Fig. 2. Relationship between reaction temperature and rotation of 2-phenylpropanal obtained from the hydrolyzate of 1-(β-methylstyryl)morphorine salt of *d*-10-camphorsulfonic acid.
Curve A; Solvent $CHCl_3$.
Curve B; Solvent $CHCl_3$: CH_3OH(9 : 1).

PPA obtained would reflect the equilibrium. Path 1 (Scheme 1) represents the former mechanism controlled kinetically and path 2 the latter mechanism controlled thermodynamically. The higher flat level (Fig. 1) corresponds to the former, and the lower flat level corresponds to the latter.

In the case of asymmetric transformation of racemic PPA *via* chiral enamines using *S*(−)-prolinamide or *N*-(L-prolyl)piperidine as an amine component, hydrolysis at low temperature gave *R*(−)-PPA and that at a high temperature *S*(+)-PPA. This phenomenon was also interpreted in the same way discussed above.[10]

Figure 2 shows the correlation between reaction temperature and the optical rotation of PPA obtained from 1-(β-methylstyryl)morphorine enamine salt of *d*-10-camphorsulfonic acid. A sharp decrease in specific rotation in the temperature range −5—0 °C (Fig. 2-A) is noted, the transient stage (Fig. 1) being almost absent. This phenomenon may be due to the fact that the existence of oxygen atom in morphorine moiety stabilizes the enaminium structure by intramolecular hydrogen bonding with the hydrogen atom attached to the nitrogen atom. It is known that severance of the hydrogen bond takes place in narrow temperature range.

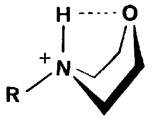

Fig. 3.

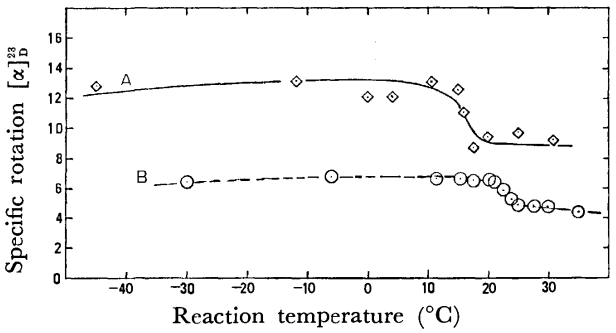

Fig. 4. Relationship between reaction temperature and rotation of 2-phenylpropanal obtained from the hydrolyzate of 1-(β-methylstyryl)-4-methylpiperazine salt.
Curve A; *d*-10-Camphorsulfonic acid : enamine (2 : 1).
Curve B; *d*-10-Camphorsulfonic acid : *p*-toluensulfonic acid : enamine (1 : 1 : 1).

Marman and Doty[11] examined the thermal transition profiles of the double helical complex of deoxyribonucleic acids into random coiles in neutral solutions and showed that the cleavage occurs in a narrow temperature range. Similar phenomena were reported by other workers.[12-15] Thus, the kinetical control disappears rapidly with severance of the hydrogen bond.

The ratio of the geometrical isomers at room temperature and the optical yield are given in Table 1. Low optical yields in the range of kinetical control (lower temperature range) are attributable to the mixture of two geometrical isomers. If the two isomers are separated from each other, higher optical yields are expected as shown by Duhamel and Plaquevent.[5] The stability of the enaminium salt of **1** at lower temperature may be responsible for the high optical yield. The stable enaminium structure controls the course of the transfer of the hydrogen atom from the nitrogen atom to the β-carbon atom.

When methanol (5 ml) was added to the solvent ($CHCl_3$, 45 ml) before hydrolysis to weaken hydrogen bonding, the curve became similar to that in the case of **2** and **3** as shown by curve B in Fig. 2. The addition gave rise to the lowering of optical yield especially in the lower temperature range. This confirms the stabilization of the enaminium structure by hydrogen bond in the case of **1**.

The relation between the rotation of PPA obtained with 1-(β-methylstyryl)-4-methylpiperazine and reaction temperature is shown in Fig. 4. The enamine could not be hydrolyzed easily by equimolar addition of acid such as *d*-10-camphorsulfonic acid monohydrate of *p*-toluenesulfonic acid monohydrate. The acid is apparently first consumed for protonation to the nitrogen atom at the 4-position, and use of double the molar quantity of acid is necessary.

Table 1. The ratio of the geometrical isomers and the optical yield

Enamine	Ratio of geometrical isomers	Optical yield (ee)[a] %	
		Lower temp range[b]	Higher temp range[c]
1	77 : 23	9.2	2.5
2	87 : 13	3.4	0.8
3	84 : 16	2.5	0.8

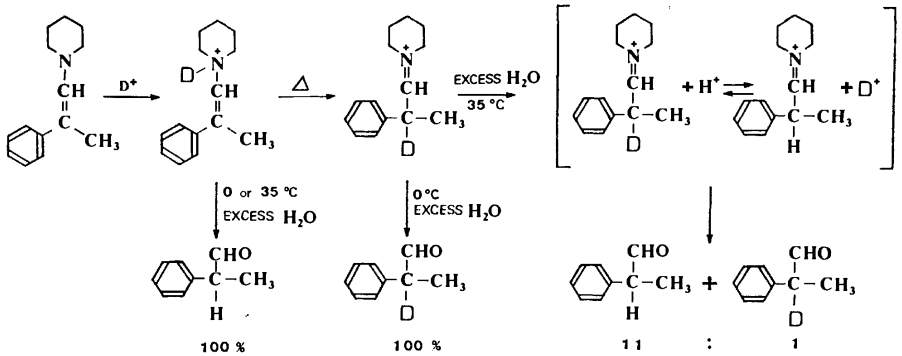
a) Optical yields are calculated based on $[\alpha]_D^{25}$ +238°.[5] b) The temperature range in which the asymmetric transformation is controlled kinetically. c) The temperature range in which the asymmetric transformation is controlled thermodynamically.

Curve A in Fig. 4 shows a case of the hydrolysis of enamine salt of *d*-10-camphorsulfonic acid monohydrate (molar ratio of the enamine and the acid; 1 : 2). It has two flat levels with a transient stage between them, as in the case of the curves in Figs. 1 and 2. The temperature range corresponding to the transient stage is 10—20 °C, narrower as compared to that of **2** and **3**. This tendency is similar to that of **1**, suggesting that the nitrogen atom at 4-position and hydrogen atom attached to the nitrogen atom at 1-position have a mutual interaction similar to the hydrogen bonding observed in the morphorine enamine salt, although the nitrogen atom at 4-position cannot operate as effectively as the oxygen atom in the morphorine enamine salt because of quaternarization.

Curve B shows a case of hydrolysis of the enamine salt of *d*-10-camphorsulfonic acid monohydrate and *p*-toluenesulfonic acid monohydrate (molar ratio of the enamine, *d*-10-camphorsulfonic acid monohydrate, and *p*-toluenesulfonic acid monohydrate; 1:1:1). The optical yield is reduced to one half its former results (Curve A, Fig. 4). An explanation of this result would be as follows: *d*-10-camphorsulfonate anion and *p*-toluenesulfonate anion form ion pairs with the two protonated nitrogen atoms in **4**, and only one acid anion of the two, probably the one that associated with the nitrogen atom at 1-position, can participate in the asymmetric transformation of PPA.

In order to get evidence for the two courses, isotopic labeling studies were carried out. As soon as dry DCl gas was added to enamine **2** in $CDCl_3$, the salt was hydrolyzed with H_2O (Scheme 2). Hydrolysis at 0 and 35 °C gave non-deuterated PPA (yield 100 %). This shows that the deuterium atom attached to the nitrogen atom exchange undergoes easily with hydrogen atoms in excess H_2O, the proton rearrangement from nitrogen atom to the β-carbon atom then occurring. Ease of this deuterium-proton exchange was already reported.[16] The above enaminium salt was completely rearranged to the corresponding iminium salt[16] and the resulting iminium salt was hydrolyzed with H_2O at 0 and 35 °C.

Hydrolysis at 0 °C gave Cα-deuterated PPA, indicating that the proton at β-carbon atom in the iminium salt is not exchangeable with hydrogen atom or deuterium atom at low temperature. In other words, optical yield is determined in the course of the rearrange-



Scheme 2.

ment from enaminium salt to iminium salt.

On the other hand, hydrolysis at 35 °C gave a mixture of the deuterated and non-deuterated PPA (1:11), indicating that the asymmetrically attached deuterium atom to the β-carbon atom in the iminium salt becomes easily exchangeable at 35 °C and the optical activation is controlled thermodynamically at the step of the iminium salt. The results of isotopic labeling studies also strongly support the existence of the two asymmetric transformation courses.

Synthesis of Hindered *t*-Alkyl Ethers

Hiromitsu MASADA* and Tadahide SAKAJIRI

Department of Industrial Chemistry, Faculty of Engineering, Kanazawa University, Kodatsuno, Kanazawa 920

(Received August 26, 1977)

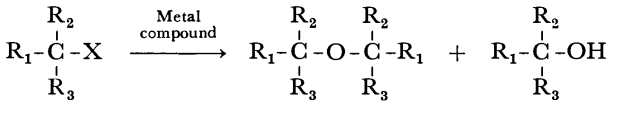
Di-*t*-butyl ether was prepared in 6—73% yields by the reactions of *t*-butyl halide with Ag_2CO_3, Ag_2O, HgO, ZnO, $ZnCO_3$, PbO_2, $Cu_2(CO_3)(OH)_2$, and Tl_2O_3 at 20—65 °C in hydrocarbons under nitrogen. Similar reactions gave seven new hindered di-*t*-alkyl ethers: di-*t*-pentyl ether, bis(1,1-dimethylbutyl) ether, bis(1-ethyl-1-methylpropyl) ether, bis(1,1-dimethylpentyl) ether, bis(1-ethyl-1-methylbutyl) ether, bis(1,1-diethylpropyl) ether, and bis(1,1-dimethylhexyl) ether. The yield of di-*t*-alkyl ether decreased as the *t*-alkyl group became bulky. A slight difference in the skeletal structure of the *t*-alkyl halide markedly influences the substitution. The reaction pathways are elucidated on the basis of the experimental results.

Sterically hindered di-*t*-alkyl ethers have never been prepared by any usual procedure, such as dehydration of alcohols or the Williamson synthesis. Only di-*t*-butyl ether has been obtained by some specific procedures.[1-3]

This work deals with the syntheses of unknown di-*t*-alkyl ethers by the reactions of *t*-alkyl halides with various metal compounds. Furthermore the reaction pathways and the steric effects of *t*-alkyl groups on their reactivity were investigated in detail.

Results and Discussion

A series of *t*-alkyl halides was allowed to react with various metal compounds in pentane and hexane under optimum conditions. The products were di-*t*-alkyl ether, *t*-alkyl alcohol, and olefins, as illustrated in Scheme 1.



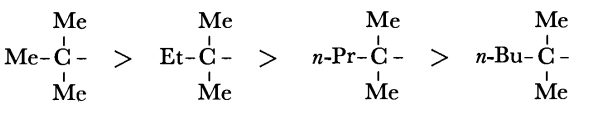
1—**8** + Olefins

1: $R_1=R_2=R_3=$Me **5**: $R_1=R_2=$Me, $R_3=n$-Bu
2: $R_1=R_2=$Me, $R_3=$Et **6**: $R_1=$Me, $R_2=$Et, $R_3=n$-Pr
3: $R_1=R_2=$Me, $R_3=n$-Pr **7**: $R_1=R_2=R_3=$Et
4: $R_1=$Me, $R_2=R_3=$Et **8**: $R_1=R_2=$Me, $R_3=n$-C_5H_{11}

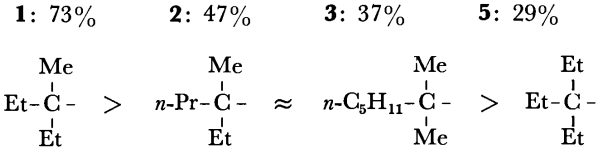
Scheme 1.

Table 1 shows the results in detail. The reaction of *t*-butyl chloride with silver carbonate at 20 °C for 20 h gave **1** in 73% yield (Run 1). A similar reaction of silver(I) oxide at 35 °C also gave **1** in 63% yield (Run 2). Mercury(II) oxide reacted more slowly with *t*-butyl and *t*-pentyl chlorides, and 2-chloro-2-methylpentane to give **1**, **2**, and **3** respectively in reasonable yields (Runs 3, 14, and 19). In the case of zinc compounds, **1** and **2** were afforded only on addition of *t*-alkyl alcohol to the system (Runs 4, 5, and 15). This result suggests the participation of the alcohol in the formation of **1** and **2**. Lead(IV) oxide and copper(II) carbonate hydroxide failed to complete the reaction even under certain strict conditions (Runs 6 and 7). Thallium(III) oxide readily reacted with *t*-butyl chloride to give **1**, but in only 6% yield (Run 8). Consequently, silver(I) oxide and carbonate gave better results than the other metal compounds. *t*-Butyl and *t*-pentyl bromides also reacted with two equivalents of silver compound at much lower temperatures than the corresponding chlorides (Runs 9, 10, and 16). Calcium hydride retarded the reaction and decreased markedly the distributions of both *t*-pentyl alcohol and **2** (Run 13).

On the whole, the yield of the ether decreased as the *t*-alkyl group became bulky (Runs 11—27). When one of the methyl groups of *t*-butyl chloride was substituted for ethyl, propyl butyl, and pentyl groups, the yields of **2**, **3**, **5**, and **8** were 47, 37, 29, and 11% respectively. The substitution of methyl groups of the chloride for two or three ethyl groups resulted in a more remarkable decrease: the yields of **4** and **7** were 21 and 2%, respectively. Scheme 2 illustrates the relationship between the structure of the *t*-alkyl group and the yield of di-*t*-alkyl ether.



1: 73% **2**: 47% **3**: 37% **5**: 29%



4: 21% **6**: 11% **8**: 11% **7**: 2%

Scheme 2.

It is interesting from a structural point of view that the yields of isomeric **3** and **4** are quite different (Runs 17 and 20). An analogous tendency is observed in isomeric **5**, **6**, and **7** (Runs 22, 24, and 26). To sum up, the yield is greatly influenced by the degree of bulkiness and the structure of the *t*-alkyl group.

Table 2 shows the time-course of the reaction of *t*-pentyl chloride with a small excess of silver carbonate at 20 °C (*cf.* Run 11). The proportions of the chloride and the products were followed by GLPC at regular time intervals. The initial step of this reaction was so fast that half of the chloride was consumed in a few hours. The proportions of **2** and of the olefins (2-methyl-1-butene and 2-methyl-2-butene) increase with an increase in reaction time, while that of *t*-pentyl alcohol remains almost constant over several hours.

a) *t*-Alkyl halide 40 mmol and metal compound 22 mmol used unless otherwise stated. b) Pentane (P) or hexane (H) 20 cm^3 used. c) GLPC yields based on *t*-alkyl halide. d) *t*-Butyl alcohol 40 mmol added. e) Calcium hydride 20 mmol added. f) *t*-Pentyl alcohol 40 mmol added.

This observation suggests that the alcohol is consumed during the reaction. The other *t*-alkyl chloride also gave similar results.

The following pathways therefore are proposed for the reaction of *t*-alkyl halide with silver carbonate:

$$R\text{-}X + Ag_2CO_3 \xrightarrow{E} R'\text{-}C{=}C + AgX + AgOH + CO_2 \quad (1)$$

$$R\text{-}X + AgOH \longrightarrow R\text{-}OH + AgX \quad (2)$$

$$R\text{-}X + R\text{-}OH + Ag_2CO_3 \xrightarrow{S} R\text{-}O\text{-}R + AgX + AgOH + CO_2 \quad (3)$$

The elimination of *t*-alkyl halide with silver carbonate gives olefins, silver halide, and silver hydroxide (Eq. 1). Silver hydroxide reacts with *t*-alkyl halide to give *t*-alkyl alcohol (Eq. 2). A desiccant such as calcium hydride would partly react with silver hydroxide and suppress the conversion into the alcohol.[4] The desired ether is formed from the halide and the alcohol in the presence of silver carbonate (Eq. 3). As the reaction is carried out in nonpolar solvents, the ether is given by bimolecular nucleophilic substitution. Such pathways can also be estimated for the reactions of the other metal compounds. These equations explain successfully the distribution of the products, the steric hindrance of the *t*-alkyl group, and the additive effect of the alcohol or calcium hydride.

Table 2. Proportions of *t*-pentyl chloride and its products during the reaction

Time h	Proportions[a] (%)			
	t-$C_5H_{11}Cl$	**2**	*t*-$C_5H_{11}OH$	Olefins[b]

15	5	44	21	30
20	0	47	21	32

a) The proportions were available from the more detailed results on Run 11 in Table 1. b) 2-Methyl-1-butene and 2-methyl-2-butene.

Experimental

Materials. All inorganic chemicals were commercial extra pure or GR grade reagents, dried over silica gel, and used without further purification. 2-Chloro-2-methylpentane, 3-chloro-3-methylpentane, 2-chloro-2-methylhexane, 3-chloro-3-methylhexane, 3-chloro-3-ethylpentane, and 2-chloro-2-methylheptane were derived from the corresponding alcohols.[5-8] Organic chemicals were distilled from calcium hydride before use and their purities were checked by GLPC.

Procedure and Analysis. In a three-necked flask, fitted with a reflux condenser, a dropping funnel, and a magnetic stirrer, 40 mmol of *t*-alkyl halide was added to 22 mmol of metal compound in 20 cm^3 of pentane or hexane medium. The mixture was stirred at a given temperature under nitrogen. The products in the solution were determined by GLPC comparison with authentic samples using toluene, *o*-xylene, and mesitylene as internal standards (Table 1). GLPC analyses were performed on a Shimadzu GC-3AH chromatograph using 3 m × 3 mm columns packed with 5% DNDP and 5% Silicone DC 550 on 80—100 mesh Celite support. NMR spectra were determined with a JEOL-PS-100 high resolution spectrometer operating at 100 MHz. Chemical shifts are reported in δ units from internal TMS. IR spectra were recorded on a JASCO DS-301 spectrometer. Mass spectra were recorded on a JEOL JMS-01SG spectrometer with ionization current 75 eV. The molecular weights of some ethers were measured by cryoscopy in benzene.

Characterization of Di-t-alkyl Ethers. The preparative scale reaction of *t*-alkyl chloride (0.2 mol) with silver carbonate (30.33 g, 0.11 mol) in pentane (100 cm^3) was carried out at 20 °C for 20 h in a manner similar to that above. The reaction mixture was filtered. The filtrate was concentrated and rectified over potassium carbonate, giving di-*t*-alkyl ether (purity > 99.5%), which was identified by its physical constants, NMR, IR, and mass spectra.

*Di-t-butyl Ether (**1**)*: Yield, 5.60 g (43%); bp 106 °C; IR (neat) 1384, 1363 (*t*-Bu), and 1173 cm^{-1} (C-O-C); NMR ($CDCl_3$) δ=1.26 (18H, s, *t*-Bu).

*Di-t-pentyl Ether (**2**)*: Yield, 5.56 g (35%); bp 151.5—152 °C; IR (neat) 1380, 1365 (*gem*-CH_3), and 1162 cm^{-1} (C-O-C); NMR ($CDCl_3$) δ=0.89 (6H, t, J=7.2 Hz, CH_2CH_3), 1.21 (12H, s, O-C-CH_3), and 1.47 (4H, q, J=7.4 Hz, CH_2).

*Bis(1,1-dimethylbutyl) Ether (**3**)*: Yield, 5.60 g (30%); bp 79.5—80 °C/17 Torr; mol wt, found, 187.9, calcd for $C_{12}H_{26}O$, 186.3; IR (neat) 1380, 1365 (*gem*-CH_3), and 1164 cm^{-1} (C-O-C); MS *m/e* (rel intensity), 143 (M^+—Pr, 50), 99 (79), 85 (PrC^+Me_2, 100), 59 (HOC^+Me_2, 83), and 43 (50).

*Bis(1-ethyl-1-methylpropyl) Ether (**4**)*: Yield, 2.40 g (13%); bp 78—79 °C/15 Torr; IR (neat) 1456, 1375, and 1142 cm^{-1} (C-O-C); NMR ($CDCl_3$) δ=0.85 (12H, t, J=7.2 Hz, CH_2CH_3), 1.20 (6H, s, O-C-CH_3), and 1.50 (8H, q, J=7.4 Hz, CH_2).

*Bis(1,1-dimethylpentyl) Ether (**5**)*: Yield, 6.00 g (28%); bp 109—110 °C/20 Torr; mol wt, found, 215.8, calcd for $C_{14}H_{30}O$, 214.4; IR (neat) 1380, 1364 (*gem*-CH_3), and 1161 cm^{-1} (C-O-C); MS *m/e* (rel intensity), 157 (M^+—Bu, 30), 101 (26), 99 (BuC^+Me_2, 100), 59 (HOC^+Me_2, 39), 57 (78), and 43 (16).

*Bis(1-ethyl-1-methylbutyl) Ether (**6**)*: Yield, 2.36 g (11%); bp 111—112 °C/20 Torr; mol wt, found, 214.6, calcd for $C_{14}H_{30}O$, 214.4; IR (neat) 1463, 1380, and 1145 cm^{-1} (C-O-C); MS *m/e* (rel intensity), 185 (M^+—Et, 8), 171 (M^+—Pr, 13), 101 (10), 99 (71), 87 (HOC^+PrMe, 58), 73 (45), 57 (100), and 43 (19).

*Bis(1,1-diethylpropyl) Ether (**7**)*: Yield, 0.20 g (1%); IR (neat) 1455, 1380, and 1131 cm^{-1} (C-O-C); MS *m/e* (rel intensity), 185 (M^+—Et, 31), 99 (C^+Et_3, 88), 87 (HOC^+Et_2, 100), 57 (98), 45 (29), and 29 (19).

*Bis(1,1-dimethylhexyl) Ether (**8**)*: Yield, 2.66 g (11%); bp 131—131.5 °C/16 Torr; IR (neat) 1382, 1367 (*gem*-CH_3), and 1152 cm^{-1} (C-O-C); MS *m/e* (rel intensity), 242 (M^+, 5), 171 ($M^+-C_5H_{11}$, 62), 115 (13), 113 ($C_5H_{11}C^+Me_2$, 80), 71 (66), 59 (HOC^+Me_2, 100), 57 (68), and 43 (79).

Synthetic Studies of Pyridomycin. II.[1] Synthesis of a Model Twelve-membered Ring Compound Related to Pyridomycin

Mitsuhiro KINOSHITA and Masaki AWAMURA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received August 31, 1977)

A prototypic compound of pyridomycin, 6-(3-hydroxypicolinoylamino)-5-methyl-8-aza-1,4-dioxacyclododecane-3,7,12-trione (**11**), was synthesized. 4-(Benzyloxycarbonylamino)butyric acid was coupled with *t*-butyl glycolate in the presence of DCCI and pyridine to afford *t*-butyl [4-(benzyloxycarbonylamino)butyryloxy] acetate (**4**). De-*t*-butylation of **4** followed by condensation with *N*-*t*-butoxycarbonyl-L-threonine benzyl ester by the DCCI method gave *O*-[{4-(benzyloxycarbonylamino)butyryloxy}acetyl]-*N*-*t*-butoxy-carbonyl-L-threonine benzyl ester (**6**). Deprotection of **6** followed by cyclization with Woodward's reagent K afforded 6-(*t*-butoxy-carbonylamino)-5-methyl-8-aza-1,4-dioxacyclododecane-3,7,12-trione (21% yield), which was transformed into the title compound **11**.

Pyridomycin is an antimycobacterial antibiotic[2] produced by *Streptomyces pyridomyceticus*.[3] The structure of pyridomycin (**1**) was determined by means of X-ray analysis[4] and chemical degradation.[5] The most striking characteristic of the structure is its novel heterocyclododecane system containing unique exocyclic *s*-butylidene and 3-pyridylmethyl side chains.

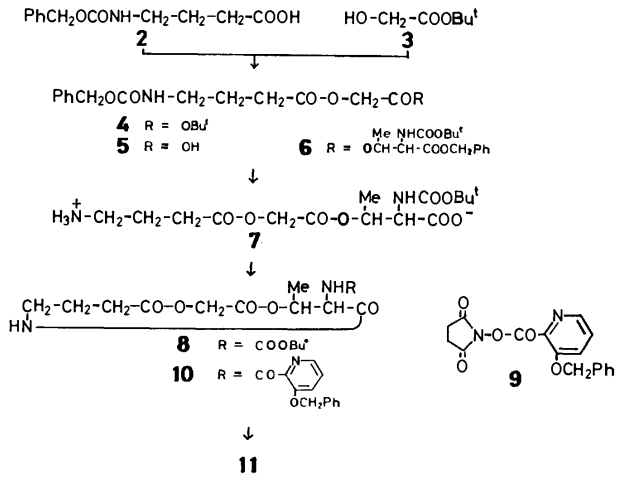

Chart 2.

During the course of studies on the total synthesis of pyridomycin, the natural (−)-4-amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic acid, which is a building block containing the 3-pyridylmethyl side chain of the pyridomycin ring system, was synthesized.[1] So far no attempt seems to have been made for the preparation of this new type of medium ring system present in pyridomycin. We therefore tried to synthesize a prototype in which, except for the moiety of L-threonine, the structure was made simpler than that of the natural antibiotic. This paper deals with the synthesis of 6-(3-hydroxypicolinoylamino)-5-methyl-8-aza-1,4-dioxacyclododecane-3,7,12-trione (**11**) whose cyclic structure is composed of *N*-(3-hydroxypicolinoyl)-L-threonine, 4-aminobutyric acid, and glycolic acid (Chart 1). In the synthesis of **11**, we adopted the method of cyclization by amide bond formation. The pathway is most commonly used for the synthesis of peptolides and peptide lactones. The synthetic scheme is shown in Chart 2.

4-(Benzyloxycarbonylamino)butyric acid (**2**) was prepared by the Schotten-Baumann reaction of 4-aminobutyric acid with benzyl chloroformate. *t*-Butyl glycolate (**3**)[6] was prepared by selective saponification of *t*-butyl acetoxyacetate[6] obtained by *t*-butylation of acetoxyacetic acid[7] with 2-methylpropene in the usual way. Condensation of **2** with **3** was carried out in the presence of dicyclohexylcarbodiimide (DCCI) and pyridine in THF to afford *t*-butyl [4-(benzyloxycarbonylamino)butyryloxy]acetate (**4**) in 64.5% yield after being subjected to silica gel chromatography. Treatment of **4** with trifluoroacetic acid gave [4-(benzyloxycarbonylamino)butyryloxy]acetic acid (**5**) in 96.7% yield. *N*-*t*-Butoxycarbonyl-L-threonine benzyl ester[8] was acylated with **5** in THF using DCCI and pyridine to afford the protected open-chain intermediate (**6**) in 90.4% yield after silica gel chromatography. Deprotection of **6** by hydrogenolysis over palladium black gave the linear system **7** with terminal amino and carboxy group in 99.5% yield. Cyclization of **7** was performed with *N*-ethyl-5-phenylisoxazolium-3'-sulfonate (Woodward's reagent K)[9] according to the procedure of Bláha and Rudinger,[10] and of Gisin and Merrifield[11] to afford the intramolecular cyclization product, 6-(*t*-butoxycarbonylamino)-5-methyl-8-aza-1,4-dioxacyclodecane-3,7-12-trione (**8**) as colorless needles in 21.1% yield. The structure of **8** was confirmed by PMR analysis and molecular weight determination by mass spectrum. The cyclization of **7** which was carried out with large excess of DCCI by the method of Vogler *et al.*,[12] or with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride in dichloromethane at 10^{-2}—10^{-3} M concentration of **7** by the method of Sheehan and Ledis,[13] yielding the cyclized product **8** in lower yields (4—8.3%). In all the cyclization reactions abovementioned, no appreciable amount of intermolecular

cyclization products could be isolated.

De-*t*-butoxycarbonylation of **8** followed by *N*-acylation with *N*-(3-benzyloxypicolinoyloxy)succinimide (**9**) gave the 3-benzyloxypicolinamide derivative **10** in 85.2% yield. Removal of the benzyl group of **10** by hydrogenolysis over palladium black afforded the pyridomycin analog **11** as colorless plates in 80.7% yield. The structure was confirmed by elemental and PMR analyses.

Experimental

Melting points were determined on a micro hot-stage and are uncorrected. IR spectra were taken on a Hitachi 225 spectrophotometer and PMR spectra on a Varian A-60D spectrometer using TMS as an internal standard. Specific rotations were determined with a Zeiss Photoelectric Polarimeter. TLC and column chromatography were performed on Wakogel B-5 and C-200, respectively. Concentration was carried out below 40 °C under reduced pressure.

4-(Benzyloxycarbonylamino)butyric Acid (2). *N*-Benzyloxycarbonylation of 4-aminobutyric acid was carried out with benzyl chloroformate and 2M NaOH solution under the Schotten-Baumann conditions to afford **2** as colorless needles in 64.9% yield: Mp 63—64 °C (ether-petroleum ether).

Found: C, 60.46; H, 6.25; N, 5.89%. Calcd for $C_{12}H_{15}NO_4$: C, 60.75%; H, 6.37; N, 5.90%.

t-*Butyl Glycolate (3).*[6] Liquid 2-methylpropene (86 ml) was added to a solution of acetoxyacetic acid[7] (16.7 g) in dichloromethane (141 ml) containing concd H_2SO_4 (1.41 ml) at −30 °C under cooling. The stoppered flask was allowed to stand at room temperature for 3 days. The usual work-up followed by distillation afforded a fraction of *t*-butyl acetoxyacetate boiling at 59—62 °C/5 Torr; yield 19.0 g (77.2%), n_D^{19} 1.4131 (lit,[6] bp 79—81 °C/12 Torr n_D^{20} 1.4142); TLC [silica gel, petroleum ether-diisopropyl ether (3 : 1)] of the sample showed a single spot detected by H_2SO_4. A solution of the ester (12.106 g, 69.52 mmol) in acetone (35 ml) was cooled to 0 °C and 2M NaOH solution (38.2 ml) was added slowly under stirring. After the addition of NaOH, stirring was continued at 0 °C for 1 h until the reaction mixture showed a constant pH value (*ca.* 9). The mixture was then neutralized with 5% citric acid and concentrated in order to remove acetone. The residue was extracted four times with ether, the combined ethereal extracts were washed with saturated $NaHCO_3$ and saturated NaCl solutions, dried, and immediately evaporated to give a colorless syrup of **3** (3.908 g, 42.6%). The fresh sample of **3** was homogeneous on TLC with petroleum ether-diisopropyl ether (3 : 1). However, when a fresh sample was stored in a desiccator overnight, it showed on TLC a new spot with lower R_f-value in addition to the original spot of the fresh sample. Although the sample of **3** could be distilled at 40—57 °C/7—14 Torr [lit,[6] bp 56 °C/12 Torr], all of the distillates were not homogeneous on TLC.

t-*Butyl [4-(Benzyloxycarbonylamino)butyryloxy]acetate (4).* A solution of **2** (7.017 g, 29.6 mmol) in dry THF (15.5 ml) was added slowly dropwise to a stirred solution of the freshly prepared sample of **3** (3.908 g, 29.6 mmol), DCCI (6.782 g, 32.9 mmol) and pyridine(2.45 ml, 31.2 mmol) in dry THF (11.6 ml), cooled at 0 °C. Stirring was continued at 0 °C for 1 h and then at room temperature for 3 days. The precipitate of *N,N'*-dicyclohexylurea (DCU) was filtered off and the filtrate was treated with acetic acid (*ca.* 0.25 ml) for 1 h. The resulting DCU was removed and the filtrate was diluted with ethyl acetate and washed with saturated $NaHCO_3$ and saturated NaCl solutions. The dried solution was evaporated to afford yellow syrup (8.533 g), which was chromatographed on silica gel (341 g) with benzene–ethyl acetate (2 : 1) to give **4** (6.701 g, 64.5%) as colorless crystals: Mp 63.5—64.5 °C from ethyl acetate); $\delta(CDCl_3)$ 1.48(s, 9H, OBu^t), *ca.* 1.9 (m, 2H, H-10*), *ca.* 2.5(m, 2H, H-11), 3.34(dd, 2H, H-9, $J_{9,10}=J_{9,NH}=6.8$ Hz), 4.57(s, 2H, H-2), 5.20(s, 2H, OCH_2-Ph), *ca.* 5.1 (br, 1H, NH), and 7.35(s, 5H, Ph).

Found: C, 61.63; H, 7.20; N, 3.79%. Calcd for $C_{18}H_{25}NO_6$: C, 61.52; H, 7.17; N, 3.99%.

[4-(Benzyloxycarbonylamino)butyryloxy]acetic Acid (5). A mixture of **4** (5.200 g, 14.8 mmol) and trifluoroacetic acid (15.9 ml) was kept at room temperature for 40 min and then evaporated. The residual syrup was coevaporated with ether repeatedly and dried over NaOH pellets in a desiccator to afford a crystalline solid, which was recrystallized from ethyl acetate to yield the first crop of **5** (3.418 g, 78.2%), mp 78—79.5 °C. From the mother liquor the second and third crops were obtained, the total yield amounting to 96.7%: $\delta(CDCl_3)$ 1.92(m, 2H, H-10), 2.53(t, 2H, H-11, $J=7$ Hz), 3.38(m, 2H, H-9), 4.72(s, 2H, H-2), 5.21(s, 2H, OCH_2Ph), 5.36(br, 1H, NH), 7.48(s, 5H, Ph), and 8.0(br, 1H, COOH).

O-[{*4-(Benzyloxycarbonylamino)butyryloxy}acetyl*]-N-t-*butoxycarbonyl*-L-*threonine Benzyl Ester (6).* A solution of **5** (1.405 g, 4.78 mmol) in THF (3.0 ml) was added slowly to a stirred solution of *N*-*t*-butoxycarbonyl-L-threonine benzyl ester[8] (1.486 g, 4.78 mmol), DCCI (1.183 g, 5.735 mmol), and pyridine (0.387 ml, 4.78 mmol) in THF (7.8 ml) at 0 °C. Stirring was continued at 0 °C for 10 min and then at room temperature for 3 days. Work-up of the reaction mixture in the same way as in the preparation of **4** afforded a yellow syrup of crude product. The product (3.103 g) was chromatographed on silica gel (175 g) with hexane–ethyl acetate(2 : 1) to give **6** (2.532 g, 90.4%). A sample of this syrup (107 mg) was chromatographed again on silica gel (5 g) with the solvent system to afford the analytical sample (84 mg) as a colorless syrup: $[\alpha]_D^{15}$ +17°(*c*, 1.0, $CHCl_3$); $\delta(CDCl_3)$ 1.38(d, 3H, 5-Me, $J=6.5$ Hz), 1.47(s, 9H, *t*-Bu), 1.90(m, 2H, H-10), 2.50 (m, 2H, H-11), 3.30(m, 2H, H-9, $J_{9,10}=J_{9,NH}=6$ Hz), 4.35 and 4.53 (each d, H-2, $J_{gem}=16$ Hz), 4.4—4.67(m, 1H, H-6), 5.15 and 5.20(each s, 4H, OCH_2Ph), 5.1—5.3(m, 2H, NH), 5.53 (dq, 1H, H-5, $J_{5,6}=3$ Hz), and 7.40(s, 10H, Ph).

Found: C, 61.51; H, 6.57; N, 4.62%. Calcd for $C_{30}H_{38}N_2O_{10}$: C, 61.42; H, 6.53; N, 4.78%.

O-[*(4-Aminobutyryloxy)acetyl*]-N-t-*butoxycarbonyl*-L-*threonine (7).* A solution of **6** (150 mg) in methanol (5.3 ml) was stirred with palladium black under bubbling with hydrogen gas for 30 min. The filtered solution was evaporated and then coevaporated with hexane to afford **7** as a colorless glassy solid showing a single spot (ninhydrin and H_2SO_4 reagents) on TLC (silica gel) with 1-butanol-acetic acid–water (4 : 1 : 1): Yield, 92.1 mg (99.5%); $\nu_{max}^{CHCl_3}$ 3430 (NH), 2800—2500(NH_3^+), 1735 (ester), 1700(amide I), 1610(COO^-), and 1490 cm^{-1}(amide II); $\delta(CDCl_3)$ 1.35(d, 3H, 5-Me, $J=6.5$ Hz), 1.46(s, 9H, *t*-Bu), 2.10(m, 2H, H-10), 2.67(m, 2H, H-11), 3.17(m, 2H, H-9), 4.30(m, 1H, H-6), 4.68(s, 2H, H-2), and 5.46—5.80(m, 2H, H-5 and NH).

6-(t-Butoxycarbonylamino)-5-methyl-8-aza-1,4-dioxacyclododecane-3,7,12-trione (8). Compound **7** (368 mg, 1.02 mmol) was activated in DMF (35 ml) with Woodward's reagent K[9] (273 mg (purity 95%), 1.02 mmol) at 0—10 °C for 3.5 h, according to the procedure of Bláha and Rudinger[10] and Gisin and Merrifield.[11] The resulting turbid solution

* Numbering of the protons corresponds to that of compound **11** in Chart 1.

was diluted with DMF (25 ml) and dichloromethane (1.02 l). Triethylamino (0.143 ml, 1.02 mmol) was added to the solution, and the mixture was stirred at room temperature for 60 h. The clear solution was evaporated and the residue was extracted with ethyl acetate. The extract was washed twice with water and the aqueous layers were extracted with ethyl acetate. The combined organic layers were washed with saturated NaCl solution, dried, and evaporated to afford a yellow syrup (356 mg). The syrup was chromatographed on silica gel (36 g) with hexane-acetone (2 : 1) to give **8** (74.2 mg, 21.1%) as colorless needles. Recrystallization from ethyl acetate afforded the analytical sample: Mp 216—217 °C(sub.); $[\alpha]_D^{14}$ −5° (*c* 1.0, $CHCl_3$); ν_{max}^{KBr} 1757, 1737 (lactone), 1715(urethane), 1654(amide I), and 1515 cm^{-1} (amide II); $\delta(CDCl_3)$, 1.26(d, 3H, 5-Me, J=6.5 Hz), 1.42 (s, 9H, *t*-Bu), *ca.* 2.0(m, 2H, H-10), *ca.* 2.5(m, 2H, H-9), 2.8—4.0(m, 2H, H-11), 4.20(dd, 1H, H-6, $J_{5,6}$=5 Hz, $J_{6,NH}$ =8 Hz), 4.50 and 4.80(each d, 2H, H-2, J_{gem}=15 Hz), 5.27 (m, 1H, H-5) and *ca.* 6.1(br, NH); molecular ion at *m/e* 344.162(calcd, 344.1583).

Found: C, 52.14; H, 6.98; N, 8.09%. Calcd for $C_{15}H_{24}N_2O_7$: C, 52.32; H, 7.03; N, 8.14%.

*N-(3-Benzyloxypicolinoyloxy)succinimide (**9**).* 3-Benzyloxypicolinic acid hydrochloride sesquihydrate[14] (500 mg, 1.71 mmol) was suspended in a mixture of ethyl acetate (7.3 ml) and triethylamine (0.25 ml) and stirred at room temperature for 1 h. The crystals of triethylamine hydrochloride were filtered off and washed with ethyl acetate. *N*-Hydroxysuccinimide (210 mg, 1.82 mmol) and DCCI (370 mg, 1.82 mmol) were added to the combined filtrates. The mixture was stirred at room temperature for 2 h, and then kept at 0 °C for 0.5 h. The resulting crystalline product (a mixture of **9** and DCU) was collected by filtration and extracted with DMF (10 ml) under stirring at room temperature for 1 h. After removal of undissolved DCU, the DMF solution was evaporated to give a crystalline solid (528 mg). The solid was again dissolved in DMF (6.9 ml) at 50 °C in order to remove DCU and the filtered solution was evaporated. The residual crude crystals of **9** (443 mg, 79.6%) were recrystallized from a mixture of DMF (3.2 ml) and ethyl acetate (68 ml) to afford a practically pure sample of **9** (348 mg, 62.3%), mp 179—183 °C. The sample was again recrystallized from the same solvent system to give an analytical sample, mp 181—183 °C.

Found: C, 62.35; H, 4.51; N, 8.49%. Calcd for $C_{17}H_{14}N_2O_5$: C, 62.57; H, 4.32; N, 8.59%.

*6-(3-Benzyloxypicolinoylamino)-5-methyl-8-aza-1,4-dioxacyclododecane-3,7,12-trione (**10**).* A sample of **9** (20.0 mg, 0.0581 mmol) was dissolved in trifluoroacetic acid (0.1 ml). The solution was kept at room temperature for 5 min and then evaporated to afford a colorless glassy solid (20.8 mg) of the trifluoroacetate of the amino peptide dilactone. 3-Benzyloxypicolinic acid active ester **9** (19.0 mg, 0.0581 mmol) was added to a solution of the trifluoroacetate(20.8 mg) in DMF (0.25 ml). Triethylamine was then added until the solution became neutral (pH 7), and the mixture was allowed to stand at 37 °C for 4 days. The reaction mixture was evaporated and dissolved in ethyl acetate. The solution was washed with water and saturated NaCl solution, dried and evaporated. The residual pale-yellow syrup (40 mg) was chromatographed on silica gel (3 g) with benzene-acetone (1 : 1) to afford a colorless syrup of **10** (22.5 mg, 85.2%); $\delta(CDCl_3)$, 1.28(d, 3H, 5-Me, J=6.8 Hz), *ca.* 2.1(m, 2H, H-10), *ca.* 2.5(m, 2H, H-9), 3.0—4.0 (m, 2H, H-11), 4.56 and 4.82(each d, 2H, H-2, J_{gem}=15 Hz), 4.77(dd, 1H, H-6, $J_{6,NH}$=8 Hz, $J_{5,6}$=5 Hz), 5.27(s, 2H, OCH_2Ph), 5.42(m, 1H, H-5), *ca.* 6.2(m, 1H, NH), 7.39 (s, 5H, Ph), *ca.* 7.5(m, 2H, picolinyl H-4′, 5′), 8.3(m, 1H, picolinyl H-6′), and 8.45(m, 1H, NH).

*6-(3-Hydroxypicolinoylamino)-5-methyl-8-aza-1,4-dioxacyclododecane-3,7,12-trione (**11**).* A solution of **10** (22.4 mg) in methanol(3 ml) was stirred with palladium black for 10 min under bubbling with hydrogen gas. Acetone was added to the reaction mixture, the catalysts were filtered off, and the filtrate was evaporated to give **11** (14.3 mg, 80.7%). TLC (silica gel, benzene-acetone(1 : 1)) of the sample showed a single spot (R_f 0.68) detected by means of $FeCl_3$ and H_2SO_4. The sample was recrystallized from acetone to afford the pure sample: Mp 253—255 °C; $[\alpha]_D^{26}$ +9° (*c* 0.45, $CHCl_3$); δ ($CDCl_3$), 1.36(d, 3H, 5-Me, J=6.8 Hz), *ca.* 2.0(m, 2H, H-10), *ca.* 2.5(m, 2H, H-9), *ca.* 3.8(m, 2H, H-11), 4.57 and 4.96(each d, 2H, J_{gem}=15 Hz), 4.60(dd, 1H, H-6, $J_{5,6}$=5 Hz, $J_{6,NH}$ =8 Hz), 5.42(m, 1H, H-5), *ca.* 6.0(br, 1H, NH), *ca.* 7.4(m, picolinyl H-4′,5′), 8.2(m, 1H, H-6′), and 8.7(m, 1H, NH).

Found: C, 52.82; H, 5.31; N, 11.61%. Calcd for $C_{16}H_{19}N_3O_7$: C, 52.60, H, 5.24; N, 11.50%.

The authors wish to thank Mr. Saburo Nakada for carrying out the microanalyses, and Mrs. Shinoka Fujita(née Yamamoto) and Mr. Haruyoshi Kawazoe for their assistance.

Biosynthesis of Aloenin in *Aloe arborescens* var. *natalensis**

Takayuki SUGA and Toshifumi HIRATA

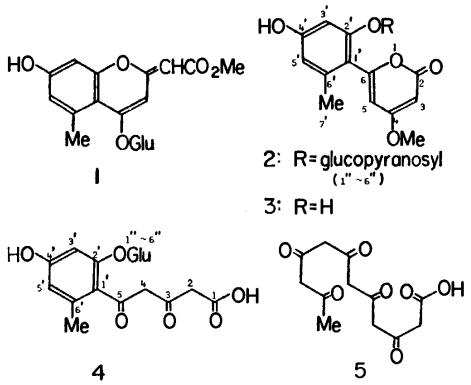
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received September 12, 1977)

The ^{14}C- and ^{3}H-labeling patterns in aloenin biosynthesized by uptake of acetate-1-^{14}C, malonate-2-^{14}C, phenylalanine-1-^{14}C and -3-^{14}C, methionine-*methyl*-^{14}C, and glucose-3-^{3}H to *Aloe arborescens* var. *natalensis* demonstrated that the carbon skeleton of aloenin is arisen *via* a biological polyketide by the acetate-malonate pathway and the *O*-methyl group originates from methionine. Further, feeding experiments of $^{3}H/^{14}C$-doubly labeled 4-methoxy-6-(2,4-dihydroxy-6-methylphenyl)-2-pyrone and 5-(2-β-D-glucopyranosyloxy-4-hydroxy-6-methylphenyl)-3,5-dioxopentanoic acid in the Aloe plant revealed that an immediate intermediate is the pyrone derivative and not the dioxopentanoic acid derivative. Aloenin was demonstrated to be biosynthesized in such a way that the first formation of the pyrone by cyclization of the biological polyketide and then *O*-methylation of the cyclized intermediate is followed by introduction of a glucose molecule into the pyrone derivative.

Aloe arborescens Mill. var. *natalensis* Berger has been widely used for folk remedies.[3–5] A new bitter glucoside, named aloenin, with an inhibitory activity for the gastric juice secretion of rats was isolated from the plant, and its structure was reported to be a chromene derivative (**1**).[6–7] However, reexaminations of the structure by means of spectroscopic and chemical methods had proposed revised structure **2**,[8] which was recently confirmed by X-ray crystallographic and ^{13}C NMR spectroscopic studies.[9–11] We also examined other bioactive components and chemical constituents of the plant.[12]

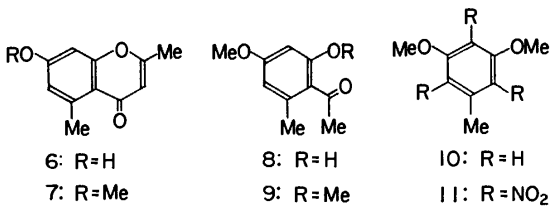
The biosynthetic pathway of aloenin (**2**) is of considerable interest because of "the masked polyketide structure".[13–15] In parallel with the structural studies of aloenin, we carried out feeding experiments of the tracer compounds, such as ^{14}C-labeled acetate, malonate, phenylalanine, and methionine, ^{3}H-labeled glucose, and $^{3}H/^{14}C$-doubly labeled 4-methoxy-6-(2,4-dihydroxy-6-methylphenyl)2-pyrone (**3**) and 5-(2-β-D-glucopyranosyloxy-4-hydroxy-6-methylphenyl)-3,5-dioxopentanoic acid (**4**), in the Aloe plants to elucidate the biosynthetic pathway for generating the carbon skeleton of aloenin, the immediate intermediate for the biosynthesis of aloenin, and the biosynthetic sequence in the stage leading to aloenin from the biological polyketide. The results have been partly outlined in the preliminary communications,[1,2] but we wish to describe *en bloc* details of the results.



Results and Discussion

Feeding experiments of the ^{14}C- and ^{3}H-labeled tracer compounds, such as sodium acetate-1-^{14}C, sodium malonate-2-^{14}C, DL-phenylalanine-1-^{14}C, DL-phenylalanine-3-^{14}C, L-methionine-*methyl*-^{14}C, and D-glucose-3-^{3}H, were carried out in the potted plants by the cotton thread method.[16] Sodium acetate-1-^{14}C and sodium malonate-2-^{14}C were incorporated to a considerable extent in contrast to the other ^{14}C- and ^{3}H-labeled tracers, as shown in Table 1. This suggests that aloenin (**2**) may be biosynthesized by the acetate-malonate pathway, which probably involves a biological polyketide intermediate **5**. Further, the seasonal changes in the incorporations of ^{14}C-labeled acetate and malonate into aloenin indicated that the biosynthesis of aloenin (**2**) was favored in April rather than in July or October.

In order to establish the biosynthetic pathway suggested by the foregoing feeding experiments, aloenin biosynthesized by incorporation of the above-described ^{14}C- and ^{3}H-labeled precursors, respectively, was subjected to the degradation to determine the labeling pattern. Aloenin was first degraded using 5% hydrochloric acid to 2,5-dimethyl-7-hydroxychromone (**6**), glucose, and carbon dioxide,[8,11] which, in turn, originate from the C-3—C-6 and C-1′—C-7′, the C-1″—C-6″, and the C-2 moieties of **2**,** respectively. The alkaline degradation of the methylated compound (**7**) derived from **6** gave 2-hydroxy-4-methoxy-6-methylacetophenone (**8**)[17] corresponding to the C-5—C-6 and C-1′—C-7′ moiety. Methylation of **8** by Hakomori's method gave 2,4-dimethoxy-6-methylacetophenone (**9**), which was then transformed to 3,5-dimethoxytoluene (**10**) on treatment with 10% hydrochloric acid. Nitra-



* Preliminary accounts of this work have been communicated in references 1 and 2.

** In this paper, for convenience, the carbon atoms of aloenin (**2**), the aglycone (**3**), and the diketo acid (**4**) are numbered as shown in the formulae.

Table 1. Incorporation of the radioactive tracers into aloenin (**2**) by the aloe plants

Exp. No.	Precursor[a] (μCi)	Feeding time (day)	Season	Sp. act. of **2** (dpm/mmol)	Incorporation (%)
1	AcNa-1-^{14}C (1.00×10^{2})	7	April	1.87×10^{5}	0.062
2	AcNa-1-^{14}C (1.00×10^{3})	7	April	2.76×10^{6}	0.030

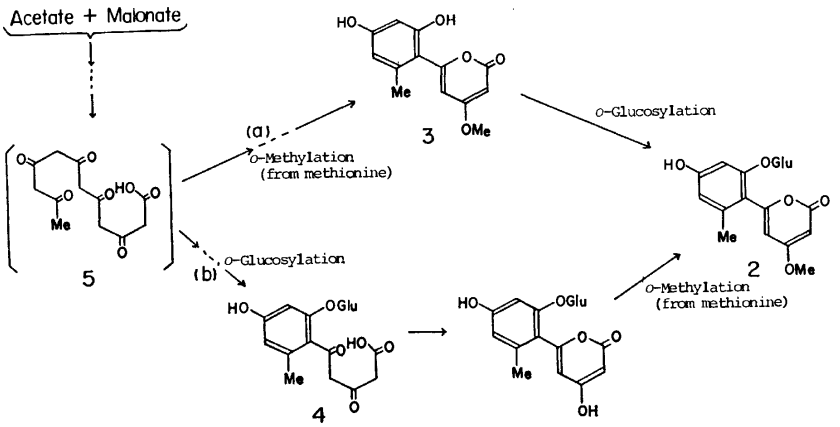
a) Theoretical values calculated on the basis that the glucose moiety of **2** is originated from D-glucose.

tion of **10** afforded the trinitro derivative (**11**), which on bromopicrin cleavage[18,19] afforded bromopicrin originated, respectively, from C-1′, C-3′, and C-5′ of **2**. The radioactivities of these compounds are listed in Tables 2—7. It was observed that the ^{14}C-labeling patterns of **2** biosynthesized from acetate-1-^{14}C and malonate-2-^{14}C, respectively, were in complete agreement with the pattern anticipated from the acetate-malonate pathway (Tables 2 and 3). In feeding experiments of phenylalanine-1-^{14}C and -3-^{14}C (Tables 1, 4, and 5), the low incorporation of the tracers and the random distribution of radioactivities were observed in contrast with the incorporations of the acetate and the malonate. These facts unambiguously establish that the carbon skeleton of aloenin is generated by the acetate-malonate pathway and not by the shikimate pathway. The above results obtained in the incorporations of phenylalanine may be explained by participation of these precursors in the formation of polyketide **5** *via* acetoacetyl-CoA which is probably produced from phenylalanine through such an intricate metabolic pathway[20] as involving the cleavage of even the aromatic ring.

After uptake of L-methionine-*methyl*-^{14}C, almost all the amount of the total radioactivities were located on the *O*-methyl group of aloenin, as shown in Table 6. The distribution of radioactivity on the C-2—C-6, C-1′—C-7′, and C-1″—C-6″ carbon atoms was negligibly small and was within the experimental error. This demonstrates that the *O*-methyl group at C-4 of aloenin (**2**) originates from the *S*-methyl group of L-methionine. On the other hand, the ^3H-labeling pattern in aloenin biosynthesized by incorporation of D-glucose-3-^3H are shown in Table 7. The pattern indicates that the glucose moiety (C-1″—C-6″) is produced by introduction of a molecule of glucose. In the stage leading to aloenin from the biological polyketide (**5**), the introduction of the glucose molecule and the creation of the methoxyl group may occur through pathway (a) or (b) involving a different compound, 4-methoxy-6-(2,4-dihydroxy-6-methylphenyl)-2-pyrone (**3**) or 5-(2-*β*-D-glucopyranosyloxy-4-hydroxy-6-methylphenyl)-3,5-dioxopentanoic acid (**4**), which are possible as an immediate intermediate for the biosynthesis of aloenin, as shown in Scheme 1. In order to prove the immediate intermediate and the biosynthetic sequence in the stage, the $^3H/^{14}C$-doubly labeled compounds, (**3**) and (**4**), were prepared from the labeled aloenin and subjected to feeding experiments as follows. The ^{14}C- and ^3H-labeled specimens of aloenin were synthesized biologically by feeding acetate-1-^{14}C, L-methionine-*methyl*-^3H, and D-glucose-3-^3H to the Aloe plant (Table 1). The incorporation of these labeled compounds into aloenin should yield 2, 4, 6, 2′, 4′, 6′-^{14}C-, *methoxyl*-^3H-, and



Scheme 1. Possible biosynthetic pathways of aloenin (**2**) in aloe plants.

TABLE 8. INCORPORATION OF THE DOUBLY LABELED TRACERS, **3** AND **4**, INTO ALOENIN (**2**) BY THE ALOE PLANTS

Exp. No.	Precursor[a,b] (μCi)	Feeding time (day)	Season	Sp. act. of **2** (dpm/mmol)[b]	Incorporation (%)[c]
16	Pyrone-^3H; ^{14}C (1.22×10^{-3})	5	July	8.44×10^2	8.1
17	Pyrone-^3H; ^{14}C (1.31×10^{-3})	5	July	6.52×10^2	5.5
18	Pyrone-^3H; ^{14}C (4.06×10^{-3})	3	August	8.48×10^2	13.4

20	Acid-^3H; ^{14}C (2.55×10^{-2})	3	August	0	0
21	Acid-^3H; ^{14}C (2.80×10^{-2})	3	August	0	0

a) Pyrone-^3H; ^{14}C and acid-^3H; ^{14}C denote 4-methoxy-6-(2,4-dihydroxy-6-methylphenyl)-2-pyrone-*methoxyl*-^3H; 2,4,6,2′,4′,6′-^{14}C (**3**) and potassium salt of 5-(2-β-D-glucopyranosyloxy-4-hydroxy-6-methylphenyl)-3,5-dioxopentanoic acid-3″-^3H; 1,3,5,2′,4′,6′-^{14}C (**4**), respectively. b) Radioactivities of the doubly labeled compounds refer to only ^{14}C. c) The incorporations were calculated with respect to only ^{14}C.

TABLE 9. THE $^3H/^{14}C$ LABELING RATIOS IN ALOENIN (**2**) AFTER UPTAKE OF DOUBLY LABELED PYRONE **3**

Exp. No.[a]	Pyrone **3** Sp. act. (dpm/mmol) ^3H	Pyrone **3** Sp. act. (dpm/mmol) ^{14}C	Pyrone **3** $^3H/^{14}C$ Ratio	Aloenin (**2**) Sp. act. (dpm/mmol) ^3H	Aloenin (**2**) Sp. act. (dpm/mmol) ^{14}C	Aloenin (**2**) $^3H/^{14}C$
16	3.30×10^5	5.01×10^1	6.59	5.34×10^3	8.44×10^2	6.33
17	3.30×10^5	5.01×10^1	6.59	4.07×10^3	6.52×10^2	6.24
18	2.80×10^5	2.46×10^1	11.4	8.74×10^3	8.48×10^2	10.3

a) "Exp. No." corresponds to the number in Table 8.

3″-^3H-labeled aloenin, respectively, since the carbon skeleton, the methoxyl group, and the glucose moiety have been established to be arisen from acetate, methionine, and glucose as described above. Aloenin-2,4,6,2′,4′,6′-^{14}C was mixed with aloenin-*methoxyl*-^3H and then the combined material was hydrolyzed[8,11] with 3% HCl–MeOH to yield 4-methoxy-6-(2,4-dihydroxy-6-methylphenyl)-2-pyrone-*methoxyl*-^3H; 2,4,6,2′,4′,6′-^{14}C (**3**). On the other hand, following the method established for the synthesis of the corresponding diketo acid by alkaline degradation of the 6-substituted 4-methoxy-2-pyrone derivatives,[8,11] a combined sample of aloenin-3″-^3H and aloenin-2,4,6,2′,4′,6′-^{14}C was treated with 5% KOH–MeOH to yield potassium salt of 5-(2-β-D-glucopyranosyloxy-4-hydroxy-6-methylphenyl)-3,5-dioxopentanoic acid-3″-^3H; 1,3,5,2′,4′,6′-^{14}C (**4**).

Feeding experiments of the doubly labeled pyrone (**3**) and the potassium salt of diketo acid **4** to the Aloe plant were carried out in the same manner as above. The labeled pyrone **3** was incorporated into aloenin to an extremely large extent (Exp. 16—18) in comparison with the incorporation of such labeled compounds as acetate-1-^{14}C, malonate-2-^{14}C, glucose-3-^3H, and methionine-*methyl*-^3H, as shown in Tables 1, 8, and 9. In contrast to this, no incorporation of the diketo acid (**4**) into aloenin occurred in all of the three trials (Exp. 19—21). These results demonstrate that the pyrone **3**, but not the diketo acid **4**, is an immediate intermediate for the biosynthesis of aloenin. Further, the $^3H/^{14}C$ ratio of the doubly labeled pyrone (**3**) was retained in aloenin biosynthesized by uptake of the labeled pyrone, as shown in Table 9. This indicates the occurrence of *O*-glucosylation at the C-2′ hydroxyl group of the pyrone **3**. Thus, the biosynthesis of aloenin (**2**) was demonstrated to proceed in pathway (a) as shown in Scheme 1, that is, the first formation of aglycone **3** by cyclization of biological polyketide 5

produced by the acetate-malonate pathway and then by creation of the C-4 methoxyl group by *O*-methylation with methionine is followed by introduction of a glucose molecule into the C-2′ hydroxyl group of the aglycone (**3**).

Experimental

The radioactive products were purified to constant specific radioactivity by a combination of preparative TLC (silica gel; 0.75 mm in thickness) and repeated recrystallization. All the products had PMR, IR, and MS spectra consistent with the structure, and the melting points and spectral data agreed with the corresponding authentic samples.[8,11] Radioactivities were measured on a liquid scintillation spectrometer using Bray's scintillation solvent.[21] The counting error was within ±2%.

Incorporation of the Labeled Compounds into Aloenin by the Aloe Plants. A phosphate buffered solution (pH 7.38) of each of the ^{14}C- and ^{3}H-labeled compounds was fed to the potted whole plants (*ca.* 30 cm in length) through the stem perforated with a cotton thread for sucking up the solution.[16] After 3—7 days, the leaves (*ca.* 200 g) were minced mechanically and extracted with MeOH by means of a Soxhlet apparatus. Removal of the solvent gave a brown viscous mass, which was chromatographed on a silica gel column with $CHCl_3$-MeOH (3:1) to give aloenin (**2**) (*ca.* 220 mg): Mp 145—147 °C (lit,[8,11] mp 145—147 °C); IR (Nujol) 3350 (OH), 1710 (C=O), and 1640 cm^{-1} (C=C); PMR (acetone-d_6) δ 2.19 (s, 3H, Ar-Me) and 3.86 (s, 3H, OMe). The radioactivities are shown in Table 1.

*Degradation of **2** with Hydrochloric Acid.* Aloenin (**2**) (100 mg), obtained by incorporating the tracer compounds, was refluxed[8,11] with 5% HCl (10 ml) for 2 h using the $Ba(OH)_2$ trap attached to the reflux apparatus. Carbon dioxide liberated was converted to $BaCO_3$ by absorbing it in the $Ba(OH)_2$ solution. The reaction mixture was then extracted with ether to give 2,5-dimethyl-7-hydroxychromone (**6**) (45 mg): Mp 245 °C (dec) (lit,[17] mp 245 °C (dec)); IR (Nujol) 1665 (C=O) and 1618 cm^{-1} (C=C). The aqueous layer was passed through an Amberlite resin IR-45 (OH) column until all chloride ions had been removed to give D-glucose (18 mg): Mp 144—145 °C. Methylation of **6** (30 mg) with CH_2N_2 gave 2,5-dimethyl-7-methoxychromone (**7**) (29 mg): Mp 116—117 °C (lit,[17] mp 116—117 °C); IR (Nujol) 3050, 1650, 1630, and 1570 cm^{-1}; PMR ($CDCl_3$) δ 2.25 (s, 3H, C(2)-Me), 2.77 (s, 3H, Ar-Me), and 3.81 (s, 3H, OMe).

*Degradation of **7** with Sodium Hydroxide.* To a solution of **7** (45 mg) in MeOH (4 ml), 30% KOH solution (10 ml) was added, and the mixture was refluxed under an atmosphere of N_2.[17] The reaction mixture, after acidification, was extracted with ether to give 2-hydroxy-4-methoxy-6-methylacetophenone (**8**) (15 mg): Mp 78.0—78.5 °C (lit,[17,22] mp 78.0—78.5 °C); IR (KBr) 1612, 1590, 1500, 859, and 821 cm^{-1}; PMR ($CDCl_3$) δ 2.53 (s, 3H, Ar-Me), 2.58 (s, 3H, COMe), 3.77 (s, 3H, OMe), 6.25 (s, 2H, arom. H), and 13.48 (s, 1H, OH). Methylation of **8** (10 mg) by Hakomori's method[23] gave 2,4-dimethoxy-6-methylacetophenone (**9**) (7 mg): Mp 41—42 °C (lit,[22] mp 41—42 °C); IR ($CDCl_3$) 1682 and 1600 cm^{-1}; PMR ($CDCl_3$) δ 2.23 (s, 3H, Ar-Me), 2.44 (s, 3H, COMe), 3.76 (s, 6H, 2×OMe), and 6.28 (s, 2H, arom. H).

*Degradation of **9** with Hydrochloric Acid.* A solution of **9** (140 mg) in 5% HCl (25 ml) was refluxed for 10 h, and the reaction mixture was extracted with ether to give an oily product (103 mg), which was separated on preparative TLC with hexane-EtOAc (3:1) to afford 3,5-dimethoxytoluene (**10**) (95 mg): Bp 130—132 °C (7.0 mmHg); n_D^{25} 1.5239; IR (liq.) 1600, 1298, and 1207 cm^{-1}; PMR ($CDCl_3$) δ 2.32 (s, 3H, Ar-Me), 3.73 (s, 6H, 2×OMe), and 6.30 (s, 3H, arom. H).

*Nitration of **10**.* To a solution of **10** (250 mg) in concd H_2SO_4 (3 ml), a mixture of concd HNO_3 (3 ml) and concd H_2SO_4 (3 ml) was added under ice-cooling. After heating for 3 min at 60 °C, the reaction mixture was poured into H_2O (60 ml) and then allowed to stand overnight to give yellow powders (119 mg). Recrystallization of the powders afforded pale yellow crystals of the trinitro derivative (**11**): Mp 70—71 °C; *m/e* 287 (M^+); IR (KBr) 1625, 1570, 1500, 1380, and 882 cm^{-1}; PMR ($CDCl_3$) δ 2.38 (s, 3H, Ar-Me) and 4.12 (s, 6H, 2×OMe).

*Bromopicrin Cleavage of **11**.* According to the procedure of bromopicrin cleavage,[18,19] a paste of $Ca(OH)_2$ (7.0 g in 30 ml of H_2O) was added at 0 °C to a solution of **11** (20 mg) in a saturated solution of $Ca(OH)_2$ (1.0 ml), and Br_2 (2.5 ml) was then dropped into the mixture under stirring. After the mixture had been kept at 10 °C for 2 h until disappearance of the yellow color, it was steam-distilled to give bromopicrin (6 mg): IR (liq.) 1560 and 1351 cm^{-1} (NO_2).

Preparation of 4-Methoxy-6-(2,4-dihydroxy-6-methylphenyl)-2-pyrone-methoxy-^{3}H;*2,4,6,2′,4′,6′*-^{14}C (***3***). The singly labeled tracers, aloenin-2,4,6,2′,4′,6′-^{14}C and *-methoxyl-*^{3}H, were synthesized biologically by administration of acetate-1-^{14}C and L-methionine-*methyl*-^{3}H, respectively, into the Aloe plant in the same manner as described above (Table 1). A mixture of the ^{14}C-labeled aloenin (40 mg) and the ^{3}H-labeled aloenin (40 mg) was refluxed[8,11] with 3% HCl-MeOH (10 ml) for 2 h. The reaction mixture was diluted with H_2O (30 ml) and extracted with ether using a continuous extractor to give a crude product (32 mg), which was purified to constant specific radioactivity by preparative TLC with MeOH-$CHCl_3$ (1:4) followed by recrystallization to afford pure doubly-labeled pyrone **3**: Mp 213—214 °C; IR (KBr) 3350, 1670, 1628, and 1600 cm^{-1}; PMR (acetone-d_6) δ 2.19 (s, 3H, Ar-Me), 3.92 (s, 3H, OMe), 5.94 (d, J=2.2 Hz, 1H), 6.07 (d, J=2.2 Hz, 1H), and 6.33 (s, 2H, arom. 2H). The radioactivities are shown in Table 8.

Preparation of Potassium Salt of 5-(2-β-D-Glucopyranosyloxy-4-hydroxy-6-methylphenyl)-3,5-dioxopentanoic acid-3″-^{3}H;*1,3,5,2′,4′,6′*-C^{14} (***4***). The singly labeled tracers, aloenin-2,4,6,2′,4′,6′-^{14}C and -3″-^{3}H, were prepared biologically from acetate-1-^{14}C and D-glucose-3-^{3}H, respectively (Table 1). According to the reported procedure,[8,11] a mixture of the ^{14}C-labeled aloenin (36 mg) and the ^{3}H-labeled aloenin (70 mg) dissolved in 5% KOH-MeOH (10 ml) was stirred at room temperature under an atmosphere of N_2. After 3 days, the reaction mixture was subjected to preparative TLC with 1-BuOH-MeOH-H_2O (7:3:3) to give potassium salt (37 mg) of doubly labeled **4**: IR (Nujol) 3400 (OH) and 1610 cm^{-1} (COO^-); PMR (D_2O) δ 2.30 (s, 3H, Ar-Me) and 6.63 (s, 2H, arom. 2H). The radioactivities are shown in Table 8.

This investigation was partially supported by a Grant-in-Aid (074176 and 047089) for Scientific Research in 1975 from the Ministry of Education.

(Received September 16, 1977)

Bottromycins B_1 and B_2, peptide antibiotics, were synthesized according to the structures proposed by Nakamura *et al.* B_1 was obtained by the condensation of the imidate, Piv–Tle–Val–ImPro–OEt·HCl with the ester, H–Gly–Phe(βMe)–β-Tha–OH in the presence of Et_3N, and B_2 by the replacement of the Z group of Z–Tle–Val–ImPro–Gly–Phe(βMe)–β-Tha–OMe by the *trans*-4-methyl-2-pentenoyl group. The structures of the synthetic B_1 and B_2 were confirmed by elemental analyses, amino acid analyses, and CI-mass spectra. However, the synthetic bottromycins differed from the natural ones in many respects, *e.g.*, IR spectra, behavior in TLC, and pK_a values. Most significantly, no antimicrobial activities were detected in the synthetic B_1. On the basis of these results, it is concluded that the structures proposed by Nakamura *et al.* for bottromycins are erroneous and should be revised.

Bottromycin is a peptide antibiotic which was first isolated from the culture broth of *Streptomyces bottropensis* by Waisvisz *et al.*[2)] They determined the *C*-terminal dipeptide to be β-methylphenylalanyl-β-(2-thiazolyl)-β-alanine methyl ester, though they gave no information about the configurations of the two amino acids. Later, Nakamura *et al.*,[3)] who studied this antibiotic in detail, were able to separate it into 5 species and gave these components the structures shown in Fig. 1. Wolf and his co-workers[4)] also isolated bottromycin and separated it into 5 species, 3 species of which, however, could not be identified. The configurations of the two unusual amino acids, β-methylphenylalanine and β-(2-thiazolyl)-β-alanine, were determined to be *erythro*-L by Arold *et al.*[5)] and L by our group,[6)] respectively.

Compared with other peptide antibiotics, the structure proposed for bottromycin is very unique, because it consists of a linear acyl peptide ester containing an iminopeptide bond[7a)] in the middle of the molecule, and contains many unusual amino acids, but no D-amino acid. These structural features had strongly aroused our interest in the relationship between the structures and the biological activities, and prompted us to synthesize bottromycin.

A preliminary trial[8)] to build up bottromycin by coupling the three known dipeptide fragments, *i.e.*, pivaloyl-*t*-leucylvaline,[9)] (iminoproly)glycine,[8)] and β-methylphenylalanyl-β-(2-thiazolyl)-β-alanine methyl ester,[10)] failed due to the easy cyclization of the (iminoprolyl)glycine fragment into an imidazolone when the carboxyl group was activated. The imidazolone formation could successfully be avoided by locating a carboxyl (or alkoxycarbonyl) group sufficiently apart from the imino group in the molecule, as seen in the syntheses of model iminopeptides.[11)] On the basis of these previous results, we adopted the synthetic routes through the condensation of the tripeptide imidate with the tripeptide ester to form an iminopeptide bond, as is shown in Schemes 1 and 2.

For the preparation of the *N*-terminal fragment of B_1, Z–Tle–OH[7b)] (**1**) was coupled with H–Val–Pro–NH_2

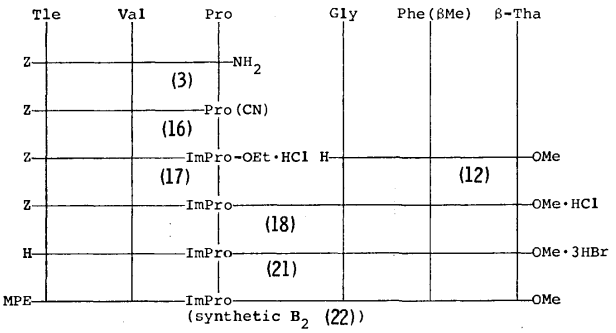

Scheme 2. Synthesis of bottromycin B_2.

(**2**) by the mixed anhydride method, and the protected tripeptide amide (**3**) was obtained in 88% yield. The Z group of the amide (**3**) was replaced by the pivaloyl group through the debenzyloxycarbonylation of **3** with hydrogen bromide in acetic acid and the successive acylation with pivaloyl chloride in the presence of *N*,*N*-diisopropylethylamine, to give *N*-pivaloyl tripeptide amide (**5**). The amide (**5**) was dehydrated to the nitrile (**6**) with phosphoryl chloride in pyridine in 87% yield, and then converted into the imidate hydrochloride (**7**) by the method of Pinner[8,11,12] in 98% yield.

The *C*-terminal fragment was prepared by the coupling of Z–Gly–ONSu with H–Phe(*β*Me)–*β*-Tha–OMe (**9**), followed by the debenzyloxycarbonylation of the resulting protected tripeptide (**10**) with hydrogen bromide in acetic acid. The tripeptide ester (**11**) was obtained as the dihydrobromide in 79% yield, based on the protected dipeptide ester[10] (**8**).

The tripeptide imidate hydrochloride (**7**) was condensed with the tripeptide ester (**12**) derived from the dihydrobromide (**11**) in methanol in the presence of triethylamine and afforded bottromycin B_1 as the monohydrochloride (**13**) in 50% yield. The free B_1 (**15**) was obtained by the treatment of the hydrochloride (**13**) with an ion exchange resin, while the treatment of the compound (**13**) with 4.7% hydrogen chloride in methanol gave the B_1 dihydrochloride (**14**).

Bottromycin B_2 was synthesized as follows: The protected tripeptide amide (**3**) was dehydrated with phosphoryl chloride in pyridine in 97% yield, and the resulting nitrile (**16**) was converted into the tripeptide imidate hydrochloride (**17**) by the method of Pinner. From the hydrochloride (**17**) and the tripeptide ester (**12**), the *N*-Z-iminohexapeptide ester (**18**) was obtained in 37% yield in the same manner as was used for the preparation of the B_1 hydrochloride (**13**). The compound (**18**) was debenzyloxycarbonylated with hydrogen bromide in acetic acid, acylated with *trans*-4-methyl-2-pentenoyl chloride (MPE-Cl) in pyridine, and treated with Amberlyst A-29; thus the desired bottromycin B_2 was obtained in 43% yield. Although no information about the geometry of the MPE group in bottromycins A_2 and B_2 had been given, we used the *trans*-MPE-Cl for the preparation of B_2 after assuming that the MPE group of the natural compounds would be in the more stable *trans* form.

Near the end of this synthetic work, we received some information[1b] about a revised study of bottromycin A_2, which was published later.[1c] The revised structure was quite different from the old one.[3] Though nothing was mentioned about bottromycins A_1 and B_1, these structures also became doubtful. Therefore, we carefully investigated the properties of the compounds synthesized here according to the structures proposed by Nakamura *et al.*, by comparing with the structure of the natural A_2.[13]

The coincidence of the structures of the synthetic bottromycins B_1 and B_2 with the proposed structures was confirmed by elemental analyses, amino acid analyses (Table 1), and the chemical ionization (CI) mass spectra (Fig. 2).

However, these synthetic bottromycins differed from the natural ones[13] in many respects: the IR spectra of the natural B_1 and the synthetic B_1 did not coincide with each other, though those of the synthetic B_1 and B_2 very much resemble each other and those of the natural B_1 and A_2 also resemble each other. It should be pointed out that the synthetic B_2 had an absorption band assigned to C–H bending deformation of *trans* disubstituted C=C at 980 cm^{-1}, while the natural A_2 had not absorption band in the same region. (Fig. 3) The R_f values (TLC, MeOH:AcOEt = 1:3) of the synthetic B_1 and B_2 were 0.37 and 0.33, respectively, while that of the natural A_2 containing some B_2[13] was

Table 1. Analytical data of synthetic bottromycins

Bottromycin	$[\alpha]_D$ (MeOH)	Molecular formula	Found (Calcd) (%) C	H	N
Synthetic B_1 (**15**)	−54.1°[a]	$C_{40}H_{60}N_8O_7S \cdot H_2O$	58.80 (58.95)	7.61 (7.67)	12.87 (13.75)
Synthetic $B_1 \cdot HCl$ (**13**)	−34.6°[b]	$C_{40}H_{60}N_8O_7S \cdot HCl \cdot 2H_2O$	55.41 (55.25)	7.41 (7.53)	12.18 (12.89)
Synthetic $B_1 \cdot 2HCl$ (**14**)	−34.2°[c]	$C_{40}H_{60}N_8O_7S \cdot 2HCl \cdot H_2O$	54.32 (54.11)	7.34 (7.26)	11.96 (12.62)
Synthetic B_2 (**22**)	−55.5°[d]	$C_{41}H_{60}N_8O_7S \cdot 2H_2O$	58.68 (58.27)	7.45 (7.63)	12.38 (13.25)

Amino acid analyses: *6 M HCl, 110 °C, 5 days in sealed tube.*
Synthetic B_1 (**15**): Tle 1.06, Val 1.09, Pro 0.98, Gly 1, Phe(*β*Me) 1.04, *β*-Tha 0.77[e]
Synthetic B_2 (**22**): Tle 1.01, Val 1.11, Pro 1.06, Gly 1, Phe(*β*Me) 1.02, *β*-Tha 0.74[e]

a) *c* 1 at 25 °C. b) *c* 1 at 20 °C. c) *c* 0.5 at 20 °C. d) *c* 0.988 at 25 °C. e) Amino acid produced from *β*-Tha in hydrolysis: Asp 0.05 (for B_1), 0.06 (for B_2).

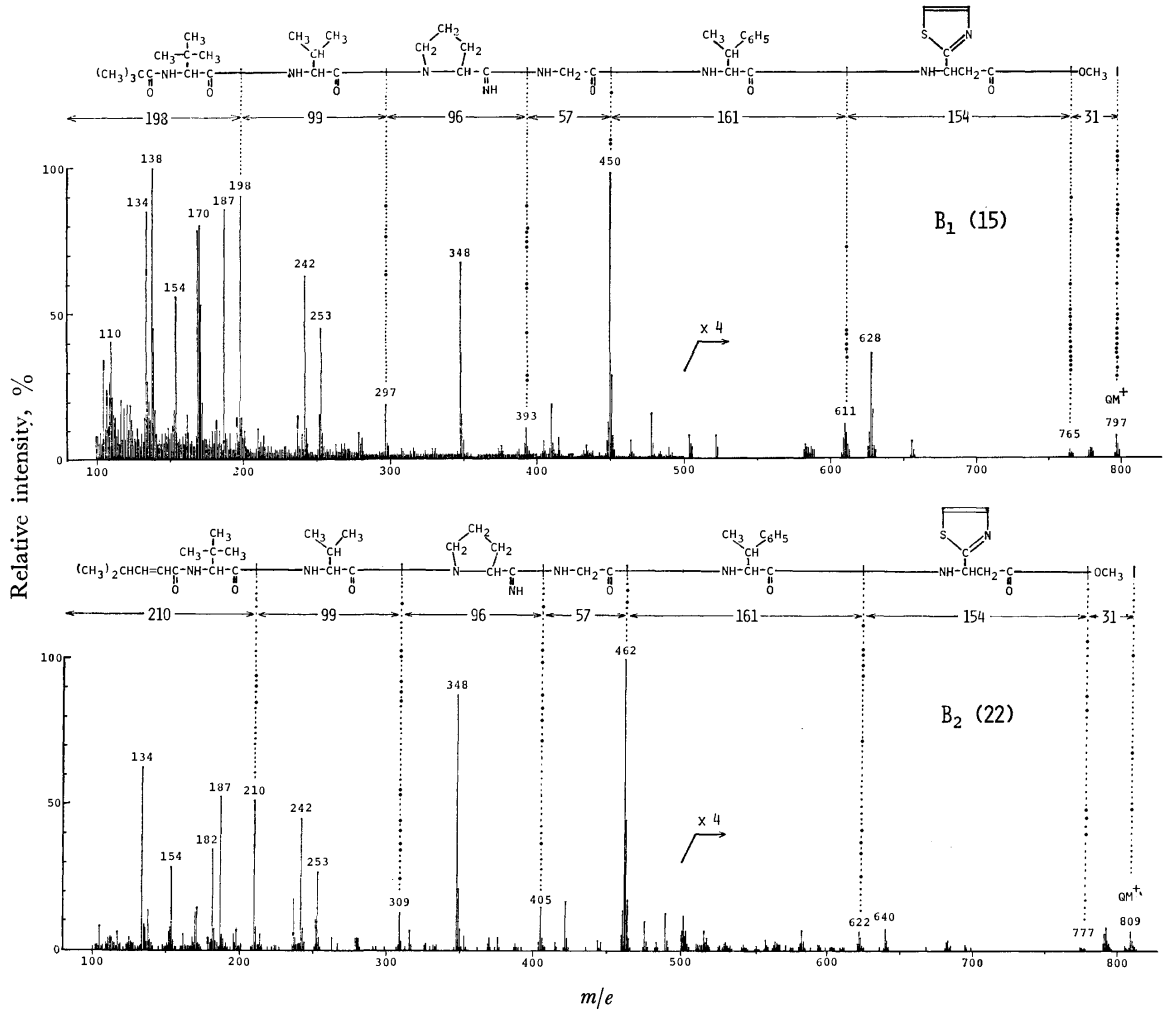

Fig. 2. CI(CH_4)-mass spectra of synthetic bottromycins B_1 (**15**) and B_2 (**22**).

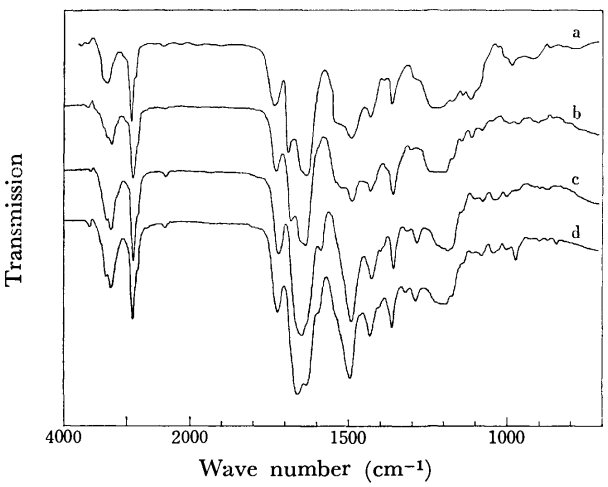

Fig. 3. IR spectra of natural and synthetic bottromycins in $CHCl_3$. a: Natural B_1 (This spectrum is reproduced from Fig. 3 in Ref. 19), b: natural A_2,[13] c: synthetic B_1 (**15**), d: synthetic B_2 (**22**).

0.78,[14] a quite different value. Further, the behavior of the synthetic B_2 and the natural A_2 against $KMnO_4$ solution was striking: when a dilute $KMnO_4$ solution was sprayed on the thin-layer chromatogram, the synthetic B_2 immediately decolorized $KMnO_4$, but, unexpectedly, the natural A_2 remained unchanged, though it has been proposed that it contains an ethylene linkage. Furthermore, the pK_a values were also different: the pK_a value (in MeOH:H_2O = 3:2) of the synthetic B_1 was 9.1, similar to those of its related iminopeptides,[11] while that of the natural A_2 was 8.3 (lit,[3c] 8.1—8.3). The most conclusive results were obtained from the comparison of the antimicrobial activities: no activities were detected in the synthetic B_1 so far examined; this can be seen in Table 2.

From all of the above results, we conclude that the structures of bottromycins proposed by Nakamura *et al.*, not only for A_2 and B_2, but also for B_1 and probably A_1, are erroneous and should be revised.

Experimental

All the melting points are uncorrected. The optical rotations were measured by means of a Yanagimoto polarimeter, OR-10, or a Perkin-Elmer 141 polarimeter. The NMR spectra were recorded on a JEOL PS-100 spectrometer or a Hitachi R-24A spectrometer. The IR spectra were recorded on a Hitachi EPI-S2 spectrophotometer. The pK_a values were measured by means of a Hitachi-Horiba pH meter, F-7. GLC analyses were carried out on a Hitachi 063 Gas

Agar dilution method: Inoculumn size: 10^6 cells/ml. Medium: Heat infusion agar (pH 7.2). Cultivation: 18 h, 37 °C.

Chromatograph. TLC was done on Merck's Kieselgel GF_{254} (Type 60) or precoated Kieselgel 60 F_{254}. For column chromatography, Merck's Kieselgel 60 (0.063—0.200 mm) was employed.

L-t-*Leucine (Tle)*.[20] This compound was prepared from DL-*t*-leucine according to the method of Weygand,[9] and was proved to be optically pure by GLC of Piv-Tle-Val-OMe[15] derived from it without any purification; mp 250.5—251 °C (sublim.), $[\alpha]_D^{21}$ −10.8° (*c* 1, H_2O). Lit, $[\alpha]_D^{21}$ −9.4° (*c* 1, H_2O);[16] $[\alpha]_{546}^{20}$ −10.9° (*c* 2, H_2O);[9] $[\alpha]_D$ −8.3° (*c* 0.53, H_2O).[17]

Z-Tle-OH (1). Into a cold solution of *t*-leucine (2.5 g, 19.1 mmol) in 1M NaOH (19.1 ml), Z-Cl (3.9 g, 22.9 mmol) and 1M NaOH (22.9 ml) were simultaneously added with vigorous stirring at 0—2 °C, and the mixture was stirred at about 0 °C for 1 h and then at room temperature for 1 h. After the usual treatment,[9] the desired compound was obtained as an oil: Yield, 4.9 g (97%); $[\alpha]_D^{20}$ −5.9° (*c* 1, MeOH); $[\alpha]_D^{20}$ +4.0° (*c* 1, DMF). Lit,[17] $[\alpha]_D$ +3.8° (*c* 0.39, DMF) *Dicyclohexylammonium Salt*: Mp 165.5—166.5 °C, $[\alpha]_D^{20}$ −8.3° (*c* 1, MeOH). Lit,[17] mp 165—168 °C, $[\alpha]_D$ −8.4° (*c* 0.59, MeOH).

Z-Tle-Val-Pro-NH_2 (3). Into a cold solution of Z-Tle-OH (**1**) (1.857 g, 7 mmol) and *N*-methylmorpholine (708 mg, 7 mmol) in THF (15 ml), isobutyl chloroformate (956 mg, 7 mmol) was added, drop by drop, with vigorous stirring below −10 °C, and the mixture was stirred at the same temperature for 15 min. To the mixture was added H-Val-Pro-NH_2·HBr[9] (**2**·HBr) (2.059 g, 7 mmol) and *N*-methylmorpholine (708 mg, 7 mmol) in DMF (15 ml) at about −10 °C. The mixture was stirred at about −10 °C for 20 min, at −5 °C for 1 h, at 0 °C for 1 h, and at room temperature overnight. After the removal of the precipitate, the yellow filtrate was evaporated under reduced pressure and the residual DMF solution was diluted with water (200 ml), extracted with AcOEt, washed with water, 1M $NaHCO_3$, and water again, and dried over $MgSO_4$. The solution was concentrated to give a colorless foamy solid: Yield, 2.845 g (88.2%). This product was used for the next reaction without further purification. The analytical sample was obtained by chromatography on a silica gel column with AcOEt–MeOH (15 : 1); $[\alpha]_D^{20}$ −88.7° (*c* 1, MeOH). Found: C, 61.97; H, 8.07; N, 12.18%. Calcd for $C_{24}H_{36}N_4O_5$: C, 62.59; H, 7.88; N, 12.16%.

H-Tle-Val-Pro-NH_2·HBr (4). This compound was prepared by the removal of the Z group from **3** (2.073 g, 4.5 mmol) with 25% HBr in AcOH (4.5 g) as usual. The crude product was recrystallized from MeOH–ether to colorless crystals: Yield, 1.570 g (85.6%); mp 193—196 °C. Found: C, 45.22; H, 8.19; N, 13.19%. Calcd for $C_{16}H_{30}N_4O_3$·HBr·H_2O: C, 45.18; H, 7.82; N, 13.17%.

Piv-Tle-Val-Pro-NH_2 (5). Into a cold solution of **4** (522 mg, 1.28 mmol) and *N,N*-diisopropylethylamine (381 mg, 2.95 mmol) in CH_2Cl_2 (4 ml), pivaloyl chloride (201 mg, 1.67 mmol) in CH_2Cl_2 (2 ml) was stirred, drop by drop, at 2—3 °C, and stirring was continued at room temperature for 1 h. To the resulting clear solution, 1-(2-aminoethyl)piperazine (99 mg, 0.77 mmol) in CH_2Cl_2 (1 ml) was added. After the mixture was stirred at room temperature for 10 min, the precipitate was filtered off. The filtrate was evaporated under reduced pressure and the residue was treated with AcOEt to remove any insoluble materials. The AcOEt solution was washed with water, 0.5 M citric acid, 1M $NaHCO_3$, and water again, and dried over $MgSO_4$. After the removal of the solvent, a foamy solid was obtained: Yield, 368 mg (69.9%). The analytical sample was obtained by chromatography on a silica gel column with AcOEt–MeOH (1 : 9); $[\alpha]_D^{20}$ −109.8° (*c* 1, MeOH). Found: C, 61.15; H, 9.45; N, 13.02%. Calcd for $C_{21}H_{38}N_4O_4$: C, 61.43; H, 9.33; N, 13.65%.

N-*(Piv-Tle-Val)-2-cyanopyrrolidine (6)*. To a stirred solution of **5** (493 mg, 1.2 mmol) in dry pyridine (2.5 ml), $POCl_3$ (0.14 ml, 1.44 mmol) in CH_2Cl_2 (0.4 ml) was added, drop by drop, below −10 °C. The solution was stirred at the same temperature for 1 h, treated with ice (10 g), and then extracted with AcOEt. The organic layer was washed with 1M HCl, 1M $NaHCO_3$, and water, and dried over $MgSO_4$: Yield, 408 mg (86.6%); a foamy solid, $[\alpha]_D^{20}$ −118.2° (*c* 1, MeOH). Found: C, 63.80; H, 9.29; N, 13.94%. Calcd for $C_{21}H_{36}N_4O_3$: C, 64.25; H, 9.24; N, 14.27%.

Piv-Tle-Val-ImPro-OEt·HCl (7). To a cold solution of **6** (385 mg, 0.98 mmol) and absolute EtOH (60 mg, 1.3 mmol) in dry ether (10 ml), dry HCl was passed with stirring at about −15 °C until saturation, and then at 0 °C for 30 min and at room temperature for 30 min. The reaction mixture was evaporated under reduced pressure to afford a colorless foamy solid: Yield, 457 mg (98.2%). This imidate hydrochloride was immediately used for the next reaction without any purification.

Z-Gly-Phe(βMe)-β-Tha-OMe (10). Into a solution

of the crude product of H–Phe(βMe)–β-Tha–OMe·2HBr (**9**·2HBr) (prepared by the removal of the Z group from Z–Phe(βMe)–β-Tha–OMe[10] (**8**) (960 mg, 1.99 mmol) with 25% HBr in AcOH as usual) and Et_3N (450 mg, 4.46 mmol) in CH_2Cl_2 (40 ml), Z-Gly-ONSu (660 mg, 2.15 mmol) was added with stirring and the mixture was allowed to stand at room temperature overnight. After the removal of the solvent, the residue was dissolved in AcOEt, washed with water, 1M HCl, water, 1M $NaHCO_3$, and water again, and dried over Na_2SO_4. The solution was evaporated under reduced pressure to leave a solid, which was recrystallized from MeOH: Yield, 852 mg (79.3%); mp 159.5—160 °C, $[\alpha]_D^{20}$ +18.4° (*c* 1, MeOH). Found: C, 60.32; H, 5.59; N, 10.25%. Calcd for $C_{27}H_{30}N_4O_6S$: C, 60.21; H, 5.61; N, 10.40%.

*H–Gly–Phe(βMe)–β-Tha–OMe·2HBr (**11**).* This compound was prepared by the treatment of **10** (539 mg, 1 mmol) with 25% HBr in AcOH (1.5 g) as usual. The crude product was purified by the reprecipitation from MeOH–ether: Yield, 581 mg (99.5%); mp 149—152 °C. Found: C, 38.96; H, 4.86; N, 9.42%. Calcd for $C_{19}H_{24}N_4O_4S\cdot 2HBr\cdot H_2O$: C, 39.06; H, 4.83; N, 9.59%.

The free ester, H–Gly–Phe(βMe)–β-Tha–OMe (**12**), was prepared by the treatment of **11** with Et_3N (in double the mole concentration of **11**) in THF, followed by the filtration of a precipitate and the removal of the solvent. The residual oil, the tripeptide ester (**12**), was used for the next reaction without any purification.

Piv–Tle–Val–ImPro–Gly–Phe(βMe)–β-Tha–OMe (Synthetic Bottromycin B_1). *a) HCl Salt (**13**):* A solution of the imidate hydrochloride (**7**) (457 mg, 0.96 mmol), the tripeptide ester (**12**) prepared from **11** (453 mg, 0.8 mmol), and Et_3N (97 mg, 0.96 mmol) in dry MeOH (5 ml) was stirred at room temperature for 3 days. The solution was then evaporated under reduced pressure, leaving a foamy solid. The solid was taken up in AcOEt and freed from any insoluble materials by filtration. The filtrate was evaporated under reduced pressure, and the residue was chromatographed on preparative layers of silica gel with $CHCl_3$–MeOH–AcOH (95 : 15 : 3) to give a foamy solid: Yield, 344 mg (49.5%).

*b) 2HCl Salt (**14**).* The hydrochloride (**13**) (100 mg) was treated with 4.7% HCl in MeOH (10 ml), and evaporated under reduced pressure, leaving a colorless solid: Yield, 98 mg; mp 156—160 °C (dec). pK_a (amidine group): 9.1 (MeOH–H_2O (3 : 2), 20 °C).

*c) Free Compound (**15**):* This compound was obtained by passing the HCl salt (**13**) (120 mg) through a Dowex 1×8 column (25% MeOH) or an Amberlyst A-29 column (90% MeOH): Yield, 112 mg, a foamy solid.

Analytical results of the compounds (**13**, **14**, and **15**) are summarized in Table 1.

*N-(Z–Tle–Val)-2-cyanopyrrolidine (**16**).* This compound was prepared by the dehydration of the tripeptide amide (**3**) (553 mg, 1.2 mmol) with $POCl_3$ (0.14 ml, 1.44 mmol) in a mixture of dry pyridine (2.5 ml) and CH_2Cl_2 (0.4 ml) at about −10 °C, as has been described above for the preparation of **6**: Yield, 455 mg (85.7%); a foamy solid, $[\alpha]_D^{20}$ −98.3° (*c* 1, MeOH). Found: C, 64.78; H, 7.97; N, 12.73%. Calcd for $C_{24}H_{34}N_4O_4$: C, 65.14; H, 7.74; N, 12.66%.

*Z–Tle–Val–ImPro–OEt·HCl (**17**).* This compound was prepared by passing dry HCl into a mixture of **16** (398 mg, 0.9 mmol) and absolute EtOH (55 mg, 1.2 mmol) in dry ether, as has been described above for the preparation of **7**: Yield, 457 mg (96.7%); a foamy solid. This product was immediately used for the next reaction.

*Z–Tle–Val–ImPro–Gly–Phe(βMe)–β-Tha–OMe·HCl (**18**).* A solution of the imidate hydrochloride (**17**) (457 mg, 0.87 mmol), the tripeptide ester (**12**) prepared from **11** (396 mg, 0.7 mmol), and Et_3N (88 mg, 0.87 mmol) in dry MeOH (5 ml) was stirred at room temperature for 3 days. After being treated as described above for **13**, the resulting foamy solid was chromatographed on preparative layers of silica gel with $CHCl_3$–MeOH–AcOH (95 : 15 : 3) to give a foamy solid: Yield, 229 mg (36.7%); $[\alpha]_D^{20}$ −21.2° (*c* 0.5, MeOH). Found: C, 58.10; H, 6.85; N, 12.19%. Calcd for $C_{43}H_{58}N_8O_8S\cdot HCl\cdot 1/2H_2O$: C, 57.87; H, 6.78; N, 12.55%.

trans-*4-Methyl-2-pentenoic Acid (**19**).* This compound was prepared from malonic acid and isobutyraldehyde in pyridine containing a small amount of piperidine.[18] This acid obtained here was proved to be the *trans* isomer by the NMR and IR spectra, as shown below: Yield, 65.1%; bp 107—109 °C/14 Torr, n_D^{19} 1.4469 (lit,[18] bp 115—116 °C/20 Torr, $n_D^{20.6}$ 1.4489); IR(neat): 985 cm^{-1} (σ C–H of *trans*-disubstituted olefin); NMR($CDCl_3$): δ=1.09 (6H, d, *J*=7 Hz, $(C\underline{H}_3)_2CH$–), 2.52 (1H, o, *J*=7 Hz, $(CH_3)_2C\underline{H}CH$=), 5.82 (1H, dd, *J*=16 and *ca.* 1 Hz, –CH=C<u>H</u>–COOH), 7.11 (1H, dd, *J*=16 and 6.5 Hz, >CH–C<u>H</u>=CH–), 12.26 (1H, s, –COO<u>H</u>).

trans-*4-Methyl-2-pentenoyl Chloride (**20**).* This compound was prepared from **19** and $SOCl_2$ as usual:[18] Yield, 73%; bp 65—66 °C/25 Torr (lit,[18] bp 58—59 °C/18 Torr); NMR($CDCl_3$): δ=1.12 (6H, d, *J*=7 Hz, $(C\underline{H}_3)_2CH$–), 2.58 (1H, o, *J*=7 Hz, $(CH_3)_2C\underline{H}CH$=), 6.04 (1H, dd, *J*=16 and *ca.* 1 Hz, –CH=C<u>H</u>–COCl), 7.19 (1H, dd, *J*=16 and 6.5 Hz, >CH–C<u>H</u>=CH–).

*MPE–Tle–Val–ImPro–Gly–Phe(βMe)–β-Tha–OMe (Synthetic Bottromycin B_2) (**22**).* The compound (**18**) (121 mg, 0.136 mmol) was treated with 25% HBr in AcOH (2 g) at room temperature. The reaction mixture was diluted with dry ether, and the separated gummy material was trituated and throughly washed with dry ether. It afforded the iminohexapeptide methyl ester trihydrobromide(**21**) as a brownish amorphous powder (133 mg). Into a solution of the crude trihydrobromide (131 mg) in pyridine (2.5 ml), was stirred *trans*-MPE-Cl (**20**) (55 mg, 0.415 mmol) in benzene (1.5 ml) under ice-cooling, and the mixture was stirred at room temperature overnight. The solvent was throughly removed by repeated concentrations under reduced pressure after each addition of benzene. The residual syrup was chromatographed on preparative layers of silica gel with $CHCl_3$–MeOH–AcOH (96 : 15 : 3) to give a foamy solid, which was then passed through an Amberlyst A-29 column with 90% MeOH as a solvent. The eluent was evaporated under reduced pressure to afford a foamy solid: yield, 52 mg (43.3% based on **18**). Analytical results are summarized in Table 1.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (14703, 1976). We thank Drs. Hamao Umezawa, Tomohisa Takita, and Hiroshi Naganawa of the Institute of Microbial Chemistry, for measuring the mass spectra and for supplying bottromycin A_2, and Dr. Ichiro Chibata and his co-workers at Tanabe Seiyaku Co., Ltd., for the amino acid analyses and the microbiological assays.

13) Throughout this investigation, we were forced to use only bottromycin A_2 containing 5% of B_2 provided by Dr. T. Takita, as a natural standard sample, because neither Umezawa's group nor Wolf's group has any A_1 and B_1 (private communications from Dr. T. Takita (September, 1976) and from Dr. F. J. Wolf (September, 1976)), and they are the only two groups who have reported that they could isolate bottromycins.

14) Although this sample of the natural A_2 contained some B_2,[13] TLC showed only one spot. This is understandable because bottromycin B_2 has been reported to behave like A_2 in TLC: *e.g.*, R_f values of A_2 and B_2 were 0.81 and 0.80 (BuOH : AcOH : H_2O = 100 : 12 : 100), respectively.[3d]

20) The configuration of *t*-leucine isolated from bottromycin has been assigned to the L-series by Nakamura *et al.*,[3b] although the compound showed the positive specific rotation, $[\alpha]_D^{22}$ +4° (*c* 1, H_2O), contrary to L-*t*-leucine prepared by us or all others.

13αH-Olean-18-ene Derivatives. Forced Wolff-Kishner Reduction Products of 19-Oxoolean-12-ene Derivatives[1]

Tadashi HONDA, Tatsushi MURAE, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 13, 1977)

Methyl 2α,3β,23-triacetoxy-13αH-olean-18-en-28-oate (**4**) and methyl 2α,3β-diacetoxy-13αH-olean-18-en-28-oate (**7**) were obtained from methyl 2α,3β,23-triacetoxy-19-oxoolean-12-en-28-oate (**2**) and from methyl 2α,3β-diacetoxy-19-oxoolean-12-en-28-oate (**5**), respectively, by the forced Wolff-Kishner reduction and subsequent acetylation and methylation. Methyl 2α,3β-diacetoxy-13βH-olean-18-en-28-oate (**10**), prepared from methyl 2,3-di-*O*-acetylarjunate (**13**) *via* methyl 2α,3β-diacetoxy-19α-hydroxy-12-oxooleanan-28-oate (**18**) and methyl 2α,3β-diacetoxy-19α-hydroxyoleanan-28-oate (**19**), was shown to be not identical with **7**. This led to a 13αH-olean-18-ene structure for **7**.

It is well known that the reduction of sterically hindered ketones, such as 11-oxosteroids, is not easily effected using the usual Wolff-Kishner procedure, while modified procedures under forced reaction conditions developed by Barton[2] or Nagata[3] are successfully applied to the reduction of hindered or masked carbonyl groups.

In connection with the structure determination of arjungenin (**1**),[4] a new constituent of *Terminalia arjuna*, a forced Wolff-Kishner reduction of methyl 2α,3β,23-triacetoxy-19-oxoolean-12-en-28-oate (**2**)[4] derived from **1**, was attempted aiming at the conversion into the known compound, methyl 2,3,23-tri-*O*-acetylarjunolate (**3**).[5] The 19-oxoolean-12-ene derivative (**2**) was subjected to a forced Wolff-Kishner reduction modified by Nagata under conditions described as procedures "A" and "B",[3] followed by acetylation and methylation. However, the resulting products were so complex that no definite product could be separated. The reduction of **2** using Barton's procedure[2] and subsequent methylation and acetylation gave a trisubstituted olefin (**4**; yield 32 %) as a sole reaction product, which was found to be not identical with methyl 2,3,23-tri-*O*-acetylarjunolate (**3**).

In order to obtain information on the structure of the reduction product (**4**), a simpler model compound of **2**, methyl 2α,3β-diacetoxy-19-oxoolean-12-en-28-oate (**5**)[6] derived from arjunic acid (**6**),[6] was subjected to the Wolff-Kishner reduction by Barton's procedure.[2] The reduction product, after acetylation and methylation, was separated by column chromatography into an olefin (**7**; yield 46 %) and an α,β-unsaturated ketone (**8**; yield 20 %). This olefin (**7**), mp 224—225 °C, $[\alpha]_D$ +71°, was indicated to be a pentacyclic trisubstituted monoolefin having a methoxycarbonyl and two acetoxyl groups by IR (1740 and 1630 cm^{-1}), PMR [δ 1.98, 2.05 (each 3H, s; 2×CH_3COO–), 3.64 (3H, s; –$COOCH_3$), and 5.30 (1H, sharp singlet)], and mass spectrum ($C_{35}H_{54}O_6$), but was shown not to be an expected deoxygenated product, methyl 2,3-di-*O*-acetylmasulinate (**9**; =methyl 2α,3β-diacetoxyolean-12-en-28-oate, mp 184—186 °C, $[\alpha]_D$ +33.5°, IR 1730, 1720, 1659, and 819 cm^{-1})[7] by comparison with their melting points and spectral data. Although the mass spectrum of **7** showed peaks at *m/e* 249, 248, and 189, characteristic for Δ^{18}-oleanene derivatives,[8] this olefin (**7**) was found to be not identical with methyl 2α,3β-diacetoxyolean-18-en-28-oate (**10**) as described below. The olefin (**7**), therefore, was inferred to be methyl 2α,3β-diacetoxy-13αH-olean-18-en-28-oate, and the proposed structure was supported by the following transformation and evidence.

On oxidation with selenium dioxide in acetic acid, the olefin (**7**) gave a known diene, methyl 2α,3β-diacetoxyoleana-12,18-dien-28-oate (**11**),[6] which was further converted into methyl 2α,3β-diacetoxyoleana-11,13(18)-dien-28-oate (**12**) by treatment with hydrochloric acid in chloroform. This diene (**12**) proved to be identical with the diene (**12**)[6] prepared by dehydration of methyl 2,3-di-*O*-acetylarjunate (**13**)[6] followed by isomerization according to the known procedures.[6]

Methyl *O*-acetylmorolate (**14**; =methyl 3β-acetoxyolean-18-en-28-oate) has been prepared from methyl 3-*O*-acetylsiaresinolate (**15**; =methyl 3β-acetoxy-19α-hydroxyolean-12-en-28-oate) *via* a 12-keto 19α-ol (**16**) and a 19α-ol (**17**) by Barton *et al.*[9] By the same procedures, methyl 2,3-di-*O*-acetylarjunate (**13**; =methyl 2α,3β-diacetoxy-19α-hydroxyolean-12-en-28-oate)[4,6] was converted into methyl 2α,3β-diacetoxyolean-18-en-28-oate (**10**). Arjunic acid (**6**), isolated from *Terminalia arjuna*,[4,6] was converted into methyl 2,3-di-*O*-acetylarjunate (**13**), which was treated with hydrogen peroxide in acetic acid to yield a 12-keto alcohol (**18**). The keto alcohol (**18**) showed IR absorption bands at 3500, 1750, 1730, 1720, and 1690 cm^{-1}. In the PMR spectrum of **18**, a signal due to $C_{(19\beta)}$–H appears at δ 4.55 as a triplet-like, which, on addition of D_2O, changes into a doublet (J=3.5 Hz). A doublet (J=7 Hz) due to $C_{(13\beta)}$–H was also observed at δ 3.10 and a double doublet (J=7 and J=3.5 Hz) due to $C_{(18\beta)}$–H at δ 2.90. The 13βH-configuration of **18** was suggested by the following attempted isomerization reaction. The ketone (**18**) was treated with potassium hydroxide in boiling ethanol and the reaction product was then acetylated to give the starting material in 50 % yield.

The ketone (**18**) was subjected to the Wolff-Kishner reduction and the product was then methylated and acetylated to give a mixture of deoxygenated alcohols (**19** and **20**), which was separated by silica gel column chromatography. An alcohol (**19**) showed a doublet (J=2 Hz) due to $C_{(19\beta)}$–H at δ 3.37, while a diastereomeric alcohol (**20**) at δ 3.40 as a doublet (J=5 Hz). The alcohols (**19** and **20**) were then oxidized with the Jones reagent to yield the corresponding ketones (**21** and **22**), respectively. In the PMR spectrum of **21**, a signal due to $C_{(18\beta)}$–H appeared at δ 3.15 as a doublet

($J_{13\beta,18\beta}$=4 Hz), while in **22** $C_{(18\beta)}$–H resonated at δ 3.28 as a doublet ($J_{13\alpha,18\beta}$=12 Hz). The CD values were $\Delta\varepsilon_{302}$=+1.60 and $\Delta\varepsilon_{302}$=−0.11 for **21** and **22**, respectively. The coupling constant, $J_{13,18}$ and CD values led to a 13β*H*- and a 13α*H*-configuration for **21** and **22**, respectively. Therefore a configuration at C-13 of the alcohol (**19**) was inferred to be 13β*H* (with an axial 19α-OH), and that of **20** 13α*H* (with an equatorial 19α-OH).

The alcohol (**19**) was treated with phosphoryl chloride in pyridine to afford an 18-ene (**10**), whose configuration at C-13 must be β*H*. The PMR spectrum of **10** showed a signal due to $C_{(19)}$–H at δ 5.10 as a singlet, and the mass spectrum gave fragment peaks characteristic for Δ^{18}-oleanene derivatives[8] at *m/e* 249 and 189, together with a molecular ion peak at *m/e* 570.3912 (M^+; *m/e* 570.3917 calcd for $C_{35}H_{54}O_6$). The isomeric alcohol (**20**), on dehydration under the same conditions, gave a 13(18)-ene (**23**), whose PMR spectrum showed no signal due to olefin proton. This olefin (**23**) was also obtainable by catalytic hydrogenation of the known methyl 2α,3β-diacetoxyoleana-11,13(18)-dien-28-oate (**12**).[6]

The 13β*H*-18-ene (**10**) thus prepared was found to be not identical with the olefin (**7**), obtained by the forced Wolff-Kishner reduction of methyl 2α,3β-diacetoxy-19-oxoolean-12-en-28-oate (**5**). The structure of the olefin (**7**) should therefore be formulated as methyl 2α,3β-diacetoxy-13α*H*-olean-18-en-28-oate.

From this observation, the structure of the trisubstituted olefin (**4**), formed by the forced Wolff-Kishner reduction of methyl 2α,3β,23-triacetoxy-19-oxoolean-12-en-28-oate (**2**)[4,10] and by successive methylation and acetylation, was suggested to be methyl 2α,3β,23-triacetoxy-13α*H*-olean-18-en-28-oate. The spectral data are compatible with the proposed structure (**4**). The mass spectrum of **4** showed peaks characteristic for Δ^{18}-oleanene derivatives[8] at *m/e* 249, 248, and 189. In the PMR spectrum, a sharp singlet due to an olefinic proton at C-19 appeared at δ 5.30. This δ-value was identical with that for $C_{(19)}$–H of methyl 2α,3β-diacetoxyolean-18-en-28-oate (**7**) with a 13α*H*-configuration, while differed from those for $C_{(19)}$–H of the 13β*H*-18-ene (**10**; δ 5.10) and of methyl *O*-acetylmorolate (**14**; δ 5.07)[11] with a 13β*H*-configuration.

Triterpenes with an olean-18-ene framework hitherto reported, germanicol (**24**),[12] miliacin (**25**),[13] morolic acid (**26**),[9,14] germanidiol (**27**; =2β-hydroxygermanicol),[15] and epigermanidiol (**28**; =2α-hydroxygermanicol)[16], are all in $C_{(13)}$-β*H* configuration, and neither isolation nor preparation of olean-18-ene derivative with a 13α*H*-configuration has yet been described. Methyl 2α,3β,23-triacetoxy-13α*H*-olean-18-en-28-oate (**4**) and methyl 2α,3β-diacetoxy-13α*H*-olean-18-en-28-oate (**7**) are the first examples of 13α*H*-olean-18-ene derivatives.

The structure of the α,β-unsaturated ketone (**8**), obtained by the forced Wolff-Kishner reduction of **5**, was inferred to be **8** from the IR (1730 and 1680 cm^{-1}), UV λ_{max} 253 nm (log ε 3.81), PMR (absence of olefinic proton), and mass spectral data *m/e* 584.3682 (M^+; *m/e* 584.3709 calcd for $C_{35}H_{52}O_7$) and *m/e* 188.

Although the formation mechanism of 13α*H*-olean-18-ene derivatives from 19-oxoolean-12-enes is not clearly elucidated, a mechanism *via* 19-oxoolean-13(18)-ene seems to be likely. It has been reported that olean-12-en-19-one derivatives undergo isomerization in the presence of alkali to give the corresponding olean-13(18)-en-19-one derivatives.[6,10,17] And α,β-unsaturated carbonyl compounds, on Wolff-Kishner reduction, often afford abnormal deoxygenated products in which a migration of the double bond has occurred, together with the normal products.[18] Under the forced Wolff-Kishner reduction conditions, a 19-oxoolean-12-ene derivative (**5**) must have isomerized into the corresponding α,β-unsaturated ketone (**8**). This compound (**8**) was subjected to the forced Wolff-Kishner reduction to give 13α*H*-olean-18-ene (**7**) in 19 % yield, after acetylation and methylation of the product, while the corresponding normal deoxygenated product, olean-13(18)-ene derivative (**23**) was not obtained.

The formation reaction of 13α*H*-olean-18-ene derivatives (**4** and **7**) was stereospecific and no 13β*H*-diastereomer was detected. The stereospecificity may be due to a structure feature around the C/D/E rings of olean-13(18)-en-19-one derivatives and/or of their nitrogen-containing intermediates.

Experimental

General indications in Experimental were the same as described in a previous paper.[4] Anhydrous hydrazine was prepared by Kusama's procedure.[19] Diethylene glycol was distilled and dried over Molecular Sieves. The forced Wolff-Kishner reduction was carried out in an argon atmosphere.

Forced Wolff-Kishner Reduction of Methyl 2α,3β,23-Triacetoxy-19-oxoolean-12-en-28-oate (2) Followed by Methylation and Acetylation. Methyl 2α,3β,23-triacetoxy-19-oxoolean-12-en-28-oate (**2**; 66 mg)[4] was treated with diethylene glycol (3 ml), sodium (68 mg), and anhydrous hydrazine (1 ml) according to the Barton procedure.[2] The reaction product, without purification, was subjected to methylation with diazomethane in ether and then to acetylation with acetic anhydride in pyridine to give a crude product (*ca.* 47 mg). The product in benzene was passed through a column of silica gel (10 g) and the following solvents were used as eluent (each 40 ml): fr. 1, benzene; fr. 2, benzene-acetone (200:3); frs. 3—8, benzene-acetone (100:3). Fractions 5 and 6 were combined (*ca.* 17 mg) and purified by preparative TLC, developed with benzene-acetone (16:1) to give methyl 2α,3β,23-triacetoxy-13α*H*-olean-18-en-28-oate (**4**; 13 mg), as amorphous solid, $[\alpha]_D$ +70° (*c* 0.16, EtOH), IR (Nujol) 1740 (br), 1730, 1715 (sh), 1240, 1225, 1045, and 1030 cm^{-1}; PMR* ($CDCl_3$) δ 0.83, 0.90, 1.12 (each 3H, s; *t*-Me), 0.98 (9H, s; 3×*t*-Me), 1.99, 2.01, 2.08 (each 3H, s; -OAc), 3.65 (3H, s; $-CO_2Me$), 3.58, 3.82 (2H, ABq, *J*=12 Hz; $C_{(23)}H_2$-OAc), 5.10 (2H, m; $C_{(2\beta)}$-H and $C_{(3\alpha)}$-H), 5.30 (1H, s; $C_{(19)}$-H); MS *m/e* 628 (M^+), 626, 569, 568, 466, 449, 448, 435, 433, 392, 262, 249, 248, 245, 203, 189 (base peak), 185, and 175.

Forced Wolff-Kishner Reduction of Methyl 2α,3β-Diacetoxy-18-oxoolean-12-en-28-oate (5) Followed by Acetylation and Methylation. Methyl 2α,3β-diacetoxy-19-oxoolean-12-en-28-oate (**5**; 120 mg) was subjected to the forced Wolff-Kishner reduction by the same procedure [diethylene glycol (*ca.* 6 ml), sodium (136 mg), and anhydrous hydrazine (1.5 ml)] as above, and the reaction product (*ca.* 84 mg) was acetylated with acetic anhydride in pyridine to give an acetylated product. This was purified by column chromatography on silica gel (15 g) eluting with the following solvents; fr. 1, benzene-acetone (100:1, 30 ml); fr. 2, benzene-acetone (50:1, 30 ml); frs. 3 and 4, benzene-acetone (100:3, each 30 ml); frs. 5—10, benzene-acetone (25:1, each 15 ml), and frs. 11—21, benzene-acetone (20:1, each 30 ml). From the fractions 6—8, a diacetate (*ca.* 52 mg) was obtained as amorphous solid, IR (KBr) 1738, 1700, 1630, 1250, 1230, 1045, and 1035 cm^{-1}; PMR ($CDCl_3$) δ 0.92, 0.98 (each 9H, s; 3×*t*-Me), 1.09 (3H, s; *t*-Me), 1.98, 2.05 (each 3H, s; -OAc), 4.75 (1H, d, *J*=11 Hz; $C_{(2\alpha)}$-H), 5.15 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\beta)}$-H), and 5.34 (1H, s; $C_{(19)}$-H); MS *m/e* 512 (M^+-CO_2), 510, 497, 452, 437, 409, 392, 349, 334, 247, 233, 215, 203, and 190 (base peak). Fractions 14—19 gave an α,β-unsaturated keto acid (23 mg).

The diacetate, above obtained, was treated with diazomethane in ether to give methyl 2α,3β-diacetoxy-13α*H*-olean-18-en-23-oate (**7**), which was crystallized from ethanol to afford white needles (38 mg), mp 224—225 °C, $[\alpha]_D$ +71° (*c* 1.38, EtOH); IR (KBr) 1740, 1725 (sh), 1630, 1250, and 1230 cm^{-1}; PMR ($CDCl_3$) δ 0.83, 1.10 (each 3H, s; *t*-Me), 0.91 (9H, s; 3×*t*-Me), 0.98 (6H, s; 2×*t*-Me), 1.98, 2.05 (each 3H, s; -OAc), 3.64 (3H, s; $-CO_2Me$), 4.75 (1H, d, *J*=11 Hz; $C_{(2\alpha)}$-H), 5.15 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\beta)}$-H), and 5.30 (1H, s; $C_{(19)}$-H); mol wt *m/e* 570.3830. Calcd for $C_{35}H_{54}O_6$: *m/e* 570.3917. MS *m/e* 570 (M^+), 568, 511, 510, 495, 450, 435, 409, 407, 334, 259, 249, 248, 247, 235, 234, 233, 215, 203, 189 (base peak), 187, and 175.

The α,β-unsaturated keto acid, on treatment with diazomethane, was converted into methyl 2α,3β-diacetoxy-19-oxo-olean-13(18)-en-28-oate (**8**), mp 223—224°C (crystallized from ether); $[\alpha]_D$ −154° (*c* 0.94, $CHCl_3$); IR (KBr) 1730, 1680, 1240, 1230, and 1040 cm^{-1}; UV (EtOH) λ_{max} 253 nm (log ε 3.81); PMR ($CDCl_3$) δ 0.85, 1.12, 1.23 (each 3H, s; *t*-Me), 0.90, 1.06 (each 6H, s; 2×*t*-Me), 1.99, 2.06 (each 3H, s; -OAc), 3.64 (3H, s; $-CO_2Me$), 4.76 (1H, d, *J*=11 Hz; $C_{(3\alpha)}$-H), 5.18 (1H, ddd, *J*=11, *J*=11 and *J*=4 Hz; $C_{(2\beta)}$-H), and the absence of olefinic proton; mol wt *m/e* 584.3682. Calcd for $C_{35}H_{52}O_7$: *m/e* 584.3709. MS *m/e* 584 (M^+), 524, 482, 464, 405, and 188 (base peak).

*Oxidation of Methyl 2α,3β-Diacetoxy-13α*H*-olean-18-en-28-oate (7) with Selenium Dioxide.* A mixture of **7** (32.5 mg) and selenium dioxide (15.2 mg) in acetic acid (3 ml) was heated under reflux for 6 h. Usual work-up gave a residue (33 mg), which was subjected to purification by preparative TLC, developed with benzene-acetone (50:3), to give methyl 2α,3β-diacetoxyoleana-12,18-dien-28-oate (**11**; 21 mg), mp 245—247 °C (crystallized from ethanol); $[\alpha]_D$ +64° (*c* 1.0, EtOH); IR (KBr) 1733, 1720 (sh), 1630, 1250, 1225, and 1040 cm^{-1}; UV (EtOH) λ_{max} 235 nm (log ε 3.9); PMR ($CDCl_3$) δ 0.90, 1.11 (each 3H, s; *t*-Me), 0.91 (6H, s; 2×*t*-Me), 1.00 (9H, s; 3×*t*-Me), 1.99, 2.05 (each 3H, s; -OAc), 3.61 (3H, s; $-CO_2Me$), 4.76 (1H, d, *J*=11 Hz; $C_{(2\alpha)}$-H), 5.16 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\beta)}$-H), 5.47 (1H, s; $C_{(19)}$-H), and 5.57 (1H, t-like; $C_{(12)}$-H); mol wt *m/e* 568.3708. Calcd for $C_{35}H_{52}O_6$: *m/e* 568.3760; MS *m/e* 568 (M^+), 509, 448, 433, 389, 367, 260, 247, and 201 (base peak).

Isomerization of Methyl 2α,3β-Diacetoxyoleana-12,18-dien-28-oate (11) into Methyl 2α,3β-Diacetoxyoleana-11,13-dien-28-oate (12). The diene (**11**; 21 mg) was dissolved in chloroform (3 ml) and dry hydrogen chloride was passed through the solution for 1.5 h. Usual treatment gave a residue (16 mg), which

* PMR spectra were measured using a Hitachi R-20 (60 MHz) spectrometer unless otherwise stated.

was shown to be completely isomerized into methyl 2α,3β-diacetoxyoleana-11,13-dien-28-oate (**12**) by PMR examination. The diene (**12**): mp 186.5—188.5 °C (crystallized from ethanol); $[\alpha]_D$ −128° (*c* 0.125, EtOH); IR (KBr) 1730, 1725 (sh), 1700 (sh), 1630, 1245, 1230 (sh), 1042, and 1030 cm^{-1}; UV (EtOH) λ_{max} 243.5 (log ε 4.31), 251.5 (4.36), and 260.5 nm (4.16); PMR ($CDCl_3$) δ 0.80 (6H, s; 2×*t*-Me), 0.91 (12H, s; 4×*t*-Me), 1.08 (3H, s; *t*-Me), 2.00, 2.06 (each 3H, s; -OAc), 3.66 (3H, s; $-CO_2Me$), 4.76 (1H, d, *J*=11 Hz; $C_{(3\alpha)}$-H), 5.15 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\beta)}$-H), 5.58 (1H, d, *J*=11 Hz; $C_{(12)}$-H), and 6.48 (1H, dd, *J*=11 and *J*=2 Hz; $C_{(11)}$-H); mol wt *m/e* 568.3698. Calcd for $C_{35}H_{52}O_6$: *m/e* 568.3760; MS *m/e* 568 (M^+), 509, 448, 433, 389, 367, and 187 (base peak). This diene was found to be identical with the diene (**12**)[6] prepared from methyl 2,3-di-*O*-acetylarjunate (**13**)[4,6] according to the known procedures.[6]

*Oxidation of Methyl 2,3-Di-O-acetylarjunate (**13**) with Hydrogen Peroxide.* A solution of methyl 2,3-di-*O*-acetylarjunate (**13**; 102 mg)[4,6] in acetic acid (8 ml) was treated dropwise at 70—75 °C with a mixture of acetic acid (1 ml) and hydrogen peroxide (35 %, 1 ml) according to the Barton procedure.[9] Usual treatment gave a residue (*ca.* 100 mg), which was purified by column chromatography on silica gel (15 g). Elution was carried out with the following solvents: fr. 1, benzene-acetone (50:1, 30 ml); fr. 2, benzene-acetone (100:3, 30 ml); frs. 3 and 4, benzene-acetone (25:1, each 15 ml), frs. 5—10 (each 10 ml), frs. 11 and 12 (each 15 ml). Fractions 6—8, on evaporation of the solvents, gave a residue (*ca.* 70 mg), which was crystallized from ether to give methyl 2α,3β-diacetoxy-19α-hydroxy-12-oxooleanan-28-oate (**18**; 32 mg) as white needles, mp 272—273 °C; $[\alpha]_D$ −25° (*c* 1.11, $CHCl_3$); IR (Nujol) 3500, 1750, 1730, 1720, 1690, 1260, 1230, and 1045 cm^{-1}; PMR ($CDCl_3$) δ 0.91, 0.98, 1.01 (each 6H, s; 2×*t*-Me), 1.15 (3H, s; *t*-Me), 1.99, 2.05 (each 3H, s; -OAc), 2.90 (1H, dd, *J*=7 and *J*=3.5 Hz; $C_{(18\alpha)}$-H), 3.10 (1H, d, *J*=7 Hz; $C_{(13\alpha)}$-H), 3.70 (3H, s; $-CO_2Me$), 4.55 [1H, t-like; $C_{(19\beta)}$-H; on addition of D_2O. this signal changes into a doublet (*J*=3.5 Hz)], 4.75 (1H, d, *J*=11 Hz; $C_{(3\alpha)}$-H), and 5.10 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\alpha)}$-H); MS *m/e* 602 (M^+), 584, 569, 543, 525, 524, 482, 465, 464, and 276 (base peak); Found: C, 68.59; H, 9.09%. Calcd for $C_{35}H_{54}O_9 \cdot 1/2\ H_2O$: C, 68.71; H, 9.06%.

*Treatment of Methyl 2α,3β-Diacetoxy-19α-hydroxy-12-oxooleanan-28-oate (**18**) with Alkali.* A mixture of **18** (28 mg) in methanol (5 ml) containing potassium hydroxide (400 mg) was heated under reflux for 2 h. After usual work-up, a residue was acetylated with acetic anhydride in pyridine and crystallized from ether to afford white needles, which were chromatographed on silica gel (5 g), eluting with the following solvents: fr. 1, benzene-acetone (50:1, 10 ml); fr. 2, benzene-acetone (100:3, 10 ml); and frs. 3—11, benzene-acetone (25:1, each 5 ml). Fractions 6—8, on evaporation of the solvents, afforded crystals, which were identical with the starting material in respect to IR, PMR, and TLC.

*Wolff-Kishner Reduction of Methyl 2α,3β-Diacetoxy-19α-hydroxy-12-oxooleanan-28-oate (**18**) Followed by Methylation and Acetylation. i) By the Barton Procedure.* To a boiling mixture of sodium (106 mg) in diethylene glycol (5 ml) and anhydrous hydrazine (1 ml), methyl 2α,3β-diacetoxy-19α-hydroxy-12-oxo-oleanan-28-oate (**18**; 100 mg) was added. The reaction mixture was treated according to the Barton procedure[2] to afford a residue, which was methylated with diazomethane and then acetylated with acetic anhydride in pyridine. The product, dissolved in benzene, was passed through a column of silica gel (15 g) and eluted with the following solvents: fr. 1, benzene-acetone (100:1, 30 ml); frs. 2 and 3, benzene-acetone (50:1, each 15 ml); frs. 4—15, benzene-acetone (100:3, each 10 ml). A 13β*H*-alcohol (**19**; 33 mg) was obtained from fractions 7 and 8, as amorphous solid, IR (Nujol) 3500, 1740, 1240, and 1230 cm^{-1}; PMR ($CDCl_3$) δ 0.88 (12H, s; 4×*t*-Me), 0.96 (6H, s; 2×*t*-Me), 1.17 (3H, s; *t*-Me), 1.97, 2.03 (each 3H, s; -OAc), 3.37 (1H, d, *J*=2 Hz; $C_{(19\beta)}$-H), 3.70 (3H, s; $-CO_2Me$), 4.75 (1H, d, *J*=11 Hz; $C_{(3\alpha)}$-H), and 5.13 (1H, ddd, *J*=11, *J*=11, *J*=4 Hz; $C_{(2\beta)}$-H); MS *m/e* 570 (M^+-H_2O), 528, 510, 495, 486, 468, 450, 435, and 189 (base peak). Fractions 9—12 gave a 13α*H*-alcohol (**20**; 26 mg) as amorphous solid, IR (Nujol) 3500, 1740, 1725 (sh), 1245, and 1225 cm^{-1}; PMR ($CDCl_3$) δ 0.90 (9H, s; 3×*t*-Me), 0.97, 1.03, 1.09, 1.25 (each 3H, s; *t*-Me), 1.98, 2.04 (each 3H, s; -OAc), 3.40 (1H, d, *J*=5 Hz; $C_{(19\beta)}$-H), 3.69 (3H, s; $-CO_2Me$), 4.75 (1H, d, *J*=11 Hz; $C_{(3\alpha)}$-H), and 5.15 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\beta)}$-H); MS *m/e* 570 (M^+-H_2O), 528, 510, 495, 486, 468, 450, 435, and 189 (base peak). *ii) By the Huang-Minlon Procedure.* A mixture of **18** (47 mg), potassium hydroxide (500 mg), anhydrous hydrazine (0.6 ml), and diethylene glycol (4.7 ml) was heated under reflux for 1.5 h and excess hydrazine and water were distilled off. Then reflux was continued at 220 °C for 7 h. After usual work-up, acetylation and methylation were followed. The reaction mixture was subjected to column chromatographic separation on silica gel (5 g), eluting with benzene-acetone (100:1, 10 ml; fr. 1); benzene-acetone (50:1, 10 ml; fr. 2), and then benzene-acetone (100:3, each 5 ml; frs. 3—12). Fractions 5 and 6 gave the 13β*H*-alcohol (**19**; 21.4 mg) and fractions 7—9 the 13α*H*-alcohol (**20**; 14.5 mg).

*Oxidation of Methyl 2α,3β-Diacetoxy-19α-hydroxyoleanan-28-oate (**19**) with Jones Reagent.* A solution of **19** (19 mg) in acetone (1.5 ml) was cooled at 0 °C and Jones reagent (0.2 ml) was added with stirring. After usual work-up, the reaction product was dissolved in benzene and passed through a column of silica gel (5 g) and eluted with the following solvents: fr. 1, benzene-acetone (200 : 1, 20 ml); frs. 2—17, benzene-acetone (50 : 1, each 2.5 ml). Fractions 10 and 11, on evaporation of the solvents, gave methyl 2α,3β-diacetoxy-19-oxooleanan-28-oate (**21**; 9.6 mg) as amorphous solid, IR (KBr) 1730, 1720 (sh), 1695 (sh), 1245, and 1230 cm^{-1}; CD (*c* 0.0024, EtOH) $\Delta\varepsilon_{302}$ +1.60; PMR (100 MHz**, $CDCl_3$) δ 0.84, 0.94, 0.98, 1.01, 1.12 (each 3H, s; *t*-Me), 0.86 (6H, s; 2×*t*-Me), 1.94, 2.01 (each 3H, s; -OAc), 3.15 (1H, d, $J_{13\beta,18\beta}$=4 Hz; $C_{(18\beta)}$-H), 3.70 (3H, s; $-CO_2Me$), 4.70 (1H, d, *J*=11 Hz; $C_{(3\alpha)}$-H), and 5.06 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\beta)}$-H); mol wt *m/e* 586.3899. Calcd for $C_{35}H_{54}O_7$: *m/e* 586.3867; MS *m/e* 586 (M^+), 527, 526, 484, 467, 466, 451, 425, 407, and 205 (base peak).

*Oxidation of Methyl 2α,3β-Diacetoxy-19α-hydroxy-13α*H*-oleanan-28-oate (**20**) with Jones Reagent.* A solution of **20** (14 mg) in acetone (1.5 ml) was oxidized with Jones reagent (0.2 ml) as the same as above. Usual treatment and purification gave methyl 2α,3β-diacetoxy-19-oxo-13α*H*-oleanan-28-oate (**22**), mp 204—209 °C; IR (KBr) 1730, 1710 (sh), 1690, 1240, and 1225 cm^{-1}; CD (*c* 0.0025, EtOH) $\Delta\varepsilon_{302}$ −0.11; PMR (100 MHz, $CDCl_3$) δ 0.86, 0.88, 1.08, 1.14 (each 3H, s; *t*-Me), 1.02 (9H, s; 3×*t*-Me), 1.95, 2.00 (each 3H, s; -OAc), 3.28 (1H, d, $J_{13\alpha,18\beta}$=12 Hz, $C_{(18\beta)}$-H), 3.64 (3H, s; $-CO_2Me$), 4.69 (1H, d, *J*=11 Hz; $C_{(3\alpha)}$-H), and 5.10 (1H, ddd, *J*=11, *J*=11, and *J*=4 Hz; $C_{(2\beta)}$-H); MW *m/e* 586.3879. Calcd for $C_{35}H_{54}O_7$: *m/e* 586.3867; MS *m/e* 586 (M^+), 527, 526, 484, 467, 466, 451, 425, 407, and 205 (base peak).

** PMR (100 MHz) spectra were measured with a JEOL 4H-100 spectrometer.

*Dehydration of Methyl 2α,3β-Diacetoxy-19α-hydroxyoleanan-28-oate (**19**).* A solution of **19** (21 mg) in pyridine (0.7 ml) and phosphoryl chloride (0.1 ml) was heated under reflux for 4 h and then treated as usual to afford a residue (19 mg). The residue was dissolved in benzene and passed through a column of silica gel (3 g) and eluted with benzene (6 ml; fr. 1), benzene-acetone (100 : 1, 6 ml; fr. 2), and with benzene–acetone (50 : 1, each 6 ml; frs. 3—9) successively. The fractions 5 and 6 were combined and further subjected to purification by preparative TLC on Kieselgel PF_{254} developed with benzene–acetone (20 : 1) to give methyl 2α,3β-diacetoxy-olean-18-en-28-oate (**10**; 6 mg), mp 232—233 °C (crystallized from ethanol), $[\alpha]_{450}$ −38° (*c* 0.13, EtOH); IR (KBr) 1740 (br), 1630, 1245, and 1230 cm^{-1}; PMR ($CDCl_3$) δ 0.78, 1.02 (each 3H, s; *t*-Me), 0.90 (6H, s; 2×*t*-Me), 0.98 (9H, s; 3×*t*-Me), 1.98, 2.04 (each 3H, s; -OAc), 3.66 (3H, s; $-CO_2Me$), 4.75 (1H, d, J=11 Hz; $C_{(3\alpha)}$-H), 5.10 (1H, s; $C_{(19)}$-H), and 5.15 (1H, ddd, J=11, J=11, and J=4 Hz; $C_{(2\beta)}$-H); mol wt *m/e* 570.3912. Calcd for $C_{35}H_{54}O_6$: *m/e* 570.3917; MS *m/e* 570 (M^+), 555, 538, 511, 510, 495, 468, 451, 450, 436, 435, 409, 407, 391, 249, 203, and 189 (base peak). This ester (**10**) gave the same R_f value on TLC as that of **7**, but the IR and PMR spectra were distinctly different to each other.

*Dehydration of Methyl 2α,3β-Diacetoxy-19α-hydroxy-13αH-oleanan-28-oate (**20**).* A solution of **20** (12 mg) in pyridine (0.7 ml) and phosphoryl chloride (0.1 ml) was refluxed for 1 h. After usual treatment, purification by preparative TLC was carried out as before. Methyl 2α,3β-diacetoxyolean-13(18)-en-28-oate (**23**) was obtained, mp 202—203 °C (crystallized from ether); IR (KBr) 1720, 1700 (sh), 1620, 1240, 1230, and 1030 cm^{-1}; PMR ($CDCl_3$) δ 0.74, 1.02, 1.15 (each 3H, s; *t*-Me), 0.90 (12H, s; 4×*t*-Me), 1.98, 2.04 (each 3H, s; -OAc), 3.65 (3H, s; $-CO_2Me$), 4.75 (1H, d, J=11 Hz; $C_{(3\alpha)}$-H), 5.15 (1H, ddd, J=11, J=11, and J=4 Hz; $C_{(2\beta)}$-H), and the absence of olefinic proton; mol wt *m/e* 570.3916. Calcd for $C_{35}H_{54}O_6$: *m/e* 570.3917; MS *m/e* 570 (M^+), 555, 538, 511, 510, 495, 468, 451, 450, 436, 435, 407, 391, 249, 203, and 189 (base peak).

*Catalytic Hydrogenation of Methyl 2α,3β-Diacetoxyoleana-11,13-dien-28-oate (**12**).* The 11,13-diene (**12**; 23 mg) in acetic acid was hydrogenated under an atmospheric pressure in the presence of platinum oxide (5 mg) for 20 h and worked up as usual to give a residue. The residue was subjected to preparative TLC on Kieselgel PF_{254} developed with benzene–acetone (50 : 3). The crude product (11 mg) was crystallized from ether to afford methyl 2α,3β-diacetoxyolean-13(18)-en-28-oate (**23**), mp 205.5—206.5 °C; $[\alpha]_{450}$ −66° (*c* 0.076, EtOH); mol wt *m/e* 570.3827. Calcd for $C_{35}H_{54}O_6$: *m/e* 570.3917. The IR, PMR, and MS spectra and TLC were completely identical with those of the specimen obtained by the dehydration of **20**.

*Forced Wolff-Kishner Reduction of Methyl 2α,3β-Diacetoxy-19-oxoolean-13(18)-en-28-oate (**8**) Followed by Acetylation and Methylation.* The α,β-unsaturated keto ester (**8**; 38 mg) was subjected to the forced Wolff-Kishner reduction (sodium 38 mg, diethylene glycol 1.5 ml, and anhydrous hydrazine 0.4 ml) under the same conditions as before. After usual work-up, a residue was acetylated with acetic anhydride in pyridine. The crude acetate was purified by column chromatography on silica gel (5 g), using the following solvents as eluent (each 10 ml): fr. 1, benzene–acetone (100 : 1); fr. 2, benzene–acetone (50 : 1); frs. 3 and 4, benzene–acetone (100 : 3); frs. 5—8, benzene-acetone (25 : 1); fr. 9, benzene–acetone (20 : 1). Fractions 5 and 6 were combined and methylated with diazomethane in ether. The reaction product was purified by preparative TLC on Kieselgel PF_{254} developed with benzene–acetone (20 : 1) to afford methyl 2α,3β-diacetoxy-13α*H*-olean-18-en-28-oate (**7**), which was shown to be identical (IR, PMR, MS, and TLC) with a specimen obtained by the forced Wolff-Kishner reduction of **5**.

Formation of Bis(methylthio)(methylsulfinyl)methane in the Reaction of Methyl (Methylthio)methyl Sulfoxide with Sodium Hydride

Katsuyuki OGURA, Nobuko KATOH, and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Nishi-Ohnuma Sagamihara, Kanagawa 229

(Received October 19, 1977)

Treatment of methyl (methylthio)methyl sulfoxide (**1**) with sodium hydride gave bis(methylthio)(methylsulfinyl)methane (**3**) which might be formed by abnormal attack of the carbanion (**2**) of **1** on the sulfide linkage of **1**. The additon of butyl iodide to this system completely suppressed the formation of **3**, showing that **2** reacts faster with butyl iodide than with **1**. The mechanism to account for these phenomena is discussed.

Recently, new synthetic methods using methyl (methylthio)methyl sulfoxide (**1**) have been developed.[1-7] This compound can be converted into the carbanion (**2**) by the action of sodium hydride, potassium hydride, or butyllithium. In tetrahydrofuran (THF), treatment of **1** with either potassium hydride[6,9] or butyllithium[6,7,9] generates **2** instantaneously at from −70 °C to an ambient temperature. On the other hand, when sodium hydride is employed as a base, warming is necessary to form **2**.[2,3,8,10] Thus, alkylation of **1** with an alkyl halide and sodium hydride can be achieved by agitation of these compounds together in THF at an elevated temperature.[2,3,8] During the course of our investigation on the solvent-effect for the formation of **2** using sodium hydride, we have found the following interesting reaction of **1** with **2** to form bis(methylthio)-(methylsulfinyl)methane (**3**) and dimethyl sulfoxide.

A solution containing **1** (34.6 mmol) and sodium hydride (22.5 mmol) in hexamethylphosphoric triamide (HMPT; 10 ml) was stirred under cooling with ice-water for 2 h and at room temperature for 36.5 h. A usual work-up gave **3** as colorless crystals, mp 69—70 °C, in 45% yield. The structure of this product was confirmed by its IR and NMR spectra, the elemental analysis, and the independent synthesis achieved by the oxidation of tris(methylthio)methane with hydrogen peroxide and a catalytic amount of sodium tungstate. Even when one equivalent of sodium hydride was employed, the similar result was obtained. The formation of **3** was also observed in THF although the reaction went more slowly than in HMPT. Furthermore, it should be noted that the addition of butyl iodide to the solution containing **1** and sodium hydride in HMPT completely suppressed the formation of **3** and a butylated product, 1-(methylsulfinyl)-1-(methylthio)pentane (**4**) was produced instead.

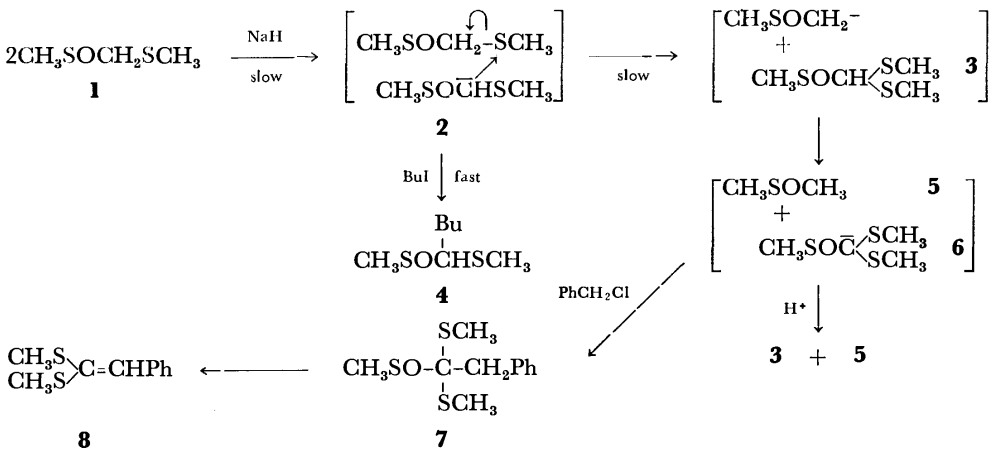
These facts may be reasonably explained by the mechanism depicted in Scheme 1. During the reaction of **1** with sodium hydride, the carbanion (**2**) coexists with the unreacted **1** because of the slow reaction of **1** with sodium hydride. Then, **2** attacks on the sulfide linkage of **1** as shown in Scheme 1, forming the carbanion of dimethyl sulfoxide (**5**) and **3** which are further converted into **5**[11] and the carbanion (**6**) of **3**, respectively, by a proton transfer. When butyl iodide is added to this system, the formed carbanion (**2**) reacts with the iodide faster than with **1** to afford the butylated product (**4**).

Existence of **6** at the final stage of the reaction might be supported by the fact that the addition of benzyl chloride, followed by stirring of the solution at from room temperature to 40 °C gave *β,β*-bis(methylthio)styrene (**8**) which was very likely formed by dehydrosulfenylation of the benzylated product (**7**) of the carbanion (**6**).

Since the alkylation of **1**, followed by the hydrolysis of the thioacetal *S*-oxide group provides a convenient synthetic route to aldehydes, we would like to emphasize that the necessary conditions for the alkylation of **1** by an alkyl halide–sodium hydride system is to stir a solution containing these reagents together at a temperature of *ca.* 50 °C.

Experimental

Formation of Bis(methylthio)(methylsulfinyl)methane (3) from Methyl (Methylthio)methyl Sulfoxide (1). To a solution



Scheme 1.

containing **1** (4.290 g, 34.6 mmol) in HMPT (10 ml), was added sodium hydride (65% oil-dispersion; 830 mg, 22.5 mmol), and the mixture was stirred under cooling with ice-water for 2 h and at room temperature for 36.5 h. After the addition of dichloromethane (150 ml) and washing with water (100 ml), the organic layer was dried over anhydrous sodium sulfate and evaporated *in vacuo*. The residue was separated by twofold column-chromatography on silica gel (eluted with dichloromethane) to afford **3** (1.337 g, 7.86 mmol; 45%) as colorless crystals. An analytical sample was obtained by recrystallization from diethyl ether–hexane: Mp 69—70 °C; IR (KBr) 1032 cm^{-1}; NMR ($CDCl_3$): δ=2.36 (6H, s), 2.72 (3H, s), and 4.53 (1H, s). Found: C, 28.11: H, 5.90%. Calcd for $C_4H_{10}OS_3$: C, 28.21; H, 5.91%.

This compound is thermally unstable even at room temperature and decomposes completely within 1 h at 50 °C.

Oxidation of Tris(methylthio)methane into ***3***. To a solution of tris(methylthio)methane(1.505 g, 9.77 mmol) in methanol (10 ml), were added sodium tungstate dihydrate (10 mg) and 30% aqueous solution (1.1 ml, 9.7 mmol) of hydrogen peroxide under cooling with ice-water. Then, the mixture was stirred under cooling with ice-water for 1 h, and water (25 ml) was added. After the extraction with four 30 ml-portions of dichloromethane, the organic layer was dried over anhydrous sodium sulfate and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (eluted with dichloromethane–ethyl acetate) to yield 927 mg (56%) of colorless crystals which were identified with **3** by the comparison of their IR and NMR spectra with those of the product obtained by the reaction of **1** with sodium hydride.

Reaction of ***1*** *with Sodium Hydride in the Presence of Butyl Iodide*. To a solution of **1** (1.385 g, 11.69 mmol) in HMPT (2 ml) were added sodium hydride (65% oil-dispersion; 538 mg, 14.6 mmol) and butyl iodide (2.888 g, 15.70 mmol). The mixture was stirred under cooling with ice-water for 2 h, at room temperature for 25 h, and at 45 °C for 24 h. After the addition of dichloromethane (30 ml), the deposited solid was filtered off and the filtrate was evaporated *in vacuo*. The residue was separated by column-chromatography on silica gel (eluted with dichloromethane and ethyl acetate) to afford 1.327 g (7.37 mmol: 66%) of **4** which was identified with the product previously reported[8] by the comparison of their NMR spectra.

*Detection of DMSO (****5****) in the Reaction of* ***2*** *with* ***1***. To a suspension of potassium hydride (24% oil-dispersion; 2.166 g, 13.0 mmol) in THF (10 ml) was added **1** (3.026 g, 24.44 mmol) under cooling with ice-water for 30 min, at room temperature for 16.5 h, and at 40 °C for 9 h. After the addition of dichloromethane (100 ml) and water (1 ml), stirring at room temperature for 5 min, and the addition of anhydrous sodium sulfate, the insoluble matter was filtered off and the filtrate was evaporated *in vacuo*. The residue was separated by column-chromatography on Florisil (eluted with dichloromethane, ethyl acetate, and methanol) to give 203 mg (10%) of **3** and 1.275 g of a colorless oil which was shown by an NMR analysis to consist of **1** (959 mg) and **5** (316 mg; 33%).

Reaction of ***6*** *with Benzyl Chloride*. A mixture containing **1** (5.159 g, 41.60 mmol) and sodium hydride (65% oil-dispersion; 860 mg, 23.3 mmol) in HMPT (15 ml) was stirred under cooling with ice-water and at room temperature for 49.5 h. After the addition of benzyl chloride (2.818 g, 22.28 mmol), the mixture was further stirred at room temperature for 1 week and at 40 °C for 4 h. Then, water (50 ml) and dichloromethane (100 ml) were added and the solution was shaken. After the organic layer was separated, the aqueous layer was extracted with two 30 ml-portions of dichloromethane. The organic layers were combined, dried over anhydrous sodium sulfate, and evaporated *in vacuo*. The residue was column-chromatographed on silica gel (eluted with hexane–benzene) to give a pale yellow oil which was shown by an NMR analysis(using piperonal as an internal standard) to contain 1.149 g (28%) of β,β-bis(methylthio) styrene (**8**). A pure sample of **8** could be obtained by distillation under reduced pressure and it was identified by comparison of its IR and NMR spectra with those of an authentic sample which was given by reduction of β-(methylsulfinyl)-β-(methylthio)styrene[12] as described in the following.

Reduction of β-(Methylsulfinyl)-β-(methylthio)styrene with Titanium Trichloride. To a solution containing β-(methylsulfinyl)-β-(methylthio)styrene[12] (7.106 g) in 30 ml of dichloromethane and 60 ml of hexane, was added 20% aqueous solution (30 ml) of titanium trichloride and the resulting mixture was stirred at room temperature for 1 h. After the addition of benzene (100 ml), the organic layer was separated, washed with water, dried over anhydrous potassium carbonate, and evaporated *in vacuo*. The residue was column-chromatographed on Florisil to give 1.595 g of a pale yellow oil, whose structure was assigned as **8** by its physical data and an elemental analysis: Bp 104—105 °C/0.3 Torr (lit,[13] bp 94—95 °C/0.25 Torr); NMR ($CDCl_3$): δ=2.27 (3H, s), 2.32 (3H, s), 6.71 (1H, s), and 7.10—7.60 (5H, m); MS(70 eV): *m/e* (rel. intensity) 196 (66), 149 (31), and 134 (100). Found: C, 61.02; H, 6.10; S, 32.56%. Calcd for $C_{10}H_{12}S_2$: C, 61.17; H, 6.16; S, 32.66%.

Substrate-Nucleophile Association in the Finkelstein Reaction System in Dipolar Aprotic Solvent. Formation of Complex between Substituted Chloromethanes and Halide Ion in Acetonitrile*

Jun-ichi HAYAMI, Tohru KOYANAGI, Nobuhisa HIHARA, and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received January 14, 1977)

Substrate-nucleophile association was found between substituted chloromethanes ($ArXCH_2Cl$: X=NONE, S, SO, SO_2, and CO) and halide ion (Cl^-, Br^-, and I^-) in dipolar aprotic solvent. The equilibrium constant (K), limiting shift (Δ_c), the enthalpy of formation ($\Delta H°$), and the entropy of formation ($\Delta S°$), for complexing were determined by NMR measurement. The measurement of spin-lattice relaxation time (T_1) gave an information on the conformation of this complex. Halide ion seems to locate closest to α-methylene protons at the site of potential S_N2 reaction.

In the course of studies on the symmetrical Finkelstein reaction in a dipolar aprotic solvent,[1,2] the present authors found the specific interaction between a strong nucleophile and a substrate (substituted chloromethanes).

$$ArXCH_2Cl + Y^- \overset{K}{\rightleftharpoons} ArXCH_2Cl \cdot Y^- \quad (1)$$

Ar = Phenyl and substituted phenyl

X = NONE, S, SO, SO_2, and CO

Y = Cl, Br, and I

Y^- was used in the form of tetraalkylammonium salt (R_4NY; R=ethyl or butyl).

The interaction was observed as a low field shift of the absorption in a PMR spectrum of substrate, on the addition of nucleophilic anion to the solution of the substrate in dipolar aprotic solvent. Martin, Hayami and Lemieux reported the formation of an anion-substrate complex for β-glycopyranosyl derivatives.[3] Green and Martin extended the study to trihalomethanes and other substrates.[4] They attributed such an interaction mainly to hydrogen bonding. Since then, such hydrogen bonding equilibria have been studied extensively between various nucleophilic anions and hydrogen donors. Typical examples were found in the interaction of carboxylic acids[5] or phenols[6] with various anions.

The most important feature of the present study lies in the fact that the complex formation is operative under the same conditions where the symmetrical Finkelstein reaction with radioactive chloride ion actually proceeds.

$$ArXCH_2Cl + *Cl \overset{k}{\longrightarrow} ArXCH_2{*}Cl + Cl^- \quad (2)$$

In the present study, thermodynamic aspects of the complex formation are described. Measurements of the proton spin-lattice relaxation time were made to indicate the partial freezing of the intramolecular rotation about the potential S_N2 reaction center.

Experimental

Materials. Acetonitrile was distilled five times from P_2O_5 and once from K_2CO_3 initially, and finally distilled with no reagent added. The dry solvent was stored in a dry box.

Substituted chloromethanes[7] were synthesized according to the standard procedure.

Tetraalkylammonium Salts: Tetraalkylammonium halides were prepared by the reaction of the corresponding alkyl halides and trialkyl amines in acetonitrile.[3] Tetraethylammonium perchlorate was prepared by the reaction of tetraethylammonium bromide and perchloric acid. Immediately before each measurement, all the salts were dried under reduced pressure over P_2O_5 at the refluxing temperature of toluene (or benzene for perchlorate) for 2 h.

Proton Magnetic Shift Measurement. An aliquot of the stock solution of substituted chloromethane (0.1 mmol) and TMS in acetonitrile was placed in volumetric tubes (1 ml) containing ammonium salts (0.2—1.2 mmol). The solutions were made up to the mark, and then were transferred to the NMR sample tubes. All the samples were prepared inside a dry box. The PMR spectra were measured in an internal lock mode for the solvent acetonitrile, with a JEOL PS-100 spectrometer operating at 100 MHz. The line positions were measured to 0.1 Hz by reading the frequencies at each resonance of substrate and the internal standard, TMS, with a built-in frequency counter at least four times and averaging the results.

Analysis of PMR Shift vs. Concentration. Equilibrium constant, K, and limiting shift of the complex, Δ_c, were determined by means of Scott's modification of the Benesi-Hildebrand equation,[8,9] assuming only 1 : 1 complex of substrate and halide ion. In this treatment the degree of dissociation of ammonium salt was assumed to be constant in the concentration range of measurements.[10,11] Analysis was repeated until a self-consistent set of values was obtained. It was carried out automatically on the programmable calculator, Canon SX-110. The use of PMR measurement is an authorized method for the study of hydrogen bonding interaction, being essentially similar to that given by Martin and coworkers.[3]

Measurements of Spin-lattice Relaxation Time (T_1). Spin-lattice relaxation curves of protons were obtained on a JEOL PS-100 NMR spectrometer equipped with a pulse Fourier-transform unit (PFT-100) and a spectrum computer (EC-100), by application of 180°-t-90° pulse sequences at 100 MHz. The spin-lattice relaxation time (T_1) was deduced by the least-squares approximation of the observed value of $I_{(t)}$ to $I_0[1-2\exp(-t/T_1)]$, where $I_{(t)}$ is longitudinal magnetization at time t, and I_0 is the equilibrium magnetization.[12] Measurements were carried out with two samples for each series of substituted chloromethanes, the standard acetonitrile solution of the substrate (0.1 M), and a solution in which the appropriate amount of tetraethylammonium chloride

* S_N2 Reactions in Dipolar Aprotic Solvents. VI. Part of this work was presented before the 2nd IUPAC Conference on Physical Organic Chemistry (Nordwijkerhout, 1974), and was published in *Tetrahedron Lett.*, **1973**, 385.

was added to the standard solution.

Since the equilibration is very fast as compared with the $1/T_1$ of the protons in both the free and the complexed substrate, the observed $T_1(T_1^{obsd})$ in the present case can be expressed as the weighted means.[13]

$$1/T_1^{obsd} = f^c/T_1^c + f^\circ/T_1^\circ = f^c R_1^c + f^\circ R_1^\circ, \quad (3)$$

where f^c and f° denote the fractions, T_1^c and T_1°, the relaxation time, and R_1^c and R_1°, the rate of relaxation of complexed and uncomplexed species, respectively. Since f^c and f° can be calculated from the equilibrium constant (K), the values of R_1^c are easily deduced. The rotational correlation time (τ_c) can be calculated from R_1 by means of

$$R_1 = (3/2)\hbar^2\gamma_H^4\tau_c/r_{HH}^6, \quad (4)$$

where $\hbar$ is the Planck constant divided by 2π, γ_H is the gyromagnetic ratio of proton, and r_{HH} is the distance between neighboring protons.[14] The effect of complexing on the intramolecular rotation is sharply reflected on τ_c. τ_c^c and τ_c° denote the rotational correlation time of the complexed and the uncomplexed species, respectively.

Results and Discussion

On addition of tetraalkylammonium halide to the acetonitrile solution of substituted chloromethanes, the PMR absorption showed low field shift. The amount of shift of each proton was analyzed by the Scott modification of the Benesi-Hildebrand equation,[3] which gave a good linear relationship in each case. α-Methylene protons of (arylsulfinyl)chloromethanes, which appear as AB quartet in acetonitrile solution, exhibit a different response on complexing; the proton in a higher field showing apparently a larger shift (Fig. 1). The difference in the response was also substantiated in the measurement of spin-lattice relaxation time (T_1). On addition of chloride ion, the rate of relaxation became higher at the proton lying in the higher field.

Effect of the Ammonium Salts. The effect of tetraalkylammonium salts on the formation of the complex was investigated by using (*p*-chlorophenylsulfonyl)chloromethane as substrate, which showed a low reactivity

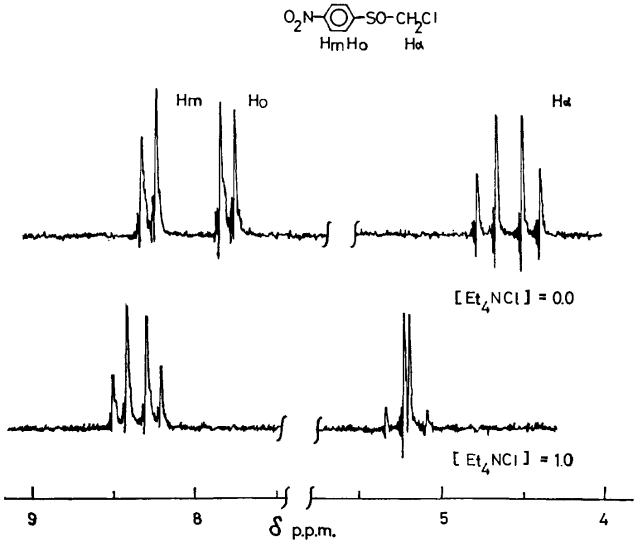

Fig. 1. Change of pmr spectra of (*p*-nitrophenylsulfinyl)chloromethane in acetonitrile after addition of TEACl.

in S_N2 reactions and gave no detectable amount of the substitution product with various halide ions under the conditions of the PMR measurement. The results are given in Table 1.

Since tetraethylammonium perchlorate showed essentially no ability in the formation of complex, and the other salts studied gave rise to significant changes in the chemical shift of the substrate, it is understood that the cation portion of the ammonium salts plays no essential role in the change of PMR shift, and that the anion portion eventually controls these equilibria.

The most electronegative chloride ion forms a more stable complex than other halide ions (Br^- or I^-) do. The results suggest that the interaction is similar to that studied by Martin and coworkers,[3,4] and that it might be of hydrogen bonding. The present results also suggest that such a phenomenon is general for substances with "acidic" proton(s) as were the cases with certain β-glycopyranosyl derivatives and with trihalomethanes.

Tetraethylammonium bromide and tetrabutylammonium bromide differ in the formation constant of the complex (K), although these salts have bromide ion in common. The difference can be ascribed to the difference in the ion pair dissociation of the salt in the organic solution.[15] Tetrabutylammonium iodide is apparently a more effective hydrogen bond acceptor than expected from the basicity of iodide ion. This might also be ascribed to the ion pairing phenomena of the ammonium iodide.[15] However, lack of information on the behavior of the ammonium salts in high concentrations allows no further discussion.

Effect of the Solvent. The substituted chloromethanes form a complex with the halide ion, not only in acetonitrile but also in other dipolar aprotic solvents (DMSO or DMF). However, addition of a protic solvent (methanol) to the solution in acetonitrile retards the substrate-anion complex formation (Table 2). This can be explained in terms of the competitive hydrogen bonding between a protic solvent and the halide ion.[16] Methanol exhibits a strong tendency to undergo hydrogen bonding association with chloride ion.[17]

PMR Shift. Equilibrium constant (K) and the limiting shift of the complex (Δ_c) for *p*-nitrophenyl derivatives of substituted chloromethanes, with tetraethylammonium chloride as hydrogen bond acceptor,[18]

are summarized in Table 3. As the substituent becomes more electron-withdrawing, the association seems to prevail. This is also in line with the view that the principal cause of this interaction should be hydrogen bonding to the α-methylene protons.[19]

The changes of chemical shift can be attributed mainly to the effect of electrostatic field originating at halide ion. The electrostatic field at the hydrogen atom is a function of the anion–hydrogen distance, and the limiting shift (Δ_c) is a function of distance and the angle. This can be seen from the simple approximation in terms of Buckingham's equation for the electrostatic field produced by the point charge:[20]

$$\Delta_c = -A(1/r_{HX}^2)\cos\theta - B(1/r_{HX}^4), \quad (7)$$

where r_{HX} is the distance from the anion center to the hydrogen nucleus, and θ is the angle between the C–H and H–anion vector.

Thus, the location of the halide ion can be inferred from the value of Δ_c. In each compound the absolute values of Δ_c decrease in the order α-$CH_2 \gg$ *ortho* > *meta*, suggesting that the chloride ion is located in a close neighborhood of α-methylene protons.

Linear Free Energy Relationship. For equilibrium constant of the complex formation (K), a linear Hammett relationship holds in every series of compounds, the positive ρ values being obtained. The results are given in Table 3. Positive ρ values indicate that substituted chloromethanes act as a hydrogen bond donor. Electron-withdrawing substituents enhance the acidity and the donor capacity of a proton.

Arrhenius Parameters for the Formation of Complex. Equilibrium constants were determined at temperatures 0—30 °C. Arrhenius parameters of formation for the anion-substrate complex are given for p-nitrophenyl derivatives as the representative in Table 4. Both the enthalpy of formation ($\Delta H°$) and the entropy of formation ($\Delta S°$) give negative values, which are in a reasonable range for the hydrogen bonding equilibria.[17,19] Negative values of $\Delta H°$ indicate that a stabilization can be attained to some extent by complex formation. The order of stabilization ($-\Delta H°$), [$-\Delta H_X^\circ$ for $ArXCH_2Cl$: $-\Delta H_{SO_2}^\circ < -\Delta H_{SO_2}^\circ < -\Delta H_S^\circ < -\Delta H_{NONE}^\circ < -\Delta H_{CO}^\circ$] is not in agreement with the order of the magnitude of K. It is in contrast to the fact that in most hydrogen bonding equilibria there is a coincidence between the order of magnitude of K and of $-\Delta H°$.[21] Negative values of $\Delta S°$ are found as is often the case with a bimolecular association. In the present case, the stabilization of the complex is counterbalanced by the entropy loss, giving rise to a K smaller than unity or close to unity. As will be suggested later from the study of proton relaxation time, it seems that the freezing of intramolecular motion plays an important role in decreasing $\Delta S°$.

Effect of the Complex Formation on Proton Spin-lattice Relaxation Time (T_1). Recently, T_1 measurements have been applied to the investigation of interactions between or within organic molecules.[22,23] The T_1 value is very sensitive to the change of environmental factors. In the present case T_1 gives unique indication of the interaction between the anionic nucleophile and the substrate.

Each proton of substituted chloromethanes shows an appreciable increase in relaxation rate ($1/T_1 = R_1$) on addition of the nucleophilic anion (Cl^-). Perchlorate ion gives no significant effect on T_1, reflecting its poor ability as a hydrogen bond acceptor (Table 5). This suggests that the influence of the increasing viscosity of the acetonitrile solution caused by the addition of ammonium salt is not detrimental under the present experimental conditions. It has also been established that the chlorine atom (from tetraethylammonium chloride), with its small gyromagnetic moment, can give no noticeable contribution to the nuclear magnetic relaxation.[25,26] Thus, one possible mechanism remains operative in altering T_1 on complexing. That is the change of the rotational correlation time (τ_c), caused by the retardation of the intramolecular rota-

tion in the complexed substrate.[27)]

For the relaxation of the α-methylene protons of substituted chloromethanes, only a single H–H distance corresponding to geminal protons should be considered, since aromatic protons are situated in too remote a position to contribute significantly to the relaxation of α-methylene protons (the interaction contributing to the spin-lattice relaxation of protons diminishes rapidly with increase in the interproton distance, as expressed by Eq. 4). The postulate is verified by the deuteruim labelling experiment. Substitution of one of the methylene protons with deuterium causes a striking increase in T_1.[26)] Similarly, for relaxation of the protons on benzene ring (*para* substituted), only a single H–H distance between the nearest neighbor, vicinal protons, needs to be considered.

Consequently, as a first approximation, T_1 can be correlated with rotational correlation time (τ_c), as expressed by Eq. 4, where 1.78 Å is taken to be the quantity r_{HH} for α-methylene protons and 2.49 Å for vicinal protons on benzene ring. Variations in the proton spin-lattice relaxation rate ($R_1=1/T_1$) and τ_c of α-methylene proton and meta proton on complexing are shown for substituted chloromethanes having a p-nitro group on the phenyl ring in Table 5. The postulate seems to be reasonable, since the τ_c^c value calculated is shoter at a more mobile α-methylene group than at a less mobile aromatic ring.

Change of T_1 (or τ_c) furnishes additional evidence that nucleophilic chloride ion interacts with the chloromethanes. The substrates studied can be classified into two groups, one group of compounds (X=S, SO, SO_2) which show little change in $\tau_c(meta)$ but a significant change in $\tau_c(CH_2)$, and the other (X=NONE, CO) in which both the ring proton and the α-methylene proton show significant change in the rate of relaxation. Such tendency is in line with that of the enthalpy and entropy of the formation of complex and with the temperature coefficient of the limiting shift ($\partial\Delta_c/\partial T$).[28)]

The former group shows small negative enthalpy and entropy of formation of the complex, their limiting shift being hardly affected at all by the change in temperature.[28)] This tendency of the parameters suggests that the nature of the association is of hydrogen bonding. On complexing, the substrate moiety becomes "rigid", the intramolecular rotation about the chloromethyl group being frozen considerably to bring about a common τ_c^c for both the ring proton and the methylene proton. Such a τ_c^c may correspond to the molecular motion of the complex as a whole. In this class of compounds, $\tau_c(meta)$ may be taken as a measure of the molecular motion of the substrate as a whole mass, since the rotation around the pheyl ring—X axis is considered to have little effect upon the relaxation of both the *ortho* and/or *meta* proton.[27)]

Thus, a reasonable explanation can be presented for the compounds of the former group. The data indicate that the important part of the loss of entropy can be attributed to the freezing of the internal rotation at the complexed species.

The latter group of compounds (X=NONE, CO) show an extensive change in τ_c (and/or R_1) for both the α-methylene and the ring proton(s). The two compounds show significant enthalpy and entropy of formation of the complex, their limiting shifts showing a significant dependency on temperature. The behavior implies that some interaction other than hydrogen bonding can be operative in the complexing of these substrates.[19,20a,20b)]

(p-Nitrophenyl)chloromethane shows a change in $\tau_c(CH_2)$ comparable to that found for the former group of compounds, however, change in $\tau_c(meta)$ is anomalously large. A tentative explanation is that some other kind of relaxation mechanism is operative for the ring proton(s), the former proposition for the relaxation being not valid for the complex derived from this substrate. Another explanation is that the complexing brings about a particular conformation in which another dipole-dipole interaction is possible between the α-methylene and the ring proton(s). A

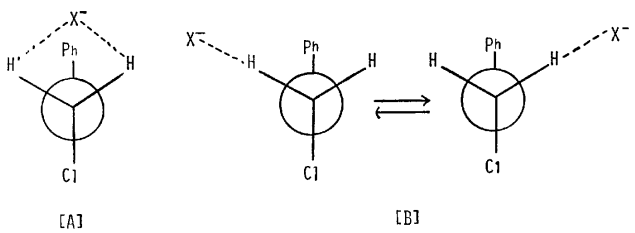

Fig. 2. Modes of coordination of halide ion to substituted chloromethanes.

reasonable change in $\tau_c(CH_2)$ for the deuterated substrate (α-d_1) seems to suggest the first possibility. An interaction between the chlorine and the phenyl ring may be responsible for the additional relaxation.

2-Chloro-1-(*p*-nitrophenyl)ethanone indicates an extensive interaction with chloride ion. Characteristic implication for this compound is that an uncomplexed substrate shows a common τ_c° at both the α-methylene and the ring proton. This suggests that intramolecular rotation is already hindered about the chloromethyl moiety. On the formation of the complex, the substrate seems to become "rigid", otherwise some additional mechanism seems to be operating. An interaction between the chloride ion and the carbonyl group was suggested in the change of CMR shift caused by the addition of chloride.[29] Such an interaction between the nucleophile and the carbonyl group is postulated in the S_N2 reactions of α-halo ketones.[30]

Mode of complexing. The data obtained seem to be indicative of the array of nucleophile and the substrate moiety in this complex. Changes of chemical shift induced by the formation of the complex (Δ_c) are much larger for α-methylene protons than for aromatic protons. There is an apparent parallelism in the magnitude of the equilibrium constant (K) and the order of the electron deficiency at the α-methylene (K_X for $ArXCH_2Cl$; $K_S < K_{SO} < K_{SO_2}$). It seems that the major site of coordination upon complexing with nucleophile is the α-methylene protons. The changes of T_1 upon complexing also are in line with the view that the major site of coordination is the α-methylene protons.

Two typical modes of coordination of nucleophile to the α-methylene protons, shown in Fig. 2, are (A) a rear side coordination of the nucleophile to the chlorine bonded to carbon, and (B) a rapidly exchanging system, where the nucleophile coordinates to one of the protons at a time, collinear to a C–H bond. These two possibilities are indistinguishable in a rapidly exchanging system as observed in the present PMR studies. However, taking into account the electrostatic repulsion between the halide ion and the chlorine atom on the substrate, (A) seems to be more feasiblle. In the case of the complex formation between β-glucopyranosyl derivatives and a halide ion, the nucleophile seems to be located between the H-1 and the H-5 (and not far from H-3) of the pyranose ring in a similar way to mode (A) in Fig. 2.[3]

It is concluded that the substrate-nucleophile complex should exist in the Finkelstein reaction mixture, and that the nucleophilic anion is located in the close neighborhood of the rear side of carbon to chlorine bond, whichever mode [(A) or (B)] of coordination is operative. Such a coordination resembles that in the transition state of S_N2 reactions. Recent MO calculation also suggests that the deep energy minimum is formed which corresponds to a strong hydrogen bonding interaction in the reaction of monofluoroethane and fluoride ion.[31]

The authors wish to express their thanks to Dr. Kazuyuki Akasaka for the discussion on the interpretation of the proton relaxation study. This work is supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 83151, 84076, 748167).

15) An interpretation for the higher K of the tetrabutylammonium (TBA) bromide or the TBA iodide is to assume the lower degree of ion pair dissociation in the concentrated solution of these two ammonium salts in acetonitrile.

At a low concentration of the salt (<0.3 M), the observed complexing shift is almost equal for both the TBA and tetraethylammonium (TEA) bromide on complexing with chloromethyl sulfones. On increasing the halide ion concentration, the observed down-field shift becomes definitely greater for TEA than for TBA salt. Upon Scott-Benesi-Hildebrand analysis, such a difference gives rise to a larger K for TBA. As the single K (Δ_c) is expected for Br^- ("effective" Br^-), one should assume a lower degree of dissociation for TBA than that for TEA bromide. Similarly, lower degree of dissociation gives rise to high apparent K for the TBA iodide.

Such a treatment is against the ion pair phenomena in a very dilute solution where TBA shows greater dissociation

than TEA does. One of the referees has pointed out this controversy. He suggested that the difference in K can be accounted for by postulating the higher degree of dissociation for TBA and that only the dissociated bromide ion is responsible for the complexing. This treatment seems to be attractive and is sound in principle. However, it should predict much smaller down-field shift for TEA bromide, compared to TBA bromide, especially on going from dilute to concentrated soultion of the ammonium salt. This is just contrary to the case.

For a compromise to both points of view, it could be proposed that the complexing (and neccssarily the bimolecular displacement in acetonitrile) proceeds by the intervention of the ion-paired nucleophile instead of the free dissociated halide ion.

However, the controversy remains unsettled.

18) TEA chloride can easily be purified, and is not very hygroscopic but sufficiently soluble in acetonitrile. With chloride ion, the observed complexing shift is greater then that with other halide ions studied. TEA fluoride attacks most of the substrates. (*cf.* J. Hayami, N. Ono, and A. Kaji, *Tetrahedron Lett.*, **1968**, 1385).

19) One of the referees suggested that value of $\Delta - H^\circ$ for (*p*-nitrophenyl)chloromethane and for 2-chloro-1-(*p*-nitrophenyl)ethanone is too large to be ascribed to a simple hydrogen bonding to carbon bound hydrogen. The peculiar behavior of the two compounds is also observed in the change of relaxation rate upon complexing and in the temperature coefficient of the limiting shift ($\partial\Delta_c/\partial T$). The tendencies in $\partial\Delta_c/\partial T$ suggest some interactions other than hydrogen bonding can be operative in the two compounds.[23] (This criterion is circumstantial, however, and one cannot rule out the view that some additional interaction is operative for the three other classes of compounds studied.) However, since the linear Hammett relationship holds in each class of the compounds studied, with respect to the XCH_2Cl group as the reference position, and in view of the analogy to the other example of substrate-nucleophile association reported,[3,4] the hydrogen bonding to the α-methylene proton can be postulated as the major driving force for the association.

24) Slight increase in R_1 was observed by the addition of TEA perchlorate to the solution of the substrate in acetonitrile. However, the change in rate was within experimental error (±10%) inherent in the measurement of T_1 and was ignored.

25) A. Carrington and A. D. McLachlan, "Introduction to Magnetic Resonance," Harper and Row, New York, N. Y. (1967).

26) In a similar way to Eq. 4, direct dipole-dipole interaction of chloride ion contributes to the rate of relaxation as shown by

$$R_1^{H\text{-}Cl} = (15/2)\hbar^2\gamma_H^2\gamma_{Cl}^2\tau_c/r_{HCl}^6 \quad (4a)$$

where γ_{Cl} is the gyromagnetic ratio of chlorine and r_{HCl} is the distance between chloride ion and the proton in question.

When one uses the values

$\gamma_H = 26753$ rad s^{-1} G^{-1} (the gyromagnetic ratio of proton)

$\gamma_{Cl} = 2516$ rad s^{-1} G^{-1} (weighted mean of the gyromagnetic ratio for ^{35}Cl and for ^{37}Cl)

$r_{HH} = 1.78$ Å (distance between geminal protons of methylene group),

one obtains, from Eqs. 4 and 4a, $R_1^{H\text{-}H}/R_1^{H\text{-}Cl} = 174$ for $r_{HCl} = 2.5$ Å (This is 0.5 Å shorter than the sum of the atomic and ionic radii, a typical hydrogen bonding distance)[3] and $R_1^{H\text{-}H}/R_1^{H\text{-}Cl} = 3.2_8$ for $r_{HCl} = 1.3$ Å (the covalent bond distance for hydrogen chloride).

These values suggest that, in the former case, the contribution of the direct interaction of the chloride ion is less than 1% of the contribution of the geminal protons. Even at the covalent bond distance, the contribution of the chloride ion is about 23% of the contribution of the geminal proton. One might assume that, at a reasonable hydrogen bond distance, the direct interaction of the chloride ion plays no important role in the spin-lattice relaxation process.

Results of the study with (*p*-nitrophenyl)chloromethane-α-d_1 support this postulate. Data from Table 5 [footnote f)] give $R_1^c(CHD)/R_1^c(CH_2) = 0.26_6$. The significantly slow relaxation of monodeuterated compound indicates that any one of the following conceivable factors does not contribute more than 30% of the spin-lattice relaxation of normal undeuterated substrate: 1) direct dipole-dipole interaction of chloride ion, 2) relaxation by the contribution of the nuclear quadrupole of the chloride ion, 3) long range interaction between methylene proton and the ring protons.

27) The observed rate of relaxation was almost identical, within experimental error, for the vicinal protons on the same phenyl ring. Thus τ_c(*meta*) and τ_c(*ortho*) calculated were almost equal. The intramolecular rotation about the axis of the phenyl-X bond is considered to be ineffective for the relaxation of the ortho and meta proton nuclei. Thus the τ_c(*meta*) can be regarded as a measure of the correlation time of molecular motion as the whole mass. There are examples where difference in τ_c is ascribed to difference in an intramolecular rotation. *Cf.* a) A. Suggett, *J. Solution Chemistry*, **5**, 33 (1976); b) E. Breitmaier, K-H Spohn, and S. Berger, *Angew. Chem. Int. Ed. Engl.*, **14**, 144 (1975).

28) As Muller has pointed out,[20b] some indication is given as to the nature of the solute-solute interaction from the temperature coefficient of $\partial\Delta_c/\partial T$. Generally, when a strong hydrogen bonding is operative, hydrogen bonding shift in PMR is little affected by the changes in temperature. In an association where significant stabilization is found with a significant $\partial\Delta_c/\partial T$, some (additional) interaction other than hydrogen bonding can be operative.

$\partial\Delta_c/\partial T$(ppm deg^{-1}) for p-NO_2PhXCH_2Cl: 1.2×10^{-2} (X=NONE), 2.0×10^{-2} (X=CO), 0.6×10^{-2} (X=S), 0.4×10^{-2} (X=SO), 0.2×10^{-2} ($X=SO_2$).

29) $Ph^{13}COCH_2Cl$ showed limiting CMR shift 5.0 ppm on complexation with chloride ion while no such a shift was observed for $Ph^{13}CH_2Cl$.

Nucleoside Analogs. 5. Synthesis of Carbocyclic Pyrimidine Nucleoside Analogs

Kin-ichi TADANO, Sumio HORIUCHI, and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received July 18, 1977)

Six carbocyclic analogs of uridine and thymidine in which the pentofuranosyl groups are replaced by a carbocyclic cyclopentane system have been synthsized. Their biological activities were determined against *HeLa* S3 cells.

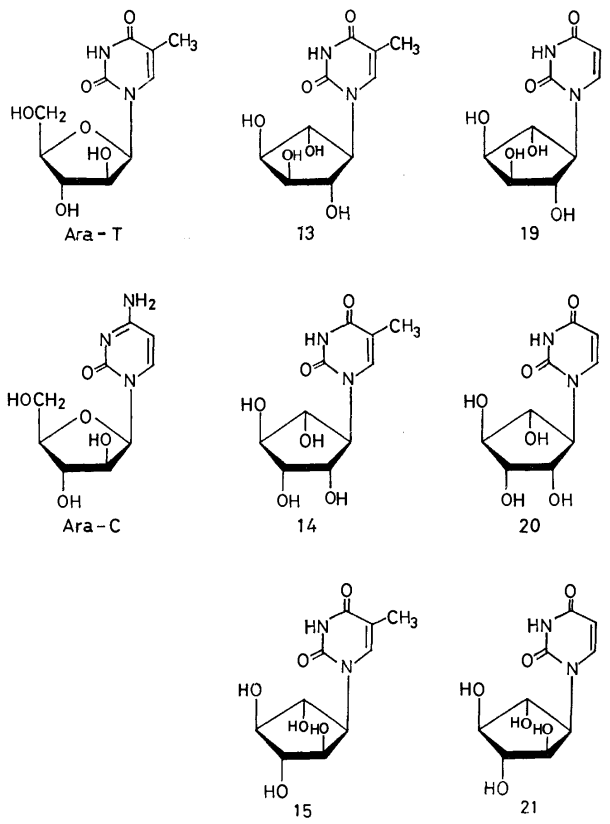
In connection with the preceding papers,[1-4] a report is given on the synthesis of carbocyclic analogs of uridine and thymidine in which the pentofuranosyl groups are replaced by a cyclopentane derivative.

1-β-D-Arabinofuranosylthymine (Ara-T),[5] which has been found in nature, has antiviral activity against 2DNA viruses, herpes virus and vaccinia virus in *HeLa* cell culture.[6]

Since 1-β-D-arabinofuranosylcytosine (Ara-C)[7] is a well known carcinostatic agent,[8] a carbocyclic analog of pyrimidine nucleoside might exhibit antineoplastic activity.

In the present study, three uridine and three thymidine analogs have been prepared and their biological activities are tested against *HeLa* cells.

Three stereoisomers of 5-amino-1,2,3,4-cyclopentanetetrol[3] **1**, **2**, and **3** were treated with nitrourea and subsequently acetylated by the conventional method to give corresponding 1,2,3,4-tetra-*O*-acetyl-5-ureido-1,2,3,4-cyclopentanetetrols **4**, **5**, and **6**, respectively.



Scheme 1.

When **4**, **5**, and **6** were treated with 3-methoxy-2-methylacryloyl chloride[9] in pyridine by an analogous method described by Naito *et al.*,[10] 1,2,3,4-tetra-*O*-acetyl-5-[*N'*-(3-methoxy-2-methylacryloyl)ureido]-1,2,3,4-cyclopentanetetrols **7**, **8**, and **9** were obtained. In their ^{1}H NMR spectra, a doublet at δ 9.21—9.31 (1H, J=8—9 Hz) is attributable to NH linked to the cyclopentane ring, a singlet at δ 8.56—8.86 (1H) being ascribed to NH where the 3-methoxy-2-methylacryloyl group is attached. This indicates that the 3-methoxy-2-methylacryloyl group is attached to the terminal amino group of **4**, **5**, and **6**.

Ring closure of **7**, **8**, and **9** in aqueous ammonia afforded 1-(2,3,4,5-tetrahydroxycyclopentyl)thymines **13** **14**, and **15**. Their successful ring closure was demonstrated by measuring their UV spectra at different pH.[11] Their *O*-acetyl derivatives **16**, **17**, and **18** were prepared by the usual acetylation.

On the other hand, when the ureido derivatives **4**, **5**, and **6** reacted with 3-ethoxyacryloyl chloride [12] by an analogous method described by Bobeck and Farkas,[13] 1,2,3,4-tetra-*O*-acetyl-5-*N'*-(3-ethoxyacryloyl) ureido-1,2,3,4-cyclopentanetetrols **10**, **11**, and **12** were obtained. Their structures were confirmed by means of ^{1}H NMR spectra.

Ring closure of **10**, **11**, and **12** in aqueous ammonia afforded 1-(2,3,4,5-tetrahydroxycyclopentyl)uracils **19**, **20**, and **21**. Their *O*-acetyl derivatives **22**, **23**, and **24** were also prepared.

Compounds **13**, **14**, **15**, **19**, **20**, and **21** showed no biological activity against *HeLa* S3 cells.

Experimental

Melting points were determined in capillary tubes and are uncorrected. Acetylation was carried out in the usual way with acetic anhydride in pyridine. Solutions were concentrated under reduced pressure at 40—50 °C. Silica gel (Wakogel C-300, Wako Pure Chemical Industries Ltd.) was used for column chromatography and TLC was performed on silica gel (Wakogel B-5FM) plates in 5:1 (v/v) benzene-ethanol system. ^{1}H NMR spectra were recorded at 60 MHz with a Varian A-60D spectrometer, peak positions being given in δ values. UV spectra were measured with a Hitachi-Perkin Elmer UV-VIS 139 spectrometer.

*1,2,3,4-Tetra-*O*-acetyl-(1,4/2,3,5)-5-ureido-1,2,3,4-cyclopentanetetrol (4).* A mixture of (1,4/2,3,5)-5-amino-1,2,3,4-cyclopentanetetrol[3] (**1**, 536 mg) and nitrourea (455 mg) in water (25 ml) was stirred at room temperature overnight. The solution was concentrated and the residue was acetylated. The solution was poured into ice-cold water (120 ml) and extracted with chloroform repeatedly. After being dried over Na_2SO_4, the chloroform extract was concentrated to dryness.

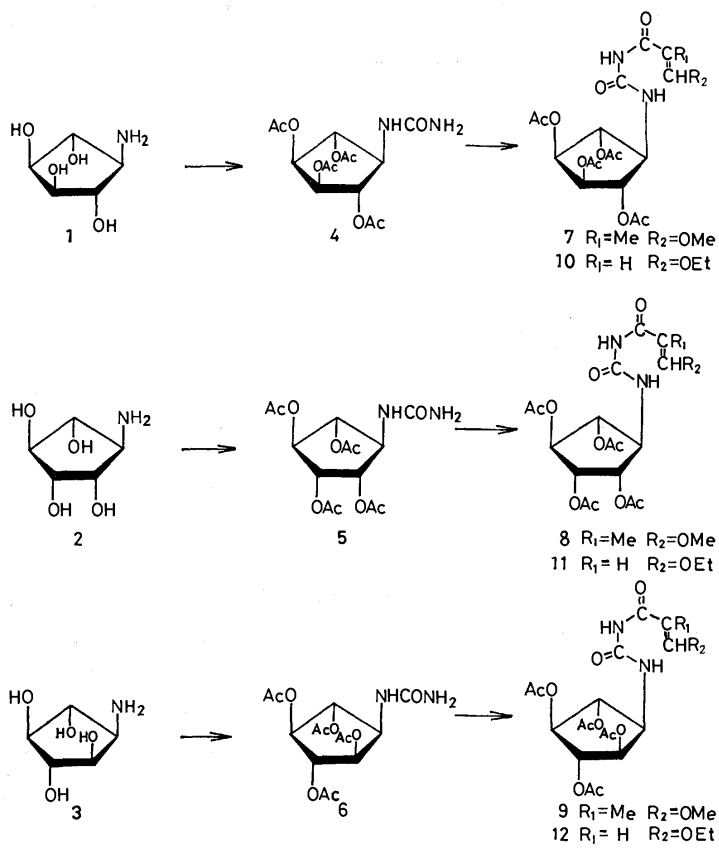
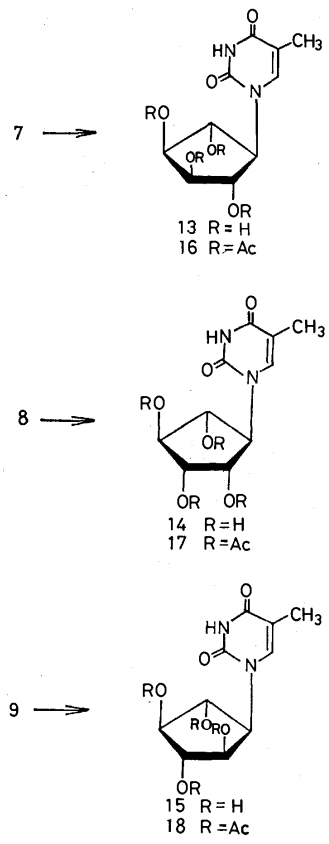
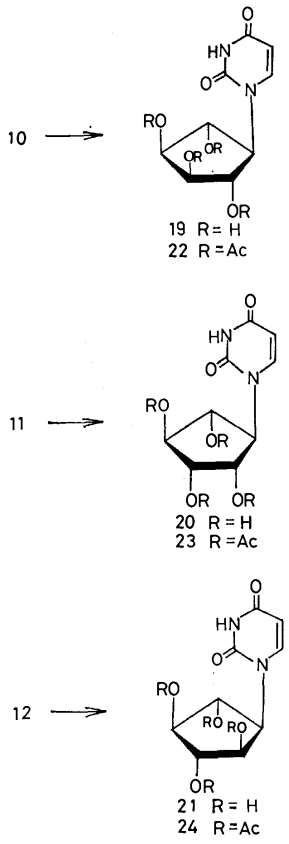


Scheme 2.



Scheme 3.



Scheme 4.

The residue was recrystallized from ethanol to give 823 mg (64%) of **4** as needles, mp 196—197 °C. ^{1}H NMR (DMSO-d_6): δ 2.02 (s, 12, 4×OAc), 3.28 (s, 2, NH_2), 6.42 (d, 1, J=9 Hz, NH).

Found: C, 47.00; H, 5.46; N, 7.77%. Calcd for $C_{14}H_{20}N_2O_9$: C, 46.67; H, 5.60; N, 7.77%.

*1,2,3,4-Tetra-O-acetyl-*DL*-(1,2,4/3,5)-5-ureido-1,2,3,4-cyclopentanetetrol (**5**).* A mixture of DL-(1,2,4/3,5)-5-amino-1,2,3,4-cyclopentanetetrol[3] (**2**, 1.23 g) and nitrourea (1.30 g) in water (60 ml) was heated under reflux for 3 h. Subsequent treatment was analogous to that described in the preparation of **4**. An oily residue was crystallized from ethyl acetate–petroleum ether to give 1.84 g (62%) of **5**, mp 165—166 °C.

Found: C, 46.51; H, 5.52; N, 7.53%. Calcd for $C_{14}H_{20}N_2O_9$: C, 46.67; H, 5.60; N, 7.77%.

*1,2,3,4-Tetra-O-acetyl-*DL*-(1,3,5/2,4)-5-ureido-1,2,3,4-cyclopentanetetrol (**6**).* 1,2,3,4-Tetra-*O*-acetyl-DL-(1,3,5/2,4)-5-acetamido-1,2,3,4-cyclopentaneterol[14] (3.26 g) was heated under reflux in 6 M hydrochloric acid (50 ml) for 1.5 h and the solution was concentrated to dryness. An aqueous solution of the residue was neutralized with Amberlite IRA-400(OH^-) resin and was concentrated. The residue was recrystallized from ethanol to give 1.25 g (93%) of DL-(1,3,5/2,4)-5-amino-1,2,3,4-cyclopentanetetrol (**3**), mp 142—144 °C.

Found: C, 39.97; H, 7.52; N, 8.66%. Calcd for $C_5H_{11}NO_4 \cdot 1/2H_2O$: C, 39.99; H, 7.93; N, 8.48%.

A mixture of **3** (1.00 g) and nitrourea (1.24 g) in water (50 ml) was heated under reflux for 4 h. The mixture was worked up as in the preparation of **4**. The crude product was recrystallized from ethanol to give 2.03 g (84%) of **6** as needles, mp 203—204 °C. ^{1}H NMR ($CDCl_3$–DMSO-d_6, 5 : 1): δ 2.08 (s, 6, 2×OAc), 2.10 (s, 3, OAc), 2.17 (s, 3, OAc), 5.57 (s, 2, NH_2), 6.46 (d, 1, J=9 Hz, NH).

Found: C, 46.64; H, 5.52; N, 7.87%. Calcd for $C_{14}H_{20}N_2O_9$: C, 46.67; H, 5.60; N, 7.77%.

*1,2,3,4-Tetra-O-acetyl-(1,4/2,3,5)-5-[N′-(3-methoxy-2-methylacryloyl)ureido]-1,2,3,4-cyclopentanetetrol (**7**).* A mixture of **4** (1.50 g), 3-methoxy-2-methylacryloyl chloride[9] (0.90 g), pyridine (5 ml) and chloroform (5 ml) was agitated at ambient temperature for 2 days. The solution was concentrated to dryness and the residue was dissolved in water (30 ml). The aqueous solution was extracted 3 times with chloroform (30 ml). After being dried over Na_2SO_4, the combined chloroform extract was concentrated. The residue was recrystallized from ethanol to give 1.31 g (68%) of **7**, mp 138—139 °C. ^{1}H NMR ($CDCl_3$): δ 1.78 (d, 3, J=1 Hz, C–CH_3), 2.07 (s, 6, 2×OAc), 2.08 (s, 6, 2×OAc), 3.86 (s, 3, C–OCH_3), 7.33 (q, 1, J=1 Hz, acryloyl CH), 8.56 (s, 1, N′H), 9.31 (d, 1, J=9 Hz, NH).

Found: C, 49.86; H, 5.68; N, 6.05%. Calcd for $C_{19}H_{26}N_2O_{11}$: C, 49.78; H, 5.72; N, 6.11%.

*1,2,3,4-Tetra-O-acetyl-*DL*-(1,2,4/3,5)-[N′-(3-methoxy-2-methylacryloyl)ureido]-1,2,3,4-cyclopentanetetrol (**8**).* A mixture of **5** (1.00 g), 3-methoxy-2-methylacryloyl choride[9] (1.12 g), pyridine (5 ml) and chloroform (5 ml) was stirred at ambient temperature for 40 h. The solution was worked up as in the preparation of **7**. A product was recrystallized from ether to give 0.59 g (47%) of **8**, mp 167—168 °C. ^{1}H NMR ($CDCl_3$): δ 1.79 (d, 3, J=1 Hz, C–CH_3), 2.04 (s, 3, OAc), 2.06 (s, 3, OAc), 2.08 (s, 6, 2×OAc), 3.87 (s, 3, C–OCH_3), 7.35 (q, 1, J=1 Hz, acryloyl CH), 8.86 (s, 1, N′H), 9.21 (d, 1, J=8 Hz, NH).

Found: C, 49.88; H, 5.74; N, 5.86%. Calcd for $C_{19}H_{26}N_2O_{11}$: C, 49.78; H, 5.72; N, 6.11%.

*1,2,3,4-Tetra-O-acetyl-*DL*-(1,3,5/2,4)-5-[N′-(3-methoxy-2-methylacryloyl)ureido]-1,2,3,4-cyclopentanetetrol (**9**).* A mixture of **6** (1.00 g), 3-methoxy-2-methylacryloyl chloride[9] (0.56 g), pyridine (5 ml) and chloroform (10 ml) was stirred for 38 h. The solution was worked up as in the preparation of **7**. A product was recrystallized from ether-petroleum ether to give 0.43 g (34%) of **9**, mp 130—131 °C. ^{1}H NMR ($CDCl_3$): δ 1.77 (s, 3, J=1 Hz, C–CH_3), 2.07 (s, 3, OAc), 2.08 (s, 3, OAc), 2.10 (s, 3, OAc), 2.16 (s, 3, OAc), 3.87 (s, 3, C–OCH_3), 7.34 (q, 1, J=1 Hz, acryloyl CH), 8.78 (s, 1, N′H), 9.22 (d, 1, J=8 Hz, NH).

Found: C, 49.48; H, 5.66; N, 5.79%. Calcd for $C_{19}H_{26}N_2O_{11}$: C, 49.78; H, 5.72; N, 6.11%.

*1,2,3,4-Tetra-O-acetyl-(1,4/2,3,5)-5-[N′-(3-ethoxyacryloyl)ureido]-1,2,3,4-cyclopentanetetrol (**10**).* A mixture of **4** (1.50 g), 3-ethoxyacryloyl chloride[12] (1.05 g), pyridine (7 ml) and chloroform (7 ml) was stirred overnight. The solution was poured into water (50 ml) and extracted with chloroform repeatedly. After being dried over Na_2SO_4, the chloroform extract was concentrated. The residue was purified on a silica gel column (110 g, 30 × 410 mm) using 10:1 (v/v) benzene–ethanol as eluent. Fractions showing a single spot on TLC (R 0.44) were combined and concentrated. The residue was recrystallized from ethyl acetate-petroleum ether to give 677 mg (35%) of **10**, mp 148—149 °C. ^{1}H NMR ($CDCl_3$): δ 1.36 (t, 3, J=7 Hz, C–$OCH_2C\underline{H}_3$), 2.08 (s, 12, 4 × OAc), 4.00 (q, 2, J=7 Hz, C–$OC\underline{H}_2CH_3$), 5.34 (d, 1, J=12 Hz, acryloyl CH), 7.60 (d, 1, J=12 Hz, acryloyl CH), 9.21 (d, 1, J=8 Hz, NH), 9.49 (s, 1, N′H).

Found: C, 49.89; H, 5.86; N, 5.90%. Calcd for $C_{19}H_{26}N_2O_{11}$: C, 49.78; H, 5.72; N, 6.11%.

*1,2,3,4-Tetra-O-acetyl-*DL*-(1,2,4/3,5)-5-[N′-(3-ethoxyacryloyl)ureido]-1,2,3,4-cyclopentanetetrol (**11**).* A mixture of **5** (0.40 g), 3-ethoxyacryloyl chloride[12] (0.50 g) and pyridine (5 ml) in chloroform (5 ml) was stirred for 13 h. The mixture was worked up as in the preparation of **10**. The product was recrystallized from ethanol to give 123 mg (24%) of **11**, mp 147—148 °C. ^{1}H NMR ($CDCl_3$): δ 1.35 (t, 3, J=7 Hz, C–$OCH_2C\underline{H}_3$), 2.06 (s, 3, OAc), 2.08 (s, 3, OAc), 2.09 (s, 3, OAc), 2.10 (s, 3, OAc), 3.98 (q, 2, J=7 Hz, C–$OC\underline{H}_2CH_3$), 5.35 (d, 1, J=12 Hz, acryloyl CH), 7.62 (d, 1, J=12 Hz, acryloyl CH), 9.11 (d, 1, J=8 Hz, NH), 9.78 (s, 1, N′H).

Found: C, 49.83; H, 5.70; N, 5.96%. Calcd for $C_{19}H_{26}N_2O_{11}$: C, 49.78; H, 5.72; N, 6.11%.

*1,2,3,4-Tetra-O-acetyl-*DL*-(1,3,5/2,4)-5-[N′-(3-ethoxyacryloyl)ureido]-1,2,3,4-cyclopentanetetrol (**12**).* A mixture of **6** (1.14 g), 3-ethoxyacryloyl chloride[12] (1.27 g) and pyridine (5 ml) in chloroform (5 ml) was worked up as in the preparation of **10**. A product was recrystallized from ethyl acetate-petroleum ether to give 589 mg (41%) of **12**, mp 132—135 °C. ^{1}H NMR ($CDCl_3$): δ 1.37 (t, 3, J=7 Hz, C–$OCH_2C\underline{H}_3$), 2.06 (s, 3, OAc), 2.09 (s, 6, 2×OAc), 2.15 (s, 3, OAc), 4.00 g (q, 2, J=7 Hz, C–$OC\underline{H}_2CH_3$), 5.33 (d, 1, J=12 Hz, acryloyl CH), 7.61 (d, 1, J=12 Hz, acryloyl CH), 9.11 (d, 1, J=9 Hz, NH), 9.52 (s, 1, N′H).

Found: C, 49.81; H, 5.88; N, 6.20%. Calcd for $C_{19}H_{26}N_2O_{11}$: C, 49.78; H, 5.72; N, 6.11%.

*1-[(1,3,4/2,5)-2,3,4,5-Tetrahydroxycyclopentyl]thymine (**13**).* A solution of **16** (741 mg) in methanol (20 ml) saturated with ammonia was stirred at ambient temperature for 15 h. The solution was concentrated, and the residue was recrystallized from ethanol to give 447 mg (99%) of **13**, mp 241—245 °C. UV: $\lambda_{max}^{0.1M\ HCl}$ 272 nm (ε=1.0×10^4), $\lambda_{max}^{H_2O}$ 273 nm (ε=0.99 ×10^4), $\lambda_{max}^{0.1M\ NaOH}$ 272 nm (ε=0.76×10^4).

Found: C, 46.61; H, 5.52; N, 10.64%. Calcd for $C_{10}H_{14}N_2O_6$: C, 46.51; H, 5.46; N, 10.85%.

*1-[*DL*-(1,3/2,4,5)-2,3,4,5-Tetrahydroxycyclopentyl]thymine (**14**).* A solution of **8** (580 mg) in 3.5% aqueous ammonia (12 ml)

was heated at 80 °C for 5 h with agitation. The solution was concentrated to dryness and the residue was recrystallized from ethanol to give 298 mg (91%) of **14**, mp 248—252 °C (dec). UV: $\lambda_{max}^{0.1M\ HCl}$ 272 nm ($\varepsilon=0.94\times10^4$), $\lambda_{max}^{H_2O}$ 272 nm ($\varepsilon=0.95\times10^4$), $\lambda_{max}^{0.1M\ NaOH}$ 272 nm ($\varepsilon=0.72\times10^4$).

Found: C, 46.53; H, 5.46; N, 10.96%. Calcd for $C_{10}H_{14}N_2O_6$: C, 46.51; H, 5.46; N, 10.85%.

*1-[DL-(1,2,4/3,5)-2,3,4,5-Tetrahydroxycyclopentyl]thymine (**15**).* A solution of **9** (295 mg) in 3.5% aqueous ammonia (10 ml) was heated at 80 °C for 5 h with agitation. The solution was concentrated to *ca.* 1 ml and the residue was stored in a refrigerator overnight to give 129 mg (77%) of **15**, mp 285—288 °C (dec). UV: $\lambda_{max}^{0.1M\ HCl}$ 272 nm ($\varepsilon=1.0\times10^4$), $\lambda_{max}^{H_2O}$ 271 nm ($\varepsilon=1.0\times10^4$), $\lambda_{max}^{0.1M\ HCl}$ 270 nm ($\varepsilon=0.8\times10^4$).

Found: C, 46.64; H, 5.53; N, 10.95%. Calcd for $C_{10}H_{14}N_2O_6$: C, 46.51; H, 5.46; N, 10.85%.

*1-[(1,3,4/2,5)-2,3,4,5-Tetraacetoxycyclopentyl]thymine (**16**).* A solution of **7** (1.20 g) in 3.5% aqueous ammonia (20 ml) was heated at 80 °C for 5 h with agitation. The solution was concentrated to dryness and the residue was acetylated. The product was recrystallized from ethanol to give 961 mg (86%) of **16**, mp 193—194 °C. ^1H NMR ($CDCl_3$): δ 1.96 (d, 3, $J=1$ Hz, C-CH_3), 2.07 (s, 6, 2×OAc), 2.11 (s, 6, 2×OAc), 7.10 (q, 1, $J=1$ Hz, pyrimidine CH), 9.45 (s, 1, pyrimidine NH).

The Formation of Alkyl Acetate in the Reaction of Trialkylborane with Lead(IV) Acetate or Phenyliodoso Acetate*

Yuzuru MASUDA and Akira ARASE

Department of Applied Chemistry, Kitami Institute of Technology, Kitami, Hokkaido 090

(Received August 8, 1977)

In the reaction of trialkylborane with lead(IV) acetate or phenyliodoso acetate in benzene, about two thirds of the alkyl groups of trialkylborane were converted to the corresponding alkyl acetate without any isomerization of the alkyl group. Lead(IV) acetate reacted preferentially with the secondary alkyl group, while phenyliodoso acetate reacted only with the primary alkyl group. In either reaction, one mole of oxidizing agent was consumed for the formation of one mole of alkyl acetate.

Synthetic reactions using organoborane[1] can be roughly classified into two types by their reaction products.[2] One is the combination of the alkyl group to the carbon atom, and the other is the combination of the alkyl group to the hetero atom. We are interested in the latter reaction and have studied the severance of the carbon-boron linkage of trialkylborane by oxidation with a metal compound, followed by the combination of the resulting alkyl group with the ligand of the metal compound.

Recently we reported that trialkylborane gave the corresponding alkyl chloride or alkyl bromide in the reaction with aqueous iron(III) chloride[3] or copper(II) bromide,[3] and also gave alkyl thiocyanate or alkyl selenocyanate in the reaction with aqueous iron(III) thiocyanate[3,5] or iron(III) selenocyanate[4,5] (Eq. 1).

$$R_3B \xrightarrow{Fe^{3+} \text{ or } Cu^{2+},\ X^-} 2\,RX + RB(OH)_2 \qquad (1)$$

X=Cl, Br, SCN, and SeCN

In these reactions, the reduction of Fe(III) to Fe(II) or Cu(II) to Cu(I) occurred; the reactions seemed to proceed in ligand-transfer oxidation by metal compounds for the alkyl radical generated from trialkylborane.[6]

Kochi described that the oxidation of alkyl radical by copper(II) acetate and lead(IV) acetate involved an electron-transfer mechanism, and now, by the former reagent,[7] olefin was formed as the major product by the elimination of hydrogen from the alkyl radical, while by the latter reagent, substitution product,[8] RX (X=H, OAc, and R′, derived from the solvent) was characteristically produced.

On the other hand, Suzuki and his co-workers[9] found that alkyl acetate was formed by an anodic oxidation of trialkylborane in an acetic acid–sodium acetate solution.

Thus, we studied the reaction of trialkylborane with lead(IV) acetate in the hope that alkyl acetate might be formed from trialkylborane.

Results and Discussion

Reaction of Trialkylboranes with Lead(IV) Acetate. As a preliminary examination, trihexylborane, prepared by the hydroboration of 1-hexene with borane in tetrahydrofuran, was subjected to a reaction with the benzene solution of lead(IV) acetate. A relatively slow reaction occurred. The reaction mixture was worked up, and then distilled to give two compounds in a ratio of 10 : 1. These compounds were identified as hexyl acetate (the major one) and 1-methylpentyl acetate (the minor one) by direct comparisons with authentic samples. When the tetrahydrofuran was taken off before the addition of lead(IV) acetate, the amount of hexyl acetates increased remarkably. Accordingly, the subsequent reactions were conducted in the absence of tetrahydrofuran.

To obtain optimum reaction conditions, the reaction was carried out using varying amounts of lead(IV) acetate under several temperatures. Some results are presented in Table 1.

In the reaction at 55 °C for 24 h, the best results were obtained giving 7.8 mmol of hexyl acetate and 0.8 mmol of 1-methylpentyl acetate from 5 mmol of trihexylborane. On the oxidation of the reaction mixture with an aqueous hydrogen peroxide solution, under weakly basic conditions, 7.8 mmol of hexyl acetate, 0.8 mmol of 1-methylpentyl acetate, 6.3 mmol of hexyl alcohol, and a trace amount of 1-methylpentyl alcohol were obtained. A characteristic feature of the reaction is revealed by these results. That is, two thirds of the alkyl group of trialkylborane can participate in the reaction, giving alkyl acetate almost exclusively, without any isomerization of the alkyl group. This characteristic is worthy of remark because, in the reaction of valeric acid with the lead(IV) acetate butyl

TABLE 1. REACTION[a] OF TRIHEXYLBORANE WITH LEAD(IV) ACETATE

Exp. no.	React. temp, °C	$Pb(OAc)_4$ mmol	Products, mmol[b]	
			Hexyl acetate	1-Methylpentyl acetate
1	20	15	0.8	0.3

6	55	5	4.7	0.3
7	55	2.5	2.2	0.2

a) The reaction was carried out in benzene for 24 h by using 5 mmol of trihexylborane, prepared from 1-hexene by hydroboration. b) Determined by GLPC, using PEG 20 M as the liquid phase.

* A preliminary report of this work was presented at the 36th National Meeting of the Chemical Society of Japan, Osaka, April, 1977.

$$\text{Valeric acid} \xrightarrow[\text{benzene}]{Pb(OAc)_4} \underset{25\%}{\text{butane}} + \underset{2\%}{\text{1-butene}} + \underset{1.1\%}{\text{2-butene}} + \underset{20.6\%}{\text{butylbenzene}} + \underset{2\%}{\text{butyl acetate}} + \underset{2\%}{\text{1-methylpropyl acetate}}$$

Scheme 1.

radical, initially formed by decarboxylation, several reaction products were given by electron-transfer oxidation[8] (Scheme 1). In the present reaction, only trace amounts of hexane, hexene, and hexylbenzene were detected.

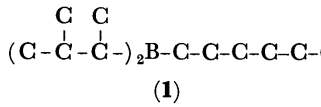
As is shown in Exp. 6 and 7, one mole of lead(IV) acetate is consumed in the formation of one mole of hexyl acetate, suggesting that two electrons take part in the formation of one molecule of hexyl acetate. Thus, the reaction may be written stoichiometrically as follows:

$$R_3B + 2Pb(OAc)_4 \longrightarrow 2\ ROAc + RB(OAc)_2 + 2Pb(OAc)_2. \quad (2)$$

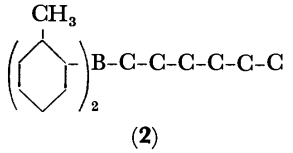
The results of the reactions of several trialkylboranes with lead(IV) acetate under the optimum reaction conditions are presented in Table 2.

Similar results were obtained in all the reactions examined. For example, 5 mmol of tri-*exo*-2-norbornylborane gave 8.5 mmol of *exo*-2-norbornyl acetate.

Another important feature of the reaction is the fact that the secondary alkyl group reacts in preference to the primary one in the case of the mixed trialkylborane, which contains primary and secondary alkyl groups on the same boron atom. That is, dicyclohexylhexylborane gave mostly cyclohexyl acetate. Further, although one third of the hexyl group still remained on the boron atom, almost all of the 1-methylpentyl group[10] was converted to 1-methylpentyl acetate in the reaction of trihexylborane. Bis(1,2-dimethylpropyl)hexylborane (**1**) and bis(2-methylcyclohexyl)hexylborane (**2**) gave only trace amounts of products, and, on oxidation with an aqueous hydrogen peroxide solution, under weakly basic conditions, the corresponding alcohols were formed quantitatively. Although, in both cases, no detailed study has been



(**1**)



(**2**)

made, the large steric hindrance on the boron atom seems to prevent any interaction between trialkylborane and lead(IV) acetate.

When 5 mmol of tricyclohexylborane was allowed to react with lead(IV) acetate in chloroform, 1.6 mmol of cyclohexyl acetate and 2.2 mmol of cyclohexyl chloride were formed. This fact strongly suggests that an alkyl

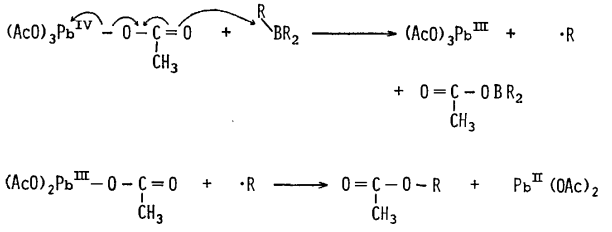
radical has an important role in the reaction. Although describing the reaction mechanism in detail is not the main purpose of this report, these results may be explained by the following reaction scheme:



Scheme 2.

Many reactions of organoborane with oxidizing agents have been studied, and in many cases characteristic products for each reaction have been obtained.[11–14] The present reaction gave alkyl acetate characteristically. On the other hand, synthetic methods of alkyl carboxylate from olefin have also been reported.[9,15] Except for the reaction cited in Ref. 9, though, they are all "Markownikoff addition" reactions of carboxylic acid to olefin. The present reaction is a practically applicable one-pot synthesis of primary alkyl acetate from α-olefin by means of the "Anti-Markownikoff addition" reaction.

Reaction of Trialkylborane with Phenyliodoso Acetate. Next, we examined the reaction of trialkylborane with phenyliodoso acetate, which is known to act in almost the same manner as lead(IV) acetate in oxidation reactions.[16] The results are presented in Table 3.

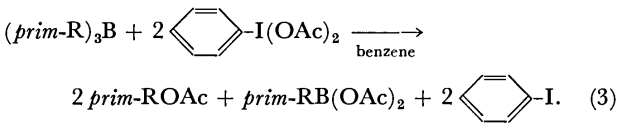
In contrast to the oxidation with lead(IV) acetate, phenyliodoso acetate converted only the primary alkyl group to primary alkyl acetate. For example, 5 mmol of dicyclohexylhexylborane gave only 4.4 mmol of hexyl acetate; on the oxidation of the reaction mixture with the aqueous hydrogen peroxide solution, under weakly basic conditions, 4.4 mmol of hexyl acetate, 10 mmol of cyclohexyl alcohol, and 0.4 mmol of hexyl alcohol were obtained. In the case of trihexylborane, hexyl acetate was formed, uncontaminated with 1-methylpentyl acetate. Thus, the reaction provides a more excellent method than that of lead(IV) acetate for the synthesis of primary alkyl acetate from α-olefin.

Table 3. Reaction[a] of trialkylboranes with phenyliodoso acetate

R_3B (5 mmol)	Product	Yield,[b] mmol
$(Hexyl)_3B$	Hexyl-OAc	9.3 (9.2)[e]
	1-Me-pentyl-OAc	trace (trace)[e]
	Hexyl-OAc	4.5[c]
		2.4[d]
$(Cyclohexyl)_3B$	Cyclohexyl-OAc	no reaction
$(Octyl)_3B$	Octyl-OAc	7.2 (7.0)[e]
	1-Me-heptyl-OAc	trace (trace)[e]
$(Cyclohexyl)_2B$-hexyl	Hexyl-OAc	4.4
	Cyclohexyl-OAc	0

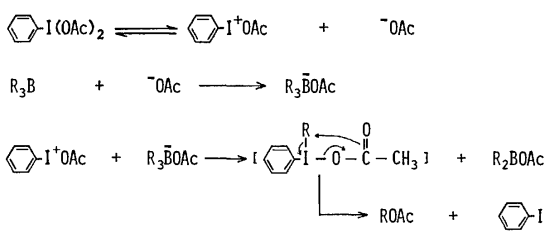
a) Carried out at 55 °C for 8 h by using 10 mmol of phenyliodoso acetate and 20 ml of benzene. b) Determined by GLPC. c) Phenyliodoso acetate, 5 mmol. d) Phenyliodoso acetate, 2.5 mmol. e) Isolated by column chromatography.

As has been shown in the reaction of trihexylborane, one mole of phenyliodoso acetate was consumed for the formation of one mole of hexyl acetate, and a comparable amount of iodobenzene was formed (Eq. 3):



$$(prim\text{-}R)_3B + 2\,C_6H_5\text{-}I(OAc)_2 \xrightarrow[\text{benzene}]{} 2\,prim\text{-}ROAc + prim\text{-}RB(OAc)_2 + 2\,C_6H_5\text{-}I \quad (3)$$

The yield of alkyl acetate was not reduced in the presence of tetrahydrofuran. Moreover, no alkyl chloride was formed in the reaction conducted in chloroform. These facts seem to show that, in contrast to the case of lead(IV) acetate, the alkyl radical is not involved in the reaction. Pelter et al. described that, in the nucleophilic migration of the alkyl group of the trialkylborane cyanate complex, the primary alkyl group is more labile than the secondary one.[17] Thus, in the reaction of trialkylboranes with phenyliodoso acetate, it is probable that the nucleophilic attack of the alkyl group on the iodonium cation is involved. The following reaction scheme may be proposed:



Scheme 3.

As has been described previously, lead(IV) acetate converts preferentially the secondary alkyl group, while phenyliodoso acetate converts only the primary one. Thus, both reactions, compensating for each other, may provide a new method of synthesizing alkyl acetates from a variety of olefins.

Experimental

Instruments. GLPC was performed using a NEVA Model 1400. The PMR spectra were obtained on a Hitachi Model R-20A spectrometer. The infrared spectra were recorded on a Shimadzu 27G spectrometer. The mass spectra were obtained on a Hitachi Model M-52 mass spectrometer.

Materials. Commercial 1-hexene, 1-octene, cyclohexene, cyclooctene, benzene, and tetrahydrofuran were dried with lithium aluminium hydride and used after distillation under an argon atmosphere. Commercial 2-norbornene and 2-butene were used without any purification. The chloroform was dried over phosphorus pentaoxide and was used after distillation under an argon atmosphere.

The tetrahydrofuran solution of borane was prepared by the method described in the literature.[11]

The lead(IV) acetate was prepared by the method described in the literature,[18] its purity was above 98%.[19]

The phenyliodoso acetate was prepared by the method described in the literature;[20] mp 157—158 °C (lit, 158 °C).

Reaction of Trialkylborane with Lead(IV) Acetate. The following procedure is representative. A dry, 50-ml, round-bottomed flask, equipped with a gas inlet, a magnetic stirring bar, a septum inlet, a reflux condenser, and a dropping funnel, was flushed with argon. In the flask 5.63 ml (15 mmol) of 1-hexene was hydroborated with 5 mmol of borane in tetrahydrofuran, and then the tetrahydrofuran was removed under reduced pressure at 40 °C. In an argon atmosphere, 6.65 g (15 mmol) of lead(IV) acetate in 25 ml of benzene was added, drop by drop, to the trihexylborane through the dropping funnel, after which the solution was stirred at 55 °C for 24 h. The lead(II) acetate was precipitated as a white solid with the progress of reaction. In the analytical experiment, the solution, to which an internal standard substance has been added, was analysed by GLPC (PEG 20M, supported on Diasolid M, was used as the liquid phase). In the preparative experiment, 10 ml of water was added to the solution to destroy any residual lead(IV) acetate. Then the mixture was saturated with sodium chloride, and the lower aqueous layer was separated and extracted with pentane several times. The combined upper organic layer and pentane extracts were washed with a saturated aqueous sodium chloride solution, and dried over anhydrous sodium sulfate. On distillation at 170 °C/757 mmHg, 1.15 g of a mixture containing 7.5 mmol of hexyl acetate and 0.7 mmol of 1-methylpentyl acetate was obtained. The IR, PMR, and mass spectra of all the alkyl acetates, except for norbornyl acetate, were consistent with those obtained from authentic samples.

exo-*2-Norbornyl Acetate*: The IR spectrum showed a strong band at 1730 cm^{-1}. The mass spectrum (20 eV) was completely consistent with the standard spectrum[21] of 2-norbornyl acetate (m/e=154, M^+). PMR (CCl_4, TMS) spectrum; δ=0.95–1.95 (m, 4H, H-3,5,6,7), 1.88 (s, 3H), 2.24 (br, s, 2H, H-1,4), 4.48 (dd, 2H, $J_{H\text{-}2\,end\text{-}H\text{-}3\,exo}$=2 Hz and $J_{H\text{-}2\,end\text{-}H\text{-}3\,end}$=9 Hz.)

Reactions of Trialkylboranes with Phenyliodoso Acetate. To trialkylborane, prepared in the same manner as in the reaction with lead(IV) acetate, a 3.22-g portion (10 mmol) of phenyliodoso acetate in 20 ml of benzene was added, drop by drop, after which the mixture was stirred at 55 °C for 8 h. A yellowish homogeneous solution resulted. In the analytical experiment, the solution, into which an internal standard substance has been added, was analysed by GLPC (PEG 20M, supported on Diasolid M, was used as the liquid phase). In the preparative experiment, the solvent was removed under reduced pressure and the products were separated by column chromatography (silica gel). Iodobenzene, formed by the reduction of phenyliodoso acetate, was effectively removed by elution with hexane, and then the alkyl acetate was eluted with benzene.

Photochemical Reactions of 2-(Alkoxycarbonyl)-, 2-Cyano-, and 2-(Phenylthio)-cycloalkanones in Alcoholic Solution. Formation of ω-Substituted Esters

Masao TOKUDA, Yasuyuki WATANABE, and the late Mitsuomi ITOH

Department of Chemical Process Engineering, Hokkaido University, Sapporo 060

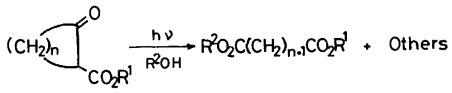
(Received August 17, 1977)

Photochemical reaction of ethyl 2-oxo-1-cyclohexanecarboxylate (**3**) in methanol gave ethyl methyl heptanedioate, *trans*- and *cis*-ethyl 7-oxo-2-heptenoate, and ethyl 7-oxo-3-heptenoate in 25, 7, 8, and 21% yields, respectively. Photochemical reactions of **3** in ethanol, isopropyl alcohol, and *t*-butyl alcohol gave the corresponding ω-alkoxycarbonyl esters. Other 2-(alkoxycarbonyl)-cyclopentanones and -cycloheptanone underwent similar reactions to give the corresponding ω-alkoxycarbonyl esters. Photochemical reactions of 2-cyanocyclohexanones in methanol similarly gave ω-cyano esters and ω-formyl α,β-unsaturated nitriles. However, photochemical reactions of 2-(phenylthio)- and 2-(methylthio)cyclohexanones in methanol did not give the corresponding ω-phenylthio or ω-methylthio carboxylic acid esters, products resulting from a preferential cleavage of a carbon-sulfur bond being obtained.

Photochemical reactions of cycloalkanones have been extensively studied.[1] Cycloalkanones undergo the Norrish Type I cleavage to give acyl alkyl biradical, which is then transformed in alcoholic solution into carboxylic acid ester *via* a ketene intermediate,[2] unsaturated aldehyde[2,3] and cyclic ether[4] as the main paths. Of these the transformation into carboxylic acid esters is of interest as regards synthesis since the employment of cycloalkanones with appropriate substituents at α-position would produce ω-substituted esters. In contrast to the photochemical reactions of 2-alkyl-substituted cycloalkanones,[1] those of other cycloalkanones substituted with alkoxycarbonyl, cyano,[5] or alkylthio groups[6] have received little attention. We have studied the photochemical reactions of such substituted cyclopentanones, cyclohexanones and cycloheptanones in alcohol solvent with emphasis placed on the ester forming reactions. Photochemical reactions of aliphatic β-keto esters undergo intermolecular hydrogen abstraction or α-cleavage to give various photoproducts.[7]

Results and Discussion

Photochemical Reaction of 2-(Alkoxycarbonyl)cycloalkanones. When a 0.16 M solution of ethyl 2-oxo-1-cyclohexanecarboxylate (**3**) in methanol was irradiated for 10 h with a 500 W high pressure mercury vapor lamp, cyclohexanone **3** was almost entirely consumed and ethyl methyl heptanedioate (**8a**), ethyl *trans*-7-oxo-2-heptenoate (**11**), ethyl *cis*-7-oxo-2-heptenoate (**12**), ethyl 7-oxo-3-heptenoate (**13**), and dimethyl heptanedioate (**14**) were produced in 25, 7, 8, 21, and 5% yields, respectively. It was confirmed that the dark reaction of **3** in methanol for 7 days gives no products. Irradiation of ethyl 2-oxo-1-cyclopentanecarboxylate (**1**), methyl 2-oxo-1-cyclopentanecarboxylate (**2**), ethyl 2-oxo-1-cycloheptanecarboxylate (**4**) and **3** in various alcohols gave the corresponding ω-alkoxycarbonyl esters (**6**—**9**) and ω-formyl unsaturated esters. We have been particularly interested in the ester forming reactions leading to products such as **6**—**9**. The yields of these products and the conversion of 2-(alkoxycarbonyl)-



1 : n=3, $R^1=C_2H_5$ 6 : n=3, $R^1=C_2H_5$ a, $R^2=CH_3$
2 : n=3, $R^1=CH_3$ 7 : n=3, $R^1=CH_3$ b, $R^2=C_2H_5$
3 : n=4, $R^1=C_2H_5$ 8 : n=4, $R^1=C_2H_5$ c, $R^2=CH(CH_3)_2$

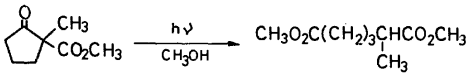
cycloalkanones are summarized in Table 1. We see that the ring size has no significant effect on the ester forming reaction, although the photochemical reaction of cyclohexanone **3** seems to be relatively slow. A large difference in conversion is seen in the photochemical reaction of **3** by employing different alcohols, but none in **1** probably due to its higher reactivity than **3**. Substitution of the alkyl group at 1-position has little effect on the yield of ω-alkoxycarbonyl ester. Irradiation of ethyl 1-methyl-2-oxo-1-cyclopentanecarboxylate (**5**) in methanol for 70 h gave dimethyl 2-methylhexanedioate (**10**) in a 29 % yield.



5 10

All the products obtained were probably formed *via* an intermediate acyl(alkoxycarbonyl)alkyl biradical, which is then transformed into ω-alkoxycarbonyl ketene or ω-formyl α,β-unsaturated ester. The ketene was converted into ω-alkoxycarbonyl ester such as **6**—**9** in alcoholic media. Decreasing conversion of cycloalkanones in methanol, ethanol, isopropyl alcohol to *t*-butyl alcohol may be due to the increase in viscosity of the latter alcohols. In more viscous alcohols such as *t*-butyl alcohol, recombination of an intermediate birad-

a) Externally irradiated with a 500 W high pressure mercury vapor lamp for 70 h. b) Based on 2-(alkoxycarbonyl)- or 2-cyanocycloalkanones consumed. c) Externally irradiated with a Pyrex filtered high pressure mercury vapor lamp for 70 h. d) Externally irradiated with a 500 W high pressure mercury vapor lamp for 90 h. e) Not isolated.

ical giving the starting cycloalkanone would occur to some extent. ω-Formyl β,γ-unsaturated ester **13** is produced by a photochemical deconjugation of ω-formyl α,β-unsaturated ester (**11**→**12**→**13**). This is seen from the results in which the decrease in the yields of **11** and **12** is accompanied by an increase in the yield of **13** with the prolongation of irradiation time. Facile photochemical isomerization of α,β-unsaturated ester to β,γ-unsaturated isomer has been studied.[8]

The UV absorption spectra of 2-(alkoxycarbonyl)cycloalkanones show a high intensity absorption of the enol tautomer in the region 255—263 nm and a low intensity absorption of the keto tautomer in the region 280—300 nm.[9] Although the latter is usually masked by the former, the non-enolizable cycloalkanones such as **5** have a low intensity absorption at 295 nm in ethanol solution, assigned to n,π^* transition of the keto tautomer. Irradiation of cycloalkanones **1**—**4** with a Pyrex filtered light (>280 nm) gave almost the same yields of ω-alkoxycarbonyl esters **6**—**9** as those with an ordinary high pressure lamp, whereas no reaction occurred when the irradiation was carried out with a 253.7 nm light. These photochemical reactions are not greatly effected by the addition of oxygen, 1,3-pentadiene,

or naphthalene. The present photochemical reactions of 2-(alkoxycarbonyl)cycloalkanones leading to ω-alkoxycarbonyl esters might proceed mainly *via* the excited n,π^* singlet of the keto tautomers.

Photochemical Reaction of 2-Cyanocycloalkanones. Photochemical reactions of 2-cyanocycloalkanones in alcohol solvent undergo similar reactions to those of 2-(alkoxycarbonyl)cycloalkanones. Irradiation of 2-oxo-1-cyclohexanecarbonitrile (**15**) and 3-methyl-2-oxo-1-cyclohexanecarbonitrile (**16**) in alcohols gave the corresponding ω-cyano esters **17** and **18** and ω-formyl α,β-unsaturated nitrile **19** and **20**. Yields and conversion in these photochemical reactions are given in Table 1.

The irradiation of 1-methyl-2-oxo-1-cyclohexanecarbonitrile in methanol has been reported to produce ω-cyano ester and ω-formyl α,β-unsaturated nitrile in a 1:13 ratio,[5] but in the present photochemical reaction of **16** they were obtained in a 2:3 ratio. In the photochemical reaction of **16**, an abstraction of tertiary hydrogen at 3-position by α-cyanoalkyl radical moiety of the intermediate biradical would occur to a considerable extent as compared with that of secondary hydrogen at 6-position by acyl radical moiety. No products resulting from the alternative cleavage of the bond between C-2 and C-3 were detected.

Photochemical Reaction of 2-(Phenylthio)cyclohexanone. Irradiation of 2-methylthiocyclohexanone (**21**) in methanol, benzene, or ether gave polymeric products. Small amounts of cyclohexanone and dimethyl disulfide were detected by GLPC analysis. Irradiation of 2-phenylthiocyclohexanone (**22**) in methanol also gave polymeric products besides a small amount of cyclohexanone. However, irradiation of **22** in benzene for 70 h gave cyclohexanone, cyclohexenone, diphenyl disulfide, diphenyl sulfide and thiophenol in the yields 34, 2, 5, 3, and 3 %, respectively. All the products obtained resulted from a preferential cleavage of a carbon–sulfur bond. Diphenyl disulfide might be formed by a combination of phenylthio radical or further photolysis of thiophenol.[6] As a result, no cleavage of Norrish Type I occurred in these photochemical reactions of 2-(phenylthio)- or 2-(methylthio)cyclohexanones.

Experimental

Gas-liquid chromatographic analyses were carried out with a Hitachi K-53 and a Hitachi 063, the preparative work being done with a Varian Autoprep 700. A SE-30 column supported on Diasolid L was mainly used in GLPC analyses. Other liquid phases were unsatisfactory because the starting 2-(alkoxycarbonyl)cycloalkanones were often decomposed in GLPC columns. Infrared spectra were obtained with a Hitachi EPI-G22, and nuclear magnetic resonance spectra were measured with a JEOL 3H-60 and a Hitachi R-22 using tetramethylsilane as an internal standard. Mass spectra were obtained with a Hitachi RM-50 GC. Quantitative GLPC analyses were carried out by an internal standard

method.

General Procedure for Irradiation. The starting cycloalkanone in alcoholic solvent (0.16 M) in a quartz tube was cooled in water and externally irradiated with a 500 W high pressure mercury vapor lamp for 70 h. Nitrogen gas was allowed to pass through the mixture during the course of irradiation. An immersion apparatus was employed for preparation. Quantitative experiments in different alcohols were carried out with a merry-go-round procedure for irradiation.

Preparations of 2-Substituted Cycloalkanones. Ethyl 2-oxo-1-cyclopentanecarboxylate (**1**), bp 107 °C/18 mmHg, was prepared from diethyl adipate and metal sodium by the method of Pinkney.[10] Methyl 2-oxo-1-cyclopentanecarboxylate (**2**), bp 105 °C/17 mmHg, was also prepared by a similar method. Ethyl 2-oxo-1-cyclohexanecarboxylate (**3**), bp 103.5 °C/12 mmHg, was prepared by the method of Snyder *et al.*[11] from cyclohexanone and diethyl oxalate. Ethyl 2-oxo-1-cycloheptanecarboxylate (**4**), bp 136 °C/22 mmHg, was prepared by the method of Krapcho *et al.*[12] from cycloheptanone and diethyl carbonate. Methyl 1-methyl-2-oxo-1-cyclopentanecarboxylate (**5**) was prepared by methylation of **2**.[13] 2-Oxo-1-cyclohexanecarbonitrile (**15**), bp 138—140 °C/15 mmHg, was prepared by the method of Satoda *et al.*[15] or Meyer[16] from 2-chlorocyclohexanone[14] and sodium cyanate. 3-Methyl-2-oxo-1-cyclohexanecarbonitrile (**16**), bp 95—96 °C/3 mmHg, was prepared by the method of Kuehne[17] from 3-methyl-2-pyrrorydino-1-cyclohexene, bp 117 °C/20 mmHg, and cyanogen chloride. 2-Methylthiocyclohexanone (**21**), bp 98—100 °C/15 mmHg, was prepared by the method of Truce *et al.*[18] from 2-chlorocyclohexanone and sodium methanethiolate. 2-Phenylthiocyclohexanone (**22**), bp 115—117 °C/3 mmHg, was prepared by the method of Seebach *et al.*[19] from cyclohexanone and diphenyl disulfide or by the method of Wilputte *et al.*[20] from 2-chlorocyclohexanone and sodium benzenethiolate. All the 2-substituted cycloalkanones were purified by a distillation or a preparative GLPC.

Photochemical Reaction of Ethyl 2-Oxo-1-cyclohexanecarboxylate (3). A mixture of 6.8 g of **3** and 250 ml of dry methanol (0.16 M) was irradiated for 10 h with an immersion apparatus using a 500 W high pressure mercury vapor lamp. After removal of the solvent, distillation gave 4.7 g of crude product; bp 60.0—85.0 °C/1 mmHg. The distillate was separated into four principal components by preparative GLPC using a SE-30 column. The second component was identified as unreacted ester **3**. The fourth component was identified as ethyl methyl hexanedioate (**8a**): IR (CCl_4) 1735 cm^{-1}; NMR (CCl_4) δ 1.22 (t, 3H), 3.59 (s, 3H), 4.05 (q, 2H), 1.62 (m, 6H), 2.22 ppm (t, 4H); *m/e* (rel intensity) 171 (M^+-OCH_3, 40), 157 ($M^+-OC_2H_5$, 48), 88 (49), 55 (100). Found: C, 59.60; H, 9.06%. Calcd for $C_{10}H_{18}O_4$: C, 59.38; H, 8.97%. The first component was further separated into two products by preparative GLPC using a CW-20 M column. One was identified as ethyl *cis*-7-oxo-2-heptenoate (**12**): IR (CCl_4) 2820, 2720, 1720, 1645 cm^{-1}; NMR (CCl_4) δ 1.30 (t, 3H), 1.77 (qi, 2H), 2.48 (t, 2H), 2.73 (q, 2H), 4.17 (q, 2H), 5.78 (dm, 1H, J=10.5 Hz), 6.24 (dt, 1H, J=10.5 Hz, J=7.5 Hz), 9.85 ppm (s, 1H); *m/e* (rel intensity) 170 (M^+, 3), 142 (16), 127 (42), 125 (50), 114 (100), 99 (93), 86 (72), 81 (83), 68 (92). Found: C, 63.20; H, 8.30%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%. The other product was identified as ethyl 7-oxo-3-heptenoate (**13**): IR (CCl_4) 2820, 2720, 1735 cm^{-1}; NMR (CCl_4) δ 1.26 (t, 3H), 2.5 (m, 4H), 3.00 (m, 2H), 4.12 (q, 2H), 5.60 (m, 2H), 9.81 ppm (s, 1H); *m/e* (rel intensity) 170 (M^+, 8), 142 (51), 127 (12), 125 (33), 124 (47), 99 (37), 97 (82), 96 (70), 79 (76), 67 (100), 55 (83). Found: C, 63.73; H, 8.21%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%. The third component was further separated into two products by preparative GLPC using a CW-20M column. One was identified as dimethyl heptanedioate (**14**) by comparison with an authentic sample, the other as ethyl *trans*-7-oxo-2-heptenoate (**11**): IR (CCl_4) 2820, 2720, 1725, 1655 cm^{-1}; NMR (CCl_4) δ 1.27 (t, 3H), 1.80 (qi, 2H), 2.24 (q, 2H), 2.48 (t, 2H), 4.17 (q, 2H), 5.80 (d, 1H, J=16.0 Hz), 6.88 (dt, 1H, J=16.0 Hz, J=6.5 Hz), 9.83 ppm (s, 1H); *m/e* (rel intensity) 170 (M^+, 2), 142 (10), 127 (36), 125 (50), 114 (82), 99 (72), 81 (100), 68 (77), 55 (53). Found: C, 63.35; H, 8.20%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%. GLPC analysis showed that the conversion of **3** was 91% and yields of **8a**, **11**, **12**, **13**, and **14** were 25, 7, 8, 21, and 5%, respectively.

When a sample of 0.16 M **3** in methanol in a quartz tube was externally irradiated for 70 h, **8a** was obtained in 25% yield.

Irradiation of **3** in ethanol for 70 h gave diethyl heptanedioate (**8b**) in 16% yield as the major product. **8b** was identified by comparison with an authentic sample.

Irradiation of **3** in isopropyl alcohol for 70 h gave ethyl isopropyl heptanedioate (**8c**) in 14% yield: IR (CCl_4) 1735 cm^{-1}; NMR (CCl_4) δ 1.18 (d, 6H), 1.24 (t, 3H), 1.65 (m, 6H), 2.20 (t, 4H), 4.05 (q, 2H), 4.90 ppm (m, 1H); *m/e* (rel intensity) 230 (M^+, 6), 185 (26), 171 (72), 143 (80), 125 (81), 101 (78), 69 (78), 55 (89), 41 (100). Found: C, 62.70; H, 9.60%. Calcd for $C_{12}H_{22}O_4$: C, 62.58; H, 9.63%.

Irradiation of **3** in *t*-butyl alcohol for 70 h gave *t*-butyl ethyl heptanedioate (**8d**) in 4% yield: IR (CCl_4) 1735 cm^{-1}; NMR (CCl_4) δ 1.23 (t, 3H), 1.40 (s, 9H), 1.55 (m, 6H), 2.13 (t, 2H), 2.22 (t, 2H), 4.06 ppm (q, 2H); *m/e* (rel intensity) 171 (28), 143 (27), 125 (27), 57 (100). Found: C, 63.63; H, 9.70%. Calcd for $C_{13}H_{24}O_4$: C, 63.90; H, 9.90%.

When a 0.08 M solution of **3** in methanol was irradiated for 42 h with a 15 W low pressure mercury vapor lamp, products such as **8a**, **11**, **12**, **13**, and **14** were not obtained. Irradiation of a 0.16 M solution of **3** in methanol in the presence of oxygen, 0.1—0.5 M 1.3-pentadiene or 0.16 M naphthalene gave **8a** in almost the same yields with nearly the same conversion.

Photochemical Reaction of Ethyl 2-Oxo-1-cyclopentanecarboxylate (1). Irradiation of a 0.16 M solution of **1** in methanol for 70 h gave ethyl methyl hexanedioate (**6a**) in 28% yield: IR (CCl_4) 1735 cm^{-1}; NMR (CCl_4) δ 1.24 (t, 3H), 1.62 (m, 4H), 2.25 (m, 4H), 3.63 (s, 3H), 4.07 ppm (q, 2H); *m/e* (rel intensity) 188 (M^+, 2), 157 (36), 143 (32), 115 (52), 111 (60), 59 (57), 55 (100). Found: C, 57.35; H, 8.50%. Calcd for $C_9H_{16}O_4$: C, 57.43; H, 8.57%.

Irradiation of a 0.16 M solution of **1** in ethanol for 70 h gave diethyl hexanedioate (**6b**) in 22% yield. **6b** was identified by comparison with an authentic sample.

Photochemical Reaction of Methyl 2-Oxo-1-cyclopentanecarboxylate (2). Irradiation of a 0.16 M solution of **2** in methanol for 70 h gave dimethyl hexanedioate (**7a**) in 32% yield. **7a** was identified by comparison with an authentic sample.

Photochemical Reaction of Ethyl 2-Oxo-1-cycloheptanecarboxylate (4). Irradiation of a 0.16 M solution of **4** in methanol for 70 h gave ethyl methyl octanedioate (**9a**) in 28% yield: IR (CCl_4) 1735 cm^{-1}; NMR (CCl_4) δ 1.24 (t, 3H), 1.6 (m, 8H), 2.25 (t, 4H), 3.65 (s, 3H), 4.08 ppm (q, 2H); *m/e* (rel intensity) 185 (M^+-OCH_3, 43), 171 (90), 143 (62), 138 (100), 129 (76), 97 (72), 88 (59), 83 (60), 69 (93), 55 (83). Found: C, 61.09; H, 9.28%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32%.

Photochemical Reaction of Methyl 1-Methyl-2-oxo-1-cyclopentanecarboxylate (5). Irradiation of a 0.16 M solution of **5** in methanol for 70 h gave dimethyl 2-methylhexanedioate

(**10**) in 29% yield: IR (CCl_4) 1735 cm^{-1}; NMR (CCl_4) δ 1.15 (d, 3H), 1.62 (m, 4H), 2.25 (t, 2H), 2.45 (m, 1H), 3.64 ppm (s, 6H); *m/e* (rel intensity) 157 (M^+-OCH_3, 17), 156 (30), 128 (48), 127 (40), 124 (47), 96 (60), 95 (59), 94 (70), 69 (100), 67 (98).

*Photochemical Reaction of 3-Methyl-2-oxo-1-cyclohexanecarbonitrile (**16**).* Irradiation of a 0.16 M solution of **16** in methanol gave three principal products. These were separated by preparative GLPC using a SE-30 column. From spectral data, the first was identified as *cis*-6-methyl-7-oxo-2-heptenenitrile (*cis*-**20**): IR (CCl_4) 2710, 2810, 2220, 1725 cm^{-1}; NMR (CCl_4) δ 1.18 (d, 3H), 1.3—2.1 (m, 2H), 2.50 (q, 2H), 2.5 (m, 1H), 5.36 (m, 1H, J=11.0 Hz), 6.47 (dt, 1H, J=11.0 Hz, J=7.5 Hz), 9.85 ppm (s, 1H), *m/e* (rel intensity) 137 (M^+), 122 (2), 108 (8), 94 (14), 81 (28), 80 (30), 67 (100), 58 (42). The second was identified as *trans*-6-methyl-7-oxo-2-heptenenitrile (*trans*-**20**): NMR (CCl_4) δ 1.14 (d, 3H), 1.3—2.0 (m, 2H), 2.27 (q, 2H), 2.54 (m, 1H), 5.37 (m, 1H, J=17.0 Hz), 6.68 (dt, 1H, J=17.0 Hz, J=7.0 Hz), 9.82 ppm (s, 1H). IR and mass spectra of *trans*-**20** were almost identical with those of *cis*-**20**. The third was identified as methyl 6-cyano-2-methylhexanoate (**18**): IR (CCl_4) 2250, 2230, 1735 cm^{-1}; NMR (CCl_4) δ 1.15 (d, 3H), 1.51 (m, 6H), 2.30 (t, 2H), 2.45 (m, 1H), 3.66 ppm (s, 3H); *m/e* (rel intensity) 138 (M^+-OCH_3, 13), 109 (47), 88 (100), 69 (44), 55 (29). Found: C, 63.75; H, 8.90; N, 8.12%. Calcd for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28%. GLPC analysis showed that the yields of *cis*-**20**, *trans*-**20**, and **18** were 5, 19, and 16%, respectively.

*Photochemical Reaction of 2-Oxo-1-cyclohexanecarbonitrile (**15**).* Irradiation of a 0.16 M solution of **15** in methanol for 70 h gave methyl 6-cyanohexanoate (**17a**) in 28% yield: IR (CCl_4) 2230, 1735 cm^{-1}; NMR (CCl_4) δ1.58 (m, 6H,) 2.31 (t, 2H), 2.32 (t, 2H), 3.66 ppm (s, 3H); *m/e* (rel intensity) 124 (M^+-OCH_3, 42), 96 (40), 74 (100), 69 (27), 59 (26), 55 (25). Found: C, 62.22; H, 8.39; N, 9.18%. Calcd for $C_8H_{13}NO_2$: C, 61.91; H, 8.44; N, 9.03%. Although product **19** was not isolated, its presence in the irradiated mixture was shown by GC-mass spectroscopy.

*Photochemical Reaction of 2-Methylthiocyclohexanone (**21**).* When a 0.16 M solution of **21** in methanol was irradiated for 70 h, the solution turned red-brown with precipitation of a solid. Removal of solvent gave tar. A slight formation of cyclohexanone was detected by GLPC analysis. Irradiation in ether or benzene afforded similar results.

*Photochemical Reaction of 2-Phenylthiocyclohexanone (**22**).* When a 0.16 M solution of **22** in methanol was irradiated for 70 h, the solution turned red-brown with precipitation of a solid. GLPC analysis showed that 76% of **22** was consumed, a slight amount of cyclohexanone being produced. Similar irradiation in benzene produced cyclohexanone, cyclohexenone, diphenyl disulfide, diphenyl sulfide, and thiophenol in 34, 2, 5, 3, and 3% yields, respectively. The conversion of **22** was 94%.

(Received August 25, 1977)

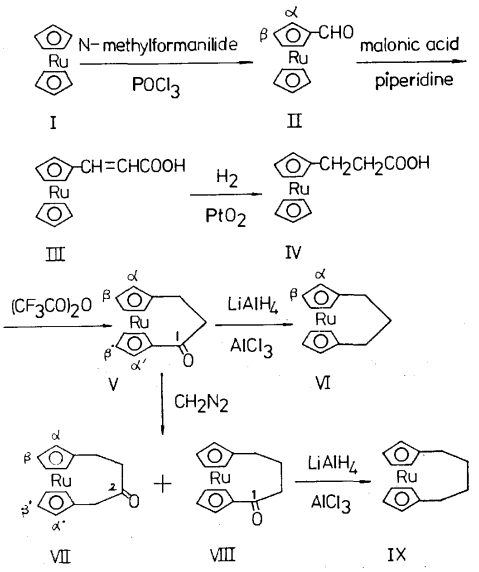
[3]- and [4]ruthenocenophanes as well as other ruthenocene derivatives were synthesized. The preparation of ruthenocenes in this experiment required more forced reaction conditions than those of the corresponding ferrocenes. Two cyclopentadienyl rings of these ruthenocenophanes are found to tilt mutually, and the degree of the ring-tilting of [3]ruthenocenophane is greater than that of the [4] homolog.

A large number of heteroannularly bridged ferrocenes, designated [m]ferrocenophanes, have played important roles in the investigations of the physical and chemical properties of the ferrocene molecule.[2] On the other hand, there have been only a few investigations of [m]ruthenocenophanes or of other ruthenocene derivatives.[3] Recently, the first synthesis of [5]ruthenocenophanes has been reported.[4] This paper will be concerned with the syntheses and characterizations of several new [3]- and [4]ruthenocenophanes. The introduction of a heteroannularly bridged carbon chain into a ruthenocene molecule will cause a distortion of the cyclopentadienyl rings from their normal parallel geometry. The degree of the tilting of two cyclopentadienyl rings and of the conformational flexibility of linking chains is expected to depend on the length of the carbon chain and on the steric circumstances. These steric effects will be discussed on the basis of proton magnetic resonance, infrared and electronic spectra.

Results and Discussion

Synthesis of [3]Ruthenocenophan-1-one (V) and [3]Ruthenocenophane (VI). The introduction of a three-carbon interannular bridge into a ruthenocene molecule was achieved by the cyclization of 3-ruthenocenylpropionic acid (IV) to V. Compound IV was prepared from formylruthenocene (II). Bublitz *et al.* have previously reported that, in the presence of $POCl_3$, the reaction of ruthenocene (I) with *N*-methylformanilide in chlorobenzene led to the formation of II in only a 8% yield.[5] However, we have found that II is formed in a reproducibly good yield (46%) by the reaction of I with *N*-methylformanilide without any solvent in the presence of $POCl_3$. The condensation of II with malonic acid afforded 3-ruthenocenylacrylic acid (III). The hydrogenation of III in ethanol over PtO_2 gave IV quantitatively. An intramolecular Friedel-Crafts-type reaction of IV with trifluoroacetic anhydride required a longer reaction time (two weeks) in refluxing cyclohexane than that needed in the case of the ferrocene derivative.[6] This difference in the reaction conditions of cyclization may be because ruthenocenes are generally less reactive and because the distance between two cyclopentadienyl rings of a ruthenocene is longer than that of a ferrocene.[7,8] Compound VI was prepared by the reduction of V with lithium aluminum hydride-aluminum trichloride in the usual manner.

Synthesis of [4]Ruthenocenophan-2-one (VII) and [4]Ruthenocenophane (IX). In a mixture of methanol and ether, the reaction of V and diazomethane led to the formation of VII, accompanied by a small amount of [4]ruthenocenophan-1-one (VIII), while the reduction of VII with lithium aluminum hydride-aluminum trichloride gave a good yield of IX (Scheme 1).



Scheme 1. Syntheses of ruthenocenophanes.

Proton Magnetic Resonance Spectra. The details of the ^1H NMR spectra of ruthenocenes, together with the reported spectra of ferrocenes,[9] are summarized in Table 1. The assignments of the signals of ruthenocene derivatives are based on those of the corresponding ferrocenes and multibridged ferrocenophanes.[10] It has previously been reported that, in the ^1H NMR spectra of ferrocene derivatives, alkyl substituents do not cause a noticeable difference in the chemical shift between α- and β-protons of the cyclopentadienyl rings to which they are attached.[9] The most striking manifestation of the ring tilt in [m]ferrocenophanes with different bridge lengths is the variation in the cyclopentadienyl ring proton patterns.[9] In the case of VI, the protons of cyclopentadienyl rings appear as two unsymmetrical triplets separated by 0.23 ppm, corresponding to an A_2B_2 system where vicinal and cross-ring coupling constants are approximately equal and considerably smaller than the chemical shift difference between unlike protons.[9] Compound IX also shows two triplets separated by 0.11 ppm. On the basis of the ^1H NMR spectrum, Rinehart *et al.*[11] have suggested that the tilting rings of [3]ferrocenophane serve to bring the α-protons of the rings closer to the Fe atom

than the β-protons, therefore, the former experience a greater shielding influence. Extending this hypothesis, the larger splitting of the ring proton resonance of VI implies a greater dihedral angle of the two rings compared to the [4] homolog (IX). Barr and Watts have reported that the singlet resonance of [4]ferrocenophane is in accord with an undistorted ferrocene nucleus.[9] On the other hand, the splitting of the ring proton resonance of IX seems to suggest that the rings are mutually inclined to some extent, in contrast to the case of [4]ferreocenophane. This difference might be due to the distance between the two cyclopentadienyl rings of a ruthenocene being longer by 1.1 Å than that of a ferrocene.[8] Since the peak separation of VI is greater than that of IX, furthermore, the rings of the former might be tilted more than those of the latter.

The bridging methylene protons of VI and IX appear as one broad singlet and two multiplets respectively. In the case of V and VII, again, bridging methylene protons appear as two triplets and as two triplets and one singlet respectively. On the other hand, the methylene protons of [3]ferrocenophan-1-one and [4]ferrocenophan-2-one appear as sharp singlets, and Barr and Watts have suggested that facile conformational interconversion within the bridge is clearly indicated by the appearance of the bridging methylene protons as sharp singlets in the ^{1}H NMR spectra of [3]- and [4]ferrocenophane classes.[9] These results, therefore, seem to indicate that [3]- and [4]ruthenocenophanes (V, VII) have a smaller conformational flexibility than the corresponding ferrocenophanes.

Infrared Spectra. The values of the carbonyl-stretching absorptions of ruthenocenes, together with the reported values of the corresponding ferrocenes,[6,7,12] are given in Table 2. The absorption bands of the ruthenocene series are located at positions similar to those of the corresponding ferrocenes except for [3]ruthenocenophan-1-one (V). The difference in the carbonyl-stretching frequencies of V and acetylruthenocene is only 2 cm^{-1}, while that of [3]ferrocenophan-1-one and acetylferrocene is 23 cm^{-1}. In view of the following three factors: (i) the distance between two cyclopentadienyl rings of a ruthenocene is longer than that of a ferrocene,[8] (ii) the ^{1}H NMR chemical shift difference between the α- and β-protons of the cyclopentadienyl rings in ruthenocenophanes is larger than that in the corresponding ferrocenophanes, and (iii) the IR absorption bands of acetylruthenocene, acetylferrocene and V, in which π-orbitals of carbonyl groups can effectively conjugate with π-systems of cyclopentadienyl rings, are located at lower frequencies than those of [4]ruthenocenophan-2-one (VII), [4]ferrocenophan-2-one, and [3]ferrocenophan-1-one,[6,13] though these spectra should have been measured in dilute solutions, it is assumed that the cyclopentadienyl rings of ruthenocenophanes are more inclined than those of the corresponding ferrocenophanes.

Electronic Spectra. The details of the electronic spectra of ruthenocene derivatives are listed in Table 3. Figure 1 shows the electronic spectra of VI and IX, along with that of ruthenocene (I) in ethanol. The

electronic spectra of d^6 metallocene including I have been thoroughly studied.[14] According to the earlier band assignments, the absorption peak in the 320—330 nm region for each compound corresponds to the spin-allowed d-d transitions (two $^1A_{1g}\rightarrow{}^1E_{1g}$ and one $^1A_{1g}\rightarrow{}^1E_{2g}$), and the intense band at *ca.* 240 nm is associated with the charge transfer transitions of metal to ligand and ligand to metal. Although the spin-allowed d-d bands of I, VI and IX are located at similar positions, the band intensity of VI is much higher than that of I or IX. On the contrary, the intensity of the charge transfer bands of VI is lower than that of I or IX. The intensity of the spin-allowed d-d bands of IX is slightly higher than that of I, though their over-all spectra resemble each other. The cyclopentadienyl rings are distorted from their normal sandwich geometry when they are connected by short chains. The ^1H NMR study suggested that the cyclopentadienyl rings of VI are more inclined than those of IX. Thus, the ring-tilting will bring about an increase in the intensity of the spin-allowed d-d bands and a depression in the intensity of the charge transfer bands. The inclination of the cyclopentadienyl rings upon the introduction of bridging chains seems to alter the degree

of the overlap between the metal d-orbitals and the p-orbitals of cyclopentadienyl rings. Furthermore, the ligand-field strength is changed with a distortion of rings from their normal parallel geometry. These effects might change the spectra of the present ruthenofcene derivatives.

Experimental

Materials. All the melting points are uncorrected. Ruthenocene (I) was prepared according to the method described by Hofer and Schlögl.[3]

Measurements. The ^1H NMR spectra were obtained with a JEOL JNM-PMX-60 spectrometer (60 MHz) at room temperature. All the chemical shifts are expressed in δ (ppm; downfield from internal Me_4Si). The IR spectra were measured in KBr pellets with a Hitachi Model 285 infrared spectrometer. The electronic spectra were recorded with a Shimadzu Double 40-R spectrophotometer at room temperature.

Formylruthenocene (II). Into a flask containing 8.0 g (0.035 mol) of ruthenocene (I), we vigorously stirred three portions of 12.46 g (0.092 mol) of *N*-methylformanilide and 8.82 g (0.057 mol) of phosphoryl chloride every 2 h at 90 °C under a nitrogen atmosphere. After the addition of 86.4 g of sodium acetate trihydrate in 400 ml of water, the solution was refluxed for 1 h, and then stirred overnight at room temperature. The solution was extracted three times with ether which had been washed successively with a hydrochloric acid solution (1 M), water, saturated sodium hydrogencarbonate, and finally brine, and then dried over anhydrous sodium sulfate. The ether extract, concentrated to 100 ml, was shaken with a solution of 36 g of sodium hydrogensulfite in 400 ml of water. The hydrogensulfite addition compound was washed with ether and then dried. The hydrogensulfite addition compound was taken up in 200 ml of a sodium hydroxide solution (2 M), and the liberated aldehyde was extracted into ether. The combined ether extract was washed with brine and then dried over anhydrous sodium sulfate. After the removal of the solvent, the sublimation of the crude product gave 4.2 g (46%) of formylruthenocene (II); mp 103—104 °C(hexane-dichloromethane), (lit,[3] 86—87 °C). IR(KBr) 1649 cm^{-1} (C=O). Found: C, 50.92; H, 3.85%. Calcd for $C_{11}H_{10}RuO$: C, 50.97; H, 3.89%.

3-Ruthenocenylacrylic Acid (III). The aldehyde (II) (5.5 g), malonic acid (5.5 g), and piperidine (1.3 ml) were dissolved in pyridine (100 ml), and the mixture was heated at 100 °C for 2 h under a nitrogen atmosphere. The cooled solution was diluted with water and extracted with chloroform. The chloroform extract was washed with dilute hydrochloric acid and water, and then extracted with a 2 M sodium hydroxide solution. The acidification of the aqueous layer precipitated 3-ruthenocenylacrylic acid (III) (5.4 g; 85%); mp 228—229 °C (dioxane-water). IR(KBr) 1666 (C=O) and 1612 cm^{-1} (C=C). Found: C, 51.71; H, 4.18%. Calcd for $C_{13}H_{12}RuO_2$: C, 51.83; H, 4.02%.

3-Ruthenocenylpropionic Acid (IV). The hydrogenation of 4.0 g (0.013 mol) of III in 400 ml of ethanol over 50 mg of PtO_2 gave 4.0 g (98%) of 3-ruthenocenylpropionic acid (IV); mp 99—100 °C (petroleum ether). IR(KBr) 1824 cm^{-1} (C=O). Found: C, 51.68; H, 4.61%. Calcd for $C_{13}H_{14}RuO_2$: C, 51.49; H, 4.65%.

[3]Ruthenocenophan-1-one (V). A solution of 3.00 g (0.0099 mol) of IV and 50 g (0.238 mol) of trifluoroacetic anhydride in 800 ml of cyclohexane was refluxed for 2 weeks under a nitrogen atmosphere. The cooled solution was poured into a saturated sodium hydrogencarbonate solution, extracted three times with ether which had been washed to neutrality, and then dried over anhydrous sodium sulfate. The removal of the solvent left 2.26 g (80%) of the crude product; mp 175—176 °C (acetone-water). Found: C, 54.74; H, 4.12%. Calcd for $C_{13}H_{12}RuO$: C, 54.74; H, 4.24%.

[3]Ruthenocenophane (VI). An ether solution (150 ml) of V (1.0 g) was added to a suspension of litihum aluminum hydride (0.2 g) and aluminum trichloride (0.8 g) in ether (50 ml). After refluxing for 4 h, the excess reagent was decomposed with moist ether and then with water. The resulting reaction mixture was extracted three times with ether which had been washed with water, saturated sodium hydrogencarbonate and finally brine, and then dried over anhydrous sodium sulfate. The removal of the solvent left 0.84 g (90%) of the crude product; mp 123—124 °C (hexane). Found: C, 57.30; H, 5.23%. Calcd for $C_{13}H_{14}Ru$: C, 57.56; H, 5.20%.

[4]Ruthenocenophan-2-one (VII) and [4]Ruthenocenophan-1-one (VIII). To a solution of 2.0 g (0.0070 mol) of V in 100 ml of methanol and 150 ml of ether, we added 100 ml of an etheral solution containing 0.050 mol of diazomethane. The solution was kept at 0 °C in the dark for 10 h, and then evaporated *in vacuo*. The residue was column-chromatographed over silica gel. The first band, eluted with benzene, yielded 1.5 g (71%) of [4]ruthenocenophan-2-one (VII); mp 165—166 °C (hexane-dichloromethane). Found: C, 56.12; H, 4.78%. Calcd for $C_{14}H_{14}RuO$: C, 56.19; H, 4.72%.

The second band, eluted with benzene-ethyl acetate (4 : 1), yielded a small amount of [4]ruthenocenophan-1-one (VIII) which was not isolated in the pure state.

[4]Ruthenocenophane (IX). This compound was prepared in a 73% yield under the same conditions as VI; mp 73—74 °C (benzene). Found: C, 58.89; H, 5.88%. Calcd for $C_{14}H_{16}Ru$: C, 58.94; H, 5.65%.

The Chlorination of Hydrocarbons. XIV. The Chlorination of Vinyl Compounds[1)]

Kiyonori SHINODA

Toyama Technical College, Hongo, Toyama 930-11

(Received September 5, 1977)

The competitive chlorination of various vinyl compounds was carried out in order to elucidate the effect of the structure on the addition rate of chlorine to a double bond. A linear free-energy relationship was found to exist between the reactivities in the presence of oxygen and Taft's σ^* constants. The ρ^* value was calculated to be -1.20. On the other hand, the plot deviated slightly from a straight line; this shows the Taft relationship between the reactivities for the photochlorination and σ^* values, known as an extra acceleration due to the hyperconjugation of the alkyl group.

Paraffin hydrocarbons have been photochlorinated in the liquid phase by Migita and his co-workers.[2,3)] The gas-phase photochlorination of several chloroethanes has also been performed by Mack.[4)] Both groups of workers found Taft's $\rho^*\sigma^*$ relationship to be obeyed. While there have been such extensive studies of the substitutional chlorination, though only a little is known about the addition of chlorine to a double bond.

The effect of the structure on the rate of chlorination was investigated by carrying out competitive reactions with various vinyl compounds.

Experimental

Reagents. All the reagents used in this work were purchased from the Tokyo Kasei Kogyo Co. except for the carbon tetrachloride and hydroquinone, which were obtained from Wako Pure Chemical Industries. They were all of a G.R. or E.P. grade and were not purified further. The chlorine and oxygen were taken from commercial cylinders and were passed through a sulfuric acid trap before use.

Photochemical Procedure. The chlorination was carried out in 100-ml, flat, cylindrical, semibatch Pyrex reactor.[5)] A mixture of two vinyl compounds (both 0.1 mol), hydroquinone (0.001 mol) and hexachloroethane (0.002 mol) in 50 ml of carbon tetrachloride was added to the reactor. Hexachloroethane was useful as the standard material of gas chromatography.

The reactor was immersed in a thermostat at 30 °C and illuminated with a 100-W mercury lamp (Ushio UM-102) placed 5.0 cm above the reaction vessel. The chlorine was fed into the reactor at the rate of 0.1 mol/h. After a period required for the attainment of steady conditions, the irradiation was started. At regular time intervals, 1-ml samples were taken from the reacting solution and analyzed by means of gas chromatography (Shimadzu GC-5, SDC 550 or PEG 6000).

Dark Chlorination Procedure in the Presence of Oxygen. The dark chlorination procedure was the same as that used in the photochemical reaction except for the use of the oxygen. The chlorine and oxygen gases were led from the cylinders through a mixer to the reactor at the rates of 0.1 and 0.04 mol/h respectively.

Results

It is well known that the liquid-phase chlorination of linear olefins gives predominantly addition products, while the chlorination of olefins with branching at the double bond gives predominantly allylic substitution products.[6)] These vinyl compounds were found to give predominantly addition products, accompanied by minor amounts of allylic substitution products. In all the runs, two vinyl compounds were competitively chlorinated in order to keep the effect of the induction period and the concentration of chlorine constant

throughout an experiment. The plots of the conversion of vinyl compounds into the addition products against the reaction time are found to be linear, as is shown in Figs. 1 and 2. Figure 1 shows the competitive photochlorination of allyl chloride and 3-chloro-1-butene as typical experimental data. The results of the competitive chlorination of these compounds for a dark run with oxygen are shown in Fig. 2. The values of the relative rate constants were calculated from the slopes of these straight lines, obtained according to the previous paper.[7] These relative rate constants are given in the first two columns of Table 1.

Discussion

As can be seen from Table 1, the rate of chlorination was increased by the electron-releasing substituent group and decreased by the electron-withdrawing group. Since the reactivity seemed to be affected by the polar nature of the substituent, Taft's equation was applied to this chlorination:

$$\log k/k_0 = \rho^*\sigma^*, \quad (1)$$

where k/k_0 is the relative rate constant with respect to the standard reaction (allyl chloride in this case).

The logarithms of the relative rate constants for the photochemical chlorination of vinyl compounds are plotted against Taft's substituent constants, σ^* (Fig. 3). Figure 4 shows also Taft's $\rho^*\sigma^*$ plot for the dark chlorination in the presence of oxygen. It is said that the chlorination of unsaturated compounds in nonpolar media proceeds according to the polar and radical pathways.[9] Then, the competitive chlorinations of methyl acrylate and cyclohexane were carried out in order to confirm that either pathway is predominant. The procedure was the same as has been described in the Experimental section. The results of such experiments are summarized in Fig. 5. A dark chlorination under oxygen produced mainly methyl 2,3-dichloropropionate, while chlorocyclohexane was detected in a trace amount. On the other hand, chlorocyclohexane was formed by the substitutive chlorination of cyclohexane for a photochemical reaction, The attack on

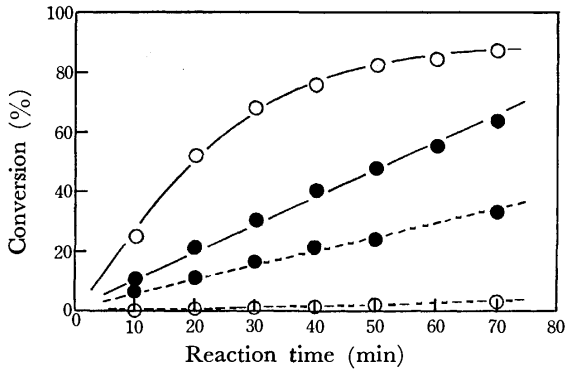

Fig. 5. Competitive chlorination of methyl acrylate and cyclohexane at 30 °C.
○: Chlorocyclohexane from cyclohexane, ●: methyl 2,3-dichloropropionate from methyl acrylate.
——: Illuminated, ----: darkness.

the completely saturated substrate, cyclohexane, is compelling evidence for the presence of free radical chains. The photochlorination took place more rapidly than the dark chlorination in the presence of oxygen, as can be seen by comparing Fig. 1 with 2. This phenomenon is also observed in Fig. 5. In general, the reaction under oxygen became just slow enough to allow a pale yellow color to appear in a solution during the chlorine addition. For a series of dark runs under oxygen, the chlorination of a substrate with an electron-withdrawing group was fairly slow (Table 1).

It has been reported that terminal and linear olefins followed the radical pathway, whereas olefins with carbon-chain branching at the double bond followed the polar pathway.[9] The polar pathway was also described to be favored by the dilution of the olefin at low olefin concentrations for the dark runs, but this effect could be counteracted with light.[10]

Therefore, it was concluded that the chlorination of these vinyl compounds at higher concentrations under illuminated conditions proceeded predominantly according to the radical pathway. The photochlorination is a radical reaction, while the dark chlorination under oxygen is an ionic one since oxygen acts as a radical inhibitor. The reactivity pattern of the chlorine atom toward vinyl compounds is similar to that of the chlorine molecule, as is shown in Figs. 3 and 4.

A linear free-energy relationship might be found to exist between the relative rate constants of the ionic reaction and Taft's σ^* constants. The ρ^* value was calculated to be -1.20. On the other hand, in the case of the radical reaction, the relative rate constants were slightly more dependent on Taft's σ^* constants than those of the dark runs and the plot seemed to deviate from a straight line, making a concave curve. This phenomenon has been known in connection with the photochlorination of chloroethanes as an extra acceleration by the hyperconjugation effects of the alkyl group.[2] Accordingly, it may be thought that the hyperconjugation of the alkyl group is similarly pronounced during the photochlorination of vinyl compounds.

In α-olefin, the electron displacement produced by the electron-releasing alkyl group renders the terminal carbon susceptible to attack by positive chlorine:

$$R\rightarrow CH=CH_2 \longleftrightarrow R-\overset{\oplus}{C}H-\overset{\ominus}{\underset{\cdot\cdot}{C}}H_2. \quad (1)$$

On the contrary, nitrile group of acrylonitrile is electron-withdrawing, and the electron displacement causes the unsubstituted carbon atom to become more positive, as is indicated in Formula (a) by a curved arrow.

$$H\equiv C-CH=CH_2 \longleftrightarrow \overset{\ominus}{\underset{\cdot\cdot}{N}}=C=CH-\overset{\oplus}{C}H_2 \quad (2)$$

(a) (b)

Owing to the electron displacement, the unsubstituted carbon atom carries a positive charge and is particularly inaccessible to the electrophilic agents (b).

The dark chlorination of vinyl compounds in the presence of the radical inhibitor oxygen proceeds through ionic intermediates. Taft[6] has suggested that these intermediates can explain an ionic-type mechanism for which the rate-determining step is the addition of a positive chlorine ion to form a carbonium ion and a negative chlorine ion. Therefore, the relative rate constants for the chlorination of various vinyl compounds under oxygen supported an electrophilic attack by the chlorine molecule.

The reactions of chlorine atom with ring-substituted toluenes[11,12] as well as chloroethanes[2,4] have been studied, and the chlorine atom might be thought of as an electrophilic radical.

Both reactions are electrophilic and have negative values of ρ^*. The negative values of ρ^* indicate that the electron-donating substituents increase the addition rate of chlorine to the double bond, in agreement with the previous data indicating that the hydrogen abstraction by a chlorine atom is an electrophilic reaction.

^{13}C NMR Chemical Shifts and Cationic Reactivity of Linear Conjugated Dienes

Kan-ichi HASEGAWA, Ryuzo ASAMI, and Kensuke TAKAHASHI

Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466

(Received October 5, 1977)

The chemical shifts of the C_1 and C_2 of *trans*-1-alkyl-1,3-butadienes were correlated with Taft's σ^*, the proportionality constants being -35.9 and 12.3 ppm/σ^*, respectively. The values 6.2 and -43.6 ppm/σ^* were obtained for the C_1 and C_2 of 2-alkyl-1,3-butadienes, respectively. The observed chemical shifts of disubstituted butadienes roughly agreed with the values estimated from those of monosubstituted butadienes by means of additivity relationship. The cationic reactivity of linear conjugated dienes should be determined by the magnitude of the steric restriction of substituents and that of the stability of the resulting cation.

The cationic polymerizability of linear conjugated dienes has been discussed in preceding papers,[1-8] with particular attention given to the relation between the structure and the reactivity of the monomers. The relative reactivity of the monomers toward a styryl cation has been explained in terms of the magnitude of both the stability of the resulting cation and the steric hindrance between substituents.[4-8]

In general, an electrophilic reagent attacks on the carbon in butadienyl framework in the mode of forming the most stable cation. Its position is considered to be that of the carbon of the highest electron density in the conjugated double bonds. Thus, knowledge of electron distribution in the ground state of the dienes is helpful for understanding the chemical reactivities of conjugated dienes.

This paper deals with the polarization of conjugated dienes in relation to their reactivity. ^{13}C NMR measurements have been made for both alkyl-1,3-butadienes and phenyl-1,3-butadienes. A discussion is given on whether ^{13}C NMR chemical shifts of the dienes, accepted as an index of the electronic distribution of monomers in the ground state, are correlative to the relative reactivity of the dienes.

Experimental

1- and 2-phenyl-1,3-butadienes,[1,2] methyl and phenyl-substituted 1,3-butadienes,[6] 1- and 2-alkyl-1,3-butadienes,[7] and dimethyl-1,3-butadienes[8] were prepared as described previously.

^{13}C NMR spectrum was measured at 10 MHz on a Hitachi R-26 spectrometer. ^{13}C chemical shifts were determined for neat liquids by using benzene as an internal reference (10% by volume) and then converted into δ_c values (TMS reference) by using $\delta(C_6H_6) = 128.7$ ppm.

Theoretical Calculation

Quantum chemical calculations were carried out by the CNDO/2 method[9] and parametrization without further modification. Convergence was judged from the energy level criterion of 1.0×10^{-3} eV in all the orbital energies. The atomic coordinates of the butadienes were determined from the following bond distances and bond angles: –C=C–, 1.34 Å; =C–C=, 1.48 Å; =C–H, 1.08 Å; –C–H, 1.09 Å; =C–C–, 1.51 Å; –C–C–, 1.54 Å; C=C (aromatics), 1.39 Å; C–C_6H_5, 1.51 Å; ∠C–C–C, ∠C–C–H, 109°28′; ∠C=C–C, ∠C=C–H, 120°. Computations were made on a FACOM 230—75 Computer at the Data Processing Center of Kyoto University.

Results

^{13}C NMR Chemical Shifts of Alkyl-1,3-butadienes. The signals for alkyl-1,3-butadienes in the ^{13}C NMR spectra were assigned by means of off-resonance proton-decoupling and additivity relationship.[10,11] The chemical shifts obtained for alkyl-1,3-butadienes are given in Table 1. The signals for butadiene skeleton appeared over a span of 50 ppm in the range 107—157 ppm. Introduction of an alkyl group on C_1 of butadiene caused the signal for C_4 in the highest field among the four butadiene carbon signals.

In the case of *trans*-isomers, the chemical shift of the substituted carbon moved toward lower field by 16—30 ppm and its neighbor carbon absorption toward higher field by 6—10 ppm. Although the magnitude for the γ effect was small, the signal for the C_3 nucleus showed an upfield shift of 0.6—1.0 ppm. The signal for the C_4 was shifted to higher field by 2 ppm regardless of the kind of alkyl substituent. Alkyl substituents such as methyl, ethyl, and *t*-butyl groups deshielded the C_1 nuclei by 16.6, 19.7, and 29.2 ppm, and shielded the C_2 nuclei by 7.7, 6.3, and 10.4 ppm, respectively.

The alkyl substitution of the corresponding ethylenes also produced consistent changes such as 10.3, 17.4, and 25.6 ppm for the C_α shielding in downfield shift and 7.8, 10.0, and 14.4 ppm for the C_β shielding in upfield shift, respectively.[12,13] The deshielding effect of the alkyl group on the C_α is greater in 1-alkyl-1,3-butadienes than in 1-alkenes, the reverse being true for the shielding effect of the alkyl group on the C_β. The signals for the butadienyl carbons of the *cis* isomers appeared at higher field than those of their *trans* isomers except for the C_4 nucleus.

In the ^{13}C NMR spectra of 2-alkyl-1,3-butadienes, the signal for the C_1 appeared at the highest field. The signals for the C_1 and C_4 nuclei moved to higher field in comparison with those of butadiene. The reverse was true for both the C_2 and C_3 nuclei. The difference between C_1 and C_2 chemical shifts increased with an increase in the bulkiness of alkyl group. Introduction of an alkyl group such as methyl, ethyl, isopropyl, and *t*-butyl groups on the C_2 of butadiene gives rise to the deshielding of the C_2 nuclei by 5.7, 11.1, 16.0, and 20.0 ppm and the shielding of the C_1 nuclei by 3.2, 3.7,

a) $\overset{6}{C}-\overset{5}{C}-\overset{1}{C}=\overset{2}{C}-\overset{3}{C}=\overset{4}{C}$, $\overset{1}{C}=\overset{2}{C}-\overset{3}{C}=\overset{4}{C}$ neat sample, room temperature. b) Downfield from TMS. c) See Ref. 10.

$\overset{5}{C}-\overset{6}{C}$

d) $\overset{1}{C}=\overset{2}{C}-\overset{3}{C}=\overset{4}{C}$ (with $\overset{5}{C}$ and $\overset{6}{C}$) e) $\overset{1}{C}=\overset{2}{C}-\overset{3}{C}=\overset{4}{C}$ (with $\overset{5}{C}$ and $\overset{6}{C}$)

4.2, and 9.0 ppm, respectively, in comparison with those of butadiene. These changes of the chemical shifts of the C_1 and C_2 of 2-alkyl-1,3-butadiene were smaller than those of either 1-alkyl-1,3-butadienes or 1-alkenes.

The signal due to the central carbon of the alkyl group in the neighborhood of butadiene skeleton moved to lower field by 4—12 ppm for the substitution of an α-hydrogen by methyl group, *i.e.*, $-C-H \rightarrow -C-CH_3$. This deshielding effect was larger in 1-alkyl-1,3-butadiene than in 2-alkyl-1,3-butadiene.

The chemical shifts of dimethyl-1,3-butadienes roughly agreed with the values estimated from the data of both 1,3-pentadiene and isoprene by means of the additivity relationship. The difference between the observed and the estimated values was the largest for the chemical shift of 1,2-dimethyl-1,3-butadiene. The chemical shifts of the C_4 nuclei in dimethyl-1,3-butadienes moved to higher field in the order 2,4-hexadiene < 1,3-dimethyl-1,3-butadiene < 2,3-dimethyl-1,3-butadiene < 1,2-dimethyl-1,3-butadiene.

^{13}C NMR Chemical Shifts of Phenyl-1,3-butadienes. The ^{13}C chemical shifts of phenyl-1,3-butadienes are summarized in Table 2. A certain uncertainty is inevitable in the assignment of closely spaced signals within *ca.* 1 ppm. Introduction of a phenyl group on either the C_1 or C_2 of butadiene gives rise to a deshielding of the C_4 nucleus by 1 ppm. The chemical shifts of the C_1 and C_2 of 1-phenyl-1,3-butadiene moved 16.5 ppm to downfield and 7.5 ppm to upfield relative to those of butadiene, respectively. In the case of styrene, these values have been reported to be 13.9 ppm and 9.6 ppm, respectively.[14)] The chemical shift of the C_3 was not affected by introduction of 1-phenyl group. On comparing the data for 2-phenyl-1,3-butadiene with butadiene, we find a change of 11.6 ppm for the C_2 and 0.7—1.5 ppm for the C_1, C_3, and C_4. The chemical shifts of the C_1 and C_4 of 2-phenyl-1,3-butadiene were the same as that of the C_4 of 1-phenyl-1,3-butadiene.

Table 2. ^{13}C Shieldings of phenyl-1,3-butadienes[a)]

Compound	Chemical shift (ppm)[b)]

a) Neat sample, room temperature. b) Downfield from TMS. c) 1-PB=1-phenyl-1,3-butadiene, 2-PB=2-phenyl-1,3-butadiene.

The substituent effect on the shieldings of the butadienyl skeleton of methyl and phenyl-substituted 1,3-butadienes can also be estimated by means of the additivity relationship. An application of the additivity relationship for the chemical shift of methyl and phenyl-substituted 1,3-butadiene was shown to be more relevant than that of dimethyl-1,3-butadienes. Methyl substitution on the C_1 position of 1-phenyl-1,3-butadiene

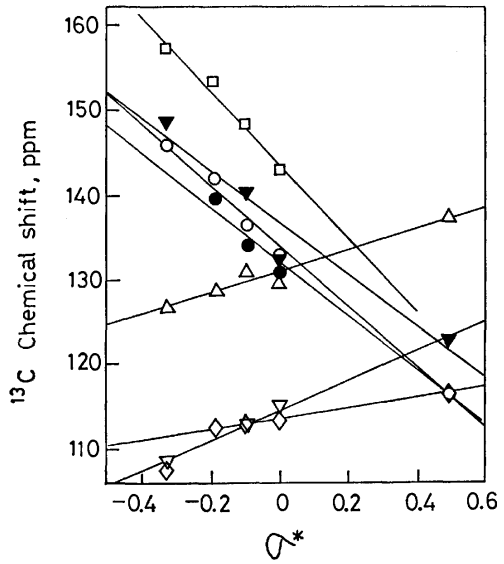

Fig. 1. Hammett plots of the ^{13}C chemical shifts of alkyl-1,3-butadienes and 1-alkenes against Taft's σ*: *trans*-1-alkyl-1,3-butadienes; ○, C_1 ($\rho^* = -35.9 \pm 1.7$ ppm/σ*); △, C_2, ($\rho^* = 12.3 \pm 1.7$ ppm/σ*); *cis*-1-alkyl-1,3-butadienes; ●, C_1, ($\rho^* = -32.3 \pm 3.3$ ppm/σ*); 2-alkyl-1,3-butadienes; ◇, C_1 ($\rho^* = 6.2 \pm 0.3$ ppm/σ*) □, C_2 ($\rho^* = -43.6 \pm 5.0$ ppm/σ*), 1-alkenes; ▽, C_1 ($\rho^* = 17.4 \pm 0.8$ ppm/σ*); ▼, C_2 ($\rho^* = -30.7 \pm 4.9$ ppm/σ*).

gives rise to the upfield shift of the C_2 as known for its β-effect. The signal for the C_4 also shifted to higher field than that estimated by means of the additivity relationship. The chemical shift of the C_4 of 1-phenyl-1,3-butadiene was not affected by introduction of a methyl group on the C_3. In 1-phenyl-1,3-pentadiene, the C_4 was no longer the most electron-rich carbon in the butadienyl framework. The signal for the C_4 of 1-methyl-1-phenyl-1,3-butadiene appeared at the highest field among the butadienyl groups of these nine phenyl-1,3-butadienes.

Discussion

Sensitivity Constants for the ^{13}C Chemical Shifts of Alkyl-1,3-butadienes. Figure 1 shows the Hammett plots of the chemical shifts of both alkyl-1,3-butadienes and 1-alkenes against Taft's σ*. A slope of −35.9 ppm/σ* was obtained from the correlation of the C_1 chemical shifts of *trans*-1-alkyl-1,3-butadienes with σ*. The value is slightly more negative than that for the C_2 chemical shifts of 1-alkenes whereas the reverse is true for the C_2 chemical shifts. No linear correlation with σ* was found for the C_3 and C_4 shieldings of 1-alkyl-1,3-butadienes; the signals for the C_3 and C_4 showed a downfield shift of 0.5—1.0 ppm and an upfield shift of 2 ppm, respectively, regardless of the kind of alkyl group.

Thus, the 1-alkyl group caused the shielding of both the C_2 and C_4 and the deshielding of both the C_1 and C_3 in the butadiene framework. The results suggest that the substituent effect is transmitted on the conjugated framework by alternation in a mode of decaying. On the ^{13}C chemical shifts along the conjugated framework of *trans*-1-substituted-1,3-butadiene, Kajimoto and Fueno[15] also concluded that the substituent effect in conjugated dienes is transmitted mainly through its π-framework by successive polarization of the –CH=CH– groups involved. However, the polarization of conjugated double bonds by the alkyl group was so small that the chemical shifts of the C_3 and C_4 were not correlated with Taft's σ*. The rearrangement of a charge caused by the introduction of an alkyl group was mainly the polarization between the C_1 and C_2 rather than a net transfer of charge from the alkyl group to the butadienyl framework, as shown in the results of CNDO/2 calculation of 1,3-pentadiene (Table 3).

In 2-alkyl-1,3-butadienes, linear correlations with σ* were found for both the C_1 chemical shifts excluding that of 2-*t*-butyl-1,3-butadiene and the C_2 chemical shifts. The ρ* value obtained for the C_1 shielding, 6.2 ppm/σ*, was smaller than that for the C_1 of the corresponding 1-alkenes. The ρ* value of −43.6 ppm/σ* obtained for the C_2 chemical shifts is 1.4 times as negative as that for the C_2 of the 1-alkenes. No correlation is found between the C_4 and σ*.

Hyperconjugation, polarization through π- and σ-bonds, and a field effect directly operative through space are seen in transmitting the substituent effect of alkyl group in 2-alkyl-1,3-butadienes. The results showing that the shielding of the C_4 approaches that of the C_1 in the order methyl<ethyl<isopropyl might be explained in terms of the field effect of the alkyl group. Unexpected values of the C_1 and C_4 chemical shifts of 2-*t*-alkyl-1,3-butadiene were observed since this compound cannot take a coplanar transoid form owing

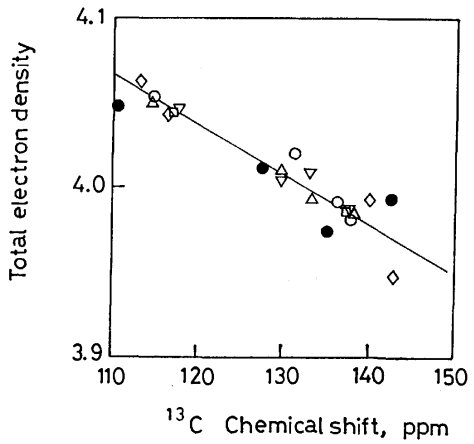

Fig. 2. Correlation of the ^{13}C chemical shifts of 1,3-butadienes with the total electron densities calculated by using the CNDO/2 method: ○, *trans*-1,3-hexadiene; △, *trans*-1,3-pentadiene; □, 1,3-butadiene; ▽, *trans*-1-phenyl-1,3-butadiene; ◇, isoprene; ●, 1,2-dimethyl-1,3-butadiene.

to the steric hindrance.[16]

Correlation of ^{13}C Chemical Shift with Total Electron Density. Figure 2 shows a correlation of ^{13}C chemical shift of 1,3-butadienes with the total electron density of carbon. Proportionality constant 340 ppm/e was obtained; this is about twice as large as the generally accepted value of 160 ppm/e for the π-electron densities in aromatics. The electron density of the butadienyl carbon can be estimated by means of its ^{13}C chemical shift.

Position Attacked by a Carbonium Ion. In general, propagating ends attack on the C_4 of 1-alkyl-1,3-butadienes and mainly the C_1 of 2-alkyl-1,3-butadienes.[6] These selective positions are due to both the carbon of the greatest electron density in the butadienyl framework and the highest stability of the resulting cation. These factors can be applied to the determination of the attacked position of dimethyl-1,3-butadienes. An attack of styryl cation on the most electron-rich carbon in the conjugated double bonds results in the highest stable cation. In nine phenyl-1,3-butadienes (Table 2), however, the positions of *trans*/*cis*-4-methyl-1-phenyl-1,3-butadienes and 1-methyl-2-phenyl-1,3-butadiene attacked by a styryl cation coincide not with that of the carbon of the highest electron density in the conjugated double bonds but the position forming the highest stable cation. Thus, the latter is the predominant factor in determining the position attacked by a carbonium ion.

Reactivity of Linear Conjugated Dienes. The relative reactivity of linear conjugated dienes toward a styryl cation is given in Table 4. The reactivities of 1- and 2-alkyl-1,3-butadienes decrease with an increase of the bulkiness of alkyl group.[7] The chemical shift of the C_4 of 1-alkyl-1,3-butadienes is unaffected whereas that of the C_1 of 2-alkyl-1,3-butadienes moves to higher field with an increase of the inductive effect of alkyl group. Thus, the order of reactivity of the alkyl-1,3-butadienes is related not to the electron density of the carbon in the ground state but to the magnitude of the steric hindrance between the monomer and an attacking cation.

Table 4. Reactivity of conjugated dienes toward a styryl cation[a]

Substituents	$1/r_1$[b]	Relative reactivity[c]	Chemical shift[d] (ppm)

2-Phenyl-	0.59	0.35	117.3
1-Methyl-2-phenyl-	0.95	0.57	131.9
3-Methyl-2-phenyl-	0.63	0.38	117.8

a) Using $SnCl_4$·TCA in methylene chloride at −78 °C. b) Styrene (M_1)-diene (M_2). c) Relative reactivity for 1-phenyl-1,3-butadiene. d) ^{13}C shielding of the butadienyl carbon, attacked by a styryl cation, downfield from TMS.

The reactivity of dimethyl-1,3-butadiene can be explained not in terms of the electron density of either the C_4 or the C_1 in the ground state but the stability of the resulting allylic cation. In the case of dimethyl-1,3-butadienes, no steric hindrance in transition state on the electrophilic reaction needs to be taken into consideration except for 2,4-hexadiene.

When steric hindrance in the propagation of phenyl-1,3-butadiene series toward a styryl cation is of minor importantance or almost the same, the reactivity of the monomer increases with an increase in the stability of the resulting cation rather than in the electron density of the carbon attacked by cation. The methyl group introduced on either the β- or the δ-carbon, numbered from the terminal carbon attacked by the cation, enhances the reactivity to the extent of about 15—20, whereas methyl substitution on the γ-carbon produces a small increase or decrease in the reactivity up to the extent of 1.1.

The relative reactivity of linear conjugated dienes toward an electrophilic reagent can be determined by both the magnitude of the steric restriction of substituents and that of the stability of the resulting cation. Thus, for a detailed discussion on the reactivity of the butadienes, the above factors should be taken into consideration in addition to the information on ^{13}C NMR spectra.

The authors wish to express their gratitude to Mr. Kunimi Fujieda for the measurements of ^{13}C NMR spectra.

The Reaction of 2,4,6-Trimethylbenzonitrile *N*-Oxide with Polysubstituted *p*-Benzoquinones

Shinsaku SHIRAISHI, Satoru IKEUCHI, Manabu SENŌ, and Teruzo ASAHARA
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received November 4, 1977)

The reaction of 2,4,6-trimethylbenzonitrile *N*-oxide with various di- and tetrasubstituted *p*-benzoquinones and the structures of the products were studied. All of the tetrasubstituted quinones gave dioxazole derivatives through addition at the carbonyl site, whereas the disubstituted quinones gave dioxazoles or isoxazoline derivatives depending on the substituents. The reactivity of the quinone carbonyl toward the nitrile oxide varies with the substituents and with the substitution pattern; this phenomenon is discussed in terms of the resonance and inductive effects of the substituents.

Nitrile *N*-oxide is known to be a typical 1,3-dipole and to undergo 1,3-dipolar cycloaddition reaction with various unsaturated compounds to give heterocycles. *p*-Benzoquinones have two kinds of potential reactive sites, *i.e.*, two C=C and two C=O bonds. Cycloaddition with unsubstituted *p*-benzoquinone is known to occur at the C=C bond to give isoxazoline derivatives, which are then oxidized to isoxazoles.[1] In general, C=C bonds are more reactive than C=O bonds toward 1,3-dipoles, and so cycloaddition preferentially takes place at a C=C bond.[2] In a previous paper,[3] however, we reported that tetrahalo-*p*-benzopuinones (*p*-haloanils) make C=O addition with aromatic nitrile *N*-oxides to form dioxazole derivatives. Recently, cyclobutenediones have been reported to undergo this type of addition with mesitonitrile *N*-oxide.[4] The carbonyl addition has also been reported in the reaction of diazomethane with *p*-benzoquinones having all of the hydrogens replaced by electronegative groups.[5] 2,6-Dimethoxy-*p*-benzoquinone has also been shown to make carbonyl addition with diazomethane.[6] The dependence of the addition site on the substituents and the substitution pattern of the quinone will give a certain clue to the consideration of the exact nature of the cycloaddition reaction. In this respect, the reactions of mesitonitrile *N*-oxide with various polysubstituted *p*-benzoquinones were investigated; the results will be discussed in this paper. The effects of substituents on the reactivity of quinone carbonyls will also be discussed in terms of both inductive and resonance effects.

Results and Discussion

Mesitonitrile *N*-oxide (2,4,6-trimethylbenzonitrile *N*-oxide, MNO) was allowed to react with tetramethyl-*p*-benzoquinone (DQ), tetramethoxy-*p*-benzoquinone (TMOQ), 2,5-dichloro-3,6-dimethoxy-*p*-benzoquinone (25DCMOQ), 2,6-dichloro-3,5-dimethoxy-*p*-benzoquinone (26DCMOQ), 2,6-dibromo-3,5-dimethoxy-*p*-benzoquinone (26DBMOQ), 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), 2,3-dichloro-1,4-naphthoquinone (23DCNQ), 2,6-dimethyl-*p*-benzoquinone (26DMQ), 2,5-dimethyl-*p*-benzoquinone (25DMQ), 2,6-dimethoxy-*p*-benzoquinone (26DMOQ), 2,5-dimethoxy-*p*-benzoquinone (25DMOQ), and 2,6-dichloro-*p*-benzoquinone (26DCQ) in chloroform at room temperature.

All of the tetrasubstituted quinones gave 1 : 1-carbonyl addition products, some of which added another MNO to give 1 : 2-adducts. The PMR spectrum of the 1 : 1-adduct from DQ and MNO (**1**) shows two singlets, at 1.92 and 2.10 ppm(δ), with a relative area corresponding to each six protons due to methyl groups on the quinone moiety, and that of the 1 : 2-adduct (**2**) shows a singlet resonance signal, at 1.98 ppm, with a relative area corresponding to twelve protons due to four methyl groups on the quinone residue. The IR spectrum of the latter has no absorption band in the $\nu_{C=O}$ region (1650—1750 cm^{-1}). TMOQ gave a 1 : 1-adduct (**3**) and no 1 : 2-adduct because of its very low reactivity. The adduct **3** has two singlet resonance signals in its PMR spectrum due to methoxyl groups on the quinone moiety. 25DCMOQ gave one 1 : 1-adduct and one 1 : 2-adduct. The PMR and IR spectroscopic aspects are substantially similar to those of the corresponding adducts from DQ. Thus, the

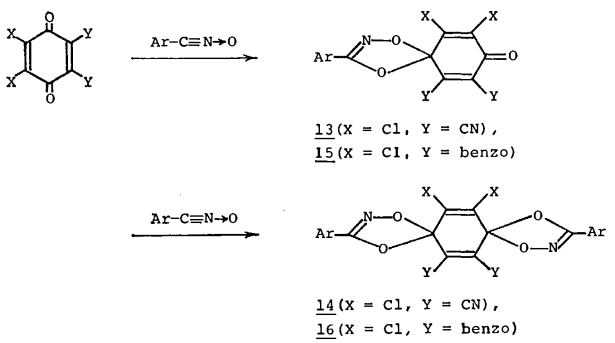
a) All of the reactions were conducted in chloroform at room temperature, unless otherwise cited. b) All of the products were purified by recrystallization from hexane, unless otherwise noted. c) Unreacted starting materials were recovered. The yields based on the reacted starting materials were almost quantitative. d) The 1 : 1-adduct **1** was also obtained in a 32% yield based on DQ. e) Recrystallized from methanol. f) Recrystallized from a mixture of hexane and chloroform. g) DNO means 2,3,5,6-teramethylbenzonitrile *N*-oxide. h) See the experimental section. i) This reaction gave a complicated mixture of products. Attempts to separate and characterize the other products were not successful.



Scheme 3.

quinones with two carbonyls with equal structural surroundings gave only one 1 : 1-adduct, as is shown in Schemes 1 and 3. On the other hand, some of the quinones with two carbonyls with different structural surroundings, such as 26DCMOQ and 26DBMOQ, gave two 1 : 1-adducts, which then gave the same 1 : 2-adduct upon the addition of another MNO. The addition site of the 1 : 1-adduct was determined by PMR spectroscopy, as will be discussed later. All of the 1 : 2-adducts obtained here may be mixtures of *cis* and *trans* isomers, as was observed for the 1 : 2-adduct from chroranil and MNO.[3] Attempts to separate them, however, have not yet been successful.

Disubstituted quinones also gave 1 : 1-adducts; their structures were also determined to be those of carbonyl addition products except for those from dimethylquinones, 25DMQ and 26DMQ, which gave isoxazoline derivatives as the main products and some other unisolable by-products. Between the C=O and C=C addition products, a distinct difference is observed in their PMR spectra. The resonance signal due to 2- and 6- methyls on the mesityl residue of the C=O adduct appears as a single peak at a lower field than that due to 4-methyl protons, which always appears around 2.3 ppm, independently of the substitution patterns of the starting quinones. On the other hand, the resonance signal of the C=C adduct appears at a higher field than that of 4-methyl, which also appears at about 2.3 ppm. The upper-field shift of the 2- and 6-methyl signals can be interpreted in terms of their increased shielding by the magnetic anisotropy of the carbonyl in the C=C addition product, where the two methyls are located in the vicinity of the carbonyl group and where one methyl is above, and the other below, the plane of the group. Furthermore, some differences are observed in the spectra of the quinone moieties. For example, the methoxyl and methine on the quinone moiety of the adduct from 26DMOQ (**9**) resonate at 3.80 and 5.48 ppm respectively, each as one singlet, whereas those of the adduct from 26DMQ (**11**) each appear at two different positions. This can reasonably be explained only by considering that **9** is a spiro-dioxazole derivative and **11** is an isoxazoline derivative, as is shown in Scheme 2. The two singlets, each with relative areas corresponding to three protons in the PMR spectrum of **11**, are due to aliphatic and olefinic methyls respectively, while the other two singlets, each corresponding to one proton, are due to angular and olefinic hydrogens respectively. The structure of the C=C addition products may be considered to be that shown in Schemes 1 and 2, judging from the chemical shifts of the angular methyl and methine

protons of the adducts. The characterization data for all of the addition products are summarized in Table 1, and the PMR data, in Table 2.

The structures of the 1 : 1-carbonyl addition products from such quinones as are shown in Scheme 2, the carbonyls of which have different structural surroundings, were determined by means of their PMR spectra, as will be described below. A comparison of the chemical shifts of the 2- and 6-methyls on the mesityl residue among the six 1 : 1-adducts, **3**, **6a**, **6b**, **9**, **10**, and the 1 : 1-adduct from MNO and chloranil,[3] reveals that the adduct from chloranil, **6b**, and **10** have the same chemical shift of 2.46—2.47 ppm, while the others have one of 2.39—2.40. This fact can be explained by assuming that the methyls of the former adducts interract with the chlorine atoms on the quinone moieties, and those of the latter, with the methoxyl groups. Thus the structures of the **6a**, **6b**, **9**, and **10** adducts were determined to be such as are shown in Scheme 2. As to the two isomereric adducts from MNO and 26DBMOQ ,the **7a** isomer, the signal due to the 2- and 6-methyls of which appears at 2.40 ppm, is determined to be formed by the addition of MNO to the carbonyl with methoxyl substituents on its α and α' positions, and the **7b** isomer, the signal of which is at 2.52 ppm, by such an addition to the carbonyl on the other side. This assignment was made by the comparison of the chemical shift of the corresponding methyl groups of the adduct from MNO and bromanil, the signal of which appears at 2.53 ppm.[3] This is supported by the fact that **7a** and **7b** gave the same 1 : 2-adduct upon the addition of another MNO and that the 1 : 2-adduct shows two signals, at 2.40 and 2.53 ppm, due to the 2- and 6-methyls on the mesityl residues attached to the two sides.

The structure determination presented above reveals the following facts: 26DMOQ and 26DCQ added MNO at more sterically hindered carbonyl, and made no further addition. DQ gave a 1 : 2-adduct with MNO, but TMOQ gave only a 1 : 1-adduct. 26-DCMOQ and 26DBMOQ gave two isomers of the 1 : 1-adducts, and the major products were those formed by addition to the carbonyls on the methoxyl-substituted side.

These results imply that the carbonyl addition is governed by the resonance and inductive effects of the quinone substituents. The resonance effect reduces the reactivity of the carbonyl on its meta-position, while the positive inductive effect enhances the reactivity of the carbonyl. This conclusion is very qualitative, but it can explain the facts described above and also the fact that the reactivity of tetrasubstituted quinones decreases in the order of; DDQ, tetrahalo-*p*-benzoquinones, 26DCMOQ, and 26DBMOQ. A marked reduction in the reactivity by the resonance effect is clearly seen in the facts that 25DMOQ does not react at all with MNO under the given reaction conditions and that the reactivity of 25DCMOQ is much less than that of 26DCMOQ.

Experimental

All the melting points cited are uncorrected. The characterization data for the products are given in Table 1. The PMR spectra were recorded with a Hitachi R-20A or a R-22 spectrometer. The Mass spectra were determined with a Hitachi RMU-7L high-resolution mass spectrometer.

Materials. The 2,6-dichloro-*p*-benzoquinone (26DCQ) 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), and 2,3-dichloro-1,4-naphthoquinone (23DCNQ) were commercially obtained and were used after recrystallization. The 2,5- and 2,6-dimethyl-*p*-benzoquinones (25 and 26DMQ) were prepared from 2,5- and 3,5- dimethylphenols respectively.[7] The 2,6-dimethoxy-*p*-benzoquinone (26DMOQ) was prepared by the nitric acid oxidation of pyrogallol trimethyl ether, which had itself been obtained by the methylation of pyrogallol with dimethyl sulfate.[8] The 2,6-dichloro- and 2,6-dibromo-3,5-dimethoxy-*p*-benzoquinones (26DCMOQ and 26DBMOQ) were prepared from 26DMOQ by chlorination and bromination respectively.[8] The tetramethoxy-*p*-benzoquinone (TMOQ) was synthesized by treating 26-DBMOQ with sodium methoxide.[8] The tetramethyl-*p*-benzoquinone (DQ) was prepared from durene,[9] and the 2,5-dichloro-3,6-dimethoxy-*p*-benzoquinone (25DCMOQ), from chloranilic acid.[10]

Reaction of Quinones with Mesitonitrile N-*Oxide (MNO).* The reactions were conducted by dissolving the reactants in chloroform in a concentration of about 5 mmol/300 ml and by then allowing the mixture to react at ambient temperatures for a given period. After the reaction, the solvent was evaporated and the residue was treated by means of column chromatography on silica gel (Wako gel C-100), with a benzene or chloroform eluent. The reaction conditions and the results are tabulated in Table 1. Some typical examples follow.

*6,10-Dichloro-3-mesityl-1,4-dioxa-2-azaspiro[4.5]deca-2,6,9-trien-8-one (**10**)*: A solution of 1.00 g (5.65 mmol) of 26DCQ and 0.910 g (5.65 mmol) of MNO in 300 ml of chloroform was stirred for 15 h at room temperature. Then, the solvent was evaporated under a reduced pressure, and the residue was treated with column chromatography on silica gel with benzene. The elute was recrystallized from hexane to give the title compound, which weighed 1.47 g (77%).

*7,9-Dibromo-3-mesityl-6,10-dimethoxy-1,4-dioxa-2-azaspiro[4.5]-deca-2,6,9-trien-8-one (**7a**) and 6,10-Dibromo-3-mesityl-7,9-dimethoxy-1,4-dioxa-2-azaspiro[4.5]deca-2,6,9-trien-8-one (**7b**)*: A solution of 1.60 g (4.91 mmol) of 26DBMOQ and 0.790 g (4.91 mmol) of MNO in 300 ml of chloroform was stirred for 24 h at room temperature. The solvent was then evaporated to complete dryness under a reduced pressure, without heating, to give a reddish brown solid. The solid was treated with hot hexane to separate the hexane-soluble part from the insoluble one. Cooling the hot solution gave 0.50 g (21%) of the crystals of **7a**. The subsequent evaporation of the filtrate gave 1.40 g of the residue, most of which was determined to be **7a**. The hexane-insoluble part weighed 0.30 g (13%) and was recrystallized from methanol to give 0.13 g of **7b**. The PMR spectrum of the reddish-brown solid above showed that the reaction was almost completed; the product composition ratio of **7a** to **7b** was estimated to be about 7 : 1 by a comparison of the intensities of the signals at 4.20 and 3.96, which are due to the methoxyl groups on the quinone moieties of **7a** and **7b** respectively.

*6,14-Dibromo-3,11-dimesityl-7,13-dimethoxy-1,4,9,12-tetraoxa-2,10-diazadispiro[4.2.4.2]tetradeca-2,6,10,13-tetraene (**8**)*: A solution of 1.60 g (4.91 mmol) of 26DBMOQ and 1.58 g

(9.82 mmol) of MNO in 300 ml of chloroform was stirred at room temperature for 70 h. The subsequent evaporation of the solvent and recrystallization of the residue from hexane gave 2.39 g (75%) of the title compound.

*3-Mesityl-6,7,9,10-tetramethyl-1,4-dioxa-2-azaspiro[4.5]deca-2,6,9-trien-8-one (**1**)*: A solution of 1.00 g (6.1 mmol) of DQ and 1.00 g (6.2 mmol) of MNO in 200 ml of chloroform was allowed to stand at an ambient temperature for 20 days, after which the solvent was evaporated to give a yellow viscous oil, which was subsequently treated by means of column chromatography on silica gel with benzene. MNO, DQ, and the title compound were eluted out in that order. The product weighed 1.0 g (50%), and the recovered MNO and DQ weighed 0.5 g each.

*3,11-Dimesityl-6,7,13,14-tetramethyl-1,4,9,12-tetraoxa-2,10-diazadispiro[4.2.4.2]tetradeca-2,6,10,13-tetraene (**2**)*: A reaction of 0.82 g (5.1 mmol) of MNO with 0.40 g (2.5 mmol) of DQ in 150 ml of chloroform at an ambient temperature for 30 days gave 0.62 g (51%) of the title compound and 0.26 g (32%) of the 1 : 1-adduct, **1**, upon the column chromatography of the reaction products.

*3-Mesityl-3a,5(or 6,7a)-dimethyl-3a,4,7,7a-tetrahydrobenzisoxazole-4,7-dione (**11**)*: A solution of 0.70 g (5.1 mmol) of 26DMQ and 0.82 g (5.1 mmol) in 200 ml of chloroform was let stand at room temperature for 15 h; solvent was then evaporated to leave a tan yellow solid, which was washed with hexane to remove the hexane-highly soluble part. The residue was recrystallized from hexane to give 0.50 g (33%) of the title compound. Several components were observed in the hexane washing by TLC, but all attempts at their separation have not yet been successful.

Reaction of Benzonitrile N*-Oxide (BNO) with 26DCQ. 6,10-Dichloro-3-phenyl-1,4-dioxa-2-azaspiro[4.5]deca-2,6,9-trien-8-one (**18**)*: Into a solution of 0.55 g (3.53 mmol) of benzhydroxamoyl chloride in 20 ml of tetrahydrofuran (THF), was added, drop by drop, a solution of 0.36 g (3.54 mmol) of triethylamine in 10 ml of THF at a temperature below 0 °C. The triethylammonium chloride thus precipitated was removed by filtration, and the filtrate was added to a solution of 0.48 g (2.71 mmol) of 26DCQ in 30 ml of THF. The mixture was allowed to react with stirring at room temperature for 6 h, and then the solvent was removed by evaporation. The residue was treated with column chromatography on silica gel with benzene to give 0.10 g (24% based on the starting benzhydroxamoyl chloride) of 3,4-diphenyl-1,2,5-oxadiazole 2-oxide (diphenylfuroxan), 0.40 g of an unidentified oil, and 0.33 g (36% based on the quinone) of the title compound.

Abnormal Wallach Rearrangement of 4-Alkylazoxybenzenes

Ichiro SHIMAO and Shigenori MATSUMURA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi, Toyama 933

(Received June 20, 1977)

The major product in the reaction of 4-alkylazoxybenzenes with sulfuric acid is not 4-(*p*-alkylphenylazo)phenol, which is regarded as the usual product of Wallach rearrangement. The following azophenols were obtained as major products; 2-alkyl-5-(phenylazo)phenol (R : Me), 2-alkyl-4-(phenylazo)phenol (R : Et), and 4-(phenylazo)phenol (R : *i*-Pr and *t*-Bu).

In a previous paper,[1] the present authors reported abnormal Wallach rearrangement for 4,4'-dialkylazoxybenzenes. For example, it was found that, in the reaction of 4,4'-dimethylazoxybenzene, the hydroxyl group was mainly introduced into the meta position of the azo group, and that reactions of 4,4'-dialkylazoxybenzenes take place more rapidly than does that of azoxybenzene.

On the other hand, it was reported that, when α-4-methylazoxybenzene was treated with concentrated sulfuric acid, the main product is 4-(*p*-tolylazo)phenol.[2,3] In order to evaluate the effect of the alkyl group, it appears important to investigate the rearrangement of 4-alkylazoxybenzenes (**1**). It was found that the main rearrangement product of 4-methylazoxybenzene (**1a**) differs from that described in the literature.[2,3] Furthermore, in the present paper, the reactions of some 4-alkylazoxybenzenes are discussed.

Results and Discussion

4-Alkylazoxybenzenes were treated with 85% sulfuric acid at 50 °C. The reaction products were separated by column chromatography in most cases.

Table 1 shows the results for the reactions of *p*-tolyl-NNO-azoxybenzene (**1aα**) and *p*-tolyl-ONN-azoxybenzene (**1aβ**). Both **1aα** and **1aβ** gave 2-methyl-5-(phenylazo)phenol (**2a**) as the major rearrangement product. The structure of **2a** was confirmed in the following way. This compound (**2a**) was acetylated using a conventional method. The acetate was identified by comparison with a sample obtained by condensation of 3-acetoxy-4-methylaniline and nitrosobenzene. Contrary to earlier reports,[2,3] 4-(*p*-tolylazo)-phenol (**4a**) was obtained only as a minor product.

The α isomer of **1a** reacted somewhat faster than the β isomer. This agrees with the results of kinetic studies reported by Hahn, *et al.*[4] The mp and IR spectra of the recovered azoxy compounds were identical with those the respective starting materials. Consequently, **1aα** and **1aβ** do not rapidly isomerize with each other under the reaction conditions. Furthermore, **1aα** and **1aβ** gave similar proportions of reaction products.

Since the α and β isomers of **1** were not separately available, excepting **1a**, mixtures of α and β isomers of **1** were used. These were prepared by hydrogen peroxide oxidation of the corresponding 4-alkylazobenzene (**6**). It has been reported that the oxidation of asymmetrical azobenzenes give a mixture of azoxybenzene isomers (the isomer ratio is about 1 : 1), excepting azobenzenes having special substituents in the ortho position.[5] The results for the reaction of **1** (in a mixture of the α and β isomers) are also shown in Table 1.

In the reaction of **1b**, the main rearrangement product was 2-ethyl-4-(phenylazo)phenol (**3b**), and azophenols, **2b**, **4b**, and **5**, were also formed. 4-Isopropyl- and 4-*t*-butyl-azoxybenzenes, **1c** and **1d**, gave mainly **5**. The reaction products varies with the type of alkyl group. Except for the formation of **4**, the effect of the alkyl group on the distribution of reaction products is similar to that in reactions of 4,4'-dialkylazoxybenzenes.[6] Gaschromatographic analysis of the reaction products showed that a small amount of a 2-hydroxyazo compound was formed in each case. However, it could not be determined whether the azophenol was 5-alkyl-2-(phenylazo)phenol or 2-(*p*-alkylphenylazo)phenol.

The formation of various azophenols may be interpreted by the mechanism shown in Scheme 1. Normal Wallach rearrangement is generally explained by a dicationic intermediate mechanism,[7] which consists of

Table 1. Reaction of 4-alkylazoxybenzenes with sulfuric acid

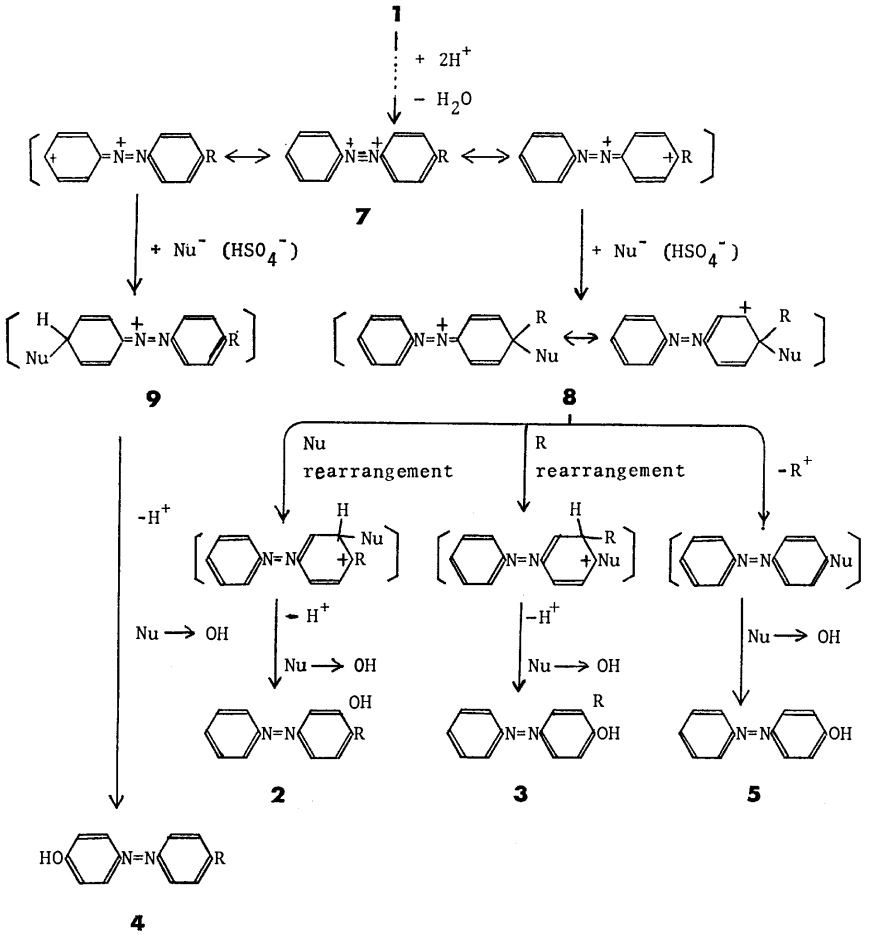


Scheme 1.

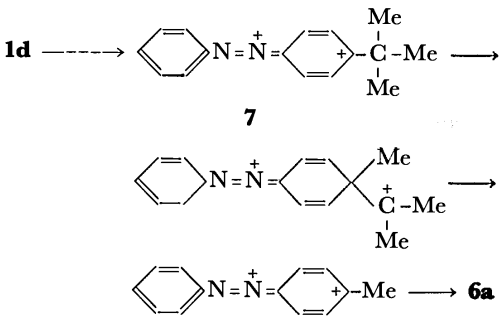
the formation and the nucleophilic attack of dicationic intermediate (**7**), followed by the deprotonation of **9**, and the conversion of the nucleophilic group into a hydroxyl group to give **4**. The following explanations involve some modification of the dicationic mechanism.

The dicationic intermediate (**7**) is formed by the diprotonation and subsequent dehydration of **1**. Subsequently, when the nucleophile, probably HSO_4^-, attacks the carbon atom having an alkyl group in **7**, the intermediate ion (**8**) is formed. The routes for the formation of azophenols, **2**, **3**, and **5**, from **8** are similar to those proposed previously for the Wallach rearrangement of 4,4'-dialkylazoxybenzenes.[1]

It is generally stated that 4-substituted 4'-hydroxyazobenzenes are the main products of Wallach rearrangement of 4-monosubstituted azoxybenzenes.[2,3,8] However, **1a** and **1b** gave only small amounts of **4**, that is, the reactions proceed weakly along this route in the case of **1**. The benzene ring having an alkyl group of **7** is preferentially attacked by a nucleophile yielding **8**, because of the electron-releasing effect of the alkyl group.

Similarly, in the reaction of an azoxybenzene with an electron-releasing group at its meta position, a hydroxyl group was found to be introduced mainly into the benzene ring having the substituent. For example, 3-methylazoxybenzene (a mixture of the α and β isomers) gave 2-methyl-4-(phenylazo)phenol (yield 30%) and only a 2% yield of 4-(*m*-tolylazo)-phenol,[9] while 3-methoxyazoxybenzene (a mixture of the α and β isomers) gave 2-methoxy-4-(phenylazo)-phenol (yield 26%).

In all case, substituted azobenzenes were also formed. Furthermore, **1d** gave **6a** in a 5% yield, namely, the *t*-butyl group was replaced by a methyl group. The mechanism of azobenzene formation is still unknown. Although the pathway from **7** to **6** is obscure, it appears likely that a methyl group in the *t*-butyl group migrates to the carbon atom of the benzene ring in **7** and then the isopropyl moiety is eliminated.



Experimental

The IR spectra were recorded with a JASCO IRA-1 spectrophotometer. The NMR spectra were obtained with a JEOL MH-100 spectrometer using TMS as the internal standard. The gas-chromatographic analysis was carried out

using a Shimadzu GC-2C apparatus on a 0.75 m × 3 mm column packed with 2% Silicone OV-225. The high-speed liquid-chromatographic analysis was carried out using a JASCO-FLC 150 apparatus on a 0.5 m × 2.1 mm column packed with JASCODAC SV-02 (the solvent was methanol-water), JASCOSIL WC-01 (the solvent was hexane-chloroform), or WC-03 (the solvent was hexane). All melting points are uncorrected.

Azoxybenzenes. 4-Methylazoxybenzenes, **1a**α and **1a**β, were prepared using methods described in the literature. **1a**α, mp 50.5—51.5 °C (lit,[10] 50—51 °C). **1a**β, mp 62—64 °C (lit,[5] 63.5—64 °C). Compounds **1a**—**1d** were obtained by oxidation of the corresponding azobenzenes with hydrogen peroxide.[11] The products were recrystallized from hexane, or subjected to chromatography on an alumina column (the solvent was benzene), yield: 85%. It was shown by a comparison of their NMR spectra with those of **1a**α and **1a**β that the products were mixtures of the α and β isomers. However, the isomer ratios, α/β, could not be determined. **1a**, mp 30—36 °C (lit,[12] 30—35 °C). **1b**, oil, Found: C, 74.48; H, 6.40; N, 12.34%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%. **1c**, mp 36—45 °C. Found: C, 75.05; H, 6.83; N, 11.59%. Calcd for $C_{15}H_{16}N_2O$: C, 74.97; H, 6.71; N, 11.66%. **1d**, mp 25—36 °C. Found: C, 75.40; H, 7.00; N, 11.15%. Calcd for $C_{16}H_{18}N_2O$: C, 75.56; H, 7.13; N, 11.02%.

4-Alkylazobenzenes. Compounds **6a**—**6d** were prepared by the condensation of nitrosobenzene and the corresponding 4-alkylaniline in acetic acid.[13] The products were purified by chromatography on alumina column (the solvent was benzene) and by recrystallization from ethanol. **6a**, mp 66—67 °C (lit,[14] 66—67 °C). **6b** (yield, 71%), mp 26—27 °C. Found: C, 79.69; H, 6.84; N, 13.33%. Calcd for $C_{14}H_{14}N_2$: C, 79.96; H, 6.71; N, 13.32%. **6c** (yield, 76%), mp 46.5—47.5 °C. Found: C, 80.15; H, 7.44; N, 12.54%. Calcd for $C_{15}H_{16}N_2$: C, 80.32; H, 7.19; N, 12.49%. **6d** (yield, 70%) mp 48—49 °C. Found: C, 80.82; H, 7.60; N, 11.70%. Calcd for $C_{16}H_{18}N_2$: C, 80.63; H, 7.61; N, 11.76%.

The Reactions of 4-Alkylazoxybenzenes with Sulfuric Acid. A solution of **1** (0.005 mol) in 85% sulfuric acid (25 ml) was heated at 50 °C for 30 min. The reaction mixture was poured into cold water and then extracted with chloroform. The organic phase was washed with water, and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was subjected to chromatography on a silica gel (Wakogel C-200) column using benzene as the solvent.

First fraction. This fraction was a mixture of **1**, **6** and small amounts of 2-hydroxy-4-(or 4'-)alkylazobenzenes which were analyzed using gas chromatography. Furthermore, the mixture was again subjected to chromatography on an alumina column using hexane-benzene (2:1) as the solvent. Fraction 1 gave **6** and fraction 2 gave **1**. In the case of **1d**, fraction 2 upon rechromatography gave **6a**, mp 66.5—67 °C, and fraction 3 gave **1d**. The mp and IR spectra of azobenzenes **6a**—**6d** and of the recovered **1a**α and **1a**β were in good agreement with those of respective authentic samples. Other recovered **1a**—**1d** were identified by comparing their IR spectra and GC retention times with those of the corresponding starting materials.

Second fraction. Recrystallization from benzene gave 2-alkyl-5-(phenylazo)phenol (**2**). **2a**, mp 153.5—154.5 °C. Found: C, 73.49; H, 5.61; N, 13.40%. Calcd for $C_{13}H_{12}N_2O$: C, 73.56; H, 5.70; N, 13.20%. **2b**, mp 136—137 °C. Found: C, 74.35; H, 6.19; N, 12.29%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%.

Azophenol **2a** and **2b** were acetylated with acetic anhydride and pyridine. The products were recrystallized from hexane. The acetate of **2a**, mp 73—73.5 °C (yield 70%). The acetate of **2b**, mp 29—30 °C (yield 75%). The mp and IR spectra of both acetates were identical with those of respective authentic samples.

Third fraction. Recrystallization from hexane or ethanol-water gave 2-alkyl-4-(phenylazo)phenol (**3**). **3a**, mp 130—131.5 °C. **3c**, mp 126.5—128 °C. Since the **3b** was impure, crude **3b** was acetylated with acetic anhydride in pyridine. The product was recrystallized form hexane to yield acetate of **3b**, mp 47—48 °C. These compounds were identified by comparing their mp and IR spectra with those of authentic samples.

Fourth fraction. In the case of **1a**, recrystallization from ethanol-water gave **4a**, mp 154—155 °C. In the case of **1b**, this fraction was found by high-speed liquid-chromatographic analysis to be a mixture of **4b** and **5**. The mixture was acetylated with acetic anhydride and pyridine, and the resulting acetate was also analyzed by high-speed liquid-chromatography. In the cases of **1c** and **1d**, recrystallization from benzene gave **5**, mp 155—156 °C (lit,[15] 152 °C).

The Reactions of 3-Methyl- and 3-Methoxy-azoxybenzenes with Sulfuric Acid. The azoxy compounds were treated with sulfuric acid using the procedure described above. 3-Methylazoxybenzene gave 3-methylazobenzene (yield 6.5%) and a mixture of 2-methyl-4-(phenylazo)phenol (yield 30%) and 4-(*m*-tolylazo)phenol (yield 2%) which was analyzed by high-speed liquid-chromatography. 3-Methoxyazoxybenzene gave 3-methoxyazobenzene (yield 12%) and 2-methoxy-4-(phenylazo)phenol, mp 69—70 °C (lit,[16] 70.5—71.5 °C).

Preparation of Authentic Samples. Azophenols, **3** and **4**, were prepared by diazo-coupling of the corresponding phenols and diazonium salts.[17] The products were subjected to chromatography on a silica gel column (the eluent was benzene), and then recrystallized from hexane-benzene. **3a**, mp 132—133 °C (lit,[18] 129—130 °C) (yield 55%). **3b**, mp 89—89.5 °C (yield 40%). Found: C, 74.37; H, 6.44; N, 12.55%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%. **3c**, mp 127.5—128 °C (yield 30%). Found: C, 74.97; H, 6.72; N, 11.63%. Calcd for $C_{15}H_{16}N_2O$: C, 74.97; H, 6.71; N, 11.66%. **4a**, mp 154—154.5 °C (lit,[19] 152 °C). Compounds **4b**, **4c**, and **4d** have been repotred previously.[1]

3-Ethyl-4-acetoxyazobenzene, the acetate of **3b**, was prepared by the acetylation of **3b** with acetic anhydride and pyridine, and then recrystallized from hexane (yield 86%), mp 48—49 °C. Found: C, 71.43; H, 5.94; N, 10.66%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44%.

3-Acetoxy-4-alkylazobenzenes, the acetate of **2a** and **2b**, were prepared by condensation of 3-acetoxy-4-alkylaniline and nitrosobenzene according to the method given in a previous report.[1] The acetate of **2a**, mp 72.5—73.5 °C from hexane (yield 21%). Found: C, 71.10; H, 5.51; N, 11.28%. Calcd for $C_{15}H_{14}N_2O_2$: C, 70.85; H, 5.55; N, 11.02%. The acetate of **2b**, mp 29—30 °C from hexane (yield 28%). Found: C, 71.90; H, 6.09; N, 10.63%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44%.

We wish to express our thanks to Professor Syuzi Hirooka for valuable suggestions and encouragement.

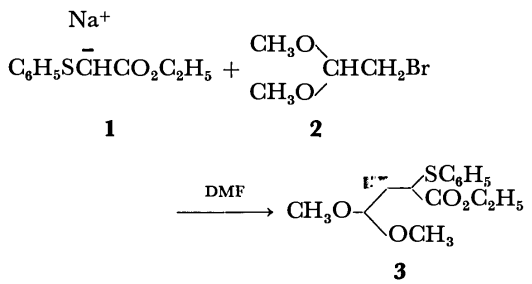
New Methods for the Preparation of 3-Substituted Furans[1)]

Katsuhiko INOMATA, Shin-ichi AOYAMA, and Hiroshi KOTAKE
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received September 12, 1977)

It was found that ethyl 4,4-dimethoxy-2-(phenylthio)butyrate and 3-tosylpropanal ethylene acetal are useful starting materials for the preparation of 3-substituted furans. Several 3-substituted furans, including dendrolasin [3-(4,8-dimethyl-3,7-nonadienyl)-furan], were prepared by the reaction of these compounds with alkyl halides in good yields.

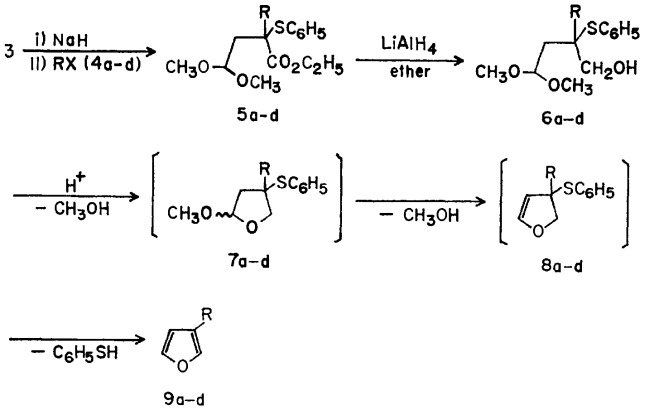
It is known that a number of furan derivatives occurring in nature are 3-substituted furans such as dendrolasin [3-(4,8-dimethyl-3,7-nonadienyl)-furan]. Although some methods for the preparation of 3-substituted furan derivatives were recently reported,[2)] they require many steps or considerably complicated pathways with low overall yields. In this paper we wish to describe new convenient methods for the preparation of 3-substituted furans in three steps starting from ethyl 4,4-dimethoxy-2-(phenylthio)butyrate (Method A) and 3-tosylpropanal ethylene acetal (Method B).

Method A. The starting material, ethyl 4,4-dimethoxy-2-(phenylthio)butyrate (**3**), was readily prepared by the reaction of sodium salt of ethyl (phenylthio)acetate (**1**) with 2-bromoacetaldehyde dimethyl acetal (**2**).



1 **2** **3**

The desired 3-substituted furans were synthesized from **3** and alkyl halide **4** according to the following scheme.



5a-d **6a-d** **7a-d** **8a-d** **9a-d**

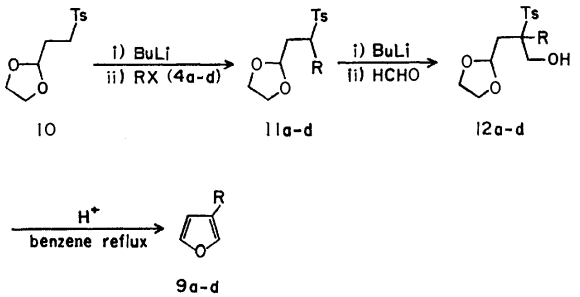
In the first place the sodium salt of **3** was allowed to react with alkyl halide in DMF at 60 °C to give the alkylated ester **5**, which was then reduced to alcohol **6** by the reaction with lithium aluminium hydride in ether at room temperature in almost quantitative yield. Finally, a benzene solution of **6** was refluxed in the presence of a catalytic amount of *p*-toluenesulfonic acid for 2 h to give the expected 3-alkylfuran **9** in good yield.

Preparation of 3-benzylfuran (**9a**), 3-octadecylfuran (**9b**), 3-geranylfuran (**9c**, nordendrolasin), and dendrolasin (**9d**) was carried out by this method (Table 1).

From the fact that the cyclic intermediate **7a** was isolated by the reaction of **6a** with an acidic catalyst at room temperature, the conversion of **6** into the corresponding 3-alkylfurans **9** appears to proceed as follows. First the cyclic intermediate **7** is formed by elimination of one molecule of methanol. By increasing temperature, another methanol is eliminated to form 3-alkyl-3-(phenylthio)dihydrofuran **8**, which has a labile phenylthio group at an allylic position and is finally converted into 3-alkylfuran **9** by elimination of benzenethiol.

Consequently, the method can be characterized by the formation of the intermediate, 4-hydroxybutanal dimethyl acetal derivative **6** having phenylthio group on C-3 as a leaving group, which is an important precursor of 3-substituted furan. This consideration provided an alternate method for the preparation of 3-substituted furans starting from crystalline 3-tosylpropanal ethylene acetal (**10**) which is accessible from acrylaldehyde, ethylene glycol, and *p*-toluenesulfinic acid.[3)]

Method B. The reduction process in Method A is not required as shown in the following scheme.



10 **11a-d** **12a-d** **9a-d**

The readily available **10** was converted into lithium salt by stirring with an equimolar amount of butyllithium in tetrahydrofuran at −78 °C for 10 min under nitrogen atmosphere. Treatment of the salt with alkyl halide at −78 °C and then at room temperature gave the alkylation product **11**. Similar lithiation of **11** in tetrahydrofuran and subsequent reaction with formaldehyde gave alcohol **12** corresponding to the key intermediate **6** in Method A. In a similar way to that for **6**, a benzene solution of **12** was refluxed in the presence of a catalytic amount of *p*-toluenesulfonic acid for 3.5 h to afford 3-alkylfuran **9** in good yield. The results are given in Table 2.

Table 1. Synthesis of 3-substituted furans by method A

RX	Isolated yield (%) 5a—d	9a—d
4a, $C_6H_5CH_2Br$	82	 89
4b, $CH_3(CH_2)_{17}I$	82	 83
4c, 	78	 83
4d, 	79	 81

Table 2. Synthesis of 3-substituted furans by method B

RX	Isolated yield (%) 11a—d	12a—d	9a—d
4a, $C_6H_5CH_2Br$	88	86	 88
4b, $CH_3(CH_2)_{17}I$	82	80	 85
4c, 	88	81	 85
4d, 	85	83	 86

Experimental

All the melting points were taken with a micro melting point apparatus (Yanagimoto-Seisakusho) and are uncorrected. The proton NMR spectra were recorded on a JEOL JNM-MH 60 spectrometer. Chemical shifts are reported in terms of the δ scale relative to TMS as an internal standard. The IR spectra were taken with a JASCO IRA-1 diffraction grating infrared spectrometer.

Materials. All the solvents were distilled according to general methods and were stored over molecular sieves or sodium metal as a drying agent. Homogeranyl iodide (4,8-dimethyl-3,7-nonadienyl iodide, **4d**, bp 58—61 °C/0.002 Torr [lit,[4] bp *ca.* 80 °C/0.04 Torr]) and 3-tosylpropanal ethylene acetal (**10**, recrystallized from ethanol. mp 83—84 °C [lit,[3] mp 83—85 °C]) were prepared by the reported procedures,[3,4] respectively. Butyllithium (about 15% in hexane) was obtained from Wako Pure Chemical Industries Co. Thin-layer chromatography (TLC) was performed on Merck's Kieselgel 60 PF_{254} (Art. 7749) using a mixture of benzene and ethyl acetate as an eluent, unless otherwise stated.

*Ethyl 4,4-Dimethoxy-2-(phenylthio)butyrate (**3**).* To a suspension of sodium hydride (33 mmol) in DMF (20 ml) was added dropwise a DMF solution (10 ml) of ethyl (phenylthio)acetate (6.10 g, 31 mmol) at room temperature under nitrogen atmosphere. After 15 min, a solution of 2-bromoacetaldehyde dimethyl acetal (**2**, 5.41 g, 32 mmol) in DMF (10 ml) was added at 60 °C. The reaction mixture was then allowed to stand at 60 °C for 3.5 h. Precipitates were removed by filtration and the filtrate was concentrated under reduced pressure. The residue was treated with a pH 7.2 buffer solution, followed by extraction with ethyl acetate. The organic extract was dried over Na_2SO_4, concentrated, and distilled, giving 6.10 g (69%) of **3**: Bp 138—141 °C/1 Torr; IR 1720, 1145, 1115, 1060 cm^{-1}; NMR (CCl_4) δ 1.15 (t, 3H), 2.02 (dd, 2H), 3.23 (s, 6H), 3.63 (t, 1H), 4.04 (q, 2H), 4.42 (t, 1H), 7.24 (m, 5H).

*Ethyl 2-Benyl-4,4-dimethoxy-2-(phenylthio)butyrate (**5a**).* To a suspension of sodium hydride (1.25 mmol) in DMF (3 ml) was added dropwise a DMF solution (1 ml) of **3** (299 mg, 1.05 mmol) at 60 °C under nitrogen atmosphere. After 5 min, a solution of benzyl bromide (**4a**, 180 mg, 1.06 mmol) in DMF (1 ml) was added at 60 °C. The reaction mixture was allowed to stand at 60 °C for 3 h and then worked up according to the above procedure. The resulting residue was separated by preparative TLC to afford **5a** (322 mg, 82%) as an oil: IR 1718, 1182, 1115, 1070, 1040 cm^{-1}; NMR ($CDCl_3$) δ 1.17 (t, 3H), 2.14 (d, 2H), 3.27 (s, 2H), 3.31 (s, 3H), 3.37 (s, 3H), 4.03 (q, 2H), 4.88 (t, 1H), 7.32 (m, 10H).

In a similar way, the corresponding alkylation products **5b**, **5c**, and **5d** were obtained by the reaction of **3** with octadecyl iodide (**4b**), geranyl bromide [(*E*)-3,7-dimethyl-2,6-octadienyl bromide, **4c**], and homogeranyl iodide [(*E*)-4,8-dimethyl-3,7-nonadienyl iodide, **4d**], respectively. Spectral data of the products are as follows.

5b: Oil, IR 1725, 1145 cm^{-1}; NMR ($CDCl_3$) δ 1.17 (t, 3H), 1.22 (s, 37H), 2.03 (d, 2H), 3.21 (s, 6H), 4.01 (q, 2H), 4.67 (t, 1H), 7.23 (m, 5H).

5c: Oil, IR 1720, 1180, 1120, 1090, 1075, 1040 cm^{-1};

NMR ($CDCl_3$) δ 1.17 (t, 3H), 1.57 (s, 6H), 1.66 (s, 3H), 2.04 (m, 6H), 2.41 (d, 2H), 3.17 (s, 6H), 4.00 (q, 2H), 4.60 (t, 1H), 5.04 (broad, 1H), 5.32 (t, 1H), 7.23 (m, 5H).

5d: Oil, IR 1720, 1180, 1120, 1095, 1060, 1045 cm^{-1}; NMR ($CDCl_3$) δ 1.22 (t, 3H), 1.60 (s, 3H), 1.64 (s, 3H), 1.66 (s, 3H), 2.00 (m, 10H), 3.28 (s, 6H), 4.09 (q, 2H), 4.75 (t, 1H), 5.06 (m, 2H), 7.34 (m, 5H).

*3-Benzyl-4-hydroxy-3-(phenylthio)butanal Dimethyl Acetal (**6a**).* The ester **5a** (390 mg, 1.04 mmol) was reduced with lithium aluminium hydride (38 mg, 1.00 mmol) in ether (7 ml) at room temperature for 30 min followed by treatment with concd NaOH. The ethreal extract dried over Na_2SO_4 was evaporated and the residue was separated by preparative TLC to afford **6a** (338 mg, 98%) as an oil: IR 3460, 1112, 1038 cm^{-1}; NMR ($CDCl_3$+D_2O) δ 1.78 (d, 2H), 2.90 (s, 2H), 3.12 (s, 6H), 3.35 (s, 2H), 4.77 (t, 1H), 7.14 (m, 10H).

In other cases, the reduction products **6b**—**d** were not isolated. The crude products were used in the subsequent cyclization reaction.

*3-Benzylfuran (**9a**).* A benzene solution of **6a** (332 mg, 1 mmol) was refluxed in the presence of a catalytic amount of *p*-toluenesulfonic acid (*ca.* 5 mg) for 2 h. The reaction mixture was washed with 1 M NaOH and dried over Na_2SO_4. After removal of the solvent, the residue was separated by preparative TLC using hexane as an eluent to afford **9a** (143 mg, 91%) as an oil: IR 1578, 870 cm^{-1}; NMR ($CDCl_3$) δ 3.61 (s, 2H), 6.08 (m, 1H), 7.05 (m, 1H), 7.07 (s, 5H), 7.16 (t, 1H).

In a similar way, other 3-alkylfurans **9b**—**d** were prepared from **6b**—**d**. Their spectral data are as follows.

9b: Melts at near 35 °C, IR 1555, 865 cm^{-1}; NMR ($CDCl_3$) δ 0.88 (t, 3H), 1.25 (s, 32H), 2.32 (t, 2H), 6.15 (m, 1H), 7.12 (m, 1H), 7.23 (t, 1H).

9c: Oil, IR 1555, 863 cm^{-1}; NMR ($CDCl_3$) δ 1.62 (s, 3H), 1.67 (s, 6H), 2.08 (m, 4H), 3.17 (d, 2H), 5.25 (broad, 1H), 5.39 (t, 1H), 6.33 (m, 1H), 7.28 (m, 1H), 7.42 (t, 1H).

9d: Oil, The following spectra are almost identical with the published ones.[5] IR 1560, 870 cm^{-1}; NMR ($CDCl_3$) δ 1.56 (s, 6H), 1.66 (s, 3H), 1.98 (m, 4H), 2.34 (m, 4H), 4.8—5.3 (m, 2H), 6.18 (m, 1H), 7.12 (m, 1H), 7.22 (t, 1H).

*4-Benzyl-2-methoxy-4-(phenylthio)oxolane (**7a**).* A benzene solution (20 ml) of **6a** (200 mg, 0.6 mmol) was stirred in the presence of a catalytic amount of *p*-toluenesulfonic acid for 30 min at room temperature. The reaction mixture was neutralized with Na_2CO_3, washed with water, and dried over Na_2SO_4. After evaporation of the solvent, the residue was separated by preparative TLC to afford **7a** (168 mg, 93%) as an oil: IR 1100, 1025 cm^{-1}; NMR ($CDCl_3$) δ 1.9—2.2 (m, 2H), 2.85 and 2.99 (s, 2H, *ca.* 1 : 3), 3.18 and 3.21 (s, 3H, *ca.* 1 : 3), 3.79 and 3.86 (s, 2H, *ca.* 3 : 1), 4.7—5.1 (m, 1H), 7.15 (m, 10H).

*3-Benzyl-3-tosylpropanal Ethylene Acetal (**11a**).* 3-Tosylpropanal ethylene acetal (**10**, 1.31 g, 5.00 mmol) was coverted into lithium salt by stirring with an equimolar amount of butyllithium in tetrahydrofuran (25 ml) at −78 °C for 10 min under nitrogen atmosphere. After treatment of the salt with benzyl bromide (**4a**, 0.86 g, 5.02 mmol) at −78 °C and then at room temperature, the mixture was concentrated on evaporation of the solvent under reduced pressure. The residue was treated with a pH 7.2 buffer solution, followed by extraction with ethyl acetate. The organic extract was dried over Na_2SO_4 and evaporated to dryness. Recrystallization from ethanol gave **11a** (1.55 g, 88%): Mp 97—99 °C, IR 1300, 1285, 1140 cm^{-1}; NMR ($CDCl_3$) δ 2.00 (m, 2H), 2.34 (s, 3H), 2.99 (m, 2H), 3.56 (m, 5H), 4.76 (t, 1H), 7.07 (m, 5H), 7.23 (d, 2H), 7.71 (d, 2H). Found: C, 65.80; H, 6.50%. Calcd for $C_{19}H_{22}O_4S$: C, 65.88; H, 6.40%.

Products **11b**—**d** were prepared in a similar way, except that **11c**, **d** were separated by preparative TLC. Physical properties and analytical data of the products are as follows.

11b: Mp 82—83 °C, IR 1300, 1285, 1140 cm^{-1}; NMR ($CDCl_3$) δ 0.87 (t, 3H), 1.23 (s, 36H), 2.45 (s, 3H), 3.16 (m, 1H), 3.84 (m, 4H), 4.97 (t, 1H), 7.31 (d, 2H), 7.74 (d, 2H), Found: C, 70.80; H, 10.44%. Calcd for $C_{30}H_{52}O_4S$: C, 70.83; H, 10.30%.

11c: Oil, IR 1300, 1290, 1280, 1130 cm^{-1}; NMR ($CDCl_3$) δ 1.51 (s, 3H), 1.54 (s, 3H), 1.62 (s, 3H), 1.90 (m, 6H), 2.34 (s, 3H), 2.46 (m, 2H), 3.17 (m, 1H), 3.17 (m, 4H), 4.92 (m, 3H), 7.23 (d, 2H), 7.67 (d, 2H).

11d: Oil, IR 1305, 1295, 1285, 1140 cm^{-1}; NMR (CCl_4) δ 1.55 (s, 6H), 1.65 (s, 3H), 1.93 (m, 10H), 2.40 (s, 3H), 3.10 (m, 1H), 3.74 (m, 4H), 4.85 (m, 3H), 7.21 (d, 2H), 7.60 (d, 2H).

*3-Benzyl-4-hydroxy-3-tosylbutanal Ethylene Acetal (**12a**).* 3-Benzyl-3-tosylpropanal ethylene acetal (**11a**, 352 mg, 1 mmol) was converted into lithium salt in tetrahydrofuran (10 ml) according to the above procedure. Gaseous formaldehyde (generated by heating paraformaldehyde) was bubbled through a solution of the salt at −78 °C. The reaction mixture was brought to room temperature for 30 min and then concentrated on evaporation of the solvent under reduced pressure. The residue was treated with a pH 7.2 buffer solution, followed by extraction with ethyl acetate. The organic extract was dried over Na_2SO_4 and concentrated. The resulting residue was separated by preparative TLC to afford **12a**, which was further recrystallized from ethanol to give pure **12a** (328 mg, 86%): mp 61—62 °C, IR 3520, 1280, 1140 cm^{-1}; NMR ($CDCl_3$ +D_2O) δ 2.03 (t, 2H), 2.39 (s, 3H), 3.14 (dd, 2H), 3.72 (m, 4H), 3.84 (dd, 2H), 4.98 (t, 1H), 7.15 (m, 5H), 7.23 (d, 2H), 7.71 (d, 2H). Found: C, 63.66; H, 6.70%. Calcd for $C_{20}H_{24}O_5S$: C, 63.82; H, 6.43%.

Products **12b**—**d** were prepared in a similar way. Physical properties and analytical data of the products are as follows.

12b: mp 57—59 °C, IR 3470, 1290, 1280, 1130 cm^{-1}; NMR ($CDCl_3$) δ 0.87 (t, 3H), 1.22 (s, 34H), 2.13 (d, 2H), 2.42 (s, 3H), 3.85 (m, 7H), 5.12 (t, 1H), 7.27 (d, 2H), 7.67 (d, 2H). Found: C, 69.19; H, 10.30%. Calcd for $C_{31}H_{54}O_5S$: C, 69.11; H, 10.10%.

12c: Oil, IR 3500, 1290, 1280, 1125 cm^{-1}; NMR ($CDCl_3$) δ 1.55 (s, 3H), 1.57 (s, 3H), 1.66 (s, 3H), 1.98 (m, 6H), 2.38 (s, 3H), 2.54 (m, 2H), 3.83 (m, 6H), 5.17 (m, 3H), 7.28 (d, 2H), 7.73 (d, 2H).

12d: Oil, IR 3500, 1295, 1280, 1130 cm^{-1}; NMR ($CDCl_3$) δ 1.55 (m, 9H), 1.95 (m, 10H), 2.36 (s, 3H), 3.21 (broad s, 1H), 3.79 (m, 6H), 4.7—5.3 (m, 3H), 7.24 (d, 2H), 7.67 (d, 2H).

Cyclization of **12a**—**d** to the corresponding 3-alkylfurans **9a**—**d** was performed according to the procedure described for 3-benzylfuran (**9a**).

Critical Micelle Concentration Reduction of Aqueous Sodium Dodecyl Sulfate Solutions upon the Addition of Alcohols

Kohji HAYASE and Shigeo HAYANO

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received July 27, 1977)

Synopsis. Linear relations were found between the critical micelle concentration (CMC) reduction and the carbon number of the alcohols added both at 313.15 K and 328.15 K. The slopes of the CMC reduction against the carbon number of the alcohols are almost the same at 298.15, 313.15, and 328.15 K.

It is well known that upon the addition of alcohols to surfactant micellar solutions, the critical micelle concentration (CMC) decreases.[1-5] Flockhart[4] has reported the effect of temperature on the CMC of sodium dodecyl sulfate (SDS) in water and in aqueous ethanol solutions. Shirahama and Kashiwabara[5] have already discussed the CMC reduction effects due to alcohols (C_2—C_4) on aqueous SDS solutions at 298.15 K.

The present authors have already reported the CMC reduction of SDS upon the addition of 1-butanol, 1-pentanol, 1-hexanol and 1-heptanol, and the distribution coefficients of the alcohols between the aqueous and micellar phases.[6] The relation between the CMC reduction, the distribution coefficients and the standard free energy changes of penetration of the alcohols has been discussed thermodynamically.[7] An important factor which governs the CMC reduction effects is the molar fraction of the alcohol in the micellar phase, because the molar fraction of the alcohol in the micellar phase has a great influence on the chemical potential of the mixed micelle.[7]

Since these results were obtained only at 298.15 K, further work is required at various other temperatures. In this paper, experimental work on the CMC reduction due to the addition of alcohols to the aqueous SDS solutions at 313.15 and 328.15 K is reported.

Experimental

Method. The CMC was determined using the electric conductivity method at 313.15 and 328.15 K. Details of the procedures have been described in a previous paper.[6]

Materials. SDS for biochemical use (Wako Pure Chemical Industries, Ltd.) was recrystallized twice from ethanol, and was carefully dried in vacuo for 50 h. 1-Butanol, 1-pentanol, 1-hexanol, and 1-heptanol of high purity (higher than 99%) were used. The water used was passed through Milli-Q2 Systems (Nihon Millipore Co.) until its specific conductivity fell below $10^{-7}\ \Omega^{-1}\ cm^{-1}$.

Results and Discussion

The CMC of aqueous SDS solutions containing 1-butanol, 1-pentanol, 1-hexanol, and 1-heptanol at 313.15 and 328.15 K are shown in Table 1. The more hydrophobic and the more concentrated the alcohols added, the more marked becomes the reduction in the CMC. These results follow the same trend as the results for 298.15 K.[6] Also at 313.15 and 328.15 K, the penetration of the alcohols into the micelle from the aqueous phase decreases the chemical potentials of the micelles and, therefore, decreases the CMC. To discuss the standard free energy changes of penetration of the alcohols from the aqueous to micellar phases at 313.15 and 328.15 K, these CMC data will be useful.

Table 1. CMC values for SDS to which a small amount of alcohol was added

	313.15 K		328.15 K	
	Alcohol concn (mmol/dm³)	CMC (mmol/dm³)	Alcohol concn (mmol/dm³)	CMC (mmol/dm³)
Pure water		8.47		9.57
1-Butanol	43.01	7.18	41.16	8.62

	2.117	6.89	2.303	7.87
	3.126	6.30	3.068	7.45

Table 2. CMC decrease upon the addition of alcohol

$\ln(-d\ln CMC/dY_a)$

	298.15 K[6]	313.15 K	328.15 K
1-Butanol	5.36	5.24	5.12
1-Pentanol	6.45	6.33	6.30
1-Hexanol	7.57	7.56	7.55
1-Heptanol	8.54	8.51	8.38

The limiting values of $\ln(-d\ln CMC/dY_a)$ at $Y_a=0$ (Y_a is the molar fraction of alcohol in the aqueous phase) were computed using the second-degree least-square method and are shown in Table 2. There are linear relations between $\ln(-d\ln CMC/dY_a)$ and the temperature for each alcohol, as illustrated in Fig. 1. Their slopes are -8.0×10^{-3}, -5.1×10^{-3}, -8.2×10^{-4}, and $-5.4\times10^{-3}\ K^{-1}$ for 1-butanol, 1-pentanol, 1-

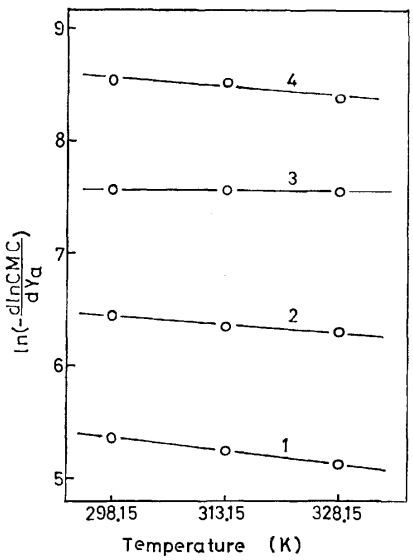

Fig. 1. $\ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a)$ as a function of temperature.
(1) 1-Butanol, (2) 1-pentanol,
(3) 1-hexanol, (4) 1-heptanol.

hexanol, and 1-heptanol, respectively. For 1-butanol, 1-pentanol, and 1-hexanol, the slopes decreases with increasing carbon number of the alcohols, but for 1-heptanol the slope is higher than expected. The reason for this is still not clear.

Linear relations between the $\ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a)$ and the carbon number of the alcohols are found again at 298.15, 313.15, and 328.15 K. The following equations were obtained using the first-degree least-squares method, thus

$$\ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a) = 1.07n + 1.11 \quad \text{at } 298.15\,\mathrm{K}, \quad (1)^{7)}$$

$$\ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a) = 1.10n + 0.84 \quad \text{at } 313.15\,\mathrm{K}, \quad (2)$$

$$\text{and } \ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a) = 1.10n + 0.77 \quad \text{at } 328.15\,\mathrm{K}, \quad (3)$$

where n is the carbon number of the alcohol.

In the papers of Shirahama and Kashiwabara[5] and of Hayase and Hayano,[7] the relation between $\ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a)$ and n were discussed combining the distribution coefficients of the alcohols between the aqueous and micellar phases. Accordingly, it was shown the relation is between $\ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a)$, instead of $\ln(-\mathrm{dCMC}/\mathrm{d}Y_a)$, and n, although a linear relation does exist between $\ln(-\mathrm{dCMC}/\mathrm{d}Y_a)$ and n.

In Eqs. 1, 2, and 3 the slopes are almost same (1.1) for the three temperatures. Namely, the CMC reduction effect of the methylene group is the same for the temperature range studied. But, the higher the temperature, the less the CMC reduction effect of each alcohol. Equations 1, 2, and 3 can be rewritten in the following equation,

$$\ln(-\mathrm{dlnCMC}/\mathrm{d}Y_a) = An + B, \quad (4)$$

where A is independent of the temperature, and B is dependent on the temperature.

Accordingly, the CMC reduction effect can be divided into an alcohol carbon number dependent part (the first term) and a temperature dependent part (the second term). Though the physical meaning of Eq. 4 is not clear at present, it is of interest to measure the validity of the equation for other surfactants and additives.

The Crystal and Molecular Structure of 4-(1-Hydroxy-2,6,6-trimethyl-2-cyclohexenyl)-3-buten-2-one

Hideo UEDA,* Chuji KATAYAMA, and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received August 26, 1977)

Synopsis. The crystal and molecular structure of a hydroxy derivative of α-ionone, 4-(hydroxy-2,6,6-trimethyl-2-cyclohexenyl)-3-buten-2-one, was studied by means of X-ray analysis. The atoms including the conjugated double bond in the side chain and those around the double bond in the ring form planes orthogonal to each other.

4-(1-Hydroxy-2,6,6-trimethyl-2-cyclohexenyl)-3-buten-2-one is an important derivative of (—)-α-ionone in its correlation to the structure of abscisic acid. Oritani and Yamashita have synthesized the optical active compounds[1-3] and provided us with crystals for X-ray analysis. The structure is interesting from the view point of CD analysis of α-ionone and abscisic acid.

Experimental

The space group of the crystal determined from the oscillation and Weissenberg photographs. The unit-cell parameters were determined by the least-squares method, using 12 reflections carefully measured on Hilger & Watts four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation(λ=1.5418 Å). Crystal data: $C_{13}H_{20}O_2$, $M.W.$=208.30, orthorhombic $P2_12_12_1$, a=12.359(1), b=13.018(1), c=7.738(1) Å, Z=4, D_m=1.109, D_c=1.111 g·cm^{-3}, μ=5.84 cm^{-1} (for Cu $K\alpha$ radiation). The intensity data were collected on a diffractometer with 2θ-ω scanning mode($2\theta \leqq 72°$). The size of the crystal used was 0.3×0.3×0.3 mm. An isotropic extinction correction was made by the method of Hamilton.[4]

Determination and Refinement of the Structure

The structure was determined by the direct method with the program MULTAN[5] using 127 reflections with $|E| \geqq 1.50$. An E map computed from the phase set with the highest figures of merit (FOM=1.21) revealed all the atoms except those of hydrogen. Refinement of the structure was performed by the block-diagonal least-squares method with 1152 independent reflections of $|F^\circ| \geqq 3\sigma$. The final refinement was carried out with anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal factors for hydrogen atoms. The R-index converged to 0.053 with an equal weight for each reflection. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[6] Part of the computation was performed at the Nagoya University Computation Center. The observed and calculated structure factors are given in Table 1.[7]

Results and Discussion

The structure is shown in Fig. 1. The atomic coordinates for all atoms are given in Table 2. Intramolecular distances and bond angles are all normal. The atoms of side chain, C(10), C(11), C(12), C(13), and O(1), are on the plane $0.0300X-0.9961Y-0.0829Z+1.075=0$, where the maximum deviation is 0.03 Å. The double bonds C(10)=C(11) and C(12)=O(1) take a *cis* conformation. The atoms around the C(5)=C(6) double bond in the ring also form a plane given by $0.0157X+0.2309Y-0.9789Z-1.801=0$, where the

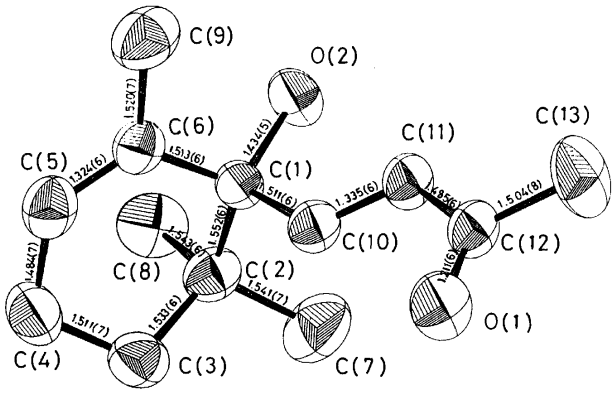

Fig. 1. The atomic labelings of (−)-1′-hydroxy-α-ionone.
Carbon and oxygen atoms are represented as thermal ellipsoids of a size such that the vibrating atoms have a 50% probability of being found within them. The absolute configuration of the melecule was drawn to be in conformity with the established configuration by a chemical correlation method.

Fluorescence of the Hindered Phenoxyl Radical*

Tadashi OKAMURA** and R. W. YIP

Division of Chemistry, National Research Council Canada, Ottawa, Canada K1A 0R6

(Received November 7, 1977)

Synopsis. Fluorescence and excitation spectra of the 2,4,6-tritertiarybutylphenoxyl radical which is stabilized by a steric hindrance have been measured in benzene at room temperature. The emitting state seems to correspond with a state visualized in the excitation spectrum.

Absorption spectra of the phenoxyl radical and its alkyl derivatives were extensively investigated by means of flash photolysis method.[1,2] The 2,4,6-tritertiarybutylphenoxyl has an almost identical spectrum with that of the phenoxyl.[1] The emissions of these free radicals have not yet been analyzed, while those of the benzyls which have the same number of conjugated π-electrons as the phenoxyls have been investigated[3-7] closely in detail. It is very interesting to study the emitting processes of these radicals comparing with that of the benzyl, in order to examine the electronic spectra of aromatic free radicals more systematically.

2,4,6-Tritertiarybutylphenol and benzene were Analytical Reagent (Aldrich Chemical) and of spectrograde, respectively. This parent material of the radical was purified by repeated recrystallizations. The 2,4,6-tritertiarybutylphenoxyl was prepared from 2,4,6-tritertiarybutylphenol dissolved in benzene at 5×10^{-2} M concentration by the addition of PbO_2 (3 g of PbO_2 in 25 ml of solution). The oxidization of the phenol was carried out under nitrogen saturated condition at room temperature. After producing the radical, the solution was transferred to a sample cell and degassed. A Farrand Mark I spectrofluorometer was used for the measurements. Bandwidth was set at 5 nm.

Fluorescence emission and excitation spectra observed are shown in Fig. 1. The radical was stable enough to be measured these spectra by the usual static method at room temperature. High stability of this radical has been reported.[8] It was suggested that tertiarybutyl substituents prevent the recombination reactions of the radicals to form quinone type products.

The excitation spectrum shows distinct peaks at 404 and 386 nm which correspond well with the reported absorption data: at 401 and 383 nm in CCl_4, and 400 and 382 nm in hexane.[2] Therefore, the emission spectrum observed by the excitation at 390 nm shown in Fig. 1 can reasonably be assigned to be the fluorescence from the 2,4,6-tritertiarybutylphenoxyl radical. The fluorescence spectrum shows a peak at 425 nm and has no distinct vibrational structure.

The first absorption bands of the phenoxyl radicals are substantially blue-shifted and stronger compared with those of the benzyl radical, and fluorescence spectra of the benzyl radicals in rigid glass are more structured than that of the radical observed. The essential difference between these two types of radicals is that the phenoxyl has a heteroatom bearing two lone pairs which may decrease electron repulsion. This repulsion is possibly considered to lower the energy of the first electronic transition. Furthermore, the lone pairs on the oxygen atom of the phenoxyl give rise to $n\rightarrow\pi^*$ transitions in the electronic spectra. Calculations of the doublet states of the phenoxyl by P-P-P[9] and CNDO/S[10] methods were reported. In both calculations, one or two low energy states in visible region which carry low or no oscillator strength were predicted, other than the observed states in near ultraviolet region. Considering these theoretical results also, one may expect the presence of a hidden emitting state in the visible region. However, the fluorescence spectrum measured in this work indicates that the emitting state possibly corresponds to a state visualized in the absorption and excitation spectra around 400 nm, because a fluorescence peak in the observed spectrum is not much separated from the absorption one. It is also possible that there exists unknown emitting state of which absorption is weaker and hidden in the apparent absorption around 400 nm.

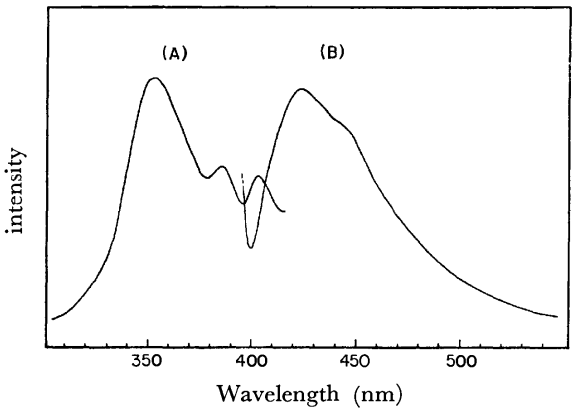

Fig. 1. Fluorescence emission and excitation spectra of 2,4,6-tritertiarybutylphenoxyl radical in benzene at room temperature.
(A) and (B) are the excitation spectrum monitored at 430 nm and the fluorescence spectrum excited at 390 nm, respectively.

The above results represent one of the few reported fluorescence from a free radical at ambient temperature in solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (3), 939—940 (1978)

A Synthesis of 2-Substituted 2-Cyclopenten-1-ones

Junya IDE, Kiyoshi SAKAI, and Yasuo YURA

Central Research Laboratories, Sankyo Co., Ltd, 1-2-58 Hiromachi, Shinagawa-ku, Tokyo 140

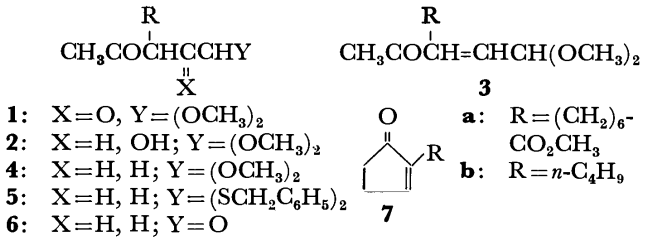
(Received October 25, 1976)

Synopsis. 2-Substituted 2-cyclopenten-1-ones, *i.e.*, 2-(6-methoxycarbonylhexyl)-2-cyclopentene-1-on and 2-butyl-2-cyclopenten-1-one were synthesized by cyclization of the corresponding 4-oxo-1-pentanals, which were obtained from 3-substituted 1,1-dimethoxy-2,4-pentadiones through several steps.

Recently a large amount of research has been devoted to developing synthetic routes to substituted 2-cyclopenten-1-ones. This has been due to the fact that many natural products possess this moiety as their major structural feature.[1] Particularly, 2-(6-carboxyhexyl)-2-cyclopenten-1-one and its esters[2] are valuable intermediates to 11-deoxyprostanoids[3] which possess potential pharmacological activities. We wish to report a new synthetic route to 2-alkyl-2-cyclopenten-1-ones.

Catalytic hydrogenation of 1,1-dimethoxy-3-(6-methoxycarbonylhexyl)-2,4-pentadione (**1a**),[4] prepared from 1,1-dimethoxy-2,4-pentadione and methyl 7-iodoheptanoate, over platinum in methanol afforded two epimeric keto alcohols **2a** and **epi-2a** in a ratio of 95 : 5 in 98% yield. Analogously, catalytic reduction of 3-butyl-1,1-dimethoxy-2,4-pentadione (**1b**) gave two epimeric alcohols **2b** and **epi-2b** in a ratio of 93 : 7 in 86% yield.[5] Treatment of the keto alcohols **2a** and **2b** with dicyclohexylcarbodiimide and a catalytic amount of copper(I) chloride in ether[6] gave the α,β-unsaturated ketones **3a** and **3b** in 81 and 92% yields, respectively. The ketone **3** was also obtained by treatment of the p-toluenesulfonate of the alcohol **2** with potassium acetate in aqueous *N,N*-dimethylformamide at 100 °C for 2.5 h in 60 and 55% yields, respectively. Hydrogenation of the α,β-unsaturated ketone **3** over 5% Pd–C in methanol gave the saturated ketones **4a** and **4b** in 85 and 88% yields, respectively.

Treatment of **4** with a slight excess of benzyl mercaptan and zinc chloride in dioxane at 50 °C for 1 h afforded bis(benzylthio)-derivatives **5a** and **5b** in 74 and 78% yields, respectively. Dethioacetalization of **5** was effected with mercury(II) chloride and cadmium carbonate in aqueous acetonitrile at 40 °C for 2 h to give the corresponding aldehyde **6**[7] in good yield. Cyclization of the keto aldehydes **6a** and **6b** with potassium carbonate in methanol afforded the 2-substituted 2-cyclopenten-1-ones **7a** and **7b** in 36 and 35% yields, respectively.



Scheme 1.

Experimental

NMR spectra were recorded on a Varian A-60 spectrometer using TMS as an internal standard in deuterio chloroform, IR spectra were taken on a Hitachi EPI-G3 in liquid films, and the results of NMR spectra and elemental analyses are shown in Table 1.

*Catalytic Hydrogenation of **1a** and **1b**.* A solution of **1a** (633 mg, 2.11 mmol) and PtO_2 (60 mg) in MeOH (35 ml) was hydrogenated under ordinary pressure. The solution was concentrated *in vacuo* to give an oily residue (622 mg), which was chromatographed (SiO_2, 10 g, hexane–benzene, 2:1) to afford the major alcohol **2a** (590 mg, 93% yield); IR: ν 3460, 1740, 1717 and 1700 cm^{-1}. Further elution with hexane–benzene–ether (1:2:0.4) gave the minor alcohol **epi-2a** (30 mg, 4.7% yield); IR: ν 3470, 1743 and 1710 cm^{-1}.

Similar hydrogenation of **1b** (2.16 g, 10 mmol) afforded the major alcohol **2b** (1.8 g, 83% yield); IR: ν 3450 and 1705 cm^{-1}, and the minor alcohol **epi-2b** (120 mg, 5.5% yield); IR: ν 3500 and 1714 cm^{-1}.

*Dehydration of **2a** and **2b**.* A solution of **2a** (20 g, 66 mmol), DCCI (16.3 g, 79 mmol) and copper(I) chloride (300 mg) in ether (230 ml) was heated under reflux for 20 h. The mixture was filtered and washed with ether. After the filtrate was evaporated *in vacuo*, the residue (25.2 g) was chromatographed (SiO_2, 250 g, benzene) to afford **3a**, (15.2 g, 81% yield), bp 140—150 °C/0.3 Torr (bath temp); IR: ν 1743, 1680, and 1650 cm^{-1}.

Similar procedure of **2b** (44.7 g, 0.204 mol) gave **3b** (35 g, 85.5% yield), bp 96—98 °C/2 Torr; IR: ν 1680 and 1655 cm^{-1}.

*Dehydration of **2a** via Its p-Toluenesulfonate.* The *p*-toluenesulfonate of **2a**, prepared from **2a** (2.1 g, 6.9 mmol) and *p*-toluenesulfonyl chloride (1.35 g, 7.1 mmol) in pyridine, were heated with potassium acetate (4.0 g) in DMF (20 ml) and H_2O (4 ml) at 100 to 110 °C for 2.5 h. The mixture was worked up as usual and the residue (1.7 g) was chromatographed (SiO_2, 17 g) to give **5a** (1.2 g, 60.1% yield).

*Catalytic Hydrogenation of **3a** and **3b**.* A solution of **3a** (7 g, 0.024 mol) in THF (70 ml) was hydrogenated over Pd-$CaCO_3$ (5 g) under ordinary pressure. After usual work-up, an oily residue (7.05 g) was distilled *in vacuo* to afford **4a** (5.7 g, 81% yield), bp 145—155 °C/0.3 Torr; IR: ν 1745 and 1720 cm^{-1}.

Analogous hydrogenation of **3b** (10 g, 0.05 mol) afforded **4b** (8.7 g, 87% yield), bp 100—110 °C/5 Torr (bath temp); IR: ν 1716 cm^{-1}.

*Benzylthioacetalization of **4a** and **4b**.* To a solution of **4a** (3.45 g, 12 mmol), benzyl mercaptan (3.47 g, 28 mmol) and Na_2SO_4 (4 g) in dioxane (15 ml) was added powdered anhyd. $ZnCl_2$ (8 g) at room temp. The mixture was stirred at 50 °C for 1 h, and poured into cold water. The aqueous solution was extracted with ether and the extracts were washed with H_2O and dried. After evaporation of the solvent *in vacuo*, the residue was chromatographed (SiO_2, 50 g, benzene–ether, 95 : 5) to afford **5a** (4.18 g, 74.1% yield); IR: ν 1743 and 1717 cm^{-1}.

Table 1. NMR spectra and elemental analyses[a)]

Compound	NMR ($CDCl_3$) in ppm	Obsd(%) C	Obsd(%) H	Calcd(%) C	Calcd(%) H
2a	(+D_2O): 2.19(3, s, $COCH_3$), 2.8(1, dt, J=3.1 and 7 Hz, COCH), 3.4 and 3.41(6, two s, OCH_3), 3.66(1, dd, J=4 and 3.1 Hz, CHOH), 4.21 (1, d, J=4 Hz, CHOMe)	59.37	8.97	59.19	9.27
epi-2a	(+D_2O): 2.22(3, s, $COCH_3$), 2.8(1, dt, J=7 and 3.5 Hz, COCH), 3.38 and 3.5(6, two s, OCH_3), 3.7(1, dd, J=3.5 and 4.2 Hz, CHOH), 4.25 (1, d, J=4.2 Hz, CHOMe)	59.01	9.45	59.19	9.27
2b	2.19(3, s, $COCH_3$), 2.8(1, dt, J=7 and 3 Hz, COCH), 3.7(1, dd, J=3 and 4 Hz, CHOH)	60.37	10.08	60.52	10.16
epi-2b	2.22(3, s, $COCH_3$), 2.8(1, dt, J=3.5 and 7 Hz, COCH), 3.71(1, dd, J=3.5 and 4 Hz, CHOH), 4.25(1, d, J=4 Hz, CHOMe)	60.74	9.87	60.52	10.16
3a	2.22(3, s, $COCH_3$), 3.38(6, s, OCH_3), 5.16(1, d, J=6.5 Hz, CHOMe), 6.43(1, d, J=6.5 Hz, =CH)	62.88	9.23	62.91	9.15
3b	2.31(3, s, $COCH_3$), 3.34(6, s, OCH_3), 6.35(1, d, J=6.5 Hz, =CH)	65.86	10.21	65.97	10.07
4a	2.15(3, s, $COCH_3$), 3.31(6, s, OCH_3), 4.32(1, t, J=5.5 Hz, CHOMe)	62.35	9.96	62.47	9.79

5a	1.94(3, s, $COCH_3$), 3.38(1, q, J=6 and 8 Hz, COCH), 3.73 and 3.78 (4, two s, SCH_2)	68.51	7.78	68.60	7.67
5b	1.94(3, s, $COCH_3$), 3.38(1, q, J=6 and 8 Hz, COCH), 3.73 and 3.78(4, two s, SCH_2)	71.41	7.58	71.45	7.82
6a	2.18(3, s, $COCH_3$), 9.66(1, t, J=1 Hz, CHO)	64.61	9.03	64.44	9.15
6b	2.18(3, s, $COCH_3$), 9.67(1, t, J=1 Hz, CHO)	68.95	10.21	69.19	10.32
7a	0.98—1.73(3, m), 1.9—2.7(8, m), 7.13(1, m, CH=)				
7b	0.93(3, t, CH_3), 1.37(4, m, CH_2CH_2), 2.2(4, m, CH_2CH=), 2.5(2, m, CH_2CO), 7.14(1, m, CH=)	78.38	10.13	78.21	10.21

a) The NMR spectra data of the substituent "R" in compounds 2 to 7 are not described.

Similar procedure of **4b** (300 mg, 1.5 mmol) gave **5b** (447 mg, 78% yield); IR:ν 1716 cm^{-1}.

Cyclization of ***5a*** *and* ***5b***. A solution of **5a** (4.72 g, 10 mmol), $HgCl_2$ (10 g) and $CdCO_3$ (5.4 g) in CH_3CN (50 ml) and H_2O (10 ml) was stirred under N_2 atmosphere at room temp. for 3 h. After removal of inorganic substances, the filtrate was washed with H_2O and dried. The solvent was evaporated *in vacuo* to give a crude aldehyde **6a** (2.2 g, 90% yield), which was practically usable; IR:ν 2730, 1745, 1725 and 1715 cm^{-1}. A solution of the crude **6a** (2.2 g) and anhyd. K_2CO_3 (7 g) in MeOH (100 ml) was stirred at room temp for 20 h. The mixture was neutralized with aq. AcOH and extracted with ether. The extracts were washed with H_2O and dried. After evaporation of the solvent *in vacuo*, the residue was chromatographed (SiO_2, 20 g, hexane-benzene, 2:1) to afford **7a**[2)] (720 mg, 36% yield); IR:ν 1745, 1706 and 1635 cm^{-1}.

Similar cyclization of **5b** (3.1 g, 8 mmol) gave **7b** (565 mg, 41% yield); IR:ν 1708 and 1637 cm^{-1}.

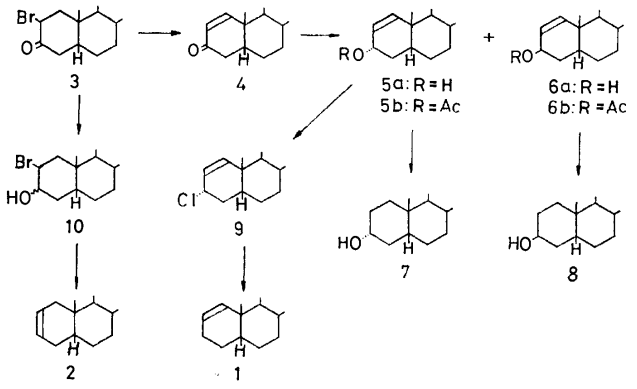
(Received June 7, 1977)

Synopsis. 5β-Cholest-1-ene has been prepared from 2β-bromo-5β-chloestan-3-one. An alternative route to 5β-cholest-2-ene has also been developed by use of bromoketone. These olefins are less stable, being oxidized gradually by air to 5β-cholest-1-en-3-one at room temperature.

In a previous paper[2] a report was given on the preparation of 5β-cholest-2-ene (**2**) by the treatment of 2β,3-bis(methylsulfonyloxy)-5β-cholestane, obtained from 2β-acetoxy-5β-chloestan-3-one *via* 5β-cholestane-2β,3-diols, with sodium iodide in boiling cyclohexanone. The process is tedious as compared with the one-step preparation from 3-substituted 5β-cholestanes[3] although undesirable contamination of 5β-cholest-3-ene can be reduced. 2β,4β-Dibromo-5β-cholestan-3-one, on treatment with chromium(II) acetate, is reduced to 2β-bromo-5β-cholestan-3-one (**3**), which is further converted into 5β-cholest-1-en-3-one (**4**) on reaction with calcium carbonate and *N*,*N*-dimethylformamide.[4] In this paper we describe the preparation of 5β-cholest-1-ene (**1**) and 2-ene (**2**) from **3**, and give some observations on the oxygenation of these olefins on exposure to air at room temperature.

The procedures for the preparation of **1** and **2** are summarized in the Scheme.



Scheme. Pathway to 5β-cholest-1-ene and 2-ene.

The reduction of **4** with lithium aluminium hydride readily gave a mixture of allyl alcohols. The major product, obtained by crystallization from acetone, was characterized as 5β-cholest-1-en-3α-ol (**5a**) on the basis of its transformation into 5β-cholestan-3α-ol (**7**) on hydrogenation in cyclohexane in the presence of palladium catalyst. Concentration of the mother liquor and crystallization several times from ether–methanol gave a small amount of the isomeric allyl alcohol, which was determined to be 5β-cholest-1-en-3β-ol (**6a**) by catalytic reduction to 5β-cholestan-3β-ol (**8**). Treatment of **5a** with thionyl chloride gave a chloro compound in 73% yield. The compound is regarded as 3α-chloro-5β-cholest-1-ene (**9**) by a comparison of its NMR spectrum with those of **5a** and **6a**: In the NMR spectrum of **9**, the signals at δ 4.50 showed double-doublet couplings, the constants (J=7.0, 10.0 Hz) of which were similar to those of the signals at δ 4.16 (J=5.0, 8.2 Hz) due to 3β-H in **5a**, but quite distinct from those of the multiplet signals at δ 3.98 ($W/2$= 8.5 Hz) due to 3α-H in **6a**. 5β-Cholest-1-ene (**1**) was obtained by the reduction of **9** with lithium aluminium hydride.

5β-Cholest-2-ene (**2**) was obtained from **3** by the method used for the preparation of 5α-cholest-2-ene.[5]

The olefins were relatively less stable at room temperature. **1** and **2** remained unchanged for a long time at room temperature. However, these olefins were gradually oxidized by air (see Table). 5β-Cholest-1-en-3-one (**4**) was mainly obtained from the samples of **1** and **2** which had been preserved for about a year at room temperature.[6] On the other hand, oxygenation scarcely took place in the samples of **1** and **2** preserved in a refrigerator kept below 5 °C. The results indicate that the oxygenation of the olefins is promoted by light and temperature. However, the mechanism of oxygenation has not been clarified because of complex factors participating in the reaction.

TABLE. OXYGENATION PRODUCTS OF THE OLEFINS AGED FOR A YEAR

Olefin	Temperature	Yield(%)	
		Recovered olefin	5β-Cholest-1-en-3-one
5β-Cholest-1-ene	r. t.[a]	15	80
	<5 °C	100	—
5β-Cholest-2-ene	r. t.[a]	20	79
	<5 °C	100	—

a) Room temperature.

Experimental

All melting points are uncorrected. IR spectra were determined with a Hitachi Model 215 grating instrument. NMR spectra were measured with a Hitachi Perkin-Elmer Model R-20A spectrometer in carbon tetrachloride with reference to tetramethylsilane as an internal standard.

Lithium Aluminium Hydride Reduction of 5β-Cholest-1-en-3-one (4). Lithium aluminium hydride (0.5 g) was added to a solution of **3**[4] (2.5 g) in dry ether (100 ml) at temperature below 0 °C. The mixture was allowed to warm to room temperature. The excess hydride was then decomposed with acetone and dil sulfuric acid. The organic layer was washed with aq sodium hydrogencarbonate and water, dried and

* Present address: Special Reference Laboratories, Inc., Nishiki, Nerima-ku, Tokyo 176.

evaporated. Crystallization from acetone gave 5β-cholest-1-en-3α-ol (**5a**, 1.6 g) as needles, melting at 122—124 °C. IR (KBr): 3300, 3020, 1650, 1065, 1047, 760, and 738 cm^{-1}; NMR δ: 0.65 (3H, s, 18-CH_3), 1.00 (3H, s, 19-CH_3), 4.16 (1H, dd, J=5.0, 8.2 Hz, 3β-H), and 5.50 (2H, s, $W/2$=3.0 Hz). Found: C, 83.80; H, 12.05%. Calcd for $C_{27}H_{46}O$: C, 83.87; H, 11.99%.

Acetylation of **5a** with pyridine–acetic anhydride gave 3α-acetate (**5b**), melting at 113—115 °C. IR (KBr): 1735, 1240, 1025, 770, and 735 cm^{-1}; NMR δ: 0.66 (3H, s, 18-CH_3), 1.02 (3H, s, 19-CH_3), 1.98 (3H, s, 3α-OAc), 5.28 (1H, t, J=9.0 Hz, 3β-H), 5.39 (1H, d, J=9.5 Hz, 2-H), and 5.67 (1H, d, J=9.5 Hz, 1-H). Found: C, 80.66; H, 10.94%. Calcd for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%.

5β-Cholest-1-en-3β-ol (**6a**, 60 mg) was obtained as plates from the mother liquor by repeated crystallization from ether–methanol. Mp 114—118 °C; IR (KBr): 3020, 1650, 1040, 1010, and 780 cm^{-1}; NMR δ: 0.65 (3H, s, 18-CH_3), 1.03 (3H, s, 19-CH_3), 3.98 (1H, m, $W/2$=8.5 Hz, 3α-H), and 5.63 (2H, s with shoulder). Found: C, 84.56; H, 12.65%. Calcd for $C_{27}H_{46}O$: C, 83.87; H, 11.99%.

Acetylation of **6a** with pyridine-acetic anhydride gave 3β-acetate (**6b**), melting at 67—69 °C. IR (KBr): 3020, 1720, 1250, 1020, 850, and 770 cm^{-1}; NMR δ: 0.67 (3H, s, 18-CH_3), 1.09 (3H, s, 19-CH_3), 1.98 (3H, s, 3β-OAc), and 4.92—5.92 (3H, complex signals). Found: C, 81.24; H, 10.65%. Calcd for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%.

*Hydrogenation of 5β-Cholest-1-en-3α-ol (**5a**) and 3β-ol (**6a**).* A mixture of **5a** (100 mg), 5% palladium–charcoal (50 mg), and cyclohexane (20 ml) was stirred vigorously under hydrogen atmosphere at room temperature for 1 h. The solution was filtered and evaporated under reduced pressure. Crystallization of the residue from ether–methanol gave 5β-cholestan-3α-ol (**7**, 45 mg) as fine needles, melting at 108—111 °C (lit,[7] mp 107—109 °C).

Similar hydrogenation of **6a** (10 mg) gave 5β-cholestan-3β-ol **8**, 6 mg) as needles, melting at 100—102 °C (lit,[7] mp 96—98 °C).

*3α-Chloro-5β-cholest-1-ene (**9**).* Thionyl chloride (1.0 ml) was added to a solution of **5a** (313 mg) in benzene (10 ml), and the mixture was stirred at room temperature for 3 h, poured into water containing ice, and extracted with ether. The organic layer was washed with aq sodium hydrogencarbonate and saline, dried and evaporated. Crystallization of the oil from acetone afforded **9** (240 mg) as fine needles. Mp 74—76 °C; IR (KBr): 3020, 1640, 775, and 665 cm^{-1}; NMR δ: 0.65 (3H, s, 18-CH_3), 1.02 (3H, s, 19-CH_3), 4.50 (1H, dd, J=7.0, 10.0 Hz, 3β-H), and 5.50 (2H, s, $W/2$=4.5 Hz). Found: C, 80.12; H, 11.18%. Calcd for $C_{27}H_{45}Cl$: C, 80.05; H, 11.20%.

*5β-Cholest-1-ene (**1**).* Lithium aluminium hydride (3.0 g) was added to a solution of **9** (5.5 g) in dry ether (500 ml), and the mixture was refluxed for 22 h. After the excess hydride had been decomposed with dil sulfuric acid, the ethereal layer was washed with aq sodium hydrogencarbonate and water, dried and evaporated. Crystallization of the oil from acetone gave **1** (3.7 g) as needles, melting at 48—51 °C. IR (KBr): 3020, 1650, 718, and 706 cm^{-1}; NMR δ: 0.65 (3H, s, 18-CH_3), 0.99 (3H, s, 19-CH_3), and 5.47 (2H, s, $W/2$=2.0 Hz). Found: C, 87.15; H, 12.85%. Calcd for $C_{27}H_{46}$: C, 87.49; H, 12.51%.

*Sodium Borohydride Reduction of 2β-Bromo-5β-cholestan-3-one (**3**).* Sodium borohydride (0.36 g) was added with stirring to a suspension of **3** (4.0 g) in absolute ethanol (160 ml). The mixture was stirred for 60 min and then concentrated under reduced pressure. The residue was dissolved in ether, and the solution was washed with water repeatedly and dried over anhydrous sodium sulfate. Evaporation of the solvent under reduced pressure gave 2β-bromo-5β-cholestan-3ξ-ol (**10**, 4.0 g) as a colorless oil, which resisted crystallization from various solvents. IR (NaCl): 3420 cm^{-1}.

*5β-Cholest-2-ene (**2**).* Zinc dust (36.0 g) was added to a solution of the bromohydrin mixture (**10**, 3.7 g) in acetic acid (40 ml), and the mixture was refluxed for 90 min. After the zinc dust had been filtered off, the filtrate was diluted with water and extracted with ether. The organic layer was neutralized with aq sodium hydrogencarbonate, washed with saline, dried and evaporated. The product (3.2 g) was chromatographed over silica gel, and the fractions eluted with hexane were collected and crystallized from acetone, giving **2** as needles (1.3 g), melting at 46—48 °C (lit,[2] mp 47—48 °C). IR (KBr): 3020, 1655, and 660 cm^{-1}; NMR δ: 0.64 (3H, s, 18-CH_3), 0.95 (3H, s, 19-CH_3), and 5.49 (2H, s, $W/2$=4.5 Hz.)

*Gas Chromatography of the Oxygenation Products of 5β-Cholest-1-ene (**1**) and 2-ene (**2**).* A Hitachi Model 063 instrument was used for gas chromatography. Oxygenation products were analyzed with use of a 2 m×5 mm column packed with 5% OV-17 on Chromosorb W (80—100 mesh) operating at 250 °C. Olefins (**1**) and (**2**) in glass tubes equipped with a screw cap were preserved for *ca.* a year at room temperature and at temperature below 5 °C.

In both samples of **1** and **2** aged at room temperature, most of the olefins were converted into **4**. On the other hand, no oxygenated product was present in **1** or **2** aged at temperature below 5 °C.

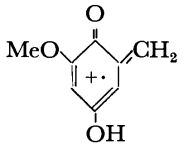
(Received June 18, 1977)

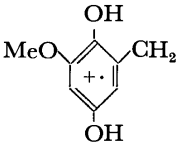
Synopsis. Ardisianone and ardisianol isolated from *Ardisia quinquegona* Blume were determined to be 2-(2-acetoxypentadecyl)-6-methoxy-1,4-benzoquinone and 4-acetoxy-2-(2-acetoxypentadecyl)-6-methoxyphenol, respectively.

In the course of our studies on constituents of Chinese herbal drugs, a yellow pigment and a phenol, designated as ardisianone and ardisianol, respectively, were found from *Ardisia quinquegona* Blume. The plants of Myrsinaceae species are known to contain many benzoquinoid pigments.[1-4] All of these quinones have been proved to possess 2-alkyl-3,6-dihydroxy(or methoxy)-1,4-benzoquinone chromophores. In contrast to these pigments, the present new pigment has been found to have 2-alkyl-6-methoxy-1,4-benzoquinone group.

The UV absorption maxima (268 and 363 nm) of ardisianone, $C_{24}H_{38}O_5$, appeared in shorter wave length than those of 2-hydroxy-5-methoxy-,[1] 2-hydroxy-6-methoxy-,[5] and 5-alkyl-3-hydroxy-2-methoxy-1,4-benzoquinones,[5] and coincided with those of 3-,[5] 5-,[5] and 6-methoxy-2-alkyl-1,4-benzoquinones.[5] The presence of the methoxybenzoquinone group was supported by the appearance of characteristic fragments[6] **a** and **b** in the mass spectrum. The PMR spectrum



a

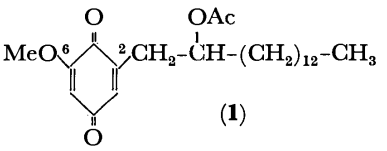


b

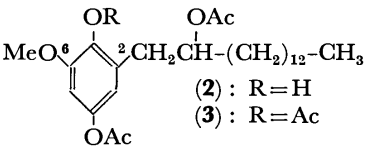
showed a pair of doublets at δ 5.84 (J=2 Hz) and 6.83 (J=2 Hz) assignable to 5- and 3-protons of 2-alkyl-6-methoxy-1,4-benzoquinone from the coupling constant. The latter doublet was broadened by coupling with methylene protons (δ 2.63) at 2-position. The PMR spectrum showed the signals of methoxyl (δ 3.80) and acetoxyl (δ 1.98) groups, in addition to a broad singlet (24 H) at δ 1.28 and a deformed triplet (3 H) at δ 0.88, which could be assigned to methylene and methyl protons of tridecyl group, respectively. Decoupling experiments revealed that two nonequivalent protons observed at δ 2.63 is coupled to a proton at δ 4.95 with J=8 and 4 Hz, and also to a quinoid proton at δ 6.83 with J= 0.5 Hz, showing the presence of Ar–CH_2–CH(OAc)– moiety. Irradiation at δ 2.63 changed the multiplet at δ 4.95 into a broad triplet and the broad doublet at δ 6.83 into a sharp doublet. From these facts the structure of ardisianone was assigned to **1**.

Ardisianol, $C_{26}H_{42}O_6$, showed UV maxima at 230 and 283 nm, which shifted to 258 and 298 nm by addition of aqueous potassium hydroxide. Its IR spectrum exhibited the absorption bands at 3400 (OH) and 1770 cm^{-1} (phenyl acetate). These spectral properties indicated that ardisianol is a phenol possessing an acetoxyl group on the aromatic ring. The intense absorptions at 2925 and 1720 cm^{-1} suggested the presence of an alkyl chain bearing another acetoxyl group. The PMR spectrum of ardisianol partly resembled that of **1**, and the presence of methoxyl and 2-acetoxypentadecyl groups was easily deduced from the signals at δ 3.81 (3H, s), 1.90 (3H, s), 2.80 (2H, ABX), 5.05 (1H, m), 1.26 (24H, bs), and 0.90 (3H, t). A sharp singlet (3H) at δ 2.20 was assignable to an acetoxyl group of phenyl acetate. The aromatic protons of ardisianol appeared as a broad singlet at δ 6.41 (2H). These facts indicated that ardisianol was tetrasubstituted (OMe, OH, OAc, and 2-acetoxypentadecyl)benzene, but the positions of these substituents were not clarified from the spectral data.

Hydrogenation of **1** over platinum catalyst in acetic anhydride followed by addition of sodium acetate afforded a colorless monoacetyl product without formation of the diacetate. The monoacetylated product was found to be identical with ardisianol. The monoacetate was further converted into the diacetate (**3**) under rather forced reaction conditions. The monoacetyl group was first incorporated at C_4–OH group by steric effect, and hence the structure of ardisianol was represented by 4-acetyldihydroardisianone (**2**). The PMR spectrum of the diacetate (**3**) showed an AB quartet centered at δ 6.54 due to aromatic protons. The coupling constant (J=2 Hz) is well consistent with the 2,6-disubstituted hydroquinone of the structure (**3**).



(**1**)



(**2**): R=H
(**3**): R=Ac

Experimental

The melting points are uncorrected. PMR spectra were recorded on a Hitachi H-60 instrument, TMS being used as an internal standard (δ, ppm). IR spectra were taken on a Hitachi EPS-3T spectrometer. Mass spectra were obtained with a Hitachi RMU-6M spectrometer.

*Isolation of Ardisianol (**2**).* The dried and pulverized stems and leaves (720 g) of *Ardisia quinquegona* Blume (Myrsinaceae) were extracted with hot hexane three times. The

combined hexane extracts were concentrated under vacuum, and the dark brown solid residue (20 g) was chromatographed on a column of silica gel (Merck, Kieselgel 60, Art, 7734, 1 Kg). Elution of the column with hexane-ethyl acetate (8 : 1) yielded a white solid, which on crystallization from hexane gave ardisianol (260 mg) as colorless needles; mp 82—84 °C. Found: C, 68.44; H, 9.39%. Calcd for $C_{26}H_{42}O_6 \cdot 1/3H_2O$: C, 68.38; H, 9.42%. UV (EtOH): 230sh (logε, 3.74) and 283 nm (3.52). IR (KBr): 3400, 2925, 2850, 1770, 1720, 1630, 1600, 1500, 1470, 1440, 1380, 1265, and 1230 cm^{-1}. MS *m/e* (rel intensity): 450 (M^+, 0.5), 422 (4), 408 (0.5), 390 (3), 380 (4), 362 (13), 348 (19), 320 (100), 154 (19), and 153 (18).

*Isolation of Ardisianone (**1**).* Further elution with hexane-ethyl acetate (8 : 1) furnished a yellow solid, which on crystallization from ethanol yielded ardisianone (350 mg) as yellow needles; mp 49—54 °C. Found: C, 70.82; H, 9.69%. Calcd for $C_{24}H_{38}O_5$: C, 70.90; H, 9.42%. UV (EtOH); 268 (logε, 4.12) and 363 nm (3.01). IR (KBr): 2925, 2850, 1730, 1690, 1655, 1625, 1605, 1470, 1380, 1330, 1240, and 1050 cm^{-1}. MS *m/e* (rel intensity): 408 (0.5), 407 (0.5), 406 (M^+, 0.5), 364 (7), 346 (27), 194 (21), 153 (20), and 152 (18).

Ardisianol from Ardisianone. A mixture of ardisianone (1; 17 mg) and platinum oxide (7 mg) in acetic anhydride (0.2 ml) was stirred under hydrogen atmosphere at room temperature. After 5 min, yellow color of the mixture disappeared. Sodium acetate (20 mg) was then added, and the mixture was stirred under hydrogen overnight. The product was taken up into ether. The ethereal solution was washed with water and brine, and dried over sodium sulfate. Evaporation of the ether yielded pale yellow crystals (17 mg). Recrystallization from hexane gave rise to white crystalline powder (mp 84—86 °C), the IR spectrum (KBr) of which was superimposable over that of ardisianol.

*1,4-Diacetoxy-3-methoxy-5-(2-acetoxypentadecyl)benzene (**3**).* A solution of ardisianol (14 mg) in pyridine (0.1 ml) and acetic anhydride (0.1 ml) was warmed at 45 °C in a sealed tube overnight. The reaction mixture was poured into water, and extracted with ether. After being washed with water, the ethereal layer was evaporated, affording colorless crystals. Recrystallization from hexane yielded ardisianol acetate (**3**); mp 60.5—62 °C. Found: C, 67.63; H, 8.94%. Calcd for $C_{22}H_{44}O_5 \cdot 1/3H_2O$: C, 67.46; H, 9.03. IR(KBr): 1750 and 1730 cm^{-1}. PMR (δ, CCl_4): 0.91 (3H, t), 1.28 (24H, bs), 1.98 (3H, s), 2.24 (3H, s), 2.30 (3H, s), 2.70 (2H, ABX, $J_{AB}=13$, $J_{AX}=6$, $J_{BX}=7$ Hz), 3.79 (3H, s), 4.75 (1H, m), and 6.55 (2H, AB, $J_{AB}=2$ Hz).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (3), 945—946 (1978)

Uptake of Ammine-Cobalt(III) Complexes into *Escherichia Coli* Cells

Kiyoshi TANABE, Kitao FUJIWARA, and Keiichiro FUWA

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received July 27, 1977)

Synopsis. The uptake of Co into *E. coli* cells was studied in various Co(III) ammine complexes. It was found to be independent of the incubating temperature and existence of Mg^{2+} ion, but dependent on the ligands, the uptake of Co being in the following order. $[Co(NH_3)_4(OH_2)_2]_2(SO_4)_3 > [Co(NH_3)_5(OH_2)]Cl_3 > [Co(NH_3)_6]Cl_3 \gg [Co(en)_3]Cl_3 > [Co(OH_2)_6]Cl_2$

Wide attention has been given to the activities or properties of various inorganic complexes of transition metals in biological fields. For example, it was found that *cis*-dichlorodiamineplatinum(II) suppresses the division of *E. coli* cells by inhibiting DNA synthesis.[1,2] Chromium, palladium, and rhodium complexes also have a similar function.[3,4] Several reports suggest that these complexes might become useful anti-cancer drugs by controlling the propagation of cancer cells in consequence of interaction between DNA molecule and the complexes.[5]

The effect of several cobalt(III) complexes which induce filamentous growth or inhibit the respiration of *E. coli* has also been reported.[6] On the assumption of quantitative estimation for the biological function of these complexes, the locomotion and distribution of the complexes in the bioorganism have not been fully elucidated. The uptake of several cobalt(III) complexes into the *E. coli* cells is given in this report.

Experimental

Escherichia coli B (ATCC 11246) was used as the test organism, which was grown in minimum nutrient media: K_2HPO_4(40 mM), KH_2PO_4(22 mM), $(NH_4)_2SO_4$ (7.6 mM), disodium citrate (2.1 mM), $MgSO_4$(0.8 mM), and glucose (27.8 mM) were dissolved in distilled water. Cobalt(III) complexes $[Co(NH_3)_6]Cl_3$, $[Co(en)_3]Cl_3$, $[Co(NH_3)_5(OH_2)]Cl_3$, and $[Co(NH_3)_4(OH_2)_2]_2(SO_4)_3$ were prepared by the usual methods.

E. coli was preincubated twice and incubated in 200 ml media at 30 °C with shaking. When turbidity of media become O.D. 0.7, the cobalt(III) complexes were added to make cobalt concentration 30 ppm. *E. coli* cells incubated with complexes for 1 h were harvested by centrifugation (5000×g 8 min), washed twice with 0.9% sodium chloride solution, dried at 105 °C until weights of harvest became constant within 0.3 mg, and ashed at 600 °C in an electric furnace. After the ashed cells had been dissolved in hydrochloric acid, the amount of cobalt was determined by atomic absorption analysis using a Hitachi 207 atomic absorption spectrophotometer.

Results and Discussion

Many mechanisms concerning the uptake of metal ions have been reported. For example, the uptake of the cobalt(II) into *E. coli* is an active transport linked with the energy metabolism,[7,8] and is suppressed in the presence of Mg^{2+} as shown in Table 1.

The uptake of cobalt(III) complexes is independent of the presence of Mg^{2+}. The amount of complexes taken up into the cell is found to be almost unchanged with incubation temperature. The results indicate that the uptake of these complexes depends on the physical adsorption on the cell surface, but not on the biological activity. This can be supported by the fact that it is difficult for hydrophilic ions to pass the biological membrane without active transport system.

Ease of uptake of the cobalt(III) complexes is in the following order: $[Co(NH_3)_4(OH_2)_2]_2(SO_4)_3 > [Co(NH_3)_5(OH_2)]Cl_3 > [Co(NH_3)_6]Cl_3 \gg [Co(en)_3]Cl_3 > [Co(OH_2)_6]Cl_2$. The amounts of taken-up complexes seem to be dominated by the number of aqua ligands. From the fact that $[Co(NH_3)_6]Cl_3$ is taken up about three times more than $[Co(en)_3]Cl_3$, the hydrophilicity of ligands seems also important in the uptake of complexes. The results indicate that the formation of hydrogen bond with cell surface *via* the hydrogen atom of ligands of the complex plays an important role in the uptake of the cobalt(III) complexes.

The authors are indebted to Dr. Shozo Toda for his useful suggestions.

An ESR Study of *N*-Sulfonylaminyls[1]

Yozo MIURA, Yuji NAKAMURA, and Masayoshi KINOSHITA

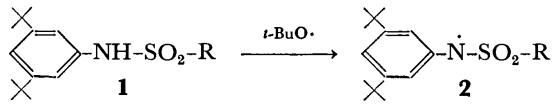
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received September 9, 1977)

Synopsis. *N*-(3,5-Di-*t*-butylphenyl)-*N*-sulfonylaminyls, 3,5-*t*-$Bu_2C_6H_3$-$\dot{N}$-SO_2-R, were investigated by means of ESR spectroscopy. The a_N values are 7.8 G, and the a_H values due to the *N*-phenyl ring protons are 5.6 (*o*-H) and 7.6 G (*p*-H). However, no couplings due to the protons in R have been detected. From these results, it is concluded that the unpaired electron is located on the nitrogen atom and the *N*-phenyl ring, negligibly delocalized onto the sulfonyl group.

N-Sulfonylaminyls have been of considerable interest as intermediates in chemical and photochemical reactions.[2] However, the radicals have little been investigated by means of ESR spectroscopy.[3] Recently, we have examined some nitrogen-centered free radicals in which one or two divalent sulfur atoms are adjacent to the central nitrogen.[1] Sulfonylaminyls are also of interest in comparison with the nitrogen-centered free radicals from the point of view of ESR spectroscopy. In this paper we will report an ESR study of *N*-(3,5-di-*t*-butylphenyl)-*N*-sulfonylaminyls (**2**).

The radicals **2** were generated in benzene by hydrogen-abstraction from sulfonamides, **1**, by *t*-butoxyl which



was obtained on the pyrolysis of di-*t*-butyl diperoxyoxalate.[4] The ESR parameters for **2** are listed in Table 1, and a typical ESR spectrum is illustrated in Fig. 1. As can be seen from the figure, well-resolved spectra were recorded in any case by this procedure. However, some peaks in the signals were gradually broadened with the passage of time (*ca.* 1 h). This may be caused by the occurrence of a secondary radical which could not be identified.

The ESR parameters for **2** are quite different from those reported for sulfonyl nitroxides, $RN(O\cdot)SO_2R'$, ruling out the possibility that **2** are nitroxides.[5]

The a_H values of **2** are considerably large and are constant within the limits of experimental error, regardless of the sulfonyl groups. On the other hand, no couplings due to the sulfonyl protons have ever been detected. From these results, it is obvious that the unpaired electron is located on the nitrogen and the *N*-phenylring, negligibly delocalized onto the sulfonyl group. The *g*-values for **2** are 2.0033, which is approximately equal to that for a typical nitrogen-centered free radical, diphenylaminyls (2.0032)[6] or 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (2.0033).[7] In contrast, the *g*-value (2.0059) of the *N*-(arylthio)aminyl, **3**, is considerably larger than those of **2**.[8]

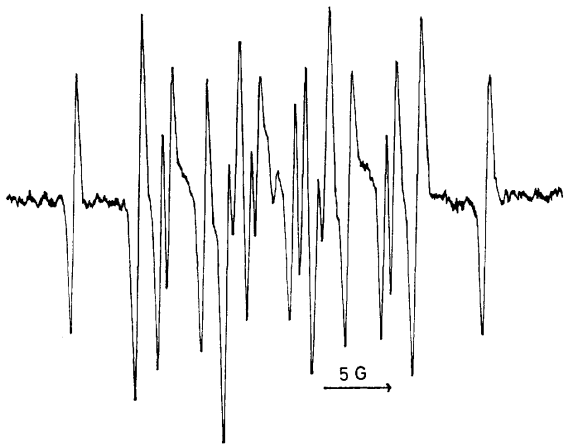


Fig. 1. An ESR spectrum of **2a** in benzene at room temperature.

The results obtained for **2** are consistent with those for the sulfonyl-conjugated radicals, $\cdot CR_1R_2SO_2R_3$,[9] in which the unpaired electron is not delocalized onto the sulfonyl group. In the case of **3**,[8] on the other hand, the unpaired electron is delocalized to some extent onto the *S*-phenyl ring.

On the basis of the results and discussion, it is concluded that sulfonyl groups have not ability to delocalize the unpaired electron in *N*-sulfonylaminyls, much as in the case of the sulfonyl-conjugated carbon radicals.[9]

Experimental

All the melting points are uncorrected. The IR spectra were run on a JASCO IR-G Spectrometer, while the NMR

spectra were recorded with a Hitachi-Perkin Elmer R-20 Spectrometer, using TMS as the internal standard. 3,5-Di-*t*-butylaniline[10] and di-*t*-butyl diperoxyoxalate[4] were prepared by the reported methods.

Preparation of Sulfonamides. A solution of sulfonyl chloride (0.010 mol), 3,5-di-*t*-butylaniline (0.0097 mol), and triethylamine (0.011 mol) in dry ether (200 ml) was stirred for two days at room temperature. After the reaction mixture was filtered, ether was removed by evaporation and the resulting residue was subjected to column-chromatography [Mallinckrodt, silica gel (100 mesh), eluent: benzene/hexane: 15/1], followed by recrystallization from appropriate solvents.

N-*(3,5-Di-*t*-butylphenyl)benzenesulfonamide (**Ia**).* Colorless prisms with a mp of 144—145 °C (from benzene/hexane: 1/5, then hexane). Yield: 80%. IR (KBr): 3200 (NH) and 1170 cm^{-1} (SO_2). NMR ($CDCl_3$): δ 1.20 (s, *t*-Bu, 18H) and 6.82—7.85(m, C_6H_3 and C_6H_5, 8H). Found: C, 69.94; H, 7.51; N, 3.98%. Calcd for $C_{20}H_{27}NO_2S$: C, 69.52; H, 7.88; N, 4.05%.

N-*(3,5-Di-*t*-butylphenyl)-*p*-toluenesulfonamide (**Ib**).* Colorless prisms with a mp of 173—175 °C (from benzene/hexane: 1/10, then hexane). Yield: 82%. IR (KBr): 3200 (NH) and 1150 cm^{-1} (SO_2). NMR ($CDCl_3$): δ 1.20 (s, *t*-Bu, 18H), 2.35 (s, CH_3, 3H), and 6.85—7.76 (m, C_6H_3 and C_6H_4, 7H). Found: C, 70.22; H, 8.20; N, 3.90%. Calcd for $C_{21}H_{29}NO_2S$: C, 70.15; H, 8.13; N, 3.90%.

N-*(3,5-Di-*t*-butylphenyl)methanesulfonamide (**Ic**).* Colorless needles with a mp of 134—136 °C (from hexane). Yield 56%. IR (KBr): 3300 and 3200 (NH) and 1160 and 1140 cm^{-1} (SO_2). NMR ($CDCl_3$): δ 1.30 (s, *t*-Bu, 18H), 2.98 (s, CH_3, 3H), 6.95 (bs, NH, 1H), and 7.05—7.27 (m, C_6H_3, 3H). Found: C, 63.87; H, 8.67; N, 5.00%. Calcd for $C_{15}H_{25}NO_2S$: C, 63.56; H, 8.89; N, 4.94%.

ESR Spectra. Sulfonamide (20 mg), di-*t*-butyl peroxyoxalate (30 mg), and benzene (0.4 ml) were placed in an ESR tube, after which the solution was degassed by three freeze-and-thaw cycles, then sealed. The ESR signals were recorded at room temperature (*ca.* 21 °C) on a JES-ME-3X Spectrometer with an X-band microwave unit and 100 KHz field modulation.

Alicyclic Terpenoids from Cyclocitryl Phenyl Sulfides. VI.[1] Syntheses of β-Ionone Derivatives

Sigeru TORII,* Kenji UNEYAMA, and Ichiro KAWAHARA
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received September 11, 1977)

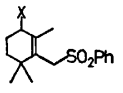
Synopsis. 4-(2,6,6-Trimethyl-3-oxo-1-cyclohexenyl)-3-buten-2-one and 4-(2,6,6-trimethyl-1,3-cyclohexadienyl)-3-buten-2-one were efficiently synthesized by alkylation of 2,4,4-trimethyl-3-(phenylsulfonylmethyl)-2-cyclohexen-1-ol and 1-(phenylsulfonylmethyl)-2,6,6-trimethyl-1,3-cyclohexadiene with propylene oxide followed by oxidation and elimination of sulfonyl group, respectively.

In connection with studies on the synthesis of terpenoids, we demonstrated a simple preparation of cyclocitryl phenyl sulfone (**1**) and its use as a synthon for cyclocitral.[2] The sulfone **1** was also converetd to β-ionone, deoxytrisporone,[3] and vitamin A acid methyl esters.[4] Here, we describe a convenient preparation of 1-phenylsulfonylmethyl-2,6,6-trimethylcyclohexa-1,3-diene (**4**) from **1**, as well as syntheses of 4-(2,6,6-trimethyl-3-oxo-1-cyclohexenyl)-3-buten-2-one (**5**), a tea aroma substance[5,6] and 4-(2,6,6-trimethyl-1,3-cyclohexadienyl)-3-buten-2-one (**6**), a tobacco flavor constituent,[7,8] from **2** and **4**, respectively.

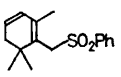
Oxidation of **1** with 1.5 equiv of SeO_2 in dioxane at 80 °C for 1.5 h gave the alcohol **2** (74%) and the starting material **1** (23%). On treatment of **2** with PBr_3 in dry ether at 0 °C,[9] the alcohol **2** was converted smoothly to the corresponding bromo compound **3**, which was dehydrobrominated by the action of 1.5 equiv of LiCl in DMF at 100 °C for 2 h, affording **4** in 92% yield.

The reaction of **2** with 2 equiv. of BuLi in THF at −70 °C, followed by reaction with propylene oxide at room temperature for 20 hours, provided the diol **7** in 86% yield. The alcohol **7** was easily purified by column chromatography (SiO_2) and was homogeneous by TLC, but the NMR was unexpectedly complex, presumably due to intramolecular hydrogen bonding between the hydroxyl group and sulfonyl oxygen and/or the presence of diastereomers on C-2 and C-4. On oxidation with Jones reagent, **7** was converted to the corresponding diketone in 92% yield, whose NMR spectrum was in agreement with the structure **8**.

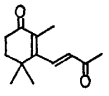
Treatment of **8** with MeONa in *t*-BuOH-EtOH at room temperature afforded **5** in 78% yield.[11]



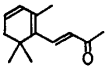
1 X=H
2 X=OH
3 X=Br



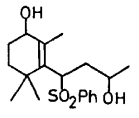
4



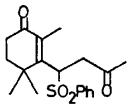
5



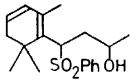
6



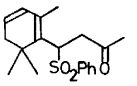
7



8



9



10

Alkylation of **4** with propylene oxide was performed similarly with 1 equiv. of BuLi, affording **9** in 95% yield. Oxidation of **9** was attempted with both Jones and Collins reagents, but the yield of the ketone **10** was unsatisfactory. However, when **9** was oxidized with pyridinium chlorochromate in anhydrous dichloromethane at room temperature as described by Corey,[12] the ketone **10** was obtained in 82% yield. Then, **10** was subjected to the base-promoted elimination of sulfonyl group with MeONa in *t*-BuOH–EtOH at room temperature to give **6** in 88% yield. The IR and NMR spectra of **6** are consistent with those reported.[7]

Experimental

Melting points are uncorrected. IR spectra were determined with a Jasco IRA-1 infrared spectrometer. NMR spectra were obtained at 60 MHz with a Hitachi R-24 spectrometer and the chemical shift values are expressed in δ value (ppm) relative to Me_4Si in $CDCl_3$.

*2,4,4-Trimethyl-3-phenylsulfonylmethyl-2-cyclohexen-1-ol (**2**).* A mixture of **1** (102 mg, 0.37 mmol) and SeO_2 (62 mg, 0.56 mmol) in 1 ml of dioxane was stirred at 80 °C for 1.5 h. After removing the precipitate with centrifuge and evaporating the solvent *in vacuo*, the residue was chromatographed (SiO_2, benzene/hexane=5/1) to give **2** (82 mg, 74%) together with **1**(24 mg, 23%): Mp 94—95 °C (benzene/hexane =1/10); IR (Nujol) 3500 (OH), 1632 (C=C), 1302, 1137 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 8.02—7.42 (5H, m, ArH), 3.98 (2H, s, CH_2SO_2), 3.80—4.10 (1H, m, CHOH), 2.98 (1H, s, OH), 1.84 (3H, s, CH_3C=), 1.12—2.22 (4H, m, CH_2), 1.08 (3H, s, CH_3), 1.01 (3H, s, CH_3).

Found: C, 65.42; H, 7.53%. Calcd for $C_{16}H_{22}O_3S$: C, 65.29; H, 7.53%.

*2,6,6-Trimethyl-1-(phenylsulfonylmethyl)-3-bromocyclohexene (**3**).* Into a solution of **2** (372 mg, 1.26 mmol) in 1.2 ml of dry ether and 0.8 ml of dry THF was added dropwise phosphorus tribromide (344 mg, 1.27 mmol) at 0 °C and the mixture was stirred for 2.5 h. After addition of saturated $NaHCO_3$, the organic substances were extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to give **3** as pale colored crystals (450 mg, 100%): Mp 129—130 °C (AcOEt/hexane=1/10); IR(Nujol)

1305, 1145 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 7.45—8.02 (5H, m, ArH), 4.58—4.75 (1H, m, CHBr), 3.96 (2H, s, CH_2SO_2), 2.07—2.26 (2H, m, CH_2), 1.86 (3H, s, CH_3), 1.27—1.68 (2H, m, CH_2), 1.06 (3H, s, CH_3), 1.03 (3H, s, CH_3).

Found: C, 53.68; H, 5.99%. Calcd for $C_{16}H_{21}O_2SBr$: C, 53.79; H, 5.93%.

*2,6,6-Trimethyl-1-(phenylsulfonylmethyl)-1,3-cyclohexadiene (**4**).* A mixture of **3** (450 mg, 1.26 mmol) and LiCl (80 mg, 1.89 mmol) in dry DMF was stirred under N_2 at 100 °C for 2 h. After addition of 5 ml of water, the organic substances were extracted with ether. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield 351 mg of crystals, which was chromatographed (SiO_2, AcOEt/hexane=1/5) to give **4** (323 mg, 93%): Mp 58—60 °C (benzene/hexane=1/10); IR (Nujol) 1305, 1145 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 7.38—8.04 (5H, m, ArH), 5.78 (2H, br s, CH=CH), 4.01 (2H, s, CH_2SO_2), 2.07 (2H, d, J=4 Hz, CH_2C=), 1.62 (3H, s, CH_3C=), 1.11 (6H, s, CH_3).

Found: C, 69.43; H, 7.42%. Calcd for $C_{16}H_{20}O_2S$: C, 69.55; H, 7.30%.

*4-Phenylsulfonyl-4-(2,6,6-trimethyl-3-hydroxy-1-cyclohexenyl)-2-butanol (**7**).* Into a solution of **2** (103 mg, 0.35 mmol) in 1.5 ml of dry THF, was added ethereal solution of BuLi (0.8 mmol) at −50 °C under N_2. After stirring for 15 min, propylene oxide (0.2 ml) was added to the mixture, which was stirred at room temperature for additional 20 h. The reaction mixture was quenched with saturated NH_4Cl and extracted with AcOEt. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield a viscous liquid, which was chromatographed (SiO_2, benzene/AcOEt=1/1) to give **7** (106 mg, 86%): IR (neat) 3407 (OH), 1291, 1137 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 7.34—8.00 (5H, m, ArH), 3.39—4.46 (3H, m, CHOH, $CHSO_2$), 2.42—3.00 (2H, m, OH), 2.08 (3H, s, CH_3C=), 1.39—2.40 (6H, m, CH_2), 0.67—1.32 (9H, m, CH_3).

Found: C, 64.92; H, 8.09%. Calcd for $C_{19}H_{28}O_4S$: C, 64.75; H, 8.01%.

*4-Phenylsulfonyl-4-(2,6,6-trimethyl-3-oxo-1-cyclohexenyl)-2-butanone (**8**).* Into a solution of **7** (46 mg, 0.13 mmol) in 0.5 ml of CH_2Cl_2, was added Jones reagent[13] (0.2 ml, 0.52 mmol) under ice-cooling and the mixture was stirred at 5 °C for 1 h. After addition of 0.5 ml of water, the organic substances were extracted with $CHCl_3$. The extracts were washed with saturated $NaHCO_3$ and water, dried (Na_2SO_4), and concentrated *in vacuo* to yield 45 mg of dark brown crystals, which were chromatographed (SiO_2, benzene/AcOEt=2/1) to give **8** (41 mg, 92%): Mp 128—129 °C (benzene/hexane=1/10); IR (Nujol) 1717 (C=O), 1658 (C=C), 1297, 1148 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 7.35—7.93 (5H, m, ArH), 4.95 (1H, dd J=6.6 and 2.4 Hz, $CHSO_2$), 3.91 (1H, dd J=6.6 and 19.2 Hz, CH_2CSO_2), 2.73 (1H, dd J=2.4 and 19.2 Hz, CH_2CSO_2), 2.28—2.52 (2H, m, CH_2), 2.10 (3H, s, CH_3), 2.07 (3H, s, CH_3), 1.64—2.00 (2H, m, CH_2), 1.17 (3H, s, CH_3), 0.97 (3H, s, CH_3).

Found: C, 65.59; H, 7.04%. Calcd for $C_{19}H_{24}O_4S$: C, 65.50; H, 6.94%.

*4-Phenylsulfonyl-4-(2,6,6-trimethyl-1,3-cyclohexadienyl)-2-butanol (**9**).* The alcohol **9** could be prepared in 95% yield under similar reaction conditions to the procedure described for **7**: IR (neat) 3493 (OH), 1303, 1143 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 7.31—8.02 (5H, m, ArH), 5.62—5.86 (2H, m, CH=CH), 4.21—4.56 (1H, m, $CHSO_2$), 3.46—4.06 (1H, m, CHOH), 1.56—2.36 (7H, m, CH_2, OH), 1.99 (3H, s, CH_3), 0.78—1.40 (9H, m, CH_3).

Found: C, 68.37; H, 7.98%. Calcd for $C_{19}H_{26}O_3S$: C, 68.24; H, 7.84%.

*4-Phenylsulfonyl-4-(2,6,6-trimethyl-1,3-cyclohexadienyl)-2-butanone (**10**).* Into a solution of pyridinium chlorochromate (74 mg, 0.34 mmol) in 1 ml of dry CH_2Cl_2, was added the alcohol **9** (58 mg, 0.17 mmol) dissolved in 0.5 ml of dry CH_2Cl_2 under N_2 and the mixture was stirred at room temperature for 8 h. After addition of 1 ml of water, the organic substances were extracted with $CHCl_3$. The extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield a dark brown oil, which was chromatographed (SiO_2, benzene/AcOEt=10/1) to give **10** (47 mg, 82%) as a colorless liquid: IR (CCl_4) 1721 (C=O), 1646 (C=C), 1302, 1145 (SO_2) cm^{-1}; NMR ($CDCl_3$) δ 7.35—8.00 (5H, m, ArH), 5.74 (2H, br s, CH=CH), 4.95 (1H, dd J=6.6 and 4.8 Hz, $CHSO_2$), 3.71 (1H, dd J=6.6 and 18.6 Hz, CH_2CSO_2), 2.79 (1H, dd J=4.8 and 18.6 Hz, CH_2CSO_2), 2.05 (3H, s, CH_3), 2.01 (3H, s, CH_3), 1.80—2.20 (2H, m, CH_2), 0.94 (3H, s, CH_3), 0.82 (3H, s, CH_3).

Found: C, 68.88; H, 7.37%. Calcd for $C_{19}H_{24}O_3S$: C, 68.66; H, 7.28%.

*4-(2,6,6-Trimethyl-3-oxo-1-cyclohexenyl)-3-buten-2-one (**5**).* A solution of **8** (74 mg, 0.21 mmol) in 4 ml of dry *t*-BuOH was added into 50 mg of MeONa under N_2 and the mixture was stirred at room temperature for 5 h. The reaction mixture was quenched with saturated NH_4Cl and extracted with ether. The ether extracts were washed with brine, dried (Na_2SO_4), and concentrated *in vacuo* to yield a dark brown oil, which was chromatographed (SiO_2, benzene/AcOEt=7/1) to give **5** (34 mg, 78%) as crystals.

*4-(2,6,6-Trimethyl-1,3-cyclohexadienyl)-3-buten-2-one (**6**).* The compound **6** could be prepared in 78% yield under similar reaction conditions to the procedure described for **5**.

Synthesis of 4-(D-Alanylamino)-2-amino-2,4-dideoxy-D-xylose*

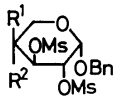
Hassan Akhtar KHAN,** Hironobu HASHIMOTO, and Juji YOSHIMURA

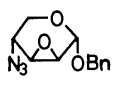
Laboratory for Chemistry of Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta-machi, Midori-ku, Yokohama, 227

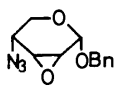
(Received September 22, 1977)

Synopsis. A prumycin diastereomer having D-configuration, 4-(D-alanylamino)-2-amino-2,4-dideoxy-D-xylose, was first synthesized from L-arabinose *via* benzyl 2,3-anhydro-4-azido-α-D-lyxopyranoside.

Prumycin, 4-(D-alanylamino)-2-amino-2,4-dideoxy-L-arabinose, is an antifungal antibiotic[2] and was synthesized independently by three Japanese groups.[3,4,5] In the course of study for the relationship between structures and biological activities, we have also synthesized prumycin and its diastereomers having L-configuration except L-lyxo one.[1] In the present paper, we would like to report the first synthesis of a prumycin diastereomer in D-series using the method developed by us for the synthesis of prumycin.[4] L-Arabinose was used as starting material instead of D-xylose, which was used for the synthesis of L-stereoisomers. 2,3,4-Tri-*O*-mesylate(**1**) of benzyl β-L-arabinopyranoside was subjected to azidolysis to give the corresponding 4-azido derivative(**2**) in excellent yield. Treatment of **2** with sodium methoxide in methanol gave a mixture of benzyl 2,3-anhydro-4-azido-α-D-lyxo(**3**) and -α-D-ribo-pyranoside (**4**), which were separated easily on a silica gel column. The yields of these epoxides depend on the reaction conditions, especially on the concentration of the bases and on the reaction times. As the rates of formation and ring opening reaction of **3** are apparently slower than those of **4**, higher base concentration and longer reaction time facilitate the predominant formation of **3**. In the optimal conditions the both epoxides were formed in 60% yield. By treatment of **2** with 0.7 M sodium methoxide in methanol under reflux for 6—7 h **3** and **4** were obtained in 20 and 15% yields, respectively. The structures of these epoxides were ascertained by the $J_{1,2}$ and $J_{3,4}$ values in their NMR spectra.[6]







1 R^1=OMs, R^2=H **3** **4**
2 R^1=H, R^2=N_3

Ammonolysis of **3** gave benzyl 2-amino-4-azido-α-D-xylopyranoside(**5**) predominantly, which was obtained in 65% yield after chromatographic separation from its ring opening isomer(**6**). The structures of these products were determined by their NMR data, especially by the coupling constants of ring protons as shown in the Experimental. Then, **5** was treated with *t*-butyl azidoformate to give the *N*-*t*-butoxycarbonylated derivative(**7**). The azido group of **7** was hydrogenated selectively in the presence of platinum oxide and condensed with *N*-benzyloxycarbonyl-D-alanine *p*-nitrophenyl ester successively as reported for the synthesis of prumycin. The condensation product(**9**) was converted into 4-(D-alanylamino)-2-amino-2,4-dideoxy-D-xylose hydrochloride(**10**) in good yield by treatment with formic acid, followed by hydrogenolysis under acidic conditions in the presence of palladium-carbon. The biological activities of **10** will be presented elsewhere.

Experimental

^{1}H NMR spectra were recorded with a JNM-PS-100 spectrometer at 100 MHz in deuteriochloroform containting tetramethylsilane as an internal standard. IR spectra were taken with a Hitachi Model EPI-GS grating spectrometer. Optical rotations were measured in chloroform(C) or methanol (M) in a 0.5 dm tube with a Carl Zeiss LEP-AL polarimeter. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

*Benzyl 2,3,4-Tri-O-mesyl-β-L-arabinopyranoside (**1**).* Benzyl β-L-arabinopyranoside[7] (50 g) was mesylated with mesyl chloride (100 g) in pyridine(400 ml) in the usual manner. Yield 75—80%. mp 100—102 °C, $[\alpha]_D$ +71.2° (*c* 1.0, C); NMR: 5.21 (d, H_1, $J_{1,2}$=3.8), 4.90 (dd, H_2, $J_{2,3}$=11.0), 5.12 (dd, H_3, $J_{3,4}$=3.3), 2.92 and 3.15 (s, 3 and 6H, OMs); IR(KBr): 1180 and 1360 (SO_2). Found: C, 38.21; H, 4.63; S, 19.91%. Calcd for $C_{15}H_{22}O_{11}S_3$: C, 37.96; H, 4.67; S, 20.27%.

*Benzyl 4-Azido-4-deoxy-2,3-di-O-mesyl-α-D-xylopyranoside (**2**).* A solution of **1**(50 g), sodium azide(8 g) and urea(1.5 g) in *N*,*N*-dimethylformamide(370 ml) containing water(40 ml) was heated at 110 °C for 24 h. The reaction mixture was evaporated, and the residue was extracted with chloroform. The extract was washed with water, dried with anhydrous sodium sulfate, and evaporated to give a syrup in 81% yield. The syrup was purified on a silica gel column (Wako gel C-200); $[\alpha]_D$ +123.5° (*c* 0.85, C); NMR: 5.15 (d, H_1, $J_{1,2}$=3.6), 4.91 (dd, H_2, $J_{2,3}$=9.5), 4.59 (dd, H_3, $J_{3,4}$=6.0), 2.95 and 3.13 (s, 3H each, OMs); IR(NaCl): 2110 (N_3), 1180 and 1360 (SO_2). Found: C, 40.16; H, 4.73; N, 9.69; S, 15.42%. Calcd for $C_{14}H_{19}N_3O_8S_2$: C, 39.90; H, 4.54; N, 9.97; S, 15.22%.

*Benzyl 2,3-Anhydro-4-azido-4-deoxy-α-D-lyxopyranoside (**3**)* and *-ribopyranoside (**4**).* A 4—5% solution of **2** in methanol containing *ca.* 6 equimolar sodium was refluxed for 6—7 h, until the most of **2** has disappeared. Methanol was evapo-

* Aminosugars XXX. For part XXIX, see Ref. 1.
** UNESCO fellow 1975—1976.

rated and the residue was dissolved in benzene. The benzene layer was washed with water, dried, and evaporated to give a syrup, which was fractionated on a silica gel column by elution with benzene to obtain at first an oily **3** and secondly **4**, in 20% and 15% yields, respectively. **3**: $[\alpha]_D$ +101.4° (*c* 1.2, M); NMR: 4.96 (s, H_1, $J_{1,2}$=0.5), 3.13 and 3.30 (dd, H_2 and H_3, $J_{2,3}$=3.3, $J_{3,4}$=0.5); IR(NaCl): 2100 (N_3). Found: C, 58.79; H, 5.26; N, 17.01%. Calcd for $C_{12}H_{13}N_3O_3$: C, 58.29; H, 5.30; N, 17.00%. **4**: $[\alpha]_D$ +181° (*c* 1.0, M); NMR: 4.94 (d, H_1, $J_{1.2}$=2.7); IR (NaCl): 2100 (N_3). Found: C, 58.61; H, 5.21; N, 16.82 %. Calcd for $C_{12}H_{13}N_3O_3$: C, 58.29; H, 5.30; N, 17.00%.

*Benzyl 2-Amino-4-azido-2,4-dideoxy-α-D-xylopyranoside (**5**) and Benzyl 3-Amino-4-azido-3,4-dideoxy-α-D-arabinopyranoside (**6**).* A methanol solution of **3**(3.5 g) was saturated with ammonia at 0 °C, and then heated in a sealed glass tube at 90 °C for 24 h. After complete evaporation of the solvent, the crystalline product obtained(3.5 g) was fractionated on a silica gel column by elution with benzene containing 5% 2-pronanol (v/v). The faster-eluting component was **5** (2.2 g, 61%) followed by the isomeric 3-amino derivative (**6**: 0.8 g, 23%). **5**: Mp 95—96 °C, $[\alpha]_D$ +184.6° (*c* 1.0, M); NMR: 4.78 (d, H_1, $J_{1,2}$=3.5), 2.69 (dd, H_2, $J_{2,3}$=9.3) and $J_{3,4}$ was found to be 9.4 Hz with the aid of $Eu(FOD)_3$. IR(KBr): 2100 (N_3), 3300 and 3350 (NH_2 and OH). Found: C, 54.40; H, 6.24; H, 21.39%. Calcd for $C_{12}H_{16}N_4O_3$: C, 54.54; H, 6.06; N, 21.21%. **6**: Mp 110—111° C, $[\alpha]_D$ −45.1° (*c* 1.0, M); NMR: 4.23 (d, H_1, $J_{1,2}$=6.9), 3.35 (dd, H_2, $J_{2,3}$=9.2), 2.81 (dd, H_3, $J_{3,4}$=3.9), 3.66 (m, H_4), 3.50 and 4.00 (dd each, H_5 and $H_{5'}$, $J_{4,5}$ and $J_{4,5'}$: 1.2 and 2.4); IR(KBr): 2100 (N_3), 2280 and 2320 (NH_2 and OH). Found: C, 54.92; H, 6.15; N, 21.51%. Calcd for $C_{12}H_{16}N_4O_3$: C, 54.54; H, 6.10; N, 21.21%.

*Benzyl 4-Azido-2-(t-butoxycarbonylamino)-2,4-dideoxy-α-D-xylopyranoside (**7**).* A solution of **5** (1.5 g), *t*-butyl azidoformate (2 g) and triethylamine(1.8 g) in dioxane (15 ml) was heated at 60—70 °C for 3—4 h. The crude product obtained was passed through a column of silica gel by elution with benzene. The first fraction was collected to give **7** (1.8 g), which was recrystallized from methanol. Mp 119—120 °C, $[\alpha]_D$ +191° (*c* 0.7, M); NMR; 4.87 (d, H_1, $J_{1,2}$=1.8) and 1.46 (s, 9H, *t*-Bu); IR(KBr): 2100 (N_3) and 1685 (urethane). Found; C, 55.78; H, 6.66; N, 15.59%. Calcd for $C_{17}H_{24}N_4O_5$: C, 56.08; H, 6.64; N, 15.38%.

*Benzyl 4-Amino-2-(t-butoxycarbonylamino)-2,4-dideoxy-α-D-xylopyranoside (**8**).* Hydrogenation of **7** (1.7 g) in methanol was carried out in the presence of platinum oxide to give **8** (1.3 g); mp 172—175 °C, $[\alpha]_D$ +157° (*c* 1.1, M); NMR (DMSO-d_6): 4.90 (d, H_1, $J_{1,2}$=3.0) and 1.46 (s, 9H, *t*-Bu); IR (KBr): 1685 (urethane) and 3370 (NH_2 and OH). Found: C, 59.81; H, 7.67; N, 8.66%. Calcd for $C_{17}H_{26}N_2O_5$: C, 60.34; H, 7.74; N, 8.28%.

*Benzyl 4-(N-Benzyloxycarbonyl-D-alanylamino)-2-(t-butoxycarbonylamino)-2,4-dideoxy-α-D-xylopyranoside (**9**).* The compound **8** was coupled with *N*-benzyloxycarbonyl-D-alanine *p*-nitrophenyl ester in *N,N*-dimethylformamide in the usual manner to give **9** in 60% yield. Mp 145—147 °C, $[\alpha]_D$ +2.3° (*c* 1.0, M), IR(KBr): 1710 and 1690 (urethane), *1650 and 1520 (amide) and 3320 (NH and OH).* Found: C, 61.92; H, 6.50; N, 7.51%. Calcd for $C_{28}H_{37}N_3O_8$: C, 61.87; H, 6.81; N, 7.73%.

*4-(D-Alanylamino)-2-amino-2,4-dideoxy-D-xylose Dihydrochloride (**10**).* Compound **9** was treated with 98% formic acid for removal of *t*-butoxycarbonyl group and then hydrogenated with palladium-charcoal (10%) in 0.1 N in 50% aqueous ethanol to give **10** in 80% yield, mp 170—175 °C (dec), $[\alpha]_D$ +76.3° (*c* 1.0, M). Found: C, 32.50; H, 6.40; N, 14.09%. Calcd for $C_8H_{19}Cl_2N_3O_4$: C, 32.88; H, 6.55; N, 14.39%.

We thank Mr. Matsumoto for measuring the NMR spectra, and the members of our organic analysis laboratory for microanalysis.

(Received October 28, 1977)

Synopsis. 5-Phenyltetrazole is obtained in a moderate yield by the mercury(II) oxide oxidation of the title hydrazidine prepared from *N*-(phenylsulfonyl)benzohydrazonoyl chloride and benzohydrazide. The tetrazole formation is interpreted in terms of an intramolecular S_N2 type process of the intermediate formazan with the removal of benzenesulfinic acid. In the absence of oxidizing agents, the hydrazidine gives 2,5-diphenyl-1,3,4-oxadiazole and 3,5-diphenyl-4-phenylsulfonylamino-4*H*-1,2,4-triazole.

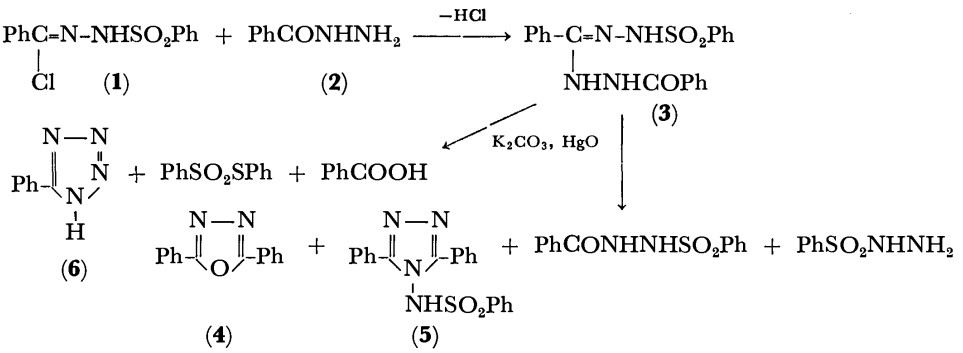
In a previous paper[1] we reported a method for preparing 2,5-disubstituted tetrazoles by the reaction of *N*-(phenylsulfonyl)benzohydrazonoyl chloride(**1**) with arylhydrazines, in which the hydrazines act as a nucleophile in the initial reaction step. This method using hydrazine is, however, not applicable to the preparation of 5-monosubstituted tetrazoles, since hydrazine acts as a base to lead to the formation of 3,6-diphenyl-1,4-bis(phenylsulfonyl)-1,4-dihydro-1,2,4,5-tetrazine. The present paper deals with the formation of 5-phenyltetrazole and other two azoles from **1** and benzohydrazide(**2**).

When a solution of **1** and two equivalent amounts of **2** in THF was stirred for 18—20 h at room temperature, the reaction mixture turned slightly acidic with the precipitation of benzohydrazide hydrochloride. Work-up gave N^2-benzoyl-N^4-(phenylsulfonyl)benzohydrazide hydrazone(**3**) or its tautomer in 92% yield together with a trace amount of 2,5-diphenyl-1,3,4-oxadiazole(**4**) and 3,5-diphenyl-4-phenylsulfonylamino-4*H*-1,2,4-triazole(**5**).

The hydrazidine(**3**) afforded 5-phenyltetrazole(**6**) in 56% yield along with *S*-phenyl benzenethiosulfonate and benzoic acid, when treated with mercury(II) oxide (yellow)–potassium carbonate.[2] With potassium carbonate alone,[3] the yield of **6** decreased to 32%.

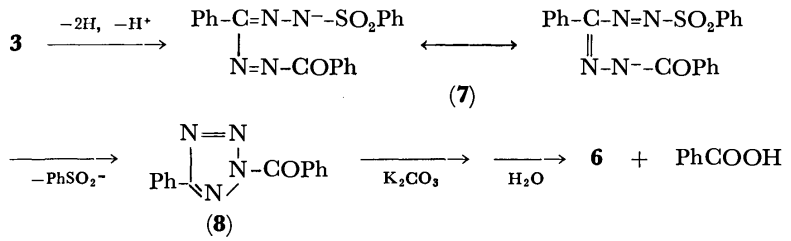
The recrystallization of **3** from methanol or THF–hexane resulted in a partial conversion of **3** into **4**, and at higher temperature the formation of **5** from **3** was also observed. Heating compound **3** at its melting point without solvent gave **5** almost quantitatively. Prolonged stirring or refluxing the mixture of **1** and **2** in THF, without the isolation of **3** formed intermediately, brought about an increase in the yields of **4** and **5** along with the formation of benzenesulfonohydrazide and 1-benzoyl-2-phenylsulfonylhydrazine (see Experimental section).

The sequence of reactions is summarized as follows (Scheme 1):



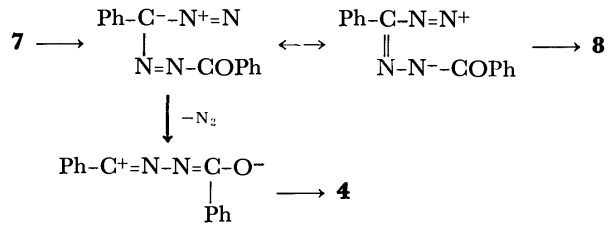
Scheme 1.

The formation of **6** from **3** can be formulated as follows (Scheme 2):[4]



Scheme 2.

For the step **7**→**8**, two mechanisms are possible: one involves the Bamford-Stevens type α-elimination of benzenesulfinic acid followed by the 1,5-dipolar cyclization of the resulting (benzoylazo)diazomethane(Scheme 3), and the other an intramolecular S_N2 type displacement of benzenesulfinate ion by the benzoylamino-anion part of **7**.



Scheme 3.

However, the azodiazomethane is also the source of **4**[5] as shown in Scheme 3. From the fact that **4** could not be obtained in this tetrazole-formation reaction, the direct displacement mechanism may be reasonable.[6] The precursor of the *S*-phenyl benzenethiosulfonate is benzenesulfinic acid[8] removed from **7**.

The formation of **4** and **5** can be easily explained in terms of an intramolecular cyclization of **3** with the removal of benzenesulfonohydrazide and water, respectively. 1-Benzoyl-2-phenylsulfonylhydrazine should be the hydrolyzed product of **3**.

Experimental

Melting points were determined with a Yanagimoto micro-melting point apparatus Model MP-S3 and are uncorrected. The microanalysis was performed on a Perkin-Elmer elemental analyzer Model 240, and the IR spectra were recorded with a JASCO DS-301 spectrometer. The products were identified by means of their analytical and spectral data and by comparison with authentic specimens prepared by other synthetic methods.

Preparation of N^2*-Benzoyl-*N^4*-(phenylsulfonyl)benzohydrazide Hydrazone (3).* A solution of **1**[1] (10 mmol) and **2**(20 mmol) in THF (40 ml) was stirred for 18—20 h at room temperature. After the removal of precipitated benzohydrazide hydrochloride by filtration, the filtrate was concentrated below 40 °C and extracted with chloroform. The chloroform extract was washed with water, dried(Na_2SO_4), and then concentrated, giving fairly pure **3**(92%) as an amorphous solid, which was purified by recrystallization from methanol or by re-precipitation from THF-hexane, mp 205—207 °C (dec).[9] IR(KBr, cm^{-1}):[10] 3270, 3205(ν_{NH}); 1640(ν_{CO}); 1300(asym ν_{SO_2}); 1162(sym ν_{SO_2}). Found: C, 61.01; H, 4.49; N, 14.45%. Calcd for $C_{20}H_{18}N_4O_3S$: C, 60.90; H, 4.60; N, 14.20%.

Oxidation of 3 with Mercury(II) Oxide(yellow). A mixture of **3**(0.395 g, 1 mmol), HgO(0.324 g, 1.5 mmol), K_2CO_3 (0.4 g, 3 mmol), $CaSO_4$(0.4 g, 3 mmol), and dioxane(15 ml) was stirred for 20 h at room temperature. The reaction mixture was filtered and washed with dioxane(20 ml), and then with water(50 ml). The filtrate combined with the washings(dioxane) was concentrated to give crude *S*-phenyl benzenethiosulfonate(0.096 g), which was purified by recrystallization from ethanol, mp 43—44 °C(lit,[11] 45 °C). The water-washings were acidified with dil. HCl, saturated with NaCl, and then extracted with ether. Chromatographic treatment (silica gel, benzene-ethanol) of the ether extract gave benzoic acid(0.072 g, 59%) and **6**(0.075 g, 56%): Mp 213—214 °C (dec)(lit,[5a] 214—215 °C, dec).

Oxadiazole(4) and Aminotriazole (5). A THF solution of **1** and **2**(1 : 2 mole ratio) was refluxed for 4 h or stirred for 5 d at room temperature. The resulting precipitates were separated by filtration and washed with water, giving almost pure **5**: mp 312—315 °C(dec)(acetone).[12]

The THF layer was concentrated, extracted with chloroform, and washed with water, After the removal of the solvent, the residue was chromatographed(silica gel, benzene-ether-ethanol), giving **4** (mp 138—139 °C; lit,[5a] 137—138 °C), 1-benzoyl-2-phenylsulfonylhydrazine(mp 197—198 °C; lit,[13] 199 °C), and benzenesulfonohydrazide, which was confirmed as acetone phenylsulfonylhydrazone: Mp 143—144 °C. IR(KBr, cm^{-1}): 3189(ν_{NH}); 1332, 1162(ν_{SO_2}). Found: C, 51.04; H, 5.71; N, 13.04%. Cacld for $C_9H_{12}N_2O_2S$: C, 50.94; H, 5.70; N, 13.20%. The results are summarized in Table 1.

Table 1. Oxadiazole(**4**) and aminotriazole(**5**)

Reaction Conditions[a]	Yield(%) of products[b]			
	4	**5**	$PhCONHNHSO_2Ph$	$PhSO_2NHNH_2$
I	37	30	27	26
II	40	13	32	40

a) I: Refluxing for 4 h. II: Stirring for 5 d at room temperature. b) Yield as mole per cent based on **1**.

COMMENTS

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (3), 955 (1978)

The Condensation of Nitromethane with Ketoses

Gerhardus J. LOURENS

Adcock-Ingram Research, P. O. Box 5932, Johannesburg 2000, Republic of South Africa

(Received December 16, 1977)

A recent paper,[1] published in *Bull. Chem. Soc. Japan* and describing an alleged new synthesis of branched-chain deoxy nitro and amino sugars, has prompted this reply. It seems quite unlikely that the author, in carrying out a proper scientific literature search, could have overlooked my original paper on this matter, as it is well documented in the chemical literature[2,3] and has been reviewed.[4]

In any event, the unusual identity of the two papers[1,3] points to the fact that Abdel-Rahman must have been in possession of the paper published in *Carbohydrate Research*. In comparing the two papers it is quite clear that most of the sentences in the entire paper were copied exactly. Furthermore, both papers describe the addition of nitromethane to 1,2-*O*-isopropylidene-5-*O*-trityl-α-D-*erythro*-pentafuranos-3-ulose in nitromethane as the solvent, and in the presence of sodium hydride at −20 °C, as well as subsequent reactions carried out on the product obtained.

In addition, the yields, melting points, optical rotations, infrared and NMR data correspond exactly with those given in the original paper,[3] which is quite unusual. If the yields given by Abdel-Rahman, which are the same as given in the *Carbohydrate Research* paper, are recalculated on the basis of the changed quantities used, one finds:

Compound	Yield recalculated	Given[1]	Literature[3]
2	71.6%	76%	76%
5	53.3%	58%	58%
6	75.3%	82%	82%

These figures speak for themselves.

In the changed description of the preparation of Compound **3**, the author did not realise that the chromatography step, as described, was absolutely necessary in order to purify the product from the less polar triphenylmethane formed in the reaction. Perhaps the most unbelievable feature about this paper is the fact that Abdel-Rahman was able to obtain a correct elementary carbon, hydrogen and nitrogen analysis of $C_{12}H_{16}NO_9$, which is in fact the M^+-15 mass for Compound **3**; in my paper[3] an accurate determination of the mass was done on the base peak of M^+-15, which calculated for $C_{12}H_{16}NO_9$.

Finally, no literature references other than those listed[5] in the original article,[3] were included; this shows that more recent literature had not been searched. Several similar additions with nitromethane, though, have been described in recent years.[6]

Reaction of Hydrogen Atoms with Acrylaldehyde

Seiichiro KODA, Kazumoto NAKAMURA, Takashi HOSHINO, and Tsutomu HIKITA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 27, 1977)

The reaction of hydrogen atoms with acrylaldehyde was investigated in a fast flow reactor equipped with a time-of-flight type mass spectrometer under reduced pressure. Main reaction products were carbon monoxide, ethylene, ethane, methane, and propanal. Consideration of the distributions of the reaction products under various reaction conditions showed that hydrogen atoms attacked the C=C double bond, especially its inner carbon side under reduced pressure. Resulting hot radicals caused subsequent reactions. The relative value of the apparent bimolecular rate constant of the reaction against that of *trans*-2-butene with hydrogen atoms was 1.6±0.2, which supported the above-mentioned initial reaction.

Hydrogen atoms add to C=C double bonds forming vibrationally excited alkyl radicals. These excited radicals can undergo unimolecular dissociation or be collisionally stabilized. On the other hand, the weak aldehydic hydrogen of saturated aldehydes is known to be abstracted by hydrogen atoms. The reaction of hydrogen atoms with simple monoolefins and aldehydes were already well elucidated, and data on respective reaction rates have also been fully reviewed.[1,2] By contrast the reactions of conjugated double bond systems with hydrogen atoms in gas phase seem not to have been fully studied. One known example is H+butadiene.[1,3] The reason for the remarkably high rate constant for this reaction seems to be still uncertain.

Acrylaldehyde is an interesting compound because it contains a conjugated double bond system, as well as a weakly bound aldehydic hydrogen. Though the reaction with oxygen atoms has been studied,[4,5] that with hydrogen atoms has never been investigated.

From the viewpoint of environmental science, acrylaldehyde is a noteworthy compound because of its possible role in photochemical smog and its strong toxicity. Only one study on the potential of smog formation of acrylaldehyde has so far been published.[6] Thus, the investigation of the reaction sequences in the mixture of acrylaldehyde with the simplest species, atomic hydrogen, will contribute to our understanding of the role of acrylaldehyde in photochemical smog.

Experimental

The experimental apparatus is illustrated in Fig. 1, which is almost similar to the apparatus of Arrington *et al.*[7] Hydrogen atoms were produced by a 2450 MHz microwave discharge in a mixture of hydrogen and argon, and were introduced into a Pyrex reaction tube (inner diam, 1.28 cm). Acrylaldehyde was added to the flow *via* an inner tube (outer diam, 0.32 cm) which was movable in order to control the reaction time. A part of the reaction mixture was directly introduced into a time-of-flight type mass spectrometer (Hokushin Denki Co., Ltd., Bendix Model) through a pin-hole (diam, 0.01 cm) positioned at the end of the reaction tube.

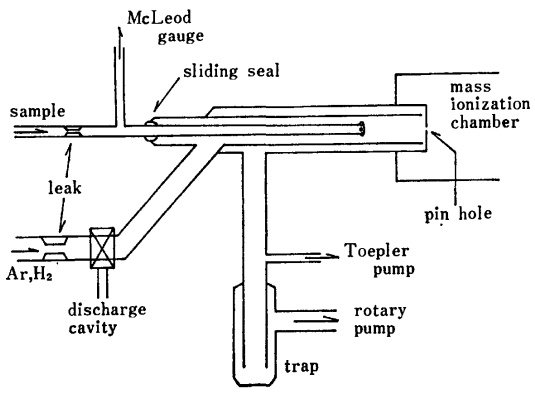

Fig. 1. Apparatus.

The reactions were carried out at room temperature (298± 5 °C). The pressure in the reaction tube (around 0.3 Torr) was measured by a McLeod gauge. The pressure drop along the reaction tube between the point of addition of acrylaldehyde and the pin-hole (maximum distance, 10 cm) was found to be negligibly small.

The mass flow velocity of each gas was calculated from the pressure drop with time in a standard volume. The linear flow velocity (about 3 m/s) was calculated from the total volume flow rate, the reactor pressure and the cross-sectional area of the reaction tube. The reaction time was calculated by dividing the length between the point of addition of acrylaldehyde and the pin-hole to the mass spectrometer by the linear flow velocity. The reaction time was varied between 3 and 33 ms by the change of the position of the inner tube.

The concentration of hydrogen atoms was determined through titration with ethylene. A similar method was adopted by Halstead *et al.*[8] The concentration of hydrogen atoms was usually around 3×10^{-7} mol/l, and that of acrylaldehyde was $(1—10)\times10^{-7}$ mol/l. The total concentration of gases was around 1.5×10^{-5} mol/l.

The major products were identified by analysis of the ionization efficiency curves of the respective parent mass peaks. The quantitative analyses were carried out based on the fragmentation patterns and relative sensitivities of standard samples.

In some experiments, a part of the reaction mixture was pumped by a Toepler pump into a gas sampler and was analyzed by means of gas chromatography with columns of Molecular Sieve 5A (for CO), Porapak Q and 3,4-dimethylsulforane (for hydrocarbons), and Polyethylene glycol 1500 (for aldehydes).

Purest hydrogen and argon (both 99.99%) obtained commercially were passed through traps cooled at liquid nitrogen temperature, and then introduced to the discharge region through leaks. Commercially obtained acrylaldehyde was purified gas-chromatographically with a column of Tritolyl phosphate. The resultant purity was at least 99%.

Results

Figure 2 shows the yields of the products estimated by use of mass spectrometry at the reaction time of

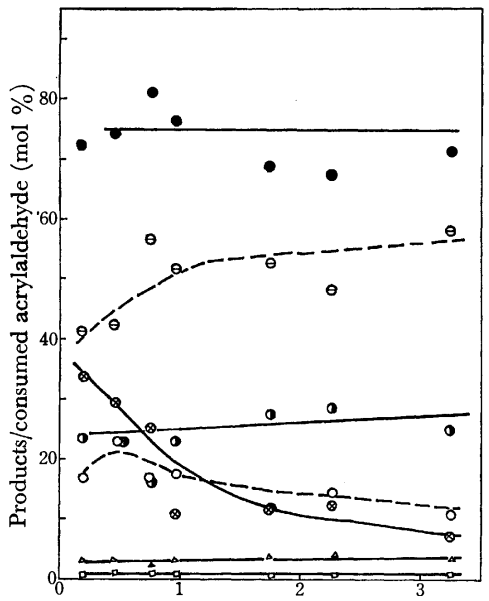

Fig. 2. The distribution of products at various different $[A]_0/[H]_0$.
Reaction conditions: total pressure, 0.38 Torr (Ar, 1.7 $\times 10^{-5}$ mol/l, H_2, 3.9×10^{-6} mol/l); $[H]_0$, 4.0×10^{-7} mol/l; $[A]_0$, 1.0×10^{-7} — 1.3×10^{-6} mol/l; reaction time, 22 ms.
Products: ● CO, ⊖ C_2H_4, ◑ C_2H_5CHO, ⊗ CH_4, ○ C_2H_6, △ CH_3CHO, □ C_3H_8.

TABLE 1. THE RESULTS OF GAS CHROMATOGRAPHIC ANALYSES

Product (mol %)	Initial concn of acrylaldehyde	
	1.1×10^{-6} mol/l	2.2×10^{-7} mol/l
Carbon monoxide	77	77
Ethylene	67	58
Propanal	15	9.8
Ethane	13	16
Methane	14	16
Acetaldehyde	1.7	2.6
Others	trace	5.4 (propane)
		2.4 (propylene)
		0.4 (acetylene)

The figures are the mole percent of the product divided by the consumed acrylaldehyde. Because the amounts of the consumed acrylaldehyde could not be measured, the equivalent concentration of the consumed acrylaldehyde was calculated from mass balance considerations, on the assumption that no products were missed. Reaction conditions: total pressure, 0.50 Torr ([Ar]= 2.6×10^{-5} mol/l, $[H_2]=6.0\times 10^{-7}$ mol/l), the initial concentration of hydrogen atoms, 1.75×10^{-7} mol/l.

22 ms. The analytical results are shown in Table 1. These two results agree with each other, though allowance should be made for the different reaction conditions and the very different time for analyses. The relatively low yield of propanal (Table 1) may be attributed to its probable adsorption in the analysis system for gas chromatography.

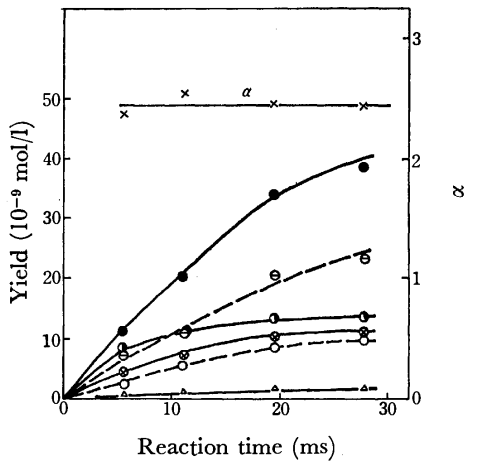

Fig. 3. Product growth curves with reaction time.
Reaction conditions: total pressure, 0.38 Torr (Ar, 1.7 $\times 10^{-5}$ mol/l, H_2, 3.9×10^{-6} mol/l); $[H]_0$, 2.3×10^{-7} mol/l; $[A]_0$, 1.0×10^{-7} mol/l.
Products: ● CO, ⊖ C_2H_4, ◑ C_2H_5CHO, ⊗ CH_4, ○ C_2H_6, △ CH_3CHO.
α(×): in this estimation, 1.5 mol of hydrogen atoms was assumed to be consumed for 1 mol production of CO, see text.

Figure 3 shows the growth of each product and the change of the stoichiometric ratio α with reaction time. Here, α is the ratio of the amount of the consumed hydrogen atoms to that of the consumed acrylaldehyde.

$$\alpha = ([H]_0-[H])/([A]_0-[A]) \quad \text{(i)}$$

[A], $[A]_0$ are the concentrations of acrylaldehyde, and [H], $[H]_0$, those of hydrogen atoms, at the reaction time t and at the initial time, respectively.

The amount of the consumed hydrogen atoms was calculated on the assumption that they were either trapped in the products (such as ethylene, methane, ethane, and propanal), or converted to hydrogen molecules. In the former case, the amount of the trapped hydrogen atoms was estimated from the yields of the products. In the latter case, carbon monoxide was produced simultaneously. The amount of the consumed hydrogen atoms ($-\Delta[H]$) was estimated to be about 1.5 times as large as the amount of the produced carbon monoxide ($\Delta[CO]$) from consideration of the hydrogen mass balance in an experiment where the initial hydrogen atoms were almost completely consumed within 33 ms. The experimental condition of the reaction were: The initial concn of the hydrogen atoms, 4.0×10^{-7} mol/l, $[A]_0/[H]_0$, 0.5. The reaction was found to be completed in about 30 ms. Because the amounts of the hydrogen atoms trapped in the products other than CO could be calculated, the ratio, $-\Delta[H]/\Delta[CO]$ could be easily estimated from the hydrogen mass balance. The ratio might depend on the initial conditions and change with reaction time, but we were obliged to adopt the constant value 1.5 in the estimation of α.

The value α was shown to be roughly constant throughout the reaction (Fig. 3). This fact allows to calculate the apparent bimolecular reaction rate constant of the reaction (ii) by the following simple

procedure.

$$\text{acrylaldehyde} + H \longrightarrow \text{products} \quad \text{(ii)}$$

The rate equation (iii) is integrated to result in (iv).

$$d[A]/dt = k_{ap}[A][H] \quad \text{(iii)}$$

$$k_{ap}t = [1/([H]_0-[A]_0)] \ln ([A]_0[H]/[A][H]_0)$$
$$= [1/([H]_0-[A]_0)] \ln [[A]_0([H]_0-\alpha([A]_0-[A]))/[A][H]_0] \quad \text{(iv)}$$

The right hand side of the above equation could be calculated from the data of $[H]_0$, $[A]_0$, $[A]$, and α. The resultant values are plotted against the reaction time t in Fig. 4. The slope of the straight line gave the bimolecular rate constant.

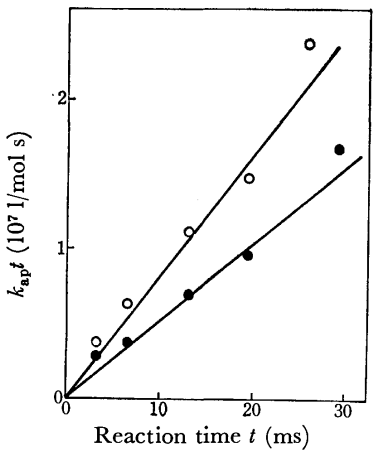

Fig. 4. The relationship between $k_{ap}t$ *vs.* reaction time. Reaction conditions: total pressure, 0.29 Torr (Ar, 1.4 $\times 10^{-6}$ mol/l, H_2, 1.4×10^{-5} mol/l); $[H]_0$, 2.84×10^{-7} mol/l, $[A]_0$ and [*trans*-2-butene]$_0$, 1.60×10^{-7} mol/l.
-●-: For reaction of *trans*-2-butene (α=2.8),
-○-: for reaction of acrylaldehyde (α=2.4).

k_{ap} for acrylaldehyde = $(8.1\pm 0.8)\times 10^8$ l/mol s

The reaction of *trans*-2-butene with hydrogen atoms was studied in the same apparatus as a reference. The apparent bimolecular rate constant was obtained similarly (Fig. 4) to be,

k_{ap} for *trans*-2-butene = $(5.1\pm 0.5)\times 10^8$ l/mol s.

Thus the relative rate constant of the reaction of acrylaldehyde, k_{ap}(for acrylaldehyde)/k_{ap}(for *trans*-2-butene), was calculated from the above absolute rate constants to be 1.6 ± 0.2. The possible incomplete mixing of the reactants and the diffusion of hydrogen atoms along the reaction tube make the exact estimation of the reaction time difficult. Thus the relative value might be more reliable than the absolute one, though it is worth nothing that the absolute constant for *trans*-2-butene agrees well with the value reported by Daby *et al.*[9]

Discussion

Reaction Mechanism. In the experiments where the initial rate $[A]_0/[H]_0$ is less than 1, the low yield of ethylene is compensated by the relatively high yields of ethane and methane, as shown in Fig. 2. This should be due to the occurrence of the secondary reactions of the product ethylene with hydrogen atoms to some extent to yield methane and ethane. The apparent reaction rate constant of ethylene with hydrogen atoms was reported by Michael *et al.* to be 0.9×10^8 l/mol s in 0.96 Torr Ar,[10] whereas our value in a similar apparatus is 0.4×10^8 l/mol s in 0.5 Torr Ar,[11] and is much smaller than that of acrylaldehyde, 8.1×10^8 l/mol s as described previously; thus the consumption of the primary product ethylene is expected to occur to any appreciable extent only when hydrogen atoms still remain after acrylaldehyde is almost completely consumed.

On the other hand, in the experiments where the ratio $[A]_0/[H]_0$ is kept larger than 1, the yield of each product is relatively constant and does not depend on that ratio. The observed product distribution should then reflect the primary reaction sequences of acrylaldehyde with hydrogen atoms.

Addition of hydrogen atoms to aldehydic CO bond has not been observed to proceed to any appreciable extent.[1] Hydrogen atoms may then either add to the C=C double bond or abstract the aldehydic hydrogen from acrylaldehyde. The rate of the reaction of saturated aldehydes with hydrogen atoms is known to be smaller than the addition to simple monoolefins by a factor of around 10. Then the abstraction of the aldehydic hydrogen is not expected to be the main reaction in the case of acrylaldehyde. This idea is supported by the experimental observation that acetylene was produced only in a negligibly small yield. Acetylene should have been produced in a relatively high yield through subsequent reactions, if the abstraction was the main primary process. The following reaction sequence is expected to follow the abstraction:

$$CH_2{=}CHCHO + H \longrightarrow CH_2{=}CH\dot{C}O + H_2$$
$$CH_2{=}CH\dot{C}O + H \longrightarrow CH{\equiv}CH + CO + H_2,\ CH_2{=}\dot{C}H + CHO$$
$$CH_2{=}\dot{C}H + H \longrightarrow CH{\equiv}CH + H_2.$$[12-14]

of course, we cannot deny the following possibility completely, based on the absence of acetylene among the reaction products.

$$CH_2{=}CHCHO + H \longrightarrow CH_2{=}CHCO + H_2$$
$$CH_2{=}CHCO + H \longrightarrow CH_2{=}CH_2 + CO$$

Thus the primary processes are considered to be the additions (1a) and (1b).

$$CH_2{=}CHCHO + H \rightleftarrows \dot{C}H_2CH_2CHO^* \ (I_a^*) \quad \text{(1a, -1a)}$$
$$\rightleftarrows CH_3\dot{C}HCHO^* \ (I_b^*) \quad \text{(1b, -1b)}$$

Here, the asterisk means that the species possesses some excess energy.

The resulting hot alkyl-like radicals I_a^* and I_b^* may either decompose unimolecularly or be stabilized.

$$I_a^* \longrightarrow CH_2{=}CH_2 + CHO \quad \text{(2)}$$
$$I_a^* + M \longrightarrow I_a + M \quad \text{(3a)}$$
$$I_b^* + M \longrightarrow I_b + M \quad \text{(3b)}$$

Though no thermochemical or structural data on the radicals I_a and I_b are known, we expect that I_a^* may behave like the hot *n*-propyl radical and I_b^* like the hot isopropyl radical produced in the reaction of

propylene with hydrogen atoms.[15,16] I_b* is assumed not to decompose because it does not seem to lead to any favorable dissociation reactions. By the analogy to the hydrogen atom-propylene system, the possible subsequent reactions are summarized as follows:

$$I_a, I_b + H \longrightarrow CH_3CH_2CHO^* \quad (4)$$

$$CH_3CH_2CHO^* + M \longrightarrow CH_3CH_2CHO + M \quad (5)$$

$$CH_3CH_2CHO^* \longrightarrow CH_3CH_2 + CHO \quad (6)$$

$$CH_3CH_2 + H \longrightarrow C_2H_6, 2CH_3 \quad (7)$$

$$CH_3 + H + M \longrightarrow CH_4 + M \quad (8)$$

$$CHO + H \longrightarrow CO + H_2 \quad (9)$$

Considerations of the fact that relatively complex radicals react with hydrogen atoms very rapidly† and of the fact that the concentration of hydrogen atoms is much higher than the possible concentrations of these radicals in the present study guarantee the neglect of any reactions other than those described above for the radicals, I_a, I_b, and C_2H_5. But for the radicals, CH_3 and CHO, radical-radical reactions may be as important as radical-atomic hydrogen reactions, because the latter reactions are not expected to be rapid enough under reduced pressure. The rate constant of Reaction 9 seems to be still uncertain,[18,19] but if a probable value of around 1×10^9 l/mol s is adopted, the reactions such as 10 and 11[19,20] cannot be neglected.

$$CHO + CHO \longrightarrow H_2 + 2CO \quad (10)$$

$$CHO + CH_3 \longrightarrow CH_4 + CO \quad (11)$$

The Reaction 12 may not be neglected, similarly.

$$CH_3 + CH_3 \longrightarrow C_2H_6 \quad (12)$$

The occurrence of Reactions 10 and 11 is expected to result in lowering the ratio, $-\Delta[H]/\Delta[CO]$, below 2. If the Reactions are limited to (1)—(9), the ratio should be 2. In fact, we have found the ratio 1.5, as described before.

According to the preceding discussions, we propose the reactions (1a, −1a) and (1b, −1b) followed by (2) through (12) as the main reaction sequence of the system of acrylaldehyde with hydrogen atoms under the reaction conditions of reduced pressure and also of $[A]_0/[H]_0\approx1$.

The net fraction of the hydrogen atom addition to the inner side of the C=C double bond is defined by Eq. v.

$$p = \frac{k_{1a}\times\dfrac{k_2+k_{3a}[M]}{k_{-1a}+k_2+k_{3a}[M]}}{k_{1a}\times\dfrac{k_2+k_{3a}[M]}{k_{-1a}+k_2+k_{3a}[M]}+k_{1b}\times\dfrac{k_{3b}[M]}{k_{-1b}+k_{3b}[M]}} \quad (v)$$

On the other hand, the following relation can be derived through a simple mass balance treatment.

$$([C_2H_5CHO]+[C_2H_6]+0.5[CH_4])/[C_2H_4] \text{ (defined as } R)$$
$$= \frac{k_{1a}k_{3a}[M]/(k_{-1a}+k_2+k_{3a}[M])+k_{1b}k_{3b}[M]/(k_{-1b}+k_{3b}[M])}{k_{1a}k_2/(k_{-1a}+k_2+k_{3a}[M])} \quad (vi)$$

We can expect $k_2\gg k_{-1a}$, assuming that the hot radical I_a* is similar to usual hot alkyl radicals, which undergo the C–C bond cleavage predominantly.[21] Moreover, the relatively low pressure of the present work allows to assume $k_2>k_{3a}[M]$. Then the following approximations results:

$$p \approx k_{1a}/(k_{1a}+k_{1b}k_{3b}[M]/(k_{-1b}+k_{3b}[M])) \quad (vii)$$

$$R \approx k_{1b}k_{3b}[M]/k_{1a}(k_{-1b}+k_{3b}[M]) \quad (viii)$$

Thus the net fraction p is related to the value R by the following equation.

$$p \approx 1/(1+R) \quad (ix)$$

We have got the value of R as 0.7 from the data shown in Fig. 2. The net fraction of the hydrogen addition to the inner side of the C=C double bond was then estimated to be about 0.60 ($=1/(1+0.7)$) under the present conditions.

Relative Reaction Rate. We wish to find out a quantum-chemical measure with which the reaction rate of the addition of the hydrogen atoms to each carbon atom among various C=C double bonds can be predicted and to know whether the addition of the atoms to acrylaldehyde is similar to the addition to simple olefins, or not.

Yang[22] showed that the activation energy of the addition to olefins were related to the corresponding localization energy. But this measure cannot be used to show the reactivity of individual carbon atom. Daby *et al.*[9] related the relative rate to the free valence. Though they got some success, they had to classify monoolefins into two groups; inner olefins and α-olefins. Thus we suspected if the atomic population might be an adequate measure for our present purpose, considering that atomic hydrogen seems to behave as an electrophilic reagent to some extent.[23]

In fact, we could find a good linear relationship between the atomic population of each carbon atom of C=C double bond of simple olefins and the logarithm of the relative rate constant (data are taken from Cvetanović *et al.*[1,24]) as shown in Fig. 5. The atomic populations were calculated by CNDO/2 for stable configurations (Table 2). In the case of symmetric olefins (*trans*- and *cis*-2-butenes and ethylene), the experimentally obtained rate constants were divided by 2; these olefins are considered to possess two equivalent reaction centers. In the case of propylene, 1-butene and 2-methylpropene, the experimental relative rate constants were plotted against the higher values of atomic population; those of terminal sides. This is reasonable because of the large difference in the atomic populations between the terminal and inner carbons. It is known that the percentage of the addition to the inner side is very small.[25]

The apparent reaction rate constant of acrylaldehyde is described by Eq. x according to the previously given reaction sequence.

$$k_{ap} = k_{1a}(k_2+k_{3a}[M])/(k_{-1a}+k_2+k_{3a}[M]) + k_{1b}k_{3b}[M]/(k_{-1b}+k_{3b}[M]) \quad (x)$$

By adopting the previous assumption, $k_2\gg k_{-1a}$, we get

$$k_{ap} \approx k_{1a} + k_{1b}k_{3b}[M]/(k_{-1b}+k_{3b}[M]) \approx k_{1a}(1+R) \quad (xi)$$

† For example, the values, 3.6×10^{10} l/mol s by Kurylo *et al.*[17] and 2×10^{10} l/mol s by Michael *et al.*[10] were reported as the rate constant of the reaction, $H+C_2H_5$, under reduced pressure.

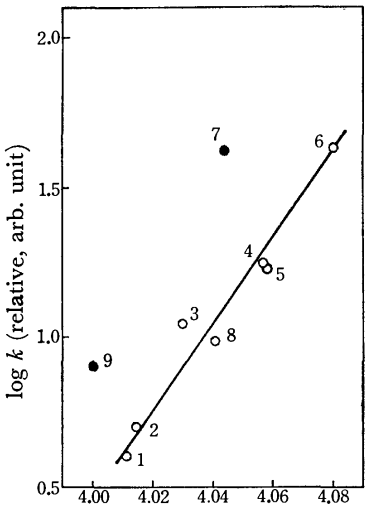

Fig. 5. The relationship between log (relative rate constant) and the atomic population.
1: *cis*-2-Butene, 2: *trans*-2-butene, 3: ethylene, 4: 1-butene, 5: propylene, 6: 2-methylpropene, 7: butadiene, 8: the inner carbon of acrylaldehyde (*vs.* k_{1a}), 9: the terminal carbon of acrylaldehyde (*vs.* $k_{1b}k_{3b}[M]/(k_{-1b}+k_{3b}[M])$).

TABLE 2. ATOMIC POPULATIONS BY CNDO/2

Substrate	C_1	C_2
$C_1=C_1$	4.0296	—
$C_1=C_2-C$	4.0573	3.9764
$C_1=C_2-C-C$	4.0568	3.9804
$C_1=C_2(-C)-C$	4.0794	3.9389
cis-$C-C_1=C_1-C$	4.0112	—
trans-$C-C_1=C_1-C$	4.0144	—
$C_1=C_2-C_2=C_1$	4.0434	3.9839
$C_1=C_2-C=O$	4.0000	4.0405

The calculations are for stable configurations. The computation program was taken from Ref. 26.

The relative rate constant, k_{ap} (for acrylaldehyde)/k_{ap}(for *trans*-2-butene) was 1.6 as described before. By adoptating 0.7 for R in Eq. xi, we estimated the value of k_{1a}(for acrylaldehyde)/k_{ap}(for *trans*-2-butene) to be 0.94. The apparent rate constant k_{ap} for *trans*-2-butene does not change over a wide pressure range, and should be equal to the primary addition rate constant, which was adopted in Ref. 24.[9] By use of this rate constant for *trans*-2-butene as a common reference, the constant k_{1a}(for acrylaldehyde) was compared with the rate constant for olefins in Fig. 5 (point 8). This point is on the line derived from the data of monoolefins. Thus the atomic population is a good quantum-chemical measure in the case of the addition to the inner carbon side of acrylaldehyde as well as in the case of monoolefins.

In spite of the reasonable relationship between the relative rate constant and the corresponding atomic population for monoolefins, the rate constant of butadiene is much higher than is predicted from its atomic population. Similarly, the rate constant k_{1b} in the case of acrylaldehyde seems to be much higher than expected. The point 9 in Fig. 5 is the lower limit of the relative value of k_{1b} against the atomic population of the terminal carbon of the C=C bond. The point indicates the relative value of $k_{1b}k_{3b}[M]/(k_{-1b}+k_{3b}[M])$ $(=k_{ap}-k_{1a})$ and should be the lower limit of k_{1b}. In these cases, the addition of atomic hydrogen results in production of stable π-allyl type radicals, and their stability should be the cause of the rapidness of the addition. It is expected that the individual atomic population can not be a good measure in this case.

Conclusion

1) Hydrogen atoms add mainly to the C=C double bond of acrylaldehyde, though some other possibilities are not completely eliminated.

2) Under reduced pressure, the net attacking position of hydrogen atoms is mainly (about 60% under the pressure of the present work, 0.3 Torr) the inner carbon side of the C=C double bond. Under higher pressures, the fraction of the addition to the terminal carbon may increase.

3) The rate of the addition to the inner carbon side can be explained by its atomic population as a quantum-chemical measure in a similar fashion as in monoolefins.

4) The subsequent reactions are regarded as unimolecular decompositions and collisional stabilizations of the resulting hot radicals in a similar fashion as in olefin-atomic hydrogen systems.

We are grateful to Professor Soji Tsuchiya, the Univ. of Tokyo, for his encouragement throughout this work. The reaction apparatus was originally constructed by him. We also acknowledge the Grant-in-Aid of the Ministry of Education given to this work.

Intramolecular Hydrogen Bond between Hydroxyl Group and π-Base in 2-Hydroxybiphenyl

Yoshikazu Ioki, Hiroko Kawana,* and Kichisuke Nishimoto*

Biophysics Division, National Cancer Center Research Institute, Tokyo 104

**Department of Chemistry, Faculty of Science, Osaka City University, Osaka 558*

(Received July 20, 1977)

In order to clarify the nature of the intramolecular hydrogen bond between the hydroxyl group and the π-electron system in 2-hydroxybiphenyl, MO calculation based on the CNDO/2 MO method has been carried out. The total electronic energy of the molecule has been divided into one- and two-atomic terms. It was found that the resonance term mainly contributes to the intramolecular hydrogen bond formation. Contribution of other terms is discussed.

Since Wulf *et al.*[1] reported the doublet of the first overtone of the O–H stretching vibration in 2-hydroxybiphenyl, many workers[2–19] have studied the nature of the hydrogen bond with π-base, such as aromatic hydrocarbons and olefins. This type of hydrogen bond might play some role in the physico-chemical properties and chemical reactivity of the molecule. By adopting the theory of Mulliken's charge-transfer complex, some workers have concluded that charge-transfer interaction makes important contribution to this type of hydrogen bond formation.[11,13,19] However, they did not make clear whether it is the main contribution, since no comparison of various terms in the interaction energies was made.

This paper describes an attempt to analyze the intramolecular hydrogen bond energy of 2-hydroxybiphenyl by the calculation based on the CNDO/2 method.[20] 2-Hydroxybiphenyl, having antiseptic activity, is a typical molecule with intramolecular interaction of H···π type. The electron correlation is not taken into account in the CNDO/2 SCF method, and the calculated value of total electronic energy is not highly reliable. However, our object is to calculate the energy difference between the non-bonded and the hydrogen bonded systems. Since the effect of electron correlation might be mostly cancelled out we have used the simple semi-empirical MO method, CNDO/2. The total energy is divided into one- and two-atomic terms, the two-atomic term being further divided into resonance, exchange, and Coulomb terms. So far energy decomposition studies on intramolecular hydrogen bond with π-electron system do not seem to have been reported. Recently a study on the intermolecular hydrogen bonds of some small systems has been made by Kitaura and Morokuma,[21] but their method can not be applied directly to the intramolecular hydrogen bond problem.

Procedure

Geometry. 2-Hydroxybiphenyl is assumed to be twisted around the central single bond (Fig. 1) because of the repulsions among non-bonded ring hydrogens. For biphenyl, the dihedral angle between phenyl planes was estimated to be *ca.* 40°.[22] There is an additional steric hindrance between the hydroxyl group and phenyl ring in 2-hydroxybiphenyl. Ōki *et al.* assumed that the dihedral angle of the present molecule

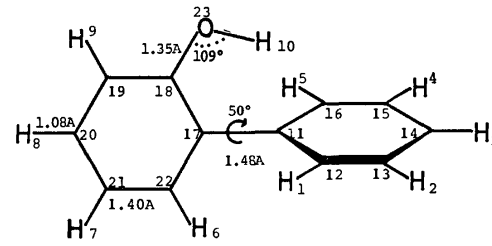

Fig. 1. Geometry and numbering adopted for the molecular orbital calculations.

is 50°.[13]

In order to confirm the validity of the assumed conformation, we have carried out SCF-MO-CI calculation by the P-P-P method[23] using variable β approximation and N-gamma for two-center electron repulsion integrals. This method provides satisfactory results for $\pi\rightarrow\pi^*$ transitions.[24] The calculated results for 2-hydroxybiphenyl are summarized in Table 1 with experimental values. The calculated and experimental results agree satisfactorily.

Table 1. Calculated transition energies and oscillator strengths of 2-hydroxybiphenyl

5.26	0.51	5.06	12
5.70	0.31		
6.05	0.33	6.00[sh]	23
6.15	0.81		
6.25	0.41		

Interaction Energies. The intramolecular hydrogen bond energy of 2-hydroxybiphenyl is given by the difference of total energies between hydrogen bonded structure **I** and non-bonded structure II shown in Fig. 2. The total energy can be expressed by the sum of one- and two-atomic terms:[20]

$$E_{\text{total}} = \sum_{A} E_A + \sum_{A<B} E_{AB}, \tag{1}$$

where

$$E_A = \sum_{\mu}^{A} P_{\mu\mu} U_{\mu\mu} + \frac{1}{2}\sum_{\mu}^{A}\sum_{\nu}^{A}\left(P_{\mu\mu}P_{\nu\nu} - \frac{1}{2}P_{\mu\nu}^2\right)\gamma_{AA}, \tag{2}$$

$$E_{AB} = \sum_{\mu}^{A}\sum_{\nu}^{B} 2P_{\mu\nu}\beta_{AB}^{\circ}S_{\mu\nu} - \sum_{\mu}^{A}\sum_{\nu}^{B}\frac{1}{2}P_{\mu\nu}^2\gamma_{AB} + (Z_A - P_{AA})(Z_B - P_{BB})\gamma_{AB}. \tag{3}$$

We refer to the first, second, and third terms of two-atomic term (Eq. 3) as resonance, exchange, and Coulombic interaction energies, respectively. The difference in these energy terms between bonded and non-bonded structures, is used for discussing the nature of the hydrogen bond.

X–H···π type interaction (<3 kcal/mol).[25] Since the CNDO/2 method usually gives larger binding energies,[26] the present result seems to be reasonable. The change of one-atomic term ($\Delta\sum E_A$) due to the formation of intramolecular hydrogen bond is quite small due to cancellation of one-atomic terms (ΔE_A) (Table 2). However, the two-atomic terms considerably stabilize the system, showing that energy of the hydrogen bond comes mostly from the two-atomic terms (Table 3). It should be noted that the interaction energy (ΔE_{HA}) between the hydrogen of hydroxyl group and the other atoms is remarkably large, more than double the value of $E(\mathbf{I})_{AB}-E(\mathrm{II})_{AB}$ (last column, Table 3). This shows that ΔE_{HA} greatly stabilizes the hydrogen bond, but some of the other two-atomic terms cause destabilization. The stabilization energy comes from the resonance (−0.532 eV) and Coulomb (−0.083 eV) terms. The exchange term (0.132 eV) plays the role of destabilization. The calculated result shows a decrease of O–H bond energy (atom 23 in Table 4), in line with the observed infrared spectral shift due to O–H vibrational lower frequency. Both the resonance and exchange terms of O–H bond energy decrease (−0.477 eV and −0.205 eV respectively), though the Coulomb term increases (0.329 eV).

It is evident that the hydrogen bond is formed mainly from resonance energy between the hydroxyl group and carbon atoms 11 (−0.339 eV) and 16 (−0.756 eV). For the sake of clarification, we have given the values of the term $P_{\mu\nu}S_{\mu\nu}$ between 1s orbital of the hydrogen of hydroxyl group and the valence orbitals of carbon atoms 11 and 16 as a measure of contribution to the resonance terms (Table 5). The amount associated with $2p_z$ orbital of carbon atom 16 is the largest (0.014), those associated with other orbitals not being small.

Table 5. Overlap integral ($S_{\mu\nu}$), bond order ($P_{\mu\nu}$), and their product ($P_{\mu\nu}S_{\mu\nu}$) between 1s orbital of hydroxyl hydrogen and valence orbitals of atoms 11 and 16

Orbital		$S_{\mu\nu}$	$P_{\mu\nu}$	$P_{\mu\nu}S_{\mu\nu}$
C_{11}	2s	0.1043	0.0318	0.0033
	$2p_x$	−0.0277	−0.0142	0.0004
	$2p_y$	0.0804	0.0309	0.0025
	$2p_z$	0.0958	0.0545	0.0052
C_{16}	2s	0.1390	0.0474	0.0066
	$2p_x$	−0.0961	−0.0433	0.0042
	$2p_y$	0.0155	0.0071	0.0001
	$2p_z$	0.1357	0.1061	0.0144

It is of interest to investigate the potential energy of O–H···π bonded system. We have calculated the total energies as a function of O–H distance, where only the position of the hydrogen of hydroxyl group is varied, all the other atoms keeping their positions unchanged. The result is shown in Fig. 3. The potential curve has a minimum at 1.04 Å of O–H distance. In the case of the non-bonded one, the calculated equilibrium O–H distance is 1.03 Å. This lengthening of O–H distance due to hydrogen bond formation leads to a decrease in the force constant, reflecting the lower shift of O–H vibrational frequency as observed in the infrared spectra.[13] The charge density on oxygen atom is minimum at 1.2 Å, increasing considerably with the O–H distance (Table 6). The charge densities of carbon atoms 11 and 16 decrease monotonously with increase in distance. This suggests that the charge-transfer structure $(O–H)^-\cdots C^+$ contributes to the intramolecular hydrogen bond formation to some extent. The present calculation shows that, when the O–H distance increases beyond 1.4 Å, the contribution of another type of charge-transfer structure $O^-\cdots(H–C)^+$ increases (Table 6). Thus double minimums in line with the experiment of infrared spectroscopy might be expected, though the CNDO/2 calculation gives no confirmation.

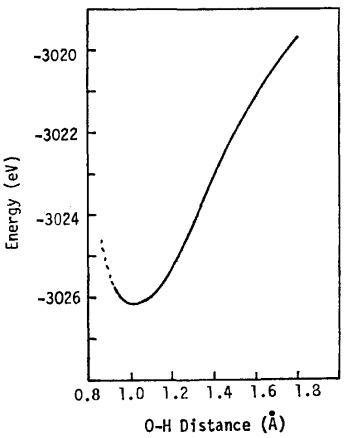

Fig. 3. Total energy of 2-hydroxybiphenyl in hydrogen bonded form as a function of O–H distance.

Table 6. Charge density on atoms in hydrogen bonded structure of 2-hydroxybiphenyl *vs.* O–H distance (Å)

O–H distance	Charge density

Conclusion

Although hydrogen bonds of X–H···π type have been extensively studied, few investigations have been made on the changes of energy terms of all the atoms in the molecule due to the formation of the hydrogen bond. In the present work, we have tried to clarify the nature of X–H···π hydrogen bond and have obtained the following results. i) The contribution of one-atomic terms to the hydrogen bond in 2-hydroxybiphenyl is quite small. ii) The interaction between the hydrogen of hydroxyl group with the other atoms mainly contributes to stabilization of the hydrogen bonded conformation. However, considerable contribution to the instability comes from interactions among the other

atoms. iii) Most of the stabilization energy comes from resonance terms of the interaction between 1s orbital of the hydrogen of hydroxyl group and orbitals of carbon atom 16, mainly of its $2p_z$ orbital. iv) Exchange interaction between the hydrogen of hydroxyl group and the other atoms destabilizes the hydrogen bond. It should be noted that if we consider only the interacting hydrogen moiety, we obtain more than double the hydrogen bond energy (Table 3). v) The calculated result of charge densities as a function of O–H distance indicates the involvement of charge-transfer structures in the hydrogen bonded formation.

The results verify at least qualitatively that the resonance term including charge-transfer is the main one to stabilize intramolecular hydrogen bond of O–H$\cdots\pi$ type. Although it was discussed that charge-transfer interaction made important contribution, this fact was not revealed concretely. The present result forms a contrast with the ordinary hydrogen bond of X–H$\cdots$n type where Coulombic interaction also makes significant contribution to the stability. This characteristic of X–H$\cdots\pi$ type is considered to be due to the neutrality of the proton acceptor benzene-ring and delocalization of the electrons. The present treatment provides a method which is convenient for clarifying the nature of intramolecular hydrogen bonds of large molecles.

Application of Infrared ATR Spectroscopy to Liquid Crystals. II.[1] Surface-induced Orientation of Nematic MBBA and Reorientation in Electric Fields

Aritada HATTA, Hideaki NOHARA, and Wataru SUĒTAKA

Laboratory of Interface Science of Metals, Faculty of Engineering, Tohoku University, Aramaki Aoba, Sendai 980

(Received August 3, 1977)

A polarized infrared ATR technique was used to demonstrate the orientation of a nematic liquid crystal, *N*-(*p*-methoxybenzylidene)-*p*-butylaniline (MBBA), due to the walls of the electrode and an externally applied DC electric field. Polarized ATR spectra were obtained as a function of the field strength on liquid films 15 μm thick between a silicon ATR prism and a brass plate serving as electrodes. The observed infrared dichroism revealed the average orientation of molecules in boundary layers about 1 μm thick on the Si electrode surface. The ordering or packing of molecules before application of the field affects the response of molecules to the electric field in a striking manner. Molecular orientations on the Si electrode are discussed in some detail.

In recent years, dramatic developments were seen in the application of liquid crystals to electro-optical display devices.[2] For example, a dynamic scattering effect[3] has now proven to be most valuable in the application of nematic liquid crystals. Another important effect of electric field on liquid crystals is the change in orientation due to the anisotropy of the dielectric constants of the liquid crystal molecule.[4]

Heilmeier and Zanoni[5] have successfully obtained color switching using a nematic liquid crystal containing dissolved pleochroic dye molecules. This method is based on the guest-host interaction[6,7] by which the orientation of the guest dye is controlled by the orientation of its nematic host in an applied electric field. For practical applications of this effect, however, a high response to the electric field is essential to the liquid crystal. However, it has been pointed out that the interaction between liquid crystal molecules and electrode surfaces may often lower the response of the liquid crystal. Despite this limitation, the field-induced orientation is very interesting for several aspects of application.[2]

On the other hand, infrared spectroscopy is a powerful tool for obtaining information about the orientational behavior of liquid crystals. In this regard, therefore, it seems interesting to observe field-induced orientation using infrared techniques. Indeed, the molecular orientation of nematic *N*-(*p*-methoxybenzylidene)-*p*-cyanoaniline in DC electric fields has been investigated by Neff, Gulrich, and Brown[8] using a transmission method. However, no other infrared study of field-induced orientation has yet appeared. This is probably due to the fact that extremely thin films are required for obtaining accurate intensity data because of the high absorption of liquid crystals, as is generally the case. This difficulty is removed when the ATR method[9] is used, because the observed intensities are determined by the electric-field penetration of infrared radiation a few microns into the sample and are independent of the sample thickness.[10] The most significant advantage of using the ATR method is that electric fields of electromagnetic radiation exist in all three spatial directions at the reflecting interface. Therefore, this technique can be used to obtain information about any orientation of the liquid crystal.

For the above reasons, the infrared ATR technique was first applied to the study of the orientation of MBBA liquid crystals, and quantitative data which enabled the determination of the orientation pattern and its degree of order were obtained.[1] The present report describes the infrared ATR spectra of MBBA under the application of DC electric fields.

Experimental

The liquid crystal cell used for the ATR measurements has already been described in a previous paper.[1] In brief, the liquid crystal was sandwiched between a silicon ATR prism and a conducting plate, which were held apart by a polyester spacer. The Si prism and the substrate plate served as electrodes; a DC electric field was applied normal to the liquid layer 15 μm thick. The Si prism served as the positive electrode. The liquid crystal was maintained at a constant temperature by an electric heater placed in a brass box in contact with the substrate plate.

The ATR spectra were measured by placing the liquid crystal cell in the sample beam of a double-beam ATR attachment, at an angle of incidence of 40 °. In order to account for the absorption of the sample prism itself, a similar Si prism was placed in the reference beam. The infrared radiation was polarized using a AgCl polarizer.

A brass plate polished to a high degree of flatness was used as an electrode opposite the Si prism. The electrode plate and Si prism were subjected to ultrasonic cleaning for 30 min in ethyl alcohol followed by rinsing in acetone. Guaranteed-grade MBBA reagent from a commercial source was used without further purification.

Results and Discussion

Infrared Dichroism from Polarized ATR Spectra. A detailed description has already been given of an approximate method of determining the orientation pattern of a liquid crystal from measured amounts of the dichroic ratio.[1] Therefore, little will be given here concerning the method itself.

An ATR spectrum is essentially the reflection loss due to the interaction of an evanescent wave with an absorbing medium. According to Flournoy and Schaffers,[11] the reflectivities of radiation having the electric vector polarized perpendicular and parallel to the plane of incidence are given respectively by

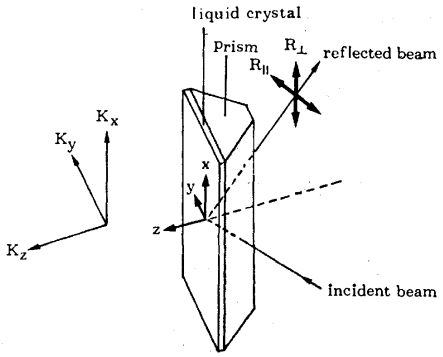

Fig. 1. Coordinate system showing the attenuated total reflection (ATR) from anisotropic absorbing liquid crystal. K_x, K_y, and K_z are the components of the absorption coefficient along the prism-fixed axes. $R_\parallel$ and $R_\perp$ indicate the reflectivities of the radiation polarized parallel and perpendicular to the plane of incidence, respectively.

$$\ln R_\perp = -pK_x$$

and

$$\ln R_\parallel = -qK_y - rK_z, \tag{1}$$

where p, q, and r are functions of the refractive indices of the absorbing medium and of the internal reflection prism, and the angle of incidence. Furthermore, K_x, K_y, and K_z are the components of the absorption coefficient along the prism-fixed axes shown in Fig. 1. In Fig. 1, the sample of the liquid crystal is assumed to be much thicker than the effective penetration depth of the evanescent wave.[10] The dichroic ratio D for a given vibration band can be written as

$$D = \frac{\log (R_\parallel^\circ/R_\parallel)}{\log (R_\perp^\circ/R_\perp)} = \frac{q}{p}\left(\frac{K_y}{K_x}\right) + \frac{r}{p}\left(\frac{K_z}{K_x}\right), \tag{2}$$

where $R_\parallel^\circ$ and $R_\perp^\circ$ are the background reflectivities measured with the radiation polarized parallel and perpendicular to the plane of incidence, respectively.

In order to calculate coefficients p, q, and r, it is desirable to know accurately the birefringence, $\Delta n = n_e - n_o$, in the infrared region for MBBA, where the extraordinary index n_e and ordinary index n_o correspond to the directions parallel and perpendicular to the optical axis of the director, respectively. In Eq. 2, the n_o contribution to the coefficients, q/p and r/p, is much smaller than the Δn contribution.[11] Therefore, n_o is conveniently assumed to be 1.54 in accordance with the value observed in the visible region,[12] as before.[1] On the other hand, the Δn for well oriented MBBA has been suggested to be 0.05—0.1 in the infrared region,[1] which is much less than 0.22 in the visible region.[12] Such a small birefringence change would, however, require a highly accurate measurement on the same system. Hence, the contribution from the birefringence was omitted in Eq. 2. Since birefringence is obviously related to the degree of order, its omission may result in an overestimation of the degree of order by about 10% for a sample of high structural order (if $\Delta n = 0.1$ in the infrared). For a less ordered sample, however, the error caused by the omission is negligibly small. Using the isotropic index of 1.54 assumed for MBBA and 3.42 for Si,[13] the coefficients were calculated for an incident angle of 40° and for one reflection at the Si-MBBA interface. The results are $p = 1.700$, $q = 1.215$, and $r = 2.384$. Upon substituting these values into Eq. 2, the observed dichroic ratio can be used to estimate the degree of anisotropy of the absorption coefficients.

This procedure can be simplified by assuming uniaxial symmetry for the nematic liquid crystals as follows. For example, if molecules in the liquid film are oriented normal to the Si prism surface (homeotropic), one finds $K_x = K_y$ from Fig. 1 and then Eq. 2 reduces to

$$D = 0.72 + 1.40\left(\frac{K_z}{K_x}\right). \tag{3}$$

If the molecules are oriented parallel, for instance, to the x axis which is perpendicular to the plane of incidence (uniformly homogeneous), one obtains

$$D = 2.12\left(\frac{K_z}{K_x}\right). \tag{4}$$

In particular, if the molecules are randomly oriented, *i.e.*, if $K_x = K_y = K_z$, the dichroic ratio becomes 2.12, regardless of the vibration type.

On the other hand, the degree of orientation order, S, is conveniently defined with respect to the orientation of the long axis of the molecule relative to the optical axis of the liquid crystal.[14] In this case the degree of order is given by

$$S = \frac{1}{2}(3\cos^2\alpha - 1) = \frac{(d-1)}{S_\beta(d+2)}, \tag{5}$$

with

$$S_\beta = \frac{1}{2}(3\cos^2\beta - 1),$$

where α is the angle between the long axis of the molecule and the optical axis of the uniaxial liquid crystal, and β is the angle between the long axis and the direction of the vibrational transition moment, as is shown in Fig. 2. In Eq. 5, $d = K_\parallel/K_\perp$, where $K_\parallel$ and $K_\perp$ are the absorption coefficients parallel and perpendicular to the optical axis, respectively, as is shown in Fig. 2. Accordingly, d is given by K_z/K_x for the homeotropic case, whereas it is given by K_x/K_z for the uniformly homogeneous case (if the preferred axis is x). Hence, the magnitude of K_z/K_x in the above examples acts as the measure for evaluating the orientation type and its

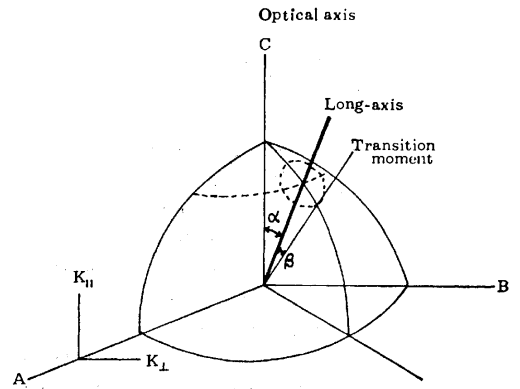

Fig. 2. Uniaxial orientation of the long-axis of the molecule around the optical axis and of the transition moment about the long-axis of the molecule. $K_\parallel$ component is taken to be parallel to the optical axis.

degree of order.

In terms of the d defined above, the degree of order S changes from 0 to 1, corresponding to a change from isotropic orientation or perfect orientation with $\alpha=54°44'$ to perfect orientation with $\alpha=0°$. It should, however, be mentioned that Eq. 5 is valid only when the molecules are packed as if they are allowed to rotate freely about their own long axes.

Based on Eq. 5, the β values of several important vibrations of MBBA were determined to within an accuracy of $\pm 10\%$ for highly-ordered homeotropic and uniformly-homogeneous liquids.[1] This fact demonstrates that Eq. 5 is a good approximation to the degree of order in terms of the orientation of the long axis of the molecule.

Orientation of Molecules at Electrode Surfaces. When a static electric field of rather low strength is applied to the liquid crystal, the primary effect of the field is the interaction with the dielectric tensor of the liquid so that the molecules tend to be oriented with their axes of maximum dielectric constant parallel to the field.[15] The reorientation is, however, often restrained by the surface orientation of the molecules at electrodes.[2] On the other hand, if the DC field is sufficiently high to produce hydrodynamic scattering, a greatly disordered texture is expected to be observed. In order to elucidate the electric-field effect on liquid crystals, it is necessary to know the original orientation produced by the electrode surfaces.

Because in the present work the Si ATR prism also served as an electrode, it is necessary to discuss the orientation of the MBBA molecules present on the Si prism surface. For this purpose, polarized ATR spectra were obtained for a thin liquid film of MBBA having an estimated thickness of 0.2 μm. The vaporized sample was deposited onto the reflection surface of the Si prism for nine internal reflections.

The observed ATR spectra are shown in Fig. 3. The absorption band assignments[1,16] and the observed D values are listed in Table 1, together with the β values[1] corresponding to these vibrations. On the other hand, when polarized infrared light was passed through the plane of the sample film at normal incidence, the spectrum was identical irrespective of the orientation of the electric field of the incident radiation. This demonstrates that the transition moments of the molecule are randomly oriented about the direction normal to the Si surface; the equality of K_x and K_y holds in the present case. Therefore, the dichroism observed from ATR spectra should be interpreted in terms of the uniaxial orientation of molecules about the z axis, which is perpendicular to the Si surface. On the basis of the assumption that the long axes of the molecules are uniaxially aligned with respect to the z axis, S values were calculated from the observed dichroic ratios[18] and the β values. The resulting S values are given in Table 1.

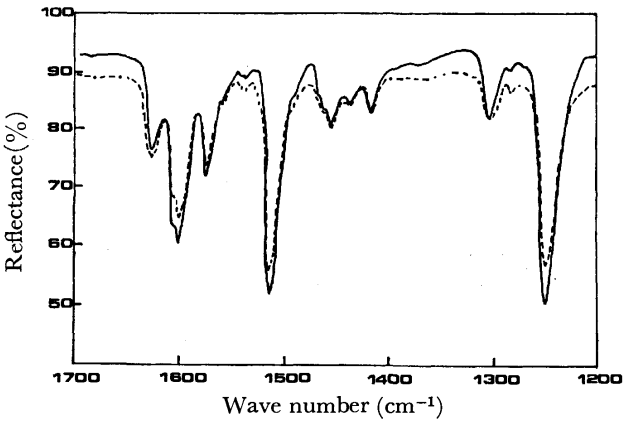

Fig. 3. Infrared polarized ATR spectra of thin MBBA liquid film (0.2 μm) at 25 °C deposited from vapor. Solid and broken lines refer to the orientation of the electric vectors of radiation parallel and perpendicular to the plane of incidence, respectively.

Thus, on the Si surface, MBBA molecules tend to be oriented with their long axes parallel to that surface in agreement with results based on other methods.[19] Nevertheless, the resulting S value for the 1630 cm^{-1} band is much larger than that for other vibration bands. This fact suggests anomalous structure of the thin film such that the molecules may not have complete freedom of rotation about the long axes of the molecules in the film. Assuming uniaxial alignment of the long axes with respect to the z axis, as mentioned above, and no molecular rotation about the long axes, the distribution of the transition moments can be calculated using the simple relation,

$$2\tan^2\gamma = \frac{K_z}{K_x}, \tag{6}$$

where γ is the angle that the transition moment makes with the surface plane. The γ values thus obtained are also given in Table 1.

While the film treated above is too thick for the determination of the orientation of the molecules adsorbed on or present near the Si surface, a "quasi-fixed" orientation may be supposed, because the orientation mechanism in thin films primarily involves the epitaxy.[20] In this connection, it appears important to examine the existence of "quasi-fixed" orientation in thick films. For this reason, we now consider the case where a voluminous sample of MBBA comes in contact with the Si surface.

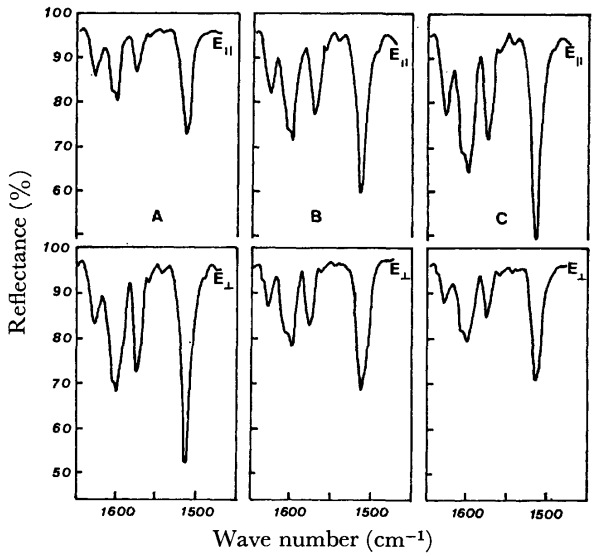

Fig. 4. Infrared polarized ATR spectra of MBBA (thickness: 2 mm).
$E_{\parallel}$ and $E_{\perp}$ refer to the polarized radiation used. A: original spectra (nematic; T=25 °C), B: spectra recorded 72 h later (nematic; T=25 °C), C: spectra of isotropic state (T=50 °C).

Figure 4 shows the polarized ATR spectra of MBBA liquid having a thickness of 2 mm. It must be mentioned here that each spectrum (A—C) appeared with the liguid layer about 1 μm thick at the Si-MBBA interface, depending upon experimental conditions. Accordingly, the three orientations that can be deduced from these spectra occur with the liquid having this thickness.

A brass plate was used as an opposite substrate. Since the substrate is very far from the Si prism surface, any possible orientation due to the substrate probably gives no contribution to the molecular orientation near the Si surface. Spectra (A) of Fig. 4 exhibit strong perpendicular dichroism, indicating that the preferred direction of the long molecular axes is parallel to the x axis, which is perpendicular to the plane of incidence, *viz.*, uniformly homogeneous orientation (see Fig. 1). This orientation almost disappears at an isotropic temperature of 50 °C, as is seen from spectra (C), but reappears upon lowering the temperature to the nematic temperature of 25 °C. The dichroic ratios taken from spectra (A) and (C) are given in Table 2.

The D values for spectra (C) are close to the value expected for isotropic orientation, but a difference of about 10% on the average is noticed between them. Since this discrepancy is greater than the limits of experimental error, the isotropic liquid may be influenced by the Si surface in contact with it.

Based on the dichroic ratios from spectra (A) and with the β values, the values of S were determined using Eqs. 3 and 5. The resulting S values are given in Table 2. As is seen in Table 2, the S values are indicative of a highly-ordered uniformly homogeneous orientation. The mechanism of the uniformly-homogeneous texture is, however, not understood in detail, but it is quite likely that the orientation is due to material flow[21] along the Si wall surface. Spectra (A) remained almost unchanged generally for as long as 24 h, but changed into spectra (B) after 72 h. The dichroic ratios taken from spectra (B) are given in Table 2.

The magnitude of the dichroic ratios is well explained by assuming a randomly-homogeneous orientation with poor order, as is shown in Table 2. Thus, the orientation pattern arising from the flow orientation is regarded as about the same as that for a liquid 0.2 μm thick, as mentioned above. In the present case, however, the "quasi-fixed" structure is greatly quenched. This fact shows that the "quasi-fixed" structure is confined to the vicinity of the Si surface and that its degree of order decreases with increasing film thickness.

Orientation Behavior of Molecules in an Electric Field. In what follows we shall deal with a relatively thin liquid layer (15 μm) contained between a Si prism and a conducting substrate plate.

Since the liquid-crystal orientation near the surface extends into the bulk, the above mentioned "asymmetric-electrode" cell would give rise to an orientation distortion at the interface of different orientations from the electrodes. However, if the opposite electrode material interacts much more strongly with the molecules than does the Si electrode, a predominant orientation probably develops over large areas and, consequently, it would overcome the flow orientation or weakly-bound

TABLE 2. POLARIZED INFRARED ATR DATA FOR LIQUID MBBA (for a thickness of 2 mm)

a) Calculated assuming that $K_x=K_y$.

orientation at the Si surface mentioned above. In fact, this is always the case provided the opposite electrode surface is specially treated to give a birefringent texture.[1] In other words, this means that the "quasi-fixed" orientation at the Si surface cannot exert any important role on the type of birefringent orientation.

To examine the DC electric-field effect on the orientation of MBBA, a brass plate was used as the opposite electrode. The surface of the brass electrode was coated with a very thin film of lecithin in order to obtain a uniform homeotropic texture in the absence of any field. Because MBBA has a negative dielectric anisotropy,[22] the molecules should be aligned perpendicular to the electric-field direction.

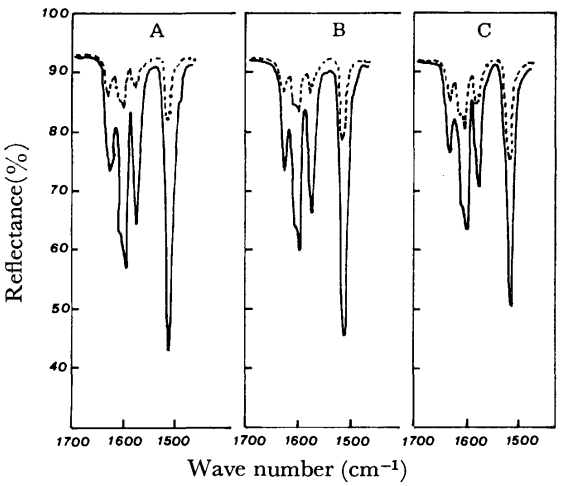

Fig. 5. Polarized infrared ATR spectra of nematic MBBA (25 °C); the opposite electrode: lecithin coated brass plate; thickness: 15 μm. Solid and broken lines refer to the electric vectors of radiation polarized parallel and perpendicular to the plane of incidence, respectively. The three sets of spectra correspond to different applied voltage; A: 0 V; B: 15 V rms; C: 30 V rms.

The polarized ATR spectra from a liquid 15 μm thick at 25 °C for different applied voltages are shown in Fig. 5. The dichroism of the vibration bands in the absence of any field indicates good homeotropic orientation of the sample. The average value of S deduced was 0.54. The dichroism of the vibration bands decreased with step increases in the voltage, indicating deformation of the homeotropic orientation. The S value can serve as an indicator of the extent of deformation.

The S value, which was obtained by averaging S over all vibration bands measured, is plotted as a function of the applied field in Fig. 6. As is shown in Fig. 6, the S value slightly decreased with increasing voltage up to 10 kV/cm and decreased more rapidly with subsequent increases in the electric field. Upon the removal of the field, the original arrangement was restored. The S value increased by 0.03, probably due to relaxation to a more stable form. Because dielectric reorientation always precedes dynamic scattering, the initial decrease in S probably arises from dielectric reorientation, whereas the second decrease in S is attributed to dynamic scattering. It is, however, significant that voltages applied above the threshold for

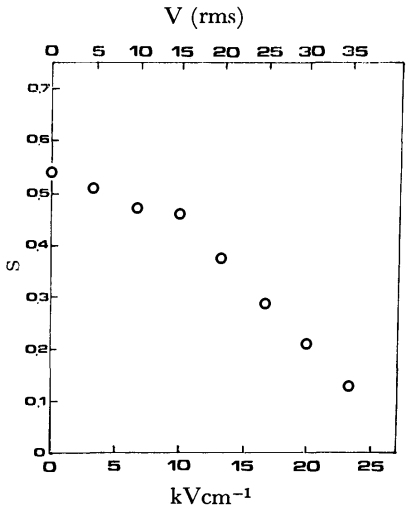

Fig. 6. The degree of order (S) of homeotropic orientation as a function of applied DC voltage.

dielectric orientation[15] produce no appreciable deformation of the homeotropic structure.

In this connection, it has generally been assumed that molecules near the electrodes are maintained in place by the boundaries in an electric field.[23] This idea is probably based on the interaction between the liquid-crystal molecules and the electrode surfaces. However, since the same result was obtained when the Si-prism surface was coated with lecithin, the above limited electric-field response is, probably, ascribed to the strong aligning force of the lecithin which aligns the molecules perpendicular to the surface. In Fig. 6, the S value decreases as the applied voltage is increased, which indicates that dynamic scattering becomes more pronounced with increasing voltage. However, it is important to note that homeotropy of the liquid is still present even at high voltages.

In the light of these results, subsequent experiments were carried out using a new brass plate as the opposite electrode. The original texture observed was a flow orientation. The polarized ATR spectra recorded are depicted in Fig. 7(A). The S value obtained for that alignment was 0.59 on the average. The flow orientation remained for long periods of time. To attain sample stabilization, the liquid cell was permitted to stand for 15 hours and was maintained at 25 °C. The results of the ATR measurements are shown in Fig. 7(B). The parallel dichroism of the spectra is indicative of the tendency for the molecules to orient themselves perpendicular to the electrodes.

Based on the foregoing discussion, it is thought that the spontaneous homeotropy arises from the brass electrode surface. The values of K_z/K_x and of S calculated from the experimental D values are given in Table 3. The generally low S value is an indication of the rather weak aligning force of the brass electrode. However, a marked difference in S is seen between the 1630 and 1030 cm^{-1} bands, suggesting poor nematic-type packing of the molecules. To establish the average initial orientation, the values of γ were calculated from the K_z/K_x values using Eq. 6. The results of γ are given in Table 3 and the molecular orientation deduced is

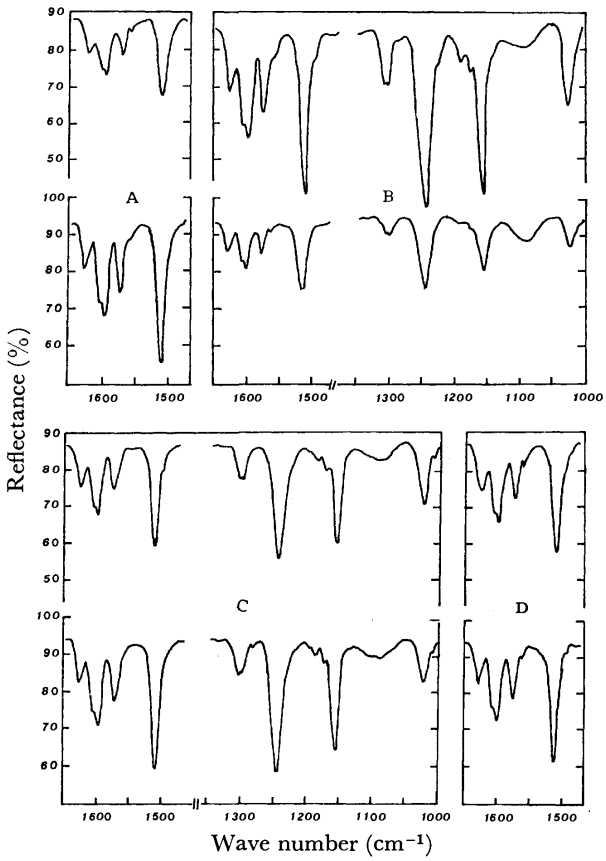

Fig. 7. Polarized infrared ATR spectra of nematic MBBA (25 °C) depending upon applied DC voltage. Upper and lower spectra were measured with the radiation polarized parallel and perpendicular to the plane of incidence, respectively. A: Initial flow orientation; B: homeotropic orientation appeared 15 h later in field-off; C: DC 5 V applied on B; D: DC 9 V applied on B.

depicted in Fig. 9(a).

A sharp change in dichroism was observed when a DC electric field was applied to this texture. In order to follow the sequence of spectral change in detail, measurements were carried out for driving voltages from 0 to 9 volts. For comparison, the polarized ATR spectra recorded at field strengths of 5 and 9 volts are reproduced in Figs. 7(C) and (D), respectively.

The dichroic ratios of the observed ATR spectra are plotted *versus* the external DC field in Fig. 8. As is

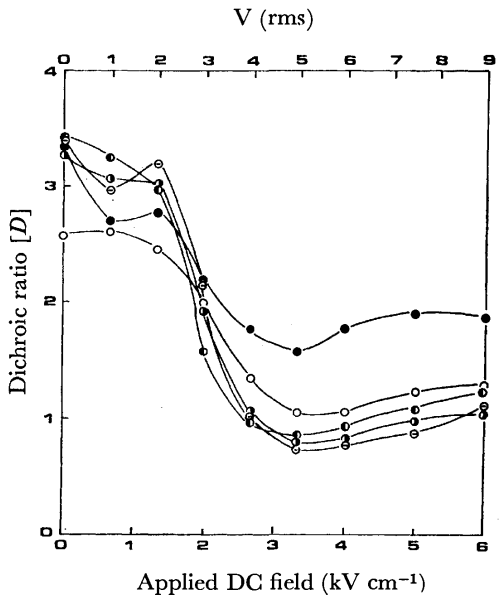

Fig. 8. Dichroic ratio (D) of various vibration bands as a function of applied DC voltage. ○: 1630 cm^{-1}; ⊖: 1578 cm^{-1}; ◑: 1520 cm^{-1}; ◐: 1250 cm^{-1}; ●: 1030 cm^{-1} band. The vibration assignments for these bands are presented in Table 1.

shown in the figure, reorientation begins at about 2 V and saturates at 5 V. Since the applied voltage exceeds 5 V, the dichroic ratios gradually decrease, probably due to domain formation[15] and the subsequent dynamic scattering, both of which interfere with the alignment.

The reorientation behavior mentioned above is in accord with that of the dielectric permittivity observed for relatively thick liquid MBBA by Ikeno *et al.*[24] Assuming the orientation at 5 V to be randomly homogeneous, the S values shown in Table 3 are obtained. The scattered values of S given in the table suggest that the molecules are packed in such a way that the rotation of the molecules about their own long axes is limited. Therefore, the γ values were calculated assuming uniaxial orientation of the long axis of the molecule, as before. The resulting values of γ are given in Table 3. Generally the change in γ with applied DC field appears to depend upon β. For example, the maximum change is found for the 1578 cm^{-1} band, whereas the minimum change is for the 1030 cm^{-1} band. Such behavior is understandable as a consequence of the negative

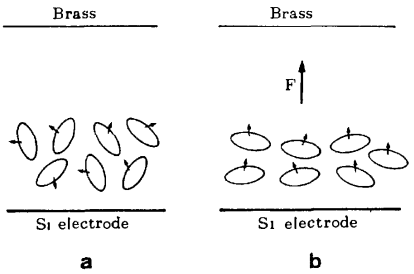

Fig. 9. Schematic representation of the molecular orientation of nematic MBBA before (a) and after (b) the application of DC electric field. Arrows indicate the dipole moments.

anisotropy of the molecule.

The molecular orientation in the DC electric field is drawn schematically in Fig. 9(b).

On the other hand, when the voltage was switched off, the sample exhibited a greatly improved homeotropy. An S value of 0.50, on the average, was obtained for this texture. This change is considered to be caused by the disturbance due to the applied field up to 9 V, as mentioned above.

When the 5 V DC voltage was subsequently applied, no appreciable dielectric distortion was observed: an average S value of 0.40 was obtained. Failure to produce a molecular reorientation comparable to that previously produced at the same voltage is consistent with the increased ordering or denser packing of the molecules before field application. Thus, the structure of the liquid film affects the response of molecules to the external electric field in a striking manner.

In conclusion, this ATR method affords three-dimensional information about the static and dynamic orientation behavior of liquid crystals in thin films. However, it must be emphasized that the surface influences of the electrodes are always important for interpreting observed results. This study will be extended to *N*-(*p*-ethoxybenzylidene)-*p*-cyanoaniline. The results for this compound will be published in the near future.

Magnetic Study of α- and β-Diamminecopper(II) Chlorides and Bromides

Takeshi Asai, Hiroshi Saheki,* Kayako Hori,** and Ryôiti Kiriyama

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita 565

(Received August 13, 1977)

The magnetic susceptibilities, χ, of α- and β-$Cu(NH_3)_2X_2$(X=Cl, Br) were measured from 4.2 to 360 K. Those of β-$Cu(NH_3)_2X_2$ obeyed the Curie-Weiss law above 50 K. The Weiss constants and effective Bohr magneton numbers are $-3.5(\pm1)$ K and $1.75(\pm0.01)$ for X=Cl, and -9.7 K and 1.82 for X=Br. α-$Cu(NH_3)_2Cl_2$ showed a rounded maximum for χ at 30 K. A linear Heisenberg model with the parameters, $J=-23.5(\pm1)$ K and $g=2.03(\pm0.03)$, gave good agreement with observations. α-$Cu(NH_3)_2Br_2$ had a peak for χ at $47(\pm2)$ K. This temperature is probably a Neèl temperature. The strong magnetic interaction of the α-form compounds is related to the compressed coordination octahedron of $[Cu(NH_3)_2X_4]^{2-}$. All samples used were solid solutions of $Cu(NH_3)_2X_2$ and NH_4X. An analysis of χ suggests that the Cu^{2+} cations in α-$Cu(NH_3)_2Cl_2$ are distributed inhomogeneously over a short range. A similar inhomogeneity was also found for the β-$Cu(NH_3)_2X_2$ samples. In this sense, the β-form may be better described as a solid solution of α-$Cu(NH_3)_2X_2$ and NH_4X rather than as a dimorph.

Diamminecopper(II) chloride and bromide have interesting stereochemical features. The copper(II) cation of these halides is situated at the center of a compressed $[Cu(NH_3)_2X_4]^{2-}$ (X=Cl, Br) octahedron, whereas in many copper(II) compounds the copper(II) cation is in an elongated octahedral environment. Studies have been made on the crystal structures of these compounds,[1-3] and their IR and optical absorption,[4] and ESR spectra.[4] Similarly, these compounds diluted with NH_4X[5] and ammonium halides doped with copper(II) ions[6-10] have also been studied. In the present study, the magnetic susceptibilities of α- and β-$Cu(NH_3)_2X_2$ were measured in order to learn the effect of a particular coordination on a magnetic property.

However, these halides are dimorphous. One of them has a chain structure of the coordination octahedra, $[Cu(NH_3)_2X_4]^{2-}$, while the other consists of isolated octahedra. Since both dimorphs exist at room temperature, it is questionable whether they are a thermodynamically-stable phase. In analyzing the magnetic susceptibility of α-$Cu(NH_3)_2Cl_2$, information on the distribution of copper(II) cations was obtained. From this information the phase relationship will be discussed.

Experimental

Preparation. Preparation of α- and β-$Cu(NH_3)_2X_2$ (X=Cl, Br) samples followed a known method.[1] The process always resulted in precipitates containing NH_4X. Moreover, the precipitates of the α-form partially transformed into the β-form during washing with an NH_4X aqueous solution. This partial transformation was prevented by washing the precipitate with acetone immediately after the parent solution had been filtered off. Ammonium halides contaminating precipitates were separated by decantation from acetone. This separation was repeated until the X-ray diffraction powder pattern of the sample indicated the disappearance of diffraction lines from NH_4X or indicated that the intensity ratio of several strong lines no longer varied.

Magnetic Measurements. The magnetic susceptibilities were measured from 4.2 to 360 K on a Faraday balance. The apparatus was calibrated for $CoHg(SCN)_4$.[11] Corrections were made for diamagnetism (-1.21 and -1.46 mm^3 mol^{-1} for the chlorides and bromides, respectively)[12] and for Van Vleck paramagnetism (0.75 mm^3 mol^{-1}).[13]

Results

The results of chemical analysis of the samples are given in Table 1. All samples obtained in this study contain more N and X than their stoichiometric composition of $Cu(NH_3)_2X_2$ (X=Cl, Br). Considering the caution exercised in their preparation, these samples are not a mixture of $Cu(NH_3)_2X_2$ and NH_4X, but are a solid solution of these two compounds. These preparations always gave solid solutions with no pure $Cu(NH_3)_2X_2$.

Table 1. Results of chemical analysis and the molar fractions of $Cu(NH_3)_2X_2$ deduced therefrom

Compound	Mass fraction[a]				Molar fraction of $Cu(NH_3)_2X_2$
	Cu	N	H	X	
α-$Cu(NH_3)_2Cl_2$	0.3520	0.174	0.041	0.4334	0.814
β-$Cu(NH_3)_2Cl_2$	0.2392	0.206	0.052	0.5069	0.353
α-$Cu(NH_3)_2Br_2$	0.2243	0.112	0.026	0.6375	0.792
β-$Cu(NH_3)_2Br_2$	0.1836	0.119	0.031	0.6662	0.525

a) Calcd for $Cu(NH_3)_2Cl_2$: Cu 0.3771, N 0.1663, H 0.0359, Cl 0.4208; for $Cu(NH_3)_2Br_2$: Cu 0.2469, N 0.1088, H 0.0235, Br 0.6208.

The magnetic susceptibilities are shown in Figs. 1—4. Throughout this paper, values of the magnetic susceptibility, χV_m, are given for one mole of copper(II) cations.

For both compounds having β-form, the magnetic susceptibility decreased monotonically with increasing temperature and obeyed the Curie-Weiss law above 50 K. The Weiss constants, θ, and effective Bohr magneton numbers, n_μ, deduced therefrom are given in Table 2.

In contrast to the features of the β-form compounds, the magnetic susceptibilities of the α-form compounds

Table 2. Weiss constants θ and effective Bohr magneton numbers n_μ obtained by application of the Curie-Weiss law

Compound	θ/K[a)]	n_μ[b)]
α-$Cu(NH_3)_2Cl_2$	−36	1.85
α-$Cu(NH_3)_2Br_2$	−70	1.95
β-$Cu(NH_3)_2Cl_2$	−3.5	1.75
β-$Cu(NH_3)_2Br_2$	−9.7	1.82

a) Maximum e.s.d. is ±2 K. b) Maximum e.s.d. is ±0.02.

clearly indicate that strong magnetic interaction occurs among copper(II) cations. The magnetic susceptibility of the α-form chloride compound exhibits a round maximum at 30 K. Combined with the crystal structure (Fig. 5), this suggests the magnetic interaction to be of a one-dimensional character. The temperature dependence agreed well with that of the linear Heisenberg spin system[14] having the parameters, $J=-23.5(\pm1)$ K and $g=2.03(\pm0.03)$. Fitting to the equation for a linear Ising spin system was unsuccessful.

Since the above-mentioned analysis neglected the fact that the sample was a solid solution, the following model was checked by taking the $Cu(NH_3)_2Cl_2$ molar fraction into account. If the cations are distributed randomly, a linear chain of $[Cu(NH_3)_2Cl_4]^{2-}$ octahedra is cut into smaller chains and the proportion of each smaller chain is determined by the $Cu(NH_3)_2Cl_2$ molar fraction. Assuming that the Heisenberg-type interaction operates only between the nearest neighbor cations in a chain and that the values of parameters J and g are the same for all types of chains, the magnetic susceptibility of the system was calculated as the statistical sum of that of each component. It indicated, however, no maximum, in contrast with the data. Therefore, this model is not applicable to the present case.

The magnetic susceptibility of α-$Cu(NH_3)_2Br_2$ showed a peak at 47(±2) K, and not a round maximum. This suggests that 47 K is a Neèl temperature and that below this temperature copper(II) spins are ordered antiferromagnetically. In support of this, the reduced magnetic

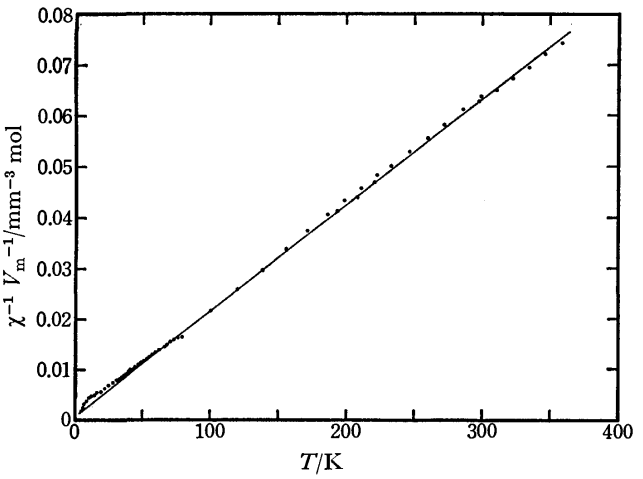

Fig. 1. Temperature dependence of the reciprocal susceptibility of β-$Cu(NH_3)_2Cl_2$. The solid line shows a Curie-Weiss relation.

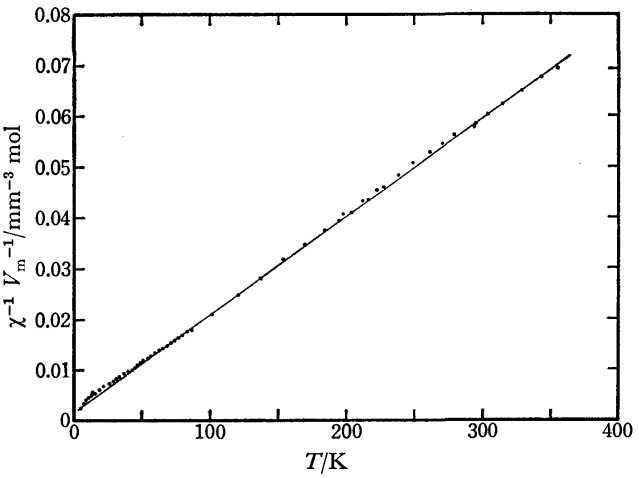

Fig. 2. Temperature dependence of the reciprocal susceptibility of β-$Cu(NH_3)_2Br_2$. The solid line shows a Curie-Weiss relation.

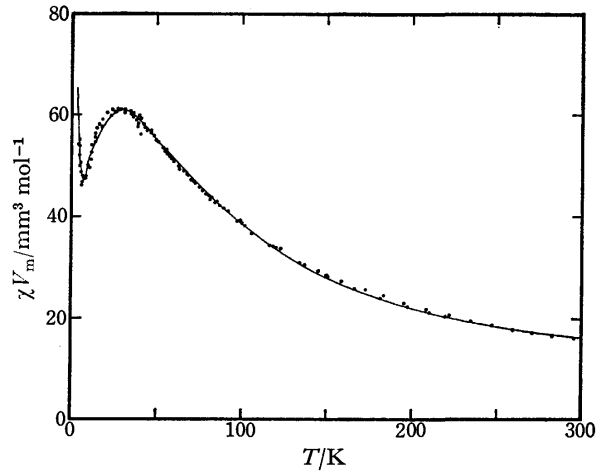

Fig. 3. Temperature dependence of the susceptibility of α-$Cu(NH_3)_2Cl_2$. The solid line shows a calculated one with contributions from a linear Heisenberg model ($J=-23.5$ K, $g=2.03$) and another paramagnetic term. The latter was included to explain the dependence below 10 K and was calculated by the relation of $\chi_p V_m$/mm^3 mol^{-1}=16.7/(T/K−3.3).

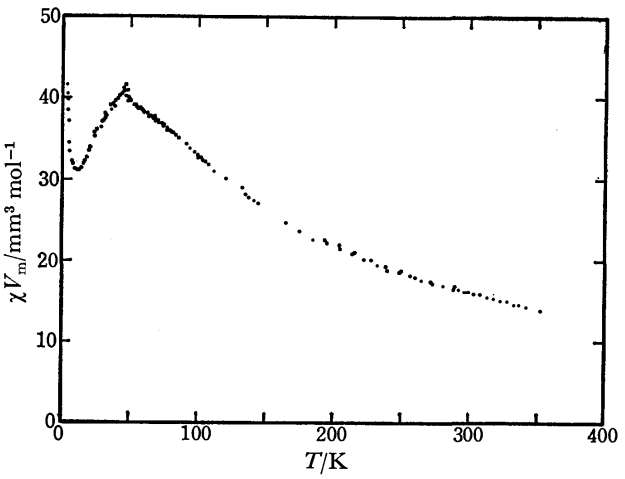

Fig. 4. Temperature dependence of the susceptibility of α-$Cu(NH_3)_2Br_2$.

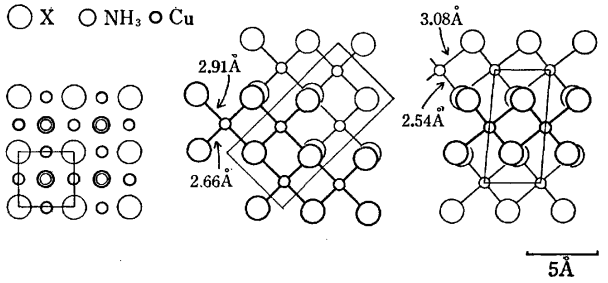
susceptibility $\chi(T)/\chi(T_N)$ below T_N agreed well with that predicted by simple molecular field theory,[18] although the theory was not applicable to the data over the entire temperature range measured.

For both α-form compounds, the values of parameters θ and n_μ were deduced from data above 110 K for the chloride and above 190 K for the bromide. They are given in Table 2.

Discussion

Crystal Structure. Diamminecopper(II) chloride and bromide are dimorphous.[1] The crystal structures of β-$Cu(NH_3)_2Br_2$[1] and β-$Cu(NH_3)_2Cl_2$ are isomorphous and belong to the cubic system (Fig. 5). The arrangement of the NH_3 molecules and halogen anions is of the CsCl type. The copper(II) cations are situated at the face-centered sites of the anion lattice, forming a $[Cu(NH_3)_2X_4]^{2-}$ compressed octahedron. These copper sites are occupied only with a small probability of 1/6 and the orientation of the octahedron is random along the three crystallographic axes.



(a) β-$Cu(NH_3)_2X_2$ (b) α-$Cu(NH_3)_2Cl_2$ (c) α-$Cu(NH_3)_2Br_2$

Fig. 5. Projection of crystal structure. Atoms at $z'=0$ is shown by a thin line and those at $z'=1/2$ by a thick one, where z' is a positional parameter along the axis perpendicular to the sheet of the paper. A nitrogen atom in α-forms is situated above and below a Cu atom and omitted for simplicity. Chlorine atoms overlapping each other in the α-chloride are shifted for easy view.

The crystal structures of the α-form result from ordering of the octahedron found in the structure of the β-form. This ordering brings about deformation of the lattice and the coordination octahedron itself. The deformation of the octahedron is such that short and long Cu–X distances are distinguished as is often seen in many halo-copper(II) complexes, $CuX_2 \cdot 2L$ (L= H_2O or organic molecules containing an N atom).[15] In α-$Cu(NH_3)_2Br_2$,[2] the coordination octahedron shares two opposite Cl–Cl edges to form an infinite linear chain like that in $CuCl_2 \cdot 2H_2O$ whereas, in α-$Cu(NH_3)_2Cl_2$,[3] zigzag chains result from the sharing of two adjacent Cl–Cl edges of the octahedron.

Magnetic Properties. For the β-forms, the observed magnetic susceptibilities show mainly the behavior expected for an isolated copper(II) ion (Figs. 1 and 2). This observation is compatible with the crystal structure together with a large dilution of NH_4X molecules (Table 1). However, deviation from the Curie-Weiss law was observed below 50 K and the Weiss constants have a non-zero value. This means that the copper(II) ions in these compounds are not fully isolated. This is discussed further below.

The magnetic susceptibility of α-$Cu(NH_3)_2Cl_2$ agrees well with a one-dimensional Heisenberg spin system having a J value of −23.5 K. Thus, an antiferromagnetic interaction must occur along the zigzag chain. Since the separation between copper(II) ions exceeds 3.9 Å, the direct interaction of copper(II) spins should be negligible. A copper(II) cation has four Cu^{2+} neighbors in a chain and two types of paths along which the superexchange interaction are possible. One of the paths passes the short (2.61 Å) and long (2.91 Å) Cu–Cl bonds between two nearest neighbor cations, whereas the other passes the two long Cu–Cl bonds between two alternate neighboring cations. Since the latter includes only long Cu–Cl bonds, only the former should be effective in this compound. This view is consistent with the result obtained from the ESR study of a doped copper ion in NH_4Cl at 4.2 K[8,10] for which a superhyperfine interaction was detected only between a copper spin and two nearest Cl nuclei in the center of the $[Cu(H_2O)_2Cl_4]^{2-}$ with orthorhombic symmetry. The value of J obtained is about twice that of a typical one-dimensional chloro-complex of $CuCl_2 \cdot 2C_5H_5N$ (J= −13.6 K).[16] The accuracy in the structural analysis of α-$Cu(NH_3)_2Cl_2$, however, is not enough to permit a discussion of the difference in the J values.

The magnetic susceptibility of α-$Cu(NH_3)_2Br_2$ indicates a three-dimensional ordering of copper(II) spins below 47 K. Therefore, a magnetic interaction must occur between linear chains, as well as within a chain. On inspection of the crystal structure, it appears that $NH_3 \cdots Br$ hydrogen bonds probably play the principal role in the interchain interaction. There are four such paths with an N···Br distance of 3.51 Å. Boettcher and Spaeth have shown that in the paramagnetic center of $[Cu(NH_3)_2Cl_4]^{2-}$ in NH_4Cl, an ammonia molecule reorients about the Cu–N bonding axis at 4.2 K.[10] The situation is probably the same in α-$Cu(NH_3)_2Br_2$ and hence the hydrogen bonding is weak. In $K_2CuCl_4 \cdot 2H_2O$, copper(II) cations interact through $H_2O \cdots Cl$ hydrogen bonding the magnitude of the interaction being of the order of 0.1 K.[17] On the other hand, Cu–Br chemical bonding plays a role in the intrachain interaction. Therefore, in α-$Cu(NH_3)_2Br_2$, the intrachain interaction should be stronger than the interchain interaction. The ratio of their magnitudes was estimated to be 1×10^{-1} from T_N and θ by application of molecular field theory.[18] This value is very large compared with the usual values of the order of 10^{-3} or less.[19] Furthermore, the value of the ratio T_N/θ, which is 0.67 for α-$Cu(NH_3)_2Br_2$, is much greater than the corresponding values, which are less than 0.2, for typical antiferromagnetic Heisenberg chains, and is close to values of 0.7—0.8 for three-dimensional Heisenberg magnets.[19] These facts indicate that the interchain interaction is very strong in α-$Cu(NH_3)_2Br_2$.

Strong magnetic interaction was observed in the α-form compounds. This is the result of the particular coordination of the copper(II) cation. As the coordination octahedron $[Cu(NH_3)_2X_4]^{2-}$ is compressed along the Cu–N bonding axis,[1] the unpaired electron of the

copper(II) cation occupies the $3d_{x^2-y^2}$ orbital.[4-10] Because the lobes of this orbital point to four chlorine neighbors, stronger magnetic interaction is expected in this case than in the case in which the unpaired electron occupies the $3d_{z^2}$ orbital in the elongated octahedral coordination.

Phase Relationship. The samples in this study were all solid solutions. However, the magnetic susceptibility of the α-$Cu(NH_3)_2Cl_2$ sample cannot be explained on the assumption that the copper(II) cations are distributed randomly and that the magnetic interaction between them is isotropic. A calculation based on this assumption showed that the maximum magnetic susceptibility χ_{max} is much larger for small chains than for an infinite chain; *e.g.* the χ_{max} of a tetramer, which is the most predominant species in the case of random distribution, is greater by 26.5% than that of the infinite chain. Therefore, the fact that the observed magnetic susceptibility agree well with an infinite linear Heisenberg model strongly suggests that the sample is not homogeneous over a short range. The copper(II) cations group together and form a chain long enough to exhibit the magnetic feature of an infinite chain.

In this connection, Tomlinson and Hathaway[4] have published an interesting observation for β-$Cu(NH_3)_2X_2$. They observed an isotropic ESR spectrum for the chloride and no signal for the bromide. They explained this by the effect of exchange coupling between the copper(II) cations. Because the occupancy factor of the copper site is only 1/6, their ESR results indicate that their samples of the β-form are inhomogeneous over a short range like the present sample of α-$Cu(NH_3)_2Cl_2$. On the contrary, the magnetic susceptibility of the β-form in the present study has primarily the character of that of an isolated copper(II) ion. The difference may be due to a greater local inhomogeneity in their samples than in the present ones. Local inhomogeneity is suggested also for the present samples due to small Weiss constants and deviation from the Curie-Weiss law below 50 K.

The preparation data[1] support this view. When a concentrated NH_4X solution was used as a solvent, the precipitate was of the β-form and remained stable. When a dilute NH_4X solution was used, the first precipitate was also of the β-form, which then transformed into the α-form. This means that, for a high concentration of copper, the system is more stabilized by clustering than by random distribution of the cations. The latter situation is probably stable only at very low copper concentrations. Thus, the local inhomogeneity needs to be taken into consideration for certain physical measurements on samples of the β-form, although a statistical distribution of copper(II) ions has been derived from X-ray analysis.[20] Together with the similarity between the crystal structures of β-$Cu(NH_3)_2X_2$ and NH_4X, the β-form may be better described as a solid solution of α-$Cu(NH_3)_2X_2$ and NH_4X rather than as one of dimorphs.

20) The idea of local inhomogeneities is not contrary to the result of X-ray analysis. Ususal X-ray analysis gives information on the average structure. Local inhomogeneities, if present, yield a large temperature factor. Hanic and Cakajdova give a large value for the temperature factor (Ref. 1). The inhomogeneities discussed here may contribute to this in some degree.

^{14}N Nuclear Quadrupole Resonance of Some Heterocyclic Compounds *via* Nuclear Double Resonance

Takuya MARUIZUMI, Yukio HIYAMA, Noriyuki WATANABE, and Eiji NIKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received August 29, 1977)

Using proton-nitrogen double resonance in the laboratory frame, the ^{14}N nuclear quadrupole resonances (NQR) of 2,4(1*H*,3*H*)-pyrimidinedione[uracil], 2,3-dihydro-2-thioxo-4(1*H*)-pyrimidinone[2-thiouracil], 2,4-(1*H*,3*H*)-pyrimidinedithione[2,4-dithiouracil], and 1,3-dihydro-2*H*-benzimidazole-2-thione[2-mercaptobenzimidazole] have been measured at room temperature. The NQR parameters of uracil and its sulfur-substituted compounds are interpreted by using the Townes and Dailey theory.

Because of pharmacological interest, many studies of sulfur-substituted pyrimidines and purines have been performed by various spectroscopic means, but not by the nuclear quadrupole resonance (NQR). In this paper we report the observation of NQR of ^{14}N in 2,4(1*H*,3*H*)-pyrimidinedione[uracil], 2,3-dihydro-2-thioxo-4(1*H*)-pyrimidinone[2-thiouracil], 2,4(1*H*,3*H*)-pyrimidinedithione[2,4-dithiouracil], and 1,3-dihydro-2*H*-benzimidazole-2-thione[2-mercaptobenzimidazole]. These data yield information about the electron density on the nitrogen nucleus and hence about the chemical bonding of these molecules.

Spin 1 nuclei such as ^{14}N have three quadrupole states in an electric field gradient, and three transitions can occur between these three states. The frequencies are given by[1]

$$\nu_{\pm} = \frac{3}{4}e^2Qq\left(1 \pm \frac{\eta}{3}\right), \quad (1)$$

$$\nu_0 = \nu_+ - \nu_- = \frac{1}{2}\eta e^2Qq, \quad (2)$$

where e^2Qq is the ^{14}N quadrupole coupling constant and η is the asymmetry parameter.

Nuclear magnetic double resonance (NMDR) in the laboratory frame was employed to detect the NQR transitions. NMDR methods —as first introduced by Hartmann and Hahn[2] and later by Lurie and Slichter[3]— facilitate observation of ^{14}N NQR whose transition frequency often lies in the region 0.3—3 MHz and is thus not accessible by conventional continuous wave techniques.

Experimental

Samples. The samples were all polycrystalline chemicals.

NMDR in the Laboratory Frame. The details of NMDR were described by Slusher and Hahn.[4] In brief, the sample is first magnetized in a high d.c. magnetic field H_0 (about 6 kG here) for a high-field spin-lattice relaxation time and then adiabatically demagnetized to zero field [(a) to (b) in Fig. 1]. The spin order of the abundant spins [protons here] is now very high but a suitably phase or pulse modulated radio frequency field H_{1B} which resonates a rare spin [^{14}N here] quadrupole transition will continuously break the spin order of the abundant spins. The loss may be observed by adiabatically remagnetizing the sample [(c) to (d)] and observing a decrease of the majority spins' nuclear magnetic signals with the help of a 90° pulse. By sweeping the frequency ν_B of the phase or pulse modulated field [in 10 kHz steps here] the entire quadrupole resonance spectrum may be recorded. In this study ν_B was swept from 450 kHz to 4 MHz. Most parts of the NMDR apparatus built in this laboratory were based on the design of Slusher and Hahn.[4]

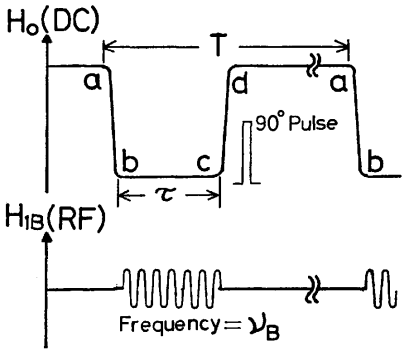

Fig. 1. Nuclear double resonance sequence.

Results and Discussion

Using the high-field and zero-field spin-lattice relaxation times for each molecule, the cycle time T [see Fig. 1] and zero field time τ were determined before performing the double resonance experiment. These data are collected in Table 1.

Table 1. High-field and zero-field spin-lattice relaxation times at room temperature and experimental conditions

Substance	T_1[a]	T_{1D}[b]	T_{1N}[c]	$[T-\tau]$[d]
Uracil	60	8	56	[90—3]
2-Thiouracil	52	3	20	[100—2]
2,4-Dithiouracil	107	8	30	[120—3]
2-Mercapto-benzimidazole	43	5	104	[60—3]

a) T_1 is the high-field spin-lattice relaxation time which is measured by 90°-τ-90° method. b) T_{1D} is the short zero-field relaxation time constant. c) T_{1N} is the long relaxation time. d) Cycle time T and zero field time τ. All the times in this table are in sec.

Figure 2 shows the zero-field proton spin-lattice relaxation, where the proton signal at first decreases quickly and later more slowly with time. This slow decay of proton magnetization is caused by the remagnetization of the proton system by cross interaction with the ^{14}N system, which has a long spin-lattice relaxation time.

Table 2. Observed ^{14}N NQR transition frequencies (kHz), coupling constants e^2Qq (kHz), asymmetry parameters η, and experimental temperature T (K)

Substance	[ν_+,	ν_-,	ν_0]	e^2Qq	η	T
Uracil	[2300,	1640,	660]	2630	0.502	294
2-Thiouracil	[2060,	1250,	810]	2207	0.734	300
	[2110,	1430,	680]	2360	0.580	300
2,4-Dithiouracil	[2030,	not obsd,	850]	2140	0.794	301
	[1970,	not obsd,	730]	2140	0.682	301
2-Mercapto-benzimidazole	[2340,	1790,	550]	2750	0.40	299

The observed transition frequencies, quadrupole coupling constants e^2Qq, and asymmetry parameters η are collected in Table 2. Though the two sets of lines corresponding to the two nitrogen atoms in uracil were observed at 77 K,[5] they could not be resolved at room temperature. In dithiouracil there remains some uncertainty when the ν_+ line is paired with the ν_0 line, since ν_- lines have not been observed. By comparing the absorption intensities of the two lines in each absorption band [ν_+ or ν_0], the pairing given in Table 2 was made. Figure 3 shows the chart recorder output of the ν_+ and ν_0 lines in the NQR spectrum of ^{14}N in dithiouracil. In the ν_0 [or ν_+] band, the dip of the resonance (a) [or (a')] is smaller than that of (b) [or (b')]. For the uracil group, the quadrupole coupling constant tends to decrease and the asymmetry parameter tends to increase as oxygen atoms are replaced by sulfur atoms. For uracil and its sulfur-substituted compounds it is very difficult to give the definitive assignment of one set of observed lines to one particular site within each molecule.

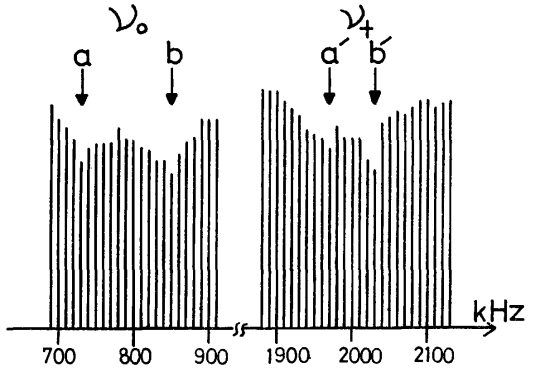

Fig. 3. Chart recorder output of the ν_+ and ν_0 lines in the NQR spectrum of ^{14}N in 2,4-dithiouracil.

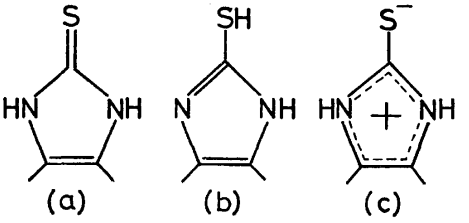

Fig. 4. Structural forms of 2-mercaptobenzimidazole.
(a) Thione, (b) thiol, (c) ionic.

Mercaptobenzimidazole can be represented by the three different structural forms illustrated in Fig. 4. When the thiol form is the predominant tautomer in the solid, we can expect two different ^{14}N NQR transitions. According to the X-ray analysis of the solid by Form *et al.*,[6] the molecule exists in the thione form with *mm* symmetry. This means the two nitrogen atoms are equivalent; our results are consistent with such a structural analysis.

The NQR parameters of uracil and its sulfur-substituted compounds are analyzed by the following formulae, (3) and (4),[1] which are used for pyrrole-type nitrogen:

$$(e^2Qq/e^2Qq_0)\left[1+\frac{\eta}{3}\right] = L - \bar{B}, \tag{3}$$

$$(e^2Qq/e^2Qq_0)\eta = \frac{3}{2}(A-\bar{B})(1-\cot^2\gamma). \tag{4}$$

Here L is the pi population, A is the N–H sigma population, $\bar{B}$ is the averaged N–C sigma population, 2γ is the CNC angle, and e^2Qq_0 is the coupling constant of an electron in a 2p orbital of nitrogen. In order to estimate L and $\bar{B}$, we assume that A is 1.33[7] and e^2Qq_0 is 7.4 MHz.[5,8] For uracil the averaged value of the two CNC angles[10] is used for 2γ. As the X-ray analysis of thiouracil has not been published, we assume 2γ is 122°. For dithiouracil the experimental values[9] are used. The results are given in Table 3. From uracil to dithiouracil, the lone pair population L is monotonically decreasing. This decrease of lone pair population suggests the increase of the ionic term $-^+NH{=}C(-S^-)-$ in the resonance structures.

Table 3. The orbital occupation numbers for nitrogen in uracil and its sulfur-substituted compounds

Substance	L (lone pair)	$\bar{B}$ (N–C)	[η][a]
Uracil	1.58	1.16	[0.502]
2-Thiouracil	1.49	1.12	[0.734]
	1.53	1.15	[0.580]
2,4-Dithiouracil	1.47	1.11	[0.794]
	1.49	1.14	[0.682]

a) The asymmetry parameters are used to distinguish the two nitrogen sites in each molecule.

Study of the Chemisorption and Hydrogenation of Propylene on Platinum by Temperature-Programmed Desorption

Susumu TSUCHIYA, Masami NAKAMURA,* and Norihiko YOSHIOKA**

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755

(Received September 2, 1977)

The temperature-programmed desorption (TPD) chromatograms of propylene from platinum black comprised four peaks: A, B, C, and D, with peak maxima at about 260, 380, 570, and higher than 720 K respectively. Peaks A and B were identified as the mixtures of propylene and propane. Peaks C and D were methane formed from chemisorbed propylene by decomposition as the temperature was raised during the subsequent TPD. The reactivities of various types of chemisorbed hydrogen previously detected by TPD were also investigated with regard to the hydrogenation of propylene. Two types of chemisorbed hydrogen, presumed to be present on the surface in the form of hydrogen atoms chemisorbed on top of platinum atoms and in the bridge form of molecular hydrogen, were found to react with propylene.

Four different types of chemisorbed hydrogen (α, β, γ, and δ) were previously found on the platinum surface, with the temperature-programmed desorption (TPD) peak maxima at about 170, 250, 360, and 570 K respectively.[1] Their participation in the H_2–D_2 exchange reaction was also examined;[2] only α and γ, were found to readily undergo surface exchange at low temperatures.

The present work has been carried out in order to obtain more information on the differences in the reactivities of the forms of chemisorbed hydrogen, and on the chemisorption and hydrogenation of propylene.

Experimental

Apparatus. The apparatus used for the present study was essentially the same as that used previously,[2] except for minor modifications. It consisted basically of two parts: an adsorption and reaction system, in which the adsorption and reaction were measured in a conventional manner, and a TPD system, in which adsorbed gas was later desorbed into a carrier-gas stream (N_2 or He) by means of the programmed heating of the catalyst. The concentration of the desorbed gas was measured and recorded by means of a thermal conductivity detector. When the ambient gas consisted of hydrocarbons, a gas chromatograph equipped with a thermal conductivity detector instead of a Pirani gauge was employed to estimate the pressure. A mercury manometer and a McLeod gauge were occasionally used to calibrate the detector, but they were then isolated from the reaction system by means of a stopcock to avoid the contamination of the catalyst by mercury vapor. An oil-diffusion pump behind the rotary oil pump was used for the evacuation of the system.

Materials. The catalyst used in the present investigation was a platinum black obtained from Wako Pure Chemical Industries, Ltd., it was pressed into tablets about 2-mm thick and 4 mm in diameter. Atomic absorption spectrophotometric analysis showed that the largest metallic impurity was Fe (130 ppm), followed by Rh (80 ppm) and Pd (20 ppm). The catalyst was first reduced in a hydrogen stream at atmospheric pressure for 35 h at 520 K, and then for 5 h at 720 K. Its surface area, as estimated by the BET method, was 3.2×10^3 cm^2/g.

Cylinder hydrogen (99.975%) supplied by the Osaka Hydrogen Co. was stored in a reservoir for use as a reactant after having been passed over platinized silica at 720 K and then through a liquid nitrogen trap. The same cylinder hydrogen could also be fed through to the reactor for the reduction of the catalyst. Matheson's deuterium (99.5%) passed through a liquid nitrogen trap was also used as a reactant. Propylene obtained from Takachiho Chemical Industry Co., Ltd., was purified by repeated distillation with liquid nitrogen traps; its gas chromatographic analysis indicated a purity of 99.9%. High-purity helium (99.995%) and high-purity nitrogen (99.999%), obtained from the Seitetsu Kagaku Co., Ltd., were used as carrier gases for TPD after having been passed through a molecular sieve trap cooled in liquid nitrogen.

Procedure. Before each run, the catalyst was treated with hydrogen for 4 h at 680 K and under atmospheric pressure, and then heated up to 820 K in the stream of carrier gas; all the hydrogen chemisorbed on the catalyst was removed by this desorption. The catalyst was then cooled to a selected temperature in the carrier gas, and the reactor was evacuated for 30 min, unless otherwise stated, using the oil-diffusion pump to remove the carrier gas. The catalyst activity fell at first, but became reasonably stable after about fifty runs. All the data reported here were obtained with the stabilized catalyst.

In a typical experiment on propylene, a known amount of propylene was adsorbed for 15 min at the experimental temperature. The reactor was then cooled to 238 K with the propylene present in the gas phase, and kept for 15 min. Following this, the carrier gas, helium, was diverted from the bypass into the reactor in order to remove the propylene in the gas phase, and then after 5 min, the catalyst was heated in a programmed manner. Before heating, hydrogen was sometimes admitted to react the adsorbed propylene after the helium had been removed by five minutes' evacuation. The reaction time in these cases was 30 min.

TPD chromatograms were obtained on the recorder chart and showed peaks due to the gas desorbed from the catalyst at different temperatures. A more detailed desorption of the TPD method has been given elsewhere.[3] The heating was stopped at about 800 K, after which the catalyst was kept in the helium stream for 20 min at the same temperature before cooling. Reproducible results were usually obtained by this procedure. When the results were not reproducible, however, the catalyst was treated with 20 to 30 kPa of oxygen for 1 h at about 770 K to oxidize any organic contamination, and was then again reduced by hydrogen as has been described above. This treatment improved the reproducibility considerably.

In the hydrogenation of propylene, various types of chemisorbed hydrogen were first prepared by the TPD technique described previously,[1,2] and then propylene was admitted to

* Present address: Central Glass Co., Ltd., Ube 755.

** Present address: Shikoku Paper Mfg. Co., Ltd., Kumagaya 360-01.

the reaction system to start the reaction. Before the propylene was admitted, however, ten minutes' evacuation was done and the α-hydrogen weakly adsorbed on the surface was removed. Helium was added to dilute the propylene when the circulating pump in the reaction system was operated. After the reaction, all the system except for the reactor was evacuated through a liquid nitrogen trap to collect any condensable hydrocarbons, which were transferred to a sampler for analysis. The carrier gas was then diverted into the reactor, and any materials adsorbed on the catalyst were removed by TPD.

Analysis. The reactants, the reaction mixtures, and the desorption products were identified by gas chromatography. The deuterio-hydrocarbons obtained after the reaction were analyzed by means of a JEOL JMS D-100 mass spectrometer. Before subjecting the reaction mixture to mass-spectrometric analysis, they were separated gas chromatographically to avoid any mutual interference of the mass spectra.

Results and Discussion

Temperature-Programmed Desorption. Figure 1 shows some typical TPD chromatograms taken after the propylene had been adsorbed on the platinum black in the absence or presence of hydrogen as indicated, with helium used as the carrier gas. The pressure of the propylene or hydrogen admitted was 6.1×10^2 Pa, and the reaction temperature was 238 K. These four TPD chromatograms resemble each other, characteristically being composed of four peaks appearing at about 260, 380, 570, and higher than 720 K. These peaks are referred to as A, B, C, and D in the order of appearance with increase in the temperature. By gas chromatographic analysis, Peaks A and B were identified as the mixtures of propylene and propane, while Peaks C and D were methane. It is suggested that the propane was formed by the self-hydrogenation of chemisorbed propylene, where hydrogen was absent. The methane may be formed by decomposition from the chemisorbed propylene heated by TPD, as was previously suggested[4] for the ethylene-platinum system. In order to observe the desorbing hydrogen more clearly, nitrogen was used as the carrier gas for the TPD; only δ-hydrogen was observed in the TPD chromatogram. The other form of hydrogen may have been removed from the surface when propylene was admitted, probably by the displacement in the adsorption and/or in the surface hydrogenation to propane. On the surface, accordingly, only the admitted propylene along with δ-hydrogen was adsorbed in the form of propylene and/or propane. The results suggest that propylene is more strongly adsorbed on platinum than hydrogen.

It is not very clear at this stage whether the propane in the Peaks A and B, where hydrogen was present, is a result of the self-hydrogenation, or of the desorption of propane formed by hydrogenation, or both.

Reactivity of Chemisorbed Hydrogen. Table 1 shows the results of the surface hydrogenation experiments with hydrogen preadsorbed on the platinum black in various forms (the surface reactant), and with gaseous propylene subsequently admitted into the reaction system (the gas-phase reactant). The amounts of propane formed in Series B with δ-hydrogen agreed approximately with those in Series A, in which propane was formed by a self-hydrogenation reaction. Apparently, δ-hydrogen hardly reacts with the gas-phase reactant under the present experimental conditions.

In Series C, with δ- and γ-hydrogen preadsorbed on the surface, however, relatively larger amounts of propane were produced than in Series B. The amounts of propane formed agreed with those of the preadsorbed γ-hydrogen. In the TPD chromatogram obtained after propylene was admitted to the preadsorbed hydrogen, where nitrogen was used as the carrier gas, the γ-hydrogen disappeared, while δ-hydrogen was still present in almost the same amount. It is, therefore, clear that γ-hydrogen is involved in the hydrogenation.

In Series D, in which β-, γ-, and δ-hydrogen were preadsorbed, the amounts of propane formed were again in approximate agreement with those of γ-hydrogen, suggesting that only preadsorbed γ-hydrogen reacted. The contribution of β-hydrogen to the hydrogenation, however, could not be observed, because the amounts of preadsorbed β-hydrogen were much smaller than those of γ-hydrogen. It was, accordingly, not clear at this stage whether or not only γ-hydrogen participates in the hydrogenation.

To elucidate the point, the preadsorbed hydrogen was partially displaced by deuterium before propylene was introduced, and the deuteropropanes formed by hydrogenation were then analyzed. The participation of the different types of chemisorbed hydrogen was consequently elucidated. For the sake of simplicity, the word "hydrogen" in the present paper will hereafter stand for both isotopes, protium and deuterium, and, where necessary, the individual isotopes will be designated as H and D. The types of surface used were as follows: (1) δ-Hydrogen was displaced by deuterium, and γ- and β-hydrogen were protium (H–H–D); (2) δ- and β-hydrogen were deuterium, and γ-hydrogen was protium (D–H–D); (3) δ- and β-hydrogen were protium, and γ-hydrogen was deuterium (H–D–H); (4) δ-hydrogen was protium, and β- and γ-hydrogen were deuterium (D–D–H). The method of preparation was described previously;[5)] the isolation of different types of chemisorbed hydrogen was confirmed by separate TPD experiments.

Table 2 shows the results of hydrogenation: the amounts of hydrogen preadsorbed and those of the individual deuteriopropanes formed by the hydrogenation are shown. The reactions were carried out at 238 K for 30 min. In the mass spectra of propylene, the reactant, the $m/e>42$ could not be observed, the ^{13}C contribution having been corrected.

Obviously, propylene is deuterated to deuteriopropane over the H–D–H, D–H–D, and D–D–H surface, but not over the H–H–D surface. These results agree quite well with the above suggestions that δ-hydrogen does not, and γ-hydrogen does, participate in the hydrogenation. The results also suggest the participation of β-hydrogen, which was not detected before. The total amount of deuteropropanes formed over the H–D–H surface was larger than that over the D–H–D surface under similar experimental conditions, and it seems that γ-hydrogen is more reactive than β-hydrogen. Over the D–D–H surface, propane-d_0 was formed, suggesting that the self-hydrogenation of propylene took place even when hydrogen was present.

On the mechanism of the hydrogenation of olefins, extensive studies have previously been reported.[6)] It is premature at present to discuss the matter on the basis of our results and to add further conclusions to other than those already reported.

It has previously been presumed that γ-hydrogen is present on the surface in the form of hydrogen atoms chemisorbed on top of platinum atoms, and that β-hydrogen is molecular hydrogen chemisorbed in a bridge form.[1)] The difference in the reactivity may, accordingly, be due to the chemisorbed state, whether or not the H–H bond has been split. In the H_2–D_2 exchange reaction, β-hydrogen is not reactive, but it is reactive in the hydrogenation of propylene. It is, accordingly, probable that a different tendency would be shown depending upon the sort of reaction; the explication of the other reactions awaits further investigations.

The authors are grateful to Mr. Shizuo Fujisaki of this faculty for obtaining the mass spectra, and also to Professor Tatsuaki Yashima and Dr. Nobuo Takahashi of Tokyo Institute of Technology for the atomic absorption spectrophotometric analysis of the catalyst. The work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, for which the authors' thanks are due.

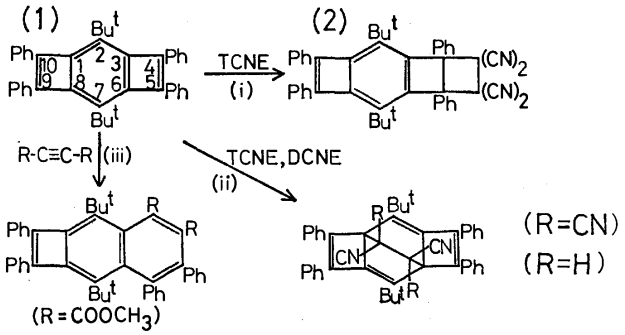
(Received September 10, 1977)

As the first step in the investigation of the reaction mechanism of a benzocyclobutene derivatives, the title compound has been determined by the X-ray diffraction method. The crystals are monoclinic; space group $P2_1/n$; $a=28.117(3)$, $b=11.148(1)$, $c=13.167(1)$ Å, and $\beta=97.26(1)°$. The asymmetric unit contains one molecule of the title compound and acetonitrile. The structure was solved by the direct method and refined by the block-diagonal least-squares method to a final R factor of 0.088 for 5456 observed reflections. The molecular framework consists of a planar ten-membered ring from benzodicyclobutene and a slightly folded four-membered ring formed by the addition of tetracyanoethylene (TCNE). Calculation has been undertaken for the non-bonded interaction energy of possible modes of approach between benzodicyclobutene and TCNE. The results are in qualitative agreement with the folding of the four-membered ring.

The Diels-Alder reactions of a benzodicyclobutene derivative (**1**)[1] with some dienophiles may be classified into three types: i) Tetracyanoethylene (TCNE) attacks the C(4)–C(5) double bond to give a "linear" adduct (**2**);[2] ii) bridged compounds across the central six-membered ring are obtained by means of a reaction with *trans*-1,2-dicyanoethylene (DCNE) and also as by-products of the reaction with TCNE,[3] and iii) some other dienophiles are added to C(1)–C(10) to produce "angular" adducts.[4] The diversity of the reactions of the molecule (**1**) should be studied stereochemically as well as electronically.



The present paper will deal with the X-ray analysis of the title compound (**2**), one of the linear adducts, as the first step in the investigation of the reaction route.

Experimental

Crystals suitable for structure determination were provided by Professor Fumio Toda of Ehime University. The crystals were orange prisms. Weissenberg photographs showed the systematic absences; $(h0l)$, $h+l\neq 2n$, and $(0k0)$, $k\neq 2n$, indicating that the space group was $P2_1/n$. Accurate unit-celldimensions and intensity data were obtained on a Rigaku automated four-circle diffractometer using graphite-monochromated Mo $K\alpha$ radiation. The crystal data are listed in Table 1. A total of 7404 independent reflections ($2\theta\leqq 50°$) were obtained, in which 5456 had intensities greater than $3\sigma(I)$. Lorentz and polarization corrections were made as usual.

Structure Determination

The structure was solved by the direct method.[5] Fourier synthesis using 545 normalized structure factors ($|E|\geqq 1.7$) clearly revealed 55 non-hydrogen atoms, including those in acetonitrile. The atomic parameters were refined by the block-diagonal least-squares method. The thermal parameters of acetonitrile became twice as large as those of the other atoms. All the hydrogen atoms except for those of acetonitrile were located on a difference map. In spite of the quite large thermal parameters, the bond lengths of acetonitrile are rather reasonable. Moreover, the difference synthesis showed no large peak near the position of these atoms. Therefore, there were no difficulties in determining the occupancy of acetonitrile. At the final stage of the refinement, anisotropic temperature factors were introduced for all the non-hydrogen atoms.

The weighting scheme was $w=1/\{1+0.2(10-|F_o|)\}$ for $|F_o|<10$, $w=1$ for $10\leqq|F_o|\leqq 30$, and $w=1/\{1+0.8(|F_o|-30)\}$ for $|F_o|>30$, so as to make the average of $w(|F_o|-|F_c|)^2$ almost equal over all the range of $|F_o|$ values. The final R factor was 0.088 for the non-zero reflections and 0.14 for all the reflections.* The atomic scattering factors were taken from *International Tables*

Table 2. Final positional ($\times 10^4$) and thermal ($\times 10^3$) parameters

The temperature factor has this form:

$$\exp[-2\pi^2(U_{11}h^2a^{*2}+U_{22}k^2b^{*2}+U_{33}l^2c^{*2}+2U_{12}hka^*b^*+2U_{13}hla^*c^*+2U_{23}klb^*c^*)].$$

for X-Ray Crystallography.[6] The final atomic parameters are listed in Table 2,* while the crystallographic numbering scheme is shown in Fig. 1.

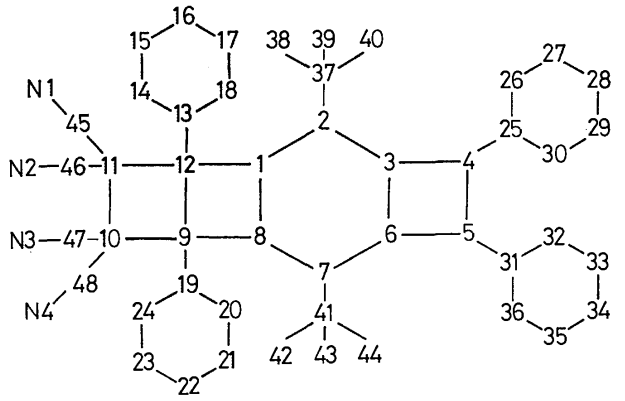

Fig. 1. Crystallographic numbering scheme.

Results and Discussion

The crystal structure is shown in Fig. 2, the molecular framework is shown in Fig. 3, and the bond lengths and angles are listed in Table 4. Ten atoms of the molecular framework, which are originally the skeleton of **1**, are nearly coplanar (Table 3). By the addition of TCNE, a new cyclobutane ring is formed, which makes a dihedral angle (109.0°) with the ten-membered ring. The corresponding dihedral angle of perchloro-3, 4,7,8-tetramethylenetricyclo[4.2.0.0^{2,5}]octane[7] is 115°. In the cyclobutane ring, all the bond lengths exceed 1.60 Å, considerably longer than the usual C(sp^3)–C(sp^3) lengths. Such an elongation effect of the four-membered ring may be attributed to the strong repulsion between the non-bonded atoms. For example, the C–C bond length is 1.56 Å in cyclobutane and 1.583 Å in *cis*-3,4-dichloro-1-cyclobutene.[8] Also elongated is that in the

unsaturated four-membered ring of the benzocyclobutene derivative (**3**),[9] a compound formed by the heat isomerization of the present compound. Our results, however, show much longer values than these compounds, indicating that the elongation effect is fortified by the bulky substituents. This suggests that this cyclobutane ring is easily cleaved. The bond between the *t*-butyl group and the skeleton is also affected by the repulsion. The averaged value, 1.54 Å, is comparable to that of the **3** molecule. The contraction of the C(1)–C(2)–C(37) and C(3)–C(2)–C(37) angles is 4.4°, and the C(1)–C(2)–C(3) angle is 108.8°. The corresponding values of the **3** molecule are 7 and 109° respectively. Although **2** and **3** are different about the cleaved ring, the resemblance in conformation of the *t*-butyl groups between **2** and **3** shows that the steric effects of the surrounding substituents are similar to each other. A detailed comparison indicates that, in **2**, one of the

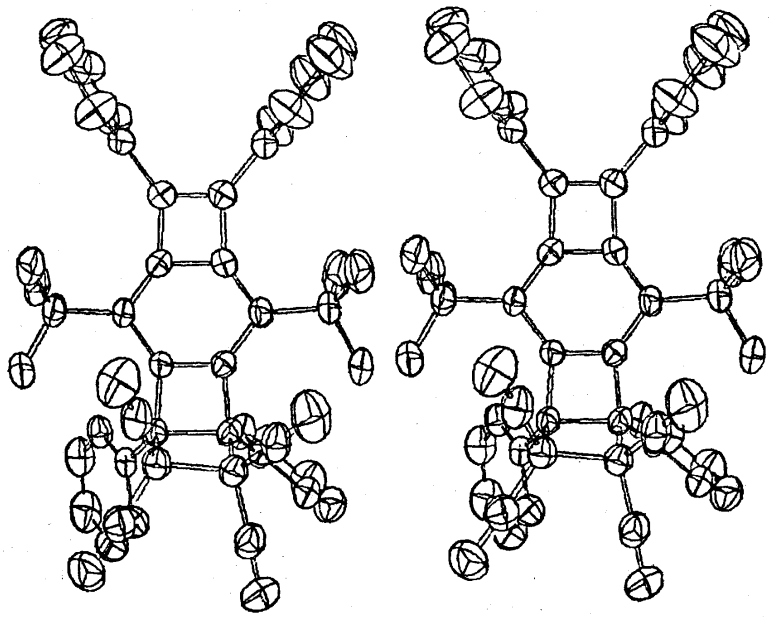

Fig. 3. A stereoscopic view perpendicular to the tenmembered ring.

methyl groups of the *t*-butyl group lies close to the skeletal plane. This is quite reasonable because, in the case of **3**, the cyano and phenyl groups jamming the in-plane methyl groups from both sides of the skeletal plane may have more freedom in their conformation than in the case of **2**. Phenyl groups attached to the unsaturated four-membered ring are rotated around the connecting bonds in both **2** and **3** molecules. The rotation angles of **2** are 80.2 and 91.7°, greater than those of **3**, 61 and 74°. These relatively large values, which may be attributed to the steric effect of the out-of-plane methyl groups, will serve to protect the reaction of one more TCNE to the unsaturated four-membered ring.

The central six-membered ring of the **2** molecule takes a shallow boat form, whereas the **3** molecule has a flattened crown conformation in which atoms deviate alternately from the plane. The four-membered rings annelated to the central six-membered ring are almost co-planar in **2**. However, the cyclobutane ring formed by the addition of TCNE is significantly non-planar. The dihedral angle between the C(9)–C(10)–C(11) and C(9)–C(12)–C(11) planes is 8.5°. The torsion angle C(9)–C(10)–C(11)–C(12) is 6.6°. This small, but significant, non-planarity may be regarded as a result of the steric effect of the bulky substituents. This effect, which also causes the elongation and distortion of some bond lengths and angles presented above, may play an intermediate role in the addition reaction as well. Therefore, we have calculated the non-bonded interaction energy for all the possible modes of approach between the **1** molecule and TCNE.

First, it was assumed that, in the stable conformation of the **1** molecule, four phenyl groups are rotated by 60° around the connecting bonds. This assumption is supported by the observation that some compounds with many phenyl groups have similar conformations; that of hexaphenylbenzene is 67.2°, for example.[10] Second, it was assumed that the plane of TCNE is parallel to that of the cyclobutene ring of **1** and that the center of the former approaches through the normal, passing the midpoint of the reactive double bond of the latter so as to make the overlap of the π-orbitals the maximum. For energy calculation, the distance between the double bonds and also the relative orientation were taken as variables. The former was varied from 4.0 to 3.4 Å, which is the van der Waals contact. The latter was every 10° of rotation up to 180° around the axis through the midpoints of both the double bonds. Some possible conformational changes of **1** in the reaction were

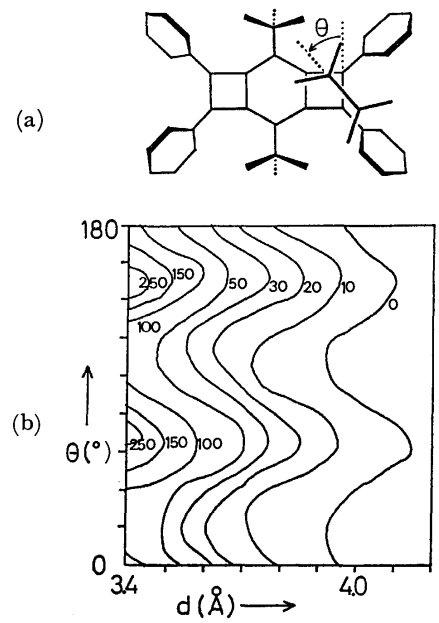

Fig. 4. (a) Relative orientation of the two molecules. (b) Two dimensional map of the non-bonded interaction energy (kcal mol^{-1}).

excluded from these calculations so as to reduce the number of parameters. For the same reason, the non-parallel approach of the two molecules was not considered. The potential functions used were those of Giglio.[11] The results are shown in Fig. 4. There are two potential grooves at the torsion angles of 20 and 110°, the former having a large overlap of the π-orbital. Therefore, the former mode of approach is preferable in the addition reaction. When the new cyclobutane is formed, strong intramolecular repulsion may modify the structure of **2** from the assumed one. However, the distortion of this cyclobutane ring, expressed in terms of the interedge angle (6.6°), is in qualitative agreement with the probable mode of approach. This indicates that such a calculation of the intermolecular interaction may be useful for the investigation of the reaction route of the **1** molecule with some dienophiles. The analyses of the other Diels-Alder adducts are in progress.

The authors are grateful to Professor Fumio Toda of Ehime University for supplying the sample and also for his valuable suggestions.

ESR Studies of Oxygen, Sulfur Oxide, and Sulfur Radicals Adsorbed on NaX Zeolite

Natsuko KANZAKI and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received September 12, 1977)

The states of O_2 and SO_2 adsorbed on NaX zeolite were investigated by means of ESR. No oxygen anion radicals were formed thermally on NaX up to 773 K. The adsorption of O_2 on γ-irradiated NaX in a vacuum, however, resulted in an ESR spectrum due to O_2^-. Several kinds of O_2^- species and O_3^- were found to be formed on NaX by γ-irradiation in the presence of O_2. These oxygen anion radicals showed different reactivities with N_2O, ethylene and propylene, and transferred electrons to SO_2 to form SO_2^-. The SO_2^- radical was also produced on NaX by raising the temperature from 298 to 573 K after the introduction of SO_2. This reacted with O_2 to form a radical, like SO_4^-, but upon evacuating the O_2, the reaction was reversed to give the original SO_2^-. When the temperature of NaX was further raised to 773 K in the presence of SO_2, a spectrum assigned to a polyatomic sulfur radical appeared indicating that SO_2 decomposition occurred at high temperature. This polymer radical was stable in an O_2 atmosphere at room temperature.

It has been verified using ESR that O_2^- and other oxygen anion radicals are formed on partially reduced oxides of molybdenum, titanium, zinc, vanadium and chromium containing trapped electrons.[1-5] It has also been found that SO_2^- is formed on these surfaces by introducing SO_2 at room temperature.[4-7] The reaction of SO_2^- with O_2 was also investigated. On magnesium oxide, this reaction produced SO_3^-.[8] SO_4^- was formed in the case of vanadium oxide.[7] A diamagnetic ion was mainly produced by a reaction on partially reduced titanium oxide.[6] These investigations are helpful for determining the intermediates in the oxidation of SO_2 on solid surfaces.

On the other hand, it is known that the O_2^- radical is produced on various cation exchanged Y-type zeolites when subjected to γ-irradiation.[9-12] Ono *et al.* have found thermal formation of SO_2^- on Y-type zeolites and have reported that SO_2^- on decationated Y zeolite reacts with O_2 to give O_2^-.[13] This finding appears rather unusual in view of the higher electron affinity of SO_2 as compared with that of O_2. On X-type zeolites, however, the adsorbed state of SO_2 has not yet been studied, and oxygen was examined only for cerium- and lanthanum-exchanged zeolites.[14] In this paper, the formation of these radicals on NaX and their reactivities are reported in some detail to obtain insight into the electron-donating power of zeolite.

Experimental

The NaX zeolite used was Linde type 13X which has a unit cell composition of $Na_{88}[(AlO_2)_{88}(SiO_2)_{104}]$. This sample was soaked in an aqueous solution of sodium acetate, supplied by the Wako Pure Chemical Ind., Ltd., to remove impurity cations and to avoid decationation.[15] Then the sample was washed thoroughly with ion-exchanged water and dried at 383 K. About 0.1 g of the sample was placed in a quartz sample tube with a breakable seal and heated under vacuum up to 823 K at a rate of 150 K/h. After degassing for 6 h at 823 K, the sample was cooled to room temperature and was exposed to the respective gases at 5—20 Torr at room temperature.

Unless otherwise noted, the ESR measurements were made at 77 K using a JES-3BS-X spectrometer with 100 kHz field modulation and a TE_{012} mode cavity. After evacuating the NaX sample at 823 K, a negligibly weak singlet signal was observed at $g=2.002$. γ-Irradiation was carried out at room temperature using a ^{60}Co γ-ray source with a total dosage of 12 Mrads. The irradiated sample was transferred into one end of the sample tube and the measuring end of the tube was heated with a flame to remove color centers generated in the wall during γ-irradiation. The gases used were of high purity and were obtained from the Takachiho Chemical Co.

Results and Discussion

Oxygen Radicals on NaX. An NaX sample was treated with O_2 at various temperatures between 298 and 773 K. No ESR spectrum, except a background, was observed. However, the ESR spectrum shown in Fig. 1(a) was observed when the sample was irradiated

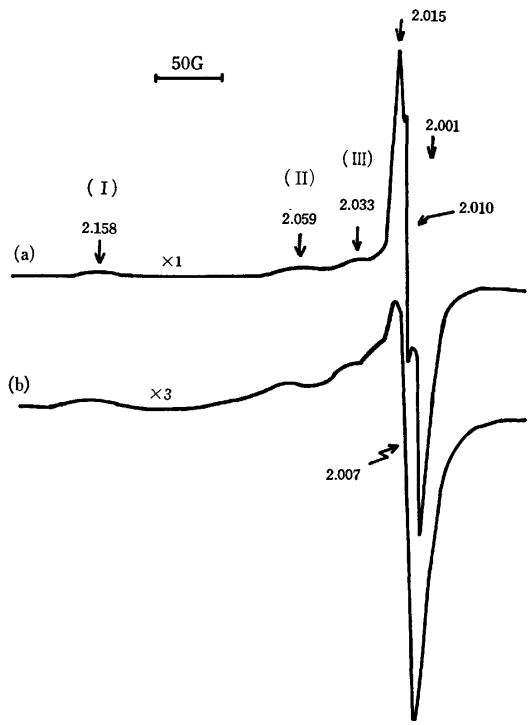

Fig. 1. ESR spectra of (a) NaX γ-irradiated in the presence of O_2 and (b) the same sample followed by N_2O addition.

in the presence of O_2. The high-field side of this signal (g_z=2.015, g_y=2.010, and g_x=2.001) is assigned to O_3^- from a comparison with ESR spectra due to various kinds of oxygen radicals.[1,11,16–22] The shape of this spectrum did not change upon evacuation at room temperature, but the intensities of all lines (the I, II, III, and O_3^- signals) were reduced to from 3/4 to 2/3 of the original values.

When N_2O was introduced into this sample after evacuation at room temperature, the spectrum due to O_3^- disappeared and a typical O_2^- spectrum[1,11,14,19] was clearly observed, as is shown in Fig. 1(b). This indicates that O_3^- is unstable compared with O_2^- and is affected by N_2O which is an efficient electron acceptor.[22] Several low-field lines correspond to O_2^- having different g_z values (g_z(I)=2.158, g_z(II)=2.059, and g_z(III)=2.033 in Fig. 1(b)) because of various crystal-field environments.[11] The lines corresponding to different g_x and g_y are superposed on each other to some extent. The spectrum in Fig. 1(b) was also obtained by heating the NaX sample at 373 K; the O_3^- signal disappeared above 373 K, while those for O_2^-(I), (II), and (III) remained up to 423, 523, and 473 K, respectively, upon heating.

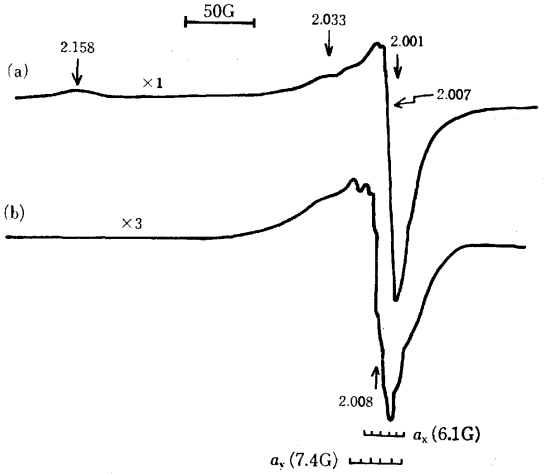

Fig. 2. ESR spectra obtained from NaX γ-irradiated in the presence of O_2 and exposed to (a) ethylene and (b) 1-butene or propylene.

Ethylene, propylene, and 1-butene were introduced in order to investigate the reactivities of the oxygen radicals. When the irradiated sample was exposed to ethylene at room temperature, the signals due to O_3^- and O_2^-(II) disappeared and the spectrum shown in Fig. 2(a) was obtained. This fact indicates that the O_3^- and O_2^-(II) can react with ethylene. For propylene and 1-butene addition, all the oxygen radicals except O_2^-(III) reacted and their ESR signals disappeared (Fig. 2(b)). A line shape characteristic of O_2^-(III) was clearly observed after this reaction, that is, g_z=2.033, g_y=2.008, and g_x=2.002. This spectrum appeares to show superhyperfine lines due to ^{27}Al (I=5/2), although they are not clearly resolved. The splittings ($|a_x|$=6.1 G, $|a_y|$=7.4 G) coincide well with those for O_2^- adsorbed on other zeolites.[10,12]

Upon further addition of oxygen (150 Torr) to the

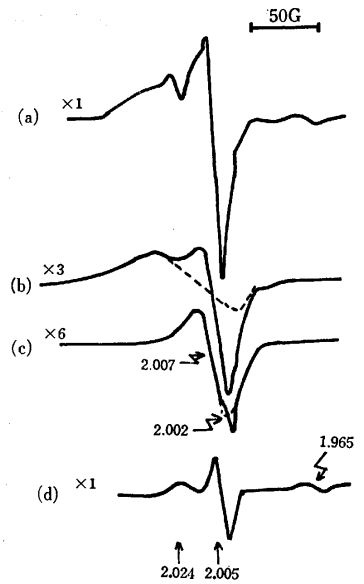

Fig. 3. ESR spectra of γ-irradiated NaX (a) under vacuum, (b) after N_2O addition, and (c) after heated at 423 K. (d) ESR spectrum obtained by subtracting (b) from (a).

sample, the spectrum due to O_2^-(III) was observed only because of the broadening of other lines. All the spectra recovered upon evacuation of the oxygen. This broadening effect indicates that O_2^-(III) exists in the sodalite unit or hexagonal prism, while O_3^-, O_2^-(I) and O_2^-(II) occur in the supercage.[11,15]

The ESR spectrum shown in Fig. 3(a) was obtained after NaX had been irradiated in a vacuum. The introduction of N_2O gradually changed this spectrum. Fig. 3(b) shows the result observed after exposure to N_2O for 24 h. This spectrum is converted to that shown in Fig. 3(c) upon heating the sample to 423 K after evacuation of the N_2O. The dotted line in Fig. 3(b) was obtained by subtracting spectrum (c) from spectrum (b). Similarly, Fig. 3(d) shows the difference between spectra (a) and (b). These spectra indicate that spectrum (a) is composed of a broad singlet signal (g=2.010, the dotted line in Fig. 3(b)), isotropic signals (g=2.007, 2.002, and 1.965, in Figs. 3(c) and (d)), and an anisotropic signal ($g_{//}$=2.024, $g_{\perp}$=2.005, in Fig. 3(d)). A comparison of the g values and the line shapes of these signals with those obtained by γ-irradiation of other samples[10,11,16,23] leads to the conclusion that the isotropic signals (g=2.007 and 2.010) and the anisotropic signal can be attributed to V centers, while the other signals (g=2.002 and 1.965) are due to F centers.

When O_2 was introduced into the NaX which had been subjected to γ-irradiation under vacuum, the signals due to the V and F centers disappeared and a new signal (g_z=2.027, g_y=2.008, and g_x=2.001, in Fig. 4), which can be assigned to O_2^-, was obtained.[11,16] It is known that the trapped electron at an anion vacancy reacts with O_2 to form O_2^-.[11,24] The spin concentration of the O_2^- formed on irradiated NaX was several times larger than those of the V and F centers of the original NaX sample, as estimated from ESR signals. This result suggests the presence of other kinds of trapped

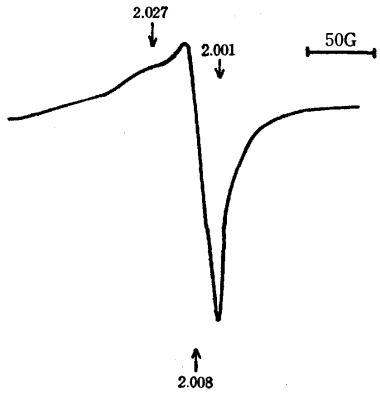

Fig. 4. ESR spectrum obtained from NaX γ-irradiated and exposed to O_2.

TABLE 1. g VALUES OF OXYGEN ANION RADICALS PRODUCED ON NaX

		g_1	g_2	g_3
γ-Irradiation in the presence of O_2	O_2^-	2.158	2.007—2.008	2.001
	O_2^-	2.059	2.007	2.002
	O_2^-	2.033	2.008	2.003
	O_3^-	2.015	2.010	2.001
Exposure to O_2 after γ-irradiation	O_2^-	2.027	2.008	2.001

electrons which are not ESR active. Table 1 summarizes the g values of the oxygen anion radicals formed on NaX after γ-irradiation. Details of the absorption sites of these O_2^- species will be discussed in a subsequent paper.

Reaction of Oxygen Radicals with SO_2. The introduction of SO_2, which has a higher electron affinity than does O_2,[6] to NaX irradiated in the presence of O_2 removes the signals due to O_3^-, O_2^-(I) and O_2^-(II), resulting in the spectrum shown in Fig. 5(a). The spectrum is composed of the O_2^-(III) signal and a new signal with principal g values of $g_{//}=2.008$ and $g_{\perp}=2.001$. This result was confirmed by the ESR spectra

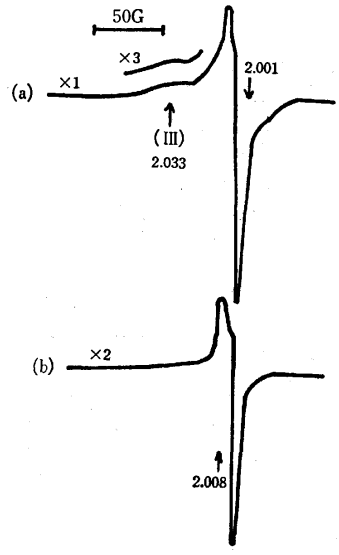

Fig. 5. ESR spectra obtained from NaX γ-irradiated in the presence of O_2 and exposed to SO_2, recorded at (a) 77 K and (b) room temperature.

obtained at room temperature, since the signal due to O_2^-(III) was broadened at this temperature and a new signal was clearly observed (Fig. 5(b)). This new signal can be attributed to SO_2^-, since the g components and the shape coincide well with those for the radical.[4,6,7] The formation of SO_2^- on NaX which was not γ-irradiated was negligibly small at room temperature. Therefore, the SO_2^- formation is considered to be caused by charge transfer from O_2^- to SO_2 (1), or electron capture from an F center (2), thus

$$O_2^- + SO_2 \longrightarrow SO_2^- + O_2 \quad (1)$$

or

$$SO_2 + e^- \longrightarrow SO_2^-. \quad (2)$$

It was found that the introduction of SO_2 into NaX irradiated under vacuum also produced an SO_2^- signal which had the same g components as that for NaX irradiated in the presence of O_2. This SO_2^- radical is formed by the capture of an electron from an F center and the amount of the radical formed is about 50% of that of the O_2^- produced on NaX upon γ-irradiation in the presence of O_2. This shows that the number of F centers produced on NaX by γ-irradiation in an O_2 atmosphere is small, since most of the electrons would be trapped by O_2 to form O_2^-. Moreover, reaction (1) appears to occur easily since the electron affinity of SO_2 is higher than that of O_2. From these points of view, it can be concluded that the transfer of an electron from O_2^- to SO_2 occurs predominantly on NaX γ-irradiated in the presence of O_2. The spin concentration of the SO_2^- produced on this NaX was found to be about 50% of that of the O_2^- which disappeared upon the introduction of SO_2. This indicates that the reaction of SO_2 with O_2^- leads partly to the formation of diamagnetic compounds.[6]

Sulfur Oxide and Sulfur Radicals on NaX. Upon heating NaX from 298 to 573 K after the introduction of SO_2, the intensity of ESR spectrum attributed to SO_2^- was found to increase. This spectrum is exactly the same as that obtained for γ-irradiated NaX. When the temperature was further raised to 673 K, the SO_2^- signal was attenuated and a new anisotropic signal appeared at low field (Fig. 6(a), $g\approx2.030$). This signal became distinct after heating to 773 K (Fig. 6(b)). It is evident that a polyatomic sulfur biradical is present on the surface from a comparison of this spectrum ($g_z=2.048$, $g_y=2.030$, $g_x=2.002$) with those obtained

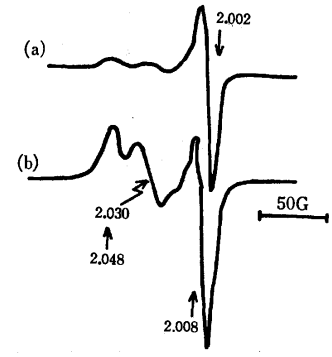

Fig. 6. ESR spectra obtained from NaX after heat treatment at 673 K (a) and 773 K (b) in the presence of SO_2.

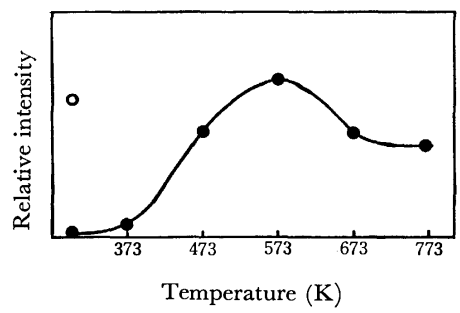

Fig. 7. Temperature dependence of SO_2^- formation on NaX (●). The radical formed on NaX γ-irradiated under vacuum at room temperature is also shown in the figure (○).

by the photolysis of solid COS,[25] sublimed sulfur[26] and sulfur-saturated zeolites 3A, 4A, and 5A.[27] The line corresponding to the smallest g value, $g=2.002$, overlaps with the spectrum of SO_2^-. Figure 7 shows the temperature dependence of the SO_2^- formation. The relative intensity for the radical produced on γ-irradiated NaX is also plotted in the figure.

It is known that both SO_2^- and O_2^- are formed on partially-reduced oxides soon after the introduction of SO_2 and O_2.[1-7] On the other hand, the amount of SO_2^- formed was small on NaX without heating in an SO_2 atmosphere and no O_2^- was formed without γ-irradiation. These results indicate that NaX is a rather weak electron donor compared with partially-reduced oxides. This fact can be attributed to the difference in the electron-donating centers on the respective surfaces: for the oxides, the center consists of low-valent metal cations, while $[AlO_{4/2}]^-$ is suggested as the center for the zeolites.[13]

When O_2 was introduced at room temperature onto NaX which was treated at 573 K in the presence of SO_2, the observed spectrum of SO_2^- after cooling to 77 K showed an appreciable change, as is shown in Fig. 8(a). In the spectrum recorded at room temperature (Fig. 8(b)), however, the SO_2^- signal with decreased intensity due to the reaction is distinguished from the new broadened signal at this temperature. The spectrum shown in Fig. 8(c) was obtained by subtracting this SO_2^- signal from the spectrum shown in Fig. 8(a). After evacuation at room temperature, the new signal almost disappeared and the intensity of the SO_2^- signal was restored.

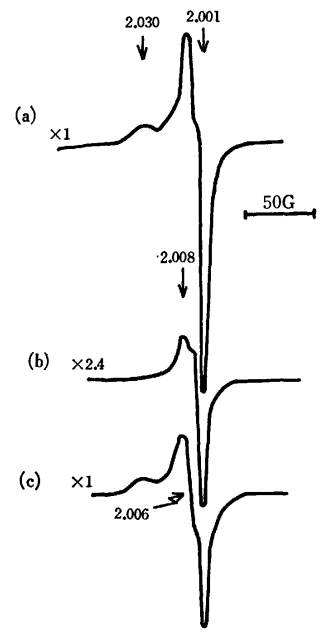

Fig. 8. ESR spectra after reaction of SO_2^- with O_2 recorded at (a) 77 K and (b) room temperature. (c) The spectrum obtained by subtracting the signal due to SO_2^- from (a).

The g_y value of the new signal was estimated to be 2.006, although the superposed SO_2^- signal decreased the accuracy of the measured value. Rao *et al.* have reported that SO_2^- adsorbed on vanadium oxide reacts with O_2 forming SO_4^-.[7] The g values of the radical obtained in the present work ($g_z=2.030$, $g_y=2.006$, $g_x=2.001$) are similar to those for SO_4^-.[7,28-30] Since the SO_2^- signal intensity was restored by evacuation, the new radical formed on NaX by the reaction of SO_2^- with O_2 appears to be a complex which has an SO_4^--like structure, although SO_2^- combines rather weakly with O_2, thus

$$SO_2^- \underset{-O_2}{\overset{+O_2}{\rightleftharpoons}} SO_4^- \ (SO_2^- \cdot O_2).$$

It is suggested that SO_2^- on decationated zeolites transfers electrons to O_2 to form O_2^-.[13] However, this formation of O_2^- appears to be difficult on NaX since no O_2^- is formed by only thermal treatment. Even with γ-irradiation, the O_2^- radicals obtained have different g tensors from this signal (Table 1). In addition, O_2 has a lower electron affinity compared with that of SO_2.[6,31,32] Thus, an electron transfer reaction, such as

$$O_2 + SO_2^- \longrightarrow O_2^- + SO_2,$$

is difficult to proceed, although the reverse reaction can easily occur.

On the other hand, when O_2 was introduced into this NaX sample, the decrease in the total SO_2^- spin reached about 65% and was accompanied by the appearance of an SO_4^--like signal. This means that the reaction of SO_2^- with O_2 also leads to the formation of diamagnetic compounds as in the case of the reaction of O_2^- with SO_2. However, when O_2 was introduced onto NaX which had been heated to 773 K in the presence of SO_2, the signals due to the existing SO_2^- and polysulfur radicals were scarcely affected. This result indicates that the state of SO_2^- is different from that of the radical formed on NaX heated below 573 K. SO_2^- may exist in the sodalite unit since the radical does not react with O_2, which is held in the supercage at room temperature,[15] while, below 573 K, SO_2^- is formed in the supercage. The SO_2 molecule must be able to penetrate into the sodalite unit at high temperature as well as does O_2.[15]

The presence of polysulfur radicals indicates that SO_2 on NaX decomposes above 673 K. As the intensity of the radical increases, the SO_2^- radicals decrease in number (Fig. 7) and exist only inside the sodalite unit.

The SO_2^- in the supercage may be converted to a polysulfur radical, while the SO_2^- in the sodalite unit may not change into this radical because the cavity is too small for polymeric formation.

Polarized Electronic Absorption Spectra and Assignment of Fluorene and Biphenyls

Tetsutaro YOSHINAGA, Hiroshi HIRATSUKA, and Yoshie TANIZAKI

Department of Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received September 22, 1977)

The divided electronic spectra polarized parallel to the long and short axes of molecules of biphenyl, THP (4,5,9,10-tetrahydropyrene), fluorene, and DHPH (9,10-dihydrophenanthrene) were determined by dichroism analysis using the stretched PVA film method. The experimental results are in good agreement with the ones calculated by the LCAO MO SCF CI method. Every compound has a very weak absorption ($f \approx 10^{-4}$) as the first band in the region of 32000—35000 cm^{-1}, which is electronically allowed and polarized parallel to the short axis. The intense band (34000—44000 cm^{-1}) of biphenyl consists of a relatively strong (39100 cm^{-1}) band and a weak (40500 cm^{-1}) band: the former is polarized parallel to the long axis and the latter to the short. Both fluorene and DHPH show five well corresponding electronic bands in the region below 45000 cm^{-1}.

The assignment of the electronic spectrum of fluorene has been studied[1-5] from the viewpoint of a biphenyl derivative. For fluorene itself, there have been few studies done in terms of the three fundamental factors: the transition energy, the polarization direction, and the oscillator strength. The agreement between the calculated and experimental results seems especially unsatisfactory for the very weak first band. On the other hand, there are a great many studies for the biphenyl spectrum, both theoretical and experimental.[6-11] These studies may be grouped into two types: the comformation and the assignment. From the conformational study, the dihedral angle of the biphenyl has been determined in crystal state (0°), in solution (20—30°) and in vapor (≈45°). As for the assignment of the biphenyl spectrum, however, no detailed experimental study in terms of the above three factors has yet been made.

In the present study, we determined the polarized absorption spectra of biphenyl, fluorene, 9,10-dihydrophenanthrene, and 4,5,9,10-tetrahydropyrene[12] in the stretched PVA [poly(vinyl alcohol)] film, and divided the spectra into two components, which are polarized along the long and short axes of the molecule, by means of the dichroism analysis.[13] And then, comparing the component spectra with the calculated results, we assigned the spectra of fluorene and the biphenyl with respect to the three fundamental factors stated above.

Experimental

Material. Commercially available biphenyl (E.P.: extra pure reagent, >99% G.C.), fluorene (U.P.: ultra pure reagent, zone refined), 9,10-dihydrophenanthrene (G.R.: guaranteed reagent; abbrev. DHPH), and 4,5,9,10-tetrahydropyrene (G. R.: abbrev. THP) were obtained from Tokyo Kasei Kogyo Co., Ltd. Biphenyl was purified by repeated recrystallization from water containing ethanol. THP was furthermore refined using a special treatment at Tokyo Kasei Kogyo Co., Ltd., at our request. PVA powder, which was used for the preparation of film, was obtained commercially (Koso Chemical Co., Ltd.) and was used without further purification.

Polarized Spectra. The polarized absorption spectra of samples in the stretched PVA films were measured with a Shimadzu QV-50 Spectrophotometer equipped with a calcite polarizer of the Glan-Thompson type and a rotation apparatus for the polarizer.

The method of dichroism analysis using the stretched PVA film has already been reported.[13] The notations cited here are as follows: R_S is the stretch ratio of the PVA film, $D_{\parallel}$ and $D_{\perp}$ are the optical densities of the sample in a stretched film for the incident light polarized parallel and perpendicular to the stretching direction, respectively, and R_d is the dichroic ratio and is defined as $D_{\parallel}/D_{\perp}$. The orientation angle θ, which was computed theoretically using the R_S and R_d values, is indicated along the R_d curve in the figure. It means the angle of the transition moment with respect to an orientation direction associated with the molecular axis.

We divided the absorption spectrum observed in the non-streched PVA film into the component spectra along the long and short axes of the molecule, according to the method already described.[13] In the present case, we chose the angle for the greatest R_d value as the orientation angle of the long axis transition, since the sum of the apparent orientation angles for the maximum and minimum R_d values is smaller than a right angle. [The reason for such a selection has been described in detail in Refs. 12 and 13.]

The experimental oscillator strength f^{exp} was determined from the divided spectra by the following formula:

$$f^{exp} = 4.32 \times 10^{-9} \int \varepsilon_\sigma d\sigma,$$

where ε_σ is the molar extinction coefficient at wave number σ and the ε_σ value in ethanol was used instead of that in PVA, since it was confirmed experimentally that the ε_σ value in PVA is nearly equal to that in ethanol.

Calculation

In the MO calculation, the LCAO ASMO SCF CI method (PPP approximation[14,15]) was employed. The one- and two-center electron repulsion integrals were evaluated by the Pariser-Parr[14] and Nishimoto-Mataga equations.[16] Substituent effects of methylene groups were taken into consideration as the conjugative effect.[17] All the molecules were assumed to be planar and the geometry of THP is shown in Fig. 1(a) as the representative of the biphenyl. The C–C bond lengths in benzene rings were taken as 1.395 Å and the bond angles $\angle CCC = 120°$. Other bond lengths were taken as $(C_4\text{–}C_5) = (C_9\text{–}C_{10}) = 1.480$ and $(C{=}H_2) = 0.900$ Å. The resonance integrals were taken as $\beta(C_9\text{–}C_{10}) = \beta(C_{10}\text{–}C_{11}) = -2.00$, $\beta(C{=}H_2) = -5.30$, and $\beta(C{=}C) = -2.236$ eV. The geometry of fluorene shown in Fig. 1(b) was assumed as follows with reference to the crystal structure.[2] The C–C bond lengths in the six-

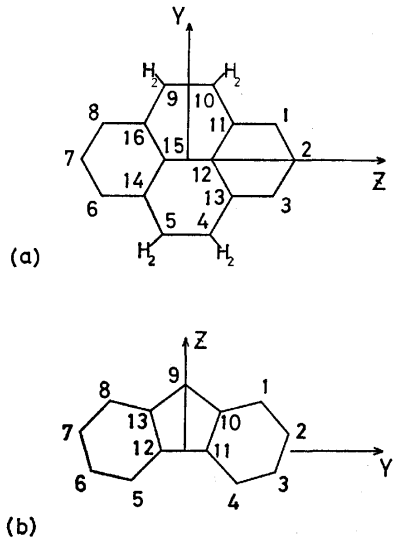

Fig. 1. Geometries of the THP (4,5,9,10-tetrahydropyrene) and fluorene molecules.

membered rings were taken as 1.400 Å and the bond angles $\angle CCC=120°$, and for the five-membered ring: $(C_{10}-C_{11})=(C_{12}-C_{13})=1.400$, $(C_{11}-C_{12})=1.480$, $(C_9-C_{10})=(C_9-C_{13})=1.460$ Å, and $\angle C_{10}C_{11}C_{12}=\angle C_{11}C_{12}C_{13}=108°$.

Results and Discussion

Dichroic Spectra and Divided Spectra. Figure 2 shows the dichroic spectra of biphenyl, fluorene, DHPH, and THP in the stretched PVA film. The spectra of these compounds are quite similar to one another, except that both the fluorene and DHPH spectra have additional bands at about 300 nm which are missing in those of biphenyl and THP.

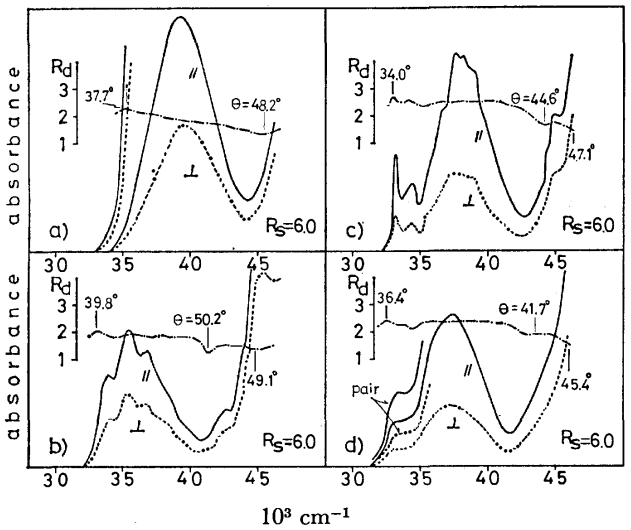

Fig. 2. Dichroic spectra and R_d curves for (a) biphenyl, (b) THP (4,5,9,10-tetrahydropyrene), (c) fluorene, and (d) DHPH (9,10-dihydrophenanthrene) in the stretched PVA films. The solid and broken lines indicate the absorbances ($D_{\parallel}$ and $D_{\perp}$) for the incident light polarized parallel and perpendicular to the stretching direction, respectively. R_d(chain line) is the dichroic ratio defined by $D_{\parallel}/D_{\perp}$.

The R_d curve of each compound has the maximum around the long wavelength side of the first absorption band and it clearly decreases toward longer wavelengths. The decrease of the R_d curve was confirmed by the dichroic spectra of the more concentrated sample films. This indicates that a weak band polarized parallel to the short axis is hidden in the longest wavelength region of the strong band polarized parallel to the long axis.

In order to reveal the two component spectra polarized parallel to the long and short axes of the molecule, we divided the spectra of the samples in the non-stretched PVA films. The divided spectra are shown in Fig. 3. The spectrum of THP shown in Fig. 3(b), which have already been reported,[12] are reproduced for the comparison with those of other samples, especially with that of biphenyl.

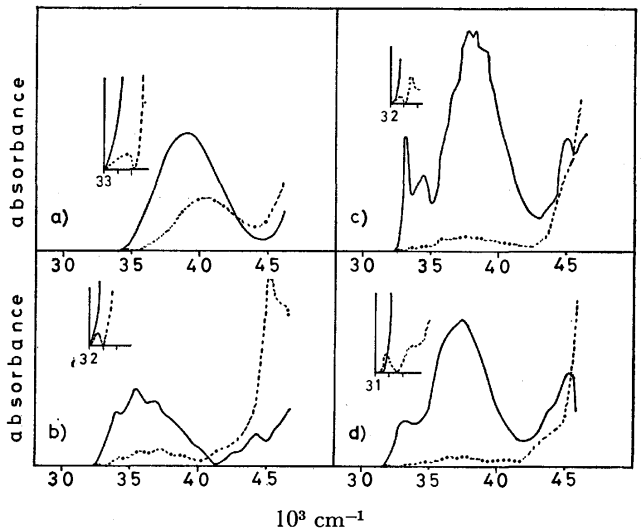

Fig. 3. Divided (component) spectra of (a) biphenyl, (b) THP (4,5,9,10-tetrahydropyrene), (c) fluorene, and (d) DHPH (9,10-dihydrophenanthrene) in the non-stretched PVA films. The solid and broken lines are long and short axis component spectra, respectively.

Figure 3(a) shows the component spectra of biphenyl. In the main absorption region of 34000—44000 cm^{-1}, there are two bands at 39100 and 40500 cm^{-1}: the former is polarized parallel to the long axis and the latter to the short. A very weak band polarized parallel to the short axis appears at 34600 cm^{-1}. In the region higher than 42000 cm^{-1}, two relatively strong bands exist, which are polarized perpendicularly to each other.

That the first absorption band (34000—44000 cm^{-1}) of biphenyl is composed of three electronic transitions has been inferred by Berlman from the investigation of the luminescence of biphenyl and its analogs.[10] These three transitions may correspond to the 34600, 39100, and 40500 cm^{-1} bands of the present work. As for the position of the very weak band (34600 cm^{-1}) of biphenyl, there are many experimental data[7] and most of them fall in the range 33000—34000 cm^{-1}.

Figures 3(c) and (d) show the component spectra of

fluorene and DHPH, respectively. These are quite similar to each other except that the vibrational structure is revealed in the fluorene spectra. Both of the component spectra also show a very weak band at about 32000 cm^{-1}, which corresponds to those of biphenyl (34600 cm^{-1}) and THP (32800 cm^{-1}).

Popov *et al.*[5] determined the dichroic spectra of fluorene in the poly(vinyl butyral) film. The dichroism clearly shows an abrupt dropping toward the corresponding wavelength region of the weak band. This dropping suggests the existence of a hidden band of a short axis polarized transition, though they did not point it out.

Both of the component spectra of fluorene and DHPH have a band of long axis polarization in the region of 32000—35000 cm^{-1}. Since this band is missing in the biphenyl and THP spectra, it is considered as an additional characteristic band for fluorene and DHPH. The appearance of this band may have some relations with the partial loss of symmetry (D_{2h}—C_{2v}).[4]

Comparison of Experimental and Calculated Results. The experimental and calculated results are compared in Tables 1—4 for biphenyl, THP, fluorene, and DHPH, respectively. The first absorption bands of all the sample molecules are extraordinarily weak and have the polarization parallel to the short axis. The experimental oscillator strengths are the order of 10^{-4} and correspond well to the calculated ones. As for the intensity of this band of biphenyl, for instance, usually zero values of the oscillator strengths have been computed, except in the calculation by Momicchioli *et al.*[3] This could be attributed to a disregard of the off-diagonal terms of the transition density matrix.[18]

As is seen from Fig. 3, only biphenyl shows very smooth component spectra, while the other samples have fine structure or a shoulder. Therefore, we could estimate experimentally, all the 0-0 transition energies except for that of biphenyl. As is shown in Tables 2—4, the experimental energies agree well with the calculated ones for the allowed transitions lower than 45000 cm^{-1} of THP, fluorene, and DHPH. For the case of biphenyl (Table 1), however, the experimental energy (39100 cm^{-1}) of the main band (the second), for example, was considerably higher than the calculated one (36400 cm^{-1}, the third transition), because we had to take the energy at the band maximum as the experimental one.

We have already pointed out that the main intense band 34000—44000 cm^{-1}) of biphenyl (Fig. 3(a)) consists of two subbands. One (39100 cm^{-1}) of these, which is polarized parallel to the long axis, could be assigned as the third transition (36400 cm^{-1}) of the calculated results. But the other band, which is polarized to the short axis and has the maximum at 40500 cm^{-1}, cannot be assigned to any allowed transition calculated (Table 1). The calculated results shown in Table 1, however, have been obtained by assuming that biphenyl

belongs to the point group D_{2h}. But, in order to explain the extra band at 40500 cm^{-1}, it is necessary to consider that the real biphenyl molecule in the PVA substrate has some non-zero dihedral angle, *i.e.*, it belongs to the point group D_2. Thus the $B_{3g}\leftarrow A_g$ transition in Table 1 should be altered to $B_3\leftarrow A$ transition which becomes an allowed transition. Moreover, strictly speaking, the statement "the polarization in the short axis direction" should be changed to "the polarization direction perpendicular to the long axis of molecule," because in dichroism analysis we cannot distinguish the difference in the two directions of the out of plane transition and the in-plane short axis transition. For that reason, the extra band (40500 cm^{-1}) of biphenyl can be explained as an allowed transition.

The other samples also show the respective extra bands in the region 33000—42000 cm^{-1}. However, the intensities are much weaker than the extra band of biphenyl. This may be attributed to some electronically forbidden transition or to intensity borrowing.

The Reflection Spectra of the Crystalline Electron Donor-Acceptor Complexes of TCNQ

Masashi TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received September 27, 1977)

The polarized reflection spectra were measured on the crystals of TCNQ complexes with phenothiazine, anthracene, pyrene, acenaphthene, carbazole, hexamethylbenzene, and 1,10-phenanthroline. The crystalline absorption spectra were obtained by the K-K transformation of the reflection spectra. The charge-transfer degree and the stabilization energy in the ground state were estimated for each complex by analysing the charge-transfer bands in the solid state. The charge-transfer degree of the TCNQ–phenothiazine complex is 19.6%, while those of the TCNQ–carbazole, anthracene, and hexamethylbenzene complexes are 12.0, 10.5, and 8.0% respectively. Furthermore, those values for TCNQ–1,10-phenanthroline, acenaphthene, and pyrene are about 5%. The relationship between the charge-transfer excitation energy and the ionization potential of a series of the donor molecules is also discussed.

7,7,8,8-Tetracyanoquinodimethane (TCNQ) is a strong electron-acceptor and forms molecular complexes with various electron donors. Investigation has been carried out extensively to elucidate the nature of the intermolecular interaction in these molecular complexes. The appearance of the charge-transfer (CT) band, absent from the constituent free molecules, is characteristic of these complexes; the correlation of the electronic states of the complexes with the absolute absorption intensity of the CT band was discussed by Tanaka.[1] That is, the charge-transfer degree in the ground state can be obtained by measuring the absorption intensity of the CT band; it can thus be found to what extent the charge-transfer structures contribute to the stabilization of the electron donor-acceptor complex in the ground state.

In this paper, the author will present the crystal reflection spectra of TCNQ complexes with phenothiazine, anthracene, pyrene, acenaphthene, carbazole, hexamethylbenzene, and 1,10-phenanthroline. These reflection spectra will then be transformed into the absorption spectra by the Kramers-Kronig (K-K) method. The transformed absorption spectra will enable us to discuss the charge-transfer degrees of a series of complexes with a common acceptor (TCNQ) and the stabilization energies in the ground state.

Experimental

Single crystals of TCNQ complexes were crystallized after hot euimolar solutions of the components had been mixed and allowed to cool very slowly.

The reflection spectra at the normal incidence have been measured over the range of 5000—40000 cm^{-1} by means of a reflection spectrophotometer made in our laboratory, while the absorption spectra have been obtained by the K-K transformation. The oscillator strength along the α axis of the crystal may be evaluated by using the following equation,

$$f^{\alpha} = 4.32\times10^{-9}\int n_{\alpha}(\sigma)\varepsilon_{\alpha}(\sigma)\mathrm{d}\sigma,$$

where the integration is effected over the whole band, where σ is the wavenumber, and where n_{α} and ε_{α} are the α components of the refractive index and the molar absorption coefficient.

Theoretical

The analysis of the electronic states of the CT complexes was discussed by Tanaka[1] and so will be only briefly summarized here.

TCNQ complexes form a configuration of the ADA type in the crystal. Then, the ground state can be described by a wavefunction,

$$\Psi_0 \simeq \Phi(\mathrm{ADA}) + \sum_i b_i\{\Phi_i(\mathrm{AD^+A^-}) + \Phi_i(\mathrm{A^-D^+A})\}/\sqrt{2},$$

where $\Phi(\mathrm{ADA})$ represents a non-bonding, and $\Phi_i(\mathrm{AD^+A^-})$ and $\Phi_i(\mathrm{A^-D^+A})$, the i-th CT configurations. The charge-transfer degree and the stabilization energy in the ground state are given as $\sum_i b_i^2$ and $\Delta E=\sum_i b_i^2 E_{\mathrm{CT}}^i$. The wavefunction $\Psi_{\mathrm{CT}}^i(-)$ for the optically allowed i-th excited state is given by

$$\Psi_{\mathrm{CT}}^i(-) \simeq \{\Phi_i(\mathrm{AD^+A^-}) - \Phi_i(\mathrm{A^-D^+A})\}/\sqrt{2},$$

and the oscillator strength is defined as follows:

$$f_i = 3\times1.085\times10^{11}E_{\mathrm{CT}}^i b_i^2|\boldsymbol{R}_{\mathrm{AD}}|^2,$$

where $\boldsymbol{R}_{\mathrm{AD}}$ is the vector between the acceptor and donor molecules in units of cm and E_{CT}^i is the excitation energy in cm^{-1}. Accordingly, by comparing the experimental and theoretical oscillator strengths, we can obtain the magnitude values of b_i^2 and also information about the electronic states of the CT complexes.

The b_i coefficient can be correlated to the so-called transfer integral, $t_{\mathrm{A}k,\mathrm{D}l}$, as follows:

$$\begin{aligned} b_i &= \sqrt{2}(\Phi(\mathrm{ADA})|H|\Phi_i(\mathrm{AD^+A^-}))/E_{\mathrm{CT}}^i, \\ &= 2(\phi_{\mathrm{A}}^k|F|\phi_{\mathrm{D}}^l)/E_{\mathrm{CT}}^i, \\ &\equiv 2t_{\mathrm{A}k,\mathrm{D}l}/E_{\mathrm{CT}}^i, \end{aligned}$$

where $\phi_{\mathrm{A}}{}^k$ is the k-th molecular unoccupied orbital of the acceptor, and $\phi_{\mathrm{D}}{}^l$, the l-th molecular occupied orbital of the donor. The transfer integral, $t_{\mathrm{A}k,\mathrm{D}l}$, may be approximated by the use of the overlap integral, $S_{\mathrm{A}k,\mathrm{D}l}$

$$t_{\mathrm{A}k,\mathrm{D}l} = -KS_{\mathrm{A}k,\mathrm{D}l} = -K(\phi_{\mathrm{A}}^k|\phi_{\mathrm{D}}^l).$$

Here, K is the constant taken as 15.0 eV and the overlap integral can be estimated by a method shown before.[2] Therefore, the comparison between the observed and calculated values of b_i^2 makes it possible to assign the character of the CT band. The molecular orbital is represented by taking the long axis of the molecule

as the y axis and the short axis as the z axis, except in the case of the hexamethylbenzene molecule. In hexamethylbenzene, the z axis is taken as the normal to the molecular plane.

All of the above-mentioned computations were carried out on a FACOM 230-75 computer at the Nagoya University Computation Center.

Results

TCNQ-Phenothiazine Complex. The complex of TCNQ-phenothiazine crystallizes in the form of needles elongated along the a axis, and the space group is C2/c.[3] TCNQ and phenothiazine molecules are stacked alternately in infinite columns parallel to the a axis. The interplanar distance is 3.44 A, and the distance between centers parallel to the a axis, R_{AD}, is 3.52 A. The mode of overlapping is shown in Fig. 1. The

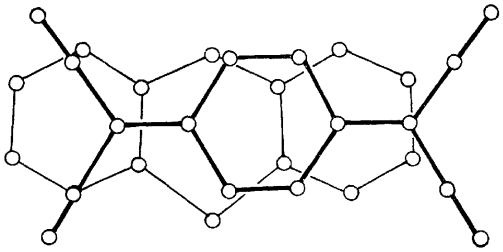

Fig. 1. The molecular overlap of the TCNQ–phenothiazine complex.

reflection spectra are observed for the polarizations parallel and perpendicular to the a axis on the (010) face, and the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Figs. 2 and 3.

The a-axis reflection spectrum shows three separate bands. The first band peak occurs at 6200 cm^{-1}, with a reflectivity of 31.6%, while the second peak occurs at 17800 cm^{-1}, with 6.6% reflectivity. The third band, in the region of 29000 cm^{-1}, has a reflectivity of 6.9%. The $a_\perp$ spectrum for (010) shows no clear structure in the region of the first a axis band at 6200 cm^{-1}. The

intense band at 18500 cm^{-1} has a reflectivity of 31.5%, and the 28400 cm^{-1} band has a 17.4% reflectivity.

In the absorption spectra, the 6200 cm^{-1} band is exclusively polarized along the a axis and can be

assigned to the CT transition from the highest occupied orbital ($\phi_D^8(b_1)$) of the phenothiazine molecule to the lowest unoccupied orbital ($\phi_A^9(b_{1g})$) of the TCNQ molecule. The oscillator strength of this band is 0.549, and the observed charge-transfer degree (19.2%) is in good agreement with the calculated value of 17.0%, as is shown in Table 1. The 18500 and 29000 cm^{-1} bands are strongly polarized along the $a_\perp$ axis. The inclination of the long axis of the molecule with respect to the stacking a axis is 75° on the (010) face, and the long-axis transitions of the TCNQ and phenothiazine molecules should be more intensely observed in the $a_\perp$ axis spectrum. Therefore, the 18500 cm^{-1} band may be regarded as due to the long-axis transition (LE_1) of the TCNQ molecule,[4] and the 29000 cm^{-1} band, as due to the long-axis transition of the phenothiazine molecule. The LE_1 band of TCNQ is 6400 cm^{-1} red-shifted from the peak occurring at 24900 cm^{-1} in the chloroform-solution spectrum. This large shift seems to be due to the large charge-transfer degree (*ca.* 19%) in the ground state of the crystal of the TCNQ-phenothiazine complex. The 29000 cm^{-1} band corresponds to the 31300 cm^{-1} band of the phenothiazine molecule in the ehtanol solution.

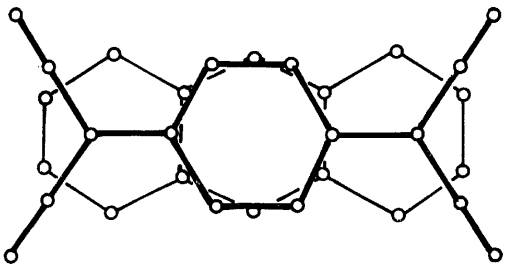

Fig. 4. The molecular overlap of the TCNQ–anthracene complex.

TCNQ–Anthracene Complex. The complex of TCNQ–anthracene forms a monoclinic crystal with a space group of C2/m,[5] and the structure consists of infinite columns of alternate TCNQ and anthracene molecules stacked in columns parallel to the c axis of the unit cell, with the mean molecular planes perpendicular to this axis. The mode of molecular overlap is such that the long axes of each molecule are parallel and their centers are superimposed, as is shown in Fig. 4. Therefore, the interplanar distance takes the same value (3.50A) as the intermolecular distance, R_{AD}. The reflection spectra are observed for the polarizations parallel and perpendicular to the c axis on the (010) face, and the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Figs. 5 and 6. These spectra coincide with the spectra measured by Eckhardt and Pennelly.[6]

The c-axis reflection spectrum shows two bands. The first band, at 11800 cm^{-1}, has a reflectivity of 7.3%, while the second band occurs at 20800 cm^{-1}, with a 5.3% reflectivity. The $c_\perp$ spectrum for (010) consists of one intense peak at 23200 cm^{-1} and one shoulder at 35300 cm^{-1}. The 23200 cm^{-1} band has a reflectivity of 35.6%.

In the absorption spectra, as there is no mixing between the CT band and the locally excited $\pi \rightarrow \pi^*$

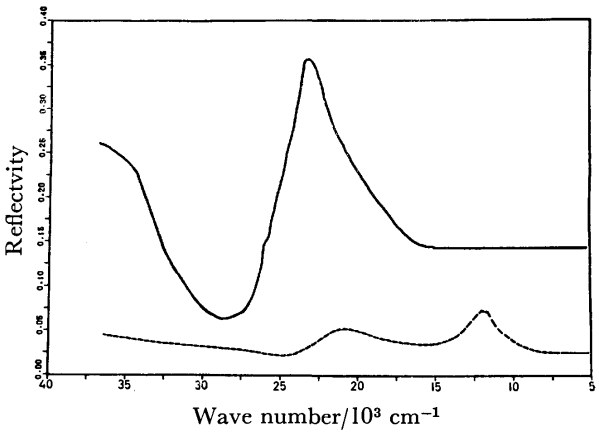

Fig. 5. The c(dashed line) and $c_\perp$(solid line) axes reflection spectra obtained on the (010) face of the crystal of TCNQ–anthracene complex.

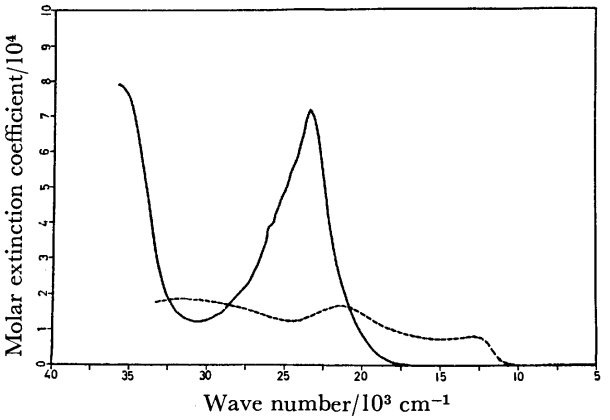

Fig. 6. The c(dashed line) and $c_\perp$(solid line) axes absorption spectra obtained by the K-K transformation of the reflection spectra of the crystal of TCNQ–anthracene complex.

bands of each molecule in the complex with a D_{2h} symmetry, the c-axis polarized band can be assigned to the charge-transfer band. Therefore, the two CT bands are observed at 12800 and 21400 cm^{-1}; it should be noted that the second CT band, at 21400 cm^{-1}, becomes more intense than the first CT band, at 12800 cm^{-1}. The oscillator strengths of these CT bands are 0.189 and 0.583, and the contributions (b_i^2) to the charge-transfer degree in the ground state are 3.7 and 6.8% respectively. According to the molecular overlap shown in Fig. 4 and the overlap integrals given in Table 1, the transition from the highest occupied anthracene orbital ($\phi_D^7(b_{2g})$) to the lowest unoccupied TCNQ orbital ($\phi_A^9(b_{1g})$) is forbidden, but the CT transition can be allowed from the third occupied anthracene orbital ($\phi_D^5(b_{1g})$) to the lowest unoccupied TCNQ orbital ($\phi_A^9(b_{1g})$). Accordingly, the weak CT band at 12800 cm^{-1} may be assigned to the $\phi_D^7(b_{2g}) \rightarrow \phi_A^9(b_{1g}$ transition, and the intense CT band at 21400 cm^{-1}, to the $\phi_D^5(b_{1g}) \rightarrow \phi_A^9(b_{1g})$ transition. The calculated charge-transfer degree supports these assignments strongly, as is shown in Table 1. The $c_\perp$ absorption spectrum has two intense bands. The first band, at 23400 cm^{-1}

corresponds to the LE_1 band of the TCNQ molecule and the second band, in the region of 35000 cm^{-1}, to the β band of the anthracene molecule, which is polarized along the long axis of the anthracene molecule.[7]

TCNQ-Pyrene Complex. The crystal of the TCNQ-pyrene complex was obtained as very dark green needles by the slow evaporation of a tetrahydrofuran solution; the space group is $P2_1/b$.[8] The crystal structure is built up from isolated TCNQ and pyrene molecules alternating in plane-to-plane stacks, and the stacking axis is the crystalline a axis (the needle axis).

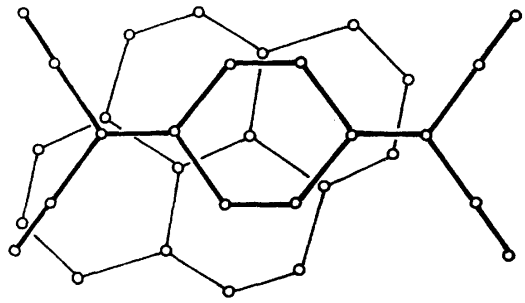

Fig. 7. The molecular overlap of the TCNQ-pyrene complex.

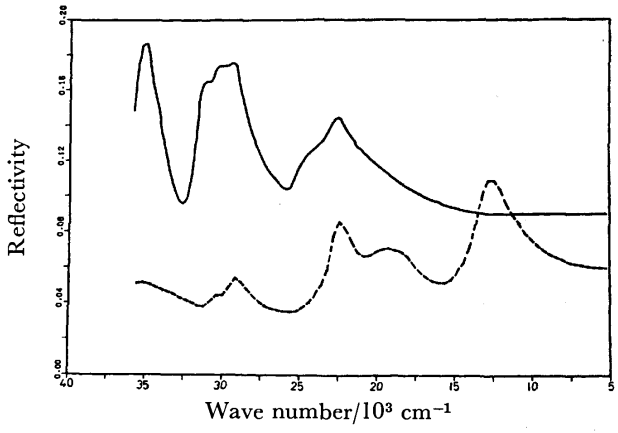

Fig. 8. The a(dashed line) and $a_\perp$(solid line) axes reflection spectra obtained on the (011) face of the crystal of TCNQ-pyrene complex.

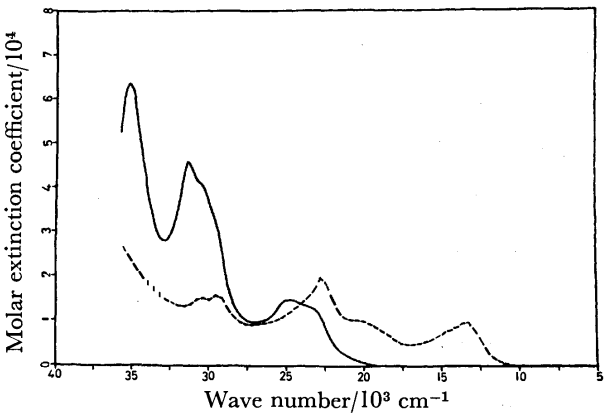

Fig. 9. The a(dashed line) and $a_\perp$(solid line) axes absorption spectra obtained by the K-K transformation of the reflection spectra of the crystal of TCNQ-pyrene complex.

The mean perpendicular separation between the planes of adjacent donor and acceptor components is 3.50 A, and the intermolecular distance along the stacking axis, R_{AD}, is 3.57 A. The molecular overlap, as viewed in the direction perpendicular to the mean molecular planes, is shown in Fig. 7. The reflection spectra are observed for the polarizations parallel and perpendicular to the a axis on the (011) face, and the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Figs. 8 and 9.

The a axis reflection spectrum has five bands at 12600, 19300, 22400, 29200, and 35200 cm^{-1}. The reflectivity of the first band at 12600 cm^{-1} is 10.9%, while the broad second band at 19300 cm^{-1} has its reflectivity of 7.1%. The third band occurs at 22400 cm^{-1}, with an 8.6% reflectivity; the higher energy bands have lower reflectivities. The $a_\perp$-axis reflection spectrum shows no clear structure in the region of the first two bands in the a-axis spectrum. The first peak appears at 22400 cm^{-1}, with a reflectivity of 14.4%, while the 29400 and 35000 cm^{-1} bands have reflectivities of 17.5 and 18.7% respectively.

In the absorption spectra, the two bands at 13200 and 19500 cm^{-1} are active for the light polarized parallel to the a axis and may reasonably be assigned to the CT bands. The oscillator strengths of these two bands are 0.212 and 0.091, and the contributions (b_i^2) to the charge-transfer degree in the ground state are 3.9 and 1.1% respectively. Judging from the overlap integrals shown in Table 1, the first CT band seems to be due to the transition from the highest occupied pyrene orbital ($\phi_D^8(b_{2g})$) to the lowest unoccupied TCNQ orbital ($\phi_A^9(b_{1g})$), while the second CT band consists of nearly degenerate transitions from the third and fourth highest occupied pyrene orbital ($\phi_D^6(b_{3u})$ and $\phi_D^5(a_u)$). The third band, in the region of 24000 cm^{-1}, has the same magnitude as the absorption intensities in the a- and $a_\perp$-axes spectra. The (011) projection shows that the long axis of the TCNQ molecule is at an angle of 55° to the a axis, and the absorption intensities of the LE_1 band must be comparable for the a- and $a_\perp$-axes spectra. Therefore, the 24000 cm^{-1} band may be assigned to the LE_1 band of the TCNQ molecule. On the other hand, the long axis of the pyrene molecule is at an angle of 78° to the a axis, and the higher energy bands at 31400 and 35200 cm^{-1} should have stronger absorption intensities in the $a_\perp$-axis spectrum than in the a-axis spectrum. Therefore, the 31400 and 35200 cm^{-1} bands

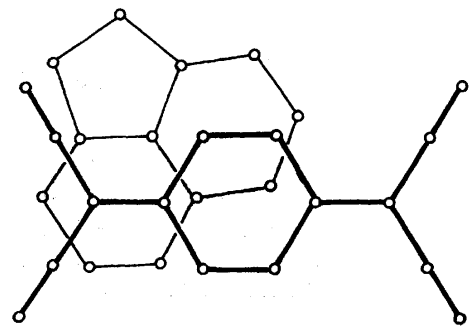

Fig. 10. The molecular overlap of the TCNQ-acenaphthene complex.

may be attributed to the long-axis transitions (p and β bands of the pyrene molecule[9] respectively).

TCNQ-Acenaphthene Complex. The complex of TCNQ-acenaphthene forms a triclinic crystal of a space group of $P\bar{1}$,[10] and TCNQ and acenaphthene are stacked alternately in infinite columns parallel to the a-axis. The intermolecular distance along the stacking axis, R_{AD}, is 3.37 A, and the molecular overlap is as is depicted in Fig. 10. The reflection spectra are observed for the polarizations parallel and perpendicular to the a-axis on the (011) face, and the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Figs. 11 and 12.

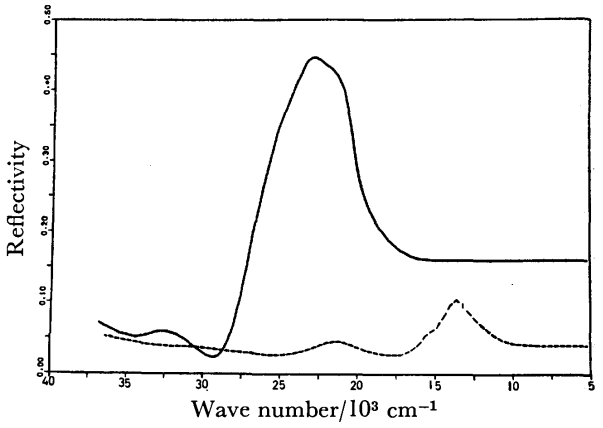

Fig. 11. The a(dashed line) and $a_\perp$(solid line) axes reflection spectra obtained on the (011) face of the crystal of TCNQ-acenaphthene complex.

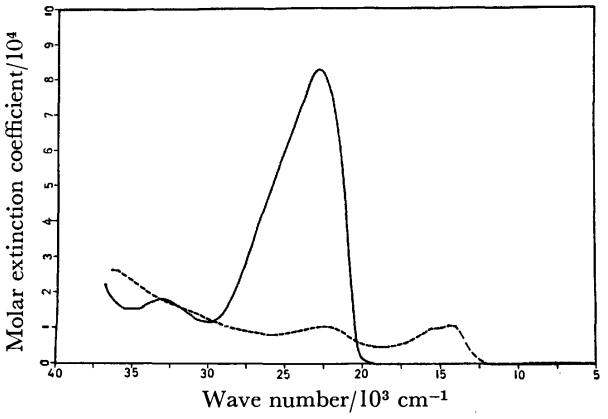

Fig. 12. The a(dashed line) and $a_\perp$(solid line) axes absorption spectra obtained by the K-K transformation of the reflection spectra of the crystal of TCNQ-acenaphthene complex.

The a-axis reflection spectrum shows two separate bands. The first band peak occurs at 13600 cm^{-1}, with a reflectivity of 10.4%, and the second band appears at 21200 cm^{-1}, with a 4.6% reflectivity. The $a_\perp$-axis reflection spectrum shows no clear structure in the first a-axis band. The intense band occurs at 23000 cm^{-1}, with a reflectivity of 44.6%, and the weak band, at 32600 cm^{-1}, with a 6.0% reflectivity.

In the absorption spectra, the first band at 14300 cm^{-1} is active for the light parallel to the a axis and may be due to the CT transition from the highest occupied acenaphthene orbital ($\phi_D{}^5(a_2)$) to the lowest unoccupied TCNQ orbital ($\phi_A{}^9(b_{1g})$). The oscillator strength of the band is 0.271, and the charge-transfer degree in the ground state is 5.1%, as is shown in Table 1. The second band, at 22800 cm^{-1}, is more strongly polarized along the $a_\perp$-axis direction than alone the a axis. The inclination of the long axis of the molecule with respect to the stacking a axis is 85°, and the long-axis transitions of the TCNQ and acenaphthene molecules should be more intensely observed in the $a_\perp$-axis spectrum than in the a-axis. Therefore, the second band may be regarded as the LE_1 band of the TCNQ molecule. The third weak band, in the region of 33000 cm^{-1}, can be assigned to the α band of the acenaphthene molecule.[11]

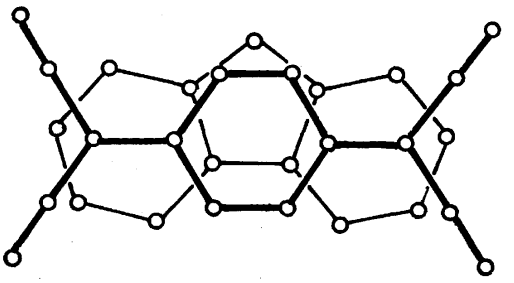

Fig. 13. The molecular overlap of the TCNQ-carbazole complex.

TCNQ-Carbazole Complex. The crystals of the TCNQ-carbazole complex are orthorhombic, and the space group is Immm.[12] The structure consists of infinite columns of alternate TCNQ and carbazole molecules, and the column is parallel to the c-axis. The molecular planes are perpendicular to the c-axis, and the long axes of each molecule are parallel to the a-axis. The molecular overlap is shown in Fig. 13. The intermolecular distance, R_{AD}, is the same as the mean perpendicular separation (3.34 A) between the molecular planes. The reflection spectra are observed for the polarizations parallel and perpendicular to the c-axis on the (010) face, and the absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Figs. 14 and 15.

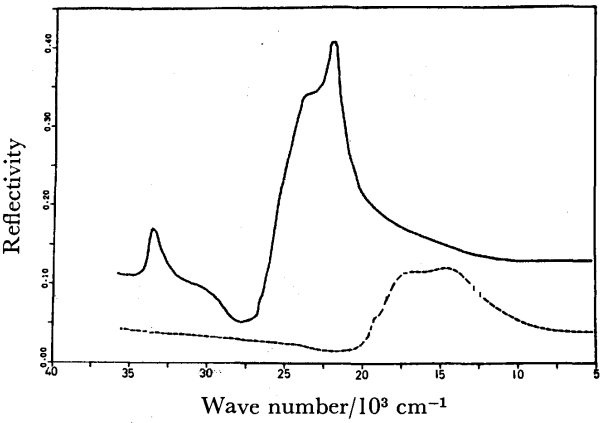

Fig. 14. The c(dashed line) and a(solid line) axes reflection spectra obtained on the (010) face of the crystal of TCNQ-carbazole complex.

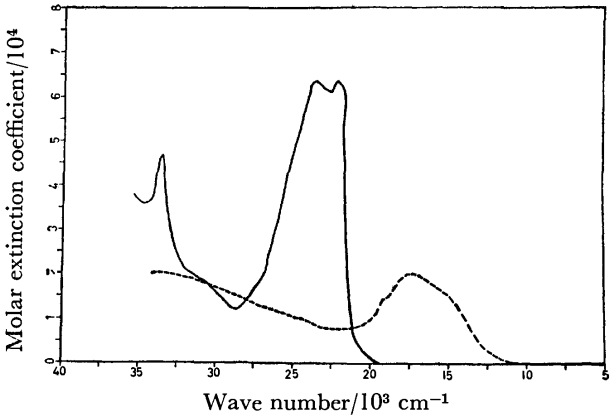

Fig. 15. The c(dashed line) and a(solid line) axes absorption spectra obtained by the K-K transformation of the reflection spectra of the crystal of TCNQ-carbazole complex.

The c-axis reflection spectrum has a band with a 12.0% reflectivity which splits into doublets at 14600 and 16600 cm^{-1}. The a-axis reflection spectrum consists of two bands. The intense band occurs at 21800 cm^{-1}, with a reflectivity of 40.6%, while the sharp band occurs at 33600 cm^{-1}, with a 17.0% reflectivity.

In the absorption spectra, the first band at 14600 cm^{-1} is active for the light parallel to the c-axis and can be assigned to the CT transition from the highest occupied carbazole orbital ($\phi_D^7(a_2)$) to the lowest unoccupied TCNQ orbital ($\phi_A^9(b_{1g})$). The oscillator strength of the CT band is 0.637, and the charge-transfer degree in the ground state is 12.0%. The second and third bands, at 22200 and 33600 cm^{-1}, are polarized along the a-axis, which is parallel to the long-axis of each molecule. Therefore, the 22200 cm^{-1} band can be regarded as the LE_1 band of TCNQ, and the 33600 cm^{-1} band as corresponding to the 34100 cm^{-1} band (α^* band) of the carbazole molecule in an ethanol solution.[13]

TCNQ-Hexamethylbenzene Complex. The crystals of the complex of TCNQ-hexamethylbenzene are monoclinic, and the space group is I2/m.[14] The structure consists of infinite columns of alternate molecules, and the column is parallel to the *a*-axis. The mean molecular separation is 3.55 A, and the intermolecular distance parallel to the a axis, R_{AD}, is 4.28 Å. The molecular overlap is illustrated in Fig. 16. The reflection spectra are obtained for the polarizations

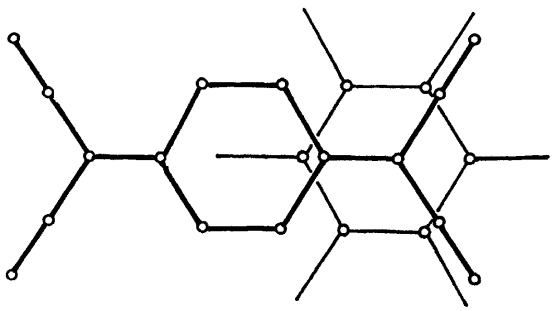

Fig. 16. The molecular overlap of the TCNQ-hexamethylbenzene complex.

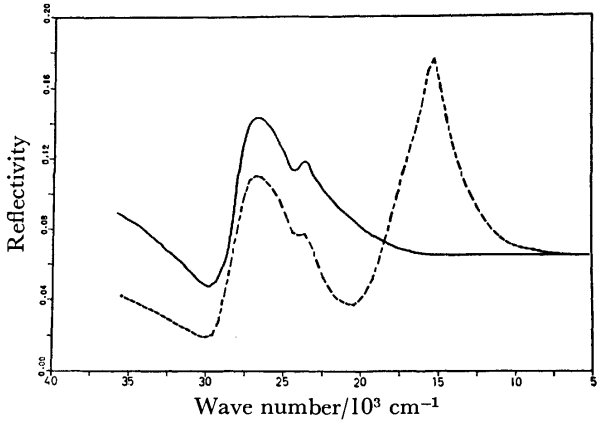

Fig. 17. The a(dashed line) and $a_\perp$(solid line) axes reflection spectra obtained on the (010) face of the crystal of TCNQ-hexamethylbenzene complex.

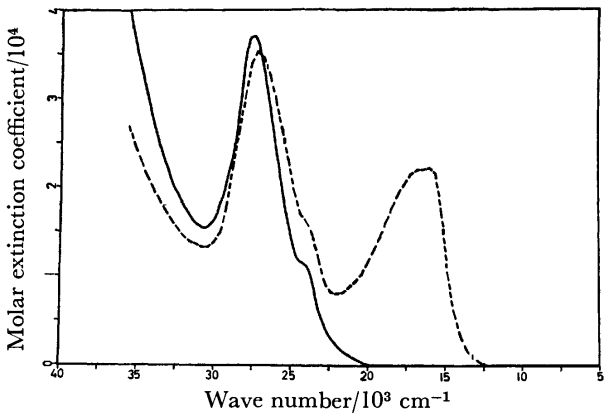

Fig. 18. The a(dashed line) and $a_\perp$(solid line) axes absorption spectra obtained by the K-K transformation of the reflection spectra of the crystal of TCNQ-hexamethylbenzene complex.

parallel and perpendicular to the a-axis on the (010) face. The absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Figs. 17 and 18.

The a-axis reflection spectrum has two bands. The first band occurs at 15200 cm^{-1}, with a reflectivity of 17.6%. The second band has the 0-0 transition at 23600 cm^{-1}, and the band peak appears at 26800 cm^{-1}, with an 11.0% reflectivity. The $a_\perp$-axis reflection spectrum shows no clear structure in the first a-axis band. The band corresponding to the second a-axis band has its first peak at 23600 cm^{-1}, while the main peak is located at 26800 cm^{-1}, with a reflectivity of 14.3%.

In the absorption spectra, the first band at 16000 cm^{-1} is polarized along the a-axis and may be assigned to the CT transition from one of the highest occupied hexamethylbenzene orbitals ($\phi_D^2(e_{1g})$) to the lowest unoccupied TCNQ orbital ($\phi_A^9(b_{1g})$). The oscillator strength of the CT band is 0.765, and the charge-transfer degree in the ground state is 8.0%. The second band at 27400 cm^{-1} has the same magnitude of absorption intensities in the a- and $a_\perp$-axes spectra. The (010) projection shows that the long-axis of the TCNQ

molecule is inclined at an angle of 56° to the stacking axis and indicates that the long-axis transition should be observed with the comparable absorption intensities for the a and $a_\perp$ axes spectra. Therefore, the 27000 cm^{-1} band can be attributed to the LE_1 transition of the TCNQ molecule.

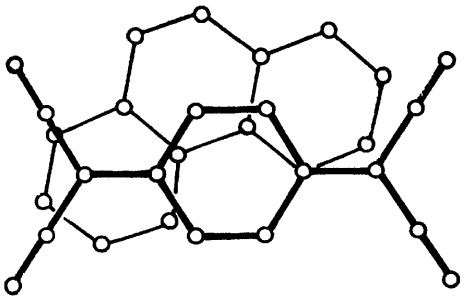

Fig. 19. The molecular overlap of the TCNQ–1,10-phenanthroline complex.

TCNQ-1,10-Phenanthroline Complex. The complex of TCNQ-1,10-phenanthroline forms a monoclinic crystal with a space group of $P2_1/n$.[15] The TCNQ and 1,10-phenanthroline molecules are packed in continuous mixed stacks usually, and the stacking axis is the c-axis. The mean interplanar donor-acceptor distance, R_{AD}, is 3.41 Å. The molecular overlap is shown in Fig. 19. The reflection spectra are observed for the polarizations parallel and perpendicular to the c-axis on the (010) face. The absorption spectra are obtained by the K-K transformation of the reflection spectra, as is shown in Figs. 20 and 21.

The c-axis reflection spectrum has a broad band at 18000 cm^{-1}, with a reflectivity of 4.6%. The $c_\perp$-axis reflection spectrum has two intense bands, at 22800 and 36800 cm^{-1}, with reflectivities of 26.7 and 19.8%.

In the absorption spectra, the first band at 20500 cm^{-1} is active for the light parallel to the c-axis and can be assigned to the CT transition from the highest occupied 1,10-phenanthroline orbital ($\phi_D^7(b_1)$) to the lowest unoccupied TCNQ orbital ($\phi_A^9(b_{1g})$). The oscillator strength of the CT band is 0.407, and the charger-transfer degree in the ground state is 5.2%.

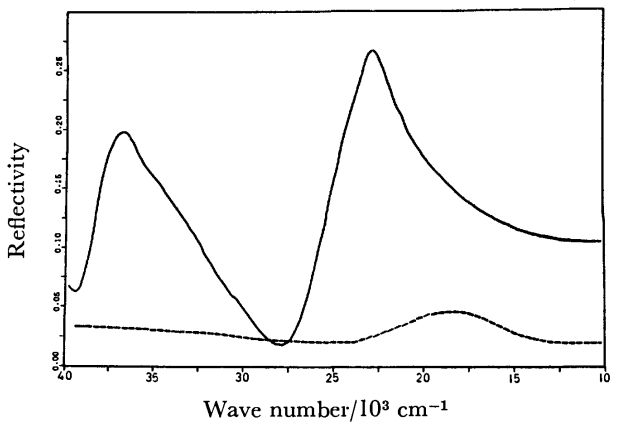

Fig. 20. The c(dashed line) and $c_\perp$(solid line) axes reflection spectra obtained on the (010) face of the crystal of TCNQ–1,10-phenanthroline complex.

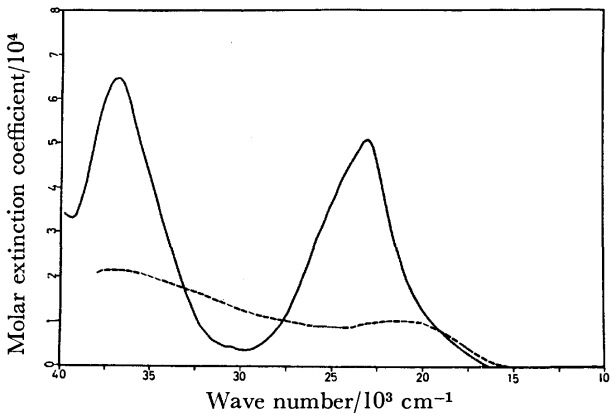

Fig. 21. The c(dashed line) and $c_\perp$(solid line) axes absorption spectra obtained by the K-K transformation of the reflection spectra of the crystal of TCNQ–1,10-phenanthroline.

The second and third bands at 23000 and 36800 cm^{-1} are polarized along the $c_\perp$-axis. The (010) projection shows that the long axes of the TCNQ and 1,10-phenanthroline molecules are nearly perpendicular to the a-axis. Therefore, the 23000 cm^{-1} band can be attributed to the LE_1 band of TCNQ, and the 36800 cm^{-1} band, to the long-axis transition of 1,10-phenanthroline.

Discussion

The energy of the CT transition, E_{CT}, is given approximately by the equation

$$E_{CT} = I_p - E_A - C - P,$$

where I_P is the ionization potential of the donor; E_A, the electron affinity of the acceptor; C, the Coulombic interaction between donor and acceptor molecules, and P, the polarization energy. That is, the observed energies (E_{CT}) of the charge-transfer transitions maintain a linear relation with the ionization potentials (I_P) of the donor molecules, as is shown in Table 1. The first CT band of the TCNQ–phenothiazine complex is located in the lowest energy region, and the CT bands of TCNQ–anthracene, pyrene, acenaphthene, and hexamethylbenzene are observed in the order of increasing energy, in the same manner as that of the ionization potential. The Coulomb energy of the first band can be estimated by the use of the Nishimoto-Mataga approximation, and the electron affinity of the TCNQ molecule was determined to be 2.80 eV by Klots, Compton, and Raaen.[16] Then, the polarzation energy, P, can be deduced as is shown in Table 1. It should be noted that the crystal of the TCNQ–phenothiazine complex has a large polarization energy (P=1.10 eV) although those of the other complexes are 0.7—0.8 eV. This extraordinary size of the crystal of the TCNQ–phenothiazine complex was also observed in the phenothiazine crystal.[17] The vertical ionization energy of a molecular crystal, I_C, is related to the ionization energy, I_P, of the corresponding gaseous molecule by the relation: $I_P = I_C + P$. Therefore, the values of $I_P - I_C$ are equal to the polarization energy, P, in the solid state; it is shown in Table 1 that the phenothiazine

crystal has a larger value of the polarization energy $P(=I_P-I_C)$ than the other compounds.

The stabilization energies in the ground state are determined by means of the equation: $\Delta E=\sum_i b_i^2 E_{CT}^i$, and are shown in Table 1. According to Table 1 and the molecular overlaps, the crystals of the complexes forming a configuration of a high symmetry like the TCNQ-anthracene and carbazole systems are more strongly stabilized by the charge-transfer force, although this seems not to be a general rule.

Bond Orbital Calculations on the Methane and Silane Molecules. II. Vertical Transition Energies of the Lower Singlet-Excited States of CH_4

Shigeyoshi KATAGIRI and Susumu KOHDA-SUDOH

Department of Chemistry, Faculty of Science, Hirosaki University, Hirosaki 036

(Received July 6, 1977)

The vertical singlet-transition energies of CH_4 were calculated using the BO method. Two types of basis sets, minimal and extended, were employed. The vertical transition energy of the lowest singlet state of CH_4 was found to be 9.1 eV using the extended-basis set. This transition is assigned to a Rydberg-type transition in agreement with experiments. The other lower excited-states of CH_4 may also be assigned to Rydberg transitions. The main features of the present BO calculations do not differ greatly from those of other extended-basis MO calculations. The total energy of the ground state is discussed briefly.

In previous bond orbital (BO) calculations[1] for the methane and silane molecules, the total energies of the ground states were calculated in this, as well as the ordinary SCF-LCAO-MO, method and the polarization parameters were approximately equal to those of the O–H and N–H bonds in the water[2] and ammonia[3] molecules, respectively. It appears interesting to investigate how well excited states are expressed by the BO method. Among the many properties of the excited molecular states our interest here is mainly in the lowest vertical transition energies for the present BO calculations. The total energy of the ground state of CH_4 will be discussed briefly.

Recently, extended-basis MO calculations are frequently carried out on the electronic structure and spectra of medium-sized molecules using Gaussian-type orbitals (GTO) as atomic orbitals (AO).[4-12] These calculations have succeeded in explaining the electronic spectra of organic molecules, especially Rydberg-type transitions. The present authors have already calculated the vertical transition energies of CH_4 using the MO method,[13] and found that the lowest excited state of CH_4 can be assigned to a transition of an electron from the $1t_2$ to the 3s-like Rydberg MO's in agreement with the electron-impact experiments of Harshbarger and Lassetre.[14] Here BO calculations for the vertical transition energies of methane obtained using two basis sets (*i.e.*, minimal and extended-basis sets) are presented. BO-type calculations have already been performed by Klessinger and McWeeny[15] using the group-function method with minimal Slater-type AO (STO) as the basis set. They discussed only two excited states, A_1 and T_2, which were described by linear combinations of four locally-excited configurations (excitons), with the results not in quantitative agreement with experiment.

In this study other excited states which can also be constructed from other types of electron promotion (*vide infra*) were investigated. The molecular geometry is assumed to be T_d and the bond distance is fixed at R(C–H)=2.05 a.u.[16] The STO are used as the basis AO, with the orbital exponents:

$$\delta_{1s}(C) = 5.7,\ \delta_{2s}(C) = \delta_{2p}(C) = 1.625,$$
$$\delta_{3s}(C) = \delta_{3p}(C) = 0.4388,\ \text{and}\ \delta_{1s}(H) = 1.2.$$

These values were obtained from Slater's rules, except for $\delta_{1s}(H)$. All molecular integrals were calculated on the HITAC 8800/8700 Computer at the University of Tokyo Computer Centre, using the library program written by Taketa (Y4TC/AD05; Molecular Integrals over CGTO), where the molecular integrals were calculated over the composite GTO's.[17] The CI calculations were carried out on the NEAC 2200 Model 700 Computer at the Tohoku University Computer Centre.

Method of Calculations

In previous BO studies, the original non-orthogonal basis set,

$$\mathbf{a} = (1s, 2s, 2p_x, 2p_y, 2p_z, H_1, H_2, H_3, H_4), \quad (1)$$

where H_i is the ith hydrogen 1s AO, was transformed into the orthonormalized basis set,

$$\mathbf{b} = (1s, b_1, h_1, b_2, h_2, b_3, h_3, b_4, h_4), \quad (2)$$

using the procedure of McWeeny and Ohno.[2] That is, all the valence orbitals were Schmidt-orthogonalized to the carbon inner shell (1s), the carbon 2s′ and 2p orbitals were tetrahedrally hybridized, and finally all the orbitals obtained were orthonormalized according to Löwdin's method. The orthonormalized orbitals, b_i and h_i, were used to construct the bond orbitals (BO) for the ith bond, thus

$$B_i = \lambda^2 h_i + \sqrt{1-\lambda^2}\, b_i, \quad (3)$$

where λ is a variational parameter. Now we assume the following antibonding BO (A_i) for constructing the excited state of CH_4,

$$A_i = \mu^2 b_i - \sqrt{1-\mu^2}\, h_i. \quad (4)$$

In order to maintain orthogonality between the ground and excited states, we make the assumption that the variational parameters, λ and μ, in Eqs. 3 and 4 are identical, such that $\lambda^2=\mu^2=0.46$, the optimum value for the ground state of CH_4, throughout the present calculations.[1] The number, and types of electron promotion taken into account will be discussed below in detail.

Extended-basis Calculations: The extra-valence AO, the 3s and 3p orbitals of the carbon atom, were added to the minimal-basis set. In the calculations, the following suppositions were made. First, the bonding BO are the same as those of the minimal-basis calculations. Second, the pseudo-antibonding BO are expressed by only the

extra-valence AO, thus

$$A_i = \frac{1}{2}(3s \pm 3p_x \pm 3p_y \pm 3p_z), \quad (5)$$

where the 3s and 3p AO are orthonormalized to the inner and valence shell AO of the C atom using the Schmidt procedure, and the signs are chosen to form directed hybridized orbitals toward to the ith H atom, as in the case of b_i in Eqs. 3 and 4. Finally, we neglect the overlap integrals between the A_i and the hydrogen 1s AO, *i.e.*, $S(A_i, B_i)=0$,[20] to insure orthogonality for the A_i and B_i. The form of the pseudo-antibonding orbitals is of great advantage to constructing symmetry adapted basis functions, and should be regarded as virtually equivalent orbitals.

Wavefunctions of the Excited States: We can consider many types of electron promotion from the bonding orbitals (B_i) to the antibonding or pseudo-antibonding orbitals (A_i). The excited electronic configurations arising from one- and two-electron promotion are taken into account in the CI calculations. The types of electron promotion actually considered are

$$\{(B_i)^2\} \longrightarrow \{(B_t)(A_j)\}, \quad (16)$$
$$\{(B_i)^2\} \longrightarrow \{(A_j)^2\}, \quad (16)$$
$$\{(B_i)^2\} \longrightarrow \{(A_t)(A_j)\}, \quad i \neq j, \quad (12)$$
$$\{(B_i)^2\} \longrightarrow \{(A_k)(A_l)\}, \quad i \neq k \neq l, \quad (12)$$
$$\{(B_i)^2(B_j)^2\} \longrightarrow \{(B_i)(B_j)(A_i)^2\}, \quad i \neq j, \quad (12)$$

and

$$\{(B_k)^2(B_l)^2\} \longrightarrow \{(B_k)(B_l)(A_i)^2\}, \quad i \neq k \neq l, \quad (12)$$

where an electron promotion, such as $\{(B_i)^2(B_j)^2\} \rightarrow \{(B_i)(B_j)(A_i)^2\}$ means that two electrons in the bonding BO, B_i and B_j, are excited to the vacant antibonding or pseudo-antibonding BO (A_i) at the same time and the other doubly-occupied orbitals remain unchanged. The numbers in parenthesis are the possible ways of exciting the electron from four bonding BO to four antibonding or pseudo-antibonding BO.

The symmetry-adapted basis functions of the excited states are easily obtained by taking appropriate linear combinations of the above excited configurations. From the fact that the direct product $(A_1+T_2)\otimes(A_1+T_2)$ is $2A_1+E+T_1+3T_2$, for example, we can take the following combinations of four singly-excited configurations as one of the CI basis functions for the states A_1 and T_2

$$\Psi(A_1 \text{ or } T_2) = c_1\psi(B_1 \rightarrow A_1) + c_2\psi(B_2 \rightarrow A_2) + c_3\psi(B_3 \rightarrow A_3) + c_4\psi(B_4 \rightarrow A_4), \quad (6)$$

where the symbol A is used to denote both the symmetry species and pseudo-antiboding BO, although being careful to avoid confusion. The final excited-state wavefunction will be expressed as a linear combination of these symmetry-adapted basis functions.

Results and Discussion

The vertical transition energies of the lower excited states are given in Table 1, along with other MO calculations and experimental results. The total enrgy of the ground state of CH_4 is improved considerably by the configuration interaction. The results of the CI are shown in Table 2, where the results indicate the extent that individual excited configurations contribute to the improvement of the total energy. In the minimal-basis calculations, the doubly-excited configurations, such as $(B_i)^2 \rightarrow (A_j)^2$, are most affected by the CI calculations. Especially, the energy lowering due only to local configurations, *i.e.*, $(B_i)^2 \rightarrow (A_i)^2$ is calculated to be -0.0535 a.u., which amounts to about 88% of the entire energy decrease. This results from inclusion of intra-bond electron correlation. This can be compared with the result (0.0517 a.u.) of previous modified BO calculations,[1] where electron correlation between orbitals of two different spins (different orbitals for different spins) were included. In the extended-basis calculations, on the other hand, the singly-excited configurations make exclusively dominant contributions to the decrease of the total energy. As for the results of the minimal-basis calculations, the energy decrease due only to local configurations, *i.e.*, $(B_i)^2 \rightarrow (B_iA_i)$, is very great ($-0.0323$ a.u.), which amounts to about 86% of the total energy decrease.

TABLE 2. ENERGY DECREASE DUE TO CI (a.u.)

Excited configuration	Minimal basis	Extended basis
$(B_t)^2 \rightarrow (B_tA_j)$	-0.0026	-0.0376
$(B_t)^2 \rightarrow (A_j)^2$	-0.0550	-0.0001
Others	-0.0035	-0.0000
Total	-0.0611	-0.0377
Total energy	-40.1658	-40.1451

Turning our attention now to the predicted excited states, the symmetry of the calculated lowest excited-state, as seen from Table 1, is T_2 in all cases except for the minimal-basis MO calculations. In spite of the

TABLE 1. VERTICAL TRANSITION ENERGIES (eV)

State	Minimal basis				Extended basis					Obsd[f]

$2A_1$	36.21	36.04			23.50	23.38	27.25				

a) Single-excitation CI. b) Double-excitation CI. c) See Ref. 13. d) See Ref. 15. e) See Ref. 11. f) See Ref. 18.

fact that the T_2 state participates in an electronically-allowed transition, the vertical transition energies calculated using the minimal-basis set are too high in comparison with the experimental results, and moreover exceed the ionization potential.[18] This is common for non-empirical calculations using the minimal-basis set.[10,15] The situation, however, is changed drastically by introducing into the basis set the extra-valence AO of the C atom. The lowest excited state is calculated to be 9.4 and 9.1 eV above the ground state for cases (I) and (II), respectively (see footnotes to Table 1). The symmetry of this state is that of the dipole-allowed T_2 state for both calculations. The agreement with experiment is fairly good. Williams and Poppinger have calculated the transition energies of CH_4 using the CI and EOM methods, for which they also used the extra-valence 3s and 3p AO of the C atom as bases.[11] As is seen from Table 1, their results show almost the same tendency as the present BO calculations with respect to the transition energies, but there are some differences for the relative ordering of the calculated excited states. The BO results do not differ in main features from the MO results, although it is of note that the BO lowest T_1 state is considerably higher than that for the MO calculations.

In the extended-basis BO calculations, the results of CI with both singly- and doubly-excited configurations give lower transition energies than do those including only single excitations. For the minimal-basis BO calculations, on the other hand, inverse results are obtained, except for only two states ($1T_2$ and $2A_1$). This appears to conflict with the conventional SCF-LCAO-MO CI results that the doubly-excited CI give higher vertical transition energies than do the singly-excited CI, because of the improvement of the ground-state total energy for the former CI calculations. This may be understood from the BO-CI results shown in Table 2.

It is interesting to examine the nature of the lowest excited state. It has already been shown, for MO calculations,[13] that the lowest vacant MO ($3a_1$) resembles the 3s AO of the C atom which is orthogonalized to the 2s and 1s AO using Schmidt procedure, and the lowest singlet excited-state is assigned to the Rydberg transition, *i.e.*, from the triply degenerate $2t_2$ MO to the above 3s-like MO. In the present BO calculations, this T_2 state is expressed as

$$\begin{aligned}{}^1\Psi(T_2) = {} & 0.212\{\psi(B_1\rightarrow A_1)+\psi(B_2\rightarrow A_2) \\ & -\psi(B_3\rightarrow A_3)-\psi(B_4\rightarrow A_4)\} \\ & +0.173\{\psi(B_1\rightarrow A_2)+\psi(B_2\rightarrow A_1) \\ & -\psi(B_3\rightarrow A_4)-\psi(B_4\rightarrow A_3)\} \\ & +0.294\{\psi(B_1\rightarrow A_3)+\psi(B_2\rightarrow A_4) \\ & -\psi(B_3\rightarrow A_1)-\psi(B_4\rightarrow A_2)\} \\ & +0.294\{\psi(B_1\rightarrow A_4)+\psi(B_2\rightarrow A_3) \\ & -\psi(B_3\rightarrow A_2)-\psi(B_4\rightarrow A_1)\} \\ & +\text{doubly-excited configurations},\end{aligned}$$

where the $\psi(B_i\rightarrow A_j)$ denote the excited singlet configurations arising from one-electron promotion from the B_i to the A_j orbitals. The lowest excited state is not expressed only by local excitation. The contribution of the doubly-excited configurations to this state is small.

It is seen that the lower excited states of CH_4 are not explained by the valence-shell transitions using the minimal-basis calculations, but can be understood to be Rydberg-type transitions obtained using the extended-basis calculations. This agrees with the results of the extended-basis MO calculations.[13] Here, no consideration was made of the interaction between the Rydberg and valence-shell transitions. However, more extended-basis MO calculations will be presented elsewhere,[19] in which the mixing of the above two types of transitions will be discussed.

The authors wish to express their thanks to Professor Hiroshi Taketa of Kyushu University for helpful communications regarding the use of the molecular integral program (Y4TC/AD05; library program at the University of Tokyo Computer Centre).

Study of Solutions of Tetraalkylammonium Salts in Acetone by Vapor Pressure Osmometry and Conductometry

Ha Chung LEE and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusaku, Nagoya 464

(Received July 12, 1977)

Vapor pressure depressions at 40.3 °C and electric conductivities at 25 and 40.3 °C have been measured for Bu_4NCl, Bu_4NBr, Bu_4NI, and Pr_4NI in acetone. Experiments were carried out with the greatest care to minimize the contact of salts and their solutions with air. A new representation of activity coefficients has been proposed for the undissociated species. Analysis by means of the representation gives better agreement between the dissociation constants and those obtained from electric conductivities. The very small dissociation constant of Bu_4NCl found previously has been corrected.

A number of papers[1,4,6,8] have appeared on the study of solutions of electrolytes in nonaqueous solvents by means of electric conductivity measurement. The dissociation of electrolyte salts is not complete in nonaqueous solvents. The dissociation constants have been determined by several authors. The activities in nonaqueous solutions of alkali halides[2] and tetraalkylammonium salts[3] were measured with a vapor pressure osmometer (VPO), and the dissociation constants of salts were estimated.

However, the dissociation constants of tetraalkylammonium salts were not in good agreement with those[4,8] determined conductometrically.

The present experiments have been undertaken in order to compare the dissociation constants obtained by two methods. The study of solutions of tetraalkylammonium salts, Bu_4NCl, Bu_4NBr, Bu_4NI, and Pr_4NI, in acetone by means of VPO has been repeated, measurements of the electric conductivities of the same solutions also being carried out.

In the calculation of dissociation constants from the VPO data, the activity coefficient of undissociated molecules has been taken into account.

Theoretical

It is well known that the tetraalkylammonium salts, MX, dissociate in acetone as

$$MX \rightleftarrows M^+ + X^-. \quad (1)$$

Thus, the Gibbs-Duhem equation gives

$$N_1 \,d\ln a_1 + m_2 \,d\ln a_2 + m_3 \,d\ln a_3 + m_4 \,d\ln a_4 = 0, \quad (2)$$

where a_2, a_3, and a_4 are the activities of MX, M^+, and X^-, respectively, and a_1 is the activity of the solvent. N_1 is the moles of 1 kg of the solvent ($=1000/M_1$: M_1 the molecular weight of the solvent), and m_2, m_3, and m_4 are the molalities of MX, M^+, and X^-, respectively. Integration of Eq. 2 gives

$$\ln a_1 = -\frac{1}{N_1}\left(m_2 + 2m_4 + \int_0^{m_4} m_2 \,d\ln\gamma_2 + 2\int_0^{m_4} m_4 \,d\ln\gamma_4\right). \quad (3)$$

We assume that the activity coefficients of ions M^+ and X^- obey the Debye-Huckel (D-H) limiting law.[3] The integration of the last term of the right-hand side of Eq. 3 is, then, given by

$$2\int_0^{m_4} m_4 \,d\ln\gamma_4 = -\frac{4.606A(\sqrt{m_4 d_0})^3}{3d_0}\sigma(X) - 2\left\{m_4 - \frac{\ln(1+0.001m_4M_2)}{0.001M_2}\right\}, \quad (4)$$

$$X = Ba_0\sqrt{m_4 d_0},$$

$$\sigma(X) = \frac{3}{X^3}\left\{(X+1) - \frac{1}{X+1} - 2\ln(X+1)\right\},$$

where A and B are the constants in the D-H equation (see Eq. 9), and d_0 the density of the solvent. The second term in the right-hand side of Eq. 4 was omitted in Eq. 10 of the previous paper.[3]

The form of activity coefficient of the undissociated molecules, γ_2, should be duly considered. In the theory of Fuoss-Onsager, it has been assumed to be unity. We have attempted to determine the dissociation constant from the concentration dependence of the activity of the solvent by means of the curve-fitting. We start from the following two assumptions with respect to γ_2.

$$\text{I} \quad \ln\gamma_2 = 0 \quad (5)$$

$$\text{II} \quad \ln\gamma_2 = -\beta_2 m_2 + (\beta_3 m_2^2 + \cdots).$$

Integration of the third term in the right-hand side of Eq. 3 leads to

$$\int_0^{m_4} m_2 \,d\ln\gamma_2 = -\frac{\beta_2}{2}m_2^2 + \left(\frac{2\beta_3}{3}m_2^3 + \cdots\right). \quad (6)$$

Assumption II shows that the deviation of γ_2 from unity caused by various unknown factors is compensated by introducing a parameter β_2.

A function h defined by

$$h = \frac{N_1 \ln a_1}{m} + 1 \quad (7)$$

was used for the analysis of the experimental results, where m is the molality of salt.

Experimental

Material. Tetraalkylammonium salts, Bu_4NCl, Bu_4NBr, Bu_4NI, and Pr_4NI, and acetone (guaranteed grade, Nakarai Chemical Co., Ltd.) were used. Before use, the salts were dried for five days in a vacuum oven at 50 °C with molecular sieves 3 Å (1/8-in. pellets). Fresh molecular sieves were used each day. Acetone was dried with anhydrous calcium sulfate and distilled in the presence of the molecular sieves. The water content was confirmed to be less than 0.01 wt % by the Karl-Fischer analysis. The molecular sieves and anhydrous calcium sulfate were dried, before use, over a period of 12 h in

an electric oven at 360 and 250 °C, respectively. KCl was dried by a similar way to that for the tetraalkylammonium salts. The conductivity water was prepared by the usual method by passing dried nitrogen gas. Great care was taken to minimize the contact of the salts and their solutions with air. A dry box filled with nitrogen gas was used.

Vapor Pressure Osmometer. A vapor pressure osmometer Hitachi-Perkinelmer 115 was used. The experimental procedures were reported.[2] The temperature of measurement was 40.3 °C.

Conductometry. The conductometer, a model CM-1DB, Toa Denpa Co., Ltd., was calibrated with a Wheatstone Bridge, Type BD-30 of Shimadzu Co., Ltd. The cell constants were determined with KCl solutions in the usual way. Temperature of measurements were 25 and 40.3 °C.

Results and Discussion

Vapor Pressure Osmometry. Proportionality constants K_s, of the apparatus obtained for several compounds of known molecular weight is given in Table 1. The plots of Δr, the change of resistance of a bridge in the apparatus, against the concentration, m, for the tetraalkylammonium salts in acetone, are given in Fig. 1. The values of h, calculated from Eq. 7 are given in Table 2. The profile of plots of h against the concentration clearly shows the existence of a dissociation equilibrium in the solutions.[3]

Table 1. Proportionality constant of VPO in acetone solutions at 40.3 °C

Numerical analysis of function h was carried out. Two parameters, K_d and β_2, were determined on assumptions I and II by the method of least-squares. A HITAC 10 computer was used for the curve fitting of function h. The best values of K_d and β_2 and their standard deviations, σ, are given in Table 3. The difference between assumptions I and II is not highly

significant, but the values obtained from assumption II seem more favorable.

Conductometry. The concentration dependence of the conductivities obtained at 25 °C by the present measurements is compared in Fig. 2 with that found in literature.[4] The results obtained were analyzed by means of the Fuoss-Onsager theory.[5] The parameters in the Fuoss-Onsager equation where C is the concentration in molarity scale, were determined by the method of least squares.[9]

$$\Lambda = \Lambda_0 - S(C\alpha)^{1/2} + EC\alpha \log_{10}(C\alpha) + JC\alpha - K_A f_\pm^2 C\alpha\Lambda, \quad (8)$$

$$\ln f_\pm^2 = -\frac{4.606A\sqrt{C\alpha}}{1+Ba_0\sqrt{C\alpha}}. \quad (9)$$

The values of conductivity parameters, K_A, a_0 (ion-size parameter), and Λ_0 at 25 °C obtained are given in Table 4, the values in literature[4,8] being given for comparison. The physical constants of acetone used in the present calculation are as follows.

t/°C	d_0/(g cm^{-3})	η/(g cm^{-1} s^{-1})	ε
25	0.7844	0.00303[4]	20.56[4]
40.3	0.7667[6]	0.00263_6[6]	19.24[6]

Analysis of the conductivity data at 40.3 °C was made by the same procedure. However, the values of a_0 used were those obtained at 25 °C (Table 4) for the sake of consistency. If the value of a_0 is determined independently by curve-fitting the best value contains some ambiguity and is not unique. The temperature change of a_0 seems to be negligible. The value of a_0 for Pr_4NI at 25 °C, 3.28 Å, was lower than the other values. Thus, the value 5.24 Å in literature was used in this case. The data of the concentrations up to 1×10^{-3} mol/dm^3 were analyzed by the Fuoss-Onsager equation. The results are shown in Table 5. The data of concentrations up to 20×10^{-3} mol/dm^3 were analyzed by the Fuoss-Hisa Equation.[7] The results are shown in Fig. 3. No tendency of the formation of poly-ions at high concentrations was observed.

Comparison of VPO and Conductometry. In a previous work,[3] the dissociation constants of the tetraalkylammonium salts in acetone obtained by VPO were compared with those found in literature. The agreement between them was not satisfactory. The results of the present study are summarized in Table 5, where the dissociation constants were obtained (1) by VPO on the assumption II, and (2) by conductometry

Table 5. Comparison of dissociation constants by VPO and conductometry at 40.3 °C (in terms of molality)

	VPO	Conductometry	VPO[3]
	Assump. II	up to 1×10^{-3} mol/dm^3	Our previous work
Bu_4NCl	3.33×10^{-3}	2.50×10^{-3}	0.55×10^{-3}
Bu_4NBr	7.10×10^{-3}	3.56×10^{-3}	4.5×10^{-3}
Bu_4NI	10.00×10^{-3}	7.39×10^{-3}	4.0×10^{-3}
Pr_4NI	9.07×10^{-3}	5.97×10^{-3}	4.4×10^{-3}

using the Fuoss-Onsager equation from the data of concentrations less than 1×10^{-3} mol/dm^3 at 40.3 °C. The previous data are also given for the sake of comparison. Concentrations in terms of molality were used. The agreement is satisfactory.

The difference between the results obtained by assumptions I and II was not serious (Tables 3 and 5). However, introduction of parameter β_2 seems reasonable, since it compensates various errors due to the assumption of ideality.

Radiation Chemical Reactions in Carbon Dioxide–Propane System. III. Formation of Oxygen Containing Products

Yasumasa IKEZOE and Shoichi SATO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11

(Received August 10, 1977)

The G value of water and 2-propanol as well as that of carbon monoxide decreased with decrease in propane concentration below 0.5%, the value of acetone remaining constant. Considering the effects of dose rate and irradiation temperature on the product yields, the results indicate that the formation of water and 2-propanol competes with the back reaction, or the reoxidation of carbon monoxide. A clustered negative ion, $O^-(CO_2)_n$ seems to be the oxidizing species responsible both for the back reaction and the formation of water and 2-propanol. The G value of $O^-(CO_2)_n$ was estimated to be 1.3. The formation of acetone is independent of the back reaction.

In the radiolysis of carbon dioxide, reoxidation of carbon monoxide, or the back reaction, is of great interest.[1] The back reaction in the carbon dioxide–propane system was studied at a low propane concentration,[2] and found to be accelerated by raising the total pressure or lowering the dose rate.

In order to clarify the relation between the two reactions and the properties of the oxidizing species present in the reaction system, we have examined the formation of oxygen containing products at the low propane concentration, where the back reaction competes with the formation of oxygen containing products.

Experimental

Carbon dioxide (Takachiho Chemical, pure gas, stated 99.99% up) and propane (Takachiho Chemical, research grade, stated 99.7% up) were used after uncondensable gas had been removed with a liquid nitrogen trap. Pyrex ampoules (160 and 64 ml) were washed with distilled water thoroughly. The reactant gas was introduced into the ampoules connected to a vacuum line, their pressure being measured with a stainless steel Bourdon gauge. Irradiation of the ampoules by ^{60}Co γ-rays and the dosimetry were carried out as described previously.[2] High temperature irradiation was carried out in an electric furnace, in which the temperature was controlled to an accuracy of ± 2 °C.

The irradiated gas was analyzed by means of mass spectrometry and gas chromatography. Three columns were used to separate eleven products; column I (molecular sieve 5A, 70 cm, 30 °C) was used to analyze carbon monoxide and methane, column II (Porapak R, 1.5 m, 120 °C) 2-propanol and hexanes,[3] column III (Porapak T; 2 m+Porapak T coated with 0.5% polyethylene glycol; 5 cm, 120 °C) water, acetone, propylene oxide, isobutane, butane, isopentane and pentane. The analysis of a small amount of water ($\approx 10^{-7}$ mol) required particular attention because of its adsorption on the wall surface of the analytical vacuum line. The effect of adsorption was minimized by conditioning the wall surface with the irradiated gas before its introduction. Details were described elsewhere.[4]

Results

Effect of Propane Concentration. The effects of propane concentration below 1.1% on the G values of various products are shown in Figs. 1 and 2. The G values were obtained at a constant dose 6.7 Mrad, total pressure 1.88×10^5 Pa, temperature 308 K and exposure rate 0.95 MR/h. The maximum G(CO) value

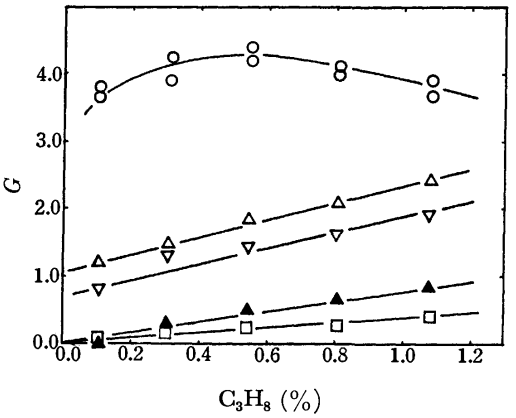

Fig. 1. Effect of propane concentration, I. 160 ml glass ampoule, $CO_2+C_3H_8$; 1.88×10^5 Pa, γ exposure rate; 0.95 MR/h, absorbed dose; 6.7 Mrad. ○; CO, △; $H_2\times3$, △; $CH_4\times3$, ▲; (hexanes) $\times5$, □; (isopentane) $\times5$.

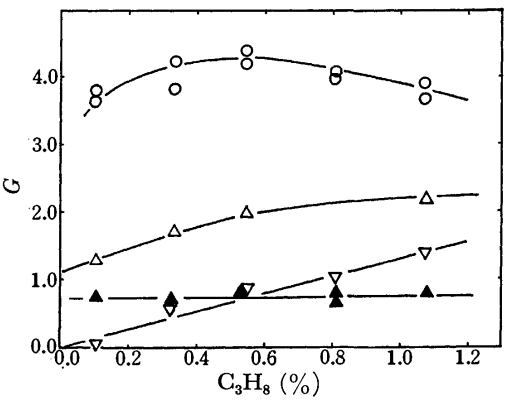

Fig. 2. Effect of propane concentration, II. ○; CO, △; H_2O, ▽; i-PrOH $\times10$, ▲; (acetone) $\times10$.

4.3 ± 0.1 and the concentration of propane 0.5% at which the maximum G(CO) value was obtained agree with our previous results within experimental error.[2] The decrease in G(CO) value with the reduction of propane concentration less than 0.5% is attributed to the back reaction.

The occurrence of the back reaction should necessarily lead to a variation in the G values of the products in this reaction system. The G values of hydrogen and methane (Fig. 1) decreased linearly with the reduction

in propane concentration, but their extrapolated values at the propane concentration of zero per cent did not reach zero. The values of isopentane and hexanes were small (<0.2), apparently converging to zero.

The effect of propane concentration on the formation of oxygen containing products is directly related to the reaction of the oxidizing species responsible for the back reaction. In the range of propane concentration investigated, formation of oxygen containing products competes with the back reaction.

Three oxygen containing products, water, 2-propanol and acetone, besides carbon monoxide were identified and measured. The G value of water (1—3) was the largest of the three. The G values of 2-propanol and acetone were of the same order of magnitude (0.1—0.2), those of other oxygen containing products, such as methanol, ethanol and propylene oxide, being smaller than 0.03. Neither propanal nor 1-propanol was detected. From the material balance of oxygen, it is obvious that unidentified oxygen containing products, not detected by the analytical procedures employed, still remain.

The G value of acetone did not decrease with decrease in propane concentration, remaining constant (0.08 ± 0.01) in the whole range of propane concentration investigated (Fig. 2). This indicates that acetone is formed by the reaction of an oxidizing species not responsible for the back reaction.

The G values of water and 2-propanol decreased with decrease in propane concentration. The G value of 2-propanol decreased linearly and converged to zero at zero per cent propane, while the G value of water did not converge to zero. This suggests that both water and 2-propanol are formed by the reaction of the oxidizing species responsible for the back reaction, but the mechanisms of their formations differ.

Effects of Dose Rate and Temperature. For the propane concentration 0.27%, the back reaction and its suppression are dynamically balanced. The back reaction has been found to be retarded by raising the dose rate, resulting in an apparent increase in G(CO) value.[2] The formation of the oxygen containing products seems to depend on the dose rate.

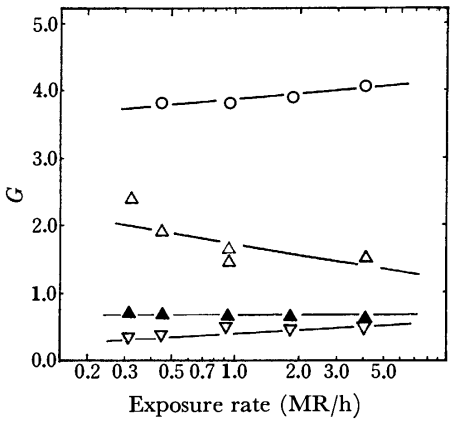

Fig. 3. Effect of dose rate. 160 ml glass ampoule, $CO_2+C_3H_8$; 1.12×10^5 Pa, C_3H_8; 0.27%, absorbed dose; 6.7 Mrad. ○; CO, △; H_2O, ▽; *i*-PrOH×10, ▲; (acetone)×10.

The effect of dose rate at 0.27% propane on the G value of carbon monoxide, water, 2-propanol, and acetone is shown in Fig. 3. The G values of other products such as hydrogen, methane, isopentane, and hexanes were also examined. They remained constant in the whole range of dose rate investigated.

The G(CO) value increased with the dose rate in agreement with the previous result.[2] The G value of water decreases with the rate, that of acetone remaining constant (0.07 ± 0.01). The G value of 2-propanol at 0.27% propane was very small (<0.05), increasing slightly with dose rate. The retardation of the back reaction by the rise in dose rate is accompanied by a decrease in the formation of water and a slight increase in the formation of 2-propanol.

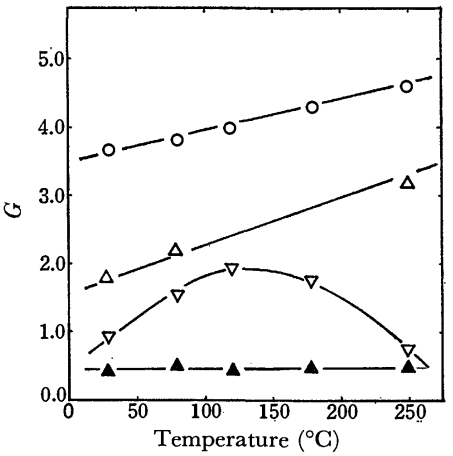

Fig. 4. Effect of irradiation temperature. 64 ml glass ampoule, $CO_2+C_3H_8$; 4.58 mg/ml, C_3H_8; 1.1%, γ exposure rate; 0.45 MR/h, absorbed dose; 6.7 Mrad. ○; CO, △; H_2O, ▽; *i*-PrOH×5, ▲; (acetone)×5.

The effect of irradiation temperature on the G values of carbon monoxide, water, 2-propanol and acetone is shown in Fig. 4. Conditions were as follows: irradiation temperature 30—250 °C, with the other conditions constant; gas density 4.58 mg/ml, propane concentration 1.1%, exposure rate 0.45 MR/h, and absorbed dose 6.7 Mrad. We see from Figs. 1 and 2 that at 1.1% propane the formation of oxygen containing products predominates over the back reaction. The mechanism of their formation seems to be the same as that at 0.27% propane.

The G value of 2-propanol shows an interesting behavior. At first, it increased from 0.2 to 0.4 with the rise in temperature from 30 to 120 °C, decreasing to 0.15 at 250 °C. That of acetone remained constant (0.1 ± 0.01).

The G values of carbon monoxide and water increased steadily with the irradiation temperature. This is in constrast to the effect of the dose rate on the G values (Fig. 3).

Discussion

Oxygen Containing Products and the Back Reaction. The formation of oxygen containing products results from the reactions of the same oxidizing species respon-

sible for the back reaction. The following reactions were proposed for the mechanism of such reactions.[2]

$$X^- + CO \longrightarrow CO_2 + Y^- + Z_1 \quad (1)$$

$$X^- + C_3H_8 \longrightarrow Y^- + Z_2 \quad (2)$$

$$X^- + R^+ \longrightarrow mCO_2 + Z_3 \quad (3)$$

$$Y^- + R^+ \longrightarrow nCO_2 + Z_4 \quad (4)$$

In these reactions, X^- denotes a clustered negative ion containing an oxygen atom or molecule, Y^- an electron or a negative ion other than X^-, R^+ any possible positive ion, and Z a neutral product.

Reactions 2 and 3 contribute to the formation of oxygen containing products. Reaction 3 contributes not only to the formation of oxygen containing products but also to the back reaction, depending on the identity of R^+.[5] Reaction 2, the scavenging of X^- by propane, leads to the formation of oxygen containing products other than carbon monoxide, competing with Reactions 1 and 3. The yield of the product in Reaction 2 becomes low with decrease in propane concentration.

Oxygen containing products are formed by reactions of the oxidizing species other than X^-. An oxygen atom (ground and excited) and the positive ion containing an oxygen atom or molecule[7] are conceivable. They are expected to react preferentially with propane even at the reduced concentration of propane, because of their high reactivity with propane. In this case propane concentration has little effect on the yield of the oxygen containing products.

Water and 2-Propanol. The results show that the G values of water and 2-propanol, as well as of carbon monoxide depend in a complicated way on propane concentration, dose rate, and irradiation temperature, indicating that there is a certain relation between the back reaction and the formation of water and 2-propanol.

It is impossible to determine the exact mechanism of the formation of water and 2-propanol which explains all the experimental results. However, the following reactions seem plausible for qualitative explanation.

ionic mechanism of water formation

$$O^-(CO_2)_n + C_3H_8 \longrightarrow (OH)^-(CO_2)_n + C_3H_7 \quad (2')$$

$$(OH)^-(CO_2)_n + C_3H_8 \longrightarrow H_2O + nCO_2 + C_3H_7 + e^- \quad (5)$$

radical mechanism of water formation

$$O + C_3H_8 \longrightarrow OH + C_3H_7 \quad (6)$$

$$OH + C_3H_8 \longrightarrow H_2O + C_3H_7 \quad (7)$$

mechanism of 2-propanol formation

$$(OH)^-(CO_2)_n + C_3H_7 \longrightarrow i\text{-PrOH} + nCO_2 + e^- \quad (8)$$

Water should be formed by at least two processes, ionic and radical. In the former, other ionic species such as $O_2^-(CO_2)_n$, $O^+(CO_2)_n$ and $O_2^+(CO_2)_n$, have been considered, in addition to $O^-(CO_2)_n$, to be the probable oxidizing species in pure carbon dioxide.[8] However, in the present reaction system, $O_2^-(CO_2)_n$ seems to be negligible since the formation of oxygen is inhibited by propane. The contribution of $O^+(CO_2)_n$ and $O_2^+(CO_2)_n$ was neglected because of their low yields.[5,7] On the other hand, O^- (and $O^-(CO_2)_n$) can be formed by the dissociative attachment of an electron to carbon dioxide.[9]

By the above mechanism, the yield of water by the ionic process will depend on the concentration of propane because of the competing back reaction 1. On the other hand, the yield by the radical process will not depend on it, since O atom preferentially reacts with propane. The G value of water which is due to the radical process, $G(H_2O)_r$, can be approximated by the extrapolated G value 1.1 of water to zero per cent propane (Fig. 1). The G value of water due to the ionic process, $G(H_2O)_i$, could be estimated by subtracting $G(H_2O)_r$ from the experimental G value of water. The maximum $G(H_2O)_i$ thus obtained is 1.1.

Formation of 2-propanol seems to be due to the ionic process (Reactions 2′ and 8). The rate of Reaction 8 should depend on the dose rate more strongly than that of Reaction 5, since the concentration of C_3H_7 is a function of dose rate, but not that of propane. Thus, the above mechanism satisfies qualitatively the experimental effect of dose rate on the formation of water and 2-propanol (Fig. 3). Reaction 8 is expected to depend on the irradiation temperature.[10]

If the above mechanism holds for the formation of water and 2-propanol, the G value of $O^-(CO_2)_n$ can be estimated by

$$G(O^-(CO_2)_n) \approx G(H_2O)_i + G(i\text{-PrOH}) = 1.3. \quad (9)$$

Acetone. The G value of acetone is costant irrespective of the reduction in propane concentration (Fig. 2). Consequently, the oxidizing species, $O^-(CO_2)_n$, responsible for the back reaction in the present reaction system, is excluded from the precursor of acetone. Moreover it kept a constant value irrespective of the variation in dose rate and irradiation temperature (Figs. 3 and 4). The results suggest that acetone is a product of a reaction of highly excited species formed by the direct action of the ionizing radiations on carbon dioxide, having a high reactivity with propane.

Excited oxygen atoms and atom ions are known to be formed in quantity in the primary process in the radiolysis of carbon dioxide.[12] Among them, $O(^1D)$ reacts with paraffins to form ketone.[13,14]

$$O(^1D) + RH \longrightarrow H_2 + \text{ketone} \quad (10)$$

The formation of acetone could be explained by an analogous reaction of $O(^1D)$ with propane, if Reaction 10′ were independent of the propane concentration and irradiation temperature.

$$O(^1D) + C_3H_8 \longrightarrow CH_3COCH_3 + H_2 \quad (10')$$

However, in the reaction system investigated, $O(^1D)$ would preferentially react with carbon dioxide and be deactivated to the ground state, $O(^3P)$.[15] The rate of Reaction 10′ should depend on the concentration of propane. Reaction 10′ for the formation of acetone is thus not compatible with the experimental result (Fig. 2). This is confirmed by the lack of 1-propanol formation, since 1-propanol is formed in a greater amount than 2-propanol[16] and probably acetone,[14] when $O(^1D)$ reacts with propane. The formation of acetone should be ascribed to the excited species other

than O(^{1}D). So far the precursor of acetone can not be identified further.

The precursor of acetone differs from the oxidizing species which is responsible for the back reaction in the present reaction system. However, the possibility that the highly excited species responsible for the formation of acetone plays a role in the back reaction in pure carbon dioxide cannot be excluded. The back reaction in pure carbon dioxide is probably not identical to that in the carbon dioxide–propane system even at very low propane concentration.

A New Expression for Excess Volumes of Binary Mixtures

Masanao KATO and Nobuo SUZUKI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received September 26, 1977)

A new expression for excess volumes of binary mixtures is derived. This equation contains four adjustable but physically-meaningful parameters: two non-randomness factors and two partial molar volumes at infinite dilution. The applicability of this equation is tested against data in the literature for several non-ideal mixtures, and it is found that this equation successfully expresses the experimental curves of excess volume, V^E, over the entire concentration range. Furthermore, it is demonstrated that the non-randomness factors used in the excess volume expression can be used to estimate the excess Gibbs energy, G^E, of binary mixtures based on the Wilson equation.

The excess volume is one of the fundamental thermodynamic quantities of liquid mixtures and an enormous amount of data has been obtained for this quantity.[1,2] Systematic attempts to describe quantitatively the properties of liquid mixtures have been based on current solution theories, *i.e.*, the Flory theory,[3] the cell model of Prigogine and co-workers,[4] regular solution theory,[5] the corresponding state theory,[6] *etc.*[7,8] These theories are almost successful in expressing the excess thermodynamic functions of non-polar binary mixtures, but only quantitative agreement has been obtained for polar binary mixtures.

Recently, Wilson and Scatchard[9] proposed an expression for G^E, H^E, and S^E, which is in excellent agreement with experimental results. Following Wilson, Prausnitz and his collaborators[10-12] introduced some equations for G^E based on the idea of a local mole or segment fraction. Unfortunately, these equations do not include terms involving pressure as a variable, so that they cannot be used to express V^E.

In this study, a new equation for V^E is derived by introducing the idea of non-random mixing. This new expression contains two measurable and two adjustable, but physically-meaningful, parameters, *i.e.*, two partial molar volumes at infinite dilution and two non-randomness factors. The applicability of the equation will be examined for several binary mixtures in the literature.

Derivation of the New Equation

As the general model of a binary mixture, we take into account non-random mixing of two components as introduced into two liquid models proposed by Scott[6] and extended by Renon and Prausnitz.[10] We assume that the probability of finding molecules of one type (i molecules) in the vicinity of a central molecule (j molecule) can be represented by the local mole fraction in a solvation sphere. Furthermore, we assume that the excess functions are determined by the local mole fraction of the first solvation sphere. We denote the local mole fraction of the component i adjacent to the central molecule j by x_{ij}, which is equal to $1-x_{jj}$.

When $x_{11}=1$, the volume occupied by one mole of the first component is equal to its molar volume in the pure state, V_1^*. For the state for which $x_{21}=1$, the volume occupied by one mole of the first component is denoted by V_{21}. Accordingly, the volume occupied by one mole of the first component in a mixture is $(V_1^*x_{11}+V_{21}x_{21})$. Similarly, the volume occupied by the second component can be represented by $(V_2^*x_{22}+V_{12}x_{12})$ in a mixture. Consequently, the molar volume of the liquid mixture can be represented by

$$V_{mix} = x_1(V_1^*x_{11}+V_{21}x_{21}) + x_2(V_2^*x_{22}+V_{12}x_{12}), \quad (1)$$

where x_1 and x_2 are the mole fractions of the first and second components, respectively. Therefore, the excess volume of the binary mixture is

$$\begin{aligned} V^E &= V_{mix} - V_{ideal} \\ &= x_1x_{21}(V_{21}-V_1^*) + x_2x_{12}(V_{12}-V_2^*). \end{aligned} \quad (2)$$

Now, we introduce the non-randomness factor, Λ_{ij}, which relates the local mole fraction to the overall mole fraction by

$$\frac{x_{ij}}{x_{jj}} = \Lambda_{ij}\frac{x_i}{x_j} \quad (x_{ij}+x_{jj}=1). \quad (3)$$

The non-randomness factor has been independently defined by different authors as follows:

$$\Lambda_{ij} = \exp\frac{-\alpha_{ij}(g_{ij}-g_{jj})}{RT} \quad \text{(by Renon and Prausnitz)} \quad (4)$$

and

$$\Lambda_{ij} = \frac{V_i^*}{V_j^*}\exp\frac{-(\lambda_{ij}-\lambda_{jj})}{RT} \quad \text{(by Wilson)}, \quad (5)$$

where g_{ij} and λ_{ij} are the parameters corresponding to the interaction energy between the i and j molecules and α_{ij} is the parameter characteristic of the reciprocal of the coordination number of lattice. These two definitions for Λ have similar physical meanings. Wilson's definition includes the fixed volume term V_i^*/V_j^*, so that it cannot be applied to the calculation of V^E. The definition of the non-randomness factor used here is

$$\Lambda_{ij} = \exp\frac{-(\lambda_{ij}-\lambda_{jj})}{RT}, \quad (6)$$

since the local mole fraction is used. Recently, Huggins[13] pointed out that the parameters, g_{ij} and λ_{ij}, are of ambiguous units. So, the value of the non-randomness factors themselves were estimated, as Wilson did, although it is possible to express the non-randomness factors as a function of $(\lambda_{ij}-\lambda_{jj})/R$.

From Eq. 3, x_{ij} can be represented as

$$x_{ij} = \frac{x_i\Lambda_{ij}}{x_j+x_i\Lambda_{ij}}, \quad (7)$$

where $\Lambda_{jj}=\Lambda_{ii}=1$. By substitution of Eq. 7 into Eq. 2, the equation for a binary mixture is obtained, thus,

$$V^E = x_1x_2\left\{\frac{\Lambda_{21}}{x_1+x_2\Lambda_{21}}(V_{21}-V_1^*)+\frac{\Lambda_{12}}{x_1\Lambda_{12}+x_2}(V_{12}-V_2^*)\right\}. \quad (8)$$

This equation can be partially differentiated with respect to x_1, according to the relations, $(\partial V^E/\partial x_1)_{x_1=0}=(V_1^\infty-V_1^*)$ and $-(\partial V^E/\partial x_1)_{x_1=1}=(V_2^\infty-V_2^*)$, where V^∞ is the partial molar volume at infinite dilution. From this procedure, we obtain

$$V^E = x_1x_2\left\{\frac{x_2\Lambda_{21}(V_1^\infty-V_1^*)+x_1\Lambda_{12}(V_2^\infty-V_2^*)}{(x_1+x_2\Lambda_{21})(x_2+x_1\Lambda_{12})}\right\}. \quad (9)$$

Equation 9 shows that if the partial molar volumes at infinite dilution and, at least, two measured values of V^E are accurately obtained, the two non-randomness factors, Λ_{21} and Λ_{12}, can be calculated.

The advantage of this analysis is that the parameters in this expression are physically meaningful and the non-randomness factors thus obtained can be used to estimate the excess Gibbs energy by combination with the Wilson equation.[9] In this case, the Wilson equation must be transformed to

$$\frac{G^E}{RT} = -x_1\ln\left(x_1+\frac{V_2^*}{V_1^*}\Lambda_{21}x_2\right)-x_2\ln\left(\frac{V_1^*}{V_2^*}\Lambda_{12}x_1+x_2\right). \quad (10)$$

Applicability of the New Equation

Figure 1 shows some typical examples of theoretical curves of V^E. For curves 1, 3, and 5, the non-randomness factors are assumed to be constant and equal to 1. When $V_1^\infty-V_1^*=V_2^\infty-V_2^*$, the curve is symmetrical, but when $V_1^\infty-V_1^*\neq V_2^\infty-V_2^*$, a skewed curve is obtained. Especially, when $V_1^\infty-V_1^*>0>V_2^\infty-V_2^*$, the curve has an S-shape. Curves 2, 4, 6, and 7 show cases of non-randomness factors of different magnitudes. Curve 2 differs in flatness from curve 1. For curve 4, the mole fraction corresponding to $V^E=0$ is shifted to the left in comparison with curve 3. For curves 5, 6, and 7, the mole fractions giving maximum V^E values differ from

each other. It is found that the shape of the V^E curve is primarily determined by the signs and magnitudes of $V_1^\infty - V_1^*$ and $V_2^\infty - V_2^*$.

These theoretical results were tested against data from the literature for 20 binary mixtures. As stated previously, two non-randomness factors can be readily calculated from accurately measured values of V^E. For this purpose, the V^E data at $x_1=0.3$ and $x_1=0.7$ obtained using a reported smoothing equation were used. The calculated non-randomness factors are listed in Table 1 with the standard deviations of the smoothing and the theoretical curves.

The agreement between the present equation and experiment is quite satisfactory. Typical examples are shown in Fig. 2. As is shown in Table 1, the standard deviations of V^E calculated from the smoothing equation and the new equation are of the same order for systems have V^E curves of simple shape. For systems having S-shaped V^E curves, such as the benzene+methanol system, however, the standard deviation calculated from the new equation is larger than that for the smoothing equation. This is probably due to the uncertainty in the $V_i^\infty - V_i^*$ value. Generally, for systems having S-shaped V^E curves, the $V_i^\infty - V_i^*$ calculated using the new equation appear to be larger than those using the smoothing equation. Small $|V_i^\infty - V_i^*|$ values produce small maximum or minimum values of the V^E curves. For systems having S-shaped V^E curves, very good estimates of V^E can be made utilizing the alternative equation with four adjustable parameters: two non-randomness factors and two partial molar volumes.

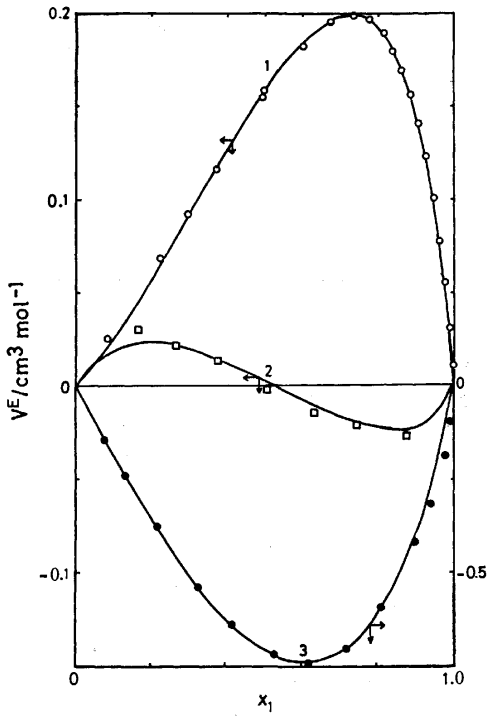

Fig. 2. The examples of the test of new equation for binary systems. Curve 1 corresponds to methanol+1-octanol system; curve 2, methanol+benzene; curve 3, water+2-butoxyethanol.

For systems containing nitroethane, the temperature dependence of V^E has been investigated by Handa *et al.*[19] It is of interest to apply the new equation to those systems. The estimated non-randomness factors are listed in Table 2. In Table 2, the system containing 2-methylpentane at 298.15 K is qualitatively fitted by Eq. 9, because of the S-shaped V^E curve. As is shown, the non-randomness factors tend to increase with temperature, which means that the mixture becomes ideal. This tendency is consistent with the expected behavior for normal mixtures. However, the temperature dependence of the non-randomness factors is larger than that predicted from either definition by Wilson and Scatchard[9] or by Renon and Prausnitz.[10] It is assumed that the molecular distribution adjacent to the central molecule is determined by two factors, *i.e.*, a combinatorial factor depending on the molecular size and shape, and a residual factor depending on the molecular interaction energy, and that the non-randomness factors account for these two factors. Furthermore, we have no method to separate the excess volume into two factors. Thus, it appears difficult to exactly express the temperature dependence.

The non-randomness factors calculated from the V^E data are not necessarily consistent with those defined in the Wilson equation, which are calculated from G^E data. Nevertheless, the G^E values for several binary mixtures calculated by applying the present non-randomness factors to the Wilson equation are in qualitative agreement with the observed value. As is shown in Fig. 3, the calculated G^E values for the benzene+*m*-xylene[20] and for the methanol+benzene[16] systems are in relatively good agreement with the observed values, while the calculated G^E values for the water+2-

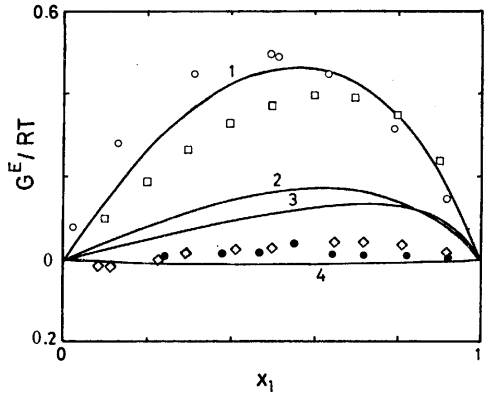

Fig. 3. Application of nonrandomness factor to Wilson equation. Curve 1 and ○ correspond to methanol+benzene system; curve 2 and □, water+2-butoxyethanol; curve 3 and ◇, methanol+1-butanol; curve 4 and ●, benzene+*m*-xylene.

butoxyethanol[17] and for the methanol+1-butanol[21] systems are in only qualitative agreement with the observed values. Recalling that the accuracy of the V^E data sensitively affect the reliability of the non-randomness factors, the poor agreement between the latter two systems is partly due to the uncertainty in the non-randomness factors.

Conclusion

The new equation with only two parameters successfully fits the excess volumes of binary mixtures to the same order as the smoothing equation. These two parameters have exact physical meanings, contrary to the traditional smoothing equation parameters. At the present stage, the G^E calculated from V^E data are in qualitative agreement with observed values.

The authors wish to thank Mr. H. Watarai for helpful discussions throughout this study.

Viscoelastic Behavior of Some Di(normal alkyl) Phthalates

Noriyuki KINJO* and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 28, 1977)

The viscoelastic behavior of a homologous series of di-*n*-alkyl phthalates varying in alkyl chain length from methyl- to nonyl- was studied by means of torsional braid analysis (TBA). The glass transition temperatures, T_g, were determined as the temperature at loss maximum. The T_g decreases with increasing alkyl chain length in the di-*n*-alkyl phthalates, up to dibutyl. Thereafter, the T_g increases gradually with further increase in the alkyl chain length. This behavior can be explained by taking into account two factors which determine the T_g, the molecular weight and the intermolecular interaction. The increase in the number of methylene groups in the phthalates brings about two effects: first, the T_g is increased with increasing molecular weight and, second, the T_g is decreased owing to shielding of the interaction between polar carbonyl groups due to the presence of non-polar methylene groups. When the number of methylene groups is four, the two effects counterbalance each other and the T_g of dibutyl phthalate is the lowest of the di-*n*-alkyl phthalate series.

It is generally recognized that the glass transition temperatures (T_g) of polymers or oligomers can vary with the chain length, and a number of studies have been reported which are concerned with the relationship between the T_g and the molecular weight of polymers and, moreover, the factors affecting the dependence of the T_g on the molecular weight.[1-6] It may be pointed out that several factors affect the T_g-molecular weight relation: these include the crystallinity, the molecular weight distribution, the complexity of the backbone chain, such as the stiffness or flexibility, the polarity, and the end-group or chain association effect.[5,6,11] In spite of its importance, the mutual relation of these factors is not clear at present. In particular, it is likely that no attention was paid to the association effect caused by end-groups, since the effect is very slight compared with that of the molecular weight.[4] It is guessed that this end-group effect is appreciable only when the chain length is very short, that is, when the molecular weight is low. It is the purpose of the present work to clarify the effectiveness of the end-groups on the T_g-molecular weight relation.

However, the relaxation behavior of low molecular-weight glassy substances was more recently noted in analogy to that of polymers.[7-10] Secondary dispersions have already been observed for 1-alkanols and lactones, and were discussed in relation to the molecular motions of methylene sequences.[7-9] It is the aim of the present paper to report whether similar behavior due to methylene sequences appears in di-*n*-alkyl phthalates.

Experimental

Samples. The samples used in this study were various di-*n*-alkyl phthalates: dimethyl phthalate (DMP), diethyl phthalate (DEP), dipropyl phthalate (DPrP), dibutyl phthalate (DBP), dipentyl phthalate (DPeP), dioctyl phthalate (DOP), and dinonyl phthalate (DNP). These phthalates received from commercial souces were washed in water, dried on molecular sieves, and then distilled *in vacuo*. The conditions were as follows: DMP −132 °C/666 Pa, DEP −141 °C/666 Pa, DPrP −158 °C/666 Pa, DBP −182 °C/666 Pa, DPeP −170 °C/66.6 Pa, DOP −165 °C/13.3 Pa, DNP −184 °C/13.3 Pa.

Measurements. The viscoelastic behavior of di-*n*-alkyl phthalates was studied using the torsional braid analysis (TBA) method at a frequency of 0.5 Hz. After dipping a glass braid used as the supporting substrate into liquid samples, these sample-braid composite systems were mounted on the torsional pendulum apparatus, quickly immersed in liquid nitrogen, and then damping measurements were made for an increasing temperature rate of 0.5 °C/min.

Using the TBA method, the elastance of sample-glass braid composite system is obtained, and not the elasticity of the samples themselves. Since it was previously confirmed that the glass braid shows no dispersion in this temperature region, the observed dispersion behavior is considered to be due to the impregnating sample itself.[12,13]

Results and Discussion

The viscoelastic behavior of di-*n*-alkyl phthalates is shown in Figs. 1 and 2. The storage elastance rapidly decreases in the temperature region in which the maximum of the loss elastance occurs. For damping measurements, the glass transition temperature (T_g) is customarily taken as the temperature of maximum loss elastance. The T_g values, which lower than the melting points by 30—60 °C, are summarized in Table 1 together with the melting points of the phthalates. T_g determined using the DTA have been reported by Garfield and Petrie[14] to be −85 °C for diethyl phthalate and −87 °C for dioctyl phthalate. This is in good agreement with the present data, taking into account the frequency of 0.5 Hz of the present TBA method.[16]

In the case of dimethyl and dioctyl phthalates, the viscoelastic behavior differs somewhat from that of the other phthalates. In the present experiments, the samples were quickly cooled down to glass form and then the temperature was gradually raised. The storage elastance first decreases near the T_g value. A subsequent increase in storage elastance is observed and may be attributed to crystallization, because, generally speaking, substances can be crystallized only in the supercooled liquid state at temperatures between the T_g and the melting point. With further increase in the temperature the storage elastance finally decreases again due to fusion. The temperature of the final decrease in storage elastance approximately coincides with the melting

point of −25 °C for dioctyl phthalate and of 0 °C for dimethyl phthalate. Corresponding to the above-mentioned behavior, the loss elastance *vs.* temperature curves show two maxima. The other phthalates may not crystallize as do the dioctyl and dimethyl phthalates, and each shows a single dispersion due to the glass transition.

It is well established that the T_g of polymers becomes higher with increasing molecular weight.[1-3] Recently, Cowie has studied the dependence of the T_g on the molecular weight for a number of oligomers and polymers.[6] The change in T_g with increasing molecular weight is more marked in the oligomeric region than in the polymeric region.

Figure 3 shows the T_g values of di-*n*-alkyl phthalates as a function of the alkyl chain length, ***n***. Compared with the case of usual polymers or oligomers, the change in the T_g with chain length is particularly interesting in the case of the di-*n*-alkyl phthalate series. The T_g decreases with increasing alkyl chain length up to dibutyl. Thereafter, the T_g increases gradually with a further increase in the alkyl chain length. This behavior is not satisfactorily explained by the conventional concept of the T_g-molecular weight relation. It is necessary to consider that there exist two factors which determine the T_g: (1) the molecular weight or chain length and (2) the intermolecular interaction. The increase in the number of methylene groups in the di-*n*-alkyl phthalates brings about two effects: first, the T_g becomes higher with increasing molecular weight and, second, the T_g decreases due to shielding of the interactions between the polar carbonyl groups and/or the aromatic rings due to the presence of non-polar methylene groups. When the number of methylene groups is four, the two effects counterbalance each other and the T_g of the dibutyl phthalate is the lowest of the di-*n*-alkyl phthalate series.

Figure 3 also shows the two sets of series of T_g *vs.* alkyl chain length plots for 1-alkanols[9] and lactones.[8] In this case, each has a different polar end-group, one having an –OH group and the other a –COO– group, respectively. An identical trend is also observed for

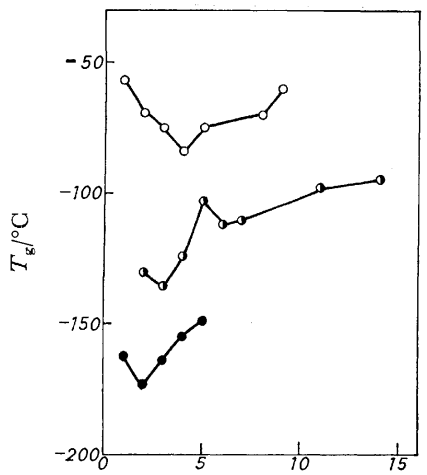

Fig. 3. Glass transition temperature T_g of di-*n*-alkyl phthalates, 1-alkanols,[9] and lactones[8] as a function of n, where n is the number of methylene groups.
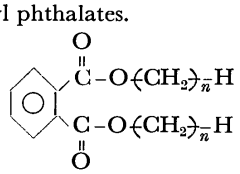
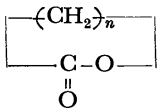
○: Di-*n*-alkyl phthalates.



◑: Lactones.[8]



●: 1-Alkanols.[9]

$H(CH_2)_nOH$

these two series. In the 1-alkanol series, a pronounced minimum T_g value is observed for ethyl alcohol, that is, $n=2$. On the other hand, in the lactone series, the minimum T_g value is situated at $n=3$, that is, γ-butyrolactone.

It is believed that the n-value which shows the minimum T_g value in a given series having methylene groups depends on the mutual interaction strength of the end-groups. The stronger the interaction between the attractive groups in molecules, the larger the n-value, since longer methylene sequences are required in order to shield the attractive force which brings about a higher T_g. Such a concept appears to be reasonable from the results shown in Fig. 3.

With regard to the secondary dispersions of low molecular-weight substances, several investigators have observed dispersions at temperatures below the T_g for 1-alkanols,[7,9] lactones,[8] glucose pentaacetate, *etc.*[10] Some were not observed in dielectric loss measurements and were assigned to molecular motions of alkyl chains. However, for the di-*n*-alkyl phthalates reported here, no secondary dispersion was observed at all, as is shown in Fig. 2. Further experiments on other systems will be necessary in order to elucidate this very interesting problem.

The authors wish to express their thanks to Professor T. Komatsu and Dr. K. Nakamura of Hokkaido University for helpful discussions. The present work was supported in part by a Grant for Scientific Research from the Ministry of Education.

Kinetics of the Reaction at the Silver Sulfide-Liquid Sulfur Interface

Jun SASAKI, Junichiro MIZUSAKI, and Kazuo FUEKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 17, 1977)

The reaction rate, v, at the $Ag_2S/S(l)$ interface was determined as a function of the silver activity a_{Ag} in Ag_2S utilizing a solid-state electrochemical cell, $Ag/AgI/Ag_2S/Pt$. The rate equation was found to be expressed by $v=k(a_{Ag})^2-k'$. On the basis of the theory by Kobayashi and Wagner, the rate-controlling step of the $Ag_2S/S(l)$ interface reaction is concluded to be $S^-(ad)+e\rightarrow S^{2-}(ad)$. The overall reaction rate of silver sulfidization by liquid sulfur can be well explained by the mixed control of a three-step reaction; the $Ag_2S/S(l)$ interface reaction, the diffusion of silver ions in Ag_2S, and the Ag/Ag_2S interface reaction.

Alpha-AgI is an ionic conductor, the conductivity of which is as high as that of aqueous ionic solutions. This extraordinarily high conductivity is due to the special crystal structure. Also, silver chalcogenides, Ag_2X, have high ionic and electronic conductivities due to their structure and non-stoichiometry. Therefore, several electrochemical investigations have been carried out using α-AgI as an electrolyte and silver chalcogenides as electrodes. The silver activity in solid Ag_2X can be determined by emf measurements using an electrochemical cell, $Ag/AgI/Ag_2X$. Conversely, when a constant voltage is applied to the cell, the silver ions flow through AgI and the electrons, through the outer circuit. As a result, silver atoms are transferred from Ag to Ag_2X or in the reverse direction, the rate of silver transfer can be measured as the electric current. When the equilibrium is established between Ag and Ag_2X under an applied constant voltage, the silver activity in Ag_2X has a constant value corresponding to the applied voltage. Therefore, the silver activity in Ag_2X can be controlled by the voltage applied to the cell.

So far, various thermodynamical and kinetic measurements have been done by means of the Ag/AgI Ag_2X cell. For example, the non-stoichiometric ranges and phase relations of Ag–S,[1,2] Ag–Se[3,4] and Ag–Te[5] systems have been investigated by the coulometric titration technique, and kinetic studies have been carried out on solid-solid[6,7] and gas-solid[8–11] interface reactions.

Electrochemical methods in which the $Ag/AgI/Ag_2X$ cell is employed give interesting results which cannot be obtained by other methods for the investigation of solid-state reactions. The present work aims to study the $Ag_2S/S(l)$ interface reaction kinetically using the $Ag/AgI/Ag_2S$ cell.

Experimental

Materials. A silver rod was prepared by melting silver powder (99.99% purity) and casting it in a silica tube, 10 mm in inner diameter. The rod was cut into pellets 10 mm thick, and a hole, 1.5 mm in diameter, was drilled along the axis of each pellet. Silver sulfide was prepared by the sulfidization of silver with liquid sulfur. One end of a glass tube, 10 mm in outer diameter and 8 mm in inner diameter, was finished as flat as possible, placed in contact with a silver pellet, and pressed by a weight. Then, sulfur purified by vacuum distillation was dropped into the glass tube to react the sulfur with silver at 200 °C. Since the lower end of the tube was so flat that leakage of liquid sulfur could be avoided. Silver sulfide grown in the glass tube was taken out and sliced into pellets 2—3 mm thick. Each pellet was pressed under a pressure of 5 t/cm² and polished to a thickness of about 1 mm. Silver iodide pellets, 10 mm thick were prepared by pressing AgI powder under a pressure of 5 t/cm².

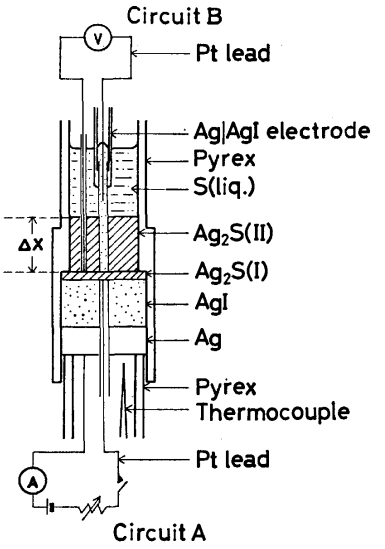

Fig. 1. Apparatus for the measurement of the rate of $Ag_2S/S(l)$ interface reaction.

Kinetic Study on the $Ag_2S/S(l)$ Interface Reaction. The apparatus and technique employed in the present study were generally similar to those used by Mizusaki and his co-investigators[12] for their investigation of the $Ag_2Se/Se(l)$ interface reaction. However, an improvement was made in the apparatus, since the dissociation pressure of Ag_2S is higher than that of Ag_2Se.[13] As is shown in Fig. 1, two glass tubes, one of which was 13 mm in inner diameter, the other being 10 mm in inner diameter, were joined. Three pellets of Ag, AgI, and $Ag_2S(I)$, 10 mm in diameter, were assembled and pressed with the joined glass tube. Since AgI tends to deform plastically, the pressing resulted in a close contact between the AgI pellet and the inner wall of the glass tube. Thus, the vaporization of sulfur from Ag_2S could be prevented. The end surface of the glass tube was finished as flat as possible so that liquid sulfur could be held in the tube without leakage when the end was placed in contact with the $Ag_2S(I)$ pellet. The Ag/AgI electrode in a small alumina tube, 1.5 mm in outer diameter, was placed in the glass tube so that the tip could be brought to contact with the surface of the $Ag_2S(I)$ pellet. The reaction rate was measured as an electric current flowing through the outer circuit A, by means of an ammeter, while the poten-

tial difference between the $Ag_2S(I)$ pellet and Ag was determined by means of potentiometer.

Rate Measurement of the Reaction between Silver and Liquid Sulfur. The same apparatus and technique as used by Mizusaki and his co-investigators[12] were employed for the measurement. A silver cylinder, 8 mm in diameter, and a Ag_2S pellet, 10 mm in diameter, were assembled and pressed with a glass tube, 10 mm in outer diameter. Then, sulfur was dropped into the glass tube, and the change in the thickness of the Ag_2S pellet was followed with time by means of a cathetometer.

Observation of the Ag_2S Surface with SEM. After the sulfidization, the liquid sulfur was poured out and the residual sulfur on the surface of Ag_2S was dissolved with CS_2. The surface of the Ag_2S thus obtained was examined by means of an SEM.

Results and Discussion

Observation on the Ag_2S Surface by Means of SEM. Observation of the surface of Ag_2S by means of SEM revealed that the surface of Ag_2S is always compact, regardless of the experimental conditions, as is shown in Fig. 2.

Results of a Kinetic Study of the $Ag_2S/S(l)$ Interface Reaction. When the circuit A is open, $Ag_2S(I)$ is in equilibrium with the liquid sulfur, and the potential difference, $E°$, appearing in the circuit B gives the standard free energy formation of Ag_2S by means of the following relation,

$$E° = -\Delta G°/2F, \tag{1}$$

where F is Faraday's constant. If metallic silver is taken as the standard state, the silver activity, a^*_{Ag}, in Ag_2S equilibrated with liquid sulfur is represented by the equation

$$a^*_{Ag} = \exp(-F\cdot E°/R\cdot T). \tag{2}$$

When the switch is turned on and a constant current, I, is allowed to flow in, the silver ions are transported from the Ag electrode to the $Ag_2S(I)/S(l)$ interface through AgI and $Ag_2S(I)$, while the electrons flow from the Ag electrode to the $Ag_2S/S(l)$ interface through the outer circuit and $Ag_2S(I)$. The silver ions and electrons arriving at the $Ag_2S(I)/S(l)$ interface react with liquid sulfur to form $Ag_2S(II)$ in the glass tube at a constant rate. Accordingly, the Ag/AgI electrode used for the measurement of the potential difference is buried in the $Ag_2S(II)$ layer. If the area of the $Ag_2S/S(l)$ interface is represented by A, the reaction at the $Ag_2S/S(l)$ interface proceeds at a rate of $I/2F\cdot A$ and a potential difference is produced at the $Ag_2S(II)/S(l)$ interface. If the silver activity in $Ag_2S(II)$ at the $Ag_2S/S(l)$ interface and that in $Ag_2S(I)$ at the tip of Ag/AgI electrode are designated by a'_{Ag} and a_{Ag} respectively, and if the thickness of $Ag_2S(II)$ layer is Δx, the following relations are obtained:

$$E' - E = \frac{I\cdot\Delta x}{\sigma_{Ag^+}\cdot A}, \tag{3}$$

$$E' = -\frac{2.303R\cdot T}{F}\log a'_{Ag}, \tag{4}$$

$$E = -\frac{2.303R\cdot T}{F}\log a_{Ag}, \tag{5}$$

where σ_{Ag^+} is the ionic conductivity of Ag^+ ions in Ag_2S. In Eq. 3, σ_{Ag^+} is assumed to be independent of the silver activity in Ag_2S.[14]

Figure 3 shows the plot of E *vs.* Δx at 200 °C. Since $I/\sigma_{Ag^+}A$ is constant under a constant current, I, E' is determined from the intercepts of the ordinate with the

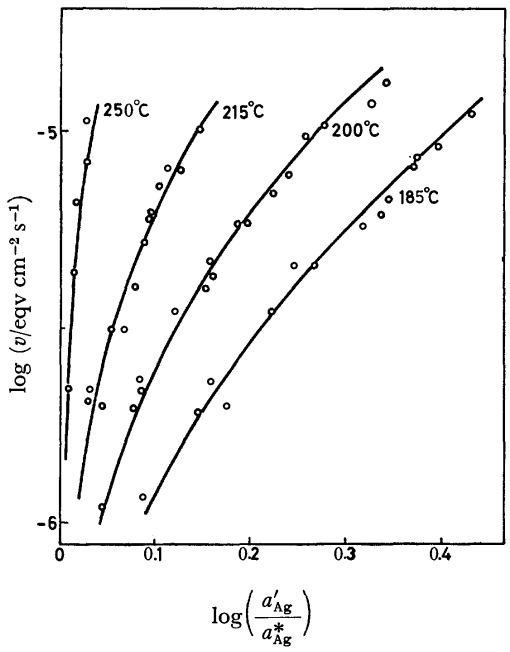

Fig. 4. Plots of log v *vs.* $\log(a'_{Ag}/a^*_{Ag})$.

extrapolated lines. The $E°$ measured in the present work is shown by an arrow. It is in good agreement with that obtained by Kiukkola and Wagner.[5] The potential difference, $E°-E'$, gives the driving force of the Ag_2S/S(l) interface reaction.

Figure 4 shows the relationship between the reaction rate and a'_{Ag}/a^*_{Ag}. The logarithm of a'_{Ag}/a^*_{Ag} is equivalent to $(E°-E')/2.303\ R\cdot T$.

Kinetics of the Ag_2S/S(l) Interface Reaction. Kobayashi and Wagner[8] studied the kinetics of the reduction of Ag_2S by H_2 and found that the rate of reduction at the gas-solid interface depends not only on the partial pressure of the reacting gases, but also on the activity of the reacting chemical species in solid. A similar dependence of the surface reaction rate on the activity of the reacting chemical species was observed in redox reactions between CO_2 or CO and metal oxides, such as FeO,[15,16] Fe_3O_4,[15] and CoO,[17] and in redox reactions between H_2S or H_2 and metal sulfides.[18,19] From these results, it is concluded that the dependence of the reaction rate on the activity of the reacting chemical species in solids would be like that for the gas-solid interface reactions. In the case of the Ag_2S/S(l) interface reaction, the reaction rate was found to depend on the silver activity of Ag_2S at the Ag_2S/S(l) interface, as is shown in Fig. 4. So, it is expected that a mechanism similar to that of the gas-solid interface reaction would be operative in the present interface reaction.

According to Gee's[20] study, the molecular species of liquid sulfur are S_8 and S_6 with a cyclic structure and polymeric sulfur in the temperature range of the present investigation. They are in equilibrium with each other. At the Ag_2S(II)/S(l) interface, S_x molecule would adsorb and dissociate in the following way:

$$S_x(l) = xS(ad). \tag{6}$$

Since the density of liquid sulfur is several thousand times that of sulfur vapor, it is considered that the surface of Ag_2S is saturated with adsorbed sulfur and that the surface concentration of S(ad) is constant.

The process whereby S(ad) is reduced to S^{2-}(ad) must be

$$S(ad) + e \longrightarrow S^-(ad), \tag{7}$$

$$S^-(ad) + e \longrightarrow S^{2-}(ad). \tag{8}$$

Since S(ad) is in equilibrium with S(l), $a_s(ad)$ is equal to $a_s(l)$. Moreover, it is assumed that S^{2-}(ad) is in equilibrium with the S^{2-} ion in Ag_2S and that equilibria are established among chemical species, Ag, Ag^+, e, S, S^-, and S^{2-}, in Ag_2S. As the activity of Ag^+, a_{Ag^+} is constant regardless of the composition of Ag_2S,[1] the activity of the respective species depends on a'_{Ag} as follows:

$$a_e \propto a'_{Ag}, \tag{9}$$

$$a_{Ag^+},\ a_{S^{2-}} = \text{const.} \tag{10}$$

a) If Reaction 7 is rate-controlling,

$$v_1 = \vec{k}_1 a_S(ad) a_e - \overleftarrow{k}_1 a_{S^-}(ad). \tag{11}$$

The $a_s(ad)$ activity is equal to $a_s(l)$ and is independent of a'_{Ag}. Since a preliminary equilibrium is established in Eq. 8,

$$\frac{a_{S^{2-}}(ad)}{a_{S^-}a_e} = K_2, \tag{12}$$

that is

$$a_{S^-} = \frac{a_{S^{2-}}(ad)}{K_2}(a_e)^{-1}. \tag{13}$$

The $a_{S^{2-}}(ad)$ activity is equal to $a_{S^{2-}}$ in the Ag_2S bulk; therefore,

$$a_{S^-} \propto a'^{-1}_{Ag}. \tag{14}$$

Thus, Eq. 11 can be rewritten in the form

$$v_1 = k_1 a'_{Ag} - k_{-1}(a'_{Ag})^{-1}. \tag{15}$$

b) If Reaction 8 is rate-controlling,

$$v_2 = \vec{k}_2 a_{S^-}(ad) a_e - \overleftarrow{k}_2 a_{S^{2-}}(ad). \tag{16}$$

Assuming that equilibrium is kept for Reaction 7, we obtain

$$\frac{a_{S^-}(ad)}{a_S(ad)a_e} = K_1. \tag{17}$$

Thus,

$$a_{S^-}(ad) = K_1 a_S(ad) a_e \propto a'_{Ag}. \tag{18}$$

Accordingly,

$$v_2 = k_2(a'_{Ag})^2 - k_{-2}. \tag{19}$$

As may be noticed from Eqs. 15 and 19, the rate equations have the general expression,

$$v = \vec{k}(a'_{Ag})^m - \overleftarrow{k}(a'_{Ag})^{-n}, \tag{20}$$

where $m=1$ and $n=1$ when the S(ad) + e → S^-(ad) reaction is slow, and $m=2$ and $n=0$ when the S^-(ad) + e → S^{2-}(ad) reaction is slow. When the equilibrium is established between Ag_2S and liquid sulfur, v in Eq. 20 is zero; therefore,

$$\vec{k}(a^*_{Ag})^m = \overleftarrow{k}(a^*_{Ag})^{-n}. \tag{21}$$

The insertion of Eq. 21 into Eq. 20 gives

$$v = \vec{k}(a^*_{Ag})^m \left\{ \left(\frac{a'_{Ag}}{a^*_{Ag}}\right)^m - \left(\frac{a'_{Ag}}{a^*_{Ag}}\right)^{-n} \right\}$$
$$= k \left\{ \left(\frac{a'_{Ag}}{a^*_{Ag}}\right)^m - \left(\frac{a'_{Ag}}{a^*_{Ag}}\right)^{-n} \right\}. \quad (22)$$

A curve-fitting calculation using data for 185 °C and 200 °C in Fig. 4 showed that a set of $m=2$ and $n=0$ gives a better agreement between the calculated and observed values than a set of $m=1$ and $n=1$. It is concluded that the $S^-(ad)+e \rightarrow S^{2-}(ad)$ reaction is rate-controlling for the $Ag_2S/S(l)$ interface reaction.

In the case of $m=2$ and $n=0$, Eq. 22 is rewritten as

$$v = k \left\{ \left(\frac{a'_{Ag}}{a^*_{Ag}}\right)^2 - 1 \right\}. \quad (23)$$

Figure 5 shows the plot of log v *vs.* log $\{(a'_{Ag}/a^*_{Ag})^2-1\}$. The data for each temperature fall on a straight line. From the intercept of the ordinate with the plotted lines, we can calculate the rate constant, k. Figure 6 shows the Arrhenius plot for k. The Arrhenius equation is

$$k = 1.22 \times 10^7 \exp\left(\frac{-26900}{RT}\right) \quad (\text{eqv cm}^{-2}\,\text{s}^{-1}) \quad (24)$$

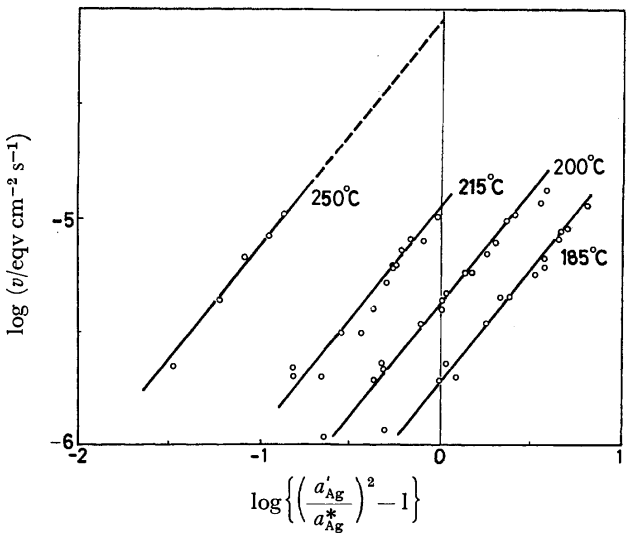

Fig. 5. Plots of log v *vs.* $\log\{(a'_{Ag}/a^*_{Ag})^2-1\}$.

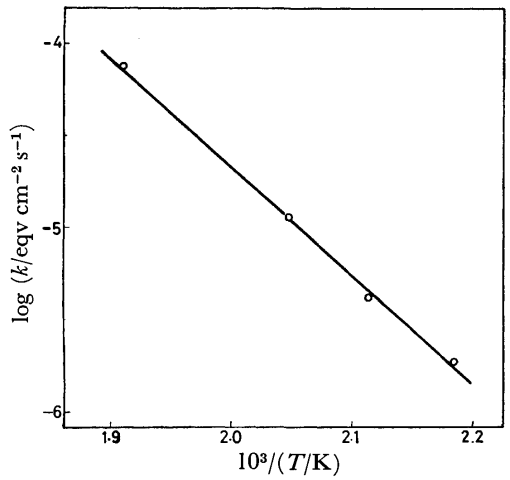

Fig. 6. Arrhenius plot of k.

Driving Forces of the Three Steps of Silver Sulfidization. The reaction of metal tarnishing consists of three elementary steps:

1) Reaction at the metal/scale interface,
2) diffusion of electrons and ions through the growing scale, and
3) reaction at the gas (or liquid)/scale interface.

If one of these steps is rate-controlling, the driving force, that is, the difference in the silver chemical potential of the step, is equal to that of the over-all reaction. If two or three steps are simultaneously slow, the driving force of the over-all reaction is divided into two or three parts.

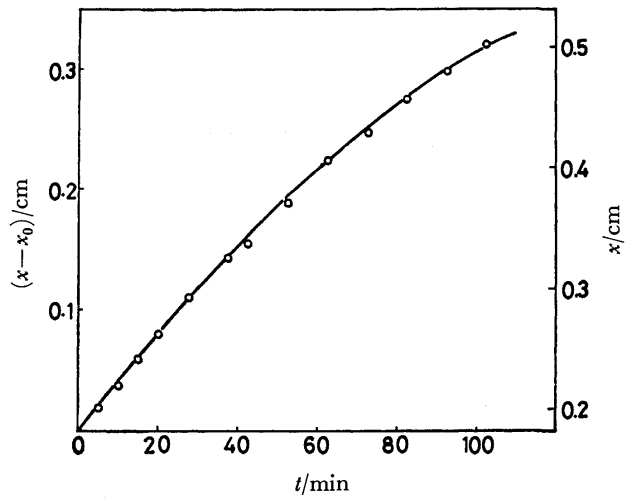

Fig. 7. Plot of x or $x-x_0$ *vs.* time.

Mizusaki and his co-investigators[12] have determined the distribution of the chemical potential of silver in a growing Ag_2Se layer in the selenization of silver, and have found that Ag_2Se and Se(l) are actually in chemical equilibrium during the reaction. In the present study, the difference in the silver chemical potential across the $Ag_2S/S(l)$ interface was observed during the sulfidization. This finding suggests that the sulfidization of silver is mixed-controlling. Therefore, the driving force for each reaction step was calculated from the sulfidization curve given in Fig. 7. In this figure, x is the total thickness of the Ag_2S layer and $x-x_0$ is the increase in the thickness of the Ag_2S layer. The over-all reaction rate is calculated by the graphical differentiation of the curve. The ionic conductivity of Ag_2S is calculated from Eq. 3 and the gradient of the straight lines in Fig. 2. Thus,

$$\sigma \cdot T = 3.8 \times 10^4 \exp\left(\frac{-2900}{RT}\right) \quad (\text{ohm}^{-1}\,\text{cm}^{-1}\,\text{K}). \quad (25)$$

The value agrees with the result obtained by means of the four-probe conductivity measurement.[21]

If the silver activity of Ag_2S at the Ag/Ag_2S interface is denoted by a''_{Ag}, the logarithm of silver activity ratio (a'_{Ag}/a''_{Ag}) is

$$\log\left(\frac{a'_{Ag}}{a''_{Ag}}\right) = \frac{I \cdot xF}{\sigma_{Ag^+} \cdot A \cdot R \cdot T}$$
$$= \frac{vx \cdot F^2}{\sigma_{Ag^+} \cdot R \cdot T}. \quad (26)$$

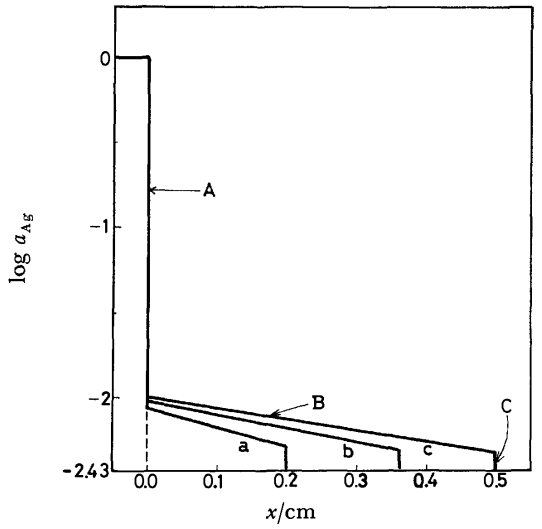

Fig. 8. Distribution of log a_{Ag} during the reaction at 200 °C.
a: $t=0$ min. b: $t=50$ min. c: $t=100$ min.
A: Potential difference at Ag/Ag_2S interface.
B: Potential difference in Ag_2S layer.
C: Potential difference at $Ag_2S/S(l)$ interface.

The activity ratio (a'_{Ag}/a^*_{Ag}) at the $Ag_2S/S(l)$ interface is obtained from the relation of v *vs.* log (a'_{Ag}/a^*_{Ag}) in Fig. 4. Since the reaction rate, v, can be obtained from Fig. 7, and since log a^*_{Ag} is calculated by means of Eq. 2, the distribution of the chemical potential of silver in the Ag_2S layer during the sulfidization can be drawn. Figure 8 shows the plots of log a_{Ag} against x. Evidently, the over-all reaction is mixed-controlling by means of three reaction steps. From Fig. 8 we can estimate the chemical potential difference at the Ag/Ag_2S interface during the reaction. The result is in good agreement with the result of the electrochemical measurement carried out by Mizusaki and his co-investigators.[7]

Summary

(1) The $Ag_2S/S(l)$ interface reaction was investigated kinetically. The rate equation was found to be represented by

$$v = 1.22\times10^{7}\exp\left(\frac{-26900}{RT}\right)\left\{\left(\frac{a'_{Ag}}{a^*_{AG}}\right)^2-1\right\}.$$

(eqv cm^{-2} s^{-1})

It was also concluded that the reaction step,

$$S^-(ad) + e \longrightarrow S^{2-}(ad),$$

is rate-controlling.

(2) The driving forces of the $Ag_2S/S(l)$ interface reaction and the diffusion of the silver ions in Ag_2S were quantitatively determined. In the initial stage of sulfidization, the over-all reaction was mixed-controlled by means of three step reactions: $Ag_2S/S(l)$ interface reaction, diffusion, and Ag/Ag_2S interface reaction.

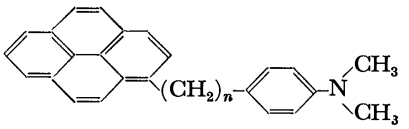
(Received October 22, 1977)

Absorption spectra of inter- and intramolecular exciplex systems of pyrene and *N,N*-dimethylaniline in alcoholic solution were obtained by means of ns laser photolysis. The spectra of intermolecular systems can be reproduced by the superposition of bands of the pyrene anion and the *N,N*-dimethylaniline cation. Similar results were obtained with intramolecular systems of P_1 and P_2, where P_n is (1-pyrenyl)-$(CH_2)_n$-(*p*-dimethylaminophenyl). The absorption band of P_3 exciplex is structureless and very broad, the position of the maximum remaining unchanged. From the relation between absorption spectra and conformation of intramolecular systems, it is concluded that the broad band is due to the sandwich type of structure of the donor cation and the acceptor anion. Anomalous behavior of intermolecular exciplexes in alcoholic solutions is discussed on the basis of their absorption spectra.

The measurement of the absorption spectra of excited molecules in solution has become possible by application of lasers. The absorption spectra of exciplex systems have been measured by several workers[1-5] and the following problems have been discussed: (a) The back CT transition from the anionic moiety to the cationic one. The absorption band due to this transition can be observed in addition to the absorption bands ascribed to the transitions localized in anion as well as cation. (b) Dependence of spectra upon solvent, which has its origin in fluorescence studies on exciplexes.[6] (c) The relation between absorption spectra of exciplexes and their geometrical conformation. We have examined these problems comparing the results of inter- and intramolecular exciplex systems in the same solvent.

The other subject of the present work is to study the exciplexes in alcohols by means of their absorption spectra. The behavior of exciplexes is very sensitive towards environments, some anomalies in alcohols being pointed out as follows. (i) According to the results on the intermolecular exciplex system composed of pyrene (Py) and *N,N*-dimethylaniline (DMA) in aprotic solvents,[7,8] quantum yield and lifetime of exciplex fluorescence decrease with increase in solvent polarity. When dielectric constant is *ca.* 12 the yield decreases sharply, ionic dissociation occurring in place of fluorescent exciplex formation.[9] However, the exciplex fluorescence in alcoholic solutions shows smaller red shift, higher quantum yield and longer lifetime as compared to the results in aprotic solvents with the same value of dielectric constant.[3,10] The experimental values in various alcohols show dependence upon solvent dielectric constant in a similar manner to that in the case of aprotic solvents. In other words, the results in protic solutions correspond to those in aprotic ones with lower value of dielectric constant. (ii) The ionic dissociation to free cation and anion was investigated in polar solvents and empirical equations representing the relationship between dissociation yield and the solvent dielectric constant were proposed.[11] Although the same type of equation is satisfied in both cases of alcohols and aprotic solvents, the parameters in the equation differ from each other.

In the present work absorption spectra of inter- and intramolecular exciplex systems of Py and DMA were observed in some alcohols by means of ns laser photolysis. The intramolecular systems of P_n, (n=1, 2, 3),



were examined in order to clarify the relation between spectra and geometrical conformation. Absorption spectra of intermolecular exciplex were observed in 1-pentanol, 2-propanol, and ethanol. The dynamics of exciplex in alcohols are discussed on the basis of these spectra.

Experimental

Laser Photolysis Apparatus. The details of our ns laser photolysis apparatus are essentially the same as those reported.[12] Improvement was made on the wiring of photomultiplier HTV 1P28 for improving S/N ratio.[13] Examined voltage larger than the standard value is supplied to 1—5 dynodes, the signal current being withdrawn from the 6th dynode with 50 Ω resistor. Negative value of 50 V was supplied to the remainder of dynodes in order to obtain correct time-response. The breeder current of the last two dynodes is 30 mA. A series of capacitors are set between successive dynodes. The linearity of an output signal was checked, the sum of intensity of fluorescence and monitoring flash lamp being confirmed to be measured correctly.

Improvement was also made by setting a simple and convenient monitoring device for exciting pulse intensity. The 347 nm pulse is partially reflected, scattered with MgO and lead to a pin photodiode HP 5082 4220. The signal is deformed to a pulse, whose height is a few volt and decay time is 10 ms, by use of a peak hold circuit.[14] Relative intensity of an exciting pulse is digitally given on solid state display, which holds the value until the next laser shot is given. This device was checked with an oscilloscope-photomultiplier system and also by a thermopile (HADRON 100).[15]

Linearity between the Intensity of an Exciting Laser Pulse and Measured Optical Density. Besides nonlinear effect due to high intensity laser excitation, geometrical correlation between exciting beam and monitoring light sometimes leads to a

*To whom all correspondence should be addressed.

deviation from linearity between the intensity of an exciting pulse and measured optical density.[16] This can be ascribed to the contribution of stray light from an exciting pulse to monitoring light, or to inhomogeneous spatial distribution of an exciting pulse. The linearity was confirmed by measuring the T-T absorption spectra of anthracene in ethanol and the bands of anions produced through the ionic dissociation of Py–DMA and 1,2,4,5-tetracyanobenzene–toluene systems in acetonitrile.

Absorption spectra of the exciplex systems were obtained by use of oscillograms at various wavelength. The fluctuation of an excitation intensity was ±6%.

Materials. Py, DMA, and P_n's are the same as used previously.[4,17] The GR grade 2-propanol, 1-pentanol and ethanol were used without purification. The concentration of solution was adjusted so that the optical density at 347 nm is about unity. This corresponds to the order of 10^{-3} and 10^{-5} M in the cases of inter- and intramolecular systems, respectively. The concentration of DMA in the former system was determined so as to quench the Py fluorescence more than 95%. All the solutions were degassed by the usual freeze-pump-thaw method.

Results

Since the exciplex consisting of aromatic hydrocarbon and amine has a large dipole moment, its electronic structure is considered to be an ion-pair of the donor cation and the acceptor anion. The absorption spectra may be similar to the sum of bands of the donor cation and the acceptor anion. The back CT transition from the anion to the cation is also expected to appear.[1,3,18] Usually the reference spectra used for the assignment of the exciplex absorption spectra are those of an anion produced by alkaline metal reduction of hydrocarbon and of a cation produced by γ-irradiation. The difference of measuring apparatus and of environments of ions lead to some ambiguity in discussing the spectral shape. The transient spectra of intermolecular Py–DMA system in acetonitrile are referred to, since their measurements can be made by the same laser photolysis apparatus and in the fluid solution. It is well known that the ionic dissociation to the Py anion and the DMA cation is the main deactivation process in acetonitrile, and its quantum yield is about 0.8.[19] Since no chemical species other than ions and triplet Py is detected, these spectra are the best reference for assigning the $S_n \leftarrow S_1$ spectra of exciplexes. The result is given in Fig. 1. The bands at about 24000 cm^{-1} and at 20100 cm^{-1} are ascribed to the triplet Py and to the Py anion, respectively. The shoulder at 22000 cm^{-1} is due to the superposition of bands of both ions. These bands are in agreement with those in literatue.[20] At a long delay the ion bands decrease and the triplet Py increases. The band shape in the region from 18000—23000 cm^{-1} is independent of delay time. Therefore, the bands in this region are mainly ascribed to the sum of the Py anion and the DMA cation, the concentration ratio of both ions being unity.

The time-resolved spectra of the intermolecular Py–DMA system in 2-propanol and 1-pentanol are given in Figs. 2 and 3. Since the decay of short-lived component agrees with that of exciplex fluorescence, the

spectra obtained at the short delay is tentatively ascribed to the exciplex. These two spectra agree with those given in Fig. 1 except for the contribution of the triplet Py. As the bands at 20200 and 22200 cm^{-1} decrease, the triplet Py increases. Similar results were obtained also in ethanol.

Observed spectra of P_1 and P_2 in 2-propanol are given in Figs. 4 and 5. The rise of the short-lived components is too fast to be analyzed, their decays being identical with those of exciplex fluorescence. As

compared with the bands of intermolecular systems the shoulder at the higher wave number side of the Py anion band is shifted to red, its intensity relative to that of the Py anion band (20000 cm^{-1}) increasing. At a long delay, only the triplet Py is identified, its characteristic peak being observed at 24100 cm^{-1}.

The absorption spectra of P_3 are very broad, the band maximum being almost at the same position as that of P_1 or P_2, as shown in Fig. 6. The half-width is about 4000 cm^{-1}. Since ionic dissociation is prohibited in the case of intramolecular compounds, exciplex is formed also in acetone in spite of its high polarity. The absorption spectra of P_3 in the latter solvent are similar to those in alcohol (Fig. 7). The absorption band due to the triplet Py of P_3 shows a peak at 24100 cm^{-1} just as in the case of P_1 and P_2.

The present results can be summarized as follows. (i) The spectra of intermolecular systems can be reproduced approximately by the superposition of bands of the acceptor anion and the donor cation. (ii) Although similar spectra are observed in the cases of P_1 and P_2, the shoulder at higher wave number side of the Py anion band is shifted to the red compared with the case of intermolecular system. (iii) P_3 exciplex shows a characteristic broad band. (iv) The T-T spectra of intramolecular systems are independent of the number of the methylene chain, the characteristic band lying at 24100 cm^{-1}. On the other hand, the triplet Py of intermolecular system shows an absorption peak at 24400 cm^{-1}.

Discussion

Absorption Spectra and Geometrical Conformation of Intramolecular Exciplex Systems. The relation between absorption spectra and geometrical conformation has been studied in detail in the case of 1,2,4,5-tetracyanobenzene complexes in the excited state.[18] However, information on exciplex is scarce.[4] Compounds P_1 and P_2 cannot take the structure of sandwich type, the distance between donor and acceptor moieties being rather long. On the other hand, both stretched and stacked forms are possible for P_3. The dipole moment of all these exciplexes is quite large.[7,8] Exciplexes can be considered approximately to be a kind of ion-pair consisting of donor cation and acceptor anion. In the cases of P_1 and P_2, the interaction between both ions seems to be rather small and the absorption spectra can be reproduced by the superposition of bands of their component ions. Similar spectra can be expected if the exciplex of P_3 is of stretched form. However, a quite broad band is observed, so that P_3 exciplex seems to take the geometry, which is impossible in the cases of P_1 and P_2. Presumably, it is a structure of sandwich type where the donor and the acceptor are in the stacked form and distance between two moieties is rather short.

The present spectra of P_3 are similar to those of intermolecular Py–*N*,*N*-diethylaniline (DEA) system in nonpolar solvents.[5] The following interpretations might be possible with respect to this broad band.

(a) The overlap between MO's of both ions causes the back CT transition from the anion to the cation.

The sum of the latter transitions and the local excitation of the Py anion leads to the broadening of the band at 20000 cm^{-1}. Since the transition moment between the CT and locally excited configurations is zero as a first approximation, the intensity of the back CT transition comparable to that of ion bands should be due to rather strong mixing of both configurations in the fluorescent state, which is inconsistent with the experimental[7,8] and theoretical[21] results indicating large dipole moment of the exciplex. An alternative interpretation may be the mixing in the higher excited state, to which the transition occurs.

(b) The electrostatic interaction between both ions may be rather strong in the case of P_3, which seems to produce the spectral broadening. This interpretation has been suggested in studies on the electronic spectra of ion-pairs produced in rigid matrix.[22]

Although correct interpretation is beyond our present knowledge, the spectral change due to the differences in distance and orientation between two moieties is demonstrated.

Intermolecular Exciplex Systems in Alcoholic Solutions. The fluorescence quantum yield of exciplex is higher and its lifetime longer in alcohols than in aprotic solvents with similar dielectric constant. This can be ascribed to high viscosity and long dielectric relaxation time of alcohols. The electron transfer from DMA to the excited Py is not followed by the solvation to free ions, which can be attributed to network structure of solvent due to hydrogen bonding. The resulting exciplex in alcohols has the same structure and property as those in nonpolar aprotic solvents. This is not in line with the results on the transient absorption spectra. The spectra of Py–DMA intermolecular system in 2-propanol and 1-pentanol are in agreement with the superposition of bands of the Py anion and the DMA cation and are similar to the spectra of P_1 and P_2 in 2-propanol, but they differ a great deal from the spectra of intermolecular Py–DEA in nonpolar solvents and of P_3 in 2-propanol.

A possible explanation is to assume the role of geminate ion-pair, introduced by Goodall *et al.*[23] It is postulated that the exciplexes in these alcohols are produced through the recombination of a geminate ion-pair or they are in equilibrium with the geminate ion-pair.[3,23,24] If the geminate ion-pair is the main chemical species which exists during the observed exciplex fluorescence lifetime, the spectra measured should be reproduced by the superposition of bands of the Py anion and the DMA cation. The excess energy corresponding to an energy gap between the encounter complex and the geminate ion-pair permits diffusional motion, which leads to a longer distance than that of the stretched P_3. However, the produced pair cannot be completely separated from each other since they are captured in the network of hydrogen bond, leading to the exciplex formation due to recombination.

In order to elucidate these problems magnetic field modulations of the Py triplet and Py anion concentrations formed through quenching of singlet excited Py molecules by amines in polar solvents have been recently investigated.[24,25] In the case of Py–DEA–methanol system, magnetic field modulation has been actually observed. The effect has been interpreted to be due to a magnetic field dependent triplet production in the geminate radical ion-pair induced by hyperfine interaction of the unpaired electrons. Thus, in this case, the existence of the geminate ion-pair is confirmed and the geminate pair as well as the dissociated radical ions can be the main product of the fluorescence quenching reaction.[25] However, in the case of Py–DEA–2-propanol system no magnetic field dependence of the triplet as well as the ion radical concentrations was observed. Thus, exciplex is a predominating species instead of a geminate ion-pair. Since the same conclusion is expected in both Py–DEA and Py–DMA systems, the main transient is exciplex, which gives the above transient absorption spectra of Py–DMA–2-propanol system.

The structure of the P_3 exciplex in 2-propanol differs from that of the Py–DMA intermolecular exciplex in the same solvent. The latter might have a more loose structure owing to the more extensive solvation as compared with the former of the sandwich type structure. The present result indicates that the structure of the exciplex is affected considerably by the properties of solvent.

Diffusional and Conductive Membrane Permeabilities to Ions in Liquid Membrane-Aqueous Inorganic Electrolyte System

Kazuo NOMURA, Akira MATSUBARA, and Hideo KIMIZUKA*

Laboratory of Chemistry, College of General Education, Kyushu University 01, Ropponmatsu, Fukuoka 810

**Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Fukuoka 812*

(Received November 4, 1977)

Utilizing a liquid membrane-aqueous inorganic electrolyte system, the membrane permeability to ion α estimated from the conductance and potential data, P_α, and that at zero electric current estimated from the salt flow and potential data, P_α^0, were determined. A solution of calcium hexadecyl sulfate dissolved in 1-octanol and calcium chloride were used as the liquid membrane and the inorganic electrolyte, respectively. The results showed that $P_{Ca}^0/P_{Cl}^0 \approx P_{Ca}/P_{Cl} \approx 10$ and $P_{Cl}^0 \approx P_s^0$, where subscript s refers to the salt. The latter result indicates that the diffusion of a salt through the membrane is governed by the co-ion permeation. It was shown that P_α^0 is smaller than P_α and that P_α decreases with increase in the concentration of external calcium chloride solution while P_α^0 is nearly independent of the concentration. The difference between P_α and P_α^0 can be explained in terms of the elements of permeability and conductance matrices estimated from the electrical and salt flow data.

Liquid membranes have been extensively investigated by analytical chemists, because of their high selectivity to a particular ion.[1] They have also drawn the attention of investigators working with biological membranes as a model for a carrier transport.[2] In spite of numerous experimental works, theories proposed for ion transport through liquid membrane are not as many as those for fixed site membranes. The theory of Eisenman *et al.*[3-6] is widely used to analyze the ion transport phenomena through liquid membranes, but it is derived on the basis of the Nernst-Plank equation.

A theory based on nonequilibrium thermodynamics was presented in a previous paper.[7] It was shown[8] that the equations describing the membrane phenomena for a fixed site membrane is applicable to a liquid membrane with mobile site.

We have carried out an electrochemical study utilizing a cation-exchange liquid membrane containing calcium hexadecyl sulfate for the experimental presentation of the theory.

Experimental

Materials. Calcium hexadecyl sulfate was prepared from sodium hexadecyl sulfate according to the method of Lottermoser and Püschel.[9] Sodium hexadecyl sulfate was prepared from purified 1-hexadecanol obtained by fractional distillation of a commercial sample.[10] All other reagents were of guranteed grade and used without further purification.

Apparatus. The cell assembly is schematically shown in Fig. 1. Two compartments are separated by a liquid membrane supported on a Teflon millipore film (Fluoro Pore, No. EP100, pore size 1.0 μm, thickness 50 μm, from Sumitomo Electric Ind., Ltd.). The liquid membrane was prepared by dissolving calcium hexadecyl sulfate in water-saturated 1-octanol at a concentration of 2.5×10^{-3} mol/dm^3. The diffusional area of the membrane was 0.2 cm^2. Small cells (1.5 cm^3) were used. The concentration of $CaCl_2$ in the internal solution (compartment II) was kept at 4×10^{-3} mol/dm^3, that of the external one (compartment I) being varied from 4×10^{-4} to 10^{-1} mol/dm^3. The whole assembly was thermostated at 25 ± 0.02 °C and the solution in each compartment was stirred with magnetic stirrer at a rate of 200 rpm. The small solubility of calcium hexadecyl sulfate in aqueous solution, an order of 10^{-6} mol/dm^3, was obtained at 25 °C.[11] The dissolution of calcium hexadecyl sulfate in the aqueous phase may be ignored. This was also confirmed by the constancy of the conductance of aqueous calcium chloride solution in contact with the liquid membrane.

Salt Flow Measurement. The salt flow was studied by measuring the change in the concentration of the solution. Concentration changes were followed by the electric conductance of the external and internal solutions measured by means of the two Pt-Pt electrodes connected to the Yanagimoto conductivity outfit Model MY-7. The solutions were replaced with fresh ones several times, until a steady membrane resistance was obtained. It took more than 24 h on some occasions to attain a steady salt flow.

A theory for the liquid membrane has been presented[8] by assuming 1) steady state, 2) absence of the flow of water as well as organic solvent, 3) the dissociation equilibrium for the mobile site-counter ion binding within the liquid membrane, and 4) presence of the mobile site only within the liquid membrane. It has been shown that the equations describing transport phenomena for the fixed site membrane[7] is equally applicable to the system with a mobile site membrane.

The membrane permeability to ion α, P^0_α, as well as that to salt, P^0_s, at zero electric current can be estimated by using the equations[7] for the flux, J^0_α and the salt flux, J_s:

$$J^0_\alpha = \nu_\alpha J_s = -P^0_\alpha \Delta\bar{a}_\alpha = -P^0_\alpha\{a^{II}_\alpha \exp(Z_\alpha \Phi_0/2) - a^I_\alpha \exp(-Z_\alpha\Phi_0/2)\}, \quad (1)$$

and

$$J_s = -P^0_s \Delta a_s = -P^0_s(a^{II}_s - a^I_s), \quad (2)$$

where

$$\Phi_0 = FV_0/RT, \quad (3)$$

ν, Z, F, α, V_0, R, and T denote the stoichiometric coefficient, the charge number, Faraday constant, the activity, the membrane potential at zero electric current, gas constant and absolute temperature, respectively. Superscripts I and II refer to compartments I and II, respectively, and subscripts α and s to ion α and salt s, respectively.

Membrane Potential and Conductance Measurements. The membrane potential was measured by means of two calomel electrodes connected to the Orion digital pH meter Model 701. The calomel electrode was connected to each compartment through an agar bridge. In experiments at lower concentrations, the solutions were replaced by fresh ones several times in order to avoid contamination with KCl diffusing from the agar bridge.

The membrane resistance was measured by means of the two Pt-Pt electrodes connected to the same conductivity outfit as used for the salt flow measurement. The membrane resistance was obtained by subtracting the solution resistance from the total one. After the steady state was attained, the membrane resistance remained constant. Errors inherent to the measurement of the membrane resistance were 4—5 percent.

The membrane permeability to ion α, P_α, is related to ion conductance, g_α, by[7]

$$g_\alpha = t_\alpha G_m = \frac{(Z_\alpha F)^2}{RT} P_\alpha (a^I_\alpha a^{II}_\alpha)^{1/2} \frac{\sinh Z_\alpha(\Phi_0 - \Phi_\alpha)/2}{Z_\alpha(\Phi_0 - \Phi_\alpha)/2}, \quad (4)$$

where

$$\Phi_\alpha = FV_\alpha/RT, \quad (5)$$

and t_α denotes the apparent transport number, G_m the membrane conductance, and V_α the equilibrium membrane potential for the ion α.

Results and Discussion

The membrane potential, V_0, the membrane conductance, G_m, and the salt flow, J_s, are plotted against the mean activity of $CaCl_2$ in the external solution ($a^I_\pm$) in Fig. 2. The apparent transport number, t_{Ca}, estimated from the potential *vs.* logarithm of mean activity relation was nearly constant, 0.96, within the range of concentration studied.

Membrane permeability at zero electric current, P^0_{Ca}, P^0_{Cl} and P^0_s, can be estimated from the potential and salt flow data according to Eqs. 1 and 2. P_{Ca} and P_{Cl} can be estimated from the potential and conductance data according to Eq. 4. The results are shown in Fig. 3.

We see that $P^0_{Ca} > P^0_{Cl}$, $P_{Ca} > P_{Cl}$, $P^0_{Ca} < P_{Ca}$, and $P^0_{Cl} \approx P^0_s < P_{Cl}$. Since the membrane is a cation exchanger, the results $P^0_{Ca} > P^0_{Cl}$ and $P_{Ca} > P_{Cl}$ are as expected. The ratio of P^0_{Ca} to P^0_{Cl} and that of P_{Ca} to P_{Cl} are both about ten. The result, $P^0_{Cl} \approx P^0_s$, indicates that the diffusion of salt through the liquid membrane is governed by co-ion permeation.

P_{Ca} and P_{Cl} decrease with the increase in the geometric mean of the activities of external and internal solutions as shown in Fig. 3. On the other hand, P^0_{Ca}, P^0_{Cl}, and P^0_s show no appreciable concentration dependence. P^0_α, P_α and P^0_α/P_α can respectively be expressed as functions of the elements of permeability matrix $P_{\alpha\beta}$'s and of conductance matrix $g_{\alpha\beta}$'s ($\alpha \neq \beta$) as follows.

$$P^0_\alpha = (P_{\alpha\alpha}P_{\beta\beta} - P_{\alpha\beta}P_{\beta\alpha})/P_\beta, \quad (6)$$

$$P_\alpha = P_{\alpha\alpha} + Z_\beta P_{\beta\alpha}/Z_\alpha, \quad (7)$$

and

$$\frac{P^0_\alpha}{P_\alpha} = 1 - \frac{Z_\beta P_{\beta\alpha}}{Z_\alpha P_\alpha} - \frac{Z_\alpha P_{\alpha\beta}}{Z_\beta P_\beta} = 1 - g_{\alpha\beta}\left(\frac{1}{g_\alpha} + \frac{1}{g_\beta}\right). \quad (8)$$

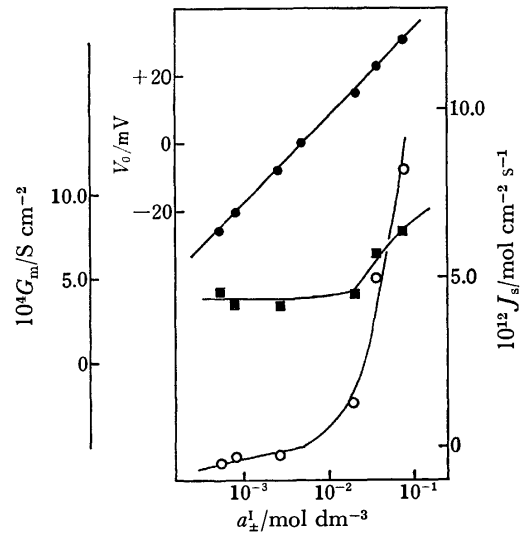

Fig. 2. The membrane potential (●), the membrane conductance (■), and the salt flow (○), each as a function of the mean activity of external solution. The concentration of the internal solution was kept at 4×10^{-3} mol/dm^3.

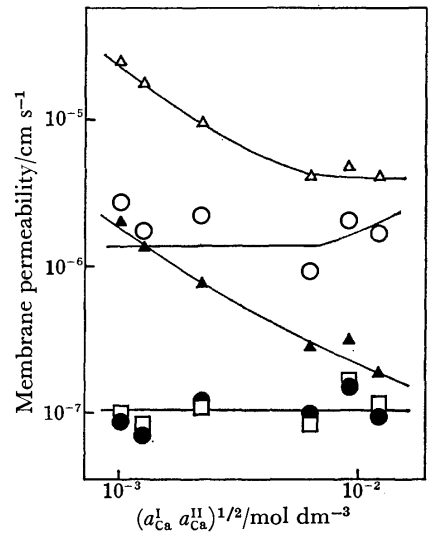

Fig. 3. The membrane permeabilities as a function of the geometric mean of the activity of external and internal solutions. △; P_{Ca}, ▲; P_{Cl}, ○; P^0_{Ca}, ●; P^0_{Cl} □; P^0_s. The solid lines indicate the values of P^0_α and P_α calculated from $P_{\alpha\beta}$ (Fig. 5) according to Eqs. 6 and 7, respectively.

$P_{\alpha\beta}$ is related to an element of conductance matrix $g_{\alpha\beta}$:

$$g_{\alpha\beta} = \frac{Z_\alpha Z_\beta F^2}{RT} P_{\alpha\beta}(a_\beta^{\mathrm{I}} a_\beta^{\mathrm{II}})^{1/2} \frac{\sinh Z_\beta(\Phi_0 - \Phi_\beta)/2}{Z_\beta(\Phi_0 - \Phi_\beta)/2}, \quad (9)$$

and $g_{\alpha\beta}$ can be estimated according to the equation

$$g_{\alpha\beta} = g_{\beta\alpha} = G_{\mathrm{m}} t_\alpha t_\beta - \frac{(Z_\alpha \nu_\alpha F)^2 P_{\mathrm{s}}^0 \Delta a_{\mathrm{s}}}{\nu_{\mathrm{s}} \Delta\mu_{\mathrm{s}}}, \quad (10)$$

where

$$\nu_{\mathrm{s}} = \nu_\alpha + \nu_\beta,$$

and $\Delta\mu_{\mathrm{s}}$ denotes the chemical potential difference of salt across membrane. The diagonal elements of conductance matrix, $g_{\alpha\alpha}$ and $g_{\beta\beta}$, are given by

$$g_{\alpha\beta} = g_\alpha - g_{\alpha\alpha} = g_\beta - g_{\beta\beta}. \quad (11)$$

The value of $g_{\alpha\beta}$ was evaluated by means of Eq. 10 where the activity data of calcium chloride in phases I and II were taken from Handbook of Chemistry (Chemical Society of Japan). The other elements $g_{\alpha\alpha}$ and $g_{\beta\beta}$ were calculated by means of Eq. 11. These elements were plotted against the mean activity of calcium chloride in phase I as shown in Fig. 4. The elements of permeability matrix were estimated by means of Eq. 9 and the results are shown in Fig. 5.

The ratio P_α^0/P_α may be calculated from Eq. 8 by using the elements of the permeability matrix. A comparison of the observed values with calculated ones is given in Fig. 6. The agreement is satisfactory.

The full lines in Fig. 3 represent P_α^0 and P_α calculated by means of Eqs. 6 and 7, respectively. We see that the agreement between theory and experiment is satisfactory.

P_α^0 can be expressed by

$$\frac{1}{P_\alpha^0} = \frac{1}{P_\alpha^0(\mathrm{I})} + \frac{1}{P_\alpha^0(\mathrm{m})} + \frac{1}{P_\alpha^0(\mathrm{II})}, \quad (12)$$

where (I) and (II) refer to the boundary layers in phases I and II, respectively, and (m) denotes the membrane phase.[7] Since the system is close to equilibrium with respect to calcium ions, we can put

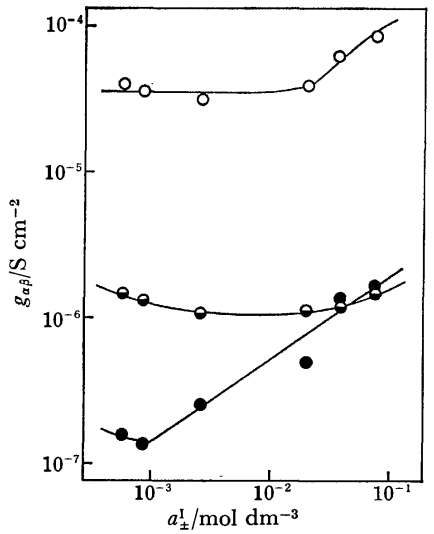

Fig. 4. The elements of the conductance matrix as a function of the mean activity of external solution. The concentration of internal solution was kept at 4×10^{-3} mol/dm^3. ○; $g_{\mathrm{Ca.Ca}}$, ◒; $g_{\mathrm{Ca.Cl}}$, ●; $g_{\mathrm{Cl.Cl}}$.

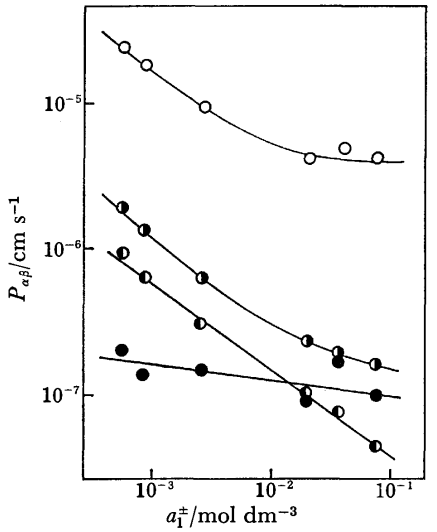

Fig. 5. The elements of the permeability matrix as a function of the mean activity of external solution. The concentration of internal solution was kept at 4×10^{-3} mol/dm^3. ○; $P_{\mathrm{Ca.Ca}}$, ◑; $-P_{\mathrm{Cl.Ca}}$, ◐; $-P_{\mathrm{Ca.Cl}}$, ●; $P_{\mathrm{Cl.Cl}}$.

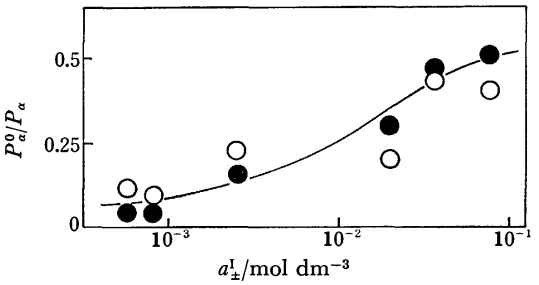

Fig. 6. The ratio P_α^0/P_α as a function of the mean activity of external solution. The concentration of internal solution was kept at 4×10^{-3} mol/dm^3. ○; $P_{\mathrm{Ca}}^0/P_{\mathrm{Ca}}$, ●; $P_{\mathrm{Cl}}^0/P_{\mathrm{Cl}}$. The solid line was calculated from $P_{\alpha\beta}$ according to Eq. 8.

$$\frac{1}{P_{\mathrm{Ca}}^0(\mathrm{I})} = \frac{l(\mathrm{I})}{D_{\mathrm{Ca}}(\mathrm{I}) \cdot C_{\mathrm{Ca}}(\mathrm{I})} (a_{\mathrm{Ca}}^{\mathrm{I}} a_{\mathrm{Ca}}^{\mathrm{II}})^{1/2} \quad (13)$$

and

$$\frac{1}{P_{\mathrm{Ca}}^0(\mathrm{II})} = \frac{l(\mathrm{II})}{D_{\mathrm{Ca}}(\mathrm{II}) \cdot C_{\mathrm{Ca}}(\mathrm{II})} (a_{\mathrm{Ca}}^{\mathrm{I}} a_{\mathrm{Ca}}^{\mathrm{II}})^{1/2}, \quad (14)$$

where l, D, and C denote the boundary layer thickness, the diffusion coefficient in boundary layer and the concentration, respectively. Assuming that the thickness of boundary layers to be 100 μm, the values of $1/P_{\mathrm{Ca}}^0$ (I) and $1/P_{\mathrm{Ca}}^0$ (II) were found to be in the order of 10^3 cm^{-1} s, while $1/P_{\mathrm{Ca}}^0$ was the order of 10^5—10^6 cm^{-1} s, *i.e.*,

$$P_{\mathrm{Ca}}^0 \approx P_{\mathrm{Ca}}^0(\mathrm{m}). \quad (15)$$

It can be concluded that the transport process is the membrane control. Since the membrane resistance was obtained by subtracting part of the solution resistance from the total one, we have

$$P_{\mathrm{Ca}} \approx P_{\mathrm{Ca}}(\mathrm{m}). \quad (16)$$

The theory based on the Nernst-Plank equation can not differentiate P_α from P_α^0.[7] Thus an explanation for the transport phenomena should be made on the basis of nonequilibrium thermodynamics.

This research has been supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Polarized Absorption Spectra of Single Crystals of Tetrathiafulvalenium Salts

Tadashi SUGANO, Kyuya YAKUSHI, and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received November 8, 1977)

The polarized absorption spectra over the range, 5000—37000 cm^{-1}, were observed on the single crystals of the highly-conductive, mixed-valence tetrathiafulvalenium salts, (TTF)$Br_{0.71}$, (TTF)$I_{0.71}$, and (TTF)$(SCN)_{0.57}$, by using a microspectrophotometer. The spectra of these crystals were very similar to each other. The observed spectra were successfully interpreted in terms of the localized model, considering the charge transfer transitions between TTF species and the local excitations associated with the intramolecular transitions of the molecule and ion of TTF. The spectrum of the (TTF)(ClO_4) crystal were also studied to aid the interpretations of the spectra of the mixed-valence TTF salts.

The crystal of the charge-transfer salt of tetrathiafulvalene (TTF) with tetracyano-*p*-quinodimethane (TCNQ) is composed of the segregated stacks of TTF and TCNQ. A variety of evidences[1-8] indicate that an incomplete charge transfer is taking place between TTF and TCNQ in this salt, so that the TTF and TCNQ stacks are of mixed-valence characters. In the case of (TTF)(TCNQ), both the TTF and TCNQ stacks are contributing to the metal-like behaviors displayed by this salt.[9,10] This situation causes considerable complexities in analysing the physical properties of (TTF)-(TCNQ).[7,8,11-13] There are a group of the mixed-valence TTF salts which display high electrical conductivities almost comparable to (TTF)(TCNQ). These are (TTF)$Br_{0.71-0.76}$,[14] (TTF)$I_{0.71}$,[14-16] (TTF)-$(SCN)_{0.54-0.58}$[16-18] and (TTF)$(SeCN)_{0.54-0.58}$.[16,17] These mixed-valence TTF salts are almost isomorphous with each other,[16-22] having nearly the same one-dimensional stack of TTF, and the metal-like electrical conductivities as well as other physical properties of these salts, are primarily determined by the nature of the mixed-valence TTF stack. Thus these salts can be regarded as the suitable model compounds for the purpose to study the electronic behaviors of the mixed-valence, one-dimentional TTF stack.

The electrical and magnetical properties of the TTF salts mentioned above have been studied by several authors.[14-18,23,24] As regards their optical properties, the observations of reflection spectra were reported on (TTF)$Br_{0.76}$,[22,25] (TTF)$I_{0.71}$[26] and (TTF)$(SeCN)_{0.54}$,[17] but no direct observation of the absorption spectra of single crystals have been hitherto reported.

In the present work, we have studied the polarized absorption spectra of small single crystals of (TTF)$Br_{0.71}$, (TTF)$I_{0.71}$ and (TTF)$(SCN)_{0.57}$, over the range of 5000—37000 cm^{-1} (0.6—4.5 eV), by use of a microspectrophotometer. For the sake of comparison, we have also studied the absorption spectrum of (TTF)-(ClO_4).

Experimental

TTF was synthesized by the method reported by Melby *et al.*,[27] recrystallized from the cyclohexane solution, and finally purified by repeating sublimation in vacuum. The mixed-valence halides, (TTF)$Br_{0.71}$ and (TTF)$I_{0.71}$, were prepared by the procedures described in our previous paper.[24,28] (TTF)(ClO_4) was prepared by the method reported by Hünig *et al.*[29] (TTF)$(SCN)_{0.57}$[18] was kindly provided by Dr. H. Kobayashi of Toho University.

The polarized absorption spectra of single crystals were measured at room temperature by means of a microspectrophotometer, Olympus MS-A-IV. In order to observe absorption spectrum, it is necessary to obtain a crystal of the size and thickness suitable for the measurement of absorption spectrum by the microspectrophotometer. We dissolved each salt in the deairated dry hot acetonitrile, dropped a small amount of the hot solution on a quartz plate, and allowed for the solvent to evaporate leaving small crystals of the salt on the quartz plate. We examined the crystals thus formed on the quartz plate, by a polarization microscope to select out a suitable crystal. The crystal habit was also checked by the observation under the polarization microscope. The sizes of the crystals used in the present study of absorption spectra were less than 1 μm in thickness, 5—20 μm in width and 20—50 μm in length.

Results and Discussion

(TTF)(ClO_4), a Simple Cation Radical Salt. (TTF)(ClO_4) is expected to be a salt composed of $(TTF)^+$ and $(ClO_4)^-$. Fig. 1 shows the infrared spectra of (TTF)(ClO_4) and (TTF)(DDQ),[30] measured by the Nujol-mull method. The infrared spectrum of (TTF)-(DDQ) shows all absorption bands characteristic of $(DDQ)^-$, which appear in the infrared spectrum of $Li^+(DDQ)^-$,[31] and exhibits no band attributable to DDQ molecule. Thus, (TTF)(DDQ) can be concluded to be a salt composed of $(TTF)^+$ and $(DDQ)^-$. We can attribute all of the residual bands in the infrared spectrum of (TTF)(DDQ) to those arising from $(TTF)^+$. When the infrared spectrum of (TTF)(ClO_4) is compared with that of (TTF)(DDQ), we can see that all bands in the former spectrum correspond to the ones which have been attributed to $(TTF)^+$ in the latter case, there being no band attributable to TTF molecule. This fact proves that (TTF)(ClO_4) is indeed the salt composed of $(TTF)^+$ and $(ClO_4)^-$.

From the Weissenberg photographs, it was found that the crystal of (TTF)(ClO_4) is orthorhombic, with the space group Pbca(D_{2h}^{15}), the approximate lattice constants being $a=16.7$, $b=20.6$, and $c=12.8$ Å. It crystallizes from the acetonitrile solution as thin crystals elongated along the a-axis with the developed face (001). We measured the polarized absorption spectra

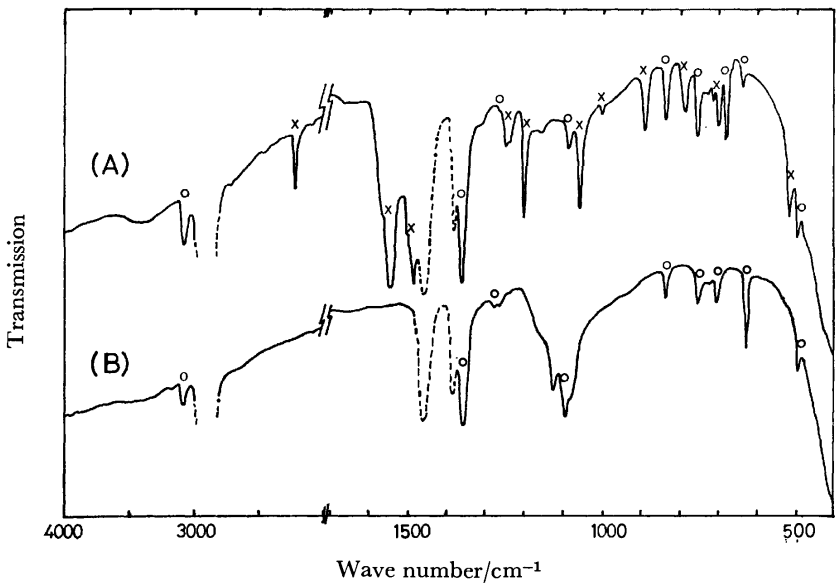

Fig. 1. Infrared spectra of TTF–DDQ(A) and TTF–ClO_4(B). The bands due to $(TTF)^+$ are indicated with a open circle and those due to $(DDQ)^-$ with a cross. The dashed line represent the absorption by Nujol.

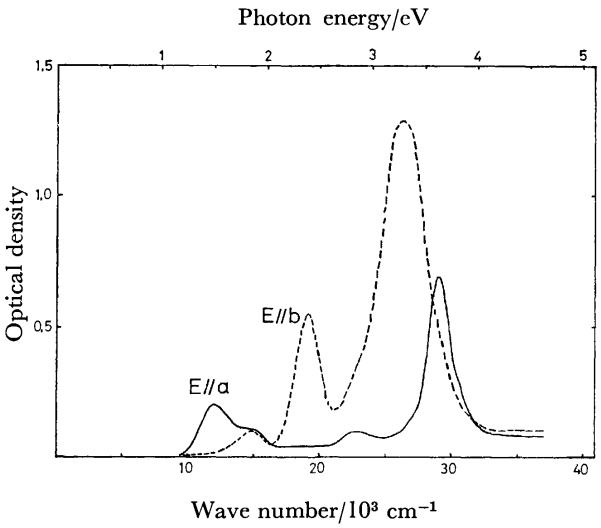

Fig. 2. Polarized absorption spectra observed on the (001) plane of a single crystal of $(TTF)(ClO_4)$.

on the (001) plane of $(TTF)(ClO_4)$ crystal, with the light polarizations, parallel to a- and b-axes respectively, and obtained the spectra shown in Fig. 2.

In the region below 17×10^3 cm^{-1}, the a-axis spectrum exhibits an absorption maxium at 12.0×10^3 cm^{-1} with a shoulder at about 15×10^3 cm^{-1}, while the b-axis spectrum shows a maxium at 15.0×10^3 cm^{-1}. Seemingly there are two absorption bands; the one is at 12.0×10^3 cm^{-1}, completely polarized in the a-axis direction, and the other is at 15.0×10^3 cm^{-1} with a transition moment in the direction inbetween the a- and b-axes. In these regions, we can not expect any local-excitation (LE) band associated with an intramolecular transition of $(TTF)^+$. Thus the observed absorption bands must be the ones arising from the charge transfer between $(TTF)^+$ ions. The fact that the first CT band (at 12.0×10^3 cm^{-1}) is completely polarized in the a-axis direction, indicates that $(TTF)^+$ ions are stacked on each other along the a-axis. The origin of the second CT band (at 15.0×10^3 cm^{-1}) is not clear. Presumably, there are two different types of the overlap between the neighboring $(TTF)^+$ ions in the crystal, and the first CT band arises from the one with the closest overlap and the second CT band arises from the other type of overlap.

TABLE 1. WAVE NUMBERS AND RELATIVE INTENSITIES (given in the parentheses)[a] OF LOCAL EXCITATION BANDS OF $(TTF)^+(ClO_4)^-$ AND THOSE OF THE SOLUTION SPECTRUM OF THE $(TTF)^+$ ION

Transition	Transition in $(TTF)^+$ (calcd)[b]			Transition in $(TTF)^+$ (exp.)[c]	$(TTF)^+(ClO_4)^-$	
	Assignment	Polarization	$\bar{\nu}$(10^3 cm^{-1})	$\bar{\nu}$(10^3 cm^{-1})	$\bar{\nu}$(10^3 cm^{-1})	Polarization
LE_1	$b_{1u}\leftarrow b_{2g}$	x	16.8(0.48[d])	17.3(0.27[e])	19.2(0.28[f])	b-axis
LE_2	$b_{3g}\leftarrow b_{1u}$	y	17.8(0.21)	20.3(sh.)	22.8(0.03)	(a-axis)
LE_3	$b_{2g}\leftarrow b_{1u}$	x	19.5(1.00)	23.0(1.00)	26.4(1.00)	b-axis
LE_4	$b_{1u}\leftarrow b_{3g}$	y	23.7(0.52)	29.6(0.32)	29.1(0.34)	(a-axis)

a) Relative to the intensity of the LE_3 band. b) See Ref. 32. The x-axis is chosen for the long axis of molecule. c) See Ref. 29. d) Relative oscillator strengths. e) Relative absorption coefficients. f) Relative peak heights (correspond to absorption coefficients).

In the region above 17×10^3 cm^{-1}, both the a-axis and b-axis spectra show two absorption bands. The wave numbers and relative intensities of these bands are listed in Table 1. The absorption spectrum of the $(TTF)^+$ ion in the solution shows four absorption bands in the corresponding region, the maxima of which are located at 17.3×10^3, 23.0×10^3, and 29.6×10^3 cm^{-1}, respectively.[29] According to the semi-empirical limited-CIS-CF-MO calculation,[32] the lowest four allowed transitions of $(TTF)^+$ are associated respectively with the following electronic excitations between π-orbitals, $b_{1u}\leftarrow b_{2g}$ (x polarized), $b_{3g}\leftarrow b_{1u}$ (y polarized), $b_{2g}\leftarrow b_{1u}$ (x polarized) and $b_{1u}\leftarrow b_{3g}$ (y polarized), where x and y stand for the long and short axes of the ion, respectively. The predicted energies and oscillartor strengths of these transitions well correspond to the four absorption bands observed in the solution spectrum, as shown in Table 1. By comparing the spectra of $(TTF)(ClO_4)$ with the solution spectrum of $(TTF)^+$, we can conclude that the 19.2×10^3 and 26.4×10^3 cm^{-1} bands of the b-axis spectrum are the local-excitation (LE) bands associated with the 17.3×10^3 and 23.0×10^3 cm^{-1} transitions of $(TTF)^+$. Note that the intensity ratio of the above two bands are in good agreement with the intensity ratio of the corresponding bands in the solution spectrum. We will call the 19.2×10^3 and 26.4×10^3 cm^{-1} bands of $(TTF)(ClO_4)$ as LE_1 and LE_3, respectively.

The 29.1×10^3 cm^{-1} band in the a-axis spectrum is likely to be the LE band associated with the 29.6×10^3 cm^{-1} transition of $(TTF)^+$. Since the LE band associated with the 20.3×10^3 cm^{-1} transition of $(TTF)^+$ should appear in the spectrum of $(TTF)(ClO_4)$ in the region of $20—24\times10^3$ cm^{-1} with the same polarization as the above LE band, we can attribute the weak absorption band at 22.8×10^3 cm^{-1} in the a-axis spectrum, to this LE band. The intensity ratio of the two absorption bands of the a-axis spectrum is consistent with this interpretation. We will call the 20.3×10^3 and 29.1×10^3 cm^{-1} bands of $(TTF)(ClO_4)$ as LE_2 and LE_4, respectively.

The LE_1, LE_2, and LE_3 bands have been shifted to higher energy by about 2×10^3 cm^{-1} as compared with the corresponding absorption bands of the solution spectrum of $(TTF)^+$. This is just the magnitude of the shift that is often found in the crystal where the intermolecular charge-transfer interaction is taking place between the constituent radical ions. According to the above interpretation of the observed spectra, the LE bands associated with the long-axis polarized transitions of $(TTF)^+$ appear only in the b-axis spectrum, showing that they have no components of the transition moments in the a-axis direction. This fact implies that the long axis of $(TTF)^+$ is in the bc plane of the $(TTF)(ClO_4)$ crystal.

Mixed-valence TTF Salts. The TTF sublattices of $(TTF)Br_{0.71}$,[19] $(TTF)I_{0.71}$,[20,21] and $(TTF)(SCN)_{0.57}$[18] are very similar to each other as illustrated in Table 2, where the unit cell of $(TTF)(SCN)_{0.57}$ has been transformed from a tetragonal simple lattice to a C-centered lattice in order to facilitate the comparison with the halides. In all of the three salts, TTF molecules (or ions)

Table 2. TTF Sublattices of $(TTF)Br_{0.71}$, $(TTF)I_{0.71}$, and $(TTF)(SCN)_{0.57}$

	a(Å)	b(Å)	c(Å)	β(deg)
$(TTF)Br_{0.71}$[a]	15.62	15.63	3.57	91.2
$(TTF)I_{0.71}$[b]	16.01	16.04	3.55	91.3
$(TTF)(SCN)_{0.57}$[c]	15.77	15.77	3.61	90.0

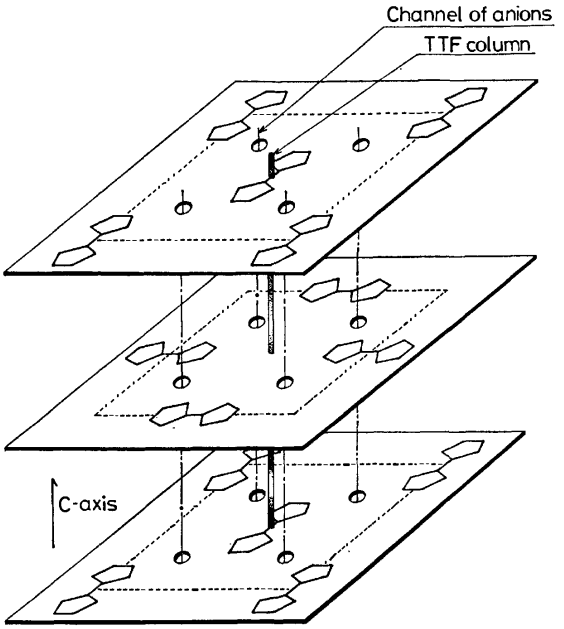

Fig. 3. Schematic picture of the TTF sublattice found for the mixed-valence TTF salts. About eight times enlarged in the c-axis direction.

are stacked along the c-axis with an eclipsed overlap, making their molecular planes almost perpendicular to the c-axis (see Fig. 3). All three salts crystallize from the hot acetonitrile solutions as crystals elongated along the a-axis with the developed face (100). The absorption spectra were measured on the (100) planes of these crystals with the light polarizations, parallel to the b- and c-axis respectively. The observed spectra are

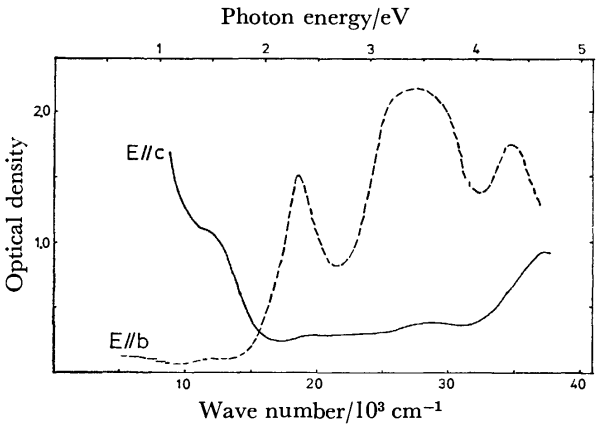

Fig. 4. Polarized absorption spectra observed on the (100) plane of a single crystal of $(TTF)Br_{0.71}$.

TABLE 3. WAVE NUMBERS OF ABSORPTION BANDS IN THE SPECTRA OF THE MIXED-VALENCE TTF SALTS

Transition character	c-axis spectra $\bar{\nu}(10^3\ cm^{-1})$			b-axis spectra $\bar{\nu}(10^3\ cm^{-1})$			Intramolecular transitions[a]

a) See Ref. 29. Absorption coefficient is given in the parenthesis.

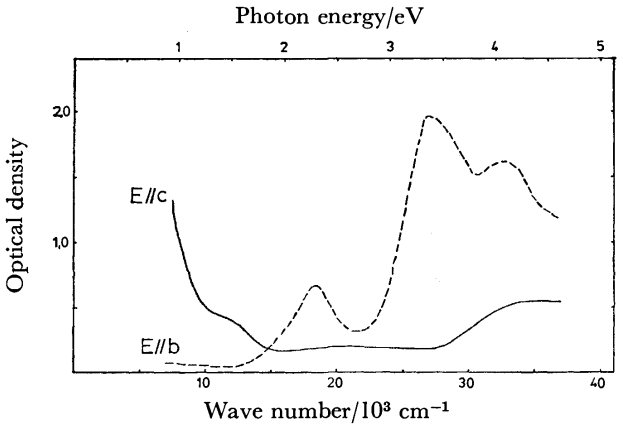

Fig. 5. Polarized absorption spectra observed on the (100) plane of a single crystal of $(TTF)I_{0.71}$.

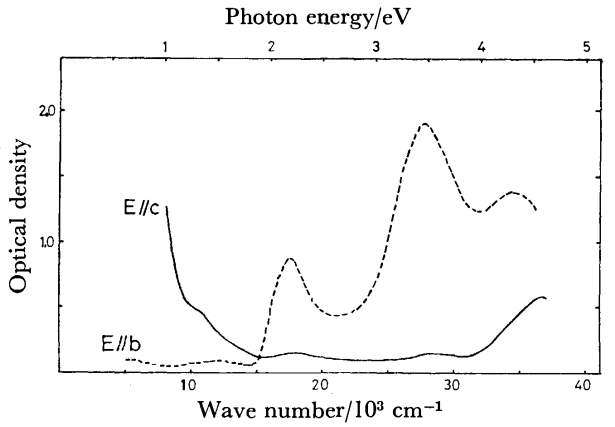

Fig. 6. Polarized absorption spectra observed on the (100) plane of a single crystal of $(TTF)(SCN)_{0.57}$.

shown in Figs. 4, 5, and 6. The wave numbers and relative intensities of the observed bands are listed in Table 3.

One can easily see from the arrangement and orientation of TTF in these salts that an absorption band associated with the intermolecular charge transfer along the TTF stack should appear exclusively in the c-axis spectrum, while the LE bands associated with the intramolecular transitions of $(TTF)^+$ ion and/or TTF molecule, both the long-axis and short-axis polarized ones, should appear only in the b-axis spectrum.

The spectra observed of the three salts are very similar to each other. The c-axis spectrum of each salt exhibit a strong absorption band in the region below $15\times10^3\ cm^{-1}$, and the b-axis spectrum shows three absorption maxima in the region above $15\times10^3\ cm^{-1}$. The former must be due to the intermolecular charge transfer and the latter must be due to the local excitations.

Let us first examine the LE bands which appear in the b-axis spectra. All salt exhibit three absorption maxima located at about 18×10^3, 27×10^3, and 34×10^3 cm^{-1}, respectively. Since the solution spectrum of TTF molecule exhibits no absorption band in the region below $22\times10^3\ cm^{-1}$, the first maximum at about $18\times10^3\ cm^{-1}$ cannot be due to the TTF neutral molecule. We can attribute it to the LE band associated with the $17.3\times10^3\ cm^{-1}$ transition of $(TTF)^+$. The second maximum is very strong, suggesting that it is associated with some strong transitions in the TTF molecule or $(TTF)^+$ ion. Although the TTF molecule has two transitions (at 22.4×10^3 and $28.0\times10^3\ cm^{-1}$) in the corresponding region, both of them are of very low oscillator strength, and cannot be taken as the origin of the observed strong absorption maximum. The possible origins of the second absorption maximum which is commonly observed in the b-axis spectra of the three mixed-valence salts, would be the 23.0×10^3 or $29.6\times10^3\ cm^{-1}$ transitions of $(TTF)^+$. It should be noted that the positions of the second absorption maxima observed for the three TTF salts are very close to that of the LE_3 band of $(TTF)(ClO_4)$, but the observed band shapes are considerably broader as compared with the latter. Seemingly, the local excitation bands associated with the 23.0×10^3 and $29.6\times10^3\ cm^{-1}$ transitions of $(TTF)^+$ are superimposed on each other to give a broad absorption maximum. TTF molecule has a srtong transition at $32.5\times10^3\ cm^{-1}$.[29,33,34] The third absorp-

tion maximum which is located at 33—35 $\times 10^3$ cm^{-1} in the b-axis spectra, is most likely to be the LE band associated with the above transition of TTF molecule.

As we have described above, all absorption bands observed in the b-axis spectra of the three salts can be interpreted either as a LE band associated with a transition of $(TTF)^+$ or that associated with a transition of $(TTF)^0$. If positive holes are completely delocalized through the TTF stack to give the same fractional charge on every TTF molecule, the TTF stack will exhibits an absorption spectrum composed of the bands which cannot be simply correlated with the transitions of $(TTF)^+$ and $(TTF)^0$. The fact that the observed spectra can be well interpreted in terms of the intramolecular transitions of $(TTF)^+$ and $(TTF)^0$, suggests that, as regards the optical properties, the TTF stack behaves as if it is composed of ions and molecules of TTF in spite of the metal-like high electrical conductivity through the TTF stack.

According to the interpretations of the spectra mentioned above, the intensity ratio of the first and third bands in the b-axis spectrum of each salt must be related to the ratio of $(TTF)^+$ and $(TTF)^0$. Using the molar extinction coefficient of the 17.3 $\times 10^3$ cm^{-1} band of the solution spectrum of $(TTF)^+$ and that of the 32.5 $\times 10^3$ cm^{-1} band of the solution spectrum of $(TTF)^0$, we estimated the ionized fraction of TTF from the observed intensity ratio. The ionized fraction of TTF thus obtained is 0.67, 0.58, and 0.62 for $(TTF)Br_{0.71}$, $(TTF)I_{0.71}$, and $(TTF)(SCN)_{0.57}$, respectively. These are very rough values since we have to expect various sources of error in the procedures of obtaining them from the observed crystal spectra. Nevertheless the results are quite reasonable. In particular, it is interesting to see that the ionized fraction is estimated to be appreciably lower in $(TTF)I_{0.71}$ than in $(TTF)Br_{0.71}$. Recently, we showed[5] that the S 2p peaks of the X-ray photoelectron spectra of mixed-valence TTF salts can be well reproduced by superimposing the S 2p peak characteristic of $(TTF)^0$ and that characteristic of $(TTF)^+$, assuming an appropriate intensity ratio. From the above analyses of the observed S 2p peaks we concluded that the ionized fraction of TTF is 0.71 and 0.52 in $(TTF)Br_{0.71}$ and $(TTF)I_{0.71}$, respectively, thus an incomplete charge transfer must be taking place in $(TTF)I_{0.71}$ while a complete charge transfer is taking place in $(TTF)Br_{0.71}$. The results obtained in the present study from the analyses of the intensity ratio of the LE bands are consistent with the above conclusion from the X-ray photoelectron spectra.

As shown in Figs. 4, 5, and 6, the c-axis spectra of these salts exhibit a strong absorption band extending to the infrared region. Because of the low-energy limit of our microspectrophotometer, we were not able to determine the wave number of the low-energy absorption maximum. The maximum was reported to be at 5000 cm^{-1} in the case of $(TTF)Br_{0.76}$.[22,35] Probably, the maximum is located in the same region also in the cases of the TTF salts studied here. This low-energy band can be safely assigned to an intermolecular CT transition.

There is a shoulder in the tail of the strong band mentioned above. This shoulder is located at 12.5 $\times 10^3$, 12.4 $\times 10^3$, and 11.0 $\times 10^3$ cm^3 cm^{-1} in $(TTF)Br_{0.71}$, $(TTF)I_{0.71}$, and $(TTF)(SCN)_{0.57}$, respectively. Seemingly, this is the second CT band. Since the ionized fraction of TTF is 0.5—0.7 in the three salts, we can expect two types of CT transition. The one is associated with the charge transfer from a $(TTF)^+$ ion to another $(TTF)^+$ ion, and the other is associated with that from a TTF molecule to a $(TTF)^+$ ion. The latter CT transition is expected to be considerably lower in energy than the former one. As we have shown in Fig. 2, the CT band of $(TTF)(ClO_4)$ appears at 12.0 $\times 10^3$ cm^{-1}, which has been attributed to the charge transfer between $(TTF)^+$ ions. The position of the shoulder observed in the spectra of the mixed-valence TTF salts is almost the same as the above CT band of $(TTF)(ClO_4)$. This fact strongly suggests that the observed shoulder is associated with the charge transfer from a $(TTF)^+$ ion to the neighboring $(TTF)^+$ ion within a TTF stack. Then the strong, low-energy band can be attributed the charge transfer from a TTF molecule to a $(TTF)^+$ ion. We will call the latter CT band as the CT(I) and the former as CT(II). The natures of these two CT transitions can be schematically expressed as follows:[6-8]

$$\text{CT(I)};\ (TTF)^+(TTF)^0 \longrightarrow (TTF)^0(TTF)^+$$

$$\text{CT(II)};\ (TTF)^+(TTF)^+ \longrightarrow (TTF)^0(TTF)^{2+}$$

If we assume the localized model with a strong electronic correlation, we could expect that TTF ions in the mixed valence TTF stack will be separated from each other by TTF molecule. Thus, when the ionized fraction is nearly one half, the following type of arrangement of ions and molecules will be dominant in the TTF stack.

$$\cdots (TTF)^+(TTF)^0(TTF)^+(TTF)^0 \cdots$$

This means that the probability of finding $(TTF)^+$-$(TTF)^+$ pairs in the TTF stack is very small as compared with the probability of finding $(TTF)^+(TTF)^0$ pairs in the salt where the ionized fraction is 0.5—0.7, so that the intensity of the CT(II) band must be very much lower than that of the CT(I) band in the cases of the mixed-valence salts studied here. This is in agreement with the observations.

In the c-axis spectra of the three mixed-valence salts, there is an absorption band with the maximum at 35—37 $\times 10^3$ cm^{-1}. This cannot be due to acceptor since neither the halogen ions (or atom), nor the $(SCN)^-$ ion, have any absorption band in the corresponding region.[36] The origin of this band is not clear at present. A possible origin would be a π-σ^* or σ-π^* transition of TTF with the transition dipole perpendicular to the molecular plane.

Summary and Conclusion

The polarized absorption spectra over the range of 5000—37000 cm^{-1} were observed on the small single crystals of the mixed-valence TTF salts, $(TTF)Br_{0.71}$, $(TTF)I_{0.71}$, and $(TTF)(SCN)_{0.57}$, which are known to be quasi-one-dimensional conductors. By comparing the observed spectra with the solution spectra of the molecule and monopositive ion of TTF and with the

spectrum of the $(TTF)^{+}(ClO_4)^{-}$ crystal, we have concluded that the observed spectra can be satisfactorily interpreted in terms of the model which assumes a strong charge localization. The observed spectra also indicate that the ionized fraction of TTF is appreciably smaller in $(TTF)I_{0.71}$ than in $(TTF)Br_{0.71}$. These features are consistent with the conclusion derived from the analyses of the X-ray photoelectron spectra of the mixed-valence TTF salts.

Thus one may conclude that the charges are strongly localized in the TTF stacks of these mixed-valence TTF salts, so that TTF molecules can be considered as being not in the fractionally-charged state, but either in the singly-charged state or in the neutral state, in spite of the metal-like high electrical conductivities displayed by these salts.

Kinetics of Oxidation of 4-Hydroxy-4-methyl-2-pentanone by Sodium *N*-Chloro-*p*-toluenesulfonamide

K. V. UMA and S. M. MAYANNA
Department of Chemistry, Central College, Bangalore University, Bangalore 560001, India
(Received May 6, 1977)

The kinetics of oxidation of 4-hydroxy-4-methyl-2-pentanone (diacetone alcohol) by sodium *N*-chloro-*p*-toluenesulfonamide (Chloramine-T, RNClNa) in presence of hydrochloric acid (0.05—0.6 M) has been studied at 30 °C. The reaction follows first order kinetics with respect to chloramine-T. The reaction rate depends on the square of the [H^+] and independent of the alcohol concentration. The energy and entropy of activation have been found to be 65.56 kJ mol^{-1} and -73.81 JK^{-1} respectively. The rate of reaction has been affected by the addition of potassium chloride and dioxane to the reaction mixture. A mechanism has been proposed involving diacetone alcohol and H_2OCl^+ formed by the hydrolysis of chloramine-T. Applying steady state condition to RNHCl, a rate expression has been given to account for the observed results. Kinetic data have been used in the analytical estimation of diacetone alcohol in acidic medium.

Sodium *N*-chloro-*p*-toluenesulfonamide (chloramine-T) acts as an oxidising agent in both acidic and alkaline media with two electron change per mole. The oxidative properties of chloramine-T have been recently applied in the analytical estimations of variety of organic compounds in relatively low acidic and basic media.[1-3] Chloramine-T decomposes slightly in concentrated mineral acid solutions.[4] Kinetics of oxidations of α-hydroxy acids,[5] ketones[6] and allyl alcohol[7,8] have been studied. 4-Hydroxy-4-methyl-2-pentanone (diacetone alcohol) as a lacquer solvent finds a number of industrial applications. Kinetics of oxidation of diacetone alcohol by Co^{3+} and H_2O_2 have been reported.[9,10] A review of literature shows that diacetone alcohol can be estimated by brominating agent,[11] colorimetric,[12] gas[13] and column[14] chromatographic techniques. However, these methods are indirect and less accurate. The present paper deals with the kinetics of oxidation and analytical estimation of diacetone alcohol by chloramine-T.

Experimental

Chloramine-T (E. Merck) was purified according to the method of Morris *et al.*[15] Diacetone alcohol (BDH, bp 164 °C, η_D—1.4300) and all acids (AR) except perchloric acid were distilled and used. Dioxane (BDH) was purified by Riche and Milas' method,[16] potassium chloride was of analytical grade. All solutions were prepared from freshly distilled water. KCl–HCl buffers were used for the pH range 1—2. An approximately decinormal solution of chloramine-T was prepared and standardized by iodometric method.[17] The required quantity of the alcohol was accurately weighed and dissolved in the proper solvent to give nearly 0.2 M solution. Several samples were made up for each run in iodine flasks, from stock solutions prepared at reaction temperature (30± 0.1 °C). Reactions were timed from the addition of diacetone alcohol. Samples were analyzed for chloramine-T by iodometric method. The reaction was studied up to 90%. Duplicate runs agreed with each other within 3%.

Stoichiometry

Reaction mixture containing excess chloramine-T over diacetone alcohol were kept at 30 °C in presence of 0.2 M HCl for 24 h. Estimation of the unchanged chloramine-T showed that one mole of diacetone alcohol consumed one mole of chloramine-T.

$$(CH_3)_2C(OH)CH_2COCH_3+RNClNa+H_2O \longrightarrow CH_3COCH_2COCH_3+CH_3OH+RNH_2+NaCl$$

2,4-Pentanedione and methanol in the reaction mixture were identified by dimethyldiacetylpyridinediol and formaldehyde tests[18] respectively.

Results

Kinetic Data. Oxidation of diacetone alcohol (DAA) by chloramine-T (CAT) was carried out at different initial concentrations of the reactants in presence of 0.2 M HCl at 30 °C. In presence of excess of alcohol, plot of $\log[CAT]_0/[CAT]_t$ against time was

linear (Fig. 1) passing through the origin showing that the order with respect to chloramine-T was unity. The first order rate constant was found to be independent of [DAA] (Table 1).

The kinetics of oxidation was studied at different concentrations of HCl (0.05—0.6 M). The rate constant increased with increase in [H+] (Table 2). A plot of log k *vs.* log [H+] gave a straight line with slope of two.

TABLE 3. EFFECT OF TEMPERATURE ON THE REACTION RATE
$[CAT]_0=0.005M$, $[DAA]_0=0.10M$,
$[H^+]=0.2M$

Temperature (K)	293	303	313	323
$10K$ (s^{-1})	2.787×10^{-3}	6.75×10^{-3}	1.635×10^{-2}	3.846×10^{-2}

Oxidation was also carried out at different temperatures (20—50 °C) in presence of 0.2 M HCl. From the corresponding data (Table 3) at 20, 30, 40, and 50 °C, the Arrhenius activation energy and entropy of activation were found to be 65.26 kJ mol^{-1} and −73.81 J K^{-1} respectively.

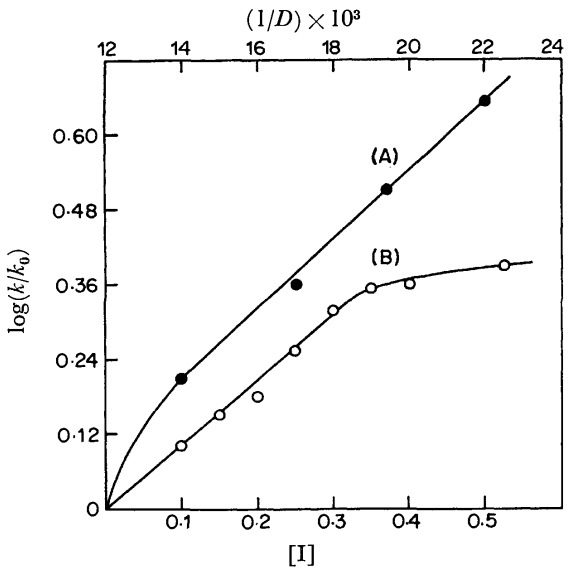

Fig. 2. Variation of rate constant with deilectric constant of the medium (B) and concentration of potassium chloride (A).

In presence of 0.2 M HCl, the effect of potassium chloride on the reaction rate at 30 °C up to ionic strength (I) 0.5 was investigated, the results of which are shown in Fig. 2. The line A shows the variation of log k/k_0 (k and k_0 are the rate constants with and without salt) with I for potassium chloride. The reaction rate was accelarated by the addition of potassium chloride.

Solvent effect on the reaction rate was studied. A series of kinetic runs were made in water–dioxane mixture of various compositions (10—40% dioxane by volume) at 30 °C in presence of 0.2 M HCl. Even in the mixture of dioxane and water, the reaction follows first order kinetics. The line B (Fig. 2) gives the variation of log k/k_0 (k and k_0 are the constants with and without dioxane respectively) with $1/D$ (D, the dielectric constant of the medium). The rate constant increased on increasing the amount of dioxane in the mixture. However, the variation is linear up to 30% dioxane in the mixture.

Analytical Data. Preliminary Studies: Known amounts of diacetone alcohol solution in the proper solvent were added to a known excessive volume (10—20%) of chloramine-T in an iodine flask placed in a thermostat at 30 °C. The reaction mixture was set aside for various intervals of time with occasional shaking. Then the excess of chloramine-T was determined by back titration.

Table 4 gives a typical set of results for the extent of oxidation of diacetone alcohol in 30 min at 30 °C by an excess of chloramine-T. It is seen that oxidation is slow in media other than hydrochloric acid. The rate of oxidation increases gradually as the concentra-

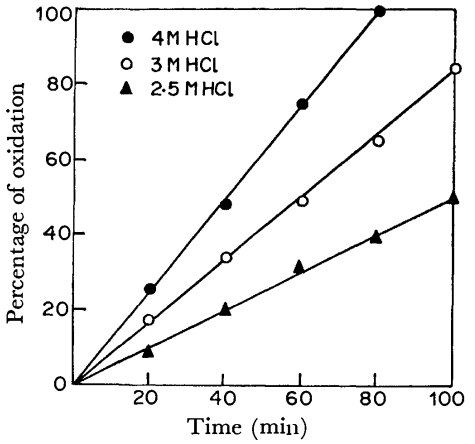

Fig. 3. Percentage of oxidation of diacetone alcohol by chloramine-T at 30 °C, at different time intervals with various concentrations of hydrochloric acid.

tion of hydrochloric acid increases, but the increase become rapid at or above 4 N acid. The extent of oxidation above 2 N hydrochloric acid is a function of time interval. Figure 3 shows the variation of extent of oxidation of diacetone alcohol with time at different concentrations of hydrochloric acid.

Recommended Procedure. Prepare an aqueous solution of diacetone alcohol (0.1 M). Add an aliquot containing 0.1—2.5 mM to a measured excessive (10—20%) volume of 0.1 N chloramine-T containing enough hydrochloric acid to make the overall acid concentration 4 N. Shake the mixture and keep it in a thermostat at 30 °C for 2 h. Add 20 ml of 10% potassium iodide solution and 10 ml of 2 N sulfuric acid and titrate with 0.1 N sodium thiosulfate. Run a blank with chloramine-T solution containing 4 N acid keeping for 2 h. The amount (mgs) of diacetone alcohol in the experimental solution is given by

$$X = 58Y(V_1 - V_2),$$

where Y is the normality of the thiosulfate, V_1 is the blank titration and V_2 the volume of thiosulfate used to titrate the excess of chloramine-T after oxidation of diacetone alcohol.

Detailed study of diacetone alcohol has brought out the following facts; (i) Foreign ions such as NO_3^-, ClO_4^-, and SO_4^{2-} have no influence up to ionic strength 0.25. (ii) Potassium chloride has slight effect on the rate of oxidation. (iii) The stoichiometry is unaffected by a reversal of the order of addition of oxidant and diacetone alcohol. (iv) The reaction rate is slightly retarded in sulfuric acid and perchloric acid (*cf.* Table 4).

Some typical results of analysis of diacetone alcohol in aqueous solutions are given in Table 5. The values obtained are accurate within 1.5%.

Discussion

Chloramine-T in aqueous solution undergoes dissociation[19]

$$RNClNa \rightleftharpoons RNCl^- + Na^+ \qquad (1)$$

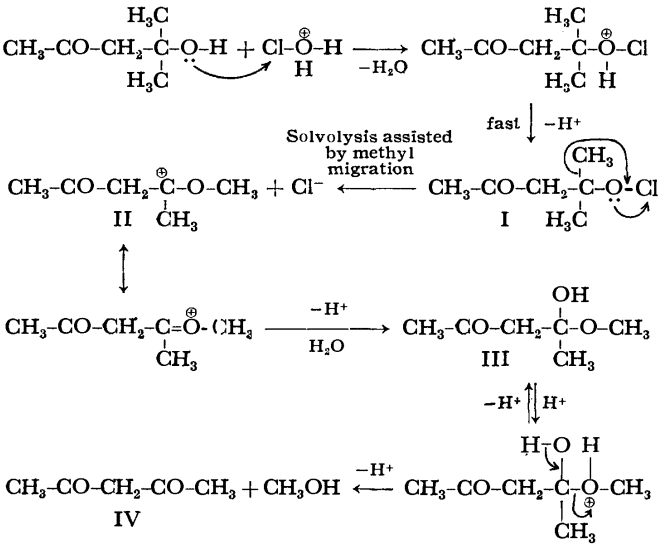
$RNCl^-$ in acidic solution gives chloronium ion (Cl^+) which reacts with water to give H_2OCl^+. The following consecutive steps have been proposed[8] for the formation of H_2OCl^+ from $RNCl^-$:

$$H^+ + RNCl^- \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} RNHCl \quad \text{slow} \qquad (2)$$

$$RNHCl + H^+ \xrightarrow{k_2} RNH_2 + Cl^+ \quad \text{still slower(rds)} \qquad (3)$$

$$Cl^+ + H_2O \xrightarrow{k_3} H_2OCl^+ \quad \text{fast} \qquad (4)$$

H_2OCl^+ attacks diacetone alcohol in a fast step as follows:



The attack of the electrophile Cl^+ on an unshared pair of electros on the oxygen of the alcohol and the elimination of H^+ produces the alkyl hypochlorite (I) in a fast step. The weak O–Cl bond may be expected to break readily by solvolytic attack by water is assisted by methyl migration to produce a stabilized carbonium ion. The attack by water produces a hemiacetal (III) which is readily hydrolysed to the diketone (VI). The key step of methyl migration to electron deficient oxygen is similar to Baeyer-Villiger oxidation of ketones.[20] In this case also, formation of a discrete oxene is unlikely and the departure of Cl^- ion and migration of methyl group is concerted.

Applying steady state conditions for RNHCl, one could derive the rate equation

$$\frac{-d[CAT]}{dt} = \frac{k_1k_2[CAT][H^+]^2}{k_1 + k_2[H^+]},$$

when $k_{-1} \gg k_2[H^+]$ the above equation reduces to

$$\frac{-d[CAT]}{dt} = \frac{k_1k_3}{k_{-1}}[CAT][H^+]^2.$$

This is in agreement with the experimental results. The increase of rate constant by the presence of potassium chloride and in dioxane–water mixture (Fig. 2) is in support of the rate determining step involving an ion and a neutral molecule[21,22] step (3).

Negative entropy of activation perhaps indicate the complex nature of the oxidation of diacetone alcohol by chloramine-T.

The authors are grateful to Dr. D. S. Mahadevappa, Professor of Chemistry, University of Mysore and Dr. V. R. Dani, of our department, for helpful discussions. One of us (K.V.U.) thanks Professor M. Shadaksharaswamy, Head of the Dept. of Chemistry, Central College, Bangalore University, Bangalore and Professor

P. S. Ambikadevi, Principal, Maharanis Science College, Bangalore, for their kind encouragement.

Pure Nuclear Quadrupole Resonance of *Ionic* Halides. I. ^{79}Br-NQR Investigation of the Hydrogen Bonding, the ^{1}H–^{2}D Isotope Effect, and the "Order-Disorder" Transition in the Anilinium Bromides $C_6H_5NH_3^{\oplus}Br^{\ominus}$, $C_6H_5ND_3^{\oplus}Br^{\ominus}$, and $C_6D_5NH_3^{\oplus}Br^{\ominus}$*,†

Wolfgang PIES and Alarich WEISS

Institut für Physikalische Chemie, Technische Hochschule Darmstadt, D-6100 Darmstadt, Germany

(Received June 30, 1977)

The ^{79}Br-NQR spectra of anilinium bromide, $C_6H_5NH_3^{\oplus}Br^{\ominus}$, of anilinium-$d_3$ bromide, $C_6H_5ND_3^{\oplus}Br^{\ominus}$, and of anilinium-$d_5$ bromide, $C_6D_5NH_3^{\oplus}Br^{\ominus}$, have been investigated in the temperature range $77 \leq T/K \leq 350$. The three compounds show an order-disorder phase transition near room temperature. The respective transition temperatures have been determined as 296.9 K ($C_6H_5NH_3^{\oplus}Br^{\ominus}$), 291.5 K ($C_6H_5ND_3^{\oplus}Br^{\ominus}$), and 297.6 K ($C_6D_5NH_3^{\oplus}Br^{\ominus}$). The large value of the ^{79}Br-NQR frequency ($\nu = 17.780$ MHz at 77 K for $C_6H_5NH_3^{\oplus}Br^{\ominus}$) and the large ^{1}H–^{2}D isotopic shift of this frequency ($\approx$400 kHz at 77 K by deuteration of the $NH_3^{\oplus}$-group) have been interpreted in terms of hydrogen bonding N–H···Br$^{\ominus}$. The state of order in the high temperature modification is discussed in the light of the ^{79}Br-NQR spectrum. The ^{79}Br-NQR frequency of the Br$^{\ominus}$ ion in the low temperature modification is related to the change in the monoclinic angle β and to the temperature dependence of the order parameter $s \propto \{(T_c - T)/T_c\}^{1/3}$.

In the course of an X-ray study of anilinium bromide, $C_6H_5NH_3^{\oplus}Br^{\ominus}$, Taguchi[1] noticed that "Weissenberg photographs prepared at different seasons of the year, using one and the same crystal, showed differences in detail." This remarkable behavior led to the discovery of the phase transition of anilinium bromide. According to him,[1] $C_6H_5NH_3^{\oplus}Br^{\ominus}$ is orthorhombic (modification **I**, D_{2h}^{10}-Pnaa, $Z=4$) above, and monoclinic (modification **II**, C_{2h}^{5}-P2$_1$/a, $Z=4$) below the transition temperature, given as $T_{II,I}=300.7$ K. The transformation was studied as well by calorimetry, DTA, and dilatometry showing a typical lambda type behavior of the heat capacity and an abnormal thermal expansion below $T_{II,I}=295$ K.[2] The X-ray diffraction analysis of the high temperature modification **I** by Nitta *et al.*[3] led to the determination of the positional parameters (hydrogen excluded). The crystal symmetry requires that the principal axis of the anilinium ion (N–C$_1$···C$_4$ axis) lies on a twofold symmetry axis. On the other hand, it is reasonable to assume a pyramidal configuration (C_{3v}) of the $-NH_3^{\oplus}$-group. The lack of correspondence between the symmetry of this group (threefold axis) and the point-group symmetry of the anilinium cation (twofold axis) indicates that there must be either a static orientational disorder of the $-NH_3^{\oplus}$-group or a rotation about the C$_1$–N bond as a "free" rotation or fast reorientation of the ammonium group. In the monoclinic structure of the low temperature modification **II** the requirement of the twofold symmetry imposed on the C$_4$···C$_1$–N axis is lost. An infrared study by Cabana and Sandorfy[4] corroborates the implications of the X-ray work.

We became interested in the phase transition of anilinium bromide in the course of ^{35}Cl-, ^{79}Br-, ^{127}I-NQR studies on chloroanilinium salts[5,6a] and on other possibly hydrogen bonded iodides and bromides (*e.g.* guanidinium halides[6b,c]). For $C_6H_5NH_3^{\oplus}Br^{\ominus}$ (**I**) one expects a ^{79}Br-NQR signal, to be observable with a nonpulse technique only if in the time scale of the NQR experiment (some 10^{-7} s) there is the same ordered arrangement of neighbors around each of the crystallographically equivalent Br$^{\ominus}$ ions. The NQR experiment, therefore, may be helpful to decide between a static orientational disorder of the $NH_3^{\oplus}$-group on the one hand, and a "free" rotation or a fast reorientation of this group on the other.

Experimental

Materials. Anilinium bromide, $C_6H_5NH_3^{\oplus}Br^{\ominus}$, and anilinium-$d_5$ bromide, $C_6D_5NH_3^{\oplus}Br^{\ominus}$, were prepared by adding freshly distilled aniline or aniline-d_5 (Merck, 99% D) to an excess of an aqueous solution of hydrobromic acid. The precipitated salts were recrystallized from aqueous HBr and dried over P_2O_5 in a desiccator. The identity of the colorless crystal powders was proven by chemical analyses [Calcd (found) for C_6H_8BrN: C, 41.41 (41.32), H, 4.63 (4.69), N, 8.05% (8.10%); for $C_6H_3D_5BrN$: C, 40.26 (40.14); ^{2,1}H: 4.50 (4.50), N: 7.81% (7.83%)]. The compounds are free of water of crystallization. $C_6H_5NH_3^{\oplus}Br^{\ominus}$ decomposes at 292 °C. The degree of deuteration of $C_6D_5NH_3^{\oplus}Br^{\ominus}$ was checked by high resolution ^{1}H-NMR to be 95% or better. Anilinium-d_3 bromide, $C_6H_5ND_3^{\oplus}Br^{\ominus}$, was prepared by dissolving $C_6H_5NH_3^{\oplus}Br^{\ominus}$ in excess D_2O (98% D) and removing the water with P_2O_5 in a desiccator system. This process was repeated twice. Again the degree of deuteration was checked by ^{1}H-NMR to be 95% or better. This last result has also been strengthened by the NQR spectra of this compound.

NQR Measurements. The ^{79,81}Br-NQR spectra were observed on polycrystalline samples with a Decca-Radar-NQR-spectrometer, using Zeeman modulation and side band suppression. The spectrometer was, in general, operated with a time constant of 10 s. The internal marker system, used for the determination of the resonance frequencies, was checked by frequent comparisons with a Rhode & Schwarz WIK BN 4421 frequency meter and a Rhode & Schwarz FEG 3 frequency counter. Additionally, the marker unit was

* Partly presented at the 76. Hauptversammlung der Deutschen Bunsengesellschaft für Physikalische Chemie, Braunschweig, Germany, May 1977.

† Part of a Dr.-Ing. thesis, to be submitted by W. Pies to the Technische Hochschule Darmstadt (D 17).

proved to be correct by giving the literature values for the ^{35}Cl-NQR frequency of α-paradichlorobenzene as described earlier.[7] The measured NQR frequencies are considered to be accurate to at least ±0.005 MHz.

Temperature Measurements. The sample temperature was achieved either by thermostating the sample holder with a Lauda Kryostat TUK 30D (temperature range $245 < T/K < 350$) or by immersing the sample holder into different slush baths[8] (for $T < 245$ K) or into liquid nitrogen ($T = 77$ K).

The temperature measurement units, each consisting of an iron-constantan thermocouple and a Metrawatt Symmetra D millivoltmeter, were calibrated in the temperature range $280 \leqq T/K \leqq 310$ (that is, within the vicinity of the transition points) with a standardized mercury thermometer with 0.1° graduation before and after use. The calibration of the thermocouple was done as well at the liquid nitrogen boiling point. During the NQR measurements the thermocouple was placed inside the sample holder very close to the sample tube. It was checked in separate runs that the temperature measured with this thermocouple and at this position, within the reading accuracy (0.1 K) of the instrument, was identical with the temperature inside the sample measured with the second thermocouple under the conditions of the NQR experiments. This condition was fulfilled, at least in the temperature range $280 \leqq T/K \leqq 310$. At $T = 77$ K, the difference between both thermocouples in their respective positions was not larger than 0.5 K, which is rather unimportant for the NQR measurements on the anilinium bromides investigated here, since the temperature coefficient of the ^{79}Br-NQR frequency drops down to $|\Delta\nu/\Delta T| \leqq 1$ kHz K^{-1} at 77 K. The temperature measurements are therefore considered to be accurate to ±0.1 K at $280 \leqq T/K \leqq 310$, and to ±0.5 K, or better, outside this range.

Results

Two NQR signals have been observed for anilinium bromide in the frequency range $7 \leqq \nu/MHz \leqq 30$ at $T = 273$ K (modification **II**) and at $T = 303$ K (modification **I**) as well. Both resonances have been ascribed to the $Br^{\ominus}$ ion as the frequency ratio is identical with the ratio of the quadrupole moments of the bromine isotopes $Q(^{79}Br)/Q(^{81}Br) = 1.1970$. This NQR spectrum gives evidence that there is only one bromide ion in the asymmetric unit of the crystallographical unit cell, in accordance with the results of the X-ray work.[1,3] In Table 1 the ^{79}Br-NQR frequencies of the investigated anilinium bromide samples are listed for $T = 77$ K, for a second temperature just below, and for a third just above the respective transition temperatures of the different species. Well defined NQR signals have been observed in both the low temperature modification **II** and the high temperature modification **I**. No change in the line shapes could be seen in passing through the

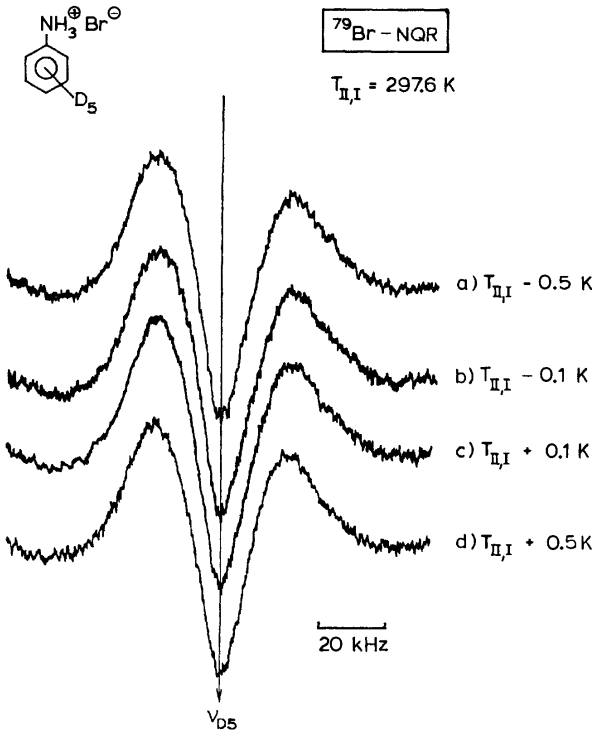

Fig. 1. ^{79}Br-NQR signal of anilinium-d_5 bromide in passing the phase transition point. The signals at four different temperatures near $T_{II,I}$ are shifted relative to each other in such a way that the center of the signals, ν_{D5}, falls together. The experimental (unshifted) results are: a) $T = 297.1$ K: $\nu_{D5} = 16.458$ MHz; b) $T = 297.5$ K: $\nu_{D5} = 16.447$ MHz; c) $T = 297.7$ K: $\nu_{D5} = 16.443$ MHz; d) $T = 298.1$ K: $\nu_{D5} = 16.441$ MHz.

b) Mechanical mixture. c) Solid solution.

transition point (Fig. 1). Deuteration of the ammonium group has a very pronounced effect on the ^{79}Br-NQR signal of the $Br^{\ominus}$ ion. The frequency is shifted by about 400 kHz or more to lower values for both modifications. In contrast, the shift of the NQR line caused by deuteration of the benzene nucleus is smaller by about an order of magnitude near room temperature, but it is at first sight unexpectedly large (92 kHz) at $T=77$ K. Again the resonance frequency is lowered. The mechanical mixture of anilinium bromide and anilinium-d_5 bromide exhibits the ^{79}Br-NQR signals of the crystalline components with reduced signal-to-noise ratio. Figure 2 demonstrates the relative frequency shift due to the ring deuteration. In the solid solution $(C_6H_5NH_3^{\oplus})_{1-x}(C_6D_5NH_3^{\oplus})_xBr^{\ominus}$ there is a statistical distribution of fully protonated and ring-deuterated anilinium cations. Therefore the electric field gradient varies statistically at the bromine nucleus. The extreme values of the EFG may be taken to be those of the pure components of the solid solution. For $T=294$ K and $T=299$ K the difference between the resonance frequencies of $C_6H_5NH_3^{\oplus}Br^{\ominus}$ and $C_6D_5NH_3^{\oplus}Br^{\ominus}$ is small, some 30 kHz at most. Consequently, one observes a single broadened ^{79}Br-NQR line, for the solid solution with $x=0.5$ approximately centered in the middle of the lines of the pure components (Figs. 2i and 2ii). At $T=77$ K the ^{79}Br-NQR signal of the solid solution is spread over $\approx$90 kHz, and in this case no signal has been found using a conventional superregenerative oscillator (Fig. 2iii). As one may expect from the large separation of the ^{79}Br-NQR signals of $C_6H_5NH_3^{\oplus}Br^{\ominus}$ and $C_6H_5ND_3^{\oplus}Br^{\ominus}$, no signal could be found for the solid solution of the anilinium bromide and anilinium-d_3 bromide, $C_6H_5NH_{3(1-x)}D_{3x}^{\oplus}Br^{\ominus}$ ($x=0.5$). In addition to the ^{1}H-NMR analysis, this result proves that the degree of deuteration of the anilinium-d_3 bromide sample is fairly high.

The temperature dependence of the ^{79}Br-NQR frequency of anilinium bromide and its two deuterated derivatives, $C_6H_5ND_3^{\oplus}Br^{\ominus}$ and $C_6D_5NH_3^{\oplus}Br^{\ominus}$, has been investigated in the temperature range $77 \leqq T/K \leqq 350$. (The crystal structure determination[3] of the high temperature modification was done at $T=343$ K.) As usual in NQR spectroscopy, the resonance frequency decreases with increasing temperature, but, moreover, the frequency *versus* temperature curves of all three species show the following peculiar behavior. At $T=$ 77 K the absolute value of the temperature coefficient $|\Delta\nu/\Delta T|$ is less than 1 kHz K^{-1}. It increases progres-

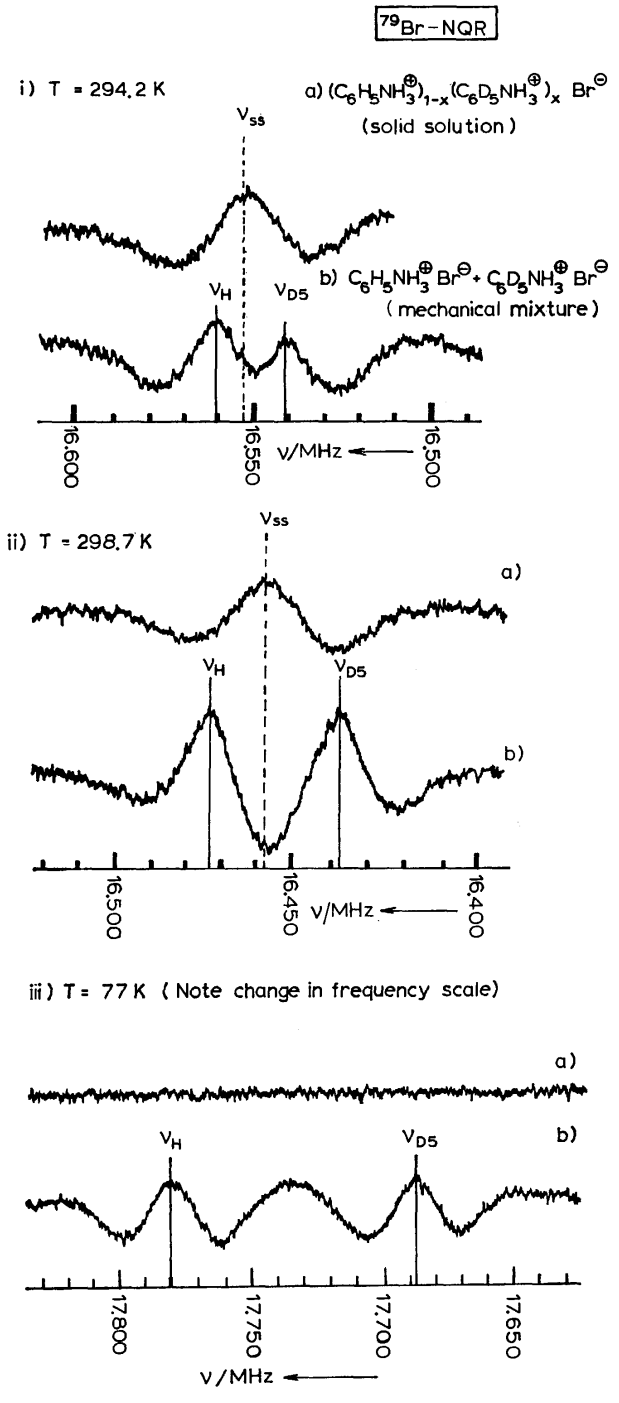

Fig. 2. ^{79}Br-NQR signals of a) the solid solution of anilinium bromide and anilinium-d_3 bromide ($x=0.5$) and of b) the mechanical mixture of an equal amount of the pure components: i) at a temperature just below the resp. $T_{II,I}$, ii) at a temperature just above the resp. $T_{II,I}$, iii) at $T=77$ K [frequency scale condensed compared with i) and ii)].

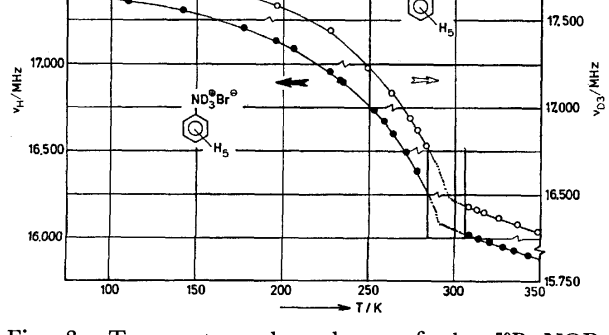

Fig. 3. Temperature dependence of the ^{79}Br-NQR frequencies of anilinium bromide (open circles: ○) and anilinium-d_3 bromide (full circles: ●) in the temperature range $77 \leqq T/K \leqq 350$. The area around the transition point is enlarged in Fig. 4.

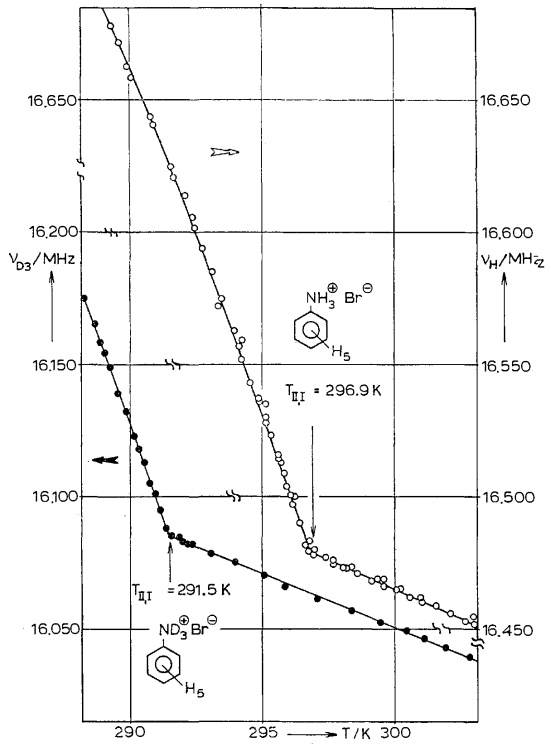

Fig. 4. Temperature dependence of the ^{79}Br-NQR frequencies of anilinium bromide (open circles: ○), and of anilinium-d_3 bromide (full circles: ●) in the close vicinity of the transition points.

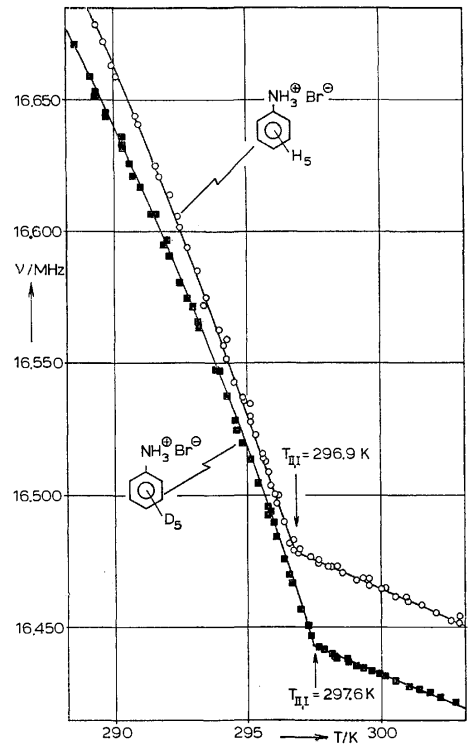

Fig. 5. Temperature dependence of the ^{79}Br-NQR frequencies of anilinium bromide (open circles: ○), and anilinium-d_5 bromide (full squares: ■) in the close in the close vicinity of the transition points.

sively with increasing temperature, reaching a maximum value of $|\Delta\nu/\Delta T| \approx 30$ kHz K^{-1}. At a certain critical temperature, which is considered to be the transition temperature $T_{II,I}$ of the respective species, each frequency *versus* temperature curve changes abruptly in slope. Above this critical temperature $|\Delta\nu/\Delta T|$ has a much lower value, approximately 4 kHz K^{-1}. The temperature dependence of the ^{79}Br-NQR frequencies of $C_6H_5NH_3^{\oplus}Br^{\ominus}$ and $C_6H_5ND_3^{\oplus}Br^{\ominus}$ is graphically displayed in Fig. 3 for the whole temperature range investigated. $\nu(T)$ of the ring-deuterated compound $C_6D_5NH_3^{\oplus}Br^{\ominus}$ has been omitted, since its respective frequencies have only been measured at $T=$ 77 K and at $247 \leqq T/K \leqq 345$; they would be nearly indistinguishable from those of the fully protonated anilinium bromide in the scale used in Fig. 3. The close similarity of the ν–T-curves is clearly seen. For $T < T_{II,I}$ the curvature is quite similar to that of the monoclinic angle β *versus* temperature in the special case of anilinium bromide.[1] More generally, $\nu(^{79}Br) = f(T)$ resembles a function "order parameter$=f(T)$" near the critical temperature. Figures 4 and 5 show sections of the $\nu(T)$-graphs in close vicinity of the transition points of the three species. Regarding the frequency scale and the strongly expanded temperature scale, the scatter of the points on these curves is rather small. For anilinium bromide and anilinium-d_5 bromide, the $\nu(^{79}Br) = f(T)$ data were collected from at least two different samples of each compound in several $\nu = f(T)$ runs. $C_6H_5ND_3^{\oplus}Br^{\ominus}$ has been studied in only one sample in a single temperature run.

In addition to the large frequency shift due to the ammonium deuteration, also the transition tempera-

TABLE 2. TEMPERATURE DEPENDENCE OF ^{79}Br-NQR FREQUENCIES OF ANILINIUM BROMIDE, ANILINIUM-d_3 BROMIDE, AND ANILINIUM-d_5 BROMIDE IN THE VICINITY OF THE TRANSITION TEMPERATURES $T_{II,I}$: $\nu_{calcd}(^{79}Br) \pm \sigma = a_0 + a_1 T + a_2 T^2$

a) σ=standard deviation; Z=Number of experimental points in the least-squares fit. b) Determined as intersection of the respective polynomials in the temperature range $290 \leqq T/K \leqq 300$K. c) For $246.5 \leqq T/K \leqq 297.5$: $\nu_{D5} = -265.1364 + 428.9561 \cdot 10^{-2} T - 2441.3889 \cdot 10^{-5} T^2 + 618.3218 \cdot 10^{-7} T^3 - 589.6038 \cdot 10^{-10} T^4$, where ν is in MHz and T in K. σ=0.0016 MHz; Z=76.

ture $T_{II,I}$ is affected strongly by the isotopic exchange in being lowered by as much as 5.4 K (see Fig. 4). However, the critical temperature of $C_6D_5NH_3^{\oplus}Br^{\ominus}$ is only slightly elevated (by 0.7 K) as compared with that of $C_6H_5NH_3^{\oplus}Br^{\ominus}$ (see Fig. 5). The transition temperatures $T_{II,I}$ of the three anilinium species have been determined as the intersection of the respective ν-T-curves of the ^{79}Br-resonances. For this reason, the function $\nu(^{79}Br)=f(T)$ have been described in a polynomial form for both modifications **I** and **II** of the three species. Table 2 gives the coefficients a_i of the polynomials

$$\nu = \sum a_i \cdot T^i \qquad (1)$$

for each of the three anilinium bromide species. Three coefficients (parabolic approximation: a_0, a_1, a_2) were found to describe $\nu(T)$ reasonably well in the given temperature range. Additionally, the standard deviation σ, the number of experimental points used in the least squares fit and the transition temperatures determined are listed. It was not possible to describe the ^{79}Br-NQR frequencies of the low temperature modification **II** analytically for the whole temperature range from 77 K to $T_{II,I}$ by either a simple Bayer-type function[9]

$$\nu = a - \frac{b}{e^{c/T}-1} \qquad (2)$$

or in a polynomial form with a reasonable number of parameters.

Discussion

In the first section we discuss the significance of the value of the ^{79}Br-NQR frequency of anilinium bromide with regard to the question of hydrogen bonding in this compound. In the second part this question will be dealt with in the light of the hydrogen-deuterium isotope effect. Then the state of order of the high temperature modification is discussed and the fourth section treats the temperature dependence of the ^{79}Br-NQR frequencies and its relation to the order parameter of the low temperature modification.

The Origin of the Finite Electric Field Gradient at the Site of the Ion $Br^{\ominus}$ in $C_6H_5NH_3^{\oplus}Br^{\ominus}$. The detection of a Br-NQR signal in anilinium bromide is interesting in itself. The charge distribution of a free bromide ion is spherically symmetric, therefore, the electric field gradient (EFG) vanishes, whereby e^2qQ/h and ν are zero. A non-zero EFG at the site of the bromine nucleus in $Br^{\ominus}$ can be created by its incorporation into a crystal lattice at a site with non-cubic point symmetry, it is considered to be small in purely ionic crystals. Additional interactions such as covalent bonding and hydrogen bonding may enlarge the EFG and thereby the resonance frequency.

The question arises, whether the rather high value of the ^{79}Br-NQR frequency in anilinium bromide is in itself a proof for N–H$^{\oplus}$···Br$^{\ominus}$ hydrogen bonding in this solid. For comparison we shall discuss briefly the ^{79}Br-frequencies of other bromides (Table 3). Having $Na^{\oplus}$ ions as next nearest neighbors of $Br^{\ominus}$ substitutionally incorporated into KBr, Andersson[10] found for $^{79}Br^{\ominus}$ $e^2qQ/h=14.03$ MHz. This shows that $\nu(^{79}Br)$-values of up to 7 MHz can be caused by a non-cubic point symmetry. Larger ^{79}Br-NQR frequencies are found for $BaBr_2$, $PbBr_2$, and $PBr_4^{\oplus}Br^{\ominus}$, compounds in which some interatomic distances metal-to-bromine and bromine-to-bromine, respectively, are smaller than the commonly accepted ionic radii sum.[11,12] Interpreting this as a sign for a small covalent bond character the high $^{79}Br^{\ominus}$-NQR frequencies of these three compounds are understandable.

In the tetragonal phase NH_4Br(**III**), where hydrogen bonding is undoubtedly present, the ^{79}Br quadrupole coupling constant does not exceed 6 MHz[13] because the hydrogen bonds are arranged in a nearly regular tetrahedron around $Br^{\ominus}$ resulting in a charge distribution which is close to spherosymmetry. This is lost if one or more of the hydrogens in the $NH_4^{\oplus}$ group are substituted by alkyl groups. For seven alkylammonium bromides Frausto da Silva and Vilas Boas[14] found ^{79}Br-NQR signals in the frequency range of $12<\nu/\text{MHz}<19$ at $T=306$ K. They claim that the distortion of the symmetry of the electron cloud of the halide ions "is so pronounced that it cannot be originated only by second order lattice effects in a 100% ionic structure" but by the formation of N–H$^{\oplus}$···X$^{\ominus}$ hydrogen bonds. These bonds had been postulated before from X-ray and IR studies.[15] Hydrogen bonding has been proposed to be present in anilinium bromide as well.[1-4] The rather high ^{79}Br-NQR frequency of anilinium bromide

a) The subscripts H and D mark the value for the protonated and the deuterated form respectively. The error in ν is ±0.005 MHz or less for the first five compounds. The error in $\nu_H-\nu_D$ is ±0.002 MHz or less for the ^{35}Cl-NQR frequencies of 3-chloroanilinium iodide and 4-chloropyridinium hexachlorostannate(IV) and for the ^{79}Br-NQR frequencies of anilinium bromide/anilinium-d_5 bromide around room temperature (see Fig. 2).

found (17.780 MHz at $T=77$ K) supports the assumption of a hydrogen-bridged bromide ion. However, the frequency value alone may not be sufficient as a reliable proof of N–$H^{\oplus}\cdots Br^{\ominus}$ hydrogen bonding.

^1H–^2D Isotope Effect. The substitution of D for H in the ammonium group of anilinium bromide was undertaken to gain some more definite NQR evidence about the hydrogen bridge N–$H^{\oplus}\cdots Br^{\ominus}$ in this compound. In case there is no hydrogen bonding N–$H^{\oplus}\cdots Br^{\ominus}$, the ion $Br^{\ominus}$ is isolated and therefore not affected by this isotopic exchange in the first approximation. If at all, only a slight shift of the resonance frequency to higher values is expected because of the reduced torsional amplitudes of the N–D modes.

In case of a hydrogen bond N–$H^{\oplus}\cdots Br^{\ominus}$, the effect of deuteration can be followed along the lines given by Coulson[16] for the isotope effect on an asymmetric O–H···O bond. In a normal isolated O–H bond, replacement of hydrogen by deuterium leads to a small shortening of the interatomic distance due to the anharmonicity of the O–H vibration. In an O–H···O hydrogen bonding system a decrease of the distance r_{O-H} causes an increase of the distance R_{O-O}[17,18,19a)]. Therefore, if $r_{O-D}<r_{O-H}$, as in the isolated bond, the O–O distance is enlarged by deuteration, $(R_{O-O})_D>(R_{O-O})_H$ (the subscripts H and D stand for the hydrogen and deuterium bond respectively). This indeed has been found experimentally for short and intermediate asymmetric O–H···O hydrogen bonds (Ubbelohde effect)[20,18b,21)]. By analogy, for the bond N–$H^{\oplus}\cdots Br^{\ominus}$ in anilinium

bromide, $r_{N-D}<r_{N-H}$ and $(R_{N-Br})_D>(R_{N-Br})_H$ is expected. Deuteration moves the bromide ion farther away from the nitrogen and the hydrogen atoms and $Br^{\ominus}$ approaches somewhat more the state of an isolated, non-hydrogen bonded ion. The ^{79}Br-NQR frequency should decrease upon deuteration and the frequency shift should be positive:

$$\Delta\nu_{H-D} = \nu_H(^{79}Br) - \nu_D(^{79}Br) > 0. \quad (3)$$

This has been found here for the anilinium bromides $C_6H_5NH_3^{\oplus}Br^{\ominus}$ and $C_6H_5ND_3^{\oplus}Br^{\ominus}$ (Tables 1 and 4). Also the magnitude of the H–D isotope effect support the assumption of hydrogen bonding in anilinium bromide. For $X^{\ominus}=I^{\ominus}$, $Cl^{\ominus}$, an analogous ^{1}H–^{2}D effect on the halogen NQR frequencies of the halide ions has been found in 3-chloroanilinium iodide,[6a] guanidinium iodide,[6b] and tris(sarcosine)calcium chloride[22] as well. Table 4 shows that the NQR frequency shifts due to deuteration, $\Delta\nu_{H-D}$, range from +1.5% to +3.5%.

The ability of complex ions like $SnCl_6^{2-}$ to form hydrogen bonds is strongly reduced compared with that of $X^{\ominus}=Cl^{\ominus}$, $Br^{\ominus}$, $I^{\ominus}$. This is seen on the infrared spectra of the corresponding guanidinium salts,[23] pyrimidinium salts,[24,25] and pyridinium salts.[26] Hydrogen bonding in 4-chloropyridinium hexachlorostannate(IV) is proposed in ^{35}Cl-NQR and X-ray work[27,28] and should be rather weak. Deuteration, therefore, has only a small influence on the ^{35}Cl frequencies of the complex ion. A frequency shift toward a more isolated $SnCl_6^{2-}$ ion is expected. Accordingly, the lowest ^{35}Cl-NQR signal attributed to the hydrogen-bonded-chlorines should move to higher frequencies and the two other signals to lower frequencies. This view is supported by experimental results.

Examples for deuteration shifts presumably caused by other effects than hydrogen bonding are also found in Table 4: the isotope effects on the NQR frequencies of the meta-Cl in 3-chloroanilinium iodide, of the *para*-Cl in 4-chloropyridinium hexachlorostannate(IV), and, as a reference, of the chlorine atoms in 2,2-dichloropropane. All these chlorines show small but definite positive or negative isotopic shifts.

The ^{1}H–^{2}D isotope effect on the ^{79}Br-NQR signal in $BaBr_2\cdot 2H_2O$[29] and on the ^{35}Cl-NQR signals of $NaAuCl_4\cdot 2H_2O$[30] does not follow the lines developed above for hydrogen bonded halides. This is not surprising in the case of the barium salt, since its bromine frequency is well within the limits of a purely ionic $Br^{\ominus}$, and the $Br^{\ominus}$ may not be hydrogen bonded at all in $BaBr_2\cdot 2H_2O$. In $NaAuCl_4\cdot 2H_2O$ the O–H···Cl bond[30–32] is a rather debatable one, the shortest O–Cl distance (3.42 Å[33]) is appreciably longer than the sum of the usually accepted van der Waals radii (3.20 Å[19b]). Here Gallagher's[20] proposal may be followed that deuteration strengthens very weak hydrogen bonds. Fryer and Smith[30] explained in this way the isotopic shift of the lowest ^{35}Cl-NQR signal, but stressed the fact that other solid state effects may also be responsible for the small H–D effect in $NaAuCl_4\cdot 2H_2O$.

The shift of the ^{79}Br-NQR frequency of the $Br^{\ominus}$ by deuteration of the benzene ring of anilinium bromide remains to be discussed. It is in the order of an effect of lattice dynamics at room temperature and above it, but quite large at liquid nitrogen temperature. The reason for this is not clear to us yet. It might be that this strong shift is due to hindered oscillations of the anilinium ion around its longest axis. Indications of such oscillations have been found by Nitta *et al.*[3] for the high temperature phase and the close similarity of the structures may allow such a behavior in the low temperature phase as well. An investigation of partially deuterated anilinium bromides, as $4\text{-}DC_6H_4NH_3^{\oplus}Br^{\ominus}$ and $2,3,5,6\text{-}D_4C_6HNH_3^{\oplus}Br^{\ominus}$, could probably be helpful in finding an explanation for this large isotope effect.

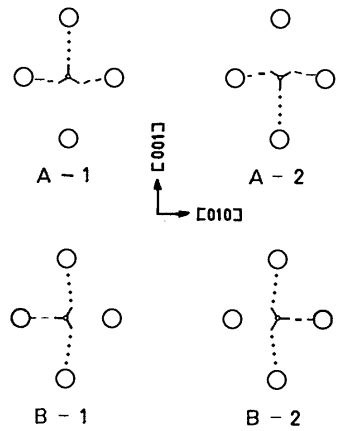

Fig. 6. Energetically favored orientations of the $-NH_3^{\oplus}$ group with respect to neighboring bromide ions $Br^{\ominus}$ according to Ref. 3. Short hydrogen bonds (R_{N-Br}= 3.30 Å) are hyphenated, long hydrogen bonds (R_{N-Br}= 3.48 Å) are dotted. ○=Br; =NH_3.

State of Order in the High Temperature Modification. The apparent discrepancy between the symmetry of the anilinium ion in the crystal (diagonal axis through $N\text{–}C_1\cdots C_4$) and the symmetry of the $-NH_3^{\oplus}$ group (threefold axis) disappears, when the three hydrogen atoms bound to the nitrogen atom "occupy statistical positions by some means."[1,3] There are two limiting cases shown by Taguchi[1] and Nitta *et al.*:[3] a static statistical distribution (model **a**) and a dynamic statistical distribution (model **b**). In both models an orientationl disorder of the $NH_3^{\oplus}$ group with respect to the four neighboring bromide ions is assumed. Four orientations of the $NH_3^{\oplus}$ group are energetically favored as shown in Fig. 6 (taken from Ref. 3). In the orientations A-1 and A-2 there are two strong and one weak hydrogen bond between the nitrogen atoms and the bromide ions. Both, A-1 and A-2, are equally probable in the high temperature modification, whereas in the monoclinic low temperature phase one of these orientations would be stabilized. Additionally, there may be a further arrangement B characterized by one strong and two weak hydrogen bonds, also with two equally probable orientations B-1 and B-2. "Static statistically distributed" means that the ammonium hydrogens occupy the positions given by A-1 and A-2 (or by A-1, A-2, B-1, and B-2) randomly in space. They remain in these position for a time, long compared to the time scale of the respective technique (here the NQR spectro-

scopy, that is the residence time is longer than about 10^{-7} s). Model **b** (dynamic statistical distribution) assumes randomness in time, that is a short correlation time (less than 10^{-8} s). The $-NH_3^{\oplus}$ group is "flipping among different orientations"[1] or even rotating freely (as incorporated into the X-ray structure factor calculations by Nitta *et al.*[3]). Model **a** fulfills the demand of the space group for a twofold symmetry along the principal axis of the anilinium ion by averaging in space, model **b** by averaging in time.

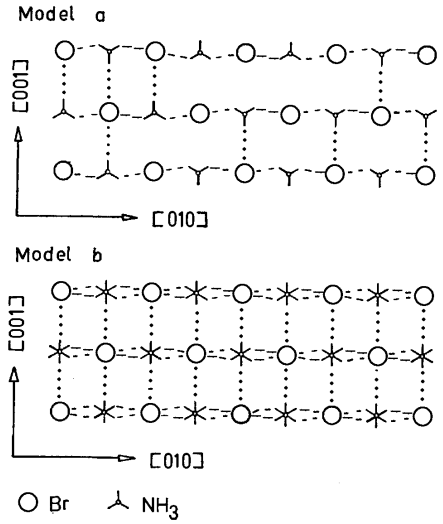

Fig. 7. Schematic representation of a static statistical distribution (random in space: model **a**) and dynamical statistic distribution (random in time: model **b**) of the hydrogen atoms of the $-NH_3^{\oplus}$ group. Only the orientations A-1 and A-2 are considered. Short hydrogen bonds are hyphenated, long hydrogen bonds are dotted. The local symmetry at the bromide ions is different in model **a**, whereas it is identical at each $Br^{\ominus}$ in model **b**.

The surrounding of the bromide ions (all $Br^{\ominus}$ are crystallographically equivalent) is shown in Fig. 7 for model **a**, representing a part of the projection of the structure of $C_6H_5NH_3^{\oplus}Br^{\ominus}$ on the plane (100). Dashed lines symbolize the strong hydrogen bonds (R_{N-Br}= 3.30 Å) and dotted lines the weak ones (R_{N-Br}=3.48 Å). The $-NH_3^{\oplus}$ groups are oriented randomly in space (only the arrangements A-1 and A-2 are considered). This distribution results in different surroundings for the $Br^{\ominus}$ which average in space to the twofold axis of symmetry for the $Br^{\ominus}$ and the ammonium nitrogen, as observed by X-ray diffraction. However, in a microscopic observation such as NQR, which observes mainly the immediate surroundings of an atom, the different arrangements around each $Br^{\ominus}$ cause different electric field gradients at each bromine nucleus due to divergent contributions of the crystal field. A broadening of the ^{79}Br-NQR line, if not separate bromine signals, should be observed, most likely suppressing the signal beyond the noise level in observing with a non-pulse technique. Since a clear, definite ^{79}Br-NQR signal has been found in the high temperature modification of anilinium bromide and since no broadening of the line could be observed within the limits of the superregenerative detection in passing through the transition point (Fig. 1), it is concluded that a static statistical distribution is incompatible with the results of ^{79}Br-NQR spectroscopy. This conclusion is emphasized by the fact that no bromine signal could be found in the solid solution $C_6H_5NH_{3(1-x)}D_{3x}^{\oplus}Br^{\ominus}$ (x=0.5), where the hydrogen and deuterium atoms are distributed "static statistically" among the ammonium nitrogens and where the surroundings of the bromide ions are random with regard to the hydrogen isotope.

The second limiting case, dynamic statistical distribution (model **b**), is also represented in Fig. 7. Here an identical surrounding is given for each $Br^{\ominus}$ also in the microscopic picture by averaging in time. This is in accord with a single, unbroadened ^{79}Br-NQR line in the high temperature phase. The dynamic disorder can be produced by i) a free rotation of the $-NH_3^{\oplus}$ group or ii) by a rapid reorientation of this group. Hydrogen bonding between $NH_3^{\oplus}$ and $Br^{\ominus}$ implies that there is no free rotation of the $-NH_3^{\oplus}$ group. X-Ray diffraction (the distance N–Br is shorter than the van der Waals distance[3]), infrared spectroscopy (low frequency of the stretching vibration and enlarged line width[4]), and ^{79}Br-NQR spectroscopy (high frequency of the NQR signal and large isotope effect $^1H \leftrightarrow ^2D$, see preceding discussion) all indicate a hydrogen bond between the anilinium nitrogen and the bromide ion. Free rotation is therefore ruled out. The only model for the disorder in the high temperature modification of anilinium bromide compatible with all experimental results is that of a $-NH_3^{\oplus}$ group which reorients rapidly in a multiple well potential with equilibrium positions given by the hydrogen bonding to the bromide ions.

Temperature Dependence and Order Parameter. In most cases the temperature dependence of NQR frequencies is adequately described in its salient features by the Bayer theory:[9a] the average internal EFG at the nucleus decreases with increasing temperature because of the increase in the amplitude of the thermal vibrations. This theory describes only the isochorus part of the temperature dependence, $(\partial\nu/\partial T)_V$. It fails in describing $\nu=f(T)$ at constant pressure if the last term in Eq. 4,

$$\left(\frac{\partial\nu}{\partial T}\right)_P = \left(\frac{\partial\nu}{\partial T}\right)_V - \frac{\alpha}{\chi}\left(\frac{\partial\nu}{\partial T}\right)_T \qquad (4)$$

(α=thermal expansion coefficient, χ=compressibility) is not negligible compared with the Bayer term $(\partial\nu/\partial T)_V$. Kushida *et al.*[9b] have shown that the volume expansion affects the temperature dependence of the EFG in ionic or nearly ionic crystals appreciably.

For the high temperature modification of anilinium bromide the temperature dependence of the $\nu(^{79}Br)$ is weak. ν decreases with increasing temperature as predicted by the Bayer theory, $\nu(T)$ being practically linear. The order of magnitude found for $(\partial\nu/\partial T)_P$ of $Br^{\ominus}$ in $C_6H_5NH_3^{\oplus}Br^{\ominus}$ (**I**) is expected from a normal increase of the thermal vibrations and a "normal" volume expansion.

The temperature variation of the ^{79}Br-NQR frequency is by far more pronounced in the low temperature modifications, especially in approaching the transition point (Figs. 3—5). In this temperature region (235≦

T/K≦303), Suga[2] found an anomalous expansion coefficient. Therefore, it is not surprising that in the low temperature modification $\nu(T)$ cannot be described with a Bayer type function (Eq. 2). At least one additional temperature dependent term has to be considered, which takes the anomalous volume expansion into account. The curvature of $\nu(T)$ reminds of the temperature dependence of an order parameter $s(T)$ near T_c (*e.g.* Ref. 34). The continuous character of the phase transition in $C_6H_5NH_3Br$ and the temperature dependence of the monoclinic deformation β strengthens this analogy. Taguchi[1] considers the monoclinic deformation as a shear, which displaces with respect to the $Br^{\ominus}$ site the nearest neighbors of the bromide ion (the nitrogen and the hydrogen atoms) in the direction of the c-axis. This displacement is proportional to $\tan \Delta\beta$, where $\Delta\beta=\beta-90°$, with $\beta=90°$ at $T=T_{II,I}$. Since $\Delta\beta<2°$ (at $T=163$ K: $\Delta\beta=1°22'$[1]), $\tan \Delta\beta \approx \Delta\beta$, and the change of the N–Br distance with the monoclinic deformation is proportional to the square of $\Delta\beta$:

$$\Delta R_{N-Br} \propto (\Delta\beta)^2. \quad (5)$$

The same proportionality holds for the $\Delta R_{H\cdots Br}$. The maximum component of the electric field gradient, eq, depends on r^{-3}. Assuming that the change in eq is mainly caused by the change in the distance of the nearest neighbors to the ion $Br^{\ominus}$, one can show that e^2qQ/h of $Br^{\ominus}$ in the monoclinic phase depends on $(\Delta\beta)^2$. Neglecting the change in the asymmetry parameter, which for $I=3/2$ affects the resonance frequency only weakly, one finds

$$\Delta\nu(^{79}Br) \propto (\Delta\beta)^2 \quad (6)$$

in the region just below the transition point, where the monoclinic deformation governs the structural changes with temperature. Figure 8 shows that the expected proportionality (Eq. 6) is well fulfilled in the temperature range 288 K$<T<T_{II,I}$. It is not expected that Eq. 6 holds outside a small temperature range just below the transition point.

Suga[2] showed that an order-disorder theory analogous to that of Bragg and Williams describes fairly well main features of the phase transition of anilinium bromide such as transition entropy, anomalous thermal expansion, and the function $\Delta\beta=f(T)$. According to Suga, $\Delta\beta$ is proportional to the order parameter s.

$$\Delta\beta \propto s \quad (7)$$

It has been shown that the order parameter s is described by a power law

$$s \propto \varepsilon^n \quad (8)$$

($\varepsilon=(T_c-T)/T_c$; T_c=critical temperature, n=critical exponent). Far from T_C the critical exponent is 1/2 (Landau theory), while it changes (*e.g.* for perovskite-type crystals) down to 1/3 for $\varepsilon<0.1$ in analogy with magnetic and fluid systems[34,35]. Combining the proportionalities (6), (7), and (8), it follows

$$\Delta\nu(^{79}Br) \propto \varepsilon^{2n}, \quad (9)$$

and close to the transition point, assuming $n=1/3$,

$$\Delta\nu(^{79}Br) \propto (T_c-T)^{2/3}. \quad (10)$$

Although the once-hoped-for universality of the values for the critical exponent n had to be abandoned,[34] it is rather satisfying that the ^{79}Br-NQR frequency in $C_6H_5NH_3^{\oplus}Br^{\ominus}$ follows this proportionality (Eq. 10) in the temperature range 295≦T/K≦260 with T_C=

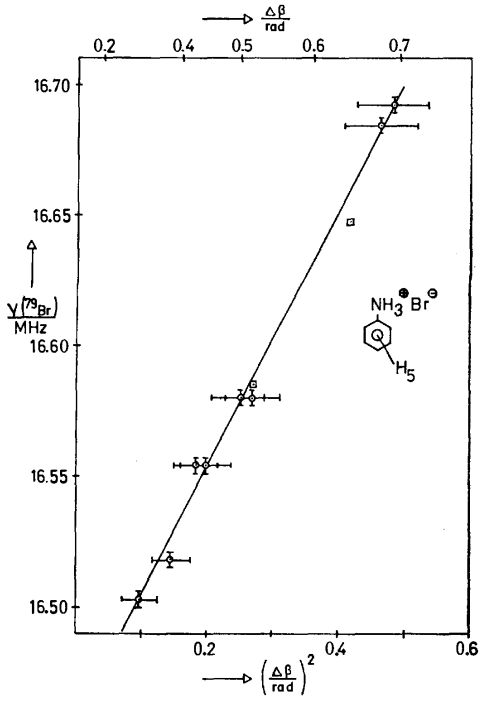

Fig. 8. ^{79}Br-NQR frequency of the low temperature modification of anilinium bromide as a function of $(\Delta\beta)^2=(\beta-90°)^2$. β=monoclinic angle of the low temperature modification **II**. Circles (⊙): the value of $\Delta\beta$ including the limits of error as taken from Fig. 3 in Ref. 1. Squares (⊡): $\Delta\beta$ as taken from Fig. 2 in Ref. 1, no limits of error are given in this case.

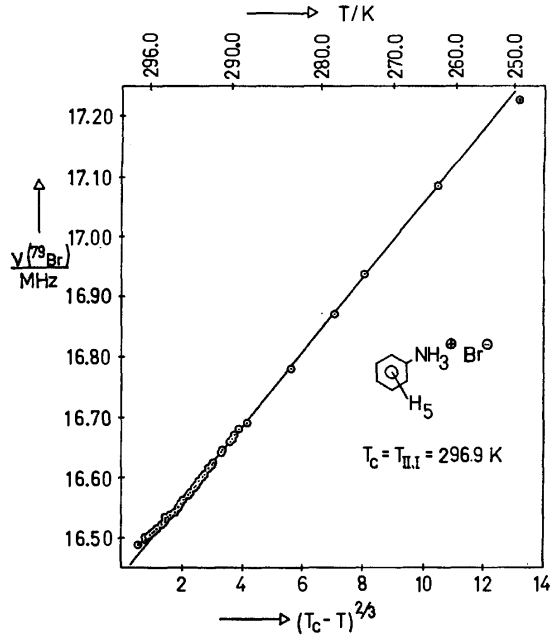

Fig. 9. ^{79}Br-NQR frequency of the low temperature modification of anilinium bromide as a function of the deviation of the temperature from the critical temperature T_c. The power of (T_c-T) indicates a non-classical critical exponent of $n=1/3$ (see text).

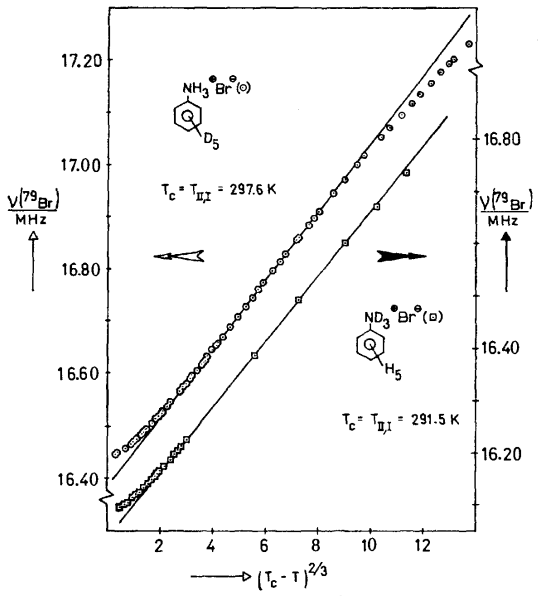

Fig. 10. ^{79}Br-NQR frequencies of the low temperature modification of anilinium-d_3 bromide and anilinium-d_5 bromide as a function of $(T_c-T)^{2/3}$. The power of (T_c-T) indicates a non-classical critical exponent of $n=1/3$ (see text).

$T_{II,I}$=296.9 K (Fig. 9). In this region the formation of the ordered monoclinic low temperature phase, expressed by the structural displacement parameter $\Delta\beta$ acting as an order parameter, governs the temperature dependence of the ^{79}Br-NQR frequency. There may be a second region, $225<T/K<260$, where $\nu(^{79}Br)$ is proportional to (T_c-T), that is, $n=1/2$, but the experimental data are too scarce to be definite in this case. Relation 10 holds also for both deuterated anilinium bromides, $C_6H_5ND_3^{\oplus}Br^{\ominus}$ and $C_6D_5NH_3^{\oplus}Br^{\ominus}$ within a range of some 30 K below $T_{II,I}$ (Fig. 10).

From this it is clear that a simple Bayer-type function (Eq. 2) or a polynomial with a small number of coefficients a_i (Eq. 1) must fail in the description of $\nu(T)$ of anilinium bromide **II**. The temperature dependence of the resonance frequency is in this case a superposition of at least three effects: i) the normal volume independent temperature dependency caused by the increase of the amplitudes of thermal vibrations with increasing temperature (Bayer-term), ii) a strong volume dependent term (second term in Eq. 4), which comes into play through the anomalous thermal expansion below $T_{II,I}$, and iii) a strong variation of the asymmetry parameter η with temperatures just below $T_{II,I}$ not allowing to disregard the η-dependency of the resonance frequency. Such a strong variation of η with temperature has been observed in the (probably isotypic) anilinium iodide below its critical temperature ($T_{II,I}$= 241 K).[6a] The description of contribution ii) is additionally complicated by the fact that a change from a Landau-type behavior (critical exponent $n=1/2$) to a non-classical behavior ($n\neq 1/2$) may occur for $\varepsilon=(T_c-T)/T_c<0.1$.

Résumé

The investigation of the ^{79}Br-NQR spectra of anilinium bromide and its partially deuterated derivatives has lead to the following conclusions:

1. The rather large ^{79}Br-NQR frequency of the $Br^{\ominus}$ ion can be explained by assuming N–H$^{\oplus}$···Br$^{\ominus}$ hydrogen bonds and, vice versa, $\nu(^{79}Br)$ of this order of magnitude can serve as an argument for hydrogen bonding in the respective solid.

2. The large frequency shift on deuteration corroborates the model of a hydrogen bonded ion $Br^{\ominus}$. The direction of the ^{1}H–^{2}D shift can be explained by assuming that deuteration enlarges the hydrogen bond length in asymmetric hydrogen bonds (Ubbelohde effect).

3. The high temperature modification of anilinium bromide can be described by a model which considers a rapid (faster than $\approx 10^{-8}$ s) reorientating $NH_3^{\oplus}$ group.

4. The strong temperature dependence of the ^{79}Br-NQR frequency found immediately below the transition point can be rationalized by a model which interprets a structural displacement parameter (in this case: $\Delta\beta$) as an order parameter. The non-classical critical exponent is 1/3 in this region for the temperature dependence of the order parameter.

We are grateful to Prof. J. L. Ragle, University of Massachusetts, and to Dr. W. Weyrich, Technische Hochschule Darmstadt, for interesting discussions. We also enjoyed the privilege of a conversation with Prof. D. Nakamura, Nagoya University, Nagoya. We wish to thank Dr. W. Weyrich and Mr. P. Bachmann, THD, for help in the least-squares calculations.

This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. We are grateful to the Chemische Fabrik Kalk GmbH., Köln-Kalk, for the supply of hydrobromic acid.

The Interaction Potential Surfaces for Alkali-trimers

S. Noor MOHAMMAD
Department of Physics, Indian Institute of Technology, Kharagpur, West Bengal, India
(Received August 27, 1977)

Semi-empirical potential energy surfaces for some alkali-trimer complexes have been calculated using the simplest form of London equation. In the calculations use has been made of two new exponential potentials for the singlet and triplet states of diatomic molecules. The calculated potential surfaces at small internuclear distances show shallow well extending into the entrance and exit valleys without an energy barrier. The complexes are seen to be stable over all configurations; they are most stable however in the linear symmetric configuration. The force constants corresponding to bending and stretching deformations have been calculated for homonuclear trimers only. It has been observed that unlike stretching, the bending deformations do not sensitively affect the energy variation of the ground state.

The alkali atom-alkali dimer exchange reaction

$$L' + L_2 \longrightarrow L'L + L, \quad (1)$$

where L and L′ are same or different atoms, are believed to be important in determining the energy transfer and condensation in supersonic alkali nozzle beams[1] and in determining nuclear relaxation times observed in the NMR of alkali dimers in optically bumped alkali vapours.[2] Recently some molecular beam reaction scattering has been measured[3] for $Na+Cs_2$, Rb_2, K_2, and $K+Rb_2$. A knowledge of potential energy surfaces of the trimer complexes formed therein is of considerable importance in order to help resolve the reaction dynamics, to determine the reaction cross-section and isotope effects, and to provide theoretical interpretation of the reactive scattering data.

Alkali trimers are intermediate of alkali atom-dimer exchange reaction. The experimental observation of Foster *et al.*[4] indicates only that they are stable molecules and suggests nothing about their binding energy and geometry. A diatomics-in-molecules calculation[5] for Li_3 shows it to be a stable molecule bound approximately by 9 kcal/mol with respect to $Li+Li_2$. The recent *ab initio* calculation[6] of Davies *et al.*, on the other hand, suggests that linear Li_3 is bound 3 kcal/mol lower in energy with respect to the same reactants. Pseudopotential calculations[7] on Na_3 and K_3 indicate that they are unbound with respect to atom-dimer dissociation. Semi-empirical valence bond calculations,[8] however, show that linear trimers are stable molecules in the ground state.

In the present study our aim is to determine semi-empirically the potential energy surfaces of some alkali trimer complexes and to obtain thereform their binding energies, equilibrium geometries and equilibrium vibrational force constants.

Method of Calculation

A non-ionic valence bond method has been used in the present calculation. Only the ns valence electron of each alkali atom is explicitly taken into consideration. All the trimers are thus reduced to three-electron three-orbital systems. The Hamiltonian operator for such systems in atomic units is

$$H = \sum_i[-\nabla_i^2/2 - \sum_a Z_a/r_{ai} + \sum_{i>j} 1/r_{ij}] + \sum_{a>b} Z_a Z_b/R_{ab}, \quad (2)$$

where the subscripts i, j, *etc.* refer to electrons and a, b, *etc.* to nuclei. There are two linearly independent canonical structures ϕ_1 and ϕ_2 coresponding to the bonding scheme (a—b,c) and (a,b—c) respectively. If one assumes that the orbitals a,b, and c are mutually orthogonal, the secular determinant written in terms of the Hamiltonian matrix elements H_{ij} and the overlap matrix elements S_{ij} will yield

$$E_\pm = Q_{ab} + Q_{bc} + Q_{ca} \pm 2^{-1/2}[(J_{ab}-J_{bc})^2 + (J_{bc}-J_{ca})^2 + (J_{ca}-J_{ab})^2]^{1/2}. \quad (3)$$

Here Q and J are the diatomic Coulomb and exchange integrals respectively. These integrals have been evaluated at the three internuclear distances R_{ab}, R_{bc}, and R_{ca}. This equation is known as London equation.[9] In Eq. 3 the zero of the energy refers to the separated atoms and since Q and J are both negative quantities E_- refers to the binding energy of more stable state. However, the diatomic integrals Q and J are more difficult to evaluate for alkali diatomics. In order to circumvent this difficulty, we adopt the semi-empirical method of Cashion and Herschbach,[10] and obtain from identical valence bond approximation

$$E_\pm = Q \pm J, \quad (4)$$

where E_+ and E_- refer to $^1\Sigma_g$ and $^3\Sigma_u$ states respectively. If these potential curves are known independently Q and J can be evaluated as

$$Q = \frac{1}{2}[E(^1\Sigma) + E(^3\Sigma)], \quad (5)$$

and

$$J = \frac{1}{2}[E(^1\Sigma) - E(^3\Sigma)]. \quad (6)$$

The problem thus reduces to obtaining accurate potential energy curves for the $^1\Sigma_g$ and $^3\Sigma_u$ electronic states of alkali diatomics.

Diatomic Potential Curves

Singlet Potential. Whitehead and Grice,[8] in their studies of atom-dimer exchange reaction of lithium and sodium, made use of *ab initio*[11-15] and RKR[16] curves for Li_2, LiNa, and Na_2. Due to lack of similar data on the other dimers of alkali atoms, it is not possible to extend their method to the trimers involving atoms other than Li and Na. Recently the classical turning

points for the vibrational levels of the $^1\Sigma_g$ state of K_2, Rb_2, and Cs_2 have also been derived.[17] One major disadvantage of these curves is that these are constructed only in the region for which sufficient spectroscopic data exist. For Li_2, data for the higher vibrational levels being not available, Krupenie *et al.*[16] fitted its RKR curve to the Lippincott potential[18-21] to get extrapolation at large internuclear distances. Another disadvantage of this method is that it gives only numerical values of the curve at a series of points, and not a suitable analytical form for the same. Further, these curves are not available for the heteronuclear diatomics of the present series. Recently Sannigrahi *et al.*[22] have used Morse[23] and Rydberg[24] potentials for the $^1\Sigma_g$ state. But in case of alkali dimers it can be seen[25] that the Morse potential predicts too much attraction at large internuclear distances. Though the Rydberg potential is much better than the Morse, in many cases it deviates greatly from the RKR curves, and on the average, predicts α_e within -3.2% and $\omega_e x_e$ within 11.74% for the fifty diatomic molecules studied.[26] In our recent study[26] of the interatomic potentials for the bound states of diatomic molecules we have proposed a new potential,

$$U_2(R) = D_e\left\{\left(\frac{R_e}{R}\right)^{2n}\exp\left[-2\alpha(R^2-R_e^2)\right] - 2\left(\frac{R_e}{R}\right)^{n}\exp\left[-\alpha(R^2-R_e^2)\right]\right\}, \quad (7)$$

where

$$\alpha = (\Delta^{1/2}-n)/2R_e^2, \quad (8)$$

$$n = 0.324 + 0.313\Delta^{1/2} + 0.01\Delta \quad \text{for } 0 \lesssim \Delta^{1/2} \lesssim 3.2$$
$$= 1.3637 - 0.206\Delta^{1/2} + 0.004\Delta \quad \text{for } 3.2 \lesssim \Delta^{1/2} < \infty, \quad (9)$$

and

$$\Delta = R_e^2 k_e/2D_e.$$

$-D_e$ is the minimum value of $U_2(R)$, R_e is the value of R at which $U_2(R)=-D_e$ and k_e is the measure of curvature of the potential curve at $R=R_e$. A detailed investigation shows that this is perhaps the best three-parameter potential over an extended region of R. It predicts α_e and $\omega_e x_e$ and other spectroscopic constants such as higher order vibrational force constants n_e and o_e almost exactly for a large number of molecules. This is, in fact, a generalisation of the Vershni III potential.[27] In Fig. 1 we have compared this potential with the corresponding Varshni III, RKR and *ab initio* curves for Li_2, LiNa, and Na_2. The curves of this figure shows that the present potential is equally applicable to the other alkali dimers also. We use this potential for the $^1\Sigma$ ground state.

Triplet Potential. Except for a long range van der Waals attraction the $^3\Sigma_u^+$ excited electronic state is a repulsive one and no experimental information is available for this. We are, therefore, to depend for this on a reliable theoretical calculation. Since the interaction of two alkali metal atoms is qualitatively similar to the interaction of two hydrogen atoms whose theoretical curve can be accurately constructed by the perturbation method of Dalgarno and Lynn,[28] Davies *et al.*[6] in their calculations of collision integrals, used the same to predict the triplet curves for alkali metal diatomics. These are given by $60.70\exp(-1.37\,R)$, $105\exp(-1.51\,R)$, $211\exp(-1.45\,R)$, $170\exp(-1.34\,R)$, and $173\exp(-1.27\,R)$ for Li_2, Na_2, K_2, Rb_2, and Cs_2 respectively. The main defect of this method is that it gives an individual potential for each dimer. Krupenie *et al.* used a method originally suggested by Keyes[29] to estimate the $^3\Sigma_u^+$ potential of Li_2. He simply changed the sign in the exchange term of the double exponential function representing the $^1\Sigma_g^+$ potential. When compared with the *ab initio* curve, this is seen to lie too high by a factor of 2 to 4.

In connection with some classical trajectory studies of alkali atom-dimer exchange reactions Whitehead[30] has recently proposed a Porter-Karplus[31] type anti-Morse potential for Li_2, LiNa, and Na_2. This is given by

$$U_w^{(3)}(R) = D_e^{(3)}[(x+1)^2-1], \quad (10)$$

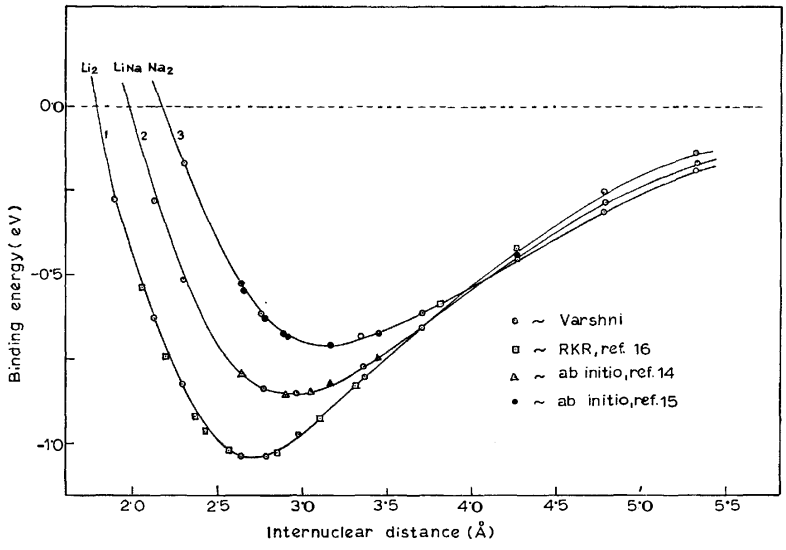

Fig. 1. Comparison of potential energy curves for the ground state of Li_2, LiNa, and Na_2.

where

$$x = \exp[-\beta^{(3)}(R-R_e)]. \quad (11)$$

$D_e^{(3)}=3.30$, 3.09, and 3.30 kcal/mol and $\beta^{(3)}=1.240$, 1.254, and 1.230 Å^{-1} for Li_2, LiNa, and Na_2 respectively. Equation 10 has been obtained by fitting to the *ab initio* data. The main objection to $U_w^{(3)}(R)$ is that it requires an independent knowledge of the triplet state potential data which uptill now are available only for Li_2, LiNa and Na_2. Consequently its applicability is limited to these dimers only.

With a view to devising a triplet potential of general validity we change the sign of the repulsive part of Eq. 7 and then fit it to the *ab initio* data[12-15] to get

$$U_2^{(3)}(R) = 0.50D_e\left\{\left(\frac{R_e}{R}\right)^{2n}\exp[-2\alpha(R^2-R_e^2)] + 0.05\left(\frac{R_e}{R}\right)^{n}\exp[-\alpha(R^2-R_e^2)]\right\}. \quad (12)$$

Like its singlet counterpart it is expected to show correct limiting behaviour at large internuclear distances. We tried to construct the triplet potential corresponding to the Varshni also and it is interesting to see that it comes out as the same as Eq. 12 with $n=1$. The identifying feature of these potentials is that they can be expressed in terms of the ground state potential parameters for which sufficient informations are available for the present systems. In Fig. 2 we have compared Eq. 12 with the corresponding Varshni (triplet) and *ab initio* curves for Li_2, LiNa and Na_2. It can be seen from this figure that the said potential agrees quite well with the latter curves. Since alkali dimers behave quite ideally with respect to semi-empirical parametrisation, we believe that this potential (which has been obtained only for the specific cases of Li_2, LiNa and Na_2) might also be useful for the rest of the diatomics in the series. We use this potential for the triplet state.

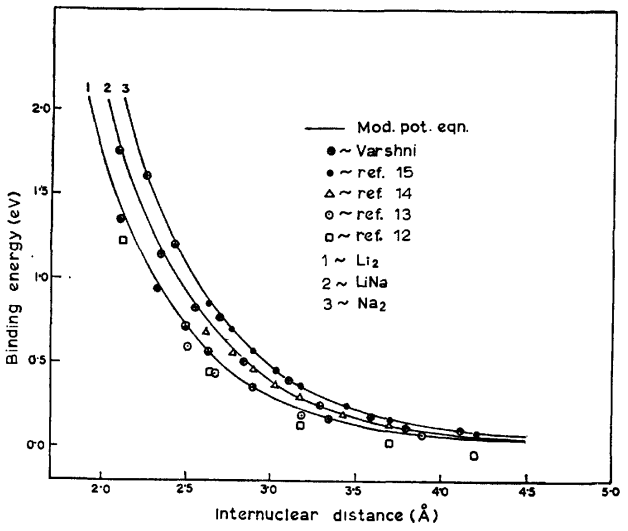

Fig. 2. Comparison of potential energy curves for the triplet state of Li_2, LiNa, and Na_2.

Results

The potential parameters D_e, R_e, and K_e needed to evaluate Eqs. 7 to 12 are given in Table 1. All these data are taken from Herzberg[32] and from the summary of Evans *et al.*[33] Using Eq. 3 potential energy surfaces consisting of a series of contour lines of constant energy are now constructed for all the triatomic complexes for both Varshni III and our own potential model. Such surfaces for the linear configuration of Li_3, LiLiNa and, NaLiNa are shown in Figs. 3 to 5. Potential energy surfaces of other trimers, which are not shown in the figure are similar to those of Li_3, LiLiNa, and NaLiNa. These surfaces are very much important in the sense that can provide useful informations towards detailed rate calculation by the solution of classical equation of motion. All these surfaces exhibit shallow potential well at small internuclear distances which extends into the entrance and exit valleys without an energy barrier.

Table 1. Ground state potential parameters for alkali-dimers

Dimer	$-D_e$(eV)[e]	r_e(Å)[e]	k_e(mdyn/Å)[e]
Li_2	1.05	2.672	0.256
Na_2	0.74	3.08	0.174

NaRb	0.57	3.565	0.122

a) Taken from Ref. 33. b) Taken from Ref. 14.
c) Determined by the formula $x_{ab}=(x_{aa}\,x_{bb})^{1/2}$, where all x_{aa} are taken from Refs. 32 and 33.
d) Calculated from the observed vibrational frequency, see Ref. 32. e) All these data except those taken from a, b, c, and d are from Ref. 32. The vibrational force constants are calculated from the observed vibrational frequency given in this reference.

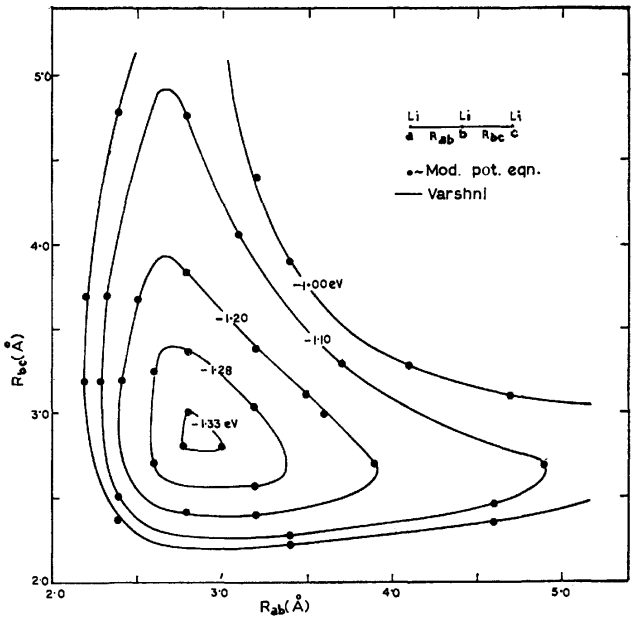

Fig. 3. Potential energy surfaces of Li_3 for linear configuration.

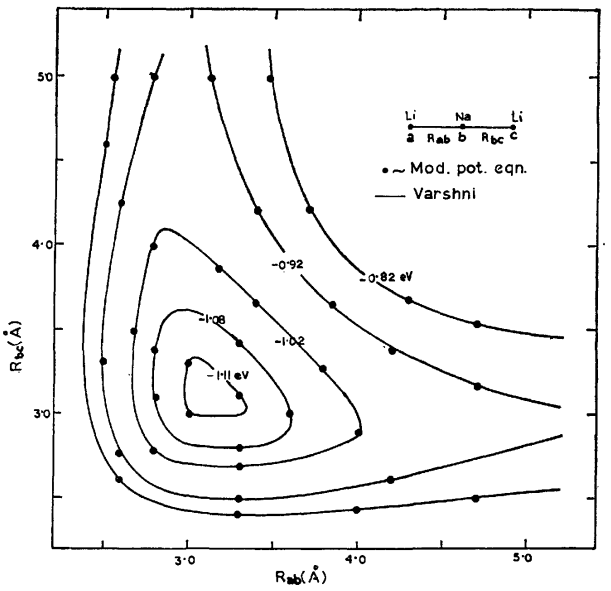

Fig. 4. Potential energy surfaces of LiNaLi for linear configuration.

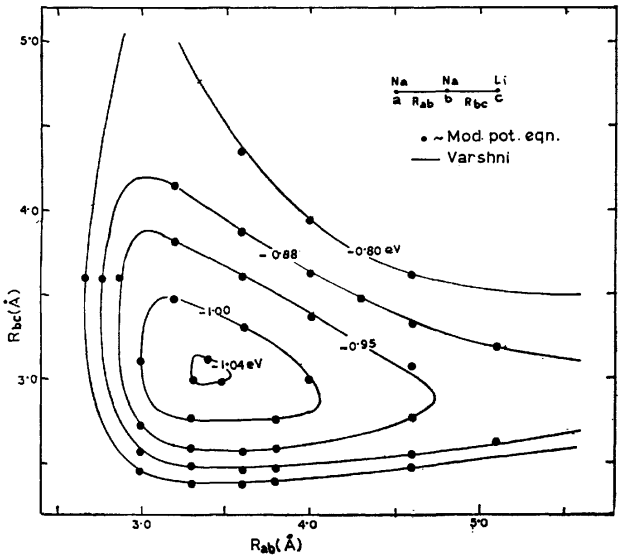

Fig. 5. Potential energy surfaces of NaNaLi for linear configuration.

The reacting atom, coming along the entrance valley is first reflected back and forth at the sides of the basin and undergoes a continual conversion of translational into vibrational energy and vice versa. As a result, the atom wanders about the potential basin until it either passes out through the gap into the exit valley which means reaction has taken place or it returns to the valley whence it entered. The depths of the potential wells are defined to be the binding energy of trimers. These binding energies in the case of symmetric trimers are found to decrease in the order $Li_3 > Na_3 > K_3 > Rb_3 > Cs_3$ in line with the bond energy values of the corresponding dimers. However, in the mixed alkali cases the potential well is deepest when the lighter alkali occupies the central position. The variation

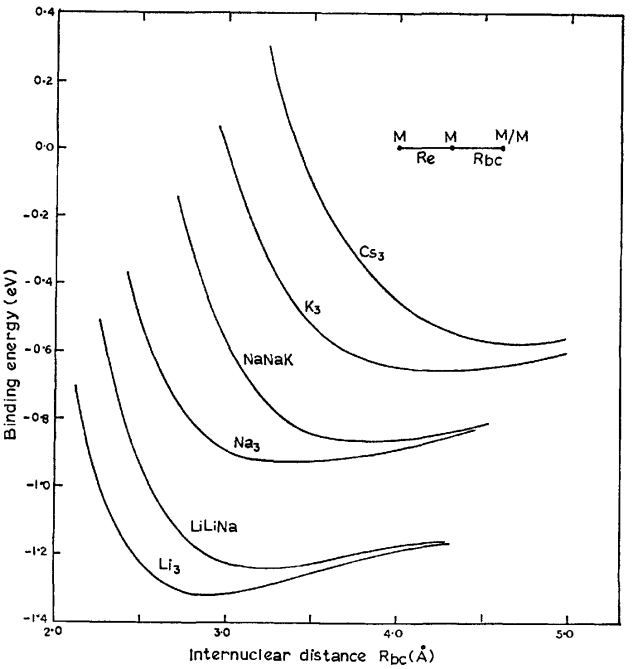

Fig. 6. Energy curves for approach of M (or M′) to M_2 fixed at M_2 equilibrium internuclear distances in the linear configuration for Li_3, LiLiNa, Na_3, NaNaK, K_3, and Cs_3.

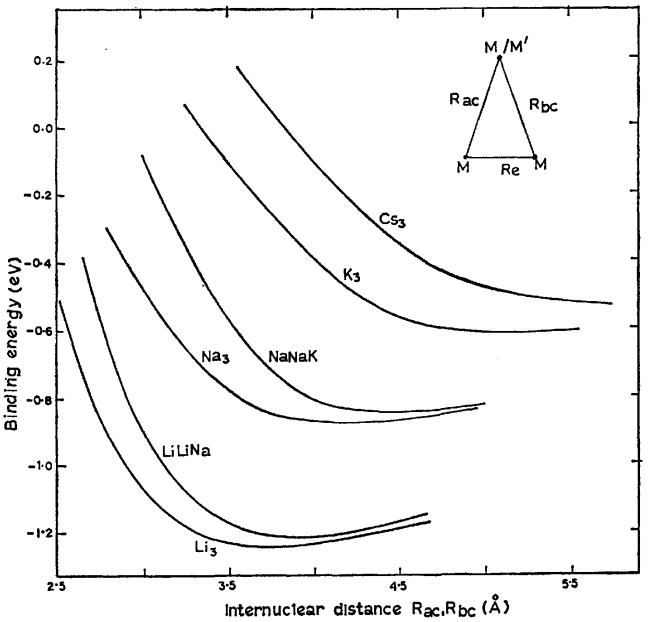

Fig. 7. Energy curves for approach of M (or M′) to M_2 fixed at M_2 equilibrium internuclear distances in the isosceles triangular configuration for Li_3, LiLiNa, Na_3, NaNaK, K_3, and Cs_3.

of binding energy of Li_3, Na_3, LiLiNa, NaNaK, K_3, and Cs_3 with bond length are shown in Figs. 6 and 7 for collinear and isosceles triangular configurations respectively. In each case the reacting alkali dimer is kept fixed at its equilibrium internuclear distance R_e, and binding energy is plotted as a function of the reactant alkali distance. Calculated values of binding energy and bond length are given in Table 2. It can

be seen from this table that the symmetric alkali trimers are most stable in the linear symmetric configuration. The bond length of a trimer is in general greater than the bond length of the corresponding dimer.

a) Δ_r and Δ_p correspond to potential well depths with respect to reactants and products respectively. The upper and lower result in each row corresponds to linerar and isosceles triangular configurations respectively.

The ground (linear symmetric) state of alkali trimers can be further characterised by the force constants of its stretching and bending deformations. If R_{01} and R_{02}, and E_0 stand respectively for the internuclear distances and energy of the minimum energy intermediate state, then variation of energy around this state, to the lowest order is given by [34]

$$2(E-E_0) = A_{11}q_1^2 + A_{22}q_2^2 + A_{33}q_3^2, \tag{13}$$

where the terms q_i are defined as

$$q_1 = \frac{1}{2}[R_{ab}+R_{bc}-(R_{01}+R_{02})],$$

$$q_2 = \frac{1}{4}[(R_{01}+R_{02})^2-R_{bc}^2]^{1/2}, \tag{14}$$

and

$$q_3 = \frac{1}{2}(R_{ab}-R_{bc}),$$

q_1 describes a symmetrical stretching, q_2 a bending, and q_3 an asymmetric stretching motion. The coefficients

$$A_{ii} = \frac{\partial^2(E_0-E_i)}{\partial q_i^2} \tag{15}$$

are the corresponding force constants. As an illustration, we have calculated these force constants for the homonuclear trimers. These are given in Table 3.

Table 3. Calculated values of force for the ground state of homonuclear trimers

Trimer	A_{11} (mdyn/Å) sym. stretching	$A_{22}\times 10$(mdyn/Å) asym. stretching	$A_{33}\times 10^3$(mdyn/Å) bending
Li_3	0.1293	0.3658	0.1264
Na_3	0.0857	0.2589	0.0406
K_3	0.0614	0.1415	0.0131
Rb_3	0.0486	0.1166	0.0119
Cs_3	0.0360	0.0995	0.0067

It can be seen from this table that the symmetric stretching force constants of the trimers are about half the magnitude of the force constants of the corresponding dimer. Again the asymmetric force constant which is important primarily in regard to "tunneling corrections" is almost one-fourth the magnitude of the symmetric force constant of an alkali trimer. Very low values of the bending force constant which determines the size of the (L, L_2) exchange cross-section near the threshold indicates that the rate of increase of potential

energy as a complex is bent from the collinear conformation is very small.

Conclusion

For lack of experimental data on alkali trimers it is not possible to test the validity of the present calculation. However, because of the semi-empiricism of the method employed certain errors are likely to enter the calculations. The omission of three-centre integrals in London equation may be a possible source of error. Pedersen and Porter[35] have shown that the three-centre integrals in the calculation of H_3 complexes almost insignificantly contribute near the collinear saddle point. Similar trend may be expected to be followed also in the case of alkali complexes. Since in alkali atoms the np valence orbital is very close to the ns orbital we should have considered their effects in the calculations. However, the use of diatomic potential curves in the calculation of Coulomb and exchange integrals includes their effects to a certain extent. Whitehead and Grice considered the inclusion of overlap integral in their calculations of Q and J, and have shown that it increases the binding energy by about 2 kcal/mol. The inclusion of this integral effectively in the London equation seems not to be theoretically consistent. We have not, therefore, studied the same in the present calculations.

The most distinguishing feature of the present calculation is that only with the knowledge of three spectroscopic constants of a dimer one can now construct its potential energy surface with much less labour and computational expenses.

I am grateful to Professor H. N. Bose for his kind interests in the work.

(Received July 4, 1977)

The following nickel(II) complexes with *meso*- or *dl*-2,3-butanediamine (abbreviated to *meso*-bn and *dl*-bn, respectively) were prepared: $[Ni(meso\text{-bn})_3]X_2\cdot 2H_2O$, $[Ni(meso\text{-bn})_2]X_2$ and $[Ni(H_2O)_2(dl\text{-bn})_2]X_2$ (X=Cl, Br). It was found from the changes in the absorption spectra and magnetic susceptibilities that $[Ni(meso\text{-bn})_3]X_2\cdot 2H_2O$ complexes, when heated to 188 (X=Cl) and to 233 °C (X=Br), respectively, undergo transformations from octahedral to square planar structures with the loss of two moles of lattice water and one mole of coordinated *meso*-bn. $[Ni(H_2O)_2(dl\text{-bn})_2]X_2$ complexes were similarly found to transform from octahedral to square planar structures at 120 (X=Cl) and at 110 °C (X=Br), respectively with the evolution of two moles of coordinated water. After this transformation, the resulting complexes underwent the inverse transformation from square planar to octahedral structure at 170 °C, without any weight change. The effect of the configurational difference between *meso*- and *dl*-bn on the formation of tris and bis(2,3-butanediamine) complexes is also discussed.

Nickel(II) ions form complexes of various structures, *e.g.*, octahedral, tetrahedral and square planar structures, depending upon the ligands, with mutual transformations often occurring among them.[1] Tsuchiya *et al.* have reported structural transformations of $[Ni(H_2O)_2(NN\text{-deen})_2]X_2$, where *NN*-deen is *N,N*-diethylethylenediamine and X is a halide ion;[2] the chloride, upon heating, evolved two moles of coordinated water accompanied by the anation of chloride ions with the retention of the original octahedral structure, whereas the bromide transformed from an octahedral to a square planar structure without anation of bromide ions after the liberation of water molecules.

The structural transformation of nickel(II) complexes upon heating in solid phase is characterized by a change in the coordination number from six to four, as is seen for the above bromide. On the other hand, an interesting thermal equilibrium has been reported on the basis of spectral measurements that the structure of bis(*N,N*-diethylethylenediamine)copper(II) tetrafluoroborate, perchlorate and nitrate changes to square planar as the temperature is lowered, but to octahedral as the temperature is raised.[3] Tsuchiya *et al.* also recently found a novel example of a transformation from square planar to octahedral structure in the benzimidazole complex, $[Ni(bimd)_4](NO_3)_2\cdot 2.5C_2H_5OH$, in the solid phase.[4]

In addition to nickel(II) complexes containing N-substituted diamine, the thermal behavior of complexes with the C-substituted diamines, 2-methyl-1,2-propanediamine and 1,2-diphenylethylenediamine, have been studied in the solid phase by Farago *et al.*[5] and by Lifschitz *et al.*,[6] respectively. Transformations from octahedral to square planar structure are observed in these examples.

The present study was undertaken to prepare various types of the nickel(II) complexes containing *meso*- and *dl*-2,3-butanediamines, as C-substituted ethylenediamines, and to investigate thermal transformations in the solid phase and steric effects due to alkyl substitution.

Experimental

Preparation and Identification of 2,3-Butanediamines. A solution containing a mixture of *meso*- and *dl*-2,3-butanediamines (*meso*-bn and *dl*-bn, respectively) was obtained by the method described in Ref. 7. From the solution, *meso*-bn and *dl*-bn were separated as dihydrochlorides by the addition of hydrochloric acid, and were identified from IR and NMR spectra.[8]

The yields were about 20% for *meso*-bn and 9% for *dl*-bn.

*Preparation of the Complexes. Tris(*meso*-2,3-butanediamine)nickel(II) Halide Dihydrates, [Ni(*meso*-bn)$_3$]Cl$_2\cdot 2H_2O$ (I) and [Ni(*meso*-bn)$_3$]Br$_2\cdot 2H_2O$ (II).* A methanolic solution of nickel chloride or bromide was added to a solution of excess amounts of the free *meso*-diamine obtained by adding KOH to the diamine dihydrochloride. The resulting solution was allowed to stand for about three days in a refrigerator, with a bluish-violet *meso*-bn complex obtained. Recrystallization was carried out from ethanol.

*Bis(*meso*-2,3-butanediamine)nickel(II) Halides, [Ni(*meso*-bn)$_2$]Cl$_2$ (III) and [Ni(*meso*-bn)$_2$]Br$_2$ (IV).* These complexes were prepared in a manner similar to that used for complexes I and II, except for ligand molar ratios of 2: 1. A mixture of methanol and water (1: 1) was used as a solvent, and yellow plates were obtained.

*Diaquabis(*dl*-2,3-butanediamine)nickel(II) Halides, [Ni(H$_2$O)$_2$(*dl*-bn)$_2$]Cl$_2$ (V) and [Ni(H$_2$O)$_2$(*dl*-bn)$_2$]Br$_2$ (VI).* By a method similar to that used for complexes III and IV, blue crystals were obtained by recrystallization from water.

Analytical data for all the complexes obtained are summarized in Table 1.

Measurements. Derivatograms for thermal reactions of the complexes, electronic spectra and magnetic susceptibilities were measured in the manner previously reported.[2,4]

Results and Discussion

Derivatography. The derivatograms for complexes I and II are shown in Fig. 1. The former chloride shows a 28.6% mass loss in the TG curve in the temperature range from 50 to 188 °C, which just corresponds to the total liberation of two moles of lattice water and one mole of *meso*-bn. On the other hand, in the latter

TABLE 1. ANALYTICAL DATA FOR NICKEL(II) COMPLEXES WITH *meso*- AND *dl*-2,3-BUTANEDIAMINES

Complex	C%		H%		N%	
	Found	Obsd	Found	Obsd	Found	Obsd
(I) $[Ni(meso\text{-bn})_3]Cl_2\cdot 2H_2O$	33.65	33.51	9.71	9.37	18.84	19.54
(II) $[Ni(meso\text{-bn})_3]Br_2\cdot 2H_2O$	27.70	27.77	8.16	7.77	16.22	16.19
(III) $[Ni(meso\text{-bn})_2]Cl_2$	31.49	31.41	8.16	7.91	17.85	18.31
(IV) $[Ni(meso\text{-bn})_2]Br_2$	24.20	24.34	6.16	6.13	14.15	14.19
(V) $[Ni(H_2O)_2(dl\text{-bn})_2]Cl_2$	27.31	28.10	8.34	8.25	16.21	16.39
(VI) $[Ni(H_2O)_2(dl\text{-bn})_2]Br_2$	22.30	22.29	6.55	6.56	13.00	12.41

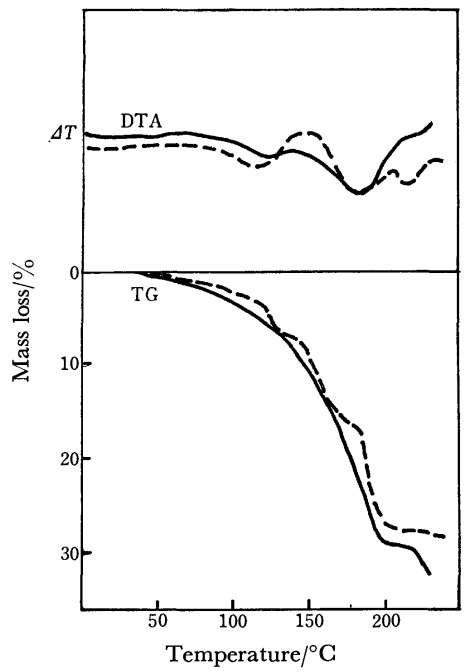

Fig. 1. Derivatograms of $[Ni(meso\text{-bn})_3]Cl_2\cdot 2H_2O$(——) and $[Ni(meso\text{-bn})_3]Br_2\ 2H_2O\cdot$(——).

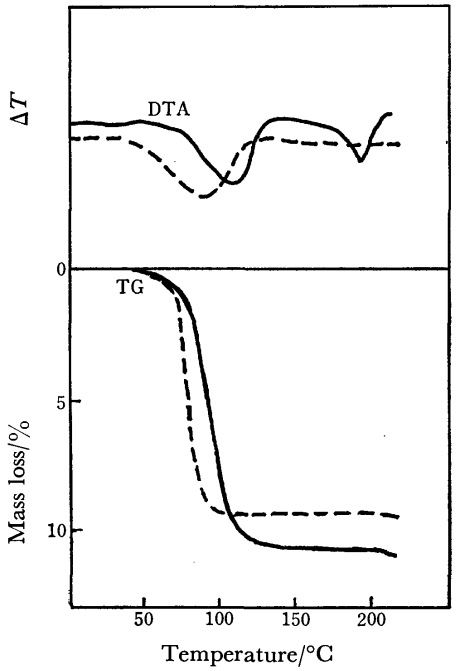

Fig. 2. Derivatograms of $[Ni(H_2O)_2(dl\text{-bn})_2]Cl_2$ (——) and $[Ni(H_2O)_2(dl\text{-bn})_2]Br_2$ (——).

bromide, three steps due to mass losses corresponding to the successive liberation of two moles of lattice water, that of a half mole of *meso*-bn and that of another half mole were found at 122, 192, and 233 °C, respectively.

The derivatograms for complexes V and VI are shown in Fig. 2. The former chloride shows a 10.4% mass loss in the TG curve between 70 and 120 °C. This mass loss matches the liberation of two moles of coordinated water. It is worth noting that an endothermic peak appears at 170 °C without any change in the TG and DTG curves, which is the basis of new information described in a later section.

For complex VI, a 8.4% mass loss was found in the range from 35 to 100 °C. This corresponds to the liberation of two moles of coordinated water. The endothermic peak was, however, not as distinctly observed as for complex V.

Electronic Spectra. Color changes of the complexes in each heating step are summarized in Table 2. This table also includes the magnetic moments which will be discussed in a later section.

The electronic spectral changes corresponding to these color changes were measured in the solid state. The diffuse reflection spectra of complex I, the sample

TABLE 2. COLOR AND MAGNETIC MOMENT OF THE COMPLEXES IN EACH HEATING STEP

Complex	Color	Magnetic moments (μ_{eff} B.M.)		Color	Magnetic moments (μ_{eff} B.M.)		Color	Magnetic moments (μ_{eff} B.M.)
(I) $[Ni(meso\text{-bn})_3]Cl_2\cdot 2H_2O$	bluish violet	3.33	50—188 °C →	yellow	diamag.			
(II) $[Ni(meso\text{-bn})_3]Br_2\cdot 2H_2O$	bluish violet	3.24	122—223 °C →	yellow	diamag.			
(V) $[Ni(H_2O)_2(dl\text{-bn})_2]Cl_2$	blue	3.39	70—120 °C →	yellow	diamag.	180 °C →	green	3.11
(VI) $[Ni(H_2O)_2(dl\text{-bn})_2]Br_2$	blue	3.28	35—110 °C →	yellow	diamag.	170 °C →	gray	3.44

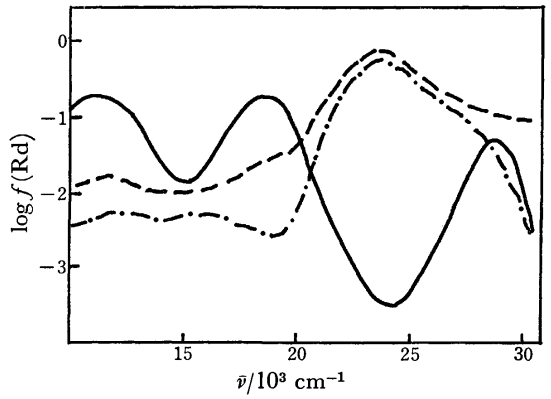

Fig. 3. Electronic spectra of $[Ni(meso\text{-bn})_3]Cl_2 \cdot 2H_2O$ (——), the sample obtained by heating it at 180 °C (– – –) and of $[Ni(meso\text{-bn})_2]Cl_2$ prepared in aqueous solution.

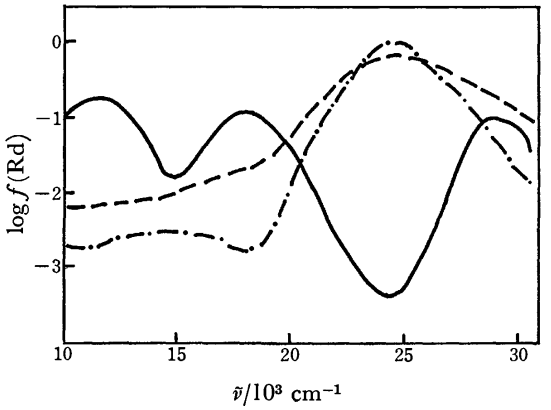

Fig. 4. Electronic spectra of $[Ni(meso\text{-bn})_3]Br_2 \cdot 2H_2O$ (——), the sample obtained by heating it at 220 °C (– – –) and of $[Ni(meso\text{-bn})_2]Br_2$ prepared in aquous solution.

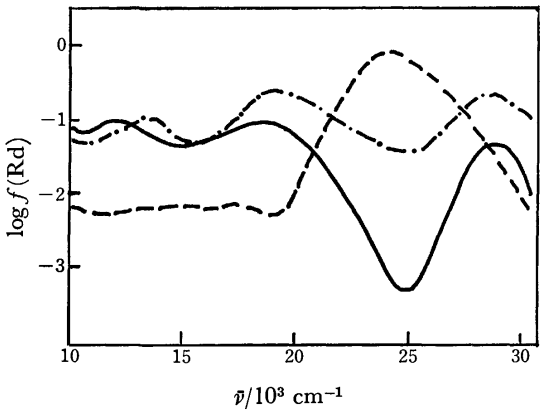

Fig. 5. Electronic spectra of $[Ni(H_2O)_2(dl\text{-bn})_2]Cl_2$ (——), the samples obtained by heating it at 120 °C (– – –) and at 180 °C (-·-·-).

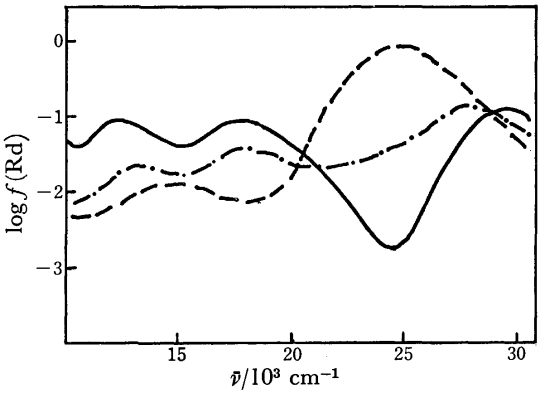

Fig. 6. Electronic spectra of $[Ni(H_2O)_2(dl\text{-bn})_2]Br_2$ (——), the samples obtained by heating it at 110 °C (– – –) and at 170 °C (-·-·-).

obtained by heating complex I to 180 °C, and of complex III are compared in Fig. 3, and the corresponding spectra of complex II, the sample obtained by heating complex II to 220 °C, and of complex IV in Fig. 4. Complexes I and II gave three characteristic maxima at 11, 18, and 28×10^3 cm^{-1}, which are assignable to the $^3A_{2g} \rightarrow {}^3T_{2g}$, $^3A_{2g} \rightarrow {}^3T_{1g}(F)$, and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions in the octahedral nickel(II) complex at room temperature. After heating, these absorption bands were almost quenched and one strong band appeared at 24×10^3 cm^{-1}, which was assigned to the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition in the square planar nickel(II) complex.[9]

The spectra of complex V and the samples obtained by heating this complex to 120 and 180 °C are shown in Fig. 5. At 120 °C, a new strong absorption band due to the formation of the square planar structure appears after the disappearance of the three absorption bands attributed to the octahedral structure, as was observed for complexes I and II. It is notable, however, that when heated to 180 °C, the three original absorption bands reappear after the disappearance of the strong band observed at 120 °C. This suggests the occurrence of a second thermal transformation from square planar to octahedral structure, an exceptional change for nickel(II) complexes.

The spectra of complex VI and the samples obtained by heating it to 110 and 170 °C are shown in Fig. 6. In a manner similar to that for complex V, the three original absorption bands disappear and one strong band appears upon heating at 110 °C, showing that the transformation from octahedral to square planar structure occurs. On the other hand, above 170 °C, the three absorption bands weakly reappear. Partial transformation from square planar to octahedral structure appears to occur.

Magnetic Moments. The magnetic moments at room temperature for complexes I, II, V, and VI and the samples obtained by heating them to each temperature at which a transformation occurs are listed in Table 2. For complexes I and II, the paramagnetic species change to diamagnetic species. By combining these results with the spectral changes due to heating, it is concluded that the change in the structure from octahedral to square planar occurs during the thermal reaction.

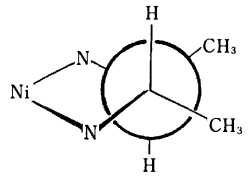
On the other hand, for complexes V and VI, the paramagnetic species change to diamagnetic species with the first heating step in a manner similar to that for complexes I and II. In the second heating step, however, the paramagnetism is recovered. Although the

tetrahedral nickel(II) complex is paramagnetic, it is known that its magnetic moment (3.7 B.M.) is significantly larger than that for the octahedral complex (3.3 B.M.).[10] A stepwise structural transformation, octahedral→square planar→octahedral, is concluded to occur in complex V.

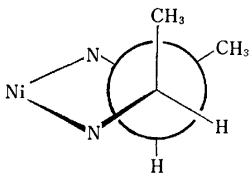
On the other hand, in complex VI having a magnetic moment of 3.44 B. M. and the three weak absorption bands when heated above 170 °C, the partial transformation from square planar to either octahedral or tetrahedral structure is presumed to take place in a second heating step. It is to be noted that such a novel transformation including the subsequent inverse change from square planar to octahedral structure was found.

Relationship between the Conformation of 2,3-bn Coordinated and Ease of Complex Formation. In the present study, diaquabis(*dl*-bn)nickel(II) complexes were prepared, but the corresponding *meso*-bn complexes could not be prepared. This difference is probably due to the difference in the conformational structures of the coordinated 2,3-bn.

The conformations of *dl*-bn and *meso*-bn coordinated to the nickel ion are depicted below.



dl-bn



meso-bn

In complexes containing two moles of *dl*-bn in a square planar structure, the four methyl groups are all equatorial and the apical positions will admit the coordination of water molecules easily forming diaquabis(*dl*-bn)nickel(II) complexes easily.

For complexes containing two *meso*-bn, on the other hand, two of the four methyl groups are axial and, therefore, the water molecules are not easily coordinated in the apical positions. This may be the principal reason why diaquabis(*meso*-bn)nickel(II) complexes could not be prepared.

Multidentate Ligand Kinetics. II. The Ligand Substitution Reactions of the Triethylenetetraminecadmium(II) Ion and the Tetraethylenepentaminecadmium(II) Ion with the Ethylenediaminetetraacetatocuprate(II) Ion

Tetsuo KATSUYAMA and Toshihiko KUMAI

Department of Basic Technology, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received August 4, 1977)

The kinetics and mechanism of the ligand-substitution reactions of triethylenetetraminecadmium(II) ion (Cd(II)-trien) and tetraethylenepentaminecadmium(II) ion (Cd(II)-tetren) with ethylenediaminetetraacetatocuprate(II) ion (Cu(II)-edta) were studied spectrophotometrically at I=0.2 M (1 M=1 mol dm^{-3}) and at 25.0 °C. The ligand-substitution reactions were catalyzed by traces of either edta or the polyamine (triethylenetetramine and tetraethylenepentamine). The substitution reactions were shown to proceed by means of a chain reaction mechanism where the chain-propagating steps are the reactions of the metal complexes with the free ligands. Each chain-propagating step was investigated. The ligand-substitution reactions of Cd(II)-trien and Cd(II)-tetren with edta were studied by the use of the chain reactions in the pH range of 8.8—10.2. The rate law is expressed as: $-d[CdR^{2+}]/dt=k_L[CdR^{2+}][edta^{4-}]+k_{HL}[CdR^{2+}][Hedta^{3-}]$, where R refers to trien or tetren. The rate constants, k_L and k_{HL}, were determined at 25.0 °C and I=0.2 M as: $k_L=(1.3\pm0.2)\times10^6$ M^{-1} s^{-1} and $k_{HL}=(6.5\pm1.5)\times10^4$ M^{-1} s^{-1} for Cd(II)-trien, and $k_L=(3.6\pm0.4)\times10^5$ M^{-1} s^{-1} and $k_{HL}=(1.0\pm0.2)\times10^4$ M^{-1} s^{-1} for Cd(II)-tetren.

Ligand-substitution reactions between two multidentate ligand complexes have been studied by Margerum *et al.*[1-4] A coordination chain reaction mechanism was proposed for the substitution reactions, where the chain-propagating steps are the reactions of the metal complexes with the free ligands.

These coordination chain reactions are useful for analytical purposes.[5-7] To widen their analytical application, though, it seemed worthwhile to find other coordination chain-reaction systems and to compare them with each other. In a previous paper,[8] the ligand-substitution reaction between the ethylenediaminetetraacetatocuprate(II) ion (Cu(II)-edta) and the triethylenetetraminezinc(II) ion (Zn(II)-trien) was studied; this reaction was found to proceed by means of a coordination chain reaction mechanism. In the present study, the ligand-substitution reaction of Cu(II)-edta with the triethylenetetraminecadmium(II) ion (Cd(II)-trien), and that with the tetraethylenepentaminecadmium(II) ion (Cd(II)-tetren) were investigated:

$$Cuedta^{2-} + CdR^{2+} \rightleftharpoons CuR^{2+} + Cdedta^{2-}, \quad (R1)$$

where R represents triethylenetetramine (trien) or tetraethylenepentamine (tetren). The results were compared with those of the other systems, which were found to proceed by means of a coordination chain-reaction mechanism. The coordination chain reactions of the present systems provide a useful method for the study of the ligand substitutions of Cd(II)-trien and Cd(II)-tetren with edta.

Experimental

Reagents. Guaranteed reagent-grade cadmium(II) oxide was dissolved in perchloric acid. Twice-recrystallized sodium carbonate was added to the solution to obtain cadmium carbonate. A cadmium(II) perchlorate solution was then prepared by dissolving the cadmium carbonate in a perchloric acid solution. GR grade trien and tetren were purified by distillation under reduced pressure. The polyamine was dissolved in water, and its concentration was determined by the use of a standard copper nitrate solution.

Solutions of Cd(II)-trien and Cd(II)-tetren were prepared by the following procedure. The cadmium(II) perchlorate was added stoichiometrically to a solution containing the ligand, after while a slight excess of the cadmium(II) perchlorate was added to the solution. The excess cadmium(II) of the solutions of Cd(II)-trien and Cd(II)-tetren was precipitated as hydroxide at about pH 9.7 and 10.0 respectively. The precipitate was filtered off, and the solution's pH was then adjusted to about 7 for storage. The concentrations of the Cd(II)-polyamine solutions were determined by a method reported previously.[8]

The way of preparing the Cu(II)-edta solution was described previously.[8] GR-grade sodium perchlorate and sodium chloride were recrystallized from its aqueous solution. The other chemicals used were of a GR grade.

Apparatus and Kinetic Measurements. The Cu(II)-polyamines are stronger complexes than Cu(II)-edta, while the opposite is true for cadmium ion, so that the ligand exchange between Cu(II)-edta and Cd(II)-polyamine goes to completion, while the reverse reaction can be neglected in the kinetic study. The kinetics was studied in the presence of a large excess of Cu(II)-edta and small amounts of edta. In the kinetic measurements, a stopped-flow technique was employed with a Hitachi Model RSP2 Rapid Scanning Spectrophotometer. After the two reactant solutions had been mixed, the reaction was followed automatically, the transmittance of the reaction system at 550 nm (in the Cd(II)-trien system) or 575 nm (in the Cd(II)-tetren system) being recorded as a function of the time. The molar absorption coefficients of Cu(II)-trien, Cu(II)-tetren, and Cu(II)-edta are as follows: ε(Cu(II)-trien)=138 M^{-1} cm^{-1} (1 M=1 mol dm^{-3}), ε(Cu(II)-edta)=5 M^{-1} cm^{-1} at 550 nm, ε(Cu(II)-tetren)=111 M^{-1} cm^{-1}, ε(Cu(II)-edta)=11 M^{-1} cm^{-1} at 575 nm, which were measured with a Hitachi 139 spectrophotometer. Cd(II)-trien, Cd(II)-tetren, and Cd(II)-edta do not absorb light in the visible region.

A mannitol–boric acid–sodium borate or sodium borate–sodium hydroxide buffer system was used to control the pH of the solution. All the pH values were measured with a Toa Electronics Model HM-15A digital pH-meter. The

ionic strength was adjusted to 0.2 M with sodium perchlorate or sodium chloride (at pH 9.0—10.2 in the Cd(II)-trien system). All the measurements were made in a thermostated room. The reaction temperature was controlled at 25.0 °C within ±0.1 °C using a thermoelectric circulating bath. Several calculations were performed with the aid of a TOSBAC 40 computer.

Results

Ligand-substitution Reaction between Cu(II)-edta and Cd(II)-trien. At pH's from 9.0 to 10.2 the rate equation can be expressed as

$$-\frac{d[Cdtrien^{2+}]}{dt} = k'_{o,1}[Cdtrien^{2+}], \quad (1)$$

where $k'_{o,1}$ is the conditional rate constant involving the concentrations of edta and hydrogen ions. The rate plots of $\log(A_\infty - A)$ *vs.* t, where A and A_∞ denote, respectively, the absorbances at time t and infinity, were linear for over 80% of the reaction. Then the conditional rate constant, $k'_{o,1}$, was determined from the slope of the straight line. The values of the conditional rate constant, $k'_{o,1}$, were found to be linearly related to the added free edta concentration: $[edta]_a$($[edta]_a = \sum_{i=0}^{4}[H_iedta^{(4-i)-}]$) in the region above a threshold value of b, provided that all the other experimental conditions were kept constant (Fig. 1). Thus, the conditional rate constant, $k'_{o,1}$, is expressed by

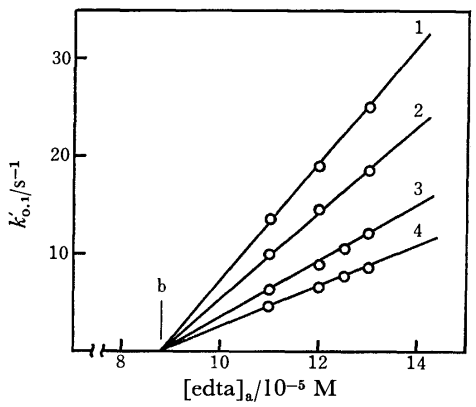

Fig. 1. $k'_{o,1}$ as a function of the concentration of added free edta.
Conditions: $[Cuedta^{2-}]=2.50\times10^{-2}$ M, $[Cdtrien^{2+}]=1.50\times10^{-3}$ M, I=0.2 M, 25.0 °C.
1: pH=10.15, 2: pH=9.89, 3: pH=9.70, 4: pH=9.44.

$$k'_{o,1} = k_{o,1}([edta]_a - b). \quad (2)$$

The values of $k_{o,1}$ determined at various pH's are plotted against the pH in Fig. 4.

On the other hand, at lower pH's from 7.5 to 8.5 the reaction was of the zeroth-order with respect to Cd(II)-trien. Thus, the rate law is given by

$$-\frac{d[Cdtrien^{2+}]}{dt} = k'_{o,0}, \quad (3)$$

where $k'_{o,0}$ is the conditional zeroth-order rate constant involving the Cu(II)-edta, the added free edta, and the hydrogen-ion concentration. The plots of A *vs.* t were linear for over 80% of the reaction. Thus, the

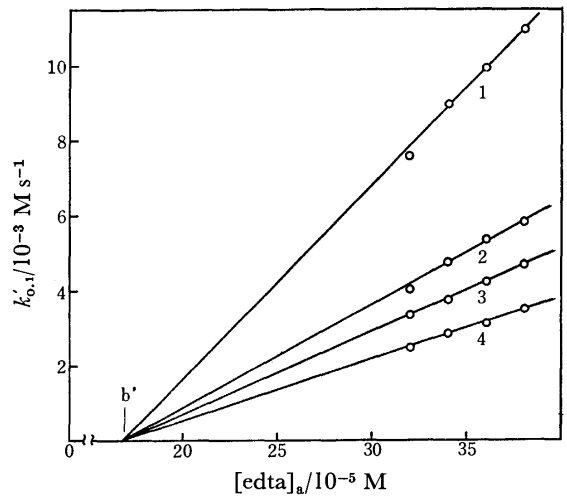

Fig. 2. $k'_{o,0}$ as a function of the concentration of added free edta.
Conditions: $[Cuedta^{2-}]=2.50\times10^{-2}$ M, $[Cdtrien^{2+}]=1.50\times10^{-3}$ M, I=0.2 M, 25.0 °C.
1: pH=8.10, 2: pH=7.81, 3: pH=7.70, 4: pH=7.50.

conditional zeroht-order rate constant, $k'_{o,0}$ was calculated from the slope of the straight line. The values of $k'_{o,0}$ at constant concentrations of the Cu(II)-edta and the hydrogen ion are linearly related to the added free edta concentration $[edta]_a$ in the region above the threshold value of b' (Fig. 2). Thus, the conditional rate constant, $k'_{o,0}$, is expressed by

$$k'_{o,0} = k_{o,0}([edta]_a - b'). \quad (4)$$

The values of the $k_{o,0}$ slope were obtained at various pH's.

Ligand-substitution Reaction between Cu(II)-edta and Cd(II)-tetren. At pH's from 8.2 to 9.7 the reaction was of the first-order with respect to Cd(II)-tetren. The rate plots of $\log(A_\infty - A)$ *vs.* t were linear for over 80% of the reaction. Then the conditional first-order rate constant, k'_o, was determined from the slope of the straight line. The conditional rate constant, k'_o, was independent of the concentration of Cu(II)-tetren. From these results, the following rate equation is derived:

$$-\frac{d[Cdtetren^{2+}]}{dt} = k'_o[Cdtetren^{2+}]. \quad (5)$$

In addition, the values of the conditional rate constant, k'_o, at a constant pH are linearly related to the added free edta concentration in the region above the threshold value of b''. Thus, the conditional rate constant, k'_o, is expressed by

$$k'_o = k_o([edta]_a - b''). \quad (6)$$

The values of k_o determined at various pH's are plotted against pH in Fig. 5.

Discussion

Reaction Mechanism. The following chain-reaction mechanism was proposed for the ligand-substitution reactions of Cd(II)-trien and Cd(II)-tetren with Cu(II)-edta:

$$\mathrm{Cuedta^{2-}} + \mathrm{R'} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{CuR^{2+}} + \mathrm{edta'}, \qquad \text{(R2)}$$

$$\mathrm{CdR^{2+}} + \mathrm{edta'} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{Cdedta^{2-}} + \mathrm{R'}, \qquad \text{(R3)}$$

where edta′ and R′ represent the sums of the uncomplexed species of edta and polyamine (trien or tetren) respectively. On the basis of the proposed mechanism, the following rate law was derived:

$$-\frac{d[CdR^{2+}]}{dt} = \frac{(k_2k_3[Cuedta^{2-}][CdR^{2+}] - k_{-2}k_{-3}[Cdedta^{2-}][CuR^{2+}])[L']}{k_2[Cuedta^{2-}] + k_{-2}[CuR^{2+}] + k_3[CdR^{2+}] + k_{-3}[Cdedta^{2-}]}, \qquad (7)$$

where [L′] is the total concentration of free ligands, edta and polyamine ([edta′]+[R′]). The rate law is derived from a steady-state treatment with the assumptions that all of the exchange is carried out by means of Reactions R2 and R3, and that the concentrations of the free ligands, edta and polyamine, remain constant throughout the exchange.

In this discussion it is necessary to calculate the conditional equilibrium constants of Reactions R2 and R3, ([CuR²⁺][edta′]/[Cuedta²⁻][R′] and [Cdedta²⁻]-[R′]/[CdR²⁺][edta′]). The conditional equilibrium constants can be calculated from the stability constants of the related complexes and the protonation constants of the related ligands.[9] The conditional equilibrium constants calculated are plotted against the pH in Fig. 3.

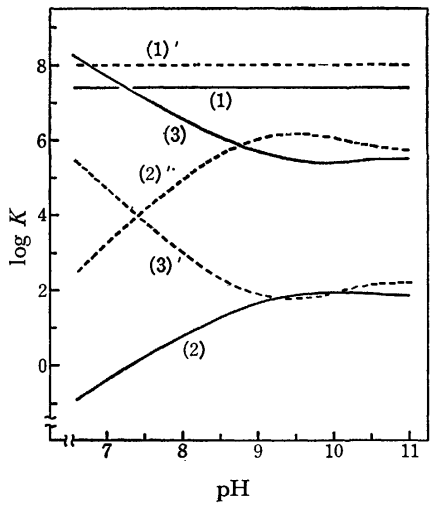

Fig. 3. Dependence of conditional equilibrium constants of reactions (R1), (R2), and (R3) on pH at 25.0 °C and I=0.2 M.
1,1′: (R1), 2,2′: (R2), 3,3′: (R3).
The full lines show the constants of the Cd(II)-trien system and the dotted lines show that of the Cd(II)-tetren system.

Cd(II)-trien System. In the Cd(II)-trien system, Equilibrium R3 much favors the right, so it appears reasonable to assume $k_3 \gg k_{-3}$. Therefore, Eq. 7 can be simplified to

$$-\frac{d[Cdtrien^{2+}]}{dt} = \frac{k_2k_3[Cuedta^{2-}][Cdtrien^{2+}][L']}{k_2[Cuedta^{2-}] + k_{-2}[Cutrien^{2+}] + k_3[Cdtrien^{2+}]}. \qquad (8)$$

The following approximation seems reasonable from Figs. 3 and 4, as will be shown later. In the denominator of Eq. 8, the k_2[Cuedta²⁻] term becomes predominant and the other terms may be neglected for the reaction with a large excess of Cu(II)-edta at pH 9.0—10.2. Thus, Eq. 8 becomes

$$-\frac{d[Cdtrien^{2+}]}{dt} = k_3[Cdtrien^{2+}][L']. \qquad (9)$$

If free metal ions (*e.g.*, metal impurity) are present in the system, the metal ions will react very rapidly with the added free edta. Consequently, the concentration of free ligands ([L′]) in the solution is written as

$$[L'] = [edta]_a - [M], \qquad (10)$$

where [M] is the concentration of free metal ions (*e.g.*, the metal impurity). Thus, Eq. 9 becomes

$$-\frac{d[Cdtrien^{2+}]}{dt} = k_3([edta]_a - [M])[Cdtrien^{2+}]. \qquad (11)$$

As has been stated above, Eq. 1 can be rewritten as

$$-\frac{d[Cdtrien^{2+}]}{dt} = k'_{o,1}[Cdtrien^{2+}] = k_{o,1}([edta]_a - b)[Cdtrien^{2+}]. \qquad (12)$$

Therefore, k_3 and [M] in Eq. 11 should correspond to $k_{o,1}$ and b respectively. In Fig. 4, the value of k_3 determined at various pH's is plotted against the pH.

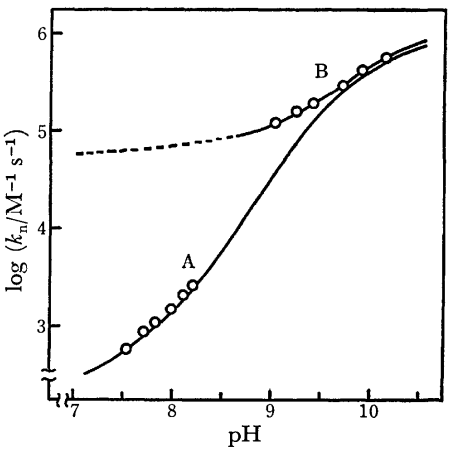

Fig. 4. Dependence of the conditional rate constants k_2 and k_3 ($=k_{o,1}$) of the Cd(II)-trien system on pH at 25.0 °C and I=0.2 M.
A: k_2, B: k_3 ($=k_{o,1}$). The lines A and B are the curves calculated with the aid of the individual rate constants. ——: Extrapolated by Eq. 21.

On the other hand, in the denominator of Eq. 8, the k_3[Cdtrien²⁺] term becomes predominant and the other terms may be neglected for pH 7.5—8.5; this can be shown to be valid from Figs. 3 and 4. Thus, Eq. 8 becomes

$$-\frac{d[Cdtrien^{2+}]}{dt} = k_2[Cuedta^{2-}][L']. \qquad (13)$$

For a large excess of Cu(II)-edta, k_2[Cuedta^{2-}] is constant during the reaction, so that Eq. 13 becomes

$$-\frac{d[Cdtrien^{2+}]}{dt} = (const)([edta]_a - [M]). \quad (14)$$

Equation 3 can be rewritten as

$$-\frac{d[Cdtrien^{2+}]}{dt} = k_{o,0}([edta]_a - b'). \quad (15)$$

Therefore, Eq. 14 agrees with the rate equation derived experimentally at lower pH's. Thus, k_2 can be calculated from the value of $k_{o,0}$. The value of k_2 thus obtained is plotted against the pH in Fig. 4. The conditional rate constant, k_2, thus obtained agrees with the conditional rate constant of the reaction of Cu(II)-edta with trien which was determined previously.[8]

Cd(II)-tetren System. In the Cd(II)-tetren system, the R2 equilibrium much favors the right, so that the $k_2 \gg k_{-2}$ inequality can be considered to hold. Therefore, Eq. 7 can be simplified to

$$-\frac{d[Cdtetren^{2+}]}{dt} = \frac{k_2 k_3[Cuedta^{2-}][Cdtetren^{2+}][L']}{k_2[Cuedta^{2-}] + k_3[Cdtetren^{2+}] + k_{-3}[Cdedta^{2-}]}. \quad (16)$$

The conditional rate constant, k_2, was calculated from the rate constants of the reaction of Cu(II)-edta with tetren which had been determined by Margerum *et al.*[10] The value of k_2 thus calculated is plotted against the pH in Fig. 5. The following approximation seems reasonable from Figs. 3 and 5. In the denominator of Eq. 16, the k_2[Cuedta^{2-}] term becomes predominant and the other terms may be neglected under the present experimental conditions. Consequently, Eq. 16 becomes

$$-\frac{d[Cdtetren^{2+}]}{dt} = k_3[Cdtetren^{2+}][L'] = k_3([edta]_a - [M])[Cdtetren^{2+}]. \quad (17)$$

Equation 5 can be rewritten as

$$-\frac{d[Cdtetren^{2+}]}{dt} = k_o([edta]_a - b'')[Cdtetren^{2+}]. \quad (18)$$

Therefore, Eq. 17 agrees with the rate equation derived experimentally. Then k_3 is equal to k_o. The value of k_3 thus determined is plotted against the pH in Fig. 5.

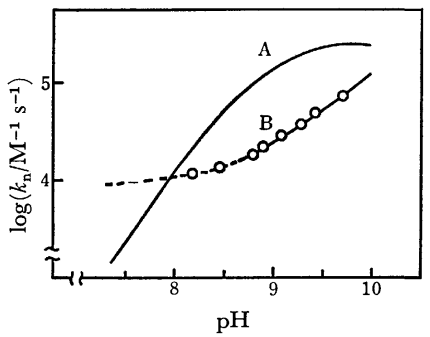

Fig. 5. Dependence of the conditional rate constants k_2 and k_3 ($=k_o$) of the Cd(II)-tetren system on pH at 25.0 °C and I=0.2 M.
A: k_2, B: k_3 ($=k_o$). The lines A and B are the curves calculated with the aid of the individual rate constants.
----: Extrapolated by Eq. 21.

Resolution of the Conditional Rate Constant, k_3. The following relation can be derived from a steady-state consideration of Reactions R2 and R3 on the assumption that the concentrations of the free ligands remain constant:

$$\frac{[edta']}{[R']} = \frac{k_2[Cuedta^{2-}] + k_{-3}[Cdedta^{2-}]}{k_{-2}[CuR^{2+}] + k_3[CdR^{2+}]} \approx \frac{k_2[Cuedta^{2-}]}{k_{-2}[CuR^{2+}] + k_3[CdR^{2+}]}. \quad (19)$$

The inequality k_2[Cuedta^{2-}]$\gg k_{-2}$[CuR^{2+}]$+k_3$[CdR^{2+}] holds under the present experimental conditions in the Cd(II)-trien and Cd(II)-tetren systems. Consequently, [edta']$\gg$[R']. Thus, [L']=[edta']+[R']$\approx$[edta']. In the pH 8.8—10.2 range, the dominant species of edta are Hedta^{3-} and edta^{4-}. Thus, the following relationship can be derived:

$$k_3[L'][CdR^{2+}] = k_3[edta'][CuR^{2+}] = k_L[edta^{4-}][CdR^{2+}] + k_{HL}[Hedta^{3-}][CdR^{2+}], \quad (20)$$

where k_L and k_{HL} are the rate constants for the following reactions

$$\begin{array}{ccc} edta^{4-} & \xrightarrow{k_L} & Cdedta^{2-} + R \\ CdR^{2+} + \uparrow\downarrow & & \\ Hedta^{3-} & \xrightarrow{k_{HL}} & Cdedta^{2-} + HR^{+} \end{array} \quad (R4)$$

With the protonation constant of Hedta^{3-}, Eq. 20 is rewritten as

$$k_3(K_1[H^+]+1) = k_{HL}K_1[H^+] + k_L, \quad (21)$$

where K_1 is the protonation constant. The plots of the left-hand side of Eq. 21 *vs.* K_1[H$^+$] give a straight line in the Cd(II)-trien and Cd(II)-tetren systems, as is shown in Figs. 6 and 7. The slopes and intercepts correspond to the k_{HL} and k_L rate constants respectively. The rate constants obtained in the two systems are summarized in Table 1.

The concentrations of the hydrogen and hydroxide complexes[9] of CdR^{2+} are negligibly small at high pH values (9—10); for example, the concentration of CdHtrien^{3+} is 0.06% of [Cd(II)-trien]$_{total}$ at pH 9.6. It seems reasonable to neglect the contribution of the hydrogen and hydroxide complexes of CdR^{2+} to the total reaction in the present pH region. Using the

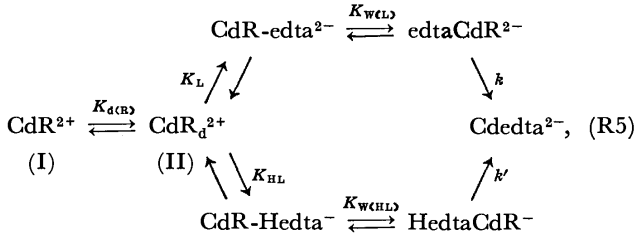
resolved rate constants, the conditional rate constant, k_3, can be calculated from Eq. 21 at pH 8.8—10.2. The values calculated for the Cd(II)-trien and Cd(II)-tetren systems are shown in Figs. 4 and 5 respectively. In Figs. 4 and 5, the dotted lines show the estimates calculated from Eq. 21.

Mechanism of the Substitution Reactions of Cd(II)-polyamine Complexes with edta. The following reaction mechanism was proposed for the ligand-substitution reactions of Cd(II)-trien and Cd(II)-tetren with edta



where $K_{d(R)}$ refers to the dissociation constant of the complex CdR^{2+} to the partially dissociated complex CdR_d^{2+}, K_L and K_{HL} are the formation constants of the outer-sphere complexes, CdR-edta^{2-} and CdR-Hedta$^-$ respectively, and $K_{W(L)}$, the equilibrium constant between CdR-edta^{2-} and the mixed ligand intermediate edtaCdR^{2-} (inner-sphere complex). According to the proposed mechanism, the rate equation of the substitution of the Cd(II)-polyamine complexes with edta can be written as

$$\begin{aligned}\frac{d[Cdedta^{2-}]}{dt} &= k[edtaCdR^{2-}] + k'[HedtaCdR^-]\\ &= K_dK_LK_{W(L)}k[CdR^{2+}][edta^{4-}]\\ &\quad + K_dK_{HL}K_{W(HL)}k'[CdR^{2+}][Hedta^{3-}]\\ &= k_L[CdR^{2+}][edta^{4-}]\\ &\quad + k_{HL}[CdR^{2+}][Hedta^{3-}]. \qquad (22)\end{aligned}$$

The estimation of the k/k' ratio is interesting. From Eq. 22 the following relationship is derived

$$\frac{k_L}{k_{HL}} = \frac{K_LK_{W(L)}k}{K_{HL}K_{W(HL)}k'} \qquad (23)$$

The release of a water molecule from the outer-sphere complex is the rate-determining step in the formation of a metal complex.[11] Therefore, the rate of the formation of edtaCdR^{2-} from CdR-edta^{2-} is expected to be equal to that of HedtaCdR$^-$ from CdR-Hedta$^-$. Further, the rate of the dissociation of edta^{4-} from edtaCdR^{2-} to the outer-sphere complex does not seem to differ from that of Hedta^{3-} from HedtaCdR$^-$. Thus, it appears reasonable to assume that $K_{W(L)}\approx K_{W(HL)}$. K_L and K_{HL} can be calculated according to the Fuoss equation.[12,13] Then, with the calculated values of K_L and K_{HL}, and the rate constants of k_L and k_{HL}, the k/k' ratio can be estimated. The ratios obtained at I=0.2 M and 25 °C are 3.1 and 5.6 for the Cd(II)-trien and Cd(II)-tetren systems respectively. In other words, the formation rate of Cdedta^{2-} from edtaCdR^{2-} is larger than that from HedtaCdR$^-$. The dipolar-ion (zwitter-ion) form of edta is known to be unreactive in the formation of many metal complexes because the NH$^+$ group of edta prevents chelation.[14] Therefore, in the formation of Cdedta^{2-} from HedtaCdR$^-$, the NH$^+$ group of the edta seems to prevent the chelation. Consequently, k' can be expected to be less than k. Thus, the coordination of the second nitrogen atom to the central metal in the mixed ligand intermediates, HedtaCdR$^-$ and edtaCdR^{2-}, is probably rate-determining.

The reaction mechanisms of the two systems (Cd(II)-trien and Cd(II)-tetren) seem to be similar except that the dissociation of the (I) complex to the partially dissociated complex (II) is different. Further, the $K_{d(Cdtrien)} > K_{d(Cdtetren)}$ inequality can be expected to hold, because the formation constant of Cd(II)-tetren is greater than that of Cd(II)-trien. Therefore, the rate of the reaction of Cd(II)-trien with edta can be expected to be faster than that of the Cd(II)-tetren system. This agrees with the experimental results.

Comparison of Chain-reaction Systems. The coordination chain-reaction systems use Cu(II)-edta as one reactant, while the other reactant consists of metal(II)-polyamine complexes. It is interesting to compare the reaction rates of the coordination chain-reaction systems. The reaction rates under the same conditions can be compared by means of the conditional rate constant, k_3, when the reaction is of the first-order with respect to the metal(II)-polyamine complex. The conditional

TABLE 2. CONDITIONAL RATE CONSTANTS FOR THE LIGAND-SUBSTITUTION REACTIONS OF THE METAL(II)-POLYAMINE COMPLEXES WITH edta AT A CERTAIN pH AT 25.0 °C AND AT I=0.2 M

	$\frac{k_3}{M^{-1}\,s^{-1}}$	pH		$\frac{k_3}{M^{-1}\,s^{-1}}$	pH
Cd(II)-trien	2.14×10^5	9.5	Cd(II)-tetren	2.52×10^4	9.0

Ni(II)-trien[5]	$1.6\times10^{3a)}$		Ni(II)-tetren[3]	$1.2^{a)}$	

a) I=0.1 M

Table 3. The lower limit of the pH region where the first-order reaction proceeds in the presence of a 15-fold excess of Cu(II)-edta

	pH		pH
Cd(II)-trien	9.44	Cd(II)-tetren	7.80
Zn(II)-trien	9.90	Zn(II)-tetren	7.30
Ni(II)-trien	7.8	Ni(II)-tetren	5.9

rate constants, k_3, of various systems at a certain pH are summarized in Table 2. Table 2 shows that the reaction rates of the cadmium and zinc systems are greater than that of the nickel system, and that the reaction rate of the trien system is greater than that of the tetren system. In fast reactions, kinetic measurements can be easily repeated using the stopped-flow technique. Therefore, in analytical applications, using the fast-coordination chain reaction, rapid analysis may be achieved by handling the results statistically with an on-line computer.

The pH region where the first-order reaction takes place can be estimated approximately from the conditional rate constants and the experimental conditions. In Table 3, the lower limits of the pH region in the presence of a 15-fold excess of Cu(II)-edta are tabulated. It may be seen from Tables 2 and 3 that the greater the value of k_3, the greater is the lower limit of the pH region. In general, the first-order reaction takes place without an excess of Cu(II)-edta when $k_2 \gg k_3$. However, a large excess of Cu(II)-edta is required for the first-order reaction when the $k_2 \gg k_3$ inequality is not satisfied.

(Received September 1, 1977)

Japanese Tea Leaves, prepared by pulverizing with an agate ball mill and sieving with a Saran fiber sieve (50 mesh) were assessed as a possible biological standard reference material for elemental analysis. The metal content of the tea leaves was determined independently at two laboratories using atomic absorption and flame emission spectrometry. Neutron activation analysis was also performed to determine the content (21 elements) of Tea Leaves. For some elements the result from the various methods were compared. The characteristics of Tea Leaves are discussed and the elemental composition is compared to that of Orchard Leaves (NBS SRM, 1571). The most significant characteristic of Tea Leaves was the high manganese content.

The need for standard reference materials in elemental analysis is steadily increasing, due primarily to the ever-increasing demand for elemental data in many scientific fields.

Standard reference materials were first prepared in 1904 by NBS.[1] They were metal samples such as cast iron in chip form. United States Geological Survey (USGS) prepared in 1955 standard rock samples, G 1 and W 1, which were distributed to analytical laboratories throughout the world.[2]

After 1960 many studies concerned with standard reference materials have taken place. Bowen's[3] study on "kale powder" began in 1960 and in this study, 42 elements were determined at many laboratories using 11 different analytical methods. Vallee[4] has studied the metal content of bone ash standard sample. Jones,[5] a member of Bowen's group has studied eight grass samples by direct-reading emission spectrometry. The present authors have determined the metal content of these grass samples by atomic absorption spectrometry.[6] Sideman's[7] work on serum samples was concerned only with Ca and involved participation by 31 laboratories. Yamagata's[8] work on Cd in rice was brought about from environmental Cd contamination resulting in abnormally high Cd level in rice production. The work by NBS research group[1,9] has been the most detailed and of the most practical use.

Recently, trace element analyses of various types of biological and/or environmental samples have been performed so extensively that it has become necessary to prepare new biological standard materials. As part of a co-operative study with NBS for the development of new biological standard materials, Japanese Tea Leaves were investigated as a possible standard reference materials. The sample was prepared on a small scale and analysis using two analytical methods, atomic absorption spectrometry and neutron activation analysis, was performed at the University of Tokyo and the National Institute for Environmental Studies.

Experimental and Results

Preparation of Tea Leaves. Three kinds of tea leaves were obtained from National Research Institute for Tea. They were (1) "Sen-cha", a middle grade green tea(Tea B), (2) old tea leaves which are not suitable for drinking(Tea C) and (3) powdered tea leaves(Tea D). The weight of the original tea samples was about 1 kg.

TABLE 1. METAL DISTRIBUTION IN TEA LEAVES (μg/g)

Sample	K	Ca	Mg	Mn	Fe	Zn
B Powder	23300	2320	1770	610	142	66
Part retained under sieve	27000	3260	1840	660	104	59
C Powder	10700	6870	1350	2650	241	19
Part retained under sieve	10200	7130	1300	2310	160	16

Tea samples B and C were pulverized with an agate ball mill and passed through a sieve made of Saran(50 mesh). The rigid parts of the leaves such as leafstalks were retained by the sieve and for both tea samples(B and C) the amount retained was approximately 100 g. Elemental analysis of both parts indicated that more Ca and less Fe were contained in the unpowdered part retained on the sieve. The powdered part which passed through the sieve was used for the further elemental analysis.

Tea D, a homogenized powder was analysed directly.

Preservation of the Samples. The powdered samples were stored in a desiccator containing silica gel and weighed periodically to determine whether the weight changed during storage. Standard materials should be preserved without any change for long periods. The results, summarized in Table 2, indicate that the dry weight did not alter significantly within 6 months.

TABLE 2. CHANGE OF WATER CONTENT DURING STORAGE OF TEA POWDER IN DESICCATOR (Silica Gel)

Sample	Water content (%)	
	Nov., 1975	May, 1976
Tea B	5.4	6.0
Tea C	7.2	6.6
Tea D	7.4	5.9

Water content was measured after 24 h drying at 90 °C.

Homogeniety of the Sample. To determine whether the powdered samples were homogeneous, the Fe content of 18 randomlly selected portions (0.5 g) of Tea C was determined

by atomic absorption spectrometry. Portions (0.5 g) of sample (C) were taken from three parts of every six bottles of Tea C. The tea powder was contained in six sample bottles and each sample bottle was sub-divided in three equal parts before the portions were selected. The results of the analysis of the 18 sub samples are shown in Table 3, and indicate that the homogeniety of the tea sample is similar to that of Orchard Leaves.

Determination of Mn, Fe, Zn, and Pb by Atomic Absorption Spectrometry. Atomic absorption determination of Mn, Fe, Zn, and Pb was performed by two laboratories, independently. The experimental conditions employed by the two laboratories are shown in Table 4. In the work, different sample pretreatments were adopted and different standard solutions were used. At the National Institute for Environmental Studies, standard metal ion solution containing nitric acid(0.1 M) was used while at the University of Tokyo, a a matrix solution which contained the particular metal ion as well as other major elements in the tea leaves was used. At the University of Tokyo, the optimum conditions of flame atomic absorption measurement for each element was decided using the response-surface plot method, details of which have been described elsewhere.[10]

Table 5. Fe, Mn and Zn contents in tea leaf samples and orchard leaves

		National Inst for Environ. Studies		The Univ. of Tokyo	(Certified value)
Fe	Tea B	135[a]	137[b]	142	
	Tea C	242	226	241	
	Tea D	375	438	423	
	Orchard leaves	268	239	281	300±20

	Orchard leaves	25	29	32	25±3

(μg/g) a) Wet ashing. b) Dry ashing.

Table 6. Pb contents in tea leaf samples and orchard leaves

	National Inst. for Environ. Studies		The Univ. of Tokyo	(Certified value)
Tea B	2.9[a]	3.4[b]	1.8	
Tea C	5.6	5.5	2.9	
Tea D	4.0	3.4	2.0	
Orchard Leaves	43.3	16.1		45±3

(μg/g) a) Wet ashing. b) Dry ashing.

The results for Mn, Fe, and Zn are shown in Table 5 and indicate that the date for the two laboratories agree within 10% in most cases and that there is no significant difference between the data obtained by wet ashing and those by dry ashing. Concentrations of Pb determined by carbon rod furnace atomic absorption spectrometry at the two laboratories do not agree. This is shown in Table 6. This discrepancy may be caused by the difference in the background correction system adopted by the two laboratories and/or by the chemical interference from the matrix elements. This is presently under investigation.

Neutron Activation Analysis. In addition to atomic absorption and flame emission spectrometry mentioned above, 21 elements including Mn, Fe, Zn, K, Ca, and Mg were determined by conventional non-destructive neutron activation analysis. Neutron irradiation were carried out in 100 KW TRIGA Mark II Reactor of Rikkyo University. Each tea sample (almost 100 mg) was irradiated under a thermal neutron flux of 5×10^{11} for 5 min. A 4048 channel pulse height analyzer coupled with a Ge(Li) detector was used to detect the γ-rays which were emitted from the radioactive nuclides. Al, V, Cu, Ca, and Mg were determined after 1 to 2 min irradiation, while Cl, Mn, K, and Na were determined after 1 to 2 h irradiation. The samples were further irradiated under a thermal neutron flux of 5×10^{11} n cm^{-1} s^{-1} for 30 h and As, Br, La, Sm, Ba, Rb, and Cr were determined after 5 to 6 days. Finally Fe, Sb, Se, Zn, and Co were determined after about 100 days. In this work,

a) Determined by neutron activation analysis. Errors correspond to the statistical errors on counting radioactivities.

elemental standards and Orchard Leaves were irradiated together with the tea samples.

The results for the three tea leaf samples(B, C, D) are shown in Table 7, together with those for Orchard Leaves. Errors cited in this table correspond to the statistical errors on counting radioactivities. The elemental composition of Orchard Leaves determined in this work compares favorably with that reported by NBS[9)]. The results for V, Cu, Na, and and K which were determined at short irradiation time (5 min) have large errors. This was due to the relatively large amount of Mn in the tea leaves which resulted in the over-production of ^{56}Mn at long irradiation time.

Discussion

Of the elements determined by neutron activation analysis, Mn, Fe, Mg, and Zn were also determined by atomic absorption spectrometry and K and Ca by flame emission spectrometry. A comparison of the data for Zn, Mn, and Ca is shown in Figs. 1—3, respectively. These results indicate that the metal

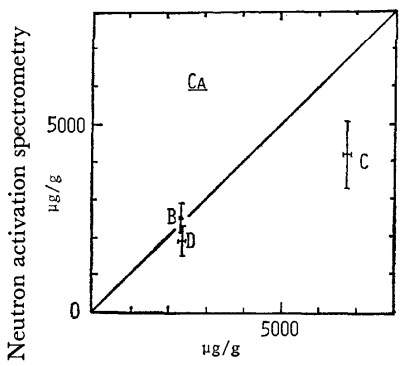

Fig. 1. Comparison of calcium content determined by activation analysis and flame emission spectrometry.

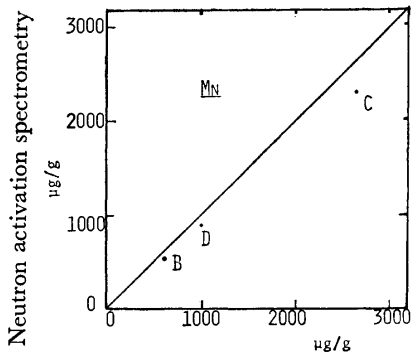

Fig. 2. Comparison of manganese content determined by activation analysis and atomic absorption spectrometry.

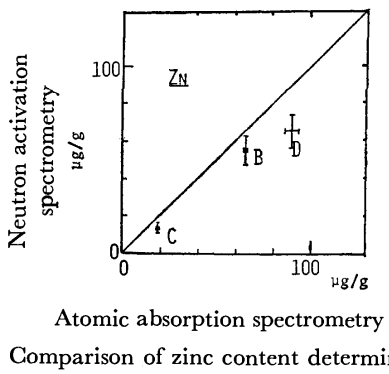

Fig. 3. Comparison of zinc content determined by activation analysis and atomic absorption spectrometry.

contents determined by activation analysis are slightly lower than those for emission or absorption spectrometry. The results also agree with the comment of Bowen:[3] "the differences (in analytical results) between techniques were usually larger than the differences between individual laboratories in which the same technique was used." In our case, the difference in analytical data for the two laboratories by the same technique (atomic absorption spectrometry) is smaller than that by the different techniques (atomic absorption or flame emission spectrometry and neutron activation analysis).

To decide whether the tea leaf samples are suitable as a new biological reference material, the results obtained must be assessed. The prerequisites for a standard reference material might be listed as follows:

1. Availability in large amount.
2. Availability at low cost.
3. Preservation for a long period.
4. Safety for transportation.
6. Appropriate elemental composition.

Point 1 and 2 are met since there is a supply of tea leaves at low cost. Tea leaf samples were shown to be preserved for at least six months. In the case of biological samples, the alteration caused by activities of microbes should be considered as well as the chemical alteration. Irradiation of the samples by ^{60}Co, as was the case in preparing Orchard leaf samples at NBS,[11] is one of the most powerful techniques to prevent biological alteration. For tea leaf samples, a steaming procedure used in commercial processing of raw tea may be a suitable sterilization process.

One of the most important criteria for a standard reference material is homogeniety. The tea leaf samples prepared in this work were shown to be homogeneous (Fe determined in 18 randomly selected sub-samples of Tea C).

As a new biological standard, the elemental composition must also be characteristic compared with other similar kinds of standard materials produced in the past. In Figs. 4—6 and in Table 7, a comparison of the elemental composition between Orchard Leaves and Tea B, Tea C, and Tea D is shown.

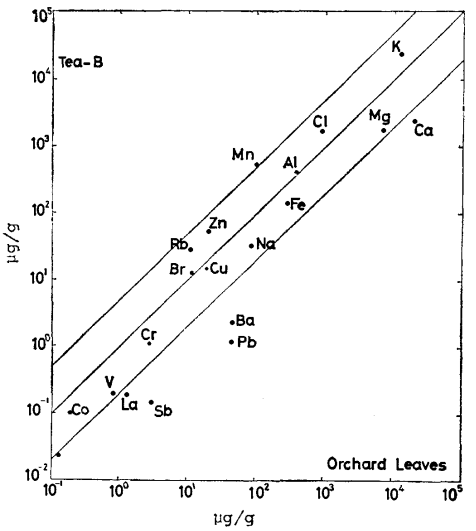

Fig. 4. Elementary compositions of Tea B and Orchard Leaves.

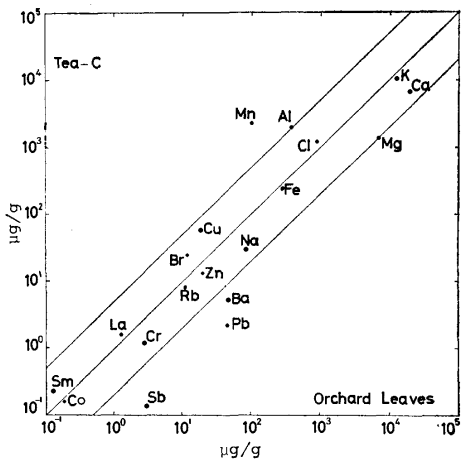

Fig. 5. Elementary compositions of Tea C and Orchard Leaves.

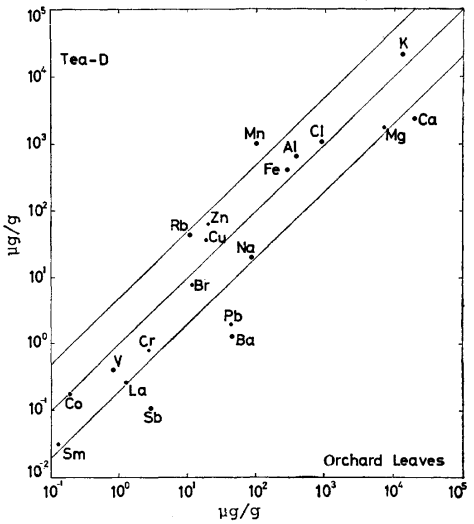

Fig. 6. Elementary compositions of Tea D and Orchard Leaves.

The characteristic features of the elemental compositions are summarized as follows:

1. The Mn content of the tea leaf samples is much higher than for Orchard Leaves.
2. The Ca and Ba contents are lower in the tea leaf samples.
3. As for the other elements, the content in the tea leaf samples is similar to that of Orchard Leaves.

Growth of the tea plant in acid soil may reflect the high content of Mn in the tea leaf samples. The high level of Mn might make tea leaf samples to be preferred as a standard reference material when acid-resistant plants such as rice, are analysed. In addition, it is necessary to eliminate contamination during the preparation procedure even if the homogeniety of the contaminant elements is certified. For example, the Pb content in Orchard Leaves is relatively greater than for most other edible plant products. This suggests that the Pb levels in Orchard Leaves may partly arise from contamination from sources such as pesticides. The low recovery of Pb in Orchard Leaves by ashing

compared to that for tea leaf samples may indicate that a certain part of Pb in Orchard Leaves is in an inorganic form which may behave differently from inert Pb at the ashing step (Table 6).

Practically, it would be difficult to eliminate contamination from foreign elements in the preparation process, but further work may resolve this and improve the sample product.

To summarize, tea leaf samples may be a candidate for a new biological standard reference material.

The authors wish to express their heartly thanks to Dr. Masayuki Nakagawa of National Research Institute of Tea, for his help in getting the raw material and to Dr. Kenji Tomura of Rikkyo University for his help in utilizing the reactor.

This work is supported partially by Japan-U.S. Cooperative Project between JSPS and NSF No. 6R023.

Trimethylenediamine Complexes. IV.* Kinetics and Mechanism of Acid and Base Hydrolysis of Tetranitro(ethylenediamine)- and Tetranitro(trimethylenediamine)cobaltates(III)

Yoshiaki Ito and Shinichi Kawaguchi

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received September 6, 1977)

Hydrolysis of $Co(NO_2)_4(AA)^-$ (AA=en or tn) was studied in acidic and basic aqueous solutions by the spectrophotometric method. In faintly acidic solution (6>pH>4) the aquation proceeds reversibly to attain an equilibrium with $Co(NO_2)_3(H_2O)(AA)$, K_{eq} being $(1.71\pm0.03)\times10^{-2}$ and $(3.55\pm0.06)\times10^{-2}$ mol·l^{-1} for AA=en and tn, respectively, at 25.0 °C and $\mu=0.1$. With increasing concentration of hydrogen ion the acid-catalyzed pathway becomes increasingly important. In basic solution (12.2>pH>9.5) $Co(NO_2)_3(OH)(AA)^-$ was formed irreversibly as the first product. Kinetic data of these hydrolysis reactions are interpreted in terms of the dissociative mechanism involving a five-coordinate intermediate $Co(NO_2)_3(AA)$. The rates of nitrite release from $Co(NO_2)_4(tn)^-$ ($(9.27\pm0.03)\times10^{-4}$ s^{-1}) and deaquation from $Co(NO_2)_3(H_2O)(tn)$ ($(3.95\pm0.12)\times10^{-4}$ s^{-1}) are several times greater than those for the corresponding ethylenediamine complexes ($(2.08\pm0.01)\times10^{-4}$ and $(5.46\pm0.10)\times10^{-5}$ s^{-1}, respectively.

Although the trans structure of Erdmann's salt $NH_4[Co(NO_2)_4(NH_3)_2]$ was confirmed by X-ray analysis,[1] two geometrical isomers are expected to exist in equilibrium in solution. Kyuno prepared analogous Erdmann-type complexes by replacing the ammine ligands with ethylenediamine and propylenediamine.[2a] The tetranitrodiammine- and tetranitro(ethylenediamine)cobaltates(III) were further used for preparation of dinitrodianionodiammine and related cobalt(III) complexes.[2b] Usually *cis*-dinitrobis(ethylenediamine)cobalt(III) nitrite is prepared by the reaction of hexanitrocobaltate(III) with ethylenediamine,[3] intermediacy of the tetranitro(ethylenediamine)cobaltate(III) complex in the series of reaction being postulated by Kettle.[4] The reaction of sodium hexanitrocobaltate(III) with diamine afforded $[Co(NO_2)_2(AA)_2][Co(NO_2)_4(AA)]$, where AA stands for ethylenediamine or trimethylenediamine.

Tetranitro(diamine)cobaltate(III) anions are interesting complexes in preparative coordination chemistry. Kinetic and equilibrium studies of the nitrite displacement have been performed in order to clarify the reaction mechanism. The effect of ring size in the ethylenediamine and trimethylenediamine chelates on the rates and equilibria has also been investigated. The acid-catalyzed aquation of the tetranitrodiamminecobaltate(III) ion was reported by Malik and McAuley.[5]

Experimental

Preparation of Complexes. Dinitrobis(diamine)cobalt(III) Tetranitro(diamine)cobaltate(III), $[Co(NO_2)_2(AA)_2][Co(NO_2)_4(AA)]$: To a cold solution (100 ml) of sodium hexanitrocobaltate(III) (20 g, 49.5 mmol) was added with stirring a 50% aqueous solution of an equimolar amount of ethylenediamine(en) or trimethylenediamine(tn). Orange yellow crystallites separated were washed with water and dried over silica gel in a desiccator. The yield was 20% (*ca.* 6 g). The results of elemental analysis correspond to the composition of $Co_2(NO_2)_6(AA)_3$, suggesting that they are complex salts of the type $[Co(NO_2)_2(AA)_2][Co(NO_2)_4(AA)]$. The ethylenediamine complex was obtained by Kyuno by the reaction of $Co(NO_2)_4(NH_3)_2^-$ with ethylenediamine and identified as a less soluble trans isomer.[2a] Found: C, 12.34; H, 4.56; N, 27.76; Co, 20.58%. Calcd for $Co_2(NO_2)_6(en)_3$: $C_6H_{24}N_{12}O_{12}Co_2$: C, 12.55; H, 4.21; N, 29.27; Co, 20.53%. Found: C, 17.38; H, 5.05; N, 26.53; Co, 19.10%. Calcd for $Co_2(NO_2)_6(tn)_3$: $C_9H_{30}N_{12}O_{12}Co_2$: C, 17.54; H, 4.91; N, 27.28; Co, 19.12%.

Potassium Tetranitro(ethylenediamine)cobaltate(III), $K[Co(NO_2)_4(en)]$ and Potassium Tetranitro(trimethylenediamine)cobaltate(III) Hemihydrate, $K[Co(NO_2)_4(tn)]\cdot1/2H_2O$: These compounds were prepared with a solution of potassium tricarbonatocobaltate(III) as the starting material,[6] and recrystallized twice from methanol–water (1:1 by volume). The yields were 40 and 46%, respectively. Found: C, 7.30; H, 2.67; N, 23.41%. Calcd for $K[Co(NO_2)_4(en)]$: $C_2H_8N_6O_8CoK$: C, 7.02; H, 2.36; N, 24.56%. Found: C, 9.95; H, 3.36; N, 22.74%. Calcd for $K[Co(NO_2)_4(tn)]\cdot1/2H_2O$: $C_3H_{11}N_6O_{8.5}CoK$: C, 9.87; H, 3.04; N, 23.01%.

Isolation in Solution of Trinitroaqua(diamine)cobalt(III), $Co(NO_2)_3(H_2O)(AA)$: About 0.3 g of potassium tetranitro(diamine)cobaltate(III) was dissolved in 20 ml of water. To the resulting solution was added 15 ml of 0.04 mol·l^{-1} sodium hydroxide and the mixture was stirred for about 30 min at 40—50 °C (AA=en) or room temperature (AA=tn). The solution was then acidified to pH 2—3 with perchloric acid, and poured into a 20 cm column of 2 cm diameter containing a mixture of equal amounts of a sodium type cation exchange resin (Dowex 50WX8, 50—100 mesh) and a perchlorate type anion exchanger (Dowex 1X8, 50—100 mesh). The column was kept cold with ice water. The trinitro complex, the product of hydrolysis, is electrically neutral, running through the column. The effluent was kept cold with ice–water and protected against light. The solution was subjected to determination of the acid dissociation constant, the cobalt(III) content being determined by the photochemical reduction to cobalt(II) followed by photometric analysis of the latter as a tetraisothiocyanatocobaltate(II) complex.[7] In order to confirm the reproducibility, the isolation and determination of the trinitroaqua(diamine) complexes were repeated three times, respectively.

Measurements. The hydrogen ion activity in solution was determined with a Beckman "Century" SS-1 pH meter with a Beckman 39301 glass electrode and a Beckman 39400 calomel electrode, and converted into the hydrogen ion concentration by virtue of the activity coefficient $f_H=0.83$ at 25 °C and $\mu=0.1$.[8] The method is applicable to solutions in which

*Part III: H. Kawaguchi and S. Kawaguchi, *Bull. Chem. Soc. Jpn.*, **46**, 3453 (1973).

10^{-3} mol·l^{-1}>[H$^+$]>10^{-11} mol·l^{-1}, and the hydrogen ion concentration in more acidic solutions was determined by titration. Absorption spectra were recorded on Hitachi EPS-3T and 139 spectrophotometers.

Determination of the Acid Dissociation Constants of the Trinitroaqua(diamine)cobalt(III) Complexes: Buffer solutions were prepared with use of potassium dihydrogen phosphate–sodium hydroxide (pH 5.68—7.16), borax–perchloric acid (pH 7.97—9.28) and borax–sodium hydroxide (pH 9.47—10.29) systems. A given quantity of the effluent solution of the trinitroaqua(diamine)cobalt(III) complex was poured into a measuring flask containing a buffer solution, and the ionic strength was adjusted to μ=0.1 with a solution of sodium perchlorate. Thus solutions with various pH were prepared at 0 °C and the spectra were recorded promptly at 2 °C.

Kinetic Studies: The desired amount of a buffer solution was placed in a dark measuring flask and kept in a thermostat. Solid K[Co(NO$_2$)$_4$(en)] (0.040 g) or K[Co(NO$_2$)$_4$(tn)]·1/2H$_2$O (0.050 g) was poured into the solution by means of thermostated pure water to make up 100 ml of the reaction mixture. The complex was readily dissolved by agitation, and the reaction started. Aliquots were pipetted at appropriate time intervals and subjected to specrtal measurement. Perchloric acid was used for the preparation of acidic solutions. Since hydrolysis was very fast in acidic solutions where [H$^+$]≥0.65 mol·l^{-1}, a Union Giken Stopped-flow, Rapid-Scan Spectrophotometer RA 1300 was used for measuring spectra in the 355—505 nm region.

Results

Acid Dissociation Constants of the Trinitroaqua(diamine)cobalt(III) Complexes. The spectra of Co(NO$_2$)$_3$(H$_2$O)(AA) complexes in aqueous solution change with pH showing an isosbestic point at 502 nm (AA=en) or 506 nm (AA=tn). The following dissociation equilibria (Eq. 1) are responsible for the spectral behavior, the limiting spectra (Fig. 1) being assigned to aqua and hydroxo complexes.

$$\underset{\mathbf{2}}{\mathrm{Co(NO_2)_3(H_2O)(AA)}} \rightleftharpoons \mathrm{H^+} + \underset{\mathbf{3}}{\mathrm{Co(NO_2)_3(OH)(AA)^-}} \quad (1)$$

The spectra at various hydrogen ion concentrations were analyzed by means of the equation

$$\log\{(A-\varepsilon_3 c_M)/(\varepsilon_2 c_M - A)\} = \mathrm{p}K_a + \log[\mathrm{H^+}], \quad (2)$$

where c_M is the total concentration of the cobalt(III) complexes, A is the optical density of a solution at a given wave length, and ε_2 and ε_3 denote the molar extinction coefficients at the same wave length of the aqua (**2**) and hydroxo (**3**) complexes, respectively. For the ethylenediamine complexes ε_2 and ε_3 are 328 and 204 l·mol^{-1}·cm^{-1}, respectively, at 410 nm where the separation of spectra is the highest, and ε_2=279 and ε_3=146 l·mol^{-1}·cm^{-1} at 420 nm in the case of the trimethylenediamine complexes.

The plots of $\log\{(A-\varepsilon_3 c_M)/(\varepsilon_2 c_M - A)\}$ against pH gave straight lines with a slope of −1.0 in either case, the pK_a values being 8.40±0.04 and 8.21±0.03 for the ethylenediamine and trimethylenediamine complexes, respectively, at 2 °C and μ=0.1.

Aquation of the Tetranitro(diamine)cobaltate(III) Complexes. In weakly acidic solutions (6>pH>4) the tetranitro complex is hydrolyzed to produce the trinitroaqua complex. The reaction is reversible, the backward anation being effected by addition of excess nitrite ions.

$$\underset{\mathbf{1}}{\mathrm{Co(NO_2)_4(AA)^-}} + \mathrm{H_2O} \rightleftharpoons \underset{\mathbf{2}}{\mathrm{Co(NO_2)_3(H_2O)(AA)}} + \mathrm{NO_2^-} \quad (3)$$

In the presence of more than ten times excess of sodium nitrite, aquation of the tetranitro complex proceeds as a pseudo first order reaction to attain an equilibrium, revealing an isosbestic point at 480 (AA=en) or 487 nm (AA=tn).

$$-\mathrm{d}\ln([\mathrm{Co(NO_2)_4(AA)^-}]_t - [\mathrm{Co(NO_2)_4(AA)^-}]_{eq})/\mathrm{d}t = k_{obsd}$$

$$\ln\{(A_0-A_{eq})/(A_t-A_{eq})\} = k_{obsd}t \quad (4)$$

Subscripts 0, t, and eq refer to the time zero, t, and the equilibrium state, respectively. The reaction was followed by measuring the absorbance A at 430 (AA=en) or 440 nm (AA=tn). The plot $\ln\{(A_0-A_{eq})/(A_t-A_{eq})\}$ *vs.* t gave straight lines over two to three half lives. The values of the pseudo first order rate constant k_{obsd} at various hydrogen and nitrite ion concentrations are summarized in Table 1.

The equilibrium constant of Reaction 3 is related to the nitrite concentration by

$$K = [\mathrm{Co(NO_2)_3(H_2O)(AA)}]_{eq}[\mathrm{NO_2^-}]_{eq}/[\mathrm{Co(NO_2)_4(AA)^-}]_{eq} = [\mathbf{2}]_{eq}[\mathrm{NO_2^-}]_{eq}/[\mathbf{1}]_{eq}$$

$$(A_{eq}-A_2)/(A_1-A_{eq}) = [\mathrm{NO_2^-}]_{eq}/K, \quad (5)$$

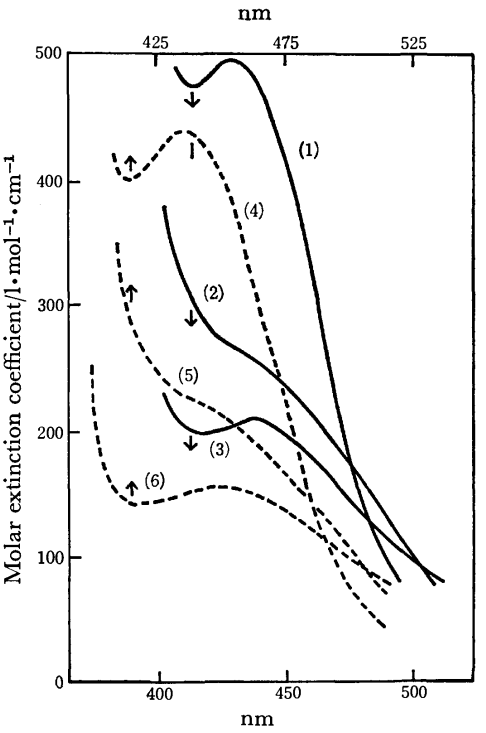

Fig. 1. Absorption spectra in the 400—500 nm region of Co(NO$_2$)$_4$(en)$^-$ (1), Co(NO$_2$)$_3$(H$_2$O)(en) (2), Co(NO$_2$)$_3$(OH)(en)$^-$ (3), Co(NO$_2$)$_4$(tn)$^-$ (4), Co(NO$_2$)$_3$(H$_2$O)(tn) (5), and Co(NO$_2$)$_3$(OH)(tn)$^-$ (6) in aqueous solution.

Table 1. Pseudo first order rate constants of aquation of the tetranitro(diamine)cobaltate(III) complexes at 25.0 °C and $\mu=0.1$, c_M being 1.169×10^{-3} and 1.369×10^{-3} mol·l^{-1} for the ethylenediamine and trimethylenediamine complexes, respectively

5.49	40.00	56.7
5.38	40.00	56.0
5.02	40.00	58.0
4.72	40.00	56.0

where **2** and **1** denote the trinitroaqua and tetranitro complexes, respectively, and $A_2=\varepsilon_2 c_M$ and $A_1=\varepsilon_1 c_M$. The molar extinction coefficients were determined as $\varepsilon_2=268$ and $\varepsilon_1=483$ l·mol^{-1}·cm^{-1} at 430 nm in the case of AA=en, and $\varepsilon_2=233$ and $\varepsilon_1=432$ l·mol^{-1}·cm^{-1} at 440 nm for AA=tn. Since the pK_a of nitrous acid lies around 2.95($\mu=0.25$)—3.15($\mu=0$) at 25 °C[9] and protonation of the nitrite ion is negligible at the present conditions (pH=4.7—6.0), the value of $[NO_2^-]_{eq}$ was calculated by

$$[NO_2^-]_{eq} = c_{NO_2} + c_M(A_1-A_{eq})/(A_1-A_2), \quad (6)$$

where c_{NO_2} denotes the concentration of nitrite ions added.

As shown in Fig. 2 the plots of the left side term of Eq. 5 against $[NO_2^-]_{eq}$ give straight lines through the origin. From the slope of each straight line the equilibrium constant of aquation of the tetranitro complex (Eq. 3) at 25.0 °C and $\mu=0.1$ was determined to be $(1.71\pm0.03)\times10^{-2}$ and $(3.55\pm0.06)\times10^{-2}$ mol·l^{-1} for AA=en and tn, respectively.

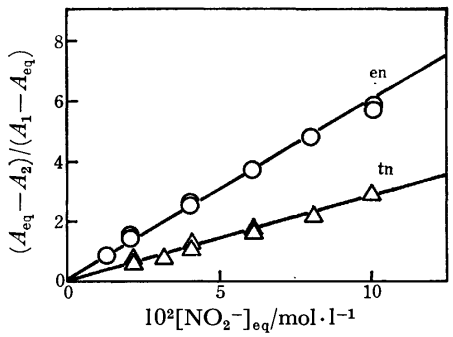

Fig. 2. The linear plot of Eq. 5 in order to determine the equilibrium constant of aquation of $Co(NO_2)_4(AA)^-$ at 25.0 °C and $\mu=0.1$. The absorbance was determined at 430 nm (AA=en) or 440 nm (AA=tn).

Acid-Catalyzed Aquation of Tetranitro(diamine)cobaltate(III) Complexes. In more acidic solutions, aquation of the tetranitro(diamine)cobaltate(III) complexes becomes fast with increasing hydrogen ion concentration. In the 2.5>pH>1.0 region, the first-order rate law holds for about two half lives. After this the spectra begin to deviate from the isosbestic point indicating the contribution of the succeeding aquation step. The observed pseudo first order rate constants are plotted against the hydrogen ion concentration in Fig. 3 to afford straight lines in line with Eq. 7.

$$k_{obsd} = k_0 + k_a[H^+] \quad (7)$$

At 25.0 °C and $\mu=0.1$, $k_0=(2.8\pm0.4)\times10^{-4}$ s^{-1} and $k_a=(2.2\pm0.1)\times10^{-2}$ l·mol^{-1}·s^{-1} for $Co(NO_2)_4(en)^-$ and $k_0=(8.6\pm1.0)\times10^{-4}$ s^{-1} and $k_a=(5.5\pm0.2)\times10^{-2}$ l·mol^{-1}·s^{-1} for $Co(NO_2)_4(tn)^-$.

In order to gain insight into the acid-catalyzed aquation (the second term in Eq. 7), rapid reactions in more acidic solutions (1.0 mol·l^{-1}>[H$^+$]>0.65 mol·l^{-1})

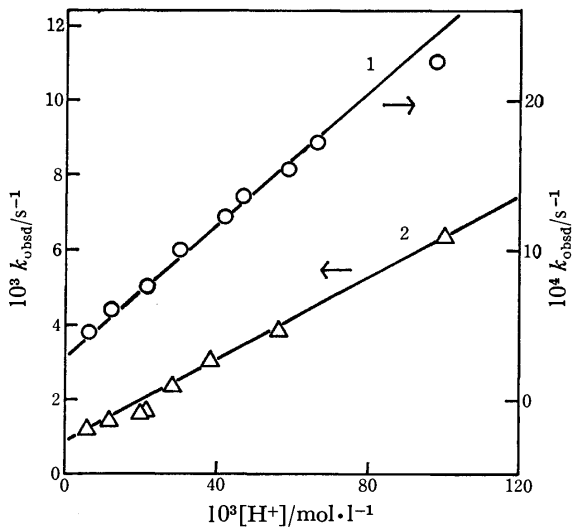

Fig. 3. The pseudo first order rate constants of aquation of $Co(NO_2)_4(AA)^-$ at various hydrogen ion concentrations (AA=en (1) and tn (2)).

were examined by following the spectral change in the 355—505 nm region with a rapid-scan spectrophotometer. For either of the ethylenediamine and trimethylenediamine complexes, the isosbestic point was maintained up to 50 s after commencement of the reaction. The pseudo first order rate constant was obtained by the Guggenheim method.[10] The result shows a linear dependence on the hydrogen ion concentration even in these highly acidic solutions, giving $k_a=1.9\times10^{-2}$ and 3.6×10^{-2} l·mol^{-1}·s^{-1} for AA=en and tn, respectively, at 25.0 °C, $\mu=2.0$ mol·l^{-1} ($NaClO_4$). These values are less accurate than but close to those obtained in the 2.5>pH>1.0 region at $\mu=0.1$.

Base Hydrolysis of the Tetranitro(diamine)cobaltate(III) Complexes. The base hydrolysis reaction of the tetranitro complex proceeds irreversibly to produce the trinitrohydroxo complex.

$$\underset{\mathbf{1}}{Co(NO_2)_4(AA)^-} + OH^- \longrightarrow \underset{\mathbf{3}}{Co(NO_2)_3(OH)(AA)^-} + NO_2^- \qquad (8)$$

When a buffer solution was employed to maintain a constant hydroxide ion concentration, the reaction followed the first order rate law (Eq. 9) during the course of two half lives.

$$\ln\{(A_0-A_\infty)/(A_t-A_\infty)\} = k'_{obsd}t, \qquad (9)$$

where $A_\infty=\varepsilon_3 c_M$, the absorbance being determined at 430 and 440 nm for AA=en and tn, respectively.

Beyond this the plot of the left side term of Eq. 9 against time begins to deviate from the straight line. Concurrently the absorption spectra begin to deviate from the isosbestic point (Fig. 4). The successive base hydrolysis of the trinitrohydroxo complex seems to contribute to the overall kinetics.

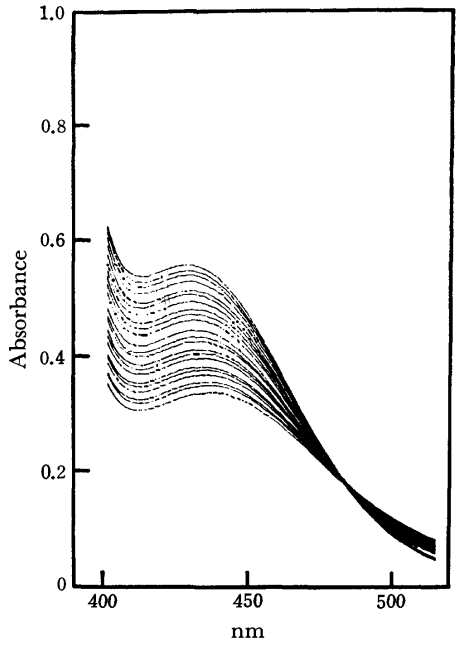

Fig. 4. The spectral change during the initial 100 min (about two half-lives) in the base hydrolysis of $Co(NO_2)_4(en)^-$ at 25.0 °C, $\mu=0.1$ and pH=11.94 with $c_M=1.169$ mmol·l^{-1}.

Table 2. Pseudo first order rate constants of the base hydrolysis of the tetranitro(diamine)cobaltate-(III) complexes at 25.0 °C and $\mu=0.1$, c_M being 1.169×10^{-3} and 1.369×10^{-3} mol·l^{-1} for the ethylenediamine and trimethylenediamine complexes, respectively

The pseudo first order rate constants k'_{obsd} of Reaction 8 at 25.0 °C and other temperatures are given in Tables 2 and 3, respectively. The Eyring plots of these data give the following activation parameters: $\Delta H^*=27.2\pm0.7$ (en) and 26.0 ± 0.4 (tn) kcal·mol^{-1}, and $\Delta S^*=15.9\pm2.0$ (en) and 14.9 ± 1.2 (tn) cal·deg^{-1}·mol^{-1}.

Discussion

Although the nitrite ion can coordinate to a metal ion as a unidentate ligand through either the nitrogen or oxygen atom, the N-bonded nitro isomer is usually more stable than the O-bonded nitrito isomer.[11] The *trans*-$Co(NO_2)_4(NH_3)_2^-$ salts[1,12] and $K[Co(NO_2)_4(en)]$[13] were confirmed by X-ray analysis to be nitro complexes. $K[Co(NO_2)_4tn]\cdot 1/2H_2O$ may also be presumed to contain the Co–N bonding.

Two geometrical isomers, facial and meridional, are conceivable for the hydrolysis products $Co(NO_2)_3(H_2O)(AA)$ and $Co(NO_2)_3(OH)(AA)^-$. Distinct isosbestic points were observed in the spectral change during the course of acid and base hydrolysis reactions of $Co(NO_2)_4(AA)^-$. The spectra of $Co(NO_2)_3(H_2O)(AA)$ at various pH's also manifest isosbestic points. The results can be satisfactorily understood on the assumption that only one of the geometrical structures is realized by both of the trinitro complexes. However, no isolation and characterization of the trinitro complexes as solid specimen have been achieved, the stereochemistry of hydrolysis reactions of the tetranitro complexes remaining unclarified.

Mechanism of the Hydrolysis Reactions. The kinetic data of the acid and base hydrolysis of $Co(NO_2)_4(AA)^-$ are satisfactorily explained on the basis of the dissociative (**D**) mechanism including the pentacoordinate intermediate, $Co(NO_2)_3(AA)$.

$$Co(NO_2)_4(AA)^- \underset{k_{NO_2}}{\overset{k_{-NO_2}}{\rightleftharpoons}} Co(NO_2)_3(AA) + NO_2^- \quad (10)$$

$$Co(NO_2)_3(AA) + H_2O \underset{k_{-H_2O}}{\overset{k_{H_2O}}{\rightleftharpoons}} Co(NO_2)_3(H_2O)(AA) \quad (11)$$

$$+H^+ \uparrow\downarrow -H^+ \text{ (fast)}$$

$$Co(NO_2)_3(AA) + OH^- \xrightarrow{k_{OH}} Co(NO_2)_3(OH)(AA)^- \quad (12)$$

In basic solution the reaction proceeds irreversibly to afford the hydroxotrinitro complex, and the reverse anation reaction need not be considered. If we assume a steady state for the pentacoordinate intermediate, the pseudo first order rate constant is given by

$$k'_{obsd} = k_{-NO_2}(k_{H_2O}+k_{OH}[OH^-])/(k_{NO_2}[NO_2^-]+k_{H_2O}+k_{OH}[OH^-]). \quad (13)$$

The observed pseudo first order rate constant is independent of pH in the 9.5—12.2 region and also of the added nitrite concentration (Table 2). The calculated k'_{obsd} in Eq. 13 can be reconciled with the experimental results only when

$$k_{OH}[OH^-] \gg k_{NO_2}[NO_2^-] + k_{H_2O}, \quad (14)$$

resulting in

$$k'_{obsd} = k_{NO_2}. \quad (15)$$

Thus the spontaneous dissociation of a nitrite ligand is the rate determining step in the base hydrolysis of $Co(NO_2)_4(AA)^-$.

The base hydrolysis of octahedral metal complexes usually follows the S_N1CB or $\mathbf{D}_{cb}$ mechanism (dissociative mechanism with respect to the conjugate base).[14] If this is the case for $Co(NO_2)_4(AA)^-$, pK_a of the complex should be much smaller than 10 in order for the deprotonation equilibrium (Eq. 16) to be completely shifted to the right rendering the rate of hydrolysis independent of pH.

$$Co(NO_2)_4(AA)^- + OH^- \rightleftharpoons Co(NO_2)_4(AA-H)^{2-} + H_2O \quad (16)$$

Such a high acidity seems unreasonable for the negative diamine complexes even if the electron attracting property of the nitro ligands is taken into account, since pK_a of $Co(NH_3)_6^{3+}$ and $Co(en)_3^{3+}$ is estimated to be larger than 14.[15] Furthermore, if the conjugate base were the predominant species in basic solution of $Co(NO_2)_4(AA)^-$, the spectrum should differ significantly from that in acidic solution. No change with pH was observed in spectra of the tetranitro complexes at 2 °C, denying the appreciable deprotonation of $Co(NO_2)_4(AA)^-$ in basic solution. Thus $\mathbf{D}_{cb}$ mechanism is not operative and **D** mechanism (Eq. 10—12) seems to be favorable for the base hydrolysis of $Co(NO_2)_4(AA)^-$.

In weakly acidic solution (6>pH>4) the pseudo first order rate constant of hydrolysis k_{obsd} is smaller than that in basic solution, being independent of pH in this region (Table 1). Since the hydroxide ion concentration is very low in this case ($<10^{-8}$ mol·l^{-1}), path 12 can be neglected to derive the rate equation

$$-d\ln([Co(NO_2)_4(AA)^-]_t - [Co(NO_2)_4(AA)^-]_{eq}) = k_{obsd} = (k_{-NO_2}k_{H_2O}+k_{NO_2}k_{-H_2O}[NO_2^-])/(k_{H_2O}+k_{NO_2}[NO_2^-]), \quad (17)$$

which is transformed into

$$\frac{1}{k_{-NO_2}-k_{obsd}} = \frac{1}{k_{-NO_2}-k_{-H_2O}} + \frac{(k_{H_2O}/k_{NO_2})}{k_{-NO_2}-k_{-H_2O}}\cdot\frac{1}{[NO_2^-]}. \quad (18)$$

Since k_{-NO_2} is obtained by measurements in basic solutions (Eq. 15), the left side term in Eq. 18 can be calculated for various nitrite concentrations. As is seen in Fig. 5, the plot of $(k_{-NO_2}-k_{obsd})^{-1}$ *vs.* $[NO_2^-]^{-1}$ gives rise to a straight line, the intercept and slope of which afford k_{-H_2O} and k_{H_2O}/k_{NO_2}, thus enabling calculation of the equilibrium constant of aquation (3).

$$K = k_{-NO_2}k_{H_2O}/k_{NO_2}k_{-H_2O} \quad (19)$$

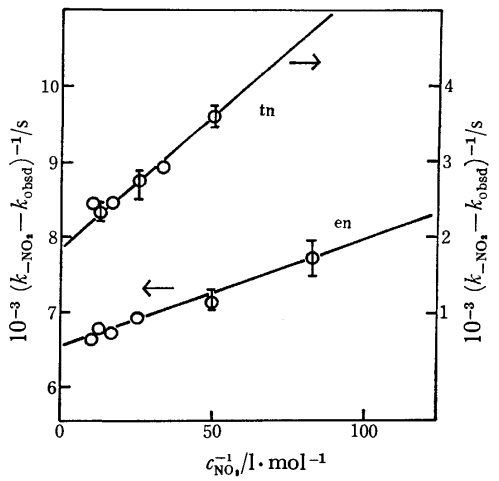

Fig. 5. Linear plots (Eq. 18) of rate data for the aquation of $Co(NO_2)_4(AA)^-$ at 25.0 °C and μ=0.1.

$K_{eq}/mol\cdot l^{-1}$ b)	$(1.71\pm0.03)\times10^{-2}$	$(3.55\pm0.06)\times10^{-2}$

a) Calculated by Eq. 19. b) Calculated by Eq. 5.

The spontaneous aquation and anation reactions of cationic cobalt(III) complexes usually follow the dissociative interchange ($\mathbf{I}_d$) mechanism.[14] However, several anionic cobalt(III) complexes such as $Co(SO_3)_2(en)_2^-$ and $Co(CN)_5(H_2O)^{2-}$ are known to follow the **D** mechanism,[16] $Co(NO_2)_4(AA)^-$ becoming a new example. The rate and equilibrium constants are summarized in Table 4. The values of equilibrium constants calculated by Eq. 19 nearly coincide with those determined directly (Eq. 5). From these data the relative nucleophilicity of H_2O, NO_2^-, and OH^- toward the pentacoordinate intermediate $Co(NO_2)_3(AA)$ is calculated as the ratio $k_{H_2O}/[H_2O]$: k_{NO_2}: k_{OH}, and found to be $1:2.6\times10^4:\gg1.3\times10^8$ for AA=en, and $1:3.1\times10^3:\gg1.6\times10^7$ for AA=tn. The nucleophilicity order coincides with the basicity order of these reagents, reflecting the hard character of $Co(NO_2)_3(AA)$.

With increasing hydrogen ion concentration the acid-catalyzed aquation of $Co(NO_2)_4(AA)^-$ becomes increasingly important, which may proceed *via* the following two steps.

$$Co(NO_2)_4(AA)^- + H^+ \overset{K_H}{\rightleftharpoons} Co(NO_2)_3(HNO_2)(AA) \quad (20)$$

$$Co(NO_2)_3(HNO_2)(AA) \xrightarrow{k_{-HNO_2}} Co(NO_2)_3(AA) + HNO_2 \quad (21)$$

In acidic solutions where pH<2, free nitrite ions are mostly protonated and the reverse step of Eq. 10 can be neglected, giving the rate law

$$k_{obsd} = (k_{-NO_2}+k_{-HNO_2}K_H[H^+])/(1+K_H[H^+]). \quad (22)$$

In the acidity region examined the simple two term rate law (Eq. 7) holds, indicating that $K_H[H^+]\ll1$, giving rise to

$$k_0 = k_{-NO_2} \text{ and } k_a = k_{-HNO_2}K_H. \quad (23)$$

The values of k_0 obtained from the intercepts of straight lines in Fig. 3 nearly coincide with those of k_{-NO_2} given in Table 4. Thus the doubly protonated species $Co(NO_2)_2(HNO_2)_2(AA)$ need not be considered. The value of k_{-HNO_2} can not be obtained independently of K_H, but seems to be much greater than 10^{-2} s^{-1}.

The acid-catalyzed aquation of nitrocobalt(III) complexes has been investigated,[17] the pseudo first order rate constant of aquation of *trans*-$Co(NO_2)_2(tn)_2^+$ in a 1.09 mol·l^{-1} sulfuric acid solution at 25.0 °C having been reported[18] to be 6.9×10^{-5} s^{-1}. As compared with this the present k_{-HNO_2} value is astonishingly larger. A similar situation is noticed in the rate of spontaneous aquation. Staples[19] stated that no aquation of *cis*- and *trans*-$Co(NO_2)_2(en)_2^+$ occurs in neutral or faintly acidic solutions. On the contrary, $Co(NO_2)_4(en)^-$ is hydrolyzed spontaneously at a fairly fast rate of $(2.08\pm0.01)\times10^{-4}$ s^{-1} at 25.0 °C, indicating that the Co–NO_2 bond in the tetranitro(diamine) complexes is remarkably weaker than that in the dinitrobis(diamine) complexes. Similar results were also obtained for $Co(NO_2)_4(NH_3)_2^-$, k_0 being reported[5] to be 1.7×10^{-4} s^{-1} at 25 °C and μ= 2.5 mol·l^{-1}.

As to the mechanism of the acid-catalyzed aquation of $CoNO_2(NH_3)_5^{2+}$ in sulfuric acid, Harris *et al.*[20] postulated from the results of ^{18}O tracer experiments that the proton-assisted nitrosonium ion release occurred, leaving $CoOH(NH_3)_5^{2+}$ which maintains one oxygen atom of the nitrite ligand. A similar N–O bond fission mechanism is also suggested for the acid-catalyzed replacement of nitro-ligand from some dinitrodiamine platinum(II) complexes.[21] It is not certain whether an analogous mechanism is operative or a simple release of nitrous acid occurs in the acid-catalyzed aquation of $Co(NO_2)_4(AA)^-$.

Kinetic Chelate Ring Size Effect. The ligand substitution rates of trimethylenediamine complexes have been compared in several instances with those of the corresponding ethylenediamine complexes. Although *trans*-$CoCl_2(tn)_2^+$ and *trans*-$CoBr_2(tn)_2^+$ aquate 1500 times and 680 times as fast as the corresponding en complexes, respectively,[22] the acid-catalyzed aquation of *trans*-$Co(NO_2)_2(tn)_2^+$ is only a few times faster than that of *trans*-$Co(NO_2)_2(en)_2$.[+18,23] The aquation rate of $CoCO_3(tn)_2^+$ is similar to that of $CoCO_3(en)_2$,[+24] while the rate of carbonate exchange of the tn complex is smaller than that of the en complex.[25] In the present case the rate of nitrite release from $Co(NO_2)_4(tn)^-$ is 4.5 times and the rate of aqua ligand release from $Co(NO_2)_3(H_2O)(tn)$ 7.2 times larger than those of the corresponding en complexes (Table 4).

Trimethylenediamine forms a six-membered chelate ring whose conformation is usually of chair form in crystals.[26] In solution, however, the energy difference between chair and skew-boat conformers is small,[27] and 30% of Δ-$Co(tn)_3^{3+}$ and *ca.* 9% of $Ni(tn)(H_2O)_4^{2+}$ are in the skew-boat form in aqueous solutions at 20 and 27 °C, respectively.[28,29] Couldwell and House[30] presumed that the tn rings of *trans*-$CoCl_2(tn)_2^+$ can adopt the skew-boat configuration and steric interaction between the central methylene protons and the chloro ligands may be responsible for the exceptionally rapid aquation.

Holmes and Williams determined the thermodynamic functions of the copper(II) and nickel(II) complexes of en and tn.[31] The difference in the enthalpy of formation of $M(en)(H_2O)_4^{2+}$ and $M(tn)(H_2O)_4^{2+}$ amounts to 1.43 ± 0.18 kcal·mol^{-1} for Cu(II) and 2.01 ± 0.14 kcal·mol^{-1} for Ni(II). It appears that if the enthalpies of free en and tn are similar to each other, the five-membered en ring has stronger bonds than the six-membered tn ring by 13 and 28% for the Cu(II) and Ni(II) complexes, respectively. The enthalpy of activation for the nitrite release from $Co(NO_2)_4(tn)^-$ is smaller by 1.2 kcal·mol^{-1} than that for $Co(NO_2)_4(en)^-$

(Table 3). The difference seems to stem from the energy difference at the ground state, and both complexes may have similar enthalpies at the transition state where the steric strain is released by dissociation of one nitrite ligand. The positive entropy of activation is also in line with the proposed **D** mechanism.

The authors are grateful to Mr. J. Gohda for the elemental analysis. Financial aid from the Ministry of Education is acknowledged.

Application of a Coagulated Mixture Prepared from Finely Divided Cation and Anion Exchange Resins to the Enrichment of Copper(II)

Masutaro ABE, Kunio OHZEKI, and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 16, 1977)

Mutual coagulation takes place, when a suspension of finely divided cation exchanger is added to that of anion exchanger. The resulting mixed resin is bulky and easily separated from the solution by filtration. A rapid and selective collection of a trace amount of copper(II) ion was carried out by the combined use of mixed resin and 8-quinolinol-5-sulfonic acid (H_2qs). The copper(II) collected on the mixed resin in the form of $[Cu(qs)_2]^{2-}$ was brought into solution from the resin with ethylenediaminetetraacetate, converted into copper(II)–diethyldithiocarbamate, extracted into methyl isobutyl ketone, and determined by atomic absorption spectrometry. The method was satisfactorily applied to the determination of a trace amount of copper(II) in well water.

Finely divided ion exchange resin particles can collect ions from solutions much more rapidly than beads of the conventional size, since the rate of ion exchange reaction is inversely proportional to the square of the radius of the resin particles.[1] One of the characteristics of such a fine resin is coagulation caused by the addition of suspensions of oppositely charged resin particles.[2] The use of the coagulated resin for rapid ion removal has been demonstrated by Pinfold and Karger.[2]

We have examined the analytical utilization of the mixed resin of finely divided cation and anion exchangers. A rapid and selective concentration of a trace amount of copper(II) ion is reported.

Experimental

Reagents. A copper(II) standard solution was prepared from nitrate and standardized against EDTA. A 10^{-2} M (mol dm^{-3}) 8-quinolinol-5-sulfonate (Hqs^-) solution was prepared by dissolving the acid (H_2qs, Wako Pure Chemicals Inc.,), in an alkaline solution. The Dotite 4 NA (Dojindo Lab.) was dissolved to give ethylenediaminetetraacetic acid tetrasodium salt (Na_4edta) solution. Sodium diethyldithiocarbamate for atomic absorption spectrometry (Naddtc, Wako) was used in a 5 w/v% aqueous solution. Methyl isobutyl ketone (MIBK) and other reagents of guaranteed grade were used. Deionized-redistilled water was used.

Apparatus. A Hitachi 508 atomic absorption spectrometer with a Fe–Co–Ni–Cu–Cr–Mn multielement hollow cathode lamp was used for the determination of copper(II) in MIBK extract under the following conditions: wavelength 324.8 nm, lamp current 10 mA, slit width 0.18 mm, acetylene flow rate 1.5 l min^{-1} at 0.5 kg cm^{-2}, and air flow rate 13 l min^{-1} at 1.8 kg cm^{-2}. A Toyo KG 25 filter holder (Toyo Roshi Co., Ltd.) was used.

Ion Exchange Resin. Macroreticular type Amberlyst 15 and A-26 (both Rohm and Haas Co.) in RSO_3Na and $RN(CH_3)_3Cl$ forms, respectively, were used. The dry cation exchange resin was washed with ethanol until the washings became colorless, and then cleaned and recycled several times between hydrogen and sodium forms. The chloride form of the anion exchange resin was regulated as usual. The wet resin was crushed into a slurry which was then diluted to a suspension. The suspension was then filtered through a 3G3 glass filter to remove resin particles larger than 30 μm. The particle sizes of the resins in the resulting stock suspension were in the range 0.2—30 μm. The lower limit was confirmed by the fact that the resin particles in the suspension could not pass a millipore filter of 0.2 μm pore size.

The ion exchange capacity of the resin in the suspension was determined as follows. In the case of the cation exchanger, the solid particles in a known amount of the suspension were collected onto a millipore filter, and the sodium ion on the resin was eluted with hydrochloric acid solution and determined by atomic absorption spectrometry. For the anion exchange resin, the chloride ion on the resin was eluted with sodium nitrate solution and determined absorptiometrically by the mercury(II) thiocyanate method.[3] The exchange capacities thus obtained were 0.031 meq ml^{-1} for the cation exchange resin suspension (CRS) and 0.030 meq ml^{-1} for the anion exchange resin suspension (ARS), respectively.

Results and Discussion

Coagulation. The mutual coagulation of the finely divided cation and anion exchangers was examined first. A 5.0-ml portion of CRS was taken into a 50-ml stoppered measuring cylinder and varying amounts of ARS were added. After adjusting the total volume to 50 ml with water, the mixture was shaken vigorously for 5 min and allowed to stand for 5 min. The coagulated material thus obtained was removed by filtration with a 3G3 glass filter. The extent of coagulation was estimated from the turbidity of the resulting filtrate.

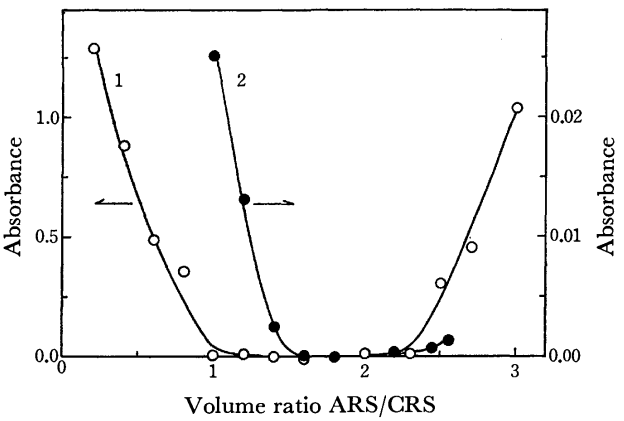

Fig. 1. Coagulation of cation and anion exchangers. Amounts of CRS involved in 50 ml of the mixtures: ●; 1.0 ml, ○; 5.0 ml.

As a measure of turbidity, the absorbance of the solution was determined in a 1-cm cell at an arbitrary wavelength of 500 nm against water. The results are shown in Fig. 1. The turbidity of the filtrate due to the remaining CRS decreased with increasing amount of ARS, almost complete coagulation being attained when 6—10 ml of ARS was added to 5.0-ml portion of CRS (curve 1, Fig. 1). With further addition of ARS, the solution became turbid due to excess ARS. The 1.0-ml portion of CRS was most satisfactorily deposited from the solution with addition of 1.6—1.8 ml of ARS (curve 2, Fig. 1).

Exchange Capacity of the Coagulated Resin. The number of ion exchange sites consumed for the association of 5.0 ml of CRS with 8.0 ml of ARS was estimated by determining the sodium and chloride ions expelled from both resins as a result of mutual coagulation. The proportions of the ion exchange sites taking part in the coagulation to the total ion exchange sites in CRS and ARS were found to be 3.7 and 5.3%, respectively. The exchange capacities of cation and anion exchangers decrease only a little by coagulation.

Effect of Concentration of Sodium Chloride on Coagulation. A 1.0-ml portion of CRS and 1.6 ml of ARS were added to 250 ml of a solution containing various amounts of sodium chloride. The mixture was shaken for 10 min. The resins coagulated on being left to stand for 10 min from a 0.1 M sodium chloride solution. With increasing concentration of sodium chloride, it took a longer time to obtain sufficient coagulation. No satisfactory coagulation was attained in the solution containing sodium chloride (0.5 M) even after long standing.

Adsorption of Copper(II). The adsorption of copper(II) ion onto the coagulated resin was investigated in the presence of calcium and chloride ions which are most commonly present in natural water. A 1.0-ml portion of CRS and 1.6 ml of ARS were taken into an eggplant type flask, and 5 μg of copper(II) and varying amounts of calcium chloride solution were then added. The mixture was diluted to *ca.* 40 ml with water and shaken for 30 min. The resulting coagulated resin was removed by filtration. The copper(II) in the filtrate was extracted as copper(II)–ddtc complex into MIBK and determined by atomic absorption spectrometry.

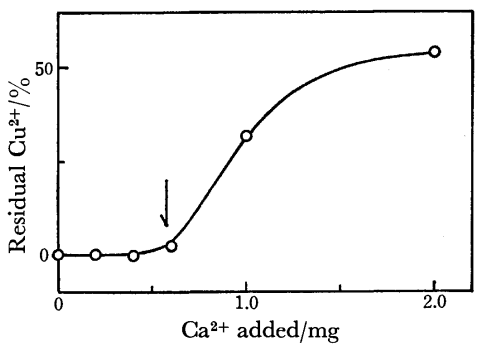

Fig. 2. Recovery of 5.0 μg of copper(II) from 40 ml of solutions containing varying amounts of calcium chloride onto the coagulated resin prepared from 1.0 ml of CRS and 1.6 ml of ARS. Arrow indicates the amount of calcium ion corresponding to the exchange capacity of CRS.

As shown in Fig. 2, copper(II) was quantitatively collected onto the mixed resin until the exchange capacity of the cation exchanger in the mixed resin was satisfied by the calcium ion. Thereafter, the amount of non-fixed copper(II) in the solution increased with increasing amount of calcium ion.

Choice of Chelating Agent. The utilization of complexation in ion exchange analysis was described by Ringbom.[4] Recently, the use of ion exchange resins in combination with chelating agents, such as 8-quinolinol-5-sulfonic acid[5] and a sulfonic acid derivative of dithizone[6] has been reported. In order to enhance the selectivity of the mixed resin for copper(II), ethylenediamine (en) and Hqs^- were examined as chelating agents. The former combined with copper(II) to form the complex cation while the latter formed the complex anion. Both complexes could be more strongly fixed onto the resin than simple ions. In the presence of 3 μmol of en, 15 μg of copper(II) were quantitatively collected from a solution containing 2 mg of calcium ion onto the coagulated resin prepared from 1.0 ml of CRS and 1.6 ml of ARS under the optimal conditions. The effect of en is obvious. However, better results were obtained by use of Hqs^-.

Effect of Hqs^-. In the presence of 2 μmol of Hqs^-, 5 μg of copper(II) were collected from 40 ml of a calcium chloride solution containing 20 mg of calcium ion onto the coagulated resin prepared from 1.0 ml of CRS and 1.6 ml of ARS (curve 1, Fig. 3).By combination of 2.5 ml of CRS and 4.0 ml of ARS, copper(II) was effectively collected onto the mixed resin in the presence of 50 mg of calcium ion (curve 2, Fig. 3).

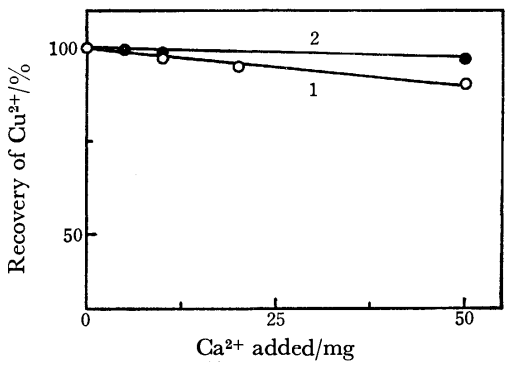

Fig. 3. Recovery of 5.0 μg of copper(II) from 40 ml of solutions containing varying amounts of calcium chloride in the presence of 2 μmol of Hqs^- onto the mixed resin: ○; 1.0 ml of CRS and 1.6 ml of ARS, and ●; 2.5 ml of CRS and 4.0 ml of ARS.

Adsorption of the Chelate. The recovery of copper(II) increased with increasing concentration of Hqs^- until the mole ratio of the reagent to copper content reached 2: 1, and thereafter, copper(II) was quantitatively collected as shown in Fig. 4. The results indicate that the copper(II) was fixed onto the resin in the form of $[Cu(qs)_2]^{2-}$. The recovery of copper(II) was retarded when the amount of the chelating agent increased beyond the exchange capacity of the anion exchanger in the coagulated resin. This is attributable to competition between anions of copper(II)–qs complex and the

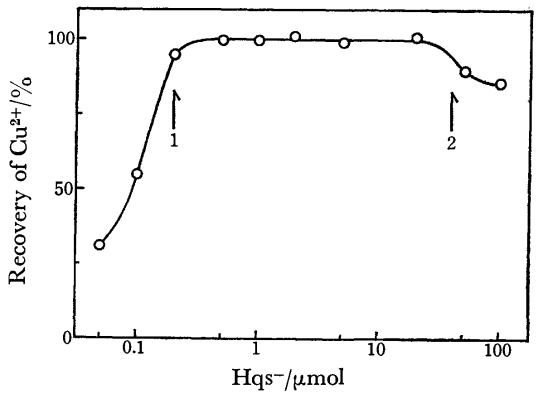

Fig. 4. Effect of the amount of Hqs^- on the recovery of 5.0 μg of copper(II) from 40 ml solutions containing 20 mg of calcium ion onto the coagulated resin prepared from 1.0 ml of CRS and 1.6 ml of ARS. Arrow 1 indicates the point where mole ratio of copper(II) to Hqs^- reached to 1 to 2, and arrow 2 shows the amount of Hqs^- corresponding to the exchange capacity of ARS in the mixed resin.

excess chelating agent for anion exchange sites in the mixed resin. Even if a molecular adsorption of the complex onto the resin matrix might exist,[7] it seems to be much less effective than the ion exchange.

Effect of pH. As shown in Fig. 5, copper(II) was quantitatively collected onto the mixed resin from the solution over the pH range 4—12. The optimal pH range confirmed was much wider than that of 3.5—6.0 observed in the liquid-liquid ion-association extraction system in which an ion-pair of $[Cu(qs)_2]^{2-}$ with quaternary ammonium cation, zephiramine, was extracted into chloroform.[8]

Shaking and Standing Times. A 5-μg portion of copper(II) in 250 ml of a sample solution containing 1.0 ml of CRS, 1.6 ml of ARS, and 2 μmol of Hqs^- was

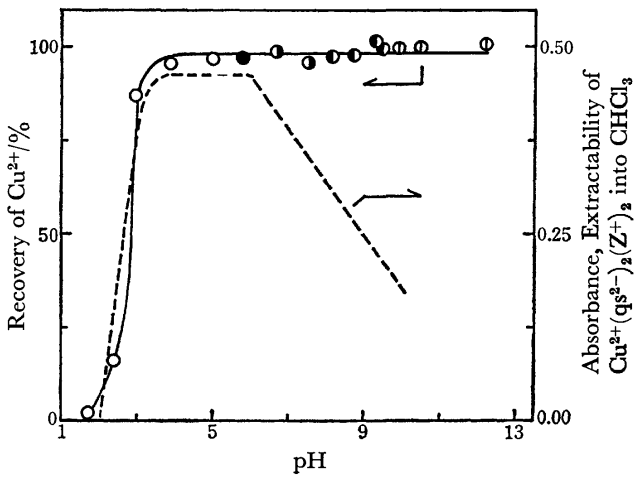

Fig. 5. Effect of pH on the recovery of 5.0 μg of copper(II) from 40 ml of solutions containing 20 mg of calcium ion and 2 μmol of Hqs^- onto the coagulated resin prepared from 1.0 ml of CRS and 1.6 ml of ARS. Dashed line indicates the results obtained in ion-association extraction system.
Buffer systems: ○; NaOAc–HCl, ●; unbuffered, ◑; γ-collidine–HCl, ◐; NH_3–NH_4Cl, ⓘ; Borax–NaOH.

well fixed onto the anion exchanger when the mixture was shaken for more than 5 min. The appreciable coagulation of the resins occurred on standing for 10 min. The resulting mixed resin was easily separated by filtration.

Elution of Copper(II) Fixed on the Resin. Of the eluting agents studied, EDTA tetrasodium salt solution was the most satisfactory. Copper(II) fixed on the resin was quantitatively eluted with 20 ml of 0.1—0.2 M of EDTA tetrasodium salt solutions at an eluting rate of 1.0—2.0 ml min^{-1}.

Extraction of Copper(II) from the Eluate. The copper(II)–edta complex in the eluate was converted into the copper(II)–ddtc complex and extracted into MIBK. The organic extract was sprayed into the flame of an atomic absorption spectrometer, resulting in the sensitivity for copper by *ca.* 4 times that obtained by spraying an aqueous solution.[9]

Established Procedure. A 50—500-ml sample solution containing 0.5—5 μg of copper(II) is taken into a separatory funnel. The pH of solution is adjusted to 4—12 with sodium hydroxide solution. Then 2 ml of a 1.0×10^{-3} M Hqs^- solution, 1.0 ml of CRS and 1.6 ml of ARS are added. After shaking for 10 min, the mixture is allowed to stand for several minutes until the coagulated resin settles. The mixed resin is separated by filtration with suction from the solution onto a filter paper (Toyo Roshi No. 2). The copper(II) species on the resin are then eluted with 20 ml of a 0.2 M EDTA tetrasodium salt solution into another separatory funnel. Five ml of 5% Naddtc solution is added and the resulting copper(II)–ddtc complex is extracted into 5.0 ml of MIBK, and the organic extract is then subjected to atomic absorption spectrometry.

Blank Value. Several blank tests were carried out according to the established procedure using 250-ml portions of deionized-redistilled water. The recorder response corresponding to *ca.* 0.2 μg of copper was found.

Effect of Foreign Ions. The concentration procedure was tested with a synthetic sample solution, the components of which are given in Table 1. The effects of iron(III) and aluminum(III) were also examined by adding various amounts to 250-ml portions of the

Table 1. Effect of various ions on the recovery of copper(II)

Composition (μg ml^{-1})		Cu^{2+} found (μg)	Recovery[a] (%)
A:	Na^+ 33, K^+ 7.8, Ca^{2+} 10, Mg^{2+} 2.4, Cl^- 57, HCO_3^- 36, SO_4^{2-} 9.6, SiO_2 7.5	5.1	102
		5.1	102
		4.9	98
B[b]: A+Fe^{3+}	0.08	5.3	106
	0.4	5.1	102
	2.0	5.1	102
C[c]: A+Al^{3+}	0.08	4.8	96
	0.4	4.8	96
	2.0	4.8	96

a) Cu^{2+} 5.0 μg, Sample 250 ml. b) Fe^{3+} added as ammonium iron(III) sulfate. c) Al^{3+} added as aluminum(III) potassium sulfate.

synthetic sample solution. Recovery of copper(II) was not affected by each addition up to 0.5 mg.

It was also found that good recovery of 5 μg of copper(II) contained in 50—500 ml of the sample solution (composition A, Table 1) can be made.

Analysis. The above developed method was applied to the determination of copper(II) in well water taken from our University campus. The standard addition method was employed using 250-ml portions of sample solution. The blank test was carried out using a 250-ml portion of deionized-redistilled water. The linear least-squares regression equation for recorder response of atomic absorption spectrometry, y cm, as a function of added amount of copper(II), x μg, is

$$y = 2.69\ x + 2.50,$$

where y is corrected for the blank value. The F-factor for regression analysis is 4918, highly significant to $F(1, 3: 0.01)=34.1$. The 95% confidence limits are 3.72 ± 0.063 ng ml^{-1}, the value for the coefficient of variation being 5.3%.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education.

The Stereochemistry of Copper(II) Complexes Containing *N,N'*-Di-8-quinolylethylenediamine and Its Optically Active Derivatives

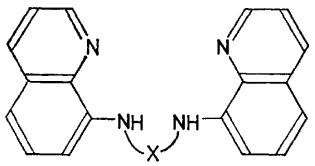
Toshishige M. SUZUKI, Shin-ichi KAMIYAMA, and Tetsuo KIMURA

Government Industrial Research Institute, Tohoku Nigatake, Haranomachi, Sendai 983

(Received October, 3, 1977)

Copper(II) complexes of a series of quadridentate ligands, *N,N'*-di-8-quinolylethylenediamine (dqen), (*R*)-*N,N'*-di-8-quinolylpropylenediamine {(*R*)-dqpn}, and (*R,R*)-*N,N'*-di-8-quinolyl-1,2-cyclohexanediamine {(*R,R*)-dqchxn}, have been prepared. Their d-d absorption spectra, magnetic moments, and molar conductivities indicate that the complexes have a five-coordinated structure, in which one of the quinoline groups of the ligands occupies an apical position. The circular dichroism (CD) spectra of the optically active ligands and their complexes exhibit exiton couplets in the ligand's $\pi^* \leftarrow \pi$ transition region. From the signs of the couplets, the preferable configurations of the (*R*)-dqpn and (*R,R*)-dqchxn complexes are assigned to Δ.

A number of papers have been published on metal complexes with 8-aminoquinoline and its derivatives.[1] Nielsen and Dahl prepared copper(II) complexes of *N,N'*-di-8-quinolylalkanediamines (dqdiamine), but conclusive evidence for the structure of the complexes is lacking.[1d] These quadridentate ligands are interesting in their intermediate character between aliphatic and aromatic systems, and also in the variety of stereochemistry of their metal complexes. The dqdiamines are structurally similar to quadridentate Schiff base-type ligands such as *N,N'*-disalicylideneethylenediamine (salen). Although stereochemical studies of the complexes with such Schiff bases have been extensively done,[2] none of bqdiamine complexes are known thus far.



X = CH_2CH_2 : dqen
= $CH_2\underset{CH_3}{CH}$: dqpn
= $\underset{}{CH}\text{-}\underset{}{CH}$: dqchxn

This paper will deal with the stereochemistry of copper(II) complexes of dqen and optically active (*R*)-dqpn and (*R,R*)-dqchxn. Molecular models predict that the steric interaction between 2 and 2' protons of the dqdiamine would prevent the formation of square-planar complexes. The deviation from co-planarity of the two coordinated quinoline nuclei will bring about a dissymmetric configuration about the metal ion. The ligands derived from optically active diamines are expected to coordinate to metal ions with sterically preferred configurations because of the conformational requirements of the diamine chelate rings.

Experimental

N,N'-*Di-8-quinolylethylenediamine (dqen).* This was prepared according to the method described in the literature.[1b] Recrystallization from ethanol gave prismatic tan crystals; mp 162—163 °C.

(R)-N,N'-*Di-8-quinolylpropylenediamine* {(R)-*dqpn*}. Racemic propylenediamine (pn) was resolved by the method of Dwyer *et al.*[3] *R*-pn was obtained by the neutralization of its tartrate (3 mol, 67.27 g) with barium hydroxide. After the filtration of barium tartrate, the filtrate was used directly for the next condensation process. To the filtrate in a 2-dm^3 three-necked flask fitted with a mechanical stirrer, a condenser, and a thermometer, were added 8-hydroxyquinoline (0.6 mol, 87.10 g) and sodium disulfite (0.6 mol, 114.13 g), after which the mixture was gently refluxed for 7 days with stirring. The reaction mixture was made alkaline with a 50% aqueous sodium hydroxide solution at 60 °C, and after cooling the mixture was extracted with benzene. The extract was washed with water and dried over anhydrous potassium carbonate. After the removal of the solvent, 40.64 g of a pale brown oil was obtained. The crude oil (10 g) was purified as a hexane solution through an Al_2O_3 column. Pale yellow small plates (6.56 g) were obtained after the removal of the solvent, and recrystallized from hexane; mp 96.3—97.0 °C.

(R,R)-*Di-8-quinolylcyclohexanediamine* {(R,R)-*dqchxn*}. This was prepared according to a method similar to that for (*R*)-dqpn, using *R,R*-cyclohexanediamine[4] (chxn) in place of R-pn. Recrystallization from benzene gave yallow needles; mp 174—174.5 °C.

[$CuCl_2$(*dqen*)]. Copper(II) chloride dihydrate (0.85 g in 20 cm^3 of ethanol) and dqen (1.6 g in 100 cm^3 of ethanol) were mixed, and the resulting green solution was stored in a refrigerator overnight. The green crystals deposited were filtered off, washed with ethanol and ether, and air-dried; 1.2 g.

[$CuCl_2$(R)-*dqpn*]·*1/2*H_2O. This was prepared by a method similar to that used for [$CuCl_2$(dqen)].

[$CuCl_2$(R,R)-*dqchxn*]. Copper(II) chloride dihydrate (0.85 g in 100 cm^3 of ethanol) and (*R,R*)-dqchxn (20 cm^3 of benzene) were mixed. The resultant dark green solution was evaporated to about 50 cm^3 and stored in a refrigerator. The dark green crystals thus deposited were filtered, washed with ethanol, and ether, and air-dried; 0.65 g.

Measurements. Electronic absorption spectra were recorded on a Shimadzu Double 40-R spectrophotometer. The circular dichroism spectra were recorded on Jasco J-20 and Jasco J-20A spectropolarimeters. The magnetic measurements were carried out at room temperature (24—25 °C) by the Gouy method, using distilled water as the calibrant. The conductivities were determined on a TOA CM-6A conductometer at 25 °C.

Results and Discussion

Optically active ligands of the type, *N,N'*-di-8-

quinolylalkanediamine, and their complexes are described for the first time. The results of the elemental analysis and other properties of the ligands and their copper(II) complexes are presented in Table 1.

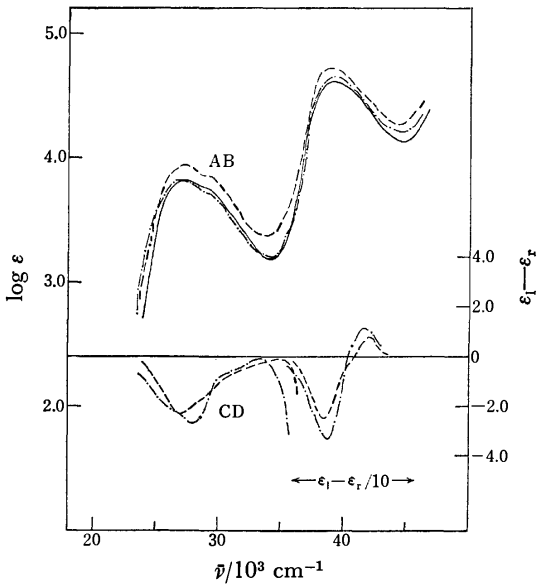

Fig. 1. Absorption(AB) and circular dichroism(CD) spectra of (——) dqen, (– – –) (*R*)-dqpn and (-·-·-) (*R,R*)-dqchxn in methanol.

Ligands. The electronic absorption and CD spectra of the ligands in methanol are shown in Fig. 1. Their band locations and intensities are summarized in Table 2. The substitution of propylenediamine or cyclohexanediamine for the ethylenediamine moiety of dqen produces little change in the absorption spectra. The two main absorption bands, centered at about 27000 and 40000 cm^{-1}, are due to the $\pi^*\leftarrow$n and $\pi^*\leftarrow\pi$ transitions of the quinoline nuclei.[5] A negative-positive CD couplet[6] (from lower to higher energy), centered at *ca.* 40000 cm^{-1}, is observed for the optically active ligands. The strong Cotton effects do not usually arise from the vicinal induction of assymmetric carbons. These CD patterns should arise from exiton splitting of the transitions of the quinoline nuclei. Similar coupled CD spectra have been reported for the optically active Schiff bases containing conjugated systems, such

as (*R*)-*N,N'*-disalicylidenepropylenediamine and (*R,R*)-*N,N'*-disalicylidenecyclohexanediamine.[2a-2c,2g] Figure 2 shows the three possible conformations of (*R*)-dqpn (a, b, c) and the only possible conformation of (*R,R*)-dqchxn (d). Of the three possible conformations of (*R*)-dqpn, (a) and (b) should give rise to strong optical activity, since in (c) the two quinoline nuclei are *trans*-parallel, resulting in inactive coupling. The pattern and intensities in the CD spectrum of the (*R*)-dqpn are quite similar to those of (*R,R*)-dqchxn, which necessarily has the (d) conformation, regulated by the fused cyclohexane ring. This result indicate that the most stable conformation of (*R*)-dqpn is the (a) conformer in

methanol.

Copper(II) Complexes. Figure 3 shows the electronic absorption and CD spectra of the series of copper(II) complexes in water. The absorption bands in the 10000—20000 cm^{-1} region are due to the d–d transitions. Each complex gives a shoulder at *ca.* 11000 cm^{-1} and a main peak at *ca.* 15000 cm^{-1}. It is known that for many copper(II) complexes, a shoulder appears at about 11000 cm^{-1} as a result of ligation along the tetragonal axis.[7-9] It might be difficult for the present ligands to take square-planar arrangements in the copper(II) complexes because of the steric hindrance between 2 and 2′ quinoline protons. The weak shoulders at *ca.* 11000 cm^{-1} suggest the apical ligation of one or two quinoline group(s) of the ligands that is, a *cis* type coordination of dqdiamine to the copper(II) ion. Although the *cis* complexes have two different geometrical arrangements, *cisα* and *cisβ*, the present complexes are probably *cisβ* (Fig. 4), since the steric interaction between the bulky terminal chelate moiety and the substituents of the central diamine chelate ring might be greater in *cisα* than in *cisβ*.[10] The magnetic moments of the three complexes (Table 1) are within the range of those reported for the five-coordinated or octahedral complexes,[1g] and higher than those of planar complexes (μ_{eff}; 1.8—1.9 B. M.).[11] The molar conductivities indicate that all the complexes are 1 : 1 electrolytes in methanol, and 1 : 2 electrolytes in an aqueous solution.[12] These results imply that the complexes have five-coordinated structure, [CuCl(dqdiamine)]Cl in the solid state, and that they dissociate into [CuCl(dqdiamine)]$^+$ and Cl$^-$ ions in methanol. When the complexes are dissolved in water, the coordinated Cl$^-$ ion will be replaced by the H_2O molecule to give bivalent complex cation, *i.e.*, [Cu(H_2O)(dqdiamine)]$^{2+}$.

The cyclohexanediamine bridge of (*R,R*)-dqchxn will exclusively take the λ-gauche[13] conformation upon coordination, because it has a *trans*-fused chelate ring. In the (*R*)-dqpn complex, however, a conformational inversion of the propylenediamine chelate moiety is possible wherein the C-methyl group is axial for the δ, and equatorial for the λ conformation. Since the overall CD pattern of the (*R*)-dqpn complex is similar to that of the (*R,R*)-dqchxn complex, the central chelate conformation and the absolute configuration of the (*R*)-dqpn complex must be the same as those of the (*R,R*)-dqchxn complex. Thus, the preferred conformation of the propylenediamine chelate moiety should be λ with the methyl group being equatorial.

The (*R*)-dqpn and (*R,R*)-dqchxn complexes give positive main Cotton effects in the d-d region. Unfortunately, the absolute configurations of the complexes cannot be known at present from the Cotton effects in this region. Sharp couplet CD components (negative and positive from lower to higher energy) centered at 42000 cm^{-1}, corresponding to the ligand $\pi^* \leftarrow \pi$ absorption bands, are seen for both complexes. The observation of a CD couplet with opposite-signed components corresponding to the ligand $\pi^* \leftarrow \pi$ transitions indicates that the two quinoline nuclei take a dissymmetric arrangements as has been mentioned. Since the CD pattern in the $\pi^* \leftarrow \pi$ couplet of the ligands did not change upon complexation, the dissymmetric arrangement of the free ligands must be maintained in their complexes. Figure 4 shows schematic drawings of the

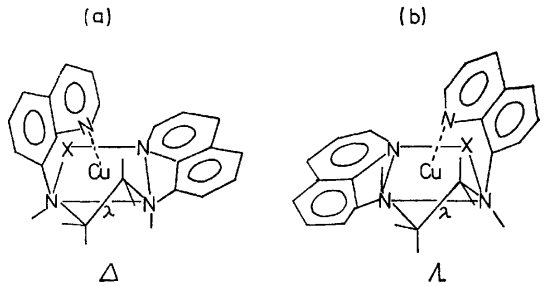

Fig. 4. Schematic structures of (a) Δ-*cisβ*[CuX(λ-dqdiamine)]$^+$, (b) Λ-*cisβ*[CuX(λ-dqdiamine)]$^+$ ions.

Δ-cisβ and *Λ-cisβ* forms of [CuX(λ-dqdiamine)]$^+$ (X= Cl^-). It is clear that the dissymmetric arrangement of the ligand does not change on complexation in the case of the *Δ-cisβ* form. The steric interaction between alkyl protons of the central chelate bridge and the π-electron cloud of the apically ligated quinoline nuclei seems to be greater in *Λ-cisβ* than in *Δ-cisβ*. Therefore, the *Δ-cisβ* might be more probable than the *Λ-cisβ* in the present complexes. Such behavior is in agreement with the exiton coupling theory. As defined by Bosnich,[14] when the configuration is *Λ*, the negative component of the $\pi^* \leftarrow \pi$ couplet will lie at higher energy, while it will lie at a lower energy when the chirality is *Δ*, the latter corresponding to the present complexes.

The authors wish to express their thanks to Dr. Yoichi Sasaki for his helpful discussions. We also would like to thank Dr. Hiroshi Yokoi for the magnetic measurements.

Reaction between Vanadium Trichloride Oxide and Hydrogen Sulfide

Akimasa YAJIMA, Ryoko MATSUZAKI, and Yuzo SAEKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259, Nagatsuta-cho, Midori-ku, Yokohama 227

(Received October 3, 1977)

The details of the reaction between vanadium trichloride oxide and hydrogen sulfide were examined at 20 and 60 °C. The main products by the reaction were vanadium dichloride oxide, sulfur, and hydrogen chloride. In addition to these products, small amounts of vanadium trichloride, vanadium tetrachloride, disulfur dichloride, and sulfur dioxide were formed. The formations of the above-mentioned reaction products can be explained as follows: The first stage is the reaction between vanadium trichloride oxide and hydrogen sulfide, $2VOCl_3(l)+H_2S(g)\rightarrow 2VOCl_2(s)+S(s)+2HCl(g)$. Then the resulting sulfur reacts with the unreacted vanadium trichloride oxide, $2VOCl_3(l)+2S(s)\rightarrow 2VOCl_2(s)+S_2Cl_2(l)$. The resulting disulfur dichloride subsequently reacts with the unreacted vanadium trichloride oxide, $2VOCl_3(l)+S_2Cl_2(l)\rightarrow 2VCl_4(l)+S(s)+SO_2(g)$. The resulting vanadium tetrachloride reacts with the sulfur formed during the reaction, $2VCl_4(l)+2S(s)\rightarrow 2VCl_3(s)+S_2Cl_2(l)$, and also reacts with hydrogen sulfide, $2VCl_4(l)+H_2S(g)\rightarrow 2VCl_3(s)+S(s)+2HCl(g)$.

As regards the reaction between vanadium trichloride oxide ($VOCl_3$) and hydrogen sulfide, Ehrlich and Siebert[1] have briefly reported that $VOCl_3$ reacts with hydrogen sulfide to form vanadium dichloride oxide ($VOCl_2$), sulfur, and hydrogen chloride. Also, there have been patents which report that the precipitate formed by the reaction between the $VOCl_3$ dissolved in titanium tetrachloride and hydrogen sulfide consists of vanadium sulfide,[2] and that the precipitate contains vanadium chiefly in the forms of vanadium trichloride (VCl_3) and $VOCl_2$.[3]

In this study, the details of the reaction between $VOCl_3$ and hydrogen sulfide were examined.

Experimental

Materials. The sample of $VOCl_3$ used was prepared by the chlorination of divadium pentaoxide, which had been obtained by the thermal decomposition of guaranteed reagent ammonium metavanadate, in the presence of carbon at 300 °C.[4] Disulfur dichloride(S_2Cl_2) was prepared by the chlorination of guaranteed reagent sulfur.[5] Vanadium tetrachloride(VCl_4) was prepared by the chlorination of high purity vanadium(V 99.8% up) at 500 °C.[6]

Experimental Procedures. The apparatus used for this experiment consisted of a Pyrex reaction vessel of 21 mm inner diameter and 70 mm height with a water-cooled condenser which was connected to a gas absorption unit. 8—9 g of $VOCl_3$ was poured into the reaction vessel and held at 20 or 60 °C in an argon atmosphere. Then pre-dried hydrogen sulfide was introduced into the reaction vessel at a flow-rate of 10 ml/min for a specified period with stirring.

The gaseous hydrogen chloride which formed was absorbed in water. The unreacted $VOCl_3$ containing the liquid product was separated from the solid product by distillation under reduced pressure at room temperature. The solid, liquid, and gaseous products were examined by chemical analysis and X-ray diffractometry.

The possible reactions which were considered to occur on the basis of the above-mentioned experiments, $VOCl_3+S$, $VOCl_3+S_2Cl_2$, VCl_4+S, and VCl_4+H_2S, were examined in the manner described above.

Throughout this work, all the chlorides and chloride oxides were handled in an argon atmosphere or in vacuo to prevent any contamination with moisture.

Analytical. X-Ray analysis of the solid product was performed using Ni filtered Cu radiation. The part of the diffractometer containing the sample was designed to be maintained in a dry nitrogen atmosphere, in order to prevent contamination of the sample with moisture during the irradiation.

Chemical analysis of the sample was performed as follows: The sample was hydrolyzed with dilute nitric acid and filtered. The vanadium content in the filtrate was determined by chelatometric titration,[7] while the chlorine and sulfur contents in the filtrate were gravimetrically determined as AgCl and $BaSO_4$, respectively. The filtered residue, solid sulfur, was dissolved in acetone and determined by titration with 0.05 N sodium cyanate solution.[8]

The gaseous hydrogen chloride which formed was determined gravimetrically as AgCl. The gaseous sulfur dioxide which formed was determined by iodometry after being absorbed in an iodine–potassium iodide solution.

Results and Discussion

Reaction Products for $VOCl_3$ and Hydrogen Sulfide. The reaction between $VOCl_3$ and hydrogen sulfide was examined with special attention given to the reaction product which formed. The variations of the amount of the solid product formed by the reaction between $VOCl_3$ and hydrogen sulfide with the reaction time

Table 1. Experimental results for the reaction between $VOCl_3$ and H_2S

Temp (°C)	$VOCl_3$ used (g)	Product: Solid: Amount (g)	Solid: $VOCl_2$ (%)	Solid: VCl_3 (%)	Solid: S (%)	Liquid: VCl_4 (g)	Liquid: S_2Cl_2 (g)	Gas HCl (g)	Note
20	8.62	5.98	84	6	10	0.05	0.00_8	1.36	Unreacted $VOCl_3$ 1.74 g
60	8.50	6.31	82	8	10	0.04	0.00_5	1.41	Unreacted $VOCl_3$ 1.18 g

were examined at 20 and 60 °C. Using these preliminary experimental results, the reaction products obtained by passing hydrogen sulfide through $VOCl_3$ for 4 h at 20 °C and 3 h at 60 °C were examined. The amounts of the solid products obtained at 20 and 60 °C are shown in Table 1.

The X-ray diffraction diagrams of the solid products obtained at 20 and 60 °C showed them to be a mixture of $VOCl_2$,[9] VCl_3,[10] and sulfur(orthorhombic),[11] as shown in Fig. 1. Chemical analysis gave V 33.0, Cl 47.2, S 10.0% for the product obtained at 20 °C, and V 32.9, Cl 47.6, S 10.0% for the product obtained at 60 °C. The percentages of $VOCl_2$, VCl_3, and S in the solid products, which were calculated from the chemical analysis (Cl base), are shown in Table 1. From these results, it was observed that the constituents of the solid products were almost the same regardless of the reaction temperature.

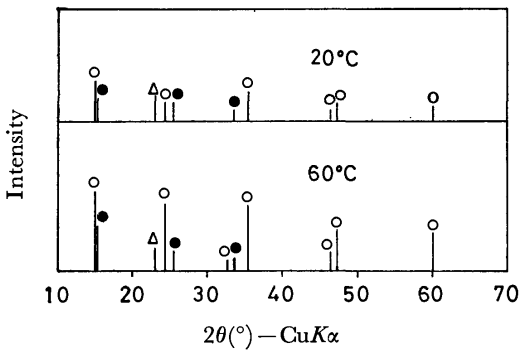

Fig. 1. X-Ray diffraction diagrams of the solid products obtained by the reaction between $VOCl_3$ and H_2S.
○: $VOCl_2$, ●: VCl_3, △: S.

Chemical analysis of the $VOCl_3$ containing the liquid product obtained at 20 and 60 °C gave V 29.1, Cl 61.5, S 0.2%. In the course of the chemical analysis of the sample, a liberation of sulfur was observed on dissolving the sample in dilute nitric acid. This indicated that the $VOCl_3$ contained S_2Cl_2[12] as a reaction product. The atomic ratio of the V content to the Cl content obtained by subtracting the Cl content corresponding to the S_2Cl_2 from the total Cl content was calculated to be $1:3.0_3$. This ratio is lower than the calculated value, 1: 3.00, for $VOCl_3$. The only vanadium chloride in the liquid state at room temperature is VCl_4, except for $VOCl_3$ itself. From these reasons, it was considered that VCl_4 was formed in addition to S_2Cl_2. The amounts of VCl_4, S_2Cl_2, and unreacted $VOCl_3$ are shown in Table 1.

The amounts of gaseous hydrogen chloride which formed during the reaction are also shown in Table 1. In addition, it was observed that a small amount of sulfur was deposited inside the glass line outside the reaction vessel. This fact indicated that sulfur dioxide was formed and reacted with hydrogen sulfide to form sulfur according to the reaction, $SO_2+2H_2S\rightarrow 3S+2H_2O$.[12]

The calculations to obtain the moles of the above-mentioned reaction products, based on the amounts shown in Table 1, showed that $VOCl_2$, sulfur, and hydrogen chloride were the main products and that the molar ratio of $VOCl_2$: S: HCl was approximately 2: 1: 2. From this result, the main reaction which occurred by passing hydrogen sulfide through $VOCl_3$ was found to be the following:

$$2VOCl_3(l) + H_2S(g) \longrightarrow 2VOCl_2(s) + S(s) + 2HCl(g). \quad (1)$$

The formations of small amounts of VCl_4, sulfur dioxide, and S_2Cl_2 were observed as mentioned above. Considering this observation and the description[13] that $VOCl_3$ reacts with sulfur to form VCl_4, SO_2, and $VOCl_2$, it seemed to be probable that the formations of VCl_4, SO_2, and S_2Cl_2 were due to the following reactions, which occurred during the reaction between the unreacted $VOCl_3$ and the sulfur which had formed:

$$2VOCl_3(l) + 2S(s) \longrightarrow 2VOCl_2(s) + S_2Cl_2(l),$$

$$2VOCl_3(l) + S_2Cl_2(l) \longrightarrow 2VCl_4(l) + S(s) + SO_2(g).$$

In addition to the above-mentioned reaction products, VCl_3 was also formed. The formation of VCl_3 was considered to be due to the reactions between the VCl_4 and the sulfur to form VCl_3 and S_2Cl_2, and between the VCl_4 and hydrogen sulfide to form VCl_3, sulfur, and hydrogen chloride.[1]

Side Reactions during the Reaction between $VOCl_3$ and Hydrogen Sulfide. In order to confirm the side reactions which were considered to occur during the reaction between $VOCl_3$ and hydrogen sulfide, experiments on these reactions: $VOCl_3+S$, $VOCl_3+S_2Cl_2$, VCl_4+S, and VCl_4+H_2S, were carried out at 20 °C for 4 h and at 60 °C for 3 h. Solid products were determined by X-ray diffractometry and chemical analysis. Liquid products were determined by chemical analysis in the same manner as described in the previous paragraph.

Experimental conditions and results for the reaction between $VOCl_3$ and sulfur are shown in Table 2.

Table 2. Experimental results for the reaction between $VOCl_3$ and S

Temp (°C)	$VOCl_3$ used (g)	S used (g)	Product: Solid $VOCl_2$ (g)	Product: Liquid S_2Cl_2 (g)	Product: Liquid VCl_4 (g)	Product: Gas SO_2 (g)
20	8.13	1.14	0.06	0.03_1	0.01	0.00_2
60	7.86	1.32	0.07	0.03_7	0.01	0.00_2

From the experimental results described later, the formations of small amounts of VCl_4 and sulfur dioxide may be due to the reaction between the unreacted $VOCl_3$ and the S_2Cl_2 which formed during the reaction. From these results, $VOCl_3$ would seem to react gradually with sulfur to form $VOCl_2$ and S_2Cl_2, as follows:

$$2VOCl_3(l) + 2S(s) \longrightarrow 2VOCl_2(s) + S_2Cl_2(l). \quad (2)$$

The experimental results for the reaction between $VOCl_3$ and S_2Cl_2 are shown in Table 3.

From these results, $VOCl_3$ reacts gradually with S_2Cl_2 to form VCl_4, sulfur, and sulfur dioxide, as

TABLE 3. EXPERIMENTAL RESULTS FOR THE REACTION BETWEEN $VOCl_3$ AND S_2Cl_2

Temp (°C)	$VOCl_3$ used (g)	S_2Cl_2 used (g)	Product: Solid S (g)	Product: Liquid VCl_4 (g)	Product: Gas SO_2 (g)
20	8.43	3.24	0.00_7	0.08	0.01_2
60	8.67	3.13	0.01_0	0.12	0.01_7

follows:

$$2VOCl_3(l) + S_2Cl_2(l) \longrightarrow 2VCl_4(l) + S(s) + SO_2(g). \quad (3)$$

It was also found that the formation of a small amount of sulfur dioxide during the reaction between $VOCl_3$ and hydrogen sulfide, described in the previous paragraph, was due to the reaction between $VOCl_3$ and S_2Cl_2.

Experimental results for the reactions between VCl_4 and sulfur and between VCl_4 and hydrogen sulfide are shown in Tables 4 and 5, respectively.

TABLE 4. EXPERIMENTAL RESULTS FOR THE REACTION BETWEEN VCl_4 AND S

20	7.78	1.29	5.37	2.30_9
60	7.79	1.30	5.64	2.42_3

TABLE 5. EXPERIMENTAL RESULTS FOR THE REACTION BETWEEN VCl_4 AND H_2S

Temp (°C)	VCl_4 used (g)	Product: Solid VCl_3 (g)	Product: Solid S (g)	Product: Liquid S_2Cl_2 (g)	Product: Gas HCl (g)
20	7.97	5.45	0.41_1	0.21_5	1.15
60	7.86	5.90	0.42_3	0.24_4	1.23

The results shown in Table 4 confirm that the reaction between VCl_4 and sulfur proceeds at an appreciable rate to form VCl_3 and S_2Cl_2, as follows:

$$2VCl_4(l) + 2S(s) \longrightarrow 2VCl_3(l) + S_2Cl_2(l). \quad (4)$$

From the result of the reaction between VCl_4 and sulfur, the small amount of S_2Cl_2 formed during the reaction between VCl_4 and hydrogen sulfide may be due to the reaction between the unreacted VCl_4 and the sulfur which formed. These results confirm that the reaction between VCl_4 and hydrogen sulfide proceeds at an appreciable rate to form VCl_3, sulfur, and hydrogen chloride, as follows:

$$2VCl_4(l) + H_2S(g) \longrightarrow 2VCl_3(s) + S(s) + 2HCl(g). \quad (5)$$

As described in the previous paragraph, $VOCl_2$, sulfur, and hydrogen chloride were formed as the main products by the reaction between $VOCl_3$ and hydrogen sulfide. In addition to these products, small amounts of VCl_3, VCl_4, S_2Cl_2, and sulfur dioxide were formed.

From the above-mentioned experimental results, the formations of the reaction products mentioned above can be explained as follows: The first stage is the reaction between $VOCl_3$ and hydrogen sulfide to form $VOCl_2$, sulfur, and hydrogen chloride according to Reaction 1. Then the resulting sulfur reacts with the unreacted $VOCl_3$ to form $VOCl_2$ and S_2Cl_2 according to Reaction 2. The resulting S_2Cl_2 subsequently reacts with the unreacted $VOCl_3$ to form VCl_4, sulfur, and sulfur dioxide according to Reaction 3. The resulting VCl_4 reacts with the sulfur formed during the reaction to form VCl_3 and S_2Cl_2 according to Reaction 4, and also reacts with hydrogen sulfide to form VCl_3, sulfur, and hydrogen chloride according to Reaction 5.

Consequently, the amonts of VCl_4, VCl_3, S_2Cl_2, and sulfur dioxide are small. Also, since Reactions 4 and 5 proceed at appreciable rates, the amount of VCl_4 is smaller than that of VCl_3.

Synthesis and Properties of Metal Complexes with 2-Thiophenealdehyde Oxime

Hiro KUMA, Kyoji MOTOBE, and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received October 17, 1977)

Cobalt(II), nickel(II), copper(II), zinc(II), and manganese(II) complexes with 2-thiophenealdehyde oxime have been prepared and characterized mainly on the basis of electronic spectra and magnetic data. The cobalt(II) and nickel(II) complexes isolated are of the general formulae: (A) $MX_2(oxime)_4$ (X=Cl, Br); (B) $M(NCS)_2(oxime)_2$. These compounds and $ZnCl_2(oxime)_4$ are all six-coordinated, and the complexes (B) are probably multinuclear. Copper(II) and manganese(II) form complexes of the formula $MX_2(oxime)_2$ (X=Cl, Br). Possible structures for these complexes are also discussed. 2-Thiophenealdehyde oxime is unidentate in all these complexes, being coordinated through the nitrogen atom.

In the course of studies on metal complexes with oximes,[1] the present authors happened to obtain cobalt(II), nickel(II), and zinc(II) complexes with 2-thiophenealdehyde oxime, which had composition different from that of previously reported complexes with this ligand.[2] Reinvestigation, therefore, was undertaken in order to examine these and related complexes in more detail. The present paper describes synthesis and characterization of 3d transition metal complexes with 2-thiophenealdehyde oxime, which is abbreviated as tox in the present paper.

Experimental

Materials. 2-Thiophenealdehyde oxime was prepared as reported previously.[3]

Analytical data of the metal complexes prepared in the present work are given in Table 1.

Dihalogenotetrakis(2-thiophenealdehyde oxime)cobalt(II), $CoX_2(tox)_4$ (X=Cl, Br). Cobalt(II) halide hexahydrate (0.01 mol) was added to a solution of 2-thiophenealdehyde oxime (0.04 mol) in ethanol (100 ml) at 65—70 °C. The reaction was continued with stirring under reflux for about two hours. The solution was filtered and allowed to stand overnight at room temperature. Yellow-brown (X=Cl) or brown (X=Br) crystals were collected by filtration and recrystallized from methanol.

$Co(NCS)_2(tox)_2$ was prepared in a manner analogous to the dihalogeno-complexes. A yellow-brown crystalline precipitate was washed with chloroform. The compound is insoluble in common organic solvents.

Dihalogenotetrakis(2-thiophenealdehyde oxime)nickel(II). *$NiX_2(tox)_4$ (X=Cl, Br)* were prepared as yellow-green crystals in a manner similar to the corresponding cobalt(II) complexes. Recrystallization was carried out from methanol.

$Ni(NCS)_2(tox)_2$. 2-Thiophenealdehyde oxime (0.03 mol) was added to a solution of $Ni(NCS)_2$ (0.01 mol) in ethanol (100 ml). The reaction was continued with stirring under reflux for about 2 h at 65—70 °C. A pale green crystalline precipitate was washed with chloroform. The compound is almost insoluble in common organic solvents.

Dichlorotetrakis(2-thiophenealdehyde oxime)zinc(II) was prepared as colorless microcrystals by a method similar to the correspoding cobalt(II) complex.

$CuX_2(tox)_2$ (X=Cl, Br) were obtained as yellow-brown (X=Cl) and brown (X=Br) crystals in a manner analogous to $CoX_2(tox)_4$. The product was recrystallized from methanol.

$MnCl_2(tox)_2$ was obtained as pale-yellow crystals in a manner analogous to the corresponding copper(II) complex. Recrystallization was carried out from methanol.

$MnBr_2(tox)_2$ was prepared as pale-yellow microcrystals in a manner similar to the chloride analogue.

Measurements. Electronic absorption spectra of the complexes were measured on a Shimadzu MPS-50L spectrophotometer. Infrared spectra were recorded as Nujol mulls using a Hitachi EPI-S2 infrared spectrophotometer and a Hitachi 215 infrared spectrophotometer.

Magnetic mesurements were carried out at room temperature by the Gouy method. Powder X-ray diffraction patterns were obtained with a Rigakudenki 4001-A2 diffractometer using Co K_α radiation and an iron filter.

TABLE 1. ANALYTICAL DATA OF METAL COMPLEXES WITH 2-THIOPHENEALDEHYDE OXIME

Compound	Found, %			Calcd, %			μ
	C	H	N	C	H	N	
$NiCl_2(tox)_4$	37.33	3.50	8.68	37.63	3.16	8.78	3.21
$NiBr_2(tox)_4$	32.90	2.95	8.02	33.05	2.77	7.71	3.15

μ: BM at room temperature

Results and Discussion

Nickel(II) Complexes. A compound of composition $NiCl_2(tox)_2$ was reported previously.[2] In the present work, however, this complex could not be isolated, but instead complexes of the formula $NiX_2(tox)_4$, X being Cl and Br, were obtained.

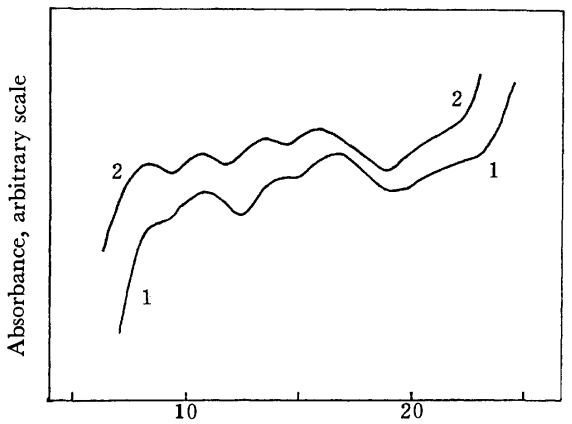

Fig. 1. Electronic absorption spectra of *trans*-dihalogenotetrakis(2-thiophenaldehyde oxime)nickel(II), *trans*-$[NiX_2(tox)_4]$, in Nujol: 1, X=Cl; 2, X=Br.

These nickel(II) complexes prepared are paramagnetic and of a high spin type (Table 1). The electronic absorption spectrum of $NiCl_2(tox)_4$ is very similar to those of *trans*-$NiCl_2(acox)_4$ and *trans*-$NiCl_2(bzox)_4$,[1] where acox and bzox denote acetaldehyde oxime and benzaldehyde oxime, respectively (Fig. 1). It is presumed that $NiCl_2(tox)_4$ has a similar structure to that of *trans*-$NiCl_2(acox)_4$, namely a six-coordinate *trans*-dichloro-structure, in which the oxime molecules are bound as unidentate ligands with the nickel(II) ion through the nitrogen atom.[1,4] It is also concluded that $NiBr_2(tox)_4$ has a six-coordinate *trans*-dibromo-structure, since its powder X-ray diffraction pattern is very similar to that of $NiCl_2(tox)_4$. In agreement with this, electronic absorption spectrum of $NiBr_2(tox)_4$ bears a close resemblance to that of *trans*-$NiBr_2(acox)_4$ (Fig. 1).[1] It is thus found that in these dihalogeno-nickel(II) complexes the ligands tox are bound with the nickel(II) ion as unidentate ligands through their nitrogen atom.

TABLE 2. BAND SPLITTING AND CRYSTAL FIELD PARAMETERS OF *trans*-$[NiX_2(tox)_4]$ IN 10^3 cm^{-1}

	X=Cl	X=Br
ν ($^3E_g^a \leftarrow {}^3B_{1g}$)	8.7	8.2
ν ($^3B_{2g} \leftarrow {}^3B_{1g}$)	10.8	10.7
ν ($^3A_{2g} \leftarrow {}^3B_{1g}$)	14.3	13.4
ν ($^3E_g^b \leftarrow {}^3B_{1g}$)	16.6	16.0
Dq^{xy}	1.08	1.07
Dq^z	0.66	0.57
Dt	0.24	0.29
Ds	0.43	0.49

The approximate symmetry of *trans*-$NiX_2(tox)_4$ is D_{4h}. Six-coordinate nickel(II) complexes of O_h symmetry show three spin-allowed d-d bands, each of which is split into two components as the symmetry of the complexes changes from O_h to D_{4h}. The band splitting observed in the spectra of $NiX_2(tox)_4$ is so remarkable that it is possible to obtain the components of the two main d-d bands from the magnitude of the splitting. The maxima of the components are shown in Table 2. From these data and using expressions derived on the basis of crystal field approximation,[5,6] values for Dq^{xy}, Dq^z, Ds, and Dt were estimated and shown in Table 2.

Comparison of the results with previous data[1,5,6] gives the following order as to the in-plane crystal field parameter: py>tox>acox>bzal$\gg$tu, where py and tu denote pyridine and thiourea, respectively. It is thus found that tox, acox, and bzox are close to py and much higher than tu in the spectrochemical series. A marked difference between tox and tu seems to be in agreement with the assumption that tox is coordinated as a unidentate ligand through its nitrogen atom with the nickel(II) ion; tu is known to be coordinated through the sulfur atom.

TABLE 3. ABSORPTION MAXIMA (in 10^3 cm^{-1}) OF METAL-(II) COMPLEXES WITH 2-THIOPHENEALDEHYDE OXIME IN NUJOL

Compound	ν
$Ni(NCS)_2(tox)_2$	8.7, 16.4
$Ni(NCS)_2(acox)_2$	8.6, 16.5
$CoCl_2(tox)_4$	8.8, 15.3 sh, 18.6
$CoBr_2(tox)_4$	8.7, 14.8 sh, 18.3
$Co(NCS)_2(tox)_2$	9.1, 15.5 sh, 18.7

sh: shoulder. Band assignment may be made as previously reported in Ref. 1 in the text.

The complex $Ni(NCS)_2(tox)_2$ is paramagnetic with a moment of 3.2 BM, and its electronic absorption spectrum is typical of the six-coordinate nickel(II) complex (Table 3). This complex shows infrared ν(C–N) and ν(C–S) vibration at 2120 and 770 cm^{-1}, respectively. These values, which are close to those of $Ni(NCS)_2(acox)_2$, lie in the range expected for the bridging NCS group.[7] It is most likely that $Ni(NCS)_2(tox)_2$ has a similar structure to that of $Ni(NCS)_2(acox)_2$, which was concluded to have a multinuclear structure with six-coordinate nickel(II) ions and bridging NCS ions.[1]

Just as in the nickel(II) complexes with acetaldehyde oxime and benzaldehyde oxime,[1] the dihalogeno-nickel-(II) complexes with 2-thiophenealdehyde oxime show hydrogen-bonded OH stretching vibrations at about 3180—3200 cm^{-1}, while $Ni(NCS)_2(tox)_2$ shows a sharp OH band at a much higher frequency, indicative of the presence of the non-hydrogen-bonded NOH group.

Cobalt(II) and Zinc(II) Complexes. Previously reported $CoCl_2(tox)_2$ and $ZnCl_2(tox)_2$[2] were not isolated, but only $CoX_2(tox)_4$ and $ZnCl_2(tox)_4$, X being Cl and Br, were obtained in the present work. The complexes $CoX_2(tox)_4$ are paramagnetic with magnetic

moments of about 5.1 BM, which are in the range expected for the six-coordinate cobalt(II) complexes. Their electronic absorption spectra are also typical of the six-coordinate cobalt(II) complexes (Table 3).

The powder X-ray diffraction patterns of $CoCl_2(tox)_4$ and $CoBr_2(tox)_4$ are very similar to those of the corresponding dichloro- and dibromo-nickel(II) analogues, respectively. Therefore, the complexes $CoX_2(tox)_4$ have a six-coordinate *trans*-dihalogeno-structure, in which the ligands tox are coordinated as unidentate ligands to the metal ion through the nitrogen atom, the sulfur atom in tox not being bound to the metal ion.

In a similar way $ZnCl_2(tox)_4$ has a *trans*-dihalogeno-structure, since its powder X-ray diffraction pattern is very similar to those of $CoCl_2(tox)_4$ and $NiCl_2(tox)_4$.

The complex $Co(NCS)_2(tox)_2$ shows a powder X-ray diffraction pattern, which is very similar to that of $Ni(NCS)_2(tox)_2$. Therefore, the cobalt(II) complex probably has a similar structure to that of the nickel(II) analogue, namely a multinuclear structure, in which the metal ions assume six-coordination with the NCS groups as bridges, just as in $Ni(NCS)_2(acox)_2$.[1] The cobalt(II) complex $Co(NCS)_2(tox)_2$ is paramagnetic with a magnetic moment of 4.95 BM, which lies in the range expected for the six-coordinate cobalt(II) complex. Its electronic spectrum is also in agreement with the six-coordinate stereochemistry. Its infrared ν(C–N) and ν(C–S) vibrations appear at 2110 and 775 cm^{-1}, respectively. The values indicate the presence of the bridging NCS group on the basis of the previously proposed criteria.[7]

Exactly like the corresponding nickel(II) complex, $CoX_2(tox)_4$ exhibit hydrogen-bonded OH stretching vibrations at about 3190—3200 cm^{-1}, while $Co(NCS)_2(tox)_2$ shows a sharp OH band at a much higher frequency, suggesting the presence of the non-hydrogen-bonded NOH group. This finding is similar to that of the corresponding complexes with acox and bzox.[1]

Copper(II) and Manganese(II) Complexes. Two copper(II) complexes $CuX_2(tox)_2$ were obtained in the present work, X being Cl and Br. One of them (X=Cl) had been reported previously.[2] In view of the results on the corresponding cobalt(II) and nickel(II)complexes, it may be reasonable to assume that tox is coordinated as a unidentate ligand through its nitrogen atom in the complexes $CuX_2(tox)_2$. Billing and Underhill[8] examined correlation between electronic absorption spectra and stereochemistry of complexes of the type CuX_2L_2, L being pyridine and its derivatives. On the basis of their conclusions, the stereochemistry of $CuX_2(acox)_2$ and $CuX_2(bzox)_2$ was discussed in a previous paper.[1]

The electronic spectra of $CuX_2(tox)_2$ have the first d-d band at about 14.3×10^3 cm^{-1}. The maxima are close to those of the multinuclear complexes $CuX_2(acox)_2$, $CuX_2(bzox)_2$, and $CuX_2(py)_2$.[1,8] According to the criteria reported previously,[1,8] and in view of the present finding that tox lies close to acox, bzox, and py in the spectrochemical series, the electronic spectra seem to indicate that $CuX_2(tox)_2$ most probably have a structure similar to that of the multinuclear forms of $CuX_2(acox)_2$, $CuX_2(bzox)_2$, and $CuX_2(py)_2$, in which the copper(II) ions are six-coordinated with halide ions as bridges.

The powder X-ray diffraction patterns of $MnCl_2(tox)_2$ and $MnBr_2(tox)_2$ are very similar to those of the corresponding dichloro- and dibromo-copper(II) analogues, respectively. It is most likely that the complexes $MnX_2(tox)_2$ may have a structure similar to that of the multinuclear $CuX_2(tox)_2$, the manganese(II) ions being in the six-coordinated environment with the halide ions as bridges. A similar structure was reported previously for $MnX_2(py)_2$.[9]

Table 4. Maxima of main d-d absorption bands and of some infrared bands of copper(II) complexes with 2-thiophenealdehyde oxime

Compound	d-d band, 10^3 cm^{-1}	Infrared bands, cm^{-1}	
		ν (M–L)	ν (M–X)
$CuCl_2(tox)_2$	14.3	272	310, 223
$CuBr_2(tox)_2$	14.3	262	221, 203
$CuCl_2(acox)_2$	14.8	272	296, 235
$CuBr_2(acox)_2$	14.8	259	243, 208
$CuCl_2(py)_2$	14.5	268	294, 235[a]
$CuBr_2(py)_2$	14.6	269	255, 202[a]
$MnCl_2(tox)_2$		213	232
$MnBr_2(tox)_2$		210	<200
$MnCl_2(py)_2$		212	233[a]
$MnBr_2(py)_2$		212	<200[a]

a) Infrared data are taken from Ref. 9 in the text.

Their infrared ν(M–X) and ν(M–L) bands also seem to correspond well to those of multinuclear $CuX_2(py)_2$, $CuX_2(acox)_2$, and $MnX_2(py)_2$ (Table 4).

The present authors are grateful to Professor Masayoshi Obashi for powder X-ray diffraction patterns.

The Crystal Structure of Iron Particles Dispersed in a Glasslike Carbon Matrix

Mamoru OMORI,* Toshio HIRAI,* and Seishi YAJIMA
The Oarai Branch, The Research Institute for Iron, Steel and Other Metals, Tohoku University, Oarai, Ibaraki 311-13
(Received October 24, 1977)

Ultra-fine iron particles were dispersed in a glasslike carbon matrix by the heat treatment of acetylferrocene-furfural resins. The dispersed iron particles were investigated by means of X-ray and electron diffraction analyses and by means of electron microscopy. In resins heat-treated at 400 °C, iron particles of varying diameters were observed by means of electron microscopy. The crystal structure of the iron particles was analyzed by means of X-ray and electron diffractions. Finely subdivided iron particles were identified as hexagonal, close-packed (hcp) and expanded, body-centered cubic (bcc) irons. The hcp iron is the high-pressure phase of iron metal. The ultra-fine iron particles were coagulated to larger particles by heat treatment above 400 °C. The size of their unit cell was the same as that of standard bcc iron.

Considerable interest is being devoted to the study of ultra-fine particles of metals and metal compounds because many of their properties are essentially different from those in the bulk state. Fine particles are prepared by means of the evaporation and condensation of metal in an inert gas at a low pressure. In the fine particles of chromium (>100 Å), a new class of crystals has been observed.[1,2] As the particle size of ferromagnetic material is reduced to a diameter of 10—100 Å, it shows a ferromagnetic-to-superparamagnetic transition. By the use of ferromagnets dispersed in glass and zeorite matrices, their superparamagnetic behavior has been investigated.[3-7] Ultra-fine particles of iron and cobalt, less than about 30 Å in diameter, which have been prepared by electrodeposition onto mercury, are superparamagnetic.[8,9] Superparamagnetic cobalt particles (<14 Å) are prepared by precipitation into Cu–2%Co alloy.[10,11] Ultra-fine nickel particles (<50 Å) are reduced from $Ni(NO_3)_2$ in a silica gel and are superparamagnetic.[12,13] Ferrite particles whose diameters are less than about 100 Å have superparamagnetic properties.[14,15] Moreover, atomic metals have been prepared in the matrices of inert gas from the vapour of metals at the temperature of liquid helium.[16-18]

As has been reported in previous papers, ultra-fine iron particles have been prepared in a glasslike carbon matrix by the heat treatment of acetylferrocene–furfural resins.[19-21] Their particle size varies with the iron content in the resin. The dispersion of iron particles is markedly related to the resin structure. The ultra-fine particles are not prepared by the heat treatment of ferrocene–phenol resin, which is different in structure from the acetylferrocene–furfural resin.[22] The glasslike carbon is stable at elevated temperatures, and does not show any strong peaks in X-ray and electron diffractions. Its absorption coefficient for X-rays and an electron beam is small, since it is an amorphous compound consisting of carbon, hydrogen, and oxygen. Therefore, the iron particles dispersed in the glasslike carbon matrix are favorable for the X-ray and electron diffraction analyses and for electron-microscopic observations.

In the present investigation, the crystal structure and size of iron particles dispersed in the glasslike carbon matrix were studied in detail. The iron atoms were liberated from ferrocene skeletons in the acetylferrocene-furfural resin by heat treatment at 400 °C. The liberated iron coagulated to ultra-fine iron particles of various sizes. The ultra-fine iron particles were coagulated in the glasslike carbon matrix by the irradiation of the electron beam and by heat treatment above 400 °C. The crystal structure of these iron particles was then analyzed by means of X-ray and electron diffractions. The size and shape of the particles were observed by means of an electron microscope.

Experimental

Preparation and Pyrolysis of Resins. The synthesis of acetylferrocene–furfural resin was described in a previous paper.[23] When the molar ratio of furfural (F) to acetylferrocene (A) in the starting material exceeded the F/A ratio of 15, the resin was not obtained. Acetone was added to the starting material containing furfural a more than the F/A ratio of 15. The furfural (1 mol) was mixed with 0.2 mol of acetylferrocene and acetone. To the mixture, concentrated sulfuric acid was then added until it amounted to 4 wt% of the total weight of furfural, acetylferrocene, and acetone. The subsequent treatment to get the resin was done in the way reported previously.[23] The resin was heated in an electric furnace under a vacuum as follows: 100—350 °C, 3.5 h; 350—400 °C, 2 h; 400—1500 °C, 100 °C/h. The heating was stopped at the desired maximum temperature. The heat-treated resin was then cooled to room temperature in an electric furnace. The heat-treated resin in a vacuum container was placed in the glovebox replaced with argon gas. The following operating procedures were carried out in the glovebox. The heat-treated resin was ground to powder using an agate mortar and a pestle. For X-ray diffraction measurements, the fine powdered sample, which had been passed through a 325-mesh screen, was loaded into a thin glass capillary and then sealed with silicone grease. The powdered sample for electron-microscopic measurements was placed in a glass tube filled with anhydrous hexane and then sealed with a rubber cap.

Elemental Analysis and Measurement of Properties. The determination of the iron was carried out with a Hitachi-207 atomic absorption spectrophotometer. The apparent densities were calculated from the weight and size of the resins.

Furan resin	0	5	1	0	63.04	3.11	0.946

The X-ray diffraction patterns were recorded on a Rigaku Geigerflex diffractometer using a Debye-Scherrer camera, Fe $K\alpha$ radiation, and a Mo filter. Electron-microscopic observation was carried out by using a JEM-100B transmission electron microscope at a direct magnification of 150000.

Results and Discussion

The synthetic results for acetylferrocene–furfural resins are summarized in Table 1. The structure of acetylferrocene–furfural resin has already been elucidated.[23] Ferrocene skeletones form a main chain in the structure. It is evident that the resin is stable above 300 °C, since the IR spectrum of resin does not change up to 300 °C. Upon heating the resin at 400 °C, though, all the absorption bands in the IR spectrum disappear.[23] Therefore, the resin can be concluded to be destroyed and converted into a glasslike carbon containing iron. It seems likely that the iron atom in the ferrocene skeleton is liberated and then forms an iron metal or its compound. When ferrocene is pyrolyzed above 400 °C, the iron metal is liberated from it. The liberated iron does not react with carbon, since iron carbides are not detected in the pyrolyzed product.[24] Moreover, body-centered cubic (bcc) iron is the only product when a graphite–$FeCl_3$ intercalate compound is heated at 950 K for 3 h.[25] Therefore, iron carbides are not produced from the liberated iron in the heat-treated resin. In addition, the formation of iron oxides has to be taken into account, since the glasslike carbon contains oxygen. It is well known that an iron monoxide is reduced with carbon at 350 °C *in vacuo*.[26] Therefore, it was considered that the liberated iron did not react *in vacuo* with the oxygen contained in the glasslike carbon. In the heat-treated resins, 10-Resin heat-treated at 400 °C [10-Resin (400 °C)] was pyrophoric on exposure to air. However, the pyrophoric phenomenon was not observed in the resin heat-treated above 400 °C. As is shown in Table 2, the quantity of hydrogen and oxygen in heat-treated resins decreased with an increase in the heat-treatment temperature, in a manner analogous to that of heat-treated glasslike carbons.[27] The iron contents of heat-treated resins increased with an increase in the heat-treatment temperatures (400—1200 °C). However, the iron contents of resins (1500 °C) decreased compared with those of resins (1200 °C). The decrease in the iron content was due to the higher vapour pressure of iron metal than that of carbon at high temperatures.[28]

Electron-microscopic Observation. The transmission electron micrographs of resins (400 °C) are shown in Photo. 1: Micrographs (1-1 and 1-2) correspond to the bright-field image of 2-Resin (400 °C); 1-3, 1-4, 1-5, 1-6, and 1-7, to the bright-field images of 10-, 10-, 30-, 40-, and 100-Resins (400 °C) respectively. The transmission electron micrograph (1-8) is based on Furan resin (400 °C). In the micrograph (1-1), iron particles 10—25 Å in diameter were uniformly dispersed, while larger iron particles (30—150 Å) were only thinly scattered. These iron particles coagulated upon irradiation by a strong electron beam, as is shown in Photo. 1-2. The coagulation of iron particles was due to the heat generated by the irradiation of the electron beam. In the case of 5-Resin (400 °C), the uniform dispersion of iron particles (10—25 Å) was similar to that of 2-Resin (400 °C). This uniform dispersion can be observed in

the micrograph (1-3) of 10-Resin (400 °C). However, iron particles of irregular sizes (10—150 Å) were dispersed in the other part of the 10-Resin (400 °C), as is shown in Photo. 1-4. Since the density of 10-Resin was less than that of 2- and 5-Resins, the coagulation of iron must be greatly affected by the small difference in the heating temperature in the resin. Iron particles of irregular sizes (10—100 Å) were also observed in the glasslike carbon matrix of 30-Resin (400 °C). However, the number of iron particles in it was less than in 10-Resin (400 °C). No iron particles were found in the glasslike carbon of 40-Resin (400 °C), as is shown in Photo. 1-6. This indicates that the iron particles are subdivided into finer particles less than about 10 Å in diameter and which cannot be detected by means of the electron microscope. In the case of 100-Resin (400 °C), the iron particles were similarly less than about 10 Å in diameter. The transmission electron micrographs of 40- and 100-Resins (400 °C) were the same as that of Furan resin (400 °C). The size of the iron particles, as observed by means of the electron microscope, is shown in Table 3. The iron

particles in resins (400 °C) did not coagulate to large particles, and their diameters were less than about 200 Å, as is shown in Table 3. Transmission electron micrographs of 2-Resin (800 °C) and 100-Resin (800 °C) are shown in Photo. 2 (2-1, 2-2). The iron particles which were not detected in 100-Resin (400 °C) were observed in 100-Resin (800 °C) as particles 30—200 Å in diameter. The uniformly dispersed iron particles (10—25 Å) coagulated to larger ones with a diameter of more than about 30 Å in 2- to 10-Resins (800 °C). The iron particles of the resins became larger in size than those of the resins, as is shown in Table 3. The pyrophoric phenomenon was due to the presence of the ultra-fine particles less than 200 Å in diameter. The reason for the pyrophoric phenomenon of 10-Resin was explained by the density being lower than those of 2- and 5-Resins and the iron content being higher than those of 20- to 100-Resins. The number of iron particles observed in 30- to 100-Resins (800 °C) was small, but was greater than that of iron particles (30—200 Å) in 2- to 30-Resins (400 °C). The size of the iron particles increased with an increase in the heat-treatment temperature from 1200 to 1500 °C, as is shown in Table 3. The largest iron particles, with a diameter of about 1000 Å, were observed in 10- and 30-Resins (1500 °C). In another resin (1500 °C), the iron particles were not able to coagulate to such large particles. The smallest particles of 2- to 5-Resins (1200 and 1500 °C) were less than those of other resins (1200 and 1500 °C), despite their high iron contents. These results show that the iron particles are finely subdivided in a glasslike carbon matrix, even at high temperatures. The dense glasslike carbon prepared from 2- to 5-Resins was

excellent in its dispersion of iron particles. The observed iron particles were nearly spherical. No characteristic shape related to the crystal structure was found.

Structural Analysis. The crystal structure of iron particles dispersed in the glasslike carbon matrix was analyzed using the X-ray diffraction data. The results are summarized in Table 4. In the X-ray diffraction patterns of 2- to 10-Resins (400 °C), lines based on two kinds of crystals were observed. One of the crystals consisted of expanded, body-centered cubic (bcc) iron, and its unit cell was $a_0=2.95$, larger than that of standard bcc iron (Ref. 29, $a_0=2.8664$). The other crystal consisted of hexagonal, close-packed (hcp) iron. The hcp iron is a high-pressure phase.[30] In the X-ray diffraction of the high-pressure-phase iron, the six diffraction lines are interpreted as being 101, 100, 110, 112, 002, and 103.[31] As is shown in Table 5, these lines

Table 5. X-ray diffraction data of the ultra-fine iron particle in 2- to 10-resins (400 °C)

d(Å)	(hkl)
2.85	(100)
2.61	(002)
2.51	(101)
1.61	(110)
1.48	(103)
1.39	(112)
1.30	(004)
1.10	(203)

were also observed in the X-ray diffraction pattern of ultra-fine iron. Moreover, two extra lines in it corresponded to the 004 and 203 lines. In the diffraction pattern of the 2- to 10-Resins (400 °C), the 110 line of hcp iron overlapped with the 200 line of the expanded bcc iron. The size of the unit cell of the high-pressure phase varies with the pressure: $a=2.465$, $c=4.050$, $c/a=1.643$ at 150 kbars; $a=2.421$, $c=3.828$, $c/a=1.580$ at 400 kbars.[31] At an atmospheric pressure of 1, the hcp phase of the binary Fe–C alloy has been prepared by means of a splat quenching; $a_0=2.502$, $c/a=1.643$.[32] The unit-cell size of ultra-fine hcp iron was $a_0=3.30$ and $c_0=5.21$ ($c/a=1.58$). The unit cell of ultra-fine iron was larger than those of the high-pressure phase and the binary alloy. However, the c/a ratio was similar to those of these hcp phases. For 20- to 100-Resins (400 °C), no diffraction lines were observed except for a broad line in the vicinity of $2\theta=50°$. The broad line was thought to be due to the glasslike carbon, since the same line was observed in Furan resin (400 °C). The few iron particles (10—150 Å) that were observed in 20- to 30-Resins (400 °C) did not contribute to the X-ray diffraction line. The line due to the bcc phase was observed in 2- to 20-Resins (800 °C). Its unit-cell size was $a_0=2.86$—2.87, equal to that of the standard bcc iron. While the iron particle was observed in 30- to 100-Resins (800 °C), the diffraction line of the iron particles was not obtained. The iron particles did not coagulate enough to give an X-ray diffraction pattern in these resins. The broad line due to the glasslike carbon was, however, present in these resins (800 °C). X-ray diffraction confirmed the presence of standard bcc iron in 2- to 100-Resins (1200° and 1500 °C), although the iron content of 100-Resin (1500 °C) was lower than 1%. In these resins the iron particles coagulated to become a large iron particle which was adequate for the X-ray diffraction. In 2- to 10-Resins (400 °C), the number of iron particles (30—200 Å) was less than that of 30- to 100-Resins (800 °C). It is most likely that the iron particles (30—200 Å) in 2- to 10-Resins (400 °C) do not reveal any diffraction lines. Therefore, the hcp and expanded bcc irons are interpreted as being iron particles with diameters 10—25 Å. According to the similarity in crystal structure, it is reasonable to imagine that the iron particles grow in this order; the hcp iron, the expanded bcc iron, and the standard bcc iron.

Table 6. Electron-diffraction analysis of iron particles dispersed in heat-treated resins

100-Resin	—	R+S	R+S	R+S

R: diffraction ring. S: diffraction spot.

The results of the electron-diffraction analysis are shown in Table 6. In the electron-diffraction profiles of 2- and 5-Resins (400 °C), diffraction rings of both hcp iron and expanded bcc iron were observed. Both rings consisted of diffraction spots. The precise dimensions of the unit cell could not be calculated from the diffraction ring. The appearance of spots suggested that the hcp and expanded bcc irons were a single crystal or a polycrystalline. Since their crystal size was less than 25 Å, it was concluded that the polycrystalline could not be formed. In 10- to 100-Resins (400 °C), there existed only a broad ring instead of the diffraction ring

based on the hcp and expanded bcc irons. The broad ring was due to the glasslike carbon. In 30- to 100-Resins (800 °C), the crystal structure of ultra-fine iron particles which were not clarified by the X-ray diffraction analysis was identified as that of the standard bcc iron. The diffraction rings and spots due to the standard bcc iron were observed in all resins (800 to 1500 °C), as is shown in Table 6.

These results lead to the following conclusions. The ultra-fine iron particles are prepared by the heat treatment of acetylferrocene-furfural resin *in vacuo*. The hcp and expanded bcc irons are identified in the ultra-fine iron particles prepared at 400 °C. The unit cell of hcp iron was larger than that of iron metal under a high pressure. Upon heating, both hcp and expanded bcc iron particles coagulate to larger particles to form the standard bcc iron.

The authors would like to thank Mr. Tsutomu Shoji and Mrs. Hide Arai, Tohoku University, for their cooperation in the iron and CH analyses. Thanks are also due to Messrs. Haruo Yotsumoto and Eiichi Watanabe of the Japan Electron Optics Laboratory for their assistance in the electron-microscopic observation.

Pyrolytic Sulfurization Gas Chromatography. II.[1] Simple Determination of the Correction Factors Using Five Standard Compounds

Tadashi HARA, Kaoru FUJINAGA, and Katsuya TSUJI

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602

(Received September 12, 1977)

An improvement has been made in the pyrolytic sulfurization gas chromatographic method, by which the atomic ratio between C, H, O, and N in a sample can be simultaneously determined. Analysis was carried out by use of the correction factors instead of calibration curves. Correction factors were obtained by use of five standard compounds, naphthalene, thiourea, cyanoguanidine, sucrose, and amidosulfuric acid. The method is simple, accurate, and applicable to various compounds.

In order to establish a new elemental analysis method by which several elements can be simultaneously determined, a combustion technique in sulfur (S) vapor instead of the conventional one in oxygen (O) atmosphere was proposed.[1] The individual elements in a sample were converted as follows: carbon (C) to carbon dioxide (CO_2), carbonyl sulfide (COS), and carbon disulfide (CS_2), hydrogen (H) to hydrogen sulfide (H_2S), O to CO_2 and COS and nitrogen (N) to nitrogen molecule (N_2). The products were determined by gas chromatography. The chemical composition of the original compound was estimated by dividing each peak area of N_2, C-, and O-containing compounds by the peak area of H_2S, and by applying the calibration curves between H and C or O or N to the quotients. In order to find the sum of individual peak areas of C- and O-containing compounds, the relation between the peak areas of CO_2, COS, and CS_2 and their mole numbers was used, the correction factors of CO_2, COS, and CS_2 being obtained from the reaction between carbon monoxide (CO) and S.

Since the chemical composition was determined by the calibration curves obtained from four compounds and the correction factors obtained by the reaction between pure CO and S, the method was not always simple and convenient.

The present method is much more convenient as compared with the previous one. Five compounds, naphthalene, thiourea, cyanoguanidine, sucrose, and amidosulfuric acid were chosen as standard and the correction factors of the individual products to H_2S were obtained on the assumption that each peak area of the products corresponds to their mole numbers in the original compound. The method is characterized by obtaining all the correction factors by five times of analysis and by estimating the weight ratio of each atom by a simple calculation using the correction factors. The method is applicable to various compounds and reasonable results are obtained.

Experimental

Apparatus and Reagents. The sampler and displacement apparatus were similar to those previously used. A transparent quartz tube, 2.5 mm i.d., 3.5 mm o.d., and 110 mm long, was used after treatment similar to that in the previous procedure. Gas chromatograms were taken on Shimadzu GC-4B and GC-4C. Naphthalene, thiourea, sucrose, and cyanoguanidine were of reagent grade for elemental analysis, and the other reagents were of analytical grade.

Procedure. The procedure was similar to that given in the previous paper except for placing the sample in a reaction tube and keeping it in a desiccator overnight.

Detection of water as a product could not be carried out by combination of the silica gel column and the molecular sieve 5A column in the previous experiment. However, it could be achieved by connecting a 0.25 m Chromosorb 104 (80—100 mesh) column with a 1.75 m Porapak Q (80—100 mesh) column in series and by raising temperature at a rate of 20 °C/min over 80—185 °C. Under these conditions, N_2, CO_2, H_2S, COS, H_2O, SO_2, and CS_2 were separated satisfactorily. Though the separation of CO from N_2 was difficult, it was found that the amount of CO evolved was negligible.

Results and Discussion

Correction Factors. The relationship between the constituent atoms of standard compounds and the products by the reaction is as follows: Naphthalene (C, H) to CS_2 and H_2S; thiourea and cyanoguanidine (C, H, N) to CS_2, H_2S, and N_2; sucrose (C, H, O) to CS_2, H_2S, CO_2, and COS; amidosulfuric acid (N, H, O) to H_2S, N_2, H_2O, and SO_2. Assuming that each peak area of the compounds corresponds to their mole numbers in the original compound, we obtain

$$\left(\frac{C}{H}\right)_t = \frac{K(CS_2)A(CS_2)}{2K(H_2S)A(H_2S)} = \frac{K(CS_2)A(CS_2)}{2A(H_2S)}, \quad (1)$$

$$\left(\frac{N}{H}\right)_t = \frac{K(N_2)A(N_2)}{K(H_2S)A(H_2S)} = \frac{K(N_2)A(N_2)}{A(H_2S)}, \quad (2)$$

$$\left(\frac{C}{H}\right)_t = \frac{K(CO_2)A(CO_2)+K(COS)A(COS)+K(CS_2)A(CS_2)}{2K(H_2S)A(H_2S)}, \quad (3)$$

$$\left(\frac{O}{H}\right)_t = \frac{2K(CO_2)A(CO_2)+K(COS)A(COS)}{2K(H_2S)A(H_2S)}, \quad (4)$$

$$\left(\frac{N}{H}\right)_t = \frac{K(N_2)A(N_2)}{K(H_2S)A(H_2S)+K(H_2O)A(H_2O)}, \quad (5)$$

$$\left(\frac{O}{H}\right)_t = \frac{2K(SO_2)A(SO_2)+K(H_2O)A(H_2O)}{2[K(H_2S)A(H_2S)+K(H_2O)A(H_2O)]}, \quad (6)$$

where $A(CS_2)$, $A(H_2S)$, $A(N_2)$, $A(CO_2)$, $A(COS)$, $A(SO_2)$, and $A(H_2O)$ are referred to the individual peak area and $(C/H)_t$, $(N/H)_t$, and $(O/H)_t$ to the theoretical atomic ratios in individual compounds. Each correction factor was obtained on the basis of $K(H_2S)=1.00$.

Table 1. Correction factors

Standard compound	Correction factor						
	$K(N_2)$	$K(CO_2)$	$K(H_2S)$	$K(COS)$	$K(H_2O)$	$K(SO_2)$	$K(CS_2)$
Naphthalene			1.00				0.609
Thiourea	1.26		1.00				0.600
Cyanoguanidine	1.18		1.00				0.601
Sucrose		1.10	1.00	0.712			
Amidosulfuric acid			1.00		2.33	0.816	
Average	1.22	1.10	1.00	0.712	2.33	0.816	0.603

Table 2. Calculation of the content of C, H, O, and N

Element	Product	Mole ratio	Weight ratio	Content %
N	N_2	$K(N_2)A(N_2)=1.22A(N_2)$	$M(N_2)K(N_2)A(N_2)=28.014[1.22A(N_2)]$	Obtained from Eq. 7
C	CO_2	$K(CO_2)A(CO_2)=1.10A(CO_2)$	$M(CO_2)K(CO_2)A(CO_2)=44.009[1.10A(CO_2)]$	
	COS	$K(COS)A(COS)=0.712A(COS)$	$M(COS)K(COS)A(COS)=28.010[0.712A(COS)]$	Obtained from Eq. 8
	CS_2	$K(CS_2)A(CS_2)=0.603A(CS_2)$	$M(CS_2)K(CS_2)A(CS_2)=12.011[0.603A(CS_2)]$	
H	H_2S	$K(H_2S)A(H_2S)=1.00A(H_2S)$	$M(H_2S)K(H_2S)A(H_2S)=2.016A(H_2S)$	Obtained from Eq. 9
	H_2O	$K(H_2O)A(H_2O)=2.33A(H_2O)$	$M(H_2O)K(H_2O)A(H_2O)=18.015[2.33A(H_2O)]$	
O	CO_2	$1.10A(CO_2)$	$44.009[1.10A(CO_2)]$	
	COS	$0.712A(COS)$	$28.010[0.712A(COS)]$	Obtained from Eq. 10
	H_2O	$2.33A(H_2O)$	$18.015[2.33A(H_2O)]$	
	SO_2	$K(SO_2)A(SO_2)=0.816A(SO_2)$	$M(SO_2)K(SO_2)A(SO_2)=31.998[0.816A(SO_2)]$	

The correction factor of CS_2, $K(CS_2)$, was calculated by Eq. 1 from the results of naphthalene, thiourea, and cyanoguanidine, and that of N_2 similarly by Eq. 2 from the results of thiourea and cyanoguanidine. $K(CO_2)$ and $K(COS)$ were obtained by Eqs. 3 and 4 from the results of sucrose, and $K(H_2O)$ and $K(SO_2)$ by Eqs. 5 and 6 from the results of amidosulfuric acid. All the correction factors (Table 1) were used in the following analysis.

Determination of the Atomic Ratio of Compounds. The atomic ratio between C, H, O, and N was calculated by use of the chromatogram data (Table 2). The mole ratios between the individual products were found by multiplying the correction factors by the peak areas. The weight ratios between the individual products were obtained by multiplying the above mole ratios by the molecular weights obtained by substracting the weight of S from the molecular weight of the products, the weight ratios of the individual products to all the products being found.

As seen from Eqs. 7—10, the weight ratios between the individual elements were obtained by multiplying the weight ratio of the desired element in the products by the weight ratios and by summing them up.

$$N_{wt\%}=\left[\frac{2E(N)}{M(N_2)}\frac{M(N_2)K(N_2)A(N_2)}{n}\right]\times 100=\left[28.014\frac{1.22A(N_2)}{n}\right]\times 100, \tag{7}$$

a) Since S atom could not be determined, it was neglected in the composition of methionine.

where n is referred to the sum of the weight ratios, $M(N_2)$, $M(CO_2)$, $M(COS)$, $M(H_2S)$, $M(H_2O)$, $M(SO_2)$, and $M(CS_2)$ to the molecular weight of each compound, and $E(N)$, $E(C)$, $E(H)$, and $E(O)$ to the atomic weight of each element.

Analysis of Various Compounds. Various amino acids and carboxylic acids were analyzed (Table 3). The accuracy of the present method is similar to that of the former. However, an erroneous result is obtained when the carbon content is high. This seems to be due to the tailing phenomena with an increasing amount of CS_2 and the subsequent and incorrect reading of the chromatogram. The former method is applicable only to compounds containing H, but the present method is applicable even to H-free inorganic compounds.

Compounds other than amino acids and carboxylic acids were analyzed (Table 4). In the previous experiment, the compounds containing nitro group and phenols gave erratic results owing to the formation of water. However, in the present experiment, good results were obtained which agree with the theoretical values. This is due to the fact that no water is formed. It was concluded that the difference resulted from the different oxygen uptake of the two chromatographs, Shimadzu GC-4B and GC-4C, and the oxygen uptake by an apparatus from air took place during charge of the next sample after completion of analysis. It is remarkable in a new apparatus. The oxygen uptake by a new apparatus is minimized by treating a stainless steel tube with an aqueous solution of water glass or disodium

hydrogenphosphate.

The analytical results of sodium 1-naphthalenesulfonate did not agree with the theoretical values as in the previous work. This is attributed to the purity of a sample judging from the results of gravimetric analysis of sodium and sulfur.

The accuracy in the determination of C, H, O, and N is shown by the following standard deviation: σ_C= 0.46, σ_H=0.24, σ_O=0.39, and σ_N=0.36%. Though five compounds were chosen as standard, they could be reduced to three if accuracy of the analysis including the reading of the chromatogram is improved.

Analysis of Acetates. The acetates of alkali and alkaline earth metal were analyzed (Table 5). No analysis could be carried out for lithium acetate since the reaction tube containing lithium acetate exploded during the course of reaction. Of the alkaline earth metal acetates, magnesium acetate gave a considerable error. This shows that magnesium, differing from other alkaline earth metals, has a larger affinity to oxygen than to sulfur. This is understandable if we take into consideration $\Delta G°$=49.16kJ/mol at 1200 K for the formation of magnesium sulfide.[2]

The Stereochemistry of 3-Hydroxy-2-methylbutyric Acid

Akira TAI and Motomasa IMAIDA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 13, 1977)

Four stereoisomers of methyl 3-hydroxy-2-methylbutyrate (I), (+)-*threo*-I, (−)-*threo*-I, (+)-*erythro*-I, and (−)-*erythro*-I, were prepared, and their absolute configurations were determined. The configurations of (+)-*threo*-I, $[\alpha]_D^{20}$ +36.80° (*c* 5, methanol) and (+)-*erythro*-I, $[\alpha]_D^{20}$ +14.32° (*c*, 5, methanol) were assigned to (2*S*, 3*S*) and (2*S*, 3*R*) respectively.

The present work was undertaken in connection with two other studies. One is the study of the stereo-differentiating (asymmetric) hydrogenation of methyl 2-methyl-3-oxobutyrate (III) into methyl 3-hydroxy-2-methylbutyrate (I) over an asymmetrically modified nickel catalyst.[1] In this study, the determinations of $[\alpha]_D$ and the absolute configuration of each stereoisomer of I are essential for the evaluation of the reaction. The other is the study of the stereochemistry of the CH_3–CH(OH)–CH(CH_3)– group of sex pheromones of sawflies.[2]

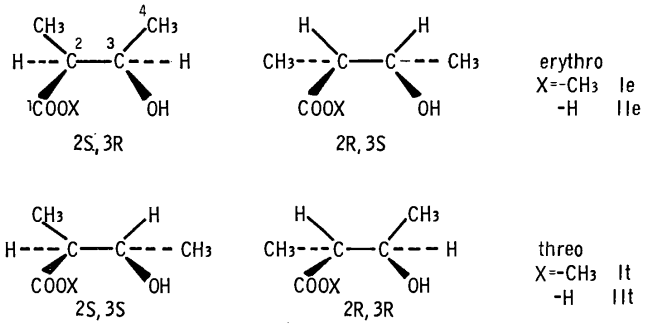

Fig. 1.

The configurations of four stereoisomers of I are shown in Fig. 1. The pair of (2*R*, 3*R*)- and (2*S*, 3*S*)-I was conventionally designated as the *threo* isomer (It), and that of (2*R*, 3*S*)- and (2*S*, 3*R*)-I, as the *erythro* isomer (Ie). Optically active I ($[\alpha]_D$+22°) was first isolated from the degradation product of tetrin B by Rinehart and co-workers.[3] The configuration at C-3 of this compound was assigned to *S*, but that at C-2 was not made clear. Masken and Polgar reported that each diastereomer of I showed a different retention time in GLC and assigned the diastereomer with long retention time to Ie based on the NMR and IR spectroscopic analyses.[4] However, neither the optical resolution of Ie and It nor the determination of the absolute configurations of optically active Ie and It has been reported.

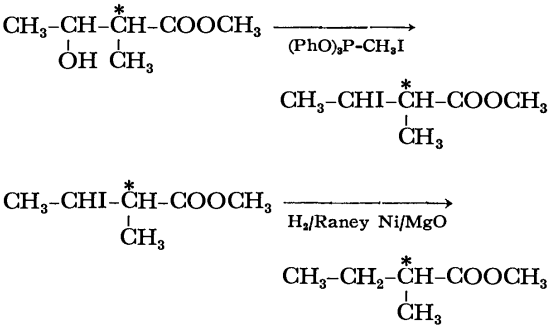
Results and Discussion

Diastereoisomeric I consisting of Ie and It in a ratio of 6 to 4 was obtained by the hydrogenation of methyl 2-methyl-3-oxobutyrate (III) over DL-tartaric acid-modified Raney nickel.[5] It is better to use modified Raney nickel for this hydrogenation, since unmodified Raney nickel is easily corroded by III and often loses its catalytic activity in the course of the hydrogenation.[6]

After the hydrolysis of I into 3-hydroxy-2-methylbutyric acid (II), II was converted to cyclohexylammonium salt. The recrystallization of the cyclohexylammonium salt from ethanol gave one of the diastereomers of II in a pure state. GLC and NMR analyses of its methyl ester indicated that the resulting isomer corresponded to the *erythro* isomer (IIe) assigned by Masken and Polgar. The cyclohexylammonium salt in the combined mother liquid was converted to sodium salt by treatment with sodium hydroxide. The recrystallization of the sodium salt from a methanol–acetone mixture gave the other diastereomer, IIt, in a pure state.

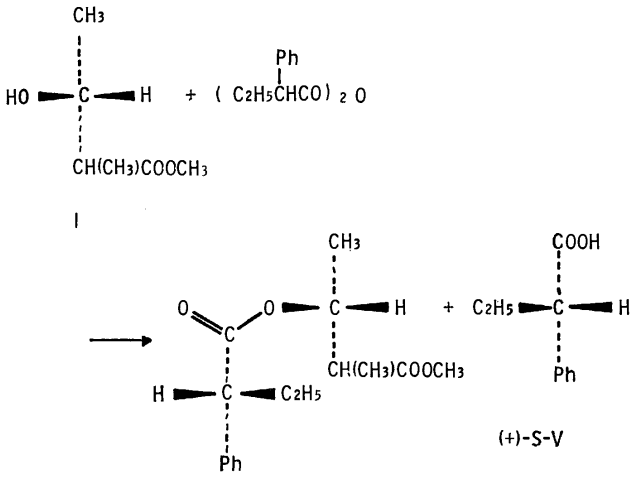
The optical resolution of each diastereomer was accomplished in the usual manner. The resulting isomer and resolving reagent were as follows: (+)-IIe and (+)-IIt by quinine, (−)-IIe by quinidine, and (−)-IIt by cinchonidine.

All the isomers of II were converted to their methyl ester (I) by the treatment of diazomethane. Thus, (+)-IIe was converted to (+)-Ie, (−)-IIe to (−)-Ie, (+)-IIt to (+)-It, and (−)-IIt to (−)-It. The configuration at the C-2 position of I was correlated to that of (+)-(*S*)-methyl 2-methylbutyrate (IV).[7] The conversion of I to IV was carried out in two steps:



From (+)-Ie and (−)-It, (+)-(*S*)-IV and (−)-(*R*)-IV were obtained respectively. Therefore, the configurations at the C-2 position of (+)-Ie and (+)-It are *S* while those of (−)-Ie and (−)-It are *R*.

The configuration at the C-3 position of I was determined by Horeau's method.[8] When an excess amount of (±)-2-phenylbutyric anhydride was treated with (+)-Ie, (+)-(*S*)-2-phenylbutyric acid was recovered. It was empirically demonstrated that when the configuration of I was that shown in Scheme 1, the recovered 2-phenylbutyric acid (V) had the (+)-(*S*)-enantiomer in excess. Therefore, the configuration at the C-3



Scheme 1.

position of (+)-Ie could be assigned to *R*. In the same manner, the reactions with both (+)-It and (−)-Ie gave (−)-(*R*)-V. Thus, the configurations at 3-C of (+)-It and (−)-Ie were assigned to *S*.

Table 1. Absolute configuration and optical rotation of methyl 3-hydroxy-2-methylbutyrate (I)

Isomer[a]	Absolute configuration	$[\alpha]_D^{20}$ (*c* 5, methanol)
(+)-*threo*-I	(2*S*,3*S*)	+36.80°
(−)-*thero*-I	(2*R*,3*R*)	
(+)-*erythro*-I	(2*S*,3*R*)	+14.32°
(−)-*erythro*-I	(2*R*,3*S*)	

a) The sign of each isomer shows the direction of α_D^{20} observed in neat.

The configuration and optical rotation of each isomer are listed in Table 1. The relative configurations at C-2 and C-3 assigned by Masken are consistent with the present results.

Experimental

The analytical GLC was carried out with a Shimadzu GC-4A gas chromatograph using a 3-m, 5-mm o.d. glass column packed with 5% NPGS on Chromosorb W at stated temperatures. The preparative GLC was carried out with a Shimadzu GC-3HA instrument using a 3-m, 8-mm o.d. stainless column packed with the same packing.

The optical rotations were measured with a Perkin Elmer 241 polarimeter at 20 °C under the stated conditions.

The NMR spectra were taken with a Hitachi R-24 spectrometer at 60 MHz. The IR spectra were taken with a Shimadzu IR-27G spectrometer. All the chemicals except as stated below were obtained from commercial sources and were used without further purification.

Methyl 2-Methyl-3-oxobutyrate (III). This was prepared from methyl acetoacetate and methyl iodide, bp 75—78 °C. GLC (at 90 °C) indicated a 98% purity; retention time, 9.1 min. Also there was 2% of methyl 2,2-dimethyl-3-oxobutyrate; retention time, 7.9 min.

Diastereoisomeric Methyl 3-Hydroxy-2-methylbutyrate (I). In an autoclave (1000 ml capacity), 300 g of III and 23 g of Raney nickel modified with DL-tartaric acid were placed. Hydrogen was added until the pressure reached 110 kg/cm², and then heating was commenced. After the temperature of the reaction mixture had become 65 °C, this temperature was maintained until the end of the reaction; after 24 h there was no fall in the pressure. After the removal of the catalyst, the distillation of the product gave 271 g of crude I, bp 79—81 °C/18 mmHg. GLC (at 90 °C) indicated that the products consisted of 39% of It (retention time 12.8 min), 58% of Ie (retention time 14.1 min), and 4% of unidentified impurities (retention times 11.0 and 15.2min).

Separation of threo-*I (It) and* erythro-*I (Ie).* The crude I (271 g) was saponified with 30% aqueous sodium hydroxide (300 ml) at room temperature. Most of the water was evaporated under reduced pressure, and the residue was acidified with 12M hydrochloric acid (120 ml) and they extracted with three 300 ml portions of ether. The evaporation of the ether from the combined extract gave 224 g of crude 3-hydroxy-2-methylbutyric acid (II). This was dissolved in 350 ml of ethanol and mixed with 180 g of cyclohexylamine under nitrogen. On cooling the solution overnight, a part of the salt was crystallized. Two successive recrystallizations of the crystalline part from 95% ethanol gave 166 g of cyclohexylammonium salt of IIe, mp 148 °C, Found: C, 59.74; H, 10.81; N, 6.34%. Calcd for $C_{11}H_{23}NO_3 \cdot (1/4)H_2O$: C, 59.56; H, 10.68; N, 6.31%. The attempts to eliminate the water from the sample resulted in failure, since the salt was decomposed with the evolution of cyclohexylamine on heating *in vacuo*. Small portions of the salt were acidified, and the liberated acid was converted to methyl ester with diazomethane. The GLC (at 90 °C) of the ester showed a single peak corresponding to the *erythro*-isomer; retention time, 14.3 min.

The mother liquids of the original crystallization and the first recrystallization were combined and concentrated to dryness. The residue was dissolved in 150 ml of 30% aqueous sodium hydroxide and washed with two 150 ml portions of ether. After reducing the water from the aqueous layer on a rotatory evaporator, the remaining dense sirup (*ca.* 70 ml) was mixed with 1100 ml of a methanol–acetone (1 : 5) mixture and crystallized at 0 °C. Two successive recrystallizations from methanol gave 48 g of sodium salt of IIt, mp 210—215 °C. The salt was too hygroscopic for the elemental analysis to be performed with a completely dried sample. The results of the elemental analysis were as follows; Found: C, 41.51; H. 6.52%. Calcd for $C_5H_9O_3Na \cdot (1/4) \cdot H_2O$: C, 41.52; H, 6.62, GLC (at 90 °C) of methyl ester derived from the sample showed a single peak of the *threo-isomer*; retention time, 12.5 min.

Optical Resolution of IIe. When a solution of cyclohexylammonium salt of IIe (150 g) in 1500 ml of water was passed through a column packed with 500 ml of Amberlite IR-120 (H^+ type), 2000 ml of an acidic eluate were collected. To the eluate 220 g of quinine was added, after which the mixture was stirred until the added base was completely dissolved. After the decoloration of the solution with activated charcoal, it was evaporated to dryness under reduced pressure to give crude quinine salt. Ethanol was added to the crude salt in portions at the boiling temperature until the salt was completely dissolved (*ca.* 180 ml of ethanol was required); on cooling, crystals of the quinine salt were precipitated. Recrystallization from ethanol was carried out in the manner described above. The progress of resolution was followed by the measurement of the optical rotation of the sodium salt derived from a small portion of quinine salt by treatment with aqueous sodium hydroxide. After three recrystallizations, the rotation reached a steady value, are unchanged by two further recrystallizations. The quinine salt of IIe

obtained amounted to 50 g; mp 140—141 °C, $[\alpha]_D^{20}$ −134 °C (*c* 1, H_2O). This was dissolved in 100 ml of water and treated with 5% aqueous sodium hydroxide with stirring until the pH of the mixture became 10. The removal of the liberated quinine by filtration and the evaporation of the filtrate gave a dense sirup, which was then dissolved in 50 ml of ethanol. After removing the insoluble matter by filtration, the filtrate was mixed with 250 ml of acetone to give 15 g of (−)-sodium salt of IIe as crystals, $[\alpha]_D^{20}$ −7.20 ° (*c* 10, H_2O), +13.61 ° (*c* 5, 3 M HCl).

The sodium salt (98 g), $[\alpha]_D^{20}$ +2.0 (*c* 10, H_2O), recovered from the combined mother liquids of the first and second crystallizations was dissolved in 1500 ml of water, after which the solution was passed through a column packed with 500 ml of Amberlite IR-120 (H^+ type). Into the acidic eluate (1700 ml), a 280-g portion of quinidine was added, and the mixture was stirred until all the base had dissolved. After removing the insoluble matter, the solution was evaporated to dryness to give crude quinidine salt. Four successive recrystallizations of the salt from acetone gave 110 g of quinidine salt of optically pure IIe; $[\alpha]_D^{20}$ 172 ° (*c* 10, H_2O), mp 100 °C. This was then converted to (+)-sodium salt of IIe in a yield of 30 g; $[\alpha]_D^{20}$ +7.53 ° (*c* 10, H_2O), −13.74 ° (*c* 10, 3M HCl).

(+)-Methyl erythro *3-Hydroxy-2-methylbutyrate (Ie).* The acid liberated from 10 g of (−)-sodium salt of IIe by treatment with 24 ml of 10 M HCl was extracted with three 30-ml portions of ether, and the combined extract was dried over anhydrous magnesium sulfate. After the solvent had been reduced, a slight excess of ethereal diazomethane was added to solution at 5 °C, and the mixture was kept at room temperature for 20 min. After the excess of diazomethane had then been decomposed with HCl, the solution was washed with water, dried over magnesium sulfate, and concentrated. The distillation of the condensate under reduced pressure gave 8.5 g of (+)-Ie, bp 75 °C/15 mmHg; α_D^{20} +11.30 ° (neat); GLC (at 90 °C); single peak; retention time, 14.0 min; NMR ($CDCl_3$, TMS), δ 1.18 (3H, d, J=6.4 Hz), 1.19 (3H d, J=7.0 Hz), 2.46 (1H, broad signal), 2.51 (1H, m), 3.70 (3H, s), 4.06 (1H, m), IR (neat) 3550, 2990, 2940, 1730, 1200, 1085, 1032 cm^{-1}. This product contains *ca.* 1% of water, as estimated from the results of the elemental analysis. A-2g portion of the product was boiled in 30 ml of dry benzene in order to remove the water as the benzene azeotrope and was then distilled at atmospheric pressure to give an analytical sample; bp 183 °C/763 mmHg; Found; C, 54.60; H, 9.46%. Calcd for $C_6H_{12}O_3$: C, 54.53; H, 9.15%. $[\alpha]_D^{20}$ +14.32 (*c* 5, CH_3OH), −4.04 (*c* 5, $CHCl_3$). The GLC, NMR, and IR data of the sample were identical with those listed above.

(−)-Methyl erythro *3-Hydroxy-2-methylbuthyrate (Ie).* By the same procedure mentioned before, 10 g of (+)-sodium salt of IIe was converted into (−)-Ie in a yield of 8.5 g, α_D^{20} −11.39° (neat). The bp, water content, retention time in GLC, and NMR and IR spectra were identical with those of the (+)-isomer.

Optical Resolution of IIt. A solution of sodium salt of IIt (98 g) in 1000 ml of water was passed through a column packed with 500 ml of Amberlite IR-120 (H^+ type). The acidic eluate (1700 ml) was mixed with 230 g of quinine and stirred until it was completely dissolved. The solution was then concentrated to 200 ml and allowed to stand overnight at 5 °C to give 137 g of quinine salt as crystals. After recrystallizing three times from water, the resulting 30-g portion of the salt (mp 154 °C, $[\alpha]_D^{20}$ −163 °(*c* 2, 50% ethanol)) was converted into (+)-sodium salt of IIt in a yield of 23 g, $[\alpha]_D^{20}$ +10.6 °(*c* 10, H_2O), +26.5 ° (*c* 5, 3M HCl).

The sodium salt (70 g, $[\alpha]_D^{20}$ −4.5 ° (*c* 10, H_2O)) recovered from the mother liquid was dissolved in 800 ml of water and treated with Amberlite IR-120 (H^+ type). The acid thus liberated was subjected to further resolution by the recrystallization of its cinchonidine salt from a mixture of acetone and 2-propanol (4 to 1). After recrystallizing five times, the salt was converted into (−)-sodium salt of IIt in a yield of 10 g, $[\alpha]_D^{20}$ −10.20 ° (*c* 10, H_2O), −26.30 ° (*c* 10, 3M HCl).

(+)- and (−)-Methyl 3-Hydroxy-2-methylbutyrate (It). (+)- and (−)-salt of IIt were converted into the methyl ester by the method described above.

From 10 g of (+)-sodium salt of IIt, 8.7 g of (+)-It were obtained; bp 83 °C/18 mmHg, water content, *ca.* 0.5%, α_D^{20} +34.80° (neat), GLC (at 90 °C), single peak; retention time, 13.0 min; NMR ($CDCl_3$, TMS) δ 1.18 (3H, d, J=7.2 Hz), 1.22 (3H, d, J=6.3 Hz), 1.19 (1H, broad signal), 2.47 (1H, m), 3.71 (3H, s), 3.82 (1H, m), IR (neat) 3550, 2990, 2960, 1730, 1200, 1100, 1045 cm^{-1}. The dehydrated analytical sample was prepared by the method described before; bp 181 °C/764 mmHg, Found: C, 54.51; H, 9.43%. Calcd for $C_6H_{12}O_3$: C, 54.53; H, 9.15%, $[\alpha]_D^{20}$ +36.80° (*c* 5, CH_3OH), +32.51° (*c* 5, $CHCl_3$). The GLC, NMR, and IR data of this sample were identical with those listed above.

From 10 g of (−)-sodium salt of IIt, 8.6 g of (−)-It were obtained; water content, *ca.* 1%, α_D^{20} −34.72° (neat). The GLC, NMR, and IR data of this compound were identical with those of the (+)-isomer.

Methyl 3-Iodo-2-methylbutyrate. Partially resolved (+)-Ie (5g, α_D^{20} +7.08° (neat)) was mixed with methyl tris-(phenoxy)phosphonium iodide prepared from 15 g of triphenyl phosphite and 4.3 g of methyl iodide. The mixture was then stirred at 50 °C overnight. As the product we extracted four 20-ml portions of hexane. The combined extract was washed with a 30-ml portion of water, dried over anhydrous sodium sulfate, and concentrated to one tenth of its original volume under reduced pressure. The distillation of the condensate gave 1.2 g of a diastereomeric mixture of methyl 3-iodo-2-methylbutyrate, bp 98—102 °C/12 mmHg. GLC (at 130 °C) indicated a 97.5% purity as a diastereomeric mixture (retention times 6.2 and 6.7 min) and 2.5% of an unidentified impurity (retention time 5.7 min). The NMR spectra (CCl_4, TMS) showed those signals; δ 1.32 and 1.33 (d, J=7.1) for the $C\underline{H}_3$–CH–$COOCH_3$ of each diastereomer, 1.90 and 1.98 (d, J=6.4) for the $C\underline{H}_3$–CHI– of each diastereomer, 2.5 (m) for –$C\underline{H}(CH_3)$–, 3.75 (s) for –O–$C\underline{H}_3$, and 4.05 (m) for –CHI–. The spectra were consistent with the structure of methyl 3-iodo-2-methylbutyrate. The IR spectra did not show any OH stretching, indicating the absence of the starting material in the product.

Partially resolved (−)-It (5 g, α_D^{20} −19.1° (neat)) was converted into methyl 3-iodo-2-methylbutyrate (1.1 g) by the method discribed before. The GLC, NMR, and IR data of the product were identical with those of the product derived from (+)-Ie.

Hydrogenolysis of Methyl 3-Iodo-2-methylbutyrate. Into an atmospheric pressure hydrogenation vessel which had been filled with hydrogen, methyl 3-iodo-2-methylbutyrate derived from (+)-Ie (0.8 g), magnesium oxide (0.5 g), and a Raney nickel catalyst (1.8 g in 10 ml of methanol) were introduced. The mixture was shaken at 45 °C for 48 h under an atmospheric pressure of hydrogen. After the removal of the insoluble matter by filtration, the filtrate was subjected to flash distillation at 50 mmHg. The distillate collected in a cold trap was transferred into an evaporator fitted with a Snyder column and was concentrated to 1.5 ml on heating under atmospheric pressure. GLC (at 50 °C) indicated that the condensate consisted of methyl 2-methylbutyrate and methanol

in a ratio of 1 to 10, with an accompanying trace amount of a high-boiling substance. The preparative GLC (at 40 °C) of the condensate gave pure methyl 2-methylbutyrate (IV), $[\alpha]_D^{20}$ +14.4° (*c* 4, methanol). The GLC, NMR, and IR data of the product were identical with those of the authentic compound prepared from racemic 2-methylbutyric acid (Tokyo Kasei Kogyo Co., Ltd.)

In the same manner as has been presented before, methyl 3-iodo-2-methylbutyrate was converted into IV, $[\alpha]_D^{20}$ −11.7° (*c* 4, methanol). The GLC, NMR, and IR data of the product were identical with those of an authentic compound.

Kinetic Resolution of (±)-2-Phenylbutyric Anhydride with I. A solution of (±)-2-phenylbutyric anhydride (0.6), (+)-Ie (0.1 g), and pyridine (2 g) in 10 ml of benzene was kept at room temperature for 12 h and then a 15-ml portion of water was added. The mixture was stirred for 30 min, a 30-ml portion of dilute hydrochloric acid was added, and the new mixture was extracted with 50 ml of ether. The ether layer was washed with water and extracted with a 50-ml portion of a 5% aqueous sodium hydrogencarbonate solution. The aqueous extract was acidified with dilute hydrochloric acid, followed by extraction with ether. The ether extract was dried over anhydrous magnesium sulfate and then evaporated to dryness to give 0.16 g of 2-phenylbutyric acid, which had α_D^{20} +0.80° in 2 ml of benzene.

The reactions of (−)-Ie and (+)-It with 2-phenylbutyric anhydride were carried out as before. The values of α_D^{20} (0.16 g of a sample in 2 ml of benzene) of the recovered 2-phenylbutyric acid were −0.73° for (−)-Ie and −0.96° for (+)-It. The NMR and IR spectra of each acid were identical with those of an authentic compound (Wako Pure Chemical Industries, Ltd.).

The authors wish to express their thanks to Professor Yoshiharu Izumi and Dr. Tadao Harada for their helpful suggestions. They also wish to thank Mmes. Aiko Kobatake and Mihoko Yamamoto for their elemental analysis. This work was supported in part by a Scientific Research Grant from the Ministry of Education, Japan (110308).

(Received June 8, 1977)

The title complex crystallizes in the monoclinic space group $P2_1/c$. The unit-cell dimensions are $a=11.287(5)$, $b=5.110(3)$, $c=26.391(3)$ Å, and $\beta=107.07(2)°$. The crystal structure was solved by a direct method. By block-diagonal least-squares refinements, the R-value dropped to 0.069. All the nitrogen and oxygen atoms in the complex participate in the hydrogen bonding. No prominent overlapping between pyridine and indole rings is observed in the crystal. Both molecules are hydrogen-bonded to form infinite-layered structures perpendicular to the c-axis; those structures are held together by van der Waals contacts.

Pullman and Pullman[1] showed that the indole moiety of tryptophan was the best electron donor in amino acids, and Isenberg and Szent-Györgyi[2] presented evidence of charge-transfer interaction in the complex of tryptophan and NAD. Since then, a number of investigations have been undertaken to establish the precise mechanism of such interactions as indole derivatives and NAD or FAD as a model for protein-coenzyme interaction,[3–7] and indole derivatives and nucleic acid or its constituent as a model for protein-nucleic acid interaction.[8–12] As a result, it has been suggested that one of the main factors controlling these interactions is a charge-transfer force between the indole ring and the aromatic ring.[13] Recently, Herriott *et al.*[14] determined the crystal structure of 1-[2-(3-indolyl)ethyl]-3-carbamoylpyridinium chloride as a model of tryptophan–NAD interaction and observed the overlapping of the indole ring and the cationic pyridinium ring. To investigate to what extent a protonation is actually important for the interaction of the indole ring and the pyridinium ring, we tried to crystallize the molecular complex, with indole-3-acetic acid (IAA) as a donor and nicotinamide (NA) or *N*-methylnicotinamide as an acceptor. The crystal size of the IAA: *N*-methylnicotinamide complex is not suitable for X-ray analysis at present. We wish to report here the crystal structure of a 1: 1 molecular complex of NA and IAA.

Experimental

Equimolar amounts of NA and IAA were dissolved in a 99.5% ethanol solution. After evaporation at room temperature, light-brown, plate-shaped crystals were obtained. The melting point of the crystals is 138—139 °C. Preliminary oscillation and Weissenberg photographs showed the crystals to be monoclinic and the space group to be $P2_1/c$, judging from the systematic absent spectra.

The crystallographic data are shown in Table 1. The density was measured by the floatation method in a benzene–carbon tetrachloride mixture. Three-dimensional intensity data were collected with a computer-controlled four-circle diffractometer with Ni-filtered Cu $K\alpha$ radiation. By means of the $\omega/2\theta$ scan technique, a total of 1918 independent reflections were collected within $\sin\theta/\lambda$ less than 0.54 Å^{-1}. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption. The intensities of three standard reflections measured for every 50 reflections of the data set showed no decrease in intensity during the run. The scan speed was 4°/min, and 5-s background measurements were performed at each terminus of the scan. All the numerical calculations were carried out on an NEAC 2200-700 computer of the Computation Center of Osaka University using "UNICS" programs (1973).[15] Atomic scattering factors in "International Tables for X-Ray Crystallography," Vol. 4 (1974)[16] were used.

TABLE 1. CRYSTAL DATA

$C_6H_6ON_2 \cdot C_{10}H_9O_2N$	
$a=11.287$ (5) Å	$F.W.$ 297.31
$b=5.110$ (3)	Space group $P2_1/c$
$c=26.391$ (3)	$Z=4$
$\beta=107.07$ (2)°	$V=1455.1$ Å^3
$D_m=1.353$ g cm^{-3}	μ(Cu $K\alpha$)$=9.21$ cm^{-1}
$D_x=1.357$	

Determination and Refinement of the Structure

The structure was solved by the direct method with the "MULTAN" program[17] using 443 reflections with $|E|\geqq 1.20$. An E-map computed with the phase set of the highest figure of merit, 1.302, revealed the positions of all the non-hydrogen atoms. After least-squares refinement, a difference map revealed the positions of all fifteen hydrogen atoms (peak height: 0.3—0.5 e Å^{-3}), which were included in all subsequent refinements with isotropic temperature factors.

The final least-squares refinement was made with a weighting scheme of this form: $w=0.15$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 34.0$, and $w=\{1+0.776(|F_o|-34.0)\}^{-1}$ for $F_o>34.0$. In the last cycle of refinement, none of the positional parameters shifted more than one-third of the estimated standard deviation. The final R-value including $F_o=0$ is 0.069. The observed and calculated structure factors are listed in Table 2.[18]

Results and Discussion

A perspective view of the NA and IAA molecules projected on each ring plane is presented in Fig. 1,

The Molecular Structure. Tables 6 and 7 show the bond lengths and angles, with their standard deviations.

NA Molecule: The NC5–NC6 bond length, 1.364 Å, is apparently smaller than the averaged C–C bond length in the pyridine ring;[19] this tendency is also observed in the crystal structures of 3,3′-dicarbamoyl-1,1′-trimethylenedipyridinium dichloride monohy-

Atoms with asterisks define the plane.

drate,[20] 3-carbamoyl-1-methylpyridinium 9-adenylacetate dihydrate[21] and 3-carbamoyl-1-methylpyridinium picrate, chloride, and iodide.[22]

The bond angles are reasonable compared with those of the other pyridine derivatives.[23–27] The dimensions of the amide group are similar to those cited by Bracher and Small.[28] The planarity of the NA molecule is given in Table 8. The NC7 atom deviates slightly from the pyridine-ring plane (0.09 Å). The amide group is almost planar, and the dihedral angle between the amide group and the pyridine-ring plane is 30.6°. The conformation of NA in the complex is different from that of the isolated molecule.[24]

The torsion angle, τ(NC2–NC3–NC7–NO9), is 29.3° in this complex and 155.9° in the isolated molecule, and they are in opposite directions to each other. The torsional angles found in the pyridine derivatives can be grouped into three angles: 150, 35, and 0°. A theoretical calculation of the conformation of the NA molecule[29] predicts that the most stable conformation has the torsional angle, τ, at 150°, and the next one, at 35°. The conformation of the present NA molecule belongs to the second stable conformation.

IAA Molecule: The bond lengths and angles are similar to those reported for IAA[30–32] and indole derivatives.[33] The planar carboxyl group is not in a resonance state because the IC11–IO13 bond has a strong double-bond character (1.192 Å). The IC10 atom is slightly out of the indole-ring plane (0.08 Å), contrary to 5-methoxyindole-3-acetic acid[31] and the isolated IAA.[30] The dihedral angle between the carboxyl group and the indole ring is 104.9°.

The torsion angle, χ(IC2–IC3–IC10–IC11), is 80.4° in this complex, 97.7° in the isolated IAA, and 113.4° in the 5-methoxytryptamine: IAA complex,[32] while the torsional angle, Ψ(IC3–IC10–IC11–IO13), is −6.4° in this complex, −11.7° in the isolated IAA, and −29.4° in the 5-methoxytryptamine: IAA complex. These facts show that such a conformation of the IAA molecule would be most stable regardless of the environmental changes in the crystal.

The Crystal Structure. Figure 2 shows the packing diagram viewed down the b-axis, where the dotted lines represent the hydrogen bonds (see Table 9). All the nitrogen and oxygen atoms in the complex participate in hydrogen bonding. The neighboring NA molecules related by a center of symmetry form a hydrogen-bonded dimer (NN8···NO9=2.913 Å, NN8–NN8HA···NO9=179.4°), similar to that found in a number of amide compounds,[34] but not in the isolated NA. The NN8

atom is also hydrogen-bonded to the NO9 atom of the NA molecule, translated to the b-axis by one unit. Therefore, these hydrogen bonds form a network system connecting the NA molecules on the ab-plane, as is shown in Fig. 3.

On the other hand, the IO12 atom of the IAA molecule participates in a strong hydrogen bond[35)] with the NN1 of the NA molecule, with a distance of 2.691 Å and the IO12–IO12H···NN1 angle of 176.3°; then, the IO13 atom is hydrogen-bonded to the IN1 atom of the neighboring indole ring, related by a diad screw axis with a distance of 3.008 Å. The hydrogen bonds and short contacts of less than 3.5 Å found in the crystal are listed in Table 9. Many short contacts were found between the carboxyl group in IAA and the pyridine ring in the neighboring NA molecule.

As a whole, both NA and IAA molecules are hydrogen-bonded to form infinite-layered structures perpendicular to the c-axis, structures which are held together by van der Waals contacts. The prominent overlapping between the pyridine and indole rings was

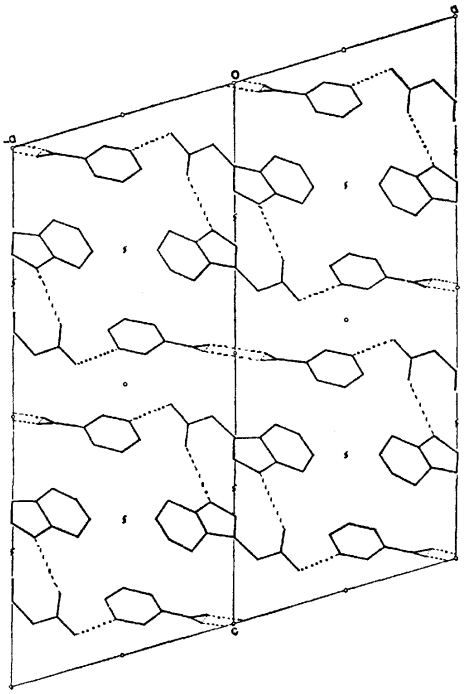

Fig. 2. Molecular packing of IAA–NA viewed down the b-axis. The dotted lines represent the possible hydrogen bonds.

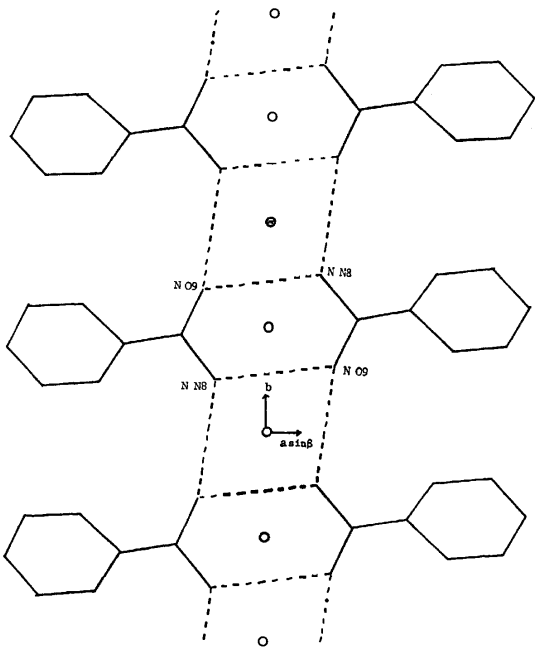

Fig. 3. The hydrogen bond network connected the NA molecules on the ab-plane.

not observed in this crystal, contrary to our expectations, but Ash *et al.*[36)] recently found a prominent overlapping between the pyridinium and indole rings, arising from the π-π interactions in the crystal of the 3-carbamoyl-1-methylpyridinium *N*-acetyl-*l*-tryptophanate complex. This fact may indicate that the quaternary nitrogen atom in 1-methylnicotinamide, similar to NAD^+, is a necessity in the case of a specific charge-transfer interaction between the indole ring and the pyridine ring.

(Received June 8, 1977)

The title complex crystallizes in the monoclinic space group of $P2_1/c$. The unit-cell dimensions are $a=6.673(4)$, $b=19.017(8)$, $c=13.394$ (7) Å, and $\beta=110.54(2)°$. The crystal structure was solved by a direct method. By block-diagonal least-squares refinements, the R-value converged to 0.062. In this complex, a salt bridge is found between the anionic carboxyl group of phenylacetic acid (PAA) and the cationic amino group of tryptamine (TPA). All the hydrogen atoms attached to the nitrogen atoms participate in the hydrogen bonding. The two complex molecules are hydrogen-bonded around a center of symmetry to form one unit, which is held together by van der Waals contacts in the b- and c-directions. Each unit is also stabilized by forming a hydrogen bond with the unit of the neighboring cell translated in the a-direction.

The 1:1 molecular complex of tryptamine (TPA) and phenylacetic acid (PAA) was crystallized, and its structure was determined in order to investigate the interaction between the benzene and indole rings, because the existence of interaction between tyrosine and tryptophan residue has been indicated by fluorescence studies.[1-4]

Experimental

Equimolar amounts of TPA and PAA were dissolved in a 50% ethanol aqueous solution. After evaporation at room temperature, transparent platelet crystals were obtained. Preliminary oscillation and Weissenberg photographs indicated the crystal to be monoclinic and the space group to be $P2_1/c$, judging from the systematic absent spectra.

TABLE 1. CRYSTAL DATA

$C_8H_8O_2 \cdot C_{10}H_{12}N_2$	
$a=6.673(4)$Å	*F.W.* 296.35
$b=19.017(8)$	Space group $P2_1/c$
$c=13.394(7)$	$Z=4$
$\beta=110.54(2)°$	$V=1591.7$Å^3
$D_m=1.230$ g cm^{-3}	μ(Cu $K\alpha$)$=7.61$ cm^{-1}
$D_x=1.237$	

The crystallographic data are shown in Table 1. The density was measured by the floatation method in a benzene-carbon tetrachloride mixture. The three-dimensional intensity data were collected with a computer-controlled four-circle diffractometer using Ni-filtered Cu $K\alpha$ radiation. By means of the ω-2θ scan technique, the intensities of a total of 2108 independent reflections within $\sin\theta/\lambda$ less than 0.54 Å^{-1} were collected and corrected for the Lorentz and polarization factors, but not for the absorption. Standard reflections measured for every 50 reflections of the data set showed no decrease in intensity during the run. The scan speed was 4°/min, and the backgrounds were measured in 5 s. All the numerical calculations were carried out on an NEAC 2200-700 computer of the Computation Center of Osaka University using the "UNICS" program (1973).[5] The atomic scattering factors used were in "International Tables for X-Ray Crystallography," Vol. 4 (1974).[6]

Determination and Refinement of the Structure

The phases of 331 reflections ($E\geqq1.2$) were determined by the symbolic addition method, and the following three-dimensional E-map revealed reasonable peaks corresponding to the heavy atoms.

The structure was refined by the least-squares method, and a difference map revealed the positions of all twenty hydrogen atoms (peak height: 0.35—0.45 e Å^{-3}). The final least-squares refinement, including hydrogen atoms with isotropic temperature factors, was performed with a weighting scheme of this form: $w=1.26$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq28$, and $w=\{1.0+2.0(F_o-28.0)\}^{-1}$ for $F_o>28.0$. In the last cycle of refinement, no parameters shifted more than one-fifth of the estimated deviation. The final R-value was 0.062, including $F_o=0$.

The residual fluctuations in the difference Fourier map were within the range from −0.3 to 0.3 e Å^{-3}. The observed and final calculated structure factors are listed in Table 2.[7]

Results and Discussion

The perspective view of the component molecule with the atomic numbering and the a-axis projection

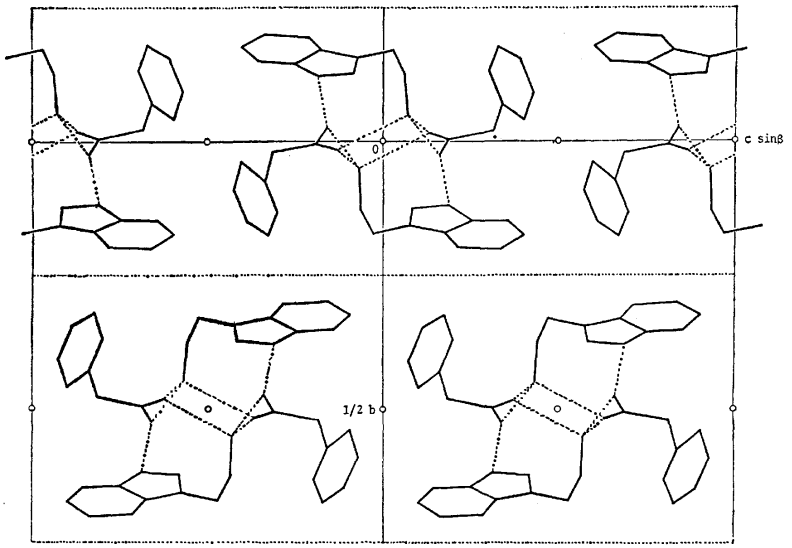

Fig. 2. Molecular packing of TPA–PAA viewed down the a-axis.

of the molecular packing are presented in Figs. 1 and 2 respectively, where the dotted lines indicate the hydrogen bonds. The atomic coordinates and thermal parameters, with their estimated standard deviations for non-hydrogen atoms, are given in Tables 3 and 4. The coordinates with isotropic thermal parameters for hydrogen atoms are shown in Table 5.

The Molecular Structure. Tables 6 and 7 show the bond lengths and angles, with their standard deviations. The equations of the least-squares planes for the benzene ring, the carboxyl group, the indole ring, and the aminoethyl group, and the deviations of the individual atoms from these planes are listed in Table 8.

PAA Molecule: The planarity of the benzene ring including the PC7 atom is good, and the bond lengths within the benzene ring are in the range of 1.377 to 1.387 Å (average value: 1.380 Å), significantly shorter than in the standard aromatic ring (1.395±0.003 Å)[8] as well as the smaller PC1–PC7 bond length (1.509 Å). The carbon-oxygen bond lengths in the carboxyl group are both short, but are nearly identical, and the PC7–PC8 bond length (1.521 Å) is close to that of the normal $C(sp^3)$–$C(sp^2)$ single bond.[9] The torsional angles, χ(PC2–PC1–PC7–PC8) and ϕ(PC1–PC7–PC8–PO9), are 64.8° and −168.1° respectively. As these values are similar to those in β-phenethylamine (χ=72.6°, ϕ=−171.1°),[10] the precursor of PAA in a living body, both conformations might be fixed in their metabolic

process.[11]

The dihedral angle between the benzene ring and the carboxyl group is 110.1°.

TPA Molecule: Three hydrogen atoms found in the difference map are tetrahedrally bound to the nitrogen atom of the aminoethyl side chain, indicating the amino group to be in a cationic form, $-NH_3^+$.

The bond length of TC11–TN12, 1.491 Å, is similar to the normal values reported previously.[12–14] The bond lengths and angles of the indole moiety are normal, in the range found in the crystal structures of indole derivatives.[11] The planarity of the indole ring is better than those of the other tryptamine derivatives.[12,13,15]

The TH1 atom deviates significantly from the indole ring plane, causing the TN1–TN1H···PO9 angle to be 163.0°. The conformation of the tryptamine molecule found in this complex, (χ(TC2–TC3–TC10–TC11)= 107.2° and ϕ(TC3–TC10–TC11–TN12)=−59.8°), is a stable one according to the energy calculation by Pullman *et al.*[16]

Although it is influenced by the various crystal-packing forces, it is noteworthy that a similar conformation is also found in the tryptamine hydrochloride[15] and tryptamine picrate[13] crystals, suggesting that this conformation is intrinsic and the most probable one for the tryptamine molecule. The dihedral angle between the indole ring and the aminoethyl group is 77.8°

The Crystal Structure. In the TPA-PAA complex, a salt bridge is formed between the anionic carboxyl group of PAA and the cationic amino group of TPA. The possible hydrogen bonds and the short contacts less than 3.5 Å are given in Table 9. All the hydrogen atoms attached to either an oxygen or nitrogen atom participate in the hydrogen bondings, forming infinite chains along the a-axis, as is shown in Fig. 3. There is no possibility of indole ring-benzene ring interaction, the dihedral angle between these planes being 119.3°.

However, the carboxyl plane of PAA lies fairly parallel to the plane of the indole ring of TPA (dihedral angle, 9.4°), with a 3.52 Å separation on the average, as is shown in Fig. 4. Even though these contact distances are slightly longer than the van der Waals separation, the possibility can not be discarded of the interaction

picrate,[14] tryptophan picrate, and tryptamine picrate.[13] As a whole, each of the two complex molecules is hydrogen-bonded around a center of symmetry to form one unit (two TPA and two PAA), and each is stabilized by forming a hydrogen bond with the unit of the neighboring cell, translated in the a-direction (see Figs. 2 and 3), a structure which is held together by van der Waals contact in the b- and c-directions.

In this hydrogen-bonding mode, as a complex of 5-methoxytryptamine–5-methoxyindole-3-acetic acid

and 5-methoxytryptamine-indole-3-acetic acid,[12] one of the carboxyl oxygen atoms forms two hydrogen bonds with two neighboring NH_3^+-groups. The other participates in two hydrogen bonds with a neighboring NH_3^+-group and a nitrogen atom in the indole ring, which may strengthen the hydrogen bond between anionic COO^- and cationic NH_3^+.

A Study of the Mass Spectrum of Phenazine

Shizuko EGUCHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received June 27, 1977)

The mass spectrum of phenazine, a nitrogen-containing aromatic compound, was investigated in detail using a combination of ion kinetic energy spectroscopy and defocusing technique. In the fragmentation of the singly charged ions the molecular ion lost H· in the first stage to give an $[M-1]^+$ or $[M-2]^+$ ion, which was degraded *via* the expulsion of CN· or C_2H_2 in the next stage and of HCN or C_2H_3· in a later stage. Doubly charged ions also appeared in considerable intensity, and the fragmentation sequence differed significantly from that of the singly charged ions.

Although there are some reports[1-4] about the mass spectra of phenazine and substituted phenazines, it cannot be said that the fragmentation mechanism has been fully clarified, because the investigations have usually been carried out in applying mass spectrometry to the analysis of bacterial metabolites. In the present paper, the mass spectrum of phenazine was investigated in detail by determining the elemental compositions of all the fragment ions using high resolution mass spectrometry and by sorting out the metastable ions using a combination of ion kinetic energy spectroscopy and the defocusing technique. Thus, many points which need to be corrected were found in the fragmentation pathway already reported for the phenazine nucleus.

Results and Discussion

In the ordinary mass spectrometry, phenazine, a nitrogen-containing aromatic compound, exhibited a simple spectrum which consisted of weak fragment peaks, except for the intense molecular peak at *m/e* 180, as shown in Fig. 1. For the purpose of determining the multiplicity of the peaks and the elemental composition of each ion, the high resolution mass spectrum was measured with a computer on-line system and/or with a pen-recording system under the conditions of slower magnetic scanning and narrower widths of entrance and collector slits. Seventeen fragment peaks, listed in Table 1, were confirmed to be constituted of two or three ions.

On the other hand, the IKE spectrum[5,6] of phen-

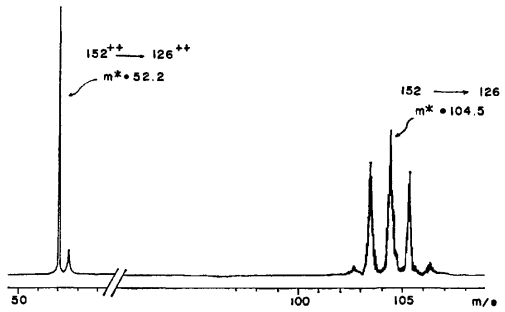

Fig. 3. Metastable ion spectrum at $0.8290E$.

azine was taken over a range of electric sector voltage from $1.0E$ to $0.5E$ (Fig. 2), and then the range corresponding to the width of each peak in this spectrum was searched with magnetic current scanning at $0.0005E$ intervals of the electric sector voltage to determine the number of metastable ions. If some metastable ions are included in a certain peak of the IKE spectrum, they appear in general as separated peaks in the metastable ion specra, such as that shown in Fig. 3. Since each of these metastable peaks, however, slightly varies in the intensity and m/e value depending upon the electric sector voltage used, the reading of the m/e value of a certain metastable ion at the maximum intensity was determined as the mass unit of this metastable ion.[7,8] Based on such analysis, peak E in the IKE spectrum of phenazine was determined to include four metastable ions, at m/e 103.5, 104.5, 105.4, and 52.2, for each of which one or several transitions were listed in Table 2. These transitions were assigned from the elemental compositions of singly and doubly charged ions which are listed in Tables 1 and 4. As shown in Table 2, the observed metastable ion value contained several metastable ions because a metastable ion value could not measured with an accuracy better than 1000 ppm in the present work. Accordingly, a few possible transitions were proposed for the observed metastable ion value; similar results had been reported in the mass spectrum of *N*-cyclohexylguanidine.[9] Similar analyses were also carried out on the other peaks (A—D, F—I) of the IKE spectrum.

Thus, peaks A, B, and C of the IKE spectrum, which were very close to the main beam ion, were characterized as the expulsion of H· or H_2 from the main beam ion and the remaining peaks, from D to I, as the expulsion of C_2H_2, CN·, C_2H_3·, or HCN from the molecular ion or several fragment ions, as listed in Table 3. Among them, transitions due to the loss of a hydrogen molecule such as 180→178+2 and 153→151+2, have not yet been reported in the mass spectra of phenazine and substituted phenazines, nor in those of other nitrogen-containing aromatic compounds. However, no metastable ions, which would correspond to the direct expulsion of fragments such as C_2H_2, CN·, C_2H_3·, or

HCN from the molecular ion, could be detected. From the above observation, it may be concluded that the major fragmentation of phenazine undergoes nuclear cleavage not directly, as described by other workers,[1-4] but after the loss of H· or H_2.

On the basis of the elemental composition of the fragment ions and the transition assignment of the metastable ions, the significant fragmentation sequence of the singly charged ion in phenazine was deduced as shown in Scheme 1. The loss of H· from the molecular ion (1) yielded a $C_{12}H_7N_2$ ion (*m/e* 179) (2) as the most abundant fragment ion in the spectrum. The ion (2) gave two kinds of *m/e* 153 ions, $C_{10}H_5N_2$ (6) and $C_{11}H_7N$ (7), in a ratio of 30: 70 under expulsion of C_2H_2 and CN·, respectively. The ion (6) produced C_9H_5N (*m/e* 127) (17) under expulsion of CN·, and the ion (7) subsequently lost C_2H_2, CN·, or H_2 to be degraded to C_9H_5N (*m/e* 127, 68%) (17), $C_{10}H_7$ (*m/e* 127, 32%) (18), or $C_{11}H_5N$ (*m/e* 151) (10). There are two pathways for the C_9H_5N ion (17), but the route *via* the $C_{11}H_7N$ (7) was thought to be predominant from the above-mentioned relative intensity of the intermediate ions.

The molecular ion was further degraded *via* the second pathway, including successive losses of H_2 and CN·, to give a $C_{11}H_6N$ ion (*m/e* 152) (8), which was then degraded to a C_8H_4 ion (*m/e* 100) (28) *via* a C_9H_4N (*m/e* 126) (19) and a $C_{10}H_6$ (*m/e* 126) (20) in a ratio of 20: 80, and which lost H· to give an ion of $C_{11}H_5N$ (*m/e* 151) (10). In the formation of $C_{12}H_8$ ion (*m/e* 152, 6%) (9) which was degraded to $C_{10}H_6$ (*m/e* 126, 20%) (20) under expulsion of C_2H_2, the metastable ion corresponding to the transition from molecular ion to the ion (9) was not detected.

Furthermore, the ion (10) which was formed by loss of H_2 from the ion (7) and of H· from the ion (8) degraded to C_8H_3 (*m/e* 99) (29) *via* a C_9H_3N (*m/e* 125) (21) and a $C_{10}H_5$ ion (*m/e* 125) (22) in a ratio of 7: 93.

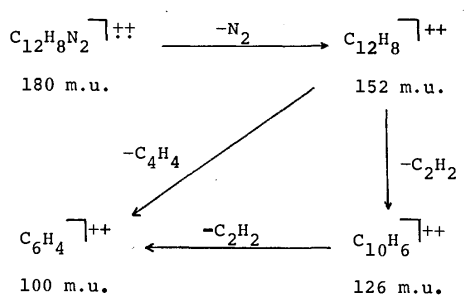
spectrum of phenazine, two ions appeared at m/e 90 and 63, and also the metastable ion corresponding to the transition between both ions could be detected at m/e 44.1 by the above-mentioned analysis of the IKE spectrum. However, the aromatic structure of phenazine and the fact that the metastable ion was far too weak (peak H in Fig. 2) compared with the intensities of the precursor and daughter ions in the ordinary mass spectrum were expected that doubly charged ions existed in the mass spectrum of phenazine. For these reason, the $2E$ doubly charged ion spectrum was taken by setting the electric sector voltage at twice the value used for accelerating.[6,10-12] This exhibited the characteristic ions shown in Fig. 4, whose elemental compositions were determined from the exact masses accordingly to a procedure[12] reported previously (Table 4). These observations revealed that m/e 90, 76, 63, and 50 ions in the ordinary spectrum were partly composed of doubly charged ions of 180, 152, 126, and 100 mass units respectively. The major fragmentation sequence of the doubly charged ions of phenazine was thus deduced to be Scheme 2.



Scheme 2. Fragmentation sequence of doubly charged ions of phenazine.

Ion kinetic energy spectra of organic molecules show peaks corresponding to ions having energies in excess of that of the main beam ion. It has been shown that the peaks correspond to charge-exchange reactions of

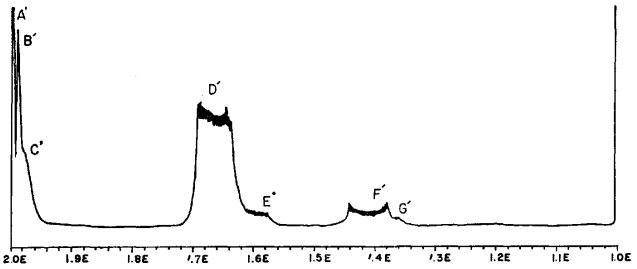


Fig. 5. High energy IKE spectrum from E to $2E$.

doubly charged ions or to decompositions of metastable clusters of ions in high energy IKE spectra of aromatic hydrocarbons.[11] The above reactions were expected from the existence of the doubly charged ions detected in the phenazine, and therefore the high energy IKE spectrum was measured over the range from E to $2E$ (Fig. 5). Peaks that appear between E to $2E$ in the high energy IKE spectrum may be due to one of two separate processes including doubly charged ions: collision-induced charge transfers and charge separation reactions. Peak A', which appears exactly at $2.0E$, is

a) γ: Electric sector voltage ratio, E_1/E.

due to the collision-induced reaction in which doubly charged ions are converted to singly charged ions without loss of any mass units. Peak B′ is due to a reaction in which a doubly charged ion not only loses a charge but also a fragment of one mass unit:

$$m_1^{2+} \xrightarrow{\text{collision}} m_1^{+} \longrightarrow (m-1)^{+}$$

or

$$m_1^{2+} \longrightarrow (m-1)^{2+} \xrightarrow{\text{collision}} (m-1)^{+}$$

But these two processes cannot be distinguished in the present work. Similarly, peak C′ is due to a reaction in which two hydrogen atoms with one charge are lost. Other peaks, D′ to G′, were constituted of some broad dish-topped peaks which were known to be attributable to $m_1^{2+} \rightarrow m_2^{+} + (m_1 - m_2)^{+}$ type decompositions of the doubly charged ions.[13] Mass analyses of the above-mentioned peaks were carefully carried out with a interval of $0.0005E$ in the electric sector voltage to determine metastable ions. The resulted assignments of reactions and transitions are listed in Table 5.

Conclusion

The metastable ion transition, which occurred in the first free region of the mass spectrometer, was analyzed in detail by utilizing the ion kinetic energy spectroscopy and the defocusing technique. It was clarified that the molecular ion of phenazine lost H· or H_2 in the first stage of the fragmentation to give $[M-H]^+$ or $[M-H_2]^+$ ion, which was degraded step by step *via* expulsion of CN· or C_2H_2 and successive expulsion of HCN or C_2H_3·.

Doubly charged ions were also confirmed to occur to a certain extent in the mass spectrum of phenazine. The metastable transition of these ions was similarly analyzed and a fragmentation sequence was proposed.

Experimental

The high resolution mass spectra were taken using an on-line system which combined a HITAC-10 computer with a Hitachi RMU-7L double focusing mass spectrometer: ionizing energy 70 eV, ionizing current 80 μA, and accelerating voltage 3.2 kV. For determining multiplicity of peaks and elemental composition of ions, singly changed ion spectra were taken at 10 and 8 μm widths of entrance and collector slits respectively (normally 20 and 17 μm). The IKE and metastable ion spectra were examined on the RMU-7L modified with a metastable defocusing attachment.

On the other hand, the $2E$ doubly charged ion spectrum was taken at an electric sector voltage twice as large as the normally used accerating voltage, under 5×10^{-6} Torr of source pressure. For analysis of the transition from a $2E$ doubly charged ion to two singly charged ions, the high energy IKE spectrum was taken over the sector voltage from E, at which the main beam of stable ion was transmitted, to $2E$, and the mass units of the metastable ions were determined under the condition of the $2E$ spectrum measurment.

The author wishes to express her hearty gratitude to Prof. Shûichi Hayashi and Asst. Prof. Mitsuru Nakayama, Faculty of Science, Hiroshima University, for suggesting this investigation and for the constant guidance in the course of this study. Thanks are also given to Prof. Hisao Nakata, Aichi Kyoiku University, for his helpful discussions.

^{13}C Spin-lattice Relaxation and Molecular Structure. II.[1] The Application of ^{13}C Spin-lattice Relaxation Times (T_1) to Assignments of Signals in the Proton-decoupled ^{13}C NMR Spectrum of 5-Ethyl-5*H*-dibenzophosphole

Teruyuki HAYASHI and Hiroshi NAKANISHI

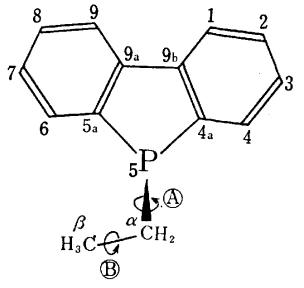
National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received July 4, 1977)

The spin-lattice relaxation times (T_1) of the ^{13}C nuclei in 5-ethyl-5*H*-dibenzophosphole (**1**) were studied. The ^{13}C NMR signals of the quarternary carbons of **1** in the aromatic region, whose assignments are very difficult by other techniques, were successfully assigned by means of the spin-lattice relaxation method. The dipolar relaxation terms and their reciprocal values were calculated by the use of the internuclear-distances between the carbon nuclei and hydrogen or phosphorus ones, and were compared with the observed T_1 values. It was found by studying the observed T_1's of the ethyl group in **1** that the rotation around the C–P bond is more strongly restricted than that around the C–C single bond.

As the recent development of the FT method in NMR spectroscopy has facilitated the measurement of ^{13}C spin-lattice relaxation times (T_1), the application of the T_1 method to the study of molecular geometries and motions is a recently developing field.[1-3] Moreover, the T_1 method has become a useful method for the assignment of signals in the ^1H-decoupled ^{13}C NMR spectra of various organic molecules.[4]

In the study of the catalytic hydroformylation of olefins by rhodium- or cobalt-tertiary phosphine complexes, dibenzophospholyl derivatives have been revealed to be efficient catalyst ligands.[5] In the course of the spectroscopic elucidation of the effectiveness of the catalysts, it was necessary to assign the ^{13}C NMR signals of the dibenzophospholes.[5] Moreover, the signal assignments of ring carbons are important for the study of the aromaticity of phospholes.[6] However, it is very difficult to assign the signals of quaternary carbons in dibenzophospholes by techniques such as those employing the chemical shifts and the coupling patterns of J_{CH} in the ^1H-undecoupled ^{13}C spectrum. In addition, the coupling constants between the carbon and phosphorus nuclei (J_{CP}) cannot give us fully conclusive information about the signal assignments, as will be described later. In the view of these factors, the spin-lattice relaxation method is expected to be useful to overcome the difficulty.



In this report, we will describe the first application of the T_1 method to the ^{13}C NMR signal assignments of a tertiary phosphine, choosing 5-ethyl-5*H*-dibenzophosphole (**1**) as an example. The internal rotation of the ethyl group of **1** will also be discussed briefly.

Experimental

Materials. The 5-ethyl-5*H*-dibenzophosphole (**1**) and ethyldiphenylphosphine (**2**) were prepared according to a procedure similar to that used for 5-benzyl-5*H*-dibenzophosphole[7] in a pure nitrogen atmosphere. **1** and **2** were NMR spectroscopically pure.

Spectral Measurements. The ^{13}C NMR spectra were recorded on a NEVA NV-14 spectrometer operating at 15.087 MHz with a Varian 620/L computer (16 K) for a pulse FT method. The T_1's were determined by the usual 180°-τ-90° pulse-sequence method. The pulse-delay time was set at five times greater than the longest T_1 to be measured. Free induction decays were accumulated for from 40 to 400 times. The spectral width was 1000 Hz for the aromatic carbon signals and 600 Hz for the alkyl carbon signals. In order to avoid the oxidation of the phosphine and the influence of the dissolved oxygen on the T_1 value of each nucleus, the sample containing degassed 20 vol% of acetone-d_6 was sealed under pure nitrogen. The T_1 values were evaluated by means of the least-squares method, using from 6 to 8 data points. The errors of the T_1 values thus obtained are smaller than *ca.* 10%.

Results and Discussion

The ^1H-decoupled ^{13}C spectrum of **1** is shown in Fig. 1. The peaks are alphabetically labelled from the lowest field as is shown in Fig. 1. Although **1** has eight kinds of carbons, the ^1H-decoupled ^{13}C spectrum consists of fourteen peaks due to various couplings (J_{CP}) between carbon-13 and phosphorus nuclei. The usual and easiest way to assign these signals is to obtain the information by investigating the coupling constants, J_{CH} in a ^1H- and ^{31}P-undecoupled ^{13}C spectrum or J_{CP} in a ^1H-decoupled ^{31}P-undecoupled ^{13}C spectrum. In the former technique, however, full information cannot be obtained because of the considerable overlapping of peaks in the aromatic region,* although in the alkyl region, the higher-field peaks of M and N can be assigned to the methyl carbon based on their coupling patterns. On the other hand, in the latter technique, it was expected that the assignment might be made by

* It can only be said that the A—D peaks are assigned to quarternary carbons at the 4a(5a) and 9a(9b) positions.

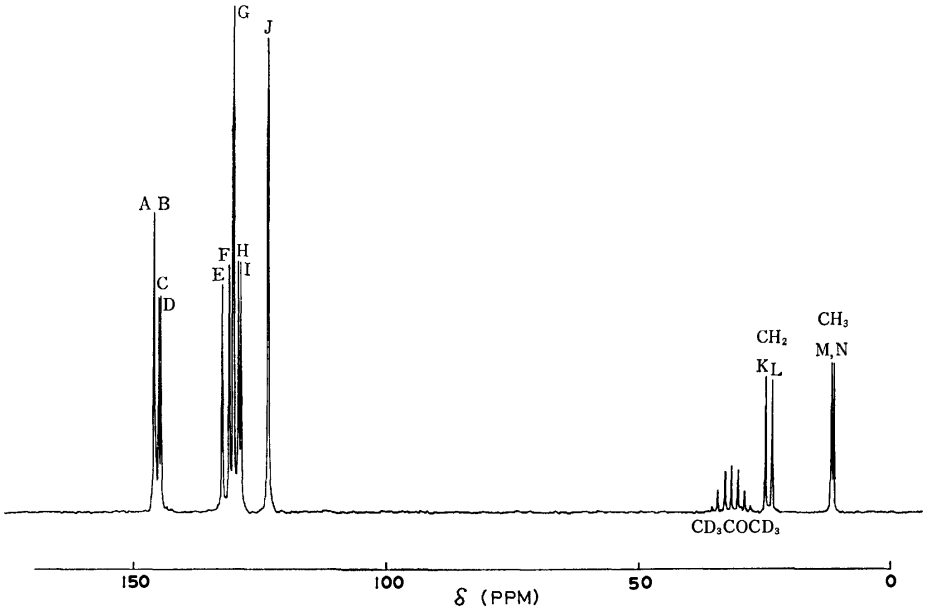


Fig. 1. The ^{1}H decoupled ^{31}P undecoupled ^{13}C NMR spectrum of **1** (at 15.087 MHz, spectrum width: 3300 Hz, pulse width: 35 μs, pulse delay: 25 s, accumulation: 3200 times, sensitivity enhancement: 0.2 s, ^{2}D lock).

considering the differences in the values of the coupling constants between the phosphorus and carbon nuclei at the α, β, γ, and δ positions. Unfortunately, however, the coupling constant between α-carbon and the phosphorus nuclei ($^{\alpha}J_{CP}$) is not always larger than that between β-carbon and the phosphorus nuclei ($^{\beta}J_{CP}$).[8,9] In addition, it was found that the order in the coupling constants of methylene and methyl carbons ($^{\alpha}J_{CP}$ and $^{\beta}J_{CP}$) is reversed in **1** and in ethyldiphenylphosphine (**2**), as is shown in Table 1. Therefore, the straightforward assignment of, for example, quarternary carbons at 4a(5a) and 9a(9b) cannot be made from the J_{CP} coupling constants.

Table 1. The coupling constants[a] between the phosphorus and α- and β-carbon nuclei of the ethyl group in **1** and **2**

Compound	$^{\alpha}J_{CP}(CH_2)$ Hz	$^{\beta}J_{CP}(CH_3)$ Hz
1	19.0	6.6
2[b]	10.9	16.9

a) The signs of these coupling constants are not taken into account. b) The values reported in Ref. 8 are the reverse of our data. Probably, the literature data is somehow a mistake.

The third method for the assignment is the comparison of chemical shifts of **1** with those of structurally analogous compounds, for example, **2**. Since the five-membered ring in **1** is strained because of the deviations of the bond angles at the sp^2 carbon and phosphorus atoms from 120 and 109.5° respectively, and since the aromaticity[6] in the ring of **1** may make the situation more complex, the chemical shifts of C(4a), C(5a), C(9a), and C(9b) in **1** cannot be directly compared with those in **2**.

Therefore, the spin-lattice relaxation method was employed to overcome these difficulties, since T_1 is a quantity closely related to molecular structures and motions.

As the ^{13}C NMR spectrum of **1** in this study is a ^{1}H-decoupled and ^{31}P-undecoupled ^{13}C spectrum, its spin system contains spin-spin couplings (J_{CP}). It is generally considered[10–16] that the T_1's in such a spin system with spin-spin coupling as **1** are complex and different from those in a spin system without spin-spin couplings, because the presence of cross-correlation phenomena between the coupling nuclei may influence the T_1 values. For example, the longitudinal components (T_1 components) of the magnetic moments in the former spin system do not show simple exponential decays by a dipole-dipole relaxation mechanism, whereas in the latter spin system (*e.g.*, in a ^{1}H- and ^{31}P-decoupled ^{13}C spectrum of **1**) they show simple exponential decays. In our case, however, the cross-correlation is expected to be negligibly small because of the extremely remote resonances of carbon-13 and the phosphorus nuclei: $|J_{CP}|/(\omega_P-\omega_C) \ll 1$, ($|J_{CP}| \leqq 21.3$ Hz, and $\omega_P-\omega_C=9.2$ MHz at 15.1 MHz for ^{13}C nuclei). If this is not the case, the decay curves of the longitudinal components of the magnetic moments in the ^{13}C nuclei of **1** cannot be described by a single exponential decay.[11] Actually, the experimentally obtained decay curves unambiguously show straight lines in all peaks of **1**. The decay curves of Peaks A—D are shown in Fig. 2 as examples. Moreover, if the cross-correlation effect is large, the T_1 value of one peak in the doublet signal in **1** must be different from that of the other peak.[10–11] However, the obtained "apparent" T_1 value** of one peak in the doublet is almost the same as that of the other counter-peak, within the limits of experimental error, as is

** T_1 values which are evaluated by means of the usual method used for a decoupled spin system.

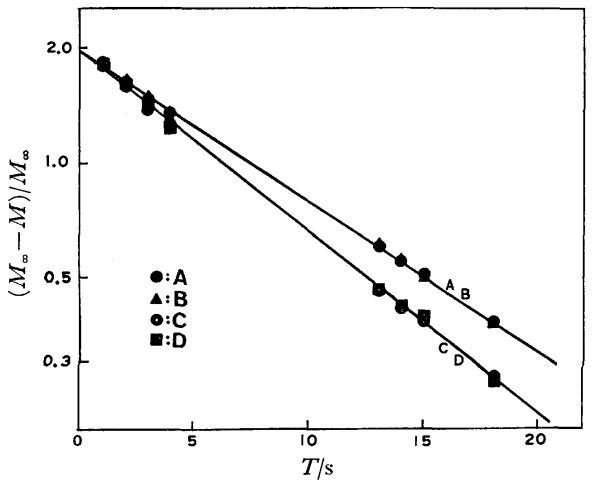

Fig. 2. The semi-log plot of $(M_\infty - M)/M_\infty$ versus pulse delay time (T) of the peaks A—D in the ^1H decoupled ^{31}P undecoupled ^{13}C NMR spectrum of **1**.

TABLE 2. THE CHEMICAL SHIFTS (δ, FROM TMS INTERNAL), COUPLING CONSTANTS ($|J_{CP}|$), T_1 VALUES, AND ASSIGNMENTS OF THE PEAKS IN **1**

Peak	δ / ppm	$\lvert J_{CP}\rvert$ / Hz	T_1 / s	Carbon
A, B	144.7	1.5	10.9, 11.3	9a, 9b
C, D	143.6	6.7	9.3, 9.2	4a, 5a
E, F	130.6	21.3	0.45, 0.44	
G	129.1	0	0.41	
H, I	127.9	7.4	0.40, 0.39	
J	122.1	0	0.44	
K, L	22.5	19.0	0.56, 0.49	$\alpha(CH_2)$
M, N	9.5	6.6	1.8, 1.9	$\beta(CH_3)$

shown in Table 2. Thus, these results indicate that, in the case of **1**, the "true" T_1 values should be almost the same as the "apparent" T_1 values of the doublet peaks of the carbon-13 signals. From now on, for convenience, in this paper we will refer to the "apparent" T_1 values as T_1 values.

Although ^{13}C nuclei can be relaxed by four mechanisms (dipole-dipole, spin-rotation, chemical shift anisotropy, and scalar mechanisms), the latter three mechanisms can be excluded in the case of **1**, because **1** is a considerably large molecule and the obtained T_1's are relatively small (<12 s). The T_1 by the dipole-dipole mechanism is described as the following equation:

$$\frac{1}{T_1^{dd}} = \hbar^2\gamma_C^2\left\{\gamma_H^2\sum_i\frac{N_i}{r_i(CH)^6} + \gamma_P^2\frac{1}{r(CP)^6}\right\}\tau_c, \quad (1)$$

where γ_C, γ_H, and γ_P are the gyromagnetic ratio of carbon-13, hydrogen, and phosphorus respectively, N is the number of equivalent nuclei, r is the internuclear distance, and τ_c is the correlation time. It can be assumed, considering the molecular shape, that an isotropic (or pseudoisotropic) overall tumbling motion

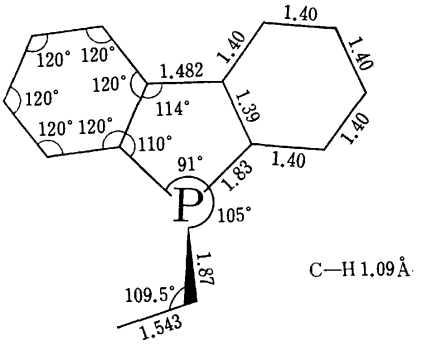

Fig. 3. The assumed bond lengths and bond angles of **1**.

occurs in **1**. Thus, the common correlation time τ_c, may be adopted for carbons in the dibenzophospholyl moiety, but for the ethyl carbons the τ_c's by both the tumbling motion and the internal rotation must be considered.

The molecular geometry of **1** was assumed to be as is shown in Fig. 3. The bond lengths and bond angles described in Fig. 3 were assumed by analogy with ethane, benzene, triphenylphosphine,[17] benzylphosphole,[18] and a metal complex of **1**.[19] According to Eq. 1, the value of the dipolar term, $[\sum_j\hbar^2\gamma_C^2\gamma_{X(j)}^2(\sum_i N_i/r_i^6)]$ (X(j): nuclei which relax the carbon-13 nucleus), and its reciprocal, $[T_1\cdot\tau_c]$, were calculated*** using the internuclear-distances, r_{CH} and r_{CP}, evaluated from these data. The results are shown in Table 3.

TABLE 3. THE CALCULATED DIPOLAR TERMS[a] AND THEIR RECIPROCAL ($T_1\cdot\tau_c$) VALUES OF THE CARBONS IN **1**

Carbon	Dipolar term / 10^{10} s^{-2}	$T_1\cdot\tau_c$ / 10^{-11} s^2
1, 9	2.18	4.59
2, 8	2.22	4.50
3, 7	2.22	4.50
4, 6	2.19	4.57
4a, 5a	0.0568	176
9a, 9b	0.0428	234
$\alpha(CH_2)$	4.41	2.27
$\beta(CH_3)$	6.51	1.54

a) $\equiv\sum_j\hbar^2\gamma_C^2\gamma_{X(j)}^2\left(\sum_i\frac{N_i}{r_i^6}\right)$.

Quarternary Carbons. C(4a) mainly relaxes by one β-hydrogen, four γ-hydrogen, and one α-phosphorus nuclei, while C(9a) mainly relaxes by one β-hydrogen, three γ-hydrogen, and one β-phosphorus nuclei. The calculations show that the contribution to the relaxation by δ-positioned nuclei is negligibly small. The differences in the number and position of the counter-atoms for relaxation cause the deviation of the dipole-dipole relaxation times of the carbons with a common tumbling

*** The deviation of the assumed bond-length from the real one is expected to be not more than the amount whose contribution is estimated to be less than 5% of the $T_1\cdot\tau_c$ value, judging from the X-ray analylsis data of triphenylphosphine,[17] benzylphosphole,[18] and the metal complex of **1**.[19]

motion. The observed T_1 values of Peaks A—D are much greater than those of Peaks E—J. This indicates that Peaks A—D must be assigned to the quarternary carbons, 4a(5a) and 9a(9b). In comparison with the observed T_1 and calculated $T_1 \cdot \tau_c$ values (see Tables 2 and 3), Peaks A and B are assigned to carbons 9a and 9b, and Peaks C and D, to carbons 4a and 5a. The observed T_1 ratio between C(9a) and C(4a) is in excellent agreement with the calculated T_1 ratio: $T_1(9a)^{obsd}/T_1(4a)^{obsd}=1.2$ and $T_1(9a)^{calcd}/T_1(4a)^{calcd}=1.3$. This means that the few assumptions made in this investigation are sufficiently valid.

Aromatic CH Carbons. All the calculated $T_1 \cdot \tau_c$ values of aromatic CH carbons are almost the same. Although the numbers and positions of the counter-atoms for the relaxation are different from each other in the aromatic CH carbons, the contribution to the relaxation by the α-hydrogen nuclei is overwhelmingly large. The observed T_1 values are almost the same, within the limits of experimental error (0.39—0.45 s). The equality in the observed T_1's of four kinds of aromatic CH carbons and the same calculated $T_1 \cdot \tau_c$ values indicate that all these carbons have a common correlation time, τ_c; an isotropic tumbling motion occurs in **1**. Therefore, we cannot obtain any information about the assignment of the aromatic CH carbons in **1** by means of the T_1 technique.

Ethyl Carbons. As has been described before, Peaks K and L were assigned to the methylene carbon, and Peaks M and N, to the methyl carbon, judging from their coupling patterns in ^{1}H-undecoupled ^{13}C spectrum. As the methylene carbon is bonded to two hydrogen (H) atoms and one phosphorus atom as the counter-atoms for the dipolar relaxation, and the methyl carbon, to three H atoms, the T_1's of these carbons may be expected to be different from each other. The calculated $T_1 \cdot \tau_c$ values are 2.27×10^{-11} s^2 for CH_2 and 1.54×10^{-11} s^2 for CH_3. However, the observed T_1's are the opposite; 0.53 s for CH_2 and 1.8 s for CH_3. The results indicate that the correlation times (τ_c) of the methylene and methyl carbons are quite different from each other, and the observed T_1's show that the rate of the internal rotation of the methyl group (B) is much faster than that of the internal rotation of the ethyl group (A) (*cf.* Eq. 1). This is an unexpected result, for the rotation around the C(sp^3)–C(sp^3) bond is known to be more strongly restricted than that around the C–P bond. For example, it is known from microwave spectroscopy that the rotational barrier around the C–C bond in isobutane is higher than that around the C–P bond in trimethylphosphine,[20] and that the barrier in ethane[21] is higher than that in methylphosphine,[22] as is shown below: V/(kcal/mol); $(CH_3)_3CH$: 3.9,[20] $(CH_3)_3P$: 2.6,[20] CH_3-CH_3: 3.0,[21] and CH_3PH_2: 1.96.[22] This interesting fact, that the A roration in **1** is more strongly restricted than the B rotation, may be explained by considering that the substituent at the phosphorus atom (*i.e.*, the *o,o'*-biphenylene group) is much bulkier than that at the β-carbon atom (*i.e.*, three hydrogen atoms); this steric repulsion effect may mainly raise the barrier to rotation around this C–P bond, although the bond-length (1.87 Å) between C_α and P atoms is considerably longer than that (1.54 Å) between C_α and C_β atoms.

The authors wish to express their hearty thanks to Drs. Ikuei Ogata, Masato Tanaka, and Osamu Yamamoto of this Laboratory for their help in this study.

(Received July 19, 1977)

The Diels-Alder reactions of cyclopentadiene with ethyl (*E*)- and (*Z*)-3-nitrocrotonate were carried out to give only the (2+4)-nitro adduct as a mixture of three diastereomers, while that of the diene with ethyl (*Z*)-3-nitrocinnamate gave two kinds of cycloaddition products, (2+2)- and (2+4)-nitro adducts. All the nitro adducts were reduced with aluminum-amalgam to give the corresponding mono- and dihydroxyamino compounds, in which vicinal *endo*-ethoxycarbonyl-*endo*-hydroxyamino derivatives cyclized readily to give tricyclic compounds containing isoxazolidinone ring. The stereochemistry of all the new compounds were established on the basis of IR and NMR spectroscopic analyses.

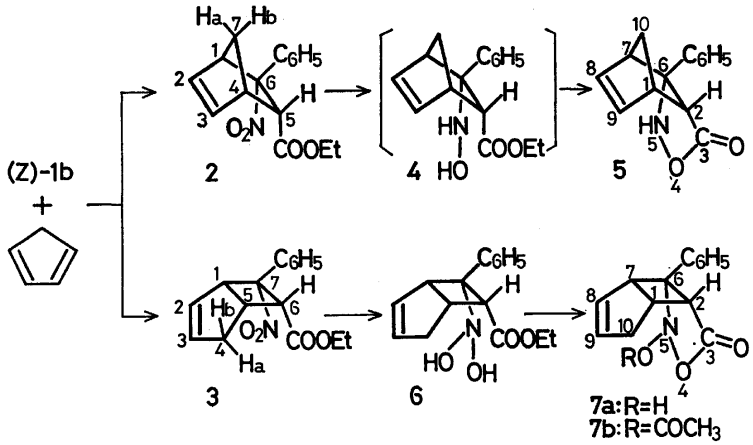
In previous papers, we reported the stereospecific formation of ethyl 3-nitro-2-alkenoate (**1**) by the elimination reaction of 2-acetoxy- or 2-chloro-3-nitroalkanoate with a base[2] and the assignment of the geometric configuration of the olefinic compounds by the photoisomerization of the (*E*)-isomer into the (*Z*)-isomer and by the their NMR analysis.[3] Although ethyl 3-nitrocinnamate (**1b**) could not be isomerized, we have recently reported on (*Z*)-geometry as a convenient configurational determination of **1b** by the application of the Diels-Alder reaction.[4]

In this paper, we wish to report further chemical proof of the configuration of ethyl (*E*)- and (*Z*)-3-nitro-2-crotonate (**1a**) by a similar method, together with a detailed description of that of (*Z*)-**1b**; *i.e.*, the cycloaddition products of **1a** with cyclopentadiene were examined to determine whether or not they form an isoxazolidinone ring between vicinal ethoxycarbonyl and hydroxyamino groups after reduction with aluminum–amalgam (Al–Hg). The structures and stereochemistry of all the new products were established on the basis of IR and NMR spectroscopic data as well as the results of elemental analyses.

Results and Discussion

Reaction of 1 with Cyclopentadiene. According to the method reported previously by Umezawa *et al.*,[5,6] a solution of **1b** and cyclopentadiene in benzene was heated in a sealed tube at 100 °C for 1 h to give a semi-solid substance. Its subsequent chromatographic separation on a silica gel column, using benzene and acetone as eluents, gave two kinds of cycloaddition products (**2** and **3**) in fairly good yields. Similarly, the reaction of (*Z*)-**1a** with cyclopentadiene gave an adduct (**10**) in a 75.5% yield. Furthermore, that of (*E*)-**1a** with cyclopentadiene in benzene with stirring at room temperature for 24 h was carried out to give two kinds of adducts (**8** and **9**) in 64.2 and 15.0% yields respectively. All the products were obtained as colorless crystals.

The IR spectrum of all the new cycloaddition products showed a strong band at 1720—1730 due to an ethoxycarbonyl group, strong bands at 1535—1550 and 1340—1360 due to a nitro group, and a weak band in the



Scheme 1.

1630—1655 cm^{-1} region due to a ring carbon-carbon double bond. Moreover, from a comparison of the NMR spectra, it was found that the spectral pattern of **3** was considerably different from those of the other products (**2**, **8**, **9**, and **10**). The chemical shifts and coupling constants were assigned as shown in Table 3 by means of the double-resonance method. In the NMR spectrum of **3** (Table 3), the signals at δ 2.12 (d, 1H, $J_{4b,5}$=2.0 Hz), 2.66 (dd, 1H, $J_{4a,4b}$=18.0 Hz), 3.86 (d, 1H, $J_{5,6}$=8.3 Hz), 3.88 (m, 1H, 5-H) and 5.60 (d, 1H, $J_{1,5}$=8.3 Hz) are attributable to geminal protons at the 4-position and *cis*-protons at the 6-, 5-, and 1-positions respectively, while, in those of **2**, **8**—**10**, the signals of the 7- and 5-protons appeared at δ 1.42—2.08 (d, 2H, $J_{7a,7b}$=9.0—9.5 Hz) and at 3.30—4.13 (d, 1H, $J_{4,5}$=2.5—3.0 Hz) respectively. In general, (2+4)-cycloaddition products such as norbornenes and (2+2)-cycloaddition products such as bicyclo[3.2.0]heptenes can be readily distinguished from each other by means of the coupling constants between their geminal protons at the 4- and 7-positions, which have been reported to range from 8 to 10 Hz in the former adduct[5-8] and from 15 to 20 Hz in the latter.[9-11] Accordingly, **3** was identified as a (2+2)-nitro adduct. Moreover, from the *cis*-addition principle and the *endo*-rule in the Diels-Alder reaction, and the absence of any long-range coupling between the 7- and 5-protons, which are out of the *W*-letter relationship, it is reasonable to conclude that Compounds **2**, **9** and **10** are 5-*endo*-ethoxycarbonyl-6-*endo*-nitro-6-*exo*-phenylbicyclo[2.2.1]hept-2-ene, 5-*endo*-ethoxycarbonyl-6-*exo*-nitro-6-*endo*-methylbicyclo[2.2.1]-hept-2-ene, and 5-*endo*-ethoxycarbonyl-6-*endo*-nitro-*exo*-methylbicyclo[2.2.1]hept-2-ene respectively. On the other hand, from the presence of the long-range coupling (d, $J_{5,7a}$=3.0 Hz) which was collapsed by the irradiation of 5- or 7a-proton, the configuration of **8** was determined to be 5-*exo*-ethoxycarbonyl-6-*endo*-nitro-6-*exo*-methylbicyclo[2.2.1]hept-2-ene. Since the two J values between *cis* protons on cyclobutane ring are equal, Compound **3** was concluded to be 6-*endo*-ethoxycarbonyl-7-*endo*-nitro-7-*exo*-phenylbicyclo[3.2.0]hept-2-ene. These results indicate that the reaction of (*Z*)-**1b** proceeds stereospecifically to form only an *endo*-adduct and that those of (*E*)- and (*Z*)-**1a** follow the *endo*-rule unambiguously (see Table 1), because the *exo*-isomer, 5-*exo*-ethoxycarbonyl-6-*exo*-nitro-6-*endo*-methylbicyclo[2.2.1]hept-2-ene (**11**), could not be obtained.

The thermal (2+2)-cycloaddition of **1b** to diene seems to be rare, although many photochemical cycloadducts from diene and dienophiles have been reported in the literature.[9,12] However, interestingly, it was found that neither the (2+2)- nor the (2+4)-cycloaddition of **1** to the diene proceeded photochemically.

Reduction of the Nitro Adducts with Al–Hg. The *cis* stereochemistry of the nitro and ethoxycarbonyl groups of Compounds **2**, **10** (5-*endo*-6-*endo*), and **3** (6-*endo*-7-*endo* structure) were further substantiated by the facts that they were reduced to give the corresponding mono- or dihydroxyamino derivatives, which were immediately cyclized between vicinal ethoxycarbonyl and hydroxyamino groups to give tricyclic isoxazolidinone derivatives.

Although Compounds **8** and **9** were treated with Al–Hg in ether to give the corresponding 6-hydroxyamino derivatives (**12** and **13** respectively), a similar reduction of **2** and **10** readily gave 6-*exo*-phenyl- and methyl-*endo*-4-oxa-5-azatricyclo[5.2.1.$0^{2,6}$]dec-8-en-3-one (**5** and **15**) respectively *via* unstable intermediates, the corresponding 6-*endo*-hydroxyamino derivatives (**4** and **14**), in which **4** could not be isolated purely. Moreover, the treatment of **14** with *N*-bromosuccinimide (NBS) in chloroform gave the *N*-bromo derivative of **15** (**16**), which could not be derived from **15** and NBS. Surprisingly, the similar reduction of **3** gave stable colorless

Measured in $CDCl_3$.

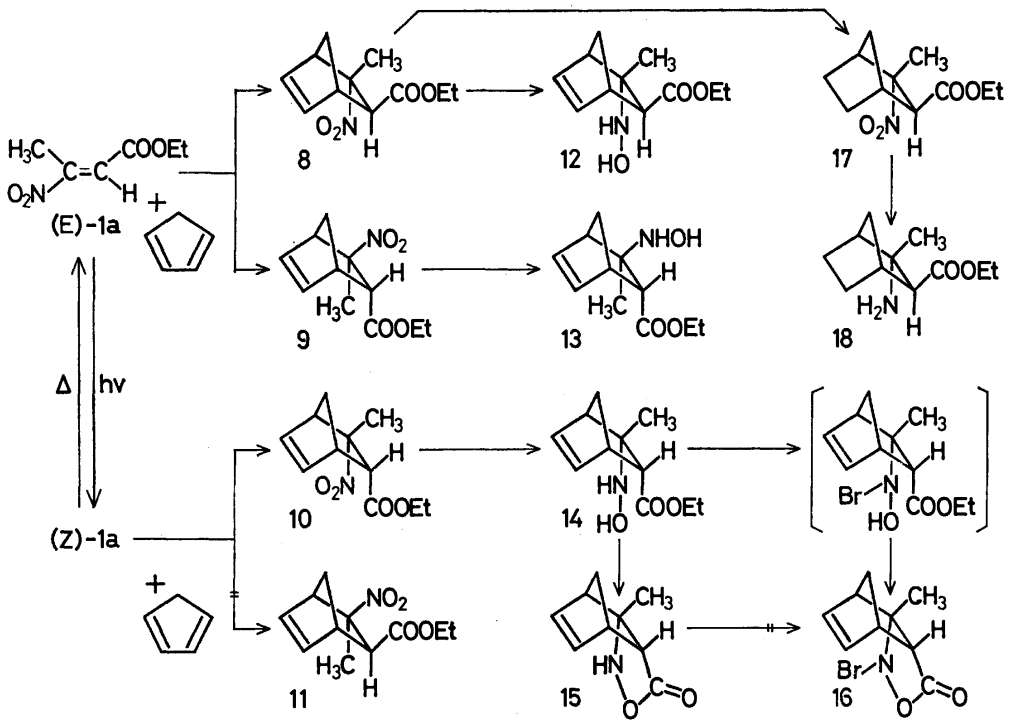
crystals of unexpected 6-*endo*-ethoxycarbonyl-7-*endo*-dihydroxyamino-7-*exo*-phenylbicyclo[3.2.0]hept-2-ene (**6**), which was subsequently heated in dry benzene at 50 °C to give the expected 5-hydroxy-6-*exo*-phenyl-*cis*-*cisoid*-*cis*-4-oxa-5-azatricyclo[5.3.0.$0^{2,6}$]dec-8-en-3-one (**7a**) in a 52.5% yield. In order to prove the presence of the hydroxy group, **7a** was acetylated by the usual procedure, using acetic anhydride and pyridine at room temperature, to give the corresponding 5-acetoxy derivative (**7b**) in a 48.5% yield.



Scheme 2.

The structures of all the new reduction products and tricyclic compounds were characterized spectroscopically (see Tables 3 and 4) and gave satisfactory elemental analyses (see Tables 1 and 2), although the attempt at the measurement of the NMR spectrum of **14** was unsuccessful.

On the other hand, the catalytic reduction of **8** with Raney-nickel in ethanol at room temperature was carried out to give the corresponding 6-nitronorbornene (**17**) in the initial step; the further reduction of **17** gave the corresponding 6-aminonorbornene (**18**) in an almost quantitative yield.

In the IR spectrum, all the hydroxyamino and the tricyclic compounds showed a weak band in the 1630—1640 cm^{-1} region due to a ring double bond. Particularly, the IR spectra of **6** and **7a** showed the strong absorption bands of hydroxyl groups at 3450 and 3225, and 3340 cm^{-1}, respectively. The disappearance of the hydroxyl absorption and the appearance of a carbonyl band at 1775 cm^{-1} upon the acetylation of **7a**, and the presence of a molecular peak (*m/e* 244 (M^+)) in the mass spectrum of **7a**, supported the presence of an *N*-hydroxyisoxazolidinone ring in **7a**.

In the NMR spectra of **12** and **13**, the signals of the two protons at δ 5.50 and 5.62 are both attributable to the hydroxyamino group, while, in that of **6**, the broad signals of two protons of dihydroxyamino groups appeared in the δ 2.05—3.00 and 7.20—7.70 regions. It seemed that the chemical shift in the lower field is due to a hydrogen bond between one of the hydroxyl groups and the ethoxycarbonyl groups.

In conclusion, the cycloaddition reaction and reduction sequences are generalized for the chemical determination of the configurations of β-nitro olefinic acids.

Experimental

All the boiling and melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrometer. The NMR spectra were measured with a JNM-PS 100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethylsilane as the internal standard.

Starting Materials. The (*E*)- and (*Z*)-isomers of **1a** and the (*Z*)-isomer of **1b** were prepared and confirmed by a method previously reported.[2-4]

Preparation of 2 and 3. A solution of (*Z*)-**1b** (2.9 g, 9 mmol) and cyclopentadiene (0.9 g, 14 mmol) in dry benzene (20 ml) was heated in a sealed tube at 100 °C for 1 h. After the removal of the benzene under reduced pressure, the residual semi-solid thus obtained was chromatographed on a silica gel column, using benzene–acetone (50: 1, V/V) as the eluent, to give two fractions. After each of the fractions had been concentrated under reduced pressure, the first one gave **2** and the second one gave **3** both as colorless crystals.

Preparation of 10. In an analogous manner, a reaction mixture of (*Z*)-**1a** (8.0 g, 50 mmol) and cyclopentadiene (4.0 g, 60 mmol) in benzene (100 ml) was worked up to give a viscous syrup, which gradually solidified to give only colorless crystalline **10**.

Preparation of 8 and 9. A solution of (*E*)-**1a** (8.0 g, 50 mmol) and cyclopentadiene (4.0 g, 60 mmol) in dry benzene (100 ml) was stirred overnight at room temperature. After the removal of the benzene under reduced pressure, a pale yellow semi-solid was obtained. The residue was recrystallized from ethanol to give colorless crystalline **8.** Subsequently, the mother liquor was evaporated to give a residual syrup. The yellowish residue was distilled under reduced pressure to give a viscous syrup, which gradually solidified to give colorless crystalline **9**.

Preparation of 5. A solution of **2** (2.9 g, 10 mmol) in ether (10 ml) was vigorously stirred into a suspension of Al–Hg (made from Al (1.5 g) and $HgCl_2$ (1.5 g))[13] in ether (50 ml)

at room temperature. After a few minutes, the ether began to reflux. During the addition of the above solution, a few drops of water were added at 20-min intervals to maintain refluxing. After the addition of the solution of **2** had been completed, the stirring was continued for 4 h. The mixture was then extracted thoroughly several times with ether (200 ml) and finally twice with ethyl acetate (60 ml). The combined extracts were dried over anhydrous magnesium sulfate and then evaporated to give colorless crystalline **5**.

Preparation of ***6***. In an analogous manner, a reaction mixture of **3** (1.5 g, 5 mmol) with Al–Hg (from Al (1.0 g) and $HgCl_2$ (1.0 g)) in ether (30 ml) was worked-up to give colorless crystalline **6**, after stirring for 3 h.

Preparation of ***12***. A mixture of **8** (4.5 g, 20 mmol) and Al–Hg (from Al (4 g) and $HgCl_2$ (4 g)) in ether (100 ml) was stirred for 6 h; there after a similar work-up gave **12**, 5-*exo*-ethoxycarbonyl-6-*endo*-hydroxyamino-6-*exo*-methylbicyclo-[2.2.1]hept-2-ene, as colorless crystals.

Preparation of ***13***. Similarly, Compound **9** was treated with Al–Hg in ether to give **13**, 5-*endo*-ethoxycarbonyl-6-*exo*-hydroxyamino-6-*endo*-methylbicyclo[2.2.1]hept-2-ene, as colorless crystals.

Preparation of ***14*** *and* ***15***. Similarly, Compound **10** was treated with Al–Hg in ether, giving colorless crystals (**14**), 5-*endo*-ethoxycarbonyl-6-*endo*-hydroxyamino-6-*exo*-methylbicyclo[2.2.1]hept-2-ene. The crystals obtained were gradually converted to **15** by refluxing in carbon tetrachloride for 1 h.

Preparation of ***16***. Into a solution of **14** (1.1 g, 5 mmol) in chloroform (20 ml) we stirred NBS (0.7 g, 5 mmol), portion by portion below 10 °C. After stirring for 1 h, the resulting solution was washed once with water and then dried over anhydrous magnesium sulfate. The solution was evaporated to give **16**, 5-bromo-6-*exo*-methyl-4-oxa-5-azatricyclo[5.2.1.$0^{2,6}$]-dec-8-en-3-one, as colorless crystals.

Preparation of ***7a***. A solution of **6** (0.3 g, 1 mmol) in dry benzene (10 ml) was refluxed for 5 min. After the removal of the benzene under reduced pressure, a residual syrup was obtained. The syrup was dissolved in hexane (5 ml), and then the hexane solution was allowed to stand at room temperature to give colorless crystalline **7a**.

Preparation of ***7b***. The acetylation of **7a** (0.12 g, 0.5 mmol) was carried out by the usual procedure using acetic anhydride (10 ml) and pyridine (3 ml) at room temperature; it gave colorless crystalline **7b**, 5-acetoxy-6-*exo*-phenyl-*cis*-*oid*-*cis*-4-oxa-5-azatricyclo[5.3.0.$0^{2,6}$]dec-8-en-3-one.

Preparation of ***17***. To a suspension of a Raney-nickel catalyst (3 ml) in ethanol (200 ml) we added **8** (6 g, 26.7 mmol). The mixture was shaken under a hydrogen atmosphere at room temperature for 24 h. After the removal of the catalyst by filtration, the resulting solution was evaporated under reduced pressure to give a residue. The residual syrup was distilled under reduced pressure to a colorless oil, which gradually crystallized to give **17**, 5-*exo*-ethoxycarbonyl-6-*endo*-nitro-6-*exo*-methylbicyclo[2.2.1]heptane, as colorless crystals. Yield, 5.7 g (97.4%); bp 118—120 °C/1 mmHg, mp 34.5—36.5 °C. NMR ($CDCl_3$): δ 1.25—2.25 (6H, m, 2-, 3- and 7-H), 1.66 (3H, s, 6-CH_3), 2.60 (2H, m, 1- and 4-H), 3.64 (1H, d, $J_{5,7b}$=2.8 Hz, 5-H). IR (KBr): 1745 (ester), 1550 and 1360 (NO_2) cm^{-1}. Found: C, 57.99; H, 7.56; N, 6.12%. Calcd for $C_{11}H_{17}NO_4$: C, 58.13; H, 7.54; N, 6.61%.

Preparation of ***18***. In an analogous manner, a mixture of **17** (5.7 g, 26.0 mmol) and Raney-nickel (3 ml) in ethanol (200 ml) was worked-up to give a colorless oil, 6-*endo*-amino-5-*exo*-ethoxycarbonyl-6-*exo*-methylbicyclo[2.2.1]heptane (**18**). Yield, 4.9 g (95.7%); bp 90—91 °C/0.7 mmHg. NMR ($CDCl_3$): δ 1.16 (2H, s, 6-NH_2), 1.25—2.25 (6H, m, 2-, 3- and 7-H), 1.54 (3H, s, 6-CH_3), 1.90 (1H, m, 4-H), 2.03 (1H, d, $J_{5,7b}$=2.3 Hz, 5-H), 2.40 (1H, m, 1-H). IR (KBr): 3350 (NH_2), 1735 (ester) cm^{-1}. Found: C, 66.78; H, 9.67; N, 7.10%. Calcd for $C_{11}H_{19}NO_2$: C, 66.97; H, 9.71; N, 7.10%.

(Received July 27, 1977)

Mixing of chitosan with sodium carboxymethyldextran having opposite charge gave rise to the formation of novel water-insoluble precipitates. The mole ratios of N/COO^- in the polyelectrolyte complexes thus prepared were estimated to be 0.248—1.658. It was found that pH, mole ratio of N/Na and the order of mixing play an important role in determining the composition ratio of N/COO^- in the polyelectrolyte complexes. IR spectroscopic studies, blood clotting test, elementary analyses, the color reaction with Toluidine Blue and studies on solubility of polyelectrolyte complexes revealed that there is no noticeable interactions between –COOH groups and –OH groups. However, the $-NH_3^+$ groups in chitosan participate in the binding with carboxymethyldextran, probably through its $-COO^-$ groups, in the polyelectrolyte complexes. It seems that the number of binding sites between $-NH_3^+$ and $-COO^-$ groups in the polyelectrolyte complexes at pH 3.0 is smaller than those prepared at pH 6.5. Both the polyelectrolyte complexes prepared at pH 3.0 and 6.5 suppressed the coagulation of blood. This anti-thrombogenic property should be related to elution of anti-thrombogenic carboxymethyldextran.

A solution of charged polyelectrolyte reacts with one of oppositely charged polyelectrolyte to form a water-insoluble hydrous complex whose composition, in general, is sensitive to the composition of reaction mixture, order of mixing and the polyion concentration. Reports in this field have been given by some investigators.[1,2]

The mechanism of polyion interaction, the probable structure of the polyelectrolyte complex (PEC), and their properties have been investigated in detail by Michaels *et al.*[3,4] However, only a few papers[5] deal with the polyion interaction between polysaccharides, or polysaccharide and synthetic macromolecules, in spite of its importance concerning biological system, membranes and industrial and biomedical application.[6]

We have reported on chemical reactions of chitosan with dextran[7,8] and of [2-(diethylamino)ethyl] dextran with dextran.[9] This paper deals with a novel chemical reaction of chitosan with sodium carboxymethyldextran (CMD) and the results of our studies on the polyelectrolyte complex thus prepared.

Experimental

Chitosan (Tokyo Kasei Co., Ltd., nitrogen content 7.65%) and CMD (Meito Sangyo Co., Ltd., sodium content 7.38%; degree of substitution 0.70/A.G.U.; viscosity of its 1% aqueous solution 970 centipoise at 20 °C) were used. Chitosan was purified by reprecipitation from its acidic solution with 20% sodium hydroxide solution; CMD was used without purification.

When the pH of solution is below 2 no precipitate is formed by mixing chitosan with CMD and when the pH of chitosan solution is higher than 6.5, chitosan remains insoluble. Thus, the reactions were carried out at pH 3.0 and pH 6.5, respectively. Purified chitosan was dissolved in 0.1% hydrochloric acid solution. The pH of solution was then adjusted to 3.0 and 6.5 with sodium hydroxide solution. CMD was dissolved in water (pH 6.5), and the solution was adjusted to pH 3.0 with hydrochloric acid solution. These chitosan solutions were added dropwise to CMD solutions, adjusted to the same pH as those of chitosan solutions, respectively, with stirring under the conditions given in Table 1. Water-insoluble precipitate (PEC) was thus obtained. After being left to stand for a half hour, the precipitate was washed with 0.01 M hydrochloric acid solution, water and methanol, and then separated by centrifugation, dried *in vacuo* for a week, until a constant weight was attained.

The blood clotting test was carried out according to the procedure of Imai and Nose.[10] 160 mg PEC was pressed (5 t/4.5 cm^2) with poly (vinyl chloride) powder, a reinforcing agent, in a vacuum for 10 min. The blood (Red Cross Hospital Blood Center) was kept in a thermostat at 4—6 °C for one or two months. The ACD blood was prepared by adding the blood to an anticoagulant citrate dextrose solution consisting of sodium citrate, citric acid and dextrose.

Elementary analyses of the PEC were performed at the Institute of Physical and Chemical Research, the infrared spectra being taken by the KBr method. Purple coloration appears by the reaction of CMD with a solution containing Toluidine Blue.[11] This is utilized for the demonstration of CMD elution from PEC.

Results and Discussion

Experimental conditions, yield and elementary analyses for the PEC are given in Tables 1 and 2, respectively. The yield of PEC becomes smaller with an increase in the mole ratio N/Na of the reaction mixture. The nitrogen content in PEC prepared at pH 6.5 (B series) is greater than that prepared at pH 3.0 (A series), while the nitrogen content in PEC of A-2 and B-2, prepared in the mixing order, CMD to chitosan, is greater than that of PEC prepared in the reverse order, chitosan to CMD. The nitrogen content in the PEC becomes greater with increase in the mole ratio N/Na of the reaction mixture.

The data on the infrared spectra and elementary analyses suggest that the $-NH_3^+$ groups in chitosan participate in the binding with CMD, probably through its $-COO^-$ group in PEC. Thus, the mole numbers of $-COO^-$ groups in PEC were calculated from its nitrogen content. The mole ratios of N/COO^- in PEC were determined (Table 2), by assuming that the sodium or chlorine content in PEC is approximately zero. The mole ratios of N/COO^- in PEC, A-1 to B-4, were estimated to be 0.248 to 1.658. The pH value, the mole ratio of N/Na in the reaction mixture and the order of mixing, play an important role in determining the

Table 1. Conditions and yields in the preparation of polyelectrolyte complexes[a)]

Sample code	Volume of chitosan solution (ml)	Volume of CMD solution (ml)	Mixing order	Mole ratio of N/Na in the reaction mixture	Yield (mg/100ml chitosan solution)

B-3	2.33	/	/	0.740
B-4	3.49	/	/	1.406

Sample codes correspond to those in Table 1.
a) Nitrogen analysis carried out according to Kjeldahl method. b) Analyses performed at the Institute of Physical and Chemical Research. c) Carbon content: 40.09%, hydrogen content: 6.05%. d) Carbon content: 38.19%, hydrogen content: 6.23%.

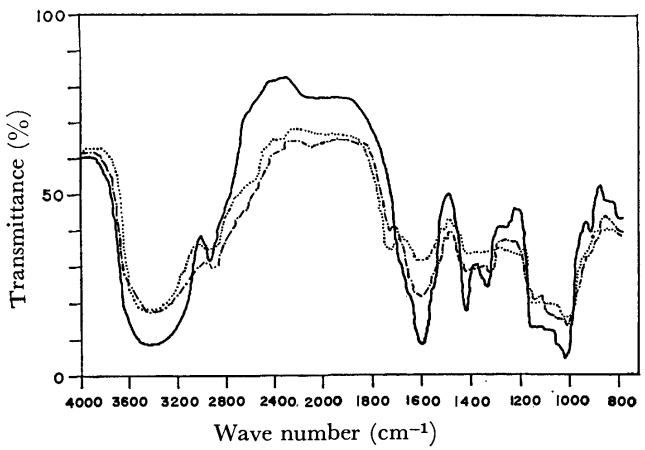

Fig. 1. IR spectra of polyelectrolyte complexes and polymer blend of chitosan with sodium carboxymethyldextran.
——: Polymer blend of chitosan with sodium carboxymethyl-dextran (mole ratio of N/Na=1.0), ·····: polyelectrolyte complex of A-1, -·-·-: polyelectrolyte complex of B-1.
Sample codes, A-1 and B-1, correspond to those in Table 1.

ratio of the reactive group of CMD to that of chitosan in the PEC. The mole ratios of N/COO^- in the PEC of series A were smaller than those of series B. Only the PEC of series A, A-1, A-2, and A-4, having not more than 0.5 of the mole ratio N/COO^-, gave slight purple coloration with Toluidine Blue. It seems that the number of binding sites between $-NH_3^+$ and $-COO^-$ groups in the PEC of series A is smaller than those of series B, and CMD in the PEC of series A should be liable to detach itself from the PEC chain.

The IR spectra of PEC are roughly similar to those of a mixture of CMD and chitosan, differing from each other in detail. PEC has an absorption band around 1740 cm^{-1}, [12] assigned to -COOH group. This is absent in the mixture of CMD and chitosan. The smaller the ratio of N/Na in the reaction mixture, or the smaller the nitrogen content in PEC, the stronger the absorption band around 1740 cm^{-1}. The absorption band in the PEC of A-2 and B-2 prepared in the mixing order, CMD to chitosan, is stronger than the band prepared in the reverse mixing order, chitosan to CMD. The stronger the absorption band around 1740 cm^{-1}, the weaker the absorption band around 1600 cm^{-1}. Though neither the shift in absorption band around

Table 3. Solubilities of polyelectrolyte complexes

Sample code	Ternary[a)] solvent-I		Ternary[b)] solvent-II		Formic acid		Dimethyl sulfoxide

A-2	△	△	△	△	△	○	×	△
A-3	△	△	△	△	△	○	×	△
A-4	△	△	△	△	△	○	×	△
B-1	△	△	△	△	△	○	×	×
B-2	△	△	△	△	△	○	△	△
B-3	△	△	△	△	△	○	△	△
B-4	△	△	△	△	△	○	△	△

Sample codes correspond to those in Table 1. All the polyelectrolyte complexes were insoluble, even on heating, in *N,N*-dimethylformamide. R: Room temperature, H: Heating. ○: Almost soluble, △: Partially soluble, ×: Insoluble. a) Aceton/potassium bromide/water (20: 20: 60 wt%). b) Hydrochloric acid/dioxane/water (45: 50: 5 wt%).

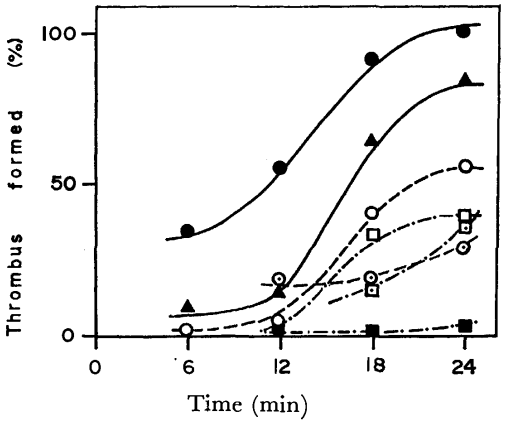

Fig. 2. Percentage of thrombus formed on polyelectrolyte complexes compared with that on glass.
●: Glass, ▲: polyvinyl chloride, ⊙: B-2, ○: B-4, ⊡: A-1, □: A-2, ■: A-2 (without reinforcing agent). Sample codes A-1, A-2, B-2, and B-4 correspond to those in Table 1.

3500 cm^{-1} assigned to –OH groups nor the change in its absorption intensity about PEC were observed appreciably in the mixture of CMD and chitosan blended in the same ratio as that of the PEC composition, there would be no appreciable interaction between the –OH group and other reactive groups, especially carboxyl group. On the other hand, there is no absorption around 1500 cm^{-1}, which is assigned to $-NH_3^+$ group,[13] in the mixture of CMD and chitosan. The sodium and chlorine contents in the PEC are distinctly smaller than those in CMD or chitosan. The results suggest that the $-NH_3^+$ groups in chitosan participate in the binding with CMD through its $-COO^-$ groups.

PEC are insoluble or hardly soluble in dimethyl sulfoxide or *N,N*-dimethylformamide, partially soluble in a ternary solvent mixture, and soluble in formic acid on heating (Table 3). The difference in solubility between the PEC of series A and those of series B is hardly discernible. However, the PEC of series B is soluble in dimethyl sulfoxide.

The blood clotting test was performed for the PEC (Table 1) by gravimetric measurement[10] of the amount of thrombus at appropriate time intervals, after addition of calcium chloride solution (0.1 M, 0.02 ml) to ACD blood (0.2 ml) which had been in contact with samples. PEC has an anti-thrombogenic character; it suppresses the coagulation of blood. The amount of thrombus on the PEC is 20—50% of that on glass (Fig. 2). The difference in anti-thrombogenic behavior between the PEC of series A and that of series B is hardly discernible. The elution of anti-thrombogenic CMD from PEC into the blood might be related to our results.

Photo-Induced Friedel-Crafts Acylation of Anthracene with Aroyl Chlorides

Takashi TAMAKI

Research Institute for Polymers and Textiles, Sawatari 4-1, Kanagawa-ku, Yokohama 221

(Received July 28, 1977)

The photo-excitation of anthracene (**1**) in the presence of benzoyl chloride and its *p*- or *m*-substituted compounds (**2**) gave the corresponding 2- and 9-aroylanthracenes. No isomeric 1-aroylanthracenes (**3**) were detected. The aroyl chlorides (**2**) were found to quench the fluorescence of **1**. The quenching constants obtained increased with increasing electron-withdrawing ability of the substituents and are in agreement with those independently obtained from the quantum yield determinations. The efficiency of the photoaroylation was dependent on the solvent polarity. The results suggest a plausible photochemical mechanism, which involves a CT complex formed from **1** in the excited singlet state and **2** in the ground state. This complex formation is supported by the positional selectivity exhibited in the product distribution.

Few papers concerning photo-induced Friedel-Crafts reactions have been published.[1-5] The photochemical mechanisms differ from case to case. For the photoacetylation of benzene with trifluoroacetic acid, an ionic intermediate was assumed.[1b] The photoalkylation of the phenyl nucleus with chloroacetyl derivatives occurs through a radical reaction,[2] while, in the presence of metallic halides, electrophilic substitution prevails.[3] Recently, positional selectivity was reported for the photobenzoylation of anthracene (**1**) with benzoyl chloride (**2d**): substitution on the aromatic ring preferentially occurs at positions 2 and 9, but scarcely at position 1.[5] This paper describes further results for photoaroylation and discusses the photochemical mechanisms.

Continuing attention has been focused on the exciplex formation between electron-rich aromatics and compounds containing an activated C–Cl or similar bond.[6] It is supposed for these systems that the chemical reactivity of the C–Cl bond plays an important role in the quenching process, although CT interaction is primarily responsible for association of an exciplex. The quenching mechanisms may be related to the case described here.

Results

Photoaroylation. The absorption spectra of a mixed solution of anthracene (**1**) and benzoyl chloride (**2d**) are shown in Fig. 1a. No new absorption bands are seen before irradiation. The solution was exposed to 365 nm mercury light in a nitrogen atmosphere. The irradiating light was absorbed by **1**, but not by the aroyl chlorides (**2**), the absorbance of **2** being negligible

above 340 nm. The major products obtained were identified, by comparison with anthentic species, to be 2- (**4d**) (19% in benzene and 24% in acetonitrile based on the amount of **1** consumed) and 9-benzoylanthracene (**5d**) (47% in benzene and 57% in acetonitrile). No isomeric 1-benzoylanthracene (**3d**) was detected. Other aroyl chlorides (**2a**—**c** and **e**—**j**) gave the corresponding products under appropriate conditions. The product yields were 20—30% for **4**, 30—60% for **5**, as listed in Table 1, and trace or nil amounts for **3**.

Besides the ketonic compounds, anthracene photodimer was also formed with less yields (10—20%) than that in the absence of **2**. Added dry hydrogen chloride prevented photoaroylation and caused the chlorination of **1**. In an oxygen stream, photoaroylation was repressed (**4d**, 5%; **5d**, 10%) and anthraquinone was formed as a major product (40%).

In the case of **2d** in acetonitrile, irradiation was also performed with the 254 nm light, which was absorbed by all starting materials. The same ketonic products, **4d** (5%) and **5d** (40%), and in addition 9,10-dibenzoylanthracene (15%) were formed. The yield of **4d** is remarkably small compared with that for 365 nm light irradiation.

Reaction Pathway. In order to elucidate the reaction pathway of the photoaroylation, the extinction

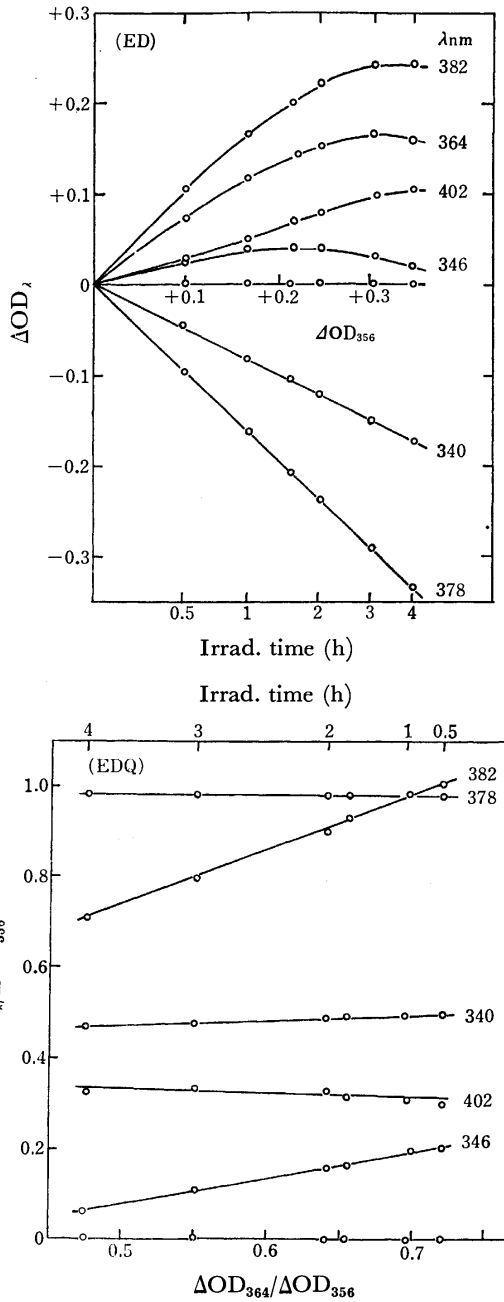

Fig. 2. Extinction difference (ED) and extinction difference quotient (EDQ) diagrams of the absorption spectra.

difference (ED) and extinction difference quotient (EDQ) diagrams[7] are plotted in Fig. 2, using the spectral data shown in Fig. 1a. The ED diagram shows linear curves at all wavelengths until about one-half of the starting amounts of **1** had been consumed. These linear relations suggest that the photoreaction proceeds only *via* a one-step reaction, *i.e.*, **1**+**2**→one product or products with a constant yield ratio. Since both isomeric ketones, **4d** and **5d**, are formed immediately after irradiation, as is shown in Fig. 1b, it can be concluded that these compounds are simultaneously produced by a bimolecular reaction of **1** and **2**. The product yield ratio of **4d** to **5d** is *ca.* 0.1 at the initial stage of the photoreaction, as is shown in Fig. 1b.

For more prolonged irradiation periods, the ED plots deviate from linear relations, particularly at wavelengths of the **5d** peak maxima (346, 364, and 382 nm). However, all the EDQ plots remain linear up to nearly complete consumption of **1**. This indicates that **5d** formed undergoes a subsequent chemical change, while **4d** unchanges. In a preliminary experiment, it was found that irradiation of **5d** in benzene gave none of the isomeric ketones, but gave a photodimer analogous to those derived from **1** or its meso substituted compounds.[8] Consequently, the photodimerization may be mainly responsible for the loss of **5** during the course of photoaroylation. The possibility of the isomerization reaction can be excluded.

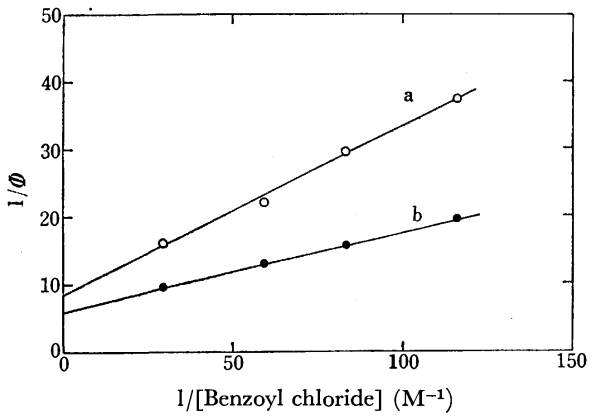

Fig. 3. Concentration dependency of the quantum yield for the loss of anthracene: (a) in benzene and (b) in acetonitrile.

Quantum Yields. The loss of **1** is dependent on the aroyl chloride concentration, as is shown in Fig. 3, where the reciprocals of the quantum yields for the disappearance of **1** are plotted against the reciprocals of the benzoyl chloride concentrations. Values of the products of the limiting quantum yield and the quenching constant, $k_q\tau$ (the ratio of intercept to slope), are listed in Table 2. Although the values of the limiting quantum yield are about the same for most reactions of **2** in benzene, they become much more enhanced in acetonitrile for the aroyl chlorides which have an electron-withdrawing substituent. On the contrary, the electron-repelling substituents relatively depress the quantum yield in acetonitrile.

Table 2. The limiting quantum yields and quenching constants in the photo-aroylation of anthracene

Aroyl chloride		Solvent: Benzene Φ_∞[a]	Benzene $k_q\tau$[b] (M^{-1})	Acetonitrile Φ_∞[a]	Acetonitrile $k_q\tau$[b] (M^{-1})

a) The slope of the Stern-Volmer plots for an excitation wavelength of 380 nm. b) Determined from the singlet lifetime of anthracene: τ 4.9 ns in benzene and 5.3 ns in acetonitrile (Ref. 10).

Fluorescence Quenching. The Stern-Volmer plots were linear for most quenchers, **2**, while upward curvature was observed for **2i** and **j**. No new emission was detected in the presence of **2**. The values of $k_q\tau$ as determined from the initial slope and of the quenching rate constant, k_q, are listed in Table 3. The values of $k_q\tau$ obtained are in agreement with those obtained from the quantum yield determinations (Table 2) to within experimental errors. The k_q increases with increasing electron-withdrawing ability of the substituent and ultimately approaches the diffusion rate canstant, k_{diff}, which is equal to 1×10^{10} $M^{-1}s^{-1}$ in benzene and 1.8×10^{10} $M^{-1}s^{-1}$ in acetonitrile, as calculated using the Debye expression.[9] The upward curvatures in the

Table 4. Quantum yields for direct photolysis of aroyl chlorides

H	(**2d**)	0.038
m-Cl	(**2h**)	0.029
m-CN	(**2i**)	0.016
p-CN	(**2j**)	0.033

Stern-Volmer plots and the large k_q values suggest that a ground-state complex is formed from **1** and the aroyl chlorides, the substituent of which is strongly electron-withdrawing (*vide infra*).

Direct Photolysis of Aroyl Chlorides. The quantum yields are listed in Table 4. The data indicate that **2** becomes more photostable when an electron-withdrawing substituent is introduced into the aroyl system. The trend of the substituent effect is distinctly different from that for photoaroylation. Furthermore, it is noteworthy that the quantum yields for direct photolysis are much smaller than the limiting quantum yields of the photoaroylation (the fourth column in Table 2).

Discussion

The agreement between the quenching constants obtained independently from the fluorescence and photochemical measurements indicates that the photoreaction occurs in the excited singlet state of **1**. As is shown in Fig. 1a, only a very weak absorption band of **2** overlaps with the fluorescence of **1**, the long wavelength absorption maxima of **2** lying in much higher energy regions (*ca.* 100 kcal/mol) than that of **1** (76 kcal/mol).[10] Therefore, it is difficult to consider that the excitation energy would be transferred to the quencher through classical mechanisms, such as trivial or resonance energy transfer.[11] If these mechanisms were operating, the photoaroylation efficiencies would be related to those for direct photolysis of the quenchers, because these quenching processes lead to the formation of excited quenchers. However, the substitution dependence of the two photoreactions is exactly opposite.

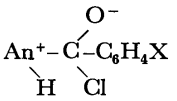
On the other hand, the increase in the quenching constant with increasing electron-abstracting ability of the aroyl system suggests that the quenching process involves an exciplex formed from the excited aromatic hydrocarbon and the quencher. The exciplex mechanism is well established for electron-donor-acceptor pairs, for which the energy transfer appears to be strongly endothermic.[12] This mechanism is favored for explaining the positional selectivity observed, as is discussed below.

Consequently, the photoreaction may conform to the following reaction scheme, which was postulated for singlet quenching by electron transfer,[13] thus

$$\underset{\mathbf{1}}{{}^1\mathrm{An}^*} + \underset{\mathbf{2}}{\mathrm{Q}} \underset{k_{-q}}{\overset{k_{diff}}{\rightleftarrows}} \underset{\mathbf{6}}{[{}^1\mathrm{An}^* \cdots \mathrm{Q}]} \xrightarrow{k_e} \underset{\mathbf{7}}{[\mathrm{An}^{\delta+} \cdots \mathrm{Q}^{\delta-}]^*}$$

$$\underset{\text{Products}}{\overset{k_r}{\swarrow}} \qquad \underset{\mathrm{An} + \mathrm{Q},}{\overset{k_d}{\downarrow}} \qquad (1)$$

where An and ^{1}An* denote **1** in the ground and excited singlet states, respectively, Q denotes the aroyl chlorides, [^{1}An*···Q] is a proximate pair in a solvent cage, [$An^{\delta+}$···$Q^{\delta-}$]* denotes an exciplex, and the k are rate constants. The exciplex is either deactivated through radiationless decay or transformed into a radical ion pair and/or a zwitterionic intermediate, **8**, which yields products by the elimination of hydrogen chloride.



8

The validity of an exciplex is substantiated by the fact that the yield of **4d** decreased when the reaction solution was irradiated with the 254 nm light. Under these conditions, the fraction of the incident light which is absorbed by **1** is relatively small, the quencher being able to absorb extensive amounts of the light. Therefore, substitution through an exciplex may compete with that through an aroyl radical generated by direct photolysis of the quencher. The latter photoreaction predominantly gives **5d**, because the carbon atom at the meso position of **1** has the greatest reactivity. It appears likely that the inefficient formation of **4d** is a response to the decrease in the probability for exciplex formation.

Furthermore, the quenching effect by oxygen may support the existence of long-lived intermediates. Judging from the fact that the photooxidation of **1** is rather inefficient in benzene[14,15] and that the singlet lifetime of **1** is very short, especially under the reaction conditions, added oxygen would not be expected to interfere by quenching ^{1}An*, but to become involved by quenching long-lived exciplex and/or radical ions.

The solvent dependence of the photoreaction is consistent with the mechanisms proposed. The higher quantum and product yields in acetonitrile *vs.* benzene are due to a greater degree of solvent stabilization for the polar exciplex in a high polarity solvent than in a poor polarity solvent. In this respect, it appears surprising that **2i** and **2j** are rather inactive in the photoaroylation, in spite of their great efficiency for fluorescence quenching. This may be the consequence of the rapid formation of solvated radical ions, since they are strong electron acceptors.

This scheme leads to the modified Strern-Volmer equation,

$$\phi_f^\circ/\phi_f = 1 + k_q\tau[\mathrm{Q}], \qquad (2)$$

where

$$k_q = \frac{k_{diff}k_e}{k_{-q}+k_e}, \qquad (3)$$

ϕ_f and ϕ_f° are the fluorescence quantum yield in the presence and absence of the quencher, respectively, k_{diff} and k_{-q} are the rate constants for diffusive formation and for separation of a proximate pair (**6**), respectively, and k_e is the rate constant for electron transfer. The quantum yield of the photoreaction, Φ, is given by

$$\Phi = \frac{k_q\tau[\mathrm{Q}]}{1+k_q\tau[\mathrm{Q}]}\,\frac{k_r}{k_r+k_d}, \qquad (4)$$

where the first term on the right-hand side is the prob-

ability for exciplex formation, the second term is the fraction of the exciplex which gives the photoproducts, and k_r and k_d are the rate constants for chemical transformation and for degradation to the starting materials, respectively. The limiting quantum yield refers to the rate-constant ratio, $k_r/(k_r+k_d)$. The data are summarized in Tables 2 and 3.

It is assumed in the reaction scheme that an exciplex is formed irreversibly. This assumption is convenient for the quenching reaction which occurs with a nearly diffusion-controlled rate.[16] Since CT interaction is mainly responsible for exciplex binding,[12] a definite relation between the k_q values measured and the Hammett substituent constant, σ, is expected. Although the k_q values given in Table 3 cannot be linearly correlated with σ, probably owing to the levelling effect, it appears possible to apply the kinetic treatment developed by Evans to the nearly diffusion-controlled quenching process.[13] On the assumption that the rate constant for the diffusive separation of a proximate pair, k_{-q}, is a constant parameter which is determined only by the properties of the solvent,[13] a linear free-energy relation is derived from Eq. 3, thus

$$\ln \frac{k_q}{k_{diff}-k_q} = \ln \frac{k_e}{k_{-q}} \propto \Delta G^{\ddagger}, \qquad (5)$$

where $\Delta G^{\ddagger}$ is the free energy of activation for the electron-transfer process.

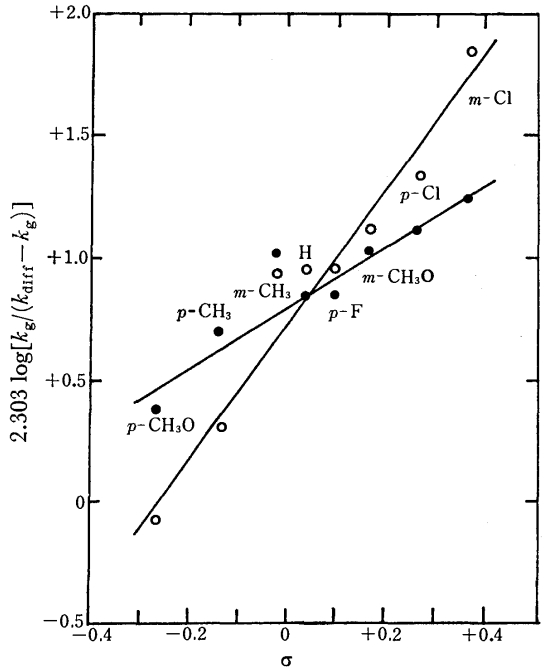


Fig. 4. Linear free-energy relation of the quenching constant: (○) in benzene and (●) in acetonitrile.

As is shown in Fig. 4, a linear relation is obtained between σ and the function, 2.303 $\log[k_q/(k_{diff}-k_q)]$, which was determined from the measured values of k_q and the calculated values of k_{diff}. The ρ values are 2.8 in benzene and 1.3 in acetonitrile. These positive ρ values strongly support CT interaction, in which electron transfer occurs from ^{1}An* to **2** in the ground state. The correctly linear relations shown in Fig. 4 confirm the validity of the reaction scheme proposed.

One should take account of a few possibilities for positional selectivity. First, there is the possibility that isomerization of the products gives rise to apparent positional selectivity. In fact, it is known that a variety of product distributions are produced in the thermal Friedel-Crafts acetylation of **1**, depending on the experimental conditions.[17] Substitution occurs prevalently at the meso position under mild conditions, whearas the acetyl group first attached at the meso position rapidly migrates to outer-ring positions under slightly drastic conditions and/or for prolonged reaction times. In contrast with the thermal reactions, the ketonic products in this system are formed from a bimolecular reaction of **1** and **2** without isomerization. Thus, the product-formation behavior is different from that in the ground-state reaction.

Second, the reactivity of the aromatic nucleus should be taken into account. As is known, low-lying excited singlet states of **1** consist of the ^1L_a and ^1L_b states, the former being much more abundant and slightly lower in energy than the latter.[18] The singlet-state reaction is, in general, expected to occur in the ^1L_a state. An MO calculation allowing for configuration interaction suggests that the increase in the reactivity of **1** upon photoexcitation is positionally dependent.[19] The reactivity sequences predicted by the free-valence index are 9> 1>2 for the ^1L_a state and 9>2>1 for the ^1L_b state. If the ^1L_a state is active, photoaroylation would be expected to form three position isomers in yields following the same order as those of the reactivity sequences. However, the product distribution given was contrary to the theoretical expectation, appearring severly selective at the outer-ring positions.

The discrepancies between the theory and experiment may be partly explained by the steric effect. But this is not conclusive, since there is no reason why meso substitution should be predominant.

Third, these considerations result in the tentative conclusion that the exciplex is important in determining positional selectivity. It appears likely that the exciplex interaction leads to considerable changes in the electronic structure of ^{1}An*, resulting in a different enhancement of the chemical reactivity from that of the original molecule. Based on strong selectivity between the positions of the outer ring, it may be supposed that the electronic structure of ^{1}An* would change increasingly, particularly when the quencher approaches the outer ring. At this time, if the CT interaction occurs along the long axis of **1**, then it would cause greater stabilization of the longitudinally polarized ^1L_b state than of the transverse-polarized ^1L_a state.

The inversion of the electronic state is intramolecularly established in the aromatic compounds into which a powerful substituent is introduced. It is well-accepted that the substituent primarily shifts toward the red and intensifies an electronic transition band lying in the same direction as that of the extending conjugation.[18,20] In this connection, it should be noted that the absorption spectra of **3d** and **4d** are quite different from that of the parent **1**, while the absorption spectrum of **5d**

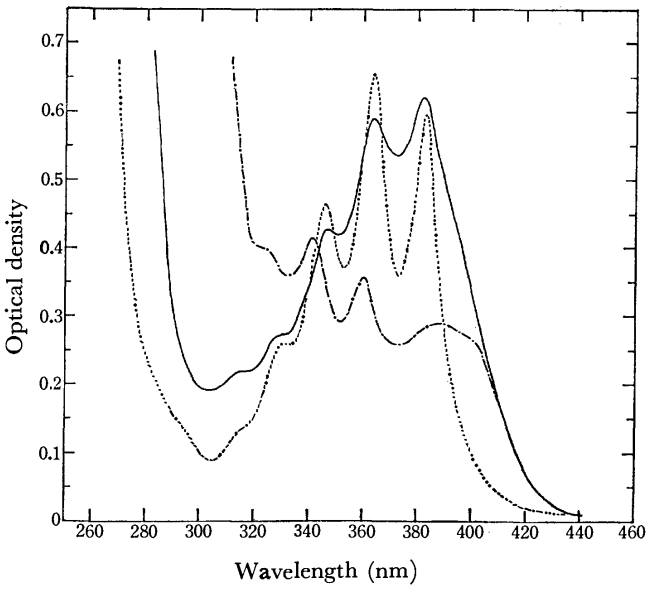

Fig. 5. Absorption spectra of 1-benzoylanthracene (solid line), 2-benzoylanthracene (broken line), and 9-benzoylanthracene (dotted line) in acetonitrile (10^{-4} M).

is similar in general shape and intensity to that of **1**, except for a slight shift to longer wavelengths, as is shown in Fig. 5. The spectral information implies that the electronic conjugation of the transition bands of the aromatic ring and benzoyl group is greatly enhanced when the substituent is introduced into the outer ring. The spectral deformation of 2-substituted **1** is known to be due to the result that the ^1L_b band emerges on the low-energy side of the ^1L_a band.[21] Such intramolecular interactions may be related to the intermolecular interaction of **1** with **2**.

Finally, ground-state complex formation will be considered. The Stern-Volmer treatment gave upward curvatures for **2h**—**j** with increasing concentration up to 2 M. This indicates that a contact complex is formed

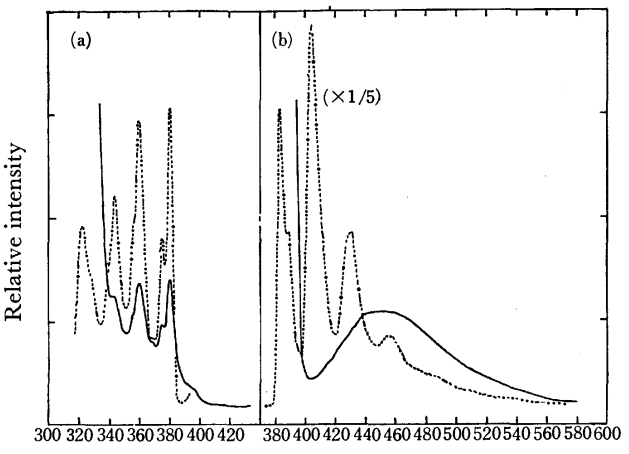

Fig. 6. Emission and excitation spectra of a mixture of anthracene (5×10^{-5} M) and *p*-chlorobenzoyl chloride (2 M) in a solid ether solution at 77 K: (a) excitation spectra for monitoring at 470 nm (solid line) and at 400 nm (dotted line); (b) emission spectra for excitation at 390 nm (solid line) and at 360 nm (broken line).

in the ground state,[22] although no change was observed in the absorption spectra, except for a slight red-shift due to the increasing dielectric constant of the solvent. A glassy ether solution containing **1** and **2g** or **h** at 77 K showed structureless fluorescence when excited at 390 nm. The corresponding absorption band was seen as a shoulder of the longest wavelength band of **1** in the excitation spectrum (Fig. 6). These spectra were confirmed to be different from those derived from anthracene aggregates,[23] since only the monomer bands were seen in the absence of the quencher. Therefore, the low-temperature emission is also indicative of the formation of CT complex related to that of the anthracene–trimesitinoyl chloride system reported by Briegleb.[24] Although very weak or no CT fluorescence was detected for the other aroyl chlorides, **2a**—**f**, which have less electron-withdrawing substituents, it appears likely that complex formation becomes feasible upon photo-excitation of the donor, since electronic excitation leads to a decrease in the ionic potential.[25]

Experimental

Reagents. Benzoyl chloride was purified by washing with cold 5% aqueous sodium hydrogencarbonate followed by fractional distillation. The other aroyl chlorides available commercially or produced by ordinary procedures using the corresponding acids and thionyl chloride, were distilled twice *in vacuo* to eliminate hydrogen chloride. Anthracene was recrystallized three times from benzene. Benzene was washed with concentrated sulfuric acid and water, dried over calcium chloride, and then distilled over sodium. Acetonitrile was dried by shaking with silica gel and diphosphorus pentaoxide, and purified by fractional distillation over diphosphorus pentaoxide.

Irradiation. Benzene was used as the solvent in a series of preparative runs, since all the starting materials and products were largely soluble in it. The 365-nm light was isolated from a 500-W medium-pressure mercury lamp equipped with a filter combination composed of Corning 7-60 and Toshiba UV-35 filters and a cupric sulfonate solution. A reaction mixture (50 ml) of **1** (1×10^{-2} M in benzene and 3×10^{-3} M in acetonitrile) and **2** (0.1—0.13 M) in a Pyrex flask was exposed to the light in a nitrogen atmosphere at about 25 °C. Irradiation was carried out for 16 h. In most cases, the loss of **1** was about 60% of the starting quantities. In the cases of **2a**, **i**, and **j**, more prolonged irradiation periods (*ca.* 40 h) were required to accomplish the same conversion. After removal of the remaining **2** with aqueous sodium hydrogencarbonate and evaporation of the solvent, the products were subjected to chromatography on a silica column. Elution with a 4: 1 cyclohexane benzene solution gave two major and several minor products. The major products were characterized by their UV, IR, and NMR spectra, coloration with concentrated sulfulic acid, and emissive behavior in ethanol, as listed in Table 1. The anthracene dimer was obtained as a precipitate in the eluting solvent.

Irradiation using the 254-nm light was performed using an 8-W low-pressure mercury lamp without any filter. An acetonitrile solution (80 ml) of **1** (3×10^{-3} M) and **2d** (0.14 M) in a quartz flask was exposed to the light in nitrogen. The procedures for product isolation were the same as those noted above.

Photoreaction of 9-Benzoylanthracene. A benzene solution was exposed to a 500-W medium-pressure lamp. After irra-

diation, the solvent was evaporated and the residues were extracted with methanol to remove the remaining monomer. A white powder was obtained and was recrystallized from benzene. The product was identified as the dimer and decomposed at 217 °C to recover the monomer. It was also found that crystalline **5d** dispersed in water gave the dimer upon irradiation in air. Although it has been reported that crystalline **5d** undergoes autooxidation in the presence of light giving anthraquinone,[26] no photooxidation was observed under the present conditions.

Quantum Yield Determinations. A low concentration of **1** (3×10^{-4} M) was employed to avoid photodimerization and to insure simple kinetics. At this concentration, the loss of **1** in the absence of the quencher was very small as compared with that in its presence. The amounts of **1** consumed in the presence of various concentrations of **2** (8×10^{-3}—3×10^{-2} M) were followed using a spectrophotometer at time intervals during the progress of the photoreaction and were subtracted from those in the absence of **2**. Since the photoproducts absorb increasing amounts of the incident light, resulting in a decrease in the photoreaction rate (see Fig. 1a), the quantum yields are based on the initial slopes of the conversion curves. Chemical changes in the dark were negligible. The incident and transmitted light intensities were monitored using potassium trioxalatoferrate(III) actinometry or an Eppley thermopile.

Errors were inevitable in determining the quantum yields. In the cases of **2i** and **j**, the conversion of **1** could not be precisely estimated, since the photoreaction rates were very slow under these conditions. A least-squares calculation was made to determine the values of the slope and the intercept in the plots of $1/\phi$ *vs.* 1/[Q]. The maximum error is $\pm30\%$.

Direct Photolysis of Aroyl Chlorides. Acetonitrile solutions of **2a, d,** and **h**—**j** (7—9×10^{-3} M) in quartz cells were exposed to an 8-W low-pressure lamp in nitrogen. The light intensity was determined using potassium trioxalatoferrate(III) actinometry. The aroyl chloride loss was estimated using the iron (III) hydroxamate method.[27] The molar absorptivities (λ_{max}) of the iron(III) hydroxamates derived from the aroyl chlorides are as follows: 1.64×10^3 (550 nm) for **2a**, 1.47×10^3 (540 nm) for **2d**, 1.62×10^3 (530 nm) for **2h**, 1.54×10^3 (525 nm) for **2i**, and 1.61×10^3 (520 nm) for **2j**.

Fluorescence Measurements. The quenching measurements were made using a Hitachi MPF-2A spectrofluorometer at 20 °C. Samples were prepared in quartz cells constructed from 1-cm square tubing. The concentrations employed for **2** were in the same range as that for the quantum-yield determinations. Sample solutions containing **1** (10^{-4} M) and **2** were deoxygenated by purging with argon for 5 min before measurement. Since the unquenched spectral distribution was the same as that in the absence of the quencher, the relative fluorescence intensity was determined by estimating the height of the peak maximum. The quenching constant was calculated from the initial slope of the Stern-Volmer plots. The error is $\pm10\%$.

The emission and excitation spectra at 77 K were measured with a low-temperature cell compartment. The spectra are uncorrected. Upon careful cooling, a transparent solid glass solution was formed from an ether solution of **1** (5×10^{-5} M) and **2** (2 M), except for **2i** and **j**, for which measurements could not be made because of precipitation upon cooling resulting in cracks in the glassy solution. The emission measurements were made for excitation at 360 and 390 nm, for which the phosphorescence of **2** was negligible. On the other hand, the phosphorescence of **2** contributed largely to the shorter-wavelength side of the excitation spectra monitored at 470 nm, while only excitation spectra attributable to **1** were observed when monitored at 400 nm.

Preparation of the Authentic Compounds. 9-Benzoylanthracene **5d** was prepared according to the thermal Friedel-Crafts method using aluminum chloride as a catalyst.[26] Mp 144—145 °C (lit,[28] 148 °C)

Found: C, 90.08; H, 4.99%. Calcd for $C_{21}H_{14}O$: C, 89.23; H, 5.00%.

The other isomeric ketones, **3d** and **4d**, were prepared using the Grignard reaction of phenylmagnesium bromide with the corresponding cyanoanthracenes. To 4.4 g of 1-anthracenecarboxylic acid were added 3.6 g of *p*-toluenesulfonamide and 8.7 g of phosphorus pentachloride and the mixture was warmed in a hot-air bath. The temperature was gradually raised to 200 °C and the volatile products were distilled out. The cooled reaction mixture was treated with 8 ml of pyridine and gently warmed. To this solution was cautiously added 40 ml of water and the solid was collected. After washing with water and a 5% sodium hydroxide, the dried products were purified using silica-column chromatography with a benzene eluent. The 1-cyanoanthracene obtained was recrystallized from ethanol: yield, 90%; mp 142 °C (lit,[29] 144.5 °C).

Found: C, 89.51; H, 4.33; N, 6.72%. Calcd for $C_{15}H_9N$; C, 88.64; H, 4.46; N, 6.89%.

2-Cyanoanthracene was prepared in a similar manner: yield, 95%; mp 195 °C (lit,[29] 200 °C).

Found: C, 88.44; H, 4.28; N, 6.79%.

To 0.3 g of cyanoanthracene in 20 ml of benzene was added an equimolar amount of phenyl magnesium bromide in ether. The reaction mixture was warmed and ether was distilled out. The residual benzene solution was refluxed for 2 h. After treatment with ammonium chloride, the ketimine was extracted with aqueous acetic acid (1:1) and hydrolyzed under reflux for 1 h. The addition of a mineral acid, such as hydrogen chloride, was important for hydrolysis of the *l*-isomer. Yellow products were extracted with benzene and purified by silica-column chromatography. Elution with benzene gave the corresponding ketones.

1-Benzoylanthracene **3d**: yield, 58%; mp 138—139 °C (lit,[29] 141 °C).

Found: C, 89.52; H, 5.04%.

2-Benzoylanthracene **4d**: yield, 86%, mp 178 °C (lit,[29] 175 °C)

Found: C, 90.07, H, 4.95%.

Oxidative Degradation of Polymers. V. Ozonization of Polypropylene and Polystyrene in Carbon Tetrachloride

Tsuneo SAITO, Etsuo NIKI,* Takeo SHIONO, and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received August 1, 1977)

The rates and products of ozonization of atactic polypropylene and polystyrene were studied in carbon tetrachloride at 30 and 70 °C. Atactic polypropylene underwent cleavage statistically by ozone to give oxygenated products. The molecular weight of polypropylene decreased with the progress of ozonization. Most chain ends of ozonized polypropylene were suggested to be carboxylic acids. Ozonization of polystyrene brought about crosslinking as well as chain scission, giving rise to broadening of molecular weight distribution. The major product from polystyrene was carboxylic acid.

Plastics and rubber deteriorate in the presence of ozone because of its powerful oxidizing action.[1] Ozonization of organic compounds, especially olefins, has been studied extensively.[2,3] The ozonization of polyethylene is reported to give peroxide, carbonyl and carboxylic compounds,[4–8] while polystyrene becomes brittle and discolored.[6,9] Razumovskii *et al.* found peroxide, carbonyl and carboxylic groups on the surface of ozonized polystyrene.[9] Both atactic and isotactic polypropylene films are also ozonized at ambient temperatures without induction period.[10] The attack of ozone on polymers was observed to result in chain scission.[11–13] However, the results so far obtained are qualitative and the arguments are speculative. More information is needed in order to clarify the nature of ozonization of polymers. In the course of our study on the oxidative degradation of polymers, we have studied the ozonization of atactic polypropylene and polystyrene in carbon tetrachloride.

Experimental

Materials. Polypropylene, kindly supplied by Mr. Fujita, Mitsui Petrochemical Ind. Co. was purified as follows. 92 g of chopped polypropylene was first soaked in 500 ml benzene at room temperature for about a week. The insoluble fraction was separated by filtration and the soluble fraction was repeatedly precipitated from the benzene solution by addition to excess methanol. It was finally dried in a vacuum at room temperature. The infrared spectrum of the purified polypropylene showed little absorption at 997 cm^{-1} but strong absorption at 975 cm^{-1}, indicating that little isotactic polypropylene was present. The intrinsic viscosity at 45 °C in carbon tetrachloride and the number average molecular weight of the purified atactic polypropylene were found to be 0.213 dl/g and 1.2×10^4, respectively.

Commercial polystyrene was purified by the conventional method using benzene and methanol as solvent and precipitant, respectively. The polystyrene solution was then washed successively with acid, water, alkali and water. Finally its 2% solution in chloroform was introduced slowly into excess methanol under vigorous stirring to give white powder polystyrene, which was dried in a vacuume at room temperature. The purified polystyrene dissolved completely into methyl ethyl ketone, indicating that it is atactic. The intrinsic viscosity at 45 °C in carbon tetrachloride was found to be 0.770 dl/g. The number average molecular weight was calculated as 2.1×10^5 by means of following equation obtained from the standard mono-dispersed polystyrenes.

$$[\eta] = 1.34 \times 10^{-4} \bar{M}_n^{0.706} \quad (1)$$

Carbon tetrachloride was treated with ozone prior to the oxidation reaction. Ozone was produced in a standard ozone generator, Nippon Ozone Co., Ltd. Model O-3-2, by charging pure oxygen dried with silica gel. The concentration of ozone in the feed gas determined by iodometric titration was 2—4%.

Procedures. Oxidation was carried out in a *ca.* 100 ml vessel equipped with a condenser. The oxidation was started by bubbling O_3–O_2 gas through the reaction mixture which was stirred vigorously with a magnetic stirrer. The amount of ozone consumed was calculated from the difference of the ozone concentration in the exhaust gases in the absence and the presence of substrate.

The reaction mixture was analyzed as follows. Viscosity was measured at 45 °C in carbon tetrachloride using a modified Ostwald viscosimeter. The molecular weight distribution was measured at 40 °C by gel permeation chromatography (DuPont-Shimadzu Model 830). Various types of crosslinked polystyrene gel columns (Shimadzu) were employed according to the molecular weight measured. Tetrahydrofuran (THF) was used as a carrier liquid at a speed of 1 ml/min. Both refractive index and ultraviolet absorption were used as a detector device. The calibration curve for the molecular weight of polystyrene was prepared by using standard, monodispersed polystyrenes; it was corrected for polypropylene with the Q-values given by Ouano and Mercier.[14]

Low-boiling products were determined by gas liquid chromatography. The conditions are given in Table 1.

Total amount of peroxides and acids formed was determined by iodometric and neutralization titrations, respectively. The

oxidized polymers were analyzed by IR, UV, and ^1H NMR spectra and also by elemental analysis. Low molecular weight acids were determined by isotachophoretic analysis. An aqueous solution of 0.01 M gultamic acid was used as the terminal solution, and an aqueous solution containing 0.01 M L-histidine and 0.01 M L-histidine hydrochloride as the leading solution.

Results and Discussion

Ozonization of Polypropylene. The results of ozonization of polypropylene are summarized in Table 2. Although the initial solution of polypropylene in carbon tetrachloride was colorless, it became pale yellow after about 30 min. Discoloration increased with increase in reaction time. The change in molecular weight can best be visualized by the analysis of gel permeation chromatography. Figure 1 shows an example of the gel permeation chromatogram of the ozonized polypropylene. The molecular weight of polypropylene decreases markedly with the progress of ozonization (Fig. 1 and Table 2). The molecular weight decreased from 12000 to 500 in 10 h. The absorption at 260 nm also increased with increase in reaction time, stronger absorption being observed for lower molecular weight fractions (Fig. 1). The infrared spectrum of the product solution showed the formation of hydroxyl (3400 cm^{-1}) and carbonyl (1710 cm^{-1}) groups. Formation of methanol, acetone, acetaldehyde and acetic acid, observed by gas liquid chromatographic analysis, was very slight except for acetic acid at high conversion: acetic acid accounts for not more than 20% of total acid observed. Acetic acid was also observed by isotachophoretic analysis.

The total number of chain ends calculated from the initial weight of polypropylene and its final average molecular weight are given in Table 2. The results would underestimate the total number of chain ends as expected from the molecular weight distribution shown in Fig. 1. However, they correspond remarkably well with those of observed acid, indicating that much of the chain ends of the ozonized polypropylene is carboxylic acid.

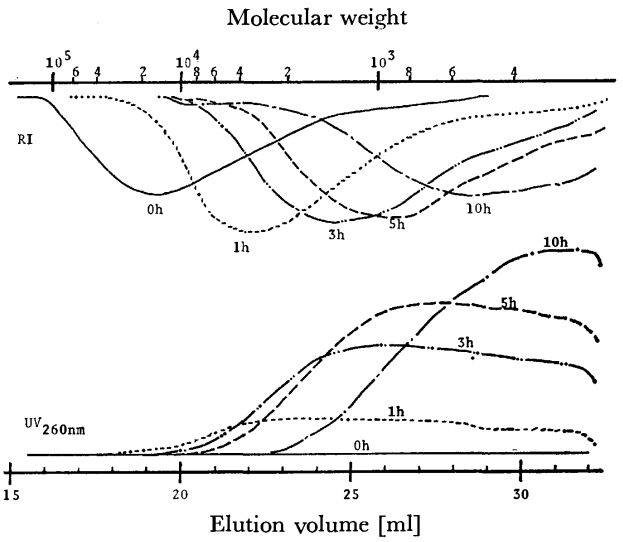

Fig. 1. Gel permeation chromatograms of polypropylene ozonized at 30 °C in carbon tetrachloride (Run No.5).

The results of elemental analysis for initial and ozonized polypropylenes are summarized in Table 3. It was confirmed that ozonized polypropylene contains no chlorine. This suggests that polymer carbon radical reacts with oxygen immediately before it attacks carbon tetrachloride and abstracts chlorine atom. Tables 2 and

3 show that the lower the molecular weight, the higher the content of oxygen and that the ratio of carbon to hydrogen atoms remains constant. Oxygen is incorporated not only as carboxylic acid but also as other functional groups such as hydroperoxide, alcohol and ketone.

The ^1H NMR analysis showed new peaks at 6.2 ppm and 5.0 ppm for ozonized polypropylene. However, they were not identified. The formation of carbon dioxide was confirmed by the formation of white precipitate when the exhaust gas was passed through the aqueous barium hydroxide solution.

Ozonization of Polystyrene. The ozonization of polystyrene was performed in a similar way to that for polypropylene. Distinct results were obtained. Discoloration of the reaction mixture to pale yellow was also observed for polystyrene. A white gummy substance was precipitated with the progress of ozonization. The substance was insoluble in carbon tetrachloride but partly soluble in acetone and tetrahydrofuran.

The pertinent results of the ozonization of polystyrene are summarized in Table 4. The effect of temperature was found to be small. Figure 2 shows an example of the gel permeation chromatograms of ozonized polystyrene. Broadening of molecular weight distribution was observed in each reaction, both lower and higher molecular weight fractions being formed. Since the column we used can not separate polymers with molecular weight higher than 10^6, the formation of crosslinked polymers, is indicated in Fig. 2.

and carbonyl (1730 cm^{-1}) groups. The UV spectrum showed the formation of a new band at 283 nm.

The results of elemental analyses, summarized in Table 4, show that much oxygen is incorporated into the polymer chain. Major products are carboxylic acid. Much of the chain ends should be acid.

Figure 4 shows the ^1H NMR spectra of initial and ozonized polystyrenes. The spectra of 6.63 and 7.10 ppm correspond respectively to *ortho* hydrogen and *meta*- and *para*-hydrogens of aromatic ring. The ratio is 2 to 3. The spectrum of ozonized polystyrene indicates the cleavage of aromatic ring. It was found by isotachophoretic analysis that formic acid was formed from polystyrene.

The results show that polypropylene is cleaved by ozone at ambient temperature to give dibasic acids as major products, polystyrene being both crosslinked and cleaved.

It has not yet been established how the initiation reactions proceed in the ozonization of saturated hydrocarbons.[15] It appears that the ozonization of carbon-hydrogen bond involves a hydrotrioxide, but the exact mode of formation of this intermediate and how it is converted into products has not been clarified. Hellman and Hamilton[16] postulated a scheme in which the ozonization of carbon-hydrogen bond proceeds through carbon radical and/or carbonium ion. The formation of 1-chloro- and 1-bromoadamantane in the ozonization of adamantane in the presence of bromotrichloromethane[17] suggests the presence of carbon radical. However, high ratio of retention of stereoregularity in the ozonization of saturated hydrocarbons[17,18] implies that this radical is not entirely free. The important role of ozone in the ozonization of polypropylene should be in the initial production of free radicals, which is supported experimentally by ESR analyses.[19,20] The adventitious impurities involved in polypropylene such as hydroperoxide, alcohol and carbonyl compounds might also contribute in the initiation reactions. Since polypropylene is relatively reactive toward oxygen, these impurities might be formed inevitably during the course of processing and storing.

After the initial production of radicals, the ozonization should resemble oxidation by molecular oxygen, where peroxyl and alkoxyl radicals are important chain carrying species.[21] The reported kinetic isotope effect and relative reactivities observed in the ozonization of aliphatic hydrocarbons[16,22] suggest the preferential attack of ozone on tertiary carbon-hydrogen bond of polypropylene to yield tertiary polypropylene radical. The characteristic feature of ozonization, when compared with autoxidation by molecular oxygen, is the rapid cleavage of polymer chain and high yield of carboxylic acid. It is not clear whether ozone is effective in direct scission of the carbon-carbon sigma bond. Carbon-carbon double bond is cleaved quite rapidly by ozone. Since the molecular weight of polypropylene decreases monotonously as the ozonization proceeds, the contribution of residual double bond involved in the initial polypropylene, if any, should be small. Since not much double bond should be formed in the autoxidation of polypropylene under sufficient oxygen, we assume that chain scission arises mostly from the β-scission of polypropylene alkoxyl radical. Primary alcohol is easily oxidized to aldehyde, which is then oxidized to carboxylic acid by ozone.

It is not clear why polystyrene behaves quite differently from polypropylene toward ozone. Ozone may attack either tertiary benzylic hydrogen or aromatic ring of polystyrene. The reactivity of the tertiary hydrogen of polystyrene is much lower than that of corresponding model compounds and polypropylene.[23] The crosslinking is not so important in the oxidation of polystyrene in solution by molecular oxygen as in the ozonization. Therefore, the cleavage of the aromatic ring should play a key role in the formation of crosslinked polystyrene. The ozonization of aromatic

compounds has been examined by many investigators, most extensively by Wibaut and his colleagues.[24] Ozone is able to function as a 1,3-dipole, an electrophile, or as a nucleophile, but it behaves primarily as an electrophilic reagent in its reactions with aromatic compounds.[24] In fact, the relative ozonization rates correlate well with the electron donating properties of alkyl substituted benzenes.[25] Thus the zwitter ion may play an important role and might be responsible for the crosslinking. The detailed mechanism of the crosslinking is now being studied with model compounds. It may be worth noting that the ozonization of simple aromatic compounds such as benzene, toluene and phenol gives insoluble polymeric materials.

The authors are grateful to Shimadzu Seisakusho for the use of the isotachophoretic analyzer.

Metal-Assisted Terpenoid Synthesis. V.[1] The Catalytic Trimerization of Isoprene to *trans*-β-Farnesene and Its Synthetic Applications for Terpenoids

Susumu AKUTAGAWA, Takanao TAKETOMI, Hidenori KUMOBAYASHI, Kiyoshi TAKAYAMA, Taichi SOMEYA, and Sei OTSUKA*

Central Research Laboratory, Takasago Perfumery Co. Ltd., 31-36, 5-Chome, Kamata, Ohta-ku, Tokyo 144

**Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560*

(Received August, 5, 1977)

Isoprene oligomerization was effected with a catalyst system Ni(OR)(η^3-C_3H_5)PPh(NEt_2)$_2$ (R=*n*-$C_{11}H_{23}$, *n*-$C_{15}H_{31}$) to give a linear trimer fraction above 70% yield. The major component of the trimer fraction is (*E*)-7,11-dimethyl-3-methylene-1,6,10-dodecatriene (*trans*-β-farnesene) (**1**). The minor constituents of the fraction are (*E*)-2,6-dimethyl-10-methylene-1,6,11-dodecatriene. As slightly higher boiling point fractions, two cyclic trimers 1,5,9-trimethyl-1,5,9-cyclododecatriene and 1,5,10-trimethyl-1,5,9-cyclododecatriene were detected. Factors that influence the reaction path leading to **1** were discussed. Sesqui- and diterpenoids, including farnesyl acetate, farnesylacetone and isophytol were synthesised starting from **1**. A regioselective tail to tail coupling of **1** was achieved with a palladium catalyst to give the dimer $C_{30}H_{48}$ which, upon catalytic hydrogenation, gave perhydrosqualene in 85% yield.

The synthesis of natural terpenoids based on isoprene has attracted the interest of organic chemists,[2] extensive investigations being made to effect selective oligomerization of isoprene with transition metal catalysts.[3] Such attempts have been less rewarding than the case of 1,3-butadiene; only a few attempts were successful for the catalytic synthesis of natural terpenoids. Until recently only monoterpenoids, 2,6-dimethyl-1,3,6- and 1,3,7-octatriene, were obtained in reasonable yields.[4] The selective linear oligomerization of isoprene[5] to give higher terpenoids appears to be difficult.

Trans-β-farnesene (**1**) and its double bond isomer, (*E*)-2,6-dimethyl-10-metflylene-1,6,11-dodecatriene (**2**) can be produced catalytically.[6] Doubtless **1** is a useful intermediate for the synthesis of sesqui- and diterpenoids. For example, farnesyl acetate, farnesylacetone, isophytol and squalane could readily be derived in good yields from **1**. This paper describes the selective linear trimerization of isoprene and the synthetic applications of **1**.

Results and Discussion

Catalytic Oligomerization. The isoprene oligomerization was effected with a nickel alkoxide catalyst, Ni(OR)(η^3-C_3H_5)L [L=PPh(NEt_2)$_2$] (*vide infra*). Conversion reaches about 45% after 8 h at 70 °C. First, the catalyst was deactivated with methanol. A mixture of the dimers and trimers (79.5% based on reacted isoprene) was then isolated by vacuum distillation. As the results of analytical GLC show (Figure), the dimer fraction contains four components and the trimer fraction consists of six isomers in the ratio **1**/**2**/**3**/**4**/**5**/**6**= 87/4/3/2/1/3. Thus the linear oligomers constitute the major components. Under appropriate reaction conditions using a nickel complex as catalyst, it is possible to obtain **1** with a selectivity approaching as high as 87% of the trimer fraction (60% based on the total oligomers produced).

By the conventional fractional distillation, the crude products were separated into three fractions, *viz.*, the dimer, linear and cyclic trimers. Each fraction was then subjected to preparative GLC to isolate the isomers. All the dimer components (**a**—**d**) are readily identified by comparing the retention times with those of authentic samples.

The structural assignments of **1** and **2** have been reported.[6] Compounds **3** and **4** were identified on the basis of the catalytic hydrogenation and their spectro-

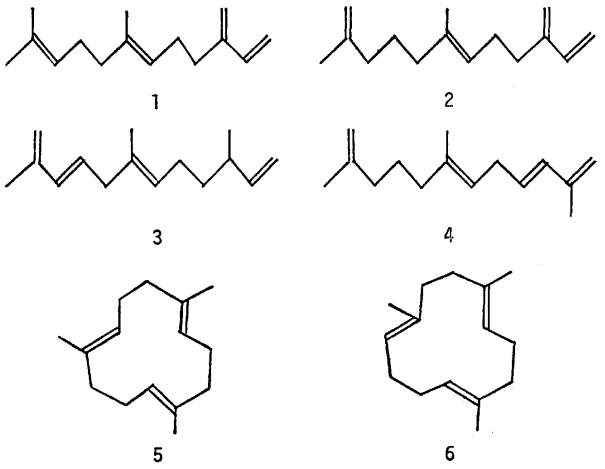
a) 60 MHz, in CCl_4, s: singlet, d: doublet, t: triplet, q: quartet, m: multiplet. b) Neat. c) Measured in ethanol.

scopic properties (Table 1). Upon catalytic hydrogenation, **3** and **4** absorbed 4 mol of hydrogen producing 2,6,10-trimethyldodecane and 2,6,11-trimethyldodecane, respectively. Their ^{1}H NMR and IR spectra are in line with the assignment of **3** as (3*E*)-2,6,10-trimethyl-1,3,6,11-dodecatetraene and of **4** as (3*E*)-2,7,11-trimethyl-1,3,6,11-dodecatetraene. Although the spectral data available do not allow unambiguous determination of the double bond geometries at C-6 in **3** and **4**, it is likely, in view of the established structures of **1** and **2**,[6] that these double bonds are of *E*-configuration. In line with this inference, the chemical shift (δ, 1.59 ppm) of the singlet signal of the inner allyl methyl protons of **3** and **4** coincides with that of the corresponding signal of **1** or **2**.

Cyclic trimers **5** and **6** can be further purified by crystallization from hexane. Isomer **5** forms less soluble crystals, mp 43.5 °C. Upon ozonization and subsequent treatment of the ozonide with dimethyl sulfide, **5** yield 4-ketopentanal as the sole product, while the mother liquid containing **5** and **6** (1/3) gives a mixture of 1,4-butanedial, 4-oxopentanal and acetonylacetone in a ratio 1/1.5/1. The structures of **5** and **6** are thus assigned as 1,5,9- and 1,5,10-trimethyl-1,5,9-cyclododecatriene, respectively. The full assignment of isoprene cyclotrimers, in spite of numerous studies on cyclotrimerizations of 1,3-butadiene, has not been established.[3c,5] Although the double bond geometries of these oligomers remain to be elucidated, the all trans configuration is tentatively assigned to isomer **5** of higher melting point.



The neutral auxiliary ligand (L) plays a role of paramount importance in the nickel mediated catalysis.[6] $[NiX(\eta^3\text{-}C_3H_5)]_2$ alone gave the linear trimers in a very low yield. The presence of electron-donating phosphines or arsine such as $PPh(NEt_2)_2$ or $As(i\text{-}C_3H_7)_3$ is necessary for efficient catalysis. Various catalysts or their precursors were prepared by use of the following mixture: (1) 1:1 $Ni(\eta^3\text{-}C_3H_5)_2$ and $PPh(NEt_2)_2$, (2) 1:1:3 $Ni(acac)_2$, $PPh(NEt_2)_2$, and $AlEt_3$, and (3) 1:1:1.2 $[NiX(\eta^3\text{-}C_3H_5)]_2$, $PPh(NEt_2)_2$ or $As(i\text{-}C_3H_7)_3$, and NaOR (R=long chain alkyl). Representative results obtained have been given.[6] Qualitatively the relative catalytic activities are (1)$\simeq$(3)$<$(2).

The anionic ligand also influences the catalysis.

Table 2. Trimerization of isoprene[a]

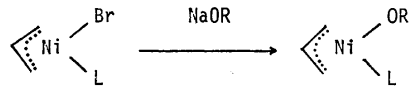
No.	Base[b]	Conversion (%)	Dimers (%)	Trimers (%)[c]	Highers (%)[d]	Content (%) of **1** in Trimers
1	—	0	—	—	—	—
2	MeONa	35.1	42.1	35.2	22.7	30.6
3	$n\text{-}C_4H_9ONa$	41.5	29.5	46.1	24.4	62.2
4	$n\text{-}C_{15}H_{31}ONa$	40.5	21.2	71.6	20.5	87.3
5	$n\text{-}C_{15}H_{31}ONa$[e]	30.7	30.5	51.0	18.5	71.0
6	$LiNEt_2$	15.6	75.2	3.5	11.3	0

a) The mol ratio of isoprene/$[NiBr(\eta^3\text{-}C_3H_5)L]$ (**7**) is 100/1, at 70 °C for 7 h. b) The ratio of **7**/base was 1.2 unless otherwise stated. c) Contains all trimers (**1**—**6**). d) Based on the reacted isoprene. e) The ratio of **7**/base was 1/2.4.

Mononuclear halide complexes, $[NiXL(\eta^3\text{-}C_3H_5)]_2$ (X= Cl, Br), were found ineffective. The halide ligand may be replaced by the diethylamino group. However, the trimer yield was much lower (Table 2). Use of acetate or thiolate anions for X completely killed the catalytic activity. When the halide X is replaced by an alkoxide, in particular by a long-chain alkoxide (recipe 3), the oligomerization occurs smoothly producing the two linear trimers (**1** and **2**) with high selectivities (>75%). Recipe (2) also gives a high selectivity for the trimers. A conspicuous difference between recipe (2) and (3) is the ratio **1**/**2**. The former gives **2** as the major trimer, the latter predominantly **1**.

The alkoxide catalyst (recipe 3) is the only nickel system so far which gives natural β-farnesene as the major product. The effect of the anionic ligand is therfore noteworthy. Both the selectivity for trimers (**1**+**2**) and the ratio **1**/**2** were found to increase in the order: $CH_3O < n\text{-}C_4H_9O < n\text{-}C_{15}H_{31}O$ (Table 2).

In view of the conspicuous tendency of related alkoxide nickel complexes $[Ni(OR)(\eta^3\text{-}C_3H_5)]_2$ to disproportionate into $Ni(\eta^3\text{-}C_3H_5)_2$ and "$Ni(OR)_2$"[7] and of the facile β-hydrogen elimination of alkoxide Pd(II) or Pt(II) compounds,[8] it is unlikely that compound **8** remains under the reaction conditions.



7 8

It was difficult to follow **8** under the reaction conditions and attempts to identify the active catalyst species were unsuccessful. However, the marked controlling effect of the alkoxide anion suggests that the anion is involved in the active species producing the linear trimers.

The linear oligomerization is always accompanied to some extent by cyclo-oligomerization. This side reaction seems to occur with a "naked" Ni(0) or Ni(0)-L species containing no alkoxide anion, as established by Jolly and Wilke for the Ni(0)-catalyzed cyclooligomerization.[3c] The Ni(0) species could be produced directly from disproportionation[7] of **8** or from reductive elimination[8]

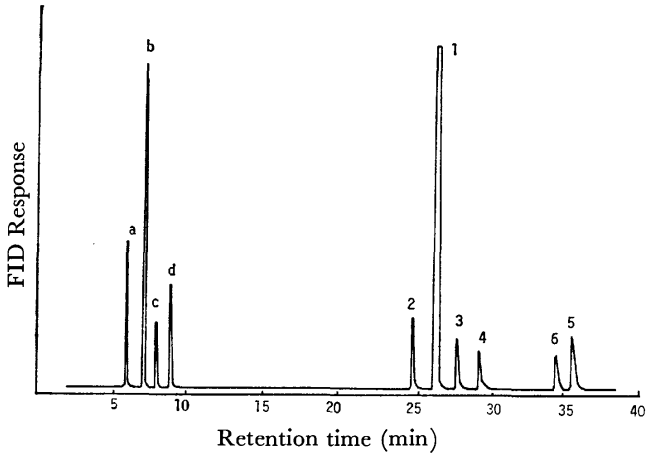


Fig. 1. Gas chromatogram[1] of the dimer and trimer fractions of the isoprene oligomerization.[2]
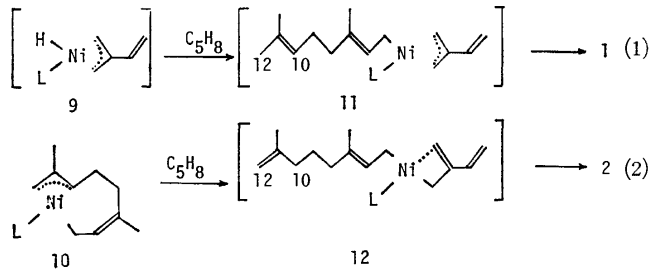
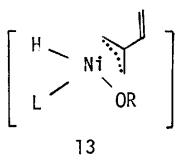
1) Column C, 130 °C; 2) Run 4 in Table 1 as representative example; **a**, 1,5-dimethyl-5-vinyl-1-cyclohexene; **b**, dipentene; **c**, 1,6-dimethyl-1,5-cyclooctadiene; **d**, 1,5-dimethyl-1,5-cyclooctadiene; **1**, *trans*-β-farnesene; **2**, (*E*)-2,6-dimethyl-10-methylene-1,6,11-dodecatriene; **3**, (3*E*)-2,6,10-trimethyl-1,3,6,11-undecateraene; **4**, (3*E*)-2,7,11-trimethyl-1,3,6,11-dodecateraene; **5**, 1,5,9-trimethyl-1,5,9-cyclododecatriene; **6**, 1,5,10-trimethyl-1,5,9-cyclododecatriene.

of **8**. It is inferred that although the major active species is the alkoxide-containing species (*vide infra*), the present catalyst systems also contains a minor amount of the "naked" Ni(0) species. The latter is responsible for the formation of the cyclotrimers.

A reaction scheme was proposed on the basis of a Ni(0)-L species.[6] Methyl hydrogen migration is assisted by an electron-donating ligand L. The hydrogen migration pathway was established by deuterium distribution studies on the trimer product **2** from 1,1,4,4-tetradeuterated isoprene. Key intermediates **9** and **10** were postulated to account for the formation of **1** and **2** (Eqs. 1 and 2).



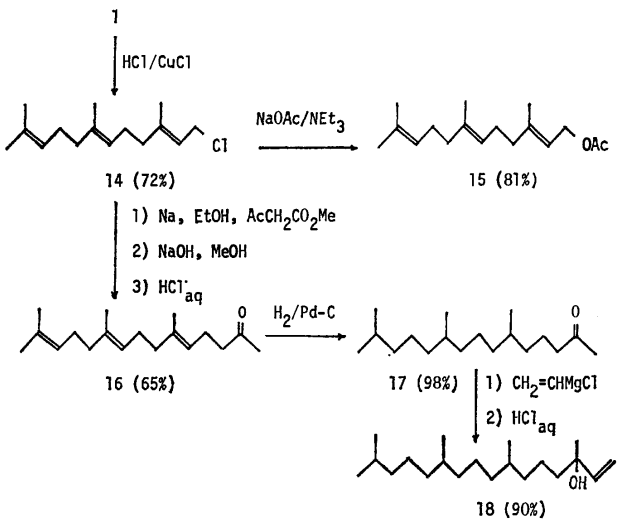
The present catalyst systems are ineffective for the isomerization of **2** to **1** suggesting two separate routes leading to the double bond isomers **1** and **2**. Intermediate **10** would lead to **12** whose dimer ligand contains a terminal double bond, since a nucleophilic hydride attack would occur at the secondary carbon in the η^3-allyl part of **10** rather than at the terminal carbon which is more anionic. Since **10** is unlikely to be a precursor of **11**, the formation of **1** is best accounted for by isoprene insertion into a Ni–H bond in the postulated intermediate **9**. The marked effect of a long chain alkoxide ligand (Table 2) invokes an intermediacy of an alkoxide complex like **13** which can not be detected.



Recipe (2) might give predominantly **12**, which in turn is derived from the dimer complex **10**. Compound **10** has been isolated by Barnett *et al.*[9] The formation of **10** does not require the methyl hydrogen migration. It appears that one role of the alkoxide is to assist hydrogen abstraction to form a hydride species NiH(OR) involved in **13**. It is also possible that the large alkoxide group stabilizes the NiH(OR) species. The increased coordination number in **13** as compared to **9** is in line with the increased formal oxidation state. We tentatively postulate a reaction scheme essentially similar to the previous one for the formation of **1** and **2**. Regarding the minor isomeric products **3** and **4**, several routes involving the dimer intermediates **10** or its σ-π valence isomer are conceivable for the formation.

Derivative Chemistry. Purification of **1** can be achieved by repeated fractional distillation of the linear trimer fraction, but with a substantial loss due to polymerization. The crude product containing over 80% **1** was found to be satisfactory for most synthetic purposes. No further purification was necessary since many functionalization reactions occur preferentially at the 2-substituted 1,3-diene terminus of **1** and **2** rather than at the 1-substituted 1,3-diene part of **3** and **4**. The isolation of products, *e.g.* oxygen-containing terpenoids, is often achieved by distillation through a short fractionation column.

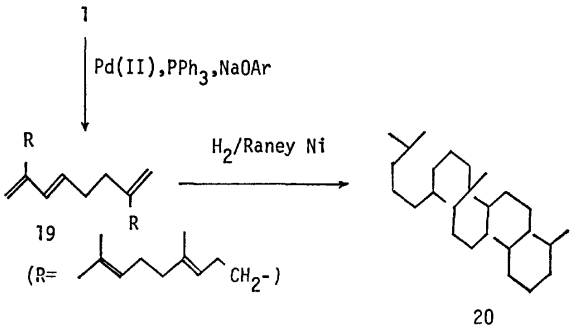
The high reactivity of the terminal group of **1** facilitates regio-selective introduction of a functional group useful for further extension of the carbon chain. Some representative examples are shown below.



These derivations[10] do not require further comment. Yield and selectivity for each process are satisfactory.

Since the starting material **1** is contaminated with a few percent of **2**, farnesyl chloride **14** or acetate **15** contains 1—3% of the corresponding double bond isomer (2,6,11-triene). Both *E* and *Z* geometries were found for the newly formed trisubstituted double bond at C-2. In the above scheme the *Z*-form is not shown for the sake of clarity.

It is known that a regioselective tail to tail coupling of isoprene molecules can be achieved by a palladium catalyst.[11] A modified palladium catalyst consisting of palladium nitrate, triphenylphosphine, and sodium *o*-methoxyphenolate (molar ratio; 1/2/4) was found to have much higher activity and excellent regioselectivity. More than one mol of **1** could be dimerized at the terminal carbon (**19**) by 1 m gram atom of palladium in 92% selectivity. Squalane (**20**) is obtained quantitatively from **19**.



Experimental

Nuclear magnetic resonance spectra were measured on a JEOL Model C-60HL (60 MHz), mass spectra on a Hitachi 6M-GC gas chromatogram-mass spectrometer, and infrared spectra on a JASCO-IRG. Analytical gaschromatograms were obtained with a Hitachi 063 instrument with a flame ionization detector using the following columns: A (20% Carbowax 20 M on Chromosorb W, 3 m×3 mm), B (7% SE-30 silicone rubber on Chromosorb W, 2 m×3 mm), **C** (Capillary, R-45, 45 m×0.5 mm), and D (Capillary, PEG 4000, 45 m×0.25 mm). Preparative separation was made on Shimadzu GC-1C gas chromatograph with a 2 m×1.5 cm column of 20% Carbowax 20 M on 60—80 Celite 545.

Bis(diethylamino)phenylphosphine (bp 145 °C/2 Torr) was prepared by treating phenylphosphonous dichloride with an excess of diethylamine. η^3-Allylnickel bromide was prepared from nickel carbonyl and allyl bromide. Isoprene was distilled over calcium hydride under nitrogen. Solvents were distilled and kept over Molecular Sieves 5A. Other reagent-grade chemicals were used without further purification. Manipulation of organometallics was performed under nitrogen atmosphere.

Preparation of Bromo(η^3-allyl)[bis(diethylamino)phenylphosphine]-nickel(I) (7). To a benzene solution of bromo(η^3-allyl)-nickel(I) (5.1 g, 28.3 mmol) was added bis(diethylamino)-phenylphosphine (7.6 g, 30 mmol) at 10 °C. After being stirred at 20 °C for 10 h, the mixture was evaporated *in vacuo* to leave a black solid. Recrystallization from hexane gave 10.3 g of **7** as violet needles, mp 215 °C (dec), in 81.5% yield based on the nickel complex; NMR (C_6D_6) 0.48 (d, J=3, $\underline{CH_2}$=CH–), 0.57 (t, $\underline{CH_3}$–CH_2–), 1.67 (d, J=6, $\underline{CH_2}$=CH–), 2.80 (q, N–$\underline{CH_2}$–), 4.32 (m, CH_2=$\underline{CH}$–) and 6.58 (s, $\underline{C_6H_5}$–). Found: C, 47.1; H, 6.7; N, 6.8%; Ni, 12.9% (chelatometric titration). Calcd for $C_{17}H_{30}N_2PBrNi$: C, 47.3; H, 7.0; N, 6.5; Ni, 13.6%.

General Procedure for Isoprene Oligomerization. To an isoprene (50 mmol) suspension of a base (1.2 mmol) was added a benzene solution of **7** (1.0 mmol) at 0 °C. The brown solution was heated at 70 °C for 7 h. The reaction product, after deactivation with 1 ml of methanol, was distilled to give a mixture of dimers and trimers (bp 60 °C/30 Torr to 85 °C/3 Torr) and residues. The mixture of dimers and trimers was then analyzed by GLC on column C.

Preparation of Isoprene Trimers in Large Scale. Isoprene (1.36 kg, 20 mol), *n*-$C_{15}H_{31}ONa$ (120 g, 0.48 mol) and a benzene solution of **7** (96 g, 0.4 mol) were charged in this order in a 5-litre stainless steel autoclave. Autoclaving was carried out to let the temperature rise from 20 to 80 °C over a period of 5.5 h. After the autoclave had been cooled, 50 ml of methanol was added to deactivate the catalyst. The unreacted isoprene (740 g) was recovered by distilling directly from the autoclave to a trap chilled at −20 °C, leaving 835 g of crude products. The reaction products were poured into ice–water (1 litre), extracted with ether (3×1 litre), and the ether solution was washed with 1% hydrogen peroxide solution (2×100 ml), 2 M hydrochloric acid (2×100 ml), saturated sodium hydrogencarbonate solution (2×200 ml) and saturated brine. The solvent was evaporated *in vacuo*, the crude liquid products weighing 621 g. Fractional distillation of the liquid products with a 70 cm Widmer column gave the dimer fraction, 103 g (21.2% based on reacted isoprene), bp 70—95 °C/30 Torr, the linear trimer fraction, 349 g (71.6%), bp 97—105 °C/3 Torr, and the cyclic trimer fraction, 35 g (7.2%), bp 107—110 °C/3 Torr, leaving a residue, 125 g (20.5%). Each fraction was analyzed by GLC on column C.

Separation of Cyclic Trimer. A hexane solution of the cyclic trimer fraction (25 g) was cooled at −30 °C and kept at this temperature overnight. The resulting crystals were rapidly filtered at this temperature and washed with chilled hexane (3×5 ml); needle (10.7 g), mp 43.5 °C. The GLC analysis on column C exhibits one peak, the retention time of which coincides with that of **5**. NMR ($CDCl_3$), 1.91 (s, $\underline{CH_3}$–C=), 2.29 (m, –$\underline{CH_2}$–C=) and 5.45 (t, J=16.0, C=$\underline{CH}$–); mass, *m/e* 204 (3.5%, M^+).

Ozonolysis of Cyclic trimers. A stream of ozone-containing (3.2%) oxygen was introduced into a solution of **5** (7.5 g) in dichloromethane (150 ml) at −10 °C for 5 h. The ozonide was decomposed by adding dimethyl sulfide (20 ml) at −15 °C and subsequent heating at 50 °C for 4 h. The mixture was then poured into ice–water (100 ml), extracted with dichloromethane (3×50 ml). The usual work-up gave a yellow oil (6.2 g), bp 72 °C/12 Torr. The oil was homogeneous on GLC (column D) and identical with an authentic sample of 4-oxopentanal in IR and NMR.

The ozonolysis of a mixture of cyclic trimers 5.5 g (the mother liquid, a 1/3 mixture of **5** and **6**) was carried out similarly to give a mixture of 1,4-butanedial (28.6%), 4-oxopentanal (42.8%) and 2,5-hexanedione (26.1%).

Attempted Isomerization of Linear Trimers. A 71.5/28.5 mixture of **1** and **2** (3.5 g) was heated in the presence of **7** (0.96 g) and *n*-$C_{15}H_{31}ONa$ (1.2 g) at 80 °C for 7 h. After adding methanol (1 ml), the mixture was worked up as usual to give 2.1 g of a mixture of **1** and **2**, bp 101 °C/3 Torr and a polymeric residue (1.4 g). The ratio of recovered **1** and **2** was the same as that of starting material.

Hydrogenation of Linear Trimers. A mixture of linear trimers (2.0 g) was hydrogenated (Pd–C, 0.1 g, H_2, 10 kg/cm² at 25 °C) to give two saturated hydrocarbons in the ratio 93.7/6.3. The abundant isomer was identical with an authentic sample of 2,6,10-trimethyldodecane in the retention time

of GLC (column C) and mass spectra. The other isomer was identified as 2,6,11-trimethyldodecane, which was prepared by reaction of 3,7-dimethyloctylmagnesium chloride with 3-methylbutanal and subsequent dehydration and hydrogenation.

Hydrochlorination of Linear Trimers. Hydrogen chloride was introduced to a solution of linear trimers (300 g) in dichloromethane (300 ml) containing a catalytic amount of copper(I) chloride (3 g) at 0 °C for 5 h (weight increase, 45 g). The mixture was neutralized with 10% aqueous sodium carbonate, the organic layer being extracted with dichloromethane (2× 200 ml). The combined extracts were washed with saturated salt solution and evaporated *in vacuo* to give **14** (341 g) as a light yellow oil; NMR ($CDCl_3$), 3.46 (d, J=8.0, $-\underline{CH_2}Cl$). Found: Cl, 12.1% (titration method) Calcd for 87.3% content of $C_{15}H_{25}Cl$: Cl, 12.9%.

Synthesis of Farnesyl Acetate (15). A mixture of **14** (137 g, 0.5 mol), anhydrous sodium acetate (49.2 g, 0.6 mol) and triethylamine (6 ml) was stirred at 60 °C for 5 h. The reaction mixture was poured into ice–water (200 ml), extracted with ether (3× 150 ml), and the ether solution was washed with 2 M hydrochloric acid (2× 30 ml), 5% aqueous sodium hydrogen carbonate (3× 50 ml) and saturated brine, dried and evaporated to give a slightly yellow oil (135 g). The fractional distillation of the crude products with a 20 cmWidmer column gave a mixture of **3** and **4** (17.8 g), bp 91 °C/2 Torr and a mixture of stereoisomers of **15** (112 g), bp 105—107 °C/2 Torr (58.9% yield based on **1**). The ratio of stereoisomers was 65/35 for (2*E*,6*E*)- and (2*Z*,6*E*)-farnesyl acetate. The products were identified by comparison with authentic samples as regards retention times of GLC and mass spectra.

Synthesis of Farnesylacetone (16). To a solution of sodium ethoxide prepared by dissolving 2.5 g (0.11 g atom) of sodium in ethanol (100 ml) was added methyl acetoacetate (12.8 g, 0.11 mol) and **14** (27.4 g, 0.1 mol). After being refluxed for 5 h with stirring, the mixture was poured into ice–water (100 ml) and extracted with ether and worked up as usual to give an oil (39.1 g). A methanol solution of 1 M sodium hydroxide (120 ml) was added to the oil and the mixture was heated at 50 °C for 3 h. After the solvent had been evaporated, the whole mixture was poured into ice–water (100 ml) and acidified with 1 M hydrochloric acid and extracted with ether (3× 100 ml). The ether solution was worked up as usual to give an oil (29.3 g). The fractional distillation of the oil with a 20 cm Widmer column gave a mixture of **3** and **4** (3.6 g), bp 90 °C/2 Torr and a mixture of stereoisomers of farnesylacetone (**16**) (19.8 g), bp 105—107 °C/2 Torr, in 47.1% yield based on **1**. The ratio of stereoisomers, (5*E*,9*E*)- and (5*Z*,9*E*)-farnesylacetone, was 72/28. They were identified by comparison with authentic samples as regards retention times of GLC (column A) and in mass spectra.

Synthesis of Isophytol (18). A sample (15 g) of **16** was hydrogenated (Pd–C, 1.0 g in 30 ml 2-propanol, H_2, 70 kg/cm² at 100 °C for 3 h) to give **17** (14.9 g), bp 103 °C/1 Torr, semicarbazone, mp 85.1 °C (lit, 85.1 °C).

To a THF solution of vinylmagnesium chloride (12 ml, 0.012 mol), prepared from magnesium and vinyl chloride in THF, was added a THF (10 ml) solution of **17** (2.72 g, 0.01 mol) at 5 °C. After being stirred for 5 h at 25 °C, the mixture was poured into ice–water (50 ml) and acidified with 1 M hydrochloric acid and extracted with ether (3× 50 ml). The ether solution was worked up as usual to give **18** (2.85 g), bp 115 °C/1 Torr in 87.7% yield based on **17**. The GLC analysis (column A) of **17** and **18** showed a 95.2 and 94.1%, respectively, purity.

Dimerization of trans-*β-Farnesene.* A mixture of palladium nitrate (0.14 g, 1.0 mmol), triphenylphosphine (0.52 g, 2.0 mmol) and sodium *o*-methoxyphenolate (0.58 g, 4.0 mmol) and the linear trimers (102 g, 0.5 mol) in 2-propanol (100 ml) was heated at 60 °C for 12 h with stirring. After 2-propanol had been distilled off *in vacuo*, the residual mixture was extracted with ether (3× 100 ml). The usual work up of the extract gave an oil (101 g) which was distilled to give a mixture of **3** and **4** (13.2 g), bp 90 °C/3 Torr, and farnesene dimer (**19**), 80.1 g, bp 95 °C/0.005 Torr (90.5% based on **1**). For 19: IR, 1800, 1640, 973, 890, and 835 (cm^{-1}); NMR (CCl_4), 1.18 (s, $\underline{CH_3}$–C=), 1.50 (m, $-CH_2-$), 2.18 (m, =C–$\underline{CH_2}-$), 4.60 (s, $-\underline{CH_2}$=C), 5.15 (t, J=7, $-\underline{CH}$=C) and 5.52 (m, $-\underline{CH}$=C); *m/e* 408 (2.5%, M^+).

Synthesis of Perhydrosqualene (squalane) (20). The hydrogenation of **19** (20 g) in the presence of Raney nickel (W-4, 1.0 g) under H_2 (80 kg/cm² at 100 °C) gave **20** (20.1 g) quantitatively, bp 102 °C/0.01 Torr; *m/e* 422 (15.2%, M^+). The GLC analysis on column B showed a main peak (91%) retention time of which was identical with that of an authentic sample of squalane.

(Received August 16, 1977)

The benzyne reaction of cyclic olefins, in competition with that of cyclohexene has been studied. The relative reactivities for ene reaction and the stereoselectivity of the reaction with 4-*t*-butylcyclohexene, which afforded *trans*-5-*t*-butyl-3-phenylcyclohexene and *cis*-3-*t*-butyl-6-phenylcyclohexene, are consistent with the stereochemical requirements along the reaction pathway.

The reaction of benzyne with cyclic olefins has been attracting interest in connection with the stereochemical course of the reaction.[1-4]

The addition of benzyne to cyclic dienes falls into three categories: [2+2]-, [2+4]-cycloaddition reactions, and ene reaction. The former is believed to be a stepwise reaction and the latter two are mostly concerted reactions.[2] Stephenson has discussed the stereochemistry of the ene reaction, which proceeded in general in a concerned manner, as depicted in Fig. 1.[5]

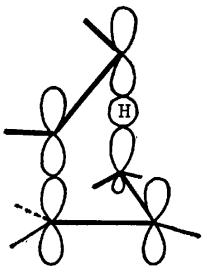

Fig. 1.

As cyclic olefins of medium-sized rings have rather mobile molecular frameworks within the limited conformations, the geometry of approach of benzyne toward cyclic olefins will be, in some cases, somewhat strained, and hence the geometry which can achieve a better overlapping of the correlated molecular orbitals in the transition state will be reflected in the reactivities for the ene reaction.

However, there is no report on the study of relative reactivities for ene reaction of olefins against benzyne, so we investigated the competition reaction of cyclic olefins in the presence of one equivalent of cyclohexene. For cyclic olefins, we chose simple ones: *i.e.*, cyclopentene (**1**), 4-*t*-butylcyclohexene (**2**), cycloheptene (**3**), *cis*-cyclooctene (**4**), and 1,2-cyclononadiene (**5**), to avoid the complexity arising from steric hindrance by substituents.

Identification of Products. Reaction with (a) Cyclopentene: From the 1: 1 addition mixture, **6** and **7** were detected as products. The fact that **6** showed no olefinic proton signal in the NMR spectrum, in addition to an integral ratio (4: 2: 6) of aromatic, benzylic, and aliphatic proton signals and to a A_2B_2 symmetry of aromatic signals, supported the [2+2]-structure. The NMR spectrum of **7** indicated that it was a phenyl substituted cyclopentene with two non-equivalent olefinic protons, which defined unequivocally the structure as 3-phenylcyclopentene.

(**10**) $n=3$
(**12**) $n=4$

Scheme 1.

(b) Cyclohexene: 3-Phenylcyclohexene (**8**)[6] was obtained as the sole product and identified on the basis of IR and NMR spectra.

(c) Cycloheptene: Compounds **9** and **10** were separated using preparative GLC and characterized on the basis of their spectral data. The former was identified with a sample obtained by hydrogenation of a [2+2]-cycloaddition product of benzyne to cycloheptatriene.[7,8]

(d) cis-*Cyclooctene*: Because the 1: 1 addition products could not be separated using preparative GLC, the product mixture dissolved in ethyl acetate was hydrogenated over 10% Pd on carbon. GLC analysis of the hydrogenation products allowed us to estimate that the original mixture contained **11** and **12** in a ratio of 1: 7.7 by weight;[9] this result was also obtained from the examination of the PMR integral ratio of the original mixture.

(e) 1,2-Cyclononadiene: The products were separated using GLC, and were identified as **13** and **14** on the basis of the spectral data.[1]

*(f) 4-*t*-Butylcyclohexene*: The 1: 1 addition products were separated into two components, **15** and **16**, in a ratio of 1: 1.2; these were carefully investigated. Catalytic hydrogenation (Pd–C) of **15** gave thermodynamically unstable *trans*-3-*t*-butyl-1-phenylcyclohexane, which was transformed to a known *cis*-isomer by treatment with potassium *t*-butoxide in DMSO. Hydrogenation of **16** over PtO_2 gave *cis*-4-*t*-butyl-1 phenylcyclohexane,[10] which was treated under the same conditions of base to give exclusively the known *trans*-isomer. The position of the double bond in **15** and **16** was determined on the basis of their spectral data. The absence of intense absorption bands near 250 nm in UV

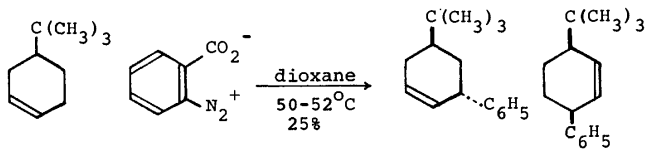
† Parts of this work were presented at the 36th Spring Meeting of the Japan Chemical Society, April 1—4, 1977 (Osaka). See the Abstracts II (1977), p. 1092.

TABLE 1. RELATIVE REACTION RATES OF CYCLIC OLEFINS WITH BENZYNE

Olefins	Relative rates [ene]	Relative rates [2+2]	θ_1	θ_1'	Preferred conformations
Cyclopentene	1.25[a]	0.19[a]	30°	30°	planar[11]
			17°	40°	envelope[12]
Cyclohexene	1.00	0	4—13°	47—56°	half-chair[12-14]
Cycloheptene	0.62	0.22	32—40°	80—88°	chair[12,15]
cis-Cyclooctene	0.88	0.11	20—56°	64—81°	twist[12,16]
4-*t*-Butyl-cyclohexene	0.89 (0.49+0.40)	0	4—13°	47—56°	half-chair[14]
1,2-Cyclo-nonadiene	7.54 (17.55)[b]	1.63 (4.40)[b]	35°	83°	rigid

a) Dichloromethane was used as solvent. b) Acetonitrile was used as solvent.

spectra of **15** and **16** eliminates phenyl-conjugated cyclohexene structures. That they showed two olefinic proton signals strongly coupled with benzylic proton signals in NMR spectra defined the structures.



(**15**) 1: 1.2 (**16**)

Scheme 2.

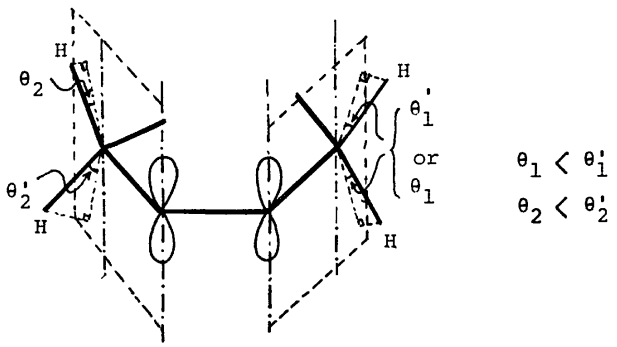


Fig. 2.

Competition Reaction with Cyclohexene. A mixture of an olefin, cyclohexene, and benzenediazonium-*o*-carboxylate in a molar ratio of 1: 1: 2 suspended in dioxane was stirred and heated at 50—52 °C. The hydrocarbon products were separated and carefully examined with the use of GLC. The results are collected in Table 1.

TABLE 2.

Cyclic olefins	Ratios of ene/[2+2]	θ_1	θ_2
cis-Cyclononene[18]	∞	0°	0°
Cyclohexene[19]	∞	13°	13°
cis-Cyclooctene[9]	8	0°	34—46°
1,2-Cyclononadiene[1]	6.2	0°	45°
Cycloheptene[7]	2.6	24°	39°
1,3,5-Cycloheptatriene[7]	2.3	36°	36°
trans-Cyclononene[17]	0.9	60°	30°
trans-Cyclooctene[9]	0	55°	65°

Results and Discussion

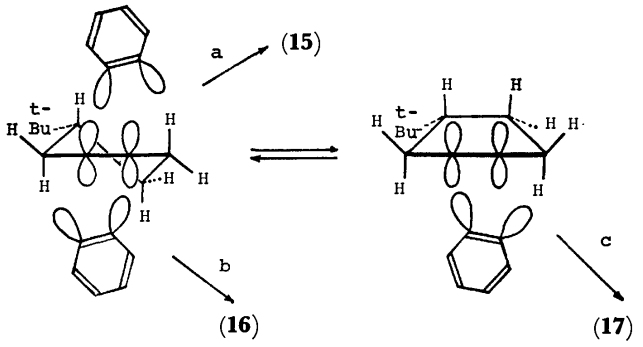
In 1973, Crews noticed that the product ratio of ene/[2+2] reaction of benzyne for cyclic olefins varies as an angle θ_1 changes (Fig. 2): the ratio and θ_1 values (in parentheses) are ∞ (4°), 3 (5°), 0.8 (33°), 0.07 (37°).[17] We had reached a similar conclusion when we studied the reaction with cycloheptatriene and cycloheptene.[7] Table 2 shows the data[7b] and includes additional values. The dihedral angles (θ_1, θ_1', θ_2, θ_2') between the axis of each *p*-orbital and the corresponding adjacent methylene C–H bonds are taken as shown in Fig. 2 and measured by the examination of the molecular models. If the molecular model is mobile, θ_2 was obtained after θ_1 was fixed by making it as small as possible. From this table, it is clear that the ene reaction becomes of no account compared to [2+2] cycloaddition when θ_1 (or θ_2) becomes an angle exceeding 55°.

Arnold and co-workers have demonstrated that the hydrogen abstraction occurs regioselectively in the ene reaction of β-pinene with benzyne. This experiment supports the assertion that the reaction proceeds in concerted mechanism.[20]

Accordingly, it is expected that the more close to zero degrees the dihedral angle (θ_1) between a relevant C–H bond and the adjacent olefinic *p*-orbital is (Fig. 2), the more smoothly the ene reaction of benzyne will proceed.

In the case of cyclohexene, however, the ene/[2+2] ratio is reported to be infinite.[6] We could not be convinced either that the [2+2] reaction with benzyne proceeded at similar rates for every olefin or that the ene reaction with cyclohexene advanced at an extraordinary rate. In order to obtain further knowledge about the transition state for the ene reaction of benzyne, we examined the reaction with a cyclohexene having a rather fixed conformation, *i.e.*, 4-*t*-butylcyclohexene. From the knowledge of conformational analysis, we need not consider a conformation of **2** keeping *t*-butyl group in axial position. If the most stable half-chair conformation of cyclohexene ring could easily flip into a half-boat form having an equatorial *t*-butyl group during the reaction (Scheme 3), *cis*-5-*t*-butyl-3-phenylcyclohexene (**17**) might be formed by way of path c. This was not the case. It is clear that the ene reaction involving a quasi-equatorial C–H bond with dihedral angle 47—56°

has not taken place, while the one involving an quasi-axial C–H bond with 4—13° has occurred. These results show undoubtedly that the transition states a and b are practically important.



Scheme 3.

In the competition reaction between 4-*t*-butylcyclohexene and cyclohexene, formation of **15** is somewhat retarded in comparison with the formation of **16**, the rate of which is almost comparable to a half of the formation of 3-phenylcyclohexene from cyclohexene. From this fact, it is assumed that cyclic olefins react with benzyne, with high probabilities, in their most thermodynamically stable conformations, which, except *cis*-cyclooctene,[16] have a plane or an axis of symmetry intersecting the middle point of the C=C double bond. Therefore, to analyze the ene reaction, it will be enough to compare the conformation of one of the two methylene groups adjacent to the double bond. The angles θ_1 and θ_1' are obtained from measurements on the molecular models.

In the electronic spectra of conjugated ketones with steric hindrance of conjugation, it is claimed that the degree of conjugation is proportional to a directly excited molecular fraction r, or a ratio of molecular extinction coefficients of hindered to unhindered ketone, $\varepsilon/\varepsilon_0$, which is approximately given by $\cos^2\theta$ (θ: dihedral angle).[21] If we suppose that the ene reaction proceeds readily in harmony with the degree of hyperconjugation between an allylic hydrogen and the double bond, the plots of relative rates as a function of $\cos^2\theta_1+\cos^2\theta_1'$ given in Fig. 3 must have some clear feature. (In case of θ_1' 55°, $\cos^2\theta_1'$ is neglected). The approximately linear relationship in them is in line with the stereochemical course of ene reaction discussed above.

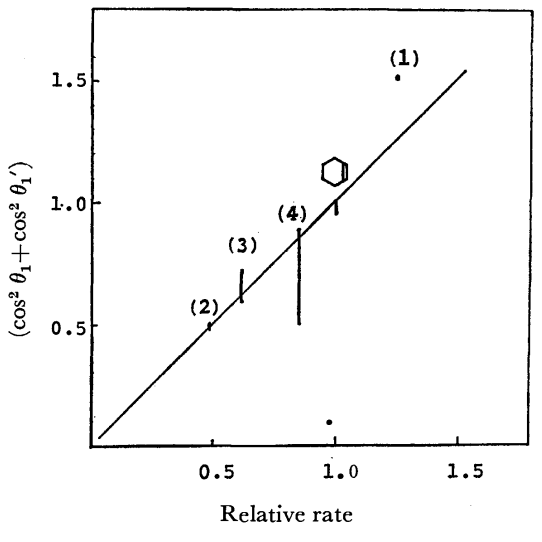


Fig. 3. Plot of relative rates against $\cos^2\theta_1+\cos^2\theta_1'$ for ene reaction of benzyne.

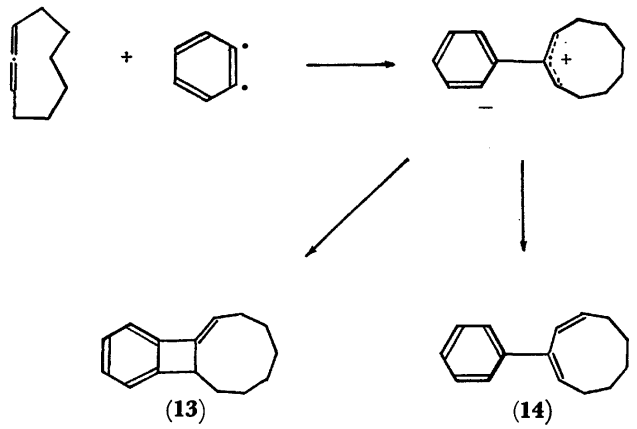
In the case of cyclopentene, if we were to choose either a planar[11] or an envelope conformation,[12] the plots deviate above the line.

In the case of *cis*-cyclooctene, the molecular framework is so labile that there are some preferable conformations,[12,16] of which the one with the smallest θ_1 satisfies the linearity.

On the other hand, at first sight, it seemed that there is no regularity between the reactivities of [2+2]-cycloaddition and the conformations of cyclic olefins. But it is interesting to note that the [2+2]-reaction proceeded in similar rates for cyclopentene and cycloheptene, while the relative rate for *cis*-cyclooctene fell to approximately a half of that for cycloheptene. This suggests that either above or below the sp^2-sp^2 plane of cyclooctene happens to be blocked from any attack of benzyne with the intramolecular methylene group, owing to the mobility of the molecular structure. We could not find any reason to justify the absence of the [2+2] product when cyclohexene was used as a substrate.

The relative rates for both ene and [2+2] reaction with 1,2-cyclononadiene are exceptional, as compared with the other olefins. The extraordinary enhancement of both reaction rates suggests a process of a different mechanism, that is, the ionic process[22] shown in Scheme 4, in addition to the ring strain. This seems to be supported by an increase in relative reactivities when the reaction was carried out in a more polar solvent such as acetonitrile. Further studies on the reactivities of allenes are now in progress.



Scheme 4.

Experimental

The NMR spectra were obtained on a JEOL Model PS-100 spectrometer with carbon tetrachloride as a solvent and TMS as an internal standard. The chemical shifts are expressed in ppm from TMS. The IR was recorded on a JASCO Model

IRE spectrometer. GLC analysis was carried out on a Varian Aerograph Model 90P gas chromatograph under quoted conditions.

Reaction of Cyclopentene with Benzyne. Solid benzenediazonium-*o*-carboxylate, prepared from 20 mmol of anthranilic acid,[23] was suspended in dichloromethane (100 ml) containing cyclopentene (1.36 g, 20 mmol) and stirred at 37 °C for 3 h. The resulting solution was washed successively with water, aq sodium bicarbonate, and water, then dried (anhyd sodium sulfate). The residue (2.06 g) from the organic layer, dissolved in benzene, was chromatographed on Silicic Acid (Mallinckrodt, 100 g) and eluted with the same solvent. The hydrocarbon fraction (1.33 g, light brown liquid) from the eluate was rechromatographed on Silicic Acid (50 g). Fraction 1—10 (417 mg) contained **6** and **7** in a ratio of 0.26: 1 and fractions 11—20 (225 mg) contained **7**. GLC separation of the samples (see below) gave pure samples of them. The physical data of **6** and **7**: **6** NMR δ: 1.1—2.1 (6H, m), 3.78 (2H, broad d), 6.75—7.2 (4H, A_2B_2 type). Found: C, 91.63; H, 8.49%. IR ν(liq. film): 3060, 2930, 2850, 1460, 1350, 1290, 1205, 1112, 1003, 997, 820, 763, 743. **7** NMR δ: 1.5—2.0 (1H, m), 2.2—2.4 (3H, m), 3.68—4.0 (1H, m), 5.6—6.0 (2H, m), 6.9—7.4 (5H, m). IR ν(liq. film): 3060, 2940, 2850, 1602, 1496, 1455, 1360, 1080, 1032, 1012, 917, 760, 730, 700. Found: C, 91.57; H, 8.46%. Calcd for $C_{11}H_{12}$: C, 91.61; H, 8.39%.

Reaction of 4-t-Butyl-1-cyclohexene with Benzyne. Solid benzenediazonium-*o*-carboxylate, prepared from 20 mmol of anthranilic acid,[23] was suspended in dioxane (100 ml) containing 4-*t*-butyl-1-cyclohexene (2.76 g, 20 mmol) and stirred under heating at 50—52 °C for 3 h. The solvent was evaporated and the residue, taken in dichloromethane, was washed successively with 5% aq sodium bicarbonate and water. After drying the organic solution, the residue, taken in benzene, was chromatographed on Silicic Acid (50 g). The yellow liquid obtained by elution with benzene was rechromatographed on Silicic Acid (50 g) with hexane–ether (90: 10 v/v) as solvent. The 1: 1 addition products (1.07 g, 25% yield) were obtained as a pale yellow oil, which was separated using preparative GLC [10% Silicone DC-QF-1 on Chromosorb WAW; 1/4 inch×3 m; Helium flow rate, 20 ml/min; column temperature, 150 °C; retention times: **15**, 15.3 min; **16**, 19.7 min]. Physical data: **15** NMR δ: 0.76 (9H, s), 0.9—2.3 (5H, m); 3.54 (1H, broad S), 5.6—6.1 (2H, m), 7.0—7.3 (5H, m); IR (liq. film) ν: 3020, 2945, 2870, 1600, 1498, 1480, 1452, 1400, 1370, 1238, 1078, 1032, 880, 785, 760, 720, 702. **16** NMR δ: 0.96 (9H, s), 1.1—2.1 (5H, m), 2.06 (s, impurity), 3.2—3.5 (1H, m), 5.6—6.1 (2H, m), 7.0—7.3 (5H, m). IR (liq. film) ν: 3020, 2940, 2860, 1600, 1495, 1480, 1452, 1398, 1370, 1226, 1075, 1032, 1020, 990, 890, 850, 818, 767, 756, 730, 700.

*Characterization of **15**.* **15** (60 mg), dissolved in ethyl acetate (5 ml) was hydrogenated over 10% Pd–C as a catalyst to give *trans*-1-*t*-butyl-3-phenylcyclohexane (**18**) (54 mg) as the sole product. **18** NMR δ: 0.87 (9H, s), 0.9—2.0 (7H, m), 2.0—2.5 (2H, m), 2.95—3.3 (1H, broad s), 6.9—7.4 (5H, m). IR (liq. film) ν: 2930, 2850, 1600, 1500, 1470—1480, 1450, 1400, 1370, 1230, 1030, 780, 757, 728, 700.

18 (20 mg), dissolved in DMSO (6 ml), was treated with potassium *t*-butoxide (100 mg) at 120—130 °C for 1.5 h under nitrogen atmosphere to give *cis*-isomer[10] of **18** (5 mg). An authentic *cis*-isomer was synthesized from 4-*t*-butyl-2-phenyl-1-cyclohexanone by Wolff-Kischner reduction (KOH–hydrazine hydrate in diethylene glycol) in 74% yield and identified. *cis*-1-*t*-Butyl-3-phenylcyclohexane NMR δ: 0.89 (9H, s), 0.9—2.1 (9H, m), 2.2—2.8 (1H, m), 6.9—7.3 ((5H, m). IR (liq. film) ν: 3030, 2930, 2850, 1602, 1500, 1480, 1450, 1400, 1370, 1240, 1072, 1032, 762, 701. Found: C, 88.89; H, 11.39%. Calcd for $C_{16}H_{24}$; C, 88.82; H, 11.18%.

*Characterization of **16**.* Catalytic hydrogenation of **16** (20 mg) over platinum oxide (5 mg), dissolved in ethyl acetate, gave *cis*-1-*t*-butyl-4-phenylcyclohexane (**19**) as a colorless liquid. **19** NMR δ: 0.81 (9H, s), 0.9—2.0 (7H, m), 2.0—2.42 (2H, broad d), 3.02 (1H, broad s), 6.95—7.4 (5H, m). IR (liq. film) ν: 2930, 2850, 1602, 1500, 1480, 1452, 1400, 1370, 1028, 802, 760, 730, 700. Found: C, 88.89; H, 11.29%. Calcd for $C_{16}H_{24}$: C, 88.82; H, 11.18%.

When 10% Pd–C was used as a catalyst in place of platium oxide, some *trans*-1-*t*-butyl-4-phenylcyclohexane was formed along with **19**. Isomerization of **19** to the *trans*-isomer was carried out (DMSO/*t*-butoxide) as described above for that of **18**.[10] *trans*-Isomer of **19**: mp 40.5—41 °C. NMR δ: 0.87 (9H, s), 0.9—2.1 (9H, m), 2.1—2.6 (1H, m), 6.9—7.3 (5H, m). IR (liq film) ν: 2930, 2840, 1600, 1498, 1480, 1450, 1400, 1370, 1230, 1018, 898, 760, 700. This compound was identified with an authentic sample.[10]

A Competitive Benzyne Reaction of a Representative Olefin with Cyclohexene. Solid benzenediazonium-*o*-carboxylate, prepared from 20 mmol of anthranilic acid,[23] suspended in dioxane (100 ml) containing 10 mmol each of cyclohexane and an olefin, was stirred under heating at 50—52 °C until the gas evolution had ceased. After the usual work-up (see above experiment on 4-*t*-butylcyclohexene), the product mixture was roughly chromatographed on Silicic Acid (100 g) using benzene as solvent. The hydrocarbon fraction was rechromatographed on Silicic Acid (50 g) with the use of hexane as solvent. The products were estimated and separated into their components with use of GLC. For GLC separation, two kinds of columns, *i.e.*, a 10% polyethylene glycol succinate on Chromosorb WAW, 1/4 inch×2 m (Column 1), and a 10% silicone DC-QF-1 on Chromosorb WAW, 1/4 inch×3 m (Column 2), were used. The retention times are: On column 1: (column temp 140 °C; Helium flow rate, 30 ml/min) **6**, 2.68; **7**, 3.6; **8**, 6.0 min; (column temp 130 °C; He, 20 ml/min) **9**, 12.4, **10**, 14.9 min; (column temp 150 °C; He, 20 ml/min) **12**, 12.4; **8**, 4.95 min. On column 2: (column temp 180 °C; He, 20 ml/min) **14**, 9.5; **13**, 11.3 min; (column temp 150 °C; He, 20 ml/min) **15**, 6.2; **16**, 7.5; **8**, 3.45 min.

The authors are grateful to Mr. Jun-ichi Goda for the analytical data.

(Received August 31, 1977)

The reaction of tetramethylbenzenedicarbonitriles and tetramethylbenzonitriles with fuming nitric acid (d=1.5) has been investigated at room temperature in the dark. 2,4,5,6-Tetramethylbenzene-1,3-dicarbonitrile and 2,3,5,6-tetramethylbenzene-1,4-dicarbonitrile gave, after aqueous work-up, 4-cyano-5,6,7-trimethyl- and 5-cyano-4,6,7-trimethylphthalides, respectively, in high yields, while 3,4,5,6-tetramethylbenzene-1,2-dicarbonitrile produced appreciable amounts of two cyanonitro-3-cyclohexen-1-ones in addition to 7-cyano-4,5,6-trimethylphthalide. Similarly, 2,3,4,6- and 2,3,5,6-tetramethylbenzonitriles afforded 4-nitro-5,6,7-trimethyl- and 5-nitro-4,6,7-trimethylphthalides, respectively, along with the expected nitro compounds. In contrast, 2,3,4,5-tetramethylbenzonitrile underwent normal nitration, giving 6-nitro derivative as the sole product. The phthalide formation was found to proceed through 1,3-dihydroisobenzofuran-1-imines presumably derived from the initially formed *o*-cyanobenzyl nitrates. The reaction appears to provide potential utility in the synthesis of some substituted phthalides and 1,3-dihydroisobenzofuran-1-imines.

Pentamethylbenzonitrile reacts with nitric acid regiospecifically at the *ortho* side-chain to give 6-cyano-2,3,4,5-tetramethylbenzyl nitrate in high yield, which on acid hydrolysis is easily converted into 4,5,6,7-tetramethylphthalide.[2] This reaction appears interesting, since it provides a new route to some substituted phthalides of pharmaceutical interest. We therefore undertook an investigation of the scope of the reaction using as substrate a series of tetramethylbenzenedicarbonitriles (**1a—c**) and tetramethylbenzonitriles (**1d—f**). Simple phthalides are usually prepared by the hydrolysis of *o*-(halomethyl)benzoic acid and its derivatives, reduction of phthalic anhydride and related compounds, or oxidation of appropriate benzene derivatives containing oxidizable adjacent carbon chains.

Tetramethylbenzenedicarbonitriles. Dinitriles **1a—c** were nearly inert toward the action of nitric acid in dichloromethane solution and were recovered almost

a) These compounds begin to sinter at around 135—150 °C and melt with partial sublimation.

unchanged under the conditions successfully employed for the reaction of pentamethylbenzonitrile. Thus, dinitriles were dissolved in fuming nitric acid (d=1.5) itself and the mixture was allowed to stand at room temperature for several days. When the reaction mixture from **1b** or **1c** was diluted with water, rather surprisingly, little precipitate was obtained. However, when the slightly turbid solution thus obtained was set aside overnight, a white crystalline solid separated out and was readily identified as cyanotrimethylphthalide (**7b**—**c**) on the basis of elemental analysis, molecular weight (m/e 201 (M^+)), and spectral data, as summarized in Table 1.

Of the three isomeric tetramethylbenzenedicarbonitriles, 3,4,5,6-tetramethylbenzene-1,2-dicarbonitrile (**1a**) was the least reactive member and behaved somewhat differently. However, by keeping it in contact with the nitrating agent for a week or longer, an appreciable amount of two cyanonitro-3-cyclohexen-1-ones (**8b** and **10**) was obtained in addition to the expected phthalide (**7a**). The structure proof for these nitro ketones and a possible mode of their formation will be the subject of the accompanying paper.

When the reaction mixture was diluted with cold water and the aqueous filtrate was immediately neutralized with sodium hydrogencarbonate, a yellow solid was obtained and crystallized from ethanol to pale yellow fine needles. Its mass spectral data (m/e 200 (M^+)) and elemental analysis were consistent with the formula $C_{12}H_{12}N_2O$. The PMR spectrum showed absorptions due to three methyl groups (δ 2.30—2.84), one methylene group (δ 5.15—5.38), and one imino proton (δ *ca.* 4—5; exchangeable with D_2O). The IR spectrum exhibited absorption bands due to the imino group at 3250—3300 and 1660—1680 cm^{-1}, in addition to the expected absorptions characteristic for a cyano group (2220—2235 cm^{-1}) and unsaturated cyclic ether (1015—1040 and 1210—1290 cm^{-1}). On acid hydrolysis it was converted into phthalide (**7a**—**c**). On the basis of the spectral evidence and the chemical transformation, the compound was identified as cyanotrimethyl-1,3-dihydroisobenzofuran-1-imine (**6a**—**c**). Few cyclic imidates of this type have been described previously, and most of these were obtained in unspecified yields by heating *o*-(halomethyl)benzamides at high temperatures.[3]

The isolation of imidate **6** provides a reasonable mechanism for the conversion of polymethylbenzonitriles into phthalides (Scheme 2). Nitronium ion makes an *ipso* attack at the site *meta* to the cyano group in **1** to form the arenium ion (**2**), which releases a proton from the activated methyl group *para* to the site of attack to give the triene (**3**), which is then transformed into the benzyl nitrate (**4**). In moderately strong protogenic acidic media, the nitrate **4** undergoes intramolecular ring closure through nucleophilic attack of the ester oxygen on the neighboring electron-deficient carbon of the nitrilium ion (**5**), giving **6** as a water-soluble salt.

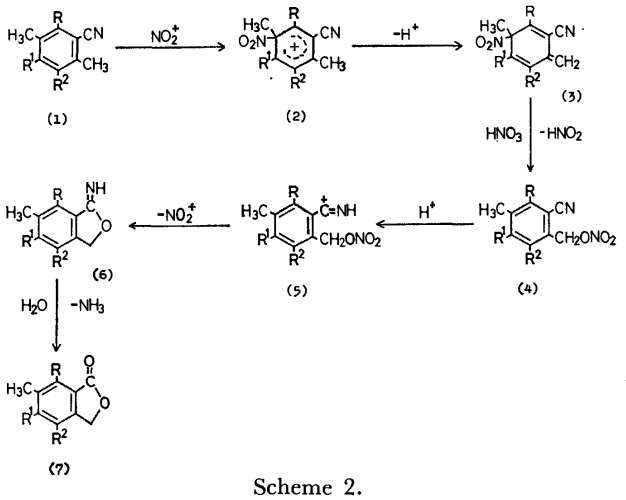

Scheme 2.

Formation of 1,3-dihydroisobenzofuran-1-imines is thus limited to those nitriles having at least one pair of methyl groups *para* to each other; others are simply nitrated on the ring or recovered unchanged. In contrast to the nitration of polymethylbenzenes in acetonitrile, in which *N*-(polymethylbenzyl)acetamides are obtained,[4] no Ritter-type reaction leading to 2,3-dihydro-1-isoindolones[5] was observed. To our knowledge, the formation reaction seems to be the first example in which the electrophilic carbon of the nitrilium ion displaces the acyl component on the ester oxygen, giving imidates as stable products.

Tetramethylbenzonitriles. The reaction of nitriles **1e—f** with fuming nitric acid proceeded with more ease, giving after the usual work-up a mixture of the corresponding nitrotrimethylphthalide (**7h—i**) and nitrotetramethylbenzonitrile (**1h—i**). In addition, a nitro ketone (**8d**) was obtained as a minor product from **1f**. When the reaction mixture was quenched with water and the aqueous filtrate was immediately neutralized with sodium hydrogencarbonate, nitrotrimethyl-1,3-dihydroisobenzofuran-1-imine (**6h—i**) was obtained. In sharp contrast, 2,3,4,5-tetramethylbenzonitrile (**1d**) was simply nitrated on the ring, giving 6-nitro-2,3,4,5-tetramethylbenzonitrile (**1g**) under the same conditions.

As a further extension of the present work, three isomeric trimethylbenzenetricarbonitriles were prepared and similarly treated with fuming nitric acid. However, the combined deactivating effect of three cyano groups surpassed the activating effect of three methyl groups and no reaction could be observed.

Although a limited number of cases have been investigated, it seems likely that many nitriles of the type **1** will yield phthalides and 1,3-dihydroisobenzofuran-1-imines in acceptable yields when appropriately treated with fuming nitric acid. Thus, the present reaction provides a simple direct route to some substituted phthalides and 1,3-dihydroisobenzofuran-1-imines for which no convenient preparative procedures have been available.

Experimental

All melting points were obtained on a hot-stage apparatus and are uncorrected. IR spectra were run as Nujol mulls on a Hitachi 215 spectrophotometer and only prominent peaks are recorded. PMR spectra were measured in deuteriochloroform with a Varian T-60 spectrometer using TMS as an internal standard. Mass spectra (MS) were obtained on a Hitachi RMS-4 mass spectrometer with 70 eV ionizing current.

Materials. Tetramethylbenzenedicarbonitriles and tetramethylbenzonitriles were prepared by allowing the corresponding iodoarenes to react with copper(I) cyanide in phosphoric tris(dimethylamide). The following typical example illustrates the general procedure used in the synthesis of the nitriles.

*2,3,5,6-Tetramethylbenzonitrile (**1f**).* A mixture of iododurene (11.7 g; 45 mmol),[6] copper(I) cyanide (5.2 g; 58 mmol), and phosphoric tris(dimethylamide) (15 ml) was heated with stirring at 90—100 °C for 2 h, and then poured into aqueous iron(III) chloride solution to decompose the complex. The light tan solid was collected by filtration and washed successively with water, aqueous sodium hydrogensulfite, and water. It was sucked as dry as possible and then placed in a filter thimble and extracted with light petroleum using a Soxhlet extractor. The extract was evaporated and the residue was crystallized from ethanol to give **1f** as fine needles: yield, 5.1 g (73%); mp 76—77 °C. PMR: δ 2.20 (s, 6H), 2.37 (s, 6H), and 6.97 (s, 1H); IR: 2205, 1010, and 890 cm^{-1}.

The above procedure applied to other iodo- and diiodotetramethylbenzenes gave the corresponding benzonitriles and benzenedicarbonitriles in 48—75% yields.

*2,3,4,5-Tetramethylbenzonitrile (**1d**)*: Mp 76—77 °C. PMR: δ 2.23 (s, 3H), 2.27 (s, 6H), 2.42 (s, 3H), and 7.17 (s, 1H).

*2,3,4,6-Tetramethylbenzonitrile (**1e**)*: Mp 66—67 °C. PMR: δ 2.17 (s, 3H), 2.28 (s, 3H), 2.44 (s, 6H), and 6.87 (s, 1H).

*3,4,5,6-Tetramethylbenzene-1,2-dicarbonitrile (**1a**)*: Mp 230—231 °C. PMR: δ 2.54 (s, 6H) and 2.35 (s, 6H).

*2,4,5,6-Tetramethylbenzene-1,3-dicarbonitrile (**1b**)*: Mp 178—180 °C. PMR: δ 2.26 (s, 3H), 2.56 (s, 6H), and 2.71 (s, 3H).

*2,3,5,6-Tetramethylbenzene-1,4-dicarbonitrile (**1c**)*: Mp 208—210 °C. PMR: δ 2.52 (s, 12H).

Reaction of Tetramethylbenzenedicarbonitriles with Fuming Nitric Acid. The procedure used in each of the reactions described in the text was identical; therefore, only a typical example of these reactions will be reported in detail.

*2,4,5,6-Tetramethylbenzene-1,3-dicarbonitrile (**1b**).* To stirred fuming nitric acid (d=1.5; 10 g) cooled at −10 — −5 °C, **1b** (0.60 g; 3.26 mmol) was added in portions, and the mixture was allowed to stand at room temperature (25—30 °C) for several days, during the course of which the initial dark brown color faded to light yellow. The mixture was diluted with water (≈100 ml) and the resulting somewhat turbid solution was filtered and set aside overnight. The crystalline deposit was collected by filtration and crystallized from aqueous methanol to furnish *4-cyano-5,6,7-trimethylphthalide (**7b**)* as fine prisms, mp 213—214 °C. Yield, 0.63 g (96%). MS: *m/e* 201 (M^+), 172 (base peak), 144, and 115. Found: C, 71.4; H, 5.4; N, 7.0%. Calcd for $C_{12}H_{11}NO_2$: C, 71.6; H, 5.5; N, 7.0%.

When the above aqueous solution was immediately neutralized with sodium hydrogencarbonate, *4-cyano-5,6,7-trimethyl-1,3-dihydroisobenzofuran-1-imine (**6b**)* was obtained as a pale yellow precipitate, mp 197—199 °C (dec). MS: *m/e* 200 (M^+), 172, 145, 130, and 115. Found: C, 71.9; H, 6.1; N, 13.9%. Calcd for $C_{12}H_{12}N_2O$: C, 72.0; H, 6.0; N, 14.0%.

By a similar treatment, dinitriles **1a** and **1c** were converted into the corresponding phthalides **7a** and **7c**, or 1,3-dihydroisobenzofuran-1-imines **6a** and **6c**, respectively, in 18—76% yield. The former dinitrile produced appreciable amounts of 3-cyclohexen-1-one derivatives **8b** and **10** in addition.

Reaction of Tetramethylbenzonitriles with Fuming Nitric Acid. The general procedure is illustrated below with the reaction of *2,3,4,6-tetramethylbenzonitrile (**1e**)*.

A solution of **1e** (1.59 g; 10 mmol) in fuming nitric acid (20 g) was allowed to stand at room temperature for several days, after which the mixture was poured onto crushed ice to give *5-nitro-2,3,4,6-tetramethylbenzonitrile (**1h**)* as a yellow solid (0.62 g). The aqueous part was filtered and set aside overnight to give a further deposit, which was collected by filtration and recrystallized from aqueous methanol, giving *4-nitro-5,6,7-trimethylphthalide (**7h**)* as fine needles, mp 191—194 °C. Yield, 0.70 g (53%). MS: *m/e* 221 (M^+), 205, and 177. Found: C, 60.0; H, 5.2; N, 6.3%. Calcd for $C_{11}H_{11}NO_4$: C, 59.7; H, 5.0; N, 6.3%.

On being neutralized with sodium hydrogencarbonate, the acid solution gave *4-nitro-5,6,7-trimethyl-1,3-dihydroisobenzofuran-1-imine (**6h**)*, mp 183—185 °C. Yield, 0.50 g (23%). MS: *m/e* 220 (M^+), 203, 175, 160, and 147. Found: C, 59.8; H, 5.5; N, 12.4%. Calcd for $C_{11}H_{12}N_2O_3$: C, 60.0; H, 5.5; N, 12.7%.

When **6h** in methanol was treated with hydrogen in the presence of Pd/C catalyst at room temperature, *4-amino-5,6,7-trimethylphthalide (7j)* was obtained, which on heating sintered and decomposed at around 235—245 °C. MS: *m/e* 191 (M^+), 176, 162, 146, and 134. Found: C, 69.4; H, 6.8; N, 7.5%. Calcd for $C_{11}H_{13}NO_2$: C, 69.1; H, 6.9; N, 7.3%.

The same procedure applied to nitrile **1f** gave *4-nitro-2,3,-5,6-tetramethylbenzonitrile* (**1i**; 8—40%), *5-nitro-4,6,7-trimethylphthalide* (**7i**; 10—23%), and a nitro ketone (**8d**; 4—9%), or *5-nitro-4,6,7-trimethyl-1,3-dihydroisobenzofuran-1-imine (6i)* as a precursor of **7i**.

2,3,4,5-Tetramethylbenzonitrile (1d). A solution of **1d** in fuming nitric acid was left to stand at room temperature for several days. The usual work-up of the reaction mixture, followed by crystallization of a solid product from ethanol, gave *6-nitro-2,3,4,5-tetramethylbenzonitrile (1g)* as the sole product; pale yellow needles, mp 175—176 °C. Found: C, 64.8; H, 6.0; N, 13.7%. Calcd for $C_{11}H_{12}N_2O_2$: C, 64.7; H, 5.9; N, 13.7%.

We are grateful to the Ministry of Education and the Saneyoshi Scientific Foundation for financial support of this work.

Formation of Cyanonitro-3-cyclohexen-1-ones in the Reaction of Tetramethylbenzonitriles with Fuming Nitric Acid[1]

Hitomi SUZUKI, Akiyoshi INOUE, Mamie KOGE, and Terukiyo HANAFUSA

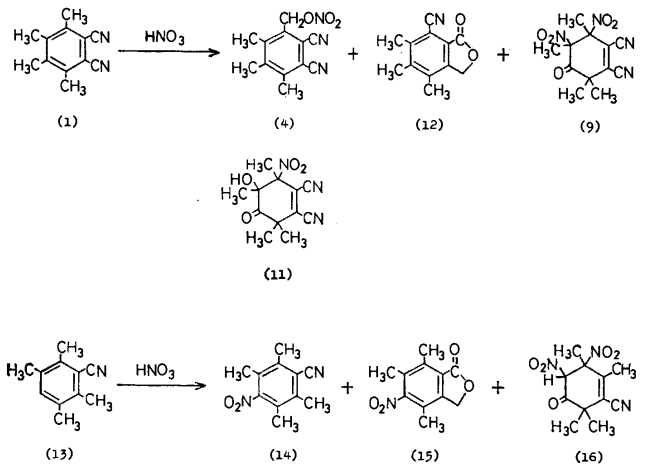
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received August 31, 1977)

The reaction of 3,4,5,6-tetramethylbenzene-1,2-dicarbonitrile with fuming nitric acid at room temperature yielded appreciable amounts of 3,4-dicyano-5,6-dinitro-2,2,5,6-tetramethyl-3-cyclohexen-1-one and 3,4-dicyano-6-hydroxy-5-nitro-2,2,5,6-tetramethyl-3-cyclohexen-1-one in addition to the expected side-chain substitution products. 2,3,5,6-Tetramethylbenzonitrile similarly gave 3-cyano-5,6-dinitro-2,2,4,5-tetramethyl-3-cyclohexen-1-ones as minor products. The structures of these nitro ketones have been assigned by spectral methods and a probable mechanistic pathway to their formation is presented.

Nuclear oxidation of polyalkylbenzenes and their derivatives with concentrated nitric acid usually leads to the formation of cross-conjugated cyclic ketones (2,5-cyclohexadien-1-ones), while linearly conjugated cyclic ketones (2,4-cyclohexadien-1-ones) are rarely formed.[2] With some moderately deactivated polyalkylbenzene derivatives, however, the latter type of oxidation seems to occur more often than has ever been considered. In the preceding paper, we have reported the isolation of nitro carbonyl compounds as side products from the reaction of tetramethylbenzonitriles with fuming nitric acid. We describe herein the structural assignments of these carbonyl compounds and a probable mechanistic pathway to their formation.

Reaction of 3,4,5,6-tetramethylbenzene-1,2-dicarbonitrile (**1**) with fuming nitric acid (d=1.5) at room temperature for several days gave appreciable amounts of two carbonyl compounds, which melted at 116—117 °C and 150—152 °C, respectively, in addition to the expected benzyl nitrate (**4**) and phthalide (**12**).



Scheme 1.

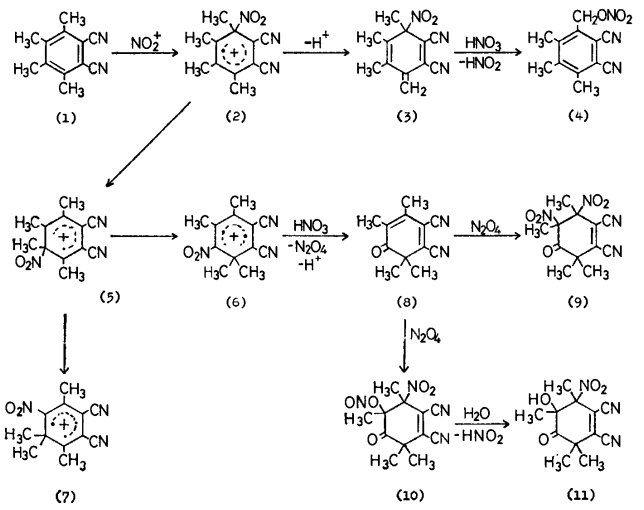
The *low-melting compound (9)* had the formula $C_{12}H_{12}N_4O_5$; its mass spectrum showed peaks at m/e 292 (M^+), 246 (M^+-NO_2), 200 (M^+-2NO_2), 185 ($M^+-2NO_2-CH_3$), 172 (M^+-2NO_2-CO), 157 (base peak; $M^+-2NO_2-CO-CH_3$), and 142 ($M^+-2NO_2-CO-2CH_3$). Its IR spectrum suggested the formation of an unsaturated nitro carbonyl compound with absorption bands due to a nitro group (1560 and 1330 cm^{-1}), a carbonyl group (1745 cm^{-1}), and the carbon-carbon double bond (1635 cm^{-1}). Its PMR spectrum with four singlets at δ 2.27, 2.05, 1.26, and 1.22 indicated the presence of four methyl groups intact. The possibility of the conjugated carbonyl compound was ruled out by the absence of an UV maximum above 220 nm.

This nitro carbonyl compound was thermally unstable and, when heated gently in ligroin, it readily released nitrogen dioxide and was converted into another new ketone (**8**), $C_{12}H_{12}N_2O$, mp 83—84 °C. Its mass spectrum was quite similar to that of the parent compound **9**, except for the lack of two minor peaks at m/e 292 and 246. The high carbon-to-hydrogen ratio of the empirical formula points to an unsaturated cyclic structure. The IR spectrum showed the presence of the cyano group (2210 cm^{-1}) and the conjugated carbonyl group (1670 and 1625 cm^{-1}), but absorptions due to the nitro group were no longer observed. An intense band at 315 nm ($\log \varepsilon$=3.61) in the UV spectrum and a characteristic mass pattern with peak clusters at m/e 102—107, 88—93, and 77—79 were in accord with the presence of a 2,4-cyclohexadien-1-one system. The PMR spectrum consisted of three singlets at δ 2.19, 2.06, and 1.44, with relative areas 1 : 1 : 2. The signal at δ 1.44 obviously represented the *gem*-dimethyl grouping, but exhibited a significant downfield shift as compared to the normal positions of this grouping, δ 1.11—1.28.[3] If we make a reasonable assumption that the vicinal disposition of the two cyano groups in **1** remains intact during the course of reaction, the *gem*-methyl groups should be placed next to the *vic*-dicyano grouping. These data were consistent with the formulation of this compound as 4,5-dicyano-2,3,6,6-tetramethyl-2,4-cyclohexadien-1-one (**8**). The original nitro carbonyl compound was, therefore, formulated as 3,4-dicyano-5,6-dinitro-2,2,5,6-tetramethyl-3-cyclohexen-1-one (**9**). This structural assignment was further substantiated by the CMR spectrum, which indicated the presence of four methyls (δ 18.6, 18.6, 23.2, and 23.5), two cyano groups (δ 110.8 and 112.0), a carbonyl carbon (δ 200.7), two olefinic carbons (δ 122.1 and 144.1), two sp^3 carbons attached to nitrogen (δ 70.0 and 87.5), and a sp^3 carbon in non-hetero atom function (δ 51.8).

The *high-melting compound (11)* was a slightly water-soluble, crystalline solid, which was obtained by extracting with ether the aqueous solution from which **4** and **12** separated out. Elemental analysis and mass spectrum established its molecular composition to be

$C_{12}H_{13}N_3O_4$, suggesting an unsaturated cyclic structure similar to **9**. The IR spectrum showed absorptions due to the hydroxyl and carbonyl groups at 3470 and 1720 cm^{-1}, respectively, in addition to those for the cyano group (2230 cm^{-1}), the carbon-carbon double bond (1640 cm^{-1}), and the nitro group (1570, 1340, and 850 cm^{-1}). A moderate fall of the carbonyl stretching frequency as compared to that in **9** suggested the location of the hydroxyl group in the vicinity of the carbonyl group. The PMR spectrum exhibited resonances for four methyl groups (δ 1.18, 1.30, 1.88, and 2.00). The CMR spectrum (in $CDCl_3/(CD_3)_2SO$ (5: 1)) indicated the presence of four methyls (δ 17.2, 18.0, 22.5, and 22.5), two cyano groups (δ 111.1 and 112.0), a carbonyl carbon (δ 200.3), two olefinic carbons (δ 120.2 and 138.7), two sp^3 carbons adjacent to nitrogen and oxygen (δ 68.9 and 94.3, respectively), and a sp^3 carbon in non-hetero atom function (δ 48.6). The UV spectrum showed no maximum above 220 nm, ruling out the possibility of a conjugated ketone. On the basis of the spectral data and reasoning similar to that used to arrive at the structures **8** and **9**, the compound was assigned the structure, 3,4-dicyano-6-hydroxy-5-nitro-2,2,5,6-tetramethyl-3-cyclohexen-1-one (**11**).

On a similar treatment, 2,3,5,6-tetramethylbenzonitrile (**13**) gave a nitro ketone (**16**) along with the expected ring and side-chain products (**14** and **15**).



Scheme 2.

Formation of these nitro ketones can be explained by a sequence of reactions involving addition-elimination and alkyl migration, as exemplified by the conversion of **1** to **9** and **11** (Scheme 2). Thus, electrophilic attack of nitronium ion on **1** will occur at C-3 position to form the arenium ion (**2**), which could react in either of the two competing pathways: proton release from the activated methyl group in **2** to form the triene intermediate (**3**) will give the nitrate (**4**), whereas the 1,2-migration of nitro group in **2** followed by the 1,2-migration of the *ipso* methyl group in ion (**5**) to form ion (**6**) will lead to the formation of the carbonyl compounds **9** and **11**.[4] In the latter path, methyl migration in **5** will occur in one preferred direction to yield **6**, since the latter ion would be more effectively stabilized by the substituent groups than that (**7**) formed by the migration in the other direction. Capture of **6** by nitric acid or nitrate ion will lead to unstable *gem*-nitro nitrate, from which nitrogen dioxide is eliminated to yield the ketone **8**. Addition of nitrogen dioxide to **8** will give **9** as the final product. The alternative mode of the addition of nitrogen dioxide to **8** will produce an unstable adduct (**10**), which on hydrolysis will give the ketone **11**.

Experimental

All melting points were taken on a hot stage apparatus and are uncorrected. The IR, PMR, and mass spectra were obtained using the same procedures and apparatus described in the preceding paper, unless otherwise stated. The CMR spectra were determined on a Hitachi R-26 spectrometer by Dr. M. Mishima of Kyushu University. The UV spectra were recorded on a Hitachi 124 spectrophotometer in methanol solutions.

Reaction of Tetramethylbenzonitriles with Fuming Nitric Acid.

a) 3,4,5,6-Tetramethylbenzene-1,2-dicarbonitrile (1). Dinitrile **1** (1.10 g; 6 mmol) was dissolved in fuming nitric acid (d=1.5; 20 g) and the mixture was allowed to stand at room temperature (20—30 °C) for several days, during the course of which the solution became dark red and nitrogen dioxide was liberated. On diluting with water, a yellow pasty precipitate (0.84 g) was obtained, which was dissolved in a minimum amount of dichloromethane and fractionally precipitated by dropwise addition of pentane. A nitro carbonyl compound was obtained as an early precipitate (0.48 g; 28%) and a nitrate (0.21 g; 14%) was also obtained from the mother liquor. These products were identified as *3,4-dicyano-5,6-dinitro-2,2,5,6-tetramethyl-3-cyclohexen-1-one (9)* and *5,6-dicyano-2,3,4-trimethylbenzyl nitrate (4)*, respectively, on the basis of elemental analyses and spectral data. **9**: Mp 116—117 °C. Found: C, 49.9; H, 4.2; N, 18.9%. Calcd for $C_{12}H_{12}N_4O_5$: C, 49.3; H, 4.1; N, 19.2%. **4**: Mp 105—106 °C. PMR: δ 2.45 (s, 3H), 2.57 (s, 3H), 2.57 (s, 3H), and 5.52 (s, 2H); IR: ν_{max} 2220 (CN), 1640, 1280, and 840 cm^{-1} (ONO_2). Found: C, 58.5; H, 4.3; N, 17.4%. Calcd for $C_{12}H_{11}N_3O_3$: C, 58.8; H, 4.5; N, 17.1%.

Heating the ketone **9** in ligroin readily eliminated nitrogen dioxide, giving a new ketone melting at 83—84 °C; this was identified as *4,5-dicyano-2,3,6,6-tetramethyl-2,4-cyclohexadien-1-one (8)*. Found: C, 71.8; H, 6.3; N, 13.6%. Calcd for $C_{12}H_{12}N_2O$: C, 72.0; H, 6.0; N, 14.0%.

The aqueous part was set aside overnight and afforded a white precipitate (0.23 g; 19%), which was collected by filtration and crystallized from aqueous ethanol to give *7-cyano-4,5,6-trimethylphthalide (12)*, mp 286—287 °C (sublim.).[5] Found: C, 71.3; H, 5.4; N, 7.4%. Calcd for $C_{12}H_{11}NO_2$: C, 71.6; H, 5.5; N, 7.0%.

The mother liquor was further extracted with ether and the combined extract was washed successively with aqueous sodium hydrogencarbonate and water, and evaporated *in vacuo* to yield a yellow syrup (0.38 g), from which *3,4-dicyano-6-hydroxy-5-nitro-2, 2, 5, 6-tetramethyl-3-cyclohexen-1-one (11)* slowly separated out as fine needles, mp 150—152 °C. Found: C, 54.6; H, 5.0; N, 16.0%. Calcd for $C_{12}H_{13}N_3O_4$: C, 54.8; H, 5.0; N, 16.0%.

b) 2,3,5,6-Tetramethylbenzonitrile (13). A solution of nitrile **13** (1.59 g; 10 mmol) in fuming nitric acid (d=1.5; 21 g) was stirred at 30 °C for 3 days, after which the mixture was poured onto crushed ice to give a yellow oily substance (0.99 g). This was triturated with small amounts of cold

dichloromethane and the white powder obtained was crystallized from ligroin, giving *3-cyano-5,6-dinitro-2,2,4,5-tetramethyl-3-cyclohexen-1-one (**16a**)* as fine needles (0.13 g; 4.9%), mp 150—151 °C. The dichloromethane solution was evaporated and the residue was fractionally crystallized from benzene/cyclohexane, giving another nitro ketone (**16b**; 0.1 g; 3.8%) isomeric with **16a**, mp 144—147 °C, and *4-nitro-2,3,5,6-tetramethylbenzonitrile* (**14**; 0.17 g; 8.3%), mp 195—198 °C.[5] **16a**: MS: *m/e* 267 (M^+), 221, 205, 191, 175 (base peak), 160, and 147; PMR ($(CD_3)_2SO$): δ 1.15 (s, 3H), 1.37 (s, 3H), 2.15 (s, 3H), 2.33 (s, 3H), and 6.10 (s, H); IR: ν_{max} 2230 (CN), 1700 and 1220 (C=O), 1570, 1360, and 1340 cm^{-1} (NO_2); UV: no maximum above 220 nm. Found: C, 49.2; H, 4.9; N, 15.5%. Calcd for $C_{11}H_{13}N_3O_5$: C, 49.4; H, 4.9; N, 15.7%. **16b**: MS: *m/e* 267 (M^+), 221, 205, 191, 175, 160, and 147; PMR ($(CD_3)_2SO$): δ 1.13 (s, 3H), 1.18 (s, 3H), 1.93 (s, 3H), 2.47 (s, 3H), and 6.07 (s, 1H); IR: ν_{max} 2240 (CN), 1710 and 1225 (C=O), 1560 and 1340 cm^{-1} (NO_2); UV: no maximum above 220 nm. Found: C, 49.1; H, 4.9; N, 15.2%. Calcd for $C_{11}H_{13}N_3O_5$: C, 49.4; H, 4.9; N, 15.7%.

The aqueous part from which **14** and **16** separated out was set aside overnight, giving *5-nitro-4,6,7-trimethylphthalide (**15**)* as a crystalline precipitate (0.23 g; 10.4%).[5] Mp 203—205 °C. Found: C, 60.0; H, 5.2; N, 6.5%. Calcd for $C_{11}H_{11}NO_4$: C, 59.7; H, 5.0; N, 6.3%.

Oxidation of 2-Aryl-4*H*-1-benzopyrans with Potassium Permanganate

Kazu KUROSAWA and Yoshihiro ASHIHARA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received September 2, 1977)

The oxidation of twelve 2-aryl-4*H*-1-benzopyrans with potassium permanganate in acetone gave the corresponding flavones in excellent yields.

Flavones can be synthesized from 2'-hydroxychalcones[1] or from flavanones[2] or they can be synthesized from *o*-(benzoyloxy)acetophenones by the Baker-Venkataraman rearrangement followed by cyclization[3] or from *o*-hydroxyacetophenone and aromatic acid anhydride by Allan-Robinson condensation.[4] Flavones can also be formed in reactions with flavylium chloride.[5] In a previous publication,[6] Ashihara *et al.* have reported that the oxidation of 2-aryl-2*H*-1-benzopyrans with potassium permanganate in acetone gives the corresponding flavones in moderate yields. The oxidation of twelve 2-aryl-4*H*-1-benzopyrans with potassium permanganate which produce flavones in 17—81% yields, are also reported by these authors. This procedure provides a simple method for the preparation of flavones.

The 2-aryl-4*H*-1-benzopyrans (Ia—i) were prepared by lithium aluminium hydride reduction[7] of 2-aryl-1-benzopyrylium chlorides. The structures of the new 2-aryl-4*H*-1-benzopyrans were confirmed by examining their NMR spectra and by elemental analysis.

When 7-methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (Ig) was oxidized in acetone with potassium permanganate for molar ratios of 1:3, 1:4, and 1:5 (entries 7, 8, and 9 in Table 1), 4',7-dimethoxyflavone (IIg) was obtained in 74, 81, and 72% yields, respectively. Therefore, the oxidation of other 2-aryl-4*H*-1-benzopyrans was carried out for molar ratios of 1:4 until all the potassium permanganate added had been consumed. When the oxidation of Ig was carried out in pyridine or in *t*-butyl alcohol (entries 10 and 11), poor yields were observed (61% in pyridine and 65% in *t*-butyl alcohol). The oxidation of Ig in acetic acid (entry 12) gave *p*-anisic acid (III). Jurd[8] has reported that hydrolysis of Ig with aqueous acetic acid gives 3-(2-hydroxy-4-methoxyphenyl)-4'-methoxypropiophenone (IV). This indicates that Ig is unstable under the reaction conditions and, in fact, upon treatment of Ig with acetic acid containing a trace of water, IV was obtained. It appears that Ig was hydrolyzed under the reaction conditions to give IV, which was then oxidized with potassium permanganate to *p*-anisic acid (III). With 5,7-dimethoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (Ik), the yield of IIk was low (17%, entry 16) accompanied by many unidentified products. For the oxidation of 2-aryl-2*H*-1-benzopyran[6] with potassium permanganate, it was observed that the methoxyl group at position 2' causes a decrease in the yield of flavone and this is ascribed to the steric hindrance of the methoxyl group towards the attacking reagent. It appears that a similar steric effect could also explain the low yield of IIk: the methoxyl group at position 5 may hinder the approach of the reagent to the methylene group in Ik. An unsuccessful attempt was made to isolate products which could be formed by the attack of the reagent at position 2 or 3.

2-*p*-Tolyl-4*H*-1-benzopyran (Ie) gave 4'-methylflavone (IIe) (entry 5), indicating that the reaction can be adapted to the preparation of alkylated flavones.

TABLE 1. OXIDATION OF 2-ARYL-4*H*-1-BENZOPYRANS (I) WITH POTASSIUM PERMANGANATE

Entry	Substrate	Reaction conditions			Product (% yield)
		Molar ratio of I: $KMnO_4$	Time (h)	Solvent	
1	Ia[13]	1:4	1	acetone	IIa[18] (64)
2	Ib	1:4	1.5	acetone	IIb[5] (78)
3	Ic	1:4	3	acetone	IIc[19] (67)
4	Id[14]	1:4	2	acetone	IId[20] (72)
5	Ie	1:4	2.5	acetone	IIe[21] (64)
6	If[15]	1:4	2	acetone	IIf[22] (77)
7	Ig[16]	1:3	0.25	acetone	IIg[23] (74)
8	Ig	1:4	2.5	acetone	IIg (81)
9	Ig	1:5	10	acetone	IIg (72)
10	Ig	1:4	6	pyridine	IIg (61)
11	Ig	1:4	2.5	*t*-butyl alcohol	IIg (65)
12	Ig	1:4	7	acetic acid	III (97)
13	Ih	1:4	2	acetone	IIh[24] (77)

Fig. 1.

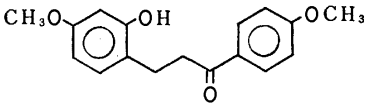

Fig. 2.

The oxidation of 2-(*p*-benzyloxyphenyl)-7-methoxy-4*H*-1-benzopyran (Ih) also gave the corresponding flavone (IIh) (entry 13). This suggests that a hydroxylated flavone can be synthesized by debenzylation of IIh.

It should be noted that the oxidation of 2-aryl-4*H*-1-benzopyran with potassium permanganate is also interesting in connection with the biogenetic type transformations of the 2-aryl-2*H*-1-benzopyrans into 3-flavanols,[9,10] 4-flavanols,[11,12] 3,4-flavandiols,[10,11] and 3,4-epoxyflavans.[10]

Experimental

All ^1H NMR spectra were recorded with a Hitachi R 24 NMR spectrometer with TMS as an internal standard. The IR spectra were recorded with a JASCO grating spectrometer. The UV spectra were recorded with a Hitachi EPS-3T spectrophotometer. Melting points were determined on a Yanagimoto micro hot-stage and are uncorrected.

Preparation of 2-Aryl-4H-1-benzopyrans (Ib,c,e,h,i,j, and l). A typical preparation of a 2-aryl-4*H*-1-benzopyran was carried out as follows. A mixture of 2-aryl-1-benzopyrylium chloride (10 mmol) (2-aryl-1-benzopyrylium chloride was prepared by condensing a *o*-hydroxybenzaldehyde and an acetophenone in ethyl acetate with dry hydrogen chloride), lithium aluminium hydride (0.7 g), and anhydrous ether (100 ml) was stirred at 0 °C until the color of the 2-aryl-1-benzopyrylium chloride disappeared (3—5 h). After the removal of the ether, the resulting solid was triturated with benzene and the benzene solution was then filtered through a short silica gel column. The filtrate was evaporated *in vacuo* to give 2-aryl-4*H*-1-benzopyran as crystals which were recrystallized from methanol. The 2-aryl-4*H*-1-benzopyrans were somewhat unstable compounds and colored on exposure to air at room temperature, but could be stored for a long time in a refrigerator.

6-Methoxy-2-phenyl-4H-1-benzopyran (Ib): Mp 104—105 °C, 74% yield, IR ($CHCl_3$) 1695 cm^{-1} (C=C), UV (MeOH) λ_{max} (ε) 245 (23800) and 296 nm (4460), NMR (CCl_4) δ=3.50 (2H, d, J=3.5 Hz, $-CH_2-$), 3.69 (3H, s, OCH_3), 5.30 (1H, t, J=3.5 Hz, $H_{(3)}$), 6.54 (1H, d, J=2.5 Hz, $H_{(5)}$), 6.55 (1H, dd, J=9.0 and 2.5 Hz, $H_{(7)}$), 6.86 (1H, d, J=9.0 Hz, $H_{(8)}$), and 7.2—7.7 (5H, m, Ph). Found: C, 80.49; H, 5.83%. Calcd for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%.

7-Methoxy-2-phenyl-4H-1-benzopyran (Ic): Mp 65—66 °C, 61 % yield, IR ($CHCl_3$) 1695 cm^{-1} (C=C), UV (MeOH) λ_{max} (ε) 237 (19100) and 279 nm (5550), NMR (CCl_4) δ=3.49 (2H, d, J=3.7 Hz, $-CH_2-$), 3.75 (3H, s, OCH_3), 5.42 (1H, t, J=3.7 Hz, $H_{(3)}$), 6.49 (1H, dd, J=9.5 and 2.5 Hz, $H_{(6)}$), 6.49 (1H, d, J=2.5 Hz, $H_{(8)}$), 6.87 (1H, m, $H_{(5)}$), and 7.2—7.7 (5H, m, Ph). Found: C, 79.13; H, 5.79%. Calcd for $C_{16}H_{14}O_2 \cdot 1/4\ H_2O$: C, 79.15; H, 6.02%.

2-p-Tolyl-4H-1-benzopyran (Ie): Mp 90—91 °C, 56% yield, IR ($CHCl_3$) 1695 cm^{-1} (C=C), UV (MeOH) λ_{max} (ε) 244 (21900) and 281 nm (5310), NMR (CCl_4) δ=2.36 (3H, s, CH_3), 3.53 (2H, d, J=3.5 Hz, $-CH_2-$), 5.36 (1H, t, J=3.5 Hz, $H_{(3)}$), 6.7—7.3 (6H, m, $H_{(3')}$, $H_{(5')}$, and $H_{(5-8)}$), and 7.53 (2H, m, $H_{(2')}$ and $H_{(6')}$). Found: C, 86.16; H, 6.37%. Calcd for $C_{16}H_{14}O$: C, 86.45; H, 6.35%.

2-(p-Benzyloxyphenyl)-7-methoxy-4H-1-benzopyran (Ih): Mp 138—139 °C, 71% yield, IR ($CHCl_3$) 1690 cm^{-1} (C=C), UV (MeOH) λ_{max} (ε) 249 (24500) and 277 nm (12100), NMR ($CDCl_3$) δ=3.47 (2H, d, J=3.8 Hz, $-CH_2-$), 3.76 (3H, s, OCH_3), 5.08 (2H, s, $-CH_2-$), 5.36 (1H, t, J=3.8 Hz, $H_{(3)}$), 6.58 (1H, dd, J=9.0 and 2.5 Hz, $H_{(6)}$), 6.58 (1H, d, J=2.5 Hz, $H_{(8)}$), 6.98 (3H, m, $H_{(5)}$, $H_{(3')}$, and $H_{(5')}$), 7.40 (5H, m, Ph), and 7.58 (2H, m, $H_{(2')}$ and $H_{(6')}$). Found: C, 80.07; H, 5.85%. Calcd for $C_{23}H_{20}O_3$: C, 80.21; H, 5.85%.

8-Methoxy-(p-methoxyphenyl)-4H-1-benzopyran (Ii): Mp 91—92 °C, 49% yield, IR ($CHCl_3$) 1697 cm^{-1} (C=C), UV (MeOH) λ_{max} (ε) 251 (22600) and 279 nm (9670), NMR (CCl_4) δ=3.48 (2H, d, J=3.5 Hz, $-CH_2-$), 3.72 (3H, s, OCH_3), 3.81 (3H, s, OCH_3), 5.31 (1H, t, J=3.5 Hz, $H_{(3)}$), 6.4—7.4 (3H, m, $H_{(5)}$, $H_{(6)}$, and $H_{(7)}$), 6.74 (2H, m, $H_{(3')}$ and $H_{(5')}$), and 7.53 (2H, m, $H_{(2')}$ and $H_{(6')}$). Found: C, 75.85; H, 6.07%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

2-(3,4-Dimethoxyphenyl)-4H-1-benzopyran (Ij): Mp 107—108 °C, 35% yield, IR ($CHCl_3$) 1696 cm^{-1} (C=C), UV (MeOH) λ_{max} (ε) 249 (17400) and 287 nm (8060), NMR (CCl_4) δ 3.54 (2H, d, J=3.5 Hz, $-CH_2-$), 3.80 (3H, s, OCH_3), 3.86 (3H, s, OCH_3), 5.27 (1H, t, J=3.5 Hz, $H_{(3)}$), 6.6—7.3 (7H, m, aromatic). Found: C, 75.80; H, 5.95%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

2-(3,4-Dimethoxyphenyl)-7-methoxy-4H-1-benzopyran (Il): Mp 128—129 °C, 66% yield, IR ($CHCl_3$) 1695 cm^{-1} (C=C), UV (MeOH) λ_{max} (ε) 249 (15600) and 280 (10100), NMR ($CDCl_3$) δ=3.46 (2H, d, J=3.5 Hz, $-CH_2-$), 3.77 (3H, s, OCH_3), 3.88 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 5.36 (1H, t, J=3.5 Hz, $H_{(3)}$), and 6.5—7.4 (6H, m, aromatic). Found: 72.28; H, 6.11%. Calcd for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

Oxidation of 2-Aryl-4H-1-benzopyrans with Potassium Permanganate. A typical oxidation of a 2-aryl-4*H*-1-benzopyran with potassium permanganate was carried out as follows. A mixture of a 2-aryl-4*H*-1-benzopyran (1 mmol), potassium permanganate (3—5 mmol), and an appropriate solvent (30 ml) was stirred at room temperature until the color of the potassium permanganate disappeared (the time required is shown in the table). The 2-aryl-4*H*-1-benzopyran was also consumed within that time, as confirmed by TLC. The reaction mixture was filtered and the manganese dioxide formed was washed with chloroform. The combined filtrate was then evaporated and the resulting solid was recrystallized to give II. In the case of Ik, products were separated on TLC by eluting with chloroform and then recrystallized. The yields are based on the amount 2-aryl-4*H*-1-benzopyran used. IIa, mp 97 °C (benzene–light

petroleum) (lit,[18] mp 97 °C); IIb, mp 160—161 °C (MeOH) (lit,[5] mp 162 °C); IIc, mp 109—110 °C (MeOH) (lit,[19] mp 110—111 °C); IId, mp 153—154 °C (benzene–light petroleum) (lit,[20] mp 157—158 °C); IIe, mp 112—113 °C (aq MeOH) (lit,[21] mp 116 °C); IIf, mp 204—205 °C (MeOH) (lit,[22] mp 194—195 °C); IIg, 150—151 °C (MeOH) (lit,[23] mp 144 °C); IIh, mp 192—193 °C (MeOH) (lit,[24] mp 194 °C); IIi, mp 138—139 °C (MeOH), IR ($CHCl_3$) 1648 cm^{-1} (C=O), UV (MeOH) $\lambda_{max}(\varepsilon)$ 231 (19400), 270 (16300), and 324 nm (28000), NMR ($CDCl_3$) $\delta=3.88$ (3H, s, OCH_3), 4.00 (3H, s, OCH_3), 6.70 (1H, s, $H_{(3)}$), 7.00 (2H, m, $H_{(3')}$ and $H_{(5')}$), 7.15 (1H, dd, $J=9.0$ and 2.5 Hz, $H_{(7)}$), 7.30 (1H, t, $J=9.0$ Hz, $H_{(6)}$), 7.38 (1H, dd, $J=9.0$ and 2.5 Hz, $H_{(5)}$), and 7.91 (2H, m, $H_{(2')}$ and $H_{(6')}$) (Found: C, 72.16; H, 5.02%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%); IIj, mp 151—152 °C(MeOH) (lit,[25] mp 155 °C); IIk, mp 155—156 °C (MeOH) (lit,[26] mp 156 °C); IIl, mp 174—175 °C (MeOH) (lit,[27] mp 176 °C).

*Hydrolysis of 7-Methoxy-2-(*p*-methoxyphenyl)-4*H*-1-benzopyran (Ig)(3-(2-Hydroxy-4-methoxyphenyl)-4'-methoxypropiophenone(IV))*.

A mixture of Ig (134 mg) and acetic acid (15 ml) containing a drop of water was stirred at room temperature for 2 h. After the removal of the acetic acid *in vacuo*, the resulting liquid was separated on a silica gel plate by eluting with chloroform. The crude material was recrystallized from aqueous methanol to give IV (109 mg, 73%), mp 77—78 °C (lit,[8] mp 78 °C).

Sulfur-Carbonyl Interaction in Rigid β-Keto Sulfides

Iwao TABUSHI, Yoshinao TAMARU, and Zen-ichi YOSHIDA
Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto 606
(Received September 3, 1977)

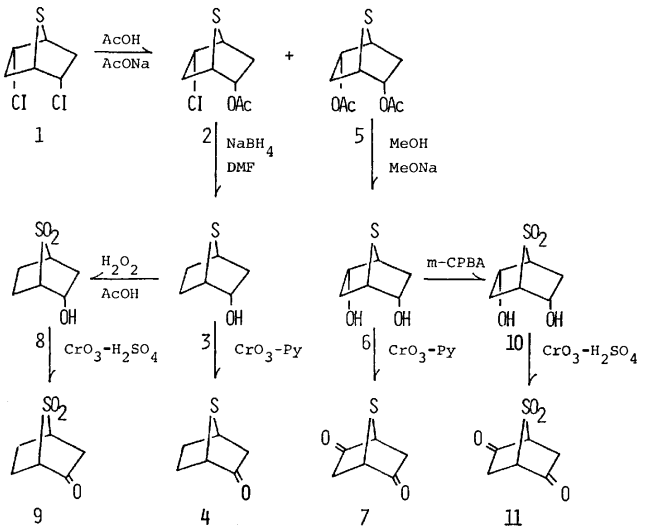
The electron donating ability of sulfur to a positively charged center through space was examined by means of ultraviolet spectroscopy. 7-Thiabicyclo[2.2.1]heptan-2-one and -2,5-dione exhibited finely separated charge transfer band (from divalent sulfide to carbonyl) at 260 nm in UV spectra, the longest wave-length for S–Cco charge transfer band so far reported. The assignment of these CT bands was confirmed by comparison with relevant reference compounds.

Recently it has been reported that the sulfur-bridge greatly accelerates the solvolysis of 2-*endo*-chloro-7-thiabicyclo[2.2.1]heptane, while it decelerates the solvolysis of 2-*exo*-chloro isomer (the former solvolyzed 4.7×10^9 times faster than the latter).[1] Spectroscopic examination of the sulfur-carbonyl interaction might give more insight into this sulfur participation. Although the interaction between sulfur (donor) and carbonyl (acceptor) has been observed in UV and IR spectroscopy,[2,3] little effort has been done to confirm under what conditions, steric and electronic, sulfur-carbonyl interaction, sulfur-positive center interaction, becomes most efficient. For this purpose, more model systems are required, especially the rigid sulfur-containing molecules of known geometry.

The aim of the present study is to examine the nature of the sulfur-carbonyl interaction in β-keto sulfides, taking 7-thiabicyclo[2.2.1]heptan-2-one (**4**),[4] 7-thiabicyclo[2.2.1]heptane-2,5-dione (**7**), and the related compounds as sterically and spacially fixed models.

Results and Discussion

Syntheses of 7-Thiabicyclo[2.2.1]heptan-2-one (4) and 7-Thiabicyclo[2.2.1]heptane-2,5-dione (7); Oxidation of Hydroxy Sulfides 3 and 6 to Oxo Sulfides 4 and 7. 7-Thiabicyclo[2.2.1]heptan-2-one (**4**), 7-thiabicyclo-[2.2.1]heptane-2,5-dione (**7**) and the corresponding sulfones (**9** and **11**) were prepared according to Scheme 1. Controlled acetolysis of 2,5-*endo-endo*-dichloro-7-thiabicyclo[2.2.1]heptane (**1**)[5] gave a mixture of 2-*endo*-acetoxy-5-*endo*-chloro-7-thiabicyclo[2.2.1]heptane (**2**) and 2,5-*endo-endo*-diacetoxy-7-thiabicyclo[2.2.1]-heptane (**5**). After separation of **2** and **5** by means of column chromatography, **2** was reduced with $NaBH_4$ to give 2-*endo*-hydroxy-7-thiabicyclo[2.2.1]heptane (**3**). 2,5-*endo-endo*-Dihydroxy-7-thiabicyclo[2.2.1]heptane (**6**) was obtained by the hydrolysis of **5**. The key step in Scheme 1 consists of the selective oxidation of hydroxyl group to ketone in the presence of the sulfide linkage highly susceptible to oxidation. The oxidation of **3** to **4** was performed by chromium trioxide-pyridine complex[6] in good yield (83%) without appreciable oxidation of sulfur. Similar oxidation of **6** gave **7** in 35% yield together with 5-*endo*-hydroxy-7-thiabicyclo[2.2.1]heptan-2-one in 35% yield. This indicates that the latter considerably resists further oxidation[7] (see Experimental). On the other hand the oxidation of **3** to **4** with Jone's reagent[8] was not successful, mainly affording a mixture of sulfoxides (2-*endo*-hydroxy-7-thiabicyclo-[2.2.1]heptane 7-oxides; a mixture of 38 and 62% of *syn* and *anti* sulfoxides, respectively) in *ca.* 60% yield and the expected keto sulfide **4** only in a low yield (*ca.* 10%).[9] Attempted Oppenauer oxidation of **3** and **6** with aluminium isopropoxide and cyclohexanone in refluxing toluene[10] was not successful. 7-Thiabicyclo-[2.2.1]heptan-2-one 7,7-dioxide (**9**) was prepared in good yield by the oxidation with Jone's reagent from 2-*endo*-hydroxy-7-thiabicyclo[2.2.1]heptane 7,7-dioxide (**8**), which was prepared from **3** by oxidation with hydrogen peroxide in acetic acid. 7-Thiabicyclo[2.2.1]-heptane-2,5-dione 7,7-dioxide (**11**) was also prepared in good yield by oxidation with Jone's reagent from **10**, which was prepared from **6** by oxidation with perbenzoic acid in chloroform. **11** decomposed readily to give hydroquinone and sulfur dioxide in the presence of acid.[11]



Scheme 1.

It seems worthwhile to note some characteristics in NMR spectra of **4** and **7** from the viewpoint of structural confirmation. For **4** the introduction of ketonic carbonyl group caused upfield shift of the bridge-head proton α to carbonyl by 0.08 ppm, while the bridge-head proton β to carbonyl shifted to downfield by 0.15 ppm as compared with 7-thiabicyclo[2.2.1]heptane (**12**) (Fig. 1). This upfield shift of bridge-head proton α to carbonyl is quite the reverse of that anticipated from the inductive effect and magnetic anisotropy of carbonyl.[12] Corey and his co-workers[13] first pointed out a similar abnormality concerning the NMR spectrum of norbornanone, *viz.*, the bridge-head proton α to carbonyl shifted down

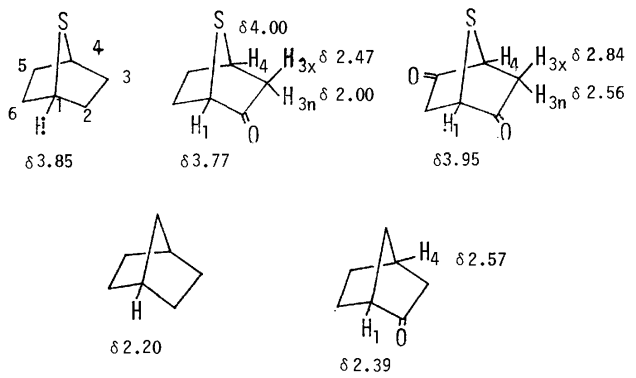


Fig. 1. Influence of carbonyl group to the bridge-head protons of bicyclo[2.2.1]heptane system.

field only by 0.19 ppm, and the bridge-head proton β to carbonyl by 0.37 ppm as compared with norbornane. The assignment was confirmed by Farnum and Mehta[14] by deuterium labeling experiments.

As a result of the substitution of methylene bridge for sulfur atom, the NMR spectra of bicyclo[2.2.1]-heptane system became simplified and well resolved.[15] The assignments were confirmed by using a shift reagent (europium dipivaloylmethanate), coupled with spin-decoupling experiments (see Experimental). The bridge head protons of **7** resonated in midway between the peaks of H_1 and H_4 of **4**. The following coupling constants were obtained by spin-decoupling experiments for **7**; $J_{H_1,H_{3x}}=1.5$ Hz, $J_{H_{3x},H_{3n}}=18$ Hz, $J_{H_4,H_{3x}}=3.5$ Hz, and $J_{H_4,H_{3n}}=0.75$ Hz. The computer simulation, with use of these values and $J_{H_1,H_4}=0$ Hz, gave a result almost superimposable on the spectrum of **7** (Fig. 2).

Transannular Sulfur-Carbonyl Interaction in the Ultraviolet Spectroscopy. The ultraviolet spectra of **4**, **7** and

C) Computer simulation.

related compounds were measured in solvents of various polarities. The absorption maxima and extinction coefficients are summarized in Table 1. The keto sulfide **4** and **7** exhibited three separated absorptions at about 220, 260 and 300 nm as shown in Fig. 3. The strong absorption at about 220 nm, similar to that of 7-thiabicyclo[2.2.1]heptane (**12**), can be assigned to n, σ*,[16] although the intensity is smaller than that of

Table 1. Ultraviolet spectra[a]

Compound	Assignment	Hexane	Acetonitrile	Ethanol	Water

a) λ_{max} was measured in nm. Molar extinction coefficient is given in parentheses. b) This band was observed as an inflection at longer wavelength side (*ca.* 220 nm) of the main absorption band.

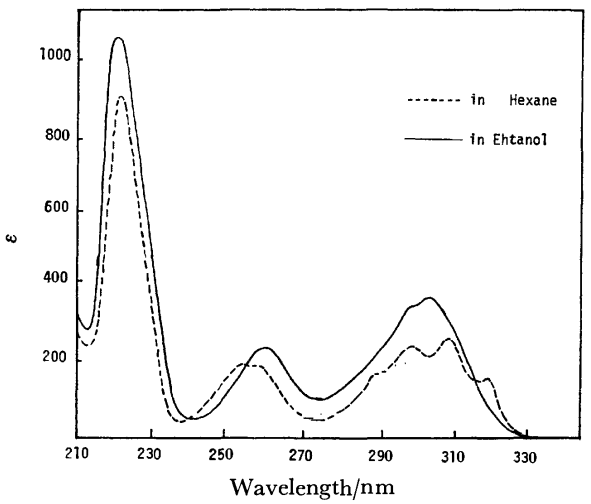

Fig. 3. Ultraviolet spectra of **4** in hexane and ethanol.

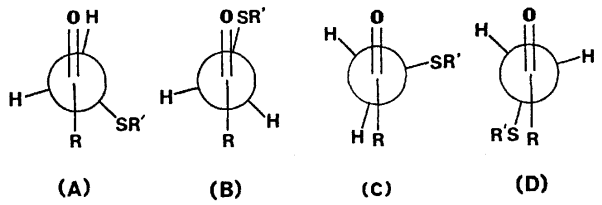
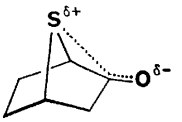
12 by a factor of three or four.[17] No absorption was observed around this region in the ultraviolet spectra of the corresponding sulfone **9**[18] or 7-thiabicyclo[2.2.1]-heptane 7,7-dioxide.

The absorption at *ca.* 300 nm, with a fine structure at intervals of *ca.* 1080 cm^{-1} for **4** and *ca.* 1130 cm^{-1} for **7** in hexane, showed a small but steady blue shift on changing the solvent from non-polar to polar. The large extinction coefficients observed for **4** (393 in water) and for **7** (666 in water) suggest that the band is due to n, π^* transition with the strong homoconjugation between sulfur and carbonyl.[19] The anomalously intense n, π^* absorption has been reported for dehydronorcamphor skeleton and was attributed to the homoconjugation between carbonyl and double bond.[20] The keto sulfides (**4** and **7**) seem to satisfy the geometrical requirements for S–CO interaction proposed by Wladislaw *et al.*[19b,19c] They suggested that of the four rotational isomers, A or C is favorable for S–CO interaction. The extinction coefficient of **7** is approximately twice as large as that of **4**.



The two bands n, σ^* and n, π^* could be assigned regarding **4** (and **7**) as a composite of 7-thiabicyclo-[2.2.1]heptane and norbornanone, but the band at 260 nm can not be explained in such a manner. The band was assigned to the charge transfer band from divalent sulfur to carbonyl based on the following. (a) The band shows a small but appreciable red shift on increasing the polarity of solvent. (b) It disappears on the oxidation of **4** to sulfone **9**. This indicates lone pair electrons on sulfur participate in the CT transition. The charge transfer band at 260 nm seems to be the longest ever reported.[21] The canonical form in the charge transfer excited state of **4** can be expressed in **13**,[2,3] which *a priori* seems to have some connection to the anchimerically assisted species by sulfur in the formation of incipient carbonium ion in solvolysis.[1]



13

In order to correlate the CT band and the ability of anchimeric assistance by sulfur, more examples of well separated CT bands are requested.

Experimental

Melting points (sealed capillary) are uncorrected. The elemental analyses were performed either at the Microanalysis Center of Kyoto University or at the Faculty of Pharmaceutical Science of Kyushu University. Infrared spectra were measured with a Hitachi Model EPI-G3 grating spectrophotometer, NMR spectra with a Varian T 60 or HA-100 spectrometer, mass spectra with a Hitachi Model RMU 6C mass spectrometer, and ultraviolet spectra with a Hitachi EPS-3T recording spectrophotometer.

Preparation and structural determination of 2-*endo*-acetoxy-5-*endo*-chloro-7-thiabicyclo[2.2.1]heptane (**2**), 2-*endo*-hydroxy-7-thiabicyclo[2.2.1]heptane (**3**), and 2,5-*endo*-*endo*-diacetoxy-7-thiabicyclo[2.2.1]heptane (**5**) have been reported.[1]

Oxidation of 3 with Jone's Reagent. Cold Jone's reagent, prepared from 114 mg (1.14 mmol) of CrO_3, 186 mg of concd H_2SO_4 and 0.5 ml of distilled water, was added dropwise with ice cooling and stirring to a solution of 174 mg (1.34 mmol) of **3** in 1.5 ml of acetone. The color of the reaction mixture turned from red to green. After being stirred for 30 min at 0 °C, the reaction mixture was diluted with 2 ml of water and extracted with 2 portions of 5 ml of dichloromethane. The combined dichloromethane extracts were dried over magnesium sulfate and condensed to 60 mg of colorless oil.

On the basis of NMR, IR, and VPC analyses, the oily product was found to consist of *ca.* 30% of 7-thianorbornan-2-one (**4**), *ca.* 50% of **3** and 20% of sulfoxide. The water layer was neutralized with sodium hydrogencarbonate and allowed to stand at room temperature to evaporate water. The solid residue was washed twice with 15 ml of acetone. Acetone extracts were evaporated and adsorbed on silica gel. Elution was benzene (10)–ethanol (2) afforded 70 mg of a *syn* and *anti* mixture of 2-*endo*-hydroxy-7-thiabicyclo[2.2.1]heptane 7-oxides. The structures of these products were confirmed by a comparison of spectra (NMR, IR) with those of sulfoxides derived from **3** by oxidation with equimolar amount of *m*-chloroperbenzoic acid. Further structural confirmation was given by the oxidation of a mixture of sulfoxides with H_2O_2 in acetic acid to give 2-*endo*-hydroxy-7-thiabicyclo[2.2.1]heptane 7,7-dioxide **8** as a sole product.

ν_{max}^{KBr} (*syn*, *anti* mixture) 3330 cm^{-1} (S), 2930 cm^{-1} (M), 1072 cm^{-1} (sh), 1030 cm^{-1} (v.s., ν_{S-O} and ν_{C-O}), and 1005 cm^{-1} (sh). $\delta_{CDCl_3}^{TMS}$ (*syn*, *anti* mixture) 5.06 (multiplet, α proton to OH of *syn*-sulfoxide, area intensity 8), 4.20 (double triplets, $J=10$ and 4 Hz, α proton to OH of *anti*-sulfoxide, 13), 3.6 (narrow multiplet, bridgehead protons and OH, 67) and 2.5—1.3 (multiplet, methylene and ethylene protons, 113). The composition ratio of *anti* to *syn* was determined on the basis of area intensities of α protons[22] to OH to be *ca.* 1.6.

2-endo-Hydroxy-7-thianorbornane 7-Oxide. *m*-Chloroperbenzoic acid (156 mg, 0.77 mmol, 85% assay) was added at room temperature to a solution of 100 mg (0.77 mmol) of **3** in 10 ml of dichloromethane. After being stirred for 1 day, the solvent was removed and the solid residue was washed with two portions of 1 ml of water to transfer sulfoxides to the water layer. Evaporation of water gave transparent solid, which was adsorbed on silica gel. Elution with benzene (10)–ethanol (2) gave 102 mg of a mixture of sulfoxides. The composition ratio of *anti*- to *syn*-sulfoxide determined by NMR spectroscopy was *ca.* 1.0.

*Oxidation of **3** with Chromium Trioxide-Pyridine Complex.* Chromium trioxide (280 mg, 2.8 mmol) was added in portions to 2.5 ml of dry pyridine with stirring in a 10 ml flask fitted with a KOH drying tube. To a yellow suspension of chromium trioxide-pyridine complex was added in one portion a solution of 150 mg (1.15 mmol) of **3** in 2.0 ml dry pyridine at room temperature. The solution was allowed to stand overnight and then poured into 50 ml of ether. The filtrate was washed with dilute hydrochloric acid and then with water saturated with NaCl. Evaporation of ether through a 10 cm Vigreux column under atmospheric pressure left 122 mg (82.5 %) of 7-thiabicyclo[2.2.1]heptan-2-one (**4**) as a white waxy solid, which was purified by preparative VPC, followed by sublimation (80 °C/760 mmHg). 7-Thiabicyclo[2.2.1]heptan-2-one (**4**): Mp 115.8—116.6 °C (in a sealed tube). $\delta^{TMS}_{CCl_4}$ 4.00 (broad singlet, H_4, 1H), 3.77 (broad singlet, H_1, 1H), 2.47 (double doublets, $J=16$ and 4 Hz, H_{3x}, 1H), 2.00 (doublet, $J=16$ Hz, H_{3n}, 1H) and 2.03 (multiplet, H_5, H_6, 4H).

To a solution of 12 mg of **4** in 0.5 ml of CCl_4 was added europium dipivaloylmethanate progressively. The downfield shifts observed were: for H_1, by 0.50 and 1.16 ppm (for 4.5 mg and 9.0 mg of dipivaloylmethanate, respectively); H_{3x}, by 0.56 and 1.16 ppm; H_{3n}, 0.53 and 1.10 ppm; H_4, by 0.16 and 0.36 ppm; H_5, H_6, by *ca.* 0.2 and 0.43 ppm.

Saturation of H_4 proton resulted in the collapse of proton H_{3x} to a doublet ($J=16$ Hz). ν^{KBr}_{max} 1745 cm^{-1} (S), 1060 cm^{-1} (M) and 446 cm^{-1} (M). *m/e*; 128 (M^+, 36), 100 (18), 85 (88), 71 (8), 67 (100), 58 (20) and 55 (35).

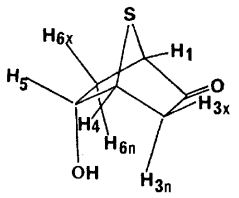
Found: C, 56.30; H, 6.00%. Calcd for C_6H_8OS: C, 56.22; H, 6.29%.

*2,5-endo-endo-Dihydroxy-7-thiabicyclo[2.2.1]heptane (**6**).* 11.5 g (50 mmol) of **5** and 50 mg of sodium were dissolved in 200 ml of absolute methanol under nitrogen. After being refluxed overnight, methanol and methyl acetate were distilled off to give a white solid. Recrystallization from benzene gave 6.95 g (95%) of white crystals of **6**. The physical and spectral properties are the same as those in the literature.[5]

*Thiabicyclo[2.2.1]hepthane-2,5-dione (**7**).* To a yellow suspension of chromium trioxide-pyridine complex (30 mmol) in 20 ml of dry pyridine was added 1.0 g (6.85 mmol) of solid **6** at room temperature. After being stirred overnight at room temperature, the reaction mixture was poured into 100 ml of ether. After the inorganic materials had been filtered off the ether extract was washed with dilute hydrochloric acid. Evaporation of ether gave 710 mg of a colorless waxy solid. The solid was adsorbed on silica gel and eluted with benzene (5)–ethanol (1) to give 350 mg of **7** and 330 mg of 5-*endo*-hydroxy-7-thiabicyclo[2.2.1]heptan-2-one. Prolonged reaction time did not affect the product ratio significantly. Dioxo sulfide **7** was recrystallized from benzene–hexane–dichloromethane: Mp 130.0—131.0 °C. $\delta^{TMS}_{CDCl_3}$ (100 MHz) 3.94 (triple doublets, $J=3.5$ and 1.5 Hz, H_1 and H_4, 2H), 2.79 (double quartets, $J=18$, 3.5 and 1.5 Hz, H_{3x} and H_{6x}, 2H) and 2.57 (double doublets, $J=18$ and 0.75 Hz, H_{3n} and H_{6n}, 2H).

ν^{KBr}_{max} 1765 cm^{-1} (sh), 1742 cm^{-1} (S), 1720 cm^{-1} (sh), 1414 cm^{-1} (M), 1200 cm^{-1} (S), 1053 cm^{-1} (M), 941 cm^{-1} (M), 901 cm^{-1} (M), 540 cm^{-1} (S), and 428 cm^{-1} (M). *m/e* 142 (M^+, 33), 114 (6) 100 (10), 98 (9), 86 (25), 72 (13), 59 (20), 58 (20), 55 (100) and 45 (30).

Found: C, 50.58; H, 4.48; O, 22.39. Calcd for $C_6H_6O_2S$: C, 50.68; H, 4.25; O, 22.50%.



14

*5-endo-Hydroxy-7-thiabicyclo[2.2.1]heptan-2-one (**14**):* $\delta^{TMS}_{CDCl_3}$ 4.76 (double triplets, $J=10$ and 3.5 Hz, H_5, 1H) 3.93 (singlet, OH, 1H), 3.9—3.6 (multiplet, H_1 and H_4, 2H), 3.00 (doublet, $J=17$ Hz, H_{3n}, 1H), 2.43 (double doublets, $J=17$ and 4 Hz, H_{3x}, 1H), 2.8—2.4 (multiplet, H_{6x}, 1H) and 1.63 (double doublets, $J=15$ and 3.5 Hz, H_{6n}, 1H). ν^{KBr}_{max} 3420 cm^{-1} (S), 1742 cm^{-1} (sh), 1728 cm^{-1} (S), 1118 cm^{-1} (W), 1096 cm^{-1} (W), 1051 cm^{-1} (M), 1032 cm^{-1} (M), and 1000 cm^{-1} (W). *m/e* 144 (M^+, 73), 57 (100).

*2-endo-Hydroxy-7-thiabicyclo[2.2.1]heptane 7,7-Dioxide (**8**).* With water cooling and stirring, 1.5 ml (13 mmol) of 30% hydrogen peroxide was added dropwise to a solution of 297 mg (2.28 mmol) of **3** in 2 ml of acetic acid. The mixture was then heated at 70—80 °C overnight. After cooling, methyl mercaptan was introduced at moderate speed into this reaction mixture until peroxide test became negative (KI-starch). Evaporation of the solvent gave 330 mg of a waxy solid. Column chromatography on silica gel eluted with benzene (10)–ethanol (1) gave 290 mg (79.5%) of **8**: Mp 227.5—229.0 °C (in a sealed tube). $\delta^{TMS}_{CDCl_3}$ 4.80 (double triplets, $J=9$ and 3 Hz, 1H), 3.03 (narrow multiplet, 2H) 2.6 (singlet, 1H), 2.7—1.9 (multiplet, 5H) and 1.50 (double doublets, $J=14$ and 2.5 Hz, 1H). ν^{KBr}_{max} 3485 cm^{-1} (S), 1297 cm^{-1} (VS), 1161 cm^{-1} (S), 1126 cm^{-1} (S), 1043 cm^{-1} (M), and 514 cm^{-1} (M).

*7-Thiabicyclo[2.2.1]heptan-2-one 7,7-Dioxide (**9**).* To a solution of 100 mg (0.62 mmol) of **8** in 2 ml of acetone chilled with ice and stirred was added dropwise Jone's reagent prepared from 470 mg (4.7 mmol) of chromium trioxide, 760 mg of concd H_2SO_4 and 1.5 ml of distilled water. After completion of addition stirring was continued for 40 min in ice and then at room temperature for 40 min. The excess oxidizing reagent was treated with 2-propanol with ice cooling. The reaction mixture was extracted with three portions of 20 ml of dichloromethane and the combined dichloromethane extracts were washed with 5 ml of water saturated with NaCl. Evaporation of the solvent gave 74 mg (74%) of white solid **9**. Recrystallization from CCl_4–hexane and sublimation under reduced pressure gave 50 mg of pure **9**; mp *ca.* 229 °C (dec in a sealed tube). $\delta^{TMS}_{CDCl_3}$ 3.53 (narrow multiplet, 2H), 3.20 (double doublets, $J=18.0$ and 3.5 Hz, 2H), 2.66 (doublet, $J=18.0$ Hz, 1H), 2.7—1.9 (multiplet, 4H). *m/e* 160 (M^+, 32), 96 ($M^+ - SO_2$, 80). 68 (100), 64 (62), and 55 (85).

Found: C, 44.91; H, 5.15; S, 19.84; O, 29.75%. Calcd for $C_6H_8SO_3$: C, 44.99; H, 5.03; S, 20.02; O, 29.96%.

*2,5-endo-endo-Dihydroxy-7-thianorbornane 7,7-Dioxide (**10**).* To a solution of 5.0 g (34.2 mmol) of **6** in 1250 ml of $CHCl_3$ was added dropwise a solution of 11.3 g (81.9 mmol) of perbenzoic acid in 150 ml of $CHCl_3$ at room temperature with stirring. After the completion of addition (3 h), the reaction mixture was refluxed for 5—6 h and then allowed to stand overnight at room temperature. After filtration of transparent

crystalline precipitate (5.30 g) of **10**, the solution was condensed to *ca.* 200 ml and into this residue was passed methyl mercaptan vigorously to destroy the excess peroxide. The mixture was cooled with ice to give additional 0.38 g of **10**: Mp 277 °C (dec, in a sealed tube) $\delta^{TMS}_{pyridine\text{-}d_5}$ 6.44 (singlet, 2H), 5.00 (quintet, J=4 Hz, 2H), 3.2 (narrow multiplet, 2H) and 2.6 (narrow multiplet, 4H). ν^{KBr}_{max} 3570 (S), 1295 (M), 1160 (S), 920 (M), and 860 cm^{-1} (M).

Found: C, 40.53; H, 5.64%. Calcd for $C_6H_{10}SO_4$: C, 40.44; H, 5.66%.

*7-Thiabicyclo[2.2.1]heptane-2,5-dione 7,7-Dioxide (**11**).* To a 1.5 ml of aqueous solution of 200 mg (1.12 mmol) of **10** chilled with ice and stirred was added dropwise Jone's reagent prepared from 7.52 mmol of chromium trioxide, 1.2 g of concd H_2SO_4 and 3.2 ml of distilled water. After completion of addition (30 min), stirring was continued for 1 h in ice and then at room temperature for 4 h. The reaction mixture was extracted with four portions of 10 ml of dichloromethane and the combined extracts were dried over calcium chloride. Evaporation of the solvent gave 90 mg of crystals. Yellow crystals of hydroquinone sublimed at the neck of the flask. Recrystallization from chloroform gave 74 mg of **11**: Mp 160 °C (dec in a sealed tube). $\delta^{TMS}_{CDCl_3}$ 4.10 (quartet, J=4.5 and 1.5 Hz, 2H), 3.44 (double quartets, J=1.5, 4.5, and 19 Hz, 2H) and 2.84 (doublet, J=19 Hz, 2H). ν^{KBr}_{max} 3000 (M), 1760 (S), 1416 (M), 1322 (S), 1218 (M), 1118 (S), 586 (S), 586 (S), and 450 cm^{-1} (M).

Found: C, 41.47; H, 3.74; S, 18.45%. Calcd for $C_6H_6SO_4$: C, 41.38; H, 3.47; S, 18.41%.

Asymmetric Reactions. III. The Asymmetric Synthesis of Methyl 2-Phenylpropionate in the Presence of Chiral Polymers

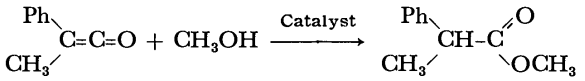
Tetsushi YAMASHITA, Hiroshi YASUEDA, Noriyuki NAKATANI, and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received September 14, 1977)

The asymmetric addition of methanol to phenylmethylketene was carried out in the presence of a chiral polymer obtained by the co-polymerization of *N*-benzyl-2-pyrrolidinylmethyl acrylate with methyl acrylate. The products obtained for the above co-polymer showed a correlation between log k_R/k_S and $1/T$ deviating from linearity, while those for poly(*N*-benzyl-2-pyrrolidinylmethyl acrylate) exhibited a linear relationship. *N*-Benzyl-2-pyrrolidinylmethyl butyrate, hexanoate, and stearate were also used as catalysts; they showed asymmetric efficiencies intermediate between those of *N*-benzyl-2-pyrrolidinylmethyl propionate and poly(*N*-benzyl-2-pyrrolidinylmethyl acrylate). The use of several high- and low-molecular-weight catalysts derived from cinchonine was similarly attempted in order to examine the polymer effect with regard to the stereoselectivity.

Several chiral polymers[1-2] derived from optically active amino alcohols have been used for the study of polymer effects in the asymmetric addition of methanol to phenylmethylketene (PMK):

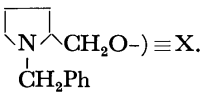


In previous papers,[1-2] poly(*N*-benzyl-2-pyrrolidinylmethylacrylate (PA) yielded optically rotational products with a sign opposite to that of products for its corresponding monomeric model compound (*N*-benzyl-2-pyrrolidinylmethyl propionate; Al).

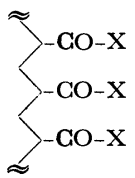
The products obtained for PA showed a linear correlation between log k_R/k_S and $1/T$, while those for Al exhibited only a non-linear relationship. (k_R and k_S: the rate constants for the *R* and *S*-isomers respectively).

The results obtained with PA were interpreted in terms of the effect of molecular immobility;[2-3] the steric bulkiness of the back-bone of the polymer increases the degree of conformational rigidity of the molecules in the side chain.

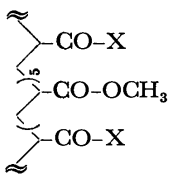
In the present work, several *N*-benzyl-2-pyrrolidinylmethanol derivatives were used to clarify these observations more precisely.



$CH_3(CH_2)_n$-CO-X Al[2], $n=1$
A2 $n=2$
A3 $n=4$
A4 $n=16$



(PA)[2]



(CPA)

The asymmetric addition of methanol to PMK was carried out in a manner similar to that reported earlier.[1-2]

Figure 1 shows the log k_R/k_S-$1/T$ relation of the addition products obtained for the above catalysts.

A soluble co-polymer (CPA) was obtained by the co-polymerization of one molar equivalent amount of *N*-benzyl-2-pyrrolidinylmethyl acrylate with five molar equivalent amounts of methyl acrylate. The products

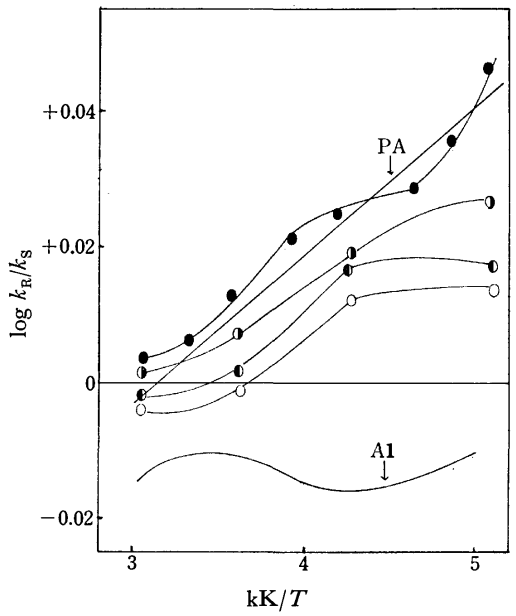


Fig. 1. Plots of log k_R/k_S against $1/T$ in case of A2 (○), A3 (◐), A4 (◑) and CPA (●).

from CPA reveal a relationship deviating somewhat from linearity (see Fig. 1). CPA decreases the degree of conformational rigidity of the molecules in the side chain in comparison with PA. The optically active molecules (X) of CPA are more mobile than those of PA because of the larger distance among the chiral pendants (X) of CPA.

A2, A3, and A4 were derived through the reaction of *N*-benzyl-2-pyrrolidinylmethanol with butyryl, hexanoyl, and stearoyl chloride respectively.

Figure 1 shows that the action of low-molecular-weight catalysts gradually became similar to that of polymeric catalysts with the increase in the length of the carbon chain in the acyl group.

Figure 2 indicates the plots of the optical yields of the addition products obtained for the *N*-benzyl-2-pyrrolidinylmethanol catalysts at −78 °C.

Al gave a product with an excess of *S*-enantiomer in a 1% optical yield, and CPA yielded a product with an excess of *R*-enantiomer in the highest optical yield (5.3%).

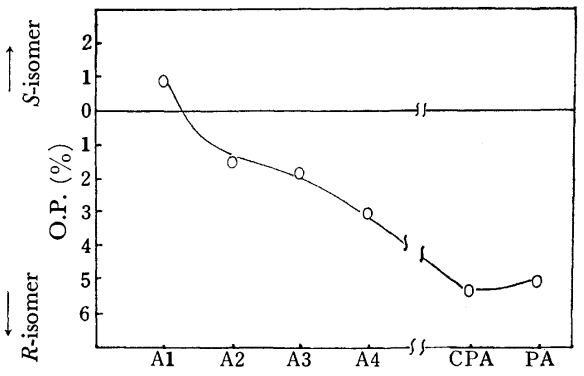

Fig. 2. The optical purities (O.P.) of the esters obtained with *N*-benzyl-2-pyrrolidinylmethanol catalysts at −78 °C.

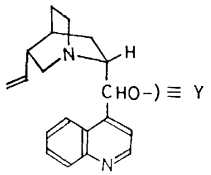
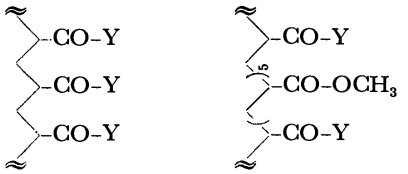
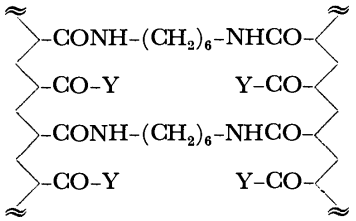
Let us also describe the use of several cinchonine catalysts in order to examine this sort of polymer effect more clearly.



$CH_3(CH_2)_n$-CO-Y B1,[2] n= 0
B2,[2] n= 1
B3, n= 2
B4, n= 4
B5, n=16





(CPB-2)[2]

B3, B4, and B5 were obtained by the reaction of cinchonine with butyryl, hexanoyl, and stearoyl chloride respectively. CPB-1 (soluble co-polymer) was derived through the co-polymerization of one molar equivalent amount of *o*-acryloylcinchonine[2] with five molar equivalent amounts of methyl acrylate. PB and CPB-2 were prepared according to the method reported previously.[2]

Figure 3 shows plots of log k_R/k_S against $1/T$ in the case of the above cinchonine catalysts.

Figure 3 shows that low-molecular-weight catalysts (B3, B4, and B5) gave the addition products of an *R*-configuration predominantly at higher reaction temperatures, and yielded the products of an *S*-configuration preferentially at lower temperatures. Figure 3 also indicates that polymeric catalysts (CPB-1, PB and

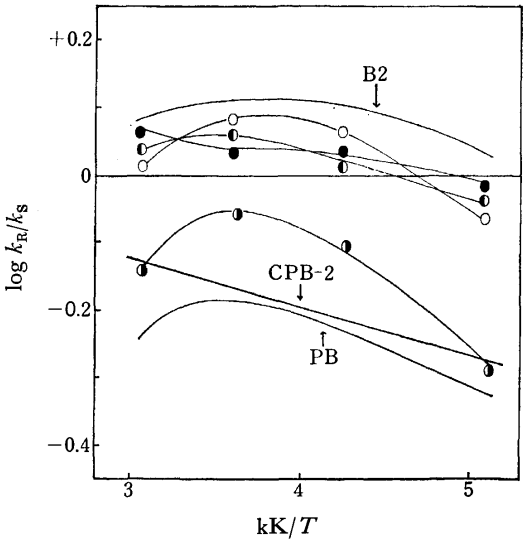


Fig. 3. Plots of log k_R/k_S against $1/T$ in case of B3 (●), B4 (◐), B5 (○) and CPB-1 (◑).

CPB-2) provided the addition products of an *S*-configuration preferably in the present range of reaction temperatures (−78 °C—+50 °C). CPB-2, in which the mobility of the chiral pendants (Y) is most strongly restricted by the cross-linking of the polymer, yielded addition products showing linear plots between log k_R/k_S and $1/T$.

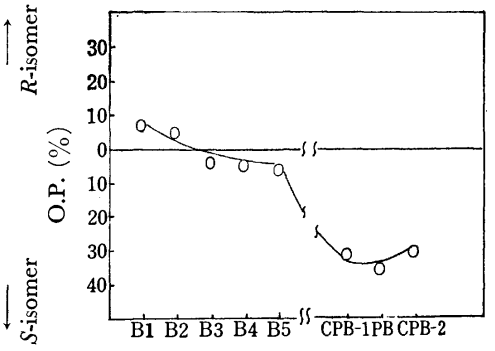

Fig. 4. The optical purities (O.P.) of the esters obtained with cinchonine catalysts at −78 °C.

Figure 4 shows the plots of the optical yields of the addition products given for cinchonine catalysts at −78 °C.

The preferable configuration of the addition products obtained for low-molecular-weight catalysts changed from *R* to *S* with an increase in the length of the carbon chain in the acyl group. Polymeric catalysts gave the addition products of an *S*-configuration predominantly; the maximum optical yield (35%) of the addition product was given in the case of PB.

Figures 3 and 4 reveal that cinchonine catalysts gave results similar to those obtained for *N*-benzyl-2-pyrrolidinylmethanol catalysts.

Experimental

N-Benzyl-2-pyrrolidinylmethyl Butyrate (A2). A solution of *N*-benzyl-2-pyrrolidinylmethanol (1 g), butyryl chloride (0.55 g), and triethylamine (0.53 g) in dry dichloromethane (100 ml) was stirred at room temperature. After 24 h, the solution was poured into water (100 ml). The organic layer thus separated out was washed with saturated sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was distilled to give a colorless oil. Yield, 70%. Bp 180—190 °C at 2 mmHg. $[\alpha]_D^{20}=-28°$ (*c* 1.4, benzene). Found: C, 73.18; H, 8.92; N, 4.99%. Calcd for $C_{16}H_{23}NO_2$; C, 73.56; H, 8.81; N, 5.36%.

N-Benzyl-2-pyrrolidinylmethyl Hexanoate (A3). Yield, 80%. Bp 180—190 °C at 1 mmHg. $[\alpha]_D^{20}=-26°$ (*c* 1, benzene). Found: C, 74.81; H, 9.44; N, 4.61%. Calcd for $C_{18}H_{27}NO_2$: C, 74.74; H, 9.34; N, 4.84%.

N-Benzyl-2-pyrrolidinylmethyl Stearate (A4). Yield, 70%. Mp 43—45 °C. $[\alpha]_D^{15}=-19°$ (*c* 1.6, benzene). Found: C, 78.71; H, 11.50; N, 2.74%. Calcd for $C_{30}H_{51}NO_2$: C, 78.77; H, 11.15; N, 3.06%.

o-Stearoylcinchonine (B5). A solution of cinchonine (1.5 g), stearoyl chloride (1.6 g), and triethylamine (0.8 g) in dry benzene (100 ml) was stirred under refluxing. After 20 h, the solution was cooled to room temperature and poured into water (100 ml). The organic layer thus separated out was washed with saturated sodium hydrogencarbonate and water, and then dried over anhydrous sodium sulfate.

After the removal of the solvent, the residue was recrystallized from ether. Yield, 71%. Mp 37 °C. $[\alpha]_D^{20}=+57°$ (*c* 2, chloroform). Found: C, 79.13; H, 10.23; N, 4.83%. Calcd for $C_{37}H_{56}N_2O_2$: C, 79.28; H, 10.00; N, 5.00%.

o-Butyrylcinchonine (B3) was similarly obtained as an oily material in a 79% yield. $[\alpha]_D^{20}=+97°$ (*c* 2, chloroform).

o-Hexanoylcinchonine (B4) was also given as a syrup in a 76% yield. $[\alpha]_D^{20}=+87°$ (*c* 2, chloroform).

The TLC of B3 (B4) gave only one spot for several solvent systems and showed it to be a single material.

Poly(N-benzyl-2-pyrrolidinylmethyl acrylate-methyl acrylate) (CPA). A mixture of *N*-benzyl-2-pyrrolidinylmethyl acrylate (0.588 g) and methyl acrylate (1.03 g) containing azobisisobutyronitrile (10 mg) was polymerized without any solvents in a sealed tube at 80 °C for 24 h, and then cooled to room temperature. The product was dissolved in a small amount of dry benzene and then poured into ether. A sticky precipitate was given in an 85% yield. $[\alpha]_D^{12}=-9.7°$ (*c* 1, benzene). Mol wt 4840 (benzene).

Poly(o-acryloylcinchonine-methyl acrylate) (CPB-1). A solution of *o*-acryloylcinchonine[2] (1 g), methyl acrylate (1.2 g), and azobisisobutyronitrile (10 mg) in dry benzene (10 ml) was refluxed with stirring in an argon atmosphere. After 20 h, the solution was cooled to room temperature and poured into ether. A precipitate (CPB-1) was filtered off and washed thoroughly with ether. Yield, 70%. $[\alpha]_D^{20}=+38°$ (*c* 2, chloroform). Mol wt 12500 (dichloromethane).

The Addition of Methanol to PMK. Freshly distilled PMK (330 mg) and CPA (17 mg) were added to 25 ml of dry toluene at −78 °C in an argon atmosphere. After the addition of methanol (82 mg), the mixture was stirred at the same temperature. After 10 h, the end point of the reaction was confirmed by the absence of the yellow color of PMK. The toluene solution was then poured into dilute hydrochloric acid and filtered off. The organic layer thus separated out was washed with saturated sodium hydrogencarbonate and water, and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was distilled to give an oil in an 80% yield. $[\alpha]_D^{20}=-5.8°$ (*c* 10, toluene).

The TLC and GLC of the product showed it to be a single material. The IR and NMR spectra of the product were completely in agreement with those of authentic methyl-2-phenylpropionate. The use of other basic catalysts was similarly attempted at various reaction temperatures.

In those experiments, a Jasco IRA-1 (IR) apparatus, a JEOL-60 MC (NMR) apparatus, a Varian M920 (GLC) apparatus, a Rex-automatic polarimeter (optical rotation; 10-cm cell), and a Knauer vapor-pressure osmometer (molecular weight) were used for the measurement of the samples.

Synthesis of Indole Derivatives by Cu_2O-Catalyzed Cyclization of *o*-(α-Cyanoalkyl)phenyl Isocyanides and *o*-[α-(Methoxycarbonyl)alkyl]phenyl Isocyanides

Yoshihiko Ito, Yoshinori Inubushi, Toru Sugaya, Kazuhiro Kobayashi, and Takeo Saegusa

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received September 29, 1977)

o-(Cyanomethyl)phenyl isocyanide and *o*-(methoxycarbonylmethyl)phenyl isocyanide were heated with a catalytic amount of Cu_2O in benzene to give 3-cyanoindole and 3-(methoxycarbonyl)indole in 86 and 92% yields, respectively. Lithiations of *o*-(cyanomethyl)phenyl isocyanide and *o*-(methoxycarbonylmethyl)phenyl isocyanide with butyllithium at −78 °C followed by the reaction with alkyl halides such as methyl iodide, allyl bromide, butyl bromide, benzyl bromide and methyl α-bromoacetate afforded the corresponding *o*-(α-cyanoalkyl)phenyl isocyanides and *o*-[α-(methoxycarbonyl)alkyl]phenyl isocyanides. *o*-(α-Cyanoalkyl)phenyl isocyanides and *o*-[α-(methoxycarbonyl)alkyl]phenyl isocyanides thus obtained were also cyclized by Cu_2O catalyst producing 3-alkyl-3-cyano-3*H*-indoles and 3-alkyl-3-(methoxycarbonyl)-3*H*-indoles, respectively, in moderate yields.

In the continuation of our studies[1] on synthetic reactions caused by Cu_2O-isonitrile complex, it has been found that the so-called active methylene compounds such as malonate, acetoacetate and cyclopentadiene were reacted with Cu_2O in the presence of isonitrile to produce organocopper(I) isonitrile complexes, which undergo an isonitrile insertion into their copper-carbon bonds.[2] On the basis of the isonitrile insertion of organocopper(I) isonitrile complexes, some heterocycle syntheses have been already reported.[3] Herein, we wish to report a new synthetic method of indole derivatives by the Cu_2O-catalyzed reactions of *o*-(cyanomethyl)phenyl isocyanide (**1a**) and *o*-(methoxycarbonylmethyl)phenyl isocyanide (**1b**),[4] in which intermediacy of the corresponding organocopper(I) isonitrile complexes (**2**) may by assumed.

Results and Discussion

Isocyanides (**1a** and **1b**) were heated with a catalytic amount of Cu_2O to give 3-cyanoindole (**3a**)[5] and 3-(methoxycarbonyl)indole (**3b**)[6] in high yields, respectively. For example, a mixture of **1a** (2 mmol) and Cu_2O (0.025 mmol) in 2 ml of benzene was heated at 55 °C for 6 h with stirring. The progress of reaction was monitored by IR absorption band ($\nu_{N\equiv C}$=2150 cm^{-1}) characteristic of the starting isocyanide. After the insoluble copper catalyst was removed by filtration, the filtrate was evaporated and then subjected to column chromatography to give 3-cyanoindole (**3a**) in 86% yield.

o-(α-Cyanoalkyl)phenyl isocyanide (**4a**) and *o*-[α-(methoxycarbonyl)alkyl]phenyl isocyanide (**4b**), which were readily prepared *via* the lithiation of **1a** and **1b** followed by the reaction with alkyl halides (Table 1), were also cyclized by Cu_2O catalyst producing 3-alkyl-3-cyano-3*H*-indole (**5a**) and 3-alkyl-3-(methoxycarbonyl)-3*H*-indole (**5b**), respectively, in moderate yields. Results are summarized in Table 2.

Table 1. Alkylations of *o*-(cyanomethyl)phenyl isocyanide (**1a**) and *o*-(methoxycarbonylmethyl)phenyl isocyanide (**1b**)[a,b]

Starting phenyl isocyanide (**1**)	Alkyl halide	Product (**4**) (%)
1a	CH_3I	**4a-i** (76)
	i-C_3HBr	**4a-ii** (44)
	CH_2=$CHCH_2Br$	**4a-iii** (94)
	$C_6H_5CH_2Br$	**4a-iv** (83)
	$BrCH_2CO_2CH_3$	**4a-v** (57)
1b	CH_3I	**4b-i** (88)
	CH_2=$CHCH_2Br$	**4b-ii** (52)
	C_4H_9Br	**4b-iii** (51)

a) Alkylations of **1a** were performed by the lithiation of **1a** (5 mmol) with butyllithium (5 mmol) in 10 ml of THF at −78 °C followed by addition of alkyl halide (6 mmol). b) Alkylations of **1b** were performed by the lithiation of **1b** (1.5 mmol) with butyllithium (1.5 mmol) in 4 ml of diglyme and 1 ml of HMPA at −78 °C followed by addition of alkyl halide (2.0 mmol).

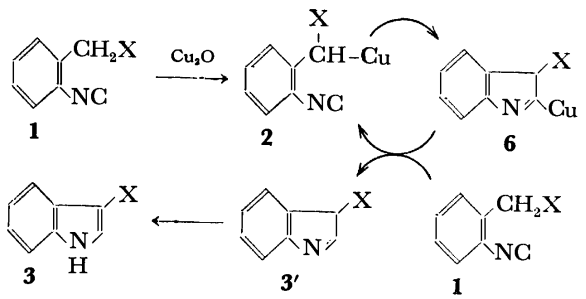
The following scheme involving organocopper(I) isonitrile complex (**2**) may be assumed for the present Cu_2O-catalyzed indole synthesis. The first step is the formation of **2**, in which an acidic hydrogen at the benzylic position of **1** is replaced by copper. The organocopper(I) isonitrile complex (**2**) subsequently undergoes an intramolecular isonitrile insertion to give a cyclic

Table 2. Indole synthiesis by Cu_2O-catalyzed cyclizations of *o*-(α-cyanoalkyl)phenyl isocyanides and *o*-[α-(methoxycarbonyl)alkyl]-phenyl isocyanides

o-(α-Cyanoalkyl)-phenyl isocyanide and *o*-[α-(methoxycarbonyl)-alkyl]phenyl isocyanide	Reaction[a] Temp (°C)	Time (h)	Product (**3**) and (**5**) (%)
1a	55	6	**3a** (86)
1b	55	6	**3b** (92)
4a-i	70	10	**5a-i** (71)
4a-ii	80	18	**5a-ii** (61)
4a-iii	80	13	**5a-iii** (60)
4a-iv	80	25	**5a-iv** (62)
4a-v	80	6	**5a-v** (43)
4b-i	80	30	**5b-i** (80)
4b-ii	80	30	**5b-ii** (71)
4b-iii	80	30	**5b-iii** (88)

a) Cyclizations of **1** (and **4**) were performed by heating **1** (or **4**) (2 mmol) and Cu_2O (0.025 mmol) in 2 ml of benzene.

organocopper(I) intermediate (**6**). The abstraction of the acidic hydrogen of **1** by **6** produces indole derivative (**3**) regenerating **2** which initiates the next cycle of reaction.



Scheme 1.

The present indole synthesis is interestingly compared with the previously reported indole synthesis *via* the selective lithiation at the benzylic position of the alkyl group in *o*-alkylphenyl isocyanide and the subsequent cyclization.[4] The Cu_2O-catalyzed synthesis of indole is only applicable to *o*-alkylphenyl isocyanides which bear a benzylic hydrogen activated by cyano and ester groups. However, in view of the feasibility of the reaction conditions (a catalytic amount of Cu_2O and reaction temperature), the present method which complements our earlier procedure[4] is practically useful for the preparation of 3-cyano- and 3-(alkoxycarbonyl)indole derivatives.

Experimental

Materials. Cu_2O was commercially available and dried *in vacuo* prior to use. Alkyl halides and organic solvents all purified by distillation under nitrogen. *o*-(Cyanomethyl)phenyl isocyanide (mp 66 °C) (**1a**) was prepared in 78% yield according to the Ugi's procedure[7] from *o*-(formylamino)phenylacetonitrile which was prepared by formylation of *o*-aminophenylacetonitrile[8] with acetic formic anhydride.[9] *o*-(Methoxycarbonylmethyl)phenyl isocyanide (**1b**), bp 95 °C (0.6 Torr), was prepared in 69% yield by the reaction of *o*-(lithiomethyl)phenyl isocyanide with methyl chloroformate.[4]

Cu_2O Catalyzed Cyclization of o-*(Cyanomethyl)phenyl Isocyanide (**1a**).* A mixture of 284 mg (2 mmol) of *o*-(cyanomethyl)-phenyl isocyanide (**1a**), 3.6 mg (0.025 mmol) of Cu_2O and 2 ml of benzen was heated at 55 °C for 6 h with stirring under nitrogen. After the reaction mixture was filtered, the filtrate was distilled *in vacuo*. The residue was subjected to column chromatography (silica gel–chloroform) giving 3-cyanoindole (**3a**) in 86% yield. **3a** was identified by comparing the spectral data with those of the authentic sample.[5]

Cyclization reaction of *o*-(methoxycarbonylmethyl)phenyl isocyanide (**1b**) was carried out in a similar way. The product of 3-(methoxycarbonyl)indole (**3b**) (92% yield) was identified by comparing the spectral data with those of the authentic sample.[6]

Reaction of o-*(Cyanomethyl)phenyl Isocyanide (**1a**) with Methyl Iodide.* To a mixture of 710 mg (5 mmol) of *o*-cyanomethylphenyl isocyanide and 10 ml of THF cooled at −78 °C with stirring under nitrogen, butyllithium (5 mmol, 1.8 M hexane solution) was added. After 15 min, 0.37 ml (6 mmol) of methyl iodide was added dropwise to the mixture, which was then allowed to warm up to room temperature. The reaction mixture was filtered to remove insoluble inorganic salts and evaporated *in vacuo*. The residue was subjected to column chromatography on silica gel eluting with benzene–chloroform (5: 1) to yield *o*-(α-cyanoethyl phenyl)isocyanide (**4a-i**) (76% yield). Product of **4a-i** was identified by IR and NMR spectra.

Other alkylations of **1a** were carried out according to the procedure mentioned above.

Reaction of o-*(Methoxycarbonylmethyl)phenyl Isocyanide (**1b**) with Allyl Bromide.* To a mixture of 263 mg (1.5 mmol) of *o*-(methoxycarbonylmethyl)phenyl isocyanide (**1b**), 4 ml of diglyme and 1 ml of HMPA cooled at −78 °C, butyllithium (1.5 mmol, 1.8 M hexane solution) was added. After 15 min, 242 mg (2 mmol) of allyl bromide was added to the mixture and stirred for 1 h at −78 °C, which was then allowed to warm up to room temperature. The reaction mixture was poured into ether and washed with water, and dried over Na_2SO_4. The ether solution was evaporated *in vacuo* and subjected to column chromatography on silica gel eluting with chloroform to give 57% yield of *o*-[1-(methoxycarbonyl)-3-butenyl]phenyl isocyanide (**4b-ii**). Product of **4b-ii** was identified by IR and NMR spectra.

Other alkylations of **1b** were carried out according to the procedure mentioned above.

General Procedure for Cu_2O Catalyzed Cyclization of o-*(α-Cyanoalkyl)phenyl Isocyanide (**4a**) and* o-*[α-(Methoxycarbonyl)alkyl]phenyl Isocyanide (**4b**).* A mixture of 312 mg (2 mmol) of *o*-(α-cyanoethyl)phenyl isocyanide (**4a-i**), 3.6 mg (0.025 mmol) of Cu_2O and 2 ml of benzene was heated at 70 °C for 10 h with stirring under nitrogen. The reaction mixture was filtered, and the filtrate was subjected to vacuum distillation to afford 3-cyano-3-methyl-3*H*-indole (**5a-i**) in 71% yield, bp 95 °C (0.8 Torr). **5a-i**: IR (neat) 2225, 1605 cm^{-1}; NMR (CCl_4 with Me_4Si) δ 1.68 (s, 3H), 7.3—7.8 (m, 4H), 7.98 (s, 1H). Found: C, 76.72; H, 5.20; N, 17.68%. Calcd for $C_{10}H_8N_2$: C, 76.90; H, 5.16; N, 17.94%.

According to the above procedure, other *o*-(α-cyanoalkyl)-phenyl isocyanides (**4a**) and *o*-[α-(methoxycarbonyl)alkyl]-phenylisocyanides (**4b**) were cyclized.

*3-Cyano-3-isopropyl-3*H*-indole (**5a-ii**)*: Bp 105—108 °C (1 Torr), IR (neat) 2220, 1600 cm^{-1}; NMR ($CDCl_3$ with Me_4Si) δ 1.10 (d, 6H), 2.40 (m, 1H), 7.20—8.00 (m, 4H), 7.19 (s,

1H). Found: C, 78.41; H, 6.65; H, 15.03%. Calcd for $C_{12}H_{12}N_2$: C, 78.23; H, 6.57; N, 15.21%.

*3-Cyano-3-allyl-3*H*-indole (**5a-iii**)*: Bp 110—112 °C (1 Torr), IR (neat) 2220, 1640, 1600 cm^{-1}; NMR (CCl_4 with Me_4Si) δ 2.71 (d, 2H), 5.18 (m, 1H), 5.45 (m, 1H), 6.00 (m, 1H), 7.30—8.00 (m, 4H), 8.15 (s, 1H). Found: C, 79.32; H, 5.77; N, 15.45%. Calcd for $C_{12}H_{10}N_2$: C, 79.09; H, 5.53; N, 15.38%.

*3-Cyano-3-benzyl-3*H*-indole (**5a-iv**)*: was isolated by column chromatography on silica gel (benzene). **5a-iv**: IR (Neat) 2220, 1600 cm^{-1}; NMR ($CDCl_3$ with Me_4Si) δ 3.19 (s, 2H), 7.00—7.90 (m, 9H), 7.10 (s, 1H). Found: C, 82.93; H, 5.01; N, 12.28%. Calcd for $C_{16}H_{12}N_2$: C, 82.73; H, 5.21; N, 12.06%.

*3-Cyano-3-(methoxycarbonylmethyl)-3*H*-indole (**5a—v**)*: was isolated by column chromatography on silica gel (chloroform). **5a—v**: IR (neat) 2210, 1740, 1600 cm^{-1}: NMR (CCl_4 with Me_4Si) δ 2.27 (s, 1H), 2.92 (s, 1H) 3.73 (s, 3H), 7.20—7.75 (m, 4H), 8.25 (s, 1H). Found: C, 67.51; H, 4.88; N, 12.91%. Calcd for $C_{12}H_{10}N_2O_2$: C, 67.28; H, 4.71; N, 13.08%.

*3-(Methoxycarbonyl)-3-methyl-3*H*-indole (**5b-i**)*: was isolated by column chromatography on silica gel (chloroform). **5b-i**: IR (neat) 1730. 1600 cm^{-1}; NMR (CCl_4 with Me_4Si) δ 1.58 (s, 3H), 3.55 (s, 3H), 6.90—7.50 (m, 4H), 7.90 (s, 1H). Found: C, 69.58; H, 5.72; N, 7.28%. Calcd for $C_{11}H_{11}NO_2$: C, 69.82; H, 5.86; N, 7.40%.

*3-(Methoxycarbonyl)-3-allyl-3*H*-indole (**5b-ii**)*: was isolated by column chromatography on silica gel (1:4 ethyl acetate–chloroform). **5b-ii**: IR (neat) 1730, 1640, 1600 cm^{-1}; NMR (CCl_4 with Me_4Si) δ 2.70 (m, 2H), 3.64 (s, 3H), 5.0—5.6 (m, 3H), 6.80—7.50 (m, 4H), 7.95 (s, 1H). Found: C, 72.80; H, 6.11; N, 6.73%. Calcd for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09; N, 6.51%.

*3-(Methoxycarbonyl)-3-butyl-3*H*-indole (**5b-iii**)*: was isolated by column chromatography on silica gel (chloroform). **5b-iii**: IR (neat) 1730, 1590 cm^{-1}; NMR ($CDCl_3$ with Me_4Si) δ 0.83 (t, 3H), 1.20—1.50 (m, 4H), 2.00 (m, 2H), 3.68 (s, 3H). 7.00—7.60 (m, 4H), 8.18 (s, 1H). Found: C, 72.88; H, 7.59; N, 5.92%. Calcd for $C_{14}H_{17}NO_2$: C, 72.70; H, 7.41; N, 6.06%.

(Received October 14, 1977)

Treatment of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside (**1**) with dimethyloxosulfonium methylide and dimethylsulfonium α-methylphenacylide afforded cyclopropane derivatives, whereas similar reactions with dimethylsulfonium phenacylide and dimethylsulfonium ethoxycarbonylmethylide gave stabilized ylides. In all cases the *S*-ylides enter the C-2 position of **1** from the side trans to the anomeric methoxyl group. The ylide structures were determined from IR and NMR data and confirmed by transformation into the desulfurized products. Anomalous stability of these ylides are attributed to the delocalization of the negative as well as positive charge over the carbonyl and the nitro group, respectively.

Only one example[2] is known of the reactions of nitro olefin with *S*-ylides (dimethyloxosulfonium methylide), in which cyclopropane derivatives are exclusively formed. Our studies[3] on the nucleophilic addition reaction to methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside (**1**) and its α-anomer and related subjects[4] strongly suggest that under kinetically controlled conditions nucleophiles approach from the equatorial side in the β-series,[5] but predominantly from the axial side in the α-series. In order to confirm the surmise we have carried out the reactions of **1** and its α-anomer with some *S*-ylides; these seem to be controlled kinetically.[6] We wish to report the reactions of **1** with *S*-ylides in this paper.

Results and Discussion

Treatment of **1** with dimethyloxosulfonium methylide in DMSO at room temperature for 1 h gave methyl (2*R*,3*R*)-4,6-*O*-benzylidine-2,3-dideoxy-2,3-*C*-methylene-3-nitro-β-D-*erythro*-hexopyranoside (**2**) in 75% yield. The configuration of **2** was assigned from the values of $J_{1,2}=0$ Hz, indicating that the conformation of **2** is similar to that of methyl 2,3-anhydro-4,6-*O*-benzylidene-3-nitro-β-D-allopyranoside.[7,4a]

On the other hand, when **1** was treated with dimethylsulfonium phenacylide in THF at room temperature for 18 h, methyl 4,6-*O*-benzylidene-2,3-dideoxy-2-*C*-[α-(dimethylsulfuranylidene)phenacyl]-3-nitro-β-D-glucopyranoside (**3**) was obtained in 78% yield instead of a cyclopropane derivative. The structure of **3** was determined by the following data: i) molecular ion peak *m/e* 473 was observed, ii) its IR spectrum (KBr) showed absorption bands due to a characteristic carbonyl group of ylide species[8] at 1505 cm^{-1} and due to a nitro group at 1555 cm^{-1}, iii) the NMR spectrum revealed the presence of a α-(dimethylsulfuranylidene)-phenacyl group (5-H of phenyl and 6-H of SMe_2) and *gluco* configuration for **3** ($J_{1,2}=7.5$ and $J_{2,3}=J_{3,4}=10$ Hz), iv) catalytic desulfurization over Pd/C afforded quantitatively methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-2-*C*-phenacyl-β-D-glucopyranoside (**5**), accompanied by the odor of dimethyl sulfide, whose *gluco* configuration was deduced from the values of $J_{1,2}=7.5$ and $J_{2,3}=J_{3,4}=10$ Hz.

A similar stabilized ylide **4** was prepared in 75% yield by treating **1** with dimethylsulfonium ethoxycarbonylmethylide in THF at room temperature for 18 h. The results of elemental analysis fit the formula $C_{20}H_{27}NO_8S$, which is confirmed by the molecular ion peak *m/e* 441.

The IR spectrum (KBr) showed the presence of an ester carbonyl group of ylide species[8] (1615 cm^{-1}) and a nitro group (1560 cm^{-1}). Catalytic desulfurization of **4** to **6** also supports the structure of **4**. The NMR spectrum of **4** shows a pattern quite different from that of **3**, indicating that compound **4** consists of two geometrical isomers (Fig. 1), formed by the restricted rotation about the C(ylide)–C(carbonyl) bond, in an approximately 1 : 1 ratio; the appearance of two doublets (at δ 4.96 and 4.71) and two triplets (at δ 5.81 and 5.40) due to H-1 and H-3, respectively, at 20 °C in $CDCl_3$. With respect to the sugar moiety, they have the same *gluco* configuration with the same $^4C_1$ conformation because of the same values for their coupling constants, $J_{1,2}=7.5$ and $J_{2,3}=J_{3,4}=10$ Hz, as well as the exclusive formation of **6** from **4**. The equilibrium of the isomers was studied by examining the temperature dependence of the NMR spectrum: At 90 °C the two doublets (H-1) and two triplets (H-3) collapse into broad singlets centered at δ 4.75 and 5.60, respectively. At 115 °C the former appears at δ 4.77 as a doublet and the latter at δ 5.48 as a triplet. A similar phenomenon was reported by Casanova, Jr. and Rutolo, Jr. concerning dimethylsulfonium methoxycarbonylmetflylide;[9] in NMR spectra, the methine proton signal, a sharp singlet at 45 °C, becomes a broad singlet at 0 °C and two singlets at −45 °C.

The formation of the different products according to the ylides used might be explained as follows. An intermediate zwitterion arising from the nucleophilic addition of the anionic center of the ylide to the C-2 position of the nitro olefin **1** should collapse to cyclopropane. However, if an acidic hydrogen atom was present on the ylide carbon atom, the proton shift predominates over the cyclopropanation giving the stabilized ylides. In fact the reaction of **1** with dimethylsulfonium α-methylphenacylide, bearing no available hydrogen atom, afforded the cyclopropane **7** in 71% yield. The cyclopropane structure for **7** was determined by comparison of its IR and NMR spectra with those of **2**. From the steric ground the benzoyl group on the cyclopropane ring seems to occupy the exo position and the methyl the endo position. However, no definite assignment has been established.

Ylides **3** and **4** are extremely stable as compared with the usual ylides having one anion stabilizing group such

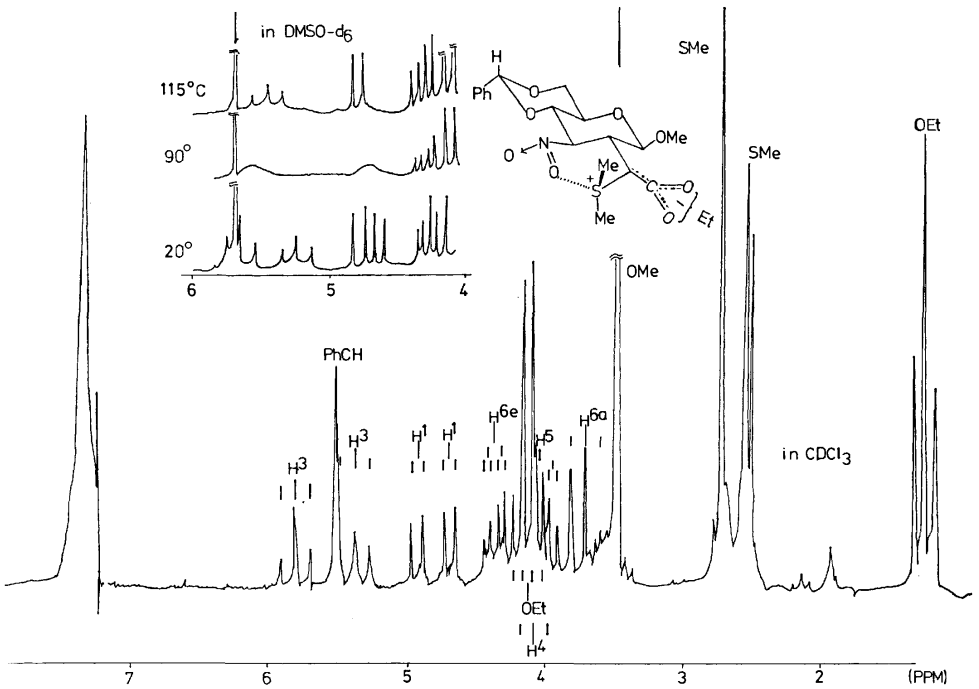

Fig. 1. The NMR spectrum of the stabilized ylide **4** (in $CDCl_3$, 100 MHz), the partial NMR spectra of **4** under the elevated temperature (in DMSO-d_6, 100 MHz), and the most plausible structure of **4**.

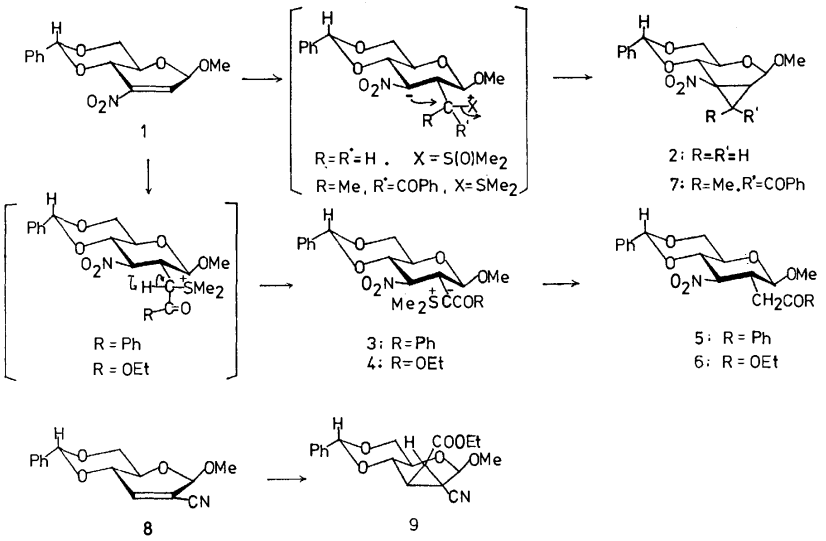

as carbonyl; *e.g.* the molecular ion peaks appear in EI-mass spectra, no change being observed on keeping the samples in open vessels at room temperature for 2 years or on treatment with silica gel column chromatograph. The anomalous stability of ylides **3** and **4** cannot be explained only in terms of the delocalization of negative charge over a ethoxycarbonyl or a carbonyl group. The most satisfactory explanation is based on the delocalization of the positive charge on the sulfur atom over the nitro group orientated in a suitable position to form the π_d–π_p bond with the sulfur atom through a stable six-membered ring system (Fig. 1).

This surmise was chemically supported. The reaction of methyl 5-*O*-benzoyl-2,3-dideoxy-3-nitro-β-D-*glycero*-pent-2-enofuranoside[10] with dimethylsulfonium ethoxycarbonylmethylide afforded complicated results, the isolation of products being unsuccessful. However, the NMR spectrum of the crude reaction mixture showed the absence of dimethylsulfonium moiety, indicating no formation of a stabilized ylide corresponding to **4**. This is reasonable if the formation of a stabilized ylide requires the delocalization of both the negative and positive charges, the latter being sterically impossible in the 2,3-*trans* furanose system. The reaction of methyl 4,6-*O*-benzylidene-2-cyano-2,3-dideoxy-β-D-*erythro*-hex-2-enopyranoside (**8**)[3,4c] with dimethylsulfonium ethoxycarbonylmethylide afforded a mixture of three compounds,at least, from which the cyclopropane derivative **9** and the starting material **8** were isolated in 23 and 10% yield, respectively. During column chromatography on silica gel, generation of dimethyl sulfide was detected by its smell, suggesting the formation of a ylide corresponding to **4** and its much less stability as compared with that of **4**. Such an interaction of the linear cyano group with the sulfur atom of the ylide is stericall difficult. The cyclopropane structure for **8** was determined from the results of elemental analsysis, IR (CN at 2250 and CO at 1725 cm^{-1}) and NMR spectra (presence of cyclopropane ring protons at δ 2.34 and 2.64; $J_{3,4}$= 1.6 Hz).

Experimental

Melting points were determined in capillaries and are uncorrected. IR spectra were recorded on KBr discs for crystals and on NaCl plates for syrup. NMR spectra were determined for solutions in chloroform-*d* (tetramethylsilane as internal standard) with a JNM-4H-100 (JEOL) spectrometer. Solutions were evaporated under reduced pressure.

*Methyl (2*R*,3*R*)-4,6-O-Benzylidene-2,3-dideoxy-2,3-C-methylene-3-nitro-β-*D-erythro-*hexopyranoside (2).* A solution of the ylide was prepared from 440 mg of sodium hydride (over 55% purity), 2.64 g (12 mmol) of trimethyloxosulfonium iodide and 6 ml of DMSO.[11] A solution of 2.93 g (10 mmol) of **1**[12] in 10 ml of DMSO was added with stirring. The mixture was stirred at room temperature for 1 h and poured into 50 ml of cold water. The precipitate was separated and washed with water and recrystallized from ethanol to give 2.3 g (72%) of **2**: Mp 147.5—148.0 °C; $[\alpha]_D^{20}$ −44.2° (*c* 1, $CHCl_3$); IR 1550 (NO_2) cm^{-1}.

Found: C, 58.63; H, 5.74; N, 4.72%. Calcd for $C_{15}H_{17}NO_6$: C, 58.63; H, 5.58; N, 4.56%.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-[α-(dimethylsulfuranylidene)phenacyl]-3-nitro-β-D-glucopyranoside (3). To a solution of **1** (293 mg, 1 mmol) in distd THF (15 ml) was added dimethylsulfonium phenacylide[13] (270 mg, 1.5 mmol) at 0 °C. The mixture was kept for 18 h, the organic solvent being evaporated. The remaining solid was washed with water and recrystallized from ethanol–acetone to give 383 mg (78%) of yellow-green crystals of **3**: Mp 157—158 °C; $[\alpha]_D^{20}$+28.8° (*c* 1, $CHCl_3$); IR 1555 (NO_2) and 1505 (CO) cm^{-1}.

Found: C, 59.03; H, 5.88; N, 2.82; S, 6.79%. Calcd for $C_{24}H_{27}NO_7S \cdot H_2O$: C, 58.64; H, 5.95; N, 2.85; S, 6.52%.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-[dimethylsulfuranylidene)ethoxycarbonylmethyl]-3-nitro-β-D-glucopyranoside (4). To a solution of **1** (586 mg, 2 mmol) in distd THF (15 ml) was added dimethylsulfonium ethoxycarbonylmethylide[14] (592mg, 4 mmol) at 0 °C. The mixture was stirred at the same temperature for 4 h, the organic solvent being evaporated. The remaining solid was washed with water and recrystallized from ethanol to give 661.5 mg (75%) of yellow-green crystals of **4**: Mp 165.5—166.0 °C; $[\alpha]_D^{20}$ +39.0° (*c* 1, $CHCl_3$); IR 1615 (COOEt) and 1560 (NO_2) cm^{-1}.

Found: C, 54.34; H, 6.12; N, 3.01; S, 7.24%. Calcd for $C_{20}H_{27}NO_8S$: C, 54.41; H, 6.16; N, 3.17; S, 7.26%.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-2-C-phenacyl-β-D-glucopyranoside (5). A solution of **4** (316 mg, 0.64 mmol) in methanol (20 ml) was hydrogenated in the presence of 10% Pd/C (200 mg). After 17 h, the catalyst was filtered off and the filtrate was evaporated and the residue was recrystallized from ethanol to give 250 mg (94%) of cotton-like, colorless crystals of **5**: Mp 173—174 °C; $[\alpha]_D^{20}$ −27.5° (*c* 1, $CHCl_3$); IR 1685 (CO) and 1550 (NO_2) cm^{-1}.

Found: C, 63.74; H, 5.75; N, 3.65%. Calcd for $C_{22}H_{23}NO_7$: C, 63.91%; H, 5.61; N, 3.39%.

Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-ethoxycarbonylmethyl-3-nitro-β-D-glucopyranoside (6). A solution of **4** (441 mg, 1 mmol) in methanol (20 ml) was hydrogenated in the presence of 10% Pd/C (250 mg). After 2 days, the catalyst was filtered off and the filtrate was evaporated. The residue was recrystallized from ethanol to afford 343 mg (90%) of colorless crystals of **6**: Mp 146—146.5 °C; $[\alpha]_D^{20}$ −46.6° (*c* 1, $CHCl_3$); IR 1730 (COOEt) and 1555 (NO_2) cm^{-1}.

Found: C, 56.65; H, 5.84; N, 3.94%. Calcd for $C_{18}H_{23}NO_8$: C, 56.68; H, 6.08; N, 3.67%.

*Methyl (2R,3S)-2,3-C-(1-Benzoylethylidene)-4,6-O-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hexopyranoside (7).* Dimethylsulfonium α-methylphenacylide (640 mg, 3.3 mmol), prepared according to a similar method to that for the preparation of dimethylsulfonium ethoxycarbonylmethylide, was added to a solution of **1** (879 mg, 3 mmol) in distd THF (20 ml) at room temperature. The mixture was kept for 9 h and the solvent was evaporated, affording crystalline residue, which was recrystallized from ethanol–acetone to give 906 mg (71%) of colorless crystals of **7**: Mp 143—144 °C; $[\alpha]_D^{20}$ −68.0° (*c* 1, $CHCl_3$); IR 1690 and 1675 (CO) and 1550 (NO_2) cm^{-1}.

Found: C, 65.04; H, 5.47; N, 3.12%. Calcd for $C_{23}H_{23}NO_7$: C, 64.93; H, 5.45; N, 3.29%.

*Methyl (2R,3R)-4,6-O-Benzylidene-2-cyano-2,3-C-(ethoxycarbonylmethylene)-2,3-dideoxy-β-D-*erythro*-hexopyranoside (9).* To a solution of **8**[3,4c] (400 mg, 1.47 mmol) in THF (10 ml) was added dimethylsulfonium ethoxycarbonylmethylide (245 mg, 1.66 mmol) at room temperature with stirring. The mixture was stirred for 4 h and the solvent was evaporated to give a syrup, which was washed with water. The NMR spectrum of the crude product revealed the presence of two products at least in an approximately 1.5: 1 ratio. After separation of starting material **8** (40 mg, 10% recovery), the syrup was chromatographed on silica gel (C-300, Wakogel) with benzene to afford 121.5 mg (23%) of **9**, whose NMR spectrum agreed with that of the major product: Mp 129—129.5 °C; $[\alpha]_D^{20}$ −72.3° (*c* 1, $CHCl_3$) IR 2250 (CN) and 1725 (COOEt) cm^{-1}.

Found: C, 63.58; H, 5.98; N, 4.10%. Calcd for $C_{19}H_{21}NO_6$: C, 63.50; H, 5.89; N, 3.90%.

Smell of dimethyl sulfide was detected during the course of column chromatography on silica gel. This suggests that the ylide formed corresponding to **4** was not stable in chromatographic separation.

Stereochemistry of Nucleophilic Addition Reactions. 6. Synthesis of Isoxazoline *N*-Oxide Derivatives from Methyl 4,6-*O*-Benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside with Some *S*-Ylides[1]

Tohru SAKAKIBARA and Rokuro SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 14, 1977)

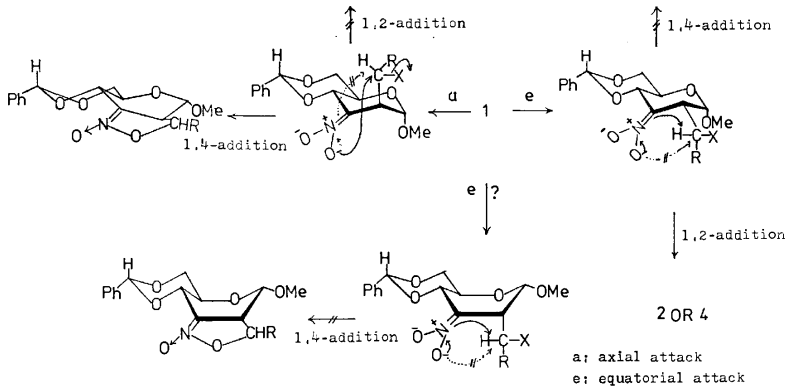
In the reactions of dimethyloxosulfonium methylide, dimethylsulfonium ethoxycarbonylmethylide, and dimethylsulfonium phenacylide with the title compound, axial attack predominates over equatorial attack, particularly in the case of dimethylsulfonium phenacylide equatorial attack being no longer observed. Axial attack afforded exclusively 1,4-addition products (isoxazoline *N*-oxide derivatives), whereas equatorial attack gave only 1,2-addition products (cyclopropane and stabilized ylide, respectively). Discussion is given on such high selectivities.

In a previous paper[2] a report was given on the reactions of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside with some *S*-ylides, where equatorial attack occurs selectively to give cyclopropane derivatives or new stabilized ylides depending on the ylide used. In order to obtain information on the stereochemistry of Michael type reaction of α-glycoside series,[3] we have carried out the reaction of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-α-D-*erythro*-hex-2-enopyranoside (**1**) with *S*-ylides and have found that axial attack predominates over equatorial attack, the former affording 1,4-addition product and the latter 1,2-addition product, exclusively.

Results and Discussion

Treatment of **1** with dimethyloxosulfonium methylide in DMSO at room temperature for 1.5 h afforded a mixture of methyl (2*R*,3*R*)-4,6-*O*-benzylidene-2,3-dideoxy-2,3-*C*-methylene-3-nitro-α-D-*erythro*-hexopyranoside (**2**) and (methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*-hexopyranosido)[3,2-*c*]isoxazoline *N*-oxide (**3**) in a 1:3.5 ratio as determined by NMR spectroscopy. After separation of **2** by crystallization, compound **3** was isolated by column chromatography on silica gel. The results of elemental analysis of both compounds correspond to the formula $C_{15}H_{17}NO_6$. The cyclopropane structure for **2** was determined from its IR (presence of NO_2 but absence of C=N absorption band) and NMR spectra (presence of cyclopropane ring protons at δ 2.61, 2.18, and 1.98). The configuration of **2** was determined from the value $J_{1,2}$=6.2 Hz[4] and long range coupling ($J_{4,exo}$=1.0 Hz) owing to "W-orientation." The IR spectrum of **3** revealed no absorption band for a nitro but a C=N group (1640 cm^{-1}). The complicated NMR spectrum of **3** due to overlap of ring protons was not completely assigned. However, the structure of **3** was deduced by comparison of its IR and NMR spectra with those of **5** and supported by conversion into hydroxyimino derivative **9**.

Reaction of **1** with dimethylsulfonium ethoxycarbonylmethylide in THF at 0 °C gave a mixture of the stabilized ylide **4** (*ca.* 22%) and isoxazoline *N*-oxide **5** (55%). After separation of crystalline compound **5**, stabilized ylide **4** was separated as a syrup by means of column chromatography on silica gel. Although **4** was not completely purified, the ylide structure for **4** was determined from its IR (the characteristic absorption band of an ester carbonyl group of the ylide species at 1630 cm^{-1} and that of a nitro group at 1560 cm^{-1}) and NMR spectra (two methyl signals for SMe_2 at δ 2.76 and 2.65).[2] Assignment of the *gluco* configuration to **4** was based on the values $J_{1,2}$=3.5, $J_{2,3}$=12.5, and $J_{3,4}$=10 Hz. The structure of **4** was confirmed by desulfurization into methyl 4,6-*O*-benzylidene-2-*C*-(ethoxycarbonylmethyl)-2,3-dideoxy-3-nitro-α-D-glucopyranoside (**6**); $J_{1,2}$=3.1 and $J_{2,3}$=$J_{3,4}$=11.1 Hz. The structure of **5** was determined on the basis of its elemental analysis (molecular formula $C_{18}H_{21}NO_8$) and IR spectra (absence of NO_2 but presence of COOEt and C=N absorption bands at 1720 and 1645 cm^{-1}, respectively). The isoxazoline *N*-oxide structure was supported by the fact that treatment of **5** with triphenylphosphine in boiling benzene for 15 h afforded isoxazoline **7** in 91% yield. Thus with the isoxazoline ring fused at C-2 and C-3, compound **5** should have the *arabino* configuration existing in a boat form or the *ribo* configuration existing in a chair form. The signals of H-1 and H-7 (the ring proton of the isoxazoline nucleus), which overlap, were clearly resolved into two doublets having spacings 6.0 and 7.0 Hz by addition of shift reagent, $Eu(DPM)_3$. The reagent probably undergoes complexation with the *N*-oxide group or the ethoxycarbonyl group, resulting in displacement of the H-7 signal to much lower field than that of the H-1 signal. The value of $J_{1,2}$=6.0 Hz suggests that **5** has the *arabino* configuration existing in a boat form. This was confirmed chemically. Catalytic hydrogenation of **5** over Raney nickel afforded a mixture of two products at least in an approximately 3:1 ratio as determined by NMR spectroscopy, from which the major product **8** was isolated in 35% yield. The IR spectrum revealed the presence of a hydroxyl (3380), an amino (3310), and an ester carbonyl group (1735 and 1700 cm^{-1}). The *altro* configuration of **8** was determined from its coupling-constant data ($J_{1,2}$=0, $J_{2,3}$=1.3, and $J_{3,4}$=3.8 Hz), the values being confirmed with the aid of spin decoupling; irradiation at δ 2.41 (H-2) and at δ 3.49 (H-3).



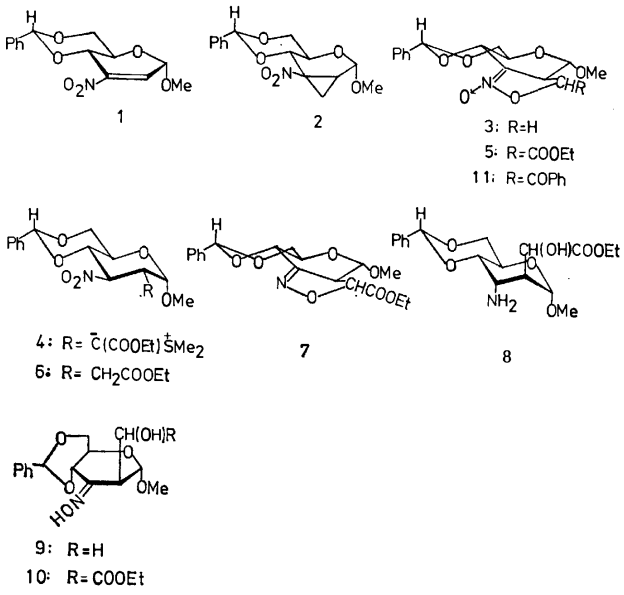
Hydrogenation of **3** and **5** over 10% Pd/C afforded hydroxyimino derivative **9** and **10**, respectively. The results of elemental analysis and IR and NMR spectra fit the hydroxyimino structures.

A similar reaction of **1** with dimethylsulfonium phenacylide in THF at room temperature afforded 5-benzoyl-(methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*-hexopyranosido)[3,2-*c*]isoxazoline *N*-oxide (**11**) in 89.9% yield, no evidence being detected for formation of stabilized ylide corresponding to **4**.[2] The structure of **11** was deduced by comparison of spectral data with those of **5**. When this reaction was carried out on a larger scale, another product was formed.

The ratio of axial attack, which affords the isoxazoline *N*-oxide **3**, **5**, and **11**, increased according to the sequence $Me_2SOCH_2 < Me_2SCHCOOEt < Me_2SCHCOPh$. The ratios of **5** to **4** were 1.6: 1 in THF at room temperature, 3.2: 1 in THF at 0 °C, and 5.3: 1 in DMSO at 0 °C. The results could be attributed to steric hindrance between incoming ylide and the glycosidic methoxyl group.

In general, conjugate addition of *S*-ylide with carbon-carbon double bond activated by electron-withdrawing substituent(s) gives preferentially a three-membered ring product. However, exceptions are reported, in which an unfavorable five-membered ring product predominates. This is explained in terms of formation of unusually stable cisoid intermediate.[5] However, the intermediary nitronate has no such cis or trans form. Thus, the explanation can not be applied to the observed high selectivity, *i.e.*, axial attack gave the 1,4-addition products, equatorial attack the 1,2-addition products. The following rationalization seems to be likely. If the ylide approaches from the axial side, an intermediary nitronate should have a chairlike transition state in which the carbon atoms at C-3 and C-2 move up and down, respectively, to afford a product. Molecular models indicate that, during this movement interaction between the oxygen atom of the nitro group and the carbon atom (C-7) bearing the sulfur atom is more efficient than that between the C-3 and C-7 carbon atom to give the isoxazoline derivative. On the other hand, when the ylide comes from the equatorial side, the orginal half-chair conformation changes into a boatlike transition state, where the incoming ylide approaches from the stereoelectronically acceptable axial direction. Although the alternative chairlike transition state is unfavorable for stereoelectronic control[6] and $A^{1,3}$ strain,[7] the transition state also seems to be possible because of the favorable anomeric effect.[8] The relationship between C-3 and C-7 in the boatlike transition state resembles that in the chairlike transition state derived by axial attack, indicating the preferred formation of 1,4-adduct. However, experimental results show selective formation of 1,2-addition products. Thus the chairlike transition state even in the case of equatorial attack is more likely, in which the favorable interaction between C-3 and C-7 carbon atoms is predicted by molecular models.

It is noteworthy that epoxidation of **1** with hydrogen peroxide in a weakly alkaline medium exclusively afforded 1,2-addition product, *i.e.*, methyl 2,3-anhydro-4,6-*O*-benzylidene-3-*C*-nitro-α-D-mannopyranoside.[3d] Though in this reaction intermediary nitronate should have a similar structure derived by axial attack of the ylides, molecular models suggest that the C-3 carbon atom is orientated in a more suitable position than the oxygen atom of the nitro group to make the displacement of hydroxide ion take place. Such a difference can be attributed to the shorter bond length of the C–O as compared with the C–C bond.



Experimental

Melting points were determined in capillaries and are uncorrected. IR spectra were recorded by use of KBr discs

and NMR spectra were determined with solutions in chloroform-*d* (tetramethylsilane as internal standard) with a JNM-4H-100 (JEOL) spectrometer. Solutions were evaporated under reduced pressure. Column chromatography was performed on silica gel (C-300, Wakogel, Japan).

*Treatment of **1** with Dimethyloxosulfonium Methylide.* To a solutions of dimethyloxosulfonium methylide, prepared from trimethyloxosulfonium iodide (770 mg) and sodium hydride (over 55% purity, 154 mg) in DMSO (7 ml), was added 6 ml of DMSO solution of **1**[9] (1.03 g, 3.5 mmol) at 0 °C. The mixture was kept at 0 °C for 30 min and for 1 h at room temperature and then poured into 70 ml of water. The precipitate was collected and washed with water. Its NMR spectrum revealed that it is a mixture consisting of **2** and **3** in the ratio 1:3.5. Recrystallization from ethanol–diisopropyl ether gave 150 mg of **2**: Mp 131—132 °C; $[\alpha]_D^{20}+35.0°$ (*c* 1, $CHCl_3$); IR 1550 cm^{-1} (NO_2); NMR $\delta=5.81$ (s, 1, PhCH), 5.04 (d, 1, H-1, $J_{1,2}=6.3$ Hz), 4.92 (d, 1, H-4, $J_{4,5}=9.4$, $J_{4,exo}=1.0$ Hz), 4.28 (q, 1, H-6e, $J_{5,6e}=5.0$, $J_{5,6a}=10$ Hz), 3.37 (six, 1, H-5), 3.37 (s, 3, OMe), 2.61 (oct, 1, H-2, $J_{2,exo}=11.3$, $J_{2,endo}=8.1$ Hz), 2.18 (oct, 1, H_{exo}, $J_{exo,\,endo}=6.3$ Hz), and 1.98 (q, 1, H_{endo}).

Found: C, 58.60; H, 5.61; N, 4.44%. Calcd for $C_{15}H_{17}NO_6$: C, 58.63; H, 5.58; N, 4.56%.

The combined mother liquors were evaporated and chromatographed with benzene as eluent. The fast running fraction was **2** (28 mg, total yield 16.5%) and the slow running fraction was **3**, which was recrystallized from ethanol–diisopropyl ether to give 607 mg (56.2%) of **3**: Mp 178.5—179.5 °C; $[\alpha]_D^{20}-139.2°$ (*c* 1, $CHCl_3$); IR 1640 cm^{-1} (C=N); NMR $\delta=5.69$ (s, 1, PhCH), 4.73 (d, 1, H-1, $J_{1,2}=6.0$ Hz), 3.41 (s, 3, OMe), and 4.8—3.8 (7-H).

Found: C, 58.57; H, 5.65; N, 4.57%. Calcd for $C_{15}H_{17}NO_6$: C, 58.63; H, 5.58; N, 4.56%.

*Treatment of **1** with Dimethylsulfonium Ethoxycarbonylmethylide.* To a solution of **1** (293 mg, 1 mmol) in THF (7 ml) was added the ylide (163 mg, 1.1 mmol) at 0 °C. The mixture was kept at 0 °C for 30 min and then at room temperature for 16 h and evaporated. The residue crystallized from ethanol to give 138 mg of **5**: Mp 151.5—152 °C; $[\alpha]_D^{20}-121°$ (*c* 1, $CHCl_3$); IR 1720 (COOEt) and 1645 (C=N) cm^{-1}; NMR $\delta=5.72$ (s, 1, PhCH), 4.95 (d, 1, H-7, $J_{2,7}=7.0$ Hz), 4.89 (d, 1, H-1, $J_{1,2}=6.0$ Hz), 3.45 (s, 3, OMe), 1.31 (t, 3, OEt), and 4.55—3.85 (7-H).

Found: C, 57.32; H, 5.65; N, 3.64%. Calcd for $C_{18}H_{21}NO_8$: C, 56.99; H, 5.58; N, 3.65%.

The mother liquor was evaporated and chromatographed on a column with benzene–ethanol (20:1, v/v) as eluent. The fast running fraction was **5** (70 mg, total yield 55%) and the slow running fraction was a light yellow syrup of **4** (80 mg). Attempts for purification by preparative TLC were unsuccessful. The syrup was hydrogenated without further purification. The syrup (143 mg) was dissolved in methanol and hydrogenated over 10% Pd/C (200 mg). After 2 days the catalyst was removed by filtration. The filtrate was evaporated to give a syrup, which crystallized from ethanol to afford 100 mg (81%) of **6**: Mp 91.5—92.0 °C; $[\alpha]_D^{20}+72°$ (*c* 1, $CHCl_3$); IR 1720 (COOEt) and 1550 (NO_2) cm^{-1}; NMR $\delta=5.55$ (s, 1, PhCH), 4.93 (d, 1, H-1, $J_{1,2}=3.1$ Hz), 4.78 (t, 1, H-3, $J_{2,3}=J_{3,4}=11.3$ Hz), 3.35 (s, 3, OMe), and 1.23 (t, 3, OEt).

Found: C, 56.55; H, 6.01; N, 3.94%. Calcd for $C_{18}H_{23}NO_8$: C, 56.68; H, 6.08; N, 3.67%.

A similar treatment in THF at room temperature or in DMSO (5 ml) at 0 °C for 30 min and then 1 h at room temperature afforded a mixture consisting of **5** and **4** in the ratios 1.6:1 and 5.3:1, respectively, as determined by NMR spectroscopy.

*5-Ethoxycarbonyl-(methyl 4,6-O-benzylidene-2,3-dideoxy-α-D-erythro-hexopyranosido)[3,2-c]isoxazoline (**7**).* To a solution of **5** (57 mg, 0.15 mmol) was added triphenylphosphine (39.3 mg, 0.15 mmol). The mixture was heated under reflux for 15 h and evaporated to give a syrup, which was chromatographed on a column with carbon tetrachloride–ethyl acetate (10:1, v/v) to afford 51 mg of **7**. Recrystallization from ethanol gave 44 mg (81%) of **7**: Mp 159—160 °C; $[\alpha]_D^{20}-120°$ (*c* 0.5, $CHCl_3$); IR 1758 (COOEt) and 1620 (C=N) cm^{-1}; NMR $\delta=5.66$ (s, 1, PhCH), 4.8—4.7 (q, 2. H-1 and H-7, overlap), 3.82 (t, 1, H-6a, $J_{5,6a}=J_{6a,6e}=10$ Hz), 3.42 (s, 3, OMe), and 1.31 (t, 3, OEt).

Found: C, 59.77; H, 5.94; N, 3.98%. Calcd for $C_{18}H_{21}NO_7$: C, 59.49; H, 5.83; N, 3.86%.

*Methyl 3-Amino-4,6-O-benzylidene-2-C-[(ethoxycarbonyl)hydroxymethyl]-2,3-dideoxy-α-D-altropyranoside (**8**).* A solution of **5** (64 mg, 0.17 mmol) in ethyl acetate (10 ml) was hydrogenated in the presence of Raney nickel (80 mg) at room temperature. After 7 days the catalyst was filtered off and washed thoroughly with chloroform. The filtrate was evaporated to give a solid, the NMR spectrum of which showed the presence of two compounds. Recrystallization from acetone afforded 21.7 mg (35%) of **8**. The signals of its NMR spectrum corresponded to those of the major product: Mp 167—168 °C; $[\alpha]_D^{20}+64.2°$ (*c* 1, $CHCl_3$); IR 3380 (OH), 3310 (NH), and 1735 and 1700 (COOEt) cm^{-1}; NMR $\delta=5.62$ (s, 1, PhCH), 4.73 (s, 1, H-1), 4.24 (q, 2, OEt), 4.22 (d, 1, H-7, $J_{2,7}=7.5$ Hz), 3.49 (broad s, 1, H-3, $J_{2,3}=1.3$, $J_{2,4}=3.8$ Hz), 3.36 (s, 3, OMe), 2.41 (broad d, 1, H-2), and 1.30 (t, 3, OEt).

Found: C, 58.75; H, 6.85; N, 3.76%. Calcd for $C_{18}H_{25}NO_7$: C, 58.84; H, 6.86; N, 3.81%.

*Methyl 4,6-O-Benzylidene-2,3-dideoxy-2-C-hydroxymethyl-3-hydroxyimino-α-D-arabinohexopyranoside (**9**).* A solution of **3** (240 mg, 0.78 mmol) in THF (10 ml) was hydrogenated in the presence of 10% Pd/C (200 mg) at room temperature. After 20 h the catalyst was removed by filtration and the filtrate was evaporated to give a white powder. Recrystallization from ethanol gave 176 mg (73%) of **9**: Mp 170.5—171.5 °C; $[\alpha]_D^{20}-68.6°$ (*c* 1, $CHCl_3$); IR 3450 and 3250 (OH) cm^{-1}; NMR $\delta=5.62$ (s, 1, PhCH), 4.73 (d, 1, H-1, $J_{1,2}=4.7$ Hz), 4.52 (q, 1, H-4, $J_{2,4}=1.0$, $J_{4,5}=9.4$ Hz), 3.38 (s, 3, OMe), and 2.90 (m, 1, H-2).

Found: C, 58.34; H, 6.24; N, 4.47%. Calcd for $C_{15}H_{19}NO_6$: C, 58.24; H, 6.19; N, 4.53%.

*Methyl 4,6-O-Benzylidene-2-C-[(ethoxycarbonyl)hydroxymethyl]-2,3-dideoxy-3-hydroxyimino-α-D-arabinohexopyranoside (**10**).* A similar treatment of **5** (139 mg, 0.37 mmol) with 10% Pd/C (100 mg) in THF (10 ml) afforded **10**. Recrystallization from ethanol gave 113 mg (81%) of **10**: Mp 163.5—164.5 °C; $[\alpha]_D^{20}-68.4°$ (*c* 1, $CHCl_3$); IR 3400 (OH) and 1720 (COOEt) cm^{-1}; NMR $\delta=5.58$ (s, 1, PhCH), 4.92 (d, 1, H-1 or H-7, $J_{1,2}=5.6$ or $J_{2,7}=5.6$ Hz), 4.49 (d, 1, H-4, $J_{4,5}=8.8$ Hz), 4.35 (d, 1, H-7 or H-1, $J_{2,7}=3.1$ or $J_{1,2}=3.1$ Hz), 3.75 (t, 1, H-6a, $J_{5,6a}=J_{6a,6e}=9.4$ Hz), 3.40 (s, 3, OMe), 3.34 (q, 1, H-2), and 1.21 (t, 3, OEt).

Found: C, 57.06; H, 6.23; N, 3.55%. Calcd for $C_{18}H_{23}NO_8$: C, 56.68; H, 6.08; 3.67%.

*5-Benzoyl-(methyl 4,6-O-benzylidene-2,3-dideoxy-α-D-erythro-hexopyranosido)[3,2-c]isoxazoline N-Oxide (**11**).* To a solution of **1** (58.6 mg, 0.2 mmol) in THF (3 ml) was added dimethylsulfonium phenacylide (45 mg, 0.25 mmol) at room temperature. The mixture was stirred for 3 h and then poured into ice-water. Extraction with chloroform and evaporation of the solvent afforded a NMR-spectroscopically pure solid (74 mg, 89.9%). Analytical sample was prepared by recrystallization from ethanol: Mp 162.5—163.0 °C; $[\alpha]_D^{20}-227°$ (*c* 1, $CHCl_3$); IR 1705 (COPh) and 1638 (C=N) cm^{-1}; NMR

δ=5.59 (s, 1, PhCH), 5.58 (d, 1, $J_{2,7}$=6.3 Hz), 4.88 (d, 1, H-1, $J_{1,2}$=6.0 Hz), and 3.37 (s, 3, OMe).

Found: C, 64.14; H, 5.21; N, 3.32%. Calcd for $C_{22}H_{21}NO_7$: C, 64.22; H, 5.15; N, 3.40%.

The Effect of Macrocyclic Polyethers on the Alkylation of Sodium 2-Naphtholate

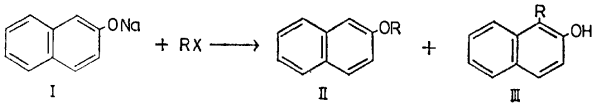
Sadatoshi AKABORI and Hiroyuki TUJI

Department of Chemistry, Faculty of Science, Tōho University, Funabashi, Chiba 274

(Received October 18, 1977)

The alkylation of sodium 2-naphtholate, in the presence of benzo-18-crown-6 or 4,7,13,16,21,24-hexaoxabicyclo[8.8.8]hexacosane is found to give high ratios of $O/O+C$ alkylation when conducted in THF, in benzene, and in water. The striking increase in the product ratio is attributed to a specific complexation of the macrocyclic polyethers, which facilitate the dissociation of the ion-pair aggregate of the sodio-derivative which exists in benzene or THF. The polyethers may act as phase-transfer catalysts when the reaction is run in water. In support of this conclusion, the reaction in DMF or acetonitrile, in which the dissociation of sodium 2-naphtholate takes place, fails to show any effect of the macrocyclic polyethers on the product ratio.

It is well known[1] that the 2-naphthoxide ion is an ambident anion capable of forming a covalent bond at either the oxygen or carbon atom on alkylation. Kornblum *et al.*[2] found that, whereas sodium 2-naphtholate (I) could be alkylated with benzyl bromide, propyl bromide, and methyl iodide, the solvent plays a decisive role in determining the reaction course of the ambident anion. For example, when sodium 2-naphtholate is treated with benzyl bromide in a dimethyl sulfoxide solution, benzyl 2-naphthyl ether (II) is produced in a 95% yield, whereas in water the main product is 1-benzyl-2-naphthol (III) (84% yield).



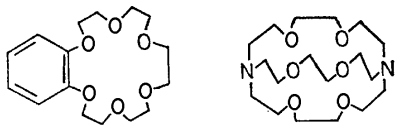
I II III

In recent years it has been generally accepted that quaternary ammonium halides and crown ethers can be used as phase-transfer catalysts[3] in two-phase ionic reactions. In addition, crown ethers possess a unique ability to fill the coordination sites of cations[4] and to convert contact ion-pairs into separated ions.[5] The combination of these two effects may affect the alkylation of sodium 2-naphtholate in a serious manner. Therefore, we have investigated the effect of benzo-18-crown-6 (IV) and 4,7,13,16,21,24-hexaoxabicyclo-[8.8.8]hexacosane (V)[6] on the reaction of alkyl and benzyl halides with sodium 2-naphtholate in various solvents.

Results and Discussion

The following reactions of sodium 2-naphtholate with benzyl and alkyl halides were run in several solvents with or without added macrocyclic polyethers (IV and V). The reactions were carried out by stirring sodium 2-naphtholate in a given solvent with benzyl bromide in the presence or absence of a small quantity of a macrocyclic polyether (IV or V). After the usual work-up, the products were analyzed by GLC.

We first investigated the homogeneous benzylation of sodium 2-naphtholate in aprotic solvents with relatively high or low dielectric constants. The yields of the *O*- and *C*-alkylation products are listed in Table 1 (Runs 10—15). As the data show, the reaction of benzyl



IV V

bromide with sodium 2-naphtholate in DMF and acetonitrile yields the *O*-alkylation product, whereas in the THF solvents, which have relatively a low dielectric constant, the *C*-alkylation occurs to a substantial extent. The addition of IV or V to the reaction mixture did not affect the product ratio in acetonitrile and DMF, but caused a remarkable increase in the ratios of *O*-alkylation to *C*-alkylation for the reaction in THF. In THF, sodium 2-naphtholate exists as ion pairs and higher aggregates.[2] Therefore, in the reaction of sodium 2-naphtholate with benzyl bromide (Run 4), the $O/O+C$ alkylation product ratio is rather low;[2] however, in the presence of IV or V (Runs 5 and 6) a reaction under similar conditions gave a high yield of the ether (II), together with a small % of the *C*-alkylation product. In this reaction, clearly, the ion-pair separating ability of the macrocyclic polyether accounts for this dramatic effect; it is known[5,7] that an equimolar amount of a crown ether suffices to convert ion-pairs into separated ions. In contrast, in a solvent with a high dielectric constant, such as acetonitrile or DMF, it is conceivable that the alkylation reaction involves free 2-naphthoxide ions (or loose ion pairs). Therefore, the polyethers fail to affect the products of alkylation.

Phase-transfer Reactions. The results are summarized in Table 1 (Runs 1—3 and 7—9). While it was difficult for the reaction of benzyl bromide with sodium 2-naphtholate to proceed in benzene (Runs 7—9), it proceeded smoothly in the presence of V to afford alkylation products totalling a 77% yield, showing that V was effective in solubilizing sodium 2-naphtholate in benzene. In the absence of the macrocyclic polyether, because of the low solubility of sodium 2-naphtholate in benzene and the low dielectric constant of benzene, a heterogeneous (solid-liquid) reaction occurred to give 1-benzyl-2-naphthol in a low yield as the main product. This result was consistent with the observation by Kornblum[8] that the heterogeneous alkylation of sodium phenolate proceeded through the

Table 1. Reaction of alkyl halides with sodium 2-naphtholate[a)]

a) All the reactions were conducted at 25 °C. b) This yield includes any alkylated products arising from the further alkylation of 1-benzyl-2-naphthol or 1-methyl-2-naphthol.

C-alkylation process. In contrast, in the presence of IV or V, the reactivity of the oxygen site became enhanced relative to that of the carbon site of the ambident anion: these results may be interpreted by thinking that sodium 2-naphtholate is solubilized in a benzene solution to produce highly reactive naked anions to cause a reaction with benzyl bromide in the homogeneous phase. Obviously the crown ether functioned as a solid-liquid phase-transfer agent. The most pronounced effect on the ratio of *O*-alkylation to *C*-alkylation was found in water. The reaction of an aqueous solution of sodium 2-naphtholate with benzyl bromide in the absence of IV or V gave a 12% yield of the *O*-alkylation product (II) and a 73% yield of the *C*-alkylation product. The explanation for this result is that strong proton donors such as water in the absence of IV or V solvated the anionic oxygen atom and thereby suppressed the *O*-alkylation. In sharp contrast, in the presence of IV or V in water, the $O/O+C$ ratios of the alkylation products markedly increased. When IV or V was added to the reaction mixture, the ambident anion produced in water could be transported into the organic layer (benzyl bromide) as a loosely separated ion pair, with a cryptated cation as an escort; the *O*-alkylation now occurred. The results are completely consistent with a phase-transfer mechanism.[9] Similar results were found in the reactions of sodium 2-naphtholate with methyl iodide in aprotic solvents and water.

Experimental

Analysis. The products were generally analyzed on a Hitachi 023 gas chromatograph equipped with a flame-ionization detector with a 1 m×3 mm column packed with 60—80 mesh Chromosorb W (washed with acid and treated with dimethyldichlorosilane) and coated with 20% Carbowax 20 M (for the analysis of benzylated products at *ca.* 240 °C) or with a 3 m×3 mm column packed with 80—100 mesh Chromosorb W (washed with acid and treated with dimethyldichlorosilane) and coated with 3% Silicone OV-17 (for the analysis of methylated products at *ca.* 210 °C).

Materials. Benzo-18-crown-6[4] and 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane[6] were prepared according to the procedures described in the literature. Authentic samples (1-benzyl-2-naphthol,[10] benzyl 2-naphthyl ether,[2] 1,1-dibenzyl-2-naphthalenone,[11] 1-methyl-2-naphthol,[12] methyl 2-naphthyl ether,[2] and methyl 1-methyl-2-naphthyl ether[2]) were also prepared according to the procedures

described in the literature. The sodium 2-naphtholate was prepared as has been described by Kornblum *et al.*,[2] while the alkyl halides (commercial samples) were used directly provided that the physical constants agreed with the reported values. The solvents used were purified by distillation.

General Procedure. The typical procedures for the reaction of alkyl halides with sodium 2-naphtholate are as follows.

Reaction of Benzyl Bromide with Sodium 2-Naphtholate. In Water: A magnetic stirring bar was placed in a 10-ml vial, after which sodium 2-naphtholate (1.06 mmol), benzo-18-crown-6 (0.3 mmol), and 4 ml of water were introduced. The mixture was stirred for 0.5 h at 25 °C. Benzyl bromide (1.2 mmol) was then added all at once, after which the mixture was stirred for a further 2.5 h. The resulting mixture was poured into 10 ml of water, acidified with 18% hydrochloric acid at 0 °C, and extracted with benzene four times. The extracts were combined and concentrated to a 5-ml volume. GLC analyses revealed the presence of four components, which were identified as 2-naphthol (17%), benzyl 2-naphthyl ether (60%), 1-benzyl-2-naphthol (9%), and 1,1-dibenzyl-2-naphthalenone (9%); the relative retention times of these components were 1.00: 2.11: 9.00: 16.6.

In Tetrahydrofuran: A mixture of sodium 2-naphtholate (0.92 mmol), benzo-18-crown-6 (0.2 mmol), and 4 ml of THF was stirred for 30 min at 25 °C. Benzyl bromide (1.0 mmol) was added all at once, after which the mixture was stirred for a further 65 h. The work-up and analysis were performed as has been described above. The analysis by GLC revealed the presence of 2-naphthol (25%), benzyl 2-naphthyl ether (65%), 1-benzyl-2-naphthol (1%), and 1,1-dibenzyl-2-naphthalenone (1%).

Reaction of Methyl Iodide with Sodium 2-Naphtholate. In Tetrahydrofuran: A mixture of sodium 2-naphtholate (6.01 mmol), benzo-18-crown-6 (0.32 mmol), and 10 ml of anhydrous THF was stirred for 30 min at 25 °C. Methyl iodide (7.2 mmol) was then added all at once, after which the mixture was stirred for a further 20 h. The resulting mixture was poured into 20 ml of water, acidified with 18% aq hydrochloric acid, and extracted with benzene. The benzene extract was washed with 10% aqueous sodium hydroxide and with water. Analysis by GLC identified the neutral fraction as consisting of methyl 2-naphthyl ether (94%) and methyl 1-methyl-2-naphthyl ether (4%); the relative retention times of these two components were 1.00: 2.26. The alkali and water extracts were combined and acidified with 18% aq hydrochloric acid at 0 °C, and then extracted with benzene. The subsequent analysis of the product by GLC indicated the presence of 2-naphthol (1%) and 1-methyl-2-naphthol (1%), whose retention times were 1.26 times that of 2-naphthol.

In Water: A mixture of sodium 2-naphtholate (6.01 mmol), benzo-18-crown-6 (0.32 mmol), and 10 ml of water was stirred for 30 min at 25 °C. Methyl iodide (7.2 mmol) was then added all at once, after which the mixture was stirred for a further 48 h. The work-up and analysis were performed as has been described above.

The authors wish to express their gratitude to Professor Michinori Ōki, the University of Tokyo, for his valuable discussion and suggestions.

Photolyses of *S,S*-Dimethyl-*N*-(ethoxycarbonyl)sulfimide in Hydrocarbons and in Oxygen Compounds

Noboru TORIMOTO, Tadao SHINGAKI,* and Toshikazu NAGAI*

Science Education Institute of Osaka Prefecture, Karita-cho, Sumiyoshi-ku, Osaka 558

**College of General Education, Osaka University, Toyonaka, Osaka 560*

(Received October 19, 1977)

The behavior of ethoxycarbonylnitrene (**3**), generated photochemically from *S,S*-dimethyl-*N*-(ethoxycarbonyl)-sulfimide (**1**), upon insertion into the C–H bonds and the O–H bonds was compared with that of **3** generated from ethyl azidoformate (**2**). Ethoxycarbonylnitrene generated from **1** was inserted preferentially into the α C–H bonds of cyclic ethers. The relative reactivity toward **3** of the primary, secondary, and tertiary C–H bonds in 2,4-dimethylpentane is in the ratio of 1 : 9 : 35. The insertion of **3** into the tertiary C–H bonds of *cis*- and *trans*-1,4-dimethylcyclohexanes proceeded stereospecifically. The reaction of **3** with alcohols gave the O–H insertion products. These results show that the insertion of **3** generated from **1**, as well as that of the nitrene from **2**, into the hydrocarbon C–H bonds and the O–H bonds proceeds only for the singlet.

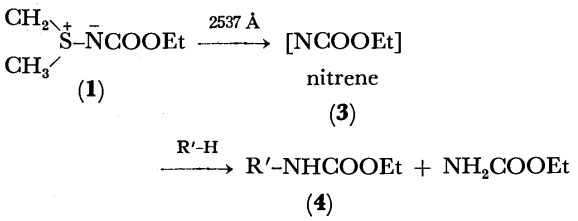
The decomposition of some amidates or sulfimides is known to be a method of generating a nitrene intermediate. For example, *N*-trimethylammoniododecanesulfonamidate was thermolyzed to give a sulfonylnitrene,[1] *S,S*-dimethyl-*N*-benzoylsulfimide was photolyzed to give benzoylnitrene,[2] and *S,S*-dimethyl-*N*-(ethoxycarbonyl)-sulfimide was photolyzed to give ethoxycarbonylnitrene.[3] Ethoxycarbonylnitrene, generated by the photolysis of *S,S*-dimethyl-*N*-(ethoxycarbonyl)sulfimide (**1**),[3] gave a product distribution similar to that resulting photochemically from the azide[4] in the reaction with cyclohexene. On the other hand, the nitrene from **1** was produced largely (more than 50%) in triplet form,[3] although the photodecomposition of the azide showed that one-fourth of the nitrene formed was in the triplet state,[4] in addition to *cis*- and *trans*-4-methyl-2-pentenes. As for C–H insertion, ethoxycarbonylnitrenes, generated by the photochemical[5] and thermal[6] decompositions of ethyl azidoformate or by the α-elimination of *N*-(*p*-nitrophenylsulfonyloxy)urethane,[5] showed nearly the same regioselectivities. It has not been reported, however, whether or not the ethoxycarbonylnitrene generated from the ylide shows, on insertion into C–H bonds, behavior similar to that of the nitrene generated from the other precursors.

In this paper, the regioselectivity and the stereospecificity of **3** derived from the precursors **1** and ethyl azidoformate (**2**) in the insertion into C–H bonds will be described.

Results and Discussion

Photolysis of 1 in Hydrocarbons and in Ethers. A solution of *N*-carbethoxyiminodimethylsulfurane (**1**) in cyclic ether or in a mixture of hydrocarbon and 1,2-dichloroethane was irradiated by the light (mainly 2537 Å) of a low-pressure mercury arc at 0 °C with stirring under an atmosphere of nitrogen. The insertion products (**4**) of **3** into the C–H bonds were obtained, accompanied by an abstraction product, urethane. The yields are listed in Table 1.

The insertion took place preferentially at the C–H bonds of the α-position of the ethers. The preferential formation of the α C–H insertion products in the ethers was also observed in the photolyses of **2**.[7–9] The reaction with 2,4-dimethylpentane gave three isomeric insertion products, resulting from an attack on all the primary (1°), secondary (2°), and tertiary (3°) C–H bonds.



(**1**) (**3**) (**4**)

(R′: hydrocarbon residue or ether residue)

Relative Reactivity. From the yields of the insertion products of **1** with 2,4-dimethylpentane, the relative reactivities of the 1, 2, and 3° C–H bonds toward **3** was calculated to be in the ratio of 1 : 9 : 35. On the other hand, **3**, generated by the photolysis of **2**, reacted with the 1, 2, and 3° C–H bonds of 2-methylbutane in the ratio of 1 : 9 : 34.[4] The values resulting from these two experiments are in remarkably good agreement, though the substrate hydrocarbons employed are not the same.

Stereochemistry. In order to investigate the stereospecificity in the C–H insertion of **3**, generated from **1**, **1** was photolyzed in *cis*- and *trans*-1,4-dimethylcyclohexanes. The results are displayed in Table 2, compared with those of **3** generated from **2**.[10]

The reaction of **3** generated from **1** with either *cis*- or *trans*-1,4-dimethylcyclohexane gave only one tertiary urethane, accompanied by urethane and two kinds of secondary urethanes; the reaction was virtually completely stereospecific. In this respect, it has the same tendency as the reaction of **3** generated from **2**.[10] Therefore, the results show that the ethoxycarbonylnitrene generated from **1** is inserted into the C–H bonds of hydrocarbon only in the singlet state, like the nitrene from the azide.

Dilution Effect. It is well known that, in the nitrene reaction, dilution with such inert solvents as dichloromethane and dibromomethane promotes the singlet-triplet intersystem crossing of nitrenes. For example, cyanonitrene, generated thermally from cyanogen azide, was inserted stereospecifically into the C–H bonds of *cis*- and *trans*-1,2-dimethylcyclohexanes in

the absence of the inert solvents. However, the insertion of the nitrene with the cyclohexanes diluted with the inert solvents proceeded non-stereospecifically, giving a mixture of *cis* and *trans* isomeric products.[11] That is, triplet cyanonitrene, produced from the decay of a singlet, is also inserted into the C–H bonds of hydrocarbons. On the other hand, the insertion of ethoxycarbonylnitrene, generated by the photochemical and the thermal decompositions of the azide or by the α-elimination of *N*-(*p*-nitrophenylsulfonyloxy)urethane, proceeded completely stereospecifically toward the C–H bond of optically active 3-methylhexane diluted with dichloromethane.[12]

As can be seen in Table 2, the insertion of **3** into the tertiary C–H bond proceeded completely stereospecifically, even at about a 5 mol % dilution with 1,2-dichloroethane. Therefore, it may be concluded that the ethoxycarbonylnitrene generated from *S,S*-dimethyl-*N*-(ethoxycarbonyl)sulfimide behaves just like those generated from the other precursors in stereochemistry as well as in the selectivity of the insertion into the C–H bonds of hydrocarbons, and that triplet ethoxycarbonylnitrene, unlike triplet cyanonitrene, can not be inserted into C–H bonds. The difference in behavior between the triplet ethoxycarbonyl and cyano-nitrenes may be explained as follows: the HN̈CN radical, produced through hydrogen abstraction by the triplet nitrene, is much more resonance-stabilized than the HN̈COOEt radical, permitting combination with the radicals derived from substrates.

Table 3. Photolysis of **1** and **2** in alcohols

Alcohol	Product (%)[a]

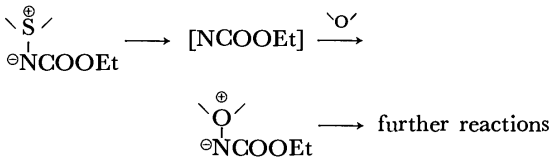
a) b) See Table 1, footnotes. c) ND: not detected.

*Photolysis of **1** in Alcohols.* The behavior toward alcohols of the **3** generated from **1** was similar to that of the **3** derived by the direct photolysis of **2**, although the insertion-abstraction ratio decreased in the present precursor (**1**) compared with that in the **2** precursor, as is shown in Table 3. The photolyses of **1**, as well as the direct photolyses of **2**, gave products for nitrene insertion into the O–H bonds, while the sensitized photolyses gave no such insertion products.[8] The insertion in the direct photolyses has been concluded to proceed *via* the formation of O–N ylide intermediate resulting from the singlet nitrene.[8] Consequently, the O–H insertion in the photolyses of **1** is also thought to involve O–N ylide formation, as is shown in the following scheme:



Scheme 1.

Experimental

The equipment and techniques have been described previously.[7]

Materials. The preparation of *cis*- and *trans*-1,4-dimethylcyclohexanes has been described previously.[13] The *S,S*-dimethyl-*N*-(ethoxycarbonyl)sulfimide (**1**) was prepared by the method of Whitfield *et al.*[14] The tetrahydrofuran, tetrahydropyran, 1,4-dioxane, cyclohexane, 2,4-dimethylpentane, 1,2-dichloroethane, ethanol, 1-propanol, and 1-butanol were used after the commercial reagents had been purified according to the published directions.[16]

Authentic Samples. The preparation of authentic samples of *N*-cyclohexylurethane (**4a**), *N*-(*cis*-1,4-dimethylcyclohexyl)urethane (*cis*-**4**), and *N*-(*trans*-1,4-dimethylcyclohexyl)urethane (*trans*-**4**) has been described previously.[13] The authentic samples of *N*-(1-isopropyl-2-methylpropyl)-urethane (**4b**$_2$) and *N*-(2,4-dimethylpentyl)urethane (**4b**$_3$) were prepared from ethyl chloroformate and the corresponding amines, which was themselves previously been prepared by the method of Breslow.[15] **4b**$_2$: IR (neat, cm^{-1}): 3350 (NH), 1710 (C=O), 1250 (C–O). NMR (CCl_4, τ): 5.42 (NH, 1H, bs), 5.95 (OCH_2, 2H, q), 6.51—7.02 (NCH, 1H, m), 7.93—8.60 (2CH, 2H, m), 8.78 (ester-CH_3, 3H, t), 9.09 ($2CH_3$, 6H, d), 9.14 ($2CH_3$, 6H, d). **4b**$_3$: IR (neat, cm^{-1}): 3350 (NH), 1710 (C=O), 1255 (C–O). NMR (CCl_4, τ): 5.10 (NH, 1H, bs), 6.00 (OCH_2, 2H, q), 6.92—7.27 (NCH_2, 2H, m), 8.04—9.02 (2CH and CH_2, 4H, m), 8.81 (ester-CH_3, 3H, t), 9.13 (CH_3, 3H, d), 9.16 ($2CH_3$, 6H, d).

*Photolyses of **1** in Hydrocarbons and in Ethers.* A solution of **1** (450 mg, 3 mmol) in ethre (0.6 mol) or in a mixture of hydrocarbon (0.4 mol) and 1,2-dichloroethane (19.8 g, 0.2 mol) was irradiated by the light (mainly 2537 Å) of a low-pressure mercury arc at 0 °C with stirring under an atmosphere of nitrogen untill the NMR signal at τ 7.30 due to the *gem*-dimethyl group of **1** has disappeared. Then, the excess substrate was evaporated under reduced pressure and the residue was analyzed by VPC.

In Hydrocarbons: In cyclohexane, **4a** (95 mg) was isolated. In 2,4-dimethylpentane, *N*-(1,1,3-trimethylbutyl)urethane (**4b**$_1$, 79 mg), **4b**$_2$ (20 mg), and **4b**$_3$ (13 mg) were isolated. **4b**$_1$: IR (neat, cm^{-1}): 3350 (NH), 1710 (C=O), 1260 (C–O). NMR (CCl_4, τ): 5.49 (NH, 1H, bs), 6.05 (OCH_2, 2H, q), 8.02—8.60 (CH and CH_2, 3H, m), 8.77 ($2CH_3$, 6H, s), 8.83 (ester-CH_3, 3H, t), 9.10 ($2CH_3$, 6H, d). Found: C, 63.98; H, 11.26; N, 7.35%. Calcd for $C_{10}H_{21}O_2N$: C, 64.13; H, 11.30; N, 7.48%. The IR and the NMR spectral data and VPC retention times of **4a**, **4b**$_2$, and **4b**$_3$ were identical with those of the authentic samples. In *cis*-1,4-dimethylcyclohexane, *cis*-**4** (50 mg) and a mixture of two kinds of secondary urethanes (*cis*-**5**, 52 mg) were isolated. The mixture of the secondary urethanes did not separate into two parts on the columns employed. The IR and the NMR spectral data and the VPC retention time of *cis*-**4** were identical with those of the authentic sample. *N*-(*cis*-2,5-Dimethylcyclohexyl)urethane (*cis*-**5**, a mixture of the isomers): IR (neat, cm^{-1}): 3320 (NH), 1700 (C=O), 1240 (C–O). NMR (CCl_4, τ): 5.2 (NH), 5.76 (OCH_2), 7.50—9.23 (ring-CH and

CH_2, ring-side CH_3, ester-CH_3). Found: C, 65.99; H, 10.48; N, 6.98%. Calcd for $C_{11}H_{21}O_2N$: C, 66.29; H, 10.62; N, 7.03%. In *trans*-1,4-dimethylcyclohexane, *trans*-**4** (66 mg) and two kinds of secondary urethane (*trans*-$\mathbf{5}_1$ and *trans*-$\mathbf{5}_2$, 70 mg), which were subsequently cleanly separated into individual isomers by VPC, were isolated. The analytical data of *trans*-**4** were identical with those of the authentic sample. One isomer of *N*-(*trans*-2,5-dimethylcyclohexyl)urethanes (*trans*-$\mathbf{5}_1$): IR (neat, cm^{-1}): 3350 (NH), 1700 (C=O), 1240 (C–O). NMR (CCl_4, τ): 5.22 (NH, 1H, bs), 5.86 (OCH_2, 2H, q), 7.93—9.30 (ring-CH and CH_2, 9H, m), 8.73 (ester-CH_3, 3H, t), 9.07 ($2CH_3$, 6H, d). Found: C, 66.11; H, 10.49; N, 7.10%. The other (*trans*-$\mathbf{5}_2$): IR (neat, cm^{-1}): 3320 (NH), 1690 (C=O), 1270 (C–O). NMR (CCl_4, τ): 5.20 (NH, 1H, bs), 5.86 (OCH_2, 2H, q), 7.60—9.36 (ring-CH and CH_2, 9H, m), 8.74 (ester-CH_3, 3H, t), 9.05 ($2CH_3$, 6H, d). Found: C, 66.41; H, 10.58; N, 6.09%.

In Ethers: In tetrahydrofuran, tetrahydropyran, and 1,4-dioxane, *N*-(2-tetrahydrofuryl)urethane (**4c**, 113 mg), *N*-(2-tetrahydropyranyl)urethane (**4d**, 104 mg), and *N*-(1,4-dioxan-2-yl)urethane (**4e**, 126 mg) were isolated respectively. The IR and the NMR spectral data of **4c**, **4d**, and **4e** have been given in previous papers.[7,8]

In cis-*1,4-Dimethylcyclohexane Diluted with Dichloroethane*: The reaction of **1** (450 mg, 3 mmol) in a solation of *cis*-1, 4-dimethylcyclohexane (14 g, 0.12 mol) and 1,2-dichloroethane (48 g, 0.48 mol) gave 31 mg of *cis*-**4** and 30 mg of *cis*-**5**. When a solution of 0.03 mol of *cis*-1,4-dimethylcyclohexane and 0.6 mol of 1,2-dichlroethane were used, the reaction gave 23 mg of *cis*-**4** and 29 mg of *cis*-**5**.

Photolyses of **1** *in Alcohols*. A solution of **1** (3 mmol) in alcohol (0.6 mol) was irradiated by the light (mainly 2537 Å) of a low-pressure mercury arc at 0 °C with stirring in an atmosphere of nitrogen. The reaction mixture was treated by the procedures described for the reaction in hydrocarbons and in ethers.

In ethanol, 1-propanol, and 1-butanol, *N*-ethoxyurethane (36 mg), *N*-propoxyurethane (48 mg), and *N*-butoxyurethane (30 mg) were isolated respectively. The IR and the NMR spectral data and elemental analyses of these products have been given in a previous paper.[8]

The authors are particulary indebted to Dr. Hisao Arakawa and Dr. Akira Matsumoto of the Science Education Institute of Osaka Prefecture for help in the peparation of this paper and for many useful suggestions.

The Benzannelated Annulenones. Syntheses and Properties of 10-Methylbenzo[*d*]-6,8-bisdehydro[15]annulenone and 12-Methylbenzo[*f*]-8,10-bisdehydro[15]annulenone

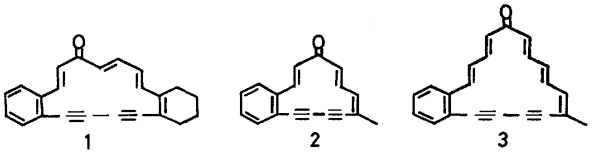
Jūro Ojima* and Yūji Shiroishi

Department of Chemistry, Faculty of Science, Toyama University, Gofuku, Toyama 930

(Received October 20, 1977)

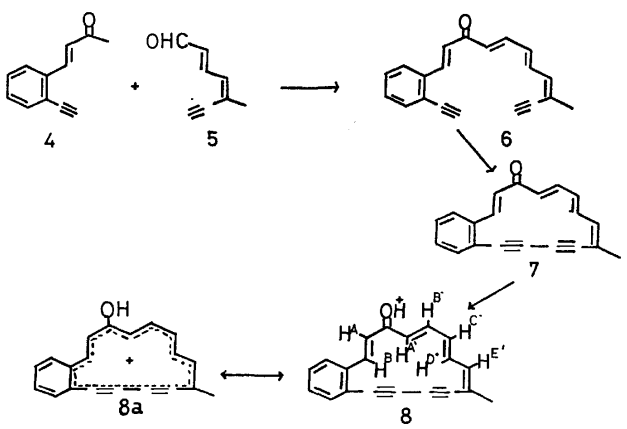
Synthesis of two methylated monobenzannelated bisdehydro[15]annulenones is described. It was found by means of ^{1}H-NMR spectra that the protonated annulenones are diatropic.

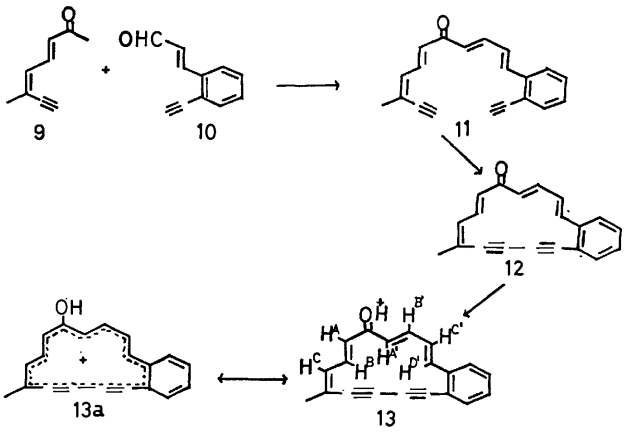
The effect of benzannelation on a conformationally fixed, potentially diatropic bisdehydro[15]annulenone was studied for compounds fused by cyclohexene and benzene rings by Weavers *et al.*[1] It was shown that the monobenzannelated annulenone **1** is atropic, protonated **1** showing diatropic nature. On the other hand, we have shown that the monobenzannelated bisdehydro[13] **2** and [17]annulenone **3** are paratropic themselves.[2] It was therefore decided to prepare the methylated monobenzobisdehydro[15]annulenones **7** and **12**, as well as



the respective protonated species **8** and **13**. As reported by Sondheimer *et al.*, the methyl substituent should be more desirable as compared with cyclohexene moiety for the study of ring current effects.[3] Information on the conjugative effects between the annulenone ring and the benzene nucleus can be obtained from these isomeric compounds, since **7** and **12** have similar geometry and planarity. The present paper deals with the synthesis and properties of two monobenzobisdehydro[15]annulenones, *viz.*, 10-methylbenzo[*d*]-6,8-bisdehydro[15]annulenone **7** and 12-methylbenzo[*f*]-8,10-bisdehydro[15]annulenone **12**.

Synthesis. Aldol condensation of the ketone **4**[4] and the dienyne aldehyde **5**[2c] by means of methanolic potassium hydroxide gave the acyclic ketone **6** in 49% yield. Oxidative coupling of **6**, under Eglinton's conditions using copper(II) acetate monohydrate in pyridine,[5] afforded the desired annulenone **7** as yellow crystals in 31% yield. The condensation of the dienyne ketone **9**[6] and the aldehyde **10**,[7] under the same conditions gave acyclic ketone **11** in 68% yield. Oxidation of **11** with copper(II) acetate monohydrate as before gave the annulenone **12** as yellow crystals in 27% yield. Treatment of **7** or **12** with trifluoroacetic acid gave the corresponding protonated species, **8** (purple; λ_{max} 272 sh, 332 sh, 367, 468 sh, 498, 559 sh, 599 nm) or **13** (red purple; λ_{max} 271, 346, 368 sh, 507 sh, 539 nm), respectively. Quenching of **8** and **13** with aqueous sodium hydrogencarbonate resulted in regeneration of **7** and **12**, respectively.





Properties. Electronic absorption maxima of **7** and **12** are given in Table 1. Little difference in these spectra seems to suggest that a difference in the annelated-position of benzene gives no essential change on the conjugative effects between the benzene nucleus and bisdehydro[15]annulenone skeleton. The NMR spectra indicate that both **7** and **12** are atropic, since not much shifts were observed for the resonances of the olefinic protons of **7** and **12** except for the slightly low field shift of methyl protons, as compared with those of the corresponding acyclic ketone **6** and **11**, respectively(see Experimental). The NMR data of the protonated

a), b), c) These are tentative assignments and may be reversed in each group, but most probable values are given in Table 2 referring to the chemical shifts of the related compounds.[1]

monobenzobisdehydro[15]annulenones **8** and **13** (in CF_3COOD) are given in Table 2. Compounds **8** and **13** are diatropic, as indicated by the relative chemical shifts of the inner and outer protons, as well as the low field methyl resonances. We expected that annulenones **7** and **12** would also exhibit the diatropic nature corresponding to the paratropic [13] **2** and [17]annulenone **3**. However, it was found that the protonated species **8** and **13** are diatropic and can be represented by delocalized formulae **8a** and **13a**, respectively. This result is in line with that obtained by Weavers *et al.*[1]

Experimental

Freshly deoxygenated ether and 20% methanolic potassium hydroxide solutions were prepared and used as reported previously.[2b,c] All melting points are uncorrected. Brockmann alumina (Act. II—III) was used for column chromatography. The ^{1}H-NMR, IR, UV, and mass spectra were taken with the instruments Varian EM-930 or Varian XL-100, Hitachi EPI-S2, Hitachi-124, and JEOL-MS-OI-SG-2, respectively. Shoulders in UV spectra are denoted by sh. Wavelength of absorption maximum is recorded in nm and ε-values are given in parentheses. Chemical shifts are given in τ-values with respect to TMS as an internal standard, while the coupling constants (J) are given in Hz.

1-(o-Ethynylphenyl)-9-methyl-1,4,6,8-undecatetraen-10-yn-3-one **6**. To a mixture of the dienyne aldehyde (**5**, 1.00 g, 8.32 mmol) and the ketone (**4**, 1.84 g, 10.8 mmol) in ether (35 ml) was added a 20% methanolic potassium hydroxide solution (3.3 ml) with stirring at −5—0 °C. The mixture was then stirred for 3.5 h at the same temperature under nitrogen atmosphere. Neutralization with acetic acid (4 ml) followed by pouring into water (100 ml) and extraction with benzene gave an organic extract which was worked up as usual. The residue obtained by evaporation of the solvent was chromatographed on alumina (150 g) with light petroleum ether −ethyl ether (20: 80) to give the ketone (**6**, 1.12 g, 49%) as yellow needles from benzene-hexane, mp *ca.* 75 °C (dec), MS: *m/e* 272 (M^+, 100); mol wt, 272.3; IR (KBr disk): 3270, 3240 (−C≡CH), 2100 (−C≡C−), 1670, 1625, 1600 (C=O, C=C), 1005 cm^{-1} (*trans* C=C); UV (ether): λ_{max} 227 (17100), 250 sh (13800), 255 (14400), 277 (10400), 292 (11100), 356 nm (30800); NMR (90 MHz, $CDCl_3$): 1.97 (d, 16, 1H, olefinic H), 2.30—3.80 (m, 10H, olefinic and benzenoid H), 6.53 (s, 2H, −C≡CH), 8.05 (s, 3H, $-CH_3$). Found: C, 88.34; H, 6.00%. Calcd for $C_{20}H_{16}O$: C, 88.20; H, 5.92%.

10-Methylbenzo[d]-*6,8-bisdehydro*[*15*]*annulenone* **7**. A solution of **6** (600 mg, 2.20 mmol) in pyridine (46 ml) was added with stirring over a period of 15 min to a solution of copper(II) acetate monohydrate (9.1 g) in pyridine (30 ml) at 50 °C; the mixture was stirred for 3 h at 63 °C. The mixture was then chilled, diluted with benzene (100 ml), and filtered through Hyflo Super-Cel. The precipitates formed were washed with benzene (100 ml×4). The filtrate was washed with dilute hydrochloric acid until it turned slightly acidic. It was then worked up in the usual way. The residual red liquid, after solvent removal, was chromatographed on alumina (150 g) with light petroleum ether-ethyl ether (80: 20—35: 65) to give **7** (185 mg, 31%). Recrystallization from benzene gave yellow needles, mp *ca.* 140 °C (dec); MS: *m/e* 270 (M^+, 45), 269 (100); mol wt, 270.3; IR (KBr disk): 2150 (−C≡C−), 1650, 1620, 1600 (C=O, C=C), 970 cm^{-1} (*trans* C=C); NMR (100 MHz, $CDCl_3$): 1.98—2.05 (m, 1H, benzenoid H), 2.65—3.54 (m, 10H, olefinic and benzenoid H), 7.90 (s, 3H, $-CH_3$); UV: see Table 1. Found: C, 88.59; H, 4.96%. Calcd for $C_{20}H_{14}O$: C, 88.86; H, 5.22%.

1-(o-Ethynylphenyl)-9-methyl-1,3,6,8-undecatetraen-10-yn-5-one **11**. A mixture of ketone (**9**, 0.98 g, 7.30 mmol) and aldehyde (**10**, 1.65 g, 10.6 mmol) in ether (30 ml) was treated with a 20% methanolic potassium hydroxide (3 ml) under nitrogen atmosphere at 0 °C, and stirred at −8—−4°C for 4 h. After addition of acetic acid (4 ml), the mixture was worked up as in the preparation of **6**, giving a red liquid. Chromatography of the liquid over alumina (180 g) with light petroleum ether–ethyl ether (75: 25—70: 30) gave the desired ketone (**11**, 1.35 g, 68%) as a partly crystalline, orange liquid, which formed yellow needles from hexane–benzene, mp 97.0—98.6 °C; MS: *m/e* 272 (M^+, 100); mol wt, 272.3; IR (KBr disk): 3300, 3250 (−C≡CH), 2100 (−C≡C−), 1660, 1600 (C=O, C=C), 1000 cm^{-1} (*trans* C=C); UV (ether): λ_{max} 228 sh (17300), 233 (17500), 255 (16300), 263 sh (15400), 295 sh (11200), 352 nm (33000); NMR (100 MHz, $CDCl_3$): 2.14—3.61 (m, 11H, olefinic and benzenoid H), 6.45 (s, 1H, −C≡CH), 6.60 (s, 1H, −C≡CH), 7.95 (s, 3H, $-CH_3$). Found: C, 87.94; H, 5.91%. Calcd for $C_{20}H_{16}O$: C, 88.20; H, 5.92%.

12-Methylbenzo[f]-*8,10-bisdehydro*[*15*]*annulenone* **12**. A solution of **11** (1.34 g, 4.92 mmol) in pyridine (50 ml) was added dropwise to a stirred solution of copper(II) acetate monohydrate (20.3 g) in pyridine (68 ml) for 15 min at 50 °C, and the reaction mixture was stirred for 3 h at 63 °C. The mixture was then worked up as in the preparation of **7**, affording a dark red liquid. The liquid was chromatographed on alumina (180 g) and annulenone (**12**, 359 mg, 27%) was eluted with light petroleum ether–ethyl ether (40: 60—30: 70). Recrystallization from benzene-hexane gave yellow needles, mp 176 °C (dec); MS: *m/e* 270 (M^+, 70), 241 (100); mol wt, 270.3; IR (KBr disk): 2150 (−C≡C−), 1645, 1615, 1600 (C=O, C=C), 985 cm^{-1} (*trans* C=C); NMR (100 MHz, $CDCl_3$): 2.12—2.23 (m, 1H, benzenoid H), 2.36—3.64 (m, 10H, olefinic and benzenoid H), 7.87 (s, 3H, $-CH_3$); UV: see Table 1. Found: C, 88.89; H, 5.09%. Calcd for $C_{20}H_{14}O$: C, 88.86; H, 5.22%.

The authors wish to thank Drs. S. Akiyama and F. Ogura, and Prof. M. Nakagawa, Osaka University, for the measurement of the NMR spectra at 100 MHz. One of the authors (J. O.) is grateful to the Ministry

of Education for financial support of this investigation through a Grant-in-Aid (054103, 1975) for Scientific Research.

Synthesis of 2,3 : 7,8-Bis(polymethylene)-4*H*,9*H*-benzo[1,2-*b* : 4,5-*b*']dipyrans and Their Oxidation to the Corresponding Benzodilactones[1)]

Jaswant Rai MAHAJAN and Maria Beatriz MONTEIRO

Departamento de Química, Universidade de Brasília, 70.000, Brasília, DF, Brasil

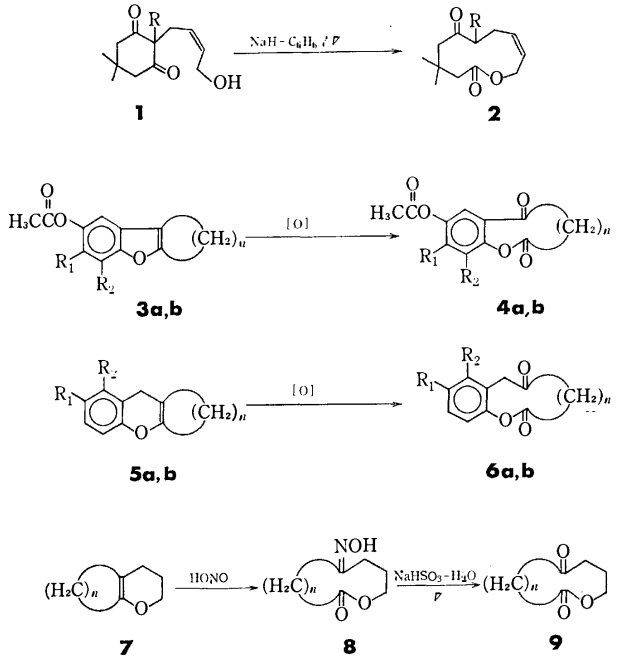
(Received June 27, 1977)

Four members of a new series of the title benzodipyrans have been synthesized through the alkylation of the pyrolidine-enamines of 6,7,8- and 12-membered cycloalkanones with 2,5-bis(dimethylaminomethyl)hydroquinone, followed by hydrolysis and subsequent cyclization of the intermediate products. Oxidation of these benzodipyrans with *m*-chloroperbenzoic acid (MCPBA) afforded the corresponding benzodilactones in 10—65% yield, the rest of the material being a mixture of hydroxylated carbonyl compounds.

We have recently reported the synthesis of several medium ring and macrocyclic keto lactones (**2, 4, 6, 9**) by the intramolecular reverse Dieckmann reaction of 2,2-dialkyl-5,5-dimethyl-1,3-cyclohexanediones (**1**) as well as by various oxidative procedures, as shown in Chart 1.[2)] Although these synthetic keto lactones have only a distant resemblance with the natural antibiotic macrolides,[3)] yet it is noteworthy that a majority of these compounds as well as some of the synthetic intermediates have shown *in vitro* biological activity against one or the other of the following microorganisms: *Staphylococcus aureus*, *Escherichia coli*, *Bacillus megatherium*, *Candida albicans*, and *Leptomonas pessoai*.[4)] These promising bioassays encouraged us to explore the synthesis of symmetrical benzodilactones (**16**) from the title compounds (**15**), by procedures successfully developed in the case of benzo- and naphtho-fused keto lactones **6**.[2c)] We now report the results of this investigation.

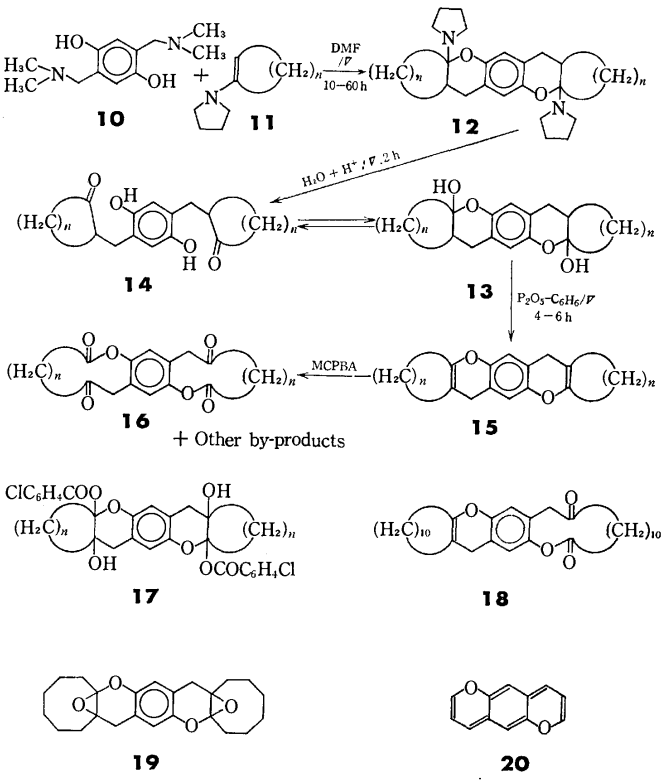
As the literature search in the ring index[5)] and chemical abstracts revealed that 4*H*,9*H*-benzo[1,2-*b*: 4,5-*b*']dipyran as well as its derivatives have not been described, we patterned the synthesis of the title compounds **15** after a successful route developed in the case of benzo- and naphthopyrans (**5a,b**), through the enamine alkylation of the Mannich bases derived from phenol and 2-naphthol.[2c,6a)] In contrast to the use of mono *o*-phenolic Mannich bases for the above purpose, there is no mention of the use of *bis* Mannich bases, derived from dihydric phenols, for the preparation of the corresponding dipyrans.[6)] We hereby describe that 2,5-bis(dimethylaminomethyl)hydroquinone[7)] (**10**) can be successfully employed for the synthesis of the title compounds **15**, as shown in Chart 2.

Although condensation between the Mannich base **10** and the enamine (**11**; n=4) could not be carried out in dioxane, according to the original method of Von Strandtmann,[6a)] the desired reaction could be successfully conducted in *N*,*N*-dimethylformamide (DMF).[2c)] The duration of reaction as well as its temperature had to be carefully controlled to obtain optimal results for



a: R_1=R_2=H, b: R_1=R_2=$(CH=CH)_2$,; n=4,5,6,10

Chart 1.



n=4,5,6,10

Chart 2.

each enamine. In most of the cases, the intermediate amino compound (**12**) was not isolated and was hydrolyzed *in situ* at the end of first step. However, in the case of enamine derived from cyclododecanone (**11**; $n=10$), the intermediate adduct (**12**; $n=10$) precipitated from the reaction mixture and was obtained as a coarse powder in 57% yield. Its hydrolysis in a two phase system containing benzene, water, and acetic acid, furnished the product (**14**; $n=10$) in 95% yield. On the other hand, the same product (**14**; $n=10$) could be obtained, in a slightly lower yield of an inferior quality, by direct hydrolysis of the reaction mixture.

Attempted extension of the present condensation to enamine derived from acetophenone[8] resulted in an intractable mixture of products.

One would expect an equilibrium between the cyclic form (**13**) and the acyclic form **14**. Moreover, the former could form diastereoisomers. In fact, only one of these compounds was present, in the solid state, entirely in the cyclic form (**13**; $n=4$), as evidenced by the absence of carbonyl absorption in its infrared spectrum, while the rest of the compounds ($n=5$, 6, 10) showed strong absorptions both in the OH and CO regions. The carbonyl absorption in these compounds (1681—1695 cm^{-1}) is shifted to lower wave numbers due to hydrogen bonding.[9] Attempted dehydration of these compounds in refluxing dioxane, containing catalytic amount of *p*-toluenesulfonic acid or phosphorus pentaoxide, proceeded in poor yield and was unsatisfactory. However, dehydration in benzene employing 2 molar equivalent of phosphorus pentaoxide furnished the desired benzodipyrans (**15**; $n=4$—6, 10) in 60—90% yield. The characteristic infrared absorption of these compounds (1692—1706 cm^{-1}) is in agreement with that observed in the corresponding benzopyran series.[2c]

One particular difficulty encountered in the present work was the poor solubility of most of the compounds described here, in the common organic solvents. Moreover, these compounds, especially the benzodipyrans **15**, suffer autoxidation while in solution. Therefore, crystallization of **14** and **15** was carried out in solutions containing catalytic amount of hydroquinone. Even so, mother liquors of benzodipyran (**15**; $n=10$) afforded, after silica gel column chromatography, a small quantity of a pure product which was characterized as keto lactone **18**, on the bases of its infrared (1751, 1712, 1695 cm^{-1}), and mass spectra. Similar autoxidations have already been observed in the benzo- and naphthopyran **5a,b** series.[2c]

As *m*-chloroperbenzoic acid (MCPBA) had proved to be the best reagent for the preparation of keto lactones **6a,b** from the corresponding benzo- and naphthopyrans **5a,b**[2c] the same reagent was used, with moderate success, in the present series. However, as the benzodipyrans **15** have two sites of reaction, the half oxidized and several other expected by-products, such as hydroxy ester (**17**), the corresponding tetrol, and combinations thereof become possible.[10] This made the isolation and purification of the desired products rather difficult in the present work. Under careful conditions, the desired dilactones **16** were obtained in 10—65% yields; the rest of the material being a mixture of products, showing both hydroxyl and carbonyl absorptions in the infrared spectrum.

Mechanistic considerations on the oxidation of cyclic enol ethers by MCPBA suggest that for optimal results, competitive reactions of the intermediate epoxide with *m*-chlorobenzoic acid and water be avoided.[10] Borowitz has attained this objective by employing 50% excess of the peracid in a limited volume of the solvent (CH_2Cl_2), the *m*-chlorobenzoic acid precipitates out of the reaction mixture as formed, because it is much less soluble than the corresponding peracid.[10] In an attempt to improve the present procedure, we treated benzodipyran (**15**; $n=6$) with MCPBA in the presence of potassium carbonate[11] and obtained the corresponding diastereoisomeric bis-epoxides (**19**; TLC, IR, NMR) as the exclusive products ($\approx$100%). Attempted posterior cleavage of this epoxide with MCPBA[10] or periodic acid in tetrahydrofuran[12] resulted in a complex mixture of products from which the isolation of the desired keto lactone appeared difficult (TLC).

Similarly, while the dipyran (**15**; $n=10$) was recovered unchanged from an attempted oxidation with potassium permanganate in acetone at room temperature, it gave complex mixture of products when ozonolyzed[2b,c] or oxidized with ruthenium tetraoxide ($RuCl_3$–$NaIO_4$) in dichloromethane–water.[13]

Due to poor solubility in most of the organic solvents, we could not obtain the NMR spectra of benzodilactones **16**. However, these products have been fully characterized by their elemental analysis, infrared and mass spectra. The molecular and fragmentation ions of these compounds are in accord with their structure, but the details of mass spectral studies will be reported elsewhere, along with other related series.

Experimental

Melting points (°C) are uncorrected and were determined on a Kofler block or, when mentioned, in capillary tube sealed under reduced pressure. The latter mps are sharper and more reproducible. The infrared (IR) spectra were taken as KBr discs on a Perkin Elmer 137 instrument and the absorption maxima (ν_{max}) are reported in wave numbers (cm^{-1}). ^1H NMR spectra were recorded on a Varian A60-D (60 MC) spectrometer and the reported values (δ ppm) are relative to internal TMS. As usual, s=singlet, m=multiplet, *etc.* The mass spectra were obtained on a Varian CH-7-spectrometer and the details will be published elsewhere; only the molecular ions (M^+) are reported here.

Progress of reaction was followed by thin layer chromatography (TLC) on silica gel G plates run in benzene, containing 5—10% ethanol. 2,5-Bis(dimethylaminomethyl)hydroquinone was prepared according to the procedure described by Caldwell and Thompson.[7] Enamines of cycloalkanones were prepared by the azeotropic method described by Stork *et al.* and in other literature references.[14] Nomenclature and numbering of the heterocyclic compounds is based on that described for the benzo[1,2-*b*: 4,5-*b'*]dipyran (**20**) in the Ring Index[5] and the Chemical Abstracts.[15]

*Condensation of 2,5-Bis(dimethylaminomethyl)hydroquinone (**10**) with Enamines (**11**; n=4,5,6,10).* General Procedure: A solution of the Mannich base (**10**; 10 mmol) and the desired

enamine (20 mmol) in *N,N*-dimethylformamide (40 ml) was heated in an oil bath (130—140 °C) during 10—60 h, while a slow stream of nitrogen was bubbled through the reaction mixture. At the end of the reaction, when the evolution of dimethylamine became neglegible, hot water (20 ml) was added, pH of the medium adjusted to 5—6 with 1 M hydrochloric acid and the heating continued another 1—2 h. The cooled reaction mixture was elaborated as described under individual compound.

*2,7-Dihydroxy-3,4,8,9-tetrahydro-2,3 : 7,8-bis(tetramethylene)-2*H,7H-*benzo*[*1,2*-b: *4,5*-b']*dipyran* (**13**: n=*4*). The reaction between the Mannich base (**10**) and enamine (**11**; *n*=4) was complete in 10—12 h. The final product precipitated from the reaction mixture during the hydrolysis step and was filtered off. It was sparingly soluble in the common organic solvents: methanol, ethanol, 1-propanol, acetone, ethyl acetate, chloroform, carbon tetrachloride, benzene, ether, tetrahydrofuran, dioxane, glyme, *etc.* It was purified by refluxing in benzene–ethanol and filtering hot to obtain a faintly yellow powdery solid (80% yield), mp 221—223 °C (dec); ν_{max} 3436 and small absorption at 1672. Analytical sample was prepared by dissolving a small quantity in a large excess of hot 1,2-dichloroethane–ethanol and filtering hot. The filtrate was concentrated on a rotary evaporator till turbidity appeared, when it was allowed to crystallize affording white fine crystals, mp 232—234 °C (dec), with softening ≈226 °C; ν_{max} 3448; no absorption in the CO region. TLC of this compound (one spot only) revealed it to be most probably a single diastereomer. Found: C, 72.53; H, 8.08%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%.

2,5-Bis[*(2-oxocycloheptyl)methyl*]*hydroquinone* (**14**; n=*5*). Enamine (**11**; *n*=5) and the Mannich base (**10**) were allowed to react for 30 h. After hydrolysis, the cooled reaction mixture was extracted with chloroform and work-up as usual to obtain a solid (60%), which was crystallized from 1,2-dichloroethane–ethanol yielding shiny plates, mp 232—235 °C (dec); ν_{max} 3448, 1686. Found: C, 73.63; H, 8.43%. Calcd for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44%.

2,5-Bis[*(2-oxocyclooctyl)methyl*]*hydroquinone* (**14**; n=*6*), was obtained in a manner just described above. Crystallization from benzene–ethanol afforded the pure product (47%) as fine white crystals, mp 228—230 °C (dec); ν_{max} 3436, 1681. Found: C, 74.46; H, 8.92%. Calcd for $C_{24}H_{34}O_4$: C, 74.58; H, 8.87%.

2,5-Bis[*(2-oxocyclododecyl)methyl*]*hydroquinone* (**14**; n=*10*), separated as an oily-solid from the reaction mixture. The supernatant was decanted and the product washed with water, followed by petroleum ether (40—60 °C). The residue was dissolved in benzene and treated with petroleum ether (40—60 °C) to afford a fine crystalline solid (50%). Further purification in the same solvent system furnished fine white crystals, mp 206—209 °C (dec); ν_{max} 3509, 1695. Found: C, 76.95; H, 10.09%. Calcd for $C_{32}H_{50}O_4$: C, 77.06; H, 10.10%.

*2,7-Di(1-pyrrolidinyl)-3,4,8,9-tetrahydro-2,3:7,8-bis(decamethylene)-2*H,7H-*benzo*[*1,2*-b: *4,5*-b']*dipyran* (**12**; n=*10*). After ≈12 h of reaction between the Mannich base (**10**) and the enamine (**11**; *n*=10), a solid began to separate. At the end of reaction (60 h), the hydrolysis step was omitted. The reaction mixture was cooled, filtered and the product washed with benzene. On refluxing in a mixture of benzene–ethanol and filtering hot, the pure amino-adduct (**12**; *n*=10) was obtained as a coarse powder (57%), mp 200—206 °C (dec); ν_{max} 2959, 1497, 1458. This product (1 mmol) was refluxed (N_2) in a mixture of water (10 ml), acetic acid (2 ml) and benzene (20 ml), containing catalytic amount of hydroquinone. After ≈2 h, a solid began to float in the benzene layer. After a reflux of 6 h, the reaction mixture was cooled, the product filtered and washed successively with water and ethanol. The dry product (95%), mp 206—209 °C (dec) had infrared spectrum identical with the product (**14**; *n*=10) described above.

*Preparation of 2,3: 7,8-Bis(polymethylene)-4*H,9H-*benzo*[*1,2*-b: *4,5*-b']*dipyranes* (**15**; n=*4,5,6,10*). A suspension of diol **13** (*n*=4) (10 mmol) or a solution of the hydroxy ketones **14** (*n*=5,6,10) (10 mmol) in benzene (300—600 ml), containing phosphorus pentaoxide (20 mmol) and hydroquinone (50 mg), was refluxed (N_2) 2—6 h, till there was no more of the starting material (TLC). The cooled reaction mixture was decanted and allowed to stand over sodium carbonate decahydrate for 1 h, when the solvent was evaporated to obtain the desired product: **15** (*n*=4) was crystallized from benzene–ethanol to obtain faintly yellow, shiny plates (63%), mp 205—207 °C (dec); ν_{max} 1706; δ (CS_2) 1.5—2.4 (m, $8CH_2$), 3.1 (s, benzylic $2CH_2$), 6.3 (s, 2H aromatic). Found: C, 81.73; H, 7.54%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%.

15 (*n*=5) was obtained as yellowish shinyl plates (85%) from the same solvent system, mp 212—217 °C (dec); 234—235 °C (dec) in a sealed capillary tube; ν_{max} 1704. Due to its sparing solubility in $CHCl_3$, CCl_4, CS_2, and acetone, it was not possible to obtain its NMR spectrum. Found: C, 82.14; H, 7.88%. Calcd for $C_{22}H_{26}O_2$: C, 81.95; H, 8.13%.

15 (*n*=6) was also crystallized from the same solvents affording (61%) faintly yellow needles, mp 172—180 °C (dec); 188—190 °C in a sealed capillary tube; ν_{max} 1701; δ (CS_2) 1.4—1.8 (m, $8CH_2$), 1.9—2.4 (m, allylic $4CH_2$), 3.2 (s, benzylic $2CH_2$), 6.3 (s, 2H aromatic). Found: C, 82.45; H, 8.67%. Calcd for $C_{24}H_{30}O_2$: C, 82.24; H, 8.63%.

15 (*n*=10) was crystallized from chloroform to furnish (90%) shinyl cottony needles, mp 180—195 °C (dec); 212—213 °C in a sealed capillary tube; ν_{max} 1692; δ (CS_2) 1.2—1.8 (m, $16CH_2$), 1.9—2.4 (m, allylic $4CH_2$), 3.2 (s, benzylic $2CH_2$), 6.3 (s, 2H aromatic). Found: C, 83.04; H, 10.06%. Calcd for $C_{32}H_{46}O_2$: C, 83.06; H, 10.02%.

The hydroquinone derivatives **14** and the benzodipyranes **15** undergo autoxidation during prolonged heating while in solution. Consequently, these compounds were recrystallized as quickly as possible and in solutions containing catalytic amount of hydroquinone. Even so an oxidized product was isolated from the mother liquors of benzodipyran **15** (*n*=10), as described below.

Isolation of Benzopyran Lactone (**18**). Mother liquors of benzodipyran **15** (*n*=10) (1.3 g) were chromatographed on a silica gel (Merck; 80 g) column, eluted with benzene containing successively increasing amount (0—3%) of ethanol. 25 fractions of 20 ml were collected and fractions 10—15 combined on the basis of TLC examination. Recrystallization from absolute ethanol gave off-white, fluffy solid (≈15 mg), mp 158—160 °C; ν_{max} 1751, 1712, 1695; *m/e* 494 (M^+).

Oxidation of Benzodipyrans (**15**) *to Benzodilactones* (**16**). To obtain consistent results, the *m*-chloroperbenzoic acid (MCPBA) bought from the Aldrich Chemical Company (85%) was dried over $CaCl_2$, under reduced pressure, while the peracid bought from BDH was used without any further treatment. The following oxidation procedure is illustrative for the series.

Dilactone **16** (n=*4*): The solid benzodipyran (**15**; *n*=4; 147 mg, 0.5 mmol) was added, in small portions during 15—20 min, to a stirred solution of MCPBA (3 mmol, 0.52 g) in dichloromethane (6 ml), kept around 15—20 °C by a cold water bath and protected by a drying tube. Soon a white solid began to separate and stirring was continued till (1 h) all the starting material had been consumed (TLC). The reaction mixture was filtered and the solids washed with

carbon tetrachloride. The filtrate was evaporated to dryness and triturated with absolute ethanol to dissolve the soluble products, leaving an insoluble portion (96 mg). Similar treatment of the filter-cake gave 20 mg of an insoluble product. Both these insoluble residues were combined (116 mg) on the bases of their IR spectra, TLC, and mp 215—220 °C (dec). This product was sparingly soluble in common organic solvents. It was purified by a short reflux in a mixture of 1,2-dichloroethane–ethanol and filtering while hot, affording shiny plates (96 mg; 54%), mp 218—221 °C (dec). An analytical sample was prepared by recrystallization of a small portion from a large excess of the same solvent mixture, yielding thin plates, mp 224—231 °C (dec); 191—194 °C (dec) in a sealed capillary tube; ν_{max} ≈3448 (overtones), 1754, 1706; *m/e* 358 (M^+). Found: C, 66.89; H, 6.15%. Calcd for $C_{20}H_{22}O_6$ (358): C, 67.02; H, 6.19%.

Dilactone ***16*** *(n=5)*, was obtained in a similar manner to afford white needles (60%), mp 251—254 °C (dec), with softening ≈247 °C; ν_{max} ≈3472 (overtones), 1738, 1706; *m/e* 386 (M^+). Found: C, 68.14; H, 6.68%. Calcd for $C_{22}H_{26}O_6$ (386): C, 68.38; H, 6.78%.

Dilactone ***16*** *(n=6)*, was obtained as shiny white needles (65%), mp 260—261 °C (dec), with softening ≈233 °C; ν_{max} ≈3472 (overtones), 1745, 1709; *m/e* 414 (M^+). Found: C, 69.37; H, 7.32%. Calcd for $C_{24}H_{30}O_6$ (414): C, 69.55; H, 7.30%.

Dilactone ***16*** *(n=10)*, was obtained as white needles (10%) from absolute ethanol, mp 238—239 °C (dec); ν_{max} ≈3484 (overtones), 1754, 1712; *m/e* 526 (M^+). Found: C, 73.18; H, 8.96%. Calcd for $C_{32}H_{46}O_6$ (526): C, 72.97; H, 8.80%.

*Preparation of the Bis-epoxide (**19**).* To a suspension of MCPBA (2 mmol) and anhydrous potassium carbonate (10 mmol) in dichloromethane (5 ml) was added slowly a suspension of the benzodipyran (**15**; *n*=6) (116 mg, 0.33 mmol) in the same solvent (2 ml), with stirring at room temperature. After 6 h the reaction mixture was filtered and the solids washed with carbon tetrachloride. The filtrate was washed with water, dried over anhydrous sodium sulfate and evaporated to afford a crystalline product (116 mg), mp 129—135 °C; ν_{max} 2941, 1513, 1464; $\delta(CDCl_3)$ 1.2—2.6 (m, 12-CH_2), 3.0—3.6 (two superimposed broad AB quartets, benzylic 2CH_2; separated due to the two forms of the bis-epoxide), 6.5 (s, 2H aromatic). Attempted recrystallization of this product resulted in the opening of the epoxides (TLC, IR).

The above experiment repeated in the presence of a limited quantity of potassium carbonate (1.33 mmol), gave only the above epoxides.

*Attempted Further Oxidation of the Epoxide (**19**) with MCPBA.* A solution of the epoxide (64 mg, 0.15 mmol) in dichloromethane (2 ml) was added to a solution of the per acid (0.5 mmol) in the same solvent (2 ml). The reaction mixture was stirred at room temperature for 2 h, when it was diluted with chloroform and washed successively with 0.5 M sodium hydroxide and water. Drying and evaporation furnished a solid (55 mg) consisting of a complex mixture of products (TLC).

Similarly, attempted oxidation of the epoxide mixture (**19**) with periodic acid in tetrahydrofuran resulted in a complex mixture of products.

We thank Drs. O. E. Edwards and H. Séguin of the NRC, Ottawa, Canada, for some of the elemental analysis and H. B. Machado of the IE-UFMG, Belo Horizonte, Brazil, for the mass spectra of benzodilactones.

Semi-Empirical Configuration Interaction Studies on the π-Electron Spectra of Nonbenzenoid Molecules

N. K. Das Gupta* and F. W. Birss

Theoretical Chemistry Division, Chemistry Department, University of Alberta, Edmonton, Canada

(Received October 26, 1976)

A modification of the method of Yamaguchi *et al.* has been used to predict the π-electronic spectra of a number of nonbenzenoid molecules containing five- and seven-membered rings. Good correlation of the theoretical and experimental transition energies is found. The calculated intensities are also reasonably consistent with experiment, to the extent of raising questions as to the source of intensity in the bands of some molecules.

Semi-empirical self-consistent-field calculations have been applied to many molecules with π-electrons with considerable success in reproducing the electronic spectra and ground state properties such as heat of atomization and sites of reactivity.[1,2] The choice of parameters in the semi-empirical context is critical in some of these predictions. In particular, the value of β, the two-centre resonance integral, has a different range of values according to whether it is electronic spectra or heats of atomization that are to be predicted by the calculation.[1]

In the case of electronic spectra, there persist discrepancies between observed and calculated frequencies and oscillator strengths, even with an apparently adequate choice of β. In this paper we therefore report attempts to improve upon the predictions of spectra for some molecules for which we have recently given the results of self-consistent-fields calculations,[3,36,38] now using configuration interaction.

In such work, three primary variations in method can occur: the choice of formula for the two-centre resonance integral, the choice of formula for the two-centre two-electron repulsion integrals and the configurations to be included in the interaction study.

A computer programme was developed which was capable of generating all configurations arising from all possible one- and two-electron excitations involving all of the occupied and unoccupied orbitals obtained in a prior molecular orbital calculation. It was found that an adequate fit of the experimental spectra could be obtained using only those configurations arising from one-electron excitations, provided the orbitals were the self-consistent-field set, and that such a choice frequently gave a better fit than did the use of the full one- and two-electron excitation set. Therefore all of this work is on the basis of configurations arising from one-electron excitations involving orbitals obtained in a prior self-consistent-field calculation. In the case of the larger molecules studied in this work, even this restricted basis is unnecessarily large since many of the configurations which, within the orbital approximation, represent excitation beyond the ionization limit, contribute very little to the functions of interest: those with energies lying within about eight electron volts of the ground state. For such molecules a restricted number of the highest occupied orbitals and the lowest unoccupied orbitals were involved in excitations to form the configurations used as basis.

In the recent literature, two methods of calculating two-centre, two-electron repulsion integrals, γ_{ij}, have been much used: the formulae of Ohno[4] and of Nishimoto and Mataga.[5] The former has been used very successfully in the context of self-consistent-field studied toward obtaining heats of atomization and resonance energies.[1,2,6] We have also found it to be good for use for similar studies directed toward obtaining electronic spectra predictions.[3,36,38] In the present work, on the other hand, we have found that the Nishimoto-Mataga formula,

$$\gamma_{ij} = 14.397/(1.293+r_{ij}). \quad \text{(eV)} \qquad (1)$$

with r_{ij} the internuclear separation (Å), yields superior fitting between the observed spectra and those calculated using the configuration interaction method. In this formula the parameter value, 1.293, is chosen so that the one-centre two-electron repulsion integral, γ_{ij}, has the value 11.134 eV, equal to the difference between the sp^2 valenece state ionization energy (11.16 eV) and electron affinity (0.026 eV) for carbon.[7] In the self-consistent-field calculation, the γ_{ij} between neighbouring atoms were varied at each interaction on the basis of the internuclear separation, r_{ij}, calculated from the bond order (p_{ij})—bond length relation[8]

$$r_{ij} = 1.520 - 0.186p_{ij}. \quad \text{(Å)} \qquad (2)$$

The γ_{ji} integrals between non-neighbouring atoms were based upon a particular choice of molecular geometry and were not varied throughout the calculation. For the benzenoid systems the choice was with all bond lengths equal to 1.40 Å, all bond angles equal to 120°. For azulene,[9] aceheptylene,[10a] pentaleno[*def*]heptalene[10b] and acepleiadylene,[11] the structures reported in the literature were used. For the other molecuels, whose experimental structures were not available reasonable geometries[3,6,36,38] were selected.

The formula used for evaluation of the two-centre resonance integral between neighbouring centres was that of Yamaguchi *et al.*,[8a]

$$\beta_{ij} = \beta_0 \exp[1.7(1.397-r_{ij})], \qquad (3)$$

with the internuclear distance, r_{ij}, calculated as described above and varied at each self-consistent-field interaction. The parameter β_0 was chosen to depend upon the number of rings[8b] in the molecule under investigation, on the basis of fitting the spectra of benzenoid systems. For benzene, $\beta_0 = -2.38$ eV, for naphthalene and azulene, $\beta_0 = -2.28$ eV, and for larger molecules, $\beta_0 = -2.15$ eV were used. Results for these

standardization molecules are included in Table 1.

Results and Discussion

The calculated electronic spectra are given in Table 1, along with any available experimental data and other theoretical predictions. The standard deviation of the differences between observed and calculated transition energies for the bands chosen for the standardization of β_0 is 0.08 eV. For these benzenoid systems the agreement between theory and experiment is generally very good, with an overall fit as good as, or better than, that achieved by other workers. The results of azulene, a subsidiary test molecule, are also of good quality.

We have reported elsewhere[3,36,38] and included here for comparison, the predicted transitions for some non-benzenoid hydrocarbons (molecules VII to XXIX) using a different parameterization and the self-consistent field method. In almost all cases the present results achieved a consistently better correlation with experiment. The comparison with the results of other workers[8,12,17,31,33–35,37] yields the same general conclusion.

In most cases there is not only reasonable agreement for the transition energies but also a definite, if rough, agreement in the trends followed by the intensities. There are, however, notable exceptions, when the theoretical intensity is reasonably large. Examples of this are the 4.5 eV transition of acenaphthylene and the 3.8 eV transition of acepleiadylene. An experimental study of such transitions to determine whether their intesity may be due to vibronic coupling would be worthwhile.

In recent years Michl *et al.*[49–53] studied the electronic structure of the excited states of some of the molecules studied here (VIII, XI, XIII, XX, XXIII, XXIV, and XXVI). If we consider single excitations then it would be clear from the table that our results are in better agreement with the experiment than those of Michl *et al.*

Conclusion. It has been found that by slight modification of the method of Yamaguchi *et al.* by making the value of β_0 dependent on the size of the molecules $\pi^* \leftarrow \pi$ spectral transitions of a large number of conjugated systems can be predicted with reasonably

good accuracy.

We are grateful to the National Research Council for a grant in aid to this research, both for computing funds and for a fellowship for N. K. Das Gupta. The use of the facilities of the Computing Services of the university is acknowledged with pleasure.

The Codimerization of Styrene and Butadiene with Three-Component Catalysts Consisting of Palladium Salt, Lewis Acid, and Tertiary Phosphine

Takehiko Ito and Yasuo Takami

National Chemical Laboratory for Industry, 1-1, Honmachi, Shibuya-ku, Tokyo 151

(Received September 29, 1977)

The reaction of styrene and butadiene in the presence of a three-component catalyst consisting of a palladium salt, a Lewis acid, and a tertiary phosphine was investigated. As the three-component catalyst, combinations of such palladium(II) salts as $(\pi\text{-}C_3H_5PdCl)_2$, $(PdCl_2\cdot C_6H_5CH{=}CH_2)_2$ and $Pd(acac)_2$, such Lewis acids as BF_3 and $AlCl_3$, and such tertiary phosphines as Ph_3P and Bu_3P were adopted. From the reaction, 1-phenyl-1,4-hexadiene (a straight-chain codimer) was obtained as the main product, together with small amounts of branched-chain codimers. The ratio of the 1-phenyl-1,4-hexadiene to the branched-chain codimers was varied to some extent by changing the molar ratio of styrene to butadiene. With an increase in the molar ratio the ratio of 1-phenyl-1,4-hexadiene to the branched-chain codimers decreased. A reaction mechanism for the selective formation of 1-phenyl-1,4-hexadiene which involves the addition of butadiene, in preference to styrene, to a palladium hydride is proposed.

Recently dimerizations and codimerizations of olefins catalyzed by organometallic complexes have attracted much attention because of the utility of the reaction products and the novelty of the type of reaction, and a number of studies have been reported. However, the codimerization between two olefins such as butadiene and styrene, both of which coordinate strongly to catalyst metals, is very difficult; only the cotrimerization of two moles of butadiene with one mole of styrene has been reported.[1]

In the course of our study of a three-component catalyst system[2] consisting of a palladium salt, a Lewis acid, and a tertiary phosphine, we have found that the codimerization of styrene with butadiene proceeds smoothly by the use of this catalyst system, thus affording 1-phenyl-1,4-hexadiene.[3] In the present paper, details of the codimerization, which is the first example of the catalytic synthesis of 1-phenyl-1,4-hexadiene, will be reported.

Experimental

Reagents. Palladium complexes and a 1:1 adduct of boron trifluoride and triphenylphosphine ($BF_3\cdot Ph_3P$) were synthesized according to the methods described in the literature. $BF_3\cdot Ph_3P$: mp 176 °C (lit,[4] mp 175 °C). The nitrobenzene was used after drying with diphosphorus pentaoxide. The other reagents were used after drying and purification according to the usual manners.

Synthesis of 1-Phenyl-1,4-hexadiene. Into a 100-ml stainless-steel autoclave cooled in a ethanol–Dry Ice bath, 30 ml (345 mmol) of butadiene, 20 ml (170 mmol) of styrene, 10 ml of dichloromethane, and a solution of 0.6 mmol of $BF_3\cdot Ph_3P$ and 0.3 mmol of di-μ-chlorobis(π-allyl)dipalladium ($(\pi\text{-}C_3H_5PdCl)_2$) in 10 ml of dichloromethane were introduced under a nitrogen atmosphere. The mixture was then stirred for 1 h at 100 °C. The unreacted butadiene was purged after cooling, and then a small amount of an aqueous solution of sodium carbonate was added to decompose the catalyst. After the precipitate has been removed by filtration, the reaction mixture was distilled, and a fraction with a bp of 95—100 °C/4 mmHg was collected. GLC analysis of this fraction showed that it contained 11.2 g (71 mmol) of 1-phenyl-1,4-hexadiene. From this fraction, 1-phenyl-1,4-hexadiene (*trans,trans*-isomer 88%, *cis,trans*-isomer 12%) (bp 94 °C/5 mmHg (lit[5], 122 °C/21 mmHg)) was easily separated by distillation using a spinning-band column (length, 50 cm).

Codimerization under Various Reaction Conditions. The codimerization reactions shown in Tables 1—4 were carried out in a manner similar to that described above. After the decomposition of the catalyst, the reaction products were analyzed in the following way.

Analysis of the Reaction Products. To the reaction mixture, biphenyl was added as an internal standard. A small amount of aliquots of the reaction mixture and its catalytic hydrogenation product with palladium–charcoal was analyzed by GLC. From the results of the GLC analysis, the yields of 1-phenyl-1,4-hexadiene, individual dimers of butadiene and styrene, and the trimer of butadiene and the composition of the skeleton isomers of the codimer were determined.

The codimers were analyzed using a Golay column after removing the nitrobenzene used as a solvent and the high-boiling products by means of a precut column. Golay column: Silicone DC 550, 45 m × 0.25 mmϕ, 130 °C. Carrier gas: N_2 1 ml/min. Precut column: PEG 9000, 40 cm × 3 mmϕ. The high-boiling products were analyzed by using a column (Silicone KF 45, 10% Diasolid M, 3 m × 3 mmϕ) at 230 °C.

Structure Determination of the Reaction Products. A typical gas chromatogram of the products in the presence of $(\pi\text{-}C_3H_5PdCl)_2$–$BF_3\cdot Ph_3P$ catalyst is shown in Fig. 1. The main components of the reaction products were separated by a combination of fractional distillation and preparative GLC, and their structures were determined by means of IR, NMR, *etc.*

Peak 1: 1,3,6-Octatriene.

Peak 2: 5-Phenyl-1,3-hexadiene. IR; 1002 cm^{-1}, 898 cm^{-1}, 1648 cm^{-1} ($H_2C{=}CH{-}CH{=}CH{-}$). Hydrogenation gave 2-phenylhexane.

Peak 3: 1-Phenyl-3-methyl-1,4-pentadiene. IR; 912 cm^{-1}, 993 cm^{-1} ($-CH{=}CH_2$), 965 cm^{-1}, 1635 cm^{-1} (*trans*-CH=CH–). Hydrogenation gave 1-phenyl-3-methylpentane.

Peak 4: From the fact that hydrogenation gave dodecane, it was presumed to be dodecatetraene (a trimer of butadiene).

Peaks 5, 6: Since hydrogenation gave 1-phenylhexane, they were presumed to be 1-phenylhexadiene.

Peak 7: *trans, trans*-1-Phenyl-1,4-hexadiene. IR; 963 cm^{-1}, 1650 cm^{-1} (*trans*-CH=CH–). NMR; 1.65 ppm (3H, m,

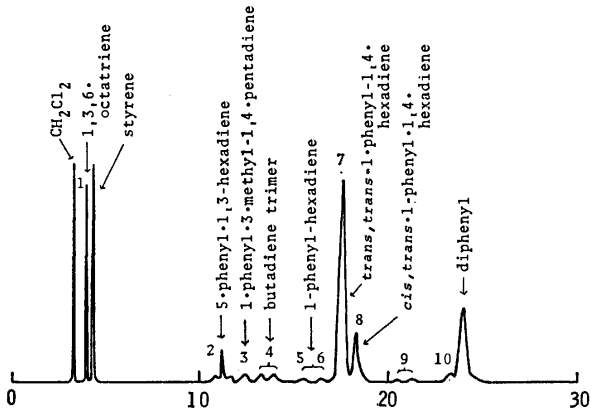

Fig. 1. Gas chromatogram of the compounds obtained by the reaction of butadiene and styrene in the presence of the catalyst consisting of $(\pi\text{-}C_3H_5PdCl)_2$–$BF_3\cdot Ph_3P$. ($(\pi\text{-}C_3H_5PdCl)_2$ 0.15 mmol, $BF_3\cdot Ph_3P$ 0.3 mmol, CH_2Cl_2 20 ml, styrene 170 mmol, butadiene 170 mmol, reaction time 1 hr, reaction temperature 100 °C). (Column. Golay column 45 m, temperature 120 °C)

CH_3–C=), 2.8 ppm (2H, m, =C–CH_2–C=), 5.2—6.3 ppm (4H, m, olefin proton), 7.25 ppm (5H, m, ring proton). Hydrogenation gave 1-phenylhexane.

Peak 8: *cis,trans*-1-Phenyl-1,4-hexadiene. IR; 963 cm^{-1}, 710 cm^{-1}, 1650 cm^{-1}. Hydrogenation gave 1-phenylhexane.

The constitutions of the products under the conditions adopted in Fig. 1 were approximately as follows: Peak 2, 6%; Peak 3, 2%; Peak 4, 4%; Peak 5+Peak 6, less than 1%; Peak 7, 77%; Peak 8, 11%; Peak 9+Peak 10, less than 1%. The constitutions of the alkylbenzene obtained by hydrogenation of the codimers formed in the above reaction were: 1-phenylhexane 89%, 2-phenylhexane 8%, 1-phenyl-3-methylpentane 3%.

Reaction of $(\pi\text{-}C_3H_5PdCl)_2$, $BF_3\cdot Ph_3P$ and Styrene. To a solution of 1.51 mmol of $(\pi\text{-}C_3H_5PdCl)_2$ and 3.03 mmol of $BF_3\cdot Ph_3P$ in 7 ml of nitrobenzene, 33.4 mmol of styrene and 1.586 mmol of decane (as an internal standard) were added under a nitrogen atmosphere, after which the mixture was stirred for 15 min at 40 °C. The resulting mixture was hydrogenated under hydrogen pressure, using palladium–charcoal in ethanol. From the GLC analysis of the hydrogenation product, the formation of 1.32 mmol of 1-phenylpentane and 0.16 mmol of 2-phenylpentane was detected.

Results and Discussion

Reaction Catalyzed by $(\pi\text{-}C_3H_5PdCl)_2$–$BF_3\cdot Ph_3P$. As the catalyst systems consisting of a palladium salt, a Lewis acid, and a tertiary phosphine, various combinations are possible. In the previous papers[2] we have reported on various combinations which are active for the codimerization of butadiene with a monoolefin such as ethylene and propylene or for the codimerization of styrene with a monoolefin. In the present study, a catalyst system consisting of a combination of $(\pi\text{-}C_3H_5PdCl)_2$ and $BF_3\cdot Ph_3P$ has been mainly used because this catalyst system is comparatively soluble in many solvents.

Composition and Structure of Reaction Products. A gas chromatogram of the products of the reaction of styrene and butadiene in the presence of a typical catalyst system, $(\pi\text{-}C_3H_5PdCl)_2$–$BF_3\cdot Ph_3P$ (molar ratio=1:2), is shown in Fig. 1. 1-Phenyl-1,4-hexadiene was obtained as the main product; the sum of its *trans,trans*-isomer and *cis,trans*-isomer reached about 88 mol % of the C_{12}-compounds consisting of a codimer of butadiene with styrene and a butadiene trimer, showing the high selectivity of 1-phenyl-1,4-hexadiene. As reaction products, the respective dimers and trimers of butadiene and styrene were also obtained along with the codimer. However, 1-phenyldecatriene, which is known to be the main product of the reaction of styrene and butadiene catalyzed by nickel-containing catalysts,[1] was scarcely obtained at all. This is of interest as a difference resulting from the metal species of the catalysts.

Effect of the Molar Ratio of Styrene to Butadiene: In the present reaction, 1-phenyl-1,4-hexadiene, which has a straight-chain structure, is obtained as the main product. As one of the factors which dominate the structure of the reaction products, the coordination strength of the olefins used can be considered. In a reaction of ethylene and styrene using the same catalyst, as in the present

a) Amount (%) of the *trans, trans*-isomer in the total 1-phenyl-1,4-hexadiene. b) Amount of the distillation residue obtained by the distillation of the reaction products at 180 °C (bath temp)/4 mmHg. c) Composition of the product obtained by the hydrogenation of the with codimer the palladium–charcoal catalyst. d) 1-Phenylhexane. e) 2-Phenylhexane. f) 1-Phenyl-3-methylpentane. g) Styrene was introduced into the reaction mixture at the rate of 0.2 ml/min throughout the reaction.

study, we have previously reported that no dimerization of ethylene occurs and that the codimers derived from the addition of ethylene to the α-position of styrene are obtained, because styrene coordinates to the catalyst in preference to ethylene.[2c] In the present reaction, both styrene and butadiene have a strong coordination ability, so it is of interest which olefin coordinates preferentially to the catalyst and, consequently, how the reaction proceeds. Therefore, the effects of the molar ratio of styrene to butadiene on the reaction were investigated. The results are shown in Table 1.

When the molar ratio was varied from 3/1 to 1/3, the yield of 1-phenyl-1,4-hexadiene decreased with the decrease in the amount of styrene or with the increase in the amount of butadiene. However, the effect of the variation in the amount of butadiene was less than that of the amount of styrene. This appears to show that butadiene coordinates to the catalyst in preference to styrene and that, hence, the effect of the concentration of butadiene is smaller than that of styrene. With the decrease in the amount of styrene relative to butadiene, the formation of the styrene dimer was greatly reduced. This also shows the preferential coordination of butadiene. When distilled, the amount of the residue increased with an increase in the amount of styrene used, and the residue is thought to be composed mainly of an oligomer of styrene.

As for the composition of the alkylbenzene obtained by the hydrogenation of the codimer, with the variation in the molar ratio of butadiene to styrene from 1/3 to 3/1 1-phenylhexane increased from 86 to 92%, and 1-phenyl-3-methylpentane slightly increased from 2.6 to 3.1%, whereas 2-phenylhexane decreased from 11 to 5%. These facts suggest that 1-phenylhexane and 1-phenyl-3-methylpentane are formed by analogous mechanisms, but 2-phenylhexane is formed by a different mechanism. It can be said that the influence of the competitive coordination of styrene and butadiene is revealed as a variation of the composition of the hydrogenation products.

The ratio of the *trans,trans* isomer to *cis,trans*-1-phenyl-1,4-hexadiene is thought to be in equilibrium, and the ratio was approximately constant, not depending upon the butadiene/styrene ratio.

Effects of Reaction Conditions: The effects of the solvent, the reaction time, the reaction temperature, and the catalyst composition upon the reaction were investigated. The results of the experiments using nitrobenzene as a solvent are shown in Table 2, while those of the experiments using dichloromethane are shown in Table 3. As is clear from the comparison of the results of Run 7 and Run 17, or the results of Run 4 and Run 18, both the yield and the composition of the codimer are little affected by the type of solvent used. However, the separation of nitrobenzene from the reaction products is troublesome because its boiling point is close to those of the products. Therefore, the use of dichloromethane is preferable, and its separation from the products is much easier than that of nitrobenzene.

A greatly increased yield of 1-phenyl-1,4-hexadiene was obtained by the elongation of the reaction time from 1 to 2 h at 100 °C (Runs 7, 8), but by the elongation from 2 to 4 h the yield of 1-phenyl-1,4-hexadiene, the amount of styrene recovered, and the amount of the distillation residue were little affected (Run 9). On the other hand, when the reaction using double amounts of styrene and butadiene was carried out for 4 h, approximately double amounts of 1-phenyl-1,4-hexadiene were obtained (Run 10). Therefore, the results of Run 9 seem to suggest the existence of some coordination equilibrium between the reaction products and monomers and that, because of the equilibrium, the reaction does not proceed.

The codimerization occurred at 70 °C and proceeded smoothly above 100 °C. The reaction between styrene and ethylene, as we have reported in a previous paper,[2-c] proceeds easily at 30 °C; on the contrary, the present codimerization does not proceed at 40 °C, showing the influence of the strong coordination of butadiene.

As for the effect of the molar ratio of $BF_3 \cdot Ph_3P/(\pi\text{-}C_3H_5PdCl)_2$, when the ratio is below 2 (*i.e.*, P/Pd atomic ratio$<$1) the yield of 1-phenyl-1,4-hexadiene decreases

with the decrease in $BF_3\cdot Ph_3P$ (Table 2), but even if 2 mol of $BF_3\cdot Ph_3P$ per atom of Pd are used, the yield does not increase (Table 3, Run 22). These results indicate that (π-$C_3H_5PdCl)_2$ is activated by 1 mol of $BF_3\cdot Ph_3P$ per atom of Pd. When triphenylphosphine is added to a (π-$C_3H_5PdCl)_2$–$BF_3\cdot Ph_3P$ catalyst system with an atomic ratio of Pd: P: B=1: 1: 1, the resulting catalyst system (Pd: P: B=1: 2: 1) has no activity (Run 23). It can be considered that excess phosphine coordinates strongly to palladium and inhibits the coordination of olefins.

Palladium compounds other than (π-$C_3H_5PdCl)_2$ can be used as catalyst components. The results obtained by using the ($PdCl_2\cdot C_6H_5CH{=}CH_2)_2$–$BF_3\cdot Ph_3P$ and $Pd(acac)_2$–$BF_3\cdot Ph_3P$ catalyst systems are given in Table 3 (Runs 20, 21). ($PdCl_2\cdot C_6H_5CH{=}CH_2)_2$ alone is ineffective as a catalyst, yielding only a small amount of a codimer (Run 24).[6] This is believed to be due to the formation of a stable complex of the palladium salt with butadiene.

Reaction with a Catalyst Consisting of Palladium Salt, Aluminum Chloride, and Tertiary Phosphine. As a Lewis acid, aluminum chloride can be used instead of boron trifluoride. The results obtained by using a (π-$C_3H_5PdCl)_2$–$AlCl_3$–R_3P catalyst system are shown in Table 4. Both the activity of the catalyst and the composition of the reaction products are not very different from those obtained by a (π-$C_3H_5PdCl)_2$–$BF_3\cdot Ph_3P$ catalyst system, though it is preferable, when aluminum chloride is used, to employ nitrobenzene as the solvent in order to carry out the reaction in a homogeneous state.

When the atomic ratio of Al/P or Al/Pd was increased from 1 to 2 by changing the quantities of palladium salt and phosphine and by using approximately constant amounts of aluminum chloride, the amounts of the

a)—f) The same as in Table 1. g) Pd means monomeric (π-C_3H_5PdCl). The ratio is equal to the atomic ratio of Pd: Al: P. h) Triphenylphosphine. i) Tributylphosphine. j) Reaction time, 1/2 h.

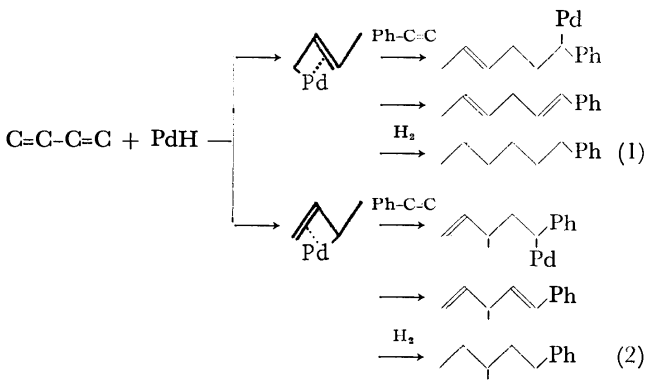
distillation residue (oligomer) per palladium atom were increased, but the yields of 1-phenyl-1,4-hexadiene per palladium atom were not increased very much (Runs 25—27). Therefore, it seems to be appropriate to use an approximately equal mole of aluminum chloride to phosphine.

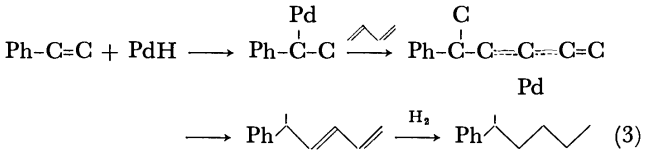
The effects of the molar ratio of styrene to butadiene were similar to those of the case using a $(\pi\text{-}C_3H_5PdCl)_2$–$BF_3\cdot Ph_3P$ catalyst system. By increasing the molar ratio, the yield of 1-phenyl-1,4-hexadiene was increased and the proportion of 2-phenylhexane was also increased.

When tributylphosphine was used instead of triphenylphosphine, the yield of 1-phenyl-1,4-hexadiene decreased and the proportion of 1-phenyl-3-methylpentane to the total hydrogenated codimers increased, suggesting that butadiene tends somewhat to react in the form of under the influence of tributylphosphine.[7]

Reaction Path. For the codimerization of styrene and ethylene using the same catalyst system as in the present codimerization, we have proposed a reaction mechanism which involves the formation of a palladium hydride as an active species of the catalyst system.[2c] In the present codimerization, the active species of the catalyst system is believed to be essentially the same as that described above. As has already been mentioned with regard to the composition of the alkylbenzene obtained by the hydrogenation of codimers, 1-phenylhexane and 1-phenyl-3-methylpentane increased with an increase in the amount of butadiene employed, while 2-phenylhexane and styrene dimer increased with an increase in the amount of styrene (Table 1). In Fig. 1, as a compound which gives 2-phenylhexane by hydrogenation, only 5-phenyl-1,3-hexadiene has a structure capable of giving 2-phenylhexane.

From these facts, it can be considered that 1-phenylhexane and 1-phenyl-3-methylpentane are formed according to Eqs. 1 and 2 respectively, and that 2-phenylhexane is formed according to Eq. 3.





However, when the reaction of styrene with allyl groups coordinating to palladium was carried out by adding excess amounts of styrene to a solution of $(\pi\text{-}C_3H_5PdCl)_2$ and $BF_3\cdot Ph_3P$ in a molar ratio of 1 : 2, and when the resulting reaction mixture was hydrogenated, phenylpentanes (*ca.* 50 mol % based on the $(\pi\text{-}C_3H_5PdCl)_2$ used) were obtained; GLC analysis showed that the phenylpentanes consisted of 1-phenylpentane (89%) and 2-phenylpentane (11%). Therefore, it seems necessary to consider the participation of the following pathway (Eq. 4) for the formation of 2-phenylhexane:

The Oxidation Mechanism of Copper in Nitrogen Oxide

Yoshio TAKASU and Yoshiharu MATSUDA

Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube, Yamaguchi 755

(Received August 22, 1977)

Synopsis. The rate-determining step of the oxidation of copper in nitrogen oxide was proposed to be the dissociation of the adsorbed nitrogen oxide on the surface of the oxide film.

Although many studies have been made of the high-temperature oxidation of metals, few investigations of reactions in nitrogen oxide are recorded.[1,2] The present authors have reported in an earlier paper[3] that the oxidation of copper in nitrogen oxide (700—820 °C, 3.5—14 Torr) followed a linear rate law, suggesting that the rate-determining step is the reaction at the gas/oxide interface. Moreover, the following total reaction was proposed for the reaction;

$$2Cu + NO(g) = Cu_2O + 1/2N_2(g),$$

with an apparent activation energy of ≈113 kJ/mol. In this study, the oxidation of copper in nitrogen oxide was examined at higher pressures (20 and 30 Torr). The oxidation mechanism is discussed in the light of the present results and those from earlier studies.[3]

The experimental procedure was the same as that described previously.[3] The oxidation process was followed in a conventional high-vacuum system. The polycrystalline specimens (99.999% Cu) were 10×5 mm in area and had a thickness of 0.5 mm. The samples were annealed in a vacuum at 700 °C for 2 h, electropolished, and then heated in a hydrogen atmosphere at 700 °C for 1 h prior to the oxidation measurements. High-purity nitrogen oxide in a glass cylinder (Takachiho Co.) was used without further purification.

Figure 1 shows the oxidation curves for copper under various pressures of nitrogen oxide at 700 °C. The data obtained from this study at 20 and 30 Torr also obeyed the linear rate law in the early stage of the oxidation. The rate at these two pressures decreased later, however,

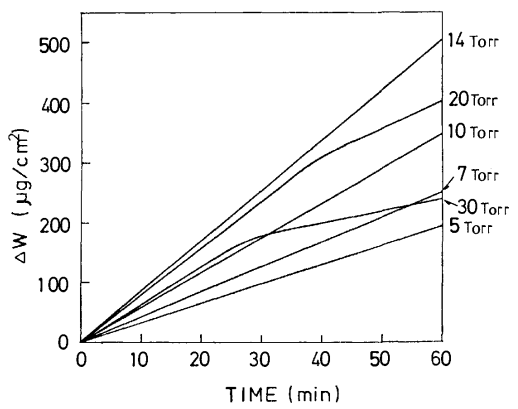

Fig. 1. Oxidation curves of copper in various pressures of nitrogen oxide at 700 °C.

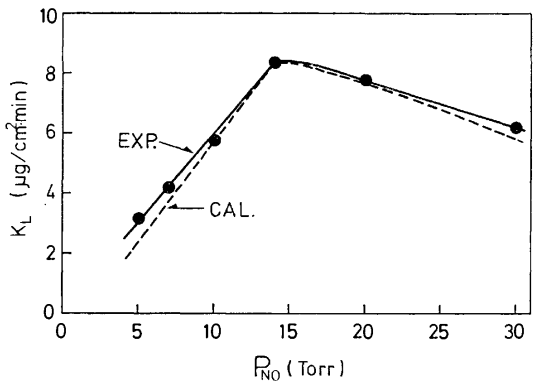

Fig. 2. The relation between the pressure of nitrogen oxide and the linear rate constant for the oxidation of copper at 700 °C. Dashed curve: theoretical result using Eq. 11 and normalized to maximum rate constant at $p=14$ Torr.

showing evidence for two stages of oxide growth. The pressure dependence of the rate constant, K_L, in the early stage of the oxidation is shown in Fig. 2. At first the rate increased with the pressure, read a maximum around 14 Torr, and then decreased. This behaviour suggests that the rate-determining step of the oxidation is to be found in the dissociation of the absorbed nitrogen oxide on the surface of the oxide film. As has been discussed by Ritchie and Hunt[4] for the oxidation in oxygen, the surface reaction sequences for the NO–Cu system could be given as follows:

$$NO(g) + S = NO(a), \quad (1)$$

$$NO(a) + S = N(a) + O(a), \quad (2)$$

$$2N(a) = N_2(a) + S, \quad (3)$$

$$N_2(a) = N_2(g) + S, \quad (4)$$

$$O(a) = O^-(a) + \oplus, \quad (5)$$

$$O^-(a) = O^{2-}(a) + \oplus, \quad (6)$$

$$O^{2-}(a) = O^{2-}(\text{Lattice}) + S, \quad (7)$$

where (g) denotes the gaseous species; (a), the adsorbed species; S, the vacant adsorption site, and ⊕, the electron hole. If we consider Step 2 to be rate-determining, then

$$K_1 = \frac{[NO(a)]}{p[S]}, \quad (8)$$

$$r = k_2[S][NO(a)], \quad (9)$$

$$G = [S] + [NO(a)], \quad (10)$$

where K_1 denotes the equilibrium constant for Step 1; p, the pressure of nitrogen oxide; r, the oxidation rate; k_2, the rate constant for Step 2, and G, the total number

of adsorption sites.

From Eqs. 8, 9, and 10 we obtain

$$r = \frac{k_2 K_1 G^2 p}{(1+K_1 p)^2}. \quad (11)$$

Equation 11 shows that r is proportional to the pressure of nitrogen oxide if $K_1 p \ll 1$, but that r is inversely proportional to the pressure if $K_1 p \gg 1$. The decrease in the reaction rate in the higher-pressure range can thus be attributed to a decrease in the number of vacant adsorption sites as a result of the adsorption of nitrogen oxide. The calculated values for the rate constant at 700 °C based on Eq. 11 are also plotted in Fig. 2, whereby the curve is normalized to the maximum rate constant at $p=14$ Torr.

The authors are grateful to Dr. A. M. Bradshaw of the Fritz-Haber-Institut, Berlin, for helpful discussion and critical reading of the manuscript.

Unusual Products of the Leuckart Reaction of 1-Acenaphthenone

Jiro TATSUGI, and Michio OKUMURA

Department of Applied Chemistry, Aichi Institute of Technology, Yakusa, Toyoda 470-03

(Received June 22, 1977)

Synopsis. In the reaction between formamide and 1-acenaphthenone, 1,1′-biacenaphthenyliden-2-one was obtained instead of 1-acenaphthenamine which is expected to be formed by the Leuckart reaction. When formic acid was incorporated in the reaction, besides 1,1′-biacenaphthenyliden-2-one two new nitrogen-containing compounds were isolated; their structures were identified to be acenaphtho[1,2-*d*]pyrimidine and diacenaphtho[1,2-*b*: 1′,2′-*d*]pyridine by independent syntheses.

The reaction of 1-acenaphthenone (**1**) with formamide or ammonium formate gave exclusively a nitrogen-free product (**2**) (75% yield). When **1** was treated with a mixture of formamide and anhydrous formic acid, two new products (**3**) and (**4**) were obtained along with the liberation of CO_2 (Table 1). When using 80% formic acid in place of the anhydrous acid, the yield of **2** increased and those of **3** and **4** were reduced. The nitrogen-free product **2** decolorized bromine and permanganate solutions, suggesting the presence of unsaturated bonds. The IR spectrum of **2** showed the presence of a carbonyl group and its NMR spectrum showed a singlet at 4.70 ppm which is assignable to allylic methylene protons. This compound was identified to be the structure shown in the scheme by independent synthesis of the compound by the aldol condensation of **1** in the presence of caustic alkali.

Table 1. Reaction of 1-acenaphthenone with the mixture of formamide and anhydrous formic acid

a) *ca.* 80% HCOOH.

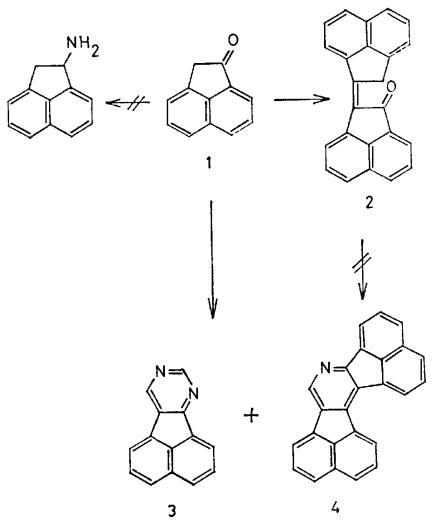

Fig. 1.

The compound **3** has an experimental formula of C_7H_4N; the structure is suggested to have a pyrimidine nucleus by the IR spectrum. Furthermore, the NMR spectrum in $CDCl_3$ is well interpreted to be acenaphtho[1,2-*d*]pyrimidine. The authentic acenaphtho[1,2-*d*]-pyrimidine was independently prepared by the reaction of 2-formyl-1-acenaphthenone (**1a**) with formamidine (Fig. 2).

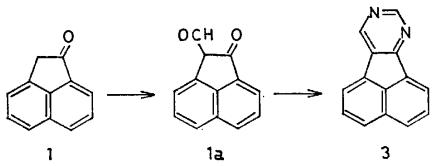

Fig. 2.

The admixture of **3** with the authentic sample showed no melting point depression and the R_f values of both compounds were the same.

The compound **4** was identified as diacenaphtho[1,2-*b*: 1′,2′-*d*]pyridine on the basis of its IR, UV, and mass spectra and elementary analysis. The independent synthesis of **4** was accomplished by converting 2-(ethoxymethylidene)-1-acenaphthenone into 2-(aminomethylidene)-1-acenaphthenone by dry ammonia and then condensing it with **1**. The authentic compound showed the same R_f value as that of **4** isolated from the Leuckart reaction products.

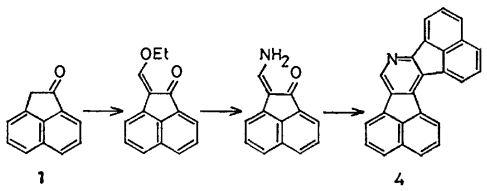

Fig. 3.

Recently, pyrimidine derivatives were isolated from the Leuckart reaction mixture in thiophene derivatives by Hill and Loev,[1)] and Srinivasan and Rampal,[2)] though the formation of the pyridine derivatives has not yet been reported.

The above mentioned **3** and **4** are new compounds which have not yet been reported in the literature.

In the reaction of **1** with formamide, which took place exclusively as an aldol condensation and showed no Leuckart reaction, formamide seemed to perform the

role of a protic solvent. In the presence of formic acid, however, the Leuckart reaction is in competition with the aldol reaction and gives **2**, **3**, and **4**, but no normal Leuckart reaction products. It may be assumed that **3** and **4** might result *via* an intermediate of the Leuckart reaction. It is worthy to note that **4** might be produced by the condensation of **2** with formamide as shown in Fig. 1. This can be ruled out since no **4** was isolated from the reaction mixture of **2** and formamide.

When 80% formic acid was used, the yield of **2** increased and those of **3** and **4** decreased. It is reasonable to consider that the presence of water favors the enolization of **1** and accelerates the aldol condensation by the dissociation of formic acid. Further experiments are necessary, however, to consider the reaction route of the formation of **3** and **4** in the Leuckart reaction conditions. This is now in progress.

Experimental

The melting points were determined on a Yanaco MP-type apparatus and are uncorrected. The IR spectra were taken in potassium bromide pellets on a Hitachi 215 grating spectrometer. The UV spectra were recorded on a Hitachi EPS-3T spectrophotometer. The NMR spectra were obtained on a JEOL JNM-C-60H spectrometer using TMS as internal standard.

Reaction of 1-Acenaphthenone ***1*** *with Formamide.* A mixture of **1** (3.36 g, 0.02 mol) and formamide (19.0 ml, 0.46 mol) was heated at 150 °C for 3 h. After cooling the reaction mixture, the precipitate was filtered and washed with methanol. The unchanged **1** was recovered from the methanol washing (13% recovery). Recrystallization of the crude product (2.53 g) from 300 ml of benzene (or chloroform) gave 2.38 g (75%) of **2**, yellow needles, mp 259—260 °C (lit, 262,[3] 258 °C[4]). IR (KBr): 1690 cm^{-1} (C=O). NMR ($CDCl_3$): δ=4.70 (2H, s) and 7.61—8.31 (12H, m). The mixed melting point with an authentic sample synthesized by Graebe's method[3] showed no depression.

The reaction of **1** with ammonium formate at 190 °C for 10 h gave a similar result.

Reaction of ***1*** *with Formamide and Formic Acid.* A mixture of **1** (1.68 g, 0.01 mol), formamide (9.5 ml, 0.23 mol), and anhydrous formic acid (8.5 ml, 0.23 mol) was heated at 150 °C for 3 h. In about 10 minutes evolution of carbon dioxide and precipitation of a colored product were observed. After heating at 150 °C for 30 min, the reaction mixture showed the presence of four spots (**1**, **2**, **3**, and **4**) on thin-layer chromatography (TLC). The colored product was separated by filtration and washed with methanol and then with ether. 0.66 g of yellow solid (two spots on TLC) was obtained. It was chromatographed by means of SiO_2 with chloroform as eluent. The first fraction collected was recrystallized from benzene to afford 0.50 g (31%) of **2**. The second fraction was recrystallized from dioxine to give 0.15 g (9%) of **4**, yellow needles, mp>300 °C, IR (KBr): 1582, 1510, 1430, and 1358 cm^{-1}. UV (dioxane) max: 332.5 nm (log ε 4.63). Found: C, 91.63; H, 4.00; N, 4.20%. Calcd for $C_{25}H_{13}N$: C, 91.72; H, 4.00; N, 4.28%. MS *m/e*: 327. The filtrate was extracted with chloroform. The chloroform layer was washed with H_2O and dried over $MgSO_4$, and then the chloroform was evaporated. The residue was recrystallized from acetone to give 0.58 g (28%) of **3**, pale yellow needles, mp 154—155 °C. IR (KBr): 1582, 1542, 1425, and 1378 cm^{-1}. UV (EtOH) max: 234 nm (log ε 4.44). NMR ($CDCl_3$) δ=9.36 (1H, s), 9.32 (1H, s), and 7.75—8.57 (6H, m). Found: C, 82.55; H, 4.02; N, 13.77%. Calcd for $C_{14}H_8N_2$: C, 82.33; H, 3.95; N, 13.72%. Picrate: yellow needles, mp 210—212 °C.

2-Formyl-1-acenaphthenone ***1a.*** A 100-ml three necked flask was equipped with a stirrer and a reflux condenser to which is attached a drying tube containing soda lime. 1-Acenaphthenone **1** (1.68 g, 0.01 mol), ethyl formate (3 ml, 0.04 mol), dioxane (40 ml), and an ethanolic solution of sodium ethoxide prepared by dissolving sodium (1.0 g, 0.04 mol) in 10 ml of absolute ethanol were added to the flask and stirred at 0 °C under nitrogen atomosphere for 12 h. The precipitate was separated by filtration and dissolved in water. The water-insoluble part **2** was filtered off. The filtrate was extracted by ether to remove the unreacted **1**. The aqueous layer was acidified with 1 M-HCl to precipitate **1a**, which was filtered, washed thoroughly with water, and dried. Recrystallization from benzene gave the purified product, 1.57 g (80%), mp 179—180 °C (lit, 180—182 °C[5]).

*Acenaphtho[1,2-*d*]pyrimidine* ***3.*** A solution of **1a** (0.98 g, 0.005 mol) and formamidine acetate (0.73 g, 0.007 mol) in 20 ml of ethanol was heated to reflux for 13 h and then the solvent was evaporated using a rotary evaporator. The residue was dissolved in 50 ml of chloroform, washed with 1M-sodium hydroxide solution, and dried over anhydrous sodium sulfate. Evaporation of chloroform gave a pale yellow residue, which was recrystallized from THF to yield 0.8 g (79%) of authentic **3**, mp 154—155 °C.

*Diacenaphtho[1,2-*b*: 1′,2′-*d*]pyridine* ***4.*** A mixture of **1** (1.68 g, 0.01 mol) and triethyl orthoformate (2.0 g, 0.014 mol) was mixed with 30 ml of acetic anhydride and heated to reflux for 12 h with stirring. The reaction mixture was then poured into ice-water and stirred at room temperature to decompose the acetic anhydride and then extracted with chloroform. The chloroform layer was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was extracted with hexane. The hexane extract was evaporated and dried *in vacuo*. The residue was dissolved in absolute ethanol and then treated with dry ammonia. The ethanol solution was evaporated to dryness. The residue and **1** (0.84 g, 0.005 mol) and were dissolved into HMPA (10 ml). The solution was heated at 150 °C for 5 h under nitrogen atmosphere. It was cooled to room temperature to precipitate a solid product, which was filtered, washed with ethanol, and recrystallized from dioxane to give purified **4**.

Attempted Reaction of ***2*** *with Formamide.* A mixture of **2** (0.795 g, 0.0025 mol) and formamide (9.5 ml, 0.23 mol) was heated at 150 °C for 3 h. After cooling the reaction mixture, the precipitate was filtered and washed with methanol. 0.771 g (97%) of the unchanged **2** was recovered. The expected product **4** was not formed.

We are grateful to Prof. Y. Yukawa of Osaka University and Prof. S. Okumura for helpful discussions.

Micellar Effects on Base-Catalyzed Isomerization of Prostaglandin A_1 and Prostaglandin A_2

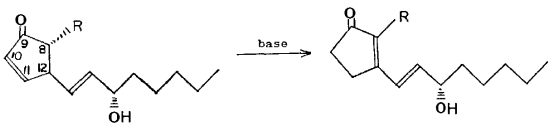
Kaneto UEKAMA, Fumitoshi HIRAYAMA, and Shyukou YAMASAKI

Faculty of Pharmaceutical Sciences, Kumamoto University, Oe-honmachi, Kumamoto 862

(Received August 25, 1977)

Synopsis. Micellar effects on base-catalyzed isomerization of A-type prostaglandins to B-type prostaglandins were studied. Cationic and non-ionic micellar systems increased the rate of isomerization, but anionic systems either decreased or had negligible effects on the rate constants. Incorporation of the prostaglandins into the hydrophobic interior of the micelles was suggested by circular dichroism spectra.

The enone moiety of A-type prostaglandins (PGA) is susceptible to isomerization in alkaline conditions to form B-type prostaglandins (PGB),[1] which consequently elicites the loss of biological activity.[2] It is well known that micellar systems influence the rate of various kinds of organic reactions, providing useful information about the reaction mechanism.[3] Thus, micellar effects on base-catalyzed isomerization of prostaglandin A_1 (PGA_1) and prostaglandin A_2 (PGA_2) were examined to better understand the nature of rearrangement reactions through substrate-surfactant interactions. The effect of surfactants on the circular dichroism (CD) spectra of PGA were also investigated, anticipating an incorporation of PGA into the hydrophobic interior of the micelles.



PGAs PGAs

PGA_1, PGB_1: $R=(CH_2)_6COOH$

PGA_2, PGB_2: $R=CH_2CH=CH(CH_2)_3COOH$

Experimental

Materials. The prostaglandins used were donated by the Ono Pharmaceutical Co., Ltd. Hexadecyltrimethylammonium chloride (CTAC), dodecyltrimethylammonium chloride (DTAC), sodium hexadecyl sulfate (NaCS), sodium dodecyl sulfate (NaLS), and poly(oxyethylene) dodecyl ether (Brij-35) were commercially obtained and purified using the usual methods.[4] All other materials and solvents were of analytical reagent grade.

Measurements. The CD and UV spectra were measured at 25 °C using a Jasco J-40 AS spectropolarimeter and a Shimadzu spectrophotometer, respectively, in a 0.1 M sodium phosphate buffer solution (pH 6.0). The CD spectra are expressed in terms of molar ellipticity, $[\theta]$. The critical micelle concentration (CMC) of the surfactants was determined spectrophotometrically[5] at 60 °C and at pH 11.2.

Kinetic Studies. The isomerization of PGA (3.8×10^{-5} M) in the presence and in the absence of surfactants was followed spectrophotometrically by measuring the apparence of PGB (284 nm) at 60 °C. The first-order dependence of the rate constants on the hydroxide ion concentration was ascertained for both PGA_1 and PGA_2, for an activation energy of 18.7 kcal/mol at pH 12.0.[6] The pH profile of the logarithm of the rate constant (k_{obsd}) for both PGA_1 and PGA_2 is linear with a slope of 0.75 from pH 9.5 to 12.0. No appreciable change in the slope was observed even in the presence of surfactants.

-○-: CTAC, -●-: NaLS, -△-: Brij-35.

Results and Discussion

As is shown in Fig. 1, cationic and non-ionic surfactants enhanced the isomerization rates, but anionic surfactants either decreased or had negligible effects on the rate constants above the CMC values. The results for ionic micellar systems suggest the development of an anionic charge on the cyclopentanone ring of PGA during the rate-determining step. It was also noted that activation of the base (toward C–H proton abstraction) in cationic micelles becames greater with increasing hydrophobic chain length of the surfactant. The observed rate constant (k_{obsd}) as a function of surfactant concentration was quantitatively evaluated[7] to yield the non-micellar (k_o) and micellar (k_m) rates, and the K/N value of the PGA-micelle complex. As is shown in Table 1, the K/N values of the PGA_1 system are larger than those of the PGA_2 system. This may be due to the greater hydrophobic tendency of PGA_1 compared to PGA_2, as is expected from their partition coefficients.[8]

Figure 2 shows the CD spectra of the PGA_1–CTAC system, as an example, where PGA_1 exhibits a strong positive band at 238 nm ($[\theta]=6.10\times10^4$) and a weak negative band at 314 nm ($[\theta]=-9.21\times10^3$) due to the π-π^* and n-π^* transitions of the enone chromophore, respectively.[9] When CTAC micelles were introduced into the PGA_1 solution, the positive peak was shifted to shorter wavelengths (by about 3 nm) and the negative

Table 1. Kinetic parameters for micellar effect on isomerization of PGA at pH 11.2 and at 60 °C

Substrate			Micellar system			
	Partition[a] coefficient	k_o (min^{-1})		CMC ($\times 10^3$ M)	k_m (min^{-1})	K/N[b] (M^{-1})
			CTAC	0.12	0.15	5000
			DTAC	1.7	0.12	590
PGA_1	80.8	0.038	NaCS	0.14	0.034	—[c]
			NaLS	2.1	0.011	110
			Brij-35	0.75	0.12	220
			CTAC		0.17	3900
			DTAC		0.14	470
PGA_2	69.4	0.044	NaCS		0.041	—[c]
			NaLS		0.012	97
			Brij-35		0.14	190

a) Determined between chloroform and 0.1 M phosphate buffer of pH 6.0 at 25 °C. b) K: association constant of PGA-micelle complex, N: aggregation number of micelle. c) Could not be determined due to a small change in the rate constant.

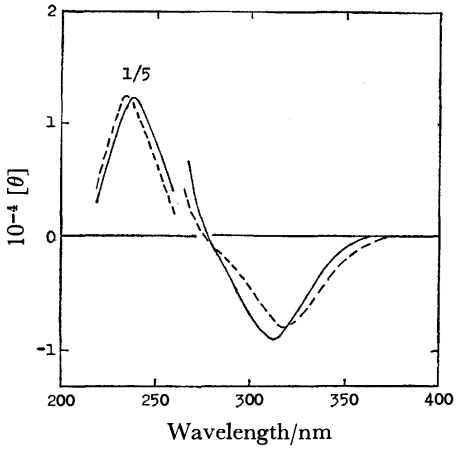

Fig. 2. The CD spectra of PGA_1 in the presence (——) and absence (——) of CTAC (1.0×10^{-3} M) in 0.1 M phosphate buffer (pH=6.0, μ=0.2) at 25°.

peak was shifted to longer wavelengths (by about 8 nm). The effect of other surfactants on the CD spectra of PGA are similar to that of the PGA_1–CTAC system, for which the magnitude and direction of the spectral changes appears to be correlated with the association constants of PGA-micelle complexes. Similar spectra changes were also observed when PGA were dissolved in less polar solvents, such as ethanol-buffer and dioxane-buffer solutions. This type of spectral shift, the bathochromic shift of the π-π^* transition and the hypsochromic shift of the n-π^* transition with decreasing solvent polarity, is a well-known solvent effect in CD spectroscopy. Thus, the above results indicate that the chromophore of the PGA may be located in the hydrophobic circumstances of the micelles.

The rate enhancement observed for non-ionic micellar systems, however, cannot be interpretable soley on the basis of hydrophobic interactions. It was found that α- and β-cyclodextrins increase the isomerization rate with almost the same order of magnitude as dose Brij-35 in alkaline conditions,[10] for which the catalytic effects of cyclodextrins may be ascribed mainly to conformational changes of the substrate within the hydrophobic cavity of cyclodextrins and/or to alternations in the structure of the surrounding water.[11] An analogous situation is proposed for PGA-non-ionic micellar systems.

Analysis of the NMR Line Shape Dually Modulated by the Chemical Exchange and by the Scalar Coupling Relaxation. ^{13}C NMR Spectrum of the Trimethylaluminum Dimer

Osamu YAMAMOTO and Masaru YANAGISAWA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received September 12, 1977)

Synopsis. ^{13}C methyl signals of the trimethylaluminum dimer, broadened by the chemical exchange and the scalar coupling interaction with ^{27}Al, were analyzed in order to obtain the rates of the bridge-terminal exchange of the methyl groups. The exchange rates were compared with those obtained from the ^{1}H resonance, and a good agreement was obtained. A brief discussion is given of some advantages and difficulties of the analysis.

It is well known that the alkyl groups of the trialkylaluminum dimer undergo a rapid exchange between the bridge and the terminal positions at ambient temperature. This exchange in the trialkylaluminum dimer has been studied extensively by ^{1}H and ^{13}C NMR spectroscopies, and the Arrhenius parameters for the exchange have been calculated.[1,2] In a previous paper[3] we have shown that, even within the slow-exchange limits, the ^{13}C signals of the methyl groups in the trimethylaluminum (TMA) dimer are broadened by the scalar coupling between the ^{13}C and ^{27}Al nuclei, which is modulated by the rapid quadrupole relaxation of the Al nucleus. By analyzing the line shape of the ^{13}C signals and using the relaxation time of ^{27}Al, we were able to obtain the scalar coupling constant between ^{13}C and ^{27}Al (J_{C-Al}) within the slow-exchange limits. In this exchanging system, under the rapid and intermidiate exchange conditions, the signals of the ^{13}C nuclei directly bonded to Al are dually modulated by two time-dependent effects, *i.e.*, the chemical exchange and the scalar coupling with ^{27}Al, in which situation the analysis of the NMR line shape is rather complicated. However, if one of the effects of the interactions on the line shape could be accurately known, we would have the possiblity of obtaining information on the other interaction by analyzing the line shape. In the present note, as an example of the line-shape analysis under such circumstances, the methyl carbon signal of TMA is studied to obtain exchange rates at various temperatures, with the ^{27}Al relaxation rates and J_{C-Al} known, and the exchange rates thus obtained are compared with those obtained from the ^{1}H resonance.

The ^{1}H and ^{13}C spectra were recorded on a NEVA NV-14 spectrometer at 60 and 15.1 MHz respectively. The sample concentration is *ca.* 10% of TMA in cyclopentane-d_{10}. The other experimental details are the same as those reported in a previous paper.[3]

The expressions for the NMR intensities at the frequency of ω under the influence of the chemical exchange and the scalar coupling relaxation have the same form,[4] both given by

$$I(\omega) = Re[\mathbf{W}\cdot\mathbf{A}^{-1}\cdot\mathbf{1}], \quad (1)$$

where the vector $\mathbf{W}$ has components proportional to the populations, $\mathbf{1}$ is a unit column vector, and *Re* means the real part. For the methyl signals of TMA undergoing the bridge-terminal exchange, $\mathbf{A}$ has the form:

$$\mathbf{A} = i(\mathbf{\Omega}-\omega\mathbf{E}) + \mathbf{Q} + \mathbf{K}, \quad (2)$$

in which $\mathbf{\Omega}$ is the diagonal matrix whose elements are the chemical shifts of each site, and $\mathbf{E}$, the unit matrix. $\mathbf{Q}$ and $\mathbf{K}$ are the matrices representing the effects of the scalar coupling relaxation and the chemical exchange respectively, and are further decomposed as

$$\mathbf{Q}+\mathbf{K} = \begin{pmatrix} \mathbf{Q}^{b}+\mathbf{K}_1{}^{b} & \mathbf{K}_2{}^{b} \\ \mathbf{K}_2{}^{t} & \mathbf{Q}^{t}+\mathbf{K}_1{}^{t} \end{pmatrix}, \quad (3)$$

where the superscripts b and t refer to the bridge and the terminal positions respectively. $\mathbf{Q}^{b}$, $\mathbf{K}_1{}^{b}$, *etc.* are also matrices whose components are referred to the ^{13}C lines which would be split by ^{27}Al if the scalar relaxation mechanism were absent. The detailed expressions for $\mathbf{Q}^{b}$, $\mathbf{Q}^{t}$ and $\mathbf{W}$ of TMA were presented in the previous paper.[3] $\mathbf{Q}$ contains information about the J_{C-Al} and ^{27}Al relaxation times, conversely, if the two quantities are known, the line shape of ^{13}C under the influence of the scalar relaxation can be calculated.

$\mathbf{K}_1{}^{b}$ and $\mathbf{K}_1{}^{t}$ are simple diagonal matrices whose diagonal elements are $-1/\tau_b$ and $-1/\tau_t$ respectively. τ_b and τ_t are the life-time of the methyl group at the bridge and the terminal positions respectively, and $2\tau_b=\tau_t$, since the population at the bridge position is one-half of that of the terminal. $\mathbf{K}_2{}^{b}$ and $\mathbf{K}_2{}^{t}$ correspond to the off-diagonal parts of the kinetic transfer matrix, $\mathbf{A}$, in the usual expression for the exchanging system. In constructing $\mathbf{K}_2{}^{b}$ and $\mathbf{K}_2{}^{t}$, we assume that the exchange process is "intramolecular"[2] and one bridge bond is broken during the exchange. Thus, the methyl carbon at the terminal position which sees the ^{27}Al spin state of, say, $\left|\frac{5}{2}\right>$ goes to the bridge position at which the methyl carbon coupled with two Al nuclei, and sees one of the six composite ^{27}Al spin states; $\left|\frac{5}{2}\right>\left|\frac{5}{2}\right>$, $\left|\frac{5}{2}\right>\left|\frac{3}{2}\right>$, ... $\left|\frac{5}{2}\right>\left|-\frac{5}{2}\right>$. Thus, the elements of the corresponding column in the corresponding row of $\mathbf{K}_2{}^{t}$ have the values of $1/6\tau_t$, and the other elements of the row are 0. The bridge carbon, after exchange, goes to a site which corresponds to one of the spin states of ^{27}Al with which the bridge carbon couples before exchange. (For example, from the site of $\left|\frac{5}{2}\right>\left|\frac{3}{2}\right>$ to either $\left|\frac{5}{2}\right>$ or $\left|\frac{3}{2}\right>$ but from the site of $\left|\frac{5}{2}\right>\left|\frac{5}{2}\right>$ only to the site of $\left|\frac{5}{2}\right>$.) Consequently, $\mathbf{K}_2{}^{b}$

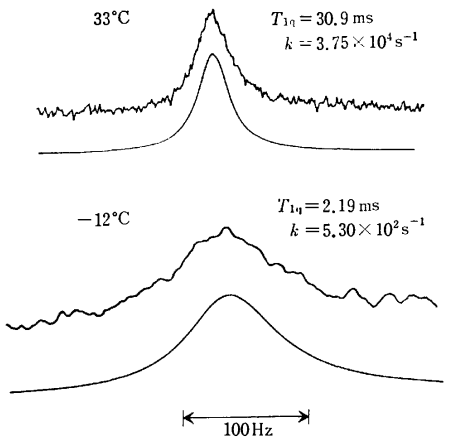

Fig. 1. Observed and calculated ^{13}C spectra of TMA at various temperature. The chemical shift difference between the bridge and the terminal carbons is 60 Hz at 15.1 MHz.

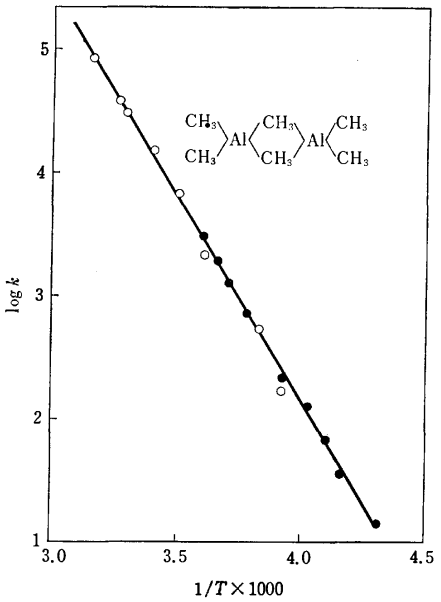

Fig. 2. Arrhenius plot of the exchange rates in TMA. ● from the ^{1}H resonance and ○ from the ^{13}C resonance. The straight line was obtained by the least squares fit of only the ^{1}H resonance data. The Arrhenius parametrs obtained from both ^{1}H and ^{13}C data are $E_a=15.2\pm0.8$, $\Delta H^*=14.6\pm0.8$, $\Delta G^*=11.6\pm0.1$ kcal /mol, and $\Delta S^*=10.0\pm2.0$ e.u. at 25 °C. These are in good agreement with literature valaues.[1,2]

has the elements $1/\tau_t$, $1/2\tau_t$ or 0. In this way, the matrices $\mathbf{K}_2{}^b$ and $\mathbf{K}_2{}^t$ can be easily constructed.

The rate constant for the exchange $k=1/\tau_b$ can be calculated from Eq. 1 by a visual fitting of the observed spectra with the calulated ones in a try-and-error method if the coupling constant, J_{C-Al}, and the ^{27}Al relaxation time, T_{1q}, are known. The J_{C-Al}'s in TMA were found to be 19 and 110 Hz for the bridge and the terminal carbons respectively, and the ^{27}Al relaxation time, T_{1q}, were obtained from the line-widths of the ^{27}Al resonance lines.[3]

The results obtained are shown in Figs. 1 and 2. The exchange rates were also obtained from the ^{1}H resonance, for which the usual line-shape analyses were carried out. It can be seen from Fig. 2 that the exchange rates obtained from the ^{13}C resonance fit well with the straight line which is obtained from the ^{1}H resonance, particularly in the higher temperature range. Thus, the procedure presented here, though complicated in its calculation, can be successfully used to obtain the exchange rates with an accuracy comparable with that of the usual line-shape analysis when the latter method cannot be employed. The results obtained in this work also provide a cross-check on the validity of the method and the accuracy in the values of the J_{C-Al}'s in TMA reported in the previous paper.[3]

A difficulty in the line-shape analysis mentioned above arises from the different NOE-enhancement factors for the bridge and the terminal carbons in the ^{1}H decoupled ^{13}C spectra. The intensity ratio of the terminal to the bridge carbons is about 1.8 at −70 °C (at the slow-exchange limit). This indicates that the NOE factor for the bridge carbon is larger than that of the terminal. Since the J_{C-Al} is smaller in the bridge than in the terminal carbon, the contribution of the scalar coupling mechanism to the relaxation rate of ^{13}C is smaller, and thus that of the dipole-dipole interaction is larger, in the bridge carbon than in the terminal, which leads to the larger NOE factor in the bridge carbon. Therefore, the spectra calculated without taking account of the difference in the NOE factor will not agree with the observed one.

Indeed, this is the case for the spectra with intermediate and slow exchange rates (below *ca.* −30 °C). However, the difference in the NOE factor can be assumed to be negligible provided that the exchange rate is much faster than the ^{13}C relaxation rates, because the redistribution of the spin population among the various energy levels, which causes the NOE factors to be different, does not occur during the short life-time at each site. Thus, Eq. 1 can be safely employed in the high-temperature range.

Note that, in the ^{1}H resonance, the line-widths at temperatures of 10 °C or higher are too narrow to obtain accurate values of the exchange rates. In the ^{13}C resonance, however, the line-widths are sufficiently wide at room temperature because of the scalar coupling interaction, and accurate values are obtained in the high-temperature range, in which the ^{1}H resonance cannot be applied for the TMA system. This is another advantage of the present method.

The Reactions of the $(ZrO)_2P_2O_7$-NiO System and the ZrP_2O_7-NiO System

Makio KINOSHITA, Saburo BABA,* Akira KISHIOKA, and Michio AMAGASA**

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo 102

(Received July 1, 1977)

Synopsis. The reaction between $(ZrO)_2P_2O_7$ and NiO at elevated temperatures up to 1340 °C yielded $Ni_3(PO_4)_2$ and ZrO_2 over the whole composition. The reaction between ZrP_2O_7 and NiO yielded $NiO \cdot 4ZrO_2 \cdot 3P_2O_5$ and $Ni_3(PO_4)_2$ in the molar ratios up to equimolarity.

The ternary ZrO_2–CaO–P_2O_5 system was investigated by Bremser,[1] who reported the formation of $CaZr(PO_4)_2$ in the reaction of ZrP_2O_7 with $CaCO_3$. Recently, Šljukić *et al.* obtained the compound $M^{I}M_2'^{IV}(PO_4)_3$ (M=alkali metal and M'=Zr, Ti, Th, and U) by reacting the quadrivalent metal oxide with the alkali metal phosphate in the presence of B_2O_3 flux and investigated these compounds crystallographically.[2] They found that only $NaTh_2(PO_4)_3$ among these compounds showed piezoelectricity.[3] More recently, Allulli *et al.* prepared $ZrM(PO_4)_2 \cdot 4H_2O$ ($M=Mn^{II}$, Co^{II}, NiO^{II}, Cu^{II}, and Zn^{II}) by treating ionexchangeable $ZrHNa(PO_4)_2 \cdot 5H_2O$ with bivalent metal ions and obtained anhydrous phosphates $MZr(PO_4)_2$ by heating the resultant phosphates at higher temperature. These phosphates showed X-ray diffraction patterns similar to those of $CaZr(PO_4)_2$.[4]

However, few studies have been reported concerning the reaction of $(ZrO)_2P_2O_7$ and ZrP_2O_7 with other metal oxides, so the investigation of these reactions will be of interest.

Experimental

Materials. ZrP_2O_7 was prepared by a method similar to that used by Amphlett *et al.*[5] Zirconium phosphate gel was precipitated by adding 1.0 mol dm^{-3} H_3PO_4 to 0.4 mol dm^{-3} $ZrO(NO_3)_2$ solution containing 0.1 mol dm^{-3} HNO_3, the molar ratio of PO_4/Zr being 2.5. The gel was calcined at 1050 °C for 5 h. $(ZrO)_2P_2O_7$ was obtained by calcining ZrP_2O_7 at about 1600 °C for 1 h in a propane-oxygen furnace.

The calcined powder of ZrP_2O_7 and $(ZrO)_2P_2O_7$ was separately pulverized to particles under 74 μm in diameter with an agate ball mill. The purity of these materials was 99.5 wt% or more.

NiO was prepared by calcining nickel hydroxide, which was obtained by mixing 0.5 mol dm^{-3} $Ni(NO_3)_2$ solution with an excess of 0.5 mol dm^{-3} NaOH solution. The nickel hydroxide was calcined at 300 and 600 °C for 3 h.

Reactions at the Contact Surface of One-paired Tablets. The specimen powder was pressed into a tablet of 20 mm in diameter by about 5 mm in thickness under a pressure of 500 kg cm^{-2}. The NiO-tablet was placed on a $(ZrO)_2P_2O_7$-tablet and was heated for 24 h at 1200 °C in a SiC-furnace. After these tablets were removed from the furnace, the reaction products in the surface layers of the tablets were scraped off and examined by X-ray powder diffractometry. ZrP_2O_7 and NiO tablets were similarly heated at 1000 °C for 24 h.

Reactions in the Mixtures of Various Concentrations. The mixture of $(ZrO)_2P_2O_7$ and NiO or that of ZrP_2O_7 and NiO was wet with acetone and thoughly mixed for 30 min in an agate mortar. Then the mixture was pressed under a pressure of 500 kg cm^{-2} to form tablets weighing 0.3 g (10 mm in diameter and about 1.5 mm in thickness). The molar fraction of NiO in both systems was varied from 0.1 up to 0.9 at intervals of 0.1. The tablets were heated at 1200 °C for 24 h. The reaction products in the samples were determined by X-ray diffraction analysis.

Equimolar powder mixtures of both systems were subjected to DTA (heating rate: 10 °C/min, in air).

Isolation and Chemical Analysis of the Reaction Product Insoluble in HCl. The equimolar mixture of ZrP_2O_7 and NiO was heated at 1100 °C for 24 h and for an additional hour at 1400 °C. After $Ni_3(PO_4)_2$ was dissolved by boiling with 6 mol dm^{-3} HCl for 1 h, ZrO_2 in the insoluble residue was removed by flotation with 0.04 mol dm^{-3} sodium lauryl sulfate solution. The final residue thus obtained could not be identified from the known data. The P_2O_5, ZrO_2, and NiO in this unknown product were gravimetrically determined as $Mg_2P_2O_7$,[6] ZrO_2,[7] and bis(dimethylglyoximato)nickel(II)[8] respectively.

Results

Products. In the products of all systems, $Ni_3(PO_4)_2$ and monoclinic ZrO_2 were found. Nickel orthophosphate agreed with the compound existing in the NiO–P_2O_5 binary phase diagram.[9] The chemical formula of the unknown product was $NiO \cdot 4ZrO_2 \cdot$

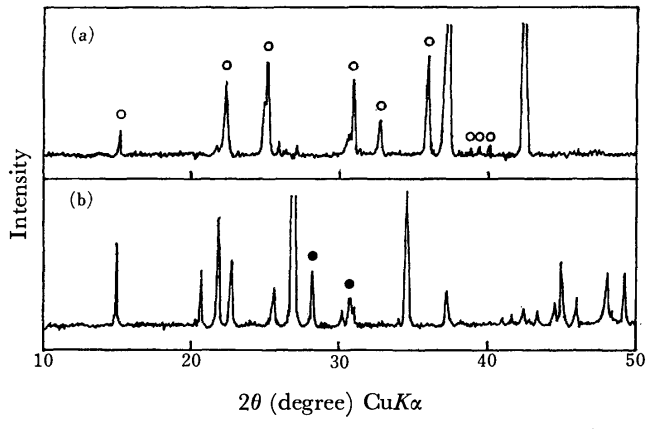

Fig. 1. X-Ray powder diffraction patterns of the surface layer of (a) NiO and (b) $(ZrO)_2P_2O_7$ tablet. (1200 °C). (a) ○: $Ni_3(PO_4)_2$, no mark: NiO, (b) ●: ZrO_2 (monoclinic), no mark: $(ZrO)_2P_2O_7$.

** Present address: Zengyo, Fujisawa-shi, Kanagawa 251.

$3P_2O_5$ or $NiZr_4(PO_4)_6$ (Found: NiO, 7.77; ZrO_2, 48.88; P_2O_5, 43.77 wt %. Calcd: NiO, 7.52; ZrO_2, 49.60; P_2O_5, 42.88 wt %). The color of this substance was purple-red. The X-ray powder diffraction pattern of this substance was quite different from that of $NaZr_2(PO_4)_3$ or $CaZr(PO_4)_2$.[10]

Reactions at the Contact Surface of One-paired Tablets. $(ZrO)_2P_2O_7$–NiO System: X-Ray diffraction patterns of the surface layers of pair of NiO–$(ZrO)_2P_2O_7$ tablets are shown in Fig. 1. The $Ni_3(PO_4)_2$ was formed in the surface layer of the NiO-tablet and ZrO_2 in that of the ZrP_2O_7-tabelt. Hence, the reaction in each tabelt can be represented by the following equations:

$$(ZrO)_2P_2O_7 \longrightarrow 2ZrO_2 + P_2O_5, \quad (1)$$

$$3NiO + P_2O_5 \longrightarrow Ni_3(PO_4)_2. \quad (2)$$

This result is similar to that for the MgO–$Mg_2P_2O_7$ system reported by Jagisch and Bengtson, that is, $Mg_3(PO_4)_2$ was formed in the surface layer of the MgO-tablet by the cross diffusion of P_2O_5.[11]

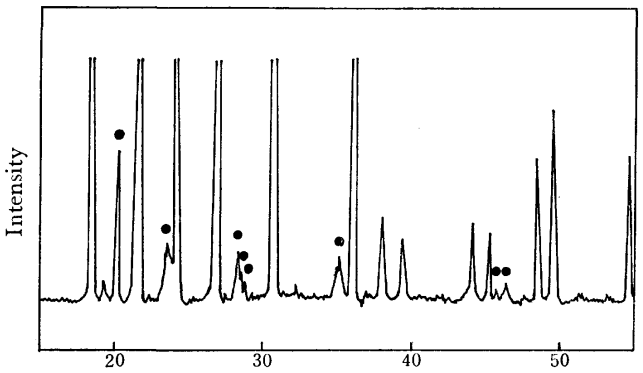

Fig. 2. X-ray diffraction pattern of the surface layer of ZrP_2O_7 tablet. (1000 °C).
●: $NiO \cdot 4ZrO_2 \cdot 3P_2O_5$, no mark: ZrP_2O_7.

ZrP_2O_7–NiO System: X-Ray diffraction pattern of the surface layer of the ZrP_2O_7-tablet is shown in Fig. 2. In the surface layer of the NiO-tablet, $Ni_3(PO_4)_2$ was formed as shown in Fig. 1(a). The $NiO \cdot 4ZrO_2 \cdot 3P_2O_5$ was formed in the surface layer of the ZrP_2O_7-tablet. Accordingly, this reaction proceeded *via* inter-diffusion. The reaction in each tablet can be represented by the following equations:

$$4ZrP_2O_7 + NiO \longrightarrow NiO \cdot 4ZrO_2 \cdot 3P_2O_5 + P_2O_5, \quad (3)$$

$$3NiO + P_2O_5 \longrightarrow Ni_3(PO_4)_2. \quad (4)$$

Reactions in the Mixtures of Various Concentrations. In the $(ZrO)_2P_2O_7$–NiO system, $Ni_3(PO_4)_2$ and ZrO_2 were formed over the whole composition, although the maximum in the formation of these products were found at the $NiO/(ZrO)_2P_2O_7$ ratio of 3. In the ZrP_2O_7–NiO system, the formation of $NiO \cdot 4ZrO_2 \cdot 3P_2O_5$ increased with the increasing molar ratio up to unity. When the ratio of NiO/ZrP_2O_7 exceeded one, $NiO \cdot 4ZrO_2 \cdot 3P_2O_5$ was not formed, but $Ni_3(PO_4)_2$ and ZrO_2 were formed. In the reaction of the equimolar mixture, $NiO \cdot 4ZrO_2 \cdot 3P_2O_5/Ni_3(PO_4)_2$ was nearly equal to unity. Accordingly, the reaction can be represented by the following equation:

$$4ZrP_2O_7 + 4NiO \longrightarrow NiO \cdot 4ZrO_2 \cdot 3P_2O_5 + Ni_3(PO_4)_2 \quad (5)$$

DTA thermograms of both systems of the equimolar mixture showed a broad exothermic peak ranging between 800 and 1150 °C and a sharp endothermic peak at 1340 °C. The former was attributed to the formation of certain reaction products and the latter to the elutectic point[9] of $Ni_3(PO_4)_2$ and NiO. A small endothermic peak at 300 °C in the ZrP_2O_7–NiO system was due to the structural conversion[12] of ZrP_2O_7 from cubic to tetragonal.

The Anodic Voltammetry of Deoxyribonucleic Acid at a Glassy Carbon Electrode

Toshio YAO, Tamotsu WASA, and Soichiro MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozuumemachi, Sakai 591

(Received July 6, 1977)

Synopsis. Deoxyribonucleic acid was oxidized in two steps at a glassy carbon electrode. The peak currents had the characteristics of adsorption currents, but if the surface of the electrode was not fully covered by the adsorbed polynucleotide molecule the peak currents had rather the characteristics of diffusion-controlled currents.

Electrochemical methods have been used for the investigation of the chemical and physical properties of solutions of deoxyribonucleic acids (DNA). It has been established that two of the four bases usually found in every DNA, adenine and cytosine, are reducible at the dropping mercury electrode, both in a free form[1-3] and bound to the nucleotide chain.[4-6] However, the two reducible bases are reduced only in a pH range where they are converted to the protonated form,[7] and their half-wave potentials are very close.

A few studies of the electrochemical oxidation of the purine bases were done at the pyrolytic graphite electrode[8-10] and the glassy carbon electrode (GCE).[11] Guanine and adenine, which are constituent bases of DNA, were voltammetrically oxidized at different potentials over the pH range of 0—14. In the present work, the electrochemical oxidation of DNA and its adsorption behavior on the electrode surface were investigated by means of a linear-sweep voltammetry using a stationary GCE.

Experimental

Chemicals. The herring-sperm DNA used throughout this work was obtained from the Wako Pure Chemical Co. All the other reagents were of a reagent grade.

Apparatus. The anodic voltammograms were recorded using a Yanagimoto P-8 type Polarograph at a scan rate of 3.3 mV/s. A three-electrode voltammetric cell maintained at (20±0.1) °C was used for all the experiments. An aqueous saturated calomel electrode (SCE) was used as the reference electrode, and a platinum wire served as the counter electrode. The working electrode was constructed from a glassy carbon rod 3 mm in diameter (Grade GC-20, Tokai Electrode Co.). The rod was cut into a length of 10 mm and was sealed in one end of a glass tube 3 mm in diameter with epoxy cement. The end of the glass tube-carbon rod assembly was polished with 400-grade emery paper until it was quite smooth.

Voltammetric Procedure. In order to obtain reproducible results, a standard pretreatment procedure was applied before recording each voltammogram. The GCE was polished for 30 s with 1500-grade emery paper, and then for 60 s with a paste of sedimented calcium carbonate. The surface of the electrode was washed with a fine spray of distilled water. Any water remaining on the electrode surface was then removed by touching the surface very gently with a piece of soft absorbent paper. The test solutions were not deaerated. The GCE was inserted into the test solutions, and then the solutions were stirred gently for a few seconds. The voltage scan was commenced after quiescency for 20 s at the starting potential (always 0.0 V *vs.* SCE). At least three replicate voltammograms were recorded for each test solution.

Results and Discussion

Figure 1 shows the typical anodic voltammograms of DNA obtained at the stationary GCE. The voltammetric oxidation of DNA took place in two steps; the first and second peaks can be attributed to the oxidation of the guanine and adenine contained in the DNA molecules. The half-peak potentials ($E_{P/2}$) of the voltammetric oxidation peaks shifted linearly towards negative potentials with an increase in the pH; $E_{P/2}$(*vs.* SCE)/V= 1.06−0.060 pH for the first peak and $E_{P/2}$(*vs.* SCE)/V= 1.41−0.065 pH for the second peak over the pH range of 2—12. The peak current (i_P) did not change much with the pH.

DNA concentration; 0.4 mg/ml, GCE geometric area; 7.1 mm², scan rate; 3.3 mV/s.

As is shown in Fig. 2, the peak current reached a limiting value as the DNA concentration was increased, but in the concentration range below 0.8 mg/ml a linear relationship was observed between the peak current and the concentration. This behavior is probably connected with the coverage of the GCE surface by polynucleotide molecules. Also, the peak potentials for both peaks were dependent on the DNA concentration and shifted slightly to more positive values with the increase in the concentration. Over the concentration range of 0.1—1 mg/ml this shift was about 30—50 mV for both peaks.

In order to study the adsorption of DNA on the GCE surface, the effect of the voltage scan rate on the peak

current was examined. The electrochemical oxidation of DNA was irreversible; cyclic voltammetric experiments have shown that no cathodic peak corresponding to the rereduction of the oxidation product was observed at any scan rate. For a linear diffusion-controlled irreversible peak, the peak current function, $i_P/ACV^{1/2}$, should be a constant,[12] and a plot of this function *vs.* $V^{1/2}$ should be a straight line parallel to the $V^{1/2}$ axis, where A is the area of the electrode surface; C, the bulk concentration of the depolarizer, and V, the scan rate. At the various pH values, the peak current functions of both peaks were almost independent of the scan rate. However, at DNA concentrations higher than 1.0 mg/ml the peak current functions of the two peaks of DNA clearly increased with the increase in the scan rate. This behavior is typical of an electrode process where the reactant is adsorbed on the electrode.[13]

These effects of the concentration and the scan rate on the peak current imply that the voltammetric oxidation of DNA takes place in the adsorbed state on the surface of the electrode. The peak currents of DNA have the characteristics of adsorption currents when the surface of GCE is fully covered by adsorbed polynucleotide molecules. However, if the surface is not fully covered, the peak currents have rather the characteristics of diffusion-controlled currents.

In the DNA molecule, the number of guanine equals the number of cytosine, while the number of adenine equals that of thymine (Chargaff's rule). Thus, the ratio of the sum of the voltammetrically active groups of adenine and guanine to the sum of the nonactive groups of cytosine and thymine is approximately one. The herring-sperm DNA contained 14.5% (mass fraction) of guanine and 16.7% of adenine. The value of the diffusion coefficient of guanine was 1.22×10^{-5} cm²/s. The value of the diffusion coefficient of DNA, which was determined from the peak current of the guanine contained in DNA, was 7.3×10^{-7} cm²/s. Also, the value of the diffusion coefficient of DNA, computed with the aid of the Einstein-Stokes law, was 3.6×10^{-7} cm²/s,[4] from the presumed value of the molecular weight of 1×10^{6}.

The Nitrogen Oxide Complex of the Iron(II) Protoporphyrin IX Dimethyl Ester

Tetsuhiko YOSHIMURA

The Environmental Science Institute of Hyogo Prefecture, Suma-ku, Kobe, Hyogo 654

(Received July 22, 1977)

Synopsis. A nitrogen oxide complex of the iron(II) protoporphyrin IX dimethyl ester was synthesized and characterized by means of its infrared spectrum and electron paramagnetic resonance (EPR) spectra at the X- and Q-band frequencies. The EPR spectra in the glass state and in the polycrystalline powder state distinctly indicated the existence of three *g*-values, showing a rhombic symmetry.

Since the nitrogen oxide molecule has an unpaired electron and coordinates to iron(II) hemoproteins, it has been widely used as a probe for investigating the symmetry around the heme iron and the electronic structure of the heme group.[1] The nitrogen oxide complex of the iron(II) protoporphyrin IX dimethyl ester, ONFe(PPDME), is an interesting model compound in relation to such nitrosylhemoproteins.

TABLE 1. IR DATA OF ONFe(PPDME) (in cm^{-1})

Method or solvent	Dielectric constant	Strteching frequency	
		CO (ester)	NO
Nujol mull		1739	1656
KBr disk		1735	1655
CCl_4	2.24	1743	1684
Benzene	2.28	1741	1672
Toluene	2.38	1739	1673
$CHCl_3$	4.81	1732	1675
CH_2Cl_2	7.77	1735	1669
$ClCH_2CH_2Cl$	10.7	1737	1665
N-Methyl imidazole		1735	1616

Table 1 shows the infrared stretching frequencies of the NO (ν_{NO}) and carbonyl groups (ν_{CO}) at the porphyrin periphery for ONFe(PPDME). The ν_{NO} values, measured by the KBr disk technique, are smaller than those for nitrosyltetraphenylporphinatoiron(II), ONFe(TPP),[2] and nitrosyloctaethylporphinatoiron(II)[3] (1670 and 1671 cm^{-1} respectively). In addition, the ν_{NO} value in *N*-methylimidazole (NMIm), which occupies an axial position *trans* to the nitrosyl group, is smaller than that (1625 cm^{-1}) for ONFe(TPP)(NMIm),[4] while it is nearly identical with that (1615 cm^{-1}) for nitrosylhemoglobin (NOHb),[5] in which the imidazole group of proximal histidine is a *trans* axial ligand. Thus, differences in substituents on the porphyrin periphery affect the NO stretching mode for the nitrosyl porphyrin Fe(II) complex. As is shown in Table 1, the ν_{CO} and ν_{NO} values are sensitive to the solvent. Contrary to the case of the ν_{CO} value, the ν_{NO} value shifts essentially to a lower frequency with an increase in the polarity of the solvent, in agreement with the results of Maxwell and Caughey.[5] Such a solvent effect may reflect a considerable degree of polarization in ONFe(PPDME) resulting from the delocalization of the unpaired electron of the nitrosyl group and the d_π–p_π back bonding.[6]

The X-band EPR spectra in the acetone, dichloromethane, and toluene glass states distinctly indicate the existence of three *g*-values, suggesting a bending of the Fe–N–O unit and rhombic symmetry (Fig. 1 and Table 2). In chloroform glass and polycrystalline powder states, the three *g*-values can not be estimated from the X-band spectra, but they can from the Q-band spectra (Fig. 2). As is shown in Table 2, the *g*-values in the glass state for ONFe(PPDME) are comparable to those for ONFe(TPP),[7] while the coupling constants of the ^{14}N hyperfine splitting (hfs) for the former are slightly smaller than those for the latter. From the facts that the observed g_3-value is essentially equal to the free spin value and that the hfs of NO nitrogen is clearly

a) RT, room temp; LNT, liquid nitrogen temp; Q, measured at the Q-band freq.

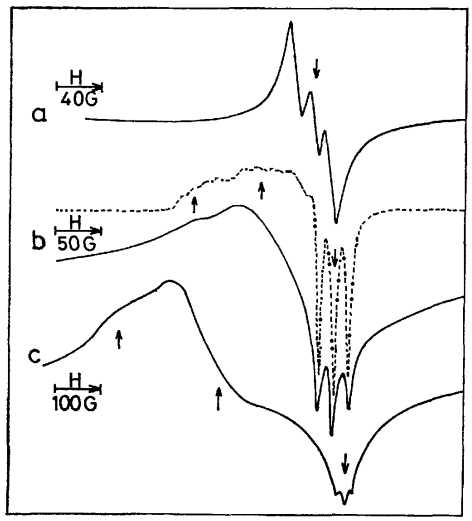

Fig. 1. EPR spectra for ONFe(PPDME) in $CHCl_3$ (——) and in acetone (——): (a) X-band spectra at room temp (soln); (b) X- and (c) Q-band spectra at liq N_2 temp (frozen glass).

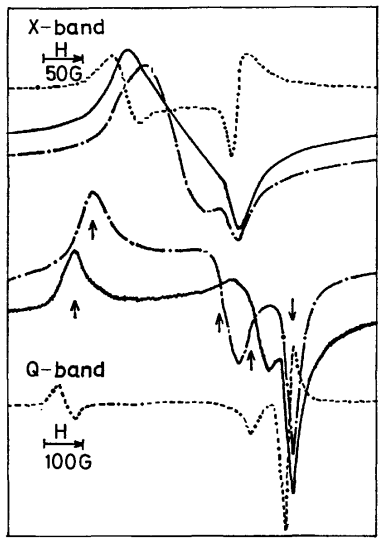

Fig. 2. X- and Q-band EPR spectra for ONFe(PPDME) in polycrystalline powder state at room temp (-•••-, lst derivative) and at liq N_2 temp (——, lst derv.;----, 2nd derv.).

resolved at g_3 absorption, it may be inferred that the g_3 absorption is to be assigned to the g_z absorption and that the unpaired electron of the nitrosyl group is considerably delocalized to the iron d_{z^2} orbital. The g-values for ONFe(PPDME) are found to vary with the experimental conditions, such as the temperature and the powder or solution states, and, among the rest, the g_2-value is especially highly sensitive to such conditions. The g_y-value for NO-protoheme complexes with different nitrogenous bases has been reported to be particularly sensitive to the kind of base.[6] The g_y-value for the $(d_{z^2})^1$ configuration is dependent on the energy separation between d_{z^2} and d_{xz} orbitals and the electron population in each orbital.[8] Thus, the energy and the electron population of the d_π orbital can be expected to be sensitive to environments around Fe–N–O unit in the nitrosylprotoheme complexes.

It has been found that, upon the addition of inositol hexaphosphate (IHP) to NOHb, the hfs from imidazole ^{14}N of proximal histidine (N_ε) is weakened and that from ^{14}NO is intensified.[9] The coupling constant (16.5 G) and the g-value (about 2.0) of the central peak for the ^{14}NO triplet in IHP-treated NOHb are nearly identical with those of ONFe(PPDME) in the glass state, showing that the structure of the nitrosylprotoheme in IHP-treated NOHb is similar to that of ONFe(PPDME). These EPR results suggest that the Fe–N_ε bond in IHP-treated NOHb is stretched or cleaved.[5]

Experimental

Synthesis. ONFe(PPDME) was synthesized by a procedure analogous to that used for ONFe(TPP).[2] One gram of ClFe(PPDME) was added to a chloroform(10 ml)–dry pyridine(1 ml) mixture. The solution thus obtained was deoxidized by bubbling pure N_2 for 10 min. Nitrogen oxide, passed through a KOH column to free it of higher nitrogen oxides, was bubbled into the solution for an hour, and then the excess nitrogen oxide was removed by bubbling N_2 through the solution. Methanol, distilled from Mg, was added to the solution until crystals began to precipitate. The products were filtered off, washed with methanol, and recrystallized from chloroform-methanol, to obtain dark purple crystals of ONFe(PPDME). Calcd for $FeC_{36}H_{36}N_5O_5$: C, 64.10; H, 5.38; N, 10.38; Fe, 8.28%. Found: C, 63.85; H, 5.47; N, 10.35; Fe, 8.22%. The analytical results and the IR spectrum confirmed the absence of pyridine in the product. The procdut was handled in a dry box filled with nitrogen.

Measurements. The IR absorption spectra were recorded on Jasco DS-402G and IR-G IR grating spectrophotometers. The EPR measurements were carried out using a JES-ME-3X (X-band) spectrometer and a JES-PE-3Q (Q-band) spectrometer, both with 100 KHz field modulation. The second derivative display was obtained by the use of the 80 Hz field modulation. As a standard, DPPH powder and MgO powder doped with Mn^{2+} were used. All the solvents were spectrograde reagents and were deoxidized by bubbling pure N_2 prior to use.

The Concentration and Separation of a Trace Amount of Cobalt(II) in Sea Water as Its 1-Nitroso-2-naphtholate by Extraction Chromatography

Takaharu Honjo, Shuhei Abe, and Toshiyasu Kiba

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa 920

(Received August 16, 1977)

Synopsis. The behavior of a trace amount of cobalt(II) in extraction and back extraction has been examined with 1-nitroso-2-naphthol in carbon tetrachloride, and the results have also been applied to the concentration and separation of a trace amount of cobalt(II) in sea water as its 1-nitroso-2-naphtholate by extraction chromatography.

Extraction chromatography has been proved to be a powerful technique in the mutual separation of various metals,[1] because the extraction and back extraction may repeatedly accompany it during the process in the chromatographic column. However, this technique has not yet been applied to the concentration and separation of trace amounts of metals in natural waters. In this investigation, the behavior of a trace amount of cobalt(II) in extraction and back extraction with 1-nitroso-2-naphthol in carbon tetrachloride has been examined in detail, and the results have also been applied to the concentration and separation of a trace amount of cobalt(II) in sea water by using a Kel-F column, with 1-nitroso-2-naphthol in carbon tetrachloride as the stationary phase.

Experimental

The experimental procedures for the liquid-liquid extraction and the extraction chromatography were the same as have previously been described.[2,3] 1-Nitroso-2-naphthol was purified by recrystallization from cold petroleum ether. The behavior of cobalt(II) in extraction and extraction chromatography was checked by using a ^{60}Co tracer. The chromatographic column was prepared as follows: to 6.0 g of Kel-F powder of 42—80 mesh, a 15-ml portion of a solution containing 10^{-2} M 1-nitroso-2-naphthol in carbon tetrachloride was added. The mixture was then stirred until it became homogeneous. After having then stood for one night, the mixture was poured into a column which had been filled with a pre-equilibrated eluting solution of pH 3.8. The chromatographic column bed thus prepared (20—22 cm in height) was washed with 50—200 ml of the eluting solution of pH 3.8 at the flow rate of 1.0 ml/min in order to eliminate the excess organic solution. A solution containing a trace amount of cobalt(II) ($<10^{-5}$ M) with the ^{60}Co tracer was then poured onto the column, and the cobalt was collected on the column by passing through an aqueous solution of pH 3.8 at a flow rate of 0.6—4.0 ml/min. The cobalt was strongly held in the stationary phase, but was finally washed down as cobalt chelate in carbon tetrachloride by passing 30 ml of acetone through the column, because the cobalt was not eluted even with a concentrated HCl solution.

Results and Discussion

First of all, the behavior of a trace amount of cobalt(II) in extraction and back extraction has been studied with 10^{-5}—10^{-2} M of various chelating agents in carbon tetrachloride. The results (Fig. 1) revealed that 1-nitroso-2-naphthol gave rise to an extraction behavior of cobalt(II) similar to that of STTA;[4] that is, the back extraction of the cobalt chelate extracted did not occur at all even when the organic phase was shaken with an aqueous solution of 12 M HCl and of 1 M NaOH, by both of which other interfering ions, such as iron(III), nickel(II), and copper(II), and the free ligand could be stripped out from the organic phase. This abnormal behavior of cobalt chelates seems to be caused by the formation of certain inert complexes such as trivalent cobalt chelates.[5] The quantitative extractability of cobalt(II) (trace—10^{-4} M) is attained in about one minute's shaking, and the volume of the initial aqueous solution seems to have no effect on the extraction recovery of cobalt(II), even at a fourteen-fold volume of the organic phase (Fig. 2). On the basis of the experimental results described above, the chromatographic behavior of a trace amount of cobalt(II) was

studied by means of the Kel-F column, which consists of 8.3 ml of 1-nitroso-2-naphthol in carbon tetrachloride as the stationary phase and of 3.8 ml of an eluting solution as the mobile phase; it was loaded with 50 ml of a pre-equilibrated test solution of pH 3.8 at the flow rate of 0.6—4.0 ml/min, followed by 50—1000 ml of acidified sea water of pH 3.0—4.0 containing a trace amount of cobalt(II) with a ^{60}Co tracer at the flow rate of 0.6—2.0 ml/min. When the sea water was passed through the column, it turned the upper side of the column bed pink, and the length of the band expanded to 5 cm for 400 ml of the effluent, 8 cm for 600 ml of the effluent, and 11 cm for 800 ml of the effluent. It was found that 30—40% of 1-nitroso-2-naphthol in the stationary phase flowed down for about 400—500 ml of the effluent. This fact—that is, the loss of 1-nitroso-2-naphthol from the stationary phase during the chromatographic process—is a weak point in extraction chromatography and may decrease the usefulness of the column for the concentration of a trace amount of cobalt(II) in sea water. In all cases, the cobalt in about 1000 ml of sea water and a distilled water was collected quantitatively with the use of the Kel-F

column and was not eluted, not even with a concentrated HCl solution, as could have been predicted from the extraction behavior. The cobalt was finally washed down as metal chelates, together with the excess 1-nitroso-2-naphthol in carbon tetrachloride, by passing 30 ml of acetone through the column. When the organic phase was shaken with a 1 M NaOH solution, the excess of the free 1-nitroso-2-naphthol was almost entirely transferred into an aqueous solution, leaving only the cobalt chelate in the organic phase (Fig. 3). The cobalt chelate with 1-nitroso-2-naphthol could be determined selectively by measuring its absorbance in carbon tetrachloride at 410 nm with a 1 cm quartz cell (Fig. 4), as has briefly been pointed out in a previous short communications on the determination of cobalt(II) in sea water.[6] The recovery of cobalt(II) was about 97—99% under the conditions of this investigation.

Synthesis and Spectral Studies of Dichloroacetates of Lanthanoids

Megh SINGH, M. P. BHUTRA, P. P. VAISHNAVA, and S. N. MISRA
Department of Chemistry and Physics, University of Jodhpur, Jodhpur, India

(Received May 30, 1977)

Synopsis. Dichloroacetates of lanthanoids (Pr, Nd, Sm, Ho, and Er) have been synthesized and characterized by elemental analysis, absorption and IR spectral data, and the X-ray power patterns. Magnetic moments of these derivatives have been measured. Molecular weights determined ebullioscopically in acetic acid showed them to be dimeric.

The halogen substituted acetates of d transition elements have been extentively studied.[1,2,6,7] However, there has been only a very limited effort made in the study of halogen substituted acetates of lanthanoids.[3,4] The trihydrated dichloroacetates (DCA) separate out from the reaction of lanthanoids carbonates and dichloroacetic acid. These can be made anhydrous by keeping in a vacuum desiccator over P_2O_5 for 4 days or heating at 60 °C for 6 h at 0.01 Torr pressure.

Experimental

Crystalline lanthanoids dichloroacetates were prepared by adding slight excess lanthanoids carbonates to dichloroacetic acid (Fluka).

Absorption spectra were measured on Carl Zeiss VSU-2 Spectrophotometer in water and infrared spectra of the KBr pellets were run on a Perkin-Elmer 521 Spectrophotometer.

X-Ray diffraction patterns were obtained using a Phillips diffractometer with nickel filtered Cu$K\alpha$ radiation. Magnetic properties of the compounds were measured by Gouy method at 295 K. The molar susceptibilities were corrected for the diamagnetism of the constituent atoms by means of Pascal's constant.[5] Molecular weights were determined in acetic acid by Gallenkemp semimicro ebulliometer with thermistor ensing.

Results and Discussion

Stretching frequencies $\gamma_s COO^-$ in acetates have been found to be sensitive to both coordination to a metal and substitution in acetate group.[6,7] During the complex formation $\gamma_s COO^-$ shifts to higher frequency, while $\gamma_a COO^-$ shifts in opposite direction. Comparing the values of $\gamma_a COO^-$ in sodium dichloroacetate,[8] Cu(II)[2] and lanthanoids dichloroacetates we have observed that the $\gamma_a COO^-$ values lie inbetween highly ionic sodium dichloroacetate and covalent Cu(II) dichloroacetate. In the lower lanthanoids (Pr and Nd) the values are closer to sodium analogue, while in the higher lanthanoids (Ho and Er) dichloroacetates the values lie closer to copper analogue. This appears well in the conformity of lanthanoids contraction. The $\gamma_a COO^-$ of lanthanoids dichloroacetates, a strong band occuring at 1615—1622 cm^{-1} shows a decrease as compared to sodium analogue, which can be interpreted in terms of dimeric COO^- group, as parallel behavior was observed in the case of Cu(II) dichloroacetate[2]. The existence of dimeric nature of dichloroacetate group is also supported by our mol wt data which point toward dimeric units for dichloroacetate thus involving both bidentate and dimeric dichloroacetate grouping.

C–Halogen Stretching. In lanthanoids dichloroacetates we find high C–halogen and weak low C–halogen stretching frequencies pointing towards the existence of both trans and gauche conformation on the line suggested by Spinner.[8] In general, we find high C–halogen stretching frequencies generally increase with

the rise of atomic number of lanthanoids, again in conformity with the lanthanoids contraction. Absorption in 500—350 cm^{-1} of dichloroacetates probably arises from C–halogen bending vibrations. Faniran and Patel[2] reported four bands for Cu(II) dichloroacetate, while in lanthanoids dichloroacetates we observe three bands. The higher frequency band in dichloroacetates can be identified with antisymmetric motion, while those at lower frequencies are attributed to the symmetrical deformations.

Table 3. Nephelauxetic ratio (β), covelency parameter (δ) and bonding parameter ($b^{1/2}$) of the DCA of lanthanoids

Compound	β	δ (%)	$b^{1/2}$

Ho DCA	1.0052	−0.5174	—
Er DCA	1.0051	−0.5173	—

Karraker[9] showed that the symmetry coordination number of a lanthanoids could be predicted from the shape, intensity and wavelength of its hypersensitive transitions in the visible absorption spectrum. The shape of the hypersensitive transition of Nd dichloroacetate ($^4I_{9/2}\rightarrow{}^4G_{5/2}$, $^2G_{7/2}$) in water is quite identical with the bands of the nonacoordinated $Nd(BrO_3)_3\cdot 9H_2O$ in water as well as in solid.[9] The similarlity among the spectra indicate that in these solutions at least the dichloroacetates are most likely nonaccordinated. It is, of course, risky to transfer conclusions from solution measurement to solid compounds, but we feel that the evidence in hand suggests that these compounds are most likely nonacoordinated in solid state as well.

The values of nephelauxetic ratio (β) which are less than one, and covalency parameters (δ) which are positive indicate thereby that the nature of bonding

between metal and ligand is covalent as compared to lanthanoids aqua ions. Like Sinha[10] we find negative values for δ in case of Ho and Er, which he interpreted in terms of ionic characters in the complexes as compared to respective aqua ions. This behavior is quite surprising in view of the highly coordinated nature of the dichloroacetate grouping. The smaller values of bonding parameter $b^{1/2}$ [11] suggests that 4f orbitals are very slightly involved in bonding in lanthanoids dichloroacetates. The magnetic susceptibilities of Pr, Nd, Sm, Ho, and Er dichloroacetates have been measured and the values of magnetic moments of these derivatives have been found to be quite closer to the values reported by earlier workers.[12–15] X-Ray diffraction studies indicate the compounds to be isomorphous within a group by virtue of similar interplanar spacing d and the line intensities.

An Investigation on the Effect of Structural Variation on Thermal Decomposition of Rare Earth Chromates(V)

Ajoy Roy, M. Chaudhury, and K. Nag

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received July 22, 1977)

Synopsis. Non-isothermal decomposition kinetics of $LaCrO_4$, $PrCrO_4$, and $NdCrO_4$ have been investigated. In each case, first order decomposition takes place. The energy of activation, E_a^* has been evaluated by applying five different computational procedures based on the data of TG, DTA, and DTG. These values are fairly in good agreement with each other and the average activation energies per mole of the compounds are : $LaCrO_4$: 240 kcal, $PrCrO_4$: 180 kcal and $NdCrO_4$: 170 kcal. The above trend in E_a^* has been rationalized by taking into consideration the packing of atoms in rare earth chromates(V).

In previous publications[1-3] we have shown that rare earth (Ln) trisoxalato complexes, $LnM(C_2O_4)_3 \cdot nH_2O$ (M=Fe(III), Co(III), and Cr(III)) serve as excellent precursors for the corresponding rare earth perovskites, $LnMO_3$. Rare earth trisoxalatochromates(III) are additionally interesting because not only the rare earth orthochromites but also the rare earth chromates(V), $LnCrO_4$ can be obtained from them.[3] An important feature of the rare earth chromates(V) is the variation of structure in the series. While $LaCrO_4$ is monoclinic and $NdCrO_4$ and other higher members are tetragonal, $PrCrO_4$ is dimorphic.[4] We have been intrigued therefore, to see how variation on structure of these compounds influence the activation energies of their thermal decomposition. While the present work was in progress Doyle and Pryde have reported[5] isothermal decomposition kinetics of several rare earth chromates(V). The present study intends to report the activation energies for the decomposition of $LaCrO_4$, $PrCrO_4$, and $NdCrO_4$ from TG, DTA, and DTG under nonisothermal condition by applying several computational procedures. The results obtained here are significantly at variance with those reported by Doyle and Pryde.

Experimental

$LnCrO_4$ were prepared[3] by heating $LnCr(C_2O_4)_3 \cdot nH_2O$ at 520 °C for 2 h. The purity of the products were checked by chemical analysis and from their X-ray powder patterns.[4] Thermal analysis were carried out in a MOM Derivatograph. The sample size was *ca.* 750 mg and the particle size was *ca.* 200 mesh. The samples were heated in air and the heating rate was maintained to 6 °C/min. The enthalpy change was evaluated in a way described earlier.[6]

Results and Discussion

The sole feature of the decomposition reaction

$$LnCrO_4 \longrightarrow LnCrO_2 + 1/2O_2$$

is the endothermic evolution of oxygen in the temperature range 700—800 °C. The observed weight losses are in good agreement with the expected values showing the purity of the compounds. The first order decomposition behavior of these compounds has been established by applying five different computational procedures.[7-11] Table 1 summarizes the E_a^* values for each of the compounds obtained from these methods. The results show that for each compounds, the E_a^* values are fairly in good agreement, the variation is within 10%. The average values of E_a^* for these compounds are: $LaCrO_4$, 240 kcal; $PrCrO_4$, 180 kcal; $NdCrO_4$, 170 kcal. In Table 1 the values reported by Doyle and Pryde[5] are also shown for comparison. It may be noted that activation energies reported by Doyle and Pryde are quite low compared to our values. While the present study shows that the decreasing order of the activation energies are $LaCrO_4 > PrCrO_4 > NdCrO_4$, the trend observed by Doyle and Pryde is $PrCrO_4 > LaCrO_4 > NdCrO_4$.

The trend in E_a^* observed by us can be rationalized if the structures of rare earth chromates are taken into consideration. It may be pointed out that $LaCrO_4$ is isostructural to the monoclinic modification of $CePO_4$ whose crystal structure has been determined.[12] $CePO_4$ structure may be described by a space-filling network in which the cation has an irregular coordination of eight oxygen. For each Ce atom, four short bonds, given as 2.37 Å extend to the corner of four different phosphate groups. Four longer bonds 2.66 Å, connect to the edges of two additional tetrahedra. On the other hand, $NdCrO_4$ is isostructural to zircon, $ZrSiO_4$. In zircon, Si–O bond length is 1.62 Å within the SiO_4 tetrahedra and Zr–O distance is 2.05 Å within the longer ZrO_4 tetrahedra.[13] Buisson *et al.*[14] have shown that in $YCrO_4$, the shortest Cr–O distance is 1.66 Å and the shortest Y–O bond length is 2.44 Å. The stereoscopic models of $CePO_4$ and $ZrSiO_4$ reveal that $CePO_4$ is having a much more close packed structure than $ZrSiO_4$.

Inasmuch as the thermal energy required to activate

a) From TG. b) From DTA. c) From DTG.
d) The values reported in Ref. 5.

a compound having tight packing of atoms will be more than a compound having less packed structure, the activation energy for $LaCrO_4$, therefore, is expected to be greater than $NdCrO_4$. Although $PrCrO_4$ is dimorphic, powder diffraction pattern reveals that the lines due to the tetragonal phase are much abundant. It is reasonable therefore to expect that the activation energy for $PrCrO_4$ will be closer to $NdCrO_4$ rather than $LaCrO_4$. Table 1 shows such is actually the case.

The enthalpy change involved in the decomposition of the rare earth chromates are almost same for each of the compounds and is about 4 kcal/mol.

Manganese Dioxide Oxidation of Thioureas

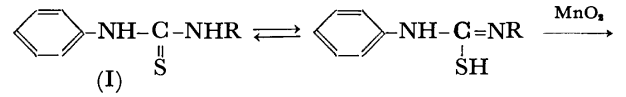
T. C. SHARMA, N. S. SAHNI, and Amba LAL
School of Studies in Chemistry, Vikram University, Ujjain 456010, India

(Received June 6, 1977)

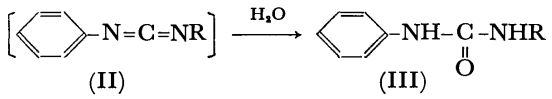
Synopsis. Manganese dioxide oxidation of thioureas in chloroform at room temperature gave the corresponding ureas.

The oxidation of thiourea and its derivatives has received wide attention due to its potential importance in the biological activity of these compounds. The oxidation of these compounds is reported to give rise to a variety of products, depending upon the nature of the oxidant and the reaction conditions. Thus, thiourea and its alkyl and aryl derivatives have been oxidized to the corresponding disulfide with potassium bromate in sulfuric acid medium,[1] whereas *N,N'*-dialkylthioureas are readily oxidized to the corresponding carbodiimides by alkaline hypochlorites.[2] Carbodiimides have also been prepared by the desulfurization of *N,N'*-disubstituted thioureas with various metal oxides such as mercury(II) oxide,[3] lead oxide,[4,5] and arsenic oxide.[6] However, thiourea, when oxidized with potassium permanganate, gave urea.[7] In the oxidation of thioureas with bromine or thionyl chloride, bis(*N*-substituted amidino) disulfides were isolated as hydrobromide salts.[8–13]

In this laboratory we have oxidized thioureas to ureas by manganese dioxide, a very mild and selective reagent. The reactions have been completed at room temperature by shaking a mixture of the oxidant and the substrate in chloroform. In every case, the corresponding urea has been obtained as the end product, identified by its melting point, elemental analysis, and IR spectrum. The IR spectra of these compounds showed intense absorption in the 1655—1670 cm^{-1} region due to carbonyl stretching.



(I)



(II) (III)

(a) R=H (b) R=C_6H_5
(c) R=$C_6H_4CH_3$(*p*-) (d) R=C_6H_4Cl(*p*-)
(e) R=$C_6H_4OCH_3$(*p*-) (f) R=C_6H_4Cl(*m*-)

A probable mechanism for this reaction may involve the initial formation of carbodiimide(II) which reacts with water, under the experimental conditions, to afford the corresponding urea (III).

Experimental

Starting Materials. Active manganese dioxide was prepard from manganese sulfate dihydrate and potassium permanganate according to the literature method.[14] All thioureas were prepared by mixing phenyl isothiocyanate and corresponding anilines in molecular ratio in ethanol and heating the mixture.

Oxidation of Phenylthiourea. A mixture of phenylthiourea (2 g), manganese dioxide (10 g) and chloroform (150 ml) was shaken at room temperature for 5 h. The mixture was filtered and the oxide was washed with chloroform. The combined filtrate and washings were evaporated to afford a residue (1.1 g), which on crystallization from benzene gave colorless crystals of phenylurea (IIIa), mp 148 °C (lit,[15] mp 147 °C). (Found: C, 61.7; H, 5.8; N, 20.4%. Calcd for $C_7H_8N_2O$: C, 61.8; H, 5.9; N, 20.6%). λ_{max} (KBr); 3435, 3315, 1670, 1625, 1605, 1565, 1507, 1460, 1365, 1295, 1265, 755, and 705 cm^{-1}.

The other products of this series obtained similarly are listed in Table 1. These compounds have been crystallized from benzene.

The authors thank Professor M. M. Bokadia for providing laboratory facilities.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (4), 1247—1248 (1978)

Asymmetric, Partial Acetylation of *dl*-1-Phenylethanol by Means of Chiral Polymers

Tetsushi YAMASHITA, Hiroshi YASUEDA, and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 20, 1977)

Synopsis. The partial esterification of *dl*-1-phenylethanol with acetic anhydride was carried out in the presence of poly(*O*-acryloylquinine), poly(*N*-benzyl-2-pyrrolidinylmethylacrylate), and poly(*O*-acryloyl-*N*-benzylephedrine). The propionyl esters of quinine, *N*-benzyl-2-pyrrolidinylmethanol and *N*-benzylephedrine were also used as low molecular weight catalysts. The above polymeric and monomeric catalysts showed poor, asymmetric efficiencies for this esterification.

Several synthetic polymers[1,2] derived from optically active amino alcohols have been used for the study of polymeric effects and asymmetric reactions. Some polymeric catalysts have yielded products with higher optical yields than their corresponding monomeric catalysts.

This report describes the use of poly(*O*-acryloylquinine)[2] (P-1), poly(*N*-benzyl-2-pyrrolidinylmethyl acrylate)[2] (P-2), and poly(*O*-acryloyl-*N*-benzylephedrine)[1] (P-3) in the asymmetric, partial acetylation[3-5] of *dl*-1-phenylethanol. The use of *O*-propionylquinine[2] (A-1), *N*-benzyl-2-pyrrolidinylmethyl propionate[2] (A-2), and *O*-propionyl-*N*-benzylephedrine[1] (A-3) was also examined. The acetylation was carried out in a manner similar to that reported by Wegler.[3]

$$2\ \mathrm{Ph{-}\underset{\underset{CH_3}{|}}{CH}{-}OH} + (CH_3CO)_2O \xrightarrow[\text{Catalyst}]{} \mathrm{Ph{-}\underset{\underset{CH_3}{|}}{CH}{-}OH} + \mathrm{Ph{-}\underset{\underset{CH_3}{|}}{CH}{-}OCOCH_3}$$

Two equivalent amounts of *dl*-1-phenylethanol were allowed to react with one equivalent amount of acetic anhydride in the presence of one equivalent amount of a catalyst. The molar equivalent amount of the polymeric catalyst was calculated on the basis of that of the monomer used in the polymerization (*e.g.*, 100 mg of P-1 corresponds to 100 mg of A-1).

TABLE 1. THE OPTICAL YIELDS AND CONFIGURATIONS OF α-METHYLBENZYL ACETATE

Catalyst	O.Y.[a] (%)	Conf.[b]
A-1	1.12	*S*
P-1	0.21	*S*
P-1[c]	0.74	*S*
P-1[d]	1.13	*S*
A-2	0.14	*R*
P-2	0.08	*R*
A-3	0.09	*S*
P-3	0.00	—

a) The O.Y. (optical yield, %) was calculated with respect to the value for optically pure (*S*)-α-methylbenzyl acetate,[6] $[\alpha]_D^{28} = -118°$ in benzene. b) The configuration of the predominant isomer. c) P-1/acetic anhydride=5. d) P-1/acetic anhydride=10.

Table 1 shows the optical yields and configurations of α-methylbenzyl acetate obtained with these catalysts.

Table 1 indicates that asymmetric acetylation was carried out more effectively with monomeric than with polymeric catalysts.

Ten equivalent amounts of P-1 to one equivalent amount of acetic anhydride were required to obtain α-methylbenzyl acetate in a 1.13% optical yield, while one equivalent amount of A-1 was needed to obtain acetylated alcohol with the same value of optical yield. These results suggest that no favorable polymer effect with regard to stereoselectivity is observed for this esterification.

Dumont *et al.*[7] have also reported that a chiral polymeric rhodium complex catalyzed the asymmetric hydrogenation of olefins with a lower efficiency than did the corresponding monomeric complex.

Experimental

(A). To a solution of A-1 (2.28 g) and *dl*-1-phenylethanol (1.46 g) in 10 ml of carbon tetrachloride was added acetic anhydride (0.61 g). The mixture was stirred under reflux for 15 h. After removal of the solvent, the residue was dissolved in ether. The ethereal solution was washed with 1 M-hydrochloric acid to remove A-1, successively with saturated sodium hydrogencarbonate and water, and dried. The solution was evaporated to dryness under reduced pressure. The residue was distilled to give a colorless oil (1.50 g). Bp 90 °C at 13 mmHg. $[\alpha]_D^{17} = -0.604°$ (*c* 50, benzene). GLC and TLC of this oil showed it to be composed of two materials. The mixture was subjected to column chromatography on alumina (2×30 cm, 200 mesh, neutral).

Elution with hexane gave 0.73 g of acetylated alcohol. $[\alpha]_D^{13} = -1.32°$ (*c* 25, benzene). Further elution with ether gave 0.61 g of unreacted 1-phenylethanol. $[\alpha]_D^{16} = +0.65°$ (*c* 25, benzene).

The above acetylated and unreacted alcohols were distilled and their optical rotations were measured again. α-Methylbenzyl acetate, bp 105—108 °C at 15 mmHg. $[\alpha]_D^{15} = -1.34°$ (*c* 20, benzene). 1-Phenylethanol, bp 93 °C at 12 mmHg. $[\alpha]_D^{15} = +0.67°$ (*c* 20, benzene). The structure of acetate and unreacted alcohol was confirmed by NMR and IR.

(B). To a solution of P-1 (2.28 g) and *dl*-1-phenylethanol (1.46 g) in 10 ml of carbon tetrachloride was added acetic anhydride (0.61 g), and the mixture was refluxed with stirring. After 15 h, the solution was evaporated to dryness *in vacuo*. Ether was added to the residue, and a precipitate of P-1 was filtered off. The filtrate was evaporated to give a mixture of acetate and unreacted alcohol in a 90% yield. After having been distilled, the mixture was separated into 1-phenylethanol and α-methylbenzyl acetate by column chromatography in a manner similar to that described in (A). The use of other monomeric and polymeric catalysts was attempted according to methods similar to those described in (A) and (B).

The optical rotations of l-phenylethanol and α-methylbenzyl acetate were measured by means of a JASCO DIP-4 automatic polarimeter (10 cm cell, *c* 20—50, benzene).

A JASCO IRA-1 (IR), a JEOL-60 MC (NMR) and a Varian M 920 (GLC) were used for the measurement of the samples in this experiment.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (4), 1249—1250 (1978)

Conformational Analysis of 9,14-Dihydrotribenzo[*a,c,f*]cyclooctene and Its Derivatives

Yasuo SHIGEMITSU, Masayoshi JURO, Yuji MUKUNO, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received August 16, 1977)

Synopsis. 9,14-Dihydrotribenzo[*a,c,f*]cyclooctene, 9,14-dihydrotribenzo[*a,c,f*]cycloocten-9-one, and 9,14-dihydrotribenzo[*a,c,f*]cyclooctene-9,14-dione, which are all new bridged aromatics containing a biphenyl moiety, have been prepared. Saddle conformations have been suggested for all of them on the basis of the spectra data.

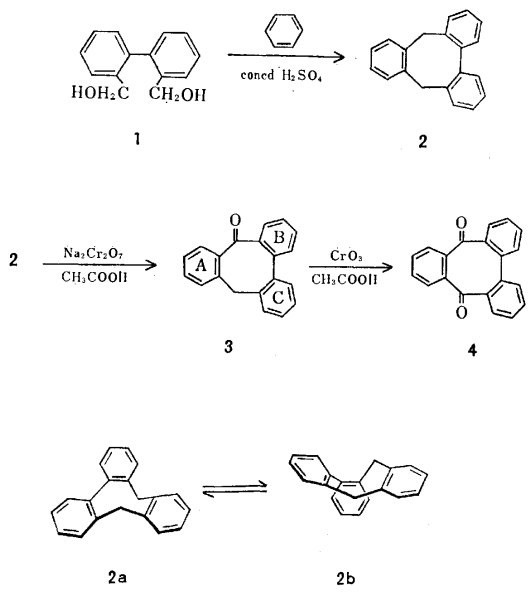
The chemistry of bridged aromatics containing three or more benzene rings has received increasing interest in recent years. There have been a number of reports on the synthesis and conformational analysis of 10,15-dihydro-5*H*-tribenzo[*a,d,g*]cyclononene and its derivatives.[1] Little attention, however, has been paid to the chemistry of 9,14-dihydrotribenzo[*a,c,f*]cyclooctene derivatives, which are new bridged aromatics containing a biphenyl moiety. We wish to report here the preparation and conformational determination of 9,14-dihydrotribenzo[*a,c,f*]cyclooctene (**2**), 9,14-dihydrotribenzo[*a,c,f*] cycloocten-9-one (**3**), and 9,14-dihydrotribenzo[*a,c,f*]-cyclooctene-9,14-dione (**4**).[2]

The hydrocarbon **2** was prepared by the acid-catalyzed cycloalkylation of benzene with 2,2′-bis-(hydroxymethyl)biphenyl (**1**) in almost quantitative yield.[1d,1e,3] Oxidation of **2** with sodium dichromate in acetic acid under reflux gave **3** in 62% yield.[1c,1e] The monoketone **3** resisted further oxidation under the same conditions, but could be oxidized with chromic anhydride in acetic acid under reflux to give **4** in 17% yield.

The PMR spectrum of **2** showed the benzylic protons as a singlet at δ 3.65, indicating that **2** takes a flexible conformation. On lowering the temperature the singlet began to split and at about −40 °C it separated into a distinct AB quartet at δ 3.59 and 3.74 (J=15.0 Hz). The UV absorption spectrum of **2** was the same in shape and band position as that of 2,2′-dimethylbiphenyl.[4] This result suggests that the two benzene rings of the biphenyl moiety in **2** would be twisted by about 70°.[5] A molecular model of **2** shows that the two benzene rings of the biphenyl moiety are nearly coplanar in the crown form, while they are quite twisted in the saddle form. These facts allow assignment of a saddle conformation for **2**. The hydrocarbon **2** undergoes inversion between the two possible saddle forms **2a** and **2b** at normal temperatures, but is frozen in one form at lower temperatures. The free energy of activation ($\Delta F^{\ddagger}$) for the inversion process is calculated to be 15.3 kcal/mol at 25 °C in CD_2Cl_2.[6]

The monoketone **3**, on the other hand, is a rigid molecule at room temperature, since its PMR spectrum showed the benzylic protons as an AB quartet at δ 3.7 and 4.1 (J=14.3 Hz). On raising the temperature the two doublets were observed to broaden and finally at 84 °C to coalesce into a broad singlet, thus permitting calculation of $\Delta F^{\ddagger}$ for the inversion: 17.5 kcal/mol at 84 °C in C_7D_8. The band position of the carbonyl absorption at 1643 cm^{-1} for **3** is approximately the same as that for benzophenone (1647 cm^{-1}), suggesting that the carbonyl group of **3** would conjugate strongly with a benzene ring. A molecular model of **3** reveals that in a crown conformation such a strong conjugation may not be possible because of the non-coplanarity of the carbonyl group with the benzene rings. The alternative assignment of a saddle conformation to **3** would be more compatible with its UV spectrum, which showed a much more intense band at long wavelength (>310 nm) than that of an open chain model compound, *o*-benzylbenzophenone (**5**).[7] This intense band indicates the presence of a longer conjugative system in **3** than in **5**. If the carbonyl group is coplanar with the benzene ring A, the angle of the twist in the biphenyl moiety should be as large as that of 2,2′-disubstituted biphenyl (≈70°). In this case the UV spectrum of **3** should be more similar to that of **5**. On the other hand, if the carbonyl group is coplanar with the benzene ring B, the twist in the biphenyl moiety would be small enough for the benzene rings B and C to be conjugated. Based on the spectral data and the above considerations, we would like to propose that the monoketone **3** may possess the saddle conformation in which the carbonyl group is coplanar with the benzene ring of the biphenyl moiety.

The ^{13}C NMR spectrum of **4** showed a carbonyl carbon resonance at 200.7 ppm and its IR spectrum showed a carbonyl band at 1670 cm^{-1}, indicating that the two carbonyl groups would take the same conformation. The carbonyl stretching frequency for **4** is 12 cm^{-1} higher than that for the open chain compound, *o*-dibenzoylbenzene (**6**) (1658 cm^{-1}). The carbonyl bond force constant for **4**, calculated by using the equation proposed by Halford,[8] is greater by 0.12 than that for **6**.[9] This result suggests that the two carbonyl groups of **4** would not lie in the plane of any benzene ring, but would make a certain angle with the benzene rings. The angle, however, would not be so large as to impede completely the conjugation of the carbonyl group with the benzene ring, since the UV spectrum of **4** showed a much more intense band at 330 nm (ε 641) than that for **6** (ε 269). This intense band, compared with that of **6**, may be explained in terms of the conjugation of the two carbonyl groups with the benzene ring. Thus the UV data are inconsistent with the assignment of a crown conformation for **4**, because the crown conformation would lead to inhibition of the conjugation due to the orthogonality of the carbonyl groups with the benzene rings. Consequently, we feel that it is reasonable to assign a saddle conformation for **4**, although the



present spectral data are not sufficient to confirm the definitive structure of **4**.

Experimental

All melting points are uncorrected. The IR spectra were obtained on a JASCO IR-G spectrophotometer or a Hitachi Perkin-Elmer 225 grating infrared spectrophotometer in a potassium bromide pellet. The PMR spectra were recorded on a JEOL JNM-PS-100 spectrometer using tetramethylsilane as an internal standard. The ^{13}C NMR spectra were recorded on a JEOL PS 100-EC 100 spectrometer. The mass spectra were taken on a Hitachi RMU-6E mass spectrometer and the UV spectra on a Hitachi two-wavelength double beam spectrophotometer 356. 2,2′-Bis(hydroxymethyl)biphenyl (**1**) (mp 110—111 °C, lit,[10] 112 °C) was prepared from dimethyl diphenate according to the procedure of Kakis *et al.*[10]

9,14-Dihydrotribenzo[a,c,f]*cyclooctene (2).* The hydrocarbon **2** was prepared according to the procedure of Dagan and Rabinovitz.[1e,3] The crude product was recrystallized from petroleum ether–benzene to give pure **2** as colorless plates, mp 137—139 °C. IR: 3060, 3030, 2920, 1475, 1430, 775, 745 cm^{-1}; MS: *m/e* 256 (M^+, base peak); PMR (CD_2Cl_2): δ 3.65 (s, 4H), 7.16 (bs, 4H), 7.32 (bs, 8H); UV: $\lambda_{max}^{95\%EtOH}$ 233 (ε 7970), 263 (1130), 272 nm (733). Found: C, 93.54; H, 6.22%. Calcd for $C_{20}H_{16}$: C, 93.71; H, 6.29%.

9,14-Dihydrotribenzo[a,c,f]*cyclooctene-9-one (3).* The hydrocarbon **2** (423 mg, 1.65 mmol) and sodium dichromate (2.8 g, 9.4 mmol) in acetic acid (140 ml) and water (25 ml) were refluxed for 53 h. The reaction mixture was poured into ice–water and the product was collected by filtration, washed successively with aqueous sodium hydrogencarbonate and water, and then chromatographed on a silica gel column. Elution with petroleum ether recovered the unreacted **2** (113 mg). Elution with benzene–petroleum ether (2:3) afforded the monoketone **3** (213 mg, 62%) which was recrystallized from methanol to give colorless prisms, mp 131—133 °C. IR: 1643 cm^{-1}; MS: *m/e* 270 (M^+, base peak); PMR ($CDCl_3$): δ 3.7 (d, 1H, J=14.3 Hz), 4.1 (d, 1H, J=14.3 Hz), 7.1—7.5 (m, 11H), 7.9 (bd, 1H), ^{13}C NMR ($CDCl_3$): δ 40.0 (>CH_2), 200.0 ppm (>C=O); UV: $\lambda_{max}^{95\%EtOH}$ 235 (ε 16750), 255 sh (8710), 295 sh (1380), 335 sh nm (367). Found: C, 88.76; H, 5.07%. Calcd for $C_{20}H_{14}O$: C, 88.86; H, 5.22%.

9,14-Dihydrotribenzo[a,c,f]*cyclooctene-9,14-dione (4).* An acetic acid solution (20 ml) of **3** (350 mg, 1.3 mmol) and chromic anhydride (1.2 g. 12 mmol) was refluxed for 44 h. The same workup as that described above and purification by column chromatography on silica gel gave the unreacted monoketone **3** (110 mg) and the desired diketone **4** (36 mg, 17%). Recrystallization from methanol gave pure **4** as colorless needles, mp 201—203 °C. IR: 1670 cm^{-1}; MS: *m/e* 284 (M^+), 255 (base peak); PMR ($CDCl_3$): δ 6.94—7.74 (m); ^{13}C NMR (C_6D_6): δ 200.7 ppm (>C=O); UV: $\lambda_{max}^{95\%EtOH}$ 230 (ε 29400), 285 sh (2840), 330 sh nm (641). Found: C, 84.57; H, 4.30%. Calcd for $C_{20}H_{12}O_2$: C, 84.49; H, 4.25%.

The authors wish to thank Professor M. Ogawa and Dr. Y. Ishii of Kansai University for the measurements of the ^{13}C NMR spectra.

Synthesis of 4-Methyl-1,2-oxathiin 2,2-Dioxide

Tetsuo AKIYAMA, Masaki SUGIHARA, Takeshi IMAGAWA, and Mituyosi KAWANISI

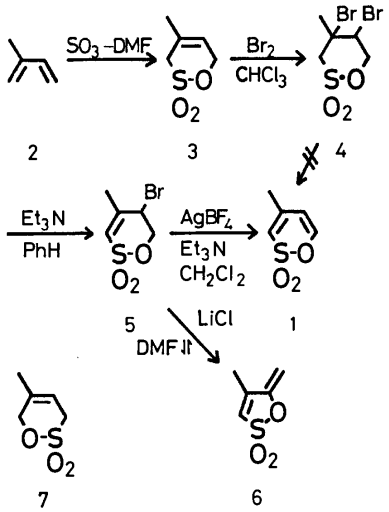
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received September 3, 1977)

Synopsis. The reaction of isoprene with the SO_3–DMF complex afforded isoprene δ-sultone (**3**) in a 48% yield. The addition of bromine to **3** gave a dibromo product (**4**) and successive treatment of **4** with triethylamine in benzene and with triethylamine in the presence of silver tetrafluoroborate gave 4-methyl-1,2-oxathiin 2,2-dioxide in an 18% yield.

A δ-sultone, 1,2-oxathiin 2,2-dioxide is a structurally interesting compound since it is equivalent to 2-pyrone, the C=O group of which is replaced by a sulfonyl group (SO_2). In addition, 1,2-oxathiin 2,2-dioxides, which readily release sulfur dioxide to give furans,[1] can be regarded as potential starting materials for the synthesis of furan derivatives. From the viewpoint of synthesis, the 1,2-oxathiin 2,2-dioxides which have one substituent at the 4 or 5 position appear to be useful in the preparation of 3-substituted furans.[2] In the present paper, the first synthesis of 4-methyl-1,2-oxathiin 2,2-dioxide (**1**) is reported.

Up to the present time, no preparations of 1,2-oxathiin 2,2-dioxide and its monosubstituted derivatives, except the 6-substituted derivative[3] have been reported. Even in this case, the detailed method of preparation was not reported. The reaction sequence is depicted in the following scheme.



Scheme 1.

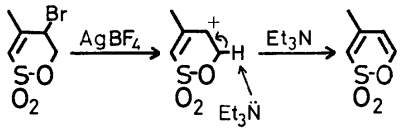
To the best of the authors' knowledge, only a few cases of successful formation of six-membered δ-sultones by way of the cycloaddition of SO_3 with a 1,3-diene are known,[4] although the reactions between SO_3 and olefinic compounds have been widely investigated.[5]

The reaction of isoprene (**2**) with the SO_3-*N*,*N*-dimethylformamide (DMF) complex[4a] was attempted and isoprene δ-sultone (**3**) was obtained as the sole product, in a 48% yield. The structure of **3** was differentiated from that of the alternate, **7**, in view of the fact that the methylene protons adjacent to the SO_2 group exhibited a broad singlet peak and did not couple with the olefinic proton in the ^{1}H-NMR spectra. This was further confirmed by chemical transformation (*vide infra*).

Similarly, 2,3-dimethyl-1,3-butadiene gave a δ-sultone (18% yield), but none of these products was formed in the case of 1,3-butadiene, 1,3-pentadiene and 1,3-cyclohexadiene. The reaction between SO_3 and 1,3-butadiene following a published procedure[5b] gave a δ-sultone, but the yield was extremely low.

The addition of bromine to isopren δ-sultone (**3**) in a chloroform solution afforded the corresponding dibromo derivative (**4**: 91%). Treatment of **4** with triethylamine in benzene induced monodehydrobromination giving **5** (95%). The additional treatment of **5** with bases, such as pyridine or potassium *t*-butoxide, in addition to triethylamine failed to produce a dienic compound. However, dehydrobromination of **5** by means of lithium chloride and calcium carbonate in refluxing *N*,*N*-dimethylformamide afforded a dienic compound in a 60% yield the structure of which was found to be 4-methyl-5-methylene-1,2-oxathiole 2,2-dioxide (**6**) from elemental analysis and spectral data. The formation of the ring-contracted product (**6**) is intriguing, but the true mechanism is not known as yet.

The following procedure gave the target compound, (**1**). Thus, treatment of **5** with triethylamine in dichloromethane in the presence of silver tetrafluoroborate gave **1** in an 18% yield. Support for this structural assignment comes from ^{1}H- and ^{13}C-NMR spectra. The signals of protons at C_5 and C_6 in the ^{1}H-NMR spectra display a typical AX pattern (J=5.9 Hz) and the ^{13}C-NMR spectra show that three olefinic carbons at the 3, 5, and 6 positions attach to one proton, respectively. The reaction appears to proceed as in the following scheme.



Scheme 2.

Experimental

All temperatures are uncorrected. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The mass spectra were taken using a Hitachi RMS-4 mass spectrometer. The NMR spectra were obtained on Varian EM-360 and CFT-20 spectrometers, TMS being chosen as the internal standard.

Isoprene δ-Sultone (3). To a solution of SO_3 (13.3 g; 0.166 mol) in 60 ml of DMF were added 10.0 g (0.147 mol) of isoprene all at once at room temperature. After the slightly exothermic reaction subsided within about one-half hour, the reaction mixture was stirred for 24 h at room temperature and neutralized with cold $NaHCO_3$ aq and extracted with benzene. The extract was washed with water to remove DMF and dried (Na_2SO_4). After removal of the solvent *in vacuo*, the residue slowly crystallized. Recrystallization from EtOH gave 10.5 g (48.0%) of 4-methyl-3,6-dihydro-1,2-oxathiin 2,2-dioxide (**3**), mp 35—36 °C; MS: *m/e* 148 (M^+, 21%); IR (Nujol): 1180, 1360 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 5.54 (m, 1H, –CH=), 4.83 (m, 2H, OCH_2), 3.58 (broad s, 2H, CH_2SO_2), 1.83 ppm (broad s, 3H, CH_3); ^{13}C-NMR ($CDCl_3$): δ 128.2 (>C=), 117.2 (=CH–), 71.5 (CH_2O), 50.1 (CH_2SO_2), and 22.5 ppm (CH_3). Found: C, 40.55; H, 5.54%. Calcd for $C_5H_8SO_3$: C, 40.52; H, 5.44%.

2,3-Dimethyl-1,3-butadiene δ-Sultone. In a similar manner, the reaction of 2,3-dimethyl-1,3-butadiene with the SO_3–DMF complex gave 3,4-dimethyl-3,6-dihydro-1,2-oxathiin 2,2-dioxide in an 18% yield; ^{1}H-NMR ($CDCl_3$): δ 4.70 (broad s, 2H, OCH_2), 3.55 (broad s, 2H, CH_2SO_2) and 1.77 ppm (two s, 6H, $2CH_3$): ^{13}C-NMR ($CDCl_3$): δ 122.8 and 119.6 (2>C=), 74.5 (CH_2O), 50.0 (CH_2SO_2), 19.1 and 13.8 ppm ($2CH_3$).

Dibromo δ-Sultone (4). A solution of 1.13 g (7.6 mmol) of **3** and 1.22 g (8.0 mmol) of bromine in chloroform (20 ml) was stirred at room temperature for 24 h. The reaction mixture was treated with $NaHSO_3$ aq to remove excess bromine. Extraction with chloroform and evaporation of the solvent followed by distillation gave 2.14 g (91%) of 4,5-dibromo-4-methyl-1,2-oxathiane 2,2-dioxide (**4**), bp 130 °C/5 mmHg, mp 99—100 °C; MS: *m/e* 227, 229 (M^+—Br, 40%); IR: 1170, 1360 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 5.1—4.4 (m, 3H, OCH_2-CHBr), 3.87 (s, 2H, CH_2SO_2) and 2.17 ppm (s, 3H, CH_3); ^{13}C-NMR ($CDCl_3$): δ 71.5 (OCH_2), 58.8 (CH_2SO_2), 57.6 (–C–Br), 52.8 (>CHBr), and 30.2 ppm (CH_3). Found: C, 19.41; H, 2.60%. Calcd for $C_5H_8Br_2SO_3$: C, 19.50; H, 2.62%,

Bromo δ-Sultone (5). A solution of 231 mg (0.75 mmol) of **4** and 1 ml of triethylamine in benzene (20 ml) was heated under reflux for 2 h. After filtration of triethylamine hydrobromide and evaporation of the solvent, distillation gave 163 mg (94.7%) of 5-bromo-4-methyl-5,6-dihydro-1,2-oxathiin 2,2-dioxide (**5**); bp 180 °C/16 mmHg, mp 129—130 °C, MS: *m/e* 226, 228 (M^+, 7%), 147 (M^+—Br, 100%); ^{1}H-NMR ($CDCl_3$): δ 6.10 (broad s, 1H, –CH=), 5.2—4.3 (m, 3H, OCH_2CHBr) and 2.15 ppm (d, 3H, CH_3); ^{13}C-NMR: δ 131.3 (>C=), 122.4 (–CH=), 73.9 (CH_2O), 41.7 (CHBr), and 21.6 ppm (CH_3). Found: C, 26.66; H, 3.08%. Calcd for $C_5H_7BrSO_3$: C, 26.45; H, 3.11%.

4-Methyl-5-methylene-1,2-oxathiole 2,2-Dioxide (6). To a solution of 680 mg (3 mmol) of **5** in *N,N*-dimethylformamide was added 127 mg (3 mmol) of lithium chloride and the reaction mixture was refluxed for 6 h. After the addition of water, the reaction mixture was extracted with benzene. The extract was washed with water to remove DMF and dried (Na_2SO_4). After removal of the solvent *in vacuo*, the residue crystallized. Recrystallization from ethanol gave 263 mg (60%) of **6**; mp 51—52 °C; MS: *m/e* 146 (M^+, 43%), 82 (M^+—SO_2, 14%); IR: 1650, 1600, 1440, 1330, 1180, 880, and 750 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 6.63 (broad s, 1H, –CH=), 4.87—5.22 (m, 2H, $=CH_2$) and 2.17 ppm (d, 3H, CH_3); ^{13}C-NMR: δ 152.2 and 142.7 (2 >C=), 121.1 (–CH=), 94.4 ($=CH_2$) and 12.2 ppm (CH_3); Found: C, 40.86; H, 4.36%. Calcd for $C_5H_6SO_3$: C, 41.15; H, 4.14%.

4-Methyl-1,2-oxathiin 2,2-Dioxide (1). To a solution of 1.05 g (4.6 mmol) of **5** and 1.3 ml of triethylamine in dichloromethane (20 ml) was added 0.90 g (4.6 mmol) of silver tetrafluoroborate. The reaction mixture was stirred for 48 h at room temperature. Removal of silver bromide by filtration and isolation by column chromatography on silica gel gave 125 mg (18.5%) of **1**; bp 120—125 °C/20 mmHg; MS: *m/e* 146 (M^+, 100%), 82 (M^+—SO_2, 20%); ^{1}H-NMR ($CDCl_3$): δ 6.96 (d, 1H, =CH–O), 6.38 (broad s, 1H, =CH–SO_2), 5.85 (d, 1H, –CH=), and 2.08 ppm (d, 3H, CH_3); ^{13}C-NMR: δ 145.8 (=CH–O), 145.6 (>C=), 116.4 (=$CHSO_2$), 109.3 (–CH=), and 21.6 ppm (CH_3). Found: C, 40.98; H, 4.28%. Calcd for $C_5H_6SO_3$: C, 41.15; H, 4.14%.

Gas Phase Photochemical Reactions of Nitrogen Dioxide. Effect of Oxygen on the Conversion of Benzene into Nitrobenzene

Kazuo WATANABE, Hiroshi ISHIKAWA, and Wataru ANDO

Department of Chemistry, The University of Tsukuba, Niiharigun, Ibaraki 300-31

(Received September 3, 1977)

Synopsis. Gas phase photochemical nitration of benzene with nitrogen dioxide in the presence of oxygen was studied. Conversion of benzene into nitrobenzene was drastically accelerated by oxygen.

Vapor phase nitration of benzene with nitrogen dioxide to produce nitrobenzene has been studied to some extent under thermal and photochemical conditions in oxygen free systems,[1] but no examination has been reported on the effect of oxygen. From the viewpoint that the role of oxygen is significant in photoreaction, studies were carried out in the gas phase photochemical reaction of hydrocarbons with nitrogen dioxide in the presence and absence of oxygen. We would like to report that addition of oxygen remarkably causes a high conversion of benzene into nitrobenzene in gas phase nitration.

A cylindrical reaction vessel made of Pyrex glass (350 ml) and equipped with Teflon stopcocks and silicon rubber septum was used. Commercial benzene was dried completely and distilled, first and last fractions being rejected until it became gas chromatographically pure. Nitrogen dioxide dried over phosphorus pentaoxide was purified by repeated trap to trap distillation in a vacuum. Extra pure dry nitrogen and oxygen (Nihon Tokusyu Gas Co.) were used. Known amounts of benzene and nitrogen dioxide were admitted to the reaction vessel under reduced pressure, and diluted with either dry nitrogen or oxygen. Samples were irradiated externally for period of 2 h with a 400 W high-pressure mercury lamp at the temperature of running water. The irradiated products were extracted with dry dichloromethane and analyzed with a Hitachi 163 flame ionization detector with a 20 m OV-101 capillary glass column. Gas chromatographic peaks were identified by comparison of their retention times and of mass spectra with those of authentic samples.

Results and Discussion

A solution of 5.48×10^{-4} mol of benzene and 22.3×10^{-4} mol of nitrogen dioxide was introduced into the reaction vessel with a syringe and irradiated for 2 h. The irradiated mixture was extracted with dry dichloromethane and analyzed by GLC. Nitrobenzene was obtained in 28% yield on the basis of starting benzene. Neither phenol nor nitrophenol was obtained in a detectable yield.[2]

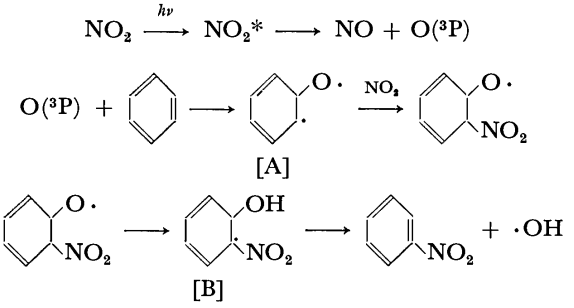
The same reaction was carried out in the presence of oxygen. Irradiation of a mixture of 5.48×10^{-4} mol of benzene and 22.3×10^{-4} mol of nitrogen dioxide and 22.3×10^{-4} mol of oxygen afforded nitrobenzene in 55% yield. The presence of oxygen increases the yield of nitrobenzene. The yield of nitrobenzene on the photolysis of nitrogen dioxide and benzene with a variable concentration of oxygen was examined. The results are given in Table 1. We see a remarkable increase in the yield of nitrobenzene in the presence of oxygen. Although we did not measure the absolute rate of reaction, results show that oxygen accelerates the conversion rate into nitrobenzene in the vapor phase photochemical reactions.

Table 1. Yields of nitrobenzene in C_6H_6–NO_2–O_2 system[a]

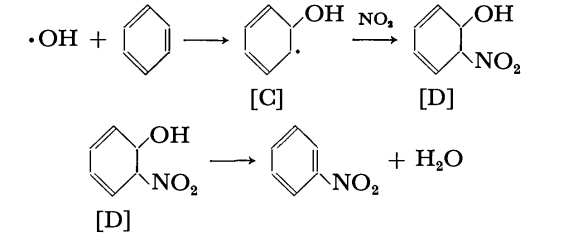
Run	Reaction conditions			Yields of nitrobenzene (%)
	NO_2 (mol)	O_2 (mol)	N_2 (mol)	
1	4.1×10^{-4}	0	0	trace
2	4.1×10^{-4}	22.3×10^{-4}	0	3
3	4.1×10^{-4}	0	22.3×10^{-4}	trace
4	4.1×10^{-4}	44.6×10^{-4}	0	21
5	4.1×10^{-4}	0	44.6×10^{-4}	1
6	22.3×10^{-4}	0	0	28
7	22.3×10^{-4}	11.2×10^{-4}	0	50
8	22.3×10^{-4}	22.3×10^{-4}	0	55
9	22.3×10^{-4}	33.5×10^{-4}	0	71
10	22.3×10^{-4}	44.6×10^{-4}	0	82
11	22.3×10^{-4}	66.9×10^{-4}	0	85
12	22.3×10^{-4}	0	44.6×10^{-4}	11

a) 5.48×10^{-4} mol of benzene was used in each run.

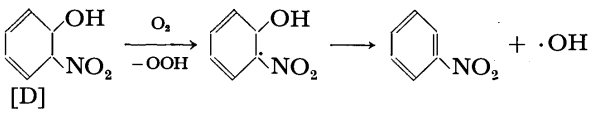
The following scheme might account for the formation of nitrobenzene. Oxygen atom, generated by photodissociation of nitrogen dioxide, adds benzene ring to produce biradical [A], which reacts with nitrogen



Scheme 1.



Scheme 2.



[D]

$$\cdot OOH + NO \longrightarrow \cdot OH + NO_2$$

$$2NO + O_2 + M \text{ (surface of wall)} \longrightarrow 2NO_2 + M$$

Scheme 3.

dioxide to produce adduct [B] with concomitant migration of hydrogen atom (intramolecular hydrogen abstraction by oxyl radical). Here, monoradical species [B] should smoothly eliminate hydroxy radical to produce nitrobenzene (Scheme 1). Hydroxy radical generated herein effectively undergoes addition to benzene ring to produce [C], which reacts with nitrogen dioxide to produce 6-nitro-2,4-cyclohexadiene-1-ol [D]. The formation of nitrobenzene by direct dehydration from [D] might be expected (Scheme 2). The mechanisms indicate that nitrobenzene formation is significantly affected by oxygen. In the presence of oxygen, there are two additional routes for the efficient formation of nitrobenzene. The first mechanism assumes the effective conversion of nitric oxide into nitrogen dioxide by oxygen, keeping the high concentration of nitrogen dioxide in the system. An alternative route on the participation of oxygen involves the formation of hydroperoxy radical from [D] which will oxidize nitric oxide to form nitrogen dioxide and hydroxy radical. These ideas are summarized in Scheme 3. Reproduction of nitrogen dioxide would be important for increasing the yield of nitrobenzene.

New Synthetic Methods for Benzyloxycarbonyl-L-arginine-*p*-nitroanilide, Benzoyl-L-arginine-*p*-nitroanilide, and Acetyl-L-arginine-*p*-nitroanilide*

Oyin SOMORIN,** Norio NISHI, and Junzo NOGUCHI

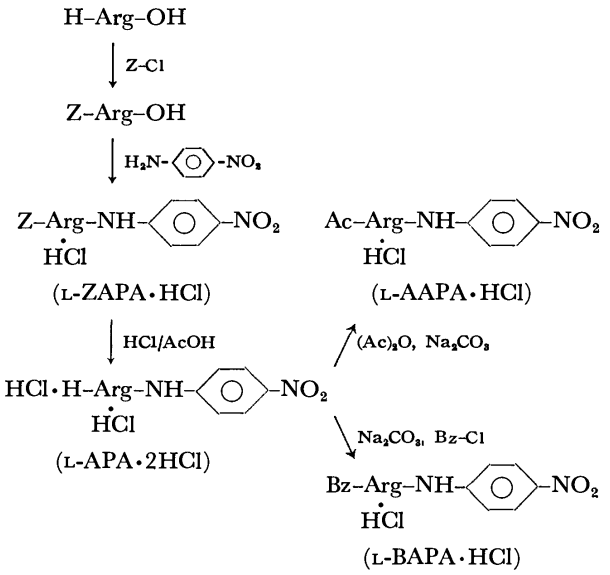
Department of Polymer Science, Faculty of Science, Hokkaido University, Kita-ku, Sapporo 060

(Received September 5, 1977)

Synopsis. The optically active substrates for two peptidases, benzoyl-L-arginine-*p*-nitroanilide hydrochloride (L-BAPA·HCl) and acetyl-L-arginine-*p*-nitroanilide(L-AAPA·HCl), were readily prepared through the synthesis of benzyloxycarbonyl-L-arginine-*p*-nitroanilide hydrochloride(L-ZAPA·HCl). Benzyloxycarbonyl-L-arginine and *p*-nitroaniline were directly coupled without any racemization. The product, L-ZAPA·HCl, was quantitatively debenzyloxycarbonylated with hydrogen chloride in glacial acetic acid at 50 °C to L-arginine-*p*-nitroanilide dihydrochloride(L-APA·2HCl) which gave, on benzoylation or acetylation, L-BAPA·HCl or L-AAPA·HCl respectively.

N^{α}-Acylated arginine-*p*-nitroanilides are well known to be suitable substrates for trypsin and papain.[1,2] The low basicity of the amino group of *p*-nitroaniline makes it difficult for it to couple with the carboxyl group of arginine activated by the DCCI-, azide-, or active ester-method. The activation of the amino group of *p*-nitroaniline seems to be necessary to facilitate coupling with the carboxyl group of arginine. Hence, in our previous papers on the syntheses of L-BAPA·HCl[3] and other acylated L-arginine-*p*-nitroanilides,[4] the amino group of *p*-nitroaniline was activated by converting it to the isocyanate and the guanidino group of arginine was masked with the nitro group. The synthetic routes reported previously,[3,4] however, are complicated because of the several reaction steps involved.

Convenient syntheses of L-ZAPA·HCl, L-BAPA·HCl, and L-AAPA·HCl have now been achieved, as is shown in Scheme 1. L-ZAPA·HCl was prepared by the direct coupling of N^{α}-benzyloxycarbonyl-L-arginine and *p*-nitroaniline using a modification of the procedure of Erlanger *et al.*[5] for the synthesis of DL-BAPA·HCl. As it had been expected, there was no racemization in the synthesis of L-ZAPA·HCl, unlike as in the case of the benzoyl analog. In the modified coupling procedure, only one equivalent mole of the tertiary amine was used, since two equivalent moles as in the procedure of Erlanger *et al.*[5] caused a decrease in the yield of L-ZAPA·HCl. The order of the addition of reagents affected the yield of L-ZAPA·HCl. The optimum yield was obtained by the following procedure: a mixture of triethylamine and *p*-nitroaniline in diethyl phosphite was added to a solution of phosphorus pentoxide in diethyl phosphite. A solution of benzyloxycarbonyl-L-arginine containing phosphoric acid in diethyl phosphite was then added to the above mixture. The addition of reagents in this order is consistent with the mechanism of reaction proposed by Schramm and Wissmann.[6] L-ZAPA·HCl was successfully debenzyloxycarbonylated to L-APA·2HCl with hydrogen chloride in acetic acid at 50 °C. The yield of L-APA·2HCl was quantitative, and its melting point and its specific optical rotation were identical with those previously reported.[4] L-AAPA·HCl and L-BAPA·HCl have the same physical constants (melting points and specific optical rotations) as those reported by Nishi *et al.*[4]



Scheme 1. Improved and simplified synthetic routes for benzoyl-L-arginine-*p*-nitroanilide hydrochloride (L-BAPA·HCl) and acetyl-L-arginine-*p*-nitroanilide hydrochloride (L-AAPA·HCl). Z: Benzyloxycarbonyl, Ac: acetyl, Bz: benzoyl.

From the result of the enzymatic hydrolysis of L-ZAPA·HCl by trypsin, the new substrate, L-ZAPA·HCl seems to be more excellent than L-BAPA·HCl and tosyl-L-arginine-*p*-nitroanilide hydrochloride (L-TAPA·HCl) because it can be prepared easily and because of its higher solubility in water and higher susceptibility to tryptic hydrolysis, as is shown in Fig. 1. The details of L-ZAPA·HCl as a substrate for peptidases are under investigation.

Experimental

The ultraviolet and visible absorption spectra were measured with a Hitachi 323 Automatic Spectrophotometer. The optical rotations were measured with a Yanagimoto Automatic

* This work was presented at the 14th Meeting of the Hokkaido Branch of the Biochemical Society of Japan, July 1977.

Recording Polarimeter, Model OR-1. The elemental analyses were carried out by means of a Yanagimoto CHN Corder, Model MT-2; the results for the known products agreed with the theoretical values. The melting points for samples over 220 °C were determined with a Mitamura hot-stage apparatus.

*N^{α}-Benzyloxycarbonyl-*L*-arginine-*p*-nitroanilide Hydrochloride (*L*-ZAPA·HCl).* Solution A, containing *p*-nitroaniline(4.14 g, 0.03 mol) and triethylamine(4.2 ml, 0.03 mol) in diethyl phosphite(15 ml), was added to Solution B, containing phosphorus pentaoxide(8.55 g, 0.06 mol) in diethyl phosphite(30 ml). A solution of N^{α}-benzyloxycarbonyl-L-arginine(9.24 g, 0.03 mol) containing 85% phosphoric acid (2.1 ml, 0.03 mol) in diethyl phosphite(30 ml) was then added to the mixture of Solution A and B. The reaction mixture was heated on a water bath with stirring for 2 h in a well-ventilated hood. Diethyl phosphite was removed *in vacuo*, and the residual oil dissolved in 300 ml of 1 M HCl after heating at 85 °C for about 5 min. After the solution had stood in the refrigerator overnight, a semisolid oil was precipitated. This semisolid oil was separated by decanting off the acid solution, washed with cold water, and then dried. The oily product which crystallized on triturating with ethyl acetate was filtered and washed with small quantities of ethyl acetate and cold acetone. The crystalline product was recrystallized by dissolving it in hot water, and after it had been cooled to about 50 °C, an equal volume of 1M HCl was added After the solution had stood at 4 °C overnight, an almost colorless crystalline product was obtained. Yield, 7.2 g (50%); mp 181—182 °C; $[\alpha]_D^{20}$ −16.0° (*c* 1, ethanol) Found: C, 51.62; H, 5.29; N, 18.05; Cl, 7.59%. Calcd for $C_{20}H_{25}N_6O_5Cl$: C, 51.64; H, 5.42; N, 18.08; Cl, 7.64%.

L-Arginine-p-nitroanilide Dihydrochloride(L-APA·2HCl). A solution of L-ZAPA·HCl (5 g) in pure glacial acetic acid (200 ml) was saturated with dry hydrogen chloride at 50 °C for 90 min. The reaction mixture was then evaporated *in vacuo* to a small volume, and the crystalline product was precipitated with dry ether. The product was recrystallized from water/acetone. Yield, 3.55 g (90%); mp 245 °C; $[\alpha]_D^{20}$ +80.6° (*c* 1, water)

Benzoyl-L-arginine-p-nitroanilide Hydrochloride(L-BAPA·HCl) and Acetyl-L-arginine-p-nitroanilide Hydrochloride(L-AAPA·HCl). L-BAPA·HCl and L-AAPA·HCl were prepared from L-APA·2HCl by the procedures reported by Nishi and Noguchi.[4] The melting points and specific optical rotations were identical with those previously reported.[4]

The Absorption Spectra and Tryptic Digestion of L-ZAPA·HCl and Other L-Arginine-p-nitroanilides. The wavelength of maximum absorption, λ_{max}, for L-ZAPA·HCl at a concentration of 7.8×10^{-5} M was 315 nm with a molar extinction coefficient of 1.41×10^4. The enzymatic hydrolyses of L-ZAPA·HCl, L-BAPA·HCl, and L-TAPA·HCl are shown in Fig. 1; they were determined by the measurement of *p*-nitroaniline at 410 nm, at which wavelength neither the L-ZAPA·HCl nor any of the other L-arginine-*p*-nitroanilides[4] has any absorbance.

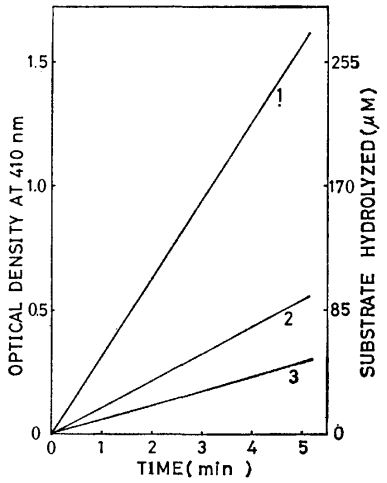

Fig. 1. Tryptic hydrolyses of 1. L-ZAPA·HCl, 2. L-BAPA·HCl, and 3. L-TAPA·HCl as a function of time. Initial concentration of *p*-nitroanilide substrate: 10^{-3}M in 0.05M tris-HCl buffer (pH 8.2) containing 0.02M $CaCl_2$ and 1% dimethylformamide. Trypsin concentration was 10 μg/ml and incubation period was 300 s at 25 °C.

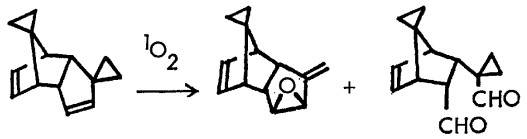
(Received September 8, 1977)

Synopsis. The dye-sensitized photooxidation of the Diels-Alder adducts prepared from 2-substituted tropones and spiro[2.4]hepta-4,6-diene was caried out. A marked difference in the reactivities was observed between the two structural types of adducts; 3,3-ethylene derivatives gave nor-epoxides, but 5,5-ethylene derivatives resulted in the recovery of the starting materials.

Previously, we have reported[2] the occurrence of a novel degradation process to form an epoxy norolefin, **B**, by the singlet oxygen oxidation of **A**, a spirocyclic vinylcyclopropane, in addition to the splitting into a dialdehyde, **C**. In considering this new process, we wanted to extend the reaction to other spiro olefins in order to ascertain its applicability and limitations. Looking for suitable substrates, we noticed a report by Tanida *et al.*[3] which described the Diels-Alder reaction of spiro[2.4]hepta-4,6-diene (**1**) with tropone (**2**) to form two *endo*-(4+2)π-adducts (**3** and **4**); we ourselves repeated the experiments to obtain some analogues from 2-chlorotropone (**5**) and 2-methoxytropone (**6**). Tropolone (**7**) was unreactive under similar conditions. We will herein describe the results of the photo-sensitized oxygenation of the adducts.



(**A**) (**B**) (**C**)

Diels-Alder Reaction of Troponoids and Spiroheptadiene (1). Slightly modifying Tanida's conditions, we have carried out the reaction with **5** and **6** and have confirmed the formation of similar types of adducts (**8**, **9**, **12**, and **13**), together with new 1 : 2-adducts (**10** and **14**). In addition, an *exo*-(4+2)π-adduct, **11**, was obtained from **1** and **5**.[4]

Sensitized Photooxidation of the Adducts. When a chloroform solution of **3** was irradiated by means of a 500 W tungsten lamp in the presence of Methylene Blue for 86 h, a single compound, colorless crystals (**15**), was obtained in a 79% yield. The NMR [δ: 2.73 (2H, br s), 3.31 (1H, d, J=2.5 Hz), 3.45 (2H, m), 3.60 (1H, d, J=2.5 Hz), 5.24 (1H, br s), 5.41 (1H, d, J=2 Hz), 5.64 (1H, dd, J=11, 2.5 Hz), 5.97 (1H, t, J=8 Hz), 6.31 (1H, t, J=8 Hz), and 7.13 (1H, dd, J=11, 9 Hz)] spectrum revealed the formation of an epoxy group and a terminal ethylene group, suggesting an oxidative fragmentation product related to **B**. Thus, the carbonyl group in the molecule suppressed the formation of a dialdehyde.

On the other hand, the isomer (**4**) afforded no product when similarly irradiated for 144 h.

When a chloroform solution of **8** and Methylene Blue was similarly irradiated for 77 h, the sole product (**16**), also a vinyloxirane, was obtained in a 64% yield. The NMR [δ: 3.03 (2H, br s), 3.45 (1H, dd, J=9, 8 Hz), 3.54 (1H, d, J=3 Hz), 3.75 (1H, d, J=3 Hz), 3.82 (1H, d, J=8 Hz), and 7.50 (1H, d, J=9 Hz)] and the IR [ν: 925, 880 cm^{-1}] spectra indicated the structure of **16**. **9** was inert against the oxygenation.

Similarly, **12** afforded only **17** in an 89% yield, but **13** was inert. The NMR [δ: 2.95 (2H, br s), 3.50 (3H, s), 3.38—3.72 (4H, m), 5.25 (1H, br s), 5.45 (1H, br s), 5.95 (1H, dd, J=9, 8 Hz), 6.17 (1H, dm, J=10 Hz), and 6.38 (1H, t, J=8 Hz)] and IR [ν: 930, 890 cm^{-1}] spectra of **17** indicated the structure.

The continuous exposure of the adducts to oxygen in the dark caused no reaction; thus, the formation of vinyloxiranes is photochemical. Meanwhile, we have recently shown[6] that, during the oxygenation of **A**, a quenching of singlet oxygen by sodium azide has resulted in the complete suppression of both **B** and **C**, with the alternative production of free radical products. Therefore, the vinyloxiranes must be related to the singlet-oxygen oxidation,[7] and the location of the carbonyl group in the spirocyclic vinylcyclopropanes controlled the whole oxidation reaction. We have to admit that, compared to the reaction with a hydrocarbon, **A**, the reaction with the present series has revealed a critical rate decrease for usual singlet-oxygen oxidation, but this might be explained in terms of a quenching effect by the carbonyl group, as has already been described in connection with the photooxidation of tropinone derivatives.[8] Together with this quenching

effect, the observed change in the product controle is probably also attributable to the carbonyl group, but these remote effects are not fully understandable at the present stage.

Experimental

Addition Reaction of Tropone (2) and Spiro[2.4]hepta-4,6-diene (1). A mixture of **2** (355 mg) and **1** (0.4 g) were heated in a sealed tube at 110—115 °C for 72 h, with a slight modification of the reported conditions.[3] A work-up of the mixture gave **3** (232 mg (35%)), and **4** (185 mg (28%)).

Addition Reaction of 2-Chlorotropone (5) and 1. **1** (2.5 ml) and **5** (1.00 g) were mixed in a sealed tube and then heated at 130—135 °C for 72 h. Repeated chromatography of the mixtures with benzene to benzene-ether afforded **8** (741 mg, 44%) as colorless needles; mp 133—135 °C (from benzene)[Found: C, 72.45; H, 5.62%. Calcd for $C_{14}H_{13}OCl$: C, 72.26; H, 5.63%. δ: 0.5—0.9 (4H, m), 2.61 (1H, dd, J=9, 2 Hz), 3.46 (1H, dddm, J=9.5, 8, 2 Hz), 3.52 (1H, ddm, J=2, 1 Hz), 3.74 (1H, dq, J=9, 2 Hz), 5.17 (1H, dd, J=5.5, 2 Hz), 5.37 (1H, dd, J=5.5, 2 Hz), 6.10 (1H, tt, J=8, 1 Hz), 6.40 (1H, tm, J=8 Hz), and 7.45 (1H, d, J=9.5 Hz); ν: 1680 cm^{-1}; λ_{max}^{MeOH}: 237 nm (ε: 3100), 273 (2200)], **9** (303 mg, 18%); pale yellow needles, mp 67—68 °C (from ethanol)[Found: C, 72.42; H, 5.70%. δ: 0.5—1.0 (4H, m), 2.93 (1H, dd, J=8.5, 2 Hz), 2.94 (1H, td, J=8, 2 Hz), 3.65 (1H, dt, J=8.5, 2 Hz), 5.29 (1H, dd, J=5.5, 2 Hz), 5.85 (1H, dd, J=5.5, 2 Hz), 5.94 (1H, dd, J=11, 0.7 Hz), 6.08 (1H, dt, J=9, 0.7 Hz), 6.36 (1H, ddm, J=9, 8 Hz), and 7.04 (1H, dd, J=11, 8 Hz); ν: 1680 cm^{-1}], **11** (16.8 mg, 1%); a pale yellow oil[Found: *M. W.*, 232.0645 (M$^+$). Calcd for $C_{14}H_{13}OCl$: 232.0655. δ: 0.76 (4H m). 2.71 (1H, dd, J=10, 5 Hz), 3.27 (1H, dddm, J=8, 7.5, 5 Hz), 4.02 (1H, dt, J=10, 2 Hz), 5.26 (1H, dd, J=6, 2 Hz), 5.63 (1H, dd, J=6, 2 Hz), 5.92 (1H, d, J=11 Hz), 6.07 (1H, d, J=9 Hz), 6.42 (1H, dd, J=9, 7.5 Hz), and 6.96 (1H, dd, J=11, 8 Hz); ν: 1690 cm^{-1}], and **10** (as a mixture with **8**), 78.3 mg.

Isolation of 10. A mixture (75 mg) of **8** and **10** was dissolved in chloroform (20 ml) and was then irradiated by means of a tungsten lamp in the presence of Methylene Blue (20 mg) under an oxygen stream. The mixture was then chromatographed on a silica gel column to give **10** as colorless needles; mp 150—151 °C, 21 mg (0.9% overall from **5**) [Found: *M. W.*, 324.1295. Calcd for $C_{21}H_{21}OCl$: 324.1281. δ: 0.3—0.9 (8H, m), 2.12 (1H, br s), 2.26 (1H, ddm, J=8, 2.5 Hz), 2.75 (1H, dt, J=9, 2.5 Hz), 2.88 (1H, dm, J=4 Hz), 2.98 (1H, ddm, J=9, 2.5 Hz), 3.28 (1H, dd, J=9, 4 Hz), 3.78 (1H, dt, J=9, 1.5 Hz), 5.36 (1H, dd, J=6, 1.5 Hz), 5.37 (1H, d, J=9.5 Hz), and 5.8—6.2 (4H, m, 3-H, 12-H, 2′-H, and 3′-H); ν: 1710 cm^{-1}; λ_{max}^{MeOH}: 225 nm (ε: 5000, sh), 254 (1800)].

Addition Reaction of 2-Methoxytropone (6) with 1. A mixture of **1** (2.5 ml) and **6** (1.00 g) was heated in a sealed tube at 130—135 °C for 94 h. The mixture thus formed, a dark brownish oil, was fractionated by chromatography using silica gel to give **12**, 395 mg (23.5%) of a pale yellow oil[Found: C, 77.12; H, 6.98%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%. δ: 0.50—0.90 (4H, m), 2.62 (1H, dm, J=9 Hz), 3.35—3.82 (3H, m), 3.56 (3H, s), 5.16 (1H, dd, J=6, 2 Hz), 5.40 (1H, dd, J=6, 2 Hz), 6.00 (1H, t, J=8 Hz), 6.17 (1H, d, J=9 Hz), and 6.43 (1H, t, J=8 Hz); ν: 1670 cm^{-1}, λ_{max}^{MeOH}: 234 nm (ε: 9200), 282 (8050)], **13**, 160 mg (9.5%), pale yellow needles, mp 123—125 °C (from ethanol) [Found: C, 78.72; H, 7.12%. δ: 0.50—0.80 (4H, m), 2.82 (1H, dd, J=9, 2 Hz), 2.99 (1H, ddm, J=9, 7 Hz), 3.59 (3H, s), 3.66 (1H, dt, J=9, 2 Hz), 5.24 (1H, dd, J=6, 2 Hz), 5.66 (1H, dd, J=6, 2 Hz), 5.80 (1H, d, J=11 Hz), 6.01 (1H, dm, J=9 Hz), 6.37 (1H, dd, J=9, 7 Hz), and 7.00 (1H, dd, J=11, 9 Hz); ν: 1680 cm^{-1}; λ_{max}^{MeOH}: 225 nm (δ: 7800), 250 (6500)], and **14**, 246 mg (10.5%), colorless needles, mp 148—150 °C (from ethanol) [Found: *M. W.*, 230. δ: 0.20—0.90 (8H, m), 2.08 (1H, tm, J=3 Hz), 2.24 (1H, ddm, J=8, 3 Hz), 2.66 (1H, dt, J=10, 3 Hz), 2.84 (1H, dd, J=4, 3 Hz), 2.89 (1H, dm, J=10 Hz), 3.13 (1H, dd, J=10, 4 Hz), 3.38 (3H, s), 3.88 (1H, dt, J=10, 2Hz), 5.19 (1H, d, J=9 Hz), 5.32 (1H, dd, J=6, 2 Hz), 5.63 (1H, dd, J=6, 2 Hz), 5.91 (1H, dd, J=9, 8 Hz), 5.94 (1H, dd, J=6, 3 Hz), and 6.10 (1H, dd, J=6, 3 Hz); ν: 1710 cm^{-1}].

An Attempted Addition Reaction of Tropolone (7) and 1. **7** (214 mg) and **1** (0.6 ml) were mixed in a sealed tube and heated for 72 h at 130—135 °C. The mixture was then treated with acetic anhydride (0.5 ml) and evaporated *in vacuo*; the residual mass was chromatographed through a silica gel column with benzene. Only **7** as the acetate (203 mg (93%)), and the dimer of **1** (355 mg) were obtained.

Sensitized Photooxidation of 3. **3** (690 mg) was dissolved in chloroform (40 ml), and was irradiated by a 500-W tungsten lamp in the presence of Methylene Blue (20 mg) under oxygen bubbling. After 86 h, the mixture was chromatographed to give colorless needles (**15**) (mp 82—83 °C (from methanol); 386 mg (79%) [Found: C, 77.67; H, 6.07%. Calcd for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04%]), together with **3** (195 mg). Inspections of every chromatographic fraction confirmed the absence of any other product.

Sensitized Photooxidation of 8. **8** (600 mg) and Methylene Blue (20 mg) were dissolved in chloroform (30 ml), and the mixture was irradiated by means of a 500-W tungsten lamp for 77 h, with a continuous bubbling of oxygen, at −5—0 °C. The mixture was then fractionated by chromatography to give **16** (colorless needles, mp 125—126 °C (from ethanol), 150 mg (64%) [Found: *M. W.*, 234.0474 (M$^+$). Calcd for $C_{13}H_{11}O_2Cl$: 234.0448. ν: 1680 cm^{-1}]), along with only **8** (365 mg).

Sensitized Photooxidation of 12. **12** (609 mg) and Methylene Blue (20 mg) were dissolved in chloroform (30 ml), and the mixture was irradiated by means of a 500-W tungsten lamp for 204 h with a bubbling oxygen stream at −5—0 °C. After a chromatography, the mixture gave a pale yellow oil, **17** (446 mg (89%) [Found: C, 73.55; H, 6.61%. Calcd for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13%. ν: 1680 cm^{-1}]), together with **12** (110 mg). No other product was detectable.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (4), 1259—1260 (1978)

The Reaction of Decaborane with Carbonyl Compounds

Toyosuke TANAKA, Tsuneo MATSUDA, Katsunori KIMIJIMA, and Yuichi IWASAKI

Faculty of Engineering, Saitama University, Shimoohkubo, Urawa, Saitama 338

(Received September 12, 1977)

Synopsis. Decaborane formed adducts with cyclohexanones, 2-octanone, acetaldehyde, or acetone, which were cleft in the presence of water into alcohols, boric acid, and hydrogen. Olefins and boroxins as secondary products were identified.

Several addition compounds[1] of decaborane, $B_{10}H_{14}$,[2] have been studied since Stock's first observation[3] of $B_{10}H_{14}\cdot(NH_3)_6$, formed by the evaporation of a liquid ammonia solution of decaborane. In this study, new reactions of decaborane with carbonyl compounds, such as acetaldehyde, acetone, 2-octanone, cyclohexanone, 2-methylcyclohexanone, 3-methylcyclohexanone, and 4-methylcyclohexanone, were carried out.

When solid decaborane was treated with a carbonyl compound ($RCH_2R'CO$) in the range from room temperature to 120 °C, the 1 : 1 adduct from both reactants was formed in a pasty mass of the reaction mixture. Though the adduct could not be isolated because of its unstability for oxygen or moisture, its parent peak in the mass spectra and the lack of any absorption associated with the carbonyl group in IR observed in the adduct.

$$B_{10}H_{14} + RCH_2R'CO \longrightarrow RCH_2R'CO\cdot B_{10}H_{14}.$$

The addition of water as an additional reactant to decaborane and a carbonyl compound accelerated both adduct formation and their decomposition into alcohol, boric acid, and H_2. Based upon the measured molar yields of the products, the primary decomposition of the adduct may be stoichiometrically expressed as follows

$$RCH_2R'CO\cdot B_{10}H_{14} + 30\,H_2O \longrightarrow RCH_2R'CHOH + 10\,H_3BO_3 + 21\,H_2.$$

Beside the primary decomposition products, olefins and boroxin compounds were observed in the reaction. The formation of olefins may be brought about by the dehydration of the alcohols primarily yielded:

$$RCH_2R'CHOH \longrightarrow RCH{=}CHR' + H_2O.$$

Just after the reaction of decaborane with acetone in H_2O, three compounds, 2-propanol and boric acid in a pasty mass, and H_2, were found. Tri(isopropoxy)-boroxin, however, was identified in the pasty mixture after the mixture was put aside without any treatment for 24 h. Thus, the boroxine may be formed by the condensation of alcohol and metaboric acid resulting from the dehydration of boric acid as the first product. No formation of boroxine from alcohol with boric acid was proven.

$$3\,H_3BO_3 \longrightarrow H_3B_3O_6 + 3\,H_2O,$$

$$3\,RCH_2R'CHOH + H_3B_3O_6 \longrightarrow (RCH_2R'CHO\text{-}\underset{|}{B}\text{-}O\text{-})_3 + 3\,H_2O.$$

The yields of the alcohols and olefins, together with their isomers as the main reaction products from decaborane with carbonyl compounds, are summarized in Table 1.

TABLE 1. ALCOHOL AND OLEFIN FROM THE REACTION OF DECABORANE WITH CARBONYL COMPOUNDS

Carbonyl compd	Alcohol,[a] %		Olefin,[a] %		Conditions
Cyclohexanone	Cyclohexanol	72.0	Cyclohexene	18.7	90 °C, in the absence of H_2O
Cyclohexanone	Cyclohexanol	15.4	Cyclohexene	80.0	Room temp, in the presence of H_2O
Cyclohexanone	Cyclohexanol	60.5	Cyclohexene	32.5	120 °C, in the absence of H_2O
2-Methylcyclohexanone	*cis*-2-Methylcyclohexanol	4.0	1-Methylcyclohexene	4.7	The same as above
	trans-2-Methylcyclohexanol	7.8	3-Methylcyclohexene	44.2	
3-Methylcyclohexanone	*cis*-3-Methylcyclohexanol	15.8	3-Methylcyclohexene	2.3	The same as above
	trans-3-Methylcyclohexanol	6.4	4-Methylcyclohexene	48.1	
4-Methylcyclohexanone	*cis*-4-Methylcyclohexanol	4.8	4-Methylcyclohexene	49.7	The same as above
	trans-4-Methylcyclohexanol	25.8			
2-Octanone	2-Octanol	8.6	1-Octene	4.7	50 °C, in the absence of H_2O
			cis-2-Octene	21.7	
			trans-2-Octene	65.2	
2-Octanone	2-Octanol	26.0	Octenes	traces	Room temp, in the presence of H_2O
Acetaldehyde	Ethanol	26.0			The same as above
Acetone	2-Propanol	90.0			The same as above

a) The yields of alcohol and olefin were calcd based on decaborane.

Experimental

The decaborane, supplied by the Callery Chem. Co., U.S.A., was purified by recrystallization from hexane. The other liquid reagents were distilled before the reaction. The experiments were performed in an atmosphere of dry nitrogen or of argon. The products were examined with an infrared spectrometer, a mass spectrometer, and by gas chromatography, In the gas-chromatographic analysis a Molecular sieve 5A column was used for H_2, with He as the carrier gas. A didecyl phthalate column was also used for the liquid products.

Reaction of Decaborane with Cyclohexanone. A solution of 1.227 g (0.01 mol) of decaborane and 0.980 g (0.01 mol) cyclohexanone in 17 g of cyclohexane was kept at 80—83 °C for 4 h. The subsequent removal of the solvent and the excess constituents *in vacuo* gave 2.11 g of a pasty solid; IR (in CS_2) 1338, 1360 cm^{-1} (B–O); mass spectrum *m/e* 222 (M^+ $B_{10}H_{14}COC_5H_{10}$).

The pasty solid product decomposes mainly into boric acid and cyclohexanol, upon filtration, drying, and so on.

Reaction of Decaborane with Cyclohexanone in the Presence of Water. The mixture from 0.086 g (0.71 mmol) of decaborane 1.3 g (13 mmol) of cyclohexanone and 0.3 g (17 mmol) of water was stirred at room temperature for 15 min. During the reaction, the 156-ml portion (760.8 mmHg, 17 °C) of gas evolved was put in a gas receiver and was analyzed by gas chromatography; the gas was found to be a mixture of H_2 (99.0%) and N_2(1.0%).

The liquid portion of the reaction mixture was distilled off under reduced pressure. The liquid distillate, which weighed 0.14 g, was then subjected to gas-chromatographic analysis. Four constituents—cyclohexanone recovered (35%), cyclohexanol (8%), cyclohexene (30%), and an unknown compound (10%)—were found.

The mixture remaining after evacuation was extracted with light petroleum, after which the solvent was evaporated; this gave a residue which, on recrystallization from benzene-light petroleum, yielded 0.02 g of tris(cyclohexyloxy)boroxin. The mp and mixed mp with an authentic sample[4] was 166—167 °C; IR 720, 735 cm^{-1} (out-of-plane boroxin skeletal vibration) 1338, 1360 cm^{-1} (stretch B–O); mass spectrum *m/e* 378.

Found: B, 8.58%. Calcd for $C_{18}H_{33}O_6B_3$: B, 8.58%.

The remainder after extraction with light petroleum gave 0.3 g boric acid. The mp and mixed mp with an authentic sample was 184—185 °C.

Found: B, 17.16%. Calcd for H_3BO_3: B, 17.48%.

Reaction of Decaborane with Acetone in the Presence of Water. To a mixture of 0.37 g (3 mmol) of decaborane and 3.48 g (60 mmol) of acetone we added 1.80 g (100 mmol) of H_2O. A reaction took place, and 1425 ml (776.5 mmHg, 20 °C) (60.5 mmol) of hydrogen were evolved. The rectification of the reaction mixture gave a liquid distillate which was determined by gas chromatography to contain 0.16 g (2.7 mmol) of 2-propanol. The recrystallization of the solid residue with aqueousethanol yielded 0.18 g (29 mmol) of boric acid, which was identical in its mp and IR spectrum with the authentic sample.

Boroxin Formation from Decaborane, Acetone, and Water. A mixture of 0.32 g (2.6 mmol) of decaborane, 2.6 g (45 mmol) of acetone, and 0.35 g (10.5 mmol) of H_2O was allowed to stand for 24 h at room temperature. The subsequent removal of the liquid portion and the recrystallization of the resulting solid residue by using light petroleum and benzene-petroleum gave 1.0 g of tris(isopropyl)boroxin, mp 45—46 °C; IR (in CS_2) 720, 735 cm^{-1} (B–O in boroxin skeleton); mass spectrum *m/e* 258 (M^+).

Found: B, 12.60%. Calcd for $C_9H_{21}B_6O_3$: B, 12.58%.

New Synthesis of γ-Hydroxyglutamic Acid

Takenori KUSUMI, Hiroshi KAKISAWA, Shinnichiro SUZUKI, Kaoru HARADA, and Choji KASHIMA*

Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received September 16, 1977)

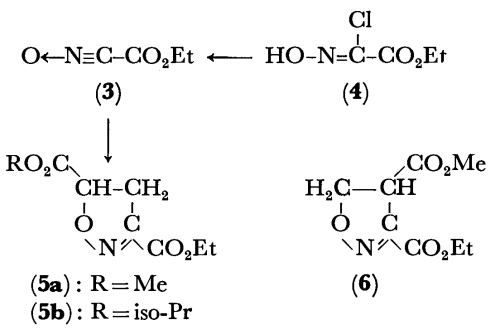
Synopsis. γ-Hydroxyglutamic acid was prepared easily via 3-ethoxycarbonyl-5-methoxycarbonyl-2-isoxazoline, which was the 1,3-dipolar adduct of methyl acrylate and ethyl cyanoformate *N*-oxide.

It has been reported that γ-hydroxy α-amino acids occur in some kinds of plants.[1a,b,c] γ-Hydroxyglutamic acid (**1**) has been found in the green parts of the plants, *Phlox decussa*[2] and *Linaria vulgaris*.[3] By enzymatic decarboxylation, this γ-hydroxyglutamic acid gives 4-amino-2-hydroxybutyric acid (**2**), which is known to accelarate the activity of antibiotics such as kanamycin.[4,5] γ-Hydroxyglutamic acid (**1**) is expected to have the biological activity.

(**1**) (**2**)

In this paper, we describe the new synthesis of **1**, *via* the 1,3-dipolar addition of ethyl cyanoformate *N*-oxide (**3**) and acrylic esters.

Glycine ethyl ester hydrochloride was treated with sodium nitrite to give ethyl chloro(hydroxyimino)acetate (**4**). It was reported that chloro oxime (**4**) smoothly yielded nitrile oxide (**3**) by the treatment with bases such as triethylamine.[6] Therefore, **4** was slowly added to a mixture of triethylamine and methyl acrylate in chloroform at room temperature. After standing for 2 days, the products were purified by distillation giving an oil. From the spectral properties, the product was found to be 3-ethoxycarbonyl-5-methoxycarbonyl-2-isoxazoline (**5a**) (71% yield). Another expected compound (**6**) was not detected.



(**3**) (**4**)

(**5a**): R=Me
(**5b**): R=iso-Pr

(**6**)

For the cleavage of N–O bond, **5a** was hydrogenated over platinum in the presence of 1 equivalent of hydrochloric acid. By the direct hydrolysis of the reduced product (**7**) with 20% hydrochloric acid, a disatereomeric mixture of lactam, lactone and free amino acid forms of γ-hydroxyglutamic acid was obtained. The reaction mixture was dissolved in a small volume of water, and the solution was saturated with hydrogen chloride at 0 °C. The precipitate, which was assigned to the *threo*-γ-hydroxyglutamic acid lactone (**8a**) hydrochloride[7] was obtained in 40% yield. By the ion exchange chromatography of the filtrate, the free *erythro*-γ-hydroxyglutamic acid (**1b**)[7] was isolated in 20% yield. Also the mixture of lactams, (**9a**) and (**9b**), was eluted. However, *erythro* lactone (**8b**) could not be isolated from the reaction mixture.

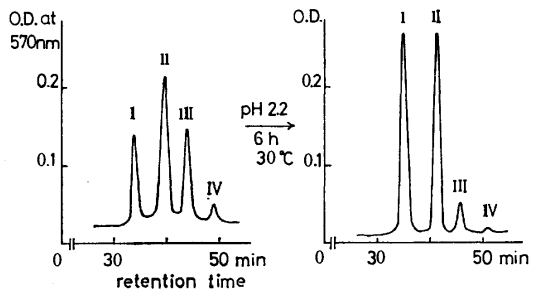


Fig. 1. Amino acid analysis of hydrolyzed product of **7**. Column: Yanagimoto SCX-1001; temp: 55 °C; elution buffer: citrate buffer, pH 3.25.

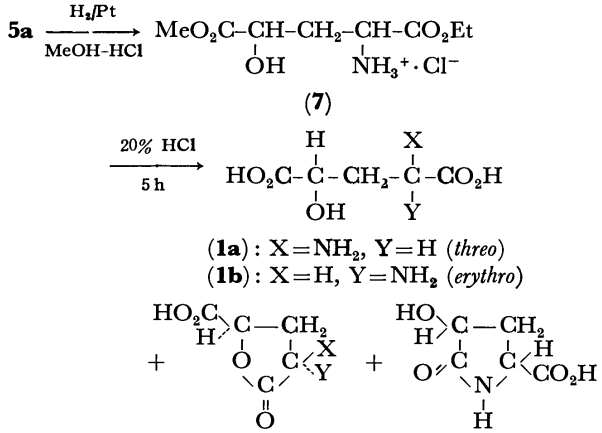
The product ratio of the amino acid and its lactone was determined by amino acid analyzer. In the amino acid chromatogram (Fig. 1), the reaction mixture showed four peaks (I—IV). After the buffered solution (sodium citrate buffer, pH 2.2) of the mixture was kept at room temperature for 6 hours, the peaks III and IV remarkably decreased, and the peaks I and II increased. When the solution of **8a** was allowed to stand in similar conditions, the peak III of **8a** gradually decreased, while the peak I increased. The peak II was found to correspond to **1b**. Thus, these four peaks (I—IV) were assigned to the compounds (**1a**), (**1b**), (**8a**), and (**8b**), respectively. After the peaks III and IV were diminished, the ratio of **1a** and **1b** was evaluated as 4: 6 from the



(**7**)

(**1a**): X=NH_2, Y=H (*threo*)
(**1b**): X=H, Y=NH_2 (*erythro*)

(**8a**): X=NH_2, Y=H (*threo*) (**9a**), (**9b**)
(**8b**): X=H, Y=NH_2 (*erythro*)

result of amino acid analysis.

In the hydrogenation on platinum, the isoxazolines are expected to change the ratio of the diastereomers by a bulky group on C-5 position. Therefore, 3-ethoxycarbonyl-5-isopropoxycarbonyl-2-isoxazoline (**5b**) was synthesized from isopropyl acrylate and the nitrile oxide (**3**). After hydrogenation and hydrolysis as described above, the ratio of **1a** and **1b** was determined as 4: 6. The isopropoxycarbonyl group has no effect on the ratio of the diastereomers. The lack of specificity of the hydrogenation must be due to facile rapture of the N–O bond prior to the reduction of the C=N bond.

In conclusion, the method described above is considered to have the general utility in the γ-hydroxyamino acid synthesis. This method for the γ-hydroxyamino acid synthesis is in progress.

Experimental

The melting points and boiling points are uncorrected. PMR spectra were recorded on a Hitachi R-24A instrument, TMS being used as an internal standard (δ, ppm). IR spectra were taken on a Hitachi EPI-S2 spectrometer. The amino acid chromatograms were recorded on a Yanagimoto amino acid analyzer LC-5S.

3-Ethoxycarbonyl-5-methoxycarbonyl-2-isoxazoline (5a). A solution of ethyl chloro(hydroxyimino)acetate[6] (**4**; 6.73 g) in dry chloroform (150 ml) was added to a solution of methyl acrylate (15 ml) and triethylamine (30 ml) in chloroform (50 ml) during 2.5 h at room temperature. The slightly brown solution was stirred at room temperature for two days, and the solution was washed with dilute hydrochloric acid and water. After drying over magnesium sulfate, the chloroform was evaporated under vacuum affording a brown liquid. Fractional distillation produced **5a** as a pale yellow liquid: Bp 107—121 °C/3 mmHg (7.0 g); NMR ($CDCl_3$): 1.35 (1H, t, J=7 Hz), 3.51 (2H, d, J=8 Hz), 3.78 (3H, s), 4.34 (2H, q, J=7 Hz), and 5.18 (1H, t, J=8 Hz); IR (film): 1740, 1600, 1260, 1120, 1020, and 920 cm^{-1}. Found: C, 47.77, H, 5.51, N, 6.84%. Calcd for $C_8H_{11}NO_5$: C, 47.76, H, 5.51, N, 6.96%.

Hydrogenation of 5a and Subsequent Hydrolysis. The isoxazoline (**5a**) (3.02 g) was hydrogenated over platinum oxide (0.30 g) in methanol (100 ml)–3M hydrochloric acid (5 ml) at room temperature for 24 hr. The catalyst was filtered away, and the filtrate was concentrated to a colorless oil. The oil was refluxed in 20% hydrochloric acid (130 ml) for 5 h, and the yellow solution was treated with charcoal. After the charcoal was removed by filtration, the filtrate was concentrated giving a pale green oil (3.0 g), which partyl crystallized on standing. The oil (3.0 g) was dissolved in water (1.2 ml), and the solution was saturated with hydrogen chloride at 0 °C. The resulting mixture was allowed to stand in a refrigerator for two days. The precipitated *threo*-γ-hydroxyglutamic acid lactone hydrochloride (**8a**) (736 mg) was collected by filtration: Mp 228—230 °C (dec) [lit,[7] 228—230 °C (dec)]. IR (KBr): 3600—2400 (br), 1785, 1755, 1200, 1045 cm^{-1}; MS *m/e* 145 (M^+−HCl), 101 (145−CO_2), 100 (145−CO_2H), 84 (101−NH_3), 83 (100−NH_3), 72 (100−CO), 56 (100−CO_2), and 55 (83−CO).

The filtrate was concentrated, and a small volume of water was added. The solution was again saturated with hydrogen chloride. The second crop (343 mg) of **8a**, mp 225 °C (dec), was collected by filtration. The filtrate was concentrated producing a yellow oily residue (1.5 g), which was chromatographed on a cation exchange (Dowex-50, 100 g). Elution with water afforded a pale green oil (360 mg), from which the diastereomeric mixture of the lactams (**9a** and **9b**) was separated as semisolid by trituration (200 mg): IR (KBr): 3700—2300 (br), 1730, 1685, and 1100 cm^{-1}. This mixture afforded *threo* and *erythro* γ-hydroxyglutamic acid (by amino acid analysis) when it was heated with 6M hydrochloric acid at 100 °C for one day.

Further elution with 15% trimethylamine solution afforded a light yellow oil (1.05 g). The oil (965 mg) was dissolved in water (0.5 ml). Hydrochloric acid (3M) was added in small portions until the pH of the solution reached 3. The precipitated *erythro*-γ-hydroxyglutamic acid was collected by filtration (417 mg), mp 165—166 °C (dec) [lit,[7] 166 °C (dec)]. Analytical sample was obtained by recrystallization from water–ethanol. (Found: C, 36.82; H, 5.49; N, 8.67%. Calcd for $C_5H_9NO_5$: C, 36.81; H, 5.56; N, 8.59%).

3-Ethoxycarbonyl-5-isopropoxycarbonyl-2-isoxazoline (5b). In a 100-ml flask was placed isopropyl acrylate (1.96 g) in dry chloroform (5 ml), and to this mixture was added triethylamine (5 ml). A solution of the chloro oxime (**4**) (1.9 g) in chloroform (10 ml) was added to the mixture with stirring during 1 h at room temperature. The mixture was stirred at room temperature for 20 h, and diluted with chloroform. The solution was washed with several portions of water, and dried over sodium sulfate. The solution was concentrated affording a light brown oil, which was distilled under vacuum (1.63 g); bp 130—134 °C/3 mmHg. NMR ($CDCl_3$): 1.39 (6H, d, J=7 Hz), 1.43 (3H, t, J=7 Hz), 3.43 (2H, d, J=10 Hz), 4.32 (2H, q, J=7 Hz), 5.10 (1H, t, J=10 Hz), and 5.05 (1H, heptet, J=7 Hz). Found: C, 52.18; H, 6.67; N, 6.01%. Calcd for $C_{10}H_{15}O_5N$: C, 52.39; H, 6.60; N, 6.11%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (4), 1263—1264 (1978)

Formation of (4*S*,5*R*)-4-(Nitrovinyl)-2-phenyl-1,3-dioxan-5-yl Formate from Methyl 4,6-*O*-Benzylidene-2-deoxy-2-nitro-β-D-glucopyranoside

Tohru SAKAKIBARA and Rokuro SUDOH

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

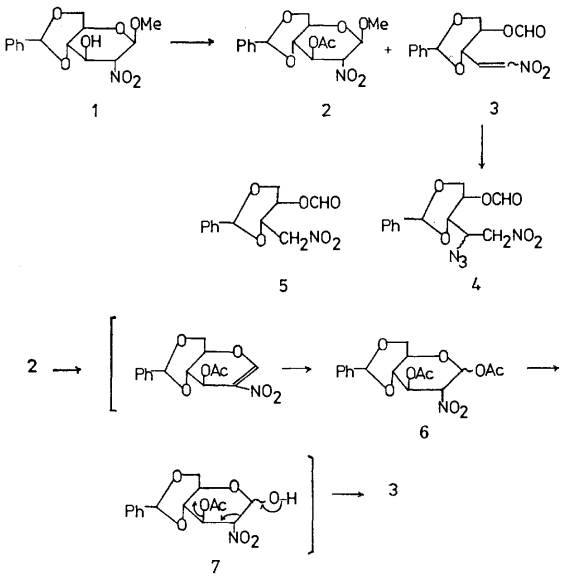
(Received September 19, 1977)

Synopsis. Acetylation of methyl 4,6-*O*-benzylidene-2-deoxy-2-nitro-β-D-glucopyranoside with acetic anhydride–pyridine afforded a mixture of the expected 3-*O*-acetate and the title compound in a *ca.* 1: 1 ratio; the structure of the latter compound was confirmed by conversion into an adduct with hydrazoic acid.

Acetylation of the nitro alcohol **1** with acetic anhydride–sodium acetate gave the corresponding 3-*O*-acetate **2** in 70% yield,[1] but treatment of **1** with acetic anhydride–pyridine unexpectedly gave the title compound **3** besides the acetate **2**. In this paper we wish to report on the structural determination of **3**.

Treatment of **1** with acetic anhydride and pyridine at room temperature for 4 h gave a mixture of **2** and **3** in a ratio of *ca.* 1: 1 as determined by NMR spectroscopy. Both compounds were isolated by fractional crystallization. The results of elemental analysis of **3** correspond to the formula $C_{13}H_{13}NO_6$, confirmed by the appearance of the molecular ion peak at *m/e* 279, and its IR spectrum shows the presence of a carbonyl (1715) and nitro olefin (1660 and 1515 cm^{-1}) group but the absence of a hydroxyl and an *O*-acetyl group. The NMR spectrum revealed that the product had lost the glycosidic methoxyl group but retained the benzylidene group. One proton singlet at δ 8.08 was assigned to the formyl proton, its chemical shift agreeing with that of (4*S*,5*R*)-4-nitromethyl-2-phenyl-1,3-dioxan-5-yl formate (**5**).[2] The signals of olefinic protons (H-1 and H-2) overlapped to give a singlet at δ 7.24 with two proton intensity. In order to confirm the structure, the nitro olefin **3** was treated with hydrazoic acid to give the adduct **4**, the IR spectrum of which showed the presence of azide (2170), formyl (1725), and nitro (1560 cm^{-1}) groups, and NMR spectrum exhibited a singlet at δ 8.06 (–OCHO) but no signal at δ 7.24 region due to olefinic protons. Although all the signals expected for **4** were observed and their assignments were verified by double-resonance experiments, the configuration at C-2 position has not been determined.

When acetylation was carried out at 0 °C and stopped after 20 min, the acetate **2** was formed almost exclusively. From this result and the fact[3] that hydration or the addition of acetic acid occurs readily to methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*erythro*-hex-2-enopyranoside in aqueous pyridine or in pyridine–acetic acid solution the following route seems to be reasonable. Under the reaction conditions, elimination of methnol followed by the addition of acetic acid should give rise to the diacetate **6**,[4] which would be converted into the unstable nitro alcohol **7** during the course of isolation process. The C_1–C_2 bond cleavage of **7** facilitated by the nitro group[2] and the subsequent elimination of acetic acid should afford the nitro olefin **3**.



Experimental

Melting points were determined in capillaries and are uncorrected. IR spectra were recorded for KBr discs and NMR spectra for solutions in $CDCl_3$ (tetramethylsilane as internal standard) with a JNM-4H-100 (JEOL). Commercial acetic anhydride and pyridine were used without purification.

Acetylation of Methyl 4,6-O-Benzylidene-2-deoxy-2-nitro-β-D-glucopyranoside (1) with Acetic Anhydride–Pyridine. To a solution of the nitro alcohol **1** (1.02 g) in pyridine (8 ml) was added acetic anhydride (4 ml) at room temperature. The mixture was kept for 4 h and poured into 100 ml of ice water. The precipitate was filtered and washed thoroughly with water to give 964 mg of a crude product. The IR and NMR spectra indicated it to be a mixture of **2** and **3** (approximately 1: 1). The crude product was recrystallized from ethyl acetate; the first crop was colorless crystals of **3** (410 mg): Mp 137.0—137.5 °C; $[\alpha]_D^{20}$ 0° (*c* 1, $CHCl_3$); IR 1715 (CO), 1660 and 1515 cm^{-1} (C=C–NO_2); NMR δ=8.08 (s, 1, CHO), 7.24 (s, 2, H-1 and H-2), 5.60 (s, 1, PhCH), 4.93 (sex, 1, H-4, $J_{3,4}$=10.0, $J_{4,5e}$=5.6, $J_{4,5a}$=10.0 Hz), 4.58 (d, 1, H-3), 4.51 (q, 1, H-5e, $J_{5a,5e}$=10.0 Hz), 3.71 (t, 1, H-5a), and 7.42 (broad s, 5, Ph).

Found: C, 56.11; H, 4.65; N, 4.92%. Calcd for $C_{13}H_{13}NO_6$: C, 55.91; H, 4.70; N, 5.02%.

The second crop (430 mg) was **2** containing small amounts of **3** as judged by its IR spectrum. Recrystallization from ethyl acetate gave pure **2** (380 mg), identical with an authentic sample.[1]

Addition of Hydrazoic Acid to the Nitro Olefin 3. To a solution of **3** (45 mg) in THF (3 ml) was added a chloroform solution containing hydrazoic acid (*ca.* 1.6 N, 0.15 ml). The mixture was stirred for 3 h at room temperature and then

evaporated *in vacuo* to give a crystalline residue (52 mg). The NMR spectrum showed the presence of two products in a ratio of approximately 5: 1. The major product crystallized from ethanol was 34.8 mg of **4**: Mp 137.5—138.0 °C; $[\alpha]_D^{20}$ +0.31° (*c* 0.6, $CHCl_3$); IR 2170 (N_3), 1725 (CHO), and 1560 cm^{-1} (NO_2); NMR δ=8.06 (s, 1, CHO), 7.38 (broad s, 5, Ph), 5.48 (s, 1, PhCH), 5.28 (sex, 1, H-4, $J_{3,4}$=9.7, $J_{4,5e}$=5.0, $J_{4,5a}$=10.0 Hz), 4.66 (d, 1, H-1, $J_{1,2}$=8.8 Hz), 4.65 (d, 1, H-1′, $J_{1',2}$=5.0 Hz), 4.51 (q, 1, H-5e, $J_{5e,5a}$=11.3 Hz), 4.21 (oct, 1, H-2, $J_{2,3}$=2.2 Hz), 4.01 (q, 1, H-3), and 3.68 (t, 1, H-5a).

Found: C, 48.62; H, 4.34; N, 17.51%. Calcd for $C_{13}H_{14}N_4O_6$: C, 48.45; H, 4.38; N, 17.39%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (4), 1265—1266 (1978)

The Reaction of Benzeneseleninic Acid with Olefins in Acetic Acid. A New Method of Acetoxyselenation

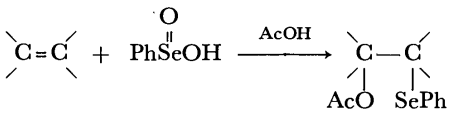
Noritaka MIYOSHI, Yoshitsugu TAKAI, Shinji MURAI, and Noboru SONODA*

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received October 4, 1977)

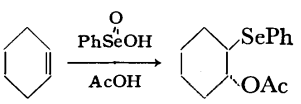
Synopsis. The reaction of benzeneseleninic acid with olefins in acetic acid gave 2-acetoxyalkyl phenyl selenides in good yields.

During the course of studies on oxyselenation,[1,2] a new and convenient method was found for the synthesis of 2-acetoxyalkyl phenyl selenides by use of benzeneseleninic acid.[3] The acetoxyselenation was carried out



(1)

by heating in acetic acid an equimolar mixture of olefin and benzeneseleninic acid, prepared from diphenyl diselenide by the procedure of Ayrey *et al.*[4] Acetoxyselenated products, 2-acetoxyalkyl phenyl selenides (**1**), were easily isolated by distillation under reduced pressure in good yields. The results of acetoxyselenation of cyclohexene, styrene, 1-hexene, and 1-octene are given in Table 1. The structure of (**1**) was determined by spectroscopic methods and elemental analyses. The



(2)

(**1a**)

reaction of cyclohexene with benzeneseleninic acid in acetic acid at 80 °C gave *trans*-2-acetoxycyclohexyl phenyl selenide (**1a**) as the sole product (Eq. 2). In the acetoxyselenation of styrene, addition of the phenylseleno group occurred selectively at the terminal methylene carbon atom to give 2-acetoxy-2-phenylethyl phenyl selenide (**1b**), whereas a similar reaction of aliphatic terminal olefin such as 1-hexene or 1-octene gave two isomers, the primary selenide as a major product and the secondary selenide as shown below.

TABLE 1. REACTION OF BENZENESELENINIC ACID WITH OLEFINS IN ACETIC ACID

Olefin	Acetoxyselenated product (**1**)		Yield (%)
Cyclohexene	 **1a**		81
Styrene	 **1b**		80
1-Hexene	n-$C_4H_9CH(OAc)CH_2SePh$ **1c** n-$C_4H_9CH(SePh)CH_2OAc$ **1d**	[82:18]	87
1-Octene	n-$C_6H_{13}CH(OAc)CH_2SePh$ **1e** n-$C_6H_{13}CH(SePh)CH_2OAc$ **1f**	[86:14]	86

(3)

It is likely that the attack of phenylselenenyl acetate (PhSeOAc)[5] to olefinic double bond takes place judging from the cationic mode of addition of phenylseleno group observed in the present acetoxyselenation. The destiny of the oxygen atom which was originally bonded to the selenium atom of the seleninic acid is not clear. However, evolution of a considerable amount of carbon dioxide (one fifth moles per one mole of the seleninic acid used) was observed in all cases. Oxidation of the solvent seems likely to take place concurrently.

Considerable interest has developed in the chemistry of selenoxide,[6] the syn elimination of phenyl selenoxide having recently been found to be a convenient and high-yield method for the preparation of various olefinic compounds.[7] The present oxyselenation may provide a useful procedure for the preparation of the precursor of an allyl acetate[8] from olefin.

Experimental

Materials. Commercial olefins (styrene, 1-hexene and 1-octene) were purified by distillation before use. Cyclohexene was prepared by the dehydration of cyclohexanol.[9] Benzeneseleninic acid was prepared from diphenyl diselenide according to the procedure of Ayrey *et al.*[4]

Apparatus. IR spectra were measured with a Shimalzu Model IR-27C grating infrared spectrometer, proton NMR spectra with a JEOL Model JNM-3H-60 and JNM-PS-100 using tetrachloromethane as a solvent and tetramethylsilane-(TMS) as an internal standard, and mass spectra with a Hitachi Model RM-60 mass spectrometer operating at 70 eV.

Reaction of Cyclohexene with Benzeneseleninic Acid. A solution of cyclohexene(10 mmol, 0.82g) and benzeneseleninic acid(10 mmol, 1.90 g) in acetic acid (30 ml) was heated at 80 °C for 24 h under stirring. After completion of the reaction, evaporation of acetic acid gave a dark orange oil, which was purified by distillation to give 2-acetoxycyclohexyl phenyl selenide(**1a**, 2.41 g, 81%), bp 137—138 °C/1 Torr; Found: 56.52; H, 6.26%. Calcd for $C_{14}H_{18}O_2Se$: C, 56.57; H, 6.10%. IR (neat), 1740 cm^{-1} ($\nu_{c=o}$). MS *m/e*, 298 (M^+), 238 (M^+—AcOH). NMR (100 MHz) δ 1.92 (3H, s, OC(=O)C<u>H</u>$_3$), 1.36—2.06 (8H, m, ring methylene), 3.12 (1H, d-t, J=4.1 and 9.2 Hz, C<u>H</u>SePh), 4.72 (1H, d-t, J=4.1 and 9.2 Hz, C<u>H</u>OAc), 7.15—7.40 (3H, m, phenyl), 7.40—7.56 (2H, m, phenyl).

Reaction of Styrene with Benzeneseleninic Acid. A solution of styrene (10 mmol, 1.04 g) and benzeneseleninic acid (10 mmol, 1.90 g) in acetic acid (30 ml) was heated at 80° for 24 h under stirring. Removal of the solvent gave a dark orange oil, which was purified by distillation to give 2-acetoxy-2-phenylethyl phenyl selenide (**1b**, 2.56 g, 80%), bp 166—167 °C/0.5

Torr; Found: C, 59.89; H, 5.19%. Calcd for $C_{16}H_{16}O_2Se$: C, 60.19; H, 5.05%. IR (neat), 1748 cm^{-1}. MS *m/e* 320 (M^+), 260 (M^+-AcOH). NMR (60 MHz) δ 1.96 (3H, s, OC(=O)C$\underline{H}_3$), 3.16 (1H, d-d, J=6 Hz, C$\underline{H}_2$SePh), 3.22 (1H, d, J=7.5 Hz, C$\underline{H}_2$SePh), 5.83 (1H, d-d, J=6 and 7.5 Hz, C$\underline{H}$OAc), 7.14—7.55 (10H, m, phenyl).

Reaction of 1-Hexene with Benzeneseleninic Acid. A solution of 1-hexene (10 mmol, 0.84 g) and benzeneseleninic Acid (10 mmol, 1.90 g) in acetic acid (30 ml) was heated at 80 °C for 24 h under stirring. Removal of the solvent by distillation gave a dark orange oil, which was distilled under reduced pressure to give a mixture of isomeric acetoxyselenated products (2.60 g) [Table 1], bp 122—134 °C/0.6 Torr; MS *m/e* 300 (M^+), 240 (M^+-AcOH). Found: C, 55.92; H, 6.75%. Calcd for $C_{14}H_{20}O_2Se$: C, 56.19; H, 6.74%. The NMR spectrum of the distillate showed the presence of two isomers. 2-Acetoxyhexyl phenyl selenide (**1c**) was isolated by repeated distillation of the mixture. Attempts to isolate **1d** were unsuccessful. NMR (CCl_4) of **1c**; δ 1.92 (3H, s, OC(=O)C$\underline{H}_3$), 0.70—0.90 (9H, m, *n*-$C_4\underline{H}_9$), 2.99 (2H, d, J=6 Hz, C$\underline{H}_2$SePh), 4.90—5.15 (1H, quintet centered at δ 4.93, J=6 Hz, C$\underline{H}$OAc). 2-(Phenylseleno)hexyl acetate (**1d**) was characterized by analysis of the NMR spectrum of a mixture of **1c** and **1d**. The methine (CHSePh) and methylene (CH_2OAc) signals of **1d** were observed at δ 3.32—3.60 (m, 1H) and δ 4.00—4.40 (m, 2H), respectively. The amount of **1d** in the mixture of two isomers was estimated from the NMR spectrum of the mixture by comparison of the integrated peak area of methylene of **1c** (d, δ 2.99, C$\underline{H}_2$SePh) with that of **1d** (m, δ 4.00—4.40, C$\underline{H}_2$OAc). The NMR spectrum of the mixture of two isomers (**1c** and **1d**) showed the ratio of **1c**: **1d** to be 82: 18.

Reaction of 1-Octene with Benzeneseleninic Acid. A solution of 1-octene (10 mmol, 1.02 g) and benzeneseleninic acid (10 mmol, 1.90 g) in acetic acid (30 ml) was heated at 80 °C for 24 h under stirring. Removal of the solvent by distillation gave a dark orange oil, which was distilled under reduced pressure to give a mixture of isomeric acetoxyselenated products (2.82 g) [Table 1], bp 135—148 °C/0.8 Torr; MS *m/e* 328 (M^+), 268 (M^+-AcOH). Found: C, 58.54; H, 7.67%. Calcd for $C_{16}H_{24}O_2Se$: C, 58.71; H, 7.39%. The NMR spectrum of the distillate showed the presence of two isomers. 2-Acetoxyoctyl phenyl selenide (**1e**) was isolated by repeated distillation of the mixture. Attempts to isolate **1f** were unsuccessful. NMR (CCl_4) of **1e**; δ 1.93 (3H, s, OC(=O)C$\underline{H}_3$), 0.90—2.15 (13H, m, *n*-$C_6\underline{H}_{13}$), 2.98 (2H, d, J=6 Hz, C$\underline{H}_2$SePH), 4.70—5.15 (1H, quintet centered at δ 4.92, C$\underline{H}$OAc), 7.11—7.50 (5H, m, phenyl). 2-(Phenylseleno)octyl acetate (**1f**) was characterized on the basis of the NMR spectrum of a mixture of **1e** and **1f**. The methine (C$\underline{H}$SePh) and methylene (C$\underline{H}_2$OAc) signals of **1f** were observed at δ 3.30—3.70 (m, 1H) and δ 4.00—4.40 (m, 2H), respectively. The amount of **1f** in the mixture of two isomers was estimated from the NMR spectrum of the mixture by comparison of the integrated peak area of methylene of **1e** (d, δ 2.98, C$\underline{H}_2$SePh) with that of **1f** (m, δ 4.00—4.40, C$\underline{H}_2$OAc). The NMR spectrum of the mixture of two isomers (**1e** and **1f**) showed the ratio of **1e**: **1f** to be 86: 14.

Preparation of Aroyl and Arenesulfonyl Fluorides from the Corresponding Chlorides Using Zinc Fluoride–Pyridine System

Akira SEKIYA and Nobuo ISHIKAWA

Department of Chemical Technology, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 17, 1977)

Synopsis. Convenient preparation of aroyl and arenesulfonyl fluorides in high yields was achieved by the reaction of the corresponding chlorides with zinc fluoride in pyridine.

A number of methods for the conversion of carboxylic acid chlorides or bromides into fluorides have been reported. In earlier days, various metal fluorides such as SbF_3,[1a,b] AsF_3, AgF,[1a] KF, KHF_2,[1c] HgF_2,[1d] and ZnF_2[1e] were used for this purpose, although they do not give satisfactory results. In recent years, more complex fluorides, such as Na_2SiF_6,[2] potassium fluorosulfinate,[3] triethylammonium fluoride,[4] hexafluoroacetone-KF adduct[5] or morpholinosulfur trifluoride[6] have been reported as fluorinating reagents.

In our earlier paper[7] it was mentioned that smooth formation of a ketone from (heptafluoro-1-methylethyl)-zinc iodide and benzoyl chloride was induced in the zinc fluoride–pyridine system, in which an in situ conversion of benzoyl chloride into fluoride was recognized. Further investigation has revealed that zinc fluoride is surprisingly effective in pyridine for the conversion of not only aroyl chlorides but also arenesulfonyl chlorides into the corresponding fluorides under mild conditions.

Several decades ago, the reaction of zinc fluoride with acetyl chloride (no solvents) for three days[8] and the reaction of zinc fluoride with organic sulfonyl chlorides in water were reported,[9] the results being, however, unsatisfactory yields of the corresponding fluorides. We describe here a practically useful method for the preparation of aroyl and arenesulfonyl fluorides by reaction in the zinc fluoride–pyridine system.

After addition of benzoyl chloride to an equimolar amount of zinc fluoride in pyridine at room temperature (25 °C), tracing of the reaction by ^{19}F NMR analyses revealed rapid conversion of the chloride into fluoride, which was completed quantitatively within 20 min. However, on using a half-molar amount of zinc fluoride the reaction was much slower, and 73 and 88% conversions after 40 min and 12 h respectively were observed.

Replacement of zinc fluoride by potassium fluoride, or of pyridine by other tertiary amines (Et_3N, $PhNMe_2$, or *N*-methylpiperidine) or by other solvents (DMSO, DMF, MeCN, or THF) gave no satisfactory results, showing almost no occurrence of conversion. The exclusive effectiveness of pyridine is presumably due

to its ability to weaken the Zn–F linkage through an appropriate coordination to the zinc atom.

The reaction was extensively studied using aroyl chlorides with varied substituents. As summarized in Table 1, the corresponding fluorides were obtained in sufficiently high yields in all the runs. However, when phenylacetyl chloride, an aliphatic acid chloride, was employed, the yield of fluoride was only 57% (^{19}F NMR analysis) even after 4 h's reaction.

Conversion of arenesulfonyl chlorides into fluorides was also examined in a similar manner. For example, conversion of benzenesulfonyl chloride into the fluoride occurred quantitatively after 2 h (^{19}F NMR). Results of experiments with several other arenesulfonyl chlorides are shown in Table 1.

Experimental

Anhydrous Zinc Fluoride. Anhydrous zinc fluoride was easily prepared as follows. An aqueous solution of zinc chloride (two molar equiv.) was added to an aqueous solution of potassium fluoride and the precipitates obtained were collected by filtration, washed thoroughly with water and dried over phosphorus pentaoxide at 180 °C in vacuo. Yield was almost quantitative.

General Procedures for Fluorination. To a solution of zinc fluoride (0.03 mol) in pyridine (30 ml) aroyl chloride or arenesulfonyl chloride (0.03 mol) was added with stirring at room temperature (25 °C). Stirring was continued until the reaction was completed (checked by ^{19}F NMR) then treated by either method (A) or (B), as follows:

(A) In the case of low-boiling products resistant to hydrolysis; the reaction mixture was poured into ice-cold 25% hydrochloric acid. The liberated aroyl fluoride was extracted with ether and the ethereal solution was washed with water and dried over magnesium sulfate. Evaporation of ether gave the aroyl fluoride, which was purified by distillation under reduced pressure.

(B) The reaction mixture was concentrated under reduced pressure and the resulting residue was extracted with warm hexane or benzene. Evaporation of the solvent gave crude aroyl fluoride or arenesulfonyl fluoride which was purified by distillation under reduced pressure or by recrystallization.

TEA CO_2 Laser Induced Photoreactions of Ethylene, Chloroethylenes and Chloroethanes

Keiichi NAGAI and Mikio KATAYAMA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received June 15, 1977)

TEA CO_2 laser induced chemical reactions of ethylene, chloroethylenes and chloroethanes have been investigated. Since these compounds have absorptions at wavelengths of 10.6 or 9.6 μm band of the CO_2 laser, strong excitation of the molecular vibration gives rise to an infrared photochemical reaction. In chlorine derivatives, the cleavage of the C–Cl bond by the laser irradiation appears to initiate decompositions of these materials. The final products were mainly brought about by molecular elimination of HCl, H_2, or Cl_2. The present results demonstrate that the CO_2 laser induced reactions differ form their thermal reactions.

Since the development of infrared lasers, a considerable number of investigations on infrared photochemical reactions induced by continuous wave (CW) or transverse excited atomospheric (TEA) CO_2 laser irradiation have been reported.[1-4] Braun and Tsang[5] have observed TEA CO_2 laser induced chemical reactions for isobutyl and ethyl chlorides, bromides and iodides. For all except the iodides the reaction took place *via* the molecular elimination of hydrogen halides. With respect to the iodides, cleavage of the C–I bond competed with the elimination of hydrogen halide. The infrared photochemical reactions of ethylene, chloroethylenes, chloroethanes and mixtures of these compounds with SF_6 or H_2 induced by TEA CO_2 laser irradiation have been observed. In those cases, the vibrationally excited molecules took direct part in chemical reactions. Irradiation by infrared laser pulse gives rise to an elevation of the specific vibrational temperature of molecule, keeping the translational temperature almost unchanged. Therefore, in this respect the infrared laser induced reactions differ from the thermally induced ones, although the reaction products are similar.

Experimental

The TEA CO_2 laser constructed and used was a double discharge type with three pairs of Rogowski electrodes of 60 cm length each.[6] The cavity length was about 200 cm, being formed by a 20 m radius aluminum-coated concave mirror and a flat uncoated germanium output ethalon. Under ordinary conditions, the simultaneous oscillation of multiple lines of multi-modes was observed, and the strongest line was P(20) of the 10.6 μm band. The oscillations of P(14)—P(22) and R(16) of this band with less than 1/10 of the intensity of the P(20) line were also observed. The power output was about 1 J with a pulse duration of 100 ns; its repetition rate was about 1 Hz. The absorption cell of about 3 cm length was inserted into the laser cavity for a selective oscillation of appropriate lines of the laser. When SF_6 gas of 150 Torr was introduced into the cell, the oscillation of the 9.6 μm band was accomplished, and its power output was slightly less than that of the 10.6 μm band. The oscillation of R branch of the 9.6 μm band was obtained by using C_2H_3Cl gas of about 150 Torr.

Reaction cells made of duralmine were used. One had the dimensions of 100 mm length and inner diameter of 30 mm, and the other was 50 mm length and 20 mm diameter. The reaction cell was closed by two KCl windows permitting passage of the laser beam. The sample gas in the reaction cell was irradiated by the laser pulse focused with germanium lens of f=5 cm; the diameter of the focal spot was ≈0.5 mm. The peak power of the laser at the focus was more than 1 GW/cm², but its irradiation did not show any appreciable temperature elevation of the sample gas. The products of the infrared photoreaction were examined by infrared absorption. No appreciable differences of products were found with changing cell dimensions.

Results and Discussion

For a pressure of sample gas higher than 50 Torr, the irradiation by high power laser gives rise to a dielectric breakdown. This produces an avalanche of electrons, and the reactions caused by the breakdown have been shown to be the same as those initiated by an electric discharge.[8] Therefore, the infrared laser induced reactions have been observed in the pressure range of 10—50 Torr, where the reaction was mainly infrared-photochemical. Although the dielectric breakdown was unobserved at these pressures, the emission of visible luminescence was observed around the focus of the lens.

Typical results, including the experimental conditions, are presented in Table 1. The products listed in this table were obtained after an irradiation of 30—60 min. A more detailed examination of the results is now given.

Ethylene. The reaction product of C_2H_4 was C_2H_2 and the yield was proportional to the pressure of ethylene in the range of 10—50 Torr. The reaction is one of elimination of the H_2 molecule. When the mixture of C_2H_4 and H_2 (20 Torr: 20 Torr) was irradiated, the partial pressure of the product C_2H_2 was found to be 1.5 Torr, which is almost the same order of magnitude as that of the pure C_2H_4. The addition of H_2 did not produce any detectable change in the rate of decomposition of ethylene.

Chloroethylene. The main reaction of the chloroethylenes was the elimination of hydrogen chloride from the initial reagent. Under the irradiation conditions, C_2H_3Cl at 22 Torr produced C_2H_2 at 2.2 Torr. The presence of C_2HCl was not detected in the products, indicating the difficulty of eliminating H_2 compared with that of HCl. It is reasonable to predict this since the energy required for the elimination of H_2 is estimated to be 75 kcal/mol from the energies of C–H and H–H bonds, while the energy required for the elimina-

a) A smaller reaction cell was used.

tion of HCl is about 50 kcal/mol.[5,7] Since this molecule absorbs at a wavelength of 9.6 μm, the 9.6 μm laser photochemical reaction was also observed. However, the production of C_2H_2 was slightly less than that by the 10.6 μm irradiation.

The ν_8 vibrational mode of $Cl_2C=CH_2$ is infrared active and the absorption can be observed at the 9.6 μm R branch of the CO_2 laser. Hence, the reaction was induced by the irradiation of the TEA CO_2 laser with the R branch of 9.6 μm radiation. The reaction products were C_2HCl and C_2H_2 at a ratio 5:1. The following processes may be suggested for the production of the C_2H_2 molecule.

1) The infrared laser irradiation brings about a cleavage of the C–Cl bond and creates a $ClC=CH_2$ radical.

2) The transfer of an H atom produces a HClC=CH radical.

3) The cleavage of the C–Cl bond of the radical HClC=CH by the laser irradiation yields the C_2H_2 molecule.

The process assumed above is equivalent to the elimination of a Cl_2 molecule, following the scrambling of the H atom.

Since $Cl_2C=CH_2$ has no absorption at the wavelength of 10.6 μm TEA CO_2 laser, its irradiation produced no reaction in the pure sample. However, the SF_6 sensitized reaction of $Cl_2C=CH_2$ was induced by the 10.6 μm laser irradiation, but the quantity of products was too small for complete identification. The results of the direct and sensitized reactions are listed in Table 2. The absorption coefficients of the mixture of $Cl_2C=CH_2$ and SF_6 (14 Torr: 1 Torr) were measured by using the laser with 4 mJ output. The observed value at 10.6 μm was 5 times as large as the absorption coefficient at 9.6 μm. Although the irradiated laser power of 10.6 μm was about 1.5 times as large as the power of 9.6 μm band, the reaction rate of the direct process was larger by an order of magnitude. In the mixture of SF_6 and $Cl_2C=CH_2$, the ν_3 mode of SF_6 was excited successively to its higher vibrational levels by the incident 10.6 μm laser. The vibrational energies of SF_6 transfered to the vibrationally excited levels of $Cl_2C=CH_2$, giving rise to the dissociation of this molecule. It should be noted that any decomposition of SF_6 molecule in the present mixture was not detected. The observed results in Table 2 indicate that the direct laser excitation of the ν_6 vibration of $Cl_2C=CH_2$ (CH rocking mode) accelerates the reaction rate significantly.

TABLE 2. TEA CO_2 LASER INDUCED CHEMICAL REACTION OF $Cl_2C=CH_2$

	Direct excitation	SF_6 sensitized reaction
Sample	$Cl_2C=CH_2$ (14 Torr)	+ SF_6 (1 Torr)
Laser line	9.6 μm R	10.6 μm P
Relative laser power	1	≈1.5
Relative absorption coefficient (4 mJ)	1	≈5
Reaction rate	>6	1

In a previous paper the TEA CO_2 laser induced isomerization and decomposition of ClHC=CHCl has been reported.[8] The observed reactions promoted by the direct excitation or SF_6 sensitization using TEA CO_2 laser are listed in Table 3. The absorption coefficient of the mixture of ClHC=CHCl (*trans*) and SF_6 (10 Torr: 1 Torr) at 10.6 μm is 50 times as large as that of the pure substance, but the reaction rate of the sensitized excitation is only 6 times as fast as the rate of the direct excitation. Although the main reaction was the *trans-cis* isomerization in both cases, the production of C_2H_2 and C_2HCl were also observed in the

TABLE 3. TEA CO_2 LASER INDUCED CHEMICAL REACTION OF ClHC=CHCl (*trans*)

	Direct excitation	SF_6 sensitized reaction
Sample	ClHC=CHCl (10 Torr)	ClHC=CHCl (10 Torr) + SF_6 (1 Torr)
Laser line	10.6 μm P	10.6 μm P
Relative absorption coefficient (4 mJ)	1	≈50
Relative reaction rate	1	6
Ratio of products C_2H_2/C_2HCl	0.6	0

case of direct excitation. In the SF_6 sensitized reaction, only the C_2HCl molecule was obtained, indicating that the reaction resembles the pyrolysis of ClHC=CHCl.[9] The infrared photoreaction induced by the direct excitation of ClHC=CHCl differs then from the thermal one.

The frequency of the ν_{12} vibrational mode of ClHC=CCl_2 coincides with the 10.6 μm TEA laser, and the irradiation of 3000 shots produced 5 Torr of C_2Cl_2 and 0.5 Torr of C_2HCl from 18 Torr of this molecule. The ratio of the products, C_2Cl_2 and C_2HCl, may be given by the activation energies of the elimination of HCl and Cl_2 molecules. Goodall and Howlett reported that the thermal reaction products of $ClHC=CCl_2$ were C_6Cl_6 and HCl.[10] Although the presence of C_2Cl_2 molecules has not been detected in the pyrolysis of $ClHC=CCl_2$, the C_6Cl_6 molecule may be formed at higher translational temperatures from activated C_2Cl_2 molecules, which are presumably produced by the elimination of hydrogen chloride from the parent molecules. Appreciable amounts of C_6Cl_6 were not detected in the laser induced reaction products, suggesting that elevation of the translational temperature is insufficient to allow the reaction $3\ C_2Cl_2 \rightarrow C_6Cl_6$. It is evident from our observation that the infrared laser induced reaction of $ClHC=CCl_2$ is significantly different from that of the pyrolysis. Furthermore, in the 10.6 μm laser induced reaction of the mixture of $ClHC=CCl_2$ and H_2 (20 Torr : 20 Torr) the products were C_2H_2 of 2.7 Torr, $Cl_2C=CH_2$ of 0.7 Torr and C_2HCl less than 0.1 Torr, but C_2Cl_2 was not detected in contrast to the case of pure $ClHC=CCl_2$. The major products obtained from the 10.6 μm laser irradiated mixture of $ClHC=CCl_2$ and D_2 were $CHD=CCl_2$, $CD_2=CCl_2$, and $H_2C=CCl_2$. The productions of C_2D_2, C_2HD, and a trace of C_2H_2 were also observed. These results seem to indicate that the CO_2 laser irradiation gives rise to a cleavage of C–Cl bond of $ClHC=CCl_2$ molecule.

Chloroethanes. The reaction products of C_2H_5Cl at 25 Torr were C_2H_4 and C_2H_2 with partial pressure of 5 and 1.5 Torr respectively. At less than 25 Torr, the quantities of the products were proportional to the initial pressures of the samples. When increased to 40 Torr, the partial pressures of the products, C_2H_4 and C_2H_2, reached 6 and 3 Torr respectively. Assuming that the infrared laser irradiated C_2H_5Cl gives rise to the production of C_2H_4 alone and the reaction product C_2H_2 of the present experiment is brought about by the irradiation of C_2H_4 by the same laser, then the partial pressure of C_2H_2 must be less than 1/5 of the really observed value. Therefore, we may conclude that the major part of C_2H_2 must be directly, and almost simultaneously, produced from C_2H_5Cl by the CO_2 laser irradiation. Barton and Howlett have reported that the pyrolysis of this material gives rise to the production of C_2H_4 but not to noticeable amounts of C_2H_2.[11] These experimental results demonstrate that the mechanism in both reactions is different.

Infrared absorption of $Cl_2HC–CH_3$ was observed at wavelengths of the 9.6 μm P, R and 10.6 μm R bands of the CO_2 laser, but not at the 10.6 μm P band. Hence, the irradiation of the R branch of 10.6 μm laser pulse produced C_2H_3Cl of 1.7 Torr and C_2H_2 of 1 Torr from 10 Torr of $Cl_2HC–CH_3$. The irradiated products with the P branch of the 9.6 μm band were C_2H_3Cl of 4.4 Torr and C_2H_2 of 1.4 Torr. Since the production of C_2H_2 is almost of the same order as that of C_2H_3Cl, only a small part of C_2H_2 may be assumed to be produced by the laser induced reaction of C_2H_3Cl which is given from $Cl_2HC–CH_3$ by the 9.6 or 10.6 μm R infrared photodissociation. This is because the yield of C_2H_2 from the laser induced reaction of C_2H_3Cl is less than 10% of the parent molecule. The 9.6 μm R laser irradiation produced 1.2 Torr of C_2H_3Cl and 0.3 Torr of C_2H_2 from 10 Torr of $Cl_2HC–CH_3$. Since the C_2H_3Cl molecule does not absorb in the 9.6 μm R line, C_2H_2 in the present observation must be directly produced from $Cl_2HC–CH_3$ by the 9.6 μm R laser irradiation. The experimental results obtained by Barton and Howlett indicate that C_2H_2, the thermal decomposition product of $Cl_2HC–CH_3$, is only 3% of the major pyrolysis product C_2H_3Cl,[11] suggesting the different mechanisms between the pyrolysis and the infrared laser induced reaction.

The infrared photochemical decomposition of $CHCl_2–CH_2Cl$ was also investigated. The decomposition products were *cis*- and *trans*-CHCl=CHCl and $CCl_2=CH_2$ in a concentration ratio of 0.5:0.3:1.1. The pyrolysis of $CHCl_2–CH_2Cl$ has been investigated by Williams[12] and by Teramoto *et al.*,[13] and they have proposed both processes—radical chain and unimolecular reactions—for the decomposition. The ratio of the decomposition products $H_2C=CCl_2$ and ClHC=CHCl was found to be 0.7. Teramoto *et al.* have also confirmed that the product $H_2C=CCl_2$ decreased when the radical chain reaction was inhibited. In the infrared laser induced reaction, we obtained a value 1.4 for the ratio of the products, $H_2C=CCl_2$ and ClHC=CHCl. From our experimental results it may be concluded that the infrared laser induced reaction of $CHCl_2–CH_2Cl$ is mainly promoted by the radical reaction.

Translational and Vibrational Temperatures. Recently the impulsive opto-acoustic effect has been reported. This gives rise to a temperature change in a certain gas by the absorption of the CO_2 laser pulse.[14] When the infrared laser pulse is absorbed by the gas, the population of relevant vibrational levels deviates from the thermal equilibrium for the short duration of the laser pulse. The energy supplied by the laser pulse as an increment of the vibrational energy is finaly transformed into translational energy of the molecule by the vibrational-translational relaxation, giving rise to elevation of the translational temperature. When the pressure of gas is 20 Torr, about 10 ms after irradiation the translational temperature of the molecules decreases to the initial value. This is caused by the dissipation of the translational energy to the cell wall or other surroundings.

In the present study of the laser induced reaction, the translational temperature increase of sample gas may be observed only in a short duration of about 10 ms. Ambartzumian *et al.*[15] have estimated that the temperature increase of ClHC=CHCl by the TEA CO_2 laser

irradiation was less than 350 °C which gave the maximum temperature of the gas at about 650 °C. Furthermore, they observed that the gas was kept at around 650 °C only for a short duration of 10^{-4} s. Under these conditions thermal reaction was assumed to be negligible. The same discussion may be applied in our case. In the present study, the temperature increase of sample gas by the irradiation of 3000 laser pulses was assumed to be negligible. Therefore, the energy supplied by the laser provided the elevation of vibrational temperature which gave rise to the infrared photochemical reaction. The experimental results support the present assumption that the thermal and infrared laser reactions are not the same.

The infrared laser dissociation of SF_6 molecules was understood on the assumption that the molecules are excited to the true continuum of the levels above the dissociation limit through the exciattion of quasicontinuum of the vibrational levels. From the measurement of dissociation thresholds of SF_6, almost 20 photons/molecule were deposited by the ultrashort laser pulse, implying a vibrational temperature of $T=1800$ K.[16]

The numbers of photons needed for dissociation of molecules in the present investigation are in the order of 20—40, which depends upon the molecules. Since the threshold power for molecular dissociation was unobserved in the present case, the vibrational temperature at the threshold could not be determined, even if it could be defined. However, the number of normal modes and the process of the laser dissociation may be almost the same as those of SF_6. The vibrational temperature at around the dissociation threshold may be an order of 2000 K.

Conclusion

The TEA CO_2 laser induced chemical reactions of ethylene, chloroethylenes and chloroethanes have been observed. The results demonstrate that the reactions are caused by multiple steps or multiple absorptions of the infrared photons, following the elimination of hydrogen or hydrogen chloride molecules, or by the cleavage of the C–Cl bond. Furthermore, the experimental results indicate that the products and the reaction mechanisms are somewhat different from those of thermal reactions. It is rather difficult to elucidate the complete mechanism of the infrared laser induced photoreaction from the present observations, since its mechanism seems to vary with molecules. However, the detailed studies on the reaction of the individual substances will give information on the reactions of molecules whose vibrations of a certain mode are highly excited.

This research was supported partly by the Grant-in-Aid from the Ministry of Education.

Bromine-81 Nuclear Quadrupole Resonance and Aluminum-27 Nuclear Magnetic Resonance in $AlBr_3$ Complexes

Tsutomu OKUDA, Hideta ISHIHARA, Koji YAMADA, and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received July 7, 1977)

The Zeeman effect on ^{81}Br NQR and the quadrupole effect on ^{27}Al NMR in $L \cdot AlBr_3$ complexes (L=KBr, $POBr_3$, and H_2S) were studied at room temperature. It was found that the ^{27}Al quadrupole-coupling constant for these complexes decreases with decreasing coupling constant of the ^{81}Br atom in $-AlBr_3$ and that the atomic arrangement about the Al atom has C_{3v} symmetry in $POBr_3 \cdot AlBr_3$ and $H_2S \cdot AlBr_3$. In the latter complex, H_2S molecule is reorientated at room temperature. The amount of charge transfer in these complexes was estimated on the basis of the Townes-Dailey theory and the bond angle $\angle$Br–Al–Br was found to depend on the amount of the charge transfer. The temperature dependence of the ^{81}Br NQR frequencies was observed in order to obtain information about molecular motion in $H_2S \cdot AlBr_3$ and $POBr_3 \cdot AlBr_3$.

For $L \cdot AlBr_3$ molecular complexes (L=ligand), the charge distribution of the acceptor molecule can be determined on the basis of the Townes-Dailey theory which is relatively simple but appears to still be valuable.[1,2] In order to estimate the charge distribution using this procedure, it is necessary to determine the $\angle$Br–Al–Br bond angles and the quadrupole-coupling constants for both Al and Br atoms. Some research employing NQR has already been reported on $L \cdot AlBr_3$ molecular complexes.[3-5] All, however, was performed on polycrystalline samples. Therefore, an attempt was made to observe the Zeeman effect on ^{81}Br NQR and the quadrupole effect on ^{27}Al NMR using single crystals.

Experimental

$KBr \cdot AlBr_3$ and $POBr_3 \cdot AlBr_3$ were prepared by mixing equimolar amounts of the relevant compounds. $H_2S \cdot AlBr_3$ was prepared by passing hydrogen sulfide through a carbon disulfide solution of aluminum bromide.[6] The single crystals were grown employing the Bridgman-Stockbarger method. The melting points of these complexes are as follows: 191 °C for $KBr \cdot AlBr_3$, 181 °C for $POBr_3 \cdot AlBr_3$, and 83 °C for $H_2S \cdot AlBr_3$. The bromine content was determined using the Fajans method. Found: Br, 83.6%. Calcd for $KBr \cdot AlBr_3$: Br, 82.9%. Found: Br, 87.5%. Calcd for $POBr_3 \cdot AlBr_3$: Br, 86.6%. Found: Br, 78.5%. Calcd for $H_2S \cdot AlBr_3$: Br, 79.7%.

The NQR spectrometer was a self-quenching super-regenerative oscillator with frequency modulation and the resonance lines were displayed on an oscilloscope. The Zeeman effect on ^{81}Br NQR was studied using the zero-splitting cone method. A magnetic field of *ca.* 250 G was applied by means of a Helmholtz coil. ^{81}Br NQR frequencies were observed at various temperatures which were attained in a Dewar vessel by cooling petroleum ether with liquid nitrogen or heating liquid paraffin with an electric heater.

^{27}Al NMR was observed using a broad-line NMR spectrometer (Model JES-ME 1) from the Japan Electron Optics Lab. Co., Ltd. The resonance frequency was fixed at 13.00 MHz and the magnetic field was varied to obtain the resonance.

Results and Discussion

^{81}Br NQR. The NQR frequencies of ^{81}Br atoms at room temperature are listed in Table 1. For $H_2S \cdot AlBr_3$, only one ^{81}Br NQR line was observed. This is consistent with the results of X-ray analysis,[6] that is, the bromine atoms of the complex are situated at equivalent positions in the crystal. For $POBr_3 \cdot AlBr_3$, two ^{81}Br NQR lines were observed. Although its crystal structure is not known at present, the formation of the O–Al bond is obvious from infrared spectroscopic studies.[7] Therefore, the structure of the complex is assumed to be Br_3P–O–$AlBr_3$. Consequently, the lower and higher resonance lines can be assigned to the Br atoms linked to the Al and P atoms, respectively, referring to the ^{81}Br NQR frequencies of Al_2Br_6 and $POBr_3$ in their pure states.[8,9] For $KBr \cdot AlBr_3$, four ^{81}Br NQR lines were observed. The average frequency was in the same range as those of $LiAlBr_4$ and $NaAlBr_4$ and was considerably lower than that of the terminal ^{81}Br atoms of KAl_2Br_7.[10] One of the constituents of the complex was assumed to be a distorted tetrahedral ion, $AlBr_4^-$.

Table 1. NQR parameters for ^{81}Br at room temperature

Compound		Frequency (MHz)	η (%)	$e^2Qq_{zz}h^{-1}$ (MHz)
$H_2S \cdot AlBr_3$		81.69	8.1±0.8	163.20
$POBr_3 \cdot AlBr_3$	ν_a	78.70	1.9±0.7	157.39
	ν_b	211.07	2.6±0.6	422.09
$KBr \cdot AlBr_3$	ν_a	76.31	3.1±0.3	152.60
	ν_b	77.56	24.4±0.7	153.60
	ν_c	78.27	10.8±0.7	156.23
	ν_d	79.91	7.5±0.7	159.66

The zero-splitting patterns were obtained from the Zeeman effect at room temperature and are shown in Figs. 1—3. The bond angles $\angle$Br–M–Br (M=Al and P) can be deduced, if the principal z axis of the ^{81}Br EFG tensor is assumed to be parallel to the direction of the M–Br bond. The results thus obtained are listed in Table 2.

For $H_2S \cdot AlBr_3$, X-ray analysis of the powder sample shows that there is only one type of $AlBr_3$ unit in the crystal, and three zero-splitting patterns are expected.[6] However, six zero-splitting patterns were obtained, as is shown in Fig. 1. Accordingly, it is evident that there are two kinds of $AlBr_3$ units which differ only in the orientation in the crystal. More precise X-ray analysis is necessary in order to clarify the crystal structure of this complex.

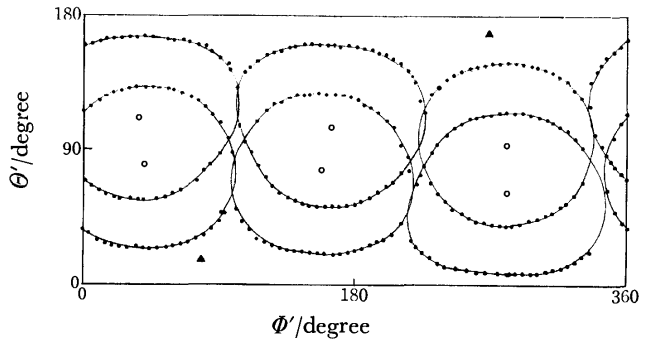

Fig. 1. Zero-splitting patterns of ^{81}Br Zeeman lines in $H_2S \cdot AlBr_3$. The direction of the three-fold axis is indicated by ▲. Θ' and Φ' are polar and azimuthal angles, respectively, in the coordinate fixed to the sample.

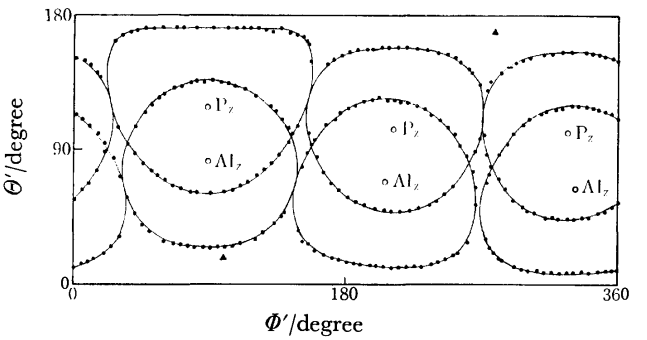

Fig. 2. Zero-splitting patterns of ^{81}Br Zeeman lines in $POBr_3 \cdot AlBr$. The direction of the principal z axes of the EFG tensors at the ^{81}Br atoms linked to the Al and P atom are indicated by Al_z and P_z, respectively. The direction of the three-fold axis is indicated by ▲. Θ' and Φ' are polar and azimuthal angles, respectively, in the coordinate fixed to the sample.

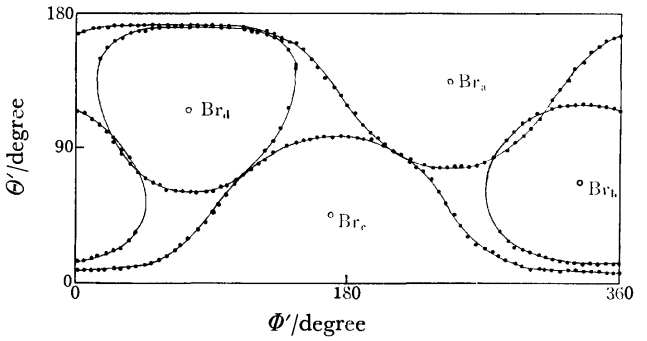

Fig. 3. Zero-splitting patterns of ^{81}Br Zeeman lines in $KBr \cdot AlBr_3$. The subscripts correspond to those of the resonance lines. Θ' and Φ' are polar and azimuthal angles, respectively, in the coordinate fixed to the sample.

For $POBr_3 \cdot AlBr_3$, the three-fold axis is found to be parallel to the P–O–Al bond which has a bond angle of 180.0±0.7°, because the three-fold axis of $AlBr_3$ is parallel to that of $POBr_3$ to within 0.7° from the result of the Zeeman effect. The configuration of $AlBr_3$ relative to $POBr_3$ is eclipsed, as is shown in Fig. 2. In $KBr \cdot AlBr_3$, the atomic arrangement about the Al atom is approximately tetrahedral, as is shown in Table 2, and the average bond angle is 109.5°.

Table 2. Bond angles ∠Br-M-Br

Compound	M	∠Br-M-Br (degree)	
$H_2S \cdot AlBr_3$	Al	112.7±0.4	
$POBr_3 \cdot AlBr_3$	Al	111.8±0.7	
	P	109.4±0.5	
$KBr \cdot AlBr_3$[a)]	Al	105.8±0.4	108.2±0.3
		109.4±0.5	110.1±0.3
		111.7±0.3	111.8±0.1

a) Six bond angles can be determined because four bromine atoms are nonequivalent.

The value of the asymmetry parameter, η, was determined using the following equation,[11]

$$\sin^2\Theta = 2/(3-\eta\cos 2\Phi), \quad (1)$$

where Θ and Φ are the polar and azimuthal angles of the Zeeman magnetic field with respect to the principal coordinates of the EFG tensor at the resonating nucleus. Consequently, the quadrupole-coupling constant, e^2Qq_{zz}/h, of the ^{81}Br atom was calculated using

$$\nu = (e^2Qq_{zz}/2h)(1+\eta^2/3)^{1/2}, \quad (2)$$

where ν is the ^{81}Br NQR frequency. The value of η and e^2Qq_{zz}/h thus obtained are listed in Table 1.

^{27}Al NMR. Only one central resonance line ($m=+1/2 \leftrightarrow m=-1/2$), which was affected by the second-order quadrupole interaction, was observed for both $H_2S \cdot AlBr_3$ and $POBr_3 \cdot AlBr_3$. The rotation patterns of the central line were obtained by measuring the shift, ΔH, from the magnetic field H_L corresponding to a Larmor frequency ν_L of 13.00 MHz, when the sample was rotated about the rotation axis perpendicular to the external magnetic field. The results are shown in Fig. 4. The frequency shift, $\Delta\nu$, can be represented in terms of the magnetic field by the following equation:[12]

$$\Delta\nu = -\nu_L(\Delta H/H_L^2)(\Delta H+H_L). \quad (3)$$

Since the components >S–$AlBr_3$ in $H_2S \cdot AlBr_3$ and –O–$AlBr_3$ in $POBr_3 \cdot AlBr_3$ have C_{3v} symmetry, respectively, the frequency shift of the central line was analyzed using the following equation derived from second-order perturbation theory with $\eta=0$,[13]

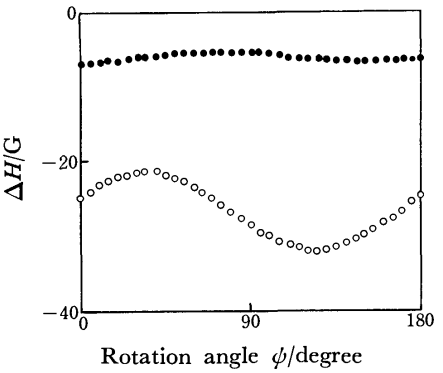

Fig. 4. Rotation patterns of ^{27}Al NMR central lines. $H_2S \cdot AlBr_3$ (○) for $\delta=10.5°$ and $\phi_0=35.0°$. $POBr_3 \cdot AlBr_3$ (●) for $\delta=8.5°$ and $\phi_0=70.0°$.

$$\Delta\nu = -(\nu_Q^2/16\nu_L)(a-3/4)(1-\mu^2)(9\mu^2-1), \quad (4)$$

where $\nu_Q=3e^2Qq/2I(2I-1)h$, $a=I(I+1)$, and $\mu=\sin\delta\cos(\psi-\psi_0)$. δ is the angle between the rotation axis and the principal z axis of the ^{27}Al EFG tensor. ψ is the rotation angle and ψ_0 is the value when the principal z axis lies in the plane formed by the rotation axis and the magnetic field.

Neither first- nor second-order splitting of ^{27}Al NMR spectra in $KBr\cdot AlBr_3$ were observed, so that the ^{27}Al quadrupole-coupling constant is estimated to be less than 1.3 MHz from the line width of the spectrum in the polycrystalline sample.

The ^{27}Al quadrupole-coupling constants thus obtained are as follows: 9.1±0.1 MHz for $H_2S\cdot AlBr_3$, 4.2±0.1 MHz for $POBr_3\cdot AlBr_3$, and less than 1.3 MHz for $KBr\cdot AlBr_3$. It was found that the ^{27}Al quadrupole-coupling constants for these complexes decrease with decreasing coupling-constant of the ^{81}Br atom in the $-AlBr_3$ components. A similar relation has been obtained by Tong[14] between the NQR frequencies of ^{69}Ga and ^{35}Cl atoms in L–$GaCl_3$ molecular complexes (L=ligand).

The Bond Character. The amount of charge transfer in these molecular complexes were estimated according to the Townes-Dailey theory. Supposing C_{3v} symmetry for hybrid orbitals centered at the Al atom, the four orthonormal hybrid wavefunctions can be expressed by[2]

$$\begin{aligned}
\psi_1 &= s_1\phi_s + (1-s_1^2)^{1/2}\phi_{p_z},\\
\psi_2 &= s_2\phi_s + (1-s_2^2)^{1/2}\{\phi_{p_z}\cos\theta-\phi_{p_x}\sin\theta\},\\
\psi_3 &= s_2\phi_s + (1-s_2^2)^{1/2}\{\phi_{p_z}\cos\theta+(1/2)\phi_{p_x}\sin\theta\\
&\qquad -(\sqrt{3}/2)\phi_{p_y}\sin\theta\},
\end{aligned} \quad (5)$$

and

$$\psi_4 = s_2\phi_s + (1-s_2^2)^{1/2}\{\phi_{p_z}\cos\theta+(1/2)\phi_{p_x}\sin\theta + (\sqrt{3}/2)\phi_{p_y}\sin\theta\},$$

where θ is the angle ∠Br–Al–L (L=ligand). s_1^2 and s_2^2 represent the fractional s character of the Al–L and Al–Br bonds, respectively. The population of orbital ψ_1, which is directed toward the ligand, is denoted by a_{Al} and the population of orbitals ψ_2, ψ_3, and ψ_4, which are directed toward the Br atoms, by b_{Al}. Then, the total electric field gradient of the Al atom is given by

$$q_{zz}(^{27}Al) = (b_{Al}-a_{Al})\{3-2/\sin^2\theta\}q_{at}. \quad (6)$$

It is evident that from the spherical triangle that there exists a relation such that $\cos^2\theta=(2\cos\alpha+1)/3$, where α is the ∠Br–Al–Br angle. Considering the increase in the EFG due to positive ionization of the Al atom, the quadrupole-coupling constant is given by

$$e^2Qq_{zz}/h(^{27}Al) = (b_{Al}-a_{Al})\{-3\cos\alpha/(1-\cos\alpha)\} \times (1+\varepsilon_{Al}\rho_{Al})e^2Qq_{at}/h(^{27}Al). \quad (7)$$

On the other hand, the ^{81}Br quadrupole-coupling constant is given by[2]

$$e^2Qq_{zz}/h(^{81}Br) = \{(1-s^2)(2-b_{Br})/(1+\varepsilon_{Br}\rho_{Br})\} \times e^2Qq_{at}/h(^{81}Br), \quad (8)$$

where s^2 is the fractional s character of the Br–Al σ orbital and b_{Br} is the population of this orbital. In Eqs. 7 and 8, $e^2Qq_{at}/h(^{27}Al)$ and $e^2Qq_{at}/h(^{81}Br)$ are the atomic quadrupole-coupling constants, the ε are parameters which correct for the ionization, and ρ_{Al} and ρ_{Br} are the positive and negative charges, respectively. The ρ are related to the population numbers by $\rho_{Al}=3-(3b_{Al}+a_{Al})$ and $\rho_{Br}=b_{Br}-1$. It is assumed that $b_{Al}+b_{Br}=2$ and $b_{Al}>a_{Al}$. Furthermore, s and ε the were chosen such that $s^2=0.15$, $\varepsilon_{Br}=0.13$, and $\varepsilon_{Al}=0.27$.[15]

Table 3. Population numbers a_{Al}, b_{Al}, and b_{Br}

Compound	a_{Al}	b_{Al}	b_{Br}
$H_2S\cdot AlBr_3$	0.13	0.33	1.67
$POBr_3\cdot AlBr_3$	0.22	0.31	1.69
$KBr\cdot AlBr_3$	0.30	0.30	1.70
	0.31	0.31	1.69
	0.31	0.31	1.69
	0.32	0.32	1.68

The values of a_{Al}, b_{Al}, and b_{Br} can be calculated from Eqs. 7 and 8, using the values of the bond angles and the quadrupole-coupling constants. The results are listed in Table 3. For $KBr\cdot AlBr_3$, a_{Al} is assumed to be equal to b_{Al}, because it cannot be specifield which bromine atom participate in the coordinate ion. Then it is evident that the donor powers of the ligands increase in the order $H_2S<POBr_3<Br^-$, provided that a_{Al} is regarded as a measure of the amount of charge transfer. In this connection, both ^{81}Br and ^{27}Al quadrupole-coupling constants in $-AlBr_3$ decrease with increasing a_{Al} or increasing degrees of charge transfer. In addition, it is seen that the bond angle approaches the tetrahedral angle with increasing a_{Al}. Therefore, in consideration of the results of the molecular-orbital calculation shown below, it appears that as the $AlBr_3$ in the complex approaches the tetrahedral arrangement, the strength of the donor-acceptor bond increases.

For BCl_3 and BF_3, the effect of reorganization has been explained using the results of CNDO/2 molecular-orbital calculations.[16] In the present investigation, an extended Hückel method for $AlBr_3$ was carried out.[17] The calculated lowest unoccupied virtual-orbital energy, E(LUMO), and the total electronic energy, E(ELEC), are presented as a function of the bond angle ∠Br–Al–Br in Fig. 5. This figure shows that E(LUMO) decreases with the reorganization of the planar molecule to the pyramidal form, in other words, the electron affinity of $AlBr_3$ increases with the reorganization, resulting in the formation of a stronger donor-acceptor bond. Meanwhile, the energy required to reorganize the planar molecule to the pyramidal form has been estimated by Cotton and Leto[18] to be 27.9 kcal/mol for $AlBr_3$, and this cannot be explained by only the change in E(ELEC) upon reorganization, as is shown in Fig. 5.

Upon the formation of a complex, the reorganization of a ligand is also considered to play an important role. According to the Zeeman effect on ^{81}Br NQR, the bond angle ∠Br–P–Br in $POBr_3\cdot AlBr_3$ is greater than that in $POBr_3$. Analogously, the H–H distance in H_2S is found from the results of the ^{1}H NMR studies to become larger upon the formation of $H_2S\cdot AlBr_3$, as is shown below. The second moment of the ^{1}H

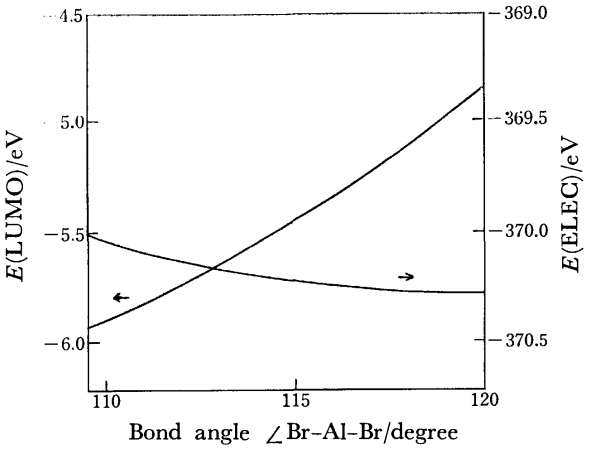

Fig. 5. Calculated energies for E(LUMO) and E(ELEC) as a function of the bond angle ∠Br-Al-Br.

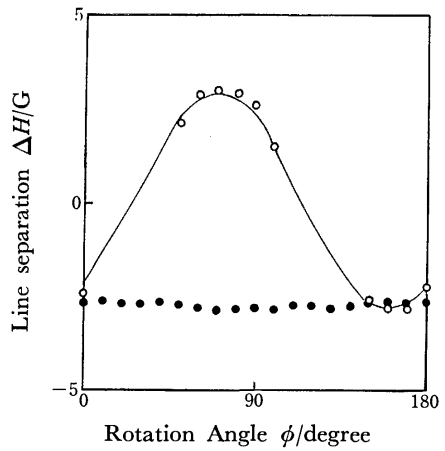

Fig. 6. Line separations in ^{1}H NMR spectra for $H_2S \cdot AlBr_3$. Sample A (○) for $\delta' = 22.8°$ and $\phi_0' = 71.4°$ Sample B (●) for $\delta' = 79.5°$ and $\phi_0' = 160.0°$.

NMR spectrum for the polycrystalline sample is 1.8—2.5 G[2] over the temperature range from 108 to 300 K and this suggests that reorientation of a proton pair takes place. The rotation patterns of the line separation of the ^{1}H NMR spectrum for two different single crystals were observed at room temperature and are shown in Fig. 6. Since the reorientation is considered to take place about the apparent three-fold axis along the S–Al bond, the line separation was analyzed according to[19]

$$\Delta H = (3/2)\mu r^{-3}\{3\cos^2\delta' \cos^2(\phi' - \phi_0') - 1\} \, |(3\cos^2\gamma - 1)|, \quad (9)$$

where the notations are the same with those used by Rangarajan and Ramakrishna. From this analysis, the reorientation axis was found to be consistent with the three-fold axis to within 3° and it was found that $|(3/2)\mu r^{-3}(3\cos^2\gamma - 1)| = 2.27$ G. Using this value and a Gaussian component line chosen by Pake,[20] $S(H - H_0) = \exp\{-(H - H_0)^2/2\beta^2\}$ with $\beta = 0.8$ G, the spectrum for the polycrystalline sample at room temperature can be reproduced. If the H–H line is assumed to be perpendicular to the apparent three-fold axis, the H–H distance is estimated to be 2.1 Å, which is larger than 1.88 Å from the result of NMR for H_2S in the solid phase.[21]

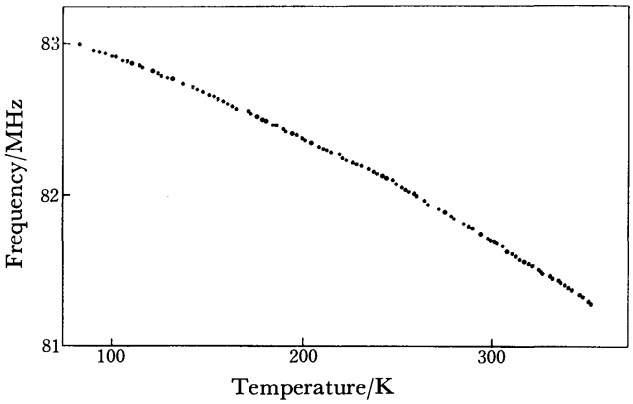

Fig. 7. Temperature dependence of ^{81}Br NQR frequency in $H_2S \cdot AlBr_3$.

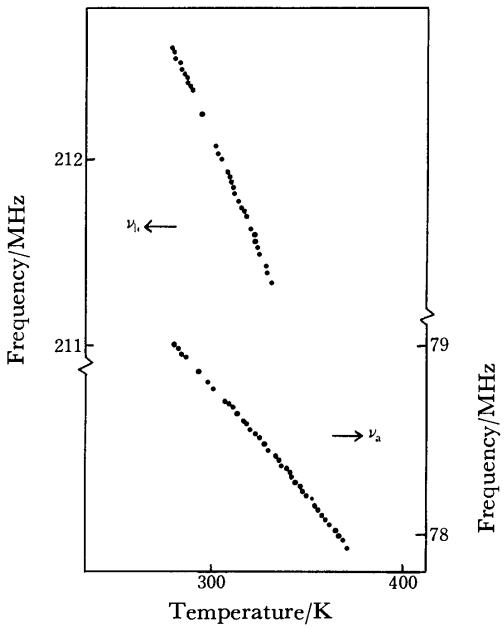

Fig. 8. Temperature depences of ^{81}Br NQR frequencies, ν_a and ν_b in $POBr \cdot AlBr_3$.

Temperature Dependence of the ^{81}Br NQR Frequencies. For $H_2S \cdot AlBr_3$, one ^{81}Br NQR line was observed at temperatures from 77 K to the melting point and the frequency decreases monotonically with increasing temperature, as is shown in Fig. 7. For $POBr_3 \cdot AlBr_3$, upon cooling, both ^{81}Br NQR lines of $AlBr_3$ and $POBr_3$ fade out around 273 K, whereas upon warming, the resonance lines of $AlBr_3$ and $POBr_3$ fade out at around 373 and 333 K, respectively, as is shown in Fig. 8. The fading out in the high temperature range may be caused by reorientation about the three-fold axis. Similar behavior has been observed for $POCl_3 \cdot GaCl_3$,[22] although the resonance lines fade out at temperatures different from those for $POBr_3 \cdot AlBr_3$. The reason for the fading out at a lower temperature, 273 K, is not apparent at the present time.

We wish to express our gratitude to Dr. Masaru

Ohsaku and Mr. Norihisa Bingo of Hiroshima University for the molecular-orbital calculations.

Static and Kinetic Studies of the Interaction of Toluidine Blue with Chondroitin-4-sulfate

Kojiro TAKAHASHI,* Zengo HORIUCHI, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-Senda Machi, Hiroshima 730

(Received August 12, 1977)

The binding of Toluidine Blue to chondroitin-4-sulfate was investigated by absorption spectra, titration curves, and temperature-jump relaxation spectra. The results were well interpreted by a basic model of binding to a linear lattice, where the cooperative interaction is restricted to the nearest-neighbor binding sites. The parameters g (number of binding sites per disaccharide repeating unit), K (cooperative binding constant), and q (strength factor of cooperativity) in 0.015 M phosphate buffer (pH 7.0) were determined to be 2, 1.02×10^5 M^{-1}, and 270 $\pm$60, respectively. The fastest process of the three relaxations observed in the system of Toluidine Blue-chondroitin-4-sulfate, could be interpreted as the aggregation process for cooperative binding. The rate constant $\tilde{k}_R$ was determined to be 1.6×10^8 M^{-1} s^{-1} at 28 °C.

The cooperative binding of dye to linear biopolymer has been well known as the aggregation of dye molecules on the charged polymer.[1] Schwarz's theory has well interpreted the static and dynamic phenomena of the cooperative binding of dye molecules to such polymers as polyglutamic acid, polyacrylic acid, and polyphosphate.[2-6] Recently, an extensive model for competitive cooperative bindings has been derived theoretically and has been applied to the investigations on the mechanisms of proflavin binding to poly(A) and DNA.[7,8]

The interactions of dyes with glucosaminoglycans, which have been known to adopt helical conformations in the solid state,[9-13] have been studied by the measurements of absorption spectra, optical rotatory dispersion, and circular dichroism.[14-18] One approach employing such measurements and using cationic dye has been performed as a probe of the glucosaminoglycan conformation in dilute aqueous solution. However, the kinetics of the conformational changes of glucosaminoglycans and the interactions of dyes with polymers have not been examined.

In the present paper, the first kinetical attempt to explain the interaction of dye with polysaccharide will be made systematically in the system of Toluidine Blue–chondroitin-4-sulfate by referring to a basic model of cooperative binding of a small ligand to a linear polymer.

Experimental

Chondroitin-4-sulfate (Ch4-S) from whale cartilage was purchased from Seikagaku Kogyo Co., Ltd. (Tokyo). The molecular weight was determined to be 24000 by means of an intrinsic viscosity measurement in 0.015 M phosphate buffer (pH 7.0) containing 0.2 M NaCl at 25 °C, using the following relation:[19]

$$(\eta) = 3.1\times10^{-4} M_W^{0.74},$$

where η is the intrinsic viscosity and M_w is the weight-average molecular weight. Toluidine Blue (TB) was purchased from Chroma Gesellschaft and was purified by washing with chloroform until the chloroform was colorless. Solutions of TB were made fresh for each experiment. The polymer-dye complex was prepared by adding TB to Ch4-S solutions with stirring. The pH was adjusted by the addition of NaOH or HCl. The measurements of the pH dependencies of the absorption spectra and the titration curves were performed without controlling the ionic strength. All sample solutions except those used for these two measurements were prepared with 0.015 M phosphate buffer solution (pH 7.0 and constant ionic strength (μ=0.06)). The concentration of Ch4-S (C_p) was calculated as the mole concentration of disaccharide repeating units. The weighing-in concentration of TB (C_A°) was checked by the measurement of absorbance at 630 nm. The pH values of solutions were measured with a Hitachi-Horiba Type F-5 pH meter. The absorption spectra were observed with a Union Giken SM 401 spectrophtometer. The extinction coefficient (ε) in the solution was obtained from E(absorbance)/C_A°. The extinction coefficients of pure monomer (ε_A) and pure dimer (ε_D) in TB were 4.2×10^4 and 0.13×10^4 M^{-1} cm^{-1} at 630 nm, respectively.

Titrations were performed in a closed 500-ml flask. After the addition of a very small amount of the standardized HCl titrant, a solution of 10 ml was removed for pH measurement. The percent protonation of Ch4-S as a function of pH was computed from the amount of added titrant minus the solvent blank volume.

Details of the Joule-heating temperature-jump apparatus have already been described elsewhere.[20] A temperature-jump of 8 °C was produced by a 20 kV capacitor discharge, giving a heating time of about 50 μs. All static experiments were performed at 25$\pm$0.5 °C.

Results

Static Studies. The absorption spectra of Ch4-S–TB complexes under the various polymer-to-dye ratios ($P/D=C_p/C_A^\circ$) at pH 7.0 are shown in Fig. 1. The solid line at P/D=0 exhibits two peaks, around 630 nm (due to the monomer of TB molecular) and 600 nm (due to the dimer). By adding Ch4-S to TB solution, a new band appears around 550 nm. The metachromatic effect becomes prominent with increasing P/D. The metachromatic band shift, however, is not observed within the range of P/D=5—50. With a P/D above 50, the band shifts to the longer wavelength side. The negative metachromatic effect may be attributed to the occurrence of isolated dye molecules from the polymer–dye complexes.

Figure 2 shows that the pH values of TB are approxi-

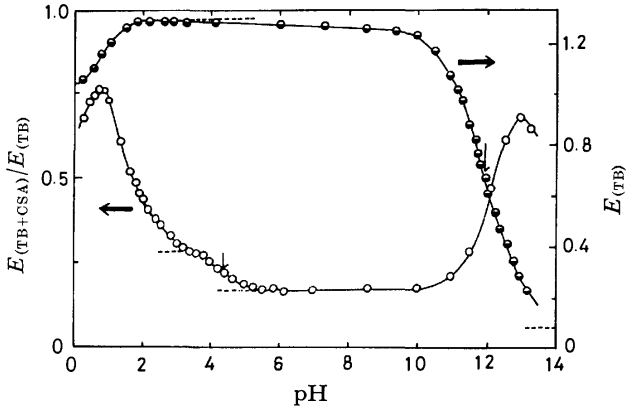

Fig. 2. pH dependencies of absorbances of TB and TB-Ch4-S at 630 nm, where E means the total absorbance: (◒) $C_A^\circ = 4\times10^{-5}$ M; (○) $C_A^\circ = 4\times10^{-5}$ M, $C_P = 2\times10^{-4}$ M.

mately 12 and 1, and that a small shoulder appears over the pH range of 3.5—5.5 in the Ch4-S–TB system. The titration curves of the Ch4-S and Ch4-S–TB complexes are demonstrated in Fig. 3 by plots of (pH—log $\alpha/(1-\alpha)$) against α, where α denotes the degree of ionization of the acid. The titration curve (a) suggests that there exist three conformations of Ch4-S in solution at least.** The titration curve (b), however, presents more simple features than Ch4-S alone. The extrapolated lines from the higher α values of the two curves give the pK values of 3.38 for (a) and 4.25 for (b). Their

** The analysis of the corresponding titration curve has been reported in the paper of the potentiometric titration study for the helix-coil transition of polyglutamic acid by M. Nagasawa *et al.*[22]

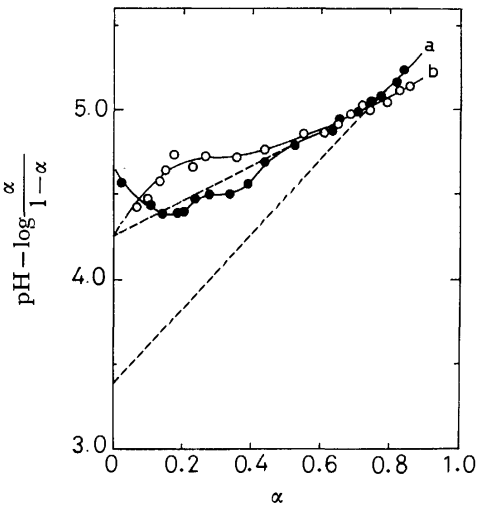

Fig. 3. Titration curves of Ch4-S and TB-Ch4-S complex at 25 °C: (●) $C_P = 2\times10^{-4}$ M; (○) $C_A^\circ = 4\times10^{-5}$ M, $C_P = 2\times10^{-4}$ M. The solid lines are the smooth curves between the experimental points. The dashed lines are the extrapolated lines from the higher α values.

values are in good agreement with the one obtained in 0.1 M NaCl solution by M.B. Mathews[21] for the former and with the one estimated from the pH dependency of the absorbance in Fig. 2 for the latter.

The representations of both measured and interpolated extinction coefficients at 630 nm in the solutions of TB and TB–Ch4-S can be found in Fig. 4. The curve at $P/D=0$ means that the aggregation of dye molecules causes the monomer concentration to decrease: the extinction coefficients (ε) in the variable solutions approach to the (ε_D) of the pure dimer from the (ε_A) of the pure monomer. Such smooth curves, however, do not appear upon adding Ch4-S in TB solution. The reversely sigmoid curves may occur by the cooperative binding of TB to Ch4-S. In the binding process where the cooperative interaction of nearest neighbor binding sites can be considered, there exist at least two different types of intrinsic binding processes:[2]

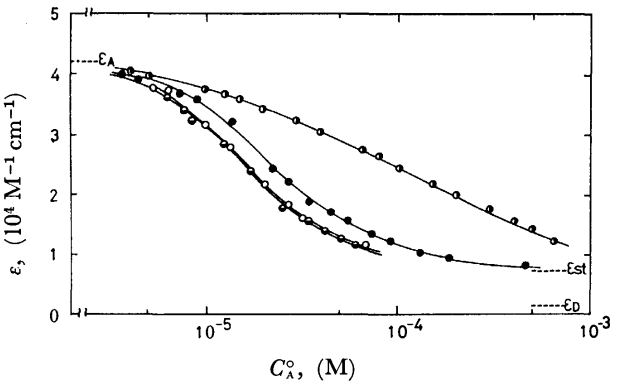

Fig. 4. Plots of molar extinction of TB solutions against C_A° in 0.015 M phosphate buffer (pH 7.0) at 630 nm: (◑) $P/D=0$; (●) $P/D=0.55$; (◒) $P/D=5.85$; (○) $P/D=55.2$.

I: an initial nucleation of binding $uuu + A \overset{K^*}{\rightleftharpoons} uau$,

II: the aggregation (or growth) process

$$uau + A \overset{K}{\rightleftharpoons} uaa,$$

where A, u, and a are the free monomeric ligand, the unoccupide binding site, and the binding site occupied by ligand, respectively. The binding constant for the initial nucleation process is defined to be $K^*=\overline{C}_{uau}/(\overline{C}_A\cdot\overline{C}_{uuu})$, while the cooperative binding constant is $K=\overline{C}_{uaa}/(\overline{C}_A\cdot\overline{C}_{uau})$. In order to analyse quantitatively the cooperative binding process, some constants should be estimated from the curves of Fig. 4. First, the dimerization constant K_d of TB in the absence of Ch4-S was calculated by using the following equation:

$$[(\varepsilon_A-\varepsilon)/C_A^\circ]^{1/2} = (2K_d/\Delta\varepsilon)^{1/2}[\Delta\varepsilon-(\varepsilon_A-\varepsilon)], \quad (1)$$

where $\Delta\varepsilon=(\varepsilon_A-\varepsilon_D)$. The value of $K_d=6.1\times10^3$ M^{-1} at pH 7.0 and 25 °C is in agreement with that estimated by H. Ushio *et al.*[6] It is also necessary to obtain the extinction coefficient ε_{st} of the dye molecules stacked on the Ch4-S molecules. The extinction coefficient is expressed by the following relation:

$$\varepsilon = \bar{\gamma}_A\varepsilon_A + 2K_dC_A^\circ\bar{\gamma}_A^2\varepsilon_D + \bar{\theta}\,gp\varepsilon_{st}, \quad (2)$$

where $\bar{\gamma}_A$ is the fraction of free monomeric dye, $\bar{\theta}$ is the fraction of occupied sites of polymer, g is the number of binding sites per disaccharide repeating unit of Ch4-S, and $p=P/D$. With the reduced version of mass conservation

$$\bar{\gamma}_A + 2K_dC_A^\circ\bar{\gamma}_A^2 + \bar{\theta}gp_{st}=1, \quad (3)$$

the transformation of Eq. 2 gives the following equation:

$$\varepsilon = \varepsilon_{st} + (\varepsilon_A-\varepsilon_{st})\bar{\gamma}_A + (\varepsilon_D-\varepsilon_{st})2K_dC_A^\circ\bar{\gamma}_A^2. \quad (4)$$

Quantitative estimations show that the last term of Eq. 4 can be practically neglected. By further introducing the cooperative binding constant K and the variable S $(=\overline{C}_{uaa}/\overline{C}_{uau}=K\overline{C}_A=KC_A^\circ\bar{\gamma}_A)$ for the calculation of equilibrium concentrations of any desired binding state, the following equation is obtained:

$$\varepsilon = \varepsilon_{st} + (\varepsilon_A-\varepsilon_{st})(S/K)C_A^{\circ-1}. \quad (5)$$

The plots of ε *versus* $C_A^{\circ-1}$ are shown in Fig. 5. If the parameter S becomes almost constant with respect to changes of C_A° at strong cooperativity and medium p, the plots should eventually result in the straight lines. Linear relationships do occur obviously for the smaller values of $C_A^{\circ-1}$. Extrapolation of $C_A^{\circ-1}\to0$ yields $\varepsilon_{st}=0.7\times10^4$ M^{-1} cm^{-1}.

For obtaining the value of g, Eq. 3 can be rewritten as the following relation:[3]

$$1-\bar{\theta}gp = \bar{\gamma}_A(1+2K_dC_A^\circ\bar{\gamma}_A) \equiv \gamma_A^*, \quad (6)$$

where γ_A^* is the total fraction of free dye. The values of γ_A^* calculated by using Eq. 5 and $\bar{\gamma}_A=(S/K)C_A^{\circ-1}$ are plotted against the P/D at constant C_A° in Fig. 6. The intercept on the P/D axis of the common limiting straight line for small P/D (<0.5) yields $g=2.0$. From the value of γ_A^* of the intersection point of the experimental curve and an auxiliary straight line with half

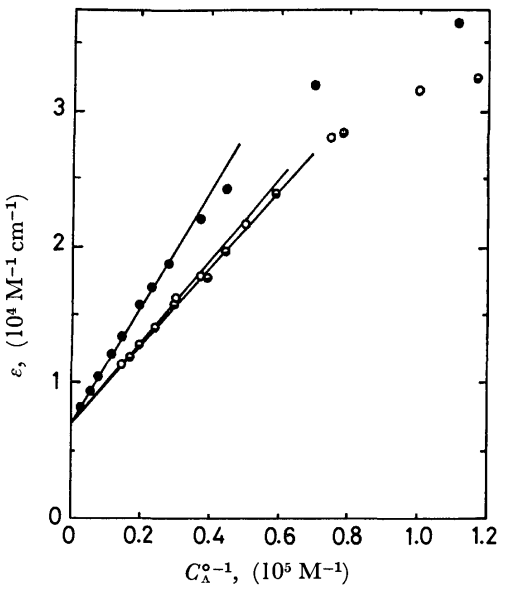

Fig. 5. Plots of molar extinction of TB solutions against $C_A^{\circ-1}$: (●) $P/D=0.55$; (○) $P/D=5.85$; (◒) $P/D=55.2$.

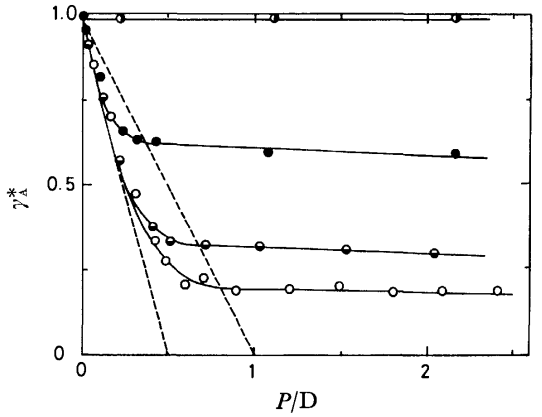

Fig. 6. Plots of total fraction of free dye against various P/D in 0.015 M phosphate buffer (pH 7.0) at 25 °C: (◑) $C_A^\circ=9.2\times10^{-6}$ M; (●) $C_A^\circ=1.9\times10^{-5}$ M; (◒) $C_A^\circ=3.9\times10^{-5}$ M; (○) $C_A^\circ=6.7\times10^{-5}$ M.

the slope of the first one in the figure, the value of K was determined to be 1.02×10^5 M^{-1} by

$$K = (\overset{\circ}{\gamma}_A^*\cdot C_A^\circ)^{-1} + 2K_d, \quad (7)$$

where $\overset{\circ}{\gamma}_A^*$ denotes the γ_A^* at the intersection point.[3] Since the values of $\bar{\theta}$ at the various initial concentrations of dye are easily accessible from Eq. 6 at constant P/D, the cooperativity parameter $(q=K/K^*)$ was calculated by the following relation:[2]

$$[1-2\bar{\theta}/\{\bar{\theta}(1-\bar{\theta})\}^{1/2}]\cdot\overline{C}_A^{1/2} = (g/K)^{1/2} - (gK)^{1/2}\overline{C}_A. \quad (8)$$

The average value of q was estimated to be 270±60 from the two straight lines shown in Fig. 7.

Using the values of ε_A, ε_D, ε_{st}, and K_d obtained above, the concentrations of stacked dye molecules $\overline{C}_{st}$ were estimated by using the following relation:

$$E = \varepsilon_A\overline{C}_A + 2\varepsilon_D\overline{C}_D + \varepsilon_{st}\overline{C}_{st}, \quad (9)$$

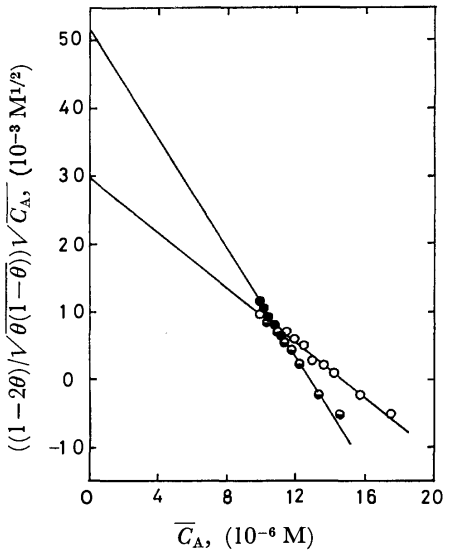

Fig. 7. Plots to determine cooperative parameter q for the TB-Ch4-S system: (●) $C_A^\circ = 1.9\times10^{-5}$ M; (◒) $C_A^\circ = 3.9\times10^{-5}$ M; (○) $C_A^\circ = 6.7\times10^{-5}$ M.

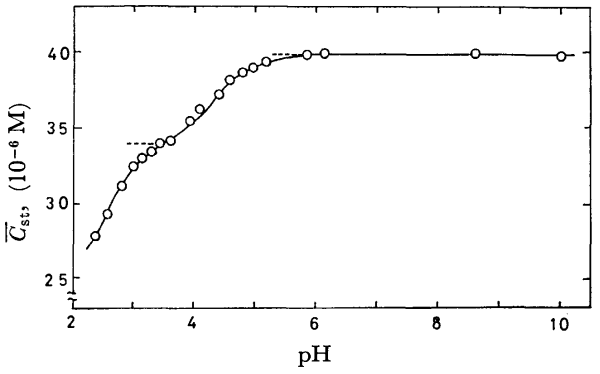

Fig. 8. pH dependence of the concentration of stacked dye molecule $\overline{C}_{st}$ in the TB-Ch4-S system at $C_A^\circ = 4\times10^{-5}$ M, $C_p = 2\times10^{-4}$ M and 25 °C.

where E denotes the total absorbance of the solution. The pH dependency of $\overline{C}_{st}$ is demonstrated in Fig. 8. The two-step saturation curve implies the existence of two interactions involving ionizing groups, that is, TB interacts with a sulfuryl group and a carboxyl group of Ch4-S.

Kinetic Studies. Some typical relaxation curves are shown in Fig. 9. At the metachromatic band (550 nm), a fast single relaxation spectrum was observed with the relaxation time of 10^{-4} s order, as shown in Fig. 9(a), while at 630 nm due to monomeric dye a faster change of absorbance was followed by two slower changes with the relaxation times of the order of 10^{-2} and 10^{-1} s, as shown in Fig. 9(b). This faster change appears to be relaxation with the same order of rate as the one observed at 550 nm. The relaxation amplitude, however, was very small and could not be analyzed. The dichroic effect due to optical anisotropy, which is caused by the induced orientation of the macromolecules in the direction of the electric field, was checked by two observations. At 550 and 630 nm, no change of relaxation amplitudes was observed by using

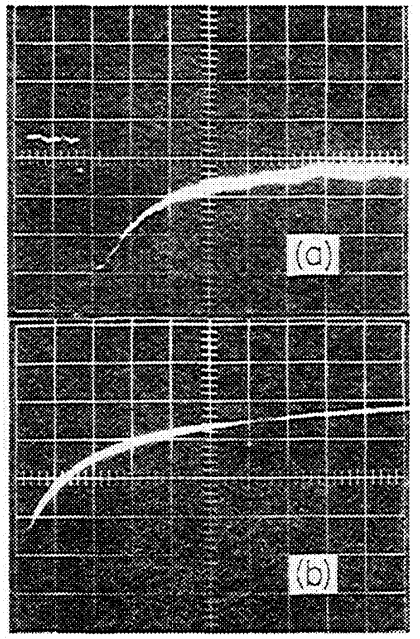

Fig. 9. Typical relaxation curves of the TB-Ch4-S system in 0.015 M phosphate buffer (pH 7.0) at 28 °C: $C_A^\circ = 4\times10^{-5}$ M, $P/D = 5.1$; (a) 550 nm, sweep of 0.2 ms, vertical scale of 0.1 V/div.; (b) 630 nm, sweep of 50 ms, vertical scale of 0.1 V/div.

a polarizer and no relaxation spectrum was detected at any isosbestic point. Furthermore, a more rapid change was observed at 630 nm in the dye solution. The absorbance change, however, was smaller than the fastest one observed at 630 nm in the presence of Ch4-S and was completed within the heating time of the apparatus. This change probably corresponds to a monomer-dimer reaction of the dye which appears under a certain ionic strength (μ=0.06 in the present work). In the presence of Ch4-S, however, the contribution to the monomer-dimer reaction of free dye was within the experimental error of the spectrum change shown in Fig. 9(b). From the variety of observations described above, the faster relaxation at the metachromatic band was analysed quantitatively as the chemical relaxation due to the equilibrium shift between the monomeric dye and the stacked dye molecules. In the present paper, two slower relaxations at 630 nm which may be interpreted by the conformational changes of TB–Ch4-S complex are not treated; this problem will be reported later.

According to the theory of cooperative binding, the binding of dye to linear polymers consists of the following two elementary steps:[2,4]

$$\text{auu} + \text{A} \underset{k_D}{\overset{k_R}{\rightleftharpoons}} \text{aau} \qquad (k_R/k_D = K), \tag{10}$$

$$\text{auuu} + \text{A}_2 \underset{k_{D'}}{\overset{k_{R'}}{\rightleftharpoons}} \text{aaau} \qquad (k_{R'}/k_{D'} = K^2/K_d). \tag{11}$$

The mean relaxation time τ_b^* of the binding process is[2,4]

$$1/\tau_b^* = 2\tilde{k}_R(g/q^{1/2})\{\bar{\theta}(1-\bar{\theta})\}^{1/2}\cdot p\cdot C_A^\circ, \tag{12}$$

where

$$\tilde{k}_R = \beta k_R + (1-\beta)k_{R'}, \tag{13}$$

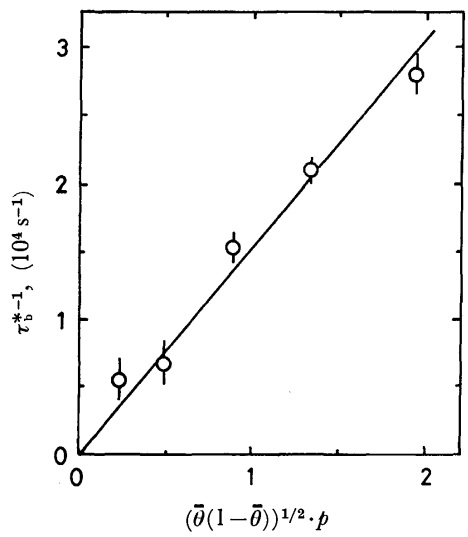

Fig. 10. Plot of the reciprocal mean relaxation time of cooperative binding τ_b^{*-1} against $\{\bar{\theta}(1-\bar{\theta})\}^{1/2}\cdot p$: $C_A^\circ = 4\times10^{-5}$ M.

$$\beta = 1/(1+4K_d\bar{C}_A) \simeq K/(K+4K_d). \quad (14)$$

The plot of τ_b^{*-1} againt $\{\bar{\theta}(1-\bar{\theta})\}^{1/2}\cdot p$ at constant C_A° value is shown in Fig. 10. From the slope of the straight line traversing the origin, $\tilde{k}_R$ was calculated to be 1.6×10^8 M^{-1} s^{-1}. By using the obtained K and K_d values, the β value was found to be approximately 0.8.

Discussion

The nature of the conformations of Ch4-S, which are known to adopt helical states in the solid state,[9,12] has not been estabilshed yet in solution. Chondroitin-6-sulfate, which has two ordered structures containing single helixes,[11,13] forms two states, flexible coil and rigid rod, in solution at a certain ionic strength.[23] As shown in Fig. 3, the titration curve of Ch4-S may imply that Ch4-S has three conformations in solution at least (for example: rigid rod, flexible coil, and random coil). The titration curve in the presence of TB may also imply that the transition between helical conformations (rigid rod$\rightleftharpoons$flexible coil) of Ch4-S is disturbed by masking the ionizing groups of Ch4-S with TB. Above pH 6, however, the deprotonations of Ch4-S are perhaps completed and the conformation of Ch4-S may be random coil in either the absence or the presence of TB. Therefore, the interaction of Ch4-S with TB at pH 7.0 would be also interpreted by a basic model of the cooperative binding of dye to linear biopolymer.

The number of binding sites per disaccharide repeating unit of Ch4-S was estimated to be $g=2.0$. Apparently the disaccharide repeating unit does not have specific binding sites for TB molecules. The unit of Ch4-S is electrically negative due to the carboxyl and sulfuryl groups and the TB molecule is electrically positive. Starting from the negative charges of the unit, it may be easily explained that the polymer chain only serves as a template favoring the formation of stacked aggregates by reducing the electrostatic repulsion between the positive charges of TB ions. On the other hand, the concentration of $\bar{C}_{st}$ increases with ionizations of sulfuryl and carboxyl groups. From these results, the binding of TB to Ch4-S is considered to be essentially an electrostatic interaction.

The cooperative binding constant K contains the contributions of two binding processes, the nucleation process (denoted by K^*) and the growth process (denoted by q). With a value of $q=270$ the average number of ligands in a stacked aggregate*** is 17.4 at $S=1$ and $\bar{\theta}=1/2$. This value is smaller than the total number of binding sites on one polymer chain (about 100). This may imply that a basic model of binding to a linear polymer can also be applied to a relatively shorter chain such as Ch4-S. On the other hand, the binding constant of the nucleation process K^*, which can be calculated with the relation $K^*=K/q$, is about 380 M^{-1}. The value is the same order of magnitude as K^* in the proflavine–polyglutamic acid system.[5] This means that the binding of isolated (*i.e.*, unstacked) TB molecules to Ch4-S is an electrostatic binding.

The obtained value of the rate constant for the growth process $\tilde{k}_R$ is reasonable considering the ionic strength used in the present work, because it is of the same order of magnitude as those obtained in the systems of acridine orange-polyglutamic acid[4] and proflavine–polyacrylic acid.[5] Since the value of β is about 0.8, it may be suggested qualitatively that the binding of free monomeric dye is approximately 80% in the aggregation process, under the assumption that k_R is the same order of magnitude as $k_{R'}$.

On the basis of the above considerations of the static and kinetic data, it is confirmed that the binding of TB to Ch4-S is essentially an electrostatic interaction but consists of a strong cooperative interaction ($K \gg K^*$), and that the recombination of dye molecules with binding sites in the immediate neighborhood of already occupied sites is a diffusion controlled process.

Isotope Effect in Thermal Ionic Reactions of Isomeric Transition-Activated ^{80}Br and ^{82}Br in the HBr–CH_4 System

Kenjiro KONDO and Masuo YAGI

Laboratory of Nuclear Science, Faculty of Science, Tohoku University, Kanayama, Tomizawa, Sendai 982

(Received August 26, 1977)

The reactions of isomeric-transition activated ^{82}Br were studied in the gaseous $H^{82m}Br$–CH_4(HBr/CH_4= 0.1±0.01) system. $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ were identified as the reaction products; their absolute yields were 0.8% for $CH_3{}^{82}Br$ and 3.7% for $CH_2{}^{82}BrBr$ respectively. The results were compared with those obtained in the $H^{80m}Br$–CH_4 and $^{80m}Br_2$ (or $^{82m}Br_2$)–CH_4 systems. The effect of Kr and Xe additives showed that these products were formed only through kinetic energy-independent (thermal-ionic) reactions, as opposed to the results obtained in the $^{80m}Br_2$ (or $^{82m}Br_2$)–CH_4 system. This difference was explained on the basis of the kinetic energies initially acquired by the bromine atoms in the molecular-explosion process. In addition, an outstanding isotope effect resulting from the difference in the decay schemes of ^{80m}Br and ^{82m}Br was observed between the I. T.-activated ^{80}Br and ^{82}Br reactions in the $H^{80m}Br$–CH_4 and $H^{82m}Br$–CH_4 systems, and it was pointed out from the analysis of the ^{80m}Br-data that the two successive internal conversions in the ^{80m}Br decay were responsible for this isotope effect. It was considered that the second internal conversion started in a liquid-like condition such as ion-clusters containing the ^{80}Br in the intermediate state; this idea is supported by the experimental results obtained in the condensed phase.

There is a definite difference between the decay schemes of ^{80m}Br and ^{82m}Br.[1] ^{80m}Br($t_{1/2}$=4.38 h) is de-excited to the ground state of ^{80}Br through the intermediate state with a half-life of 7.4 ns, whereas ^{82m}Br ($t_{1/2}$=6.1 min) is de-excited by a one-stage transition. The first transition of ^{80m}Br and the single transition of ^{82m}Br are fully converted (≈100%), while the second transition of ^{80m}Br is partly converted (≈61%). These internal conversions are followed by the Auger-electron emission, and the resulting atom is left with a high positive charge.[2–4] Furthermore, the intramolecular electron transfer between the highly positively charged bromine and the remainder in a source molecule results a molecular explosion; consequently, the bromine atom acquires an appreciable kinetic energy.

So far it has been reported that both the kinetic energy and the positive charge of the I. T.-activated ^{80}Br and ^{82}Br play very important roles in determining the chemical reactions of these atoms in the $^{80m}Br_2$ and/or $^{82m}Br_2$–CH_4 systems.[5–9] However, the present authors have previously pointed out that the ^{80m}Br undergoes only kinetic energy-independent (thermal-ionic) reactions in the $H^{80m}Br$–CH_4 system,[10] in which the kinetic energy imparted to the ^{80}Br is 0.75 eV[11] on an average, being greatly different from the kinetic energy (40.3 eV)[12] for the $^{80m}Br_2$. In order to elucidate further the roles of the kinetic energy and the charge in the recombination reactions, the I. T.-activated ^{82}Br reactions were studied in this work by using $H^{82m}Br$ as a source molecule in gaseous CH_4.

On the other hand, several experimental evidences have been accumulated for the isotope effect in the reactions of ^{80}Br and ^{82}Br activated by the isomeric transition in the CH_4[13] and CH_3Br[14b] systems. Previously Tachikawa has reported that the isotope effect resulting from the difference of the above decay modes appears in the energetic process to form CH_3Br, but not in the thermal process in the gaseous CH_4 system, using Br_2 as a source molecule.[13] Similarly, it is very interesting to examine an isotope effect by using $H^{80m}Br$ and $H^{82m}Br$ as source molecules in gaseous CH_4. The chief purpose of this paper is to search for a possible isotope effect, especially between thermal ionic reactions in the two systems. Furthermore, the mechanisms of the formation of individual products were examined by the addition of HCl and $CH_2{=}CH_2$ to the system instead of inert gases, and discussed on the basis of ion-molecule reactions involving $^{82}Br^+$.

Experimental

Materials. All the gaseous reagents used, supplied by the Takachiho Chemical Co., were used directly without additional purification. The listed purities were 99.95% for CH_4, Kr, and HCl, 99.8% for $CH_2{=}CH_2$, and 99.9% for Xe respectively. All the other reagents were of an extremely pure grade, purchased from the Junsei Chemical Co., Ltd.

Preparation of $H^{80m}Br$ and $H^{82m}Br$. $H^{80m}Br$ was synthesized from the $^{80m}Br_2$, obtained by the thermal decomposition of palladium bromide irradiated by the bremsstrahlung which was produced by the impact of a 40—60 MeV electron on a Pt converter in the linear-electron accelerator of Tohoku University. The details of preparation have been shown in previous papers.[10,14a] On the other hand, $H^{82m}Br$ was prepared by the thermal neutron irradiation of liquid HBr, sealed in a thin quartz ampoule. Thermal neutron irradiations were performed for 1—2 min by using the pneumatic tube No. 3 of the Kyoto University Reactor at a neutron flux of 3×10^{13} n cm^{-2} s^{-1}, with a concomitant gamm-ray dose rate of about 10^6 R h^{-1}. A trace amount of bromine, produced by the radiation-induced decomposition of HBr, was observed. In order to remove the Br_2 thus formed, the irradiated ampoule was broken by a mechanical shock in the vacuum line, and then the $H^{82m}Br$ purified was distilled into a storage bulb through a Dry Ice trap. The $H^{80m}Br$ produced at the same time by thermal-neutron irradiations was used in several runs to find out if there is a difference between the yields in the two experiments using HBr prepared by the above two different methods.

Sample Preparation. The quantities of CH_4, HBr (^{80m}Br or ^{82m}Br labeled), and other additive gases required were measured with a mercury manometer. These gases were introduced into cylindrical Pyrex glass ampoules (50, 100, and 200 ml in capacity) with a long neck of capil-

lary tubing cooled at the temperature of liquid nitrogen, and then sealed off. All these procedures were carried out by using a vacuum line composed of greaseless stop-cocks and joints. A quick sample preparation was requested to provide as many ^{82m}Br as possible for the isomeric transition experiments because of the short-life of ^{82m}Br($t_{1/2}$=6.1 min). The volatilization of the reaction mixtures by immersing the ampoule into hot water was done just 6 minutes after the end of irradiation; about 60% of the ^{82m}Br remained, provided for the I.T-induced reaction. The ratio of HBr to CH_4 and the total pressure were kept constant at 0.1±0.01 and 660±30 mmHg, respectively, throughout the series of gas-phase experiments. On the other hand, in the solid-phase experiment using $H^{80m}Br$ as a source molecule, reaction mixtures of HBr(65 cmHg), CH_4(130 cmHg), and/or HCl (130 cmHg) were solidified at the temperature of liquid nitrogen. The CH_4 deposited on the wall of the reaction vessel was thawed and mixed well with HBr and/or HCl by shaking, and then the mixture was solidified again at the bottom of the vessel.

Extraction, Activity Measurement, and Yield Determination. The radioactive bromine was separated into organic and inorganic layers by solvent extraction after the reaction mixture has been allowed to stand for more than 2 h in a dark place at 40 °C. The solvent extraction procedure was the same as that in the earlier experiments.[10,14a] A portion of the organic fraction was submitted to a gas chromatograph, while the product analysis was carried out by the use of a column (75 cm in length, 3 mm in diameter) filled with 60—80 mesh Celite 545, and coated with silicon oil (20% in weight). The fraction of each product was collected in glass tubes cooled in a Dry Ice ethanol bath at the outlet of the column. The radioactivity of each fraction was counted with a NaI(Tl) scintillation counter and/or a Ge(Li) semiconductor detector. Thus, the relative yields of the individual products were determined.

On the other hand, given volumes of organic and inorganic fractions were pipetted to test tubes. The photopeaks of 0.618 MeV from the ^{80}Br and/or 0.554 MeV from the ^{82}Br in both fractions were counted with a high resolution Ge(Li) semiconductor detector connected to a multichannel pulse-height analyser. In the ^{82m}Br-experiments, the solvent extraction and the activity measurement were performed after the ^{80m}Br had completely decayed out. The activities of both the inorganic and organic fractions were corrected for the separation time.

The organic yields were determined as the ratio (in percentage) of the activity of the organic fraction to the total activity, while the individual product yield was obtained by simply multiplying the relative yield of each product by the organic yield. For the several runs in the $H^{82m}Br$–CH_4 system, the individual product yields were determined directly by the radio-gas chromatograph technique adopted by Tachikawa *et al.* in the ^{80m}BrBr–CH_4 system.[5] However, there was no difference between the yields in the two methods, as well as the result previously obtained in the $H^{80m}Br$ experiments.[10]

The experimental errors arising from the standard deviation due to statistical fluctuations in the counting and chemical procedures were 7—15% for the ^{80m}Br-experiments and less than 10% for the ^{82m}Br.

Results

From the product analysis using a radio-gas chromatograph, we identified the $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ in the $H^{82m}Br$–CH_4 system, as well as the early observations obtained in the $H^{80m}Br$–CH_4 system.[10] The effect of Kr and Xe additives on the yield distribution is shown in Table 1 and depicted graphically in Fig. 1, together with the results in the $H^{80m}Br$–CH_4 system.[10,14a] The $H^{80m}Br$ prepared by thermal-neutron irradiations was used in several runs to find out if the results are different from those previously obtained by using the $H^{80m}Br$ prepared by the (γ, n) reaction.[10,14] However, no difference in the yields was observed between them. The $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ yields were 0.8% and

3.7%, respectively, at 0 mf of additives. The $CH_2{}^{82}BrBr$ yield was much greater than the $CH_3{}^{82}Br$ yield over the whole range of additive concentrations, contrary to the results in the I.T.-experiments of the $^{80m}Br_2$ and/or the $^{82m}Br_2$–CH_4 system.[13]

The organic yields were slightly greater in the $H^{82m}Br$–CH_4 than in the $H^{80m}Br$–CH_4 system, and no change in the yield distributions upon the addition of Kr and Xe was observed in the range of 0—0.5 mf. The additional formation of $CH_2{}^{82}BrBr$ was observed in additive concentrations over about 0.6 mf, as well as in the early findings reported by the present authors and Tachikawa *et al.* in the $H^{80m}Br$–CH_4[10] and $^{80m}Br_2$–CH_4[16,17] systems respectively.

The outstanding difference between the results in the $H^{82m}Br$–CH_4 and $H^{80m}Br$–CH_4 systems was found in the distribution of individual products, as can be seen in Fig. 1. The yield ratio of $CH_3{}^{82}Br$ to $CH_2{}^{82}BrBr$ was 0.22, very different from the value of 0.59 obtained in the $H^{80m}Br$–CH_4 system. Obviously there is an isotope effect between the reactions of I.T.-activated ^{80}Br and ^{82}Br in the $H^{80m}Br$ and/or $H^{82m}Br$–CH_4 systems. The effect of the HCl additive instead of inert gases was also examined in the $H^{82m}Br$–CH_4 system; the results are shown in Fig. 2. The $CH_2{}^{82}BrCl$ and $CH_3CH^{82}BrCl$ were observed to be other than the $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ from its radio-gas chromatogram. The organic yield was almost constant in 0—0.7 mf of HCl, and the decrease in $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ yields almost offset the increase in $CH_2{}^{82}BrCl$ and $CH_3CH^{82}BrCl$ yields. The results suggested that these products were formed through the reactions of the same precursor.

In addition, the $CH_3CH_2{}^{82}Br$ was observed in the experiment using $CH_2{=}CH_2$ additive other than the $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$, much as in the findings obtained in the $H^{80m}Br$–CH_4–$CH_2{=}CH_2$ system.[10]

The relative yield ratio of each product to the $CH_2{}^{80}BrBr$ obtained in the solid phase are shown in Table 3. The yield ratios of $CH_3{}^{80}Br$ to $CH_2{}^{80}BrBr$ were about 1.2 for the $H^{80m}Br$–CH_4 and 1.6 for the $H^{80m}Br$–CH_4–HCl system, different from the value of 0.22 for the gas-phase experiment in the $H^{82m}Br$–CH_4 system.

Discussion

Contribution of Charge and the Kinetic Energy to the I.T.-Induced ^{80}Br and ^{82}Br Reactions. The most convenient method of differentiating the energetic reaction from thermal ionic reactions is through the addition of inert gas as an energy sink of the energetic bromine atom. Especially, Kr moderates most effectively the kinetic energy of the bromine atom, since the mass of Kr is almost equal to that of bromine. In addition, Kr, and Xe, used in the present experiment, are chemically inert; also, the charge transfer from the Br^+ ion to the inert gas molecules seems not to be important, judging from the ionization potentials of the Br atom (11.8 eV) and the inert gases (Kr: 13.9 eV, Xe: 12.1 eV). Therefore, if the organic yields decrease upon the addition of Kr and Xe, it must be due to the removal of ^{82}Br kinetic energy; the rest, insensitive to these inert-gas additives, must be derived from thermal ionic reactions.

As Fig. 1 shows, the addition of Kr and Xe did not cause any changes in either the organic or the individual product yields in the concentration of 0—0.5

mf. This fact is indicative that the I.T.-activated ^{82}Br enters the organic chemical combination only through a thermal ionic process in the $H^{82m}Br$–CH_4 system, much as in the early findings obtained in the $H^{80m}Br$–CH_4 system.[10] The thermal ionic yields were 0.8% for CH_3Br and 3.7% for CH_2Br_2. The present results are summarized in Table 2, together with those previously obatined in the I.T.-[10,13] and (n,γ)-experiments[15] in gaseous CH_4. As is shown in Table 2, the recombination reactions of I.T.-activated ^{80}Br and ^{82}Br in both $H^{80m}Br$–CH_4 and $H^{82m}Br$–CH_4 systems are greatly different from those in other systems, in which the reaction proceeds mainly through kinetic energy dependent reactions. This difference can be explained on the basis of the kinetic energies initially acquired by the Br atom, which depend on the nature of the source molecule. In the case of the isomeric transition of ^{80m}Br and ^{82m}Br, the kinetic energy of the bromine atom ranges from 0 eV to maximum (E_{max}) of 1.3 and 158 eV respectively for the HBr and Br_2 used as source molecules, the most probable energies being 0.75 and 37 eV.[11] On the other hand, the ^{80}Br born from the (n,γ) activation has kinetic energy spectrum ranging from 0 to 417 eV.[11] The thermal ionic yields increase with a decrease in E_{max}, while, on the contrary, the kinetic energy-dependent yields tend to increase with an increase in E_{max}.

Previously it has been pointed out that the thermal ionic yield depends largely on the probability of the bromine ion reaching the thermal energy region by escaping from the charge neutralization.[10] From a comparison of the cross-sections for the charge-transfer reaction of bromine ions and for the formation of a capture-collision complex as a function of the velocity of the Br^+ ion, it was indicated that the charge neutralization takes place predominantly in the high-energy region over than about 1 eV, while the capture-collision complex is formed favourably at the energies below 1 eV.[10,17] Therefore, it is considered that most of the $^{80}Br^+$ and $^{82}Br^+$ produced by the (n,γ) reaction and the I.T. in Br_2 lose their charges before they reach the energy region in which the collision complex formation occurs preferentially. Thus, in these systems, the reactions are thought to be mainly due to a kinetic (hot) process involving neutral bromine atoms. On the other hand, it is considered that the formation of complex ions, such as ^{80}Br and/or ^{82}Br labeled CH_4Br^+ and $HBrBr^+$, proceeds at first in the I.T.-induced reaction in HBr; even if the charge neutralization takes place, the Br atom thus formed cannot undergo kinetic energy-dependent reactions because its kinetic energy is not sufficient for the Br to replace directly the H atom of CH_4. As has been mentioned in the following section, the CH_4Br^+ is considered to be a precursor of the formation of individual products.

Isotope-Effects in the Reactions of I.T.-Activated ^{80}Br and ^{82}Br. There have been several studies relating to the isotope effects (differences in organic yields) of (n,γ)- and I.T.-activated bromine reactions in the condensed and gas phases. Tachikawa[13] and Helton *et al.*[18] observed the kinetic-energy isotope effects of I.T.-and (n,γ)-activated bromine reactions in gaseous $^{80m}Br_2$ (or $^{82m}Br_2$)–CH_4 and Br_2–CH_3F systems respectively; these results were explained on the basis of the average number of possible collisions of the energetic bromine atom in the E_1—E_2 reactive region,[19] in which the energetic (hot) reactions take place. However, thus far no thermal ionic isotope effect has been reported in the bromine reactions induced by unclear transformations. As Fig. 1 shows, obviously there is the isotope effect between thermal ionic reactions in the $H^{80m}Br$–CH_4 and $H^{82m}Br$–CH_4 systems; also the yield distributions in the system of the HCl additive shown in Fig. 2 were greatly different from those previously obtained in the $H^{80m}Br$–CH_4–HCl system.[10]

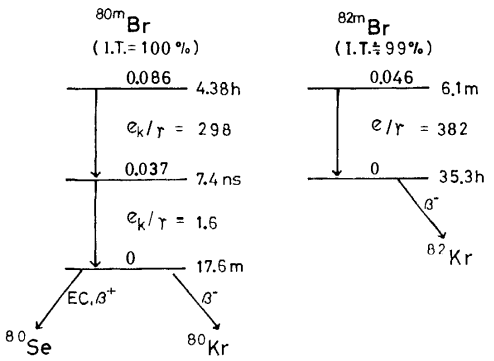

Fig. 3. Decay schemes of ^{80m}Br and ^{82m}Br.

Since the mass difference between ^{80}Br and ^{82}Br can not be considered to be responsible for the above isotope effect, this isotope effect may be brought about by the difference in the decay schemes of ^{80m}Br and ^{82m}Br,[1] shown in Fig. 3. The ^{80m}Br is de-excited in two stages through the intermediate state with a half-life of 7.4 ns; the first stage is a M3 transition of 49 keV, and the second, an El transition of 37 keV. From the internal conversion coefficients, the first transition is internally almost 100% converted, while the second is only 61% converted. On the other hand, the isomer of ^{82}Br is de-excited in a single stage by means of a M3 transition with an internal conversion coefficient of 382 (fully converted, $\approx$100%). Since the M3 transitions in ^{80m}Br and ^{82m}Br are essentially the same, the charge and kinetic-energy distribution on the excited ^{80}Br should be identical with those on the ^{82}Br. However, the excited ^{80}Br has a successive transition to the ground state. 61% of the excited ^{80}Br is de-excited through the second internal conversion process, while the remaining 39% undergoes de-excitation to the ground state by means of 37 keV γ-ray emission. However, even if the ^{80}Br is in a chemical combination, the chemical consequence resulting from this γ-emission is considered to be negligible since the kinetic energy achieved on the ^{80}Br is of an order of 10^{-2} eV, which is not sufficient to break any bond in the molecule, only enough to produce a little excitation of it. From these considerations, the reaction processes of isomeric transition-activated ^{80}Br can be classified into the following two types:

Process (A): 39%

internal conversion+37 keV γ-ray emission

(no chemical effect)

Process (B): 61%
internal conversion+internal conversion

Since the chemical effect resulting from Process (A) is essentially identical to those in the $H^{82m}Br$–CH_4 system, the yields due to Process (A) is equal to 39% of that obtained in the $H^{82m}Br$–CH_4 system. Therefore, the yield due to Process (B) is provided by subtracting that due to Process (A) from the organic yield in the $H^{80m}Br$–CH_4 system. The organic yields due to Process (B) were calculated by means of the following equation (I); they are depicted in Figs. 4 and 5, where the yields have been normalized by multiplying them by the factor of 100/61=1.64:

Yield (%) due to Process (B)

$$= \frac{100}{61}(^{80m}\text{Br-Yield} - 39\% \text{ of } ^{82m}\text{Br-Yield}) \qquad \text{(I)}$$

As Fig. 4 shows both the $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ yields were constant in 0—0.6 mf of Kr; this indicates that these products due to Process (B) are also formed through reactions independent of the kinetic energy of the ^{80}Br. The yield ratio of CH_3Br to CH_2Br_2 in Process (B) was 1.14, very different from the value of 0.22 for Process (A). This fact indicates that the $CH_3{}^{80}Br$ is formed more preferentially in Process (B) than in Process (A). Similarly, the $CH_3CH^{80}BrCl$ was found to be formed mainly in Process (B) in the $H^{80m}Br$–CH_4–HCl system, and the yield ratio of CH_3Br to CH_2Br_2 was close to unity over a wide range of HCl concentration, as can be seen in Fig. 5. Thus, there is a striking difference between the yield distributions of individual products for Process (A) and Process (B), and it is evident that Process (B) is responsible for the above isotope effect.

If the life-time of the intermediate of ^{80m}Br(1.1×10^{-8} s) is too short for the excited bromine atom to undergo chemical reactions prior to the transition to the ground state, the successive transition will result in only an additional build-up of the charge on the free atom, and this process will not give any kinetic energy to the ^{80}Br. In this case, no isotope effect will appear. The existence of an isotope effect, therefore, supports the idea that its life-time is long enough for the bromine atom to undergo chemical reactions prior to the second transition. However, this does not necessarily mean that all of the excited ^{80}Br react with surroundings to enter into certain chemical combinations within its life-time.

As has been stated in the previous section, the kinetic energy of ^{80}Br freed *via* the molecular explosion following the second internal conversion is very much dependent on the remainder of the molecule containing the excited ^{80}Br. However, both the $CH_3{}^{80}Br$ and the $CH_2{}^{80}BrBr$ due to Process (B) are formed only through kinetic energy-independent reactions. This fact may be suggestive that the second molecular explosion occurs from such chemical species as $H^{80}Br$, $H^{80}Br^+$, and $H_2{}^{80}Br^+$,[20] but if so, its chemical consequence will also be identical to the one due to Process (A) and no isotope effect will appear between them. From these considerations, it seems to be more likely that, even if the excited ^{80}Br is in certain chemical combinations, the environment surrounding the ^{80}Br is different from that in Process (A).

From an energy standpoint, it is considered that the $^{82}Br^+$ and $^{80}Br^+$ ions undergo at first ion-molecule reactions to form the capture collision complexes, $CH_4{}^*Br^+$ and HBr^*Br^+, since generally no activation energy is required for these reactions (Eqs. 1 and 2);

$$^*Br^+ + CH_4 \rightarrow CH_4{}^*Br^+, \qquad (1)$$

$$^*Br^+ + HBr \rightarrow HBr^*Br^+. \qquad (2)$$

(Here, the Br^+ with a star sign shows the $^{82}Br^+$ and/or excited $^{80}Br^+$.)

So far the presence of sticky collision complexes of such a type has been confirmed by using a mass-spectrometer in the various alkyl halide and hydrocarbon systems.[21–23] Further, it is expected, from a rough calculation by using the equation proposed by Magee *et al.*,[24] that the life-times of complex ions are at least longer than that of the ^{80}Br intermediate state (1.1×10^{-8} s).[10] Therefore, these complex ions have an ample opportunity to collide with surroundings prior to the successive transition in Process (B), since the collision time is about 10^{-9} s under the present experimental conditions. In the study of the radiation chemistry in the gas phase, Lind has suggested that thermal ions have a big chance to form an ion-cluster containing several molecules before they give the final products.[25] The attractive force considered here is that arising between the ion and the ion-induced dipole or

dipole moment on the molecule; also, it is generally known that thermal ions at high pressures form, more preferentially, ion-clusters.[26-28] In the present experiment, it is thought that the $CH_4{}^{80}Br^+$ and $HBr^{80}Br^+$ complex ions interact with surrounding molecules to form the ion-cluster before the second isomeric transition occurs. Therefore, the chemical effect due to Process (B) is considered to be very similar to that in the condensed phase. This idea was confirmed by the fact that the yield distributions of CH_3Br and CH_2Br_2 in the solid phase were very similar to those due to Process (B). That is, the yield ratios of CH_3Br to CH_2Br_2 obtained in the solid phase experiments were 1.2 for the $H^{80m}Br$–CH_4 and 1.6 for the $H^{80m}Br$–CH_4–HCl system, as is shown in Table 3; these values are very close to those obtained in Process (B). Thus, this ion-cluster model is qualitatively supported by the fact that the $CH_3{}^{80}Br$ is formed more preferentially than the $CH_2{}^{80}BrBr$ in the condensed phase. The large amount of energy evolved from the second molecular explosion is considered to be dissipated readily to the rigid sphere of the cluster and spent in the formation of ions, radicals, and excited species, which contribute directly or indirectly to the individual product formation.

Thus, the isotope effect found in the thermal ionic reactions of I.T.-activated ^{80}Br and ^{82}Br can be qualitatively explained by introducing the idea that the ion-cluster containing the ^{80}Br in Process (B) is formed in the intermediate state. However, the details of the reactions in such a field must await until further experiments.

The Formation of $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ via Thermal Ionic Reactions. As a possible explanation for the formation of $CH_2{}^{80}BrBr$ *via* the thermal ionic process in the I.T.-experiment on the $^{80m}BrBr$–CH_4 system, Tachikawa has previously suggested that the $CH_4{}^{80}Br^+$ complex ion undergoes charge neutralization following its decomposition to such fragments as $CH_3{}^{80}Br$, and $CH_2{}^{80}Br$, and that the $CH_2{}^{80}Br$ radical thus formed can be easily scavenged by Br_2 to form the $CH_2{}^{80}BrBr$.[13] However, the present authors previously pointed out that the $CH_2{}^{80}Br$ and $CH^{80}Br$ radicals would not be present in the $H^{80m}Br$–CH_4 as precursors for the formation of $CH_2{}^{80}BrBr$.[10,14]

Similarly, it was confirmed experimentally in this work that the precursors responsible for the formation of $CH_2{}^{82}BrBr$ were not the $CH_2{}^{82}Br$ and $CH^{82}Br$ radicals. That is, if the $CH_2{}^{82}Br$ is present in the system, the radical reacts with HBr to form $CH_3{}^{82}Br$ more preferentially than to form $CH_2{}^{82}BrBr$, since the reaction leading to the $CH_3{}^{82}Br$ is more exothermic by about 18 kcal/mol than that giving the $CH_2{}^{82}BrBr$. Similarly, the $CH_2{}^{82}Br$ radical reacts with HCl to form the $CH_3{}^{82}Br$ more preferentially than to form the $CH_2{}^{82}BrCl$ in the system of the HCl additive. However, as Figs. 1 and 2 show, the $CH_2{}^{82}BrBr$ yields were greater than those of $CH_3{}^{82}Br$ over the entire range of additive concentrations; further, the $CH_2{}^{82}BrCl$ yields increased with an increase in the HCl concentration in the system of the HCl additive. Furthermore, if the $CH^{82}Br$ is present in the system, it is considered that the radical reacts readily with $CH_2{=}CH_2$ to give ^{82}Br labeled-bromocyclopropane and/or aryl bromide in the system of the $CH_2{=}CH_2$ additive,[24] but no radioactive peak corresponding to these products was observed on the radio-gas chromatograms, as is shown in Table 4. Thus, the radicals such as $CH_2{}^{82}Br$ and $CH^{82}Br$ are not considered to be the precursors leading to the formation of $CH_2{}^{82}BrBr$ *via* a thermal-ionic process.

Table 4. Effect of $CH_2{=}CH_2$ additive on the yield distributions ($H^{82m}Br/CH_4 = 0.1 \pm 0.01$)

$CH_2{=}CH_2$ mf	Organic yield (%)	CH_3Br (%)	CH_3CH_2Br (%)	CH_2Br_2 (%)
0.1	40.3	0.8	39.3	0.2
0.3	49.3	0.4	48.9	<0.1

Although there are no precise information on the ion-molecule reactions leading to the $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ in Process (A) because of lack of knowledge concerning the chemical behaviour of complex ions under high pressures, the possibility of the formation of these products by the ion-molecule reactions involving $CH_4{}^{82}Br^+$ was evaluated from a thermodynamical point of view. Most ion-molecule reactions of $^{82}Br^+$, $CH_4{}^{82}Br^+$, and $HBr^{82}Br^+$ with additives, leading directly to the formation of $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$, are not favoured because of their high endothermicities. However, the H^+-transfer reaction from $CH_4{}^{82}Br^+$ to CH_4 and/or HBr are considered to be the principal reactions for the formation of $CH_3{}^{80}Br$, since Reactions 3 and 4 are roughly exothermic by 47 and 63 kcal/mol respectively for the $^{82}Br^+$ ground state:[10]

$$CH_4{}^{82}Br^+ + CH_4 \rightarrow CH_3{}^{82}Br + CH_5^+ \quad (3)$$

$$CH_4{}^{82}Br^+ + HBr \rightarrow CH_3{}^{82}Br + H_2Br^+ \quad (4)$$

On the other hand, among the various types of ion-molecule reactions involving the $^{82}Br^+$, $CH_4{}^{82}Br^+$, and $HBr^{82}Br^+$, only the following reactions, 5 and 6, are conceivable as steps in the reaction routes leading to the formation of $CH_2{}^{82}BrBr$ and $CH_2{}^{82}BrCl$, since these reactions are exothermic by about 45 and 28 kcal/mol respectively:[10]

$$CH_4{}^{82}Br^+ + HBr \rightarrow CH^{82}BrBr^+ + 2H_2 \quad (5)$$

$$CH_4{}^{82}Br^+ + HCl \rightarrow CH^{82}BrCl^+ + 2H_2 \quad (6)$$

As was pointed out in a previous paper,[10] it is considered that these ions lose their charges through charge-transfer reactions with impurities present in the system or with the wall of the reaction vessel, and that the radicals thus formed undergo H-abstraction from surrounding molecules to give $CH_2{}^{82}BrBr$ and $CH_2{}^{82}BrCl$ respectively. The details of these reactions will be revealed by accumulating data concerning ion-molecule reactions of these ions under high pressures.

The additional formation of $CH_2{}^{82}BrBr$ in concentrations of Kr and Xe over than 0.5 mf might be explained by ion-molecule reactions involving such ions as $Kr^{82}Br^+$ (or $Xe^{82}Br^+$), as well as by the explanation previously proposed in the $H^{80m}Br$–CH_4 system.[10] However, the answer to this problem must await more information concerning the ion-molecule reactions of Br^+ with inert gases and the reactivities of these complex

ions containing an inert molecule.

The authors wish to thank the staff members of the Hot Laboratory of the Kyoto University Reactor for their pneumatic-tube operations in neutron irradiations and the Linac crew of the Laboratory of Nuclear Science of Tohoku University for their accelerator operations.

Generation of Olefin Metathesis Catalysts from $W(CO)_6$ and Group IVa Metal Halides under Photochemical Conditions[1)]

Megumu NAGASAWA, Kiyoshi KIKUKAWA, Makoto TAKAGI, and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 5, 1977)

Irradiation of a solution of $W(CO)_6$ and group IV_a metal halides in benzene by UV light gave the olefin metathesis catalysts, of which the combination $W(CO)_6$–$TiCl_4$ was the most effective. Association of the coordinatively unsaturated $W(CO)_5$ and $TiCl_4$ was suggested to be a key step in the formation of a catalytically active complex. A survery was also made for other $W(CO)_6$–MX_n combinations for photo-generation of metathesis catalyst.

Much effort has been made in search for the olefin metathesis catalysts and elucidation of the reaction mechanism.[2,3)] A mechanism involving intermediate formation of carbene complex has been strongly suggested.[3)] However, in view of catalyst preparation, most of the effective catalysts appear to consist of W or Mo compounds in their medium oxidation states. A combination such as WCl_6–R_nAlCl_{3-n} is typical, where the former component is partially reduced by the latter during the course of preparation. As a new access to metathesis-active W species of medium oxidation state, photochemical energy can be used to activate the otherwise inactive combination between W compounds and the cocatalytic oxidizing or reducing components. Two possible combinations can be considered: i) $W(CO)_6$–MX_n, where MX_n is a transition metal halide in high oxidation state, and ii) WCl_6–ML_n, where ML_n stands for the metal complex in low oxidation state. The latter photosystem has so far been unsuccessful, but the former gave a number of new metathesis catalysts, the results of which are given in the present communication. A metathesis catalyst from photosystem has recently been reported by Krausz *et al.*[4)] and by Agapiou and McNelis,[5)] in which $W(CO)_6$–CCl_4 was irradiated.

Results

A solution of $W(CO)_6$ and MX_n, each 4.3×10^{-3} M in benzene, was irradiated by a high pressure mercury lamp at room temperature for 1 h. To the resulting solution was added 260 fold molar amount of 1-octene, and the mixture was stirred at 30 °C in the dark. The product was found to be a mixture of straight-chain internal olefins of carbon number between 3 and 14. It is obvious that the catalysts effected both isomerization and metathesis of the substrate olefin. The result of the analysis of the product after 18—20 h reaction is summarized in Table 1. The yields of C_3 to C_7 olefins are not included, since the determination of these olefins was less reliable under our experimental conditions. $TiCl_4$ was the most effective cocatalyst, followed by $ZrCl_4$ and $HfCl_4$. No metathesis catalyst from $W(CO)_6$-group IVa metal halides has so far been reported. The catalyst mixture before the addition of olefin was brownish and homogeneous for $TiCl_4$, but it was slightly turbid for $ZrCl_4$ and $HfCl_4$ because of their low solubility in benzene. In each case, the turbidity gradually increased in the reaction with olefin. The catalyst activity of $W(CO)_6$–$TiCl_4$ was roughly comparable to that of $W(CO)_6$–CCl_4, the major side reactions being the isomerization of olefin in the former and the addition of CCl_3–Cl component to olefin in the latter system.[6)] It should be emphasized that all these MX_n compounds either alone or as combined with $W(CO)_6$ showed no activity for metathesis unless the mixture with $W(CO)_6$ was irradiated. Among other MX_n compounds tested, $AlCl_3$, $SnCl_4$ and $TaCl_5$ were found effective, but the activity of the resulting catalyst was slight at room temperature. The metal salts, $MoCl_5$, $NbCl_5$, $VOCl_3$, VCl_4, $(C_5H_5)_2TiCl_2$, $FeCl_3$, $ZnCl_2$, and $AgClO_4$ were totally inactive under comparative reaction conditions.

The $W(CO)_6$–WCl_6 system was studied in some detail. Due to the strong Lewis acidity of WCl_6, this photosystem gave only C_8-substituted benzenes (Friedel-Crafts alkylation, 74%) and oligomers from 1-octene (22%) under the standard conditions. Alkylation of the aromatic solvent was also the major reaction in the absence of irradiation. Even under irradiation, a proper selection of parameters, such as the concentration of catalyst or olefin, was required to suppress the alkylation and to make the metathesis activity ob-

TABLE 1. CATALYSIS OF PHOTOSYSTEM $W(CO)_6$–MX_n IN THE METATHESIS OF 1-OCTENE[a)]

WCl_6[c)]	24	tr	tr	2	6	7

a) Catalyst solution: Unless otherwise noted, 4.3×10^{-3} M $W(CO)_6+4.3\times10^{-3}$ M MX_n in benzene was irradiated for 1 h by high pressure mercury lamp through a pyrex filter at 20—25 °C. Metathesis reaction: $W(CO)_6$/1-octene (mol ratio)=260, 18—20 h at 30 °C in the dark after addition of olefin.
b) Yield: (mol product/mol 1-octene added to catalyst solution)×100; tr, trace. C_n : linear internal olefins in trans coefiguration with n carbon atoms. c) $[W(CO)_6]=4.3\times10^{-3}$ M. $W(CO)_6$: WCl_6 : 1-octene=1 : 0.5 : 260. The reaction mixture was refluxed for 4 h after addition of olefin.

servable. Low $WCl_6/W(CO)_6$ ratio (<0.5) combined with high concentration of olefin appeared to favor metathesis. No alkylation was observed under conditions of the run given in Table 1. A competition between alkylation and metathesis depending on the catalyst concentrations as well as on the olefin concentration has been reported by Hocks *et al.*[7] The general trends observed in the present system were similar to those reported. The effect of irradiation time was not critical in our conditions so far as the irradiation time of 40—70 min was adopted. Low pressure mercury lamp could be used instead of the high pressure lamp, but this introduced the formation of hydrogen chloride, and the products became more complex.[8]

In order to reduce the complexity due to isomerization of the terminal olefin, 3-heptene was subjected to metathesis with $W(CO)_6$–TiX_4 catalyst under conditions similar to those in Table 1. The effect of the isomerization could not be eliminated, the products containing the olefins derived from 2-heptene in addition to those from 3-heptene. Figure 1 illustrates a typical conversion-time profile. The reaction is seen to reach some "equilibrium" olefin composition after 6 h. The yields of complementary olefins, *e.g.*, hexene and octene, were in 1 : 1 molar ratio. Similar conversion-time profiles are shown for various catalyst compositions in Fig. 2, where only the combined yields of hexenes and octenes are indicated. The combination, $W(CO)_6$–$TiCl_4$, was more effective than $W(CO)_6$–$TiBr_4$. A change in the ratio $TiCl_4/W(CO)_6$ exerted considerable influence on the rate of metathesis reaction. With the optimum ratio at 1.0, both the increase and decrease in the ratio resulted in lowering the catalyst activity. A similar behavior was also confirmed in the reaction of 1-octene. The increase in the total catalyst concentration increased the reaction rate as expected, but in a complicated manner. The catalyst underwent a considerable temperature effect, the reaction not proceeding below 15 °C. The selectivity of the catalyst defined as per cent molar ratio of the combined yield of octenes and hexenes to the amount of the substrate heptene consumed was dependent on

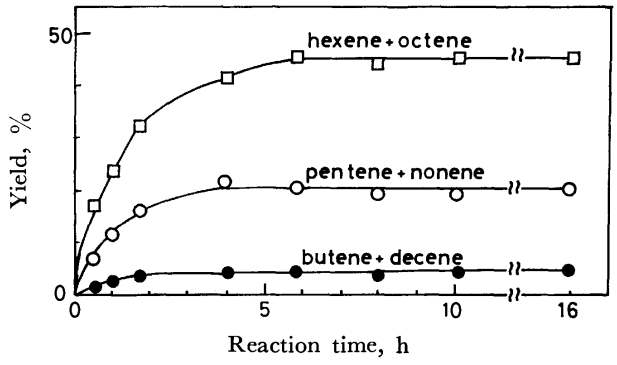

Fig. 1. Metathesis of 3-heptene by photosystem $W(CO)_6$–$TiCl_4$. Reaction conditions are similar to those in Table 1.
$[W(CO)_6]=4.3\times10^{-3}$ M; W : Ti : 3-heptene = 1 : 1 : 260; yield (%), (combined molar yield of complementary olenfins/mol 3-heptene added to the catalyst solution) × 100.

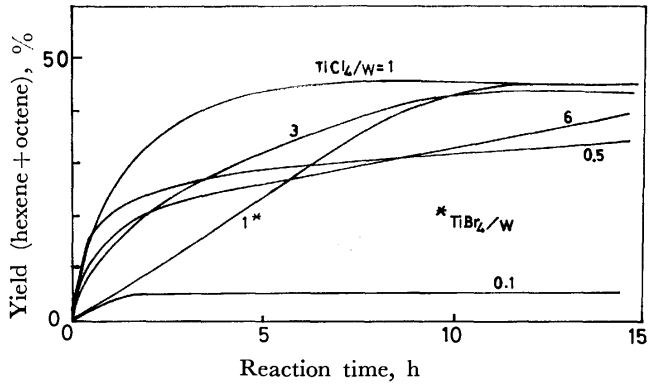

Fig. 2. Effect of catalyst composition on the rate of metathesis. Conditions are similar to those in Fig. 1 and Table 1.
$[W(CO)_6]=4.3\times10^{-3}$ M, 3-heptene/W = 260.

Ti/W ratio. The selectivity increased with the increase in Ti/W ratio, the effect being slight: $TiCl_4/W(CO)_6$ ratio, % selectively; 0.5, 57; 1, 63; 3, 72; 6, 71; 1 ($TiBr_4$ in place of $TiCl_4$), 60.

Discussion

One CO molecule dissociates from $W(CO)_6$ to from coordinatively unsaturated $W(CO)_5$ on irradiation by UV light.[9] Examination with a high pressure mercury lamp indicates that exactly one mole of carbon monoxide is evolved per mole of $W(CO)_6$ irrespective of the combination $W(CO)_6$–WCl_6 or $W(CO)_6$–$TiCl_4$. Since no further gas evolution was observed on prolonged irradiation, it is most probable that $W(CO)_5$ is the species involved in the formation of metathetically active complex. The observation that the maximum metathetic activity is obtained for the photosystem with $TiCl_4/W(CO)_6$ ratio of 1 suggests that 1 : 1 molar reaction of $TiCl_4$ and $W(CO)_5$ is essential for the formation of the caralyst. The catalyst solution was also prepared by adding $TiCl_4$ to the irradiated solution of $W(CO)_6$ in benzene, the activity being considerably lower than that by the standard procedure. Krausz *et al.* reported that the reaction of $W(CO)_5$ with CCl_4 produces $W(CO)_5Cl$ and this complex is an essential intermediate in the photochemically induced olefin metathesis (Reaction 1).[4] In our system, the over-all process may be delineated as in reaction 2, since the CO gas escapes out of the system. In reaction 1 the zero-valent tungsten complex $W(CO)_6$ was oxidized by CCl_4 to $W(CO)_5Cl$, in which tungsten is formally in +1 oxidation state. The oxidation state of tungsten in the association complex $W(CO)_5TiCl_4$ in Reaction 2 might be in +1.

$$W(CO)_6 \xrightarrow{h\nu} W(CO)_5 + CO \xrightarrow{CCl_4} W(CO)_5Cl + COCl_2 + \text{other products} \quad (1)$$

$$W(CO)_6 \xrightarrow{h\nu} W(CO)_5 \xrightarrow{TiCl_4} W(CO)_5TiCl_4 \quad (2)$$

If $W(CO)_5X$ species can be a potential precursor

for the metathesis catalyst, several other routes to the catalytically active systems can be envisaged. The reaction of $W(CO)_6$ in benzene with halogens (I_2, ICl, ICl_3, and Br_2) in the presence or in the absence of light failed to produce the catalyst. The solution of $W(CO)_6$ in various halogenated organic solvents was irradiated as a possible extension of the photosystem $W(CO)_6$–CCl_4. Tetrachloroethylene, trichloroethylene and chlorobenzene[10] were found to give the catalyst of varying activity and selectivity depending on the irradiation conditions. *In situ* generation of the catalyst in which a $W(CO)_6$–MX_n–olefin mixture in benzene was irradiated, sometimes proved to be much more effective than the standard procedure. This suggests a possibility of improving the catalytic activity by proper selection of irradiation conditions and the catalytic cofactors which trap the photo-generated intermediate such as $W(CO)_5$.

Experimental

Materials. $W(CO)_6$ was purified by vacuum sublimation. Contaminations in WCl_6 were removed by sublimation at 200 °C. Commercial metal halides were used. 1-Octene and 3-heptene were distilled from sodium, and organic solvents were purified by standard methods. All these reagents were kept and handled under dry nitrogen.

Catalyst Solutions. Irradiation of benzene solution containing appropriate catalyst precursor ($W(CO)_6+MX_n$) was achieved either by a 100 W immersion-type high pressure mercury lamp (Riko UVL-100HA) equipped with a water-jacketted pyrex cell of 100 ml content or by an 80 W coil-type low pressure mercury lamp (Ushio UL1-8HQ) with a jacketted quartz cell of 100 ml content which was placed inside the coiled lamp. Eighty milliliters of the solution was utilized. After irradiation the required amount of olefin was added under stirring. Often, aliquots of the catalyst solution were transfered from the photo-cell to another reaction vessel, and the subsequent reaction was conducted in the latter. All the manipulations were carried out under dry nitrogen. Irradiation of the benzene solution containing both olefin and metal compounds, though effective for metathesis reaction, was not employed as a standard procedure, since it sometimes introduced more complexity in the product.

Metathesis Products. The progress of the reaction was monitored by GLC, using octadecane or octane as an internal standard. Metathesis products were isolated from the final reaction mixture and identified by the conventional spectroscopic method as well as by comparison with standard samples of saturated hydrocarbon after the products had been hydrogenated. All of the internal olefins showed a strong IR band at 960 cm^{-1} indicating *trans* configuration. In the work-up of the reaction mixture from 3-heptene, most of the solvent (benzene) had to be removed by refrigeration followed by filtration, before the products were subjected to preparative GLC.

6) Detailed metathesis study with the photosystem $W(CO)_6$–CCl_4 is not available.[4,5] In the present study, $W(CO)_6$–CCl_4 system, in which the latter component was employed either as solvent or as an additive in benzene solution, was irradiated in a manner similar to that described for $W(CO)_6$–MX_n (see Experimental). The conditions were thus different from those reported. The addition of CCl_4 to olefin, which under our conditions proceeded to a comparable extent to metathesis in the reaction of 1-octene, was not described in the literature.[4,5]

(Received September 21, 1977)

The complexation of homogeneous polyethylene glycols and their dimethyl ethers(glymes) with alkali and alkaline-earth metal cations was studied by PMR spectroscopy on the basis of a comparison with crown ethers. The ethylene proton signal of octaethylene glycol in methanol-d_4 was split into three lines by the addition of a potassium, rubidium, caesium, strontium, or barium cation. The latter two cations also caused large downfield shifts of the signals, which are quite comparable with those of 15-crown-5 and 18-crown-6 caused by the same metal cations. As for heptaethylene glycol, a splitting was observed in the presence of a strontium ion or an alkali metal cation except for a lithium ion. A large downfield shift was also observed in the presence of a strontium or barium ion. As for hexaethylene glycol, the signal was split only by a sodium ion, and the optimal interaction with a calcium ion was confirmed on the basis of the downfield shift. In methanol-d_4, lithium and magnesium ions did not cause any change in the PMR spectra of either the crown ethers or the glycols. The PMR downfield-shift method also disclosed the metal-ion complexation of the glycols in water. The terminal hydroxyl groups play an important role in the complexation.

In the preceding paper,[1] we clarified, by solvent extraction, that acyclic poly(oxyethylene)(POE) derivatives with at least seven oxyethylene units complex fairly well with alkali metal ions in water and that their extracting power is comparable with that of 18-crown-6. In the cases of alkaline-earth metal ions, however, the solvent-extraction method was found inadequate to evaluate their complexation because of the poor solubility of the complexes in dichloromethane.

Of the instrumental methods used for the evaluation of the metal-ion complexation of organic ligands, NMR spectroscopy has proven to be the most facile and informative under various conditions.[2-8] In general, complexation with metal cations or the ion pairs leads to a change in the conformation of the ligands and, as a result, the splitting or broadening of the absorption signals. When the charged complex and the anion are separately solvated and the ion pairing is negligible, which means the absence of an anion effect, a downfield shift can be exclusively expected due to the increased electronegativity of the donor atoms in the ligands. Thus, the change in the PMR spectra can be a qualitative measure of the extent of the complexation in a series of ligands.

With these facts in mind, we have undertaken the present studies to ascertain the complexation of relatively short but homogeneous polyethylene glycols (PEG) and their dimethyl ethers(glymes) with alkali and alkaline-earth metal cations in methanol and in water. The thiocyanates again turned out to be convenient salts for these studies because of their high solubility in methanol.

Experimental

Materials. RuSCN, CsSCN, and $Sr(SCN)_2$ were prepared according to the method reported for $Ba(SCN)_2$.[9] $LiSCN \cdot 2H_2O$ was obtained from Mitsuwa Pure Chemicals. The other salts were the same materials as in the preceding paper. The anhydrous thiocyanates were prepared by vacuum dehydration at 100 °C. The following chemicals were obtained in the highest available purity from the sources indicated: methanol-d_4 and deuterium oxide(CEA products through Nakarai Chemicals, Ltd.); ethylene glycol(EO1), ethylene glycol dimethyl ether(glyme)(MeEO1Me), diethylene glycol(EO2), and triethylene glycol(EO3)(Wako Pure Chemicals Industries, Ltd.); diethylene glycol dimethyl ether(diglyme)(MeEO2Me) (Yoneyama Chemical Industries Ltd.); triethylene glycol dimethyl ether (triglyme)(MeEO3Me)-(Nakarai Chemicals, Ltd.); tetraethylene glycol (EO4) (Japan Catalytic Chemical Industry, Ltd.); tetraethylene glycol dimethyl ether(tetraglyme)(MeEO4Me)(Tokyo Kasei Kogyo Co., Ltd.) and 12-crown-4(Bokusui Brown Co., Ltd.). They were all used after distillation.

Penta-, hexa-, hepta-, and octaethylene glycols(EO5—EO8) were prepared according to the method reported previously;[10] bp(°C/mmHg) EO5, 165—168/0.2; EO6, 180—189/0.3; EO7, 210—212/0.35; EO8, 214—218/0.27. Their dimethyl ethers, *e.g.*, penta-, hexa-, hepta-, and octaglymes (MeEO5Me, MeEO6Me, MeEO7Me, and MeEO8Me) were prepared similarly the from sodium salt of EO1 monomethyl ether and the dichloride of EO3, from the sodium salt of EO2 monomethyl ether and the dichloride of EO2, from the sodium salt of EO2 monomethyl ether and the dichloride of EO3, and the from sodium salt of EO2 monomethyl ether and the dichloride of EO4, respectively; bp(°C/mmHg): MeEO5Me, 120—123/0.25; MeEO6Me, 145—148/0.1; MeEO7Me, 175—180/0.5; MeEO8Me, 215—218/0.45. Hexaethylene glycol monomethyl ether(137—141/0.05) and octaethylene glycol monomethyl ether (MeEO8)(212—216/0.16) were prepared from EO2 chloroethyl methyl ether and the sodium salt of EO3, and that of EO5, respectively.

Measurment of PMR Spectra. The PMR spectra were obtained using a JEOL LMN-PS-100 spectrometer on an expanded scale(sweep width, 270 Hz), with 8% dioxane in benzene as the external reference. The chemical shifts are expressed in Hz downfield, without any bulk magnetic susceptibility correction. The differences in the chemical shifts of the main oxyethylene protons and methyl protons were determined by the successive measurement of the signals of

* A preliminary report of this work was presented at the 36th National Meeting of the Chemical Society of Japan, Higashi Osaka, April 1977.

a plain 1% POE solution and those of 1% POE solution containing metal salt(0.04—0.05 mol/kg). The molar ratio of the salt to POE ranged from about 2 to 7, depending on the molecular weight of the POE. For the measurement in deuterium oxide, the salt concentration was increased to 0.2 mol/kg.

Results and Discussion

Downfield Shifts for Crown Ethers in the Presence of Alkali or Alkaline-earth Thiocyanates. In Table 1 we summarize the downfield shifts for 15-crown-5 and 18-crown-6 caused by the presence of alkali and alkaline-earth metal thiocyanates. Alkali and ammonium ions caused small downfield shifts in methanol, but all alkaline-earth metal ions except the magnesium ion caused downfield shifts which are large enough to be a measure of metal-ion complexations both in methanol and in water. These facts are consistent with the recent observations made using 220 MHz PMR spectroscopy.[7]

On the other hand, lithium and magnesium ions did not bring about any observable shifts in methanol-d_4, not even for 12-crown-4.

Recently, Izatt *et al.*[11] have reported the association constants for the reactions of several crown ethers with alkali and alkaline-earth metal cations in water and in aqueous methanol. Compared with the log K values, the downfield shifts are not necessarily proportional to the corresponding log K values; also, surprisingly, the calcium ion induced larger downfield shifts for both the crown ethers than would be expected from the respective log K values. Further, the shift induced by the calcium ion for 18-crown-6 is larger than that for 15-crown-5 both in methanol and in water, and the barium ion caused a larger shift for 15-crown-5 than for 18-crown-6. These facts are quite in conflict with the ion radius cavity concept.[13,14] The ioslation of some stable calcium ion-crown ethers complexes[15,16] substantiates the strong interaction with the crown ethers as well as the large downfield shifts. The interaction of the crown ethers with the calcium ion seems to have been underestimated thus far.[17]

Interaction of Polyethylene Glycols(PEG) and Their Dimethyl Ethers (Glymes) with Alkali Metal and Ammonium Ions in Methanol. The downfield shift in the 60 MHz PMR spectra of PEG in the presence of potassium iodide was too small to draw any decisive conclusion on their interaction.[3] A reinvestigation of the high resolution PMR spectroscopy(100 MHz) using various thiocyanate salts has, however, revealed the following facts: (1) the downfield shifts are all quite small, just as for the crown ethers(Table 2); (2) the spectrum of hexaethylene glycol was changed into two partially resolved peaks in the presence of sodium thiocyanate (Table 2, Fig. 1); (3) the sharp signal of heptaethylene glycol was split into two or three peaks by all alkali metal thiocyanates except lithium thiocyanate (Table 2, Fig. 1); (4) the sharp signal of octaethylene glycol was changed into three partially resolved peaks, accompanied by small downfield shifts in the presence of potassium, rubidium, and caesium thiocyanates (Table 2, Fig. 1); (5) the potassium ion caused downfield shifts for glymes which are proportional to the log K values (Table 3); (6) in the presence of ammonium

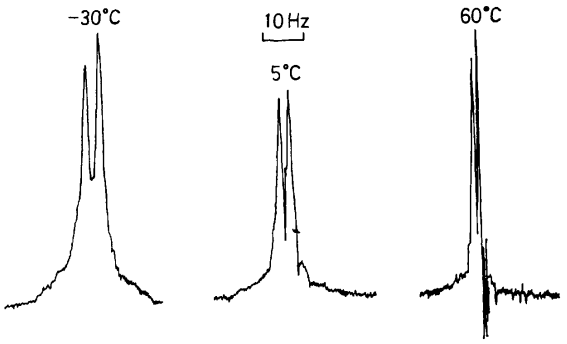

Fig. 2. PMR signals at various temperature of Hexaethylene glycol with KSCN in methanol-d_4.

thiocyanate, small shifts were observed for the higher glycols as well as for the crown ethers(Table 2); (7) the potassium ion caused partial splitting in octaglyme (Table 3, Fig. 1), and (8) the resolved spectrum of heptaethylene glycol in the presence of potassium thiocyanate was identical with that observed in the presence of potassium iodide and showed a tendency to coalesce with the elevation of the temperature (Fig. 2).

Liu[3] also reported the partial splitting for heptaethylene glycol in the presence of potassium iodide. However, the splitting was strangely ascribed to the drastic conformational change which originally exists rather than to that provoked by the interaction with potassium iodide.[19] On the other hand, Reinhoudt *et al.*[8] recently noted the splitting of the PMR signal of the alkali metal ion-crown ether complexes, in which the size of the crown ether cavity is more than sufficient to accommodate the cation. Considering these facts and the similar phenomena caused by some alkaline-earth metal ions (Fig. 6), the splitting of the signals in the presence of metal cations can be ascribed to the strong complexation with the metal cations. Therefore, it can be concluded that, in methanol, the complexation with the sodium ion becomes significant for hexaethylene glycol, while those with potassium, rubidium, or caesium are significant for heptaethylene glycol.

Complexation of PEG and Glymes with Alkaline-earth Metal Cations in Methanol. As expected, calcium, strontium, and barium ions caused appreciable downfield shifts for PEG and glymes, while the magnesium ion did not. In Figs. 3, 4, and 5, their shifts are plotted as a function of the number of oxyethylene units(n).

The calcium ion caused the maximum downfield shift for hexaethylene glycol, which is comparable with that of 15-crown-5. In the cases of hexaglyme and heptaglyme, small shifts were recorded, indicating their

weak interaction. On the other hand, hexaethylene glycol monomethyl ether showed a medium shifts, accompanied by the splitting of the main signal. These facts suggest that the terminal hydroxyl groups play an important role in the complexation with the calcium ion in methanol (Fig. 3).

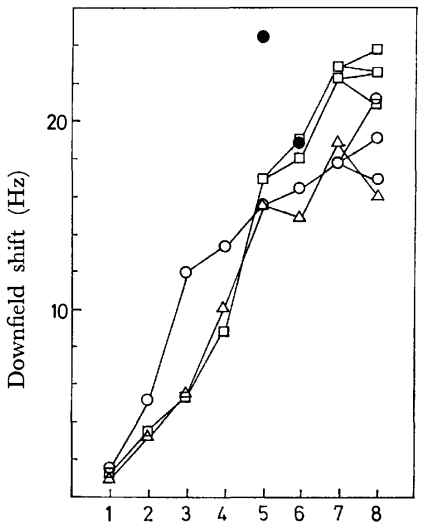

Fig. 5. Barium-ion induced Downfield shifts for the homogeneous poly(oxyethylene) derivatives in D_2O.
●, Oxyethylene protons of the crown ethers; ○, oxyethylene protons of the PEG; □, oxyethylene protons of the glymes; △, methyl protons of the glymes.

In the case of the strontium ion (Fig. 4), the interaction becomes significant above triethylene glycol and the complexing tendency increases remarkably with the number of oxyethylene units. Interestingly, the downfield shifts for hepta- and octaethylene glycols are quite comparable with those for the crown ethers, and their signals are split into two or three peaks respectively (Fig. 6). Heating at 60 °C led to the coalescence of the split signal of heptaethylene glycol with a slight upfield shift. (The difference between the chemical shifts with and without the strontium ion was found to be 21 Hz.) Since it was reported that the splitting due to the conformational change for heptaethylene glycol in a nonpolar solvent does not disappear easily with an increase in the temperature,[19] the easy coalescence supports the cation-induced splitting.

Glymes with more than four oxyethylene units also interact strongly with the strontium ion, and the averaged downfield shifts for hepta- and octaglymes and the shifts for their methyl protons indicate that the heptaglyme attain the optimal interaction. Judging from the differences in the downfield shifts between PEG and glymes, the terminal hydroxyl groups are important to some extent in creating effective interaction with the strontium ion.
