),[16] 3-phenyl-2,3-dihydrobenzothiazol-2-one (**6c**, mp 73—74 °C, 0.29 g, 1.28 mmol, benzene),[17] bis[*o*-{*N*-phenyl-*N*-(3-phenyl-2,3-dihydrobenzothiazol-2-ylidenecarbamoyl)amino}-pheyl] disulfide [**7c**, mp 231—232 °C, 0.60 g, 0.66 mmol, benzene-ether (5: 1)], 2-cyanoimino-3-phenyl-2,3-dihydrobenzothiazole [**9c**, mp 190—191.2 °C, 0.03 g, 0.12 mmol, benzene-ether (5: 1)], **2c** [mp 74—75 °C, 0.93 g, 4.12 mmol, ether and ether-acetone (2: 1)],[11] tris(3-phenyl-2,3-dihydrobenzothiazol-2-ylideneamino) carbonium chloride [**10c**, mp>360 °C, 0.10 g, 0.14 mmol, UV: λ_{max}^{EtOH} 401 nm (ε 6.4×10^3): EA of **10c**: Found: C, 62.77: H, 3.75; N, 10.20: S, 12.06%. Calcd for $C_{40}H_{27}N_6ClO_4S_3$: C, 61.02; H, 3.46; N, 10.67; S, 12.22%, acetone and acetone-ethanol (2: 1)], and **3c, c** [mp 301—302 °C, 1.86 mmol, acetone-ethanol(1:2)]. An authentic sample of **9c** was prepared by refluxing of **2c** (2.78 g, 12.3 mmol) in benzene (20 ml) with cyanogen bromide (0.83 g, 7.79 mmol) in benzene (50 ml) for 3 h. The resulting ppt., hydrobromide of **2c** (1.86 g), were filtered off and the filtrate was shaken with aq sodium hydroxide. The product, **9c**, 1.52 g, mp 190—191.2 °C, was obtained by the usual work-up. EA of **9c**: Found: C, 66.97; H, 3.35; N, 16.46%. Calcd for $C_{14}H_9N_3S$: C, 66.91; H, 3.61; N, 16.72%.

Reduction of 10c with Zinc Dust and Hydrochloric Acid. Zinc dust (100 mg) was added with stirring to **10c** (68 mg, 0.097 mmol) dissolved in acetic acid (10 ml) and ethanol (2 ml).

Since the reaction proceeded very slowly, concd HCl (2 ml) was first added, and then zinc dust (200 mg) and concd HCl (3 ml) were added in two portions over a period of 7 h. The precipitates were filtered and washed with ethanol (10 ml). The filtrate and washings were combined and evaporated to dryness. The residue was extracted with dichloromethane (15 ml × 4) after addition of concd HCl (2 ml) and water (20 ml).

a) Chlorine analyzed for **3a,a**, found 8.62 and calcd 8.61; for **3c,c** found 6.77 and calcd 6.61%. b) In $CDCl_3$. c) Perchlorate in (CD_3OD+$CDCl_3$). IR (KBr): A very strong band at 1520—1540 cm^{-1} is common to all **3** and **5**. A band at 750—760 cm^{-1} (m) is common to all **3** and **5**, and a band at 690—695 cm^{-1} (m) appears when there is N-Ph, *i.e.*, **3c,a**; **c,b**, and **c,c** and **5a** and **b**. Bands at 1100 (s) and 620 cm^{-1} (m) are ascribed to ClO_4^-.

Hexane was added to the concetrated extract dried with anhydrous magnesium sulfate in order to precipitate the hydrochloride of **2c** (mp 278—279 °C, 64 mg, 0.244 mmol, 84%). The hydrochloride was nitrosated to give **1c** almost quantitatively.

Hydrolysis of ***10c*** *with Potassium Carbonate.* When a suspension of **10c** (21 mg, 0.03 mmol) in benzene (20 ml) was stirred with potassium carbonate (*ca.* 30 mg) at room temperature, two poducts were obtained: *N,N'*-bis(3-phenyl-2,3-dihydrobenzothiazol-2-ylidene)urea [**11c**, mp 357.5—358.7 °C, 13 mg, 0.027 mmol; MS: *m/e* 478 (M^+, 8%) and 253 (100%): IR (KBr): 1470 cm^{-1} (very strong)] and **2c** (5.4 mg, 0.024 mmol).

An authentic sample of the urea (**11c**) was prepared quantitatively from Grignard-type reagent of **2c** (15 mmol) in THF (100 ml) and ethyl chloroformate (0.48 ml, 5 mmol) by refluxing the solution for 30 min, which showed the same character as above. EA of **11c**: Found: C, 68.98; H, 4.11; N, 12.07%. Calcd for $C_{27}H_{18}N_4OS_2$: C, 67.76; H, 3.80; N, 11.71%.

Reaction of ***1a*** *with Lithium Reagent of* ***2a***. A solution of butyllithium (12.5 mmol) in hexane (8 ml) and THF (25 ml) was added dropwise at 0 °C to a stirred solution of **2a** (2.15 g, 13 mmol) in THF (100 ml). The solution was stirred for 10 min and then **1a** (2.01 g, 10.5 mmol) was added portionwise. After the mixture had been stirred for 1.5 h, the solvents were evaporated under reduced pressure. The residue was extracted with dichloromethane (50 ml×3) after addition of water (100 ml) and the extract was dried over anhydrous magnesium sulfate. After the solvent had been evaporated, the residue was chromatographed on silica gel. Bis[*o*-{*N*-methyl-*N*-(3-methyl-2,3-dihydrobenzothiazol-2-ylidenecarbamoyl)amino}phenyl] disulfide (**7a**, 2.70 g, 78.3%) was eluted with dichloromethane and dichloromethane–ether (1: 1), mp 253.0—253.5 °C (from ether–hexane).

Cyanine chloride (**3'a**, **a**, 0.37 g, 10.9%) was eluted with acetone, mp 278.0—279.0 °C (from ethanol).

A trace amount of 3-methyl-2,3-dihydrobenzothiazol-2-one (**6a**, mp 75—76 °C) was eluted with dichloromethane.

*Alkaline Hydrolysis of Azamonomethinecyanine Chloride (****3'****).* Sodium hydroxide (1 g) in water (1 ml) was added to a solution of **3'** (0.35 mmol) in ethanol (30 ml) at room temperature. After being stirred for 4 h, the solvent was evaporated under reduced pressure. The residue was extracted with dichloromethane (20 ml×3) after addition of water (20 ml).

The extract was dried over anhydrous magnesium sulfate and the solvent was evaporated. The residue was recrystallized from ether–hexane to give disulfide (**7**).

The results are given in Table 3 and elemental analyses and spectral data in Table 5.

Low Temperature Photolysis of *o*-Benzoquinones. Spectroscopic Detection of Cyclopentadienones and Bis-Ketenes[1)]

Hideo TOMIOKA,* Hiroshi FUKAO, and Yasuji IZAWA

Department of Industrial Chemistry, Faculty of Engineering, Mie University, Tsu, Mie 514

(Received June 10, 1977)

The photodecarbonylation of *o*-benzoquinone to cyclopentadienone at low temperature was monitored by infrared and ultraviolet spectra which showed that the reaction is highly sensitive to substituents. 3,5-Di-*t*-butyl-*o*-benzoquinone undergoes clean decarbonylation to give cyclopentadienone under irradiation at −170 °C. Similar irradiation of 4-*t*-butyl-, 4-methyl-, 3-methyl-, and unsubstituted *o*-benzoquinones also leads to decarbonylation to cyclopentadienones. However, competitive α-cleavage to bis-ketene becomes important in these systems. Direct spectroscopic observation of the elusive cyclopentadienone was unsuccessful because of the overlapping absorption of the by-product. The infrared spectrum of bis-ketene from 4-*t*-butyl-*o*-benzoquinone shows that it exists as a mixture of rotamers, not undergoing thermal interconversion even at −170 °C.

Much attention has been paid to the preparation and properties of cyclopentadienones[2)] because of the theoretical interest in this system. The classic problem concerning their isolation and direct spectroscopic observation as a monomer is their pronounced facility to dimerize in a mode of the Diels-Alder reaction. While relatively many tri- and tetra-substituted derivatives have been isolated as monomer, minimally substituted derivatives thus far isolated were di-*t*-butyl derivatives.[3)] Further, it was not until 1971 that the parent compounds was detected spectroscopically in the pyrolytic decarbonylation of *o*-benzoquinone.[4)] Recently, however, a similar decarbonylation was observed[5)] also in the UV irradiation of 3,5- and 3,6-di-*t*-butyl-*o*-benzoquinones at room temperature to yield the corresponding cyclopentadienones. During the course of studies on the low temperature photochemistry of organic molecules,[1,6)] it was found that the photodecarbonylation of 3,5-di-*t*-butyl-*o*-benzoquinone occurs equally efficiently upon irradiation in infrared cell even at low temperature. Although there have been many reports on the syntheses of cyclopentadienones, only a few examples[7)] exist on the ingenious approaches for the generation of cyclopentadienone and its simply substituted derivatives under the conditions associated with general spectroscopic observation.

The present reaction, thus, might be expected to provide another convenient route which permits the spectroscopic observation of unstable cyclopentadienones as monomer if the reaction could be applied to the other simply substituted *o*-benzoquinones (**1b—d**) as well as the parent. The irradiation of *o*-benzoquinones at low temperature monitored by infrared and ultraviolet spectroscopy revealed that the photodecarbonylation is highly sensitive to the substituents on benzoquinone and the competitive α-fission to give interesting bis-ketene becomes more important in simpler benzoquinones.

Results and Discussion

A thin film of 3,5-di-*t*-butyl-*o*-benzoquinone (**1a**) as a suspension in Nujol in a liquid nitrogen-cooled infrared cell equipped with a vacuum shroud and dewar was irradiated with a 250 W mercury lamp through a pyrex window and monitored by infrared spectra. As shown in

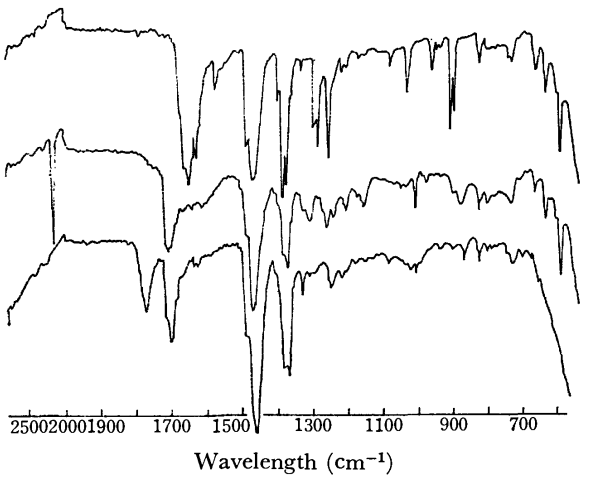

Fig. 1. IR spectra of **1a** in Nujol mulls at −170 °C before irradiation (top), after irradiation for 150 min (center), and after standing at room temperature for 1 day (bottom).

Fig. 1, irradiation led to rapid disappearance of the absorption of the starting material and concurrent appearance of new bands at 2138, 1702, 1320, 1300, 1196, 1145, 1003, 956, and 867 cm^{-1}. A strong and sharp band appearing at 2138 cm^{-1} is easily attributable to carbon monoxide by comparison with the reported value.[8)] The new carbonyl band at 1702 cm^{-1} did not change upon warming the cell slowly to room temperature. After the photomixture had been allowed to stand at room temperature for one day, a new band appeared at 1768 cm^{-1} concomitant with slight shift and change in shape of the original carbonyl band. 2,4-Di-*t*-butylcyclopentadienone (1708 cm^{-1}) is thermally stable at room temperature but slowly dimerizes to

give a single Diels-Alder dimer (1700 and 1765 cm^{-1}) upon standing at the same temperature.[3] TLC analysis of the photomixture within the cell after standing overnight showed the presence of the dimer **3a**. The above results strongly suggest that the photodecarbonylation of **1a** to **2a** occurs within the infrared cell at low temperature.

A similar photolysis of 4-*t*-butyl-*o*-benzoquinone (**1b**) in the infrared cell, however, gave different results. Irradiation caused the starting band to disappear rapidly and the carbon monoxide band to appear along with a broad new absorption at around 1700 cm^{-1} (Fig. 2). Warming the cell to room temperature resulted in the disappearance of the 2138 cm^{-1} band but the broad carbonyl band remained unchanged and no new band appeared even on standing for 2 days. The results exclude the possible assignment of the broad carbonyl band to 3-*t*-butylcyclopentadienone **2b**, since it dimerizes rapidly above −80 °C to give **3b** which has new carbonyl bands at 1790 and 1710 cm^{-1}.[3] Inefficient increase in the intensity of a rather broad band at 2138 cm^{-1} on continued irradiation prompted us to investigate the reaction on a wider scale in the wave number range 2000—2300 cm^{-1}. The results (Fig. 3) revealed that two more new bands at 2125 and 2156 cm^{-1}, probably attributable to bis-ketene arising from the α-cleavage of *o*-benzoquinone, appear along with the carbon monoxide band in this region. Warming in the dark shows that one of the ketene bands at 2125 cm^{-1} rapidly disappears above −90 °C, while the other at 2156 cm^{-1} remains unchanged until −70 °C. This indicates that each band is associated with two different ketenes. Similar irradiation of 4-methyl-(**1c**), 3-methyl-(**1d**), and parent *o*-benzoquinones (**1e**) also resulted in rapid disappearance of the starting materials and concurrent formation of carbon monoxide and bis-ketene. No distinct new carbonyl band was observed in these compounds. Only one ketene band appeared at 2125 cm^{-1}, disappearing upon warming above −90 °C.

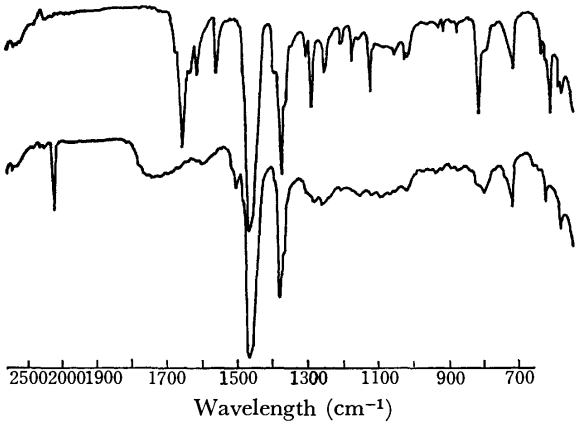

Fig. 2. IR spectra of **1b** in Nujol mulls at −170 °C before irradiation (top), after irradiation for 60 min (bottom).

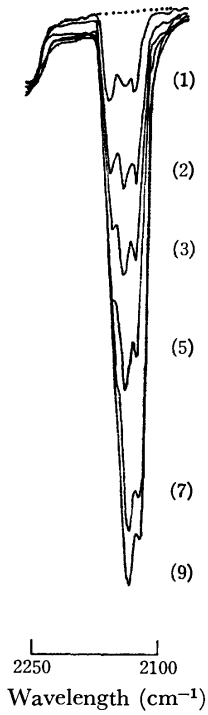

Fig. 3. IR spectra of **1b** in Nujol mulls at −170 °C in the region at 2100—2250 cm^{-1} in expanded scale, ----: before irradiation, ——: after irradiation. Numbers in parentheses refer to irradiation time in min.

Thus, the results show that the photodecarbonylation is quite general for other *o*-benzoquinones, but the photo-α-cleavage to give the bis-ketene occurs concurrently as a relatively important pathway in the photolysis of less substituted *o*-benzoquinones (**1b—e**). However, direct observation of cyclopentadienones was unsuccessful since the broad and thermally stable band[9] in the carbonyl region interferes with the expected carbonyl absorption of cyclopentadienones.

The possibility that carbon monoxide can be formed in the photodecarbonylation[10] of bis-ketene initially formed was excluded, since plots of the intensities of carbon monoxide and ketene absorption as a function of irradiation time indicate that both compounds are the primary photoproduct of *o*-benzoquinones (Fig. 4). Strong chemical evidence of the intervention of cyclopentadienone and bis-ketene were provided by GLPC and TLC analyses of the photomixture obtained in the low temperature irradiation of *o*-benzoquinone (**1e**) in the presence of ethanol. Both analyses show the presence

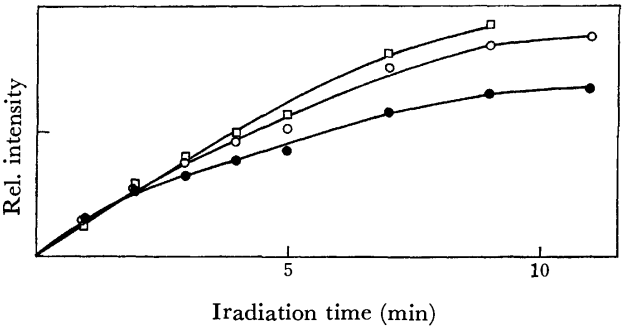

Fig. 4. Plot of relative intensity of bis-ketene and carbon monoxide bands as a function of irradiation time obtained from IR spectra on Fig. 3: -□-, CO (2138 cm^{-1}); -○-, $\nu_{C=O}$ (2125 cm^{-1}) and -●-, $\nu_{C=O}$ (2156 cm^{-1}) of bis-ketene **4b**.

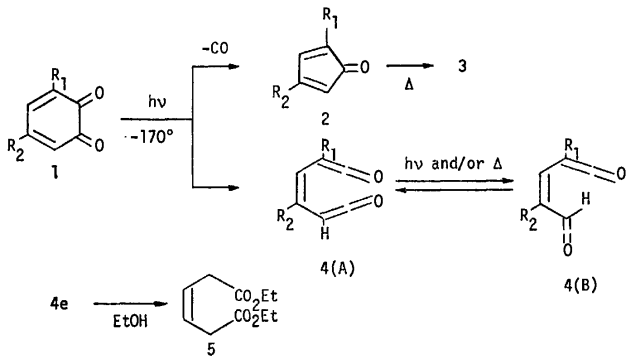
of dicyclopentadienone (**3e**) and diethyl 3-hexenedioate (**5**), a trapped product of bis-ketene by ethanol.

The presence of two ketene bands with different thermal stability in the spectrum of photolyzed **1a** reminds us of the photochemical cleavage[11a-c] of α-pyrone to ketene–aldehyde in Ar matrix at 8 K. Four ketene bands observed at 2022, 2129, 2136, and 2146 cm^{-1} have been attributed to the four possible rotamers available by rotation about C–C single bond. Thus, we assigned the two ketene bands from **1a** to a mixture of bis-ketene rotamers **4A** and **4B**. The band at 2125 cm^{-1} would be associated with bis-ketene **4A**, which is formed first and rapidly rotates photochemically and/or thermally around C–C single bond to the more stable isomer **4B** (2156 cm^{-1}).[12]



Direct observation of a mixture of rotamers at −170 °C seems to have achieved for the first time. Apparently, the energy barrier to single bond rotation is large with respect to kT at 8 K and the rotamers are essentially different compounds at this temperature. However, the relative intensities of each ketene–aldehyde absorption in the spectrum of photolyzed α-pyrone change remarkably upon warming the sample to 35 K from 8 K in the dark,[11b] suggesting that thermal rotation around C–C single bond occurrs at this low temperature.[13] This, along with the failure to observe a mixture of rotamer in bis-ketene **4c—e** at −170 °C implies that the barrier to the rotation in bis-ketene **4b** is raised by the bulky group to the extent of permitting the observation of each rotamer at this temperature.

Photolysis of **1b—e** in EPA matrix at −196 °C monitored by ultraviolet spectra resulted in rapid decrease in the intensity of original absorption to a very broad and weak absorption at around 380 nm, which disappeared on thawing of the matrix. This might be attributed to either the elusive cyclopentadiene or bis-ketene.[14]

In conclusion we have found that *o*-benzoquinones undergo two important photochemical transformations, *i.e.*, decarbonylation and α-cleavage, depending on the position and bulkiness of the substituent. An interesting bis-ketene has been observed for the first time as a mixture of rotamers at −170 °C.

Experimental

The IR spectra were measured with a JASCO IR-G grating instrument and the UV spectra with a Shimadzu UV-200 spectrophotometer. The GLPC analysis was carried out on a Yanagimoto GC-1800 apparatus equipped with hydrogen-flame detectors using a column consisting of 5% silicone SE-30 on Diasolid L (5.0 mm × 2.0 m).

Materials. *o*-Benzoquinone (**1e**) was prepared[15] by the oxidation of catecohol with silver oxide in anhydrous ether. The fine red crystals of **1e** ($\nu_{C=O}$ 1662 cm^{-1}) turned to black powder upon standing and hence were used immediately. 3-Methyl derivative (**1d**) was similarly prepared immediately before use; IR (Nujol): $\nu_{C=O}$ 1660 cm^{-1}. **1a**, mp 113—114 °C (lit,[5a] mp 114—115 °C); **1b**, mp 67—67.5 °C (lit,[16] mp 68 °C); **1c**, mp 80—81 °C (lit,[16] mp 80—82 °C). Diels-Alder dimer (**3a**) of 2,4-di-*t*-butylcyclopentadienone was prepared by the irradiation[5a] of **1a** in acetonitrile, followed by standing for 2 days at room temperature, mp 152—153 °C (lit,[5a] mp 152.5—153.0 °C). Dicyclopentadienone (**3e**) was prepared[17] by the hydrolysis of the dimer of cyclopentadienone dioxime,[18] mp 101—102 °C (lit,[17] mp 101—101.5 °C). Diethyl *cis*-3-hexendioate (**5**) was prepared by the esterification[19] of the corresponding diacid, bp 125 °C/10 mmHg (lit,[19] bp 125—127 °C/10 mmHg.

Irradiation of 1 Monitored by Infrared Spectra. A thin film of *o*-benzoquinone as a suspension of Nujol was prepared between two polished sodium chloride plates which were mounted in the metal cell holder of the Air Product low temperature infrared spectroscopy unit fitted with a potassium bromide and pyrex windows. The cell was then cooled with liquid nitrogen and at the same time gradually evacuated in order to prevent the condensation of moisture and carbon dioxide. The temperature of the cell was monitored through a copper-constantan thermocouple during the course of the operation as well as irradiation. The infrared spectra of the sample at low temperature was recorded through the potassium bromide windows. A slight increase in intensity of all the peaks in the spectrum was observed upon cooling. The vacuum shroud was then rotated 90° for irradiation through the pyrex window with an Ushio 250 W high-pressure point-source mercury-arc lamp. The spectrum of the sample was recorded periodically until almost all the absorptions of the starting materials disappeared. When irradiation was accomplished, the liquid nitrogen was removed from the cooling unit of the cell and the temperature of the cell was continuously monitored while specific regions (*i.e.*, 2000—2300 and 1500—1850 cm^{-1}) of the spectrum were scanned to observed changes of reactive intermediates upon warming. At the end of warming, the sample was washed from the cell and further characterized by comparison of thin layer and gas chromatographic behavior with that of authentic specimens.

Irradiations of 1 Monitored by Ultraviolet Spectra. Photolysis of **1** in EPA at −196 °C was performed by immersing the reaction cell directly in a transparent quartz Dewar vessel containing liquid nitrogen. A rectangular quartz cell (1 × 0.2 × 5 cm) was used for the reaction.

The authors wish to express their thanks to Professor Jiro Tsuji, Tokyo Institute of Technology, for the supply of *cis*-3-hexenedioic acid and to Prof. Katsumasa Sakanishi, Suzuka College of Techlogy, for that of *o*-benzoquinones.

Formation of 1,3-Di(2-fluorenyl)-1-butene from 2-(1-Bromoethyl)-fluorene with Silver Powder

Masahiro MINABE, Makoto SUZUKI,* Takao OOYA,** and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321-31

(Received June 20, 1977)

An unexpected compound, 1,3-di(2-fluorenyl)-1-butene, was formed as the major product, accompanied by *meso*- and *dl*-2,3-di(2-fluorenyl)butane as the minor products, in the reaction of 2-(1-bromoethyl)fluorene with silver powder. The structure of the butene was confirmed to be the *E* form by a comparison of the UV spectra of the related compounds.

The Wurtz-Fittig-type reaction of 2-(1-bromoethyl)-fluorene (**1**)[1] afforded the unexpected 1,3-di(2-fluorenyl)-1-butene (**2**) as the major product in addition to the expected diastereomers, *meso*-(**3a**) and *dl*-2,3-di(2-fluorenyl)butane (**3b**),[1] as minor products. The present paper is concerned with the formation, the stepwise synthesis, and the configurational assignment of **2**.

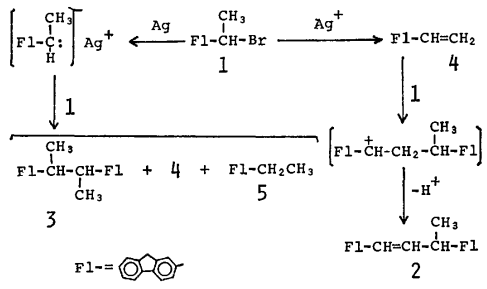
Results and Discussion

The reaction of **1** with silver powder in benzene gave **2** as the main product, and **3a**, **3b**, 2-vinylfluorene (**4**), and 2-ethylfluorene (**5**) as by-products accompanied by a considerable amount of resinous material. An appreciable quantity of hydrogen bromide was produced in this system.

The yield of **2** is higher than that of **3**, which may be formed by the usual Wurtz-Fittig reaction (Scheme 1). This finding is due to the fact that the unstable **1** is decomposed into **4** *via* 1-(2-fluorenyl)ethyl cation instead of 1-(2-fluorenyl)ethanide anion, and presumably to the smaller extent of the ionization of silver compared with that of sodium.

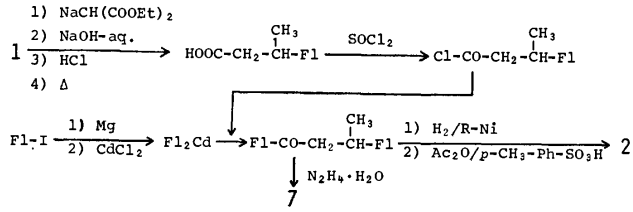
The reactive **1** is cleft easily into the olefin **4**, with elimination of hydrogen bromide, in the presence of the silver ions which are formed. The electrophilic attack of the α-carbon atom on the alkyl group of **1** to the methylidene carbon of **4** would form **2** through 1,3-di(2-fluorenyl)butyl cation.

The compound **2** (17%) was obtained by the reaction[1] of 1-(2-fluorenyl)ethanol (**6**) with potassium hydrogensulfate. Moreover, **2** was isolated by the Friedel-Crafts reaction between **1** and **4** (11%), and by treatment of **6** with polyphosphoric acid (2%).



Scheme 1.

Hydrogenation of **2** yielded 1,3-di(2-fluorenyl)butane (**7**) and oxidation of **2** with potassium permanganate gave 2-acetyl-9-fluorenone and 9-oxofluorene-2-carboxylic acid. The structural proof of **2** was established by the independent synthesis using a procedure similar to that of Ela and Cram[2] (Scheme 2).



Scheme 2.

Geometrical isomers of **2** can, in principle, exist in analogy with the case of 1,3-diphenyl-1-butene.[2] The UV spectrum of **2** is strikingly similar to that of **4** (I in Fig. 1). A solution of **2** in cyclohexane was irradiated by ultraviolet light and the progress of the isomerization was traced by UV spectra, as shown in Fig. 1. After a short irradiation (for example, 3 min), the absorption maximum shifted to a shorter wavelength and showed some resemblance to that of **7** (II in Fig. 1). The spectrum obtained after a longer period (60 min) irradiation showed a further shift to a shorter wave-

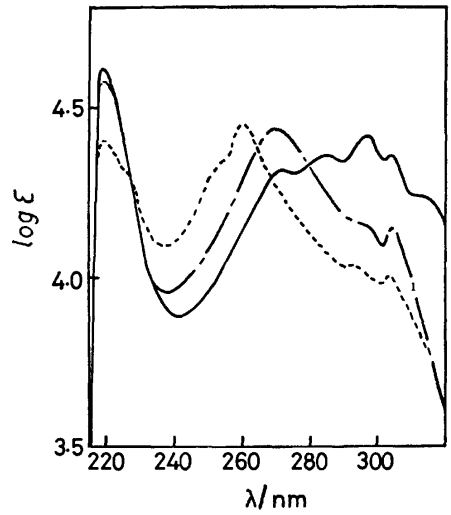


Fig. 1. UV spectra of **2** under ultraviolet irradiation. ——: Original (I), —·—: 3 min (II), ——: 60 min (III).

* Present address: Obu City Office, Obu 474.

** Present address: Institute of Pharmacology, Banyu Pharmaceutical Co., Ltd., Meguro, Tokyo 153.

length and was like that of the parent fluorene (III in Fig. 1).

The consideration of molecular models indicates that the vinylene bond of the *E* configuration in **2** can be situated on the same plane with respect to the adjacent 2-fluorenyl group. The absorption maximum of this conjugated system shifts to a bathochromic region, as in the case of **4**. However, the *Z* form of **2** can not be situated in the same plane as that of the *E* form, due to the steric interference between the two bulky fluorenyl rings at the 1- and 3-positions or between the fluorenyl ring at the 1-position and the methyl group at the 3-position in **2**. Therefore, the vinylene and fluorenyl π-electron systems might exist independently of each other and give spectra similar to that of fluorene. Accordingly, the configuration of the isolated **2** can be assigned to be the *E* form, and the compound having the UV spectrum of III may be the *Z*-isomer.

The compound obtained by a long irradiation (14 h) was first separated by silica gel column chromatography and dried *in vacuo* at 120 °C. The NMR spectrum shows that the resulting mixture consists of *E*- (**2**-*E*) and *Z*-isomers (**2**-*Z*) in a ratio of *ca.* 1 : 1. The UV spectrum of the mixture has a shape similar to that of II. Repeated recrystallization of the mixture afforded only **2**-*E*, whose spectrum was identical with that of I. Consequently, the attempt to isolate pure **2**-*Z* failed. These findings suggest that **2**-*E* can be isomerized to **2**-*Z* by ultraviolet irradiation and that the **2**-*Z* is converted gradually to **2**-*E* upon heating and/or standing in solution.

Experimental[3)]

The instruments used in this experiment were the same as those described elsewhere.[1)] UV spectra were recorded at a scanning speed of 0.76 s/nm in cyclohexane.

*Reaction of **1** with Silver Powder.* A solution of 8.19 g of **1** in 140 ml of dry benzene was refluxed with 3.24 g of silver powder for 40 h. A considerable amount of hydrogen bromide evolved during this period.

After cooling, the precipitate was filtered and extracted with benzene. The combined benzene solution was evaporated to dryness and the residue was distilled with steam. The distillate was recrystallized fractionally from hexane to give 0.005 g (0.09%) of **4**, mp 135—137 °C, and 0.015 g (0.26%) of **5**, mp 99—100 °C. The sticky residue was recrystallized fractionally from ethyl acetate to give 0.18 g (3.3%) of **3a**, mp 306—308 °C, and 0.08 g (1.4%) of **3b**, mp 234—235 °C. The mother liquor was evaporated to dryness and the residual solid was recrystallized from benzene–cyclohexane (1 : 1) to yield 2.20 g (38%) of **2**: mp 176—178 °C; NMR (pyridine-d_5) δ=1.54 (3H, d, J=6.9 Hz), 3.79 (1H, m), 3.83 (4H, s), 6.67 (2H, d, J=2.4 Hz), and 7.18—7.97 (14H, m); MS, *m/e*, 384 (M^+), 369, 353, 339, 218, 203, 192, 179, 165, and 152.

Complex of **2** with 2,4,7-trinitro-9-fluorenone (mole ratio= 1/2): mp 142—143 °C (dec); IR 1732 cm^{-1} (>C=O).

*Photo-irradiation of **2**.* A sample of **2** was prepared with the density of 9.54×10^{-6} mol per 1000 ml solution. The solution (5 ml) was sealed in a quartz cell and irradiated using a 100-W high-pressure mercury lamp. After each time interval, the UV spectrum was recorded immediately without any treatment.

A second irradiation of **2** (0.50 g) in cyclohexane (400 ml) was carried out for 14 h under an atmosphere of nitrogen. The mixture was concentrated to 100 ml and chromatographed on a silica gel column. The colorless eluate was evaporated *in vacuo* at 120 °C during a period of 5 h to leave a powder (0.40 g), which was found to be pure by means of thin layer chromatography and gas chromatography. NMR (benzene-d_6) δ=1.46 (-CH_3 of 2-*Z*, J=7.0 Hz, 45%) and 1.52 (-CH_3 of 2-*E*, J=7.0 Hz, 55%).

The materials gave 0.26 g of **2**-*E*, mp 176—178 °C, by repeated recrystallization from cyclohexane, cyclohexane–hexane, and cyclohexane–benzene.

*Reaction of **6** with Copper Powder and Potassium Hydrogensulfate.* A powdered mixture of 12.6 g of **6**, 2.73 g of potassium hydrogensulfate, and 1.36 g of copper powder was sublimed at 180—200 °C under reduced pressure for 30 min; the sublimate gave 3.61 g of **4**. The residual part was recrystallized from cyclohexane–benzene (1: 1) to yield 2.01 g (17%) of **2**.

*Friedel-Crafts Reaction of **4** with **1**.* A mixture of 1.37 g of **1**, 0.96 g of **4**, and 0.035 g of fused zinc chloride in 60 ml of carbon disulfide was refluxed for 2.5 h to give 0.216 g (11%) of **2**.

*Hydrogenation of **2**.* Butene **2** (1.00 g) was hydrogenated with hydrogen, using 10 g of Raney nickel (W-4) as catalyst in benzene (70 ml); 0.72 g (72%) of **7**, mp 161—163 °C, was obtained. UV_{max} 219 (log ε 4.70), 264 (4.48), 268 (4.50), 293 (4.01), and 304 nm (4.06); NMR (pyridine-d_5) δ=1.35 (3H, d, J=6.9 Hz), 2.07 (2H, t), 2.45—2.93 (3H, m), 3.86 (4H, s), and 7.23—8.05 (14H, m); MS, *m/e*, 386 (M^+).

*Oxidation of **2**.* A mixture of 0.38 g of **2**, 2.0 g of potassium permanganate, and 100 ml of acetone was stirred at room temperature for 2 h; 0.27 g (61%) of 9-oxofluorene-2-carboxylic acid, mp 336 °C (dec), and 0.04 g (18%) of 2-acetyl-9-fluorenone, mp 159—161 °C, were isolated.

3-(2-Fluorenyl)butanoic Acid. Dry ether (10 ml) containing diethyl malonate (6.4 g) was added to an ice-cooled solution of sodium ethoxide (2.7 g) in ether (30 ml) over a 10 min period with stirring under an atmosphere of nitrogen. To this was added a solution of 10.9 g of **1** in 50 ml of dry benzene, and the reaction mixture was stirred for an additional hour. After standing overnight at room temperature, the mixture was refluxed for 5.5 h and filtered, and the filtrate was evaporated to dryness to give diethyl 2-(2-fluorenyl)-1,1-propanedicarboxylate: mp 71—72 °C; IR 1740 and 1714 cm^{-1} (>C=O); NMR (CCl_4) δ=0.95 (3H, t), 1.21 (6H, t), 3.78 (2H, s), 3.43—4.33 (6H, m), and 7.05—7.70 (7H, m); MS, *m/e*, 352 (M^+).

The diester was refluxed with 12.8 g of sodium hydroxide in 100 ml of water for 4 h. After filtration, the filtrate was neutralized with hydrochloric acid to yield dicarboxylic acid: mp 195—196 °C (dec); IR 1723 cm^{-1} (>C=O).

The dibasic acid was heated at 150—160 °C for 1 h and the residue was sublimed *in vacuo* at 180 °C; the sublimate was recrystallized from benzene to give 7.63 g (76% based on **1**) of 3-(2-fluorenyl)butanoic acid: mp 155.5—157.0 °C; IR 2900 (-OH) and 1692 cm^{-1} (>C=O); NMR (benzene-d_6) δ=1.13 (3H, d, J=7.2 Hz), 2.43 (2H, d), 3.15 (1H, sex), 3.45 (2H, s), 6.93—7.73 (7H, m), and 11.55 (1H, s); MS, *m/e*, 252 (M^+).

Acid chloride (92% yield); mp 68—70 °C (dec); IR 1796 cm^{-1} (>C=O).

Methyl ester (93% yield): mp 86.5—87.0 °C; IR 1732 cm^{-1} (>C=O); NMR (CCl_4) δ=1.30 (3H, d), 2.48 (2H, d), 3.26 (1H, sex), 3.53 (3H, s), 3.76 (2H, s), and 6.97—7.68 (7H, m); MS, *m/e*, 266 (M^+).

3-(2-Fluorenyl)-1-butanol. The above methyl ester was reduced to the alcohol (98%): mp 82—83 °C; IR 3326 cm^{-1} (-OH); MS, *m/e*, 238 (M^+).

Corresponding acetate: mp 51.5—52.5 °C; IR 1732 cm^{-1} (>C=O); NMR (benzene-d_6) δ=1.15 (3H, d, J=6.9 Hz), 1.65 (3H, s), 1.77 (2H, q), 2.71 (1H, sex), 3.49 (2H, s), 3.96 (2H, t), and 6.92—7.67 (7H, m); MS, *m/e*, 280 (M^+).

1,3-Di(2-fluorenyl)-1-butanone. To the active magnesium prepared from 2.04 g of anhydrous magnesium chloride according to the literature,[4] there was added 4.38 g of 2-iodofluorene in 70 ml of dry tetrahydrofuran (THF) for 30 min at room temperature, and the reaction mixture was stirred for 1.5 h. Anhydrous cadmium chloride (1.4 g) was added all at once and the mixture was stirred for 2 h. To the solution of difluorenylcadmium, there was added the foregoing butanoyl chloride (prepared from 1.76 g of acid) in 20 ml of THF for 10 min at room temperature. The mixture was refluxed for 1 h and allowed to stand overnight at room temperature. This provided 0.50 g (18%) of 1,3-di(2-fluorenyl)-1-butanone: mp 175—176 °C; IR 1668 cm^{-1} (>C=O); MS, *m/e*, 400 (M^+).

Wolff-Kishner Reduction of 1,3-Di(2-fluorenyl)-1-butanone. A mixture of 0.10 g of the above ketone, 0.03 g of potassium hydroxide, 0.10 ml of hydrazine hydrate (90%), and 20 ml of diethylene glycol was treated in the usual manner to give 0.088 g (91%) of **7**: mp 161—163 °C.

1,3-Di(2-fluorenyl)-1-buthanol. The ketone (0.86 g) was reduced over Raney nickel (3.0 g) under an atmosphere of hydrogen at room temperature to afford 0.70 g (81%) of the alcohol: mp 151—153 °C; IR 3585 cm^{-1} (-OH); MS, *m/e*, 402 (M^+).

Dehydration of 1,3-Di(2-fluorenyl)-1-butanol. A solution of 0.30 g of the alcohol, 0.3 ml of acetic anhydride, 0.03 g of *p*-toluenesulfonic acid monohydrate, and 80 ml of acetic acid was refluxed for 4 h to yield 0.254 g (89%) of **2**: mp 176—178 °C.

A Modified Synthesis of 2,15-Hexadecanedione, a Precursor of Muscone, from a Butadiene Telomer

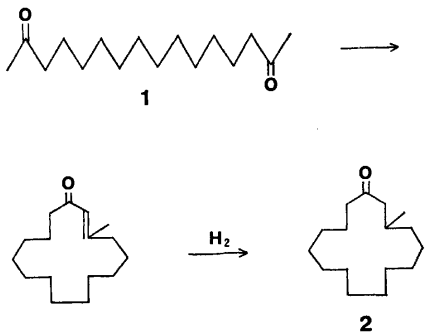
Jiro TSUJI, Mitsumasa KAITO, and Takashi TAKAHASHI

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo 152

(Received June 20, 1977)

8-Acetoxy-1,6-octadiene was oxidized with $PdCl_2/CuCl/O_2$ to give 8-acetoxy-6-octen-2-one. Hydrolysis and hydrogenation of the ketone produced 8-hydroxy-2-octanone, which was converted to the tosylate after protection of the ketone. The tosylate was converted into the iodide and bromide. The bromide was converted into the Grignard reagent, and coupled with the iodide by the catalysis of CuI coordinated by 2,2′-bipyridyl to give 2,15-hexadecanedione.

Muscone (3-methylcyclopentadecanone **2**) is a naturally occurring fragrant compound with musk odor. Many synthetic attempts for this unique natural product have been carried out. One method carried out by Stoll is based on the intramolecular aldol condensation of 2,15-hexadecanedione (**1**) to form the 15-membered cyclic ketone.[1]

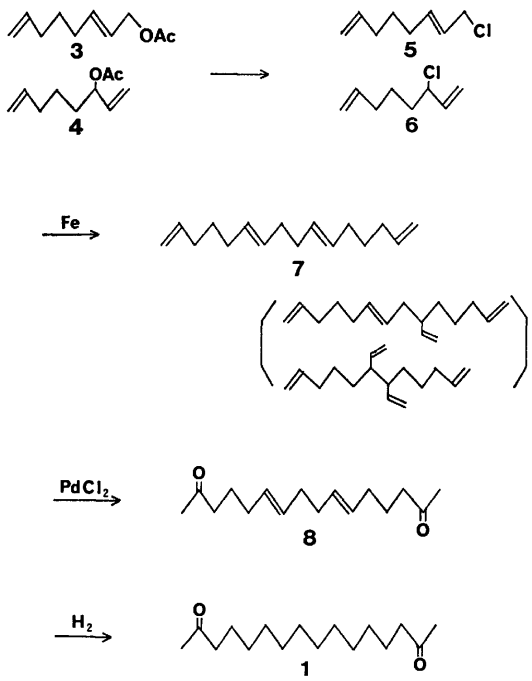


One drawback of the Stoll method is a low yield of the intramolecular aldol condensation, which competes with the intermolecular reaction. In order to make this method more useful and make up for the low yield of the aldol condensation, it is essential to synthesize the diketone **1** as the precursor easily in high yield. Only a few synthetic methods are known for this diketone. For example Stoll synthesized this diketone by the reaction of 1,10-dibromodecane with ethyl acetoacetate, followed by decarboxylation.[2] Another method is the cross Kolbe reaction of 10-oxoundecanoic acid and 6-oxoheptanoic acid.[1] The cross coupling inevitably produced a mixture of coupled products. We have reported the simple synthetic method for this diketone starting from a butadiene telomer easily obtained by the palladium catalyzed telomerization of butadiene with acetic acid.[3] We have carried out further elaboration of the synthesis from the telomer and results of the modification are presented in this paper.

Results and Discussion

Our original synthesis of the diketone **1** was carried out by the following sequence.[4]

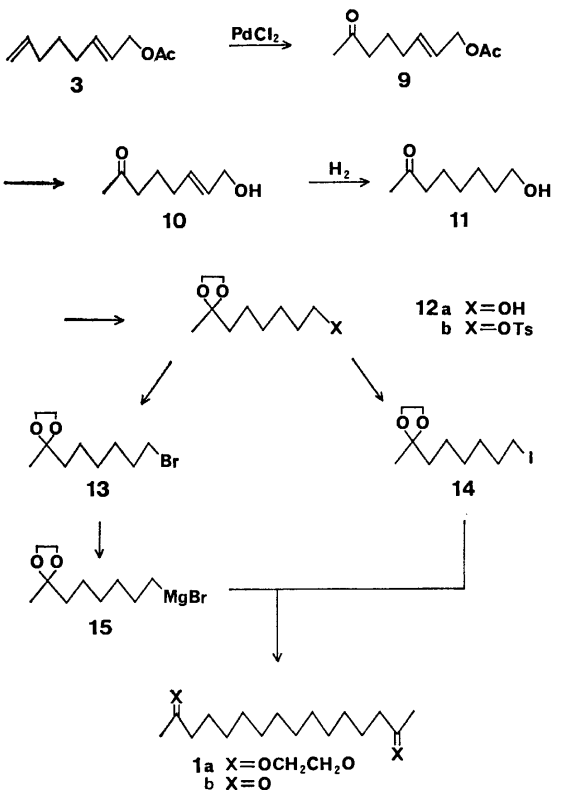
In this synthetic method, there are two problems to be improved. The first one is the iron catalyzed coupling of the allylic chlorides **5** and **6**. Although the desired tetraene **7** was obtained as a main product in 55%, the



formation of the branched isomers as by-products cannot be avoided. The coupling of even pure 8-chloro-1,6-octadiene (**5**) produced the same mixture as expected for a usual allylic coupling. Another problem is the selective oxidation. The oxidation of the terminal double bonds of the tetraene **7** catalyzed by $PdCl_2/CuCl/O_2$ produced the unsaturated diketone **8**. Usually the oxidation of the internal double bond is very sluggish and the selective formation of **8** is expected. However, the prolonged oxidation of **7** caused the slow oxidation of the internal olefin to form a trione. This is due to the fact that these internal olefins are 1,5-diolefins and can coordinate easily to palladium as bidentate ligand. Therefore, in order to avoid over-oxidation, the oxidation must be stopped before the complete consumption of the tetraene, and hence chromatographic separation of the products is necessary. In order to solve these problems, the present study has been carried out.

The new method starts from 8-acetoxy-1,6-octadiene (**3**)[3] and the synthesis of the diketone **1b** was carried out by the following sequence of reactions.

In this method, the selective oxidation of **3** was carried out at first. Also the formation of by-product in the coupling reaction was avoided by applying a reaction



of the saturated Grignard reagent **15** with the saturated iodide **14**. Thus the above mentioned problems of the first method were solved.

The selective oxidation[5] of the terminal olefin of **3** with $PdCl_2/CuCl/O_2$ in aqueous DMF at room temperature proceeded smoothly with high selectivity to form the keto acetate **9** in 82% yield. The hydrolysis of **9** with K_2CO_3 in aqueous ethanol, followed by hydrogenation using Raney nickel catalyst produced the keto alcohol **11** in 87% yield. When the hydrogenation of the allylic acetate **9** was carried out, extensive hydrogenolysis was observed to give 2-octanone. The ketone moiety of **11** was protected as an ethylene acetal and the resulting alcohol **12a** was converted into the tosylate **12b**. The tosylate **12b** was transformed into the bromide **13** and the iodide **14** by treatment with LiBr and NaI in acetone in 72 and 74% overall yields from the alcohol **12a**, respectively. A direct bromination of the alcohol gave **13** in rather poor yield.

The formation of the C_{16} diketone **1b** was carried out by the coupling of the C_8 halide with the corresponding Grignard reagent. In general, a satisfactory coupling of a Grignard reagent with an aryl or vinyl halide proceeds by using transition metal complexes, especially nickel compounds, as catalyst.[6-8] On the other hand, the coupling of alkyl halides is more difficult, although several catalysts are known.[9,10] At first nickel complexes of phosphine or 2,2'-bipyridyl were used, but these complexes did not give satisfactory results. The coupling by the catalysis of $CuCl_2/LiCl$ and CuCl/LiCl[11] was tried without much success. The most satisfactory results were obtained by the use of CuI coordinated by 2,2'-bipyridyl. The reaction of the bromide **13** with the Grignard reagent **15** with this catalyst gave the coupled product in 60% yield. Then the iodide **14** was used for the reaction together with a slight excess of the Gringnard reagent **15** in THF, the yield increased to 83%. The hydrolysis of the acetal under mild conditions produced 2,15-hexadecanedione as colorless crystals, which was identified on the basis of its melting point,[2] spectral data and elemental analysis.

Experimental

Melting points were taken on SHIBATA (No. 297) melting point apparatus. Infrared spectra were determined on a JASCO (IRA-2) spectrophotometer. NMR spectra were determined in CCl_4 solution on a HITACHI (R-24A) spectrometer using tetramethylsilane as an internal standard.

Oxidation of 8-Acetoxy-1,6-octadiene (3). A mixture of $PdCl_2$ (1.60 g, 9.03 mmol), CuCl (8.86 g, 89.5 mmol), *N,N*-dimethylformamide (45 ml) and water (5.4 ml) was placed in a 200 ml glass vessel fitted with a gas inlet tube and shaken under oxygen atmosphere for 1 h, during which time 430 ml of oxygen was absorbed. 8-Acetoxy-1,6-octadiene (14.9 g, 88.4 mmol) was added and the reaction mixture was shaken for 6 h (total absorption was 1080 ml). The reaction was quenched with 3N-hydrochloric acid (50 ml). The mixture was extracted with dichloromethane. The extract was washed with brine and dried over Na_2SO_4. Filtration and concentration of the extract *in vacuo* gave a crude product (15.7 g) as yellow oil, which was distilled (bp 67—85 °C/2.5 Torr) to give 8-acetoxy-6-octen-2-one (**9**) (13.2 g, 72.0 mmol, 81.5%). NMR (CCl_4): δ 5.75 (double d, J=4 and 14 Hz, 1H), 5.40 (double d, J=6 and 14 Hz, 1H) 4.45 (d, J=4 Hz, 2H), 2.40 (t, J=7 Hz, 2H), 2.2—1.8 (m, 2H), 2.05 (s, 3H), 1.95 (s, 3H), and 1.62 (m, 2H). IR (neat): 2950, 1740, 1710, 1670, 1370, 1240, 1165, 1030, 980, and 610 cm^{-1}.

Preparations of 8-Hydroxy-6-octen-2-one (10). A mixture of the keto acetate **9** (10.3 g, 55.9 mmol), 13% aqueous K_2CO_3 (50 ml) and ethanol (100 ml) was stirred for 72 h at room temperature. The reaction mixture was extracted with dichloromethane. The aqueous layer was extracted with dichloromethane several times. The combined extract was washed with brine and dried over Na_2SO_4. Filtration and concentration of the extract *in vacuo* gave a crude product (7.68 g), which was further purified by distillation (bp 78—81 °C/3 Torr) to give 8-hydroxy-6-octen-2-one (6.92 g, 48.7 mmol) 87.2%). NMR (CCl_4): δ 5.2—5.8 (m, 2H), 3.95 (broad, 2H), 3.20 (broad, 1H, -OH), 2.40 (t, J=7.0 Hz, 2H), 2.10 (s, 3H), 1.80—2.10 (broad, 2H), and 1.40—1.70 (broad, 2H). IR (neat): 3600—2950, 2925, 1710, 1360, 1160, 1090, 1000, and 970 cm^{-1}.

Preparation of 8-Hydroxy-2-octanone (11). 8-Hydroxy-6-octen-2-one (3.86 g, 27.2 mmol) in ethanol (20 ml) was hydrogenated with a Raney nickel catalyst (80 mg) under 11.5 atm of hydrogen at 25 °C with stirring for 1.5 h, during which time 650 ml of hydrogen was absorbed. The reaction mixture was filtered through celite and the celite was washed with ethanol. The combined filtrate was evaporated *in vacuo* to give 8-hydroxy-2-octanone (**11**) (3.89 g) which was used without purification. NMR (CCl_4): δ 3.80 (broad, 1H, -OH), 3.60 (t, J=7.0 Hz, 2H), 2.45 (t, J=7.0 Hz, 2H), 2.10 (s, 3H), and 1.10—1.80 (broad, 8H). IR (neat): 3600—2950, 2920, 1710, 1360, 1165, 1055, 720, and 600 cm^{-1}.

Acetalization of 8-Hydroxy-2-octanone. A mixture of the alcohol **11** (2.71 g, 18.8 mmol), ethylene glycol (30 g, 480 mmol), benzene (120 ml) and a catalytic amount of *p*-toluenesulfonic acid was placed in a 200 ml flask, equipped with a

water-separator and a condenser. The reaction mixture was refluxed for 8 h. After the usual work-up, a crude product (3.20 g) was chromatographed on silica gel. Elution with 1% isopropyl alcohol in hexane gave the acetal **12a** (2.96 g, 15.8 mmol, 83.6%). NMR (CCl_4): δ 4.30 (s, 4H), 3.90 (t, J=7.0 Hz, 2H), 3.0 (broad, 1H, -OH), 1.30—1.80 (broad, 10H), and 1.40 (s, 3H). IR (neat): 3600—3100, 2925, 1380, 1250, 1220, 1140, 1060, 950, and 850 cm^{-1}.

Preparation of 6-(2-Methyl-1,3-dioxolan-2-yl)hexyl p-*Toluenesulfonate (**12b**).* A solution of the acetal **12a** (1.08 g, 5.77 mmol) in dry pyridine (10 ml) was treated at 0 °C under nitrogen with freshly recrystallized *p*-toluenesulfonyl chloride (2.0 g, 10.6 mmol) overnight. The reaction mixture was poured into dichloromethane, and the dichloromethane solution was washed with ice-cold 1N-hydrochloric acid (until the aqueous layer reached pH 4). The aqueous layer was extracted with dichloromethane several times, the combined extract was washed with an ice-cold $NaHCO_3$ solution and brine and dried over $MgSO_4$. Filtration and concentration of the extract *in vacuo* gave the tosylate **12b** (1.92 g, 5.60 mmol, 97%), which was used without purification. NMR (CCl_4): δ 7.7 (d, J= 8.0 Hz, 2H), 7.25 (d, J=8.0 Hz, 2H), 3.90 (t, J=6.0 Hz, 2H), 3.80 (s, 4H), 2.4 (s, 3H), 1.1—1.8 (broad, 10H), and 1.20 (s, 3H). IR (neat): 2925, 1600, 1360, 1180, 1100, 955, 920, 810, 660, and 560 cm^{-1}.

*Preparation of 1-Bromo-6-(2-methyl-1,3-dioxolan-2-yl)hexane (**13**).* A mixture of the tosylate **12b** (4.5 g, 13.4 mmol), LiBr (6.71 g, 77.2 mmol) and dry acetone (80 ml) was refluxed for 3 h. Most of acetone was removed *in vacuo* at 25 °C. The residue was diluted with ether, insoluble material was removed by filtration and the ethereal filtrate was washed with water. The aqueous layer was extracted with ether several times and the combined ethereal extract was washed with brine and dried over $MgSO_4$. Filtration and concentration of the extract *in vacuo* gave a crude product (3.08 g), which was chromatographed on silica gel. Elution with 20% ether in hexane gave pure bromide **13** (2.50 g, 9.97 mmol, 72.2% (2 steps) based on **12a**). NMR (CCl_4): δ 3.80 (s, 4H), 3.3 (t, J=6.0 Hz, 2H), 1.2—2.0 (broad, 10H), and 1.20 (s, 3H). IR (neat): 2925, 1380, 1250, 1220, 1060, 950, 870, 730, 650, 560, and 530 cm^{-1}.

*Preparation of 1-Iodo-6-(2-methyl-1,3-dioxolan-2-yl)hexane (**14**).* The iodide **14** was prepared by the same procedure as described above, from the tosylate **12b** (1.48 g, 4.34 mmol) and NaI (3.10 g, 20.7 mmol) in dry acetone (40 ml). Chromatography on silica gel and elution with 20% ether in hexane gave the iodide **14** (0.99 g, 3.32 mmol, 74.2% (2 steps) based on **12a**). NMR (CCl_4): δ 3.75 (s, 4H), 3.10 (t, J=6.0 Hz, 2H), 1.1—2.0 (broad, 10H), and 1.2 (s, 3H). IR (neat): 2925. 1380, 1260, 1220, 1060, 950, 870, 710, 600, and 530 cm^{-1}.

*Preparation of the Grignard Reagent (**15**).* A 25 ml two neck round bottom flask, equipped with a magnetic bar, a condenser, a rubber septum and a gas inlet was flame-dried. Sliced metal magnesium (154 mg, 6.34 mmol) was added to the flask, and nitrogen was introduced into the apparatus, to which a solution of the bromide **13** (1.02 g, 4.05 mmol) in dry tetrahydrofuran (2 ml) was added dropwise with stirring at room temperature over 10 min. A catalytic amount of 1,2-dibromoethane was added as an initiator, and then the reaction mixture was stirred for 1 h at 40 °C. The Grignard reagent was titrated with 0.1N-hydrochloric acid. The normality of the Grignard reagent was 0.24N.

*Coupling of the Grignard Reagent **15** and the Iodide **14**.* A 25 ml two neck round bottom flask equipped with a magnetic bar, a rubber septum and a gas inlet was flame dried. Purified CuI (40.4 mg, 0.2 mmol) and 2,2'-bipyridyl (31.7 mg, 0.2 mmol) were added to the flask, and nitrogen was introduced. Then dry tetrahydrofuran (2 ml) was added to the flask. The mixture was stirred for 30 min at room temperature and cooled to 2 °C to which a solution of the iodide **14** (299 mg, 1.0 mmol) in dry tetrahydrofuran (2 ml) was added at once at 2 °C and the mixture was stirred for 10 min. To this solution a solution of the Grignard reagent **15** in tetrahydrofuran (6.3 ml of 0.24N solution, 1.5 mmol) was added dropwise at 2 °C over 10 min. The reaction mixture was stirred for 2 h at 2 °C and quenched with a saturated NH_4Cl solution. The reaction mixture was extracted with dichloromethane and the organic layer was washed with a saturated NH_4Cl solution (until the aqueous layer remained colorless), brine and dried over $MgSO_4$. Filtration and concentration of the extract *in vacuo* gave colorless oil, which was purified by chromatography on silica gel. The column was eluted with 20% ether in hexane. Concentration of the eluent *in vacuo* gave the coupled product **1a** (269 mg, 0.79 mmol, 79%) as a crystalline material. Further purification by recrystallization from methanol gave pure 1,12-bis(2-methyl-1,3-dioxolan-2-yl)dodecane (**1a**) mp 69.0—70.5 °C). NMR (CCl_4): δ 3.80 (s, 8H), 1.1—1.7 (broad, 24H), and 1.2 (s, 6H). IR (KBr disk): 2965, 2900, 2850, 1465, 1450, 1370, 1250, 1230, 1140, 1070, 1050, 1030, 950, 860, 810, 730 and, 580 cm^{-1}.

*2,15-Hexadecanedione (**1b**) by Deacetalization of **1a**.* The diacetal **1a** (42 mg, 0.12 mmol) and $CuSO_4$ (50 mg) in MeOH (2 ml) and water (0.5 ml) were heated under reflux for 15 min. Undissolved $CuSO_4$ was filtered off, and most of methanol was removed *in vacuo* at room temperature. The residue was dissolved in ether, and the ethereal solution was washed with brine and dried over $MgSO_4$. Filtration and concentration of the solution *in vacuo* gave the diketone **1b** (25.6 mg) as a crystalline material. Further purification by recrystallization from MeOH gave pure 2,15-hexadecanedione **1b** (mp 83.5—84.5 °C. reported mp 83—84 °C[2]). NMR (CCl_4): δ 2.2 (t, J=7.0 Hz, 4H), 1.95 (s, 6H), and 1.0—1.7 (broad, 20H). IR (KBr): 2900, 2830, 1710, 1460, 1160, 800, 720, and 600 cm^{-1}. Found: C, 75.77; H, 11.81, Calcd for $C_{16}H_{30}O_2$: C, 75.54; H, 11.89%.

α,β-Unsaturated Carboxylic Acid Derivatives. XIII. The Synthesis and Configuration of Alkyl 2-Acylamino-2-alkenoates and Their Cyclized 2,5-Piperazinedione Derivatives[1)]

Chung-gi SHIN, Masato HAYAKAWA, Takamichi SUZUKI, Akira OHTSUKA,* and Juji YOSHIMURA**

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

***Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received June 24, 1977)

It is described that alkyl (*E*)- and (*Z*)-2-halo (Cl, Br, and I)-acetylamino-2-alkenoate (DHA), obtained by the condensation of alkyl 2-oxoalkanoate with chloro- or bromoacetamide and by halogen exchange from the chlorine of DHA to iodine, are cyclized with ammonia or hydroxylamine to give the (*E*)- and (*Z*)-isomers of unsymmetric 3-alkylidene-2,5-piperazinediones and their 1-hydroxy derivatives respectively. Alkyl (*E*)- and (*Z*)-2-iodoacetylamino-2-alkenoates were converted into the corresponding acetylamino- and phthalimidoacetylamino derivatives. The configurations of all the DHA and 2,5-piperazinedione derivatives were determined from the NMR spectra data.

Although there have been many works on the synthesis of 2-acylamino-2-alkenoic acids (α-dehydroamino acids; DHA), only a few papers have been recently reported on the geometric stereochemistry. Especially with regard to the chemical proof for the configurational assignment of the geometric isomers, only one example has been recently reported.[2)] Austel and Steglich distingiushed the configuration of (*Z*)-3-methyl-5,5,5-trifluoro-2-trifluoroacetyl-4-trifluoroacetoxy-2-pentenoic acid by successfully converting it into the corresponding lactone, whereas the (*E*)-isomer did not cyclize. The NMR data of this compound indicated that methyl or methine protons *cis* to the trifluoroacetyl group appeared downfield relative to the occupied *trans* position. More recently, Srinivasan *et al.*[3)] and another workers[4)] have also commented that the low chemical shifts of 3-methyl groups *cis* to the alkoxycarbonyl group of DHA form a more reliable criterion for the assignment of stereochemistry than that of those *trans*.

Previously, Shin *et al.* reported briefly on the possibility of the available chemical determination of alkyl (*E*)- and (*Z*)-2-chloroacetylamino-2-alkenoates (**1**) on the basis of the chemical behavior of 3-alkylidene-2,5-piperazinediones (**6**), cyclization products of **1**, in acetylation.[5,6)]

In this paper, we wish to report in detail an NMR method which can be used for the configurational determination of several DHA's and the stereochemistry of 3-alkylidene-(**6**)- and 3-alkylidene-1-hydroxy-2,5-piperazinediones (**7**), obtained by the cyclization of DHA with ammonia and hydroxylamine respectively.

Results and Discussion

Alkyl 2-Acylamino-2-alkenoates. The alkyl 2-chloroacetyl-(**1**)- and bromoacetylamino-2-alkenoate (**2**) were prepared in one step by the reaction of alkyl 2-oxoalkanoates with chloroacetamide or bromoacetamide in benzene under reflux for *ca.* 15 h, as has been reported previously.[5)] Since the DHA thus obtained was found to be a mixture of (*E*)- and (*Z*)-isomers, the mixture was separated by chromatography on a silica gel column, using benzene as the eluent, to give, first, a colorless syrup and then crystals.

According to a method previously reported,[2-6)] the geometric stereochemistry of the above DHA was readily determined by a comparison of the NH, vinyl, and 3-alkyl protons between (*E*)- and (*Z*)-isomers. The NMR data in Table 2 show that all the chemical shifts of the NH, vinyl, and 3-alkyl protons of **1** and **2** obtained in the oily state resonate at fields lower by 0.51—0.69, 0.26—0.54, and 0.33—0.76 ppm respectively than those of **1** and **2** in the crystalline state, indicating that the former syrup has the (*E*)-configuration, while the latter crystals have the (*Z*)-configuration.

Moreover, the syntheses of both alkyl (*E*)- and (*Z*)-2-iodoacetylamino-2-alkenoates (**3**) were readily achieved and in fairly good yields by the treatment of pure (*E*)- or (*Z*)-**1** with potassium iodide in acetone under reflux for 3 h (Table 1). The NMR spectrum shows a tendency similar to that described above, resonating the chemical shifts of the NH, vinyl, and 3-alkyl protons of the (*E*)-isomer at fields lower by 0.35—0.74, 0.26—0.35, and 0.30—0.68 ppm respectively than that of the (*Z*)-isomer. It is noteworthy that the chemical shifts of not only methylene but also of NH protons in the haloacetylamino groups in both (*E*)- and (*Z*)-isomers in the same series were lower by the order of **1**, **2**, or **3**, indicating that the substituent effect of halogen atoms reaches the nitrogen atom beyond the carbonyl function.

On the other hand, the configuration of one isomer of the alkyl 2-acetylamino-(**4**)- and 2-(phthalimidoacetylamino)-2-alkenoate (**5**),[7,8)] obtained previously by the elimination of alkyl 2-(acetoxyamino)- or 2-(*N,O*-diacetylhydroxyamino)-2-alkenoates with a base, was confirmed unambiguously to have the (*Z*)-geometry by the agreement of the physical constants and spectral data with those derived here by the reaction of (*Z*)-**3** with zinc powder or potassium phthalimide. A similar treatment of (*E*)-**3** gave (*E*)-**4** and **5** in fairly good yields

* Present address: Kokusan Kagaku Co., Ltd., Itabashi-ku, Tokyo 174.

(Table 3). The NMR spectral pattern of **4** is very similar to those of **1**, **2**, and **3**, whereas in the case of **5** the chemical shifts of the NH and 3-alkyl protons of the (*E*)-isomer resonate at fields lower by 0.26—0.35 and 0.19—0.27 ppm respectively than that of the (*Z*)-isomer, while that of the vinyl proton of the (*E*)-isomer appears at field higher by 0.50—0.58 ppm, as has been reported recently.[3]

The evidence regarding the NMR data of DHA mentioned here can also be used to determine the configurations of other alkyl 2-(2-halopropionylamino)- and 2-(ethoxycarbonylamino)-2-alkenoate[1] and 2-azido-2-alkenoate[9] as well as 2-amino-2-alkenoate[10] by a comparison of the NH, vinyl, and 3-alkyl protons. These results will be reported and discussed elsewhere.

In the IR spectral data on **1**—**4** and **5**, the characteristic differences between the (*E*)- and (*Z*)-geometric isomers could not be recognized. The absorption bands of NH in the 3150—3350 cm^{-1} region, the ester carbonyl in the 1720—1735 cm^{-1} region, and the amide carbonyl in the 1645—1690 cm^{-1} region supported these structures, but that of the carbon-carbon double bond overlapped the amide carbonyl region.

The yields, physical constants, and spectral data of **1**—**4** and **5** are summarized in Tables 1, 2, and 3.

Cyclization Reactions. According to the method previously reported by us[5,6,8] and by Cook and Slater,[11] the cyclization reaction of individual (*E*)- and (*Z*)-**1** with ammonia and that of (*E*)- and (*Z*)-**2** and **3** with hydroxylamine were carried out. Pure (*E*)- or (*Z*)-**1** was treated with excess gaseous ammonia in ethanol to convert it into (*E*)- and (*Z*)-**6** respectively in *ca.* 50% yields. Since the cyclization of **1** with hydroxylamine in ethanol did not proceed, a similar treatment of the pure (*E*)- or (*Z*)-**2** with hydroxylamine under reflux in a stream of nitrogen for 18 h gave the expected (*E*)- and (*Z*)-**7** respectively as pinkish crystals, although the yields were low. However, in the case of **3**, it was found that the similar cyclization proceeded to give **7** in a comparatively good yield. The **7** thus obtained turned deep violet upon coloration with ferric chloride in methanol, indicating the presence of a hydroxamic acid structure. This seems to be the first example of the formation of unsymmetric cyclic monohydroxamic acid (**7**). This result offers many useful suggestions for the synthesis of antibiotics mycelianamide,[12] which has a cyclic dihydroxamic acid structure.

The yields, physical constants, and spectral data of **6** and **7** are summarized in Tables 4 and 5.

The NMR data of **6** and **7** may be summarized as follows:

1) Chemical shifts of NH and methylene protons of these cyclic compounds: **6** and **7** are lower, but those of vinyl protons are higher than those of **1**—**4**, reflecting

Table 1. The yields, physical constants, and elemental analyses of **1**, **2**, and **3**

Compound	R		Yield (%)	Bp °C/mmHg (Mp °C)[a]	Formula	Found (Calcd), % C	H	N

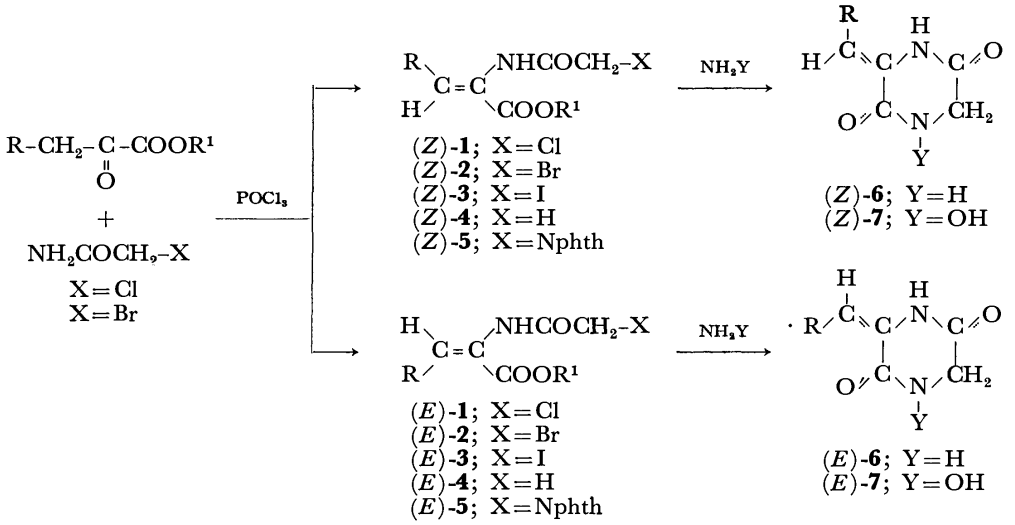
a) From Compound **2**. b) From Compound **3**. c) cm^{-1} in KBr. d) Multiplet. e) Elemental analyses of the mixture of the (*E*)- and (*Z*)-isomers.



a; R=CH_3, **b**; R=C_2H_5, **c**; R=*n*-C_3H_7, **d**; R=*i*-C_3H_7, **e**; R=C_6H_5
R^1=C_2H_5 (excepting R^1=CH_3 in the case of R=*i*-C_3H_7)

Scheme 1.

the change in the coplanarity of the molecules.

2) The chemical shifts of the methylene, vinyl, and 3α-alkyl protons of **7** are higher than those of **6**, indicating the introduction of an electron-releasing hydroxyl group into **6**.

3) The vinyl and methylene protons of the (*Z*)-isomer of **6** and **7** resonate at a lower magnetic field ($\Delta\delta$ 0.35—0.54 and 0.04—0.10 ppm respectively) compared with that of the (*E*)-isomer, whereas 3α-alkyl protons of (*Z*)-isomer resonate at a higher magnetic field ($\Delta\delta$ 0.27—0.91 ppm). These facts seem to indicate a flattened boat-conformation[13] for these cyclic compounds (**6** and **7**).

The IR spectrum of **7** showed a characteristic absorption band in the 2760—2930 cm^{-1} region due to a hydroxamic acid, supporting the structure of **7**.

Experimental

All the boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethylsilane as the internal standard.

Materials. The (*E*)- and (*Z*)-isomers of **1** were prepared by the method previously reported.[5] The mixture of (*E*)- and (*Z*)-isomers thus obtained was separated by chromatography on a silica gel column using benzene; the earlier eluted one was an oil thought to be the (*E*)-isomer, and the latter, crystals thought to consist of the (*Z*)-isomer.

*Preparation of **2**.* According to the above method, when a solution of ethyl or methyl 2-oxoalkanoate (0.10 mol) and bromoacetamide (0.12 mol) in benzene (100 ml) in the presence of phosphoryl chloride (0.02 mol) was refluxed for *ca.* 15 h, a colorless syrup was obtained in *ca.* a 40% yield after the removal of the benzene and the subsequent distillation of the residue under reduced pressure. The mixture syrup of (*E*)- and (*Z*)-isomers thus obtained was similarly worked up to give an oil ((*E*)-isomer) and crystals ((*Z*)-isomer).

*Preparation of **3**.* The purely isolated (*E*)- and (*Z*)-isomers of **1** (0.01 mol) were treated separately with potassium iodide (0.02 mol) in acetone (50 ml) under reflux for 3 h to convert it into the (*E*)- and (*Z*)-isomers of **3** respectively as colorless crystals in an almost quantitative yield, after the removal of the potassium chloride deposited and the acetone.

*Preparation of **4**.* A mixture of the (*E*)- or (*Z*)-isomer of **3** (0.01 mol) and zinc powder (6.54 g, 0.1 mol) in ethanol (50 ml) was stirred at room temperature for 5 h. After the subsequent removal of the zinc and the ethanol, the residue was distilled under reduced pressure to give a colorless oil or crystals ((*E*)- and (*Z*)-isomers of **4** respectively).

*Preparation of **5**.* A solution of the (*E*)- or (*Z*)-isomer of **3** (0.01 mol) and potassium phthalimide (0.01 mol) in dimethyl sulfoxide (30 ml) was stirred at room temperature for 5 h. When the reaction solution was then poured into ice water (100 ml), colorless crystals (**5**) were separated out.

*Preparation of **6**.* According to the method previously reported,[5] the individual (*E*)- and (*Z*)-isomer of **6** was prepared by the reaction of the (*E*)- or (*Z*)-isomer of **1** with ammonia.

*Preparation of **7**.* A solution of the individual (*E*)- and (*Z*)-isomer of **2** or **3** (0.005 mol) and hydroxylamine (made from hydroxylamine hydrochloride (0.02 mol) and sodium (0.02 mol) in dry ethanol (5 ml)) in dry ethanol (50 ml) was refluxed under nitrogen gas for 18 h. The reaction solution was then evaporated to dryness under reduced pressure, the residue obtained was dissolved in water (1000 ml), and the aqueous solution was passed successively through columns of Dowex 50 WX-12 cation-exchange regin and Dowex 1-X8 anion-exchange regin (acetate form). The aqueous fraction thus eluted evaporated under reduced pressure to give faint pinkish crystals (**7**).

An aminocyclitol antibiotic neamine has been modified in its 2-deoxystreptamine moiety by converting the hydroxyl group into an amino group to give three antibiotic amino-deoxyneamines. Their antimicrobial activities were determined against several microorganisms.

In connection with preceding papers[1-3] directed toward a synthesis of a more active antibiotic than the parent neamine, an amino group was introduced to the 2-deoxystreptamine moiety of neamine.

In the present article, we wish to report a preparation of three antibiotic amino-deoxyneamines (**3**, **7**, and **11**).

5-Amino-5-deoxyneamine (3). *O*-Deacetylation of 6,3′,4′-tri-*O*-acetyl-5-chloro-5-deoxy-1,3,2′,6′-tetra-*N*-(ethoxycarbonyl)-5-epineamine[2] (**1**) in methanolic ammonia, followed by azidolysis and acetylation gave 6,3′,4′-tri-*O*-acetyl-5-azido-5-deoxy-1,3,2′,6′-tetra-*N*-(ethoxycarbonyl)neamine (**2**) as crystals in 54% yield.

Catalytic hydrogenation of **2** in the presence of platinum oxide, followed by hydrolysis in aqueous barium hydroxide afforded 5-amino-5-deoxyneamine (**3**) as amorphous powder in 58% yield. *N*-Acetylation of **3** with acetic anhydride in methanol gave 1,3,5,2′,6′-penta-*N*-acetyl-5-amino-5-deoxyneamine (**4**).

The structure of **3** was established by a degradation of **3** in 8.8 M hydrobromic acid. From the degradation mixture, the known 1,3,5-triacetamido-4,6-di-*O*-acetyl-1,2,3,5-tetradeoxy-*scyllo*-inositol[4] was obtained.

6-Amino-6-deoxyneamine (7). When 5,3′,4′-tri-*O*-acetyl-6-chloro-6-deoxy-1,3,2′,6′-tetra-*N*-(ethoxycarbonyl)-6-epineamine[2] (**5**) was *O*-deacetylated and subsequently treated with sodium azide in *N*,*N*-dimethylformamide, 5,3′,4′-tri-*O*-acetyl-6-azido-6-deoxy-1,3,-2′,6′-tetra-*N*-(ethoxycarbonyl)neamine (**6**) was obtained in 30% yield. Catalytic hydrogenation of **6** in the presence of platinum oxide, followed by hydrolysis in aqueous barium hydroxide gave 6-amino-6-deoxyneamine (**7**) as chromatographically homogeneous powder in 71% yield. *N*-Acetylation of **7** with acetic anhydride in methanol gave 1,3,6,2′,6′-penta-*N*-acetyl-6-amino-6-deoxyneamine (**8**).

The structure of **7** was established by the analogous degradation of **3** as described above, where L-1,3,4-triacetamido-5,6-di-*O*-acetyl-1,2,3,4-tetradeoxy-*scyllo*-inositol was obtained as crystals. The compound showed identical IR and ^{1}H NMR spectra with its racemate.[5]

5-Amino-5-deoxy-5,6-diepineamine (11). When 3′,4′-di-*O*-acetyl-5,6-anhydro-1,3,2′,6′-tetra-*N*-(ethoxycarbonyl)-6-epineamine[6] (**9**) was treated with freshly distilled boron trifluoride etherate in acetonitrile, two products (**10a** and **10b**) were obtained in 35 and 28% yield respectively. Considering from the reaction mechanism proposed by Fox *et al.*[7] on the reaction of

nucleoside 2′,3′-epoxide with boron trifluoride etherate in acetonitrile, an introduction of an acetamido group into the 2-deoxystreptamine moiety of neamine might occur on C-5 or C-6. Therefore, compound **10a** and **10b** might be positional isomers, since both compounds gave a correct elemental analysis for the predicted structures.

However, degradation of **10a** or **10b** in 8.8 M hydrobromic acid gave the same compound: L-1,3,5-triacetamido-4,6-di-*O*-acetyl-1,2,3,5-tetradeoxy-*allo*-inositol. Its structure was established by the ^{1}H NMR spectra in comparison with its *O*-trideuterioacetyl derivative. This fact indicated that an introduction of an acetamido group occurred only at the C-5 position in a manner of trans diaxial opening. Therefore, the structures of **10a** and **10b** were comprehensible in terms of a possible migration of an ethoxycarbonyl group between an amino group on C-1 and a hydroxyl group on C-6.

An intact mixture of **10a** and **10b** was hydrolyzed in aqueous barium hydroxide and the hydrolyzate was purified by an ion-exchange resin chromatography to give 5-amino-5-deoxy-5,6-diepineamine (**11**) as amorphous powder.

Also, compound **11** was prepared by an alternative reaction process *via* an azido derivative in the following manner. When compound **9**[6] was heated with sodium

azide and ammonium chloride in 2-methoxyethanol, an azido derivative was obtained. The product was hydrogenated in the presence of Raney nickel and the reduction product was treated with ethyl chloroformate in sodium carbonate solution. After acetylation, the product was purified by column chromatography to give 6,3',4'-tri-*O*-acetyl-5-amino-5-deoxy-1,3,5,2',6'-penta-*N*-(ethoxycarbonyl)-5,6-diepineamine (**12**) in 17% yield. Compound **12** was heated in aqueous barium hydroxide to give **11** as chromatographically homogeneous solid. *N*-Acetylation of **11** gave 1,3,5,2',6'-penta-*N*-acetyl-5-amino-5-deoxy-5,6-diepineamine (**13**).

Compound **3** was slightly less active than neamine, but active against *E. coli* ML-1629 resistant strain. Compounds **7** and **11** showed a considerably lower activity against the microorganisms tested in comparison with neamine (Table 1).

Experimental

General Methods. Melting points were determined in capillary tubes and are uncorrected. Solutions were evaporated under diminished pressure. Optical rotations were measured with a Japan Spectroscopic DIP-SL polarimeter. ^{1}H NMR spectra were recorded at 60 MHz with a Varian A-60D spectrometer in chloroform-*d*, unless otherwise noted, with tetramethylsilane as the internal standard and the peak positions are given in δ values. IR spectra were recorded on potassium bromide disks with a Hitachi-Perkin-Elmer 225 spectrophotometer. Acetylation was performed conventionally with acetic anhydride in pyridine. TLC was performed on Wakogel B-10 (Wako Pure Chemical Co., Ltd.) plates. Silica gel (Wakogel C-300) was employed for column chromatography. Elemental analyses were performed by Mr. Saburo Nakada.

6,3',4'-Tri-O-acetyl-5-azido-5-deoxy-1,3,2',6'-tetra-N-(ethoxycarbonyl)neamine (2). A 402 mg portion of 6,3',4'-tri-*O*-acethyl-5-chloro-5-deoxy-1,3,2',6'-tetra-*N*-(ethoxycarbonyl)-5-epineamine[2] (**1**) was dissolved in methanolic ammonia (7 ml) and the solution was settled in a refrigerator overnight to give 5-chloro-5-deoxy-1,3,2',6'-tetra-*N*-(ethoxycarbonyl)-5-epineamine (310 mg) as precipitates. The deacetylation product was heated with sodium azide (310 mg) in *N*,*N*-dimethylformamide (5 ml) at 100 °C for 19 h under agitation. The mixture was filtered and the filtrate was evaporated. The residue was acetylated and the product was recrystallized from ethanol–ether to give 193 mg of **2**, mp 228—229 °C; $[\alpha]_D^{23}$ +64.9° (*c* 0.97, chloroform). The second crop (24 mg) of the product was obtained from the mother liquor by column chromatography. Total yield was 54%. IR: 2175 cm^{-1} (N_3). ^{1}H NMR: δ 1.10—1.37 (m, 12, 4×$CO_2CH_2C\underline{H}_3$), 2.01 (s, 3, OAc), 2.03 (s, 3, OAc), 2.14 (s, 3, OAc).

Found: C, 47.05; H, 6.16; N, 12.59%. Calcd for $C_{30}H_{47}N_7O_{16}$: C, 47.30; H, 6.22; N, 12.87%.

5-Amino-5-deoxyneamine (3). Compound **2** (611 mg) was hydrogenated in the presence of platinum oxide (50 mg) in methanol (35 ml) under hydrogen atmosphere (3.4 kg/cm^2) for 45 h in a Parr apparatus. The mixture was filtered and the filtrate was evaporated. The residue was heated in water

(10 ml) containing barium hydroxide (7.6 g) for 10 h under reflux. Carbon dioxide was bubbled into the mixture, and the precipitate was filtered off. The filtrate was evaporated and the residue was purified on a column of Amberlite CG-50 (NH_4^+). The column was washed with water, 0.1M, and 0.2M aqueous ammonia and then eluted with 0.3M aqueous ammonia to give 150 mg (58%) of **3**, mp 135 °C (dec); $[\alpha]_D^{21}$ +92.0° (*c* 0.81, water). The product showed a single spot at R_f 0.23 on TLC in 5: 8: 10: 7 (v/v) 28% ammonia–1-butanol–ethanol–water. IR: 1570 cm^{-1} (NH_2). ^1H NMR (D_2O at pD 1): δ 5.86 (d, 1, J=3 Hz, H-1′).

*1,3,5,2′,6′-Penta-*N*-acetyl-5-amino-5-deoxyneamine (**4**).* Compound **3** (17 mg) was acetylated with acetic anhydride (0.5 ml) in methanol (1 ml) to give 24 mg (83%) of **4**, mp 255—260 °C (dec); $[\alpha]_D^{20}$ +71.2° (*c* 0.69, water). IR: 1630 (amide I), 1540 cm^{-1} (amide II). ^1H NMR (D_2O): δ 1.94 (s, 3, NAc), 1.99 (s, 6, 2×NAc), 2.03 (s, 3, NAc), 2.04 (s, 3, NAc), 5.18 (d, 1, J=3.5 Hz, H-1′).

Found: C, 48.25; H, 6.87; N, 12.51%. Calcd for $C_{22}H_{37}N_5O_{10}\cdot H_2O$: C, 48.08; H, 7.15; N, 12.74%.

*Degradation of **3** in 8.8M Hydrobromic Acid.* Compound **3** (72 mg) was heated in 8.8M hydrobromic acid (4 ml) for 43 h under reflux. The solution was diluted with water and neutralized with Dowex 1×2 (OH^-) resin. The solution was evaporated and the residue was purified on a column of Amberlite CG-50 (NH_4^+). After washed with water and 0.1M aqueous ammonia, the column was eluted with 0.3M aqueous ammonia and a ninhydrin positive fraction was collected and evaporated. The residue was acetylated and the product was recrystallized from ethanol–ethyl acetate to give 36 mg (43%) of 1,3,5-triacetamido-4,6-di-*O*-acetyl-1,2,3,5-tetradeoxy-*scyllo*-inositol which was identical with an authentic sample,[4] mp 308—309 °C (dec). (Found: C, 51.92; H, 6.77; N, 11.38%).

*5,3′,4′-Tri-O-acetyl-6-azido-6-deoxy-1,3,2′,6′-tetra-*N*-(ethoxycarbonyl)neamine (**6**).* 5,3′,4′-Tri-*O*-acetyl-6-chloro-6-deoxy-1,3,2′,6′-tetra-*N*-(ethoxycarbonyl)-6-epineamine[2] (**5**, 1.48 g) was dissolved in methanolic ammnia (50 ml) and the solution was settled overnight at ambient temperature. The solution was evaporated and the residue was washed with ether, and then heated with sodium azide (1.28 g) in *N*,*N*-dimethylformamide (15 ml) at 95 °C for 16 h with mechanical agitation. The solution was evaporated and the residue was acetylated. The acetylation product was purified by a column chromatography using 30: 1 (v/v) chloroform–ethanol as eluant. Fractions showing a single spot at R_f 0.30 on TLC in 20: 1 (v/v) chloroform–ethanol were combined and evaporated to give 449 mg (30%) of **6** as amorphous powder, mp 110—117 °C; $[\alpha]_D^{20}$ +54.4° (*c* 1.3, chloroform). IR: 2140 cm^{-1} (N_3). ^1H NMR: δ 1.25 (t, 12, J=7 Hz, 4×$CO_2CH_2C\underline{H}_3$), 1.98 (s, 3, OAc), 2.02 (s, 3, OAc), 2.07 (s, 3, OAc).

Found: C, 47.25; H, 6.05; N, 12.48%. Calcd for $C_{30}H_{47}N_7O_{16}$: C, 47.30; H, 6.22; N, 12.87%.

*6-Amino-6-deoxyneamine (**7**).* Compound **6** (434 mg) was hydrogenated, followed by hydrolysis in barium hydroxide solution as described in the preparation of **3** to give 129 mg (71%) of **7** as amorphous powder, mp 118—121 °C (dec); $[\alpha]_D^{20}$ +81.9° (*c* 1.4, water). The product showed a single spot at R_f 0.32 on TLC in the same solvent as described for **3**. ^1H NMR (D_2O at pD 1): δ 6.09 (d, 1, J=3.5 Hz, H-1′).

*1,3,6,2′,6′-Penta-*N*-acetyl-6-amino-6-deoxyneamine (**8**).* Compound **7** (28 mg) was acetylated with acetic anhydride (0.1 ml) in methanol (1.5 ml) to give 35 mg (73%) of **8** as amorphous powder, mp above 290 °C; $[\alpha]_D^{17}$ +89.1° (*c* 0.9, water). ^1H NMR (D_2O): δ 1.95 (s, 3, NAc), 2.00 (s, 3, NAc), 2.02 (s, 3, NAc), 2.05 (s, 3, NAc), 2.07 (s, 3, NAc), 5.42 (d, 1, J=3 Hz, H-1′).

*Reaction of Epoxide **9** with Boron Trifluoride Etherate in Acetonitrile.* 3′,4′-Di-*O*-acetyl-5,6-anhydro-1,3,2′,6′-tetra-*N*-(ethoxycarbonyl)-6-epineamine[6] (**9**, 1.19 g) was dissolved in freshly distilled dry acetonitrile (15 ml), and freshly distilled boron trifluoride etherate (2.5 ml) was added gradually to the solution. The mixture was settled at ambient temperature for 20 h. The solution was poured into saturated sodium hydrogencarbonate solution (50 ml) and extracted with chloroform. After dried over anhydrous sodium sulfate, the chloroform solution was evaporated. The residue was purified by a column chromatography using 30: 1 (v/v) chloroform–ethanol.

Fractions showing a single spot at R_f 0.40 on TLC in 20: 1 (v/v) chloroform–ethanol were combined and evaporated. The residue was dissolved in benzene and hexane was added to the solution to give 450 mg (35%) of **10a**, mp 110—121 °C (dec); $[\alpha]_D^{16}$ +100.7° (*c* 1.1, chloroform). ^1H NMR: δ 1.1—1.4 (m, 12, 4×$CO_2CH_2C\underline{H}_3$), 2.00 (s, 3, OAc), 2.03 (s, 3, OAc), 2.12 (s, 3, NAc).

Found: C, 48.76; H, 6.57; N, 9.27%. Calcd for $C_{30}H_{49}N_5O_{16}$: C, 48.97; H, 6.71; N, 9.52%.

Fractions showing a single spot at R_f 0.15 on TLC in the same solvent were combined and evaporated to give 360 mg (28%) of **10b**, mp 149—157 °C (dec); $[\alpha]_D^{20}$ +72.5° (*c* 1.6, chloroform). ^1H NMR: δ 1.1—1.5 (m, 12, 4×$CO_2CH_2C\underline{H}_3$), 1.99 (s, 3, OAc), 2.01 (s, 3, OAc), 2.04 (s, 3, NAc).

Found: C, 48.83; H, 6.51; N, 9.32%. Calcd for $C_{30}H_{49}N_5O_{16}$: C, 48.97; H, 6.71; N, 9.52%.

*Degradation of **10a** and **10b** in 8.8M Hydrobromic Acid.*
a) Compound **10a** (184 mg) was heated in 8.8M hydrobromic acid (5 ml) under reflux for 48 h. The reaction mixture was treated analogously as described in the degradation of **3** to give 47 mg (51%) of 1L-1,3,5-triacetamido-4,6-di-*O*-acetyl-1,2,3,5-tetradeoxy-*allo*-inositol, mp 178—182 °C; $[\alpha]_D^{20}$ +14° (*c* 0.43, methanol). ^1H NMR (DMSO-d_6): δ 1.79 (s, 6, 2×NAc), 1.88 (s, 3, OAc), 1.91 (s, 3, NAc), 2.12 (s, 3, OAc).

Found: C, 51.95; H, 6.73; N, 11.36%. Calcd for $C_{16}H_{25}N_3O_7$: C, 51.74; H, 6.79; N, 11.31%.

b) Compound **10b** (159 mg) was treated with the above procedure to afford the same inosatriamine derivative (24 mg, 30%). (Found: C, 51.87; H, 6.61; N, 11.39%).

5L-1,3,5-triacetamido-1,2,3,5-tetradeoxy-4,6-di-O-trideuterioacetyl-allo-inositol. 1L-1,3,5-triacetamido-4,6-di-*O*-acetyl-1,2,3,5-tetradeoxy-*allo*-inositol (47 mg) was dissolved in 0.02M methanolic hydrogen chloride (2 ml) and the solution was settled overnight. The solution was evaporated and the residue was acylated with acetic anhydride-d_6 (0.3 ml) in pyridine (0.5 ml) to give 32 mg (67%) of crystalline product, mp 189—198 °C (dec); $[\alpha]_D^{20}$ +14° (*c* 0.5, methanol). ^1H NMR (DMSO-d_6): δ 1.79 (s, 6, 2×NAc), 1.91 (s, 3, NAc).

*5-Amino-5-deoxy-5,6-diepineamine (**11**).* a) Compound **9**[6] (800 mg) was treated analogously as described above to give a mixture of **10a** and **10b** (820 mg). The product was hydrolyzed in a mixture of barium hydroxide (9 g) and water (30 ml) at 100 °C for 24 h. The hydrolyzate was purified analogously as described in the preparation of **3** to give 112 mg

(29%) of **11**, mp 165—196 °C (dec); $[\alpha]_D^{20}$ +126° (*c* 1.0, water). ^{1}H NMR (D_2O at pD 1): δ 5.90 (d, 1, J=3.5 Hz, H-1′).

b) Compound **9** (930 mg) was heated with sodium azide (319 mg) and ammonium chloride (270 mg) in 2-methoxyethanol (7 ml) for 20 h under reflux. The mixture was evaporated and the residue was acetylated. The product was dissolved in chloroform and the solution was passed through a short column of activated alumina. The effluent was evaporated to give 923 mg of a syrup. The syrup was dissolved in 0.5M ethanolic sodium ethoxide (10 ml). After overnight, the solution was neutralized with Amberlite IR-120 (H^+) ion-exchange resin and evaporated. The residue was hydrogenated in the presence of Raney nickel in an atmosphere of hydrogen (3.4 kg/cm^2) for 3 h to give 513 mg of a product. The product was dissolved in 1:1 (v/v) aqueous methanol containing sodium carbonate (1.2 g), and ethyl chloroformate (1 ml) was added to the solution under ice cooling. After 48 h, the solution was neutralized with 6M hydrochloric acid and evaporated. The residue was acetylated and subsequently purified by a column chromatography using 30:1 (v/v) chloroform–ethanol as eluant. Fractions showing a single spot at R_f 0.17 on TLC in 20:1 (v/v) chloroform–ethanol were combined and evaporated to give 187 mg of 6,3′,4′-tri-*O*-acetyl-5-amino-5-deoxy-1,3,5,2′,6′-penta-*N*-(ethoxycarbonyl)-5,6-diepineamine (**12**), mp 158—160 °C (dec); $[\alpha]_D^{19}$ +72.5° (*c* 1.0, chloroform). ^{1}H NMR: δ 1.1—1.4 (m, 15, 5×CO_2-$CH_2C\underline{H}_3$), 1.99 (s, 3, OAc), 2.02 (s, 3, OAc), 2.14 (s, 3,OAc).

Found: C, 48.30; H, 6.43; N, 8.29%. Calcd for $C_{33}H_{53}N_5O_9$: C, 48.11; H, 6.48; N, 8.50%.

Compound **12** (179 mg) was hydrolyzed in aqueous barium hydroxide as described in the preparation of **3** to give 27 mg (39%) of **11**.

1,3,5,2′,6′-Penta-N-*acetyl-5-amino-5-deoxy-5,6-diepineamine(**13**)*. Compound **11** (36 mg) was acetylated with acetic anhydride (0.1 ml) in methanol (1 ml) to give 52 mg (83%) of **13**, mp 216 °C (dec); $[\alpha]_D^{16}$ +104.9° (*c* 1.5, water). ^{1}H NMR (D_2O): δ 1.97 (s, 3, NAc), 1.98 (s, 3, NAc), 2.00 (s, 3, NAc), 2.02 (s, 6, 2×NAc), 4.85 (d, 1, J=3.3 Hz, H-1′).

Found: C, 47.50; H, 7.46; N, 12.50%. Calcd for $C_{22}H_{37}N_5O_{10}\cdot 3/2H_2O$: C, 47.30; H, 7.22; N, 12.5%.

Synthesis of Carbamic Ester by a Reaction of Carbon Dioxide, Tetrakis(dimethylamido)titanium(IV) and Epoxide

Yasuhiko YOSHIDA and Shohei INOUE

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Hongo, Tokyo 113

(Received July 11, 1977)

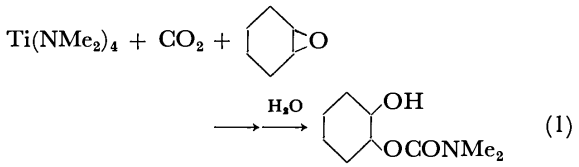
2-Hydroxycyclohexyl dimethylcarbamate was synthesized quantitatively by a reaction of carbon dioxide, tetrakis(dimethylamido)titanium(IV) and 1,2-epoxycyclohexane.

Carbon dioxide was inserted into the metal-nitrogen bond or the metal-oxygen bond to give metal carbamate or carbonate,[1] and the products were easily decomposed by water to regenerate carbon dioxide.

Since studies by Inoue *et al.*[2] suggested the possibility of the reaction of metal carbamate with epoxide to form carbamic ester resulting in the irreversible fixation of carbon dioxide, the reaction of tetrakis(dimethylamido)titanium(IV) ($Ti(NMe_2)_4$), carbon dioxide (CO_2) and 1,2-epoxycyclohexane was examined.

Results and Discussion

A reaction of $Ti(NMe_2)_4$, CO_2 and 1,2-epoxycyclohexane, followed by hydrolysis of the reaction mixture, was found to give 2-hydroxycyclohexyl dimethylcarbamate (**1**) in a high yield, thus

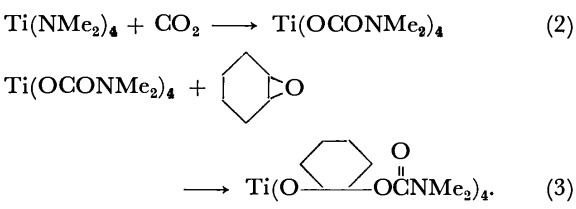


(1)

The carbamic ester (**1**) was confirmed to be in *trans*-form by comparison with an authentic sample prepared by a reaction of *trans*-1,2-cyclohexanediol with dimethylcarbamoyl chloride in the presence of pyridine. The main product of this reaction was carbamic ester (**1**), accompanied by small amounts of CO_2-epoxide copolymer (**2**), cyclic carbonate and a homopolymer of 1,2-epoxycyclohexane, depending upon the reaction conditions.

As shown in Table 1, the reactions were carried out under CO_2 pressure (50 kg/cm^2), since the reaction did not occur at atmospheric pressure at room temperature. The reaction at 80 °C in a large excess of epoxide gave carbamic ester (**1**) in a quantitative yield (Run 7). Reactions carried out in benzene and THF (Runs 4 and 5) gave similar results. However, for the reaction carried out in dichloromethane, the yield of carbamic ester (**1**) was low and the by-products, such as CO_2-epoxide copolymer (**2**), cyclic carbonate and polyether were formed, although in small amounts. At 35 °C (Runs 1 and 2), carbamic ester (**1**) was obtained in a lower yield, but with no by-products. For the reaction of 1,2-epoxypropane, instead of 1,2-epoxycyclohexane, in THF at 80 °C over a period of 160 h, the carbamic ester yield was 58% and the amount of cyclic carbonate formed was 1/3 by weight of carbamic ester.

Since $Ti(NMe_2)_4$ has been reported to react rapidly with CO_2 to form $Ti(OCONMe_2)_4$,[3,4] the formation of carbamic ester is considered to proceed as follows:



This reaction is the first example of a metal carbamate and epoxide reaction resulting in the fixation of carbon dioxide.

$Ti(NMe_2)_4$ is considered to react preferentially with CO_2 even in the presence of epoxide, since $Ti(NMe_2)_4$ does not react with epoxyethane and 1,2-epoxypropane, as reported previously.[4] It was found that 1,2-epoxycyclohexane did not react with $Ti(NMe_2)_4$ at room temperature, but at 80 °C gave the polymer (poly-

Table 1. Reaction of tetrakis(dimethylamido)titanium, carbon dioxide and 1,2-epoxycyclohexane[a]

Run	$Ti(NMe_2)_4$ (g)	Epoxide (g)	Solvent	Temp (°C)	Time (h)	Product (**1**)[b] (g)	(**1**)[b] (%)[c]	Product (**2**)[d] (g)

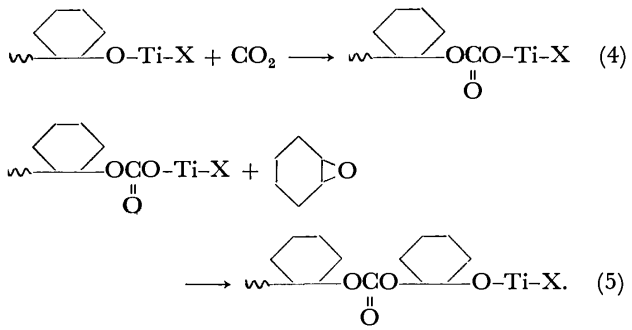
ether) in a 10% yield after 12 days. In the presence of CO_2, the homopolymerization of 1,2-epoxycyclohexane by $Ti(NMe_2)_4$ was not observed, except for the reaction in dichloromethane (Run 3).

It can be considered that the carbamic ester (**1**) is formed by the reaction of $Ti(NMe_2)_4$ with cyclic carbonate, the latter having been produced from CO_2 and epoxide. This mechanism, however, is believed to be negligible, since, in the reaction of 1,2-epoxycyclohexane under the present conditions, cyclic carbonate was hardly formed. Furthermore, the existence of unchanged $Ti(NMe_2)_4$ is most unlikely because of its extremely high reactivity with CO_2, which gives rise to $Ti(OCONMe_2)_4$.

An alternative mechanism for the formation of **1** would be the reaction of epoxide with carbamic acid, the latter being formed from carbon dioxide and amine which may be present in trace amounts. **1** would then react with titanium carbamate to regenerate carbamic acid. However, such a reaction requires the liberation of a stronger acid (carbamic acid) upon the reaction of the salt with a weaker acid (alcoholic group of **1**).

Concerning the formation of CO_2-epoxide copolymer as a by-product, the following mechanism can be considered, referring to the mechanism proposed for the formation of the CO_2-epoxide copolymer by an organozinc catalyst.[5,6]



In accord with this mechanism, the reaction of 1,2-epoxycyclohexane and CO_2, with titanium isopropoxide as a catalyst, in THF at 80 °C for 210 h gave the copolymer (**2**), although in a low yield.

Experimental

Materials. Tetrakis(dimethylamido)titanium(IV) was synthesized from lithium dimethylamide and titanium tetrachloride in diethyl ether.[7] After lithium chloride was filtered off and the solvent removed, distillation of the residual liquid afforded a yellow liquid product ($Ti(NMe_2)_4$), bp 75 °C/3 mmHg (lit,[7] bp 44 °C/0.006 mmHg).

Commercially available epoxides, such as 1,2-epoxycyclohexane and 1,2-epoxypropane, and solvents, such as THF, benzene, and dichloromethane, were purified employing usual procedures and stored in a nitrogen atmosphere.

Commerical high-purity carbon dioxide gas was introduced into an autoclave directly from a gas cylinder without further purification.

Procedure. All reactions were carried out in a manner similar to that for Run 4, as follows.

A mixture of $Ti(NMe_2)_4$ (1 g, 4.5 mmol) and 1,2-epoxycyclohexane (10 ml, 99 mmol) in benzene (40 ml) was placed in a 200 ml autoclave and constantly stirred at 80 °C under CO_2 pressure (50 kg/cm^2). After 210 h of reaction, a few drops of water were added to the reaction mixture, the latter was filtered to remove insoluble materials, and the filtrate was concentrated under reduced pressure at room temperature. To the filtrate concentrate was added about 100 ml of petroleum ether with stirring. The mixture was seeded by a small amount of pure crystalline **1** and cooled in a refrigerator overnight, during which time white needles separated out. The crystals were filtered off and dried at room temperature *in vacuo*.

White needle-like crystals, *trans*-2-hydroxycyclohexyl dimethylcarbamate (**1**), mp 52—53 °C, (Found: C, 57.75; H, 9.31; N, 7.52; mol wt, 196 (V. P. O.), Calcd for $C_9H_{17}NO_3$: C, 57.71; H, 9.15; N, 7.48; mol wt, 187), was obtained in a 50% yield (1.7 g). NMR (chloroform-*d*): δ=1.2—2.2 (8H, m, cyclohexane-ring methylenes), 2.92 (6H, s, $N(CH_3)_2$), 3.41 (1H, s, OH), 3.56 (1H, m, hydroxyl-group methine), 4.48 (1H, m, carbamoyloxy-group methine). IR (KBr tablet method): 3500 cm^{-1} (O–H) and 1700 cm^{-1} (C=O).

After separation of the carbamic ester (**1**), the filtrate was concentrated and added to a large amount of methanol to give CO_2-epoxide copolymer, which was identified by IR spectrum,[5] as a methanol insoluble fraction (27 mg).

We are grateful to Professor Teiji Tsuruta for valuable discussions.

Syntheses of Polymerizable Aromatic Mannich Bases by Means of Amine Exchange Reaction

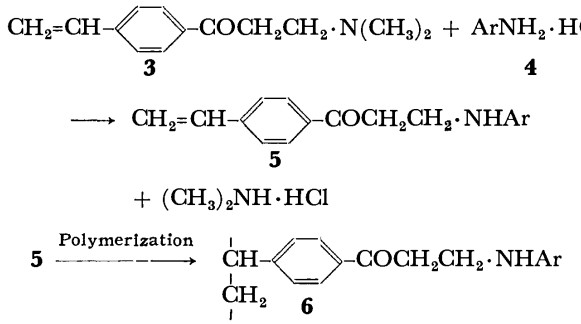
Hiroyoshi KAMOGAWA, Kuniaki KUBOTA, and Masato NANASAWA
Department of Applied Chemistry, Yamanashi University, Takeda, Kofu 400
(Received July 21, 1977)

Amine exchange reactions between *p*-vinyl-*β*-dimethylaminopropiophenone and arylamine hydrochloride provided six novel aromatic Mannich bases bearing a vinyl group which were otherwise hardly accessible. Thus, by refluxing in ethanol–water (1: 1), *p*-vinyl-*β*-(*p*-anisidino)-, *p*-vinyl-*β*-(*p*-toluidino)-, *p*-vinyl-*β*-(*p*-hydroxyanilino)-, *p*-vinyl-*β*-anilino-, *p*-vinyl-*β*-(*p*-carboxyanilino)-, and *p*-vinyl-*β*-(*p*-nitroanilino)-propiophenones were obtained in 62.0, 55.2, 24.5, 32.0, 47.3, and 29.1% yields, respectively. The Mannich bases thus synthesized underwent ready radical polymerizations to afford the corresponding vinyl polymers, bearing aromatic Mannich base units as pendants.

Amine exchange reactions between aliphatic Mannich bases and arylamines[1] are useful for the syntheses of aromatic Mannich bases, since direct syntheses do not usually provide satisfactory results.[2] In the course of our studies of the amine exchange reactions between various Mannich bases and arylamines, we have found that *p*-vinyl-*β*-dimethylaminopropiophenone, a Mannich base with a vinyl group, which possesses the potentiality of a Michael acceptor, brings about amine exchange reactions with arylamines smoothly, keeping the vinyl group intact, thereby affording a novel group of aromatic Mannich bases bearing a vinyl group, which is otherwise hardly accessible.

p-Vinyl-*β*-dimethylaminopropiophenone (**3**) was prepared by the dehydrobromination of *p*-(2-bromoethyl)-*β*-dimethylaminopropiophenone hydrochloride (**2**), which had itself been synthesized by Mannich-base formation from *p*-(2-bromoethyl)acetophenone (**1**).[3,4]

The amine exchange reactions take place as follows:



4a, **5a**, **6a**: Ar=*p*-$CH_3OC_6H_4$
4b, **5b**, **6b**: Ar=*p*-$CH_3C_6H_4$
4c, **5c**, **6c**: Ar=*p*-HOC_6H_4
4d, **5d**, **6d**: Ar=C_6H_5
4e, **5e**, **6e**: Ar=*p*-$HOOCC_6H_4$
4f, **5f**, **6f**: Ar=*p*-O_2N-C_6H_4

The novel aromatic Mannich bases synthesized (**5**) underwent radical polymerizations under conventional conditions to afford the corresponding polymers (**6**).

Table 1 summarizes the results obtained in the amine exchange reactions. It can be seen from this table that electron-donating para substituents, such as methoxyl and methyl groups in the starting arylamine hydrochlorides (**4**), provide higher yields than the electron-withdrawing ones, such as the nitro group, in spite of the prolonged reaction times assigned to the latter.

Table 1. Effect of the *p*-substituents on the yields of the aromatic Mannich bases produced in the amine exchange reactions

Product	*p*-Substituent	Reaction time h	Yield %
5a	CH_3O	2	62.0
5b	CH_3	2	55.2
5c	OH	2	24.5 (50.8)[a]
5d	H	2	32.0
5e	COOH	10	47.3
5f	NO_2	25	29.1

a) Under nitrogen.

The fact that the yield for the electron-donating hydroxyl group (**5c**) was low indicates that the starting arylamine (*p*-aminophenol) was very susceptible to air oxidation, thereby affording considerable amounts of oxidation products.

Craig and Moyle[1] proposed three mechanisms for the amine exchange reactions of *β*-diethylaminopropiophenones: S_N1, S_N2, and the Michael addition to the vinyl ketone produced. The step common to all three mechanisms is the nucleophilic attack of the arylamines produced from **4** by the hydrogen chloride exchange with **3**. Accordingly, it appears reasonable that more nucleophilic arylamines bearing more electron-donating para substituents promote the reaction.

Table 2 indicates the polymerization behavior of the **5** monomers. As expected, the **5a** and **5b** monomers, with electron-donating para substituents, provide lower values of $[\eta]$ than do **5e** and **5f**, with electron-withdrawing ones, presumably because of the enhanced radical

Table 2. Polymerization behavior of the **5a**—**f** monomers

Monomer	Conversion %	Appearance of polymer	$[\eta]$dl[a]/g
5a	77	Light yellow powder	0.25
5b	80	Light yellow powder	0.30
5c	84	Light brown powder[b]	0.33
5d	83	Light yellow powder	0.33
5e	93	Light brown powder	0.65
5f	84	Yellow powder	0.41

a) Intrinsic viscosity at 25°C in a *N*,*N*-dimethylformamide solution. b) Insolubilized by air oxidation.

trapping actions of the ArNH– portions in the former.

The synthetic procedure described here leads readily to vinyl polymers with pendant aromatic Mannich base units which are novel and which may be used for various purposes, including the preparation of functional polymers.

Experimental

The IR, ^{1}H-NMR, and mass spectra were obtained with Hitachi EPI-G spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively, under standard measurement conditions. The elemental analyses were carried out using a Perkin-Elmer 240 instrument.

p-*Vinyl-β-dimethylaminopropiophenone (**3**).* A 5.5-g (17 mmol) portion of **2** in 60 ml of methanol containing 2.4 g (43 mmol) of potassium hydroxide was stirred at room temperature for 24 h in the presence of a small amount of hydroquinone. To the resulting dark solution we then added 2.4 g (43 mmol) of potassium hydroxide, after which stirring was continued for 3 more h. The reaction mixture was then poured into iced water and extracted with ether. The organic layer was washed with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo* at 40 °C to leave a crude product, which was recrystallized from petroleum ether to afford colorless needles of mp 52—55 °C (lit,[3] 54.5—58.5 °C) in a 46.4% yield. The IR, NMR, and mass spectra as well as the CHN analyses identified it as **3**.

General Procedure for Amine Exchange Reactions. A mixture of 8 mmol of **3**, 9 mmol of an arylamine hydrochloride (**4**), a small amount of hydroquinone, and 7 ml of water–ethanol (1 : 1) was refluxed for 2—25 h in an oil bath. The reaction mixture, sometimes with the crystalline precipitates thus produced, was cooled in a refrigerator overnight with or without the addition of water to provide the crude product, which was then purified by repeated recrystallizations.

p-*Vinyl-β-(*p-*anisidino)propiophenone (**5a**).* Recrystallizations of the crude product from ethanol provided lustrous, pale yellow needles with a mp of 140—141 °C. Found: C, 76.72; H, 6.84; N, 5.01%. Calcd for $C_{18}H_{19}NO_2$: C, 76.84; H, 6.81; N, 4.98%. IR(KBr): 1660 (C=O), 990, 930 (vinyl) cm^{-1}. NMR ($CDCl_3$): δ 3.2 (d, 2H, CH_2), 3.5 (d, 2H, CH_2), 3.8 (s, 3H, OCH_3), 5.4 (d, 1H, vinyl), 5.8 (d, 1H, vinyl), 6.5—8.0 (m, 9H, vinyl+ArH) ppm. Mass (*m/e*): 281 (M$^+$, 100).

p-*Vinyl-β-(*p-*toluidino)propiophenone (**5c**).* Lustrous, pale yellow plates (mp 142—143 °C) were isolated from ethanol. Found: C, 81.33; H, 7.33; N, 5.27%. Calcd for $C_{18}H_{19}NO$: C, 81.47; H, 7.22: N, 5.28%. IR(KBr): 1670 (C=O), 990, 910 (vinyl) cm^{-1}. NMR ($CDCl_3$): δ 2.3 (s, 3H, CH_3), 3.2 (t, 2H, CH_2), 3.6 (t, 2H, CH_2), 5.35 (d, 1H, vinyl), 5.7 (d, 1H, vinyl), 6.5—8.0 (m, 9H, vinyl+ArH) ppm. Mass (*m/e*): 265 (M$^+$, 80), 120 (100).

p-*Vinyl-β-(*p-*hydroxyanilino)propiophenone (**5c**).* A yellow, crystalline powder (mp 136—137 °C) was obtained by recrystallization from ethanol. Found: C, 76.72; H, 6.58; N, 4.73%. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24%. IR(KBr): 3370 (OH), 1660 (C=O), 990, 920 (vinyl) cm^{-1}. NMR (DMSO-d_6+CCl_4): δ 3.1—3.9 (m, 4H, $2CH_2$), 5.4 (d, 1H, vinyl), 5.8 (d, 1H, vinyl), 6.3—8.2 (m, 10H, vinyl+OH+ArH) ppm. Mass (*m/e*): 267 (M$^+$, 63), 131 (100).

p-*Vinyl-β-anilinopropiophenone (**5d**).* Recrystallizations from ethanol afforded a lustrous, yellow, crystalline powder (mp 111—113 °C). Found: C, 81.24; H, 6.76; N, 5.62%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%. IR(KBr): 1660 (C=O), 990, 910 (vinyl) cm^{-1}. NMR ($CDCl_3$): δ 3.4—3.9 (m, 4H, $2CH_2$), 5.6 (d, 1H, vinyl), 6.0 (d, 1H, vinyl), 6.8—8.1 (m, 10H, vinyl+ArH) ppm. Mass (*m/e*): 251 (M$^+$, 9), 18 (100).

p-*Vinyl-β-(*p-*carboxyanilino)propiophenone (**5e**).* Recrystallizations from *N,N*-dimethylformamide–water afforded a colorless, crystalline powder with a mp of 205—206 °C. Found: C, 73.19; H, 5.95; N, 4.62%. Calcd for $C_{18}H_{17}NO_3$: C, 73.20; H, 5.80; N, 4.72%. IR(KBr): 1660 (C=O), 985, 915 (vinyl) cm^{-1}. NMR (DMSO-d_6+CCl_4): δ 3.0—3.8 (m, 4H, $2CH_2$), 5.4 (d, 1H, vinyl), 5.9 (d, 1H, vinyl), 6.5—8.0 (m, 9H, vinyl+ArH) ppm. Mass (*m/e*): 295 (M$^+$, 20), 131 (100).

p-*Vinyl-β-(*p-*nitroanilino)propiophenone (**5f**).* A yellow crystalline powder (mp 136—137 °C) was isolated from ethanol–water. Found: C, 68.99; H, 5.42; N, 9.32%. Calcd for $C_{18}H_{16}NO_3$: C, 68.91; H, 5.44; N, 9.45%. IR(KBr): 1660 (C=O), 1300 (NO_2), 990, 935 (vinyl) cm^{-1}. NMR (DMSO-d_6+$CDCl_3$): δ 3.4 (d, 2H, CH_2), 3.6 (d, 2H, CH_2), 5.5 (d, 1H, vinyl), 5.9 (d, 1H, vinyl), 6.9—8.2 (m, 9H, vinyl+ArH) ppm. Mass (*m/e*): 296 (M$^+$, 100).

*Polymerization of the **5a**—**f** Monomers.* A solution of 0.3 g of a monomer, 0.003 g of α,α′-azobisisobutyronitrile, and 2 ml of *N,N*-dimethylformamide in a deaerated Pyrex glass ampoule was kept at 70 °C for 48 h. The resulting viscous solution was poured into ethanol to precipitate the polymer. The IR spectra of all the polymers thus synthesized indicated no vinyl absorptions in the 900—930 cm^{-1} region, only strong CH_2 absorptions attributable to the polymer backbone at 1930 and 1860 cm^{-1}, together with characteristic absorptions of the aromatic Mannich bases.

Reaction of Nitrile Oxides with *N*-Aryl-*S,S*-dimethylsulfimides

Shinsaku SHIRAISHI, Tadashi SHIGEMOTO, and Shojiro OGAWA

Institute of Industrial Science, The University of Tokyo, Roppongi Minato-ku, Tokyo 106

(Received July 21, 1977)

Both benzimidazole 3-oxides and 1,2,4-benzoxadiazines were formed in reactions of sterically-stabilized benzonitrile oxides with *N*-aryl-*S,S*-dimethylsulfimides, whereas only 1,2,4-benzoxadiazines were produced in reactions of 2,6-unsubstituted benzonitrile oxides. The reactions are thought to proceed *via* the intermediacy of a nitroso compound formed by the nucleophilic attack of sulfimide on the carbon atom of the nitrile oxide and the subsequent release of dimethyl sulfide. The nitrogen or the oxygen atom of the nitroso group of this intermediate can attack the ortho position of the benzene ring originating from sulfimide to form benzimidazole 3-oxide or 1,2,4-benzoxadiazine, respectively, Conjugation of the nitroso group with the *C*-aryl group can be attained in *s-cis* form for the intermediate derived from 2,6-unsubstituted benzonitrile oxide, and thus, exclusive O-attack takes place to afford 1,2,4-benzoxadiazines. On the other hand, conjugation of the nitroso group with the *C*-aryl group cannot be considered for the intermediate derived from 2,6-disubstituted benzonitrile oxide because of the steric hindrance of the substituents. In this case, the intermediate nitroso compound is either in *s-cis* or in *s-trans* form. This causes the formation of both benzimidazole 3-oxide and 1,2,4-benzoxadiazine. Characterization data of benzimidazole 3-oxides are also described.

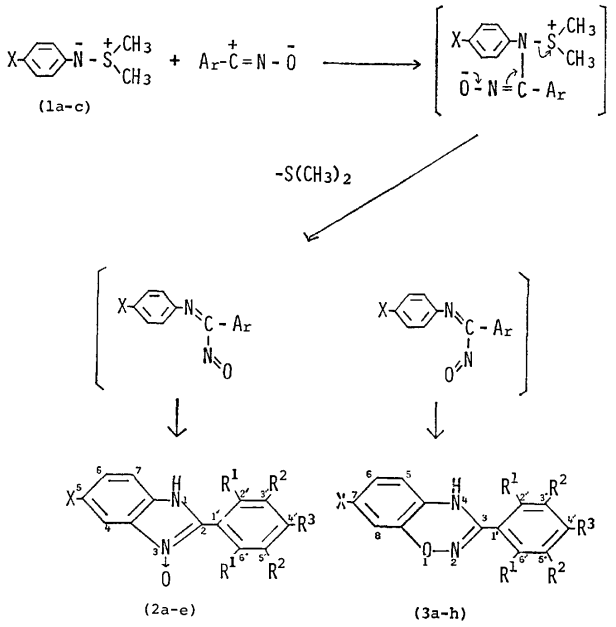
In the field of heterocyclic chemistry, the 1,3-dipolar cycloaddition reaction represents a very useful synthetic method. Nitrile oxides, which are typical 1,3-dipoles, are known to react with various unsaturated bonds to form heterocycles. Furthermore, many studies have been reported on the reactions of nitrile oxides with ylide compounds.[1] However, very few examples of reactions with N–S unsaturated bonds have been reported.[2–4] This is due to the difficulty of synthesizing compounds having such functional groups, except for *N*-(*p*-tosyl)-sulfimides.[5] *N*-(*p*-Tosyl)sulfimides are very stable and easily synthesized, but do not react with nitrile oxides and nitrones.

Recently, Sharma and his collaborators improved the synthetic method of *N*-arylsulfimides,[6] and Claus *et al.* also synthesized these compounds by a different route.[7] Most are unstable, but *S,S*-dimethyl-*N*-(*p*-nitrophenyl)-sulfimide is stable enough to remain unchanged in a refluxing benzene solution for 10 h. The reactions of nitrile oxides with *N*-arylsulfimides are being investigated in this laboratory in order to elucidate the ionic character of 1,3-dipolar cycloaddition reactions. In the course of the investigation, it was found that both benzimidazole 3-oxides and 1,2,4-benzoxadiazines were formed in the reactions of 2,6-disubstituted benzonitrile oxides with *N*-arylsulfimides, though 1,2,4-benzoxadiazines were the sole products in the reactions of 2,6-unsubstituted benzonitrile oxides.

Gilchrist *et al.* have reported on reactions of nitrile oxides with *N*-aryl-*S,S*-dimethylsulfimides from the viewpoint of 1,2,4-benzoxadiazine synthesis.[8] They used only 2,6-unsubstituted benzonitrile oxides and other aliphatic nitrile oxides, and therefore, paid no attention to the formation of benzimidazole 3-oxides.

Results and Discussion

Sterically-stabilized 2,3,5,6-tetramethylbenzonitrile oxide (DNO), 2,4,6-trimethylbenzonitrile oxide (MNO), and 2,6-dichlorobenzonitrile oxide (DCNO) were allowed to react with some *N*-aryl-*S,S*-dimethylsulfimides (**1**). In almost all cases, two types of products were obtained as main products, benzimidazole 3-oxides (**2**) and 1,2,4-benzoxadiazines (**3**), although the yields were poor. In addition, some minor products formed by the decomposition or isomerization of the starting materials were found. The reaction conditions and yields are shown in Table 1. The reactions of 2,6-unsubstituted benzonitrile oxides with *S,S*-dimethyl-*N*-(*p*-nitrophenyl)sulfimide (**1a**) were also carefully studied, but the formation of benzimidazole 3-oxide was not observed. These results are also shown in Table 1.



Scheme 1. Reaction route to the benzimidazole 3-oxide and benzoxadiazine.

The formation of benzimidazole 3-oxides in reactions of benzonitrile oxides with *N*-aryl-*S,S*-dimethylsulfimides has not been reported as yet. Characterization data of the benzimidazole 3-oxides are summarized in Table 2. Benzimidazole 3-oxides were formed as fleecy crystals during the reactions. High melting points and poor solubilities in the usual solvents are common to products of this type. Their IR spectra show characteristic broad absorptions in the range from 2100 to 2800 cm^{-1}

Table 1. Reaction conditions and yields of reactions of nitrile oxides with *N*-aryl-*S*,*S*-dimethylsulfimides

Nitrile oxide (Ar)	Sulfimide	Reaction conditions			Yields

(Fig. 1). Chua *et al.* have attributed the broad absorption in this range to intermolecular hydrogen bonding.[9] Mass spectra also support the structure. All products of this type show similar fragmentation patterns. It should be emphasized that the (M^+-16) fragment ion peak is very characteristic, because the oxygen atom of usual *N*-oxide compounds is thought to be easily stripped off during the ionization process.[10] And the intensity of the (M^++1) ion peak is much stronger than the value calculated from the natural isotope abundance, because of intermolecular hydrogen bonding. The NMR spectra are understandable on the basis of this structure. The signal due to the proton at the 6-position appears in doublet-doublet form, because of interactions with the protons at the 4- and 7-positions. The coupling constant between the protons at 4- and 6-positions is consistent with those of the protons at the meta-positions. The signal due to the proton at the 4-position appears at a field lower than that of the corresponding signal for the 1,2,4-benzoxadiazines. This suggests that the proton is in the neighborhood of and affected by the magnetic anisotropy of the *N*-oxide moiety.

Characterization data of the benzoxadiazines are listed in Table 3. In the mass spectra of the oxadiazines obtained here, the (M^+-15) fragment is very characteristic and this is attributed to NH splitting. This agrees well with the results reported by Gilchrist *et al.*[8] A methanolic solution of 7-nitro-1,2,4-benzoxadiazines produced a color change from yellow to violet, upon addition to an alkaline solution. This color change was

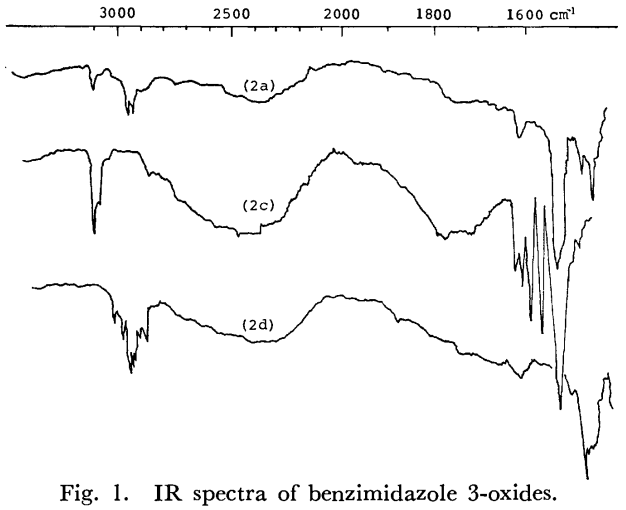

Fig. 1. IR spectra of benzimidazole 3-oxides.

reversible and the violet color returned to its original color upon neutralization.

As seen in Table 1, the reactions of 2,6-disubstituted benzonitrile oxides with *N*-aryl-*S*,*S*-dimethylsulfimides gave both benzimidazole 3-oxides and 1,2,4-benzoxadiazines, whereas 2,6-unsubstituted benzonitrile oxides gave no benzimidazole 3-oxides. The reaction leading to the formation of a benzimidazole 3-oxide or a 1,2,4-benzoxadiazine is considered to proceed by the nucleophilic attack of the nitrogen atom of the sulfimide on the carbon atom of the nitrile oxide followed by the liberation of dimethyl sulfide to form an intermediate nitroso compound. When the nitrogen atom of the nitroso group attacks the ortho-position of the benzene ring, benzimidazole 3-oxide is produced. On the contrary, when the oxygen atom of the nitroso group attacks, 1,2,4-benzoxadiazine is formed (Scheme 1). For the intermediate nitroso compounds, there are two conformational structures, which are *s-cis* and *s-trans* with respect to the –N=C–N=O structure, as shown in Scheme 1. In the *s-trans* form, the lone pair of nitrogen atom faces the *N*-phenyl substituent and, from this structure benzimidazole 3-oxide is produced. In the *s-cis* form, the lone pair faces the opposite side, and nitrogen attack on the *N*-phenyl substituent is inconceivable. Regarding the nitroso intermediate, it is considered to be somewhat more stable when the –N=C–N=O group is in the plane of the aryl group attached to the carbon atom, than when this is not the case. In the case of the reaction of a 2,6-unsubstituted benzonitrile oxide with a sulfimide, the nitroso intermediate can take the more stable *s-cis* form and, therefore, gave only a 1,2,4-benzoxadiazine. However, in the case of the reaction of a 2,6-substituted benzonitrile oxide, coplanarity between the –N=C–N=O and the aryl group attached to the carbon atom is not attained at all due to steric hindrance and thus the intermediate can take either the *s-cis* or the *s-trans* form leading to both 1,2,4-benzoxadiazine and benzimidazole 3-oxide.

When THF was used as the reaction solvent, no benzimidazole 3-oxide formation was observed and the decomposition of the sulfimide to the corresponding

s-cis form *s-trans* form

Fig. 2. Conformational structures of the intermediate nitroso compounds.

aniline was marked. The reason is not clear, but this may be attributed to the solvation of the zwitterionic intermediate which permits annellation only by the attack of anionic oxygen.

Gilchrist and co-workers have reported the formation of 1,2,4-triazolo[1,5-*a*]pyridin 3-oxides in the reactions of nitrile oxides with *S,S*-dimethyl-*N*-(2-pyridyl)sulfimide.[11] In these reactions, the intermediates are also thought to be nitroso compounds, however, the reaction proceeds by attack of the nitrogen atom of the pyridine ring on the nitroso group. If the lone pair of nitrogen atom of the nitroso group attacks, annellation on the carbon atom at another ortho-position of the pyridine must also occur. However, no such product has been reported.

Furthermore, other two reaction products, isocyanate and 2-amino-5-nitrobenzyl methyl sulfide which are isomerization products of each starting material, were isolated in a reaction of a sterically-stabilized nitrile oxide with *S,S*-dimethyl-*N*-(*p*-nitrophenyl)sulfimide. It is well known that sterically-stabilized benzonitrile oxides isomerize to the appropriate isocyanates either thermally or photochemically.[2] However, when the sulfimide alone was subject to the identical and more severe conditions, it remained unchanged. The decomposition of sulfimide to the *p*-nitroaniline is induced also in alcohols. The mechanism is now under investigation.

Experimental

Melting points were measured using a micro-melting-point measuring apparatus (Yazawa Co., Ltd.) and are uncorrected. IR spectra were recorded with a Hitachi infrared spectrometer 215. Mass spectra were recorded with a Hitachi RMU-7M high-resolution mass spectrometer. NMR spectra were recorded with a Hitachi Perkin-Elmer 20R-A high-resolution NMR spectrometer (60 MHz).

Materials. Stable nitrile oxides were synthesized using the method of Grundmann *et al.*[12] 2,6-Unsubstituted benzonitrile oxides were generated *in situ* from the appropriate benzhydroxamoyl chlorides, which were synthesized by the usual methods.[13] *N*-Aryl-*S,S*-dimethylsulfimides were synthesized with DMSO, substituted anilines, and sulfur trioxide.[6]

Reaction of 2,3,5,6-Tetramethylbenzonitrile Oxide (DNO) with S,S-*Dimethyl*-N-*(*p*-nitrophenyl)sulfimide (***1a***).* *a) In Chloroform under Reflux*: A solution of 351 mg (2.00 mmol) of DNO and 377 mg (1.90 mmol) of **1a** in 30 ml of chloroform was heated to reflux with the precipitation of fleecy crystals. After 10 h, the solid product was separated by filtration while the reaction mixture was hot, and was then washed with hot chloroform. The solid product weighed 67 mg (11.3%) and was identified to be 2-duryl-5-nitro-1*H*-benzimidazole 3-oxide (**2a**). The combined filtrate and washing were evaporated giving an oily residue, which was worked up using column chromatography on silica gel (Wacogel C-200) eluted with chloroform. From the elutes, the following were isolated; 199 mg of DNO (56.7% recovery), 19 mg of 2-amino-5-nitrobenzyl methyl sulfide (5.1%), 171 mg of 3-duryl-7-nitro-4*H*-1,2,4-benzoxadiazine (**3a**) (28.9%), and 19 mg of *p*-nitroaniline (7.2%).

b) In Benzene under Reflux: In 50 ml of dry benzene, 877 mg (5.01 mmol) of DNO and 992 mg (5.00 mmol) of **1a** were dissolved and the solution was heated to reflux. Fleecy crystals were deposited during the reaction. After 4 h, the crystals were separated by filtration while hot and washed with hot benzene. They were identified to be **2a**, which weighed 186 mg (11.9%). The combined solution was allowed to stand overnight at room temperature to precipitate the starting ylide, which was removed by filtration (328 mg, 33.1% recovery). The filtrate was evaporated under reduced pressure to give a viscous oil, the trituration of which with a small amount of ether gave a solid. This solid was identified to be **3a** and weighed 286 mg. From the residual ethereal solution, further 48 mg of **3a** was obtained upon trituration with benzene. The residual solution was evaporated and treated on silica-gel column chromatograph with chloroform, and the following substances were isolated: 2,3,5,6-tetramethylphenyl isocyanate (128 mg, 15.7%), DNO (289 mg, 32.9% recovery), 2-amino-5-nitrobenzyl methyl sulfide (109 mg, 11.0%), and **3a** (50 mg). The total amount of **3a** was 384 mg (24.7%).

c) In THF under Refulx: DNO and **1a** (5.00 mmol each) were dissolved in 50 ml of THF and the solution was heated to reflux for 4 h. No crystal formation was observed even upon prolonged heating. The solution was evaporated under reduced pressure. Trituration of the residual oil with cold chloroform gave 144 mg of the starting ylide (14.6% recovery). The chloroform solution was worked up using column chromatography on silica gel (Wacogel C-200) with chloroform. The following substances were isolated: DNO (729 mg, 93.0% recovery), 2-amino-5-nitrobenzyl methyl sulfide (38 mg, 3.8%), **2a** (106 mg, 6.8%), and *p*-nitroaniline (502 mg, 72.6%).

Reaction of p-*Chlorobenzonitrile Oxide with* ***1a***. *In Chloroform*: In a cold solution (below 0 °C) of 496 mg (2.50 mmol) of **1a** in 30 ml of chloroform, 0.40 ml of triethylamine was added with stirring, and then a solution of *p*-chlorobenzhydroxamoyl chloride (475 mg, 2.50 mmol) in 20 ml of chloroform was added dropwise for thirty minutes. After the addition, the cooling bath was removed and the reaction mixture was allowed to stand overnight at ambient temperature. The solvent was removed by evaporation under reduced pressure. The residue was washed with THF to give white crystals of triethylammonium chloride (316 mg, 91.7%). From the THF-soluble part, 274 mg (37.8%) of 3-(*p*-chlorophenyl)-7-nitro-4*H*-1,2,4-benzoxadiazine (**3g**) was obtained upon trituration with chloroform. The residual oil was worked up using column-chromatography on alumina with chloroform to give 260 mg (52.5% recovery) of the starting

ylide (**1a**). No 2-(*p*-chlorophenyl)-5-nitrobenzimidazole 3-oxide was obtained.

Reaction of p-*Nitrobenzonitrile Oxide with* ***1a***. *In Chloroform*: In a cold solution (below 0 °C) of 496 mg (2.50 mmol) of **1a** in 20 ml of chloroform, 0.38 ml of triethylamine was added with stirring, and then a solution of *p*-nitrobenzhydroxamoyl chloride (502 mg, 2.50 mmol) in 30 ml of chloroform was added dropwise for 30 m. During the reaction, a brownish-red precipitate appeared. After the addition, the cooling bath was removed and the reaction mixture was allowed to stand overnight at ambient temperature. The brownish-red precipitate was filtered off and dried, and was identified to be 3-(*p*-nitrophenyl)-7-nitro-4*H*-1,2,4-benzoxadiazine (**3h**). It weighed 396 mg. The filtrate was evaporated under educed pressure to give an oily product. Washing the oily product with THF produced white crystals of triethylammonium chloride (331 mg, 96.2%). The residual THF solution was evaporated and triturated with a small amount of chloroform to give 27 mg of the 3-(*p*-nitrophenyl)-7-nitro-4*H*-1,2,4-benzoxadiazine (**3h**). The total amount of **3h** was 358 mg (56.3%). No 2-(*p*-nitrophenyl)-5-nitrobenzimidazole 3-oxide was found.

Reaction of Benzonitrile Oxide with ***1a***. *In THF*: In a cold solution (below 0 °C) of 496 mg (2.50 mmol) of **1a** in 30 ml of THF, 0.40 ml of triethylamine was added with stirring, and then a solution of benzhydroxamoyl chloride (391 mg, 2.51 mmol) in 20 ml of THF was added for 30 m. After the addition, the cooling bath was removed and the reaction mixture was allowed to stand over-night at ambient temperature. The first drop of benzhydroxamoyl chloride caused the precipitation of triethylammonium chloride. The precipitate was removed by filtration and washed with THF. The solid was almost pure salt and weighed 296 mg (86.0%). The filtrate was evaporated under reduced pressure giving an oil. Trituration of the oil with a small amount of chloroform gave 250 mg of 3-phenyl-7-nitro-4*H*-1,2,4-benzoxadiazine (**3f**). The residue was worked up employing column chromatography on alumina eluted with chloroform. From the elutes, 139 mg of **3f** and 47 mg of **1a** (5.7% recovery) were isolated. The total amount of **3f** was 389 mg (61.0%).

Structure and Absolute Configuration of α-Pompene. II. An X-Ray Analysis of the Mono *p*-Bromobenzoate of the Diol Derived from α-Pompene

Hiroshi NOZAKI, Akihiko MATSUO, Mitsuru NAKAYAMA, Yoshihiko KUSHI, Nagao KAMIJO,* and Shûichi HAYASHI**

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
**Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda 536*

(Received July 23, 1977)

The mono *p*-bromobenzoate of the diol derived from α-pompene has been studied by X-ray crystal structure analysis and determined to be 9-*p*-bromobenzoxy-8-hydroxy-1,2,6,8-tetramethyltricyclo[5.3.1.$0^{2,6}$]undecane. The crystals are of the orthorhombic space group $P2_12_12_1$, $a=46.53(2)$, $b=12.20(2)$, $c=7.39(2)$ Å, $Z=8$, and hence there are two independent molecules per asymmetric unit. The structure was solved by the heavy-atom methods, and refined by block-diagonal least-squares calculations to a final R value of 0.103 for 2493 observed reflections. The structures of the two independent molecules in the asymmetric unit are quite similar. Both molecules contain a tricyclo[5.3.1.$0^{2,6}$]undecane ring in which three fused rings (cyclohexane, cyclopentane, and cyclopentane) are present. The overall configuration of these three fused rings can be described as a "*cis*" type. The conformation of the cyclohexane ring is of a chair form, and the two cyclopentane rings exhibit envelope forms. Based on the anomalous X-ray dispersion effect of the bromine atoms, the absolute configuration of the title compound was also determined.

(+)-α-Pompene, $C_{15}H_{24}$, is a novel tricyclic sesquiterpene hydrocarbon which was isolated from the extract of a liverwort, *Bazzania pompeana* (Lac.) Mitt. together with (−)-β-pompene. We have previously assigned the structure (I) for (+)-α-pompene on the basis of the chemical and spectral evidence.[1] For the purpose of confirming this structure, α-pompene was converted to a diol. Its mono *p*-bromobenzoate was prepared for examination by X-ray crystallographic analysis. The conclusion was that the structures of (+)-α- and (−)-β-pompene should be represented by 1,2,6,8-tetramethyltricyclo[5.3.1.$0^{2,6}$]undec-8-ene (II) and 1,2,6,8-tetramethyltricyclo[5.3.1.$0^{2,6}$]undec-8(15)-ene (III), respectively.[2] A portion of this result has already been reported briefly, together with the absolute configurations of the hydrocarbons, which were determined by the CD measurement.[3] We report here the detailed results of the X-ray crystal structure analysis of α-pompene diol mono *p*-bromobenzoate.

Experimental

The crystals of mono *p*-bromobenzoate, $C_{22}H_{29}O_3Br$, mp 79—80 °C were recrystallized from a hexane–EtOAc (4: 1) mixture at room temperature.[3] The colorless crystals thus obtained were well-formed needles elongated along the c-axis. Crystal data are as follows: $C_{22}H_{29}O_3Br$, $M=421.4$, Orthorhombic, $a=46.53(2)$, $b=12.20(2)$, $c=7.39(2)$ Å, $U=4195$ Å^3, $D_m=1.31$ (by flotation in $ZnCl_2$ solution), $Z=8$, $D_c=1.33$ g/cm^3, $F(000)=1760$; Ni $K\alpha$ radiation ($\lambda=1.6591$ Å), $\mu=38.2$ cm^{-1}. The space group is shown to be $P2_12_12_1$ (D_2^4) from the following systematic absences: $h00$ when $h=2n+1$, $0k0$ when $k=2n+1$, and $00l$ when $l=2n+1$. The unit-cell dimensions were evaluated from the least-squares refinement of the $hk0$, $h0l$, and $0kl$ reflection data recorded on Weissenberg photographs calibrated with a sodium chloride crystal. The data for the intensity measurements were recorded by equi-inclination multiple-film Weissenberg photographs (Ni $K\alpha$ radiation) of the $hk0$-$hk5$ and $h0l$ reciprocal lattice levels. The intensity data obtained (maximum $\sin\theta/\lambda=0.55$) were estimated visually by the comparison with a calibrated intensity scale. Spot-shape and the usual Lorentz and polarization corrections were applied, and 2840 independent observed structure amplitudes were obtained. No correction was made for absorption ($\mu r=0.5$).

Solution and Refinement of the Structure

The structure was solved by the heavy-atom methods. Initial coordinates for the two independent bromine atoms were derived from the three-dimensional Patterson map. The subsequent electron density syntheses, though complicated in the first step by the false inversion center, finally gave the non-hydrogen atom skeleton of both molecules.

This model was refined by several cycles of the block-diagonal least-squares adjustment of the positional and the isotropic thermal parameters using the HBLS program.[4] Cruickshank's weighting scheme was used, in which $W=1/(A+B|F_o|+C|F_o|^2)$, and $A=5.0$, $B=1.0$, and $C=0.024$.[5] The scattering factors from the "International Table" were used.[6] The final difference electron density map showed no spurious peak. However, it was difficult to estimate the hydrogen-atom positions clearly. Hydrogen atoms, except for methyl groups, were therefore located by assuming the C–H bond length of 1.08 Å and the tetrahedral angle for each carbon atom. Contributions for hydrogen atoms with fixed position and isotropic thermal factor $B=4.5$ were included in further least-squares iterations, during which the non-hydrogen atoms were allowed to assume anisotropic temperature factors. The final R value was 0.103 for 2493 non-zero reflections.

In the final stage of the refinements the absolute configuration of the molecule was determined by the anomalous dispersion method.[7] In order to estimate the differences between $I_o(hkl)$ and $I_o(\bar{h}\bar{k}\bar{l})$ values, both intensities were measured visually from the Weissenberg

** To whom the correspondence should be addressed.

photographs rotated around the c-axis, as taken with Ni $K\alpha$ radiation. Structure factors were calculated for all the hkl and $\bar{h}\bar{k}\bar{l}$ reflections, using an atomic scattering factor for the bromine atom of the form $f_{Br}=f_{Br}+\Delta f'_{Br}+i\Delta f''_{Br}$, where $\Delta f'_{Br}=-0.86$ and $\Delta f''_{Br}=1.63$.[8] The results are summarized in Table 1. These results also indicate that the parameters of Table 2 represent the true absolute configuration. The table of observed and calculated structure factors is kept as Document No. 7803 at the Chemical Society of Japan.

Result and Discussion

The final atomic coordinates and anisotropic thermal parameters ($\times 10^4$) are listed in Table 2. The interatomic distances and valency angles, with the estimated standard deviations in parentheses, are also listed in Table 3. The atomic arrangement in the two crystallographically independent molecules of α-pompene diol *p*-bromobenzoate viewed along the c-axis is shown in Fig. 1. The numbering scheme of the atoms in this figure agrees with the conventional chemical sequence employed in the chemical formula (IVb). The two molecules have very similar conformations; the skeleton of each molecule consists of three rings: cyclohexane and the two cyclopentanes. For purposes of comparison, the values for the two molecules of the asymmetric unit are labeled A and B respectively, and those for the latter data are shown in square brackets. From the above results, the structure of α-pompene diol can be shown by the chemical formula 1,2,6,8-tetramethyltricyclo[5.3.1.$0^{2,6}$]undecan-8,9-diol, with the stereochemistry (IVa) and the overall molecular conformation (IVb). Therefore, the structure assigned previously to α-pompene should be revised to be 1,2,6,8-tetramethyltricyclo[5.3.1.$0^{2,6}$]undec-8-ene, while that of β-pompene is 1,2,6,8-tetramethyltricyclo[5.3.1.$0^{2,6}$]undec-8(15)-ene. The absolute configurations of their compounds are presented by stereostructures (II) and (III). The equations of planes and the displacements of the atoms from the mean planes are listed in Table 4.

The tricyclo[5.3.1.$0^{2,6}$]undecane framework of the α-pompene derivative has a crowded "*cis*" configuration.[9] In relation to the chemical formula, tricyclo-[5.3.1.$0^{2,6}$]undecane, this new framework is in agreement with that of α-caryophyllene alcohol (Va).[10] However, the configurations of the bicyclo[3.3.0]octane fragment in the two molecules are completely different. The α-caryophyllene alcohol framework has a strain free "*trans*" configuration (Vb).[9]

The cyclohexane ring, (C(7), C(8), C(9), C(10), C(1), and C(11)), in both A and B molecules adopts a chair conformation. As shown in Fig. 1, the two oxygen atoms which belong to the diol groups occupy the axial position for the O(1) atom and the equatorial position

TABLE 3. BOND LENGTHS AND BOND ANGLES (e.s.d.'s IN PARENTHESES)
The values of molecule B are shown in square brackets.

(a) Bond lengths [Å]

C(17)	−0.04 [0.04]				

for the O(2) atom in this cyclohexane ring. The atoms C(1), C(7), C(8), and C(10) of this ring are closely coplanar and atoms C(11) and C(9) are displaced by −0.88 [0.85] and 0.60 [−0.64] Å from the plane.

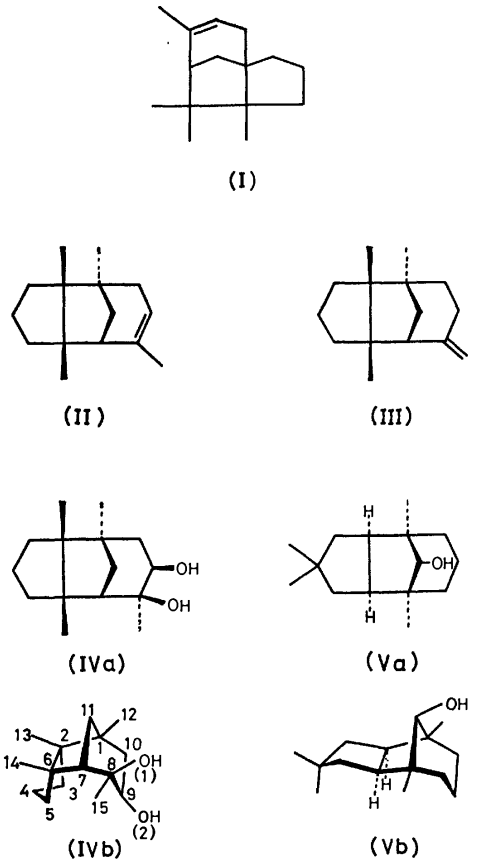
Substituted carbocyclic and heterocyclic bicyclo-[3.2.1]octane moieties are found in a wide variety of natural products. Available X-ray results[10] show that the displacement of the unique bridging atom, C(11), of bicyclo[3.2.1]octane moieties from the plane which is defined by the four carbon atoms (C(1), C(7), C(8), and C(10)) in the cyclohexane ring (−0.88 [0.85] Å in the present α-pompene derivative and 0.80 Å in α-caryophyllene alcohol) exceeds the value of 0.73 Å appropriate to an ideal cyclohexane ring.[11]

The distortion of the cyclohexane ring in α-pompene derivative is also reflected in the valency angles, which are similar to those in α-caryophyllene alcohol.[10] The angle C(1)–C(11)–C(7), 101 [104]°, (α-caryophyllene alcohol 104°) is considerably less than, and the angles C(1)–C(10)–C(9), 115 [111]°, and C(7)–C(8)–C(9), 110 [110]°, (α-caryophyllene alcohol 112 and 112°) are slightly greater than the ideal tetrahedral value. In addition, C(10)–C(1)–C(11), 106 [108], and C(8)–C(7)–C(11), 108 [104]° are also slightly less than the tetrahedral value (α-caryophyllene alcohol 111 and 110°).

The cyclopentane angles in the present α-pompene derivative average 102 [103] in the central ring (C(1), C(2), C(6), C(7), and C(11)) and 104 [103]° in the terminal ring (C(2), C(3), C(4), C(5), and C(6)); these values are consistent with the values which observed in a typical envelope type. Both five-membered rings adopt envelope conformations, in which atoms C(11) and C(4) constitute the flap of the envelopes and have displacements of 0.76 [−0.69] and 0.65 [−0.65] Å, respectively, from the four-atom planes (C(1), C(2), C(6), C(7) and C(2), C(3), C(5), C(6)) of the envelope forms.

The five-membered rings of the bicyclo[3.2.1]octane fragments in α-caryophyllene alcohol derivative[10] and in beyeran-3α-ol derivative[12] exist in envelope conformations. But in a number of other natural product derivatives the conformation of the five-membered ring in the bicyclo[3.2.1]octane fragment is intermediate between the half-chair and envelope forms and closer to the former.[11]

The twin-envelope conformation of the bicyclo[3.3.0]-octane fragment in the present α-pompene derivative has a notable resemblance to the "extended crown" conformation of the eight-membered ring in several cyclooctane derivatives.[13] In contrast to this, the conformation of the bicyclo[3.3.0]octane fragment in



α-caryophyllene alcohol derivative[10] is similar to the "boat-chair" conformation of the eight-membered ring.[13]

The angles C(10)–C(1)–C(2) and C(8)–C(7)–C(6) are both 113 [115] and 118 [115]°, respectively, and the corresponding angles in bicyclo[3.2.1]octane have a mean value of 109°.[11] The bridgehead angles C(1)–C(2)–C(3) and C(7)–C(6)–C(5) of the bicyclo[3.3.0]-octane fragment in the present α-pompene derivative are 119 [112] and 121 [127]° respectively, and are noticeably greater than the ideal tetrahedral value. On the other hand, the mean C(sp^3)–C(sp^3) bond length in the present molecule is 1.56 [1.57] Å, but the C(2)–C(6) length, 1.67 [1.76], and the C(8)–C(15) length, 1.62 [1.69] Å, are appreciably longer than the expected value. These values suggest that the following non-bonded contacts cause greater strain to the α-pompene derivative: C(3)···C(10), 3.01 [3.02], C(3)···C(9), 3.31 [3.21], C(5)···C(15), 3.31 [3.35], C(5)···C(9), 3.17 [3.20], and C(13)···C(14), 2.89 [2.93] Å. The angles C(1)–C(2)–C(13), 111 [113] and C(2)–C(1)–C(12), 116 [112]°, are also significantly greater than the tetrahedral value, because of the repulsion of the two adjacent methyl groups, C(12) and C(13). In order to clarify the presence of such a greater strain, the conformational analysis by Boyd's method[14] of the α-pompene derivative and related compounds is now under investigation.[15]

The bond distances in the *p*-bromobenzoate group are within the expected values: C–C ring system 1.37

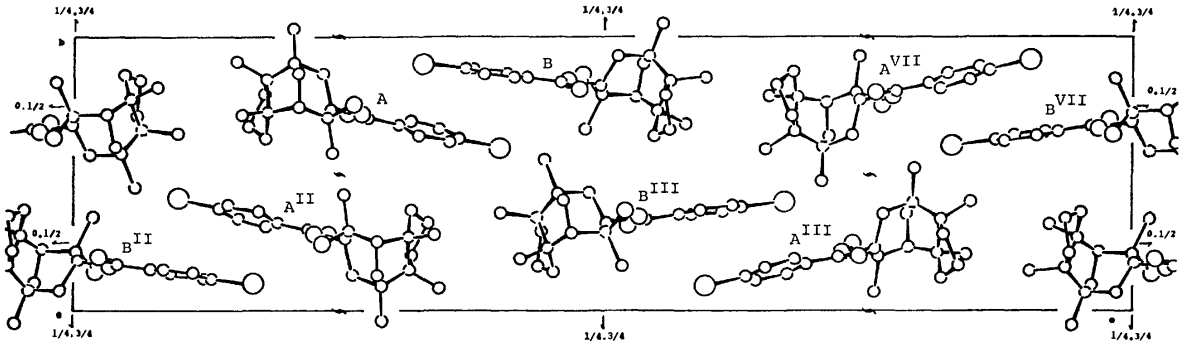


Fig. 2. The molecular arrangement in this crystal viewed along the c-axis.

Table 5. Intermolecular distances (≤3.8 Å)

O(1)A···O(3)A^{I}	2.72	C(15)B···C(11)B^{III}	3.80
O(3)B···O(1)B^{I}	2.77	O(3)B···C(14)B^{IV}	3.61
O(1)A···C(16)A^{I}	3.66	C(5)B···C(17)B^{IV}	3.67
O(1)A···C(18)A^{I}	3.27	C(16)B···C(12)B^{IV}	3.68
O(3)B···C(9)B^{I}	3.64	C(17)B···C(12)B^{IV}	3.70
C(7)A···O(3)A^{I}	3.65	C(13)B···C(14)A^{V}	3.67
C(8)A···O(3)A^{I}	3.57	O(1)A···C(12)A^{VI}	3.61
C(18)B···O(1)B^{I}	3.66	C(12)A···O(3)A^{VI}	3.52
C(15)A···O(3)A^{II}	3.48	C(12)A···C(16)A^{VI}	3.70
C(15)A···C(16)A^{II}	3.53	C(12)A···C(18)A^{VI}	3.72

Roman numerals as superscripts refer to the following equivalent positions relative to the reference molecule at x, y, z:

I	$x, y, z+1$	II	$1/2-x, 1-y, 1/2+z$
III	$1-x, -1/2+y, 1/2-z$	IV	$1-x, -1/2+y, 3/2-z$
V	$1/2+x, 3/2-y, 2-z$	VI	$1/2-x, 2-y, 1/2+z$
VII	$1/2+x, 3/2-y, 1+z$		

[1.38], C–C single bond 1.53 [1.55], C–O 1.31 [1.29], C=O 1.21 [1.24] and C–Br 1.88 [1.85] Å. These distances are in good agreement with those found in other *p*-bromobenzoate groups.[16] The *p*-bromobenzoate ester moieties are not completely planar; the dihedral angle between the plane of C(16)—C(22) and the plane C(16), C(17), O(2), O(3) is 16.6 [5.9]°. The bromine atom (Br–A) is displaced by a small amount from the C(17)—C(20) plane (0.11 Å). This small displacement from coplanarity is probably due to the effects of the non-bonded interaction: Br–A···C(15)B, 3.83; C(21)A···C(21)B, 3.51; and Br–B···C(22)A, 3.61 Å. The molecular arrangement in this crystal viewed along the c-axis is shown in Fig. 2. Selected intermolecular distances were calculated, and the most significant contacts ($\leq$3.80 Å) are summarized in Table 5. The two molecules in an asymmetric unit form a dimeric unit with van der Waals contacts between the *p*-bromobenzoate moieties. Along the c-axis these dimeric unit are connected by the intermolecular hydrogen bonds, O(1)A···O(3)A^{I}, 2.72 and O(3)B···O(1)B^{I}, 2.77 Å; therefore, a linear chain is present parallel to this direction. Moreover, several short contacts are found, as shown in Table 5. The shortest contact except for the hydrogen bond is O(1)A··· C(18)A^{I}, 3.27 Å.

We thank the Hiroshima University Computer Center for a generous allocation of computer time.

Electrophilic Sulfides(II) as a Novel Catalyst. VI.[1] Reaction of Sulfonium Ylides with Arenesulfenyl Thiocyanates

Haruo MATSUYAMA,* Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received July 28, 1977)

Arenesulfenyl thiocyanates (Ar–S–SCN) reacted with sulfonium ylides ($MeR\overset{\oplus}{S}\text{-}\overset{\ominus}{C}(COOMe)_2$) in chloroform at room temperature, forming sulfonium ion, $MeRS^{\oplus}\text{-}C(SAr)(COOMe)_2\ SCN^{\ominus}$, which further reacted. The mechanism of this reaction was discussed.

We have reported that the disulfides containing electron-withdrawing substituents, $\overset{\delta-}{R}\leftarrow\overset{\delta+}{S}\text{—}\overset{\delta+}{S}\rightarrow\overset{\delta-}{R}$ (R= OMe, CN, CF_3, and COPh), react as novel catalysts for several reactions of sulfonium ylides.[2–5] In the presence of these disulfides as catalysts, the following reactions take place smoothly at room temperature.

a) Formation of sulfonium ylides by condensation between alkyl sulfides and diazo esters:[2]

$$\begin{matrix}R^1\\ \quad S\\ R^2\end{matrix} + N_2C(COOMe)_2 \longrightarrow \begin{matrix}R^1\\ \quad \overset{\oplus}{S}\text{-}\overset{\ominus}{C}(COOMe)_2\\ R^2\end{matrix} + N_2$$

b) Transylidation of sulfonium ylides:[3,5]

$$\begin{matrix}Ph\\ \quad \overset{\oplus}{S}\text{-}\overset{\ominus}{C}(COOMe)_2\\ Me\end{matrix} \xrightarrow{CHCl_3}$$

$$\xrightarrow{R^1SR^2} \begin{matrix}R^1\\ \quad \overset{\oplus}{S}\text{-}\overset{\ominus}{C}(COOMe)_2\\ R^2\end{matrix} + PhSMe$$

$$\xrightarrow{X\text{-}C_5H_4N} X\text{-}C_5H_4\overset{\oplus}{N}\text{-}\overset{\ominus}{C}(COOMe)_2 + PhSMe$$

c) Olefin formation:[4]

$$2\ Me_2\overset{\oplus}{S}\text{-}\overset{\ominus}{C}(COOMe)_2 \xrightarrow{CHCl_3} (MeOOC)_2C{=}C(COOMe)_2 + 2Me_2S$$

$$2\ Me_2\overset{\oplus}{S}\text{-}\overset{\ominus}{C}(CN)_2 \xrightarrow{CHCl_3} (NC)_2C{=}C(CN)_2 + 2Me_2S$$

Under the above reaction conditions, these disulfides are not reactants, but catalysts.

Recently, we found that arenesulfenyl thiocyanates (Ar–S–SCN) react with sulfonium ylides $MeR\overset{\oplus}{S}\text{-}\overset{\ominus}{C}(COOMe)_2$. Very little has been published on the reaction of sulfonium ylides with disulfides.[6] The results are described and the mechanism of the reactions are discussed in this paper.

Results and Discussion

As is shown in Table, arenesulfenyl thiocyanates reacted with sulfonium ylides in chloroform at room temperature. In these reactions, alkanesulfenyl thiocyanates R–S–SCN (R=Et, *t*-Bu) did not react with sulfonium ylide **1a**, but arenesulfenyl thiocyanates Ar–S–SCN (Ar=Ph, p-Me–C_6H_4, and 2-$C_{10}H_7$) reacted smoothly with ylides **1a—e**. The above results are probably ascribable to the smaller electron density on the sulfur atoms of arenesulfenyl thiocyanates compared with that of alkanesulfenyl thiocyanates due to the presence of the electron-withdrawing aryl groups.

$$\overset{\delta-}{Ar}\text{—}\leftarrow\overset{\delta+}{S}\text{—}\rightarrow\overset{\delta-}{SCN} \qquad R\text{—}\rightarrow\overset{\delta\delta+}{S}\text{—}\rightarrow\overset{\delta-}{SCN}$$

The S–S bonds of disulfides containing two different substituents are easily cleaved by nucleophilic attacks, compared to those of disulfides containing two equal substituents.[7] As is shown in Table, ylides **1a—e** and arenesulfenyl thiocyanates react, forming sulfonium ions and anion $SCN^{\ominus}$, which further react in three different ways (namely, Me-attack, R-attack, and C(SAr)-

Table 1. Reaction of sulfonium ylides with arenesulfenyl thiocyanates

1	R	Ar	Products (mol %)					
			Me-attack		R-attack		C(SAr)Q_2-attack	
			Me–SCN[a]	RS(ArS)CQ_2[b,c]	R–SCN[d]	MeS(ArS)CQ_2[a,c]	MeSR[a]	ArS(SCN)CQ_2[c,e]
1a	Ph	Et			no reaction			
1a	Ph	*t*-Bu			no reaction

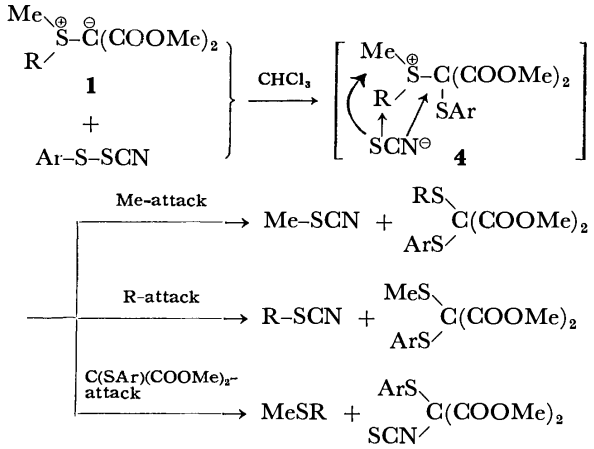
a) Determined from its methyl singlet absorption. b) The amount of RS(ArS)CQ_2 was estimated by assuming the equimolar formation of Me–SCN and RS(ArS)CQ_2. c) Q=COOMe. d) The amount of $PhCH_2$–SCN was determined from its singlet δ=4.11 ppm. The amounts of other R–SCN's were estimated from the assumption of the equimolar formation of R–SCN and MeS(ArS)CQ_2 (determined from its MeS singlet). e) The amount of ArS(SCN)CQ_2 was estimated by assuming the equimolar formation of MeSR and ArS(SCN)CQ_2.

$(COOMe)_2$-attack).



Usually **1** and arenesulfenyl thiocyanates were allowed to react without isolating intermediates **4**. However, when **4′** shown below was separately prepared and allowed to react with ammonium thiocyanate, the results obtained were consistent with those shown in Table.

$$Me_2\overset{\oplus}{S}\text{–}C(COOMe)_2 + NH_4^{\oplus}\,SCN^{\ominus} \longrightarrow$$
$$\underset{\text{4′}}{\overset{|}{\underset{|}{SPh}}\;ClO_4^{\ominus}}$$

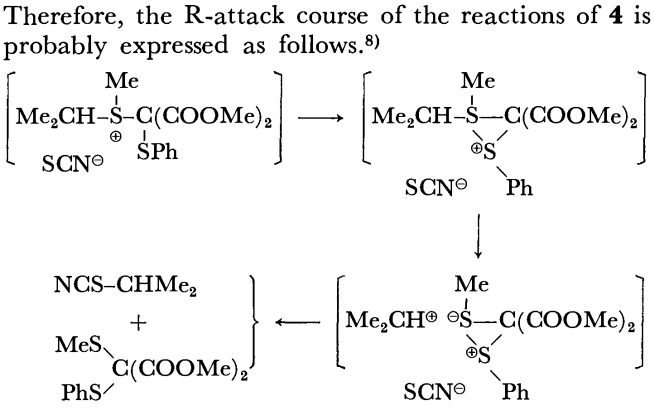
$$\text{Me–SCN} + \text{MeS–}\underset{|}{\overset{|}{C}}(COOMe)_2 + Me_2S$$
$$SPh$$

(86%) (60%) (14%)

When R in **4** is an alkyl group, competitive S_N2 attacks on the methyl and alkyl groups are expected. The relative reactivities of alkyl groups on sulfonium ions with anion $SCN^{\ominus}$ (the ratios between the yields of methylated and alkylated products) are $PhCH_2$ 10.0, *i*-Pr 2.0, Me 1.0, and Et 0.60. These results suggest that these reactions involve an S_N1-like process. The order of the reactivity of alkyl groups for the reaction between $MeR\overset{\oplus}{S}\text{–}C(SPh)(COOMe)_2$ and anion $Cl^{\ominus}$ is:[8]

$$PhCH_2\,(\infty) > i\text{-Pr}\,(4.2) > \text{Me}\,(1.0) > \text{Et}\,(0.85)$$

Therefore, the R-attack course of the reactions of **4** is probably expressed as follows.[8]



Experimental

Materials. Sulfonium bis(methoxycarbonyl)methylides **1a—e** were prepared by copper sulfate-catalyzed decomposition of dimethyl diazomalonate in large excess sulfides[9] and by transylidation.[3,5] Ethanesulfenyl thiocyanate (bp 40—45 °C/8 mmHg), 2-methyl-2-propanesulfenyl thiocyanate, benzenesulfenyl thiocyanate, *p*-toluenesulfenyl thiocyanate and 2-naphthalenesulfenyl thiocyanate (mp 62.5—63 °C (lit, 61.5—63 °C)) were synthesized by the methods described in the literature.[10] Sulfonium salt **4′** was prepared by the dropwise addition of a CCl_4 solution of benzenesulfenyl chloride (1.45 g) to a nitromethane solution of **1a** (1.94 g) and silver perchlorate (2.07 g) at 0 °C. Yield, 3.6 g (90%); recrystallized from ethanol; mp 105—106 °C; IR (KBr), 1740 cm^{-1} (ν_{CO}); NMR (DMSO-d_6), δ=7.60 (5H, s, PhS), 3.93 (6H, s, COOMe) and 3.20 (6H, s, $Me\overset{\oplus}{S}$). Found: C, 38.76; H, 4.25. Calcd for $C_{13}H_{17}O_8ClS_2$: C, 38.96; H, 4.27.

*Reactions of Ylide **1a** with Alkanesulfenyl Thiocyanates.* a) A $CDCl_3$ solution of **1a** (0.57 mmol) and ethanesulfenyl thiocyanate (0.78 mmol) did not react. After 1 day, ylide **1a** (80%) was recovered. b) A $CDCl_3$ solution of **1a** (0.80 mmol) and 2-methyl-2-propanesulfenyl thiocyanate (0.82 mmol) did not react under the same condition. After 1 day, ylide **1a** (80%) was recovered.

*Reactions of Ylides **1a** and **1b** with Arenesulfenyl Thiocyanates.* a) A chloroform (13 g) solution of **1b** (2.08 g, 10.9 mmol) was mixed with PhS–SCN (2.0 g, 11.9 mmol) at room temperature. After 30 min, the ylide carbonyl absorption (1630 and 1670 cm^{-1}) were replaced by the ester absorption (1730 cm^{-1}). The NMR spectra of the reaction mixture showed the presence of MeSCN (δ=2.56, s; 78%), Me_2S (2.01, s; 14%) and MeS-(PhS)C(COOMe)$_2$ (2.15, s, MeS; 74%). The low-boiling fractions from the mixture were trapped in liquid nitrogen, and the presence of MeSCN was shown by NMR (δ=2.59, s) and IR (ν_{SCN} 2150 cm^{-1}, strong and sharp) spectroscopy. The high-boiling fractions were chromatographed (Florisil), and the white crystals obtained from the benzene eluates were found to be MeS(PhS)C(COOMe)$_2$ (2.30 g, 8.07 mmol; 74%); mp 71—72 °C; IR (KBr), 1730 cm^{-1} (ν_{CO}); NMR (CCl_4), δ=2.15 (3H, s, MeS), 3.64 (6H, s, COOMe) and 7.30 (5H, s, PhS). Found: C, 50.52; H, 4.93%. Calcd for $C_{12}H_{14}O_4S_2$: C, 50.33; H, 4.93%. b) In a similar manner, a mixture of **1b** (3.10 g, 16.2 mmol) and *p*-Me–C_6H_4–S–SCN (3.0 g, 16.6 mmol) in chloroform (23 g) gave MeSCN (δ= 2.55, s; 80%), Me_2S (2.10, s; 13%) and MeS (*p*-Me–C_6H_4S)-C(COOMe)$_2$ (from benzene eluates; 3.54 g, 11.8 mmol; 73%); mp 60—61 °C; IR (KBr), 1740 cm^{-1} (ν_{CO}); NMR (CCl_4), δ=2.15 (3H, s, MeS), 2.33 (3H, s, *p*-Me), 3.67 (6H, s, COOMe) and 7.18 (4H, q, C_6H_4). Found: C, 51.85; H, 5.33%. Calcd for $C_{13}H_{16}O_4S_2$: C, 52.00; H, 5.37%. c) A mixture of a $CHCl_3$ (27 g) solution of **1b** (1.00 g, 5.21 mmol) and 2-$C_{10}H_7$S–SCN (1.09 g, 5.64 mmol) gave MeSCN (δ= 2.51, s; 76%), Me_2S (2.09, s; 21%) and MeS (2-$C_{10}H_7$S)-C(COOMe)$_2$ (from benzene eluates; 1.33 g, 3.96 mmol; 75%); mp 84—85 °C; IR (KBr), 1740 cm^{-1} (ν_{CO}); NMR ($CDCl_3$), δ=2.27 (3H, s, MeS), 3.73 (6H, s, COOMe) and 7.20—8.05 (7H, m, 2-$C_{10}H_7$). Found: C, 57.00; H, 4.82%. Calcd for $C_{16}H_{16}O_4S_2$: C, 57.14; H, 4.80. d) In a similar manner, a mixture of **1a** (1.75 g, 6.87 mmol) and PhS–SCN (1.17 g, 7.0 mmol) in chloroform (9 g) gave MeSPh (from hexane eluates; 0.71 g, 5.75 mmol; 84%) and PhS(S=C=N–)-C(COOMe)$_2$ (oil from benzene eluates; 1.19 g, 4.0 mmol; 58%; IR (neat), 1740 cm^{-1} (ν_{CO}) and 2100 cm^{-1} ($\nu_{N=C=S}$, strong and broad);[11] NMR (CCl_4), δ=3.75 (6H, s, COOMe) and 7.16—7.55 (5H, m, PhS)).

*Reaction of Sulfonium Ion **4′** with Thiocyanate Ion.* A DMSO-d_6 solution of **4′** (1.0 mmol) and ammonium thiocyanate (2.0 mmol) was heated at 50 °C for 5 min. The NMR spectrum of the reaction mixture showed the presence of MeSCN (δ=2.67, s; 86%), MeS(PhS)C(COOMe)$_2$ (2.20, s, MeS; 60%) and Me_2S (2.07, s; 14%).

Reactions of Ylides ***1c—e*** *with Benzenesulfenyl Thiocyanate.* The $CDCl_3$ solution of ylides **1c—e** (0.7—1.0 mmol) and PhS–SCN (0.8—1.1 mmol) containing nitromethane (internal standard, 50 μl, 0.79 mmol) were allowed to react in NMR tubes at 25 °C, and the amounts of the reaction products were determined from their singlet methyl absorption by NMR spectroscopy (see Table); Me–SCN (δ=2.56), Me_2S (2.0—2.10), MeSEt (2.05—2.12), MeSPr-*i* (2.10) and MeS(PhS)-$C(COOMe)_2$ (2.19—2.20).

Kharasch, Pergamon Press, New York (1961); Thiocyanates exhibit a strong, sharp band, due to the C≡N stretching vibration, at ≈2140 cm^{-1}, while isothiocyanates exhibit a very strong and broad band at≈2040—2180 cm^{-1}. The ease of formation of isothiocyanate increases from primary to secondary to tertiary carbon derivatives, and is favored by the presence of carbonyl groups on the carbon atom at which substitution occurs.

Photoaddition Reaction of *N*-Acetyldiphenylmethyleneamine with Cyclic and Acyclic Olefins. An Example of Heavy Atom Effect in Photoreaction

Naoki Toshima, Shuichiro Asao, and Hidefumi Hirai

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 29, 1977)

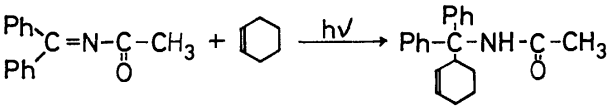
Irradiation of *N*-(diphenylmethylene)acetamide (*N*-acetyldiphenylmethyleneamine, **1**) in cyclopentene gave *N*-[1,1-diphenyl-1-(cyclopenta-2′-enyl)methyl]acetamide, the addition product of cyclopentene to the C=N bond of imine **1**, in 31% yield. The photoreaction of **1** was observed in other cyclic and acyclic olefins. The reactivity of the olefins decreases in the order; cyclopentene>cyclohexene>cyclooctene>2-pentene≃2-hexene. The photoreaction is promoted by the presence of the heavy atom solvent or the sensitizer. The mechanism of photoreaction is discussed in terms of the excited triplet state of the imine.

Increasing attention is being paid to the photochemistry of carbon-nitrogen double bonds.[1] Hydrogen abstraction is the most popular reaction occurring on irradiation of the imine. In 1969 Padwa and co-workers explained the photoreduction of *N*-alkylketimine in terms of chemical sensitization, where the carbonyl compound present in the reactant system as an impurity abstracts a hydrogen atom on irradiation and the ketyl radical produced transfers the hydrogen to the ketimine.[2] They applied a similar mechanism to the photoreduction of *N*-benzoylketimine in 2-propanol.[3] All photochemical hydrogen abstraction reactions of the imine seem to be explained by this chemical sensitization mechanism, the excited state of the imine not taking part. Padwa and co-workers suggested that only the cyclic imine has reactivity, the excited acyclic imine having none, since the acyclic imine easily undergoes syn-anti isomerization by which the excited energy should be consumed.[2]

There are some observations on the photochemistry of the acyclic imines that cannot be explained without taking participation of the excited state of the imine into account. Examples of the photoreaction of the acyclic imine through the excited states contain the deuterium exchange in *ortho*-alkyl derivatives of *N*-(*o*-tolylphenylmethylene)acetamide[4] and the cleavage of the bond between benzylic carbon and imino nitrogen on irradiation of *N*-benzylidenebenzylamine.[5]

Furthermore, even a simple cyclic imine was found to have low reactivity in the photochemical hydrogen abstraction, showing that the low photoreactivity of the imine is not due to the syn-anti isomerization.[6] In fact, the lowest excited states of the imine have been suggested to have the (π,π^*) character rather than the (n,π^*) character.[6,7] The hydrogen abstraction property is characteristic of the $^3(n,\pi^*)$ state rather than of the $^3(\pi,\pi^*)$ state.[8] *N*-(α-Alkylbenzylidene)benzamide has been reported to be reduced photochemically in 2-propanol through the excited triplet state, rather than *via* the chemical sensitization,[9] the mechanism of photochemical hydrogen abstraction thus differing entirely with the reaction system.

In a preliminary communication, a report was given on the photoreaction of *N*-(diphenylmethylene)acetamide (**1**) in cyclohexene.[10] The addition product was the only product isolated, although four kinds of

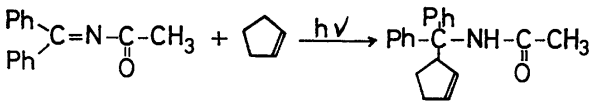


(1) (2b)

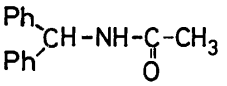
products were reported to be obtained in the photoreaction of benzophenone in cyclohexene.[11] This suggests the photoreaction through the excited state of the acyclic imine. Further studies on this system have been carried out including the external heavy atom effect, which has been found to be convenient for demonstrating the participation of the excited state in the light-induced reaction.[12]

Results

Photoreaction of N-*(Diphenylmethylene)acetamide (*N-*Acetyldiphenylmethyleneamine, 1) with Cyclopentene.* Irradiation of cyclopentene solution of *N*-(diphenylmethylene)-acetamide (*N*-acetyldiphenylmethyleneamine, **1**) was carried out in a quartz tube under nitrogen atmosphere with a 500 W high pressure mercury lamp for 100 h. After irradiation, cyclopentene was distilled off and the residues were chromatographed over silica gel. The addition product (**2a**) of the imine **1** to cyclopentene



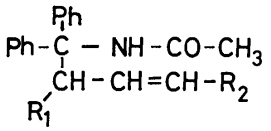
(1) (2a)



(3)

detected by HLC was obtained almost selectively except for a trace amount of the hydrogenation product, *N*-(diphenylmethyl)acetamide (**3**). The structure of **2a** was inferred from its composition ($C_{20}H_{21}NO$), olefin tests such as the Bayer test and bromine test, and spectral data. The spectral data included mass spectra

(M^+/e=291) and the infrared absorption bands for an amide group (ν_{NH} 3280, ν_{CO} 1658, δ_{NH} 1548 cm^{-1}). The structure of **2a** was confirmed by the NMR spectrum showing acetyl protons (3H, δ 1.90 ppm), methylene protons (4H, δ 2.08—2.20), a methine proton (1H, δ 4.29—4.66), olefin protons (2H, δ 5.71), an NH proton (1H, δ 6.02—6.42), and phenyl protons (10H, δ 6.93—7.51).



2a	$R_1,R_2=-(CH_2)_2-$
2b	$R_1,R_2=-(CH_2)_3-$
2c	$R_1,R_2=-(CH_2)_5-$
2d	$R_1=R_2=-CH_3$
2e	$R_1=-C_2H_5, R_2=-CH_3$
2e'	$R_1=-CH_3, R_2=-C_2H_5$

Comparison of Photoreactivity of N-*Acetyldiphenylmethyleneamine (1) toward Several Kinds of Olefins.* On irradiation of imine **1** in other cyclic olefins such as cyclohexene and cyclooctene, and in the acylic olefins such as 2-pentene and 2-hexene, the same kind of product (**2**) as the amide **2a** was obtained. Amide **2** is the C–C bond formation product between the iminoyl carbon of imine **1** and the allylic carbon of the olefin. The results of the photoreaction are summarized in

Table 1. Photoreaction of *N*-(diphenylmethylene)-acetamide (**1**) with olefins[a]

1	Amount of 1 (mmol)	Olefin	Amount of olefin (mmol)	Yield[b] (%)
a	4.8	Cyclopentene	72	31
b	5.7	Cyclohexene	54	15
c	5.6	Cyclooctene	48	2
d	16	2-Pentene	37	0.9
e	16	2-Hexene	30	1.1

a) Olefinic solutions (*ca.* 5 ml) of **1** (1—3 g) were irradiated in quartz tubes under nitrogen atmosphere with a 500 W high pressure mercury lamp for 100 h. b) Conversion of the starting imine **1**. See Experimental.

Table 1. Product yields determined by the silica gel column chromatography indicate the conversion of the starting imine under the given conditions, since amide **2** is the only product in this reaction, the yield increasing with irradiation time.

Effect of Additives on Photoreaction of Imine 1 with Cyclohexene. The photoreaction of imine **1** with cyclohexene was carried out in the presence of several kinds of additives (Table 2). A cyclohexene (55 mmol) solution of imine **1** (4.6 mmol) with benzophenone (4.6 mmol) in a quartz tube under nitrogen atmosphere was irradiated for 100 h giving the adduct **2b** in 38% yield. Benzophenone (E_T=68.5 kcal/mol[13]) and acetophenone (E_T=73.6 kcal/mol[13]) acted as good sensitizers, benzil (E_T=53.7 kcal/mol[13]) sensitizing the reaction only slightly. Piperylene quenched the reaction completely. The results are nearly compatible with those of the photoreaction of imine **1** in toluene.[14]

Table 2. Dependence of the photoreaction yield of *N*-acetyldiphenylmethyleneamine (**1**) with cyclohexene in the presence of several kinds of additives[a]

Additive	Amount of additive (mmol)	E_T[b] (kcal/mol)	Product yield[c] (%)
None[d]	—	—	9
Benzophenone	4.6	68.5	38
Acetophenone	6.7	73.6	25
Benzil	4.1	53.7	12
Piperylene[e]	23	*trans* 59.3 *cis* 56.9	0

a) A solution of 4.6 mmol of **1** and 55 mmol of cyclohexene in the presence of the additive in a quartz tube was irradiated with a 500 W high pressure mercury lamp for 100 h. b) Excited triplet energy. See Ref. 13. c) Conversion of the starting imine **1**. See text. d) The starting imine **1** contained a small amount of benzophenone as an impurity (<3%). e) Mixtures of *cis*- and *trans*-piperylene.

Dependence of the Yield of Photoreaction of Imine 1 with Cyclohexene upon the Concentration of Benzophenone. Since benzophenone acts as a sensitizer on the photoreaction of *N*-acetyldiphenylmethyleneamine (**1**) with cyclohexene, the dependence of the reaction yield of **2b** upon the concentration of benzophenone was investigated. The data are plotted in Fig. 1. The starting sample **1** contains a small amount of benzophenone, the hydrolysis product of imine **1** which is easily hydrolyzed. The amount of benzophenone is the sum of that determined by GLPC in the starting imine as an impurity and that added separately. The full line in Fig. 1 indicates the experimental data and the dashed line the extrapolation of the results. The yield of product **2b** increases linearly with the concentration of benzophenone.

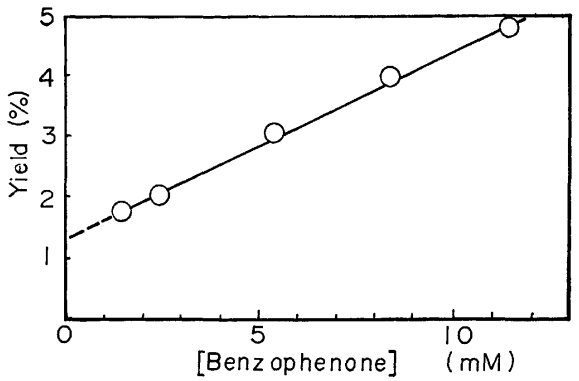


Fig. 1. Dependence of the yields of the photoaddition reaction of *N*-acetyldiphenylmethyleneamine (**1**) with cyclohexene on the concentration of benzophenone: [*N*-Acetyldiphenylmethyleneamine] 0.23 mol/l, [cyclohexene] 10 ml. Irradiation was carried out above 300 nm for 70 h at 25 °C.

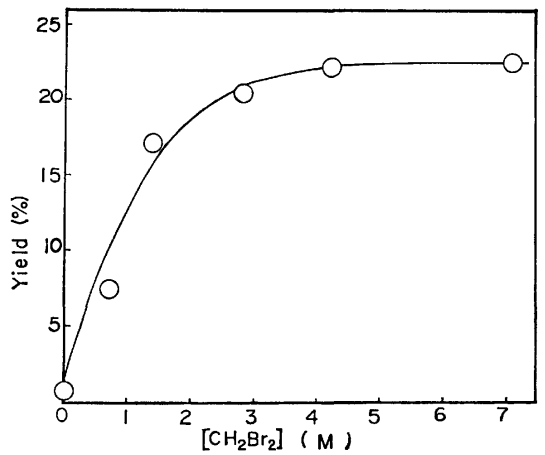

Fig. 2. Dependence of product yield on the concentration of dibromomethane in the photoreaction of *N*-acetyldiphenylmethyleneamine (**1**) in cyclohexene. A solution of **1** (1.22 mmol) and cyclohexene (5 ml) in benzene was irradiated.

Dependence of the Yield of Photoreaction of Imine **1** *with Cyclohexene upon the Concentration of the Heavy Atom Solvent.* The photoaddition product of imine **1** with alkylbenzene increases in yield in the presence of the heavy atom solvent.[14] In the case of the photoreaction of imine **1** with cyclohexene, the yield of **2b** also increases remarkably in the presence of the heavy atom solvent. The photoreaction of imine **1** with cyclohexene was carried out using various concentrations of dibromomethane. The results are shown in Fig. 2. The product yield increases noticeably as the concentration of dibromomethane increases from 0 to 2 M. Further increase in the concentration of heavy atom solvent over 3 M, however, resulted in constant yields.

Discussion

Effect of Additives. The effect of additives on the photoreaction of imine **1** in cyclohexene (Table 2) is in fair agreement with that of the imine in toluene.[14] Benzophenone (E_T=68.5 kcal/mol) and acetophenone (E_T=73.6 kcal/mol) act as sensitizers, and piperylene (*trans*-piperylene, E_T=59.3 kcal/mol; *cis*-piperylene E_T=56.9 kcal/mol) as a quencher. The results suggest that the reaction proceeds *via* a triplet state. However, benzil, whose triplet energy (E_T=53.7 kcal/mol) is lower than that of piperylene, can also sensitize the reaction a little. The curious result indicates that the sensitization concerns the hydrogen transfer *via* "chemical sensitization."[2] The hydrogen abstracting property is a character common to the compounds which sensitize the reaction. As shown in Scheme 1, benzophenone as well as benzil can act as a chemical sensitizer.[2,15]

Dependence of the Yield on the Concentration of Benzophenone. The photoproduct yields increase linearly with the amount of benzophenone (Fig. 1). The usual steady state treatment of Scheme 1 gives the following equation for the product (A_d):[16]

$$\frac{d[A_d]}{dt} = k_r[\text{Olefin}][Ph_2CO^*(T_1)] + k_r'[\text{Olefin}][Ph_2CNAc^*(T_1)]. \quad (1)$$

This shows that the yield should be proportional to the concentration of benzophenone ([Ph_2CO]) since [$Ph_2CO^*(T_1)$] is proportional to [Ph_2CO],[17] and [Olefin] and [$Ph_2CNAc^*(T_1)$] are almost constant.[18] The linear relation between the yield and the concentration of benzophenone (Fig. 1) agrees with the equation.

If imine **1** in excited state cannot abstract a hydrogen atom and the reaction proceeds only by chemical sensitization mechanism (only processes a—e taking place in Scheme 1), the reaction yields should converge to 0% at the point of no benzophenone according to the following equation:

$$\frac{d[A_d]}{dt} = k_r[\text{Olefin}][Ph_2CO^*(T_1)]. \quad (2)$$

Actually, however, Fig. 1 clearly shows the formation of 1.3% of the product without benzophenone. This is exactly the yield derived from the excited state of imine **1** itself, based on the second term of Eq. 1.

Relative Reactivity of Olefins towards N-Acetyldiphenylmethyleneamine (1). The yields in Table 1 show the relative reactivity of olefins toward imine **1**. The yields decrease in the following order depending on the kind of olefin: Cyclopentene>Cyclohexene>Cyclooctene>2-Hexene≃2-Pentene. The results indicate that the reactivity of an olefin is correlated with the stability of the allyl radical derived by hydrogen abstraction from the olefin, and that the lower reactivity of an acyclic olefin than that of a cyclic olefin is due to smaller conjugation of the allyl radical because of the flexibility of the molecule.

Heavy Atom Effect in Photoreaction. The heavy atom effect for increasing the yields in photoreactions

$$Ph_2CO \xrightarrow{h\nu} Ph_2CO^*(S_1) \longrightarrow Ph_2CO^*(T_1) \quad (a)$$

$$Ph_2CO^*(T_1) \xrightarrow{k_d} Ph_2CO \quad (b)$$

$$Ph_2CO^*(T_1) + R_1\text{-}CH{=}CH\text{-}CH_2\text{-}R_2 \xrightarrow{k_r} Ph_2\dot{C}OH + R_1\dot{C}H{\cdots}CH{\cdots}CH\text{-}R_2 \quad (c)$$

$$Ph_2\dot{C}OH + Ph_2C{=}NAc \xrightarrow{k_H} Ph_2\dot{C}NHAc + Ph_2CO \quad (d)$$

$$Ph_2\dot{C}NHAc + R_1\text{-}\dot{C}H{\cdots}CH{\cdots}CH\text{-}R_2 \xrightarrow{k_{cc}} \begin{matrix} Ph_2CNHAc & & Ph_2CNHAc \\ | & \text{and/or} & | \\ R_1\text{-}CH\text{-}CH{=}CH\text{-}R_2 & & R_2\text{-}CH\text{-}CH{=}CH\text{-}R_1 \end{matrix} \quad (e)$$

$$Ph_2CNAc \xrightarrow{h\nu'} Ph_2CNAc^*(S_1) \longrightarrow Ph_2CNAc^*(T_1) \quad (f)$$

$$Ph_2C{=}NAc^*(T_1) + R_1\text{-}CH{=}CH\text{-}CH_2\text{-}R_2 \xrightarrow{k_r'} Ph_2\dot{C}NHAc + R_1\text{-}\dot{C}H{\cdots}CH{\cdots}CH\text{-}R_2 \quad (h)$$

Scheme 1.

could be of importance for effective utilization of photoenergy. However, only a few examples are known.[12,19] The heavy atom effect in the present photoreaction was investigated in order to clarify the initial step of the photoreaction. The photoreaction of imine **1** with olefins is greatly susceptible to the heavy atom solvent, as observed in the photoreaction of imine **1** with alkylbenzenes.[12] Carbonyl compounds such as benzophenone are known not to be influenced by the heavy atom effect.[20] Thus chemical sensitization by the action of benzophenone would not be influenced by the heavy atom effect, though the excited state of imine **1** might be susceptible. The heavy atom effect is known to increase the probability of the transition between the singlet state and triplet state of a π,π^* character,[21,22] and the reactive state of the imine **1** would be the triplet state with some π,π^* character.[23] The reaction was confirmed to proceed *via* the excited triplet state of imine **1** by the fact that the photoreaction of **1** with cyclohexene was completely quenched by piperylene (Table 2).

The variation of the reaction yield depending on the concentration of dibromomethane shown in Fig. 2 seems to arise from the influence of the heavy atom effect toward the initial step of the excited state of imine **1** as shown in Scheme 2, where D is *N*-acetyldiphenylmethyleneamine (**1**) and the superscript is the multiplicity of the excited state of **1**.

$$D \xrightarrow{h\nu'} {}^1D \qquad (i)$$

$$^1D \xrightarrow{k_{1c}} D \qquad (j)$$

$$^1D \xrightarrow{k_{1s}} {}^3D \qquad (k)$$

$$^3D \xrightarrow{k_d} D \qquad (l)$$

$$D \xrightarrow{h\nu''} {}^3D \qquad (m)$$

Scheme 2.

The main processes influenced by the heavy atom effect are (a) an intersystemcrossing from the lowest singlet state to the triplet state of **1** (Eq. k), and (b) a radiative or radiationless decay from the triplet state to the ground state (Eq. 1). Increase of the yield with concentration of heavy atom solvent demonstrates the importance of Step k in the heavy atom effect. This indicates that the excited triplet state of **1** is mainly produced by the singlet excited state of **1** and not by the energy transfer of benzophenone. The behavior of the excited imine **1** in the reaction with olefins is just the same as that in the reaction with alkylbenzenes.[12]

Experimental

Materials. Cyclopentene, cyclooctene, 2-pentene, 2-hexene, piperylene (Tokyo Chemical Industry), and cyclohexene (Yoneyama Chemical Industry) were dried over sodium by refluxing and distilled. Acetophenone (Yoneyama Chemical Industry) and dibromomethane were dried over magnesium sulfate and distilled. Benzophenone (Yoneyama Chemical Industry) and benzil (Tokyo Chemical Industry) were recrystalized from ethanol. Commercial cyclohexane, benzene, dichloromethane, chloroform, and ethanol were used as eluting solvents for column chromatograpy. The reagent for the bromine test was 2% carbon tetrachloride solution of bromine and that for the Bayer test 0.5% aq solution of potasium permanganate. *N*-Acetyldiphenylmethyleneamine (**1**), bp 168—170 °C/1 mmHg (lit,[24] bp 168—170 °C/1 mmHg), was prepared by the reaction of diphenylketimine[25] with acetic anhydride and distilled repeatedly.

Instrumentations. Irradiation was performed with a 500 W Halos high pressure mercury lamp (Eikosha Ltd.). Most comparative runs were carried out on a merry-go-round type reactor (Rikokagaku Ltd.) with a turntable device holding the rotating pyrex tubes. The turntable also rotates around the lamp in a water cooled quartz immersion well. The turntable and tubes were held in a constant temperature water bath maintained at 25 °C. GLPC analysis was carried out on an Ohkura Rikagaku gas chromatograph with a flame ionization detector employing a 2 m×3 mmϕ stainless steel column packed with 10% Apiezon Grease L on 60—80 mesh Diasolid A. High speed liquid chromatography (HLC) was performed with a Waters ALC-202 high speed liquid chromatograph with a 600 type high pressure pump, a U6K universal injector, and a 660 type solvent programmer equipped with a stainless steel colum packed with Microporasil. Chloroform was used as an eluting solvent. Infrared spectra were taken on a JASCO IR-E spectrometer. NMR spectra were obtained on a JEOL C-60, 4H-100, PS-100 or a Hitachi Perkin-Elmer R-20B spectrometer. Mass spectra were recorded on a Hitachi RMS-4 spectrometer. Melting points were determined on a Yanagimoto micro melting point apparatus, and were uncorrected.

Photoreaction of N-*Acetyldiphenylmethyleneamine (1) and Cyclopentene.* A cyclopentene (72 mmol) solution of *N*-acetyldiphenylmethyleneamine (4.8 mmol) in a quartz tube was degassed in three successive freeze-thaw cycles, and then irradiated under nitrogen with a 500 W high pressure mercury lamp for 100 h. After irradiation cyclopentene was distilled off and the residue was chromatographed over silica gel. The fraction eluted with benzene contained imine **1** and benzophenone, most of which was produced by the hydrolysis of **1** in a column. The product **2a** was eluted with chloroform in 31% yield. The yield represents the conversion percentage of starting imine **1** since **2a** is the only product in the reaction. The product was purified by recrystalization several times from the mixed solvent of cyclohexane and ethanol. The structure of **2a** (mp 147.0—147.8 °C) was inferred from its composition (Found: C, 82.41; H, 7.11; N, 4.76%; mol wt, 291 by mass spectra. Calcd for $C_{20}H_{21}NO$: C, 82.44; H, 7.26; N, 4.81%; mol wt, 291.38), the results of olefin tests, and its spectral data. The bromine test and the Bayer test indicated the presence of a C=C bond in the molecule. Infrared spectra showed an amide absorption (ν_{NH}, 3280; ν_{CO}, 1658; δ_{NH}, 1548 cm^{-1}); NMR spectra (in $CDCl_3$) showed ten phenyl protons (δ 7.51—6.93), an NH proton (δ 6.42—6.02), two olefinic protons (δ 5.71), a methine proton (δ 4.66—4.29), four methylene protons (δ 2.20—2.08), and three acetyl protons (δ 1.90).

Photoreaction of N-*Acetyldiphenylmethyleneamine (1) with Cyclohexene.* A cyclohexene (54 mmol) solution of imine **1** (5.7 mmol) in a qaurtz tube was irradiated in the same way as given above, the photoproduct **2b** being obtained in 15% yield. Its structure was identified as *N*-(1,1-diphenyl-1-cyclohexa-2′-enylmethyl)acetamide: mp 181 °C. Found: C, 82.37; H, 7.32; N, 4.61%; mol wt 305 by mass spectra. Calcd for $C_{21}H_{23}NO$: C, 82.58; H, 7.59; N, 4.59%; mol wt, 305.42. Infrared spectra showed an amide band (ν_{NH}, 3290, ν_{CO}, 1660; δ_{NH}, 1548 cm^{-1}). NMR spectra (in $CDCl_3$) showed ten phenyl protons at δ 7.70—6.99, an NH proton at δ 6.42—6.20, two

olefin protons at δ 5.65, a methine proton at δ 4.00—3.65, six methylene protons at δ 2.08—0.85, and three acetyl protons at δ 1.89. An NH proton was assigned by disappearance in the present of deuteruim oxide. UV spectra gave four peaks of 253.6 nm (ε_{max} 5.12×10^2), 259.4 (5.58×10^2), 265.0 (4.69×10^2), and 270.5 (2.92×10^2).

Photoreaction of N-*Acetyldiphenylmethyleneamine (1) with Cyclooctene.* A cyclooctene (48 mmol) solution of *N*-acetyldiphenylmethyleneamine (5.6 mmol) was irradiated in the same way as above, the product **2c** being obtained in 2% yield. Its structure (mp 233 °C) was determined by mass spectra (mol wt 333) and other spectral analysis: Infrared spectra have an amide group (ν_{NH}, 3310; ν_{CO}, 1667; δ_{NH}, 1525 cm^{-1}), and NMR spectra showed ten phenyl protons (δ 7.58—6.02), an NH proton (δ 6.24), two olefin protons (δ 5.83—5.39, 5.32—4.91), a methine proton (δ 4.40—4.00), three acetyl protons (δ 1.82), and ten methylene protons (δ 2.60—0.52).

Photoreaction of N-*Acetyldiphenylmethyleneamine (1) with 2-Pentene.* A solution of imine **1** (16 mmol) and 2-pentene (37 mmol) was irradiated in the same way as given above, the product **2d** being given in 0.9% yield. Its structure was dentified to be *N*-(1,1-diphenyl-2-methyl-3-pentenyl)acetamide, from its spectral data and the results of the olefin tests. Infrared spectra showed an amide band (ν_{NH}, 3300; ν_{CO}, 1670; δ_{NH}, 1530 cm^{-1}) and molecular weight was observed to be 293 by mass spectra. NMR spectra showed ten phenyl protons (δ 7.50—6.70), an NH proton (δ 6.56—6.24), two olefinic protons (δ 5.62—4.99), a methine proton (δ 4.64—4.16), three acetyl protons (δ 1.79), three methyl protons adjacent to the olefinic carbon (δ 1.51), and three methyl protons adjacent to the methine carbon (δ 0.73).

Photoreaction of N-*Acetyldiphenylmethyleneamine (1) with 2-Hexene.* A solution of imine **1** (16 mmol) and 2-hexene (30 mmol) was irradiated in the same way as described above. The products were eluted with 5% benzene solution of ether in 1.1% yield. They were identified to be two kinds of isomers (**2e** and **2e'**) by the spectral data. Mass spectra showed the molecular weight ($M^+/e=307$); the infrared spectra showed an amide group (ν_{NH}, 3300; ν_{CO}, 1670; δ_{NH}, 1530 cm^{-1}); NMR spectra showed the phenyl protons (δ 8.10—6.72), the NH proton (δ 6.63), the olefinic protons (δ 5.80—4.90), the methine proton (δ 4.59—4.24), the allylic methylene protons (δ 1.94), the allylic methyl protons (δ 1.45), the acetyl protons (δ 1.83), and the methyl protons adjacent to the tertiary carbon (δ 0.95).

Photoreaction of N-*Acetyldiphenylmethyleneamine (1) with Cyclohexene in the Presence of the Additives.* A cyclohexene (55 mmol) solution of imine **1** (4.6 mmol) and the additive was irradiated in a quartz tube under nitrogen atmosphere after being degassed in three freeze-thaw cycles at 15 °C for 100 h. Separation was carried out in the same way as described in the photoreaction of the imine **1** with cyclopentene. No products derived from the additive were detected.

Dependence of Photoreaction of N-*Acetyldiphenylmethyleneamine (1) with Cyclohexene upon the Concentration of Benzophenone.* A cyclohexene (10 ml) solution of imine **1** (0.23 M) in the presence of a fixed amount of the heavy atom solvents in a Pyrex tube was degassed in three successive freeze-thaw cycles and irradiated under nitrogen with a 500 W high pressure mercury lamp at 25 ± 1 °C for 70 h. After irradiation cyclohexene was distilled off and the reaction mixtures were analyzed with a gas chromatograph equipped with a 80 cm×3 mmϕ stainless steel column with 10% Apiezon Greese L on 60—80 mesh Diasolid A. Yields are given in terms of the conversion percentage of the starting imine.

Dependence of Photoreaction of N-*Acetyldiphenylmethyleneamine(1) with Cyclohexene upon the Concentration of Dibromomethane.* A cyclohexene (5 ml) solution of imine **1** (1.2 mmol) in the presence of benzene solutions (5 ml) of varying amounts of dibromomethane in a Pyrex tube was degassed and irradiated under nitrogen with a 500 W high pressure mercury lamp at 25 ± 1 °C for 10 h. After irradiation solvents were distilled off, and the residue was analyzed by high speed liquid chromatography of Microporasil using chloroform as an eluting solvent. Yields are given in terms of the conversion percentage of the starting imine **1**.

16) The possibility of contribution of photochemical hydrolysis of imine **1** to Scheme 1 was pointed out by a referee. However, photochemical hydrolysis of the imine is known only in the presence of oxygen (*cf.* R. L. Furey and R. O. Kan, *Tetrahedron*, **24**, 3085 (1968)) or in ether or methanol probably containing water in the case of a special imine.[7] In the present study, irradiation was carried out in a dry solvent under nitrogen. Lack of photochemical hydrolysis of imine **1** in the present case is further supported by the fact that the product yield increases linearly with irradiation time.
17) The concentration of excited triplet benzophenone is not proportional to the benzophenone concentration, but follows the equation

$$[Ph_2CO^*(T_1)] = Ia/(k_r[\text{Olefin}]+k_d)$$

where, Ia is the rate of light absorption of benzophenone to form triplet state of benzophenone, k_r and k_d are constants. The concentration of olefin ([Olefin]) is very high and con-

sidered to be constant during the course of reaction.

18) $[Ph_2CNAc^*(T_1)]$ is proportional to the concentration of imine **1** ($[Ph_2CNAc]$), which changes with reaction time. In this experiment, however, the change is less than 5% and the concentration of the imine is kept almost constant, since the conversion of the reactant imine is less than 5%.

23) It is difficult to determine whether hydrogen abstraction by the excited *N*-acylimine occurs on the oxygen atom or on the nitrogen atom of the acylimine chromophore. We have suggested the abstraction on the oxygen atom in the photoreduction of *N*-acylimine by the term "intramolecular chemical sensitization" (T. Okada, M. Kawanisi, H. Nozaki, N. Toshima, and H. Hirai, *Tetrahedron Lett.*, **1969**, 927). Padwa and co-workers also made the same suggestion on the basis of the failure of the imine nitrogen to initiate Norrish type II reactions.[9]

Cyclic Peptides. IV.[1] Synthesis of Diastereomeric Dihydro-AM-toxin I and Its Analogs[2]

Yasuyuki SHIMOHIGASHI, Sannamu LEE, Tetsuo KATO, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science 33, Kyushu University, Higashi-ku, Fukuoka 812

(Received August 1, 1977)

Diastereomeric cyclotetradepsipeptides [L-Ala²]- and [D-Ala²]-AM-toxin I, corresponding to the hydrogenated products of AM-toxin I, were synthesized by the conventional method and their biological activities were tested. [D-Ala²]-AM-toxin I exhibits weak but recognizable necrotic activity (5—10 μg/ml) on apple leaves. [L-Ala²]-AM-toxin I is inactive even in a high concentration of 100 μg/ml. The results of NMR and ORD measurements of [D-Ala²]-AM-toxin I and [L-Tyr(Me)¹, D-Ala²]-AM-toxin indicates the presence of a common conformer. The results on [L-Ala²]-AM-toxin I and [L-Tyr(Me)¹, L-Ala²]-AM-toxin revealed the presence of more than two conformers, the predominant conformation differing from that of D-isomers. Difference in activity between [D-Ala²]- and [L-Ala²]-AM-toxin I can be attributed to the difference in conformation of the diastereomers.

AM-toxins are host-specific phytotoxins produced by *Alternaria mali* causing necrosis on apple leaves.[3] The structures of AM-toxin I (**1a**) and its analog [L-Tyr-(Me)¹]-AM-toxin (**1b**) are shown in Fig. 1.[4] Peptide **1a** and its analogs such as **1b** and di-AM-toxin I (cyclic octadepsipeptide) were synthesized in this laboratory, the minimum toxic activity of **1a**, **1b**, and di-AM-toxin I being determined to be 0.002, 20, and 10—20 μg/ml, respectively.[5]

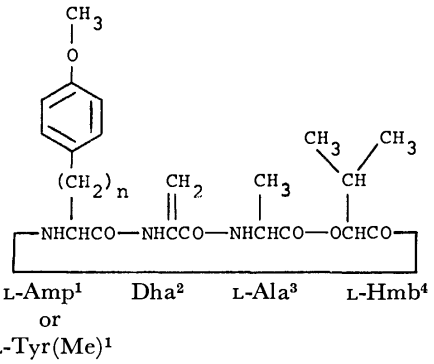

Fig. 1. Structure of AM-toxin I (**1a**) and [L-Tyr(Me)¹]-AM-toxin (**1b**). **1a**, $n=3$; **1b**, $n=1$.

This paper describes studies on the role of a double bond in the Dha² residue in **1a**. Since hydrogenation of natural **1a** produces a mixture of [L-Ala²]- and [D-Ala²]-AM-toxin I (**8a**-L and **8a**-D), pure **8a**-L and **8a**-D were prepared by the conventional method of peptide synthesis. The biological activities of the synthesized peptides were tested. Analogs (**8b**-L and **8b**-D) containing *O*-methyl-L-tyrosine (**2b**) in place of L-2-amino-5-(*p*-methoxyphenyl)pentanoic acid (**2a**) were also synthesized in order to investigate the influence of variation of the side chain in **2a** on necrotic activity and on conformation. When the synthesis of **1a** and **1b** was carried out in a previous study, a mixture of cyclic oligomers was obtained by the cyclization reaction of the corresponding linear tetradepsipeptides. The cyclic oligomers behaved chromatographically in a very similar way to each other, and thus purification with silica gel column was tedious and complete separation difficult.[5] In the present study, effective separation of cyclic oligomers was attained by fractional crystallization

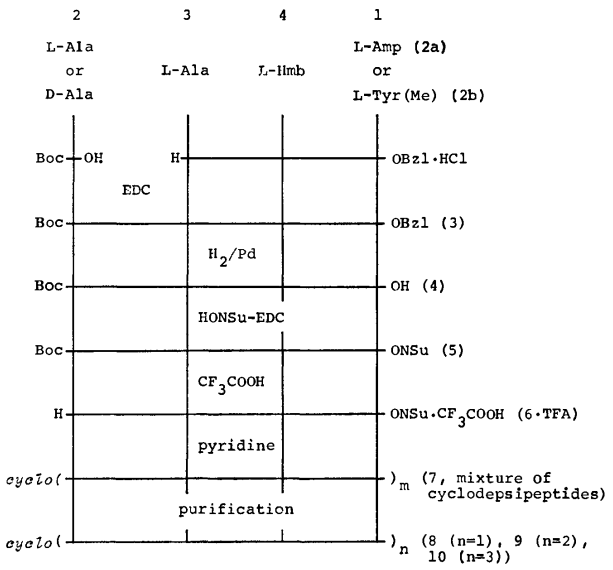

Fig. 2. Synthetic route for dihydro-AM-toxin I (**8a**-L and **8a**-D) an [DL-Tyr(Me)¹]-dihydro-AM-toxin (**8b**-L and **8b**-D).

with use of minute differences in the solubility of the oligomers.

Figure 2 shows the reaction route for the synthesis. L-Amp was prepared by the resolution of Ac-DL-Amp-OH with acylase.[6] Ester H-L-Ala-L-Hmb-L-Amp-OBzl·HCl[1] was coupled with Boc-L- or Boc-D-Ala-OH by the EDC method to give Boc-L- or Boc-D-Ala-L-Ala-L-Hmb-L-Amp-OBzl (**3a**-L or **3a**-D). Ester **3a**-L or **3a**-D was catalytically hydrogenated to give tetradepsipeptide acid (**4a**-L or **4a**-D), the acid being converted into active ester **5a**-L or **5a**-D with the use of HONSu and EDC. The active ester **5a**-L was treated with TFA at 0 °C for 20 min, the salt **6a**-L·TFA obtained was dissolved in DMF, and the solution was subjected to cyclization reaction in pyridine. A mixture (**7a**-L) of cyclodepsipeptides was obtained showing three spots on a thin layer chromatogram corresponding to cyclic monomer (**8a**-L), dimer (**9a**-L), and trimer (**10a**-L). In order to isolate each of the pure products, reprecipitation with dioxane was carried out. Less soluble fraction of **7a**-L was treated with DMF-dioxane to give pure **8a**-L and **10a**-L. Similar precipitation of

more soluble fraction of **7a**-L gave pure dimer **9a**-L. On the other hand, cyclization of **6a**-D gave monomer **8a**-D exclusively. Analogous cyclic depsipeptides containing L-Tyr(Me) (**2b**) were obtained similarly.

When natural **1a** was catalytically hydrogenated in acetic acid, a mixture consisting of **8a**-L and **8a**-D was found on a thin layer chromatogram. In order to determine the ratio of **8a**-L to **8a**-D in the mixture, the procedure of Shimohigashi *et al.*[6] was applied; the hydrogenated residue of the mixture was hydrolyzed in hydrochloric acid and the hydrolyzate was acylated with Z-L-Leu-ONSu in aqueous dioxane. Upon debenzyloxycarbonylation, leucyl dipeptides obtained were applied to an amino acid analyzer. The calculated ratio of L-Leu-L-Ala to L-Leu-D-Ala was 2.21: 1.00. From the result, the ratio of **8a**-L to **8a**-D in the hydrogenated mixture was determined to be 38: 62.

Experimental

All the melting points are uncorrected. TLC was carried out on silica gel G (Merck) with the following solvent systems, the ratio in parentheses being indicated by vol: R_f^1, $CHCl_3$–MeOH (5: 1); R_f^2, $CHCl_3$–MeOH–AcOH (95: 5: 1); R_f^3, $CHCl_3$–MeOH (9: 1). Optical rotations were measured with a Union high sensitivity polarimeter PM-71. Mass spectra were taken on a Hitachi RMS-4 mass spectrometer with a direct inlet system operating at 70 eV, UV spectra on a Hitachi 124 spectrophotometer, and NMR spectra on a JEOL JNM PS-100 spectrometer, tetramethylsilane being used as an internal reference. ORD measurements were carried out with a JASCO ORD/UV-5 spectropolarimeter using a 0.1 cm cell; sample concentration, 0.01%. Amino acid analyses were determined with a Hitachi amino acid analyzer KLA-5. Details of the synthetic procedures are described mainly for [L-Ala²]-AM-toxin I and its derivatives as a representative case. Other compounds were synthesized in a similar way. Physical constants, yields, and the results of elemental analyses are summarized in Table 1.

Boc-L-Ala-L-Ala-L-Hmb-L-Amp-OBzl (3a-L). Boc-L-Ala-OH (0.45 g, 2.37 mmol), H-L-Ala-L-Hmb-L-Amp-OBzl·HCl[1] (1.23 g, 2.37 mmol), and Et_3N (0.33 ml, 2.37 mmol) were dissolved in $CHCl_3$ (15 ml). To the solution was added EDC·HCl (0.50 g, 2.61 mmol) at 0 °C. The mixture was stirred for 2 h at 0 °C and overnight at room temperature, evaporated *in vacuo*, and the residue was treated with a mixture of water and EtOAc. The organic layer was washed with 4% $NaHCO_3$, 10% citric acid and water, dried (Na_2SO_4), and evaporated to leave an oil, which was crystallized by the addition of ether and petroleum ether; yield, 1.39 g. The solid was contaminated with a small amount of by-products and was purified with a silica gel column (3.3×40 cm) using a solvent of $CHCl_3$–EtOAc (1: 1). The fractions (260—380 ml) were collected and evaporated, and the residual solid was recrystallized from EtOAc–ether–petroleum ether; yield, 1.24 g (79%).

Boc-L-Ala-L-Ala-L-Hmb-L-Amp-OH (4a-L). Ester **3a**-L (1.12 g, 1.70 mmol) was dissolved in THF (20 ml) and hydrogenated in the presence of Pd black. The filtrate from the catalyst was evaporated and the residue was crystallized from $CHCl_3$–petroleum ether; yield, 0.89 g (93%).

Boc-L-Ala-L-Ala-L-Hmb-L-Amp-ONSu (5a-L). To a chilled solution of **4a**-L (453 mg, 0.80 mmol) in DMF (5 ml), HONSu (138 mg, 1.20 mmol) and EDC·HCl (184 mg, 0.96 mmol) were added at 0 °C. After 24 h at 0 °C the solution was evaporated, and the residual oil was solidified by the addition of water. Powder obtained was filtered off quickly and dried over P_2O_5; yield, 531 mg (100%); R_f^1 0.87.

A Mixture of Cyclopeptides (7a-L). Ester **5a**-L (531 mg, 0.80 mmol) was dissolved in TFA (5 ml) at 0 °C. After 20 min the solution was evaporated to leave an oil, which was solidified by the addition of ether. The solid (**6a**-L·TFA) obtained was dissolved in DMF (5 ml) and stirred in pyridine (260 ml) at room temperature. After 24 h the solution was evaporated, and the residue was triturated with cold water and 10% citric acid; yield of solid (**7a**-L), 300 mg (84%). TLC of **7a**-L showed three spots by monomer (**8a**-L), dimer (**9a**-L), and trimer (**10a**-L).

Cyclo(-L-Amp-L-Ala-L-Ala-L-Hmb-) ([L-Ala²]-AM-toxin I) (8a-L). Mixture **7a**-L (300 mg) was added to dioxane (20 ml) and the suspension was stirred at room temperature for 1 day. The insoluble solid was collected and washed with hot dioxane (yield of the solid, 180 mg), the filtrate (**7a**-L-**f**)

being put aside for the isolation of **9a**-L. The solid was dissolved in hot DMF (2 ml) and cooled to room temperature. The resulting precipitate was collected with the aid of dioxane (yield of the precipitate, 34 mg), the precipitate (**7a**-L-**p**) being used for the isolation of **10a**-L. The filtrate was evaporated, and the residue was repeatedly recrystallized from the following solvent systems: DMF–EtOAc, DMF–dioxane, and DMF–EtOAc–ether; yield of **8a**-L, 95 mg (27%).

Cyclo[-(L-*Amp*-L-*Ala*-L-*Ala*-L-*Hmb*)$_2$-] (**9a**-L). The filtrate **7a**-L-**f** mentioned above was evaporated, and the residue (107 mg) was crystallized from dioxane–EtOAc–ether–petroleum ether; yield, 66 mg. Further recrystallization from dioxane–ether–petroleum ether gave 60 mg (17%).

Cyclo[-(L-*Amp*-L-*Ala*-L-*Ala*-L-*Hmb*)$_3$-] (**10a**-L). The precipitate **7a**-L-**p** mentioned above was crystallized from DMF–EtOAc–ether; yield, 29 mg (8%).

Cyclo(-L-*Amp*-D-*Ala*-L-*Ala*-L-*Hmb*-) ([D-*Ala*^{2}]-*AM-toxin I*) (**8a**-D). Ester **5a**-D (332 mg) obtained from **4a**-D (283 mg, 0.50 mmol) was treated with TFA as described for **7a**-L, and **6a**-D·TFA obtained was subjected to cyclization reaction for three days. After evaporation of pyridine the residue was triturated with cold water and filtered off. Recrystallization of the solid from DMF–EtOAc gave 161 mg (72%).

Hydrogenation of Natural AM-toxin I. Natural **1a** (4 mg, 9 μmol) was dissolved in AcOH (5 ml) and hydrogenated in the presence of Pd black. The filtrate from the catalyst was evaporated, and the residue (3.2 mg) showed two spots on TLC corresponding to **8a**-L and **8a**-D. A portion (1.6 mg) of this residue was dissolved in 6 M HCl (1 ml) and hydrolyzed at 110 °C for 24 h. After evaporation the residue was dissolved in a mixture of water (0.5 ml) and dioxane (0.5 ml) and the mixture was neutralized by the addition of Et_3N. To this mixture were added a solution of Z-L-Leu-ONSu (7.8 mg, 21 μmol) in dioxane (0.5 ml) and Et_3N (14 μmol) at 0 °C. The reaction mixture was stirred for 2 h at 0 °C and overnight at room temperature. After evaporation, the residue was dissolved in a mixture (3 ml) of MeOH–AcOH–water (5:1:1) and hydrogenated in the presence of Pd black. The product was evaporated, and an aliquot of the diastereomeric dipeptides obtained was applied to an amino acid analyzer.[6] The molar ratio of L-Leu-L-Ala to L-Leu-D-Ala was determined to be 2.21: 1.00. After the correction of one equivalent of L-alanine present in **1a** as L-Ala^3, the ratio of **8a**-L to **8a**-D in the hydrogenated product was calculated to be 0.38: 0.62. When natural **1a** was hydrogenated in dioxane instead of AcOH, the ratio was 0.41: 0.59.

NMR Spectroscopy. Figure 3 shows the NMR spectra of **8a**-L and **8a**-D in TFA at ambient temperature with sample concentration at 15 mg/0.4 ml. Signals of **8b**-D were assigned as follows: δ=0.92 (3H, d, J=7.0 Hz, HmbCH$_3$), 1.04 (3H, d, J=7.0 Hz, HmbCH$_3$), 1.38 (3H, d, J=7.0 Hz, D-Ala^2-CH$_3$), 1.58 (3H, d, J=7.0 Hz, L-Ala^{3}CH$_3$), 2.2 (1H, m, HmbβH), 3.0—3.4 (2H, ABX, Tyr(Me)CH$_2$), 4.00 (3H, s, OCH$_3$), 4.5—5.0 (3H, m, αH), 5.12 (1H, d, HmbαH), 6.98—7.30 (5H, aromatic H and NH), 7.58 (1H, d, J=10.0 Hz, Tyr(Me)NH), 7.80 (1H, d, J=9.0 Hz, D-Ala^{2}NH). Because of poor solubility of **8a**-D and **8b**-D the use of other solvents was not attempted.

Biological Assay. Biological assay on apple leaves (susceptible cultivar, Indo) was carried out as described previously.[7] The minimum toxic concentrations of **8a**-D and **1a** were 5—10 and 0.002 μg/ml, respectively. **8a**-L, **8b**-L, and **8b**-D showed no activity in high concentration up to 100 μg/ml.

Results and Discussion

Since the results of the bioassay revealed a distinct difference between the activity of **8a**-L and that of **8a**-D, we investigated the conformations of these diastereomeric peptides in order to clarify the structure-activity relationship. The NMR spectra of **8a**-D and **8b**-D

showed well resolved but very similar patterns (one difference between them being the splitting of the Hmb side chain), suggesting the presence of a common and stable conformation for **8a**-D and **8b**-D. On the other hand, **8a**-L and **8b**-L displayed complex spectra indicating that each of these L-peptides is a mixture of at least two conformers. For example, **8a**-L and **8b**-L gave the complex signals of α-CH and NH protons in contrast with the well resolved signals of the corresponding protons of **8a**-D and **8b**-D. Furthermore, **8a**-L revealed weak signals with the same chemical shifts at those obtained in **8a**-D or **8b**-D spectra, such as doublets at 1.40 ppm and at 7.80 ppm.

These observations suggest that predominant conformations of **8a**-L and **8b**-L differ from those of **8a**-D and **8b**-D. Unfortunately, information obtained from the NMR spectra was not sufficient to deduce a definite conformation for **8a**-D and **8b**-D. At least two conformations were in line with the results of NMR study; one with the all-*trans* backbone system[8] and the other with the *cis-trans-cis-trans* backbone.[9] In general the presence of *cis* peptide bond is observed only for α-imino acid such as proline. In case of cyclotetrapeptides, however, the all-*trans* backbone system has to be strained because of steric constraint.[10] Thus, the presence of a conformation containing a *cis* bond can not be excluded. Natural **1a** showed similar NMR spectra to those of **8a**-D. However, rapid decomposition of **1a** in TFA made further study difficult.

The ORD curves of selected synthetic peptides are shown in Figs. 4 and 5. All cyclic tetradepsipeptides show a significant trough, [α]=−6000—−9000°, around 245 nm region in their ORD curves. In contrast, ORD curves of dimers (**9a**-L and **9b**-L) and a trimer(**10a**-L) show a shallow trough around 245 nm, the depth being less than −2500°. The results suggest that peptide

chromophores in cyclic tetradepsipeptides have a certain distinct spatial orientation, but chromophores in peptides with larger ring structure together with linear tetradepsipeptide derivatives have no such definite orientation. In contrast to NMR spectra, there is no

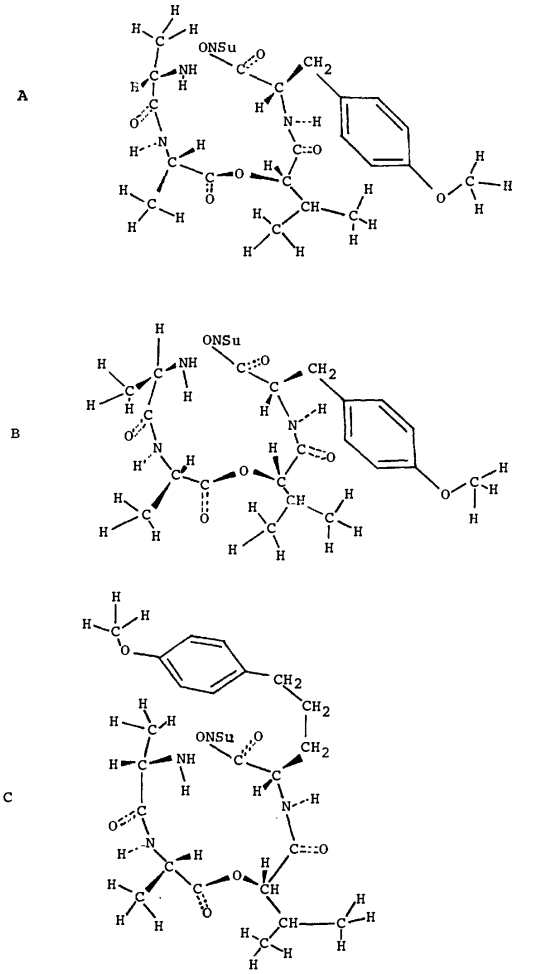

Fig. 6. Supposed conformation of reaction-intermediates in cyclization reaction starting from: A, H-L-Ala-L-Ala-L-Hmb-L-Tyr(Me)-ONSu (**6b**-L); B, H-D-Ala-L-Hmb-L-Tyr(Me)-ONSu (**6b**-D); C, H-L-Ala-L-Ala-L-Hmb-L-Amp-ONSu (**6a**-L).

distinct difference between **8a**-D or **8b**-D and **8a**-L or **8b**-L in their ORD curves. All these cyclotetradepsipeptides should have a similar orientation of chromophores.

Previous results showed that cyclic tetradepsipeptides containing one ester bond are obtained in high yields by cyclization reaction when a hydroxy acid residue occupies the third position from N-terminus in linear precursors.[5] An explanation for this finding has been presented.[7] Results obtained in this study indicate that not only the sequence of linear peptides but also the presence of D-amino acid in the N-terminus is important for giving a cyclic monomer in high yield. Exclusive formation of monomers (**8a**-D and **8b**-D) is of particular interest. This and the corresponding NMR data suggest that monomeric cyclization can readily proceed when a D-amino acid residue is present in a linear precursor. A possible substance of the intermediate having a *cis-trans-cis-trans* backbone is shown in Fig. 6. The methyl group in N-terminal L-Ala may hinder the access of the active ester group in Tyr(Me) (Fig. 6-A). In case of **6b**-D, the methyl group in D-Ala leads to a leftward direction away from the active ester (Fig. 6-B). Not only the active ester but also the bulky side chain in Amp was sterically hindered by the methyl group in L-Ala (Fig. 6-C). The fact that **6a**-L yielded much more dimer and trimer than **6b**-L supports this view. A similar discussion holds for another conformer with all-*trans* backbone.

Rich *et al.* reported that tentoxin, a similar phytotoxic cyclotetrapeptide, loses its activity upon hydrogenation even in high concentrations.[11] Since saturation of the double bond in the Dha^2 residue in **1a** results in about 2000—5000 times lowering in activity, the presence of the double bond in Dha^2 is undoubtedly important. However, while **8a**-D still retains recognizable activity (5—10 μg/ml), **8a**-L is inactive even in 100 μg/ml. This shows that the presence of a double bond is not an exclusive factor for revealing activity and that some other unknown factor seems to play a role in the activity. NMR studies indicate the presence of a common conformer of **8a**-D and **8b**-D. On the other hand, the content of the same conformer of **8a**-L and **8b**-L, if any, must be extremely low. This suggests the specific conformation is related to biological activity.

We thank Dr. H. Aoyagi, Kyushu University, for his skillful technical assistance and valuable discussion. We also thank Prof. H. Fukami and Dr. T. Ueno, Kyoto University, for the supply of natural AM-toxin I.

Dehalogenative Coupling of *gem*-Dihalides and Benzyl Halides by Means of Hexacarbonyltungsten(0) and Related Compounds

Yuzo FUJIWARA* Ryuichi ISHIKAWA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 8, 1977)

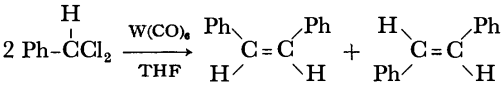
$W(CO)_6$ and WCl_6–$LiAlH_4$ systems have been found to cause coupling of *gem*-dihalides and benzyl halides giving olefins and bibenzyl derivatives, respectively. The tungsten reagents also cause coupling of some alcohols. The carbene intermediate was suggested from the formation of a cyclopropane derivative.

Dehalogenative coupling of organic halides by transition metal complexes is of importance for the formation of carbon-carbon bond.[1] Transition metal complexes such as iron, nickel, cobalt, and palladium complexes cause coupling of *gem*-dihalides to give olefins or cyclopropane derivatives.[2]

Coffey reported that metal carbonyls such as $Fe(CO)_5$ or $W(CO)_4$(pyridine)$_2$ cause coupling of *gem*-dihalides, but not $W(CO)_6$ probably because of the complete shielding of tungsten atom by carbon monoxide ligands.[3] However, in the course of studies on the reactions with tungsten compounds, we found that $W(CO)_6$ as well as WCl_6–$LiAlH_4$ is highly reactive for the reactions of *gem*-dihalides, benzyl halides, and also alcohols at room temperature. In this paper, we report on the coupling reactions of *gem*-dihalides, benzyl halides and some alcohols by lower valent tungsten compounds to give coupling products, the mechanism also being given.

Results and Discussion

Reaction of gem-*Dihalides.* The reaction of hexacarbonyltungsten(0), $W(CO)_6$, with benzylidene dichloride in THF at room temperature under nitrogen atmosphere gave (*E*)- and (*Z*)-stilbenes in 41 and 7% yields, respectively.[4]



The coupling reactions of benzylidene dichloride by zerovalent tungsten carbonyl complexes, and also tungsten hexachloride, WCl_6, plus lithium aluminum hydride, $LiAlH_4$, are summarized in Table 1. In order to attain good yields, it was important to use a half equivalent amount of *gem*-dihalides to tungsten reagents.

Table 1. Coupling of benzylidene dichloride by tungsten(0) carbonyls

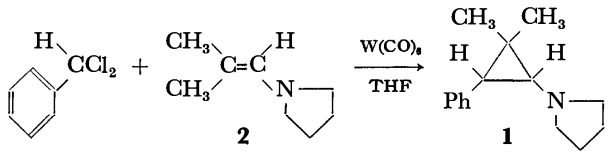
Tungsten carbonyl	Stilbene yield,% [a]	
	E	*Z*
$W(CO)_6$	41	7
$W(CO)_6$–$AlCl_3$ [b]	64	8
$W(CO)_5PPh_3$	56	7
$W(CO)_5NH_2C_6H_{11}$	40	5
WCl_6–$LiAlH_4$ [b]	43	8

a) Based on benzylidene dichloride. b) An amount (0.4 mmol) equivalent to tungsten compounds was added.

Coffey reported that $W(CO)_6$ causes no coupling of *gem*-dihalides in refluxing benzene.[3] On the contrary, $W(CO)_6$ was found to cause readily coupling of the dihalides even at room temperature. Addition of an equivalent amount of $AlCl_3$ to the $W(CO)_6$ system increases the yield. This is probably because $AlCl_3$ eliminates CO ligand from $W(CO)_6$ furnishing the coordinatively unsaturated site. Triphenylphosphine-pentacarbonyltungsten(0) is as reactive as $W(CO)_6$–$AlCl_3$. WCl_6 alone is not reactive for the reaction. However, addition of $LiAlH_4$ causes the reaction. This suggests that WCl_6 is reduced by $LiAlH_4$ to some lower valent tungsten species such as W(II) which is active for the reaction.

The coupling reactions of other *gem*-dihalides by $W(CO)_6$ and WCl_6–$LiAlH_4$ reagents are summarized in Table 2. We see that $W(CO)_6$ is as reactive as WCl_6–$LiAlH_4$ for the coupling reaction. Although the coupling occurs with alkyl dihalides, the yield is lower than that of aromatic halides. Since $W(CO)_6$ is relatively stable against air and easy to handle, this provides a convenient synthetic route for symmetric olefins.

Mechanism. Coffey[3] and Joshi[5] suggested a carbene mechanism for transition metal carbonyl-promoted coupling reaction. Furukawa and Kiji also suggested a carbenoid intermediate in the reaction of $Ni(COD)_2$, $Fe(CO)_5$ or $Co(CO)_8$ with *gem*-dihalides by obtaining cyclopropane derivatives.[2] On the other hand, the reaction with $Co_2(CO)_8$ proceeds step by step by a radical process.[6] In order to investigate the intermediate, we attempted to trap a carbene intermediate. From the reaction of benzylidene dichloride and $W(CO)_6$ in the presence of 1-(2-methyl-1-propenyl)-pyrrolidine (**2**), cyclopropane derivative (**1**) was obtained in 13% yield together with 9% yield of stilbene. This shows that a carbene intermediate is involved during the course of reaction. Similarly cyclopropane (**1**) was formed in 1% yield by the reaction with WCl_6–$LiAlH_4$ system.



It should be pointed out that $W(CO)_6$ catalyzes the olefin metathesis reaction involving a carbene intermediate.[7] Thus there is another route for the formation of **1**, *viz.*, $W(CO)_6$ and the stilbene formed by the

a) Based on *gem*-dihalides. b) A: WCl_6–$LiAlH_4$, B: $W(CO)_6$. c) D. F. Hoeg and D. I. Lusk, *J. Organomet. Chem.*, **5**, 1 (1966). d) W.D. Emmons, *Org. Synth.*, **47**, 34 (1967).

coupling of benzylidene dichloride, give rise to a carbene complex, $XW{=}C\langle^{Ph}_{H}$ which then would react with olefin **2** to give **1**. However, this possibility could be ruled out from the fact that only 0.5% yield of **1** was obtained when the reaction of stilbene and $W(CO)_6$ was performed under similar reaction conditions. Thus we suggest the following reaction path involving the formation of a carbene-W complex (**3**) from the reaction

$$R_2CCl_2 + W(CO)_6 \longrightarrow \underset{\mathbf{3}}{\left[(CO)_xCl_2W{=}CR_2\right]}$$

$$\mathbf{3} \longrightarrow R_2C{=}CR_2 + WCl_2(CO)_x$$

of *gem*-dihalides and $W(CO)_6$, and subsequent dimerization of the carbene derived from the carbene complex (**3**).

Cross Coupling of Benzylidene Dichloride with Benzaldehyde. Benzaldehyde has been found to react with $W(CO)_6$ or WCl_6–$LiAlH_4$ to give stilbene derivatives in a high yield. Carbene-W complex is thought to be an intermediate of this coupling reaction.[8] It is expected that cross coupling between *gem*-dihalides and benzaldehyde could take place on being treated with $W(CO)_6$ or WCl_6–$LiAlH_4$. We found that from the reaction of benzylidene dichloride and *p*-methoxybenzaldehyde in the presence of WCl_6–$LiAlH_4$, *p*-methoxystilbene (*E* and *Z*) was obtained in 8% yield together with stilbene (*E*, 5%, *Z*, 1%) and *p*,*p*-dimethoxystilbene (*E*, 44%, *Z*, 2%). $W(CO)_6$ similarly brings about the cross coupling.

Reaction of Alcohols and Benzyl Halides. The transition metal-promoted dehydroxygenative coupling of alcohols to dimeric compounds is known.[9] In connection with coupling of *gem*-dihalides described above, we carried out reactions of alcohols, and found that $W(CO)_6$ and WCl_6–$LiAlH_4$ are also active for coupling reaction. In this case, reaction gives saturated hydrocarbons but no olefins. The results are summarized in Table 3. Coupling of benzyl alcohols proceeds smoothly to give bibenzyl derivatives. However, alkyl alcohols are far less reactive. Benzyl halides were also found to undergo coupling to give bibenzyl derivatives.

In conclusion it was made clear that zerovalent tungsten carbonyls such as $W(CO)_5L$ (L=CO, $P(Ph)_3$, and $C_6H_{11}NH_2$) and WCl_6–$LiAlH_4$ cause coupling of *gem*-dihalides, benzyl halides, and some alcohols to give olefins or dimeric hydrocarbons.

Experimental

Materials. Benzylidene dibromide,[10] diphenyldibromomethane,[11] *p*-methoxybenzylidene dichloride,[12] *p*-chlorobenzylidene dichloride,[13] and 1-(2-methyl-1-propenyl)pyrrolidine,[14] were prepared according to the reported methods. Other starting materials were of commercial grade. THF was refluxed and distilled from a dark purple solution of sodium benzophenone dianion under nitrogen. WCl_6 was purified by sublimation. $W(CO)_5PPh_3$ was prepared from $W(CO)_6$ and triphenylphosphine according to the literature.[15] Cyclohexylaminepentacarbonyltungsten(0) was prepared from $W(CO)_6$ and cyclohexylamine.[16]

General Procedure for Coupling of gem*-Dihalides by Tungsten Carbonyls.* In a flame-dried, 50-ml centrifuge tube containing a magnetic stirring bar, were placed 10 ml of THF and tungsten carbonyl (0.4 mmol), the tube then being sealed with a No-Air stopper. After the tube had been flushed with nitrogen, 0.2 mmol of *gem*-dihalides was added by means of a syringe. The mixture was stirred for 6 h at room temp under nitrogen atmosphere. The tube was then cooled to −78 °C, and the precipitated tungsten complexes were removed by filtration. The filtrate was poured into ether and the ether layer was washed with water and dried with Na_2SO_4. After evaporation of the solvent, the products were analyzed and isolated by gas chromatography. The products were identified by comparison of melting point, IR, NMR, and retention time with those of authentic samples. The results are summarized in Tables 1 and 2.

General Procedure for Coupling of gem*-Dihalides by WCl_6–$LiAlH_4$.* In a flame-dried, 50-ml centrifuge tube containing a magnetic stirring bar, was placed 10 ml of THF by means of a syringe, and the tube was sealed with a No-Air stopper. After the tube had been flushed with nitrogen, the solvent was cooled to −78 °C, and WCl_6 (0.4 mmol) and $LiAlH_4$ (0.4 mmol) were added under nitrogen atmosphere. The solution turned dark brown from green. Then 0.2 mmol of *gem*-dihalides was added with a syringe. The mixture was stirred for 6 h at room temp under nitrogen atmosphere. The reaction mixtures were quenched with 20% aq NaOH. The organic materials were extracted with ether. The ethereal solution was washed with water and concentrated. The products were analyzed by VPC. The results are summarized in Tables 1 and 2.

Trapping of Carbene Intermediate. In a flame-dried, 50-ml centrifuge tube containing a magnetic stirring bar, were placed 10 ml of THF and 0.4 mmol of $W(CO)_6$ and the tube was sealed with a No-Air stopper. After the tube had been flushed with nitrogen, 0.2 mmol of benzylidene dichloride and excess amounts (10 ml) of 1-(2-methyl-1-propenyl)pyrrolidine (**2**) were added. The mixture was stirred for 6 h at room temp under nitrogen atmosphere. After the same work-up as described above the products were analyzed by VPC to obtain 1-(2,2-dimethyl-3-phenylcyclopropyl)pyrrolidine (**1**) and stilbene in 13 and 9% yields, respectively. These products were identified by comparison with standard samples.

Cross Coupling of Benzyl Chloride with Benzaldehyde. Reaction was carried out using the same procedure as described above charging WCl_6, $LiAlH_4$ (0.8 mmol each), benzylidene dichloride (0.2 mmol), *p*-methoxybenzaldehyde (0.2 mmol), and THF (10 ml). Products analysis was carried out by VPC using authentic samples. The products were *p*-methoxystilbene (*E* and *Z*, 8%), stilbene (*E*, 5%, *Z*, 1%), and *p*,*p*-dimethoxystilbene (*E*, 44%, *Z*, 2%).

Coupling of Alcohols. Reactions were performed as in the coupling of *gem*-dihalides under the same reaction conditions. The results are given in Table 3. The products were identified by comparison with authentic samples.

*Preparation of 1-(2,2-Dimethyl-3-phenylcyclopropyl)pyrrolidine (**1**).* In a 300-ml, three-necked, round-bottomed flask equipped with a magnetic stirring bar, dropping funnel, nitrogen inlet, and a condenser with a bubble counter at the top was placed a solution of 3.5 g of CuCl, 45 ml of 1-(2-methyl-1-propenyl)pyrrolidine (**2**) and 200 ml of abs ether. Then 20 ml of phenyldiazomethane in 50 ml of ether was added dropwise over 2 h under nitrogen. The mixture was stirred for 20 h at room temp and then filtered, ether being evaporated. The residue was distilled to give the starting pyrrolidine (**2**) and colorless oil, bp 103—105 °C/1 Torr (*ca.* 1 g) which was purified by preparative VPC (column OV-17) and assigned to 1-(2,2-dimethyl-3-phenylcyclopropyl)pyrrolidine. IR (neat): 2992, 1445, 1456, 1183, 754, and 703 cm^{-1}. NMR (C_6D_6): δ 7.12(s, 5H), 2.80—2.12(m, 4H), 1.85(d, 1H, J= 6.6 Hz), 1.78—1.48 (m, 4H), 1.41 (s, 3H), 1.12 (d, 1H, J= 6.6 Hz), and 0.84 (s, 3H). MS: *m/e* 215 (M^+). Found: C, 83.92; H, 9.59%. Calcd for $C_{15}H_{21}N$: C, 83.67; H, 9.83%. Infrared spectra were recorded on a Japan Spectroscopic IR-E spectrometer. NMR spectra were obtained with a JEOL C-60HL spectrometer with TMS as an internal standard. Mass spectra were obtained with a Hitachi RMS-4 spectrometer.

Some Aspects on the Mechanism of Palladium-complex-catalyzed Decomposition of and Cyclopropanation with Ethyl Diazoacetate

Akira NAKAMURA, Teruhisa KOYAMA, and Sei OTSUKA

Department of Chemistry, Faculty of Engineering Science, and Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

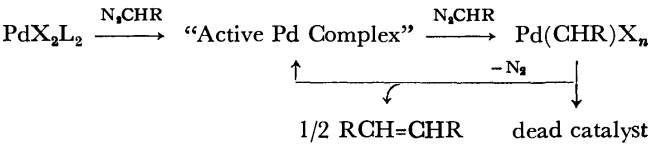
(Received August 11, 1977)

Carbenoid decomposition of ethyl diazoacetate in the presence of various palladium complexes as catalysts was found to kinetically depend on the identity of halide ligands. The use of several chiral ligands did not induce appreciable enantioselective catalytic cyclopropanation between ethyl diazoacetate and styrene. The active catalyst species is not under the influence of the chiral ligands but under control of halides which are bound more strongly to the metal.

Transition metal-catalyzed cyclopropanation reactions are one of the important organic synthesis.[1] Although (a) various Ag and Cu salts, (b) ligand-modified Cu, Pd, and Rh catalysts and (c) Lewis-acidic metal halides have been known[1-10] to induce homo- or heterogeneously-catalyzed decomposition of diazoalkanes, the mechanism or the nature of active species, however, has remained to be elucidated. Since a variety of ligand-modified palladium complexes act as efficient catalysts, we have examined the Pd-catalyzed reaction in some detail and the results are reported here.

Results and Discussion

Palladium(II) complexes of type, PdX_2L_2 (X= halide, L=neutral ligand), are active for decomposition of ethyl diazoacetate at room temperature in homogeneous solutions. The ligand effect was studied to obtain information on the active species. The catalytic activity can be assesed by rates of nitrogen evolution from the diazo compound (Table 1). An induction period is generally observed. After attaining the maximum rate, the decomposition by $PdCl_2(PPh_3)_2$ and $PdBr_2(PPh_3)_2$ slowed down according to apparent first- to third-order kinetics with respect to concentration of the free diazoacetate. The order also depends on concentration of the catalyst (Table 1). The rate for the corresponding iodide, however, seemed to obey zero- to first-order kinetics depending on the initial concentration of the catalyst. The length of the induction period was proportional to the initial catalyst concentration. The maximum rate attained after the induction period was also roughly proportional to the catalyst concentration but independent of the diazo concentration (*cf.* Table 1). The rate especially at low catalyst concentrations fell rapidly as the reaction proceeds. Apparently this is due to deterioration of the active catalyst. The following reaction scheme is consistent with the kinetics.



The reaction of the active Pd species with diazo acetate becomes the rate-determining step after the induction period. In the case of the decomposition by $PdI_2(PPh_3)_2$, the subsequent unimolecular decomposition of $Pd(CHR)I_n$ becomes rate-determining. The rate-determining step thus varies depending on the halide ligands.

The palladium-complex-catalyzed carbenoid reaction in neat cyclohexene gave a mixture of carbene dimers and cyclopropanation products (*endo*- and *exo*-norcarane-7-carboxylates) listed in Table 2. The isomeric product ratios obtained by the several palladium complexes catalysts are not critically influenced by the identity of the neutral ligands. By contranst, the length of induction period depends on L when a comparison was made among five $PdCl(\eta^3\text{-}C_3H_5)L$ catalysts; L=Py, 2 min, PPh_3 10 min, P-*n*-Bu_3, 15 min, $P(OPh)_3$ 15 min; P(O-*n*-Bu)$_3$, 2 min. The results contrasts with the catalysis by cobalt(II) dioximato chelates[11,12] which show a dramatic effect by added donor molecules, *e.g.* pyridine. Asymmetric synthesis of ethyl 2-phenylcyclopropanecarboxylate was attempted by reaction of ethyl diazoacetate with styrene in the presence of the following chiral palladium complexes; dichlorobis((*S*)-α-methylbenzylamine) palladium, di-μ-chlorobis(7,1,2-η^3(−)-pinenyl) dipalladium, bis[(−)-hydroxymethylenecamphorato] palladium, di-μ-chlorobis[(*S*)-*N*,*N*-dimethyl-α-methylbenzylamine-2-*C*, *N*]dipalladium,[21] di-μ-chlorobis[(*S*)-*N*,*N*-dimethyl-2-naphthylamine-3-*C*,*N*]palladium,[22] and bis(β-camphorquinone dioximato)palladium.[16] However, the optical yields of the cyclopropane isomers were only 0—2% although

Table 1. Dependence of apparent order of the carbenoid reaction of ethyl diazoacetate and induction periods on concentration of palladium(II) catalysts

Catalyst	Catalyst concentration (mmol/l)	Apparent[a] order with [N_2CHCO_2-Et] concn	Induction periods (min)	Max. rates (N_2 evolved/min) (ml)
$PdCl_2(PPh_3)_2$	4	2.0	33	3.3
	2	2.2	25	2.0
	1	4.0	15	0.9
$PdBr_2(PPh_3)_2$	4	1.5	15	3.2
	2	2.1	14	1.7
	1	2.8	8	0.9
$PdI_2(PPh_3)_2$	4	0	35	0.5
	2	1.0	30	0.7
	1	1.6	30	0.4

a) The order was determined graphically by plotting the rate (ml/min) *vs.* time after the maximum rate is attained.

TABLE 2. RATIOS OF ISOMERIC CARBENOID REACTION PRODUCTS FORMED BY Pd-COMPLEX-CATALYZED REACTION BETWEEN ETHYL DIAZOACETATE AND CYCLOHEXENE[a)]

Catalyst precursor	Temp (°C)	Isomer ratios of products: Diethyl fumarate/diethyl maleate	Isomer ratios of products: *exo/endo* in ethyl norcaranecarboxylate
$PdCl_2(cod)$	60	2.5	4
$PdCl_2(PPh_3)_2$	20	2.5	10
$[PdCl(C,N\text{-phe})]_2$[b)]	60	2	5
$[PdCl(C,N\text{-phe})]_2$[b)]	20	1.3	8

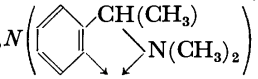
$PdCl(\eta\text{-}C_3H_5)\cdot[P\text{-}(n\text{-}Bu_3)]$	20	4	10
$PdCl(\eta\text{-}C_3H_5)\cdot[P(OPh)_3]$	20	5	10
$PdCl(\eta\text{-}C_3H_5)\cdot[P(O\text{-}n\text{-}Bu)_3]$	20	4	10

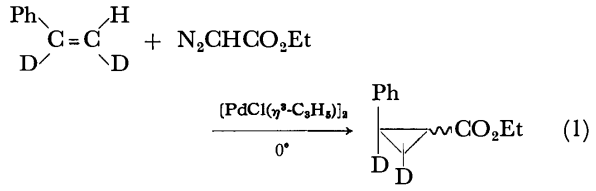
a) Reaction conditions: catalyst concentration; 0.01 mol/l, diazoacetate concentration 2 mol/l in neat cyclohexene. b) C,N-phe=*N,N*-Dimethyl-α-methylbenzylamine-2*C,N*



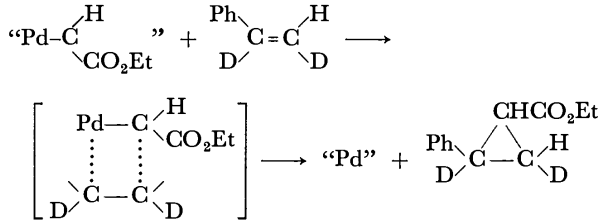
the chemical yields were good (*ca.* 70%). The absence of the appreciable chiral ligand effect implies that the neutral, η^3(C), C,N-, N,N-, or O,O-ligands are mostly eliminated during the formation step of the active species. The elimination of these ligands seems to take place by the reaction of transient reactive carbene-metal moiety generated from diazo compounds. The reaction of coordinated η^3-C_3H_5, phosphines, or isocyanides with diazoalkanes has been known to give CH_2=CH–CH_2=CHR,[15] alkylidenephosphorane (R_3P=CHR)[1] or ketenimine (RCH=C=NR).[1,14] The corresponding reaction with coordinated halides seems to be a very slow process.[13]

Some palladium complexes at the formal oxidation state of one and zero are also examined. A chloro-bridged Pd(I) complex, $[PdCl(t\text{-BuNC})_2]_2$, was found active without an induction period. The catalysis of $[PdCl(\eta^3\text{-}C_3H_5)]_2$ also belongs to this category. Pd-$(PPh_3)_4$ and $Pd_2(t\text{-BuNC})_4$ were weakly active at room temperature, but the catalysis deteriorated readily. These observations indicate formal oxidation state of the metal to be unimportant. The catalysis critically depends on the identity of the metal in a similar ligand environment. Thus, $PtCl_2(PPh_3)_2$ showed only a weak activity even at 60 °C. By contrast $[RhCl(CO)_2]_2$, $[RhCl(C_8H_{12})]_2$, $[RhCl(C_2H_4)_2]_2$, and $RuCl_2(PPh_3)_3$ have very high activity at room temperature. No activity was found for $NiCl_2(PPh_3)_2$ or $CoCl_2(PPh_3)_2$.

The stereochemical paths of the $[PdCl(\eta^3\text{-}C_3H_5)]_2$-catalyzed cyclopropanation was investigated by using *cis*-dideuteriostyrene. As shown in Eq. 1, an almost complete retention of the original stereochemistry at the olefin was observed.



This contrasts to the bis(camphorquinone dioximato)-cobalt-catalysis where a considerable stereochemical inversion (up to 35%) is involved.[16] Thus, the Pd-catalysis is characterized with a stereochemical retention for the olefin component implying a multicentered transition state.



Since free carbenes with CO_2Et substituents are known to be triplet especially in the presence of compounds with heavy atoms, this result suggests the catalytically active species is not the free carbene.

We have a already studied thermal reactions of Pd(0) diazoalkane complexes, $PdL_2(dfl)$: L=PPh_3, *t*-BuNC; dfl=9-diazofluorene, where *N,N*-η^2-coordination of the diazoalkane was established.[14,17] The coordination retards the decomposition with nitrogen evolution and hinders the olefin attack leading to cyclopropanes. The observed low activity of Pd(0) complexes is thus understood. In contrast to the retardation of decomposition by virtue of these metal complexes with high metal electron densities, a Lewis acidic center, *e.g.* $ZnCl_2$, or $FeCl_3$, acts as an effective catalyst site.[1,10] The present palladium or rhodium catalysis does not involve such a strong Lewis acidic site. A different orbital interaction must be postulated for the present catalysis. Clearly, a further study including molecular orbital analysis is required.

Experimental

The following metal complexes were prepared by the methods in literature; $[PdCl(t\text{-BuNC})_2]_2$,[18] $PdCl_2(cod)$,[19] $[PdCl(\eta\text{-}C_3H_5)]_2$,[20] and known chiral Pd complexes[21,22] mentioned in the text. Some new chiral Pd complexes were prepared as follows.

a) Bis(hydroxymethylenecamphorato)palladium(II): An ethanol solution (4 ml) of (−)-hydroxymethylenecamphor (1.8 g) was mixed with an aq suspension of $PdCl_2$(0.6 g, 3.4 mmol) at 80 °C and then with aq KOH (1 M, 1.5 ml). The brown suspension turned into a yellow precipitate in 30 min. which was filtered and dried. Recrystallization from a mixture of hot benzene and hexane gave orange crystals (78% yield, mp 170 °C dec, $[\alpha]_D^{23}$ +153° (c=0.4)).

b) Dichlorobis(α-methylbenzylamine)palladium(II): A methanol solution (5 ml) of K_2PdCl_4 (0.22 g, 0.7 mmol) was mixed with (−)-α-methylbenzylamine (0.29 g, 2.4 mmol) with stirring to give a yellow precipitate which was filtered, dried, and recrystallized from a mixture of benzene and hexane (yield 87%, mp 131—134 °C, $[\alpha]_D^{23}$ −39.0° (c=4.95)).

Kinetics of Catalytic Decomposition of Ethyl Diazoacetate. A palladium complex in question (0.04—0.01 mmol) dissolved in benzene (20 ml) was mixed with a benzene solution (2 ml) of ethyl diazoacetate (0.23 g) under nitrogen in a 50 ml flask connected with gas burettes at 30.0°. The reaction mixture was stirred magnetically in a flask covered with aluminum foil to prevent any photodecomposition of the diazo compound during the catalysis. The amount of evolved gas was followed to measure the decomposition rate. The reaction mixture remained apparently homogeneous throughout the kinetic runs, but after the prolonged standing a small amount of metallic palladium deposited. The products from the catalyzed cyclopropanation in cyclohexene performed under the conditions described in Table 2 were analyzed by GLC (Apiezon Grease L).

Cyclopropanation of cis-*Dideuteriostyrene with Ethyl Diazoacetate by* $[PdCl(\eta\text{-}C_3H_5)]_2$. *cis*-Dideuteriostyrene was prepared by selective hydrogenation of phenylacetylene with deuterium gas in the presence of Lindlar catalyst and found to be stereochemically 86% pure. A solution of ethyl diazoacetate (2.09 g, 18.3 mmol) in the styrene-d_2 (1.3 ml) was added to a solution of $[PdCl(\eta\text{-}C_3H_5)]_2$ (0.21 g, 0.56 mmol) in the styrene-d_2 (2.5 ml) at 0° with stirring. After vigorous nitrogen evolution had ceased, the reaction mixture was distilled (85—87°C/2 Torr) to give ethyl 2,3-dideuterio-*cis*- and -*trans*-2-phenylcyclopropanecarboxylate (0.3 g, 8.6% yield, *trans*/*cis*=1.5). Each isomer of the cyclopropanes was separated by GLC and hydrolyzed to the corresponding acids. Since the ^{1}H-NMR spectra of each isomeric acids had been already assigned, the stereochemical distribution of deuterium was determined by the nmr to find *cis*-d_2/*trans*-d_2=6.1 for the *trans*-phenyl compound and *cis*-d_2/*trans*-d_2=2.6 for the *cis*-phenyl compounds. Corrections due to the stereochemical purity of 86% of the starting styrene were made to find the stereochemical process at the cyclopropanation leading to the *trans*-phenyl compounds to be completely retention.

The authors acknowledge the experimental assistance of Mr. A. Konishi and M. Kudo.

(Received August 13, 1977)

Rate constants of solvolysis of 3′- and 4′-substituted 1-(4-biphenylyl)ethyl chlorides were measured in 80% (v/v) aqueous acetone. The effect of substituents could be correlated excellently with the LArSR relationship.

$$\log k/k_0 = -1.56(\sigma^0+0.84\Delta\bar{\sigma}_R^+)$$

The ρ and r^+ values are smaller than those in the corresponding phenyl system under identical conditions ($\rho=-4.95$, $r^+=1.15$). The difference of the r^+ values is interpreted in terms of twisting of the two phenyls around the pivot bond in biphenyl. The same treatment has been applied successfully to other sets of reactivity data; solvolysis, protodesilylation, alkaline hydrolysis, and piperidinodebromination. The results indicate a consistently reduced effectiveness of *pi*-electronic transmission in biphenylyl relative to phenyl system in all reactions studied.

In our continuing interest in substituent effects, the LArSR relationship, Eq. 1,[1,2] has been investigated in order to apply it to reactivities for the *pi*-systems beyond the phenyl system; extensive rate studies have already been performed in the solvolysis of substituted 1-phenylethyl chlorides.[2]

$$\log k/k_0 = \rho(\sigma^0+r^+\Delta\bar{\sigma}_R^++r^-\Delta\bar{\sigma}_R^-) \quad (1)$$

In the substituted 1-naphthyl system,[3] the substituent effect was successfully separated into a reaction-independent inductive (*I*) effect and a reaction-dependent *pi*-electronic (*Pi*) effect.

To check the general applicability of the LArSR Eq. 1 to substituent effects in the biphenylyl system and to compare the resulting substituent-effect parameters with those of the corresponding phenyl system,[2] we have studied the solvolysis of 3′- and 4′-substituted 1-(4-biphenylyl)ethyl chlorides. The present paper discusses (i) the LArSR treatment for the biphenylyl reactivities, where the different types of electrophilic and nucleophilic reactions available[4a] are included, and (ii) the comparisons of the resulting parameters with those obtained in the phenyl systems under the same conditions. These results must reflect the characteristic features of the intervening biphenylyl *pi*-system between substituents and the reaction center.

Results and Discussion

Rate constants for the solvolysis of nine 3′- and 4′-substituted 1-(4-biphenylyl)ethyl chlorides were determined in 80% (v/v) aqueous acetone at convenient temperatures to give moderate rates which were followed with the usual acid-base titration method. All kinetic runs followed accurately the first-order kinetic law. The reproducibility of the rate constants from repeated runs was within ±1.5%. The 4′-substituted derivatives were confirmed to be of 99—100% purity, based on their infinity readings, while the 3′-halogeno derivatives, which were used for kinetic measurements immediately after the evaporation of solvent and without purification, were estimated to be of *ca.* 97% purity.

The rate constants at various temperatures and the relative rates with respect to substituents are listed in Table 1,[4b] together with the activation parameters. The activation entropies obtained are quite constant at −11.8±1.5 eu (10.7±0.3 log A unit) over the range of substituent, suggesting the operation of a constant mechanism throughout the series.[2] Logarithms of the relative rates at 45 °C are linearly correlated in excellent precision (corr coeff, $r=0.9997$, $s=\pm0.016$) with those at 25 °C, giving a slope of 0.950. The temperature change provides a negligibly small effect on the ρ value with a change of only a few percent. As anticipated from the intervention of the second phenyl group between substituents and the reaction center, apparent substituent effects in the biphenylyl system are much smaller than those in the corresponding phenyl system, for the electronic effects of substituents are transmitted across a longer distance or a larger number of bonds to the reaction center.

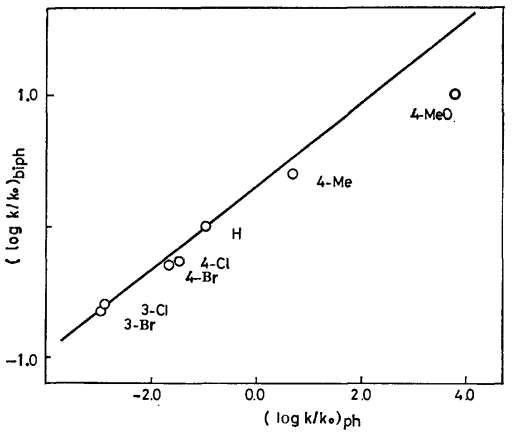

Fig. 1. The log-log plot of biphenylyl *vs.* phenyl system in the present solvolysis.

The log *k*-log *k* plot of the solvolysis rates between the biphenylyl and the phenyl systems under identical conditions does not show a linear relation (Fig. 1). All −*R*(*pi*-donor) 4′-substituted derivatives deviate downward from the line drawn through the 3′-substituted and unsubstituted derivatives, suggesting not only a far smaller ρ value but also a smaller r^+ value for the 4-biphenylyl system than for the phenyl system ($\rho=$

a) Extrapolated or interpolated from other temperatures.

−4.95, $r^+=1.15$).[2]

A plot of the biphenylyl data at 45 °C against Brown's σ^+ [5,8] appears to give a good linear relation with a ρ^+ value of −1.46 ($r=0.9988$, $s=\pm0.037$, $n=9$); the dotted line in Fig. 2. An unfavorable deviation is seen for the unsubstituted point; this amounts to 0.08 log-unit, which corresponds to a 20% change in the rate constant obtained. Such an error should not be expected for the rate measurements.

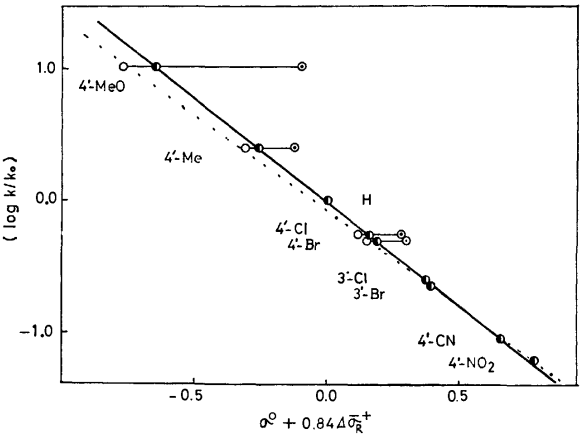

Fig. 2. The LArSR plot for the solvolysis of 1-(4-biphenylyl)ethyl chlorides at 45 °C (◐). A dotted line shows Brown's σ^+ correlation; ○ and ⊙ indicate σ^+ and σ° plots for $-R$ substituents, respectively.

The application of Eq. 1[1,2] provides an excellent correlation, with a standard deviation of ±0.023 and a correlation coefficient of 0.9996 (Fig. 2).[6]

$$\log k/k_0 = -1.56(\sigma^0+0.84\Delta\bar{\sigma}_R^+) - 0.03$$

In this plot, there is no particular deviation. The $\rho(-1.56)$ obtained is identical with the ρ value determined from the 3′-substituents and $+R$(*pi*-acceptor) 4′-substituents ($\rho=-1.57$, $r=0.9987$, $s=\pm0.028$, and $n=5$). The identity indicates that the effects of 3′-substituents (and $+R$ 4′-ones) in the 4-biphenylyl system can be practically treated just as those of the *meta* (and $+R$ *para*) substituents in the phenyl system.

Inukai has reported[7] that the solvolysis data of 1-(4-biphenylyl)-1-methylethyl chlorides also showed downward deviations for $-R$ substituents on the simple σ^+ plot, although the reaction center was the same as that for the reference reaction of σ^+. It was well understood that such deviations resulted from the r^+ (0.67) value, which was smaller than unity (Table 2, Reaction C). Similarly, the recent results of Bolton and Burley for the substituent effects on α-(4-biphenylyl)benzyl chlorides[27] are also best treated with a r^+ value of 0.75 (Table 2, Reaction B). These facts illustrate the assertion that our LArSR Eq. 1 can describe the solvolyses in the 4-biphenylyl system more precisely than does Brown's treatment. The lower r^+ values indicate that the resonance contribution from $-R$ substituents in 4′-position to the stabilization of the transition state is less effective in the biphenylyl system.

The LArSR treatment has been found to be generally applicable to other reactivities in the biphenylyl systems. The results of the correlation analysis are shown in Table 2, in comparison with those in the phenyl systems under the same conditions for the respective reactivities, although the substituent-effect data available are too limited to check the applicability thoroughly. The table includes six typical electrophilic reactions[4a] (solvolyses of secondary and tertiary chlorides, protodesilylation, alkaline hydrolysis of esters, and acid dissociation) and a typical nucleophilic reaction[16] (piperidinodebromination). It is clear at a glance that the correlation for

Substituents involved are too limited (from *p*-Me to *m*-Br) to get an accurate ρ. f) For the corresponding phenyl system, the r^- of 0.77 was employed (see Text). g) Correlation coefficient. h) Standard deviation. i) Number of substituents involved.

every reaction is excellent ($R>0.99$), except for F reaction, where the biphenylyl system has a very small ρ. Thus, in general, the LArSR treatment is equally applicable to 4-biphenylyl reactivities.

In the comparison between the biphenylyl and phenyl systems, the ratio of ρ values, ρ_{Biph}/ρ_{Ph}, is as a good approximation *ca.* 0.3 in all cases; the ratios of r, r^+_{Biph}/r^+_{Ph}, for A, B, C, and D reaction series (in Table 2) are of the magnitude of 0.5—0.7. For the solvolysis of benzhydryl chlorides, $r^+_{Ph}=1.17$ (in EtOH)[28] was employed for this calculation. The r^+_{Biph} values for E and F series are not quite as reliable as the others, because of the low sensitivities to substituent change ($\rho_{Biph}\simeq 0.5$). In the case of the nucleophilic reaction[4a] of G series, we could not find the substituent-effect data in the phenyl system which corresponded to the same conditions as those in the biphenylyl system. Most recently, we have studied the reactions of 4-substituted 1-chloro-2-nitrobenzenes and 4-substituted 1-fluoro-2-nitrobenzenes with piperidine in MeOH,[17] which could be correlated excellently by means of the LArSR Eq. 1; in the former piperidinodechlorination at 80 °C, $\rho=3.86$, $r^-=0.77$ ($R=0.998$, $s=\pm 0.106$, $n=14$) and in the latter piperidinodefluorination at 25 °C, $\rho=4.02$, $r^-=0.78$ ($R=0.999$, $s=\pm 0.08$, $n=7$). Since the leaving groups of Cl and F gave identical r^- values, it is reasonably estimated that the piperidinodebromination may have a similar amount of nucleophilic resonance exaltation ($r^-=0.77$).[18] Then, the ratio of r^-, r^-_{Biph}/r^-_{Ph}, for G reaction will be of the magnitude of 0.5.

These features of the ratios of r^+ and r^- lead us to the view that there is no simple linear log k-log k relationship between the biphenylyl and phenyl systems for a reaction with $r^\pm_{Ph}>0.5$. However, if a given reaction shows a smaller contribution from the resonance effect ($r^\pm_{Ph}<0.5$), such a linearity may hold practically within experimental uncertainty; in fact both E and F series belong to this case.[11,12]

As far as the comparison of substituent effects between the biphenylyl and phenyl systems are concerned, the relative ρ can be taken as a measure of the transmission of polar effects (more exactly inductive effects) of substituents in biphenylyl relative to the phenyl system. According to a field effect model by Kirkwood-Westheimer,[19] ρ is derived to be proportional to the reciprocal of the square of the distance R,

$$\rho = A\cos\theta/R^2,$$

where A is a constant under given reaction conditions, θ is the angle between a C–X (substituent) dipole and a distance vector to a reaction center, and R is the distance between them. Since $\cos\theta\simeq 1$ (4′- or *para* position of substituents) and $A_{Biph}/A_{Ph}\simeq 1$ can reasonably be expected, the following relation may hold to a first approximation:

$$\rho_{Biph}/\rho_{Ph} = (A_{Biph}/A_{Ph})(R^2_{Ph}/R^2_{Biph}) \simeq R^2_{Ph}/R^2_{Biph}.$$

The relative ρ values are in good agreement with the respective values calculated by using simplified distances (Table 3); this seems to suggest the importance of the transmission mode through the field, as far as the

present comparisons are concerned.

Dewar and Grisdale assumed that the factor controlling the inductive effect in ΔpK_a of substituted naphthoic and biphenylcarboxylic acids is solely the electrostatic field effect, the magnitude of which is expressed by a function of the reciprocal of the distance.[20a] As summarized in Tables 2 and 3, the data sets accumulated for biphenylyl reactivities and the results properly analyzed have come to show that the $1/R^2$ approximation is likely to be a more precise description of the ρ (inductive effect) than the Dewar approximation. An alternative mode based on successive polarizations through intervening bonds, however, is not completely ruled out. The transmission factor per one phenyl ring is calculated to be 0.31, as an average of A and C reactions. This figure results in a transmission factor of 0.63[20b] per a sp^2 carbon unit, which is slightly smaller than the values estimated from 1-naphthyl[3] and other side chain reactivities.[4c]

Comparisons of r values in both biphenylyl and phenyl systems also give us interesting facts concerning the loss of resonance in the intervening *pi*-electronic system. Since the apparent substituent constants can be rewritten in terms of σ_i and σ_π,[1] the use of the relative q_r value, instead of the relative r, is reasonable for a net comparison of *pi*-electronic effect.

$$\bar{\sigma} = \sigma^0 + r^+\Delta\bar{\sigma}_R^+ + r^-\Delta\bar{\sigma}_R^- = \sigma_i + q_r^+\sigma_\pi^+ + q_r^-\sigma_\pi^-, \quad (2)$$

where $q_r^+=1+r^+/0.415$ and $q_r^-=1+r^-/0.73$. The relative q_r values, as tabulated in Table 3, reflect the effectiveness of resonance in the biphenylyl relative to the phenyl system and show nearly a constant value of 0.76 ± 0.04. The q_r^+ ratios obtained from the four electrophilic exalted resonance reactions,[4a] A, B, C, and D, agree quite well with the q_r^- ratio of the nucleophilic exalted resonance reaction,[4a] G. It should be noted here that the same type of treatment can be successfully performed with the $+R$ class of substituents in nucleophilic exalted reactions. The resulting relative q_r^- is just equivalent with the well-examined relative q_r^+'s in the electrophilic cases. It is then concluded that the relative effectiveness of *pi*-electronic transmission in the biphenylyl to the phenyl system remains constant in spite of the quite different types of reactions.

In the usual approximation, the reduced effectiveness may be explained in terms of a twisting of two phenyls around the pivot bond in biphenyl.[21] If the total reduced effect is to be caused only by the factor of twisting, the angle can be calculated to be *ca.* 30° from the relation of $\cos^2\theta=0.75$. The angle in a solution has been estimated to be around 35° from some sources.[22] Then the two phenyl rings in biphenyl probably act as if the twisting angle remains nearly the same in all reactions.

The reactivity difference between the present biphenylyl and phenyl derivatives may also be considered as a factor affording lower r^+ values for the biphenylyl system: in the present solvolysis, the former is *ca.* 10 times more reactive than the latter. The increased stabilization of the transition state by the second phenyl ring in biphenylyl should cause a decreased demand for the electron releasing resonance contribution from 4'-substituents. This may predict a lower r^+ value. If this is the case, a much lower r^+ value would be expected in the corresponding fluorenyl system because of the coplanarity of the second phenyl ring. Our experimental results[4c] show clearly that this is not the major factor. A more detailed discussion on the twisting should be done with an alternative comparison between the biphenylyl and fluorenyl systems.

Finally, it is worth particular emphasis that the LArSR relationship, which is based on reactions in the phenyl system, applies equally excellently to reactivities in the other *pi*-system of biphenylyls.

Experimental

Materials. 4-Methyl-, 4-chloro-, 4-bromo-, and 3-chlorobiphenyls were prepared by the Gomberg-Bachmann reaction.[23] 4-Methoxybiphenyl was made by methylation of commercial 4-hydroxybiphenyl in an alkaline solution with slight modifications of the standard Hier's method[24] (87% yield). 3-Bromobiphenyl was prepared as directed by Mowry from 2-aminobiphenyl *via* 2-amino-5-bromobiphenyl.[25]

Almost all 4-acetylbiphenyls were obtained by the usual Friedel-Crafts acetylation of the above monosubstituted biphenyls. 3-Bromo-4'-acetylbiphenyl was prepared by following a slight modification of Berliner's directions.[12] After decomposition of the complex produced, the simple procedure of cooling its solution, instead of successive extraction procedures, gave crude crops (mp 36—37 °C) in 64% yield (recrystd from ligroin; mp 40.5—41 °C). 4-Cyano-4'-acetylbiphenyl was prepared from 4-bromo-4'-acetylbiphenyl by using CuCN in DMF[26] (50% yield, mp 117—120 °C). 4-Nitro-4'-acetylbiphenyl (mp 150—151 °C) was obtained in 27% yield by an acetylation ($AlCl_3$, Ac_2O, nitrobenzene solvent) of 4-nitrobiphenyl. Melting and boiling points of all monosubstituted biphenyls and substituted 4-acetylbiphenyls prepared were equal or very close to the literature values[12,25] and the elemental analysis data agreed with the calculated values.

The acetylbiphenyls were reduced with lithium aluminium hydride or sodium borohydride (especially for the CN and NO_2 derivatives) to the corresponding 1-(4-biphenylyl)ethanol by standard methods. Except for the CN and NO_2 derivatives, every chloride was prepared with dry HCl gas in dry ether as described before.[2] After evaporation of the solvent, crude crops of chlorides were purified by recrystallization from appropriate solvents. 3'-Chloro and 3'-bromo derivatives (liquid) were employed for kinetics without purification; the respective alcohols were purified and, just before kinetics, they were converted into the chlorides for rate measurements. 4'-Cyano and 4'-nitro substituted chlorides were made by the

method of thionyl chloride[2] and purified by recrystallization from hexane-benzene. The physical constants are listed in Table 4.

Solvent and Kinetic Measurements. The 80%(V/V) aqueous acetone was prepared by mixing 4 volumes of purified acetone and 1 volume of distilled water at room temparature (*ca.* 20 °C). Different batches of the solvent in this study were found to give an identical solvolysis rate for the 4′-chloro (or 4′-bromo) derivative within experimental errors; the interpolated rate for the unsubstituted derivative at 45 °C reasonably agreed with the previous rate measured at 45 °C.[2] The determination of the first-order rate constants in 80% aq acetone followed the method described previously;[2] Bromothymol Blue was used as an indicator. Temperatures were controlled within ±0.02 °C.

(Received August 13, 1977)

Two sets of rate constants for (i) solvolysis of 1-(7-substituted 2-fluorenyl)ethyl chlorides in both 90 and 80% aqueous acetone and (ii) alkaline hydrolysis of ethyl 7-substituted 2-fluorenecarboxylates in 85% aq EtOH have been determined. Both substituent effects could be correlated excellently with the LArSR relationship; the resulting r^+ values (0.82 and 0.47, respectively) were comparable with the r^+'s in the corresponding biphenylyl system under the same conditions. The comparison of ρ_π^+ values clearly indicates a more efficient transmission of the *pi*-electronic effect in the fluorenyl than in the biphenylyl ststem (1 : 0.75). This can be attributed to a factor of twisting in the latter *pi*-system. The attenuation of the transmission of the *Pi* effect was found to be characteristic of the intervening *pi*-systems independent of reactions: 1.00(4-X-1-phenyl), 0.55(6-X-2-naphthyl), 0.35(7-X-2-fluorenyl), and 0.25(4′-X-4-biphenylyl).

In previous papers of this series, we demonstrated successful applications of the LArSR relationship (Eq. 1), which is based on reactivities in the phenyl system, to reactivities in some extended *pi*-systems, such as 4-biphenylyl[1] and 1-naphthyl systems.[2]

$$\log k/k_0 = \rho(\sigma^0 + r^+\Delta\bar{\sigma}_R^+ + r^-\Delta\bar{\sigma}_R^-) \quad (1)$$

We have been interested further in substituent effects in the fluorenyl system from the viewpoint of the structural similarity in the biphenylyl system,[1] but disregarding the problem of planarity.[3] It can then, be expected that comparisons of substituent effects between fluorenyl and biphenylyl systems under the same conditions can provide important information on the transmission of electronic effects, especially the *pi*-electronic effect, across these *pi*-systems, if Eq. 1 is generally valid.

Although fragmentary data on the pK_a values for some fluorenols and fluorenylamines are available,[4,5] systematic studies of substituent effects in the fluorenyl system have been scarcely reported. Available is only a set of reactivity data for detritiation in CF_3COOH, coupled with biphenylyl data.[6] The reactivity range covered is, however, too limited to estimate and compare the *pi*-electronic effects for our present purposes because of the use of a strongly acidic solvent.[9] Two typical electrophilic reactions in 7-substituted 2-fluorenyl systems with very different amounts of resonance exaltation have been chosen. The one is solvolysis of 1-(2-fluorenyl)ethyl chlorides (Ia), while the other is alkaline hydrolysis of ethyl 2-fluorenecarboxylates. Just before this article was to be submitted, another set of solvolysis data appeared in the literature:[6b] a pair of substituent effects in α-(2-fluorenyl)benzyl chlorides (Ib) and α-(4-biphenylyl)benzyl chlorides (IIb) in 9 : 1 EtOH–acetone. Our systematic substituent-effect data coupled with those in the literature show clearly the characteristics of the intervening fluorenyl and biphenylyl systems.

Results and Discussion

The rates for the solvolysis of seven 1-(7-substituted 2-fluorenyl)ethyl chlorides Ia in 90% (v/v) aqueous acetone were determined at convenient temperatures by means of the usual acid-base titration method. First-order rate constants, $k_1(s^{-1})$, at various temperatures and the relative rates in 2-fluorenyl system with respect to substituents at the 7-position at 25 °C are listed in Table 1, together with some activation parameters; for the MeO, CN, and NO_2 derivatives, the k_1 values at 25 °C were extrapolated from those at other temperatures by means of the Arrhenius equation. Further, the rates for the solvolysis of the same chlorides in 80% (v/v) aq acetone were also determined for the

a) Extrapolated from a linear free-energy relation between rates in 80 and 90% aq acetone (see Text).

sake of comparison. In the latter solvent, apparent substituent effects in the fluorenyl system can be directly compared with those in biphenylyl and phenyl systems under identical conditions.[1,7] Table 2 contains the kinetic data in 80% aq acetone obtained in the same manner as those in 90% aq acetone.

The k_1 for 7-MeO-2 derivative in 80% aq acetone was extrapolated from the following linear $\log k/k_0$-$\log k/k_0$ correlation between substituent effects in 80 and 90% aq acetone with a high precision (corr coeff, $r=0.9996$, $s=\pm0.031$, $n=6$):

$$(\log k/k_0)_{80\%} = 1.065(\log k/k_0)_{90\%} - 0.029.$$

The minor solvent change from 80 to 90% causes only a small change in the ρ value, but none in the r^+ value of Eq. 1.[8]

On the other hand, the rates for the alkaline hydrolysis of seven ethyl 7-substituted 2-fluorenecarboxylates in 85% (w/w) aq EtOH at 50 °C were measured by means of usual conductivity and/or titration methods. The second-order rate constants, k_2(s^{-1} M^{-1}), and the logarithmic relative rates are listed in Table 3. Unfortunately, we could not get a k_2 for the NO_2 derivative in this ester hydrolysis because the solubility was insufficient to measure it.

a) We could not get a k_2 of the NO_2 deriv. because of the solubility problem. b) T: titration method, C: conductivity method.

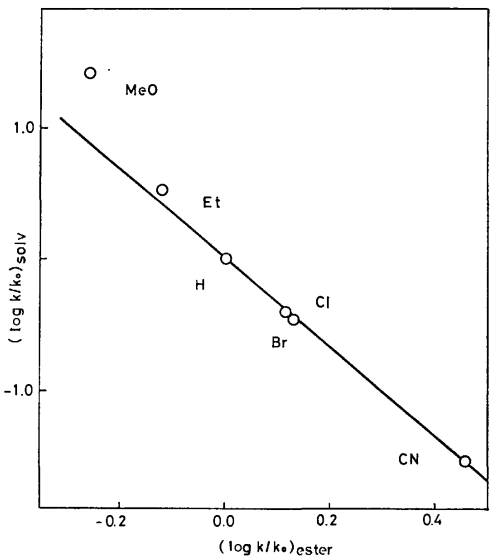

Fig. 1. A plot of $\log k/k_0$ for the solvolysis A (90% acetone, 25 °C) *vs.* the ester hydrolysis D(85% EtOH, 50 °C) in the present 7-X-2-fluorenyl system.

Logarithms of the relative rates for the solvolysis (90% aq acetone) in the fluorenyl system are plotted against those for the ester hydrolysis in Fig. 1. The $-R$(*pi*-donor) substituents deviate upward from the line made with CN and H substituents, for which no exaltation of resonance might be expected. The more electron-releasing the $-R$ substituent at such a conjugative position, the larger the upward deviation. The deviations indicate that the contribution of through-conjugation between substituents and the reaction center for the solvolysis is much more important to the apparent substituent effects than those for the ester hydrolysis, at least at the conjugative (7-)position in the 2-fluorenyl system. Similar upward deviations had also been obtained in the biphenylyl system on the log-log plot of the relative rates between the corresponding solvolysis and ester hydrolysis.[1]

An interesting feature which we found in this study is that there exists an excellent linearity (Fig. 2) of the solvolysis rates (25 °C) between fluorenyl (90%) and biphenylyl (80%) systems, covering a range of substituents from MeO to NO_2 ($r=0.9998$, $s=\pm0.026$, $n=7$):

$$(\log k/k_0)_{\text{Fluo}} = 1.362(\log k/k_0)_{\text{Biph}} - 0.028.$$

The linearity suggests that the blends of the *pi*-electronic (*Pi*) effect and the inductive (*I*) effect are practically equivalent in the two systems for the present solvolysis.

Eaborn *et al.* first observed this kind of behavior in detritiation and pointed out that the effects of 7-substituents in the 2-fluorenyl are similar to those of 4'-substituents in the 4-biphenylyl system;[6] a correlation analysis of their detritiation data in CF_3COOH at 70 °C provides high precision with this relation: $(\log k/k_0)_{\text{Fluo}} = 1.11\ (\log k/k_0)_{\text{Biph}}$ ($r=0.9986$, $s=\pm0.08$, $n=6$). Even though the detritiation has been established as a typical electrophilic exalted resonance reaction, since it inevitably contains serious solvent-substituent interaction, MeO derivatives in both *pi*-systems are less reactive than Me ones; therefore, the reactivity range is limited for only

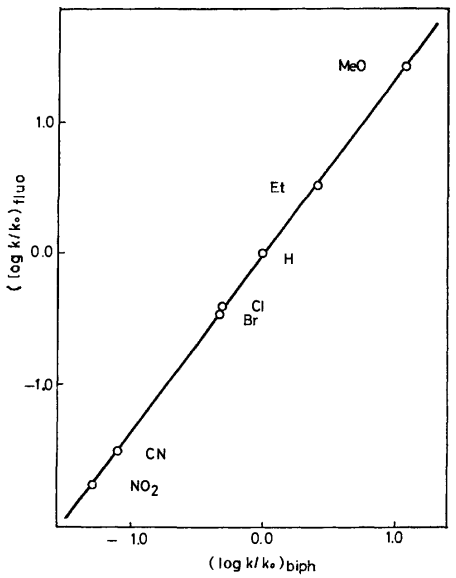

Fig. 2. The linear log k/k_0 —log k/k_0 plot between fluorenyl (90% acetone, 25 °C) and biphenylyl (80% acetone, 25 °C) in the present solvolysis A (Ia *vs.* IIa).

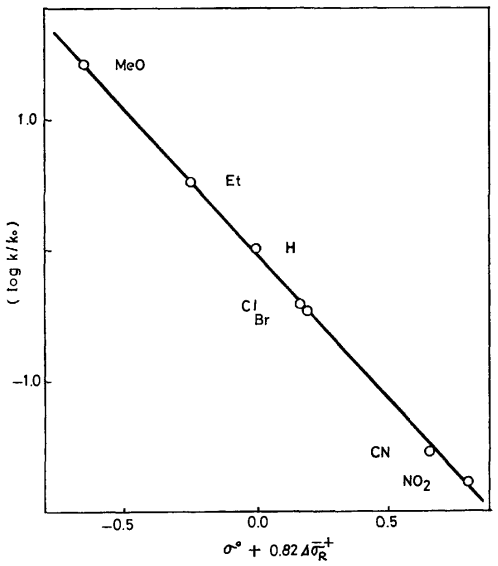

Fig. 3. The LArSR plot for the solvolysis A of 1-(7-X-2-fluorenyl)ethyl chlorides (90%, 25 °C).

weakly conjugating substituents.[9] Bolton and Burley have recently observed a similar linearity between the solvolyses of Ib and IIb (with a slope of 1.45, $r=0.999$), which covers nearly the same range of substituents as ours.

As another example for comparison between the fluorenyl and the biphenylyl systems, the present data of ester hydrolysis are correlated linearly with Berliner's data on the alkaline hydrolysis of ethyl biphenylcarboxylates[10] ($r=0.9935$, $n=5$); since the rates are not very sensitive to substituent changes in either system, it is hard to ascertain whether or not their *Pi* effects relative to *I* effects are different. From the findings in the above reactions, the linear relationships of the substituent effects between the fluorenyl and the biphenylyl systems seem to be quite general.

The present solvolysis of the Ia fluorenyl system

correlates linearly with a single set of neither σ^0 nor σ^+, as has been discussed in the biphenylyl system.[1] The application of the LArSR Eq. 1 to the data Ia in 90% aq acetone (25 °C) gives an excellent correlation (Fig. 3) with the correlation coefficient of 0.9993 and the standard deviation of ± 0.053 ($n=7$), providing nearly the same r^+ value (0.82) as that in the biphenylyl system (0.84):[1]

$$(\log k/k_0)^{\text{Solv}}_{\text{Fluo}} = -2.231(\sigma^0+0.815\Delta\bar{\sigma}_R^+) - 0.050.$$

Further, the substituent effects on the alkaline hydrolysis of ethyl 2-fluorenecarboxylates can be accommodated simply with neither σ^0 nor σ, but can be accommodated successfully with the LArSR Eq. 1:[11]

$$(\log k/k_0)^{\text{Ester}}_{\text{Fluo}} = 0.628(\sigma^0+0.470\Delta\bar{\sigma}_R^+).$$

The results of correlation analysis for the present and the related reactivity data available under closely similar conditions are summarized in Table 4, covering three solvolyses and ester hydrolysis. For comparisons of representative *pi*-systems through which the effects of substituents are effectively transmitted, the table also includes some naphthyl systems as well as the fluorenyl and biphenylyl ones. From nearly perfect fits in every case (Table 4), it may be concluded that substituent effects from conjugative positions in any extended *pi*-systems for any reactions can generally be described by means of the LArSR Eq. 1, at least in electrophilic exalted resonance reactions.

Table 4 shows clearly that substituent effects depend greatly on the structures of the intervening *pi*-systems. The ρ values decrease systematically in the following order: phenyl$\simeq$(1-naphthyl)>2-naphthyl>2-fluorenyl >4-biphenylyl. The ρ values relative to that in the phenyl system (see Table 5) appear to remain constant for the other systems: phenyl (1.00), 2-naphthyl (0.65), 2-fluorenyl (0.46), and 4-biphenylyl (0.32); slight deviations from such a quantitative regularity are found only in the fluorenyl and biphenylyl systems for ester hydrolysis (*ca.* 0.25 and 0.20 respectively). The relative ρ values for 1-naphthyl can not be fairly compared, because their ρ's are usually subject to variation with the steric effects of peri-hydrogen; *e.g.*, on solvation at the reaction center.

On the other hand, each solvolysis gives nearly equal apparent r^+ values for the 2-fluorenyl, 4-biphenylyl, and 2-naphthyl systems in spite of the different ρ values, while the ester hydrolysis offers an apparently larger r^+ in the fluorenyl system. However, it is worth noting that the resonance contribution given by ρr^+ is clearly larger for the 2-fluorenyl than for the 4-biphenylyl system in all the reactions listed (Table 4). As long as the parameters of σ^0 and $\Delta\bar{\sigma}_R^+$ derived from the original phenyl system are utilized for the present LArSR analysis in the fluorenyl and biphenylyl systems, the comparison of ρr^+ is much more reasonable than that of simple r^+ as a measure of the resonance contribution in such extended *pi*-systems.[37] The larger ρr^+ values are exactly in line with the concept of the planar-fluorenyl and nonplanar-biphenylyl systems.

In previous papers,[2] we demonstrated the validity of a more fundamental LSFE Eq. 2 for separating substituent effects into *Pi* and *I* effects in variously substituted 1-naphthyl systems. As the LSFE treatment has been much more useful,[2,18,38] especially in extended *pi*-systems beyond original phenyl systems, it is actually very important to get reliable ρ_i and ρ_π parameters:

$$\log k/k_0 = \rho_i\sigma_i + \rho_\pi^+\sigma_\pi^+ + \rho_\pi^-\sigma_\pi^-. \quad (2)$$

Only when a given set of substituent-effect data covers a sufficient range of reactivity and sufficient numbers of substituents for both $-R$ and $+R$ classes of substituents, we can get reliable ρ_i, ρ_π^+, and ρ_π^- values statistically.[38] In the case of the present data sets, which contain only a few $+R$ substituents, it is, however, perhaps rather dangerous to use statistical ρ_π^- values and then ρ_π^+ values for discussions because of the too limited number of substituents. If it is assumed that ρ_π^- is equal to ρ_i (as in the LArSR treatment), and if σ_i' is provided as $\sigma_i+\sigma_\pi^-$ for $+R$ substituents in electrophilic reactions (and $\sigma_i'=\sigma_i$ for $-R$ substituents), then Eq. 2 should be rewritten as

$$\log k/k_0 = \rho_i\sigma_i' + \rho_\pi^+\sigma_\pi^+,$$

for both $-R$ and $+R$ groups. Consequently, the statistically derived ρ_i and ρ_π^+ values (on the basis of the σ_i' and σ_π^+ correlations) should cover the same range of substituents and should have the same accuracy as in the LArSR treatment. Usually, a data set of an electrophilic reaction involves a few $+R$ substituents such as NO_2 and CN. Therefore, it is recommended in practice that the substituent effects be separated into *Pi* and *I* effects by interconversions of the LArSR parameters to the LSFE parameters, instead of by a direct determination from the LSFE Eq. 2. Based on the definitions of $\sigma^0=\sigma_i+\sigma_\pi^+$ and $\sigma_\pi^+=0.415\ \Delta\bar{\sigma}_R^+$, the LSFE parameters hold the following mathematical relations with the LArSR parameters:[19]

$$\rho_i = \rho, \quad \rho_\pi^+ = \rho(1+r^+/0.415). \quad (3)$$

The ρ_i and ρ_π^+ values can be evaluated by means of Eq. 3 from the ρ and r^+ values in Table 4. Table 5 illustrates the ρ_i, ρ_π^+ values relative to those in the phenyl system; these values show the corresponding

Table 5. Relative ρ_i and ρ_π^+ values in some *pi*-systems

Reaction[a]	*Pi*-system[a]	Relative[b] ρ_i	Relative[b] ρ_π^+

relative effectiveness through which *Pi* and *I* effects are transmitted.

It is worth emphasizing that there exists a remarkable regularity in the attenuation behavior on the transmission of *Pi* effects. That is, a decrement remains constant for any given *pi*-system independent of the reactions or, more exactly, independent of the varied contributions of *Pi* effects in any type of reaction. The effectiveness of transmission is generally 55% for the 2-naphthyl, 35% for the 2-fluorenyl, and 25% for the 4-biphenylyl, as large as that for the phenyl *pi*-system. The variations probably reflect characteristics of the systems.

Because of their geometrical similarity, substituent effects between fluorenyl and biphenylyl systems can be compared most interestingly. The ratio of the *Pi* effects, biphenylyl/fluorenyl, for the present solvolysis is calculated to be 0.72, reflecting the obviously decreased effectiveness of the transmission across the intervening biphenylyl relative to the fluorenyl system. This figure must be well related with the twisting angle of both phenyl rings in biphenyl, because such a twisting is expected to decrease the *Pi* contribution. In the case of ester hydrolysis, the ratio shows a slightly larger value (0.78), probably the result of slight differences in the reaction conditions. Some proper correction will provide a value closer to 0.72. At any rate, the averaged value of 0.75 ± 0.03 is remarkably the same as the previous value obtained on the basis of a different comparison between the biphenylyl and phenyl systems.[1] Table 5 also indicates that the 6-X-2-naphthyl system is 1.6 times more effective than 7-X-2-fluorenyl in transmitting the *Pi* effects, although their r^+ values appear to be equal.

On the other hand, we can not get any regularity in the attenuation of relative *I* effects among the systems studied, though a limited regularity probably holds in three solvolyses, A, B, and C, in Table 4, as has been mentioned above. The results of the A solvolysis (ArCHMeCl) show the ρ_i in the fluorenyl system to be larger than that in the biphenylyl system. Further, for another solvolysis, B (ArCHPhCl), the same thing is true.

These findings are not consistent with the transmission mode of the *I* effect through a field, since the simplified distance between substituents and the reaction center is equivalent for this pair. As a factor controlling the magnitude of the apparent ρ_i, the nature of the intervening bonds, such as the bond-order in the pivot bond in the biphenyl component, may be incorporated with another factor of distance.[1] The excellent linearity between the 2-fluorenyl and the 4-biphenylyl systems may, therefore, imply that the ρ_i is also a function of the interplanar angle. This suggests that the higher the bond-order character of the intervening bond, the larger the ρ_i, even if the simplified distance is equal. This suggestion seems to be consistent with the results shown in Table 6.

The table compares the results of the LArSR treatment for the substituent-effect data available on ester hydrolysis under similar conditions. A major point in which we are interested is the nature of the intervening bond. When the intervening group between a substituted phenyl group and COOEt changes from $-CH_2CH_2-$ to -cyclopropyl- to $-CH=CH-$, the ρ's obviously change from 0.6 to *ca.* 0.9, and *ca.* 1.2 respectively. This suggests some operation of intervening bond-order effects on the transmission of the *I* effect.

In summary, it is particularly important to note that the LArSR relationship can be applied equally well to reactivities in extended *pi*-systems such as 7-X-2-fluorenyl and 6-X-2-naphthyl, other than the phenyl system.

Experimental

Materials. *2-Substituted Fluorenes*: 2-Acetylfluorene (mp 127.5—128 °C),[24] 2-nitrofluorene (mp 160.5 °C), and 2-ethylfluorene (mp 99—100 °C) were prepared by the standard procedures previously reported.[25-27] 2-Chlorofluorene was made as has been described by Sengupta,[28] with slight modifications; chlorine gas was passed through a $CHCl_3$ solution of fluorene under cooling, until the IR absorbance at 764cm^{-1} of the product periodically extracted from the reaction mixture became larger than that at 725 cm^{-1}. Although the product (recrystallized from MeOH) was contaminated with dichloro derivative, it was used without purification in the next acetylation step. 2-Bromofluorene was also prepared by bromination. Bromine (100 g) was rapidly added to a dioxane (600 g) solution of fluorene (70 g) at room temperature. After stirring for 3 h and the subsequent decomposition of the excess Br_2, the solution was poured into water and the precipitate was recrystallized from MeOH–benzene, giving 2-bromofluorene in an 85% yield (mp 109—110 °C, lit,[29] mp 110—111 °C).

7-Substituted 2-Acetylfluorenes: As has been described by Arene

and Taylor in connection with the preparation of 7-methoxy-2-acetylfluorene,[30] 7-ethyl-2-acetylfluorene was obtained by the acetylation of 2-ethylfluorene (with Ac_2O and $AlCl_3$ in nitrobenzene) in an 85% yield; recrystd from EtOH, mp 125.5—126.5 °C. 7-Chloro- or 7-bromo-2-acetylfluorene was synthesized by the addition of Ac_2O(0.6 mol) to a nitrobenzene solution (800 ml) of the respective halofluorene (0.4 mol) and $AlCl_3$ (0.83 mol) under cooling. The mixture was stirred for 3 h and then allowed to stand overnight. After a usual work-up, the product was recrystallized from benzene and then CCl_4; 7-chloro-2-acetylfluorene (83% yield, mp 141—142 °C) and 7-bromo-2-acetylfluorene (75% yield, mp 144—146 °C). 7-Cyano-2-acetylfluorene (recrystd from EtOH–benzene; mp 117—120 °C) was prepared by the use of CuCN from 7-bromo-2-acetylfluorene (60% yield) according to the method described by Fridmann and Shechter.[31]

7-Nitro-2-acetylfluorene was obtained by the literature method[32] in a 72% yield (mp 233—233.5 °C, lit,[32] mp 228 °C); however, because of its low solubility, the purification by recrystallization was difficult. The nitro derivative (50.6 g) was reduced with $SnCl_2 \cdot 2H_2O$(226 g) and concd HCl(280 ml) in AcOH(3500 ml). After treatment with aq KOH, 7-amino-2-acetylfluorene was obtained in a 52% yield; mp 221—221.5 °C. The amine was converted to 7-hydroxy-2-acetylfluorene in a 43% yield *via* diazonium sulfate (recrystd from MeOH–acetone, mp *ca.* 140 °C, dec). The methylation of the hydroxy derivative with Me_2SO_4 afforded 7-methoxy-2-acetylfluorene: mp 137—138 °C, lit,[30] mp 134—135 °C.

All of the above acetylfluorenes except the NO_2 and CN derivatives (low solubilities) were further purified by column chromatography on Al_2O_3 with a benzene eluent[24] and subsequently reduced by appropriate methods to the following alcohols.

1-(7-Substituted 2-Fluorenyl)ethyl Alcohols and Chlorides Ia: The substituted and unsubstituted 2-acetylfluorenes were converted to the corresponding alcohols by a standard reduction with $LiAlH_4$ (for the MeO, Et, H, and Cl derivatives) or $NaBH_4$ (for the Br, CN, and NO_2 derivatives). All the alcohols were recrystallized from benzene–hexane or EtOH–benzene. The physical properties are tabulated in Table 7.

Table 7. Physical constants and analytical data of 1-(7-X-2-fluorenyl)ethyl alcohols

X	Mp(°C)	Calcd(Found) C,%	H,%
MeO	147	79.97(80.08)	6.71(6.62)
C_2H_5	153—154.5	85.67(85.61)	7.61(7.64)
H	131.5—133	85.68(85.66)	6.71(6.51)
Cl	110—111	73.63(73.54)	5.35(5.57)
Br	155—156	62.30(62.57)	4.53(4.50)
CN	151—152	81.68(81.07)	5.57(4.80)
NO_2	178—180,dec	70.58(70.75)	5.13(5.11)

With the exception of the CN and NO_2 derivatives, the 1-(7-substituted 2-fluorenyl)ethyl chlorides were prepared by passing dry HCl gas through an ether (200 ml) solution of the alcohol (*ca.* 5 g); although the solubility of some alcohols was less sufficient, HCl gas was bubbled in and, as the reaction proceeded, the alcohol was dissolved into a solution. After the treatment as has been described before,[7] the chlorides were purified by recrystallization from hexane or ether–petroleum ether and used for kinetics immediately after the evaporation of the solvents *in vacuo*. The CN and NO_2 derivatives were made by the SO_2Cl method[7] and were recrystallized from hexane–benzene.

7-Substituted 2-Fluorenecarboxylic Acids[33] *and Their Ethyl Esters*: The 7-methoxy-, 7-ethyl-, 7-chloro-, 7-bromo-, and unsubstituted 2-acetylfluorenes were moderately oxidized to the respective 7-substituted 2-fluorenecarboxylic acids by the use of iodine in pyridine (20—89% yields) using a method similar to that described by Barnett *et al.*[34] The 7-nitro-2-acetylfluorene was converted to the corresponding acid by following the procedure of Weisburger *et al.*[5] The acid hydrolysis of 7-cyano-2-acetylfluorene gave 7-acetyl-2-fluorenecarboxylic acid (80% yield).

All of the ethyl 7-substituted 2-fluorenecarboxylates were prepared by the esterification of the corresponding acids or acid chlorides with EtOH, except in the case of ethyl 7-cyano-2-fluorenecarboxylate, which was obtained from the bromo derivative (39% yield) in the same manner as was used for 7-cyano-2-acetylfluorene. Every ester was purified by column chromatography on Al_2O_3 with a benzene eluent and by subsequent recrystallization from hexane or hexane–EtOH. The physical properties and analytical data of the esters are given in Table 8.

Table 8. Physical constants and analytical data of ethyl 7-X-2-fluorenecarboxylates

X	Mp(°C)	Calcd(Found) C,%	H,%

COMe	149—149.5	77.12(76.90)	5.75(5.70)
CN	187—188	77.55(77.53)	4.98(4.90)
NO_2	200.5	67.84(67.62)	4.63(4.46)

a) Lit,[35] mp 81—82 °C.

The protone NMR spectra for the esters, chlorides, and their precursors (the alcohols and ketones) were consistent with the respective assigned structures.

Kinetics and Solvents. *Solvolysis*: The 80%(V/V) and 90%(V/V) aqueous acetones were prepared by mixing nominal volumes of each component at 25 °C. Kinetics were carried out in the concentration of each chloride at *ca.* 0.02 M^{-1}, and the reaction was followed by titration with aq NaOH(*ca.* 0.02 M^{-1}), using Bromothymol Blue or Bromocresol Green as an indicator. All the kinetic runs accurately obeyed the first-order kinetic law, and the determination of $k_1(s^{-1})$ followed the method which we have previously described.[7] The reproducibility of the rate constants from repeated runs was within $\pm 1\%$.

Alkaline Hydrolysis: The 85%(w/w) aqueous EtOH was prepared by mixing 4000 ml of abs EtOH and 545 ml of water at 25 °C;[15] this gave $d_4^{25}=0.826_6$ by means of a pycnometer. A NaOH solution (*ca.* 0.08 M^{-1}) in the solvent was made by dissolving sodium in the solvent and then standardizing it with benzoic acid. The temperature was controlled at 50 ± 0.02 °C.

A polyethylene cell equipped with Pt plates was employed for the conductivity measurements. Bromothymol Blue was used as an indicator for the titration method. The $k_2(s^{-1}M^{-1})$ values from the equimolar reactions of the ester and the OH^- were determined by the method which will be described elsewhere.[15] No initial concentration effects could be detected in the concentration range of 0.012—0.036 M^{-1} of the ester

and the OH^-. Ethyl 7-nitro-2-fluorenecarboxylate showed a low solubility (less than 0.005 M^{-1}), and so the determination of an accurate k_2 value was given up in the present study. The titration and conductivity methods gave the same k_2. The reproducibility of the rate constants from repeated runs was within $\pm 1\%$.

Organic Photochemical Reactions. XXVI. Photoaddition of Singlet and Triplet Methyl Pyruvate with 2,3-Dimethyl-2-butene[1]

Kensuke SHIMA, Taisuke SAWADA, and Hiroyuki YOSHINAGA

Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Miyazaki 880

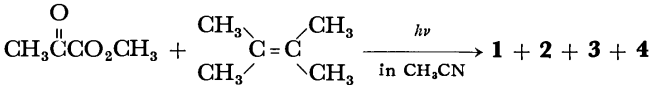
(Received September 7, 1977)

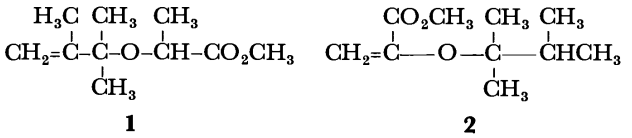
UV irradiation of methyl pyruvate in the presence of 2,3-dimethyl-2-butene leads to the formation of four primary photo-products in reasonable quantum yield: two unsaturated ethers (**1** and **2**) and two unsaturated alcohols (**3** and **4**). The effects of olefin concentration on the quantum yield of product formation, as well as quenching studies, suggest that **3** and **4** are formed from the excited singlet state of methyl pyruvate, while **1** and **2** are produced from the triplet state of methyl pyruvate. The role of exciplexes in this reaction is discussed. Quenching data of fluorescence of methyl pyruvate and the kinetic analysis of this reaction support these considerations.

The photocycloaddition of carbonyl compounds with olefins to form oxetanes is a topic of recent preparative and mechanistic interest. An attack of the $^3(n\pi^*)$ carbonyl compound on a ground state olefin is not the only allowed mechanism for photoaddition reaction. Alkanals and alkanones can attack olefins or conjugated dienes by a mechanism involving the singlet excited state of the carbonyl compounds.[2] In some cases, photoaddition may occur by both singlet and triplet mechanisms concurrently, as in the addition of acetone to 1-methoxy-1-butene,[3] or the addition of fluorenone to a ketenimine.[4] Recently, it has been suggested that an exciplex which leads to oxetane formation is formed between excited carbonyl compounds and olefins.[2a,2f,5] Some years ago, we reported that biacetyl and methyl pyruvate add to 2,3-dimethyl-2-butene to afford allylic ethers.[6] In these photoadditions, no detectable amounts of oxetanes were isolated. These results were explained by the reactivity of the 1,4-biradical intermediates. In this paper we wish to report some results concerning the photoaddition of methyl pyruvate to 2,3-dimethyl-2-butene, and our studies concerning the mechanism of this addition.

Results and Discussion

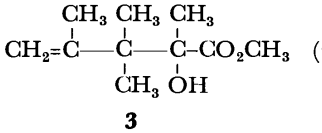
Products Studies. A preparative UV photoreaction of methyl pyruvate in solution in the presence of 2,3-dimethyl-2-butene leads to the formation of four products, which can be detected by VPC analysis. These are separated by preparative VPC and assigned the structures **1**—**4**.



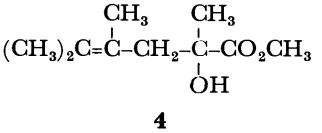


1

2



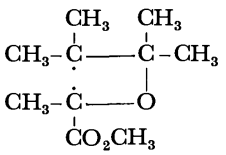
3



4

Compound **1** was assigned the allylic ether structure on the basis of its IR and NMR spectra (isopropenyl and $-OCH(CH_3)-$ groups). Compound **2** was identified as the isomeric vinyl ether by its IR and NMR spectra (isopropyl and $CH_2=C(CO_2CH_3)-O-$ groups). The compound slowly decomposed on standing and thus the isolation of **2** had to be performed carefully. The structures of the unsaturated alcohols (**3** and **4**) were apparent from an examination and comparison of their IR and NMR spectra. **3** showed terminal methylene absorption in the IR and NMR spectra, and only one $CH_3\dot{C}=$ signal in the NMR spectrum; **4** showed no vinyl proton, but signals for three $CH_3\dot{C}=$ groups and an allylic methylene in the NMR spectrum.

1 and **2** are the products derived from the disproportionation of the 1,4-biradical intermediate (**5**), and **3** and **4** are the products expected from the hydrogen abstraction of excited methyl pyruvate from 2,3-dimethyl-2-butene.



5

Quantum Yields. In order to investigate the quantum yield for product formation as a function of the concentration of reactants, Pyrex tubes containing known concentrations of methyl pyruvate and 2,3-dimethyl-2-butene in acetonitrile were irradiated in a merry-go-round reactor. After irradiation, the photoproduct in each tube was subjected to VPC analysis. The quantum yields for product formation were obtained by tris(oxalato)ferrate(III) actinometry.

Figure 1 shows plots of the reciprocal of quantum yields for the formation of products against the reciprocal of concentration of 2,3-dimethyl-2-butene. This indicates that different precursors exist for the formation of unsaturated alcohols (**3** and **4**) and unsaturated ethers (**1** and **2**). The upward curvature for **1** and **2** seen in Fig. 1 at higher olefin concentration is due to the deactivation of the excited singlet state of methyl pyruvate by interaction with 2,3-dimethyl-2-butene.[7]

Quenching Studies. Quantitative studies were carried out using 2,3-dimethyl-1,3-butadiene as a triplet quencher in acetonitrile in the presence of methyl pyruvate and 2,3-dimethyl-2-butene. Plots of relative

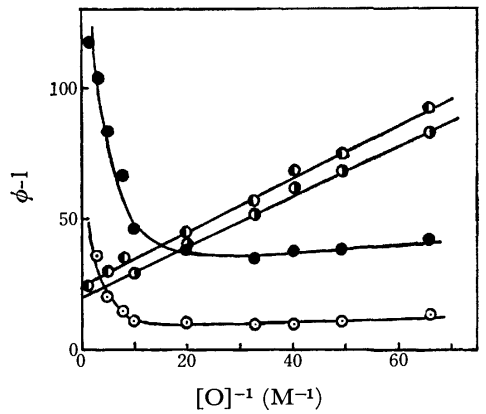


Fig. 1. Dependence of the reciprocal of the quantum yield for products formation on the reciprocal of 2,3-dimethyl-2-butene concentration.
●: Product **1**, ⊙: product **2**, ◐: product **3**, ◑: product **4**. [MP]=0.1 M in acetonitrile.

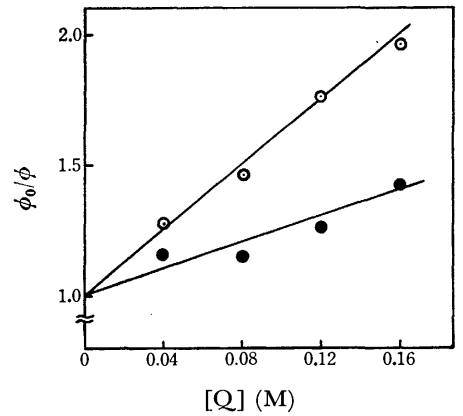

Fig. 2. Stern-Volmer plot of quenching of products **1**+**2** and **3**+**4** against 2,3-dimethyl-1,3-butadiene concentration.
⊙: **1**+**2**, ●: **3**+**4**. [MP]=0.1 M, [O]=0.2 M in acetonitrile.

quantum yields for **1**+**2** and **3**+**4** *vs.* quencher concentration in the presence of 0.2 M olefin concentration in acetonitrile are shown in Fig. 2. Apparently, **1**+**2** are more efficiently quenched than **3**+**4** are. It now seems established that, while conjugated dienes act as efficient quenchers of the triplet state of carbonyl compounds, dienes may also act as quenchers of the carbonyl singlet state.[2a] From the above experiment, we propose that **3**+**4** are formed from the excited singlet state of methyl pyruvate, probably *via* an exciplex, and **1**+**2** are formed from the triplet state of methyl pyruvate. This is confirmed by the kinetic treatment discussed later.

Fluorescence Quenching. 2,3-Dimethyl-2-butene and 2,3-dimethyl-1,3-butadiene quench the fluorescence of methyl pyruvate, as the Stern-Volmer plots in Fig. 3 show. This quenching effect is not due to a ground-state charge-transfer formation between methyl pyruvate and quenchers. Absorption spectra taken of methyl pyruvate with higher concentrations of 2,3-dimethyl-2-butene or 2,3-dimethyl-1,3-butadiene than

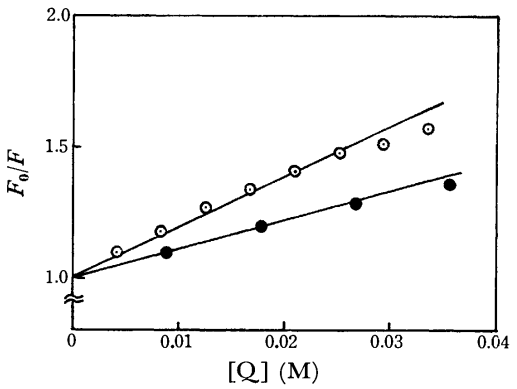

Fig. 3. Stern-Volmer plots for the fluorescence quenching of methyl pyruvate by 2,3-dimethyl-2-butene (⊙) and 2,3-dimethyl-1,3-butadiene (●) in acetonitrile.
[MP]=0.1 M.

those used in the kinetic experiments are identical with the spectra of methyl pyruvate in the absence of quenchers. The fluorescence of methyl pyruvate was also quenched by other dienes and olefins (Table 1). In Fig. 4 the function log k_q is plotted against the ionization potentials of several dienes and olefins. The moderately good linear behavior indicates that a charge

Table 1. Quenching rate constants and ionization potentials of unsaturated compounds

Unsaturated compound	$k_q\tau_s$[a] M^{-1}	$k_q \times 10^{-9}$ $M^{-1}s^{-1}$	IP[b] eV
2,5-Dimethyl-2,4-hexadiene	94.8	11.56	7.84
1,3-Cyclohexadiene	32.1	3.91	8.30
2,3-Dimethyl-2-butene	19.0	2.32	8.42
1,3-Pentadiene	13.4	1.63	8.59, 8.65
2,3-Dimethyl-1,3-butadiene	10.4	1.27	8.72
2-Methyl-1,3-butadiene	10.8	1.32	8.85
2-Methyl-2-butene	11.0	1.34	8.85

a) [MP]=0.1M in CH_3CN, τ_s=8.2 ns. b) Vertical ionization potentials; see Refs. 2a and 8.

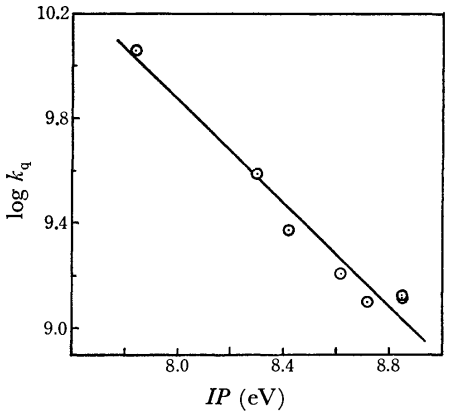

Fig. 4. Dependence of rates of methyl pyruvate fluorescence quenching by unsaturated compounds on their ionization potentials.

transfer interaction contributes to the stabilization of this quenching process. Similar correlations for fluorescence quenching of aromatic hydrocarbons,[8] alkanones,[2a] alkanals,[2e] azoalkanes,[9] and vinylene carbonates[10] by dienes or olefins have been attributed to exciplex formation.

Kinetic Analysis. The following mechanism is consistent with the above experiments:

	Rate Constant
$MP \xrightarrow{h\nu} {}^1MP$	
${}^1MP \longrightarrow MP + \Delta$ or $h\nu$	k_d^1
${}^1MP \longrightarrow {}^3MP$	k_{ST}
${}^1MP + O \longrightarrow {}^1(MP\cdots O)$	k_c^1
${}^1(MP\cdots O) \longrightarrow MP + O$	k_a^1
${}^1(MP\cdots O) \longrightarrow \mathbf{3} + \mathbf{4}$	k_p^1
${}^1MP + Q \longrightarrow MP + Q$	k_q^1
${}^3MP \longrightarrow MP$	k_d^3
${}^3MP + O \longrightarrow {}^3(MP\cdots O)$	k_c^3
${}^3(MP\cdots O) \longrightarrow MP + O$	k_a^3
${}^3(MP\cdots O) \longrightarrow \mathbf{1} + \mathbf{2}$	k_p^3
${}^3MP + Q \longrightarrow MP + {}^3Q$	k_q^3

MP: methyl pyruvate; O: 2,3-dimethyl-2-butene; Q: 2,3-dimethyl-1,3-butadiene; ${}^1(MP\cdots O)$, ${}^3(MP\cdots O)$: singlet and triplet exciplex, respectively.

Steady-state treatment of the species ${}^1MP$, ${}^3MP$, ${}^1(MP\cdots O)$, and ${}^3(MP\cdots O)$ leads to the expressions

$$\phi_{3+4} = \phi_A = \left(\frac{k_p^1}{k_a^1+k_p^1}\right)\left(\frac{k_c^1[O]}{k_d^1+k_{ST}+k_c^1[O]+k_q^1[Q]}\right), \quad (1)$$

$$\phi_{1+2} = \phi_E = \left(\frac{k_{ST}}{k_d^1+k_{ST}+k_c^1[O]+k_q^1[Q]}\right)\left(\frac{k_p^3}{k_a^3+k_p^3}\right) \times\left(\frac{k_c^3[O]}{k_d^3+k_c^3[O]+k_q^3[Q]}\right), \quad (2)$$

where ϕ_E and ϕ_A are the quantum yields for the formation of unsaturated ethers (**1**+**2**) and unsaturated alcohols (**3**+**4**), respectively.

First, consider the formation of **3**+**4**. In the absence of quenching by 2,3-dimethyl-1,3-butadiene, Eq. 1 becomes

$$\phi_A^{-1} = \left(1+\frac{k_a^1}{k_p^1}\right)\left(1+\frac{k_d^1+k_{ST}}{k_c^1[O]}\right). \quad (3)$$

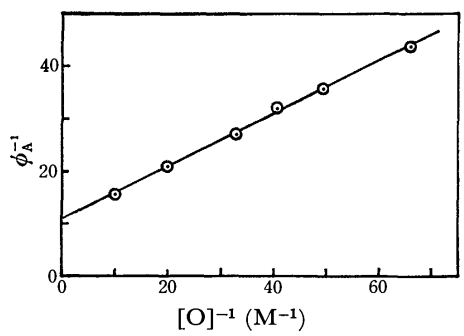

Fig. 5. Dependence of the reciprocal of the quantum yield for the formation of **3**+**4** on the reciprocal of 2,3-dimethyl-2-butene concentration. Slope=0.51 M, Intercept=10.7.

Figure 5 shows plots of the reciprocal of quantum yields for the formation of **3**+**4** against the reciprocal of concentration of 2,3-dimethyl-2-butene. A least-squares analysis of the points gave an intercept of 10.7 and a slope of 0.51 M. The intercept of Fig. 5 is now associated with $1+k_a^1/k_p^1$, and using this value in conjunction with the slope, we obtain the limiting quantum yield, $\phi_A^{lim}=0.0937$, $k_a^1/k_p^1=9.67$, and $k_c^1/(k_d^1+k_{ST})=21.0$.

In the presence of the quencher, Q,

$$\frac{\phi_A^\circ}{\phi_A} = 1 + \frac{k_q^1[Q]}{k_d^1+k_{ST}+k_c^1[O]} = 1 + k_q^1\tau_s[Q], \quad (4)$$

where ϕ_A is the quantum yield for the formation of **3**+**4** in the presence of Q, ϕ_A° is the quantum yield for the formation of **3**+**4** in the absence of Q, and τ_s is the lifetime of the excited singlet state in the absence of Q. 2,3-Dimethyl-1,3-butadiene quenches the formation of **3**+**4** in the presence of 0.2 M 2,3-dimethyl-2-butene in acetonitrile, as the Stern-Volmer plots in Fig. 2 show. From the slope in Fig. 2 we obtain the $k_q^1\tau_s$ value of 2.44; thus, $k_c^1/k_q^1=1.65$. A Stern-Volmer treatment of the fluorescence quenching in Fig. 3 yields a slope of 19.0 M^{-1} for 2,3-dimethyl-2-butene and 10.8 M^{-1} for 2,3-dimethyl-1,3-butadiene; thus, we get $k_c^1/k_q^1=1.82$. This is in good agreement with the value of k_c^1/k_q^1 (=1.65) obtained from the above calculation. These results indicate that the fluorescence quenching and the formation of **3**+**4** proceed *via* the excited singlet state of methyl pyruvate.

Next, consider the formation of **1**+**2**. In the absence of 2,3-dimethyl-1,3-butadiene, Eq. 2 leads to Eq. 5 by taking $k_{ST}\gg k_d^1$, since the triplet quantum yield for carbonyl compound is high:[11]

$$\phi_E^{-1} = \left(\frac{k_{ST}+k_c^1[O]}{k_{ST}}\right)\left(1+\frac{k_a^3}{k_p^3}\right)\left(1+\frac{k_d^3}{k_c^3[O]}\right). \quad (5)$$

Rearranging Eq. 5 gives

$$\left(\frac{k_{ST}}{k_{ST}+k_c^1[O]}\right)\phi_E^{-1} = \left(1+\frac{k_a^3}{k_p^3}\right)\left(1+\frac{k_d^3}{k_c^3[O]}\right). \quad (6)$$

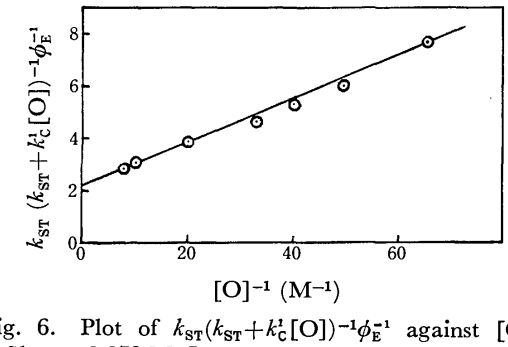

Fig. 6. Plot of $k_{ST}(k_{ST}+k_c^1[O])^{-1}\phi_E^{-1}$ against $[O]^{-1}$. Slope=0.079 M, Intercept=2.22.

Figure 6 shows a plot of $k_{ST}(k_{ST}+k_c^1[O])^{-1}\phi_E^{-1}$ against reciprocal olefin concentration. From the slope (=0.079 M) and intercept (=2.22) in Fig. 6, we obtain $k_a^3/k_p^3=1.22$, and $k_c^3/k_d^3=28.1$.

In the presence of Q,

$$\frac{\phi_E^\circ}{\phi_E} = \left(1+\frac{k_q^1[Q]}{k_d^1+k_{ST}+k_c^1[O]}\right)\left(1+\frac{k_q^3[Q]}{k_d^3+k_c^3[O]}\right). \quad (7)$$

Rearranging Eq. 7 gives

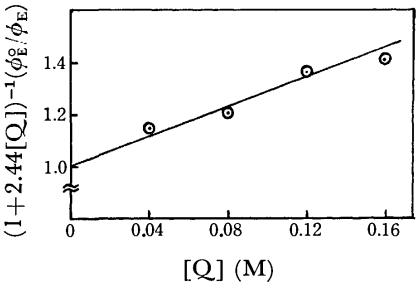

Fig. 7. Plot of $(1+2.44[Q])^{-1}$ (ϕ_E°/ϕ_E) against [Q]. Slope=2.78 M^{-1}.

Table 2. The ratio of rate constants of elementary reactions in acetonitrile and in benzene[a)]

	CH_3CN	C_6H_6
k_c^1/k_{ST}	21.0	22.3
k_c^1/k_q^1	1.65	1.64
k_a^1/k_p^1	9.67	14.5
k_c^3/k_d^3	28.1	37.4
k_c^3/k_q^3	1.53	1.50
k_a^3/k_p^3	1.22	1.05
$k_c^{1b)}$ ($M^{-1}s^{-1}$)	2.5×10^9	2.7×10^9

a) [MP]=0.1 M. b) Fluorescence lifetime of methyl pyruvate: 8.2 ns (in benzene).

$$\left(1+\frac{k_q^1[Q]}{k_d^1+k_{ST}+k_c^1[O]}\right)^{-1}\left(\frac{\phi_E^\circ}{\phi_E}\right)=1+\frac{k_q^3[Q]}{k_d^3+k_c^3[O]}. \quad (8)$$

At 0.2 M olefin concentration, $k_q^1/(k_d^1+k_{ST}+k_c^1[O])=2.44$; the dependence of $(1+2.44[Q])^{-1}(\phi_E^\circ/\phi_E)$ on [Q] are shown in Fig. 7. From the slope (=2.78 M^{-1}) in Fig. 7, we get $k_c^3/k_q^3=1.53$. The results are summarized in Table 2. Table 2 also includes the results in benzene solution. From the above experiments, we could calculate the ratio of the rate constants of elementary reactions; and if we take $\tau_S\simeq k_{ST}^{-1}=8.2$ ns, the rate constant of 2.5×10^9 M^{-1} s^{-1} for the singlet exciplex formation from methyl pyruvate and 2,3-dimethyl-2-butene in acetonitrile can be obtained. In this photoreaction, no predominant solvent effects were observed. In the case of biacetyl and 2,3-dimethyl-2-butene, the unsaturated ether formation and biacetyl phosphorescence quenching by 2,3-dimethyl-2-butene are 3—5 times larger in acetonitrile solution than in benzene solution.[12)]

Experimental

General. NMR spectra were recorded on a JEOL JNM-MH 100 machine, IR spectra on a JASCO IRA-1 spectrometer, mass spectra on a Hitachi Perkin-Elmer RMU-60 spectrometer, and fluorescence spectra on a Hitachi MPF-4 spectrofluorimeter. The fluorescence lifetime was measured using a Hitachi Time Resolved Photometer. VPC were performed on a Shimadzu GC-3BF or GC-6AM apparatus using a column of Carbowax 20M (20% on Celite 545, 3m) at 120 °C.

Methyl pyruvate was prepared by the reaction of pyruvic acid with methanol in the presence of catalytic amounts of *p*-toluenesulfonic acid.[13)] 2,3-Dimethyl-2-butene was prepared by the dehydration of 2,3-dimethyl-2-butanol,[14)] formed from the reaction of isopropylmagnesium bromide with acetone in ether. It was purified by efficient fractional distillation. 2,3-Dimethyl-1,3-butadiene was prepared by dehydration of pinacol with hydrobromic acid, followed by distillation.[15)] 1,3-Cyclohexadiene was prepared as described by Marvel and Hartzell.[16)] 2-Methyl-2-butene was prepared by the method of Whitmore *et al.*[17)] 2,5-Dimethyl-2,4-hexadiene, 1,3-pentadiene, and 2-methyl-1,3-butadiene were obtained commercially, and were purified by distillation before use. Acetonitrile was distilled three times from phosphorus pentaoxide and once from potassium carbonate.

Irradiation of Methyl Pyruvate with 2,3-Dimethyl-2-butene. A solution of methyl pyruvate (10.2 g) and 2,3-dimethyl-2-butene (8.4 g) in acetonitrile was irradiated for 120 h with a 300-W high pressure mercury lamp filtered through a hexane solution of naphthalene. After removal of the unreacted materials under vacuum, the remaining liquid was distilled under reduced pressure to give a liquid (5 g, bp 110—125 °C/30 mmHg) and leave a viscous liquid (1 g). VPC of the distillate showed four products (**1**—**4**) with the area ratios of 22: 15: 26: 37. These products were isolated by preparative VPC on a 3 m 20% Carbowax 20M column at 120 °C.

Methyl 2-(1,1,2-Trimethyl-2-propenyloxy)propionate (**1**): NMR (CCl_4) δ=1.23 (3H, s), 1.25 (3H, d, J=7 Hz), 1.29 (3H, s), 1.73 (3H, s), 3.62 (3H, s), 3.79 (1H, q, J=7 Hz), and 4.86 (2H, s); IR 3100, 2995, 2975, 1740, 1643, and 1120 cm^{-1}.

Methyl 2-(1,1,2-Trimethylpropoxy)acrylate (**2**): NMR (CCl_4) δ=0.97 (6H, d, J=7 Hz), 1.21 (6H, s), 1.92 (1H, sept, J=7 Hz), 3.66 (3H, s), 4.81 (1H, s), and 5.51 (1H, s); IR 2980, 2875, 1740, 1620, and 1140 cm^{-1}.

Methyl 2-Hydroxy-2,3,3,4-tetramethyl-4-pentenoate (**3**): NMR (CCl_4) δ=1.14 (3H, s), 1.16 (3H, s), 1.30 (3H, s), 1.75 (3H, s), 3.37 (1H, s), 3.67 (3H, s), and 4.77 (2H, m); IR 3540, 3085, 2980, 2960, 1720, and 1630 cm^{-1}.

Methyl 2-Hydroxy-2,4,5-trimethyl-4-hexenoate (**4**): NMR (CCl_4) δ=1.33 (3H, s), 1.63 (9H, s), 2.40 (1H, s), 2.45 (1H, s), 3.44 (1H, s), and 3.66 (3H, s); IR 3560, 2960, and 1730 cm^{-1}.

Quantum Yield Studies. Samples (4 ml) containing 0.1 M methyl pyruvate and varying concentrations of 2,3-dimethyl-2-butene in acetonitrile were placed in 10-mm o.d. Pyrex tubes. The samples were degassed using four freeze-pump-thaw cycles at $\approx5\times10^{-4}$ mmHg and sealed. The tubes were photolyzed to $<10\%$ conversion on a merry-go-round apparatus using a HALOS PIH 300 mercury lamp and a potassium chromate filter solution to isolate the 313-nm irradiation. The entire apparatus was immersed in a water bath. After irradiation, an internal standard (naphthalene) was added to each tube, and product yields were measured by VPC analysis on machines with flame ionization detectors. The area ratios of the peak for pure samples of the products (**1**—**4**) and for naphthalene were plotted against the ratios of the amounts actually present. The calibration factors thus obtained were 1.84 for **1**, 4.79 for **2**, 2.74 for **3**, and 2.01 for **4**. Peak areas were measured by a planimeter. Light intensities were measured by tris(oxalato)ferrate(III) actinometry.[18)]

Quenching of Products by 2,3-Dimethyl-1,3-butadiene. Acetonitrile solutions containing 0.1 M methyl pyruvate, 0.2 M 2,3-dimethyl-2-butene, and various concentrations of 2,3-dimethyl-1,3-butadiene (0—0.16 M) were prepared. Four milliliters of each sample were degassed and irradiated at 313 nm. Photolyzed solutions were analyzed for product formation using a VPC column.

Fluorescence Quenching. Solutions of methyl pyruvate (0.1 M) with various concentrations of 2,3-dimethyl-2-butene

or 2,3-dimethyl-1,3-butadiene were made up in acetonitrile. Solutions were placed in a quartz fluorescence cell and the fluorescence spectra were recorded. The excitation wavelength was 360 nm; the intensities of methyl pyruvate fluorescence at the maximum (410 nm) were measured in the absence (F_0) and presence (F) of various concentrations of quenchers. Stern-Volmer quenching plots were drawn of F_0/F against quencher molarity. No shifts in fluorescence maxima were observed upon increase in quencher concentration, and no new fluorescence bands were discernible in any of the measurements.

The authors are grateful to Nissei Sangyo Co. for measuring the fluorescence lifetime of methyl pyruvate. This research was supported by Grants-in-Aid for Scientific Research from the Ministry of Education (No. 747020 and 154163).

Kinetic Studies on the Lime Sulfurated Solution (Calcium Polysulfide) Process for Removal of Heavy Metals from Wastewater

Kiyochika YAHIKOZAWA, Toshiro ARATANI,* Ryuzo ITO,** Takataro SUDO, and Takeo YANO*

Department of Chemical Engineering, College of Textile Science and Technology, Shinshu University, Tokida, Ueda 386

***Department of Chemical Engineering, College of Engineering Science, Osaka University, Toneyama, Toyonaka 560*

(Received April 1, 1977)

A new process has been developed for wastewater purification, utilizing "Lime Sulfurated Solution" as a coagulant. Calcium polysulfide, the main component of this solution, decomposes in water on contact with a gas (atmospheric air or CO_2 gas) and reacts with heavy metals. The heavy metals are removed as practically insoluble precipitates. The kinetics of this process were studied in a batch stirred tank vessel to obtain the fundamental data needed for development of a commercial continuous process. The findings are as follows: (1) Processing of bivalent metals Hg^{2+}, Cd^{2+}, Zn^{2+}, Pb^{2+}, and Cu^{2+} are completed in a few minutes to achieve the water quality standards in Japan. (2) Cr^{3+} is flocculated as $Cr(OH)_3$ by the strong alkaline base of CaS_x solution. It takes about 60 minutes for the precipitation with CO_2 blowing, and 30 min with aeration. Cr(VI) is quickly reduced to Cr^{3+} and removed as $Cr(OH)_3$. (3) A simulated wastewater simultaneously contaminated with 6 kinds of heavy metals can be brought well within the standards within 20 min of processing time.

The development of a new process for removal of heavy metals from industrial wastewater is essential for the protection of the environment. A variety of processes have already been proposed and some have been put into practice. For example, ion exchange, reverse osmosis, chemical precipitation, and others have been developed. Among these, the chemical precipitation process is now the most practical and the least expensive.[5] This process can be further divided into the "Hydroxide process" and the "Sulfide process." In the former, heavy metals are precipitated as metal hydroxides. In the ferrite process, which is one kind of hydroxide process, heavy metals are removed by being occluded in the ferrite crystals. Thus, the sludge from this process is less soluble than that from the other hydroxide processes. In the latter process, the heavy metal ions are removed as metal sulfides. A typical example of coagulant is sodium sulfide. The precipitated metal sulfides of a sodium sulfide process, however, are often colloidal and do not grow large enough to allow easy filtration. Consequently, the sodium sulfide process is inevitably followed by the injection of another coagulant (iron(III) chloride or sulfate) for coprecipitation of these colloidal metal sulfides. The sulfide process has the advantage of removing mercury more effectively than the other process, because HgS has the very low solubility products of 10^{-52}.

In the present study, a new sulfide process has been developed, utilizing "Lime Sulfurated Solution" as a single coagulant. The main component of this solution is calcium polysulfide, whose chemical formula is CaS_x, $x=4.7—5.4$.[6] Hereafter, lime sulfurated solution will be briefly written as CaS_x solution. This solution is well known as an insecticide or a disinfectant in agriculture.[1] When used as an insecticide, CaS_x solution decomposes slowly in contact with atmospheric air and produces calcium thiosulfate, hydrogen sulfide, and solid sulfur.[7] For the purification of wastewater contaminated with heavy metals, CaS_x solution decomposes rapidly by blowing a decomposing gas (air or CO_2 gas); heavy metals react with calcium thiosulfate or hydrogen sulfide and are precipitated as metal sulfides or hydroxides. However, the kinetics of these reactions have not been well studied. Thus, some experiments in a batch stirred tank reactor with air or CO_2 blowing were conducted aimed at the removal of heavy metals in order to gain the fundamental kinetic data needed for the design of a commercial continuous process.

Experimental

Apparatus. A batch stirred tank reactor of 2 dm^3 in volume was constructed, as illustrated in Fig. 1, to study the kinetics for the removal of heavy metals from wastewater by CaS_x. The decomposing gas (air or CO_2; flow rate, 500 cm^3/min) is blown in and dispersed into bubbles. The revolution of the impeller was 10 Hz. These revolution and gas flow rates were ascertained to be sufficient for the finest dispersion of the gas bubbles. The excess hydrogen sulfide was caught by the adsorber A, which was packed with appropriate adsorbing pellets. The pH and the temperature in the reactor were measured with a pH meter and a thermometer T.

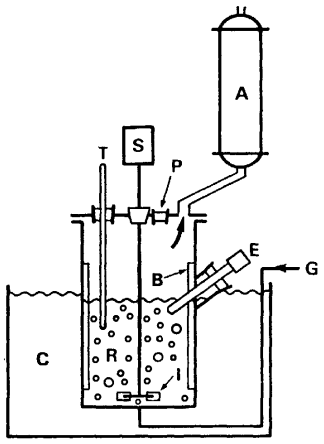

Fig. 1. Experimental apparatus. A: H_2S adsorber, B: baffle plate, C: constant temperature bath, E: glass electrode for pH measurement, G: pipe for gas aspiration, I: turbine impeller, P: plug for CaS_x injection, R: batch reactor, S: stirrer, T: thermometer.

Method. Water contaminated with 6 kinds of heavy metal ions: Hg^{2+}, Cd^{2+}, Pb^{2+}, Cu^{2+}, Zn^{2+}, and Cr^{3+}, was used as simulated wastewater in this experiment. Cr(VI) was also provided for the removal test by dissolving crystals of potassium dichromate. 2 dm^3 of the simulated wastewater was first placed in a constant temperature bath of 25 °C. The brown-colored CaS_x solution was injected into the reactor, and the blowing of the decomposing gas was immediately started. The sample liquors of 20 cm^3 were taken at the predetermined time intervals and filtered through No. 5C filter paper. The concentration of heavy metals in the filtrates was analyzed by an atomic absorption spectrophotometer according to JIS-K0102.[2] Sample liquors were concentrated by extraction with chloroform solution of dithizone, if high sensibilities were required. The initial pH of the simulated wastewater was set at 5.0. The simulated wastewaters were prepared in two ways. One set contained only one chemical species from among 6 heavy metals to investigate the behavior of each metal. The other was simultaneously contaminated with 6 kinds of heavy metals to determine the practical application requirements.

Results

Heavy metal concentrations in the treated water are compared with the water quality standards (criteria) in Japan. The batch processing time to clear the criteria is also checked to obtain the required residence time (or reactor volume) of a continuous process.

Typical examples of the heavy metal concentrations in the filtrate are plotted against the processing time in Figs. 2 to 5. As for the removal of mercury (Fig. 2), the severe criterion (5 ppb) is clearly covered by this CaS_x process; pure H_2S gas blowing and the Na_2S process can not cope with this criterion. The S^{2-} ion which may dissolve HgS can be eliminated by the decomposition of CaS_x with air or CO_2 gas in the case of the CaS_x process. Calcium salts and solid sulfur are also liberated from CaS_x and they work as flocculating aids to precipitate the metal sulfide (HgS). This flocculating ability was ascertained by an auxiliary experiment, in which precipitation of HgS from colloidal HgS solution was observed by adding a solution that had contained only air-decomposed CaS_x. R_m in the figures indicates the mole ratio of sulfur in CaS_x or Na_2S to heavy metal. For quantities of Na_2S injected larger than $R_m=25$, the processing results in a less effective removal of Hg^{2+}. A limited duration (10 s) blowing of H_2S gas does not give any better removal than the $R_m=2$ injection of Na_2S.

For the conditions of $R_m=25$ and the initial metal concentration of 25 ppm, the other metals were tested. For Cd^{2+} and Zn^{2+} (Fig. 3), CO_2 gas blowing can reduce the processing time compared with the aeration.

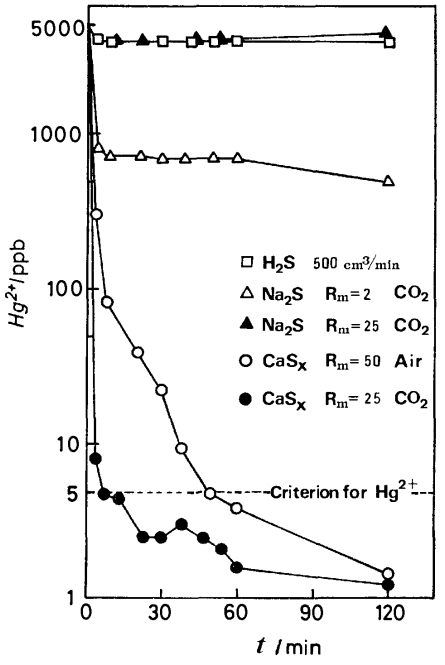

Fig. 2. Removal of Hg^{2+}, initial concentration of Hg^{2+} =5 ppm.

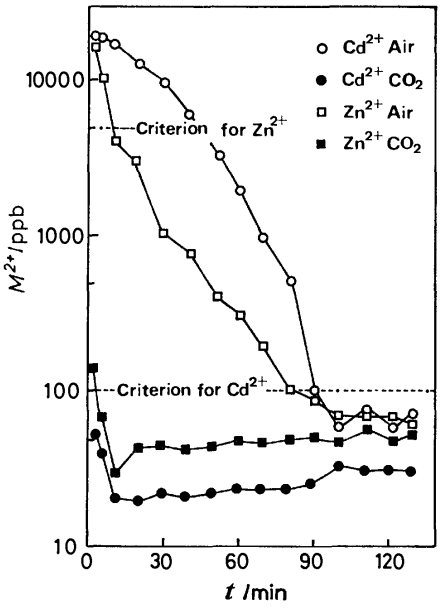

Fig. 3. Removal of Cd^{2+} or Zn^{2+}.

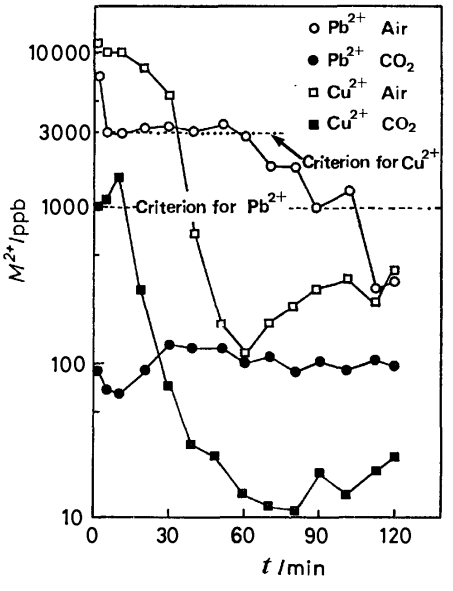

Fig. 4. Removal of Pb^{2+} or Cu^{2+}.

The same tendency is found for Pb^{2+} and Cu^{2+} (Fig. 4). For Cr^{3+} and Cr(VI), the aeration is desirable to shorten the processing time, as illustrated in Fig. 5.

Removal of heavy metals from the simulated wastewater simultaneously contaminated with 6 kinds of heavy metals is shown in Figs. 6 and 7. Long processing time is required for the aeration. CO_2 gas blowing, however, can reduce the processing time to within 30 min.

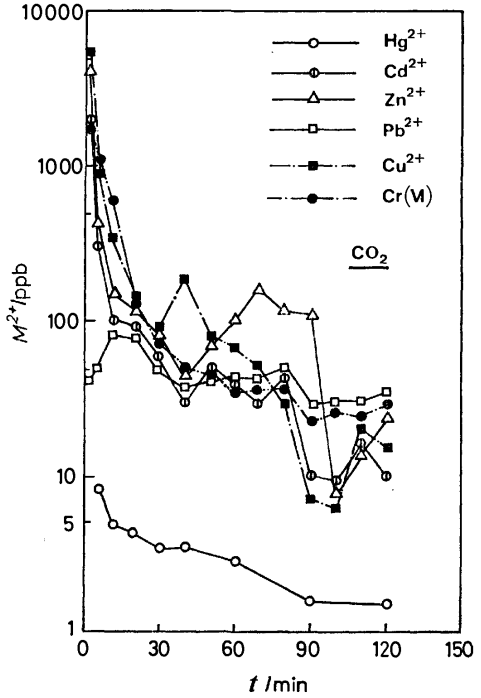

Fig. 7. Simultaneous removal of heavy metals with CO_2 blowing.

Discussion

Apparent kinetic data have been obtained, but it is unsettled question whether the processing time is needed for the decomposition of CaS_x or for the flocculation of the precipitates. The reactions for the decomposition of CaS_x by air or CO_2 and for the precipitation of heavy metals need to be discussed.

The changes in color of the precipitates (or suspended solids) and of the liquid phase were observed while CaS_x was decomposed by air or CO_2, with and without heavy metals. Without any charging of metal ions, the water in the reactor become light brown after the injection of CaS_x, because the CaS_x solution has a reddish brown color.

After the aeration, white particles (solid sulfur) which were liberated from CaS_x could be recognized as a suspension or scum, while the liquid phase was still brown. 60 min after the start of aeration, the brown color had gradually disappeared. When the heavy metal ions were in the water, the color of the suspended particles of metal sulfide was gradually predominating over the color of the sulfur particles. Yellow suspended particles (CdS) could vividly be seen in the water containing Cd^{2+}. Similarly, white (ZnS) for Zn^{2+}, dark gray (PbS) for Pb^{2+}, brown (CuS) for Cu^{2+}, and black particles (HgS) for Hg^{2+} were observed.

Upon blowing CO_2, on the other hand, the brown color of CaS_x solution instantaneously disappeared and white sulfur particles were produced. With the presence of heavy metal ions, the color of the suspended metal sulfide, which was different for each heavy metal, was observed immediately (within 1 s) after the start of CO_2 blowing. Thus the decomposition of CaS_x and the precipitation of bivalent metal ions by aeration was found to be considerably slower than that

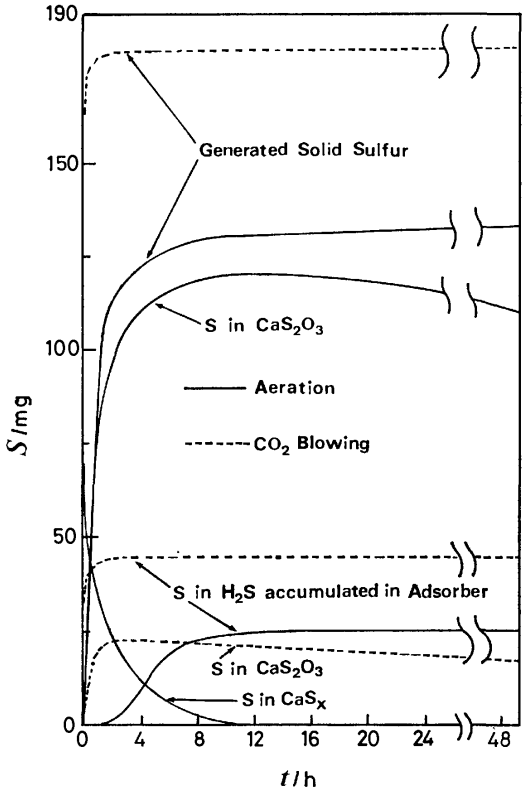

Fig. 8. Decomposition of CaS_x in a flask by aeration or CO_2 blowing; 1 cm^3 of CaS_x solution was added per 1 dm^3 of water.

by CO_2 blowing.

For more detailed research about the reaction kinetics for the decomposition of CaS_x, an auxiliary experiment was undertaken to determine quantitatively how the amounts of generated chemicals vary with time when CaS_x was decomposed in water without heavy metals. The decomposition of CaS_x by air or CO_2 was performed in a flask with a blowing pipe. The substances obtained after the decomposition were chemically analyzed[3,4] as shown in Fig. 8. Hydrogen sulfide, calcium thiosulfate, and solid sulfur (as suspended particles) were clearly recognized. Figure 8 indicates that CO_2 blowing gives rise to a more rapid decomposition of CaS_x than does aeration. This is consistent with the observations of color changes.

From another experiment for the decomposition of CaS_x with pure oxygen gas, it was found that hydrogen sulfide was not evolved by O_2.

The principal reactions of the decomposition of CaS_x by CO_2 and O_2 can be represented as Eqs. 1 and 2, following the above information:

$$CaS_x + \frac{3}{2}O_2 \longrightarrow CaS_2O_3 + (x-2)S, \quad (1)$$

$$CaS_x + CO_2 + H_2O \longrightarrow CaCO_3 + H_2S + (x-1)S. \quad (2)$$

Equations 1 and 2 imply that the decomposition of CaS_x by CO_2 generates a larger quantity of sulfur than that by O_2 or air. This agreed with the result of Fig. 8. Some H_2S, though only a small amount, was detected for the aerated case in Fig. 8. This H_2S was generated due to the decomposition by trace CO_2 in air, according to Eq. 2. For the wastewater containing heavy metal ions, the precipitating reactions can be written as

$$M^{2+} + CaS_2O_3 + H_2O \longrightarrow MS + CaSO_4 + 2H^+, \quad (3)$$

$$M^{2+} + H_2S \longrightarrow MS + 2H^+. \quad (4)$$

The rate of reaction for Eq. 3 was measured experimentally by a batch test. The test showed that formation of CdS precipitate was observed immediately after the injection of Cd^{2+} into the calcium thiosulfate solution. Equation 3 was found to proceed as quickly as the reaction with Eq. 4.

These processes, from Eq. 1 to 4, are known as the heterogeneous gas-liquid reaction with the formation of precipitates. An analytical treatment by a mathematical model is difficult. In the present study, the apparent kinetics are discussed experimentally.

An interesting result was the color change with the processing of Zn^{2+}. As the solid precipitates (ZnS, S, $CaSO_4$, and $CaCO_3$) are all white and CaS_x is brown, the time needed for the decomposition of CaS_x can be observed as the color change in the solution. With aeration, complete decomposition of CaS_x was observed at about 60 minutes of processing. The time when the steep decrease in the concentration of Zn^{2+} ended agreed exactly with the time when the brown color of injected CaS_x had disappeared (see Fig. 3). For removal of heavy metal ions by aeration, Eq. 1 is thought to be rate-controlling step. This slow decomposition was partly supported by pH measurements, for CaS_x which might dissolve heavy metal ions was thought to be stable in the alkaline side until the base of CaS_x solution was neutralized by the trace of CO_2 in air. The initial pH (pH=5) become rapidly alkaline (about pH=11 in this experimental condition with the simulated wastewater contaminated with a heavy metal) on the injection of CaS_x solution, which has a strong alkaline base. After aeration, the pH gradually returned to neutral (pH=7). With CO_2 blowing, the pH returned rapidly to the slightly acidic side (pH=6). These speeds of pH change may have a relation to the neutralizing speeds of alkaline base of CaS_x solution by CO_2 gas (in air or pure CO_2) and, therefore, partly relate to the rate of decomposition of CaS_x. In applying this CaS_x process to wastewater treatment, the treated water has pH values ranging from 6 to 7, and so can pass the water quality criteria for pH range without injecting any other alkaline reagents. Thus, a more economical treatment is expected than the usual chemical precipitation processes.

For the removal of Cr^{3+}, since the sulfide of Cr^{3+} is unstable in water, Cr^{3+} is not precipitated as Cr_2S_3, but easily removed as $Cr(OH)_3$ by the strong alkaline nature of CaS_x solution. The reduction of Cr(VI) (dichromate) to Cr^{3+} ion is easily attained by H_2S or CaS_2O_3 according to either pair of Eqs. 5 and 6 or 5 and 7.

$$Cr_2O_7^{2-} + 2OH^- \longrightarrow 2CrO_4^{2-} + H_2O, \quad (5)$$

$$2CrO_4^{2-} + 3H_2S + 10H^+ \longrightarrow 2Cr^{3+} + 3S + 8H_2O, \quad (6)$$

$$2CrO_4^{2-} + 3S_2O_3^{2-} + 10H^+ \longrightarrow 2Cr^{3+} + 3SO_4^{2-} + 3S + 5H_2O. \quad (7)$$

The reduction sheme from Cr(VI) to Cr^{3+} through CrO_4^{2-} was also confirmed by the observation of the color change in the solution. The color of the solution was initially brown (dichromate), and changed to yellow (chromate) on injection of CaS_x and further to light green ($Cr(OH)_3$). With the aeration, these changes were observed within 10 min. For the CO_2 blowing, however, the changes ended in a few seconds, and a fine floc of $Cr(OH)_3$ which partly passed through the No. 5C filter paper was generated. As shown in Fig. 5, the aeration is more effectively than CO_2 gas blowing, for the faster precipitation of Cr^{3+} and Cr(VI). For the precipitation of Cr^{3+}, the slow change in pH with aeration is thought to be favorable to the flocculation of $Cr(OH)_3$ particles. Rapid decomposition of CaS_x with CO_2 blowing may give to the fast formation of a fine floc of $Cr(OH)_3$ by the alkaline base which has been coordinated to CaS_x and freed by the decomposition. The processing rate of Cr^{3+} may be determined by the step of flocculation of the hydroxide floc. For the aeration, the difference between the curves of Cr^{3+} and Cr(VI) in Fig. 5 shows the time required for the reduction of Cr(VI) to Cr^{3+} according to Eqs. 5, 6, and 7. Figure 7 also indicates that chromium can be precipitated faster in the simultaneous removal than in the removal for the case when the water was contaminated only with chromium. This effect is thought to be due to the coprecipitation of $Cr(OH)_3$ with the other sulfides.

Minimum values are observed in the detected concentrations in Figs. 2 to 7. Thus, in the continuous CaS_x process, the mean residence time of the reactor used for the treatment should be so designed as to be equal to the time when the minimum values in the concentrations are attained in batch tests.

Conclusion

From the preceding experiments and discussion, the kinetics of the CaS_x process can be summarized as follows.

(1) CaS_x is decomposed slowly by aeration and rapidly by CO_2 gas blowing, and produces H_2S, $CaCO_3$, $CaSO_4$, and solid sulfur particles. Bivalent heavy metals are precipitated as metal sulfides. The precipitating rate is determined by the step of CaS_x decomposition. Cr^{3+} can also be precipitated as a metal hydroxide more rapidly with aeration than with CO_2 blowing. The precipitating rate of the hydroxide is determined by the step of the flocculation. Cr(VI) is easily precipitated as $Cr(OH)_3$ after rapid reduction from Cr(VI) to Cr^{3+} by H_2S or CaS_2O_3. The solid sulfur and calcium salts work effectively to coprecipitate the metal sulfides and the hydroxide.

(2) The water treated by a single coagulant, CaS_x, can pass the water quality standards in Japan for 6 kinds of heavy metals, within 60 min of processing time. Based on these batch kinetic data, development of a continuous purification process is thought to be easily possible.

The authors wish to express their thanks to Mr. Shigeki Yasuhara and Mr. Teruyuki Miyazawa for assistance in the experimental work. The present work was partially supported by a Grant-in-Aid for Developmental Scientific Research from the Ministry of Education.

The Hydrocracking of Polynuclear Aromatic Hydrocarbons over Molten Salt Catalysts[1)]

Yohji NAKATSUJI, Toshio KUBO, Masakatsu NOMURA, and Shōichi KIKKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 31, 1977)

The hydrocracking of phenanthrene, anthracene, pyrene, chrysene, and fluoranthene over molten salt catalysts at 400 °C in the batch autoclave systems was examined. The products were mainly identified by means of GC-MS, but the representative products were isolated by preparative GLC and characterized by using NMR, IR, UV, and mass spectrometry. Most of the isolated products are compounds not previously confirmed in detail, although their formation has been expected in the hydrocracking of the corresponding aromatic compounds. Probable reaction routes are offered based on the product distributions. The binary mixture of zinc chloride and copper(I) chloride is considered to act as a molten dual-functional catalyst.

The hydrocracking of the model compounds, which are supposed to be structural units of coal, has frequently been carried out in order to examine the function of catalysts and the reaction process. In the investigation reported by Qader,[2)] the hydrocracking of naphthalene, anthracene, and pyrene was found to proceed through a sequential occurence of hydrogenation, isomerization, and cracking reactions over silica-alumina-based dual-functional catalysts, which are extensively used in the industrial processing of petroleum feedstocks. Zielke *et al.*[3)] had shown molten zinc chloride to be a superior acidic catalyst for the hydrocracking of pyrene and coal extracts when used in high concentrations.

As a part of a study of organic reactions in molten salts,[4)] we examined the catalytic activity of molten salts in the hydrocracking of a heavy anthracene oil.[5)] In this experiment, a binary mixture of CuCl and $ZnCl_2$ was found to be more effective than $ZnCl_2$ alone in obtaining many lower-boiling fractions; both the analysis of the starting oil and the confirmation of the products were also carried out extensively. However, in this hydrocracking of the heavy anthracene oil, the behavior of the representative constituents of the starting oil, that is, anthracene, phenanthrene, chrysene, pyrene, and fluoranthene, could not be clarified in detail. Concerning the hydrocracking of anthracene, the efficient catalytic activity of the binary mixture of $ZnCl_2$ and CuCl was reported in a preliminary paper.[6)] In addition to the above results, this paper will describe the application of this catalyst to the hydrocracking of phenanthrene, chrysene, pyrene, and fluoranthene and their characteristic properties. The effects of two different-batch autoclave systems on their product distributions are also investigated. Moreover, the probable reaction routes for the respective reactions of phenanthrene, chrysene, and fluoranthene will be offered and discussed.

Experimental

Product Analysis. The GLC analyses were performed on a Shimadzu GC-3AH for the gaseous products and on a Shimadzu GC-4BPTF for the liquid and solid products. The GC-MS spectra were taken at 20 eV with a Hitachi RMU-6MG spectrometer connected with a Hitachi M 5201 gas chromatograph by using a 3 m×3 mm column of 5% Silicone OV-1 on Uniport KS. The main products were isolated on a Shimadzu GC-3BT using a 3 m×3 mm column of 10% Pluronic L 84 on Neopack IA (for products from phenanthrene) or a 3 m×3 mm column of 20% Silicone DC 550 on Celite 545 (for products from pyrene, chrysene, and fluoranthene). The NMR spectra were recorded on a Jeol JNM-PS-100 spectrometer, using tetramethylsilane as the internal standard. CCl_4 was used as the solvent for all the compounds. The UV spectra and the IR spectra were taken with a Hitachi 124 spectrometer and a Jasco IR-E spectrometer respectively.

Materials. The chrysene (G.R.), fluoranthene (E.P.), and phenanthrene (E.P.) were obtained from the Tokyo Kasei Kogyo Co., Ltd. The pyrene (G.R.) and anthracene (E.P.) were obtained from Nakarai Chemicals, Ltd., and Wako Pure Chemical Industries, Ltd., respectively. The anthracene and phenanthrene were recrystallized from ethanol. The fluoranthene (98% purity by GLC) contained a small amount of cyclopenta[*j*,*k*]phenanthrene. This impurity was not removed before use. The zinc iodide and the copper(I) bromide were obtained from the Mitsuwa Chemicals Co., Ltd., while the other metal halides used in this investigation were obtained from Nakarai Chemicals, Ltd. These salts were dried before use at 400 °C for 1 h in nitrogen.

General Procedure. All the experiments were carried out in the two different systems (A and B) as follows:

A) A stainless steel vessel containing 8 g of feed and an equimolar amount of the catalyst was placed in a stainless steel (SUS 32) autoclave with a capacity of 200 ml. The system was flashed and filled with hydrogen to 100 kg/cm^2; then the autoclave was heated up to the desired temperature. The time taken to reach the stage was from 60 to 70 min. The reaction system shaken in a horizontal direction (68 strokes/min) was maintained at 400 °C for the desired reaction period. No attempts were made to maintain the hydrogen pressure at a constant level during the reaction.

B) A stainless steel vessel containing 10 g of feed and an equimolar amount of the catalyst was placed in a stainless steel (SUS 32) autoclave with a capacity of 500 ml. Hydrogen was introduced into the autoclave to 100 kg/cm^2. The rate of the temperature rise was controlled to about 3 °C/min up to 400 °C, after which the temperature was held for the desired reaction period. The autoclave was shaken in a horizontal direction (70 strokes/min). No attempts were made to maintain the hydrogen pressure at a constant level during the reaction.

After the system (A or B) had been cooled to room temperature, gases were collected in a gas holder and analyzed by GLC (60—80 mesh Silica gel column). When the products were obtained in a solid state, they were dissolved in a proper solvent and analyzed by GLC (4.5 m×3 mm packed with 20% SE-30 on Uniport B 60—80 mesh, programmed from 30 to 270 °C, 5 °C/min, TCD, H_2 carrier). The products

obtained in a liquid state were also analyzed by GLC in neat. The actual quantitative interpretation of a chromatogram is based on the peak area. The weight correction factors were determined by the measurement of the relative areas of authentic compounds. The values conveniently used in this study were as follows: retention time, 0—11 min, 0.9; 11—32 min, 1.0; 32—37 min, 1.1; 37—42 min, 1.2; 42—50 min, 1.3; 50 min-, 1.4 (Figs. 1—5). The mixture of coke and catalyst obtained after the extraction of the products was washed with hydrochloric acid in order to remove the catalyst. The coke obtained in this manner was dried and weighed.

Classification of Products. In order to characterize the activity of molten salt catalysts, the products were conveniently classified into 27 groups as follows: I, C_1—C_4 gases; II, C_5—C_7 alkanes; III, cycloalkanes; IV, monocyclic aromatics; V, indans and tetralins; VI, bicyclic aromatics; VII, dihydrophenanthrene; VIII, tetrahydrophenanthrene and its isomers; IX, octahydrophenanthrene and its isomers; X, phenanthrene; XI, higher-boiling compounds; XII, coke; XIII, benzindans, tricyclic aromatics, and their hydrogenated compounds; XIV, perhydropyrenes; XV, decahydropyrenes; XVI, tetrahydropyrene; XVII, hexahydropyrenes; XVIII, dihydropyrene; XIX, pyrene; XX, dodecahydrochrysene and its isomers; XXI, octahydrochrysene and its isomers; XXII, dihydrochrysene; XXIII, hexahydrochrysene and its isomers; XXIV, tetrahydrochrysene and its isomers; XXV, chrysene; XXVI, tetrahydrofluoranthene; XXVII, fluoranthene.

Results and Discussion

Identification of Products. The mass spectra of all the products in this study were obtained by means of GC-MS. The molecular weights of the products are given, and the chemical structures can be fairly deduced when specific cleavage patterns are found in the mass spectra. We previously published the results of the identification of the hydrocracked products of anthracene by considering their mass spectra in combination with the eluted order on the gas chromatogram estimated from their boiling points.[7] In that case, the isomerization of the skeleton of anthracene seemed not to occur. However, the isomerization between *sym*-octahydrophenanthrene and *sym*-octahydroanthracene was clearly found in this hydrocracking of anthracene over acidic molten salts,[6,8] so additional analytical methods were considered necessary for more detailed analyses. The main products were isolated by preparative GLC and analyzed by using NMR spectrometry. The NMR spectral data obtained for the isolated products were as follows: 6-butyltetralin, δ=0.92 (3H, t), 1.08—1.68 (4H, m), 1.78 (4H, m), 2.46 (2H, t), 2.66 (4H, m), and 6.6—7.0 (3H, m); 1,2,3,4,4a,9,10,10a-octahydrophenanthrene, 6.90 (4H, s); 1,2,3,4,5,6,7,8-octahydrophenanthrene, 1.75 (8H, m), 2.48 (4H, m), 2.65 (4H, m), and 6.60 (2H, s); 9,10-dihydrophenanthrene, 2.81 (4H, s), 7.02—7.33 (6H, m), and 7.48—7.72 (2H, m); 1,2,3,4-tetrahydrophenanthrene, 1.82 (4H, m), 2.88 (2H,m), 3.07 (2H, m), and 6.96—7.96 (6H, m); 1,2,3,3a,4,5,9,10,10a,10b-decahydropyrene, 6.5—7.0 (3H, m); 1,2,3,3a,4,5,5a,6,7,8-decahydropyrene, 6.64 (2H, s); 4,5,9,10-tetrahydropyrene, 2.84 (8H, s) and 6.92 (6H, s); 1,2,3,3a,4,5-hexahydropyrene, 1.2—2.4 (6H, m), 2.6—3.4 (5H, m), and 6.8—7.7 (5H, m); 1,2,3,6,7,8-hexahydropyrene, 2.01 (4H, m), 3.0 (8H, t), and 6.92 (4H, s); 4,5-dihydropyrene, 3.24 (4H, s) and 7.16—7.68 (8H, m); 5,6,8,9,10,11-hexahydrobenz[*a*]anthracene, 1.80 (4H, m), 2.72 (8H, m) and 6.76—7.80 (6H, m); 1,2,3,4,5,6-hexahydrochrysene, 1.84 (4H, m), 2.73 (8H, m), and 6.8—7.7 (6H, m); 8,9,10,11-tetrahydrobenz[*a*]anthracene, 1.80 (4H, m), 2.92 (4H, m), and 7.3—8.6 (8H, m); 1,2,3,4-tetrahydrochrysene, 1.96 (4H, m), 2.94 (2H, m), 3.16 (2H, m), and 7.2—8.8 (8H, m); 5,6-dihydrochrysene, 2.86 (2H, m), 3.20 (2H, m), and 6.8—8.1 (10H, m); 6-phenyltetralin, 1.82 (4H, m), 2.77 (4H, m), and 6.9—7.6 (8H, m); 5-phenyltetralin, 1.76 (4H, m), 2.56 (2H, m), 2.80 (2H, m), and 6.8—7.5 (8H, m). When the NMR spectrum of an isolated compound is complicated, the information about the molecular weight obtained from the mass-spectral measurements and the ratio of aromatic hydrogen to non-aromatic hydrogen from the NMR method often gave the correct structure (*e.g.*, the distinction between 1,2,3,3a,4,5,9,10,10a,10b-decahydropyrene and 1,2,3,3a,4,5,5a,6,7,8-decahydropyrene). When the amount of a compound isolated was small, UV spectrometry was conventionally used for the structural confirmation. The type of aromatic hydrocarbon (that is, benzene, naphthalene, biphenyl, anthracene, phenanthrene, pyrene, fluoranthene, chrysene, and so on) is clarified based on the characteristic absorption bands. For example, the absorption wave numbers of phenanthrene, 4,5-dihydropyrene, 1,2,3,4-tetrahydrochrysene, and 8,9,10,11-tetrahydrobenz[*a*]-anthracene differed to some degree, but their characteristic absorption bands were similar. This indicates that these compounds all have a phenanthrene skeleton. Of course, IR spectrometry played an important role

in the analysis. The cleavage patterns of the mass spectra of the compounds identified by using these analytical methods could then be applied to other compounds. The GC charts of the hydrocracked products are shown in Figs. 1—5, where the structures characterized or assumed are listed. The structures of benzindan derivatives and their hydrogenated compounds are not certain because the distinction between 2,3-dihydro-1*H*-benz[*e*]indene and 2,3-dihydro-1*H*-benz[*f*]indene is not clear only by considering their mass spectra. Consequently, the structures for these compounds listed in these figures are chosen for convenience. By this exhaustive analysis, the probable reaction process can be estimated and the difference in catalytic activity among the molten salt catalysts can be clarified.

Hydrocracking of Phenanthrene. The most probable reaction process is shown in Fig. 6. The most important characteristic of the hydrocracking of phenanthrene is the isomerization between *sym*-octahydrophenanthrene and *sym*-octahydroanthracene. We also observed the isomerization in the hydrocracking of anthracene in the presence of a Lewis acid.[6,8] A constant ratio of them in equilibrium was observed, so this isomerization is considered to be reversible. This finding is consistent with that observed over aluminum chloride by Schroeter.[9] On the other hand, this isomerization was not observed in their hydrogenation in the presence of alkali metals.[10] These findings suggest that the decomposition process of *sym*-octahydroanthracene must also be considered in the hydrocracking of phenanthrene over acidic catalysts.

The formation of 1-cyclohexyl-2-phenylethane was found in the products[δ=2.56(2H,t,J=8 Hz)]. *unsym*-Octahydrophenanthrene is considered to be cleaved and hydrogenated to that compound, judging from the similarity of the structures of these two compounds. In the presence of aluminum chloride, secondary alkyl-

benzene was dealkylated in preference to primary alkylbenzene.[11] If this finding is extended to the case of *unsym*-octahydrophenanthrene, the preferable scisson of its C_{4a}–C_{4b} bond to produce 1-cyclohexyl-2-phenylethane may be reasonable. Although the above decomposition process has never been indicated in this connection, it is one of the most important decomposition routes in the hydrocracking of phenanthrene.

The product distributions are shown in Table 1. From the standpoint of the distribution of the gaseous products, especially the ratio of iso to normal isomers, the catalytic action of molten salts was discussed in a previous paper.[5] The constituents of the gaseous products in Run 2 were as follows: methane, 8.0 wt %; ethane, 7.5%; propane, 33.6%; isobutane, 38.0%; butane, 9.3%; butenes, 3.6%. Since the ratio of isobutane to butane is higher than that in the thermodynamic equilibrium, this hydrocracking is considered to proceed by means of a carbonium-ion mechanism.[12]

The catalytic activity of the binary mixture of zinc iodide and potassium iodide is superior to that of zinc chloride in the hydrogenation of phenanthrene (Runs 1 and 2). In this case, attention must be paid to the fact that the intrinsic cracking activity is lowered by the addition of potassium iodide because of the formation of the complex ions.[5,13] The conversion in the presence of the zinc chloride containing 10 mol % nickel(II) chloride is lower than that in the presence of zinc chloride containing 40 mol % copper(I) chloride, but the product distributions obtained over these two catalysts are similar (Runs 2 and 4). Therefore, the decomposition process of phenanthrene over $NiCl_2/ZnCl_2$ is considered to be intermediate between that over $ZnCl_2$ and that over $ZnCl_2$/CuCl. This finding suggests that zinc chloride has a good intrinsic cracking activity under these reaction conditions, but its hydrogenating activity is not so high. The addition of a good hydrogenating catalyst to zinc chloride will produce an excellent catalyst for the hydrocracking of polynuclear aromatic hydrocarbons. Consequently, these molten salt catalysts act as dual-functional catalysts, and appropriate molten mixtures of metal salts with the hydrogenating activity and metal salts with the cracking activity may be able to become effective catalysts.

A remarkable catalytic action of $ZnCl_2$/CuCl was observed in this investigation (Runs 1 and 2). The hydrogenating activity of zinc chloride is very low in this temperature range (Run 1). The intrinsic cracking activity of zinc chloride may not be able to operate because phenanthrene is little hydrogenated. The addition of copper(I) chloride to zinc chloride must contribute to the improvement of the hydrogenating activity of the catalyst. The difference in the yield of octahydrophenanthrene and its isomers (IX) between Run 6 and Run 7 indicates this improvement in the hydrogenating activity.

By comparing the results of Run 1 and Run 6, phenanthrene was found to be more hydrogenated in Run 6 than in Run 1. From this fact, it can be seen that the ratio of hydrogen to the feed must affect the product distributions. In addition, the material, the capacity, the stirring pattern, and the memory effect of the autoclave are also important factors in dominating these reactions. Therefore, even if the pressure, the temperature, and the ratio of hydrogen to the feed should be maintained at constant levels in the different systems, similar results may not be obtained.

Hydrocracking of Pyrene. Pyrene is liable to accept the hydrogenation (Runs 1 and 9), but is fairly stable to the catalytic cracking (Runs 2 and 10), com-

pared with phenanthrene. If the decomposition of dihydropyrene to phenanthrene takes place, the hydrocracking may occur easily. In practice, however, dihydropyrene was converted further to highly hydrogenated pyrenes, and so the probable decomposition routes of pyrene could not be clarified in detail in this investigation. In the hydrocracking of pyrene, a binary mixture of zinc bromide and copper(I) bromide was used for the purpose of examining the effect of the difference of halide (Run 12). A high catalytic activity was found, but a fairly large amount of coke was also formed. This is probably the reason why the reaction conditions are not adequate for this catalyst. There is still much room for an examination of the reaction conditions. No remarkable difference in the product distributions of Runs 13 and 14 was observed because the large amount of hydrogen and the other factors mentioned above might serve to make uniform the characteristics of these two catalysts. This may be considered to be indirect evidence for the improvement of the hydrogenating activity by the addition of copper(I) chloride. The binary mixture of zinc iodide and potassium iodide displayed an excellent hydrogenating activity and a lack of the cracking activity (Run 11).

Hydrocracking of Chrysene. The results of the hydrocracking of chrysene are shown in Table 3. Chrysene is hydrogenated to hydrochrysenes, which then isomerize to hydrobenz[*a*]anthracenes (Fig. 7). For example, 1,2,3,4,5,6-hexahydrochrysene (containing a *sym*-octahydrophenanthrene skeleton) isomerizes to 5,6,8,9,10,11-hexahydrobenz[*a*]anthracene (containing a *sym*-octahydroanthracene skeleton) in the presence of a Lewis acid. The formation of 8,9,10,11-tetrahydrobenz[*a*]anthracene is attributed to either the isomerization of 1,2,3,4-tetrahydrochrysene or the dehydrogenation of 5,6,8,9,10,11-hexahydrobenz[*a*]anthracene; it is not certain which occurred in practice. The main decomposition pathways of hydrochrysenes and their isomers are probably the formations of butylphenanthrene and the hydrogenated compounds. These phenanthrene-type compounds are hydrocracked in a manner similar to that described in the hydrocracking of phenanthrene. The decomposition route from dodecahydrochrysene and benz[*a*]anthracene to 5- and 6-(2-cyclohexylethyl)-tetralin respectively becomes fairly important in the B system (Run 18), because the extent of the hydrogenation is relatively high. Of course, the saturated six-member rings of tetra-, octa-, dodecahydrochrysenes, and hydrobenz[*a*]anthracenes isomerize to five-member rings. The probable reaction process of chrysene is shown in Fig. 7. A high catalytic activity of $ZnCl_2$/CuCl was also observed in the hydrocracking of chrysene. Chrysene accepts hydrogenation relatively easily in comparison with phenanthrene (Runs 1 and 15).

tetralin in the presence of hydrogen, followed by isomerization to 6-phenyltetralin. Consequently, the amounts of biphenyl derivatives were fairly large. The great formation of biphenyls in the hydrocracking of a heavy anthracene oil[5] may be attributed to this decomposition pathway. The decomposition process of fluoranthene is shown in Fig. 8.[14]

Hydrocracking of Anthracene. The details of the hydrocracking of anthracene have been reported in a preliminary study.[6] Anthracene is more easily hydrogenated than phenanthrene. The product distribution of anthracene is similar to that of phenanthrene when the hydrocracking proceeds to some degree. This phenomenon is attributable to the fact that the marginal hydrogenated ring is ruptured in preference to the central ring in a dihydro derivative, for the cleavage of a saturated single C–C bond of dihydroanthracene or phenanthrene should result in a different type of compound. In addition, it is necessary to take into account the fact that the isomerization between *sym*-octahydroanthracene and *sym*-octahydrophenanthrene does away with the difference in their product distributions.

Concerning the reaction routes over these molten salt catalysts, the findings in this investigation may be outlined as follows: 1) the isomerization between *sym*-octahydrophenanthrene and *sym*-octahydroanthracene in the hydrocracking of phenanthrene and anthracene, and a similar isomerization in the hydrocracking of chrysene; 2) the decomposition of *unsym*-octahydrophenanthrene to 1-cyclohexyl-2-phenylethane in the hydrocracking of phenanthrene and a similar cleavage in the hydrocracking of chrysene; 3) a decomposition pathway leading to biphenyls in the hydrocracking of fluoranthene. On the other hand, $ZnCl_2$/CuCl salt, which is considered to act as a dual-functional catalyst, displayed a more efficient catalytic activity for *cata*-condensed aromatic hydrocarbons (phenanthrene, anthracene, and chrysene) than for *peri*-condensed aromatic hydrocarbons (pyrene). Moreover, these results (listed in Figs. 1—5) were useful in the identification of the hydrocracked products of Yūbari coal.[16]

Reclamation of Vulcanized Rubbers by Chemical Degradation. IX. Oxidative Degradation of *cis*-1,4-Polyisoprene by Phenylhydrazine-Iron(II) Chloride System

Nariyoshi KAWABATA, Shinzo YAMASHITA, and Yoshinori FURUKAWA

Department of Chemistry, Faculty of Polytechnic Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606

(Received June 29, 1977)

Degradation of *cis*-1,4-polyisoprene by phenylhydrazine–iron(II) chloride system was investigated in benzene solution at 30 °C in the air. Separate use of the two chemicals was much less effective for degradation. The number of chain scission was found to depend upon only the amount of phenylhydrazine, independent of that of iron(II) chloride, indicating that phenylhydrazine plays the leading part of the phenylhydrazine–iron(II) chloride system in the degradation. When iron(III) chloride was used instead of iron(II) chloride, the degradation became slower, but the number of chain scission was not significantly affected.

Reclaiming processes are well established for natural rubber scrap, and the reclaimed matter can be used in the compounding of new rubber products. However, devulcanization and depolymerization is performed by heating at *ca.* 200 °C, which is not desirable from an economical point of view, for several hours under pressure in the presence of cheap oil and organic chemicals. Moreover, the process is limited to natural rubber scrap. The devulcanization and depolymerization stage should be modified for synthetic rubber scrap. Natural rubber vulcanizates behave well under the present reclaiming conditions, since they soften with heat, but it is difficult to reclaim synthetic rubber vulcanizates. As an example, styrene-butadiene rubber (SBR) vulcanizates, after initial softening by heating, quickly harden on further heating.

The phenylhydrazine–iron(II) chloride system is a good reagent for the reclamation of scrap tire[1] and various types of synthetic rubber vulcanizates[2] during several hours at room temperature. Useful elastomers can be obtained by the vulcanization of these reclaimed product. Devulcanization and depolymerization stage of the new reclaiming procedure was shown to be an oxidative degradation of vulcanized rubbers by the atmospheric oxygen.[3] In the presence of iron(II) chloride, phenylhydrazine rapidly absorbs an equimolar amount of oxygen, evolving an equimolar amount of nitrogen.[4] When *cis*-1,4-polyisoprene was added to the reaction mixture, additional oxygen absorption was observed, the molecular weight of polymer decreasing during the course of additional oxygen absorption. The scission efficiency based on the additionally absorbed oxygen was found to be much higher than that for autoxidation of natural rubber. The high scission efficiency seems to be the source of the strong ability of the phenylhydrazine–iron(II) chloride system as a reagent for the reclamation of vulcanized rubbers. In this work, we have investigated the mechanism of the degradation, with attention focussed on the dependence of the number of chain scission upon the composition of the phenylhydrazine–iron(II) chloride system in the degradation.

Experimental

Materials. *cis*-1,4-Polyisoprene (IR-2200, Japan Synthetic Rubber Co., Ltd.) was masticated at room temperature for 20 min, and dissolved in benzene. The gel was removed by filtration, and the soluble polymer recovered by pouring the filtrate into a large excess of methanol was purified by reprecipitation, followed by drying *in vacuo* at room temperature. Benzene was purified by washing with sulfuric acid. After repeated washing with water, it was dried with calcium chloride, then refluxed over calcium hydride and distilled. Commercial phenylhydrazine, iron(II) chloride, anhydrous iron(III) chloride, methanol, and other chemicals were used without further purification. Thermogravimetric analysis of the iron(II) chloride indicated the presence of 40.8 wt% of water.

Procedure. Viscosity measurements of degraded and undegraded *cis*-1,4-polyisoprene solutions were carried out in benzene at 30°C with an Ubbelohde-type dilution viscometer.

The degradation reaction was carried out in a round-bottomed 100 ml flask equipped with a mechanical stirrer in the air. Phenylhydrazine was added *via* a hypodermic syringe to a mixture of 0.5 g of *cis*-1,4-polyisoprene in 48.0 ml of benzene and a prescribed amount of iron(II) chloride or iron(III) chloride in 2.0 ml of methanol at 30 °C under stirring. Part of the reaction mixture was taken out, and the intrinsic viscosity of the solution was immediately determined at 30 °C using Baker's equation[5]

$$[\eta] = a(\eta_r^{1/a} - 1)/c,$$

parameter a for the equation was determined to be 3 prior to experiments on degradation. The dependence of the intrinsic viscosity upon the reaction time was plotted. After the decrease of viscosity became constant, the residue of the reaction mixture was poured into a large excess of methanol, and the polymer was recovered from the solution. The recovered polymer was dried *in vacuo* at room temperature, and the number average molecular weight was determined based on the intrinsic viscosity in benzene solution at 30 °C using the viscosity—molecular weight relationship.[4] The number of chain scission was determined from the decrease in the number average molecular weight during the course of degradation.

Results and Discussion

The relation between the intrinsic viscosity of the reaction mixture determined by use of Baker's equation and the reaction time for the degradation of *cis*-1,4-polyisoprene by the phenylhydrazine–Iron(II) chloride system in benzene at 30 °C, is shown in Fig. 1. In the absence of both chemicals, the intrinsic viscosity did not significantly change at 30 °C within 30 min. Curve 1

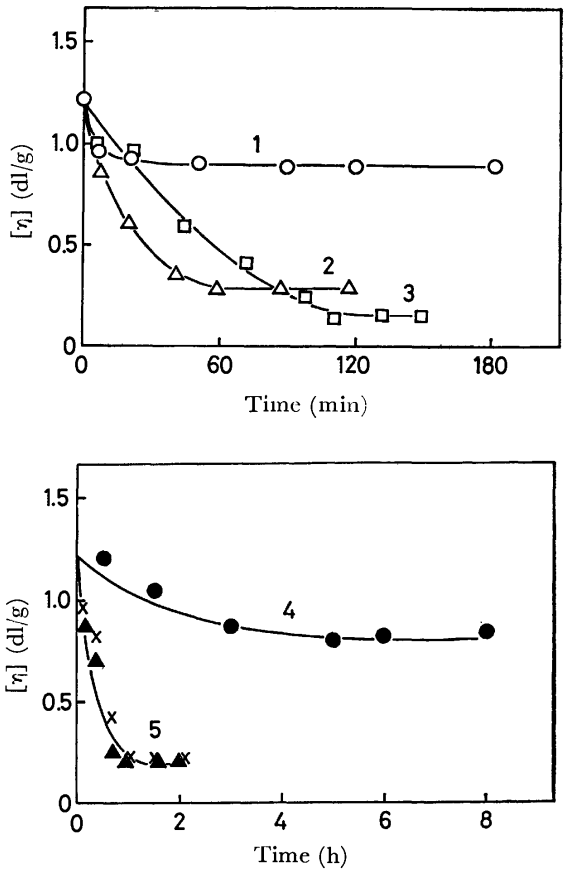

Fig. 1. Time dependence of the intrinsic viscosity of the reaction mixture for the degradation of *cis*-1,4-polyisoprene by the phenylhydrazine–iron(II) chloride system in benzene solution at 30 °C under the atmosphere of air. Conditions: *cis*-1,4-polyisoprene, 0.5 g; benzene, 48.0 ml; methanol, 2.0 ml. (○) iron(II) chloride, 0.10 mmol; phenylhydrazine, 0 mmol. (△) iron(II) chloride, 0.10 mmol; phenylhydrazine, 0.45 mmol. (□) iron(II) chloride, 0.10 mmol; phenylhydrazine, 2.00 mmol. (●) iron(II) chloride 0 mmol; phenylhydrazine, 1.00 mmol. (▲) iron(II) chloride, 0.02 mmol; phenylhydrazine, 1.00 mmol. (×) iron(II) chloride, 0.10 mmol; phenylhydrazine, 1.00 mmol.

was obtained in the presence of iron(II) chloride but in the absence of phenylhydrazine, whereas curves 2 and 3 were obtained in the presence of both compounds. A comparison of the curves indicates that the presence of phenylhydrazine considerably increases the rate of the degradation. Curves 2 and 3 show that degradation was almost complete within 2 h, the number of chain scission increasing with the amount of phenylhydrazine.

Curve 4 was obtained in the presence of phenylhydrazine but in the absence of iron(II) chloride, whereas curve 5 was obtained in the presence of both compounds. We see that separate use of phenylhydrazine and iron(II) chloride is less effective for the degradation of the polymer. This is in line with the fact that separate use of the two compounds is much less effective for the reclamation of scrap tire.

A comparison of curves 4 and 5 indicates that the presence of iron(II) chloride remarkably increases the rate of the degradation. However, curve 5 shows that the number of chain scission is not sensitive to the amount of iron(II) chloride.

After the decrease in the intrinsic viscosity of the reaction mixture (Fig. 1) ceased, the degraded polymer was recovered from the reaction mixture. Based on the number average molecular weight of the degraded and undegraded polymer, the number of chain scission was calculated. The number of chain scission versus the amount of phenylhydrazine is plotted in Fig. 2. Curve A was obtained for the degradation by the phenylhydrazine–iron(II) chloride system. Curve B was obtained for the degradation in the presence of phenylhydrazine but in the absence of iron(II) chloride. Fig. 2 indicates that iron(II) chloride considerably increases not only the rate of the degradation but also the number of chain scission. However, the number of chain scission depends upon only the amount of phenylhydrazine, independent of that of iron(II) chloride. This indicates that phenylhydrazine plays the principal part in the phenylhydrazine–iron(II) chloride system for the degradation of the polymer. Iron(II) chloride seems to be a catalyst in the oxidative degradation of the polymer by phenylhydrazine.

Phenylhydrazine is an accelerator for the mastication of rubber.[6,7] Mastication and our new method of reclamation appear to be closely related to each other. Phenylhydrazine was reported to be oxidized on exposure to free oxygen.[8] Iron(II) chloride seems to accelerate the oxidation.[4] Analysis of the products of the reaction of phenylhydrazine with iron(II) chloride under the atmosphere of oxygen and air showed the formation of benzene, phenol, and biphenyl.[4] Thus it seems that the formation of phenyl radical by the oxidation of phenylhydrazine is accelerated by iron(II)

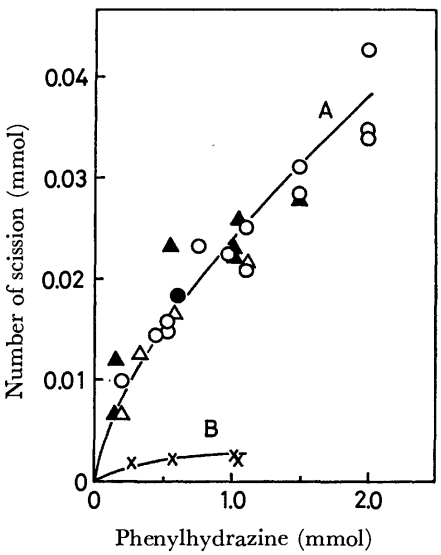

Fig. 2. Plot of the number of chain scission versus the amount of phenylhydrazine for the degradation of *cis*-1,4-polyisoprene by the phenylhydrazine-iron(II) chloride system in benzene solution at 30 °C under the atmosphere of air. Conditions: *cis*-1,4-polyisoprene, 0.5 g; benzene, 48.0 ml; methanol, 2.0 ml; iron(II) chloride, (●) 0.20 mmol, (○) 0.10 mmol, (▲) 0.02 mol, (△) 0.004 mmol, (×) 0 mmol.

chloride. The phenyl radical and related reactive species might attack *cis*-1,4-polyisoprene, causing the degradation of the polymer. Thus the number of the chain scission of the polymer considerably increases with the presence of iron(II) chloride, but not with the amount of iron(II) chloride.

Color change takes place during the course of degradation, showing the change of iron(II) to iron(III). In connection with this the degradation of *cis*-1,4-polyisoprene by the phenylhydrazine–iron(III) chloride system was also studied. The relation between the intrinsic viscosity of the reaction mixture determined by use of Baker's equation and the reaction time for the degradation in benzene at 30 °C, is shown in Fig. 3.

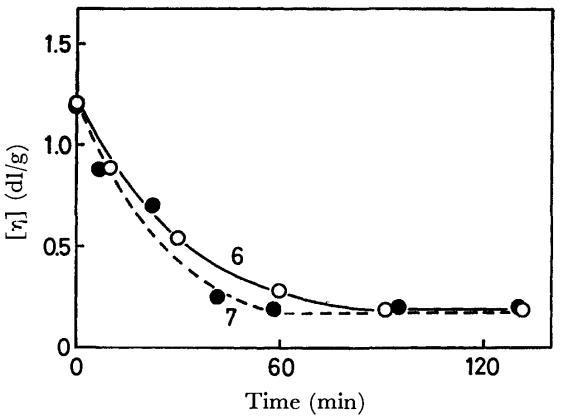

Fig. 3. Time dependence of the intrinsic viscosity of the reaction mixture for the degradation of *cis*-1,4-polyisoprene by the phenylhydrazine–iron(II) chloride system and the phenylhydrazine–iron(III) chloride system in benzene solution at 30 °C under the atmosphere of air. Conditions: *cis*-1,4-polyisoprene, 0.5 g; benzene, 48.0 ml; methanol, 2.0 ml. (●) iron(II) chloride, 0.02 mmol; phenylhydrazine, 1.00 mmol. (○) iron(III) chloride, 0.02 mmol; phenylhydrazine, 1.00 mmol.

Curve 6 was obtained for the degradation by the phenylhydrazine–iron(III) chloride system, and curve 7 for the degradation by the phenylhydrazine–iron(II) chloride system. Iron(III) chloride also considerably increases the rate of degradation of the polymer by phenylhydrazine. However, the degradation becomes slower when iron(III) chloride is used instead of iron(II) chloride, as shown in Fig. 3. This is in line with the fact that phenylhydrazine–iron(III) chloride system is less effective than the phenylhydrazine–iron(II) chloride system in the reclamation of scrap tire.[1] The number of chain scission versus the amount of phenylhydrazine for the degradation of the polymer by the phenylhydrazine–iron(III) chloride system is plotted in Fig. 4. Curve D was obtained in the absence of iron(III) chloride. We see that iron(III) chloride also considerably increases not only the rate of the degradation but also the number of chain scission. However, the number of chain scission depends only upon the amount of phenylhydrazine and not upon the amount of iron(III) chloride. Phenylhydrazine also seems to play the principal role in the phenylhydrazine–iron(III) chloride

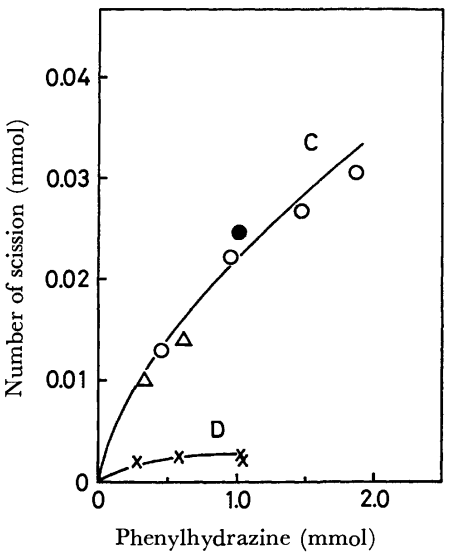

Fig. 4. Plot of the number of chain scission versus the amount of phenylhydrazine for the degradation of *cis*-1,4-polyisoprene by the phenylhydrazine–iron(III) chloride system in benzene solution at 30 °C under the atmosphere of air. Conditions: *cis*-1,4-polyisoprene, 0.5 g; benzene, 48.0 ml; methanol, 2.0 ml; iron(III) chloride, (○) 0.10 mmol, (△) 0.05 mmol, (●) 0.02 mmol, (×) 0 mmol.

system in the degradation of the polymer. A comparison of curve C in Fig. 4 with curve A in Fig. 2 leads us to conclude that the efficiency of the chain scission based on the amount of phenylhydrazine is in the same order of magnitude regardless of whether iron(II) chloride or iron(III) chloride is used. Iron(II) chloride and iron(III) chloride could recycle during the degradation.

The results of the present and previous works suggest a reasonable interpretation of the mechanism of reaction. Experimental evidences are as follows:

1. The infrared spectra of the soluble fractions obtained from various rubber vulcanizates by the treatment with phenlhydrazine–iron(II) chloride system show the presence of carbonyl and hydroxyl groups.[2]

2. The treatment of vulcanized *cis*-1,4-polyisoprene by the phenylhydrazine–iron(II) chloride system in the air reduces the effective network chain density of the vulcanizates, giving a soluble fraction of rubber. Treatment in sealed vessels in the absence of oxygen gives no soluble fraction, not decreasing the effective network chain density.[3]

3. From the decrease of the effective network chain density and the increase of the soluble fraction, it is concluded that the network chain of the vulcanized rubber undergoes a severance reaction by the phenylhydrazine–iron(II) chloride system in the order: polysulfide linkage>monosulfide linkage>carbon-carbon crosslink.[3]

4. Although Chattaway[8] indicated that phenylhydrazine is oxidized on exposure to free oxygen, it has been found that iron(II) chloride considerably accelerates oxidation.[4]

5. In the presence of iron(II) chloride under air or

oxygen atmosphere, phenylhydrazine rapidly absorbs an equimolar amount of oxygen, evolving an equimolar amount of nitrogen.[4] Gas chromatographic analysis of the reaction mixture shows the presence of benzene, phenol, and biphenyl in 37, 35—60, and 4—8% yields, respectively, based on phenylhydrazine.[4] When *cis*-1,4-polyisoprene is added to the reaction mixture, additional absorption of oxygen is observed, the molecular weight of the polymer decreasing during course of additional oxygen absorption.[4]

6. Under nitrogen atmosphere, the reaction of phenylhydrazine with iron(II) chloride in benzene solution rapidly gives a 2: 1 complex, a white solid which is relatively stable under nitrogen but rapidly decomposes in the presence of oxygen; in the air, it is a very effective reagent for the reclamation of vulcanized rubbers.[9]

7. Separate use of phenylhydrazine and iron(II) chloride is much less effective for the degradation of *cis*-1,4-polyisoprene. However, the number of chain scission depends only upon the amount of phenylhydrazine and not upon that of iron(II) chloride.

8. When iron(III) chloride is used instead of iron(II) chloride, the degradation becomes slower, the number of chain scission not being significantly affected.

9. Color change takes place during the course of degradation, showing the change of iron(II) to iron(III).

We postulate the following mechanism for the reclamation of vulcanized rubbers by the phenylhydrazine–iron(II) chloride system. Devulcanization and the depolymerization stage of the new reclaiming procedure is an oxidative degradation of vulcanized rubber by atmospheric oxygen. The function of the phenylhydrazine–iron(II) chloride system is essentially the acceleration of autoxidation of vulcanized rubber.

$$2PhNHNH_2 + FeCl_2 \longrightarrow \underset{\mathbf{1}}{[2PhNHNH_2 \cdot FeCl_2]}, \quad (1)$$

$$\mathbf{1} \xrightarrow{O_2} \underset{\mathbf{2}}{Ph\cdot} + \underset{\mathbf{3}}{PhOOH} + \underset{\mathbf{4}}{HOO\cdot} + N_2, \quad (2)$$

The Extraction of Alkali Metal Picrates into Benzene by Means of 18-Crown-6

**Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700*

(Received May 30, 1977)

Synopsis. The distribution of alkali metal picrates between water and benzene was investigated in the presence of 18-crown-6. The overall equilibrium constants, K_{ex}, and some constituent equilibrium constants were determined. The K_{ex} value increases, passes through a maximum (at potassium), and falls off as the size of the alkali metal cation increases.

18-Crown-6 (CR) combines stoichiometrically with alkali metal cations to form complexes, in which the cation is accommodated into the hydrophilic molecular hole of the ligand (diameter: 0.26—0.32 nm).[1-3] The outer surface is then formed by the hydrophobic groups. From the 'metal in the hole' picture, the resulting complexes may be expected to be identical in size and in hydrophobicity. It is well known that there is a striking correlation between the stability of the complex and the size of the cation.[4] Among alkali metal cations, the potassium cation forms the most stable complex with the ligand; cations larger (Rb^+, Cs^+) or smaller (Li^+, Na^+) than the optimum size form destabilized complexes because, in the former, these cations are too large to fit into the ligand hole, while, in the latter, the hydration energy of these cations is predominant.[5]

In this paper, methods for obtaining the overall equilibrium constants will be reported. The extractability of alkali metal cations by CR will be discussed in terms of the stability constant of the complex.

Experimental

Materials. Commercial CR (Nisso Co., Ltd.) was used without further purification. The alkali metal picrates were prepared and purified as has previously been described.[6]

Extraction Procedure. The picrates were each dissolved in water containing lithium hydroxide at a concentration of 5×10^{-5} M (1 M = 1 mol dm^{-3}). The concentrations were 10^{-2} M for sodium picrate, 10^{-3} M for potassium and rubidium picrates, and 5×10^{-3} M for caesium picrate. The CR was made up in benzene solutions, the concentration range being $(0.15-2)\times10^{-3}$ M. Equal volumes (20 cm^3) of the aqueous and benzene solutions were transferred into a 50-cm^3 centrifuge tube equipped with a stopper, shaken in a water bath thermostated at (25±0.01)°C for 20 min, and then allowed to stand for about 20 min. The picrate concentration in the benzene phase was determined spectrophotometrically at 425 nm. The molar absorption coefficients, ε, of the picrates in the benzene phase were determined to be ε=8900, 9400, 9100, and 9000 M^{-1} cm^{-1} at 425 nm for sodium, potassium, rubidium, and caesium picrates respectively. For this purpose, each of the benzene solutions was equilibrated with each of the aqueous picrate solutions as in the above procedure, after which the picrates extracted were completely back-extracted into water. The picrate concentrations were determined spectrophotometrically (ε=14400 M^{-1} cm^{-1} at 354 nm).

The Distribution Coefficient of CR. The CR was made up in benzene solutions ranging in concentration from 0.7×10^{-4} to 3.5×10^{-4} M. Each of the solutions was equilibrated with an aqueous 0.1 M potassium chloride solution containing lithium hydroxide (0.01 M) at 25 °C. The benzene phases separated from the aqueous phase were each shaken with the aqueous potassium chloride solution in the presence of an excess of the potassium salt of 2,2′,4,4′,6,6′-hexanitrodiphenylamine. The concentration of the resulting complex in the benzene phase was determined spectrophotometrically at 425 nm by means of the calibration method. The distribution constants thus obtained were averaged for use in subsequent calculations.

Results and Discussion

The equilibrium between an aqueous solution containing an alkali metal cation, M^+, and a picrate anion, A^-, and a benzene solution containing CR can be written as

$$M^+ + CR_o + A^- \rightleftharpoons MCRA_o,$$

$$K_{ex} = \frac{[MCRA]_o}{[M^+][CR]_o[A^-]}, \quad (1)$$

where MCRA designates ion-pairs between alkali metal complexes, MCR^+, and picrate anions; the subscript o refers to the benzene phase, and the lack of a subscript, to the aqueous phase; the molar concentrations are given in brackets. The constituent equilibria are

$$CR \rightleftharpoons CR_o, \qquad D_c = \frac{[CR]_o}{[CR]}, \quad (2)$$

$$M^+ + CR \rightleftharpoons MCR^+, \qquad K_s = \frac{[MCR^+]}{[M^+][CR]}, \quad (3)$$

$$MCR^+ + A^- \rightleftharpoons MCRA, \qquad K_{ass} = \frac{[MCRA]}{[MCR^+][A^-]}, \quad (4)$$

$$MCRA \rightleftharpoons MCRA_o, \qquad D_{ip} = \frac{[MCRA]_o}{[MCRA]}. \quad (5)$$

The mass balances are

$$T_M = [M^+] + [MCR^+] + [MCRA] + [MCRA]_o, \quad (6)$$

$$T_{CR} = [CR] + [CR]_o + [MCR^+] + [MCRA] + [MCRA]_o, \quad (7)$$

$$T_A = [A^-] + [MCRA] + [MCRA]_o, \quad (8)$$

where T denotes the total concentration.

Table 1. Equilibrium constants for extraction of picrate with 18-crown-6 (CR) and dibenzo-18-crown-6 (DBC)

Ligand	Cation	Ionic diameter (nm)	D_c	log K_{ex}	log K_s	log ($K_{ass}D_{ip}$)	D_{ip}	K_{ass}
CR			0.0572					
	Na^+	0.194		3.31	<0.3[a]	>1.8	>0.4	
	K^+	0.266		6.00	2.06[a]	2.70	3.7	140
	Rb^+	0.294		5.43	1.5	2.7	>1[b]	
	Cs^+	0.334		4.28	0.8[a]	2.2	>1	
DBC			800					
	Na^+			2.21[c]	1.2[d]	3.9		
	K^+			4.65[c]	1.7[d]	5.9		
	Rb^+			3.75[c]	1.1[d]	5.6		
	Cs^+			3.07[c]	0.8[d]	5.2		

a) From Ref. 5. b) Estimated value. c) From Ref. 6. d) From Ref. 7.

Substituting Eqs. 2, 3, and 5 into Eq. 6, we obtain

$$[M^+] = \frac{T_M - [MCRA]_o(1+1/D_{ip})}{1+(K_s/D_c)[CR]_o}. \quad (9)$$

Equations 2, 6, and 7 are combined to give

$$[CR]_o = \frac{[M^+] - T_M + T_{CR}}{1+1/D_c}. \quad (10)$$

From Eq. 8, we obtain

$$[A^-] = T_A - [MCRA]_o(1+1/D_{ip}). \quad (11)$$

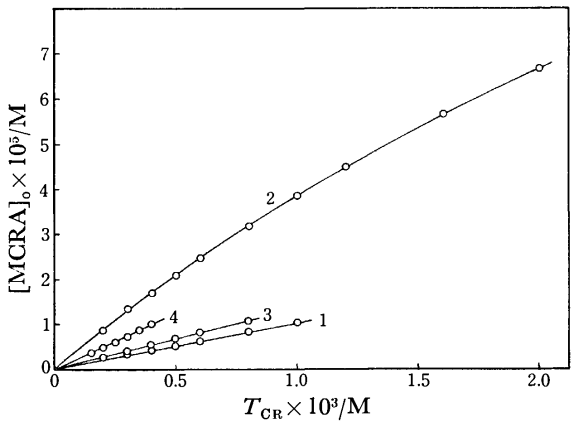

Fig. 1. Extraction of alkali metal picrate into benzene by 18-crwon-6. 1: Na, 2: K, 3: Rb, 4: Cs.

Combining Eqs. 1, 9, 10, and 11, we obtain a single relation with two unknowns, K_{ex} and D_{ip}. These were evaluated by a nonlinear regression fitting of 6—10 points per system, the deviation of the measured variable $[MCRA]_o$ being minimized in the process. In the case of rubidium, the relation thus obtained contains one more unknown, K_s. In view of the structural resemblance between $RbCR^+$ and $CsCR^+$, it is reasonable to estimate that $D_{ip}>1$ for rubidium. Thus, we can likewise estimate K_{ex} and K_s by regression analysis. As can be seen from Fig. 1, the calculated (solid line) and found (open circle) data agree within 2 percent. From Eqs. 9, 10, and 11, on the other hand, it is expected that a much simpler relation will hold between $[MCRA]_o$ and K_{ex} for MCRA of a low extractability:

$$[MCRA]_o = \frac{K_{ex}(T_M)^2}{1+1/D_c} T_{CR}. \quad (12)$$

The K_{ex} values obtained from the slope of each straight line in Fig. 1 ($\log K_{ex}=3.30$ and 4.27 for Na^+ and Cs^+ respectively) are in good agreement with those listed in Table 1. The ion-association constant, K_{ass}, for potassium is calculated from the equation

$$K_{ex} = \frac{1}{D_c}(K_s K_{ass} D_{ip}). \quad (13)$$

The data obtained, together with the values from the literature for dibenzo-18-crown-6 (DBC), are summarized in Table 1.

Table 1 shows that the log ($K_{ass}D_{ip}$) values for CR are almost all equal in magnitude except for sodium. The same is true for its aromatic analogue, DBC. It follows from this finding that the observed sequence of K_{ex} for a given ligand is determined primarily by that of the stability constant, K_s.

Table 1 also shows that the distribution coefficient, D_c, of DBC is more than four decades greater than that of CR; this finding indicates that DBC is much more hydrophobic than CR. The hydrophobicity of the ligand shows virtually no effect on the stability of the complex, but it does have a slight effect on K_{ex}. It follows that the magnitude of K_{ex} for a given alkali metal is chiefly governed by that of $K_{ass}D_{ip}/D_c$ (*cf.* Eq. 13). It is noticeable that the less hydrophobic ligand is preferred as an extracting agent.

Electronic Spectra and Charge-Transfer Absorption of Solid Anion Radical Salts of 2,3-Dicyano-*p*-benzoquinone and 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 9, 1977)

Synopsis. The diffuse reflection spectra were measured with solid anion radical salts of 2,3-dicyano-*p*-benzoquinone and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone with rubidium and caesium cations. Strong charge-transfer transition between anion radicals was observed in the low-energy region. The spectroscopic features of the charge-transfer absorption were discussed in terms of one-dimensional Hubbard model.

In most solid ion radical salts, the planar ion radical molecules are known to form, in themselves, a segregated face-to-face stacking into infinite one-dimensional columns so as to make a large overlap between their half-occupied molecular orbitals.[1-3] In this case, since any individual radical molecule interacts through charge-transfer most strongly with two other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution but shows a charge-transfer transition between ion radicals in the low-energy region.[1-3]

Several years ago,[1] we examined the solid-state spectra of some stable anion radical salts derived from 2,3-dicyano-*p*-benzoquinone (p-H_2QCy_2) and 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (p-Cl_2QCy_2). We prepared such crystalline salts as Na^+ p-$H_2QCy_2^{\cdot-}$, K^+ p-$H_2QCy_2^{\cdot-}$, Na^+ p-$Cl_2QCy_2^{\cdot-}$, and K^+ p-$Cl_2QCy_2^{\cdot-}$, where we found strong absorptions due to the charge-transfer transition between anion radicals in the low-energy region. In the case of Na^+ p-$Cl_2QCy_2^{\cdot-}$ and K^+ p-$Cl_2QCy_2^{\cdot-}$ salts, the band shape of the charge-transfer absorption was found to be almost symmetrical with respect to the axis of peak energy. However, in the case of Na^+ p-$H_2QCy_2^{\cdot-}$ and K^+ p-$H_2QCy_2^{\cdot-}$ salts, the band shape is no longer symmetrical with respect to the axis of peak energy, but has a distinct shoulder in the higher-energy region. Recently, we could well explain those spectroscopic features of the charge-transfer absorptions in terms of one-dimensional Hubbard model.[2,3] In the present paper, we further examined the solid-state spectra of the anion radical salts of p-H_2QCy_2 and p-Cl_2QCy_2 with rubidium and caesium cations.

p-H_2QCy_2 was synthesized from *p*-benzoquinone according to the method of Thiele *et al.*,[4] while p-Cl_2QCy_2 was commercially available. The anion radical salts of Rb^+ p-$H_2QCy_2^{\cdot-}$, Cs^+ p-$H_2QCy_2^{\cdot-}$, Rb^+ p-$Cl_2QCy_2^{\cdot-}$, and Cs^+ p-$Cl_2QCy_2^{\cdot-}$ were prepared according to the method described in the previous paper.[1] The solid-state spectra of these anion radical salts were measured by diffuse reflection method. The spectra were recorded on a Beckman DK-2A spectroreflectometer in the range from 4000 to 30800 cm^{-1} at room temperature. In order to avoid cation exchange between the salt and the diluent, the samples were ground and diluted with pure naphthalene. The solid-state spectra were obtained by plotting the diffuse reflection spectra using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, in which R is the reflectance.

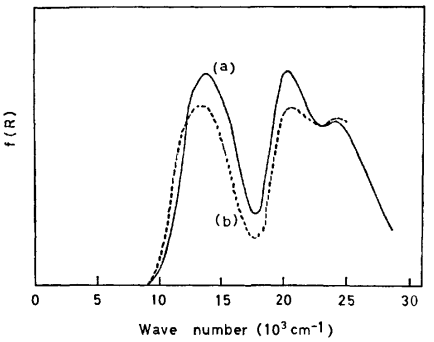

Fig. 1. The solid-state spectra of (a) Rb^+ p-$Cl_2QCy_2^{\cdot-}$ and (b) Cs^+ p-$Cl_2QCy_2^{\cdot-}$.

Figure 1, curve (a), is the observed solid-state spectrum of Rb^+ p-$Cl_2QCy_2^{\cdot-}$ salt, which shows a strong absorption at 13600 cm^{-1} and high-energy bands at 20100 and 24000. These spectroscopic features are found to be very similar to those previously reported on Na^+ p-$Cl_2QCy_2^{\cdot-}$ or K^+ p-$Cl_2QCy_2^{\cdot-}$.[1] The band peaked at 13600 cm^{-1} appears in the low-energy region where the p-Cl_2QCy_2 anion radical monomer does not absorb.[1] This low-energy band seems to be attributable to the charge-transfer transition between the p-Cl_2QCy_2 anion radicals in the segregated stack of the anion radicals, while the bands at 20100 and 24000, cm^{-1} to the shifted bands of the anion radical monomer at 17100 and 21900 cm^{-1}, respectively. Here, we note that the line shape of the charge-transfer absorption at 13600 cm^{-1} is almost symmetrical with respect to the peak-energy axis and that the high-energy bands at 20100 and 24000 cm^{-1} are appreciably blue-shifted, compared to the corresponding absorptions of the monomer spectrum. On the other hand, Fig. 1, curve (b), is the observed solid-state spectrum of Cs^+ p-$Cl_2QCy_2^{\cdot-}$ salt, which also shows a strong charge-transfer band peaked at 13400 cm^{-1} and high-energy bands at 20500 and 24200. In this salt, the line shape of the charge-transfer absorption is again almost symmetrical with respect to the peak-energy axis. As the charge-transfer transition occurs in the segregated stack of the p-Cl_2QCy_2 anion radicals, we can well understand the fact that the energy of the charge-transfer absorption remains nearly constant in going from the rubidium salt to the caesium salt.

On the other hand, Fig. 2, curve (a), is the observed solid-state spectrum of Rb^+ p-$H_2QCy_2^{\cdot-}$. A strong low-

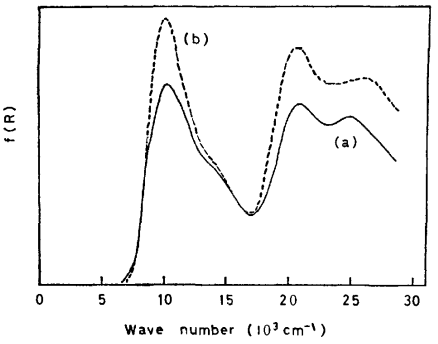

Fig. 2. The solid-state spectra of (a) Rb$^+$ p-$H_2QCy_2^-$ and (b) Cs$^+$ p-$H_2QCy_2^-$.

energy charge-transfer absorption, which arises from the segregated stack of the p-H_2QCy_2 anion radicals, is found at 10300 cm^{-1} with a shoulder around 13500. High-energy bands are located at 20800 and 25000 cm^{-1}, which originate from the monomer absorptions of the p-H_2QCy_2 anion radical at 17100 and 21500 cm^{-1}, respectively.[1] Here, we note that the charge-transfer band is broad and has the shoulder in the higher-energy side and that its line shape is no longer symmetrical with respect to the peak-energy axis. The solid-state spectrum of Cs$^+$ p-$H_2QCy_2^-$ is given in Fig. 2, curve (b). In this case, the charge-transfer band and the high-energy bands are located at 10000 cm^{-1} with a shoulder around 13500 and at 20500 and 25800 cm^{-1}, respectively.

Hereafter, we only discuss the spectroscopic features of the observed charge-transfer absorptions on the basis of our previous theoretical approach.[2] To the segregated stacks of the p-Cl_2QCy_2 or p-H_2QCy_2 anion radicals in their solid salts, we apply non-alternant one-dimensional Hubbard model composed of ion radical molecules with half-occupied orbitals. In the case of paramagnetic state, the intermolecular charge-transfer absorption, $\sigma(\omega)$, is given by

$$\sigma(\omega) \propto \frac{e^2}{4} \frac{I^2}{\omega^2\sqrt{\omega^2-I^2}} \sqrt{4T^2-\omega^2+I^2}. \quad (1)$$

Here, a δ-function was assumed for each elementary transition in which the spin and the wave vector of an electron are conserved; I is the intra-site Coulomb repulsion energy, and T (<0) is the transfer matrix element between nearest neighbor ion radicals in one-dimensional Hubbard model. A schematic representation of the absorption line shape of Eq. 1 has been given in Fig. 1 of Ref. 2. The theoretical charge-transfer absorption has a sharp divergent peak at $\omega=I$. The spectrum has no absorption in the region $\omega<I$, but has a distinct shoulder in the region $I<\omega<\sqrt{I^2+4T^2}$. Actually, however, the elementary absorption is not a δ-function but involves a finite width, and the spectrum will become more smoothed,[2] so that the observed charge-transfer absorption has an intensity even in the energy region lower than the peak position. Therefore, the absorption peak of the observed charge-transfer band corresponds to $\omega=I$, and its band width comes partly from the width due to the elementary absorptions but partly from the width due to non-zero transfer matrix element, $\sqrt{I^2+4T^2}-I$. We divide the two contributions of the widths in a way similar to the previous work.[3] With respect to $\omega=I$, we subtract the lower-energy side from the higher-energy side of the observed charge-transfer absorption. Then, the part symmetrical with respect to $\omega=I$ will correspond to the contribution of the elementary absorptions, while the remaining asymmetric part, to the width due to non-zero transfer matrix element, $\sqrt{I^2+4T^2}-I$, because the absorption in the $\omega<I$ region is solely attributable to the elementary absorptions and the absorption of Eq. 1 appears only in the $\omega>I$ region.

As for the charge-transfer absorptions of Rb$^+$ p-$Cl_2QCy_2^-$ and Cs$^+$ p-$Cl_2QCy_2^-$, the I values for the rubidium and caesium salts are estimated to be 13600 and 13400 cm^{-1}, respectively, from the observed peak energies. In both salts, the band width due to the transfer matrix element, $\sqrt{I^2+4T^2}-I$, is found to be 400 cm^{-1} or less, and the $|T|$ values are estimated to be 1500 cm^{-1} or less by using the observed I values.

On the other hand, from the observed peak energy, the I values for Rb$^+$ p-$H_2QCy_2^-$ and Cs$^+$ p-$H_2QCy_2^-$ are estimated to be 10300 and 10000 cm^{-1}, respectively. In both salts, however, the broad asymmetric charge-transfer absorption with a distinct shoulder in the $\omega>I$ region implies that the band width due to the transfer matrix element is comparable to the width of elementary absorption. By using the above-mentioned method, the asymmetric part in the higher-energy side of the charge-transfer absorption, $\sqrt{I^2+4T^2}-I$, is found to be 2000 cm^{-1} or less for Rb$^+$ p-$H_2QCy_2^-$ and about 2400 cm^{-1} or less for Cs$^+$ p-$H_2QCy_2^-$. Thus, the $|T|$ values for the rubidium and caesium salts are estimated to be $\leq$3400 and $\leq$3700 cm^{-1}, respectively. These values are found to be considerably larger than the corresponding values for the Rb$^+$ p-$Cl_2QCy_2^-$ and Cs$^+$ p-$Cl_2QCy_2^-$ salts.

In conclusion, the solid-state spectra of M$^+$ p-$Cl_2QCy_2^-$ and M$^+$ p-$H_2QCy_2^-$, (M=Na, K, Rb, and Cs), are predominantly governed by the manner of the segregated stacks of the anion radicals, but are hardly influenced by the species of the counter cations. In such stacks of the anion radicals, the p-H_2QCy_2 anion radicals stack more closely than do the p-Cl_2QCy_2 anion radicals. This results in remarkable difference in the charge-transfer absorptions between the p-Cl_2QCy_2 and p-H_2QCy_2 anion radical salts.

Synopsis. Heats of adsorption of ammonia on silica–alumina at very low surface coverage were measured in details. The effects of ammonia adsorption on the glass wall and on the greese were corrected. The initial heat value agreed fairly well with the heat of neutralization of NH_3(G) and HCl(G). The diffusion of the gas had little effect on the value of heat of adsorption.

The integral heat of adsorption ($\Delta Q/\Delta n_S$) can be obtained by the measurement of heat effect (ΔQ) accompanying adsorption of a small dose (Δn_S) of gas. In order to obtain the differential heat of adsorption ($q=\partial Q/\partial n_S$), a calorimeter is required which is capable of measuring small amount of adsorbed gas and heats evoloved as accurately as possible.

In this study, the heat of adsorption of ammonia on silica–alumina was measured, particularly at very low surface coverage and also the influence of the diffusion of the gas on heat effects was examined.

Experimental

Heats of adsorption were determined in a twin conduction type calorimeter (Tokyo Riko Co., Ltd.) fitted with the apparatus which is schematically drawn in Fig. 1. The heat of adsorption was measured at 25 °C. The amount adsorbed was calculated from pressure change before and after adsorption measured by a MKS capacitance manometer (below≈10 Torr) and a mercury manometer (above≈10 Torr).

Silica–alumina (Al_2O_3, 13 wt%) was supplied by Shokubai Kasei Co., Ltd. and used as granules of 28—60 mesh. The surface area of silica–alumina measured by nitrogen adsorption was 557 m^2/g. About 0.5 g of silica–alumina was placed in a sample cell and pretreated at 400 °C under 10^{-5} Torr for 5 h.

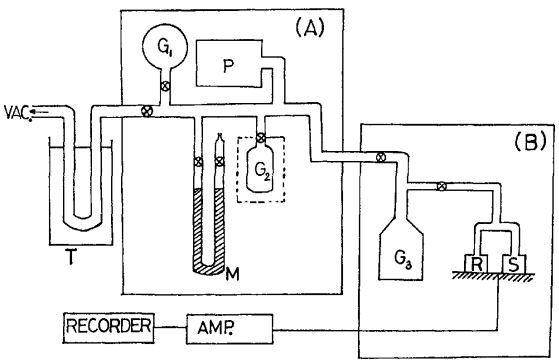

Fig. 1. Schematic diagram of vacuum system [A] and micro calorimeter [B].
T: Liquid nitrogen trap, M: mercury manometer,
P: capacitance manometer, G_1, G_2: gas storage bulb,
G_3: adsorbate reservoir, R: reference cell,
S: sample cell.
Temperatures of [A] and [B] were maintained at 25± 0.1 °C and at 25±0.01 °C, respectively.

The twin conduction type calorimeter contained a reference cell constructed as similarly as the sample cell which eliminates the effects of external thermal disturbance and other effects such as the slight temperature difference between admitted gas and the calorimeter or heat of adiabatic compression. In this apparatus, when herium gas was admitted to the evacuated cell up to 2 Torr, no deflection of base line was detected in 50 μV full scale.

Results and Discussion

The adsorption of ammonia at extremely low coverage must be quite important with regard to the surface acidic nature of silica-alumina. However, detailed studies in this field have been lacking. In Fig. 2, the differential heat curve in the coverage lower than 0.007 is shown. The plots of a—d shown by open circles are the results obtained when about 0.41, 0.81, 2.62, and 4.8 μmol/g of ammonia were admitted several times in each case. In these experiments, no residual gas the pressure of which was higher than 10^{-4} Torr was detected. As can be seen from Fig. 2, discontinuous differential heat curves were obtained along with the difference of the amount of admitted gas. These discontinuity probably resulted from the adsorption of ammonia on the glass wall and on the greese system of gas holder G_3 in Fig. 1, which caused errors of the caluculation of amounts of ammonia adsorbed on the sample. Therefore, the effect of ammonia adsorption on the glass wall and on the greese was corrected by a conventional way.[1] The corrected results of differential heat are shown by closed circles in Fig. 2. The initial heat value was observed to be 41 kcal/mol. This value agrees fairly well to the heat of neutralization of NH_3

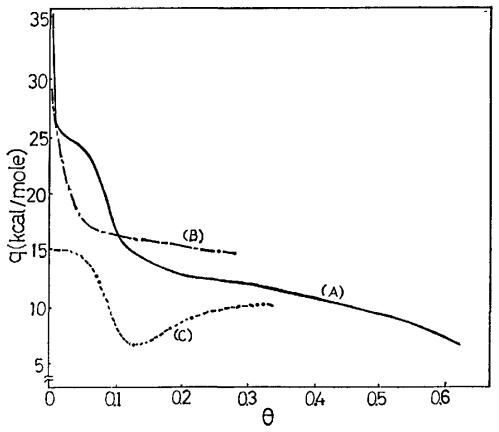

Fig. 4. Heats of adsorption of ammonia on silica–alumina. Curve A, present work (at 25 °C), Curve B, F. S. Stone *et al*, (at 30 °C), Curve C, P. Y. Hsieh (at 0 °C).

(G) and HCl (G). Moreover, differential heat curve decreased progressively and no anomalous behavior was observed.

In Fig. 3, a stepped curve A which shows the heats evolved during adsorptions of larger doses is compared with a stepped curve B which was obtained by integration of the values of differential heats in Fig. 2 (closed circles) in order to examine the influence of diffusion of ammonia in the sample layer. The fact that both curves are well coincident suggests that the diffusion of gas has little effect on the value of heat of adsorption.[2] The use of small dose is, therefore, favorable for adsorption studies on heterogeneous adsorbents and make it possible to measure heats of adsorption approaching true differential ones $(\partial Q/\partial n_S)$.

The differential heat curve up to 0.6 of θ is shown in Fig. 4 together with the results of Hsieh[3] and Stone.[4] Their results, especially that of Hsieh, are very different from ours. The discrepancy may be ascribed to the difference of sensitivity of calorimeters used and also to the fact that they measured the heat by admission of larger dose of ammonia as well as to the difference of sample preparation methods. Our results indicate that there exist very strong chemisorption sites up to 0.02 of θ and almost homogeneous chemisorption sites between 0.02 and 0.06.

Work is in progress to examine the availability of micro calorimetric measurement in the field of acidic character of solid catalysts and will be published.

This work was partly supported by a Grant-in-Aid for Science Research from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 51 (2), 635—636 (1978)

A Simple Method for the Calculation of the Polycrystalline ESR Lineshape

Kazuo SHIMOKOSHI

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received September 3, 1977)

Synopsis. A simple interpolation method is developed for calculating the magnetic resonance lineshapes of the polycrystalline samples. The method uses the *spline* function with the optional number of calculated points, at which the spin Hamiltonian is solved most accurately. The calculation procedure and some examples will be given.

The polycrystalline lineshapes of the ESR spectra are generally calculated by integrating the transition fields and probabilities, which are themselves obtained by solving the spin Hamiltonian (1), over the orientational distribution of the spin system:

$$\boldsymbol{H} = \boldsymbol{B}\tilde{\boldsymbol{g}}\boldsymbol{S} + \boldsymbol{S}\tilde{\boldsymbol{D}}\boldsymbol{S} + \sum_i (\boldsymbol{I}_i\tilde{\boldsymbol{A}}_i\boldsymbol{S} + \boldsymbol{I}_i\tilde{\boldsymbol{P}}_i\boldsymbol{I}_i - g_n\beta_n\boldsymbol{B}\boldsymbol{I}_i). \quad (1)$$

Most organic and inorganic free radicals have magnetic nuclei, whose hyperfine tensors do not, in general, have common axes. When these non-coaxial tensors are involved in the Hamiltonian, it takes much time to compute the transition fields accurately, even for a single orientation of the applied field. However, since the resonance field is generally a smoothly varying function of the polar and azimuthal angles (θ, ϕ), the lineshape can be calculated by the use of a suitable interpolation function with a minimum number of data points obtainced by the best solution of the Hamiltonian (1). Herring *et al.*[1] have used Newton's divided-difference polynominal as such an interpolation function. In the present note the application of the *spline* function to the calculation of the polycrystalline ESR lineshapes will be described.

From the transition field $(\boldsymbol{H}_i)$ and the probability $(\boldsymbol{q}_i)$ obtained by the solution of Eq. 1 for a specified transition (i), the monocrystalline component with a given width, λ, can be given as follows:

$$F_i(H, \theta, \phi) = (1/\lambda)(2/\pi)^{1/2} \exp\{-[H-\boldsymbol{H}_i(\theta, \phi)]^2/\lambda^2\}, \quad (2)$$

for the Gaussian, and

$$F_i(H, \theta, \phi) = (2/\lambda)/\{1+(2\pi/\lambda)^2[H-\boldsymbol{H}_i(\theta, \phi)]^2\}, \quad (3)$$

for the Lorentzian. The polycrystalline spectrum is, then, given by

$$S_i(H) = 1/4\pi \int_0^{2\pi} d\phi \int_0^{\pi} d\theta \sin\theta F_i(H, \theta, \phi)\boldsymbol{q}_i(\theta, \phi). \quad (4)$$

This integration 4 is, thereby not generally possible by analytical means. Lefebvre and Maruani[2] have applied the Gaussian quadrature to the numerical integration with an optional number of the data points. However, if one has a sufficient number of functional values in the θ-ϕ space, the integration can be approximated by the corresponding summation (Eq. 5):

$$S_i(H) = \sum_{\theta}\sum_{\phi} F_i(H, \theta, \phi)\boldsymbol{q}_i(\theta, \phi). \quad (5)$$

In order to obtain a sufficient number of F_i and $\boldsymbol{q}_i$ values as functions of θ and ϕ from the least number of calculated grid points, the *spline* function[3] was used as an example of the interpolation function with a better quality.

The *spline* method for the interpolation divides the interval into N consecutive subintervals. In each, the function is approximated by a different polynominal with a certain degree, M. At points between two such intervals, the polynominals of the two sides are connected so as to have the same values and derivatives (up to the M-1th derivative). In the present work, the simplest one with $M=3$ was used. The *spline* function, $f(x)$, with the data points of $x^{(j)}$ and $y^{(j)}$ and with equally spaced variables, $x^{(j)}$ $(j=0,1,2,\ldots,n)$, can be defined as follows:

$$f(x) = \sum_{j=0}^{n} C(j, j'; x)y^{(j)}; \ (x^{(j'-1)} \leq x \leq x^{(j')}), \quad (6)$$

where $y^{(j)}$ is the data value at $x=x^{(j)}$ and where j' specifies the interval at which the variable (x) is found. From the definition of the *spline* function, the coefficient, $C(j,j'; x)$, in Eq. 6 is given as follows:

$$C(j, j'; x) = b_{j'}(x)a_{j'-1,j} + b_{j'-1}(x)a_{j',j} + (x^{(j')}-x)\delta_{j'-1,j}/h + (x-x^{(j'-1)})\delta_{j',j}/h, \quad (7)$$

where $h=x^{(j)}-x^{(j-1)}(=\text{constant})$, $\delta_{j',j}$ is the usual Kronecker delta, and the b's and a's are given by

$$b_{j'}(x) = (x^{(j')}-x)^3/(6h) - (x^{(j')}-x)h/6$$

$$a_{j',j} = h^2[(\boldsymbol{A}^{-1})_{j',j+1} - 2(\boldsymbol{A}^{-1})_{j',j} + (\boldsymbol{A}^{-1})_{j',j+1}]/3.$$

The elements of the inverse matrix $(\boldsymbol{A}^{-1})$ are

$$(\boldsymbol{A}^{-1})_{j',j} = (-1)^{j'+j}D_{j'-1}D_{n-1-j}/(2^{j-j'}D_{n-1}), \quad (1 \leq j' \leq j \leq n)$$

$$(\boldsymbol{A}^{-1})_{j',j} = (-1)^{j'+j}D_{j-1}D_{n-1-j'}/(2^{j'-j}D_{n-1}), \quad (1 \leq j \leq j' \leq n)$$

and

$$(\boldsymbol{A}^{-1})_{j',-1} = (\boldsymbol{A}^{-1})_{j',0} = (\boldsymbol{A}^{-1})_{j',n} = (\boldsymbol{A}^{-1})_{j',n+1} = 0,$$

where D_n is given by $D_n=[(1+\sqrt{3}/2)^{n+1}-(1-\sqrt{3}/2)^{n+1}]\sqrt{3}$. For the present purposes, the interpolation should generally be extended to the case with two variables (θ, ϕ). This can be done by simply multiplying the coefficients for each variable,[3] as is shown in Eq. 8.

$$f(x_1, x_2) = \sum_{i_1}\sum_{i_1} C_1(i_1, i_1'; x_1)C_2(i_2, i_2'; x_2)y^{(i_1, i_2)}, \quad (8)$$

where $x_1^{(i_1'-1)} \leq x_1 \leq x_1^{(i_1')}$ and $x_2^{(i_2'-1)} \leq x_2 \leq x_2^{(i_2')}$. The expanded transition fields and probabilities can be calculated from the original data points $(\boldsymbol{H}_i^0, \boldsymbol{q}_i^0)$ by using the *spline* coefficients as follows:

$$\boldsymbol{H}_i(\theta, \phi) = \sum_{j=0}^{n_\theta}\sum_{k=0}^{n_\phi} C_1(j, j'; \theta)C_2(k, k'; \phi)\boldsymbol{H}_i^0(j, k),$$

$$\boldsymbol{q}_i(\theta, \phi) = \sum_{j=0}^{n_\theta}\sum_{k=0}^{n_\phi} C_1(j, j'; \theta)C_2(k, k'; \phi)\boldsymbol{q}_i^0(j, k), \quad (9)$$

where n_θ and n_ϕ are the number of the original data

points minus one in each direction. By putting Eq. 9 into Eqs. 2 or 3, and using Eq. 5, the lineshape due to the i transition can be obtained. When the system contains many transitions, the total lineshape will be given by the summation of $S_i(H)$ (Eq. 10):

$$S(H) = \sum_i S_i(H). \tag{10}$$

In the calculation of Eq. 9, we need only the tabulated data and the spline coefficients, $C(j,j';x)$. The coefficients can be determined without the values of the variable (x) if the original data are calculated for equally spaced variables. For calculation on a computer, therefore, the *spline* coefficients can be calculated independently and stored for common use in a file specified with the total number of the data points and the desired number of the interpolated points in each interval. Using these tabulated *spline* coefficients and the processes described above, the computation of the polycrystalline spectrum can be much simplified. Thus, we believe the spline interpolation is easier to handle and more convenient than the polynominal interpolation in Ref. 1.

Figure 1 shows the spectrum of the randomly oriented NO_2 radical, where both n_θ and n_ϕ are equal to 5. For the sake of simplicity, the second-order perturbation solution of the spin Hamiltonian[4] was used in the calculation of the original data points. The spectrum is comparable to that of NO_2 observed (Fig. 2).[5]

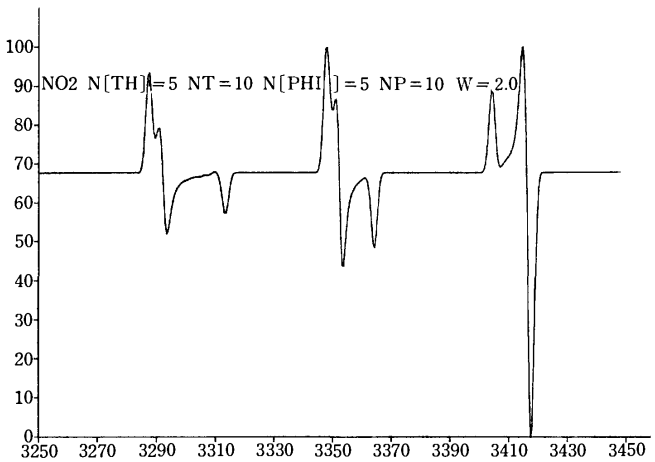

Fig. 1. The X-band spectrum of the randomly oriented NO_2 ($S=1/2$, $I=1$) calculated by the use of the spline function. The number of the data points $n_\theta=n_\phi=5$ ($0\leq\theta$, $\phi\leq\pi/2$) and each interval is further interpolated by 10 points. The magnetic parameters used in the calculation are $g_1=2.0056$, $g_2=1.9956$, $g_3=2.0029$; $A_1=56.0$, $A_2=51.0$, $A_3=65.0$ (G), and component width 2.0 G.

Fig. 2. The X-band spectrum of NO_2 adsorbed on silica gel and measured at 77 K. The resolution of the spectrum is somewhat poor, but the magnetic parameters derived from the spectrum is comparable to those of the spectrum in Fig. 1.

As in the case of the Gaussian integration,[2] the accuracy of of the calculated lineshapes is dependent on the number of the original data points, and also on the smoothness of the angular variation. The smoothness of the variation depends on the anisotropy of the tensors. It is, therefore, necessary to calculate more data points to obtain an accurate lineshape when the anisotropy of the tensors is large. In the case of the spectrum in Fig. 1, the lineshape did not change when the data points were increased from 5 to 10 in each variable if the total interpolated number of the transition field is large enough.

In the above calculations there is no restriction on the source of the transition fields and probabilities. This technique can, therefore, easily be applied to the calculation of the NMR lineshape of the polycrystalline samples by using the nuclear-spin transitions instead of the electron spin's.

Potassium-Sodium Ion Exchange Isotherm of Crystalline Zirconium Arsenate

Junko SUGISAWA, Takao YONEZAWA, Kazunori TAKAGUCHI, and Isao TOMITA*

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received June 16, 1977)

Synopsis. When the forward and reverse Na^+–K^+ exchange isotherm was investigated for the α-zirconium arsenate ion exchanger, a large hysteresis loop was observed. The interlayer distance of the exchanger decreased with an increase in the ionic fraction of Na^+ in the exchanger. The result may be interpreted in terms of the formation of different types of solid solutions during the processes in both directions.

The ion-exchange behavior of alkali metal ions on zirconium bis(monohydrogen orthoarsenate)monohydrate, $Zr(HAsO_4)_2 \cdot H_2O$ (referred to as α-ZA), has been investigated by several authors.[1-3] A recent study has shown that α-ZA can be converted to a half-exchanged phase, $Zr(HAsO_4)(MAsO_4) \cdot xH_2O$, and a fully exchanged phase, $Zr(MAsO_4)_2 \cdot yH_2O$, for each of the lithium, sodium, and potassium ions as the ion exchange proceeds.[3] With regard to a sodium- or potassium-form exchanger, a half-exchanged form is a monohydrate, while a fully exchanged form is a trihydrate. An attempt has been made to study the forward and reverse exchange isotherm by using both disodium and dipotassium form as the starting exchangers.

Experimental

Preparation of the Materials. The α-ZA was synthesized as has been reported previously.[3] The alkali-metal-form exchanger was prepared by titrating α-ZA with a 0.1 M KOH or NaOH solution by the use of a potentiometric titrimeter. The titration was carried out very slowly (for the period of 60 to 70 h) lest the pH of the solution should exceed 9. The hydrolysis of the exchanger could be avoided in this way as much as possible. At the end point the pH was about 8. The prepared materials were filtered and stored over a saturated LiCl solution (the relative humidity was about 10%).

Ion Exchange. The ion-exchange reaction, $\overline{K}+Na^+ \rightleftharpoons \overline{Na}+K^+$, was studied, here, the superscript bars refer to the exchanger phase. The experiments were carried out by the batch method, the procedure being as follows. Mixed solutions of 0.1 M NaCl and 0.1 M KCl in various mixing ratios were prepared to give various ionic fractions of Na^+ or K^+. Each alkali chloride solution had been adjusted to pH 9 by adding a small amount of the corresponding alkali hydroxide solution. Then, 250 mg of α-ZA in the Na or K form was placed in contact with 25 ml of the above-mentioned mixed solution and the slurry was shaken for 4 days at 25 °C. The reaction vessel had been filled with nitrogen gas to avoid the hydrolytic conversion of the salt form into the hydrogen form. The resulting slurry was centrifuged, and the supernatant was analyzed for K^+ and Na^+ by means of flame photometry. The exchanger phase was subjected to X-ray powder diffractometry and thermal analysis (TG and DSC).

* Present address: Department of Chemistry, The University of Tsukuba, Ibaraki 300-31.

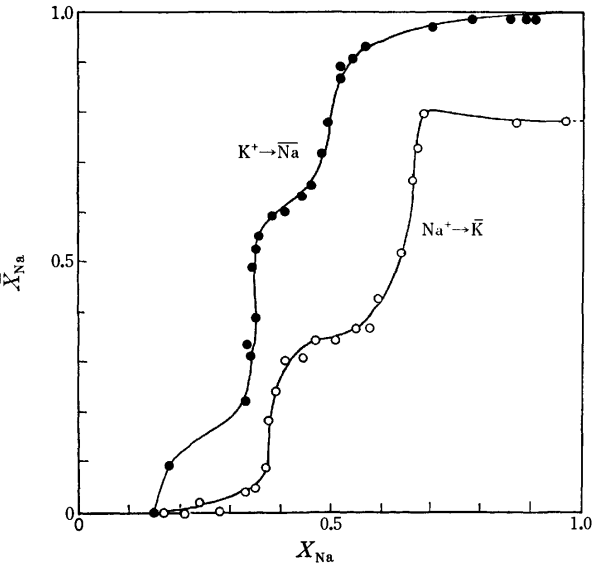

Fig. 1. The forward and reverse Na^+–K^+ exchange isotherm. $Na^+ \rightarrow \overline{K}$ denotes that K^+ ion in the exchanger is replaced with Na^+ ion. $K^+ \rightarrow \overline{Na}$ denotes that Na^+ ion in the exchanger is replaced with K^+ ion.

Results and Discussion

In Fig. 1 the Na^+–K^+ ion-exchange isotherm is shown. It should be noted that about 20% of the total K^+ could not be released from the exchanger, even when the exchanger in the K form was in contact with the solution containing Na^+ ions, *i.e.*, when the ionic fraction of Na^+ in the solution (X_{Na}) was unity. It has previously been found that K^+ could not be released into acidic media with a pH of about 1.5.[3] These facts suggest that the ions with large ionic radii have difficulty in diffusing rapidly inside the exchanger for steric reasons.

In comparison with the Na^+–K^+ exchange isotherm on crystalline zirconium phosphate (α-ZP), quite a large hysteresis loop was observed in α-ZA. Two vertical portions exist on both the forward and reverse exchange isotherm—at the ionic fraction (X_{Na}) of 0.38 and 0.65 for the $Na^+ \rightarrow \overline{K}$ process, while at 0.48 and 0.34 for the $K^+ \rightarrow \overline{Na}$ process. Generally, the presence of vertical portions in the isotherm suggests that two immiscible phases coexist in the exchanger, according to the phase rule.[5] From this point of view, the X-ray powder patterns of the exchanged solid phases were examined carefully. In the $Na^+ \rightarrow \overline{K}$ process, a single (002) reflection peak was observed for each of the samples at various stages of exchange, but the interlayer distance of the exchanger decreased with an increase in $\bar{X}_{Na}$, the ionic fraction of Na^+ in the exchanger: 10.83A

for $\bar{X}_{Na}=0$, 10.55A for $\bar{X}_{Na}=0.30$, 10.34A for $\bar{X}_{Na}=0.43$, and 9.99A for $\bar{X}_{Na}=0.57$—0.80.

In the $K^+\rightarrow\overline{Na}$ process, the interlayer distance again decreased with an increase in $\bar{X}_{Na}$: 10.75A for $\bar{X}_{Na}=0.09$, 10.55A for $\bar{X}_{Na}=0.31$, 10.30A for $\bar{X}_{Na}=0.58$ and 9.35A for $\bar{X}_{Na}=0.89$. However, here the (002) peak width was somewhat broader than those in the $Na\rightarrow\overline{K}$ process, indicating a close overlapping of the two peaks. In fact, at $\bar{X}_{Na}=0.66$ (the corresponding X_{Na} is in the vicinity of 0.48), a splitting into two peaks was clearly observed.

Continuous changes in the interlayer distance can usually be explained by the formation of a solid solution. However, this interpretation can not be accepted in the present case, since the phase rule requires the coexistence of two phases in the $\bar{X}_{Na}$ regions, which give vertical portions in the isotherm. The only possibility is that two kinds of solid solutions with very close interlayer distances are formed. As has been mentioned above, the evidence is found only in the $\bar{X}_{Na}$ regions, 0.7—0.6, in the $K^+\rightarrow\overline{Na}$ process, but the possibility can not be excluded in other regions also if one take the unsatisfactory dissolution of X-ray powder diffractometry into account.

The powder patterns of the solid, in which the exchange reaction proceeded to the same extent, but in the opposite direction, gave somewhat different small peaks. The formation of different solid solutions during the forward and reverse processes should result in a hysteresis loop.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Polarographic Behavior of Chloramine-T in an Alkaline Solution at a Rotating Platinum Electrode

Toshio MATSUDA

Department of Chemistry, Ritsumeikan University, Kyoto 603

(Received June 22, 1977)

Synopsis. Chloramine-T in alkaline solutions at pH higher than 8 gives a single reduction wave at a rotating platinum electrode. This wave results from the two-electron reduction of the anionic species of *N*-chloro-*p*-toluenesulfonamide. The electrode reaction is polarographically irreversible. Reproducible waves were observed with a freshly reduced electrode. The diffusion current was proportional to the concentration over the range from 0.05 to 0.6 mM chloramine-T.

Chloramine-T (CAT) exhibits a reduction wave in alkaline solutions at a rotating platinum electrode (RPE), as reported previously.[1,2] In this report, the polarographic behavior of CAT at the RPE was further investigated over the pH range from 7 to 13 in order to elucidate the nature of the wave from an analytical viewpoint.

Experimental

The polarograph and synchronous rotator used were the same as those described previously.[1] A vertical platinum-wire microelectrode (5.0 mm, 0.5 mm in diameter) was used at 600 r.p.m. The sensitivity of the electrode was 8.90 μA/mM for hexacyanoferrate(III) in 0.1 M KNO_3 and a Britton-Robinson (B.R.) buffer at pH 10.

Pretreatment of the electrode was performed by means of repetition of electrolytic oxidation and reduction in 0.1 M $HClO_4$.[3] Polarograms were recorded by either forward or backward scans. For forward scans, the electrode potential was shifted from positive to negative potential, and *vice versa*. The scan rate was 200 mV per minute. The cathodic current was taken to be positive.

Preparation of the solutions and other experimental conditions have been reported elsewhere.[1]

Results and Discussion

Polarographic waves of CAT at pH 10 are shown in Fig. 1, and similar waves were obtained over the pH range from 8 to 13. A single reduction wave appeared at a potential near the reduction potential of platinum oxide. Although the slope of the wave was dependent on the direction of scanning, well-developed and reproducible waves were obtained for backward scans with a freshly reduced electrode (curve 1). The values of the half-wave potential of the waves obtained in a manner similar to those shown in curve 1 were reproducible to within ±10 mV. The value of $\Delta E_{1/2}/\Delta$pH was −50 mV per unit pH over the pH range from 8 to 13 (Table 1).

The magnitude of the limiting current was independent of the direction of scanning, provided that a correction for the residual current in each case was applied. This correction remained constant to within ±2% over the above pH range (Table 1), and was

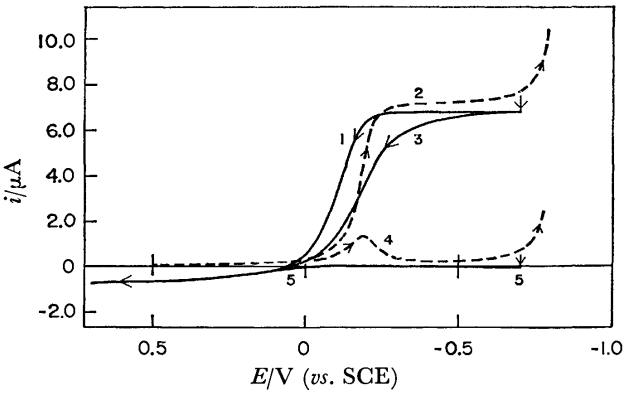

Fig. 1. Polarograms of 0.4 mM CAT in a solution containing 0.1 M KNO_3 and B. R. buffer pH 9.95. Recording procedures: (1) Backward from −0.7 V after preoxidation at +1.3 V for 2 min; (2) forward from +0.5 V after preoxidation at +1.3 V for 2 min; (3) backward from −0.7 V after polarization at −0.5 V for about 5 min; (4) same as in curve 2 (residual current); (5) same as in curve 1 (residual current).

Table 1. Polarographic data for the reduction wave of 0.4 mM CAT[a]

pH	i_d/μA	i_dC^{-1}/μAmM^{-1}	$E_{1/2}$/V (*vs.* SCE)
7.15	6.91	17.3	—[b]
8.20	6.92	17.3	−0.040
9.04	6.95	17.4	−0.080
9.95	6.93	17.3	−0.122
11.05	6.91	17.3	−0.177
11.85	6.93	17.3	−0.220
12.89	6.81	17.0	−0.265

a) These values were obtained in a supporting electrolyte solution containing 0.1 M KNO_3 and a B.R. buffer for various pH values and in the case of backward polarograms. b) No single wave appeared.

proportional to concentrations from 0.05 to 0.6 mM CAT. A plot of log i_d *vs.* log N (N is the number of revolutions per minute, which varied from 600 to 1200 min^{-1}) gave a straight line with a slope of 1/2.7. A similar result was obtained for the diffusion current of the hexacyanoferrate(III) ion. The temperature coefficient of i_d measured in the temperature range from 15 to 40 °C was 1.7% per degree. The limiting current can be concluded to be controlled by diffusion.

The value of i_d/C was found to be (17.3±0.3) μA/mM in the above pH range. This value corresponds to a two-electron reduction, which was calculated from a comparison with the value of i_d/C for the hexacyanoferrate(III) ion. This result suggests that monovalent

positive chlorine is reduced to a chloride ion by the electrode reaction. According to a previous report[4] the *N*-chloro-*p*-toluenesulfonamide anion predominates in alkaline solutions of CAT. It is, therefore, concluded that a single wave results from the reduction of the anion given by the reaction

$$RSO_2NCl^- + 2H_2O + 2e^- \longrightarrow RSO_2NH_2 + Cl^- + 2OH^-,$$

where $R=CH_3C_6H_4$. For the wave obtained in the backward scan with a freshly reduced electrode, a plot of log $[i/(i_d-i)]$ *vs.* E showed a straight line. The values of these slopes were found to be (85 ± 10) mV per log unit over the pH range from 8 to 13. The electrode reduction is considered to be polarographically irreversible.

It has been stated[5] that CAT is hydrolyzed in alkaline solutions and then the hypochlorite produced acts as an active species. In this study, the hypochlorite added to the CAT solution gave a single wave, the half-wave potential of which was more positive than that of the reduction wave of CAT. The value of the half-wave potential for the reduction wave of hypochlorite was the same as that reported previously.[6,7] It is concluded, therefore, that the reduction wave in the CAT solution is free from reduction of the hypochlorite.

The effect of the direction of scanning on the polarogram, as is shown in Fig. 1, can be explained as follows. When the curve was recorded for forward scan with the oxidized electrode, a deformed wave was observed, with the rising portion shifted to more negative potentials (curve 2). This result means that the electrode reduction of CAT is inhibited in the rising portion of the wave by the partially remaining oxide. In fact, the wave obtained for forward scan from 0 V with the reduced electrode was well-defined.

When the curve was recorded in backward scan with the electrode previously polarized at -0.5 V for about 5 min, the wave became markedly ill-defined (curve 3). The half-wave potential tended to shift to more negative potentials with increasing polarization time. The results are considered to be due to the deactivation of the electrode surface that occurred during polarization. This deactivation may be attributed to the adsorption of some constituents on the electrode surface. For example, adsorption of *p*-toluenesulfonamide (TSA), one of the reduction products, could be considered responsible on the basis of the following result. The a.c. polarographic base current used with the RPE with a reduced surface was recorded either in the presence or the absence of TSA. The base current decreased in the presence of 0.2 mM TSA in the potential region over which the platinum electrode had been reduced.

On the other hand, when the curve was recorded in backward scan with a freshly-reduced electrode, after preoxidation, the value of the half-wave potential was more positive than values obtained by other procedures, and the slope was independent of the starting potential (curve 1). This indicates that the electrode surface is free from formation of the oxide and the adsorption of constituents. This result is in line with the fact[3,8] that the electrode reaction tended to be more reversible on the platinum electrode with a fresh layer of finely-divided platinum.

The results described above indicate that the slope of the wave is strongly dependent on the history of the electrode, and that, for amperometric studies, careful attention should be paid to the selection of the potential for which the current is measured.

The author wishes to express his sincere thanks to Professor Taitiro Fujinaga of Kyoto University and to Professor Toyoshi Nagai of Ritsumeikan University.

The Preparation and the Structure of Cobalt(III) Complexes Containing a *cis*-2-Butene-1,4-diamine Chelate Ring

Yoshikuni SOMA* and Fujio MIZUKAMI**

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

***National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151*

(Received July 13, 1977)

Synopsis. New cobalt(III) complexes containing a seven-membered chelate ring, $[Co(en)_2(dcb)]^{3+}$, $[Co(acac)_2(dcb)]^+$ and $[Co(dcbta)]^-$, were synthesized and resolved into optical isomers, and their structures were determined; dcb=*cis*-2-butene-1,4-diamine, dcbta=*cis*-2-butene-1,4-diamine-*N,N,N',N'*-tetraacetate ion.

cis-2-Butene-1,4-diamine (dcb) can coordinate to a metal ion as a bidentate or terdentate ligand because dcb has two amino groups and one double bond. However, there have been no reports on the metal complex of dcb. This Note will deal with the preparation and the structure of complexes in which dcb coordinates to a trivalent cobalt ion with two amino groups.

Experimental

cis-*2-Butene-1,4-diamine (dcb).* This was prepared *via* 1,4-diphthalimido-*cis*-2-butene from *cis*-2-butene-1,4-diol according to the usual method;[1,2] yield, 45%. The ^1H NMR spectrum of the diamine gave the following signals: $-NH_2$, δ 1.27 singlet; $-CH_2-$, δ 3.33 doublet; $-CH=$, δ 5.53 double triplets. The diamine was converted to the picrate for analysis. Found: C, 35.35; H, 3.22; N, 20.29%. Calcd for $C_{16}H_{16}N_8O_{14}$: C, 35.30; H, 2.96; N, 20.59%.

Sodium cis-*2-Butene-1,4-diamine*-N,N,N',N'-*tetraacetate (dcbta-Na$_4$).* This was synthesized by a method similar to that used for trimethylenediaminetetraacetate.[3] Chloroacetic acid (10.5 g) in 30 cm^3 of water was neutralized with 4 g of NaOH in 30 cm^3 of water below 20 °C. To the solution we added 2.2 g of dcb, after which the solution was heated at 80 °C for 3 h. During the heating, the pH of the solution was kept at 8 by adding 3 g of NaOH in 30 cm^3 of water in small portions. This solution itself was used for the synthesis of the dcbta complex.

[Co(en)$_2$(dcb)]Br$_3$. This was synthesized by a method similar to that used for $[Co(en)_2(tmd^{***})]Br_3$.[4] To 200 cm^3 of DMSO containing 3 g of *cis*-$[CoCl_2(en)_2]Cl$ we added 0.9 g of dcb in 50 cm^3 of DMSO. The solution was kept at 20—30 °C for two days. The remainder of the procedure used to obtain the complex was identical with the method used for $[Co(en)_2(tmd)]Br_3$. Yield, 0.5 g. Found: C, 19.04; H, 5.32; N, 16.46%. Calcd for $C_8H_{26}N_6CoBr_3$: C, 19.03; H, 5.20; N, 16.65%.

(−)$_{405}$-[Co(en)$_2$(dcb)]Cl$_3$·H$_2$O·HCl. The racemate was resolved according to a method similar to that used for $[Co(amb^{****})(en)_2]^{2+}$.[5] The racemate (0.28 g), adsorbed on an SP-Sephadex column (ϕ4×150 cm), was eluted with a solution of 0.15 M potassium $(+)_{589}$-tartratoantimonate. The eluate containing the $(-)_{405}$-isomer was again passed through an SP-Sephadex column (ϕ1.8×20 cm), and the adsorbed band was eluted with a 0.36 M HCl solution. The eluate was evaporated to dryness in a vacuum desiccator over KOH. Found: C, 22.74; H, 7.00; N, 19.19%. Calcd for $C_8H_{29}N_6Cl_4Co$: C, 22.54; H, 6.87; N, 19.72%.

[Co(acac)$_2$(dcb)]ClO$_4$. The procedure used here is identical with the method used for $[Co(acac)_2(en)]ClO_4$,[6] except for using dcb instead of ethylenediamine. The dcb complex was prepared by mixing $Na[Co(acac)_2(NO_2)_2]\cdot 5H_2O$ and dcb (1:1) in aqueous methanol in the presence of charcol and by then adding $NaClO_4$. Found: C, 38.23; H, 5.41; N, 6.47%. Calcd for $C_{14}H_{26}N_2O_8ClCo$: C, 37.81; H, 5.89; N, 6.30%.

(−)$_{405}$-[Co(acac)$_2$(dcb)]$^+$. The racemate was resolved according to a method similar to that used for $[Co(acac)_2(RS\text{-}2,4\text{-ptn}^{\dagger})]ClO_4$.[7] The racemate and sodium hydrogen dibenzoyltartrate were dissolved in water at 65 °C. A violet powder was precipitated by cooling the solution to 20 °C and then filtered off. The powder was recrystallized from water fractionally until the ratio of the $\Delta\varepsilon$ and ε values of the powder became constant. The pure powder was converted into perchlorate by treating it with aqueous methanol containing $AgClO_4$. The perchlorate of the $(-)_{405}$-isomer was hygroscopic and was obtained in only a slight amount. The quantitative CD curve of this isomer was determined with the aid of the ε values of the racemate.

Na[Co(dcbta)]·2H$_2$O. The procedure used here is almost identical with the method used for $[Co(RR\text{- and }SS\text{-}2,4\text{-ptnta}^{\dagger\dagger})]^-$.[8] To a solution containing 26 mmol of $dcbtaNa_4$ we added 8.1 g of $Na_3[Co(NO_2)_6]$[9], after which the solution was warmed at 55 °C for 40 h. Crystals were obtained by gradually evaporating the solution at 30 °C. Found: C, 33.26; H, 4.07; N, 6.42%. Calcd for $C_{12}H_{18}N_2O_{10}NaCo$: C, 33.35; H, 4.20; N, 6.48%.

K(+)$_{589}$-[Co(dcbta)]·2H$_2$O. The silver salt of the racemate was dissolved in 30 cm^3 of water. To the solution we then added 0.9 g of $(+)_{589}$-$[Co(NO_2)_2(en)_2]Br$[10] in 20 cm^3 of water. The solution was then warmed at 50 °C, and the AgBr was filtered off. The filtrate was evaporated to dryness, and the residue was suspended in a small amount of water. The undissolved powder was filtered off and dissolved in a large amount of hot water. Crystals were obtained fractionally from the solution by evaporation in a vacuum desiccator over P_2O_5. Each fraction was checked by means of its CD, and pure crystals were obtained by repeating such fractional recrystallizations. The pure crystals were suspended in water and converted into potassium salt by stirring with a cation exchanger, Dowex 50W-X8. Found: C, 32.44; H, 3.97; N, 6.44%. Calcd for $C_{12}H_{18}N_2O_{10}KCo$: C, 32.15; H, 4.06; N, 6.25%.

Measurements. The visible and ultraviolet absorption spectra were recorded with a Hitachi 323 spectrophotometer.

*** 1,4-Butanediamine.

**** 4-Aminobutanoate ion.

† (2*R*,4*S*)-2,4-Pentanediamine.

†† 2,4-Pentanediamine-*N,N,N',N'*-tetraacetate ion.

The CD curves were obtained on a JASCO Model ORD/UV-5 spectrophotometer with a CD attachment. The ^1H NMR spectra in D_2O were obtained on Varian T-60 and HA-100 spectrometers, using Na–TMS as the internal standard.

Results and Discussion

The ^1H NMR spectrum of $(-)_{405}$-$[Co(en)_2(dcb)]^{3+}$ (**1**) exhibits only two kinds of broad signals (δ 2.84 and 3.40) and a multiplet signal (δ 5.98). The ^1H NMR spectrum of $(-)_{405}$-$[Co(acac)_2(dcb)]^+$ (**2**) gives only two kinds of singlet signals (δ 1.20 and 1.28) on the methyl groups. These facts suggest that **1** and **2** have a symmetry element other than C_1 and, so the dcb in the

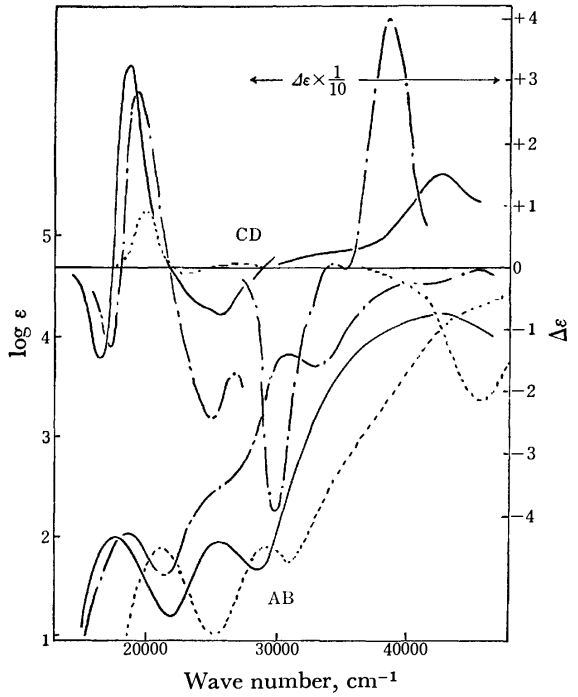

Fig. 1. Absorption (AB) and CD spectra of (----) $(-)_{405}$-$[Co(en)_2(dcb)]^{3+}$, (-·-): $(-)_{405}$-$[Co(acac)_2(dcb)]^+$, (——): $(+)_{589}$-$[Co(dcbta)]^-$ in water.

complexes acts as a bidentate ligand. As Fig. 1 shows, the absorption spectra of **1** and **2** are similar to those of the analogous complexes, $[Co(en)_2(tmd)]^{3+}$,[4] and $[Co(acac)_2(2,4\text{-ptn})]^+$,[7] respectively. The CD curve of **1** is very similar to that of $\Lambda(+)_{589}$-$[Co(en)_3]^{3+}$.[11] In the region from 15000 to 40000 cm^{-1}, the CD curve of **2** is almost enantiomeric with that of $\Lambda(-)_{546}$-$[Co(acac)_2(RR\text{-}2,4\text{-ptn})]^+$.[7] It is thus clear that **1** and **2** have a *cis*-2-butene-1,4-diamine chelate ring (seven-membered ring). In addition, **1** and **2** seem to be assignable to the Λ- and Δ-configurations respectively.

In the region from 15000 to 40000 cm^{-1}, the absorption and CD spectra of $(+)_{589}$-$[Co(dcbta)]^-$ (**3**) are very similar to those of $\Delta(+)_{589}$-$[Co(RR\text{-}2,4\text{-ptnta})]^-$,[8] respectively. This suggests that the dcbta coordinates to the cobalt(III) ion as a sexadentate ligand such as 2,4-ptnta and that **3** has the $\Delta(\lambda)$ structure (C_2 symmetry), as is shown in Fig. 2. This $\Delta(\lambda)$ structure seems also to be supported by the ^1H NMR spectrum of **3**

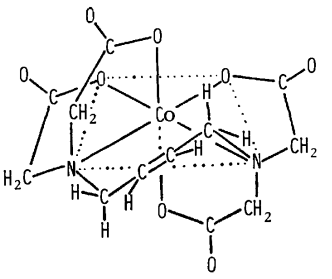

Fig. 2. Schematic structure of $\Delta(\lambda)$-$[Co(dcbta)]^-$.

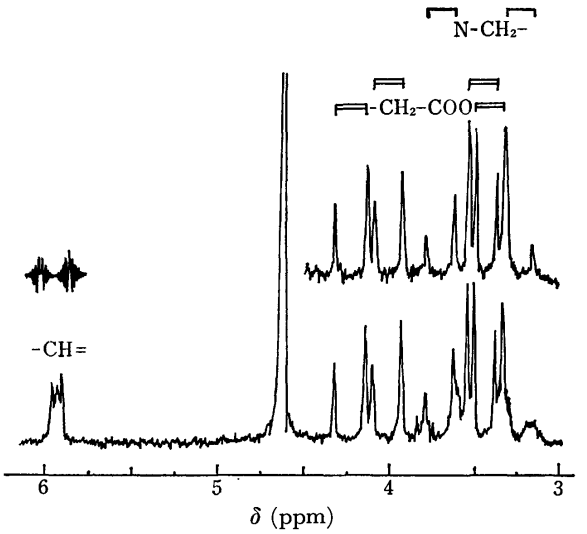

Fig. 3. ^1H NMR spectrum (100 MHz) of $(+)_{589}$-$[Co(dcbta)]^-$ in D_2O.

shown in Fig. 3. The spectrum exhibits a kind of –CH= signal, two kinds of $-CH_2-COO$ signals (two kinds of double doublets), and a kind of $N-CH_2-$ signal. The assignment of the $N-CH_2-$ signal is confirmed by the fact that the complicated signal becomes double doublets (axial H and equatorial H) upon irradiation at δ 5.95.

Nuclear Magnetic Resonance Studies of Cobalt Complexes. Cobalt-59 Nuclear Magnetic Resonance Spectrum of the Hexakis-(trimethyl phosphite)cobalt(III) Complex

Akira YAMASAKI,* Takashi AOYAMA, Shizuo FUJIWARA, and Keikichi NAKAMURA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received July 18, 1977)

Synopsis. The well-resolved septet spectrum was recorded for cobalt-59 NMR of $[Co(P(OCH_3)_3)_6](BF_4)_3$ in an acetonitrile solution. The obtained NMR parameters are: σ(Co-59)=+304 ppm (upfield from $[Co(CN)_6]^{3-}$), ^1J(Co–P)=414 Hz, and ΔH(Co)=340 Hz.

The last member of the symmetric diamagnetic $Co^{III}L_6$-type complexes, the $Co^{III}P_6$-type hexakis(trimethyl phosphite)cobalt(III) complex, was examined by cobalt-59 nuclear magnetic resonance (NMR) spectroscopy. The coordination character of such a $Co^{III}P_6$-type complex seems very interesting because the relatively hard metal ion, Co(III), and the typically soft ligand, $P(OCH_3)_3$, form an octahedral complex which seems to have a very crowded configuration around the small central metal ion.[1] The result of the cobalt-59 NMR study is reported in this paper mainly because of the interest in the metal-ligand coordination bonding.

Experimental

Hexakis(trimethyl phosphite)cobalt(III) tetrafluoroborate was synthesized by a process similar to that of its perchlorate.[1] (Cobalt(II) tetrafluoroborate was used instead of cobalt(II) perchlorate.) The analyses of Co, P, and BF_4 were carried out gravimetrically. (Found: Co, 5.50; P, 17.89; BF_4, 25.03; Calcd for $C_{18}H_{54}O_{18}P_6CoB_3F_{12}$(=$[Co(P(OCH_3)_3)_6](BF_4)_3$): Co, 5.54; P, 17.47; BF_4, 24.48). The ultraviolet spectra and proton NMR spectra (100 MHz) were almost the same as those of the corresponding perchlorate in an acetonitrile solution: ν_{1max}=350 nm, log ε=2.3; $\delta(OCH_3)$=4.00 ppm (symmetric multiplet).

Cobalt-59 NMR spectral measurements were carried out with a Varian VF-16 NMR spectrometer operating at 7.9650 MHz (modulation of about 0.1 gauss). Potassium hexacyanocobaltate(III) was used as an external standard. The complex was dissolved in an acetonitrile, and poured into a 14 mmϕ sample tube for the spectral measurement.

Results and Discussion

The recorded cobalt-59 NMR spectrum is shown in Fig. 1. The well-resolved septet is clearly observed. The origin of this septet can be attributed to the scalar coupling of six equivalent phosphorus-31 nuclei (I=1/2) directly coordinated to the central cobalt-59 nucleus. The chemical shift was +304 ppm from the external standard $[Co(CN)_6]^{3-}$; this is the largest value for high-field resonance among the numerous tervalent cobalt complexes. The discussion of the chemical shifts will be published elsewhere. The line-shape simulation was carried out using the HITAC 8700/8800 computer of the Computer Centre, The University of Tokyo. The best-fitted parameters are: ^1J(Co–P)=414 Hz, and ΔH(Co)=340 Hz (assuming Gaussian curves). Simulation with the Lorentzian curves did not succeed in giving the approximate curves.

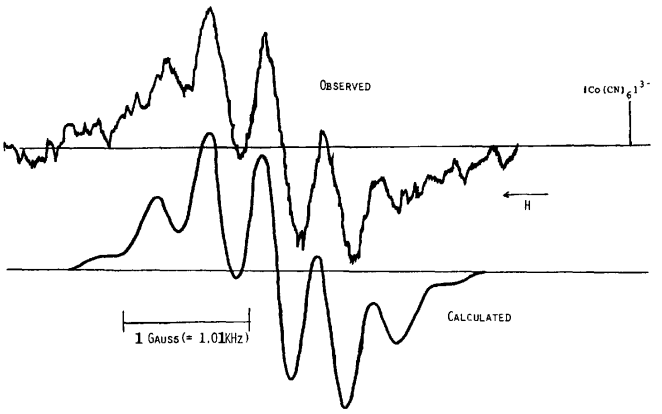

Fig. 1. Cobalt-59 nuclear magnetic resonance spectrum of $[Co(P(OCH_3)_3)_6](BF_4)_3$ in CH_3CN solution (7.9650 MHz), and its simulated spectrum with ^1J(Co–P) of 414 Hz, and ΔH=340 Hz (Gaussian curves).

This multiplet confirms that the quadrupolar relaxation of the central cobalt-59 in this complex is not so effective as those of the other $Co^{III}L_6$-type complexes. The octahedral coordination of the six phosphorus ligands is also confirmed from the septet spectrum.

The magnitude of the spin-spin coupling constant, ^1J(Co–P) is noticeably smaller than that for the $[Co(PF_3)_4]^-$,[2] which was the only previously reported coupling constant between cobalt-59 and phosphorus-31. The coordinating characters of trifluorophosphine and trialkyl phosphite have been assumed to be quite similar, or almost the same.[3,4] Therefore, the difference in the ^1J(Co–P) values between $[Co(PF_3)_4]^-$ and $[Co(P(OCH_3)_3)_6]^{3+}$ can be attributed to the differences in the oxidation state or coordination number of the central cobalt ions. It has been noted that the s-characters of bonding atoms have a large influence on the spin-spin coupling constants.[3,5] For rhodium and platinum complexes, the metal-ligand coupling constants of tetracoordinated complexes (Rh(I), Pt(II)) are about 1.5 times those of the corresponding hexacoordinated complexes (Rh(III), Pt(IV))[3]: tetracoordinated complexes have an s-character of one fourth, while octahedral complexes have one sixth.

Although the contribution of the s-characters of the

* Present address: Laboratory of Applied Chemistry, The University of Electro-Communications, Chofu, Tokyo 182.

** National Research Institute for Metals, Nakameguro, Meguro-ku, Tokyo 153.

coordination bonds to the magnitude of the spin-spin coupling constants is quite attractive as an explanation of the differences among the many complexes, it is not sufficient to describe the quite small coupling constant ^1J(Co–P) in our $[Co(P(OCH_3)_3)_6]^{3+}$ complex. The ^1J(Co–P) in $[Co(PF_3)_4]^-$ is reported to be 1225 Hz,[2] and the corresponding coupling constant in our complex is only 414 Hz, which is much smaller than two thirds of the ^1J(Co–P) in $[Co(PF_3)_4]^-$. Therefore, further contributions should be taken into account.

Another possible factor which would decrease the coupling constants is the bond weakening due to steric or other repulsive interactions, such as so-called trans-effects. The geometric factors should be important in considering the complexes of bulky ligands such as phosphines and phosphites. Tolman[4] studied the steric hindrances by the ligand-cone angles, which is the apex angle of the minimum cones contered several angstroms (metal–phosphorus bond lengths) away from the center of the phosphorus atom along the threefold axis of phosphorus ligands which just touch the outermost extremities of a folded back ligand while maintaining C_3 symmetry. According to his study with CPK models, the cone angle of PF_3 (when coordinated to Ni(0)) is about 104°, and that of $P(OCH_3)_3$ is 107° (uncertainly of ±2°). He used the metal–phosphorus bond length of 2.28 Å, but he suggested that it was too long.

His cone angle estimation cannot be directly applied to our case, because the proton NMR showed that all fifty-four protons in $[Co(P(OCH_3)_3)_6]^{3+}$ are strictly equivalent. The equivalence of the six phosphorus-31 nuclei also confirms that there are no differences in the six phosphite groups. This means that the free rotation of each phosphite group occurs around the threefold axis, namely, the cobalt(III)–phosphorus bond. Therefore, the ligand-cone angles of phosphite esters in the $[Co(P(OCH_3)_3)_6]^{3+}$ should be smaller the 90°, and the bond length between the central cobalt(III) and the ligand phosphorus atom must be elongated to allow the free rotation of phosphite groups. Such bond stretching might cause a smaller spin-spin coupling constant than would occur in the case of no steric hindrances.

One of the authors (A. Y.) wishes to thank Professor Dr. Ekkehard Fluck, Institut für anorganische Chemie, Universität Stuttgart, where a part of this work was carried out. He is also grateful to the Alexander-von-Humboldt Stiftung for the financial support of his stay in the Institute.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 51 (2), 645—646 (1978)

The Solvent Extraction of Thallium(I) as a Dibenzo-18-crown-6 Complex with the Picrate Ion

Tatsuya SEKINE, Hiroji WAKABAYASHI, and Yuko HASEGAWA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo, 162

(Received August 5, 1977)

Synopsis. The solvent extraction of thallium(I) with dibenzo-18-crown-6 (DBC) as the picrate into chloroform and benzene was measured at 25 °C. The extraction was nearly the same as that of potassium(I) and much better than rubidium(I); this tendency was mainly attributed to the difference in the stability of the DBC complexes in the aqueous phase. Thallium(III) was extracted only poorly.

The solvent extraction of alkali metal ions with various macrocyclic polyethers of different ring sizes was employed in the early work on these compounds as a measure of the stability of the complexes of the metal ions with them.[1,2] It was found that, among the alkali metal ions, 18-crown-6 polyethers extracted potassium(I) most effectively; this was explained in terms of the size of K^+ being the most favorable fit for the 18-crown-6 polyether rings. The relationship between the extractability and the stability of the macrocyclic polyether complexes was further considered statistically.[3-5] It was assumed that metal ions trapped in the ring were not hydrated or that they were hydrated similarly.[5]

The extraction of metal ions with macrocyclic polyethers has been further studied by several inorganic chemists with regard to alkali metal ions[4-7] and alkaline earth ions,[4] and the extraction equilibria as well as the nature of the complexes have been discussed in details. Furthermore, extraction with macrocyclic polyethers has been used in the substoichiometric determination of sodium(I)[8] and the separation of strontium(II) from macro amounts of calcium(II).[9]

In the present study, we have measured the solvent extraction of thallium(I) as a dibenzo-18-crown-6 (DBC) complex with the picrate ion into benzene and chloroform. The results were compared with previous data on alkali metal ions obtained under similar conditions.[6]

Experimental

All the procedures were performed at 25±0.3 °C. The DBC was obtained from the Aldrich Co., U.S.A., and was recrystallized several times from chloroform. The other reagents were of an analytical grade. The lithium picrate solution was prepared from lithium hydroxide and picric acid. The standard thallium(I) solution was prepared from thallium(I) nitrate, the concentration being checked by a colorimetric method.[10] A 5-ml portion of an aqueous solution containing lithium picrate and 1×10^{-4} mol dm^{-3} of thallium(I) (pH about 3.3) and the same volume of benzene or chloroform containing a certain amount of DBC were placed in a stoppered glass tube and agitated mechanically until the distribution equilibrium was attained. The two phases were then centrifuged off, and the thallium(I) in the organic phase was back-extracted with 0.1 mol dm^{-3} perchloric acid. The amount of thallium thus back-extracted and that remained in the aqueous phase was measured by an atomic absorption method. The distribution ratio was defined by means of the following equation and was calculated from the experimental data:

$$D = [\mathrm{Tl(I)}]_{\mathrm{org,total}}/[\mathrm{Tl(I)}]_{\mathrm{total}}. \quad (1)$$

Results and Discussion

In the following statistical treatment, a unipositive metal ion, DBC, and a picrate ion are denoted by M^+, E, and A^-, respectively, and the chemical species in the organic and aqueous phases by the subscript "org" and by the lack of any subscript respectively. Then the following equilibrium constants may be defined:

$$\beta_1 = [\mathrm{ME^+}][\mathrm{M^+}]^{-1}[\mathrm{E}]^{-1}, \quad (2)$$

$$K_{\mathrm{ex0}} = [\mathrm{ME^+A^-}]_{\mathrm{org}}[\mathrm{M^+}]^{-1}[\mathrm{E}]_{\mathrm{org}}^{-1}[\mathrm{A^-}]^{-1}, \quad (3)$$

$$K_{\mathrm{ex}} = [\mathrm{ME^+A^-}]_{\mathrm{org}}[\mathrm{ME^+}]^{-1}[\mathrm{A^-}]^{-1}, \quad (4)$$

$$K_{\mathrm{d}} = [\mathrm{E}]_{\mathrm{org}}[\mathrm{E}]^{-1}. \quad (5)$$

Thus,

$$K_{\mathrm{ex}} = K_{\mathrm{ex0}}K_{\mathrm{d}}\beta_1^{-1} \text{ or } K_{\mathrm{ex0}} = K_{\mathrm{ex}}\beta_1 K_{\mathrm{d}}^{-1}. \quad (6)$$

The distribution ratio may generally be written as

$$D = ([\mathrm{ME^+A^-}]_{\mathrm{org}}+[\mathrm{ME^+}]_{\mathrm{org}})([\mathrm{M^+}]+[\mathrm{ME^+}])^{-1}. \quad (7)$$

However, since the dissociation of the ion-pair in the non-polar solvents may be negligible, and since $[ME^+]$ was found to be much smaller than $[M^+]$ under the conditions of the present work, as will be seen, Eq. 7 is written in the present paper as

$$D = K_{\mathrm{ex0}}[\mathrm{E}]_{\mathrm{org}}[\mathrm{A^-}]. \quad (8)$$

The distribution ratio as a function of the DBC concentration showed a straight line with a slope of 1, as is seen from Fig. 1; that as a function of the picrate ion also showed a straight line with a slope of 1 in the picrate concentration range from 10^{-3} to 10^{-2} mol dm^{-3}, although it deviated slightly from the line above this range.

The equilibrium constants obtained from these data are listed in Table 1, together with those from the literature.

It may be seen from these data that the extraction of thallium(I) is much better than that of rubidium(I) and nearly the same as that of potassium(I), which is extracted most effectively with 18-crown-6 polyethers among the alkali metal ions.

By separate experiments, it was found that the extraction of thallium(III) was much poorer than that of thallium(I). For example, the distribution ratio of the former into chloroform, was $10^{-1.14}$ when $[\mathrm{E}]_{\mathrm{org}}$ was 1×10^{-2} mol dm^{-3} and $[A^-]$ was 7.5×10^{-3} mol dm^{-3}, and under identical conditions the distribution ratio

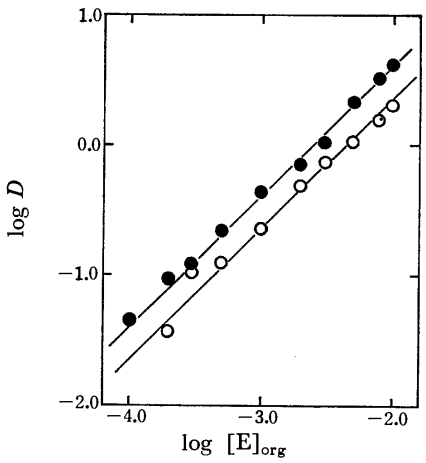

Fig. 1. Extraction curves of thallium(I) complex with DBC as picrate into chloroform (●) and benzene (○). The aqueous phase contained 7.4×10^{-3} mol dm^{-3} of lithium picrate and was at pH about 3.3. The straight lines are calculated by introducing the values of K_{ex0} in Table 1 and the above picrate concentration into Eq. 8.

Table 1. Summary of constants

Metal ion	Na^+	K^+	Rb^+	Cs^+	Tl^+	Remarks
Diameter (nm)	0.19	0.27	0.29	0.33	0.29	Ref. 11
$\log K_{ex0}$ into $CHCl_3$	—	—	—	—	4.74[a]	
$\log K_{ex0}$ into C_6H_6	2.2	4.65	3.75	3.07	4.49[a]	
$\log \beta_1$	1.2	1.7	1.1	0.8	1.5	Ref. 11
$\log K_{ex}$ into C_6H_6[b]	3.9	5.9	5.6	5.2	5.9	

a) Present work, others taken from Ref. 6.
b) $\log K_{ex}=\log K_{ex0}K_d\beta_1^{-1}$ in which $\log K_d=2.9$ (Ref. 6) was employed.

of thallium(I) was $10^{0.62}$.

The apparent tendency of the extraction given by K_{ex0} in Eq. 3 for different metal ions is affected by both the stability and the extractability of the complex in the aqueous phase, as may be seen from Eq. 6. The value of K_{ex}, which represents the latter property of the complex, should be affected by the molar volume of the extracted species and also by the interactions of the complex, probabaly mainly by those of the central metal ion, with water molecules and/or solvent molecules. The molar volumes of the extractable complexes of different metal ions with the same polyether should be rather similar to each other. Thus, when the K_{ex} values of metal ions with the same macrocyclic polyether are different, it is probably due to the difference in the hydration of the complex if no special interactions with the solvent molecules are to be expected.

As may be seen from Table 1, the value of K_{ex} of thallium(I) is similar to that of potassium(I) and not very much different from rubidium(I). Thus, the difference in the extractability of these three ions into benzene may be attributed mainly to the difference in the stability of the complex. The fact that the stability of the thallium(I) complex with 18-crown-6 polyethers is very similar to that of the corresponding potassium(I) complexes has already been pointed out.[11,12]

Since thallium(I) is much more effectively extracted with DBC than thallium(III), the separation of thallium in these oxidation states may be achieved by extraction with this reagent, and, since this tendency is the inverse of that observed in many other extraction systems, it should be useful for such purposes as to separate a small amount of thallium(I) from a large amount of thallium(III).

The authors are very grateful to Dr. Yasuyuki Takeda of the Department of Chemistry, Chiba University, for his valuable discussion and experimental aid in the early stage of this work.

Binuclear Metal Complexes. XXI.[1] Copper(I)-Copper(II) Mixed-Valence Complexes with Quadridentate Schiff Bases

Hisashi OKAWA, Visit KASEMPIMOLPORN, and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 12, 1977)

Synopsis. Copper(I)–copper(II) mixed-valence complexes of the quadridentate Schiff bases were obtained and characterized. ESR and visible spectra showed no evidence for the delocalization of an unpaired electron between copper(I) and copper(II) ions.

It is well known[2] that *N,N'*-di(salicylidene)ethylenediaminatocopper(II) and its homologues react with bivalent metal ions to form binuclear and trinuclear metal complexes. In the previous paper[3] of this series it was shown that vanadium(V)–copper(I) hetero-metal complexes with *N,N'*-di(salicylidene)ethylenediamine and its derivatives are obtained by reacting oxovanadium(IV) complexes with the Schiff bases and copper(II) halides. This fact implies that the "outside" coordination site of these ligands is sterically suitable for a copper(I) ion which prefers tetrahedral or trigonal configuration to square-planar configuration. Thus, it seems possible to synthesize copper(I)–copper(II) mixed-valence complexes using the quadridentate Schiff bases. This report relates to the synthesis and characterization of the mixed-valence complexes, $[Cu_2(R_1,R_2\text{-en})an]ClO_4$, $[Cu_2(H,H\text{-ph})an]ClO_4$, and $[Cu_2(H,H\text{-tn})]ClO_4$ (R_1,R_2=H, CH_3; an=CH_3CN), where $H_2(R_1,R_2\text{-en})$ denotes *N,N'*-di(salicylidene)ethylenediamine with the substituents R_1 and R_2 at the 5- and α-positions respectively, and H_2(H,H-ph) and H_2(H,H-tn) indicate *N,N'*-di(salicylidene)-*o*-phenylenediamine and *N,N'*-di(salicylidene)trimethylenediamine respectively.

Experimental

Syntheses. The synthetic methods of the copper(I)–copper(II) mixed-valence complexes are practically the same. The synthesis of $[Cu_2(H,H\text{-en})an]ClO_4$ is exemplified. Nitrogen was bubbled through a suspension of Cu(H,H-en) (330 mg) in dry methanol (50 ml) for 10 min. Then $[Cu(an)_4]ClO_4$ (326 mg) was added and the mixture was stirred for 3 h under nitrogen atomosphere. Red-purple prisms which separated were collected, washed with dry methanol, and dried over P_2O_5 in vacuum. Elemental analyses are given in Table 1.

The compound used for the ESR study was prepared by a method similar to that described above except for using $Ni(R_1,R_2\text{-en})$ containing a slight amount of copper(II) ion instead of using $Cu(R_1,R_2\text{-en})$. $Cu(R_1,R_2\text{-en})ZnCl_2$ was obtained after the method described by Sinn *et al.*[4]

Measurements. IR spectra were measured with a Hitachi 215 Grating Spectrophotometer on a KBr disk. Reflectance spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000. Magnetic susceptibilities were measured by the Faraday method. Effective magnetic moments were calculated by the expression, $\mu_{eff}=2.828\sqrt{(\chi_M-60\times10^{-6})T}$, where χ_M is molar magnetic susceptibility corrected by the use of Pascal's constants.

Results and Discussion

Selected IR bands, visible spectral bands and effective magnetic moments of the present complexes as well as $Cu(R_1,R_2\text{-en})ZnCl_2$ are given in Table 2. Magnetic moments clearly indicate that the present complexes contain one bivalent and one univalent copper ions in each molecule. One of the skeletal vibrations (near 1550 cm^{-1}) of the mixed-valence complexes is higher in frequency than that of the corresponding mononuclear complex. Furthermore, the frequency of this band is practically the same as that of $Cu(R_1,R_2\text{-en})ZnCl_2$, whose binuclear structure has been demonstrated.[4] These facts imply that the copper atoms in the mixed-valence complexes are bridged by the phenolic oxygens.

$[Cu_2(H,H\text{-tn})]ClO_4$											
T(K)	81.5	102.0	124.7	145.5	167.4	187.0	207.0	229.0	250.2	274.4	297.4
μ_{eff}	1.54	1.57	1.59	1.60	1.61	1.63	1.67	1.70	1.74	1.77	1.79

The IR spectra of $[Cu_2(R_1,R_2\text{-en})an]ClO_4$ and $Cu(R_1,R_2\text{-en})ZnCl_2$ resemble each other except the bands at 2300—2280 and 1100—1080 cm^{-1} of the former. They are assigned to coordinated acetonitrile and non-coordinated perchlorate ion respectively. Therefore, it is likely that $[Cu_2(R_1,R_2\text{-en})an]ClO_4$ and $[Cu_2(H,H\text{-en})an]ClO_4$ have a structure shown in Fig. 1.

On the other hand, $[Cu_2(H,H\text{-tn})]ClO_4$ differs from the other complexes in lacking acetonitrile in composition. It is likely that the "outside" copper(I) ion is coordinated by a donating atom of another molecule at the third (and forth) coordination position to form a polymeric structure. In fact, the magnetic moment of $[Cu_2(H,H\text{-tn})]ClO_4$ decreases with lowering of temperature, while the moments of $[Cu_2(H,H\text{-en})an]ClO_4$ and $[Cu_2(H,Me\text{-en})an]ClO_4$ are almost constant in the temperature range 78—300 K (Table 3).

The electronic spectra of $[Cu_2(H,H\text{-ph})an]ClO_4$ and $[Cu_2(H,H\text{-tn})]ClO_4$ are practically the same as those of Cu(H,H-ph) and Cu(H,H-tn), respectively. On the other hand, each spectrum of $[Cu_2(R_1,R_2\text{-en})an]ClO_4$ markedly differs from that of $Cu(R_1,R_2\text{-en})$, a new band being found around 19500 cm^{-1}. This band can not be an inter-valence transfer band, but should be one component of the d-d bands of the "inside" copper(II) ion, judging from the fact that the electronic spectra of $[Cu_2(R_1,R_2\text{-en})an]ClO_4$ and $Cu(R_1,R_2\text{-en})ZnCl_2$ resemble each other. It can be concluded that there is no appreciable delocalization of the unpaired electron over the binuclear unit, since the ESR spectra of $Ni(Cu)(R_1,R_2\text{-en})$ and $[Ni(Cu)Cu(R_1,R_2\text{-en})an]ClO_4$ show nearly the same $g_{\parallel}$ and $A_{\parallel}$, respectively.

The authors are grateful to the Ministry of Education for a Scientific Research Grant-in-Aid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 51 (2), 649—650 (1978)

Isolation and Photolysis of 2,3-Bis(diphenylmethylene)-5,6-diazaspiro[3.4]octa-5,7-dien-1-ones

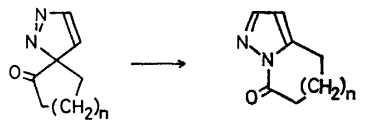
Kozaburo UEDA and Fumio TODA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

(Received June 6, 1977)

Synopsis. Pyrazole given in the title was prepared by the reaction of 2-diazo-3,4-bis(diphenylmethylene)cyclobutanone with acetylenes. Photolysis of the pyrazole afforded 1,2-dihydro-3*H*-benzo[*a*]cyclobuta[*c*]cycloheptan-1-one.

All attempts to isolate 3-acyl-3*H*-pyrazole (**1**) have been unsuccessful because of its easy isomerization to *N*-substituted pyrazole (**2**).[1-3] We report the isolation of the title pyrazole (**4**) and its photochemical conversion into 1,2-dihydro-3*H*-benzo[*a*]cyclobuta[*c*]cycloheptan-1-one (**8**).



1 2

Treatment of 2-diazo-3,4-bis(diphenylmethylene)-cyclobutanone (**3**) with dimethyl acetylenedicarboxylate, benzoylacetylene, and dibenzoylacetylene afforded 7,8-bis(methoxycarbonyl)- (**4a**, 78%), 7-benzoyl- (**4b**, 82%), and 7,8-dibenzoyl-2,3-bis(diphenylmethylene)-5,6-diazaspiro[3.4]octa-5,7-dien-1-one (**4c**, 80%), respectively. The formation of 3*H*-pyrazole by 1,3-dipolar

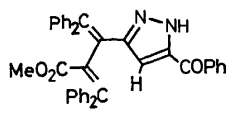
b; $R^1=H$, $R^2=COPh$
c; $R^1=R^2=COPh$

Scheme 1.

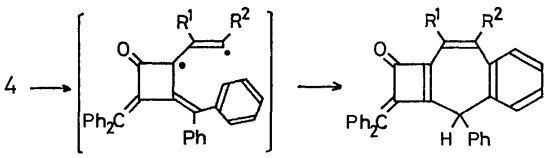
cycloaddition of diazo ketone to acetylene is well established.[1,4,5] The structure of **4b** was characterized by the following experiment. Treatment of **4b** with $ZnCl_2$ in MeOH afforded 3-(1-diphenylmethylene-2-methoxycarbonyl-3,3-diphenyl-2-propenyl)-5-benzoyl pyrazole (**6**, 90%).



6

Frank-Neumann and Buchecker[2] reported that the easy thermal conversion of **1** into **2** is due to the stability of **2** bearing heteroaromatic pyrazole ring. However, no analogous thermal conversion of **4** into **5** took place even in boiling xylene. The contrast would be due to destabilization of **5** which may not be planar because of ring strain and/or steric repulsion between the two diphenylmethylene groups. This is supported by examination of molecular models.

In contrast to the photochemical conversion of 3*H*-pyrazole into cyclopropane,[6,7] photolysis of **4a—c** afforded 8,9-bis(methoxycarbonyl)- (**8a**), 8-benzoyl- (**8b**), and 8,9-dibenzoyl-3-phenyl-2-diphenylmethylene-1,2-dihydro-3*H*-benzo[*a*]cyclobuta[*c*]cycloheptan-1-one (**8c**), respectively, in quantitative yields. The reaction sequence can be formulated by successive cyclization and hydrogen migration of the initially formed biradical intermediate (**7**),[8,9] as shown in Scheme 2.



7 8

Scheme 2.

Experimental

All the melting points are uncorrected. Photolysis was carried out at room temperature under N_2, using light from a 100-W high-pressure mercury lamp (Riko Kagaku Sangyo Co.) The IR, UV, and NMR were measured in KBr disk, $CHCl_3$, and $CDCl_3$, respectively. The mass spectra were obtained with an ionization energy of 75 eV.

Cycloaddition of 3 to Acetylenes. A solution of **3**[10] (3 mmol) and an equimolar amount of the acetylenes in benzene (50 ml) was kept at 0 °C for 1 day. Crude crystals remaining after evaporation of the solvent were recrystallized from AcOEt to give cycloadduct as red prisms.

4a: 78%; mp 158—159 °C. IR: 1765, 1740 cm^{-1}; λ_{max}: 335 (22600), 415 nm (ε, 5000); NMR: δ=7.7—6.5 (m, 20H), 3.90 (s, 3H), 3.39 (s, 3H); MS: *m/e* (rel intensity) 566 (M^+, 32), 507 (M^+-CO_2Me, 56), 479 (100). Found: C, 76.15; H, 4.78; N, 4.92%. Calcd for $C_{36}H_{26}O_5N_2$: C, 76.31; H, 4.63; N, 4.94%.

4b: 82%; mp 147—148 °C. IR: 1750, 1640 cm^{-1}; λ_{max}: 325 (25800), 427 nm (ε, 5500); NMR: δ=8.5—8.2 (m, 2H), 7.4—6.5 (m, 23H), 6.06 (s, 1H); MS: *m/e* (rel intensity) 554 (M^+, 25), 449 (M^+-PhCO, 10), 105 ($PhCO^+$, 100). Found: C, 84.30; H, 4.98; N, 5.13%. Calcd for $C_{39}H_{26}O_2N_2$: C, 84.45; H, 4.73; N, 5.05%.

4c: 80%; mp 124—125 °C. IR: 1755, 1660 cm^{-1}; λ_{max}: 320 (26000), 432 nm (ε, 5000); NMR: δ=8.3—6.4 (m); MS:

m/e (rel intensity) 658 (M^+, 22), 553 (M^+-PhCO, 6), 105 ($PhCO^+$, 100). Found: C, 83.64; H, 4.72; N, 4.38%. Calcd for $C_{46}H_{30}O_3N_2$: C, 83.87; H, 4.59; N, 4.25%.

Formation of ***6***. A mixture of **4b** (555 mg, 1 mmol), $ZnCl_2$ (150 mg, 1.1 mmol), and MeOH (20 ml) was stirred at room temperature for 15 min. The reaction mixture was decomposed with dil HCl, and then extracted with benzene. Crude crystals remaining after evaporation of the solvent were recrystallized from MeCN to give **6** as pale yellow needles; 510 mg (90%); mp 176—177 °C. IR: 3350, 1715 cm^{-1}; λ_{max}: 252 (29800), 290 (22300), 335 nm sh (ε, 11000); NMR: δ=9.05 (br s, 1H), 7.9—6.7 (m, 25H), 6.43 (s, 1H),[11] 3.35 (s, 3H). Found: C, 81.62; H, 5.12%. Calcd for $C_{40}H_{30}O_3N_2$: C, 81.88; H, 5.15%.

Photolysis of ***4***. A solution of **4a** (1.13 g, 2 mmol) in MeOH (150 ml) was irradiated for 30 min. Crude crystals remaining after evaporation of the solvent were recrystallized from CH_2Cl_2-MeOH to give **8a** as colorless prisms in a quantitative yield; mp 273—273.5°C. IR: 1785, 1750, 1730 cm^{-1}; λ_{max}: 320 (14500), 343 nm (ε, 16600); NMR: δ= 7.7—6.4 (m, 19H), 5.10 (s, 1H), 3.80 (s, 3H), 3.08 (s, 3H); MS: *m/e* 538 (M^+). Found: C, 80.12; H, 4.86%. Calcd for $C_{36}H_{26}O_5$: C, 80.28; H, 4.87%.

Similar photolysis of **4b** and **4c** afforded **8b** and **8c**, respectively, in quantitative yields.

8b: Colorless prisms: mp 268—270 °C. IR: 1780, 1660 cm^{-1}; λ_{max}: 245 (25200), 329 nm (ε, 17200); NMR: δ=8.3—8.1 (m, 2H), 7.7—6.7 (m, 22H), 6.17 (s, 1H), 5.10 (s, 1H). Found: C, 88.76; H, 4.69%. Calcd for $C_{39}H_{26}O_2$: C, 88.95; H, 4.98%.

8c: Colorless prisms: mp 257—258 °C. IR: 1780, 1660 cm^{-1}; λ_{max}: 258 (30000), 330 nm (ε, 21600); NMR: δ=8.3—6.6 (m, 29H), 5.19 (s, 1H); MS: *m/e* 630 (M^+). Found: C, 87.37; H, 4.76%. Calcd for $C_{46}H_{30}O_3$: C, 87.59; H, 4.79%.

NMR Spectroscopic Studies of the Tautomerism in Tetramic Acid Analogs and Their Anilides. III.[1] Polar Solvent Effects on the Tautomeric Populations*

Kimitoshi SAITO** and Tatsuaki YAMAGUCHI

Laboratory of Organic Chemistry, Chiba Institute of Technology, Tsudanuma, Narashino-shi, Chiba 275

(Received June 10, 1977)

Synopsis. NMR spectroscopic studies of 3-acetyltetramic acid† (3-acetyl-2,4-azolidinedione), 3-acetyltetronic acid† (3-acetyl-2,4-oxolanedione), 3-acetylthiotetronic acid† (3-acetyl-2,4-thiolanedione) and their anilides† (3-(2-phenyliminoethyl) derivatives) showed variations in the tautomeric equilibria with certain polar solvents. For example, the strong solvation effect of DMSO-d_6 causes a predominance of the lactim forms of 3-acetyltetramic acid over the lactam forms and up-field shifts of the enolic protons.

Previously, the tautomeric equilibria of 3-acetyltetramic acid analogs (I—III)† and their anilides (IA—IIIA)† in chloroform-*d* were studied by means of NMR spectroscopy.[1,2] In chloroform-*d*, the spectra of I—III showed the splitting of methylene proton signals by "external" (*cis-trans*) tautomerization (a, b ⇌ c, d), besides the splitting of methyl proton signals by the "internal" prototropy (a⇌b, c⇌d), caused by the different anisotropic effect of the carbonyl group in each tautomer (Chart 1, a—d).[1]

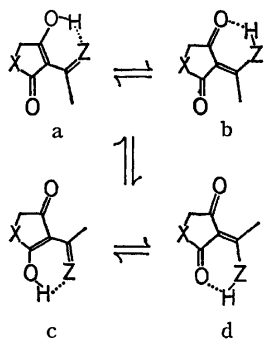

Chart 1.

However, with some exceptions, the splittings in methyl and methylene signals could not be observed in any solvents other than chloroform-*d* (Table 1). For this disappearance of the splittings, two reasons can be considered. The one is the rapid tautomeric interconversion accelerated by the polar solvent over the NMR time-scale. The other is the inclination of the tautomeric equilibria to one side as a result of the solvation effect. When DMSO-d_6 was added to the solution of 3-acetyltetramic acid (I) in chloroform-*d*, the intensity of the methylene signal of the c, d form was successively decreased and extinguished at a DMSO-d_6 content of *ca.* 25%, whereas that of the a, b form was increased. Figure 1a shows the variations in the intensity ratio (c+d)/(a+b) with the DMSO-d_6 content. From this fact, it can be concluded that the acceleration of the prototropy by the polar solvent does not happen in this case.

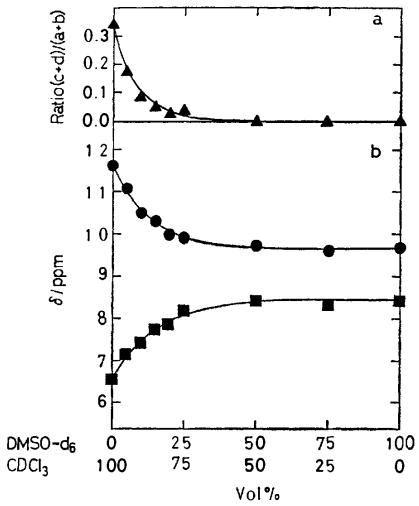

Fig. 1. Variations of the chemical shifts and the tautomeric ratio of 3-acetyltetramic acid (I) in $CDCl_3$-DMSO-d_6 mixed solvent system.
▲: Ratio of c, d form to a, b form, ●: enolic proton, ■: lactam-lactim proton.

Furthermore, along with the addition of DMSO-d_6, the down-field shift of the NH proton signal and the up-field shift of the enolic proton signal were observed throughout this experiment (Fig. 1b). The down-field shift of the NH proton signal suggests the formation of the lactim form, which is then rapidly interconverted with the corresponding lactam form. With the addition of DMSO-d_6, the lactim form should become predominant over the lactam form, since DMSO-d_6 might solvate and stabilize the more polar lactim form.[3]

The up-field shift of the enolic proton is probably caused by the formation of an intermolecular hydrogen

* A preliminary report of this work was presented at the 36th National Meeting of the Chemical Society of Japan, Osaka, April 1977.

** Present address: Department of Applied Chemistry, School of Science and Technology, Waseda University, Nishi-Okubo, Shinjuku-ku, Tokyo 160.

† Common names are consciously introduced for these compounds in order to express the mixed systems of the complicated tautomers. However, the IUPAC names of their keto forms are as follows: 3-acetyl-2,4-azolidinedione (I), 3-acetyl-2,4-oxolanedione (II), 3-acetyl-2,4-thiolandione (III), 3-(2-phenyliminoethyl)-2,4-azolidinedione (IA), 3-(2-phenyliminoethyl)-2,4-oxolanedione (IIA), and 3-(2-phenyliminoethyl)-2,4-thiolanedione (IIIA).

Chart 2.

bonding between I and the DMSO-d_6 molecule. Similar shifts could be observed with respect to II and III. However, further investigations might be necessary with regard to this problem.

In a similar way, major tautomers of the other analogs in various solvents were determined by the measurement of the variations in the methylene signal intensities in mixed solvent systems with chloroform-*d*.

Experimental

The compounds (I—IIIA) were prepared by the methods of the literature cited in the preceding papers.[1,2] All the deuterated solvents were obtained from E. Merck, Ltd. Solutions for the measurements were made so as to contain 1.5×10^{-4} mol of the compounds in 0.4 ml of the solvents. The NMR spectra were recorded on a JEOL PS-100 spectrometer at 100 MHz at 34 °C, using TMS as the internal standard.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 51 (2), 653—654 (1978)

The Derivation of a Brominated Algal Component from Myrcene

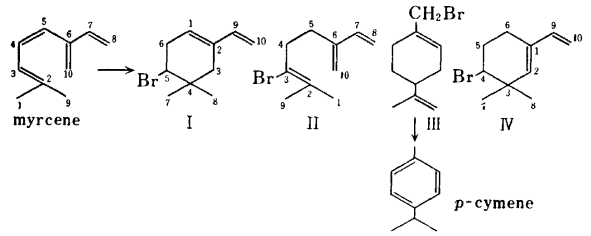
Kazuo YOSHIHARA and Yoshio HIROSE

The Institute of Food Chemistry, Wakayamadai 1-chome, Shimamotocho, Mishima-gun, Osaka 618

(Received June 24, 1977)

Synopsis. The supposed structure, 5-bromo-4,4-dimethyl-2-vinyl-1-cyclohexene, for a brominated monoterpene from *Desmia (Chondrococuus) hornemanni* was derived from myrcene through a one-step reaction, and the structure was confirmed.

Many halogenated monoterpenes have been isolated from *D. hornemanni* and characterized.[1-4] Most of them are acyclic myrcene derivatives, and one cyclic compound from Japanese *hornemanni* has been supposed to have the structure of 5-bromo-4,4-dimethyl-2-vinyl-1-cyclohexene (I).[2] We presumed that those halogenated monoterpenes were the products of a halogenium-ion attack on the double bond of myrcene, and tried to derive I by the cyclization of myrcene with the bromonium ion.



Several cyclizations were carried out. Among the reagents tested, 2,4,4,6-tetrabromo-2,5-cyclohexadien-1-one (TBCO)[5] was the most desirable for our purposes. The reaction of myrcene with TBCO in nitromethane at 0 °C afforded a mixture containing five monobromides and the starting hydrocarbon. The mixture was run out through SiO_2-column and gas chromatography (GC), thus isolating three monobromides. One of them was identified with the natural cyclic monobromide mentioned above in its IR and NMR spectra, except for one singlet signal at δ 1.21. This signal is found in the NMR spectrum of the natural compound, but not in the synthetic one, therefore, we may conclude that this signal is due to contamination. The NMR spectrum (including the irradiation technique), the IR and the mass spectra of the synthetic compound were satisfied with the supposed structure (I). Two other bromides were also isolated, their structures were assigned as 3-bromomyrcene (II) and 7-bromolimonene (III) from a comparison of the NMR spectra with those of 3-bromo-7-chloromyrcene[1] and limonene respectively. The double bond isomer of I, 4-bromo-3,3-dimethyl-1-vinyl-1-cyclohexene (IV), was not separated from I, but from the NMR and GC-mass spectra of the mixture the existence of compound (IV) was sopposed. In our experiment, the isolation using preparative GC was often accompanied with decomposition, and especially, the allyl bromide (III) was coverted to *p*-cymene. I, as well as II, were unstable for long storage, even in an ice stocker. We think that II can be used for the synthesis of 3-bromo-7-chloromyrcene, *etc.* Other attempts at cyclization, such as HOBr attack by NBS–H_2O or NBA–H_2O in acetone and the acid-catalyzed cyclization of myrcene-2,3-epoxide, followed by bromination, could not afford our expected compounds.

Experimental

An analytical GC was performed with a Hitachi 063-type apparatus equipped with a HB-2000 capillary column, and preparative GC with Varian's model 90 fitted OV-17 on Chromosorb-W, operated at 100 °C with a detection filament current of 70 mA. In the operation of the latter apparatus over a filament current of 100 mA, allyl bromide (III) was dehydrobrominated in a detector, as was shown by the unusual base-line dropping. For the measurement of the physical data, Hitachi RM-50GC-type GC-mass (fitted with a OV-17 glass capillary column and operated at an ionization voltage of 70 eV) spectrometer were used.

The Reaction of Myrcene with TBCO. To a solution of CH_3NO_2 (500 ml) containing myrcene (20 g), TBCO (40 g) was added, after which the mixture was stirred for 30 min at 0 °C. The resulting mixture was extracted with pentane. The extract (18.4 g) was chromatographed through a SiO_2 column several times, using pentane as the carrier, the process was monitored by means of analytical GC. First myrcene (10.3 g) was extracted, then a mixture of I, II, and IV (3.3 g), and at last a mixture of I and III (2.8 g). The ratio of the products, I: II: III: IV, was 3: 1: 2: 1.

5-Bromo-4,4-dimethyl-2-vinyl-1-cyclohexene (I). NMR (CCl_4) δ 1.03 and 1.07 (each s, 3H, assigned to C-7 and C-8 dimethyl respectively), 2.02—2.40 (m, 2H, C-3 methylene), 2.69—2.90 (m, centered at 2.75, 2H, C-6 methylene), 4.03 (dd, 1H, J=7.5 and 6.0 Hz, C-5 methylene which changed into a singlet signal upon irradiation with C-6 methylene), 4.88 and 5.00 (each d, 1H, J=11 and 17 Hz, *cis*- and *trans*-olefin protons on C-10, respectively; irradiation with the C-9 olefin proton changed those signals into two broad s, signals), 5.49 (m, 1H, C-1 olefin, which changed into a broad s, upon irradiation with C-6 methylene), and 6.73 (dd, 1H, J=11 and 17 Hz); IR ν 3080, 1660, 1600, 1370, 1350, and 890 cm^{-1}; MS *m/e* 216 and 214 (M^+, $C_{10}H_{16}Br$, 9.7%), 201 and 199 (−Me, $C_9H_{13}Br$, 1%), 135 (−Br, $C_{10}H_{15}$, base peak), 119 (C_9H_{11}, 32%), 107 (30%), 93 (50%), and 79 (36%).

3-Bromomyrcene (II). NMR δ 1.73 and 1.83 (allyl-coupled broad s, each 3H, C-1 and C-9 vinyl methyl), a signal centered at 2.25 (m, 4H, C-4 and C-5 methylenes), 4.98 and 5.20 (each d, 1H, J=12 and 18 Hz, *cis*- and *trans*-olefin protons on C-8), 5.00 (broad s, 2H, C-10 olefin), and 6.22 (dd, 1H, J=12 and 18 Hz, C-7 olefin proton); IR ν 3070, 1640, 1375, 1200, 990, 895, and 660 cm^{-1}; MS *m/e* 216 and 214 (M^+, $C_{10}H_{15}Br$, 3%), 173 and 171 (7%), 135 (−Br, $C_{10}H_{15}$, base peak), 119 (34%), 107 (27%), and 79 (49%).

7-Bromolimonene (III). NMR δ 1.73 (s, 3H, C-9 methyl), 3.83 (s, 2H, C-7 methylene), 4.68 (s, 2H, C-10 olefin protons), and 5.38 (m, 1H, C-2 olefin proton); IR ν 3060,

1640, 1200, 885, 810, and 600 cm^{-1}; MS *m/e* 216 and 214 (M^+, $C_{10}H_{15}Br$, 7%), 171 and 173 ($-C_3H_7$, C_7H_8Br, 15%), 135 ($-Br$, $C_{10}H_{15}$, base peak), 119 (37%), 93 (72%), and 68 (C_6H_6, 67%). The decomposed product in a GC detector with a filament current of 150 mA, *p*-cymene, was identified by a comparison of its IR and mass spectra with those of an authentic sample.

4-Bromo-3,3-dimethyl-1-vinyl-1-cyclohexene (IV). This compound was not purified, but some NMR signals in a mixture with I and the mass spectrum were obtained. NMR 1.15 (s, C-7 and C-8 *gem.* dimethyl), 1.60—2.00 (complex), 5.43 (broad s, C-4 methylene), and 6.25 (dd, $J=12$ and 18 Hz, C-9 vinyl methyl); MS *m/e* 216 and 214 (7%), 201 and 199 (3%), 135 (base peak), 119 (38%), 109 (27%), 93 (52%), and 79 (23%).

We wish to thank Professor Toshio Miwa of Osaka City Univ. for the measurement of 100 MHz NMR, to Mr Hiroshi Nii of the Nagaoka Perfumery Co., Ltd., for providing the myrcene, to Dr. Kiichi Nishimura of the Suntory Co., Ltd., for the measurements using the GC-mass spectrometer, and to Dr. Yoko Naya for providing the spectral data on haloterpenes and useful suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 51 (2), 655—656 (1978)

The Michael Type Alkylation of α,β-Unsaturated Sulfoxide and Reaction of the Resulting α-Sulfinyl Carbanion

Hideki SUGIHARA, Rikuhei TANIKAGA, Kazuhiko TANAKA, and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606

(Received July 4, 1977)

Synopsis. Aryl vinyl sulfoxide was alkylated *via* the Michael-type addition with lithium dialkylcuprates, and the resulting α-sulfinyl carbanions were reacted with various electrophiles (*i.e.* aldehydes, ketones, and alkyl halides) to afford α-substituted alkyl sulfoxides.

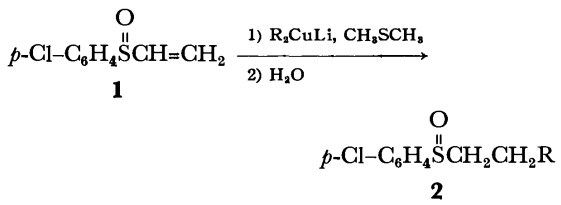
α,β-Unsaturated sulfoxides undergo Michael-type addition in the presence of a base.[1] However, no Michael-type alkylation to α,β-unsaturated sulfoxides has been investigated,[2] only a few reactions of secondary α-sulfinyl carbanions being reported.[3]

This paper describes the Michael-type alkylation to aryl vinyl sulfoxides, and the reaction of the initially formed α-sulfinyl carbanions with various electrophiles in one pot.

Results and Discussion

p-Chlorophenyl vinyl sulfoxide (**1**) was polymerised by alkyllithium, and was inert with the Grignard reagents.

On the other hand, vinyl sulfoxide **1** was alkylated by lithium dimethylcuprate, lithium dibutylcuprate and lithium di-*t*-butylcuprate to give *p*-chlorophenyl propyl sulfoxide (**2a**), *p*-chlorophenyl hexyl sulfoxide (**2b**), and *p*-chlorophenyl 3,3-dimethylbutyl sulfoxide (**2c**), respectively.



In the above Michael-type reaction, α-sulfinyl carbanion (**3**) was trapped by various electrophiles. β-Hydroxy sulfoxides (**4a**, **b**, **c**) were obtained when benzophenone was added to a solution of **3**. No 1,2-adduct of benzophenone was obtained even when benzophenone and **1** were added to lithium dialkylcuprate at the same time.[4]

Enolizable ketones and aldehydes such as cyclohexanone and propionaldehyde were treated in the same way to give the corresponding condensation products (**4e**, **f**) and **2b**.

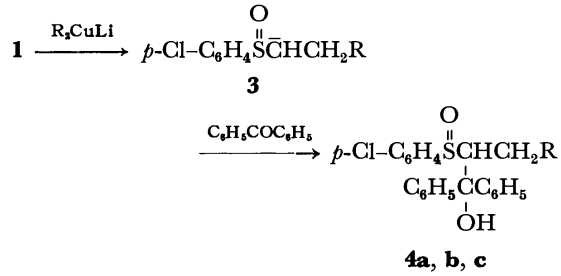


Table 1. Reaction of α-sulfinyl carbanion with electrophiles (yield of **2**, **4**, **5**)

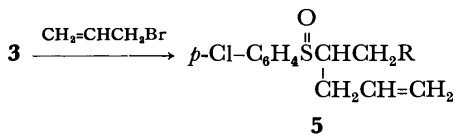
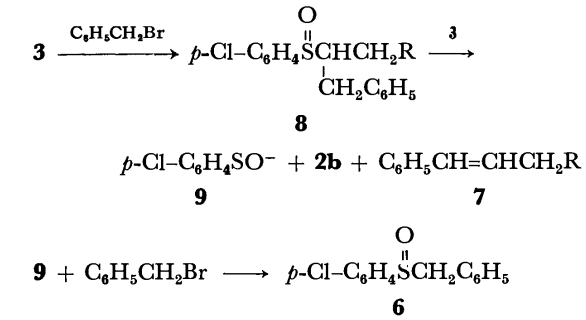
Electrophile	R_2CuLi R= CH_3	n-C_4H_9	t-C_4H_9
H^+	30	75	34
$(C_6H_5)_2CO$	80	73	45
C_6H_5CHO	—	67	—
	—	26	—
C_2H_5CHO	—	13	—
CH_2=$CHCH_2Br$	—	73	—

Allyl bromide underwent substitution reaction with **3** to afford *p*-chlorophenyl 1-allylhexyl sulfoxide (**5**). The results are given in Table 1.



Benzyl *p*-chlorophenyl sulfoxide (**6**), **2b** and 1-phenyl-1-heptene (**7**) were obtained when benzyl bromide was treated in the same way. It is assumed that **3** reacts with benzyl bromide to give alkylated sulfoxide (**8**), and the first formed **8** easily eliminates sulfenate (**9**) under basic conditions to give **7**,[5] the residual benzyl bromide combining with liberated **9** to produce **6**.



Experimental

Alkylation of p-*Chlorophenyl Vinyl Sulfoxide* ***1***.

p-*Chlorophenyl Propyl Sulfoxide* ***2a***: To an ether–dimethyl sulfide (1: 1, v/v) solution (30 ml) of copper(I) bromide–dimethyl sulfide complex[6] (1.03 g, 5 mmol) was added an ethereal solution of methyllithium (9 mmol) at 0 °C under nitrogen. The solutions was cooled to −60 °C, and **1** (1.31 g, 7 mmol) in ether (10 ml) was added. The temperature of the

mixture was allowed to rise to room temperature. The mixture was then extracted with ether, and dried over magnesium sulfate dehydrate. After removal of the solvent, **2a** was isolated (0.43 g, 30%) by chromatography on silica gel; oil: IR (film) 1030 (S=O) cm^{-1}; NMR (CCl_4) δ=1.02 (3H, t, J=7 Hz), 1.60 (2H, m), 2.64 (2H, t, J=7 Hz), 7.45 (4H, m).

p-*Chlorophenyl Hexyl Sulfoxide* ***2b***: To a solution of the copper(I) bromide complex (5 mmol) was added a hexane solution of butyllithium (9 mmol) at −60 °C under nitrogen. After being left to stand for 30 min, **1** (7 mmol) in ether was added to the mixture. The temperature of the mixture was allowed to rise to room temperature. After the usual work-up **2b** was isolated (1.28 g, 75%) by chromatography on silica gel: oil; IR (film) 1030 (S=O) cm^{-1}; NMR (CCl_4) δ=0.87 (3H, m), 1.30 (8H, m), 2.72 (2H, t, J=7 Hz), 7.48 (4H, m).

p-*Chlorophenyl 3,3-Dimethylbutyl Sulfoxide* ***2c***: To a solution of the copper(I) bromide complex (5 mmol) was added a pentane solution of *t*-butyllithium (9 mmol) at −78 °C under nitrogen. After being left to stand for 30 min, **1** (7 mmol) was added to the mixture. After the usual work-up **2c** (0.57 g, 34%) and *p*-chlorophenyl 1,1-dimethylethyl sulfoxide (0.17 g, 11%) were isolated by chromatography on silica gel. **2c**: mp 65—68 °C; IR (KBr) 1030 (S=O) cm^{-1}; NMR (CCl_4) δ=0.90 (9H, s), 1.50 (2H, m), 2.68 (2H, m), 7.50 (4H, m). *p*-Chlorophenyl 1,1-dimethylethyl sulfoxide: oil; IR (film) 1030 (S=O) cm^{-1}; NMR (CCl_4) δ=1.08 (9H, s), 7.45 (4H, m).

Reaction of α-Sulfinyl Carbanion ***3*** *with Electrophiles.*

p-*Chlorophenyl 1-(Diphenylhydroxymethyl)propyl Sulfoxide* ***4a***: To a solution of lithium dimethylcuprate was added an ethereal solution of **1** (7 mmol) and benzophenone (7 mmol) at −60 °C under nitrogen. The temperature of the mixture was allowed to rise to room temperature. After the usual work-up **4a** (2.16 g, 80%) was obtained: mp 129—131 °C; IR(KBr) 3420 (OH), 1005 (S=O) cm^{-1}; NMR ($CDCl_3$) δ= 0.20 (3H, t, J=7 Hz), 1.80 (2H, m), 3.42 (1H, m), 4.65 (1H, m), 7.42 (14H, m).

p-*Chlorophenyl 1-(Diphenylhydroxymethyl)hexyl Sulfoxide* ***4b***: To a solution of lithium dibutylcuprate was added an ethereal solution of **1** (7 mmol) and benzophenone (7 mmol) at −60 °C. The temperature of the mixture was allowed to rise to room temperature. After the usual work-up **4b** (2.18 g, 73%) was obtained: mp 120—121 °C; IR (KBr) 3420 (OH), 1000 (S=O) cm^{-1}; NMR ($CDCl_3$) δ=0.70 (9H, m), 1.76 (2H, m), 3.43 (1H, m), 7.40 (15H, m).

p-*Chlorophenyl 3,3-Dimethyl-1-(diphenylhydroxymethyl)butyl Sulfoxide* ***4c***: To a solution of lithium di-*t*-butylcuprate was added an ethereal solution of **1** (7 mmol) and benzophenone (7 mmol) at −78 °C. The mixture was treated in a similar way as described in the previous section, and **4c** (1.35 g, 45%) was obtained: mp 119—120 °C; IR (KBr) 3420 (OH), 1005 (S=O) cm^{-1}; NMR ($CDCl_3$) δ=0.12 (7.7 Hz, s), 0.90 (1.3H, s), 1.80 (2H, m), 3.35 (1H, t, J=4 Hz), 4.95 (1H, m), 7.34 (14H, m).

p-*Chlorophenyl 1-(α-Hydroxybenzyl)hexyl Sulfoxide* ***4d***: To a solution of lithium dibutylcuprate was added an ethereal solution of **1** (7 mmol) at −60 °C under nitrogen, an ethereal solution of benzaldehyde (7 mmol) being added after having been left to stand for 30 min. The mixture was then treated in a similar way as described in the section for **4c**, and **4d** (diastereomers) (1.57 g, 67%) were isolated by chromatography on silica gel: mp 80—82 °C; IR (KBr) 3420 (OH), 1000 (S=O) cm^{-1}; NMR ($CDCl_3$) δ=0.80 (11H, m), 1.62 (1H, m), 2.70 (1H, m), 4.80 (1H, d, J=8 Hz), 7.22 (9H, m): mp 103—105 °C; IR (KBr) 3420 (OH), 1000 (S=O) cm^{-1}; NMR ($CDCl_3$) δ=0.80 (11H, m), 1.62 (1H, m), 2.70 (1H, m), 5.22 (1H, d, J=4 Hz), 7.22 (9H, m).

p-*Chlorophenyl 1-(1-Hydroxycyclohexyl)hexyl Sulfoxide* ***4e***: Cyclohexanone (7 mmol) was treated in a similar way as described in the preceding sections **4e** (0.62 g, 26%) and **2b** (0.64 g, 37%) were isolated by chromatography on silica gel. **4e**: mp 130—132 °C; IR (KBr) 3420 (OH), 1005 (S=O) cm^{-1}; NMR ($CDCl_3$) δ=1.20 (21H, m) 2.62 (1H, t, J=4 Hz), 4.23 (1H, s), 7.50 (4H, m).

p-*Chlorophenyl 1-(1-Hydroxypropyl)hexyl Sulfoxide* ***4f***: Propionaldehyde (7 mmol) was treated in a similar way as described in the preceding sections, **4f** (0.26 g, 13%) and **2b** (0.63 g, 37%) were isolated. **4f**: oil; IR (film) 3420 (OH), 1005 (S=O) cm^{-1}; NMR (CCl_4) δ=1.20 (17H, m), 2.42 (1H, m), 3.78 (1H, m), 7.48 (4H, m).

p-*Chlorophenyl 1-Allylhexyl Sulfoxide* ***5***: Allyl bromide (7 mmol) was treated in a similar way as described in the preceding sections, **5** (1.45 g, 73%) was obtained: oil; IR (film) 1030 (S=O) cm^{-1}; NMR (CCl_4) δ=1.40 (14H, m), 5.00 (2H, m), 5.52 (1H, m), 6.45 (4H, m).

Reaction of ***3*** *with Benzyl Bromide*: Benzyl bromide (7 mmol) was treated in a similar way as described in the preceding sections. After the work-up, **2b** (0.40 g, 47%), benzyl *p*-chlorophenyl sulfoxide **6** (0.40 g, 46%) and 1-phenyl-1-hexene **7** (0.25 g, 41%) were isolated by chromatography on silica gel. **6**: mp 133—134 °C; IR (KBr) 1030 (S=O) cm^{-1}; NMR ($CDCl_3$) δ=4.03 (2H, d, J=4 Hz), 7.24 (5H, m). **7**: oil; NMR (CCl_4) δ=0.92 (3H, m), 1.38 (6H, m), 2.20 (2H, m), 6.20 (2H, m), 7.17 (5H, m).

This work was partly supported by a Grant-in-Aid of the Ministry.

Lactones of Hydrogenated 5,8-Dihydroxy-4-methylnaphthalene-1-carboxylic Acids

Hajime IRIKAWA and Yasuaki OKUMURA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received July 5, 1977)

Synopsis. The γ- and δ-lactones were derived from the Diels-Alder adduct of *p*-benzoquinone and methyl sorbate.

Generally, whether a γ- or δ-lactone is formed in a reaction depends mainly on the stability of the lactone under the reaction conditions.[1] This paper deals with the lactones of *cis*-octahydro- and *cis*-decahydro-5β,8β-dihydroxy-4β-methylnaphthalene-1β-carboxylic acids.

The Diels-Alder adduct[2] of *p*-benzoquinone and methyl sorbate was reduced with zinc to **1**, which was hydrogenated to **2a** in the presence of palladium-carbon, and to **3a** with platinum oxide. Lactonization of **3a** in methanolic hydrogen chloride afforded the keto δ-lactone (**4**), supporting the cis ring junctions in **1**, **2a**, and **3a**.

4

Fig. 1.

The reduction of **1** with sodium borohydride followed by treatment with acetic anhydride and pyridine gave the acetoxy δ-lactone (**5**) and the $\Delta^{1,2}$-γ-lactone (**6**), the latter of which afforded the acetate (**7**) by acetylation at elevated temperature. Treatment of **5** with sodium methoxide gave **6**. An attempt to convert **6** into the corresponding saturated γ-lactone (**8a**) by catalytic hydrogenation with platinum oxide failed, but gave the δ-lactone (**9**) and the $\Delta^{1,9}$-γ-lactone (**10**). The δ-lactone **9**, which was stable against treatment with sodium methoxide, was obtained from **2a** or **3a** by sodium borohydride reduction, or from **4** by hydrogenation under the similar conditions to those in the preparation of **3a**. The C-8 carbonyl group of **4** is obviously less hindered than that of **3a**.

On the other hand, Wheeler *et al.* reported the reduction of **2b** under Meerwein-Ponndorf conditions to **8b**, which was also obtained from **8c** by catalytic hydrogenation or sodium borohydride reduction.[3,4]

It is interesting to infer the conformations of **2a** and **3a**. The signal for the equatorial proton on C-5 (CH–O–) in the ^{1}H NMR spectrum of **4** appears at 4.95 ppm as a broad singlet (W_H=7 Hz), while a multiplet signal at 4.40 ppm (W_H=17 Hz) in the spectrum of **3a** must be attributed to the axial proton on C-5 (CH–OH). Fig. 2.

signals for C-1 in the ^{13}C NMR spectra of **3a** and **3b** appear at nearly the same fields. The signals for C-2 and -9 in **3a** are observed at fields higher than those of the corresponding carbons in **3b** as a consequence of the γ gauche effect of the methyl group. The similar shielding trends are also found for C-1, -2, and -9 in the spectra of **2a** and **2b**. These data indicate that **2a** and **3a** exist predominantly in the conformations similar to those of **2b** and **3b** which bear the equatorial methoxycarbonyl groups. Details will be published elsewhere.

Therefore, the conformations of the intermediate diol esters from **2a** and **2b** might affect the way of lactonization. The formation of **8b** seems to proceed through the preferred conformer **A** (R=H) similar to those of **2b** and **3b**. In the case of R=Me, **9** might be formed *via* the stable conformer **B**, since **A** is unstable on account of the steric effect of the methyl group.

Experimental

Melting points are uncorrected. The IR spectra were recorded on a Hitachi Infrared Spectrometer EPI-G_3 in

nujol, unless otherwise noted. The UV spectra were recorded on a Shimadzu MPS-50L in EtOH. The ^1H and ^{13}C NMR spectra were obtained on a JNM-PS-100 or JNM-PFT-60 in $CDCl_3$. Chemical shifts are given in δ-values with respect to TMS as an internal standard. Assignment of chemical shifts for close-lying peaks marked with asterisk may be reversed. Compounds **2b** and **3b** were prepared according to literature procedures.[5]

Preparation of ***1***. A solution of 18.0 g of *p*-benzoquinone and 17.6 g of methyl sorbate in 150 ml of benzene was refluxed for 19 h, and concentrated *in vacuo*. The residue was treated with 50 g of zinc in 150 ml of AcOH at room temperature for 2 h to give 2.30 g of the unreduced adduct[2] and 6.95 g of **1**: mp 136—137 °C (from EtOH); IR 1735 and 1702 cm^{-1}; ^1H NMR 0.88 (3H, d, J=7 Hz, CMe), 2.4—3.4 (7H), 3.71 (3H, s, OMe), *ca.* 3.8 (1H, m), 5.65 (1H, m, -CH=), and 6.04 ppm (1H, br d, J=11 Hz, -CH=); ^{13}C NMR 17.04 (CMe), 30.55 (C-4), 34.73 (C-6), 37.61 (C-7), 39.44 (C-1), 46.05 (C-9), 48.33 (C-10), 52.10 (OMe), 121.37 (C-2), 131.27 (C-3), 172.06 (COO), 207.85 (C-5*), and 210.29 ppm (C-8*). Found: C, 66.19; H, 6.86%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Preparation of ***2a***. Hydrogenation of 2.84 g of **1** with 266 mg of 5% Pd-C in 120 ml of MeOH gave 2.51 g of **2a**: mp 110—111 °C (from EtOH); IR 1721 and 1706 cm^{-1}; ^1H NMR 0.84 (3H, d, J=7 Hz, CMe), 1.4—3.1 (11H), *ca.* 3.5 (1H, m), and 3.69 ppm (3H, s, OMe); ^{13}C NMR 15.82 (CMe), 20.08 (C-2), 30.47 (C-3), 31.45 (C-4), 35.10 (C-6), 37.41 (C-7), 41.35 (C-1), 47.68 (C-9), 51.13 (C-10), 51.78 (OMe), 173.52 (COO), 208.91 (C-5*), and 209.80 ppm (C-8*). Found: C, 65.32; H, 7.68%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

^{13}C NMR of ***2b***. 23.49 (C-3*), 23.98 (C-2*), 26.62 (C-4), 35.83 (C-6), 36.56 (C-7), 41.23 (C-1), 48.41 (C-10), 49.22 (C-9), 51.82 (OMe), 173.60 (COO), 207.85 (C-8*), and 209.56 ppm (C-5*).

Preparation of ***3a***. Hydrogenation of 2.92 g of **1** with 95 mg of PtO_2 in 120 ml of MeOH gave 2.33 g of **3a**: mp 124—125 °C (from benzene); IR 3370, 1744, and 1693 cm^{-1}; ^1H NMR 0.97 (3H, d, J=7 Hz, CMe), 1.3—2.8 (12H), 3.18 (1H, br t, J=5 Hz), 3.65 (3H, s, OMe), and 4.40 ppm (1H, m, W_H=17 Hz, C<u>H</u>-OH); ^{13}C NMR 17.12 (CMe), 19.55 (C-2), 27.67 (C-4), 31.61 (C-6), 34.04 (C-3), 37.90 (C-7), 42.69 (C-1), 47.27 (C-9*), 47.56 (C-10*), 51.61 (OMe), 70.20 (C-5), 174.57 (COO), and 210.94 ppm (C-8). Found: C, 64.97; H, 8.65%. Calcd for $C_{13}H_{20}O_4$: C, 64.98; H, 8.39%.

^{13}C NMR of ***3b***. 21.18 (C-4), 23.98 (C-2*), 24.83 (C-3*), 29.21 (C-6), 38.51 (C-7), 42.56 (C-1), 45.69 (C-10), 49.75 (C-9), 51.70 (OMe), 70.45 (C-5), 174.57 (COO), and 209.48 ppm (C-8).

Lactonization of ***3a*** *to* ***4***. Treatment of 160 mg of **3a** with 5 ml of 6% methanolic hydrogen chloride at 20 °C overnight gave 101 mg of **4**: mp 100—101 °C (from benzene–hexane); IR 1733 and 1712 cm^{-1}; ^1H NMR 1.14 (3H, d, J=6 Hz, CMe), 1.3—2.9 (12H), and 4.95 ppm (1H, br s W_H=7 Hz, CH-O-). Found: C, 69.18; H, 7.91%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

$NaBH_4$ Reduction of ***1*** *and Subsequent Acetylation.* Reduction of 1.69 g of **1** with 0.8 g of $NaBH_4$ in 80 ml of MeOH at 0 °C for 1.5 h gave an oily product, which was treated with 7 ml of Ac_2O and 10 ml of pyridine at room temperature overnight to afforded 527 mg of **5** and 356 mg of **6**. **5**: mp 114—116 °C (from benzene–hexane); IR 1733 and 1252 cm^{-1}; ^1H NMR 1.21 (3H, d, J=7 Hz, CMe), 1.5—2.9 (7H), 2.08 (3H, s, OAc), 3.25 (1H, m, W_H=10 Hz, CH-COO), 4.76 (1H, br s, W_H=8 Hz, CH-O-), 4.98 (1H, m, W_H=18 Hz, C<u>H</u>-OAc), 5.70 (1H, dd, J=10 and 3 Hz, -CH=), and 5.93 ppm (1H, m, -CH=). Found: C, 67.26; H, 7.35%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%. **6**: mp 155—157 °C (from EtOH); IR ($CHCl_3$) 3600, 3480, 1754, and 1691 cm^{-1}; UV max 225 nm (ε 8500); ^1H NMR 1.23 (3H, d, J=6 Hz, CMe), 1.3—2.6 (9H), 3.05 (1H, m), 4.23 (1H, br s, W_H= 13 Hz, C<u>H</u>-OH), 4.70 (1H, m, W_H=14 Hz, CH-O-), and 6.85 ppm (1H, q, J=6 and 3 Hz, -CH=). Found: C, 69.37; H, 7.84%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

The Acetate ***7***. Treatment of 257 mg of **6** with 5 ml of Ac_2O and 7 ml of pyridine at 100—105 °C for 6 h gave 177 mg of **7**: mp 138—139 °C (from benzene–hexane); IR 1760, 1733, 1689, and 1250 cm^{-1}; UV max 222 nm (ε 9700); ^1H NMR 1.09 (3H, d, J=6 Hz, CMe), 1.2—2.7 (8H), 1.97 (3H, s, OAc), 3.15 (1H, m), 4.77 (1H, m, W_H=14 Hz, CH-O-), 5.25 (1H, br s, W_H=8 Hz, CH-OAc), and 6.90 ppm (1H, br d, J=3 Hz, -CH=). Found: C, 67.01; H, 7.25%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

Conversion of ***5*** *into* ***6***. Treatment of 99 mg of **5** with 3 ml of 1 M NaOMe at room temperature overnight gave 41 mg of **6**.

Catalytic Hydrogenation of ***6***. Hydrogenation of 343 mg of **6** with 36 mg of PtO_2 in 50 ml of AcOEt gave 125 mg of **9** and 142 mg of **10**. **9**: mp 105—106 °C (from benzene–hexane); IR ($CHCl_3$) 3600, 3430, and 1725 cm^{-1}; ^1H NMR 1.08 (3H, d, J=6 Hz, CMe), 1.3—2.4 (11H), 2.95 (2H, br s, W_H=9 Hz, O<u>H</u> and C<u>H</u>-COO), 3.80 (1H, m, W_H=17 Hz, C<u>H</u>-OH), and 4.70 ppm (1H, br s, W_H=8 Hz, CH-O-). Found: C, 68.42; H, 8.82%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%. **9** was stable against teratment with 1 M NaOMe at room temperature overnight. **10**: mp 181—182 °C (from benzene); IR ($CHCl_3$) 3600, 3470, 1750, and 1696 cm^{-1}; UV max 223 nm (ε 12500); ^1H NMR 1.21 (3H, d, J=6 Hz, CMe), 1.3—2.6 (11H), 4.30 (1H, m, W_H=12 Hz, C<u>H</u>-OH), and 4.70 ppm (1H, m, W_H=15 Hz, CH-O-). Found: C, 69.34; H, 7.71%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

$NaBH_4$ Reduction of ***2a***. Reduction of 1.56 g of **2a** with 0.7 g of $NaBH_4$ in 50 ml of MeOH at 0 °C for 2 h gave 1.07 g of **9**. In a similar way, **9** was obtained from **3a** (204 mg from 323 mg of **3a**).

Catalytic Hydrogenation of ***4***. Hydrogenation of 81 mg of **4** with 2 mg of PtO_2 in 20 ml of MeOH gave 75 mg of **9**.

The Reaction of Cyclohexyl Isocyanide with Aromatic Diacyl Disulfides

Sakuya TANAKA, Kenji MASUE, and Masaya OKANO*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

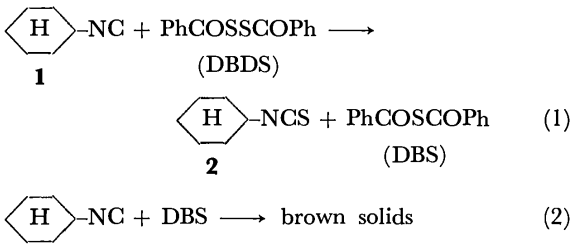
(Received July 30, 1977)

Synopsis. The reaction of cyclohexyl isocyanide with dibenzoyl disulfide in toluene at a reflux temperature gives cyclohexyl isothiocyanate, together with some unidentified compounds. Based on the substituent effects on the rate, a probable reaction path is proposed. The distinction between two reactions conducted in the absence and in the presence of soft metal salts is also described.

It has been reported previously that diacyl disulfides reacted smoothly with isocyanides in boiling chloroform (61 °C) to give only isothiocyanates in the presence of the salts of such soft metal ions as Tl^{I} and Pb^{II}, while without added metal salts there was only a low yield of the product.[1] It seemed that it would be of interest to investigate what kind of reaction occurs between isocyanide and dibenzoyl disulfide (DBDS) in the absence of metal salts, but at a higher temperature where a radical fission of the disulfide is still unexpected.[2] In relation to this, Shono *et al.* have reported that cyclohexyl isocyanide reacted with dibenzoyl peroxide at 80—90 °C to afford products derived from benzoyloxyl radical ($PhCO_2\cdot$).[3]

Results and Discussion

When cyclohexyl isocyanide (**1**) was heated with an equimolar amount of DBDS in toluene at a reflux temperature (111 °C) for 24 h, cyclohexyl isothiocyanate (**2**) was formed in a 49% yield; **1** was completely consumed, while 24% of DBDS was recovered (Scheme 1). At the same time we observed the formation of considerable amounts of brown solids which seemed to be a mixture of the reaction products between **1** and the initially formed dibenzoyl sulfide (DBS) (as determined by a study of the NMR, IR, and mass spectra) (Scheme 2); this was confirmed by a separate experiment (See Experimental). Several attempts to separate the solids into pure components have failed, and so each of them remains unidentified. It should be noted that the reaction (2) was accompanied by the formation of only a very low yield (3%) of **2**. The fact that the yield of **2** from DBDS does not exceed 50% in this



case may suggest that the latter reaction is faster than the former one. In fact, when two equivalents of **1** were treated with DBDS, the yield of **2** increased to 94% (based on DBDS). Some typical results are shown in Table 1, together with those obtained by the use of *p,p'*-disubstituted DBDS. The addition of several radical scavengers, such as *p*-benzoquinone and *p-t*-butylcatechol, had no effect on the yield of the product, suggesting an ionic nature of the reaction. In accordance with this, the reaction rate increased with an increase in the solvent polarity; the treatment of DBDS with two equivalents of **1** in refluxing acetonitrile (bp 82 °C, $\varepsilon=37.5$) and in refluxing cyclohexane (bp 81 °C, $\varepsilon=2.02$) for 10 h gave **2** in 68% and 4% yields respectively.

Table 1. The reaction of **1** with aromatic diacyl disulfides[a]

R'=*p*-$MeOC_6H_4CO$	5	9	9
	10	11	16

a) **1** (1 mmol). b) Toluene (10 ml) was used as the solvent; at reflux. c) By GLC (based on disulfide).

In order to ascertain some characteristics of the reaction, the following experiments were also carried out. First, the rates of the formation of **2** from **1** and aromatic diacyl disulfides were roughly examined in refluxing toluene. The results in Table 2 show that rates decrease in the following order; *p*-NO_2>H>*p*-

* To whom correspondence should be addressed.

MeO. Second, the competitive reaction between **1** and phenyl isocyanide with DBDS (1 mmol of each reactant) in refluxing toluene (10 ml) for 6 h afforded **2** (20%) and phenyl isothiocyanate (14%), in addition to unreacted **1** (33%) and phenyl isocyanide (84%), showing that the more nucleophilic **1** reacted faster.

Based on all our results, we propose Scheme 3 for this reaction. It involves the initial nucleophilic attack of isocyanide on the sulfur atom of DBDS. The subsequent removal of benzoyl cation from the transient imidoyl cation affords isothiocyanate. The combination of the benzoyl cation with thiobenzoate anion gives DBS, which then reacts with **1** to give brown solids.

$$\mathrm{RNC + ArCOSSCOAr} \xrightarrow{(A)} \mathrm{R{-}N{=}\overset{+}{C}{-}SCOAr + ArCOS^-}$$

$$\mathrm{R{-}N{=}\overset{+}{C}{-}SCOAr} \longrightarrow \mathrm{R{-}NCS + ArCO^+} \qquad (3)$$

$$\mathrm{ArCO^+ + ArCOS^-} \longrightarrow \mathrm{ArCOSCOAr} \xrightarrow[(B)]{\mathrm{RNC}} \text{brown solids}$$

Now we can compare the reactions with or without added soft metal salts. In the absence of metal salts, the rates of (A) and (B) are comparable, or Step (B) may be faster than (A). On the other hand, the presence of soft metal salts considerably accelerates Step (A) by coordination with the sulfur atom, as was clarified in the previous report,[1] and therefore Step (B) becomes comparatively very slow if such acceleration is not significant in it. In fact, when **1** was treated with DBS in the presence of TlSCOPh in chloroform at reflux for 3 h (1 mmol of each reactant), the consumption of **1** was only 25%, much lower than that in the case of DBDS (79%).

Experimental

The IR and NMR spectra analyses and GLC analyses were carried out as has been described in a previous paper.[1] The mass spectra were recorded on a JEOL-01SG spectrometer.

Materials. The isocyanides (RNC: R=*c*-C_6H_{11}, Ph) and disulfides (R'SSR': R'=PhCO, *p*-$MeOC_6H_4CO$, *p*-$NO_2C_6H_4CO$) were prepared by a method reported previously.[1] Dibenzoyl sulfide was prepared by a modification of the method of Kodomari *et al.*[4] Cyclohexyl isothiocyanate (**2**) prepared previously in our laboratory and commercial phenyl isothiocyanate were used as authentic samples for the GLC analyses. TlSCOPh was prepared by the reported method.[5]

*Reaction of **1** with DBDS.* A mixture of **1** (0.545 g, 5 mmol) and DBDS (1.37 g, 5 mmol) in toluene (10 ml) was stirred at reflux for 24 h. After it had been cooled, the GLC analysis of toluene solution revealed the presence of 2.45 mmol of **2** (49% yield: based on DBDS). The evaporation of the solvent, followed by the addition of ether to the residue, gave 0.33 g (24%) of DBDS as an insoluble precipitate. By removing the ether from the above ether washing and by adding hexane to the residue, brown solids (1.12 g, mp 186—192 °C) were separated out as precipitates. The hexane washing contained **2**. The NMR spectrum of this solid revealed the presence of cyclohexyl and phenyl groups, and the IR spectrum had strong absorptions at 1660 and 1630 cm^{-1}, these spectra being the same as those of the solids obtained from **1** and DBS (in toluene, 111 °C, 14 h). The mass spectrum showed peaks at *m/e* 351, 460, and 569 which may correspond to the three adducts of DBS-**1**, 1:1, 1:2, and 1:3 respectively. None of the compounds could be separated by column chromatography or preparative TLC on activated alumina.

The helpful comments of Dr. Sakae Uemura are gratefully acknowledged.

Absolute Stereochemistry of Cacalol

Mahito TERABE, Masahiro TADA, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received August 11, 1977)

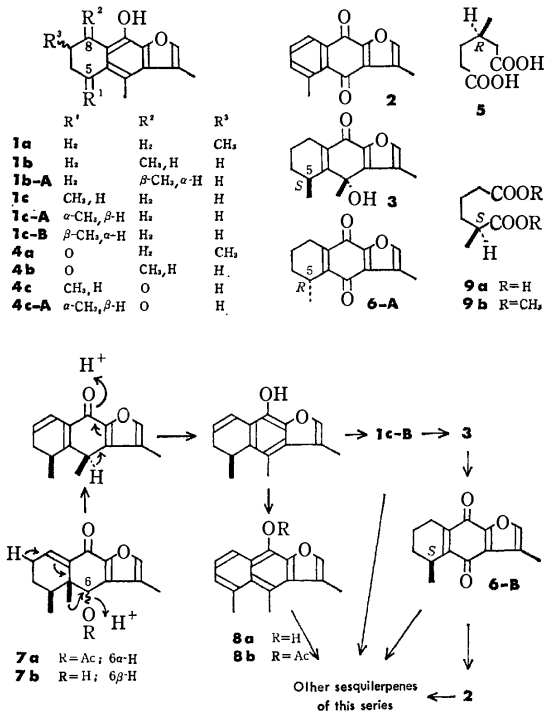
Synopsis. Descriptions on the absolute configuration at C-5 of cacalol have been confused. Ozonolysis of cacalol afforded (*S*)-(+)-2-methylhexanedioic acid. The asymmetric center at C-5 of cacalol, cacalone, and of sesquiterpenes related to these compounds was therefore established to be (*S*)-configuration.

Since cacalol and cacalone were isolated from *Cacalia decomposita* A. Gray,[1] a number of sesquiterpenes related to these compounds have been isolated from plants of the genus *Cacalia*.[2–7] Among these sesquiterpenes, cacalone,[1] maturinone,[2–8] and decompostin[3,9,10] have been chemically correlated with cacalol. Through a series of revisions (**1a**,[1] **1b**,[8] and **1c**), the structure of cacalol was established to be 5,6,7,8-tetrahydro-3,4,5-trimethylnaphtho[2,3-*b*]furan-9-ol (**1c**)[9,11–15] by unambiguous syntheses of maturinone (**2**)[9,11–13] and (±)-cacalol (**1c**).[12,14,15] Based on conversion of cacalol into cacalone,[16,17] a *p*-quinol structure (**3**)[16–18] was recently shown for cacalone, and previously presented formulas (**4a**,[1] **4b**,[8] and **4c**[9,11,13]) were excluded.

Descriptions on the absolute configuration at C-5 hitherto reported for cacalol have been confused. In the present paper, we wish to report evidence leading to a (5*S*)-configuration for cacalol (**1c-B**).

In early studies on cacalol and cacalone, a stereostructure (**1b-A**) with 8β-methyl group was proposed for cacalol because of the formation of (*R*)-(+)-β-methyladipic acid [**5**; (*R*)-(+)-3-methylhexanedioic acid] on ozonolysis of cacalol.[8] However, the formation of **5** from cacalol can not be explained by the present structure (**1c**) for cacalol. The stereostructures (**1c-A**, **4c-A**, and **6A**) with (5*R*)-configuration were then suggested[19] for cacalol, cacalone, and for a nor-*p*-quinone,[1,7,20] respectively, based on an interpretation of their anomalous ORD curves by means of the presence of inherently dissymmetric chromophores.[19] This result[19] seems to be inconvincing, as the reference compounds cited therein[19] are inadequate for the arguments, and the structure of cacalone was later revised from **4c** to **3**.[16,17]

Decompostin is a natural eremophilane derivertive coexisting with cacalol, cacalone, and maturinone in *C. decomposita*.[3] Biogenetic considerations that cacalol and its related compounds are derived from sesquiterpenes of eremophilane type such as decompostin have been proposed.[13,21] As an absolute configuration of decompostin was determined to be **7a**,[3,22] the biogenetic pathway is shown as in Scheme 1, suggesting a (5*S*)-configuration for cacalol (**1c**) and for its related sesquiterpenes (**3**, **6**, *etc.*).[20] It was reported that deacetyl-6-epidecompostin (**7b**)[9] [or its mesylate[10]] was converted chemically into naphthofuran derivertive (**8b**)[9,10] which was derived from cacalol.[1] However, no information on the stereochemistry at C-5 of cacalol can be



Scheme 1.

drawn from the above result, as **8b** bears no asymmetric center. Therefore, the ozonolysis of cacalol (**1c**) was reexamined.

Cacalol was ozonized in acetic acid and treated successively with hydrogen peroxide and with palladium on charcoal. The major component of acidic products was shown to be 2-methylhexanedioic acid by PMR examination. Purification of the acid fraction using an ion-exchange resin column and then by recrystallization gave (*S*)-(+)-2-methylhexanedioic acid (**9a**),[23,24] mp 76.5—77.5 °C, $[\alpha]_D$ +12° (EtOH), whose IR ($CHCl_3$) and PMR ($CDCl_3$) spectra were found to be identical with those of authentic (±)-**9a** prepared from 2-methyl-1-cyclohexanone. This led to a (5*S*)-configuration for cacalol and for its related sesquiterpenes in accordance with the biogenetic considerations (Scheme 1).

Experimental

Melting points were determined on a Mel-temp capillary melting point apparatus (Laboratory Devices) and are uncorrected. IR and UV spectra were measured on a Hitachi EPI-G2 spectrometer and a Hitachi EPS-3 spectrometer, respectively. Optical rotations were measured on a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer operating at 70 eV. PMR spectra were taken on a Hitachi R-20 spectrometer using TMS as internal standard. For column chromatography

Wakogel C-200 (Wako Pure Chem. Ind.) was used.

*Isolation of Cacalol (**1c-B**).* Cacalol was isolated from *Cacalia delphiniifolia* Sieb. et Zucc. according to the descriptions reported by Naya *et al.*[7] Crystallization from ether–hexane gave pure cacalol (**1c-B**), mp 92—93 °C (lit,[1] 92—94 °C), $[\alpha]_D^{24}$ +6° (*c* 1.0, $CHCl_3$) [lit,[1] +10° ($CHCl_3$)]. For an identification purpose, this natural product was acetylated (acetic anhydride, pyridine, at room temperature) to give cacalol acetate, mp 104—105 °C (lit,[1] 103—104 °C; lit,[7] 103.5—104.5 °C), $[\alpha]_D^{20}$ −10° (*c* 1.0, $CHCl_3$) [lit,[1] −9° ($CHCl_3$); lit,[7] −96.5° ($CHCl_3$)[25]]. Spectral data (IR, UV, and PMR) of cacalol and of its acetate were identical with the reported values.[1]

*Ozonolysis of Cacalol (**1c-B**).* Oxygen containing ozone (*ca.* 3%) was passed through the solution of cacalol (500 mg) in acetic acid (20 ml) at room temperature for 12 h. To this solution was added 30% hydrogen peroxide (2.5 ml), and the mixture was stirred at room temperature for 2 h and then at 60 °C for 2.5 h. After addition of water (10 ml) and 10% palladium–charcoal (100 mg), the reaction mixture was stirred at room temperature for 17 h to complete decomposition of the peracid. The catalyst was filtered off and the solution was evaporated to give an oil, which was dissolved in ether, washed with saturated aqueous sodium chloride solution, and extracted with 5% sodium hydrogencarbonate. The aqueous layer was acidified (pH 1) with concentrated hydrochloric acid and extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and evaporated to give an oil (174 mg). This oil was shown to consist mainly of 2-methylhexanedioic acid by PMR ($CDCl_3$) examination [δ 1.21 (3H, d, J=7 Hz), 1.70 (4H, m), 2.42 (3H, m), and 9.41 (2H, br s)]. The oil was dissolved in water (2 ml), neutralized with 1 M sodium hydroxide, and chromatographed on an Amberlite IR-120 cation exchange resin column (50 g; elution with water). Several fractions gave crystals [$[\alpha]_D^{20}$ +18° (*c* 0.5, EtOH)] on removal of water. These were combined and recrystallized from ether–hexane to afford (*S*)-(+)-2-methylhexanedioic acid (**9a**), mp 76.5—77.5 °C (lit,[23] 81—83 °C; lit,[24] 81—82 °C), $[\alpha]_D^{25}$ +12° (*c* 0.2, EtOH) [lit,[23] +13.8° (*c* 1.91, EtOH); lit,[24] −13.4° (*c* 2.15, EtOH)]; IR ($CHCl_3$) 3100, 2940, 2890, and 1700 cm^{-1}; PMR ($CDCl_3$) δ 1.20 (3H, d, J=7 Hz), 1.68 (4H, m), 2.36 (3H, m), and 8.9 (2H, br s) [lit,[24] PMR ($CDCl_3$) δ 1.22 (3H, d, J=7 Hz), 1.67 (4H, m), 2.38 (3H, m), and 11.6 (2H, s)]. The IR and PMR spectra were identical with those [IR ($CHCl_3$) and PMR ($CDCl_3$)] of authentic (±)-2-methylhexanedioic acid, respectively.

The acid (**9a**) was treated with diazomethane in ether to give a dimethyl ester (**9b**), an oil, IR (neat) 2960, 1735, 1435, and 1165 cm^{-1}; PMR (CCl_4) δ 1.15 (3H, d, J=7 Hz), *ca.* 1.5 (4H, m), 2.23 (3H, m), and 3.62 (6H, s) [lit,[26] PMR (CCl_4) δ 1.13 (3H, d, J=7 Hz), 1.57 (4H, m), *ca.* 2.30 (1H, m), 2.25 (2H, m), and 3.62 (6H, s)]; mass spectrum *m/e* 157 [$(M-OCH_3)^+$], *m/e* 129 [$(M-CO_2CH_3)^+$], *m/e* 128, *m/e* 88, and *m/e* 74. The IR, PMR, and mass spectra were found to be identical with those [IR (neat), PMR (CCl_4), and mass spectra)] of authentic dimethyl (±)-2-methylhexanedioate, respectively.

(±)-2-Methylhexanedioic Acid from 2-Methyl-1-cyclohexanone. 2-Formyl-6-methyl-1-cyclohexanone was prepared from 2-methyl-1-cyclohexanone according to the procedures described by Dallacker *et al.*[27] The formylated ketone in acetone was oxidized with potassium permanganate in a usual manner to give (±)-2-methylhexanedioic acid [(±)-**9a**].[28] This acid was esterified with diazomethane in ether to afford dimethyl (±)-2-methylhexanedioate [(±)-**9b**].[26]

The authors wish to thank Mr. Masaya Sakata and Mr. Noboru Saito, University Forest at Chichibu, the University of Tokyo, for collecting *Cacalia delphiniifolia* Sieb. et Zucc.

The Reaction of *ortho*-Palladated Ferrocene Complexes with Olefins

Taeko IZUMI, Kazuyoshi ENDO, Osamu SAITO, Iwao SHIMIZU,
Mitsugi MAEMURA, and Akira KASAHARA
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa 992

(Received August 22, 1977)

Synopsis. *ortho*-Palladation products of (dimethylaminomethyl)ferrocene and 2-pyridylferrocene were treated with various olefins under mild conditions. A variety of unusual 1,2-disubstituted ferrocene derivatives were obtained from these reactions.

Following the first report that a palladium-carbon bond is formed directly upon the reaction of palladium(II) salt with azobenzene,[1] considerable interest developed in this area.[2] The *ortho*-palladation reaction is ideally suited for use in the synthesis of *ortho*-disubstituted compounds, since the metalated complexes can be made directly from monosubstituted aromatics. Previously, for example, the reactions of *ortho*-palladation products from numerous α-aryl nitrogen derivatives with carbon monoxide,[3,4] halogen,[5] alkyllithium or a Grignard reagent,[6] and olefins[7-9] have been reported. Furthermore, we ourselves have reported the reactions of an *ortho*-palladated complex of 2-pyridylferrocene with carbon monoxide, alkyllithium, and bromine.[10] In this report, we wish to report on the reactions of various olefins with *ortho*-palladated ferrocenyl derivatives: di-μ-chloro-bis[2-(dimethylaminomethyl)ferrocenyl]dipalladium(II) (**1**) and di-μ-chloro-bis[2-(2-pyridyl)ferrocenyl]dipalladium(II) (**2**).

Tsuji[7] has previously reported that the reaction of the *ortho*-palladated *N,N*-dimethylbenzylamine complex with styrene in acetic acid led to the formation of the arylated styrene derivative. Holton[9] has also reported the reaction of *ortho*-palladated benzylamine-type complexes with enones in the presence of triethylamine. The attempted reaction of olefin with **1** in acetic acid was unsuccessful even at 100 °C. On the other hand, in the presence of triethylamine, the **1** complex reacted with simple olefins, such as styrene, ethyl acrylate, methyl methacrylate, acrylonitrile, methyl vinyl ketone, and phenyl vinyl ketone, in toluene at 100 °C, leading to the formation of 1-dimethylaminomethyl-2-alkenyl ferrocene (**3**—**8**) in moderate yields. Compounds **3**—**8** exhibited absorptions near 1100, 1000, and 910 cm^{-1} characteristic of homoannularly 1,2-disubstituted ferrocene derivatives.[11] Moreover, the NMR and mass spectra of Compounds **3**—**8** were all consistent with the proposed structures. Complex **2**, similarly, reacted with olefins, such as methyl vinyl ketone and phenyl vinyl ketone, to afford the substitution products (**9** and **10**). The order of the reactivity of the complexes with olefin is **1**>**2**. The reactions carried out are summarized in Table 1, while the properties of the products are given in Table 2.

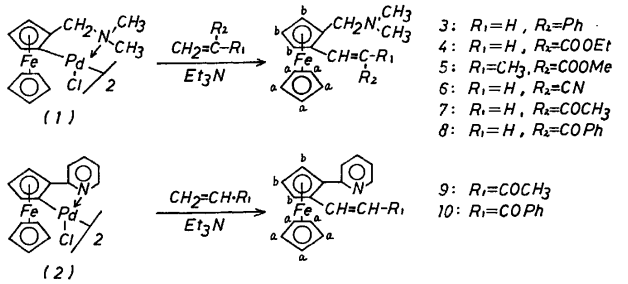

Fig. 1.

Experimental

Materials. The following compounds were synthesized by the methods described in the literature: di-μ-chloro-bis-[2-(dimethylaminomethyl)ferrocenyl]dipalladium(II) (**1**)[12] and di-μ-chloro-bis[2-(2-pyridyl)ferrocenyl]dipalladium(II) (**2**).[10]

General Procedure for the Reaction of a Complex with Olefins. A mixture of 2 mmol of a complex (**1** or **2**), 5 mmol of olefin, and 0.29 g (5 mmol) of triethylamine in toluene (40 ml) was heated at 100 °C under a nitrogen atmosphere. The reaction mixture was then cooled and filtered to remove the precipitated palladium, 100 ml of toluene was added, and the mixture was washed with water, dried over anhydrous magnesium sulfate, filtered, and concentrated under reduced pressure. The residue was then purified by column chromatography (Al_2O_3–benzene or chloroform). The structure of the products

TABLE 1. REACTIONS OF *ortho*-PALLADATED FERROCENYL COMPLEXES WITH OLEFINS

Complex	olefin	Reaction time (h)	Product	Yield[a]
1	Styrene	5	1-Dimethylaminomethyl-2-styrylferrocene (**3**)	33
1	Ethyl acrylate	5	1-Dimethylaminomethyl-2-(2-ethoxycarbonylvinyl)ferrocene (**4**)	55
1	Methyl methacrylate	5	1-Dimethylaminomethyl-2-(2-methoxycarbonyl-2-methylvinyl)-ferrocene (**5**)	28
1	Acrylonitrile	5	1-(2-Cyanovinyl)-2-(dimethylaminomethyl)ferrocene (**6**)	30
1	Methyl vinyl ketone	5	1-(2-Acetylvinyl)-2-(dimethylaminomethyl)ferrocene (**7**)	27
1	Phenyl vinyl ketone	5	1-(2-Benzoylvinyl)-2-(dimethylaminomethyl)ferrocene (**8**)	59
2	Methyl vinyl ketone	19	1-(2-Acetylvinyl)-2-(2-pyridyl)ferrocene (**9**)	8
2	Phenyl vinyl ketone	12	1-(2-Benzoylvinyl)-2-(2-pyridyl)ferrocene (**10**)	20

a) The yields are based upon Complex **1** or **2**.

IR: 1655 (C=O); 1630, 960 (*trans* -CH=CH-); 1100, 1000, 910 (1,2-disubstituted ferrocene); 1600, 1500, 745, 690 cm^{-1} (phenyl). NMR: δ 4.02 (s, 5H, H_a), 4.68 (m, 3H, H_b), 6.98 (d, J=12 Hz, 1H, -C=CH-CO-), 7.18—8.13 ppm (m, 10H, Fc-CH=C-+phenyl and pyridyl protons).

a) The IR and mass spectra were measured using a Hitachi 215 spectrophotometer and a Model RMU-6M mass spectrometer at 70 eV. The NMR spectra were observed in $CDCl_3$ on a Hitachi Model R-22 (90 MHz), using TMS as the internal standard (δ, ppm). The chemical shifts were followed by means of the splitting pattern (s, singlet; d, doublet; d-d, double doublet; t, triplet; q, quartet; m, multiplet) and the relative strengths.

was confirmed by an elemental analysis and by the observation of the IR, NMR, and mass spectra. The results are summarized in Tables 1 and 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 51 (2), 665—666 (1978)

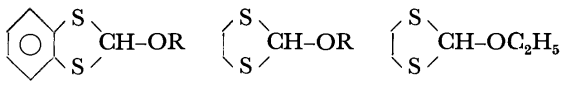
A Convenient Method for the Introduction of 1,3-Dithiolan-2-yl Group into Active Methylene Compounds

Shigeo TANIMOTO, Yasuo MATSUMURA, Toyonari SUGIMOTO, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received August 22, 1977)

Synopsis. The reaction of 2-ethoxy-1,3-dithiolane with a variety of active methylene compounds in the presence of a zinc chloride catalyst was investigated. By this reaction the introduction of a 1,3-dithiolan-2-yl group into the active methylene compounds was achieved. Some behavior of the 1,3-dithiolan-2-yl derivative of ethyl acetoacetate, which is one of the newly obtained compounds, was also briefly examined.

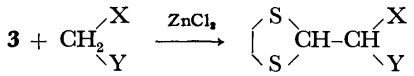
Recently, 2-alkoxy-1,3-benzodithioles (**1**) have become readily available by means of the action of benzyne on carbon disulfide in the presence of alcohols,[1] and their behavior toward carbon nucleophiles has been studied.[2,3]



1 **2** **3**

In contrast, no description of the chemistry of 2-alkoxy-1,3-dithiolanes (**2**), the corresponding saturated system of **1**, is to be found in the literature, except for our own earlier report,[4] which involves the synthesis of 2-ethoxy-1,3-dithiolane (**3**) and its reaction with *n*-BuLi.

We wish now to report the reaction of **3** with a variety of active methylene compounds (**4**), by which the introduction of a 1,3-dithiolan-2-yl group into **4** was conveniently achieved.

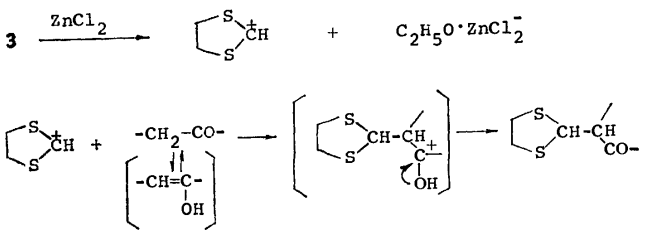


4 **5**

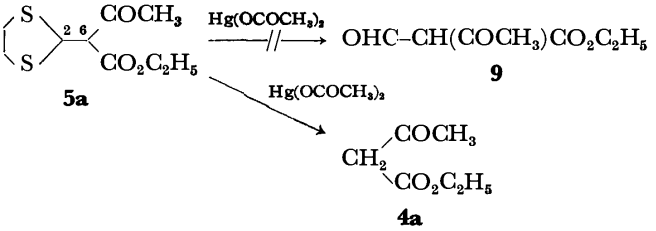
a: X=$COCH_3$, Y=$CO_2C_2H_5$
b: X=$COCH_3$, Y=CO_2CH_3
c: X=Y=$CO_2C_2H_5$
d: X=Y=CO_2CH_3
e: X=Y=$COCH_3$
f: X=CN, Y=$CO_2C_2H_5$
g: X=COC_6H_5, Y=$CO_2C_2H_5$

The reaction of **4** with **3** proceeded smoothly without a solvent under the catalytic action of a metal halide such as zinc chloride or iron(III) chloride, and 1,3-dithiolan-2-yl derivatives of **4** (**5**) could be isolated in quite good yields (Table 1).

The reaction may involve the initial loss of the exocyclic ethoxyl group of **3** to give the 1,3-dithiolan-2-ium ion and its subsequent attack on the active methylene compound.

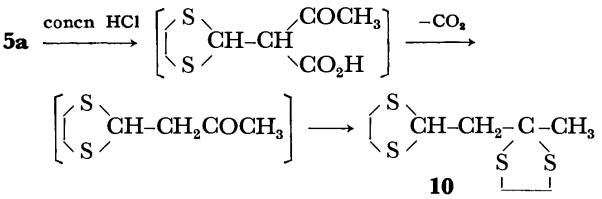


In order to investigate the possibility of the synthesis of a novel class of compound (**9**) with three different carbonyl groups at the same carbon atom, we examined the reaction of **5a** with mercury(II) acetate[6] under conditions similar to those employed for the cleavage of cyclic ethylene thioacetals.[7] However, the product thus obtained was ethyl acetoacetate, and no trace of **9** was isolated. This means that the reaction proceeded only with an exclusive bond fission between 2-C and 6-C.



5a **9** **4a**

On the other hand, the hydrolysis of **5a** with a large excess of boiling conc. HCl for 5—6 h gave a bis(1,3-dithiolan-2-yl) derivative, acetoacetaldehyde bis(ethylene thioacetal) (**10**), in a 48% yield[mp 31—33 °C (hexane) (lit,[8] 30—32 °C)], but formylacetone or its derivative, which seems to be simultaneously obtainable, could not be detected.



10

Experimental

Reaction of 2-Ethoxy-1,3-dithiolane (3) with Active Methylene Compounds (4). General Procedure: A mixture of 33 mmol of **3**, 39—40 mmol of an active methylene compound, and *ca.* 15 mmol of a catalyst was stirred at room temperature for 24 h, with the exclusion of any moisture, and then poured into a large quantity of an aqueous sodium carbonate solution. The organic layer was separated, combined with an ethereal extract of the aqueous phase, and dried ($MgSO_4$), and the ether was removed. The oily residue was distilled *in vacuo* to afford the desired product. The product can be purified further by column chromatography if necessary. Only in the case of the reaction with ethyl benzoylacetate, the removal of ether and the excess ethyl benzoylacetate leave a solid residue, which was purified by recrystallization from ethanol.

Reaction of 1,3-Dithiolan-2-yl Derivative of Ethyl Acetoacetate (5a) with Mercury(II) Acetate. To a solution of 5 g (21 mmol) of **5a** in 200 ml of acetone, we added 50 ml of water,

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 51 (2), 667—668 (1978)

Studies on Heterocyclic Analogs of Azulenes. III.[1] The Reactions of 2-Chloro-3-ethoxycarbonylcyclohepta[*b*]pyrrole with the Carbanions Derived from Active Methylene Compounds

Noritaka ABE and Tarozaemon NISHIWAKI*

Department of Chemistry, Yamaguchi University, Yamaguchi 753

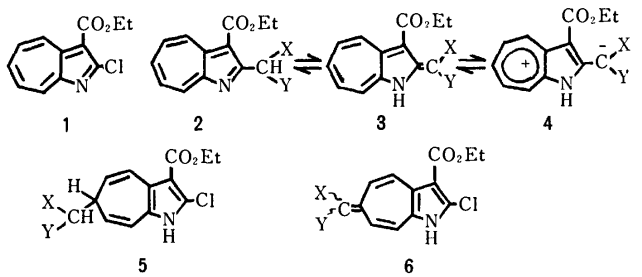
(Received September 1, 1977)

Synopsis. 2-Chloro-3-ethoxycarbonylcyclohepta[*b*]-pyrrole reacts with the carbanions derived from active methylene compounds to give substitution products and/or addition products depending on the reaction conditions.

2-Chloro-3-ethoxycarbonylcyclohepta[*b*]pyrrole (**1**) was reported by Matsumura to be substituted at C-2 with malononitrile in hot dioxane.[2] As our findings that **1** affords an addition product at C-8 when treated with Grignard reagents[3] led us to suspect the claim of Matsumura, we repeated his reaction. In our hands the reaction was more complicated than reported,[2] giving a number of products depending on the reaction conditions.

Treatment of **1** with malononitrile in boiling dioxane in the presence of sodium hydride produced two compounds in the ratio of 19: 1. The major one was the Matsumura's compound (**3a**), which is present as the methide form as confirmed by spectral methods, and the minor one was 1,6-dihydro-2-chloro-6-(dicyanomethylene)-3-(ethoxycarbonyl)cyclohepta[*b*]pyrrole(**6a**), a product formed by addition at C-6 of **1** followed by dehydrogenation. Reaction of **1** with ethyl cyanoacetate under the similar conditions afforded the corresponding **3b** and **6b** is the ratio of 4: 1. Although the reaction of **1** with phenylacetonitrile proceeded to give a substitution product and the compound (**6c**) in the ratio of 35: 1, the former takes the structure of 3-ethoxycarbonyl-2-(α-cyanobenzyl)cyclohepta[*b*]pyrrole (**2c**) in solid and in solution as shown by IR and NMR spectra. Predominant shift of the tautomeric equilibrium in favor of the 2-methylene forms (**3a**) and (**3b**), though unusual,[4] must be due to the high stability of the formal negative charge in **4**.

However, the product ratio changed dramatically when the reaction of **1** with ethyl cyanoacetate or phenylacetonitrile was undertaken at room temperature. For instance, the reaction with phenylacetonitrile yielded 1,6-dihydro-2-chloro-3-ethoxycarbonyl-6-(α-cyanobenzyl)cyclohepta[*b*]pyrrole (**5c**) (65%) and **6c** (2%) without giving a trace of **2c**. The structure of **5c** was proved by the presence of a 1H quartet at δ 2.63 and a 1H doublet at δ 4.05 in its NMR spectrum. **5** was unstable, changing into **6** on storage in air.



a: X=Y=CN; b: X=CN, Y=CO_2Et; c: X=CN, Y=Ph

Formation of the addition product **5** or its dehydrogenation product **6** was also observed when the reaction was carried out in ethanol in the presence of sodium ethoxide at room temperature or under reflux. These results are collected in Table 1. Dependence of the formations of the substitution product and the addition product[5] (or its dehydrogenation product) of **1** upon the solvent polarity and the reaction temperature is interesting, but we were unable to advance a rationale for these observations.

Table 1. Ratio of the substitution and addition products of **1**

Reagent	Conditions		Ratio (%)	
	Solvent	Temperature (°C)	Substitution (**2** or **3**)	Addition (**5**+**6**)
$CH_2(CN)_2$	Dioxane	25	70	30
$CH_2(CN)_2$	Dioxane	101	95	5
$CH_2(CN)_2$	EtOH	78	11	89

$PhCH_2CN$	EtOH	78	1	99

Experimental

Melting points were uncorrected. NMR spectra were recorded in $CDCl_3$ unless otherwise stated with a Varian HA-100 spectrometer at 100 MHz and the assignments were confirmed by decoupling techniques where necessary. IR spectra were obtained as Nujol mulls, and UV spectra were measured for chloroform solutions unless otherwise stated. Chromatography was performed on Kiesel gel 60 with chloroform. Yields are based on unrecovered starting materials.

*Reaction of **1** with Malononitrile.* (a) Malononitrile (2.00 g) was added into dry dioxane (100 ml) in which sodium hydride (66% in mineral oil) (0.70 g) was suspended. A solution of **1** (1.00 g) in dry dioxane (50 ml) was added into this mixture, stirred at room temperature for 2 days, acidified with acetic acid, and extracted with chloroform. The dried (Na_2SO_4) extracts were evaporated and the residue was chromatographed to give the starting material (0.771 g), **3a** (0.083 g, 30%), and **6a** (0.036 g, 17%), successively. **3a**: Red prisms

A solution of **1** (1.00 g) in abs ethanol (40 ml) was added into this mixture, heated under reflux for 1 h, and worked up as above to give **5a** (0.037 g, 4%), the starting material (0.306 g), **3a** (0.060 g, 7%), and **6a** (0.461 g, 52%), successively. **5a**: Needles (from cyclohexane), mp 118—120 °C, NMR δ=1.40 (3H, t, J=7 Hz), 2.46 (1H, q, J=7 Hz), 4.30 (1H, d, J=7 Hz), 4.35 (2H, q, J=7 Hz), 5.2—5.6 (2H, m), 6.40 (1H, d, J=9.5 Hz), 7.01 (1H, d, J=9.5 Hz), 8.92 (1H, bs); IR 3200 (NH), 2200 (C≡N), 1670 cm^{-1} (C=O). **5a** was unstable, changing into **6a** in 27% yield on storage for 5 days.

Reaction of 1 with Ethyl Cyanoacetate. (a) A solution of **1** (1.00 g) in dry dioxane (40 ml) was added into a mixture of ethyl cyanoacetate (1.00 g), sodium hydride (0.70 g), and dry dioxane (40 ml), stirred at room temperature for 1 day, and worked up as above to give **5b** (0.210 g, 16%), the starting material (0.133 g), **3b** (0.206 g, 18%), and **6b** (0.576 g, 52%), successively. **5b**: Needles (from cyclohexane), mp 130—132 °C, NMR δ=1.37 (3H, t, J=7 Hz), 1.39 (3H, t, J=7 Hz), 2.39 (1H, t, J=6.5 Hz), 3.05 (1H, d, J=6.5 Hz), 4.32 (2H, q, J=7 Hz), 4.34 (2H, q, J=7 Hz), 5.4—5.6 (2H, m), 6.39 (1H, d, J=10 Hz), 7.00 (1H, d, J=10 Hz), 8.85 (1H, bs); IR 3200 (NH), 2200 (C≡N), 1675 (C=O), 1663 cm^{-1} (C=O). **3b**: Red needles (from benzene), mp 163—165 °C (lit,[2] mp 163—165 °C), NMR δ=1.37 (3H, t, J=7 Hz), 1.46 (3H, t, J=7 Hz), 4.31 (2H, q, J=7 Hz), 4.51 (2H, q, J=7 Hz), 7.3—7.7 (4H, m), 8.53 (1H, bd, J=10.5 Hz); UV_{max} 259 nm (log ε 4.39), 292 (4.42), 341 (3.98), 500 (4.18). **6b**: Orange plates (from benzene), mp 255—256 °C (dec), NMR (DMSO-d_6) δ=1.27 (6H, t, J=7 Hz), 1.35 (6H, t, J=7 Hz), 4.15 (4H, q, J=7 Hz), 4.27 (4H, q, J=7 Hz), 7.14 (1H, dd, J=12 and 2 Hz), 7.21 (2H, d, J=12.5 Hz), 7.36 (1H, d, J=12 Hz), 7.94 (1H, d, J=12.5 Hz), 8.04 (1H, d, J=12.5 Hz), 8.48 (1H, dd, J=12.5 and 1.5 Hz), 8.56 (1H, d, J=12.5 and 2 Hz);[6,7] UV_{max} 258 nm (log ε 4.42), 281 (4.17), 444 (4.56); IR 3150 (NH), 2200 (C≡N), 1695 (C=O), 1650 cm^{-1} (C=O). Found: C, 58.69; H, 4.29; Cl, 10.38; N, 7.96%. Calcd for $C_{17}H_{15}ClN_2O_4$: C, 58.85; H, 4.32; Cl, 10.23; N, 8.07%. **5b** changed into **6b** in 45% yield on storage for 4 days. (b) The above reaction was carried out under reflux for 1 h to give the starting material (0.028 g), **3b** (1.005 g, 78%), and **6b** (0.228 g, 16%). (c) A solution of 1 (1.00 g) in abs ethanol (40 ml) was added into a mixture of the ester (1.00 g), sodium (0.40 g), and abs ethanol (60 ml) and stirred at room temperature for 1 days. Works-up gave **5b** (0.096 g, 11%), the starting material (0.347 g), **3b** (0.198 g, 24%), and **6b** (0.516 g, 56%).

Reaction of 1 with Phenylacetonitrile. (a) A solution of **1** (2.00 g) in dry dioxane (80 ml) was added into a mixture of phenylacetonitrile (2.00 g), sodium hydride (1.40 g), and dry dioxane (120 ml), stirred at room temperature for 1 day, and worked up as above to give **5c** (1.950 g, 65%) and **6c** (0.054 g, 2%), successively. **5c**: Needles (from methanol), mp 184—185 °C, NMR δ=1.40 (3H, t, J=7 Hz), 2.63 (1H, bq, J=9 Hz), 4.05 (1H, d, J=9 Hz), 4.35 (2H, q, J=7 Hz), 5.1—5.6 (2H, m), 6.42 (1H, d, J=9.5 Hz), 7.19 (1H, d, J=9.5 Hz), 7.32 (5H, s), 8.68 (1H, bs); UV_{max} 280 nm (log ε 3.89); IR: 3200 (NH), 2240 (C≡N), 1657 cm^{-1} (C=O). Found: C, 68.24; H, 4.92; Cl, 10.31; N, 7.79%. Calcd for $C_{20}H_{17}ClN_2O_2$: C, 68.07; H, 4.85; Cl, 10.05; N, 7.94%. **6c**: Yellow prisms (from benzene), mp 249.5—250 °C, NMR δ=1.50 (3H, t, J=7 Hz), 4.50 (2H, q, J=7 Hz), 7.4—7.9 (5H, m), 8.22 (2H, d, J=11 Hz), 8.73 (1H, d, J=11 Hz), 9.60 (1H, d, J=11 Hz);[6] UV_{max} 257 nm (log ε 4.46), 290 (4.25), 400 (4.45); IR 3190 (NH), 2200 (C≡N), 1707 cm^{-1} (C=O). Found: C, 68.14; H, 4.52; Cl, 10.21; N, 7.68%. Calcd for $C_{20}H_{15}ClN_2O_2$: C, 68.45; H, 4.31; Cl, 10.10; N, 7.98%. When a solution of **5c** in benzene was set aside for 4 days, **6c** was obtained in 24% yield. (b) The above reaction (**1** (1.00 g), dioxane (50 ml), the nitrile (0.50 g), and NaH (0.154 g) in dioxane (50 ml)) was carried out under reflux for 1 h to give the starting material (0.240 g), **2c** (0.882 g, 87%), and **6c** (0.025 g, 3%). **2c**: Yellow prisms (from benzene), mp 165—166 °C, NMR δ=1.43 (3H, t, J=7 Hz), 4.43 (2H, q, J=7 Hz), 6.57 (1H, s), 7.2—7.7 (5H, m), 7.8—8.2 (3H, m), 8.87 (1H, bd, J=9 Hz), 9.95 (1H, bd, J=9 Hz); UV_{max} 287 nm (log ε 4.59), 324 (3.90), 345 (3.58), 462 (2.97); IR 2250 (C≡N), 1675 cm^{-1} (C=O). Found: C, 75.63; H, 5.22; N, 8.58%. Calcd for $C_{20}H_{16}N_2O_2$: C, 75.93; H, 5.10; N, 8.86%. (c) A solution of **1** (1.00 g) in abs ethanol (30 ml) was added into a mixture of the nitrile (1.00 g), sodium (0.20 g), and abs ethanol (70 ml), heated under reflux for 1 h, and worked up to give **2c** (0.008 g, 1%), **5c** (1.05 g, 70%), and **6c** (0.025 g, 2%), successively.

We thank Dr. T. Morita, Tohoku University, for NMR spectral determinations.

Oxyhydrative Scission of *trans*-2-Butene in the Liquid Phase under Pressure

Yusaku TAKITA, Takashi MAEHARA, Noboru YAMAZOE, and Tetsuro SEIYAMA

Department of Materials Science and Technology, Faculty of Engineering, Kyushu University 36, Hakozaki, Higashi-ku, Fukuoka 812

(Received June 25, 1977)

Synopsis. The liquid phase oxidation of *trans*-2-butene under pressure using a V_2O_5–MoO_3 catalyst suspended in water has been proved to yield acetic acid and aldehyde selectively at 170 °C. Taking into account the results of the oxidation of intermediate compounds, it is suggested that the reaction follows the same oxyhydrative scission mechanism as has been proposed for the gas phase oxidation.

The authors have reported the partial oxidation of lower olefins over V_2O_5–MoO_3 catalyst in the presence of water vapor at 160—290 °C.[1,2] The reaction is unique in that the carbon skeletons are oxidatively cleaved into smaller aldehydes and/or carboxylic acids. The following "Oxyhydrative Scission" mechanism has been proposed.[3]

$$\mathrm{R\text{-}CH{=}CH\text{-}R' \xrightarrow{H^+} R\text{-}\overset{+}{C}H_2\text{-}CH\text{-}R' \xrightarrow[\text{or } OH^-]{H_2O}}$$

$$\mathrm{R\text{-}CH_2\text{-}\underset{\displaystyle OH}{\underset{|}{CH}}\text{-}R' \xrightarrow{[O]} R\text{-}CH_2\text{-}\underset{\displaystyle O}{\overset{\|}{C}}\text{-}R' \xrightarrow{[O]}}$$

$$\mathrm{RCHO + R'COOH} \qquad (1)$$

In the oxidation of higher olefins, however, desorption of acidic products from the catalyst surface requires higher reaction temperatures, which are less favorable for the hydration process involved in Eq. 1. Too great a rise in temperature is also undesirable for the selectivity of the reaction. This dilemma may be solved if the same reaction can be carried out effectively in the liquid phase. Therefore, oxidation of *trans*-2-butene and the proposed intermediate products has been examined in various solvents by using a V_2O_5–MoO_3 catalyst suspension.

Experimental

The V_2O_5–MoO_3 (V/Mo=9/1) catalyst was prepared from aqueous solutions of ammonium methavanadate and ammonium paramolybdate. The powder obtained was calcined at 550 °C for 5 h in air, and sieved to 30—40 mesh.

The liquid phase oxidation under atmospheric pressure was examined in a closed gas-liquid reactor equipped with a gas burette. The catalyst (2 g) was suspended in water or other solvents (30 cm^3) in the reactor. After degassing the reactor briefly, a gaseous reactant (*trans*-2-butene) was introduced as a mixture with oxygen, while the liquid reactants (10—50 mmol) were injected into the reactor through a sampling port. Oxidation under pressure was carried out in a SUS autoclave with an internal volume of 300 cm^3. After introduction of 3 g of catalyst and 60 g of water, *trans*-2-butene (38.57 mmol) and oxygen were introduced to a total pressure of 20 kg/cm^2 at 0 °C. After the reaction, the liquid and gas phases were separately subjected to gas chromatographic analyses.

Results and Discussion

In the gas phase oxidation, butenes are oxidized to acetic acid and acetaldehyde *via* *s*-butyl alcohol (*s*-BuOH) and ethyl methyl ketone (EMK).

1) Liquid Phase Oxidation under Ordinary Pressure. Gaseous mixtures of *trans*-2-butene and oxygen with the butene/O_2 ratios of 1/9 and 9/1 were brought into contact with the V_2O_5–MoO_3 catalyst suspended in water at 50, 70, and 90 °C, but no oxidation products could be detected. This appears to be due to insufficient reaction conditions. For the oxidation of *trans*-2-butene, solvents other than water were not examined, because the first step of the reaction (Eq. 1) necessitates the presence of water.

The liquid phase oxidation of *s*-BuOH was examined in various solvents. As a result, while no reaction occurred in water, benzene, or chlorobenzene, EMK was selectively obtained in dimethyl sulfoxide (DMSO). For example, the oxidation in DMSO at 125 °C for 13 h converted 10.8% of *s*-BuOH and the selectivity to EMK was 89%. No reaction of *s*-BuOH took place in DMSO without catalyst. In contrast to the gas phase oxidation of *s*-BuOH over the same catalyst, where considerable amounts of butenes are co-produced, no butenes were detected. The role of DMSO is not clear.

Liquid EMK could be oxidized at a considerable

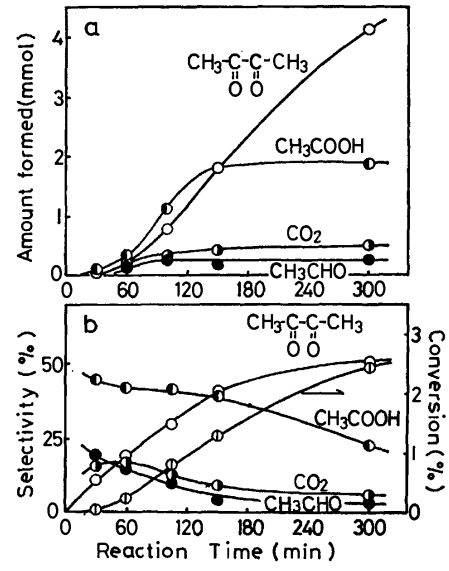

Fig. 1. Liquid phase oxidation of ethyl methyl ketone (EMK). Catalyst: V_2O_5–MoO_3 (V/Mo=9/1) 2 g, EMK: 335.4 mmol, 55 °C, 1 atm.

rate even at 55 °C without the addition of any other solvents (Fig. 1). Acetic acid, acetaldehyde, and CO_2 were formed only in the earlier periods up to 150 min, while the formation of biacetyl continued over the whole reaction period. It is known that the autoxidation of ketone in a homogeneous liquid phase proceeds *via* a hydroperoxide intermediate which is formed by the abstraction of a hydrogen atom at the α-position, followed by the addition of an oxygen molecule there.[4-6] The hydroperoxide intermediate then decomposes in the following two ways.[7]

$$\mathrm{R\text{-}CH(OOH)\text{-}C(=O)\text{-}R'} \longrightarrow \mathrm{R\text{-}C(=O)\text{-}C(=O)\text{-}R' + H_2O} \quad (2)$$

$$\mathrm{R\text{-}CH(OOH)\text{-}C(=O)\text{-}R'} \longrightarrow \mathrm{RCHO + R'COOH} \quad (3)$$

This mechanism can account for the main products in the present reaction. However, the time course of the reaction does not seem to be fully consistent with this mechanism. It is known that the latter reaction (Eq. 3) is accelerated in the presence of carboxylic acids owing to the intervention of a carbonium ion mechanism, and the formation of acetic acid should then increase with time in an autocatalytic manner, provided that a hydroperoxide is a substantial intermediate. This is not the case in the present reaction, suggesting an intermediate other than a hydroperoxide. A surface complex between molecular oxygen adsorbed on the catalyst and EMK might be suggested as the intermediate by analogy with the gas phase oxidation.

2) Liquid Phase Oxidation of trans-*2-Butene under Pressure.* As described above, neither the hydration of *trans*-2-butene nor the oxidative dehydrogenation of *s*-BuOH could be attained in the liquid phase under atmospheric pressure below 90 °C. Accordingly, the liquid phase oxidation of *trans*-2-butene was examined at temperatures above 100 °C under pressure.

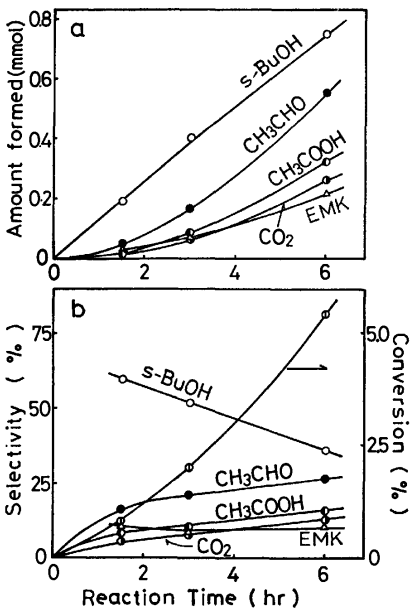

Fig. 2. Oxidation of *trans*-2-butene.
Catalyst; V_2O_5–MoO_3 (V/Mo=9/1) 3.0 g *trans*-2-butene 38.57 mmol, H_2O 60 cm³, O_2 20 kg/cm², 170 °C, total pressure 36 kg/cm².

Figure 2 shows the results of the oxidation at 170 °C under pressure of 36 kg/cm². *s*-BuOH, EMK, acetaldehyde, acetic acid, and CO_2 were obtained, together with small amounts of propionic and butyric acids.

In the homogeneous oxidation of paraffins in nonaqueous solvents in the presence of soluble metal naphthenate catalysts, it has been reported that the formation of hydroperoxides (HPO) and their decomposition to alcohols, ketones, and acids proceed *via* the Haber-Weiss mechanism.[8] In the autoxidation of lower olefins, however, it is known that the product distributions are different. Imamura *et al.*[9] have investigated the oxidation of butenes in benzene at 145 and 175 °C under a pressure of 45 atm with a homogeneous catalyst of manganese naphthenate, and obtained butene oxides (19—26% selectivity), butanediol esters (≈15.8%), and a residue with higher boiling points (41—48%), together with small amounts of aldehydes, ketones, and carboxylic acids.

In the present heterogeneous reaction, the product distribution was similar to that in the catalytic oxidation of butenes in the gas phase, and did not include products characteristic of autoxidation, such as epoxides and glycol esters. While the yields of all the products increased with time, the selectivity to *s*-BuOH was relatively high in the initial stage. This fact suggests that *s*-BuOH is a primary product from the starting olefin, as in the gas phase catalytic oxidation. The *s*-BuOH formed is likely to be oxidized to EMK and then to acetaldehyde and acetic acid, as in the gas phase oxidation. It seems reasonable to assume that these oxidation processes also take place on the catalyst surface, though further experiments are needed to verify this assumption. We consider that the mechanism of the liquid phase oxidation of *trans*-2-butene over the suspended V_2O_5–MoO_3 catalyst would be similar to that of the gas phase oxidation over the same catalyst.

A Study of Ion-Solvent Interaction of Tetraalkylammonium and Common Alkali Metal Ions in Ethylene Carbonate from Electrolytic Conductance Data

Ram GOPAL and Sudha SINGH

Chemistry Department, Lucknow University, Lucknow, U. P., India

(Received May 6, 1977)

Synopsis. Ion-solvent interaction in solutions of some tetraalkylammonium and common alkali metal iodides in ethylene carbonate, from the point of view, of electrical conductance and the derived Walden product, has been examined in this communication. The Debye-Hückel-Onsager equation appears to hold good for all the salts in the temperature and concentration range studied here. Dependence of the Walden product on temperature and radius of cation reveals that the R_4N^+ ions do not interact appreciably with the solvent but Li^+, Na^+, K^+, and Rb^+ ions appear to be solvated.

Ion-solvent interaction studies in some highly polar and non-hydrogen bonded solvents, having medium dielectric constant, namely, dimethylsulfoxide (DMSO)[1,2] and propylene carbonate (PC),[3,4] have been reported in earlier communications from this laboratory. It appears interesting to study the behavior of these salts in an aprotic, dipolar solvent of high dielectric constant like ethylene carbonate (EC) in order to have a wider picture of solute-solvent interaction. This solvent is, like DMSO and PC, highly polar and non-hydrogen bonded; its dielectric constant[5] is 85.81 at 40 °C. A few studies on conductance of electrolytes have been reported in this solvent,[6] but these are confined to 40 °C only and hence of little use in studying ion-solvent interaction. This situation and the interesting solvent properties of ethylene carbonate prompted the investigation reported in this communication.

Experimental

Ethylene carbonate (Fluka, purum) was fractionally crystallized three times. The sample thus obtained was distilled under reduced pressure. The middle fraction of the distillate was collected in a dark colored bottle and kept in a dry box. The sample was found to melt sharply at 36.5 °C and its electrical conductance was of the order of 10^{-6} Ω^{-1} cm^{-1}.

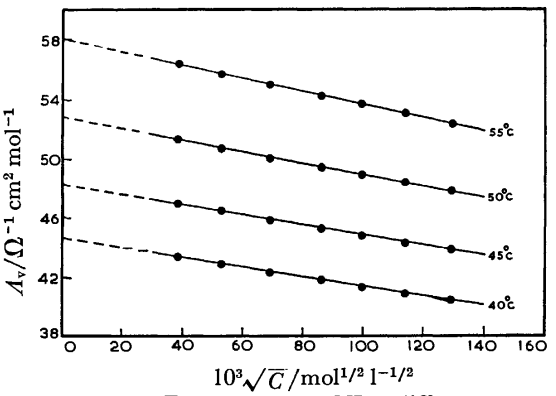

Fig. 1. Λ_v *vs.* $\sqrt{C}$ curves for Me_4NI at different temperatures in ethylene carbonate.

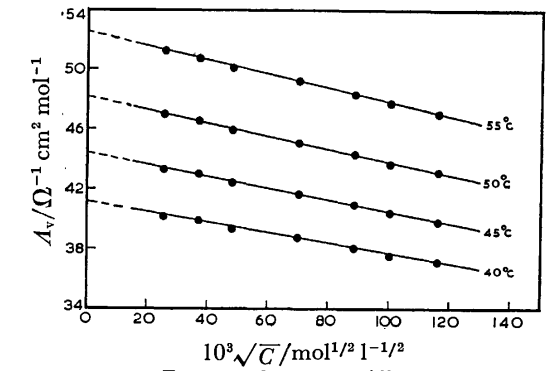

Fig. 2. Λ_v *vs.* $\sqrt{C}$ curves for KI at different temperatures in ethylene carbonate.

Tetraalkylammonium iodides (DPI, USA) and the common salts (BDH, AR) were purified in the usual manner.[7] The experimental procedure for measuring the electrical conductance was the same as described earlier. The precision of measurement was about ±0.03%.

Results and Discussion

From the electrolytic conductance data thus obtained, Λ_v *vs.* $\sqrt{C}$ curves were drawn for different salts at various temperatures. The plots for Me_4NI and KI are given in Figs. 1 and 2, as typicals of tetraalkylammonium and common salts respectively. It may be noted that the plots are almost straight lines suggesting that the simple Debye-Hückel-Onsager theory of electrolytic conductance is applicable to these solutions and the salts are completely ionized in ethylene carbonate. The limiting equivalent conductivities of different salts at various temperatures, obtained from the usual extrapolation procedure, are given in Table 1.

The theoretical slope S_T of the Λ_v *vs.* $\sqrt{C}$ curves, according to Debye-Hückel theory is given by

$$S_T = A + B\Lambda_0,$$

where $A = \frac{82.42}{\eta_0(\varepsilon T)^{1/2}}$ and $B = \frac{8.203\times 10^5}{(\varepsilon T)^{3/2}}$.

From the Λ_0 values given in Table 1, S_T values for different cases at 40 °C have been calculated and compared with the corresponding experimental slopes S_E in Table 2. The value of the dielectric constant used for calculating the experimental slope is $\varepsilon_{40\,°C}=85.81$ and viscosity η/g m^{-1} s^{-1}=1.850, as determined experimentally in this laboratory. Table 2 clearly shows that there is a good agreement between the experimental and theoretical slopes indicating that the simple Debye-Hückel-Onsager theory of strong electrolytic conductivity is applicable to these solutions.

The nature of ion-solvent interaction in EC may be examined from the temperature and ionic radius dependence of the Walden product. Unfortunately, due to lack of the ionic conductance data, at different temperature, only the electrolytic Walden product can be used for the present study. It is assumed that the variations in the Walden product are mainly due to cations since large anions do not interact appreciably in aprotic solvents. Viscosities of the solvent at different temperatures, required to calculate the Walden product, were obtained experimentally and are η/g m^{-1} s^{-1}= 1.850 (40 °C), 1.722 (45 °C), 1.590 (50 °C) and 1.459 (55 °C). The values of the Walden product, $\Lambda_0\eta_0$, for different salts at various temperatures, are given in Table 3.

Although the temperature dependence of the Walden product, can be examined from the data given in Table 3, the plots of $\Lambda_0\eta_0$ against temperature, given in Fig. 3, make it more explicit. It may be noted that $\Lambda_0\eta_0$ for the smaller alkali metal iodides appears to increase slightly with the rise in temperature, indicating a net structure promoting effect of these salts in EC. As pointed out in the earlier paragraph, anions, more particularly the larger ones, are not expected to interact strongly with the aprotic solvents, it is reasonable to presume that the structure enhancement is due to the cation-solvent interaction. Besides, since the Walden product of the larger alkali metal and R_4N-iodides in which the cation may be expected to interact very weakly, if at all, with the solvent, is almost independent of temperature, I^- ion would also be more or less unsolvated. Thus increase in the Walden product with the rise of temperature for smaller alkali metal iodides must be ascribed to the cations which interact appreciably with the solvent molecules and are solvated. The large R_4N^+ ions do not appear to interact significantly, with EC.

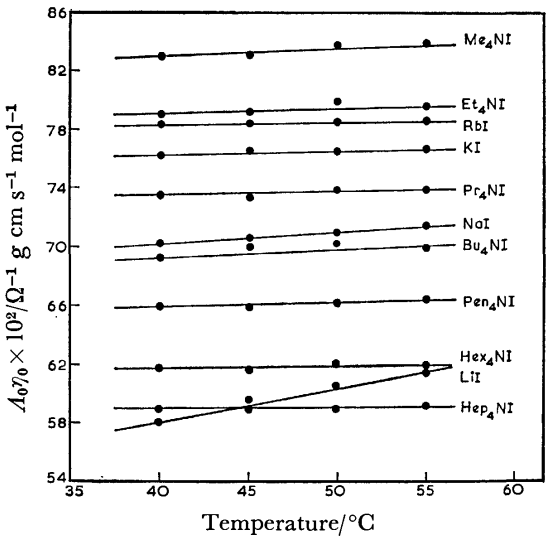

Fig. 3. Walden product $\Lambda_0\eta_0$ *vs.* temperature plots in ethylene carbonate for some electrolytes.

The same conclusions can be arrived at if the variation of the Walden product with the radius of the cation is examined. Since iodide ion is common to all the salts studied here, it may be assumed, as before, that the variation in the Walden product is due to cation only. It may be noted that for the alkali metal salts, the Walden product varies directly with the radius of the cation; this indicates that the size of the cation in solution is larger, the smaller its radius or in other words, the smaller the cation, the more highly solvated it is. Opposite appears to be the case with the R_4N^+ ions. for which the Walden product varies inversely as the radius showing that these ions are not solvated to any appreciable extent. Their size remains almost unchanged in solution and there is no appreciable electrostatic ion-solvent interaction with EC.

Authors are grateful to the Society of the Sigma Xi of USA for financial assistance and to the Head, Chemistry Department, Lucknow University, for research facilities for undertaking this investigation.

The Microenvironmental Effect of Cyclodextrin on the Acid Dissociation of Some Azo Dyes in Aqueous Solutions

Yoshihisa MATSUI and Kazuo MOCHIDA

Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue 690

(Received May 14, 1977)

The effects of α- and β-cyclodextrins (CD) on the acid dissociations and tautomeric equilibria of sodium 4-(4′-hydroxy-1′-naphthylazo)-1-naphthalenesulfonate (**1**) and of the conjugate acid (**2**) of Methyl Orange were spectrophotometrically examined and were compared with the effect of a nonpolar solvent (THF). The apparent pK_a values for the dyes decreased with increasing CD concentration. The effect of CD is mainly explained in terms of the hydrophobic interactions between the azo dyes and CD, resulting in a shift in the tautomeric equilibria from less acidic azonium or hydrazone forms to more acidic azo forms of **1** and **2** in an aqueous solution.

The acid dissociation of an indicator dye is generally facilitated by the formation of an inclusion complex between the dye and cyclodextrin (CD) in an aqueous solution.[1-6] This phenomenon is interesting in connection with the microenvironmental effect of an enzyme on the acid dissociation of ionizing groups at the bonding or catalytic site.[7,8] The decrease in pK_a of a dye upon formation of a CD complex has been tentatively attributed to the space alkalinity of CD[1,2] which involves a number of electronegative oxygen atoms in a molecule. On the other hand, Broser *et al.*[4-6] have explained the change in pK_a in terms of a dipole-ion interaction between CD and a dye as follows. A dissociated dye may be more polarizable than the corresponding undissociated dye, so that a dipolar CD molecule associates more tightly to the former than the latter, resulting in enhancement of the acid dissociation of the dye. These arguments, however, completely neglect the hydrophobic property of the cavity of a CD molecule, a property later recognized to play an important role in the binding and catalytic processes of CD.[3,9] In a protein-[7,8] or micellar-[10] dye system, it has frequently been shown that the hydrophobic microenvironment of a binding site significantly affects the pK_a value of a dye. Recently, Connors and Lipari[11] and Miyaji *et al.*[12] reported that the dissociation of carboxylic and barbituric acids in aqueous solutions is retarded by the addition of CD. These observations cannot be explained in terms of the idea of Broser *et al.*, but are well explained in terms of the hydrophobic microenvironment of the CD cavity.

The present study was undertaken to elucidate the contribution of the hydrophobicity of the CD cavity to the acid dissociation of indicator dyes. For this purpose, the behavior of sodium 4-(4′-hydroxy-1′-naphthylazo)-1-naphthalenesulfonate (**1**) and of the conjugate acid (**2**) of Methyl Orange was examined in detail. Both dyes ate known to be good hydrophobic probes, which exhibit absorption spectra that are very sensitive to the microscopic environment around the dye molecules.[13-16] The association of CD with **2** has been examined in some detail by Broser *et al.*[4-6] and Yamada *et al.*[17]

Experimental

Materials. α-CD and β-CD were prepared by the method of Lane and Pirt.[18] These substances were separated and purified according to the directions given by Cramer and Henglein.[19] Methyl α-D-glucopyranoside and Methyl Orange of reagent grade were used without further purification. Dye **1** was prepared by coupling 4-diazonio-1-naphthalenesulfonate to 1-naphthol. The crude product was purified by repeated salting-out from an aqueous solution with sodium acetate, followed by recrystallization from water and then washing with hot ethanol. Tetrahydrofuran (THF) of reagent grade was used after distillation, bp 66—67 °C. The aqueous buffer solutions used in the present study were H_2SO_4–Na_2SO_4 (pH 1—2), sodium citrate–HCl (pH 2—4), citric acid–Na_2HPO_4 (pH 3—7), citric acid–NaOH (pH 4—6), Na_2HPO_4–KH_2PO_4 (pH 6—7), KH_2PO_4–$Na_2B_4O_7$ (pH 6—9), and $Na_2B_4O_7$–NaOH (pH 9—12). The ionic strengths (I_c) of buffer solutions were adjusted using Na_2SO_4 to 0.05 M for CD–**1** systems and 0.50 M for CD–**2** systems unless otherwise noted.

Apparatus. Absorption spectra were recorded using a Hitachi Model 124 spectrophotometer. The cells (1.0 cm) were maintained at 25±0.1 °C by means of a jacket through which water was circulated from a constant-temperature bath. The pH of each aqueous solution was measured by means of an Orion Model 801 A digital pH/mV meter.

Spectrophotometric Determination of an Apparent Dissociation Constant for a CD-Dye Inclusion Complex. The absorption spectra of dyes **1** and **2**, at a given concentration (*ca.* 0.03 mM for **1** and *ca.* 0.02 mM for **2**) and at a given pH, were recorded for various CD concentrations (0.0—2.0 mM). Each CD–dye system gave an isosbestic point, indicating the formation of a 1 : 1 complex of CD and the dye. The changes in absorbance with CD concentration were measured at 482 and 528 nm for β-CD–**1** systems in acidic and basic solutions, respectively, and at 507 and 530 nm for CD–**2** systems in strongly and weakly acidic solutions, respectively. According to Hildebrand and Benesi,[20] the change in absorbance (ΔA) is related to the total concentration (c_0) of CD by the following equation:

$$\frac{c_0 s_0}{\Delta A} = \frac{K_d}{\Delta\varepsilon} + \frac{c_0}{\Delta\varepsilon}, \quad (1)$$

where s_0 is the total dye concentration, and K_d and $\Delta\varepsilon$, the apparent dissociation constant of a CD–dye inclusion complex and the difference in the molar absorption coefficient between the free and complexed dyes, respectively. The plot of $c_0 s_0/\Delta A$ *vs.* c_0 gave a straight line for each CD–dye system, and the values of K_d and $\Delta\varepsilon$ were determined from the slope and intercept of the line.

Spectrophotometric Determination of the Apparent Acid Dissocia-

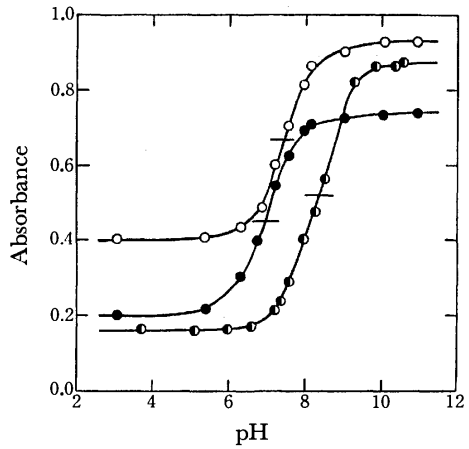

Fig. 1. Plots of absorbances of **1** (3×10^{-5} M) *vs.* pH's at 25 °C.
○: No additive and $\lambda=528$ nm, ●: [β-CD] = 2.02 mM and $\lambda=528$ nm, ◐: [THF] = 3.72 M and $\lambda=535$ nm.

tion Constant ($K_{a,app}$) for an Indicator Dye. Seven to ten buffer solutions were prepared with given concentrations of a dye and an additive, such as CD or THF, and with different pH values. The absorbance at an appropriate wavelength for each solution was plotted against the pH of the solution. Figure 1 illustrates examples of such plots for **1**. The $pK_{a,app}$ values were determined by graphical evaluations of the pH at which $A=(A_a+A_b)/2$, where A_a and A_b are the absorbances under sufficiently acidic and basic conditions, respectively.

Results and Discussion

Change in Absorption Spectrum of a Dye upon the Addition of CD. The absorption spectra of dyes **1** and **2** in a sufficiently acidic solution were markedly changed by the addition of CD, except for the case of the α-CD–**1** system for which the addition of α-CD gave only a slight change in the spectrum of **1**. The molecular cavity of α-CD may be too small to include the naphthyl groups of **1**. Methyl α-D-glucopyranoside had virtually no effect on the spectra of **1** and **2**. The spectral change in the β-CD–**1** system is illustrated in Fig. 2.

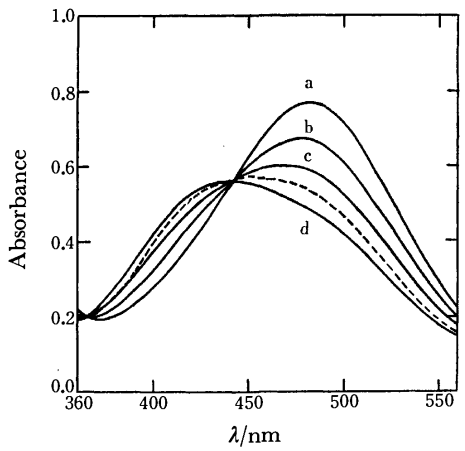

Fig. 2. Absorption spectra of **1** (3.97×10^{-5} M) at pH 4.19 and 25 °C.
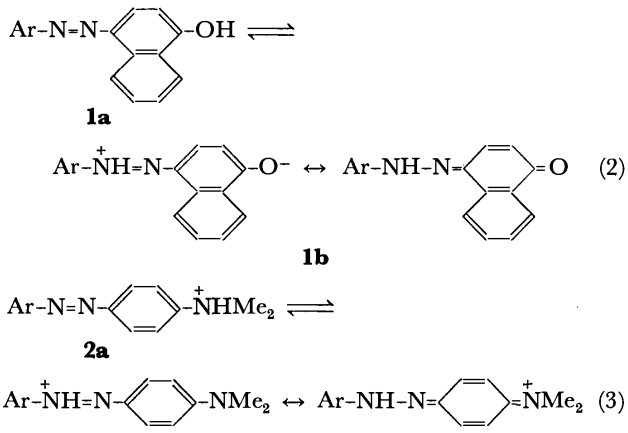
Solid line: [β-CD] = (a) 0.00 mM, (b) 0.20 mM, (c) 0.51 mM, (d) 2.03 mM.
Dashed line: [THF] = 3.77 M.

The absorbance around 480 nm markedly decreased and that around 420 nm increased with increasing β-CD concentrations. Isosbestic points were observed at 365 and 441 nm, indicating that β-CD forms a 1 : 1 complex with **1**. The spectral change in **2** upon the addition of α- or β-CD was also very large as reported by Broser,[5] who also showed that both α- and β-CD form 1 : 1 complexes with **2** at low CD concentrations.

When a nonpolar solvent, THF, was added to a sufficiently acidic solution of **1** or **2**, a significant spectral change was observed, which was quite similar to that caused by the addition of CD. An absorption spectrum of **1** in the presence of THF is shown by the dashed line in Fig. 2. It is known that 4-(arylazo)-1-naphthols[14,16,21] and the conjugate acids of 4-aminoazobenzene derivatives[5,13,21] are in tautomeric equilibria.



The azonium or hydrazone forms (**1b** and **2b**) are predominant species in aqueous solutions, whereas the azo forms (**1a** and **2a**) are predominant in apolar solutions or microenvironments. Thus, the above spectral changes indicate that both **1** and **2** are bound to the hydrophobic regions of CD molecules to give mainly **1a**– and **2a**–CD complexes, respectively.

Effect of Ionic Strength on the K_d Values for CD–Dye Complexes. In order to determine which dipole-ion interactions and hydrophobic interactions contribute

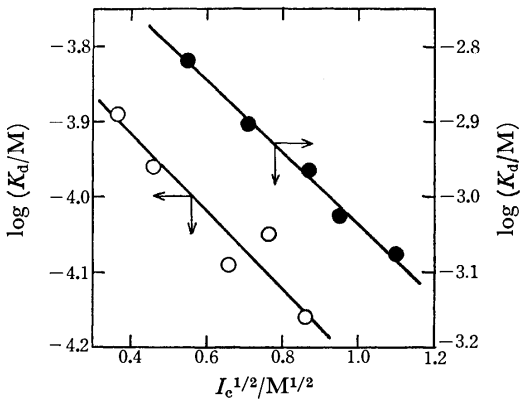


Fig. 3. Plots of log K_d *vs.* $I_c^{1/2}$ for α-CD–**2** systems at 25 °C. The I_c's were adjusted by the addition of Na_2SO_4.
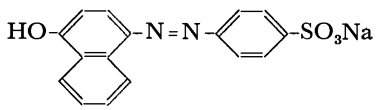
○: pH = 6.7±0.1 (phosphate buffer),
●: 0.10 M H_2SO_4.

mainly to the association of the CD with the dyes, the effect of ionic strength (I_c) on the K_d values were examined for the CD–dye complexes. Electrostatic interactions, in general, weaken with increasing I_c.[7] If the dipole-ion interactions are dominant, as has been suggested by Broser,[5] the K_d value should increase with increasing I_c. On the other hand, hydrophobic interactions are generally enhanced by an increase in I_c (salting-out effect).[22] Figure 3 shows the plot of $\log K_d$ *vs.* $I_c^{1/2}$ for complexes of α-CD with **2** and its conjugate base. All $\log K_d$ values decrease with increasing I_c.

Dye **1** is too insoluble in an aqueous solution for I_c above 0.05 M to permit a precise examination of the effect of I_c on the K_d value for a β-CD–**1** system. However, Mochida *et al.* previously showed[23] that the K_d value for the complex of β-CD with Orange I (**3**), an analog of **1**, decreases with increasing I_c.

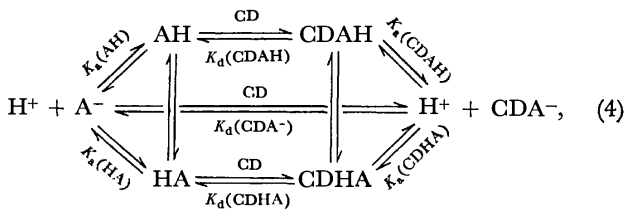


3

These observations strongly suggest that hydrophobic, rather than electrostatic, interactions play a dominant role in the associations of CD with dyes.

Effect of CD on the $pK_{a,app}$ *Values of Azo Dyes.* Table 1 gives the $pK_{a,app}$ values for dyes **1**—**3** in the absence and in the presence of α-CD, β-CD, and/or THF. The observed $pK_{a,app}$ values decrease with increasing CD concentration for all CD–dye systems. The addition of methyl α-D-glucopyranoside up to 100 mM had virtually no effect on the $pK_{a,app}$ values of the azo dyes.

In order to explain the dependence of the $pK_{a,app}$ values on the CD concentrations, a reaction system is postulated which involves inclusion, acid-dissociation, and tautomeric equilibrium processes, thus



where AH and HA represent the azo form and the azonium or hydrazone form of the azo dye, respectively, K_d and K_a, the dissociation constant of the inclusion complex and the acid-dissociation constant, respectively, for each species given in parenthesis. From reaction

		0.520	2.72	2.68
		1.00	2.58	2.53
	β-CD	0.402	3.16	3.12
		1.00	2.96	2.95
	THF	3720	2.88	—
3[c]	none	0.000	8.20	(8.20)
	β-CD	0.500	8.00	8.01
		1.00	7.89	7.89
		2.50	7.72	7.74
		5.00	7.62	7.65
		10.0	7.60	7.59

a) $I_c=0.050$ M; b) $I_c=0.50$ M; c) $I_c=0.025$ M.

4, we can easily derive the following relations from the law of mass action:

$$pK_{a,app}(c_0=0) = \log\{K_a(AH)^{-1}+K_a(HA)^{-1}\}, \quad (5)$$

$$pK_{a,app} = pK_{a,app}(c_0=0) - \log\frac{1+c_0K_d(CDA^-)^{-1}}{1+c_0\{K_d(CDAH)+K_d(CDHA)\}^{-1}}, \quad (6)$$

and

$$pK_{a,app}(c_0=\infty) = pK_{a,app}(c_0=0) - \log\frac{K_d(CDAH)+K_d(CDHA)}{K_d(CDA^-)}, \quad (7)$$

where $pK_{a,app}$ $(c_0=0)$ and $pK_{a,app}$ $(c_0=\infty)$ are the $pK_{a,app}$ values at null and infinite CD concentrations, respectively. Equations similar to Eq. 6 have been derived[11,12] for reaction systems which involve inclusion and acid-dissociation processes, but which did not involve tautomeric equilibrium processes. The values of $\{K_d(CDAH)+K_d(CDHA)\}$ and $K_d(CDA^-)$ in Eqs. 6 and 7 are equal to the K_d in Eq. 1 for each CD–dye system in sufficiently acidic and basic solutions, respectively, and can be experimentally determined (Table 2). The $pK_{a,app}$ values in the presence of CD were calculated on the basis of Eq. 6 using the data in Table 2 and the $pK_{a,app}$ $(c_0=0)$ values determined experimentally, and are compared with the observed values (Table 1). They are in good agreement with

Table 2. The values of $\{K_d(CDAH)+K_d(CDHA)\}$, $K_d(CDA^-)$ and $\{pK_{a,app}(c_0=0)-pK_{a,app}(c_0=\infty)\}$ for CD-azo dye systems at 25 °C

System	$K_d(CDAH)+K_d(CDHA)$ / mM	$K_d(CDA^-)$ / mM	$pK_{a,app}(c_0=0)-pK_{a,app}(c_0=\infty)$
β-CD-**1**	0.390	0.134	0.46
α-CD-**2**	1.25	0.0882	1.15
β-CD-**2**	2.70	0.380	0.85
β-CD-**3**	3.00	0.588	0.71

each other to within the experimental error. This fact indicates that the chemical equilibria of Reaction 4 are valid.

The azonium and hydrazone forms (HA in Eq. 4) are the dominant species in aqueous solutions. This fact means that they are of weaker acidity than the corresponding azo form (AH).[21] However, the latter becomes dominant in the CD complexes. This shift in tautomeric equilibrium may contribute significantly to the decrease in the $pK_{a,app}$ of the dye. The change in microscopic dielectric constant around the dissociative groups of the dyes upon inclusion in the hydrophobic CD cavity may also affect the $pK_{a,app}$ values.[11,12] As the effect of THF on the $pK_{a,app}$ values shows (Table 1), the decrease in dielectric constant causes an increase in the $pK_{a,app}$ of **1**, but a decrease in that of **2**. Thus, the decrease in $pK_{a,app}$ with the formation of the inclusion complexes should be larger for the CD–**2** system than for the CD–**1** system. Indeed, this is the case, as the differences between the $pK_{a,app}(c_0=0)$ and $pK_{a,app}(c_0=\infty)$, calculated on the basis of Eq. 7, show (Table 2).

The authors are indebted to Mr. Etsuji Abe for his help in making some of the measurements.

A Carbon-13 Spin-Lattice Relaxation Study of Side Chains of Poly(alkyl methacrylate)

Yoshiyuki HIRAI, Taizo ITO, and Yoshio IMAMURA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 26, 1977)

The carbon-13 spin-lattice relaxation times (T_1) of the carbons in the alkyl side chains of poly(alkyl methacrylate) (butyl, octyl, dodecyl, and octadecyl), including poly(butyl methacrylate) of low molecular weights, were determined from partially-relaxed Fourier transform spectra. The T_1 for polymers of high molecular weights were found to be determined by the internal motion of the side chains, and not by the overall motion of the polymer molecules. The relaxation data indicate that the internal motion of the short side chains (butyl and octyl) is restricted by interactions between the side chains, although this effect was ineffective near the free ends of long chains (dodecyl and octadecyl). These observations are interpreted in terms of the local environment around the side chains.

The measurements of carbon-13 spin-lattice relaxation times (^{13}C-T_1) have been applied to investigations of the molecular dynamics of polymers in solutions.[1] Many of those investigations were concerned with the segmental mobility of backbone chains. On the other hand, a few papers have been published on localized motion, such as the internal motion of side groups, the internal motion of methyl groups of polypropyrene[2] and the ring motion of pyrrolidine residues of polypeptides.[3]

In a previous study, Hirai *et al.* evaluated the internal motion of the side groups of polyacrylamides having various molecular weights using ^{1}H-NMR spectroscopy and discussed the change in the local environment around the side groups arising from increase in molecular weight.[4] In the present investigation, samples of poly(normal alkyl methacrylate), including poly(butyl methacrylate) of low molecular weights, were studied. In these polymers, one end of the alkyl side chains is attached to the polymer backbone; such alkyl chains are termed anchored chains. In such cases, a marked gradation of the ^{13}C-T_1 along the alkyl chains was observed.[5] The gradation of T_1 reflects a change in internal motion along the side chains. Therefore, poly(alkyl methacrylate) is an ideal sample for discussing the internal motion of side groups.

The ^{13}C-T_1 for the side chains of poly(alkyl methacrylate) (butyl, octyl, dodecyl, and octadecyl) were determined from partially-relaxed Fourier transform spectra, and the correlation times were estimated. The internal motion of the side chains and the local environment around these chains is discussed on the basis of the relaxation data.

Experimental

Samples of poly(butyl methacrylate), poly(octyl methacrylate), poly(dodecyl methacrylate), and poly(octadecyl methacrylate) were prepared by polymerization of 10 g of the respective monomers in 20 ml of carbon tetrachloride for 5 h at 70 °C, using about 0.1 g of α,α'-azobisisobutyronitrile as an initiator. Samples of poly(butyl methacrylate) of various molecular weights were also prepared by changing the amount of the initiator (over the range from 0.3 to 3 g). The polymers were precipitated in a large amount of methanol in order to free them from any residual monomer, and were dried *in vacuo*. The number-average molecular weights of these polymers were determined using a Kunauar membrane osmometer and a vapor-pressure osmometer in chloroform solutions at 37 °C. The average molecular weights of the polymer samples were as follows: poly(butyl methacrylate) 1.36×10^3—7.95×10^4, poly(octyl methacrylate) 13.4×10^4, poly(dodecyl methacrylate) 8.26×10^4, and poly(octadecyl methacrylate) 11.3×10^4.

Polymer solutions for ^{13}C-NMR spectral measurements were prepared by dissolving of 0.3 g of the polymers in 0.7 ml of chloroform-*d*; the concentration of the polymers was 30% (wt/vol). The solutions were transferred to 8 mm o.d. NMR tubes, which were sealed after the air had been replaced with nitrogen gas. The sample volume was confined to a volume which was designed to be about 15% less than that of the rf sample coil, since it has been pointed out by Farrar and Becker[6] that, in order to avoid systematic errors introduced in T_1, the sample volume should not extend above or below the rf sample coil.

The carbon-13 NMR spectra were measured using a JEOL JNM PS-100 spectrometer equipped with a PFT-100 Fourier transform system operating at 25.03 MHz, and a EC-100 computer with a memory capacity of 16 kirowords. The 90° pulse width was about 23 μs. The apparatus was equipped with an internal ^{2}D field-frequency lock and a noise-modulated proton decoupler. The time-domain signal was digitized in 8192 channels, to provide 4096 data points after Fourier transformation. The recycle times of the 90° pulse were chosen to be at least four times the longest spin-lattice relaxation time. The experiments on spin-lattice relaxation were restricted to a spectral width of 2000 Hz. Over this widths, the ^{13}C rf field is sufficiently effective. All spectra were observed at 27 °C.

The T_1 were calculated, for six significant time intervals in the range from 30 ms to 6.0 s, using the least-squares method. The error in T_1 was estimated from the values of $\lim_{t\to0} \ln\{A_0-A(t)\}/A_0$; the maximum error was within ±10%.

Results and Discussion

^{13}C-NMR Spectra of Poly(alkyl methacrylate). Figure 1 shows the proton-decoupled ^{13}C-NMR spectra of poly(alkyl methacrylate) (butyl, octyl, dodecyl, and octadecyl). In examining these spectra, attention is called to the peaks of the side chain carbons.

The chemical shifts of the carbons of alkyl chains can be estimated from the empirical equation of Grant and Paul[7] or that of Lindeman and Adams;[8] these equations are often used for spectral assignments. The chemical shifts of the carbons of the alkyl side chains were estimated using the equation of Lindeman and Adams.[8] In the calculations, the effect of substitution

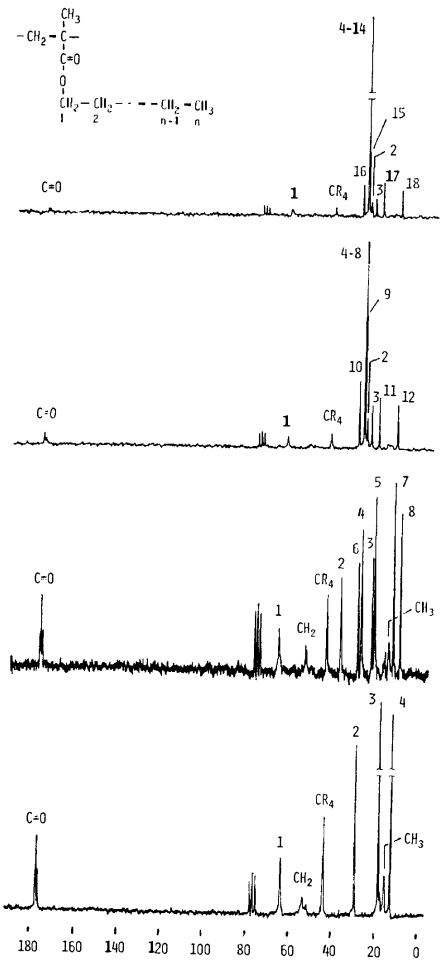

Fig. 1. Proton-decoupled natural-abundance ^{13}C Fourier transform NMR spectra of poly(alkyl methacrylate) in chloroform-*d* (30% (w/v)), at 25.03 MHz and 27 °C. From the top, poly(octadecyl methacrylate), poly(dodecyl methacrylate), poly(octyl methacrylate), and poly(butyl methacrylate). Assignments are indicated near the top of each peak. The numbering system for the alkyl chain starts at the $O-CH_2$ carbon. The horizontal scale is ^{13}C chemical shifts (ppm) relative to tetramethylsilane.

by –OCOR groups[9] was also taken into account. The calculated values are listed in the column marked "Calcd" in Table 1.

The values of the observed chemical shifts are given in the column marked "Obsd". For carbons near the anchored end, the chemical shifts of the peaks yielding short spin-lattice relaxation times are given (the ^{13}C-T_1 values are given in the following section). The basis for this arrangement of the observed chemical shifts is as follows. The ^{13}C-T_1 values for various anchored chains (one end of alkyl chains is anchored to massive materials or to some solvent matrix) have been measured by various investigators.[5,10–14] The ^{13}C-T_1 for all anchored chains increases along the chain from the carbon at the anchored end toward the terminal methyl carbon; there are no exceptions to this rule. One end of each of the alkyl side chains of poly(alkyl methacrylate) is anchored to the polymer backbone; the T_1 for the side chains should be similar to those for the anchored chains already examined.[5,10–14]

For poly(butyl methacrylate), poly(dodecyl methacrylate), and poly(octadecyl methacrylate), the calculated values are in fair agreement with the observed values. Only for poly(octyl methacrylate), is the agreement poor. The origin of this disagreement is obscure; in the assignment of the octyl chain the rule of chemical shifts for linear alkanes was also taken into account. However, it is evident that the assignments for carbons 7 and 8, which have long relaxation times, can be made without error. This means that the disagreement for the octyl chain does not affect the main discussion of the present study given in the following section.

Internal Motion of Alkyl Side Chains. The spin-lattice relaxation times of ^{13}C nuclei in polymers are determined predominantly by ^{13}C–H dipolar interactions.[15] Other possible relaxation mechanisms can be ignored.[1,15] Therefore, only the intramolecular dipolar interactions between a carbon and nearby completely saturated spin-spin decoupled protons are assumed here. If the "extreme narrowing condition" is satisfied, the relaxation time T_1 is given as follows (this condition is valid for side-chain carbons having moderately long spin-lattice relaxation times):

a) ppm relative to tetramethylsilane. b) $-(-CH_2-\underset{\displaystyle C-O-CH_2-CH_2\cdots\cdots CH_2-CH_3}{\overset{\displaystyle CH_3}{\overset{|}{C}}}-)-$ (1 2 $n-1$ n; O)

$$1/T_1 = \hbar^2\gamma_C^2\gamma_H^2\tau \sum_N r_N^{-6}, \quad (1)$$

where $\hbar$ is Planck's constant divided by 2π, γ_C and γ_H are the carbon and proton gyromagnetic ratios, respectively, τ is the correlation time (τ is often expressed as τ_{eff}, the "effective correlation time"), and r_N is the internuclear C–H distance for the N-th proton. In the calculation of $\sum_N r_N^{-6}$, account is taken of the directly bonded protons only.

T_1 of Butyl Chains and Molecular Weights: Table 2 shows the T_1 values for the side chains of poly(butyl methacrylate) of various molecular weights. The effective correlation times (τ_{eff}) were calculated from Eq. 1 using these T_1 values and are listed in Table 3.

Tables 2 and 3 indicate the typical behavior of T_1 and τ_{eff} for anchored chains: the values of T_1 increase steeply from the 1-CH_2 carbon to the terminal carbon (of course, τ_{eff} decreases steeply). These findings are similar to the observations of Levy.[5] The gradation of T_1 and τ_{eff} reflects increasing internal motion toward the terminal methyl groups. Tables 2 and 3 also indicate that the values of T_1 and τ_{eff} for each carbon depend on the molecular weight in the region of low molecular weights. The values of T_1 for each carbon decrease with increasing molecular weight, while τ_{eff} increases with increasing molecular weight. For polymers of high molecular weight, T_1 and τ_{eff} are independent of the molecular weight. Similar results have also been reported for the ^{13}C-T_1 of polystyrene[16] and polyisobutylene[17] in solutions. These findings indicate that T_1 and τ_{eff} for polymers of high molecular weight (in the present experiment, $\overline{M}_n \geq 24900$) are determined by the internal motion of the side chains and not by the overall motion of the polymer molecules. The reciprocal of the correlation time $(\tau_{eff})^{-1}$ can be taken as the sum of the rates for internal and overall motion, *i.e.*, $(\tau_{eff})^{-1}=(\tau_o)^{-1}+(\tau_1)^{-1}$. For polymers having $\overline{M}_n \geq 24900$, the condition $(\tau_o)^{-1} \ll (\tau_1)^{-1}$ is valid, and $(\tau_{eff})^{-1}$ is approximately equal to $(\tau_1)^{-1}$.

T_1 of Alkyl Side Chains: Table 4 shows the values of T_1 for the side chains of poly(butyl methacrylate), poly(octyl methacrylate), poly(dodecyl methacrylate), and poly(octadecyl methacrylate). From these values of T_1, the effective correlation times ($^j\tau_{eff}$, where j is the j-carbon) for each carbon of the side chains can be calculated. Table 5 shows the reciprocals of the correlation times, $^j\tau_{eff}^{-1}$. $^j\tau_{eff}^{-1}$ reflects only the rate of internal motion of the j-carbon in the chain, because, as described in the preceding section, the condition $(\tau_o)^{-1} \ll (\tau_1)^{-1}$ is valid for these polymer samples. Figure 2 shows a plot of $^j\tau_{eff}^{-1}$-j for the side-chain carbons of poly(alkyl methacrylate).

The values of $^j\tau_{eff}^{-1}$ for the butyl and octyl chains increase progressively toward the free end. The $^j\tau_{eff}^{-1}$ curves for the dodecyl and octadecyl chains have flat regions (dotted lines in Fig. 2), which contain carbons 4 to 8 and carbons 4 to 14. The $^j\tau_{eff}^{-1}$ values for the last four carbons (the four carbons near the free end) of these chains increase sharply. Figure 2 also indicates that the $^j\tau_{eff}^{-1}$ for the last four carbons depends on the chain length of these side chains. The $^j\tau_{eff}^{-1}$ values for the butyl chain are small, and those for the octyl chain are comparably small. The $^j\tau_{eff}^{-1}$ values for the last four carbons of the dodecyl and octadecyl chains are rather large. This $^j\tau_{eff}^{-1}$ behavior resembles that of the anchored chains discussed below.

Figure 3 shows the $^j\tau_{eff}^{-1}$ curves for various anchored

chains (the alkyl chains of the butylammonium ion, 1-decanol, and dipalmitoyllecithin). These curves were prepared from ^{13}C-T_1 data for these chains.[10,13,14] The $^jT_{eff}^{-1}$ behavior of the last four carbons of these alkyl chains is different from that of the side chains of poly(alkyl methacrylate). In the case of these anchored chains, the $^jT_{eff}^{-1}$ values for the four carbons is large and give quite similar curves, in spite of the very different properties of these alkyl chains (the curves for *N*,*N*-di-*n*-butyl formamide[12] and lecithin derivatives[11] are also similar to these curves). This constancy of $^jT_{eff}^{-1}$ for the last carbons is called the "limiting microviscosity effect."[18,19] The $^jT_{eff}^{-1}$ values for the last four carbons of these chains do not depend on the chain length or on the type of molecular anchor.

However, the change of $^jT_{eff}^{-1}$ for anchored chains shown in Fig. 3 results only from the restriction of the motion of the anchored end (the anchoring effect). For the side chains of poly(alkyl methacrylate), in addition to this "anchoring effect", the effect of intramolecular packing of the side chains[4] should also be considered. The local environment of the alkyl side chains of poly(alkyl methacrylate) differs from that of the anchored chains in Fig. 3 only in the existence of this intramolecular packing of chains. Therefore, the difference in the $^jT_{eff}^{-1}$ behavior for the last carbons of the side chains of poly(alkyl methacrylate) from those for the various anchored chains, namely the dependence of the $^jT_{eff}^{-1}$ curves on the chain length, can be attributed to this intramolecular packing effect.

The relaxation data presented above indicate that the intramolecular packing effect is ineffective for the last four carbons of the dodecyl and octadecyl chains, although it is effective for the butyl and octyl chains.

The effect of intramolecular packing on internal motion should become measurable when the side chains are unable to escape each other due to the increase in the backbone-chain length[4,20] (this requires that side groups be bulky and rigid). Such examples, in fact, have been observed for the internal rotation of amide groups of polyacrylamide[4] or the tumbling motion of phenyl groups of polystyrene.[21]

The side chains of poly(alkyl methacrylate) differ considerably from the side groups of polyacrylamide and polystyrene in the degree of freedom for interanl motion. Evidently, the degree of freedom for internal motion of alkyl side chains is larger than that of the side groups of polyacrylamide and polystyrene. The degree of freedom of the alkyl side chains is very large at carbons remote from the anchored end. In such cases, the carbons of the side chains can easily exchange equilibrium positions, even if intramolecular packing of the side chains occurs for the polymer chains. As a result, the packing effect is ineffective for restricting internal motion; the side chains behave similarly to the anchored chains, for which the intramolecular packing effect is absent.

From these considerations, the $^jT_{eff}^{-1}$ behavior for the alkyl side chains of poly(alkyl methacrylate) can be interpreted as follows. The internal motion of the last four carbons of the dodecyl and octadecyl chains is not affected by the intramolecular packing of the side chains, because these chains can easily exchange positions with each other. On the other hand, the degrees of freedom of the internal motion for the butyl and octyl chains are less than those for the carbons near the free ends of the dodecyl and octadecyl chains. The butyl and octyl chains are not long enough to permit relaxation of the packing effects, and reduced $^jT_{eff}^{-1}$ values, which arise from the intramolecular packing of the side chains, can be observed. The observations for the side chains of poly(alkyl methacrylate) are interpreted well using the above considerations.

It is concluded that the internal motion of the short side chains (butyl and octyl) is restricted by the intramolecular packing of the side groups, but that this effect is ineffective near the free ends of long chains (dodecyl and octadecyl).

A Molecular-orbital Calculation of Chemically-interacting Systems. Interaction between Two Radicals. Self-reaction of Peroxyl Radicals

Tsutomu MINATO, Shinichi YAMABE,* Hiroshi FUJIMOTO, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

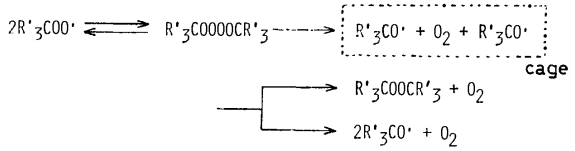
** Department of Chemistry, Nara University of Education, Takabatake-cho, Nara 630*

(Received May 31, 1977)

The path of the termination reaction of peroxyl radicals (self-reaction) was studied by means of a perturbational method and its reaction mechanism was elucidated theoretically. It was ascertained from this calculation that the self-reaction of tertiary alkylperoxyl radicals yielding a tetroxide does not have a four-centered transition state with four oxygen atoms of the two peroxyl radicals participating, but has a two-centered transition state with only the terminal oxygen atoms. The self-reaction of primary or secondary alkylperoxyl radicals is found to have a six-centered transition state. The self-reaction of acylperoxyl radicals is also shown to have a six-centered transition state. The mechanism of these self-reactions is clarified in terms of the mode of the particular orbital interaction.

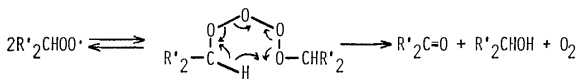
One of the termination reactions of autoxidation is the reaction wherein two peroxyl radicals are converted into non-radical products (self-reaction). Such self-reactions of peroxyl radicals have been studied and various kinds of products have been reported.[1] When a peroxyl radical is represented by ROO·, the products of the self-reaction can be shown to be a function of R. This is displayed in Table 1. When R is a *t*-alkyl group (T) or an acyl group (A), the products of the self-reaction are a peroxide and an oxygen molecule (self-reaction T or A). When R is a *p*-alkyl group (P) or an *s*-alkyl group (S), the products are a carbonyl, an alcohol, and an oxygen molecule (self-reaction SP).

The mechanism involved in these self-reactions has received considerable attention in the last few years because of the fundamental importance of these reactions to a complete understanding of autoxidation. For self-reaction T, the overall process can be represented as follows:[1]



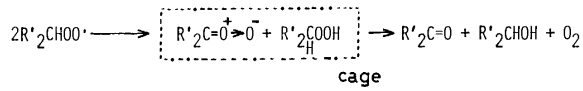
Scheme 1. (for self-reaction T).

This scheme is generally accepted and Bartlett and Guaraldi[2] have provided convincing evidence for the existence of the tetroxide by direct monitoring, using ESR, the concentration of the *t*-butylperoxyl radical, which is present in equilibrium with the tetroxide at very low temperature. Regarding self-reaction SP, its exact mechanism is not yet clear. In this reaction, the carbonyl compounds and alcohol are obtained in high yields, whereas no peroxide, which is present for self-reaction T, was detected.[3] In addtion, when the α-hydrogens of the *s*-, or *p*-alkylperoxyl radicals are replaced by deuterium, an isotopic effect on the rate constant of the overall termination process (*i.e.*, $k_t^H/k_t^D = 1.4$) is observed.[4] k_t is the rate constant of the overall termination process. To explain these experimental results, Russell[5] has proposed a unique mechanism for self-reaction SP which involves the intermediacy of a "cyclic" transition state, as is shown in the following figure:



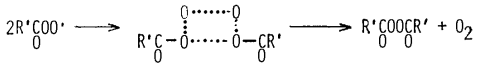
Scheme 2. (for self-reaction SP).

While a mechanism analogous to Scheme 1 with the intermediacy of alkoxyl radicals can be discounted on the basis of experimental results,[3,5] the mechanism of Scheme 2 is supported by most data. However, it has been pointed out that some doubt still remains as to the validity of Russell's mechanism of Scheme 2.[6] Bowman and co-workers[6a] have concluded from thermochemical calculations that, if Scheme 2 is the only viable mechanism for self-reaction SP, the overall activation energy (E_t) should be negative. This is contrary to experimental observations. For example, Howard and Bennett[6b] have found a value of +3 kcal/mol for the E_t of the self-reaction of cyclopentylperoxyl radicals. This discrepancy led Benson propose the following mechanism for self-reaction SP.[6a]



Scheme 3. (for self-reaction SP).

However, there is no experimental evidence for the production of a zwitterion and a hydroperoxide from self-reaction SP[1a] and, consequently, this mechanism is not taken into account in this work. Next, for self-reaction A, the mechanism is also controversial. McDowell and Sifniades have suggested a four-centered transition state as shown by the following scheme:[7]

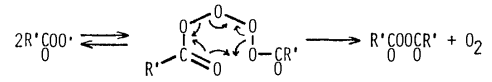


Scheme 4. (for self-reaction A).

However, this scheme appears rather unlikely. While *t*-alkylperoxyl radicals are expected to interact in a manner similar to Scheme 4, the overall rate constant of self-reaction T is much lower than that of self-reaction A, as is shown later in Table 3. Ingold has proposed a six-centered transition state for self-reaction A analogous to Scheme 2,[1b] thus we can write as

Table 1. The products of self-reactions of peroxyl radicals with various substituent groups

R	Reaction	Product	Self-reaction
t-Alkyl group (R'_3C-)	$R'_3COO\cdot + R'_3COO\cdot$	$R'_3COOCR'_3 + O_2$	Self-reaction T
s-Alkyl group (R'_2CH-)	$R'_2CHOO\cdot + R'_2CHOO\cdot$	$R'_2CHOH + R'_2C{=}O + O_2$	Self-reaction SP
p-Alkyl group ($R'CH_2$-)	$R'CH_2OO\cdot + R'CH_2OO\cdot$	$R'CH_2OH + R'CH{=}O + O_2$	Self-reaction SP
Acyl group ($R'CO$-)	$R'C(=O)OO\cdot + R'C(=O)OO\cdot$	$R'C(=O)OOC(=O)R' + O_2$	Self-reaction A



Scheme 5. (for self-reaction A).

Thus, the mechanisms of self-reactions SP and A are still in doubt, although it is accepted that the mechanism of self-reaction T is expressed by Scheme I. Under such circumstances, it is interesting to theoretically study the destruction process of peroxyl radicals. Recently, the ΔW method, which deals with a radical-radical reacting system in terms of the molecular interaction, was developed by the present authors.[8] Some calculations of the ΔW method presented in a previous paper[9] elucidated the difference between recombination and disproportionation mechanisms. In the present work, first, the self-reaction mechanisms will be examined theoretically using the ΔW method. Second, the general aspect of the self-reaction of peroxyl radicals will be explained schematically using the mode of interaction between particular molecular orbitals (MO) of several isolated peroxyl radicals. The reactivity of these radicals can be simply discussed by analyzing the extent of such MO interactions.[10]

Calculation for Assumed Reaction Models

Method of Calculation. In the ΔW method, the wavefunction (Ψ) of a chemically-interacting system consisting of two peroxyl radicals is represented by the sum of various electronic configurations according to the configuration interaction (CI) procedure. Our attention is focused on the reaction system involving singlet spin states because, for triplet spin states, a radical-radical reaction is far from occurring. In this calculation, no electronic configurations for intramolecular excitations are taken into account, as in a previous paper.[9] When the CI secular equation is expanded perturbationally, the total stabilization energy (ΔW) due to the CI mentioned above can be partitioned into the following three terms, Coulomb (E_Q), exchange (E_K) and delocalization (D) terms:

$$\Delta W = E_Q + E_K - D, \quad (1)$$

where E_Q is the classical electrostatic interaction energy between two peroxyl radicals. The exchange energy, E_K, is caused by the overlap between both occupied MO, which are doubly-occupied (DO) or singly-occupied (SO) MO. For the singlet spin state, as well as for the triplet spin state, E_K is found to be repulsive (>0) for systems composed of radicals of usual organic-chemical size.[8] E_K can be further partitioned into four terms, thus

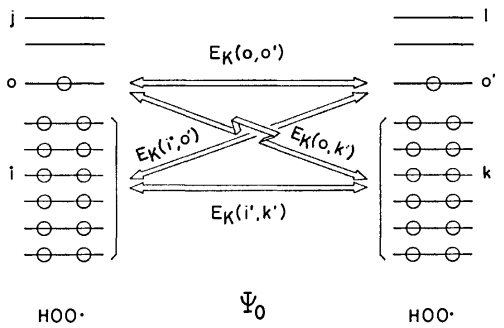


Fig. 1. The adiabatically-interacting configuration (Ψ_0) and the schematic representation of four types of exchange interaction between two hydroperoxyl radical. The lowest and second lowest DOMO's of each HOO·, *i.e.*, the 1s-type ones, are omitted in this figure.

$$E_K = E_K(i', k') + E_K(i', o') + E_K(o, k') + E_K(o, o'). \quad (2)$$

In Fig. 1, the four components of E_K are shown schematically. D is the stabilization energy due to the mixing-in of the charge-transfer configurations with the adiabatically-interacting configuration (Ψ_0). D can be represented by the sum of eight components, thus

$$D = D(i\rightarrow l) + D(k\rightarrow j) + D(i\rightarrow o') + D(k\rightarrow o) + D(o\rightarrow l) + D(o'\rightarrow j) + D(o\rightarrow o') + D(o'\rightarrow o). \quad (3)$$

A system composed of two hydroperoxyl radicals (2HOO·) is selected as the reaction model for the calculation using the ΔW method. The MO of the hydroperoxyl radical, which are needed to evaluate the CI matrix elements are obtained using the semi-empirical all-valence-electron SCF-UHF method, including overlap integrals.[11] The way of estimating the semi-empirical parameters for evaluating the MO integrals is the same as that used in a previous paper.[12] Since the hydroperoxyl radical has 17 electrons, it has six DOMO, excluding the two lowest ls-like MO.

The geometry of the assumed reaction models is illustrated in Fig. 2. The geometry of the isolated hydroperoxyl radical comes from the CNDO calculation of Pople and Beveridge[13] and is frozen in the present calculation. In Fig. 2, Model I is a reaction model representing a four-centered reaction path. This model corresponds to Scheme 4. Model II is a two-centered reaction path in which two terminal oxygen atoms (O_1 and $O_{1'}$) are close to each other. Two radical species form the trans conformation. In

TABLE 2. THE CALCULATED INTERACTION ENERGIES FOR THE REACTION OF TWO HYDROPEROXYL RADICALS
The geometrical parameters, R and θ, are those shown in Fig. 2. The smaller value of ΔW indicates higher reactivity. Due to the symmetrical arrangement of the two radicals, $E_K(i', o') = E_K(o, k')$, $D(i \rightarrow l) = D(k \rightarrow j)$, $D(i \rightarrow o') = D(k \rightarrow o)$, $D(o \rightarrow l) = D(o' \rightarrow j)$ and $D(o \rightarrow o') = D(o' \rightarrow o)$.

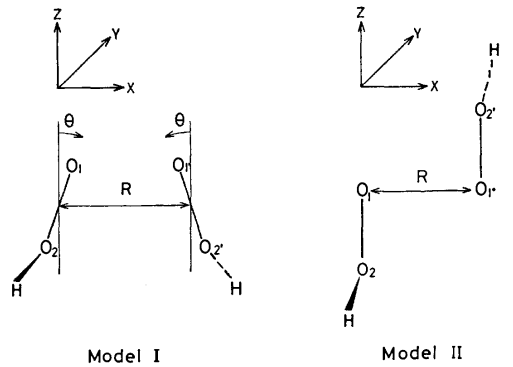

Fig. 2. Two assumed reaction models employed for the calculation of the interaction energy.

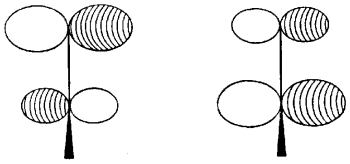
Model I, parameter R is the intermolecular distance between the center of the O_1–O_2 group and that of the O_1'–O_2' group, and θ is defined as the angle between the O_1–O_2 group and the Z-axis. In Model II, R is the distance between the two terminal oxygen atoms (O_1 and O_1'). In both models, the four oxygen atoms (O_1, O_2, O_1', and O_2') are always in the X-Z plane. In Model I, the reacting system belongs to the C_2 point group, whereas, in Model II, to the C_i point group.

Results. The interaction energies (ΔW) for Models I and II are given in Table 2. The ΔW of Model Ia (R=2.4 Å, θ=0°) is compared with that of Model II (R=2.4 Å). This comparison shows that Model II is more favorable than Model Ia for the self-reaction. At R=2.0 Å, the same result is obtained from Table 2. This preference of the self-reaction is thoroughly attributable to the exchange energy term, $E_K(i', k')$ (see Fig. 1). Here, let us examine in more detail the possibility of the four-centered reaction path. In Model I, a variation in θ may bring about a change in ΔW.[14] To see the effect of this angle variation for each energy, two other geometries of Model I are employed. In Model Ib, θ is 5° and, in Model Ic, θ is −5°. Model Ib is a closer approach of two terminal oxygen atoms than Model Ia, whereas Model Ic is a closer approach of the two inner oxygen atoms (O_2 and O_2'). At R=2.4 Å, the approach of the inner oxygen atoms is found to bring about a larger ΔW value (0.390 eV), *i.e.*, destabilization of the system. An analysis of the components of ΔW shows that this destabilization comes primarily from an increase in the exchange energy, E_K. In the three models (Ia, Ib, and Ic), the order of the numerical values of ΔW and its three components are as follows:

for E_Q, Ib>Ia>Ic
for E_K, Ic>Ib>Ia
for D, Ib>Ic>Ia
and for ΔW, Ic>Ib>Ia. } R=2.4 Å

Thus, the superiority of Model Ia is ascribed to the small repulsive terms (E_Q and E_K), in spite of the even smaller attractive term (D). The change in E_Q is very smooth as the intermolecular distance is shortened,[8] whereas E_K and D which are of second order in the MO overlap are shown to increase sharply. Since the rate of growth of D is greater than that of E_K, the approach of two radical species may render Model Ib more favorable than Model Ia. Comparing the ΔW of Model Ia (1.620 eV) with that of Model Ib (1.480 eV) at R=2.0 Å, one really finds this trend. At any rate, Model II is the more favorable pathway of the four assumed reaction models.

The difference in the interaction energies, ΔW, of the models adopted here can be interpreted qualitatively in terms of the shape of the particular MO of the hydroperoxyl radical as follows.[10] The SOMO of the hydroperoxyl radical, which is the seventh MO from the bottom shown in Fig. 1, is a π-type one along the X-axis. It has larger lobes at the terminal oxygen atom than those at the inner atom, as is depicted on the left-hand side of the figure.



The hydroperoxyl radical also has a π-type DOMO (the fifth MO from the bottom in Fig. 1), as is shown on the right-hand side of the figure, which has larger lobes at the inner oxygen atom. In Model Ic ($\theta=-5°$), the approach of the two inner oxygen atoms enlarges the overlapping between these two equivalent DOMO and, at the same time, reduces the overlap between the two SOMO. The increase of the former overlapping makes E_K(i′, k′) grow large and the reduction of the latter overlapping makes the stabilization terms, E_K(o, o′), D(o→o′) and D(o′→o), become small. The combination of such an increase and reduction results in an unfavorably large ΔW in Model Ic. Since, in Model Ib, the trend of the MO overlapping is opposite (*i.e.*, the SOMO-SOMO overlapping is larger and the DOMO-DOMO overlapping is smaller) to that in Model Ic, the ΔW of the former model becomes favorably small. The even smaller value of ΔW in Model II can be explained in the same way. The favorable results for Model II are attributed to the avoidance of the large overlap between the two DOMO (as shown above) which gives the dominant component of the repulsive term, E_K(i′, k′). Thus, the loss of the SOMO-SOMO overlapping, which produces three attractive terms, E_K(o, o′), D(o→o′), and D(o′→o), has a negligible influence on the superiority of Model II.

In order to seek the charge-transfer configuration that contributes most to the stabilization of the reaction system, the CI coefficients of Ψ were obtained with respect to Models Ib and II (R=2.0 Å), thus

$$\Psi_{\text{Model Ib}} = 0.951\Psi_0 - 0.115\Psi_{o\to o'} - 0.115\Psi_{o'\to o} + 0.052\Psi_{i_2\to o'} + 0.052\Psi_{k_2\to o} + 0.046\Psi_{i_5\to o'} + 0.046\Psi_{k_5\to o} + \cdots, \quad (4)$$

and

$$\Psi_{\text{Model II}} = 0.969\Psi_0 + 0.107\Psi_{i_5\to o'} + 0.107\Psi_{k_5\to o} - 0.049\Psi_{o\to o'} - 0.049\Psi_{o\to o'} + \cdots. \quad (5)$$

In Eqs. 4 and 5, the CI coefficients larger than 0.040 (absolute value) are shown. i_2, i_5, k_2, and k_5 denote the DOMO and the subscripts of i and k are the orbital numbers counted from the lowest DOMO (see Fig. 1). i_5 and k_5 are the π-type MO mentioned above. Equation 4 shows that, except for Ψ_0, the SOMO-SOMO interaction ($\Psi_{o\to o}$ and $\Psi_{o'\to o}$) is the most important in Model Ib, whereas Eq. 5 indicates that the charge transfer (CT) interaction from the π-type MO (i_5 and k_5) to the SOMO (o and o′) is more important than the SOMO-SOMO interaction in Model II.

In the course of the reaction, some bonds to be broken are weakened and new bonds begin to form. To see this effect of bond interchange, the atomic bond population[15] of the chemically-interacting system was calculated using wavefunction Ψ. Models Ia, Ib, and II (R=2.0 Å) were adopted for the calculation and the results are shown in Fig. 3. Judging from the energy results in Table 2, Model Ic is definitely an unfavorable pathway and will not be considered hereinafter. This figure shows that for Models Ia and Ib, a positive intermolecular bond population between the two terminal oxygen atoms (O_1 and $O_{1'}$) appears (0.0058 and 0.0061, respectively). For these two models, however, the intermolecular bond populations between the two inner oxygen atoms (O_2 and $O_{2'}$) are negative (−0.0073 in Model Ia and −0.0036 in Model Ib), which shows that the formation of the new $O_2\cdots O_{2'}$ bond cannot be expressed by them. The O_1–O_2 (or $O_{1'}$–$O_{2'}$) bond population of these two models is larger than that of the isolated HOO·. This can be explained in the following manner. The SOMO of the hydroperoxyl radical is an antibonding π-type orbital, as is sketched above, and therefore the SOMO-SOMO interaction decreases the electron occupancy of the SOMO.[16] If the reaction proceeds *via* Scheme 4, the O_1–O_2 bond should break in the course of the reaction. However, the present calculated results for the O_1–O_2 bond population together with the negative $O_2\cdots O_{2'}$ population indicate that Scheme 4 is an unfavorable pathway from the standpoint of bond interchange. This is an alternative expression of the improbability of the four-centered pathway. In Model II, a small positive population between the two terminal oxygen atoms appears (0.0005) and that of the O_1–O_2 bond increases only slightly (0.1224→0.1234). The smaller accumulation of the $O_1\cdots O_{1'}$ bond population for Model II than for Model Ib is due to the smaller SOMO-SOMO overlap which is the origin of the intermolecular bonding component.[8,9] Aside from this comparison of the $O_1\cdots O_{1'}$ bond population, the present results for the atomic bond population show that, in the self-reaction, the two terminal oxygen atoms forms a new $O_1\cdots O_{1'}$ bond, the O_1–O_2 (or $O_{1'}$–$O_{2'}$) bond of the peroxyl radical remaining un-

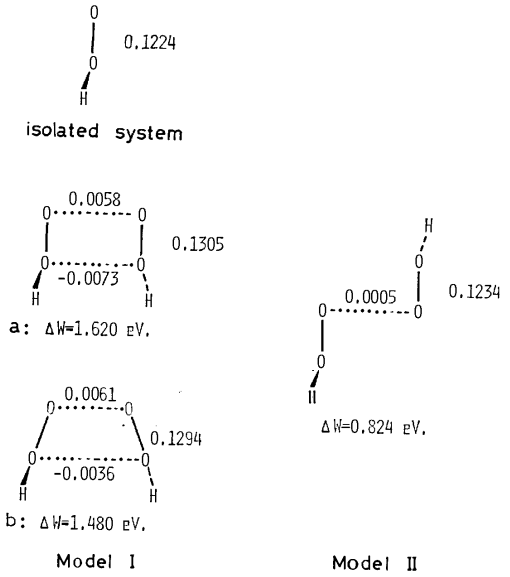


Fig. 3. The change of the atomic bond population by the exchange and CT interactions at R=2.0 Å.

cleaved. Also, the self-reaction is found to produce a tetroxide. However, we have here two incompatible results with respect to the superiority of the assumed reaction models. The value of ΔW in Table 2 shows that Model II is the most favorable reaction pathway for the self-reaction, whereas the atomic bond population in Fig. 3 shows that Model Ib is more favorable for the formation of a new $O_1 \cdots O_{1'}$ bond.

Whichever of the pathways corresponding to Model Ib and II the self-reaction takes, the present calculation demonstrates that the reaction path is that for which the two terminal oxygen atoms approach each other and the two inner oxygen atoms do not approach each other as much as the terminal atoms, with the production of a tetroxide resulting. Consequently, the self-reaction process is not that described by Scheme 4. In the present calculation, the system composed of two hydroperoxyl radicals was selected as the reaction model. It is reasonable to consider that a peroxyl radical has an SOMO which is localized mainly over the two oxygen atoms even if the H atom of the hydroperoxyl radical is replaced by any substituent group. Consequently, the results obtained from the present calculation for such a simple system do not appear to be changed markedly upon the replacement of the H atom by a substituent group.

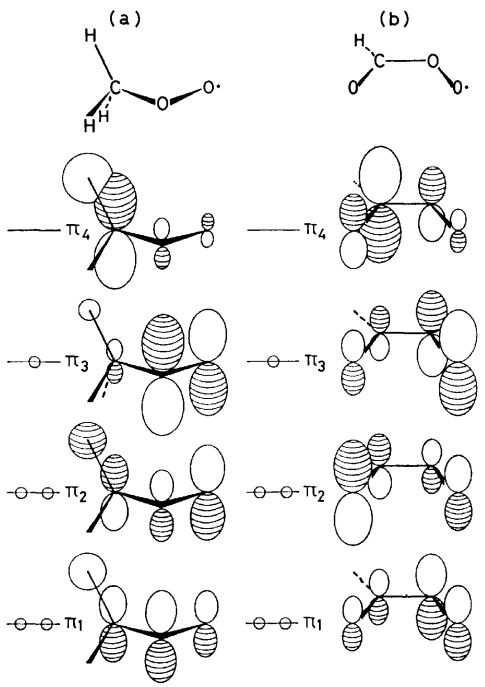

Fig. 4. (a); The schematic representation of the π-type MO's of the methylperoxyl radical. (b); The schematic representation of the π-type MO's of the formylperoxyl radical.
These MO's are obtained by the EH MO method. The geometry of these radicals is obtained from the Pople's standard bond length and bond angle (see Ref. 13).

Discussion

In the previous section, the pathways and mechanisms for the self-reactions of peroxyl radicals were investigated using the ΔW method and the self-reaction was shown to give a tetroxide if the terminal oxygen atoms are initially in contact with each other. However, the overall rate constant ($2k_t$) of self-reaction T is quite different from those of self-reactions SP and A, as is shown in Table 3.[1b] The slowness of self-reaction T is primarily due to the fact that the decomposition of the tetroxide intermediate into two alkoxyl radicals and an oxygen molecule requires significant activation energy.[17] Generally, the difference in the rate constants for the three types of self-reactions is ascribed mainly to the differences in the activation energy for tetroxide decomposition.[17b] However, since the difference in the rate constants between self-reaction T and self-reaction SP (or self-reaction A) is much more significant than that expected from the tetroxide decomposition, these may have quite different mechanisms.

The interaction energy, ΔW, is entirely dependent upon the extent of MO overlapping obtained independently for two peroxyl radicals and, therefore, its value can be estimated roughly by analyzing the shape of these MO.[10] Then, even without actually calculating the ΔW, the self-reaction mechanism can be conveniently discussed in terms of the shape of some particular (*frontier*) MO. On this basis, the mechanism of self-reaction SP and self-reaction A will be discussed.

Self-reaction of p- *and* s-*Alkylperoxyl Radicals.* First, the shapes of the MO of a methylperoxyl radical are obtained conveniently by the extended Hückel (EH) MO method[18] and are sketched in Fig. 4(a). In this figure, only the π-type MO are illustrated, because none of the residual MO are as active in causing the important orbital interaction. It was found that the π_3 orbital is the SOMO of the methylperoxyl radical localized over two oxygen atoms. In self-reaction SP, one peroxyl radical abstracts the methyl hydrogen atom of the other and an alcohol is produced. For the geometrical position of two methylperoxyl radicals such that the SOMO-SOMO interaction becomes large, the tetroxide may be produced as was discussed in the previous section. However, for this geometry, the process of hydrogen abstraction cannot be explained. In consideration of this, the CT interaction between the MO of one radical species localized at the C–H bond of a methyl group and the SOMO (π_3) of the other appears to be important in causing reactions other than that producing the tetroxide. In Fig. 4(a), the π_2 orbital is the highest occupied (HO) MO spreading over the C–H bond. When the reacting system has the geometry shown in Fig. 5, the CT interaction from the HOMO (π_2) to the SOMO (π_3) shown in Fig. 5(a and b) is found to contribute to the stabilization of the system. This stabilization corresponds to the higher reactivity of each radical species. This is because, in the reacting regions ($H_4 \cdots O_{2'}$ and $O_1 \cdots O_{1'}$), the lobes of two MO's (π_2 and π_3) overlap in phase. On the other hand, for this geometry, the SOMO-SOMO interaction does not contribute as much because of its nodal properties. Especially, the (HOMO→SOMO) CT interaction shown in Fig. 5(b) is more important than that shown in Fig. 5(a), for these MO have large lobes at the reacting regions ($H_4 \cdots O_{2'}$ and $O_1 \cdots O_{1'}$). The roles of the CT interactions other

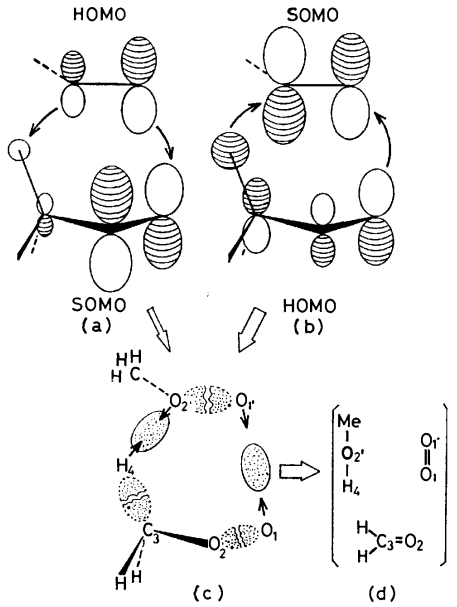

Fig. 5. The CT interaction between the HOMO and SOMO in the self-reaction of the methylperoxyl radicals.

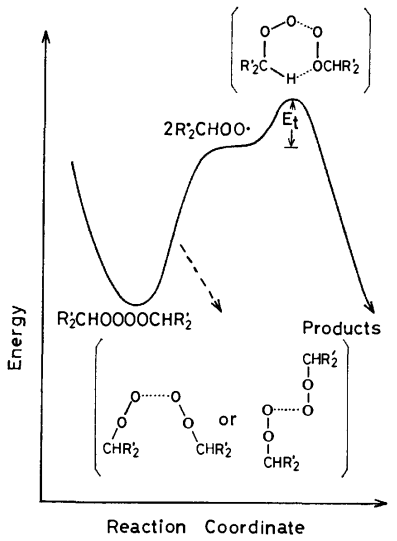

Fig. 6. The potential energy-reaction coordinate curve of the self-reaction SP taken from Ref. 6(b). The six-centered transition state obtained in the present work is additionally depicted and the two-centered path producing a tetroxide is also pictured.

than those depicted in Fig. 5 are minor due to the small value of the corresponding MO overlapping. The CT interaction depicted in Fig. 5(b) will be examined in more detail. This CT interaction contributes to the formation of the new $O_1 \cdots O_{1'}$ and $H_4 \cdots O_{2'}$ bonds and the disappearance of the C_3–H_4 and O_1–O_2 bonds through the loss of bonding electrons. Furthermore, the formation of the C_3=O_2 double bond and the disappearance of the $O_{1'}$–$O_{2'}$ bond can also be explained in terms of this CT interaction. Thus, self-reaction SP gives an alcohol, a carbonyl and an oxygen molecule *via* the *six-centered configuration.*

From the above discussion, self-reaction SP can be described as follows. In the initial stage of the reaction, two terminal oxygen atoms (O_1 and $O_{1'}$ in Fig. 5) approach each other. In this step, if the tetroxide intermediate is not produced, then the reaction system has the six-centered configuration shown in Fig. 5. In this case, the CT interaction between the HOMO spreading over the C_3–H_4 bond and the SOMO is of importance in causing the above-mentioned bond interchange. At this point, the self-reaction produces non-radical products without forming a tetroxide intermediate, as proposed by Russell (see Scheme 2). This picture of the reaction mechanism corresponds to a single-step concerted reaction. However, the bond formation is considered to be concerted, but non-synchronous, as is proposed in many cases of concerted cycloaddition.[14,19] While for cycloaddition (*e.g.*, 1,3-dipolar cycloaddition) two bonds are formed, the bond formation of one of these is, however, advanced with respect to that of the other in the transition state. When self-reaction SP does not have the six-centered configuration, it may readily produce a tetroxide. There is ESR evidence for the formation of a diamagnetic dimer (probably a tetroxide) from two cyclopentylperoxyl radicals.[6b] In short, there are probably two paths for self-reaction SP. One is the path in which a tetroxide is produced, and the other gives an alcohol, a carbonyl and an oxygen molecule. This reaction picture is in agreement with that suggested by Howard and Bennett.[6b] Although these authors gave no detailed discussion of the structure of the transition state in their mechanism, they suggested that in self-reaction SP one pathway giving non-radical products is different from the other which produces a tetroxide. Furthermore, they represented this suggestion schematically using the potential energy-reaction coordinate curve drawn in Fig. 6. When we examine the six-centered configuration of the transition state introduced in this work, it is seen that the present picture of self-reaction SP is in line with their suggestion. According to this picture and the experimental evidence mentioned above, the products and, furthermore, the isotopic effect are easily interpreted. If two peroxyl radicals react in the singlet spin state, the spin-conservation rule requires either that the oxygen molecule evolved in the self-reaction should be formed in an excited singlet spin state or that it should be in a ground triplet state and the carbonyl in an excited triplet state.[1b] Many experiments show that the oxygen molecule is formed in an excited singlet state.[20] Such data is in line with the present picture of the single-step concerted reaction. Thus, it is probable that self-reaction SP has a six-centered transition state as proposed by Russell, although the Russell scheme (Scheme 2) should be somewhat modified to the present picture mentioned above.

Self-reaction of Acylperoxyl Radicals. The overall rate constant for self-reaction A is much larger than that of self-reaction T, as is shown in Table 3. The acylperoxyl radical has a C=O bond at the α-carbon atom which corresponds to the C–H bond of the *p*- and *s*-alkylperoxyl radicals. For self-reaction A, the possibility of a six-centered transition state of the self-reaction

TABLE 3. THE OVERALL RATE CONSTANTS ($2k_t$) FOR THE SELF-REACTIONS[1b)]

Radical	$2k_t$, $M^{-1}s^{-1}$	Self-reaction[a)]

Acylperoxyl	$10^6—10^{11}$	A

a) The classification of the self-reactions is given in Table 1.

will be examined. To determine the shape of the MO of the acylperoxyl radical, those of a formylperoxyl radical were obtained simply using the EH MO method. In Fig. 4(b), only the π-type MO are depicted according to the same criterion as that for the methylperoxyl radical. From Fig. 4(b), it is found that the π_3 orbital is an SOMO localized appreciably about two oxygen atoms (O–O bond) and that the π_2 orbital is the HOMO spread over the C=O double bond. In Fig. 7 is shown the mode of the mutual CT interaction between the HOMO of one radical species and the SOMO of the other. The CT interactions other than those are not as important for the same reason as the case of the methylperoxyl radical. The (HOMO→SOMO) CT interaction in Fig. 7(a) is more important than that in Fig. 7(b) in the sense that the former interaction is caused by the larger overlap in the reacting regions ($O_2\cdots O_4'$ and $O_1\cdots O_1'$). Looking at the mode of the (HOMO→SOMO) CT interaction of Fig. 7(a and b), one can reasonably understand the process of bond interchange which is similar to the case of the methylperoxyl radical. The intermolecular $O_1\cdots O_1'$ and $O_2\cdots O_4'$ bonds are formed and the O_2'–C_3' single bond is converted to the O_2'=C_3' double bond. Furthermore, the O_1–O_2 and O_1'–O_2' bonds disappear and the C_3'=O_4' double bond is converted to the C_3'–O_4' single bond. Thus, it is anticipated that, in order to

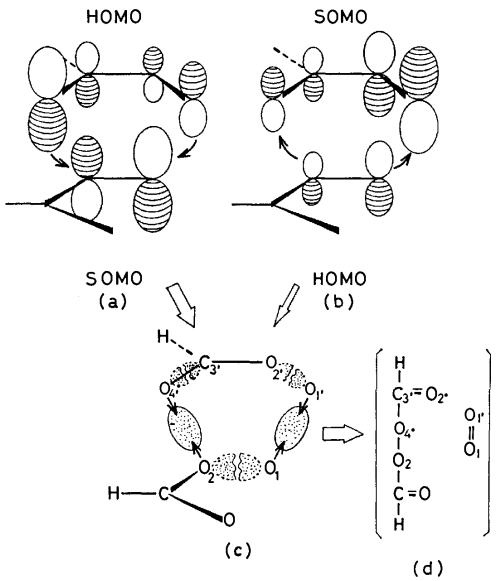

Fig. 7. The CT interaction between the HOMO and SOMO in the self-reaction of the formylperoxyl radicals.

bring about effective (HOMO→SOMO) CT interactions, self-reaction A has the six-centered configuration giving no tetroxide, but non-radical products (the peroxide and oxygen molecules). This picture of the reaction mechanism also corresponds to a single-step concerted reaction. If self-reaction A proceeds along this reaction path, it leads again to the prediction that self-reaction A gives an oxygen molecule in the excited singlet state. Unfortunately, since the data for the spin state of the oxygen molecule produced in self-reaction A do not yet appear to be available, further experimental verification is desirable. It should be noted that in the approach of the two terminal oxygen atoms, self-reaction A may also give a tetroxide as in the case of self-reaction SP.

Conclusion

From this work, a discussion based on the ΔW method was made with respect to the self-reaction of peroxyl radicals. First, the interaction energy, ΔW, was calculated using the simplest peroxyl radical (HOO·). One implication derived from this calculation is that, aside from the superiority of either the trapezoid or trans configurations, the two-centered transition state is more probable than the four-centered one. Second, when three types of substituents (*t*-alkyl, *s*- and *p*-alkyl, and acyl) are taken into account, other reaction mechanisms involving them are introduced. In the case of the self-reaction of both *s*- and *p*-alkylperoxyl and acylperoxyl radicals, the termination is a single-step concerted reaction with a six-centered geometrical configuration. In the former self-reaction, a C_α–H bond is ruptured whereas, in the latter self-reaction, a C_α=O double bond is converted into a single C_α–O bond. There, the CT interaction between the HOMO spread over the C–H or the C=O bond of one peroxyl radical and the SOMO of the other is of importance in triggering the bond interchange. However, in the self-reaction, *t*-alkylperoxyl radicals which do not have a C_α–H bond cannot undergo this termination reaction, but produce solely a tetroxide.

The authors would like to express their graditude to the Data Processing Center of Kyoto University for its generous permission to use the FACOM 230-75 computer. The MO calculations were carried out under financial support from the Ministry of Education of Japan (Grant-in-Aid No. 139012).

Mixed Monolayers of Long Normal Chain Fatty Acids with Long Normal Chain Fatty Alcohols

Hirosi MATUO, Kimio HIROMOTO, Kinsi MOTOMURA, and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received June 23, 1977)

The mixed monolayers of long normal chain fatty acids with long normal chain fatty alcohols were studied at various compositions and temperatures. The π-A curves of these systems were measured and the two-dimensional phase diagrams were obtained. The partial molar enthalpy change from the expanded to the condensed state was calculated. It was observed that the phase diagram and enthalpy change of these systems are similar to those previously obtained from the mixed monolayers of long normal chain fatty acids. The miscibility of these systems changes with the increase in the difference of the chain length, as in the systems of fatty acids. It was concluded that the monolayer behavior of the mixed system of an acid and an alcohol is analogous to that of the mixed system of the acid and an acid which contains one more carbon atom in a molecule than the corresponding alcohol.

Many workers have extensively studied the monolayers of long normal chain fatty acids.[1-3] Previously we reported some mixed monolayers of these acids and analyzed the phase behavior of the mixed films.[4,5] The thermodynamic treatment of multicomponent surface films was employed.[6,7] It was found that the miscibility of these films varies with the difference of the chain length. But investigations of mixed films of acids with alcohols have been reported much less frequently. The aim of this paper is to clarify the thermodynamic behavior of the mixed film of a fatty acid and an alcohol by taking advantage of the results for mixed films of fatty acids.

Experimental

Tetradecanoic (C_{14}), pentadecanoic (C_{15}), and octadecanoic (C_{18}) acids were employed in this experiment. 1-Tetradecanol ($C_{14}OH$) and 1-hexadecanol ($C_{16}OH$) were used as the long normal chain fatty alcohols. They were purified by fractional distillation and recrystallizations. Benzene, a spreading solvent, was purified carefully by the usual method. The substrate, 0.001 M HCl, was prepared by using twice distilled water and hydrochloric acid (Wako super special grade).

The surface pressure of the monolayers was measured by a Wilhelmy-type surface balance. The temperature was kept constant within $\pm$0.2 °C during the experiment.

Results and Discussion

Typical surface pressure-area curves obtained for the C_{14}–$C_{14}OH$ and C_{14}–$C_{16}OH$ systems at 25 °C are shown in Figs. 1 and 2, respectively. These isotherms are similar to those previously reported for the C_{14}–C_{15} and C_{14}–C_{17} (acid–acid) systems.[4,7] The characteristics of each system may be expressed briefly as follows:

C_{14}–$C_{14}OH$ system (Fig. 1) : the π-A curves of pure tetradecanoic acid and 1-tetradecanol are of the expanded type at 25 °C. When they are mixed, the transition pressure decreases from the value of C_{14} to that of $C_{14}OH$ with increase in the content of the latter. Recently, Roberts, Österlund, and Axberg[8] have claimed that a mixture of 6.12×10^{15} molecules tetradecanoic acid and 1.53×10^{15} molecules 1-hexadecanol spread from petroleum ether together has no transition from the liquid expanded state to the liquid condensed state at 20 °C and pH 2. But in our experimental data at 20 °C and pH 3, the mixed monolayer of the system in which the mole fraction of C_{14} is 0.8 clearly shows a transition at the surface pressure 2.9 dyne/cm.

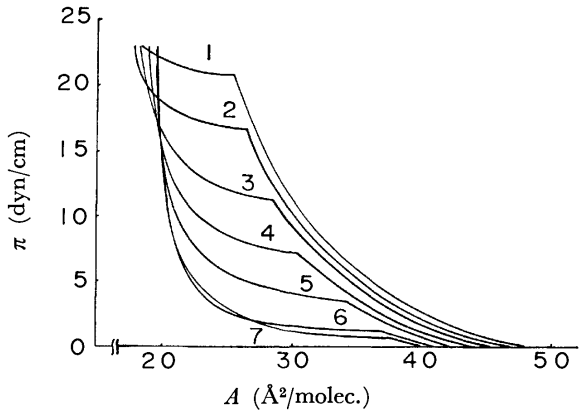

Fig. 1. Surface pressure *vs.* mean area curves of the tetradecanoic acid–1-tetradecanol monolayers at 25 °C: 1, $X_2^\sigma=1$(tetradecanoic acid); 2, 0.9; 3, 0.7; 4, 0.5; 5, 0.3; 6, 0.1; 7, 0(1-tetradecanol).

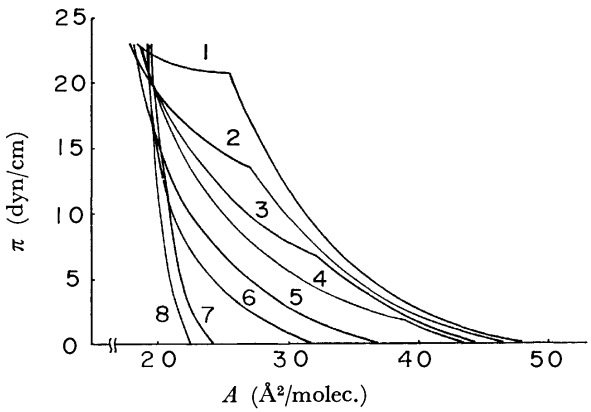

Fig. 2. Surface pressure *vs.* mean area curves of the tetradecanoic acid–1-hexadecanol mixed monolayers at 25 °C: 1, $X_2^\sigma=1$(tetradecanoic acid); 2, 0.9; 3, 0.8; 4, 0.7; 5, 0.6, 6, 0.5; 7, 0.3; 8, 0(1-hexadecanol).

C_{14}–$C_{16}OH$ system (Fig. 2) : the pure $C_{16}OH$ forms a stable condensed film. The mixtures of the acid and alcohol with molar ratios from 9:1 to 7:3 give expanded monolayers which have transition pressures. On the other hand, in mixtures less than 3 : 2 in the

molar ratio, the monolayers are considerably condensed and the transition pressure disappears.

When a binary condensed monolayer is in equilibrium with a binary expanded monolayer, the variation of the equilibrium surface pressure π^{eq} with mole fraction of component 2 in the expanded monolayer $X_2^{\pi,e}$ is related to thermodynamic quantities of the monolayers.[6] According to Eq. 38 in the preceding paper,[6]

$$X_2^{\pi,c} = X_2^{\pi,e} + [(A^c - A^e)X_1^{\pi,e}X_2^{\pi,e}/kT] \times (\partial\pi^{eq}/X_2^{\pi,e})_{T,p}, \quad (1)$$

where the mean area per molecule A has been used with superscripts c and e indicating condensed and expanded films, respectively. We can calculate the numerical values of $X_2^{\pi,c}$, the mole fraction of component 2 in the condensed film, from the dependence of π^{eq} on $X_2^{\pi,e}$. The results evaluated for the C_{14}–$C_{14}OH$ and C_{14}–$C_{16}OH$ systems at 25 °C are shown in Figs. 3 and 4.

The C_{14}–$C_{14}OH$ system (Fig. 3) gives a typical pattern of a simple mixed system in which the two components are miscible in all compositions. This behavior is identical with that of the C_{14}–C_{15} system previously obtained at 20 °C.[7] In the C_{14}–$C_{16}OH$ system, as shown in Fig. 4, the situation of miscibility is somewhat different from the C_{14}–$C_{14}OH$ system. The expanded phase disappeared in the monolayers in which the mole fractions of tetradecanoic acid are below 0.65. A similar phase diagram has been observed for the C_{14}–C_{17}[7] and C_{14}–$C_{14}OH$ systems at 20 °C. We consider that, in this region, the mixed film changes from the expanded to the condensed state in the process of compression at low surface pressures. This shows that the miscibility of the two components at the same temperature gradually decreases with increase in the difference of carbon number between the two film components. When the surface pressure reaches 20.8 dyne/cm, the transition pressure of the pure tetradecanoic acid monolayer at 25 °C, the mixed film perfectly changes into the condensed film.

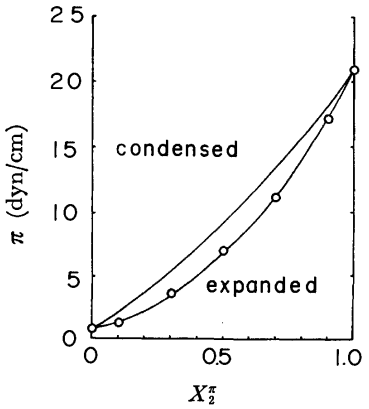

Fig. 3. Phase diagram of the tetradecanoic acid-1-tetradecanol mixed monolayer at 25 °C.

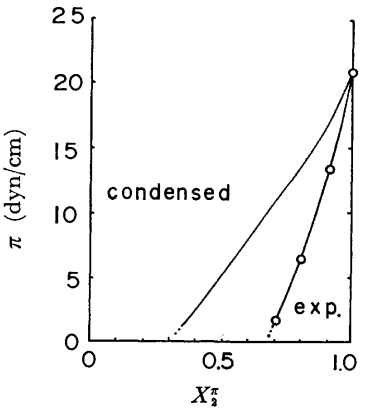

Fig. 4. Phase diagram of the tetradecanoic acid-1-hexadecanol mixed monolayer at 25 °C.

Phase diagrams of the C_{15}–$C_{14}OH$ and C_{15}–$C_{16}OH$ systems are also shown in Figs. 5 and 6. The appearance of these phase diagrams corresponds to that of the C_{14}–$C_{14}OH$ and C_{14}–$C_{16}OH$ systems, respectively. In the C_{15}–$C_{14}OH$ system, as shown in Fig. 5, the transition range is somewhat smaller in composition than that in the C_{14}–$C_{14}OH$ system. This indicates that the miscibility of the C_{15}–$C_{14}OH$ system is likely to be more ideal than that of the latter.[7] This is also applicable to the C_{15}–$C_{16}OH$ system (Fig. 6) as compared with the C_{14}–$C_{16}OH$ system. According to these results, we would conclude that the monolayer of a long normal chain fatty alcohol is analogous to that of a fatty acid which has one more carbon atom than the corresponding alcohol molecule.

The π^{eq}-$X_2^{\pi,e}$ curves obtained for the $C_{14}OH$–$C_{16}OH$ and C_{18}–$C_{14}OH$ systems at 30 °C are shown in Figs. 7 and 8. The two-dimensional phase diagram for the $C_{14}OH$–$C_{16}OH$ system (Fig. 7) seems to be the same type as that of the C_{14}–$C_{16}OH$ and C_{15}–$C_{16}OH$ systems.

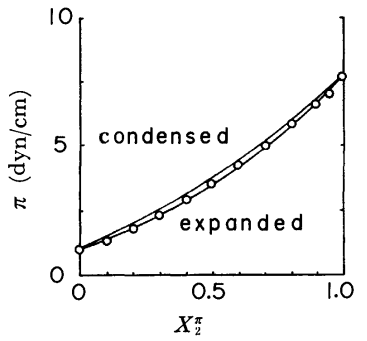

Fig. 5. Phase diagram of the pentadecanoic acid-1-tetradecanol mixed monolayer at 25 °C.

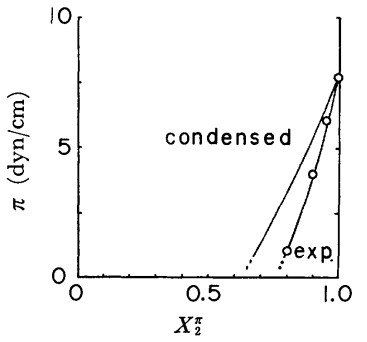

Fig. 6. Phase diagram of the pentadecanoic acid-1-hexadecanol mixed monolayer at 25 °C.

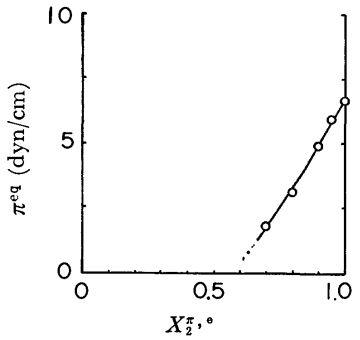

Fig. 7. π^{eq}-$X_2^{\pi,e}$ curve of the 1-tetradecanol-1-hexadecanol mixed monolayer at 30 °C.

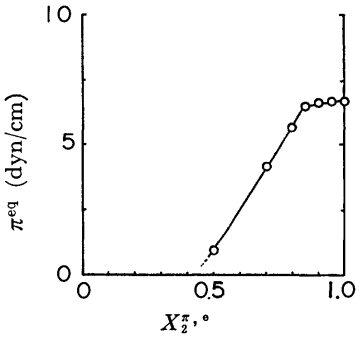

Fig. 8. π^{eq}-$X_2^{\pi,e}$ curve of the octadecanoic acid–1-tetradecanol mixed monolayer at 30 °C.

In the C_{18}–$C_{14}OH$ system (Fig. 8), the π^{eq}-$X_2^{\pi,e}$ curve is complicated because of the presence of the break point. However, by the analysis of the fatty acid's phase diagram,[7] it was found that this system is similar to the C_{14}–C_{19} system.

From the variation of the transition pressure with temperature, we can calculate the thermodynamic quantities such as the partial molar entropy and enthalpy of the transfer from expanded to condensed phase. We have reported the following expression (Eq. 42 in Ref. 6):

$$\bar{s}_i^c - \bar{s}_i^e = (\bar{s}_i^{\pi,c} - \bar{s}_i^{\pi,e}) + (a^e - \bar{a}_i^e)(\partial\pi^e/\partial T)_{p,x_w^e,x_2^{\pi,e}} - (\bar{a}_i^c - \bar{a}_i^e)(\partial\gamma^0/\partial T)_p, \quad i = 1, 2 \qquad (2)$$

where $\bar{a}_i$ is the partial molar area of component i in the monolayer $\partial\pi^e/\partial T$ is the variation of surface pressure with respect to temperature at a given state of the expanded monolayer, γ^0 is the surface tension of water, and the subscript w represents water. In the above equation, $\bar{s}_i^\pi$ is the partial molar entropy of component i in the equilibrium monolayer, and $\bar{s}_i^c - \bar{s}_i^e$ is the thermodynamically well-defined partial molar change in entropy at the phase transition from the expanded to the condensed state.[5,6] The corresponding enthalpy change can be evaluated by the following expression, which has been obtained as Eq. 43 in Ref. 6:

$$\bar{h}_i^c - \bar{h}_i^e = T(\bar{s}_i^c - \bar{s}_i^e). \qquad (3)$$

We have assumed that $\bar{A}_1^e = \bar{A}_2^e = 20$ Å^2/molec. and $\bar{A}_1^c = \bar{A}_2^c = 18$ Å^2/molec.; then we can calculate the values of $\bar{s}_i^c - \bar{s}_i^e$ from Eq. 2. $\bar{h}_i^c - \bar{h}_i^e$ can also be evaluated from Eq. 3.

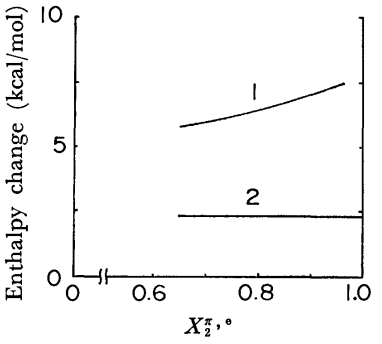

Fig. 9. Partial molar enthalpy change of the phase transition, $-(\bar{h}_i^c - \bar{h}_i^e)$ *vs.* mole fraction in the expanded monolayer, $X_2^{\pi,e}$, curves of the tetradecanoic acid–1-tetradecanol at 20 °C: 1, 1-tetradecanol; 2, tetradecanoic acid.

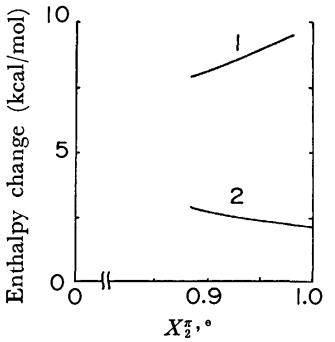

Fig. 10. Partial molar enthalpy change of the phase transition, $-(\bar{h}_i^c - \bar{h}_i^e)$ *vs.* mole fraction in the expanded monolayer, $X_2^{\pi,e}$, curves of the tetradecanoic acid–1-hexadecanol at 20 °C: 1, 1-hexadecanol; 2, tetradecanoic acid.

The calculated values for the C_{14}–$C_{14}OH$ and C_{14}–$C_{16}OH$ systems at 20 °C are shown in Figs. 9 and 10. In the former system (Fig. 9), the enthalpy change of the tetradecanoic acid has a nearly constant value independent of $X_2^{\pi,e}$ in the range of the composition shown. The partial molar enthalpy change of the tetradecanoic acid, 2.2 kcal/mol, is fully acceptable in comparison with that of a mixed film of long normal chain fatty acids.[7] On the other hand, the partial molar enthalpy change of the 1-tetradecanol decreases slightly with decreasing $X_2^{\pi,e}$. The enthalpy change of 1-tetradecanol is larger than that of tetradecanoic acid at the same composition. This indicates that this alcohol is less stable in the expanded state and needs much more heat for the transition from the liquid condensed to the expanded state. This agrees with the experimental result that the transition pressure is elevated by the addition of tetradecanoic acid. In the case of the C_{14}–$C_{16}OH$ system (Fig. 10), the change of partial molar enthalpy of the tetradecanoic acid decreases, while that of the 1-hexadecanol increases, with increasing $X_2^{\pi,e}$, in the range of the composition shown in the figure. The pattern of these two curves is identical with that of the C_{14}–C_{17} system,[7] but the slope of these curves is smaller than that of the latter. This is related to

the miscibility of the two components. Taking advantage of the results for C_{14}–C_{15}, C_{14}–C_{17}, and C_{14}–C_{19} systems,[7] it seems that the more ideal the miscibility, the smaller the inclination is.

In conclusion, mixed monolayers of long normal chain fatty acids with long normal chain fatty alcohols have the same behavior as that of mixed monolayers of fatty acids. That is to say, the acids and alcohols are miscible with each other in the expanded as well as in the condensed state. And the miscibility of two components gradually decreases with an increase in the difference of carbon number between the two components. Finally, we conclude that the monolayer of the alcohol is analogous to that of a fatty acid which contains one more carbon atom in the molecule than the corresponding alcohol.

The application of an Improved d.c. Polarization Technique to the Electronic Conductivity Measurements of α-AgI and AgBr

Junichiro MIZUSAKI, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 27, 1977)

An improvement was made in the d.c. polarization technique which is used for the measurement of the electronic conductivity of solid electrolytes. In the electrochemical cell, Ag/AgX (X=Br or I)/carbon, the carbon electrode was sealed with AgX in the bottom of a Pyrex tube so that the electrode reaction at the AgX/carbon interface could be suppressed in the steady state. Using the improved d.c. polarization cell, measurement was made of the electronic conductivity of AgI in the temperature range from 330 to 500 °C, and that of AgBr, at temperatures from 375 to 400 °C, as a function of the halogen partial pressure, P_{X_2}. It was found that the electronic conduction of α-AgI is *p*-type and that the electronic conductivity is proportional to $P_{I_2}^{1/2}$. The electronic conductivity of AgBr was found to be proportional to $P_{Br_2}^{-1/2}$ in a low-pressure range of bromine, and proportional to $P_{Br_2}^{1/2}$ in a high-pressure range.

Hebb-Wagner's d.c. polarization technique[1,2] is generally used for the determination of the electronic conductivity of solid electrolytes. For the determination of electronic conductivity by this technique, a complete blocking of the ionic current is necessary. Thus far, the following two types of cell arrangement have been employed for the measurement of AgI and AgBr:

(I) ⊖ Ag/AgX/carbon, inert atmospere ⊕

(II) ⊖ carbon, inert atmospere/AgX/carbon, halogen gas atmospere ⊕

where AgX denotes AgI or AgBr. However, in these cells the ionic current can not be blocked completely, because one of the carbon electrodes is open to the inert atmospere, and the chemical equilibrium can not be established at the electrode/AgX interface.

Using a cell of Type (I), Ilschner[3] measured the electronic conductivity of AgI and AgBr and found that AgI shows the *p*-type electronic conduction in the temperature range from 267 to 332 °C, but the slope of the logarithmic plots of the current against the applied potential difference was 1.2 times larger than that expected by Wagner's theory.[2] Above 332 °C, the electronic conductivity could not be determined because of the increased decomposition current. In the case of AgBr, the *n*-type conduction was observed under the small applied potential difference in the temperature range from 333 to 372 °C, but the decomposition current increased with the increase in the applied potential difference.

Raleigh investigated the electronic conduction of AgBr at temperatures between 250 and 400 °C using a cell of Type (II); he observed both *n*- and *p*-type conductions, in accordance with the applied potential difference, but the decomposition current became large with a decrease in the applied potential difference.[4]

As has been mentioned above, as to α-AgI (stable above 146 °C) and AgBr, no work[3-6] has succeeded in showing whether or not the relation between the current and the applied potential difference coincides with the prediction by Wagner's theory.

The purpose of the present study is to devise a d.c. polarization cell in which the decomposition current is completely blocked and to determine the electronic conductivity of α-AgI and AgBr as a function of the halogen partial pressure.

Improved d.c. Polarization Cell

A conventional d.c. polarization cell of Type (I) is shown in Fig. 1. In the cell, inert gas flows over the electrodes and carries halogen gas from the AgX/carbon interface. Therefore, a polarization cell of this type can not block the decomposition current completely.

In order to obtain a complete ion-blocking condition, the authors devised the d.c. polarization cell shown in Fig. 2. In this cell, AgX seals the carbon electrode completely in a small space at the bottom of a Pyrex tube. When an electrical potential difference is applied between the carbon (positive) and the silver (negative) electrodes, the partial pressure of halogen gas, P_{X_2}*, in the space changes as a result of charging and discharging, finally reaching the value

$$P_{X_2}^* = P_{X_2}^\circ \exp\left(\frac{2FE}{RT}\right), \quad (1)$$

where $P_{X_2}^\circ$ denotes the halogen partial pressure in equilibrium with the AgX co-existing with metallic silver and where E denotes the applied potential difference. Under this condition, the ionic current ceases to flow and Hebb-Wagner's d.c. polarization technique can be applied. We call a cell of this type an improved

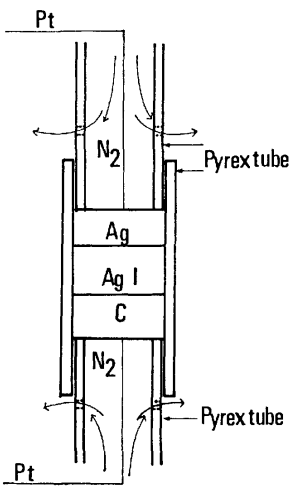

Fig. 1. Conventional type cell.

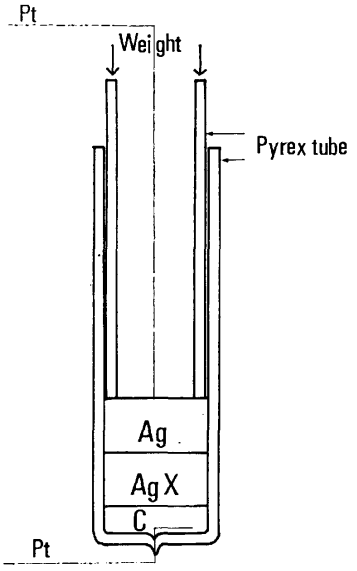

Fig. 2. Improved cell.

d.c. polarization cell.

Equation 1 can be rewritten as follows by using the silver chemical potential, μ_{Ag}:

$$EF = \mu_{Ag}^{\circ} - \mu_{Ag}^{*}, \quad (2)$$

where μ_{Ag}° denotes μ_{Ag} in AgX in equilibrium with metallic silver and where μ_{Ag}^{*} is that of AgX at the AgX/carbon interface. Using the silver activity, a_{Ag}, we obtain

$$EF = -RT \ln a_{Ag}^{*}, \quad (3)$$

where a_{Ag}^{*} denotes the a_{Ag} in AgX at the AgX/carbon interface and where the a_{Ag} in AgX co-existing with metallic silver is taken as unity.

Experimental

Cells and Samples. In order to compare the improved cell with the conventional-type cell, measurements were carried out using both types of cells (Figs. 1 and 2). The cells were constructed in a Pyrex tube, 10 mm in inner diameter. The silver electrode, carbon electrode, and AgX pellet used were the same as those used in a previous work.[7] The AgX pellet was sandwiched by the silver and carbon electrodes and pressed by means of a spring to ensure contact. In a conventional-type cell, purified nitrogen gas was let flow over the surface of the electrodes. In an improved cell, a Pt lead wire was sealed at the lower end of the Pyrex tube. Then the cell was heated at about 400 °C so that the AgX pellet could deform plastically by a slight pressure and come in close contact with the wall of the Pyrex tube. Thus, the carbon electrode was completely sealed in a small space.

Coulometric Study. Prior to the construction of the cells, the weights of the silver electrode and the AgI pellet were measured. After the cell construction, a constant potential difference of 400 or 450 mV was applied at 500 °C for several days. The current decay was recorded by means of an electric recorder. The electricity passed through the cell was calculated by integrating the current-time curve. Then, the cell was disassembled and the weights of the silver electrode and AgI pellet were measured again.

Measurement of the Current and Potential in the Steady State. Measurements were performed at temperatures from 330 to 500 °C for AgI, and at 375 and 400 °C for AgBr, by the use of the improved cell. For comparison, a conventional-type cell was also used for AgI at 500 °C. When the steady state current exceeds about 5 μA, the measurement could be carried out by applying a constant potential difference between the electrodes by means of a d.c. voltage regulator. However, current fluctuation was caused even in the steady state by the unavoidable slight fluctuations in the temperature or the applied potential difference. This current fluctuation became a serious obstacle to the measurement when the steady-state current was lower than about 5 μA. The use of the circuit shown in Fig. 3 was found to be very effective in avoiding such difficulty, and so it was mainly employed in the present work. In this circuit, the standard resistance, R, was connected in series with the cell, and a constant potential difference was applied between the two ends of the series. The resistance showed a kind of buffer action on the fluctuation. When E deviated positively from the relation in Eq. 1, the drop in the current or the ohmic value due to the resistance increased. Consequently, the potential difference loaded to the cell E decreased. Thus, the fluctuation was dampened. When the value of R was chosen so that the ohmic drop at this resistance was 1 to 10% of the applied potential difference in the steady state, the fluctuation of the current and E was effectively suppressed.

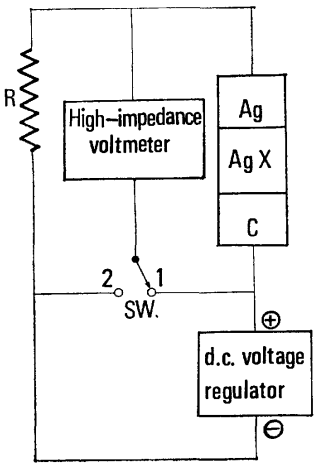

Fig. 3. Circuit diagram for the measurement.
$R = 100\ \Omega - 10\ k\Omega$

The current passed through the cell was determined from the ohmic drop at the resistance measured by means of a high-impedance voltmeter, which was also used for the measurement of the applied potential difference between the electrodes. The steady state was confirmed from the current and potential difference, which had been kept constant for at least 2 or 3 h.

The electric furnace and the temperature-controlling system were already described in a previous paper.[7]

Results and Discussion

Comparison of the Improved Cell with the Conventional-type One. The results of coulometry using both types of cells are shown in Table 1. When AgI is electrolysed, silver deposits on the silver electrode and iodine gas is released in the nitrogen atmosphere or diffuses into the carbon electrode. Therefore, the change in the sum of the weights of the silver electrode and the AgI pellet is equal to the quantity of iodine gas released by the electrolysis. The difference between the quantity

Table 1. Estimation of the ratio of the decomposition current to the electronic current

	Conventional-type cell		Improved cell	
	Run 1	Run 2	Run 11	Run 12
E/mV	450	400	450	400
Quantity of electricity passed through the cell; $[A]$/Faraday	1.90×10^{-3}	1.20×10^{-3}	11×10^{-4}	55×10^{-5}
Initial weight/g of sample				
Ag	2.41	2.65	2.72	7.37
AgI	1.51	1.43	1.37	1.66
Ag+AgI	3.93	4.08	4.09	9.02
Final weight/g of sample				
Ag+AgI	3.74	3.94	4.07	9.01
Weight loss/g	0.19	0.14	0.02	0.01
Released iodine; $[B]$/eqv.	1.5×10^{-3}	1.1×10^{-3}	2×10^{-4}	8×10^{-5}
The ratio; $[B]/([A]-[B])$	3.8	1.1×10	0.2	0.2

of the electricity passed through the cell in Faraday, $[A]$, and the quantity of released iodine in the equvalent, $[B]$, is equal to the quantity of electricity carried by the electrons. Thus, $[B]/([A]-[B])$ gives the ratio of the decomposition current to the electronic current. As is clearly shown in Table 1, the decomposition current is predominant in the conventional-type cell, while the electronic current is predominant in the improved cell.

It should be noted that even when an improved cell is used, the electrolysis of AgI occurs until the carbon electrode is saturated with iodine gas with a partial pressure of P_{I_2}*. The weight loss and the quantity of electricity, due to the electrolysis, are included in the values in Table 1. In the steady state, ion blocking would be effected more completely than that indicated in Table 1.

According to Wagner,[2] when AgX shows a p-type electronic conduction and when the electronic conductivity due to electron holes is expressed by Eq. 4, the relation between the current density, I and E under the complete ion-blocking condition can be represented by Eq. 5:

$$\sigma_h = \sigma_h^\circ \exp\left(\frac{\mu_{Ag}^\circ - \mu_{Ag}}{RT}\right), \quad (4)$$

$$\frac{IFL}{RT} = \sigma_h^\circ \left\{\exp\left(\frac{EF}{RT}\right) - 1\right\}, \quad (5)$$

where σ_h denotes the electronic conductivity in AgX, the silver chemical potential of which is kept at μ_{Ag}, where σ_h° denotes the σ_h of AgX in equilibrium with the metallic silver, and where L denotes the thickness of the AgX pellet. In the previous paper,[7] the authors showed, by the measurement of the chemical potential profile, that Eq. 5 holds for AgI at 500 °C.

When $EF \gg RT$, Eq. 5 can be rewritten as

$$\frac{IFL}{RT} = \sigma_h^\circ \exp\left(\frac{EF}{RT}\right), \quad (6)$$

that is

$$\log\frac{IFL}{RT} = \log\sigma_h^\circ + \frac{EF}{2.303RT}. \quad (7)$$

Therefore, if the decomposition current is completely blocked, the slope of the $\log I$-E plot should be $F(2.303RT)^{-1}$ and I should depend on L. However, if the decomposition current is predominant, I should be independent of L.

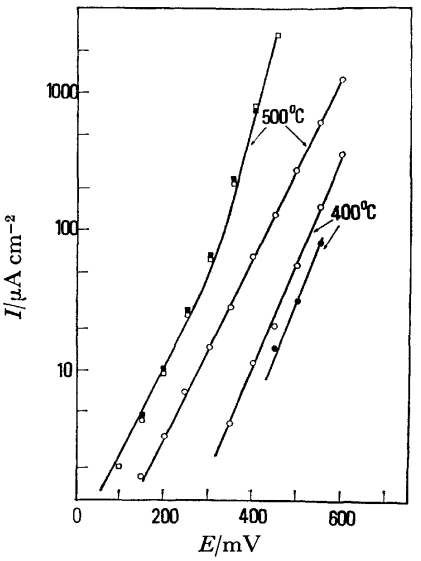

Fig. 4. Plots of I *vs.* E for AgI.
□: Conventional type cell, L=2.7 mm, ■: conventional type cell, L=6.0 mm, ○; improved cell, L=3.3 mm, ●: improved cell, L=6.5 mm.

The plots of the logarithm of I against E in the steady state, obtained by the use of both types of cells, are shown in Fig. 4. When the conventional-type cell is used, the slope of the plots is equal to $F(2.303RT)^{-1}$ in the $E<300$ mV region, while in the $E>300$ mV region the slope is $2F(2.303RT)^{-1}$. The current density is independent of L. When the improved cell is used, the slope of the plots is $F(2.303RT)^{-1}$ and is independent of E. The current density depends on L.

Those results indicate that the improved cell blocks the ionic current completely in the steady state and that the improved cell makes it possible to apply the d.c. polarization technique even when the conventional-type cell can not be used because of the predominant decomposition current.

The results obtained by means of the improved cell will be given below.

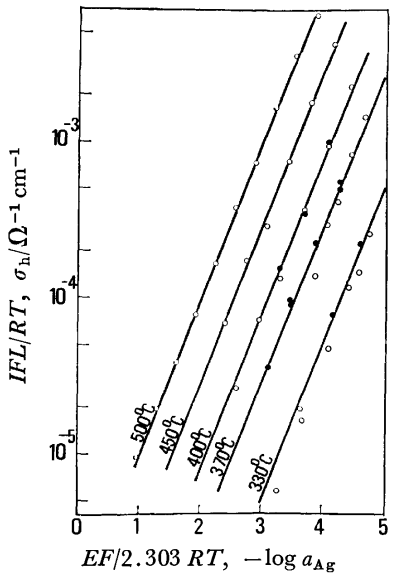

Fig. 5. Plots of σ_h *vs.* $\log a_{Ag}$ for AgI.
○: L=3.8 mm, ●: L=6.5 mm.

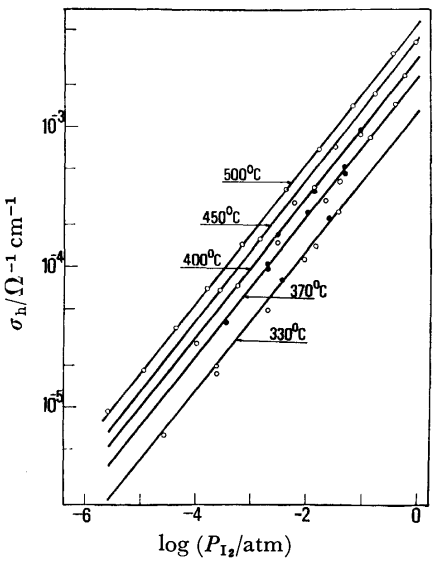

Fig. 6. Plots of σ_h *vs.* $\log P_{I_2}$ for AgI.
○: L=3.8 mm, ●: L=6.5 mm.

Electronic Conductivity of α-AgI. The results for AgI are given in Fig. 5 as a semi-logarithmic plot of $IFL(RT)^{-1}$ against $EF(2.303RT)^{-1}$. Using Eqs. 2, 4, and 6, we obtain

$$\sigma_h^* = \frac{IFL}{RT}, \tag{8}$$

where σ_h^* is the electronic conductivity of AgI at the AgI/carbon interface. By the help of Eq. 3. $EF(2.303RT)^{-1}$ can be substitued for $\log a_{Ag}^*$. Therefore, Fig. 5 also indicates the plots of σ_h against the a_{Ag} of AgI. The combination of Eqs. 1 and 3 yields

$$\log a_{Ag}^* = -\frac{1}{2}\log\frac{P_{I_2}^*}{P_{I_2}^\circ}. \tag{9}$$

Thus, $\log a_{Ag}^*$ can be expressed in terms of $P_{I_2}^*$. The plots of σ_h against P_{I_2} are shown in Fig. 6. The thermodynamic data summarized by Worrell and Hladik[8] are used for the calculation of $P_{I_2}^\circ$ in Eq. 9. We can see from Fig. 6 that the σ_h of AgI is proportional to $P_{I_2}^{1/2}$.

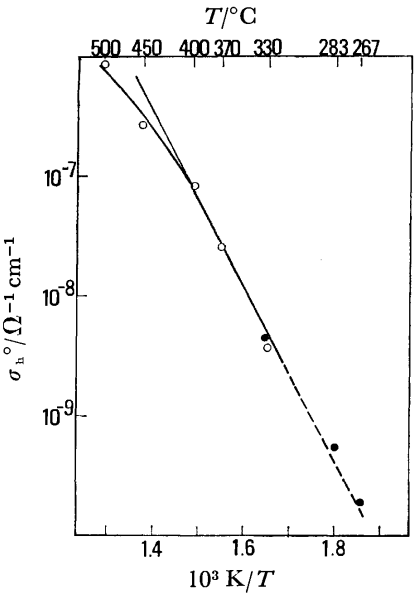

Fig. 7. Arrhenius plots of σ_h° for AgI.
○: This work, ●: by Ilschner.

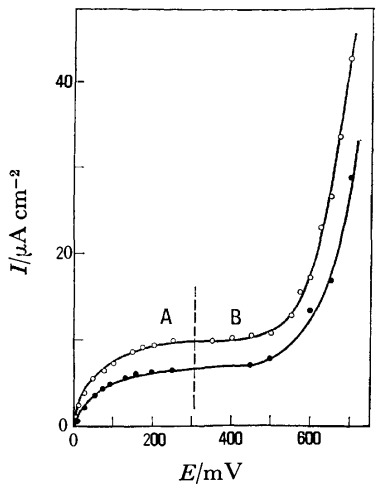

Fig. 8. Plots of I *vs.* E for AgBr at 400 °C.
○: L=2.2 mm, ●: L=3.3 mm.

The plots of σ_h° against T^{-1} are shown in Fig. 7. In the figure, the σ_h° values obtained by Ilschner[3] by the use of the conventional-type cell in a lower temperature range are also shown for the sake of comparison. The two sets of data agree well with each other. The data for the σ_h° of AgI in the temperature range from 267 to 400 °C are expressed as

$$\sigma_h^\circ = 2.76\times10^3 \exp(-1.64\times10^4\,T^{-1})\ (ohm^{-1}\,cm^{-1}). \tag{10}$$

Above 400 °C, the Arrhenius plot for σ_h° is curved. The reason for this is not clear, since the drift mobility or the concentration of electron holes have not been measured in this temperature range.

Electronic Conductivity of AgBr. The plots of I against E at 400 °C are shown in Fig. 8. In the present results, I is proportional to L^{-1}, so a complete ion

blocking is indicated. The curve can be divided into two parts, A and B. In Part A ($E<300$ mV) I asymptotically reaches a plateau, I_{pl}, while in Part B ($E>300$ mV) I increases exponentially from the plateau. It is known that AgBr shows an n-type electronic conduction when $E<300$ mV[7] and shows a p-type electronic conduction when the equilibrium bromine partial pressure is high. Therefore, Part A may correspond to the n-type region, and Part B to the region in which the p-type electronic conduction is predominant.

According to Wagner,[2] when the electronic conductivity of AgBr due to the conduction electrons is expressed by Eq. 11, the I-E relation under the complete ion-blocking condition can be represented by Eq. 12;

$$\sigma_e = \sigma_e^\circ \exp\left(\frac{\mu_{Ag}-\mu_{Ag}^\circ}{RT}\right), \tag{11}$$

$$\frac{IFL}{RT} = \sigma_e^\circ \left\{1-\exp\left(-\frac{EF}{RT}\right)\right\}. \tag{12}$$

Here, σ_e denotes the electronic conductivity at μ_{Ag}, while σ_e° denotes the σ_e of AgBr in equilibrium with metallic silver. The authors showed in the previous paper[7] that Eq. 12 holds for AgBr in the temperature range from 350 to 400 °C when $E<300$ mV.

Equation 12 indicates that, when $EF \gg RT$, I is equal to a constant value, I_{pl}, that is,

$$\frac{I_{pl}FL}{RT} = \sigma_e^\circ. \tag{13}$$

Using Eqs. 12 and 13, we obtain

$$\frac{(I_{pl}-I)}{RT} = \sigma_e^\circ \exp\left(-\frac{EF}{RT}\right), \tag{14}$$

or

$$\log \frac{(I_{pl}-I)FL}{RT} = \log \sigma_e^\circ - \frac{EF}{2.303RT}. \tag{15}$$

The semi-logarithmic plots of $(I_{pl}-I)FL(RT)^{-1}$ against $EF(2.303RT)^{-1}$ for Part A are shown in Fig. 9. The data fall on a straight line with a slope of -1. Clearly, the present results obey Eq. 15. This confirms that Eq. 11 holds for AgBr when $E<300$ mV.

On the assumption that Eq. 4 holds for AgBr under the conditions of complete ion blocking and when $E>300$ mV, we obtain[2]

$$\frac{IFL}{RT} = \sigma_e^\circ + \sigma_h^\circ \exp\left(\frac{EF}{RT}\right). \tag{16}$$

Using Eq. 13, we obtain

$$\frac{(I-I_{pl})FL}{RT} = \sigma_h^\circ \exp\left(\frac{EF}{RT}\right), \tag{17}$$

or

$$\log \frac{(I-I_{pl})FL}{RT} = \log \sigma_h^\circ + \frac{EF}{2.303RT}. \tag{18}$$

The semi-logarithmic plots of $(I-I_{pl})FL(RT)^{-1}$ against $EF(2.303RT)^{-1}$ for Part B are also shown in Fig. 9. The solpe of the plots is unity. Therefore, Eq. 18 holds when $E>300$ mV. This result indicates that the electronic conduction in AgBr under a high bromine partial pressure can be well interpreted as the predominant electron-hole conduction expressed by Eq. 4.

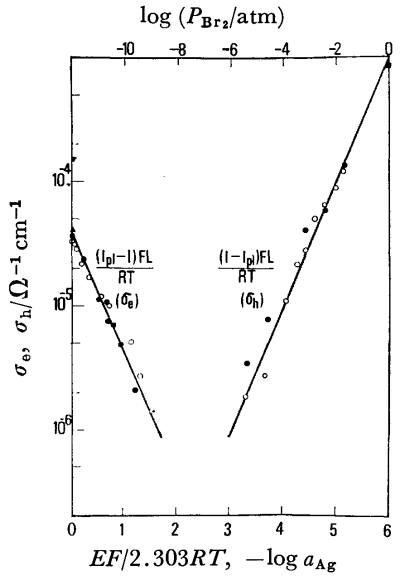

Fig. 9. Plots of σ_e and σ_h *vs.* $\log a_{Ag}$ and $\log P_{Br_2}$ at 400 °C for AgBr.
○: $L=2.2$ mm, ●: $L=3.3$ mm, ▼: by Weiss, ▲; by Ilschner, ■: by Raleigh.

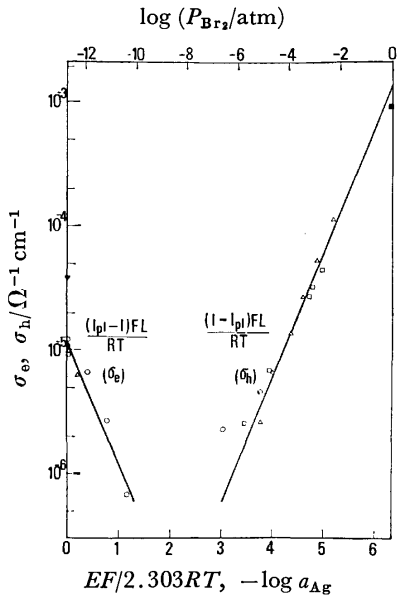

Fig. 10. Plots of σ_e and σ_h *vs.* $\log a_{Ag}$ and $\log P_{Br_2}$ at 375 °C for AgBr.
△: $L=2.5$ mm, □: $L=1.3$ mm, ○: $L=2.2$ mm, ▼: by Weiss, ▲: by Ilschner, ■: by Raleigh.

By inserting Eq. 2 into Eqs. 14 and 17 respectively, we obtain

$$\frac{(I_{pl}-I)FL}{RT} = \sigma_e^* \tag{19}$$

and

$$\frac{(I-I_{pl})FL}{RT} = \sigma_h^*, \tag{20}$$

where σ_e^* and σ_h^* denote the σ_e and σ_h of AgBr at the AgBr/carbon interface respectively. Using Eqs. 1 and 3, $EF(2.303RT)^{-1}$ is rewritten in terms of $\log a_{Ag}^*$ and $\log P_{Br_2}^*$. Figure 9 shows the plots of σ_e and σ_h against $\log a_{Ag}$ and $\log P_{Br_2}$. The corresponding values

of log a_{Ag} and log P_{Br_2} are also shown in Fig. 9. For the calculation of P_{Br_2}, the data in the literature were employed.[8]

The results at 375 °C are shown in Fig. 10. Also, Figs. 9 and 10 show the σ_e° values obtained by Ilschner[3] and Weiss[5] and the σ_h ($P_{Br_2}=1$ atm) obtained by Raleigh[4] by the use of conventional-type cells. The data by Ilschner and by Raleigh are in good agreement with the present results.

From the results presented above, it may be concluded that the improved cell can achieve complete ion blocking and that the electronic conductivity of silver halides can be determined strictly even under when the conventional-type cell can not be used.

Summary

(1) In order to block the ionic current completely in the Hebb-Wagner d.c. polarization cell, an improved cell assembly was devised and used for the accurate determination of the electronic conductivity of α-AgI and AgBr.

(2) The electronic conductivity of α-AgI (330 to 500 °C) was found to be proportional to $P_{I_2}^{1/2}$, and σ_h° (267 to 400 °C) is expressed as:

$$\sigma_h^\circ = 2.76\times10^3 \exp(-1.64\times10^4\, T^{-1}) \quad (\text{ohm}^{-1}\,\text{cm}^{-1})$$

The electronic conductivity of AgBr at 375 and 400 °C was found to be proportional to $P_{Br_2}^{-1/2}$ in the low-pressure range of bromine, and proportional to $P_{Br_2}^{1/2}$ in the high-pressure range.

Photo-effects of Metal Oxide Electrode. I. Photoelectrochemical Processes on a Silver–Silver Oxide Electrode and the Influence of Ethylene Glycol

Akira KUNUGI, Shuji MIYOSHI, and Shigeo NAGAURA
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received July 7, 1977)

The influence of light excitation on the anodic oxidation of a silver electrode in alkaline solutions has been studied. The experimental results have shown that, in addition to the formation of Ag(II) species by a reaction of Ag(I) species with photo-generated holes, illumination in the Ag_2O formation region causes the photogeneration of Ag(I) species at the metal/oxide interface. In the presence of ethylene glycol, the so-called current doubling phenomenon was found. This phenomenon has been interpreted in terms of a mechanism involving a catalytic reaction of the glycol with the photogenerated Ag(II) species, and not by a mechanism involving the oxidation of glycol by the photo-generated holes.

A silver–silver oxide electrode is very useful as a cathode in batteries with a high energy-to-mass ratio; hence, to date, the anodic behavior of silver in alkaline solutions has been extensively studied.[1] Also, the use of silver–silver oxide electrode in organic synthesis has received considerable attention[2] because silver oxides are known to react selectively with certain organic groups.[3]

In recent years, some work has been done on the photoeffects of silver–silver oxide electrodes.[4–7] Illumination definitely increases an anodic current in the Ag_2O formation region; the increment is generally accepted to be a photocurrent due to light absorption by an Ag_2O layer. There is, however, some disagreement concerning what kind of product is formed by light excitation. For example, Göhr and Breitenstein[4] explained the production of the photocurrent by assuming a photo-decomposition of Ag_2O into oxygen and silver, which is reoxidized either to Ag_2O or directly to AgO, depending on the electrode potential adjusted, whereas Memming *et al.*[5] suggested that light absorption by an Ag_2O layer leads to an anodic oxidation to AgO by the interaction of the photo-generated holes in the Ag_2O with Ag_2O. Perkins *et al.*[6] proposed that, in addition to the oxidation of interstitial Ag^+ to Ag^{2+}, which acts as a catalytic center for AgO formation, illumination enhances the rate of the primary Ag^+-formation process at the metal/oxide interface, resulting in a substantial increase in the Ag_2O formation.

In order to obtain more information about the photoelectrochemical process in the anodic oxidation of silver in alkaline solutions, the present work was performed. Furthermore, the influence of ethylene glycol on the electrode process was examined. Ethylene glycol was selected because it has a relatively high reactivity for a reaction with AgO and is virtually inactive for Ag_2O.[8]

Experimental

The working electrode was made from a wire of silver (purity > 99.99%) in the form of a disk (5 mm dia.) surrounded by a Teflon sheath. The reference electrode, against which all the potentials in the present paper are quoted, was Hg/HgO in 1 M KOH, and it was separated from the working electrode by a Luggin capillary. The electrolyte solutions were prepared from extra-pure-grade potassium hydroxide and water, twice distilled from deionized stock. Extra-pure-grade ethylene glycol was used without further purification.

The silver electrode was polished by means of a fine emery paper (number 0/8), cleaned in acetone and distilled water, and washed with a 1 M KOH solution. In addition, the electrode was subjected to the repeating of the potential cycle over the potential of from 0.0 to 0.8 V, with a sweep rate of 2.9 mV/s, in a 1 M KOH solution in the dark, using a potentiostat in conjunction with a linear sweep generator. After several cycles (in most cases, 6 times) the electrode was introduced into another cell filled with the solution to be studied, and then cyclic voltammograms were recorded on a x-y recorder. Simple H-shaped cells with a quartz window, which allowed the illumination of the working electrode, were used.

Coulomb-potential curves, which were measured simultaneously with the cyclic voltammograms, were displayed on a x-y recorder by means of a device constructed in our laboratory. From these curves, the amounts of charge for each peak were obtained.

In the experiments on the photo-effects, a 500 W Xenon arc lamp UXL-500D (Ushio Electric Inc.), which was enclosed in a lamp housing and powered by a dc power supply, was used as the light source. A fairly homogeneous and

horizontal beam was focussed on the working electrode by means of appropriate quartz lenses. For measuring photocurrents, as is shown in Fig. 1, the light was chopped with a rotated sector (35 Hz), and the resulting photocurrent was amplified and displayed on a x-y recorder, in which the dark current is eliminated. The procedure for the determination of the relative intensity of the light was described previously.[9]

The additional amount of silver oxides produced by illumination was determined as follows. Silver oxides formed under illumination in the Ag_2O formation region were dissolved into a 1 M ammonium acetate solution, and then the amount of silver ion in the solution was determined by means of atomic absorption spectrometry. The same measurements were carried out in the dark. The difference in the amount of silver ions between under illumination and in the dark was taken as equivalent to the amount of oxides produced by light excitation. The charges consumed during the formation of the silver oxides were measured by means of a Coulomb meter CLM-2A (Hokuto Denko Corp.). The composition of the oxides produced by light excitation was estimated on the basis of the data obtained above.

All measurements were carried out at ambient temperatures (25±2 °C). Oxygen was removed from solution by bubbling with nitrogen before every measurement.

Results and Discussion

Photo-effects on Oxidation to Silver Oxides in 1 M KOH. A potentiodynamic voltammogram for a silver electrode in an alkaline solution exhibits two major anodic and two major cathodic peaks corresponding to the formation and reduction of Ag_2O and AgO. A typical voltammogram run in 1 M KOH with the sweep rate of 2.9 mV/s is shown in Fig. 2, which also illustrates the effect of light during one cyclic sweep. Figure 2 definitely shows that, in addition to the increase in the magnitude of all the peaks, illumination causes the threshold potential for the commencement of AgO formation to shift to a more negative potential. This potential shift may be interpreted in terms of an overvoltage effect in the formation of AgO as well as in terms of the explanation by Parkins *et al.*;[6] *i. e.*, the overvoltage for the AgO formation is reduced by the Ag(II) species generated photoelectrochemically in the Ag_2O formation region, so that the cathodic shift occurs. The existence of such photo-generated Ag(II) species may be easily proved, as will be shown later.

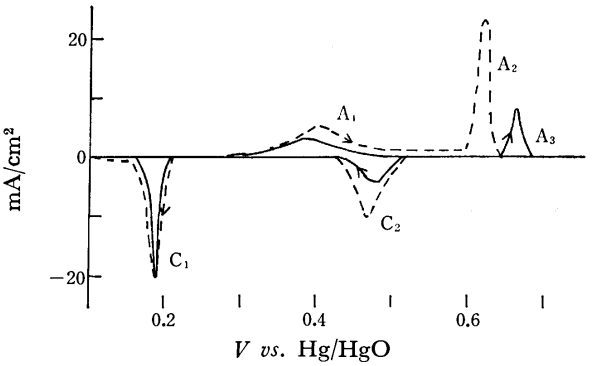

Fig. 2. Potentiodynamic current/potential profile for formation and reduction of oxides at a silver electrode in 1 M KOH. Sweep rate: 2.9 mV/s, ——: in the dark, ----: under illumination.

The potential dependence of a photocurrent was examined by using the chopped light described in a previous section. The general shape of the photocurrent-potential curve for 1 M KOH was the same as that reported by Memming *et al.*[5] The influence of the light intensity on the photocurrent is demonstrated in Fig. 3-a. Figure 3-b presents the ordinary current-potential curve measured simultaneously with Curve A in Fig. 3-a. In spite of the fact that both Ag_2O and AgO films exhibit *n*-type semiconducting behavior,[10] the anodic photocurrent arose only over the range of potentials at which the Ag_2O film exists, but did not appear at more positive potentials than the end of the AgO formation region. The maximum anodic photocurrent increased linearly with the light intensity of the illumination. In the cathodic direction of the potential sweep, photocurrents of different signs were observed in the region between the reduction peaks of AgO and Ag_2O. Such cathodic photocurrents have been examined in detail by Perkins *et al.*[6]

The charges consumed for each peak in Fig. 2 are presented in Table 1. It was found that the ratio of the total cathodic charge to the total anodic one was substantially unity, even under the illumination, indicating that the dissolution of reaction products into the alkaline solution may be neglected during one cycle of the potential. Furthermore, as can be seen from Table 1, the charge for the A_1 peak was increased by

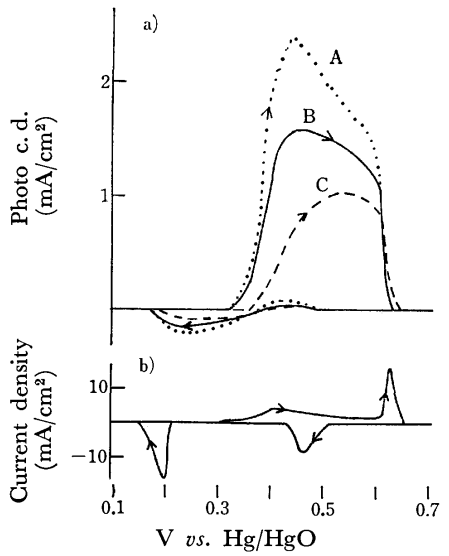

Fig. 3. (a) Photocurrent *vs.* electrode potential for a silver electrode in 1 M KOH (Dark current is eliminated). (b) Current *vs.* electrode potential measured simultaniously with the curve A in (a). Sweep rate: 2.9 mV/s, A, B, and C: light intensity of 110, 64.7, and 32.8 (a.u.), respectively.

Table 1. The amount of charge for each peak in Fig. 1 (mC/cm²)

	A_1	A_2	A_3	C_2	C_1	Total anodic charge	Total cathodic charge
Dark	103	67	0	47	125	170	168
Light	178	128	6	123	186	312	309

about 70% by the illumination, and the charge for A_2 peak under the illumination was larger by about 20% than the charge for the A_1 peak in the dark. From these facts it is clear that, in addition to the formation of Ag(II) species, illumination in the Ag_2O formation region causes a substantial increase in the formation of Ag(I) species at the metal/oxide interface. Therefore, the anodic photocurrent must be due to the photo-generation of both Ag(I) and Ag(II) species.

Composition of Photo-generated Products. In order to determine whether the photo-generated species in the Ag_2O formation region is mainly the Ag(I) or the Ag(II) species, the increment in silver species upon illumination and the corresponding charge were determined as follows. The pretreated electrode was subjected to the potential sweep from 0.0 to 0.575 V at the sweep rate of 2.9 mV/s under illumination. Immediately after the circuit had been opened, the electrode was taken out from the cell and then dipped in a 1 M ammonium acetate solution to remove from the silver substrate the silver oxides which were produced during the potential sweep. The analysis of the silver species in the acetate solution was made by atomic absorption spectrometry. The potential of 0.575 V corresponds to a less positive potential than that at which the electrochemical formation of AgO begins to appear. The anodic charge consumed during this potential sweep was simultaneously determined by means of a Coulomb meter. Blank runs in the dark were carried out as well. The results thus obtained are presented in Table 2. It was found that the illumination during the anodic sweep (0.0—0.575 V) causes the amount of silver ions to increase considerably, as well as the anodic charge. The current efficiency[11] for the additional amount of silver oxides formed by the illumination was 61%. If the photo-associated reaction were only the formation of Ag(II) species from Ag(I) species, the current efficiency for the additional amount of silver oxides would be zero. On the other hand, if only the formation of Ag(I) species from the silver substrate had arisen, the current efficiency of 100% would be obtained. No such results were obtained in this experiment. Accordingly, these experimental results also indicate that the photo-generated species are both Ag(I) and Ag(II) species.

The Ag(II)/Ag(I) ratio on the silver oxides produced only by the light excitation was estimated to be 1.8. This value was calculated on the basis of the current efficiency of 61% and by assuming that the anodic photocurrent arises according the following scheme:

$$Ag/Ag_2O \xrightarrow{h\nu} Ag(I)/Ag_2O + e, \quad (1)$$

$$Ag(I) \text{ and } Ag_2O \xrightarrow{h\nu} Ag(II) \text{ species} + e. \quad (2)$$

That is,

$$E_{eff} = \frac{q_1}{q_1+q_2} \cdot 100. \quad (3)$$

In the case of $E_{eff} > 50\%$

$$\frac{Ag(II)}{Ag(I)} = \frac{q_2}{q_1-q_2}. \quad (4)$$

From Eqs. 3 and 4, we obtain

$$\frac{Ag(II)}{Ag(I)} = \frac{100-E_{eff}}{2E_{eff}-100} = 1.8,$$

where q_1 and q_2 are the charges consumed in Eqs. 1 and 2 respectively.

From Table 1 and 2, it is clear that illumination causes the efficiency for the conversion of Ag_2O and AgO to increase. That is, the conversion was about 65% in the dark, whereas under illumination it was estimated to be almost 100%.[12] One may easily understand such a photo-effect by assuming that the photo-generated Ag(II) species, which act as nuclei for the AgO formation, exist widely within the Ag_2O film.

In further experiments, the effect of the time interval of illumination on the composition of the silver oxides was examined by the above method except for the procedures of illumination and polarization. An Ag_2O film was produced by the anodic potential sweep from 0.0 to 0.5 V (sweep rate, 2.9 mV/s), and then the electrode potential was stepped up to 0.45 V, at which no AgO is electrochemically formed. After the current had decreased to a very low value, the electrode was illuminated for a given period. Immediately afterward, the electrode was taken out from the cell and was worked up according to the above procedure. The charges consumed before and during illumination were measured by means of a Coulomb meter at the same time. In addition, the charges necessary for the reduction of the silver oxides formed under the above conditions were separately determined by sweeping back

Table 2. The composition of silver oxides produced by light excitation during the anodic potential sweep from 0.0 to 0.575 V

	Q_a[a] (mC/cm²)	M_{Ag}[b] (10^{-3}mmol/cm²)	Current efficiency (%)	Ag(II)/Ag(I) ratio
Dark	103	1.06	99	
Light	176	1.52	83	
Difference between light and dark	73	0.46	61[c]	1.8

a) Q_a: the charge consumed during the anodic sweep. b) M_{Ag}: the amount of silver ion, determined by means of atomic absorption spectrometry. c) See Ref. 11.

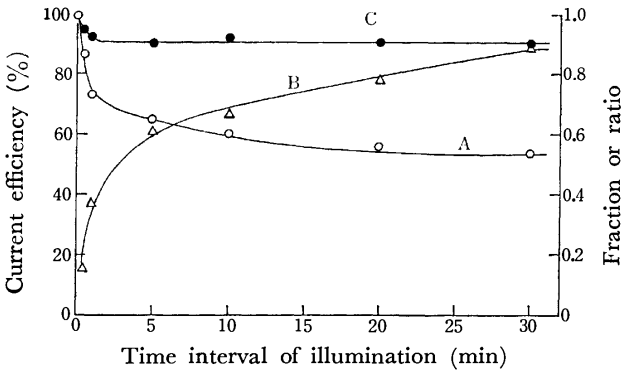

Fig. 4. Effect of illumination time on the current efficiency (curve A), the fraction of Ag(II) in the oxides (curve B), and the ratio of cathodic charge to anodic charge (curve C) about the silver oxides produced by illumination.

from 0.45 to −0.1 V as soon as the light was extinguished. Figure 4 illustrates the effect of the illumination time on the current efficiency for the photo-generated oxides (Curve A), on the fraction[13] of Ag(II) in the oxides (Curve B), and the ratio of the anodic charge consumed only during the illumination and the cathodic charge necessary for the reduction of the photo-generated oxides (Curve C). The current efficiency and the fraction of Ag(II) species varied, as is shown in Fig. 4, as the time interval of illumination increased. That is, the ratio of Ag(II)/Ag(I) increased with an increase in the time interval of illumination. On the other hand, the anodic charges, increased by the light excitation, were always somewhat larger than the corresponding cathodic charges. This fact indicates that only a small part of the anodic photocurrent was used for the photo-decomposition of Ag_2O into silver and oxygen. Therefore, the photo-decomposition of Ag_2O postulated by Göhr *et al.*[4] is not considered to be the main origin of the photocurrent.

If the photo-generation of Ag(II) species is due only to the photoelectrochemical oxidation of interstitial Ag^+, as was proposed by Perkins *et al.*,[6] or if the anodic photocurrent is due only to the formation of AgO, as was reported by Memming *et al.*,[5] the results obtained in the present experiments can not be interpreted. Our conclusion is that the anodic photocurrents are due to the formation of both Ag(I) and Ag(II) species according to Eqs. 1 and 2. In addition, it must be noted that a small part of the anodic photocurrent is used for the evolution of oxygen.

Influence of Ethylene Glycol on the Photo-effects. Figure 5 shows the influence of ethylene glycol on the photocurrent during a cyclic potential sweep of silver in 1 M KOH. The addition of the glycol to the base electrolyte caused the anodic photocurrent to increase considerably. The relation between the photocurrent and the glycol concentration is presented in Fig. 6 as plots of i_p/i_a *vs.* log C, where i_p and i_a imply the maximum photocurrent (peak value) in the presence and absence of the glycol respectively, and C, the bulk concentration of the glycol. The value of i_p/i_a increased with an increase in the glycol concentration and reached a factor of two. Such a current doubling phenomenon had previously been found at a zinc oxide single-crystal electrode by Morrison and Freund.[14] They interpreted it by means of the following two-step mechanism:

$$R + h^+ \longrightarrow R^+, \quad (5)$$

$$R^+ \longrightarrow R^{2+} + e, \quad (6)$$

where h^+ is a photo-generated hole in the crystal; R, a current-doubling agent; R^+, a radical-type species, and e, an electron. However, it seems that current-doubling phenomenon in the silver oxide electrode system can not be interpreted by the mechanism indicated above, but rather by a alternative mechanism, as will be shown below.

Figure 7 shows typical voltammograms for the silver electrode in a 1 M KOH solution containing 0.2 M ethylene glycol in the dark and under illumination. In the presence of glycol, a specific anodic peak (Peak A_4) was observed between the AgO formation and its

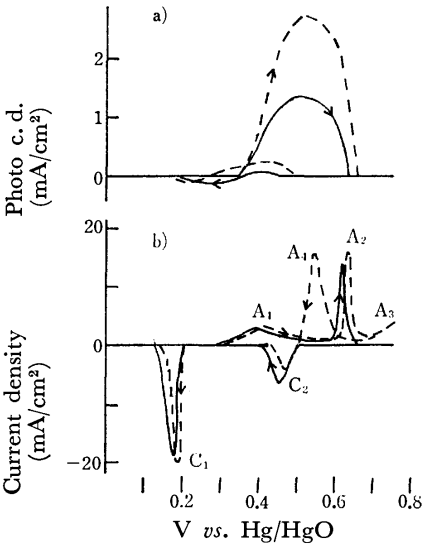

Fig. 5. (a) Influence of ethylene glycol on the photocurrent. (b) Current *vs.* electrode potential measured simultanously with the curve in (a). Sweep rate: 2.9 mV/s, ——: 1 M KOH, ----: 1 M KOH +0.2 M ethylene glycol.

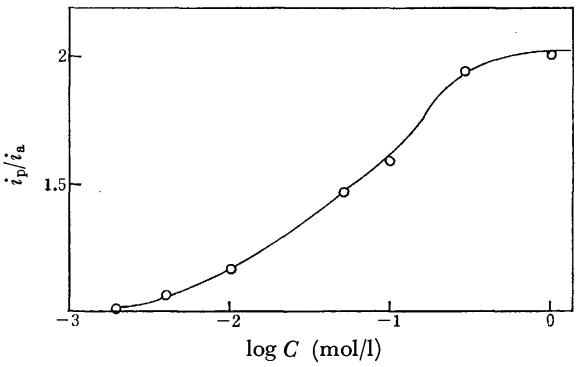

Fig. 6. Maxmum photocurrent *vs.* concentration of ethylene glycol. i_a and i_p: the maxmum photocurrent in the absence and presence of the glycol, respectively, C: the bulk concentration of the glycol.

reduction peaks under a cathodic sweep. The values in both cases, light and dark, increased linearly with an increase in the glycol concentration. The illumination increased the peak value. The appearance of such a peak can be explained by the catalytic mechanism proposed by Sasaki and Toshima,[15] in which a reaction of alcohols with AgO leads to the formation of Ag_2O (or Ag), which is then electrochemically oxidized to AgO. The question arises, however, of why such a catalytic reaction does not easily occur in the AgO formation region under an anodic sweep. This question might be answered by assuming the competitive adsorption of glycol and OH^-; *i.e.*, with an increase in the anode potential, the surface concentration of glycol decreases, whereas that of OH increases.

As can be seen from a comparison of Figs. 2 and 7, the anodic current in the region (A_3) between the AgO formation peak and the oxygen evolution was increased by the addition of glycol, and it was further increased by the illumination. We have no idea, however, how to explain such an increase at the A_3 peak.

The amounts of charge for each peak in Fig. 7 are

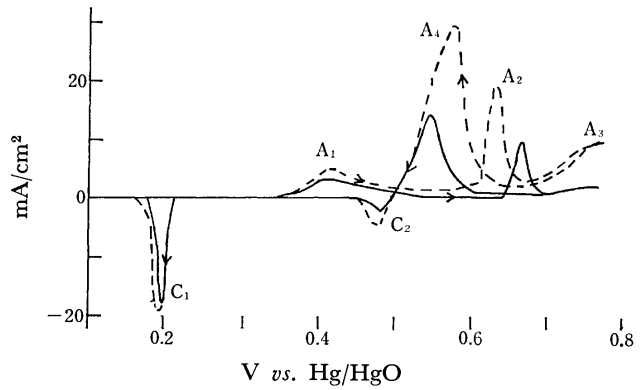

Fig. 7. Potentiodynamic voltammograms for a silver electrode in 1 M KOH +0.2 M ethylene glycol. ——: in the dark, ----: under illumination, sweep rate: 2.9 mV/s.

listed in Table 3. The illumination considerably increased the charges for all peaks. It should be noted that, in spite of the fact that the photocurrent does not arise in the region of either A_3 or A_4 as is shown in Fig. 5, the amounts of charge for these peaks (A_3 and A_4) increased remarkably under the illumination. The remarkable increase in the specific anodic current (A_4) by the illumination is considered to be due to an increase in the surface roughness of the electrode, although the variation in the roughness was not directly examined by means of a microscope. The increase in the surface roughness mainly occurs in the Ag_2O formation region. This idea came from such observations as: (i) When an upper limit of a potential cycle was set at the end of the A_2 peak, when the illumination was limited to the Ag_2O formation region, or when one cyclic voltammogram was run in the solution containing the glycol under illumination, and the next cyclic one was recorded in the dark, little change in the amount of charge for the A_4 peak was observed. (ii) In the presence of glycol, illumination rather decreased both the amount of silver oxides, which formed during the anodic sweep from 0.0 to 0.575 V, and the corresponding cathodic charge, although the anodic charge for the Ag_2O formation region was considerably increased by illumination.

If the anodic photocurrent observed in the present study had arisen according to a mechanism similar to that proposed by Morrison and Freund,[14] the increase in the surface roughness by the light excitation would not occur. Therefore, an alternative mechanism for the current-doubling phenomenon should be proposed in the case of the present electrode system. For example, the following catalytic mechanism are considered: (i) Ethylene glycol reacts with the photo-generated AgO to give a radical intermediate to inject an electron into the electrode. In this case, the AgO is reduced to Ag_2O, which is also oxidized to AgO according to Eq. 7; *i. e.*,

$$Ag_2O + h^+ \longrightarrow AgO, \quad (7)$$
$$AgO + Glycol \longrightarrow Ag_2O + Intermediate, \quad (8)$$
$$Intermediate \longrightarrow Aldehyde + e, \quad (9)$$

or (ii) similarly, the reaction of glycol with the AgO results in the formation of aldehyde and Ag, followed by the electrochemical reoxidation of the latter to Ag_2O, which is then oxidized by the photo-generated hole; *i. e.*,

$$Ag_2O + h^+ \longrightarrow AgO, \quad (7)$$
$$AgO + Glycol \longrightarrow Ag + Aldehyde, \quad (10)$$
$$Ag \longrightarrow Ag_2O + e. \quad (11)$$

Such chemical decomposition and photochemical reformation of AgO is repeated on the electrode surface, and this causes the surface roughness of the electrode to increase.

Consequently, the current-doubling phenomenon at the silver oxide electrode may be interpreted by either mechanism indicated above, and not by a mechanism involving a reaction of glycol with the photo-generated hole.

11) The current efficiency, E_{eff} was defined by: $E_{eff}=(M_1-M_D)F/(Q_L-Q_D)$. 100(%), where M and Q are the amount (mol) of silver ion formed and the charge (coulomb) consumed during the anodic sweep (0.0—0.575 V) respectively; the subscripts L and D indicate under illumination and in the dark respectively, and F is Faraday's constant.
12) The additional charge for the A_1 peak by the illumination $=(Q_{A_1})_L-(Q_{A_1})_D=178-103=75$ mC/cm², and the fraction of Ag(I) in the oxide produced by the illumination $=1-[Ag(II)/Ag(I)]/[Ag(II)/Ag(I)+1]=1-1.8/(1.8+1)=0.36$. Therefore, the charge corresponding to the amount of Ag(I) species produced by illumination $=75\times0.36=27$ mC/cm². Thus, the charge corresponding to the total amounts of Ag(I) species produced in the A_1 region $=103+27=130$ mC/cm². Consequently, the electrochemical conversion of Ag(I) to Ag(II) $=(128/130)\times100=98\%$.
13) The fraction of Ag(II) in the oxides $=[Ag(II)/Ag(I)]/[Ag(II)/Ag(I)+1]$.

(Received August 11, 1977)

The solvent extraction equilibria of acetic, propionic, and butyric acid and mono-, di-, and trichloroacetic acid (HA), as well as those of oxalic, malonic, succinic, glutaric, and adipic acid (H_2A), have been determined in liquid-liquid systems of hexane containing none or a certain amount of trioctylphosphine oxide (E) and an aqueous 1 mol dm^{-3} chloride solution at 25 °C. The constants, $K_d=[HA]_{org}/[HA]$, $K_{dim}=[(HA)_2]_{org}/[HA]_{org}^2$, $K_{ex1}'=[HAE]_{org}/[HA][E]_{org}$, $K_{ex2}'=[H_2AE_2]_{org}/[H_2A][E]_{org}^2$, and $\beta_{1(org)}=[HAE]_{org}/[HA]_{org}[E]_{org}$, have then been determined from the data. It was found that, among the three fatty acids, the value of K_{ex1}' was higher as the chain length increased, but the values of $\beta_{1(org)}$ were nearly all the same, while among the chloroacetic acids they were higher as the number of chloride atom increased. The extraction of the dicarboxylic acids with E was not very different, although the number of the $-CH_2-$ between the two carboxyl groups changed from zero to four.

In this series of reports, we have reported on the solvent extraction behavior of various inorganic acids with trioctylphosphine oxide (TOPO) in organic solvents.[1-5] In the present paper, we will study the extraction equilibria of acetic, propionic, and butyric acid, mono-, di-, and trichloroacetic acid, and oxalic, malonic, succinic, glutaric, and adipic acid, in 1 mol·dm^{-3} chloride solutions with TOPO in hexane at 25 °C.

Experimental

The experiments were performed much as has previously been described.[1-5] All the reagents were of an analytical grade. The acid was dissolved in 1 mol dm^{-3} hydrochloric acid or 1 mol dm^{-3} (H, Na)Cl ionic media, placed in contact with the same volume of hexane containing none or a certain amount of TOPO in a stoppered glass tube by means of a mechanical shaker, and centrifuged. A certain amount of the organic phase was then pipetted off and titrated with a standard barium hydroxide solution, using phenolphthalein as the indicator.

Statistical

Here the subscript "org" and the lack of subscript denote the species in the organic and aqueous phases respectively. The mono- and dicarboxylic acids are represented by HA and H_2A respectively, while TOPO is represented by E. Since the extraction of dicarboxylic acid species containing no E was negligible, and that of the HAE_2 and H_2AE species was also found to be negligible, the following equilibrium constants were employed for the data analysis:

$$K_d = [HA]_{org}[HA]^{-1}, \quad (1)$$

$$K_{dim} = [(HA)_2]_{org}[HA]_{org}^{-2}, \quad (2)$$

$$K_{ex1}' = [HAE]_{org}[HA]^{-1}[E]_{org}^{-1}, \quad (3)$$

$$K_{ex2}' = [H_2AE_2]_{org}[H_2A]^{-1}[E]_{org}^{-2}. \quad (4)$$

The distribution ratio, D, was defined by the ratio of total acid concentrations in the organic and aqueous phases. The latter was calculated from the initial acid concentration in the aqueous phase and the equilibrium acid concentration in the organic phase. The dissociation in 1 mol dm^{-3} hydrochloric acid was negligible except for trichloroacetic acid, and the observed distribution ratio of the dicarboxylic acids was found to be

$$D = [H_2AE_2]_{org}[H_2A]^{-1} = K_{ex2}'[E]_{org}^2. \quad (5)$$

The distribution ratio for the monocarboxylic acids should generally be written as

$$D = ([HA]_{org}+2[(HA)_2]_{org}+[HAE]_{org})([HA]+[A^-])^{-1} = (K_d+2K_d^2K_{dim}[HA]+K_{ex1}'[E]_{org})(1+K_a[H^+]^{-1})^{-1}. \quad (6)$$

The $[A^-]$ or $K_a[H^+]^{-1}$ term was found to be negligible except for trichloroacetic acid; furthermore, the $[HA]_{org}$ and $[(HA)_2]_{org}$ terms or the K_d and $2K_d^2K_{dim}$ [HA] terms were found to be negligible in the presence of TOPO except for the case of butyric acid.

The free TOPO concentration at equilibrium was calculated by subtracting the fraction combined with acid, which could be written as $[HAE]_{org}$ or $2[H_2AE_2]_{org}$. In the case of butyric acid, however, the extraction of the HA and $(HA)_2$ species was corrected by using the data obtained in the absence of TOPO.

The distribution ratio of the fatty acids in the absence of TOPO was plotted as a function of [HA]:

$$\log D = \log (K_d+2K_d^2K_{dim}[HA]), \quad (7)$$

and the constants were obtained by a curve-fitting method.[6]

The other equilibrium constants were obtained by introducing the experimental data into Eq. 5 or 6. Since the acid dissociation was not negligible for trichloroacetic acid, the distribution ratio was obtained at a certain $[E]_{org,initial}$ value as a function of $[H^+]$ in 1 mol dm^{-3} (H, Na)Cl solutions. Then, from these experimental data and a certain assumed value of K_a, the values of K_{ex1}' in Eq. 6 were calculated. Trials were repeated by introducing other assumed values of K_a and the standard deviation of the K_{ex1}' was calculated from each set of values of K_{ex1}'. Then, the values of the standard deviation were plotted against the K_a value. The K_a value which gave the minimum standard deviation was estimated from the plot and was subsequently employed for the data analysis of trichloroacetic acid.

Results

In the present work, a 1 mol dm^{-3} chloride solution was always employed as the aqueous phase. How-

$\log K_{ex1}'$ was calculated by using the value, $K_a=0.24$, which gave the mininum standard deviation of the K_{ex1}'.

Discussion

The extraction and dimerization of fatty acids in liquid–liquid systems have been studied for a long time.[7] Most of the previous data have been obtained by employing an aqueous fatty acid solution containing no or only a small amount of an electrolyte as the aqueous phase. In the present study, however, 1 mol dm^{-3} of chloride was always in the aqueous phase; this could cause a salting-out effect, as was found previously.[8] However, the K_d values of the fatty acids from the present ionic medium into hexane were still lower than those in the previous study[8] from an aqueous solution containing no other salts into carbon tetrachloride (the K_d values were 3.20×10^{-3}, 1.51×10^{-2}, and 3.83×10^{-2} respectively for acetic, propionic, and butyric acid).

There has been a report on the dimerization constant of acetic acid in hexane[9] and also one on the distribution and dimerization constants of propionic acid in the hexane–aqueous 0.1 mol dm^{-3} (H, Na)ClO_4 system.[10] The present dimerization constants of these fatty acids in hexane are very similar to each other. The same tendency, a constancy of the dimerization constants among fatty acids of different chain lengths, was also found in several other organic solvents.[10] At the same time, it was also reported that the values increased upon an increase in the chain length of these fatty acids in carbon tetrachloride.[8]

In Fig. 2, the extracted acid species in the organic phase in the presence of TOPO was, for all practical purposes, monomeric except the butyric acid in the lower TOPO concentration region.

From Eqs. 1 and 3, the following equation is obtained:

$$K_{ex1}' = K_d\beta_{1(org)}, \quad (8)$$

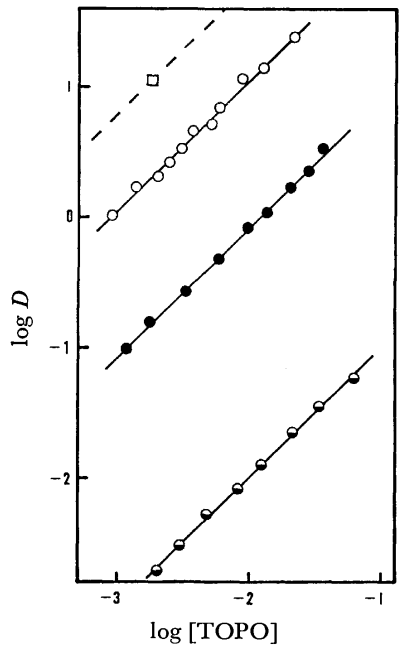

Fig. 3. Distribution ratio of mono- (●), di- (○), and trichloroacetic acid (□), and acetic acid (◒) between hexane containing various amounts of TOPO and 1 mol dm^{-3} HCl initially containing 3.2×10^{-2} and 3.0×10^{-2} mol dm^{-3} of mono- and dichloroacetic acid, respectively as a function of the free TOPO concentration. The curve for trichloroacetic acid was calculated from K_{ex1}' in Table 3 and for acetic acid was taken from Fig. 2.

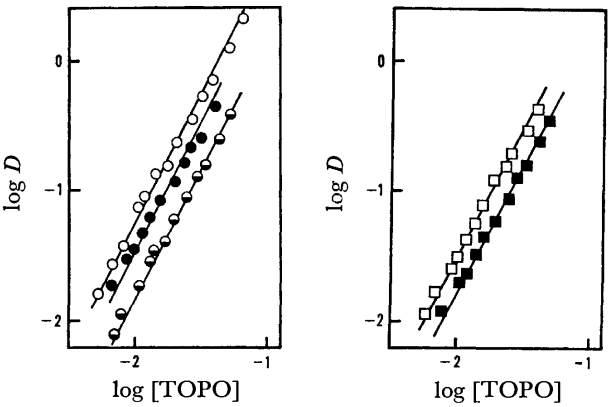

Figs. 4 and 5. Distribution ratio of five dicarboxylic acids between hexane containing various amounts of TOPO and 1 mol dm^{-3} HCl initially containing 2.6×10^{-2}, 9.6×10^{-2}, 9.9×10^{-2}, 1.0×10^{-1}, and 1.0×10^{-1} mol dm^{-3} of adipic (○), glutaric (●), succinic (◒), malonic (■), and oxalic (□) acid, respectively, as a function of the free TOPO concentration.

where $\beta_{1(org)}$ is the association constant of TOPO with monomeric acid in the organic phase. This is written for a monocarboxylic acid as

$$\beta_{1(org)} = [HAE]_{org}[HA]_{org}^{-1}[E]_{org}^{-1}. \quad (9)$$

As may be seen from Table 3, the values of $\beta_{1(org)}$ were nearly the same among all these fatty acids. Furthermore, the association constants of these acids with TOPO

Table 3. Summary of equilibrium constants

(a) Fatty acids					
Acid	pK_a	$\log K_d$	$\log K_{dim}$	$\log K_{ex1}'$	$\log \beta_{1(org)}$
CH_3COOH	4.30	−3.06	3.59	1.01	4.07
C_2H_5COOH	4.66***	−2.30	3.56	1.77	4.07
C_3H_7COOH	4.74**	−1.64	3.48	2.17	3.81
(b) Chloroacetic acids					
Acid	pK_a	$\log K_d$	$\log K_{dim}$	$\log K_{ex1}'$	$\log \beta_{1(org)}$
$CH_2ClCOOH$	2.66	−3.14	2.51	1.93	5.07
$CHCl_2COOH$	1.30†	−2.72	2.16	3.06	5.78
CCl_3COOH	0.62††	−2.63	2.89	3.78	6.41
(c) Dicarboxylic acids					
Acid	pK_{a1}	pK_{a2}	$\log K_{ex2}'$		
$(COOH)_2$	1.07	3.57	2.49		
$CH_2(COOH)_2$	2.74	5.11	2.22		
$C_2H_4(COOH)_2$	3.98	5.50	2.18		
$C_3H_6(COOH)_2$	4.09*	4.84*	2.52		
$C_4H_8(COOH)_2$	4.28***	5.00***	2.74		

The pK_a values were taken from Ref. 11. The ionic concentration and temperature were: (no mark) 1 mol dm^{-3} and at 30 °C for acetic acid, 20 °C for monochloroacetic acid and 25 °C for the others; (*) 0.5 mol dm^{-3} and at 25 °C; (**) 0.2 mol dm^{-3} and at 25 °C; (***) 0.1 mol dm^{-3} and at 20 °C for propionic acid and 25 °C for adipic acid; (†) no specification on the ionic medium and at 25 °C; (††) 1 mol dm^{-3} and at 25 °C obtained in the present work.

were larger than the values of K_{dim}. This seems to be reasonable because the phosphoryl-oxygen in TOPO should be a stronger accepter of hydroxyl-hydrogen in the carboxyl group than the carbonyl-oxygen in the carboxyl group; thus, the former can combine with the hydroxyl group more strongly than the latter.

The dissociation of mono- and dichloroacetic acid is negligible in 1 mol dm^{-3} hydrochloric acid. However, that of trichloroacetic acid should be taken into account. A pK_a value of 0.62 was finally obtained from the data analysis in 1 mol dm^{-3} (H, Na)Cl. The above present value agrees with an estimated value, 0.7, in the literature.[11]

The distribution constant of the monomer, K_d, of monochloroacetic acid was nearly the same as that of acetic acid. However, it was higher as the number of the chlorine atom increased. The replacement of a hydrogen atom with a chlorine atom should change the charge distribution in the molecule, and it could cause an decrease in the K_d by increasing the aquophilic character. However, at the same time, it should cause an increase in the molar volume, which should in turn increase the K_d value by increasing the aquofobic character. The observed value of K_d should be caused by the over-all effect of these two factors.

The extraction of three chloroacetic acids with TOPO was much better than acetic acid, and, among them, the extraction was better when the acid was stronger. The distribution ratio of trichloroacetic acid was too high to measure accurately under the conditions employed for the other two acids; only a calculated extraction curve could be obtained from the data in Table 2, as is given in Fig. 3. The extraction of these chloroacetic acids into hexane containing no TOPO was found to be very poor, as may be seen from Tables 1 and 3. Thus, the good extraction of these acids with TOPO should be attributed to their great tendency to associate with it in the organic phase.

The $\log \beta_{1(org)}$ value between dibutylphosphoric acid and TOPO in hexane was reported to be 4.88;[12] this is lower than chloroacetic acids, but higher than the fatty acids.

It was found that the distribution ratio of all the five dicarboxylic acids studied in the present work was very low in the absence of TOPO; the values of D were estimated to be always lower than 10^{-3}.

These low D values in the absence of TOPO are probably due to a strong hydration of these acids. However, these hydrating water molecules could be replaced by TOPO. Since two TOPO molecules solvated one acid molecule in the organic phase, each carboxyl group should combine with one TOPO by means of a hydrogen-bond; thus, the aquophilic character diminished. It is noticeable that the extraction constants of these dicarboxylic acids are rather similar to each other; this was not observed among the fatty acids which were extracted better when the chain was longer. Among the fatty acids, the values of pK_a are rather similar to each other; consequently, the abilities to associate with TOPO are probably also similar to each other, as is indicated by the values of $\log \beta_{1(org)}$. Thus, the chain length, in other words, the difference in the molar volume, was the main factor affecting the extraction behavior of the fatty acids. On the other hand, two inverse effects probably determine the degree of extraction of the dicarboxylic acids. The strength of the acid, especially that which dissociates first proton, is greater when the chain is shorter, and, although the values of $\beta_{1(org)}$ could not be determined for these acids, it seems a reasonable guess that the stronger the acids, the stronger the interaction with TOPO. Thus, acids of shorter chains are favorable for the extraction. An increase in the chain length, however, probably increases the aquofobic

character of the molecule, and, from this standpoint, longer chains are more favorable for the extraction. The fact that the extraction constants of these dicarboxylic acids are rather similar to each other seems to indicate that two inverse effects are cancelling each other out. We can not yet make a comment on the steric effect of the two TOPO molecules combined with one dicarboxylic acid molecule.

(Received August 12, 1977)

Nuclear quadrupole resonance (NQR) frequencies due to ^{79}Br and ^{127}I are examined in phosphorus iodides, PI_3 and P_2I_4, and the complexes $PBr_3 \cdot BBr_3$, $PBr_3 \cdot BI_3$, and $PI_3 \cdot BBr_3$. The quadrupole coupling constants and asymmetry parameters are also derived for ^{127}I in PI_3, P_2I_4, and $PBr_3 \cdot BI_3$. The resonance lines of PI_3 fade out above 257 K, at which temperature a structural phase transition is suggested. The number of resonance lines in P_2I_4 shows that the molecular symmetry of P_2I_4 is $\bar{1}$ instead of 2/m in its crystal. The similarity of the resonance patterns of the three complexes indicates that they are isomorphous with one another. The electronic structures of the halogens in the compounds mentioned above have been discussed by using the Townes-Dailey theory. On complexing, the electric charge of the halogen atoms in the donor PX_3 decreases due to the polarization of $p\sigma$ bonds, whereas that of the halogen atoms in the acceptor BY_3 increases owing to the backdonation through $p\pi$ bonds.

Two kinds of phosphorus iodides, PI_3 and P_2I_4, are known,[1] but no NQR investigation of these compounds has yet been reported. Phosphorus halides can form complexes with boron halides, in which the former act as electron donors and the latter as acceptors.[2] Only the complexes involving the heavier halogen atoms are stable at room temperature. In the case of these complexes, somewhat large shifts of the quadrupole coupling constants are expected on complexing. We have therefore observed NQR spectra due to ^{79}Br and ^{127}I in two kinds of phosphorus iodides and three complexes: $PBr_3 \cdot BBr_3$, $PBr_3 \cdot BI_3$, and $PI_3 \cdot BBr_3$, and have examined the bond character of these compounds. In the related complexes, $PI_3 \cdot BI_3$ and $P_2I_4 \cdot 2BBr_3$, NQR could not be observed. This failure may be caused by the imperfection of the samples.

Experimental

PI_3 and P_2I_4 were obtained by the reaction of the relevant elements in carbon disulfide, followed by recrystallization.[3] PBr_3 and BBr_3 were obtained from commercial sources. BI_3 was synthesized by the method of Renner[4] and was purified by sublimation. The complexes were prepared according to the methods in the literature.[2] All the procedures were performed under a nitrogen or helium atmosphere.

The NQR spectra were obtained with an externally quenched super-regenerative Lecher-line oscillator; the absorption lines were observed on an oscilloscope. The resonance frequencies were measured by the use of a signal generator and a frequency counter with an estimated accuracy of ± 0.01 MHz.

Results and Discussions

Phosphorus Iodides, PI_3 and P_2I_4. In Table 1 are listed the observed frequencies for ^{127}I at liquid nitrogen temperature with the approximate signal to noise ratios observed on an oscilloscope. These frequencies were assigned to the pairs of ν_1 and ν_2, which correspond to the transitions $m=\pm 1/2 \leftrightarrow \pm 3/2$ and $\pm 3/2 \leftrightarrow \pm 5/2$, respectively. However, there is an ambiguity in pairing the resonance frequencies of PI_3, so that the pairing was done in the order of frequency. This pairing is very likely, because the middle line of each group is slightly weaker than those of both sides. Using ν_1 and ν_2, the quadrupole coupling constants e^2Qq/h and the asymmetry parameters η were derived from the table of eigenvalues for the spin 5/2,[5] and are listed also in Table 1.

The crystal structure of PI_3 was reinvestigated recently by Lance *et al.*[6] at room temperature. The structure is hexagonal, and belongs to the space group $P6_3$ with $Z=2$. A pyramidal molecular geometry is maintained in solid PI_3. In this symmetry all the iodine atoms are equivalent and only one NQR line is expected. However, three lines of almost the same intensity were observed on each transition at low temperatures, showing the existence of three crystallographically non-equivalent iodine atoms, and no resonance was observed at room temperature. The temperature dependence of each ν_1 line of PI_3 was investigated. As the temperature rose from 77 K, the resonance frequencies decreased monotonously with the average temperature coefficients $\langle\alpha\rangle=2(\nu_{77}-\nu_{202})/(77-202)(\nu_{77}+\nu_{202})=-3.7 \times 10^{-5}$, -3.1×10^{-5}, and -2.8×10^{-5} deg^{-1} for the lowest, the middle, and the highest lines respectively. All the resonance lines faded out abruptly at about 257 K, which is far below the melting point of 334 K. This indicates that a structural phase transition may occur at about 257 K, because the existence of the three non-equivalent iodine atoms at the lower temperature is inconsistent with the crystal structure analysed at room temperature.

The X-ray analysis by Leung and Waser shows that P_2I_4 is triclinic, space group $P\bar{1}$, and $Z=1$.[7] The two P atoms are linked together, and each P atom is linked to two I atoms at the same distance within the experimental accuracy. The molecular symmetry is 2/m within the experimental accuracy, while only the inversion center is required crystallographically. However, two pairs of NQR lines corresponding to the two non-equivalent iodine atoms are observed instead of the single pair of NQR lines which is expected for the symmetry 2/m. In view of this fact the molecular symmetry should be reduced from 2/m to $\bar{1}$ in the crystalline state.

The temperature dependencies of the ν_1 lines of P_2I_4 were also investigated from 77 K to room temperature. When the temperature is above room temperature, P_2I_4(mp, 397 K) decomposes gradually and the signals

Table 1. Nuclear quadrupole resonance frequencies, quadrupole coupling constants, and asymmetry parameters in phosphorus iodides at 77 K

Compound	ν_1/MHz	S/N	ν_2/MHz	S/N	e^2Qqh^{-1}/MHz	η
PI_3	230.46	(7)	457.90	(2.5)	1527.9	0.071
	231.63	(5)	460.00	(2)	1535.1	0.074
	233.80	(7)	463.87	(2.5)	1548.2	0.079
P_2I_4	239.14	(4)	478.20	(2)	1594.1	0.011
	243.09	(4.5)	486.07	(2)	1620.3	0.013

are rapidly broadened and weakened. Within the observed temperature range the temperature dependencies of the resonance lines are normal, with the average temperature coefficients $\langle\alpha\rangle = -5.4\times10^{-5}$ and -6.3×10^{-5} deg^{-1} for the lower and the upper lines, respectively. These coefficients are larger than those of PI_3.

The observed quadrupole coupling constants of the halogen atoms were qualitatively estimated by the following equations:[8]

$$e^2Qq/h = |e^2Qq/h|_{\text{atom}}\left\{(1-s)(1-i)-\frac{f}{2}\right\}, \quad (1)$$

and

$$f = \frac{2}{3}\eta\frac{e^2Qq/h}{|e^2Qq/h|_{\text{atom}}}. \quad (2)$$

Here $|e^2Qq/h|_{\text{atom}}$ is the atomic quadrupole coupling constant, which is 2292.71 MHz for ^{127}I,[9] s is the degree of the s-hybridization, and f is the degree of the decrease of pπ electrons. s is assumed to be equal to 0.15 in accordance with Townes and Dailey.[10] Then, using the average values of e^2Qq/h and η at 77 K, i and f are calculated to be 0.19 and 0.03 for PI_3 and 0.17 and 0.01 for P_2I_4, respectively. If the π-bonding of the P–I bonds is not different in both iodides, the slightly larger value of f (or η) of PI_3 than that of P_2I_4 may be ascribed to the intermolecular bonding involving I atoms. According to the crystal structure of PI_3,[6] the shortest P···I intermolecular distance (3.670 Å) is smaller than the sum of the relevant van der Waals radii (4.0 Å). Possibly such P···I intermolecular interactions may exist in the low temperature phase as well, where NQR spectra were observed. On the other hand the shortest intermolecular P···I distance is 3.9 Å in P_2I_4.[7] The ionic character of the P–I bonds in PI_3 is somewhat larger than in P_2I_4. This may be attributed to the larger electron withdrawing ability of PI_2 groups than that of I atoms.

Complexes: $PBr_3 \cdot BBr_3$, $PBr_3 \cdot BI_3$, and $PI_3 \cdot BBr_3$. Table 2 shows the observed frequencies of ^{79}Br and ^{127}I of the complexes at liquid nitrogen temperature with the approximate signal to noise ratios. For bromine the resonances of ^{81}Br were also detected; these satisfy the quadrupole moment ratio $Q(^{79}Br)/Q(^{81}Br) = 1.1974$ within the experimental accuracy. The ν_2 lines of the I atoms of the $PI_3 \cdot BBr_3$ may probably exist in the region of about 570 MHz, at which our spectrometer did not operate.

The resonance lines of each complex are divided into two or three groups, in which two closely spaced lines exist with the intensity ratio of about 1 : 2. Referring to the fact that the resonance lines of a component in the complex are shifted to a small extent, the bromine and iodine lines can be identified easily, as shown in Table 2. This identification can be confirmed by the doublet structure,[11,12] which arises from the isotope effect of ^{10}B and ^{11}B.[12] The frequency measurements of the doublet were done at the maximum intensity position of the signals.

Table 2. Nuclear quadrupole resonance frequencies of ^{79}Br and ^{127}I in the complexes $PBr_3 \cdot BBr_3$, $PBr_3 \cdot BI_3$, and $PI_3 \cdot BBr_3$ at 77 K

Compound	Species		ν/MHz	S/N
$PBr_3 \cdot BBr_3$	PBr_3		258.93	(8)
			259.40	(4)
	BBr_3		181.89	(6)
			184.30	(12)
$PBr_3 \cdot BI_3$	PBr_3		258.78	(3)
			259.60	(1.5)
	BI_3	ν_1	203.41	(3)
			207.58	(1.5)
		ν_2	399.80	(7)
			401.22	(15)
$PI_3 \cdot BBr_3$	PI_3	ν_1	289.61	(12)
			289.91	(7)
	BBr_3		176.39	(1.5)
			180.32	(3)

The similarity of the resonance patterns of the complexes shows that these complexes are presumably isomorphous with one another, though the crystal structures of the complexes have not yet been clarified. Possibly one halogen atom is non-equivalent to the remaining two halogen atoms in each species of the complexes.

In the case of $PBr_3 \cdot BI_3$, both ν_1 and ν_2 due to ^{127}I were measured. Where the pairings were done easily due to the intensity difference of the two resonances, and the e^2Qq/h and η were obtained as 1340.3 MHz and 0.104 for the stronger line and 1340.7 MHz and 0.173 for the weaker line. The values of η are greatly decreased compared to the parent BI_3, in which η is 0.455.[12]

In Table 3 the mean values of the coupling constants $\langle e^2Qq/h\rangle_{\text{AV}}$ and asymmetry parameters $\langle\eta\rangle_{\text{AV}}$ at 77 K are listed for the complexes and the parent molecules;[11-13] here $\langle e^2Qq/h\rangle_{\text{AV}}$ were calculated by neglecting the assumed small $\langle\eta\rangle_{\text{AV}}$ for the atoms in which the asymmetry parameters could not be obtained. In the last two columns of Table 3, i and f are listed; these are calculated from Eqs. 1 and 2 with $|e^2Qq/h|_{\text{atom}}$

Table 3. Mean coupling constants, mean asymmetry parameters, ionic characters, and the degree of the decrease of pπ electrons in the complexes and the parent molecules at 77 K

$=769.756$ MHz for ^{79}Br.[14]

On complexing, the phosphorus halide molecule will transfer a charge to the boron halide without a significant change in its pyramidal form. This charge transfer will decrease the ionicity of the P–X bonds, and therefore the coupling constants of phosphorus halide in the complex will increase compared to the parent phosphorus halide, as seen in Eq.1. It is apparent from Table 3 that the $\langle e^2Qq/h\rangle_{AV}$ values increased significantly, that is, the i values decreased, in the complex as compared to the parent molecule.

On the other hand, in going from the parent molecule to the complex, the boron halide changes its structure from planar triangle to pyramid, so that the forming of a π bond between boron and halogen atoms becomes difficult. The two asymmetry parameters in $PBr_3 \cdot BI_3$ are somewhat different, as stated above. This may be attributed to the intermolecular bonding containing I atoms and/or the crystal field effects. However, since these effects can not be estimated due to the lack of information about the crystal structure, average values of η were used tentatively in order to see the extent of π bondings. From Table 3, the π bond character obviously decreases on complexing, whereas the ionic character remains almost the same. Therefore, the π electrons which participated in the π bond between I and B atoms are mostly given back to the I atom. The same situation may also be expected for BBr_3 of the complexes in which η have not been obtained. The decrease of f is accompanied by the increase in the coupling constants, as is seen from Eq. 1. This is the case for the boron halides of the complexes.

On forming the complexes of $PBr_3 \cdot BBr_3$ and $PI_3 \cdot BBr_3$, the ionic character of the P–X bond, i, decreases in PI_3 much more than in PBr_3, and i of the B–Br bond increases in the latter a little more than in the former complex. Accordingly, it is evident that electrons are transferred from PI_3 to BBr_3 much more than from PBr_3 to BBr_3. This is consistent with the order of the Lewis base strengths, $PI_3 > PBr_3$, which was determined by other methods.[15]

One of the authours (H.T.) wishes to thank Professor Takeshi Waki in Tokushima University for his encouragement throughout this research.

On the Diffusivity of Nonelectrolytes in Infinitely Dilute Solution

Koichiro NAKANISHI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received August 24, 1977)

The validity of the plot, isoviscous diffusion coefficient $D_1\eta_2$ *vs.* molar volume V_2, where D_1 is the diffusion coefficient of solute at infinite dilution, η_2 the viscosity coefficient of solvent, and V_2 the molar volume of solvent, proposed by Hammond and Stokes for carbon tetrachloride, was examined and confirmed with several solutes. General features of the behavior of diffusivity in dilute solution are discussed in terms of solvent association, complex formation and other factors. The experimental results for iodine are given.

The diffusivity of solute in dilute solution has been the subject of many studies primarily because of its practical importance. From a theoretical point of view, this quantity is of fundamental importance in describing transport properties of fluid systems. If the interdiffusion coefficients measured as a function of concentration in dilute solution are extrapolated to infinite dilution, the limiting value, D_1, represents the motion of a single particle in a medium having uniform but different intermolecular force field from that exerted by itself. Thus, the physical meaning of this quantity can be regarded to be almost the same as that of self-diffusion coefficient.

Stokes and co-workers[1,2] carried out extensive studies on the diffusion of carbon tetrachloride and iodine diluted with various organic solvents. An interesting result is a plot of the viscosity-reduced diffusion coefficient $D_1\eta_2$ (η_2; viscosity coefficient of solvent) of carbon tetrachloride against the molar volume, V_2, of the solvent. For the sake of convenience, the plot will be referred to hereafter as the HS (Hammond-Stokes) plot.[2] There are three linear relationships, each corresponding to a group of solvents, namely, spherical molecules, alcohols and the homolog of normal paraffins. All these plots have a positive slope and converge to a common point when extrapolated to $V_2=0$. This is the Stokes-Einstein limit where large particles diffuse in an essentially continuous medium.

The purpose of this paper is to examine the HS plot for other diffusates which sometimes show more complex interactions with solvents. New data are presented for iodine in six organic solvents.

Experimental

Apparatus and Procedure. The diffusion coefficient of iodine in six organic solvents was determined by the capillary cell method. The procedure was reported previously.[3] The diaphragm cell method was also used in part of the measurements. The apparatus and procedure were similar to those given by Hammond and Stokes[2] and Mills and Woolf.[4] The solution-filled procedure was adopted throughout the measurement. The diaphragm used was a micropore glass filter, No. 4. In order to determine the cell constant of the diaphragm, several runs were performed with aqueous KCl solutions. The cell constant was found to be 0.315 cm^2. The concentration changes in two compartments of the cell were determined by measuring the density of solution. A precision vibration-type densimeter(Shibayama Sci. Instr. Co., Model SS·D 200) was used. The concentration change of iodine in the diaphragm cell experiment was determined by titration using sodium thiosulfate solution. The methods of calculation of diffusion coefficient from these two types of measurement have been described.[3,4]

TABLE 1. DIFFUSION COEFFICIENTS OF IODINE DILUTE IN SIX ORGANIC SOLVENTS AT 298.15 K

Solvent	D_1 10^5 cm^2 s^{-1}	η_2 cP[a]	$D_1\eta_2$ 10^{10} dyn[b]
Heptane	3.40±0.10	0.395	1.34
2,2,4-Trimethylpentane	2.93±0.04	0.484	1.38

2-Propanol	0.89 0.84[c]	2.10	1.83

a) cP=centipoise=0.01 P. 1P=0.1 Pa s throughout this paper. b) 1 dyn=10^{-5} N throughout this paper. c) Data obtained by the diaphragm cell method.

Results. In connection with the study of diffusion in mixed solvents, the values for the diffusion coefficients of iodine diluted in nine pure solvents have been reported.[3,5,6] The six new data obtained with capillary and diaphragm cell methods are summarized in Table 1. Whenever measurements are duplicated by the two methods, both results agree fairly well with each other. The datum for iodine in heptane agrees with the literature value,[1] while there is a small discrepancy between the two data for iodine in 1,4-dioxane.[1]

Hammond-Stokes Plot for a Solute in Different Solvents

Our literature survey indicates that the diffusion coefficients of a solute in a variety of solvents are available only for limited solutes at 298.15 K. We have tested the validity of the HS plot for these solutes. In the case of CCl_4 and I_2, additional data have been reported since the original works by Stokes *et al.* The HS plots for these two solutes are shown in Figs. 1a and 1b. Other typical examples are also given in Figs. 2a—2f.

We see that the product $D_1\eta_2$ increases when V_2 becomes large. In a limited range where V_2 is between 50 and 200 cm^3 mol^{-1}, $D_1\eta_2$ *vs.* V_2 relation may be approximated by three straight lines. The line with the largest slope is associated with alcohols, aniline, and other associated solvents. Sometimes water can be included in this category. The other two lines are respectively for spherical molecules and for normal paraffins and related chain-like molecules. Extrapolation of these three straight lines may converge to a

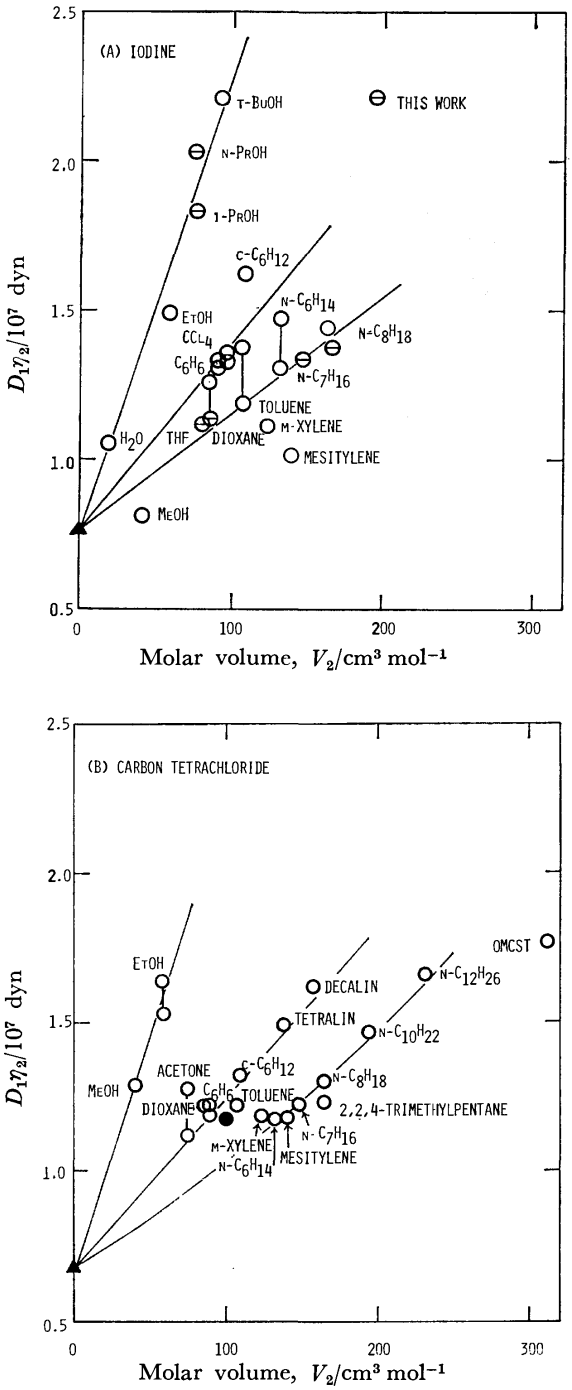

Fig. 1. Hammond-Stokes plot for the diffusion of iodine and carbon tetrachloride in various solvents at 298.15 K. (A) Iodine, (B) carbon tetrachloride. ○, ⊖: $D_1\eta_2$, ●: $(D_1)_{self}\eta_2$, ▲: $D_1\eta_2$ at the Stokes-Einstein limit. Perpendicular lines connect two or more data for the same solvent from different sources.

common point at $V_2=0$. The point given as a triangle represents the D_1 value at the Stokes-Einstein limit and its $D_1\eta_2$ value can be calculated from the Stokes-Einstein equation,

$$D_1\eta_2 = kT/6\pi r_1,$$

where the radius of solute, r_1, is given by

$$r_1 = (3V_1/4\pi N_{av})^{1/3}.$$

Here V_1 is the molar volume of solute at 298.15 K and N_{av} is the Avogadro number.

Although generalization of the original treatment by Hammond and Stokes[2] can be fully verified as above, we have made several interesting observations. In the following discussion, the self-diffusion coefficient, $(D_1)_{self}$, can be included in the correlation. The literature values of $(D_1)_{self}\eta_2$ are taken mainly from the compilations of Dullien[7] and Tyn and Calus.[8]

(1) Whenever a constant slope of $D_1\eta_2$ *vs.* V_2 relation for the same group of solvents can be established, it is almost independent of the solute used. Estimated values for the group of nearly spherical molecules are between 0.95 and 0.55×10^{-9} dyn·mol·cm³, with the exception of carbon dioxide and other smaller solutes which have a larger slope. This is to be compared with 0.60×10^{-9} for CCl_4 reported by Hammond and Stokes.[2]

(2) It should be noted that the $D_1\eta_2$ *vs.* V_2 plot for nonpolar liquids deviates upward from linearity as V_2 increases beyond 200 cm³ mol⁻¹ or so. This tendency seems to be evident for smaller solutes such as ethane (Fig. 2a) and carbon dioxide (Fig. 2b). Perhaps the larger difference in molar volume between solute and solvent may be responsible for this deviation.

(3) Benzene, cyclohexane and CCl_4 form a triplet of simple organic liquid. They are all spherical or disk-like molecules and their molar volume is as large as 100 cm³ mol⁻¹. However, when examined in detail, the molar volume is in the order, c-C_6H_{12}>CCl_4>C_6H_6, while their diffusion coefficient in the same solvent always increases in the order, C_6H_6>c-C_6H_{12}>CCl_4. This indicates that, in spite of larger molar volume, the diffusivity of cyclohexane is somewhat higher than that of CCl_4.

(4) If the diffusing solute has a strong interaction with solvent, that is, there is a solvation between unlike molecules, the product $D_1\eta_2$ takes somewhat lower values.[8,9] A typical example is the case of acetone in chloroform (Fig. 2e), a classical example of binary solution in which the hydrogen bonding between unlike molecules is a source of negative deviation from the ideal solution law. A similar decrease in $D_1\eta_2$ values is also observed for chloroform in ethers, and esters, and in the present data, I_2 in 1,4-dioxane and THF.

(5) The $D_1\eta_2$ *vs.* V_2 plot for various solutes in aliphatic alcohols has a larger slope.[2] A similar tendency is observed for the cases of ethylene glycol (Fig. 2b) and aniline (Fig. 2d) as solvents.

(6) The behavior of water as a solute in various kinds of solvents is puzzling. According to Fig. 2f, the $D_1\eta_2$ values for water in hydrophilic solvents such as alcohols, ketones, esters and carboxylic acids are generally small and close to the value at the Stokes-Einstein limit. However, they are higher in nonpolar solvents. No consistent interpretation can be given at the present stage.

Diffusivity of Different Solutes in the Same Solvent

Let us examine a variation of the diffusion coefficient of different solutes in the same solvent with the molar

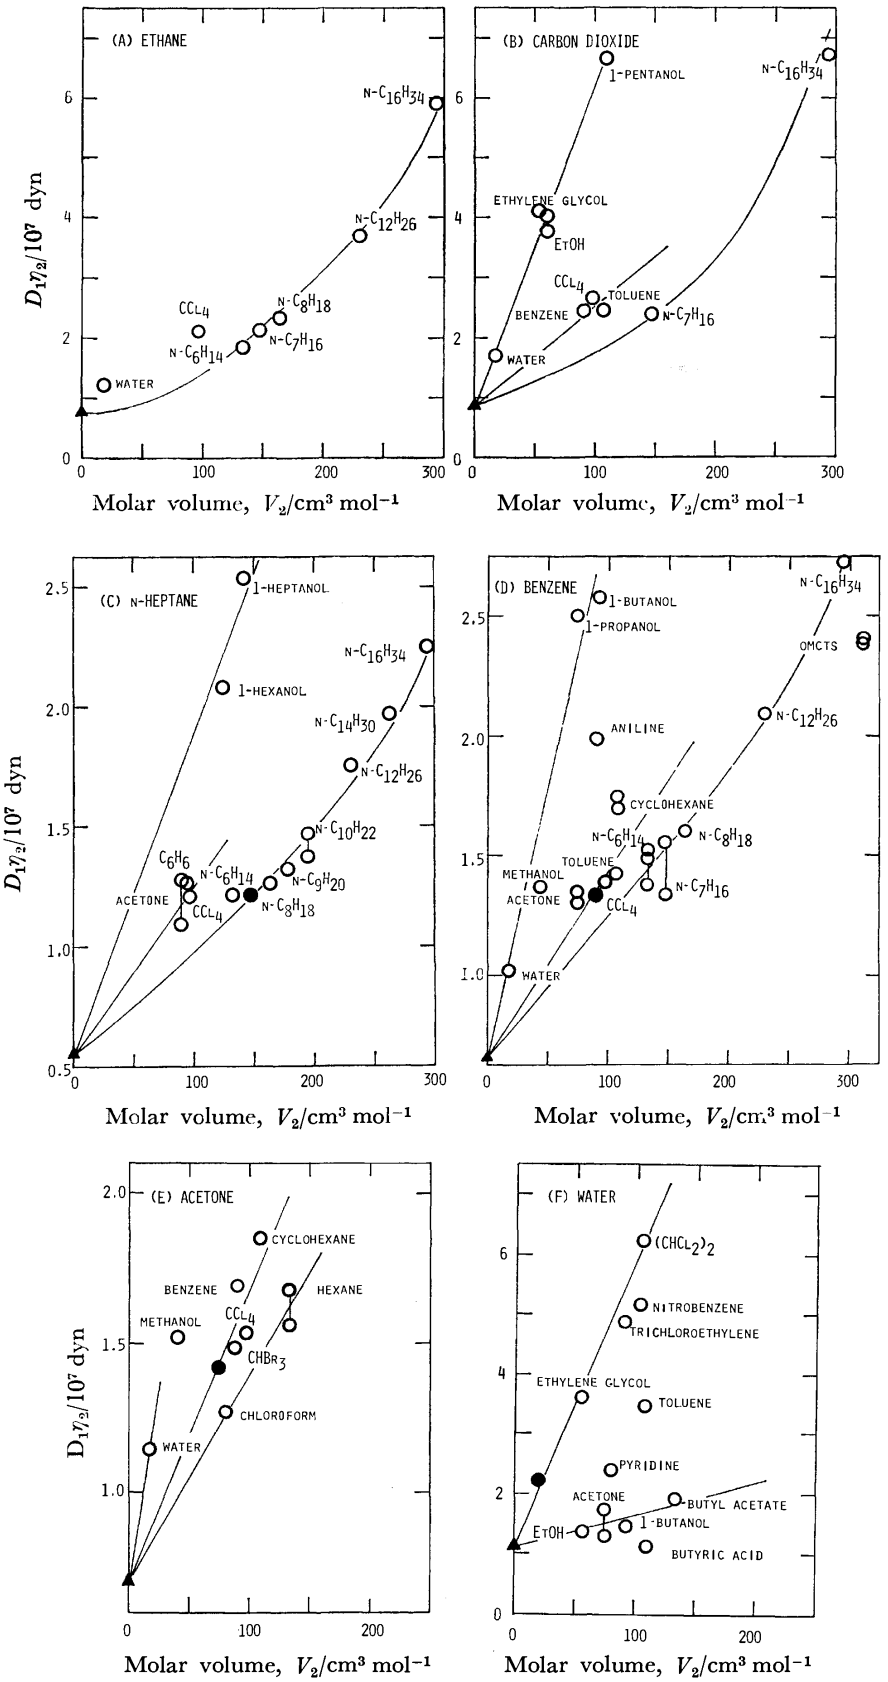

Fig. 2. Hammond-Stokes plot for six solutes at 298.15 K. (A) Ethane, (B) carbon dioxide, (C) heptane, (D) benzene, (E) acetone, (F) water. The notations are the same as those in Fig. 1.

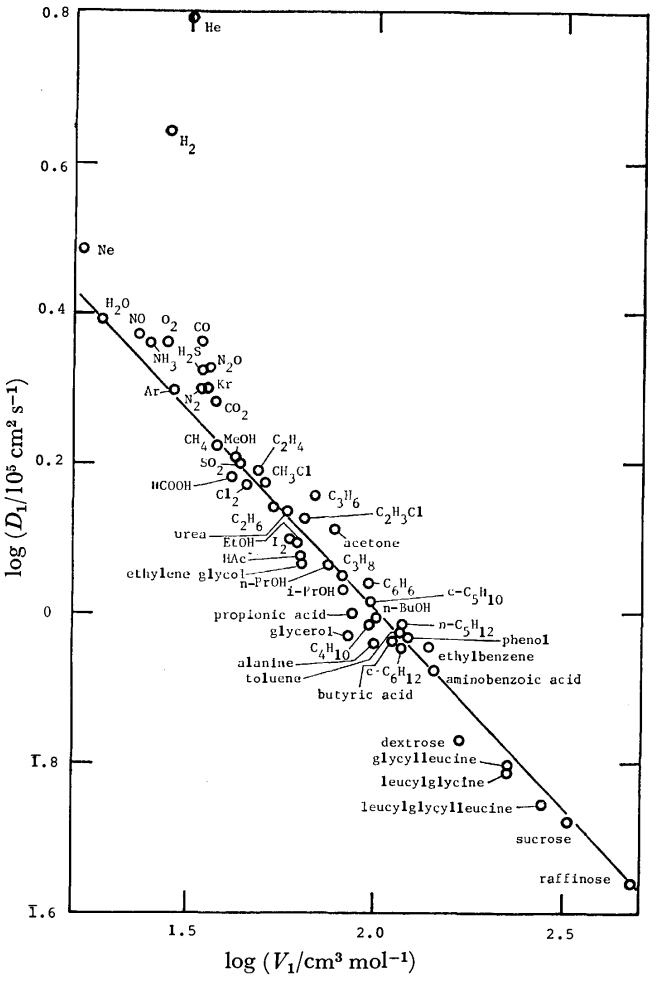

Fig. 3. Log D_1 *vs.* log V_1 plot for various solutes in water at 298.15 K.

volume of solute. Abundant data are available for only limited solvents at 298.15 K. Since no successful procedure has been given for this kind of analysis on diffusivity, we will follow a simple empirical rule proposed by Hildebrand *et al.*[10]

They claimed that the product $D_1\sigma_1^2$ or $D_1(V_c)_1^{2/3}$ where σ_1 is the diameter of molecule and V_c is the critical volume, is found to be constant for non-quantum gases diffusing in CCl_4 and $(n\text{-}C_4F_9)_3N$. We will therefore examine the log D_1 *vs.* log V_1 plot in some selected solvents at 298.15 K. The results are shown in Figs. 3 and 4.

In the case of water as solvent, we see that a good correlation can be established in a V_1 range between 16.8 (neon) and 480 (raffinose) (Fig. 3). All the points scatter properly around a straight line; and large deviations, both positive and negative, can be seen. Helium, hydrogen, and deuterium show a large positive deviation which can be ascribed to a mass effect.[10b] On the other hand, hydrophilic solutes seem to show small negative deviations. We may cite the following solutes: glycerol, ethylene glycol, carboxylic acids, and to a lesser extent, ethanol and 2-propanol The slope of the straight line in log D_1 *vs.* log V_1 plot obtained for water is very close to 2/3, which is equivalent to the rule of the constancy of $D_1\sigma_1^2$ proposed by Hildebrand.[10]

Water(0.89)–cyclohexane(0.89)–carbon tetrachloride (0.90) forms a triplet of isoviscous solvents (Values in parentheses indicate the viscosity coefficient in centipoise for each solvent). The log D_1 *vs.* log V_1 plot for solutes in the latter two solvents is illustrated in Fig. 4. The points for each solute can be classified into three groups; (i) nearly spherical molecules, (ii) normal paraffins, and (iii) other solutes. The slope of linear relation representing group (i) is slightly larger than that for group (ii). Such a difference in slope is ambiguous in the case of water, and the slope for water as solvent

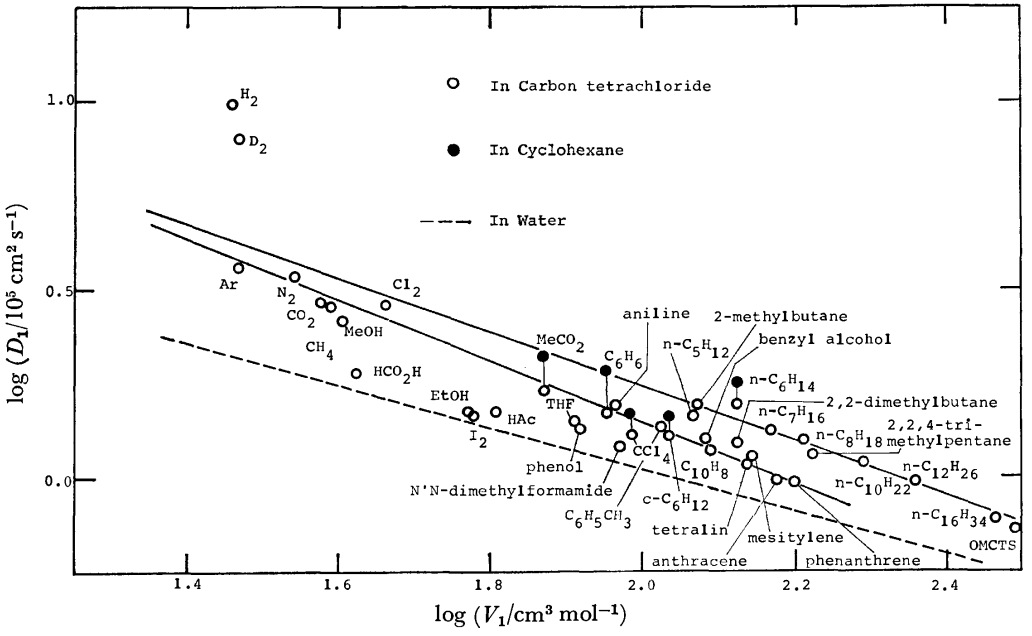

Fig. 4. Log D_1 *vs.* log V_1 plots for various solutes in carbon tetrachloride and cyclohexane at 298.15 K.

being in an intermediate between those for two groups in CCl_4 (dashed line in Fig. 4). The values of diffusion coefficient in water are generally smaller than those in CCl_4 and cyclohexane, indicating that the decrease in diffusivity due to the hydration of each solute cannot be negligible.[11]

The effect of attractive interaction on diffusivity seems to be evident as in the case of the HS plot (Figs. 3 and 4). These observations are supported by recent molecular dynamics calculations on Lennard-Jones liquid mixtures.[12]

In conclusion, the present analysis of the data for the diffusion coefficient in dilute solution reveals general validity of the Hammond-Stokes plot and the presence of the effect of strong specific interaction which causes a decrease in the diffusivity of polar and associated solutes. The analysis will be useful as the basis for empirical methods for predicting the diffusion coefficient in dilute solutions.

The author thanks Messrs. Y. Furusawa and Y. Nishimoto for carrying out the measurements with iodine solutions.

Photochemical Oxidation of Benzene, Toluene, and Ethylbenzene Initiated by OH Radicals in the Gas Phase

Mikio Hoshino, Hajime Akimoto, and Michio Okuda
The National Institute for Environmental Studies, Yatabe, Ibaraki 300-21

(Received September 2, 1977)

Photochemical oxidation of benzene, toluene, and ethylbenzene initiated by OH radicals in the presence of NO and NO_2 was studied in the air by using a 67 dm^3 reaction chamber made of Pyrex glass. OH radicals were produced by photochemical decomposition of nitrous acid, the products being phenol and nitrobenzene for benzene; cresols, benzaldehyde, *m*- and *p*-nitrotoluenes, and benzyl nitrate for toluene; ethylphenols, benzaldehyde, acetophenone, and *m*- and *p*-nitroethylbenzene for ethylbenzene. The reaction mechanisms are proposed based on the addition of OH radicals to aromatic rings and the hydrogen abstraction of OH radicals from alkyl groups.

Photochemical oxidation of hydrocarbons related to air pollution has been discussed since Haagen-Smit proposed[1] a mechanism for photochemical smog formation in Los Angeles whereby harmful oxidants were produced by nitrogen oxides and hydrocarbons under sunlight. Recent studies[2–5] have shown that OH radicals play the most important role in the photo-oxidation of hydrocarbons.

From the standpoint of air pollution, the major concerns are information on the rate constants and that on the final products of the reactions of OH radicals with hydrocarbons. The former is useful for modeling the urban atmosphere, and the latter for taking precaution against injury to both plants and humans. As far as aromatic hydrocarbons are concerned the rate constants and their Arrehenius parameters of the reactions of OH radicals have been thoroughly studied by flash-resonance fluorescence[6,7] and smog chamber experimental techniques,[8,9] but no report was given on the final products.

The present work deals with the photo-oxidation products of aromatic molecules initiated by OH radicals produced by the photolysis of nitrous acid (HNO_2). The final products observed for benzene, toluene, and ethylbenzene in the presence of NO and NO_2 are reported and the reaction mechanisms are discussed.

Experimental

The reaction cell used was a 67 dm^3 Pyrex glass chamber (diam. 22.5 cm, length 170 cm) which can be evacuated to 10^{-7} Torr by a rotary, sorption, and titanium getter and spatter ion pumps. Aromatic hydrocarbons in a 105 cm^3 glass bulb at a known pressure were first introduced into the reaction chamber. Nitrous acid was produced from sodium nitrite and sulfuric acid according to the method of Cox.[10] A round-bottomed flask (500 cm^3) containing 5% sulfuric acid was filled with pure air after evacuation. Aqueous sodium nitrite (5×10^{-2} mol/dm^3 or 5×10^{-3} mol/dm^3) was added drop by drop under a stream of pure air carrying the gaseous nitrous acid produced into the reaction chamber. To avoid excess moisture, pure air was introduced into the reaction chamber, by-passing the flask after the sodium nitrite solution had been consumed. Two Capsulon pressure gauges (Edward High Vacuum Co.) calibrated by means of a mercury manometer were used for measuring pressures.

The light source was a 500W xenon lamp. A parallel light beam of *ca.* 200 mmϕ was obtained by using an elliptic mirror, a lens, and an off-axis parabolic mirror. The reaction mixtures were irradiated through a Pyrex window. The wavelengths of the irradiated light were longer than 320 nm.

Product identification and quantitative analysis were performed using a gas chromatograph (Shimadzu 6A) and G. C. mass spectrometer (JOEL, JMS-D100). Glass columns (3 m) with 5% SE-30 on Shimalite W were used. The oven temperature was elevated from 80 to 200 °C at a programmed rate of 4 °C/min.

It should be noted that the conversion of aromatic molecules was limited to below 1% in order to avoid reactions of primary products. Dark reactions were found to be negligible. Because of the low conversion of reactants, the sampled gas had to be concentrated before introduction into the gas chromatograph or G. C. mass spectrometer. The reaction mixtures were first sampled from the reaction chamber into a 700 cm^3 glass bulb which had been evacuated before use. The sampled gas in the bulb was exhausted out slowly through a cooled spiral glass tube in order to collect products. The temperature of the spiral tube had to be kept between −80 and −60 °C, since the relatively volatile products escape above −60 °C. Nitrogen dioxide which causes thermal reaction with the reactants and products in the tube was captured below −80 °C. After the concentration the tube was warmed with hot water, and the products trapped in the tube were introduced directly into the gas chromatograph.

The concentrations of nitrogen oxides were measured with a commerical chemiluminescence NO_x analyzer (Monitor Labs, Model 8440). The analyzer is capable of measuring simultaneously the concentrations of NO and NO_x, where NO_x here is the sum of HNO_2, NO and NO_2.

$$[NO_x] = [HNO_2] + [NO] + [NO_2] \quad \text{(i)}$$

The concentrations of HNO_2, NO, and NO_2 were determined by the method of Cox[10] as follows. When the mixture of HNO_2, NO_2, and NO is bubbled through an aqueous alkaline solution (0.1 M NaOH), HNO_2 and a certain amount of NO_2 and NO are removed. Thus the concentrations of HNO_2, NO, and NO_2 are determined, from Eq. i and the following relation.

$$[NO_x]_{alkaline} = (1-a)[NO] + (1-b)[NO_2] \quad \text{(ii)}$$

Factors a and b were obtained by independent measurement of the loss of NO and NO_2 after bubbling through alkaline solution. The values of a and b were determined to be 0.1 and 0.2, respectively.

Benzene, toluene and ethylbenzene were supplied by Wako Pure Chem. Ind. Co. Pure air and nitrogen gases (Takachiho Chem. Ind. Co.) were used without purification. As an authentic sample, benzyl nitrate was prepared by fractional distillation of the reaction mixture of benzyl chloride and silver nitrate in a dried acetonitrile solution.

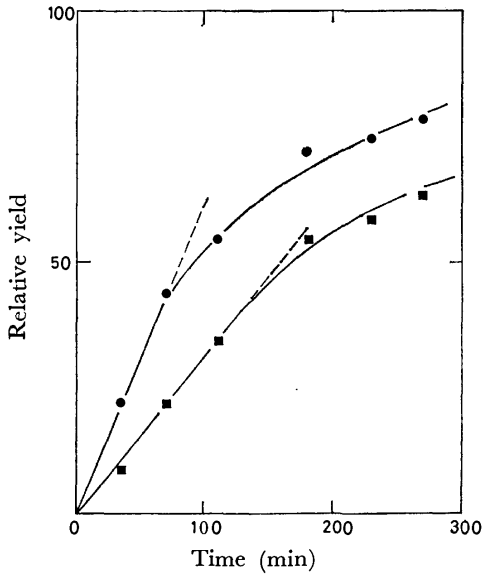

Fig. 1. Relative yields of phenol (●) and nitrobenzene (■) *vs.* irradiation time in the photo-oxidation of benzene-HNO_2-air system.

Results

Phenol and nitrobenzene were the major products when the mixture of benzene and HNO_2 in the air was irradiated. A small amount of nitrophenols was detected as well.

Figure 1 shows typical formation curves of the products as a function of irradiation time when the initial concentrations of benzene and HNO_2 were 31 and 3.2 ppm, respectively. NO_2 at 1.4 ppm and NO at 1.2 ppm were present in the initial reaction mixture, since HNO_2 partially decomposes into NO and NO_2.

As shown in Fig. 1, the amounts of phenol and nitrobenzene first increase linearly with time, then show convex curvatures, which would be due to the decrease of the concentration of HNO_2 by photochemical decomposition. The ratio of nitrobenzene to phenol was found to increase as the reaction proceeds, the increase of NO_2 concentration during irradiation being responsible for this. The ratios of nitrobenzene to phenol determined from the initial inclinations of their formation curves are shown in Table 1. The ratio changes with the initial concentration of NO_2. Nitophenols were minor products and a relative yield less than 1% of phenol was dependent on the temperature of the spiral trap. They might be produced by a thermal reaction of phenol and NO_2 in the spiral trap, although photochemical formation is not excluded.

The major products in the toluene–HNO_2–air system were cresols, benzaldehyde, and *m*-nitrotoluene. Small amounts of *p*-nitrotoluene, benzyl nitrate, and nitrocresols were observed. A trace amount of an unidentified substance giving mass peaks at *m/e*: 124(39), 123(18), 122(100), 94(93), 82(54), 66(48), and 54(69) was also observed. The relative yield of *o*-cresol was found to be *ca.* 80% of the total amount of cresols and that of *m*- and *p*-cresol *ca.* 20%. *m*- and *p*-cresols could not be separated by gas chromatograph column. The yield of nitrocresols was less than 5% that of cresols. Since most nitrocresols are considered to be produced thermally from cresol and NO_2 in the trap as in the case of nitrophenol, the yield of nitrocresols was added to that of cresols (Table 2 and Figs. 2 and 3).

Table 1. Relative product yields in the photo-oxidation of the benzene-HNO_2-NO_x-air system

Initial concentration			Relative yield	
HNO_2 ppm	NO_2 ppm	NO ppm	Phenol	Nitro-Benzene
0.52	0.02	0.06	1.0	0.08
3.2	1.4	1.2	1.0	0.50

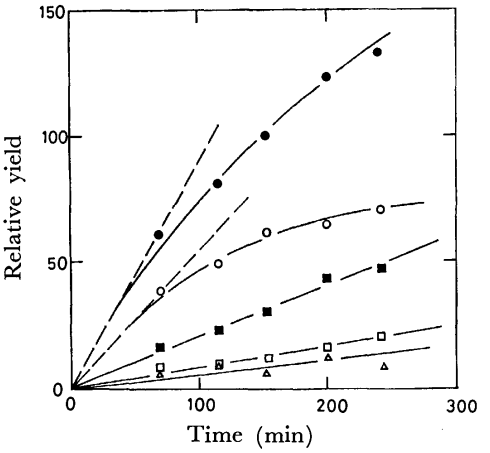

Fig. 2. Relative yields of cresols (●), benzaldehyde (○), *m*-nitrotoluene (■), *p*-nitrotoluene (□), and benzyl nitrate (△) *vs.* irradiation time in the photo-oxidation of toluene-HNO_2-air system.

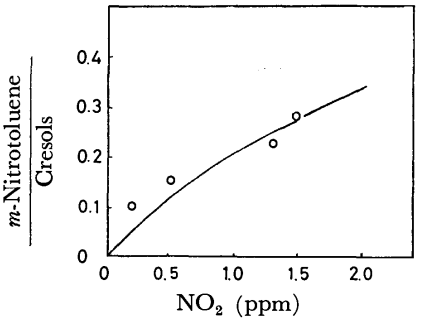

Fig. 3. Yields of *m*-nitrotoluene relative to cresols as a function of initial concentration of NO_2 in the photo-oxidation of toluene-HNO_2-air system.

The plots of [cresol+nitrocresol] and benzaldehyde *vs.* irradiation time are convex upwards. This would be due to the consumption of HNO_2 (Fig. 2). 6 ppm of HNO_2 were reduced to 2.3 ppm after 4 h irradiation. On the other hand, *m*-nitrotoluene seems to increase linearly with time. Both HNO_2 and NO_2 contribute to the formation of *m*-nitrotoluene. Thus an increase of NO_2 during the course of irradiation would compensate a decrease of HNO_2, resulting in an apparent linear increase of *m*-nitrotoluene. 1.3 ppm of NO_2 observed before irradiation was increased to 2.1 ppm after 4 h irradiation.

Table 2. Relative product yields (cresol = 1.0) in the photo-oxidation of the toluene-HNO_2-O_2/N_2 system

Initial concentration				Relative yield			
HNO_2 ppm	NO_2 ppm	NO ppm	Atmosphere	Benzaldehyde	Benzyl-nitrate	*m*-Nitro-toluene	*p*-Nitro-toluene
4	0.2	0.4	air	0.45	0.06	0.10	0.10
7	0.5	1.0	air	0.42	0.06	0.15	0.10
6	1.3	2.1	air	0.61	0.06	0.23	0.09
12	1.5	1.5	air	0.48	0.05	0.28	0.11
3	0.3	0.4	N_2	—	—	0.43	0.17
12	2.0	3.6	N_2	—	—	0.97	0.14

Table 3. Relative product yields (ethylphenol = 1.0) in the photo-oxidation of the ethylbenzene(EB)-HNO_2-NO_x-air system

Initial concentration			Relative yield			
HNO_2 ppm	NO_2 ppm	NO ppm	Benzaldehyde	Acetophenone	*m*-Nitro-EB	*p*-Nitro-EB
1.7	0.5	0.2	0.60	1.73	0.11	0.08
7.9	1.2	3.0	0.65	2.02	0.37	0.16

The ratios of products determined from the initial slopes on the formation curves of the products are shown in Table 2. It is evident that the ratio of benzaldehyde to cresols is constant irrespective of the concentration of NO_2. On the other hand, the ratio of *m*-nitrotoluene to cresols increases with increasing initial concentration of NO_2 as shown in Fig. 3.

When the reaction was carried out in a nitrogen atmosphere, the products obtained were cresols and *m*- and *p*-nitrotoluene. It should be noted that the ratio of *m*-nitrotoluene to cresols is four times greater than that observed in the air with the same concentration of NO_2. The ratio of *o*-cresol to *m*- and/or *p*-cresol was the same as that for the air system.

In the photochemical oxidation of ethylbenzene, the products identified were ethylphenols, acetophenone, benzaldehyde, *m*-nitroethylbenzene, and *p*-nitroethylbenzene. Nitroethylphenols were also observed as minor products. Phenyl acetaldehyde was not obtained. The formation curves of the products were essentially the same as in the cases of benzene and toluene.

The ratios of the products to ethylphenols are shown in Table 3. With increase in the initial concentration of NO_2 the yield of *m*-nitroethylbenzene increases markedly. The ratios of acetophenone and benzaldehyde to ethylphenols are independent of the concentrations of NO_2. The main product was acetophenone, the yield of which was approximately twice that of ethylphenols.

Discussion

In an aromatic hydrocarbon–HNO_2–air system, photochemical oxidation is initiated by OH radicals formed in the photolysis of HNO_2.[10,11]

$$HNO_2 + h\nu(330\text{—}390\ \text{nm}) \longrightarrow OH + NO. \quad (1)$$

The reaction of the OH radicals with aromatic hydrocarbons competes with the reactions,

$$OH + NO \xrightarrow{M} HNO_2, \quad (2)$$

$$OH + NO_2 \xrightarrow{M} HNO_3, \quad (3)$$

$$OH + HNO_2 \xrightarrow{M} H_2O + NO_2, \quad (4)$$

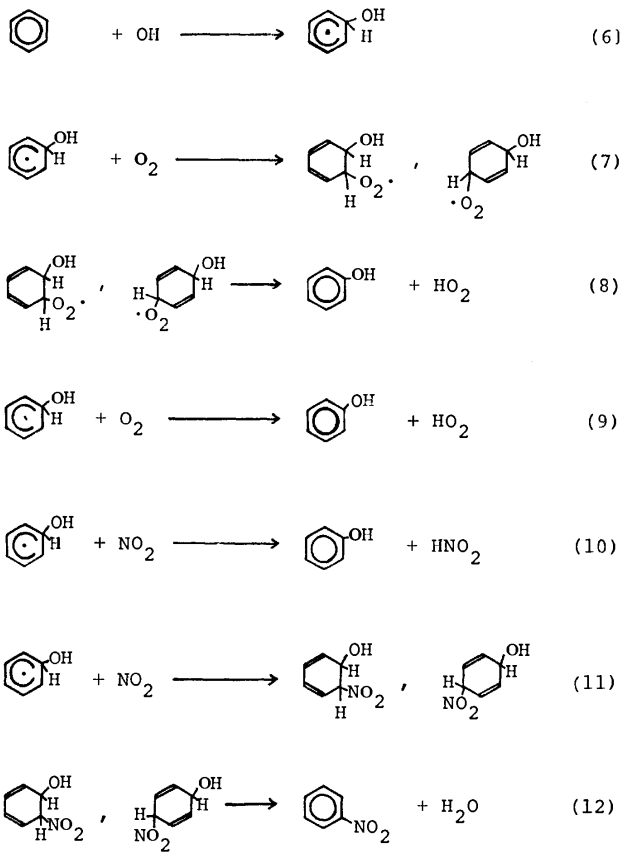
where NO and NO_2 are unavoidably present in the initial reaction mixture and also formed in the photolysis of HNO_2. In such a reaction system, a part of the OH radicals would be reproduced by the reaction

$$HO_2 + NO \longrightarrow OH + NO_2, \quad (5)$$

since HO_2 radicals are expected to be produced in the reaction of OH radicals with aromatic hydrocarbons. Thus, the photochemical oxidation in the present system is a chain process in which an OH radical acts as a chain carrier.

Benzene–HNO_2 System. In the photochemical reaction of the benzene–HNO_2–air system, the initial step should be the OH radical addition to the benzene ring followed by the reactions with O_2 and NO_2 (Scheme 1).

Addition of OH radicals to benzene has been shown to occur in the radiolysis[12,13] and photolysis[14] studies of aqueous solutions of benzene. In pulse radiolysis[12] of the aqueous solution of benzene, a transient absorption spectrum assigned to hydroxycyclohexadienyl radical has been detected. The final products in the aerated solution were phenol, peroxide, and hydroperoxide, whose yields were dependent on the pulse intensity. At low pulse intensities where the formation of peroxide and hydroperoxide due to radical-radical reactions was unfavorable, phenol was the main product and could account for 80% of the yield of OH radicals. On the other hand, photolysis[14] of benzene–H_2O_2 and γ-radiolysis[13] of benzene, both in aqueous solutions in the presence of oxygen, are known to give phenol and hydroxy-2,4-hexadienedial (CHO–C(OH)=CH–CH=CH–CHO and CHO–CH=C(OH)–CH=CH–CHO) as final products.



Scheme 1.

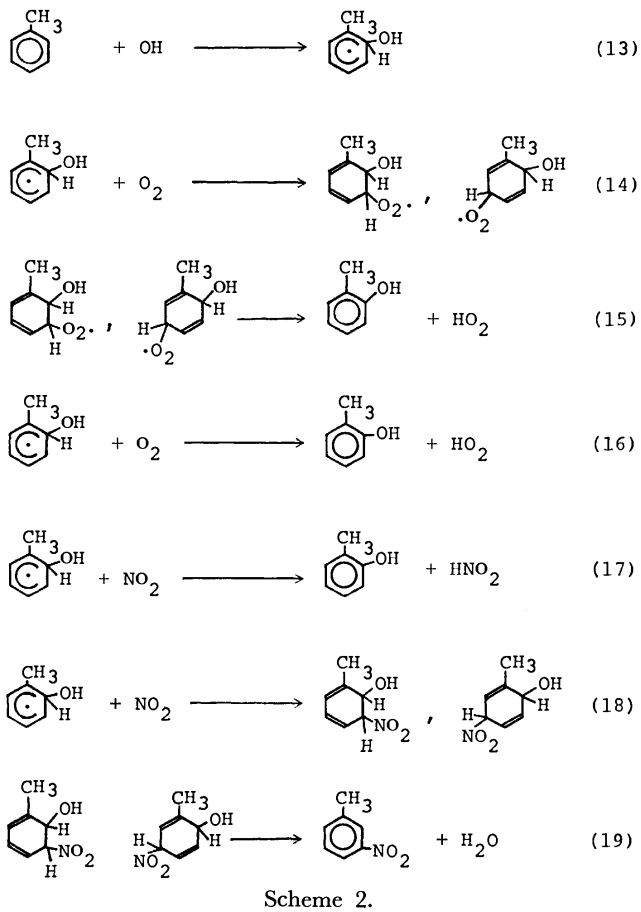
In the present reaction system, the final products were phenol and nitrobenzene and the formation mechanism can be visualized as in Scheme 1. The reaction sequence (7)—(8) is the same as the one suggested[12–14] for the formation of phenol in aqueous solutions. In the gas phase, however, Reactions 9 and 10, direct abstraction of the hydrogen atom by O_2 and NO_2, might also occur.

No formation of hydroxy-2,4-hexadienedial was observed. The compound is thought[13,14] to be formed *via* bimolecular reaction of 4-hydroxy-2,5-cyclohexadienylperoxyl radicals in aqueous systems. Since the concentration of benzene is two orders of magnitude lower than that in the aqueous studies, absence of the product due to the bimolecular radical-radical reaction is reasonable.

When NO_2 is present, it will add to the 4-hydroxy-2,5-cyclohexadienyl radicals to give nitrocyclohexadienols as a reaction intermediate and the elimination of H_2O from the intermediate will give nitrobenzene as a final product. Formation of nitrobenzene has been reported[15] in the radiolysis of aqueous $NaNO_3$ solution containing benzene, and the reaction mechanism based on the addition of NO_2 to the 4-hydroxy-2,5-cyclohexadienyl radicals followed by the elimination of H_2O has been postulated. The fact that the relative yield of nitrobenzene to phenol increases with increase in the initial concentrations of NO_2 can be explained by the mechanism shown in Scheme 1.

Nitrophenol was obtained as a very minor product. This is in line with the study of the radiolysis of aqueous $NaNO_3$–benzene system,[15] but differs from the one in the gas phase photo-oxidation systems[16,17] containing much higher concentrations ($\approx$1000 ppm of each reactant) of benzene and NO or NO_2 in the air. Formation of nitrophenol instead of phenol was probably due to the secondary nitration of phenol either in the gas phase or during the analytical procedure.

Toluene–HNO_2 System. In the reaction of the toluene–HNO_2–air system, cresols and *m*-nitrotoluene seem to be produced by the same reaction sequences as those for benzene. Approximately 80% of the total cresol formed was *o*-cresol. Predominant formation of *o*-cresol has recently been reported[18] in the reaction of toluene with oxygen atoms produced in the mercury photosensitization of N_2O. On the other hand, the formation ratio of *m*- and *p*-cresol to *o*-cresol is much higher in the radiation-induced hydroxylation[19] of toluene in aqueous solutions both in the presence and absence of metal salts. Hence it is concluded that the ortho position of toluene is regarded as the predominant reactive site both for OH radicals and oxygen atoms in the gas phase and that OH radicals discriminate the attacking site of substituted benzene more specifically in the gas phase than in aqueous solutions. The formation mechanism of cresols and *m*-nitrotoluene is proposed to be as follows.

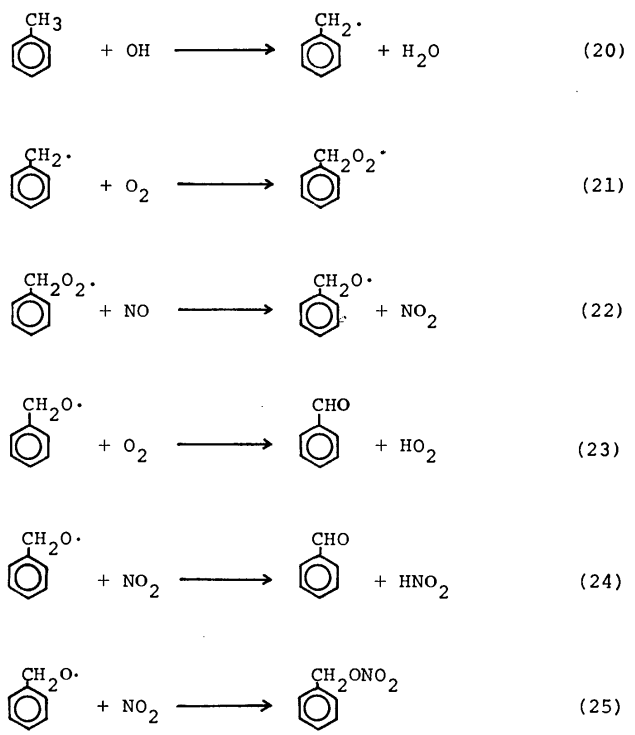


Scheme 2.

A marked increase in the yield of *m*-nitrotoluene relative to cresols with an increase of initial concentration of NO_2 (Table 2 and Fig. 3) is in line with the proposed mechanism. It should be noted that the addition

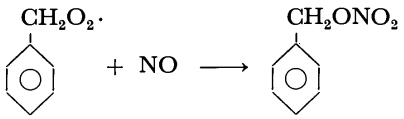
of OH radicals to the para position (not shown in Scheme 2) also leads to *m*-nitrotoluene when NO_2 adds to the methyl-substituted hydroxycyclohexadienyl radicals followed by elimination of H_2O. A minor product, *p*-nitrotoluene, might be produced *via* an intermediate radical of an OH adduct at the meta position followed by elimination of H_2O. However, the increase of *p*-nitrotoluene with an increase of the initial concentration of NO_2 is much less marked (Table 2), no *o*-nitrotoluene, which is also expected from the OH adduct at the meta position, being obtained. This suggests a different reaction path for *p*-nitrotoluene although an alternate mechanism can not be specified.

Benzaldehyde and benzyl nitrate are reasonably assumed to be formed from benzyl radicals as intermediates. Hydrogen atom abstraction by OH radicals from the methyl group of toluene occurs at slightly elevated temperatures in gas phase reactions.[20] Since the C–H bond-dissociation energy[21] in the methyl group of toluene is only 83 kcal/mol as compared to 91 kcal/mol for the tertiary C–H bond of isobutane, it is reasonable to assume that the hydrogen abstraction competes with the addition to the aromatic ring even at room temperature. Kinetic studies[6,7] on the determination of rate constants for the reaction of OH radicals with toluene also suggest the competitive abstraction of hydrogen atom from the methyl group. The formation mechanism of benzaldehyde and benzyl nitrate is thus proposed as follows, in analogy with the reaction sequence postulated[2] for alkyl radicals in the presence of O_2, NO, and NO_2.



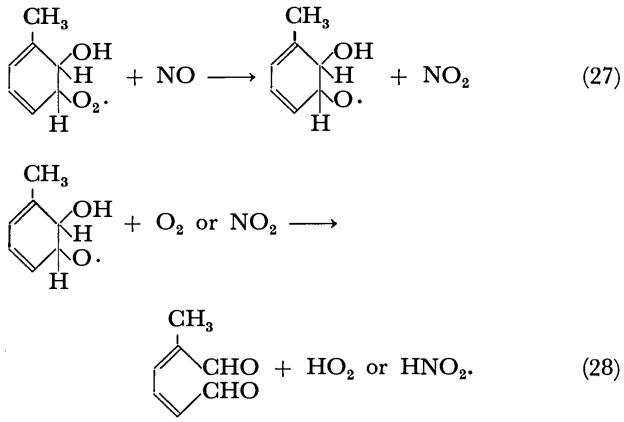
Scheme 3.

Reactions 22—25 to produce benzaldehyde and benzyl nitrate are assumed to be analogous to the reactions of methylperoxyl and methoxyl radicals to give formaldehyde and methyl nitrate.[2] If we assume the distribution of the final products given in Table 2 represents the initial step ratio of the OH addition to hydrogen atom abstraction, the percentage of the abstraction is estimated to be 25—35%. The value is in line with the suggestion by Davis *et al.*[6] that over half of the time, the reaction at room temperature proceeds *via* addition based on the pressure dependence of the rate constants. However, since no material balance has been studied, the above value should be taken as a first approximation. Formation of benzyl nitrate apparently did not increase with the increase of the initial concentration of NO_2, and an alternative path



might take place as proposed by Darnall *et al.*[22] in the case of alkylperoxyl radicals containing more than four carbon atoms.

The unidentified minor product in the photo-oxidation of toluene, giving mass peaks at *m/e*, 124, 123, 122, 94, 82, 66, and 54, might be 2-methyl-2,4-hexadienedial. A possible reaction mechanism to give the product is as follows.

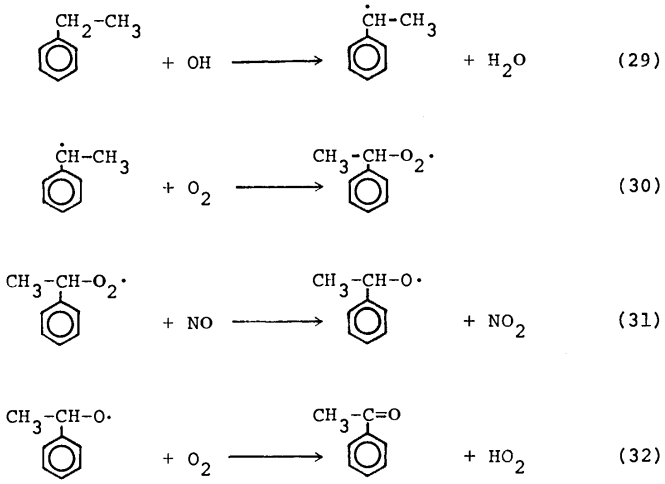


Although the mass pattern observed is what is expected for the compound, the identification is tentative since no authentic sample was available.

In an atmosphere of N_2 instead of air, the products obtained are cresols and *m*- and *p*-nitrotoluene. Benzaldehyde and benzyl nitrate, thought to be produced *via* benzylperoxyl radicals, were not observed. The results are in line with the proposed schemes 2 and 3. On the other hand, in the absence of O_2 bibenzyl and/or α-nitrotoluene derived from benzyl radicals can be expected as final products. Neither of them, however, was detected. Presumably, the poor yields of these products may be due to the low concentration of the radicals and NO_2. The ratio of *m*-nitrobenzene to phenol in the N_2 atmosphere was four times greater than that in the air. This observation is qualitatively explained by the fact that the hydrogen atom abstraction by O_2, Reactions 14, 15, and/or 16, does not contribute to the formation of cresols in the absence of O_2, resulting in a greater ratio of *m*-nitrotoluene to cresols as compared with that obtained in the air.

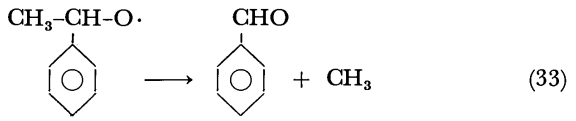
Ethylbenzene–HNO_2 System. Of the products obtained in the ethylbenzene–HNO_2–air system, ethyl

phenol and *m*- and *p*-nitroethylbenzene will be derived from the addition of OH radicals to an aromatic ring as in the case of toluene. The reaction mechanism is analogous to Scheme 2 for toluene. Acetophenone is considered to be produced *via* 1-phenylethyl radicals formed by the abstraction of an α-hydrogen atom by OH radicals. The proposed mechanism is as follows.

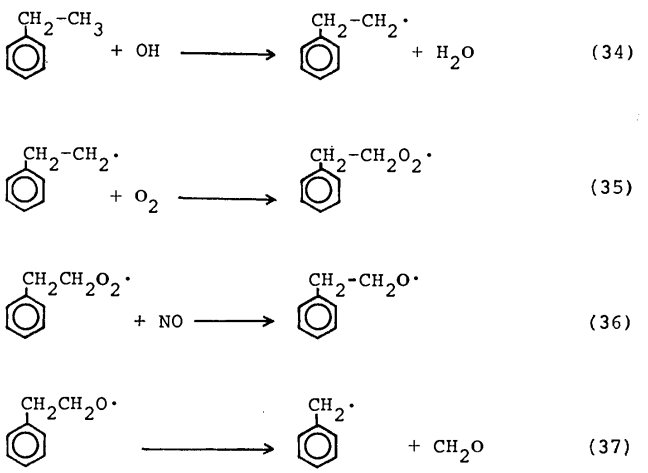


Scheme 4.

Another major product, benzaldehyde, is thought to be produced by the decomposition of 1-phenylethoxyl radicals as follows.

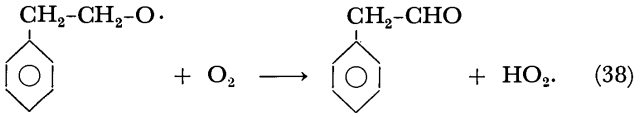


Bond cleavage in alkoxyl radicals to give a carbonyl compound and methyl radical has been assumed[23] in the photochemical oxidation of isobutane in the presence of NO and NO_2. Another possibility for the formation of benzaldehyde is the one initiated by the abstraction of a β-hydrogen atom in ethyl group of ethylbenzene. The reaction scheme is shown as Scheme 5.



Scheme 5.

According to Eqs. 21 and 22, benzyl radicals produced may be oxidized to give benzaldehyde. However, if this reaction mechanism holds, phenylacetaldehyde should also be expected as



Benzyl nitrate is also expected as in the case for toluene. Since neither of these products was obtained, we conclude that the β-hydrogen abstraction does not occur in the reaction of OH radicals with ethylbenzene, and Scheme 4 should be adopted to interpret the formation of benzaldehyde.

The ratio of yield of products formed *via* hydrogen atom abstraction to those *via* OH radical addition increases markedly for ethylbenzene as compared with the case of toluene. Thus, from the product distribution (Table 3) the percentage of the hydrogen abstraction may be deduced to be 60—70%. The apparent increase in percentage of the hydrogen abstraction reaction would be due to the weaker bond energy of α-hydrogen-carbon bond in the ethyl group of ethylbenzene than that in the methyl group of toluene.

Atmospheric Importance. It is well-known that aromatic hydrocarbons (alkylbenzenes) constitute a substantial fraction of hydrocarbons in the polluted urban atmosphere. For example, the average percentage of aromatic hydrocarbons in the Los Angeles Basin was reported[24] to be roughly 20%. In Japan, the presence of a higher percentage of aromatic hydrocarbons has been noted,[25,26] amounting to 30—35% in average. Thus it is expected that the reaction products observed in the present study should also be formed in such an ambient air. Phenols, aromatic carbonyl compounds and nitrobenzenes, and nitrates should be of concern since they are found to be formed even at atmospheric concentrations of NO and NO_2. Recently, nitrocresols were observed[16] in rain drops collected in Yokohama. This suggests that the nitration of phenols occurs easily in both gas phase secondary reactions and in aerosol droplets, since the nitrocresols are only a minor products in the primary reaction of OH radicals in the presence of atmospheric concentration of NO and NO_2.

We thank Drs. N. Washida and G. Inoue for many helpful discussions on the reaction mechanism. The assistance of Mr. K. Nagasawa throughout this study is gratefully acknowledged.

The Formation of Nitrogeneous Compounds in the γ-Radiolyses of Liquid Nitrogen Solutions of Hydrogen, Methane, and Ethane

Keiichi HORIGOME, Shun-ichi HIROKAMI,* and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 9, 1977)

The γ-radiolyses of liquid nitrogen solutions of hydrogen, methane, and ethane have been reinvestigated. A complete survey of nitrogen-containing products has been attempted. The nitrogeneous compounds observed were ammonia (0.7) and hydrogen azide (0.02) in the case of hydrogen, ammonia (0.3), hydrogen cyanide (0.1), methyl azide (0.01), and a polymer in the case of methane, and ammonia (0.3), hydrogen cyanide (0.05), acetonitrile (0.04), ethyl azide (0.01), and a polymer in the case of ethane. The values in parentheses are the *G*-values obtained at optimum conditions. The hydrolysis of the polymer obtained with methane gave formaldehyde in amounts which correspond to the fact that the *G*-value of the nitrogen atoms which were converted into the polymer is about 1.0. In order to explain these results, possible reaction mechanisms are discussed.

The reactions of nitrogen atoms with hydrocarbons have been investigated in the gas phase, using active nitrogen produced in a discharge;[1] however, probably because of the low pressure and of the high temperature, more than 90% of the nitrogeneous compounds observed were hydrogen cyanide, irrespective of the hydrocarbon used. Consequently, it was almost impossible to elucidate any details of the reaction mechanism.

A few years ago, our laboratory started to use the γ-radiolysis of liquid nitrogen as the source of nitrogen atoms and studied the reactions with several olefins which are soluble in liquid nitrogen with the hope that the addition products might not decompose into hydrogen cyanide.[2] In fact, we observed the formations of acetonitrile, propionitrile, and acrylonitrile, respectively, in the reactions with propylene, 1-butene, and allene, and we could propose a generalized reaction mechanism:[3]

$$RCH{=}CH_2 + N \rightarrow R\text{-}\underset{\displaystyle N}{\overset{\displaystyle H}{C}}\text{-}CH_2 \rightarrow RCN + CH_3.$$

However, the *G*-values of these nitrile compounds, including hydrogen cyanide obtained in the reaction with ethylene were very small—less than 0.2. During these measurements, we recognized the formation of a polymer and measured the *G*-value of the nitrogen atoms which were converted into the polymer by using Conway's method. This method is one of the techniques frequently used in biochemistry. A sample containing amine and/or imine is hydrolyzed in an alkaline solution and the ammonia evolved is absorbed in dilute sulfuric acid in a specially designed vessel, and then the amount of ammonia is measured photometrically. The *G*-value of nitrogen atoms thus estimated was strongly dependent upon the hydrocarbons used and ranged from 0.1 to 0.7.[4] We tentatively explained this dependency to be due to the solubilities of hydrocarbons into liquid nitrogen.

In a short note, Siderer and Sato reported the results obtained in the γ-radiolysis of the liquid nitrogen solution of methane. The *G*-value of hydrogen cyanide was 0.08 at the optimum condition, while that of ammonia obtained by using Conway's method was 0.6.[5] On the basis of these results, they suggested that the nitrogen atoms which give nitrile compounds are not in the ground state, ^4S, but in the excited state, ^2D and/or ^2P, while the nitrogen atoms in the ground state lead to the formation of a basic polymer.

Experimental

The dried high-purity nitrogen was purchased from the Takachiho Shoji Co., and was used after having been passed through sulfuric acid (Yotsuhata Chemical Co.). The hydrogen, methane, ethane, ammonia, and various hydrocarbons used for identification were also purchased from the Takachiho Shoji Co. The hydrogen cyanide was synthesized from sodium cyanide and sulfuric acid. The nitrile compounds were supplied by the Tokyo Kasei Co. The sodium 4,5-dihydroxy-2,7-naphthalenedisulfonate used for the quantitative estimation of formaldehyde was purchased from the Wako Chemical Co.

The samples for γ-irradiation were prepared in the same manner as has been described before;[5] *i.e.*, a known amount of hydrogen, methane, or ethane was first introduced into a sampling tube 20 cm long and 3 cm in diameter. The pressure was measured by means of an oil manometer. Then pure nitrogen was introduced into the tube at 77 K under the pressure a little higher than the atmosphere. The nitrogen was then easily liquefied. The amount of the liquid was measured by the scale on the sampling tube. Since the amounts of substrates, hydrogen, methane, and ethane introduced were small, all of the gases were assumed to be dissolved into the liquid nitrogen.[6]

The samples thus prepared were irradiated by ^{60}Co γ-rays in a liquid nitrogen-Dewar flask at a dose rate of about 1.2×10^6 R h^{-1}, usually for 1 h. After irradiation, the sampling tube was connected to a vacuum system and the inside was slowly pumped out at 77 K. Usually two hours were taken for complete evacuation. The products thus obtained were subjected to analysis.

In order to identify the volatile products, use was made of a quadrupole mass-spectrometer (Nichiden-Varian TE-600) after separating the products with a gas chromatograph, the column of which was made of 6 m Silicone SE-52 supported by Uniport KS 60—80 mesh 80% w/w. Helium was used for the carrier gas.

Several analytical methods were applied to the identification of the polymer obtained in the reaction with methane: mass-spectrometry for the solid state, NMR spectroscopy, and thin layer chromatography. However, no conclusive results could be obtained except that the polymer contains N–H bonds, which was shown by the NMR spectroscopy.

* Present address: Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, Sugitani, Toyama 930-01.

Since the polymer was easily hydrolyzed with a dilute aqueous solution of hydrochloric acid to produce formaldehyde, we measured the amount of the aldehyde photometrically using sodium 4,5-dihydroxy-2,7-naphthalenedisulfonate as a chromophoric reagent.[7]

Results

Hydrogen. As the reaction products, we observed two compounds: ammonia and hydrogen azide. Both compounds were identified by the mass-spectra. Figure 1 shows the G-values of the two products as functions of the concentration of hydrogen introduced into the sampling tube. The extrapolation of the plots between $1/G(NH_3)$ and $1/[H_2]$ gave $G(NH_3) = 0.7$ at the infinite concentration of hydrogen. We looked for hydrazine as a product, since it is another simple compound composed of nitrogen and hydrogen atoms; however, we could not observe the formation of this compound.

Methane. Ammonia, ethane, hydrogen cyanide, methyl azide, and small amounts of acetonitrile and propane were observed as volatile products. As is shown in Fig. 2, the G-values of ammonia and ethane showed a small dependence on the total dose. Figure 3 shows the G-values of the four main products at the dose of 5×10^{20} eV cm^{-3} as functions of the concentration of methane. It is noticeable that the three nitrogeneous compounds, ammonia, hydrogen cyanide, and methyl azide, showed different dependences on the concentration of methane.

Table 1 shows the G-values of formaldehyde produced by the hydrolysis of the polymer. The G-values were about 1.0 in the concentration range from 0.02 to 0.5 mol l^{-1} of methane.

Ethane. Only volatile products were analyzed. The G-values of the main products at the dose of 5×10^{20} eV cm^{-3} are shown in Fig. 4 as functions of the concentration of ethane. The nitrogeneous compounds ob-

served were ammonia, acetonitrile, hydrogen cyanide, and ethyl azide. The ethane concentration-dependence of the *G*-value of hydrogen cyanide was different from those of other products: *i.e.*, the *G*(HCN) decreased with increasing concentration of ethane. Repeated measurements showed the same dependence.

In the gas chromatographic analysis, the peaks of hydrogen azide and methyl azide overlapped with those of ethane and butane, respectively; therefore, the *G*-value of these two azides could not be measured.

Discussion

Formation of Ammonia. When ethylene was used as a solute, the formation of ammonia could not be observed in the gas chromatographic analysis.[8] As are shown in Figs. 1, 3, and 4, ammonia is one of the main products when hydrogen, methane, and ethane are used as solutes. This observation suggests that the presence of hydrogen atoms in the reacting system is indispensable for the formation of ammonia. Even at the temperature of liquid nitrogen, the addition reaction of hydrogen atoms to the double bond of olefins is a fast process.[9]

On the way to the formation of ammonia, the NH_2 radicals must be produced. If so, the formation of hydrazine, N_2H_4, can be expected; however, no hydrazine could be found even in the radiolysis of the liquid nitrogen–hydrogen system. Similarly, when methane or ethane is used as a solute, the formation of alkyl amines such as CH_3NH_2 and $C_2H_5NH_2$ can be expected; however, as stated in the Results section, no amines could be observed.

In order to explain these results, we tentatively considered the following reactions:

$$NH_2 + NH_2 \rightarrow NH_3 + NH,$$
$$CH_3 + NH_2 \rightarrow CH_4 + NH,$$
$$C_2H_5 + NH_2 \rightarrow C_2H_6 + NH,$$
$$NH + NH \rightarrow N_2 + H_2.$$

All of these reactions are exothermic by more than 10 kcal mol^{-1}. According to the measurement of Gillis,[10] the ratio of rate constants for disproportionation to combination of ethyl radicals at −181 °C is larger than four and the activation energy for combination exceeds that for disproportionation by about 300 cal mol^{-1}. Similar relations might also applicable to the reactions of NH_2 radicals and to the reactions between CH_3 and NH_2, and C_2H_5 and NH_2 radicals.

Formation of Nitrile Compounds. It is now well known that nitrogen atoms in the ground state, ^4S, are inactive to alkane molecules.[11] The formation of nitrogeneous compounds in the presence of alkane molecules, therefore, is due to the reactions of nitrogen atoms with alkyl radicals eventually formed in the system. However, the *G*-value of hydrogen cyanide obtained in the γ-radiolysis of the liquid nitrogen–methane system is only 0.1, as is shown in Fig. 3, a value which suggests that less than 10% of the nitrogen atoms are converted into nitrogeneous compounds. Consequently, as has been discussed in a previous paper,[5] we propose that the nitrile compounds observed in the gas chromatographic analysis are not the products of the reactions of nitrogen atoms in the ground state, ^4S, but those of nitrogen atoms in the excited state, ^2D.

$$CH_3 + N(^2D) \rightarrow HCN + H_2$$
$$C_2H_5 + N(^2D) \rightarrow CH_3CN + H_2$$

The presence of the excited state, ^2D, in the active nitrogen has been confirmed[12] and is known to have a long life. Moreover, if the nitrogen atoms are in the state of ^4S, the above reactions are not spin-allowed ones.

When ethane was used as a solute, the *G*-value of hydrogen cyanide decreased with increasing concentration of ethane. This decrease may be explained by the competition of nitrogen atoms (^2D) and ethylene, which is produced in the system, for methyl radicals. The formation of alkyl radicals and olefins may be described as follows:[3]

$$N_2(^3\Sigma_u^+) + CH_4 \rightarrow N_2 + CH_3 + H,$$
$$N_2(^3\Sigma_u^+) + C_2H_6 \rightarrow N_2 + 2CH_3,$$
$$\rightarrow N_2 + C_2H_5 + H,$$
$$C_2H_5 + H \rightarrow C_2H_4 + H_2,$$
$$\rightarrow C_2H_6.$$

Formation of Polymer. As has been stated in the Results section, most of nitrogen atoms produced in the methane solution contribute to the formation of a polymer. The initiating reaction must be as follows:

$$CH_3 + N(^4S) \rightarrow CH_3N \rightarrow CH_2{=}NH.$$

This type of imine is not stable at room temperature and easily polymerizes into a complex polymer.

According to the infrared spectroscopic study of the photolysis of methyl azide in a rigid matrix by Milligan,[13] methylimino radicals (CH_3N) produced in the

photolysis of methyl azide isomerize to methylene imine in the matrix, and when the product is warmed up to temperatures where the matrix material is lost, a white solid is observed to remain on the wall. He measured the infrared spectrum of this solid and suggested that a part of it is hexamethylenetetramine.

We therefore looked for hexamethylenetetramine in our polymer by using gas chromatography, but we could not find it. Probably the main polymerization process is not the formation of this compound.

Formation of Azide. Because of the characteristic mass-spectra, the formation of azides was confirmed in the present experiment. As are shown in Figs. 1, 3, and 4, the *G*-values of all azides are not affected by concentrations of solutes in excess of 2×10^{-3} mol l^{-1}. If nitrogen atoms are the precursors of these azides, the yields should change with the concentration of solutes as do those of the ammonia and nitrile compounds. The N_3 radicals, therefore, may be produced by a process which is independent of the main process of the formation of nitrogen atoms—probably ion-molecule reactions, although we cannot specify them.

The authors wish to express their thanks to Dr. Masuo Funabashi of this Institute for the measurements of NMR spectroscopy and thin layer chromatography.

Fluorescence and Dual Phosphorescence Spectra of Quinoxaline in Fluid Solution

Kohzaburo YAMAMOTO, Takeshi TAKEMURA, and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received September 21, 1977)

Fluorescence and phosphorescence spectra of quinoxaline in isooctane (2,2,4-trimethylpentane) have been measured under fluid conditions. The fluorescent emission with a spectral maximum at 410 nm is assigned to the $^1(n,\pi^*)\rightarrow S_0$ fluorescence of quinoxaline. A new phosphorescence spectrum appears in a wavelength region longer than 520 nm as the concentration of quinoxaline increases, in addition to the phosphorescence spectrum of the monomer. From the results of photostationary and transient experiments on the concentration and/or temperature dependence of phosphorescence, it has been confirmed that the phosphorescence consists of two components attributable to the monomer and the excimer.

Triplet excimers have been a subject of considerable interest.[1-8] Recently, we have confirmed the existence of the triplet excimer for naphthalene and its derivatives and phenanthrene in fluid solution by means of photostationary and transient phosphorescence measurements.[1-4] On the other hand, Chandross and Dempster showed that practically no triplet excimer is formed even with a sandwich-pair conformation of the two naphthalene rings in 1,3-di(1-naphthyl)propane in a rigid glass. Such a sandwich-pair is favorable for the formation of singlet excimer.[5]

More recently, Subudhi and Lim observed intramolecular excimer phosphorescence spectra of 1,3-di(1-naphthyl)propane[6] and 1,2-di(1-naphthyl)ethane[7] in a fluid solution. The spectra of these compounds are very similar to those of naphthalene and its derivatives reported by us.[1,2]

The experimental results described above seem to be reasonably explained in terms of the idea that there is a conformational difference between singlet and triplet excimers.[2,7] However, there still remain unsolved problems concerning the stability and geometrical structure of triplet excimers. In order to settle the problems, it is desirable to examine whether or not the triplet excimer is formed in fluid solution in compounds other than aromatic hydrocarbons.

Quinoxaline is similar to naphthalene in electronic structure except that the former has lower-lying (n,π^*) states. The presence of the (n,π^*) states will make it relatively easy to detect the phosphorescence of quinoxaline in fluid solution.

This paper reports the phosphorescence spectrum of quinoxaline in fluid solution, together with its fluorescence spectrum which has not been observed so far. The phosphorescence of quinoxaline is shown to be due to both the monomer and the excimer as in the case of aromatic hydrocarbons.

Experimental

Quinoxaline (Nakarai Chemical Co.) was purified by vacuum sublimation. Isooctane (2,2,4-trimethylpentane, Wako Pure Chemical Co.) was passed through a silica-gel column. The solution of quinoxaline in isooctane was fully degassed by repeated freeze-thaw cycles (7 or 8 times). Emission spectra were measured with a high-resolution, high-sensitivity emission spectrophotometer[1,2] equipped with a photon-counting detector. A specially designed spectrophosphorimeter was used for measuring the phosphorescence or delayed emission spectra as well as the time-resolved emission spectra with the lifetimes ranging from 10^2 to 10^{-5} s by means of the photon-counting method combined with a multichannel digital boxcar technique.[1,2] Representative emission and excitation spectra were corrected for the spectral sensitivity of the monochromator-photomultiplier system and for the spectral intensity of exciting light, respectively. The fluorescence quantum yield of quinoxaline was determined by comparing the corrected fluorescence spectrum with that of quinine sulfate in 1/2 M sulfuric acid used as a reference.

Results and Discussion

Uncorrected emission spectra are shown in Fig. 1, which were measured for both the aerated and the degassed isooctane solutions of 1.1×10^{-4} M quinoxaline at 25 °C. The emission spectrum of the aerated sample (A in Fig. 1) may be assigned to $^1(n,\pi^*)\rightarrow S_0$ fluorescence of quinoxaline on the basis of the following facts: (1) There is a mirror image relation between the emission spectrum and the lowest $^1(n,\pi^*)\leftarrow S_0$ absorption spectrum of quinoxaline; (2) the emission spectrum is very similar to the fluorescence spectrum of gaseous quinoxaline reported by McDonald and Brus,[9,10] and Soep and Tramer,[11] although it differs from the spectrum obtained by Dewey and Hadley;[12] (3) the exci-

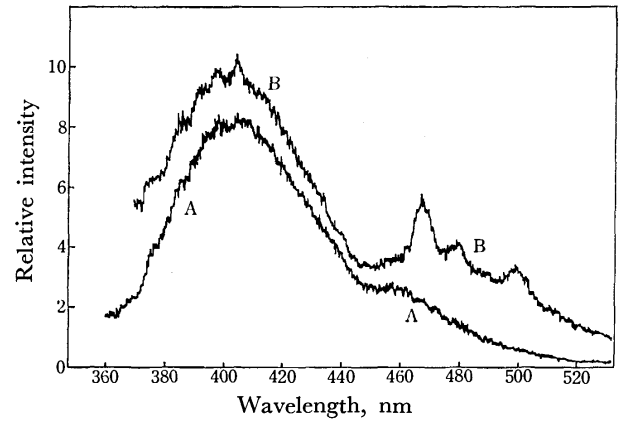

Fig. 1. Emission spectra (uncorrected) of quinoxaline in isooctane at 25 °C: A, aerated sample; B, degassed sample. The exciting wavelength is 315 nm with a band width of 10 nm; the band width for the emission is 3 nm. The concentration of quinoxaline is 1.1×10^{-4} M.

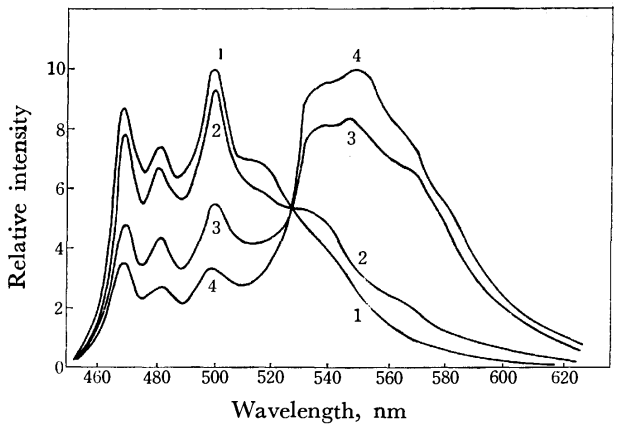

Fig. 2. Changes in the delayed emission spectrum (uncorrected) of quinoxaline in isooctane at 25 °C caused by the increase of the concentration. The concentrations of quinoxaline: (1) 1.1×10^{-4}; (2) 1.1×10^{-3}; (3) 1.1×10^{-2}; (4) 1.1×10^{-1} M. The spectral intensities are normalized at 528 nm.

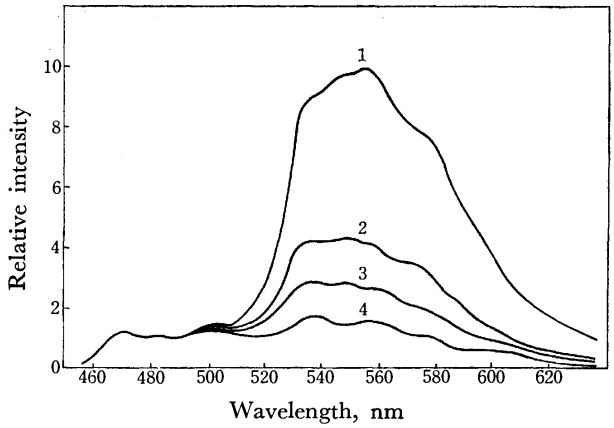

Fig. 3. Changes in the delayed emission spectrum (uncorrected) of quinoxaline in isooctane with temperature. The temperatures of the solution: (1) 0; (2) 25; (3) 43; (4) 60 °C. The concentration of quinoxaline is 6.0×10^{-2} M. The spectral intensities are normalized at 470 nm.

tation spectrum monitored at any emission wavelength between 370 and 520 nm is in fair agreement with the absorption spectrum in the range of the $^1(n,\pi^*)\leftarrow S_0$ transition of quinoxaline; (4) the emission concerned has a quantum yield of 7.5×10^{-5} and a lifetime shorter than 2 ns in isooctane at 25 °C; and (5) the quantum yield is independent of concentration and is not changed by degassing the sample solution. It should be noted here that the appearance of a shoulder at about 460 nm is due to the fact that the spectrum is not corrected for the sensitivity of the spectrophotometer used.

On the other hand, the degassed sample (B in Fig. 1) exhibits, in addition to the fluorescence spectrum described above, a structured emission spectrum in a wavelength region longer than 465 nm. This emission has an apparent lifetime of the order of 10^{-3} s. The excitation spectrum with respect to the structured emission spectrum agrees with the absorption spectrum of quinoxaline.

Figure 2 shows the delayed emission spectra (uncorrected) of quinoxaline in isooctane at 25 °C, which were measured with the spectrophosphorimeter. The emission spectrum of quinoxaline for a relatively low concentration (1.1×10^{-4} M) is in good agreement with the phosphorescence spectrum in EPA at 77 K, but the former spectrum is red-shifted by about 300 cm^{-1} compared with the latter.

The experimental results described above indicate that the structured spectrum extending from 465 nm towards longer wavelengths at a relatively low concentration is attributable to the phosphorescence from the monomer of quinoxaline.

The delayed emission spectrum, however, exhibits strong concentration dependence as shown in Fig. 2, where the spectral intensities are normalized at 528 nm. A new emission spectrum grows in a wavelength region from 520 to 620 nm with the increase of concentration; hereafter, it will be called emission spectrum E. Although the excitation spectrum cannot be obtained accuratcly by monitoring the emission spectrum E because of the high solute concentration, the onset at the longest wavelength of the excitation spectrum coincides with that of the absorption spectrum of quinoxaline. It is seen in Fig. 2 that the intensity ratio of the emission E to the monomer phosphorescence increases as the concentration increases. It should be noted that the emission E is not due to a photochemical product, because practically no change was produced in the intensity of the emission E by exposing the sample solution to UV light. It is also noted that the solvent used showed no delayed emission under the present experimental conditions.

By reference to the excimer phosphorescence of naphthalene and phenanthrene,[1-4] the experimental results regarding the concentration dependence of the delayed emission are found to suggest that the emission E is due to the excimer phosphorescence of quinoxaline. However, there still remains the possibility that the emission E is an impurity phosphorescence resulting from T-T energy transfer from quinoxaline to an impurity involved originally in the solute.

In order to decide whether the emission E is due to the triplet excimer of quinoxaline or not, temperature dependence of the phosphorescence spectrum must be examined. The temperature dependence of the delayed emission spectrum for 6.0×10^{-2} M quinoxaline in isooctane is shown in Fig. 3, where the intensities of emission spectra are normalized at 470 nm. It is clearly seen in Fig. 3 that the intensity ratio of the emission E to the monomer phosphorescence markedly decreases as the temperature rises. This means that the emission E is not due to an impurity triplet resulting from the T-T energy transfer, since in the case of T-T energy transfer in fluid solution the intensity ratio of phosphorescence of the energy donor to that of the acceptor must be independent of temperature.[13] When the sample solution is frozen, the emission E vanishes, while the monomer phosphorescence intensifies remarkably. Thus, all the experimental results obtained indicate that the emission E is the excimer phosphorescence of quinoxaline itself.

Figure 4 shows collectively the absorption spectrum

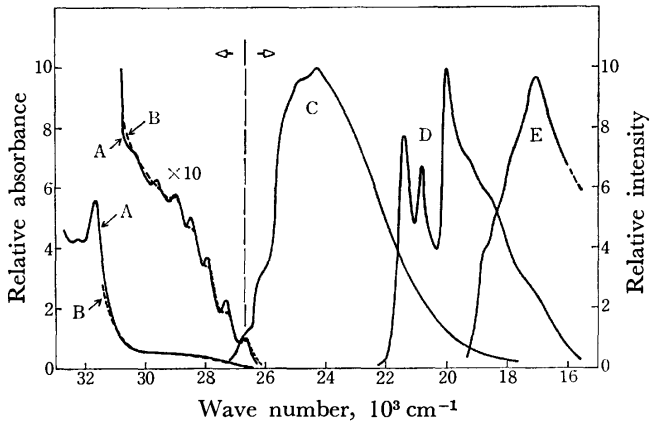

Fig. 4. Absorption, excitation (corrected), and emission (corrected) spectra of quinoxaline in isooctane at 20 °C: A, absorption; B, excitation spectra of the fluorescence and the monomer phosphorescence; C, fluorescence; D, monomer phosphorescence; and E, excimer phosphorescence.

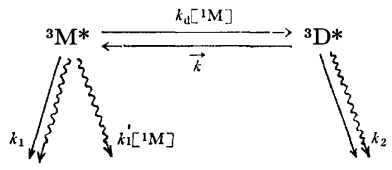
and corrected emission and excitation spectra of quinoxaline in isooctane at 20 °C.

By solving the rate equations with regard to the kinetic scheme 1 appropriate for the deactivation of the triplet state involving excimer formation,[2] one can easily obtain Eqs. 2 and 3 for the time dependence of the intensities, I, of the monomer (m) and excimer (d) phosphorescence:



(1)

$$I_m(t) = \frac{C_1(\theta_2 - X)}{\theta_2 - \theta_1}\{e^{-\theta_1 t} + Ae^{-\theta_2 t}\}, \quad (2)$$

$$I_d(t) = \frac{C_2[^1M]}{\theta_2 - \theta_1}\{e^{-\theta_1 t} - e^{-\theta_2 t}\}, \quad (3)$$

with

$$\left.\begin{matrix}\theta_1 \\ \theta_2\end{matrix}\right\} = \frac{1}{2}[X + Y \mp \{(Y-X)^2 + 4k_d\overleftarrow{k}[^1M]\}^{1/2}], \quad (4)$$

$$X = k_1 + (k_1' + k_d)[^1M], \qquad Y = k_2 + \overleftarrow{k}, \quad (5)$$

$$A = (X - \theta_1)/(\theta_2 - X), \quad (6)$$

and C_1 and C_2 are constants with positive values. Here, ^{1}M, ^{3}M*, and ^{3}D* stand for the ground singlet monomer, excited triplet monomer, and excited triplet dimer (triplet excimer), respectively; k_1 and k_2 are the sums of the radiative and nonradiative decay constants for the triplet monomer and excimer, respectively; k_d and $\overleftarrow{k}$ are the rate constants for the formation and dissociation of the triplet excimer, respectively; and k_1' is the rate constant for quenching by the ground state molecule.

Figure 5 shows representative decay curves of the phosphorescence monitored at 480 nm (M) and at 540 nm (D) for 1.1×10^{-2} M and 1.1×10^{-1} M quinoxaline in isooctane at 20 °C. According to Eqs. 2 and 3, it is expected that $I_m(t)$ should yield a curve consisting of two exponential decays, while $I_d(t)$ a rise-and-decay curve. It is clearly seen in Fig. 5 that the decay curves for the monomer phosphorescence at 480 nm correspond well to $I_m(t)$ predicted by Eq. 2 with $\theta_1 = 5.4\times10^2$ s^{-1} and $\theta_2 = 1.9\times10^4$ s^{-1} for a solute concentration of 1.1×10^{-2} M and with $\theta_1 = 1.2\times10^3$ s^{-1} and $\theta_2 = 2.7\times10^4$ s^{-1} for 1.1×10^{-1} M. The $I(t)$ curve monitored at 540 nm for 1.1×10^{-1} M shows clearly a rise-and-decay curve corresponding to $I_d(t)$ in Eq. 2, with a decaying rate constant very close to the value of θ_1 in $I_m(t)$. On the other hand, the $I(t)$ curve at 540 nm for 1.1×10^{-2} M shows almost a single exponential decay. This fact may be attributed to the coexistence of the monomer and the excimer phosphorescence emissions at 540 nm.

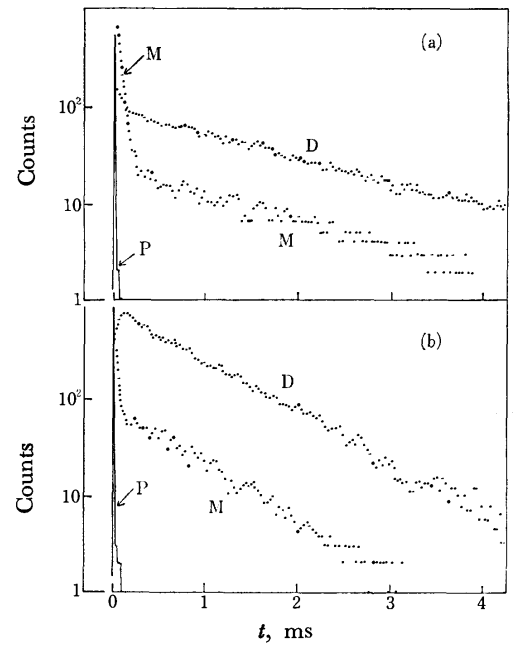


Fig. 5. Representative $I(t)$ curves for the phosphorescence of quinoxaline in isooctane at 20 °C. The concentrations of quinoxaline: (a) 1.1×10^{-2} M; and (b) 1.1×10^{-1} M. Monitoring wavelengths: M, 480 nm (monomer region); D, 540 nm (monomer+excimer region). P represents the exciting light pulse.

Here again, we shall examine the possibility that the emission E is due to an impurity. In this case, ^{1}M and ^{3}D* in the kinetic scheme (1) must be replaced by ^{1}A and ^{3}A*, respectively, where ^{1}A and ^{3}A* are the ground state and the excited triplet state of the impurity molecule. Since the energy separation between the structured phosphorescence spectrum of the quinoxaline monomer and the broad emission spectrum E is about 3000 cm^{-1}, the reverse T-T energy transfer from the triplet state of the impurity to that of quinoxaline can be completely neglected; that is, $\overleftarrow{k}=0$.

In such a case, the $I(t)$ curve of the phosphorescence observed at 480 nm should give a single exponential decay, since the phosphorescence emission at 480 nm is due to the quinoxaline monomer which is regarded as the energy donor. This contradicts the observation that the $I(t)$ curves M in Fig. 5 consist of two exponential decays. In other words, the results of dynamic measurement of the phosphorescence also indicate that the

broad emission cannot be due to an impurity.

It is thus concluded that the broad emission spectrum, which appears in the range of 520—620 nm upon increasing the concentration of quinoxaline, is ascribable to the triplet excimer of quinoxaline.

The Crystal and Molecular Structures of *trans*-Dichlorobis(dimethylneomenthylphosphine)palladium(II)* and *trans*-Dichlorobis(dimethylmenthylphosphine)palladium(II), Asymmetric Hydrosilylation Catalysts of Olefin

Kojiro KAN, Kunio MIKI, Yasushi KAI, Noritake YASUOKA, and Nobutami KASAI**

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received September 24, 1977)

The molecular structures of $[PdCl_2\{(Me_2neoMen)P\}_2]$ and $[PdCl_2\{(Me_2Men)P\}_2]$, asymmetric hydrosilylation catalysts of olefin, were determined by means of X-ray diffraction. Both complexes form yellow prismatic crystals. The former belongs to the monoclinic system: $a=13.512(5)$, $b=13.082(1)$, $c=8.472(1)$ Å, and $\beta=97.00(2)°$, space group $P2_1$ with $Z=2$; the latter belongs to the tetragonal system: $a=9.662(1)$ and $c=32.459(2)$ Å, space group $P4_32_12$ with $Z=4$. Both structures were determined by the heavy atom method and have been refined anisotropically by a least-squares procedure ($R=0.0697$ for 2606 non-zero reflections for the former and $R=0.0713$ for 1388 non-zero reflections for the latter). The former molecules is not iso-structural with its nickel analog. The central palladium atom has *trans*-square planar geometry [Pd-Cl 2.304(5) and 2.297(5), Pd-P 2.344(4) and 2.361(5) Å]. The molecule has an approximate two-fold symmetry around the normal to the co-ordination plane. The neomenthyl groups are on the same side of the co-ordination plane. The latter molecule has exact C_2 symmetry: the two-fold axis passes through the Cl(1), Pd, and Cl(2) atoms which lie on the co-ordination plane. The geometry around the palladium slightly deviates from the *trans*-square planar [Pd–Cl 2.296(9) and 2.267(9) Å and Pd–P 2.310(6) Å]. The menthyl groups are located on either side of the co-ordination plane.

In a series of structural studies of catalytically active organometallic complexes, the molecular structures of some organoaluminium complexes have been determined;[1-4] their roles in the stereospecific polymerization of acetaldehyde have also been discussed.[4,5] The X-ray molecular structure of $[Zn(OMe)_2(EtZnOMe)_6]$,*** which is considered as the key substance for the polymerization of methyloxirane, has recently been reported.[6]

A variety of dihalophosphine-transition metal(II) complexes have been found to be effective catalysts for the hydrosilylation of olefins and acetylenes by M. Kumada and co-workers.[7-9] *trans*-Dichlorobis(dimethylneomenthylphosphine)nickel(II) $[NiCl_2\{(Me_2neoMen)P\}_2]$† and -palladium(II) $[PdCl_2\{(Me_2neoMen)P\}_2]$ and *trans*-dichlorobis(dimethylmenthylphosphine)palladium(II) $[PdCl_2\{(Me_2Men)P\}_2]$† are complexes in which each phosphine has a chiral substituent; they are catalysts for the asymmetric hydrosilylation of olefin.[10]

The X-ray molecular structure of the nickel complex $[NiCl_2\{(Me_2neoMen)P\}_2]$ has been reported very recently.[11] In this paper the molecular structures of the palladium analogs $[PdCl_2\{(Me_2neoMen)P\}_2]$ and $[PdCl_2\{(Me_2Men)P\}_2]$ are described.

Experimental

Crystals of $[PdCl_2\{(Me_2neoMen)P\}_2]$ and $[PdCl_2\{(Me_2Men)P\}_2]$ were provided by Professor M. Kumada and co-workers of Kyoto University. They are both yellow and prismatic. Preliminary photographic data showed that crystals of $[PdCl_2\{(Me_2neoMen)P\}_2]$ and $[PdCl_2\{(Me_2Men)P\}_2]$ belong to monoclinic and tetragonal system, respectively. Since these complexes are both optically active, the corresponding space groups should be non-centrosymmetric. The systematic absence of reflections of the former ($0k0$, $k=2n+1$) indicated that its space group was $P2_1$; in the latter the absences ($h00$, $h=2n+1$ and $00l$, $l=2n+1$) suggested the space group $P4_12_12$ or $P4_32_12$.

The unit-cell dimensions of the two crystals were determined by the least-squares fit from 2θ values of 16 and 11 high-angle reflections measured on a G.E. single crystal orienter mounted on a Rigaku SG-2 goniometer. The crystal densities were measured by flotation in aqueous solutions of potassium tartarate. Crystal data of the two complexes are given in Table 1.

A crystal of $[PdCl_2\{(Me_2neoMen)P\}_2]$ with dimensions of $0.23\times0.20\times0.18$ mm was chosen for the intensity measurement. A Rigaku automated four-circle diffractometer was used, with Zr-filtered Mo $K\alpha$ radiation. The θ-2θ scan technique was employed. The integrated intensities of each reflection were determined by scanning over a peak at a rate of 4 °min^{-1}, and subtracting the background obtained by averaging the two values measured for 5 s at both ends of a scan. The 2θ scan width was from $-1.0°$ for the $K\alpha_1$ peak to 1.0° for the $K\alpha_2$ peak. For the intensity data collection of $[PdCl_2\{(Me_2Men)P\}_2]$ the crystal used had dimensions of

$0.20\times0.17\times0.15$ mm. This crystal was rather small to give sufficient intensity using Mo $K\alpha$ radiation, but no other good, larger crystal could be selected. It was therefore necessary to use Cu $K\alpha$ radiation in order to obtain strong reflection intensities. Intensity measurements were carried out in a way similar to those for $[PdCl_2\{(Me_2neoMen)P\}_2]$. Totals of 2814 independent reflections for $[PdCl_2\{(Me_2neoMen)P\}_2]$ and 1440 for $[PdCl_2\{(Me_2Men)P\}_2]$ were collected at room temperature. In each case three standard reflections were measured after every 50 reflections. The intensities were corrected for the usual Lorentz and polarization effects. The absorption correction was ignored. This might limit the accuracy of the structures obtained, especially that of $[PdCl_2\{(Me_2Men)P\}_2]$ (μ(Cu $K\alpha$)$=77.6$ cm^{-1}).

Solution and Refinement of the Structure

Both structures were solved by the heavy-atom method, and refined anisotropically by the block-diagonal least-squares procedure using the HBLS V program.[12] The function minimized was $\Sigma(|F_o|-k\cdot|F_c|)^2$, where k is a scale factor. The atomic scattering factors used were those of Hanson, Herman, Lea, and Skillman.[13]

[PdCl$_2${(Me$_2$neoMen)P}$_2$]. From a three-dimensional Patterson function, the approximate co-ordinates of the palladium, two chlorine, and two phosphorus atoms were easily determined. All the non-hydrogen atoms were located in the subsequent Fourier synthesis. In the least-squares refinement, the y parameter of the palladium atom was fixed at 0.25 in order to define the origin of the unit-cell. When the R value fell down to 0.075, a difference synthesis revealed some but not all positions of the hydrogen atoms. All the hydrogen atoms except methyl hydrogen were then located assuming the C–H bond length of 1.08 Å and a tetrahedral angle for each carbon atom. In the subsequent refinement their contributions were included in the structure factor calculations, under the condition of fixed parameters. The effect of anomalous dispersion[14] for palladium, chlorine, and phosphorus atoms was then corrected for. The final R values for the structure obtained and its enantiomorph were 0.0702 (R_w=0.067) and 0.0697 (R_w=0.066) for 2606 non-zero reflections. The final positional and thermal parameters of the latter, which confirmed the absolute configuration of the neomenthyl group, are given in Table 2.††

[PdCl$_2${(Me$_2$Men)P}$_2$]. Since four molecules are contained in a unit-cell with the space group $P4_12_12$ or $P4_32_12$, the molecules must have special positions. The following two cases can satisfy the requirements: (1) only the palladium atom lies on the two-fold axis normal to the co-ordination plane, or (2) the palladium and the two chlorine atoms lie on the two-fold axis on the co-ordination plane.

A three-dimensional Patterson function could be interpreted for the latter case for the space group of either $P4_12_12$ or its enantiomorph $P4_32_12$; after assuming the $P4_32_12$ group, the subsequent Fourier synthesis revealed all the non-hydrogen atoms. At the final stage of the refinement, the effect of the anomalous dispersion for heavy atoms[14] was considered, and the contributions of all the hydrogen atoms except the methyl hydrogens were included in the structure factor calculations in the same manner as in [PdCl$_2${(Me$_2$*neo*Men)P}$_2$]. The final R value for the structure obtained and its enantiomorph was 0.0713 (R_w=0.0778) and 0.0803 (R_w=0.0899) for 1388 non-zero reflections. The former structure confirmed the absolute configuration of the menthyl group and determined the space group to be $P4_32_12$. The positional and thermal parameters are also given in Table 3.†††

Results and Discussion

The molecular structures of [PdCl$_2${(Me$_2$*neo*Men)P}$_2$] and [PdCl$_2${(Me$_2$Men)P}$_2$] are shown in Figs. 1 and 2 respectively, along with the numbering scheme of the atoms. The stereoscopic drawings of the molecules are given in Figs. 3 and 4. Bond lengths and bond angles are listed in Tables 4 and 5.

[PdCl$_2${(Me$_2$neoMen)P}$_2$]. The molecule has an approximate two-fold symmetry around the normal to the co-ordination plane, which passes through the palladium atom. The present complex is not iso-struc-

tural with its Ni-analog, $[NiCl_2\{Me_2neoMen)P\}_2]$. A remarkable difference between these two complexes is the arrangement of the two neomenthyl groups about the co-ordination plane. The neomenthyl groups are located on the same side of the co-ordination plane in the present complex, whereas they are on opposite sides of the plane in the Ni-analog. This structural difference may affect the different catalytic activities of these two complexes in the hydrosilylation of olefins.

The co-ordination around the palladium atom is rather square-pyramidal, and deviates from the *trans*-square planar geometry; the deviations of the Pd, Cl(1), Cl(2), P(1), and P(2) atoms from the co-ordination plane are relatively large: 0.08, 0.02, 0.02, −0.04, and −0.06 Å, respectively. The Pd–Cl bond lengths are nearly equal, 2.304(5) and 2.297(5) Å (av 2.301 Å); these are the ordinary values found in *trans* Pd–Cl bonds.[15-20] The Cl(1)–Pd–Cl(2) is not linear, [176.7 (2)°]. The Pd–P bond lengths are unequal, 2.344(4) and 2.361(5) Å (av 2.353 Å). These are the longest values so far reported for complexes which have the *trans* Pd–P bonds.[22-28] The P(1)–Pd–P(2) angle of 173.3(2)° significantly deviates from 180° (Fig. 5), in

order to decrease the steric repulsion between two neomenthyl groups in the molecule.

The conformation about the P(1)–Pd–P(2) is approximately eclipsed (Fig. 6) in a way different from the Nickel analog. The P(1) and P(2) atoms deviates slightly away from the approximate co-ordination plane. There is no significant difference between the conformations about the P(1)–C(13) (Fig. 7) and P(2)–C(33) bonds, which are intermediates between the staggered and eclipsed conformations.

The P–C bond lengths, ranging from 1.796(21) to 1.865(14) Å, are equal within the limits of error. However, the geometries around the phosphorus atoms show distortions. The Pd–P(1)–C(13) and Pd–P(2)–C(33) angles, 124.6(5) and 123.8(6)°, deviate greatly from the tetrahedral angle, whereas the C–P–C angles are rather small [99.8(9)—104.6(8)°]. The large Pd–P(1)–C(13) and Pd–P(2)–C(33) angles are also due to the steric repulsion between the neomenthyl groups in the molecule.

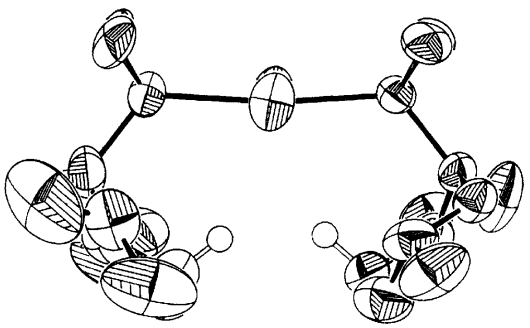

Fig. 5. $[PdCl_2\{(Me_2neoMen)P\}_2]$ molecule projected along the Cl(1)-Pd bond.

The P(1)–C(13)–C(12), P(1)–C(13)–C(14), and P(2)–C(33)–C(34) angles 114.6(10), 115.0(10), and 118.4(12)°, are larger than the normal value of 109.5°. Similar distortions of the P–C–C angles, which are considered to be due to the steric hindrance between the neomenthyl and methyl groups, were observed in the Ni-analog.[11]

$[PdCl_2\{(Me_2Men)P\}_2]$. The molecule has C_2 symmetry; the two fold axis passes through the Cl(1),

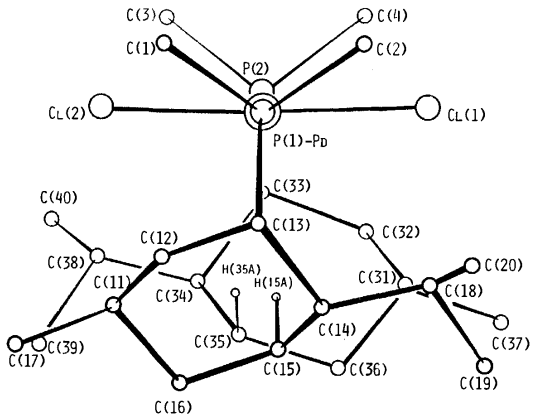

Fig. 6. The conformation about the P(1)-Pd bond in $[PdCl_2\{(Me_2neoMen)P\}_2]$.

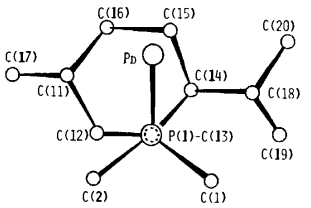

Fig. 7. The conformation about the P(1)-C(13) bond in $[PdCl_2\{(Me_2neoMen)P\}_2]$. The conformation about the P(2)-C(33) bond is similar to this.

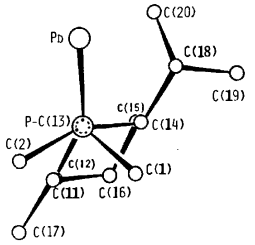

Fig. 8. The conformation about the P-C(13) bond in $[PdCl_2\{(Me_2Men)P\}_2]$.

Pd, and Cl(2) atoms which are on the co-ordination plane (Figs. 2 and 4). The geometry around the palladium atom is *trans*-square planar. The two menthyl groups are located on either side of the co-ordination plane.

The Pd–Cl bond lengths 2.296(9) and 2.267(9) Å (av 2.282 Å) are equal to those in $[PdCl_2\{(Me_2neo-Men)P\}_2]$. The Pd–P bond length 2.310(5) Å is significantly shorter than those in $[PdCl_2\{(Me_2neoMen)-P\}_2]$. The longer Pd–P lenghts in the latter are considered to result from the steric hindrance between the two neomenthyl groups. The P–Pd–P′ angle (175.5 (5)°) is not linear.

The conformation about the P–C(13) bond (Fig. 8) is an intermediate between the staggered and eclipsed conformations, which is rather similar to the one in $[NiCl_2\{Me_2neoMen)P\}_2]$.

The conformation about the C(14)–C(18) bond of the menthyl group is different from those of the neomenthyl groups in $[NiCl_2\{(Me_2neoMen)P\}_2]$ and $[PdCl_2-\{(Me_2neoMen)P\}_2]$, since the isopropyl group is rotated about 120° around the C(14)–C(18) bond. This is

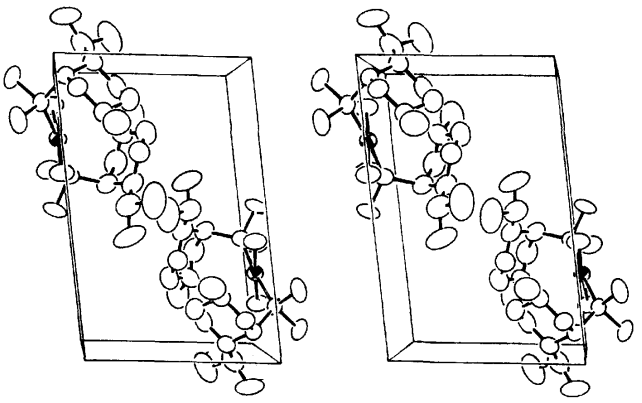

Fig. 9. A stereoscopic view of the crystal structure, $[PdCl_2\{(Me_2neoMen)P\}_2]$.

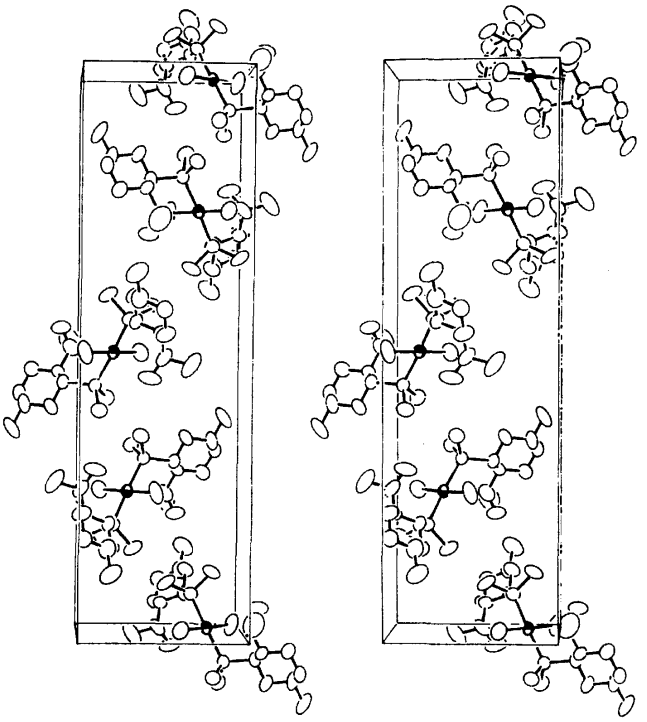

Fig. 10. A stereoscopic view of the crystal structure, $[PdCl_2\{(Me_2Men)P\}_2]$.

due to the steric interaction between the palladium atom and the isopropyl group of the menthyl group. Two hydrogen atoms, H(18) and H(18′), of the menthyl group occupy the vacant sites of the octahedron centered by the palladium and make short contacts (2.78 Å) with the palladium atom.

Crystal Structure. The Crystal structure of $[PdCl_2-\{(Me_2neoMen)P\}_2]$ is given in Fig. 9. The packing of $[PdCl_2\{(Me_2Men)P\}_2]$ molecules in a unit-cell is shown in Fig. 10. There is no short intermolecular atomic contact less than 3.8 Å between non-hydrogen atoms in either crystal.

The calculations were carried out on the NEAC 2200-700 computer at Osaka University and the FACOM 230-60 at Kyoto University. Figures 3, 4, 5, 9, and 10 were drawn on a NUMERICON 7000 system at Osaka University with a local version of ORTEP.[28]

This work was supported in part by a Grant-in-aid for Scientific Research from the Ministry of Education (No. 84305), for which the authors express their gratitude. The authors express their deep thanks to Professor Makoto Kumada and his co-workers of Kyoto University for kindly providing the crystals and for many helpful discussions.

The Spatial Distribution of Secondary Electrons Produced in the γ-Radiolysis of Water

Ken-ichi KOWARI and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 19, 1977)

The spatial distribution of secondary electrons produced in the γ-radiolysis of water in the liquid phase has been theoretically calculated. The method consists of the combination of the procedure previously developed for the calculation of the G-value of electrons with the theory proposed by Fröhlich and Platzman for the slowing down of electrons in polar liquids. The G-value of the ion-pairs initially produced was calculated to be 6.8 on the assumption that the binding energies of electrons in water are equal to those in solid water at 77K. 27% of the ion-pairs were generated in isolated spurs. Another 27% of the ion-pairs were generated in condensed spurs, each of which contains more than one hundred ion-pairs. The other ion-pairs formed less condensed spurs, each of which contains from 2 to 100 ion-pairs. A new definition was given for the classification of spurs: isolated spurs, blobs, and short tracks; the original proposal was by Mozumder and Magee. The diameter of the isolated spur was estimated to be about 100 Å. The distribution of the distance between the parent positive ion and the thermalized electron in the isolated spur was well expressed by the function proposed by Abell and Funabashi, except at very short distances.

When ionizing radiation interacts with a material in the condensed phase, the energy transfer from the radiation to the material occurs through the kinetic energy of the secondary electrons produced, and the energy deposits are heterogeneously distributed in the system. In radiation chemistry, the region in which active species are produced by radiation is called a spur. Mozumder and Magee classified these spurs into three types, on the basis of the amount of energy deposited in the region: isolated spurs, blobs, and short tracks.[1] Experimentally the distribution of such spurs can be estimated from the number of clusters produced in a cloud chamber. According to the measurement of Wilson, who used 25 keV electrons as the radiation source, 42.6% of the observed clusters contained one ion-pair, 22.5% two pairs, 12.4% three pairs, 10.1% four pairs, and 12.4% more than five pairs.[2] From the point of view of radiation chemistry, the number of ion-pairs involved in a spur is important, because the reactions occurring in a spur may be dependent upon the number of ion-pairs involved in the spur; for example, the neutralization reaction between positive ions and ejected electrons in a condensed spur may be faster than that in an isolated spur.

We have previously developed a calculation method for the G-values of ionization and excitation.[3] Using this method, we can calculate the initial energy distribution of subexcitation electrons. Therefore, if we can estimate the slowing down process of electrons in the condensed phase, we can construct the spatial distribution of secondary electrons produced in the radiolysis. As for the slowing down process of electrons in the condensed phase, Fröhlich and Platzman proposed a theory with which they estimated the rate of slowing down of electrons in water.[4] Recently Magee and Helman examined this theory numerically and estimated the rates of energy loss of electrons in a few hydrocarbons as well as in water.[5] As has been stated in their paper, the absolute value of the rate of energy loss is somewhat obscure, because the theory proposed by Fröhlich and Platzman treated only the "indirect" interaction between electrons and surrounding molecules. The treatment of the "direct" interactions, such as the formation of short-lived negative ions, has not been formulated yet. Consequently, we cannot avoid the appearance of a somewhat arbitrary factor in the estimation of the rate of slowing down of subexcitation electrons.

So far the spatial distribution of secondary electrons has been discussed in connection with the electron scavenging in the γ-irradiated hydrocarbons and with the electric conductivity of the irradiated hydrocarbons. The simplest assumed function was a Gaussian; however, it is now well known that the spatial distribution has a long tail compared with a Gaussian. Freeman and his group used a function which is composed of a Gaussian and a power function.[6] One of the present authors also discussed the spatial distribution of secondary electrons in the γ-irradiated hydrocarbons and derived a function from the experimental data of the electron scavenging by assuming a diffusion model.[7] Similar attempts have been made by several investigators.[8] Among them, Abell and Funabashi proposed a simple exponential function to express the spatial distribution and showed that this function is suitable to explain the experimental data both for the electron scavenging and for the voltage dependence of the electric conductivity of the irradiated hydrocarbons.[9] However, all of these attempts are empirical and have no rigid theoretical backgrounds. We, therefore, thought that the theoretical derivation of the function expressing the spatial distribution of secondary electrons would be worthwhile carrying out even if several assumptions are involved.

G-Value of Ionization

Procedure of Calculation. When water is exposed to the γ-rays from ^{60}Co, the energy transfer mainly occurs through the Compton effect. The energy distribution of the Compton electrons can be calculated by using the equation

$$\frac{d\sigma(T)}{dT} = \frac{\pi r_0^2}{\alpha h\nu}\left[1+\frac{T^2}{(h\nu-T)h\nu}+\left\{1-\frac{T}{\alpha(h\nu-T)}\right\}^2\right], \quad (1)$$

which was derived by Davison and Evans[10] from the

famous Klein-Nishina formula. Here, $\sigma(T)$ is the cross section for the formation of Compton electrons with the energy T, $h\nu$ is the energy of the incident γ-rays, $\alpha = h\nu/mc^2$, and $r_0 = e^2/mc^2$. m is the mass of electron, e is the charge, and c is the velocity of light.

Previously we have calculated the energy distribution of Compton electrons from helium gas irradiated by ^{60}Co γ-rays.[11] The fraction of the Compton electrons with energy of T was expressed by $f(T)$. This function is common to any material, because Eq. 1 does not discriminate target electrons. The total energy absorbed by the material, T_0, therefore, is expressed as follows:

$$T_0 = \int_0^{T_{max}} T\, f(T)\, dT. \tag{2}$$

Here, $T_{max} = 2\alpha h\nu/(1+2\alpha)$.

Using the function $f(T)$, we can calculate the degradation spectrum of the Compton electrons:

$$y_1(T) = \int_T^{T_{max}} f(T)\, dT/S(T). \tag{3}$$

$S(T)$ is the stopping power of water and may be expressed as follows:

$$S(T) = N\sum_i n_i \left\{ \int_{E_{si}}^{(T+I_i)/2} E(\sigma_{E,dir} + \sigma_{E,exc})dE + \frac{1}{2}\int_{E_{ti}}^{E_{si}} E\sigma_{E,exc}dE \right\}. \tag{4}$$

N is the number of molecules in a unit volume, n_i the number of electrons in the i-th shell of water, I_i the binding energy of the electron in the i-th shell, and E_{si} and E_{ti} the energies of the singlet and triplet excitations for the electrons in the i-th shell. $\sigma_{E,dir}$ and $\sigma_{E,exc}$ are the differential cross sections of the energy loss E due to the direct excitation and due to the excitation accompanied with the exchange of electrons, respectively.

In the procedure we developed for the calculation of G-values, the cross sections of the energy loss are estimated by using the classical binary-encounter-collision theory. For the direct excitation,

$$\sigma_{E,dir} = \frac{\pi e^4}{T+I_i+E_i}\left(\frac{1}{E^2} + \frac{4E_i}{3E^3}\right), \tag{5}$$

where E_i is the average kinetic energy of the target electron. For the excitation accompanied with the exchange of electrons, E in Eq. 5 is replaced by $T+I_i-E$.

Once the degradation spectrum of Compton electrons is obtained, we can calculate the degradation spectra of electrons ejected in the later steps of ionization due to the impact of electrons.

$$y_2(T) = \frac{N}{S(T)}\sum_i n_i \int_T^{(T_{max}-I_i)/2} \times \int_{2T_2+I_i}^{T_{max}} y_1(T_1)\sigma(T_1T_2)dT_1dT_2, \tag{6}$$

$$y_3(T) = \frac{N}{S(T)}\sum_i n_i \int_T^{(T_{max}-3I_i)/4} \times \int_{2T_2+I_i}^{(T_{max}-I_i)/2} y_2(T_1)\sigma(T_1T_2)dT_1dT_2. \tag{7}$$

Here, $\sigma(T_1T_2)$ is the differential cross section for the production of a secondary electron with energy of T_2 in the collision between the incident electron with energy of T_1 and the target electron in the i-th shell and is expressed as follows, by using Eq. 5:

$$\sigma(T_1T_2) = \frac{\pi e^4}{T+I_i+E_i}\left[\frac{1}{(T_2+I_i)^2} + \frac{4E_i}{3(T_2+I_i)^3} + \frac{1}{(T_1-T_2)^2} + \frac{4E_i}{3(T_1-T_2)^3}\right]. \tag{8}$$

Equations similar to $y_2(T)$ and $y_3(T)$ may be constructed for the later steps. The total degradation spectrum is obviously the sum of the degradation spectra of the electrons ejected in all steps:

$$y(T) = \sum_m y_m(T). \tag{9}$$

The degradation spectrum of electrons is one of the most important values for the irradiated system; from it we can deduce many interesting values concerning the reactions occurring in the system. The G-value of ionization is one of them.

In order to calculate the G-value of ionization, we need the total cross section of ionization due to the impact of an electron with the energy T, which is expressed per target electron as follows:

$$Q_{ion} = \int_{I_i}^{(T+I_i)/2} (\sigma_{E,dir} + \sigma_{E,exc})dE = \frac{\pi e^4}{T+I_i+E_i}\left[\left(\frac{1}{I_i} - \frac{1}{T}\right) + \frac{2E_i}{3}\left(\frac{1}{I_i^2} - \frac{1}{T^2}\right)\right]. \tag{10}$$

Then, the number of ions produced by the ejection of the electron in the i-th shell can be calculated by the equation

$$N_{ion} = Nn_i \int_{I_i}^{T_{max}} Ty(T)Q_{ion}(T)\, d\ln T. \tag{11}$$

The G-value of ionization through this process is obviously

$$G_{ion} = 100N_{ion}/T_0. \tag{12}$$

Similar formulations can be made for other processes, including singlet and triplet excitations.

Calculated Results. The constants used for the calculation are summarized in Table 1. Since no experimental values were available, we had to estimate them somewhat arbitrarily. For the binding energies of electrons in water in the liquid phase, we estimated the values from the spectrum of X-ray induced photoelectron spectroscopy obtained with solid state water at 77 K.[12] The E_s and E_t values for the $1b_1$ orbital are those reported for the gas phase. For other orbitals, the equations shown in the note of Table 1 were used.

TABLE 1. CONSTANTS USED FOR CALCULATION

Orbital	I_i	E_i	E_s	E_t
$1b_1$	7.6	45.0	7.42	5.0
$3a_1$	9.8	54.9	9.6[a]	7[b]
$1b_2$	14.5	74.7	14[a]	12[b]
$2a_1$	26.3	119	26[a]	24[b]
$1a_1$	533	1265	533[a]	531[b]

a) $E_s = I_i - (I_i - E_s)_{1b_1} = I_i - 0.2$.
b) $E_t = I_i - (I_i - E_t)_{1b_1} = I_i - 2.6$.

Table 2. The G-values of ionization and singlet and triplet excitations from each orbital
The values in parentheses are the G-values of superexcited states.

Orbital	G_e	G_s	G_t
$1b_1$	3.13	0.23	1.18
$3a_1$	1.87	(0.096)	0.15 (0.12)
$1b_2$	0.96	(0.075)	(0.018)
$2a_1$	0.39	(0.009)	(0.002)
$1a_1$	0.008	(5×10^{-6})	(4×10^{-7})

Table 3. The G-values of ionization, including the ionization from the superexcited state (G_{ion}) and of singlet and triplet excitations ($G_{singlet}$ and $G_{triplet}$)

G_{ion}	6.76
$G_{singlet}$	0.23
$G_{triplet}$	1.21

In order to estimate the average kinetic energies, E_i, we deduced an equation:

$$E_i = 9.15I_i^{0.785}, \quad (13)$$

by plotting the reported values of E_i and I_i for five noble gases.[13]

The G-values calculated are summarized in Table 2. In this Table, the G-values of the superexcited states which are in the parentheses are involved in those of singlet and triplet excitations. If all of the superexcited states are assumed to be ionized, then the G-value of ionization should be increased by 0.32. In Table 3 are listed the corrected G-values.

Since the G-value of ionization is sensitive to the ionization potential assumed, *i.e.*, the I_i value for the $1b_1$ orbital, we calculated the G-values by assuming several I_i values. The results are shown in Fig. 1. The value obtained with I_i=12.6 eV is that for the gas phase.

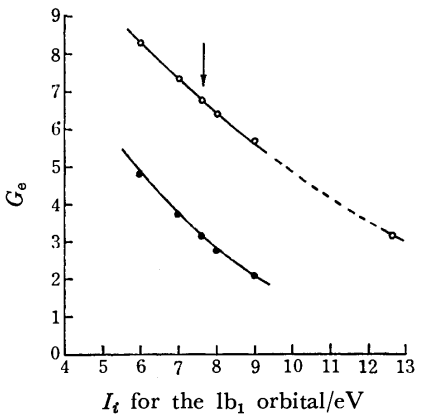

Fig. 1. The calculated G-value of electrons as a function of the energy assumed for the electron in the $1b_1$ orbital. ○, for the total; ●, for the G-value from the $1b_1$ orbital only. The arrow shows the value used in the following calculation.

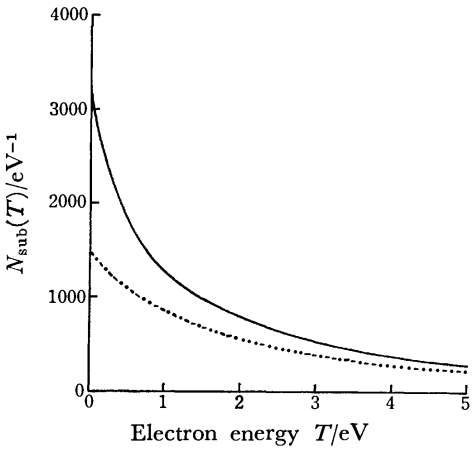

Fig. 2. The initial energy distribution of subexcitation electrons. Solid line is for the total and dotted line for the "child" electrons.

Subexcitation Electrons

Initial Energy Distribution. Since the degradation spectrum of electrons in γ-irradiated water has been obtained, the initial energy distribution of subexcitation electrons can be calculated by using the following equations:[14]

$$N_{sub}(T) = f(T) + N_p(T) + N_c(T);\ T<E_t, \quad (14)$$

$$N_p(T) = N\sum_i n_i \int_{E_t}^{T+I_i} y(T+E)\sigma(T+E,E)\mathrm{d}E,$$

$$N_c(T) = N\sum_i n_i \int_{2T+I_i}^{T_{max}} y(T')\sigma(T',T+I_i)\mathrm{d}T'.$$

The first term, $f(T)_{T<E_t}$, represents the contribution of Compton electrons and is negligibly small compared with the second and third terms when the energy of the incident γ-rays is higher than the binding energy of the electron in the innermost shell. The second term corresponds to the electrons which had the energy higher than the threshold, $E_t(1b_1)$ in the present case, before the last collision. We may call them "parent" electrons. The third term represents the electrons generated in the last collision with the energy lower than $E_t(1b_1)$, which we may call "child" electrons.

Figure 2 shows the calculated result for the initial energy distribution of subexcitation electrons produced in water. The dotted curve corresponds to the "child" electrons. The number of "child" electrons is about twice that of "parent" electrons. Douthat calculated the energy distribution of subexcitation electrons in helium gas irradiated by 1.99 keV electrons.[14] The curve reported is similar to that shown in Fig. 2.

If the irradiated material is in the gas phase at a low pressure, these subexcitation electrons are homogeneously distributed in the material and collide with the surrounding molecules to excite their vibrations and rotations. The rate of the energy loss, however, is much slower than that due to electronic excitations when the electron energy is higher than the threshold.[15]

Thermalization Distance. According to the theory proposed by Fröhlich and Platzman, the rate of the energy loss of an electron in the 1—10 eV energy region due to dielectric relaxation is expressed by this equation:

$$-\frac{dT}{dt}=\frac{2e^2}{\pi v}\int_0^\infty \frac{\omega\varepsilon^2(\omega)}{\varepsilon_1^2(\omega)+\varepsilon_2^2(\omega)}xK_0(x)K_1(x)dx. \quad (15)$$

Here v is the velocity of the moving electron, x is defined by $x=\omega b_{min}/v$, $\omega/2\pi$ is the frequency, b_{min} is the minimum value of the collision parameter, ε_1 and ε_2 are the real and imaginary part of the complex dielectric constant of the solvent, and K_0 and K_1 are the modified Bessel functions of the second kind, of order 0 and 1. In the case of polar solvents such as water, the dipolar relaxation is the main process for the energy loss and the rate of energy loss can be approximated as follows:

$$-\frac{dT}{dt}\simeq\frac{\pi e^2}{4d}\frac{\varepsilon_s-\varepsilon_{1r}}{\tau n^4}. \quad (16)$$

Here d is the intermolecular distance, τ the relaxation time, n the refractive index, ε_s the static dielectric constant, and ε_{1r} the dielectric constant at frequencies lower than the lowest main infrared absorption frequency.

Fröhlich and Platzman substituted the experimental values of water at 20 °C into Eq. 16 and obtained 10^{13} eV s^{-1} for $-dT/dt$.

Magee and Helman recently discussed Eq. 15 and calculated the rate of energy loss of subexcitation electrons in benzene and polyethylene, which have no dipole moments, as well as in water. The rates of the energy loss calculated in benzene and polyethylene were a little smaller than that in water.

As stated in the Introduction, the theory of Fröhlich and Platzman treats only the "indirect" interaction of moving electrons with surrounding molecules. Magee and Helman estimated the rate of the energy loss due to the "direct" interaction in water and suggested that $-dT/dt\simeq10^{14}$ eV s^{-1}. In the present calculation, therefore, we used two values, 10^{13} and 10^{14} eV s^{-1} for $-dT/dt$.

If the rate of energy loss is independent of the electron energy, the path length over which an electron with the energy T loses energy down to T_{min} may be calculated by the equation

$$R=\frac{2}{3}\left(\frac{2}{m}\right)^{1/2}\frac{1}{k}[T^{3/2}-T_{min}^{3/2}], \quad (17)$$

where m is the electron mass and k is the rate of energy loss.

The relation between the crooked path, R, and the straight distance, r, between the starting point and the point where the electron energy is degraded to T_{min} can be given by the theory of random walks.[16] With given R, the distribution in r, *i.e.*, the probability of arriving at a point r, $P(r)$, is given by

$$P(r)=4\pi r^2W(r) \quad (18)$$

and

$$W(r)=(2\pi RL/3)^{-3/2}\exp(-3r^2/2RL). \quad (19)$$

Here L is the mean free path of an electron in the solvent.

As will be discussed later, about 30% of the ion-pairs produced in the γ-irradiated water are generated in isolated spurs. The electrons in these do not interact with active species in other spurs before they are thermalized, and the initial energy distribution of electrons in the isolated spurs are similar to that of the "child" electrons discussed above. Consequently, the spatial

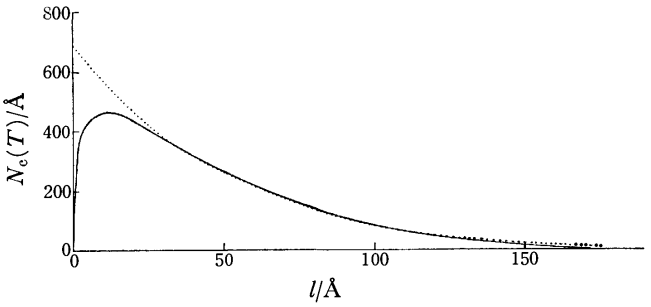

Fig. 3. The spatial distribution of thermalized electrons in the isolated spurs. $-dT/dt=10^{13}$ eV s^{-1}. For the dotted line, see the Text.

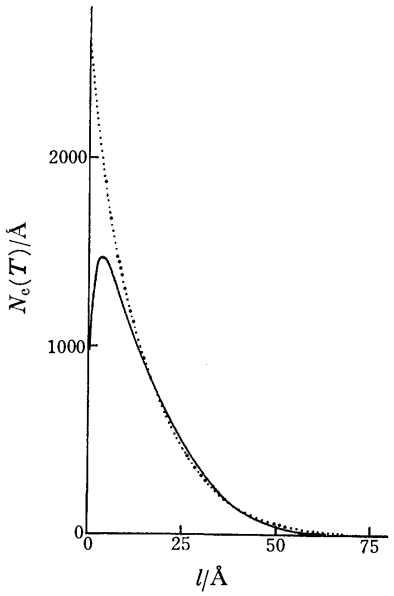

Fig. 4. The spatial distribution of thermalized electrons in the isolated spurs. $-dT/dt=10^{14}$ eV s^{-1} For the dotted line, see the Text.

distribution of electrons when they are thermalized in the isolated spurs can be expressed by

$$F(r)=\int_0^{E_t}W(r)N_e(T)dT. \quad (20)$$

Here, T_{min} should be taken as thermal energy.

For the actual calculation, we took, $L=3$ Å and $T_{min}=0$. The calculated results are shown in Figs. 3 and 4, where the rate of energy loss k is assumed to be 10^{13} and 10^{14} eV s^{-1}, respectively. The dotted lines shown in both figures are drawn by using the function $4\pi r^2F(r)=A\exp(-r/b)$; $A=690$ and $b=48$ Å for Fig. 3 and $A=3000$ and $b=14$ Å for Fig. 4. Except for the very small value of r, both curves coincide with those theoretically estimated.

The Number of Ion-pairs in a Spur

The energy of the secondary electrons ejected from the parent molecules into the solvent ranges from zero to the maximum value, T_{max}. If the initial energy is low, the electron will be thermalized close by the parent molecule ion and will make an ion-pair.

The initial energy distribution of secondary electrons

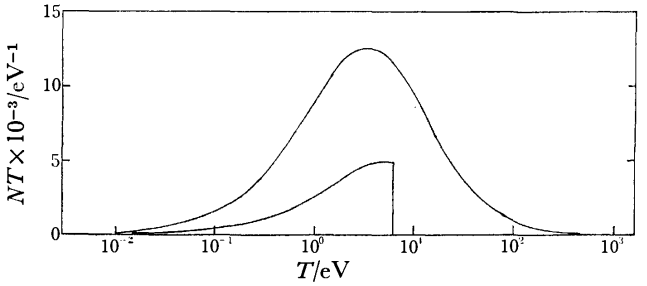

Fig. 5. The initial energy distribution of secondary electrons. The lower curve is for the subexcitation electrons in the isolated spurs.

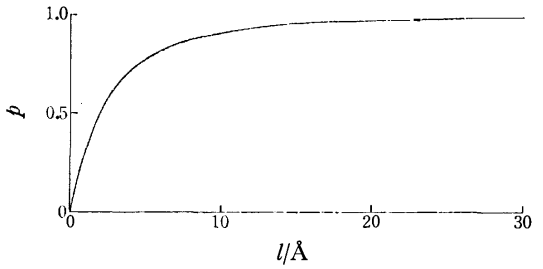

Fig. 6. The distance between two successive ionizations occurring in the γ-irradiated water.

can be calculated also from the degradation spectrum obtained above:

$$N(T) = f(T) + N\sum_i n_i \int_{2T+I_i}^{T_{max}} y(T')\sigma(T',T)\mathrm{d}T', \qquad (21)$$

where $f(T)$ is the contribution of Compton electrons. $\sigma(T',T)$ is the differential cross section which appears in Eq. 8. The calculated result for the secondary electrons in the γ-irradiated water is shown in Fig. 5. Here the relation $TN(T)$ *vs.* ln T is plotted, so that the area under the curve is proportional to the number of secondary electrons. The electrons whose energy is higher than the threshold, E_t, correspond to the "parent" electrons discussed in the previous section and the electrons whose energy is lower than E_t are the "child" electrons.

If a "parent" electron has a higher energy than the ionization potential of water, it will give rise to another ionization. The number of the "child" electrons produced in this second ionization has already been counted in Fig. 5. The average probability with which "parent" electrons give rise to such ionizations within the distance, l, from the last ionization is expressed by the following equation:

$$p = \int_I^{T_{max}} [1-\exp(-N\sum_i n_i Q_i(T)l]N(T)\mathrm{d}T/ \int_I^{T_{max}} N(T)\mathrm{d}T. \qquad (22)$$

Here $Q_i(T)$ is the total ionization cross section due to a "parent" electron with the energy T. The values of p are plotted in Fig. 6 as a function of the distance l. Obviously, most of "parent" electrons in the γ-irradiated water give rise to their second ionizations very close to the first ionizations.

As has been shown in the previous section, if two successive ionizations occur within a short distance——let us take 150 Å as the upper limit——the two ion-pairs produced may interact with each other during their thermalization; *i.e.*, these two ion-pairs may be regarded to be in the same spur.

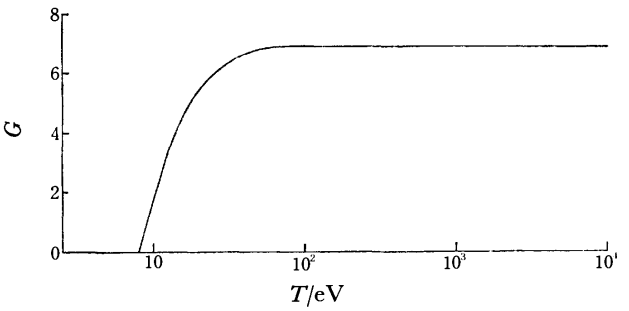

Fig. 7. The G-value of electrons as a function of the energy of the incident electron.

The energy of a "parent" electron which induces two successive ionizations within the interval of 150 Å on the average corresponds to 10 keV. Consequently, if a "parent" electron has the energy higher than 10 keV, "child" electrons produced by this "parent" electron will be isolated from other ionizations. In Fig. 5, the initial energy distribution of "child" electrons in isolated spurs is also plotted. If we plot these values in Fig. 2, the curve obtained is similar to that for N_e. The percentage of the "child" electrons in isolated spurs against the total electrons has been calculated to be 27%.

If the energy of "parent" electrons is lower than 10 keV and sufficiently higher than the ionization potential of water, these electrons will produce condensed spurs, and if the energy of "parent" electrons is a little higher than the ionization potential of water, the spurs generated will contain a few ion-pairs.

In order to calculate the number of ion-pairs in spurs, we need the relationship between the G-value of electrons and the energy of the incident electron. This type of calculation has already been made for helium gas.[11] Figure 7 is the result for water in the liquid phase. By combining this result with the number of "parent" electrons, we can calculate the number of ion-pairs produced in each spur. The calculated numbers, however, are not always integers. Therefore, we tentatively allotted the numbers proportionally to the adjacent integral numbers; for example, when the number was 2.6, we read it as 40% for two ion-pairs and 60% for three ion-pairs. The results thus calculated are summarized in Tables 4 and 5.

Table 4 shows the percentage of the number of spurs which contain different numbers of ion-pairs against the total number of spurs. This result may be compared with the observation of Wilson discussed in the Introduction. Similar observations have been made by Beekman with electrons at higher energies.[17] Both observations are included in Table 4.

On the other hand, Table 5 shows the distribution of ion-pairs in the spurs of different types. It is noticeable that 27% of the ion-pairs are generated in isolated spurs and another 27% of the ion-pairs are generated in very condensed spurs which consist of more than one

TABLE 4. CALCULATED RELATIVE FREQUENCIES OF SPURS IN WATER AND RELATIVE FREQUENCIES OF CLUSTERS OBSERVED IN A CLOUD CHAMBER

Ion-pairs per spur	1	2	3	4	>4
Relative frequency %	73.6	11.7	5.0	3.1	6.6
Ion-pairs per cluster	1	2	3	4	>4
Relative frequency %					
Source: 25 keV[2]	42.6	22.5	12.4	10.1	12.4
150 keV[17]	60	23	8	4	5
320 keV[17]	62	20	9	4	5

TABLE 5. RELATIVE NUMBERS OF ION-PAIRS IN DIFFERENT SPURS

Ion-pairs per spur	Relative number %	
1	26.8	Isolated spurs
2	8.5	Blobs
3	5.4	
4	4.5	
5—10	10.9	
11—100	16.5	Short tracks
101—	27.4	

hundred ion-pairs.

Mozumder and Magee classified spurs into three types: isolated spurs, blobs, and short tracks, on the basis of the energy deposited in them. A similar classification may be applied to the result shown in Table 5: *i.e.*, isolated spurs for the spurs containing only one ion-pair, blobs for the spurs containing two to ten ion-pairs, and short tracks for the spurs containing more than ten ion-pairs.

Discussion

G-Value of Electrons. Figure 8 shows the contribution of different portions of the electron degradation spectrum to the ionization and excitations, singlet and triplet, induced by one keV electrons in water. This type of figure has already been discussed in previous papers.[3,11] From this figure, we can estimate the number of ionizations and excitations during the slowing down of the incident electron.

Let us consider the track of ionizations in water induced by a 1keV electron. Since the ionization probability along the path of a high energy electron is roughly proportional to the reciprocal of the electron energy, the average distance between two successive ionizations near the starting point is about 15 Å. The direction of the path will not be changed so often, because the cross section for small energy loss, around 10 eV, is much larger than that for the larger energy loss. After having induced about 20 ionizations and a few electronic excitations, the energy of the "parent" electron is degraded to 500 eV, a value which is comparable to the binding energy of the electrons in the inner-most shell. After the electron energy reached 500 eV, the path of the "parent" electron may change direction often. The average interval of two successive ionizations is now 9 Å, a distance which corresponds to three times the diameter of a water molecule. Consequently, about 50 ion-pairs may be produced in a very small space at the end of the track of ionizations. Since the diameter of the isolated spur is about 100 Å, as shown in Fig. 3, the density of charged species at the end of the track must be very high. A schematic picture of a short track is shown in Fig. 9.

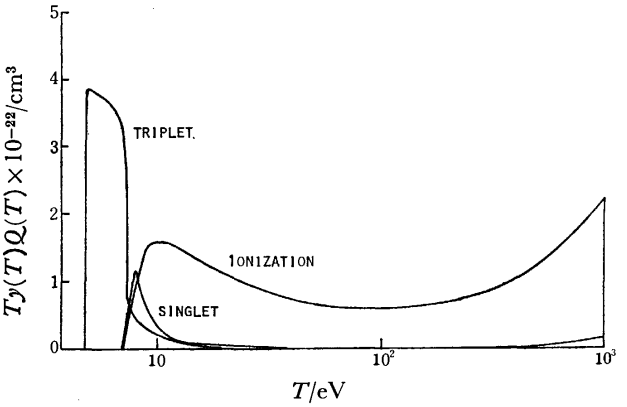

Fig. 8. The contribution of the different portions of the electron degradation spectrum to ionization and singlet and triplet excitations.

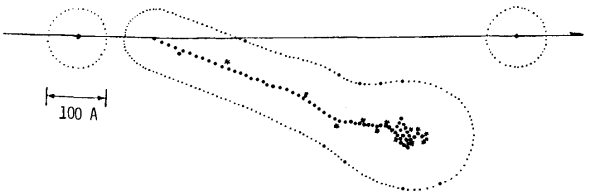

Fig. 9. A schematic picture of an example of short tracks produced by a 1 keV electron. A dot corresponds to an ionization and an asterisk to an excitation.

According to the measurement of Hunt *et al.*, the initial G-value of dry electrons in water is 4.8.[18] They used one mol l^{-1} cadmium ions as the scavenger for electrons. This concentration corresponds to one scavenger ion per 55 water molecules. At the end of the track of a high energy electron, the density of ion-pairs must be comparable to or higher than that of scavenger ions. A large part of the electrons, a percentage which we cannot calculate at present, may escape from the scavenging and be neutralized with their counter ions. Consequently, we do not think that the value $G_e=6.8$ obtained in the present calculation is absurdly large.

The Rate of Slowing Down of Subexcitation Electrons. For the rate of slowing down of subexcitation electrons, we took two values, 10^{13} and 10^{14} eV s^{-1}. These values are somewhat arbitrary, as was stated when we introduced them. If more reliable values become available, these values should be replaced by them. Another point important for the present calculation is the assumption that the rate of energy loss is independent of the electron energy. This assumption might be acceptable for the energy loss due to the "indirect" interaction, but since the "direct" interaction is a kind of resonance effect, the rate of the energy loss must be strongly dependent on the electron energy. Although this process has not been formulated yet, it may be better for the calculation to treat the "direct" interaction as if it were a kind of

electronic excitation.

In the present calculation, only one value of the rate of energy loss has been assumed for all subexcitation electrons ranging from thermal energy to the maximum, E_t. However, when the electron energy is degraded to subvibrational energy ($\approx$0.4 eV), no process of the energy loss but that due to the intermolecular vibrations remains. In a polar solvent, such a slow electron may be solvated by surrounding molecules. In non-polar solvents, however, these electrons may migrate further into the solvent, as suggested by Hummel *et al.*[19] and estimated by Mozumber and Magee.[20]

According to the estimate of Mozumder and Magee, the themalization distance of the subvibrational electrons in hexane is in the order of 50 Å, a distance which is of the same order as that estimated here to be the thermalization distance of the subexcitation electrons.

Spatial Distribution of Ion-pairs in Spurs. Most of electrons and positive ions generated in blobs and short tracks may be neutralized pairwise before they are thermalized. If the concentration is low, electron scavengers can capture only electrons which have escaped the neutralization. The spatial distribution function of ion-pairs derived for the interpretation of the experimental results of electron scavenging and of electric conductivity is, therefore, composed of the sum of two parts: one is the distribution of ion-pairs in isolated spurs and the other is the distribution of ion-pairs which have escaped the neutralization in blobs and short tracks.

As has been shown in the Results section, the spatial distribution of ion-pairs in isolated spurs was well expressed by the function proposed by Abell and Funabashi. However, we think that this agreement resulted from a somewhat fortuitous cancellation.

Let us assume that only one ion-pair is left after the neutralization in each blob and short track. Then, all spurs now contain only one ion-pair, the G-value of which is 2.5 ($\simeq 6.8 \times 26.8/73.6$). As Table 4 shows, 74% of them come from the original isolated spurs and the rest, 26%, from blobs and short tracks. Although we cannot calculate it numerically, the spatial distribution of ion-pairs which have escaped the neutralization in blobs and short tracks may be much broader than that in the original isolated spurs. If we take this contribution into account, the spatial distribution should have a long tail.

On the other hand, the function of Abell and Funabashi has been proposed to explain the experiments carried out with hydrocarbons, in which the thermalization of subvibration electrons has to be considered. As Mozumder suggested,[21] the spatial distribution of electrons during the degradation of subvibrational energies is getting close to a Gaussian, which is sharper than the function of Abell and Funabashi. This effect might cacel the broader distribution of ion-pairs which escaped the neutralization in blobs and short tracks.

Vibration Spectra and Rotational Isomerism of Chain Molecules. VII.[1] 1-Chloro-, 1-Bromo-, and 1-Iodopropanes, and 1-Chloro-, 1-Bromo-, and 1-Iodobutanes

Yoshiki OGAWA, Shuji IMAZEKI, Hiroko YAMAGUCHI, Hiroatsu MATSUURA,*
Issei HARADA, and Takehiko SHIMANOUCHI**
Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received November 8, 1977)

The Raman and infrared spectra of 1-chloro-, 1-bromo-, and 1-iodopropanes, $CH_3CH_2CH_2X$ (X=Cl, Br, and I), and 1-chloro-, 1-bromo-, and 1-iodobutanes, $CH_3CH_2CH_2CH_2X$ (X=Cl, Br, and I), were measured for the gaseous, liquid, glassy, and crystalline states. The normal vibration frequencies were calculated, a consistent set of force constants explaining the frequencies of basic halogenoalkanes being assumed. The rotational isomerism was studied on the basis of the spectral observations and the normal coordinate calculations. The enthalpy differences among the rotational isomers were examined.

The study of the vibration spectra and rotational isomerism of 1-halogenopropanes was started by Mizushima and coworkers[2] and Radinger and Wittek[3] about thirty years ago. Many studies have been made by means of Raman and infrared,[4-17] microwave,[18,19] and electron-diffraction[20] measurements. As a result, it has been established that the *trans* (T) form exists in the crystalline state except 1-fluoropropane for which the *gauche* (G) form exists[7a,b] and both the T and G forms exist in the liquid and gaseous states. The enthalpy difference between the T and G forms has also been determined by many investigators.[4-6,10,11,17-20] However, as has been indicated previously,[17] the reported values of the enthalpy difference are quite different from one another and there are some disagreements in the vibrational assignments among different authors. These problems remain to be settled.

The rotational isomerism of 1-halogenobutanes has been studied also by means of Raman and infrared,[4-9,14,16,21-25] and electron-diffraction[26] measurements. Ukaji and Bonham[26a] concluded that 1-chlorobutane had an isomer distribution of 37% TG, 24% GG', 17% GG, 11% TT, and 11% GT in the gaseous state at room temperature. Snyder and Schachtschneider[14] observed the infrared spectra of $CH_3(CH_2)_n$-Cl (n=1—5) in the crystalline (annealed solid) and glassy (unannealed solid) states and obtained the refined valence force field through the normal coordinate analysis. They indicated that the vibrational spectra of 1-chlorobutane in the crystalline state are explained by the existence of the TT form and those in the glassy state by the coexistence of the TT form and the TG form with the *gauche* CC–CCl axis. More recently, Crowder and coworkers[7,8] interpreted the vibrational spectra of 1-fluoro- and 1-iodoalkanes, taking into account only two among various isomers, the all-*trans* form and the form which has a *gauche* conformation about the CC–CX axis and a *trans* conformation about the remaining axes. Thus, the whole aspect of the rotational isomers existing in the various states of 1-halogenobutanes is still unknown and the enthalpy differences among the isomers have not yet been determined.

In the previous papers,[27-31] we compared the Raman and infrared spectra of unbranched ethers, paraffins, and sulfides in the crystalline, glassy, liquid, and gaseous states with the results of normal vibration calculations and determined the rotational isomers existing in each state. As a continuation of such studies, the same method has been applied to 1-halogenopropane and 1-halogenobutane molecules. The results show that the method is useful in the study of rotational isomerism. In the course of the research, several new findings including the identification of less stable rotational isomers and the enthalpy differences among the isomers in the liquid state have been obtained. The present paper describes the rotational isomerism and vibrational assignments of 1-halogenopropanes, $CH_3CH_2CH_2X$, and 1-halogenobutanes, $CH_3CH_2CH_2CH_2X$ (X=Cl, Br, and I).

Experimental

Samples used in the present study were purchased from Tokyo Kasei Kogyo Co., Ltd. and were distilled prior to the measurements. The Raman and infrared spectra were measured for the gaseous, liquid, glassy, and crystalline states by the method reported previously.[27,28,30]

The glassy state for the Raman measurements was obtained by immersing the sample enclosed in an ampoule in liquid nitrogen for rapid cooling, and that for the infrared measurements by depositing the sample onto a cooled window of KBr or KRS-5.

For the determination of the enthalpy difference, the Raman spectra in the liquid state were recorded twice at each of nine different temperatures between −105 and 15 °C for 1-chloropropane, nine different temperatures between −100 and 15 °C for 1-bromopropane, eight different temperatures between −85 and 15 °C for 1-iodopropane, and eight different temperatures between −90 and 15 °C for 1-chloro-, 1-bromo-, and 1-iodobutanes. The Raman spectra in the gaseous state were also measured three times at each of four different temperatures between 23 and 80 °C for 1-chloropropane.

Normal Coordinate Treatment

The normal coordinate treatment of the unbranched halogenoalkanes (see Table 1) was carried out with a computer program NCTB2[32] and a HITAC 8700/8800

Table 1. Continued

The least-squares calculation begins with the simplest halogenoalkanes given in the first step and the first set of force constants is determined so as to give the best fit between the observed and calculated frequencies. This set of force constants gives the definite vibrational assignments of the halogenoalkanes given in the second step and the second set of force constants is subsequently determined from the observed frequencies in this step in addition to those in the first step. By repeating this procedure, the final set of force constants is obtained. The figures in parentheses give the numbers of observed frequencies used for the least-squares calculation. The observed frequencies of the CH and CD stretching vibrations are not included in the calculation and accordingly the force constants associated with these vibrations are not refined. The results of the following references are utilized in the least-squares calculation. a) This study and Ref. 13. b) This study. c) Ref. 34. d) Ref. 35. e) Ref. 15. f) Ref. 7.

computer system at the Computer Center of the University of Tokyo. The calculation made it possible to assign the observed Raman and infrared bands to individual rotational isomers and to determine a consistent set of force constants of halogenoalkanes. Structural parameters and symmetry coordinates used in the calculation and a final set of the force constants will be reported in a separate paper.[33]

The force constants of halogenoalkanes were determined in the following way. The force constants associated with a methyl or methylene group which is not bound directly to a halogen atom were assumed to be the same as those for the paraffin molecules.[32] The force constants associated with the halogen atom, including those of the methyl or methylene group adjacent to the halogen atom, were refined in the least-squares adjustment. The initial values for the chlorine part were transferred from the result by Snyder and Schachtschneider.[14] The initial values for the bromine and iodine parts were estimated from the corresponding values of the chlorine part. Some of the halogenoalkane force constants including those which were unestimable from the observed frequencies were assumed to be the same values as those for the corresponding paraffin force constants.

Table 1 shows the procedure of the least-squares calculation. The calculation began with the simplest halogenoalkanes in the extended form, and then the molecules to be treated were extended to the longer halogenoalkanes and the non-extended forms. In the force constant refinement, we also used the observed frequencies of the deuterated derivatives of 1-bromopropane,[15] 1-halogenopentanes,[34] 1,3-dihalogenopropanes,[35] and 1,4-dihalogenobutanes.[34] A total of 23 force constants associated with the chlorine part were determined from 336 Raman and infrared frequencies of 21 forms of 5 molecular species, 21 force constants associated with the bromine part from 419 frequencies of 29 forms of 7 molecular species, and 23 force constants associated with the iodine part from 242 frequencies of 16 forms of 4 molecular species.

The normal vibration calculation of fluoroalkanes was also carried out in the same way as the other halogenoalkanes on the basis of the experimental data by Crowder and Mao.[7] The procedure of the least-squares calculation of fluoroalkanes is also included in Table 1. A total of 22 force constants associated with the fluorine part were determined from 100 Raman and infrared frequencies of 10 forms of 3 molecular species.

Results

Figures 1—16 show the Raman and infrared spectra in the gaseous, liquid, glassy, and crystalline states. The observed frequencies and the vibrational assignments based on the calculated potential-energy distributions are listed in Tables 2—7. The observed spectra were analyzed with reference to the results of the normal coordinate treatment. The values of enthalpy differences obtained from the intensity variation of the Raman bands with temperature are given in Figs. 17 and 18.

In the following subsections, the rotational isomerism of the individual halogenopropane and halogenobutane molecules is described.

1-Halogenopropanes. These molecules have two possible rotational isomers, T and G, as given in Table 1 of Part I of this series.[27] The observed Raman and infrared spectra and the calculated frequencies are compared in Figs. 7 and 8. These figures show that the T form exists in the crystalline state of 1-chloro-, 1-bromo-, and 1-iodopropanes and the T and G forms coexist in the glassy, liquid, and gaseous states.

The individual rotational isomers of each molecule are discriminated from each other by the Raman key bands of the liquid state, their frequencies being given in parentheses: T form (364 and 723 cm^{-1}) and G form (292, 424, 648, and 787 cm^{-1}) of 1-chloropropane, T form (311 and 648 cm^{-1}) and G form (274, 402, 563, and 777 cm^{-1}) of 1-bromopropane, and T form (288 and 593 cm^{-1}) and G form (390, 503, and 763 cm^{-1}) of 1-iodopropane. These Raman bands were used for the determination of the enthalpy difference between the T and G forms of each molecule. Figure 17 shows the obtained results of the enthalpy differences in the liquid state. As is evidently seen in Fig. 17, the G form is slightly more stable than the T form for any of 1-chloro-, 1-bromo-, and 1-iodopropanes in the liquid state.

The enthalpy difference in the gaseous state of 1-chloropropane was also determined. The ΔH_{G-T} value of 15 ± 30 cal/mol and -210 ± 100 cal/mol were obtained from the pairs of the Raman bands at 663 and 745 cm^{-1} and at 793 and 745 cm^{-1}, respectively. Thus, the G form is as stable as or slightly more stable than the T form in gaseous 1-chloropropane.

1-Halogenobutanes. These molecules have five possible isomers, TT, TG, GT, GG, and GG′,[27] where the first and second conformation symbols in each isomer designation are those for the CC–CC and CC–CX axes,

respectively. The observed Raman and infrared spectra and the calculated frequencies are compared in Figs. 15 and 16.

For 1-chlorobutane (see Figs. 15a—e and 16a—c), the spectra in the crystalline state show that only the TT form exists. The Raman band at 397 cm^{-1} and the infrared band at 400 cm^{-1} persisting in the crystalline state can be explained only by the existence of the TT form. In the glassy, liquid, and gaseous states, the observed spectra are explained by the coexistence of the TT, TG, GT, and GG forms. The Raman band at 476 cm^{-1} and the infrared band at 474 cm^{-1} in the glassy state, whose intensities relative to those of other bands increase in going from the liquid state to the glassy state, can be explained only by the existence of the TG form. The Raman band at 437 cm^{-1} and the infrared band at 436 cm^{-1} observed in the liquid state are assigned to the GT form, while the Raman bands at 458 (a shoulder of the 474 cm^{-1} band) and 370 cm^{-1} and the infrared bands at 458 (a shoulder of the 473 cm^{-1} band) and 370 cm^{-1} in the liquid state are assigned to the GG form.

For 1-bromobutane (see Figs. 15f—j and 16d—f), the comparison between the observed spectra and the calculated frequencies indicates that the TT form exist in the crystalline state. The Raman band at 397 cm^{-1} and the infrared band at 394 cm^{-1} are assigned only to the TT form. The glassy-, liquid-, and gaseous-state spectra show the coexistence of the TT, TG, GT, and GG forms in these states. The Raman band at 462 cm^{-1} and the infrared band at 459 cm^{-1} in the glassy state, whose intensities are enhanced as compared with those of the liquid state at room temperature, are assigned only to the TG form. The existence of the GT form is confirmed by the Raman and infrared bands at 417 cm^{-1} in the liquid state, and the existence of the GG form is also clear from the observation of the Raman bands at 448 (a shoulder of the 463 cm^{-1} band) and 353 cm^{-1} and the infrared bands at 445 (a shoulder of the 459 cm^{-1} band) and 352 cm^{-1} in the liquid state. In the gaseous state, the Raman spectral pattern around 450 cm^{-1} is different from that in the liquid state. The existence of the TG and GG forms is, however, confirmed definitely by the observation of the Raman bands at 1000 and 350 cm^{-1}, respectively.

For 1-iodobutane (see Figs. 15k—o and 16g—i), the spectra of the crystalline state are explained by the existence of the TT form and those of the glassy, liquid, and gaseous states by the coexistence of the TT, TG, GT, and GG forms similarly to the cases of 1-chloro- and 1-bromobutanes. The Raman band at 389 cm^{-1} and the infrared band at 387 cm^{-1} in the crystalline state are assigned only to the TT form and the Raman band at 452 cm^{-1} and the infrared band at 449 cm^{-1} in the glassy state only to the TG form. The Raman band at 407 cm^{-1} and the infrared band at 406 cm^{-1} in the liquid state indicate the existence of the GT form and the Raman bands at 438 (a shoulder of the 450

a) VS: Very strong, S: strong, M: medium, W: weak, VW: very weak, b: broad, sh: shoulder. The broadness of the band shapes in the gaseous state does not always allow us to correlate the individual bands in the liquid state to those in the gaseous state. Only approximate correlations are made in such cases and in other cases of similar situations. The bands denoted with * were observed in the liquid-state Raman spectra at lower temperature. b) For the notation and definition of the local symmetry coordinates, see Ref. 36. According to the results of the normal coordinate treatment,[33] the CH_3 rocking, CH_2 rocking, CH_2 twisting, and CC stretching coordinates are highly coupled to yield complicated vibrational modes. The listed assignments are thus only approximate ones.

a), b) See a) and b), respectively, of Table 2.

cm^{-1} band) and 339 cm^{-1} and the infrared bands at 438 (a shoulder of the 449 cm^{-1} band) and 339 cm^{-1} indicate the existence of the GG form. In the gaseous state, a trend similar to the case of 1-bromobutane is observed in the Raman spectral pattern around 440 cm^{-1}. The existence of the TG and GG forms is confirmed by the observation of the Raman bands at 995 and 337 cm^{-1}, respectively.

It is not probable that the GG′ form of 1-bromobutane exists, since no bands are observed in the gaseous, liquid, or glassy state around its characteristic frequency of 331 cm^{-1}. The distance between the terminal methyl group and the bromine atom seems to be too short for the GG′ form to be stable. Thus, it is also improbable that the GG′ form of 1-chloro- or 1-iodobutane exists, although its existence is uncertain from the normal coordinate analysis because of the coincidence of the frequencies of the GG′ and other forms.

As has been described above, the key bands for the individual isomers of each molecule in the skeletal deformation region have become clear. These key bands were used for the determination of the enthalpy differences among the isomers in the liquid state. Figure 18 shows the obtained results of the enthalpy differences.

For 1-chlorobutane, the intensity ratios of the Raman bands at 370 (GG form) and 474 cm^{-1} (TG form), those at 401 (TT form) and 474 cm^{-1}, and those at 437 (GT form) and 474 cm^{-1} gave the enthalpy differences, $\Delta H_{GG-TG}=210\pm110$ cal/mol, $\Delta H_{TT-TG}=150\pm50$ cal/

a) Refs. 7 and 19. b) Ref. 7.

mol, and $\Delta H_{GT-TG}=650\pm28$ cal/mol, respectively. The relatively large error is estimated for the ΔH_{GG-TG} value because of the very weak intensity of the band at 370 cm^{-1}. Thus, the stability of the rotational isomers in the liquid state is in the order of TG, TT, GG, and GT, with the TG form being the most stable.

For 1-bromobutane, the intensity ratios of the Raman bands at 353 (GG form) and 463 cm^{-1} (TG form), those at 393 (TT form) and 463 cm^{-1}, and those at 417 (GT form) and 463 cm^{-1} gave the enthalpy differences, $\Delta H_{GG-TG}=130\pm30$ cal/mol, $\Delta H_{TT-TG}=280\pm52$ cal/mol, and $\Delta H_{GT-TG}=680\pm44$ cal/mol, respective-

ly. In the liquid state, the stability of the rotational isomers is in the order of TG, GG, TT, and GT.

For 1-iodobutane, the enthalpy differences, $\Delta H_{GG-TG}=170\pm25$ cal/mol, $\Delta H_{TT-TG}=-75\pm29$ cal/mol, and $\Delta H_{GT-TG}=480\pm26$ cal/mol were obtained from the pairs of the Raman bands at 339 (GG form) and 450 cm^{-1} (TG form), those at 388 (TT form) and 450 cm^{-1}, and those at 407 (GT form) and 450 cm^{-1}, respectively. Thus, the stability of the rotational isomers in the liquid state is in the order of TT, TG, GG, and GT.

Comparison with Previous Results. Table 8 shows the rotational isomers of 1-halogenopropanes and 1-halogenobutanes existing in the various states, including those of 1-fluoropropane and 1-fluorobutane reported by Crowder and Mao.[7] In the crystalline state, 1-fluoropropane takes the G form and 1-fluorobutane takes the TG form, in contrast with other 1-halogenopropanes and 1-halogenobutanes.

Many investigations[2-6,8-18,20] indicated for 1-chloro-, 1-bromo-, and 1-iodopropanes that the T form exists in the crystalline state and the T and G forms coexist in the glassy, liquid, and gaseous states. These conclusions have been further confirmed by the present normal vibration calculation of these compounds in conjunction with longer halogenoalkanes.

The quite different values of the enthalpy differences were reported by many authors[4-6,10,11,18-20] for 1-halogenopropanes. Tanabe and Saëki[17] discussed this problem and obtained their values of the enthalpy differences by the absolute-intensity method and the temperature-variation method applied to the infrared spectra of the liquid state. The values by the latter method were $\Delta H_{G-T}=-140$ cal/mol for 1-chloropropane, $\Delta H_{G-T}=220$ cal/mol for 1-bromopropane, and $\Delta H_{G-T}=580$ cal/mol for 1-iodopropane. However, the present results show that the G form is more stable than the T form by about 100 cal/mol for these three compounds in common in the liquid state. Tanabe and Saëki mentioned that the good air-tightness of the high temperature cell allowed the experiment at temperatures higher than the boiling point of 1-chloro- or 1-bromopropane. This implies that the enthalpy differences obtained are those at pressures higher than 1 atm. The disagreement between their and our values is ascribed, at least in part, to the above fact. As for gaseous 1-fluoropropane, the ΔH_{G-T} value of -50 ± 30 cal/mol was obtained by the microwave measurement.[19]

There has been disagreement concerning the assignment of the CH_2 twisting bands of 1-halogenopropanes. Snyder and Schachtschneider[14] assigned the 1292 cm^{-1} band of 1-chloropropane to the *trans* CH_2 twisting mode on the basis of the normal vibration calculation of many kinds of chloroalkanes and Hayashi *et al.*[15] assigned the 1288 cm^{-1} band of 1-bromopropane to the *trans* CH_2 twisting mode. These assignments agree with those by Brown and Sheppard[9] and Komaki *et al.*[11] On the other hand, Tanabe and Saëki[17] had doubts of these assignments from the viewpoint that the twisting frequencies of the CH_2 group (adjacent to CH_3) in 1-halogenopropanes should be lower than that of propane, 1278 cm^{-1}, and that the twisting frequency of the CH_2 group (adjacent to CH_3) should be lower than the wagging frequency of the CH_2 group (adjacent to halogen) in the *trans* form. Thus, they assigned the 1256, 1200, and 1180 cm^{-1} bands of 1-chloro, 1-bromo-, and 1-iodopropanes, respectively, to the *trans* CH_2 twisting mode. In the present study, however, the Raman band of 1-chloropropane at 1288 cm^{-1}, the Raman and infrared bands of 1-bromopropane at 1289 and 1291 cm^{-1}, respectively, and the Raman and infrared bands of 1-iodopropane at 1286 and 1289 cm^{-1}, respectively, all of which are definitely observed in the crystalline state (see Figs. 1—6), are assigned consistently to the *trans* CH_2 twisting mode on the basis of our normal vibration calculation including the data of longer halogenoalkanes. Tanabe and Saëki did not assign these bands to any vibration of the T form of 1-halogenopropanes. Also, their grounds for interpreting the spectra are not appropriate, since it is generally acceptable that the twisting frequency of the CH_2 group (adjacent to CH_3) can be higher than the twisting frequency of a single isolated CH_2 group in propane owing to the vibrational coupling between the two CH_2 twisting modes in 1-halogenopropanes, and that it can be higher than the wagging frequency of the CH_2 group (adjacent to halogen) owing to the mass effect by the halogen atom. The situation is almost the same for the *gauche* twisting frequencies.

Many studies[4-9,14,16,21-26] have been made on the rotational isomerism of 1-halogenobutanes. Ukaji and Bonham[26a] proposed for 1-chlorobutane an isomer distribution of 37% TG, 24% GG′, 17% GG, 11% TT, and 11% GT in the gaseous state and Momany *et al.*[26b] proposed for 1-bromobutane 36% TT, 24% TG, 24% GT, and 16% GG in the gaseous state by the electron-diffraction method. Snyder and Schachtschneider[14] concluded for 1-chlorobutane that the TT form exists in the crystalline state and the TT and TG forms coexist in the glassy state on the basis of the comparison of the crystalline- and glassy-state spectra and of the normal coordinate analysis. Crowder and Ali[8a] interpreted the spectra of 1-iodobutane, taking into account only two among various isomers, the TT and TG forms. In the present study, it has been also found that the GT and GG forms of each of 1-halogenobutanes exist in the gaseous, liquid, and glassy states in addition to the TT and TG forms. However, the existence of the GG′ form was not identified in any state of these compounds. The skeletal deformation vibrations of 1-chlorobutane[22] and 1-bromobutane[22,23] were discussed in relation to the identification of existing rotational isomers. The results of these studies, however, do not agree with ours.

Studies concerning the relative stability of the isomers of 1-halogenobutanes have not yet been fully made. So far, only the apparent enthalpy difference between the mixture of the TT and GT forms and that of the TG and GG forms has been determined from the C–Br stretching bands of 1-bromobutane by the infrared and Raman methods,[5,6] and the relative stabilities of the *trans* and *gauche* conformations about the CC–CX and CC–CCX axes have been estimated by the electron-diffraction method.[26] In the present study, it has been possible to determine the enthalpy differences among the

individual isomers of 1-chloro-, 1-bromo-, and 1-iodobutanes, as the key bands in the skeletal deformation region have been clarified.

Discussion

Several consistent trends have been observed for 1-halogenopropanes and 1-halogenobutanes. (1) The forms existing in the various states are same for all the compounds except 1-fluoroalkanes (Table 8). (2) The enthalpy difference ΔH_{G-T} in the liquid state is about -100 cal/mol for 1-halogenopropanes studied in this work in common. For 1-halogenobutanes in the liquid state, the GT form is the least stable and the TG form is the most stable with an exception that the TT form of 1-iodobutane is slightly more stable than the TG form (Figs. 17 and 18). (3) The force constants of the halogen part[33] show a systematic trend in their values.

The diagonal force constants of the CCX skeletal deformation for different halogen atoms are about the same and the frequency shifts are mainly due to the difference in the masses of halogen atoms. Together with the similarity of the relative stabilities of the rotational isomers, this is one of the principal reasons for the similarity of the spectral patterns. Thus, the skeletal deformation region of 1-halogenobutanes has good key bands for discriminating the individual isomers. In particular, the bands in the 300—500 cm^{-1} region of 1-halogenobutanes are explicit examples, since these bands are associated predominantly with the CCC skeletal deformation (see Tables 5—7) and the frequency shift due to the mass difference is smaller than that for 1-halogenopropanes. In the study of the longer halogenoalkanes,[34] the key bands in the skeletal deformation region are efficiently used together with those in the skeletal stretching and CH_2 rocking regions.

It is noticed for the halogenoalkane molecules studied in this work except 1-iodobutane that the most stable isomer in the liquid or glassy state does not exist in the crystalline state. This is reasonably understood by considering that the T or TT form is less stable than the G or TG form by only 100—300 cal/mol in the liquid state and the intermolecular forces favoring the T or TT form in crystal may well overwhelm the intramolecular forces favoring the G or TG form.

Care must be taken in the interpretation of the Raman spectra in the gaseous state on the analogy of that in the liquid state. An apparent band or shoulder observed only in the gaseous-state Raman spectra can be that due to some rotational isomer which is not identified in the liquid-state spectra, part of the rotational contour of the vibrational band, or a hot band. The relative peak intensities of the bands belonging to the same isomer can also be different from those in the liquid state. Such examples are found in the Raman spectra of 1-iodopropane. The C–I stretching band of the G form is observed as doublet at 518 and 503 cm^{-1}. This doublet may be the contour of the B-type vibration since the corresponding infrared band is also observed as the B-type doublet. The relative peak intensities of the 602 and 285 cm^{-1} bands, both assigned to the T form, in the gaseous-state spectrum are significantly different from those in the liquid-state spectrum. In the cases of 1-bromo- and 1-iodobutanes, the relative intensities of the Raman bands in the gaseous state at 448 and 456 cm^{-1} and at 436 and 453 cm^{-1}, respectively, are different from those in the liquid state.

As has been shown in the present work, the skeletal deformation vibrations are useful for the determination of the enthalpy differences because of the relatively few overlapping bands due to different isomers. The measurement of the Raman spectra in this region is more effective for this purpose than that of the infrared spectra. Experiments of the temperature dependence of Raman intensities, especially at lower temperatures, can be performed without much difficulty, but the measurement of infrared intensities is difficult because of the interference by infrared emissions from the sample and the reference experimental apparatus.

(Received April 2, 1977)

INDO-type UHF-MO calculations were carried out for Ru(III)-ammine complexes in order to investigate their electronic structures and bonding nature. It was revealed that the ground state of $RuX(NH_3)_5^{2+}$(X=F, Cl, Br, or I) is the ^2E state and that that of *cis*-$RuX_2(NH_3)_4^+$ is the $^2A_1$ state; in $RuX(NH_3)_5^{2+}$, the odd electron exists not on the d_{xy} orbital but on the d_{xz} or d_{yz} orbital which interacts with the p_π orbital of the halide ligand, and in *cis*-$RuX_2(NH_3)_4^+$, this electron exists not on the d_{xz} or d_{xy} orbital but on the d_{yz} orbital which interacts with the p_π orbitals of the two halide ligands. Concenring the bonding nature, the following results were obtained: (1) the strength of the Ru–NH_3 bond in these complexes increases in the order, *cis*-$RuX_2(NH_3)_4^+$<$RuX(NH_3)_5^{2+}$ <$Ru(OH_2)(NH_3)_5^{3+}$<$Ru(NH_3)_6^{3+}$; (2) in the aqua-ammine complex, the Ru–OH_2 bond is weaker than the Ru–NH_3 bond; and (3) in the halogeno-ammine complexes, the *trans*-Ru–NH_3 bond is weaker than the *cis*-Ru–NH_3 bond. MO calculations were also carried out for some distorted states of $RuCl(NH_3)_5^{2+}$. From these results, a discussion is presented on the relation between the thermal reaction product and the reaction mechanism; *cis*-$RuCl_2(NH_3)_4^+$ is expected to be produced *via* an associative reaction mechanism, while the *trans*-form product is expected to result from a dissociative mechanism.

It is known that the ammine or aqua ligand of Ru(III)–ammine complexes can be substituted for the outer-sphere halide ion *via* a solid-state thermal (30—210 °C) reaction.[1–3] This reaction is interesting from the viewpoint of the synthesis of certain Ru(III)–ammine complexes, because the halide ligand is substituted for the water molecule in the aqueous solution, while the ammine or aqua ligand is substituted for the halide ion. It has been suggested that the main product of this monohalogenopentaammine complex reaction is the *cis*-dihalogenotetraammine complex,[4] although the *trans*-form is expected as the main product due to the fact that the *trans*-effect of the halide ligand is greater than that of the ammine ligand. In order to clarify the reason why this reaction gives a *cis*-form product, not only experimental results, but also theoretical work are necessary, since calculations can give meaningful information about the electronic structure and the bonding nature of these complexes. Although some experimental work, such as UV-VS spectroscopic and ESR studies have been reported, only a few studies of MO calculations have been published on these complexes.[5,6]

In this work, a semi-empirical UHF-MO study was carried out for the hexaammine-, aquapentaammine-, monohalogenopentaammine-, and *cis*-dihalogenotetraammine–ruthenium(III) complexes. A discussion is presented on thier electronic structures, including electron configuration, the bond strength between metal and ligand, and the *trans*-effect of the ligand. From the results of MO calculations on the distorted state, which is considered to be a thermally-excited state, a discussion is presented on the reaction products and the mechanism of the solid-state thermal-substitution reaction.

Calculations and Geometries

Calculations. The method used here is the INDO-type UHF-MO method, which has been presented in detail elsewhere.[7] The resonance integrals were evaluated by means of the Wolfsberg-Helmholz approximation.[8] For the Ru and Rh atoms, the valence-state ionization potentials, I_μ, were evaluated from atomic spectra.[9] One-center Coulomb-repulsion integrals, $\gamma_{\mu\mu}$, were taken from the work of Di Sipio *et al.*[10] Two-center Coulomb-repulsion integrals were approximated using a modification of the Ohno equation.[11,12] For the atoms of the ligand, the values of I_μ were taken from the Hinze and Jaffé work,[13] and those of $\gamma_{\mu\mu}$ were estimated from the same work using the Pariser-Parr approximation.[14] A double-ζ type d-orbital was used for the 4d orbitals of the Ru and Rh atoms,[15] while single Slater-type orbitals[16,17] were used for all s and p orbitals. The quantity, E_{AB}, is used as the bond index, which gives the energy contribution of the AB bond to the total energy. Thus, a large absolute value of E_{AB} indicates a strong interaction between atoms A and B.[18,19]

Geometries. The Rh–Cl bond length is taken to be 2.50 Å from that corresponding to $RhCl_6^{3-}$,[20] and that of Rh–Br is estimated to be 2.6475 Å. The geometries of (a) $RuX(NH_3)_5^{2+}$, (b) $Ru(OH_2)(NH_3)_5^{3+}$, and (c) *cis*-$RuX_2(NH_3)_4^+$(X=F, Cl, Br, and I) are shown in Fig. 1. The Ru–N and Ru–O interatomic distances are taken to be 2.23 and 2.50 Å from the corresponding values for $[Ru(OH)(NO)(NH_3)_4]Cl_2$,[21] respectively. The Ru–Cl bond length is taken to be 2.40 Å from the corresponding value of the similar $[RhCl(NH_3)_5]Cl_2$.[22] The Ru–F, Ru–Br, and Ru–I bond lengths are estimated to be 2.115, 2.5475, and 2.7191 Å, respectively. For all the complexes, the geometries of the ammine and aqua ligands are taken to be those of free molecules.[23]

Results and Discussion

Parametrization. In order to determine the values of the Wolfsberg-Helmholz parameter, K, MO calculations were carried out for $RhCl_6^{4-}$ and $RhBr_6^{4-}$, since the electronic structures of these complexes have been investigated in detail. The calculated spin densities on the ligand are given in Table 1, together with experimental values.[24] All the calculations give rather rea-

Fig. 2. Two types of electron configuration and the orbital interaction schemes[a] of $RuX(NH_3)_5^{2+}$ and *cis*-$RuX_2(NH_3)_4^+$. a) The d_π-p_π anti-bonding orbitals are shown here. The bonding orbitals are omitted, since the electron occupancy of these MO's are not different between the two types of electron configuration. b) The d_{xy}-p_{2x} interaction is given here. The d_{xz}-p_{1x} one is similar to this interaction.

sonable spin fractions, f_s, for both the Cl 3s-orbital and the Br 4s-orbital, while they give values that are too small for the spin fractions, $f_{p\sigma}$, of both the Cl $3p_\sigma$-orbital and the Br $4p_\sigma$-orbital. Calculation III (K= 0.70) appears to be the most reasonable, although the value of $f_{p\sigma}$ is also too small. When orbital exponents of Basch and Gray[16] are used instead of those of Richardson *et al.*,[15] the results for f_s and $f_{p\sigma}$ improve slightly. These results do not appear to be unreasonable, since a large uncertainty may be included in experimental spin fraction. From these calculations, the empirical parameter K was taken to be 0.70 and Basch and Richardson orbital exponents were used in the UHF-MO calculation.

Electron Configuration. Ru(III) complexes have a low-spin d^5 electron configuration. As is shown in Fig. 2, there are two possibilities: the complexes may be of configuration I or II. For $RuX(NH_3)_5^{2+}$(X=Cl and Br), Verdonck and Vanqickenborne[5] have suggested that configuration I is reasonable. Kaplan and Navon[6] have also reported from their ESR study of RuX $(NH_3)_5^{2+}$ (X=Cl and Br) that the d_{xz} and d_{yz} orbitals are unstable relative to the d_{xy} orbital. Unfortunately no theoretical interpretation has been reported on this issue. Thus, it is necessary to theoretically ascertain the orbital order.

In the present work, an investigation was made to determine which configuration, I or II, are the ground states of $RuCl(NH_3)_5^{2+}$ and *cis*-$RuCl_2(NH_3)_4^+$. As is shown in Table 2, configuration I has a lower total energy than configuration II by *ca.* 0.23 eV for the former complex and by *ca.* 1.6 eV for the latter.

To investigate the reason why configuration I is the ground state, the E_{Ru-Cl} value of that configuration are compared with that of configuration II for $RuCl(NH_3)_5^{2+}$ in Table 2. The absolute value of E_{Ru-Cl} is greater for configuration I (−15.08 eV) than for II (−14.31 eV), which suggests that the stability of these two electron configuration depends largely on the Ru–Cl bond strength.[25] In more detail, a large difference is found not between $E_{d\pi-sp\sigma}$ and $E_{p\pi-p\pi}$ but for $E_{d\pi-p\pi}$ of E_{Ru-Cl}; in configuration I ($E_{d\pi-p\pi}=-1.21$ eV), the halogen donates a p_π-electron to the d_π-orbital of the metal ion, since the d_π-orbital of the Ru atom has only one electron and is able to accept electrons from the ligand. On the other hand, the halogen cannot donate an electron in configuration II ($E_{d\pi-p\pi}=0.0$ eV), since the d_π-orbital interacting with the halogen-atom p_π-orbital is filled. The difference between the $E_{d\pi-p\pi}$ values for configurations I and II is almost the same as the difference of between their total E_{Ru-Cl} values. Thus, the d_π-p_π bonding interaction between the Ru and Cl atoms stabilizes configuration I. For *cis*-$RuCl_2(NH_3)_4^+$, the same results were obtained, as is shown in Table 2; configuration I has two d_π-p_π interactions, while configuration II has only one, which makes configuration I more stable than II.

Therefore, the π-electrons of the halide ligand delocalize onto the d_π-orbital of the Ru atom in configuration I, while they cannot do so in configuration II. These results are reflected in the electron distributions of these complexes; the electron density of the p_π-orbital of the Cl atom is smaller in configuration I than in II. The d_π-orbital of the Ru atom, on the other hand, has more electrons in configuration I than does configuration II. It should be noted that the difference in electron density of the p_π-orbitals of the Cl atoms is almost the same as that of the electron density of the d_π-orbital of the Ru atom. In conclusion, the electron configuration in the ground state is I, which results from the interaction of the Cl-atom p_π-orbital with the half-occupied d_π-orbital of the Ru atom.

Electron Density and Bond Strength. The result for Ru(III)–ammine complexes are shown in Table 3. The electron densities of the Ru atom for these complexes increase in the order: $Ru(OH_2)(NH_3)_5^{3+}$<$Ru(NH_3)_6^{3+}$ < $RuX(NH_3)_5^{2+}$ < *cis*-$RuX_2(NH_3)_4^+$. The electron numbers of the ammine ligand for these complexes decrease in the order *cis*-$RuX_2(NH_3)_4^+$ > $RuX(NH_3)_5^{2+}$ > $Ru(OH_2)(NH_3)_5^{3+}$ > $Ru(NH_3)_6^{3+}$; *i.e.*, the numbers of electrons transfered from the ammine ligand to the metal decrease in reverse order. The net charges of the Ru(III) ion decrease in the order: $Ru(OH_2)(NH_3)_5^{3+}$ > $Ru(NH_3)_6^{3+}$ > $RuX(NH_3)_5^{2+}$(X= Br,I) > *cis*-$RuX_2(NH_3)_4^+$(X=Cl,Br,I). For both halogeno ammine complexes, the electron densities of the 4d-orbital of the Ru atom increase in the order; fluoro < chloro < bromo < iodo, and the electron densities of the p_π-orbital of the halide ligand decrease in reverse order, which suggests that the d_π-p_π interactions increase in the forward order.

For both $RuX(NH_3)_5^{2+}$ and *cis*-$RuX_2(NH_3)_4^+$, the electron densities of the ammine, which is in the *cis*-position with respect to the halide ligand are smaller than those in the *trans*-position. Since the ammine ligand coordinates with the metal ion by donating its lone-pair electrons, it is expected that the *cis*-ammine coordinates more strongly with the Ru atom than the *trans*-ammine, which will be revealed in the following section on the basis of the E_{Ru-NH_3} value. In the aqua-complex, on the other hand, the electron density decreases for the ammine in *trans*-position more than for that in *cis*-position. From these results, it is conceivable that the *trans*-ammine coordination bond is stronger than that of the *cis*-ammine, which suggests that the aqua ligand has a weaker *trans*-effect than does the ammine ligand.

With the value of E_{AB} and electron-density contour maps, the bond strength of the Ru(III)–ligand can be investigated in more detail. The absolute values of E_{Ru-NH_3} for the complexes decrease in the order: $Ru(NH_3)_6^{3+}$ > $Ru(OH_2)(NH_3)_5^{3+}$ > $RuX(NH_3)_5^{2+}$ > *cis*-$RuX_2(NH_3)_4^+$ (see Table 3). It is of note that the Ru–NH_3 bond strength of $Ru(NH_3)_6^{3+}$ is the strongest of all these Ru(III)–ammine complexes. This result is in accord with the fact that the Ru–N stretching force constant of $Ru(NH_3)_6^{3+}$(2.01 mdyn/Å)[26] is the

largest of all these complexes (*ca.* 1.6—1.9 mdyn/Å for $RuX(NH_3)_5^{2+}$).[27] The Ru–NH_3 bond strength in $Ru(OH_2)(NH_3)_5^{3+}$ is almost the same as those in halogeno ammine complexes, while the Ru–OH_2 bond strength is rather weak (see the value of E_{Ru-OH_2}). A weak coordination bond of the aqua ligand is also expected from the small electron distribution between the Ru atom and the aqua ligand (see the density contour map of 0.2 e in Figs. 3a and b). For both monohalogeno and *cis*-dihalogeno ammine complexes, the Ru–NH_3 bond strength in the position *trans* to the halide ligand is weaker than in the position *cis* for all complexes by *ca.* 0.1—0.3 eV (see Table 3). These results suggest that the *trans*-effect of halide ligand is stronger than that of the ammine ligand.

Electronic Structures of Some Distorted State. As described above, the *cis*-ammine ligand coordinates with the Ru atom more strongly than does the *trans*-ammine ligand. It is unexpected that the *cis*-ammine ligand is mainly substituted for the outer-sphere halide ion in the solid-state thermal reaction in spite of the strong *cis*-Ru–NH_3 bond.[3,4] In order to clarify this problem, an MO study was carried out on the distorted state of $RuCl(NH_3)_5^{2+}$, because the distortion is expected to occur in the thermally-activated state.

UHF-MO calculations were carried out on the following distorted states of $RuCl(NH_3)_5^{2+}$: those for which (1) the angle between the z-axis and the *trans*-Ru–NH_3 bond is 20°, (2) the angle between the z-axis and the *cis*-Ru–NH_3 bond is 70° and (3) 110°. All of these distortions were examined in the plane including mainly the unpaired electron (see Fig. 4). These results are given in Table 4, accompanied by the ground state

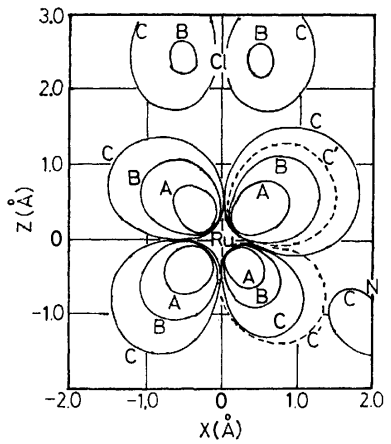

Fig. 5. LUMO contour map of $RuCl(NH_3)_5^{2+}$ ($\angle$X-Ru-NH_3=110°, A=0.25 e, B=0.05 e, C=0.005 e in distorted state and C′=0.005 e in ground state).

result. In terms of the total energy, distorted state (3) is the most stable.[28]

Thus, it is reasonable to conclude that the reaction mainly occurs from state (3). In the case of (3), the bent *cis*-Ru–NH_3 bond becomes stronger, while the *trans*-Ru–NH_3 bond becomes weaker. If the solid-state thermal-substitution reaction proceeds *via* a dissociative mechanism, the weak *trans*-Ru–NH_3 bond should dissociate to produce a complex with a *trans*-substituted structure.

The LUMO, which plays an important role in the nucleophilic attack, extends to the area between the bent Ru–NH_3 bond and the Ru–Cl bond more greatly than does that of non-distorted state, as is shown in Fig. 5. Thus, the nucleophilic attack of the outer-

sphere anion is accelerated by the distortion, and the attack occurs in the direction is shown in Fig. 5. If the reaction proceeds *via* an associative mechanism, the entering group attacks the Ru atom in the direction in which the LUMO largely extends, followed by bond dissociation of the *trans*-Ru–NH_3 bond. Then, as the *cis*-ammine ligand transfers to the vacant position, the entering group transfers to the initial position of the *cis*-ammine ligand. Since the *cis*-substituted tetraammine complex is obtained as a main product,[4] the associative mechanism is expected to be the main reaction path in the thermal-substitution reaction of halogenopentaammine complexes in the solid state, which agrees with the negative values of the activated entropy for these reactions.

In conclusion, the present INDO-type UHF-MO study of Ru(III)–ammine complexes provides useful information about their electron configurations in the ground state and the bonding nature between the metal and ligand. Some other useful information has also been obtained with this method, which successfully suggests the relation between the distribution of the reaction products and the reaction mechanism. These results agree with experimental results.

27) Unpublished work.
28) This stabilization should be due to the Jahn-Teller effect, since the ground state is the ^2E state. Therefore, distortion is brought about not only by the thermal excitation, but also by the Jahn-Teller effect.

Spectrophotometric Determination of Iron(III) and Aluminium with Semimethylxylenol Blue

Joichi UEDA

Department of Chemistry, Faculty of Education, Kanazawa University, Marunouchi, Kanazawa-shi 920

(Received June 6, 1977)

Semimethylxylenol Blue (SMXB) reacts with iron(III) and aluminium to form water-soluble colored complexes. The colored solution of the iron(III) complex shows a maximum absorption at 580—581 nm, while that of the aluminium complex shows it at 554—555 nm. The absorbances of the solutions are constant over the pH range from 1.2 to 1.5 and from 2.5 to 2.9, respectively. Beer's law is obeyed up to 1.4 μg cm^{-3} of iron(III) and 1.0 μg cm^{-3} of aluminium. Their molar extinction coefficients are 3.38×10^4 and 2.91×10^4, respectively. As a result of the investigation of the composition of the iron(III) or aluminium complex, the mole ratio of metal and SMXB was estimated to be 1 : 1. Among the 45 diverse ions examined, gallium, tin(IV), bismuth(III), zirconium, and vanadium(V) interfered with iron(III) determination, and gallium, indium, bismuth(III), scandium, titanium(IV), zirconium, vanadium(V), iron(III), fluoride, and oxalate interfered with aluminium determination. Consecutive determination of iron(III) and aluminium was also studied.

Semimethylxylenol Blue (SMXB) is obtained as one of the products in the synthesis of Methylxylenol Blue by the Mannich condensation of Paraxylenol Blue, formaldehyde, and iminodiacetic acid. It is a monosubstituted derivative of Paraxylenol Blue, while Methylxylenol Blue is a disubstituted derivative.[1] In the preceding paper,[2] the author proposed a method for the determination of thorium, based on the sensitive color reaction of SMXB with thorium. This reagent also reacts with iron(III) and aluminium to form water-soluble colored complexes. So the possibility of using this reagent for the spectrophotometric determinations of these elements was examined, and it was found that SMXB was a suitable reagent for these elements, especially for iron(III), as regards both sensitivity and selectivity, and could be applied to the determinations of up to 1.4 μg cm^{-3} of iron(III) and up to 1.0 μg cm^{-3} of aluminium. In the present methods, iron(III) interferes with the determination of aluminium, giving a positive error, but it can be determined without interference from aluminium. Utilizing these facts, the consecutive determination of iron(III) and aluminium was also studied, and satisfactory results were obtained with the solutions containing 0.16—2.0 μg cm^{-3} of iron(III) and 0.16—1.2 μg cm^{-3} of aluminium.

The present methods for both iron(III) and aluminium are nearly as specific as the methods using such reagents with similar structures to SMXB as Xylenol Orange,[3,4] Methylthymol Blue,[5,6] and Methylxylenol Blue,[7,8] and have higher sensitivities than these methods. Further, this reagent is more sensitive than the most common reagents for iron, such as 1,10-phenanthroline,[9] 4,7-dihydroxy-1,10-phenanthroline,[10] 2,2'-bipyridine,[9] and 2,4,6-tri-2-pyridyl-1,3,5-triazine,[11] and more sensitive than those for aluminium such as Aluminon,[12] Alizarin S,[12] Eriochrome Cyanine R,[13] Stilbazo,[14] and Chromazurol S.[15]

Experimental

Reagents. *Standard Iron(III) Solution*: A solution containing about 1 mg cm^{-3} of iron(III) was prepared by dissolving guaranteed reagent grade iron(III) nitrate in a small amount of nitric acid and diluting with distilled water. The solution was standardized by the complexometric back-titration with a standard solution of thorium using Xylenol Orange as an indicator. This solution was diluted as required.

Standard Aluminium Solution: A solution containing about 1 mg cm^{-3} of aluminium was prepared by dissolving guaranteed reagent grade aluminium nitrate in a small amount of hydrochloric acid and diluting with distilled water. The solution was standardized by the complexometric back-titration with a standard solution of zinc using Xylenol Orange as an indicator. This solution was diluted as required.

SMXB Solution: A 0.05% SMXB solution was prepared by dissolving a weighed amount of the reagent in distilled water. The SMXB was prepared by the method described in the preceding paper[2] : it was synthesized from Paraxylenol Blue, iminodiacetic acid, and formaldehyde by the Mannich condensation, separated from the reaction mixture on a cellulose column by 1-butanol saturated with 0.1% acetic acid, and then obtained in the free acid form by passing the fraction of SMXB through a column of cation-exchange resins.

Buffer Solutions: The pH was adjusted with 1 mol dm^{-3} sodium acetate-1 mol dm^{-3} hydrochloric acid for the determination of iron(III) and 0.1 mol dm^{-3} glycine-0.1 mol dm^{-3} sodium chloride-0.1 mol dm^{-3} hydrochloric acid for that of aluminium.

All the other reagents used were of guaranteed reagent grade.

Apparatus. A Hitachi-Perkin-Elmer model 139 spectrophotometer with 1 cm glass cells was used for the absorbance measurements, and a Hitachi-Horiba model M-5 glass electrode pH meter for the pH measurements.

Recommended Procedures. *Determination of Iron(III)*: A sample solution containing up to 35 μg of iron(III) is transferred to a 25 cm^3 volumetric flask. Then 10 cm^3 of the buffer solution of sodium acetate-hydrochloric acid and 3 cm^3 of 0.05% SMXB solution are added. After making up the volume to 25 cm^3 (the final pH: 1.3) and allowing it to stand for 20 min, the absorbance is measured at 580 nm against the reagent blank.

Determination of Aluminium: A sample solution containing up to 25 μg of aluminium is taken into a 50 cm^3 Erlenmeyer's flask. Then, 5 cm^3 of the buffer solution of glycine-sodium chloride-hydrochloric acid, 2 cm^3 of 0.05% SMXB, and 10 cm^3 of dioxane are added. After being kept for a few minutes in a boiling water bath, the solution is cooled with running water, transferred to a 25 cm^3 volumetric flask, and diluted to the mark with water (the final pH : 2.6). The absorbance is measured at 555 nm within 1 h against the reagent blank.

3, 4: Reagent blanks of 1 and 2 respectively, reference: water.

Results and Discussion

Absorption Curves. The absorption curves of iron(III) and aluminium complexes obtained by the recommended procedures are shown in Fig. 1.

The colored solution of the iron(III) complex had an absorption maximum at 580—581 nm, while that of the aluminium complex had it at 554—555 nm.

The Effect of pH. As shown in Fig. 2, the ranges in which the maximum and nearly constant absorbance was obtained were found to be pH 1.2—1.5 for iron(III) and pH 2.5—2.9 for aluminium.

The Stability of the Color. Iron(III) Complex: The full color development was obtained about 10 min after the reagent was added. The color, once developed, was very stable, and the absorbance remained constant for at least several hours.

Aluminium Complex: The color reaction of SMXB with aluminium was very slow at a room temperature. But the reaction time could be considerably shortened by heating the solution in a boiling water bath, and the maximum color development was obtained within only a few minutes. So heating for 3 min in a hot water bath was adopted in further experiments. On the other hand, the absorbance of the resultant colored solution decreased gradually with the time of standing. However, it was found that by adding 7 to 13 cm³ of dioxane the absorbance remained almost constant for at least 1 h after the color development and was higher by about 14% than the absorbance of the colored solution in the absence of dioxane. Accordingly, 10 cm³ of dioxane was always used in these experiments.

The Effect of the Amount of SMXB. The maximum and almost constant absorpances were obtained by adding from 2.7 to 6 cm³ of 0.05% SMXB solution for 20 μg of iron(III) and from 1.5 to 6 cm³ for 10 μg of aluminium.

The Effect of the Amount of the Buffer Solution. The addition of from 3 to 15 cm³ of 1 mol dm^{-3} sodium acetate–1 mol dm^{-3} hydrochloric acid buffer solution had no effect on the color intensity of the iron(III) complex. In the case of aluminium, there was no change in the absorbance when 3 to 10 cm³ of 0.1 mol dm^{-3} glycine–0.1 mol dm^{-3} sodium chloride–0.1 mol dm^{-3} hydrochloric acid buffer solution was used. In this case, the use of the acetate buffer instead of the glycine–sodium chloride–hydrochloric acid buffer was unsatisfactory, because the decrease of the absorbance was induced immediately after the color development, even if dioxane was present.

Calibration Curves. Under the conditions described in the recommended procedures, Beer's law was obeyed up to 1.4 μg cm^{-3} of iron(III) and up to 1.0 μg cm^{-3} of aluminium. The molar absorptivities calculated from the curves were found to be 3.38×10^4 for iron(III) and 2.91×10^4 for aluminium, while the sensitivities for $\log I_0/I = 0.001$ were 0.0016 μg Fe(III)/cm² and 0.0009 μg Al/cm². The reproducibilities of the methods, expressed by the relative standard deviations of the absorbances which were obtained from five repeat determinations, were 0.47% for iron(III) and 0.87% for aluminium.

The Effect of Diverse Ions. The effect of 45 diverse ions on the determination of 20 μg of iron(III) or 10 μg of aluminium was examined. The results obtained are summarized in Table 1.

For the iron(III) determination, 24 cations such as alkali metals, alkaline earth metals, lead, copper, zinc,

A: Effect on iron(III) determination (20 μg of iron(III) was taken). *B*: Effect on aluminium determination (10 μg of aluminium was taken). a) 2 cm^3 of 1 mmol dm^{-3} EDTA solution was added after color development.

lanthanoids, manganese(II), cobalt, and nickel did not interfere, even if they were present at a concentration of 50 times that of iron(III). With regard to the anions, 500 fold amounts of tartrate, citrate, phosphate, or sulfate did inotnterfere. Gallium, tin(IV), bismuth(III), zirconium, and vanadium(V), however, interfered seriously. For the aluminium determination, gallium, indium, bismuth(III), copper, scandium, titanium(IV), zirconium, thorium, vanadium(V), iron(III), fluoride, and oxalate interfered seriously, but copper and thorium could be masked partly by the addition of 2 cm^3 of 1 mmol dm^{-3} EDTA solution at room temperature after color development.

Consecutive Determination of Iron(III) and Aluminium. Iron(III) interferes with the aluminium determination at pH 2.6 by the formation of iron(III)–SMXB complex, giving a positive error, but it can be determined at pH 1.3 without interference from aluminium. Utilizing these facts, the consecutive determination of iron(III) and aluminium has also been studied. The procedure for the determination is as follows.

The sample solution containing iron(III) and aluminium is divided equally. In one solution, the absorbance of the iron(III) complex alone is measured at 580 nm by using a recommended procedure for iron(III). In the other, the sum of the absorbances of the iron(III) and aluminium complexes is measured at 555 nm by using a recommended procedure for aluminium, by adding 5 cm^3 of reagent solution. From these data, the contents of both iron(III) and aluminium in the original samplesolution can be determined by using the following equations:

$$C_{Fe} = 2 \times \frac{A_{580}}{a_{580}^{Fe}}, \qquad C_{Al} = 2 \times \frac{A_{555} - (a_{555}^{Fe}/a_{580}^{Fe})A_{580}}{a_{555}^{Al}},$$

where C_{Fe} and C_{Al} are the contents of iron(III) and aluminium, and A_{580} and A_{555} are the absorbances at 580 and 555 nm, respectively. Further, a_{580}^{Fe} and a_{555}^{Fe} are the absorbances per 1 microgram of iron(III) at 580 and 555 nm respectively, and a_{555}^{Al} is that of aluminium at 555 nm. As shown in Table 2, satisfactory results were obtained with the solutions contain-

X-Ray Fluorescence Spectroscopy of Metal Sulfides

Takashi MAEKAWA, Niro KIKUCHI, Noriyuki FUKUDA, and Toshio YOKOKAWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 8, 1977)

The S K_α spectra of the sulfur compounds were measured. The S K_α energies of metal sulfides were less than that of the pure sulfur in accordance with the theoretical prediction. The S K_α shift for CaS (−0.239 eV) is the largest among those of metal sulfides examined in this study. In the sulfur+selenium binary mixtures, the S K_α energy goes more negative than that of sulfur with increasing the selenium content. These results can be interpreted in terms of the electronegativity of the counter atoms.

The study of physico-chemical properties of non-crystalline solids has grown into one of the important fields of solid state chemistry. Various materials of this class have been studied extensively as to their thermodynamic, structural, and electrical properties.[1] In these materials all long-range order is destroyed and many of the experimental techniques for investigating structural details of crystals become of no use. However, optical spectra often remain similar if the short-range order does not change much. X-Ray emission spectroscopy might be one of the powerful means as well for exploring the short range and electronic structure.[2,3] For example, the energy of inner levels, though not participating in the chemical bonds, slightly changes depending on the valence electron configuration. Thus, the wavelengths of the X-rays due to the transitions of electrons between inner levels of an atom change from compound to compound. This is called the chemical shift of the X-ray energy. X-Ray emission studies for sulfur compounds have been examined extensively by many authors.[4–8] In the present study, a two-crystal spectrometer was applied for the close examination of the chemical shifts of metal sulfides, since they have not been surveyed as extensively as the other sulfur compounds. The sulfur + selenium amorphous mixtures were also examined. The way of analysis proposed in this paper will easily be applicable to other elements like Al, Si, and P, which are the main constituents of the inorganic amorphous materials like silicate glasses.

Experimental

The sulfur K_α emission spectra were obtained by the X-ray excitation method. The spectrometer used in this experiment is of the two crystal type (Toshiba Elec. Co. AFV-701).[9] The conditions for the measurements are listed in Table 1. The angle 2θ was scanned repeatedly to gain the spectra of an appropriate intensity. Pulses from the gas flow-proportional counter were stored in a multichannel analyzer and recorded on a paper tape. In order to minimize an error due to the thermal expansion of the analyzing crystals the measurement was performed in an air controlled room. For the sake of calibration, the same procedure as on the samples was performed on the reference material (orthorhombic sulfur) both before and after every measurement.

In Fig. 1 the upper parts of the sulfur K_α spectra of pure sulfur and CaS are shown as an example. The interval between neighboring points was 0.01 eV in this case. It is seen that K_{α_1} and K_{α_2} peaks overlap; the latter appears on a shoulder of the former one. However one easily sees a considerable shift between the maximum points of the two spectra.

In order to seek the maximum point of the spectrum, we postulated that the least square curve fit by a fourth order equation of energy can be applied to 120 intensity values (points) in the uppermost part of the spectrum, as shown in Fig. 1. The root mean square per cent deviation, σ_p, of the curve fit for the above S and CaS were 0.66 and 0.85% respectively.† The chemical shift was evaluated from the energy of the maximum referred to that of the orthorhombic sulfur.

Table 1. Conditions for the measurement of S K_α spectra

X-Ray tube	Cr
voltage	50 kV
current	30 mA
Analyzing crystal	Ge(111) ($2d$=6.533 Å)
Detector	PR Gas, Proportional counter
PHA	differential
Scan range (2θ)	110.66—110.80°
Scan speed (2θ)	0.02°/min
Storing time interval	2 s/channel, scan
Number of repeated scans	4—5

The alkaline earth sulfides were prepared by heating the corresponding carbonates in a dry H_2S stream at about 1000 °C. The sulfur+selenium mixtures were prepared by melting the desired quantities of sulfur and selenium in an evacuated glass ampoule and quenching it to the room temperature. The other compounds of commercial source were of reagent grade. These were ground and pressed into pellets of 34 mm diameter inside a poly-vinyl chloride ring.

Results and Discussion

In Table 2 are given the energy differences of sulfur K_α of several sulfides, sulfur + selenium mixtures, and sulfate referred to that of pure sulfur. The error limits were estimated by a t-distribution method which was applied to several measurements, shown in parentheses. The literature values are also included in the table. Contamination with sulfate was detected in SrS and BaS.†† In sulfur + selenium the absolute values

† $\sigma_p = 100 \times [\sum(y_i/y_i(\text{calcd}) - 1)^2/(n-1)]^{1/2}$

†† The contamination of sulfates causes large errors in the K_α shifts of sulfur in metal sulfides, because the K_α shifts of sulfates are large and opposite in direction. This contamination can be checked spectroscopically by examining the K_β spectra of sulfur. In the sulfate the so-called K_β' satellite peak appears at the lower energy side of the main peak. The intensity of the S K_β' peak of sulfates is about 20—30% of that of the main K_β peak. The detection of the sulfate by this satellite spectrum is useful, because it does not appear in the metal sulfides. Quantitative analysis, however, cannot be accomplished by this method.

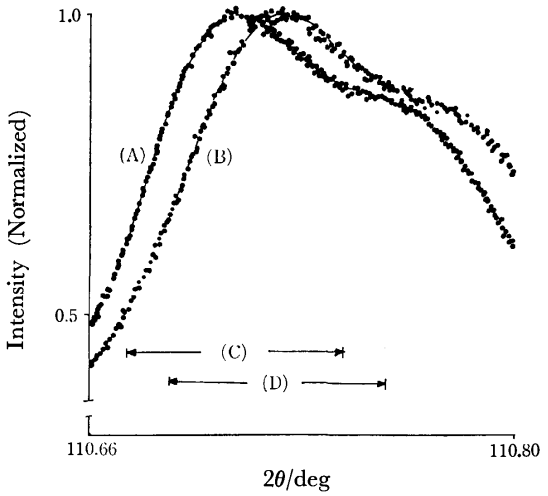

Fig. 1. Sulfur K_α spectra of pure sulfur and CaS (upper part only). The solid line is obtained by a least square fit of a fourth order equation of energy. (A), sulfur; (B), CaS; (C) and (D), ranges used in the least square. Maximum intensity; 28000 and 14000 counts for S and CaS respectively.

of the shifts are very small compared with those of the metal sulfides. It is seen, however, that the shift of S K_α became more negative with increase of the selenium content.

Data Treatment. Before considering the results, some discussion will be necessary about the data treatment employed in this work. The determination of the peak position is very difficult. However, the use of computer calculations on repeatedly stored data can avoid the complexity inherent to the graphical method. Among many proposed ways, the method in which the peak position is decided by the middle point of the half maximum is simple, but it requires the full spectrum and causes some uncertainties when the intensity is small. The most severe difficulty arises when the spectrum is not symmetric, as is observed in the present S K_α spectrum, where K_{α_1} and K_{α_2} overlap. Thus in order to seek the peak position of each component strictly, it is necessary to separate the curve into two by assuming appropriate functions, say Gaussian or Lorentzian. This procedure, however, has some mathematical complexity and gives rise to an additional uncertainty in the possible analysis. Now in the case where only the energy differences rather than the absolute values are required, almost identical results are expected to be obtained independent of the different mathematical procedures, provided the shapes of the spectra do not change as in the present case. Thus the curve fit by a polynomial equation without a process of the peak separation can also be used for the determination of the energy differences among the spectra. The parabolic fit was employed in some references.[10] However, in the spectrum obtained in this work, it is questionable whether the data can be fit by a parabola even in the top region. Actually, the range which can be approximated by a parabolic equation is restricted to the uppermost part of the spectrum and the number of points used is too small to produce a better fit. The present curve which is fit by a fourth order equation

seems to be acceptable judging from the per cent deviation of the curve fit.

Metal Sulfides. As stated previously, metal sulfides have not been thoroughly studied as to the S K_α line, because the chemical shift is not so distinct from one sulfide to the other, compared with the sulfide-sulfur-sulfite-sulfate series. The data of Sato *et al.* and of Nefedow are to be compared with the present results. The general agreement is satisfactory, although the precision was greatly improved in the present study. It is to be noted that any contamination of sulfate makes the negative shift less; some literature values of smaller shift might be explained by this reason. The same reasoning may be applicable to the values of SrS and BaS (in comparison with that of CaS).

Coulson and Zauli proposed an equation combining the chemical shifts and the partial charges on the sulfur atoms.[7] The energy shifts were expressed by a parabolic equation

$$\Delta E\, K_\alpha/\text{eV} = q(q+3)/8,$$

where q is the partial charge on the sulfur. Thus the K_α lines of sulfur shift to the lower energy side with an accumulation of electrons on the sulfur atoms, while in sulfates and sulfites the positive shifts were predicted. As is easily seen from the above equation, the magnitudes of the negative shifts, which were expected for the metal sulfides, are very small. Thus the previous authors mainly discussed the shifts for sulfates or sulfites, in which the shifts are large and can be detected comparatively easily.

In Fig. 2 the relation between the K_α energy shifts from this work and Pauling's electronegativity of the counter atoms are plotted.[11] It is seen that the negative shifts increase with decrease in the electronegativity of the metals. Since the electronegativity difference

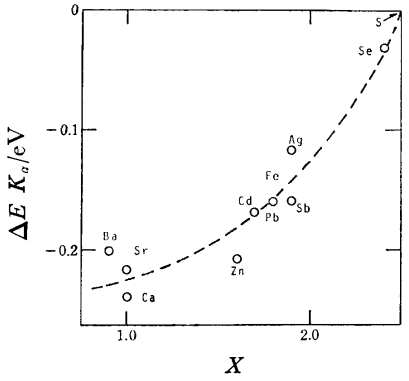

Fig. 2. Relation between S K_α energy shifts of metal sulfides ($\Delta E\ K_\alpha$) and Pauling's electronegativities of the counter metals (X). The shift at the lowest sulfur content of S+Se mixture is also included.

gives the ionicity of a bond as a first approximation, the shifts are more negative with increasing negative partial charges on the sulfur atoms. Thus it is concluded that the above theoretical equation can also be applicable to the metal sulfides. For an estimation of absolute values, however, there are some difficulties. In the condensed state the partial charges are not determined by the electronegativity difference alone. Further, since the above theoretical equation was based on the free ion model, it is not plausible to apply it straightforwardly to the estimation of the absolute charges in real crystals.

Sulfur + Selenium. Sulfur and selenium are quite similar elements. The Pauling's electronegativity of sulfur (2.5) is somewhat larger than that of selenium (2.4), while selenium is more electronegative by the Sanderson's scale.[12] Our previous enthalpy measurement of the liquid binary S + Se solution shows that the enthalpy is positive at all compositions and is symmetric.[13] The positive values of the enthalpy imply that the electrochemical effect is small, if present.[14] The present results show that if the chemical shifts are caused mainly by the partial charges on the sulfur atoms, sulfur bears some negative charges in the binary mixture. Further, if it is accepted that the direction of the charge transfer can be determined mainly by the electronegativity difference, the electronegativity of sulfur is larger than that of selenium, in accordance with Pauling. In the present samples quenched from the liquid state, sulfur and selenium are expected to mix randomly to form various co-rings and co-chains, as in the liquid mixture. In the dilute solution of sulfur, each sulfur atom is coordinated mainly by selenium atoms. Accordingly the electron transfer to sulfur from selenium is relatively large and the shifts are bigger at lower sulfur content, as is found (see Table 2). The shift at the lowest sulfur content was plotted in Fig. 2. As judged from the present results, the Pauling's scale is superior to the Sanderson's scale of electronegativity, although the latter is concerned with a condensed state and should be better applicable to the present system, compared with the former which is strictly applicable only to diatomic gas molecules.

X-Ray Fluorescence Spectroscopy of Binary Silicate Glasses

Takashi MAEKAWA, Niro KIKUCHI, Shigekazu SUMITA, and Toshio YOKOKAWA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 8, 1977)

The Si K_α emission lines of the several silicon compounds and binary silicate (Na, K, Rb, and B-silicates) glasses were measured. In the binary silicates, negative energy shifts from that of SiO_2 were observed. They were interpreted as indicating a relative decrease of the quantity of charge transfer from silicon to oxygen, when more electropositive elements like alkali metals are located on the next nearest neighbor positions of the silicon atoms. The Si K_α shifts of silicate glasses have a good correlation with the basicity of their melts.

As shown in the previous paper, the X-ray emission spectra provide important information about the chemical bonds in the compounds.[1] It is particularly useful to apply this technique to the study of non-crystalline materials, since the long range order disappears and the data on the bond character are quite limited. Among the many inorganic materials, the silicate glasses have drawn special attention in many fields. The network structure of these glasses has been confirmed from their thermodynamic as well as structural properties. However, the details of the Si–O bond, especially its relation to the chain or ring structures and their composition dependences are not satisfactorily understood. Recently, Sakka and Matusita reported Si K_α and K_β spectra of simple binary silicates.[2] Although they found some changes of the peaks of K_β spectra and their widths, no chemical shift of Si K_α was observed. On the other hand, Zopf *et al.* reported the chemical shifts of Si K_α for several silicates.[3] It has been implicitly assumed that Si–O–Si and Si–O^- bonds in silicates stay in the same energy values irrespective of the counter basic oxides. In the present work we applied an improved spectrometer to measure the chemical shifts of Si K_α, if any, and to look for a possible relation between the shifts and the basicity of the glasses.

Experimental

The apparatus used in this experiment is the same as that described in the previous paper.[1] The conditions of the measurement for the Si K_α are shown in Table 1. The features and the scanned ranges for the K_α spectra of silicon metal and SiO_2 are shown in Fig. 1. Because of the low reflecting power of the analyzing crystal (ADP) and the low concentration of silicon in the sample, the intensity of Si K_α was very weak compared with those of S K_α. The curve fit using a fourth order equation was applied to look for the maximum point of the spectrum. The chemical shifts were also obtained by the same procedure as noted in the previous paper.

Melts of M_2O+SiO_2 (M=Na, K, and Rb) were prepared by melting SiO_2 and M_2CO_3 in a platinum crucible. $PbO+SiO_2$ melts were prepared by heating the desired quantities of the two oxides in an alumina crucible. These melts were poured onto a stainless steel plate and quenched into flat glass samples. On the other hand, $B_2O_3+SiO_2$ has high viscosity and it is difficult to prepare flat glasses by such a procedure. In this case the melts were prepared and quenched in a platinum dish, which could be inserted directly into a sample holder of the spectrometer. The effects due to the surface roughness can be avoided by rotating the samples while the fluorescence spectrum was measured. SiC, Na_2SiF_6, and

Results and Discussion

In Table 2 the results of the Si K_α energy shifts of some silicon compounds referred to the energy of metallic silicon are listed. The positive shift of Si K_α in Na_2SiF_6 is the largest among them. This result agrees well with that by a previous author.[4] The silicon K_α shifts of binary silicates from that of SiO_2 are shown in Table 3 and are plotted in Fig. 2. The chemical shifts are all negative, but depend on the composition and the kind of the counter oxides. The following points may be noted from the results.

i) In M_2O+SiO_2 (M=Na, K, and Rb) systems, the Si K_α energy goes more negative with increase of M_2O concentration. No differences among the three alkali oxides can be detected.

ii) In $PbO+SiO_2$, the shifts are similar to those of the above systems. But the absolute value is somewhat smaller than that of the former systems.

iii) In $B_2O_3+SiO_2$, the shifts are too small to give any composition dependence.

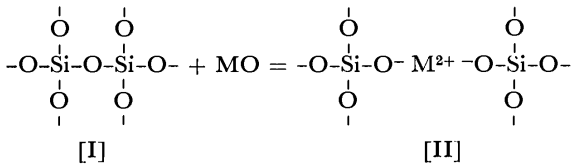
K_α Shifts and the Effective Charges. It is known that the energy of X-ray emission spectrum from an atom in its compounds depends upon the chemical environment of the atom, *i.e.* partial charges, bond lengths, and coordination numbers.[5-8] Generally the positive shifts of X-ray energy in the third period elements in the periodic table correspond chiefly to cationic charges on the atom.[6] In the previous paper we observed the relation between S K_α energy shifts of sulfides and the electronegativity of the counter atoms. The present experimental results (Table 2) coincide with the general trend that the shifts go more positive with an increase of the electronegativity differences between silicon and the combined atoms. The silicon atom in Na_2SiF_6 coordinates six fluorine atoms and cannot be compared in a straightforward way with the others.

In the homogeneous mixtures of SiO_2 with other metal oxides, the three dimensional network structure of SiO_2 is modified by the following reaction.



The size and number of the resulting descrete anions depend on the composition as well as the kind of the metal oxides.[9] Although SiO_4 tetrahedra remains as a structural unit through the above reaction, the electronic density of an Si–O bond should change from [I] to [II]. The ionic structure of an O–M bond should cause some effects on the neighboring Si–O bond character. Thus we must compare the electronic structure between Si–O–Si and $Si-O^-$–M^{2+} instead of considering the Si–O bond only. The source of the charge transferred to oxygen is restricted to silicon atoms in SiO_2, while the main source of the electron is the electropositive element (M in the above equation) in silicates. Mixing SiO_2 with a M_2O results in a relative decrease of the positive charge on the silicon

atom compared with that of SiO_2. This idea coincides with the principle of the electronegativity equalization proposed by Sanderson.[10] The positive charge on silicon atoms will decrease with the increase of the concentration of the metal oxides. This is again in accord with the experimental findings.

K_α Shifts and the Basicity. The thermodynamic studies of these liquid silicates show that the activity of SiO_2 drastically decreases from that of pure SiO_2.[11] In these mixed oxide melts, an useful idea called the basicity of the melt is often employed. Basicity is defined by the oxygen ion activity in the melts.[12] It depends on the metal oxide solute and its concentration. Thus the basicity of the lead silicates is smaller than that of alkali silicates at the same SiO_2 content. Both components of $B_2O_3+SiO_2$, on the other hand, are considered to be acidic in nature. Addition of B_2O_3 to SiO_2 gives a negligible shift of Si K_α energy. Therefore, the basicity reflects the degree of the positive charges on the silicon atoms, although the former is directly determined by the activity of the metal oxide and the latter is primarily determined by the ionic potential (Coulombic force) of a metal ion. There will even be a possibility of finding the basicity scale of the silicate melts by measuring the Si K_α energy of their glassy samples. The significance of the X-ray energy shifts will be similar to the ultraviolet spectra of a probe ion (for example, $^3P_1 \leftarrow {}^1S_0$ of Pb^{2+} ion) under the presence of polarizing elements like Si, P, and others.[13]

Experimental Studies of the Liquid Junction Potential between Electrolyte Solutions in Different Solvents. I. Water–Organic Solvent Junctions

Kosuke IZUTSU, Toshio NAKAMURA, Toshihiko KITANO, and Chieko HIRASAWA

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received June 6, 1977)

The liquid junction potential (ljp) between water and organic solvents was investigated by measuring the emfs of cells with free-diffusion junctions of various electrolyte solutions. In most experiments, the concentration of the electrolyte on one side of a junction was kept much larger than that on the other side (c MX in S//c' M'X' in S'; S or S' is H_2O and $c \gg c'$); thus the ljp was mainly determined by MX. The ljp may practically be expressed by the sum of $E_{j,ion}$ (concn) (I), $E_{j,ion}$ (ion-solv.) (II), and $E_{j,solv.}$ (III). I and II are contributions from ionic species: I is the concentration term, which can be estimated approximately from the Henderson equation, and II is the term due to the difference in ionic solvations in S and S'. III is the contribution from the transfer of solvent molecules. The sum of II and III for the case in which S=H_2O is approximately equal in absolute value but opposite in sign to that for the case in which S'=H_2O. The change of II with the anion X^- is in linear relation with free energy of transfer of the anion from S to S'. The change of III with the bridge solvent is also a linear function of the heat (or free energy) of solution of S into S'. The rate of the change with the heat of solution can be divided in two classes by the species of the cation M^+: the rate for R_4N^+ ions is just a half of that for such ions as Li^+, Na^+, Mg^{2+}, and Ba^{2+}. The effect of the mixed bridge electrolytes and the mixed bridge solvents was also examined.

Because the problem of the liquid junction potential (abbreviated 'ljp') between electrolyte solutions in different solvents is of considerable importance in the electrochemistry of non-aqueous solvents, many reports have recently appeared concerning this problem.[1–10] According to Alfenaar, DeLigny, and Remijnse,[3] the value of the ljp, E_j, at such a junction as (A) can, in principle, be estimated by carrying out the integration of Eq. 1

$$c\,\mathrm{MX}\ \text{in solvent S} \underset{\mathrm{J}}{//} c'\,\mathrm{M'X'}\ \text{in solvent S'} \qquad \text{(A)}$$

$$E_j = -\frac{1}{F}\int_S^{S'} \sum_i t_i^r \mathrm{d}\mu(i), \qquad (1)$$

where t_i^r and $\mu(i)$ are the reduced transport number[11] and the chemical potential, respectively, of chemical species i, and the sum extends over all species, charged and uncharged, present at the junction. The reduced transport number t_i^r is equal to t_i/z_i for an ion with charge z_i and transport number t_i, while t_i^r for an uncharged species can be defined by nF/Q, where n is the amount of substance of the uncharged species transported across the junction when a quantity of charge Q flows through the cell. Alfenaar *et al.*[3] considered that E_j can be expressed by the sum of two terms, *i.e.*, $E_{j,ion}$, which is the contribution from ionic species, and $E_{j,solv.}$, which is the contribution from solvent molecules:

$$E_j = E_{j,ion} + E_{j,solv.}, \qquad (2)$$

$$E_{j,ion} = -\frac{1}{F}\int_S^{S'} \sum_{ions} \frac{t_i}{z_i}\mathrm{d}\mu(i), \qquad (3)$$

$$E_{j,solv.} = -\frac{1}{F}\int_S^{S'} \sum_{\substack{solvent\\ molecules}} t_i^r \mathrm{d}\mu(i). \qquad (4)$$

To carry out the above integrations, however, is difficult because of the difficulties in getting enough knowledge concerning t_i^r and $\mathrm{d}\mu(i)$, which actually determine the ljp between different solvents. Therefore, at the present stage, it seems important to get detailed experimental information about the factors influencing the ljp. An interesting approach from this standpoint has been reported by Cox *et al.*[5] But experimental results are still too scarce to elucidate this problem completely.

In the present study, we have measured emfs of many cells with liquid junction(s) between different solvents, in order to learn how the ljp is influenced by the solvents and electrolytes present at the junction(s). A simple cell, which was constructed by using a dual four-way stopcock, gave free-diffusion junctions and was convenient for rapid, repeated measurements of the emf. We also tried to correlate the results of these emf measurements with the literature data of ion-solvent and solvent-solvent interactions. For such data, we mainly referred to the report of Parker and his coworkers.[5,12]

If we carry out the integrations in Eqs. 3 and 4 under the following simplifying assumptions

(i) c' is negligibly small compared to c,

(ii) the molar conductivity for each ion and t_i^r for each molecule do not vary throughout the boundary, and

(iii) the concentration of each ion changes linearly at the boundary, then we can get Eqs. 5—8 from Eqs. 2—4

$$E_j = E_{j,ion}(\text{concn}) + E_{j,ion}(\text{ion-solv.}) + E_{j,solv.}, \qquad (5)$$

$$E_{j,ion}(\text{concn}) = \frac{RT}{F}(t_{M^+} - t_{X^-})\ln\frac{c\Lambda(\mathrm{MX})}{c'\Lambda(\mathrm{M'X'})}, \qquad (6)$$

$$E_{j,ion}(\text{ion-solv.}) = -\frac{1}{F}[t_{M^+}{}^S\Delta\mu^{S'}(M^+) - t_{X^-}{}^S\Delta\mu^{S'}(X^-)], \qquad (7)$$

$$E_{j,solv.} = -\frac{1}{F}t_S^r{}^S\Delta\mu^{S'}(S), \qquad (8)$$

where ${}^S\Delta\mu^{S'}(M^+)$, ${}^S\Delta\mu^{S'}(X^-)$, and ${}^S\Delta\mu^{S'}(S)$ represent changes in standard chemical potentials of M^+, X^-, and S, respectively, on crossing the boundary from S to S' in the process which actually determines the ljp. Equations 6 and 7 are similar to those recently reported by Gaboriaud.[8] In obtaining Eq. 8, we consider that $E_{j,solv.}$ receives its chief contribution from the solvent

molecule S which is transported from S to S′ with the transfer of electrolyte MX. As is apparent from Eqs. 5 to 8, when condition (i) is satisfied, the effect of M′X′ appears only in the term $E_{j,ion}$(concn) and the ljp should be almost independent of the species of M′X′, provided that c' and Λ(M′X′) are kept constant. In the present study, we carried out most experiments in cells in which condition (i) is satisfied, after confirming experimentally that the above prediction actually holds.*

By the help of the above simplified equations, we could find some correlations between the ljp and the literature data of ion-solvent and solvent-solvent interactions. In this report, we present the results obtained concerning the water-organic solvent junctions. Detailed results concerning the ljp between different organic solvents will be reported elsewhere.

Experimental

Reagents. The preparation and purification of all tetraethylammonium and tetrabutylammonium salts used in this study were carried out by the conventional procedures. Tetramethylammonium perchlorate was obtained from the Nakarai Chemicals Co., Ltd., and was a product for polarographic use. Anhydrous silver perchlorate and lithium perchlorate, both obtained commercially, were used after drying at 70 and 200 °C, respectively, under a vacuum. Anhydrous sodium perchlorate was prepared by recrystallizing from a hot aqueous solution and was dried at 200 °C under a vacuum. All the other reagents were of analytical reagent grade.

Dimethyl sulfoxide (DMSO), *N,N*-dimethylformamide (DMF), propylene carbonate (PC), and acetonitrile (AN) were purified following the methods described in Ref. 13. Nitromethane (NM), acetone (Ac), and methanol (MeOH) were of analytical reagent grade and were purified by distillation.

Apparatus. For emf measurements, the cell shown schematically in Fig. 1 was constructed by using a dual four-way stopcock obtained from the Kyowa Seimitsu Co., Ltd. This stopcock is the one used for high speed liquid chromatography; its liquid path is made of Teflon and has a bore of 1 mm. By turning the stopcock to the position of Fig. 1(A), each of the three compartments of the cell is filled with an appropriate solution. The stopcock is then turned to the position of Fig. 1(B), which results in the formation of sharp liquid boundaries (free-diffusion junctions) at J_1 and J_2. The emf of the cell is established soon after turning the stopcock and remains constant within ±1 mV for a few minutes. After the measurement of the emf, the stopcock is turned back to the position of Fig. 1(A) and the solution in each compartment is renewed. Then, by turning the stopcock to the position of Fig. 1(B), the emf can be measured repeatedly. The ljps obtained with this cell were reproducible within ±1 mV. The emf was measured with a voltmeter with an input impedance of 10^{11} ohms. All measurements were carried out in a room thermostated at about 25 °C.

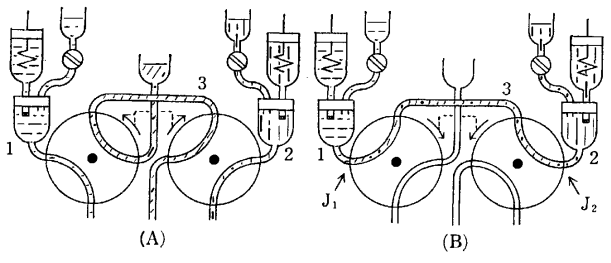

Fig. 1. Cell for emf measurements.

* An example of such an experiment was that the emf of the cell, Ag/0.01 M $AgClO_4$, 0.1 M Et_4NClO_4(AN)//0.1 M Et_4NClO_4(AN)$//_{j1}$$10^{-3}$ M Et_4NX(AN)$//_{j3}$0.1 M Et_4NClO_4(H_2O)//0.01 M $AgClO_4$, 0.1 M Et_4NClO_4(H_2O)/Ag, was constant within several millivolts even when the anion X^- was changed from Pic^- to Cl^-. When compared with the large emf changes of cell III with the anion X^- (Fig. 4(C)), this result may be regarded as a confirmation of the above prediction.

Results and Discussion

Emf Measurements of Cells I and II. Emfs of cells I and II were measured by changing solvents S_1 and S_2 and electrolyte MX:

Ag/10^{-3} M $AgClO_4$, 1M $NaClO_4(S_1)//_{j1}$1M $NaClO_4(S_1)//_{j1}$ 0.1 M $MX(S_1)//_{j2}$$10^{-3}$ M $Et_4NClO_4(S_2=S_1$ or $H_2O)//_{j2}$5×10^{-3} M $AgClO_4$, 5×10^{-3} M $Et_4NClO_4(S_2=S_1$ or $H_2O)$/Ag Cell I**

aq SCE$//_{j1}$3M $NaCl(S_1=H_2O)//_{j1}$0.1 M $MX(S_1=H_2O)//_{j2}$ 10^{-3} M $Et_4NClO_4(S_2)//_{j2}$5×10^{-3} M $AgClO_4$, 5×10^{-3} M $Et_4NClO_4(S_2)$/Ag Cell II

where S_1 in cell I was MeOH, AN, PC, DMSO, or DMF, S_2 in cell II was H_2O, MeOH, AN, PC, DMSO, or DMF, and MX was Me_4NClO_4, Et_4NClO_4, Pr_4NClO_4, Bu_4NClO_4, $LiClO_4$, $NaClO_4$, $Mg(ClO_4)_2$, $Ba(ClO_4)_2$, Et$_4$NPic, Et_4NI, Et_4NBr, Et_4NCl, or Et_4NNO_3. The measured emf values were corrected for the ljps at j_1, j_2, and J_1, which were calculated by using the Henderson equation (Eq. 23 in Ref. 14) and the conductivity data.[15] The corrected emf values are shown in Tables 1 and 2. The change in corrected emf values with the change of MX corresponds to the change in the ljp at J_2. In Table 3, the values of ΔE(I)=[corrected emf($S_2=H_2O$)−corrected emf($S_2=S_1$)] for cell I and ΔE(II)=[corrected emf($S_2\neq H_2O$)−corrected emf($S_2=H_2O$)] for cell II are tabulated. If we consider that $E_{j,ion}$(concn) for the case in which $S_2\neq S_1$ is nearly equal to that for the case in which $S_2=S_1$ (see Eq. 6), then we can think that ΔE(I) and ΔE(II) are nearly equal to $[E_{Ag/Ag^+}(S_2=H_2O)-E_{Ag/Ag^+}(S_2=S_1)+E_{j,ion}$(ion-solv.)$+E_{j,solv.}]$ for cell I and $[E_{Ag/Ag^+}(S_2\neq H_2O)-E_{Ag/Ag^+}(S_2=H_2O)+E_{j,ion}$(ion-solv.)$+E_{j,solv.}]$ for cell II, respectively. Though both ΔE(I) and ΔE(II) changed considerably (sometimes by more than 200 mV) with the change of MX, it is interesting to note that, for most kinds of MX used, the absolute values of ΔE(I) and ΔE(II) for the case in which S_1 for cell I and S_2 for cell II were the same organic solvent agreed with each other within several millivolts. Because, in this case, $E_{Ag/Ag^+}(S_2=H_2O)$ and $E_{Ag/Ag^+}(S_2=S_1)$ for cell I should be equal to $E_{Ag/Ag^+}(S_2=H_2O)$ and $E_{Ag/Ag^+}(S_2\neq H_2O)$ for cell II, the

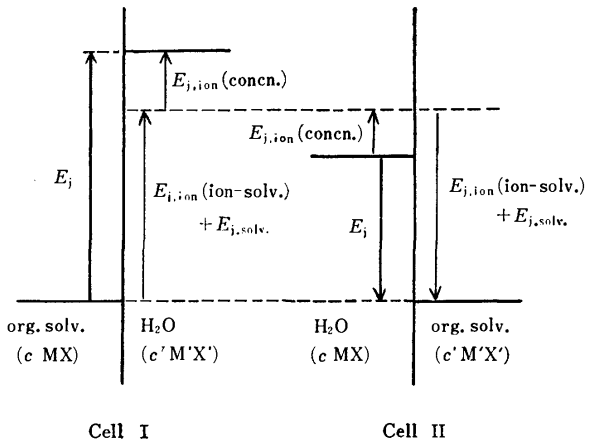

Fig. 2. Schematic representation of the ljp at J_2 in cells I and II ($c \gg c'$).

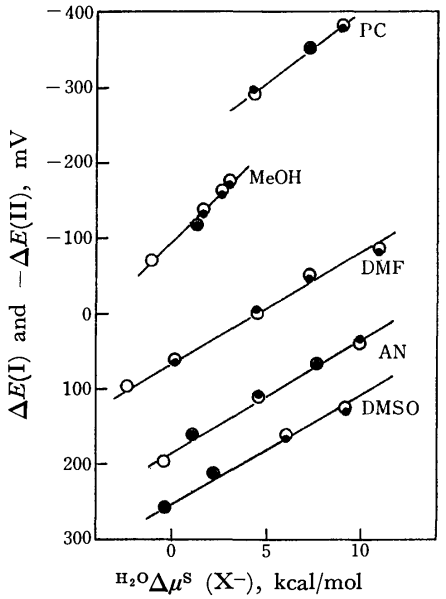

Fig. 3. ΔE(I) (○) and $-\Delta E$(II) (●) as the function of $^{H_2O}\Delta\mu^S(X^-)$. Organic solvent is given along each line. X^- on each line are, from right to left, Cl^-, Br^-, I^-, ClO_4^-, and Pic^-. (Plots for ClO_4^- and Pic^- are not given when the values of $^{H_2O}\Delta\mu^S(X^-)$ are not available.)

above results seem to show that the absolute values of $E_{j,ion}$(ion-solv.)$+E_{j,solv.}$ for cells I and II agree with each other within several millivolts. (We found that similar relations can be obtained at any junctions possible between such organic solvents as MeOH, AN, DMSO, and DMF.[16]) This situation is illustrated schematically in Fig. 2. Probably it would be reasonable to consider that the above statement holds for each $E_{j,ion}$(ion-solv.) and $E_{j,solv.}$.

In Fig. 3, the values of ΔE(I) and ΔE(II) at various water-organic solvent junctions with Et_4NX as MX are plotted as functions of the free energies of transfer of X^- from H_2O to organic solvent S, $^{H_2O}\Delta\mu^S(X^-)$. For $^{H_2O}\Delta\mu^S(X^-)$, we referred to the values of Ref. 12 which were obtained under the extrathermodynamic assumption of $^{H_2O}\Delta\mu^S(Ph_4As^+)=^{H_2O}\Delta\mu^S(Ph_4B^-)$. Excellent linear correlations are always obtained between ΔE and $^{H_2O}\Delta\mu^S(X^-)$, as can be expected from Eq. 7. (If $E_{j,solv.}$ is independent of X^-, the change in ΔE can be considered to correspond to that in $E_{j,ion}$(ion-solv.). Because the molar ion conductivities of the anions other than picrate are nearly equal to each other,[15] t_{M^+} and t_{X^-} in the present case may be considered to remain approximately constant, irrespective of the species of X^-.) The slopes, however, change with the organic solvents: the slopes are between 14 and 15 mV/(kcal/mol) for AN, DMSO, and DMF, but *ca.* 17 mV/(kcal/mol) for PC and *ca.* 25 mV/(kcal/mol) for MeOH. According to Eq. 7, the slopes in Fig. 3 for such organic solvents as AN, DMSO, and DMF correspond to t_{X^-} of about 0.3_5, which seems to be smaller than that expected from the conductivity data ($t_{X^-}>0.6$).[15] Therefore, the linear correlation in Fig. 3 cannot be regarded as in quantitative agreement with Eq. 7. The larger slopes for PC and MeOH cannot be explained from the conductivity data. Though the mechanism determining these slopes cannot be elucidated from the present study, it may be that $\Delta\mu(X^-)$ and/or t_{X^-} expected from the literature data are effective only partially in the processes which determine the ljp.

The change in E_j with the cations of MX is somewhat more complicated and will be discussed in the next section.

Emf Measurements of Cell III. The emf of cell III was measured by changing the bridge electrolytes and solvents:

$$\mathrm{Ag/5\times10^{-3}\,M\ AgClO_4,\ 5\times10^{-3}\,M\ Et_4NClO_4(S_1{=}AN)}\underset{j1}{//}$$

$$\mathrm{10^{-3}\,M\ Et_4NClO_4(S_1{=}AN)}\underset{j1}{//}\mathrm{0.1\,M\ MX(S_3)}\underset{j2}{//}\mathrm{10^{-3}\,M}$$

$$\mathrm{Et_4NClO_4(S_2{=}H_2O)}\underset{j2}{//}\mathrm{5\times10^{-3}\,M\ AgClO_4,\ 5\times10^{-3}\,M}$$

$$\mathrm{Et_4NClO_4(S_2{=}H_2O)/Ag} \qquad \text{Cell III}$$

where S_3 was AN, PC, NM, Ac, DMSO, or DMF, and MX was Et_4NClO_4, Me_4NClO_4, Pr_4NClO_4, Bu_4NClO_4, $LiClO_4$, $NaClO_4$, $Mg(ClO_4)_2$, $Ba(ClO_4)_2$, Et_4NPic, Et_4NBF_4, Et_4NI, Et_4NBr, Et_4NCl, or Et_4NNO_3. The results are summarized in Fig. 4. Solvents S_3 are designated on the abscissa at the corresponding emfs of cell III, in which the bridge electrolyte is 0.1 M Et_4NClO_4.

Figures 4(A) and 4(B) show that the emf for each bridge electrolyte changes approximately linearly against the abscissa, and that the slopes of these straight lines can be classified according to the bridge cations in two groups, *i.e.*, one for tetraalkylammonium ions and the other for such cations as Li^+, Na^+, Mg^{2+}, and Ba^{2+}. The slope of the second group is just twice that of the first group.*** In Fig. 4(A) the values of $\Delta\Delta H_s=^{S3}\Delta H^{S1}(S_3)-^{S3}\Delta H^{S2}(S_3)$ obtained from Table I in Ref. 5 are also plotted against a similar abscissa (here, $^{S3}\Delta H^{S1}(S_3)$ represents the heat per mole of transfer of S_3 from S_3 to S_1). A good linear relation is observed for all aprotic solvents used as S_3 (*cf.* Ref. 5).

When the bridge solvent S_3 in cell III changes, the ljps at both J_1 and J_2 may change. From Eqs. 6 to 8,

*** A similar phenomenon was also observed when picrates, instead of perchlorates, were used as MX.

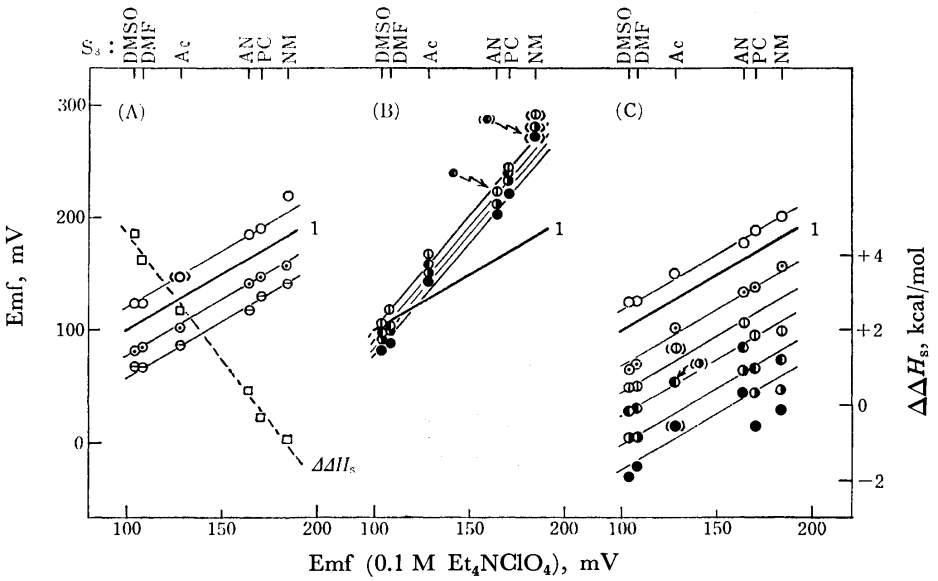

Fig. 4. Emf of cell III and $\Delta\Delta H_s$ (see text).
(A) and (B) for $MX=MClO_4$. M^+: 1 Et_4N^+; ○ Me_4N^+; ⊙ Pr_4N^+; ⊖ Bu_4N^+; ⓘ Na^+; ◑ Li^+; ◐ Ba^{2+}; and ● Mg^{2+}. (C) for $MX=Et_4NX$. X^-: 1 ClO_4^-; ○ Pic^-; ⊙ BF_4^-; ⓘ I^-; ◐ NO_3^-; ◑ Br^-; and ● Cl^-.

the sum of the ljps at J_1 and J_2 can be expressed by the sum of the following three terms:

$$E_{j,ion}(\text{concn})_{(J1+J2)} \approx 0, \quad (9)$$

$$E_{j,ion}(\text{ion-solv.})_{(J1+J2)} = -\frac{1}{F}[t_{M^+}{}^{S1}\Delta\mu^{S2}(M^+) - t_{X^-}{}^{S1}\Delta\mu^{S2}(X^-)], \quad (10)$$

$$E_{j,solv.(J1+J2)} = \frac{1}{F}t^r_{S3}[{}^{S3}\Delta\mu^{S1}(S_3) - {}^{S3}\Delta\mu^{S2}(S_3)] = \frac{1}{F}t^r_{S3}\Delta\Delta\mu_s. \quad (11)$$

If these simplified equations may be assumed to hold in cell III, the change of the bridge solvent (S_3) affects only the term of $E_{j,solv.(J1+J2)}$, and the emf of cell III is expected to change linearly with the change of $\Delta\Delta\mu_s = [{}^{S3}\Delta\mu^{S1}(S_3) - {}^{S3}\Delta\mu^{S2}(S_3)]$. Here, the following relations have been found by Cox *et al.*:[5] ${}^{S}\Delta\mu^{H_2O}(S) \approx ({}^{S}\Delta H^{H_2O}(S) + 3 \text{ kcal mol}^{-1})/2$ and ${}^{S}\Delta\mu^{AN}(S) \approx {}^{S}\Delta H^{AN}(S)/2$, where S denotes an organic solvent. Therefore, the good linear correlations in Figs. 4(A) and 4(B) between $\Delta\Delta H_s$ and the change in emf indicate that Eq. 11 is, at least qualitatively, a reasonable representation.† Here we must point out that, as was found by Cox *et al.*,[5] the change in ${}^{S}\Delta\mu^{H_2O}(S)$ is generally much larger than the change in ${}^{S}\Delta\mu^{AN}(S)$. Thus, most of the change in emf of cell III with the bridge solvent should be attributed to the change in $E_{j,solv.}$ at J_2 (water–organic solvent junction). This has been confirmed experimentally from the investigation of the ljp between different aprotic solvents.[16]

In deriving Eq. 8, we assumed that solvent molecules which are transferred across the boundary with the bridge electrolyte determine $E_{j,solv.}$. The fact that two classes of straight lines with a simple slope ratio (1 : 2) are obtained might be an indication that solvent molecules are really carried across the junction with the bridge electrolyte and that the number of the solvent molecules determines the ljp. It is difficult, however, to understand why the slopes are the same for all tetraalkylammonium perchlorates, on one hand, and for the perchlorates of Li^+, Na^+, Mg^{2+}, and Ba^{2+}, on the other hand, even though there exist considerable differences in ionic mobilities and solvations among the cations in each group.

We showed in Table 3 that the difference of ΔE between such bridge cations as Li^+, Na^+, Mg^{2+}, and Ba^{2+} is relatively small. The results in Fig. 4(B) also show that these cations behave in approximately the same way. Similar phenomena have also been observed at junctions between different organic solvents.[16] Cox *et al.*[5] tried to attribute this small difference in ljp among these cations to the compensating effect of two factors, the free energies of transfer of cations and their mobilities. We would rather consider, however, that it is because the contribution from these cations to $E_{j,ion}$(ion-solv.) is actually relatively small. This can be supported by the following reasoning: Parker and his coworkers[4,5] considered that, when the bridge electrolyte is 0.1 M Et_4NPic, the value of $E_{j,ion}$(ion-solv.) is generally small. If this is correct, the ljp of cell III with 0.1 M Et_4NPic as the bridge electrolyte may be considered to be small when $\Delta\Delta H_s$ becomes +3 kcal/mol, because $\Delta\Delta\mu_s$ is then approximately zero and $E_{j,solv.}$ may also be expected to be small. From Fig. 4(C), the emf of cell III with 0.1 M Et_4NPic bridge electrolyte is *ca.* 140 mV at 123 mV of the abscissa at which $\Delta\Delta H_s = +3$ kcal/mol. We find from Fig. 4(B) that the emfs of cell III with such bridge cations as Li^+, Na^+, Mg^{2+}, and Ba^{2+} are also near 140 (±15) mV at $\Delta\Delta H_s = +3$ kcal/mol, a good coincidence with the above emf value (here the contribution from the perchlorate ion may be considered to be relatively

† The results in Fig 4 show that t^r_{S3} in Eq. 11 has negative values.

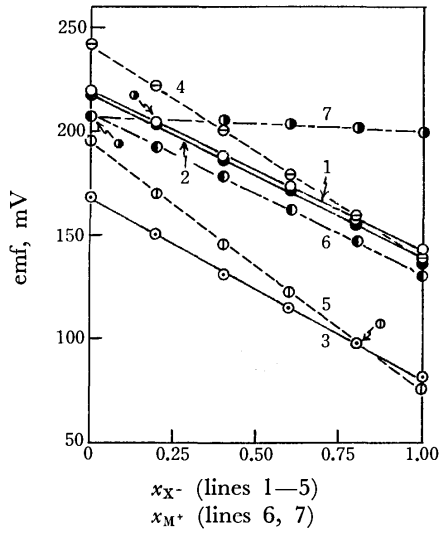

Fig. 5. Changes of emfs of cells IV and IV′ with the molar ratios of the mixed bridge electrolytes.
Lines 1—5 are for cell IV and lines 6 and 7 for cell IV′. $X^-=Br^-$ and $Y^-=ClO_4^-$ for lines 1(○), 2(●), and 3(⊙), $X^-=Br^-$ and $Y^-=Pic^-$ for lines 4(⊖) and 5(◫), $M^+=Bu_4N^+$ and $N^+=Na^+$ for line 6(◐), and $M^+=Li^+$ and $N^+=Na^+$ for line 7(◑). Solvent S_3 is AN for lines 2, 4, 6, and 7, H_2O for line 1, and DMF for lines 3 and 5.

small). A similar coincidence between the emf of the cell with 0.1 M Et_4NPic bridge electrolyte and those with 0.1 M bridge electrolytes of the perchlorates of these cations was observed at $\Delta\Delta\mu_s\approx 0$ also in the case in which MeOH, instead of H_2O, was used as S_2 in cell III.[16]

The effect of tetraalkylammonium ions on the ljp at water–organic solvent junctions was considerable, as is shown in Table 3. When these ions were used as the bridge cations in cell III, the emf decreased with the increase of the cationic size, as can be expected from Eq. 10 (Fig. 4(A)). But quantitative study is difficult because the available data concerning the free energy of transfer of these ions is insufficient.

Figure 4(C) shows that the effect of bridge anions on the emf of cell III is quite large. If we consider the emfs of the cell in which the bridge solvents are AN, DMSO, and DMF, we find that the emf changes linearly with the bridge solvents, with slopes approximately equal for all bridge anions, and the lines shift to smaller emf values from picrate to chloride ions. Because ${}^{S}\Delta\mu^{AN}(X^-)$ is smaller than ${}^{S}\Delta\mu^{H_2O}(X^-)$, most of the change in the emf with the bridge anions corresponds to the change in ljp at J_2 (see Fig. 3). When the bridge solvent was PC or NM, however, deviations from linearity occurred, especially with halogenide and nitrate ions, as can also be expected from the results in Fig. 3.

Use of a Salt Bridge Consisting of Mixed Electrolytes or Mixed Solvents. Salt Bridge Consisting of Mixed Electrolytes: The emfs of cells IV and IV′ were measured by changing the ratio of the mixed electrolytes in the salt bridge. The results are represented in Fig. 5.

$$Ag/5\times10^{-3}\,M\ AgClO_4,\ 10^{-2}\,M\ Et_4NClO_4(AN)\underset{j1}{//}10^{-2}\,M\ Et_4NClO_4(AN)\underset{J1}{//}0.1\,xM\ Et_4NX\text{-}0.1(1-x)M\ Et_4NY(S_3)\underset{J2}{//}$$
$$10^{-2}\,M\ Et_4NClO_4(H_2O)\underset{j2}{//}5\times10^{-3}\,M\ AgClO_4,\ 10^{-2}\,M\ Et_4NClO_4(H_2O)/Ag \qquad \text{Cell IV}$$

$$Ag/10^{-2}\,M\ AgClO_4(AN)\underset{J1}{//}0.1x\,M\ MClO_4\text{=}0.1(1-x)M\ NClO_4(S_3)\underset{J2}{//}10^{-2}\,M\ AgClO_4(H_2O)/Ag \qquad \text{Cell IV′}$$

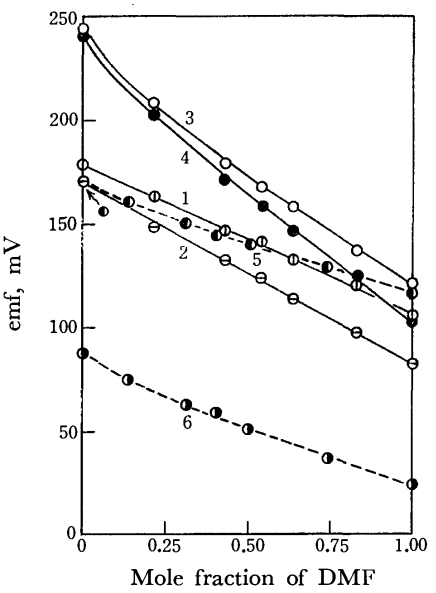

Fig. 6. Changes of emfs of cells V and V′ with the mole fractions of mixed bridge solvents.
Lines 1—4 for cell V′. M^+: 1(◫) Et_4N^+; 2(⊖) Bu_4N^+; 3(○) Na^+; and 4(●) Li^+. Lines 5 and 6 for cell V. X^-: 5(◐) ClO_4^-; and 6(◑) Br^-.

Lines 1—3 were obtained for cell IV in which $X^-=Br^-$, $Y^-=ClO_4^-$, and solvent S_3 was AN, H_2O, and DMF, respectively. All these lines were straight. Because the molar conductivities of Br^- and ClO_4^- are approximately equal in all the solvents concerned, this linear relation is what can be expected. If $X^-=Br^-$ and $Y^-=Pic^-$ in cell IV or $M^+=Bu_4N^+$ or Li^+ and $N^+=Na^+$ in cell IV′, there exist some differences between the molar conductivities of X^- and Y^- or M^+ and N^+.[15] But the changes of emfs with the molar ratio of the mixed electrolyte were also almost linear, as shown by lines 4 to 7. This can be understood if we consider that the relations $x\Lambda_{Et_4NX}/[x\Lambda_{Et_4NX}+(1-x)\Lambda_{Et_4NY}]$ *vs.* x and $x\Lambda_{MClO_4}/[x\Lambda_{MClO_4}+(1-x)\Lambda_{NClO_4}]$ *vs.* x are almost linear even when there exist some differences in molar conductivities.

Salt Bridge Consisting of Mixed Solvents: The results in Fig. 6 were obtained by measuring emfs of cells V and V′ for various ratios of the mixed bridge solvents.

$$Ag/5\times10^{-3}\,M\ AgClO_4,\ 10^{-2}\,M\ Et_4NClO_4(AN)\underset{j1}{//}10^{-2}\,M\ Et_4NClO_4(AN)\underset{J1}{//}0.1\ M\ Et_4NX(AN+DMF)\underset{J2}{//}10^{-2}\,M$$
$$Et_4NClO_4(H_2O)\underset{j2}{//}5\times10^{-3}\,M\ AgClO_4,\ 10^{-2}\,M\ Et_4NClO_4(H_2O)/Ag \qquad \text{Cell V}$$

$$Ag/10^{-2}\,M\ AgClO_4(AN)\underset{J1}{//}0.1\ M\ MClO_4(PC+DMF)\underset{J2}{//}10^{-2}\,M\ AgClO_4(H_2O)/Ag \qquad \text{Cell V′}$$

When M^+ in cell V′ was Et_4N^+ or Bu_4N^+, the emfs changed almost linearly with the mole fraction of the solvents. But deviations from linearity occurred when M^+ in cell V′ was Na^+ or Li^+, and X^- in cell V was Br^- or ClO_4^-. To predict the effect of the mixed solvents is rather difficult. Besides the effect to the solvent component of the ljp, $E_{j,solv.}$, the effect of the preferential ionic solvation by one of the mixed solvents must be taken into account. In the cases of Fig. 6, lines 3 and 4, the deviation from linearity seems to be due to the preferential solvation of DMF to the bridge cations (Na^+ and Li^+).

In the present report, we have examined in detail how the ljps between water and organic solvents are influenced by the solvents and electrolytes present at the junctions and found that some of the influence can be correlated, at least qualitatively, with the literature data concerning ion-solvent and solvent-solvent interactions. The influence at the junctions between water and organic solvents is much larger than that at any junctions possible between such organic solvents as MeOH, AN, PC, DMF, and DMSO.[16] Therefore, we must take this influence carefully into account when we measure emfs of cells involving water-organic solvent junctions. The results in the present report will be of use in such cases.

The Crystal Structure of the Ammonium Bromide Complex of 1,4,7,10,13,16-Hexaoxacyclooctadecane (18-Crown-6), $C_{12}H_{24}O_6 \cdot NH_4Br \cdot 2H_2O$

Osamu NAGANO, Akiko KOBAYASHI, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received July 1, 1977)

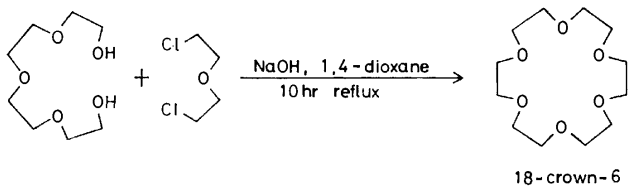
Ammonium bromide forms a 1 : 1 complex with cyclic polyether "18-crown-6." The crystals of $C_{12}H_{24}O_6 \cdot NH_4Br \cdot 2H_2O$ are orthorhombic, with the space group of Pnam and with cell constants of $a=10.002(3)$, $b=12.716(4)$, $c=15.073(4)$ Å, and $Z=4$. The structure was solved by the conventional heavy-atom technique and refined by the full matrix least-squares method to $R=0.099$ for 1033 independent reflections. The 18-crown-6 has a conformation with a pseudo D_{3d} symmetry. The ammonium cation is displaced by 1.00 Å from the mean oxygen plane of the 18-crown-6 and interacts with the nearest bromide anion. The relationship between the cation and the 18-crown-6 resembles those of the $C_{12}H_{24}O_6 \cdot RbNCS$ and $C_{12}H_{24}O_6 \cdot CsNCS$ complexes. On the difference Fourier maps, four electron-density peaks were detected at reasonable positions for the hydrogen atoms of the amonium cation.

Macrocyclic polyethers, often called "crown" compounds, form complexes with many different inorganic cations, such as alkaline metal, alkaline-earth metal, and ammonium cations.[1] They have the possibility to increase the salt solubility and the anion reactivity in organic solvents.

In the last decade, therefore, many macrocyclic polyethers have been studied as catalysts for organic syntheses,[2,3] reagents for solvent extraction in analytical chemistry,[4,5] and packing material for the separation of *d,l*-amino acids by column chromatography.[7-9] Our main interest in the present structure study of $C_{12}H_{24}O_6 \cdot NH_4Br \cdot 2H_2O$ lies in the difference between the interaction of an alkaline or alkaline-earth metal cation-crown compound[10-16] and that of an ammonium cation-crown compound.

Experimental

18-Crown-6 was synthesized from bis(2-chloroethyl) ether and tetraethylene glycol according to the following scheme:[17,18]



18-crown-6

The crystal of $C_{12}H_{24}O_6 \cdot NH_4Br \cdot 2H_2O$ was obtained from an aqueous solution of the 18-crown-6 and ammonium bromide (18-crown-6 : NH_4Br = 1 : 1). The crystal used was made nearly spherical, and its radius was 0.18 mm.

The intensities of the reflections were measured with a Rigaku automatic four-circle diffractometer (graphite monochrometer, Mo $K\alpha$ radiation, ω-2θ scan method). The scanning range was determined according to the formula of $1.2° + 0.6° \tan\theta$, and the scanning rate was 0.5° per min in ω when $2\theta < 60°$. Background counts of 10 s were taken at both limits of the scanning range. Three reference reflections were measured after every 50 reflections; no significant changes were observed over the period of data collection. The intensities of 1033 reflections ($\sigma(F) > 3.0$) were adopted for the structure determination.

The crystal data are: $C_{12}H_{24}O_6 \cdot NH_4Br \cdot 2H_2O$, orthorhombic, space group Pnam, $a=10.002(3)$, $b=12.716(4)$ $c=15.073(4)$ Å, $U=1917.1(9)$ Å^3 at 23 °C, $Z=4$, $D_m=1.35$, $D_x=1.380$ g cm^{-3}, $F.W.=398.29$ and μ(Mo $K\alpha$)$=23.07$ cm^{-1}.

Structure Determination

The structure was solved by the heavy-atom technique and refined by the full matrix least-squares program LINUS.[19] The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, where $w=1/\sigma^2(F)$. The atomic scattering factors used were taken from the International Tables for X-Ray Crystallography, Vol. IV.[20] Corrections for anomalous dispersion and absorption were included in the refinement. An extinction correction was applied at the final stage of the refinement, but the R value, 0.099 ($R=\Sigma w||F_o|-|F_c||/\Sigma w|F_o|$), did not change. The R value was relatively large, possibly because of the sensitivity of the crystal to X-ray, but possibly also because of the release of water molecules from the crystal during the measurement. In a test of the R-factor ratio based on the hypothesis that $Pna2_1$ was the correct space group, the R-factor ratio, $R(\text{Pnam})/R(Pna2_1)$, was found to be 1.016. We could not reject, at the 50% significance level, the hypothesis that Pnam was the correct space group. However, the result for $Pna2_1$ indicated unreasonable values in the bond distances and bond angles. Hence, we selected centro-symmetric Pnam as the space group of the crystal.[21] The atomic coordinates and temperature factors are listed in Tables 1—3. The F_o-F_c table is kept at the office of this Bulletin as Document No. 7807.

Results and Discussion

Crystal Structure. The two oxygen atoms of the 18-crown-6, O(1) and O(4), the nitrogen atom and two hydrogen atoms, H_{Br} and $H_{O(4)}$, of the ammonium cation and the bromide anion lie on the mirror plane at $z=1/4$ and 3/4. The cation interacts with the 18-crown-6 and the nearest bromide anion, which is weakly bound to four water molecules. The NH_4^+–Br^- distance (3.438 Å) is slightly longer than the sum of the two corresponding ionic radii (3.39 Å = 1.43 + 1.96 Å). The Br^-–OH_2 distances (average, 3.365 Å) are in fair agreement with the sum of corresponding ionic and van der Waals radii (3.36 Å = 1.96 + 1.40 Å). There is

no direct interaction between the cation and the water molecules. The TG measurement of $C_{12}H_{24}O_6·NH_4Br·2H_2O$ showed that the water molecules of crystallization were released from the crystal lattice at *ca.* 55 °C. They are distributed in the holes of the crystal lattice as is shown in Fig. 1.

The Structure of the NH_4^+·18-Crown-6 Complex Cation. The pseudo D_{3d} symmetrical conformation of the 18-crown-6 is the same as those found in the KNCS, RbNCS, and CsNCS complexes.[22] Table 4 shows the bond distances, the bond angles, and the torsion angles in the 18-membered ring. The six oxygen atoms of the 18-crown-6 are alternately 0.25 Å above and below their mean plane and form a nearly planar hexagon of approximately 2.84 Å (2.819—2.853 Å; average, 2.840 Å). The C–C distances (1.474—1.506 Å; average, 1.492 Å) and the C–O distances (1.403—1.424 Å; average, 1.416 Å) appear to be somewhat shorter than those in the $C_{12}H_{24}O_6$·KNCS complex, possibly because of the internal motion in the ring, as is observed in other complexes.[16-20,22] The temperature factors of the oxygen and carbon atoms are remarkably anisotropic (Table 3). The C–O–C bond angles (110.8—115.1°; average, 113.0°) are larger than the C–C–O bond angles (106.8—111.5°; average, 109.0°). The average of the torsion angles about C–C bonds is 67.9°, while that about C–O bonds is 4.3°. All the C–H distances are between 0.96 and 1.05 Å.

The nitrogen atom of the ammonium cation has the smallest thermal ellipsoid of all the non-hydrogen atoms,

N-$H_{O(4)}$	0.93		

suggesting that the cation strongly interacts with the 18-crown-6 as is shown in Figs. 2 and 3. This nitrogen atom is displaced by 1.00 Å from the mean oxygen plane of the 18-crown-6. The ammonium cation is too large to fit in the cavity of the 18-crown-6. Dunitz *et al.*[22] reported that, in the RbNCS and CsNCS complexes of the 18-crown-6, the cations were displaced from the mean oxygen plane by 1.19 Å (Rb^+) and 1.44 Å (Cs^+). The distance, 1.00 Å for NH_4^+, is a suitable length considering the size of the cations and that of the cavity of the 18-crown-6 (cavity < NH_4^+ < Rb^+ < Cs^+). The straight line passing through the bromine and nitrogen atoms intersects the mean oxygen plane at an angle of 68.8° (Fig. 3). The N–O distances are divided into two groups (3.000—3.128 Å; average, 3.064 Å for N–O(1), N–O(3) and N–O(3'); 2.857—2.844 Å; average, 2.871 Å for N–O(2), N–O(2') and N–O(4)). On the difference Fourier maps, four electron-density peaks (0.6—0.8 e/Å^3) were detected at reasonable positions for the hydrogen atoms of the ammonium caion. The electron-densities of the ghost peaks around the nitrogen atom were lower than 0.55 e/Å^3. Three peaks are between N and O(2), N and O(2'), and N and O(4), suggesting the existence of three hydrogen bonds (Fig. 2). The last peak is between N and Br^- (Fig. 3). The N–H distances are between 0.9 and 1.1 Å. Table 5 shows the distances in-

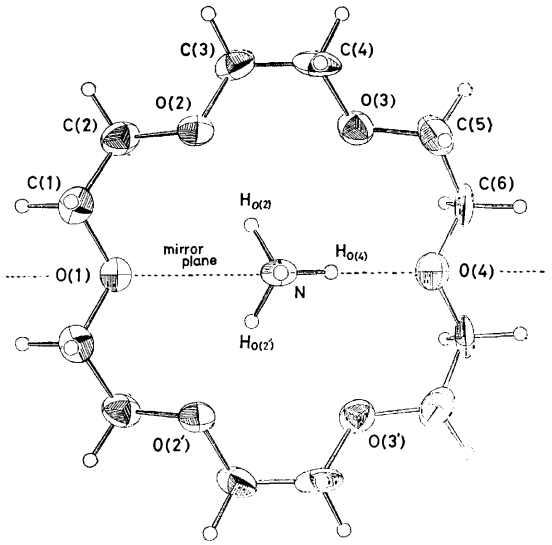

Fig. 2. $NH_4^+ \cdot C_{12}H_{24}O_6$ complex cation viewed in direction normal to the mean plane. The vibration ellipsoids are drawn at the 30% probability level.[23]

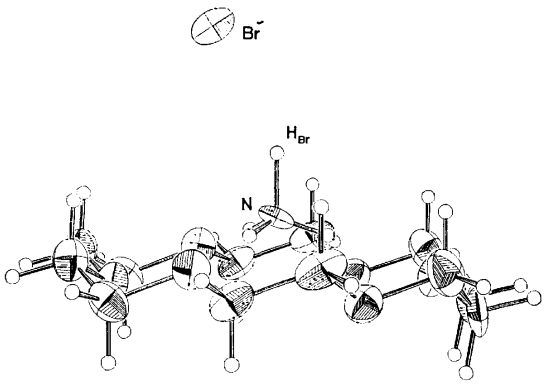

Fig. 3. $NH_4^+ \cdot C_{12}H_{24}O_6$ complex cation viewed along a direction in the mean plane. The vibration ellipsoids are drawn at the 30% probability level.[23]

volving the ammonium and bromide ions. The structure of $NH_4^+ \cdot$18-crown-6 closely resembles those of $Rb^+ \cdot$ 18-crown-6 and $Cs^+ \cdot$18-crown-6, but the distortion from the D_{3d} symmetry in $NH_4^+ \cdot$18-crown-6 is slightly larger than those in $Rb^+ \cdot$18-crown-6 and $Cs^+ \cdot$18-crown-6 because of the hydrogen bonds. In brief, the present complex differs from alkaline or alkaline-earth metal salts-"crown" complexes in the presence of the hydrogen bonds.

Studies of the Hydrous Titanium Oxide Ion Exchanger. IV. The Effect of Radiation and Heat Treatment*

Yasushi INOUE and Masamichi TSUJI**

Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received July 20, 1977)

The effects of ^{60}Co γ-ray irradiation and of heat treatment in air have been studied on the properties of the hydrous titanium oxide ion exchanger. The ion-exchange capacity of the sodium form did not change at all, while that of the hydrogen form decreased a little, by the exposure of 5.2×10^8 R. The color of the exchanger, initially white, turned yellow upon irradiation. This exchanger was stable against heat treatment up to around 80 °C; thereafter the exchange capacity gradually decreased with the temperature until 324 °C, where it was abruptly reduced to about a quarter of the initial value. The examination of the titration curves showed that the most acidic exchange site was weaker than less acidic sites against heat treatment. The structural formula of this hydrous titanium oxide ion exchanger has been suggested on the basis of the ion-exchange capacity, the thermal decomposition curves, and such auxiliary data as the X-ray diffraction and the infrared spectra.

In the field of nuclear chemical engineering, an ion exchanger is often exposed to an intense radiation and to a high temperature. Since most inorganic ion exchangers are expected to be superior to ion-exchange resins in these respects,[1] it is very important to study their radiation- and thermal stabilities. Moreover, these studies may be helpful in considering the structure of the exchanger. However, the radiation- and thermal stabilities of the hydrous titanium oxide ion exchanger have not yet been studied in detail. On the other hand, many propositions have been made concerning the structure of hydrous titanium oxide based on various circumstantial evidence.[4-11] However, neither the composition nor the ion-exchange properties, such as the ion-exchange capacity and the acid-base property, deduced from these structural formulas are compatible with those actually observed in the hydrous titanium ion exchanger prepared by the method previously proposed by the present authors.[2,3]

The present paper will describe the effect of ^{60}Co γ-ray irradiation and of heat treatment in air on the ion-exchange properties of the hydrous titanium oxide. Furthermore, the structural formula of the exchanger have been inferred from those results and from the data obtained by the previous studies.[2,3]

Experimental

Reagents and Apparatus. The hydrous titanium oxide ion exchanger was prepared by the method described previously[2] and then converted into H^+ or Na^+ forms. The other chemicals were of the highest purity grade and were obtained from Wako Pure Chemical Industries, Ltd.

γ-Ray irradiation was carried out using the ^{60}Co γ-ray irradiation facility of Tôhoku University. About 6 g of the exchanger in a desired ionic form was placed in a stoppered test tube with either 10 cm^3 of water or a 0.1 M NaOH (1 M= mol/dm^3) solution, or without them, and irradiated intermittently at an average exposure rate of 3.2×10^5 or 2.5×10^5 R/h (1 R=258 μC/kg).

The thermal analysis was undertaken with a Shimadzu micro thermal analyzer, Model DT-20B, connected to a thermal balance, Model TGC-20H, for thermogravimetric analysis (TGA), and a high-temperature-sample holder, Model MDH-20, for differential thermal analysis (DTA). The reference material for DTA was α-alumina. The measurement was performed in air at a heating rate of 10 °C/min.

The infrared (IR) absorption spectra were measured with a Nihon Bunko infrared spectrometer, Model IRA-I, using the KBr disk method. The wave number was calibrated with polystyrene.

Heat Treatment. The exchanger in a desired ionic form was heated in air to a constant weight at a constant temperature. After cooling, the sample in the Na^+-form was converted into the H^+ form by immersing it in a 0.1 M HCl solution, while that in the H^+-form was immersed in water. Thereafter, they were both subjected to the humidifying operation described previously.[3]

The other experimental procedures were the same as those previously been described.[2,3]

Results and Discussion

Radiation Stability. Table 1 represents the effect of γ-irradiation on the properties of the exchanger, together with that of the ion-exchange resin, Dowex-50, for comparison. It took 1.5 y to reach a total exposure of 5.2×10^8 R. Even if the exchanger was not irradiated, the ion-exchange capacity decreased to about a half of the initial value when the exchanger in the hydrogen from was allowed to stand for 1.5 y. The decrease in the ion-exchange capacity is, thus, largely due to aging of the exchanger, and only slightly to the effect of the γ-rays. The ion-exchange capacity of the sodium form, however, did not change at all upon a γ-ray irradiation of up to 5.2×10^8 R. The amount of titanium dissolved in the supernatant solution during irradiation was 7.2×10^{-5} g. Since this value is compatible with the data concerning chemical stability described previously,[2] it can be said that γ-ray irradiation does not influence the solubility of the material. After irradiation, all the samples turned yellow except for the sample in the hydrogen form exposed up to 2.2×10^8 R. The yellow color of the exchanger in the hydrogen form disappeared when it was immersed in a 1.0 M sodium hydroxide solution, but appeared again by reconversion to the hydrogen form. In contrast, the yellow color

in the sodium form did not disappear when the sample was converted to the hydrogen form, but it almost disappeared when it was converted back to the sodium form again. Moreover, a sodium hydroxide solution wherein the sodium-form exchanger was immersed turned brownish yellow.

The change in color might be caused by the reaction of titanium with the radiolytic products of water. The absorption spectra were measured in order to identify the species responsible for yellow coloration (*cf.* Fig. 1). Sample No. 3 in Table 1 was dissolved with heating it in concentrated sulfuric or perchloric acid, followed by dilution to an acidity of 1 M. The absorption spectra of these solutions showed a single peak. Its position agreed approximately with one of the two peaks which appeared in the spectra of the solutions prepared by diluting the supernatant solution of the same sample with the respective acids. This observation leads to the conclusion that, besides the species formed in the exchanger, some other species are present in the supernatant solution. These absorption spectra differ from those of sulfuric acid—hydrogen peroxide and sulfuric acid solutions of titanium(IV) and of a sulfuric acid solution of iron(III)[13)], which may be present as an impurity. The peroxoc-omplex of titanium contained in solid titanium dioxide is reported to show the absorption band in the same position as in the sulfuric acid solution.[14)] Therefore, the species giving rise to the yellow color appearing in the irradiated hydrous titanium oxide and in the supernatant solution cannot be ascribed to the peroxo-complex. From these observations we can conclude that the sodium form is suitable for the preservation of the hydrous titanium oxide ion exchanger. Compared with Dowex-50, this ex-

changer is stable against radiation, at least to the same extent as the ion-exchange resin. Further studies are, however, required to reach a definite conclusion on the radiation stability; irradiation by γ-rays in much higher doses and by α- or β-rays emitted from isotopes adsorbed on the exchanger, and the identification of the yellow species.

Thermal Stability. The results for the hydrogen-form exchanger are shown in Table 2. It should be noted that the left of the three columns showing the exchange capacity represents the exchange capacity per 1 g of a humidified sample. The middle column shows the normalized exchange capacity per 1 mol of titanium. The right shows the amount of water per 1 mol of titanium that should be liberated by the condensation of the hydroxyl group which may act as an exchange site (bound water).

The exchange capacity did not change up to 80 °C; then it gradually decreased with the temperature, while at 324 °C it was suddenly reduced to a quarter of the original value. At 623 °C more than 90% of the exchange site was destroyed.

The amount of water contained in the exchanger immediately after the heat treatment (the fourth column in Table 2) at temperatures below 122 °C was more than that of the bound water, but the relation was reversed at a higher temperature. The latter relation indicates that the exchanger recovers bound water to a certain degree during the humidifying operation. However, no bound water was recovered for the sample heated at 623 °C.

Next, let us consider the relation between the water content after heat treatment and the water content of the exchanger subjected to the humidifying operation (the fifth column in Table 2). In the case of heat treatment in the range of 80—159 °C, the difference between these water contents, that is, the amount of water recovered by humidifying, is almost constant, 1.1—1.2 mol per mol of titanium. The exchanger heated at 623 °C recovered water only slightly.

The sudden decrease in both the exchange capacity and the degree of recovery of water at a heating temperature of 324 °C might be associated with the crystallization of the exchanger, because no X-ray diffraction pattern appeared until 324 °C, where two weak and broad peaks (d=3.52, 3.42 Å) appeared. (1 Å=0.1nm)

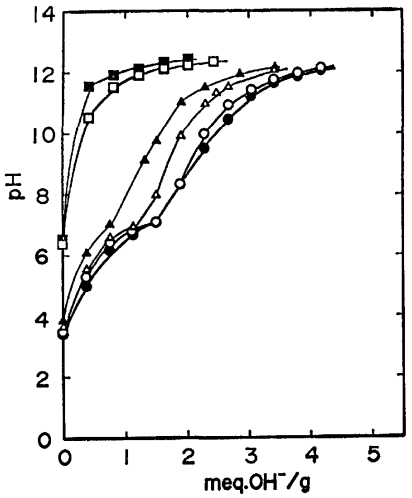

Fig. 2. Titration curves of the exchanger subjected to heat treatment in H^+-form.
I (Ionic strength); 0.10 M, ●: R.T. ○: 80 °C, △: 122 °C, ▲: 159 °C, □: 324 °C, ■: 623 °C.

When the heating temperature was raised to 623 °C, the diffraction line, d=3.52 Å, became sharper and many other lines appeared. This pattern is attributable to the mixture of anatase and brookite.

In order to examine the effect of heat treatment on the acid-base property of the exchanger, the titration curves were measured and found to be as shown in Fig. 2. For samples heated at a temperature not higher than 159 °C, the pH of the breaking point in the titration curves was independent of the temperature and the curves in the pH range higher than that point were parallel with each other. On the other hand, when the exchangers were heat-treated at 324 °C or higher, the curves started at pH 6.5, the point of breaking mentioned above. This means that the exchange site with the smallest pK_a value is responsible for the decrease in the capacity of the exchanger with heating at a temperature lower than 159 °C. The most acidic sites were completely destroyed at 324 °C, and the loss of less acidic sites began to occur at the same temperature. At 623 °C, almost all of the exchange sites were destroyed.

The effect of heat treatment on the sodium form is shown in Table 3 and Fig. 3. Obviously, the change

in both the exchange capacity and the acid-base property with a rise in the temperature followed a tendency similar to that of the exchanger heat-treated in hydrogen form. On the other hand, a considerable difference in the release of water by heat treatment between the sodium and the hydrogen forms was observed; that is, at 80 °C the former left twice as much water behind as the latter, in which major part of the residual water was bound water. This cannot be understood by simply considering the hydrating power of the cations, because that of the sodium ion is weaker than that of the hydrogen ion; instead, it must be considered that the sodium ion hinders the release of water by exerting some special effect on the structure. X-Ray analysis exhibited no sign of crystallization until 850 °C, where the diffraction pattern attributable to rutile began to appear. These observations suggest a difference between the two ionic forms in the mechanism for the decrease in the exchange capacity with heat treatment. In the hydrogen form, the dehydrating condensation of hydroxyl groups plays an important role in both the loss in exchange capacity and the crystallization of the material, while, in the sodium form, the sodium ion forms a stable chemical bond with titanium dioxide and the exchange site loses its function as a result.

Structure. The structural formula of the hydrous titanium oxide ion exchanger can be deduced from the various properties described previously as well as by such supplementary data as DTA, TGA, the IR spectra, and X-ray diffraction.

The titration curves and the effect of heat treatment on them strongly suggest that the most acidic exchange site differs intrinsically from the others and accounts for a half of the total exchange capacity. The other, less acidic sites might be distinguished from each other by the change in the electronic structure caused by the adsorption of the sodium ion. When the exchange capacities corresponding to the first-, second-, and third plus fourth dissociable exchange sites are converted to the simplest integral ratio, it is 2 : 1 : 1. Considering this fact and the total exchange capacity of 0.5 eq./mol of titanium, the unit structure must contain 4 hydroxyl groups per 8 atoms of titanium.

Figure 4 shows the TGA and DTA curves of the exchanger in hydrogen form. The TGA curves indicate that the samples heat-treated at 159 °C and lower lost weight suddenly up to about 150 °C, and then gradually up to about 500 °C, where the weight became constant. In contrast, most of the water in the sample heat-treated at 324 °C was released below 80 °C. In the DTA curves, large endothermic peaks appearing in the temperature range lower than 150 °C sharpened as the temperature for heat treatment became higher. The position of the peak, initially at 100 °C, shifted to 75 °C when the exchanger was heat-treated at 80 °C. The shoulder observed in the peak became less pronounced with the rise in the temperature for heat treatment. When the sample was heated at 324 °C, it showed a sharp peak with a very small shoulder.

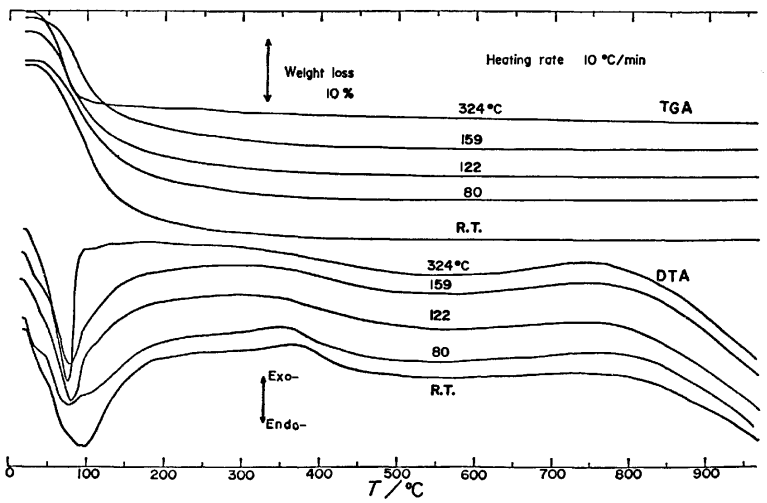

Fig. 4. TGA and DTA curves of the exchanger subjected to heat treatment in H^+-form.

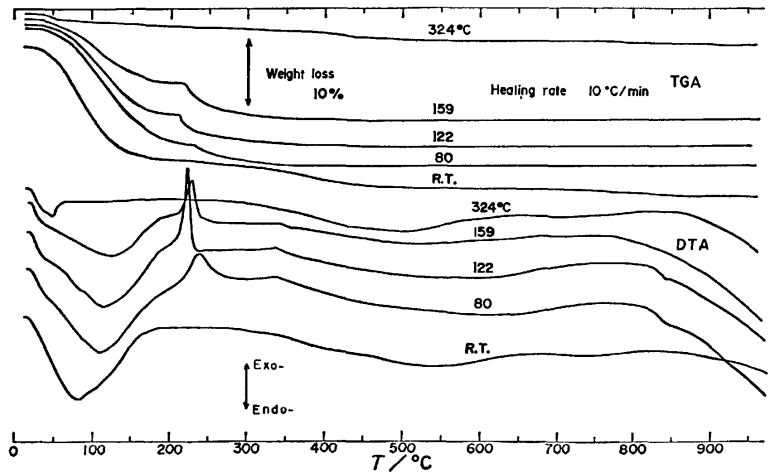

Fig. 5. TGA and DTA curves of the exchanger subjected to heat treatment in Na^+-form, followed by conditioning.

Apparently, the observation just described is compatible with the change in the exchange capacity and in the degree of the recovery of water with temperatures for heat treatment, if the peak near 75 °C is considered to correspond to the water recoverable by humidifying, and the shoulder, to the bound water.

The observations described above can be summarized as follows. When the exchanger in the hydrogen form is heated at 80 °C, the release of water is accompanied by the stabilization of the network structure. By the heat treatment at 122—159 °C the network structure remains essentially unchanged except for a slight modification. This stabilized network can accommodate an approximately constant amount of water. The release of the bound water becomes pronounced at temperatures higher than 324 °C and a partial crystallization occurs. Therby the exchange capacity decreases suddenly. At 623 °C the crystallization proceeds to an extreme end and the structure changes completely. Therefore, almost all the water, including the bound water lost by heat-treatment at 623 °C, is not recovered by the humidifying operation.

Figure 5 shows the DTA and TGA curves of the exchanger heat-treated as the sodium form. The TGA curve of the sodium form dried at room temperature consists of three steps: R.T.—170 °C, 350—450 °C, and 730—900 °C. The samples heat-treated at 80, 122, and 159 °C lost weight in two steps. The TGA curve observed for the sample subjected to heat treatment at 324 °C corresponds to the poor recovery of water. The slight weight loss above 730 °C, which is also observed for the exchanger dried at room temperature, is probably due to the decomposition of the sodium carbonate accidentally remaining in the exchanger after treatment with a 0.1 M hydrochloric acid solution. In the DTA curves, the endothermic peak corresponding to dehydration was displaced toward a temperature higher by about 30 °C by heat treatment at a temperature lower than 324 °C. After this shift, the position of the peak approximately agrees with that of the hydrogen form dried at room temperature. These samples also showed the exothermic peak in the range of 210—230 °C, where some weight loss was observed on the

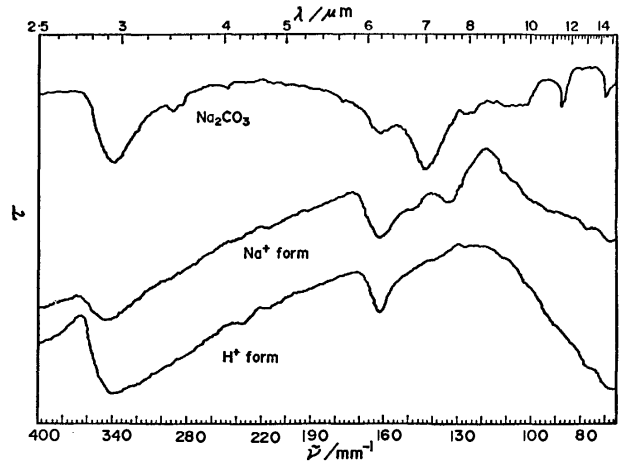

Fig. 6. IR spectra of the exchanger.

corresponding TGA curves. Because dehydration is an endothermic reaction, this peak cannot be accounted for by dehydration. This kind of exothermic peak has also been reported to be observed for the hydrous titanium oxide synthesized by the addition of ammonia water to a titanium tetrachloride solution.[10,12] Imoto *et al.*[10] ascribed the peak to the release of ammonia, while Vivien *et al.*[12] attributed it to crystallization. Since the present hydrous titanium oxide ion exchanger contains no ammonia, this exothermic peak cannot be attributed to the release of ammonia, but to the reaction which is responsible for the sudden decrease in the exchange capacity mentioned above.

Figure 6 shows the IR spectra of the exchanger in the hydrogen and the sodium forms dried at room temperature. The asymmetric absorption band observed near 3400 cm^{-1} is attributable to the sum of the contributions from water and hydroxyl-group bonding to titanium, the former at the lower, and the latter at the higher, wave number sides respectively.[12] The absorption band near 1625 cm^{-1} is due to the bending mode of water, and the absorption in the <1000 cm^{-1} range, the titanium–oxygen bond. The IR spectrum of the exchanger in the sodium form is similar to that of the exchanger in the hydrogen form except for the appear-

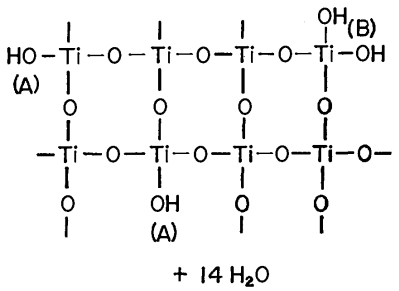

Fig. 7. Structural formula of the exchanger.

ance of the absorption band in 1380—1300 cm^{-1}. This absorption band disappeared when the samples was subjected to heat treatment at 825 °C. Further study is needed before this absorption band can be identified.

On the basis of the results concerning the properties of the exchanger presented above, the structural formula represented in Fig. 7 is inferred for the exchanger in the hydrogen form, though the arrangement of such a unit structure is not very regular because the X-ray diffraction pattern displays a nearly amorphous structure. Of the exchange sites in this model, (A) is the most acidic, and (B), the least acidic, ion-exchange group. The exchange site (A) is easily destroyed by condensation with the neighboring exchange site of the same kind. The appearance of anatase and brookite in the first crystallization step can also be understood by assuming this structure.

The authors wish to express their thanks to Professor Wataru Suëtaka, Department of Metal Processing and Mechanical Metallurgy, Faculty of Engineering, Tohoku University, for his valuable suggestions on the measurement of IR spectra. They also would like to thank Mr. Shigenori Sakagami for obtaining some of the data.

Polarographic Behavior of Tris(acetylactonato)ruthenium(III) in Aqueous and Acetonitrile Solutions

Akira ENDO, Masayuki WATANABE,* Sadayuki HAYASHI,**
Kunio SHIMIZU, and Gen P. SATÔ

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received September 12, 1977)

In tetraethylammonium perchlorate–acetonitrile solution, $[Ru(acac)_3]$ was reversibly reduced at the dropping mercury electrode to $[Ru(acac)_3]^-$ with a conditional electrode reaction rate-contsant estimated to be *ca.* 0.2 cm s^{-1} or larger. The reduced form was stable in the solution under an inert gas atmosphere. In aqueous solutions, $[Ru(acac)_3]$ was reduced reversibly when the depolarizer concentration was less than 0.07 mol m^{-3} at 25 °C. At higher depolarizer concentrations, $[Ru(acac)_3]$ molecules were adsorbed onto the mercury surface, and the free molecules in solution were reduced through the adsorbed layer at a smaller rate; the adsorbed layer was removed at a certain negative potential, and the reversible reduction took place normally at the bare surface. The difference between reversible half-wave potentials observed in acetonitrile and aqueous solutions was discussed in terms of solvation energies of the oxidized and reduced forms.

Many electrochemical investigations have been carried out on various metal acetylacetonato-complexes.[1–5] In the course of studying some ruthenium complexes, tris(acetylacetonato)ruthenium(III), $[Ru(acac)_3]$, attracted our attention. It is known to act as a catalyst in organic reactions, for instance, hydrogenation of nitroarenes to amines.[6] Since tris(acetylacetonato)-metal complexes are usually poorly soluble in water, they have been studied in non-aqueous solvents such as acetonitrile and *N*,*N*-dimethylformamide. However, $[Ru(acac)_3]$ is exceptionally soluble in aqueous solution to as much as about 0.5 mmol dm^{-3} at 25 °C. In the present work its electrochemical behavior was examined in acetonitrile and aqueous solutions.

Experimental

Materials. The complex was prepared by the following procedure.[7] Ruthenium(III) chloride (1.9 g as Ru, dissolved in 150 cm^3 of 1 mol dm^{-3} HCl) was reduced with ethanol, and the mixture was evaporated nearly to dryness on a water bath. The blue residue was dissolved in 50 cm^3 of water, and the pH of the solution was adjusted to about 6 with 1 mol dm^{-3} KOH solution. The solution was refluxed with 15 cm^3 of acetylacetone and 50 cm^3 of ethanol for about 4 h. Then the solution was concentrated to about one-fifth the initial volume. Crystals of crude $[Ru(acac)_3]$ precipitated on cooling. The product, after being thoroughly washed with ethyl ether, was recrystallized from methanol and dried under vacuum at room temperature. The recrystallized, dark red crystals were readily soluble in acetonitrile, methanol, ethanol, and to a lesser extent in water. Found: C, 45.2; H, 5.2%. Calcd for $RuC_{15}H_{21}O_6$: C, 45.2; H, 5.3%. Further purification, when required, was carried out by sublimatography;[8] the crystals which condensed at 120 °C under a vacuum were collected.

Tetraethylammonium perchlorate (TEAP) was prepared from perchloric acid and tetraethylammonium iodide according to Given *et al.*[9] Acetonitrile was purified according to the procedure described by Forcier and Olver[10] and used within 10 days at the most. The water content of the solvent as determined by the Karl Fischer titration was less than 1 mmol dm^{-3}.

Other chemicals were of guaranteed reagent grade and used as received except for aluminium perchlorate, which was prepared by dissolving aluminium hydroxide in perchloric acid. Water was obtained by distilling deionized water in an all-glass apparatus and used throughout the experiments except for syntheses, in which deionized water was used.

Measurements. All the potentials were measured against an aqueous saturated calomel electrode (SCE), and all the measurements were carried out at (25.0±0.1) °C unless otherwise stated. For aqueous systems, an H-type salt bridge (saturated KCl solution) with filter-paper plugs was used for connecting the test solution with the SCE; for acetonitrile systems, the connection was made through an aqueous agar-plugged KCl bridge. As counter electrode, a spiral of platinum wire was used.

Deoxygenation of aqueous solutions was carried out with nitrogen which had been passed through an acidic vanadium(II) sulfate solution and water, successively; for acetonitrile systems, the purified nitrogen was passed through a calcium chloride column and then a wash bottle containing the solvent kept at 25 °C.

For acetonitrile systems, 0.05 mol dm^{-3} TEAP and 0.05 mol dm^{-3} $NaClO_4$ base solutions were used. Seven base solutions were used for aqueous systems: 0.2 mol dm^{-3} KCl, 0.033 mol dm^{-3} $Al(ClO_4)_3$, 0.066 mol dm^{-3} Na_2SO_4, 0.2 mol dm^{-3} $NaNO_3$, 0.2 mol dm^{-3} sodium *p*-toluenesulfonate, Sørensen buffer ($4.49 \leqq pH \leqq 6.81$), and Kolthoff buffer (pH = 7.0).

Dc and conventional ac polarograms were recorded with a potentiostat-type polarograph constructed in this laboratory. The instrument for phase selective ac (PSAC) polarography has been described elsewhere.[11] The root-mean-square amplitude of the superimposed ac signal was 3 mV for PSAC and 5 mV for conventional ac polarography. Two dropping mercury electrodes (DME) were used; their *m* values were as follows at 25 °C under a mercury head of 50 cm: No. 1, 1.78 mg s^{-1}; No. 2, 1.36 mg s^{-1}. Instantaneous currents at 3.50 s after beginning of drop growth were sampled by means of a dislodger-cutoff device previously described,[12,13] unless otherwise stated.

In PSAC measurements, correction was made for the uncompensated resistance, which was calculated from the PSAC polarograms of the base solution by assuming that the admittance was purely capacitive. The faradaic conductance (G_f) and susceptance (B_f) were obtained by subtracting the corresponding values for the base solution from the electrode conductance and susceptance in the presence of the depolar-

** Present Address: Meiji Senior High School, Shiroganedai 1, Minato-ku, Tokyo 108.

izer.[11]

Controlled potential coulometry was carried out as described earlier[14] except that integration of the electrolytic current was carried out on a digital counter (Takedariken, Universal Counter TR-5104) by converting the current signal into pulses with a voltage-frequency converter (Aiko, VF500).[15] The electrolytic cell with a mercury pool working elecrode (surface area, about 7.1 cm^2) previously described[14] was used for both systems. When an acetonitrile test solution was placed in the working electrode compartment, the counter and reference electrode compartments were filled with aqueous potassium chloride solution. Contamination by a small amount of water leaking from the bridges was inevitable when electrolysis was prolonged, but no appreciable effect was noticed.

Cyclic voltammetry was carried out by means of the dc polarograph to which a programmable triangular signal generator[16] was connected. Voltammograms were displayed on an X-Y recorder (Riken Denshi, Model F-3D) for lower scan rates or on a cathode ray oscilloscope screen (National, Model VP-526) for higher scan rates. A Princeton Applied Research hanging mercury electrode assembly (Model 9323) was used, the radius of the mercury drops being about 0.44 mm.

A Hitachi 624 digital spectrophotometer was used for recording absorption spectra. Quartz cells of 1 cm and 0.5 cm were used for lower concentrations and a spacer cell of 1 mm, for higher concentrations.

Results and Discussion

Acetonitrile Systems. In 0.05 mol dm^{-3} TEAP solutions, a reduction step with half-wave potential ($E_{1/2}$) of -0.72_5 V was observed on the dc polarogram. The limiting current of the step was directly proportional to the depolarizer concentration and inversely proportional to the square root of the drop time of a mercury electrode dropping freely. As described below the step corresponds to the one-electron reduction to [Ru(acac)$_3$]$^-$. The log-plot resulted in a straight line with a reciprocal slope of -61 mV.

When the complex was partially reduced at the mercury pool electrode kept at a potential of the diffusion current plateau (-1.0 V), a single redox step appeared at the same half-wave potential. When the cathodic and anodic diffusion currents recorded intermittently in the course of the electrolytic reduction were plotted against the quantity of electricity, the magnitude of the former decreased and the latter increased linearly, and the plots indicated that the process was a one-electron reduction to [Ru^{II}(acac)$_3$]$^-$.

The reduced form was quantitatively reoxidized when it was electrolyzed at a potential of the anodic diffusion current plateau. It was readily oxidized also by atmospheric oxygen, but was not oxidized by perchlorate ions in the solution.

The polarographically reversible nature of the reduction is more clearly shown by the results of PSAC polarography (Table 1 and Fig. 1). Both the conductance and susceptance peak potentials coincided with $E_{1/2}$. The peak conductance and susceptance measured in the frequency range of 35—90 Hz agreed reasonably well with the theoretical value for a reversible or nernstian one-electron transfer. At higher frequencies

Table 1. cot ϕ of 0.50 mmol dm^{-3} [Ru(acac)$_3$] in acetonitrile 0.05 mol dm^{-3} TEAP solution, 25 °C

f/Hz	35	70	90	190	270
cot ϕ	1.0_3	0.9_2	0.9_3	1.4_4	1.5_7

f, frequency; ϕ, phase angle of faradaic admittance; estimated error in cot ϕ is about 10%.

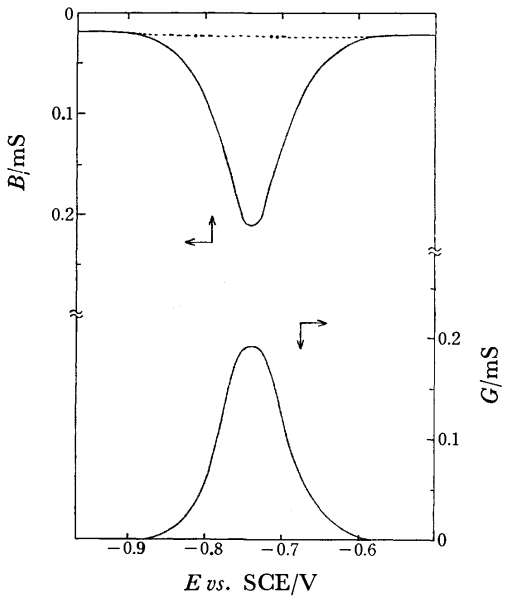

Fig. 1. PSAC polarograms of 0.50 mmol dm^{-3} [Ru(acac)$_3$] in acetonitrile 0.05 mol dm^{-3} TEAP solution. 35 Hz, 3 mV (r.m.s.); DME, No. 1; 25 °C; dashed line, base solution.

cot ϕ, where ϕ is the phase angle of the faradaic admittance, tended to increase. The limited accuracy of the instrument, however, allowed us only to estimate that the lower limit of the conditional electrode reaction rate constant (at $E_{1/2}$) was about 0.2 cm s^{-1}.

Aqueous Systems. Typical dc and ac polarograms are shown in Fig. 2. When the depolarizer concentration was less than 0.07 mmol dm^{-3}, a one-electron reduction dc step with $E_{1/2}=-0.51_6$ (curve A) and the corresponding ac wave, similar to those observed in acetonitrile solution, were observed. This step was reversible, as demonstrated by the PSAC polarographic data (Table 2).

At higher depolarizer concentrations, however, peculiar dc and ac polarograms were observed. The dc polarogram showed a small step prior to the main reduction step and a kink or a sudden increase in current magnitude at a potential of the shoulder of the main step. The ac polarogram was characterized by a marked depression of admittance starting from the potential of the small dc step and continuing to a round wave corresponding to the main dc step followed by a sharp peak at the potential where the sudden increase in dc current took place. When the temperature of the solution was varied (15—40 °C), the effect of its increase on the shape of the polarograms was similar to that of the decrease in the concentration: the potential of the small dc step shifted to negative, while that of the kink on the shoulder remained almost the same, and the ac polarogram changed correspondingly.

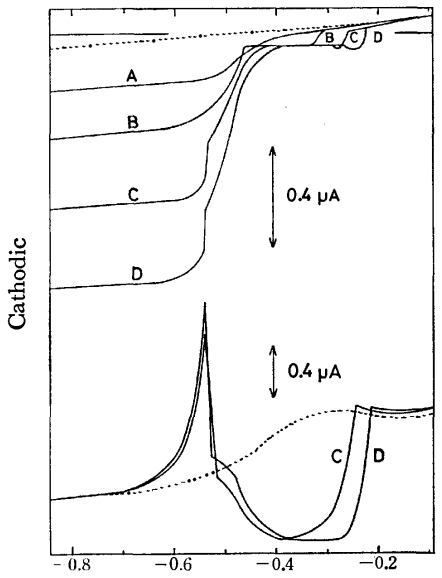

Fig. 2. Dc (upper) and conventional ac (lower) polarograms of $[Ru(acac)_3]$ in aqueous 0.2 mol dm^{-3} KCl solution.
Depolarizer concentration/mmol dm^{-3} = 0.05 (A), 0.1 (B), 0.2 (C), 0.3 (D). 35 Hz, 5 mV (r.m.s.); DME, no. 1; 25 °C; dashed lines, base solution. Ac polarograms for A and B are not shown for the sake of simplicity.

Scan rate, 168 mV s^{-1}; 25 °C.

Table 2. Faradaic peak conductance of 0.05 mmol dm^{-3} $[Ru(acac)_3]$ in aqueous 0.2 mol dm^{-3} $NaNO_3$ solution, 25 °C

f/Hz	$G_{p,N}$/μS	$G_{p,obs}$/μS
23	24.15	24.7_2
58	38.36	39.5_9
90	47.78	50.3_7

f, frequency; $G_{p,N}$, peak conductance calculated for nernstian one-electron transfer; $G_{p,obsd}$, observed peak conductance.

The controlled potential coulometry of $[Ru(acac)_3]$ at −0.7 V showed that the reduction was one-electron process and the reduced form was stable in the absence of oxygen. A partially reduced solution showed a single redox dc step at the same half-wave potential; the anodic step was accompanied by a small kink at the potential where the small step had appeared on the polarogram before the electrolysis. The reduced form was not oxidized by perchlorate ions, in contradistinction to the case of $[Ru^{II}(Hedta)(H_2O)]^-$, which was reoxidized in aqueous perchlorate solutions.[14] The reduced form reacted with formate ions to produce electro-inactive entities, most probably some carbonyl species. The details of the reaction are under investigation; but the rate was much less than that of $[Ru^{II}(Hedta)(H_2O)]^-$–formate reaction.[17] That $[Ru^{II}(acac)_3]^-$ is less reactive than $[Ru(Hedta)(H_2O)]^-$ seems to be attributable to its symmetrical shape.

The dc and ac polarograms at higher depolarizer concentrations indicate the presence of adsorption; it was more clearly shown by the electrocapillary curves, in which a decrease in the interfacial tension was observed at the potentials between the small dc step and the kink. The possibility that the adsorption might be due to some impurities contained in the sample was excluded by the fact that the dc and ac polarograms of a purer sample obtained by sublimatography were identical with those of the simply recrystallized sample.

The concentration dependence of the dc polarogram clearly suggests that the adsorbed species is the oxidized form, not the reduced form (Fig. 2). This view is supported by the shape of the electrocapillary curve showing the adsorption of a neutral species and by the fact that the polarograms remained practically unchanged irrespective of the supporting electrolytes: KCl, $NaNO_3$, Na_2SO_4, $Al(ClO_4)_3$, and Sørensen and Kolthoff buffers of various pH (with the exception of sodium *p*-toluenesulfonate; see below).

Bis(acetylacetonato)cobalt(II)[18] and bis(acetylacetonato)nickel(II)[19] are known to dimerize in some non-aqueous solutions at higher concentrations. In the case of aqueous solutions of $[Ru(acac)_3]$, however, no indication of such association was detected by the visible and ultraviolet spectra in the range of 190—650 nm even at 0.4 mmol dm^{-3} (about 80% of saturation), and the spectra agreed with those in acetonitrile solution.

These observations lead us to conclude that $[Ru(acac)_3]$ is adsorbed onto the mercury surface in the potential region between the small step and the kink.

A typical cyclic voltammogram shown in Fig. 3 reflects the same situation: on each of the cathodic and anodic branches, two sharp adsorption-desorption peaks appeared, between which a round peak corresponding to the main dc step was seen. At higher scan rates the relative heights of the adsorption-desorption peaks to the round peak increased; at the same time, the potential separations between the anodic and cathodic peaks for each of the two pairs of the sharp peaks increased, suggesting that the adsorption-desorption process involved some kinetic character.

In the PSAC polarograms of 0.05 mmol dm^{-3} [Ru-

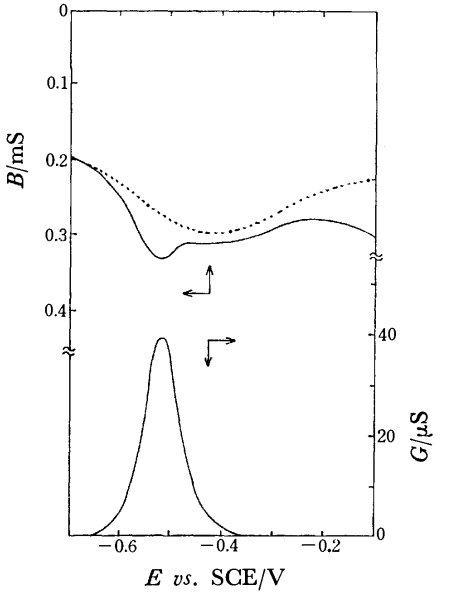

Fig. 4. PSAC polarograms of 0.05 mmol dm^{-3} [Ru(acac)$_3$] in aqueous 0.2 mol dm^{-3} $NaNO_3$ solution. 58 Hz, 3 mV (r.m.s.); DME, No. 2; 25 °C; dashed line, base solution.

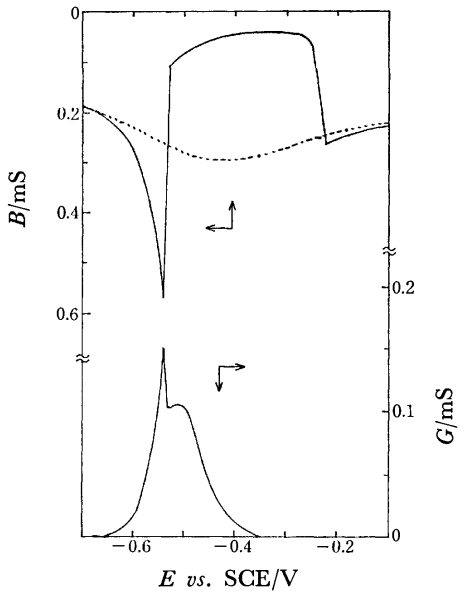

Fig. 5. PSAC polarograms of 0.3 mmol dm^{-3} [Ru(acac)$_3$] in aqueous 0.2 mol dm^{-3} KNO_3 solution. Conditions are the same as in Fig. 4.

(acac)$_3$] (Fig. 4) a shoulder at the positive side of the susceptance polarogram indicates that even at this concentration there was still some adsorption. However, the conductance component corresponded to a nernstian one-electron transfer as indicated by the value of the peak conductance (Table 2; the excessive values of the experimental peak conductance at higher frequencies may be due to the contribution of adsorption and/or instrumental errors).

The adsorption seems to affect the electron transfer. When the concentration was 0.30 mmol dm^{-3}, the susceptance polarogram showed a well-like depression corresponding to the adsorption, and the conductance polarogram showed a round peak followed by a sharp rise at its negative shoulder (Fig. 5). The potential of the latter coincided with the potential at which the sudden increase in current was observed on the dc polarogram. The height of the round peak was much less than the theoretical value for a nerstian one-electron transfer, but the values of the conductance at the potentials more negative than the sharp rise were roughly equal to those expected for a hypothetical nernstian wave with a peak potential of −0.52 V.

The susceptance polarogram showed a small peak at the positive edge of the depression (−0.23 V) when the frequency was 23 Hz, but no appreciable peak was observed at this potential on the conductance polarogram, so that the process was essentially capacitive. The susceptance peak became less clear with increasing frequency, probably owing to the kinetic character of the adsorption-desorption process as observed in the cyclic voltammetry.

The electrochemical behavior of [Ru(acac)$_3$] in the aqueous solutions is interpreted as follows. The complex is reduced at the mercury electrode to the corresponding Ru(II) species. This process is essentially reversible or nerstian as indicated by the results obtained at the lower concentrations. However, the Ru(III) complex molecules are adsorbed onto the electrode when the concentration is higher. The adsorbed molecules are stabilized and its reduction potential becomes more negative than that of the free molecules. The free molecules undergo reduction through the layer of adsorbed [Ru(acac)$_3$] at a lower rate. Beyond a certain potential (−0.54 V) the adsorbed layer of [Ru(acac)$_3$] no longer exists, and the reversible reduction takes place normally at the bare surface of the electrode. In view of the fact that this potential was practically independent of the depolarizer concentration and temperature, the adsorbed [Ru(acac)$_3$] molecules seem to be reduced at this potential to [Ru(acac)$_3$]$^-$, which is not adsorbable.

Interestingly, in 0.2 mol dm^{-3} aqueous sodium *p*-toluenesulfonate solution, a reversible one-electron dc step was observed even at higher depolarizer concentrations. The half-wave potential was the same as that of the reversible step observed at lower concentrations in the other aqueous base solutions. The positive branch of the electrocapillary curve of [Ru(acac)$_3$] in this solution lied below those obtained in the other supporting electrolyte solutions, whereas the negative branch was essentially the same. Probably, *p*-toluenesulfonate ions replaced the adsorbed [Ru(acac)$_3$] at least partially, and the adsorbed layer of the anions did not retard the electron transfer to any appreciable extent.

Half-wave Potentials. The observed reversible half-wave potentials of [Ru(acac)$_3$] in acetonitrile–TEAP system and in aqueous potassium chloride and other systems were -0.72_5 V and -0.51_6 V, respectively, both being measured against the aqueous SCE as described. The liquid-junction potential between the acetonitrile and the aqueous phases is unknown, but Coetzee and Campion[20] have given a semiempirical value of 0.034 V (aqueous side positive) for the junc-

tion Et_4NClO_4 (0.1 mol dm^{-3} in acetonitrile)|KCl (saturated in water). Correcting the half-wave potential in acetonitrile for this value, we have a net difference of $E_{1/2}$(acetonitrile)$-E_{1/2}$(water)$=-0.17_5$ V, which may be related to the activities of $[Ru(acac)_3]$ and $[Ru(acac)_3]^-$ in both systems by the following equation:

$$\Delta E_{1/2} = -\frac{1}{nF}(\Delta\mu_{II}^{\ominus} - \Delta\mu_{III}^{\ominus}), \quad (1)$$

where $\Delta\mu_{III}^{\ominus}$ and $\Delta\mu_{III}^{\ominus}$ are the differences of the standard chemical potentials of $[Ru^{II}(acac)_3]^-$ and $[Ru^{III}(acac)_3]$, respectively, when each species is transferred from water to acetonitrile. The diffusion coefficients of the two species are assumed to be equal for each solvent, and the contribution of the activity coefficients are ignored.

We assume that $\Delta\mu_{II}^{\ominus}$ is approximated by the Born equation[21]

$$\Delta\mu_{II}^{\ominus} = -\frac{z^2 e^2 N}{8\pi \varepsilon_0 a}\left\{\frac{1}{\varepsilon_W} - \frac{1}{\varepsilon_{AN}}\right\}, \quad (2)$$

and $\Delta\mu_{III}^{\ominus}$ by

$$\Delta\mu_{III}^{\ominus} = -RT\ln(c_{AN}^s/c_W^s), \quad (3)$$

where e is the elementary charge; N, Avogadro constant; z, the charge number of the ion ($=-1$); ε_0, the permittivity of vacuum; ε_W and ε_{AN}, the relative permittivities of water and acetonitrile, respectively; c_W^s and c_{AN}^s, the concentrations of the saturated solutions of $[Ru^{III}(acac)_3]$ in the respective solvent. Estimating the ionic radius a to be 0.5 nm, a not unreasonable value, we obtain $\Delta\mu_{II}^{\ominus} \approx 1.9$ kJ mol^{-1} from Eq. 1. The solubility of $[Ru^{III}(acac)_3]$ in water was about 0.5 mmol dm^{-3}; no reliable estimate of its solubility in acetonitrile was made, but it seemed to be soluble up to about 0.2 mol dm^{-3}. These values lead to $\Delta\mu_{III}^{\ominus} \approx -14.8$ kJ mol^{-1}. The value of $\Delta E_{1/2}$ thus estimated is about -0.17 V. This unexpectedly good agreement should not be given much confidence in view of the oversimplified model and very rough estimation involved. However, it does suggest that the half-wave potential observed in the acetonitrile–TEAP system represents the reversible half-wave potential of the $[Ru^{III}(acac)_3]/[Ru^{II}(acac)_3]^-$ couple in this solvent.

The reduction step in acetonitrile was shifted to positive potential when TEAP was replaced by sodium perchlorate. But the half-wave potential was independent of the depolarizer concentration at a given concentration of sodium ions. If the half-wave potential in the absence of sodium ions corresponds to the simple reduction as discussed above, this shift must be attributed to sodium ions. Such a shift of half-wave potential caused by alkali metal ions in solvents of lower dielectric constants have been explained by ion-pairing interaction or coordinative relaxation between the reduced form and the cation.[22,23] In the former case the half-wave potential is independent of the depolarizer concentration. Thus, the observed half-wave potential shifts were accounted for by ion-pair formation between $[Ru(acac)_3]^-$ and sodium ions. The details will be reported separately.

Authors' thanks are due to Assistant Professor Shinichi Saito of Sophia University for his halp in sublimatographic purification of the complex. They also thank Sr. Jean Michalec for correcting the manuscript. The present work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Thermodynamic Study on Adduct Formation of Copper(II) β-Diketonates with Heterocyclic Bases

Kazumasa UEDA

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received September 14, 1977)

The stability constants and thermodynamic functions for 1:1 adduct formation of unidentate heterocyclic bases with copper(II) β-diketonates were determined in non-aqueous solvents by the spectrophotometric method. The main factors controlling the stability of the adducts were investigated and the bases were classified into two groups in adduct formation from the plots of the stability constants against pK_H values of the bases: steric hindered and unhindered bases. Large negative entropy changes were observed for pyridine, β-picoline, and γ-picoline; these were ascribed to the π-bond character of the adduct bonds. A solvent effect was observed; the order of increasing adduct stability was as follows: acetone < butyl acetate < 4-methyl-2-pentanone < chloroform < nitrobenzene < toluene ≃ benzene < chlorobenzene. This order agreed with the decreasing order of the solvent-chelate interaction and of the solvent-base interaction. In all cases, the adducts were stabilized by large exothermic enthalpy changes. Moreover, the introduction of a CF_3 group into β-diketones also brought about a considerable entropy change which promoted the stabilization of the chelate. The effect of the other terminal groups was not clearly observed.

It is well known that copper(II) β-diketonates behave as Lewis acids and react with nitrogen bases to form addition compounds.[1] The formation equilibria of such synergistic adducts have been widely investigated for many metals under a variety of conditions.[2,3]

Most investigations of the adduct formation have been carried out by means of solvent extraction. Therefore, complications inherent to the heterogeneous equilibrium, *e.g.*, the displacement reaction of a Lewis base for water molecules in metal chelates, would be involved.

Since the direct observation of the equilibria in non-aqueous solvents is free from these complications, some detailed studies have been undertaken by using spectrophotometric,[4-6] titrimetric,[7,8] ESR, and NMR[9,10] techniques. Planar, four-coordinate copper(II) complexes of β-diketones react with Lewis bases to form five-coordinate 1:1 adducts and six-coordinate 1:2 adducts, and the formation constants for 1:1 adducts with various bases have been determined. Nevertheless, comparatively little information is available about the thermodynamics of these equilibria.

In the present investigation, the author has undertaken to obtain the thermodynamic data for the adduct formation of several different β-diketonato complexes of copper with a variety of bases, and quantitative information on factors affecting the stability of the adducts formed in non-aqueous solvents.

Experimental

Apparatus and Materials. The absorption measurements were carried out with a Hitachi 124 spectrophotometer equipped with a thermostated cell holder, which was held at the required temperature by water from a HAAKE FJ thermoelectric circulating bath. β-Diketones with a CF_3 terminal group such as benzoyltrifluoroacetone(Hbfa), 2-thenoyltrifluoroacetone(Htta), 2-furoyltrifluoroacetone(Hfta), pivaloyltrifluoroacetone(Hpta), trifluoroacetylacetone(Htaa), and the nonfluorinated β-diketones such as acetylacetone(Haa), benzoylacetone(Hba), and dipivaloylmethane(Hdpm) were commercially available and used without further purification. All the nitrogen bases were of guaranteed grade and usually dried over potassium hydroxide; a constant boiling fraction was collected under a reduced pressure. Solvents were of guaranteed grade and freshly distilled before use.

Preparation of Copper Chelates. The copper chelates were prepared by mixing equivalent quantities of copper(II) chloride solution and β-diketone methanol solution and adding 2M sodium acetate solution under continuous stirring. The mixture was allowed to stand in a refrigerator for several hours, after heated for a short while on a hot plate. The filtered complex was washed with water and dried in a desiccator. After being recrystallized from benzene, the crystalline chelate was dried by standing over diphosphorus pentaoxide *in vacuo*. The results of elementary analysis are shown in Table 1.

Calculation of Stability Constants and Thermodynamic Functions. The stability constants of the 1:1 adduct in non-aqueous solvent were obtained by the following equation:

$$K = \frac{[\text{Adduct}]}{[\text{Diketonate}][\text{Base}]} = \frac{1-\alpha}{\alpha[\text{Base}]}. \quad (1)$$

The concentration of the free base is

$$[\text{Base}] = B_0 - C_0(1-\alpha), \quad (2)$$

where α is the fraction of the free diketonate and B_0 and C_0 are the total concentrations of the base and the copper chelate. Since the bases do not absorb at the wavelength concerned,

$$A = A_0\alpha + A_\infty(1-\alpha), \quad (3)$$

where A and A_0 are the absorbances of the system and the diketonate only. A_∞ is the absorbance found, by trial and error, to give the most reproducible value of K.[4,11] The stability constant can be expressed in terms of the absorbance

Table 1. Analysis of copper(II) chelates

Chelate	Found (Calcd) %		
	C	H	Cu
$Cu(bfa)_2$	48.55 (48.64)	2.48 (2.44)	12.84 (12.86)
$Cu(tta)_2$	38.00 (37.99)	1.60 (1.59)	12.54 (12.56)
$Cu(fta)_2$	40.53 (40.56)	1.71 (1.70)	13.45 (13.41)
$Cu(pta)_2$	41.84 (42.34)	4.37 (4.44)	14.08 (14.00)
$Cu(taa)_2$	32.38 (32.48)	2.11 (2.18)	17.17 (17.18)
$Cu(ba)_2$	62.14 (62.24)	4.62 (4.70)	16.38 (16.38)
$Cu(aa)_2$	45.65 (45.88)	5.35 (5.39)	24.10 (24.09)
$Cu(dpm)_2$	61.51 (61.43)	8.86 (8.90)	14.73 (14.71)

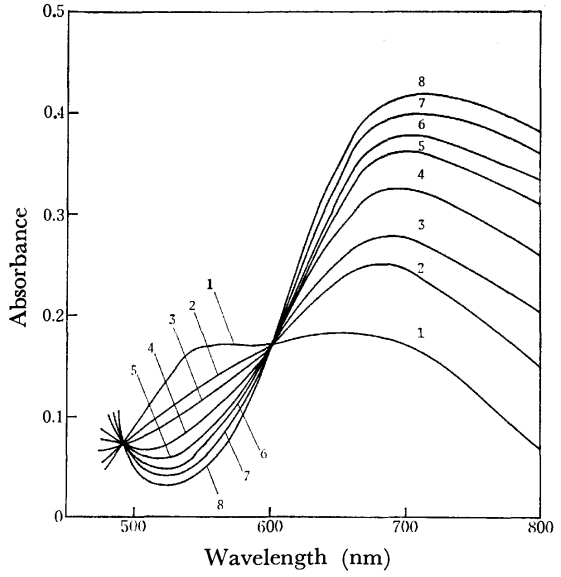

Fig. 1. Absorption spectra of $Cu(bfa)_2$-pyridine system in benzene at 298 K. $[Cu(bfa)_2]=0.005$ M, [pyridine]; 1: 0, 2: 0.002 M, 3: 0.003 M, 4: 0.005 M, 5: 0.007 M, 6: 0.01 M, 7: 0.015 M, 8: 0.04 M.

from Eqs. 1, 2, and 3:

$$K=\frac{[A-A_0]}{[A_\infty-A]B_0-C_0[A-A_0]/[A_\infty-A_0]}. \quad (4)$$

At least ten experimental points were used in each system and each measured absorbance was the average of three independent determinations. The standard molar thermodynamic functions were calculated by the usual methods: $-RT\ln K=\Delta G^\circ=\Delta H^\circ-T\Delta S^\circ$ and $\Delta H^\circ/RT^\circ=d\ln K/dT$. ΔH° was constant within the experimental error over the range of temperature, as shown in Fig. 3. Under the present experimental conditions, the values of $\log K$ were reproducible within ±0.05, values of ΔG within ±0.9 kJ mol^{-1}, and the values of ΔS within ±0.2 J K^{-1} mol^{-1}.

Results and Discussion

It has already been recognized that copper(II) β-diketonates react with nitrogen bases to form several adducts and that the 1:1 adduct is preferentially formed in non-polar organic solvents.[2,12] The absorption spectra of $Cu(bfa)_2$–pyridine system are shown in Fig. 1, as a typical example. These spectra form a family with isobestic points at these intersections, indicating the formation of a mono-adduct. Similar spectra with sharp isobestic points are obtained for all the bases employed. The analytical results by the molar ratio method also show that the present chelates form only 1:1 type adducts and 1:2 type equilibria do not take place, as shown in Fig. 2. Therefore, the author investigated only 1:1 type adduct formation equilibria with unidentate nitrogen bases, though several types of adducts with unidentate nitrogen bases have been identified, especially when the neutral ligand is a strong base and the chelate ligand contains an electron withdrawing nitro- or cyano-group.[13,14]

Stability Constants of Base Adducts. Figure 3 shows the changes in the stability constants of $Cu(bfa)_2$ adduct as a function of temperature. The stabilities decrease

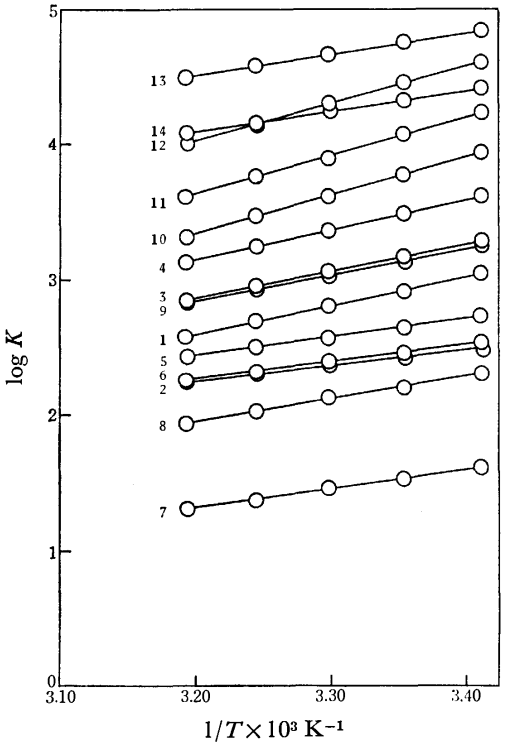

Fig. 3. Temperature dependence of stability constants for $Cu(bfa)_2$ adduct. For numerals, see Table 2.

linearly on every base as temperature rises. The adduct chelate dissociation must be much enhanced with the increase of thermal energy. From the slope of these linear plots, the standard enthalpy change of adduct formation was obtained. It seems remarkable that the enthalpies for pyrrolidine and piperidine show smaller changes in spite of their high stabilities. The stability constants increase in the following order: 2,6-lutidine $\ll$ quinoline $<$ α-picoline $\leq$ 2,5-lutidine $<$ 2,4-lutidine $<$ pyridine $<$ isoquinoline $<$ β-picoline $<$

γ-picoline < 2-methylpiperidine < 3-methylpiperidine < piperidine < 4-methylpiperidine < pyrrolidine. The order is related not only to the basicity of the bases, but also to the steric effect due to substitution. The high stabilities in the secondary cyclic amines correspond to their large donor properties. The higher stability of γ-picoline as compared with that of pyridine also reflects the increased donor power of the nitrogen atom due to the introduction of a methyl group. A similar effect would be expected for α-picoline and lutidines from these pK_H values, but much lower stabilities were observed. This fact may be caused by the steric interference of the α-methyl group. In order to make the point clearer, the stability constants of these mono-adducts are plotted against the pK_H values of the bases, as shown in Fig. 4. The values of the stability constants are classified roughly into two types, the higher and lower stability groups. The values of 2,6-lutidine and quinoline lie apart from these two groups. The lower stabilities of the second group compared to those of the first may be attributed to the steric hindrance of the methyl group in the α-position. This interference is significant in 2,6-lutidine. Owing to the steric hindrance from the hydrogen atom attached to the nitrogen atom of pyrrolidine and piperidine, the adduct stabilities of those bases are reduced to the second group. The lower stability of quinoline may be caused by the steric effect of the adjacent benzene ring. Thus, both the pK_H and the steric hindrance of the bases have an effect on the stability of the base adduct.

Thermodynamics of Adduct Formation. The stability constants of Cu(bfa)$_2$ adduct in benzene at 298 K and some related thermodynamic functions are summarized in Table 2. The values of ΔG for all the donor systems are negative, so it is obvious that the acceptor mother chelate is stabilized by the adduct chelate formation. Both the enthalpy and the entropy terms contribute to the negative values of the free energy. The introduction of a fluorine atom into β-diketone greatly increases the stability of its base adduct.[6,15] This is supported by the highly negative values of ΔH.

In the present system, the energy contribution from the structural rearrangement is significant. The enthalpy values for α-substituted pyridines are less negative and the entropy more positive than those for the other substituted pyridines. These differences may confirm the presence of some motional freedoms of α-substituted pyridines. In the α-substituted pyridines, the free rotation of the α-methyl group prevents any base with an α-methyl group from penetrating easily the chelate plane. Consequently, the approach of the base to the central copper atom will be hindered, and the chelate rings are distorted. Quinoline shows a structural difference from the α-substituted pyridines. The planar aromatic molecules will tend to arrange themselves in one of the two planes perpendicular to the coordination plane of the copper atom. Thus, the hydrogen atom of the ortho C–H group can easily penetrate the chelate plane; the rotational freedom of isoquinoline is more effective than quinoline.

In the case of pyrrolidine and piperidine, ΔG is exceedingly negative, while ΔH is not so much; as for ΔS, it is even close to zero. On the other hand, pyridine gives appreciably negative values of ΔH and ΔS, but not so great a negative value of ΔG. The difference between these two sets of data is probably owing, at least in part, to the smaller size of pyridine molecules. However, there is evidence that a π-bond is formed

Table 3. The effect of organic solvents on adduct formation

Solvent	log K_{298}	$-\Delta G_{298}$ (kJ mol^{-1})	$-\Delta H$ (kJ mol^{-1})	$-\Delta S_{298}$ (J K^{-1} mol^{-1})

between the silver and the heterocyclic bases.[16] Though the systems are different, a π-bond is operative also in the case of the non-ortho-substituted pyridines. Thus, these pyridines make strong adduct bonds through their large π-bonding character, and the systems are generally rigid, owing to the restriction of rotational freedom. On the other hand, in pyrrolidine and piperidine there would be free rotation of the base molecule in the adduct bond with σ-bond character. The disorder of those systems will be attributed mostly to the rotational freedom of the bases. The smaller pyrrolidine has more kinetic freedom. It is surprising that the adduct bond in pipecolines is most rigid and is little influenced by the position of the substituent group. This will depend upon the larger size of the base molecules and their high basicity, even though the π-bond character is low.

Effect of Organic Solvents. The effect of solvents on the $Cu(bfa)_2$–pyridine system is shown in Table 3. The chelate is generally soluble in polar solvents but sparingly soluble in non-polar solvents, *e.g.*, hexane, cyclohexane, cyclohexanon, and carbon tetrachloride, though the latter solvents show a remarkable synergistic enhancement in the solvent extraction of metal chelates.[2,17] Among the non-polar solvents, benzene dissolves the chelate easily. The general order of increasing adduct stability is: acetone<butyl acetate <4-methyl-2-pentanone <chloroform <nitrobenzene < toluene≃benzene <chlorobenzene.

This order does not agree with that of the dipole moments, the dielectric constants, nor the transition energy of ligand field of the solvents, but it agrees with the decreasing order of the interaction between the solvent and the copper chelate or of the solvation energy of pyridine with various solvents. Libutti[18] measured the solvation energy of pyridine in benzene(—0.01 kcal/mol) and chloroform(—1.82 kcal/mol) and suggested that chloroform interacts very strongly with pyridine through hydrogen bonding. Data from NMR[19] and calorimetry[20] convince us of a weak interaction of pyridine with benzene. The existence of a large solvation energy will lower the activity and base strength of pyridine. This leads to the decrease of adduct stability and would account for the less exothermic nature observed in nitrobenzene and chloroform. On the contrary, chlorobenzene and benzene form weak solvates, which serve to reduce the endothermic effect of deaggregating pyridine molecules in these solvents. In 4-methyl-2-pentanone, butyl acetate, and acetone, the adduct stabilities are very low, and the reactions are least exothermic. This phenomena may be explained by the solvation of the copper chelate. The electron-withdrawing CF_3 group of the chelate ligand decreases the electron density around the central copper atom and, at the same time, it enhances the ability to solvate with such polar oxygen-containing solvents as 4-methyl-2-pentanone, butyl acetate, and acetone, although even weak solvates are not produced in non-fluorinated β-diketonate chelates.[21] It will require much energy to substitute a solvent molecule in addition to removing the dipole interaction of the pyridine with the solvent, and this fact promotes the irregular nature of the systems.

Effect of Chelate Ligands. Adduct stability will be much influenced by the Lewis acidity of the chelate, which is affected by the terminal group of the chelate ligand. The effect of chelate ligands involving non-fluorinated β-diketones in the pyridine system is shown in Table 4. The adduct stabilities in the fluorinated ligands differ little from those expected from the pK_H values. The constants increase in the following order: Hdpm < Haa < Hba ≪ Htaa < Hpta ≤ Hbfa < Hfta< Htta. For the fluorinated ligands, the electron-withdrawing effect of the CF_3 group is quite large, and the effect of the other terminal substituent is not so obviously recognized. But the order seems to correlate with the pK_H values, except Hpta, and to be just the reverse of the trend that the weaker the acidity of

the ligand is, the weaker is the adduct stability.[17] To a certain extent, thenoyl, furoyl, and phenyl groups contribute to the resonance stabilization of those adducts, and the pivaloyl group shows some steric interference. However, we have no independent data available on the dissociation constants of the β-diketones in benzene solution; hence, further investigation will be required before a detailed discussion can be done. Nevertheless, the effect of bases definitely appears in the present experiment.

In the reaction of non-fluorinated copper chelates with nitrogen bases, Graddon pointed out a linear relationship between ΔH and ΔS, which was interpreted as indicating a common interaction mechanism.[22] The isoequilibrium temperature of the system containing 2-substituted 1,3-diketones was 310 K in benzene solution. A similar relationship was observed in the present fluorinated ligands, though a few points did not fit well in the case of Hbfa, as shown in Fig. 5. The line itself is situated considerably above that for the non-fluorinated ligands, and possesses a large slope. The isoequilibrium temperature is 413 K. These facts indicate rather clearly that fluorinated adducts are entropy-stabilized, while the non-fluorinated adducts show higher entropy-resistance. Thus, the extra stability of fluorinated adducts can mainly be ascribed to the entropy factor.

The author wishes to express his deep gratitude to Professor Shunzo Ueda, of Kanazawa University, for his continual encouragement and advice throughout this work. The author also wishes to express his thanks to Professor Tsunenobu Shigematsu and Assistant Professor Masakazu Matsui, of Kyoto University, for their valuable guidance and discussion.

(Received May 11, 1977)

The geometry and electronic properties of methylene, methylcarbene, carboxycarbene, phenylcarbene, trimethylsilylcarbene, silylcarbene, carboxysilylcarbene, and phenylsilylcarbene have been determined by MINDO/3 calculation. Introduction of a silyl group results in considerable decrease in ionization potential of carbenes. The electron affinity is increased to some extent by such substitution. The computation suggests a bent geometry for optimized triplet trimethylsilylcarbene structure, in conflict with a recent postulate that the ground-state molecule has an essentially linear structure.

Silylcarbenes generated by photolysis of the corresponding diazo compounds display intriguing behavior.[1-9] One is the relative reactivity of alkenes in the cyclopropanation of these carbenes. Ordinary carbenes are electrophilic and in most cases undergo cycloaddition preferentially to the more alkylated alkenes,[10] whereas the reactivity of ethoxycarbonyltrimethylsilylcarbene toward alkenes decreases with increasing methyl substitution on the double bond.[3] Another is the mode of reaction with dialkyl sulfides. Most carbenes react with sulfides in an electrophilic manner to produce sulfur ylides;[10] in contrast, reaction of silylcarbenes results in the formation of formal sulfur–carbon bond

$$RC(N_2)COOC_2H_5 \xrightarrow{h\nu} RCCOOC_2H_5 + N_2$$

R=H or $Si(CH_3)_3$

$$RCCOOC_2H_5 + \text{Olefin} \longrightarrow \text{cyclopropane-}COOC_2H_5$$

$$HCCOOC_2H_5 + R'_2S \longrightarrow R'_2\overset{+}{S}-\overset{-}{C}HCOOC_2H_5$$

$$(CH_3)_3SiCCOOC_2H_5 + R'_2S \longrightarrow R'S-\underset{\displaystyle COOC_2H_5}{\overset{\displaystyle Si(CH_3)_3}{\overset{|}{\underset{|}{C}}}}-R'$$

insertion products.[11] In addition, trimethylsilylcarbene has received attention as a precursor of a silaethylene.[6-9] These interesting features have prompted us

$$(CH_3)_3SiCHN_2 \xrightarrow{h\nu} (CH_3)_3SiCH + N_2$$

$$(CH_3)_3SiCH \longrightarrow (CH_3)_2Si{=}CHCH_3$$

to examine the electronic structures of the carbenes by semi-empirical SCF MO calculations.

Results and Discussion

A linear carbene has two perpendicular 2p orbitals into which two valence electrons are to be placed. Degeneracy is removed on bending, giving a σ orbital (in the plane in which bending takes place) and leaving p orbital (perpendicular to the plane).[12] When a conjugative group is attached to the divalent carbon, bending can occur in either in-plane or out-of-plane manner. The levels of these orbitals are affected in various ways by interaction with the adjacent carbene substituents. Thus total molecular energies vary as a function of bond angle, θ. We calculated the structures of four silylcarbenes and some related species according to the MINDO/3 method.[13] Contribution of silicon d orbitals was not explicitly considered. In order to perform the calculation, the program supplied by the Quantum Chemistry Program Exchange (QCPE) was modified for use with the FACOM 230-60 computer at Nagoya University. For carbenes **1**—**7**, the bond lengths, bond angles, and torsional angle were optimized. For large substituents such as phenyl or carboxyl, some fixed parameters were used. The molecular structures thus obtained are given in the molecular formulas; the details are summarized in Table 1. Geometries of the triplet states were determined by this method and the electronic structures by unrestricted Hartree-Fock type SCF calculations, not by the conventional *half-electron method*.[13] Electronic properties of the carbenes are given in Table 2. The ionization potential (IP) of the carbenes and the electron affinity (EA),

as estimated as IP of the corresponding radical anions, provide the indication of nucleophilicity and electrophilicity, respectively. Electron density of the formally vacant p orbital ($d_{p\pi}$) and net atomic charge of the carbenic center might be related to the reactivity of these carbenes as well.[17]

Methylene (1). Calculations indicate that the triplet state (**1T**) is the ground state with minimum energy at an HCH bond angle of 135.7°, lying 11.8 kcal/mol below the lowest singlet state (**1S**) with bond angle of 100.2°. Calculated IP of **1S** is 9.94 eV. The result for this parent carbene species is in good agreement with experimental results.[18,19] The calculated EA value, 0.09 eV, is somewhat lower than the observed value, 0.21 eV.[18] The MINDO/3 calculation for **1** has been carried out,[13] but the IP of **1T** has not been reported.[20]

Methylcarbene (2). The 140.8° triplet (**2T**) was found to be the ground state. The 108.1° singlet (**2S**) lies 16.9 kcal/mol above **2T** and has IP of 8.86 eV. This value is 1.08 eV lower than that of **1S**. The EA value, 0.83 eV, is larger than that of simple methylene. Introduction of methyl group increases $d_{p\pi}$ by 0.12.[21]

Carboxycarbene (3). The carboxyl group was used as a model of the alkoxycarbonyl group. Both singlets and triplets with minimum energies have bent structures. The in-plane triplet is more stable than the singlet of out-of-plane bent structure. This is to be noted because alkoxycarbonylcarbenes formed from diazoacetates are known to behave usually as a singlet species.[22,23] The orbital stabilization of **3S** is attained as a result of both bending to acquire s character and π conjugation between the occupied σ orbital and carboxyl group. IP of **3S** is nearly identical with that of **1S**. As expected, this electron-withdrawing group increases the EA value, predicting the eminent electrophilic nature of carbene.

Phenylcarbene (4). In both **4S** and **4T**, all the atoms lie nearly on the same plane. In accord with experimental findings,[24] the ground state is a bent triplet (**4T**). The low IP (8.22 eV) and high EA (1.55 eV) for the singlet species (**4S**) characterize the electronic property. Its $d_{p\pi}$, 0.20 is rather high.[25]

Trimethylsilylcarbene (5). The ground state was indicated to be triplet, as has recently been demonstrated by experiments.[9] According to the present calculation, however, the ground state has a 147° bent structure (**5T**), which lies in marked contrast with the recent postulate that **5T** has a linear structure.[9] The lowest singlet state (**5S**) with bond angle of 115.6°, lying 32.9 kcal/mol above **5T**, has an IP of 8.25 eV. The IP is much lower than that of **1S** (9.94 eV) or **2S** (8.86 eV) but comparable with the one of the phenylated carbene **4S**. Electron density of the carbenic carbon, $d_{p\pi}$, is smaller than that in the case of **2S**. Thus the trimethylsilyl group, as compared with the methyl group, has been shown to decrease IP greatly but not to increase electron density of the divalent carbon. Lack of hyperconjugative stabilization of the vacant orbital may be the cause. On going from **2S** to **5S**, EA value increases by 0.93 eV.

Silylcarbene (6). The optimized geometry and electronic properties are quite similar to those of the trimethyl derivative **5**.

Carboxysilylcarbene (7). For the sake of economy of calculation, silyl group was used as a model of the trimethylsilyl group. The carbene has also triplet ground state (**7T**). Unlike carboxy- or silylcarbene, the triplet state with minimum energy is of linear structure. The lowest singlet state (**7S**) of 170.6° bent structure, lying 23.5 kcal/mol above the ground state **7T**, is stabilized to a considerable extent through conjugation of the σ orbital (99.9% p-character) containing paired electrons with the adjacent carboxyl group. Notably, silyl group introduced into the carbene **3S** decreases the IP value by 1.11 eV, suggesting endowment of nucleophilicity. On the other hand, no change in electrophilicity can be expected, as seen from the comparable EA value. The $d_{p\pi}$ and net atomic charge of the carbene center were found to increase to some extent.

Phenylsilylcarbene (8). The structure could not be optimized because of the large framework. The ground

state was estimated to be *ca.* 140° bent triplet (**8T**), the lowest singlet (**8S**) prefering an in-plane bent (*ca.* 120°) geometry.

Thus MINDO/3 method shows that introduction of silyl groups into the carbene center results in considerable decrease in IP's, thereby increasing nucleophilic character. The same perturbation, however, is observed with other substituents, particularly phenyl and methyl groups. Electrophilicity, as judged from the EA's, is affected by silyl substitution, the effect being highly dependent on the nature of other substituents on divalent carbon. Silyl moieties increase

electron density, $d_{p\pi}$, of the carbenic carbon, but the degree of the effect is less than methyl or phenyl substituent. Thus when the electronic properties of the silylcarbenes are compared with those of the related nonsilylated carbenes of the same singlet electronic configuration, we cannot anticipate any peculiar behavior of the former species. In order to interpret the unique reactivity of silylcarbenes, the bulkiness of silyl group[3] and efficiency of the S-T intersystem crossing should be taken into account. The silyl groups may exert strong influence on the nature of the transition state or intermediate of carbene *reactions* rather than the properties of the divalent species itself.

The MINDO/3 procedure is the most sophisticated semi-empirical SCF MO method at present and the accuracy of the calculations has been demonstrated by excellent agreement with experimental observations for a large number of ground state molecules. This is also the case for organosilicon compounds.[16] Nevertheless, the calculated bent geometry of **5** is inconsistent with the recent postulate that ground-state trimethylsilylcarbene has a linear geometry.[9] If the conclusion based on ESR study is correct,[26] one of the major causes of this controversy might be the influence of possible $d\pi$-$p\pi$ interaction, although such orbital effect is usually considered to be negligible.[27-29] If this were the case, it might present a rare example of d-orbital participation.

28) In special cases, however, such interaction is significant. See L. M. Loew and W. R. MacArthur, *J. Am. Chem. Soc.*, **99**, 1019 (1977).
29) In order to estimate the effect of d functions of silicon atom, CNDO/2 calculation[30] was carried out for singlet silylcarbene (6S). When only s and p atomic orbitals were considered, a 123° bent geometry was obtained as the optimal structure. The computation using an spd basis set[31] afforded nearly the same optimized geometry, $\theta=125°$. As usual, the addition of d orbital lowered the total energy of the carbene because of the polarization effect, but did not alter the shape of potential surface curve. This result implies relative unimportance of the d-orbital participation.
30) J. A. Pople and D. L. Beveride, "Approximate Molecular Orbital Theory," McGraw-Hill, New York, N. Y. (1970). In the original CNDO/2 program, same values have been used for 3s-, 3p-, and 3d-orbital exponents. However, the 3d-orbital exponent value 0.30 was used in this calculation.[31]

Reaction of Organic Tin(II) Compounds with Ethyl Isocyanate

Ikuko WAKESHIMA and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received June 3, 1977)

The reaction of Sn–OC bond-containing tin(II) compounds with ethyl isocyanate was investigated. From the ν_{NCO} absorption bands, it is recognized that the reactivity, in terms of tin(II) compounds, decreases in the order: bis[2-(dimethylamino)ethoxo]tin(II) > bis[*o*-(ethoxycarbonyl)phenolato]tin(II) > di(phenolato)tin(II)> bis(ethoxycarbonylacetonato)tin(II) > bis(3-ethoxycarbonyl-2-pentanoato)tin(II) > bis(1-phenylbutane-1,3-dionato)tin(II) > bis(dibenzoylmethanato)tin(II). Bis[2-(dimethylamino)ethoxo]tin(II), bis[*o*-(ethoxycarbonyl)-phenolato]tin(II), and di(phenolato)tin(II) yielded triethyl isocyanurate as a main product from reactions with ethyl isocyanate, while bis(ethoxycarbonylacetonato)tin(II), bis(3-ethoxycarbonyl-2-pentanoato)tin(II), bis(1-phenylbutane-1,3-dionato)tin(II), and bis(dibenzoylmethanato)tin(II) gave mixtures of the isocyanurate and 6-ethylimino-1,3,5-triethylhexahydro-1,3,5-triazine-2,4-dione. The mechanism for the formation of these products is discussed.

Certain kinds of organic tin(II) compounds are widely used as catalysts for the synthesis of polyurethanes and as curing agents for silicones. Recently, many kinds of organic tin(II) compounds[1–10] have been prepared, and the reactivities of some have been investigated. Previously, the present authors reported that the reaction of bis(acetylacetonato)tin(II) with ethyl isocyanate resulted in 6-ethylimino-1,3,5-triethylhexahydro-1,3,5-triazine-2,4-dione in an excellent yield.[11] In the present paper, the reaction of several organic tin(II) compounds with ethy isocyanate will be described.

Results and Discussion

Reaction of Tin(II) Dialkoxide with Ethyl Isocyanate. Ethyl isocyanate was added to a solution of bis[2-(dimethylamino)ethoxo]tin(II) (**1**), bis[*o*-(ethoxycarbonyl)phenolato]tin(II) (**2**), and di(phenolato)tin(II) (**3**) in benzene at room temperature and then heated for several hours (as indicated in Table 1). The reaction mixtures were hydrolyzed to isolate the products. There results are shown in Table 1.

In the reaction of tin(II) compound **1** with ethyl isocyanate at 20—24 °C, IR spectroscopy demonstrated the absence of the characteristic absorption band of the ν_{NCO} group within 1 h. When the reaction mixture was further refluxed for 3 h, the yield of triethyl isocyanurate was much higher compared with that of the reaction without heating (runs 1 and 2). This indicates that the reaction proceeds through the intermolecular reaction of the intermediate, as described in a previous paper.[13] Judging from the time required for the disappearance of the ν_{NCO} absorption band observed in ethyl isocyanate, it was found that tin(II) compounds **2** and **3** were less reactive than tin(II) compound **1**, and that the reactivity of tin(II) compound **3** was inferior to that of tin(II) compound **2**. These facts indicate that the reduction in the electron density on the oxygen atom of the Sn–OC bond due to the M-effect of the R group results in a decrease in the nucleophilicity of the oxygen atom toward ethyl isocyanate and that the low solubility[6] of tin(II) compound **3** reduced the reaction of that compound **3** toward ethyl isocyanate. In the reaction of tin(II) compound **2**, triethyl isocyanurate was obtained as the main product accompanied by a small amount of the carbamate derivative and tin(II) compound **3** gave triethyl isocyanurate as the only product. This suggests that the Sn–N bond formed by the insertion of ethyl isocyanate into the Sn–OC bond is considerably more active.

Table 1. Reaction of $Sn(OR)_2$ with ethyl isocyanate in benzene[a]

Run	$Sn(OR)_2$	Reaction time (h)	Yield (%) of products[b]	
			$C_2H_5NHCO_2R$	$(C_2H_5NCO)_3$

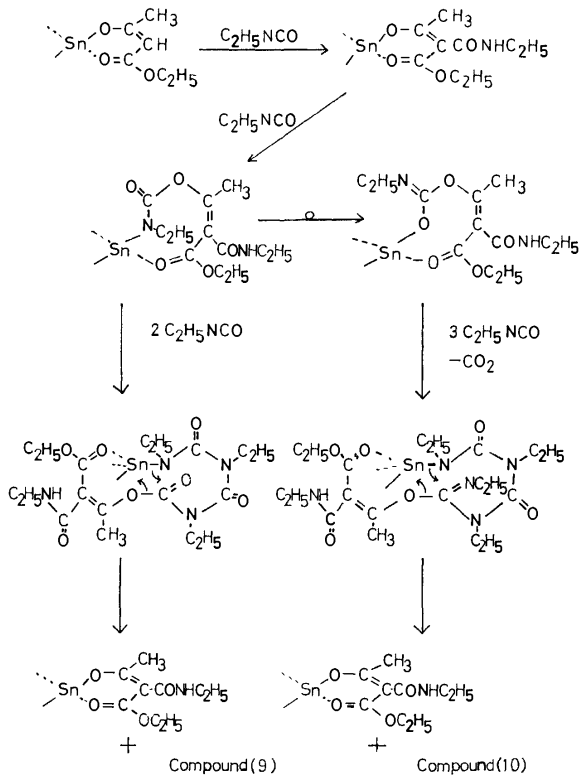
(**10**) (**11**) (1)

Judging from the reaction time required for the completion of the reaction, β-keto ester tin(II) compounds have been found to be less reactive toward ethyl isocyanate than tin(II) alkoxides. Although all of the reactions between bis(acetylacetonato)tin(II) (**8**) and ethyl isocyanate in various molar ratios gave only compound **11**, the reaction of tin(II) compound **4** with ethyl isocyanate of a molar ratio of 1 : 2 (run 6) yielded compound **9** in a yield of 79.6%. This difference may be related to the lesser nucleophilicity of the oxygen atom of the Sn–OC bond and the preferential reactivity of the methine proton in the chelate ring due to the greater electron-withdrawing force of the ethoxyl group. The reaction of a molar ratio of 1 : 4 (run 7) yielded compound **10** (13.9%) besides the formation of compound **9** (60.0%). In the cases of $n=8$ (run 8) and 50 (run 9), compound **11** was obtained in yields of 9.6 and 27.7%, respectively, together with the formation of compound **10** in 22.1 and 40 % yields, respectively. From these results, it is clear that the yield of compound **11** increases with increasing molar ratio of ethyl isocyanate to tin(II) compound **4**. The reaction of bis(3-ethoxycarbamoyl-2-pentanoato)tin(II) (**5**) with ethyl isocyanate in a molar ratio of 1 : 4 (run 10) gave compound **10** as a main product accompanied by a small amount of compound **11**. When a large amount of ethyl isocyanate ($n=50$, run 11) was treated with tin(II) compound **5**, compounds **10** and **11** were obtained in yields of 47.7 and 34.4 %, respectively. It is worth noting that compound **11** is produced by a reaction with the β-keto ester tin(II) compound, in which the methin proton of the chelate ring is substituted by an ethyl or ethylcarbamoyl group. From these results, the following scheme is given as a plausible reaction path:

TABLE 3. YIELD AND PROPORTION OF PRODUCTS FROM IN THE REACTION OF VARIOUS TIN(II) COMPOUNDS WITH ETHYL ISOCYANATE

$Sn(OC(R)=CHCOR')_2$			Total yield of product (%)	Proportion of products	
	R	R′		**10**	**11**
8	CH_3	CH_3	89		100
6	C_6H_5	CH_3	85	29	71
7	C_6H_5	C_6H_5	54	31	69
4	CH_3	OC_2H_5	68	59	41



Scheme.

The extent to which N→O migration of the tin atom correlates with the formation of compounds **10** and **11** is considerable.

The Reaction of Bis(β-diketonato)tin(II) Derivatives with Ethyl Isocyanate: When bis(1-phenylbutane-1,3-dionato)tin(II) (**6**) was allowed to react with ethyl isocyanate, compounds **10** and **11** were obtained without the forma-

tion of 2-ethylcarbamoyl-1-phenyl-1,3-butanedione. The reaction in a 1:4 molar ratio required 4 h for the disappearance of the ν_{NCO} absorption band at about 2270 cm^{-1} and 26 h in a 1:50 molar ratio. On the other hand, it was found that the reaction of bis(dibenzoylmethanato)tin(II) (**7**) with ethyl isocyanate was very slow; after heating for 40 h, 96 % of tin(II) compound **7** and 45.6% of ethyl isocyanate were recovered and compounds **10** and **11** were obtained in low yields. Tin(II) compound **8** gave only compound **11** and the other bis(β-diketonato)tin(II) derivatives afforded a mixture of compounds **10** and **11** as reaction products. The bis(β-diketonato)tin(II) derivatives provided compound **11** in higher yields in comparison with the bis(β-keto ester)tin(II) derivatives as described above. It may be assumed that N→O migration of the tin atom occurs more easily in tin(II) compounds **6** and **7** than in tin(II) compounds **4** and **5**.

As can be seen from Table 3, the proportion of products is influenced by the substituent, R′, bonded to the chelate ring; the production of compound **11** increases in the order: $CH_3 > C_6H_5 > OC_2H_5$. Taking account of the $\nu_{C=O}$ absorption band of tin(II) compound **4** ($\nu_{C=O}$ 1600 cm^{-1}),[1] tin(II) compound **6** ($\nu_{C=O}$ 1565 cm^{-1}),[4] tin(II) compound **7** ($\nu_{C=O}$ 1548 cm^{-1}),[4] and tin(II) compound **8** ($\nu_{C=O}$ 1567 cm^{-1}),[1] the strength of co-ordination of the oxygen atom on the R′CO group toward the tin atom appears to play an important role in the formation of compounds **10** and **11**.

Experimental

Experiments were carried out in a nitrogen atmosphere dried using liquid nitrogen. The measured melting and boiling points are uncorrected. The IR spectra were recorded with a Hitachi EPI-2S spectrometer and the ^{1}H-NMR spectra on a Hitachi R-24 (60 MHz) using TMS as an internal standard. The abbreviations s, t, q, br, and m in the NMR spectra denote singlet, triplet, quartet, broad, and multiplet, respectively. Elemental analysis were carried out using a Yanagimoto M-2 CHN corder.

Reagents. Hexane, benzene, and ethanol were dried using the methods given a previous paper.[6] Ethyl acetoacetate, ethyl salicylate, benzoylacetone, phenol, and 2-(dimethylamino)ethanol were dried using an azeotropic distillation method using benzene. Ethyl 3-ethylacetoacetate was prepared by a method given in the litrature.[11] Ethyl isocyanate was obtained commercially and purified by distillation just prior to use. Tin(II) derivatives were prepared by reactions of tin(II) diethoxide with the corresponding alcohol, phenol, ester, or ketone.

General Procedure. Ethyl isocyanate was added dropwise to a benzene (1.4—1.5 ml/$Sn(OR)_2$ mmol) solution of $Sn(OR)_2$ (100 mmol) at 25—30 °C with stirring. After standing at room temperature for 1 h, the solution was heated to 79—81 °C for fixed time intervals and the disappearance of the ν_{NCO} absorption band was observed. After the solution distilled off, the oily residue was hydrolyzed with a water (5—6 ml) and acetone (100 ml) or benzene mixed solution. Removal of the inorganic tin with a centrifugal separator gave a pale yellow solution, which was then concentrated and distilled *in vacuo*. Products **9** and **11** were fractionally distilled under reduced pressure through a 20-cm Widmer fractionating column. The residue (compound **10**) was recrystallized from hexane. In the case of the reaction with tin(II) compound **3**, the unreacted tin(II) compound was filtered off before hydrolysis. The products obtained were identified on the basis of IR, NMR, and mass spectra and elemental analysis. Proof of the structure of compound **11** was also provided by its conversion to triethyl isocyanurate a 2M-HCl alcoholic solution.[11]

Syntheses of Unsymmetrical Sulfides and Bis(alkylthio)methanes from Diphenylphosphinodithioate Esters

Koshiro GODA, Fumito HANAFUSA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 7, 1977)

Unsymmetrical sulfides were prepared by the reactions of diphenylphosphinodithioate esters with organolithiums in tetrahydrofuran (THF) at −78 °C or at room temperature in fairly good or excellent yields. Similarly, methylene bis(diphenylphosphinodithioate) gave bis(alkylthio)methanes by reactions with organolithiums in good yields. The use of bad-smelling thiols is avoided and the phosphorus part can be recycled after sulfurization and esterification. Allyl diphenylphosphinodithioate gave allylbenzene *via* $S_N2(C)$ reaction upon treatment with phenylmagnesium bromide in refluxing THF.

The reaction of alkyl diphenylphosphinodithioates (**1**) with butyllithium affords [Ph_2PS]Li and butyl sulfides by $S_N2(S)$ mechanism.[1]

$$Ph_2P(S)SR + R'Li \longrightarrow [Ph_2PS]Li + R\text{-}S\text{-}R' \quad (1)$$
1 **2**

This is utilized for the preparation of unsymmetrical sulfides (**2**).[2] This paper describes in detail the syntheses of unsymmetrical sulfides and bis(alkylthio)-methanes from diphenylphosphinodithioate esters.

Preparation of Unsymmetrical Sulfides. The esters (**1**) were allowed to react with organolithiums in tetrahydrofuran (THF) at −78 °C or at room temperature for 0.5 h. After the reaction mixture had been quenched with water, the yields of sulfides (**2**) obtained were determined by gas chromatography (GLC) or by isolation with dry column chromatography (DCC). The results are summarized in Table 1.

In the case of the allyl ester, the yield of the corresponding sulfide is comparatively low, probably because of competitive Wittig type rearrangement.[1]

The reactions with Grignard reagents in refluxing THF, except for phenylmagnesium bromide, gave the corresponding sulfides (**2**) only in low yields accompanied by recovery of the starting esters (**1**).[1] The reaction of the allyl ester with phenylmagnesium bromide in THF at room temperature afforded allyldiphenylphosphine sulfide (**3**) (7%) and diphenylphosphinodithioic acid (19%) accompanied by 41% of unchanged ester and a small amount of allylbenzene. In refluxing THF, the reaction gave allylbenzene (70%) and diphenylphosphinodithioic acid (89%) together with a trace amount of triphenylphosphine sulfide ($S_N2(P)$ reaction).

	Ph	r. t.	90
$PhCH_2$	Bu	−78	86
	Ph	−78	79[b]
	Ph	r. t.	60[b]
CH_2=$CHCH_2$	Bu	−78	63
	Ph	r. t.	72[b]

a) Determined by GLC unless noted otherwise. b) Isolated by DCC.

The formation of allylbenzene and **3** is illustrated as follows:

$$Ph_2P(S)SCH_2CH{=}CH_2 + PhMgBr \xrightarrow{S_N2(C)} Ph_2P(S)SMgBr + PhCH_2CH{=}CH_2$$

$$Ph_2P(S)\bar{S}CHCH{=}CH_2 \xrightarrow[\text{rearr.}]{\text{Wittig}} Ph_2P(S)CH(S^-)CH{=}CH_2 \xrightarrow{-S} \xrightarrow{H^+} Ph_2P(S)CH_2CH{=}CH_2$$
3

Namely, phenylmagnesium bromide attacks the α-carbon atom of the ester in $S_N2(C)$ manner at higher temperature to afford allylbenzene, while it abstracts the α-hydrogen atom in the ester at room temperature to form **3** through Wittig type rearrangement followed by desulfurization by a small amount of [Ph_2PS]MgBr produced according to Eq. 1.

A possibility of $S_N2'(C)$ mechanism for the formation of allylbenzene can be excluded based on the results of the reactions of phenylmagnesium bromide with the 2-butenyl and 1-methylallyl esters, as shown below.

$$Ph_2P(S)SCH_2CH{=}CHCH_3 + PhMgBr \longrightarrow PhCH_2CH{=}CHCH_3 + PhCH(CH_3)CH{=}CH_2 \quad (94 : 6)$$
$$+ Ph_2P(S)SH$$

$$Ph_2P(S)SCH(CH_3)CH{=}CH_2 + Ph_2P(S)SCH_2CH{=}CHCH_3 \quad (54 : 46)$$
$$\xrightarrow{PhMgBr} PhCH(CH_3)CH{=}CH_2 + PhCH_2CH{=}CHCH_3 \quad (44 : 56)$$
$$+ Ph_2P(S)SH$$

However, the $S_N2'(C)$ mechanism is not completely ruled out.

Thus, the Grignard reagents can not be used for the preparation of **2**, because of the low thiophilicity.[1]

Unsymmetrical sulfides are usually prepared by the reactions of alkali thiolates with alkyl halides,[3] alkyl phosphinates,[4] or dialkyl carbonates,[5] and by the reaction of 1-methyl-2-fluoropyridinium salt with alcohols and then thiols.[6] On the other hand, the present method can be carried out without the use of bad-smelling thiol, and [Ph_2PS]Li produced in the reaction can be reconverted into diphenylphosphinodi-

Table 2. Reactions of **4** with RLi (at −78 °C in THF)

R	**5** (%)
Me	89[a]
Et	61[a]
Bu	99[b]

a) By GLC. b) By isolation.

thioic acid, which is converted easily into the ester, by treatment with sulfur, indicating that the phosphorus part can be recycled.

Organosodiums can be used. For example, phenylsodium reacted with methyl and phenyl esters at room temperature to afford methyl phenyl sulfide and diphenyl sulfide in 67 and 82% yields, respectively.

Preparation of Bis(alkylthio)methanes. If methylene bis(diphenylphosphinodithioate) (**4**) is prepared from diphenylphosphinodithioic acid and dihalomethane, the preparation of bis(alkylthio)methanes (**5**) would be possible as follows.

$$2Ph_2P(S)SH + CH_2X_2 \longrightarrow (Ph_2P(S)S)_2CH_2 \xrightarrow{2RLi} (RS)_2CH_2$$

4 **5**

Compound **4** was prepared from dibromo- and diiodomethanes in 14 and 67% yields, respectively, but not from dichloromethane.

The reactions of **4** with organolithiums are summarized in Table 2. The yields of **5** are good or excellent.

When **4** is allowed to react with more than three moles of organolithium and the reaction mixture is treated with alkyl halides, 1,1-bis(alkylthio)alkanes can be prepared by one-pot reaction (see Experimental), which can be easily converted into the corresponding aldehydes.

It is interesting that the diphenylphosphinodithioates act as alkylthio-transfer reagent.

Experimental

Materials. Methyl-, ethyl-, and phenyllithiums were prepared by the method of Gilman *et al.*[7] Alkyl diphenylphosphinodithioates (**1**) were prepared by the methods described in the preceding paper.[1] 1-Phenyl-2-butene and 3-phenyl-1-butene were prepared by the reported method[8] and purified by fractional distillation.

The reactions were carried out under nitrogen or argon.

Preparation of Unsymmetrical Sulfides. General Procedure. Organolithium (*ca.* 3 mmol) was added to a solution of **1** (*ca.* 1.5 mmol) in THF (20 ml) cooled at −78 °C and the mixture was stirred for 0.5 h. After addition of water (0.5 ml) to a small amount of the reaction mixture was added an internal reference such as mesitylene, naphthalene, butyl ethyl sulfide, or phenanthrene. The yield of sulfide (**2**) was determined by GLC (H 523 on Diasolid at 100—150 °C). The sulfide was isolated from the residual part of the reaction mixture by DCC (SiO_2, CCl_4).

Reaction of [Ph_2PS]Li with Sulfur. To the reaction mixture from phenyl diphenylphosphinodithioate (0.99 g, 3.0 mmol) and butyllithium (3.0 mmol) in THF (100 ml) was added an excess amount of sulfur, and the mixture was allowed to stand overnight. After addition of 10% aq sodium hydroxide, the reaction mixture was washed with benzene in order to extract sulfide, and filtered for removal of excess sulfur. The filtrate was acidified with hydrochloric acid and extracted with benzene to give diphenylphosphinodithioic acid (0.635 g, 84%).

Reaction of Allyl Diphenylphosphinodithioate with Phenylmagnesium Bromide. 1) A mixture of the ester (1.12 g, 3.8 mmol) in THF (10 ml) and phenylmagnesium bromide (10.6 mmol) in THF (15 ml) was heated for several minutes and then stirred for 4 h at room temperature. The reaction mixture was acidified with dilute hydrochloric acid and extracted with benzene. The benzene extract was washed with aq sodium hydroxide. The aq alkaline extract gave diphenylphosphinodithioic acid (0.19 g, 19%) after acidification. The benzene solution was treated with DCC (SiO_2, AcOEt). The unchanged ester (0.45 g, 41%) was recovered and allyldiphenylphosphine sulfide (69 mg, 7%) was obtained as an oily substance. IR (neat): 1590 (C=C), 1430, 1110 (P–Ph), and 640 cm^{-1} (P=S); NMR (CCl_4): δ 3.30 (dd, J_{PCH}=16 Hz, J_{HH}=6 Hz, 2H, PCH_2), 4.85—5.15 (m, 1H, CH=C), 5.25 (d, J_{HH}=5 Hz, 1H, CH), 5.55—6.10 (m, 1H, –CH=), and 7.25—8.10 (m, 10H, 2P–Ph); MS: *m/e* 258 (M^+, 23%) and 217 (Ph_2PS^+, 100).

Found: C, 70.00; H, 6.12%. Calcd for $C_{15}H_{15}PS$: C, 69.74; H, 5.85%.

2) A mixture of the ester (0.345 g, 1.2 mmol) and phenylmagnesium bromide (2 mmol) in THF (12 ml) was refluxed for 2 h. The yield of allylbenzene was determined to be 70% by GLC using dibutyl ether as an internal reference. Ethyl acetate was added to the reaction mixture, and the mixture was washed with aq sodium hydroxide. The aq layer was acidified with hydrochloric acid and extracted with ethyl acetate to give diphenylphosphinodithioic acid (0.264 g, 89%). A trace amount of triphenylphosphine sulfide was isolated by DCC of the first ethyl acetate solution.

Preparation of 2-Butenyl Diphenylphosphinodithioate. A mixture of diphenylphosphinodithioic acid (25 g, 0.10 mol) and sodium hydroxide (4 g, 0.10 mol) in THF (50 ml) was stirred at room temperature for 1.5 h. 2-Butenyl chloride (9.3 g, 0.10 mol) was then added, and the mixture was refluxed for 2 h. After removal of THF, the residue was extracted with benzene to give crude ester (30.0 g, 98%) as oil, which was purified by means of DCC, because of the decomposition on vacuum distillation. IR (neat): 1420, 1100 (P–Ph), and 650 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.52 (d, J=6 Hz, 3H), 3.55 (dd, J_{PSCH}=14 Hz, J=6 Hz, 2H), 5.50 (m, 2H), and 7.3—8.3 (m, 10H).

Reaction of 2-Butenyl Diphenylphosphinodithioate with Phenylmagnesium Bromide. A mixture of the ester (1.16 g, 3.60 mmol) and phenylmagnesium bromide (5 mmol) in THF (30 ml) was refluxed for 4.5 h. After treatment with 0.2 M hydrochloric acid, the reaction mixture was extracted with carbon tetrachloride. The carbon tetrachloride extract was further extracted with aq sodium hydroxide. The aqueous layer afforded diphenylphosphinodithioic acid (0.21 g, 22%) after acidification and extraction with benzene. A mixture of 1-phenyl-2-butene and 3-phenyl-1-butene (94 : 6) was obtained from the carbon tetrachloride layer in 71% yield (by GLC).

Reaction of Sodium Diphenylphosphinodithioate with 1-Methylallyl Chloride Followed by Reaction with Phenylmagnesium Bromide. A mixture of diphenylphosphinodithioic acid (17.1 g, 68 mmol) and sodium hydroxide (3 g, 75 mmol) in THF (50 ml) was stirred at room temperature for 1.5 h. After addition of 1-methylallyl chloride (6.5 g, 72 mmol) the mixture was refluxed for 3 h. After removal of THF the residue was

extracted with benzene and the dried benzene extract was evaporated to afford a mixture of 1-methylallyl and 2-butenyl diphenylphosphinodithioates (54 : 46 by NMR), yield 4.2 g (20%). NMR ($CDCl_3$; due to 1-methylallyl ester): δ 1.38 (d, J=6 Hz), 3.9—4.4 (m), 4.9—5.2 (m), 5.4—6.0 (m), and 7.3—8.3 (m). The ratio of both esters was determined on the basis of the peak areas at δ 3.55 (due to 2-butenyl ester, NMR data of which have been described already) and 3.9—4.4 (due to 1-methylallyl ester). Since separation of the two esters was unsuccessful, the mixture was used for the following reaction.

A solution of the ester mixture (0.72 g, 2.40 mmol) and phenylmagnesium bromide (3.5 mmol) in THF (30 ml) was refluxed for 4 h and the reaction mixture was subjected to the treatment similar to that in the reaction of 2-butenyl ester. Diphenylphosphinodithioic acid and a mixture of 1-phenyl-2-butene and 3-phenyl-1-butene (56 : 44 by GLC) were obtained in 57 and 51% yields, respectively.

Preparation of **4**. *1) From Dibromomethane*: Dibromomethane (25 g, 0.14 mol) was added to a mixture of diphenylphosphinodithioic acid (30 g, 0.12 mol) and sodium hydroxide (5 g, 0.13 mol) in ethanol (200 ml), and the mixture was refluxed for 3 h. The reaction mixture was washed with water and extracted with benzene. After evaporation of benzene from the benzene extract, a small amount of ethanol was added to the residual oil and the mixture was allowed to stand at 0 °C. The resulting crystals were collected and recrystallized from acetonitrile, mp 90—91 °C, yield 4.4 g (14%). IR (KBr): 1425, 1095 (P–Ph), 650 (P=S), and 520 cm^{-1} (P–S); ^{1}H-NMR ($CDCl_3$): δ 4.56 (t, J_{PSCH}=16 Hz, 2H, CH_2) and 7.10—8.10 (m, 20H, 4Ph); ^{31}P-NMR (THF): δ_P −63.8 ppm.

Found: C, 58,32; H. 4.33; S, 24.86%. Calcd for $C_{25}H_{22}P_2S_4$: C, 58.57; H, 4.33; S, 25.02%.

2) From Diiodomethane: Diiodomethane (25 g, 0.09 mmol) was added to a mixture of diphenylphosphinodithioic acid (45 g, 0.18 mol) and sodium hydroxide (7.4 g, 0.19 mol) in THF (200 ml), and the mixture was refluxed for 16 h under stirring. A similar treatment of the reaction mixture gave 32 g (67%) of **4**, mp 90—91 °C.

Reaction of **4** *with Butyllithium*. A typical procedure is as follows.

Butyllithium (3.0 mmol) in hexane (2 ml) was added to a solution of **4** (0.425 g, 0.83 mmol) in THF (15 ml) at —78 °C, and the mixture was stirred for 15 min. After addition of methyl iodide (1 ml), the reaction mixture was subjected to DCC (SiO_2, CCl_4) to give methyl diphenylphosphinodithioate (0.36 g, 85%) and bis(butylthio)methane (0.16 g, 99%); NMR (CCl_4): δ 0.91 (t, J_{HH}=6 Hz, 6H, 2Me), 1.53 (m, 8H, $4CH_2$), 2.63 (t, J_{HH}=7 Hz, 4H, $2SCH_2$), and 3.68 (s, 2H, S–CH_2–S).

One-Pot Synthesis of 1,1-Bis(phenylthio)ethane from **4**. To a solution of **4** (1.14 g, 2.2 mmol) in THF (20 ml) was added phenyllithium (10 mmol) in ether (10 ml) at −78 °C and the mixture was stirred at this temperature for 30 min. After addition of methyl iodide (0.7 ml, 10 mmol) at 0 °C, the mixture was stirred for 20 min and subjected to DCC (SiO_2, CCl_4) to give 1,1-bis(phenylthio)ethane (0.21 g, 41%); NMR (CCl_4): δ 1.68 (d, J=7 Hz, 3H, $CHC\underline{H}_3$), 4.62 (q, J=7 Hz, 1H, C$\underline{H}$Me), and 7.20—7.60 (m, 10H, 2Ph), and methyl phenyl sulfide (50 mg).

Reactions of Phenylsodium. *1) With Methyl Diphenylphosphinoditioate*: Phenylsodium (8 mmol) in THF (3 ml) was added to a solution of the ester (0.54 g, 2.0 mmol) in THF (15 ml) and the mixture was stirred at room temperature for 1 h. After addition of methanol, the reaction mixture was evaporated and analyzed by GLC. The yield of methyl phenyl sulfide was 67%.

2) With Phenyl Diphenylphosphinoditioate: Phenylsodium (8 mmol) in THF (3 ml) was added to a solution of the ester (0.49 g, 1.5 mmol) in THF (15 ml) and the mixture was stirred at room temperature for 1 h. After addition of methanol, diphenyl sulfide (0.23 g, 82%) was isolated from the reaction mixture by DCC (SiO_2, $CHCl_3$, and then SiO_2, CCl_4).

The Template-directed Synthesis of Oligonucleotide. II.[1] The Interactive Properties of Nucleic Acid Base-binding Poly(4-vinylpyridine) and Its Related Compound with Nucleotides

Takeo SHIMIDZU,* Akira MURAKAMI, Yoshiyuki KONISHI, and Manabu MINAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received June 11, 1977)

The interactive properties of positively charged polynucleotide analogs, such as nucleic acid base-binding poly(4-vinylpyridine)s and their derivatives, with nucleotides have been investigated. The interactions of the positively charged polynucleotide analogs such as *N*-alkylated poly(4-vinylpyridine)s with 9-(ω-chloroalkyl)adenine and of *N*-alkylated poly(4-vinylpyridine) with 1-(2-bromoethyl)thymine with nucleotides were attributed predominantly to a base-base stacking under reinforcement by the coulombic attractive force. The purine-purine base interaction was found to be stronger than the purine-pyrimidine and the pyrimidine-pyrimidine interactions. The interaction was reduced by an increase in the ionic strength. The higher the charge density of the nucleotide was, the stronger was the interaction observed. On the other hand, a cross-linked positively charged polynucleotide analog such as *N*-alkylated cross-linked poly(4-vinylpyridine) with 9-(2-chloroethyl)adenine showed considerable selective interaction with the complementary nucleotide, uridine-5′-phosphate (pU), in both aqueous and pyridine solutions.

Various kinds of polynucleotide analogs have been prepared by the literature procedures.[2–12] Template-directed syntheses of oligonucleotide have also been attempted using neutral polynucleotide analogs such as poly(1-vinyluracil)[13] and oligonucleotide whose phosphoric acid moiety was blocked.[1] In general, interactions between the condensing nucleotide and the polynucleotide analogs are not very strong except for the interaction between the nucleotide and the polynucleotide analog with a positive charge. The polynucleotide analog with a positive charge is noteworthy for its coulombic interactive force with the condensing nucleotide. One of the polynucleotide analogs with a positive charge has been materialized by Okubo and Ise with poly(4-vinylpyridine) *N*-alkylated with a halogenoalkylated nucleic acid base;[14,15] they have also reported a noteworthy study of the interactions with polynucleotide and a nucleic acid base. The contribution of the coulombic force to the interaction is remarkable. However, the base-base stacking takes place predominantly in the interaction.

On the template-directed condensation of nucleotide, the most essential requirement for the template is a selective interaction between the template molecule and the condensing nucleotide. In this paper, we will describe our studies of the interactive properties of nucleotides with nucleic acid base binding poly(4-vinylpyridine)s and their derivatives.

Results and Discussion

Nucleic acid base-binding poly(4-vinylpyridine)s were synthesized by the alkylation of poly(4-vinylpyridine) with the halogenoalkyl derivatives of nucleic acid bases. The nucleic acid base-binding poly(4-vinylpyridine)s and their related compounds adopted in the present paper are shown on the right.

The polymers, nucleic acid base-binding poly(4-vinylpyridine)s (PVP)–C$_l'$–Ade$_n$ and (PVP)–C$_l'$–Thy$_n$ and their related compounds, were soluble in water and interacted with nucleotides. The solution of the nucleic acid base-binding poly(4-vinylpyridine) followed Beer's law in the range from 10^{-5} mol/dm^3 to 8×10^{-4} mol/dm^3. No conformational change which affects an intramolecular base-base interaction occurred in the present concentration range.

For example, the mixing curve of (PVP)–C$_2'$–Ade$_{48}$ and adenosine-5′-phosphate, pA, is shown in Fig. 1. The hypochromicity was calculated at the wavelength where the differences in the UV absorbances of the solu-

a) Disodium salts of nucleotides were used. b) This shows the ratio of the polynucleotide analog and nucleotide where the maximum hypochromicity was given. c) This shows the wavelength where the hypochromicity was calculated. d) Concentration shows the total concentration of nucleic acid bases in the mixture.

tion mixtures were most extended. However, the magnitude of the hypochromicity was effectively the same as that observed at 260 nm. The hypochromicity is seen as resulting from interaction between the nucleic acid bases of two molecules. In the present paper, the maximum hypochromicities are listed in the Tables. The maximum hypochromicities were not given at a 1 : 1 molar ratio of those two molecules.

Tables 1 and 2 show the maximum hypochromicities in the mixing curves of (PVP)–C_l'–Ade_n and nucleoside, (PVP)–C_l'–Thy_n and nucleoside, (PVP)–C_l'–Ade_n and nucleotide, and (PVP)–C_l'–Thy_n and nucleotide. Polynucleotide analogs, such as (PVP)–C_l'–Ade_n (l=2, 3, 4, 6) and (PVP)–C_l'–Thy_n (l=2), had a stronger interaction with a purine base than with a pyrimidine base. This tendency is similar to the result which was obtained by Okubo *et al.*[15] in the cases of the interactions of the nucleic acid base-binding poly(4-vinylpyridine) both with polynucleotide and with a nucleic acid base. It was also observed that the interaction of the poly-

nucleotide analog with nucleotide was stronger than that with nucleoside. On the interaction of the polynucleotide analog with adenosine triphosphate, ATP, a precipitation took place. Generally, a UV hypochromicity is not observed in mixtures of polynucleotide and nucleotide in the present concentration range. Such a stronger interaction suggests a dominant contribution of a coulombic force in the interaction between a polynucleotide analog with a positive charge and a nucleotide with a negative charge. Even in the case of the interaction of the polynucleotide analog with nucleoside, no repulsive coulombic force takes place. In neither cases was the quantitative ratio of the bases in the interaction, which was shown as the ratio at the maximum hypochromicity being given, always unity. This fact shows that the hydrogen-bond formation between complementary bases is not main force participating in the intermolecular interactions of the bases; rather, it suggests that a hydrophobic interaction is overwhelming. The influence of the side-chain length of the polynucleotide analog, (PVP)-C_l'-Ade_n, in the interaction between (PVP)-C_l'-Ade_n and nucleotide was not obvious where the length, l was below 6.

Table 3 shows the pH dependence of the interaction of (PVP)-C_2'-Ade_{48} with adenosine-5'-phosphate, pA. A decrease of the pH of the solution made the maximum hypochromicity decrease. This result can be explained as follows; the lower pH makes the dissociation of the phosphate group in the nucleotide, pA, decrease and the amino group in the adenine moiety protonate, followed by a repulsion between the positively charged amino group and the positively charged (PVP)-C_2'-Ade_{48} upon the interaction.

In general, the addition of salt to the solution reduces the coulombic interaction of charged molecules. Figure 2 shows the influence of KCl added to the solution of the maximum hypochromicity of the (PVP)-C_2'-Thy_{100}-pA mixture. An increase in the ionic strength made the hypochromicity decrease. This shows that the interaction between the polynucleotide analog and nucleotide is governed by the coulombic attractive force.

Table 4 shows the maximum hypochromicity in the mixing curve of (PVP)-C_3'-CH_3 and nucleotide. In the case of (PVP)-C_3'-CH_3-monoculeotide, the magnitude of the hypochromicity was low. This result indicates that the interaction among the nucleotides which are concentrated in the vicinity of the positively charged polynucleotide analog can scarecely be evaluated. The result also shows that it is not necessary to take the interaction between the pyridinium moiety and the nucleotide into account in considering the hypochromicity. On the other hand, the certain magnitude of the hypochromicity for (PVP)-C_3'-CH_3 and ATP suggests that there exists a stacking among the ATPs concentrated at the cationic (PVP)-C_3'-CH_3. The distinction between the nucleotides and the ATP may be due to the charge density following its concentration.

The monomeric analogs of such polynucleotide analogs as Py-C_2'-Ade and Py-C_2'-Thy all have a single cationic charge. Table 5 shows the muximum hypochromicity in the mixing curve of the monomeric analogs and the nucleotides. The hypochromicity was not observed in the single-single charge system, although the two species were oppositely charged. On the other hand, a definite interaction between the monomeric

analogs and ATP, which has a multi-charge, was observed. This result suggests that an effective interaction requires the charge of one interactive species to be more than unity, at least.

The nucleic acid base-binding cross-linked poly(4-vinylpyridine) such as [PVP]$_2$–C_2′–Ade$_{61}$ was synthesized by the reaction of 9-(2-chloroethyl)adenine and poly(4-vinylpyridine), which had been cross-linked by divinylbenzene. Tables 6 and 7 show the adsorptions of nucleotides on [PVP]$_2$–C_2′–Ade$_{61}$ in water and in pyridine, respectively. Compared with the above-described water-soluble polynucleotide analogs such as (PVP)–C_l'–Ade$_n$ and (PVP)–C_l'–Thy$_n$, the [PVP]$_2$–C_2′–Ade$_{61}$ had a considerable tendency to interact with the complementary nucleotide. In both solvent systems, the total amount of the adsorbed nucleotides on the [PVP]$_2$–C_l'–Ade$_{61}$ was constant, independent of the kind of nucleotide. That is, the total amount of the nucleotide adsorbed depended on the total number of charges in the [PVP]$_2$–C_2′–Ade$_{61}$. The selectivity in the adsorption as the complementary interaction rose and appeared to be marginal when more than one nucleotides were used. The order of the addition of the nucleotide did not affect the selectivity in the adsorption. This means that the adsorption is reversible. The occurrence of the considerable complementary base-base interaction in this case is important in connection with the template molecule in the template-directed synthesis of oligonucleotide. The formation of the cross-linked structure is preferable to the complementary base-base interaction, though it gives a heterogeneous reaction system. It is though that a matrix which is formed by the cross-linked structure is advantageous for the stability of the hydrogen-bond formation. The adsorbed nucleotide can be eluted with a concentrated salt solution. These properties suggest that the nucleic acid base-binding cross-linked poly(4-vinylpyridine) is useful for the template-directed synthesis of oligonucleotide and for affinity chromatography.

Experimental

UV Measurements. Standardized solutions of the polynucleotide analogs, nucleotides, their analogs, and nucleosides were mixed in varying proportions. The solutions were not buffered. The mixtures were stored for periods of up to 6 h at 5 °C, until no further optical density change occurred. UV measurements were then carried out on Hitachi EPS-3T spectrophotometer at 15 °C. The hypochromicity was calculated according to the following equation:[18)]

$$\text{Hypochromicity } (\%) = \left(1-\frac{I_{a+b}}{mI_a+nI_b}\right)\times 100,$$

where m and n are the volume fractions of the a and b solutions and where I_a, I_b, and I_{a+b} are the absorbances of solutions of the a, the b, and the mixture solution, respectively.

Alkylating Reagents. 9-(2-Chloroethyl)adenine was synthesized by a literature procedure.[16)]

All the 9-(ω-chloroalkyl)adenines except 9-(2-chloroethyl)-adenine were synthesized by a literature procedure.[17)]

1-(2-Bromoethyl)thymine was synthesized by a modification of the procedure of Ueda *et al.*[16)] A mixture of 31.6 g (0.19 mol) of 1-(2-hydroxyethyl)thymine and 126 g (0.61 mol) of thionyl bromide, plus a few drops of pyridine, was heated under reflux for 45 min. Then the excess thionyl bromide was removed under reduced pressure, and the remainder was washed with water. The residual solid was extracted with chloroform in a Soxleht extractor. A white, powdery 1-(2-bromoethyl)thymine was obtained from the chloroform solution (18.1 g, 41 %); IR(KBr): 3000, 2330, 1710, 1663, 1360, 1280, 900, 515 cm^{-1}; R_f (2-propanol : concn NH_4OH : H_2O = 7 : 1 : 2, Whatman 3MM) : 0.72; Found: C, 35.57; H, 3.79; N, 11.94; Br, 32.13%. Calcd for $C_7H_9N_2O_2Br$: C, 36.07; H, 3.89; N, 12.02; Br, 34.29%.

Polynucleotide Analogs, (PVP)–C_l'–Ade$_n$ and (PVP)–C_l'–Thy$_n$. The alkylations of poly(4-vinylpyridine) were carried out using the corresponding ω-halogenoalkylated nucleic acid bases mentioned above, according to a literature procedure.[14)] The degree of alkylation was estimated by means of elementary analysis. The results are tabulated in Table 8.

Cross-linked Polynucleotide Analog, [PVP]$_2$–C_2'–Ade$_{61}$. Freshly distilled 4-vinylpyridine and 1.5 mol% of divinylbenzene (55% solution of ethylbenzene) were placed in a flask with a few seeds of cross-linked polystyrene. After the reaction mixture has then been kept at 60 °C for 1 day, a faint coral-reddish, porous popcorn polymer was obtained. The polymer was ground and thoroughly washed with ethanol. The degree of the cross-linkage was calculated to be 2 % by means of the C/N ratio in the elementary analysis (Found: C, 79.81; H, 7.27; N, 12.92%).

Two grams of the resulting polymer, 4.0 g of 9-(2-chloro-

Table 8. Results of the alkylation of poly(4-vinylpyridine) with halogenoalkylated nucleic acid bases

Alkylating reagent g		DMF cm³	Time h	Degree of alkylation %	λ_{max} nm
9-(2-Chloroethyl)adenine	1.0	1.5	73	48	261
9-(2-Chloroethyl)adenine	1.5	2.0	72	52	261
1-(2-Bromoethyl)thymine	11.8	10.8	72	100	267
9-(3-Chloropropyl)adenine	1.7	2.0	72	56	261
9-(4-Chlorobutyl)adenine	2.0	2.5	70	39	261
9-(6-Chlorohexyl)adenine	2.0	2.5	85	47	261

Poly(4-vinylpyridine) 0.5 g was used. React. temp, 95—100 °C. Products were washed with alcohol and ether, until no ultraviolet absorption was observed in the washings.

ethyl)adenine, and 7 cm³ of DMF were placed in a sealed bottle, and the mixture was heated at 80 °C with stirring for a week. The resulting material was thoroughly washed with hot ethanol and water. The degree of alkylation was calculated to be 63 % (*cf.* the pyridine moiety in the polymer) by the change in the C/N ratio in the elementary analysis from that of the starting polymer (Found: C, 60.50; H, 5.62; N, 24.59, Cl, 9.29%).

Poly(1-butyl-4-vinylpyridinium bromide), (PVP)–C_3'–CH_3.

Twenty-six cm³ of 4-vinylpyridine and 32 cm³ of butyl bromide were dissolved in 100 cm³ of benzene, and the mixture was heated at 50 °C with stirring for 115 h. A reddish violet solution resulted. The benzene was then removed, and the residue was dissolved in water, followed by dialysis. The resulting solution was lyophilized. A hygroscopic, faint yellow, powdery product was thus obtained (11.2 g).

1-[2-(Adenin-9-yl)ethyl]pyridinium Chloride, Py–C_2'–Ade.

In 2 cm³ of a freshly distilled pyridine, 0.11 g of 9-(2-chloroethyl)adenine was dissolved. The mixture was sealed under nitrogen and then heated in boiling water for 68 h. A white precipitate was filtered, washed with ethyl acetate, and then dried (46 mg); mp 290—291 °C, $\lambda_{max}^{H_2O}$, 260 nm; $\varepsilon_{max}^{H_2O}$, 1.63×10^4; Found: C, 52.16; H, 4.90; N, 30.30; Cl, 12.69%. Calcd for $C_{12}H_{13}N_6Cl$: C,52.08; H,4.74; N,30.37; Cl,12.81%.

1-[2-(Thymin-1-yl)ethyl]pyridinium Chloride, Py–C_2'–Thy.

In 5 cm³ of freshly distilled pyridine, 1.0 g of 1-(2-chloroethyl)thymine was dissolved. The mixture was then refluxed on a steam bath for 5 h. A white needle crystal was obtained after cooling. It was washed with ethanol and then dried (230 mg): $\lambda_{max}^{H_2O}$, 266 nm; $\varepsilon_{max}^{H_2O}$, 1.3×10^4; Found: C, 52.33; H, 5.34; N, 15.14; Cl, 13.15%. Calcd for $C_{12}H_{14}N_3O_2Cl$: C, 53.84; H, 5.27; N, 15.70; Cl, 13.24%.

Adosorption. One half mmol of nucleotide was dissolved in a certain amount of water and then placed on 100 mg (2.5×10^{-4} mol equiv) of the [PVP]$_2$–C_2'–Ade$_{61}$. The adsorption of the nucleotide on the [PVP]$_2$–C_2'–Ade$_{61}$ was completed within 1 h, with stirring. The whole mixture was then placed in a column whose inner diameter was 2 mm. Then the column was washed by the addition, drop by drop, of 20 cm³ of water for a 10 min period. The content of the nucleotide in the effluent was analyzed by paper chromatography and by liquid chromatography (Shimadzu-Dupont 830, Permaphase AAX). From the composition of the nucleotides in the effluents, the amounts of nucleotides adsorbed on the [PVP]$_2$–C_2'–Ade$_{61}$ were calculated. For the experiment in the pyridine-solution system, the pyridinium form of the nucleotides was used, and pyridine was used as the effluent in lieu of water. Before analysis, the pyridine was evaporated; the residue was dissolved in water and then analyzed.

The authors are indebted to Professor K. Fukui for his encouragement and to Mr. H. Azuma and Mr. Y. Yonehara for their technical assistances. The present work was supported by a Grant-in-Aid from the Ministry of Education.

Regioselective, Abnormal Ring Opening of the Epoxide of Quinone Epoxide-Cyclopentadiene Adducts

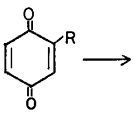
Akitami ICHIHARA, Makio KOBAYASHI, Kengo ODA, and Sadao SAKAMURA

Department of Agricultural Chemistry, Faculty of Agriculture, Hokkaido University, Sapporo 060

(Received June 28, 1977)

Treatment of quinone epoxide-cyclopentadiene adducts with sulfuric acid gave abnormal ring opening products, whose structures were determined by the spectral data and identification of the degradation product. Regioselectivity of the reaction was confirmed. The mechanism of the reaction is discussed.

In the course of the synthetic studies of highly oxygenated cyclohexane derivatives,[1] it was needed to prepare compound **5** which would be served as a pertinent intermediate for the synthesis of crotepoxide[2] and senepoxide.[3] For this purpose, a derivative **3a** which was obtained by epoxidation of the benzoate **2d** of Diels-Alder adduct **2a** from cyclopentadiene and 2-(hydroxymethyl)-1,4-benzoquinone **1a** was prepared. The stereochemistry of **3a** was deduced from analogy and the spectral similarity with those of **3b** and **3c**, whose stereo-



1a R=CH_2OH

6 **7**

structure has been unequivocally established.[4] Treatment of the epoxide **3a** with various acids yielded only complex mixtures resulting from polymerization and decomposition. However, when the epoxide **3a** was treated with acetic acid–sulfuric acid (10:1 v/v) at 25 °C for 3 days, an unknown product, $C_{21}H_{18}O_6$, was obtained. The infrared spectrum showed absorption bands at 1728 cm^{-1} due to acetoxy carbonyl group and at 1673 cm^{-1} attributed to enedione carbonyl and benzoyl carbonyl groups. In the PMR spectrum (Table 1), a signal at δ 6.65 (1H, t) due to a β-olefinic proton of enedione moiety and a signal at δ 2.04 (3H, s) due to an acetate methyl group were observed. Epoxidation of **4a** with hydrogen peroxide in alkaline solution gave, with loss of acetic acid, a diepoxide **6**, whose structure was supported by elemental analysis, $C_{19}H_{14}O_6$, and the spectral data. From these observations **4a** or **7** was deduced for the product as possible structures. At this stage, however, it was difficult to decide the correct structure on the basis of spectral data. In order to confirm the structure, further investigation was carried out on the adduct **3b** of toluquinone epoxide, since the quinone **1b** is easily available and retro Diels-Alder reaction of the product **4b** would yield known compound, 5-acetoxytoluquinone. Thus, the epoxide **3b** was prepared and treated with sulfuric acid in acetic acid at 25 °C for 3 days in the same manner. The resultant product, $C_{14}H_{12}O_4$, exhibited absorption bands at 1733 cm^{-1} ascribable to acetate carbonyl group and at 1688 cm^{-1} due to enedione system in the IR spectrum. In the PMR spectrum (Table 1), signals at δ 2.02 due to acetoxy methyl group and at δ 6.52 due to a vinylic proton in enedione moiety were observed. These data are certainly in accord with the structure of the abnormal ring opening product. In order to confirm the correct structure, retro Diels-Alder reaction was carried out by heating the compound **4b** at 350 °C under an atmosphere of nitrogen to give a product, mp 72—73 °C, whose structure is compatible to an acetoxyquinone. Since the location of the acetoxyl group was still not obvious, the acetoxyquinone was reduced with lithium aluminum hydride to yield a 1,2,4-benzenetriol. The PMR spectrum exhibited two signals at δ 6.38 and 6.56 as singlets, which indicate that these protons are located in a *para* position and the structure was deduced to be 5-methyl-1,2,4-benzenetriol. This means that the abnormal reaction product must be **4b**. Conclusive result was obtained by the direct comparison of the acetoxyquinone with an authentic sample, 2-acetoxy-1,4-benzoquinone, which was prepared according to the known procedure.[5] The sample thus prepared was identical with thermally decomposed product of **4b** in all respects. Accordingly, the structure of the abnormal reaction product was unambiguously identified as **4b**. The stereochemistry of **4b** was assigned to have the *endo*-configuration on the basis of following facts. Since in those compounds having *endo*-structure with 4a-substituent, the H-8a appears as a doublet with a coupling constant of 3 to 4Hz,[4] the signal at δ 2.95 with a coupling constant,

Table 1. PMR Spectra of abnormal ring cleavage products

PMR (δ) in $CDCl_3$

4 R	H-9	$OCCH_3$ (O)	H-8a	H-8	H-5	H-6,7	H-3	R
CH_2OCOPh (**4a**)	1.70 1.90 ABq J=9 Hz	2.04 s	2.98 d J=4 Hz	3.28 br s	3.41 br s	5.94, d d J=3 and 6 Hz 6.20, d d J=3 and 6 Hz	6.65 t J=2 Hz	5.07 d, J=2 Hz 8.03 7.42, J=5 Hz
CH_3(**4b**)	1.66 1.87 ABq J= 9Hz	2.02 s	2.95 d J=4 Hz	3.26 br s	3.46 br s	5.93, d d J=3 and 6 Hz 6.14, d d	6.52 q J=1.5 Hz	1.88 d J=1.5 Hz

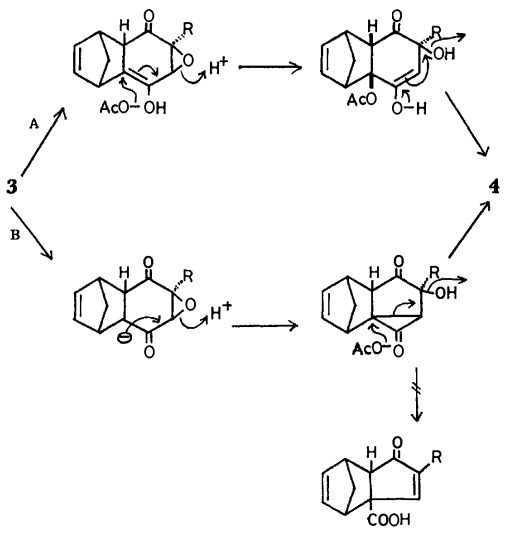
J=4Hz, in **4b** is also consistent with the *endo*-assignment. The structure of **4a** (**4c** and **4d**) was deduced from the PMR spectrum which shows similar spectral pattern with that of **4b** (Table 1).

For the purpose to investigate generality of this reaction, two more compounds, **3c** and **3d**, were prepared from **1c** and **1d** respectively and treated with sulfuric acid under the same conditions to yield analogous compounds, **4c** and **4d**. The PMR spectral data of the abnormal ring opening products are summarized in Table 1.

The results mentioned above are of quite interest since in the case of substituted quinone epoxide adducts (**3a**, **3b**, and **3d**), all of the reactions proceeded regioselectively to give **4a**, **4b**, and **4d**.

Finally, the mechanism of the abnormal reaction was presumed as follow. Ring contraction of piperitone epoxide, an α-epoxy ketone, under basic conditions was reported, for which Favorskii type mechanism was postulated.[6] On the other hand, in the reaction of a steroid α-epoxy ketone with acids, another plausible mechanism which involves an enol intermediate was suggested.[7] Since extremely strained structure resulted from Favorskii type reaction (path B in Scheme 1) excludes the possibility involving cyclopropanone intermediate and in fact, none of the compounds as **i** derived *via* the intermediate was obtained, enol intermediate (path A) might be involved in the present reaction as shown in Scheme 1. From the mechanistic point of view, it is interesting to note that another possible product **7** had not been recognized in the reaction.



i

Scheme 1.

The abnormal ring opening reaction would be useful for the synthesis of some 2-acetoxy-1,4-benzoquinones *via* retro Diels-Alder reaction.

Experimental

All melting points were uncorrected. The IR spectra were taken on a Hitachi EPI-S2 Spectrophotometer and the PMR spectra were measured with a Hitachi R-22 Spectrometer (90MHz), using tetramethylsilane as an internal standard.

*2-(Hydroxymethyl)-1,4-benzoquinone (**1a**).* This compound was prepared according to the known procedure involving oxidation of 2,5-dihydroxybenzyl alcohol with lead tertaacetate.[8]

endo-*2-Hydroxymethyl-5,8-methano-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (**2a**).* A solution of 1.5 g of the benzoquinone **1a** and 2 ml of cyclopentadiene in 6 ml of methanol was allowed to stand until the spot of the starting material disappeared on TLC. The reaction mixture was concentrated *in vacuo* to give a residue, which was recrystallized from benzene to yield pure **2a**, mp 65—66 °C; IR ν_{max}^{KBr} 1653, 3530 cm^{-1}; PMR ($CDCl_3$) δ 1.42 (2H, m, CH_2), 3.10 (2H, br s, $=CH$), 6.52 (1H, t, J=3Hz, $=CH$). Found: C, 70.72; H, 5.95%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; 5.92%.

endo-*2-(Benzoyloxymethyl)-5,8-methano-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (**2d**).* A solution of 2.1 g of the adduct and 1.6 ml of benzoyl chloride in 10 ml of pyridine was allowed to stand at room temperature. The reaction mixture was washed with water and organic layer was separated. The water layer was extracted twice with benzene and the combined extracts were dried over anhydrous sodium sulfate and concentrated. The resultant crystals were recrystallized from

benzene to give 2.86 g of the benzoate, mp 147—148 °C; IR ν_{max}^{KBr} 1723, 1664, 1636, 1600 cm^{-1}; PMR ($CDCl_3$) δ 1.34—1.58 (2H, m, CH_2), 3.22 (2H, m, CH), 3.52 (2H, br s, -CH), 5.08 (2H, d, J=2Hz, CH_2), 6.06 (2H, t, J=2Hz, =CH), 6.60 (1H, t, J=2Hz, =CH), 7.33—7.59 (3H, m, ArH), 8.03 (2H, dd, J=2Hz, J=8Hz, ArH). Found: C, 73.79; H, 5.17%. Calcd for $C_{19}H_{16}O_4$: C, 74.01; H, 5.23%.

*r-2-(Benzoyloxymethyl)-2,3-epoxy-t-5,8-methano-2,c-3,t-4a,5,8,t-8a-hexahydro-1,4-naphthoquinone (**3a**).* A mixture of 100 mg of the benzoate **2d** and 2 ml of solution made from 25 ml of hydrogen peroxide (30%) and 5 g of sodium carbonate in 125 ml of water was allowed to stand for *ca.* 40 min. The reaction mixture was extracted with benzene and the combined extracts were dried on anhydrous sodium sulfate. Removal of the solvent gave 66 mg of crystals which were recrystallized from benzene to yield the pure epoxide **3a**, mp 139—140 °C; IR ν_{max}^{KBr} 1715, 1600 cm^{-1}; PMR ($CDCl_3$) δ 1.22, 1.44 (2H, ABq, J=8Hz, CH_2), 3.25 (2H, br s, CH), 3.38 (2H, br s, CH), 3.52 (1H, s, COCH), 4.82, 4.54 (2H, ABq, J=13Hz, CH_2), 6.00 (2H, t, J=2Hz, =CH), 7.20—7.49 (3H, m, ArH), 7.90 (2H, dd, J=8Hz, J=2Hz, ArH); MS *m/e* 324 (M^+). Found: C, 70.21; H, 4.97%. Calcd for $C_{19}H_{16}O_5$: C, 70.36; H, 4.98%.

*endo-4a-Acetoxy-2-(benzoyloxymenthyl)-5,8-methano-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (**4a**).* To a solution of 139.7 mg of the epoxide **3a** in 2 ml of acetic acid was added a mixture of 2.2 ml of sulfuric acid-acetic acid (1 : 10 v/v), and the mixture was stand for 3 days at 25 °C and the completion of the reaction was checked by TLC. The reaction mixture was extracted with chloroform and washed with water. The combined extracts were dried on anhydrous sodium sulfate and concentrated *in vacuo*. The residue was chromatographed on silicic acid and eluted with benzene-ethyl acetate (95 : 5 v/v) to give 34.5 mg of a crystalline material. The crude crystals were recrystallized from benzene to give a pure compound, **4a**, mp 166—167 °C. IR ν_{max}^{KBr} 1728, 1673, 1640 cm^{-1}; PMR spectra are cited on Table 1. MS *m/e* 367 (M^+ + 1). Found: C, 67.89; H, 4.75%. Calcd for $C_{21}H_{18}O_6$: C, 68.84; H, 4.95%.

*Epoxidation of **4a**.* To a solution of 546 mg of **4a** in 6 ml of tetrahydrofuran was added a mixture of 0.2 g of potassium carbonate and 1 ml of hydrogen peroxide (30%) in 5 ml of water. After 10 min, the reaction mixture was extracted with chloroform and the extracts were dried on anhydrous sodium sulfate and concentrated. The residue was chromatographed on 20 g of silicic acid using benzene-ethyl acetate (95 : 5 v/v) as eluent to give 82 mg **6** as crystals, mp 132—133 °C; IR ν_{max}^{KBr} 1732, 1704, 1604 cm^{-1}; PMR ($CDCl_3$) δ 1.47 (2H, m, CH_2), 3.23 (2H, m, CH), 3.65 (1H, s, COCH), 4.53, 4.76 (2H, ABq, J=13Hz, $-CH_2O$), 6.42 (2H, t, J=2Hz, =CH), 7.32—7.57 (3H, m, ArH), 7.92 (2H, dd, J=8Hz, 2Hz, ArH); MS *m/e* 338 (M^+). Found C, 67.53; H, 4.16%. Calcd for $C_{19}H_{14}O_6$: C, 67.45; H, 4.17%.

*2-Methyl-5,8-methano-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (**2b**).* This compound was prepared from toluquinone **1b** and cyclopentadiene in methanol heating at 50 °C for 4 h.[4] Mp 61—62.4 °C.

*r-2,3-Epoxy-2-methyl-c-5,8-methano-2,3,c-4a,5,8,c-8a-hexahydro-1,4-naphthoquinone (**3b**).* This compound was prepared in the same way used for the synthesis of **3a** starting from toluquinone.[4]

*endo-4a-Acetoxy-2-methyl-5,8-methano-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (**4b**).* To a solution of 8 g of the epoxide **3b** in 40 ml of acetic acid was added a mixture of 70 ml of acetic acid and 7 ml of sulfuric acid. After allowing to stand for two days at room temperature, the reaction mixture was extracted with chloroform and the extracts were concentrated *in vacuo* to give a residue which was chromatographed on silicic acid to yield 10 g of the product. Pure **4b** was obtained by recrystallization from benzene, mp 61—62 °C, IR ν_{max}^{KBr} 1733, 1668 cm^{-1}; PMR data, see Table 1. MS *m/e* 246 (M^+); Found: C 68.50; H, 6.00%, Calcd for $C_{14}H_{12}O_4$: C, 68.28; H, 5.73%.

5-Acetoxy-2-methyl-1,4-benzoquinone. A column packed with glass beads was evacuated from lower end of the column with an aspirator at 0.4 mmHg and heated at 350 °C. From the bottle equipped on the column, 100 mg of **4a** was dropped five times into the column, and after cooling, the reaction vessel was washed with chloroform to give a crude product, which was chromatographed on silicic acid using benzene-ethyl acetate (95 : 5 v/v) to yield 53 mg of 5-acetoxytoluquinone, mp 72—73.5 °C (lit,[5] 74.5—76 °C).

Reduction of 5-Acetoxy-2-methyl-1,4-benzoquinone. A mixture of 20 mg of the quinone in 7 ml of anhydrous ether and 17 mg of $LiAlH_4$ was refluxed for 2 h. To the reaction mixture was added ethyl acetate to decompose excess $LiAlH_4$, and then 10%-sulfuric acid to acidify. The mixture was extracted with ethyl acetate and the extracts were dried over anhydrous sodium sulfate, and evaporated *in vacuo* to give a residue. PMR ($CDCl_3$) δ 6.38 (1H, s, ArH), 6.55 (1H, s, ArH), 7.90—6.78 (3H, br, ArOH).

*endo-4a-Acetoxy-5,8-methano-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (**4c**).* The epoxide **3c** prepared from 1 g of *p*-benzoquinone (**1c**) according to the known procedure[5] was dissolved into 10 ml of acetic acid. To the solution was added a mixture of 3 ml of concd sulfuric acid and 30 ml of acetic acid. After allowing to stand for 3 days at room temperature, the reaction mixture was extracted with chloroform and the extracts were washed with brine and dried over anhydrous sodium sulfate, evaporated *in vacuo* to give a crude residue. The residue was chromatographed on silicic acid to give 600 mg of **4c**, mp 102—103 °C, IR ν_{max}^{KBr} 1736, 1683, 1671 cm^{-1}; PMR data (Table 1); MS *m/e* 232 (M^+). Found: C, 67.31; H, 5.34%. Calcd for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21%.

*r-2-(Acetoxymethyl)-2,3-epoxy-t-5,8-methano-2,c-3,t-4a,5,8,t-8a-hexahydro-1,4-naphthoquinone (**3d**).* A solution of 13 g of 3-(acetoxymethyl)-1,4-benzoquinone (**1d**) and 8 ml of cyclopentadiene was allowed to stand for 1 h at room temperature. The reaction mixture was concentrated *in vacuo*. To the residue dissolved into tetrahydrofuran was added 100 ml of hydrogen peroxide (30%) under ice-cooling. The mixture was heated at 55—60 °C for 1 h and then cooled at room temperature. After excess hydrogen peroxide had been decomposed with sodium bisulfite, the reaction mixture was extracted twice with benzene and the extracts were dried on anhydrous sodium sulfate and concentrated *in vacuo* to yield a product, which was recrystallized from benzene to give 3.07 g of the epoxide **3d**, mp 125—126 °C, IR ν_{max}^{KBr} 1725, 1260 cm^{-1}; PMR ($CDCl_3$) δ 1.27, 1.47 (2H, ABq, J=9Hz, CH_2), 2.02 (3H, s, $COCH_3$), 3.32 (2H, br s, CH), 3.49 (2H, br. s, CH), 3.54 (1H, s, COCH), 4.69, 4.31 (2H, ABq, J=13Hz, CH_2OAc), 6.09 (2H, t, J=2Hz, =CH); MS *m/e* 262 (M^+): Found C, 64.22; H, 5.39%. Calcd for $C_{14}H_{14}O_5$: C, 64.11; H, 5.38%.

*endo-4a-Acetoxy-2-(acetoxymethyl)-5,8-methano-4a,5,8,8a-tetrahydro-1,4-naphthoquinone (**4d**).* To a solution of 3.07 g of the epoxide **3d** in 10 ml of acetic acid was added a mixture of 6 ml of concd sulfuric acid and 60 ml of acetic acid, and the reaction mixture was allowed to stand for 3 days at room temperature and extracted with chloroform. The extracts

were washed with brine and dried on anhydrous sodium sulfate and concentrated *in vacuo*. The residue was chromatographed on silicic acid eluting with benzene-ethyl acetate (95 : 5 v/v) to yield 1 g of the product, **4d**, mp 102—103 °C. IR ν_{max}^{KBr} 1752, 1732, 1682 cm^{-1}; PMR data, see Table 1. MS *m/e* 304 (M^+). Found: C, 67.31; H, 5.34%. Calcd for $C_{16}H_{16}O_6$: C, 67.23; H, 5.21%.

Ligand Effects of 2,2′-Bipyridine in the Decomposition of 1,2,3,4-Tetrahydro-1-naphthyl Hydroperoxide Catalyzed by Cobalt(II) Salt

Teruaki YAMADA and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 28, 1977)

The ligand effect of 2,2′-bipyridine on the rate of the decomposition of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide catalyzed by cobalt(II) decanoate in chlorobenzene was kinetically studied and compared with the redox potentials and the spectral data of cobalt(II) complexes. The activity of the anhydrous cobalt(II) decanoate increased by a factor of from three to seven by the addition of 2,2′-bipyridine when the molar ratio of 2,2′-bipyridine to cobalt was 0.25 to 2. It was found that the catalytic activity of the anhydrous cobalt(II) decanoate–2,2′-bipyridine complex shows a remarkable maximum value at the molar ratio of 2,2′-bipyridine to cobalt of 0.5. This novel finding can be explained on the basis of the redox potential measured by cyclic voltammetry in dichloromethane, the IR data, and the structure of the catalyst. The coordination of 2,2′-bipyridine causes the redox potential to change from 0.80—0.84 V to 0.60—0.64 V (*vs.* SCE) and also weakens the Co–O(decanoate) bond strength, resulting in a facile coordination of hydroperoxide to the cobalt ion as well as the acceleration of cleavage of hydroperoxide. The maximum activity was explained by the proposed structure of the cobalt(II) decanoate–2,2′-bipyridine (1 : 1/2) complex with a fairly low redox potential and a vacant coordination site.

The metal-catalyzed decomposition of alkyl hydroperoxide is the most common pathway of catalysis by transition-metal complexes in the autoxidation reaction. A catalytic cycle is possible *via* the following reduction oxidation reaction by two valency-state metal ions:

$$ROOH + M^{(n-1)+} \longrightarrow RO\cdot + M^{n+} + OH^-$$

$$ROOH + M^{n+} \longrightarrow RO_2\cdot + M^{(n-1)+} + H^+$$

Many kinetic investigations[1] of metal-catalyzed decomposition have been undertaken, but many points about the role of the metal are still obscure. A "ligand-effect" investigation must be one of the most valid probes to elucidate the role of the metal and also to serve as a gateway to many applications. Although, in some works[2] dealing with the kinetics of autoxidation, the fact of the activation or deactivation of a metal catalyst by a chelating agent has been mentioned, no systematic study has yet been presented.

The ligand effect in autoxidation seems to depend on the kind of metal, ligand and solvent, but it is hard to explain it because of its complexity. The difficulties derived from its complexity will be clarified only by the quantitative investigation of each factor affecting the catalytic activity. Not only a kinetic but also a structural study is needed to clarify the reaction mechanism. In this paper, we will report the interesting ligand effect of 2,2′-bipyridine in the cobalt salt-catalyzed decomposition of hydroperoxide.

Experimental

Materials. Cobalt(II) decanoate ($CoDe_2$) was prepared according to the method of Heaton and Uri.[3] An aqueous solution of cobalt(II) sulfate was added to an aqueous solution of sodium decanoate. The resulting precipitate was washed with hot water and dried in two ways. The pink-colored catalyst, defined as the cobalt(II) decanoate (A) ($CoDe_2$(A)), was air-dried at room temperature. The other, blue-colored catalyst, defined as the cobalt(II) decanoate (B) ($CoDe_2$(B)), was obtained by drying under a vacuum at 70 °C for 5 h. Elemental analyses were carried out on both $CoDe_2$(A) and $CoDe_2$(B). Found: C, 54.6; H, 10.4%. Calcd for $CoDe_2$(A) [$Co(C_{10}H_{19}O_2)_2\cdot 2H_2O$]: C, 54.9; H, 10.0%. Found: C, 58.2; H, 10.0%. Calcd for $CoDe_2$(B) [$Co(C_{10}H_{19}O_2)_2$]: C, 59.8; H, 9.0%. 2,2′-Bipyridine (bpy) was further purified by recrystallization from heptane and dried under a vacuum at room temperature. Mixed solutions of cobalt(II) decanoate and 2,2′-bipyridine, a very strong chelating agents with a high stability constant,[4] were allowed to stand at room temperature for 15 h to equilibrate and then submitted to the reaction and other measurements. 1,2,3,4-Tetrahydro-1-naphthyl hydrperoxide (THP) was prepared by a modification of the conventional method.[5] After the autoxidation of 1,2,3,4-tetrahydronaphthalene (tetralin) initiated by azobisisobutyronitrile at 50 °C for 60 h, the oxidation products were concentrated by distillation under reduced pressure and then crystallized from a solution upon cooling to 0 °C. This crystal was recrystallized from heptane and then dried under a vacuum at room temperature. The purified hydroperoxide was confirmed to be 99.0% pure by iodometric titration. Dichloromethane was dried by calcium chloride and purified by repeated distillations. All the other chemicals were of a reagent grade.

Decomposition of THP. A 50-ml three-necked round-bottomed flask was filled with a solution (40 ml) containing a catalyst and maintained at the reaction temperature. Argon gas was introduced into the system to remove any dissolved oxygen. A solution of THP (10 ml) was prepared separately and heated to the reaction temperature. The reaction was started by the addition of all the THP solution. A certain portion of the solution (2 ml) was withdrawn from the reaction mixture at regular intervals and subjected to iodometric titration to determine the concentration of hydroperoxide. The decomposition products were analyzed by gas chromatography on a 3-m column packed with PEG-20M. The carrier gas was helium, and the column temperature was 200 °C.

Electrochemical and Spectral Measurements. Cyclic voltammetry was done using a potentiostat, a function generator, and a X-Y recorder. The electrode system consisted of a saturated calomel reference electrode (SCE), a platinum plate used as working electrode, and a platinum wire used as a counter electrode. Measurements were made at room temperature in a glass cell to which the reference electrode was connected with a double salt bridge. A solution of the complex (1—10 mM) was prepared by dissolving a weighed quantity in a measured volume of dichloromethane. As the supporting electrolyte tetrabutylammonium perchlorate was added to this solution, which was flushed with nitrogen for ten minutes prior to measurement. The visible and ultra-

violet spectra were obtained in chlorobenzene using a Hitachi-124 spectrophotometer. The infrared spectra were obtained by the Nujol method using a JASCO-IRA 2 spectrophotometer.

Results

Effects of 2,2'-Bipyridine in Chlorobenzene. The effect of 2,2'-bipyridine on the rate of the $CoDe_2$-catalyzed decomposition of THP in chlorobenzene is shown in Fig. 1. The rate of decomposition was increased by the addition of 2,2'-bipyridine. The $CoDe_2$(A)–bpy complexes showed a monotonous increase in their activity, but surprisingly, the $CoDe_2$(B)–bpy complexes showed a maximum activity at the molar ratio of [bpy]/[$CoDe_2$]=1/2. Both $CoDe_2$(A)–bpy and $CoDe_2$(B)–bpy complexes showed almost the same activity at ratios of [bpy]/[$CoDe_2$] higher than 1. Incidentally, the rate of the autoxidation of tetralin was increased by the addition of 2,2'-bipyridine and did not exceed

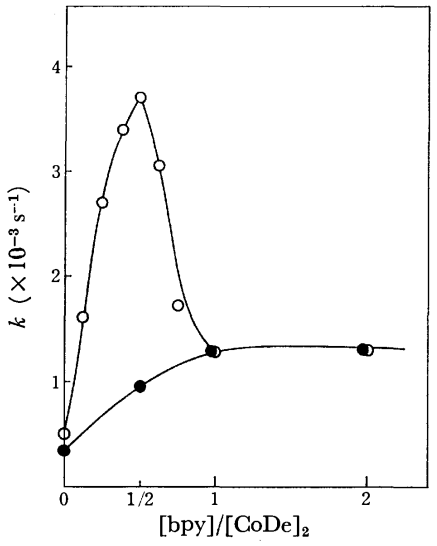

Fig. 1. Effect of 2,2'-biyridine on the rate of decomposition of THP catalyzed by $CoDe_2$ in chlorobenzene at 45 °C.
(-●-) $CoDe_2$(A), (-○-) $CoDe_2$(B), [$CoDe_2$]=2×10⁻⁴ M, [THP]=5×10⁻² M.

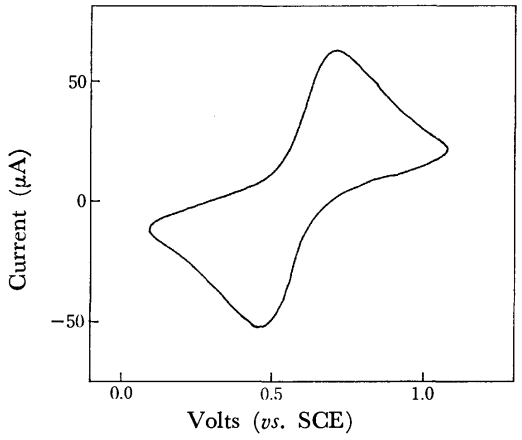

Fig. 2. Cyclic voltammogram of $CoDe_2$(B)-bpy(1:1) in dichloromethane.
Scan rate was 0.05 V/s.

Table 1. Comparison of the voltammetric data with the decomposition rates of THP for $CoDe_2$-bpy complexes

Complex	Electrode reaction	$E_{1/2}$, V	k, 10^{-3} s^{-1}
$CoDe_2$(B)	Co(II) − e → Co(III)	0.80	0.5
	Co(III) + e → Co(II)	0.84	
$CoDe_2$(B)-bpy(1 : 1/2)	Co(II) − e → Co(III)	0.67	3.7
	Co(III) + e → Co(II)	0.70	
$CoDe_2$(B)-bpy(1 : 1)	Co(II) − e → Co(III)	0.60	1.3
	Co(III) + e → Co(II)	0.63	
$CoDe_2$(B)-bpy(1 : 2)	Co(II) − e → Co(III)	0.59	1.3
	Co(III) + e → Co(II)	0.59	

Table 2. Infrared absorption bands and decomposition rates of THP for $CoDe_2$-bpy complexes

Complex	C–O st., cm^{-1}	k, ×10^{-3} s^{-1}
$CoDe_2$(B)	1550	0.5
$CoDe_2$(B)-bpy(1 : 1/2)	1570	3.7
$CoDe_2$(B)-bpy(1 : 1)	1590	1.3
$CoDe_2$(B)-bpy(1 : 2)	1595	1.3

the limiting rate. A large excess of 2,2'-bipyridine, one hundred times the quantity of $CoDe_2$(B), decreased the decomposition rate to half the value of $CoDe_2$(B) alone.

The redox potentials of the $CoDe_2$(B)–bpy complexes, the determining factor for the activity of a catalyst in the redox reaction, were measured by cyclic voltammetry in dichloromethane. Table 1 shows the values of the redox potential and the decomposition rates for $CoDe_2$(B)–bpy complexes. The redox potential was shifted in the negative direction by the coordination of 2,2'-bipyridine. This shows that the reductive force of a cobalt(II) ion or the electron density on a cobalt(II) ion is increased by the coordination of 2,2'-bipyridine. Figure 2 shows the reversible change in the potential for anodic and cathodic sweeps of the Co(II)-Co(III) couple as established by cyclic voltammetry.

Table 2 shows the C–O stretching absorptions of the decanoate ligands of $CoDe_2$(B)–bpy complexes. The absorption peak shifts to a higher wave number with an increase in the amount of 2,2'-bipyridine added. This shows the increase in the double-bond character in the C–O bond. The C-T bands and d-d bands measured on $CoDe_2$(A)–bpy, and $CoDe_2$(B)–bpy complexes are shown in Table 3. The C-T band shifted to a longer wavelength, and the d-d band, to a shorter are, upon the addition of 2,2'-bipyridine. Both $CoDe_2$(A)–bpy and $CoDe_2$(B)–bpy complexes have shown the same absorption band at the [bpy]/[$CoDe_2$] ratios of both 1 and 2.

As is shown in Fig. 3, product analysis[6] showed that the ratio of [C]/([C]+[D]) was about 0.29 for the $CoDe_2$(B) complex and about 0.39—0.45 for the $CoDe_2$(B)–bpy complexes; C and D are 1,2,3,4-tetrahydro-1-naphthol (α-tetralol) and 1,2,3,4-tetrahydro-1-naphthalenone (α-tetralone) respectively. The ratio of α-tetralol to α-tetralone was independent of the metal or hydroperoxide concentration.

TABLE 3. ULTRAVIOLET AND VISIBLE ABSORPTION BANDS OF $CoDe_2$-bpy COMPLEXES

Complex	d-d band, nm (ε, $1\,mol^{-1}\,cm^{-1}$)		C-T band, nm (ε, $1\,mol^{-1}\,cm^{-1}$)

$CoDe_2$(B)-(4,4′-dimethyl-2,2′-bipuinoline)	6.5

[bipyridine derivative]/$[CoDe_2]=2$,
$[CoDe_2]=2\times10^{-4}$ M, $[THP]=5\times10^{-2}$ M.

Table 4 shows the catalytic activities of the $CoDe_2$(B)–bipyridine derivative complexes. These results show that the activity of a catalyst increases with an increase in the electron-donating property of the ligand; this supports the proposition that the increase in the electron density of the cobalt(II) ion causes an increase in the catalytic activity. The deviation of 6,6′-dimethyl-2,2′-bipyridine can be ascribed to the steric hindrance to the coordination to the cobalt(II) ion.

Effects of 2,2′-Bipyridine in Acids. Figure 4 shows the effect of 2,2′-bipyridine on the rate of the cobalt(II) acetate ($Co(OAc)_2$)-catalyzed decomposition of THP in acetic acid. Unlike the case of the decomposition in chlorobenzene, the decomposition rate in acetic acid decreased with an increase in the amount of 2,2′-bipyridine added. Similar reactions were carried out in various acid solvents as is shown in Table 5. The decomposition rate was decreased by the addition of 2,2′-bipyridine to all the solvents, suggesting that the inhibitive effect of 2,2′-bipyridine is independent of the strength of acids.

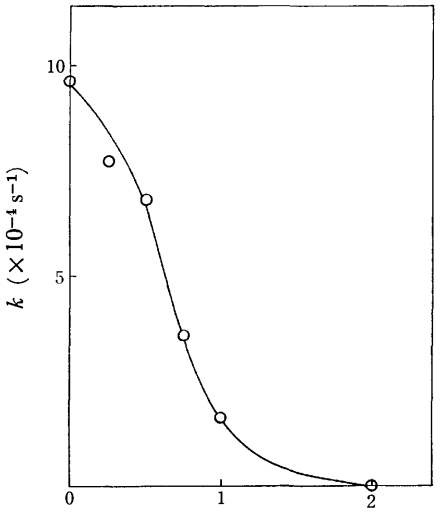

Fig. 4. Effect of 2,2′-bipyridine on the rate of decomposition of THP catalyzed by $Co(OAc)_2$ in acetic acid at 50 °C.
$[Co(OAc)_2]=10^{-3}$ M, $[THP]=5\times10^{-2}$ M.

TABLE 5. DECOMPOSITION RATE OF THP IN FATTY ACIDS[a]

a) k and k_2 are pseudo-first-order rate constants of the THP decomposition reactions by 10^{-3} M $Co(OAc)_2$ and 10^{-3} M $Co(OAc)_2$-bpy(1 : 1) respectively. $[THP]=5\times10^{-2}$ M, temperature = 50 °C.

Discussion

Increase in Activity. It can be presumed that the redox potential of a catalyst is the most influential factor in hydroperoxide decomposition. The redox potentials of

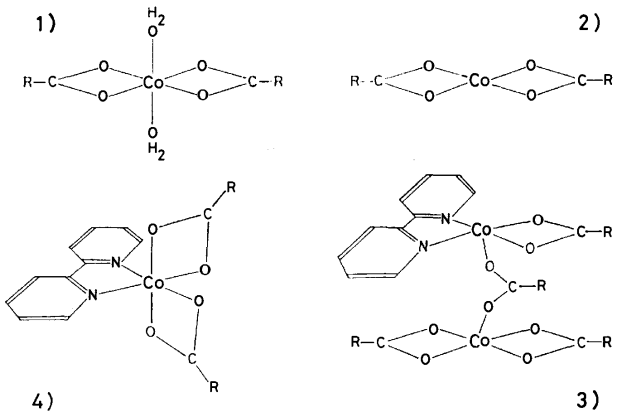

Fig. 5. Proposed structure of $CoDe_2$-bpy complexes. 1) $CoDe_2$(A), 2) $CoDe_2$(B), 3) $CoDe_2$(B)-bpy(1 : 1/2), 4) $CoDe_2$(B)-bpy(1 : 1).

metal ions were compared with the catalytic activity in oxidation reactions by Chalk and Smith,[7] who reported that the redox potentials of metal ions in aqueous solution could not be correlated with the catlytic activity in non-polar media, though the values in absolute alcohol could be correlated fairly well.

As redox potentials are very sensitive to the ligand and the solvent, it is necessary to measure them in a similar non-polar solvent in order to make a comparison with the catalytic activities of the hydroperoxide decomposition in chlorobenzene. Recent progress in the field of electrochemistry in non-aqueous media[8] enable us to measure the redox potentials of many complexes in various non-aqueous solvents. We measured the redox potentials of the $CoDe_2$(B)–bpy complexes in dichloromethane and compared them to their catalytic activities (Table 1). The catalytic activities seem to be correlated to their redox potentials except in the case of $CoDe_2$(B)–bpy(1:1/2). The increase in the activity upon the addition of 2,2′-bipyridine can be attributed to the change in the redox potential of the catalyst. Such a change in the redox potential of the cobalt ion by 2,2′-bipyridine will bring about two effects; one is the increase in the reductive force of the cobalt(II) ion, which accelerates the cleavage of the hydroperoxide molecule, while the other is the increase in the electron density on the cobalt(II) ion, which will stabilize the $CoDe_2$–hydroperoxide complex.

From the IR data (Table 2), another change was found in the first ligand decanoate, an increase in the double-bond character of the C–O bond. This suggests a weakening in the Co–O bond strength, which must bring about the facile coordination of the hydroperoxide molecule to the central cobalt(II) ion. The decomposition of hydroperoxide by the metal ion must take the pathway in which the coordination of hydroperoxide to the metal ion occurs. Then the facile coordination of hydroperoxide to the metal ion must lead to a higher decomposition rate.

Therefore, the increase in the rate of decomposition of hydroperoxide due to 2,2′-bipyridine can be ascribed to the change in the redox potential of the cobalt(II) ion and the weakening of the Co–O bond strength. The results of product analysis seem to indicate that there is a non-radical decomposition in the $CoDe_2$(B)–THP system and that the portion of radical decomposition increases upon the addition of 2,2′-bipyridine.

In acetic or other fatty acids, the effect of 2,2′-bipyridine was quite the reverse of that in chlorobenzene. The acid solvent may suppress the positive ligand effect; that is, there may be no weakening of the Co–O(acetate) bond strength in an acetic acid solvent. The 2,2′-bipyridine will just retard the decomposition of hydroperoxide by occupying the coordination site of the cobalt(II) ion.

Maximum Activity. The electrochemical and spectral data can not fully explain the maximum activity of the $CoDe_2$(B)–bpy(1:1/2). It can, however, be explained on the basis of the structural variation in the complexes. Figure 5 shows the proposed structure of these complexes. $CoDe_2$(A) (Structure 1) was pink and a six-coordination complex.[9] The disappearance of the OH absorption at 3420 cm^{-1} and the weight decrease correspond to the loss of two coordinated H_2O molecules by drying Complex 1 under a vacuum at 70 °C for 5 h, leading inevitably to Structure 2. This is a four-coordination complex. The color change from pink to blue[10] is consistent with the above structural change. From the spectral and electrochemical data and from the steric difficulties of 2,2′-bipyridine, it seems that $CoDe_2$–bpy(1:1) and $CoDe_2$–bpy(1:2) will take Structure 4. We propose Structure 3 for $CoDe_2$(B)–bpy(1:1/2), though a five-coordination complex with one vacant coordination site can not be excluded.

These catalytic activities can be explained according to these structures. The fact that the activities of $CoDe_2$(A) and $CoDe_2$(B) are lower than the others can be attributed to their weak reductive force because of no coordination of 2,2′-bipyridine. The slight difference in activity between $CoDe_2$(A) and $CoDe_2$(B) might be brought about by the two vacant coordination sites of $CoDe_2$(B). $CoDe_2$(B)–bpy(1:1/2) shows the highest activity of all the catalysts. This is explained by Structure 3 having a vacant coordination site and an adequate reductive force to cleave the hydroperoxide molecule. $CoDe_2$(A)–bpy (1:1/2) may not have the highest activity because of the coordinated H_2O molecule, which probably interferes with the coordination of the hydroperoxide molecule. The activity of $CoDe_2$(B)–bpy(1:1), which is between those of $CoDe_2$(B) and $CoDe_2$(B)–bpy(1:1/2), can be attributed to Structure 4, which may have a strong reductive force but no vacant coordination site. The fact that the activity is higher than that of $CoDe_2$(B) may be attributed to the strong reductive force, while the lower activity than $CoDe_2$(B)–bpy(1:1/2) may be attributable to the lack of any vacant coordination site. Judging from their spectral data, $CoDe_2$(A)–bpy(1:1) and $CoDe_2$(B)–bpy(1:1) must take the same structure; the data show a complete agreement with the results of catalytic activity.

We would like to thank Professor Testuo Osa (Tohoku University) for his assistance with the cyclic voltammetry.

(Received July 18, 1977)

The Knoevenagel condensates prepared from 2,4-pentanedione with aldehydes were allowed to react with the tetracarbonylhydridoferrate(0) anion in ethanol to give reductively deacylated monoketones in high yields. However, the exclusive reduction of the α,β-unsaturated double bond of the same condensates was encountered when the reaction was carried out in such a solvent as tetrahydrofuran and acetone. The Knoevenagel condensates, derived from the reaction of ethyl acetoacetate and/or ethyl benzoylacetate with aldehydes, were simply reduced even in ethanol. The reaction mechanism is briefly discussed.

The tetracarbonylhydridoferrate anion $[FeH(CO)_4]^-$ (**1**) is a useful reagent for the dehalogenation of organic halides,[1,2] the reductive alkylation[3,4] and amination[5,6] of carbonyl compounds, the desulfurization of thioketones,[7] and so on. The **1** ferrate is also an effective hydrogenating reagent for α,β-unsaturated carbonyl compounds, giving saturated ones.[8] Conjugated dienes can be converted into monoenes,[9] and the C=N double bond of *N*-benzylideneaniline can also be hydrogenated to give *N*-benzylaniline.[5]

Previously, we briefly reported the reaction of **1** with 3-alkylidene-2,4-pentanedione, **2**, a Knoevenagel condensate.[10] In this reaction, reductively deacetylated products, alkyl methyl ketones, **3**, were obtained in high yields.

This study will deal with the unusual reaction of **1** with 3-alkylidene-2,4-pentanediones, along with several other types of Knoevenagel condensates, **5**, **6**, **7**, and **8**.

Results and Discussion

3-Alkylidene-2,4-pentanediones, prepared from aldehydes and 2,4-pentanedione, such as 3-butylidene-2,4-pentanedione and 3-benzylidene-2,4-pentanedione, were allowed to react with an equimolar amount of **1** for 1 h at room temperature under an argon atmosphere in ethanol. The reaction proceeded rapidly, with a color change from pale yellow to red-brown, giving only the corresponding alkyl methyl ketones, **3**, in high yields (Table 1).

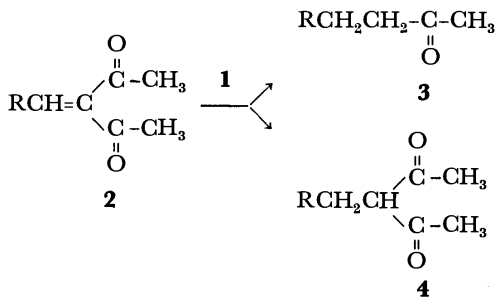

Table 1 shows that this reaction is dramatically affected by the solvent employed. In ethanol, the methyl ketones, **3**, were unexpectedly obtained as products, whereas in tetrahydrofuran or acetone, only the expected reduced products, **4**, were isolated.

The crude condensates, **2**, prepared from 2,4-pentanedione and aldehydes after the removal of the unreacted substrates by distillation, could be converted into **3** smoothly. The results are shown in Table 2.

In the reduction of enamines,[11] Schiff's bases,[12] or α,β-unsaturated carbonyl compounds[12] with **1**, the yields of the products, amines or saturated carbonyl compounds, do not exceed 1.0 mol*** under an argon or nitrogen atmosphere. However, under a carbon monoxide atmosphere, the reaction proceeds with the absorption of carbon monoxide, yielding the products in amounts of about 2—3 mol without forming carbonylated products. In these reactions, it is considered that a major portion of the carbon monoxide absorbed is used to generate the pentacarbonyliron, which is then converted by the base into the ferrate, **1**.

The reaction of **2** (R=Ph) with **1** gave 1.6 mol of 4-phenyl-2-butanone, **3** (R=Ph), even under an argon atmosphere, showing that an active species was reproduced in the course of this reaction. In the reaction in tetrahydrofuran, the yield of 3-benzyl-2,4-pentanedione (**4**, R=Ph) did not exceed 1.0 mol under argon. Now we assume that the carbon monoxide used for the reproduction of pentacarbonyliron might be provided by the eliminated acetyl group.

In further KOH is added to the reaction solution, **1** may be generated according to Eq. 1.[13] Therefore, we examined the effect of the addition of KOH. The results are shown in Table 3.

$$Fe(CO)_5 + 3KOH \longrightarrow KHFe(CO)_4 + K_2CO_3 + H_2O. \quad (1)$$

The yield of **3** (R=Ph) increased to about 4 mol at a maximum (Run 15), supporting the above assumption. However, the addition of a large excess of KOH disturbed the reaction (Run 16). In this case, the concentration of the active hydride, **1**, decreases according to

$$KHFe(CO)_4 + KOH \rightleftarrows K_2Fe(CO)_4 + H_2O. \quad (2)$$

In order to investigate the scope and limitation of this reductive deacylation reaction with **1**, the re-

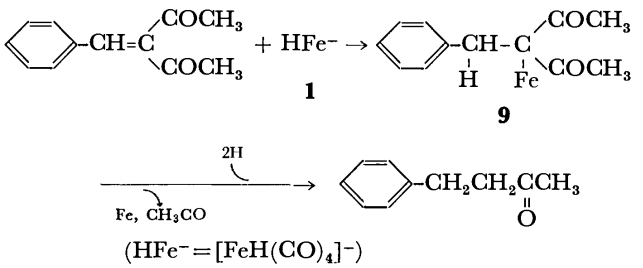
benzoyl group under these reaction conditions. However, the reaction of the **7** condensates with **1** in ethanol gave simply reduced compounds, along with a trace of deacetylated compounds, at room temperature. However, at higher temperatures, 4-phenyl-2-butanone was obtained in a 39% yield. The condensate of ethyl benzoylacetate and propionaldehyde (**8**, R=Et) gave similar results.

A tentative mechanism of the reductive deacylation reactions of 3-benzylidene-2,4-pentanedione with **1** is illustrated in Scheme 1. First, **1** attacks an olefinic



Scheme 1.

double bond of **2** to give a complex, **9**. It has been reported that the iron atom is attached to the α-carbon of the olefinic bond in the reduction of α,β-unsaturated carbonyl compounds[8] and the hydroacylation of α,β-unsaturated carboxylic esters.[14] The elimination of carbonyliron and acetyl groups, followed with the abstraction of the proton from the solvent, would then give **3**. Some of the products obtained by the elimination of acyl and carbonyliron groups are assumed to be exist as acylcarbonylferrates ($[RCOFe(CO)_4]^-$), which are then protonated to give aldehydes.[15,16] In the reaction of **1** with 2-benzylidenebenzoylacetone, about 10% of the benzaldehyde was detected in the reaction mixture by GLPC, a finding which would support the formation of acylcarbonylferrate.

Experimental

All the melting points and boiling points are uncorrected. The acetylacetone, dibenzoylmethane, benzoylacetone, ethyl acetoacetate, ethyl benzoylacetate, and aldehydes were all commercial products. The benzene, tetrahydrofuran, and piperidine were obtained from commercial sources and were dehydrated and distilled before use. The pentacarbonyliron was also a commercial product and was used without purification.

3-Alkylidene-2,4-pentanedione. General procedure was as follows. After an equimolar mixture of 2,4-pentanedione and an aldehyde had been cooled in an ice-bath, 0.4—0.5 mol% of piperidine was added, drop by drop; thereafter the mixture was stirred for 5 h at 0 °C and then at room temperature for 5 h. The reaction mixture was then subjected to fractional distillation. The yields were 60—75% in all cases. The analytical data were as follows. 3-Propylidene-2,4-pentanedione; bp 81—89 °C/14.5 mmHg. Found: C, 68.64; H, 8.80%. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.90%. 3-Butylidene-2,4-pentanedione; bp 104—109 °C/13 mmHg. 3-Benzylidene-2,4-pentanedione; bp 108 °C/0.09 mmHg.

Found: C, 76.30; H, 6.61%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%. 3-Furfurylidene-2,4-pentanedione; bp 116 °C/0.8 mmHg (lit,[17] bp 128—129 °C/4 mmHg). 3-Isobutylidene-2,4-pentanedione; bp 89—93 °C/14 mmHg. These compounds gave satisfactory IR and NMR spectroscopic data.

Other Knoevenagel Condensates. The condensates of aldehydes with ethyl acetoacetate or ethyl benzoylacetate were prepared according to a method similar to that used for 3-alkylidene-2,4-pentanediones. Ethyl 2-acetyl-2-hexenoate; bp 100—109 °C/15 mmHg. Found: C, 65.17; H, 8.67%. Calcd for $C_{10}H_{16}O_3$: C, 65.19; H, 8.76%. Ethyl 2-acetyl-3-phenyl-2-propenoate; bp 110—114 °C/0.2 mmHg. Found: C, 71.58; H, 6.51%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%. Ethyl 2-benzoyl-2-pentenoate; bp 108—109 °C/0.38 mmHg. Found: C, 72.35; H, 6.69%. Calcd for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94%. Satisfactory IR and NMR data were obtained for these compounds. The 2-benzylidenedibenzoylmethane and 2-benzylidenebenzoylacetone were prepared according to the methods described in the literature.[18]

*Preparation of Tetracarbonylhydridoferrate (**1**).* All the reactions were carried out in a 200-ml, three-necked flask equipped with a buret and a magnetic stirrer under an argon atmosphere. **1** in ethanol was prepared according to the method described in a previous paper.[19] **1** in tetrahydrofuran was prepared as follows. To a stirred suspension of the sodium amalgam in dry tetrahydrofuran (50 ml) prepared from mercury (100 g) and sodium (0.70 g), pentacarbonyliron (1.5 ml, 11 mmol) was added, drop by drop, under argon. The mixture was then stirred for 2 h at room temperature, and the excess of the amalgam was removed through a side arm. The suspension containing the dianion, disodium tetracarbonylferrate(−II) ($Na_2Fe(CO)_4$), was treated with acetic acid (11 mmol).[20] **1** in acetone was prepared by adding 1.5 ml (11 mmol) of $Fe(CO)_5$ to a mixture of acetone (30 ml) and a 10-M KOH aqueous solution (3 ml).

*Reaction of the Knoevenagel Condensates with **1**.* The reaction of 3-benzylidene-2,4-pentanedione with **1** illustrates a typical procedure. To an ethanol solution (33 ml) of **1** (11 mmol), an ethanol solution of 3-benzylidene-2,4-pentanedione (11 mmol) was added, after which the reaction mixture was stirred for 1 h at room temperature under argon. After the solvent had then been evaporated, the residue was extracted with diethyl ether and the ether layer was washed twice with water and dried over sodium sulfate. The solvent was removed *in vacuo*, and the liquid remaining was then subjected to fractional distillation. The product was identified as 4-phenyl-2-butanone by IR, NMR, and GLPC using an authentic sample; bp 106 °C/12.5 mmHg. Yield, 76% (GLPC yield, 90%). The analytical data of some of the other results were as follows. 4-(2-Furyl)-2-butanone; bp 76—77 °C/13 mmHg. Found: C, 69.29; H, 7.23%. Calcd for $C_8H_{10}O_2$: C, 69.54; H, 7.30%. 3-Benzyl-2,4-pentanedione; bp 95—97 °C/0.25 mmHg (lit,[21] bp 115—118 °C/4 mmHg). Found: C, 75.87; H, 7.46%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%. Ethyl 2-acetyl-3-phenylpropionate; bp 85 °C/0.06 mmHg. Found: C, 71.51; H, 7.53%. Calcd for $C_{13}H_{16}O_3$: C, 70.88; H, 7.32%.

*The Successive Reaction of the Mixtures of Aldehydes and 2,4-Pentanedione with **1**.* The synthesis of 4-(*p*-tolyl)-2-butanone from *p*-tolualdehyde illustrates a typical procedure. After a mixture of *p*-tolualdehyde (11 mmol) and 2,4-pentanedione had been cooled in an ice-bath, 0.05 mmol of piperidine was added, drop by drop, by the use of a micro syringe, after which the mixture was stirred for 5 h at 0 °C and then at room temperature for 5 h. The reaction mixture was then evaporated, and the residual liquid was added to the ethanol solution of **1** (11 mmol). The mixture was stirred for 1 h at room temperature under argon. After the solvent had been evaporated, the residue was extracted with diethyl ether, and the ether layer was washed twice with water and dried over sodium sulfate. The solvent was evaporated, and the liquid remaining was subjected to fractional distillation. The product was identified as 4-(*p*-tolyl)-2-butanone by IR, NMR, and elemental analysis; bp 69 °C/0.6 mmHg; yield, 54%. Found: C, 81.36; H, 8.84%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%. The analytical data of the other results were as follows. 4-(α-Naphthyl)-2-butanone; bp 100—102 °C/0.15 mmHg. Found: C, 84.83; H, 7.10%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%. 4-(*p*-Methoxyphenyl)-2-butanone; bp 100—103 °C/0.23 mmHg. 4-(*p*-Chlorophenyl)-2-butanone; bp 89—90 °C/0.26 mmHg. Found: C, 65.55; H, 6.25%. Calcd for $C_{10}H_{11}ClO$: C, 65.76; H, 6.07%. Satisfactory IR and NMR data were obtained for these compounds.

The Photo-cycloaddition of 3-Cyano-2,4-pentanedione with Cyclohexene and Its Quenching by Enol Ether

Masaru TADA, Hidetoshi HARADA, and Kyo MIURA

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received July 28, 1977)

The 1,3-dicarbonyl compound, with an electro-negative substituent, 3-cyano-2,4-pentanedione, gives the photo-addition product with cyclohexane. The adduct must be formed by the retro-aldol reaction of the "2+2" cyclo-addition product and the hemiacetalization of the resulting 1,5-dicarbonyl compound. Enol ether, with a lower ionization potential, does not photoadd to 3-cyano-2,4-pentanedione but quenches the photoaddition between 3-cyano-2,4-pentanedione and cyclohexene. The solvent effect, the ionization potential, and quenching experiments show that the photoaddition follows a process involving a singlet excited complex.

It is well known that 2,4-pentanedione (**1**), a non-cyclic 1,3-dicarbonyl compound, gives a photoaddition product with olefin through its enol form. The classical work by de Mayo *et al.*,[1] however, was not followed by frequent application, even though this type of reaction seems to be a useful method for the preparation of 1,5-diketone and cyclohexenone derivative by the base-catalyzed condensation of the diketone (Eq. 1). To determine the scope and limitation of this type of reaction, we attempted the photocycloaddition of Compounds **2**—**6** with cyclohexene. None of these compounds, however, showed any photo-reactivity. Several factors may influence the reactivity of these compounds such as; a) the electronic configuration of the lowest excited state, $n\pi^*$ or $\pi\pi^*$; b) the importance of the enol form in keto-enol equilibrium; c) the fixation of the cyclic *s-cis* conformation by intramolecular hydrogen bonding, and d) the effect of excitation on the intramolecular hydrogen bonding. Non-cyclic 1,3-dicarbonyl compounds with an additional electronegative group, such as methyl 2,4-dioxopentanoate (**7**) or 2-(methoxycarbonyl)-1,3-propanedial (**8**), have been reported to give photo-adducts with olefins.[2,3] This fact strongly suggests the importance of charge transfer interaction between these electronegative dicarbonyl compounds and olefin for the photo-cycloaddition. We selected 3-cyano-2,4-pentanedione (**9**) as a dicarbonyl compound and wish to report on the nature of the photo-cycloaddition of **9** with olefin.

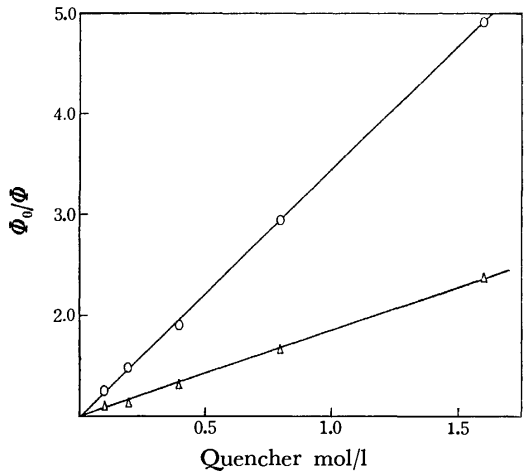

Fig. 1. Quenching of photo-cycloaddition of **9** to cyclohexene by enol ethers.

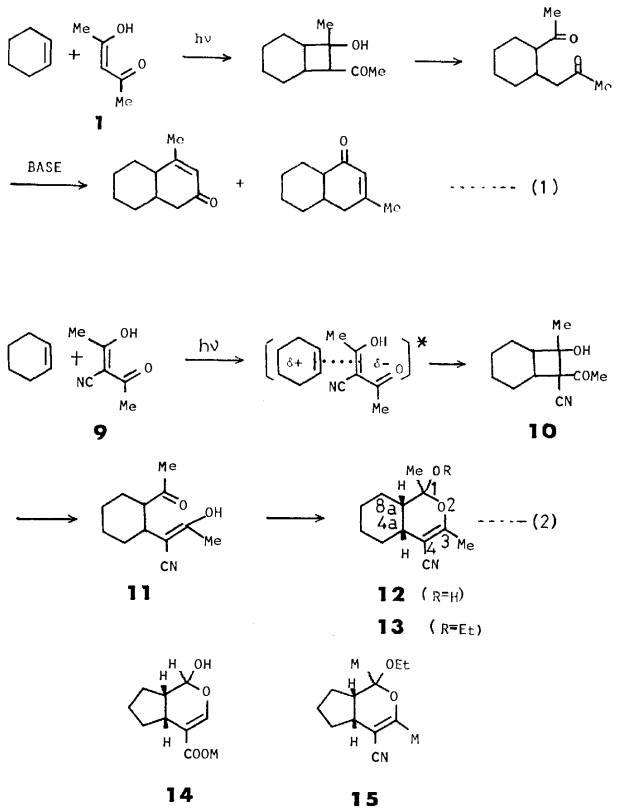

The irradiation of 3-cyano-2,4-pentanedione (**9**) in the presence of excess cyclohexene in variety of solvents gave the photoadduct **12** in variable yields; a cyclic ethyl acetal, **13**, was obtained when absolute ethanol was used as the solvent. The structure of **12** was deduced from the spectral data and by analogy with the structure of the adduct between 2-(methoxycarbonyl)-1,3-propanedial (**8**).[3]

	R_1	R_2	R_3
1	Me	H	Me
2	Me	Me	Me
3	Me	Ph	Me
4	Me	H	Ph
5	Me	H	OMe
6	Ph	H	OEt
7	Me	H	COOMe
8	H	COOMe	H
9	Me	CN	Me

As a precedent, the photoadduct **12** must be derived from the 2+2 adduct, **10**, of 3-cyano-2,4-pentanedione and cyclohexene, which opens the cyclobutane ring by means of retro-aldol-type cleavage, giving the 1,5-dicarbonyl compound, **11**, followed by the hemiacetalization (Eq. 2). The sharp IR absorptions at 3420, 2210, and 1617 cm^{-1} show the presence of hydroxyl, conjugate cyano, and conjugate enol ether groups respectively. The NMR signals at $\delta=1.53$ (singlet) and 2.10 ppm (doublet, $J=2$ Hz) are due to the methyls at the hemiacetal carbon (C_1) and enol ether moieties. The long-range coupling of the latter signal with the hydrogen at C_{4a} (2.96 ppm) has been evidenced by a decoupling experiment.[4] The NMR signal at $\delta=2.96$ due to the hydrogen at C_{4a} is a multiplet with the half-band width of 10 Hz, which shows the lack of vicinal diaxial coupling and the equatorial nature of the H_{4a} on the cyclohexane ring. The observation of Dreiding molecular models indicates that H_{4a} bisects the methylene at C_5 and that the dihedral angle between H_{4a} and H_{8a} is *ca.* 50°. The vicinal couplings between these hydrogens, in addition to the long-range coupling between H_{4a} and C_3-methyl, meet the requirements for H_{4a} being equatorial. These aspects of the NMR spectrum lead us to deduce that the stereochemistry of the ring junction of the adduct is *cis*.

The photoreaction between 3-cyano-2,4-pentanedione (**9**) and cyclopentene in absolute ethanol gave a similar product, **15**, with *cis*-ring fusion, this is completely parallel to the photoreaction of 2-(methoxycarbonyl)-1,3-propanedial to cyclopentene to give the adduct **14**. The photoreaction of **9** was carried out in a variety of solvents, such as hexane, benzene, ether, THF, ethanol, methanol, and methanol–acetonitrile (1 : 1); the yield of the adduct **12** is generally better in alcoholic solvents than in non-polar solvents or in acetonitrile. Casal *et al.*[5] reported that an aromatic 1,3-dicarbonyl compound, **4**, adds photochemically to styrenes or stilbens, though in our trial **4** failed to enter the photo-addition to cyclohexene. From the discussion above, the 1,3-dicarbonyl system with an electronegative group or the conjugated olefin with an aromatic system seems to be required for the photo-addition. The UV spectrum of mixture of **9** and cyclohexene does not show any evidence for the formation of a CT complex, at least in dilute concentrations, in the ground state. These results, in conjunction with the solvent effect, suggest that the photo-addition takes an excited complex process of charge transfer. The attempted photoreaction of **9** with an olefin having a lower ionization potential, such as ethyl vinyl ether (I_p: 8.6 eV),[6] 2,3-dihydro-1,4-dioxin (I_p: *ca.* 7.6 eV),[7] or *cis*-1,2-dimethoxyethylene (I_p: 8.0 eV)[6] in ether, does not give any photoadduct, but the starting material is recovered. On the other hand, cyclohexene (I_p: 8.9 eV), with higher ionization potential, shows photoreactivity in the same solvent; hence, the excited complexes with olefins having lower ionization potentials are considered to be dissociated into radical-ion pairs by electron transfer in ether. Since the excited complex formation is favored with such olefins, enol ethers are expected to quench the photo-addition between **9** and cyclohexene. Such was found to be true in the photo-addition of 2-buten-4-olide with olefins and its quenching by 1,1-dimethoxyethylene.[9] Stern-Volmer plots of the quenching experiments on the photoaddition of **9** indeed show a straight line with the slopes of 2.46 and 0.85 M^{-1} for 2,3-dihydro-1,4-dioxin and ethyl vinyl ether respectively (Fig. 1). The importance of charge transfer and electron transfer for this quenching is evident from the quenching-rate constants being dependent upon the ionization potential of the quencher. 1,3-Pentadiene (I_p: 8.7 eV)[8] and oxygen do not quench the photo-addition of **9** in a normal manner for a triplet quenching, but a higher concentration of 1,3-pentadiene quenches the reaction and gives the 1 : 1 adduct, in a poor yield, from the excited complex between **9** and 1,3-pentadiene.

In conclusion, the photo-cycloaddition of 3-cyano-2,4-pentenedione (**9**) to olefin takes a singlet excited complex process, and the cyclization competes with the electron-transfer process, employing **9** as an electron accepter (A) and olefin as a donor (D).

Experimental

Preparation of Materials. The 3-cyano-2,4-pentanedione (**9**) (mp 51 °C, UV: λ_{max}^{EtOH} 276 nm (10300)), was synthesized by the method of Traub[10] from 2,4-pentanedione and cyanogen generated by the addition of a sodium cyanide solution to a solution of copper(II) sulfate.[11] The cyclohexene was prepared by the acid-catalyzed dehydration of cyclohexanol and was distilled before use. Commercially available ethyl vinyl ether was distilled (bp 36—37 °C) immediately before use to remove the stabilizer. The 2,3-dihydro-1,4-dioxin (bp 94—95 °C) was prepared by the method of Sammerbell *et al.*[12,13] by the dechlorination of *trans*-2,3-dichloro-1,4-dioxane. The *cis*-1,2-dimethoxyethylene (bp 97 °C) was prepared by the method of Shostakoviskii *et al.*[14] by the gas-phase elimination of methanol from 1,1,2-trimethoxyethane[15] catalyzed by silica gel–BaO at 350—370 °C. The collection of the fraction boiling at 97 °C by repeated distillations gave *cis*-1,2-dimethoxyethylene.

Photo-cycloaddition of 3-Cyano-2,4-pentanedione(9) with Cyclohexene. To **9** (125 mg, 1 mmol) and cyclohexene (5 g, 60 mmol) we added one of the solvents, and the total volume was adjusted to 10 ml. The solution, placed in a Pyrex tube was sealed by means of a rubber septum and the solution was bubbled by argon for several minutes through a syringe needle. Irradiation was carried out externally with a 450-W high-pressure mercury lamp mounted in the center of a rotary irradiation apparatus (Rikosha Merry-go-round type; the distance between the lamp and the tube is *ca.* 5 cm) for 50—60 h, the reaction being monitored by TLC analyses. In the case of the methanol solution, the starting **9** disappeared after 55 hs' irradiation, at this time the solution was condensed *in vacuo*. The chromatography of the residue on alumina (Merck act. II-III) eluted with 1) benzene, 2) benzene–ether (1:1), and 3) ether gave a crystal of the adduct **12** from the benzene-ether eluate (125 mg, 60%). **12**, mp 113.8—114.3

°C(recrystalyzed from ether). Found: C, 70.01; H, 8.37; N, 6.98%. Calcd for $C_{12}H_{17}NO_2$: C, 69.54; H, 8.27; N, 6.76%. MS (80 eV): *m/e*(%) 207(M^+, 10), 189(7), 165(50), 164(39), 149(19), 136(53), 125(100), 122(75), 81(72), 71(66), and 43(92). UV: λ_{max}^{EtOH} 236 nm (16900). IR(Nujol): 3420, 2210, 1617, 1275, 1155, and 1065 cm^{-1}. NMR($CDCl_3$): (δ) 4.00(3H, s), 2.96(1H, diff. s $W_{1/2}$: 10 Hz), 2.10(3H, d, J=2 Hz), 1.53(3H, s), and 2.1—0.8 ppm(10H). The yield of the adduct **12** was best in methanol or ethanol (60—70%), and worse in a non-polar solvent or in acetonitrile. Ethyl acetal was obtained when absolute ethanol was used as a solvent. The refluxing of the methanol solution of **9** without irradiation as a dark reference gave no adduct at all.

Quenching Experiments. *a) Quenching by Enol Ether or 1,3-Pentadiene*: A solution of 3-cyano-2,4-pentenedione (**9**) (0.05 mol/l), cyclohexene (1.5 mol/l), and 0—0.6 mol/l of a quencher (2,3-dihydro-1,4-dioxin, ethyl vinyl ether, or 1,3-pentadiene) in ether was placed in Pyrex tubes and irradiated by using a rotary irradiation apparatus after the deoxygenation of the system. After irradiation for 17 h, GLC analyses showed that the starting material was still a major component in the reaction mixture; to each reaction mixture we added the same amount of 1,2-di-*m*-tolylethane as an internal reference. Stern-Volmer plots obtained by GLC analyses of the adduct in each reaction mixture gave the straight lines with the slopes of 2.46 and 0.85 M^{-1} for 2,3-dihydro-1,4-dioxin and ethyl vinyl ether respectively.

b) Quenching by Oxygen: The mixture of **9** (0.05 mol/l) and cyclohexene (1.5 mol/l) in ether was placed in two Pyrex tubes; one of the solutions was bubbled by oxygen under cooling in an ice-salt bath, while the other was purged with argon. Irradiation of both solutions for 15 h and GLC analyses did not show any distinct difference in the photoreactivity.

Structure of Aloenin, a New Biologically-active Bitter Glucoside from *Aloe arborescens* var. *natalensis*

Toshifumi HIRATA and Takayuki SUGA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received August 5, 1977)

Aloenin, a new bitter glucoside with an inhibitory activity for the gastric juice secretion of rats, was isolated from the leaves of *Aloe arborescens* Mill. var. *natalensis* Berger, and the structure was confirmed to be 4-methoxy-6-(2-β-D-glucopyranosyloxy-4-hydroxy-6-methylphenyl)-2-pyrone by means of chemical, spectroscopic, and X-ray crystallographic methods. Ambiguity in the assignment of 2-pyrone-ring carbon signals was clarified by examination of the ^{13}C-NMR spectra of aloenin and the related compounds.

The plants of Aloe species have been widely used for folk remedies, and their chemical constituents have been studied by several workers.[1-11] Recently, Soeda[12] and Yamamoto[13] have tested the effectiveness of "Cape Aloe" as material for medical treatment. In Japan, *Aloe arborescens* Mill. var. *natalensis* Berger (Kidachirokai or Kidachiaroe in Japanese) has been traditionally used as material for folk remedies for gastro-intestinal disturbances, burns, insect bites, athlete's foot, *etc.* In the course of chemical and biochemical examinations of this plant, a new bitter glucoside, named aloenin, was isolated, its structure being postulated to be a chromene derivative (**1**).[8] Aloenin was identified with aloearbonaside which was independently isolated and named by Makino *et al.*[9] They also assigned the same structure **1** to this compound. It was decided upon mutual agreement to use thereafter the name "aloenin".[8] However, doubts concerning the proposed structure were aroused by anomalous intensity enhancement found in intramolecular nuclear Overhauser effect (NOE)[14] of some derivatives of aloenin, as well as ambiguity in assignments of the ^{13}C-NMR spectrum. The structure of aloenin was reexamined by means of chemical, spectroscopic, and X-ray crystallographic methods, and a report given on a revised structure of aloenin.[15-17] We wish to describe *en bloc* the results of studies on the revised structure **2** for aloenin, the assignment of 2-pyrone-ring carbon signals in the ^{13}C-NMR spectra of aloenin and its derivatives, and tests of the inhibitory activity to the gastric juice secretion of rats.

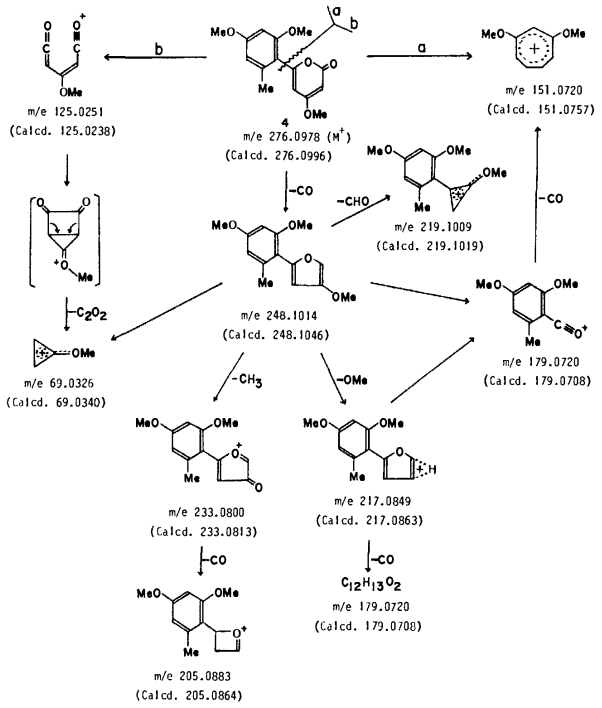
Results and Discussion

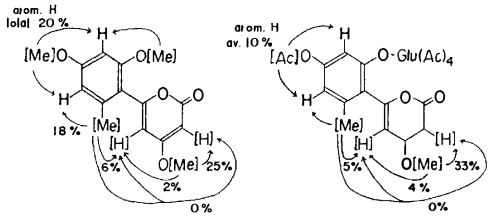
Structure Elucidation. Aloenin (**2**)** was isolated as a major component by chromatography on silica gel from the leaf juice of the Aloe plants cultivated in pots. The IR spectrum of aloenin exhibited bands (1714 and 1642 cm^{-1}) due to a conjugated ester or a lactone group. The UV spectrum in an alkaline solution showed a bathochromic shift by 46 nm. The IR and UV spectra closely resemble those of 2-pyrone derivatives.[18] The PMR spectrum in acetone-d_6 showed the presence of an aromatic methyl, a methoxyl, and four olefinic or aromatic protons.

Hydrolysis of aloenin with 3% methanolic hydrochloric acid afforded an aglycone **3** and D-glucose. Methylation of **3** with diazomethane gave a trimethyl ether **4**, whose PMR spectrum in $CDCl_3$ showed signals due to an aromatic methyl, three methoxyl, and four olefinic or aromatic protons. Exhaustive methylation of aloenin by Hakomori's method[19] yielded a hexamethyl ether **5**, which could be hydrolyzed with 3% methanolic hydrochloric acid to a dimethyl ether **6** and 2,3,4,6-tetra-*O*-methyl-D-glucose. This suggests that the sugar moiety is linked with the aglycone through the C-1 hydroxyl group of D-glucose. Methylation of **6** with diazomethane afforded **4**. Treatment of **4** with 5% methanolic potassium hydroxide at room temperature yielded potassium salt of the corresponding β-diketo acid, which on acidification with dilute hydrochloric acid gave an unstable β-diketo acid **7**. The structure of **7** was assigned by the fact that it



Scheme 1. Fragmentation patterns in the mass spectrum of **4**.

** In this paper, for convenience, the carbon atoms of aloenin (**2**) and its derivatives are numbered as shown in the structural formulae.



4 **20**

Fig. 1. NOE values of **4** and **20** in $CDCl_3$.

underwent facile decarboxylation on heating to yield 1-(2,4-dimethoxy-6-methylphenyl)butane-1,3-dione (**8**), which was identified by comparison with an authentic sample synthesized from 3,5-dihydroxytoluene by acetoacetic ester condensation. The results demonstrate the presence of a C-4 hydroxylated 2-pyrone skeleton.[20] The product **8** possesses a new acetyl group which is not present in the parent compound **4**. The absence of the acetyl group in **4** warrants a carboxyl group in **7** to be attached to the end of the side chain of **8**. This indicates that the structure of **4** should be represented as 4-methoxy-6-(2,4-dimethoxy-6-methylphenyl)-2-pyrone. A typical mass-spectral fragmentation pattern of C-6 substituted 4-methoxy-2-pyrone derivatives[21] was observed for **4**. The fragments were completely characterized by high-resolution mass-spectral measurements as shown in Scheme 1. The results of the NOE experiments are in line with structure **4** for the dimethyl ether of aglycone **3** as shown in Fig. 1.

Structure **4** was further confirmed by synthesis according to the following procedure. β-Diketone (**8**) prepared from 2,4-dimethoxy-6-methylacetophenone (**9**)[22] was first converted into **7** by treatment with sodium amide in liquid ammonia followed by carbon dioxide.[23] Cyclization of **7** in the presence of acetic anhydride gave 2-pyrone derivative,[23] which was then converted into trimethyl ether **4** with diazomethane. Trimethyl ether **4** derived from aloenin was found to be identical with the synthesized trimethyl ether (**4**). In the course of synthetic studies of **4**, we found that some 2,4,6-trisubstituted acetophenones had been erroneously correlated[24] with their PMR and IR spectra, *i.e.*, the 2,4,6-trisubstituted acetophenones prepared from 3,5-dihydroxytoluene and acetyl chloride by the Friedel-Crafts reaction were identified as 2,6-dimethoxy-4-methyl-, 2,4-dimethoxy-6-methyl-, 2-hydroxy-6-methoxy-4-methyl-, and 2-hydroxy-4-methoxy-6-methyl-acetophenones. However, the acetophenone derivatives were established to be 2,4-dimethoxy-6-methyl-, 2,6-dimethoxy-4-methyl-, 2-hydroxy-4-methoxy-6-methyl-, and 2-hydroxy-6-methoxy-4-methyl-acetophenones, respectively, by reexamination of the signal assignments in the PMR spectra and the conversion of the acetophenone derivatives into known *o*- or *p*-orsellinates.[22]

The alkaline degradation of a monomethylated product **10** of aloenin by refluxing with 5% methanolic potassium hydroxide yielded a glucoside **11**, which could be hydrolyzed to 2-hydroxy-4-methoxy-6-methylacetophenone (**12**)[22] and D-glucose. This shows that the glucose moiety in aloenin is located on the C-2' hydroxyl group of the aglycone **3**. The aglycone (**3**) was converted into 2,5-dimethyl-7-hydroxychromone

(**13**)[25] by treatment with 5% hydrochloric acid. On the other hand, a similar treatment of **6** gave 2,5-dimethyl-7-methoxychromone (**14**). This suggests the presence of a hydroxyl group attached to the C-4′ position of the aromatic ring in aloenin. The authentic chromones, **13** and **14**, were obtained by the Pechman condensation, followed by decarboxylation, of *p*-orsellinic acid with ethyl acetoacetate.[25] Sethna and Shah[26] reported that such reactions as above yield 4,5-dimethyl-7-hydroxycoumarin. We reexamined the reported structure by spectroscopic and chemical methods in connection with the syntheses of the chromones, **13** and **14**, and found that the product is 2,5-dimethyl-7-hydroxychromone, not coumarin.

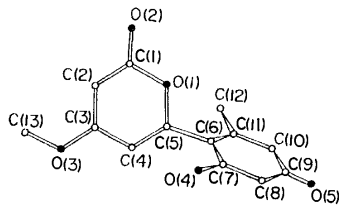

Fig. 2. Atomic numbering in aglycone **3** for X-ray analysis. The atoms indicated with ○ and ● denote carbon and oxygen atoms, respectively.

In order to establish the complete structure of aloenin, we examined the structure by X-ray crystallographic analysis. However, due to the lack of a good single crystal of aloenin, the analysis was carried out with aglycone **3**. Cell dimentions were obtained by least-squares calculations from 2θ values of 13 well-centered, resolved Cu $K\alpha$ diffraction peaks. Crystal data: monoclinic (space group $P2_1/c$), four molecules per unit cell with dimensions $a=7.422(2)$, $b=10.719(4)$, $c=14.393(4)$ Å, $\beta=99.54(2)°$; $U=1129.1$ Å^3; $D_c=1.46$ g cm^{-3}. A total of 2292 reflections were collected on a four circle automatic diffractometer; 198 reflections were smaller than 1.96 times of the standard deviations in intensity and were recorded as "unobserved." The phases of 153 strong reflections with $|E| > 1.85$ were determined by direct methods using the program MULTAN.[27] The E map for the best solution showed the 18 non-hydrogen atoms as the largest peaks. The structure was refined by full-matrix least-squares method. Four cycles of anisotropic refinement for carbon and oxygen atoms and of isotropic refinement for hydrogen atoms reduced the R index to 0.073. The final atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms are given in Tables 1 and 2, and bond distances and angles in Tables 3 and 4, with atoms designated as shown in Fig. 2. The results indicate that the structure of the aglycone is of structural formula **3**.

The crystal structure consists of two stackings of the planes of phenyl and pyrone groups of the aglycone molecules, which are packed along the a-axis and the c-axis, respectively (Fig. 3), the dihedral angle between the planes being 117°. One carbonyl and two hydroxyl groups participate in the formation of the

a) Determined in C_5D_5N at 60°. b) Determined in $CDCl_3$-CD_3OD (9 : 1). c) Determined in $CDCl_3$ (TMS = 0). d) The δ_c values for the tetraacetyl groups at glucose moiety are 20.5×4, 170.1, 169.7, 169.1, and 168.8 ppm. e) Figures in parentheses are shift values observed in $CDCl_3$: CD_3OH(1 : 1) in ppm. f), g), and h) Assignments are interchangeable.

intermolecular hydrogen bond. One chain is formed through O(2)-carbonyl and O(5)-hydroxyl groups. The other chains O(4)- and O(5)-hydroxyl groups belonging to the neighboring molecules are correlated by a 2_1 screw axis. The crystal structure is stabilized by the networks of these hydrogen bonds.

The β-glucopyranosyloxyl structure was established by the enzymic hydrolysis of **2** with β-glucosidase (emulsin) and the J-value of 5.5 Hz obtained from the anomeric proton signal at δ 4.78 in the PMR spectrum of **5**. The structure of aloenin has now been established as 4-methoxy-6-(2-β-D-glucopyranosyloxy-4-hydroxy-6-methylphenyl)-2-pyrone (**2**).

^{13}C-NMR Study. In the ^{13}C-NMR spectroscopic study of aloenin (**2**) and its derivatives during the course of structure confirmation, it was found that preliminary assignments[15] in accord with reported results[30] differ from those for yangonin (**15**).[28] In order to clarify the ambiguity and disagreement[28–31] in the signal assignment of C-2, C-4, and C-6 in 6-

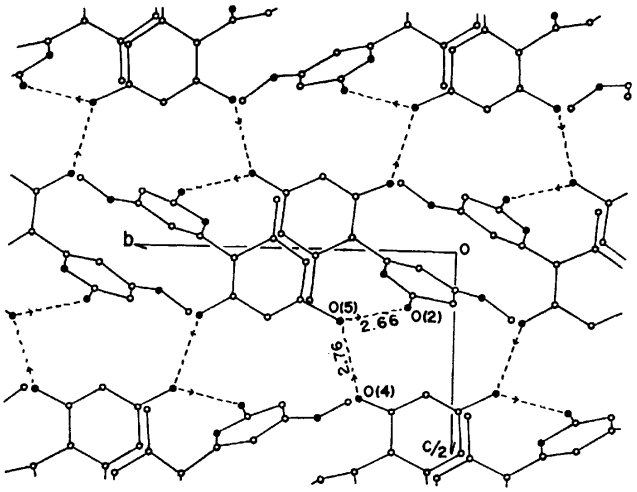

Fig. 3. The projection of aglycone **3** viewed along the a-axis. Hydrogen bonds are shown by a broken line. The atoms indicated with ○ and ● denote carbon and oxygen atoms, respectively.

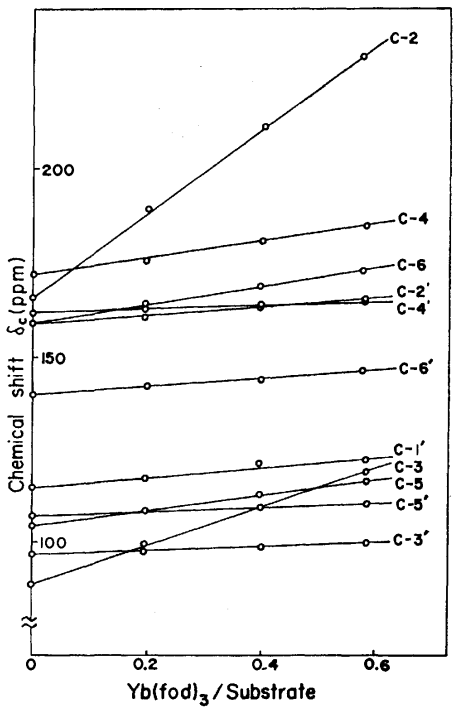

Fig. 4. Variations in the ^{13}C chemical shift of **4** in $CDCl_3$ with increasing concentration of $Yb(fod)_3$.

substituted 4-methoxy-2-pyrone rings, we investigated natural-abundance ^1H noise-decoupled ^{13}C FT NMR spectra of aloenin (**2**) and its derivatives (Tables 5 and 6).

Signals due to C-2, C-4, and C-6 in the 2-pyrone ring were distinguished as follows. Selective ^1H decoupling irradiated at H-3, H-5, and 4-OCH_3 frequencies revealed the C-2, C-4, and C-6 signal assignments, since $^2J_{C(2)-C(3)-H(3)} < ^2J_{C(6)-C(5)-H(5)}$ is known for 2-pyrone.[32] Hydrogen-bonding shifts[33] of the C-2 carbonyl peaks were distinguished when a $CDCl_3$–CD_3OH (1 : 1) mixed solvent was used for **4**, **18**, and **19**

a) Determined in $CDCl_3$ (TMS=0).

Table 7. Inhibition of gastric juice secretion of rats by aloenin (**2**)

Compound	Dose (mg/kg)	pH	Secretion (ml/100 g body weight)	Inhibition (%)
Control	—	1.8	4.7	0
Aloenin (**2**)	100	1.8	3.6	23

(Table 5). The lanthanide-induced shift (LIS) method[34,35] was applied to **4** employing $Yb(fod)_3$ in $CDCl_3$. The largest lanthanide-induced shift value was obtained for the C-2 peak as indicated in Fig. 4.

For assignments of the benzene ring carbons, we examined the substituent effects[36] of some acetophenone derivatives, **9**, **12**, **16**, and **17** (Table 6). The methylation and acetylation shifts in *o*-hydroxyacetophenone[37,38] were utilized for assigning the benzene ring carbons of all the compounds examined. The deuteration effect[39] (−0.6 ppm) was detected for C-2 of **12**, which has an abnormal chemical shift due to an intramolecular hydrogen-bond. The substituent effects were useful for assigning the benzene-ring carbons of aloenin derivatives (Table 5).

The signals due to the sugar moiety of **2** appear at almost the same positions as those of methyl β-D-glucopyranoside[32] in pyridine-d_5 except for the anomeric C-1 signal which was shifted upfield by about −3 ppm from the position of the C-1 signal of methyl glucoside. A similar behavior was observed for the sugar moieties of **17**, **18**, and **19** and methyl tetra-*O*-acetyl-β-D-glucopyranoside in $CDCl_3$. On the other hand, anomeric carbon signals in sugar moieties of some steroid and triterpenoid glycosides were found to resonate at almost the same position as that in the corresponding methyl glycosides.[40] Chemical shift changes in aromatic aglycone carbons due to glycosidation (**6**→**19** as shown in Table 5) will also be useful for structure determination of natural glycosides having aromatic aglycones.

Thus, the assignments for all carbon atoms of aloenin (**2**) and its derivatives were established as shown in Tables 5 and 6; the present ^{13}C-NMR data on derivatives, **4**, **6**, **9**, **12**, and **16**—**21**, are in line with the structure of aloenin (**2**).

Test of Inhibitory Action on Gastric Juice Secretion. Since Aloe juice is widely used as domestic medicine for gastro-intestinal disturbance, the action of aloenin (**2**) on the gastric juice secretion of rats was tested by the method of Shay *et al.*[41] (Table 7). Aloenin (**2**) was found to exhibit an inhibitory action on gastric juice secretion.

Experimental

MS analyses were performed on Hitachi mass spectrometers, Model RMU-7L (for the high-resolution mass spectrum measurements) and Model RMS-4 (for the usual measurements), ionizing at the order of 70 eV. The 100 MHz and 60 MHz PMR spectra were recorded on Varian HA-100 and Hitachi Perkin-Elmer R-20 spectrometers, respectively, using TMS as an internal standard. The natural-abundance ^{13}C FT NMR spectra were taken on a Varian NV-14 FT NMR spectrometer operating at 15.087 MHz at 30 °C, using TMS as an internal reference ($\delta_c=0$) in a 8-mm spining tube, precision of δ_c being *ca.* ±0.1. The ^{13}C signals were assigned using known chemical shift rules,[33] ^1H single-frequency off-resonance (SFORD) and/or selective decoupling techniques[33] in combination with C_6D_6-induced ^1H shifts.[42] The NOE experiments were carried out on a Varian HA-100 spectrometer operating at 100 MHz in the frequency-swept and internal-TMS-locked mode. Samples were prepared in concentration of 5% (w/v) in $CDCl_3$ and carefully degassed just prior to measurements. The NOE values are represented by an increase in integrated intensities, precision of the values being *ca.* $\pm2\%$. Crystallographic analysis was performed on a Syntex $P2_1$ diffractometer using ω-scan technique with Cu $K\alpha$ radiation and a Ni-filter. The differential thermal and thermal gravimetric analyses were carried out on a Rigakudenki 8002 DTA-TGA analyzer. Melting points determined with a micro hot stage apparatus are uncorrected.

Extraction and Isolation. The leaves (3.7 kg) of *Aloe arborescens* Mill. var. *natalensis* Berger, which had been cultivated in pots for 3—4 years after planting the cuttings of lateral buds *ca.* 5 cm long, were collected in late April, minced mechanically, and squeezed on a three fold gauze to give a green leaf juice. The leaf juice on evaporation of water on a steam bath afforded a brown viscous mass, which was subjected to column chromatography on silica gel with a $CHCl_3$–MeOH mixture with MeOH increasing from 0 to 100% and then preparative TLC on silica gel with a $CHCl_3$–MeOH (3:1) mixture to give aloenin (**2**) (1.78 g).

*Aloenin (**2**).* Mp 145—147 °C (monohydrate) and 204—205 °C (anhydrous): the melting points and water of crystallization were determined by differential thermal and thermal gravimetric analyses; $[\alpha]_D^{25}$ −26.79° (*c* 2.2, MeOH); IR (dioxane) 3300, 1714, 1642, 1608, 1560 cm^{-1}; UV (EtOH) λ_{max} 307 nm (log ε 3.91), 245 (3.81), 232 (3.87), (0.05 M KOH-EtOH) 353 nm (log ε 4.16), 253 (4.14), 225 (3.98); PMR (Acetone-d_6) δ 2.19 (s, 3H, C(6′)-Me), 3.86 (s, 3H, C(4)-Me), 5.47 (d, J=2.5 Hz, 1H, C(3)-H), 6.15 (d, J=2.5 Hz, 1H, C(5)-H), 6.45 (d, J=2.2 Hz, 1H, arom. H), 6.62 (d, J=2.2 Hz, 1H, arom. H); ^{13}C-NMR (C_5D_5N) (Table 5). Found: C, 53.02; H, 5.76%. Calcd for $C_{19}H_{22}O_{10}\cdot H_2O$: C, 53.27; H, 5.65%.

*Dimethyl Ether **10**.* Methylation of **2** (100 mg) with diazomethane gave dimethyl ether **10** (102 mg): Mp 117—118 °C; IR (KBr) 3400, 1680, 1635, 1610, 1561 cm^{-1}; PMR (C_5D_5N) δ 2.29 (s, 3H, C(6′)-Me), 3.54 (s, 3H, C(4′)-OMe), 3.71 (s, 3H, C(4)-OMe), 5.60 (d, J=2.5 Hz, 1H, C(3)-H), 6.05 (d, J=2.5 Hz, 1H, C(5)-H). Found: C, 56.35; H, 5.65%. Calcd for $C_{20}H_{24}O_{10}$: C, 56.60; H, 5.70%.

*Pentaacetate **18**.* A pentaacetate derivative (**18**) of **2** was prepared by treatment with acetic anhydride in pyridine for 1 day at room temp: Mp 192—193 °C; IR ($CHCl_3$) 1758, 1714, 1698, 1645, 1608, 1567 cm^{-1}; PMR ($CDCl_3$) δ 1.98 (s, 6H, 2×OAc), 2.02 (s, 3H, OAc), 2.08 (s, 3H, OAc), 2.27 (s, 3H, C(6′)-Me), 2.29 (s, 3H, C(4′)-OAc), 3.86 (s, 3H, C(4)-OMe), 5.52 (d, J=2.5 Hz, 1H, C(3)-H), 5.99 (d, J=2.5 Hz, 1H, C(5)-H), 6.72 (bs, 2H, arom. 2H), 3.5—5.3 (7H); NOE (Fig. 1); ^{13}C-NMR ($CDCl_3$) (Table 5). Found: C, 49.60; H, 4.52%. Calcd for $C_{29}H_{32}O_{20}$: C, 49.72; H, 4.60%.

*Exhaustive Methylation of Aloenin (**2**).* Aloenin (**2**) (120 mg) was treated according to Hakomori's method[19] with sodium hydride and methyl iodide in dimethyl sulfoxide to give hexamethyl ether **5** (67 mg): Mp 143—143.5 °C; IR (KBr) 3050, 1720, 1648, 1615, 1572 cm^{-1}; PMR ($CDCl_3$) δ 2.22 (s, 3H, C(6′)-Me), 3.35 (s, 3H, OMe), 3.38 (s, 3H, OMe), 3.49 (s, 3H, OMe), 3.58 (s, 3H, OMe), 3.76 (s, 3H, OMe), 3.78 (s, 3H, OMe), 4.78 (d, J=5.5 Hz, 1H, C(1″)-H), 5.46 (d, J=2.0 Hz, 1H, C(3)-H), 6.08 (d, J=2.0 Hz, 1H, C(5)-H), 6.46 (d, J=2.0 Hz, 1H, arom. H), 6.59 (d, J=2.0 Hz, 1H, arom. H). Found: C, 59.71; H, 6.75%. Calcd for $C_{24}H_{32}O_{10}$: C, 59.99; H, 6.71%.

*Acid Hydrolysis of Aloenin (**2**).* After aloenin (**2**) (100 mg) dissolved in 3% methanolic hydrochloric acid (5 ml) had been heated under reflux for 2 h, the mixture was diluted with water and extracted with ether. The ether extract gave the aglycone (**3**) (41 mg): Mp 213—214 °C; IR (KBr) 3350, 1670, 1628, 1600, 1562 cm^{-1}; PMR (C_5D_5N) δ 2.33 (s, 3H, C(6′)-Me), 3.61 (s, 3H, C(4)-OMe), 5.67 (d, J=2.5 Hz, 1H, C(3)-H), 6.38 (d, J=2.5 Hz, 1H, C(5)-H). Found: C, 62.75; H, 4.81%. Calcd for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87%. The aqueous layer was passed through an Amberlite resin IR-45 (OH) column until all chloride ions had been removed. The neutral solution on concentration under reduced pressure gave D-glucose (30 mg): mp 144—145 °C, $[\alpha]_D^{25}$ +109°→+49° (*c* 0.2, H_2O).

*Enzymic Hydrolysis of Aloenin (**2**).* A suspension of aloenin (**2**) (20 mg) and emulsin (50 mg) in a phosphate buffer solution (pH 6.5) (5 ml) was stirred at 35 °C for 2 days. Formation of the aglycone (**3**) and glucose was confirmed by TLC and PPC analyses.

*Trimethyl Ether **4**.* Methylation of aglycone (**3**) (20 mg) with diazomethane gave the trimethyl ether **4** (20 mg): Mp 133—134 °C; IR (Nujol) 1725, 1641, 1613 cm^{-1}; PMR ($CDCl_3$) δ 2.26 (s, 3H, C(6′)-Me), 3.74 (s, 3H, C(2′)-OMe), 3.81 (s, 3H, C(4′)-OMe), 3.83 (s, 3H, C(4)-OMe), 5.50 (d, J=2.5 Hz, 1H, C(3)-H), 5.99 (d, J=2.5 Hz, 1H, C(5)-H), 6.34 (s, 2H, C(3′)- and C(5′)-H); NOE (Fig. 1); MS *m/e* (rel intensity) 276 (M^+, 100), 261 (5), 248 (52), 233 (33), 217 (12), 205 (44), 191 (13), 189 (17), 179 (29), 178 (30); High-resolution MS (Scheme 1); ^{13}C-NMR ($CDCl_3$) (Table 5). Found: C, 65.00; H, 5.72%. Calcd for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84%.

*Acid Hydrolysis of the Hexamethyl Ether (**5**).* The hexamethyl ether (**5**) (100 mg) was refluxed with 5 ml of 3% methanolic hydrochloric acid for 2 h and then the mixture, after being diluted with water, was extracted with chloroform. The chloroform extract gave a product **6** (35 mg) [mp 194—195 °C; IR (KBr) 1665, 1605, 1546, 1504, 844, 810, 750 cm^{-1}; PMR ($CDCl_3$) δ 2.32 (s, 3H, C(6′)-Me), 3.78 (s, 3H, C(4′)-OMe), 3.85 (s, 3H, C(4)-OMe); ^{13}C-NMR ($CDCl_3$) (Table 5)] and 2,3,4,6-tetra-*O*-methyl-D-glucose (mp 90—94 °C). Methylation of the product (**6**) (10 mg) with diazomethane gave trimethyl ether (**4**) (10 mg). The tetra-*O*-methyl-D-glucose was identified by comparing the mp and IR spectrum

with those of a synthetic sample.

*Acid Hydrolysis of the Dimethyl Ether (**10**).* The dimethyl ether (**10**) (50 mg) was refluxed with 3 ml of 3% methanolic hydrochloric acid for 2 h. The same treatment as in the case of **5** gave the compound **6** (17 mg) [mp 194—195 °C; IR (KBr) 1665, 1605, 1546, 1504 cm^{-1}] and glucose.

*Conversion of **3** and **6** into Chromone Derivatives.* The aglycone (**3**) (50 mg) was heated with 5% hydrochloric acid (5 ml) under reflux for 1 h, giving 2,5-dimethyl-7-hydroxychromone (**13**) (30 mg; mp 244—245 °C).[25] The same treatment of **6** as above gave 2,5-dimethyl-7-methoxychromone (**14**) (32 mg; mp 116—117 °C).

*Alkaline Cleavage of the Trimethyl Ether (**4**).* A solution of trimethyl ether (**4**) (200 mg) in 5% methanolic potassium hydroxide (20 ml) was stirred at room temp in an atmosphere of nitrogen. Crystals which started to appear after 12 h were filtered after 2 days and washed with absolute ethanol and then chloroform. They showed red coloration with ethanolic ferric chloride. A solution of the crystals (132 mg) in water (10 ml) was acidified carefully with a few drops of dilute hydrochloric acid and then immediately extracted with ether to give β-keto acid **7** (110 mg): IR (liquid) 3500—2500, 1725, 1600 cm^{-1}; PMR ($CDCl_3$) δ 2.33 (s, 3H, arom. Me), 3.73 (s, 6H, 2×OMe), 6.62 (s, 2H, arom. 2H); the reddish violet coloration is characteristic of β-keto acids with ethanolic ferric chloride. The keto acid (**7**) underwent facile decarboxylation during the course of purification by recrystallization. Without any purification, **7** (80 mg) dissolved in $CHCl_3$ (10 ml) was heated under reflux for 5 h in a stream of nitrogen to undergo decarboxylation. This was confirmed by the formation of barium carbonate in a barium hydroxide trap attached to the reflux apparatus. Removal of the solvent from the chloroform solution gave 1-(2,4-dimethoxy-6-methylphenyl)butane-1,3-dione (**8**) (61 mg; mp 72—73 °C, M^+ 236), which was identified by direct comparison with a synthetic specimen described below.

*Alkaline Cleavage of the Dimethyl Ether (**10**).* A solution of the dimethyl ether (**10**) (100 mg) in 5% methanolic potassium hydroxide (10 ml) was refluxed for 12 h. The mixture, after neutralization with hydrochloric acid and subsequent removal of the solvent, was subjected to preparative TLC on silica gel to give an oily product **11** (32 mg): IR (Nujol) 3450, 1600, 1180 cm^{-1}, which was treated with acetic anhydride in pyridine at room temp to afford tetraacetate **17**: mp 144—146 °C; IR (KBr) 1753, 1690, 1610, 1382, 1320, 1239 cm^{-1}; PMR ($CDCl_3$) δ 2.00 (s, 3H, OAc), 2.05 (s, 6H, 2×OAc), 2.10 (s, 3H, OAc), 2.22 (s, 3H, Me), 2.40 (s, 3H, COMe), 3.78 (s, 3H, OMe), 6.52 (s, 2H, arom. 2H); ^{13}C-NMR (Table 6). Found: C, 64.37; H, 6.70%. Calcd for $C_{24}H_{30}O_8$: C, 64.56; H, 6.77%. Hydrolysis of **11** (20 mg) with 3% methanolic hydrochloric acid (5 ml) gave 11 mg of 2-hydroxy-4-methoxy-6-methylacetophenone (**12**) (mp 78.0—78.5 °C; *m/e* 180 (M^+)), a trace of 2,5-dimethyl-7-methoxychromone (**14**), and glucose. The products, **12** and **14**, were identified by comparison with an authentic specimen,[22,25] glucose being detected by TLC and PPC analyses.

*2-Acetoxy-4-methoxy-6-methylacetophenone (**16**).* Acetylation of **12** (66 mg) with acetic anhydride in pyridine at room temp gave a methylacetophenone derivative (**17**) (80 mg): IR (liquid) 1760, 1680, 1605 cm^{-1}; PMR ($CDCl_3$) δ 2.28 (s, 3H, OAc), 2.33 (s, 3H, Me), 2.44 (s, 3H, COAc), 3.78 (s, 3H, OMe), 6.52 (d, J=2.0 Hz, 1H, arom. H), 6.65 (d, J=2.0 Hz, 1H, arom. H); ^{13}C-NMR (Table 6).

*Tetraacetate **19**.* Acetylation of the dimethyl ether (**10**) (50 mg) with acetic anhydride in pyridine at room temp gave tetraacetate **19** (53 mg): Mp 182—183 °C; IR (KBr) 1755, 1720, 1650, 1615, 1574 cm^{-1}; PMR ($CDCl_3$): δ 1.98 (s, 6H, 2×OAc), 2.03 (s, 3H, OAc), 2.10 (s, 3H, OAc), 2.30 (s, 3H, arom. Me), 3.82 (s, 3H, OMe), 3.87 (s, 3H, OMe), 5.50 (d, J=2.5 Hz, 1H, C(3)–H), 5.98 (d, J=2 Hz, 1H, C(5)–H), 6.50 (s, 2H, C(3′)- and C(5)–H); ^{13}C-NMR (Table 5).

*Methoxyacetate **20**.* Acetylation of the compound **6** (61 mg) with acetic anhydride in pyridine at room temp gave methoxyacetate **20** (58 mg): Mp 159—160 °C; IR (KBr) 1765, 1735, 1635, 1620, 1560 cm^{-1}; PMR ($CDCl_3$) δ 2.20 (s, OAc) 2.32 (s, Me), 3.83 (s, C(4′)–OMe), 3.86 (s, C(4)–OMe), 5.52 (d, J=2.0 Hz, C(3)–H), 5.95 (d, J=2.0 Hz, C(5)–H), 6.53 (d, J=2.0 Hz, arom. H), 6.72 (d, J=2.0 Hz, arom. H); ^{13}C-NMR (Table 5).

*Diacetate **21**.* Acetylation of the aglycone (**3**) (100 mg) with acetic anhydride in pyridine at room temp gave diacetate **21** (32 mg): Mp 151—152.5 °C; IR (KBr) 1764, 1725, 1640, 1614, 1565 cm^{-1}; PMR ($CDCl_3$) δ 2.20 (s, 3H, OAc), 2.30 (s, 3H, OAc), 2.33 (s, 3H, Me), 3.87 (s, 3H, OMe), 5.52 (d, J=2.0 Hz, 1H, C(3)–H), 5.98 (d, J=2.0 Hz, 1H, C(5)–H), 6.87 (m, 2H, arom. 2H); ^{13}C-NMR (Table 5).

*Synthesis of 1-(2,4-Dimethoxy-6-methylphenyl)butane-1,3-dione (**8**).* Sliced metallic sodium (25 mg) was added under ice-cooling to a mixture of ethyl acetate (0.5 ml) and 2,4-dimethoxy-6-methylacetophenone (**9**) (100 mg), which was prepared from 3,5-dihydroxytoluene by acetoacetic ester condensation.[22] The reaction mixture was left to stand at room temp for 5 min and then heated at 110 °C for 2 h. The mixture, after cooling and addition of water (5 ml), was extracted with ether to remove the unchanged substance. The separated alkaline solution was acidified with dilute acetic acid and extracted with ether to yield dione **8** (55 mg): Mp 72—73 °C; IR (KBr) 3500—2500, 1600 cm^{-1} (enol form of β-diketone); UV (EtOH) λ_{max} 282 nm (log ε 4.04), 222 (3.92); PMR ($CDCl_3$) δ 2.15 (s, 3H, COMe), 2.34 (s, 3H, arom. Me), 3.78 (s, 6H, 2×OMe), 5.69 (s, 1H, C(2)–H (enol form)), 6.32 (bs, 2H, arom. 2H); MS *m/e* (rel intensity) 236 (M^+, 31), 219 (30), 205 (20), 179 (100), 152 (36). Found: C, 66.02; H, 6.57%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%. The product (**8**) gave a reddish violet coloration characteristic of a β-diketone structure by the ferric chloride test.

*Test of Inhibitory Action of Aloenin (**2**) on Gastric Juice Secretion.* Inhibitory activity to gastric juice secretion was tested by the method of Shay *et al.*[41] Male rats of Donryu strain, 130—170 g in weight, were used for the tests. Table 7 gives the amount and pH of the gastric juice secreted during a period of 4 h after oral administration of the sample through a gastro-tube, together with the results of the control experiment.

We are grateful to Dr. Kazuo Tori, Shionogi Research Laboratory, Shionogi & Co., Ltd. and Mr. Osamu Koshitani, Hiroshima University, for their help in the ^{13}C-NMR study, and to Dr. Yoshihiko Kushi, Hiroshima University, and Dr. Arild Christensen, Syntex Analytical Instruments, Inc., for their assistance in the X-ray study. The investigation was partially supported by a Grant-in-Aid (074176, 047089, and 034058) for Scientific Research in 1975 from the Ministry of Education.

Chemical Studies on Tuberactinomycin. XIV.[1] Novel Synthesis of DL-Capreomycidine[2]

Tateaki WAKAMIYA, Katsutoshi MIZUNO, Tatsuzo UKITA, Tadashi TESHIMA, and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 8, 1977)

Cyclic guanidino amino acid, capreomycidine, is a component of antituberculous peptides, capreomycin and tuberactinomycin N and O. Its epimer was also found in protease inhibitors, chymostatin and elastatinal. A new synthetic approach to DL-capreomycidine *via* β-hydroxyornithine was studied for the purpose of total synthesis of capreomycidine and epicapreomycidine of natural forms or its hydroxy derivative, tuberactidine.

Antituberculous peptide, capreomycin, contains a unique cyclic guanidino amino acid capreomycidine (**1**) as a component.[3] A second case of its natural occurrence was revealed in the recent studies on similar antibiotics, tuberactinomycins, also as a constituent amino acid of two congeners N and O.[4] After the chemical structure of capreomycidine had been determined by Herr,[3] its stereochemistry was assumed by Bycroft *et al.*[5,6] to be (*S*)-α-[(4*R*)-2-iminohexahydro-4-pyrimidyl]glycine (L-capreomycidine) (**1**) and confirmed by X-ray analysis of tuberactinomycin O.[4a] A diastereoisomer of L-capreomycidine, (*S*)-α-[(4*S*)-2-iminohexahydro-4-pyrimidyl]glycine (L-epicapreomycidine) (**2**) was recently found as a component amino acid in protease inhibitors such as chymostatin[7] and elastatinal.[8] Occurrence of two diastereoisomers of one amino acid in nature is not so rare, particularly in the field of peptide antibiotics, but capreomycidine can be regarded as an example for consideration of amino acid biosynthesis from the view point of stereochemistry.

Concerning the synthesis of capreomycidine, Bycroft *et al.* presented a synthetic approach to DL-compound in 1971.[9] Their method is based on oximation of methyl (2-amino-4-pyrimidyl)acetate (**3**) followed by hydrogenation. However, according to their scheme, synthesis of an optically active form of this amino acid would require much effort particularly in the procedure of optical resolution. In fact they have not yet succeeded in preparing L-capreomycidine. As regards their failure in the synthesis of viomycidine (**4**) from 6-hydroxy analog of **3**, the approach seems unpromising for the synthesis of tuberactidine (**5**) which is another cyclic guanidino amino acid in tuberactinomycin group. The situation prompted us to search for a more favorable synthetic route to secure a common intermediate from which both optically active capreomycidine and tuberactidine could be obtained. This may offer a requisite tool for the synthesis of biologically important peptides containing cyclic guanidino amino acid.

In this connection, we describe a new synthetic method of DL-capreomycidine through β-hydroxyornithine for the preparation of optically active isomer. β-Hydroxyornithine was prepared in a previous synthesis of γ-hydroxy-β-lysine through rather tedious steps *via* 5-phthalimino-2-pentenoic acid.[10] We have improved the approach by a completely different method based on aldol condensation of 3-phthalimidopropionaldehyde (**6**)[11] with [*N*-(1-carboxylatoethylidene)glycinato]aquacopper(II) (**7**)[12] introduced by Ichikawa *et al.*[13] (Scheme 1).

After removal of copper(II) ion from the condensate, N^{δ}-phthaloyl-β-hydroxyornithine (**8**) was obtained as a mixture of *threo* (**8a**) and *erythro* (**8b**) forms in the ratio 89 : 11.[14] Each isomer was separated by fractional crystallization from water. Such a remarkable stereoselectivity was favorable for our purpose of preparing

capreomycidine of natural *threo* form, if the β-hydroxyl group could be converted into amino group without inversion of its configuration.

Removal of phthaloyl group from **8a** gave *threo*-β-hydroxyornithine (**9a**) which was anew benzyloxycarbonylated selectively at δ-amino group *via* copper(II) complex. Such an exchange of the protecting group was required for smooth deprotection in later synthetic step. N^{δ}-Benzyloxycarbonyl derivative **10** thus obtained was then tosylated at α-amino group to afford N^{δ}-benzyloxycarbonyl-N^{α}-tosyl-β-hydroxyornithine (**11**). (Scheme 2).

For conversion of β-hydroxyl into β-amino group, *O*-tosylation had been first carried out. However, *O*-tosylate of β-hydroxy acid is liable to turn to α,β-unsaturated compound by treatment with base when carboxyl group is free or esterified, whereas its acid amide often gives the desired *O*-tosylate.[15] In fact, methyl ester **12** readily gave α,β-unsaturated compound **13** even during the course of *O*-tosylation of **12** in pyridine. Thus, we converted methyl ester **12** into amide **14** with ammonia in methanol prior to *O*-tosylation. Amide **14** thus obtained afforded the desired *O*-tosyl derivative **15** in a satisfactory yield. *O*-Tosylate **15** was treated with diethylamine in tetrahydrofuran to yield aziridine compound **16**,[15] which was then converted into β-aminoornithine derivative **17** with ammonia in methanol (Scheme 3). In order to confirm the position and configuration of the newly introduced amino group, **17** was reversely deaminated with sodium nitrite to give hydroxy compound identified with the starting material **14** on thin-layer chromatography, affording *threo*-β-hydroxyornithine (**9a**) on hydrolysis. The fact that *threo* configuration was maintained in **17** was elucidated by the double inversion throughout the course of reaction (Scheme 3). Triamino deriva-

tive **17** thus established was debenzyloxycarbonylated by catalytic hydrogenation and then guanidinated with *N*-(*p*-tolylsulfonyl)bis(methylthio)methanimine[16] to afford a cyclic guanidino compound **19**, which, without isolation, was hydrolyzed with hydrobromic acid to give the final product (**1**). (Scheme 4). It was identical with that of natural L-capreomycidine on thin-layer chromatogram and amino acid analysis. IR and NMR spectra of the synthetic flavianate were also superposable with those of a natural specimen.

The novel synthesis of DL-capreomycidine, being entirely different from the former method,[9] is promising in view of preparation of an optically active guanidino amino acid particularly L-capreomycidine, L-epicapreomycidine or L-tuberactidine.[17]

Experimental

N$^{\delta}$-*Phthaloyl-β-hydroxyornithine (**8**).* Phthalimide (147 g, 1.00 mol) was suspended in 300 ml of absolute ethanol in which sodium metal (0.45 g) had been dissolved. Acrylaldehyde (56.1 g, 1.00 mol) in 50 ml of absolute ethanol was added dropwise to the suspension at room temperature for 50 min with stirring under nitrogen atmosphere. [*N*-(1-carboxylatoethylidene)glycinato]aquacopper(II) dihydrate (**7**)[13] (162 g, 0.621 mol) and 350 ml of absolute methanol were immediately added to the viscous pale yellow solution obtained. To the suspension was added sodium methoxide (54.0 g, 1.00 mol) in 150 ml of absolute methanol for 50 min. After being stirred at 30 °C overnight under nitrogen atmosphere, the reaction mixture was neutralized with 9 ml of acetic acid, and diluted with 1 litre of water. Greenish viscous precipitate was filtered off, and the filtrate was kept for further treatment (filtrate A).

The precipitate was dissolved in 1 M hydrochloric acid and the insoluble material was filtered off. Hydrogen sulfide was bubbled through the filtrate for 1 h. Cupric sulfide was filtered off and washed with 1 M hydrochloric acid. Filtrate and washings were combined, aerated, concentrated *in vacuo*, and neutralized with pyridine. Addition of ethanol gave precipitate of crude *threo* *N*$^{\delta}$-phthaloyl compound **8a** (77.6 g). This was recrystallized from water to give pure **8a**: yield 48.2 g (28%), mp 214.5 °C (dec).

Found: C, 52.65; H, 5.59; N, 9.46%. Calcd for $C_{13}H_{14}N_2O_5 \cdot H_2O$: C, 52.70; H, 5.44; N, 9.46%.

Filtrate A was treated as above to recover **8a** (2.28 g, 1.3%). Pure *erythro* compound (**8b**) was obtained from the mother liquor: yield 0.71 g (0.4%), mp 245 °C (dec).

Found: C, 55.49; H, 5.12; N, 10.03%. Calcd for $C_{13}H_{14}N_2O_5$: C, 56.11; H, 5.07; N, 10.07%.

threo-*β-Hydroxyornithine Hydrochloride (**9a**).* *N*$^{\delta}$-Phthaloyl-*threo*-*β*-hydroxyornithine (**8a**) (5.40 g, 18.2 mmol) was dissolved in 130 ml of 6 M hydrochloric acid and heated under reflux for 12 h. Phthalic acid was filtered off and the filtrate was extracted with ethyl acetate. Aqueous layer was concentrated *in vacuo*. Concentration after addition of a small amount of water was repeated several times to remove excess hydrochloric acid. Oily product was dissolved in a small amount of water, neutralized with pyridine, and then precipitated by addition of ethanol. Crystallization from water and ethanol gave **9a**: yield 3.20 g (87%), mp 189—190 °C (dec).

Found: C, 29.54; H, 7.56; N, 13.97; Cl, 17.47%. Calcd for $C_5H_{13}N_2O_3Cl \cdot H_2O$: C, 29.63; H, 7.46; N, 13.83; Cl, 17.50%.

erythro-*β-Hydroxyornithine Hydrochloride (**9b**).* *N*$^{\delta}$-Phthaloyl-*erythro*-*β*-hydroxyornithine (**8b**) (1.00 g, 3.60 mmol) was hydrolyzed with 60 ml of 6 M hydrochloric acid and treated as above: yield 580 mg (87%), mp 225 °C (dec).

Found: C, 32.26; H, 7.18; N, 15.30; Cl, 19.29%. Calcd for $C_5H_{13}N_2O_3Cl$: C, 32.53; H, 7.10; N, 15.17; Cl, 19.20%.

N$^{\delta}$-*Benzyloxycarbonyl*-threo-*β-hydroxyornithine (**10**).* Basic copper carbonate (23.9 g, 100 mmol) was added portionwise under boiling to a solution of *threo*-*β*-hydroxyornithine hydrochloride (**9a**) (10.1 g, 50.0 mmol) in 250 ml water. After additional 15 min boiling, excess copper carbonate was filtered off and washed with hot water. The combined filtrate and washings were subjected to acylation with benzyloxycarbonyl chloride (14.5 g, 85.0 mmol) and sodium hydrogencarbonate in the usual way. The reaction product precipitated was filtered, suspended in 200 ml of water, and 6 M hydrochloric acid was added to the suspension until precipitate dissolved. Hydrogen sulfide was passed through the solution, and the resulting cupric sulfide was filtered off. Neutralization of the solution with sodium hydrogencarbonate gave crystals (12.4 g) which were recrystallized from water: yield 10.3 g (71%), mp 212—213 °C (dec).

Found: C, 53.55; H, 6.58; N, 9.61%. Calcd for $C_{13}H_{18}N_2O_5 \cdot 1/2H_2O$: C, 53.60; H, 6.57; N, 9.62%.

N$^{\alpha}$-*Benzyloxycarbonyl*-N$^{\alpha}$-p-*tolylsulfonyl*-threo-*β-hydroxyornithine (**11**).* Triethylamine (3.00 g, 29.7 mmol) and *p*-toluenesulfonyl chloride (2.80 g, 14.7 mmol) were added portionwise during a period of 30 min to a suspension of *N*$^{\delta}$-benzyloxycarbonyl-*threo*-*β*-hydroxyornithine (**10**) (2.77 g, 9.52 mmol) in 24 ml of aqueous tetrahydrofuran (H_2O–THF = 2 : 1). The reaction mixture was stirred at room temperature for 1.5 h, concentrated to approximately 8 ml *in vacuo*, and extracted several times with ether. The aqueous layer was acidified with 2 M hydrochloric acid to produce an oily material which was extracted with ethyl acetate. The extract was washed with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. The oily residue was triturated with ether to crystallize. It was recrystallized from ethanol, ether, and hexane: yield 3.75 g (90%), mp 169.5—170 °C.

Found: C, 54.69; H, 5.59; N, 6.41; S, 7.20%. Calcd for $C_{20}H_{24}N_2O_7S$: C, 55.03; H, 5.54; N, 6.42; S, 7.32%.

N$^{\delta}$-*Benzyloxycarbonyl*-N$^{\delta}$-p-*tolylsulfonyl*-threo-*β-hydroxyornithine Methyl Ester (**12**).* Compound **11** (5.62 g, 12.9 mmol) was dissolved in a mixture of 15 ml each of anhydrous dioxane and anhydrous tetrahydrofuran. Diazomethane in ether was added to the solution under ice cooling until its yellow color remained. Excess diazomethane was decomposed with acetic acid with stirring for 30 min. The reaction mixture was concentrated *in vacuo* to give an oily residue, which was crystallized by addition of a small amount of ether.

It was recrystallized from ethyl acetate and hexane: yield 5.37 g (93%), mp 127—128 °C.

Found: C, 55.81; H, 5.83; N, 6.20; S, 7.19%. Calcd for $C_{21}H_{26}N_2O_7S$: C, 55.99; H, 5.82; N, 6.22; S, 7.12%.

N$^{\delta}$-*Benzyloxycarbonyl*-N$^{\delta}$-p-*tolylsulfonyl*-*α,β-dehydroornithine Methyl Ester (**13**).* To a solution of methyl ester **12** (1.02 g, 2.27 mmol) in 3 ml of anhydrous pyridine was added dropwise a solution of *p*-toluenesulfonyl chloride (864 mg, 4.53 mmol) in anhydrous pyridine with stirring under ice cooling. Stirring was continued under cooling for 30 min and then at room temperature overnight. The reaction mixture was concentrated *in vacuo*, dissolved in 20 ml of water, and extracted three times with 10 ml of ethyl acetate. The extract was washed with water, 1 M hydrochloric acid, saturated sodium chloride solution and dried over anhydrous sodium sulfate. The oily residue obtained after vacuum concentration was purified on silica gel column using benzene–ethyl acetate (3 : 1) as a solvent. Pure unsaturated compound

was obtained from the eluate: yield 0.70 g (71%), mp 85—86 °C, after recrystallization from ethyl acetate and hexane.

Found: C, 58.33; H, 5.60; N, 6.58; S, 7.36%. Calcd for $C_{21}H_{24}N_2O_6S$: C, 58.32; H, 5.59; N, 6.48; S, 7.41%.

*N$^{\delta}$-Benzyloxycarbonyl-N$^{\delta}$-p-tolylsulfonyl-threo-β-hydroxyornithine Amide (**14**).* Methyl ester **12** (4.50 g, 10.0 mmol) was dissolved in 80 ml of methanol. The solution was saturated with ammonia in a pressure bottle and kept at room temperature for 2 days. Concentration *in vacuo* gave an oily residue, which was crystallized by trituration with hexane. It was recrystallized from ethyl acetate and hexane: yield 4.17 g (96%), mp 134.5 °C.

Found: C, 54.94; H, 5.83; N, 9.48; S, 7.44%. Calcd for $C_{20}H_{25}N_3O_6S$: C, 55.16; H, 5.79; N, 9.65; S, 7.36%.

*N$^{\delta}$-Benzyloxycarbonyl-N$^{\alpha}$,O-bis(p-tolylsulfonyl)-threo-β-hydroxyornithine Amide (**15**).* *p*-Toluenesulfonyl chloride (9.33 g, 48.9 mmol) in 20 ml of pyridine was added dropwise to a solution of amide **14** (3.55 g, 8.15 mmol) in 15 ml of pyridine for 4 h under stirring and cooling in ice–salt bath. After additional 4 h stirring in a chilled bath, the reaction mixture was poured on crushed ice in 35 ml of concentrated hydrochloric acid. Aqueous solution was extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate, and concentrated *in vacuo*. The oily residue obtained was purified by silica gel column chromatography: Silica gel 50 g; column 2.3 × 30 cm; each 10 g fraction. The following solvents were used successively, benzene (100 ml), benzene–ethyl acetate (4 : 1 = 250 ml, 3 : 1 = 400 ml, 2 : 1 = 350 ml), ethyl acetate (850 ml). Fractions 16 to 35 gave α,β-unsaturated amide as an oily substance (340 mg, 10%). Desired *O*-tosylate was obtained as crystals from fractions 36—84 (2.35 g, 49%), the starting material **14** being recovered from fractions 101—145 (1.15 g, 32%). *O*-Tosylate was recrystallized from chloroform and ether for elemental analysis, mp 146—147 °C.

Found: C, 55.03; H, 5.32; N, 7.10; S, 10.82%. Calcd for $C_{27}H_{31}N_3O_8S_2$: C, 54.99; H, 5.30; N, 7.13; S, 10.88%.

*5-Benzyloxycarbonylamino-cis-2,3-(p-tolylsulfonylepimino)pentanamide (**16**).* Diethylamine (114 mg, 1.55 mmol) was added at 35—37 °C to a solution of ditosyl amide **15** (457 mg, 0.774 mmol) in 5 ml of anhydrous tetrahydrofuran. The reaction mixture was stirred for 3 h at the temperature and concentrated *in vacuo*. The residue was dissolved in ethyl acetate and washed with water, 1 M hydrochloric acid, and again water to neutral. Organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The crystalline residue was recrystallized from chloroform and ether: yield 289 mg (89%), mp 136—137 °C.

Found: C, 57.16; H, 5.62; N, 10.08; S, 7.71%. Calcd for $C_{20}H_{23}N_3O_5S$: C, 57.54; H, 5.55; N, 10.07; S, 7.68%.

*threo-3-Amino-5-benzyloxycarbonylamino-2-(p-tolylsulfonylamino)-pentanamide (**17**).* Gaseous ammonia was bubbled into a solution of aziridine compound **16** (1.02 g, 2.44 mmol) in 200 ml of methanol until saturation. It was kept in a pressure bottle at room temperature for 4 days, and concentrated *in vacuo*. Evaporation was repeated twice after dissolution of the residue in methanol. Finally, residual oil was dissolved in 15 ml of 0.2 M hydrochloric acid and extracted with ethyl acetate. The aqueous layer was concentrated *in vacuo* and the oily residue was crystallized by trituration with ether: yield 1.01 g (87%). It was recrystallized from methanol and ether, mp 115—117 °C.

Found: C, 49.26; H, 5.86; N, 11.58; S, 6.52; Cl, 7.25%. Calcd for $C_{20}H_{26}N_4O_5S \cdot HCl \cdot H_2O$: C, 49.12; H, 5.98; N, 11.46; S, 6.56; Cl, 7.25%.

*threo-3,5-Diamino-2-(p-tolylsulfonylamino)pentanamide (**18**).* 3-Amino compound **17** (1.01 g, 2.14 mmol) obtained above was dissolved in 20 ml of methanol containing 0.18 ml (2.16 mmol) of concentrated hydrochloric acid and hydrogenated in the presence of palladium black. After the completion of reduction had been checked on TLC, the catalyst was filtered off and the filtrate was concentrated *in vacuo*. The crystalline residue was recrystallized from methanol and ether: yield 0.73 g (91%), mp 189—191 °C.

Found: C, 37.00; H, 5.93; N, 14.62; S, 8.31; Cl, 18.11%. Calcd for $C_{12}H_{20}N_4O_3S \cdot 2HCl \cdot H_2O$: C, 36.83; H, 6.18; N, 14.32; S, 8.19; Cl, 18.12%.

*DL-Capreomycidine (**1**) Diflavianate.* 3,5-Diamino compound **18** (200 mg, 0.511 mmol), *N-(p*-tolylsulfonyl)bis(methylthio)methanimine[16] (141 mg, 0.511 mmol) and 0.51 ml of 1 M sodium hydroxide were dissolved in 95% ethanol. The solution was heated under reflux for 3 h. After addition of 0.51 ml of 1 M sodium hydroxide, heating was continued for 6 h. The reaction mixture was concentrated *in vacuo* to yield a residue which was extracted with ethyl acetate. The extract was washed with saturated sodium chloride solution, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. The oily residue was immediately hydrolyzed with 47% hydrobromic acid in the presence of 2 ml of anisole under reflux for 24 h. The hydrolyzate was extracted with benzene several times, diluted with water, and extracted with ethyl acetate. The aqueous layer was concentrated *in vacuo* and ethanol was added to the residue. After removal of insoluble material by filtration, the filtrate was concentrated again. The residue was dissolved in 2 ml of water containing excess flavianic acid, 2 ml of ethanol being added. It was allowed to stand to yield yellow needles: Yield 90 mg (21%). For elemental analysis, it was recrystallized from water, mp 217—219 °C (dec).

Found: C, 36.42; H, 3.55; N, 13.34; S, 7.49%. Calcd for $C_{26}H_{24}N_8O_{18}S_2 \cdot 3H_2O$: C, 36.54; H, 3.54; N, 13.11; S, 7.50%.

Nucleoside Analogs. 6. A Synthesis of Carbocyclic Puromycin Analogs[1)]

Tetsuo SUAMI,* Kin-ichi TADANO, Mitsukuni AYABE, and the late Yasufumi EMORI
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223
(Received August 9, 1977)

Eight carbocyclic puromycin analogs, in which the furanosyl ring of puromycin is replaced with a cyclopentyl system, were synthesized. Their minimum degeneration concentration (MDC) was determined against *HeLa* cells in a tissue culture. The two analogs were found to be remarkably active.

A nucleoside antibiotic puromycin (**1**) was isolated from a culture broth of *Streptomyces alboniger* by Porter *et al.*,[2)] its synthesis being accomplished by Baker *et al.*[3)] Various analogs have been prepared for clarification of the relationship between structure and biological activity.[4-7)]

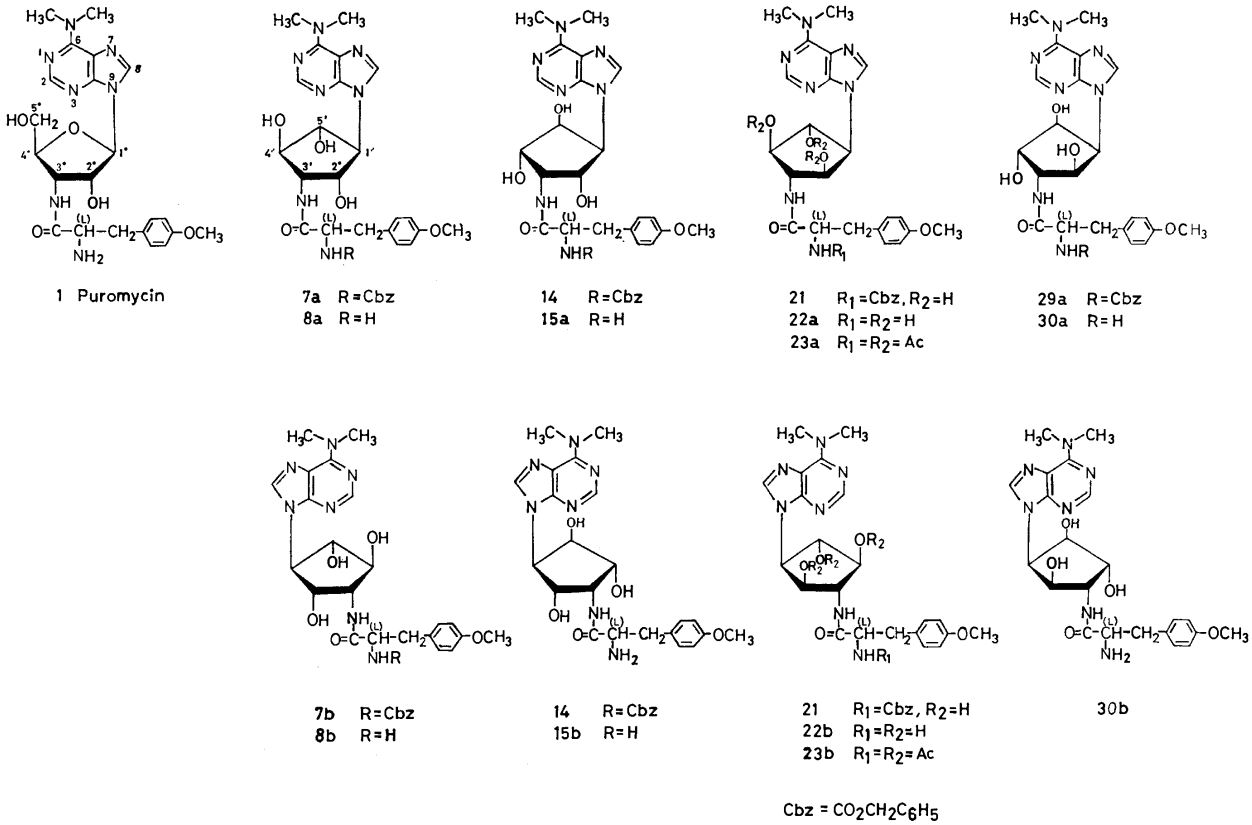
In particular, Daluge and Vince[7)] demonstrated the essential structural requirement for biological activity in puromycin analogs by the synthesis of a carbocyclic analog: 6-dimethylamino-9-[(1*R*,2*R*,3*R*)-2-hydroxy-3-(*p*-methoxyphenyl-L-alanylamino)cyclopentyl]purine. They showed that the removal of the hydroxymethyl moiety from the puromycin molecule is not detrimental to activity and the furanosyl ring can be replaced with a cyclopentane ring with no loss in activity. Their assessment of the structural requirement in the puromycin molecule stimulated us to prepare a carbocyclic puromycin analog in which the 3-amino-3-deoxy-β-D-ribofuranosyl moiety of puromycin is replaced by 3-amino-2,4,5-trihydroxycyclopentyl group.

The structure of puromycin resembles that of the aminoacyl–adenyl terminus of aminoacyl-tRNA, this being strongly connected with its biological activity. Since a cyclopentane ring is conformationally similar to a furanosyl ring, 3-amino-2,4,5-trihydroxycyclopentyl group might replace the furanosyl moiety of puromycin, favorably resulting in biological activity.

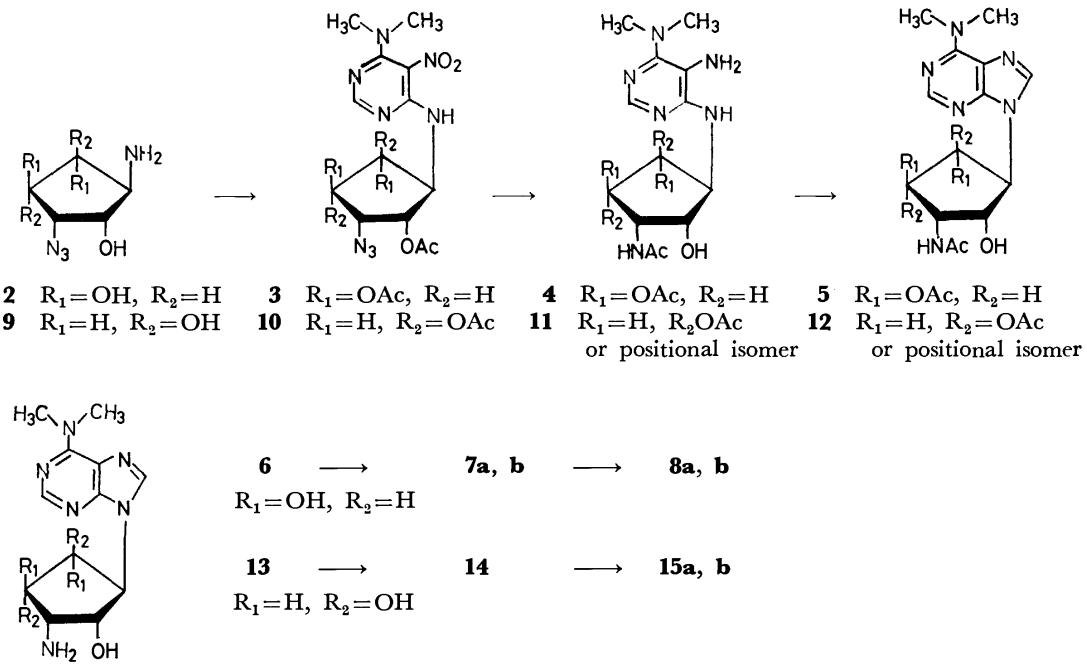
Carbocyclic analogs of adenosine and pyrimidine nucleosides, in which the ribofuranosyl moiety was replaced by the polyhydroxycyclopentyl or polyhydroxycyclohexyl group, have been prepared.[8-12)] In connection with the preceding studies and to extend the Daluge and Vince evaluation of the structural requirement of the puromycin molecule, we have synthesized eight diastereoisomeric 6-dimethylamino-9-[2,4,5-trihydroxy-3-(*p*-methoxyphenyl-L-alanylamino)cyclopentyl]purines (**8a,b, 15a,b, 22a,b,** and **30a,b**), and their biological activities were dtermined against *HeLa* cells.

Results and Discussion

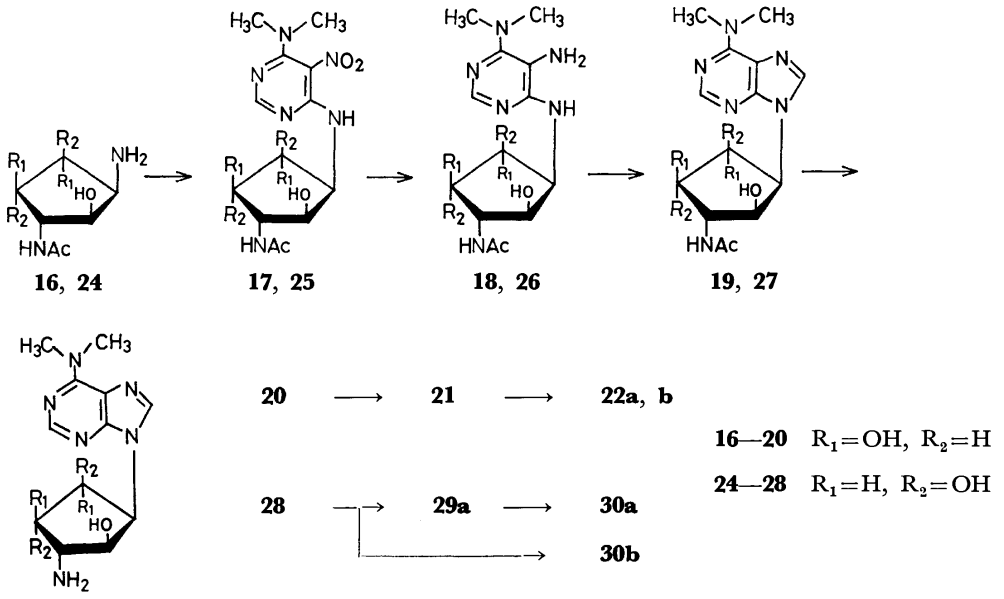
The carbocyclic puromycin analogs were prepared by the reaction processes shown in Schemes 2 and



Scheme 1.



Scheme 2.[19]



Scheme 3.[19]

3. The processes are divided into two categories, 1-amino-3-azido-2,4,5-cyclopentanetriols (**2** and **9**) being used as the starting material in the former two (Scheme 2) and 3-acetamino-1-amino-2,4,5-cyclopentanetriols (**16** and **24**) in the latter two.

When 1-amino-3-azido-2,4,5-cyclopentanetriol[11] (**2**) was heated with 6-chloro-4-dimethylamino-5-nitropyrimidine[13] in 2-methoxyethanol in the presence of triethylamine, 6-[(3-azido-2,4,5-triacetoxycyclopentyl)-amino]-4-dimethylamino-5-nitropyrimidine (**3**) was obtained, after acetylation. The structure of **3** was confirmed by the ^{1}H NMR spectrum in which NH revealed a doublet at δ 8.38 (J=7 Hz).

Catalytic hydrogenation of **3** with Raney nickel afforded 6-[(3-acetamido-4,5-diacetoxy-2-hydroxycyclopentyl)amino]-5-amino-4-dimethylaminopyrimidine (**4**). During the course of the reaction, acetyl group migration took place from O to N in the *cis*-arrangement.

Ring closure of **4** was performed with triethyl orthoformate in the presence of *p*-toluenesulfonic acid to give the purine derivative (**5**) in 87% yield. Hydrolysis of **5** in aqueous barium hydroxide, followed by purification on a column of Amberlite CG-120(H$^+$) resin gave 9-(3-amino-2,4,5-trihydroxycyclopentyl)-6-dimethylaminopurine (**6**). Compound **6** was converted into the crystalline hydrochloride which was proved to be the 9-substituted adenine derivative by a characteristic UV absorption.[16]

Table 1. Minimum degeneration concentration (MDC) with *HeLa S3* cells in a tissue culture by the two-fold serial liquid medium dilution method[18]

Compound	MDC (μg/ml)
8a	15.6
8b	250
15a	31.2
15b	125
22a	1000
22b	1000
30a	250
30b	500

When **6** was treated with *N*-benzyloxycarbonyl-*p*-methoxyphenyl-L-alanine[14] and *N*-hydroxysuccinimide in the presence of dicyclohexylcarbodiimide, a mixture of two diastereoisomers (**7a** and **7b**) was obtained, since **6** is of DL form. Compounds **7a** and **7b** were successfully separated by fractional recrystallization. Hydrogenolysis of **7a** and **7b** in glacial acetic acid with palladium black gave **8a** and **8b**, respectively. The overall yields of **8a** and **8b** were 11 and 19%, respectively.

Compounds **15a** and **15b** were obtained by analogous reactions (Scheme 2) in 7 and 8% overall yields, respectively.

On the other hand, when 3-acetamido-1-amino-2,4,5-cyclopentanetriol (**16**) was subjected to react with 6-chloro-4-dimethylamino-5-nitropyrimidine,[13] 6-[(3-acetamido-2,4,5-trihydroxycyclopentyl)amino]-4-dimethylamino-5-nitropyrimidine (**17**) was obtained in 77% yield. The successive reactions leading to **22a** and **22b** were carried out by following the reactions used in the preparation of **8a** and **8b** (Scheme 3). The overall yields of **22a** and **22b** were 8 and 14%, respectively.

By an analogous reaction (Scheme 3), **30a** and **30b** were obtained each in 8% overall yield.

A biological activity of the carbocyclic puromycin analogs thus obtained was determined by the usual two-fold serial liquid medium dilution method with *HeLa S3* cells in a tissue culture. The minimum degeneration concentration (MDC) was appraised, the result being given in Table 1. We see that **8a** and **15a** are remarkably active, in contrast with other diastereoisomers.

The stereochemistry of **8a** and **15a** is tentatively assigned as that depicted in Scheme 1, on the basis of their biological activity and the absolute configuration of puromycin with respect to that on C-1′, 2′, and 3′.

The stereochemistry of **22a** and **30a** is assigned tentatively on the observation that, in the cases of **8a** and **15a**, their specific rotations are more levorotatory than those of the respective diastereoisomers: **8b** and **15b**. Therefore, the absolute configurations of **22a** and **30a** depicted in Scheme 1 are assigned to the strongly levorotatory diastereoisomers.

Experimental

Melting points were determined in capillary tubes in a liquid bath and are uncorrected. Solutions were evaporated under reduced pressure. Optical rotations were measured with a Japan Spectroscopic DIL-SL polarimeter. ^{1}H NMR spectra were recorded at 60 MHz with a Varian A-60D spectrometer for solutions in chloroform-*d*, unless otherwise stated, with tetramethylsilane as an internal standard, the peak positions being given in δ values.[17] IR spectra were recorded on potassium bromide disks with a Hitachi Perkin-Elmer 225 spectrometer. UV spectra were determined with a Hitachi Perkin-Elmer UV-VIS 139 spectrometer. Acetylation was performed with acetic anhydride and pyridine. Catalytic hydrogenation of a nitro group to an amino group was carried out in the presence of Raney nickel in a hydrogen atmosphere (3.4 kg/cm^2) with a Parr apparatus. TLC was performed on Wakogel B-10 Wako Pure Chemical Co. Ltd.) plates. Silica gel (Wakogel C-300) was used for column chromatography.

DL-(1,4/2,3,5)-1-Amino-3-azido-2,4,5-cyclopentanetriol (2). The compound was prepared by the method of Tadano *et al.*[11]

6-[(DL-(1,4/2,3,5)-3-Azido-2,4,5-triacetoxycyclopentyl)amino]-4-dimethylamino-5-nitropyrimidine (3). A mixture of **2** (1.0 g) and 6-chloro-4-dimethylamino-5-nitropyrimidine[13] (2.33 g) in 2-methoxyethanol (50 ml) containing triethylamine (1 ml) was heated at 100 °C for 5 h with mechanical agitation. The mixture was evaporated and the residue was dissolved in warm water (50 ml). The aqueous solution was washed with benzene repeatedly and the aqueous layer was evaporated. The residue was acetylated and the resulting solution was poured into ice cold water. The solution was extracted with chloroform and the chloroform solution was evaporated to give a pale yellow crystalline residue. The residue was washed with warm ethyl acetate to give 1.92 g (72%) of **3**, mp 190—191 °C. ^{1}H NMR: δ 2.06 (s, 3, OAc), 2.14 (s, 3, OAc), 2.15 (s, 3, OAc), 3.08 (s, 6, 2×NCH$_3$), 8.04 (s, 1, pyrimidine H-2), 8.38 (d, 1, J=7 Hz, NH).

Found: C, 43.98; H, 4.79; N, 24.26%. Calcd for $C_{17}H_{22}N_8O_8$: C, 43.78; H, 4.76; N, 24.03%.

6-[(DL-(1,4/2,3,5)-3-Acetamido-4,5-diacetoxy-2-hydroxycyclopentyl)amino]-5-amino-4-dimethylaminopyrimidine (4). Compound **3** (300 mg) was catalytically hydrogenated in ethyl acetate (50 ml) for 3 h. The catalyst was filtered off and the filtrate was evaporated to give 253 mg (96%) of **4** as crystals, mp 206—207 °C (dec). ^{1}H NMR (DMSO-d_6): δ 1.94 (s, 3, NAc), 2.05 (s, 3, OAc), 2.06 (s, 3, OAc), 2.81 (s, 6, 2×NCH$_3$), 5.73 (d, 1, J=4 Hz, OH), 6.75 (d, 1, J=7 Hz, pyrimidine H-6), 8.08 (s, 1, pyrimidine H-2), 8.13 (d, 1, J=8 Hz, NH).

Found: C, 50.05; H, 6.50; N, 20.20%. Calcd for $C_{17}H_{26}N_6O_6$: C, 49.75; H, 6.39; N, 20.48%.

9-[DL-(1,4/2,3,5)-3-Acetamido-4,5-diacetoxy-2-hydroxycyclopentyl]-6-dimethylaminopurine (5). A mixture of **4** (204 mg) and triethyl orthoformate (0.11 ml) in *N*,*N*-dimethylformamide (10 ml) was stirred for 6 h in the presence of *p*-toluenesulfonic acid (9 mg). After being neutralized with Amberlite IRA-400 (OH$^-$) resin, the solution was evaporated. The residue was recrystallized from ethyl acetate to give 182 mg (87%) of **5**, mp 200—201 °C. ^{1}H NMR (DMSO-d_6): δ 1.95 (s, 3, NAc), 1.97 (s, 3, OAc), 2.12 (s, 3, OAc), 3.59 (s, 6, 2×NCH$_3$), 5.95 (d, 1, J=5 Hz, OH), 8.31 (d, 1, J=8 Hz, NH), 8.56 (s, 1, purine H-2 or 8), 8.60 (s, 1, purine H-8 or 2).

Found: C, 51.64; H, 5.75; N, 19.74%. Calcd for $C_{18}H_{24}N_6O_6$: C, 51.42; H, 5.75; N, 19.99%.

*9-[DL-(1,4/2,3,5)-3-Amino-2,4,5-trihydroxycyclopentyl]-6-dimethylaminopurine (**6**).* A mixture of **5** (1.65 g) and barium hydroxide octahydrate (8.0 g) in water (96 ml) was heated at 100 °C for 3 h with mechanical agitation. Carbon dioxide was bubbled into the solution and barium carbonate was filtered off. The filtrate was concentrated and the residue was purified on a column of Amberlite CG-120(H^+) resin. After being washed with water, the column was eluted with dil NH_4OH and the effluent was concentrated to give 1.14 g of **6** as a crude product. A part of the product was converted into crystalline hydrochloride, mp 250 °C (dec). UV: $\lambda_{max}^{0.1M\ HCl}$ 269 nm ($\varepsilon=1.7\times10^4$), $\lambda_{max}^{H_2O}$ 277 nm ($\varepsilon=1.7\times10^4$), $\lambda_{max}^{0.1M\ NaOH}$ 277 nm ($\varepsilon=1.7\times10^4$).

Found: C, 43.35; H, 5.74; N, 25.19; Cl, 10.88%. Calcd for $C_{12}H_{19}N_6O_3Cl$: C, 43.57; H, 5.79; N, 25.41; Cl, 10.72%.

*6-Dimethylamino-9-[(1S,2R,4R,5R)-2,4,5-trihydroxy-3-(N-benzyloxycarbonyl-p-methoxyphenyl-L-alanylamino)cyclopentyl]purine (**7a**)* and *6-Dimethylamino-9-[(1R,2S,4S,5S)-2,4,5-trihydroxy-3-(N-benzyloxycarbonyl-p-methoxyphenyl-L-alanylamino)cyclopentyl]-purine (**7b**).* Dicyclohexylcarbodiimide (DCC, 838 mg) was added under ice-cooling with agitation to a solution of **6** (1.14 g) and *N*-benzyloxycarbonyl-*p*-methoxyphenyl-L-alanine[14] (1.34 g) in *N,N*-dimethylformamide (DMF, 57 ml) containing *N*-hydroxysuccinimide (468 mg). After 30 min, the solution was left to settle at ambient temperature for 18 h. The mixture was filtered in order to remove *N,N'*-dicyclohexylurea and the filtrate was concentrated. The residue was recrystallized from ethanol to give 670 mg (29%) of **7a** as needles, mp 179—180 °C, $[\alpha]_D^{20}$ −24.4° (*c* 1.07, DMF). ^{1}H NMR (DMSO-d_6): 3.62 (s, 6, 2×NCH_3), 3.90 (s, 3, OCH_3), 5.18 (s, 2, benzyl CH_2), 7.34 (q, 4, C_6H_4), 7.58 (s, 5, C_6H_5), 8.28 (d, 1, J=8 Hz, NH on C-3'), 8.54 (s, 1, purine H-2 or 8), 8.57 (s, 1, purine H-8 or 2).

Found: C, 59.62; H, 5.86; N, 16.20%. Calcd for $C_{30}H_{35}N_7O_7$: C, 59.49; H, 5.83; N, 16.19%.

The ethanolic mother liquor of **7a** was stored in a refrigerator to give 1.12 g of a product. Recrystallization from methanol gave 931 mg (40%) of **7b** as needles, mp 210—211 °C, $[\alpha]_D^{20}$ +17.5° (*c* 1.03, DMF). ^{1}H NMR (DMSO-d_6): 3.64 (s, 6, 2×NCH_3), 3.90 (s, 3, OCH_3), 5.21 (s, 2, benzyl CH_2), 7.36 (q, 4, C_6H_4), 7.62 (s, 5, C_6H_5), 8.27 (d, 1, J=6 Hz, NH on C-3'), 8.57 (s, 1, purine H-2 or 8), 8.61 (s, 1, purine H-8 or 2).

Found: C, 59.23; H, 5.83; N, 16.33%. Calcd for $C_{30}H_{35}N_7O_7$: C, 59.49; H, 5.83; N, 16.19%.

*6-Dimethylamino-9-[(1S,2R,4R,5R)-2,4,5-trihydroxy-3-(p-methoxyphenyl-L-alanylamino)cyclopentyl]purine (**8a**).* A solution of **7a** (300 mg) in glacial acetic acid (20 ml) was hydrogenated in the presence of palladium black (200 mg) in a hydrogen atmosphere (1.4 kg/cm^2) for 3 h. The catalyst was filtered off, and the filtrate was concentrated. A methanolic solution of the residue was passed through a column of Amberlite IRA-400(OH^-) resin and the effluent was concentrated. The residue was recrystallized from methanol to give 146 mg (63%) of **8a**, mp 190—191 °C (dec), $[\alpha]_D^{19}$ −55.0° (*c* 0.98, DMF). UV: $\lambda_{max}^{0.1M\ HCl}$ 268 nm ($\varepsilon=2.7\times10^4$), $\lambda_{max}^{H_2O}$ 276 nm ($\varepsilon=1.9\times10^4$), $\lambda_{max}^{0.1M\ NaOH}$ 275 nm ($\varepsilon=2.1\times10^4$). ^{1}H NMR (DMSO-$d_6$): 3.62 (s, 6, 2×$NCH_3$), 3.89 (s, 3, OCH_3), 7.31 (q, 4, C_6H_4), 8.54 (s, 1, purine H-2 or 8), 8.57 (s, 1, purine H-8 or 2).

Found: C, 55.92; H, 6.28; N, 20.54%. Calcd for $C_{22}H_{29}N_7O_5$: C, 56.04; H, 6.20; N, 20.79%.

*6-Dimethylamino-9-[(1R,2S,4S,5S)-2,4,5-trihydroxy-3-(p-methoxyphenyl-L-alanylamino)cyclopentyl]purine (**8b**).* Catalytic hydrogenation of **7b** (300 mg) was carried out as in the preparation of **8a**. The product was recrystallized from methanol to give 182 mg (78%) of **8b**, mp 196—197 °C, $[\alpha]_D^{19}$ +0.39° (*c* 0.98, DMF). UV: $\lambda_{max}^{0.1M\ HCl}$ 269 nm ($\varepsilon=1.8\times10^4$), $\lambda_{max}^{H_2O}$ 276 nm ($\varepsilon=2.0\times10^4$), $\lambda_{max}^{0.1M\ NaOH}$ 276 nm ($\varepsilon=2.3\times10^4$). ^{1}H NMR (DMSO-$d_6$): 3.61 (s, 6, 2×$NCH_3$), 3.89 (s, 3, OCH_3), 7.35 (q, 4, C_6H_4), 8.56 (s, 1, purine H-2 or 8), 8.58 (s, 1, purine H-8 or 2).

Found: C, 55.95; H, 6.18; N, 20.52%. Calcd for $C_{22}H_{29}N_7O_5$: C, 56.04; H, 6.20; N, 20.79%.

*DL-(1,5/2,3,4)-1-Amino-3-azido-2,4,5-cyclopentanetriol (**9**).* Hydrolysis of DL-(1,5/2,3,4)-1-acetamido-3-azido-2,4,5-triacetoxycyclopentane[15] (1.68 g) in 3 M HCl, followed by deionization with Amberlite IRA-400 (OH^-) resin gave 837 mg (98%) of **9** as a crude syrup. The product was used for successive reaction without purification.

*6-[(DL-(1,5/2,3,4)-3-Azido-2,4,5-triacetoxycyclopentyl)amino]-4-dimethylamino-5-nitropyrimidine (**10**).* A mixture of **9** (837 mg) and 6-chloro-4-dimethylamino-5-nitropyrimidine[13] (1.46 g) in 2-methoxyethanol (42 ml) containing triethylamine (1 ml) was heated at 90 °C for 3.5 h. The mixture was treated as in the preparation of **3**. The product was recrystallized from ethanol to give 1.15 g (51%) of **10**, mp 146—147 °C. ^{1}H NMR: 2.03 (s, 3, OAc), 2.11 (s, 3, OAc), 2.15 (s, 3, OAc), 3.05 (s, 6, 2×NCH_3), 7.97 (s, 1, pyrimidine H-2), 8.22 (d, 1, J=6 Hz, NH).

Found: C, 44.00; H, 4.87; N, 23.70%. Calcd for $C_{17}H_{22}N_8O_8$: C, 43.78; H, 4.76; N, 24.03%.

The mixture was worked up as in the preparation of **6** to give 1.16 g (90%) of **20**, mp 204—205 °C (dec). An analytically pure sample was obtained by recrystallization from aqueous ethanol.

Found: C, 48.72; H, 6.20; N, 28.71%. Calcd for $C_{12}H_{18}N_6O_3$: C, 48.97; H, 6.16; N, 28.55%.

*A Mixture of 6-Dimethylamino-9-[(1*S,*2*S,*4*R,*5*R*)-2,4,5-trihydroxy-3-(N-benzyloxycarbonyl-p-methoxyphenyl-L-alanylamino)cyclopentyl]purine and 6-Dimethylamino-9-[(1*R,*2*R,*4*S,*5*S*)-2,4,5-trihydroxy-3-(N-benzyloxycarbonyl-p-methoxyphenyl-L-alanylamino)-cyclopentyl]purine (**21**).* To a solution of **20** (218 mg) and *N*-benzyloxycarbonyl-*p*-methoxyphenyl-L-alanine[14] (256 mg) in DMF (10 ml) containing *N*-hydroxysuccinimide (90 mg), DCC (161 mg) was added under ice-cooling. The mixture was worked up as in the preparation of **7a** and **7b** to give 334 mg (74%) of **21**, mp 214—216 °C.

Found: C, 59.52; H, 5.84: N, 16.37%. Calcd for $C_{30}H_{35}N_7O_7$: C, 59.49; H, 5.83; N, 16.19%.

*6-Dimethylamino-9-[(1*S,*2*S,*4*R,*5*R*)-2,4,5-trihydroxy-3-(p-methoxyphenyl-L-alanylamino)cyclopentyl]purine (**22a**)* and *6-Dimethylamino-9-[(1*R,*2*R,*4*S,*5*S*)-2,4,5-trihydroxy-3-(p-methoxyphenyl-L-alanylamino)cyclopentyl]purine (**22b**).* A solution of **21** (500 mg) in glacial acetic acid (15 ml) was hydrogenated in the presence of 10% palladium on charcoal in a hydrogen atmosphere (3.0 kg/cm^2) for 2 h. The solution was worked up as in the preparation of **8a**, and the product was purified by column chromatography using 3 : 1 (v/v) chloroform–methanol. Fractions showing a single spot at R_f 0.45 on TLC in the same solvent system were combined and concentrated to give 90 mg (23%) of **22a**, mp 259—261 °C (dec), $[\alpha]_D^{20}$ −31.9° (*c*, 0.99, DMF).

Found: C, 55.85; H, 6.24; N, 20.47%. Calcd for $C_{22}H_{29}N_7O_5$: C, 56.04, H, 6.20; N, 20.79%.

Fractions showing a single spot at R_f 0.31 on TLC in the same solvent were combined and concentrated to give 104 mg (27%) of **22b**, mp 258—260 °C (dec), $[\alpha]_D^{20}$ −3.6° (*c* 1.01, DMF).

Found: C, 56.04; H, 6.19; N, 20.60%. Calcd for $C_{22}H_{29}N_7O_5$: C, 56.04; H, 6.20; N, 20.79%.

N,O-*Tetraacetyl Derivative of **22a** (**23a**).* Compound **22a** (30 mg) was acetylated and the product was purified by a column chromatography using 5 : 1 (v/v) benzene–ethanol. The product was washed with ether to give 37 mg (91%) of **23a**, mp 188—189 °C. ^{1}H NMR: δ 1.80 (s, 3, NAc), 1.91 (s, 3, OAc), 1.97 (s, 3, OAc), 2.06 (s, 3, OAc), 3.01 (d, 2, J= 7 Hz, $C\underline{H}_2C_6H_4$), 3.46 (s, 6, $2\times NCH_3$), 3.69 (s, 3, OCH_3), 6.58 (d, 1, J=8 Hz, NH), 6.89 (q, 4, C_6H_4), 7.67 (d, 1, J= 6 Hz, NH), 7.72 (s, 1, purine H-2 or 8), 8.18 (s, 1, purine H-8 or 2).

Found: C, 56.28; H, 5.90; N, 15.04%. Calcd for $C_{30}H_{37}N_7O_9$: C, 56.33; H, 5.83; N, 15.33%.

N,O-*Tetraacetyl Derivative of **22b** (**23b**).* Compound **22b** (30 mg) was acetylated and the product was purified as in the preparation of **23a** to give 28 mg (69%) of **23b** as a glass. ^{1}H NMR: δ 1.83 (s, 3, NAc), 1.90 (s, 3, OAc), 1.98 (s, 3, OAc), 2.05 (s, 3, OAc), 3.00 (d, 2, J=6 Hz, $C\underline{H}_2C_6H_4$), 3.47 (s, 6, $2\times NCH_3$), 3.69 (s, OCH_3), 6.45 (d, 1, J=8 Hz, NH), 6.87 (q, 4, $CH_2C_6\underline{H}_4$), 7.56 (d, 1, J=7 Hz, NH), 7.72 (s, 1, purine H-2 or 8), 8.18 (s, 1, purine H-8 or 2).

Found: C, 56.29; H, 6.09; N, 14.95%. Calcd for $C_{30}H_{37}N_7O_9$: C, 56.33; H, 5.83; N, 15.33%.

*DL-(1,2,5/3,4)-3-Acetamido-1-amino-2,4,5-cyclopentanetriol (**24**)* The compound was prepared by the method of Tadano *et al.*[11]

*6-[(DL-(1,2,5/3,4)-3-Acetamido-2,4,5-trihydroxycyclopentyl)-amino]-4-dimethylamino-5-nitropyrimidine (**25**).* A mixture of **24** (402 mg) and 6-chloro-4-dimethylamino-5-nitropyrim-

idine[13] (514 mg) in 2-methoxyethanol (21 ml) containing triethylamine (1 ml) was heated at 80 °C for 2.5 h. The solution was evaporated and the residue was washed with warm ethanol to give 564 mg (75%) of **25**, mp 215—216 °C (dec).

Found: C, 43.96; H, 5.64; N, 23.72%. Calcd for $C_{13}H_{20}N_6O_6$: C, 43.82; H, 5.66; N, 23.58%.

*6-[(DL-(1,2,5/3,4)-3-Acetamido-2,4,5-trihydroxycyclopentyl)-amino]-5-amino-4-dimethylaminopyrimidine (**26**).* Compound **25** (796 mg) was catalytically hydrogenated in water (50 ml) for 5.5 h. The catalyst was filtered off and the filtrate was evaporated to give 635 mg (87%) of **26**, mp 229—230 °C (dec).

Found: C, 48.13; H, 6.75; N, 26.10%. Calcd for $C_{13}H_{22}N_6O_4$: C, 47.84; H, 6.80; N, 25.75%.

*9-[DL-(1,2,5/3,4)-3-Acetamido-2,4,5-trihydroxycyclopentyl]-6-dimethylaminopurine (**27**).* A mixture of **26** (319 mg) and triethyl orthoformate (1.6 ml) in DMF (53 ml) was heated at 67 °C for 4 h in the presence of *p*-toluenesulfonic acid (10 mg). After being neutralized with Amberlite IRA-400 (OH^-) resin, the solution was evaporated. The residue was dissolved in 0.1 M HCl (33 ml). After 2 h, the solution was evaporated. The residue was dissolved in water and neutralized with 0.1 M NaOH. The solution was allowed to settle in a refrigerator to give 291 mg (89%) of **27** as crystals, mp 233—234 °C (dec).

Found: C, 49.71; H, 5.95; N, 24.65%. Calcd for $C_{14}H_{20}N_6O_4$: C, 49.99; H, 5.99; N, 24.99%.

*9-[DL-(1,2,5/3,4)-3-Amino-2,4,5-trihydroxycyclopentyl]-6-dimethylaminopurine (**28**).* A mixture of **27** (340 mg) and barium hydroxide octahydrate (2.7 g) in water (34 ml) was heated at 100 °C for 4 h. The solution was worked up as in the preparation of **6** to give 278 mg (93%) of **28**. UV: $\lambda_{max}^{0.1M\ HCl}$ 268 nm ($\varepsilon=1.48\times10^4$), $\lambda_{max}^{H_2O}$ 275 nm ($\varepsilon=1.64\times10^4$), $\lambda_{max}^{0.1M\ NaOH}$ 275 nm ($\varepsilon=1.64\times10^4$). ^1H NMR (DMSO-d_6): δ 3.63 (s, 6, $2\times NCH_3$), 8.47 s, (1, purine H-2 or 8), 8.58 (s, 1, purine H-8 or 2).

Hydrochloride of **28** was obtained as crystals in 46% yield by recrystallization from methanol, mp 163—164 °C.

Found: C, 41.67; H, 5.97; N, 23.86; Cl, 10.01%. Calcd for $C_{12}H_{19}N_6O_3Cl\cdot H_2O$: C, 41.32; H, 6.06; N, 24.09; Cl, 10.16%.

*6-Dimethylamino-9-[(1S,2S,4S,5S,)-2,4,5-trihydroxy-3-(N-benzyloxycarbonyl-p-methoxyphenyl-L-alanylamino)cyclopentyl] Purine (**29a**).* DCC (202 mg) was added under ice-cooling with agitation to a solution of **28** (274 mg) and *N*-benzyloxycarbonyl-*p*-methoxyphenyl-L-alanine[14] (323 mg) in DMF (11 ml) containing *N*-hydroxysuccinimide (113 mg). The mixture was worked up as in the preparation of **7a** to give 165 mg (29%) of **29a**, mp 222—223 °C (dec) (from methanol).

Found: C, 58.52; H, 5.80; N, 15.58%. Calcd for $C_{30}H_{35}N_7O_7$–CH_3OH: C, 58.39; H, 6.16; N, 15.38%.

The product was acetylated to give tri-*O*-acetyl derivative of **29a** in a quantitative yield as a syrup. ^1H NMR (DMSO-d_6): δ 1.85 (s, 3, OAc), 1.97 (s, 3, OAc), 2.00 (s, 3, OAc), 2.98 (d, 2, $J=7$ Hz, $CH_2C_6H_4$), 3.46 (s, 6, $2\times NCH_3$), 3.70 (s, 3, OCH_3), 5.02 (s, 2, benzyl CH_2), 7.79 (s, 1, purine H-2 or 8), 8.23 (s, 1, purine H-8 or 2).

Found: C, 59.06; H, 5.76; N, 13.14%. Calcd for $C_{36}H_{41}N_7O_{10}$: C, 59.09; H, 5.65; N, 13.40%.

*6-Dimethylamino-6-[(1S,2S,4S,5S)-2,4,5-trihydroxy-3-(p-methoxyphenyl-L-alanylamino)cyclopentyl]purine (**30a**).* A solution of **29a** (32 mg) in glacial acetic acid (8 ml) was hydrogenated in the presence of palladium black in a hydrogen atmosphere (3.0 kg/cm²) for 4 h. The solution was worked up as in the preparation of **8a** to give 12 mg (48%) of **30a**, mp 139—140 °C (from methanol), $[\alpha]^{19}$ −49.4° (*c* 1.13, methanol). UV: $\lambda_{max}^{0.1M\ HCl}$ 269 nm ($\varepsilon=2.11\times10^4$), $\lambda_{max}^{H_2O}$ 275 nm ($\varepsilon=2.15\times10^4$), $\lambda_{max}^{0.1M\ NaOH}$ 275 nm ($\varepsilon=2.00\times10^4$). ^1H NMR (DMSO-d_6): δ 3.64 (s, 6, $2\times NCH_3$), 3.90 (s, 3, OCH_3), 8.55 (s, 1, purine H-2 or 8), 8.61 (s, 1, purine H-8 or 2).

Found: C, 55.78; H, 6.35; N, 20.41%. Calcd for $C_{22}H_{29}N_7O_5$: C, 56.04; H, 6.20; N, 20.79%.

*6-Dimethylamino-9-[(1R,2R,4R,5R)-2,4,5-trihydroxy-3-(p-methoxyphenyl-L-alanylamino)cyclopentyl]purine (**30b**).* The methanolic mother liquor of **29a** was concentrated to give 741 mg of a residual syrup. A solution of the residue in glacial acetic acid (14 ml) was hydrogenated in the presence of palladium black in a hydrogen atmosphere (3.0 kg/cm²) for 3 h. The solution was worked up as in the preparation of **8a**. The product was purified by column chromatography using 5 : 1 (v/v) chloroform–methanol. Fractions showing a single spot at R_f 0.27 on TLC in the same solvent were combined and evaporated to give 51 mg of **30a**. Fractions showing a single spot at R_f 0.21 on TLC in the same solvent were combined and evaporated to give 113 mg (26% from **28**) of **30b**, mp 201—202 °C (dec), $[\alpha]_D^{19}$ +42.0° (*c* 1.13, methanol). UV: $\lambda_{max}^{0.1M\ HCl}$ 269 nm ($\varepsilon=1.96\times10^4$), $\lambda_{max}^{H_2O}$ 275 nm ($\varepsilon=2.05\times10^4$), $\lambda_{max}^{0.1M\ NaOH}$ 276 nm ($\varepsilon=2.19\times10^4$). ^1H NMR (DMSO-d_6): δ 3.63 (s, 6, $2\times NCH_3$), 3.89 (s, 3, OCH_3), 8.53 (s, 1, purine H-2 or 8), 8.59 (s, 1, purine H-8 or 2).

Found: C, 55.78; H, 6.29; N, 20.64%. Calcd for $C_{22}H_{29}N_7O_5$: C, 56.04; H, 6.20; N, 20.79%.

The authors are indebted to Mr. Saburo Nakada for Carrying out elemental analyses.

Central Research Institute, The Japan Tobacco and Salt Public Corporation, Umegaoka, Midori-ku, Yokohama, Kanagawa 227

** Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113*

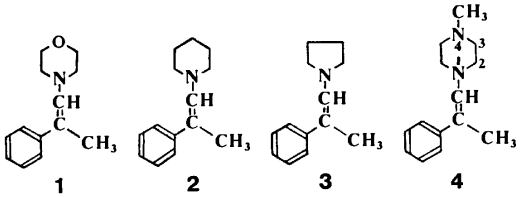
(Received August 16, 1977)

The temperature dependence of asymmetric transformation of 2-phenylpropanal *via* achiral enamine salt of *d*-10-camphorsulfonic acid was examined. The relation between the rotation of 2-phenylpropanal obtained and reaction temperature showed a notable change in specific rotation of the aldehyde obtained. Two courses are postulated for the optical activation.

Asymmetric transformation of racemic α-substituted carbonyl compounds was achieved by treatment of the enamines with chiral acids.[1] This is attributed to the difference in free energy between mutually interconvertible diastereoisomeric iminium salt (thermodynamical control).[2-4] However, Duhamel and Plaquevent recently reported some experimental facts explicable in terms of kinetic control, though the mechanism was not described in detail.[5]

The rotation of the α-substituted carbonyl compounds obtained depends remarkably on the reaction temperature as well as the solvent used.[1] Accordingly, the temperature effect on the asymmetric transformation was examined in detail using 2-phenylpropanal (hereafter called PPA) as a model α-substituted carbonyl compound. From the relation between reaction temperature and specific rotations of PPA, it was found that thermodynamical control or kinetic control alone is not sufficient to account for the results.

Achiral enamines **1**, **2**, **3**, and **4** are morphorine, piperidine, pyrrolidine, and *N*-methylpiperazine enamines, respectively, of racemic PPA.



1 **2** **3** **4**

Experimental

Optical rotations were determined with a JASCO Digital Automatic Polarimeter Model DIP 181. Gas chromatographic analyses were carried out using a 2 m column of 20% SE-30 on Chromosorb W with a Hitachi Gas Chromatograph Model K53. Nuclear magnetic resonance spectra were measured with a JNM-PS-100 Spectrometer using tetramethylsilane as an internal standard. Chemical shifts are given in δ values. Infrared spectra were obtained with a JASCO Model IR-G and mass spectra with a Hitachi GC-MS RM-50 (column: 10% SE-30 on Chromosorb W, 3 mm × 1 m).

Reagents and Solvent. *d*-10-Camphorsulfonic acid was prepared according to the directions of Reychler.[6] $[\alpha]_D^{23}$ +21.8° (*c* 8.81 H_2O), lit, $[\alpha]_D^{20}$ +22.6° (*c* 8.3, H_2O). Chloroform was purified by being shaken 7 times with water, dried over calcium chloride, and distilled.

Preparation of Enamines. Enamines were prepared by the usual azeotropic procedure using benzene as a solvent.

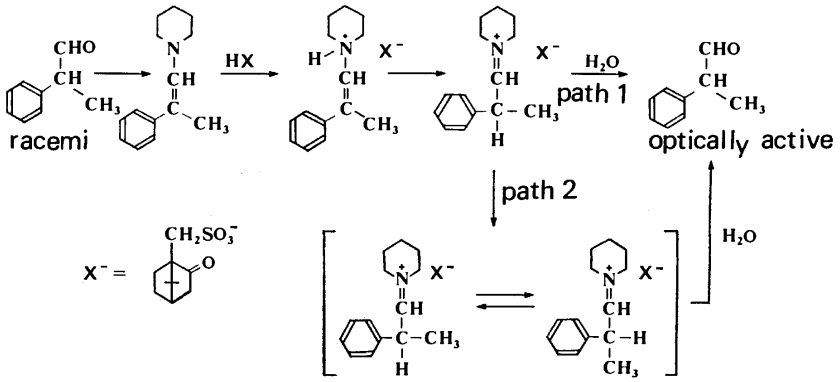
*1-(β-Methylstyryl)morphorine (**1**)*: Bp 108—111 °C (0.5 mmHg). Yield 90.8%. Mp 59.5—62 °C. MS *m/e* 203 (M^+), 144 (base), 130, 91. IR (film) 1685, 1640, 1600, 1499, 1450, 1378, 1298, 1260, 1120, 865, 760, 705, 650, 605, 545 cm^{-1}. NMR ($CDCl_3$) mixture of two geometrical isomers in the ratio 77 : 23 at room temperature. Major isomer 1.08 (d, J=1.1 Hz, CH=C-CH_3), 2.78 (m), 3.7 (m), 6.02 (q, J=1.1 Hz, CH=C-CH_3), 7.3 (m, phenyl). Minor isomer 1.96 (d, J=1.3 Hz, CH=C-CH_3), 2.64 (m), 3.55 (m), 5.76 (q, J=1.3 Hz, CH-C-CH_3), 7.3 (m, phenyl). Found: C, 76.53; H, 8.50; N, 6.88%. Calcd for $C_{13}H_{17}ON$: C, 76.81; H, 8.48; N, 6.89%.

*1-(β-Methylstyryl)piperidine (**2**)*: Reported previously.[1] Found: C, 83.46; H, 9.91; N, 6.83%. Calcd for $C_{14}H_{19}N$: C, 83.53; H, 9.51; N, 6.96%.

*1-(β-Methylstyryl)pyrrolidine (**3**)*: Also reported.[1] Found: C, 83.11; H, 9.26; N, 7.37%. Calcd for $C_{13}H_{17}N$: C, 83.37; H, 9.15; N, 7.48%.

*1-(β-Methylstyryl)-4-methylpiperazine (**4**)*: Bp 111—114 °C (2.5 mmHg). Yield 97.7%. MS *m/e* 216 (M^+, base), 144, 131, 115, 91. IR (film) 2950, 2800, 1640, ($\nu_{C=C}$), 1600, 1495, 1455, 1375, 1290, 1118, 1148, 1015, 760, 700 cm^{-1}. NMR ($CDCl_3$) mixture of two geometrical isomers in the ratio 7 : 4 at room temperature. Major isomer 2.09 (d, J=1.0 Hz, CH=C-CH_3), 2.30 (s, N-CH_3), 2.5 (m), 6.12 (q, J=1.0 Hz, N-CH=C), 7.3 (m, phenyl). Minor isomer 1.97 (d, J=1.2 Hz, CH=C-CH_3), 2.22 (s, N-CH_3), 2.3 (m), 2.7 (m), 5.89 (q, J=1.2 Hz, N-CH=C), 7.5 (m, phenyl). Found: C, 77.68; H, 9.42; N, 12. 84%. Calcd for $C_{14}H_{20}N_2$: C, 77.73; H, 9.32; N, 12.95%.

Asymmetric Transformation of Enamine. Under vigorous stirring with a homogenizer, enamine **1**, **2**, or **3** (0.01 mol) and *d*-10-camphorsulfonic acid monohydrate (0.01 mol) were added to 50 ml of chloroform. In order to control the temperature in the reaction flask, the temperature of the bath in which the flask was immersed was regulated with Dry Ice–ethanol or ice–water. Temperature in the flask was measured with a thermocouple. The reaction was continued for 30 min. The reaction mixture was washed with three 20 ml portions of water in order to remove *d*-10-camphorsulfonic acid completely. After the chloroform layer had been dried, the optical rotation was measured. The concentration of PPA in the chloroform solution was measured gas chromatographically. The yield of PPA was 90—100% in every case. Use of double the molar quantity of the acid to be hydrolyzed is necessary for enamine **4**. Two cases were examined: (a) 0.01 mol of **4** was treated with 0.02 mol of *d*-10-camphorsulfonic acid monohydrate, and (b) 0.01 mol of **4** was treated with a mixture of 0.01 mol of *d*-10-camphorsulfonic acid



Scheme 1.

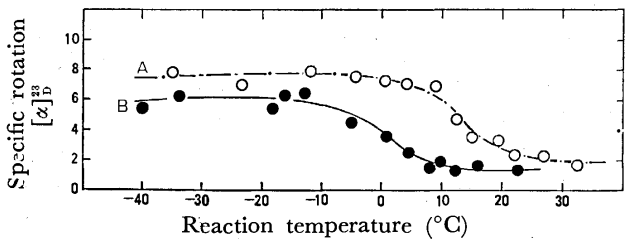


Fig. 1. Relationship between reaction temperature and rotation of 2-phenylpropanal.

Curve B; 1-(β-Methylstyryl)pyrrolidine (**3**).

monohydrate and 0.01 mol of *p*-toluenesulfonic acid monohydrate. The subsequent procedure is identical with that described in the hydrolyses of **1**, **2**, and **3**.

Results and Discussion

1-(β-methylstyryl)piperidine and 1-(β-methylstyryl)-pyrrolidine salts of *d*-10-camphorsulfonic acid were hydrolyzed at various temperatures. The relation between the rotation of PPA obtained from the hydrolyzates and the hydrolysis temperature is shown in Fig. 1.

Two flat levels and a transient stage between them are seen in each case, suggesting that optical activation is induced by two courses. In the transient stage, the two reaction courses would participate in the induction of optical activity. There are two types of enamine salt, enaminium and iminium.[7,8] Protonation to an enamine first occurs rapidly on a nitrogen atom, transfer of the proton to the β-carbon atom taking place. The following two reaction courses are presumed: a) asymmetric rearrangement of the proton from the nitrogen atom in the enaminium salt to the β-carbon atom in the iminium salt under the asymmetric circumstance caused by chiral acid anion, and b) a thermodynamic equilibrium between the resulting two enantiomeric iminium salts since the proton attached to the β-carbon atom is fairly labile.[9] On account of the instability of enaminium structure, the optical activity induced by the former course might be retained at a low temperature. At a high temperature, the asymmetrically attached proton to the β-carbon atom in the iminium salt becomes easily exchangeable, and a thermodynamic equilibrium would be attained between the two diastereomeric iminium salts. The optical activities of the
