With regard to the barium ion (Fig. 5), the series of PEG and glymes showed quite similar downfield shifts, which turned out to be more than that of 18-crown-6 when they have more than seven oxyethylene units. The main signal of pentaglyme broadened and those of hexaglyme and heptaglyme split into two peaks, while that of heptaethylene glycol resulted in broadening, and that of octaethylene glycol, in three resolved lines(Fig. 6). The rather large shifts and splitting for glymes imply that the terminal hydroxyl groups do not already play a characteristic role in the

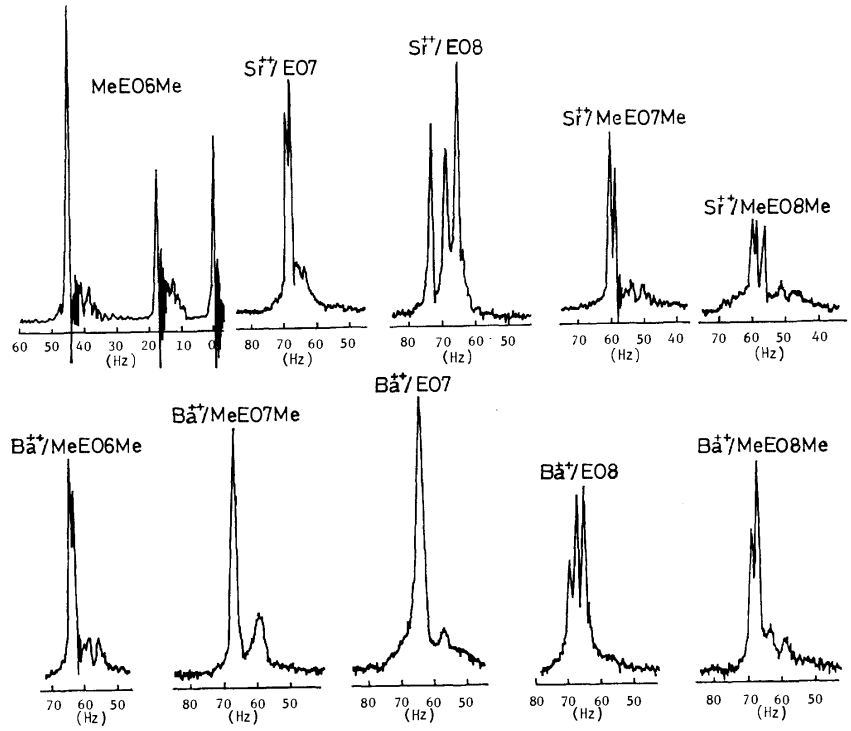

Fig. 6. NMR signals in methanol-d_4 of oxyethylene protons of the homogeneous PEG and glymes in the absence or the presence of alkaline-earth metal cation.

complexation with the barium ion in methanol.

It is interesting to note that one of the three split lines for octaethylene glycol in the presence of the strontium or barium ion was observed upfield (Fig. 6). The eighth oxyethylene unit may not be utilized in complexation, probably because of the crowding in the complexed ion.

Metal-ion Complexation of PEG in Water. Hitherto, no one has succeeded in observing by PMR the metal-ion complexation of acyclic POE derivatives in water.[3] As is shown in Table 1, we found that calcium strontium, and barium ions caused appreciable downfield shifts of the crowns' proton signals even in water, while the potassium ion did not.

In the presence of calcium thiocyanate, hexaethylene glycol, which showed the maximum interaction with the calcium ion in methanol, gave partially resolved peaks in water with a slight downfield shift (Fig. 7). The signal of heptaethylene glycol was shifted 5.6 Hz downfield by the strontium ion(0.12 mol/kg) and 7.9 Hz downfield by the barium ion (0.02 mol/kg). In view of the larger shift by the barium ion, the shifts for a series of polyethylene glycols were determined; they are plotted as a function of the oxyethylene units(n)

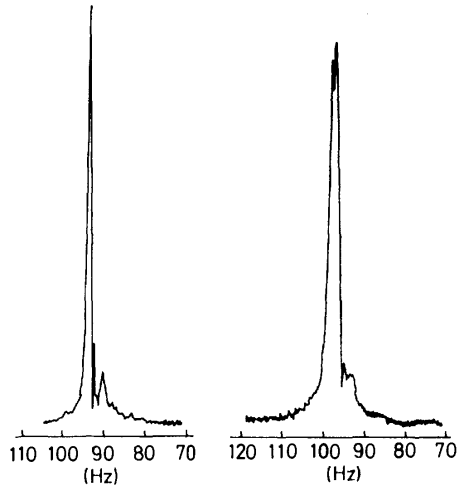

Fig. 7. PMR signals in D_2O of hexaethylene glycol in the absence (the left) and the presence (the right) of calcium thiocyanate.

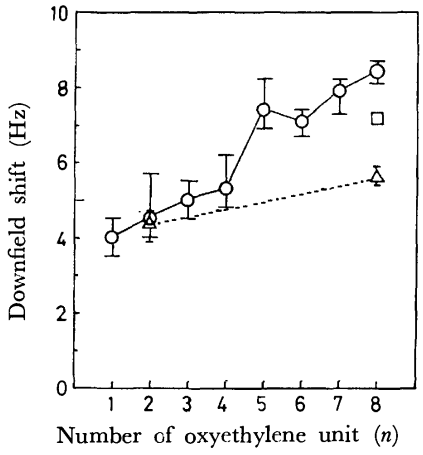

Fig. 8. Barium-ion induced downfield shifts for the homogeneous poly(oxyethylene) derivatives in D_2O. ○, Oxyethylene protons of the PEG; △, oxyethylene protons of the glymes; □, oxyethylene protons of the octaethylene glycol monomethyl ether.

in Fig. 8. The downfield shifts increased rapidly at pentaethylene glycol and then gradually with the increase in the number of oxyethylene units. The shift for monomethyl octaethylene glycol is reduced slightly, but the shift for octaglyme dropped to the extent of that for tetraethylene glycol. It is apparent that the terminal hydroxyl group is important in obtaining a high complexation in water. The smaller downfield shifts for PEG than those for the crown ethers, however, imply that the topology control, *e.g.*, the macrocyclic effect, plays a much more important role in the complexation in water.

Conclusion. It is now clear that polyethylene glycols show a strong ion-dipole binding affinity in methanol, especially toward the potassium, rubidium, caesium, calcium, strontium and barium ions, in spite of the absence of the topology control based on the ionic radius and the cavity size. In addition, there seem to be an optimum number of oxyethylene units in the glycols for a given cation; *e.g.*, the sodium and calcium ions are for six oxyethylene units; the potassium, rubidium, caesium, and strontium ions, for seven oxyethylene units, and the barium ion, for five or seven oxyethylene units.

The conformation of the oxyethylene unit in PEG has recently been clarified to favor the TGT conformation, even in an aqueous medium.[20] Such a conformation is apparently convenient to form stable five-membered ring chelates.[14] The optimal arrangement of the repeating oxyethylene units with the TGT conformation would work cooperatively and would lead to effective complexation with alkali and alkaline-earth cations. In other words, the energetically favorable TGT conformation and entropically favorable[21] oxyethylene chain must be the origins of the chelating ability of POE.

The isolation of some homogeneous PEG–metal cation complexes substantiating the PMR studies will be disclosed in a subsequent paper.

The authors wish to express their thanks to Mrs. Yoko Miyaji for her kind performance of the elaborative PMR measurment. They also wish to acknowledge the generous gift of the tetraethylene glycol used in this work by Mr. Naotsugu Kurata of the Japan Catalytic Chemical Industry, Ltd.

The Kinetics of the Radiation-induced Chain Dechlorination of Hexachloroethane in Alcohols

Takeshi SAWAI, Naoki OHARA, and Toshinari SHIMOKAWA

Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya, Tokyo 158

(Received September 24, 1977)

The kinetics of the radiation-induced dechlorination of hexachloroethane was investigated in deoxygenated alcohol solutions. The major products were hydrogen chloride, pentachloroethane, 1,1,2,2-tetrachloroethane, tetrachloroethylene, and aldehydes or acetone. No 1,1,1,2-tetrachloroethane was observed. The radiation-chemical yields of these products and the disappearance of hexachloroethane were quite high; these facts indicate that a chain reaction is involved in these processes. After the hexachloroethane had effectively dechlorinated down to tetrachloro compounds, there were no marked changes in the lower chlorinated compound upon continuous irradiation. Tetrachloroethane was formed *via* pentachloroethane, but tetrachloroethylene was produced by means of $C_2Cl_5 \rightarrow C_2Cl_4 + Cl$ reaction and the yield was paticularly high in methanol compared with the other alcohols. The chain length of the dechlorination from hexachloroethane to pentachloroethane and from pentachloroethane to tetrachloroethane increased in the order of 2-propanol > ethanol > methanol. The $G(-C_2Cl_6)$ and G(products) were proportional to (dose rate)$^{-1/2}$, and the ratio of $G(C_2HCl_5)$ to $G(C_2Cl_4)$ was a constant in each alcohol solution, regardless of the dose rate. The α-hydroxy alkyl radical is the chain carrier for the dechlorination reaction of hexachloroethane in alcohol solutions. The relative rates of the dechlorination were found to be 1, 3, and 14 for $\dot{C}H_2OH$, $CH_3\dot{C}HOH$, and $(CH_3)_2\dot{C}OH$, respectively. The order in the rate is in agreement with that of the redox potential of these radicals. The effect of the irradiation temperature on the products yields was also examined.

Halocarbons are important for examining the fundamental processes in radiation chemistry because of their high electron affinity, and the main reaction of the radiolysis is dehalogenation.[1] It is known that the radiation-induced chain dehalogenation of some organic halocompounds proceeds in aqueous solutions containing a small amount of alcohol[2,3] and in the solutions of alcohols[4-6] or cyclohexane.[7-11] Sherman *et al.* showed that tetrachloromethane[4] and 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT)[5] were dechlorinated to trichloromethane and 1,1-dichloro-2,2-bis-(*p*-chlorophenyl)ethane (DDE) by a relatively short chain reaction in γ-irradiated 1- and 2-propanol solutions at room temperature. Rajbenbach *et al.* indicated that the chain-dechlorination process was induced by the γ-irradiation of dilute cyclohexane solutions of chloroethanes at temperatures of 25—250 °C.[7-11] The dechlorination yield was not so high at room temperature (for example, $G(HCl) \approx 100$ in 0.1 M hexachloroethane), and a relatively high temperature was required for a high G-value.

On the other hand, it is known that a chain dechlorination reaction took place upon the γ-irradiation of dilute alkaline 2-propanol solutions of alkyl halides,[12] polychlorinated biphenyls[13,14] and of penta and trichlorobenzene[15] at room temperature (for instance, $G(Cl^-) \approx 6500$ in a 0.2 M KOH-2-propanol solution of 0.07 M pentachlorobenzene). These substances were changed to the lower chlorinated compounds, producing potassium chloride and acetone. The chain reaction is probably caused by the $(CH_3)_2\dot{C}O^-$ formed by the reaction of the hydroxide ion with the $(CH_3)_2\dot{C}OH$ radical. On the other hand, no marked chain dechlorination occurred in alkaline methanol and ethanol solutions or in neutral simple aliphatic alcohols.

The purpose of this study is to investigate the kinetics of the radiation-induced chain dechlorination in simple, neutral aliphatic alcohol solutions of hexachloroethane with a half-wave potential lower than tetrachloromethane, DDT, and pentachlorobenzene.

Experimental

Materials. The methanol, ethanol, and 2-propanol (Dojin Chemical's spectrophotometric reagent or super special grade) were used as received. The chloroethanes and tetrachloroethylene used were special reagent grade from the Tokyo Kasei Co., Ltd.

Procedure. Aliquots(4 ml) of freshly prepared alcohol solutions of $1—2 \times 10^{-2}$ M hexachloroethane in a 12-mm OD Pyrex tube equipped with a stopper were irradiated with ^{60}Co γ-rays at room temperature after having been deoxygenated by flushing the solutions for about 30 min with pure nitrogen gas. The dose rate was determined by means of a ferrous sulfate dosimeter, and the absorbed dose in the samples was calculated by correcting for the electron density of the solutions. Irradiation was performed at the dose rate of $5.25 \times 10^{17}—2.80 \times 10^{19}$ eV/g h. The irradiation under a constant temperature was carried out in a water bath with a regulator.

Analysis. The hydrochloric acid was analysed by titration with a 0.02 M sodium hydroxide solution and with a 0.01 M silver nitrate solution. The determination of the other substances was carried out by means of a Shimadzu 4B gas chromatograph equipped with a flame-ionization detector. Chloroethanes (hexa-, penta-, and tetra chloroethane) were determined at 80 °C by the use of a 3-m glass column filled with silicon OV-17 on chromosorb. For tetrachloroethylene and aldehydes, a 2-m glass column packed with polyethylene glycol-200 was used. The acetone was measured at 50 °C by using a 2-m glass column of polyethylene glycol-20M. These substances were quantitatively determined by a comparison of their peak heights with those of authentic samples. A formalin solution(about 37%) was used as a standard for formaldehyde, and the concentration was measured in advance by iodometry. All the products except hydrochloric acid were identified by the use of a gas chromatograph-mass spectrometer(Nihondenshi Model JMS-D100).

Results and Discussion

Yield-dose Curve in Alcohol Solutions of Hexachloroethane. The products identified in the radiolysis of deoxygenated alcohol solutions of hexachloroethane were hydrogen chloride, pentachloroethane(C_2HCl_5), 1,1,2,2-tetrachloroethane($C_2H_2Cl_4$), tetrachloroethylene(C_2Cl_4), and some carbonyl compounds. No 1,1,1,2-tetrachloroethane was observed.

2-Propanol Solution: Figure 1 shows the concentrations of C_2Cl_6, HCl, C_2HCl_5, $C_2H_2Cl_4$, and C_2Cl_4 as functions of the dose. The chloride ion increased with a very high yield up to about 7×10^{17} eV/g, and then showed an almost constant value above 1.5×10^{18} eV/g. The hexachloroethane decreased rapidly with the dose until most of it disappeared at about 3×10^{17} eV/g. On the other hand, the C_2HCl_5 increased with the decrease in C_2Cl_6, and the concentration of C_2HCl_5 was practically comparable to that of the C_2Cl_6 consumption. Further irradiation caused a rapid decrease in C_2HCl_5 and a concomitant increase in $C_2H_2Cl_4$. The concentrations of $C_2H_2Cl_4$ formation and C_2HCl_5 consumption were almost equal in the dose range from 0.58 to 1.8×10^{18} eV/g, and above 2×10^{18} eV/g there were also no marked change in the concentration of $C_2H_2Cl_4$, which was a half of that of the chloride ion and was equal to the initial concentration of C_2Cl_6. Only a tetrachloroethylene was observed in the whole dose region. The radiation-chemical yields(*G*-values) at the dose of 3.42×10^{17} eV/g are calculated to be 2300, 1700, 60, and 2000 for the chloride ion, C_2HCl_5, C_2Cl_4, and, $-C_2Cl_6$ respectively. It was confirmed in other experimental series that the yield of acetone was almost equivalent to that of the chloride ion. These results suggest that C_2Cl_6 in the deoxygenated 2-propanol solution is effectively dechlorinated by a chain reaction to $C_2H_2Cl_4$ via C_2HCl_5, thus forming hydrochloric acid and acetone.

Methanol Solution: The yield-dose plots in methanol solution of C_2Cl_6 are shown in Fig. 2. The concentrations of HCl, $C_2H_2Cl_4$, C_2Cl_4, and formaldehyde increased monotonously with the decrease in C_2Cl_6 up to about 1.3×10^{19} eV/g; on the other hand, C_2HCl_5 decreased very slowly with the dose above $\approx6\times10^{18}$ eV/g. These *G*-values, which were calculated from the linear portions of these curves in Fig. 2, were 540, 110, 200, 290, and 320 for HCl, C_2HCl_5, C_2Cl_4, $-C_2Cl_6$, and formaldehyde.

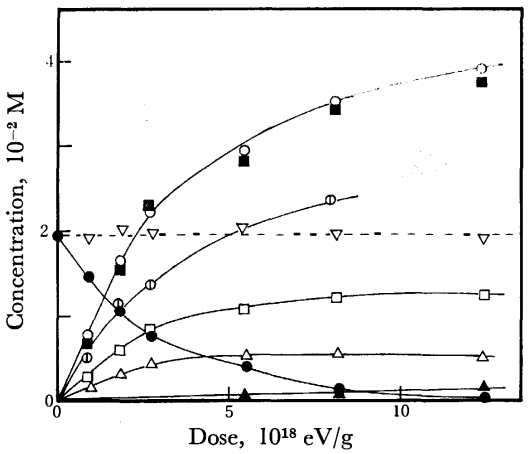

Fig. 2. Product yields as a function of dose from 1.96×10^{-2} M C_2Cl_6 in methanol.
Dose rate, 5.43×10^{18} eV/g h.
○: Cl^-, ■: H^+, ●: C_2Cl_6, △: C_2HCl_5, ▲: $C_2H_2Cl_4$, □: C_2Cl_4, ⓘ: HCHO, ▽: sum of C_2Cl_6, C_2HCl_5, $C_2H_2Cl_4$, and C_2Cl_4.

The largest differences in comparison with the results for 2-propanol solutions are found to be as follows:

a. All the *G*-values in the methanol except $G(C_2Cl_4)$ are much lower than those of 2-propanol.

b. $G(-C_2Cl_6)$ is considerably lower than $G(Cl^-)$ and, on the contrary, is about three times as high as $G(C_2HCl_5)$.

c. $G(C_2Cl_4)$ is two times as high as $G(C_2HCl_5)$.

d. A considerable amount of formaldehyde is produced instead of acetone in the 2-propanol, and the concentration of formaldehyde is remarkably lower than that of the chloride ion.

e. After almost all of the C_2Cl_6 has disappeared (above 8×10^{18} eV/g), the decrease of C_2HCl_5 with the dose is only a little.

The effect of the initial concentration of C_2Cl_6 on the *G*-values is given in Table 1. These values increased with the initial concentration.

Ethanol Solution: The relationship between the concentrations of products and the dose was relatively similar to the result for 2-propanol, as is shown in Fig.

Table 1. Effects of the concentration of C_2Cl_6 in methanol on the *G*-values

C_2Cl_6 10^{-2} M	*G*-value				
	Cl^-	$-C_2Cl_6$	C_2HCl_5	C_2Cl_4	HCHO
0.54	161	90	29	58	93
1.96	542	288	109	218	320
4.91	730	445	147	277	490

Dose rate : 5.43×10^{18} eV/g h.

3. Further irradiation suppressed the C_2HCl_5 completely, and the concentrations of the chloride ion and $C_2H_2Cl_4$ reached an almost constant value. At that time, the concentration of $C_2H_2Cl_4$ was equivalent to the initial C_2Cl_6 concentration and was one half of the chloride ion.

As can be seen in Figs. 1, 2, and 3, the fact that the sums of the concentrations of C_2Cl_6, C_2HCl_5, C_2Cl_4, and $C_2H_2Cl_4$ observed in the irradiated solutions were always correspondent to the initial concentration of C_2Cl_6 indicates that the production of other chlorinated compounds can be ignored.

Dechlorination of C_2HCl_5, $C_2H_2Cl_4$, and C_2Cl_4 in Alcohol Solutions. The results in the methanol and 2-propanol solutions of 1×10^{-2} M C_2HCl_5 are given in Fig. 4. In the 2-propanol, the concentrations of the chloride ion, $-C_2HCl_5$, and acetone were almost equal to $G\approx700$. This fact shows that C_2HCl_5 is also dechlorinated by the chain reaction to form $C_2H_2Cl_4$, the chloride ion, and acetone. On the other hand, the $G(Cl^-)$ in the methanol was merely 24, and no C_2Cl_4 was observed in either solution.

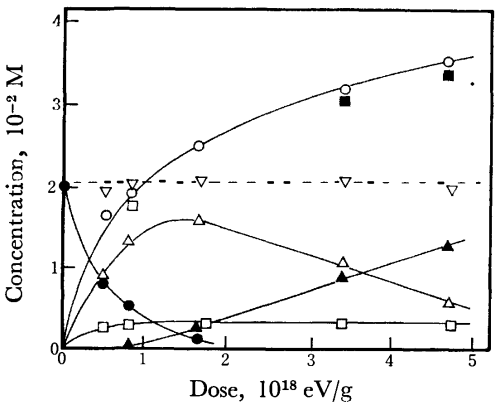

Fig. 3. Product yields as a function of dose from 2.01 $\times10^{-2}$ M C_2Cl_6 in ethanol.
Dose rate, 1.68×10^{18} eV/g h.
○: Cl^-, ■: H^+, ●: C_2Cl_6, △: C_2HCl_5, ▲: $C_2H_2Cl_4$, □: C_2Cl_4, ▽: sum of C_2Cl_6, C_2HCl_5, $C_2H_2Cl_4$, and C_2Cl_4.

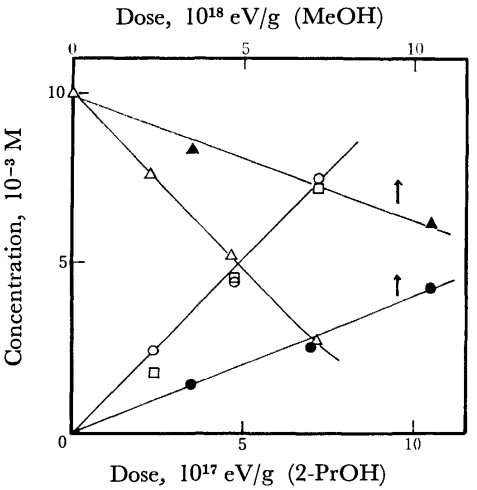

Fig. 4. Product yields as a function of dose from 1.0 $\times10^{-2}$ M C_2HCl_5 in methanol and in 2-propanol.
Dose rate, 5.22×10^{18} eV/g h in methanol (closed symbol), 1.43×10^{18} eV/g h in 2-propanol (open symbol).
○, ●: Cl^-, △, ▲: C_2HCl_5, □: $C_2H_2Cl_4$.

Upon irradiating the solutions of 1×10^{-2} M $C_2H_2Cl_4$ and C_2Cl_4, the hydrochloric acid increased linearly with the dose. The *G*-values in the $C_2H_2Cl_4$ solutions were 4.3, 4.2 (dose rate, 1.1×10^{19} eV/g h), and 3.5 (dose rate, 7.6×10^{18} eV/g h) for 2-propanol, ethanol, and methanol. For C_2Cl_4, these values were 6 in 2-propanol (dose rate, 2.1×10^{19} eV/g h) and 2.2 in methanol (dose rate, 1.1×10^{19} eV/g h). Therefore, it is found that $C_2H_2Cl_4$ and C_2Cl_4 are not dechlorinated by the chain reaction any longer. These findings are in good agreement with the results for C_2Cl_6 solutions presented in Figs. 1, 2, and 3.

$C_2Cl_6=2.0\times10^{-2}$ M, R_1,R_2 : CH_3 or H.

the G-values are summarized in Table 2. All the G-values, except $G(C_2Cl_4)$, decreased with an increase in the dose rate and, at the same dose rate, became lower in the order of 2-propanol, ethanol, and methanol. On the G-values shown in Table 2, the following relations can be seen, within the limits of experimental error;

a. $G(Cl^-)$ equals the sum of $G(-C_2Cl_6)$ and $G(C_2Cl_4)$.

b. $G(-C_2Cl_6)$ is approximately correspondent to $G(R_1R_2CO)$, and also to $G(C_2HCl_5)$ plus $G(C_2Cl_4)$.

c. The ratio of $G(C_2HCl_5)/G(C_2Cl_4)$ is a constant for each solution and decreases in the order of 2-propanol, ethanol, and methanol.

Dechlorination of C_2Cl_6 in Alkaline Solutions of 2-Propanol and Methanol. In the irradiation of deoxygenated alkaline(KOH) alcohol solutions of C_2Cl_6, potassium chloride precipitated much as in the alkaline 2-propanol solutions of polychlorinated biphenyls[13,14] and chlorobenzenes.[15] The yield of the chloride ion increased with the dose, as is shown in Table 3. The initial $G(Cl^-)$s were $\gtrsim$13000 and $\gtrsim$1900 for the 2-propanol and methanol respectively. These values are found to be considerably higher than those of the neutral solutions at the same dose rate in Table 2. Moreover, in the neutral solutions, the percentage of the dechlorination did not exceed 33% within this dose range, but in the alkaline solutions it did so at a relatively low dose and the chloride ion was still produced with a fairly high yield. Thus, the $G(Cl^-)$s were calculated to be 230 and 50 at the doses between 0.90 and 4.5×10^{18} eV/g in the 2-propanol, and between 2.6 and 19.2×10^{18} eV/g in the methanol respectively. The product analysis by gas chromatography was not carried out, but these high G-values indicate that C_2Cl_6 may be more dechlorinated by the chain reaction to the lower chlorinated compound than to tetrachloro compound in the alkaline solutions.

Dechlorination Reaction of Chloroethanes in Alcohols. The hexachloroethane in the solutions of methanol, ethanol, and 2-propanol was dechlorinated to form hydrochloric acid, C_2HCl_5, C_2Cl_4, and aldehydes or acetone. These high G-values (see Table 2) show that all the products are produced by a chain-reaction mechanism. Sherman *et al.* proposed the following radical chain reaction for the dechlorinations of tetrachloromethane[4] and DDT[5] to trichloromethane and DDE in the 2-propanol solutions:

Initiation

$$(CH_3)_2CHOH \xrightarrow{\sim\sim} X \text{ (radicals, } e^-_{solv.}) \quad (1)$$

$$X + RCl_n \longrightarrow XCl + \dot{R}Cl_{n-1} \quad (2)$$

(where RCl_n is CCl_4 or DDT)

Propagation

$$\dot{R}Cl_{n-1} + (CH_3)_2CHOH \longrightarrow RCl_{n-1}H + (CH_3)_2\dot{C}OH \quad (3)$$

$$(CH_3)_2\dot{C}OH + RCl_n \longrightarrow (CH_3)_2CO + HCl + \dot{R}Cl_{n-1} \quad (4)$$

If the chain dechlorination of C_2Cl_6 in the alcohol solutions follows the above mechanisms, the $G(HCl)$ should be in agreement with $G(-C_2Cl_6)$, $G(C_2HCl_5)$, and $G(R_1R_2CO)$; moreover, C_2Cl_4 should not be found as a product. On the other hand, the results in Table 2 do not apparently support the above findings because of the large discrepancy among G-values, especially in the methanol, and also the formation of a considerable amonut of C_2Cl_4. Therefore, some additional reaction may be required for the direct formation of C_2Cl_4 from C_2Cl_6, since C_2Cl_4 was observed immediately after irradiation (Figs. 1, 2, and 3) and was not formed from C_2HCl_5 (Fig. 4).

Horowitz *et al.* showed that HCl, C_2HCl_5, monochlorocyclohexane, and C_2Cl_4 were produced in high yields by the γ-radiolysis of C_2Cl_6 in cyclohexane at 24—100 °C; for example, $G(HCl)$ and $G(C_2Cl_4)$ reached to $\approx$4000 in a 0.1 M C_2Cl_6 solution at 100 °C. They suggested that these high G-values arose from sequence of reactions:[7]

$$2\,c\text{-}C_6H_{12} \xrightarrow{\sim\sim} 2\,c\text{-}\dot{C}_6H_{11} + H_2 \quad (5)$$

$$c\text{-}\dot{C}_6H_{11} + C_2Cl_6 \longrightarrow c\text{-}C_6H_{11}Cl + \dot{C}_2Cl_5 \quad (6)$$

$$\dot{C}_2Cl_5 + c\text{-}C_6H_{12} \longrightarrow C_2HCl_5 + c\text{-}\dot{C}_6H_{11} \quad (7)$$

$$\dot{C}_2Cl_5 \longrightarrow C_2Cl_4 + Cl \quad (8)$$

$$Cl + c\text{-}C_6H_{12} \longrightarrow HCl + c\text{-}\dot{C}_6H_{11} \quad (9)$$

Assuming that C_2Cl_4 is formed by Reaction 8 in the alcohol solutions, the following correlation can be expected to hold for the G-values in Table 2 on the bases of Reactions 1, 2, 3, 4, 8, and 9′:

$$Cl + R_1R_2CHOH \longrightarrow HCl + R_1R_2\dot{C}OH \quad (9')$$

a. $G(HCl)$ equals the sum of $G(-C_2Cl_6)$ and $G(C_2Cl_4)$.

b. $G(-C_2Cl_6)$ is equal to the sum of $G(C_2HCl_5)$ and $G(C_2Cl_4)$, and also to $G((CH_3)_2CO)$ or $G(HCHO)$. As can be seen in Tables 1 and 2, the above correlations

Table 3. The chloride-ion yield as a function of the dose in 0.2 M KOH alkaline solutions of 2.0×10^{-2} M C_2Cl_6

Solution	Dose 10^{18} eV/g						
	0.10	0.90	1.75	2.60	4.25	7.70	19.2
2-Propanol	3.1	4.1			5.4		
Methanol		2.7	3.8	4.1		4.5	5.4

Cl^- yield : $\times10^{-2}$ M,
Dose rate : 8.35×10^{17} eV/g h in 2-propanol
5.22×10^{18} eV/g h in methanol.

hold within the limits of experimental error. Therefore, the chain-dechlorination reaction of C_2Cl_6 in alcohol solutions can be described as follows:

Initiation

$$R_1R_2CHOH \rightsquigarrow X,\ e^-_{solv.} \quad (10)$$

(where R_1 and R_2 are CH_3 or H)

$$X + R_1R_2CHOH \longrightarrow XH + R_1R_2\dot{C}OH \quad (11)$$

$$e^-_{solv.} + C_2Cl_6 \longrightarrow \dot{C}_2Cl_5 + Cl^- \quad (12)$$

Propagation

$$R_1R_2\dot{C}OH + C_2Cl_6 \longrightarrow R_1R_2CO + \dot{C}_2Cl_5 + HCl \quad (13)$$

$$\dot{C}_2Cl_5 + R_1R_2CHOH \longrightarrow C_2HCl_5 + R_1R_2\dot{C}OH \quad (14)$$

$$\dot{C}_2Cl_5 \longrightarrow C_2Cl_4 + Cl \quad (15)$$

$$Cl + R_1R_2CHOH \longrightarrow HCl + R_1R_2\dot{C}OH \quad (16)$$

The steady-state treatment for Reactions 14 and 15 leads to the following expression:

$$G(C_2HCl_5) = k_{14}[R_1R_2CHOH]/k_{15} \times G(C_2Cl_4) \quad (I)$$

Thus, $G(C_2HCl_5)$ should be proportional to $G(C_2Cl_4)$. The relationship between the two G-values is given in Fig. 5 for the methanol, ethanol, and 2-propanol solutions. From the slopes in Fig. 5, k_{14}/k_{15} is obtained as 0.02, 0.59, and 3.1 for methanol, ethanol, and 2-propanol respectively. These results show that Reaction 14 is more predominant in the 2-propanol than in the methanol. Thus, the ratio of $G(C_2Cl_4)$ to $G(C_2HCl_5)$ was very low in the former solution, but, on the contrary, was quite high in the latter solution. The values of k_{14}/k_{15} show that hydrogen abstraction from 2-propanol by the C_2Cl_5 radical is much faster than that from methanol and ethanol. The order of the hydrogen abstraction from alcohols is in agreement with that by the CF_3,[3] OH,[16] and H[17] radicals.

If the termination of the chain involves a reaction between two alcohol radicals ($2k_{17}=1-3\times10^9$ M^{-1} s^{-1}):[18-23]

$$2\,R_1R_2\dot{C}OH \begin{cases} \longrightarrow R_1R_2CHOH + R_1R_2CO & (17a) \\ \longrightarrow R_1R_2COH \\ \quad\quad\quad R_1R_2COH & (17b) \end{cases}$$

the G-values shown in Table 2 are given by following expressions under steady irradiation:

$$G(-C_2Cl_6) = G(\dot{C}_2Cl_5) = G(X) + 10k_{13}[C_2Cl_6](G(X)/k_{17}I)^{1/2} \quad (II)$$

$$G(C_2HCl_5) = G(\dot{C}_2Cl_5)k_{14}[R_1R_2CHOH]/k_{15} \quad (III)$$

$$G(C_2Cl_4) = G(\dot{C}_2Cl_5)k_{15}/k_{14}[R_1R_2CHOH] \quad (IV)$$

$$G(HCl) = G(-C_2Cl_6) + G(C_2Cl_4) = G(\dot{C}_2Cl_5)(1+k_{15}/k_{14}[R_1R_2CHOH]) \quad (V)$$

where I is the dose rate.

It is known that the ratio of the combination reaction 17b to the disproportionation 17a depends on the nature of the R_1R_2COH radical. For the CH_2OH radical, the ratio of 17b to 17a is 10; in contrast, $(CH_3)_2\dot{C}OH$ more probable results in acetone.[24] Assuming that the production of acetone by Reaction 17a can be neglected in comparison with that by Reaction 13, $G((CH_3)_2CO)$ can be also expressed by Equation II. The predicated linear dependence of the G-values on $I^{-1/2}$ is in agreement with the experimental data (Figs. 6 and 7). From the slopes of $G(-C_2Cl_6)$ *vs.* $I^{-1/2}$, the ratio of k_{13} for methanol, ethanol, and 2-propanol is obtained to be 1 : 3 : 14 by using $2k_{17}=2.7\times10^9$,[22] 2.0×10^9,[19] and 1.4×10^9 M^{-1} s^{-1} [20] for $\dot{C}H_2OH$, $CH_3\dot{C}HOH$, and $(CH_3)_2\dot{C}OH$, respectively.

It is very interesting that the dechlorination yield is dependent on the kinds of chloroethanes and solvents. Sherman showed that the following charge-transfer process seems most likely to be involved in the dechlorination of CCl_4:[4]

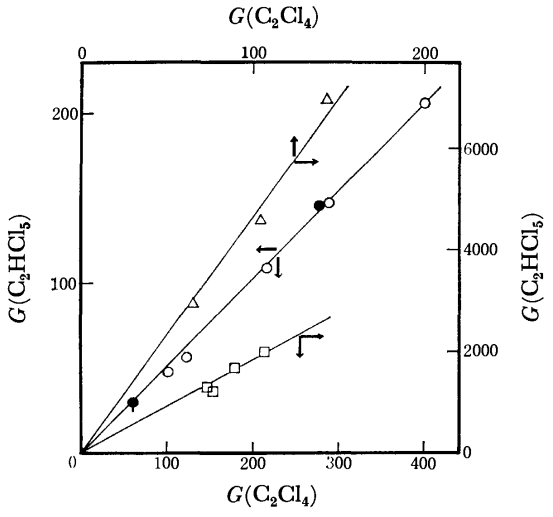

Fig. 5. $G(C_2HCl_5)$ as a function of $G(C_2Cl_4)$ in the solutions of 2.0×10^{-2} M C_2Cl_6.

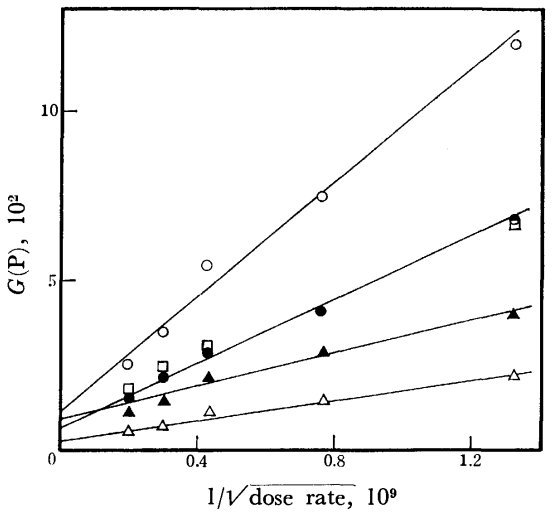

Fig. 7. G-values as a function of (dose rate)$^{-1/2}$ from 2×10^{-2} M C_2Cl_6 in methanol.
○: Cl^-, ●: $-C_2Cl_6$, △: C_2HCl_5, ▲: C_2Cl_4, □: HCHO.

$$(CH_3)_2\dot{C}OH + CCl_4 \longrightarrow (CH_3)_2C{=}OH^+ + \dot{C}Cl_3 + Cl$$

$$(CH_3)_2C{=}OH^+ + \text{solvent} \longrightarrow (CH_3)_2CO + H^+$$

In the investigation of the dehalogenation of aliphatic halogen compounds, such as bromoacetic acid, by an aliphatic free radical in aqueous solutions, Andar *et al.* also indicated that the dehalogenation was due to a charge-transfer mechanism rather than halogen abstraction and that the reactivity of charge-transfer followed the sequence of $(CH_3)_2\dot{C}OH > CH_3\dot{C}HOH > \dot{C}H_2OH$ for simple aliphatic alcohol radicals. For instance, the $G(Br^-)$s were 9.5, 61, and >350 for methanol, ethanol, and 2-propanol in the aqueous solutions of 1×10^{-3} M bromoacetic acid containing 5M alcohol. The reactivity of halogen compounds toward the radical, on the other hand, increased in this order: $ClCH_2COOH < BrCH_2COOH < CBr_3COOH$.[2]

It is also known that the α-hydroxy alkyl radical acts as a reducing agent.[25] The $RH+A\rightarrow R+A^-+H^+$ reaction occurs at an appreciable rate whenever the redox potential (E) of A(acceptor molecule) is lower than that of RH(donor radical), and the electron-transfer reaction is dependent on the difference of the E between RH and A.[26] In our case, A and RH correspond to C_2Cl_6 and $R_1R_2\dot{C}OH$. The redox potential is generally proportional to the half-wave potential ($E_{1/2}$) of polarography($E=E_{1/2}+0.244$).[26] The values for C_2Cl_6, $\dot{C}H_2OH$, $CH_3\dot{C}HOH$, and $(CH_3)_2\dot{C}OH$ are known to be −0.66,[27] −0.98, −1.18, and −1.30 V.[28] Therefore, the dechlorination of C_2Cl_6 occurs significantly in all solutions; therefore, the finding that $G(-C_2Cl_6)$ was highest in the 2-propanol is reasonable.

It is clear that $C_2H_2Cl_4$ is formed by the dechlorination of C_2HCl_5 from the change in the concentrations of the chloride ion, C_2HCl_5, and $C_2H_2Cl_4$ after consuming C_2Cl_6 (Figs. 1 and 3), and from the correlation of $G(Cl^-)=G(-C_2HCl_5)=G(C_2H_2Cl_4)$(Fig. 4). The G-value of $-C_2HCl_5$ was about 600 in the 2-propanol and 24 in the methanol(Fig. 4). For the ethanol, a mean G-value between the 2-propanol and methanol should be obtainable by judging from the decrease in C_2HCl_5 shown in Fig. 3. The chain dechlorination of C_2HCl_5 in alcohol solutions seems to proceed in the same way as the reaction of C_2Cl_6. The large difference in $G(-C_2HCl_5)$ for the 2-propanol and the methanol may be due to the difference in their redox potentials between C_2HCl_5 and $R_1R_2\dot{C}OH$. On the other hand, C_2Cl_4 and $C_2H_2Cl_4$ were not dechlorinated by the chain reaction any longer. This is because their half-wave potentials are apparently higher than those of $R_1R_2\dot{C}OH$ ($C_2Cl_4\approx-1.8$ V, $C_2H_2Cl_4\approx-2$ V).[27]

On the other hand, it is known that the α-hydroxy alkyl radical behaves as either an acid or a base[28] and that the half-wave potentials in the basic form are ≈-1.8 and −2.2 V for $\dot{C}H_2O^-$ and $(CH_3)_2\dot{C}O^-$.[25,29]

$$R_1R_2\dot{C}OH \rightleftharpoons R_1R_2\dot{C}O^- + H^+ \qquad (pK\approx12)$$

In this case, the potentials in the basic form are apparently higher than those in the basic form; moreover, the potentials of $(CH_3)_2\dot{C}O^-$ and $\dot{C}H_2OH$ are higher than, or almost equal to, those of $C_2H_2Cl_4$ and C_2Cl_4. Therefore, in the alkaline alcohols, the initial $G(Cl^-)$ was higher than that in the neutral solutions; C_2Cl_6 might thus be more easily dechlorinated to the lower chlorinated compound than the tetrachloro compound.

Effect of Temperature on the Product Yields. The yields of products are shown in Table 4 upon irradiating $1.6-1.7\times10^{-2}$ M C_2Cl_6 in solutions of methanol and

Table 4. Effect of the temperature on the product yields

Solution	Temp (°C)	Concentration, 10^{-2} M								
		Cl^-	$-C_2Cl_6(a)$	$C_2HCl_5(b)$	$C_2Cl_4(c)$	$C_2H_2Cl_4(d)$	Σ	b/c	$a+c$	$b+c$
Methanol	0	0.70	0.45	0.21	0.18	0	1.54	1.2	0.63	0.39
	25	1.84	1.01	0.34	0.66	0.01	1.60	0.52	1.67	1.0

2-Propanol	0	2.29	1.69	1.38	0.05	0.31	1.75		2.05[a]	1.74[b]
	25	2.86	1.70	0.66	0.09	1.03	1.78		2.82[a]	1.75[b]
	50	3.40	1.70	0.04	0.18	1.59	1.81		3.47[a]	1.81[b]

Methanol : 1.6×10^{-2} M C_2Cl_6, 1.6×10^{18} eV/g,
2-propanol : 1.7×10^{-2} M C_2Cl_6, 0.8×10^{18} eV/g,
Σ, a) $a+c+d$, b) $b+c+d$.

2-propanol at 0, 25, and 50° C. The chloride ion increased with the temperature, and the total concentration of chlorocompounds observed in the irradiated solutions was a constant(=the initial concentration of C_2Cl_6) in both the solutions.

In the methanol, the concentrations of the chloride ion and $-C_2Cl_6$ were correspondent to those of $-C_2Cl_6$ plus C_2Cl_4, and C_2HCl_5 plus C_2Cl_4, respectively at each temperature. On the other hand, in the 2-propanol, the above correlations were not found because almost all of the C_2Cl_6 disappeared, to be followed by the formation of a considerable amount of $C_2H_2Cl_4$. However, taking into consideration the fact that all the $C_2H_2Cl_4$ was produced from C_2HCl_5, the sum of $-C_2Cl_6$ C_2Cl_4, and $C_2H_2Cl_4$ equals the concentration of the chloride ion(last column in Table 4). Therefore, the dechlorination reaction is likely to be the same at temperatures of 0—50 °C. The decrease in the ratio of C_2HCl_5 to C_2Cl_4 in the methanol with the temperature may be caused by the fact that Reaction 14 was much more promoted than Reaction 15 at high temperatures.

The authors are indebted to Dr. Kinji Anda and Mr. Masao Usui, Tokyo Metropolitan Industrial Technic Institute, for making available their gas chromatograph-mass spectrometer.

Conductometric Studies on the Ion-pair Formations of $[Cr(NH_3)_6]^{3+}$, $[Co(NH_3)_6]^{3+}$, $[Cr(en)_3]^{3+}$, and $[Co(en)_3]^{3+}$ with Several Anions in Aqueous Solutions

Tatsuo Takahashi and Takefumi Koiso

Department of Chemistry, Fukushima Technical College, Iwaki 970

(Received September 24, 1977)

The thermodynamic ion-association constants (K) of $[Cr(NH_3)_6]^{3+}$, $[Co(NH_3)_6]^{3+}$, $[Cr(en)_3]^{3+}$, and $[Co(en)_3]^{3+}$ with several anions in aqueous solutions were determined using the conductometric method. The log K values obtained at 25.0 °C are 1.1_7 for $[Cr(NH_3)_6]^{3+}$–SCN^-, 1.3_4 for $[Cr(en)_3]^{3+}$–SCN^-, 1.3_0 for $[Co(NH_3)_6]^{3+}$–SCN^-, 1.3_4 for $[Co(en)_3]^{3+}$–SCN^-, 1.6_8 for $[Co(en)_3]^{3+}$–Br^-, 1.4_6 for $[Co(en)_3]^{3+}$–I^-, 1.3_7 for $[Co(en)_3]^{3+}$–ClO_4^-, 3.2_0 for $[Cr(NH_3)_6]^{3+}$–$C_2O_4^{2-}$, and 2.9_7 for $[Cr(en)_3]^{3+}$–$C_2O_4^{2-}$. The results indicate that the SCN^- ion has less of a tendency to associate with the complex cations than do other univalent anions, the K values of SCN^- being of the same order of magnitude as those of ClO_4^-, and that the K values of chromium(III) complex cations with several anions are slightly smaller than those of the corresponding cobalt(III) complex cations.

In order to clarify the factors that influence the extent to which ions associate in aqueous solutions, the ion-association constants of ion-pairs have been determined by various researchers[1–10] using various methods. In previous papers,[11,12] Takahashi *et al.* have reported that the ion-association constants determined using the conductometric and spectrophotometric methods were not very different from each other, and that the electrostatic interaction between ions is the dominant influence.

Also, it was found that the internal conjugate base (ICB) effect[13] should be considered in ion-pair formation.

In the present paper, conductometric studies of the ion-pairs, $[Co(en)_3]^{3+}$–X^- (X=SCN, Br, I, ClO_4), $[Cr(NH_3)_6]^{3+}$–SCN^-, $[Cr(en)_3]^{3+}$–SCN^-, $[Co(NH_3)_6]^{3+}$–SCN^-, $[Cr(NH_3)_6]^{3+}$–$C_2O_4^{2-}$, and $[Cr(en)_3]^{3+}$–$C_2O_4^{2-}$ are presented. Some factors are briefly discussed from the viewpoint given in previous papers.[11,12]

Experimental

The compounds used in this study were prepared according to procedures described in the literature. Each compound was carefully purified by triple recrystallization from redistilled water. The purity was examined using conventional chemical analysis of the components; the results are in very good agreement with the theoretical values. Solutions of different concentrations were carefully prepared using conductivity water having an electrolytic conductivity lower than 4×10^{-7} S cm^{-1}. The electrolytic conductivities were measured with the same apparatus and using the same procedures previously described.[11,12]

Results and Discussion

The relations between the molar conductivities, Λ, of the complexes and the ionic strength (I) are shown in Figs. 1—3; the broken lines indicate the theoretical Onsager lines for the fully ionized electrolyte. The molar conductivities of the oxalates shown in Fig. 3 have large deviations, indicating that there is strong ion-association between $[Cr(NH_3)_6]^{3+}$ or $[Cr(en)_3]^{3+}$ and $C_2O_4^{2-}$.

Table 1 presents the limiting molar conductivity, $\Lambda°$, of each complex determined by the Onsager extrapolation method,[14] and also the limiting molar conductivity, $\lambda°$, of each complex cation calculated from the $\Lambda°$ value. However, the $\Lambda°$ (1/6 M_2 $(C_2O_4)_3$) was assumed to be equal to the sum of the $\lambda°$ (1/3 M^{3+}) value for the corresponding complex cation obtained in this study and in previous studies[11,12] and the value (74.2 S cm^2 mol^{-1}) for $\lambda°$ (1/2 $C_2O_4^{2-}$), because the Onsager method was not considered to be appropriate for higher-valent electrolytes; the $\Lambda°$ (1/6 $[Cr(NH_3)_6]_2(C_2O_4)_3\cdot5H_2O$) and $\Lambda°([Cr(en)_3]_2(C_2O_4)_3)$ values thus estimated are 172.6 and 147.8 S cm^2 mol^{-1}, respectively.* The so-called Stokes radii, r_s, of these complex cations

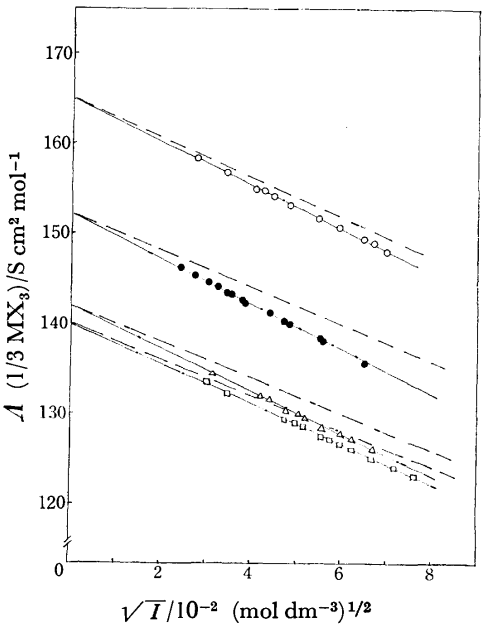

Fig. 1. The Onsager plots of hexaamminechromium(III) thiocyanate (-○-), tris(ethylenediamine)cobalt(III) iodide (-●-), tris(ethylenediamine)cobalt(III) perchlorate (-△-), and tris(ethylenediamine)-chromium(III) thiocyanate (-□-) in aqueous solutions at 25.0 °C.

* When Onsager's method for determining the $\Lambda°$ values is applied to the conductivities of the oxalates, the approximate $\Lambda°(1/6[Cr(NH_3)_6]_2(C_2O_4)_3\cdot5H_2O)$ and $\Lambda°(1/6[Cr(en)_3]_2(C_2O_4)_3$ values are 173 and 148 S cm^2 mol^{-1}, respectively.

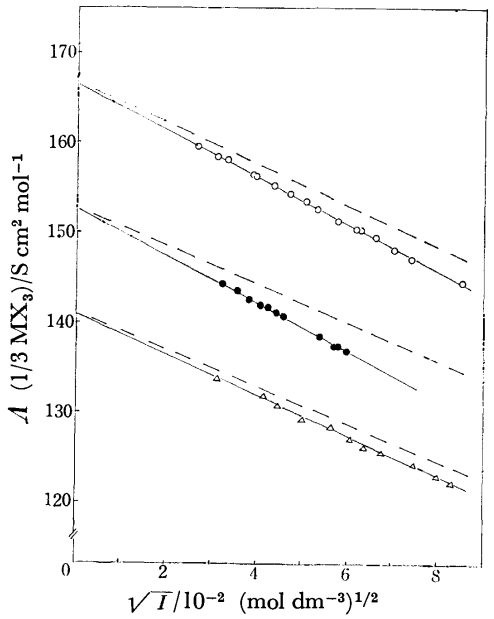

Fig. 2. The Onsager plots of hexaamminecobalt(III) thiocyanate (-○-), tris(ethylenediamine)cobalt(III) bromide (-●-), and tris(ethylenediamine)cobalt(III) thiocyanate (-△-) in aqueous solutions at 25.0 °C.

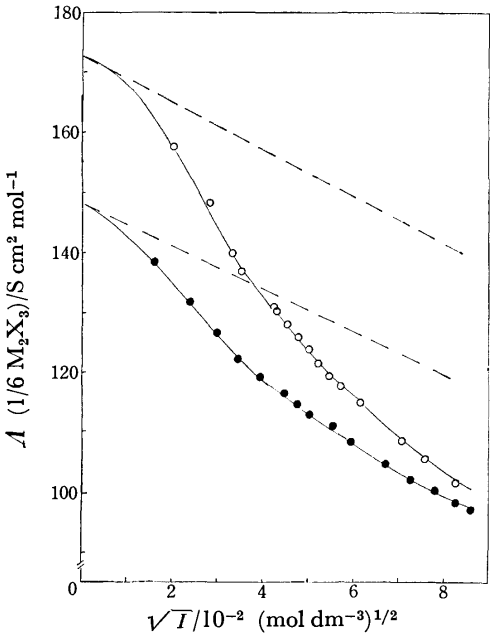

Fig. 3. The Onsager plots of hexaamminechromium(III) oxalate (-○-) and tris(ethylenediamine)chromium(III) oxalate (-●-) in aqueous solutions at 25.0 °C.

determined from the conductivity data of this study are summarized in Table 2, in which the results reported previously are also presented. The degrees of dissociation of the possible ion-pairs were determined according to the successive approximation method described by Jenkins and Monk[1] and, then, the thermodynamic ion-association constants, K, were calculated from both the degree of dissociation obtained and the activity coefficients of the ions as estimated from the Debye-Hückel limiting equation. In the present calculation, the limiting conductivities of the ion-pairs

was estimated from the relations,

$$\frac{\lambda^\circ(1/2M^{3+}X^-)}{\lambda^\circ(1/3M^{3+})} = \frac{2}{3}$$

and

$$\frac{\lambda^\circ(M^{3+}C_2O_4^{2-})}{\lambda^\circ(1/3M^{3+})} = \frac{1}{3}.$$

The results are given in Table 3, together with those which have been determined by various researchers using various methods.

If the closest approach of the two ions of the ion-pair is assumed to be equal to the sum of their Stokes radii, the K value can be estimated from the Bjerrum theory.[15] Table 4 shows the log K values calculated theoretically.

On the basis of the results given in Table 3, it appears reasonable to conclude that the K values of chromium(III) complex cations with several anions are a little smaller than those of the corresponding cobalt(III) complex cations. A similar conclusion has been drawn in previous studies.[11,12] Although the detailed comparison of the K values obtained using the same method on a given ion-pair was limited, it was also likely that the K values for $[M(NH_3)_6]^{3+}$ (M=Cr, Co) with such ions as ClO_4^-, NO_3^-, $C_2O_4^{2-}$, and SO_4^{2-} are a little larger than those for $[M(en)_3]^{3+}$ with the respective anions. Since the Stokes radii of $[M(en)_3]^{3+}$ are larger

than that of $[M(NH_3)_6]^{3+}$, this view is to be expected so far as the ion-association is assumed to depend only on Coulombic interaction between the ions. Therefore, it appears appropriate to state that the electrostatic interaction between ions is the dominant influence among various factors in the process of ion-pair formation of the complex cation with oxoacid anions, such as ClO_4^-, NO_3^-, $C_2O_4^{2-}$, and SO_4^{2-}. Furthermore, Table 2 also indicates that the K values of the complex cations with SCN^- are smaller than those with other univalent anions, except for ClO_4^-. That is, the extent of association is about the same in the perchlorate and thiocyanate systems. The smaller tendency of the complex cations to associate with SCN^- is probably due to the fact that the SCN^- is not only of low charge and large size, but also that it is a linear ion. Thus, the SCN^- ion may possess rotational entropy which would be lost on ion-association.[16]

N,N-Disubstituted 1,3-Dithiolan-2-iminium–TCNQ^{-} Salts: Effect of the Substituents on the Nitrogen Atom on the Composition and the Electrical Conductivity

Shingo Araki and Toshio Tanaka

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received September 27, 1977)

Following 10 simple and complex salts of TCNQ^{-} with *N,N*-disubstituted 1,3-dithiolan-2-iminium cations; $(CH_2)_2\langle S \rangle C{=}\overset{+}{N}R^1R^2 \cdot (TCNQ)_n^{-}$ (n=1 when R^1=R^2=*n*-Pr, *n*-C_6H_{13}, *n*-C_8H_{17}, Ph, and R^1=Me and R^2=Ph; n=2 when R^1= R^2=*n*-Pr, *n*-Bu, Ph, and R^1=Me and R^2=Ph), and $[(CH_2)_2\langle S \rangle C{=}\overset{+}{N}(n\text{-}C_{10}H_{21})_2]_2 \cdot (TCNQ)_3^{2-}$ were prepared. Of these, simple salt $(CH_2)_2\langle S \rangle C{=}\overset{+}{N}(n\text{-}C_8H_{17})_2 \cdot TCNQ^{-}$ was obtained in two different crystalline forms; unstable violet needles and green plates. All the salts as compacted samples displayed semi-conducting behaviors in the 20—90 °C range. Electrical resistivities of the 1:2 complex salts fell in the range of 5—90 ohm cm at 25 °C, while the simple and 2:3 complex salts showed much large resistivities (the order of 10^3—10^9 ohm cm). The measurements of electronic absorption spectra and magnetic susceptibilities indicated that the simple salts in the solid state involve dimeric $(TCNQ)_2^{2-}$, except for the green salt of $(CH_2)_2\langle S \rangle C{=}\overset{+}{N}(n\text{-}C_8H_{17})_2 \cdot TCNQ^{-}$ which consists of the iminium cation and discrete TCNQ^{-} radical anion. Electronic spectra of the 1 : 2 and 2 : 3 complex salts also are discussed in comparison with analogous TCNQ^{-} salts reported so far.

In the previous paper,[1] we reported the preparation and electrical resistivity of some simple and complex salts formed between *N,N*-dialkyl-1,3-dichalcogenacycloalkan-2-iminium cations and 7,7,8,8-tetracyanoquinodimethane (TCNQ) radical anion; $(CH_2)_n\langle Y \rangle C{=}\overset{+}{N}R_2 \cdot TCNQ^{-}$ and $(CH_2)_n\langle Y \rangle C{=}\overset{+}{N}R_2 \cdot (TCNQ)_2^{-}$ (n=2, 3; Y=S, Se; R=Me, Et; but not all combinations). The resistivities of the simple salts as compacted samples fell in the 10^4—10^5 ohm cm range at 25 °C with the activation energies of 0.27—0.37 eV. The complex salts (compacted samples) exhibited the resistivities of 2.4 to 4.0 ohm cm with very small activation energies (0.018—0.087 eV); there was no appreciable difference of the resistivity between the *N,N*-dimethyl- and *N,N*-diethyliminium–$(TCNQ)_2^{-}$.

The present work was undertaken to study the effect of the *N*-substituents of the iminium cations on the composition and electrical resistivity of the TCNQ^{-} salts. This paper reports the preparation and electrical resistivity of a series of simple and complex salts of TCNQ^{-} radical anion with *N,N*-disubstituted 1,3-dithiolan-2-iminium cations, $(CH_2)_2\langle S \rangle C{=}\overset{+}{N}R^1R^2$ (R^1=R^2=*n*-Pr, *n*-Bu, *n*-C_6H_{13}, *n*-C_8H_{17}, *n*-$C_{10}H_{21}$, Ph, and R^1=Me and R^2=Ph). The resistivity is discussed in terms of stacking of TCNQ^{-} on the basis of electronic absorption spectra and magnetic susceptibilities in the solid state.

Experimental

Materials. Bis(*N,N*-disubstituted 1,3-dithiolan-2-iminium) tetrabromodimethylstannate(IV), $[(CH_2)_2\langle S \rangle C{=}\overset{+}{N}R_2]_2 \cdot [SnBr_4Me_2]^{2-}$, was synthesized by reaction of bis(*N,N*-disubstituted dithiocarbamato)dimethyltin(IV), $Me_2Sn(S_2CNR_2)_2$, with 1,2-dibromoethane by a manner similar to the *N,N*-dimethyliminium analog.[2] R=*n*-Pr, mp 143.5—145.5 °C. Found: C, 27.28; H, 4.73; N, 3.32%. Calcd for $C_{20}H_{42}N_2S_4Br_4Sn$: C, 27.38; H, 4.84; N, 3.19%. R=*n*-Bu, mp 121—122.5 °C. Found: C, 30.74; H, 5.38; N, 3.02%. Calcd for $C_{24}H_{50}N_2S_4Br_4Sn$: C, 30.88; H, 5.41; N, 3.00%. R=*n*-C_6H_{13}, mp 86—87 °C. Found: C, 36.54; H, 6.28; N, 2.78%. Calcd for $C_{32}H_{66}N_2S_4Br_4Sn$: C, 36.76; H, 6.38; N, 2.68%. R=*n*-C_8H_{17}, mp 86—88 °C. Found: C, 41.31; H, 7.10; N, 2.48%. Calcd for $C_{40}H_{82}N_2S_4Br_4Sn$: C, 41.49; H, 7.15; N, 2.42%. R=*n*-$C_{10}H_{21}$, mp 88—91 °C. Found: C, 45.07; H, 7.79; N, 2.24%. Calcd for $C_{48}H_{98}N_2S_4Br_4Sn$: C, 45.39; H, 7.79; N, 2.21%. R=Ph, mp 153—157 °C. Found: C, 37.47; H, 3.37; N, 2.74%. Calcd for $C_{32}H_{34}N_2S_4Br_4Sn$: C, 37.93; H, 3.39; N, 2.77%.

N-Methyl-*N*-phenyl-1,3-dithiolan-2-iminium trichlorodimethyl-stannate(IV), $(CH_2)_2\langle S \rangle C{=}\overset{+}{N}MePh \cdot [SnCl_3Me_2]^{-}$,[2] was prepared as described in the literature.

*N,N-Disubstituted 1,3-Dithiolan-2-iminium–TCNQ Simple Salts, $(CH_2)_2\langle S \rangle C{=}\overset{+}{N}R^1R^2 \cdot TCNQ^{-}$ (R^1=R^2=n-Pr (**1**), n-C_6H_{13} (**2**), n-C_8H_{17} (**3**), Ph (**4**), and R^1=Me and R^2=Ph (**5**).)* To a solution of Li^+TCNQ^{-} (2.4 mmol) in hot ethanol was added a hot ethanol solution of $[(CH_2)_2\langle S \rangle C{=}\overset{+}{N}(n\text{-}Pr)_2]_2 \cdot [SnBr_4Me_2]^{2-}$ (1.2 mmol). The mixture was filtered. The filtrate was allowed to stand in a refrigerator overnight to afford **1**, which was recrystallized from acetonitrile, 71% yield. Other four simple salts were similarly prepared by reaction of TCNQ^{-} with the appropriate iminium cation in ethanol, 70—83% yields. Of these salts, **3** was obtained as a mixture of violet crystals (**3a**) and green ones (**3b**). These were separated by fractional crystallization from ethanol.

*N,N-Disubstituted 1,3-Dithiolan-2-iminium–TCNQ Complex Salts, $(CH_2)_2\langle S \rangle C{=}\overset{+}{N}R^1R^2 \cdot (TCNQ)_2^{-}$ (R^1=R^2=n-Pr (**6**), Ph (**8**), and R^1=Me and R^2=Ph (**9**)).* To a hot acetonitrile solution of **1** obtained as above (1.5 mmol) was added neutral TCNQ (1.5 mmol) in hot acetonitrile. After filtration, the mixture was allowed to stand in a refrigerator overnight to afford **6**, 73% yield. Complex salts **8** and **9** were similarly prepared by reaction of **4** or **5** with TCNQ at the mole ratio of 1:1 in acetonitrile, 75 and 78% yields respectively.

N,N-Dibutyl- and N,N-Didecyl-1,3-dithiolan-2-iminium-TCNQ Complex Salts, $(CH_2)_2\langle^{S}_{S}\!\!>\!C\!=\!\overset{+}{N}(n\text{-Bu})_2\cdot(TCNQ)_2^{-}$ (7) and $[(CH_2)_2\langle^{S}_{S}\!\!>\!C\!=\!\overset{+}{N}(n\text{-}C_{10}H_{21})_2]_2\cdot(TCNQ)_3^{2-}$ (10). The reaction of $Li^{+}TCNQ^{-}$ (2.4 mmol) with $[(CH_2)_2\langle^{S}_{S}\!\!>\!C\!=\!\overset{+}{N}(n\text{-Bu})_2]_2\cdot[SnBr_4Me_2]^{2-}$ (1.2 mmol) in hot ethanol was carried out as described in **1**, giving **7**, which was recrystallized from acetonitrile, 65% yield based on $Li^{+}TCNQ^{-}$. Similarly, $Li^{+}TCNQ^{-}$ reacted with $[(CH_2)_2\langle^{S}_{S}\!\!>\!C\!=\!\overset{+}{N}(n\text{-}C_{10}H_{21})_2]_2\cdot[SnBr_4Me_2]^{2-}$ at the mole ratio of 2:1 in ethanol to afford **10**, 63% yield based on $Li^{+}TCNQ^{-}$.

Elemental analyses and properties of the simple and complex salts obtained are listed in Table 1.

Physical Measurements. Electrical resistivities, electronic absorption and infrared spectra, and magnetic susceptibilities were measured as described previously.[1]

Results and Discussion

Synthesis and Electrical Properties. The reaction of *N,N*-dibutyl- and *N,N*-didecyl-1,3-dithiolan-2-iminium cations with $TCNQ^{-}$ radical anion gave the 1 : 2 and 2 : 3 complex salts, **7** and **10**, respectively, irrespective of the mole ratio of the reactants. These results are analogous to the reaction of the *N,N*-diethyliminium cation with $TCNQ^{-}$.[1] There are two possible oxidizing agents in the reaction mixture. One is the iminium cation, because the cation easily undergoes a nucleophilic attack on the carbon atom at the 2, 4, or 5 position.[3] The other is the $[SnBr_4Me_2]^{2-}$ anion which may be reduced to give any Sn(II) species. However, no reduced product has been obtained in the present study. On the other hand, the other iminium cations used here reacted with $TCNQ^{-}$ to give simple salts **1**—**5**, of which **3** was obtained in two crystalline forms with different colors; violet needles (**3a**) and green plates (**3b**). Crystals **3a** slowly changed in color to green at room temperature irreversibly, suggesting that **3a** is in a metastable state. This color change occurred instantly on heating **3a** at 70 °C. Simple salts **1**, **4**, and **5** further reacted with an equimolar amount of neutral TCNQ to yield complex salts **6**, **8**, and **9**, respec-

a) The values in parentheses were obtained by the four-probe method.

tively. On the other hand, **2** and **3** were only recovered in their reactions with neutral TCNQ in acetonitrile.

The electrical resistivities (ρ) of simple and complex salts at 25 °C and the activation energies (E_a) calculated from the equation $\rho=\rho_0\exp(E_a/kT)$ are listed in Table 2. The resistivity of **3a** has not been measured for its thermal instability as described above. All the simple and complex salts show typical semi-conducting behavior in the temperature range measured. The resistivity of **9** is low in the same degree as those of the corresponding *N,N*-dimethyl- and *N,N*-diethyliminium salts, $(CH_2)_2\langle^{S}_{S}\rangle C{=}\overset{+}{N}R_2\cdot(TCNQ)_2^-$ (3.8 and 3.3 ohm cm for R=Me and Et, respectively).[1] Other 1 : 2 complex salts obtained here showed about 10 times higher resistivities than **9** as well as the *N,N*-dimethyl- and *N,N*-diethyliminium analogs. This result seems to indicate that the electrical resistivity of the 1 : 2 complex salts increases by introducing bulky substituents on the iminium nitrogen.

Electronic Spectra and Magnetic Susceptibilities. Figure 1 shows the electronic absorption spectra of **1** and **2** in the solid state. These spectral patterns closely resemble those of analogous simple salts, $(CH_2)_n\langle^{S}_{S}\rangle C{=}\overset{+}{N}Me_2\cdot TCNQ^-$ (n=2 or 3) and $(CH_2)_2\langle^{Se}_{Se}\rangle C{=}\overset{+}{N}Me_2\cdot TCNQ^-$, which have been reported to involve dimeric $(TCNQ)_2^{2-}$.[1] The existence of the $(TCNQ)_2^{2-}$ dimer in **1** and **2** is also suggested from their diamagnetic properties in the solid state ($\chi_M=-3.4\times10^{-4}$ and -4.5×10^{-4} emu mol^{-1}, respectively). Many TCNQ⁻ simple salts reported so far exhibit a band in the 8000—10000 cm^{-1} region, which has been assigned to the charge-transfer (CT) transition between TCNQ⁻ radical anions.[1,4,5] It is noted that the CT band of **2** was fairly blue-shifted compared with **1**. This fact may be correlated with the higher electrical resistivity and the larger activation energy of **2** than **1**. Simple salts **4** and **5** in the solid state exhibited electronic absorption spectra similar to that of **1**, as shown in Table 3. They also showed diamagnetic properties at room temperature. These facts confirm that dimeric $(TCNQ)_2^{2-}$ also exists in solid **4** and **5**.

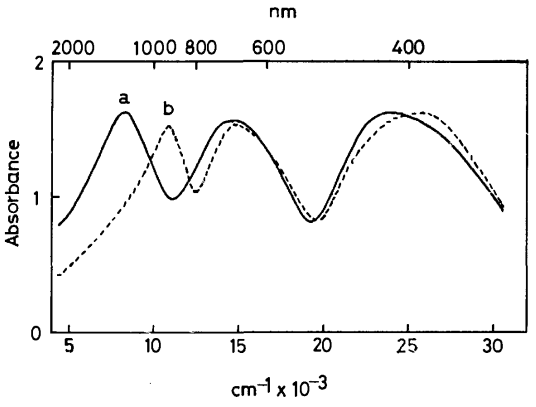

Fig. 1. Absorption spectra of **1** (a) and **2** (b) in Nujol mulls.

Table 3. Absorption maxima of the electronic spectra of the TCNQ⁻ salts in Nujol mulls

Compound	cm$^{-1}\times10^{-3}$ a)

10	5.3	11.2			17.7	24.4 26.3

a) Shoulders in parentheses.

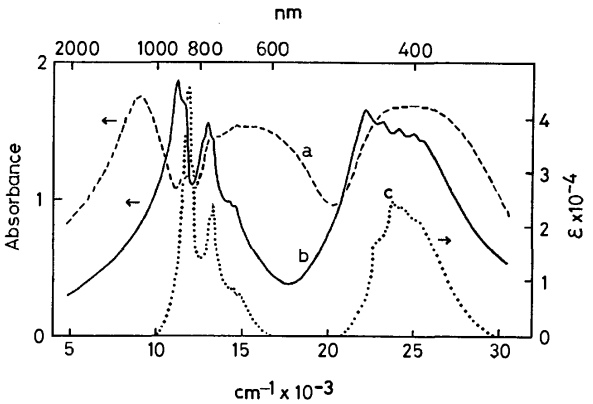

Fig. 2. Absorption spectra of **3a** (a) **3b** (b) in Nujol mulls, and of **3a** or **3b** in acetonitrile (c).

Figure 2 illustrates the electronic absorption spectra of **3a** and **3b** in the solid state and in acetonitrile. Solid **3a** exhibited three absorptions, and the spectral pattern resembles that of **1** shown in Fig. 1, suggesting that the stacking of TCNQ⁻ in **3a** can be described in terms of a dimeric pair. On the other hand, solid **3b** displayed a quite different spectrum from those of other simple salts; the spectrum of **3b** is rather similar in appearance to that of **3a** or **3b** in acetonitrile, where the salt is expected to dissociate into the iminium cation and TCNQ⁻ radical anion.[1] This observation shows that solid **3b** essentially consists of the iminium cation and the discrete TCNQ⁻ radical anion. This is also supported from the observation that **3b** exhibited a large paramagentic susceptibility ($\chi_M=1.2\times10^{-3}$ emu mol^{-1}) in the solid state at room temperature, while **3a** showed a diamagentic property ($\chi_M=-5.7\times10^{-4}$ emu mol^{-1}). This result is consistent with high electrical resistivity and large activation energy of **3b** compared with other simple salts (Table 2).

Figure 3 shows the electronic absorption spectra of complex salts **8** and **10** in the solid state. The spectrum of **8** resembles not only those of the *N,N*-dimethyl- and *N,N*-diethyliminium analogs[1] but also the reflectance spectra of several TCNQ⁻ complex salts such as with $MePh_3P^+$ and *N*-propylquinolinium$^+$.[4] Similar spectra were observed in other 1 :2 complex salts, **6**, **7**, and

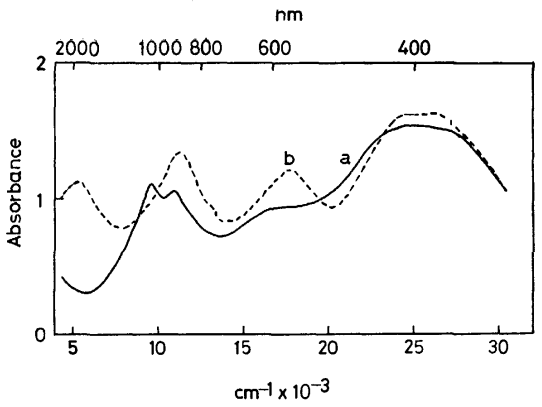

Fig. 3. Absorption spectra of **8** (a) and **10** (b) in Nujol mulls.

9 (Table 3). Furthermore, complex salts **6**—**9** exhibited the CT band between $TCNQ^{-}$ and TCNQ in the 3400—2700 cm^{-1} range in the infrared spectra, as the *N,N*-dimethyl- and *N,N*-diethyliminium analogs[1] and $MePh_3P^{+}(TCNQ)_2^{-}$[4] did.

The spectrum of 2:3 complex salt **10** in the solid state showed four absorption bands (Table 3). Except for the lowest energy band at 5300 cm^{-1}, the appearance of the spectrum roughly resembles those of the simple salts except for **3b**, suggesting the existence of dimeric $(TCNQ)_2^{2-}$. This is compatible with the diamagnetism of **10** ($\chi_M = -5.2 \times 10^{-4}$ emu mol^{-1}). The lowest energy band may tentatively be assigned to the CT transition between $TCNQ^{-}$ and TCNQ. The spectral features of **10** are nearly coincident with those of the reflectance spectra of $(Cs^{+})_2(TCNQ)_3^{2-}$ and $(morpholinium^{+})_2(TCNQ)_3^{2-}$.[4] Complex salt **10** is therefore suggested to have a stacking of TCNQ moiety similar to the Cs^{+} and $morpholinium^{+}$ salts, whose X-ray structure analyses revealed that interplanar separations of the TCNQ moieties are short enough to cause a CT interaction, while there exists the unit consisting of two $TCNQ^{-}$ radical anions and one neutral TCNQ.[6,7]

Electrostatic Force Study with Floating Wave Function. Comparative Study on the Origins of the Molecular Shapes of CH_3^+ and NH_3

Hiroshi NAKATSUJI, Kazuo MATSUDA, and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received October 7, 1977)

The force and density origins of the molecular shapes of CH_3^+ and NH_3 are studied comparatively on the basis of the floating wave functions which satisfy the Hellmann-Feynman theorem for the forces acting on the terminal protons. It is confirmed quantitatively that the previous concepts of the electrostatic force (ESF) theory correctly grasp the origins of the molecular shapes. Namely, the *density-guiding rule* which states that the nuclei are pulled in the direction of the electron-cloud reorganization (*i.e.*, the electron-cloud preceding and incomplete following), is verified as the density origin. The force origin which is the AD and EC forces reflects and quantifies the density origin. The roles of the other forces are also easily predicted by the ESF theory.

It is now well established that the force concept based on the Hellmann-Feynman (H-F) theorem[1] gives a quite intuitive basis for the understandings of various chemical phenomena.[2–13] Though such approaches had been thought to have a difficulty in the reliability of the *calculated* H-F force,[14] it is well known that if we use the floating wave function[15–17] the H-F theorem is satisfied, so that the intuitive force concept gains also a sufficient reliability, which is the same as in the conventional energetics.[18] In this series of papers,[19] we investigate quantitatively the force and density origins of some molecular geometries and chemical reactions on the basis of the floating wave functions. A purpose of this series is to give a sufficient quantitative basis for the force theoretic approach. This is an urgent necessary step in comparison with the conventional energetics, and moreover such studies will give a basis to investigate more complex phenomena than those studied so far by this approach. Another purpose of this series (especially in the first few ones) lies in the verification of the concepts of the electrostatic force (ESF) theory[8–11] from a purely theoretical *ab initio* point of view. Though the success of the ESF theory, especially in the field of molecular geometry[8] (*i. e.*, the theory has predicted the geometries of various molecules *without* calculations in agreement with *experiments*), is itself a strong proof for the validity of the ESF concepts, we aim in these studies a more direct verification.

Due to the H-F theorem[1] the force acting on a nucleus is determined solely by the electron density $\rho(\boldsymbol{r})$ (the nuclear part is trivial). It is one of the basic observables in quantum mechanics, and due to Hohenberg and Kohn's theorem,[20] it includes all of the informations of the system. Therefore, we can express the origins of various molecular processes with either the force or the density behaviors along the processes.[21] The density origin is the reorganization of the electron density along the process,[7,9] which is characterized generally as the electron-cloud preceding or the electron cloud incomplete following which works respectively to accelerate or resist the process.[9] In other words, *the nuclei are pulled in the direction of the electron-cloud reorganization.* This simple rule constitutes a guiding principle for nuclear rearrangement processes on the basis of the behaviors of the electron density alone,[8b,9] and may be called a *density guide* or *density-guiding rule.* The force origin reflects and quantifies this origin. The partitioning of the H-F force into the atomic dipole (AD), exchange (EC), and extended gross charge (EGC) forces[8] gives a way to study quantitatively the regional role of the electron density. They are parallel with the chemical concepts like lone pair, bond, and gross charge, respectively.[8] The AD and EC forces are of particular importance since the electron-cloud preceding and incomplete following manifest themselves mainly in the AD and EC forces.[9] This is a reason[9] why these forces have played such important roles in the ESF theory applied to molecular geometries,[8b,9] chemical reactions, [10]and long-range forces.[11]

When the ESF concepts are applied to the AH_3 molecules, the origins of their shapes are expected as follows.[8,9] Namely, when the molecule is bent slightly from the planar form, the electron density in the atomic (A and H) and overlap (A–H) regions will precede (in the pyramidal molecules) or incompletely follow (in the planar molecules) the nuclear bending displacement. The constituent nuclei will therefore be pulled by the AD and EC forces in the bending or planarizing direction, respectively, and will move in the direction to the equilibrium geometry. Though we tried to verify this picture in the previous paper,[9b] it was insufficient since the wave function used there did not satisfy the H-F theorem. Here, we want to examine this picture quantitatively on the basis of the floating wavefunctions.

In the previous communication of this series,[19] we have reported a simpler way of obtaining the floating wave function. Namely, if we limit ourselves to the force $\boldsymbol{F}_A$ acting on a special nucleus A of the system, it is sufficient that only the AO's belonging to the atom A be floated and their centers be determined variationally. The resultant wave function gives a reliable H-F force $\boldsymbol{F}_A$ which satisfies the H-F theorem. Based on this fact, we have studied quantitatively the force and density origins of the molecular shape of H_2O, limiting ourselves to the transverse force acting on the terminal protons. It has been confirmed that the ESF picture as described in the preceding paragraph correctly grasps the origin of the bent geometry of H_2O.[19] In this paper, we will examine further such ESF concept of the origins of the molecular shapes of CH_3^+ and NH_3. We will again limit ourselves to the transverse force acting on the terminal protons and investigate

the behaviors of the electron density in the A–H region during the out-of-plane bending process. It will give a comparative basis for the origins of the molecular shapes of planar and pyramidal molecules.

We note that in the previous extensive applications of the ESF theory to various molecular geometries,[8] we have mostly concerned with the force acting on the central nucleus (*e.g.* the nucleus A in the AH_3 molecule). It is clear from these studies that such method is easier and more fruitful for constructing a predictive theory of molecular geometries without calculations.[8] However, for the AH_3 molecules, the calculations of the floating wave functions become more elaborate for the force $\boldsymbol{F}_A$ than for the force $\boldsymbol{F}_H$, since the numbers of the basis AO's are smaller for H than for the heavier atom A. Therefore, we will postpone the *ab initio* study of $\boldsymbol{F}_A$ in the subsequent paper. We remark however that for general molecules (*e.g.* AX_n molecules) the floating wave function is more easily obtained for $\boldsymbol{F}_A$ than for $\boldsymbol{F}_X$, in contrast to the AH_3 molecules.

Floating Wave Functions for CH_3^+ and NH_3

The SCF-MO calculations have been carried out with the use of the minimal STO-3G bases[22] with the standard exponents reported by Hehre *et al.*[23] We have used the modified version of the Gaussian 70 Program. In obtaining the floating wave function, we have adopted a simpler procedure noted previously.[19] Namely, we have floated only the 1s AO's on the terminal protons and the other AO's on carbon and nitrogen, which are the 1s, 2s, $2p_x$, $2p_y$, and $2p_z$ AO's were kept fixed on the nuclei. Therefore, the present wave functions satisfy the H-F theorem for the forces acting on the terminal protons. The C–H and N–H lengths of CH_3^+ and NH_3 were kept fixed at, respectively, 1.120 and 1.033 Å which are the lengths optimized by the STO-3G calculations.[24] The experimental N–H length is 1.012 Å.[24] We have calculated the transverse force acting on the terminal protons and also the behaviors of the electron density in the A–H region at various out-of-plane bending angles θ. Several quantities pertinent to the present analysis are defined in Fig. 1.

Tables 1 and 2 give the variationally best positions of the $1s_H$ floating AO's (FAO's) of CH_3^+ and NH_3, respectively, and the effects of floating on the SCF energy and the H-F transverse force $\boldsymbol{F}_{H\perp}$ acting on the terminal protons. The H-F force is partitioned

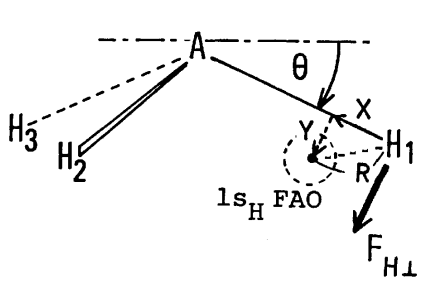

Fig. 1. Definitions of the out-of-plane bending coordinate θ, the centers of the $1s_H$ FAO's and the transverse force acting on the terminal protons $\boldsymbol{F}_{H\perp}$ for the AH_3 molecules.

into the atomic dipole (AD), exchange (EC), and extended gross charge (EGC) forces with a slight modification of the previous ones used for the non-floating wave function.[8,25] The values in parentheses are those obtained from the non-floating wave functions. The distance R of the FAO center from the proton is about 0.04 Å for CH_3^+ and about 0.02 Å for NH_3. It was about 0.03 Å for H_2O.[19] They are all in the same order of magnitude as those reported previously for H_2 by Shull and Ebbing.[26] Though the FAO center of CH_3^+ lies outside of the pyramid ($Y<0$), that of NH_3 lies inside of the pyramid ($Y>0$). For both cases, the distance Y is sensitive to the bending angle θ, though the distance X is insensitive. (The latter would be sensitive to the stretching mode). As will be seen later, these behaviors of the FAO's are closely related with the manners of the electron-cloud reorganization during the out-of-plane bending processes. The floating of the AO's gives a freedom in the wave function to describe such behaviors of the electron density especially in the atomic regions.

The floating of the $1s_H$ AO's was not effective to improve the SCF energy, as studied earier by Shull and Ebbing for the hydrogen molecule.[26] The energy lowering obtained by the floating is about 0.008 a.u. (5 kcal/mol) for CH_3^+ and 0.003 a.u. (2 kcal/mol) for NH_3. They are very small in comparison with those obtained by the other ways of improving the wave function. For example, the addition of the polarization function on hydrogen, which also describes the polarization of the electron density in the atomic region, lowers the SCF energy of NH_3 by 0.058 a.u. in the similar calculations of the STO-3G level[10b] and by 0.039 a.u. in the calculations of double-zeta accuracy.[27] However, in contrast to the floating method, it is generally difficult in such procedures to assure the complete satisfaction of the H-F theorem, so long as the basis set is incomplete.

Though the effect of floating is quite small for the SCF energy, it is very large and important for the H-F force. As seen from Tables 1 and 2, the errors for the H-F theorem are essentially zero in the floating wave functions, though they are large in the non-floating wave functions especially for NH_3. The small non-zero errors still remaining in the floating wave functions of CH_3^+ are the numerical errors in determining the optimal FAO centers. These error values have been obtained by calculating directly the error term for the H-F theorem, *i.e.*, the term $\langle \partial\Psi/\partial \boldsymbol{R}_A | H | \Psi\rangle + \langle \Psi | H | \partial\Psi/\partial \boldsymbol{R}_A\rangle$, by the method developed by Moccia *et al.*[28] Thus, it is confirmed that the present floating wave function satisfies the H-F theorem for the force acting on the terminal protons.

As seen from Table 1, the equilibrium shape of CH_3^+ is calculated to be planar from both the floating and non-floating wave functions. The planar geometry of CH_3^+ is well established by the previous studies.[24,29] The out-of-plane bending force constant calculated from the H-F force is 0.93 md/Å with the floating wave function and 0.82 md/Å with the non-floating wave function. The former should of course be identical with the result obtained from the SCF energy

a) The values in parentheses are obtained from the non-floating wave functions. b) This value is the sum of the two identical EC(H--H) forces.

curve. On the other hand, for NH_3 (Table 2), the effect of the floating on the H-F force is essential even for the qualitative calculation of the equilibrium shape. With the non-floating wave function, the shape is calculated to be planar! This is because the minimal STO-3G basis fixed on the nuclei is far from complete and can not describe the polarization of the electron density in the atomic region near the proton (see below). However, with the floating wave function, NH_3 is calculated to be pyramidal with $\theta_{eq}=24.3°$ ($\angle HNH=104.2°$) which is just the same as the STO-3G geometry.[24] The experimental value is $\theta_{eq}=22.1°$ ($\angle HNH=106.7°$).[24]

The partitioning of the H-F force into the AD, EC, and EGC forces clarifies the details how the floating of the $1s_H$ AO's improves the H-F force. As seen in Tables 1 and 2, the largest effect of the floating occurs for the AD force. It improves most of the errors included in the non-fioating H-F force (50—80% for CH_3^+ and 70—80% for NH_3). This is because the H-F force is most sensitive to the errors in the region near the nucleus. In the non-floating wave function, the AD force was always zero since the present basis AO's do not include the polarization functions on the hydrogen atom. In the floating wave function, it arises because the $1s_H$ AO density floating apart from the proton pulls it in the direction of the floating. For CH_3^+, Y is negative so that the induced AD force is negative, while for NH_3, Y is positive so that the AD force is positive. In both cases, the distance Y and the AD force are parallel. The second largest effect of the floating occurs for the EGC force. For CH_3^+ the floating enlarges the repulsive EGC force, whereas for NH_3 it diminishes: in CH_3^+ the outward floating ($Y<0$) of the $1s_H$ AO makes its proton more bare so that the repulsion increases, while in NH_3 the AO floated inward of the proton ($Y>0$) shields it more effectively from the repulsion with the other protons. These "self-shielding" effects have arisen from the modification of the partitioning as given in Ref. 25. The effect of floating is smallest for the EC force as expected from the small distance Y in comparison with the bond distance. The effect is smaller for CH_3^+ than for NH_3 since Y is smaller for CH_3^+.

Origin of the Molecular Shape

In this section we study quantitatively the force and density origins of the molecular shapes of CH_3^+ and NH_3. We investigate the behaviors of the electron density and the induced forces acting on the terminal protons during the out-of-plane bending process. Since the present floating wave function satisfies the H-F theorem, we can examine quantitatively the concepts developed previously in the ESF theory.

First, we study the density and force origins of the planar geometry of CH_3^+. Figure 2 shows the change in the electron density of CH_3^+ when it is bent by 15° from the planar form. The density at $\theta=0°$, which is symmetric with respect to the CH_3 plane, was subtracted from that at $\theta=15°$ with superposing the C–H_1 axis on the right hand side.[30] This figure is then meaningful only in the region near the C–H_1 axis. The real and dotted lines show respectively the increase and decrease in the electron density. From this figure, we see that the reorganization of the C–H bond density of CH_3^+ shows a typical feature of the electron-cloud incomplete following in the out-of-plane bending process. Namely, as seen from the increase and the decrease in the regions above and below the C–H_1 axis, respectively, the C–H bond density at $\theta=15°$ does not lie on the C–H axis, but follows with lag the out-of-plane bending displacement of the C–H axis. The bond density, following back of the C–H axis, will pull the terminal proton in the reverse direction to θ, so that the molecule will be restored again to the planar form: i.e., the equilibrium geometry of CH_3^+ is expected to be planar in accordance with the previous studies.[29] This is the result of the density-guiding rule applied to the geometry of CH_3^+.

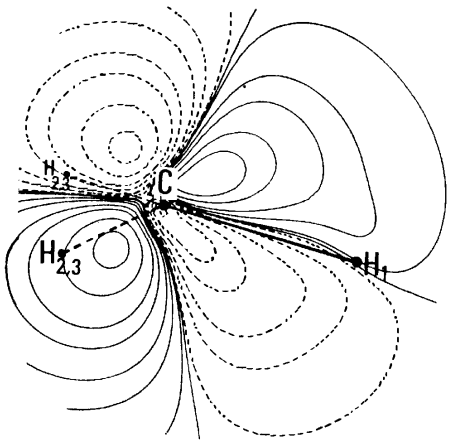

Fig. 2. Electron-cloud reorganization in CH_3^+ at $\theta=15°$ in the C-H_1 region. The density at $\theta=0°$ was subtracted from that at $\theta=15°$ with superposing the C-H_1 axes. The contours are at 0.0, ±0.001, ±0.005, ±0.01, +0.015, −0.02, +0.025, ±0.04, ±0.07, ±0.1, and ±0.15 au (real lines ≥0, dashed lines <0).

The above density origin is verified from Fig. 3 which shows the analysis of the transverse force $\boldsymbol{F}_{H\perp}$ acting in CH_3^+ during the bending process. The dotted line shows the SCF energy curve. Throughout the bending process, the protons of CH_3^+ receive the planarizing forces; *i.e.*, the molecule is calculated to be planar. In CH_3^+ all of the force components are cooperative to make the molecule planar. Among these, the dominant force origin is the EC(H–C) force. It arises from the incomplete following of the C–H bond density as depicted in Fig. 2. [If the C–H bond density always lies on the C–H axis (complete following), it does not induce the *transverse* EC(H–C) force.] The electron-cloud incomplete following in the atomic region manifests itself in the AD force. It has arisen through the floating of the $1s_H$ AO's. The behaviors of the $1s_H$ FAO's seen from the distance Y given in Table 1 clearly show the occurrence of the electron-cloud incomplete following in the atomic region. The sum of the EC (H–C) force and the AD force accounts most (≈70%) of the total planarizing force.

Thus, we conclude that the density origin of the

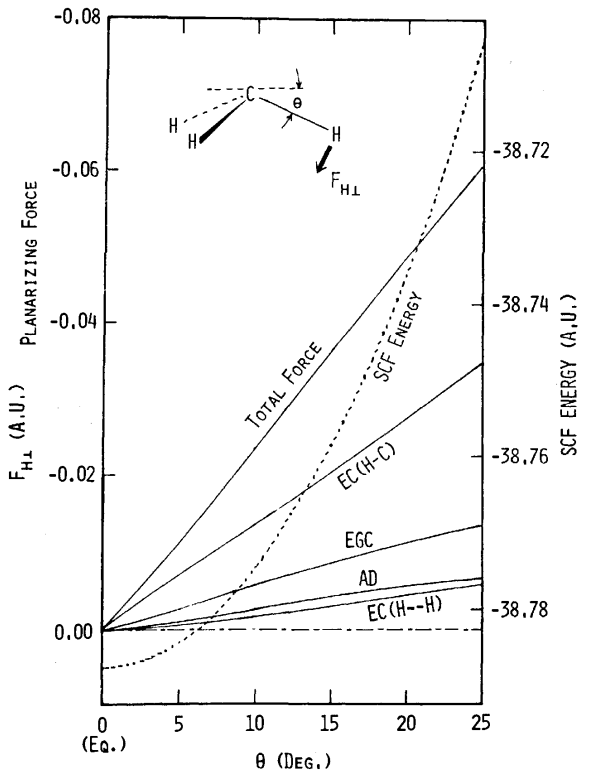

Fig. 3. The transverse force $\boldsymbol{F}_{H\perp}$ and the SCF energy *vs.* the out-of-plane bending angle θ for CH_3^+.

planar shape of CH_3^+ lies in the occurrence of the electron-cloud incomplete following of the C–H bond density during the out-of-plane bending process. We have confirmed that the electron-cloud incomplete following as depicted in Fig. 2 occurs over the all angular range studied here ($0°<\theta<24.3°$) and that the extent increases with the increase in the bending angle θ. The force origin, which is the EC(H–C) and AD forces (mostly the EC(H–C) force), reflects and confirms this density origin.

In Fig. 3, the other minor force components, *i.e.*, the EGC and EC(H--H) forces are also cooperative to make CH_3^+ planar. We note that the roles of these forces are also naturally understood. Namely, in CH_3^+, the net gross charges of the terminal hydrogens are positive, so that the EGC force which represents the interaction between the shielded protons would be repulsive. The EC(H--H) force would also be repulsive since it arises from the exchange interaction between the doubly occupied C–H bond orbitals. Among these, the origin of the EC(H--H) force may be included in the electron-cloud incomplete following as has been discussed previously for the similar interaction during the internal rotation of ethane.[8]

We next investigate the density and force origins of the pyramidal shape of NH_3. In Fig. 4 we have depicted the electron-cloud reorganizations in NH_3 at the bending angles $\theta=15$, 24.3 (calculated equilibrium), and 40°. They are defined similarly to Fig. 2.[30,31] As seen from Fig. 4, the electron-cloud reorganization in NH_3 is quite different from that in CH_3^+. At $\theta=15°$ (Fig. 4(A)), the behavior of the N–H bond density of NH_3 shows a typical feature of the electron-

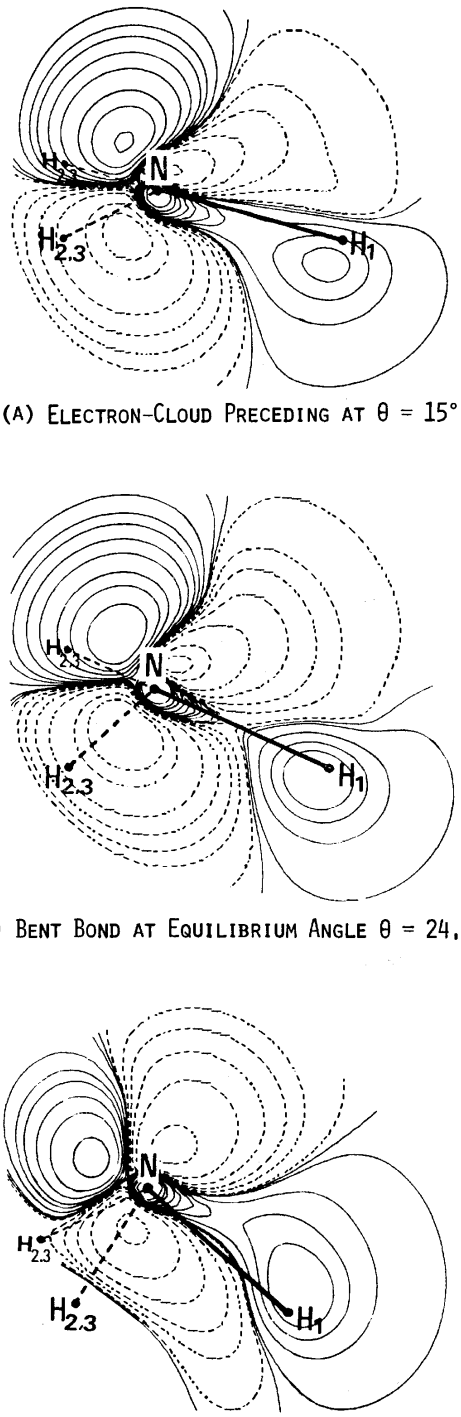

Fig. 4. Electron-cloud reorganization in NH_3 in the $N\text{-}H_1$ region during the out-of-plane bending process. (A) $\Delta\rho(15°)=\rho(15°)-\rho(0°)$, (B) $\Delta\rho(24.3°)=\rho(24.3°)-\rho(0°)$, (C) $\Delta\rho(40°)=\rho(40°)-\rho(24.3°)$. In subtracting the reference density, the $N\text{-}H_1$ axes were superposed. The levels of the contours are the same as those given in Fig. 2.

cloud preceding.[9] Namely, the increase and the decrease in the electron density in the regions below and above the $N\text{-}H_1$ axis, respectively, shows that the N–H bond density does not lie on the N–H axis, but

bends more than the N–H axis. The N–H density, preceding ahead of the bending movement of the N–H axis, will pull the terminal proton in the bending direction, so that the bending process will be accelerated further. Therefore, the stable shape of NH_3 is expected to be pyramidal in agreement with the experiment. When the molecule reaches the equilibrium angle (θ=24.3°), such preceding character almost vanishes as seen in Fig. 4(B). The bond electron density becomes almost symmetric with respect to the N–H axis in order to keep the terminal proton in an electrostatic equilibrium with respect to the transverse force. A small preceding character seen especially in the atomic region near H shows an inward bent bond which is necessary to cancel with the interproton repulsions at the equilibrium geometry.[9b] When the molecule is bent further from the equilibrium angle, the N–H bond density again dispart from the N–H axis, and the electron-cloud incomplete following occurs as seen in Fig. 4(C). This behavior is just reverse to that seen at θ=15° (Fig. 4(A)). The N–H bond density, following back of the N–H axis, will pull the terminal proton upwards so that the molecule will be restored again to the equilibrium angle. In summary, the electron-cloud reorganization in NH_3 during the out-of-plane bending process is characterized by the electron-cloud preceding in the region $0°<\theta<24.3°$ and the electron-cloud incomplete following in the region $\theta>24.3°$. From the density guide, we may expect the equilibrium angle at about 24.3° where the density behavior turns reverse from the preceding to the incomplete following.

In Fig. 5 we have shown the analysis of the transverse force $\boldsymbol{F}_{H\perp}$ in NH_3 during the out-of-plane bending process. By virtue of the floating, the equilibrium angle calculated from the H-F force agrees with that obtained from the SCF energy curve. Among the force components shown in Fig. 5, only the AD and EC(H–N) forces work to accelerate the bending process in the range $0°<\theta<\theta_{eq}$. Therefore, the force orgin of the pyramidal shape of NH_3 is the AD and EC(H–N) forces which reflect the electron-cloud preceding in the atomic and overlap regions, respectively. The other forces, *i.e.*, the EGC and EC(H--H) forces, work to resist the bending process by the same reason as explained for CH_3^+. This fact clearly confirms the importance of the electron-cloud preceding in the region $0°<\theta<\theta_{eq}$. Without it, the pyramidal shape of NH_3 can not be realized. At the equilibrium angle (24.3°), the repulsive EGC and EC(H--H) forces are canceled out by the AD force. The EC(H–N) force is almost zero at this angle. This means that the inward bent bond character at the equilibrium geometry, which is necessary to cancel the interproton repulsions, occurs mostly in the atomic region near the proton (see Fig. 4(B)). In the angular region $\theta>\theta_{eq}$, the force on the proton works to restore the molecule again to the equilibrium angle. It arises from the EC(H–N), EGC, and EC(H–H) forces. The AD force contributes to the restoring force by diminishing its bending role. Among these, the slope of the EC(H–N) force is steepest so that it becomes the most important component of the restoring force. It reflects the electron-cloud incomplete following depicted in Fig. 4(C) at θ=40°. Thus, it is confirmed that the density guide applied to the geometry of NH_3 certainly grasps the most important factors of the force components. The dominant force origin, which is the AD and EC(H–N) forces, reflects and confirms the density origin summarized in the preceding paragraph.

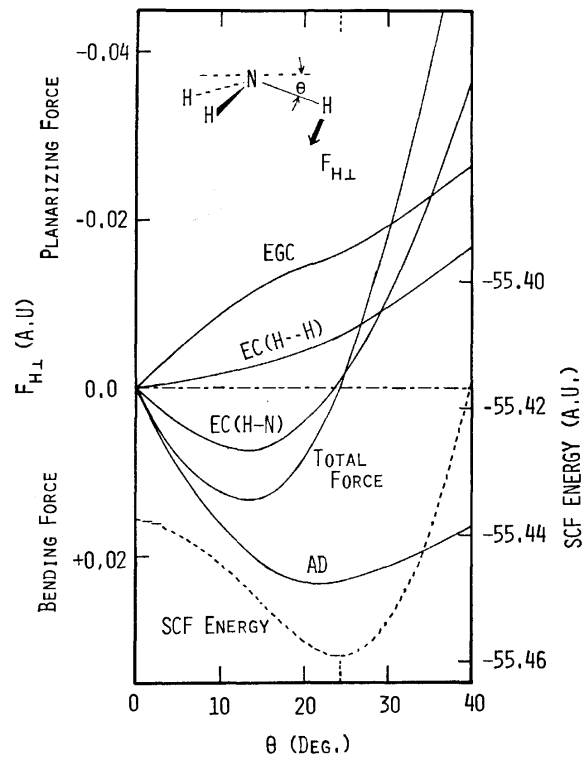

Fig. 5. The transverse force $\boldsymbol{F}_{H\perp}$ and the SCF energy *vs.* the out-of-plane bending angle θ for NH_3.

It is interesting to note that the density and force origins of the pyramidal shape of NH_3 are quite similar to those of the bent geometry of H_2O reported previously.[19] On the basis of the generality of the density-guiding rule as discussed in the previous paper,[9] we believe that this similarlity in the force and density origin is actually a more general one which is correct at least for any kind of AH_2, AH_3, and related substituted molecules having bent or pyramidal geometries. By the same reason, the force and density origins shown here for CH_3^+ would also be common to the above types of molecules having linear or planar geometries.

It would also be worthwhile to remark that for both CH_3^+ and NH_3, the curves for the EC(H–A) forces cross the zero line at about the equilibrium angle; *i.e.*, at θ=0° for CH_3^+ and at θ=23° for NH_3. The same is also true for H_2O; *i.e.*, just at $\theta=\theta_{eq}$ (=40°) (see Fig. 3 in Ref. 19). If this is true more generally, we can estimate the equilibrium angle only from the EC(H–A) force, and furthermore, since the effect of the floating is small for the EC(H–A) force, this procedure would be possible *even* with the *non*-floating wave functions. Actually, such procedure with the use of the non-floating wave function gives the equilibrium angle 0° for CH_3^+, 25° for NH_3 (see Tables 1 and 2), and 40° for H_2O. These values agree surprisingly well

with those obtained from the floating wave functions which are 0, 24.3, and 40°, respectively. The experimental values are 0, 22.1, and 37.8°, respectively.[24]

Density Behavior Reflected in the Potential Energy Curve

It is well known that the energy is an explicit function of not only the electron density $\rho(\boldsymbol{r})$ but also the off-diagonal first-order density matrix $\rho(\boldsymbol{r}|\boldsymbol{r}')$ and the second-order density matrix $\Gamma(\boldsymbol{r}_1, \boldsymbol{r}_2)$.[32] The latter two functions are much more complicated than the electron density. On the other hand, the H–F theorem states that the force acting on a nucleus is determined solely by the electron density $\rho(\boldsymbol{r})$ surrounding the nucleus. The nuclear repulsion term is trivial. Therefore, if we integrate the H-F force along the process, we can obtain the potential energy curve solely from the dynamic behavior of the electron density during the nuclear rearrangement process. Though this is trivial, the underlying concept of this procedure is simpler and more visual than that of the conventional energetics. A condition for the (numerical) equivalence between the conventional energetics and the *integrated* H-F force approach is the holdness of the H-F theorem, which the present floating wave function satisfies. Then, we examine here such idea for CH_3^+ and NH_3 by integrating the force curves given in Figs. 3 and 5.

Figures 6 and 7 show the enrgy curves for CH_3^+ and NH_3, respectively, obtained by the direct integration of the H-F force curves given in Figs. 3 and 5. By virtue of the floating, the curves of the integrated

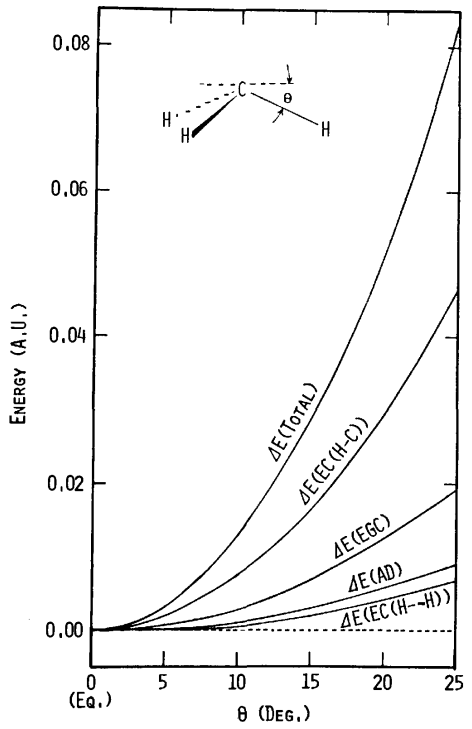

Fig. 6. Partitioning of the potential energy curve into the force theoretic terms for CH_3^+.

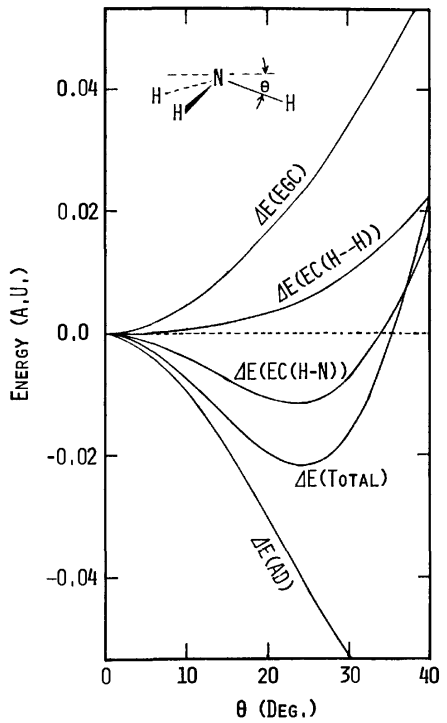

Fig. 7. Partitioning of the potential energy curve into the force theoretic terms for NH_3.

H-F forces (denoted as ΔE(Total)) are just superposable with the SCF energy curves shown in Figs. 3 and 5. The partitioning of the ΔE(Total) curve into the force theoretic terms given in Figs. 6 and 7 helps to analyze the potentical energy curve in terms of the regional roles of the electron-cloud reorganization during the bending process. The electron-cloud incomplete following in CH_3^+ shown in Fig. 2 works to destabilize the system as seen in the ΔE(EC(H–C)) and ΔE(AD) curves given in Fig. 6. It is the main origin of the potential energy curve ΔE(Total). For NH_3, the electron-cloud preceding in the atomic and overlap regions works to stabilize the molecule as seen from the ΔE(AD) and ΔE(EC(H–N)) curves in the angular region $0°< 0<\theta_{eq}$. In the region $\theta>\theta_{eq}$, the electron-cloud incomplete following works to destabilize the system as seen in the ΔE(EC(H–N)) curve. For both CH_3^+ and NH_3, the parallelism between the ΔE(EC(H–A)) curve and the total curve is surprising. The same trend was also seen previously for H_2O.[19] Thus, it is confirmed that the density-guiding rule certainly shows the path along which the energy becomes lower most effectively.

Concluding Remarks

In this paper, we have studied the force and density origins of the molecular shapes of CH_3^+ and NH_3 on the basis of the floating wavefunctions which satisfy the H-F theorem for the force acting on the terminal protons. The present results may be summarized as follows:

1) The floating of the AO's gives a freedom in the wave function to describe an appropriate behavior of

the electron density especially in the atomic region. The direction and the extent of the floating of the FAO's accord with those expected from the general behaviors of the electron density, *i.e.*, the electron-cloud preceding and incomplete following. The effect of the floating on the H-F force is largest for the AD force.

2) For the floating wave function, the simple and pictorial concepts of the force theory holds in a sufficient accuracy. On this basis, we have confirmed that the previous concepts of the ESF theory correctly grasp the origins of the molecular shapes. The density-guiding rule based on the behaviors of the electron density is verified as the rule for the density origin. The force origin which is the AD and EC(H–A) forces reflects and quantifies the density origin. The roles of the other forces are also easily predicted by the ESF theory.

Lastly, it would be important to remark about an interpretation why the electron-cloud preceding or the incomplete following occurs in the A–H bond region under the bending process. Recently, Deb has given a postulate that the highest occupied molecular orbital (HOMO) would be most responsible for these behaviors since the HOMO is most weakly bound to the nuclear framework.[13] He has tried to systematize various molecular geometries on the basis of the "HOMO postulate."[12,13] Though this idea is interesting, this assumption seems to feel difficulty for larger molecules since they have many levels in the vicinity of the HOMO. The electron-cloud preceding and the incomplete following, which should be the density origin even for larger molecules,[9] are the behaviors of the *total* electron density. On the other hand, when we focus our attention on the force acting on the central atom (*e. g.* the atom A of the AH_3), we can easily predict the behaviors of the electron density on the basis of the chemically transferable concepts like lone pair, bond, gross charge, and the various effects on them (*e. g.* substituent effect), as has been shown previously in the ESF theory.[8] Therefore, we believe that for predictive applications, it is easier and more fruitful to focus our attention to the force acting on the central atom, except for the problems of the internal rotation barrier.[8] An *ab initio* verification of this approach will be given in the succeeding paper.

The authors would like to thank Dr. S. Yamabe, Dr. K. Kitaura, and Professor K. Morokuma for the use of the modified version of the Gaussian 70 Program, and Mr. S. Kanayama for the assistance of some computations. This study has been supported partially by the Scientific Research Grants from the Ministry of Education and by the Japan-U.S. Cooperative Science Program from the Japan Society for the Promotion of Science.

30) Though the electron-cloud preceding and incomplete following are the behaviors of the *total* electron density, they are more visually depicted when an appropriate reference density is introduced. Since we are concerned here only in the electron density in the A–H region, we have introduced as the reference density the one obtained at $\theta=0°$ since it is symmetric with respect to the A–H axis. Therefore, the present difference density maps show chiefly the electron-cloud reorganization induced by the out-of-plane bending displacements.
31) At $\theta=40°$ we have used as the difference density the density obtained at $\theta=24.3°$ (calculated equilibrium), since there the transverse force is zero and the N–H bond density is almost symmetric with respect to the N–H axis. These two features are common to the planar form used as the reference at $\theta=15$ and 24.3°.

(Received October 15, 1977)

The infrared and Raman spectra of dimethylaminosulfonyl chloride and its *C*-deuterated derivative have been recorded in the liquid state. The fundamental frequencies have been assigned by referring to the band intensities, Raman depolarization ratios and isotopic frequency shifts. A normal coordinate analysis based on a planar C_s molecular model has been carried out by using a simple Urey-Bradley force field for stretching and bending coordinates and a valence force field for torsional coordinates. The calculated frequencies based on a refined set of force constants agree well with the observed ones.

Infrared and Raman spectra of dimethylaminosulfonyl chloride, $(CH_3)_2NSO_2Cl$, have been reported by Bürger *et al.*[1] and Schneider *et al.*[2] The latter authors have also carried out a normal coordinate analysis for the simplified 7 body model, C_2NSO_2Cl. There seems to remain, however, much ambiguity on assignments of several skeletal vibrations which are expected to couple with the methyl group modes. The present work has been undertaken to clarify this point by referring to the spectral change on deuterating the two methyl groups, and to compare the related force constants with those of other sulfonyl compounds. A normal coordinate analysis has been carried out for the complete molecular model including the motion of the hydrogen atoms. By using a refined set of 25 force constants, the observed frequencies of both the isotopic compounds have been reproduced satisfactorily.

Experimental

Materials. Dimethylaminosulfonyl chloride, DMSCl, was prepared by the reaction between sulfuryl chloride and dimethylamine hydrochloride (reagent grade).[3] Dimethyl-d_6-aminosulfonyl chloride, DMSCl-d_6, was synthesized by the same reaction with the use of dimethyl-d_6-amine hydrochloride (Merck AG., 98% deuterated), and distilled twice under reduced pressure (bp 83—85 °C at 25 mmHg). The isotopic purity of the product was estimated to be more than 98% by NMR spectra.

Measurements. The infrared spectra were measured in the liquid state on a JASCO DS 403G grating spectrophotometer. The absorption frequencies were calibrated by the standard absorptions of polystyrene, indene and water vapor. The Raman spectra were measured for the liquid samples sealed in 1 mm unheparinized haematocript tubes on a JEOL S-1 laser Raman spectrophotometer. The 488.0 nm line of a Coherent 52G Ar^+ laser was used as the excitation source.

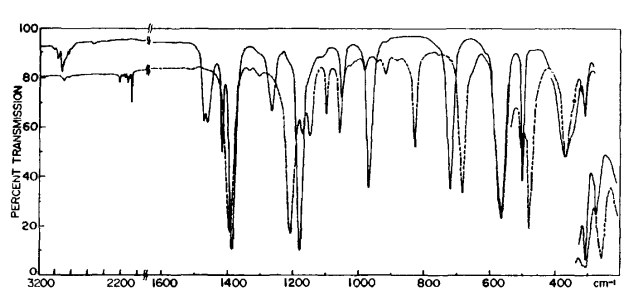

Fig. 1. Infrared spectra of DMSCl(——) and DMSCl-d_6 (----).

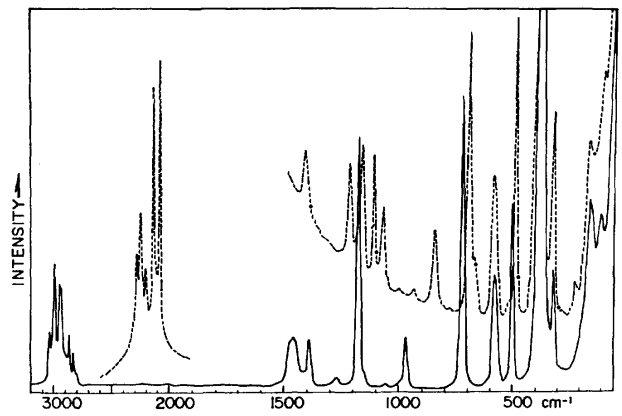

Fig. 2. Raman spectra of DMSCl (——) and DMSCl-d_6 (----).

The infrared spectra are shown in Fig. 1 and the Raman spectra in Fig. 2. The observed frequencies are listed in Table 1 together with approximate band intensities and assignments.

Vibrational Assignments

The fundamental frequencies of dimethylaminosulfonyl chloride were given rough assignments by Bürger *et al.*[1] and Schneider *et al.*[2] on the assumption that the vibrations of the methyl hydrogen atoms were virtually independent of the skeletal vibrations of the molecule. The spectral change on the *C*-deuteration of the methyl groups in this work revealed, however, that there are considerable vibrational couplings between the methyl groups and the other part of the molecule. The infrared bands at 1470 and 1459 cm^{-1} and the Raman band at 1456 cm^{-1} are assigned clearly to the CH_3 asymmetric deformation vibrations and the infrared band at 1416 cm^{-1} to the CH_3 symmetric deformation. On the *C*-deuteration, these bands disappear and the corresponding bands due to the CD_3 groups appear around 1150, 1100, and 1060 cm^{-1}. At the same time the strong infrared and Raman bands at 1177 cm^{-1} due certainly to the SO_2 symmetric stretching vibration shift to 1207 cm^{-1}. In the infrared spectrum no appreciable change in relative intensity is observed with these fre-

quency shifts, while in the Raman spectrum the intensity of the 1177 cm^{-1} band of DMSCl seems to be partitioned among the 1207, 1155, and 1102 cm^{-1} bands of DMSCl-d_6. This result suggests that the SO_2 symmetric stretching vibration of DMSCl-d_6 couples strongly with the CD_3 deformation vibrations. On the contrary, the SO_2 asymmetric stretching band around 1390 cm^{-1} undergoes only a slight isotope shift in both the infrared and Raman spectra. The infrared band at 1264 cm^{-1} assigned previously to the CH_3 rocking vibration[1,2] proved to disappear on the *C*-deuteration. According to the calculated normal modes, the contribution of the skeletal stretching vibrations to this band is also important. The infrared bands at 1115, 1049, and 966 cm^{-1} vanishing on the *C*-deuteration were assigned to the CH_3 rocking vibrations and were classified into the a′ and the a″ species by referring to the depolarization ratios of the corresponding Raman bands and the results of a preliminary calculation. The 1049 and the 966 cm^{-1} bands were assigned to the skeletal stretching vibrations by the previous authors.[1,2] Similarly, the infrared bands at 919, 827, and 755 cm^{-1} of DMSCl-d_6 newly appearing on the *C*-deuteration were assigned to the CD_3 rocking vibrations. The infrared band at 716 cm^{-1} of DMSCl shifts to 682 cm^{-1} on the *C*-deuteration and can be assigned to the S–N stretching vibration in agreement with the assignment of Bürger *et al.*[1] According to the calculated normal modes, the S–N stretching vibration contributes also to the infrared bands at 1264, 1177 and 966 cm^{-1} of DMSCl and at 1207, 1153, 1099, and 755 cm^{-1} of DMSCl-d_6.

The polarized Raman band at 374 cm^{-1} is extremely strong and remains unshifted on the *C*-deuteration. This band is assigned certainly to the S–Cl stretching vibration from analogy with the spectra of CH_3SO_2Cl and CD_3SO_2Cl.[4] The previous authors assigned this band to the C–N–C deformation vibration,[1,2] but such a strong band is missing in the Raman spectrum of $(CH_3)_2NSO_2NH_2$.[5] On the *C*-deuteration of DMSCl, the infrared bands at 562 and 309 cm^{-1} remain unshifted but those at 500 and 276 cm^{-1} shift to lower frequencies by about 20 cm^{-1}. By referring to the Raman depolarization ratios and the assignments of the related compounds,[4,6-9] the 562, 500, and 309 cm^{-1} bands were assigned to the SO_2 bending, wagging and twisting vibrations, respectively, and the 276 cm^{-1} band to the skeletal deforamtion vibration. The present as-

signments of the SO_2 deformation vibration are considerably different from those of the previous authors.[1,2] An infrared band at 505 cm^{-1} and a Raman band at 218 cm^{-1} of DMSCl-d_6 newly appearing on the *C*-deuteration are assignable to the a″ skeletal deformation and the SO_2 rocking vibrations, respectively. The corresponding bands of DMSCl seem to be overlapped by the neighboring bands at the higher frequency side. The weak Raman band at 105 cm^{-1} of DMSCl is assigned to the S–N torsional vibration since the observed shift to 95 cm^{-1} on the *C*-deuteration is too small for the CH_3 torsion. No bands assignable to the CH_3 or the CD_3 torsional vibrations were observed.

Normal Coordinate Analysis

Following Schneider *et al.*,[2] we assumed that dimethylaminosulfonyl chloride takes the C_s structure in which each SO bond is at the trans position of a CH_3–N bond. In this model, the normal modes of DMSCl are classified as 18a′+15a″. The structure parameters used in the calculation are shown in Fig. 3. The bond lengths and the valence angles related to the C_2NS skeleton were taken from tetramethylsulfuric diamide[10] and those related to the SO_2 group from sulfuryl chloride.[11] The tetrahedral angle was assumed for the methyl group. The local symmetry coordinates were constructed in the usual form[12] and the redundant coordinate associated with the $-SO_2-$ group was eliminated numerically on diagonalizing the G matrices. The torsional coordinates were those defined by Miyazawa and Fukushima.[13]

A simple Urey-Bradley force field including 25 force constants was employed for the stretching and the bending coordinates and a valence force field for the torsional coordinates. Initially, the force constants for the $(CH_3)_2N-$ group were transferred from methylamine,[14] those for the $-SO_2Cl$ group from sulfuryl chloride[7] and those around the S–N bond from sulfuric diamide.[9] The torsional force constants τ(C–N) and τ(S–N) were assumed to be equal to the constants for the C–C and the C–S torsional coordinates of dialkyl disulfide,[15] respectively. On refining the force constants, the observed frequencies were taken mostly from the infrared

a) Raman frequency.

data. These frequencies satisfied the isotopic product rule[16] and the modified sum rule[17] fairly well as shown in Table 2. The force constants were refined first by referring to the Jacobian matrix elements, and then by the method of least squares. The final set of the force constants is listed in Table 3, and the calculated frequencies are compared with the observed ones in Table 4.

In support of the empirical assignments given in the preceding section, the observed shifts of the skeletal frequencies below 750 cm^{-1} on the *C*-deuteration were reproduced well by the calculation. The stretching constant K(SN) is appreciably smaller than the corresponding constants of $NH_2SO_2NH_2$[9] and $CH_3SO_2NH_2$,[6] probably because the electron drawing effect of the chlorine atom tends to reduce the S–N bond order. The constant K(SCl) is also smaller than that of $ClSO_2Cl$[7] but is comparable with that of CH_3SO_2Cl.[4] The value of K(SO) is close to the average of those of $NH_2SO_2NH_2$[9] and $ClSO_2Cl$,[7] reflecting well the intermediate structure, NSO_2Cl, of DMSCl. Regarding K(SO), it may be also pointed out that $CH_3SO_2NH_2$,[6] $CH_3SO_2CH_3$[8] and $NH_2SO_2NH_2$[9] are all alike while DMSCl resembles CH_3SO_2Cl.[4] Thus, the effect of the NR_2(R=H or CH_3) group on the S–O bond order is similar to that of the CH_3 group, and in this respect the SO_2 group differs markedly from the C=O group as pointed out by Bellamy and Williams.[18]

The authors wish to express their sincere gratitude to Professor Toyozo Uno of Kyoto University for his encouragement throughout this work and to Mr. Akimasa Iwado of Okayama University for the measurement of the NMR spectra. The calculation in this work was performed on FACOM 230 series computers at Data Processing Center, Kyoto University and on a NEAC 2200/500 computer at Okayama University Computer Center.

Light Scattering Study of Local Structure in Solution. Double-Layered Structure Formation in Chloroform Solution of Surfactant

Tadashi KATO and Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received October 17, 1977)

Light scattering spectra have been observed for binary solutions of chloroform–tetrabutylammonium chloride (TBACl) and chloroform–hexadecyltrimethylammonium chloride (HTACl) at various concentrations. The Rayleigh intensities have been reduced to concentration fluctuations. The observed concentration dependence of the concentration fluctuation was explained in terms of the existence of aggregates which were composed of a few surfactant molecules and several decades of chloroform molecules. Using the infrared data, the structures of the aggregates were demonstrated to be double-layered. In HTACl solution, a singular concentration dependence of concentration fluctuation was observed in the concentration range below 0.004 mole fraction.

In previous reports,[1,2] quantitative analysis of the infrared absorption intensities of some water soluble surfactants in chloroform solutions has been reported. In these reports it has been postulated that those surfactants dissolve in chloroform by forming hydrogen bonds with several solvent chloroform molecules. As the hydrogen bonds were not of the 1 : 1 type, an investigation to elucidate the structure of these complexes was undertaken.

Recently, a method has been reported for determining the local structures existing in binary solutions by observing the concentration fluctuation at different concentrations. This has been applied to various liquid mixtures.[3–7] In the present study, the light scattering method has been applied in chloroform solutions of the surfactants. Hexadecyltrimethylammonium chloride (HTACl) and tetrabutylammonium chloride (TBACl) were chosen since their specific refractive index incriments are large enough to measure the concentration fluctuation accurately and reliable infrared data are available for thier chloroform solutions. Elucidation of the double-layered structures may be determined by the complementary use of vibration spectra and light scattering spectra for these solutions. The experimental part of the light scattering study on HTACl–chloroform solution has been published already.[8]

Experimental

All chemicals used in the present study were commercial products. Chloroform was purified by column chromatography on alumina in order to eliminate water and ethanol. HTACl and TBACl were dried over P_2O_5 under vacuum for several days. The sample solutions were made dust-free by the use of a millipore filter FG of 0.2 μm pore size.

Light scattering spectra were observed by the use of a spectrometer designed and constructed in the laboratory.[3] The refractive indices of the sample solutions were measured by means of an Abbe refractometer (Atago). All the measurements were performed at 24±0.5 °C for CTACl solution and 21±0.5 °C for TBACl solution.

Results and Discussion

Light Scattering Spectra and Concentration Fluctuation. Figure 1 illustrates the light scattering spectra for chloroform solutions of TBACl in the concentration range of 0—0.036 mole fractions (for the spectra of HTACl, see Ref. 8). After separating the Rayleigh part from the observed spectra, the Rayleigh intensity was expressed relative to the Rayleigh intensity of pure chloroform. Then, the concentration fluctuation of the surfactants, $N\langle(\Delta x)^2\rangle$, was calculated from the equation[4]

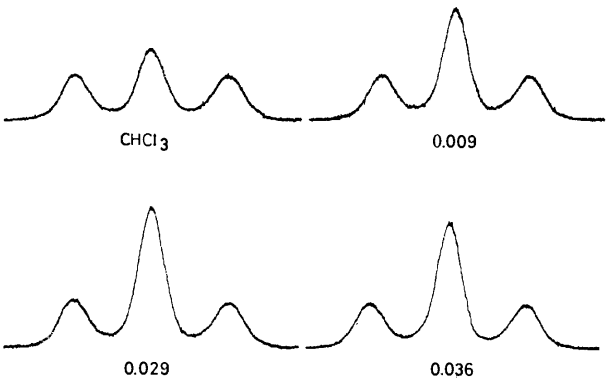

Fig. 1. Observed light scattering spectra for TBACl–chloroform system at 21 °C. Concentration is expressed in terms of mole fraction of TBACl.

$$N\langle(\Delta x)^2\rangle = \frac{RT^2}{M(\partial n/\partial x)^2_{P,T}}\left[\frac{S}{S_0}\left(\frac{n_0}{n}\right)^2\frac{\rho}{\rho_0}\frac{(\partial n_0/\partial T)^2_{P,x}}{C_{Pg^0}} - \frac{(\partial n/\partial T)^2_{P,x}}{C_{Pg}}\right], \quad (1)$$

where R is the gas constant, M the mean molecular weight, T the absolute temperature, n the refractive index, ρ the density, C_{P_g} the specific heat per gram, N the total number of molecules of the field within which the concentration fluctuation is considered, and (S/S_0) is the intensity ratio of Rayleigh lines. The suffix zero specifies quantities related to pure chloroform.

In Fig. 2, the concentration fluctuation thus obtained was plotted as a function of mole fraction, $\bar{x}$, of the surfactants. The broken line in Fig. 2 corresponds to the concentration fluctuation expected for an ideal binary solution. From the figure the observed concentration flutuation is seen to take larger values than those of an ideal binary solution at low concentration and smaller values as the concentration increases. Therefore, the concentration fluctuation of each system has a maximum value. The concentration at which the concentration fluctuation of TBACl takes a maximum value is higher than that of HTACl. In the region

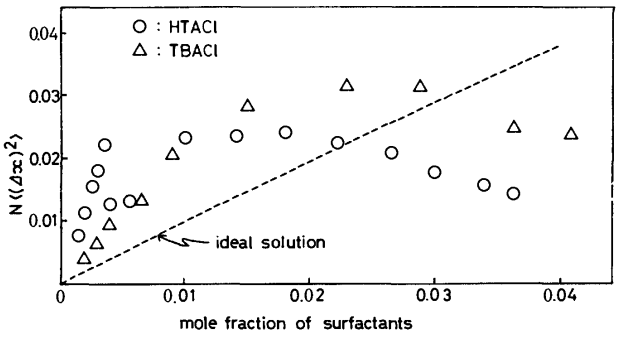

Fig. 2. Observed concentration fluctuation for TBACl-chloroform system.

where $\bar{x}$ is smaller than 0.004, the concentration fluctuation of HTACl increases rapidly with increasing $\bar{x}$, and decreases sharply at $\bar{x}=0.004$. In the concentration range of $\bar{x}>0.004$, it again increases gradually with increasing $\bar{x}$. The concentration flutuaction of TBACl, however, does not exhibit such singular concentration dependence in the low concentration region. These results suggest that the surfactant molecules aggregate with each other, in addition to the aggregation with chloroform molecules. The infrared data, on the other hand, suggests that these surfactant molecules form strong hydrogen bonds with chloroform molecules. Therefore, it is expected that an aggregate of the type A_lB_{ln} exist in these solutions, where l is the aggregation number of surfactants and n is the solvation number of chloroform per one surfactant molecule, where A and B refer to surfactant and chloroform molecules, respectively.

Analysis of $N\langle(\Delta x)^2\rangle$. Analysis of the observed concentration fluctuation employed the so-called association complex model.[5,6] From the discussion in the preceding paragraph, it may be assumed that an aggregate of the type A_lB_{ln} and a free chloroform molecule, B_1, behave as independent molecules in the solution. Aggregates of the type A_l may be assumed negligible since the analysis of infrared absorption intensity has shown that all surfactant molecules form hydrogen bonds with chloroform molecules in this concentration range. Aggregates of the type B_l may be assumed negligible since the hydrogen bonding between chloroform molecules is very weak in comparison with that between chloroform and surfactant molecules.[9]

Assuming that A_lB_{ln} and B_1 behave as independent molecules in the solution, the probability, $f(N_A)$, of finding N_A numbers of A molecules within the region which contains a constant number, N, of molecules may be expressed as[6]

$$f(N_A)=\frac{(N_1+N_2)!}{N_1!N_2!}P^{N_1}(1-P)^{N_2}, \tag{2}$$

with

$$N_1 = N - nN_A$$
$$N_2 = N_A/l$$
$$P = \bar{N}_1/(\bar{N}_1+\bar{N}_2)$$

where N_1 and N_2 are molecular numbers of aggregates, B_1 and A_lB_{ln}, respectively. Then, the number fluctuation of A molecules in the region considered may be calculated thus

$$\langle(\Delta N_A)^2\rangle_N = \frac{-1}{(\partial^2 \ln f(\bar{N}_A)/\partial \bar{N}_A{}^2)_N}$$
$$= \frac{\bar{N}_A}{N^2}[N-(n+1)\bar{N}_A] \times [lN-\{l(n+1)-1\}\bar{N}_A]. \tag{3}$$

Therefore, the concentration fluctuation may be expressed as:

$$N\langle(\Delta x_A)^2\rangle = \bar{x}_A[1-(n+1)\bar{x}_A] \times [l-\{l(n+1)-1\}\bar{x}_A]. \tag{4}$$

Figure 3 demonstrates the concentration dependence of the concentration fluctuation calculated from Eq. 4 for $l=2$ and for various n-values, together with the observed concentration fluctuation values for TBACl solution. The figure demonstrates that the concentration fluctuation decreases in magnitude as n increases. The theoretical curve for $n=10$ best explains the curve in the sence that the concentration fluctuation takes a maximum value at $\bar{x} \approx 0.03$. Figure 4 demonstrates the concentration dependence of the concentration fluctuation calculated from Eq. 4 for $n=10$ and various l-values. The figure demonstrates that the concentration fluctuation increases in magnitude as l increases

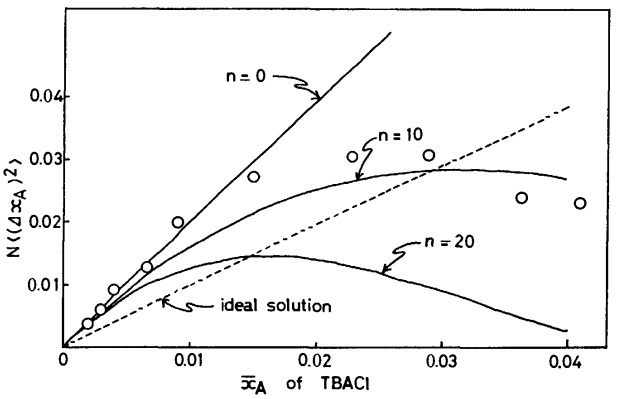

Fig. 3. Theoretical values of concentration fluctuation calculated from Eq. 4 for $l=2$ and $n=0$, 10, and 20. The open circles correspond to observed values for TBACl-chloroform system.

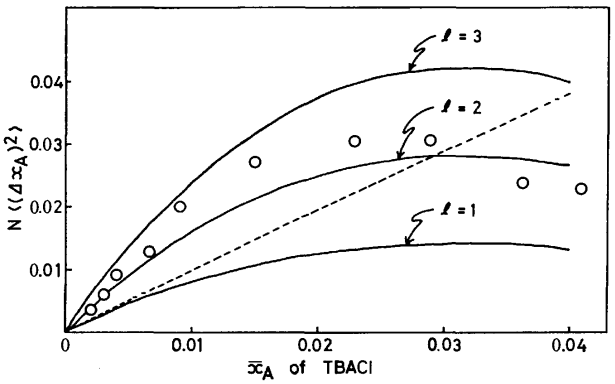

Fig. 4. Theoretical values of concentration calculated from Eq. 4 for $n=10$, and $l=1$, 2, and 3.

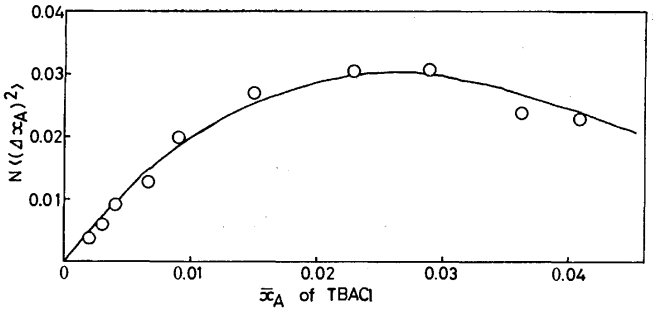

Fig. 5. Final results of theoretical calculation for TBACl-chloroform system ($l=2.6$, $n=12$).

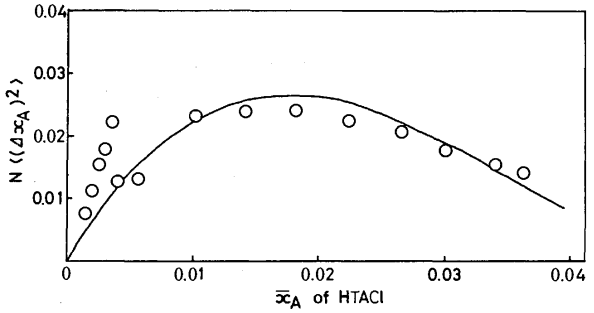

Fig. 6. Final results of theoretical calculation for HTACl-chloroform system ($l=3.4$, $n=18$).

without change in function, *i.e.*, the concentration at which the concentration fluctuation takes a maximum value is almost independent of l-values. The best fit between the calculated and the observed concentration fluctuation curves was obtained by setting $l=2.6$ and $n=12$ for TBACl solution and $l=3.4$ and $n=18$ for HTACl solution. The theoretical calculations are shown in Figs. 5 and 6.

Local Structure in the Solution. The present results may be summarized as follows. The surfactants studied dissolve in chloroform by forming an aggregate which is made up of a few surfactant molecules and several decades of chloroform molecules. This conclusion is in apparent contrast to the conclusion drawn from the infrared analysis, in that there, the indication is that the surfactants dissolve in chloroform by forming complexes which are made up of several chloroform molecules and one surfactant molecule.[1] Table 1 shows the value of l and n obtained from the present study, together with the n-values obtained from the infrared study, n_{IR}. It was to be expected that the n and n_{IR} values would not agree and the difference is thought to be real. From the intensity ratio of the infrared absorption bands corresponding to the free and the bonded chloroform molecules, the number ratio of free and bonded chloroform molecules may be determined. Therefore, the infrared result affords rigorous information about the number of chloroform molecules which are directly attached to the surfactant molecules by hydrogen bonds. In the light scattering study, however, the molecular aggregate which behaves as a single molecule in solution is important, since concentration fluctuation is determined by the spatial distribution of component molecules in solution.

Table 1. l and n values obtained in the present study and n_{IR} values obtained from the infrared absorption study for chloroform solutions of TBACl and HTACl

	TBACl	HTACl
l	2—3	3—4
n	12	18
n_{IR}[a)]	2	4—4.5

a) See Ref. 1.

Combining results obtained from these light scattering and infrared absorption studies indicate a double-layered aggregate structure formed in the solutions; l numbers of surfactant molecules make a core of the aggregate and the core is surrounded by $(l\times n)$ numbers of chloroform molecules. Among the $(l\times n)$ numbers of chloroform molecules in one aggregate, $(l\times n_{IR})$ numbers of chloroform molecules form hydrogen bonds directly with the surfactant molecules and make a first shell. The remaining $l(n-n_{IR})$ numbers of chloroform molecules envelope the first shell by weak intermolecular interactions.

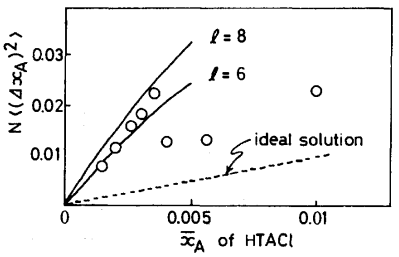

Fig. 7. Observed and calculated concentration fluctuation for HTACl-chloroform system in the region of $x_A \leq 0.01$.

The singular behavior of the concentration fluctuation observed for HTACl solution at low concentration is of some interest. Figure 7 shows the observed and calculated concentration fluctuation in the region where $\bar{x}_A$ is smaller than 0.01. As can be seen from Eq. 4, concentration fluctuation is only marginally affected by n for small values of $\bar{x}_A$, that is, it is largely dependent on l. Therefore, a dummy number of 18 was set for the n-value in the theoretical calculation. From the figure the number of the surfactant molecules making an aggregate was determined to be 6—8 for HTACl. In TBACl solution, on the other hand, such singular concentration dependence of concentration fluctuation was not observed. This difference may arise from the molecular structure of HTACl which favors the aggregation of HTACl in chloroform.[10]

This work was partly supported by a research grant from the Ministry of Education.

10) The refree's comment has been against the experimental result itself. It says that this singular behavior of the concentration fluctuation may arise from the existence of "impurity" in the observed system. We think this may or may not be so, because we could not recognize the existence of any impurities by the use of our experimental technique. We feel it is more important to report the fact that the *l*-value of 6—8 was obtained from our experimental result and from our theoretical analysis, because it suggests the fact that the aggregation number in the low concentration range is larger than that in the high concentration range.

The Reactions of Dichlorotriazinyl Reactive Dyes with Cellulose and Simultaneous Diffusion in Cellulose

Hiromi MOTOMURA and Zenzo MORITA

Department of Textiles and Polymer Science, Faculty of Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received October 17, 1977)

The diffusion coefficients and rate constants of the reactions of C. I. Reactive Yellow 4, Orange 1, and Red 1 were measured at 30 °C by means of a cylindrical cellophane film roll. The diffusion coefficients of the three hydrolyzed dyes were nearly constant at all the pH values examined. The apparent diffusion coefficients of all the active species of Orange 1 and Red 1 except Yellow 4 were gradually decreased with an increase in the pH of the dyebath; this decrease was due to the hydrolysis of the active species in the cellulose substrate. The rate constants of the reactions with cellulose were of a pseudo-first-order; *i.e.*, the second-order rate constants of reactions with cellulose were constant up to a certain pH, and thereafter they decreased with an increase in the pH of the dyebath. The pH dependence of the reactivity with cellulose was similar to that of the hydrolysis reported previously. The concentration profiles of the removed and immobilized species in cellulose dyed from a weakly alkaline dyebath agreed with the theoretical profiles of active and reacted species respectively. From a highly alkaline dyebath, those of the immobilized species agreed with the theoretical profiles of reacted species, while those of the removed ones did not agree with theoretical profiles of active species because of hydrolysis.

Only a few works on the reaction of reactive dyes with cellulose have been reported,[1-3] though there have been many studies of the mechanisms on the reactive dyeing.[4,5] The reactivities of mono- and dichlorotriazinyl reactive dyes have been examined through reactions with water[6-15] and with alcohols as a model for cellulose.[1,7,10-13] The rate of the reaction of reactive dyes with cellulose must be derived from the theory of the diffusion with a simultaneous reaction in solid cellulose. Preston and Fern have obtained the diffusion coefficients and the rate constants of reactions with cellulose from Danckwart's equation by measuring the total amount of reactive dye on the substrate.[1]

In a previous paper, the theoretical equations which described the concentration profile of the immobilized species of reactive dyes in the substrate were derived from the diffusion equation with a chemical reaction of the first-order or pseudo-first-order.[3] A new method by which the reaction-rate constants of dye with cellulose could be obtained from the concentration profiles of reactive dyes was presented, though the basic diffusion equation used was the same as that of Preston and Fern. The profiles were measured from the cylindrical-film-roll method, where, after the diffusion, the immobilized profile was experimentally obtained by removing the active and hydrolyzed species by scouring; it corresponded to the theoretical distribution of reactive dyes fixed by the chemical reaction with cellulose.

In the present paper, the reaction-rate constants of dichlorotriazinyl reactive dyes will be obtained from the concentration profiles of the immobilized species by using the same method as in the previous paper[3] and will be discussed in comparison with those of hydrolysis and alcoholysis.[6-15] The diffusion coefficients of active and hydrolyzed species will also be measured.

Experimental

Films. Cellophane films (#300, Tokyo Cellophane Sheet Co., Ltd.) were cut 5 cm wide and 60 cm long and scoured several times in boiling water for 2 h. The thickness of a swollen film was measured to be 3.68×10^{-3} cm. The cylindrical film roll was made by the usual method.

Reactive Dyes and Reactive Dyeing. Three reactve dyes manufactured and supplied by the Nippon Kayaku Co., Ltd., were used, and the dyeing was performed at 30 °C under the dyebath conditions shown in Table 1. The reagents for the buffer solutions used in order to adjust the pH of the dyebath were KH_2PO_4 and $Na_2B_4O_7$ from pH 6.8 to 9.0, $Na_2B_4O_7$ and Na_2CO_3 from 9.2 to 11.0, and Na_2HPO_4 and NaOH at pH 12. NaCl was added to adjust the ionic strength of the dyebath.

In order to exclude the influence of the hydrolyzed species in the dyebath, a constant feed of the stock solutions of both the reactive dye and the buffer was carried out by the use of a quantitative pump, and the same amount of solutions used as feed was allowed to overflow. A cylindrical cellophane roll was dipped into the dyebath for a prescribed time. After the dyeing, it was immediately opened and the layers from the surface were cut off in halves. One film cut off was promptly scoured in boiling water for 20 min to remove the unreacted dye with cellulose and was dried after scouring. The other one was also dried, but without scouring.

TABLE 1. DYEING CONDITIONS

C. I. Reactive	Mikacion dyes	Ionic strength	Concentration of dyebath (mol/dm³)	Concentration of dyebath (g/dm³)	Dyeing time (h)
Yellow 4	Yellow RS	0.15	1.93×10^{-4}	0.15	1—12
		0.15	3.86×10^{-4}	0.30	
Orange 1	Brilliant Orange GS	0.15	5.36×10^{-4}	0.60	1— 6
Red 1	Brilliant Red 2BS	0.15	6.45×10^{-4}	1.0	1— 4
		0.50	6.45×10^{-4}	1.0	

Dyeing with Hydrolyzed Dyes at Various pHs and with Reactive Dyes at pH 6.8. As the reactions with cellulose were not observed, the diffusion coefficients of the reactive dye at pH 6.8 and those of the hydrolyzed one at various pHs were measured by the Sekido-Matsui method using a cylindrical cellophane film roll, as the concentration profiles in this case were Fickian.[16] The concentration profiles obtained in these experiments or the dyes adsorbed could be completely removed by the scouring of the films dyed with the hydrolyzed species and the active ones at pH 6.8. A purified sample of the hydrolyzed species was prepared by the hydrolysis of the reactive dyes and by salting-out with sodium acetate.[3]

Concentration Profiles of Immobilized and Removed Dyes and Determination of Reaction-Rate Constants, k. The concentrations of the dyes in the films were obtained by measuring the optical densities at the wavelength of the maximum absorption of the dye by means of a Shimadzu 40S spectrophotometer. The calibration curves of the reactive dyes in the film were made with the hydrolyzed and purified dye as the reference in molar concentration. The concentration profile of the immobilized dyes was obtained from the scoured film after dyeing, and that of the removed dyes, from the difference between the concentrations of the scoured and unscoured films at each layer. The former corresponds to the concentration of reactive dye reacted with cellulose, and the latter, theoretically to the active species not yet reacted with cellulose if there were no or little reaction with water in cellulose. The dyes reacted with cellulose were not removed, as was confirmed by no coloration of the renewed scouring solution and by no hydrolysis of the dye-fiber bond under all the dyeing conditions.

The reaction rate-constant, k, was approximately determined from the relation between k and the ratio of the fixed dye to the total dye in the first layer (*cf.* Ref. 3, Fig. 6). The surface concentration, C_o, could be obtained by the extrapolation of the profile of the removed dye. The diffusion coefficients, D, k, and C_o, obtained above were modified so as to fit the experimental profile to the theoretical one by means of a trial-and-error method with a computer. Under highly alkaline conditions, they were obtained from the fitting of the experimental profile for the immobilized species to the theoretical one. In order to avoid the contrary modification of C_o and obtain a highly reliable value of C_o, several experiments were carried out for different dyeing times under certain dyebath conditions. The most satisfactory values of C_o, k, and D especially were evaluated from the experimental profiles for different dyeing times.

Results and Discussion

Diffusion of Reactive Dyes. Some experimental profiles of the immobilized and removed species in cellulose are shown in Figs. 1—3. As has been mentioned previously, the concentration profiles of immobilized and active species for reactive dyes in cellulose could be described by theoretical equations derived from the diffusion equation with a chemical reaction of a pseudo-first-order:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - kC, \qquad (1)$$

where C(mol/kg) was the concentration of active species, t(min) was the time, x(cm) was the distance, and k (min^{-1}) was the pseudo-first-order rate constant of the reaction with cellulose, provided that the diffusion coefficient, D(cm^2/min), of the active species was constant. This equation was solved under the conditions of an infinite dyebath, *i.e.*, a constant surface concentration, C_o.[3] The theoretical profiles of the fixed and active species are also shown in the figures.

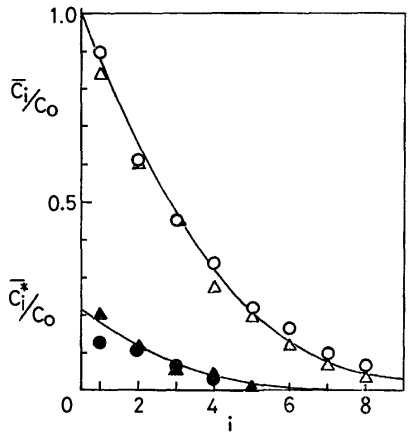

Fig. 1. Concentration profiles of the active (○, △) and immobilized species (●, ▲) of C. I. Reactive Red 1 at pH 7.6 (I=0.5), 30 °C and for 2 h. Results from two experiments under the same condition are shown. The lines in figure are the theoretical ones for $D=8.2\times10^{-7}$ cm^2/min and $k=2.0\times10^{-3}$ min^{-1}.

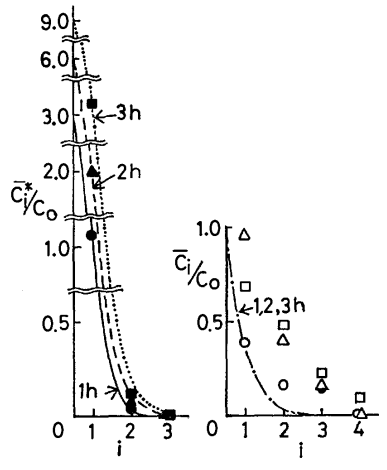

Fig. 2. Concentration profiles of the active (○ at 1 h, △ at 2 h, and □ at 3 h) and immobilized species (● at 1 h, ▲ at 2 h, and ■ at 3 h) of C. I. Reactive Orange 1 at pH 11.6 (I=0.15) and 30 °C. The lines in figure are the theoretical ones for $D=1.0\times10^{-7}$ cm^2/min and $k=5.0\times10^{-2}$ min^{-1}.

The concentration profiles obtained experimentally are classified into three types by comparing them with the theoretical profiles of the immobilized and active species. Type 1 consists of profiles dyed from a weakly alkaline dyebath; a typical example is shown in Fig. 1, where the agreements between the experimental profiles of the immobilized and removed species and the theoretical profiles of fixed and active species, and their reproducibility are fairly good. Type 2 consists of profiles dyed from a moderately alkaline dyebath; it is shown in Fig. 2, where the experimental immobilized profiles for different diffusion times are in agreement

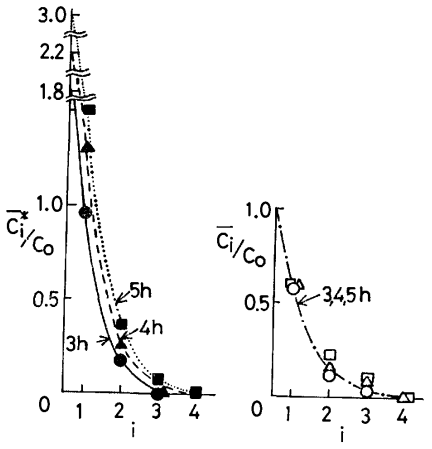

Fig. 3. Concentration profiles of the active (○ at 3 h, △ at 4 h, and □ at 5 h) and immobilized species (◐ at 3 h, ▲ at 4 h, and ■ at 5 h) of C. I. Reactive Yellow 4 at pH 9.2 (I=0.15) and 30 °C. The lines on figure are theoretically described by Eqs. 7 and 8 of Ref. 3 (D=9.0×10^{-8} cm^2/min, k=1.0×10^{-2} min^{-1}).

with the theoretical profiles for the fixed species, but the removed ones are not in agreement with that for the active species. Type 3 is intermediate between them and is shown in Fig. 3, where the profiles of the immobilized species for different diffusion times are in agreement with the theoretical profiles of the fixed species, but the experimental profiles of the removed species penetrated more deeply than the theoretical ones. The theoretical profiles for the active species shown in Figs. 2 and 3 are asymptote and show that no active species can penetrate more deeply than the line. Theoretically, all the active species adsorbed from the dyebath are reacted with cellulose, and the distribution of active species is in the equilibrium state. The experimental profiles of the removed species shown in Fig. 2, however, penetrated the more deeply, the longer the diffusion times. As the penetrations of fixed and active species must be theoretically in agreement with each other,[3] there should be inactive or hydrolyzed species in cellulose during diffusion. There would be other reasons for the minor possibility that the hydrolyzed dyes in the alkaline dyebath were also adsorbed, though the concentration of active species in the dyebath was kept constant and the surface concentration of active species was not varied during the dyeing, or that the species immobilized by the reaction with cellulose were mobilized again by the hydrolysis of the dye-fiber bond. The last possibility was experimentally confirmed to be so small that the reaction-rate constant, k, was not practically influenced at 30 °C below pH 12.0 under the experimental conditions of the present study.

Because of the agreement between the experimental and theoretical profiles for the immobilized species, and because of the disagreement between the removed or experimental profile and the active or theoretical one under highly alkaline conditions, the D and k of active species were determined from the immobilized profiles. The D and C_0 at various pHs are compared with those

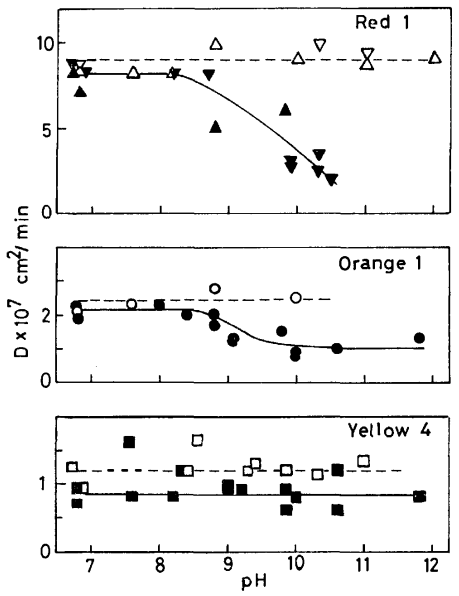

Fig. 4. Apparent diffusion coefficients of the active (solid symbols) and hydrolyzed species (open symbols) at 30 °C and I=0.15. In the case of Red 1, results for I=0.15 (▽ and ▼) and for I=0.5 (△ and ▲) are shown.

of hydrolyzed species in Figs. 4 and 5. Though the C_0 of the hydrolyzed species were slightly decreased with an increase in the pH, the C_0's of the active species were almost constant under the alkaline conditions above pH 8. This shows that C_0 can actually be kept constant at a highly alkaline pH if a sufficient amount of electrolytes is added to the dyebath. Sumner and Taylor have reported, after using the dye base and diamino derivatives of three Procion dyes, the complicated findings that the affinities of Yellow 4 were constant over the whole pH range between 8 and 13, while those of Red 1 were constant up to pH 10 and then decreased slightly with an increase in the pH.[17] Although the standard affinities of reactive dyes for cellulose could not be calculated, as no alkaline adsorption by cellulose was measured in the present study, the adsorption behavior of the active and hydrolyzed species for the three reactive dyes used all appeared to have the same pH dependence.

At pH 6.8, the D values of the hydrolyzed species for the three dyes were slightly larger than those of the active species (Fig. 4). Sumner and Taylor also observed that the D values of the dye bases for three Procion dyes were larger than those of diamino derivatives and estimated that those of active species were intermediate.[17] Although they reported the complicated diffusional behavior of three Procion dyes at various pH values between 8 and 13, the D values of the hydrolyzed species for the three reactive dyes used in the present study appeared to be constant over the whole pH range examined (Fig. 4). However this behavior for Yellow 4 appeared to be in accordance with their results.

On the other hand, the D values of the active species for Orange 1 and Red 1, as estimated from the diffusion profiles of the immobilized species, apparently decreased with an increase in the pH, and that for Yellow 4 was nearly constant over the whole pH range examined. The decreasing tendency of the D for Red 1 was larger than that for Orange 1. As was mentioned in the previous paper (*cf.* Ref. 3, Fig. 1), some combinations of D and k described theoretically the concentration

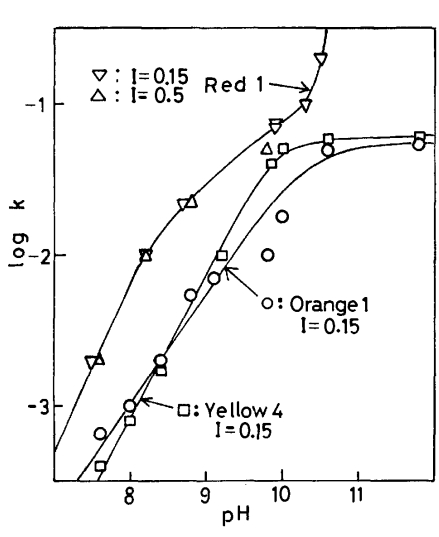

Fig. 6. Effect of pH on the rate constants of reaction with cellulose at 30 °C.

profiles of the immobilized and active species obtained from a diffusion experiment. Because the k values of active species could be estimated by various methods, because their obtained values coincided with each other, and because the pH dependence of k was similar to that of the rate constants of hydrolysis (*cf.* Fig. 6), the values of k obtained can be considered reasonable. If the D of an active species was estimated from the profile of the immobilized species with the value of k obtained above, however, it was smaller than the D of the hydrolyzed species under highly alkaline conditions. It is notable that the dyes with larger D values of the active species have a larger decreasing tendency than those with smaller ones do. It has been also shown in the previous paper that the larger the D of the active species and the smaller the k, the deeper was the penetration of immobilized and active species of reactive dyes into the substrate.[3] Thus, the dyes with larger k values are hindered in penetrating into the substrate. In spite of the fact that the D in the present study was estimated considering this effect, a cosiderably large rate of reaction with water in cellulose would be expected under highly alkaline conditions if the D of active species was constant over the whole pH range and was equal to that at pH 6.8. However, the detailed studies of the mechanism of the pH dependence for D and of the differences among the reactive dyes are now under way.

Reaction with Cellulose. The reaction-rate constants, k, determined from the immobilized profiles at various pHs are shown as relationships between log k and pH in Fig. 6. The relationships were similar to that of hydrolysis measured by Ingamells *et al.* at 20 °C.[7] They observed two kinds of relations between the rate of hydrolysis and the pH. Such a relation is also found in Fig. 6; *i.e.*, the effect of the pH on the reactivity for Yellow 4 and Orange 1 is different from that for Red 1. In the cases of Yellow 4 and Orange 1, log k had a constant slope up to pH 11. The rate constants of the hydrolysis for Yellow 4 and Red 1 were measured to be 0.016 and 0.060 min^{-1} respectively by Sumner and Vickerstaff at pH 11 and 30 °C.[18] According to Dawson *et al.*, they were 0.0175 min^{-1} for Yellow 4 and 0.055 min^{-1} for Red 1.[6] Comparing the rate constants of the reaction with cellulose for Yellow 4 in the present study with those of hydrolysis quoted above, the former value was about 5 times larger than the latter at pH 11, though the ionic strength and the kind of buffer solution were different. Although the k of Red 1 at pH 11 was too large to be obtained by measuring the optical densities of the immobilized species on cellophane, it was estimated by extrapolation of the k-pH relationship in Fig. 6 and thus found to have the value of 0.6—1.0 min^{-1}, 10—17 times larger than that of the hydrolysis. The rate constants of the reaction with cellulose for Red 1 measured by Preston and Fern at 20 °C were 25—11 times larger than those of the hydrolysis over the pH range between 9.5 and 12.8.[1] The ratio of the constants of the reaction with cellulose to those of hydrolysis may differ with the kind of reactive dye. On the other hand, the effect of the ionic strength on the rate of reaction with

cellulose for Red 1 was investigated by changing the salt concentration added to the dyebath. As is shown in Fig. 6, no influences on the rate constants by the ionic strength were observed within the range of experimental error.

The authors would like to thank the Nippon Kayaku Co., Ltd., for the assistance of its staff in the preparation of this paper.

The Effects of Halide Ions on the Radiation-induced Decoloration of Azo and Anthraquinone Dyes in N_2O-saturated Aqueous Solutions

Nobutake SUZUKI, Okihiro TOKUNAGA, and Masamitsu WASHINO

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma 370-12

(Received November 18, 1977)

The radiation-induced decoloration of azo and anthraquinone dyes was studied in N_2O-saturated aqueous solutions containing halide ions. In the N_2O-saturated solutions, the decoloration yield, $G(-\text{Dye})$, increased markedly upon the addition of Br^- and I^-, which are efficient scavengers of the OH radical. In the nitrogen-saturated solutions, however, the $G(-\text{Dye})$ decreased upon the addition of Br^- and I^-. Such an increase in the $G(-\text{Dye})$ upon the addition of Br^- and I^- in the N_2O-saturated solutions is mainly attributable to the attacks of the halide radical anions, Br_2^- and I_2^-, on the ring structure of the dyes. On the other hand, the $G(-\text{Dye})$ was not changed upon the addition of Cl^- in the N_2O-saturated solution. This may be attributable to the very slow rate of the formation of Cl_2^- in a neutral solution.

In a preceding paper,[1] we studied the effect of NCS^- on the radiation-induced decoloration of Acid Red 265 (azo dye) and Acid Blue 40 (anthraquinone dye) in N_2O-saturated aqueous solutions and found that the $G(-\text{Dye})$ increased markedly upon the addition of NCS^-, which is an efficient scavenger of the OH radical; we concluded that such an increase in the $G(-\text{Dye})$ was mainly attributable to the attack of the radical anion $(NCS)_2^-$, which is formed through Reactions 1 and 2, on the ring structure of the dyes;

$$NCS^- + OH \longrightarrow NCS + OH^-, \quad (1)$$

$$NCS + NCS^- \rightleftarrows (NCS)_2^-. \quad (2)$$

It is known that, in analogy with NCS^-,[2,3] in pulse-irradiated N_2O-saturated solutions halide ions, X^-, react rapidly and quantitatively with the OH radicals to form halide radicals, following the formation of halide radical anions, X_2^-:[3-7]

$$X^- + OH \xrightarrow{k_3} X + OH^-, \quad (3)$$

$$X + X^- \rightleftarrows X_2^-. \quad (4)$$

An effect similar to that of NCS^- on the radiation-induced decoloration of dyes may, therefore, be expected in the N_2O-saturated solutions containing halide ions. In this paper, the effects of Cl^-, Br^-, and I^- on the radiation-induced decoloration of azo and anthraquinone dyes were investigated in order to demonstrate the reaction scheme of inorganic radical anions with the dyes more clearly.

Experimental

The experimental procedures were the same as in the preceding work.[1,8,9] The dye solutions were prepared by dissolving recrystallized Acid Red 265 (C. I. 18129)[8] or Acid Blue 40 (C. I. 62125)[9] in triply distilled water. The dye solutions were bubbled with N_2O for 20 min prior to irradiation and were then irradiated with cobalt-60 gamma rays at room temperature. In some experiments, nitrogen was bubbled in for 30 min prior to irradiation.

The absorption spectra were measured with a Shimadzu UV-200 spectrophotometer. The decoloration yield, $G(-\text{Dye})$, was determined by measuring the optical density at 542 nm for Acid Red 265 and at 610 nm for Acid Blue 40.

Results and Discussion

N_2O-saturated Acid Blue 40 Solutions. The $G(-\text{Dye})$ for the N_2O-saturated 0.1 mM Acid Blue 40 solutions containing halide ions (Cl^-, Br^-, and I^-) (initial pH 6.1—6.8) is shown as a function of the halide ion concentrations in Fig. 1. In the solutions containing Br^- and I^-, the $G(-\text{Dye})$ increased steeply with an increase in the Br^- and I^- concentrations up to about 4 mM Br^- and 0.4 mM I^-; then it increased gradually above about 4 mM Br^- and 0.4 mM I^-. The $G(-\text{Dye})$ increased up to 2.07 (at 10 mM Br^-) and 1.84 (at 1 mM I^-) upon the addition of halide ions from 0.51 for the N_2O-saturated solution without halide ions. In the N_2O-saturated solution containing Cl^-, however, the $G(-\text{Dye})$ was almost equal to that (0.51) for the N_2O-saturated solution without halide ions, even upon the addition of 20 mM Cl^-. It is noteworthy that the tendency of the $G(-\text{Dye})$—Br^- and I^--concentration curves is similar to that of the $G(-\text{Dye})$—NCS^--concentration curve, shown in Fig. 2 in our preceding paper.[1] The increase in the G-

Dye concentration: 0.1 mM. Dose: 1.8×10^4 rad.
Cl^- (□), Br^- (○), and I^- (△).

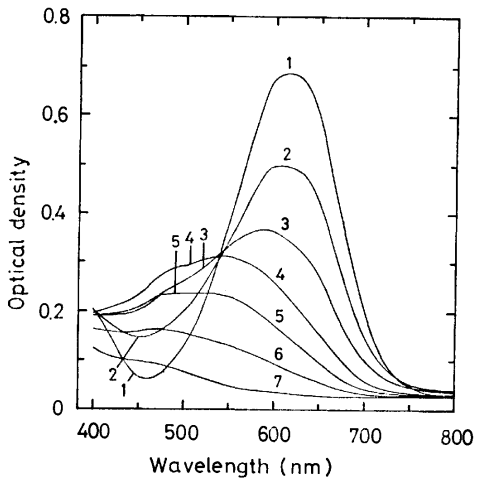

Fig. 2. Absorption spectra of unirradiated and irradiated N_2O-saturated Acid Blue 40 solutions containing 10 mM Br^-.
Dye concentration: 0.1 mM. Doses (rad): 0 (Curve 1), 1.8×10^4 (Curve 2), 3.7×10^4 (Curve 3), 5.5×10^4 (Curve 4), 1.1×10^5 (Curve 5), 2.2×10^5 (Curve 6), and 3.9×10^5 (Curve 7).

(—Dye) upon the addition of halide ions was in the order of $I^->Br^->Cl^-$ at the same concentrations. This order almost corresponds to the order of the rate constants for the reactions of halide ions with OH radicals in neutral solutions[10,11] (the rate constant for Cl^- was referred to the value at pH 9). The absorption spectrum of an unirradiated N_2O-saturated solution did not change upon the addition of halide ions. Also, scarcely no new absorption bands appeared in the wavelength range of 400 to 800 nm upon the irradiation of the N_2O-saturated Cl^-, Br^-, and I^- solutions without the dye. On the other hand, the G(—Dye) in the nitrogen-saturated solutions decreased to 0.10 (at 10 mM Br^-) and 0.07 (at 1 mM I^-) upon the addition of halide ions from 0.18 for the nitrogen-saturated solution without halide ions. In the nitrogen-saturated solution containing Cl^-, the G(—Dye) was almost equal to that (0.18) for the nitrogen-saturated solution without halide ions, even upon the addition of 20 mM Cl^-.

The radiation-induced decoloration scheme of Acid Blue 40 in the nitrogen-saturated solution has been presented in a preceding paper[9] as follows:

$$AB + OH \xrightarrow{k_5} ABOH \longrightarrow \text{decolored product}, \quad (5)$$

$$AB + OH \longrightarrow ABOH' \longrightarrow \text{colored product}, \quad (6)$$

$$AB + e^-_{aq} \longrightarrow AB_{red} \text{ (decolored product)}, \quad (7)$$

$$AB + e^-_{aq} \longrightarrow AB'_{red} \text{ (colored product)}, \quad (8)$$

where AB, ABOH, and AB_{red} are Acid Blue 40, its OH adduct, and its reduction product by the attack of the hydrated electron respectively. In the N_2O-saturated solution, however, the hydrated electrons are converted into the OH radicals by Reaction 9:[12]

$$N_2O + e^-_{aq} \longrightarrow OH + OH^- + N_2. \quad (9)$$

In such systems, the rate constants of the hydrated electron with N_2O and Acid Blue 40 are $8.7\times10^9\ M^{-1}\ s^{-1}$ at pH 7[13] and $1.5\times10^{10}\ M^{-1}\ s^{-1}$ at pH 5.1—6.3[9] respectively. In the N_2O-saturated 0.1 mM Acid Blue 40 solution, since the N_2O concentration (about 3×10^{-2} M) is about 300 times larger than the dye concentration, a large portion of the hydrated electrons are converted into the OH radicals, because $(8.7\times10^9\ M^{-1}\ s^{-1})\times(3\times10^{-2}\ M)\gg(1.5\times10^{10}\ M^{-1}\ s^{-1})\times(1\times10^{-4}\ M)$. In the N_2O-saturated solution, therefore, Acid Blue 40 is decolored only by Reaction 5.

In the N_2O-saturated 0.1 mM Acid Blue 40 solutions containing Br^- and I^-, most of the OH radicals react rapidly with Br^- and I^- to form the Br and I radicals above about 2 mM Br^- and 0.2 mM I^-, because k_3 $(1.2\times10^9\ M^{-1}\ s^{-1}$ at pH 7 for Br^-[10]$)\times[Br^-]$ and k_3 $(1.02\times10^{10}\ M^{-1}\ s^{-1}$ at neutral for I^-[10]$)\times[I^-]$ are larger than k_5 $(6.6\times10^9\ M^{-1}\ s^{-1}$ at pH 5.1—6.3[9]$)\times$ [Dye], following the formation of the halide radical anions, Br_2^- and I_2^-, by Reactions 3 and 4.[3,5-7] In a neutral solution containing Cl^-, however, the rate of the formation of Cl_2^- by Reactions 3 and 4 is very slow.[4,10,14]

In our preceding paper,[1] we concluded that the increase in the G(—Dye) upon the addition of NCS^- in the N_2O-saturated solution was mainly attributable to the attack of the radical anion $(NCS)_2^-$ formed through Reactions 1 and 2 on the ring structure of the dye as follows:

$$AB + (NCS)_2^- \longrightarrow (AB(NCS)_2)^- \longrightarrow \text{decolored product}, \quad (10)$$

$$AB + (NCS)_2^- \longrightarrow (AB(NCS)_2)^{-\prime} \longrightarrow \text{colored product}. \quad (11)$$

According to the earlier studies of the radiation-induced inactivation of lysozyme in the N_2O-saturated solutions containing halide ions,[14,15] the inactivation was caused by a reaction between lysozyme and the halide radical anion:

$$\text{lysozyme} + X_2^- \longrightarrow \text{inactive product}. \quad (12)$$

Adams *et al.*[14,15] suggested the possibility that the site of the X_2^- attack is the ring structure of tryptophan in lysozyme; that is, the reaction with X_2^- is a direct addition to the ring structure of tryptophan (T):

$$T + X_2^- \longrightarrow (TX_2)^-. \quad (13)$$

Consequently, it may be concluded from these facts that the increase in the G(—Dye) upon the addition of Br^- and I^- in the N_2O-saturated solutions is mainly attributable to the attacks of the halide radical anions, Br_2^- and I_2^-, formed through Reactions 3 and 4 on the Acid Blue 40 molecule as follows:

$$AB + Br_2^- \text{ (or } I_2^-) \longrightarrow (ABBr_2)^- \text{ (or } (ABI_2)^-) \longrightarrow \text{decolored product}, \quad (14)$$

$$AB + Br_2^- \text{ (or } I_2^-) \longrightarrow (ABBr_2)^{-\prime} \text{ (or } (ABI_2)^{-\prime}) \longrightarrow \text{colored product}. \quad (15)$$

The Acid Blue 40 molecule has two kinds of reaction sites for Reactions 14 and 15: (a) the anthraquinone ring, and (b) the substituted benzene ring, not conjugated to the carbonyl group in the anthraquinone ring. The attack of the halide radical anions, Br_2^- and I_2^-, on Site b is independent of the decoloration

reaction. The increase in the $G(-\text{Dye})$ in Fig. 1 indicates that the halide radical anions, Br_2^- and I_2^-, destroy the dye chromophore more efficiently than does the OH radical. As has already been described, the $G(-\text{Dye})$ was not changed upon the addition of Cl^- in the N_2O-saturated solution. This may be attributable to the very slow rate of the formation of Cl_2^- in a neutral solution.[4,10,14]

The absorption spectra for the unirradiated and irradiated N_2O-saturated solutions containing 10 mM Br^- and 1 mM I^- are shown in Figs. 2 and 3 respectively. The absorption band at 610 nm in both the solutions disappear with an increase in the dose; at the same time, a new absorption band near 460—490 nm seems to appear slightly at a higher dose (Curves 4—7 in Figs. 2 and 3). This new absorption band scarcely appeared at all in the N_2O-saturated solutions without halide ions, however, as may be seen in Fig. 4 in the preceding paper.[1] The absorption band near 460—490 nm coincides approximately with that for the reduction products of Acid Blue 40 formed by the attacks of the hydrated electron and the alcohol radical on the carbonyl group in the anthraquinone ring.[9] The new absorption band which appeared in the solutions containing Br^- and I^- was also similar to that which appeared in the solution containing NCS^-, as may be seen in Fig. 3 in our preceding paper.[1] Consequently, it may be assumed that a part of the Acid Blue 40 is reduced by the attack of the halide radical anions, Br_2^- and I_2^-, on the carbonyl group in the anthraquinone ring, thus forming the reduction product as follows:

$$AB + Br_2^- \text{ (or } I_2^-) \longrightarrow AB_{red} \text{ (decolored product at 610 nm)}. \quad (16)$$

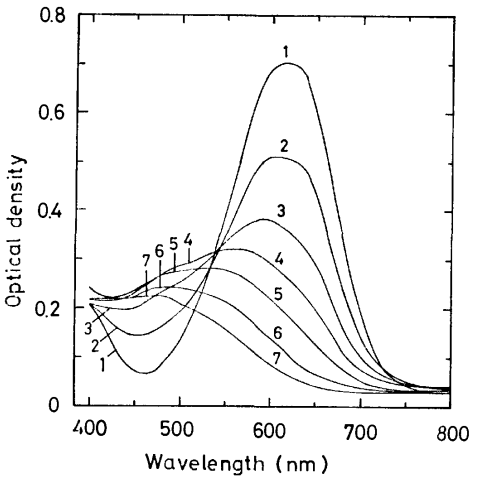

Fig. 3. Absorption spectra of unirradiated and irradiated N_2O-saturated Acid Blue 40 solutions containing 1 mM I^-.
Dye concentration: 0.1 mM. The number of the curves is the same with Fig. 2.

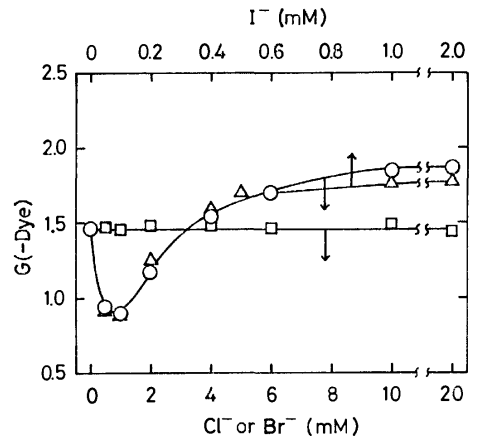

Fig. 4. Effect of halide ions on $G(-\text{Dye})$ in the N_2O-saturated Acid Red 265 solutions.
Dye concentration: 0.1 mM. Dose: 1.8×10^4 rad.
Cl^- (□), Br^- (○), and I^- (△).

On the other hand, the $G(-\text{Dye})$ for the nitrogen-saturated solutions decreased upon the addition of Br^- and I^-, as has already been described, in contrast to that for the N_2O-saturated solutions. This phenomenon was similar to that for the nitrogen-saturated solution containing NCS^-.[1] Reactions 17 and 18 may be considered as the reactions responsible for the decrease in the $G(-\text{Dye})$ upon the addition of Br^- and I^- in the nitrogen-saturated solution,[5,13] that is, the reactions of the hydrated electron with the halide radical anions, X_2^-, and the halide radicals, X, decreasing the X_2^- concentration:

$$X_2^- + e_{aq}^- \longrightarrow 2X^-, \quad (17)$$

$$X + e_{aq}^- \longrightarrow X^-. \quad (18)$$

Under the conditions of this study, the contribution of Reaction 17 to the decrease in the $G(-\text{Dye})$ is very large and that of Reaction 18 is very small, because the X and hydrated electron concentrations are negligibly small compared with the X^- concentration and the rate constants of the reactions of X with X^- [3,5] and of the hydrated electron with X_2^- [13] are very large.

N_2O-saturated Acid Red 265 Solutions. The $G(-\text{Dye})$ for the N_2O-saturated 0.1 mM Acid Red 265 solutions containing halide ions (Cl^-, Br^-, and I^-) (initial pH 6.4—6.9) is shown as a function of the halide ion concentrations in Fig. 4. In the solutions containing Br^- and I^-, the $G(-\text{Dye})$ decreased at first to 0.90 (at 1 mM Br^-) and 0.88 (at 0.1 mM I^-) upon the addition of halide ions, and then it increased with an increase in the Br^- and I^- concentrations up to about 10 mM Br^- and 1 mM I^-, in contrast to the results for the Acid Blue 40 solution in Fig. 1. The $G(-\text{Dye})$ increased up to 1.85 (at 10 mM Br^-) and 1.76 (at 1 mM I^-) upon the addition of halide ions from 1.46 for the N_2O-saturated solution without halide ions. In the N_2O-saturated solution containing Cl^-, however, the $G(-\text{Dye})$ was almost equal to that (1.46) for the N_2O-saturated solution without halide ions, even upon the addition of 20 mM Cl^-, analogous with the results for the Acid Blue 40 solution in Fig. 1. It is noteworthy that the tendency of the $G(-\text{Dye})$ —$Br^-$and I^- concentrations curves is similar to that of the $G(-\text{Dye})$—NCS^- concentration curve, shown in Fig. 5 in our preceding paper[1]. The absorption spectrum of an unirradiated N_2O-saturated solution was not changed upon the addition of halide ions. On the other hand,

the $G(-\text{Dye})$ in the nitrogen-saturated solution decreased to 0.25 (at 10 mM Br^-) and 0.27 (at 1 mM I^-) upon the addition of halide ions from 1.00 for the nitrogen-saturated solution without halide ions. In the nitrogen-saturated solution containing Cl^-, the $G(-\text{Dye})$ was almost equal to that (1.00) for the nitrogen-saturated solution without halide ions, even upon the addition of 20 mM Cl^-.

The radiation-induced decoloration scheme of Acid Red 265 in the nitrogen-saturated solution has been presented in a preceding paper[8] as follows:

$$AR + OH \longrightarrow AROH \longrightarrow \text{decolored product}, \quad (19)$$

$$AR + OH \longrightarrow AROH' \longrightarrow \text{colored product}, \quad (20)$$

where AR and AROH are Acid Red 265 and its OH adduct respectively.

In the N_2O-saturated Acid Red 265 solutions containing Br^- and I^-, the increase in the $G(-\text{Dye})$ is also mainly attributable to the attack of the halide radical anions, Br_2^- and I_2^-, formed through Reactions 3 and 4 on the Acid Red 265 molecule as follows:

$$AR + Br_2^- \text{ (or } I_2^-) \longrightarrow (ARBr_2)^- \text{ (or } (ARI_2)^-) \longrightarrow \text{decolored product}, \quad (21)$$

$$AR + Br_2^- \text{ (or } I_2^-) \longrightarrow (ARBr_2)^{-\prime} \text{ (or } (ARI_2)^{-\prime}) \longrightarrow \text{colored product}. \quad (22)$$

The Acid Red 265 molecule has two kinds of reaction sites for Reactions 21 and 22: (a) the aromatic rings connected directly to the azo group, and (b) the substituted benzene ring, not conjugated to the azo group. The attack of the halide radical anions, Br_2^- and I_2^-, on Site b is independent of the decoloration reaction. It is difficult for the direct attack of the halide radical anions, Br_2^- and I_2^-, on the azo group to take place because the azo group is stabilized by the hydrogen bonding with an adjacent OH group in a naphthalene ring.[8] Furthermore, the masking of the azo group can be expected because of the steric effect of the adjacent SO_3Na and CH_3 groups.[8]

The decrease in the $G(-\text{Dye})$ upon the addition of Br^- (up to 1 mM) and I^- (up to 0.1 mM) in Fig. 4 may be explained as follows.[1] At low Br^- and I^- concentrations, the halide radicals formed by Reaction 3 react with Acid Red 265 rather than with the halide ions to form mainly the colored product as in Reaction 23:

$$AR + X \longrightarrow ARX' \longrightarrow \text{colored product}, \quad (23)$$

thus decreasing the $G(-\text{Dye})$. As the Br^- and I^- concentrations increase, the halide radicals react with the halide ions rather than with Acid Red 265 to form the halide radical anions as in Reaction 4, thus increasing the $G(-\text{Dye})$. On the other hand, the decrease in the $G(-\text{Dye})$ upon the addition of Br^- and I^- was not observed in the N_2O-saturated Acid Blue 40 solution (Fig. 1). This may be attributable to the formation of both the decolored and colored products by the reaction of the halide radicals with Acid Blue 40 as in Reactions 24 and 25:

$$AB + X \longrightarrow ABX \longrightarrow \text{decolored product}, \quad (24)$$

$$AB + X \longrightarrow ABX' \longrightarrow \text{colored product}. \quad (25)$$

Linear Response Polarizability Theory of the UV, ORD, and CD Bandshapes of Helical Biopolymers. Single- and Double-Stranded Polyadenylic Acids

Hirotoshi Ito, Yasumasa J. I'Haya, and Toshiyuki Eri

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo 182

(Received November 24, 1977)

The UV, ORD, and CD spectral bandshapes of polyadenylic acid (poly A) have been investigated theoretically in order to challenge the problems of whether discrimination of the single- and double-stranded poly A's is computationally possible and of what structure poly A holds in a neutral solution. A linear response polarizability theory is applied to the derivation of UV, ORD, and CD bandshape functions of a polymer composed of N identical monomers. Using the observed and/or assumed values for the spectral bandshape of the adenine monomer, the UV, ORD, and CD spectra of both single- and double-stranded poly A's are calculated by changing geometrical parameters. The single-stranded poly A at neutral pH is assumed to have a regular helical structure which is regarded as a counterpart of the double helix form of the double-stranded poly A. This model leads to the chain-length (N) effect which in turn suggests that the structure of poly A in a neutral solution is very flexible and is such that it can be approximated as a random assembly of adenine dimers and/or trimers, when the theoretical spectra of both the single- and double-stranded poly A's are compared.

Amalgamation of the UV, ORD, and CD spectra in large molecules and molecular aggregates provides valuable information on conformation and property of the system, by which we are often able to disentangle the knots of incoherent prefiguration that has been attained from other experimental and/or theoretical sources in advance. In order to make good use of such an operation, however, a reliable theory is needed for a simultaneous analysis of these spectral bandshapes, in which working formulas for theoretical prediction of the bandshapes should be put together on an equal footing of approximations with one another. The case of helical biopolymers certainly falls under this category.

Recently, toward the analysis of the ORD and CD spectral curves of the single-stranded polyadenylic acid (poly A), we have demonstrated the promising reliability and wide applicability of the linear response polarizability theory[1] which is essentially a unified theory of the Fano-DeVoe model[2-5] with Applequist's polarizability theory of optical rotation[6]. As a closely equivalent treatment to ours, Cech *et al.*[7] have shown that DeVoe's all-orders-coupled oscillator polarizability model[3,4] successfully reproduces the CD spectrum of poly A. However, in contrast to such an extensive application of DeVoe's model, we like to point out that our model for the UV, ORD, and CD spectral bandshapes has a more convenient merit in correlating and explaining the molecular properties of biopolymers in terms of a small number of parameters; *i.e.*, transition energies, oscillator strengths, directions of transition moments, and half-widths of the absorption spectra of constituent monomer molecules.

The observed ORD and CD spectra of poly A are entirely different in acid (pH 4.6) and neutral solutions, indicating the existence of conformations of different kinds.[8-10] Optical absorption spectra,[8,10] viscosity measurement,[8] and X-ray analysis[11] offer an evidence that poly A shapes into the single-stranded helix in neutral solution and into the double-stranded helix in low pH solution, at room temperature. A possible explanation for such difference in conformation is a matter of main concern in the present paper. We therefore carry out comparative calculations of the UV, ORD, and CD spectral bandshapes of poly A by making use of the linear response theory, and show how the molecular conformations are reflected in these spectral bandshapes computed by varying the necessary molecular geometrical parameters. Afterward, we will discuss a problem of whether the discrimination of the single- and double-stranded poly A's can be made on the basis of the theoretical prediction of spectral bandshapes.

In the following, we first define a polarizability tensor of a homopolymer, and next outline the derivation of the UV, ORD, and CD bandshape functions by making use of the polarizability tensor. We then mention the geometrical properties of a helical polymer, by which we compute the bandshapes under a variety of conditions.

Polymer Polarizability Tensor

Let us consider the matrix elements of the polarizability tensor, $\boldsymbol{\alpha}^{P}_{mn}(\bar{\nu})$, of a polymer composed of N identical monomers (N-mer). The polymer polarizability tensor can be bulit up from the polarizability tensors, $\boldsymbol{\alpha}^{M}_{mn}(\bar{\nu})$, of individual monomers by making use of the Green's function method, when we know the unperturbed monomer polarizability tensor,

$$\begin{aligned}\boldsymbol{\alpha}^{M}_{mn}(\bar{\nu}) &= \boldsymbol{\alpha}^{M}_{mn}(\bar{\nu})\delta_{mn} = \boldsymbol{\alpha}^{M}_{m}(\bar{\nu}) \\ &= +(hc)^{-1}\sum_{\lambda}\boldsymbol{\mu}^{(m)}_{0\lambda}\boldsymbol{\mu}^{(m)}_{\lambda 0}[(\bar{\nu}-\tilde{\nu}^{(m)}_{\lambda 0}+i\eta_{\lambda})^{-1} \\ &\qquad -(\bar{\nu}+\tilde{\nu}^{(m)}_{\lambda 0}-i\eta_{\lambda})^{-1}], \qquad (1)\end{aligned}$$

where

$$\boldsymbol{\mu}^{(m)}_{0\lambda} = \langle 0^{(m)}|\sum_{i} e(\mathbf{r}_i-\mathbf{r}_m)|\lambda^{(m)}\rangle \equiv \langle 0^{(m)}|\boldsymbol{\mu}_m|\lambda^{(m)}\rangle. \qquad (2)$$

$\boldsymbol{\mu}^{(m)}_{0\lambda}\boldsymbol{\mu}^{(m)}_{\lambda 0}$ is a dyadic product of the transition moment between the λth excited state $|\lambda^{(m)}\rangle$ and the ground state $|0^{(m)}\rangle$ of the mth monomer; $\mathbf{r}_i$ and $\mathbf{r}_m$ are the vectors going from the origin of the system to the ith electron of the mth monomer and to the center of the mth monomer, respectively; η_{λ} is a positive and infinitesimally small quantity. $\boldsymbol{\alpha}^{M}_{m}(\bar{\nu})$ is given in units of cm^3 when $(\boldsymbol{\mu}^{(m)}_{\lambda 0}/e)$ is measured in units of cm, $\bar{\nu}$ is in units of cm^{-1}, and $e^2/(hc)=1.1614093\times10^{-3}$. Note

that the plus sign before $(hc)^{-1}$ of Eq. 1 defines the sign convention for the polarizability adopted in the present paper, which is different from the usual one. Hereafter, the superscripts, (1), (2), ···, denote the successive numbers of residues.

In the treatment mentioned above, the excited states of the polymer system is actually regarded as perturbed excited states of a hypothetically non-interacting molecular aggregate of N identical monomers, which are created by the intermolecular Coulomb interaction upon excitation. We do not consider the intermolecular exchange of electrons. Now, let us calculate the Coulomb interaction V_{mn} between the mth and nth monomers by the dipole-dipole approximation. It is then convenient to expand the Coulomb interaction V_{mn} in terms of the dipole operators $\boldsymbol{\mu}_m$ and $\boldsymbol{\mu}_n$ and the unit dipole interaction tensor $\mathbf{U}_{mn}$;

$$V_{mn} = \sum_{i\in m}\sum_{j\in n}(e^2/r_{ij}) \approx \sum_i e(\mathbf{r}_i-\mathbf{r}_m)\cdot\mathbf{U}_{mn}\cdot\sum_j e(\mathbf{r}_j-\mathbf{r}_n) = \boldsymbol{\mu}_m\cdot\mathbf{U}_{mn}\cdot\boldsymbol{\mu}'_n. \tag{3}$$

Instead, we use the following notation for V_{mn} hereafter;

$$\{V(\mathbf{r},\mathbf{r}')\}_{mn} \approx e(\mathbf{r}-\mathbf{r}_m)\cdot\mathbf{U}_{mn}\cdot e(\mathbf{r}'-\mathbf{r}'_n), \tag{4}$$

where

$$\mathbf{U}_{mn} = (1/r_{mn}^3)(\mathbf{1}_{mn}-3\mathbf{r}_{mn}\mathbf{r}_{mn}/r_{mn}^2) = -(3/r_{mn}^5)\begin{pmatrix} x_{mn}^2-(r_{mn}^2/3) & x_{mn}y_{mn} & x_{mn}z_{mn} \\ y_{mn}x_{mn} & y_{mn}^2-(r_{mn}^2/3) & y_{mn}z_{mn} \\ z_{mn}x_{mn} & z_{mn}y_{mn} & z_{mn}^2-(r_{mn}^2/3)\end{pmatrix}. \tag{5}$$

In Eqs. 3 and 4, the single dot denotes the single contraction and $\mathbf{r}_{mn}$ is a vector for intermolecular distance,

$$\mathbf{r}_{mn} = \mathbf{r}_n - \mathbf{r}_m = x_{mn}\hat{\mathbf{i}} + y_{mn}\hat{\mathbf{j}} + z_{mn}\hat{\mathbf{k}}. \tag{6}$$

The polarizability tensor is derived from the polarization propagator[5] $G(\mathbf{r},\mathbf{r}';E)$, which describes the propagation of the electronic density fluctuation, the propagator of the mth monomer being given by

$$G_m^{\mathrm{M}}(\mathbf{r},\mathbf{r}';E) = G_{mn}^{\mathrm{M}}(\mathbf{r},\mathbf{r}';E)\delta_{mn} = \sum_\lambda\left(\frac{\langle 0^{(m)}|\rho(\mathbf{r})|\lambda^{(m)}\rangle\langle\lambda^{(m)}|\rho(\mathbf{r}')|0^{(m)}\rangle}{E-E_{\lambda 0}^{(m)}+i\eta_\lambda} - \frac{\langle 0^{(m)}|\rho(\mathbf{r}')|\lambda^{(m)}\rangle\langle\lambda^{(m)}|\rho(\mathbf{r})|0^{(m)}\rangle}{E+E_{\lambda 0}^{(m)}-i\eta_\lambda}\right)\delta_{mn}, \tag{7}$$

with

$$\rho(\mathbf{r}) = \sum_i \delta([\mathbf{r}-\mathbf{r}_m]-\mathbf{r}_i), \qquad \rho(\mathbf{r}') = \sum_i \delta([\mathbf{r}'-\mathbf{r}_n]-\mathbf{r}_i), \tag{8}$$

where $E=hc\tilde{\nu}$ and $E_{\lambda 0}^{(m)}=hc\tilde{\nu}_{\lambda 0}^{(m)}$.

The electronic density disturbance and fluctuation induced by the external light source are accompanied with the transition dipole moment, the measure of which defines the polarizability. Then, the monomer polarizability tensor can naturally be defined by

$$\boldsymbol{\alpha}_{mn}^{\mathrm{M}}(E) = \int_m \mathrm{d}^3\mathbf{r}\int_n \mathrm{d}^3\mathbf{r}' e(\mathbf{r}-\mathbf{r}_m)G_{mn}^{\mathrm{M}}(\mathbf{r},\mathbf{r}';E)e(\mathbf{r}'-\mathbf{r}'_n), \tag{9}$$

where m and n close by the integral signs denote the integration only over such domains that $\mathbf{r}$ and $\mathbf{r}'$ lie in the mth and nth monomers, respectively. From Eq. 7, $\langle 0^{(m)}|\rho(r)|\lambda^{(m)}\rangle$ is obviously found to be the transition density, so that Eq. 2 is rewritten as

$$\boldsymbol{\mu}_{0\lambda}^{(m)} = \int \mathrm{d}^3\mathbf{r} e(\mathbf{r}-\mathbf{r}_m)\langle 0^{(m)}|\rho(\mathbf{r})|\lambda^{(m)}\rangle. \tag{10}$$

In the zeroth order, the polarization propagator for the polymer is hypothetically assumed to be

$$\{G^{\mathrm{HP}}(\mathbf{r},\mathbf{r}';E)\}_{mn} = G_m^{\mathrm{M}}(\mathbf{r},\mathbf{r}';E)\delta_{mn}. \tag{11}$$

It is then preferable to write down the higher order terms in the following manner:[5]

$$G^{\mathrm{P}}(\mathbf{r},\mathbf{r}';E) = G^{\mathrm{HP}}(\mathbf{r},\mathbf{r}';E) + \int \mathrm{d}^3\mathbf{r}''\int \mathrm{d}^3\mathbf{r}''' G^{\mathrm{HP}}(\mathbf{r},\mathbf{r}'';E)V(\mathbf{r}'',\mathbf{r}''')G^{\mathrm{P}}(\mathbf{r}''',\mathbf{r}';E), \tag{12}$$

or in its matrix element representation,

$$G_{mn}^{\mathrm{P}}(\mathbf{r},\mathbf{r}';E) = G_m^{\mathrm{M}}(\mathbf{r},\mathbf{r}';E)\delta_{mn} + \int_m \mathrm{d}^3\mathbf{r}''\int_n \mathrm{d}^3\mathbf{r}''' G_m^{\mathrm{M}}(\mathbf{r},\mathbf{r}'';E)\{V(\mathbf{r}'',\mathbf{r}''')\}_{mn}\cdot G_n^{\mathrm{M}}(\mathbf{r}''',\mathbf{r}';E) + \cdots \tag{13}$$

Finally, we have the following expression for the polymer polarizability tensor:

$$\boldsymbol{\alpha}_{mn}^{\mathrm{P}}(\tilde{\nu}) = \int_m \mathrm{d}^3\mathbf{r}\int_n \mathrm{d}^3\mathbf{r}' e(\mathbf{r}-\mathbf{r}_m)G_{mn}^{\mathrm{P}}(\mathbf{r},\mathbf{r}';hc\tilde{\nu})e(\mathbf{r}'-\mathbf{r}'_n) = \boldsymbol{\alpha}_m^{\mathrm{M}}(\tilde{\nu})\delta_{mn} + \boldsymbol{\alpha}_m^{\mathrm{M}}(\tilde{\nu})\cdot\mathbf{U}_{mn}\cdot\boldsymbol{\alpha}_n^{\mathrm{M}}(\tilde{\nu}) + \sum_l \boldsymbol{\alpha}_m^{\mathrm{M}}(\tilde{\nu})\cdot\mathbf{U}_{ml}\cdot\boldsymbol{\alpha}_l^{\mathrm{M}}(\tilde{\nu})\cdot\mathbf{U}_{ln}\cdot\boldsymbol{\alpha}_n^{\mathrm{M}}(\tilde{\nu}) + \cdots \tag{14}$$

UV, ORD, and CD Bandshape Functions of an N-mer

In the present paper, optical rotation of a helical polymer is ragarded as optical rotation induced conformationally by the regular aggregation of achiral residues in the absorption region of the residues. This means that the optical activity is derived from the electronic interaction among the achiral residues. In fact, it is known that the magnitudes of conformationally induced optical rotation of natural and synthetic polynucleotides are much larger than those of intrinsic optical rotation of isolated mononucleotides having chrial structures.[8] In order to predict optical activity of polynucleotides in the present formalism, chiral residues such as mononucleotides can therefore be approximated by achiral residues such as nucleic acid bases, neglecting the sugar-phosphate backbones. In the following, we also derive a scalar representation for the polarizability of such polymers, which is rather convenient for practical computations of UV spectral bandshapes compared with Eq. 14.

The total dipole moment of the polymer induced by the applied external field $\mathbf{E}(\mathbf{r}_n)$ is given by

$$\boldsymbol{\mu}^{\mathrm{P}}(\tilde{\nu}) = \sum_m^{\mathrm{N}}\boldsymbol{\mu}_m^{\mathrm{P}}(\tilde{\nu}) = \sum_m^{\mathrm{N}}\sum_n^{\mathrm{N}}\boldsymbol{\alpha}_{mn}^{\mathrm{P}}(\tilde{\nu})\cdot\mathbf{E}(\mathbf{r}_n) = \sum_m^{\mathrm{N}}\sum_n^{\mathrm{N}}\boldsymbol{\alpha}_{mn}^{\mathrm{P}}(\tilde{\nu})\cdot[\mathbf{E}(0)+\mathbf{r}_n\cdot\nabla\mathbf{E}(0)], \tag{15}$$

where the second line is obtained by Taylor's expansion of $\mathbf{E}(\mathbf{r}_n)$ about the origin of the polymer coordinate system. Taking the average over all orientations with

respect to the laboratory-fixed coordinate system, we obtain the following relationship, which is the same as that derived by Applequist:[6]

$$\langle \boldsymbol{\mu}^{\mathrm{P}}(\tilde{\nu})\rangle_{\mathrm{av}} = (1/3)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}[\mathrm{tr}\,\boldsymbol{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu})]\mathbf{E}(0) + (1/6)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\mathbf{r}_n\cdot(\boldsymbol{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu}):\boldsymbol{\varepsilon})\nabla\times\mathbf{E}(0) = \sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\bar{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu})\mathbf{E}(0) + \beta(\tilde{\nu})\,\mathrm{Rot}\,\mathbf{E}(0), \quad (16)$$

where $\boldsymbol{\varepsilon}$ is the isotropic third order tensor. The double-dot product of the two tensors in the parentheses reduces to

$$\boldsymbol{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu}):\boldsymbol{\varepsilon} = [\alpha^{\mathrm{Pxy}}_{mn}-\alpha^{\mathrm{Pyz}}_{mn}]\hat{\mathbf{i}} + [\alpha^{\mathrm{Pxz}}_{mn}-\alpha^{\mathrm{Pzx}}_{mn}]\hat{\mathbf{j}} + [\alpha^{\mathrm{Pyx}}_{mn}-\alpha^{\mathrm{Pxy}}_{mn}]\hat{\mathbf{k}}, \quad (17)$$

where the superscripts zy, yz, *etc.* indicate the tensor components. $\bar{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu})$ in the second line of Eq. 16 defines the scalar polarizability of the polymer. The coefficient before Rot $\mathbf{E}(0)$ in Eq. 16 is the molecular rotatory parameter $\beta(\nu)$ which measures the rotation of the electric field vector of the light wave passing through the medium at the point $\mathbf{r}_n$ measured from the origin;

$$\begin{aligned}\beta(\tilde{\nu}) &= (1/6)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\mathbf{r}_n\cdot(\boldsymbol{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu}):\boldsymbol{\varepsilon})\\ &= -(1/6)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\mathbf{r}_m\cdot(\boldsymbol{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu}):\boldsymbol{\varepsilon})\\ &= (1/12)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\mathbf{r}_{mn}\cdot(\boldsymbol{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu}):\boldsymbol{\varepsilon})\\ &= (1/12)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\{x_{mn}(\alpha^{\mathrm{Pzy}}_{mn}(\tilde{\nu})-\alpha^{\mathrm{Pyz}}_{mn}(\tilde{\nu}))\\ &\qquad + y_{mn}(\alpha^{\mathrm{Pxz}}_{mn}(\tilde{\nu})-\alpha^{\mathrm{Pzx}}_{mn}(\tilde{\nu}))\\ &\qquad + z_{mn}(\alpha^{\mathrm{Pyx}}_{mn}(\tilde{\nu})-\alpha^{\mathrm{Pxy}}_{mn}(\tilde{\nu}))\}. \end{aligned} \quad (18)$$

Here, it should be noticed that in the third line the factor (1/2) is introduced by combining the first line with the second one. The minus sign before the second line follows from Eq. 17, by interchanging suffixes m and n and also by allowing for the fact that $\boldsymbol{\alpha}^{\mathrm{P}}_{mn}$ is equal to the transposed element of $\boldsymbol{\alpha}^{\mathrm{P}}_{mn}$.

By relating β to the macroscopic quantities, molar rotation and ellipticity,[1] one obtains the bandshape functions $[\Psi(\tilde{\nu})]$ and $[\Xi(\tilde{\nu})]$ of the ORD and CD spectra, respectively;

$$[\Psi(\tilde{\nu})] = -288\pi^2 N_{\mathrm{A}}\tilde{\nu}^2(1/N)\,\mathrm{Re}\,\beta(\tilde{\nu}) \quad (\mathrm{deg\,cm^2\,dmol^{-1}}), \quad (19)$$

$$[\Xi(\tilde{\nu})] = -288\pi^2 N_{\mathrm{A}}\tilde{\nu}^2(1/N)\,\mathrm{Im}\,\beta(\tilde{\nu}) \quad (\mathrm{deg\,cm^2\,dmol^{-1}}), \quad (20)$$

where N_{A} is Avogadro's number.

The bandshape function of the UV absorption spectrum is derived from the coefficient of $\mathbf{E}(0)$ in the first term of Eq. 16. The wave number-dependent molar extinction coefficient[12] is then computed by

$$\varepsilon(\tilde{\nu}) = -(8\pi^2 N_{\mathrm{A}}/2302.6)\tilde{\nu}[(1/N)\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\mathrm{Im}\,\bar{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu})], \quad (\mathrm{l\,mol^{-1}\,cm^{-1}}). \quad (21)$$

Note that the factor (1/3) is involved in $\bar{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu})$.

For a model polymer composed of translationally and/or helically arranged equivalent monomers,[13] neglecting an end effect, we can derive

$$\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\bar{\alpha}^{\mathrm{P}}_{mn}(\tilde{\nu}) = (1-\sum_{m}^{\mathrm{N}}\overline{U}_{nm}\bar{\alpha}^{\mathrm{M}}_{n}(\tilde{\nu}))^{-1}\sum_{m}^{\mathrm{N}}\sum_{n}^{\mathrm{N}}\bar{\alpha}^{\mathrm{M}}_{n}(\tilde{\nu})\delta_{nm} = N\bar{\alpha}^{\mathrm{M}}_{n}(\tilde{\nu})(1-\sum_{m}^{\mathrm{N}}\overline{U}_{nm}\bar{\alpha}^{\mathrm{M}}_{m}(\tilde{\nu}))^{-1}, \quad (22)$$

which involves the dipole-dipole interactions to infinite orders. $\overline{U}_{nm}$ is the scalar interaction potential between unit dipoles,

$$\overline{U}_{nm} = \mathbf{e}_n\cdot\mathbf{e}_m/r^3_{nm} - 3(\mathbf{e}_n\cdot\mathbf{r}_{nm})(\mathbf{e}_m\cdot\mathbf{r}_{nm})/r^5_{nm}, \quad (23)$$

where the unit vector $\mathbf{e}_m$ is defined by

$$\boldsymbol{\mu}^{(m)}_{0\lambda} = |\boldsymbol{\mu}^{(m)}_{0\lambda}|\mathbf{e}_m. \quad (24)$$

Equation 22 is a scalar representation for the polymer polarizability, which is convenient for the evaluation of UV spectral bandshapes. However, we do not employ Eq. 22 in actual computations, because we want to compute UV, ORD, and CD bandshapes altogether on the same approximate grounds. Therefore, we use Eq. 14, in which terms higher than the third terms are truncated, for all the bandshape calculations.

For the calculations of Eqs. 19—21, which reduce to those of the real and imaginary parts of $\boldsymbol{\alpha}^{\mathrm{M}}_{m}(\tilde{\nu})$, the necessary formulas[1,13] are obtained as follows:

$$\begin{aligned}\mathrm{Im}\,\boldsymbol{\alpha}^{\mathrm{M}}_{m}(\tilde{\nu}) &= -\pi(hc)^{-1}\sum_{\lambda}\boldsymbol{\mu}^{(m)}_{0\lambda}\boldsymbol{\mu}^{(m)}_{\lambda 0}\{\delta(\tilde{\nu}-\tilde{\nu}^{(m)}_{\lambda 0}) + \delta(\tilde{\nu}+\tilde{\nu}^{(m)}_{\lambda 0})\}\\ &= -(hc)^{-1}\sum_{\lambda}\boldsymbol{\mu}^{(m)}_{0\lambda}\boldsymbol{\mu}^{(m)}_{\lambda 0}\{\eta_\lambda[(\tilde{\nu}-\tilde{\nu}^{(m)}_{\lambda 0})^2+\eta^2_\lambda]^{-1}\\ &\qquad +\eta_\lambda[(\tilde{\nu}+\tilde{\nu}^{(m)}_{\lambda 0})^2+\eta^2_\lambda]^{-1}\}, \end{aligned} \quad (25)$$

and

$$\begin{aligned}\mathrm{Re}\,\boldsymbol{\alpha}^{\mathrm{M}}_{m}(\tilde{\nu}) &= -(\mathcal{P}/\pi)\int_{-\infty}^{\infty}dE\,\mathrm{Im}\,\boldsymbol{\alpha}^{\mathrm{M}}_{m}(E)\,\mathrm{sign}\,(E)(\tilde{\nu}-E)^{-1}\\ &= +(hc)^{-1}\sum_{\lambda}\boldsymbol{\mu}^{(m)}_{0\lambda}\boldsymbol{\mu}^{(m)}_{\lambda 0}\{(\tilde{\nu}-\tilde{\nu}^{(m)}_{\lambda 0})[(\tilde{\nu}-\tilde{\nu}^{(m)}_{\lambda 0})^2+\eta^2_\lambda]^{-1}\\ &\qquad -(\tilde{\nu}+\tilde{\nu}^{(m)}_{\lambda 0})[(\tilde{\nu}+\tilde{\nu}^{(m)}_{\lambda 0})^2+\eta^2_\lambda]^{-1}\}, \end{aligned} \quad (26)$$

both of which represent features of the Lorentzian bandshape.

In this computation, the damping factor $\eta_\lambda=(1/2)$ (half-width) is treated as an empirical parameter, with the condition $\eta_\lambda \ll \tilde{\nu}^{(m)}_{\lambda 0}$. From Eqs. 21 and 25, we can derive the approximate working formula for estimating η_λ (in $\mathrm{cm^{-1}}$) from the experimental values for the molar extinction coefficient ε^{M} and the oscillator strength $f_{\lambda 0}$ of the monomer molecule;

$$[\varepsilon^{\mathrm{M}}(\tilde{\nu}^{(m)}_{\lambda 0})]_{\max} \approx 7.37126\times 10^7(f_{\lambda 0}/\eta_\lambda), \quad (27)$$

when the second term of Eq. 25 is neglected (this is justified because the second term is usually much smaller than the first term in Eq. 25). By substituting these approximate η_λ's into Eqs. 25 and 26, real and imaginary parts of the monomer polarizability tensor are computed.

It should finally be noted that the sum rule[1,13] holds for the UV, ORD, and CD spectral intensities. In the present scheme, it is clearly understood that the total polarizability tensor given in Eq. 14 for the conformationally induced optically active polymer becomes a 3×3 antisymmetric matrix which is derived from the monomer 3×3 (diagonal and/or symmetric) polariz-

ability tensors. In other words, the absorption spectrum is given by the diagonal terms of the polymer polarizability tensor, while the optical activity is determined by the off-diagonal terms.

Geometrical Properties for a Helical Polymer

In the computational work, it is necessary to know the geometrical properties of the regular polymers such as single- and double-stranded poly A's.

(i) For a single-stranded helical homopolymer, let the origin of the whole system be the center of the circle cut off perpendicularly to the helix axis, in which the center of one of the monomers (called the first monomer) is involved. The unit vector $\hat{\mathbf{i}}$ is taken perpendicularly to the helix axis to the center of the first monomer (radial), $\hat{\mathbf{j}}$ perpendicular to $\hat{\mathbf{i}}$ (tangential to the helix), both in the plane of the section, and $\hat{\mathbf{k}}$ along the helix axis (Figs. 1 and 2). Then the vector $\mathbf{r}_n$ going from the origin to the center of the nth monomer is expressed by

$$\mathbf{r}_n = a\cos(n\phi)\hat{\mathbf{i}} + a\sin(n\phi)\hat{\mathbf{j}} + nL\hat{\mathbf{k}}, \tag{28}$$

where a is the radius of the sectional circule, L the pitch of the helix (the advance parallel to the helix axis), and ϕ is the angle of rotation transferring a given monomer, n say, to the next nearest one, $n+1$. The distance vector between the mth and nth monomers is then defined by Eq. 6. By making use of the rotational operator, $\mathbf{R}((n-1)\phi)$, we can relate the polarizability tensor of the nth monomer to that of the first monomer;

$$\boldsymbol{\alpha}_n^{\mathrm{M}}(\bar{\nu}) = \mathbf{R}((n-1)\phi)\cdot\boldsymbol{\alpha}_1^{\mathrm{M}}(\bar{\nu})\cdot\mathbf{R}(-(n-1)\phi), \tag{29}$$

since

$$\boldsymbol{\mu}_{0\lambda}^{(n)} = [\mathbf{R}(\phi)]^{n-1}\cdot\boldsymbol{\mu}_{0\lambda}^{(1)} = \mathbf{R}((n-1)\phi)\cdot\boldsymbol{\mu}_{0\lambda}^{(1)}$$
$$\equiv \begin{pmatrix} \cos((n-1)\phi) & -\sin((n-1)\phi) & 0 \\ \sin((n-1)\phi) & \cos((n-1)\phi) & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} [\mu_{0\lambda}^{(1)}]_{\hat{\mathbf{i}}} \\ [\mu_{0\lambda}^{(1)}]_{\hat{\mathbf{j}}} \\ [\mu_{0\lambda}^{(1)}]_{\hat{\mathbf{k}}} \end{pmatrix}, \tag{30}$$

where $[\mu_{0\lambda}^{(1)}]_{\hat{\mathbf{i}}}$ *etc.* are the components of the transition moment of the first monomer in the directions of $\hat{\mathbf{i}}$ (ridial), $\hat{\mathbf{j}}$ (tangential), and $\hat{\mathbf{k}}$ fixed as the center of the first monomer.

(ii) For a double-stranded helical homopolymer like (poly A)·(poly A), we assign the odd integers $\{2m'-1, 2n'-1\}$ for the numberings of the positions of the residues (placed in the x'y'-plane of Fig. 3 or displaced translationally along the helix axis) in one of the strands and the even numbers $\{2m', 2n'\}$ for those (in the x″y″-plane) in another strand.

Let us obtain the intermolecular distances in the double-stranded polymers. The position vectors for the double-strands are now given by

$$\mathbf{r}_{2m'-1} = a\cos(m'\phi)\hat{\mathbf{i}} + a\sin(m'\phi)\hat{\mathbf{j}} + m'L\hat{\mathbf{k}}, \tag{31}$$

$$\mathbf{r}_{2m'} = a\cos(m'\phi+\gamma')\hat{\mathbf{i}} + a\sin(m'\phi+\gamma')\hat{\mathbf{j}} + (m'L+L')\hat{\mathbf{k}}, \tag{32}$$

where a translation L' along the helix axis followed by

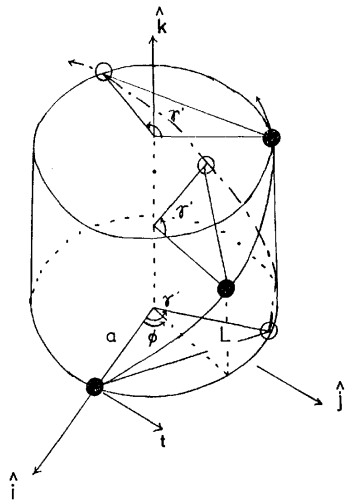

Fig. 1. Double-stranded helix and its geometrical parameters (a, ϕ, L, γ', L'). Solid circles represent the residues on one of the strands and open circles those on the other strand. $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$ and $\hat{\mathbf{k}}$ are the unit vectors in the Cartesian coordinate, $\hat{\mathbf{k}}$ being along the helical axis.

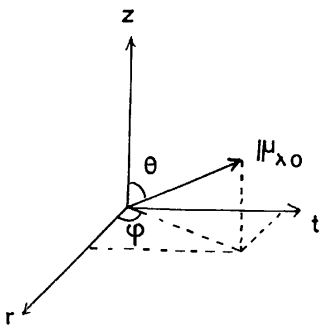

Fig. 2. Coordinate system for transition moment of a residue. r is the radial direction and t is tangential to the helix, z being along the helical axis.

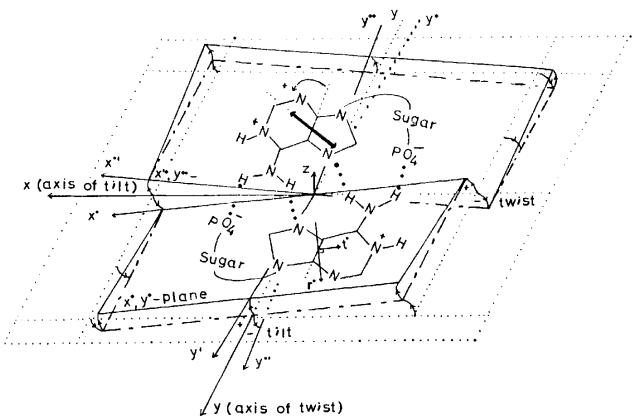

Fig. 3. Perspective drawing of a hydrogen-bonded base pair in the double-stranded polyadenylic acid. The bold arrow represents the direction of the transition moment. r' and t' are, respectively, the radial and tangential directions of the residue on the x',y'-plane. As for the other notations, see the text.

a rotation γ' about the axis brings about either of strands onto another strand as shown in Fig. 1. The vector for the intermolecular distance is again calculated from Eq. 6.

The following relationships produced by the screw operation in this polymer system also make it easy to carry out the actual computation. For one of the strands, we can relate the $(2n'+1)$th monomer with the first monomer in the following manner:

$$\boldsymbol{\mu}_{0\lambda}^{(2n'+1)} = \mathbf{R}(n'\phi)\cdot\boldsymbol{\mu}_{0\lambda}^{(1)}, \tag{33}$$

$$\boldsymbol{\alpha}_{2m'+1,2n'+1}^{M}(\tilde{\nu}) = \mathbf{R}(m'\phi)\cdot\boldsymbol{\alpha}_{11}^{M}(\tilde{\nu})\cdot\mathbf{R}(-n'\phi). \tag{34}$$

For the other strand, we also have similar relationships;

$$\boldsymbol{\mu}_{0\lambda}^{(2n'+2)} = \mathbf{R}(n'\phi)\cdot\boldsymbol{\mu}_{0\lambda}^{(2)}, \tag{35}$$

$$\boldsymbol{\alpha}_{2m'+2,2n'+2}^{M}(\tilde{\nu}) = \mathbf{R}(m'\phi)\cdot\boldsymbol{\alpha}_{22}^{M}(\tilde{\nu})\cdot\mathbf{R}(-n'\phi). \tag{36}$$

From Eqs. 34 and 36, we can derive

$$\boldsymbol{\alpha}_{2m'+2,2n'+2}^{M}(\tilde{\nu}) = \mathbf{R}(\gamma')\cdot\boldsymbol{\alpha}_{2m'+1,2n'+1}^{M}(\tilde{\nu})\cdot\mathbf{R}(-\gamma'), \tag{37}$$

since

$$\boldsymbol{\mu}_{0\lambda}^{(2)} = \mathbf{R}(\gamma')\cdot\boldsymbol{\mu}_{0\lambda}^{(1)} \equiv \mathbf{R}_z(-\gamma')\cdot\boldsymbol{\mu}_{0\lambda}^{(1)}, \tag{38}$$

where $\mathbf{R}_z$ denotes an operator defined by the rotation of the coordinate system about the helix axis.

(iii) Since the two planes which involve one adenine molecule each, the x',y',- and x'',y''-planes in Fig. 3, are inclined each other, it is not very easy to specify relative positions of the monomer transition moments by a polar coordinate fixed at each monomer position so as to fit the X-ray data. Instead, one can easily relate the components of these moments, $[\mu_{0\lambda}^{(m)}]\hat{\mathrm{i}}$ *etc.*, to those described by the Cartesian coordinate system fixed at the adenine molecule (the X-axis is taken along the central C_4–C_5 bond, the X, Y-axes being in the molecular plane), specifying the following five angles as shown in Fig. 3 (let the plane perpendicular to the helix axis be the x,y-plane): An angle of rotation about the y-axis (*twist*); an angle of rotation about the x-axis (tilt); an angle between the x-axis and the original radial direction $\mathbf{r}$ $(\widehat{\mathrm{xr}})$; an angle between the molecular X-axis and the radial direction $\mathbf{r}$ $(\widehat{\mathrm{Xr}})$; an angle between the x'-axis and the radial direction $\mathbf{r}'$ on the x',y'-plane $(\widehat{\mathrm{x'r'}})$. Values of the latter three angles are estimated from the observed values for the original x, y-plane.[11] A plus sign of the rotation angle is defined to be counterclockwise with respect to the right-handed coordinate system. Then we have

$$\begin{pmatrix} [\mu_{0\lambda}^{(1)}]_{\hat{\mathrm{r}}} \\ [\mu_{0\lambda}^{(1)}]_{\hat{\mathrm{j}}} \\ [\mu_{0\lambda}^{(1)}]_{\hat{\mathrm{k}}} \end{pmatrix} = \mathbf{R}_z(\widehat{xr})\cdot\mathbf{R}_y(-twist)\cdot\mathbf{R}_{x'}(-tilt)\cdot \mathbf{R}_{z'}(-\widehat{x'r'})\cdot\mathbf{R}_{z'}(\widehat{Xr}) \begin{pmatrix} [\mu_{0\lambda}^{(1)}]_X \\ [\mu_{0\lambda}^{(1)}]_Y \\ [\mu_{0\lambda}^{(1)}]_Z \end{pmatrix}, \tag{39}$$

where

$$\mathbf{R}_{x'}(-tilt) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos(-tilt) & \sin(-tilt) \\ 0 & -\sin(-tilt) & \cos(-tilt) \end{pmatrix}, \tag{40}$$

$$\mathbf{R}_y(-twist) = \begin{pmatrix} \cos(-twist) & 0 & -\sin(-twist) \\ 0 & 1 & 0 \\ \sin(-twist) & 0 & \cos(-twist) \end{pmatrix}, \tag{41}$$

and

$$\mathbf{R}_\zeta(Q) = \begin{pmatrix} \cos Q & \sin Q & 0 \\ -\sin Q & \cos Q & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{42}$$

for $\mathbf{R}_z(\widehat{xr})$, $\mathbf{R}_{z'}(-\widehat{x'r'})$, and $\mathbf{R}_{z'}(\widehat{Xr})$. These relationships are convenient for actual calculation of the polymer polarizability.

The transition moment of the second monomer can be related to that of the first one by

$$\mu_{0\lambda}^{(2)} = \mathbf{R}(180°)\cdot\mu_{0\lambda}^{(1)}, \tag{43}$$

where the definition of $\mathbf{R}(180°)$ follows Eq. 30.

Results and Discussion

The spectral parameters necessary for computations of the UV, ORD, and CD spectral bandshapes are listed in Table 1. These are the observed and/or assumed transition energies, oscillator strengths, damping factors, and directions of the transition moments of the adenine monomer. The damping factors are determined as described above so that a starting UV absorption bandshape function for adenine can reproduce roughly well the observed spectrum of adenine.

It is known experimentally that poly A in neutral solution takes a flexibly stacked conformation of single strand, while at low pH it becomes a protonated structure like

$$2(\text{poly A}) + 2H^+ \rightleftharpoons (\text{poly A}^+\text{H})\cdot(\text{poly A}^+\text{H}).$$

In this case, the base-pairing illustrated in Fig. 3 forms a rigid double-stranded helix (Fig. 1) for which we assume a parallelly interwound structure analyzed by Rich *et al.*;[11] pitch 3.8 Å at 45° rotation, a=2.97 Å, *tilt*=+4°, *twist*=+10°, $\widehat{Xr}$=−23.2°, $\widehat{x'r'}$=−117.4°. A number of model calculations are carried out by chang-

ing values of the parameters from those for the reference structure cited above. In Table 2 are listed the values of these parameters and the figure numbers in which the predicted UV, ORD, and CD spectra are drawn. For convenience, it is assumed that the model for the single-stranded helix is not a flexibly and/or randomly stacked but has a regularly and rigidly stacked structure; in other words, it is regarded as a counterpart of the double helix (*vide infra*).

We show the bandshapes computed for the single-stranded poly A in Figs. 4—6 and those for the double-stranded poly A in Fig. 7. First of all, the effect of the chain-length (N) of the single-stranded poly A on bandshapes is examined in Fig. 4. Here we set $\widehat{x'r'}=0°$ (*i.e.*, the *tilt* axis is taken along the radial direction and the *twist* axis along the tangential direction), *tilt*$=-4.0°$, and *twist*$=0°$. It is to be noted that a helical structure appears to begin even in the *dimer* ($N=2$) and *trimer* models ($N=3$), as can be seen in Fig. 4. With an increase of N, the UV, ORD, and CD bandshapes are likely to converge to respective certain shapes (Fig. 4), the trend being pointed out before by Tinoco *et al.* in the treatment of the exciton theory.[14] In comparison with the monomer UV bandshapes, a large hypochromism appears in the 260 nm region of all the polymer UV bandshapes in the pH 7 model calculations (Figs. 4—7), which is well compared with the UV absorption spectrum of poly A observed by Michelson,[15] and Beers and Steiner.[16] As for the ORD and CD bandshapes as well, the calculated curves are qualitatively in accord with those observed.[8-10]

The intensities of the ORD and CD spectra decrease and the UV bandshapes look like that of the free adenine molecule as the radius (a) of the helix increase, as can be seen in Fig. 5 where the X-ray data of the double-stranded poly A are used for the $N=8$ single-stranded poly A model calculations. The parameters, $\widehat{x'r'}=-27.4°$, *twist*$=+10°$, and *tilt*$=-4°$, in the $N=8$ model predict well the observed ORD[8], CD[9], and UV[10,15,16] spectral shapes (see Fig. 6), while the parameters taken from the X-ray data of the double-stranded poly A, $\widehat{x'r'}=-117.4°$, *twist*$=+10°$, and *tilt*$=+4°$, do not produce reasonable ORD and CD curves (a figure is not shown). This is particularly true for ORD and CD spectral features in the 230 nm region; the latter param-

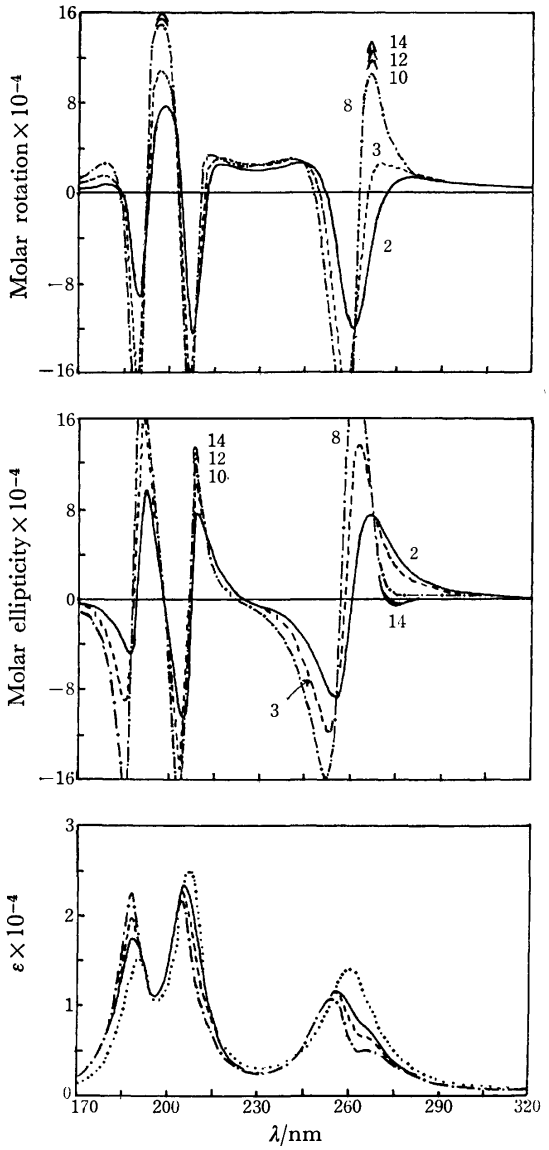

Fig. 4. The chain-length dependence ($N=2$, 3, 8, 10, 12, 14) of the ORD (top), CD (middle), and UV (bottom) bandshapes of the singlestranded polyadenylic acid ($a=2.97$Å, *tilt*$=-4.0°$, *twist*$=0°$, $\widehat{x'r}=0°$). The dotted line (·····) in the bottom shows the observed UV absorption spectrum of adenine.

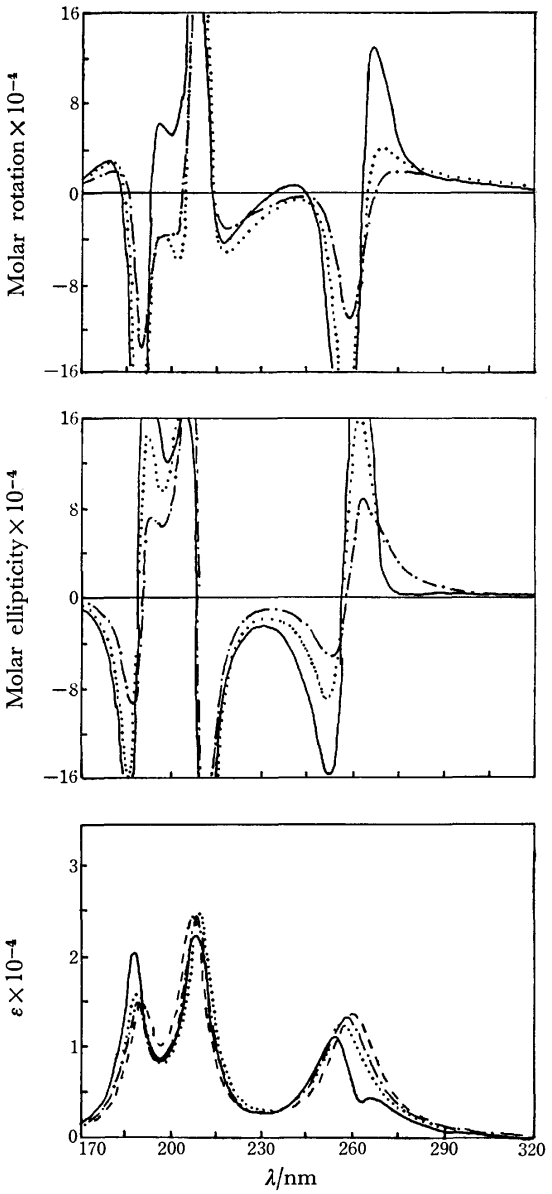

Fig. 5. Dependence of the ORD (top), CD (middle), and UV (bottom) bandshapes of the single-stranded polyadenylic acid on the radius (a) of the helix ($N=8$, $a=2.97$Å, $tilt=4°$, $twist=+10°$, $\widehat{Xr}=-23.2°$, $\widehat{x'r'}=-117.4°$). (——): $a=2.97$Å, (……): $a=5.0$Å; (—·—): $a=7.0$Å. The broken line (- - -) in the bottom shows the observed UV absorption spectrum of adenine.

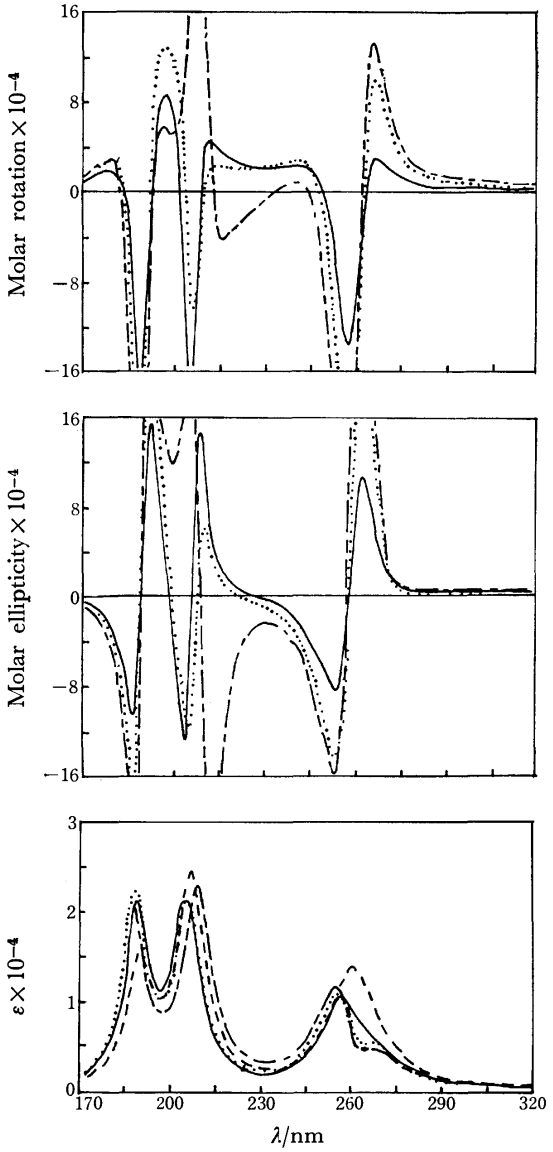

Fig. 6. Comparison of the selected theoretical ORD (top), CD (middle), and UV (bottom) bandshapes of the single-stranded polyadenylic acid in the $N=8$ model. (——): $tilt=-4°$, $twist=+10°$, $\widehat{x'r'}=-27.4°$; (……): $tilt=-2°$, $twist=0°$, $\widehat{x'r'}=-27.4°$; (—·—): $tilt=+4°$, $twist=+10°$, $\widehat{x'r'}=-117.4°$. The broken line (- - -) in the bottom shows the observed UV absorption spectrum of adenine.

eters bring about a too small peak in the ORD 230 nm region and no positive peak in the CD 220 nm region. This is probably due to the assumption of the orderly arranged rigid structure for the single-stranded poly A which may be considered to have a considerably flexible structure in nature. The predicted ORD and CD curves are therefore slightly stronger in intensity at their peaks and troughs and the predicted UV spectral shapes show rather strong hypochromism, compared with the observed spectra to which rather loose conformations of poly A may contribute; the model can be considered to be in between the real single- and double-stranded poly A's.

In Fig. 7 are compared the bandshapes of the double-stranded poly A, one calculated with the spectral parameters for the pH 7 adenine and the other with those for the pH 2.5 adenine. This is because the ORD and CD spectra of the double-stranded poly A have been measured around pH 4.5, while the spectroscopic data for the pH 4.5 free adenine molecule are not available. The molecular geometries are taken from the X-ray data in either case. As a matter of course, the predicted UV, ORD, and CD spectral bandshapes markedly

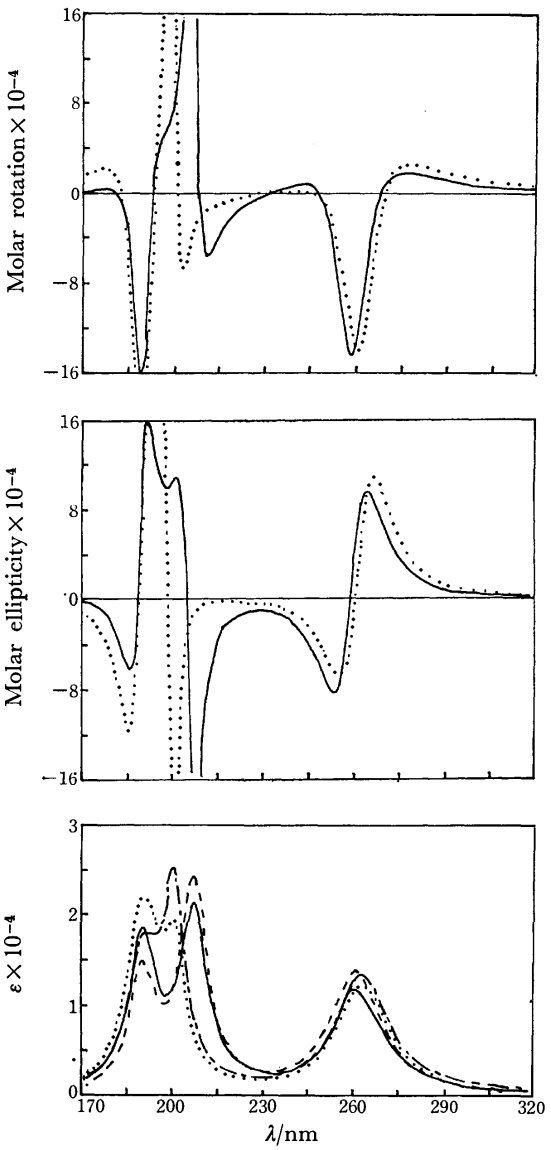

Fig. 7. Predicted ORD (top), CD (middle), and UV (bottom) bandshapes of the double-stranded polyadeylic acid ($N=8$, $a=2.97$Å, $titl=+4°$, $twist=+10°$, $\widehat{x'r'}=-117.4°$). (——): Calculated with the spectral parameters for pH=7 adenine; (·····): Calculated with the spectral parameters for pH=2.5 adenine. The broken line (- - -) in the bottom shows the observed UV absorption spectrum of adenine.

depend upon the pH values. In contrast with Fig. 6, the ORD and CD spectra turn out to be broader when the double-stranded helix is formed, which features agree in general with experiment.

Going into detail however, the predicted UV, ORD, and CD spectral intensities are in direct opposition to observations; in the observed spectra, the UV hypochromicity at the longer wavelength side enhances, and the ORD peak at 280 nm and the trough at 250 nm and the CD peak at 260 nm all gain their intensities at low pH, the CD trough at 240 nm being unchanged.

We now try to explain this discrepancy. The chain-length effect is notable as shown in Fig. 4, but it is to be recalled that a model for the single-stranded poly A adopted there corresponds to a counterpart of the double-stranded poly A. An actual structure of poly A in neutral solution is considered to be not so rigid as the present model but flexible to a certain extent. In fact, only small chain-length effect has been observed for poly A in neutral solution.[17] If we approximate a structure of poly A in the pH 7 solution as the dimer model ($N=2$ in Fig. 4), the relation between the UV hypochromicities and also the ORD and CD spectral intensities of the single- and double-stranded poly A's can be explained without difficulty. In other words, we may speculate that the structure of poly A in neutral solution is such that it can be approximated as an assembly of adenine dimer and/or trimer.

In alternative way of looking is possible. As Fig. 6 shows, the UV, ORD, and CD bandshapes of the single-stranded poly A approach those of free adenine as the position of the residues (a) gets away from the helix axis, simply because the relative distance between the two monomers located nearly on a level surface becomes larger and hence $\mathbf{U}_{mn}$ becomes smaller. Even when one does not throw over the rigid single-stranded model therefore, one only has to give larger values for a in order to get out of the above-mentioned dilemma.

An experimental fact must be mentioned to judge which view is right. Blake and Peacocke[18] observed a distinct Cotton effect around 440 nm due to proflavine bound to poly A in acid solution but no optical activity for the same system in neutral solution. This probably comes from the fact that in the poly A–proflavine complex the dyes are regularly arranged around the poly A double-helices in acid solution, while they are not because poly A does not take a regular helical structure in neutral solution.

The present treatment must await further improvements on quantitative description of spectral bandshapes of helical and non-helical biopolymers. We have not undertaken calculations with finer parametrization, since the spectral data available for the residue and the polymer in different pH solutions seem to be far from perfect. Nevertheless, we believe that the present theory and results provide a useful step for the understanding of the many-body aspect and the determination of conformations of helical biopolymers.

ESR Study of Hot Ions in Solid Solutions of $K_2[(Zn,Cd,Hg)(CN)_4]$

Henryk KOZLOWSKI,* Jun-ichi ISOYA, and Shizuo FUJIWARA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 19, 1977)

The ESR spectra of Cd(I) hot ions produced in solid solutions of $K_2[(Zn, Cd, Hg)(CN)_4]$ indicate that there are paramagnetic species of hot-ion molecules characteristic of the single phase of $K_2[Zn(CN)_4]$ and of the solid solution. The total contribution from the s and p orbitals to the spin density of the Cd(I) hot ions is constant, although the relative contributions from these two orbitals vary. It is shown that the mother lattice surrounding the hot ions determines the electronic structure and stability of the hot ions. These results suggest that the investigation of hot ions in a solid solution is useful for the study of microstructure of the solid solution.

Electron spin resonance (ESR) is useful for the investigation of the "hot ions"[1] which are produced by the X-ray or γ-ray irradiation of diamagnetic complexes. A large number of investigations have been carried out on various species of central metal ions.[2-5] An unpaired electron in a hot-ion molecule of Zn(I), Cd(I), Hg(I) can be described in terms of a ground state with a large s-orbital character. As a matter of fact, a considerable contribution of the s-orbital to the ground state of the metal ions has been experimentally evidenced by the large isotropic hyperfine coupling constants.[3-6]

This paper will report on the effect of a "solid solution" on the character of hot ions. It will be shown how the mother lattice of hot ions affects the electronic state of the latter, particularly with respect to their stabilities. Two different kinds of metal ions were mixed together, thus being made into cyanide complexes, where each of the metal ions produces hot ions with the unpaired electron in the s-orbital. By the γ-ray irradiation of the cyanide complexes, hot ions were produced therein. ESR was observed in the products. The ESR spectra thus obtained were compared to those of the hot ions produced in the complex compound of one of the composing metal ions (which will be referred to, hereafter, as the single-phase compound). It was found that the solid-solution sample presented new lines besides the lines of the latter which were found in the single-phase compound. This result seems to refer to the fact that the components of the sample of a solid solution are not homogenous with respect to the distribution of the components; rather each component exists in two forms, one surrounded by the metal ions of the same kind, and the other, by those of other species. The lifetimes of the hot ions differ from each other according to the type. The observed results will be discussed in correlation with the electronic structures of the hot ions.

Experimental

Samples of the cyanides of the mixed metal ions were prepared by the evaporation of a mixed aqueous solution of $K_2[M(CN)_4]$ and $K_2[M'(CN)_4]$, where M and M' are one of three combinations; Zn and Cd, Zn and Hg, and Cd and Hg. The samples were sealed *in vacuo* (10^{-6} mmHg) and irradiated by γ-rays from a ^{60}Co source at the temperature of liquid nitrogen. After the irradiation, the ESR spectra of the samples were recorded with a JELCO 3BSX spectrometer at the temperature of liquid nitrogen.

* On leave from Institute of Chemistry, University of Wroclaw, Wroclaw, Poland.

Results

The ESR spectra of the γ-ray irradiated solid solutions are shown in Figs. 1—4. All the spectra were almost symmetrical with respect to the center of $g=2$, presenting a structure of very large hyperfine coupling constants. (In order to save space, each figure shows only half of each spectrum.) The ratios which can be seen in the figures refer to the compositions of the mother solutions, not to the compositions of the solid samples. However, we assume that this fact will not disturb any of the discussions to be given below. In the case of the $K_2[(Zn,Cd)(CN)_4]$ system (Fig. 1), one can distinguish three lines, I, II, and III. All these lines are

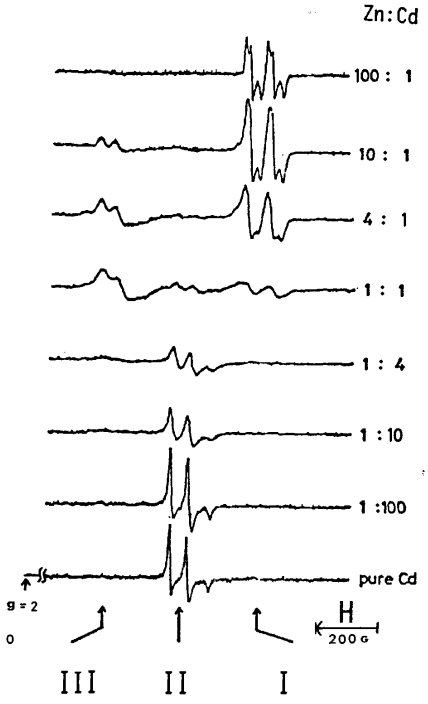

Fig. 1. ESR spectra of the Cd(I) hot ion in the $K_2[Zn(CN)_4]$-$K_2[Cd(CN)_4]$ solid solution. ($F=0$, $m_F=0$) ($F=1$, $m_F=+1$) transition for the ^{111}Cd and ^{113}Cd isotopes. The spectrum in the figure represents a half of the lower-field side of the hfs of Cd(I).

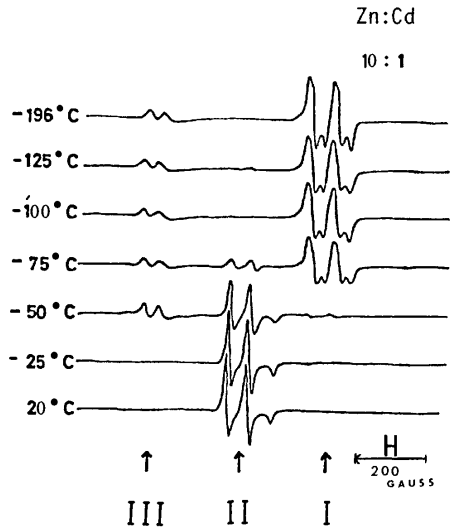

Fig. 2. ESR spectra of the Cd(I) hot ion in the $K_2[Zn(CN)_4]$-$K_2[Cd(CN)_4]$ solid solution with the molar ratio of 10 : 1. The spectra were measured at 77 K after the solution has been annealed at the temperatures indicated in the figure.

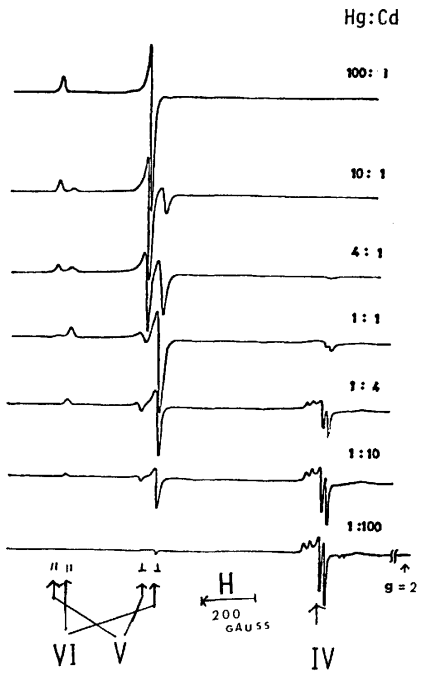

Fig. 3. ESR spectra ($(F=1, m_F=-1)$ $(F=1, m_F=0)$) of the Cd(I) (high field) and Hg(I) hot ions in the $K_2[Hg(CN)_4]$-$K_2[Cd(CN)_4]$ solid solution. Only the high-field side of the hf line is shown.

formed of two lines which have already been recognized as those of Cd(I) in the single-phase compound of cadmium. Those two lines are attributable to the isotopes of ^{111}Cd and ^{113}Cd. Each of the two lines shows a composite structure attributable to the contribution of the anisotropic nature of the electron. A comparison of the spectrum of Fig. 1 to that of the Cd(I) hot ion in the single-phase compound shows that Line II is attributable to Cd(I), which is surrounded by Cd(I), whereas Lines I and III are new lines of Cd(I)

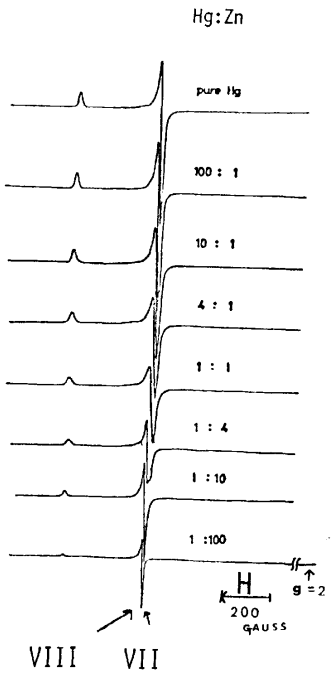

Fig. 4. ESR spectra of the Hg(I) hot ion in the $K_2[Hg(CN)_4]$-$K_2[Zn(CN)_4]$ solid solution. $(F=1, m_F=-1)$, $(F=1, m_F=0)$ transition of the ^{199}Hg isotope.

which have appeared in the solid-solution sample. Both of them are stable at the temperature of liquid nitrogen. However, they show an appreciable temperature dependence when they are annealed for 15 min at some elevated temperature and then cooled to the temperature of liquid nitrogen for the performance of the ESR measurements. Figure 2 shows the spectra at the temperature of liquid nitrogen after annealing at different temperatures. Lines I and III vanish with the elevation of the temperature. It is remarkable that the intensity of II increases parallel with the decreses in I and III. This seems to suggest that the unpaired electrons in I and III are transferrable to II. As may be seen in Fig. 3, similar results are also observed with the system of $K_2[(Cd,Hg)(CN)_4]$, where the lines of VI refer to Hg(I), characteristic of a solid-solution system; the V lines, to Hg(I) in $K_2[Hg(CN)_4]$, and the IV lines, to Cd(I) in $K_2[Cd(CN)_4]$. In the case of $K_2[(Zn,Hg)(CN)_4]$, it is noted that the position of Line VIII, which can be assigned to Hg(I) in the solid solution, is close to that of Hg(I) in the single-phase compound, VII (*cf.* Fig. 4). The solid-solution signals of Hg(I) in $K_2[(Cd,Hg)(CN)_4]$ become observable upon slight warming, even if they cannot be detected immediately just after irradiation. The observed results can be summarized as follows: 1) the hot ions are produced in the γ-ray irradiated mixed solid solutions, $K_2[(M,M')(CN)_4]$; 2) they are classified into two types, one characteristic of the mixed solution (Signals I, III in Fig. 1, VI in Fig. 3, and VIII in Fig. 4), and the other the same as that produced in the single-phase compound (to be referred to as the pure sample hereafter), $K_2[M(CN)_4]$ (II in Fig. 1, IV and V in Fig. 3, and VII in Fig. 4). were obtained for the Cd(I) hot ions, Species I in the $K_2[Zn(CN)_4]$ lattice, and Species II in the $K_2[Cd(CN)_4]$ lattice. All these results are shown in Table 1.

Discussion

The aforementioned results refer to the effect of a solid solution—that the hot ions differ depending on their surroundings, whether they are embedded in a lattice of metal ions of same kind or in one of ions of a different kind. The difference in the electronic natures of these two cases can be derived from the ESR parameters below.

A $K_2[Cd(CN)_4]$ molecule has a Td symmetry. Assuming that the Cd(I) hot ion still holds the position of Cd(II) in the mother lattice, the ground state may be expressed as

$$\phi^\circ = c_i\phi_{ns} + \sum_j K_j\phi_{j,lig}, \quad (1)$$

where ϕ_{ns} is the s-orbital of the metal ion and where $\phi_{j,lig}$ are the wave functions of the ligand; the symmetry of this state is A_1. In Cd(I) hot ions, however, the symmetries of the g and A tensors are C_{3v} in the pure salt[3] and orthorhombic in the $K_2[Zn(CN)_4]$ lattice. Therefore, the contribution from the np and the nd orbitals must be added to the ground state in the case of Cd(I) hot ions. The energy of the nd orbitals is assumed to be much higher than that of ns. Hence, it seems reasonable to represent a ground-state function as

$$\phi^\circ = c_1\phi_{ns} + c_2\phi_{np_z} + \sum_j K_j\phi_{j,lig}. \quad (2)$$

The np_z orbital is assumed to have an A_1 symmetry as ns. Accordingly, the two orbitals of np_z and ns are assumed to be able to mix with each other. The spin-orbit interaction between the ground state and the np_x and np_y orbitals contributes to the g anisotropy. Neglecting the overlap integrals with ligands, the g-shift at the axial component is given by

$$\Delta g = -\frac{2\xi_{np}}{\Delta E}c_2^2, \quad (3)$$

where ξ_{np} is a spin-orbit coupling constant and where ΔE is the energy difference between the ground state and the $np_{x,y}$ orbitals.[7] This equation enables us to estimate the contribution of the p_z orbital to the ground state.

Using these values: $\xi_{np}=1000$ and $4000\ cm^{-1}$, and $\Delta E=33000$ and $40000\ cm^{-1}$ for Cd(I) and Hg(I) ions respectively,[8] the values of c_2^2 for the pure salt are obtained, with the use of the g-values reported in a previous paper,[3] to be as shown in parentheses in

TABLE 2a. MOLECULAR ORBITAL PARAMETERS FOR HOT ION AT THE TEMPERATURE OF LIQUID NITROGEN

Type of hot ion	c_1^2	c_2^2	$c_1^2+c_2^2$

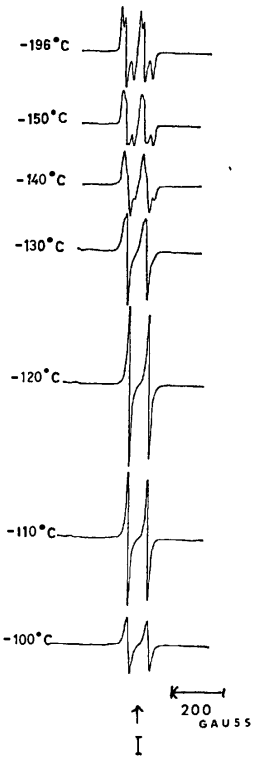

Fig. 5. Temperature dependence of the ESR spectra of the Cd(I) hot ion (Species I) in the $K_2[Zn(CN)_4]$ lattice.

Table 2. With the use of the A tensor components, the contributions from the s-orbital, c_1^2, and those of the p orbital, c_2^2, to the graund state are also calculated (*cf.* Table 2). The good agreement between the two c_2^2 values obtained from the g and A tensors justifies the formerly presented assumption that the overlap integral is negligible. In Fig. 5, the temperature dependence of the ESR spectra of Species I is presented. The spectra in the figure were measured at the temperatures cited. For the Cd(I) hot ion (Species I) in the $K_2[Zn(CN)_4]$ lattice, the values of c_1^2 and c_2^2 can be evaluated from the values of the A tensor, as is shown in Table 2. From the axial spectra at rather high temperatures, only c_1^2 can be determined. This value increases with the temperature; the averaged g value also increases slightly. From Table 2 it can be seen that, for the Cd(I) ion, the total contribution from the s and p_z orbitals is almost constant in all the cases examined, even if the relative contributions from the s and p_z orbitals vary. This may also refer to the fact that all of the ESR spectra arise from the same chemical species, which are little different with respect to the nature of the symmetry of the ion. The magnitude of the ratio of the s- and p-orbital contributions may serve as a measure of the distortion of the symmetry. The increase in the c_1^2 and g values suggests that the symmetry of the molecule becomes higher with an increase in the temperature. For a better understanding of this dynamic phenomenon, though, a further study of the ESR on a single crystal is necessary.

From a comparison between the pure salt and the solid-solution data for the Cd(I) ion, it is concluded that the symmetry of the hot ion in the $K_2[Zn(CN)_4]$ lattice (Species I) is higher than that of any other species in the pure salts.

In order to interpret the fact that Species II appear along with the decay of Species I and III (*cf.* Fig. 2), we have to assume that some aggregates of the Cd(II)-ion molecules exist in the sample. When Species I and III dacay, excess electrons are transferred to those aggregates and produce Cd(I) hot ions in the lattice of $K_2[Cd(CN)_4]$, which has been produced locally. As a result, this kind of species is relatively stable and can be observed even at higher temperatures. As to the exact nature of Species III, a further investigation of the single-crystal sample will be needed.

(Received July 6, 1977)

Three isomers of L-histidinatoiminodiacetatocobalt(III) complex have been prepared and characterized on the basis of their absorption, circular dichroism and proton magnetic resonance spectra. These isomers isomerized mutually in water at 80 °C. The equilibrium mole fractions of these isomers in water were found for *cisN*, *transN* and *fac* to be 0.91, 0.04, and 0.05, respectively.

In previous papers,[1,2] the preparation and the isomer distribution at equilibrium in water in the presence of active carbon were studied for the mixed cobalt(III) complexes with D-aspartate and L-2,4-diaminobutyrate ions. The distribution in favor of one isomer was found. In the present paper, the preparation of mixed cobalt(III) complexes containing iminodiacetate (=ida) and L-histidinate (=his) ions will be reported. Their absorption, PMR, and CD spectra are discussed. These isomers were found to isomerize in water in the absence of active carbon as in the case of [Co(L-prolinato)$_3$].[3] The relative rate constants for the isomerizations were determined by using a network analysis.[4]

Experimental

Preparations. Iminodiacetic acid (1.33 g) and L-histidine (1.55 g) were dissolved in 15 cm^3 of water. To this solution was added 1M-sodium hydroxide until the pH of the solution became *ca.* 9. To this mixture was added a solution (20 cm^3) of $CoCl_2 \cdot 6H_2O$ (2.38 g) containing 5 cm^3 of 10% H_2O_2. The mixture was stirred at 80 °C for 30 min and filtered to remove the small amount of precipitate. The filtrate was passed through a colum (30×500 mm) containing strong cation exchange resin, Dowex 50WX8 (100—200 mesh, sodium form). Elution with water produced a violet band followed by a red band. The violet eluate was condensed to about 10 cm^3 and allowed to stand at room temperature for one week. Violet crystals (M1) and a gray violet powder (M2) appeared and were separated by a spatula. The product in the third red eluate isomerized with ease at room temperature, and consequently was kept in a refrigerator. Only a small amount of crystals were obtained (M3). Found M1: C, 34.82; H, 3.72; N, 16.10%. Calcd for $CoC_{10}H_{13}N_4O_6$: C, 34.95; H, 3.81; N, 16.30%. Found M2: C, 33.85; H, 3.89; N, 15.72%. Calcd for $CoC_{10}H_{13}N_4O_6 \cdot 0.5H_2O$: C, 34.06; H, 4.00; N, 15.89%. Found M3: C, 33.33; H, 4.00; N, 15.41%. Calcd for $CoC_{10}H_{13}N_4O_6 \cdot H_2O$: C, 33.21; H, 4.18; N, 15.49%.

Isomerization. A solution containing one isomer was stirred and maintained at 80 °C in a temperature-controlled reaction vessel. The concentrations of M1, M2, and M3 were determined as follows. Initially, the concentrations of the M3 isomer (*fac*) was determined using high speed liquid chromatography and optical density. The concentrations of the M1 and M2 isomers could not be determined by chromatography since their bands overlaped. These were determined by measuring molar rotations [ϕ] at 454 and 500 nm. The values of the isomers are as follows.

	454 nm	500 nm
M1	4706	0
M2	0	−3029
M3	2066	3214

The concentrations of the M1 and M2 isomers were calculated using the following equation

$$[\phi]_{M1}x+[\phi]_{M2}y+[\phi]_{M3}(1-x-y)=\alpha[\text{molecular weight}]/cl,$$

where $[\phi]_{M1}$, $[\phi]_{M2}$, and $[\phi]_{M3}$ are the molar rotations, x and y are the concentrations of the M1 and M2 isomers, respectively. c is the initial concentration of the isomer, α the observed rotation expressed in degrees, and l the cell length. Since the concentration loss of the complexes due to reactions other than the isomerization was less than 2 percent, the concentration of the complex was assumed to be constant throughout the experiment. The isomerization of M3 was not attempted because of its insufficient yield.

Measurements. The electronic absorption spectra and optical rotatory dispersion curves were measured with a JASCO ORD-UV-5 spectrometer. The CD spectra were measured with a JASCO J-20 spectrometer, and the PMR spectra (60 MHz) in D_2O with a JEOL MH-60 spectrometer using sodium 2,3-dimethyl-2-silapentane-5-sulfonate as an internal reference.

Results and Discussion

Figure 1 shows the possible isomers of [Co(ida)(L-his)]. The two meridional isomers (a and b) are denoted by *cisN* and *transN* (the nitrogen atom of ida is cis or trans to the amine nitrogen atom of L-his). Figure 2 shows the absorption spectra of the three isomers of [Co(ida)(L-his)] and the numerical data are listed in Table 1. Zompa assigned the configurations of the three isomers of [Co(L-his)$_2$]$^+$ [5] by comparing their absorption spectra with those of the three isomers of [Co(L-2,4-dba)$_2$]$^+$ [6] (dba=diaminobutyrate ion). From previous spectroscopic studies,[7] it appears that the nitrogen atom of imidazole and that of ammine occupy nearly the same positions in the spectrochemical series. Since the nitrogen atom of amine lies at a higher position in the spectrochemical series than that of ammine, the nitrogen (Nα) attached to the α-carbon atom of L-his lies at a higher position than that of the imidazole ring (Ni). Yamatera's parameters[8] concerning the first band were estimated from the absorption maxima of the $[Co(NH_3)_6]^{3+}$,[9] $[Co(ox)_3]^{3-}$ [10] and *trans*(*N*)-K$[Co(ida)_2]^-$,[11] complexes ($\delta(NH_3\text{-ox})=4500$ and $\delta(N\alpha\text{-ox})=7400$ cm^{-1}). The estimated positions

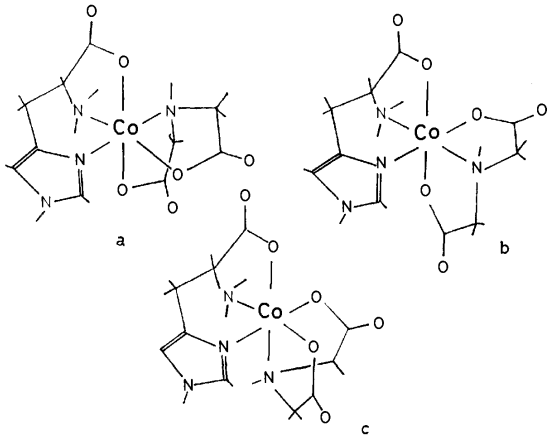

Fig. 1. The three possible geometrical isomers of the [Co(ida)(L-his)] complexes, a: *mer-cisN*, b: *mer-transN*, c: *fac*. The isomers are named by considering 5-membered N and O atoms.

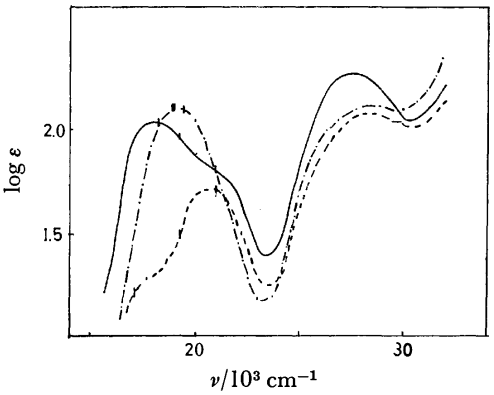

Fig. 2. Visible absorption spectra of [Co(ida)(L-his)]. *cisN* (——) *transN* (- - -), and *fac* (—·—·).

of the first absorption bands of the isomers are illustrated in Fig. 2. The isomer(M1) having a shoulder at the highest wave number in the first absorption band region can be assigned to the *cisN* isomer and one(M2) having a shoulder at the lowest wave number to the *transN* isomer.

PMR Spectra. Figure 3 shows the PMR spectra of [Co(ida)(L-his)]. We have reported that when X is an oxygen atom in the moity –CH–NH_2–Co(III)–X

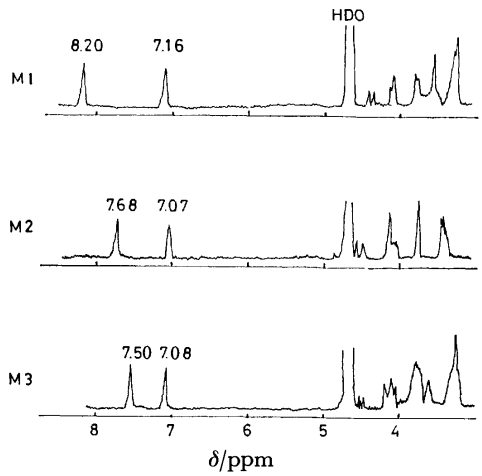

Fig. 3. PMR spectra of M1 (*cisN*), M2 (*transN*), and M3 (*fac*).

(X is trans to NH_2), the methine proton signals appear at a slightly higher magnetic field strength than in the case when X is a nitrogen atom. The sharp peaks in the low magnetic field region may be due to the imidazole protons attached to the 2-carbon (Fig. 3). This assings the *cisN* isomer for M1 and the *transN* for M2, since the sharp peak for M1 is located in a lower magnetic field than those for M2 and M3.

CD Spectra. Figure 4 shows the CD spectra of the isomers of [Co(ida)(L-his)]. The configurational effect of the complexes having one or two optically active tridentate ligands can not be well classified in terms of Δ and Λ chirality. These are for example $[Co(L\text{-}asp)_2]^-$,[12] *mer*-$[Co(dien)_2]^{3+}$,[13] (dien=diethylenetriamine), $[Co(L\text{-}2,4\text{-}dba)_2]^+$,[6] $[Co(L\text{-}2,3\text{-}dpa)_2]^+$[14] (dpa = diaminopropionate ion), and [Co(ida)(L-asp)]$^-$.[15] The complication of their CD spectra may be chiefly attributed to the vicinal effect due to the branch from the α-carbon atom. If such a vicinal effect can be eliminated from the CD curves, the calculated CD spectra may be compared with those of the known simple complexes. The assumption that the vicinal and the configurational effects is additive leads to the following additivity formulae:

$$\Delta\varepsilon(M1) = \Lambda(5\text{—}5) + \Lambda(5\text{—}5) + \Lambda(5\text{—}6) + L$$
$$\Delta\varepsilon(M2) = \Lambda(5\text{—}5) + \Lambda(5\text{—}6) + L$$
$$\Delta\varepsilon(M3) = \Lambda(5\text{—}5) + \Lambda(5\text{—}6) + \Lambda(5\text{—}6) + L$$

Table 1. Absorption and CD data of [Co(ida)(L-his)]

Complex	I band				II band			
	Aasorption		CD		Absorption		CD	
	$\bar{\nu}$ max[a]	log ε	$\bar{\nu}$ max	Δε	$\bar{\nu}$ max	log ε	$\bar{\nu}$ max	Δε

			20.0	0.48				

a) Wave numbers are given in 10^3 cm^{-1}.

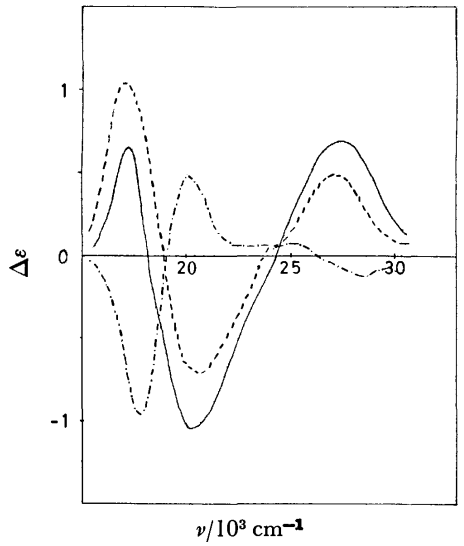

Fig. 4. CD spectra of three isomers of [Co(ida)(L-his)]. *cisN* (——), *transN* (- - -), and *fac* (—•—•).

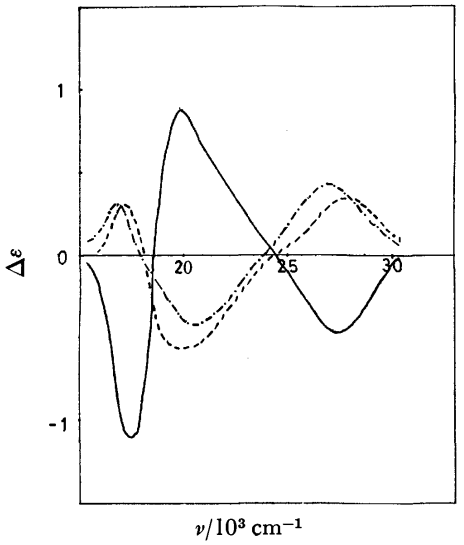

Fig. 5. Curve analysis of [Co(ida)(L-his)]. L(—•—•), Δ(5—5) (——), and Δ(5—6) (- - -).

where Δ(5—5) means the configurational effect between 5- and 5-membered chelate rings and L the vicinal effect due to L-his. It is reasonably assumed that $\Delta(5—5)+\Delta(5—5)=0$ and $\Delta(5—6)+\Delta(5—6)=0$. Then $\Delta(5—5)=\Delta\varepsilon(M3)-L$, $\Delta(5—6)=\Delta\varepsilon(M1)-L$. The calculated curves of Δ(5—5) and Δ(5—6) are shown in Fig. 5. The sign of Δ(5—5) in the lower wave number side of the first absorption band is negative and that of Δ(5—6) positive. The intensity of the Δ(5—6) ($=-\Delta(5—6)$) is smaller than that of Δ(5—5). The decrease in the intensity appears to correspond to the change in the CD intensity between $[Co(en)_3]^{3+}$ and $[Co(tn)_3]^{3+}$ [16] (tn=trimethylenediamine). The configurational curve, Δ(5—5) compare favorably with those for Δ-*cis*(*N*)-$[Co(ida)_2]^-$ [17] and Δ-*cis*(*N*)-$[Co(L\text{-}alama)_2]^-$ [18] (alama=alanine-*N*-acetate ion) though its intensity is small. The above results show that the structures of all the isomers may be assigned

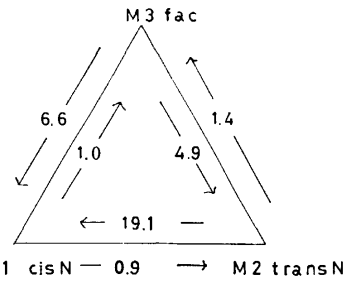

Fig. 6. The network of the isomerzation system.

on the basis of their CD spectra.

Isomerization. The three isomers of [Co(ida)(L-his)] isomerized in water without any catalysis. The mole fractions of these three isomers at equilibrium were 0.91 for *cisN*, 0.04 for *transN*, and 0.05 for *fac*. Such a distribution in favor of the *cisN* isomer is remarkable. The free energy differences at 25 °C are as follows; $\Delta G_{12}=G(M1)-G(M2)=-RT\ln(91/4)=-7.7$kJ and $\Delta G_{13}=-7.2$kJ. Figure 6 shows the relative rate constants calculated by means of the same method as that in the previous paper.[2] The molecular model concept suggests that the five-membered chelate rings of the coordinated ida can twist to some extent. The nearest atoms between the two coordinated ligands are the 2-proton of the imidazole and one of the methylene protons of ida for *cisN*, and the 2-proton of the imidazole and the imino proton of ida for *transN*. However, these distances do not appear to cause steric hindrance. In the case of the *fac* isomer, the distance between the one proton of L-his and the imino proton of ida is nearly 2.3—2.5 Å. This may cause some steric hindrance between these two ligands. However, the large free energy differences obtained are not reasonably accounted for by steric hindrance only. The electronic effect which is transmitted through the bonds may explain this distribution although this can not be deduced from the data.

Phase Equilibria in the Lu_2O_3–V_2O_3–V_2O_5 System at 1200 °C

Kenzo KITAYAMA and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 11, 1977)

The phase equilibria in the Lu_2O_3–V_2O_3–V_2O_5 system were established at 1200 °C. In this system, Lu_2O_3, $LuVO_3$, $LuVO_4$, V_2O_3, V_3O_5, V_4O_7, V_5O_9, V_6O_{11}, V_7O_{13}, and three new compounds $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8 are stable. $LuVO_4$, V_2O_3, VO_2, $Lu_7V_3O_{16}$, $Lu_2V_2O_7$, and LuV_4O_8 have non-stoichiometric compositions. The relationships between the composition and the $-\log P_{O_2}$ values of the solid solutions were obtained from the thermogravimetric results. On the basis of the phase equilibria, the standard Gibbs free energies of several reactions were determined. The spacings, relative intensities, and densities of new compounds were also determined.

In a previous paper,[1] the authors have established the phase equilibria in the Sm_2O_3–V_2O_3–V_2O_5 system at 1200 °C. In this system, we reported the existence of three ternary compounds, $Sm_{10}V_2O_{20}$ ($5Sm_2O_3 \cdot V_2O_5$), $SmVO_3$, and $SmVO_4$, and the homologous series of V_nO_{2n-1} of n=2—7. They also determined the standard Gibb energies of formation referred to reactions, $SmVO_3+1/2O_2=SmVO_4$ and $4Sm_2O_3+2SmVO_3+2O_2=Sm_{10}V_2O_{20}$, and the standard Gibbs energies of oxidation of the vanadium oxides found in the system.

In this paper, we choose Lu_2O_3 as one of the rare earth sesquioxides in the Lu_2O_3–V_2O_3–V_2O_5 system because its ionic radius is the smallest of the lanthanoid elements. The precise phase equilibria in the Lu_2O_3–V_2O_3 system have not yet been investigated, but the existence of orthorhombic $LuVO_3$ as a ternary compound in the system is well known, and its crystallographic properties have been reported.[2]

Recently, Brusset *et al.*[3] have studied the Lu_2O_3–V_2O_5 system in the temperature range from 600 to 1500 °C. They showed the existence of $4Lu_2O_3 \cdot V_2O_5$ together with a well-known tetragonal $LuVO_4$ phase, although the stable temperature range was not clear. As for the crystallographic properties of $4Lu_2O_3 \cdot V_2O_5$, they showed a simple X-ray diffraction diagram with only three peaks 2θ by Cu $K\alpha$(about 29.5, 31.9, and 32.3). However, the possibility of the existence of $4Lu_2O_3 \cdot V_2O_5$ was so ambiguous that they said that the diagram was incomplete.

The objectives of the present study are:(1) to establish the detailed phase equilibria in the Lu_2O_3–$V_2O_3 \cdot V_2O_5$ system at 1200 °C by changing the oxygen partial pressure; (2) to calculate the thermochemical properties based on the phase equilibria; and (3) to ascertain, upon the completion of the studies of the Ln–V–O system, whether or not the relationship between related standard Gibbs free energies of reaction and the ionic radii of rare earth ions as in the Ln–Fe–O system.[4]

Experimental

Analytical grades of Lu_2O_3(99.9%) and V_2O_5, which was obtained by heating the guaranteed grade of NH_4VO_3 at 500 °C in air for 24 h, have been employed as the starting materials. The desired ratios of Lu_2O_3/V_2O_5 were obtained by mixing thoroughly in an agate mortar under ethyl alcohol. The mixtures thus obtained were treated by the procedures described previously.[1]

The apparatus and procedures for controlling the oxygen partial pressure, keeping at a constant temperature, the method of thermogravimetry, the criterion for equilibrium establishment, the method of identifying solid phases after quenching, the method of lattice constant determination, the method of measuring the actual oxygen partial pressures, and the method of wet chemical analysis are the same as those discussed in previous papers.[1,5-7]

The oxygen partial pressure of $10^{-12.00}$ atm was chosen as the reference weight standard as was determined in the Sm_2O_3–V_2O_3–V_2O_5 system.

Results and Discussion

Phase Equilibria. Eleven samples with the different Lu_2O_3/V_2O_5 compositions of 0.1111, 0.2500, 0.3333, 0.4286, 0.5385, 1.0000, 1.500, 1.857, 2.333, and 4.000 were prepared. In Fig. 1, the relationships between the oxygen partial pressures and the compositions, W_{O_2}/W_T, of the samples with Lu_2O_3/V_2O_5 compositions of 0.1111, 0.2500, 0.4286, 1.500, 2.333, and 4.000 are shown as representative, where W_{O_2} is the weight gain from the reference weight standard, and W_T the toal weight gain of the samples as if the $V_2O_3+O_2=V_2O_5$ reaction were to be completed. In Table 1, the results of the identification of phases are shown; in the first column are the compositions of the starting material; in the second column, the experimental con-

ditions of log P_{O_2}, and in the third, the experimental time duration. Based on the experimental results of the thermogravimetry and the identification of the phases, the phase diagram shown in Fig. 2 was obtained. Following phases are stable under the present experimental conditions; Lu_2O_3(R), $LuVO_4$(B), $LuVO_3$(C), V_2O_3(D), V_3O_5(E), V_4O_7(F), V_5O_9(G), V_6O_{11}(H), V_7O_{13}(I), VO_2(J), and three new compounds, $Lu_2V_2O_7$(K), $Lu_7V_3O_{16}$(L), and LuV_4O_8(M). The letters in parentheses are the abbreviations of the compounds. $4Lu_2O_3 \cdot V_2O_5$, which has been reported by Brusset *et al.*,[3] did not appeared under the present experimental conditions. From the present results and Brusset's, $4Lu_2O_3 \cdot V_2O_5$ seems not to be stable, at least below 1500 °C.

Lu_2O_3 was stable under the present experimental conditions, as has already pointed out by Sekine and Katsura[8]. $LuVO_4$, $Lu_2V_2O_7$, $Lu_7V_3O_{16}$, LuV_4O_8, V_2O_3, and VO_2 have apparent deviations from the

a) The stability range in $\log P_{O_2}$ may be higher than −0.68. b) This value was obtained by extrapolation by using the experimental values. c) The stability range in $\log P_{O_2}$ may be lower than −12.00.

stoichiometric composition, judging from the results of thermogravimetry. The relationship between the N_o/N_d and the $\log P_{O_2}$ of the solid solutions is obtained by using the results of the thermogravimetry and by the method of the least squares with the general quadratic equation; $N_o/N_d=a+b\log P_{O_2}+c(\log P_{O_2})^2$. Here, N_o/N_d indicates the deviation of the oxygen atoms from the stoichiometric compound d.[6] The factors used to obtain a, b, and c, for each solid solution are given in Table 2. As for the V_2O_3 solid solution, previous data[1] were used to obtain a, b, and c. In Table 3, the compositions, the stability ranges in the oxygen partial pressures, and the abbreviations of the compounds are tabulated. The deviations from the

stoichiometric composition of $LuVO_4$ extended up to $LuVO_{3.99}$ at $\log P_{O_2}=-8.05$. $Lu_2V_2O_7$ has the composition ranges from $Lu_2V_2O_{6.89}$ at $\log P_{O_2}=-8.50$ to $Lu_2V_2O_{6.95}$ at $\log P_{O_2}=-9.58$ to $Lu_7V_3O_{16.4}$ at $\log P_{O_2}=-7.50$, and LuV_4O_8 from $LuV_4O_{7.93}$ at $\log P_{O_2}=-8.90$ to $LuV_4O_{8.05}$ at $\log P_{O_2}=-7.67$.

The relative intensities, spacings, assignments of indices, and density of $Lu_2V_2O_7$ have already been reported.[10] Recently, Bazuev *et al.*[11] reported the existence of $Lu_2V_2O_7$. According to them, $Lu_2V_2O_7$ was prepared from a mixture of Lu_2O_3 and VO_2 using the ceramic technique and had a ferromagnetic property. The lattice constant, 9.932±0.001 Å, is in very good agreement with ours, 9.934±0.001 Å.

In this study, we did not succeed in assigning the indices for new compounds, $Lu_7V_3O_{16}$ and LuV_4O_8. The relative intensities and spacings are given in Table 4. The sample powders of $Lu_7V_3O_{16}$ and LuV_4O_8 which were used in the X-ray diffraction and in the measurement of the density were prepared at an oxygen partial pressure of $\log P_{O_2}=-8.30$ and for 72 h and 92 h heating respectively. The densities of $Lu_7V_3O_{16}$ and LuV_4O_8 were determined to be 8.63 and 6.66 g/cm^3 respectively, using the powder picnometric method; they are given in Table 5, together with the powder color. The values in the second column in Table 5 imply the oxygen partial pressures at which the samples were prepared.

Table 5. Densities and colors of new compounds

Compound	$-\log P_{O_2}$ (atm)	Density (g/cm^3)	Color
$Lu_7V_3O_{16}$	8.30	8.63	dark brown
$Lu_2V_2O_7$	8.30	7.64	black
LuV_4O_8	8.20	6.66	black

The lattice constants of $LuVO_4$ and $LuVO_3$ are given in Table 6, together with the previous data.[2,3,12] Both data are in good agreement with the previous data, and neither depends on the oxygen partial pressure at which the samples were prepared.

The results and discussion of the V–O system have been presented in a previous paper.[1]

Calculation of Standard Gibbs Engergies of Reactions.

On the basis of the phase equilibria, the standard Gibbs energies of reaction, referred to the equations in Table 7, can be calculated from the equation; $\Delta G^\circ=-RT\ln K$, where R is the gas constant; T the absolute temperature, and K the equilibrium constant of each reaction. The activity of each component, $LuVO_4$, V_2O_3, $Lu_2V_2O_7$, $Lu_7V_3O_{16}$, and LuV_4O_8, in each solid solution at the compositions of B_3, D, K, L, and M may be set equal to unity. The activity of each component in the solid solution can readily be calculated by means of the Gibbs-Duhem equation on the basis of the experimental results presented in Table 2. A detailed calculation method has been described in a paper of Kimizuka and Katsura.[13] Activities which are necessary to calculate the standard Gibbs energies of the reaction are listed in the fifth column in Table 3. As an example, we will calculate the standard Gibbs energy of the reaction

$$2Lu_2O_3 + 3LuVO_3 + 1/2O_2 = Lu_7V_3O_{16}. \quad (1)$$

The equilibrium constant of Reaction 1 is represented as follows:

$$K(1) = a_{Lu_7V_3O_{16}}/(a_{Lu_2O_3}\cdot a^3_{LuVO_3}\cdot P^{-1/2}_{O_2}) = P^{-1/2}_{O_2}.$$

Here, $a_{Lu_2O_3}$ and a_{LuVO_3} are unity and $a_{Lu_7V_3O_{16}}$ may

be set as equal to unity, as has been described above. Using the above equation, $\Delta G^\circ=-RT\ln K=1/2\,P_{O_2}$, $\Delta G^\circ(1)=-32.3$ kcal/mol is obtained, where P_{O_2} implies the equilibrium oxygen partial pressure of Reaction 1. The standard Gibbs energies of reaction, referred to Eqs. 1 to 7, are summarized in Table 7. The values of Reaction 5 are obtained by using the values of Reactions 3 and 4.

Analysis of Tin Corrosion Products Using Conversion Electron Mössbauer Spectroscopy, Transmission Mössbauer Spectroscopy, and X-Ray Diffractometry

Mamoru SHIBUYA, Kazutoyo ENDO, and Hirotoshi SANO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received September 2, 1977)

Tin plates corroded by various acids were nondestructively analyzed by a ^{119}Sn conversion electron Mössbauer spectroscopy, a transmission Mössbauer spectroscopy, and an X-ray diffractometry. The conversion electron method was shown to be useful for analysis of some corrosion products which could not be easily observed by the transmission method. By using both the Mössbauer spectroscopy and the X-ray diffractometry, the corrosion products formed by 6.7M-HNO_3, 5.7M-HCl, and 9.0M-H_2SO_4 were determined to be $SnO_2 \cdot nH_2O$, $Sn_4(OH)_6Cl_2$, and $SnSO_4$, respectively.

Since Swanson and Spijkerman reported Mössbauer spectra of thin foil of ^{57}Fe by a conversion electron method,[1] the potential of this technique has been explored and its practical use has been recognized in such investigations as oxidation products,[2-4] corrosion products,[5] ion implantations,[6-8] and metallurgy.[9] The measurement is performed by detecting conversion electrons and Auger electrons. Although a transmission measurement gives information on the total bulk of a sample, the method has the restriction that the sample should be thin. However, the conversion electron method can provide information on the surface layers of a bulky sample because of the limited penetration range of the electrons. In a thick sample, which can be neither destroyed nor transformed in shape, most Mössbauer spectroscopic analyses have been so far made in a reflection geometry by detecting the scattered X- or γ-rays associated with the resonance of nuclei.[10,11] However, the conversion electron method is available for analysis of the chemical compositions and structures in thinner surface layers than can be studied with the scattered X- or γ-ray methods.

In the present paper, we describe the systematic studies of tin metals corroded by a variety of acids by means of the conversion electron method and the transmission method. An X-ray diffractometry was also applied to complement the Mössbauer spectroscopic analysis. Model compounds were synthesized in separate experiments in order to identify the corroded products.

Experimental

In order to detect conversion electrons, we constructed a gas-flow type proportional counter, which is essentially the same as that designed by Swanson and Spijkerman.[1] Our counter is made of a 2 mm thick brass plate and is rectangular in shape, $15 \times 20 \times 15$ cm^3. The anode consists of two tungsten wires of 0.00254 cm diameter which are 7.5 cm apart from each other and symmetrically located with respect to the centerline. The top plate is removable to facilitate placing the sample inside the counter and varying the number and the location of the anode wires.

Conversion electron Mössbauer spectra were determined at room temperature by placing a sample inside the counter. During accumulation of the spectra the anode was kept at a positive potential of 1370V with respect to the grounded brass plate and a helium-methane gas(*e.g.* Q gas) was passed through the counter at the flow-rate of *ca.* 10 cm^3/min. Transmission spectra were recorded by using a NaI(Tl) scintillation counter mounted behind the proportional counter. Both the Mössbauer spectra were measured against a 2 mCi $Ca^{119m}SnO_3$ source moving in a constant acceleration mode at room temperature. X-Ray diffraction data were obtained by using Rigakudenki No. 2001.

Samples studied were prepared by corroding 1 mm thick tin plates in various acid solutions at room temperature and by drying them at room temperature.

Results and Discussion

Mössbauer Spectra. Figure 1 shows Mössbauer spectra of a tin plate corroded by 6.7M-HNO_3 for 5 min. A transmission spectrum (a) gives two peaks, the isomer shift(I. S.) values of which are 0.00 mm/s and 2.56 mm/s with respect to calcium stannate. A conversion electron spectrum (b) consists of only one peak, which corresponds to the less intense line observed in the transmission spectrum. The main peak found in the transmission spectrum is assigned to β-Sn from its peak position. The peak of 0.00 mm/s isomer shift is assigned to the corrosion species formed on the tin

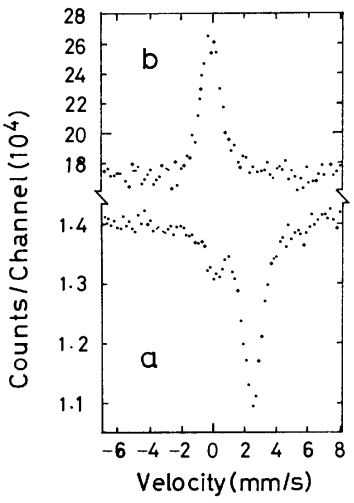

Fig. 1. Mössbauer spectra of a tin plate corroded by 6.7 M-HNO_3 for 5 min. a) Transmission spectrum, b) conversion electron spectrum.

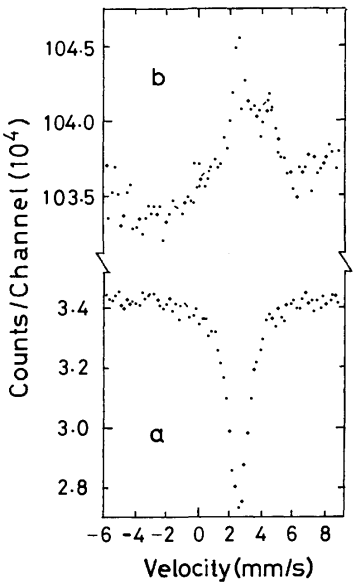

Fig. 2. Mössbauer spectra of a tin plate corroded by 5.7 M-HCl for 6.5 h. a) Transmission spectrum, b) conversion electron spectrum.

plate surface by reacting with 6.7M-HNO_3 because the spectrum of an uncorroded tin plate reveals only one peak, with the I. S. value of 2.56 mm/s.

Mössbauer spectra obtained from a tin plate corroded by 5.7M-HCl for 6.5 h are shown in Fig. 2. The transmission spectrum(a) gives a single peak assigned to β-Sn. The conversion electron spectrum(b) shows two peaks, the I. S. values of which are 4.44 mm/s and 2.56 mm/s; the latter peak has a shoulder at the I. S. value of nearly 0.00 mm/s.

As seen in Fig. 3, the transmission spectrum(a) of a tin plate corroded by 9.0M-H_2SO_4 for 3.8 d consists of a single peak, while the conversion electron Mössbauer spectrum(b) gives another peak around 4.40 mm/s.

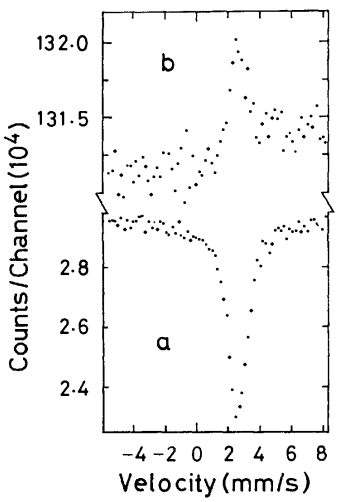

Fig. 4. Mössbauer spectra of a tin plate corroded by 27.0 M-HF for 6.2 d. a) Transmission spectrum, b) conversion electron spectrum.

The conversion electron spectrum of a tin plate corroded by 27.0M-HF for 6.2 d (Fig. 4 b) shows an intensive peak corresponding to β-Sn; no other peak can be clearly observed.

Thickness of Corrosion Layers. It was found from the experimental results that the line width of the substrate observed for the scattered electron is narrower than that for the γ-ray transmission method. For example, the comparsion of the β-Sn peaks observed in the two detection methods for the sample treated by sulfuric acid shows that the line width (fwhm) is 0.85 mm/s for the scattered electron method and 1.56 mm/s for the transmission method. This narrowing is quantitatively explained in terms of the decreased range of the electrons in the substrate, β-Sn. The electrons emitted from the substrate, β-Sn, are scattered through the corroded layers. If the corrosion layers exceed the effective range of the scattered electrons, the peak assinged to the substrate cannot be observed in the conversion electron spectrum. Therefore, it is concluded that corrosion layers for the sample treated by nitric acid nearly exceed the effective range of the conversion electrons. In order to determine the thickness of the corrosion layers, we estimated the effective range of the resonantly scattered electrons from ^{119}Sn for typical inorganic compounds; SnO_2, $CaSnO_3$, and $BaSnO_3$. The line width of a γ-ray transmission spectrum is proportional to an effective thikness, T, which is represented as

$$T = n\sigma tf. \quad (1)$$

Here n is the concentration of ^{119}Sn atoms in a unit volume; σ, the resonance cross-section; t, the absorber thickness; and f, the recoilless fraction. The experimental line width increases linearly with the increase in the concentration of the resonance atoms. In a previous communication, we demonstrated that the relation between the experimental line width and the effective thickness for γ-rays can be roughly applicable to the scattered electron method.[12] The

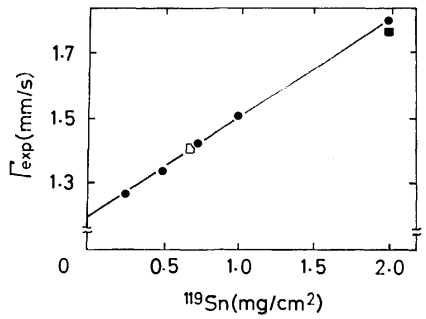

Fig. 5. Experimental line width *vs.* the apparent thickness of ^{119}Sn for SnO_2 by γ-ray transmission method (●). The line width observed by the scattered electron method (□) for the same sample as those by the γ-ray transmission method (■).

thickness dependence of the experimental line width in the γ-ray transmission method is shown in Fig. 5, together with the experimental line width obtained for the scattered electron method. For SnO_2 of 2.0 mg $^{119}Sn/cm^2$, the line width found in the γ-ray transimssion method is 1.79 mm/s and that found in the scattered electron method is 1.41 mm/s. The apparent thickness for the electron method obtained graphically from Fig. 5 is 0.72 mg/cm^2 in SnO_2. The value of apparent thickness for each sample is shown in the second column on Table 1. Electrons interact with surrounding atoms and ionize them during their passages. The Bethe's approximated equation concerning the energy loss of electrons shows that the stopping power of materials for electrons is proportional to the atomic number(Z) and inversely to the atomic weight(A) of the interacting atom. By assuming that the value of Z/A is nearly constant for each element concerned, the apparent effective thickness obtained from Fig. 5 is listed in the third column of Table 1. The values are in good agreement with each other, and do not depend on the kind of compounds with which the electrons interact. In the comparison of the line width of the scattered electron spectra with those of the γ-ray transmission spectra, it is found that the apparent cross-section is not identical for the two different kinds of detection methods. The apparent cross-section for emission of conversion electrons is approximately greater than that of γ-ray radiations by a conversion coefficient, α. The values shown in the third column in Table 1 must be divided by the conversion coefficient, 5.12, since the values were taken from the γ-ray transmission method. The value 2.21+0.38 mg/cm^2 is estimated for the effective range of scattered electrons of ^{119}Sn. Auger electrons are also emitted as a result of the deexcitation of ^{119}Sn atoms, and these electrons will enhance the intensity of the conversion electron Mössbauer spectrum. Moreover, Tricker *et al.* pointed out that non-Mössbauer atoms (chromium or aluminium) enhanced the intensity of a Mössbauer spectrum when these atoms were evaporated on iron foil.[13] They concluded that electrons were emitted from the chromium or aluminium atoms by the X-rays which accompany the Mossbauer effect. Although the effects on the line width of the spectrum remain unsolved, the contribution may be assumed to be small.

Table 1. The effective ranges determined for the resonantly scattered electrons in tin compounds

	Mean value :	11.30±1.81

X-Ray Diffraction Analysis. X-Ray diffractometry is a useful method for assignment of chemical species of a solid sample. In order to compare the characteristics of the X-ray diffractometry with the conversion electron Mössbauer spectroscopy for the corrosion sample, we examined the results obtained by using both these detection methods. For the purpose of the identification of corrosion products, we synthesized the chemically pure tin compounds which can be attributed to the corroded products based on the conversion electron Mössbauer spectroscopy, and measured their X-ray diffraction and transmission Mössbauer spectrum.

The Mössbauer data of the corrosion species produced by nitric acid indicate the presence of tin(IV) species similar to SnO_2. It is also known that a metallic tin plate reacts with diluted nitric acid to form metastannic acid, $SnO_2\cdot nH_2O$. The compound was prepared by according to the procedure of Weiser and Milligan,[14] and was checked by the X-ray diffractometry (see Fig. 7). We found good agreement between the pattern of the prepared sample and that of the tin plate corroded by 6.7M-nitric acid for 5.0 min, although those

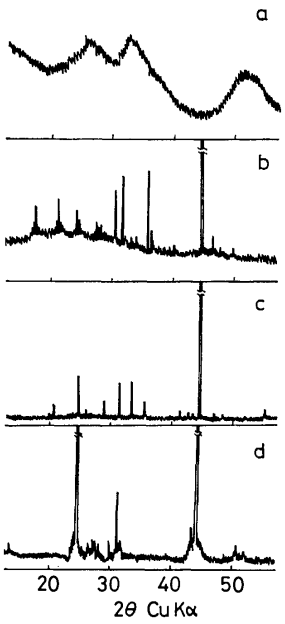

Fig. 6. X-Ray diffraction patterns. a) A tin plate corroded by 6.7 M-HNO_3 for 5 min, b) a tin plate corroded by 5.7 M-HCl for 6.5 h, c) a tin plate corroded by 9.0 M-H_2SO_4 for 3.8 d, d) a tin plate corroded by 27.0 M-HF for 6.2 d.

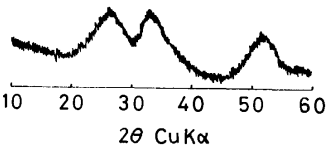

Fig. 7. X-Ray diffraction pattern of metastannic acid.

patterns are very broad, indicating an amorphous state. Transmission Mössbauer spectrum gives the I. S. value of 0.00 mm/s at room temperature for both samples. These results indicate the formation of metastannic acid, $SnO_2 \cdot nH_2O$, on the tin plate treated by 6.7M-nitric acid.

Mössbauer data of the tin plate corroded by 5.7M-hydrochloric acid for 6.5 h indicate a presence of Sn(II) and Sn(IV) corroded species. The X-ray diffraction pattern consists of many sharp lines and a broad line ranging from 20 to 35 deg. In order to identify the corroded products, the X-ray diffraction data were compared with those of Sn(II) compounds such as $SnCl_2$, $SnCl_2 \cdot 2H_2O$, and $Sn_4(OH)_6Cl_2$, and with $SnCl_4 \cdot 5H_2O$. X-Ray diffraction data of $Sn_4(OH)_6Cl_2$ agree the best with those of the corroded sample, as shown in Table 2. Since the Mössbauer parameters have not been reported for the compound, we prepared it by the procedure of Donaldson *et al.*[15] and accumulated the transmission spectrum at room temperature. The I. S. value and the quadrupole splitting (Q. S.) value are found to be 3.76 mm/s and 0.76 mm/s, respectively. The values are in good agreement with those of the corroded product found in a conversion electron spectrum. The conversion electron Mössbauer spectrum shows the presence of Sn(IV)

a) JCPDS data.

species with weak intensity in addition to the main peak of $Sn_4(OH)_6Cl_2$; the X-ray diffraction pattern also indicates the presence of amorphous species which may be ascribed to tin(IV) species produced on the tin plate. These observations lead us to the conclusion that $Sn_4(OH)_6Cl_2$ is the main product and some tin-(IV) species are produced on a tin plate treated by 5.7M-HCl.

Mössbauer spectra of the tin plate corroded by 9.0M-sulfuric acid for 3.8 d indicate the presence of Sn(II) compound. The X-ray diffraction data were compared with those of Sn(II) compound, as mentioned for the sample corroded by hydrochloric acid. The data of $SnSO_4$ are in good agreement with those of the tin plate corroded by 9.0M-sulfuric acid for 3.8 d (Table 3). The values of I. S. and Q. S. of $SnSO_4$ at room temperature are 3.98 mm/s and 0.95 mm/s, respectively. These values are in good agreement with those of the corroded species. The results indicate the formation of $SnSO_4$ of the tin plate corroded by 9.0M-sulfuric acid.

In the case of the sample corroded by 27.0M-hydrofluoric acid for 6.2 d, the conversion electron Mössbauer spectrum gives no definite peaks, the transmission spectrum gives only the β-Sn peak, and the X-ray diffraction pattern of the sample does not agree with any of the JCPDS data available for tin fluoride compounds.

The present results indicate the following conclusion: In order to determine the thin corrosion products formed on a metal surface, the observed peaks of X-ray diffraction pattern are so weak, as shown in Fig. 6, that the identification of the products is tedious and difficult. The transmission Mössbauer technique gives only the spectrum of the major substrate in a limited time of accumulation of the spectrum. The conversion electron Mössbauer technique, on the other hand, provides information concerning the chemical state of the products through the isomer shift and quadrupole splitting. Although the complete chemical form of the corroded products may not be determined, the conversion electron Mössbauer technique makes it very easy to cross-assign the weak peaks of the X-ray diffractometry to the possible chemical species.

Equilibrium Study of the Fe–V–S System by Thermogravimetry

Hiroaki WADA

National Institute for Researches in Inorganic Materials, Kurakake, Sakura-Mura, Niihari-Gun, Ibaraki 300-31

(Received September 7, 1977)

An equilibrium study of the Fe–V–S system was carried out in the range of $\log(P_{S_2}/\text{atm}) = -4$ to -0.8 at temperatures between 723 and 1093 K. The gravimetric method was employed by making use of a quartz spring balance. The partial pressure of sulfur was controlled in an N_2–sulfur vapor system by temperature regulation. The partial pressure of S_2 was calculated from the thermodynamic data, taking account of the existence of different molecular species: S_2 through S_8. Three kinds of ternary sulfides with different Fe/V ratios were used as starting material. The P_{S_2}-T-X relation was established through *in situ* measurements at high temperatures. It was found that the Fe–V–S system has an extensive ternary solid solution with the NiAs type of fundamental structure.

The compounds in the Fe–V–S system have not received much attention in the past, because they seem to occur in nature rather infrequently. Only the synthetic FeV_2S_4 compound, which is related to the ternary transition metal chalcogenides MM'_2S_4(M=Fe, Co,Ni; M′=Ti,V; X=S,Se), has recently been studied by solid state physicists, who reported its structural, magnetic and electrical properties.[1-4] However, very few studies have been published on the thermochemical aspects needed to determine the ternary phase relations in the Fe–V–S system.

Much information has now been obtained on the phase relations and crystal structures in the binary systems Fe–S[5] and V–S.[6] Vanadium sulfides, where the sulfur atoms are in hexagonal close packing, form the B8 (NiAs-type) structure at the composition VS, and the C6 ($Cd(OH)_2$-type) structure at VS_2. Within the composition limits VS–VS_2, structures intermediate between the B8 and C6 types are formed due to the removal of metal atoms from every second metal layer in the B8 structure. At lower temperatures, the vanadium vacancies are ordered within alternate metal layers, giving rise to ordered superstructures such as monoclinic V_3S_4(nonreduced space group I2/m referred to the fundamental NiAs-type cell) and monoclinic V_5S_8 (nonreduced space group F2/m).[7] With increasing temperature, the homogeneity ranges within those structures tend to be broadened. On the other hand, iron sulfides do not show the complete transition between the B8 and C6 structure types. The composition Fe_7S_8 is the stable limit of the B8 structure in the Fe–S system. When the number of metal vacancies increases beyond that in Fe_7S_8, a different structure type, such as cubic FeS_2(space group Pa3), becomes stable.

Accordingly, it is expected that the Fe–V–S system contains complicated ternary solid solutions based on the NiAs-type fundamental structure. In the solid solution, one end member is iron sulfide, FeS_x (NiAs-type) in the compositional range FeS–Fe_7S_8, while the other is one of the vanadium sulfides, such as VS_x (NiAs-type) in the compositional range VS–V_7S_8, V_3S_4 (distorted NiAs-type), or V_5S_8 (distorted NiAs-type). In order to clarify the behavior of ternary sulfides of the Fe–V–S system, it is important to determine in detail at high temperatures the phase relations and the compositional stability of the ternary solid solutions included in the system. Thus, the purpose of the present investigation was to establish the equilibrium diagrams of the sulfur-rich portion of the Fe–V–S system from the thermochemical viewpoint.

The equilibrium study was carried out mainly with a gravimetric method by making use of a quartz spring balance at 773—1093 K. The partial pressure of sulfur was controlled in an N_2–sulfur vapor system only by temperature regulation. The present paper is concerned with the calculation of the partial pressure of S_2 at specimen temperature in the employed experimental system and the P_{S_2} (equilibrium sulfur pressure)-T (temperature)-X (composition) relations of the Fe–V–S system at high temperatures.

Experimental

Materials. Reagent grade $VOSO_4 \cdot 3H_2O$ was mixed in ethanol with a reagent grade $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ in an agate mortar in desired quantitites. The mixture was dried, put in a quartz boat, and heated in an H_2S atmosphere at 1323 K for 4 h. The sulfide powder thus synthesized was quenched to room temperature and was used as the starting material. Prior to the experiments, the composition of the powder samples was determined by colorimetric methods for vanadium and ion and by weight-loss on oxidation to $xFe_2O_3 \cdot yV_2O_5$ at 873 K for sulfur. Fe/(Fe+V) ratios of the synthesized sulfides were in good agreement with those of mechanical mixtures of source materials within the accuracy of $\pm 0.5\%$. The over-all errors involved in the chemical analysis were $\pm 0.2\%$ by weight.

Sulfur Pressure Control. A direct sulfur pressure control method was employed in the equilibrium studies. The principal procedure is similar to that described by Wakihara *et al.*[8] The apparatus used for the equilibrium runs is shown schematically in Fig. 1. All this apparatus was constructed of quartz glass. The heating system was divided into five parts in order to keep each portion of the apparatus at the desired temperature. Nichrome wire (0.8 and 0.45 mm) and Pt–40%Rh wire (0.8 mm) were wound directly outside the quartz assembly as shown in Fig. 1 and fixed with an alumina cement. The temperatures of five portions of the system were controlled by chromel-alumel thermocouples.

Five hundred grams of guaranteed reagent grade sulfur was kept in the round-bottom reservoir A (2 dm^3). After passing nitrogen gas through the apparatus for 12 h, the sulfur was heated at 673 K and changed to the molten state by means of the heating mantle. Prior to use, the nitrogen gas was purifired by means of an MCN-005 type gas purifier

(Japan Pure Hydrogen Co.) in order to remove oxygen and water impurities. The saturated sulfur vapor over the molten sulfur was transported to the upper part of the apparatus by nitrogen gas at a constant rate (2 cm^3 of N_2/s). The central zone (width: 10 cm) of part B was held at the minimum temperature in all this apparatus so that the transported sulfur vapor from the reservoir became supersaturated and excess sulfur was condensed at this zone. Only the sulfur vapor which equilibriated at the minimum temperature zone was carried to the reaction chamber C. Thus, a desired partial pressure of sulfur was obtained by controlling the temperature within ±0.5 K at the minimum temperature zone. The upper portions, D and E, were also heated at higher temperatures than that of the minimum temperature zone so as to avoid any condensation of sulfur in the course of passing the atmosphere. At the outlet, F, sulfur was collected into a U-tube cooled by liquid nitrogen, and the weight of sulfur was measured for the calculation of partial pressure of S_2.

Thermogravimetry. For study of equilibrium experiments, a gravimetric method was employed, in which the elongation of a McBain balance could be followed by means of a cathetometer. The spring balance manufactured from a quartz glass fiber has the sensitivity of 67 mm per g weight at room temperature. The balance was suspended from a solid hook of a quartz rod in the center of the cap E. About 1 g of sulfide powder sample was placed in a quartz crucible (diameter: 16 mm, length: 16 mm, and weight: 280 mg) suspended from the top of the spring by strands of thin gold wire (0.2 mm). The length of the wire was adjusted in order that the crucible might be situated in the middle of the reaction chamber C. In order to observe the target visually, the spring chamber D was equipped with a transparent window (12×2.5 cm), which was not covered by the cement. A fluorescent lamp gave illumination from the rear side of the window. By making use of a quartz reference rod, the elongation of the spring was measured with the aid of a travelling microscope. The error in composition of sulfide specimens was estimated to be ±0.002 or sulfur to metal ratios, because the weighing could be read accurately to 0.2 mg, which corresponded to 0.001 cm of the smallest scale division.

Equilibrium was judged to be attained when the sample weight was constant. For log P_{S_2} of −2 and above, three hours were sufficient to attain equilibrium. For log P_{S_2} less than −3, twelve hours were found to be sufficient. The composition of the sulfide was calculated from the weight loss of the sample, assuming iron and vanadium to be involatile.

Besides the measurements described above, some supplemental experiments were carried out in order to examine the X-ray powder diffraction patterns of sulfides. A sample was placed in the crucible suspended from the cap E with a long platinum wire (0.2 mm) into the apparatus. After equilibrium was attained, the crucible was lifted up to the upper portion of the apparatus, taken out, and quenched in liquid nitrogen. Sulfides thus obtained were identified by using an X-ray diffractometer set up for Ni-filtered CuK_α radiation. The measurement was carried out at a goniometer scanning speed of 0.5° min^{-1}.

Results and Discussion

Calculation of Partial Pressure of S_2. The experimental results of the sulfur pressure measurements, in terms of the weight of collected sulfur at F, are presented in Table 1. The relationship between the weight of sulfur transported by unit volume of nitrogen and the temperature of the minimum temperature zone is given very well by the following formula (least squares treatment): $\log (w/mg\,dm^{-3}) = -3787\frac{1}{T/K} + 9.281$. This linear relationship indicates that the sulfur pressure was controlled precisely by the temperature regulation at the minimum temperature zone in the selected experimental system.

According to Rau *et al.*,[9] sulfur vapor contains molecular species from S_2 to S_8 at high temperatures below 1173 K. Therefore, it is necessary to calculate the partial pressure S_2 while considering the equilibrium between the different molecular species from S_2 to S_8.

Table 1. Relationships between the mass flow rate of sulfur and the temperature of the minimum temperature zone

Temperature (K)	Mass flow rate of sulfur (mg/dm^3 of N_2)
403	0.763
424	2.164
426	2.653
471	16.907
505	61.753
536	164.360
567	398.730

The partial pressure of S_2 at the specimen temperature was computed in the following way from the thermodynamic data of Rau *et al.* Assumptions were made that the sulfur vapor behaved ideally as a perfect gas and that a steady state of mass flow was set up in the experimental system. Then, P_{S_2} is given by the following equation:

$$P_{S_2} = \frac{m_2}{n + \sum_{i=2}^{8} m_i}, \quad (1)$$

where m_i and n are the number of moles of the sulfur vapor species S_i and of nitrogen, respectively, in the mass flow of gas for a given time interval t. A perfect gas obeys the following relations:

$$PV = (n + m_2 + m_3 + \cdots + m_8)RT, \quad (2)$$

and

$$P_{S_i} = m_i RT. \quad (3)$$

Substituting for m_i from Eq. 3 into Eq. 1, and rearranging, we obtain the following equation:

$$1 - \sum_{i=2}^{8} P_{S_i} = \frac{32.064\,n}{W} \sum_{i=2}^{8} iP_{S_i}, \quad (4)$$

where W represents the total amount of sulfur collected at the outlet within a time interval t. The equilibria connecting the various molecular species with S_2

$$S_i = (i/2)S_2 \quad (5)$$

are given by the equilibrium constant K_i

$$K_i = P_{S_2}^{i/2}/P_{S_i}. \quad (6)$$

Therefore, substitution of values of the equilibrium constant K_i into Eq. 4 through Eq. 6 yields the following expression as a function of P_{S_2}:

$$(2A+1)X^2 + \sum_{i=3}^{8} \frac{iA+1}{K_{S_i}} X^i - 1 = 0, \quad (7)$$

where $A = \frac{32.064n}{W}$ and $X = P_{S_2}^{1/2}$. Prior to the calculation of P_{S_2}, the equilibrium constant K_i was computed from the thermodynamic data of Rau *et al.* According to Eq. 7, the partial pressures of S_2, which were in equilibrium with the specimens, were calculated in the iterative Newton method from the data in Table 1. The physically meaningful value for P_{S_2} was selected. Values of log P_{S_2} are drawn in Fig. 2 as a function of the temperature at the minimum temperature zone with the specimen temperature as a parameter. The results for each given series are tied together by a smooth curve, which shows that the logarithmic values of P_{S_2} ranged from -4 to -0.8, corresponding to the change of temperature from 373 to 573 K. The uncertainty of log P_{S_2} was estimated to be ± 0.02 or less throughout the experimental range. From those smooth curves, the correction of P_{S_2} for specimen temperature could be made with sufficient accuracy. It will be seen that for specimen temperatures below 1000 K and also for values of log P_{S_2} higher than -2, the correction is not negligible.

Composition vs. P_{S_2} *Diagrams in the Fe–V–S System.* Representative selections of ternary sulfides in the Fe–V–S system (Fe/(Fe+V) mole ratios=0.05, 0.26, 0.35,

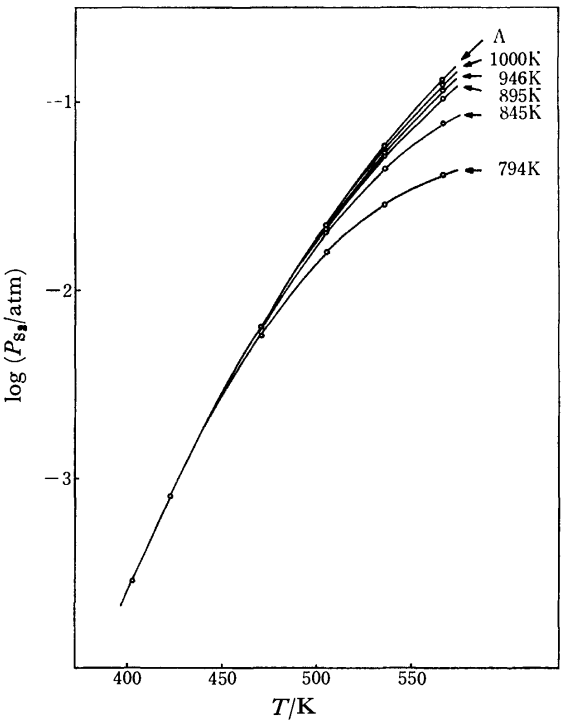

Fig. 2. Log P_{S_2} curve as a function of the temperature at the minimum temperature zone with the specimen temperature as a parameter.
A: Theoretical value, which is deduced from calculation of P_{S_2} on the basis of the assumption that sulfur vapor consists of only S_2 species.

respectively) have been subjected to an equilibrium study by the thermogravimetry. The experimental results of the investigation are shown graphically in Figs. 3—5. The isotherms drawn in Figs. 3—5 give the variation of equilibrium sulfur pressure P_{S_2} in relation to the composition of sulfides. The abscissa and ordinate are sulfur to metal ratio (S/(Fe+V)=X) and log P_{S_2}, respectively. Also, the phases as revealed by X-ray diffraction of the quenched specimens are given in the figures together with those judged from results of *in situ* measurements.

Figure 3 shows isotherms of the ternary sulfide with composition $Fe_{0.05}V_{0.95}S_x$. The composition covered between $Fe_{0.05}V_{0.95}S_{1.33}$ and $Fe_{0.05}V_{0.95}S_{1.60}$. Two discontinuities are found in the composition-P_{S_2} diagrams for 895 K in this region. One is in the range d—e ($1.45 \leqq X \leqq 1.46$), and the other in the range f—g ($1.55 \leqq X \leqq 1.56$). The horizontal isotherm described above represents a two-phase equilibrium. It becomes narrower and eventually vanishes with increasing temperature.

From Fig. 3, it is evident that the specimens at 895 K contain three phases: A, B, C. The tangent to the isothermal curves approaches gradually to a vertical line at the specific compositions of a ($X=1.33$) and c ($X=1.60$) in the phase A and C regions, respectively. At the same time, the sulfur pressure changes rapidly. Judging from this feature of the isotherms, it can be suggested that the A and C phases correspond to (Fe+V) : S=3 : 4 and (Fe+V) : S=5 : 8 phases, respectively. The sulfur-rich limit of the former extends to the com-

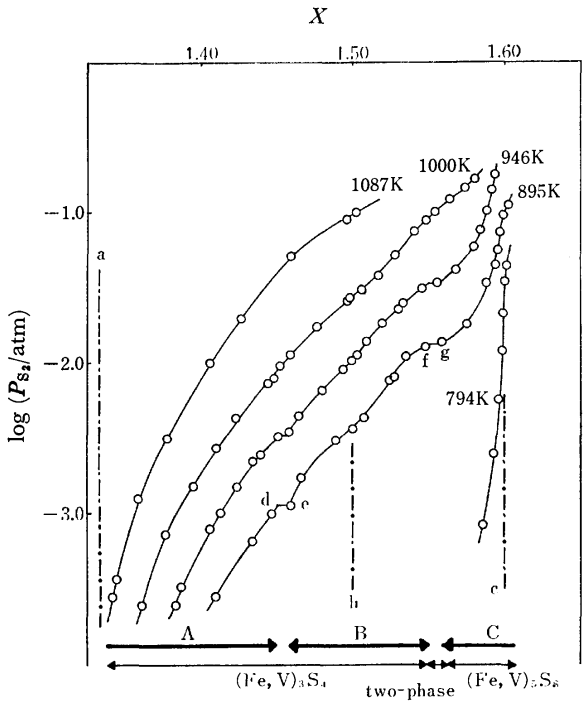

Fig. 3. P_{S_2}-composition (S/(Fe+V)=X) isotherms of $Fe_{0.05}V_{0.95}S_x$. Results of powder phase identifications are shown in lower part of figure together with results of phase identifications by thermogravimetry.
a: $(Fe_{0.05}V_{0.95})_3S_4$, b: $(Fe_{0.05}V_{0.95})_2S_3$,
c: $(Fe_{0.05}V_{0.95})_5S_8$.

position of X=1.45 and the metal-rich limit of the latter to X=1.56, where the isotherm becomes horizontal at 895 K. Within the phase B region ($1.46<X<1.55$), however, rapid change in the pressure at a specific composition is not observed. Instead, at the composition X=1.50 the curvature changes. A relatively small change in the pressure causes an appreciable variation of the composition, suggesting the flatness of the free energy surface. As evident in the curves for 1000 and 1087 K, the phases exhibit large mutual solubilities with increasing temperature.

A few remarks should be made here regarding the powder X-ray diffraction patterns of the quenched specimens. In contrast to the *in situ* observations described above, only two phases were detected in the range $1.33\leqq X\leqq 1.60$. Their X-ray powder patterns were similar to those of V_3S_4 and V_5S_8, respectively, in the V–S system. This suggests that Fe can substitute for V in both V_3S_4 and V_5S_8 phases due to the formation of ternary solid solutions. In the range, $1.55\leqq X\leqq 1.56$, a mixture of (Fe, V)$_3$S$_4$ and (Fe,V)$_5$S$_8$ patterns was obtained.

In the range, $1.45<X<1.55$, however, no mixture was obtained in the X-ray powder diffraction pattern; this result is inconsistent with the observation in Fig. 3. This is considered to originate from the difficulties that the phase in the range $1.46<X<1.55$ can hardly be distingushed from the (Fe,V)$_3$S$_4$ phase by X-ray powder analysis, due to the similarity of crystal structure. In fact, both phases show a large mutual solubility with increasing temperature (above 1000 K in Fig. 3). The unknown phase, B, may be inferred to be (Fe,V)$_2$S$_3$ phase, on the analogy of sesquisulfide V_2S_3, from a study of the V–S system.[10,11] In the present study, therefore, the phase described above is designated as the (Fe,V)$_2$S$_3$ phase for convenience throughout the paper.

Figure 4 shows isotherms with the composition $Fe_{0.264}V_{0.736}S_x$, richer in Fe than that in Fig. 3. The region covered experimentally lies between the composition $Fe_{0.264}V_{0.736}S_{1.333}$ and $Fe_{0.264}V_{0.736}S_{1.520}$. Two phases, A and B, exist in this range. Rapid increase of the pressure is observed near the stoichiometric compositions, $(Fe_{0.264}V_{0.736})_3S_4$ and $(Fe_{0.264}V_{0.736})_2S_3$. This indicates the existence of extensive ternary solid solutions such as (Fe,V)$_3$S$_4$ and (Fe,V)$_2$S$_3$, one end member of which is one of vanadium sulfides such as V_3S_4 and V_2S_3.

Again, the X-ray powder diffraction of the quenched specimen exhibits no difference between the two phases.

Figure 5 shows isotherms with the composition $Fe_{0.349}V_{0.651}S_x$. Within the present experimental pressure range, a large change in the pressure is observed only near the composition, X=1.33, in the phase A region. Therefore, it is considered that this phase is included in the region of the solid solution of the (Fe,V)$_3$S$_4$ phase.

As shown in Figs. 3—5, within the present experimental temperatures and Fe/V ratios, the features of isotherms depend upon compositions and temperature. With respect to isotherms, it is found that the sulfur content in the ternary sulfide which is equilibriated at the respective P_{S_2} values decreases with increasing Fe/V ratio.

This indicates that the equilibrium sulfur pressure of sulfides in the Fe–V–S system increases with decreasing vanadium content, when the S/(Fe+V) ratio is held

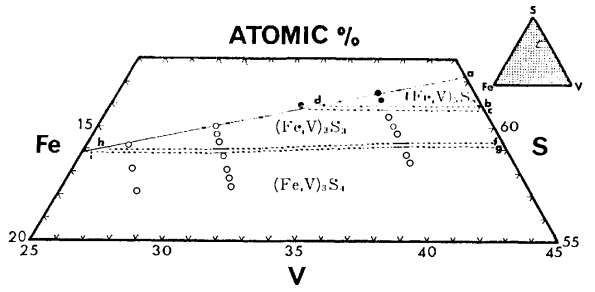

Fig. 6. Tentative phase diagram of the sulfur-rich portion of the Fe–V–S system for 895 K.
Two-phase fields are represented as follows
Area b-c-d-e: $(Fe,V)_5S_8+(Fe,V)_2S_3$, and Area f-g-h-i: $(Fe,V)_2S_3+(Fe,V)_3S_4$.
Phase identifications of quenched specimens by X-ray powder diffraction method are shown as follows
○: monoclinic V_3S_4-type structure,
●: monoclinic V_5S_8-type structure.

constant. From the experimental results described before, it is concluded that within the range Fe/(Fe+V) =0.05, 0.26, and 0.35, solid solution phases of $(Fe,V)_3S_4$, $(Fe,V)_2S_3$, and $(Fe,V)_5S_8$ are found and that the mutual solubility increases with increasing temperature (Figs. 3—5).

The tentative isothermal phase diagram in the sulfur-rich portion of the Fe–V–S system for 895 K was constructed on the basis of the results of thermogravimetry. The phase relations and their compositional limits are summarized in Fig. 6.

The iron-rich limits of solid solution phases such as $(Fe,V)_5S_8$ and $(Fe,V)_2S_3$ are determined by a smooth fitting of data points which are obtained under the highest sulfur pressure condition ($\log(P_{S_2}/\text{atm})=-0.95$) in this study. This boundary is drawn approximately as a straight line. The extension of this line intersects the boundary line, V–S, at the point a, whose composition is given as about 62.2 atomic % of sulfur. This value is in good agreement with that of the sulfur-rich limit of V_5S_8 phase ($VS_{1.64}$) which was reported by Saeki *et al.*[12] However, phase relations outside the line showing the iron-rich limits of solid solutions could not be determined owing to the limitation of the direct sulfur pressure control method and are omitted in Fig. 6.

With experimental data obtained in this study and with the homogeneity range of the compounds from the V–S system, as previously determined by De Vries and Jellinek[6] for V_5S_8 phase and by Nakahira *et al.*[11] for V_2S_3 and V_3S_4 phases, it was possible to draw two-phase fields. The boundaries of two-phase fields which show discontinuity of isotherms are represented as dotted lines nearly in parallel with the FeS–VS join. As shown in Fig. 6, two-phase mixtures of $(Fe,V)_5S_8+(Fe,V)_2S_3$ and $(Fe,V)_2S_3+(Fe,V)_3S_4$ are found in the range of S/(Fe+V) atomic ratios, 1.55—1.56 and 1.44—1.45 or 1.45—1.46, respectively.

Judging from the behavior of the iron-rich limits of solid solution fields, it was expected that the monoclinic $(Fe,V)_3S_4$ phase was stable over a wide compositional range. With the aid of a supplemental experiment using iron-rich ternary sulfides, the phase boundary of $(Fe,V)_3S_4$ was confirmed to be reached to the position of about 0.30 Fe/(Fe+V) ratio. Some representative unit-cell dimensions of quenched specimens in the $(Fe,V)_3S_4$ phase field are listed in Table 2. It is indicated that the axial dimensions, especially of the a- and c-axis, change smoothly with corresponding variations in Fe composition. From the results mentioned above, it is concluded that stoichiometric FeV_2S_4, as reported by many investigators, is not a specific ternary phase, but is included in the $(Fe,V)_3S_4$ solid solution fields.

The author is at present extending the present work to the iron-rich portion of the composition triangle of FeS–VS–S.

The author wishes to express his hearty thanks to Professor Mitsuoki Nakahira of Okayama College of Science for his encouragement and helpful discussions throughout this study.

TABLE 2. UNIT-CELL DIMENTIONS OF $(Fe,V)_3S_4$ SOLID SOLUTION

Composition	a(Å)	b(Å)	c(Å)	β(°)	Volume (Å^3)
$Fe_{0.05}V_{0.95}S_{1.39}$	5.860±3	3.285±2	11.355±1	91.97	218.5
$Fe_{0.26}V_{0.74}S_{1.38}$	5.855±2	3.291±1	11.297±5	91.94	217.5
$Fe_{0.35}V_{0.65}S_{1.39}$	5.848±2	3.291±1	11.237±5	91.95	216.2

Raman and Infrared Spectra of μ-O_2 Dicobalt(III) Complexes*

Takashi SHIBAHARA and Masayasu MORI

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received October 8, 1977)

Raman and infrared spectra of μ-hyperoxo and μ-peroxo ammine and cyano dicobalt(III) complexes have been studied and isotopic shifts of ν(OO) and ν(CoO) examined using ^{18}O. A μ-hyperoxo complex, $[(NH_3)_5Co(O_2)Co(NH_3)_5]X_5$ shows peaks around 1110, 620, and 440 cm^{-1} assignable to ν(OO), sν(CoO), and asν(CoO), respectively, whereas a μ-peroxo complex, $[(NH_3)_5Co(O_2)Co(NH_3)_5]X_4$ shows peaks around 805, 645, and 545 cm^{-1} assignable to ν(OO), sν(CoO), asν(CoO), respectively. These observed values are best reproduced, when the following force constants are assumed in the UBFF calculation: K(OO)=5.6, K(CoO)=1.40 mdyn/Å for μ-hyperoxo complexes and K(OO)=2.7, K(CoO)=2.15 mdyn/Å for μ-peroxo complexes. The calculated isotopic shifts are in good agreement with the observed ones. Raman and infrared spectra of dibridged μ-amido-μ-O_2 (both peroxo and hyperoxo) dicobalt(III) complex have also been characterized. A linear relationship has been found between ν(OO) and the bond order of the O_2 moiety in O_2-complexes in different oxidation states including alkali hyperoxide, alkali peroxide, hydrogen peroxide, oxygen, and O_2^+ species.

Although much work has been done on the preparation, reaction mechanisms and X-ray crystallography of O_2-bridged binuclear cobalt(III) complexes,[1] the information about the vibration of oxygen–oxygen and cobalt–oxygen bonding in the complexes has been relatively poor.[2-7]

The variation of O–O and Co–O stretching frequencies with the change in the oxidation state (*i.e.* peroxo to hyperoxo species) will give important information on the nature of the O–O and Co–O bonding.

As has been pointed out in the earlier communication,[7] the use of Raman spectroscopy is indispensable to obtaining the O–O stretching frequencies of substances having center of symmetry, since infrared spectroscopy does not give information in these cases. The recent development of the laser light source is beginning to afford Raman spectroscopy of colored substances such as many metal complexes, and is becoming to be a useful weapon in attacking these problems.

This paper will describe the O–O and Co–O stretching vibrations of μ-hyperoxo and μ-peroxo binuclear cobalt(III) complexes with and without additional NH_2-bridge as examined by using laser-Raman and infrared spectroscopy.

Experimental

Preparation. $[(NH_3)_5Co(O_2)Co(NH_3)_5]Cl_5\cdot 3H_2O$,[8] $[(NH_3)_5Co(O_2)Co(NH_3)_5](NO_3)_5$,[9] $[(NH_3)_5Co(O_2)Co(NH_3)_5](SO_4)_2HSO_4\cdot 3H_2O$,[10] $K_5[(CN)_5Co(O_2)Co(CN)_5]\cdot H_2O$,[11] $[(NH_3)_5Co(O_2)Co(NH_3)_5]Cl_4\cdot H_2O$,[12] $[(NH_3)_5Co(O_2)Co(NH_3)_5](NO_3)_4\cdot 2H_2O$,[12] $[(NH_3)_5Co(O_2)Co(NH_3)_5](SO_4)_2\cdot 3H_2O$,[12] $K_6[(CN)_5Co(O_2)Co(CN)_5]\cdot H_2O$,[13] $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Na(ClO_4)_4$,[3] and $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Cl_4\cdot 2H_2O$[3] were prepared as described in the references. In addition to the dihydrate of $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Cl_4$ cited above, the trihydrate $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Cl_4\cdot 3H_2O$ was also prepared. Although the factors which decide the number of water of crystallization have not yet been clarified, these two types are easily distinguished by infrared spectra, which will be discussed later.

Found: Co, 24.57; H, 6.17; N, 26.02%. Calcd for $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Cl_4\cdot 2H_2O$: Co, 24.56; H, 6.30; N, 26.26%.

Found: Co, 23.98; H, 6.32; N, 25.40%. Calcd for $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Cl_4\cdot 3H_2O$: Co, 23.67; H, 6.48; N, 25.31%.

$[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4](NO_3)_4$ was prepared as described in Ref. 3. Two types (which we shall name α and β) of crystals were obtained by different ways of cooling. Rapid cooling with ice at the final stage of preparation tended to give crystals of the α-type, whereas slow cooling at room temperature gave crystals of the β-type. These two types are easily distinguished by infrared spectra (see below). From the X-ray powder pattern, it was made clear that the structure previously determined by X-ray single crystal analysis[14] was that of our β-type.

Found: α-type, Co, 21.37; N, 32.40%, β-type, Co, 21.26; N, 32.68%. Calcd for $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4](NO_3)_4$: Co, 21.42; N, 33.10%.

The following ^{18}O-labeled substances were prepared using $^{18}O_2$ gas (90%) obtained from International Chemical Nuclear Nuclear Corp.: $[(NH_3)_5Co(^{18}O_2)Co(NH_3)_5](NO_3)_5$, $[(NH_3)_5Co(^{18}O_2)Co(NH_3)_5]Cl_5\cdot 3H_2O$, $[(NH_3)_4Co(NH_2)(^{18}O_2)Co(NH_3)_4](NO_3)_4$, $[(NH_3)_4Co(NH_2)(^{18}O_2)Co(NH_3)_4]Cl_4\cdot 2H_2O$.

Spectroscopic Measurements. Raman spectra of the complexes in the solid state and in aqueous solutions were recorded on a JEOL JRS-Sl laser Raman spectrophotometer equipped with a rotating cell to avoid decomposition of samples. Krypton ion laser (5682 Å) was used as a light source. Infrared spectra were recorded as KBr disks and in Nujol mulls on a JASCO IR-S spectrophotometer (4000—400 cm^{-1}) and a DS-402G spectrophotometer (700—400 cm^{-1}). Samples dispersed homogeneously in polyethylene or Nujol mulls were used for the measurements in the far infrared region (400—30 cm^{-1}) with a Hitachi FIS-3 spectrophotometer.

Results and Discussion

Single-bridged μ-Hyperoxo Dicobalt(III) Complexes. Raman (solid samples) and infrared spectra of several single-bridged μ-hyperoxo dicobalt(III) complexes ((**1**), $[(NH_3)_5Co(O_2)Co(NH_3)_5]Cl_5\cdot 3H_2O$; (**2**), $[(NH_3)_5Co(O_2)Co(NH_3)_5](NO_3)_5$; (**3**), $[(NH_3)_5Co(O_2)Co(NH_3)_5](SO_4)_2\,HSO_4\cdot 3H_2O$; (**4**), $K_5[(CN)_5Co(O_2)Co(CN)_5]\cdot H_2O$) are shown in Fig. 1. Raman spectra of **1**, **2**, **3**, and **4** show strong peaks at about 1100 cm^{-1}, whereas no peak appears in the 900—1300 cm^{-1} region of the infrared spectra except in the case of **3**, which exhibits absorptions due to sulfate and hydrogensulfate

* Some parts of this paper have already been reported at XVIth International Conference on Coordination Chemistry, Dublin, 1974.

ions. X-Ray analyses by several authors[15–17] all revealed the Co–O–O–Co moieties of these complexes to be trans-planar (C_{2h} symmetry) or close to so. The in-plane vibrational modes can therefore be classified to A_g (Raman active and infrared inactive) and B_u (Raman inactive and infrared active) species. The Raman active band (A_g) at *ca.* 1100 cm^{-1} can be assigned to ν(OO); other vibrations belonging to A_g species (sν(CoO) and sδ(CoOO)) have too high frequencies to be assigned to these bands. As shown in Fig. 2, the degree of depolarization of Raman band at *ca.* 1100 cm^{-1} of a solution sample of the chloride is about one-half indicating that this vibration is totally symmetric. The Raman spectrum of $[CoCl(NH_3)_5]Cl_2$, having the same local symmetry (C_{4v}) as that around each cobalt atom in the μ-hyperoxo-bis[pentaamminecobalt(III)] complex has no peak in the 900—1250 cm^{-1} region. These facts also support the above assignment.

Infrared and Raman spectra of single-bridged μ-hyperoxo dicobalt(III) complexes in the KBr region are shown in Fig. 3, together with the infrared spectra of the chloride and nitrate of ^{18}O-substituted complexes. As shown in Fig. 3, the peaks at *ca.* 440 cm^{-1} in the infrared spectra are lowered by *ca.* 19 cm^{-1} by the substitution with ^{18}O. This confirms the conclusion by Ikawa *et al.*[4] who assigned the band to asν(CoO) from comparison of the infrared spectra of μ-hyperoxo complexes with those of μ-peroxo complexes and hexaammine cobalt(III) complex. The peaks in the range 505—470 cm^{-1} of the infrared spectra hardly shift indicating that the peaks are due to ν(CoN). Absence of any remarkable difference between ordinary and ^{18}O-substituted complexes in the far infrared region makes it difficult to assign δ(CoOO)(Fig. 4).[4] As regards to decaammine dicobalt(III) complexes, **1**, **2**, and **3**, the peaks at *ca.* 620 cm^{-1} in the Raman spectra (Fig. 3) are assigned to sν(CoO) by comparison with the infrared spectra (no peak around 620 cm^{-1}), although Strekas and Spiro[15] assigned the Raman band at 500 cm^{-1} to ν(CoO). The strong peaks at about 500 cm^{-1} in the Raman spectra can rather be assigned to ν(CoN), since $[CoCl(NH_3)_5]Cl_2$ also shows a strong peak at 494 cm^{-1} in the Raman spectrum. The Raman spectrum of the cyano complex **4** shows peaks at 610, 542, and 528 cm^{-1} and the peak at 610 cm^{-1} is assigned to sν(CoO) and the other two peaks are assigned to ν(CoC). A weak band assignable to sν(CoO) was observed at 618 cm^{-1} in the infrared spectrum, too. Appearance of this band can be attributed to the nonplanarity of the Co–O–O–Co moiety of the cyano complex; the following values were obtained from X-ray crystallography for the torsional angles: nitrate of the ammine complex,[16] 180°; sulfate tris-hydrogensulfate of the ammine complex,[17] 175°; potassium salt of the cyano complex,[18] 180 and 166° (two independent binuclear anions in the unit cell). The peaks at 551 and 543 cm^{-1} are assigned to ν(CoC) in the infrared spectrum of the cyano complex, since a peak assignable to ν(CoC) was observed at 565 cm^{-1} in the infrared spectrum of $K_3[Co(CN)_6]$.[19]

μ-Amido-μ-hyperoxo Dicobalt(III) Complexes. The Raman and infrared spectra of μ-amido-μ-hyperoxo bis[tetraamminecobalt(III)] chloride trihydrate (**5**) have peaks at 1075 and 1068 cm^{-1}, respectively, as shown in Fig. 5. These bands are assigned to ν(OO)

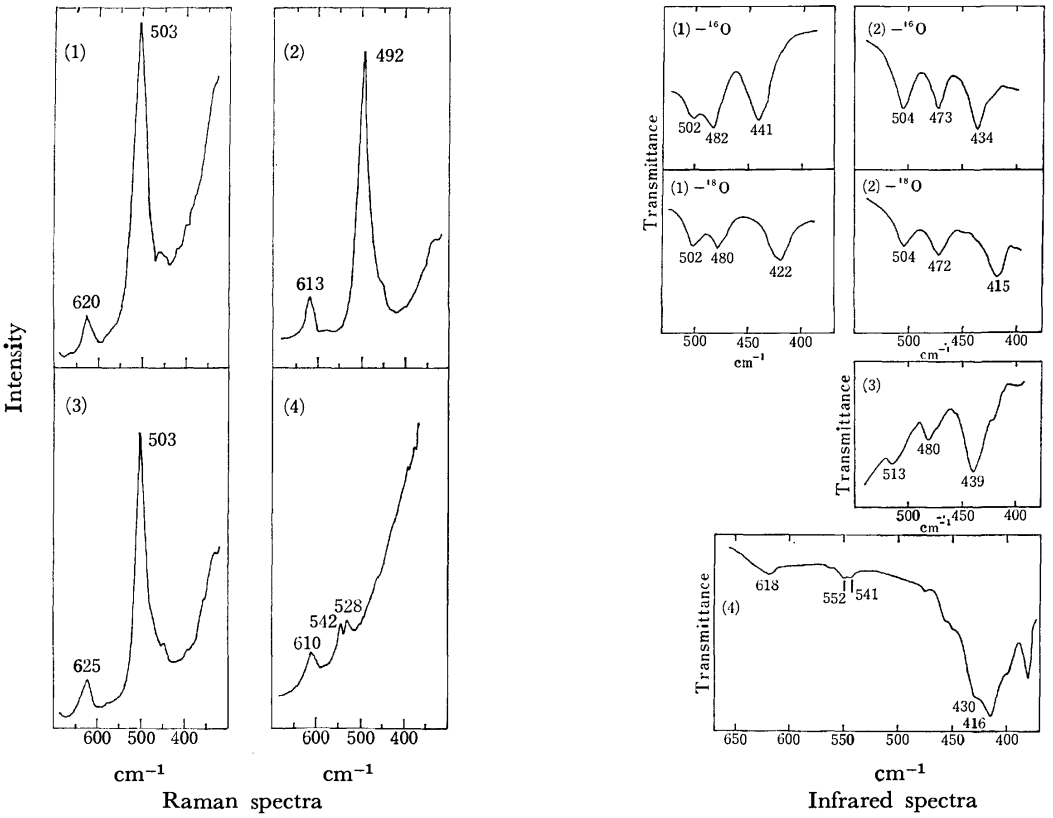

Fig. 3. Raman and infrared spectra of single-bridged μ-hyperoxodicobalt(III) complexes in the region 700—400 cm^{-1}. Each number represents the same compound as in Fig. 1.

(A): ^{16}O-$[(NH_3)_5Co(O_2)Co(NH_3)_5]Cl_5 \cdot 3H_2O$,
(B): ^{18}O-$[(NH_3)_5Co(O_2)Co(NH_3)_5]Cl_5 \cdot 3H_2O$.

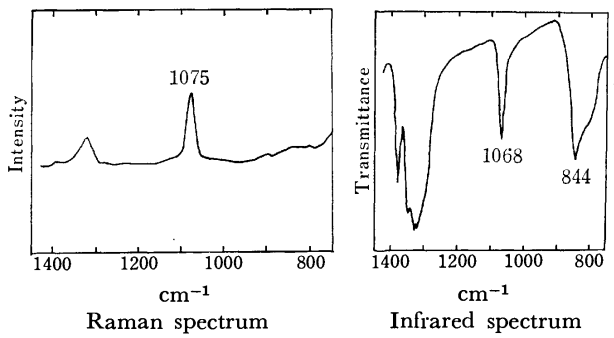

Fig. 5. Raman and infrared spectra of μ-amido-μ-hyperoxo bis[tetraamminecobalt(III)] chloride trihydrate, $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Cl_4 \cdot 3H_2O$.

by comparison with the peak positions in the Raman spectra of single-bridged μ-hyperoxo complexes and also by consideration of the degree of depolarization (*ca.* one-half) of the Raman band at *ca.* 1100 cm^{-1} of a solution samples of **5**, as shown in Fig. 6. Since the dibridged complex ion has no center of symmetry, any vibration should be both infrared and Raman active.

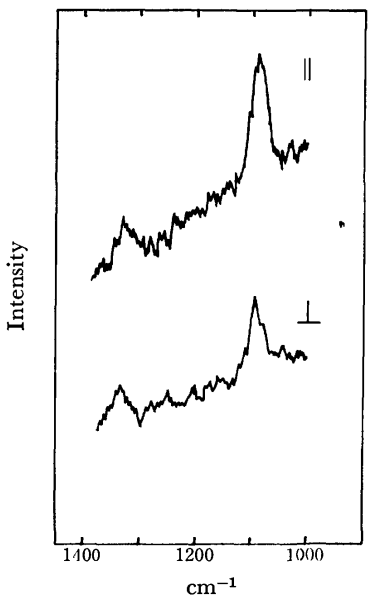

Fig. 6. Polarized Raman spectra of $[(NH_3)_4Co(NH_2)-(O_2)Co(NH_3)_4]Cl_4 \cdot 3H_2O$.

This is in accordance with the above observation. The chloride crystallizes in two forms, one with two moles of water and the other with three. They can easily be distinguished by the infrared spectra. The peak positions due to ν(OO) differ slightly (dihydrate, 1078 cm^{-1}; trihydrate, 1068 cm^{-1}) from each other and the band assigned to $\rho_r(NH_3)$ shows splitting in the dihydrate (dihydrate, 844 and 815 cm^{-1}; trihydrate, 844 cm^{-1}). The nitrate also has two crystal forms (cf. Experimental, Preparation.). Both are anhydrous and can be distinguished easily by infrared spectra. In addition to the difference in the peak position of ν(OO) (α-type, 1063 cm^{-1}; β-type, 1088 cm^{-1}), the spectrum of α-type shows a splitting of the band due to $\rho_r(NH_3)$ (α-type, 840 and 827 cm^{-1}; β-type, 830 cm^{-1}). As shown in Fig. 7, the O-O streching frequencies in the infrared spectra of ^{18}O-substituted complexes of the chloride ((A), $2H_2O$-type) and the nitrate ((B), α-type) are lower than those of the corresponding ^{16}O-complexes by 60 cm^{-1}. Since the difference in ν(OO) frequency between two crystal forms (in both chloride and

nitrate) is not negligible, it is important to compare the ν(OO) frequency of ^{16}O- and ^{18}O-compounds of the same crystal form.

Infrared spectra of ordinary and ^{18}O-substituted samples, of the nitrate (α-type) in the 650—350 cm^{-1} region are shown in Fig. 8, A and B, respectively. The peak at 429 cm^{-1} in A shifts to 410 cm^{-1} in B, whereas that at 374 cm^{-1} in A probably to *ca.* 360 cm^{-1} in B (overlapping with a peak at 359 cm^{-1} which does not shift). The peak at a higher frequency is assigned to sν(CoO) and that at a lower frequency to asν(CoO). Shifts of some other bands can also be observed; the peaks at 608 and 578 cm^{-1} in A disappeared and a new peak appeared at 594 cm^{-1} and a shoulder at 560 cm^{-1} in B. These two peaks are tentatively assigned to the combination bands of ν(CoO), ν(CoN), and ring deformation; if they were genuine ν(CoO)'s, the magnitude of the shifts would be expected to be *ca.* 25 cm^{-1}.

Single-bridged μ-Peroxo Dicobalt(III) Complexes. The Raman (1100—450 cm^{-1}) and infrared spectra (700—300 cm^{-1}) of single-bridged μ-peroxo dicobalt(III) complexes ((**6**), $[(NH_3)_5Co(O_2)Co(NH_3)_5]Cl_4\cdot H_2O$; (**7**), $[(NH_3)_5Co(O_2)Co(NH_3)_5](NO_3)_4\cdot 2H_2O$; (**8**), $[(NH_3)_5Co(O_2)Co(NH_3)_5](SO_4)_2\cdot 3H_2O$; (**9**), $K_6[(CN)_5Co(O_2)Co(CN)_5]\cdot H_2O$) are shown in Fig. 9. Strong bands assignable to ν(OO) are found around 800 cm^{-1} in the Raman spectra.[5-7] The degree of depolarization of these bands is *ca.* 0.3 indicating that the vibration is totally symmetric. The band at 600—660 cm^{-1} ((**6**), 653; (**7**), 642; (**8**), 648; (**9**), 604 cm^{-1}) in the Raman spectra are assigned to sν(CoO). Other bands in the Raman spectra are assigned to ν(CoN) for the compounds **6**(484, 465, and 435 cm^{-1}), **7**(496, 461, and 436 cm^{-1}), and **8**(500, 465, and 440 cm^{-1}). The bands with the highest wave number and at the same time the highest intensity in the KBr region of the infrared spectra of decaammine μ-peroxo compounds (**6**, 566 cm^{-1} and possibly 529 also; **7**, 547; **8**, 525 cm^{-1}) are assigned to asν(CoO). The bands in the region from 503 to 400 cm^{-1} are assigned to ν(CoN). As for the cyano compound **9**, the band at 515 cm^{-1} in the infrared spectrum is assigned to the asν(CoO), and the band at 544 cm^{-1} and the bands from 470 to 374 cm^{-1} are assigned to ν(CoC)+δ(CoCN), by the comparison with the infrared spectra of $K_3[Co(CN)_6]$.[19] The bands at 542 and 408 cm^{-1} in the Raman spectrum of **9** are also assigned to ν(CoC)+δ(CoCN).

μ-Amido-μ-peroxo Dicobalt(III) Complexes. The Raman and infrared spectra of $[(NH_3)_4Co(NH_2)(O_2)Co(NH_3)_4]Na(ClO_4)_4$ are shown in Fig. 10A and 10B, respectively. The ν(OO) in the infrared spectrum has been reported by Mori *et al.*[3] to be at 828 cm^{-1}. The Raman spectrum of this sample shows a distinct peak at 832 cm^{-1} which confirms the previous assignment. The band at 533 cm^{-1} in the infrared spectrum and

the bands at 593 and 532 cm^{-1} in the Raman spectrum are assigned tentatively to ν(CoO). Peaks at 762 cm^{-1} (Raman) and 758 cm^{-1} (infrared) are assigned to $\rho_r(NH_3)$.

Relationship between the Bond Order and the Oxygen–Oxygen Stretching Frequencies of O_2-compounds. An approximately linear relationship exists between the bond order of oxygen–oxygen bonding and ν(OO) as shown in Fig. 11. The relationship can be expressed by the following equation

$$\nu(OO) = 710 \times BO + 70,$$

where ν(OO) is the wave number of the O–O stretching vibration in cm^{-1} and BO is the bond order. The large differences of ν(OO) between μ-hyperoxo and μ-peroxo complexes clearly support the idea that these two kinds of complex have different oxidation states of bridging O_2-moieties, and that the cobalt atoms in both types of complex are of oxidation state three.[20] The substitution of ammonia with cyanide ions gives little influence on ν(OO) in both μ-hyperoxo and μ-peroxo complexes.

Calculations of Force Constants. The force constants of the single-bridged μ-hyperoxo and μ-peroxo complexes were calculated using UBFF and a four-body model (μ-hyperoxo, trans planar; μ-peroxo, torsional angle of 146°). The change of the torsional angle gave only a small influence on the calculated values. Bond lengths and angles used for the calculation were those of the nitrate[16] in the case of the μ-hyperoxo complex and those of the sulfate[22] in the case of the μ-peroxo complex. The calculated and observed values are summarized in Table 1, together with the force constants employed. The calculated isotopic shift of asν(CoO) for μ-hyperoxo complex is in good agreement with the observed ones.

Table 1. Observed and calculated frequencies of μ-hyperoxo and μ-peroxo dicobalt(III) complexes in cm^{-1}

	(A) $[(NH_3)_5Co(O_2)Co(NH_3)_5]X_5$				
			ν(OO)	sν(CoO)	asν(CoO)
Obsd	nitrate	^{16}O	1123	613	434
		^{18}O	—	—	415
	chloride	^{16}O	1122	620	441
		^{18}O	—	—	422
	sulfate	^{16}O	1108	625	439
Calcd		^{16}O	1114	621	439
		^{18}O	1050	587	420
(K(OO)=5.6, K(CoO)=1.40, H(CoOO)=0.30, F(CoO)=0.05 mdyn/Å)					
	(B) $[(NH_3)_5Co(O_2)Co(NH_3)_5]X_4$				
			ν(OO)	sν(CoO)	asν(CoO)
Obsd	nitrate	^{16}O	805	642	547
	chloride	^{16}O	824	653	566, 529
	sulfate	^{16}O	788	648	525
Calcd		^{16}O	799	649	543
(K(OO)=2.7, K(CoO)=2.15, H(CoOO)=0.30, F(CoO)=0.05 mdyn/Å)					

The O–O stretching frequencies in the Raman as well as the infrared spectra of the ^{18}O-substituted μ-amido-μ-hyperoxo complexes are lower by 60 cm^{-1} than those for the corresponding ^{16}O-complexes. The isotopic shift calculated from a simple valence force field and a five membered ring model Co–N–Co–O–O is 61 cm^{-1} with a force constant K(OO) of 5.1 mdyn/Å.

The authors are grateful to Professor T. Miyazawa of the University of Tokyo for valuable suggestions and to Drs. S. Hirai and T. Hinomoto of JEOL Ltd. for the measurement of Raman spectra.

Kinetics and Mechanisms of the Reduction of Cobalt(III) Complexes by the Chromium(II) Complex Ligating *N*-(2-Hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′-triacetate

Hiroshi Ogino, Makoto Shimura, and Nobuyuki Tanaka
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received October 17, 1977)

The reduction of the cobalt(III) complexes, $CoX(NH_3)_5^{(3-m)+}$ (X^{m-}=Cl^-, Br^-, NCS^-, and H_2O) and $Co(en)_3^{3+}$, by Cr(II)-HEDTRA was studied by the stopped-flow method, where en and HEDTRA denote ethylenediamine and *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetatic acid respectively. From the kinetic behavior and the spectral properties of the immediate chromium(III) products, it is concluded that the Cr(II)-HEDTRA reductions of $CoX(NH_3)_5^{2+}$ (X^-=Cl^-, Br^-, and NCS^-) are of an inner-sphere type. The effect of the HEDTRA coordinated to chromium(II) on the rates of the electron-transfer reactions is discussed.

There has been much interest in the mechanisms of the electron-transfer reactions of $MX(NH_3)_5^{(3-m)+}$ (M= Co^{III} or Cr^{III}) with $Cr^{II}L(H_2O)^{(n-2)-}$, where X^{m-} denotes a potential bridging ligand.[1-7] The present authors proposed an inner-sphere mechanism for the reactions of $CrX(NH_3)_5^{2+}$ ($X=F^-$, Cl^-, Br^-, NCS^-, and OH^-) with $Cr^{II}(edta)(H_2O)^{2-}$ on the basis of the reactivity pattern.[2,3] A similar proposal has been made by Earley and Davies for the reactions of $CrX(NH_3)_5^{2+}$ ($X=Cl^-$ and OH^-) with several chromium(II)–amino polycarboxylates by considering the linear free energy relationship.[4,5] Diebler *et al.* reported that, from the findings on the isotopic fractionation effects, the reaction of $Co(OH)(NH_3)_5^{2+}$ with $Cr^{II}(edta)(H_2O)^{2-}$ is of an inner-sphere type.[6] Thorneley *et al.* investigated the reactions of several oxidants containing potential halide bridges with $Cr^{II}(edta)(H_2O)^{2-}$ and found that the final spectra recorded within 3 min of mixing always agreed with that of $Cr^{III}(edta)(H_2O)^-$.[7] Therefore, they proposed an outer-sphere mechanism for these reactions, because it was difficult to accept the idea the aquation of $Cr^{III}X(edta)^{2-}$ is rapid and complete within 3 min in view of the substitution inertness of chromium(III) complexes.

Quite recently, the present authors presented evidence that the reaction of $Co(OAc)(NH_3)_5^{2+}$ with $Cr^{II}L(H_2O)^{(n-2)-}$ is of an inner-sphere type, because the immediate chromium(III) product was $Cr^{III}(OAc)L^{(n-2)-}$ and aquated rapidly.[8] Therefore, the over-all reaction can be expressed in the following two stages:

$$Co(OAc)(NH_3)_5^{2+} + Cr^{II}L(H_2O)^{(n-2)-} \xrightarrow{k_{et}} Co^{2+} + 5NH_3 + Cr^{III}(OAc)L^{(n-2)-} + H_2O, \quad (1)$$

$$Cr^{III}(OAc)L^{(n-2)-} + H_2O \rightleftharpoons Cr^{III}L(H_2O)^{(n-3)-} + OAc^-. \quad (2)$$

It is also known that Reaction 3, involving OAc^-,[9] N_3^-,[10,11] or some other anions[12] as X^-, is reversible and extremely rapid:

$$Cr^{III}L(H_2O)^{(n-3)-} + X^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} Cr^{III}XL^{(n-2)-} + H_2O. \quad (3)$$

These observations indicate that the detection of the immediate chromium(III) product after the electron-transfer is the key to distinguishing the mechanisms. In order to ascertain the role of the coordinated amino polycarboxylates in the electron-transfer reactions and to elucidate the mechanism of the reactions, the previous work[8] has now been extended to the electron-transfer reactions of $CoCl(NH_3)_5^{2+}$, $CoBr(NH_3)_5^{2+}$, $Co(NCS)(NH_3)_5^{2+}$, $Co(NH_3)_5(H_2O)^{3+}$, and $Co(en)_3^{3+}$ ions with $Cr^{II}(hedtra)(H_2O)^-$. The findings on the reaction of $Co(en)_3^{3+}$ with $Cr^{II}(edta)(H_2O)^{2-}$ will also be given in this paper.

Experimental

Materials. The cobalt(III) complexes, $[CoCl(NH_3)_5](ClO_4)_2$,[13] $[CoBr(NH_3)_5](ClO_4)_2$,[14] $[Co(NCS)(NH_3)_5](ClO_4)_2$,[15] $[Co(NH_3)_5(H_2O)](ClO_4)_3$,[14] and $[Co(en)_3](ClO_4)_3$,[16] were prepared according to the literature. The solutions of $[Cr(H_2O)_6](ClO_4)_3$ and $[Cr(H_2O)_6](ClO_4)_2$ were prepared as has been described previously.[2] The $Cr^{II}(hedtra)(H_2O)^-$ and $Cr^{II}(edta)(H_2O)^{2-}$ were generated *in situ* by the injection of $Cr(H_2O)_6^{2+}$ solutions into excess HEDTRA and EDTA solutions respectively. All the solutions were prepared with redistilled water.

Kinetic Procedure. Many of the kinetic measurements were made with a Union-Giken RA 401 stopped-flow spectrophotometer and a Hitachi RSP-2 rapid scanning spectrophotometer. The dead time of mixing was approximately 0.5 ms for the former instrument and 20 ms for the latter instrument. Slow kinetic measurements were made with a Union-Giken SM 401 and a Hitachi EPS-3 recording spectrophotometer. All the kinetic measurements were made at I=1.0 ($NaClO_4$) under an atmosphere of nitrogen. The temperature was kept at 25.0 °C, unless otherwise stated. The hydrogen-ion concentrations of the solutions were adjusted with HEDTRA solutions as buffers, except for the reactions of $Co(en)_3^{3+}$ with $Cr^{II}(hedtra)(H_2O)^-$ and $Cr^{II}(edta)(H_2O)^{2-}$, which were performed in acetate buffer solutions. A Hitachi F-5 pH meter was used for the determination of the hydrogen-ion concentrations; the meter readings were calibrated against standard perchloric acid solutions.

The kinetics of the electron-transfer reactions was studied under the condition of $[Co(III)]_0 > [Cr(II)]_0$, where $[\ ]_0$ represents the initial concentration of the given species. The reactions were usually monitored by the appearance of the Cr(III)-HEDTRA or -EDTA complex at 545—550 nm. On the assumption that the electron-transfer reaction:

$$Co(III) + Cr(II)\text{-}L \xrightarrow{k_{et}} Co(II) + Cr(III)\text{-}L \quad (4)$$

proceeds by means of the second order rate law;

$$\frac{d[Cr(III)\text{-}Y]}{dt} = k_{et}[Co(III)][Cr(II)\text{-}L], \quad (5)$$

the following equation was derived:

$$\ln\left\{1+\frac{\varepsilon_{Co(III)}+\varepsilon_{Cr(II)}-\varepsilon_{Co(II)}-\varepsilon_{Cr(III)}}{A_t-A_\infty}[Co(III)]_\infty\right\} = [Co(III)]_\infty k_{et}t + \ln\frac{[Co(III)]_0}{[Cr(II)]_0}, \quad (6)$$

where A_t and A_∞ denote the absorbancies at time t and infinity respectively; $\varepsilon_{Co(III)}$, $\varepsilon_{Cr(II)}$, $\varepsilon_{Co(II)}$, and $\varepsilon_{Cr(III)}$, the molar absorption coefficients of the given species, and $[Co(III)]_\infty$, the concentration of Co(III) after the completion of the reaction. The value of the $\varepsilon_{Cr(II)}$ is so small that it can be neglected. The $[Co(III)]_\infty$ quantity was determined as follows. A known volume of the product solution was poured into an SP-Sephadex C-25 cation exchanger column in the Na^+ form. When the column was washed with water, only the unreacted cobalt(III) ions remained in the column, and they were eluted with 0.5—1.0 M NaCl solutions. The eluate was then acidified with hydrochloric acid. After the cobalt(III) ions in the solution has been reduced to cobalt(II) ions with amalgamated zinc, the cobalt(II) content was determined by Kitson's method.[17] The subtraction of $[Co(III)]_\infty$ from $[Co(III)]_0$ left $[Cr(II)]_0$. The plots of the left-hand side of Eq. 6 *vs.* the time gave straight lines for all the electron-transfer reactions within three half-lives.

The dependence of the observed rate constants on the hydrogen-ion concentrations was examined for all the electron-transfer reactions studied. Except for the reaction of $Co(NH_3)_5(H_2O)^{3+}$ with $Cr^{II}(hedtra)(H_2O)^-$, the observed rate constants were found to be independent of the hydrogen-ion concentrations under the present experimental conditions.

Results

Reaction of $Co(NH_3)_5(H_2O)^{3+}$ with $Cr^{II}(hedtra)(H_2O)^-$. The observed rate constants(k_{obsd}) of the electron-transfer reaction were dependent on the hydrogen-ion concentrations, as is shown in Table 1. The plots of k_{obsd} *vs.* $[H^+]^{-1}$ give a good linear relation. Therefore, the reaction obeys the rate law given in Eqs. 7 and 8:

$$\frac{d[Cr(III)\text{-}HEDTRA]}{dt} = k_{obsd}[Co(III)][Cr(II)], \quad (7)$$

$$k_{obsd} = \frac{a}{[H^+]} + b. \quad (8)$$

The values of a and b were determined to be 12.5± 0.5 s^{-1} and $(1.30\pm0.10)\times10^5$ M^{-1} s^{-1} respectively. No absorbance change subsequent to the electron-transfer reaction was observed.

Reactions of $Co(en)_3^{3+}$ with $Cr^{II}(hedtra)(H_2O)^-$ and $Cr^{II}(edta)(H_2O)^{2-}$. The rate constants of the electron-transfer reactions(k_{et}) are given in Table 2.

Reaction of $Co(NCS)(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$. The rate constant of the electron-transfer reaction of $Co(NCS)(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ was determined and is given in Table 2. The electron-transfer reaction was found to be practically completed within 50 ms under the present experimental conditions. After this rapid reaction had been completed, the spectrum changed slowly, as is shown in Fig. 1. The absorption maxima of the immediate chromium(III) species produced by the electron-transfer reaction initially shifted to shorter wavelengths and then to longer wavelengths. These spectral changes indicate that the immediate chromium(III) species is converted to some other species in a complicated manner.

Reaction of $CoBr(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$. The electron-transfer reaction of this system was found to be completed within the time of mixing (<0.5 ms), so the k_{et} value was estimated to be more than 1×10^6 M^{-1} s^{-1}. The spectrum obtained immediately after the electron-transfer reaction (Curve A in Fig. 2) changed to that of $Cr^{III}(hedtra)(H_2O)$ (Curve B in Fig. 2) with the time scale of s, and the reaction was practically completed within 4 s. This spectral change obeyed the first-order kinetics; hence, the conventional plots, $\ln|A_t-A_\infty|$ *vs.* t at 430 nm, gave a linear relation

Table 2. The second-order rate constants (k_{et}/M^{-1} s^{-1}) for the electron-transfer reactions of cobalt(III) complexes with chromium(II) complexes

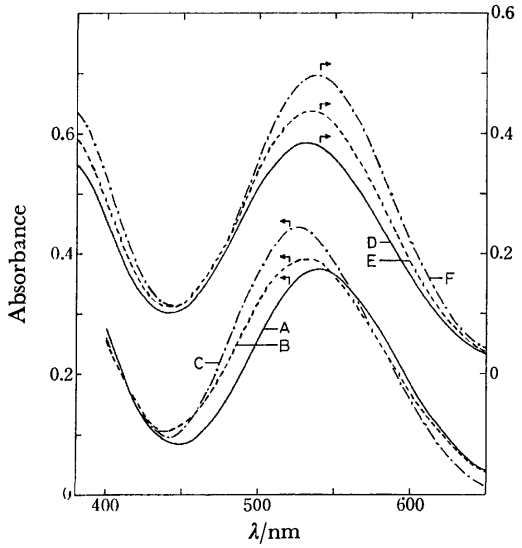

Fig. 1. Spectral changes after the electron-transfer reaction of $Co(NCS)(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ at $[H^+]=1.99\times10^{-4}$ M, $[Co(NCS)(NH_3)_5^{2+}]_0=2.25\times10^{-3}$ M, $[Cr^{II}(hedtra)(H_2O)^-]_0=1.76\times10^{-3}$ M, and cell length=1 cm. Curves A, B, C, D, E, and F show the spectra obtained at $t=0.25$ s, 60 s, 120 s, 5 h, 49 h, and 147 h after the mixing respectively. The absorptions due to $Co(NCS)(NH_3)_5^{2+}$ unreacted and $Co^{II}(hedtra)(H_2O)^-$ produced are subtracted.

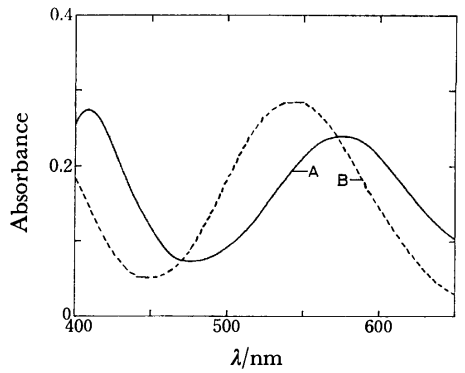

Fig. 2. Spectra obtained after the electron-transfer reaction of $CoBr(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ at $[H^+]=1.73\times10^{-5}$ M, $[CoBr(NH_3)_5^{2+}]_0=4.00\times10^{-3}$ M, $[Cr^{II}(hedtra)(H_2O)^-]_0=1.89\times10^{-3}$ M, and cell length=1 cm. Curves A and B show the spectrum extraporated to $t=0$ and that obtained at $t=$ 25 s after the mixing respectively. The absorptions due to $CoBr(NH_3)_5^{2+}$ unreacted and $Co^{II}(hedtra)(H_2O)^-$ produced are subtracted.

within two half-lives. The observed rate constant was 2.0 s^{-1}. Therefore, the over-all reactions can be expressed in two stages given in Eqs. 9 and 10:

$$CoBr(NH_3)_5^{2+} + Cr^{II}(hedtra)(H_2O)^- \xrightarrow[\text{immeasurably fast}]{k_{et}} Co(II) + \text{Intermediate of Cr(III)}, \quad (9)$$

$$\text{Intermediate of Cr(III)} \xrightarrow[2.0\,s^{-1}]{} Cr^{III}(hedtra)(H_2O). \quad (10)$$

Reaction of $CoCl(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$. The electron-transfer reaction of this system was found to be completed within the time of mixing. The spectrum obtained immediately after the electron-transfer reaction did not change to that of $Cr^{III}(hedtra)(H_2O)$ directly. Figure 3 shows the spectral changes subsequent to the electron-transfer reaction of $CoCl(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$. The final spectrum, obtained 10 s after the electron-transfer reaction, was found to correspond to the absorption of $Cr^{III}(hedtra)(H_2O)$. The spectral changes shown in Fig. 3 can be reasonably explained by the occurrence of the following reactions:

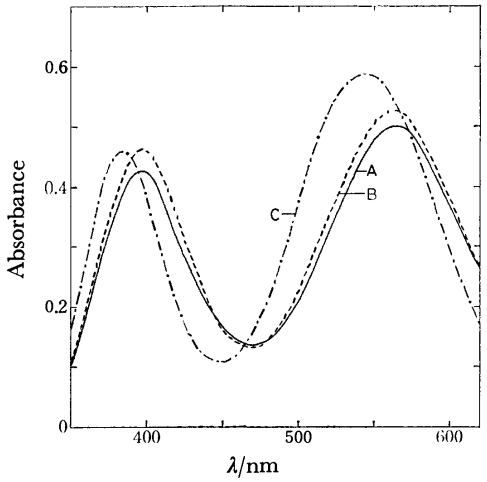

Fig. 3. Spectra obtained after the electron-transfer reaction of $CoCl(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ at $[H^+]=1.14\times10^{-5}$ M, $[CoCl(NH_3)_5^{2+}]_0=4.83\times10^{-3}$ M, $[Cr^{II}(hedtra)(H_2O)^-]_0=3.91\times10^{-3}$ M, and cell length=1 cm. Curves A, B, and C show the spectra obtained at $t=0$, 0.12, and 10 s after the mixing. The absorptions due to $CoCl(NH_3)_5^{2+}$ unreacted and $Co^{II}(hedtra)(H_2O)^-$ produced are subtracted.

$$CoCl(NH_3)_5^{2+} + Cr^{II}(hedtra)(H_2O)^- \xrightarrow[\text{immeasurably fast}]{k_{et}} + \text{Intermediate (A) of Cr(III)} \ (Int_A), \quad (11)$$

$$Int_A \xrightarrow{k_A} \text{Intermediate (B) of Cr(III)} \ (Int_B), \quad (12)$$

$$Int_B \xrightarrow{k_B} Cr^{III}(hedtra)(H_2O). \quad (13)$$

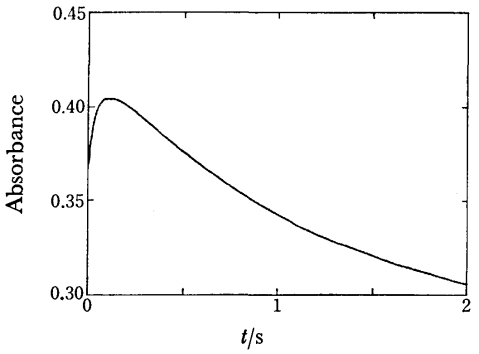

Fig. 4. The change of absorbance with time for the reactions subsequent to the electron-transfer reaction of $CoCl(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ at 420 nm, $[H^+]=1.14\times10^{-5}$ M, $[CoCl(NH_3)_5^{2+}]_0=4.83\times10^{-3}$ M, $[Cr^{II}(hedtra)(H_2O)^-]_0=3.91\times10^{-3}$ M, and cell length=1 cm.

Table 3. The rate constants of Reaction 12 (k_A) and Reaction 13 (k_B)

$[Cr]_T$ / 10^{-3} M	$[H^+]$ / 10^{-5} M	T / °C	k_A / s^{-1}	k_B / s^{-1}
1.32	2.23	20.7	14.0±1.3	0.469±0.016
1.77	0.635	25.0	—	0.741±0.012
2.01	2.81	25.0	13.0±1.0	0.670±0.036
2.18	7.91	25.0	—	0.681±0.015
1.89	3.15	34.8	29.7±4.3	1.44 ±0.03
2.24	3.15	47.1	65±16	3.14 ±0.11

The change in the absorbance against time at 420 nm is exemplified in Fig. 4. The initial increase in the absorbance was assigned to the occurrence of Reaction 12, and the subsequent decrease in the absorbance, to that of Reaction 13. In accordance with these assignments, both the absorbance changes fit the first-order kinetics. The rate constant of Reaction 12 (k_A) was determined at 390 and 567 nm, while that of Reaction 13 (k_B) was determined at 420 and 510 nm. The values thus obtained are given in Table 3.

Discussion

Mechanism of the Reaction of $Co(NH_3)_5(H_2O)^{3+}$ with $Cr^{II}(hedtra)(H_2O)^-$. The observed second-order rate constants were considerably dependent on $[H^+]$, as is expressed in Eq. 8. If the acid-base equilibria for $Cr^{II}(hedtra)(H_2O)^-$ and $Co(NH_3)_5(H_2O)^{3+}$ are taken into consideration, the reaction in question can be expressed as the following four parallel reactions:

$$Co(OH)(NH_3)_5^{2+} + Cr^{II}(hedtra)(H_2O)^- \xrightarrow{k_1} \text{products}, \quad (14)$$

$$Co(NH_3)_5(H_2O)^{3+} + Cr^{II}(hedtra)(H_2O)^- \xrightarrow{k_2} \text{products}, \quad (15)$$

$$Co(OH)(NH_3)_5^{2+} + Cr^{II}(Hhedtra)(H_2O)_2 \xrightarrow{k_3} \text{products} \quad (16)$$

$$Co(NH_3)_5(H_2O)^{3+} + Cr^{II}(Hhedtra)(H_2O)_2 \xrightarrow{k_4} \text{products}. \quad (17)$$

Then, the following equation can be derived for the observed rate constant:

$$k_{obs} = \frac{\frac{k_1K_{Co}^H}{[H^+]} + k_2 + \frac{k_3K_{Co}^H}{K_{Cr}^H} + \frac{k_4[H^+]}{K_{Cr}^H}}{\left(1+\frac{K_{Co}^H}{[H^+]}\right)\left(1+\frac{[H^+]}{K_{Cr}^H}\right)}, \quad (18)$$

where k_1—k_4 denote the rate constants of Reactions 14—17 and where K_{Co}^H and K_{Cr}^H are defined as the equiliblium constants given by Eqs. 19 and 20 respectively:

$$K_{Co}^H = \frac{[H^+][Co(OH)(NH_3)_5^{2+}]}{[Co(NH_3)_5(H_2O)^{3+}]}, \quad (19)$$

$$K_{Cr}^H = \frac{[H^+][Cr^{II}(hedtra)(H_2O)^-]}{[Cr^{II}(Hhedtra)(H_2O)_2]}. \quad (20)$$

Although the value of K_{Cr}^H has not been reported, it may be estimated to be approximately $10^{-2.5}$ M from the corresponding values of the related complexes.[23] The value of K_{Co}^H has been reported to be $10^{-6.22}$ M at $I=0.3$ and 25 °C.[24] If the range of $[H^+]$ values employed in this work (2×10^{-5} M$<[H^+]<5\times10^{-4}$ M) and the magnitudes of K_{Cr}^H and K_{Co}^H values are taken into consideration, Eq. 18 can be simplified to

$$k_{obs} = \frac{k_1K_{Co}^H}{[H^+]} + k_2 + \frac{k_3K_{Co}^H}{K_{Cr}^H} + \frac{k_4[H^+]}{K_{Cr}^H}. \quad (21)$$

When Eq. 21 is compared with Eq. 8, it is evident that the last term on the right-hand side of Eq. 21 is negligibly small. The value of k_1 is calculated to be $(2.06\pm0.13)\times10^7$ M^{-1} s^{-1}. The value of b in Eq. 8 corresponds to the relation

$$b = k_2 + \frac{k_3K_{Co}^H}{K_{Cr}^H}. \quad (22)$$

This provides an example of a so-called proton ambiguity.[25,26] It would be reasonable to assume that the rate constant of the reaction of $Co(OH)(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ (k_1) is larger than that with $Cr^{II}(Hhedtra)(H_2O)_2$ (k_3), because, in a closely related system, it has been shown that $Cr^{II}Y(H_2O)^{(n-2)-}$ is more reactive than its protonated form, $Cr^{II}(HY)(H_2O)^{(n-3)-}$; that is, the reaction of $Cr(OH)(NH_3)_5^{2+}$ with $Cr^{II}(edta)(H_2O)^{2-}$ has been found to proceed much faster than that with $Cr^{II}(Hedta)(H_2O)^-$.[3] Even if k_3 is equal to k_1, the value of $k_3K_{Co}^H/K_{Cr}^H$ amounts to 4×10^3 M^{-1} s^{-1}, whose contribution to the b value of Eq. 22 is only a small percentage. Hence the b value is considered to represent k_2 value itself.

Mechanisms of the Electron-transfer Reactions. The rate constants of the electron-transfer reactions of Co(III) complexes with $Cr^{II}Y(H_2O)^{(n-2)-}$ are summarized in Table 2, together with those with $Cr(H_2O)_6^{2+}$. Among them, the reactions of $Co(en)_3^{3+}$ with Cr(II) complexes are considered to proceed through an outer-sphere mechanism, because $Co(en)_3^{3+}$ has no bridging ligand.

On the bases of the extremely low basicity of a coordinated water molecule and a consideration of Marcus' cross reaction equation,[27] it has been proposed that water coordinated to a metal ion does not act as a bridging ligand in reduction by $Cr(H_2O)_6^{2+}$.[21] This proposal can be tested by a similar consideration of whether or not the electron-transfer reaction of $Co(NH_3)_5(H_2O)^{3+}$ with $Cr^{II}(hedtra)(H_2O)^-$ is of an outer-sphere type. According to Marcus' theory, the rate constant (k_{12}) of a cross reaction

$$Oxidant_1 + Reductant_2 \xrightarrow{k_{12}} Reductant_1 + Oxidant_2 \quad (23)$$

can be given as

$$k_{12} = \sqrt{k_{11}k_{22}K_{12}f}, \quad (24)$$

where k_{11} and k_{22} denote the rate constants of the exchange reactions; K_{12}, the equilibrium constant of Reaction 23; $\ln f=(\ln K_{12})^2/\{4\ln(k_{11}k_{22}/Z^2)\}$, and Z, the collision frequency. If Eq. 24 is compared for the two oxidants 1 and 1', say $Co(NH_3)_5(H_2O)^{3+}$ and $Co(en)_3^{3+}$, and a common reductant 2, the ratio of the rate constants can be expressed as

$$\frac{k_{12}}{k_{1'2}} = \sqrt{\frac{k_{11}}{k_{1'1'}}K_{11'}}, \quad (25)$$

Table 4. Comparison of the rate constants of the electron-transfer reactions of $Co(NH_3)_5(H_2O)^{3+}$ and $Co(en)_3^{3+}$ with various reductants

Reductant	$k_{et}/M^{-1}s^{-1}$		Rate ratio
	$Co(NH_3)_5(H_2O)^{3+}$	$Co(en)_3^{3+}$	$k(Co(NH_3)_5(H_2O)^{3+})/k(Co(en)_3^{3+})$
$Cr^{II}(hedtra)(H_2O)^-$	1.3×10^5 a)	3.14×10^3 a)	41
$Cr(bpy)_3^{2+}$	5×10^1 b,c)	1.8×10^2 b,c)	2.8×10^2
$Eu(H_2O)_6^{2+}$	1.5×10^{-1} b)	$\approx5\times10^{-3}$ b)	≈30
$V(H_2O)_6^{2+}$	5.3×10^{-1} d)	7.2×10^{-4} e)	7.4×10^2

a) This work. b) Ref. 20. c) at $I=0.1$ ($NaClO_4$). d) Ref. 28. e) Ref. 18.

where the f terms are ignored or considered to be cancelled. Equation 25 indicates that the rate ratio of $k_{12}/k_{1'2}$ is dependent only on the properties of the two oxidants 1 and 1'. The values of the rate ratios for the reductions of $Co(NH_3)_5(H_2O)^{3+}$ and $Co(en)_3^{3+}$ with various reductants are summarized in Table 4; they are quite similar to one another. This may support the thought that the $Cr^{II}(hedtra)(H_2O)^-$ reduction of $Co(NH_3)_5(H_2O)^{3+}$ is of an outer-sphere type.

It has been reported previously that the immediate chromium(III) product of the electron-transfer reaction of $Co(OAc)(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ is $Cr^{III}(OAc)(hedtra)^-$ and that the inner-sphere electron-transfer is the dominant path of this reaction.[8] It would be reasonable to consider that the intermediate given in Eq. 9 is $Cr^{III}Br(hedtra)^-$. When it is assumed that the reaction proceeds exclusively through an inner-sphere mechanism, the absorption spectrum of $Cr^{III}Br(hedtra)^-$ can be estimated from the spectrum measured immediately after the electron-transfer reaction (see Fig. 2). The spectral data thus obtained and those of the related chromium(III) and cobalt(III) complexes are listed in Table 5. It is well known that the spectral shapes and absorption positions of the d-d bands of chromium(III) complexes are quite similar to those of the corresponding cobalt(III) complexes. The d-d absorption bands of the intermediate in question shift to longer wavelengths than those of $Cr^{III}(hedtra)(H_2O)$. A comparison of the data given in Table 5 will indicate that the assignment of the intermediate to $Cr^{III}Br(hedtra)^-$ is reasonable.

The intermediate formed by the reaction of $CoCl(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ (Int_A) was found to be converted into another intermediate, Int_B, and finally into $Cr^{III}(hedtra)(H_2O)$ (see Eqs. 11—13). The spectral data of Int_A and Int_B, both given in Table 5, are very similar to each other, and so it is not unreasonable to conclude that both of the intermediates are $Cr^{III}Cl(hedtra)^-$. However, data sufficient to characterize the structural difference between these two intermediates are not available at present.

If the electron-transfer reaction of $Co(NCS)(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ is of an outer-sphere type, the immediate product should be $Cr^{III}(hedtra)(H_2O)$. However, the spectrum of the immediate chromium(III) product in the electron-transfer reaction does not agree with that of $Cr^{III}(hedtra)(H_2O)$. This suggests that the possibility of an outer-sphere mechanism can be ruled out. The reactions of $Co(NCS)(NH_3)_5^{2+}$ and $Co(SCN)(NH_3)_5^{2+}$ with $Cr(H_2O)_6^{2+}$ have been observed to give $Cr(SCN)(H_2O)_5^{2+}$ and a mixture of $Cr(SCN)(H_2O)_5^{2+}$ and $Cr(NCS)(H_2O)_5^{2+}$ respectively.[31] Therefore, if the electron-transfer reaction of the present system proceeds through only an inner-sphere mechanism, it would be possible to assume the formation of $Cr^{III}(SCN)(hedtra)^-$ and/or $Cr^{III}(NCS)(hedtra)^-$. From independent experiments,[12] the reaction of $Cr^{III}(hedtra)(H_2O)$ with NCS^- was found to occur quite rapidly and reversibly as

$$Cr^{III}(hedtra)(H_2O) + NCS^- \rightleftharpoons Cr^{III}(NCS)(hedtra)^- + H_2O. \quad (26)$$

The absorption positions and intensities of the $Cr^{III}(NCS)(hedtra)^-$, which were determined from the equilibrium study of Reaction 26, are also given in Table 5. The spectrum of the immediate chromium(III) product in the present system does not agree with that of $Cr^{III}(NCS)(hedtra)^-$. The spectral changes after the electron-transfer reaction shown in Fig. 1 are very slow. This also indicates that the immediate product is not $Cr^{III}(NCS)(hedtra)^-$. Although the complicated spectral changes after the electron-transfer reaction cannot be explained thoroughly, the over-all features of the reaction of $Co(NCS)(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ suggest that the reaction proceeds through an inner-sphere mechanism to give $Cr^{III}X(hedtra)^{n-}$, where X is an unidentified ligand.

Table 5. Absorption maxima (λ) and molar absorption coefficients (ε) of chromium(III) and cobalt(III) complexes of the $M^{III}X(hedtra)^{n-}$ type

Complex	λ/nm (ε/$M^{-1}cm^{-1}$)		Ref.
	First band	Second band	
$Cr(hedtra)(H_2O)$	545 (151)	385 (117)	9

$CrCl(hedtra)^-$ (Int_B) a)	563 (136)	398 (121)	This work
$CoCl(hedtra)^-$	585 (278)	403 (251)	30
$CrBr(hedtra)^-$ a)	575 (127)	408 (145)	This work
$CoBr(hedtra)^-$	588 (241)	400 (243)	30

a) The spectral data were estimated on the assumption that the electron-transfer reaction of $CoCl(NH_3)_5^{2+}$ or $CoBr(NH_3)_5^{2+}$ with $Cr^{II}(hedtra)(H_2O)^-$ proceeds exclusively through the inner-sphere mechanism.

Rate Constants of the Electron-transfer Reactions. In the previous papers,[2,3] it was reported that Cr^{II}-

(edta) $(H_2O)^{2-}$ reacts with $CrX(NH_3)_5^{2+}$ ($X=F^-$, Cl^-, Br^-, NCS^-, and OH^-) much faster than $Cr(H_2O)_6^{2+}$ does, and this was explained by considering the change in the standard oxidation-reduction potentials of the Cr(II)–Cr(III) couples. Recently, Davies and Earley reported that the electron-transfer reactions of $CrCl(NH_3)_5^{2+}$ with some Cr(II)–amino polycarboxylate complexes followed the linear free-energy relationship with the slope ($\Delta\Delta G^*/\Delta\Delta G^\circ$) of 0.48, where $\Delta\Delta G^*$ and $\Delta\Delta G^\circ$ denote the change in the free energy of activation of the electron-transfer reactions and the free-energy difference between the chromium(II) and chromium(III) species respectively.[5] The data given in Table 2 show that the rate constants of the electron-transfer reactions of the cobalt(III) complexes with $Cr^{II}(hedtra)(H_2O)^-$ and $Cr^{II}(edta)(H_2O)^{2-}$ are larger than those of the corresponding reactions with $Cr(H_2O)_6^{2+}$. This rate enhancement may also be understood qualitatively by considering the free-energy change in the reactions. If the electron-transfer reactions of a common cobalt(III) complex with $Cr^{III}(H_2O)^{(n-2)-}$ and $Cr(H_2O)_6^{2+}$ follow the linear free-energy relationship with the slope of 0.5, 6×10^4 and 7×10^4 may be expected for the values of k(Cr-hedtra)/k(Cr) and k(Cr-edta)/k(Cr) respectively. Among the data shown in Table 2, the observed values of $Co(en)_3^{3+}$, $Co(NH_3)_5(H_2O)^{3+}$, and $Co(OH)(NH_3)_5^{2+}$ deviate considerably from the expected values. This may suggest that the assumption mentioned above is not satisfied for, at least, these systems, and that the other factors controlling the rates should be considered. The observed value for $Co(OH)(NH_3)_5^{2+}$ may be nearly a rate limit in the inner-sphere electron-transfer reactions containing Cr(II) ions as reductants.[32] This leads to the understanding that the free-energy change in the reaction by the coordination of HEDTRA to Cr(II) affects only slightly the rate of electron-transfer for, at least, the $Co(OH)(NH_3)_5^{2+}$ system.

Aquation Reactions of $Cr^{III}Cl(hedtra)^-$ and $Cr^{III}Br(hedtra)^-$ Subsequent to the Electron-transfer Reactions. It has been shown previously that the water position in the $Cr^{III}(hedtra)(H_2O)$ is a substitution-labile site.[9,10] This has been so postulated that the free $-CH_2CH_2OH$ existing in the complex ion acts as a nucleophile and catalyzes the substitution. It was found in this work that $Cr^{III}Cl(hedtra)^-$ and $Cr^{III}Br(hedtra)^-$ also aquate rapidly to give $Cr^{III}(hedtra)(H_2O)$. However, no formation of $Cr^{III}Cl(hedtra)^-$ or $Cr^{III}Br(hedtra)^-$ was observed upon the addition of an NaCl or NaBr solution up to a 1 M to $Cr^{III}(hedtra)(H_2O)$ solution. This may allow one to estimate that the formation constants of these mixed ligand complexes are less than 0.1 M^{-1}. The Eyring plot for the rate constants of the aquation reaction of $Cr^{III}Cl(hedtra)^-$ (the k_2 values are given in Table 3) gives activation parameters of $\Delta H^*=53.9\pm3.3$ kJ mol^{-1} and $\Delta S^*=-68\pm11$ J K^{-1} mol^{-1}. The large negative entropy of activation suggests an associative nature in the mechanism of this aquation reaction.

The authors wish to thank the Ministry of Education for Scientific Research Grant-in-Aid No. 147043. They also wish to thank Professor Kahei Takase of this department for allowing us to use a rapid-scanning spectrophotometer.

The Crystal Structure of Monoaquabis(1,10-phenanthroline)copper(II) Tetrafluoroborate $[Cu(H_2O)(phen)_2](BF_4)_2$

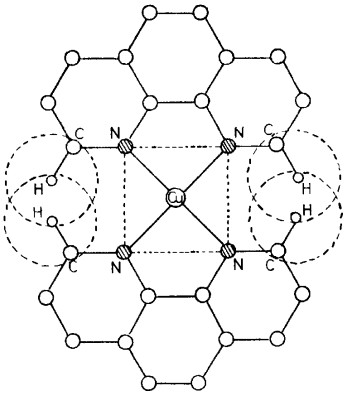
Hisayoshi NAKAI and Yukinao NODA

Department of Chemistry, Hyogo College of Medicine, Mukogawa-cho, Nishinomiya, Hyogo 663

(Received November 14, 1977)

The crystal of the title compound is monoclinic, with $a=19.099(6)$, $b=8.100(3)$, $c=16.177(5)$ Å, $\beta=100.54(5)°$, the space group of C2/c, and $Z=4$. The structure was determined from the counter data and was refined to $R=0.083$ for 1736 non-zero reflections. The coordination geometry of the copper atom is best described as a distorted trigonal bipyramid, in which the equatorial plane is composed of Cu, two N, and water O atoms, and the axial positions are occupied by two N atoms. The complex has a crystallographically imposed twofold axis which passes through the copper and the water oxygen atoms at the equatorial plane. The two phenanthroline ligands are related with each other by this axis.

In bis(bipyridine) and bis(phenanthroline)copper(II) complexes, the $Cu(chelate)_2^{2+}$ (chelate=bpy or phen) group is unable to assume a coplanar disposition about the copper atom because of the steric repulsions between the hydrogen atoms of these two chelates(I). Therefore, it has been shown that the bis(bipyridine)copper(II) complexes take a variety of stereochemistries, a distorted trigonal bipyramid[1-5] and *cis*-[6] and *trans*-distorted octahedra,[7,8] while the structure of the bis(phenanthroline)copper(II) complexes has not yet been investigated in detail.[9,10] As a part of our structural studies of such complexes, a single-crystal X-ray analysis has been carried out on $[Cu(H_2O)(phen)_2](BF_4)_2$.



I

Experimental

The green crystals of $[Cu(H_2O)(phen)_2](BF_4)_2$ were prepared by a method similar to that used for the preparation of the corresponding nitrate;[9] they were then recrystallized from a water-methanol mixture. Found: C, 46.93; H, 2.96; N, 9.31%. Calcd for $Cu(phen)_2(BF_4)_2\cdot H_2O$: C, 46.83; H, 2.95; N, 9.10%.

Preliminary X-ray photographs taken with Cu$K\alpha$ radiation showed a Laue symmetry of 2/m, with systematic absences of hkl for $h+k=2n+1$ and $h0l$ for $l=2n+1$. The space group is either C2/c or Cc; the former was confirmed by a successful refinement of the structure.

A crystal with dimensions of $0.35\times0.36\times0.38$ mm was mounted on a glass fiber for data collection. The unit-cell dimensions were determined by a least-squares fit using 21 θ-values measured accurately on a diffractometer. Crystal data: $[Cu(H_2O)(phen)_2](BF_4)_2$, $M.W.=615.6$, monoclinic, $a=19.099(6)$, $b=8.100(3)$, $c=16.177(5)$ Å, $\beta=100.54(5)°$, $U=2460.5$ Å^3, $Z=4$, $D_c=1.66$, $D_m=1.64$ g cm^{-3}, Mo$K\alpha$ radiation($\lambda=0.71069$ Å), μ(Mo$K\alpha$)$=10.1$ cm^{-1}, space group C2/c.

The intensity data with $6°\leqq2\theta\leqq60°$ were collected at room temperature by the ω-2θ scan technique on a Philips PW1100 four-circle diffractometer using graphite-monochromated Mo$K\alpha$ radiation, a scan speed of 0.03° s^{-1}, a scan width of $(1.0+0.2\tan\theta)°$, and two 10-s background counts. Three standard reflections ($\bar{2}04$, $0\bar{2}0$, and 604), monitored every 4 h throughout the data collection, showed no significant variation in intensity. A total of 1736 intensities with $I_{top}-2\sqrt{I_{top}}\geqq I_{back}$ were classified as observed; I_{top} is the intensity(counts/s) measured at the top of the peak, and I_{back} is the mean background intensity(counts/s) obtained from the preliminary background measurement for 5 s on each side of the peak. The intensity data were processed with the computer program of Hornstra and Stubbe.[11] No absorption correction was made.

Structure Determination

The positions of the copper atoms were determined from a three-dimensional Patterson map, the space group being assumed to be C2/c. The structure was solved by the heavy-atom technique, and the positional and thermal parameters were refined by the block-diagonal least-squares method. The minimized function was $\Sigma w(F_o-|F_c|)^2$. A weighting scheme of the type suggested by Hughes[14] was applied using $w=1.0$ for $F_o\leqq F_{max}$ and $w=(F_{max}/F_o)^2$ for $F_o>F_{max}$; $F_{max}=31.0$ was found to be optimum. The atomic scattering curves were taken from Ref. 15. The initial refinement was carried out with isotropic thermal parameters. The thermal parameters of all the atoms except those of the BF_4^- ion converged at 3—5 Å^2, while those of the B and F atoms were found to be unusually large. In the subsequent refinement, the anisotropic thermal parameters were used for the Cu, C, N, and O atoms, but not for the B and F atoms. The R value was reduced to 0.116. Although introduction of anisotropic temperature factors for the B and F atoms as well as the other atoms reduced the R value further to 0.087, some of the F–B–F bond angles were found to be far from the tetrahedral angle (109°28′). In order to investigate carefully the electron-density distribution for the BF_4^- anion, we calculated a difference Fourier map in which the electron

a) The anisotropic thermal factors are of the form: $\exp\{-(h^2B_{11}+k^2B_{22}+l^2B_{33}+hkB_{12}+hlB_{13}+klB_{23})\}$.

density due to the complex cation was eliminated. Figure 3 shows the resulting electron-density distribution, which can virtually account for the two azimuthally different BF_4^- ions in a statistical distribution. The weights of 0.6 and 0.4 for the BF_4^- ion with the subscript a and that with b(Fig. 3) were found to be optimum in view of the R value. Seven of the nine crystallographically independent hydrogen atoms could be located on the difference Fourier map calculated at this point. These seven hydrogen atoms were included in the final refinement, with an isotropic thermal parameter of 4.0 Å^2. The final R value was 0.083 for 1736 observed reflections. All the parameter shifts were less than 0.1σ in the final cycle of the refinement. The atomic coordinates and thermal parameters are listed in Tables 1 and 2. The observed and calculated structure factors are preserved at the Chemical Society of Japan(Document Number 7812). The computer programs used in the calculations were as follows: RSSFR-5[12] (Fourier synthesis), HBLS-V[13] (least-squares calculation), and DAPH[13] (interatomic distances and angles, least-squares plane, and coordinates of the H atoms). All the computations were carried out on a NEAC2200—700 computer at Osaka University.

Results and Discussion

The crystal is composed of the $[Cu(H_2O)(phen)_2]^{2+}$ cations and the tetrafluoroborate anions. The bond lengths and angles, with their estimated standard deviations, are given in Table 3.

Figure 1 shows a schematic drawing of the complex cation. There is a twofold axis which passes through the copper and the water-oxygen atoms and which relates the two phenanthroline ligands with each other. The central copper atom is surrounded by the four nitrogen atoms of the two phenanthroline ligands and one water-oxygen atom. The two Cu–N distances of 1.985(6) and 2.041(7) Å in the chelate ring are appreciably different. The Cu–O bond is 2.238(8) Å long.

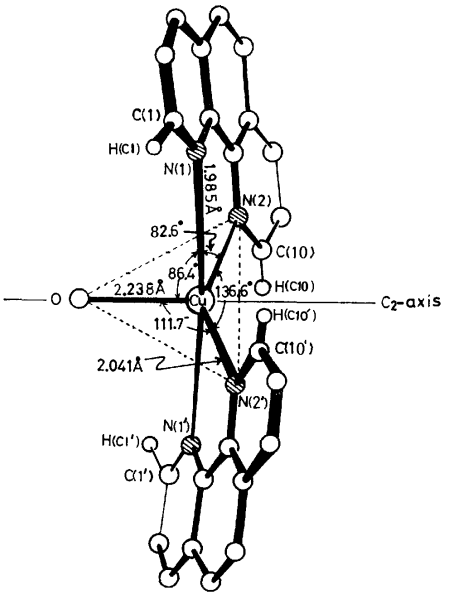

Fig. 1. A schematic drawing of the complex cation $[Cu(H_2O)(phen)_2]^{2+}$.

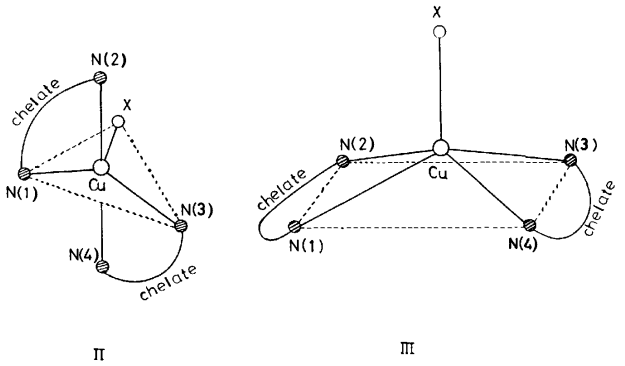
Among possible configurations for the five-coordinate complex, a trigonal-bipyramidal arrangement, II, and a square-pyramidal one, III, may be considered to be common in the $[Cu(chelate)_2X]^{n+}$ cations(chelate= phen or bpy).



Several complexes with a II trigonal-bipyramidal stereochemistry have been found in $[Cu(bpy)_2X]^{n+}$-type complexes (X=I, NH_3, Cl, $CS(NH_2)_2$, and Cu^ICl_2).[1-5] As has been suggested by Stephens *et al.*, it is characteristic that the four Cu–N(bpy) distances in all those complexes except $[Cu(bpy)_2I]^+$ fall into two sets: the axial Cu–N(bpy) distances range from 1.96 to 2.00 Å and are significantly shorter (0.06—0.12 Å) than the equatorial ones. The N(1)–Cu–N(3) angle in the equatorial plane has been shown to be in the range of 109—123° in those complexes.[1-5]

On the other hand, a complex with a square-pyramidal stereochemistry, III, has not yet been found in the bis(phenanthroline)- and bis(bipyridine)copper(II) complexes. However, it has been recently shown that, when the two bipyridine ligands are coordinated to a copper atom in a square-planar arrangement, they must be twisted out of the central copper atom, in opposite directions about their individual C_2-axis by 15—20° towards a tetrahedral stereochemistry, because of the steric repulsions between the hydrogen atoms of the bipyridine ligands in the square-coplanar $Cu(bpy)_2^{2+}$ moiety(I).[7,8] Therefore, if a $[Cu(phen)_2X]^{n+}$ cation takes a square-pyramidal stereochemistry(III), the four nitrogen atoms of the $Cu(phen)_2^{2+}$ moiety in the basal plane should have a flattened tetrahedral disposition. Therefore, the N(1)–Cu–N(3) or N(2)–Cu–N(4) angle in III is presumably in the range of 150—160°. However, there must be no significant difference between the four Cu–N(phen) distances.

Judging from the details described above, the coordination geometry about the copper atom should be described as a distorted trigonal-bipyramid, because the two Cu–N distances for a given phenanthroline ligand are significantly different(Cu–N(1)=1.985(6) and Cu–N(2)=2.041(7) Å); the axial positions are occupied by N(1) and N(1'), while the Cu, N(2), N(2'), and O atoms lie on the trigonal plane. The angle of N(2)–Cu–N(2') in the trigonal plane is 137°; this value is, however, considerably larger than those (108—123°) found in the trigonal-bipyramidal complexes.[1-5] The

b) Plane formed by Cu, N(2), and O atoms: $-0.8942X+0.0000Y-0.4477Z+1.1184=0$

c) Plane formed by Cu, N(1), and N(2) atoms: $0.2710X+0.9227Y-0.2743Z+0.7658=0$

d) Plane formed by Cu, N(1), and O atoms: $0.5880X-0.0000Y-0.8089Z+3.6511=0$

N(1)–Cu–O angle is 86.4°, and the N–Cu–N angle in the chelate ring is 82.8°.

On the basis of our previous X-ray examination of $[Cu(H_2O)(phen)_2](NO_3)_2$,[9] which was performed by the use of photographic data, the $[Cu(H_2O)(phen)_2]^{2+}$ cation was assigned a trigonal-bipyramidal structure, in which the axial and equatorial Cu–N distances were 1.99(1) and 2.03(1) Å respectively. Although the unit-cell dimensions of the $[Cu(H_2O)(phen)_2](BF_4)_2$ are different from those of the nitrate salt, the disposition of anions around the cation in the former resembles that in the latter; that is, these two crystal structures are roughly in agreement with each other. In the complex cation, there is no significant difference in the Cu–N distances, while the Cu–O distances are 2.18(1) Å in the NO_3^- salt and 2.238(8) Å in the BF_4^- salt, a difference of about 0.06 Å. However, the e.s.d. in the NO_3^- salt might be underestimated because it is based on photographic data. Therefore, we may regard the coordination geometries of these two complexes as essentially identical.

The phenanthroline ligands are planar within a maximum deviation of 0.04 Å(Table 4). The angle between the best planes of these two phenanthroline ligands is 47°. The H(C1)···H(C10′) distance is 2.43 Å; this value is equal to the sum of the van der Waals radii of the hydrogen atoms (Fig. 2). The bond lengths and angles agree with the values usually found in Cu(II)–phen complexes.[9,10,16,17] However, it is noted that the distances of C(2)–C(3), C(5)–C(6), and C(8)–C(9) are shorter than the others by 0.03—0.10 Å; such a trend has also been observed in the Cu(II)–phen complexes.

The arrangement of tetrafluoroborate ions is linked to the coordinated water molecules through O–H···F hydrogen bonding (O···F(1a)=2.75 Å) (Fig. 3). The B–F bond distances range from 1.32 to 1.45 Å, and the F–B–F angles, from 99 to 117°.

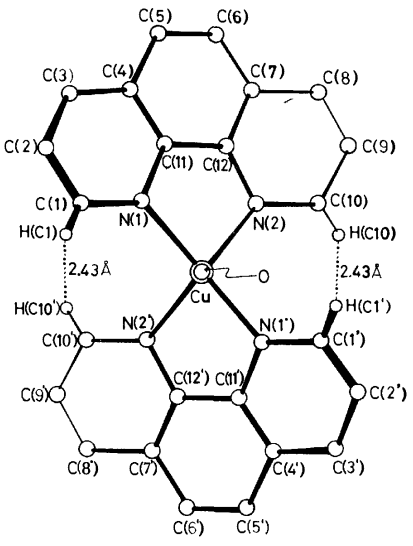

Fig. 2. The b axis projection of the complex cation $[Cu(H_2O)(phen)_2]^{2+}$.

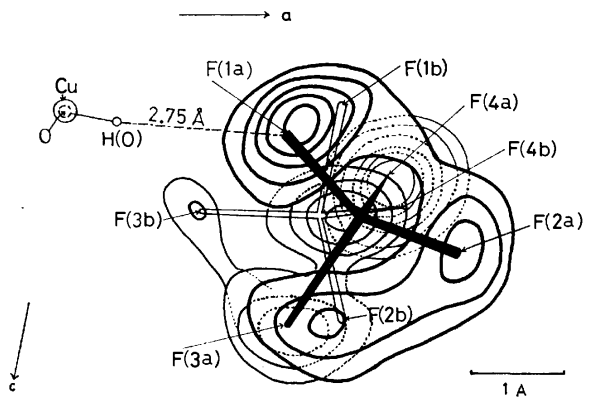

Fig. 3. The electron-density distribution of the disordered BF_4^- ion(O–H···F(BF_4^-) hydrogen bond, ——). The contours are at an arbitrary interval.

This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 164174), for which the authors are grateful. The authors also wish to express their deep thanks to Professor Hisao Kuroya, Dr. Shun'ichiro Ooi, and Dr. Keiji Matsumoto of Osaka City University for allowing them to use a Philips PW1100 diffractometer.

(Received November 16, 1977)

On the basis of a tetragonal (D_{4h}) model, the procedures for calculating the vibronically induced transition moment have been described, and a correlation in the band intensity between two nondegenerate transition components (A_2 and B_2) has been shown. The correlation has then been applied to understanding the characteristic absorption spectra of the *trans*-$[CrClF(NH_3)_4]^+$ and *trans*-$[CrF_2(NH_3)_4]^+$ complexes. Furthermore, an effect upon the band intensity caused by the configuration interactions among the E states has been proposed in order to explain the characteristic spectra of the *trans*-$[Co(C_2O_4)_2(py)_2]^-$ and *trans*-$[Co(CO_3)_2(py)_2]^-$ complexes. This treatment has been applied also to the spectra of cobalt(III) complexes with C_{4v} symmetry.

It is well known that the absorption spectra of *trans* complexes of the $[MX_2(NH_3)_4]^+$ type (M=Co and Cr; X=Cl and Br) exhibit marked splittings in the first absorption bands, this fact being well understood on the basis of the ligand-field theory.[1] Recently, it has been reported that the absorption spectra of a few chromium(III) complexes, such as *trans*-$[Cr(OH)_2(NH_3)_4]^+$, *trans*-$[CrF(OH)(NH_3)_4]^+$ and *trans*-$[CrF_2(NH_3)_4]^+$, show marked splittings in the second absorption bands, while the first bands are at the same time poorly or clearly split, the assignments of the bands being made on the basis of the angular overlap model.[2] Similar splittings in the second absorption bands have been reported with the *trans* complexes of the $[Co(OO)_2(py)_2]^-$ type (OO represents CO_3^{2-} or $C_2O_4^{2-}$), and the assignment of the split bands has been attempted by means of the angular overlap model.[3] These interesting aspects of the behavior of the splittings suggest that there is a certain correlation among the intensities of the split bands.

Early works on the band intensities of the ligand-field transitions were carried out by several workers[4–8] with respect to cubic complexes. Griffith[9] first applied the so-called tensor method to the calculation of the intensity, and then several workers[10–12] used the method for the parameterization of the band intensity with respect to complexes of rare earth elements.

There have also been a few investigations of the band intensity with respect to complexes with symmetry lower than the cubic. Dubicki and Day[13] measured the temperature dependence of the intensity of the ^4E_g ($^4T_{2g}$ parentage) band for *trans*-$[CrX_2(en)_2]ClO_4$ (X= Br or Cl) and found that the ^4E_g band borrows its intensity from the charge-transfer (CT) bands by means of the vibronic mechanism. In their treatment, however, only the admixtures of the excited ligand-field states with the ligand-to-metal CT states were taken into consideration.

The purpose of the present work was to find the correlation of the band intensities in a tetragonal cobalt(III) or a chromium(III) complex by applying the treatment of Dubicki and Day, with some modifications. That is, all kinds of admixtures of the ligand-field states with the CT states were considered in our treatment. In the first part of this paper, the mathematic formulation of the relative intensities of the ligand-field transitions will be described according to a model distorted weakly from a regular octahedron, and then the resultant formula will be proved by means of the spectral data of a few chromium(III) complexes. In the later part, the effect due to configuration interactions among the E states upon the band intensity will be discussed in connection with the spectral data for several cobalt(III) complexes.

Experimental

The *trans*-$[CoCl_2(NH_3)_4]Cl$, $[CoCl(NH_3)_5]Cl_2$, $[CoBr(NH_3)_5]Br_2$ and $[Cr(NH_3)_6](ClO_4)_3$ complexes were synthesized by the usual methods, while the *trans*-$[Co(CN)_2(NH_3)_4]Cl$ complex was prepared according to the literature.[14] The measurements of the absorption spectra in an aqueous solution were carried out with a Hitachi 323 recording spectrophotometer at room temperature. However, the spectrum of *trans*-$[CoCl_2(NH_3)_4]Cl$ was measured in a DMF solution. The absorption spectral data of the *trans*-$[CrF_2(NH_3)_4]^+$, *trans*-$[CrClF(NH_3)_4]^+$ and $[CoCl(CN)_5]^{3-}$ complexes were cited from the literature.[2,15] The curve analysis[3] of the absorption spectra was carried out at the Data Processing Center, Kanazawa University.

Methods of Calculation

Matrix Elements. The ligand-field transition between even-parity states is induced through odd-parity vibrations. The dipole-moment matrix element for the A′→B′ transition is given by[6]

$$\langle A'|\mathbf{P}|B'\rangle = \sum_D \frac{\langle A|\mathbf{P}|D\rangle\langle D|\mathbf{H}_v|B\rangle}{E_B - E_D} + \sum_C \frac{\langle B|\mathbf{P}|C\rangle\langle C|\mathbf{H}_v|A\rangle}{E_A - E_C}, \quad (1)$$

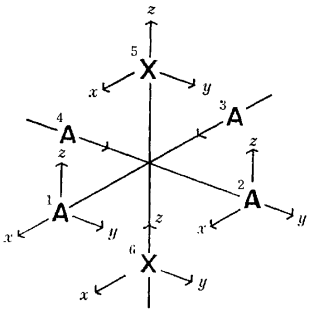

Fig. 1. Coordinate system in a D_{4h} model.

where the first term expresses the part caused by the admixtures of the D odd-parity states with the B excited-ligand-field states, and the second term, the part caused by the admixtures of the C odd-parity states with the A ground state. The $\mathbf{H}_v$ symbol denotes the vibrational Hamiltonian in a tetragonal complex. By adopting the coordinate system as in Fig. 1, $\mathbf{H}_v$ is written as follows:[16]

$$\begin{aligned}
\mathbf{H}_v(E_u^x(a)) &= (x_5+x_6-2x_0)(\partial/\partial x)(V_5+V_6)/2,\\
\mathbf{H}_v(E_u^x(b)) &= (x_2+x_4-2x_0)(\partial/\partial x)(V_2+V_4)/2,\\
\mathbf{H}_v(E_u^x(c)) &= (x_1+x_3-2x_0)(\partial/\partial x)(V_1+V_3)/2,\\
\mathbf{H}_v(A_{2u}(a)) &= (z_1+z_2+z_3+z_4-4z_0),\\
&\quad\times(\partial/\partial z)(V_1+V_2+V_3+V_4)/4,\\
\mathbf{H}_v(A_{2u}(b)) &= (z_5+z_6-2z_0)(\partial/\partial z)(V_5+V_6)/2,\\
\mathbf{H}_v(B_{2u}) &= (z_1+z_3-z_2-z_4)(\partial/\partial z)(V_1+V_3-V_2-V_4)/4,
\end{aligned} \tag{2}$$

where $V_j(j=1\text{—}6)$ represents the ligand-field potential at the jth position, and where x_j and z_j denote the nuclear displacements.

In a model of octahedron with weak tetragonal distortion, the excited-ligand-field states in a Co(III) complex are usually approximated by[8]

$$\begin{aligned}
|E_g^x(a)\rangle &= \{(yz)(y^2-z^2)\},\\
|E_g^x(b)\rangle &= \{(yz)(x^2)\},\\
|A_{2g}\rangle &= \{(xy)(x^2-y^2)\},\\
|B_{2g}\rangle &= \{(xy)(z^2)\}.
\end{aligned} \tag{3}$$

In the above determinants, each state is represented by a d-orbital component of the t_{2g} "hole" (yz or xy) and a d-orbital component of the occupied e_g orbital (y^2-z^2, x^2, x^2-y^2 or z^2). Thus, the wave function for $E_g^x(a)$ is:

$$\{(yz)(y^2-z^2)\} = \{|\cdots(\overset{+}{yz})(\overset{-}{y^2-z^2})(\overset{+}{zx})(\overset{-}{zx})(\overset{+}{xy})(\overset{-}{xy})| + |\cdots(\overset{+}{y^2-z^2})(\overset{-}{yz})\cdots|\}/\sqrt{2}.$$

On the other hand, there are two CT states which can be used as the odd-parity states; one is that of the ligand-to-metal charge transfer (LMCT), and the other, the metal-to-ligand charge transfer (MLCT). The CT states obtained by the use of the symmetry ligand orbitals listed in Table 1 are given in Table 2.

Our attention was given to the matrix elements in (1) in order to determine the CT states which contribute greatly to the intensities of the ligand-field transition bands; the Wigner-Eckart theorem[17] was useful in finding the non-vanishing matrix elements (the vibronic selection rule used in the calculation is given in Table 3). Among the non-vanishing matrix elements thus found, the elements such as $\langle y^2-z^2|\Gamma|\pi_\eta\rangle$, $\langle y^2-z^2|\Gamma|\sigma_\alpha\rangle$ and $\langle xy|\Gamma|\pi_\alpha\rangle$ (Γ represents $\mathbf{H}_v$ and $\mathbf{P}$) were considered to have small values because of the poor overlap integrals of the metal orbitals with the ligand orbitals. Furthermore, when the ligand-field potentials in a $\mathbf{H}_v$ lay outside the positions of the ligand orbitals used, the matrix elements associated with the $\mathbf{H}_v$ were considered to be quite small because of the three-centered integral. Since the numerators in (1) were expressed by products of the matrix elements of the $\mathbf{P}$ and those of the $\mathbf{H}_v$, the contribution from a product to the induced dipole moment was regarded to be negligible, at least when either of the two matrix elements was extraordinarily small.

Using the curled determinants, the states in a Cr(III) complex were easily correlated with the corresponding states in a Co(III) complex. The correlation table thus obtained is listed in Table 4. The states belonging to the A and B representations in the Co(III) complex correspond in turn to the states belonging to the B and A representations in the Cr(III) complex, while

the states belonging to the E representation are common to both metal complexes.

Fenske[8] has stated that the $LM(t_{2g})CT$ transitions make no contribution to the intensities of the ligand-field transition bands. On this basis, the CT states listed in Table 2 were used for a Cr(III) complex only by exchanging A for B (or B for A). The intensity calculation for Cr(III) complexes was performed in the same way as that for Co(III) complexes.

Relative Intensities. Admixture with LMCT: In the case of Co(III) complexes, the matrix elements of the $^1A_{1g}\rightarrow{}^1A_{2g}$ transition were found to be the same as those of the $^1A_{1g}\rightarrow{}^1B_{2g}$ transition, although the coefficients differed from one another (see Table 5). On the basis of this result, in the case of a complex with only a σ-donating ligand such as NH_3 in the xy plane, the ratio of the oscillator strengths[18] of the $^1A_{2g}$ transition, $f(A_2)$, to that of the $^1B_{2g}$ transition, $f(B_2)$, was expressed by

$$\frac{f(A_2)}{f(B_2)} = k\frac{E(A_2)}{E(B_2)} \times \left(\frac{E(CT)-E(B_2)}{E(CT)-E(A_2)}\right)^2. \quad (4)$$

In this equation, $E(A_2)$, $E(B_2)$, and $E(CT)$ denote energy corresponding to each transition, and k is a coefficient, found to be 3 in this case. Hereinafter, the mechanism associated with $L(\sigma)MCT$ (or $ML(\sigma)$ CT) will be called the $L(\sigma)$-vibronic mechanism.

As is shown in Table 5, two $L(\pi)MCT$ participated in each transition through the vibronic mechanism (hereinafter called the $L(\pi)$-vibronic mechanism); for instance, with regard to the $^1A_{2g}$ transition, the $\langle x^2|\mathbf{P}|\pi_\xi\rangle$ and $\langle y^2-z^2|\mathbf{P}|\pi_\xi\rangle$ dipole moments appeared in the summation of the first term in (1). From the differences in the normalization constants of the (y^2-z^2) and (x^2) orbitals, it can easily be shown that

$$\langle y^2-z^2|\mathbf{P}|\pi_\xi\rangle = \sqrt{3}\langle x^2|\mathbf{P}|\pi_\xi\rangle. \quad (5)$$

On this basis, if the denominators in (1) were replaced by a mean value of the $L(\pi)MCT$ transition energies, the oscillator strengths in this $L(\pi)$-vibronic mechanism were evaluated by adding the two products of the matrix elements; consequently, the same equation as (4) was obtained, with the coefficient of 3/5. Similar equations were also derived between the $f(E_g(a))$ of the $^1E_g(a)$ and the $f(E_g(b))$ of the $^1E_g(b)$ transitions in both the $L(\sigma)$- and $L(\pi)$-vibronic mechanisms.

Admixture with MLCT: As is shown in Table 5, the matrix elements of the $^1T_{1g}$ parentage bands dif-

fered from those of the $^1T_{2g}$ parentage bands, though every coefficient was equal to $\sqrt{2}$ in both parentages. However, we could also show similar relations to (5) between the matrix elements in the transitions to the nondegenerate states (and between those in the transitions to the degenerate states). The same equations as (4) could be derived in both the L(σ)- and L(π)-vibronic mechanisms, where the k values were equal to 3.

In the case of the Cr(III) complexes, the resultant equations were also expressed by (4); however, the A_2 subscript (or B_2) had to be exchanged with B_2 (or A_2).

Results and Discussion

Nature of the A_2 and B_2 Transitions. Only a half of the calculated matrix elements of the first term in (1) are listed in Table 5, because the other half can easily be obtained by considering the symmetry. The matrix elements concerning the second term in (1) were obtained by exchanging the **P** in the first term with the $\mathbf{H}_v$.

From the present model of weak tetragonal distortion, it can be predicted that the intensities of the transitions to the nondegenerate excited states are independent of the ligand on the z axis (X in Fig. 1), since they are only related with the ligand orbitals on the xy plane (π_ξ, π_η, σ_α, and σ_β) through the E odd-vibrations occurring on the plane. This prediction is confirmed by the fact that the intensities of the $^4A_{2g}$ band in *trans*-$[CrX_2(NH_3)_4]^+$ (X=F^- and OH^-), whose tetragonal distortions seem to be small, are almost invariable, in comparison with the considerable variations in the intensities of the ^4E_g(b) bands. Moreover, the fact that the intensities of the $^4A_{2g}$ (or $^4B_{2g}$) bands are nearly equal to one-third of the intensity of the $^4T_{1g}$ (or $^4T_{2g}$) band in $[Cr(NH_3)_6]^{3+}$ supports the prediction from the present model.

The present model is applicable to the problem of A_2 and B_2 transitions in a C_{4v} complex for the following reason: The wave functions associated with the ligand orbitals on the xy plane are the same as those in the D_{4h} complexes. According to the ligand-field theory,[19] the ligand-field potential in a C_{4v} complex can be divided into two potentials in D_{4h} symmetry:

$$U_{C_{4v}} = U_{D_{4h}(A_{2u})} + U_{D_{4h}(A_{1g})}.$$

The first term can mix the states coming from even-parity states in D_{4h} with the states coming from odd-parity states under static conditions, and contributes only to the intensities of the E bands. On the other hand, the second term can mix the states coming from the odd-parity states in D_{4h} symmetry under vibronic conditions. In fact, in *trans*-$[CrF(OH)(NH_3)_4]^+$ the above-mentioned prediction holds.

Application to Tetragonal Complexes. As for Co(III) complexes, no absorption spectrum has been reported to exhibit distinct splittings in both the first and second absorption band regions. However, as for Cr(III) complexes, it has been reported that the absorption spectra in *trans*-$[CrF_2(NH_3)_4]^+$ and *trans*-$[CrClF(NH_3)_4]^+$ [2] show such splittings. Now, let us apply (4) to these complexes. Note that, in this application, the A_2 and B_2 subscripts in (4) must be exchanged with B_2 and A_2 respectively. The E(CT) values in these complexes are assumed to be *ca.* 55000 cm^{-1}, while the E(CT) value in $[Cr(NH_3)_6](ClO_4)_3$ lies above 52000 cm^{-1}. The $f(B_2)/f(A_2)$ value in (4) was calculated from the numerical data listed in Table 6, and found to be 1.36. On the other hand, the ratio calculated from the observed $f(B_2)$ and $f(A_2)$ values was 1.24 for the difluoro complex. As for *trans*-$[CrClF(NH_3)_4]^+$, the value calculated from the data of Table 6 was 1.52, and the value calculated from the observed data was 1.34, the two being roughly equal.

The angular overlap model[20] suggested that the extent of the tetragonal distortion due to M-L σ-bonding is expressed by the difference between two antibonding energies, $\sqrt{3}/4\{\langle z^2|\mathbf{A}|z^2\rangle - \langle x^2-y^2|\mathbf{A}|x^2-y^2\rangle\}$. In the case of the *trans*-$[M(X)_2(A)_4]$-type complex, the difference is rewritten as $\sqrt{3}(e_\sigma(X) - e_\sigma(A))/2$, where e_σ denotes the σ-antibonding parameter. It is known[2] that the σ-parameter related with the Cr–F bonding, e_σ(F), is slightly larger than that of the Cr–NH_3 bonding, e_σ(N). When these findings are taken into consideration, the tetragonal distortions in the Cr(III) complexes concerned are regarded as very small, and the excited states are sufficiently approximated by Eq. 3. Thus, it seems reasonable to use our model for the Cr(III) complexes with small distortions.

The Effect of Configuration Interactions. In a previous paper,[3] the band intensity in *trans*-$[Co(C_2O_4)_2$-

a) Ref. 3. b) Ref. 15.

$(py_2)]^-$ was treated by considering only the L(σ)-vibronic mechanism under a weak tetragonal distortion, and the intensity of the $^1A_{2g}$ band, which was not observed in the absorption spectrum, was estimated. The value reported there, $\varepsilon_{max}=19$, now seems to somewhat large in the light of the maximum ($\varepsilon_{max}=57.5$) of the observed band (the spectral data are summarized in Table 7). If the L(π)MCT contributes to the $^1A_{2g}$ band intensity, the ε_{max} value may be evaluated as a smaller one. However, in the case of *trans*-$[Co(C_2O_4)_2(py)_2]^-$, such a contribution seems to be negligible because the π-ligand orbitals of the O donors on the xy plane are utilized for σ-hybridizations. Thus, we re-evaluated that value by considering the configuration interactions among the E states.

When the distortion becomes large, the one-electron wave functions, y^2-z^2, x^2, z^2-x^2, and y^2, which have been used in the E states must be altered by the following respective functions:[20]

$$\begin{aligned}
\phi_a(x) &= a\phi(y^2-z^2) - b\phi(x^2),\\
\phi_b(x) &= b\phi(y^2-z^2) + a\phi(x^2),\\
\phi_a(y) &= -a\phi(z^2-x^2) - b\phi(y^2),\\
\phi_b(y) &= -b\phi(z^2-x^2) + a\phi(y^2),\\
&\text{where } a^2+b^2=1.
\end{aligned} \qquad (6)$$

When an expression for the $f(A_2)/f(B_2)$ ratio in a Co(III) complex was derived from these new wave functions of the E states, the expression was found to be the same as (4), although the k value varied as a function of the a coefficient. The change is illustrated in Fig. 2. When the L(σ)-vibronic mechanism participates and the e_σ(X) is larger than the e_σ(A), the k value decreases rapidly from 3 to 1.5 in the initial section of the a^2 value. On the other hand, in the case of $e_\sigma(X)<e_\sigma(A)$, the change of k with a^2 is quite different.

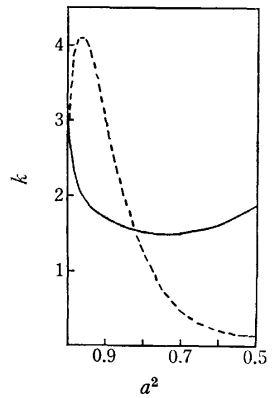

Fig. 2. Relationships between the coefficients k and a^2; —— $e_\sigma(X) > e_\sigma(A)$, ---- $e_\sigma(X)<e_\sigma(A)$.

It is reasonable to consider that e_σ(py) is larger than e_σ(O) in *trans*-$[Co(C_2O_4)_2(py)_2]^-$; if a sufficiently strong distortion is considered, the ε_{max} value of the $^1A_{2g}$ band is evaluated to be 10 for the bis(oxalato) complex. When the same calculations are carried out with a related dicarbonato complex, the results give $\varepsilon_{max}=16$. These values are much smaller than the observed ε_{max} values in the first absorption-band region ($\varepsilon_{max}=57.5$ for the bis(oxalato) complex and $\varepsilon_{max}=89.1$ for the dicarbonato complex). It is also possible to find an effect of the same kind in the polarized crystal spectra of *trans*-$K_2[Co(CN)(mal)_2(OH_2)]\cdot H_2O$;[21] two split bands have been observed in the second absorption-band region, while only one band assignable to E(a) has been observed in the first absorption-band region. This phenomenon can now be understood by considering the intensity of the A_2 band, which is too weak, compared with that of the B_2 band.

Whether or not a band splitting can be observed depends upon both the magnitude of the intensities and the extent of the energy separation of the split bands, but the latter is not discussed in this paper. The formula (4) derived in this paper is useful in evaluating the intensity of an unobservable band from the observed intensity of the other band. Thus, let us discuss the behavior of band intensities in cobalt(III) complexes in terms of the tetragonal distortion. Three cases—Case a, $e_\sigma(X)>e_\sigma(A)$; Case b, $e_\sigma(X)\simeq e_\sigma(A)$, and Case c, $e_\sigma(X)<e_\sigma(A)$—will be considered. In Case a, the intensity of the $^1A_{2g}$ band observed at the longest wavelength is quite small in comparison with that of the $^1B_{2g}$ band, because the calculated value of the energy part in (4) becomes small as a result of the large separation between the $^1A_{2g}$ and $^1B_{2g}$ bands, and because k also has a small value. This kind of complex will often exhibit marked

splittings in the $^1T_{2g}$ bands. In Case b, the $^1A_{2g}$-band intensity is anticipated to be comparable to the $^1B_{2g}$-band intensity because of the large k value ($k \simeq 3$). In this case, band splittings will be observed only in a complex with ligands showing a strong π-bonding or π-antibonding contribution. No typical example of this is found in Co(III) complexes, but the spectrum of *trans*-$[Co(CN)_2(NH_3)_4]^+$ probably is such a case, for the intensity of the $^1A_{2g}$ band is almost one-third of the intensity of the $^1T_{1g}$ band in $[Co(NH_3)_6]^{3+}$. This probability is supported by the fact that the π-bonding contribution of the CN^- ligand has been found through the infrared spectral[22] and the absorption spectral studies.[23] In Case c, the $f(A_2)/f(B_2)$ ratio becomes larger than unity, except for an extremely distorted complex, because the energy part in (4) takes a large value as a result of the small separation of the $^1A_{2g}$ and $^1B_{2g}$ bands, and because k also takes a large value. In this case, it will be easier to observe band splitting in the $^1T_{1g}$-band region rather than in the $^1T_{2g}$-band region. This seems to correspond to the large intensities of the $^1A_2$ bands in $[CoX(NH_3)_5]^{2+}$ ($X=Cl^-$ and Br^-) and $[CoCl(CN)_5]^{3-}$. When the distortion becomes extremely large, the $f(A_2)/f(B_2)$ ratio takes a value of roughly unity on account of the small value of k. An example is seen in the spectrum of *trans*-$[CoCl_2(NH_3)_4]^+$; the broad band in the $^1T_{2g}$-band region suggests that the $^1B_{2g}$-band intensity is comparable to the $^1A_{2g}$-band intensity.

Synthesis and Unusual Properties of Trimethylsilylmethyl, Neopentyl, and Related Alkylthallium Compounds

Hideo KUROSAWA,* Shigeaki NUMATA, Toshifumi KONISHI, and Rokuro OKAWARA

Department of Petroleum Chemistry, Osaka University, Yamadakami, Suita, Osaka 565

(Received November 25, 1977)

Synthesis of some new trimethylsilylmethyl, neopentyl, and isobutylthallium compounds is described. Dialkylthallium halides containing these bulky alkyl substituents were found to be dimeric, in marked contrast to the polymeric dimethylthallium halide analogs. Trimethylsilylmethylthallium diisobutyrate possesses much higher stability than the methyl and ethylthallium analogs. These facts were discussed in terms of the steric bulk of the alkyl groups attached to thallium.

Organometallic compounds containing the trimethylsilylmethyl or neopentyl groups are of current interest because of abilities of these groups to apparently stabilize metal–carbon bonds.[1] Of particular importance in considering factors which affect kinetic stabilities and structural aspects of such a class of organometallic compounds is clearly bulkiness of the alkyl groups. We wish to describe synthesis of some new organothallium compounds containing bulky alkyl substituents whose unique properties may be contrasted with those of common, less bulky alkyl derivatives of thallium.[2]

Experimental

The infrared spectra were run on a Hitachi 225 or EPI-2G grating spectrophotometer. The ^{1}H NMR spectra were measured on a Japan Electron Optics JNM-PS-100 spectrometer. Molecular weights were determined in $CHCl_3$ at 25 °C using a Mechlorab vapor pressure osmometer Model 302. Tetrahydrofuran for the preparation of the Grignard and lithium reagents was dried with $LiAlH_4$.

Preparation of New Compounds. *Dialkylthallium Chlorides*: R_2TlCl ($R=Me_3CCH_2$, Me_2CHCH_2) were prepared in a manner similar to that[3] for obtaining $Pr^n{}_2TlCl$ from $TlCl_3$ and the appropriate Grignard reagents in tetrahydrofuran. Recrystallization from CH_2Cl_2 or $CHCl_3$ gave colorless needle-like crystals. *$(Me_3SiCH_2)_2TlCl$*: To a tetrahydrofuran solution (20 ml) of $TlCl_3$ (0.75 g; 2.4 mmol) was added lithiomethyltrimethylsilane,[4] which was prepared from Me_4Si (2.0 g; 24 mmol), *N,N,N′,N′*-tetramethylethylenediammine (2.8 g; 24 mmol) and 15 ml of 1.5 M Bu^nLi in hexane. Immediately metallic thallium formed and the solution became black. After stirring for 2 h, the reaction mixture was hydrolyzed with saturated aqueous ammonium chloride. The tetrahydrofuran extract was concentrated to give an oily product which was washed with water several times. Recrystallization from $CHCl_3$ gave white needles of $(Me_3SiCH_2)_2TlCl$ (0.34 g; 0.82 mmol). $(Me_3SiCH_2)_2TlBr$ was prepared from TlBr and Me_3SiCH_2Li in a similar manner. *$Me_3SiCH_2Tl(OOCPr^i)_2$*: Mercuric isobutyrate (0.30 g; 0.81 mmol) and $(Me_3SiCH_2)_2TlOOCPr^i$ (0.38 g; 0.81 mmol), which was prepared from $(Me_3SiCH_2)_2TlCl$ and $TlOOCPr^i$ in $CHCl_3$, were mixed in $CHCl_3$ (10 ml) at room temperature. The solid products obtained by vacuum evaporation of the solvent after 1 day were recrystallized from hexane to give 0.10 g (0.22 mmol) of $Me_3SiCH_2Tl(OOCPr^i)_2$. *$Me(Me_3SiCH_2)TlBr$*: Pyridinium perbromide (0.05 g; 0.19 mmol) and $(Me_3SiCH_2)_2TlCl$ (0.08 g; 0.19 mmol) were dissolved in 10 ml of $CHCl_3$. After 30 min tetramethyltin (0.04 g; 0.24 mmol) was added to the solution in order to methylate[5] a monoalkylthallium species produced *in situ*. After 1 h the solution was filtered. The solid products obtained by vacuum evaporation of the filtrate were recrystallized from $CHCl_3$ to give 0.06 g (0.16 mmol) of $Me(Me_3SiCH_2)TlBr$. $Me(Me_3SiCH_2)TlOOCPr^i$ was prepared from $Me(Me_3SiCH_2)TlBr$ and $TlOOCPr^i$ in $CHCl_3$. Recrystallization from hexane gave fine needles of the compound.

Analytical data of the new compounds thus obtained are summarized in Table 1. Infrared and ^{1}H NMR spectral data of the representative trimethylsilylmethyl compounds are shown in Table 2.

Pyrolysis of $(Me_2CHCH_2)_2TlCl$. 100 mg (0.28 mmol) of a solid sample of $(Me_2CHCH_2)_2TlCl$ in a sealed tube under reduced pressure (10^{-1} mmHg) was heated at 170 °C for 3 h. Sixty-five mg (0.27 mmol) of white powdery TlCl remained in the tube, and GLC analysis of gaseous products indicated

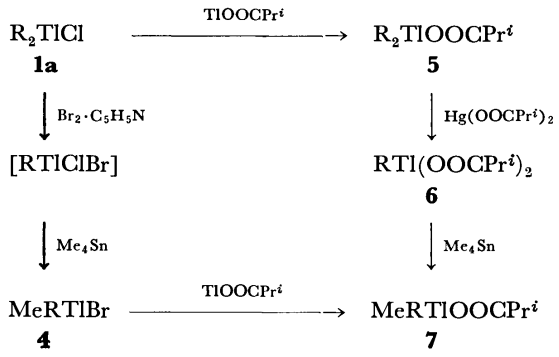
the presence of only isobutane and isobutene in almost 1 : 1 mole ratio. Also, 0.4 ml of $CDCl_3$ was added to a residual mixture, while kept at −78 °C, after a separate pyrolysis run carried out under the identical condition. The ^{1}H NMR spectrum of this $CDCl_3$ solution again confirmed the formation of only isobutane and isobutene (1 : 1) as chloroform-soluble products. No indication of the presence of 2,5-dimethylhexane could be obtained through GLC and ^{1}H NMR analyses.

Results and Discussion

Synthetic Route. Dialkylthallium halides, $(Me_3SiCH_2)_2TlX$ (**1a** X=Cl; **1b** X=Br) and $(Me_2RCCH_2)_2TlCl$ (**2** R=Me; **3** R=H) were prepared using the appropriate lithium or the Grignard reagents. **1a** was further derivatized to other trimethylsilylmethyl compounds of thallium as outlined in Scheme 1.



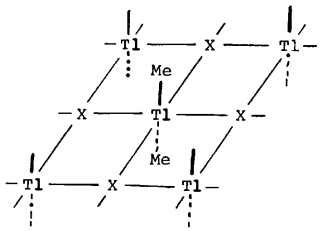
Scheme 1. R=Me_3SiCH_2.

Dialkylthallium Compounds. The trimethylsilylmethyl and neopentylthallium halides, **1a**, **1b**, **2**, and **4** possess good thermal stabilities comparable to those of dimethyl, diethyl or dipropyl analogs. However, interestingly, the diisobutylthallium derivative, **3** was found to be much less stable than not only **2** but Pr^n_2TlCl. Thus, even standing a crystalline sample of **3** at room temperature gradually caused decomposition to result in contamination of the sample with TlCl. Approximately 1 : 1 molar mixture of isobutane and isobutene was detected in the gaseous products from pyrolysis of the solid sample of **3** at 170 °C under reduced pressure for 3 h. 2,5-Dimethylhexane was not formed.

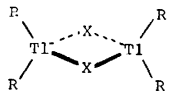
$$\underset{\mathbf{3}}{(Me_2CHCH_2)_2TlCl} \xrightarrow{\Delta} Me_3CH + Me_2C{=}CH_2 + TlCl$$

On the contrary, **2** and Pr^n_2TlCl were found to be totally stable under the same conditions. In view of this fact, it seems unlikely that the Tl–C bond strength in **3** is exceptionally weak. Although the precise mechanism of the decomposition of **3** yet remains to be elucidated, the presence of the labile β-methine hydrogen in the isobutyl group apparently is essential to the unique instability of this compound. In this regard, it should be mentioned that the removal of the β-methine hydrogen of the isobutyl group in $R(Me_2CHCH_2)Hg$ by a radical species promoted the liberation of isobutene and the homolytic fission of the Hg–R bond.[6]

Dimethylthallium halides are insoluble in non-coordinating solvents possibly due to the occurrence of the polymeric structure with a linear C–Tl–C unit lying perpendicular to the $(Tl–X)_n$ network as shown in **A** below.[7] It is well recognized[8] that the linear C–Tl–C configuration is energetically most favored in dialkylthallium compounds. On the contrary, **1**—**4** are all fairly soluble in $CHCl_3$ and benzene, and were found to be dimeric in $CHCl_3$ (Table 1) with a bent C–Tl–C configuration as suggested for **1a** and **1b** by the appearance of two TlC_2 stretching modes (Table 2).



A (X=Cl, Br, I)



B (R=Me_3SiCH_2, Me_3CCH_2, Me_2CHCH_2; X=Cl, Br)

However, Pr^n_2TlCl was too insoluble to determine its molecular weight. We assume that a part of the reasons for the increased solubilities of **1**—**4**, compared to those of Me_2TlX and Pr^n_2TlCl, is steric; the steric bulk of the alkyl groups in **1**—**4** may have precluded the formation of the polymeric network with the Tl-X interaction as strong as that in $(Me_2TlX)_n$, as will be explained below. Thus, in molecular models for **1**, **2**, and **4** having a hypothetical structure similar to **A**, it is almost impossible to attach the Me_3SiCH_2 or Me_3CCH_2 groups, totally free of steric constraint, to each thallium atom in the $(Tl–X)_n$ layer which was constructed assuming the Tl–X bond length equal to that[7] in $(Me_2TlX)_n$. The most dominant repulsions observed in such models are those between the β-methyl substituents of one alkyl group and the CH_2 protons of the nearest alkyl or those between the former and the halogen atoms There exist similar kinds of, though to a lesser extent, steric repulsions in the similar model structure for **3**, while such model for Pr^n_2TlCl can now be readily constructed free of constraints without elongating the Tl–Cl distance found in $(Me_2TlCl)_n$.

A brief comparison of the electronic effects of the Me_3SiCH_2 and Me groups can be made on the basis of ^{1}H NMR spectral data. As shown in Table 2, J_{Tl-CH_2} and J_{Tl-CH_3} values of **7** are almost the same as those of **5** and $Me_2TlOOCPr^i$(377 Hz)[9], respectively.

Similarly, J_{Tl-CH_2} value of **1b** is very close to that of **4**. In view of the proposition[10] that thallium-proton spin-spin coupling constant is dominated by Fermi contact term, the results shown above suggest a similarity in the ability of the Me_3SiCH_2 and Me groups to affect the s-character in the bonds between thallium and these groups. A similar trend was also reported[11] that trans influences of the two groups are comparable in square planar Pt^{II} complexes.

Monoalkylthallium Compounds. It should be noted that **6** is much more stable than its methyl or ethyl analogs. Thus, for example, **6** can be recovered unchanged from hot methanol or dimethyl sulfoxide, while the latter two readily decomposed under the similar conditions to give thallium isobutyrate and $ROOCPr^i$ (R=Me, Et).[9] Kinetic studies on the similar decomposition of $MeTl(OAc)_2$ indicated the reaction to proceed through the nucleophilic attack of the acetate anion at the methyl carbon.[12] Therefore, the bulkiness of the Me_3SiCH_2 group almost certainly depresses the approach of a nucleophile at the α-carbon in **6**. A much higher stability of $PhCH(OMe)CH_2TlCl_2$[13] or a mononeopentylthallium halide species[14] than $MeTlX_2$ (X=Cl, Br) was also interpreted on similar grounds, although no detailed description on the isolation of the neopentyl derivative has yet appeared since its preliminary publication.

ESR Studies of an Oxo-Bridged Manganese(III, IV) Complex of 2,2′-Bipyridine

Motomichi INOUE

Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received October 13, 1977)

ESR spectra were recorded on the single crystal of di-μ-oxo-tetrakis(2,2′-bipyridine)dimanganese(III,IV) perchlorate trihydrate. ESR signals attributable to the excited quartet state were observed in addition to an ESR signal due to the ground doublet state. From the temperature dependence of the signal intensities, the exchange integral was determined as $J/k=-207$ K. The spectrum of the quartet state exhibits a fine structure: $|D|$ and $|E|$ were estimated to be equal to 0.39 and 0.12 cm^{-1}, respectively. The constants are interpreted in terms of the dipole-dipole interaction and the crystal-field effect; the anisotropic part of the exchange interaction is negligibly small. The hyperfine structure in the spectrum of the doublet state indicates that odd electrons are distributed unequally on two manganese atoms in the dimer. This is due to an odd e electron (in the t_2^3-$t_2^3e^1$ system) localized mostly on one of the paired manganese atoms.

X-Ray crystal analysis and magnetic susceptibility measurement[1] showed that di-μ-oxo-tetrakis(2,2′-bipyridine)dimanganese(III,IV) perchlorate trihydrate, $[(bipy)_2Mn^{III}O_2Mn^{IV}(bipy)_2](ClO_4)_3\cdot 3H_2O$, is a good model compound for studying magnetic interaction between metal atoms in different oxidation states. As shown in Fig. 1, two manganese atoms bridged by two oxygen atoms are in different coordination fields. From the fact, it was suggested that Mn1 is a high spin d^4 ion, Mn^{3+}, and Mn2 a d^3 ion, Mn^{4+}. For a 2-3/2 spin system, four spin levels are derived with the energies $E_{1/2}=0$, $E_{3/2}=-3$, $E_{5/2}=-8$, and $E_{7/2}=-15J$ on the basis of the Hamiltonian,

$$\mathscr{H} = -2J\mathbf{S}_1\cdot\mathbf{S}_2. \quad (1)$$

The magnetic susceptibility[1] indicates that an antiferromagnetic interaction ($J/k=-147$ K) operates between the dissimilar ions. In the ESR spectrum,[2] a weak signal attributable to the excited states was observed in a region corresponding to $g=4$, in addition to a strong signal due to the ground state at a field of $g=2$. An ESR study of the excited states is expected to provide valuable information on the magnetic interaction. However, no detailed investigation has been undertaken. In the present investigation, ESR experiments have been carried out on the single crystal of the novel compound.

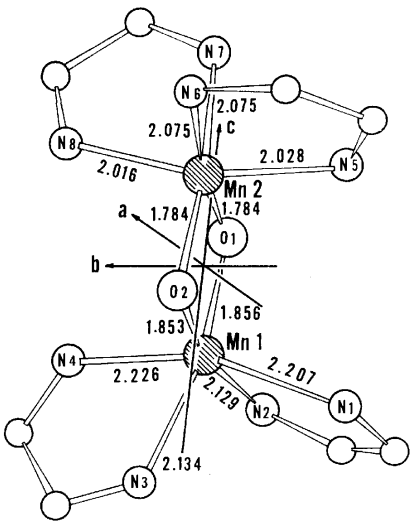

Fig. 1. Dimer structure of $[(bipy)_2MnO_2Mn(bipy)_2]^{3+}$.

Experimental

Single crystals of the complex were prepared by the method reported by Plaksin.[2] Deep green crystals were grown in the form of plates with well developed ab faces.

The ESR spectra were recorded by means of a JEOL ES-SCXA X-band ESR spectrometer equipped with a JEOL JM 350-MR electromagnet. Crystalline powders of MgO doped with Mn(II) ions were employed as a standard.

The crystal has a monoclinic space group $P2_1/c$ with four molecules per unit cell.[1,2] The Mn–Mn axis lies almost parallel to the bc plane and makes an angle of about 20° with the c axis. In a magnetic field applied along the ac plane, all molecules are magnetically equivalent. The ESR spectra were first recorded by rotating the crystal about its b axis, which coincides with one of the principal magnetic axes. An ESR signal exhibiting a hyperfine structure was observed at a field of $g=2$ (Fig. 2). Although the exact g factor was difficult to determine owing to the composite and asymmetric ESR curve, the anisotropy of the g factor was estimated to be 0.01 at most. The hyperfine structure showed no appreciable angular dependence. In addition to the main signal, weak signals were observed in regions of 1—2 and 5—11 kG (the unit G corresponds to 10^{-4} T in the SI unit system). Figure 2 shows an ESR spectrum for crystal orientation with the a axis perpendicular to magnetic field H_0. The positions of the weak signals exhibited marked angular dependence (Fig. 3). The maximum separation between the two signals was observed for $H_0\perp$a. The axis

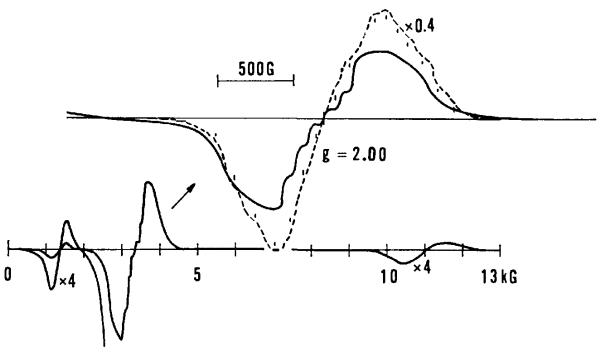

Fig. 2. ESR spectrum observed for H_0 applied along the K_m axis at 300 K. The broken curve displays the main signal ($g=2$) recorded at 183 K.

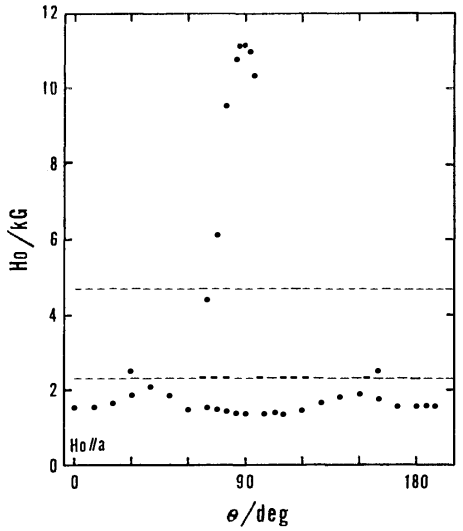

Fig. 3. Angular dependence of the positions of weak signals attributed to the quartet state for H_0 perpendicular to the b axis. The main signal ($g=2$) masks weak signals at fields between the broken lines.

K_m related to the maximum separation can be defined as one of the principal magnetic axes. Hence, the third axis coincides with the a axis. The ESR spectra were recorded by rotating the crystal about the K_m and a axes.

The temperature dependence of signal intensity was determined for the crystal orientations $K_m//H_0$ and b$//H_0$ (H_0 was applied along the bK_m plane) in a temperature range of 100—300 K.

Results

Temperature Dependence of Signal Intensity. The relative reciprocal intensity $I(293)/I(T)$ of the main signal observed at the field of $g=2$ is plotted against the temperature in Fig. 4. The intensity increases with decreasing temperature. On the other hand, the intensities of the weak signals decrease with decreasing temperature. The relative intensity $I(T)/I(293)$ of the signal at the lower field is shown in Fig. 4.

In a spin system having an exchange integral much larger than energies due to the zero-field splitting and the Zeeman term, the intensity $I_s(T)$ of an ESR signal attributed to the level S is proportional to $1/T$ and the unpaired-electron population $P_s(T)$ in the level:

$$I_S(T)\propto\frac{P_S(T)}{T}=\frac{(2S+1)\exp(-E_S/kT)}{T\sum_S(2S+1)\exp(-E_S/kT)}. \quad (2)$$

The population in each level is estimated as $P_{1/2}=0.66$, $P_{3/2}=0.30$, $P_{5/2}=0.04$, and $P_{7/2}=0.002$ at 300 K with the exchange integral determined from the magnetic susceptibility. The main signal is attributable to the ground doublet state, while the weak signals are attributable to the quartet state because contributions from the sextet and octet states are negligibly small. The intensity ratio of the weak signal to the main signal is expected to be proportional to $\exp(-3J/kT)$. The semilogarithmic plot of the ratio against $1/T$ yields a straight line over the temperature range investigated. From the slope, the exchange integral is determined

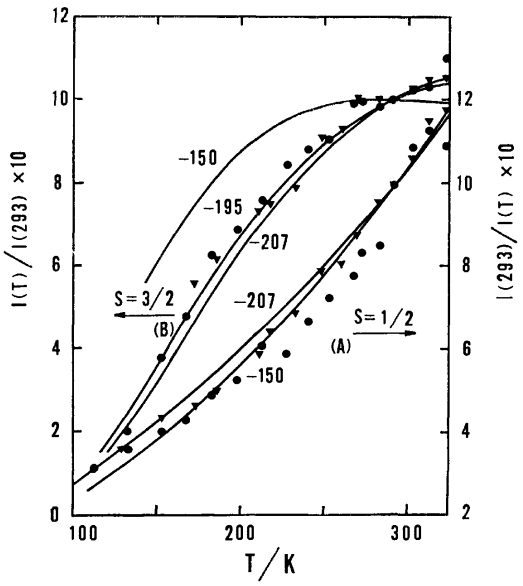

Fig. 4. Temperature dependence of signal intensities observed for $H_0//K_m$ (●) and $H_0\perp K_m$ (▼). The main signal (A) at $g=2$ and the weak signal (B) at the lower field are attributable to $S=1/2$ and $S=3/2$, respectively. The curves display relative intensities calculated with various J/k values.

to be −204 K (−142 cm^{-1}) for H_0//b and −210 K (−146 cm^{-1}) for $H_0//K_m$. The difference between the values cannot directly lead to the conclusion that the exchange interaction has an anisotropy, because the error of the integrated intensity amounts to about ±10 % and the uncertainty of temperature is estimated to be about 4°. Relative intensities calculated with the averaged value −207 K reproduce well the corresponding data (Fig. 4). Usually, magnetic susceptibility experiments give more accurate exchange integrals than ESR experiments. For the complex, however, the signal intensities can be determined separately for the two spin levels, and so the exchange integral determined by the present experiment seems to be highly reliable.

Spectrum of the Doublet State. The main signal attributed to the doublet state exhibits a hyperfine structure due to manganese nucleus-electron coupling. At low temperatures, the structure appears clearly on either side of the derivative curve as seen in Fig. 2. At least 16 lines can be found with spacings equal to 70—100 G: the structure consists of more than 11 lines expected for a pair of equivalent manganese atoms. This suggests that two manganese atoms in the dimer are not equivalent with each other, in line with the X-ray result showing that the two manganese atoms are in different oxidation states.

For H_0 along the aK_m plane, the g factor is approximately estimated to be equal to 2.00, the anisotropy being 0.01 at most. For crystal orientation in the ab plane, the g anisotropy is estimated to be less than 0.01.

Spectrum of the Quartet State. The shape and the resonance field of the signals depend markedly on the crystal orientation, but show no appreciable temperature dependence. The angular dependence of the position is shown in Fig. 3 for the crystal orientation in

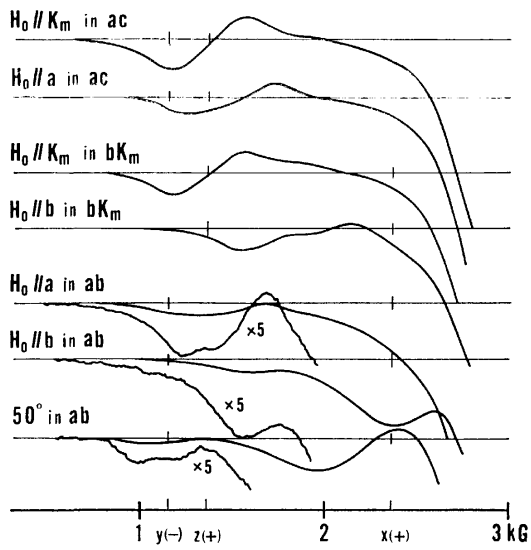

Fig. 5. Some spectra of the weak signal in the lower-field region.

H_0 along the ac plane. The intensity of the signals also depends on the crystal orientation. Especially, the signal in the higher field region is markedly angular dependent: no resonance line is observed above 100° of angle. An ESR pattern for H_0 along the bK_m plane resembles that for H_0 along the ac plane. When H_0 is applied along the ab plane, the crystal shows no ESR signal in the high field region. Figure 5 shows some spectra at the lower fields. The crystal oriented with its b axis parallel to H_0 shows different signals according to the direction of the microwave field H_1.

Because the exchange interaction energy is much larger than the Zeeman energy, the rate of mutual spin flipping is so high that only an average of two dissimilar spins is significant. In this case, the spin Hamiltonian for a pair of similar ions is applicable to the quartet state:

$$\mathscr{H} = g\mu_B \mathbf{S}\cdot\mathbf{H}_0 + D[S_z^2 - S(S+1)/3] + E(S_x^2 - S_y^2), \quad (3)$$

where x, y, and z axes are defined as local or molecular magnetic axes. The zero-field splitting constants D and E arise from the dipole-dipole interaction between two manganese atoms in the dimer, the anisotropic part of the exchange interaction, and the crystal field effect. When magnetic field is applied along the z axis, the following states and energy levels are derived.[3]

$$\theta_{\pm 3/2} = \cos\alpha_\pm |\pm\frac{3}{2}> + \sin\alpha_\pm |\mp\frac{1}{2}>, \quad (4)$$

$$\theta_{\mp 1/2} = -\sin\alpha_\pm |\pm\frac{3}{2}> + \cos\alpha_\pm |\mp\frac{1}{2}>, \quad (5)$$

$$W_{\pm 3/2} = \pm g_z\mu_B H_0/2 + [(D \pm g_z\mu_B H_0)^2 + 3E^2]^{1/2}, \quad (6)$$

$$W_{\mp 1/2} = \pm g_z\mu_B H_0/2 - [(D \pm g_z\mu_B H_0)^2 + 3E^2]^{1/2}. \quad (7)$$

In these expressions, $\tan 2\alpha_\pm = \sqrt{2}E/(g_z\mu_B H_0 \pm D)$. The energy levels for $H_0//x$ are derived as

$$W_{\pm 3/2} = \pm g_x\mu_B H_0/2 \pm [(g_x\mu_B H_0)^2 \mp (D-3E) g_x\mu_B H_0 + D^2 + 3E^2]^{1/2}, \quad (8)$$

$$W_{\pm 1/2} = \mp g_x\mu_B H_0/2 \pm [(g_x\mu_B H_0)^2 \pm (D-3E) g_x\mu_B H_0 + D^2 + 3E^2]^{1/2}. \quad (9)$$

The energy levels for $H_0//y$ are obtained by replacing $(D-3E)$ by $(D+3E)$. The transitions $\theta_{+3/2} \leftrightarrow \theta_{+1/2}$, $\theta_{+1/2} \leftrightarrow \theta_{-1/2}$, and $\theta_{-1/2} \leftrightarrow \theta_{-3/2}$ in H_0 directed to the i (x, y, or z) axis are abbreviated as i(+), i(0), and i(−), respectively. The transition probability depends on the $\alpha_\pm$ values and the direction of H_1 as well as H_0,[3] giving rise to the angular dependence of the signal intensity.

Four molecules in the unit cell are divided into two magnetically different groups: the Mn–Mn axes, which lie almost parallel to the ac plane, are inclined at +20 and −20°, respectively, with respect to the c axis, and the O–O axes are inclined at +40 and −40°, respectively, with the a axis. Thus, the principal zero-field splitting constants of the molecule cannot be determined definitely from the principal values of the crystal, since D and E in Eq. 3 are difficult to express as functions of angle. The following tentative analysis has been carried out. The Mn–Mn axis can be defined as one of the local principal axes, showing small deviation from the c axis approximately parallel to the K_m axis. Thus, the magnetic fields of z(+) and z(−) can be assumed to be equal to a set of the resonance fields observed for H_0 along K_m. The g values of the quartet state are presumed to be equal to those of the doublet state. On the basis of the assumptions, $|D|$ and $|E|$ are evaluated as 0.39 and 0.21 cm^{-1}, respectively. By use of the values, the transitions for H_0 directed to other principal axes are expected to take place at the fields $H_{y(+)}$=14.2, $H_{y(-)}$=1.15, $H_{x(+)}$=2.38, and $H_{x(-)}$=5.09 kG. The $|D|$ and $|E|$ values are so large that no i(0) transitions are allowed. The positions of the transitions in a magnetic field applied along the ab plane vary with crystal orientation in regions of $H_{x(+)}$–$H_{y(+)}$ and $H_{x(-)}$–$H_{y(-)}$. When H_0 makes 40 or 50° with the a axis, the spectrum shows resonance peaks at 1.36 and 2.27 kG (Fig. 5). A clear hump is observed at the high field side of the main signal, showing the presence of a signal at about 4 kG. The three transitions can be explained by $H_{y(-)}$, $H_{x(+)}$, and $H_{x(-)}$ fairly well, indicating that the tentative $|D|$ and $|E|$ values do not differ much from the inherent values. One of the principal axes is normal to the Mn–O_2–Mn plane, and the third axis is parallel to the O–O axis. It is noteworthy that $|E/D|$ of the complex is very large compared with the ratio ($\lesssim 1/3$) normally observed for metal complexes.

Discussion

The zero-field splitting constant arising from the dipole-dipole interaction between manganese atoms is evaluated as $D_{dip} \approx -3g^2\mu_B{}^2 r^{-3} = -0.26$ cm^{-1}, with the Mn–Mn distance 2.716 Å. The anisotropy of the exchange interaction is of the order of the magnitude $|D_{ex}| \approx |J(2-g)^2|$. Because the g factor is very close to 2.00, $|D_{ex}|$ is estimated to be less than 0.01 cm^{-1}. The value is negligibly small compared with $|D_{dip}|$. An additional contribution comes from the crystal field effect. Usually, the zero-field splitting constants of d^4 ions are much larger than those of d^3 ions.[4] Hence, Mnl makes a dominant contribution. The

constants of d^4 complexes are given by[3]

$$D_{cf} = -3\left(\rho+\frac{\lambda^2}{\Delta}\right)\left[\frac{2\Delta}{8\lambda}(2-g_{z'})-1\right], \quad (10)$$

$$E_{cf} = -\frac{1}{4}\left(\rho+\frac{\lambda^2}{\Delta}\right)\left(\frac{\Delta}{\lambda}\right)(g_{x'}-g_{y'}), \quad (11)$$

where x', y', and z' are defined as the local axes of the crystal field, λ is the spin-orbit coupling constant, Δ is the energy separation between Γ_3 and Γ_5 levels, and ρ is the constant of the spin-spin interaction. The values of λ and ρ are estimated to be equal to 88 and 0.18 cm^{-1}, respectively.[3] Usual manganese(III) complexes have Δ equal to 20 000 cm^{-1}. When $|g_{z'}-2| \approx 0.01$ and $|g_{x'}-g_{y'}|<0.01$, $|D_{cf}|$ is approximated to be equal to 0.7 cm^{-1}, and $|E_{cf}|$ is less than 0.3 cm^{-1}. The $|D_{cf}|$ and $|E_{cf}|$ values of Mn^{3+} in TiO_2 amount to 3.4 and 1.2 cm^{-1}, respectively.[3] This is the only example reported for Mn^{3+}, indicating that the aforementioned values of the complex are not overestimated. This suggests that the contribution from the crystal-field effect may be comparable to that from the dipole-dipole interaction. The octahedron of MnI is elongated along N1 and N4 directions, which are practically normal to the Mn–O_2–Mn plane. Because the z' axis is defined as a direction perpendicular to the plane, it is normal to the principal z axis of D_{dip}. Hence, D arises from D_{dip} and E_{cf}, and E is due to D_{cf}. This explains the large $|E/D|$ value. Although the uncertainty of the crystal orientation amounts to $\pm 5°$, the K_m axis deviates from the axis of D_{dip} directed to the Mn–Mn axis. This is probably due to a slight discordance between the crystal-field axis and dipolar-interaction axis systems. The zero-field splitting constants can be interpreted in terms of the dipole-dipole interaction and the crystal-field effect. The anisotropy of the exchange interaction is so small that the Hamiltonian (Eq. 1) of ideally isotropic interaction is valid for the complex.

The hyperfine structure in the ESR spectrum of the doublet state suggests that the odd electrons are unequally distributed on the two manganese atoms in the dimer. This situation is different from that in cobalt(III,IV) complexes, $[(NH_3)_5CoO_2Co(NH_3)_5]X_5$, in which an odd electron is distributed over the Co–O–O–Co system and the two cobalt atoms are equivalent with each other.[5] In the manganese(III,IV) complex, the spin delocalization takes place through the p orbitals of bridging oxygen atoms, giving rise to the antiferromagnetic interaction between the t_2^3 and $t_2^3e^1$ systems. The t_2 electrons forming $d\pi$–$p\pi$ bonds can be delocalized through the π systems, while the e electron occupying mostly the d_{z^2} orbital makes little contribution to the formation of Mn–O π bonding for symmetric and steric reasons, so that the e electron is stably localized on one of the paired manganese atoms or on MnI having the more distorted coordination field. For this reason, the two manganese atoms in the dimer differ from each other despite the strong exchange interaction operating between them.

This work was carried out preliminarily by use of a Varian E-3 ESR spectrometer at the Department of Chemistry, University of Florida. The author is much indebted to Dr. W. S. Brey, Jr. and Dr. R. C. Stoufer for their suggestions and support. The JEOL ESR spectrometer was purchased with a Grant-in-Aid for Scientific Research from the Ministry of Education.

Liquid-phase Oxidation of Hydrocarbons with Molecular Oxygen. I. The Effects of Metal Ions and Their Ligands on Product Distribution in the Oxidation of Tetralin in Acetic Acid

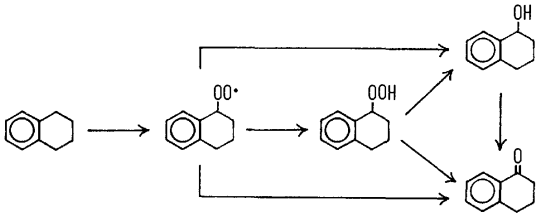
Fujio MIZUKAMI and Juichi IMAMURA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received June 30, 1977)

Metal-ion catalyzed oxidation of tetralin and metal-ion catalyzed decomposition of α-tetralin hydroperoxide (THP) were carried out in acetic acid in both the presence and absence of an additive. It was found that the rate-determining step in the oxidation of tetralin is the decomposition of THP. The results also suggest that the decomposition of THP with cobalt catalysts proceeds by the inner-sphere mechanism. In the oxidation of tetralin catalyzed by first-transition-metal ions, excepting vanadium, cobalt showed the highest activity and the lowest selectivity of hydroperoxide, and chromium showed the highest ratio of α-tetralone to α-tetralol (On/Ol). The order of the activities of metal acetates in producing oxidation is in agreement with that of the activities of metal acetates in producing decomposition. Such agreement was also found for $Co(acac)_3$, $Cr(acac)_3$, $Mn(acac)_2$, and $Fe(acac)_3$ catalysts. For oxidation with $Co(OAc)_2 \cdot 4H_2O$ and $Cr(OAc)_3$, the product distributions were examined for various conversions of tetralin. In the both cases, the On/Ol ratios increase with increasing tetralin conversion. However, the mechanisms responsible for the increase in the On/Ol ratio appear to be different.

Liquid-phase oxidation of tetralin has been widely studied in both the presence and absence of a catalyst. The main products are known to be α-tetralin hydroperoxide (THP), α-tetralone and α-tetralol. According to previous studies,[1–10] the formation mechanism is understood as follows:



However, previous reports dealt mainly with kinetics and thus with reactions at low conversion in order to avoid complications. There are few data in the literature on the distribution of the products at high conversion.[6]

It is well known that transition-metal ions catalyze the oxidation of hydrocarbons and their catalytic activities are frequently related to their redox potentials.[11,12] It is also clear that metal ions in solution form complexes with solvent molecules, counter anions, *etc.*, and that the redox potentials of these ions are affected by ligands in the complex. However, there are not many reports dealing with the influence of ligands on the distribution of the products for metal-ion catalyzed autoxidation of aromatic hydrocarbons.

The aim of the present study is to elucidate the effects of various metal ions and their ligands on the oxidation of tetralin, in addition to the dependence of the product distribution on the catalyst and the substrate concentration at various reaction temperatures.

Experimental

Materials. The tetralin and metal salts employed were of reagent grade and were used without further purification. THP was synthesized according to the procedure of Knight and Swern.[13] This hydroperoxide was 99.8% pure as confirmed by iodometric titration.

Oxidation of Tetralin. A mixture (150 cm^3) of tetralin and acetic acid containing a catalyst was placed into an autoclave (sus-316) equipped with a magnetic stirrer and a thermocouple, and was warmed to the desired temperature. Oxygen was introduced into the autoclave through a pressure controller (the oxygen pressure was 20 kg/cm^2). The reaction temperature was controlled to within ±1.0 °C of the desired temperature by occasional cooling with water.

The reaction was terminated by stopping the oxygen feed and by quickly cooling the vessel in an ice-cold bath.

Decomposition of THP. A four-necked flask (200 cm^3, round-bottomed) equipped with a thermometer, a reflux condenser, a dropping funnel and a nitrogen inlet was filled with nitrogen gas. Into the flask, were placed a teflon stirring bar and a 50-cm^3 solution of acetic acid containing a catalyst. A stream of nitrogen was gently bubbled through the solution. The solution was then stirred and warmed to the desired temperature. To the vigorously stirred solution, was added a 25-cm^3 solution of acetic acid containing 2.50 g of THP and then the nitrogen stream was stopped. At hourly intervals, 1.5-cm^3 portions of the reaction mixture were withdrawn in a nitrogen atmosphere and were analyzed.

Analysis. The hydroperoxide concentration was determined by the usual method.[14]

α-Tetralone, α-tetralol and tetralin in the reaction mixture were identified and their amounts were determined using gas chromatography with a Shimadzu GC-4CPT chromatograph (2 m × 3 mm column packed with 10% Carbowax 4000 on Chromosorb AW, programming 5 °C/min from 120 to 170°, He 40 cm^3/min). *o*-Bromoanisole was used as an internal standard. Before GLC analysis, the remaining peroxide was reduced with an excess of triphenylphosphine.[15] The "net α-tetralol" is the difference between the total amount of α-tetralol after reduction and the amount of hydroperoxide before reduction.

Results and Discussion

The dissolving rate for molecular oxygen in a solution is frequently the rate-determining step in the liqid-phase autoxidation of hydrocarbons at atmospheric pressure. In the present study, the oxidation rate of tetralin in acetic acid was actually faster at higher pressure than at atmospheric pressure, and was nearly constant at oxygen pressures greater than 4 kg/cm^2. All runs in

the present study were, therefore, carried out at an oxygen pressure of 20 kg/cm².

The Effects of the Cobalt and Tetralin Concentrations and the Reaction Temperature. The effect of the Co(OAc)₂·4H₂O concentration on the formation of products in the oxidation of tetralin in acetic acid at 72.5 °C is shown in Fig. 1. The dependence of the product distribution on the initial concentration of tetralin is shown in Fig. 2. Figure 3 shows the selectivities* of products at various reaction temperatures in the range from 50 to 110 °C. At reaction temperatures greater than 130 °C, hydroperoxide, α-tetralol and α-tetralone were obtained with lower selectivities than at reaction temperatures below 110 °C. At reaction temperatures

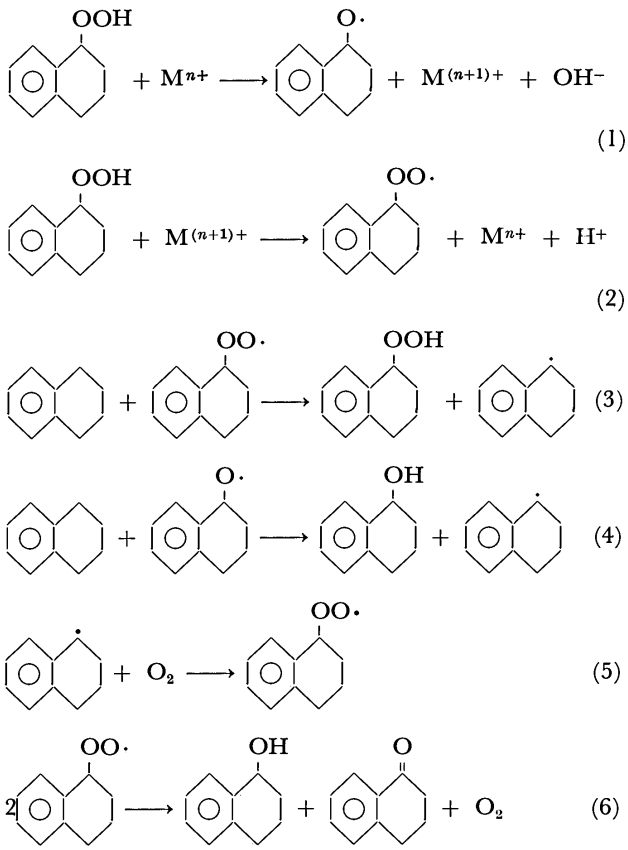
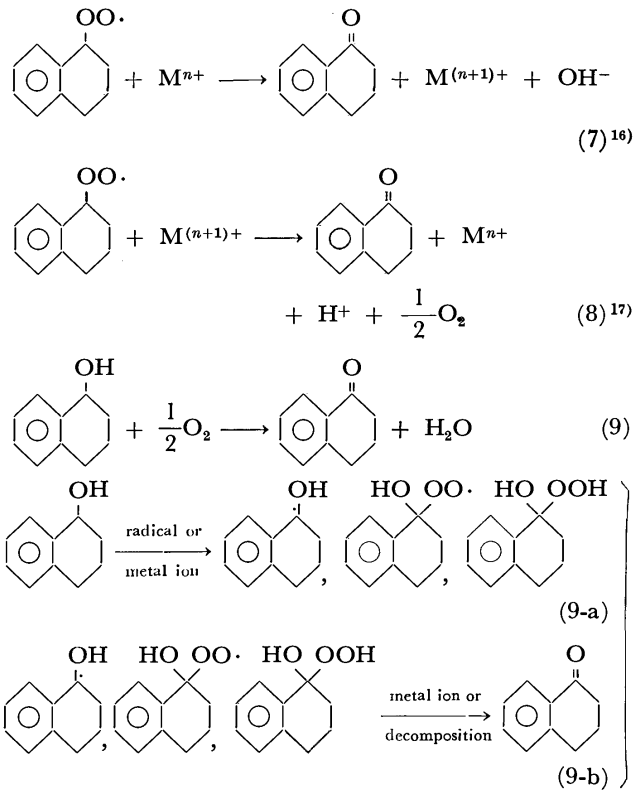
Reaction conditions: $[\text{Co(OAc)}_2\cdot 4\text{H}_2\text{O}]=4.77\times10^{-2}$ M; $[\text{tetralin}]_{\text{initial}}=3.85$ M; O_2 pressure, 20 kg/cm².
△: Tetralone, ⓘ: tetralol, ⊕: peroxide, ○: total.

above 120 °C, it was also difficult to carry out the oxidation of tetralin at an approximately constant temperature.

The selectivity of hydroperoxide formation decreases rapidly with increasing $\text{Co(OAc)}_2\cdot 4\text{H}_2\text{O}$ concentration (Fig. 1) and upon decreasing the initial tetralin concentration (Fig. 2). This result can be explained by the following reaction scheme which has been proposed





by other workers.[1-10,16,17] Transition-metal ions generally promote the decomposition of hydroperoxide following Reactions 1 and 2. Accordingly, the selectivity of hydroperoxide decreases with increasing $Co(OAc)_2 \cdot 4H_2O$ concentration.

Figures 4 and 5 show the product formation for various tetralin conversions. The product distributions shown in Fig. 4 are similar in tendency to those shown in Fig. 5, although the catalyst concentration depicted in Fig. 4 is different from that in Fig. 5. The α-tetralone selectivity increases with increasing tetralin conversion. For tetralin conversions above 20%, the percentage of the decrease in α-tetralol selectivity is

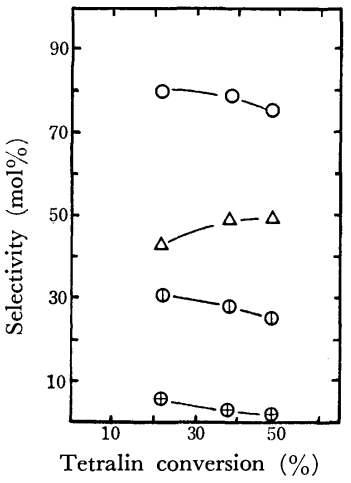

Fig. 5. The cobalt acetate catalyzed oxidation of tetralin in acetic acid at 72.0±2.0 °C.
Reaction conditions: $[Co(OAc)_2 \cdot 4H_2O] = 1.46 \times 10^{-2}$ M; $[tetralin]_{initial} = 3.50$ M; O_2 pressure, 20 kg/cm².
△: Tetralone, ⊖: tetralol, ⊕: peroxide, ○: total.

nearly equal to that of the increase in α-tetralone selectivity (Fig. 4). Martan *et al.*[6] have stated that, in the $Co(OAc)_2$-catalyzed co-oxidation of tetralin and α-tetralol in acetic acid at 80 °C, α-tetralol is oxidized at a rate 1.5 times faster than tetralin and gives α-tetralone in a 75% yield. Accordingly, the increase in α-tetralone selectivity for tetralin conversions above 20% appears to be mainly due to Reaction 9.

From Figs. 1—5, when cobalt(II) acetate is used as a catalyst and acetic acid as a solvent, the optimum conditions for obtaining α-tetralone are concluded to be as follows: a reaction temperature below 80 °C, an initial concentration of tetralin from 2.5 to 5 M, a catalyst concentration above 4.5×10^{-2} M and a tetralin conversion above 50%.

The Effect of Ligands. The effects of various counter anions and additives on the oxidation of tetralin catalyzed by cobalt ions are shown in Tables 1—4 and Fig. 6. It is clear that the additives used coordinate to the cobalt ion in a solution of acetic acid because the color of the solution containing cobalt acetate changes upon introduction of the additive.

As shown in Tables 1 and 3 and in Fig. 6, it is clear that cobalt(II) dibromide has a low catalytic activity although the rate of cobalt-catalyzed oxidation of tetralin is accelerated by adding potassium bromide to cobalt(II) acetate solutions (Co : KBr=1 : 1, molar ratio). This has already been observed and demonstrated kinetically.[7,10]

The tris(acetylacetonate)cobalt(III) complex ($Co(acac)_3$) showed a higher selectivity for hydroperoxide formation and a slower rate of oxidation than catalysts such as cobalt(II) carboxylates, cobalt(II) nitrate and bis(acetylacetonato)cobalt(II) complexes ($Co(acac)_2$ and $Co(acac)_2 \cdot 2H_2O$) (Tables 1 and 2, and Fig. 6). The addition of KF, pyridine (py) and 2,2'-bipyridine (bipy) to the $Co(OAc)_2 \cdot 4H_2O$ solution (Co-F, Co-py and Co-bipy) decreased the tetralin oxidation rate and increased the hydroperoxide selectivity (Tables 3 and 4, and Fig. 6). Thus, when hydroperoxide was ob-

tained in high selectivities, the oxidation rate of tetralin was low.

The decomposition of THP with five kinds of cobalt catalysts was also carried out in acetic acid at 51 °C in a nitrogen atmosphere. This was carried out at lower catalyst concentrations than those for the oxidation of tetralin, because the decomposition was too fast at high catalyst ([$Co(OAc)_2\cdot 4H_2O$]>6.0×10^{-3} M) concentrations. The decomposition rates were first order with respect to the hydroperoxide concentration. The decomposition order is $Co(acac)_2\simeq Co(OAc)_2\cdot 4H_2O$>Co-py>Co-F≫$Co(acac)_3$, as shown in Table 5 and Fig. 7. This order is consistent with that of the oxidation rates of tetralin at 50°, that is, $Co(acac)_2\simeq Co(OAc)_2\cdot 4H_2O$>Co-py>Co-F≫$Co(acac)_3$ (Tables 2 and 3, and Fig. 6) and also corresponds to the order of increasing hydroperoxide selectivities for oxidation ($Co(OAc)_2\cdot 4H_2O\simeq Co(acac)_2$ < Co-py < Co-F ≪ $Co(acac)_3$) (Tables 2 and 3, and Fig. 6). Yamada and Kamiya[18] have reported that the rate of $Co(OAc)_2$-catalyzed decomposition of THP in acetic acid at 50 °C lowers as the molar ratio of the bipy added to the cobalt(II) acetate is increased from zero to two. For the $Co(OAc)_2\cdot 4H_2O$-catalyzed oxidation of tetralin in acetic acid at

Table 5. Rate constants for the decomposition of THP in acetic acid

Catalyst: Metal salt or metal complex	Catalyst: Concentration (M)	Reaction temperature (°C)	Rate constant ($\times 10^{-3}$ min^{-1})

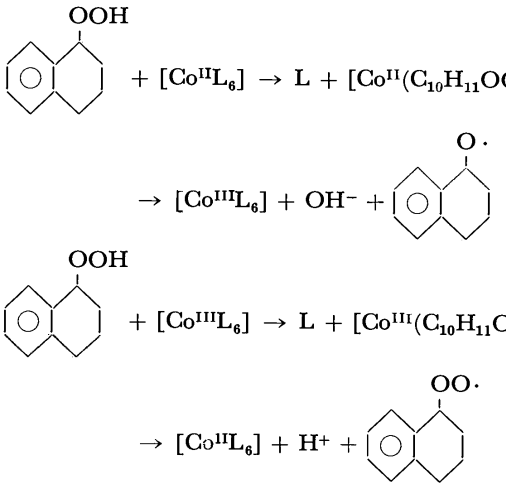
a) $Co^{II}(OAc)_2\cdot 4H_2O$: pyridine=1 : 1 (molar ratio). b) $Co^{II}(OAc)_2\cdot 4H_2O$: KF=1 : 1 (molar ratio). [THP]$_{initial}$=2.00×10^{-1} M.

72.5 °C, the hydroperoxide selectivity increases as the ratio of the bipy to the cobalt(II) acetate is increased from zero to two (Table 4). Accordingly, the tetralin oxidation rate and the selectivity for the formation of hydroperoxide, for such cobalt catalysts, depend on the hydroperoxide decomposition rate.

From the above results, the decomposition mechanism of hydroperoxide can also be considered to be as follows. The catalytic decomposition of hydroperoxide by metal ions is thought to proceed *via* the formation of inner-sphere and/or outer-sphere complexes of metal ions with hydroperoxide[19] (inner-sphere[20-23] and/or outer-sphere mechanisms[20-23]). For the inner-sphere mechanism, the ligand attached to the metal ion must be replaced by the hydroperoxide, *i.e.*, $[ML_5Y]+ROOH \rightarrow [ML_5(ROOH)]+Y$. Such replacement is not required for the formation of the outer-sphere complex. Accordingly, decomposition by the outer-sphere mechanism will depend mainly on the redox potential of the complex. On the other hand, decomposition by the inner-sphere mechanism appears to depend on the mobility of the ligands attached to the metal ion, as well as on the redox potential of the metal ion.

The following facts are well known in coordination chemistry. Ligands such as py and F^- form strong coordination bonds with cobalt ions in comparison with ligands such as NO_3^-, Br^-, Cl^-, H_2O, and RCO_2^-.[20-24] For hydrolysis of the type, $[ML_5Y]+H_2O \rightarrow [ML_5(H_2O)]+Y$ ($M=Co^{III}$ or Cr^{III}, $L=NH_3$ or H_2O), the order of reactivities as far as the leaving group (Y) is concerned is $NO_3^- > Br^- > H_2O > AcO^- > F^- > NH_3$.[20,23,25] This is in good agreement with the order of stability constants of $[ML_5Y]$.[20,23] The cobalt complex having the $(t_{2g})^5(e_g)^2$ electron configuration ($Co^{II}(acac)_2L_2$, $L=H_2O$ or AcOH) has a faster rate for the ligand-replacement reaction than the corresponding cobalt complex having the $(t_{2g})^6(e_g)^0$ electron configuration ($Co^{III}(acac)_2L_2$, $L=H_2O$ or AcOH, L_2= acac).[20,23,25] In solution, $Co^{II}(acac)_2$ forms $Co^{II}(acac)_2L_2$ with solvent molecules such as AcOH and H_2O, although $Co^{II}(acac)_2$ has a tetrameric structure in the solid state.[22] 2,2'-Bipyridine coordinated to transition-metal ions generally can be replaced by other ligands only with difficulty.[20-24] Therefore, the fact that catalysts such as $Co(acac)_3$, Co-F, Co-py, and Co-bipy have high hydroperoxide selectivities for the oxidation of tetralin and low rates for the decomposition of THP is mainly correlated with the stability of the ligands attached to the cobalt ion if Reaction 1 and/or Reaction 2 proceed by the inner-sphere mechanism as follows:



L : RCO_2^-, Br^-, Cl^-, F^-, OH^-, AcOH, H_2O, py,
L_2 : $acac^-$, bipy.

However, the possibility cannot be completely excluded that the high hydroperoxide selectivity and the low tetralin oxidation rate in the case of Co-py and Co-bipy are attributable to retarding effects of py and bipy on the autoxidation of hydrocarbons.[26,27]

When the bis(acetylacetonato)cobalt(II) complex is used as a catalyst, the oxygen absorption curve for the oxidation of tetralin has an irregular bending point (Fig. 6) and the decomposition of THP has two rate constants (Fig. 7 and Table 5). On the other hand, $Co(acac)_3$ shows neither such a bending point in the oxidation curve nor two decomposition rate constants. These results are interpreted as follows. Acetylacetonate in $Co(acac)_2L_2$ appears to be easily oxidized compared with that in $Co(acac)_3$ because $Co(acac)_2L_2$ is relatively labile. On the contrary, acetylacetonate in $Co(acac)_3$ is relatively difficult to oxidize because of the stability of $Co(acac)_3$. The redox potential and the rate of ligand replacement are also different from those for $Co(acac)_2L_2$ and the complex containing the new ligands which result from the oxidation of acetylacetonate. Therefore, the bis(acetylacetonato)-cobalt(II) complex is thought to show an irregular bending point in the oxidation and two decomposition rate constants.

The Effect of Metal Ions. The effects of various

Table 6. Product distribution for the metal acetate catalyzed oxidation of tetralin

Catalyst	Tetralin conversion (%)	Selectivity (mol%)				Molar ratio tetralone/tetralol	Reaction time (min)
		Tetralone	Tetralol	Peroxide	Total

metal acetates and acetylacetonato complexes on the oxidation of tetralin in acetic acid at 72.5 °C are shown in Figs. 8—10 and Tables 6 and 7. The decomposition of THP with various metal acetates and acetylacetonato complexes was also carried out in acetic acid at 72.0 °C in a nitrogen atmosphere (Fig. 7 and Table 5).

In the oxidation of tetralin catalyzed by five kinds of metal acetates, the hydroperoxide selectivities increase in the order Co≪Mn≃Cr<Cu<Ni and the activity order of these catalysts is Co≫Mn≃Cr≃Ni>Cu (Table 6 and Fig. 8). This is in agreement with the order of activities for the decomposition of THP by these catalysts (Fig. 7 and Table 5). Therefore, the orders of the hydroperoxide selectivities and the oxidations rate are thought to arise from the differences in the decomposition rates of hydroperoxide produced in the oxidation of tetralin. The differences between the decomposition rates also appear to be mainly attributable to differences between the redox potentials of the five metal acetates in acetic acid because the activity order of these five metal acetates for the decomposition of THP is not consistent with the reactivity sequence predicted on the basis of crystal field theory[20,23] for the ligand-replacement reactions of the five

metal acetato complexes. The fact that $Cu(OAc)_2\cdot H_2O$ exhibits a lower hydroperoxide selectivity than $Ni(OAc)_2\cdot4H_2O$ appears to involve the prolonged oxidation time of $Cu(OAc)_2\cdot H_2O$. The extent of thermal decomposition appears to become gradually greater with increasing reaction time. As a second reason, it is thought that the concentration of monomeric $Cu(OAc)_2\cdot H_2O$ increases during the prolonged reaction time. It has been reported that $Cu(OAc)_2\cdot H_2O$ is dimeric in many nonaqueous solvents[28,29] and partially dissociates into its monomeric form in acetic acid.[30] Imamura *et al.*[31] have also found that in the $Cu(OAc)_2\cdot H_2O$-catalyzed decomposition of THP in acetic acid at 80 °C, the addition of LiCl to the solution increases the concentration of monomeric copper(II) acetate and accelerates the decomposition of THP.

Agreement between the oxidation of tetralin and the decomposition of THP is also found for four acetylacetonato complexes, excepting $TiO(acac)_2$, as well as, for the five kinds of metal acetate catalysts. Specifically, the catalyst which exhibits a high hydroperoxide selectivity and a slow oxidation rate has a relatively low decomposition rate, *i.e.*, the orders of activities for oxidation, as well as for decomposition, are Co≫Cr≃Mn>Fe (Tables 5 and 7, and Fig. 7). This order appears to arise mainly from the differences in the redox potentials of the four acetylacetonato complexes in acetic acid because this order is inconsistent with the reactivity sequence expected on the basis of the stability constants[23,32,33] of acetylacetonato complexes for the ligand-replacement reaction. $TiO(acac)_2$, which has a d^0 system, is abnormal with respect to the acetylacetonato complexes used in the present work. This result cannot be interpreted explicitly at present.

As shown in Tables 6 and 7, the ratio of α-tetralone to α-tetralol (On/Ol) obtained for oxidation with a chromium catalyst is relatively high. The product distributions for oxidation with $Cr(OAc)_3$ were examined at various tetralin conversion. The selectivity of α-tetralone rises and that of hydroperoxide decreases as the conversion of tetralin increases for oxidation (Figs. 9 and 10). The degree of the increase in the α-tetralone selectivity is nearly equal to that of the decrease in the hydroperoxide selectivity. For $Cr(OAc)_3$-catalyzed decomposition of THP in acetic acid at 72.0 °C in a nitrogen atmosphere, α-tetralone and α-acetoxytetralin were obtained in about 70 and 10% selectivities, respectively, at 10—25% THP conversions.

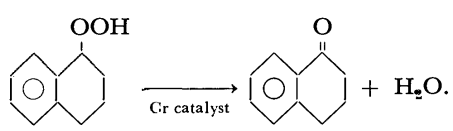
α-Tetralol was produced only in small amounts. Therefore, it is thought that for $Cr(OAc)_3$-catalyzed oxidation, the main pathway which contributes to the increase of α-tetralone is not Reaction 9 but the THP dehydration reaction:



This dehydration reaction can be resolved into Reactions 2 (Cr^{3+} consumption) and 7 (Cr^{3+} regeneration) as far as the variable valence of the chromium ion is concerned. If hydroperoxide is dehydrated by a process in which the chromium valence remains unchanged, the formation of α-tetralone will be related to the hydration energy of the chromium ion. However, this is not the usual process for the decomposition of hydroperoxide catalyzed by a transition-metal ion. In addition, the increasing order of the On/Ol ratios for the metal-catalyzed oxidation of tetralin (Tables 6 and 7) is inconsistent with the order of hydration heats[20,23] of the first-transition-metal ions.

For the purposes of obtaining α-tetralone in higher yields, binary metal ions (Cr and Co) were used as a catalyst for the oxidation of tetralin (Fig. 10). However, the binary catalyst showed only a slight increase in the α-tetralone selectivity compared with the $Co(OAc)_2\cdot4H_2O$ catalyst (Figs. 4 and 10).

A Synthetic Route to 3,3-Diphenyl-2-indolinone Derivatives

Manabu SENŌ, Shinsaku SHIRAISHI, Yukio SUZUKI, and Teruzō ASAHARA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received July 4, 1977)

N-Aryl-α-chloro-α,α-diphenylacetimidoyl chlorides were prepared from Schiff bases and dichlorocarbene generated by use of the phase transfer catalyst. Treatment in sulfuric acid gave 3,3-diphenyl-2-indolinone derivatives. The synthetic route to 2-indolinone was found to give a higher overall yield than that by other methods. 2,2-Dichloro-1,3-diphenylaziridine gives α-chloro, α-acetoxy or α-hydroxy-α,α-diphenylacetanilide on treatment with sulfuric acid. Comparison of 2,2-dichloro-1,3-diphenylaziridine, 2,2-dichloro-1,3,3-triphenylaziridine and *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chloride in their reactivities with sulfuric acid shows that the pathway of the reaction is governed by the character and number of substituents at the reaction center where carbonium ions are developed.

3,3-Diaryl-2-indolinone derivatives have pharmaceutical properties such as mothproofing,[1] laxative,[2] antibacterial and antiprotozoal[3] activities. Isacene (3,3-bis(*p*-acetoxy-phenyl)-2-indolinone) is used as a purgative. Copolymer of 3,3-bis(*p*-aminophenyl)-2-indolinone and benzophenone-tetracarboxylic dianhydride is useful as adhesive laminating resin for instrument boards, fiber and coating.[4] 3,3-Diaryl-2-indolinone derivatives were synthesized in various ways: from 2,3-indolinedione by the Grignard reaction,[5,6] from 2,3-indolinedione and diphenylurea with aluminium chloride,[8] form 3,3-dihalo-2-indolinone[5,7] or trichloroacetanilide[5] by the Friedel-Crafts reaction with benzene, by the reaction of *N'*-phenyldiphenylacetohydrazide with sodium,[9] α-acetoxy-α,α-diphenylacetyl chloride with aniline,[5] α-chloro-α,α-diphenylacetanilide with sodium hydride[10] or boron trifluoride etherate,[3] and by the treatment of α-hydroxy-α,α-diphenylacetanilide with sulfuric acid.[5,11-14] In a previous paper, we reported a synthetic route to various lactams from *gem*-dichloroaziridines or α-chloro-α,α-diphenylacetimidoyl chloride.[15] *gem*-Dichloroaziridines were prepared by the reaction of Schiff bases with dichlorocarbene. Makosza showed that the phase-transfer catalyst provides an excellent method for generation of dichlorocarbene.[16] Applying this method to the synthesis of 1-aryl-2,2-dichloro-3,3-diphenylaziridines, we obtained not 1-aryl-2,2-dichloro-3,3-diphenylaziridines but their isomerization products, *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chlorides, in good yields. From these various 2-indolinone derivatives were obtained in good yields.

Results and Discussion

N-Benzhydrylideneanilines were prepared from benzhydrylidene dichloride and the corresponding aromatic amines in 40—60% yields(Table 1). The method[17] seems to give higher yields under moderate reaction conditions as compared with the other methods.[18,19] The *N*-benzhydrylideneanilines(**1a**—**e**) were allowed to react with dichlorocarbene generated by the method using phase-transfer catalyst. A chloroform solution of **1a**—**e** and an aqueous solution of 33.3 wt% NaOH

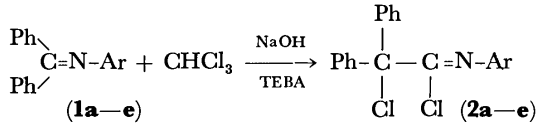
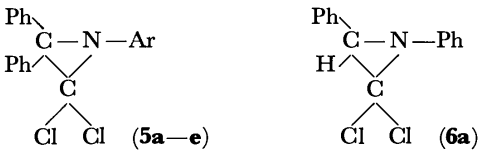
and triethylbenzylammonium chloride(TEBA) were mixed and strirred at room temperature for 2 h to give the corresponding *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chloride(**2a**—**e**) in quantitative yield. IR spectra of these compounds showed the characteristic strong absorption in the region 1650—1690cm^{-1}. The results are shown in Table 2.



(**1a**—**e**) (**2a**—**e**)

In this formula, Ar stands for phenyl(**a**), *o*-tolyl(**b**), *p*-tolyl(**c**), *p*-chlorophenyl(**d**) and α-naphtyl(**e**).

The reaction would proceed *via* the formation of 1-aryl-2,2-dichloro-3,3-diphenylaziridines(**5a**—**e**) followed by its isomerization.



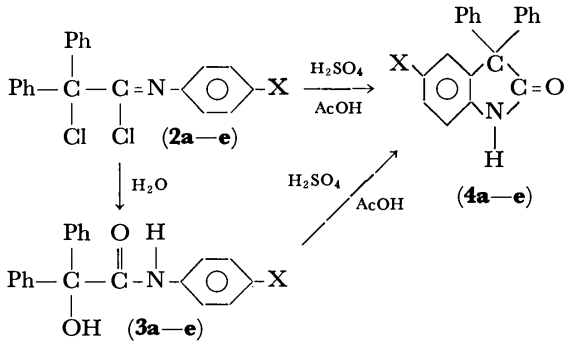
(**5a**—**e**) (**6a**)

Under the present reaction conditions, however, the aziridines(**5a**—**e**) were not isolated. Dichlorocarbenes generated in the phase-transfer catalytic system are known to be rich in reactivity.[23] The reactions take place at 5 °C or higher, since the reaction mixture becomes semi-solid at lower temperatures. Thus, the aziridines are not stabilized and isomerize into the corresponding *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chloride.

On the other hand, the reaction of *N*-benzylideneaniline with chloroform in the presence of phase-transfer catalyst affords 2,2-dichloro-1,3-diphenylaziridine (**6a**) in a good yield, which dose not isomerize in this reaction system.[24] The difference in reactivity of aziridines 5 and 6 was revealed by DSC analyses. The DSC measurement of 2,2-dichloro-1-(*p*-chlorophenyl)-3,3-diphenylaziridine(**5d**), prepared by the reaction of **1d** with dichlorocarbene generated from *t*-BuOK–$CHCl_3$ in hexane at −5 °C, shows an exothermic peak at 362 K. It was confirmed from IR spectra before and after this peak that this transition is due to isomerization. Isomerization is accompanied by melting of the isomerized product **2d**, as revealed by observation under a microscope. The heat of transition combined with the heat of melting was determined to be −38.1 kJ mol^{-1}.

On the other hand, a separate run of **2d** showed an exothermic peak due to melting at 380 K, the heat of melting being 30.5 kJ mol^{-1}. Because of the melting point depression of the mixture, melting would be observed at the temperature of isomerization. By subtracting the heat of melting the heat of isomerization of **5d** into **2d** was determined to be −68.6 kJ mol^{-1}. On the other hand, aziridine **6a** was stable up to 404 K, where it was decomposed into several fragments. The difference in thermal behavior between **5d** and **6a** should be ascribed to the existence of two phenyl substituents at 3-position of **5d**. The substituents greatly affect the reactivity of aziridines.

N-aryl-α-chloro-α,α-diphenylacetimidoyl chlorides (**2a**—**e**) derived from **1a**—**e** were treated with sulfuric acid in acetic acid at room temperature for 2 h to give 3,3-diphenyl-2-indolinone derivatives(**4a**—**e**) in good yields. The formation of 3,3-diphenyl-2-indolinones proceeded also *via* *N*-aryl-α-hydroxy-α,α-diphenylacetamide(**3a**—**e**) obtained from hydrolysis of the corresponding *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chlorides. The results are given in Tables 3 and 4.



In the above formula, X denotes H(**a**), *o*-CH_3(**b**), *p*-CH_3(**c**), *p*-Cl(**d**) and 5,6-benzo(**e**).

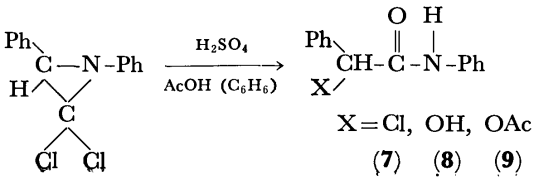
IR spectra of these 2-indolinones show strong bands at 3160—3250cm^{-1} and 1670—1720cm^{-1}, assigned to cis bonded NH stretching and amide I, respectively. Compounds **4c** and **4d** show two bands ascribed to amide I, which seem to be due to free amide and dimer, since dilute solutions of **4c** and **4d** in chloroform show only a single band at 1721cm^{-1} and 1726cm^{-1}, respectively.

The reaction of **6a** with sulfuric acid gave α-chloro-α-phenylacetanilide(**7**) in 60% yield[15] Reexamination of this reaction confirmed that no intramolecular condensation of **6a** into 3-phenyl-2-indolinone occurs in H_2SO_4–AcOH mixture. The crude reaction product was carefully examined by silicagel column chromatography and α-hydroxy-α-phenylacetanilide(8) and α-acetoxy-α-phenylacetanilide(**9**) were isolated together with **7**. When **7** separated from the other products was treated with H_2SO_4–AcOH under similar conditions to those above, it remained unchanged. A similar treatment of **8** or **9** showed that they could be converted into each other.



The results show that ring-opening of **6a** proceeds *via* an ion pair which can exchange its counter ions to some extent. However, **7** dose not undergo nucleophilic substitution. This would reflect lack in its ability of carbonium ion formation in H_2SO_4–AcOH.

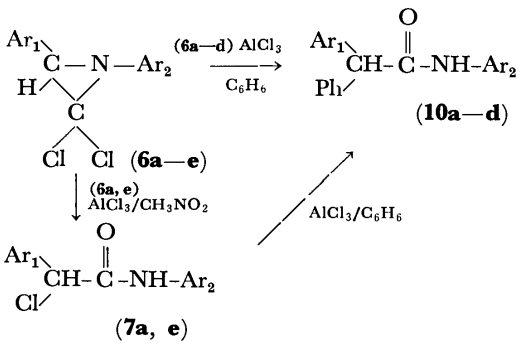
To compare the catalytic ability of sulfuric acid with that of Lewis acid, some *gem*-dichloroaziridines were treated with aluminium chloride in benzene.* The reaction gave tarry products, from which Friedel-Crafts reaction products were isolated. From spectroscopic and elemental analyses these compounds were identified to be α,α-diphenylacetanilide derivatives(**10a—c**). The results are given in Table 5.

When **6a** was treated with sulfuric acid in the presence of benzene, the resulting products were **7**, **8** and **9**, **10a** not being obtained.

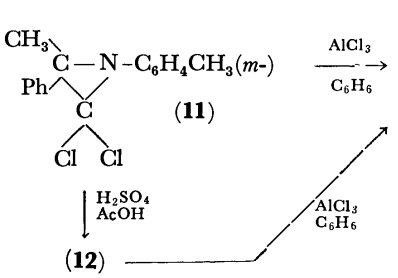
Treatment of **7a** with aluminium chloride in benzene afforded **10a**. This suggests that, if the reactions were carried out without addition of benzene, 3-phenyl-2-indolinone would be formed by intramolecular condensation. The reaction of *gem*-dichloroaziridines(**6a**,**6e**) with aluminium chloride was conducted in nitromethane, which dissolves aluminium chloride to form complexes. Compound **6d** stands for 2,2-dich-

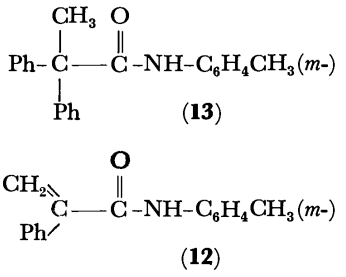
* *gem*-Dichloroaziridines used were **6a**, 2,2-dichloro-1-(*p*-chlorophenyl)-3-phenylaziridine(**6b**), and 2,2-dichloro-3-(*p*-chlorophenyl)-1-phenylaziridine(**6c**).

loro-3-phenyl-1-(*m*-tolyl)aziridine. The reaction was carried out at various ratios of aluminium chloride to substrate, but the isolated products were acetanilide derivatives(**7a**,**7e**) in 30-60% yields.



Treatment of 3-methyl-3-phenyl-1-(*m*-tolyl)-2,2-dichloro-aziridine(**11**) with H_2SO_4–AcOH gave *N*-(*m*-tolyl)-2-phenylpropene-amide(12). On the other hand, treatment of compound(**11**) with aluminium chloride in benzene gave *N*-(*m*-tolyl)-α-methyl-α,α-diphenylacetamide(**13**) and **12** in 41% and 6.3% yields, respectively. Treatment of **12** with aluminium chloride in benzene also gave **13**, probably owing to the presence of a small amount of water;2-indolinone derivative could not be obtained from 1-aryl-2,2-dichloro-3-methyl-3-phenylaziridine.





From a comparison of reactivities of these compounds, we see that intramolecular condensation into 2-indolinone occurs effectively only when stable carbonium ions are formed and the reaction pathway of dichloroaziridines is strongly governed by the character and number of substituents at the reaction center where carbonium ion is generated.

Experimental

*Preparation of Schiff Bases(**1a—e**).* A mixture of 0.3 mol of aromatic amine and 0.1 mol benzhydrylidene dichloride in 200 ml of benzene was heated to reflux with stirring for 2 h. The mixture was cooled and shaken with water to remove the amine hydrochloride. The organic layer was dried over anhydrous sodium sulfate and evaporated. Recrystalization of the residue from ethanol gave the corresponding Schiff base. The results are summarized in Table 1.

*Syntheses of N-Aryl-α-chloro-α,α-diphenylacetimidoyl Chlorides (**2a—e**) by Using Phase Transfer Catalyst.* A solution of 0.03 mol of *N*-benzhydrylideneaniline and 1 mmol of triethylbenzylammonium chloride in 50 ml of chloroform, and 75 g of an aqueous solution of 33.3 wt % sodium hydroxide were mixed and stirred at 5 °C for 30 min and then at room temperature for 2 h. The chloroform layer was separated and washed with dil. hydrochloric acid and then water. It was dried over sodium sulfate and evaporated. Recrystalization of the residue from hexane gave the corresponding *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chloride. The results are summarized in Table 2.

*Syntheses of 2-Indolinones(**4a—e**).* 20 ml of concd H_2SO_4 was slowly added dropwise to a solution of *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chloride(6 mmol) in 20 ml of glacial acetic acid. The mixture was then poured into 80 ml of water to form precipitates, which were collected by filtration. The crystals were dissolved in chloroform and washed with 0.5 M sodium hydrogencarbonate solution and then water. The chloroform solution was dried over anhydrous sodium sulfate. Evaporation of the solvent and recrystalization of the residue from an appropriate solvent gave a pure product. The results are summarized in Table 4.

*Hydrolysis of N-Aryl-α-chloro-α,α-diphenylacetimidoyl Chloride (**2a—e**).* A solution of 0.01 mol of *N*-aryl-α-chloro-α,α-diphenylacetimidoyl chloride in 50 ml of 33.3% aqueous dioxane was heated to reflux for 2 h. Evaporation of the solvent and recrystalization of the residue from ethanol gave *N*-aryl-α-hydroxy-α,α-diphenylacetamide(**3a—e**) quantitatively. The results are summarized in Table 3.

*Reaction of 2,2-Dichloro-1,3-diphenylaziridine(**6a**) in the Presence of Sulfuric Acid.* 50 ml of concd H_2SO_4 was slowly added dropwise to a solution of 15 mmol of 2,2-dichloro-1,3-diphenylaziridine in 50 ml of acetic acid. The mixture was heated at 60 °C for 30 min and then poured into 400 ml of water to form precipitates which were collected by filtration. The precipitates were dissolved in chloroform and the solution was washed with 0.5 M sodium hydrogencarbonate solution and then water. The combined aqueous layer was saturated with sodium chloride and shaken with chloroform. The combined chloroform solution was dried over anhydrous sodium sulfate and evaporated in vacuo. The residue was subjected to silicagel column chromatography: 9.6 mmol(64%) of α-chloro-α-phenylacetanilide(**7**) was eluted with chloroform and then 1.9 mmol(13%) of α-acetoxy-α-phenylacetanilide(**9**) and 1.5 mmol (10%) of α-hydroxy-α-phenylacetanilide(**8**) were separated with chloroform-ethyl acetate eluent in the order described. α-Chloro-α-phenylacetanilide(**7**); mp 149—150 °C (lit, 147—148 °C).[28] α-Hydroxy-α-phenylacetanilide(**8**); mp 150—151 °C (lit, 151—152 °C).[29] α-Acetoxy-α-phenylacetanilide(**9**); mp 118—119 °C(lit, 117.5 °C);[30] IR(KBr) 1738 cm^{-1}(CH_3COO, CO stretching), 1675 cm^{-1} (CONH, CO stretching); NMR($CDCl_3$), δ(ppm), 6.8—7.7 (m, aromatic, 10), 6.17(s, methyn, 1), 2.17(s, methyl, 3).

Reaction of gem*-Dichloroaziridines(**6a—c**) with Aluminium Chloride in Benzene.* A solution of 0.02 mol of *gem*-dichloroaziridine in 30 ml of benzene was slowly added dropwise to a solution of aluminium chloride(0.02 mol) in 10 ml of benzene. The mixture was stirred for 2 h and then poured into a hydrochloric acid solution. The organic layer separated

was washed with 0.5 M sodium hydrogencarbonate and then with water. It was dried over anhydrous sodium sulfate. After evaporation of benzene *in vacuo*, the residue was subjected to silicagel column chromatography using benzene as an eluent. The results are summarized in Table 5.

Reaction of gem-*Dichloroaziridines(**6a,d**) with Aluminium Chloride.* 0.02 mol of *gem*-dichloroaziridine in 30 ml of nitromethane was slowly added dropwise to a solution of aluminium chloride(0.02 mol) in 30 ml of nitromethane. The mixture was stirred for 2 h at room temperature. The resulting solution was treated as described in the preceding section. α-Chloro-α-phenylacetanilide(**7a**); mp 149—150 °C(lit, 147—148 °C).[28] α-Chloro-*N*-(*m*-tolyl)-α-phenylacetanilide(**7d**); mp 123.6—124.3 °C; IR(KBr) 3280 cm^{-1} (NH), 1670 cm^{-1} (CO); NMR($CDCl_3$) δ(ppm) 8.4(broad, 1, NH), 7.3(m, aromatic, 9), 5.44(s, methyn, 1), 2.29(s, methyl, 3); Found: C, 69.29; H, 5.49; N, 5.56%. Calcd for $C_{15}H_{14}NOCl$: C, 69.37; H, 5.43; N, 5.39%.

DSC Analyses. DSC analyses were performed on a Perkin-Elmer DSC-2 under the following conditions: heating rate 1.25 K/min, range 5 mcal/s, chart speed 10 mm/min. The DSC measurement of **5d** shows an exothermic peak of isomerization at 362 K, the heat of which was evaluated by comparison with a heat of fusion of indium. The heat of fusion of α-chloro-α,α-diphenylacetimidoyl chloride was determined in a similar way. DSC analysis of 2,2-dichloro-1,3-diphenylaziridine shows that it decomposes at 404 K.

Application of Electrochemical Recycle of Ti^{4+}-Ti^{3+} to Additive Dimerization of Butadiene with Hydroxylamine

Toshiro CHIBA and Yoshiyuki TAKATA*

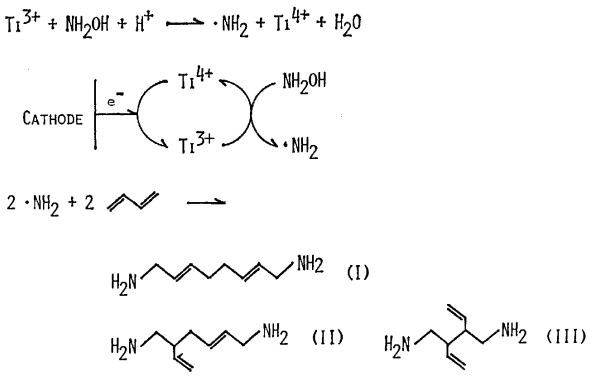
Department of Applied Chemistry, Kitami Institute of Technology, Koen-chyo 165, Kitami 090

**Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received July 9, 1977)

The electrolytic recycle of Ti^{4+}-Ti^{3+} has been employed for a redox-system consisting of hydroxylamine and Ti^{3+} which can produce amino radicals. From electroanalytical measurements, it was found that titanium(IV) chloride in hydrochloric methanol was reducible to Ti^{3+} with a sufficient current efficiency at the platinum electrode and the reduction was speeded up by an addition of hydroxylamine. On macro-scale electrolysis using a small amount of titanium(IV) chloride in the presence of 1,3-butadiene and hydroxylamine, the generated amino radical undergoes additive dimerization with butadiene and gives diaminooctadienes in reasonable yields.

The action of titanium(III) chloride on hydroxylamine in acid solution brings about the formation of an amino radical.[1] Previously, Coffman and his co-workers[2] showed that the amino radical generated in this way gave rise to additive dimerization with olefins to form the corresponding diamines. In these processes, one mole of titanium(III) chloride is consumed per mole of hydroxylamine, because Ti^{4+} produced in the redox-system cannot be rereduced by hydroxylamine. On the other hand, the electrocatalytic mechanism for the regeneration of Ti^{3+} from Ti^{4+} in the presence of hydroxylamine has been studied by different electroanalytical techniques,[3] but in most cases, oxalic acid was used as radical scavenger. Here we have examined the applicability of the Ti^{4+}-Ti^{3+} recycle by means of electrochemical reduction to Coffman's method, as depicted in Scheme 1.



Scheme 1.

Ti^{3+} produced by the cathodic reduction of titanium(IV) chloride reduces hydroxylamine to amino radical along with the oxidation of itself to Ti^{4+}. The generated amino radical attacks 1,3-butadiene followed by additive dimerization to give diaminooctadienes, whereas the resulting Ti^{4+} undergoes rereduction at the cathode. According to the above recycle, this reaction is expected to occur sufficiently even when a small amount of titanium(IV) chloride is used.

Analogous processes, indirect electrochemical reductions which employ low-valent transition metal ions as a mediator, have been reviewed by Dietz and Lund.[4]

Results and Discussion

In the preliminary experiments, current-potential measurements were carried out on 2 M hydrochloric methanol, in both the presence and absence of titanium(IV) chloride.

As can be seen in Fig. 1, when a mercury pool was used as the cathode, the hydrochloric methanol without titanium(IV) chloride was not reduced below the potential of −1.1 V (SCE). An addition of hydroxylamine to the catholyte showed a similar current-potential curve; therefore, its reduction potential should be approximately −1.1 V or more cathodic. Hydrochloric methanol containing titanium(IV) chloride showed two reduction waves: the first wave was at −0.15 V and the

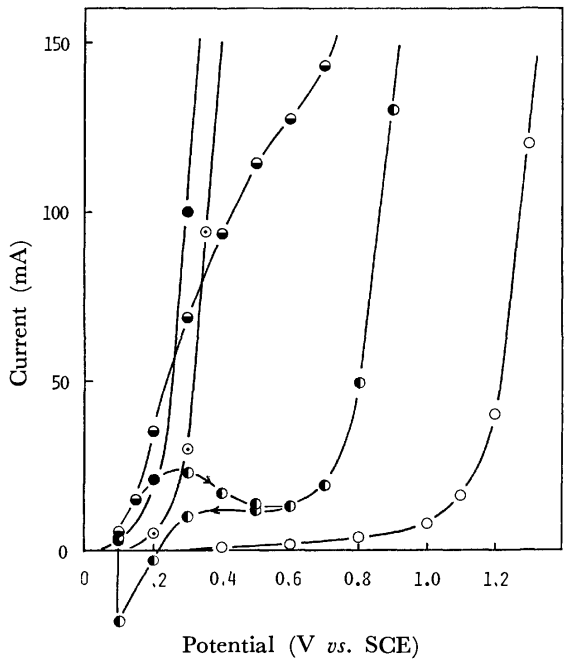


Fig. 1. Plots of current *vs.* cathode potential:
The relationships between current and potential were recorded automatically (sweep rate of 50 mV/s was used) but to economize on space tracings were prepared for reproduction herein. The measurements were carried out in 2 M HCl-MeOH at 25 °C.
a) On mercury; -○- in the absence and presence of $NH_2OH \cdot HCl$ (0.06 M), -◐- stationary curve in the presence of $TiCl_4$ (0.05 M), -◒- initial curve recorded immediately after adding $NH_2OH \cdot HCl$ (0.06 M). b) On platinum; -⊙- in the absence and presence of $NH_2OH \cdot HCl$ (0.06 M), -●- in the presence of $TiCl_4$ (0.05 M).

Table 1. Analytical results of Ti^{3+} generated on Pt cathode[a)]

No.	Catholyte		Constant current (A)	Consumed current (mF)	Cathode potential (V *vs.* SCE)	Conversion Found/Theoretical (%)
	$TiCl_4$ (mmol)	HCl-MeOH 80 ml				
1	9.3	2 M	1.0	3.1	0.21—0.26	80
2	9.3	2 M	1.0	6.2	0.20—0.30	64
3	9.3	2 M	1.0	9.3	0.21—0.35	56
4	9.3	2 M	0.5	3.1	0.19—0.23	84

7	9.3	2 M	0.2	9.3	0.13—0.33	74
8	9.3	0.5 M	1.0	9.3	0.21—0.36	49
9	18.6	2 M	1.0	9.3	0.19—0.26	71
10	18.6	5 M	1.0	9.3	0.20—0.28	71

a) Electrolyses were carried out in an ice bath. For volumetric determination of Ti^{3+}, the electrolysis solution was directly titrated with standard $FeCl_3$ solution in nitrogen atmosphere.

second was at −0.80 V. Further, an oxidation wave was observed on the anodic sweep in the vicinity of −0.15 V, which corresponded to the oxidation of the first reduction peak. It would arise from a reversible charge transfer of titanium ions. In polarographic studies,[5)] it has been confirmed that a mixture of titanium(IV)–titanium(III) chlorides in dilute hydrochloric acid showed a cathodic half-wave potential of −0.80 V where the Ti^{4+}-Ti^{3+} couple did not behave reversibly; however, in relatively concentrated solutions of hydrochloric acid, the wave was markedly shifted to a more positive position and was close to −0.15 V. Accordingly, the second wave may be attributed to the irreversible reduction of Ti^{4+}.

Under conditions of controlled potential electrolysis of titanium(IV) chloride in hydrochloric methanol at −0.3 V, the catholyte soon changed to a blue color, which suggests the occurrence of Ti^{3+}, and hence the first wave described above was undoubtedly exhibited by the reduction of Ti^{4+} to Ti^{3+}. Later, on addition of hydroxylamine to the catholyte, the electrolytic current suddenly increased, accompanied by a color change from blue to yellow. These observations indicate that Ti^{3+} is consumed for the reduction of hydroxylamine as soon as it is formed, and that the presence of hydroxylamine results in an acceleration of the cathodic reduction of Ti^{4+} by an electrocatalytic mechanism.

On the other hand, when platinum was used as the cathode, titanium(IV) chloride in hydrochloric methanol was reduced at a potential of −0.15 V, whereas the hydrochloric methanol alone initiated the reduction at −0.25V. Owing to the insignificant difference between the two potentials, platinum seemed entirely unsatisfactory as the generator cathode of Ti^{3+}. However, as shown in Table 1, titanium(IV) chloride was effectively reduced to Ti^{3+} even at the low concentration at the platinum cathode, although hydrogen evolution was observed at the end of the electrolysis. In fact, Malmstadt and Roberts[6)] reduced titanium(IV) chloride at a platinum cathode with 100% current efficiency in hydrochloric acid greater than 7 M. Since platinum was found to be available as the cathode, the mercury cathode was not used for macro-scale electrolysis, in spite of its much greater hydrogen overvoltage, because it is troublesome to handle.

On the basis of the electroanalytical results, preparative electrolyses were conducted under several conditions at the platinum cathode.

Figure 2 shows the results of constant current electrolyses of hydrochloric methanol containing hydroxylamine, 1,3-butadiene, and various amounts of titanium(IV) chloride. When the mol ratio of titanium(IV) chloride to hydroxylamine was more than 0.2, diaminooctadienes were obtained in yields of *ca.* 60% based on hydroxylamine. Immediately before the end of the electrolyses, namely, when the current

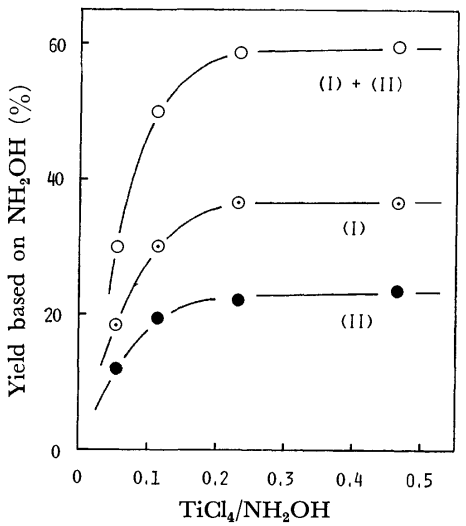

Fig. 2. Electrolyses of hydrochloric methanol containing hydroxylamine, butadiene, and various amounts of titanium (IV) chloride:
Catholyte: $NH_2OH \cdot HCl$, 36 mmol; C_4H_6, 180 mmol; 2 M HCl-MeOH, 80 ml. Constant current, 1.0 A. Consumed current, 37.3 mF.
(I) H_2N-CH_2CH=$CHCH_2CH_2CH$=$CHCH_2$-NH_2
(II) H_2N-$CH_2CH(-CH$=$CH_2)CH_2CH$=$CHCH_2$-NH_2

was consumed in slight excess of the quantity of electricity required to convert hydroxylamine, the catholyte assumed a blue color. This indicates that the reduction of Ti^{4+} and the subsequent reaction of Ti^{3+} with hydroxylamine proceed almost quantitatively. Consequently, under these conditions, the material yield would be governed by the reactivity of the amino radical with butadiene rather than the current efficiency for the generation of Ti^{3+}, although a certain amount of titanuim ions would be inactivated.

In the present reaction, three kinds of isomers of diaminooctadiene were considered, but (III) could not be detected in our experiments. The relative amounts of (I) and (II) were invariably 62:38. This is in agreement with the results in free radical polymerizations of 1,3-butadiene, in which the 1,4-addition reaction is more favorable than the 1,2-addition.[7]

Figure 3 shows the relationships among the consumed current, the current efficiency, and the product yield. The current efficiency for the formation of diamines linearly decreased with the increase of the consumed current, whereas the material yield based on hydroxylamine increased below the consumed current of 50 m farady (the theoretical extent of conversion of hydroxylamine is 67%), but above this value diamines were no longer produced.

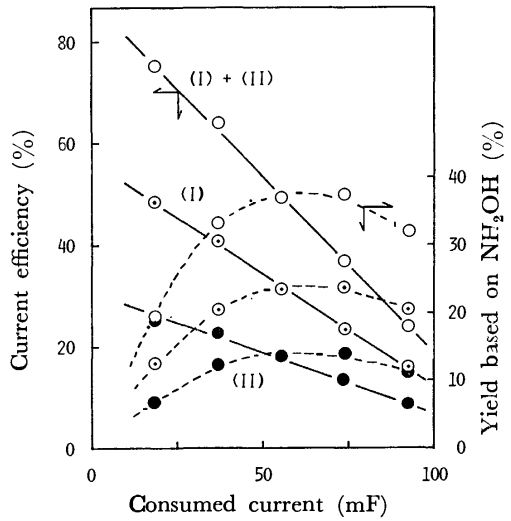

Fig. 3. The relationships among the current efficiency, consumed current, and the product yield:
Catholyte: $TiCl_4$, 9.3 mmol; C_4H_6, 72 mmol; $NH_2OH \cdot HCl$, 72 mmol; 2 M HCl-MeOH, 80 ml. Constant current, 1.0 A.

From the results in Figs. 2 and 3, Ti^{4+} is presumed to be rereduced 4—5 times on the electrode. Moreover, it is probable that water produced as the reaction proceeds renders Ti^{4+} inactive and gives rise to the side reaction. In fact, an addition of water to the catholyte greatly inhibited the electrolysis for the formation of diamines and caused the precipitation of titanium salt, gas evolution, and adhesion of tarry materials on the cathode.

Figure 4 shows the dependence of the amount of butadiene on the product yield. The use of a large excess of butadiene showed a tendency to increase the

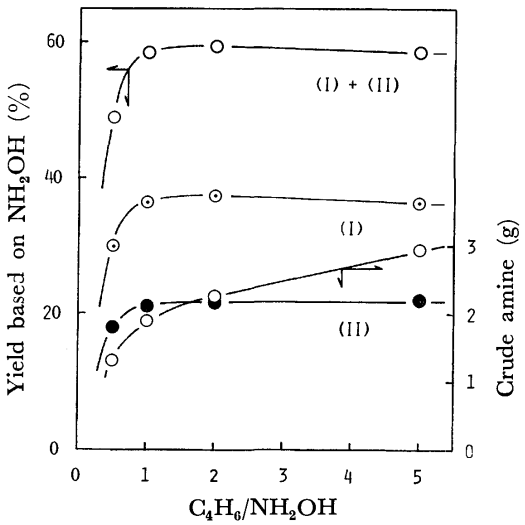

Fig. 4. The dependence of the amount of butadiene on the product yield:
Catholyte: $TiCl_4$, 9.3 mmol; $NH_2OH \cdot HCl$, 36 mmol; 2M HCl-MeOH, 80 ml. Constant current, 1.0 A. Consumed current, 37.3 mF.

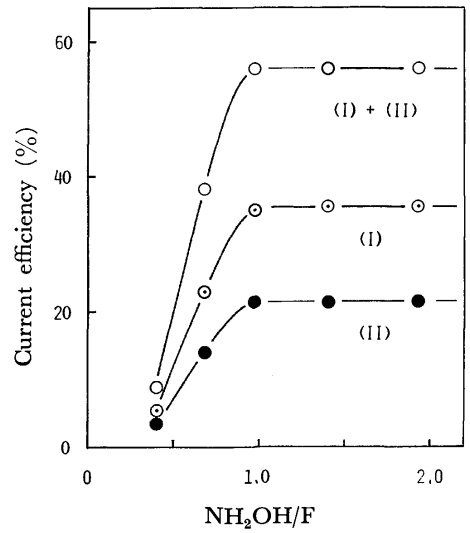

Fig. 5. The dependence of the amount of hydroxylamine:
Catholyte: $TiCl_4$, 9.3 mmol; C_4H_6, 180 mmol; 2 M HCl-MeOH, 80 ml. Constant current, 1.0A. Consumed current, 37.3 mF.

formation of materials with a high boiling point which were soluble in acidic solution. Thus it is probable that polymerization would occur. On the contrary, by the use of less than the theoretical amounts, for example, when the mol ratio of butadiene to hydroxylamine was 0.5, the yield of diaminooctadienes based on butadiene increased to over 90%.

Furthermore, as shown in Fig. 5, the product yield was hardly affected by even significant amounts of hydroxylamine, but was dependent on the consumed current. In order to run the electrolysis effectively, therefore, equimolar amounts of butadiene and hydroxylamine should be used.

Experimental

Reagents. Titanium(IV) chloride was purified by distillation after heating over mercury. Reagent grade hydroxylamine hydrochloride and 1,3-butadiene were used without purifications. Hydrochloride methanol was prepared by passage of dry hydrochloride through distilled methanol.

Apparatus. The instrument used to control potential and current for electroanalytical studies was a Nichia HP-E500H type potentiostat and a constant current unit. The electrode potential was scanned by means of a Nichia S-5A type potential programer. The relationship between current and potential was recorded on a Yokogawa 3077 X-Y recorder. Large scale electrolyses were performed with a Yanagimoto VE-8 potentiostat.

Current-potential measurements were made at 20 °C in a two-compartment H-type cell with a glass frit separating the compartments. The main compartment (25 ml) was provided with a working electrode (a smooth platinum plate or mercury pool, each area is 4 cm^2), a nitrogen gas bubbler, gas outlet, and a sce reference electrode. The other compartment (15 ml) contained a platinum wire as a counter electrode. All potentials were referred to the saturated calomel electrode.

Constant current electrolyses for preparative studies were carried out in a 100 ml-separable flask shielded from the anode compartment by a porous cup, and a reflux condenser (−10 °C) was connected to the cathode compartment. A cylindrical platinum net (4.5 cm in height, 11.0 cm in circumference, 55 mesh) was used at the cathode and the anode was a coil of platinum wire (0.8 mmϕ, 20 cm). The reference electrode was situated adjacent to the working electrode when necessary. The cell was cooled with ice water and nitrogen was bubbled through the cell during electrolysis.

Analytical. The amines were identified titrimetrically and spectroscopically. The amino nitrogen was analyzed by titration with perchloric acid in acetic acid in the usual manner. IR and mass spectra were recorded on a Hitachi 295 spectrophotometer and a Hitachi M-52 mass spectrometer, respectively. ^{1}H-NMR spectra were measured with a Hitachi 20A spectrometer using $CDCl_3$ as the solvent. Chemical shifts are given in ppm from TMS as the internal standard. Gas chromatographic analyses were conducted with a Hitachi 163 gas chromatograph using a 2-m glass column packed with 20% Apieson grease and 10% potassium hydroxyde on a 60—80 mesh Chromosorb W AW, a column temperature of 170 °C (preheater 200 °C), and a flow rate of 40 ml/min (nitrogen gas). Retention times for (I) and (II) isomers were 13.5 and 10.0 min, respectively.

For volumetric determination of Ti^{3+} generated cathodically, the electrolysis solution was directly titrated with 1.0 M ferric chloride in nitrogen atmosphere.

Electrolyses for Preparative Studies. A typical experimental procedure is as follows. The catholyte contained 36 mmol of $NH_2OH \cdot HCl$, 37 mmol of butadiene, and 9.3 mmol of $TiCl_4$ dissolved in 80 ml of 2 M HCl–MeOH. The electrolysis was carried out under a constant current at 1.0 A for 1 h. After the electrolysis, the blue catholyte was evaporated under reduced pressure. Then the residue was poured into a strong alkaline solution, and was extracted twice with a 20 ml portion of ether. The combined extracts were analyzed by GLPC. Analytical samples were obtained by fractional distillation. (I): Bp 91—94 °C/3 mmHg; IR (neat) ν 3370, 3280, 1600 (NH_2), 970 cm^{-1} (*trans* C=C); NMR ($CDCl_3$) δ 1.2 (4H, $-CH_2-\underline{NH_2}$), 2.1 (4H, $-\underline{CH_2}-CH=$), 3.2 (4H, $=CH-\underline{CH_2}-NH_2$), 5.5 ppm (4H, $-CH_2-\underline{CH}=\underline{CH}-CH_2-$); *MW* 140 (mass); Found: neut. equiv., 69.5. Calcd for $C_8H_{16}N_2$: neut. equiv., 70.1. (II): Bp 74—75 °C/3 mmHg; IR (neat) ν 3370, 3280, 1640, 1600 (NH_2), 970 (*trans* C=C), 910 cm^{-1} (term. vinyl); NMR ($CDCl_3$) δ 1.1 (4H, $-CH_2-\underline{NH_2}$), 2.1 (3H, $=CH-\underline{CH_2}-\underline{CH}-CH=$), 2.6 (2H, $-CH-\underline{CH_2}-NH_2$), 3.2 (2H, $=CH-\underline{CH_2}-NH_2$), *ca.* 5 (2H, $-CH=\underline{CH_2}$), 5.5 ppm (3H, $-CH_2-\underline{CH}=\underline{CH}-CH_2-$, $-\underline{CH}=CH_2$); *MW* 140 (mass); Found: neut. equiv., 69.8. Calcd for $C_8H_{16}N_2$: neut. equiv., 70.1.

Catalytic Hydrogenolysis of Phenothiazine, Thianthrene, and Phenoxathiin

Masatoshi NAGAI* and Noriyuki SAKIKAWA

Department of Industrial Chemistry, Faculty of Science and Engineering, Nihon University, Chiyoda-ku, Tokyo 101

(Received August 2, 1977)

Catalytic hydrogenolysis of phenothiazine, thianthrene, and phenoxathiin as appropriate model reactants in the competing reactions of sulfur, nitrogen, and oxygen removal over NH_4Y zeolite, pre-sulfided Co–Mo–Al_2O_3, and Ni–W–$SiO_2Al_2O_3$ catalysts has been carried out using the batch method. The cleavage patterns and the schemes in the hydrogenolysis of the three compounds and the active sites of an NH_4Y zeolite for the hydrogenolysis are discussed. The C–S bond in phenoxathiin was more prone to cleavage than the C–O bond, and the C–N bond in phenothiazine was not broken in our experiments. Sulfur removal from the three compounds took place more than the removal of nitrogen or oxygen. The reactivity over the zeolite Y, pre-sulfided Co–Mo–Al_2O_3, and Ni–W–$SiO_2Al_2O_3$ catalysts decreased in the order of phenothiazine > phenoxathiin > thianthrene, but in the absence of the catalyst the thermal stability was phenoxathiin > thianthrene > phenothiazine. In the hydrogenolysis of the three compounds over the NH_4Y catalyst the desulfurization activity of the zeolite Y catalyst was maximized when calcined at 500 °C. The reaction of phenoxathiin was found to be accelerated by Brönsted acid, but this did not hold true in the case of phenothiazine and thianthrene.

In previous papers,[1,2] catalytic hydrodesulfurization of dibenzothiophene, one of the condensed thiophene compounds in residual oils, over an NH_4Y or CoY zeolite catalyst has been studied in order to elucidate the behavior of high-molecular-weight aromatic sulfur compounds.

Catalitic hydrodesulfurization of petroleum fractions or coal oils occurs concurrently with the removal of nitrogen and oxygen. Consequently, we carried out a model experiment on the competitive reactions of S, N, and O removal during the hydrogenolysis of fuel oils. Thianthrene, phenothiazine, and phenoxathiin containing two atoms of sulfur and nitrogen or oxygen atoms in the compounds are regarded as appropriate model reactants.

There have been many studies of the hydrogenolysis of sulfur, nitrogen or oxygen compounds alone.[3-6] However, the only studies of hydrogenolysis of thianthrene on a silica–alumina catalyst were reported by Tits-Skvortsova *et al.*[7] Badger *et al.*[8] studied the mechanism of the desulfurization reaction using Raney nickel. Aiken *et al.*[9] studied the behavior of cyclic sulfur compounds such as dibenzothiophene and thianthrene. There have been no studies of the reaction of phenoxathiin or phenothiazine.

In the present paper, the hydrogenolysis of thianthrene, phenothiazine, and phenoxathiin as the model compounds over NH_4Y zeolite, pre-sulfided Co–Mo–Al_2O_3, and Ni–W–$SiO_2Al_2O_3$ catalysts has been carried out in order to study the competitive reactions of desulfurization, denitrogenation, and deoxygenation. The mechanism of hydrogenolysis of the three compounds and the active sites of the NH_4Y zeolite are discussed.

Experimental

Reactants and Catalysts. Thianthrene was prepared by our modification of the procedure given by Shirley.[10] Phenothiazine and phenoxathiin were prepared by methods previously described;[11,12] thianthrene: mp 157—158.5 °C (lit,[10] 149—154 °C); phenothiazine: 186.5—187.5 °C (lit,[13a] 187 °C); phenoxathiin: 57—58.5 °C (lit,[12] 57.5—58 °C).

NH_4(61%)NaY zeolite was prepared from NaY by a conventional ion exchange procedure using a solution of NH_4Cl–NH_4OH. The exchanged zeolite was then washed thoroughly with decationized water and dried at 100 °C in air. The pretreatment of zeolite was as follows. Glass ampoules containing 0.65 g of zeolite were placed in a furnance. The temperature was slowly raised to the desired calcination temperature and maintained for 4 h, at which time equilibrium had been established, and then the ampoules were sealed. Co–Mo–Al_2O_3 and Ni–W–$SiO_2Al_2O_3$ catalysts obtained commercially were pre-sulfided with a H_2S/H_2 volume ratio of 1/5 at 350 °C for a period of 3 h in the autoclave.

Apparatus and Procedure. Hydrogenolysis of the three compounds was carried out in a 100 ml autoclave with a stirrer driven magnetically. The catalyst and the substrate (0.017 mol) were put into the autoclave, which was then charged with hydrogen to the required pressure. The autoclave was placed in an electric furnance and the temperature was slowly raised to 350 °C and was kept constant, hydrogenolysis being allowed to start after 2 h. After the reaction was completed the autoclave was cooled to room temperature and the liquid reaction mixture and hydrogen sulfide in the autoclave were collected for analysis.

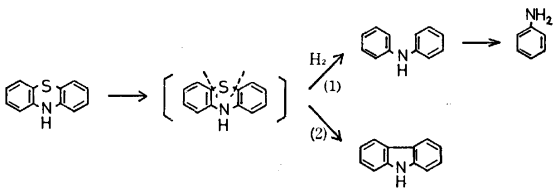
Analytical. Analysis of the liquid reaction mixture was made by gas chromatography using a 3 m column filled with a 5% Silicone OV-17 supported on Chromosorb W. The column was maintained at 70 °C (in the case of the analysis of benzene, benzenethiol, and phenol), 80 °C (for aniline), or 200 °C (for other high boiling compounds). A helium carrier gas was used at the flow rate of 40 ml/min. Ethylbenzene (70, 80 °C) and acenaphthene (200 °C) were used as internal standards for the measurement of the weight of compounds. Hydrogen sulfide in the gaseous products was trapped by lead acetate solution, resulting in the formation of lead sulfide, which was determined by gravimetric analysis. Most of the components were identified through their characteristic retention times in the columns. However, diphenyl disulfide produced during thianthrene hydrogenolysis was isolated by gas chromatography, and was identified by comparing the retention time on gas chromatography, mp 58—60 °C (lit,[13b] 61 °C), IR spectrum, and the fragmentation of the mass spectrum with those of the authentic sample. The stability of the zeolite structure was checked by an X-ray

* Present address: Department of Chemical Engineering, Faculty of Engineering, Tokyo University of Agriculture and Technology, Koganei-shi, Tokyo 184.

diffraction study. The degree of ion exchange was calculated from the sodium content of NH_4Y zeolite after ion exchange. Sodium was determined by chelate titration, using both uranyl acetate and nickel nitrate with a MX indicator.

Results and Discussion

The Cleavage Patterns. *Phenothiazine*: Phenothiazine was desulfided in the highest compounds of thianthrene, phenoxathiin, and phenothiazine; the results for the hydrogenolysis of phenothiazine are given in Table 1. The data where the zeloite Y and no catalyst were used indicated that diphenylamine and a small amount of carbazole and aniline were observed in the products. Hence, the cleavage pattern and the pathways in phenothiazine hydrogenolysis over the NH_4Y catalyst were considered with Scheme 1. As diphenylamine was usualy produced in the presence of the pre-sulfided Co–Mo–Al_2O_3 and Ni–W–$SiO_2Al_2O_3$ catalysts, only pathway (1) appeared to be followed. Degradation reactions of diphenylamine and carbazole occur hardly at all, because benzene was not observed and very little aniline was produced. Because no dibenzothiophene was produced while carbazole was produced in the phenothiazine reaction, we concluded that the C–N bond in the molecule is not broken, while the C–S bond is easily broken.



Scheme 1.

Thianthrene: The results for the hydrogenolysis of thianthrene over the pre-sulfided Co–Mo–Al_2O_3, Ni–W–$SiO_2Al_2O_3$, and zeolite Y catalysts, and for the hydrogenolysis without catalysts are given in Table 2. Obolentsev and Mashkina[14] identified *o*-(phenylthio)-benzenethiol in thianthrene hydrogenolysis over a sulfided Co–Mo–Al_2O_3 catalyst and proposed Reaction Scheme 2. In our experiment, however, the products of thianthrene hydrogenolysis over the catalysts used were primarily benzene, diphenyl sulfide and diphenyl disulfide, and *o*-(phenylthio)benzenethiol could not be confirmed. Hence, Scheme 2 is doubtful.

Scheme 2.

It seems likely that the thianthrene molecule is distorted on the S–S line,[15] and that the molecule is adsorbed to the catalyst at one or usually at two sulfur atoms, while 2 or more of the 4 C–S bonds in the molecule

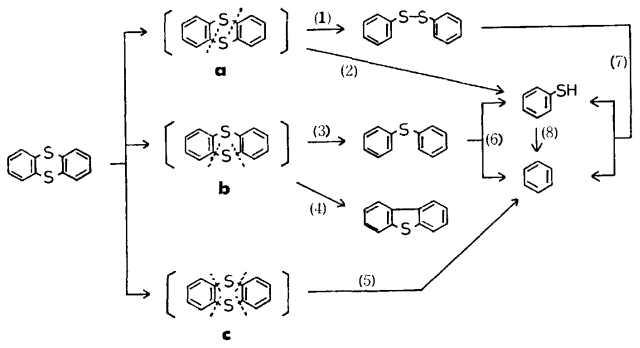
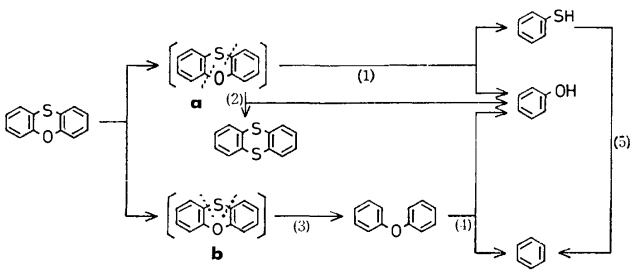


Scheme 3.



Scheme 4.

are broken. We propose Scheme 3, which occurs with the three ways of cleavage (**a**, **b**, **c**), as a modification of Scheme 2 for thianthrene hydrogenolysis. When only an atom of sulfur is adsorbed and two C–S bonds are broken, and cleavage pattern (**b**) is expected to occur, pathways (3) and (4) are thought to take place. If it is assumed that thianthrene is adsorbed at both sulfur atoms, the hydrogenolysis of thianthrene proceeds according to cleavage patterns (**a**) and (**c**). In pattern (**a**), the two diagonal C–S bonds in thianthrene are simultaneously broken to give benzenethiol (2), or the S–S bonds form to give diphenyl disulfide, which is desorbed (1). On the other hand, in pattern (**c**) the simultaneous loss of two sulfur atoms from thianthrene results in the formation of benzene in pathway (5).

The amounts of the products given in Table 2 suggest that cleavage patterns (**a**) and (**c**) predominate in thianthrene hydrogenolysis over the pre-sulfided Co–Mo–Al_2O_3 and Ni–W–$SiO_2Al_2O_3$ catalysts. During pyrolysis, only pattern (**b**) occurred and the loss of an atom of sulfur allowed thianthrene to pass to the more stable planar form of dibenzothiophene (4).[16] In the presence of the zeolite Y catalyst, pattern (**b**) appeared to predominate over pattern (**a**).

Phenoxathiin: The data for phenoxathiin hydrogenolysis over various catalysts are given in Table 3. The table shows that thianthrene and benzenethiol were produced in phenoxathiin hydrogenolysis over the NH_4Y zeolite catalyst, but were not observed over the pre-sulfided Co–Mo–Al_2O_3 and Ni–W–$SiO_2Al_2O_3$ catalysts and without catalysts. Grib *et al.*[17] reported that thianthrene and phenoxathiin were obtained by the reaction of diphenyl sulfide and diphenyl ether over an $AlCl_3$ catalyst, and that the formation of phenoxathiin was apparent, while that of thianthrene was not. We will now consider the hydrogenolysis mechanism (Scheme 4) which includes two kinds of cleavage patterns in order to explain the formation of thianthrene and benzenethiol and the absence of diphenyl sulfide in the products. For cleavage pattern (**a**) in Scheme 4 we assumed that the desorption of phenol is faster than that of benzenethiol, and that two molecules of benzenethiol combine on the surface of the catalyst to form thianthrene, which is then desorbed. Only in the case of the pre-sulfided Co–Mo–Al_2O_3 and Ni–W–$SiO_2Al_2O_3$ catalysts does cleavage pattern (**b**) take place.  and  are not thought to take place because diphenyl sulfide and dibenzothiophene were not observed in the products and because a little benzene was produced. The distribution of the products in Table 3 shows that the primary product was diphenyl ether produced by the fission of the C–S bond in phenoxathiin. The fact that cleavage of the C–S bond in one-point adsorption is easier than the simultaneous cleavage of the C–O and C–S bonds in two-point adsorption of the sulfur and oxygen atoms can be explained by the greater electron density of sulfur atoms compared with oxygen atoms.[18] When comparing the reactivity of the three compounds where no catalyst was used in Tables 1, 2 and 3, phenoxathiin is the most stable of the three compounds, and the thermal stability order is pheno-

a) The conditions in this table are similar to those in Table 1. b) Unidentified product.

xathiin > thianthrene > phenothiazine. The reactivity of the compounds over the zeolite Y, pre-sulfided Co–Mo–Al_2O_3, and Ni–W–$SiO_2Al_2O_3$ catalysts, however, decreased in the order phenothiazine>phenoxathiin> thianthrene, which is different from the order in the absence of catalysts. The product percentages in Tables 1 and 2 show that diphenyl ether is less readily decomposed than diphenyl sulfide.

The Active Sites of NH_4Y Zeolite in the Hydrogenolysis. The percentage of sulfur removed (H_2S produced) in the hydrogenolysis of phenothiazine, thianthrene, and phenoxathiin over the NH_4Y zeolite catalyst as a function of the calcination temperature is shown in Fig. 1. The percentage of sulfur removed from all three substrates was greatest at a calcination temperature of *ca.* 500 °C, just as in the case of dibenzothiophene over the NH_4Y catalyst. The percentage of sulfur removed decreased in the order of phenothiazine>phenoxathiin>thianthrene. This order was the same when the Co–Mo–Al_2O_3 and Ni–W–$SiO_2Al_2O_3$ catalysts were used, as can be seen in Tables 1, 2, and 3. The activity

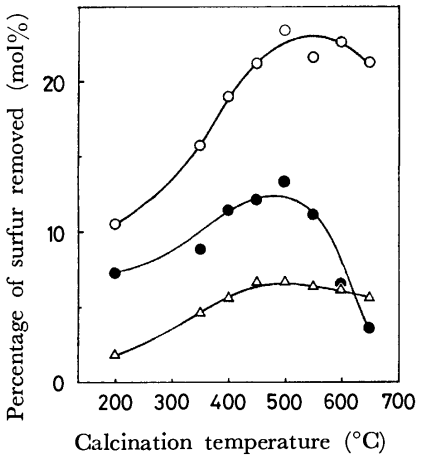

Fig. 1. The relations between the percentage of sulfur removed and calcination temperatures of the NH_4Y zeolite in the hydrogenolysis of phenothiazine (○), thianthrene (△), and phenoxathiin (●).

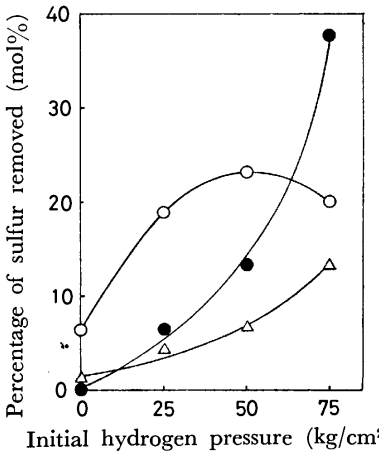

Fig. 2. The effect of the initial hydrogen pressure on the percentage of sulfur removed in the hydrogenolysis of phenothiazine (○), thianthrene (△), and phenoxathiin (●) over the NH_4Y catalyst calcined 500 °C.

of the zeolite catalyst during thianthrene reaction did not appreciably vary for calcination temperatures of the catalyst above 500 °C. The percentage of sulfur removed from phenoxathiin was greatly affected by the pretreatment temperature, reaching a maximum at 500 °C. The percentage of sulfur removed decreased sharply at temperatures above 500 °C. It has been proposed that the Brönsted acid sites on the NH_4Y zeolite are converted to Lewis acid sites when pretreatment is carried out at temperatures higher than 500 °C, as a result of the elimination of water.[19,20] Hence, the percentage of sulfur removed from phenoxathiin would be expected to decrease rapidly with decreasing Brönsted acid sites. The effect of the initial hydrogen pressure on the percentage of sulfur removed is given in Fig. 2. Sulfur removed during phenoxathiin hydrogenolysis increased considerably with increasing pressure of initial hydrogen. Therefore, the hydrogenolysis of phenoxathiin over the NH_4Y catalyst is accelerated by the Brönsted acid sites produced during calcination.

More phenol than phenyl ether was formed in phenoxathiin hydrogenolysis over the NH_4Y catalyst calcined at 350 °C, but less phenol than phenyl ether was produced over the NH_4Y catalyst at calcination temperatures above 500 °C. This is thought to be due to the fact that the reaction:

is accelerated by the Brönsted acid sites produced at the lower calcination temperatures.

In the hydrogenolysis of phenothiazine and thianthrene it is not yet understood what acid sites promote the reaction. As in the hydrodesulfurization of dibenzothiopene, however, sulfur removal was greatest when zeolite prepared by calcination of NH_4Y at temperatures of *ca.* 500 °C was used. There can therefore be no doubt that the acid sites play a role in the hydrogenolysis reaction.

We are grateful to Professor Kunio Itabashi and Dr. Hideo Urimoto, of Nihon University, and Associate Professor Toshiaki Kabe, the Tokyo University of Agriculture and Technology, for valuable discussions. We are also indebted to Mr. Hiroshi Tokita for assistance during the course of the experiments.

Heterofulvalenes. I. 5-Aza- and 6-Aza-1,4-dithiafulvalenes

Jyuzo NAKAYAMA, Yukie WATABE, and Masamatsu HOSHINO

Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338

(Received August 16, 1977)

5-Aza, 2,3-benzo-5-aza-, 6-aza-, and 2,3-benzo-6-aza-1,4-dithiafulvalenes were synthesized and their spectroscopic properties are described. For example, the reaction of 2-methylthio-1,3-dithiolylium iodide with pyrrole gave 2-(2-pyrrolyl)-1,3-dithiolylium iodide in a 92% yield, which was treated with DBU, giving rise to 5-aza-1,4-dithiafulvalene as thermally-stable orange crystals in an 82% yield. Several reactions found during the course of these synthetic studies are also reported.

Recent findings concerning the highly-conductive charge-transfer salt (**1**) of tetrathiafulvalene and tetracyanoquinodimethane have created a wide and expanding interest in convenient methods of synthesizing a variety of tetrathiafulvalene derivatives and their tetraselenafulvalene analogs.[1] The synthesis of azadithiafulvalenes, **2b** and **c**, and **3c** and **d**, has been reported by Gompper and Weiss.[2] However, no report of the synthesis of the parent compounds, **2a** and **3a**, has appeared, although 1,4-dithiafulvalene (**4**) has already been synthesized.[3] Compounds **2** and **3** are iso-π-electronic with **4** and sesquifulvalene (**5**)[4] and may be aromatic if dipolar structures such as **2'** or **3'** contribute to the ground state of these molecules. Here, the synthesis of **2a**, **3b**, their benzo-derivatives, and their spectroscopic properties are reported. At the beginning of these studies, parent

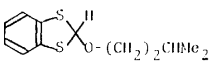
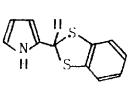
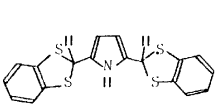
compounds **2a** and **3a** were considered too thermally unstable to be isolated because Gompper and Weiss were not able to isolate **2b** and **3c** (they can be maintained in acetonitrile at room temperature for several hours).[2] The synthesis of benzo-derivatives of **2** and **3** were then undertaken in the expectation that they would be more stable than the parent compounds. The starting materials, **7**, **8**, and **9**, were easily obtained by reactions of benzodithiole **6** with pyrroles in acetic acid.[5]



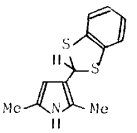
6



7

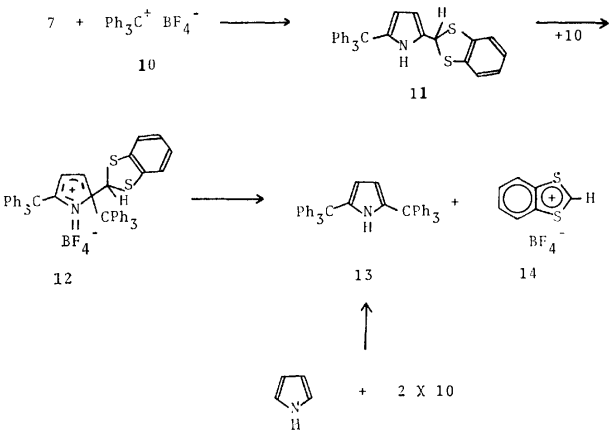


8

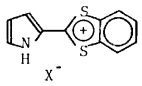


9

Tritly tetrafluoroborate (**10**) can abstract a hydride from 1,3-benzodithiole to give 1,3-benzodithiolylium tetrafluoroborate (**14**) in a good yield.[6] Thus, the reaction of **7** with an equimolar amount of **10** was carried out in acetonitrile at room temperature with the expectation of obtaining the dithiolylium salt, **15a**. However, the reaction gave 2,5-tritylpyrrole (**13**) in a 54% yield (based on **10**). The use of 2 molar amounts of **10** gave **13** in a 62% yield. The structure of **13** was confirmed by comparison with an authentic sample prepared in a 71% yield by the reaction of 2 equivalents of **10** with pyrrole. The formation of **13** from **7** and **10** may proceed *via* the formation of **11** as a transient intermediate. This would not be unexpected in view of the facile formation of **13** by the action of 2 equivalents of **10** with pyrrole. Ipso-substitution to form a sterically-unfavorable intermediate, **12**, and subsequent elimination of the dithiolylium salt (**14**) produced **13** The formation of the heteroaromatic salt, **14**, serves as a driving force for the latter reaction. Actually, evidence of the formation of **14** is found in the fact that treatment of the reaction mixture with triethylamine gave dibenzotetrathiafulvalene (**16**) in a low yield (2%). The formation of **16** from **14** by treatment



10 11 12 13 14

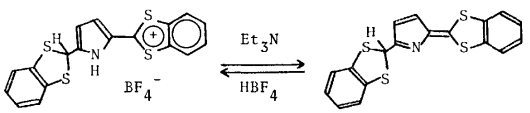


15a; X = BF_4
b; X = ClO_4

16

with a base is well documented.[6]

Although the reaction of **7** with **10** failed to give the expected product, treatment of **8** with **10** gave salt **17** as unstable yellowish-brown crystals in a 51% yield. Treatment of **17** with triethylamine in acetonitrile at room temperature quantitatively gave the azadithiafulvalene, **18**. Compound **18**, on being treated with tetrafluoroboric acid, gave salt **17**, but neither methyl iodide nor benzoyl chloride reacted with **18** in boiling acetonitrile or in acetonitrile at room temperature, respectively.



17 18

The reaction of **9** with **10** gave compound **19** (17%) and triphenylmethane (56%). Although the formation of triphenylmethane is indicative of the formation of the expected salt, **20a**, it was not isolated in pure form. Salt **14** also serves as hydride acceptor and is a milder reagent than **10**.[6,7] Therefore, **9** was allowed to react with **14**. The reaction carried out in acetonitrile at room temperature gave **20a** (20%), **21** (36%), and **22** (15%). Compound **14** in the reaction with **9** undergoes both hydride abstraction to form **20a** and electrophilic substitution to form **21**. The formation of compound **22** is the result of hydride abstraction from **21** by **14**. Salts **20a** and **22** could not be separated from each other, but the ratio of **20a** to **22** formed was easily determined by NMR analysis since both salts could be prepared by other methods described below. Compound **21** was prepared in a 93% yield from 2,5-dimethylpyrrole and 2 equivalents of **6** in acetic acid. Treatment of **21** with an equimolar amount of **14** gave salt **22** in a 76% yield. The reaction of **21** with **10** gave impure **22** in a diminished

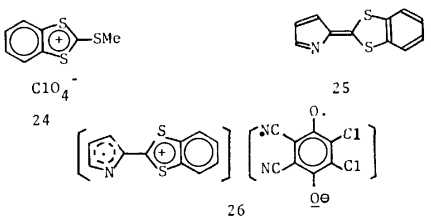
23; R = 1,3-Benzodithiol-2-yl
27; R = H

yield. Treating **22** with diazabicyclo[5.4.0]-undec-7-ene(DBU) gave the azathiafulvalene, **23**, in a 92% yield.

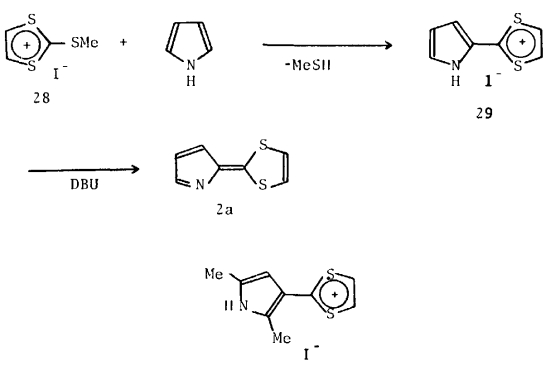
Since the reactions described above failed to produce clean samples of salts **15a** and **20a**, synthesis of these salts from salt **24**[8] was attempted. Pyrrole reacted smoothly with **24** in acetonitrile at room temperature and the expected perchlorate, **15b**, was obtained in an 84% yield. Similarly, salt **20b** was prepared from **24** and 2,5-dimethylpyrrole in a 67% yield. Treatment of an acetonitrile solution of **15b** with DBU gave the azadithiafulvalene, **25**, as an orange crystalline precipitate in a 31% yield. The addition of 2,3-dichloro-5,6-dicyano-*p*-benzo-quinone (DDQ) to the filtrate gave 1 : 1 charge transfer salt **26** of DDQ and **25** in a 37% yield. Salt **26** may consist of the radical anion of DDQ and the radical cation of **25** (the structure of **25** under active investigation in this laboratory). In a similar manner, salt **20b** was converted to **27** in a 68% yield.



24 25

26

The finding that **25** and **27** thus obtained are thermally more stable than expected was encouragement to prepare parent compound **2a**. Thus, pyrrole was allowed to react with an equimolar amount of iodide **28**[9] in acetonitrile at room temperature for 2 days to gave the dithiolylium iodide, **29**, in a 92% yield. Treatment of **29** with DBU gave 5-aza-1,4-dithiafulvalene (**2a**) as orange crystals in an 82% yield. **2a** is thermally stable and can be stored in a refrigerator indefinitely. Similarly, salt **30** was prepared in an 83% yield from 2,5-dimethylpyrrole and **28**. Salt **30** was also converted to the thermally-stable azadithiafulvalene, **3b**, by treatment with DBU in



28 29

2a

30

a 70% yield. **3b** is less stable than **2a** and decomposed to tarry materials in solution.

NMR data for 1,3-dithiolylium salts and azadithiafulvalenes are summarized in Table 1. For comparison with these compounds, data for **7**, **8**, and **9** were also included. In the NMR spectrum of **8**, the pyrrole-ring proton signal appears at δ 6.07 as a doublet (due to long-range coupling with the N–H proton[10]).

On the other hand, the pyrrole-ring proton signal of the dithiolylium salt, **17**, occurs as two doublets at δ 6.78 and 7.52. A large low-field shift observed in going from **8** to **17** is attributed to the inductive effect of the positively-charged 1,3-benzodithiolylium nuclei. The high-field doublet of **17** can be assigned to the C-4 H of the pyrrole ring because the influence of the dithiolylium nuclei is less at this position. For the same reason, the pair of doublets of **29** at δ 6.66(J=5 and 3 Hz) can be assigned to the C-4 H of the pyrrole rings. The coupling constant between the C-3 H and C-4 H is 5 Hz for **17**. Therefore, the pair of doublets of **29** at δ 7.69 (J=5 and 1 Hz) and δ 7.88(J=3 and 1 Hz) can be assigned to C-3 H and C-5 H, respectively. The appearance of the benzene-ring proton signal of the 1,3-dithiolylium nuclei of **17** an **15b** as a typical AA'XX' pattern symmetrical about its center indicates that the conjugation between the two rings is not strong enough to hinder free rotation about the pinch bond. The same holds true for **29** since the dithiolylium-ring proton signal appears as a sharp singlet at δ 8.56. However, the chemical-shift value of δ 8.56, when compared to the value of δ 8.66 observed for the ring protons of **28** in deuteriofluoroacetic acid, suggests a significant contribution of structure **29'** to the ground state of

Table 1. NMR data

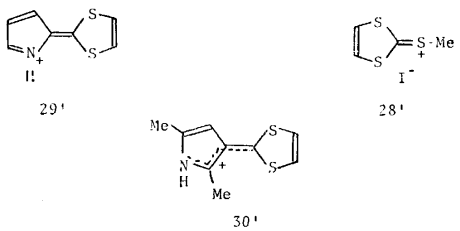
9	$CDCl_3$	2.16 (3H, s, 5-C methyl), 2.18 (3H, s, C-2 methyl), 6.08 (1H, d, J=2.5 Hz, C-4 H of pyrrole ring), 6.40 (1H, s, methine), 6.9—7.3 (4H, AA'BB' m, benzene ring), 7.45 (1H, broad m, NH)
20b	DMSO-d_6	2.22 (3H, s, 5-C methyl), 2.62 (3H, s, 2-C methyl), 6.55 (1H, broad s, 4-C H), 7.7—8.5 (4H, AA'XX' m, benzodithiolylium nucleus)
27	$CDCl_3$	2.17 (3H, broad s, 7-C methyl), 2.40 (3H, s, 5-C methyl), 5.95 (1H, broad s, 8-C H), 7.1—7.6 (4H, complex m, benzene ring)
22	DMSO-d_6	2.45 (3H, s, 5-C methyl), 2.72 (3H, s, 2-C methyl), 7.42 (1H, s, methine), 7.0—7.6 (4H, AA'BB' m, benzene ring protons of benzodithiol-2-yl group), 7.7—8.7 (4H, AA'XX' m, benzodithiolylium nucleus)
23	$CDCl_3$	2.47 (3H, s, methyl), 2.52 (3H, s, methyl), 6.8—7.7 (9H, m, benzene ring protons+methine proton)
30	DMSO-d_6	2.23 (3H, broad s, 5-C methyl), 2.55 (3H, s, 2-C methyl), 6.48 (1H, broad s, 4-C H), 8.49 (2H, s, dithiolylium ring)
3b	$CDCl_3$	2.15 (3H, broad s, 7-C methyl), 2.32 (3H, s, 5-C methyl), 5.86 (1H, broad s, 8-C H), 6.73 (2H, s, dithiole ring)
	CH_3CN	6.05 (1H, broad s, 8-C H), 7.10 (2H, s, dithiole ring)
	$(CH_3)_2CO$	5.95 (1H, broad s, 8-C H), 7.23 (2H, s, dithiole ring)

29, since **28'** is known to contribute significantly to the ground state of **28**.[11]



The formation of dithiolylium salt **20b** from **9** was also accompanied by a large low-field shift of the pyrrole-ring protons. The singlet due to the C-2 methyl of the pyrrole ring of **20b** is shifted to lower field by 0.44 ppm compared the that of **9**, whereas the singlet due to the C-5 methyl, which is broadened by long-range coupling with the C-4 H, is shifted to lower field by only 0.06 ppm and the broad singlet due to the C-4 H to lower field by only 0.47 ppm. This indicates that structure **30'** contributes significantly to the ground state of **30**. The chemical shift value of δ 8.49 of the dithiolyium-ring proton signal of **30** is also indicative of the contribution of **30'** as described for **29**. Free rotation about the pinch bond also occurs in this case.

In azadithiafulvalene **18**, the doublet at δ 6.65 can be assigned to the C-7 H (the C-8 H signal was obscured by signals due to the benzene-ring protons), which is less influenced than is the C-8 H by the electronegative nitogen atom and hence is expected to resonate at a higher value of the field than the C-8 H. The coupling constant between the C-7 H and C-8 H is 4 Hz in **18**. Accordingly, the doublet of **25** at δ 6.55 (J=4 Hz) and that of **2a** at δ 6.40 (J=4 Hz) can be assigned to the C-7 H, the doublet of **2a** at δ 6.94 (J=4 Hz) to the C-8H, and the singlet of **25** at δ 7.71 and that of **2a** at δ 7.52 to the C-6 H. The dithiole-ring proton signals of **2a** and **3b** appear as a singlet at δ 6.78 in carbon tetrachloride and at δ 6.73 in deuteriochloroform. This may be due to accidental equivalence of the two protons rather than rotation about the pinch bond. Evidence for this description comes from the fact that the benzene-ring proton signals of **25** and **27** appear as a complex multiplet, but not as a symmetrical AA'BB' pattern. The chemical-shift values of δ 6.78 and 6.73 of the dithiole-ring proton signals of **2a** and **3b** are slightly lower than the reported value (δ 6.60) of the dithiole-ring protons of 1,4-dithiafulvalene (**4**),[3] thus suggesting that the contribution of a dipolar structure is somewhat larger in **2a** and **3b** than in **4** due to the influence of the electronegative nitrogen atom. Here, of particular interest, is the large solvent effect observed with **2a** and **3b**. The dithiole-ring proton signals of **2a** were shifted to lower field by 0.45 ppm upon changing the solvent from carbon tetrachloride to acetonitrile, the other protons also being shifted to lower field (0.06 ppm for C-6 H, 0.22 ppm for C-7 H, and 0.14 ppm for C-8 H). The dithiole-ring protons of **3b** were also shifted to lower field by 0.37 and 0.50 ppm upon changing the solvent from deuteriochloroform to acetonitrile and acetone, respectively. This may be ascribed to the increased contribution of dipolar structures, such as **2'** and **3'**, in the polar solvents. A contribution from a dipolar structure increases the dithiolylium character of the dithiole ring of **2** and **3**, and the ring-current effect induced by the aromatic sextet formed in both rings may result in a shift to lower field. However, the possibility cannot be excluded that this low-field shift is the result of charge-transfer interactions of **2a** and **3b** with the solvent molecules, in which **2a** and **3b** serve as electron donors and acetonitrile or acetone as electron acceptors. UV data for dithiolylium salts, **29** and **30**, and azadithiafulvalenes, **2a** and **3b**, are listed in Table 2. The resemblance of the spectral features of **29** and **2a** probably reflects the similarity between the electronic structures of both compounds. On the other hand, conversion of **30** to **3b** resulted in a considerable change in spectral features. Changing the solvent from carbon tetrachloride to acetonitrile causes a slight bathochromic shift of the longest absorptions of **2a** and **3b**, probably because these strong absorptions are π-π^* transitions and, therefore, the more polar excited states are more stabilized in the polar solvent than are the ground states.

TABLE 2. UV DATA

a) Accurate log ε values could not be obtained because of the instability of the sample in solutions.

Experimental

2-Isopentoyloxy-1,3-benzodithiole (**6**),[12] 2-(1,3-benzodithiol-2-yl)-, 2,5-bis(1,3-benzodithiol-2-yl)-, and 2,5-dimethyl-3-(1,3-benzodithol-2-yl)pyrroles (**7**, **8**, and **9**),[5] trityl tetrafluoroborate (**10**),[13] 1,3-benzodithiolylium tetrafluoroborate (**14**),[6] 2-methylthio-1,3-benzodithiolylium perchlorate (**24**),[8] and 2-methylthio-1,3-dithiolylium iodide (**28**)[9] were prepared by methods in the literature. Acetonitrile was refluxed and distilled from calcium hydride, and stored over molecular sieves. Ether was distilled and dried over molecular sieves.

Reaction of 7 with 10. To a stirred and ice-cooled solution of **7** (1.10 g; 5 mmol) in dry acetonitrile (15 ml) was added dropwise a solution of **10** (1.65 g; 5 mmol) in dry acetonitrile (10 ml) over a period of 20 min. Stirring was continued for 0.5 h while the mixture was brought to room temperature. The resulting precipitate was collected by filtration, washed with acetonitrile (10 ml), and dried to give 0.61 g (44%) of 2,5-ditritylpyrrole (**13**). The combined filtrate and washings were evaporated and the residue was subjected to silica gel column chromatography. Elution with carbon tetrachloride gave additional **13** (0.14 g; 10%). **13**; mp 229–230 °C (from benzene), colorless granules, IR (Nujol) 3400 cm^{-1} (NH), NMR ($CDCl_3$) δ 5.87 (2H, d, J=*ca.* 2.6 Hz)

and 7.0—7.3 (30 H, m). Found: C, 91.42; H, 5.97; N, 2.31%. Calcd for $C_{42}H_{33}N$: C, 91.43; H, 6.03; N, 2.54%.

To a stirred and ice-cooled solution of **7** (1.10 g; 5 mmol) in acetonitrile (15 ml) was added dropwise an acetonitrile solution (10 ml) of **10** (3.30 g; 10 mmol) over a period of 25 min. The ice bath was removed and the mixture was stirred for 1 h. The precipitate was filtered, washed with acetonitrile, and dried to give 1.32 g (48%) of **13**. Triethylamine (2 ml) was added to the dark reddish-brown filtrate and the mixture was evaporated. The residue was subjected to chromatography on silica gel. Elution with carbon tetrachloride gave triphenylmethane (0.32 g), dibenzotetrathiafulvalene (**16**) (0.02 g; 2%), mp and mixed mp with an authentic specimen[6] 236—237 °C, **13** (0.39 g; 14%), and trityl alcohol (0.43 g).

*2,5-Ditritylpyrrole (**13**) from **10** and Pyrrole.* To a stirred and ice-cooled solution of pyrrole (0.34 g; 5 mmol) in 15 ml of acetonitrile was added dropwise a solution of **10** (3.30 g; 10 mmol) in 20 ml of acetonitrile over a period of 0.5 h. A white solid began to precipitate during the addition. The mixture was stirred for 1.5 h at room temperature and then 2 ml of triethylamine was added. The precipitate was collected, washed with acetonitrile, and dried, yielding 1.95 g (71%) of **13**, mp 229—230 °C, undepressed on admixture with the products from **7** and **10**.

*2-[5-(1,3-Benzodithiol-2-yl)-2-pyrrolyl]-1,3-benzodithiolylium Tetrafluoroborate (**17**).* A solution of **10** (3.9 g; 12 mmol) in 25 ml of acetonitrile was added dropwise to a stirred and ice-cooled suspension of **8** (3.72 g; 10 mmol) in acetonitrile (80 ml) over a period of 20 min. The mixture was warmed to room temperature for 20 min and stirred for an additional 45 min. Ether (150 ml) was added to the mixture to precipitate the product. The precipitate was collected and washed with ether to give 2.32 g (51%) of **17** as yellowish-brown crystals. This was purified by dissolution in acetonitrile and reprecipitation with ether (attempted recrystallization from several solvents produced tarry materials). **17**; mp 179—180 °C (dec.), IR (Nujol) 3405 (NH) and 1000—1100 cm^{-1} (BF_4^-). Found: C, 46.50; H, 2.63; N, 2.87%. Calcd for $C_{18}H_{12}NS_4BF_4$: C, 47.27; H, 2.64; N, 3.06%.

*6-(1,3-Benzodithiol-2-yl)-2,3-benzo-5-aza-1,4-dithiafulvalene (**18**).* Triethylamine (1.5 ml) was added with stirring to an ice-cooled solution of **17** (1.08 g; 2.4 mmol) in acetonitrile (30 ml). Immediately, a yellow precipitate of **18** was separated out, which was then collected and washed with acetonitrile to give 0.85 g (98%) of **18**, which melted at 147—151 °C (decomp.). The crude material gave satisfactory results upon elemental analysis. Found: C, 58.50; H, 3.06; N, 3.79; S, 34.39%. Calcd for $C_{18}H_{11}NS_4$: C, 58.54; H, 3.00; N, 3.79; S, 34.66%.

***17** from **18** by Treatment with Tetrafluoroboric Acid.* **18** (185 mg; 0.5 mmol) was added with stirring to 4 ml of ice-cooled tetrafluoroboric acid. The mixture was stirred for 0.5 h at 0 °C. The yellowish-brown precipitate of **17** was filtered, washed with ether, and dried. It weighed 222 mg (97%).

*Reaction of **9** and **10**.* To a stirred and ice-cooled solution of **9** (1.24 g; 5 mmol) in 15 ml of acetonitrile was added dropwise a solution of **10** (1.65 g; 5 mmol) in 15 ml of acetonitrile over a period of 25 min. Stirring was continued for 2.5 h while the mixture was brought to room temperature. The precipitate was collected by filtration to give 0.5 g of a brown solid. The filtrate was diluted with 200 ml of ether and filtration of the resulting precipitate gave an additional 0.7 g of the brown solid; the IR spectrum of the solid had characteristic absorptions due to NH and BF_4^- groupings (3200 and 1000—1100 cm^{-1}), but did not result in a pure material upon repeated recrystallization. The filtrate was evaporated. The residue along with the brown solid from the reaction mixture were subjected to chromatography on silica gel. Elution with carbon tetrachloride gave 0.68 g of triphenylmethane, 0.50 g (17%) of 2,5-dimethyl-3-(1,3-benzodithiol-2-yl)-4-tritylpyrrole (**19**), and small amounts of a few unidentified products. **19**; mp 258—261 °C (dec.) (from benzene), colorless granules, IR (Nujol) 3360 cm^{-1} (NH). Found: C, 78.52; H, 5.55; N, 2.72%. Calcd for $C_{32}H_{27}NS_2$: C, 78.51; H, 5.56; N, 2.86%.

*Reaction of **9** with **14**.* 1.44 g (6 mmol) of **14** dissolved in 15 ml of acetonitrile was added dropwise to a stirred and ice-cooled suspension of 1.23 g (5 mmol) of **9** in 15 ml of acetonitrile over a period of 15 min. Stirring was continued for 2 h while the mixture was brought to room temperature. Filtration of the resulting precipitate and washing with acetonitrile gave 0.71 g (36%) of **21**. Ether (250 ml) was added to the brown filtrate and the precipitate was filtered to give 0.68 g of orange crystals which melted at 186—192 °C (dec). NMR analysis showed that the precipitate consisted of **20a** and **22** in a ratio of *ca.* 4:3 (in 20 and 15% yield, respectively). 2,5-Dimethyl-3,4-bis(1,3-benzodithiol-2-yl)pyrrole (**21**); mp 242—245 °C (dec) (from benzene), faint pale yellow granules, IR (Nujol) 3350 cm^{-1} (NH). Found: C, 60.45; H, 4.34; N, 3.15%. Calcd for $C_{20}H_{17}NS_4$: C, 60.11; H, 4.29; N, 3.51%.

***21** from **6** and 2,5-Dimethylpyrrole.* 2,5-Dimethylpyrrole (0.48 g; 5 mmol) and **6** (2.40 g; 10 mmol) were dissolved in 10 ml of acetic acid. The mixture was allowed to stand at room temperature overnight. The resulting crystalline precipitate was filtered and washed with methanol. The near-white solid weighed 1.86 g (93%), mp 242—245 °C (dec), undepressed upon admixture with a specimen from **9** and **14**.

*2-[2,5-Dimethyl-4-(1,3-benzodithiol-2-yl)-3-pyrrolyl]-1,3-benzodithiolylium Tetrafluoroborate (**22**).* To a suspension of **21** (1.67 g; 4.2 mmol) in acetonitrile (25 ml) was added dropwise a solution of **14** (1.44 g; 6 mmol) in 15 ml of acetonitrile over a period 20 min. The mixture was stirred overnight and the resulting precipitate was filtered and washed with ether to give 1.06 g (52%) of **22**. Dilution of the filtrate with ether (150 ml) gave additional **22** (0.48 g; 24%). **22**: mp 223—226 °C (dec) (from acetonitrile), orange needles, IR (Nujol) 3250 (NH) and 1000—1100 cm^{-1} (BF_4^-). Found: C, 49.52; H, 3.35; N, 2.80; S, 26.79%. Calcd for $C_{20}H_{16}NS_4BF_4$: C, 49.48; H, 3.32; N, 2.89; S, 26.42%.

*5,7-Dimethyl-8-(1,3-benzodithiol-2-yl)-2,3-benzo-6-aza-1,4-dithiafulvalene (**23**).* 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU) (0.5 ml) was added with stirring to an ice-cooled suspension of formation of **22** (0.20 g; 0.41 mmol) in 10 ml of acetonitrile. Immediately, a bright orange precipitate of **23** appeared with the disappearance of **22**. Filtration of the precipitate and washing with acetonitrile (5 ml) gave 0.15 g (92%) of **23**, mp 204—209 °C (dec), which gave satisfactory results upon elemental analysis without further purification. Found: C, 60.55; H, 3.99; N, 3.51%. Calcd for $C_{20}H_{15}NS_4$: C, 60.45; H, 3.81; N, 3.53%.

*2-(2-Pyrrolyl)-1,3-benzodithiolylium Perchlorate (**15b**).* Salt **24** (0.60 g; 2 mmol) was added in small portions to a stirred solution of pyrrole (134 mg; 2 mmol) in acetonitrile (20 ml). The mixture was stirred for 3 days. The precipitate was filtered, washed with ether, and dried to give 0.53 g (84%) of **15b**, mp>230 °C (dec) (from acetonitrile-ether), yellowish-brown needles. Found: C, 41.61; H, 2.54; N, 4.47; S, 20.28%. Calcd for $C_{11}H_8NS_2ClO_4$: C, 41.57;

H, 2.54; N, 4.41; S, 20.18%.

*2-(2,5-Dimethyl-3-pyrrolyl)-1,3-benzodithiolylium Perchlorate (**20b**).* A mixture of **24** (0.60 g; 2 mmol) and 2,5-dimethylpyrrole (0.19 g; 2 mmol) was stirred overnight at room temperature. The precipitate was filtered, washed with ether, and dried to give 0.35 g (51%) of **20b**. Dilution of the filtrate and collection of the resulting precipitate gave another crop of **20b** (0.12 g; 16%). **20b**; mp 225—227 °C (from acetonitrile), yellow needles, IR (Nujol) 3200 cm^{-1} (NH). Found: C, 45.14; H, 3.50; N, 4.07; S, 18.77%. Calcd for $C_{13}H_{12}NS_2ClO_4$: C, 45.15; H, 3.50; N, 4.05; S, 18.54%.

*2-(2-Pyrrolyl)-1,3-dithiolylium Iodide (**29**).* A mixture of pyrrole (0.27 g; 4 mmol) and **28** (1.10 g; 4 mmol) in acetonitrile (40 ml) was stirred for 2 days at room temperature. The precipitate was collected, washed with ether, and dried to give 1.08 g (92%) of **29**, mp 190—191 °C (dec) (from acetonitrile) yellowish-brown scales, IR (KBr), 3050, 1550, 1425, 1400, 1140, 1050, and 862 cm^{-1}. Found: C, 28.54; H, 2.05; N, 4.35; S, 21.71%. Calcd for $C_7H_6INS_2$: C, 28.48; H, 2.05; N, 4.75; S, 21.73%.

*2-(2,5-Dimethyl-3-pyrrolyl)-1,3-dithiolylium Iodide (**30**).* 2,5-Dimethylpyrrole (0.57 g; 6 mmol) and **28** (1.66 g; 6 mmol) was stirred in 40 ml of acetonitrile at room temperature for 2 days. The precipitate was filtered, washed with acetonitrile, and dried to give 1.60 g (83%) of **30**, mp 214—219 °C (dec) (from acetonitrile), yellowish-brown needles, IR (KBr) 3050, 2980, 1605, 1430, 1350, 1260, 1020, 920, 780, 725, and 710 cm^{-1}. Found: C, 33.46; H, 3.09; N, 4.48; S, 19.80%. Calcd for $C_9H_{10}INS_2$: C, 33.44; H, 3.12; N, 4.33; S, 19.84%.

*2,3-Benzo-5-aza-1,4-dithiafulvalene (**25**) and Its Charge-transfer Salt, **26**, with DDQ.* DBU (0.2 ml) was added to a stirred and ice-cooled suspensin of **15b** (0.20 g; 0.6 mmol) in acetonitrile (10 ml). Immediately, the formation of a yellow precipitate of **25** occurred with the disappearance of **15b**. After 5 min, the precipitate was filtered quickly, washed with acetonitrile, and dried to give 40 mg (31%) of **25**, mp>130 °C (dec) Found: C, 60.81; H, 3.25; N, 6.15; S, 29.54%. Calcd for $C_{11}H_7NS_2$: C, 60.83; H, 3.25; N, 6.45, S, 29.47%. DDQ (*ca.* 0.2 g) was added to the combined filtrate and washings. The resulting dark violet precipitate was filtered, washed with methanol, and dried to give 163 mg (37%) of **26**, which melted at 225—226 °C (dec). IR (Nujol) 2200 (CN), 1570, and 1550 cm^{-1}. Found: C, 50.80; H, 1.87; N, 9.11%. Calcd for $C_{19}H_7O_2Cl_2N_3S_2$: C, 51.35; H, 1.59; N, 9.46%.

*5,7-Dimethyl-2,3-benzo-6-aza-1,4-dithiafulvalene (**27**).* DBU (0.2 ml) was added to a stirred and ice-cooled suspension of **20b** (173 mg; 0.5 mmol) in 6 ml of acetonitrile. The precipitate was filtered after 5 min, washed with acetonitrile, and dried to give 83 mg (68%) of **27** as orange crystals, which melted at 182—185 °C (dec). Found: C, 63.50; H, 4.54; N, 5.70; S, 25.64%. Calcd for $C_{13}H_{11}NS_2$: C, 63.67; H, 4.52; N, 5.71; S, 26.10%.

*5-Aza-1,4-dithiafulvalene (**2a**).* DBU (0.5 ml) was added with stirring to an ice-cooled suspension of **29** (0.40 g; 1.36 mmol) in 7 ml of acetonitrile. Immediately, the mixture turned dark red with the disappearance of **29**. After 10 min, the mixture was diluted with 100 ml of ether, washed with saturated an aqueous sodium chloride solution (50 ml × 5), and dried. Evaporation of the ether left a red oily residue, to which hexane (10 ml) was added. It was allowed to stand in a refrigerator for 2 days. The oil crystallized, and was filtered and washed with hexane to give 0.18 g (82%) of **2a** as orange needles, which melted at 85—87 °C. IR (KBr) 1538, 1500, 1355, 1012, 842, and 740 cm^{-1}. Found: C, 50.21; H, 3.05; N, 8.26; S, 38.15%. Calcd for $C_7H_5NS_2$: C, 50.31; H, 3.02; N, 8.38; S, 38.30%.

*5,7-Dimethyl-6-aza-1,4-dithiafulvalene (**3b**).* To a stirred and ice-cooled suspension of **30** (323 mg; 1 mmol) was added DBU (0.2 ml). Immediately, the mixture turned red with the disappearance of **30** and the separation of an orange precipitate. After 10 min, the precipitate was filtered, washed with acetonitrile, and dried to give 117 mg (70%) of **3b** as orange crystals, which melted at 105—109 °C (dec). IR (KBr) 2920, 1535, 1475, 1315, 1270, 1000, 980, and 700 cm^{-1}. Found: C, 55.17; H, 4.64; N, 6.88; S, 32.71%. Calcd for $C_9H_9NS_2$: C, 55.38; H, 4.65; N, 7.18; S, 32.79%. The addition of tetracyanoquinodimethane (TCNQ) (*ca.* 0.1 g) to the filtrate gave a small amount of a greenish-black precipitate, which was assumed to be a charge-transfer salt of **3b** and TCNQ.

Structure-taste Relationship of Novel α-L-Aspartyl Dipeptide Sweetners*

Muneji Miyoshi, Ken-ichi Nunami, Hiroshi Sugano, and Toshiyuki Fujii

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co. Ltd., Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received August 18, 1977)

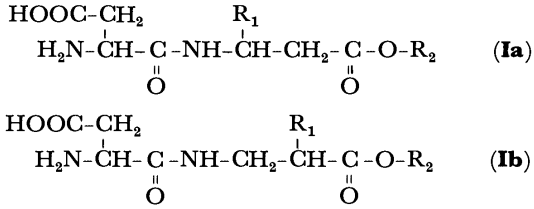
A sweetness potency was found in novel α-L-aspartyl dipeptide analogs which were quite stable on heating in an aqueous solution. The insertion of a methylene group into the peptide chain of α-L-aspartyl dipeptide esters mostly decreased the potency of the sweetness. However, the further exchange of the carbonyl and oxygen functions with each other on the ester group of a *C*-terminal β-alkyl-β-aminopropionic acid was found to increase the sweetness. Thus, *N*-(α-L-aspartyl)-*O*-pivaroyl-D-alaninol, *N*-(α-L-aspartyl)-*O*-cyclobutylcarbonyl-D-alaninol and *N*-(α-L-aspartyl)-*O*-cyclopropylcarbonyl-D-alaninol were all more than 200 times as sucrose.

Since the discovery[1] of the potent sweet taste of the α-L-aspartyl-L-phenylalanine methyl ester (APM), the special interest in dipeptide sweetners has increased and a large number of analogs related to APM have been synthesized. In the light of the data on the structure-taste relationship so far accumulated,[2-6] L-aspartic acid with unsubstituted α-amino and β-carboxyl groups is rather essential for sweetness. However, a considerable modification of a *C*-terminal amino acid may increase the sweetness when both the steric and hydrophobic properties fall into the requirements of a receptor site. In fact, Fujino[7] replaced the phenylalanine moiety with aminomalonates and found that α-L-aspartylaminomalonic acid with methyl fenchyl diester groups has, surprisingly, a potency 22000—33000 times as sweet as sucrose.

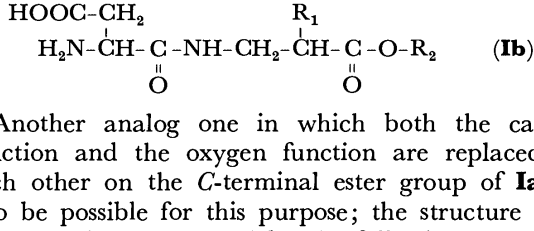
Some of the α-L-aspartyl-D-alanyl and α-L-aspartyl-D-seryl dipeptides which have relatively larger ester groups on the *C*-terminal D-amino acid have also been found to show considerable sweetness. It has been elucidated that both of the substituents on the α-carbon of a *C*-terminal amino acid should be strictly restricted as to sterical requirements; one is "a smaller part", while the other is "a larger part" with a hydrophobic group. When both of the parts involve a carboxyl group such as the aminomalonates, the potency of the sweetness of the dipeptide is greater than any other analogs so far reported. We are interested in such a role of the carboxyl group as the third hydrophobic group.

On the other hand, the dipeptide ester has a serious disadvantage in its practical use as a low-calory sweetner. On heating the aqueous solution of a dipeptide ester, the presence of the ester group readily causes the formation of a piperazinedione, which in turn leads to a loss of sweetness. In order to exclude the cyclization of the dipeptide esters to piperazinedione, it would be of interest to synthesize a series of dipeptide analogs whose backbones are elongated by one more methylene group.

For inserting a methylene group, two potential positions are conceivable with respect to the α-L-aspartyl dipeptide ester, *i.e.*, two types of dipeptide esters with the following structures, (**Ia** and **Ib**), respectively:

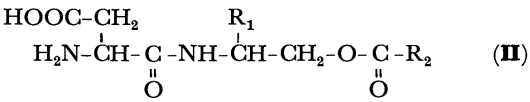


(**Ia**)



(**Ib**)

Another analog one in which both the carbonyl function and the oxygen function are replaced with each other on the *C*-terminal ester group of **Ia** may also be possible for this purpose; the structure of this type may be represented by the following general formula (**II**):



(**II**)

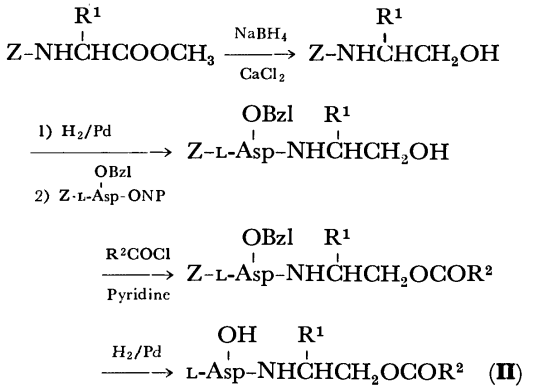
In the present paper, we wish to report on the structure–taste relationship of α-L-aspartyl dipeptide analogs of the above three types; all of them have both an elongated peptide chain and a carboxyl group in the molecule.

Results and Discussion

Synthesis of α-L-Aspartyl Dipeptide Analogs. The types of **Ia** and **Ib** correspond to the dipeptide esters in which a *C*-terminal amino acid is replaced by either β-alkyl-β-amino-propionic acid or α-alkyl-β-aminopropionic acid respectively. Several β-alkyl-β-aminopropionic acids were synthesized from the corresponding diazoketones according to the method reported by Shiba.[8] α-Alkyl-β-aminopropionic acids were obtained by the condensation of *N*-(chloromethyl)phthalimide with the diethyl alkylmalonates according to the method reported by Buco[9] and Böhme.[10] Some α-aminomethylmalonic acid esters were synthesized *via* a new method[11] recently developed in our laboratory; the condensation of alkylmalonate with *N*-(benzyloxycarbonyl)-acetoxymethylamine, which had been prepared from benzyloxycarbonylglycine by an electrochemical oxidation. The synthesis of the desired dipeptide esters of **Ia** and **Ib** was carried out by the DCC coupling of O^4-benzyl *N*-benzyloxycarbonyl-α-L-aspartate with β-alkyl-β-aminopropionic acid or α-alkyl-β-aminopropionic acid respectively as an amino component, followed by catalytic hydrogenolysis. 2-Amino-D-alkanols were derived from the corresponding *N*-benzyloxycarbonyl

* A part of this work was presented at the 34th National Meeting of the Chemical Society of Japan, Hiratsuka, April 4, 1976.

D-amino acid esters by $NaBH_4$ reduction,[12] followed by catalytic hydrogenolysis After coupling with O^1-*p*-nitrophenyl O^4-benzyl *N*-benzyloxycarbonyl-α-L-aspartate, *O*-acylation was carried out with various acyl halides in pyridine to give protected *O*-acyl-2-(α-L-aspartylamino)-alkanols. Subsequent hydrogenolysis afforded the desired dipeptide esters of the **II** type, as is shown in Scheme 1.



Scheme 1.

Stability in an Aqueous Solution. All of the α-L-aspartyl dipeptide analogs synthesized in the present study were found to be quite stable on heating in an aqueous solution. Table 1 presents the results of the stability test between APM and *N*-(α-L-aspartyl)-*O*-cyclobutylcarbonyl-D-alaninol (**46**), which is 220 times as sucrose. Aqueous solutions and the buffer solutions (pH 4 and pH 7), each containing 0.2% of one of the above compounds, were heated in a sealed tube at 100 °C for 1 h. The unchanged amounts of the compounds in each solution were determined by means of an amino-acid analyzer. All of the taste panelers felt that the solution of **46** was substantially unchanged in taste after heating as compared with the corresponding unheated solutions.

Table 1. Unchanged amounts after heating each solution at 100 °C for 1 h

Solution	APM (%)	**46** (%)
Water	94.5	96.6
pH 4 soln.	91.1	97.0
pH 7 soln.	9.2	85.8

Structure-taste Relationship. It has widely been accepted that in the structure of α-L-aspartyl dipeptide esters a side chain (R_1) of a *C*-terminal amino acid must be a larger hydrophobic group when the configuration is L-form, while the D-form is required when R_1 is a smaller one. In a series of APM, the ester group corresponds to the "smaller part" and the sweetness decreases as an alkyl chain (R_2) of the ester group becomes larger. In a series of α-L-aspartyl-D-alanine esters, the ester group comes to serve as the "larger part", thus, there would be room to elongate the ester group by the insertion of a methylene group within the allowable steric requirements mentioned above.

However, the elongation of a peptide chain would cause its bond angle to be more or less distorted and make it difficult to maintain the same conformation, even when both the configuration and the bulkiness of R_1 and R_2 are equal to those of the parent α-L-aspartyl dipeptide esters. As a typical example of how to estimate briefly such a steric effect of distortion, Table 2 shows a comparison of the sweetness among the analogs of L-Asp–D-Ala–OPr, all of which have, as a whole, the same chain length. Compound **Ib** scarcely showed any sweetness, probably because the insertion of a methylene into this position would effect a conformational change at both the side chain and the ester group of the *C*-terminal amino acid. On the contrary, in the cases of **Ia** and **II**, such a distortion can occur only at the position of the ester group; thus, a less conformational change would result in the exhibition of a considerable sweetness. It is of interest that **II** shows a greater sweetness than **Ia**. A CPK model of L-Asp–D-Ala–OPr is found to resemble the former rather than the latter because of the exchange of the carbonyl function and the oxygen atom.

Table 2. Analogs of L-Asp-D-Ala-OPr

Type	L-Asp-X	Sweetness
D-Ala-OPr	-NH-CH(CH₃)-C(=O)-O-CH₂-CH₂-CH₃	170[3]
Ia (**1**)	-NH-CH(CH₃)-CH₂-C(=O)-O-CH₂-CH₃	20
Ib (**18**)	-NH-CH₂-CH(CH₃)-C(=O)-O-CH(CH₃)₂	2
II (**34**)	-NH-CH(CH₃)-CH₂-O-C(=O)-CH₂-CH₂-CH₃	100

None of the analogs in the types of **Ia** and **Ib** synthesized in the present study showed a potency than 20 times as sucrose. Further, α-L-aspartyl-aminomethylmalonates, which involve one more methylene group in the skeleton of α-L-aspartyl-amino-malonates reported by Fujino, had no sweetness at all. The results are summarized in Tables 3 and 4. Mazur[3] synthesized various L-aspartic acid amides and found that most of them showed less sweetness. The **Ib** type should, rather, be regarded as a kind of L-aspartic acid amide, one which has a branched primary amine with one or two carbonyl groups among its substituents. Taking the above observations into account, we mainly focused on the type of **II** and synthesized the analogs with various chain lengths at the ester group.

The potencies of the sweetness of *O*-acyl-2-(α-L-aspartylamino)alkanols (Type **II**) are listed in Table 5. The side chain (R_1) of 2-amino-D-alkanols corresponds to the "smaller part," and when R_1 is methyl, that is, D-alaninol, most of the analogs showed a considerable sweetness with a good aftertaste, like sucrose. In this case, the potency of the sweetness tends to in-

crease as an alkyl group (R_2) of the *O*-acyl residue—"a larger part"—becomes bulky with a branched short chain: *iso*-propyl and *t*-butyl isomers (**38**, **44**) are sweeter than those with less branched chains (**37**, **41**, **42**, **43**). Cycloalkyl isomers are also sweet. Thus, among the series of D-alaninol synthesized, *O*-pivaroyl (**44**) and *O*-cyclobutylcarbonyl (**46**) analogs become 240 and 220 times as sweet as sucrose respectively. When R_2 is a linear alkyl group, the potency of the sweetness decreases as the carbon number of an alkyl chain becomes greater, showing that the chain length of the dipeptide molecule must be strictly restricted; the order of sweetness is ethyl (**34**)> methyl (**33**)>butyl (**41**). A similar result was observed in the cycloalkyl groups: cyclobutyl (**46**)> cyclopropyl (**40**)>cyclopentyl (**49**), and the analogs with 3,3-dimethylcyclobutyl (**50**), cyclohexyl (**51**), or phenyl (**52**) were not sweet any more.

In a series of D-serinol, in which R_1 is the hydroxymethyl group, R_2 must be rather small to exhibit a considerable sweetness: the potency becomes 135 times as sucrose when R_2 is ethyl (**54**) or cyclopropyl (**55**), while it decreases as R_2 becomes bulky (**60** and **61**). Ariyoshi[5] reported on the dipeptide esters of β-hydroxy α-(α-L-aspartylamino)acids and found that L-Asp–D-Ser–OPr was the sweetest (320 times as sucrose). It is noted that this compound has the same chain length on the *C*-terminal amino acid as our *N*-(α-L-aspartyl)-*O*-propionyl-D-serinol (**54**).

In the cases of 2-amino-1-butanol (R_1; ethyl, **62**-**68**), *O*-methylserinol (R_1; methoxymethyl, **69**, **70**), and valinol (R_1; *iso*-propyl, **71**—**77**). the potency of the sweetness tends to decrease as compared with those of D-alaninol and D-serinol, though a tendency similar to that described above was observed concerning the requirement of the size of R_2. It was found that leucinol (**80**), isoleucinol (**81**), and phenylalaninol (**82**), which have such bulky groups on the side chain, showed no sweetness, not even when R_2 was the methyl group.

On the contrary, 2-aminoethanol (R_1; H), which has no side chain and which is the smallest analog

of this series, was found to show some sweetness (**26**—**32**). It is noted that none of the *O*-acyl-2-(α-L-aspartylamino)-L-alkanol synthesized was sweet, showing that the configuration of the *C*-terminal amino acid must be D-form to exhibit the taste.

Summarizing the above observations, we may derive the following conclusions concerning the structure-taste relationship of our L-aspartyl dipeptide sweetners: (1) the insertion of a methylene group into the peptide chain generally causes a significant disadvantage; (2) the further exchange of the carbonyl and oxygen functions on the ester group of a *C*-terminal α-alkyl-β-aminopropionic acid has rather a good effect on exhibiting sweetness; (3) in the series of *O*-acyl-2-(α-L-aspartylamino)alkanols, the structural requirements for the mutual sizes between the side chain (R_1) and the alkyl group (R_2) of the *O*-acyl residue are nearly equal to those previously proposed for the structure-taste relationship of α-L-aspartyl dipeptide esters, and (4) the configuration of the 2-aminoalkanol esters should be D-form, the same as the corresponding α-L-aspartyl-D-alanine esters.

Experimental

The melting points were determined using a Yamato melting-point apparatus and were uncorrected. The IR spectra were measured with a Shimadzu IR-27G infrared spectrometer; the H^1 NMR spectra, with a Hitachi Perkin-Elmer R-20A high-resolution NMR spectrometer, using tetramethylsilane as the internal standard, and the optical rotations, with a Perkin-Elmer 141 polarimeter. The quantitative determination on peptides was performed by the use of a Hitachi KLA-3B automatic amino-acid analyzer.

*Typical Procedure for the Preparation of β-Alkyl-β-amino-propionic Acid and α-Alkyl-β-aminopropionic Acid Derivatives (**Ia** and **Ib**).* *D-3-(Benzyloxycarbonylamino)butyric Acid*: Methyl D-3-(benzyloxycarbonylamino)butyrate was obtained as a colorless oil from *N*-benzyloxycarbonyl-D-alanine (8.92 g) by means of the previously reported method.[8] This methyl ester was saponified with methanolic sodium hydroxide in the usual manner to give the title compound as colorless needles, which were then recrystallized from ethyl acetate-petroleum ether; yield, 4.0 g (42.2%); mp 104—104.5 °C; $[\alpha]_D^{22}$ −5.5° (*c* 1, acetone); IR (Nujol) 3300, 1685, 1550 cm^{-1}; NMR ($CDCl_3$) δ 1.24 (d, 3H, *J*=6 Hz), 2.54 (d, 2H, *J*=6 Hz), 3.8—4.4 (m, 1H), 5.10 (s, 2H), 5.0—5.8 (broad, 1H), 7.32 (s, 5H), 7.2—7.5 (broad, 1H); Found: C, 60.81; H, 6.42; N, 5.81%. Calcd for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

DL-2-Methyl-3-(benzyloxycarbonylamino)propionic Acid: Diethyl phthalimidomethyl-methylmalonate was prepared from diethyl methylmalonate (21 g in THF 50 ml) with 65% sodium hydride (4.1 g) and *N*-(chloromethyl)phthalimide (19.5 g in THF 150 ml) by means of the previously reported method.[10] These crystals obtained were recrystallized from ethyl acetate-hexane; yield, 28.6 g (85.5%); mp 98—99 °C. The hydrolysis of the compound obtained above was followed by column chromatography (Dianion SK 1b, H^+ form). The eluate with 5% aqueous ammonia was concentrated to dryness *in vacuo* to afford DL-2-methyl-3-aminopropionic acid as colorless crystals, which were used without further purification. The benzyloxycarbonylation of this compound was carried out by Schotten-Baumann's method to afford the title compound as colorless needles, which were then recrystallized from ethyl acetate-hexane; yield, 7.0 g (73.8%); mp 65—66.5 °C; IR (Nujol) 3340, 1715, 1685 cm^{-1}; NMR ($CDCl_3$) δ 1.23 (d, 3H, *J*=7 Hz), 2.4—3.1 (m, 1H), 3.40 (t, 2H, *J*=7 Hz), 5.10 (s, 2H), 5.1—5.6 (broad, 1H), 7.33 (s, 5H), 10.70 (s, 1H); Found: C, 60.68; H, 6.45; N, 5.79%. Calcd for $C_{12}H_{15}NO_4$: C, 60.72; H, 6.37; N, 5.90%.

Ethyl D-3-[(N-Benzyloxycarbonyl-O⁴-benzyl-α-L-aspartyl)-amino]butyrate: Ethyl D-3-(benzyloxycarbonylamino)butyrate was obtained as a colorless oil by treating D-3-(benzyloxycarbonylamino)butyric acid (2.73 g) with thionyl chloride (2 ml) in ethanol (10 ml). The oil was then dissolved in a mixture of *N*,*N*-dimethylformamide (5 ml) and tetrahydrofuran (20 ml), and the solution was cooled to 0 °C. To this were added O^4-benzyl *N*-benzyloxycarbonyl-α-L-aspartate (3.57 g), 1-hydroxybenzotriazole (1.35 g), and dicyclohexylcarbodiimide (2.1 g). The reaction mixture was stirred for 1 h at 0 °C and for 5 h at room temperature, and then the insoluble materials were filtered off. The filtrate was concentrated to dryness *in vacuo*, and the residue was dissolved in ethyl acetate (50 ml). The solution was washed with aqueous saturated sodium hydrogencarbonate (10 ml), 1% hydrochloric acid (10 ml), and water (10 ml), and then dried over magnesium sulfate. The solution was concentrated to dryness *in vacuo*, and the oily residue thus obtained was purified by chromatography on silica gel (80 g, Kiesel gel 60) with benzene-ethyl acetate (9:1) to afford the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate-petroleum ether; yield, 2.7 g (57.4%); mp 91—92 °C; $[\alpha]_D^{22}$ −7.0° (*c* 0.5, MeOH), IR (Nujol) 3310, 1730, 1695, 1650 cm^{-1}; NMR ($CDCl_3$) δ 1.16 (d, 3H, *J*=7 Hz), 1.22 (t, 3H, *J*=7 Hz), 2.45 (d, 2H, *J*=6 Hz), 2.5—3.27 (m, 2H), 4.11 (quartet, 2H, *J*=7 Hz), 4.1—4.8 (m, 2H), 5.12 (s, 4H), 5.92 (broad d, 1H, *J*=9 Hz), 6.89 (broad d, 1H, *J*=9 Hz), 7.33 (s, 10H); Found: C, 63.77; H, 6.53; N, 5.86%. Calcd for $C_{25}H_{30}N_2O_7$: C, 63.82; H, 6.43; N, 5.95%.

*Ethyl D-3-(α-L-Aspartylamino)butyrate (**1**)*: Ethyl D-3-[(*N*-benzyloxycarbonyl-O^4-benzyl-α-L-aspartyl)amino]butyrate (1.2 g) was dissolved in methanol (20 ml). The hydrogenolysis of this compound was then carried out over palladium black (0.1 g) for 2 h at room temperature under an atmospheric pressure of hydrogen. After the catalyst had been filtered off, the filtrate was concentrated to dryness *in vacuo* to give **1** as crystals, which were then triturated with ether and filtered; yield 0.54 g (85.6%); mp 150—154 °C; $[\alpha]_D^{22}$ −9.7° (*c* 0.5, DMF); IR (Nujol) 3300, 1730, 1660 cm^{-1}; NMR (DMSO-d_6) δ 1.15 (d, 3H, *J*=7 Hz), 1.21 (t, 3H, *J*=7 Hz), 2.2—2.7 (m, 4H), 3.6—4.4 (m, 2H), 4.10 (quartet, 2H, *J*=7 Hz), 5.49 (s, 3H), 8.2—8.7 (broad, 1H); Found: C, 48.59; H, 7.51; N, 11.20%. Calcd for $C_{10}H_{18}N_2O_5$: C, 48.77; H, 7.36; N, 11.37%.

*Typical Procedure for the Preparation of (Aminomethyl)-Malonic Acid Derivatives (**Ib**).* *N-(Benzyloxycarbonyl)acetoxymethylamine*: Benzyloxycarbonylglycine (14.6 g) was dissolved in acetic acid (80 ml), to which we then added solium acetate (2.05 g). The solution was electrolyzed at 15—20 °C using 3×4 cm^2 of the carbon anode which was placed 0.5 cm apart from the carbon cathode. An electrolysis current was maintained at 1A during the electrolysis. After 6 h, the electrolyzed solution was evaporated to dryness *in vacuo*. The oily residue was dissolved in ethyl acetate, and the solution was washed with aqueous saturated sodium hydrogencarbonate and water, and then dried over magnesium sulfate. This solution was concentrated to dryness *in vacuo* to give the title compound as a colorless oil; yield, 12.7 g (79.4%); IR (film) 3340, 1730, 1520 cm^{-1}; NMR ($CDCl_3$), δ 2.0 (s, 3H), 5.13 (s, 2H), 5.16 (d, 2H), 5.9—6.5 (broad s, 1H), 7.35 (s, 5H).

Dicyclohexylammonium Cyclopentyl Malonate: The condensation of malonic acid (20.8 g) was carried out under reflux in benzene (150 ml) containing *p*-toluenesulfonic acid monohydrate (3.8 g), using a Dean-Stark's apparatus, to give dicyclopentyl malonate as a colorless oil. This compound was subsequently saponified with 2.5 M methanolic potassium hydroxide (80 ml) at room temperature for 2 h. After acidification with 6 M hydrochloric acid, the solution was extracted with ether (300 ml). The organic layer was washed with water (30 ml) and then dried over magnesium sulfate. To the solution we added dicyclohexylamine (36.2 g) to afford the title compound as colorless needles; yield, 32.6 g (46.2%); mp 113—115 °C; IR (Nujol) 1735, 1635, 1570 cm^{-1}; NMR (DMSO-d_6), δ 0.7—2.3 (m, 28H), 2.65—3.20 (broad, 2H), 2.94 (s, 2H), 4.85—5.20 (broad, 1H), 6.8—7.4 (broad, 2H); Found: C, 67.59; H, 9.98; N, 3.96%, Calcd for $C_{20}H_{35}NO_4$: C, 67.30; H, 10.11; N, 4.03%.

Cyclopentyl Methyl Malonate: Dicyclohexylammonium cyclopentyl malonate (10.6 g) was suspended in ether (200 ml), and 1 M sulfuric acid (20 ml) was added to the mixture under stirring. The organic layer was washed with water (20 ml) and dried over magnesium sulfate. The solution was concentrated to dryness *in vacuo*, the oily residue was dissolved in ether (50 ml), and then diazomethane in ether was added to this solution. The reaction mixture was concentrated to dryness *in vacuo* to afford the title compound as a colorless oil, which was distilled at 93 °C at 3 mmHg; yield, 4.6 g (82.4%); IR (film) 1730 cm^{-1}; NMR ($CDCl_3$), δ 1.5—2.1 (m, 8H), 3.32 (s, 2H), 3.72 (s, 3H), 5.05—5.4 (broad, 1H).

Cyclopentyl Methyl (Benzyloxycarbonylaminomethyl)malonate: *N*-(Benzyloxycarbonyl)acetoxymethylamine (2.23 g) was dissolved in *N,N*-dimethylformamide (10 ml), after which the mixture was cooled to 0 °C. To this we added cyclopentyl methyl malonate (1.86 g) and 65% sodium hydride (0.4 g) in *N,N*-dimethylformamide under vigorous stirring. The reaction mixture was stirred at room temperature for 15 h and then concentrated to dryness *in vacuo*. The oily residue thus obtained was dissolved in ethyl acetate, and the solution was washed with water saturated with sodium hydrogencarbonate, 1% hydrochloric acid, and water, and then dried over magnesium sulfate. The dried solution was concentrated to dryness *in vacuo*, and the residue was purified on a silica gel column (80 g, Kiesel gel 60), using benzene–ethyl acetate (95:5) as the eluate, to give the title compound as a colorless oil; yield, 2.84 g (79.3%); IR (film) 3370, 1730, 1520 cm^{-1}; NMR ($CDCl_3$), δ 1.4—1.9 (m, 8H), 3.65 (2H), 3.72 (s, 3H), 5.1 (s, 2H), 5.1—5.7 (m, 3H), 7.36 (s, 5H).

Cyclopentyl Methyl (N-Benzyloxycarbonyl-O⁴-benzyl-α-L-aspartylamino)malonate: Cyclopentyl methyl (benzyloxycarbonylaminomethyl)malonate (1.1 g) and oxalic acid dihydrate (0.2 g) were dissolved in methanol (20 ml). To this solution we added palladium black (0.1 g), and the hydrogenolysis was carried out under an atmospheric pressure of hydrogen. After the catalyst had been filtered off, the filtrate was concentrated to dryness *in vacuo* to give cyclopentyl methyl (aminomethyl)malonate as crystalline hemioxalic acid salt.

These crystals, O^1-*p*-nitrophenyl O^4-benzyl *N*-benzylocycarbonyl-α-L-aspartate (1.43 g), and 1-hydroxybenzotriazole (0.44 g), were dissolved in *N,N*-dimethylformamide (20 ml), after which the solution was cooled to 0 °C. Into this triethylamine (0.42 ml) was stirred. The reaction mixture was stirred at the same temperature for 30 min, and then diluted with ethyl acetate (100 ml). The solution was washed with aqueous saturated sodium hydrogencarbonate, 1% hydrochloric acid, and water, and then dried over magnesium sulfate. The dried solution was concentrated to dryness *in vacuo*, and the oily residue thus obtained was purified on a silica gel column (45 g, Kiesel gel 60), using benzene–ethyl acetate (83:17) as the eluate, to afford the title compound as a colorless oil; yield, 0.44 g (26.0%); IR (film) 3340, 1730, 1670, 1530 cm^{-1}; NMR ($CDCl_3$), δ 1.5—1.9 (m, 8H), 2.45—3.2 (m, 2H), 3.65 (2H), 3.72 (s, 3H), 3.7—3.85 (m, 1H), 4.45—4.7 (m, 1H), 5.12 (s, 4H), 5.1—5.3 (m, 1H), 5.82 (d, 1H, J=9 Hz), 6.7—7.1 (m, 1H), 7.32 (s, 10H).

Cyclopentyl Methyl (α-L-Aspartylaminomethyl)malonate (24): The hydrogenolysis of cyclopentyl methyl (*N*-benzyloxycarbonyl-O^4-benzyl-α-L-aspartylamino)malonate (0.4 g) was carried out in methanol using palladium black (0.1 g) under an atmospheric pressure of hydrogen. After the catalyst had been filtered off, the filtrate was concentrated to dryness *in vacuo*. The residue was dissolved in a small amount of water and then lyophylized; yield, 0.17 g (71.0%); mp 80—84 °C (dec); IR (Nujol) 1730, 1675 cm^{-1}; NMR (DMSO-d_6) δ 1.65 (broad s, 8H), 2.2—2.6 (2H), 3.65 (d, 2H, J=8 Hz), 3.68 (s, 3H), 3.7—3.9 (broad, 2H), 5.0—5.3 (broad s, 1H), 5.9—6.5 (broad s, 3H), 8.2—9.0 (broad s, 1H); Found: C, 48.16; H, 7.09; N, 7.89%. Calcd for $C_{14}H_{22}N_2O_7 \cdot H_2O$: C, 48.27; H, 6.74; N, 8.04%.

Typical Procedure for the Preparation of 2-Amino-D-alkanol Derivatives (II). *Methyl* N-*Acetyl*-O-*benzyl*-D-*serinate*: Thionyl chloride (16 g) was vigorously stirred, drop by drop, into methanol (80 ml) at −10 °C. To this solution we then added *N*-acetyl-*O*-benzyl-D-serine (19 g) at the same temperature. The reaction mixture was stirred at room temperature for 2 h and then concentrated to dryness *in vacuo* below 30 °C. The residue was disolved in ethyl acetate (100 ml), and the solution was washed with aqueous saturated sodium hydrogencarbonate (10 ml), 1% hydrochloric acid (10 ml), and water, and then dried over magnesium sulfate. The solution was concentrated to dryness *in vacuo* to give the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate–petroleum ether; yield, 19.3 g (96.1%); mp 66—67 °C; $[\alpha]_D^{25}$ −11.8° (*c* 1.02, MeOH); IR (Nujol) 3290, 1750, 1635 cm^{-1}; NMR ($CDCl_3$) δ 2.01 (s, 3H), 3.55—4.00 (m, 2H), 3.72 (s, 3H), 4.50 (s, 2H), 4.65—4.88 (m, 1H), 6.50 (broad d, 1H, J=10 Hz), 7.30 (s, 5H); Found: C, 62.30; H, 6.86; N, 5.60%. Calcd for $C_{13}H_{17}NO_4$: C, 62.14; H, 6.82; N, 5.57%.

Methyl N-*Benzyloxycarbonyl*-D-*alaninate*: Thionyl chloride (6 ml) was vigorously stirred, drop by drop, into methanol (30 ml) at −10 °C. To this solution we then added *N*-benzyloxycarbonyl-D-alanine (6.7 g) at the same temperature. The reaction mixture was treated in the manner described above to give the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate–hexane; yield, 6.40 g (90.0%); mp 48—49 °C; $[\alpha]_D^{25}$ +34.7° (*c* 1, MeOH); IR (Nujol) 3350, 1750, 1680 cm^{-1}; NMR ($CDCl_3$) δ 1.41 (d, 3H, J=7 Hz), 3.73 (s, 3H), 4.39 (quartet, 1H, J=7 Hz), 5.12 (s, 2H), 5.1—5.65 (broad, 1H), 7.35 (s, 5H); Found: C, 60.39; H, 6.44; N, 6.20%. Calcd for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

" N-*Acetyl*-O-*benzyl*-D-*serinol*: To a suspension of sodium borohydride (3.42 g) and calcium chloride (10 g) in tetrahydrofuran (75 ml), we added methyl *N*-acetyl-*O*-benzyl-D-serinate (7.5 g) in tetrahydrofuran (75 ml) at room temperature. After the reaction mixture had then been stirred for 2 h at the same temperature, the insoluble materials were removed by filtration and the filtrate was concentrated to dryness *in vacuo*. The oily residue was dissolved in ethyl acetate (100 ml). The solution was washed with water (20 ml) and dried over magnesium sulfate. The dried solution was concentrat-

ed to dryness *in vacuo* to give the title compound as a colorless oil; yield, 6.2 g (93.0%); $[\alpha]_D^{22}$ −28.6° (*c* 0.71, MeOH); IR (film) 3300, 1650, 1550 cm^{-1}; NMR ($CDCl_3$) δ 2.00 (s, 3H), 3.19 (broad s, 1H), 3.55—4.34 (m, 5H), 4.52 (s, 2H), 6.36 (broad d, 1H, J=8 Hz), 7.33 (s, 5H).

N-*Benzyloxycarbonyl*-D-*alaninol*: To a suspension of sodium borohydride (3.4 g) and calcium chloride (10 g) in tetrahydrofuran (75 ml), we added methyl *N*-benzyloxycarbonyl-D-alaninate (7.11 g) in tetrahydrofuran (75 ml) at room temperature. The reaction mixture was then treated in the manner described above to give the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate–hexane; yield, 4.7 g (75.0%); mp 81—82 °C; $[\alpha]_D^{25}$ +4.9° (*c* 0.87, MeOH); IR (Nujol) 3460, 1695, 1660 cm^{-1}; NMR ($CDCl_3$) δ 1.12 (d, 3H, J=7 Hz), 2.93 (broad s, 1H), 3.41—4.15 (m, 3H), 5.09 (s, 2H), 5.10—5.40 (broad, 1H), 7.32 (s, 5H); Found: C, 62.78; H, 7.25; N, 6.74%. Calcd for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23; N, 6.69%.

O^3-*Benzyl*-D-*serinol Hydrochloride*: A solution of *N*-acetyl-O^3-benzyl-D-serinol (6.2 g) in 4 M hydrochloric acid (15 ml) was heated at 70 °C for 100 min under vigorous stirring. The reaction mixture was concentrated to dryness *in vacuo* to give the title compound as colorless needles, which were then recrystallized from methanol–ether; yield, 5.25 g (86.8%); mp 133.5—134.5 °C; $[\alpha]_D^{25}$ +4.6° (*c* 1.01, MeOH); IR (Nujol) 3360, 1590, 1380 cm^{-1}; NMR (DMSO-d_6) δ 3.00—3.90 (m, 5H), 4.56 (s, 2H), 4.20—5.00 (broad, 1H), 7.39 (s, 5H), 8.36 (broad s, 3H); Found: C, 55.00; H, 7.41; N, 6.43; Cl, 16.41%. Calcd for $C_{10}H_{16}NO_2Cl$: C, 55.17; H, 7.41; N, 6.44; Cl, 16.29%.

N-*(*N-*Benzyloxycarbonyl*-O^4-*benzyl*-α-L-*aspartyl)*-O^3-*benzyl*-D-*serinol*: To a solution of O^3-benzyl-D-serinol hydrochloride (2.2 g), triethylamine (1.4 ml), and 1-hydroxybenzotriazole (1.4 g) in *N,N*-dimethylformamide (30 ml), we added O^1-*p*-nitrophenyl O^4-benzyl *N*-benzyloxycarbonyl-α-L-aspartate (4.8 g). The reaction mixture was stirred for 30 min at 0 °C and then diluted with ethyl acetate (100 ml). The solution was washed with 3% aqueous ammonia, 1% hydrochloric acid, and water, and then dried over magnesium sulfate. The dried solution was concentrated to dryness *in vacuo* to give the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate–petroleum ether; yield, 3.25 g (62.5%); mp 102—104 °C; $[\alpha]_D^{22}$ −22.3° (*c* 0.65, MeOH); IR (Nujol) 3450, 3300, 1730, 1680, 1650 cm^{-1}; NMR ($CDCl_3$) δ 2.50—3.30 (m, 3H), 3.50—4.35 (m, 5H), 4.47 (s, 2H), 4.40—4.90 (m, 1H), 5.10 (s, 4H), 6.00 (d, 1H, J=10 Hz), 6.80—7.15 (m, 1H), 7.32 (s, 15H); Found: C, 66.87; H, 6.25; N, 5.20%. Calcd for $C_{29}H_{32}N_2O_7$: C, 66.91; H, 6.20; N, 5.38%.

N-*(*N-*Benzyloxycarbonyl*-O^4-*benzyl*-α-L-*aspartyl)*-D-*alaninol*: The hydrogenolysis of *N*-benzyloxycarbonyl-D-alaninol (1 g) in methanol over palladium black (0.1 g) was carried out for 1.5 h under an atmospheric pressure of hydrogen. After the catalyst had been filtered off, the filtrate was concentrated to dryness *in vacuo* to give D-alaninol as a colorless oil. The D-alaninol thus obtained and 1-hydroxybenzotriazole (0.7 g) were dissolved in *N,N*-dimethylformamide (15 ml) and the solution was cooled to 0 °C. To this solution we then added O^1-*p*-nitrophenyl O^4-benzyl *N*-benzyloxycarbonyl-α-L-aspartate (2.3 g). The reaction mixture was stirred for 30 min at 0 °C, and then diluted with ethyl acetate (10 ml). The solution was washed with 3% aqueous ammonia, 1% hydrochloric acid, and water, and then dried over magnesium sulfate. The dried solution was concentrated to dryness *in vacuo* to give the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate-hexane; yield, 1.3 g (65.9%); mp 111—113 °C; $[\alpha]_D^{25}$ −0.7° (*c* 0.76, MeOH); IR (Nujol) 3460, 3300, 1740, 1690, 1640 cm^{-1}; NMR ($CDCl_3$) δ 1.07 (d, 3H, J=7 Hz), 2.60—3.20 (m, 3H), 3.30—4.25 (m, 3H), 4.30—4.85 (m, 1H), 5.09 (s, 4H), 6.08 (broad d, 1H, J=10 Hz), 6.47—6.85 (broad, 1H), 7.32 (s, 10H); Found: C, 63.72; H, 6.49; N, 6.93%. Calcd for $C_{22}H_{26}N_2O_6$: C, 63.75; H, 6.32; N, 6.76%.

N-*(*N-*Benzyloxycarbonyl*-O^4-*benzyl*-α-L-*aspartyl*-O^1-*isobutyryl*-O^3-*benzyl*-D-*serinol*: *N*-(*N*-Benzyloxycarbonyl-O^4-benzyl-α-L-aspartyl)-O^3-benzyl-D-serinol (1.6 g) was dissolved in pyridine (20 ml), and the solution was cooled to 0 °C. To the solution we then added, drop by drop, isobutyryl chloride (0.96 g), after which the reaction mixture was stirred at room temperature for 1.5 h. The solution was concentrated to dryness *in vacuo*, and the resulting residue was dissolved in ethyl acetate (100 ml). The solution was washed with 1% hydrochloric acid, aqueous saturated sodium hydrogencarborate, and water, and then dried over magnesium sulfate. The dried solution was concentrated to dryness *in vacuo*, and the oily residue thus obtained was subjected to column chromatography on silica gel (50 g, Kiesel gel 60), using benzene–ethyl acetate (4:1). The eluate was concentrated to dryness *in vacuo* to give the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate–petroleum ether; yield, 1.66 g (91.2%); mp 103—103.2 °C; $[\alpha]_D^{22}$ −6.6° (*c* 1, MeOH); IR (Nujol) 3300, 3270, 1725, 1685, 1665 cm^{-1}; NMR ($CDCl_3$) δ 1.11 (d, 6H, J=7 Hz), 2.26—3.26 (m, 3H), 3.27—3.67 (m, 2H), 4.04—4.80 (m, 4H), 4.47 (s, 2H), 5.10 (s, 4H), 5.90 (broad d, 1H, J=10 Hz), 6.85 (broad d, 1H, J=8 Hz), 7.32 (s, 15H); Found: C, 67.11; H, 6.60; N, 4.90%. Calcd for $C_{33}H_{28}N_2O_8$: C, 67.10; H, 6.49; N, 4.74%.

N-*(*N-*Benzyloxycarbonyl*-O^4-*benzyl*-α-L-*aspartyl)*-O-*propionyl*-D-*alaninol*: *N*-(*N*-Benzyloxycarbonyl-O^4-benzyl-α-L-aspartyl)-D-alaninol (0.88 g) was dissolved in pyridine (15 ml), and the solution was cooled to 0 °C. To the solution propionyl chloride (0.6 g) was added, drop by drop, after which the reaction mixture was stirred at room temperature for 1.5 h. The solution was treated in the manner described above to give the title compound as colorless needles, which were subsequently recrystallized from ethyl acetate-hexane; yield, 0.88 g (88.0%); mp 90—91 °C; $[\alpha]_D^{25}$ −4.0° (*c* 1, MeOH); IR (Nujol) 3310, 1740, 1700, 1660 cm^{-1}; NMR ($CDCl_3$) δ 1.10 (d, 3H, J=6 Hz), 1.12 (t, 3H, J=7 Hz), 2.33 (quartet, 2H, J=7 Hz), 2.50—3.25 (m, 2H), 3.80—4.85 (m, 4H), 5.12 (s, 4H), 5.92 (broad d, 1H, J=9 Hz), 6.30—6.80 (broad, 1H), 7.33 (s, 10H); Found: C, 63.91; H, 6.55; N, 5.92%. Measurement of the Potency of Sweetness. The relative potencies of sweetness were determined based on a panel evaluation by six persons. A 100 mg portion of *O*-acyl-2-(α-L-aspartylamino)alkanol was dissolved in 5 ml of water. Various concentrations of aqueous solutions of sucrose (2, 4, 6, 8, 10, and 12%) were prepared as standard solutions. Every paneler kept 5 ml of the samples in his mouth for 5 s and compared the relative potencies of sweetness with that of the standard solution. When the potency of sweetness of a sample was higher than that of the standard solution, the solution of the sample was diluted more than twice in order to obtain the potency of sweetness more exactly.

The authors are indebted to Dr. Ichiro Chibata for his kind guidance throughout this study. Their thanks are also due to Drs. Hiroshi Itoh and Keisuke Kawashima for their valuable discussions and participation in the panel evaluation of the relative potencies of sweetness.

Boron Trifluoride Hydrate-catalyzed Ethylation of Benzene with Ethyl-1-^{13}C Fluoride and Ethyl-1,1-d_2 Fluoride

Toshiyuki OYAMA, Toshio HAMANO,* Katsuyuki NAGUMO,* and Ryohei NAKANE

The Institute of Physical and Chemical Research, Wako, Saitama 351

**Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo 160*

(Received August 22, 1977)

In the ethylation of benzene with ethyl-1-^{13}C fluoride and ethyl-1,1-d_2 fluoride in boron trifluoride hydrate, almost a 50% isotope position rearrangement in the ethyl group of ethylbenzene was found, whereas in the boron trifluoride-catalyzed ethylation in excess benzene no rearrangement was observed. Based on these results, it was suggested that an electrophile is an ethyl cation in the ethylation of benzene in excess boron trifluoride hydrate and a nonionized polar complex in the boron trifluoride-catalyzed ethylation in excess benzene.

The ethylation of benzene with ethyl fluoride in donor solvents using boron trifluoride as the catalyst proceeds through the formation of a nonionized polar complex, $C_2\overset{\delta+}{H}_5F\cdot\overset{\delta+}{B}F_3$, and the relative rates of toluene to benzene, k_T/k_B, were found to be 2.7 in nitromethane and 2.3 in excess aromatics.[1] On the other hand, in the boron trifluoride-catalyzed ethylation carried out in a nonpolar solvent such as hexane or cyclohexane, the electrophile is an ethyl carbocation, since the ethylation with ethyl fluoride-2-^{14}C indicated the migration of radioactivity from the β- to the α-carbon atom of the ethyl group.[2] In ethylation and isopropylation in hexane, an anomalous substrate selectivity was found (k_T/k_B=0.61 and 0.70 respectively).[3] The nonpolar solvents in which the alkylations are carried out contain a trace of water. Therefore, an alkylation catalyst in nonpolar solvents would be a hydrate of boron trifluoride, which is a strong proton-acid catalyst.[3]

In the present investigation, the ethylation of benzene with ethyl-1-^{13}C fluoride and ethyl-1,1-d_2 fluoride in boron trifluoride monohydrate has been carried out to obtain evidence of the incipient ethyl carbocation as an ethylation agent.

Experimental

Materials. The benzene was dried over calcium hydride. The boron trifluoride was obtained from the Hashimoto Kasei Co., Ltd. The ethyl-1-^{13}C fluoride was prepared from ethyl-1-^{13}C iodide (*ca.* 20 ^{13}C atom%. Prochem, The British oxygen Co., Ltd.) by reaction with mercuric fluoride[4], which had itself been prepared from mercuric chloride with elemental fluorine (Daikin Kogyo Co.) and purified by distillation at low temperatures. The ethyl-1,1-d_2 fluoride was prepared from ethyl-1,1-d_2 alcohol,[5] which had itself been obtained by the reduction of phenyl acetate with lithium aluminium deuteride[6] (99 D atom%. Merck Sharp and Dohme Co., Ltd.); yield: 80.6%, IR(gas): ν_{max} 2240, 2140 (C-D) 1180, 1170, 1155, 970, 960, and 955 (C-F) cm^{-1}; NMR (−40 °C): δ 1.05 (m of d, J_{CH-CF}=25.8 Hz, J_{CH-CD}= 1.02 Hz). The ethylbenzene-2,2-d_2 was prepared by the hydrolysis of 2-phenylethyl-1,1-d_2 magnesium bromide prepared from the bromide and magnesium turnings in dry ether at the reflux temperature for 1.5 hours. IR(neat): ν_{max} 2955, 2880, 2220, and 2130 cm^{-1}; MS:*m/e* 108 (M^+), 91 (base peak). The 2-phenylethyl-1,1-d_2 bromide was prepared from 2-phenylethyl-1,1-d_2 alcohol and a 47% solution of hydrogen bromide by the method in the literature.[7] IR: ν_{max} 2280, 2240, and 2160 cm^{-1}. The alcohol was obtained by the reduction of ethyl phenylacetate with lithium aluminium deuteride in an ether solution.

Procedure. The boron trifluoride monohydrate was prepared by passing anhydrous boron trifluoride gas into distilled water cooled in an ice bath. The resultant hydrate was a heavy, fuming liquid with a specific gravity of 1.77 at 25 °C; it made a clean homogeneous solution with a small amount of benzene (0.5 g benzene/1000 g BF_3-hydrate). Ethylation was carried out by bubbling ethyl fluoride gas into the solution (424 g) for 30 min at room temperature. After the introduction of ethyl fluoride (2.4 mmol), the solution was quenched in ice water. A small amount of unreacted benzene and the products were extracted with dichloromethane. The organic layer was washed with a 5% $NaHCO_3$ aq solution and then with water. The organic solution was dried over calcium chloride, and the solvent was removed by fractional distillation. The products were subjected to GLC, NMR, and GC-MS measurements. Boron trifluoride catalyzed ethylation with ethyl fluoride in excess benzene as a donor solvent was carried out according to the previously described method.[2] GLC analysis was carried out on a Hitachi Perkin Elmer gas chromatograph F6-D. The ^{1}H-NMR spectra were determined on a JEOL C-60HL. apparatus. The ^{13}C-NMR spectra were measured on a JEOL JNM-FX100 Fourier-transform NMR spectrometer. Tetramethylsilane was used as an internal reference. The mass spectra were obtained on a Hitachi RMU-6M mass spectrometer. The IR spectra were taken on a Shimadzu grating Infrared Spectrophotometer IR-27G.

Results and Discussion

In the ^{13}C-NMR spectrum (shown in Fig. 1) of the products of the ethylation of benzene with ethyl-1-^{13}C fluoride in boron trifluoride hydrate, both methyl and methylene carbon signals (15.63 and 28.89 ppm respectively) appeared strongly in a ratio of 40:60 (corrected by relative sensitivity) as compared with those of the aromatic ring (para:125.55 ppm, ortho:127.81 ppm, meta:128.29 ppm). This indicates that almost equal amounts of ethyl-1-^{13}C-benzene and ethyl-2-^{13}C-benzene were produced in this reaction. In the boron trifluoride-catalyzed ethylation with ethyl-1-^{13}C fluoride in excess benzene, it was estimated from the ^{13}C-NMR spectrum (shown in Fig. 2) that about 95% of the products consisted of ethyl-1-^{13}C-benzene. The ^{1}H-NMR spectrum of the product of the same reaction with ethyl-1,1-d_2 fluoride consists only of a methyl-group proton peak at δ=1.23 ppm, with a multiplicity due to H–D coupling (J_{H-D}=1.4 Hz), as is shown in

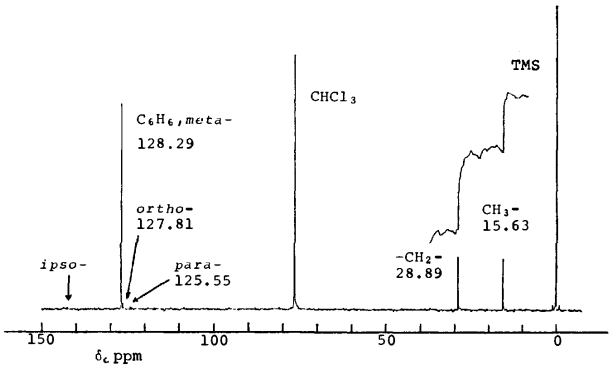

Fig. 1. ^{13}C-NMR spectrum (25 MHz FT) of ethylbenzene (in $CHCl_3$ and C_6H_6) obtained from the ethylation of benzene in boron trifluoride hydrate.

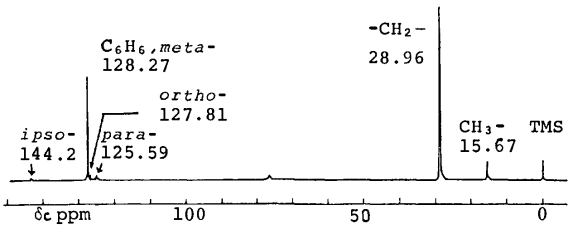

Fig. 2. ^{13}C-NMR spectrum (25 MHz FT) of ethylbenzene (in benzene) obtained from the boron trifluoride catalyzed ethylation in excess benzene.

Fig. 3; no resonance peak due to the methylene proton was observed. Therefore, it is evident that the only ethylated product was ethyl-1,1-d_2-benzene. On the other hand, the ^{1}H-NMR spectrum of the ethylbenzene (shown in Fig. 4) produced in boron trifluoride hydrate displays a multiplet peak of a methylene proton besides a multiplet peak of a methyl group. This product was also analyzed by GC-MS. It was determined from the peak-heights ratio of the $C_6H_5CH_2^+$, $C_6H_5CDH^+$, and $C_6H_5CD_2^+$ ions that the ethylbenzene produced was a mixture of $C_6H_5CH_2CD_2H$, $C_6H_5CDHCDH_2$, and $C_6H_5CD_2CH_3$ in a ratio of 68:95:42. Therefore, the obtained ^{1}H-NMR spectrum is a superposition of the resonance peaks of the isotopic ethyl group with a multiplet due to H–H and H–D coupling.

In order to confirm that the rearranged ethylbenzene

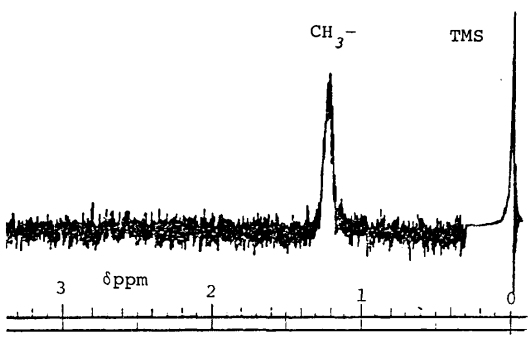

Fig. 3. ^{1}H-NMR spectrum (60 MHz methyl and methylene region) of ethylbenzene (in CCl_4) obtained from the boron trifluoride catalyzed ethylation in excess benzene.

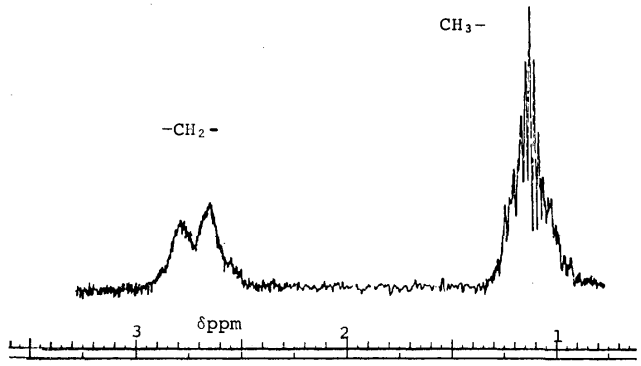

Fig. 4. ^{1}H-NMR spectrum (60 MHz methyl and methylene region) of ethylbenezene (in CCl_4) obtained from the ethylation of benzene in boron trifluoride hydrate.

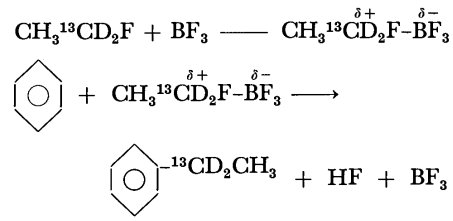
was obtained by the ethylation reaction in the first step, and not by the secondary isotope-position scrambling of the ethylbenzene which is formed in the first step, ethyl-1-^{13}C-benzene and ethyl-2,2-d_2-benzene were placed in contact with boron trifluoride hydrate under the same conditions as in the ethylation reaction. No isotope-position rearrangement in the ethyl group was observed.

It is well known that, in the consideration of primary alkyl halides with aromatics under the Friedel-Crafts condition, a rearrangement of the alkyl group usually results; this has been interpreted in terms of carbocation formation and rearrangement. All such mechanisms, however, involve primary-to-secondary carbocation conversions. Therefore, it seemed of interest to investigate the primary-to-primary rearrangement of the ethyl group. Roberts *et al.*[8] and Lee *et al.*[9] have reported that the ethylation with ethyl-2-^{14}C halide gave unrearranged products. One of the present authors[2] previously found that, in the boron trifluoride-catalyzed ethyaltion of benzene with ethyl-2-^{14}C fluoride in nitromethane, only a little isotope position rearrangement in the ethyl group took place.

Now, in the ethylation with ethyl-1-^{13}C fluoride and ethyl-1,1-d_2 fluoride in excess benzene, no isotope-position-rearranged product was obtained. These facts show that the boron trifluoride catalyst forms, with ethyl fluoride, the nonionized complex in the Friedel-Crafts ethylation in the donor solvent and that the complex attacks the aromatic ring carbon without rearrangement. The ethylation proceeds *via* an S_N2 displacement reaction on the complex.

Boron trifluoride monohydrate,[10] which is formed by introducing an equal amount of boron trifluoride into



Scheme 1.

water, is a heavy, fuming liquid and is a strong proton acid of the hydroxyfluoroboric-acid type. This hydrate is used as a catalyst for polymerizations and alkylations.[11] When the hydrate of boron trifluoride reacts with ethyl fluoride, an ethyl cation or its ion pair is produced, and internal 1,2-hydride and deuteride shifts occur almost completely in the ethyl group before the ethyl cation combines with the benzene ring. Thus,

$$CH_3{}^{13}CH_2F + HBF_3OH \rightleftharpoons CH_3{}^{13}CH_2{}^+\text{-}HOBF_3{}^- + HF$$

$$\begin{array}{ccc} CH_3{}^{13}CH_2{}^+ & \overset{\sim H^-}{\rightleftharpoons} & {}^{13}CH_3CH_2{}^+ \\ \downarrow \text{PhH} & & \downarrow \text{PhH} \\ Ph{}^{13}CH_2CH_3 & & PhCH_2{}^{13}CH_3 \end{array}$$

$$\begin{array}{ccccc} CH_3CD_2{}^+ & \overset{\sim H^-}{\rightleftharpoons} & CD_2HCH_2{}^+ & \overset{\sim D^-}{\rightleftharpoons} & CDH_2CDH^+ \\ \downarrow \text{PhH} & & \downarrow \text{PhH} & & \downarrow \text{PhH} \\ PhCD_2CH_3 & & PhCH_2CD_2H & & PhCDHCDH_2 \end{array}$$

Scheme 2.

the ethylation with the isotope-position-rearranged ethyl cation or its ion pair gave a mixture of isotopic ethylbenzene. These facts suggest that the ethyl cation of its ion pair is the electrophile in boron trifluoride hydrate-catalyzed ethylation. In a competitive ethylation an anomalous relative rate ($k_T/k_B=0.8$), as in a nonpolar solvent, was obtained in boron trifluoride hydrate.[12] The ethylation of benzene with boron trifluoride and ethyl-2-^{14}C fluoride, carried out in a nonpolar solvent such as hexane and cyclohexane, gave isotope-position-rearranged ethylbenzene, indicating the ethyl-cation formation in the course of the reaction.[2] Therefore, it may be concluded that the ethylation catalyst in a nonpolar solvent is a boron trifluoride hydrate.

The authors wish to thank Mr. Jun Uzawa for measuring the NMR spectra.

Metalloporphyrins. III.[1] Photoinduced Acylamination of Zinc Porphyrins by Use of Acyl Azides

Kunihiro ICHIMURA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received August 31, 1977)

Visible light irradiation of a solution of zinc octaethylporphin (ZnOEP) in the presence of acyl azide gives zinc complex of 5-acylamino-2,3,7,8,12,13,17,18-octaethylporphin together with a small amount of zinc complex of 21-acylamino-2,3,7,8,12,13,17,18-octaethylporphin. Zinc 5,10,15,20-tetraphenylporphin (ZnTPP) is coverted into zinc complex of 21-acylamino-5,10,15,20-tetraphenylporphin in a similar way. The pyrolysis of the *N*-acylaminated ZnOEP affords the rearrangement product in addition to ZnOEP, while *N*-acylaminated ZnTPP is converted into ZnTPP on heating. The spectroscopic properties of these photoproducts are given.

Photochemical studies on metalloporphyrins have hitherto been focused on their photoreduction and photooxidation in particular in relation to the function of photosynthetic pigments and the degradation of biological macrocycles. Little work has been done regarding other photochemical reactions of the macrocyclic ligands.[2] During the course of an investigation on the fluorescence quenching of metalloporphyrins, acyl azide was found to effectively quench the emission of zinc octaethylporphin (ZnOEP) (**1**), the fluorescence intensity decreasing gradually during the course of measurement. These observations prompted us to study the photolysis of ZnOEP–acyl azide system.[3] This paper describes the photoinduced acylamination at the *meso*-position and at the pyrrolic nitrogen of the macrocycle resulting from the sensitized decomposition of acyl azide. This type of photochemical conversion was extended to zinc tetraphenylporphin (ZnTPP) (**2**), yielding *N*-acylaminated ZnTPP. This seems to be a first example of the photoinduced substitution on metalloporphyrins.

Results and Discussion

When a dichloromethane solution of ZnOEP was irradiated with light of wavelength>450 nm in the presence of a slight excess of aromatic acyl azide under argon stream, the color of the solution immediately darkend. The irradiation period was dependent upon the nature of acyl azide; an electron-withdrawing group except nitro group on benzoyl residue accelerates the photolysis (Table 1). The reaction was followed by TLC, and two photolytic products were isolated by preparative TLC. The red major product showing larger R_f-value has typical visible bands of metal complexes and the CO stretching vibration owing to amide

a) A small amount of ZnOEP recovered unchanged on photolysis is not taken into consideration.

group (Table 2). From the NMR spectra the amide group can be ascribed to the *meso*-substituent of the macrocyclic ligand, since the ethyl protons are no longer equivalent and three *meso*-protons are observed in the intensity ratio 1:2.[4,5] Appearance of new NMR proton signals due to aryl ring derived from acyl azide as well as the elementary analyses suggest that ZnOEP is substituted by ArCONH– or ArNHCO– group at the *meso*-position (Table 1 and 3). The structure having the former group for the major product (**3**; Ar=Ph) was unequivocally elucidated by identification of the photoproduct from ZnOEP–benzoyl azide system with the authentic sample prepared by the benzoylation of *meso*-aminooctaethylporphin,[5] followed by metallization.

The NMR spectra of the minor photoproducts chelated by zinc (Table 4) show the presence of four *meso*-protons in the intensity ratio 2:2 and the remarkable high field shift of the aryl protons derived from acyl azide, indicating that acylimino (ArCON) or its isomer (ArNCO) is bound to the pyrrolic nitrogen of ZnOEP (Table 5). Determination of the structure having the former group (**4**) was made by IR spectral analysis of the photoproduct starting from ZnOEP-*p*-cyanobenzoyl azide; $\bar{\nu}_{CN}$ at 2232 cm^{-1} is in line with that of *p*-cyanobenzoyl-*p*-toluide (**5**) and *N'*,*N'*-dimethylhydrazide (**6**) at 2233 cm^{-1} rather than that of *N*,*N*-dimethyl-*N'*-(*p*-cyanophenyl)urea (**7**) at 2223 cm^{-1}. The shift of the amide carbonyl frequency to lower wavelength at *ca.* 1610 cm^{-1} of this type of compound can be interpreted in terms of the bond formation between zinc and the acylamino nitrogen[6] (Table 6). The metal complexes exist as neutral species, in contrast to *N*-alkylporphins which require counter anion like halogenide

to form the metal complexes.[7-12] Another metal complex of this type of anomalous coordination has been reported.[13]

The photochemical acylamination on porphyrin ring has been extended to ZnTPP (**2**) (Table 7). The structure of the zinc complex of the photoproduct has been clarified by NMR spectra (Table 8). Protons attributable to acyl group derived from acyl azide undergo considerable high field shift as in the case of **4**. The number of β-pyrrolic protons remains eight; two singlets for four protons and an AB quartet for four protons. The zinc macrocycles show similar polarization of the amide CO and the cyano group like **4**, supporting the structure (**8**) (Table 9).

The structure of the photoproducts in the present work demonstrates the resemblance of the photolysis to the nitrene reaction. The reactions of nitrene or carbene with metalloporphyrins investigated so far fall into four categories, although no photochemically induced reaction has been reported; *a*) insertion at the *meso*-position,[14,15] *b*) addition on the pyrrolic nitrogen atom,[7-9,16] *c*) addition to the β,β-double bond of pyrrolic ring to give cyclopropane derivatives,[7,15,17] and *d*) formation of a metal-carbon bond.[18] The *meso*-acylaminated photoproducts (**3**) seem to be formed by reaction *a*), and the *N*-acylaminated macrocycles (**4**) and (**8**) by reaction *b*). The azacyclopropane derivative according to reaction *c*) has not yet been isolated in the photolysis of ZnOEP–acyl azide.

The photolysis of zinc porphyrin–acyl azide system is of synthetic value for the introduction of a functional group at the *meso*-position of the symmetrical macrocycles and particularly for the preparation of *N*-substituted macrocycles which are attracting attention as regards structural problems and chemical reactivity. Since the *N*-acylaminated porphins are the first example of the macrocycle bearing *N*-substituent other than alkyl, the NMR spectra and chemical reactivity of **4** and **8** have

been studied in detail. First the magnetic shielding effect of the macrocycles on the protons of *N*-acylamino group should be mentioned. Storm and Corwin showed that a plot of the incremental shift of *N*-alkyl substitutent (Δ in ppm) *vs.* the square of the reciprocal of the distance (r in Å) of the alkyl group from the current loop gives a straight line.[19] *N*-Acylamino group of **4** and **8** is approximately perpendicular to the plane of the macrocycles, as in the case of metal-free and metal containing *N*-alkylporphyrins (Fig. 1).[13,20-22] When the distance of protons on acyl including cinnamoyl group from the plane is estimated in the same way as in the work of Storm and Corwin, a plot of Δ between *N*-acylaminoporphin and the corresponding acyl amide as the reference compound against r^{-2} is found to give a straight line coinciding with the line for *N*-alkyl porphin (Fig. 2).

It was found that **4** and **8** are readily demetallized even when a solution of the complexes in dichloromethane was passed through a silica gel column. The anomalous instability of the zinc chelation reflects the

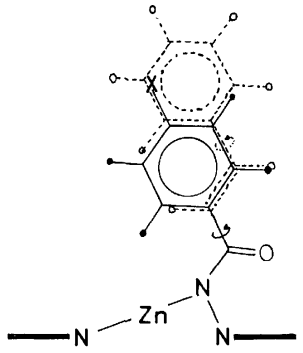

Fig. 1. The presumable stereochemistry of the zinc complexes of *N*-(*p*-substituted benzoylamino)porphin (full line) and *N*-(cinnamoylamino)porphin (broken line).

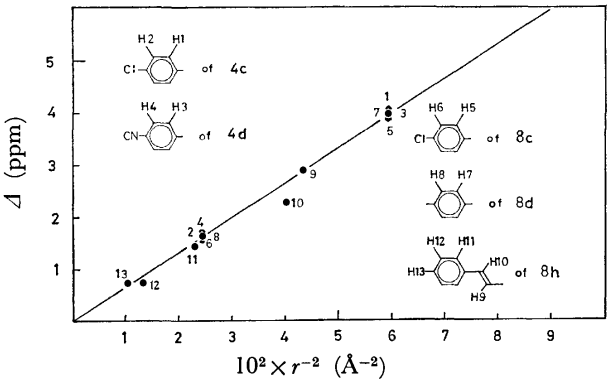

Fig. 2. A plot of the difference in chemical shift (Δ) between zinc complexes of *N*-acylaminoporphin and the corresponding acyl amide against the square of the reciprocal of the distance of the acyl protons from the current loop (r). This line is obtained by Storm and Corwin for *N*-alkyletioporphyrin-II.[19] The number of the plot refers to the acyl proton sketched in the Figure.

sp^3 character of the pyrrolic nitrogen bounded by the acylamino group. The stronger basicity of this nitrogen may accelerate the removal of zinc. The metal-free *N*-acylaminooctaethylporphins give characteristic spectroscopic data. The CO frequency of the acylamino group shows a considerable shift to lower wavenumber at *ca.* 1610 cm^{-1} (Table 6), indicating a strong polarization of the CO bond. The visible spectra are no longer similar to those of *N*-methyloctaethylporphin (**9**) having four visible bands but resemble that of monocation of **9** (Fig. 3). This suggests that the metal-free *N*-acylaminoporphin possesses the betaine structure (**10**) which has a strong polarized acylamino residue and monocationic macrocyclic system. Furthermore, two magnetically equivalent protons attributable to the ring protons support the structure. The unusually good solubility of this compound in methanol is also consistent with the polar structure.

The thermal decomposition of *N*-alkylated porphyrins leads to *a*) elimination of the alkyl,[7,23] *b*) isomerization to *meso*-alkylporphin,[16] *c*) migration of the alkyl to the β-pyrrolic position,[7,20] and *d*) formation of a novel macrocyclic system, homoporphyrin.[16] It was found that *N*-acylaminoporphyrins and their zinc complexes show similar pyrolytic behavior. When the crystals of **4d** were heated above 200 °C, ZnOEP and 3d were isolated in the ratio 1:2.1. The thermal conversion was also carried out in boiling *o*-dichloroben-

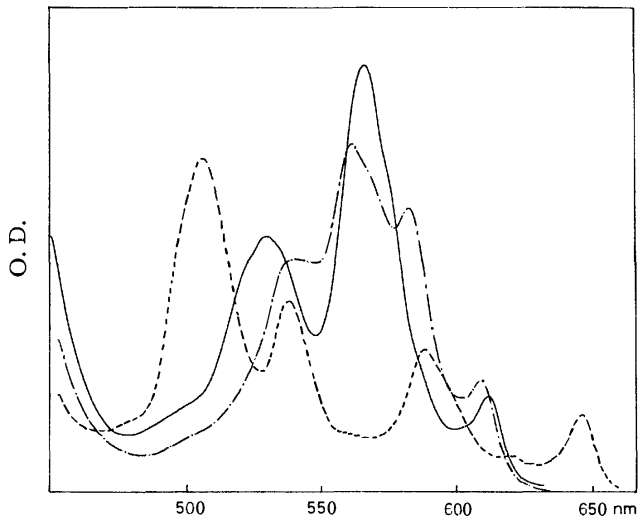

Fig. 3. The visible electronic absorption spectsa of *N*-benzoylaminooctaethylporphin (**10a**) in CH_2Cl_2 (——), *N*-methyloctaethylporphin (**9**) in CH_2Cl_2 (----), and **9** in CH_2Cl_2 containing acetic acid (—·—·—·—).

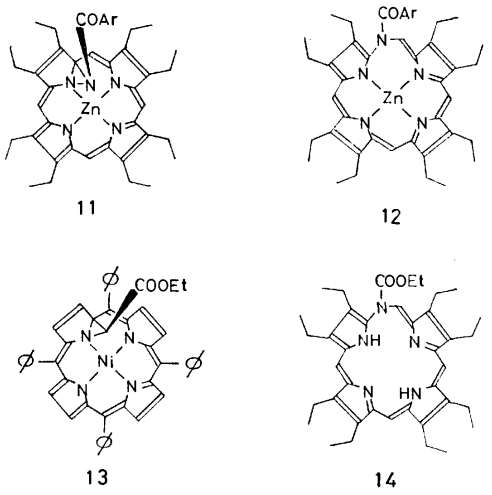

zene whithin a few minutes. The thermolysis of **10d** required more drastic conditions, giving OEP and the free base of **3d** in the product ratio 1:0.1. **8d** decomposed smoothly on heating in boiling *o*-dichlorobenzene.

The rearrangement of **4** to **3** occurs presumably through the diaziridine (**11**) and the azahomoporphyrin (**12**) as in the case of *N*-alkylporphyrins.[16] Although the aziridine intermediate (**13**) corresponding to **11** has been isolated in the thermal conversion of *N*-ethoxycarbonylethyltetraphenylporphinatonickel,[16] rapid ring contraction of **12** to the *meso*-substituted porphyrin takes place either upon heating or chelation.[14] Observation of the isosbestic points in the spectral change of **4d** and **8d** in boiling toluene suggests that both **11** and **12** are extremely short-lived.

Experimental

All melting points are not corrected. Visible, IR, and NMR spectra were recorded on a Hitachi type 323 spectrophotometer, and Hitachi EPI-3G spectrophotometer, and a JEOL C-60 HL type nuclear magnetic spectrometer, respectively. The preparative TLC was carried out with use of silica gel plates activated at 130 °C for 3 h.

Materials. Zinc octaethylporphin was recrystallized from toluene, and determination of its purity was made by means of visible spectrum and TLC on silica gel using benzene–hexane as an eluent. Commercial tetraphenylporphinatozinc (Strem Chemicals Inc.) was used without purification. Acyl azides were purified by passing a dichloromethane solution through a short column of silica gel, followed by recrystallization.

5-Benzoylamino-2,3,7,8,12,13,17,18-octaethylporphin. 5-Amino-2,3,7,8,12,13,17,18-octaethylporphin[5] (12.1 mg) was dissolved in 1 ml dry pyridine, and 50.0 mg of benzoyl chloride was added to the solution under stirring. A color change, violet→blue→olive green→violet, was observed. After 40 min stirring, the solution was poured into chloroform–water and the chloroform layer was separated, washed with dil acetic acid (×1), water (×3) and dried over anhydrous magnesium sulfate. After the solvent has been evaporated, the residue was chromatographed on silica gel plates with use of dichloromethane as an eluent. A red band was collected, and the product was extracted with dichloromethane containing methanol and recrystallized from dichloromethane–hexane. Red violet needles (6 mg) of mp 312—313 °C with decomposition was obtained. Found: C, 79.21; H, 8.10; N, 10.25%. Calcd for $C_{43}H_{49}N_5$: C, 78.96; H, 7.87; N, 10.72%. $\bar{\nu}_{max}$ (KBr): 3280 and 1643 cm^{-1}. λ_{max} in CH_2Cl_2: 405, 502, 536, 570, and 623 nm. Treatment with zinc acetate in chloroform–methanol gave the zinc complex.

Photolysis of Octaethylporphinatozinc in the Presence of Acyl Azide. To a solution of ZnOEP (120 mg) in 200 ml dichloromethane was added 1.5 molar amount of acyl azide, and the solution was irradiated with a 450 W high pressure mercury arc filtered with a Corning filter C. S. No.3—69 under argon bubbling and efficient stirring. The photolysis was followed by TLC and visible spectra. The irradiated solution was evaporated under reduced pressure, and the residue was chromatographed on silica gel plates with use of chloroform or dichloromethane–acetone as an eluent. The chromatogram was complex, two red bands being collected. The main red band having larger R_f-value gave red violet crystals of 5-acylamino-2,3,7,8,12,13-17,18-octaethylporphinatozinc (**3**) which were recrystallized from dichloromethane–methylcyclohexane. Identification of the benzoylamino derivative (**3a**) as well as its metal-free macrocycle with the authentic samples prepared as above was performed by TLC, IR, and visible spectra. The results are summarized in Table 1. The visible and IR spectra are given in Table 2. Methyl protons of ethyl group at the β-pyrrole positions undergo deshielding in the NMR spectra. The *meso*-protons are also influenced by the introduction of the *meso*-substitutent, being split into two signals in the intensity ratio 1:2. When the spectra are measured in trifluoroacetic acid, **3** is demetallized to form the dication and exhibits four ring NH protons in the intensity ratio 2:2. All the NMR signals are characteristic to *meso*-substituted octaethylporphin.[24] The protons of aroyl group show down field shift (Δ=*ca.* 0.8 ppm for protons at the *ortho*-position of phenyl) as a result of magnetic anisotropy of the porphyrin ring system. The acylamino group is thus positioned within the loop of the macrocycles. It is noteworthy that cinnamoylamino group in **3h** is in the *trans*-configuration (J=15 Hz); no sensitized isomerization of the cinnamoyl group exists during the course of photolysis.

The second product with smaller R_f-value was in some cases isolated in a demetallized state and recrystallzied from

dichloromethane–methylcyclohexane. Treatment of the metal-free products with zinc acetate gave zinc complexes which were found to be demetallized during the chromatographic work-up. This anomalous instability of the zinc complex indicates that the demetallization takes place not during the course of photolysis but on the chromatographic separation. When purified dichloromethane was used as an eluent, the zinc complexes were isolated from the photoproducts by TLC on silica gel. The demetallization must be caused by trace amount of acidic impurity in the eluent. The second TLC fraction was treated with zinc acetate, washed with water, and evaporated to dryness to give 20-acylamino-2,3,7,8,12,13,17,18-octaethylporphinatozinc (**4**) which was recrystallized from chloroform–methylcyclohexane. The results are given in Table 4. NMR, and visible and IR spectra are given in Tables 5 and 6, respectively.

Photolysis of 5,10,15,20-Tetraphenylporphinatozinc–Acyl Azide. A solution of ZnTPP (200 mg) and 5 molar amount of acyl azide in 100 ml of dichloromethane was irradiated in the same way as in the case of ZnOEP. The resulting dark brown solution was evaporated to dryness, and the residue was chromatographed on a silica gel column with use of dichloromethane as an eluent. After eluting recovered ZnTPP, the eluent turned into a dichloromethane–acetone mixture (100:1 v/v). An emerald-green fraction was obtained and evaporated to dryness. TLC of the residue on silica gel revealed that the fraction is composed of two products. The one with larger R_f-value having λ_{max} at 438, 554, 586, 609, and 636 nm was converted, on treatment with hydrochloric acid, into the other with smaller R_f-value having λ_{max} at 433, 460, 550, 590, and 649 nm. The latter was reversely converted into the former on treatment with zinc acetate. Accordingly, the residue of the mixture was treated with zinc acetate in chloroform–methanol, followed by washing with water and drying with anhydrous sodium sulfate. 21-Acylamino-5,10,15,20-tetraphenylporphinatozinc (**8**) was recrystallized from dichloromethane–hexane as dark blue crystals. The results are given in Table 7. NMR, and visible and IR spectra are given in Tables 8 and 9, respectively.

Pyrolysis of N-Acylaminoporphyrins and the Zinc Complexes. The crystals of 21-(*p*-cyanobenzoylamino)-2,3,7,8,12,13,17,18-octaethylporphinatozinc (**8d**) were heated at *ca.* 200 °C for a short time and chromatographed on a silica gel column with use of dichloromethane as an eluent. The first red fraction was identified with ZnOEP by TLC and visible spectrum. The second red fraction was identified with 5-(*p*-cyanobenzoylamino)-2,3,7,8,12,13,17,18-octaethylporphinatozinc (**3d**) (TLC and visible spectrum). The product ratio of ZnOEP to **3d** was determined spectrophotometrically to be 1 : 2.1. The crystals of the metal-free 21-(*p*-cyanobenzoylamino)-2,3,7,8,12,13,17,18-octaethylporphin (**10d**) were heated at *ca.* 270 °C, and the products were separated and identified to be OEP and 5-(*p*-cyanobenzoylamino)-2,3,7,8,12,13,17,18-octaethylporphin (TLC and visible spectrum). The product ratio of OEP to the rearranged product was 1 : 0.1. The pyrolytic product of 21-(*p*-cyanobenzoylamino)-5,10,15,20-tetraphenylporphinatozinc (**8d**) in the crystalline state was identified with ZnTPP.

Heating of the zinc complexes (**4d** and **8d**) in boiling *o*-dichlorobenzene resulted in the same products as those obtained by pyrolysis in the crystalline state, while the metal-free *N*-(*p*-cyanobenzoylamino)octaethylporphin was recovered unchanged under the same pyrolytic conditions. A solution of the *N*-acylaminated zinc complexes was heated in benzene or toluene. Samples were taken at intervals, and the reaction was followed spectrophotometrically. The spectral changes demonstrated isosbestic points for both zinc complexes.

A Comparative Study of the Photo-induced Berson-Willcott Rearrangement of Methyl 3-Isopropyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene-1-*exo*- and 1-*endo*-acetate

Masahiko KATO, Masakazu TSUJI, and Toshio MIWA

Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

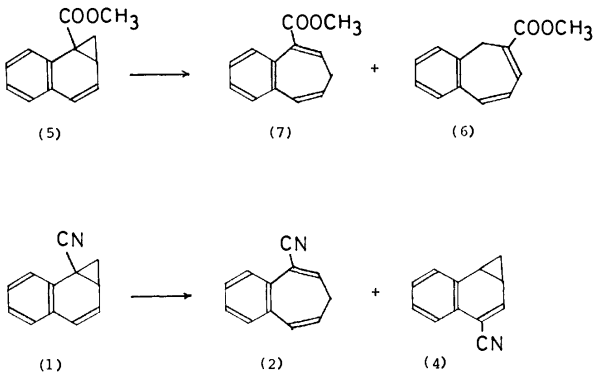
(Received September 6, 1977)

The effect of 1-*exo*- and 1-*endo*-methoxycarbonylmethyl groups on the course of the photo-induced Berson-Willcott rearrangement of methyl 1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene-1-acetate have been studied. Different reaction rates with the same final products have been observed and are discussed from the view of the stereochemical course of the reaction, which strongly supports the 60°-mechanism, *i.e.*, a slither motion of C-1 with inversion of configuration.

The photo-induced rearrangements of some benzonorcaradiene derivatives have been studied extensively.[1-5]

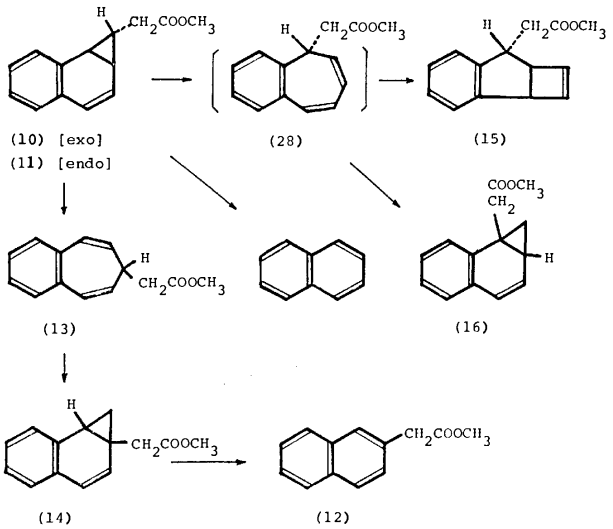
Swenton *et al.* demonstrated that the direct irradiation of 7b-cyano-1a,7b-dihydrocyclopropa[*a*]naphthalene (**1**) lead smoothly to products, **2** and **4**, through intermediate **3**. They discussed a decrease in the quantum yield of disappearance of 7b-methoxycarbonyl-1a,7b-dihydrocyclopropa[*a*]naphthalene (**5**) compared with that of **1** and the rearrangement towards **6**, in addition to **7**, on irradiation of **5** in terms of increased peri-interaction, which retarded the formation of **7**, in the intermediate **8**.

Such interaction was not observed in the intermediates, **3** and **9**, leading to **2** and **6** respectively; thus the formation of the latters becomes favorable.[3]



Scheme 1.

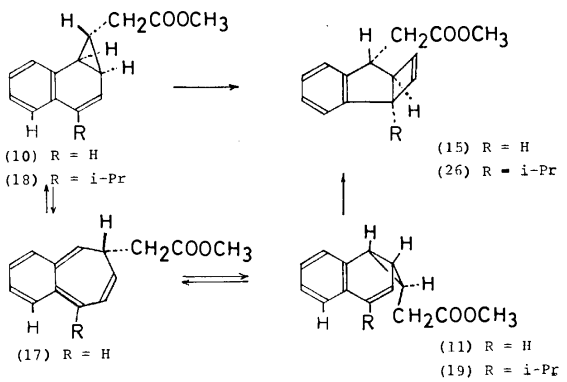
The photo-induced rearrangement of an *exo-endo* mixture of methyl 1a,7b-dihydro-1*H*-cyclopropa[*a*]-naphthalene-1-acetates, (**10**) and (**11**), has been investigated and gives, in addition to naphthalene, **12**, **13**—**16**.[4] The stereochemical course of the rearrangement of **10** and/or **11** to methyl 2a,7a-dihydro-7*H*-cyclobut[*a*]indene-7-*anti*-acetate (**15**) has been reported.[5] However, since compounds **10** and **11**



Scheme 2.

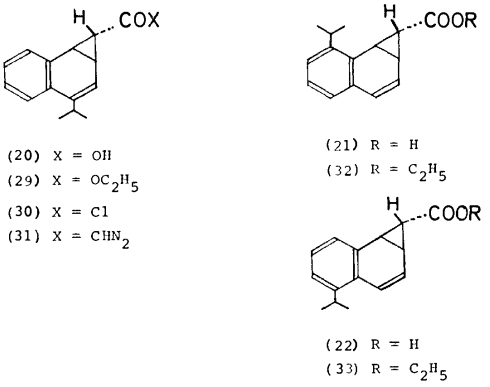
interconvert with each other under thermal (90 °C, 5 min) and photolytic conditions,[4] it was uncertain as to whether either one or both of the isomeric esters had actually rearranged to **15**.

The *exo-endo* interconversion between **10** and **11** occurs apparently through **17** by the fission of the C_{1a}–C_{7b} bond.[4] Since substitution on the C_3 with a bulky group (R) would retard the interconversion by way of peri-interaction, this would be expected to effect the photochemical reaction pathways as reported by Swenton *et al.* Therefore isopropyl derivatives, **18** and **19**, were selected as candidates for the present study.



Scheme 3.

These compounds were thought to be suitable in order to gain more profound insight into the stereochemical course of the benzonorcaradiene system. Up to date, there have been no reports about the comparative study on the photochemical behavior of *exo* and *endo* isomers of 1-substituted 1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene derivatives. The *endo* isomer was of special interest since it should exibit a repulsive interaction between the pi-electron(s) on the six-membered ring and the substituent on C-1. The presence of such an interaction may possibly cause an alteration of the reaction rates or pathway.



Scheme 4.

Results and Discussion

3-Isopropyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene-1-*exo*-carboxylic acid (**20**) was formed as the main product, along with **21** and **22**, from the reaction of 1-isopropylnaphthalene (**23**) with ethyl diazoacetate and subsequent hydrolysis. Arndt-Eistert reaction of **20** gave the desired compound **18**, the 3-isopropyl derivative of **10**, as a crystalline product, mp 84.5—85.5 °C. Compound **18** exhibited a well defined NMR spectrum (100 MHz); an olefinic proton doublet at δ=6.01 and isopropyl signals at 1.12(d) and 1.13(d) (6H) and 2.90 (1H, septet). Signals attributable to three protons on the cyclopropane ring were similar in their chemical shifts and coupling constants to those of **10**,[4] which indicated that the configuration of the methoxycarbonylmethyl group was *exo*. The UV spectrum was also similar in shape to that of **10**[4] but the maximum (278 nm) showed a small bathochromic shift effected by the substitution with the isopropyl group.

Heating **18** to 130 °C for 30 min, gave an equilibrium mixture composed of **18** and **19** in the ratio of 3 : 2. Isolation of **19** from the mixture was achieved using column chromatography on Silicic Acid with hexane–ether (95:5 v/v) eluant. The structure of **19** was assigned on the basis of the spectral data. The UV spectrum was superimposable with that of **18**. The NMR spectrum of **19** showed signals attributable to the three protons on the cyclopropane ring at δ=1.6—1.9 (H_1), 2.24 (H_{1a}), and 2.57 (H_{7b}, t). Double resonance spectrum obtained by irradiation at H_2 gave the coupling constants ($J_{H_1-H_{1a}}=J_{H_1-H_{7b}}=7.5$; $J_{H_{7b}-H_{1a}}=9$), which defined a *cis* relation to each other. The *endo* configuration of the methoxycarbonylmethyl group was further supported by the higher field resonance of the methylene proton signals compared with those of the *exo*-isomer **18**. When heated above 130 °C, **19** gave the same mixture of **18** and **19** as that obtained from **18** by the same treatment.

Both **18** and **19** were found to be thermally stable below 100 °C, and did not interconvert under the influence of UV irradiation, as expected from the above data.

Direct irradiation of **18** in methanol through a Pyrex filter with use of a HPL for 20 min gave **23**, methyl 9-isopropyl-5*H*-benzocycloheptene-5-acetate (**24**), methyl 5-isopropyl-7*H*-benzocycloheptene-7-acetate (**25**), *exo*-and *endo*-isomers of methyl 2a-isopropyl-2a,7a-dihydro-7*H*-cyclobut[*a*]indene-7-acetate (**26**, **27**), in 10, 35, 15, 12, and 6% yields, respectively, estimated by GLC (15% polydiethylene glycol adipate

Table 1. Estimated yields of products in the course of irradiation of **18** and **19** (8×10^{-4} mol/l MeOH)

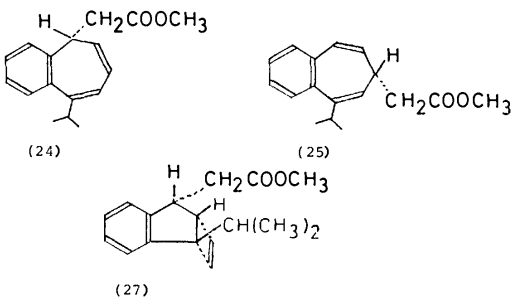
a) The amount of each compound was estimated by their peak areas relative to that of eicosane.



Scheme 5.

on Chromosorb WAW). Photolysis of the *endo* isomer (**19**) gave essentially the same products, except in their yields (Table 1).

The structures of these compounds were determined on the basis of their spectral data. The UV spectrum of **24** showed a maximum at 271 nm which suggested the presence of 5*H*-benzocycloheptene moiety (λ_{max} 275 nm).[7] Although the NMR spectrum taken at room temperature was too broad to investigate spin-spin coupling, those obtained at +2——45 °C clearly demonstrated fine splitting. The presence of three vicinal olefinic protons was observed from the NMR spectra (δ=5.45, 5.91, 6.45; $J_{H_4-H_5}$=5.5; $J_{H_5-H_6}$=9.5; $J_{H_6-H_7}$=5 Hz). The coupling pattenrs of the benzylic methine proton and the acetate-methylene protons defined the position of the substituents.

The UV spectrum of **25** was similar to that of 7*H*-benzocycloheptene (λ_{max} 228 (ε 44000); 256 ^{sh} nm (ε 5200).[7] The presence of 1H signal (δ=6.47), corresponding to the proton alpha to phenyl group, determined the position of the isopropyl group to be C-2. The proton-proton coupling pattern of >CH–CH_2–COO [ABX type: J_{AB}=15.5; J_{AX}=10; J_{BX}= 5.5 Hz] supported that of methyl 7*H*-benzocycloheptene-7-acetate. Direct irradiation of **24** gave mainly a mixture of **26** and **27** in a ratio of 2 : 1. The UV spectra, together with the coupling pattern of the olefinic proton signals in the NMR spectra suggested the presence of the 2a,7a-dihydro-7*H*-cyclobut[*a*]-indene structure. The absence of a lower field signal characteristic of the benzylic methine proton on the cyclobutene ring for both compounds, **26** and **27**, assigned the position of the isopropyl group on C-1. The *endo* structure for **27** was assigned from a larger separation of the two olefinic proton signals, caused by the proximity effect of the methoxycarbonyl group, and the larger splitting signal of the proton on C-5, coupled with the proton on C-4, compared with those of **26**.

It was observed in the photochemical reactions of **18** and **19** that the primary rearrangement products, **24** and **25**, were formed as the major products. Benzonorcaradiene derivatives were not detected in the products. In the photolysis of **10**, **28** was not detected and **13** was obtained in a small amount in the photolysate; further rearranged products were formed, even if the reaction was interupted at the initial stage.[4,7] Cycloheptatrienes are not planar molecules but have the boat conformations,[8] therefore

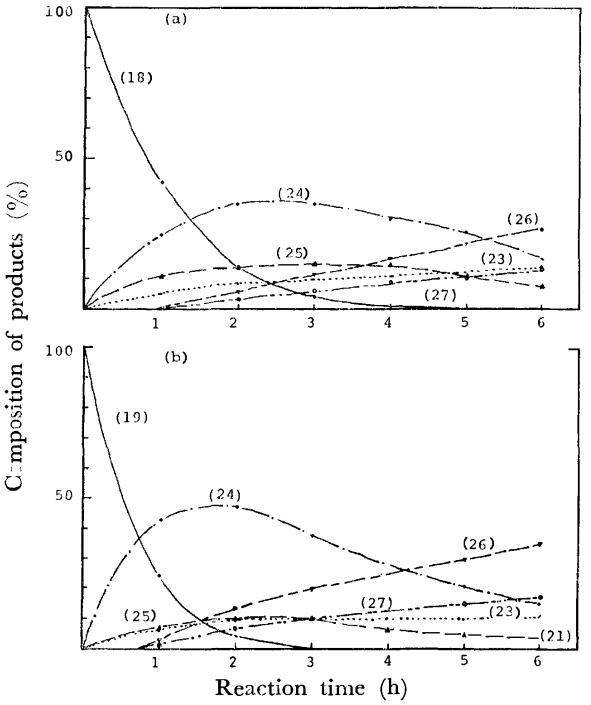


Fig. 1. Plots of the products composition *versus* irradiation time. Starting materials; (a) **18** and (b) **19**.
·····: (**23**), —·—·—: (**24**), ———: (**25**), – – – –: (**26**), ————————: (**27**).

the isopropyl group in **24** and **25** appears to be fixed in a non-coplanar position with respect to the peri C–H bond thereby minimising the mutual steric interaction. The isopropyl group on C-3 in **14** or **16** appears to be fixed near the coplanar position to the peri C–H bond, causing a large repulsive interaction. These steric repulsions give rise to interupt further rearrangement of the primary photo-products, **24** and **25**, to benzonorcaradienes.

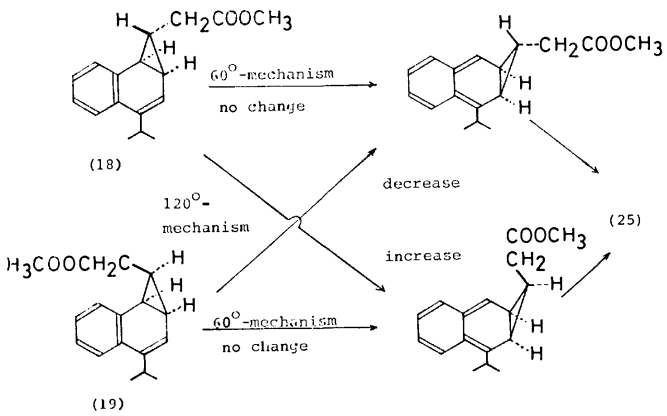
To determine the relative reactivities of the isomeric esters, **18** and **19**, they were photolyzed independently in methanol at the same concentrations (8×10^{-4} mol/l). Eicosane was added as an internal standard and the merry-go-round apparatus was used. The products were analysed for by GLC at regular time intervals and the results are given in Fig. 1.

At the initial stage of the reaction, it may be seen that the rate of formation of **24** from **19** was twice as effective as that of **24** from **18**, in conjugation with the disappearance of **19** which disappeared twice as fast as that of **18**. Initially the rate of formation of **25** from **19** looks slower than that from **18**. However, as the decrease in concentration of **19** is much faster than that of **18**, the ratio of concentrations of **25**/**19** and that of **25**/**18** at low conversion (after one hour irradiation) are important and are almost similar (0.30 and 0.26, respectively).

Since the UV spectra of the isomeric esters, **18** and **19**, are superimposable, the methoxycarbonylmethyl group on C-1 appears to have little influence on the electronic state of the cyclopropane ring. Assuming that the electronic structures of the esters

are quite similar to each other except for steric requirements, the differences in reactivities between **18** and **19** will be determined by the degree of steric freedom in the intermediates from **18** and **19**. Berson,[9] Woodward and Hoffman[10] have suggested that the Berson-Willcott rearrangement of simple norcaradienes must follow after either one of the two possible modes of mechanisms, *i.e.*, the 60°- and the 120°-mechanism. When these mechanisms are applied to the present photo-induced rearrangement of **18** and **19**, the change in steric interference will govern the reaction pathway as shown in Schemes 6 and 7.

Path a



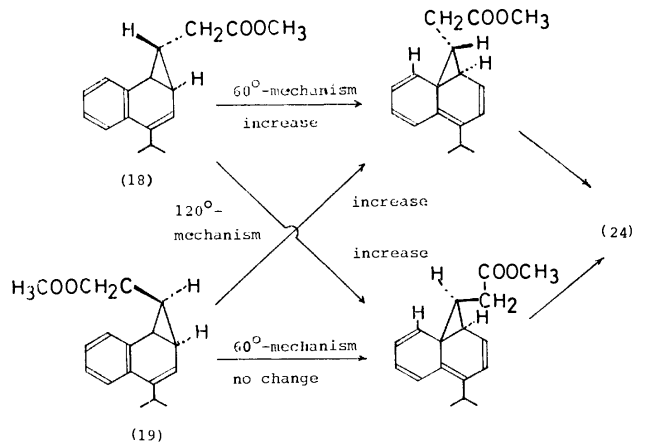
Scheme 6.

As observed from previous experiments on optically active **10**,[10] high stereospecificity of these reactions suggests that the reaction may follow either of the two mechanisms.

If the reactions toward Path a follow 60°-mechanism, formation of **25** from both **18** and **19** will proceed at similar rates. If it follows 120°-mechanism, formation of **25** from **18** will become less than that from **19**. The results on the ratios of concentrations (**25**/**19** and **25**/**18**) at low conversion discussed above support the 60°-mechanism.

Similarly, since formation of **24** from **18** is apparently retarded compared with that from **19** (Fig. 1), another Path b clearly follows the 60°-mechanism, that is, slither motion of C-1 with inversion of the

Path b



Scheme 7.

configuration. This latter claim is in line with the results obtained from the study on an photo-induced rearrangement of optically active substance **10**.[5]

The data supports the 60°-mechanism for the photo-induced rearrangement of methyl 3-isopropyl-1a,7b-dihydro-1*H*-cyclopropa[*a*]naphthalene-1-acetate in both directions. The precise stereochemistry for Path a has recently been established with use of the optically active 3-*t*-butyl derivative of **10** and the results will be reported elswhere.

Experimental

The NMR spectra were obtained on a JEOL Model PS-100 spectrometer with carbon tetrachloride as the solvent and TMS as the internal standard, unless otherwise specified. The chemical shifts are expressed in ppm from TMS. The IR spectra were recorded on a JASCO spectrometer Model IRE and the UV on a Hitachi Recording Spectrometer Model 323. GLC analysis was carried out on a Varian Aerograph Model 90P gas chromatograph under quoted conditions. The light source for photolysis, used throughout this experiments, was a Ushio high pressure mercury lamp, UM-452, with Pyrex filter.

*Synthesis of 3-Isopropyl-1a,7b-dihydro-1*H*-cyclopropa*[a]*naphthalene-1-*exo*-carboxylic Acid (**20**). Reaction of Isopropylnaphthalene (**23**) with Ethyl Diazoacetate*: To 24.6 g (0.144 mol) of **23**, containing 195 mg of copper powder heated at 145—150 °C, was added drop by drop 2.88 g (25.2 mmol) of ethyl diazoacetate over a period of 1 h with vigorous stirring. The mixture was further stirred for 2 h at 145 °C (gas evolution; 610 ml at 25 °C, 95% of theoretical), and then 21.5 g of **23** was recovered by distillation (97—100 °C/7 mmHg). The experiment was repeated three times and the collected residue taken in CH_2Cl_2 was filtered from copper powder and subsequently distilled to give 7.34 g of yellow liquid, bp 136—140.5 °C (1 mmHg). Repeated column chromatography of the distillate on Silicic Acid[11] (hexane-ether 19 : 1 v/v) gave three fractions: Fr. 1; 2.32 g [**29**+**32**]; Fr. 2; 1.73 g [**29**+**32**+**33**]; Fr. 3; 2.08 g [**29**+**33**].

Alkaline Hydrolysis of Fraction 3. The above Fr. 3 (2.08 g), dissolved in 0.5 M 85% aq ethanolic KOH (32 ml) was refluxed for 3 h. The resulting solution was then diluted with water (32 ml) and reduced to half volume under reduced pressure. After being washed with ether, the ice-cooled aq solution was acidified carefully with cold 2 M HCl in the presence of 30 ml of ether. The separated aq solution was extracted three times with ether, and the combined ether extracts were washed with saturated aq NaCl and dried (anhyd Na_2SO_4). After subsequent evaporation of ether, the remaining crystalline acid mixture was recrystallized from aq methanol to give **20** (647 mg) and a 1 : 1 mixture of **20** and **22** (390 mg). **20** mp 200—201.5 °C. IR ν_{max}^{Nujol}: 2650, 2560, 1680, 955 cm^{-1}. NMR ($CDCl_3$) δ=0.78 (1H, t, J=3.5 Hz), 1.14 (3H, d, J=6.5 Hz), 1.17 (3H, d, J=6.5 Hz), 2.75 (1H, d,d,d, J=8, 5.5, 3.5 Hz), 3.01 (1H, septet, J=6.5 Hz), 3.16 (1H, d,d, J=8, 3.5 Hz), 6.16 (1H, d, J=5.5 Hz), 7—7.6 (4H, m), 7.9 (1H, b). Found: C, 78.66; H, 7.10%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

*Preparation of Methyl 3-Isopropyl-1a,7b-dihydro-1*H*-cyclopropa*[a]*naphthalene-1-*exo*-acetate (**18**).* To a cold solution of **20** (3.03 g, 13.3 mmol) dissolved in benzene (66 ml), was added oxalyl chloride (10 g, 80 mmol). After stirring for 4 h at room temperature, the solution was evaporated below 20 °C and the residue was evaporated with benzene (three times, each 10 ml) under reduced pressure to give an acid

chloride (**30**) as an orange liquid. **30** IR $\nu_{max}^{liq.film}$: 1758 cm^{-1}.

To the dried ether solution of diazomethane, prepared from *N*-nitroso-*N*-methylurea (24 g), 50% aq KOH (75 ml) and ether (240 ml), was added drop by drop **30**, dissolved in benzene (15 ml), over a period of 2 h with cooling (ice-water). After further stirring for 1.5 h at that temperature, the mixture was evaporated and taken in dichloromethane. After drying, the solution was evaporated below 20 °C under reduced pressure to give an orange solid (**31**) (4.06 g). IR ν_{max}^{Nujol}: 2055, 1610 cm^{-1}.

The diazomethyl ketone (**31**), dissolved in 1240 ml of methanol was divided into three portions. Each portion was independently irradiated under nitrogen with an HPL for 40 min with external cooling (ice-water) and collected. Subsequent evaporation of solvent left an orange liquid (3.74 g), which was chromatographed on Silicic Acid (120 g) using hexane-ether (9:1 v/v) as the solvent to give **18** as light yellow crystals (1.86 g; 54.4%). Recrystallization from hexane gave colorless crystals, **18**, 1.26 g; mp 84.5—85.5 °C. **18** IR ν_{max}^{Nujol}: 1730, 1460, 1380, 1207, 1192, 1168, 995, 762, 740 cm^{-1}. UV λ_{max}^{EtOH} (log ε): 224.5 (4.29), 231 (4.28), 237.5 $^{infl.}$(4.13), 278 (3.77), 307$^{infl.}$nm(3.35). NMR δ=0.26 (1H, t,t, J=7, 4.3 Hz), 1.12 (3H, d, J=6.5 Hz), 1.13 (3H, d, J=6.5 Hz), 1.76 (1H, d,d,d, J=4.3, 5.5, 8.2 Hz), 2.18 (1H, d,d, J=4.3, 8.2 Hz), 2.31 and 2.34 (-CH_2-CH<, J_{AB}=15.8 Hz, J_{AX}=J_{BX}=7 Hz), 2.90 (1H, septet, J=6.5 Hz), 3.56 (3H, s), 6.01 (1H, J=5.5 Hz), 6.95—7.6 (4H, m). Found: C, 79.60; H, 7.86%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

*Methyl 3-Isopropyl-1a,7b-dihydro-1*H*-cyclopropa*[a]*naphthalene-1*-endo-*acetate (19)*. Compound **18** (20 mg), dissolved in DMSO-d_6 (0.5 ml) in a sealed NMR tube, was kept at 130 °C to give a mixture of **18** and **19**. The product ratios were estimated every 10 min by means of the NMR spectra. Ratio (**18**:**19**): After 10 min (2:1) 20 min (3:2); 30 min (3:2).

To obtain **19** in quantity, **18** (250 mg) was heated at 140 °C for 30 min and the product was chromatographed on 60 g of Silicic Acid (hexane-ether 95 : 5 v/v). Following to **18**, a mixture of **18** and **19** (rich in **19**) was obtained. Further chromatography gave a sample of **19** (50 mg) as a colorless liquid. This was further purified by distillation at 60 °C (1 mmHg) with the aid of a sublimation apparatus. **19** NMR δ=1.20 (3H, d, J=7 Hz), 1.25 (3H, d, J=7 Hz), 1.6—1.9 (-CH_2-CH<), 2.24 (H_{1a}, m), 2.57 (H_{7b}, t, J=7.5 Hz), 3.06 (1H, septet, J=7 Hz), 3.53 (3H, s), 5.89 (1H, d, J=5.5 Hz), 7.08—7.5 (4H, m). UV λ_{max}^{EtOH} (log ε): 224.5 (4.22), 231(4.21), 237.5$^{infl.}$(4.08), 278(3.70), 307$^{infl.}$nm(3.21). Mass spectrum (JMS-D300); M^+ (*m/e*): 256.145; Calcd for $C_{17}H_{20}O_2$; 256.146.

Irradiation of 18 in Methanol: Identification of Products. Compound **18** (300 mg), dissolved in methanol (320 ml), was irradiated using an HPL under nitrogen for 15 min with external cooling (ice-water). After evaporation of the solvent, the residue (303 mg), taken in hexane-ether (90 : 10 v/v), was developed on 30 g of Silicic Acid and elution was continued with the same solvent (95:5 v/v). Each 15 ml-fraction was collected separately and the solvent evaporated to give fractions as follows: Fr. 1—3, 15 mg (**23**); Fr. 6—7, 5 mg (**26**, **27**, and **25**); Fr. 8—9, 76 mg (**25** (main) and **24** (minor)); Fr. 10, 31 mg (**24**); Fr. 11—15, 100 mg (**18**).

Fraction 8 and 9 were rechromatographed on 20 g of Silicic Acid (hexane-ether 95 : 5 v/v) to give a pale yellow liquid (14 mg; **25**), which was purified by means of GLC [5% Silicone OV-17 on Chromosorb WAW, 1/4″×3 m; column temperature, 173 °C; He flow rate, 40 ml/min; retention time, **25** 12.6 min]. **25** NMR δ=0.735 (3H, d, J=7 Hz), 1.20 (3H, d, J=7 Hz), 2.2—2.45 (1H) and 2.48—2.65 (2H) [AB_2 type], 2.93 (1H, septet, J=7 Hz), 3.60 (3H, s), 5.44 (1H, d, J=5 Hz), 5.80 (1H, d,d, J=5, 10 Hz), 6.47 (1H, d, J=10 Hz), 7.05—7.2 (3H, m), 7.24—7.65 (1H, m). UV λ_{max}^{EtOH} (log ε): 227 (4.55), 255$^{infl.}$nm(3.85). Found: C, 79.66; H, 7.90%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

Fraction 10 (31 mg) was rechromatographed on 8 g of Silicic Acid (hexane-ether 95 : 5 v/v) to give a sample of **24** (10 mg). This compound could not be purified by GLC owing to a very slow isomerization to isomer(s) with the same retention time under these conditions. For CH analysis, GLC separation was carried out [5% Silicone OV-17, 170 °C; He, 40 ml/min]. **24** NMR δ=0.9—1.5 (6H, bm), 2.2—3.1 (3H, bm), 3.22 (1H, septet, J=7 Hz), 3.65 (3H, bs), 5.35—5.6 (1H, bm), 5.8—6.1 (1H, bm), 6.25—6.5 (1H, bm), 7.0—7.7 (4H, m); (CD_3OD) at +1 °C δ=0.96 (3H, d, J=7 Hz), 1.35 (3H, d, J=7 Hz), 2.77—2.99 (1H) and 3.07 (2H) [AB_2 type], 3.51 (weak s, axial-$COOCH_3$?)[12], 3.65 (3H, s, $COOCH_3$), 5.45 (1H, d,d, J=9.5, 5.5 Hz), 5.97 (1H, bd, d, J=9.5, 5 Hz), 6.45 (1H, d, J=5.5 Hz), 7.11—7.75 (4H, m). UV λ_{max}^{EtOH} (log ε): 271 (3.82); λ_{min} 246 nm (3.61). Found: C, 79.68; H, 7.91%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

To obtain **26** and **27** in quantity, photolysis of **18** was performed for 30 min. Fractions corresponding to Fr. 6—7 of the above mentioned chromatography were separated and purified by means of GLC [15% polydiethylene glycol adipate, 184 °C; He, 40 ml/min; retention times; **26**, 10 min; **27**, 12 min]. **26** (solidified) IR $\nu_{max}^{liq.film}$: 1730, 1480, 1460, 1440, 1365, 1250, 1165, 1040, 1000, 770, 759, 742 cm^{-1}. NMR δ=0.82(3H, d, J=6.5 Hz), 0.99(3H, d, J=6.5 Hz), 2.22 (1H, septet, J=6.5Hz), 2.21 and 2.51(CH_2, AB part of ABX type, J_{AB}=15.5 Hz, J_{AX}=10 Hz, J_{BX}=5.5 Hz), 2.84 (1H, bs, $\Delta\tau_{1/2}$=3.5 Hz), 3.31 (1H, d,d,d, J=10, 5.5, 1.5Hz), 3.62(3H,s), 6.04(1H, d, J=2.7Hz), 6.25 (1H, d, J=2.7Hz), 6.98—7.18 (4H, m). UV λ_{max}^{EtOH} (log ε): 262 (2.89), 268.5 (3.07), 275.5 nm (3.10). Found: C, 79.69; H, 7.91%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%. **27** IR $\nu_{max}^{liq.film}$: 1730, 1480, 1460, 1440, 1390, 1366, 1165, 995, 880 ,855, 812, 778, 760, 725 cm^{-1}. NMR δ=0.84 (3H, d, J=6.5Hz), 1.01 (3H, d, J=6.5Hz), 2.23 (1H, septet, J=6.5 Hz), 2.32—3.1(2H, m), 3.48(2H, bs, $\Delta\tau_{1/2}$=8 Hz), 3.64 (3H, s), 5.95(1H, d, J=2.7 Hz), 6.37 (1H, d, J=2.7Hz), 6.9—7.3 (4H, m). UV λ_{max}^{EtOH}: 262, 268.5, 275.5 nm.

Short Period Irradiation of 18 and 19 in Methanol. Compound **19** (40 mg), dissolved in methanol (105 ml), was irradiated for 5 min using an HPL with external cooling (ice-water) under nitrogen. After the solvent had been carefully evaporated below 20 °C, the products were analyzed by NMR and GLC. The NMR spectrum revealed that the mixture did not contain any of the *exo*-isomer, **18**. The GLC analysis [15% polydiethylene glycol adipate on Chromosorb WAW, 187 °C; He, 40 ml/min] showed it contained six species, estimated as follows: Retention time (product ratio) : 4.9 min (**23**, 7.5%), 12.8 min (**26**, 5.2%), 14.4 min (**27**, 3.4%), 18.2 min (**25**, 9.0%), 21 min (**24**, 44%), 28.4 min (**19**, 30%).

An identical experiment using the same concentration of **18**, instead of **19**, in methanol was carried out. The products did not contain any of **19** and the ratio of products were obtained as follows: **23**, 9.7%; **26**, 3.2%; **27**, 1.5%, **25**, 14.5% **24**, 33%; **18**, 38.3%.

Irradiation of 24. Compound **24** (60 mg), dissolved in methanol (130 ml), was irradiated with an HPL under nitrogen with external cooling. The occurrence of **26** and

27, in compensation for **24**, was observed by monitoring the reaction using GLC [10% Apiezone L on Chromosorb WAW, 190 °C; He, 40 ml/min: Compound (retention time); **26** (8.8 min), **27** (10 min), **24** (13.2 min)] and NMR [**26** δ=6.04 (d), 6.25 (d): **27** δ=5.95 (d), 6.37 (d): **24** δ=5.35—5.6 (bm)] measurements.

*Competitive Photo-induced Reaction of **18** and **19**.* Each 15 ml of a solution of **18** or **19**, (each 50 mg) dissolved in methanol (244ml) separately, was charged in Pyrex test tubes (ϕ1.5×13 cm), which were stoppered after flushing with nitrogen. Seven tubes each were arranged in a merry-go-round apparatus, cooled with ice-water, and irradiated concurrently with an HPL settled in the center of the apparatus. The reaction products from **18** and **19** were monitored every hour using GLC [15% polydiethylene glycol adipate on Chromosorb WAW, 175 °C; He, 40 ml/min]. The results are given in Table 1.

The authors are grateful to Mr. Jun-ichi Goda for the analytical data and to Mr. Kozo Shibata for measurement of the high resolution mass spectrum.

12) It has been found that methyl 5*H*-benzocycloheptene-5-carboxylate exists in an equilibrated mixture of the two conformers with pseudo-equatorial and a pseudo-axial methoxycarbonyl groups, which were detected by a low temperature NMR spectroscopy (below −90 °C)[M. Kato, K. Takatoku, S. Ito, and T. Miwa, unpublished work]. Likewise, **24** seems to exist in such mixture and the presence of 9-isopropyl group in **24** would make the interconversion much more difficult.

Vinyl Polymerization. 368.[1] Polymerization of Methyl Methacrylate with the System of RNA, Water and Cu(II) Ion

Minoru IMOTO, Yoshiyuki NISHIDA, Toshiyuki YOSHIKAWA, and Tatsuro OUCHI

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita, Osaka 564

(Received September 14, 1977)

The radical polymerization of methyl methacrylate (MMA) was carried out with the system of ribonucleic acid (RNA), Cu(II) ion and water. The generation of free radical was found to take place in the water layer where RNA and Cu(II) ion exist. Urea shows a promoting activity. The effects of pH of water medium and temperature on the conversion of MMA were investigated. A reaction mechanism was proposed.

The so-called uncatalyzed polymerization is a novel reaction, in which macromolecule (or oligomer) in water phase incorporates vinyl monomer from monomer phase, forms a complex with water, monomer and Cu(II) ion, and generates free radicals. The radical polymerization proceeds in the water phase, *i.e.*, predominantly in the hydrophobic area formed by macromolecules. The present paper deals with radical polymerization of methyl methacrylate (MMA) initiated with a system of aqueous copper(II) chloride solution and RNA which was used as macromolecule. Sugiyama and Lee independently reported the polymerization of MMA with the system of RNA, water and Cu(II) ion in the presence or absence of carbon tetrachloride.[2] They investigated in detail only the case in which carbon tetrachloride is present. The present paper is concerned with the case in which it is absent and might be of value for reference.

Experimental

Materials. Commercial RNA from yeast (Sigma Chemical Co. 6750, Lot. 124C-8150) was used. Water was ion-exchanged and redistilled. Copper(II) chloride of special commercial grade was used without further purification. MMA, styrene, and acrylonitrile were purified by the usual method and redistilled before use.

Preparation of Buffer Solutions. These were prepared by use of following systems: pH 3.0—6.0: M/10 citric acid-M/5 Na_2HPO_4; pH 7: M/15 Na_2HPO_4-M/15 KH_2PO_4; pH 8—9: M/10 HCl-M/20 $Na_2B_4O_7$; pH 10: M/20 $Na_2B_4O_7$-M/10 NaOH; pH 11—12 M/10 NaOH-M/10 Na_2HPO_4.

Procedure. Monomer, the aqueous solution of RNA and $CuCl_2 \cdot 2H_2O$ were placed in an ampoule. The ampoule was flushed with nitrogen, frozen, evacuated at 0.1 mmHg, and scaled. The ampoule was shaken in a thermostat. After the reaction, the contents of the ampoule were poured into a large amount of methanol in order to precipitate the polymer. The polymer was collected on a glass filter, thoroughly washed with methanol and water and dried. The number-average degree of polymerization (P_n) of poly-MMA was estimated by gel permeation chromagraphy, using tetrahydrofuran as an eluent.

Results and Discussion

Selectivity of Vinyl Monomer. Polymerization of vinyl monomers was carried out in the presence of RNA, water and Cu(II) ion. The results are given in Table 1. The polymerization of acrylonitrile took place easily in the absence of RNA, by the charge transfer polymerization with Cu(II) ion.[3] The conversion of styrene was due to thermal polymerization.

Table 1. Selectivity of vinyl monomer
(Monomer 3 cm³, H_2O 10 cm³, $CuCl_2 \cdot 2H_2O$ 5×10^{-4} g; 85 °C, 5 h)

RNA/g	Conversion/%		
	MMA	AN	St
0	1.2	8.7	4.2
0.02	6.2	1.3	3.8

Table 2. Activity of metallic salts
(Metallic salts 2.9×10^{-6} mol. MMA 3 cm³, H_2O 10 cm³; 85 °C, 5 h)

RNA/g	Conversion/%				
	$MgCl_2 \cdot 6H_2O$	$FeCl_3 \cdot 6H_2O$	$FeCl_2 \cdot (4H_2O)$	$MnCl_2 \cdot 4H_2O$	$CuCl_2 \cdot 2H_2O$
0.02	1.7	2.6	2.5	2.6	6.2
0	1.2	1.7	1.8	1.8	1.2

It is evident that only MMA was polymerized by RNA.

Effect of Metallic Ion on Polymerization. In order to investigate the effect of metallic ion on polymerization, five kinds of metallic chlorides were added to the reaction system. The results are given in Table 2. Copper(II) chloride was the most active promotor for polymerization, and was thus used in subsequent polymerizations.

Figure 1 shows the effect of the amount of Cu(II) ion on the conversion of MMA. A maximum conver-

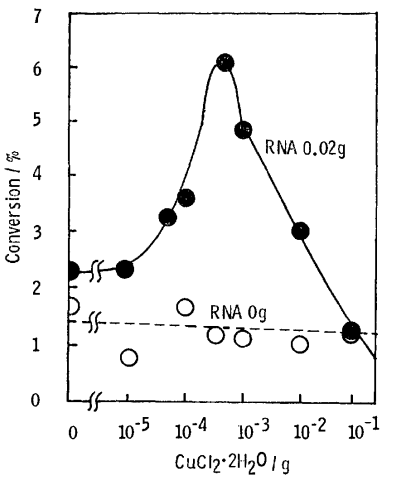

Fig. 1. Conversion of MMA *vs.* amount of Cu(II) ion. MMA 3 cm³, H_2O 10 cm³; 85 °C, 5 h.

sion of MMA was obtained at 5×10^{-4} g of copper(II) chloride. On the other hand, in the absence of Cu(II) ion, the polymerizations was hardly accelerated at all. The open circles indicate the conversion of MMA by thermal polymerization (1.2% in average). Cu(II) ion was found to be very effective.

Proof of Radical Mechanism. In order to confirm the view that polymerization proceeds through a radical mechanism, the copolymerization of MMA with styrene was carried out. The results are shown in Fig. 2. A radical mechanism was verified from the curve.

Locale of the Reaction. In order to find the locale of the generation of the initiating radical, polymerization of MMA was carried out without shaking. The ampoule containing 3 cm^3 of MMA, 0.02 g of RNA, 5×10^{-4} g of $CuCl_2\cdot2H_2O$ and 10 cm^3 of water was allowed to stand at 85 °C. The contents consist of two layers (Fig. 3(a)). As the polymerization proceeded, the water layer became turbid by the polymerized MMA (Fig. 3(b)). After 7 h, the MMA-layer was pipetted out and poured into methanol (conversion: 1.4%, $\bar{P}_n$ of poly-MMA: 1.3×10^4). The water layer was also poured into methanol (conversion: 9.8%, $\bar{P}_n$ of poly-MMA: 1.4×10^{-4}). From the results, it was concluded that the polymerization initiated with RNA takes place in the water layer. The conversion of 1.4% in MMA phase was the result of thermal polymerization.

Effects of the pH of Water Layer on the Conversion of MMA. The results obtained are shown in Fig. 4. The conversion of MMA shows a maximum at pH 8, it being

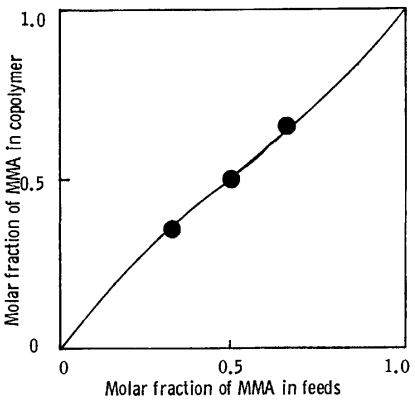

Fig. 2. Copolymerization of MMA and styrene. RNA 0.02 g, $CuCl_2\cdot2H_2O$ 5×10^{-4} g, H_2O 10 cm^3; 85 °C, 5 h.

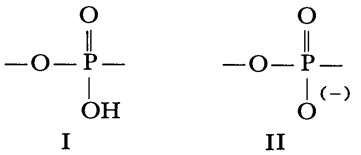
assumed that in the acidic medium, the phosphonate group has the undissociated form I. The decrease in the conversion in acidic medium can be explained by the loss of ionized form II. In the basic medium, the conversion decreased. It seems that NH_2 or NH group of nucleic acid bases becomes free from protonated structure and can easily form a complex with copper(II) ion. Thus when too much NH_2 or NH group exists, the effective activity of Cu(II) ion is lost and the



conversion decreases. Such a retarding effect of free NH_2 group was discussed in the polymerization of MMA initiated with Nylon-3[4].

Effect of Urea on Conversion of MMA. Recently, it was found by Imoto *et al.* that urea can promote the conversion of MMA remarkably in radical polymerization initiated by the system of Cu(II) ion, water and Nylon-3[5] or α-amylase.[6] Urea is known as a denaturing agent of proteins. The tertiary structure of a protein molecule can be unfolded to form new hydrogen bonds between urea and peptide chain. Urea reveals its activity as shown in Table 3, even though the promoting effect is not so large.

Table 3. Effect of urea on the polymerization (RNA 0.02 g, MMA 3 cm^3, $CuCl_2\cdot2H_2O$ 5×10^{-4} g, H_2O 10 cm^3; 85 °C, 5 h)

hydrophobic area formed by RNA molecules. RNA then forms a complex with Cu(II) ion, MMA and water. This is verified partially by the spectral study (Fig. 6). $CuCl_2$ solution in water showed a peak at 208 nm which corresponds to the complex $[Cu(II)\text{-}(OH^-)_x(H_2O)_{4-x}]$. The λ_{max} of water (vapor) is 167 nm[7]. By complexing with Cu(II) ion, this absorption maximum is consisdered to shift to 208 nm, *i.e.*, the λ_{max} of 208 nm corresponds to $Cu(II)(OH^-)_x(H_2O)_{4-x}$. The value of x may be small in the present measurement. RNA solution in water showed a peak at 260 nm which is due to RNA. The peak shifted to 275 nm in the RNA–$CuCl_2$–H_2O solution. This is considered to be an evidence of complex formation of Cu(II) ion with RNA. However, further addition of MMA to the solution of RNA and $CuCl_2$ showed no peak of complexed MMA in this region of wavelength. The ionized phosphonate group was assumed to be necessary, too much free NH_2 or NH group retarding the polymerization. The complex is indicated in Fig. 7(a). As regards the generation of the free radical, we have repeatedly proposed the hydrogen atom transfer from water molecule to MMA as shown in Fig. 7(b).

The Reactions of a Variety of Diazo Compounds with Sulfur Dioxide in Ethanol

Toyoshige TANABE and Toshikazu NAGAI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received September 16, 1977)

The reactions of several diazomethanes bearing a variety of substituents with sulfur dioxide were carried out in ethanol. The reaction of a diazomethane possessing an electron-releasing group gave the olefin as the major product. On the contrary, the ethyl ethers were predominantly afforded from the reactions of the diazomethanes containing an electron-withdrawing group. Moreover, the ethyl alkanesulfonates were obtained in the cases bearing the substituent of an intermediate electronic character. The observed product distribution is interpreted in terms of the nucleophilicity of the α-carbon atom of the diazomethane: the preference of the formation of sulfene by the electrophilic attack of SO_2 on the diazomethane to the acid-catalyzed decomposition by ethyl hydrogen sulfite reflects the nucleophilicity of the α-carbon atom in the diazomethane.

The reactions of diazoalkanes with sulfur dioxide in aprotic solvents are well known to lead to a sulfene intermediate *in situ* followed by the formation of episulfone, olefin, and the carbonyl compounds.[1] In a previous paper,[2] we demonstrated that this reaction certainly proceeds *via* sulfene by the use of enamine as a trapping reagent. Ethanol, one of the typical protic solvents, is also known to act as a trapping agent of the sulfene derived from alkanesulfonyl chloride and triethylamine.[3] However, in the system of diazoalkane and sulfur dioxide, contrary to the amine–chloride system, diazoalkane is liable to undergo decomposition by ethyl hydrogen sulfite, which is at equilibrium with ethanol and sulfur dioxide(Scheme 1, Route B). For example, Hesse and Majmudar[4] reported that ethyl ethoxyacetate was afforded from ethyl diazoacetate and that benzhydryl ethyl sulfite, whose structure had not yet been entirely established, was obtained from diphenyldiazomethane; therefore, the reaction proceeds not by a sulfene mechanism, but by a mechanism involving a protic acid.

In the present paper, we will describe how the possibility of an electrophilic attack of sulfur dioxide on the diazo compound to form sulfene(Scheme 1, Route A) can not be precluded as the initial stage of the reaction even in the system of ethanol and sulfur dioxide, depending on the substituents of diazomethane. Furthermore, as for the follow-up reaction of sulfene (formed *via* Route A), the reaction of sulfene with a new molecule of a diazo compound to give olefin (Route A_1) was found possibly to take place in competition with the trapping of sulfene by ethanol to yield the sulfonate(Route A_2).

Results and Discussion

NMR Study of the Interaction between Ethanol and SO_2. In order to obtain information on the interaction of ethanol and SO_2, the NMR spectra of these solvent mixtures at various ratios were measured, adding CCl_4 to keep the concentration of ethanol constant. The results are listed in the table. Upon an increase in the relative amount of SO_2, the signal of the hydroxylic hydrogen atom gradually shifts to a higher magnetic field, as may be seen in the table. This observation may be attributed to the cleavage of the hydrogen-bonding self association of ethanol by a weak interaction between the oxygen atom of ethanol and the sulfur atom of SO_2, like I as well as the methanol–SO_2 system which was previously reported.[5] If ethyl hydrogen sulfite(II), the OH-proton signal of

$$(C_2H_5OH)_4 \overset{SO_2}{\rightleftharpoons} 4\ \underset{\mathbf{I}}{\begin{matrix} C_2H_5 \\ H \end{matrix}\!\!>\!O\cdots S<\!\!\begin{matrix} O \\ O \end{matrix}} \rightleftarrows 4\ \underset{\mathbf{II}}{C_2H_5O\text{-}S\text{-}OH \\ \quad\quad\ \ \| \\ \quad\quad\ \ O}$$

which would appear in a very low field, were formed in an appreciable amount, the observed chemical shift (δOH) should go to a lower field because δOH must be the average chemical shift of two exchangeable hydroxylic protons of ethanol and II. Therefore, an

Scheme 2. The reactions of diazo compounds(**1**) with SO_2 in ethanol.

a) The yields are in mol% based on the **1** used for **3**, **5**, **6**, and **7**, and based on a half mole of the **1** used for **2** and **4**.

ethanol solution of SO_2 consists largely, if not entirely, of ethanol and SO_2 rather than of ethyl hydrogen sulfite.

Reactions of Diazo Compounds in Ethanol–SO_2 System. The reactions of diazoalkanes(**1**) bearing a variety of substituting groups were carried out by passing gaseous SO_2 through an ethanol solution of **1** for a period of 1 h at 20 °C. The results are summarized in Scheme 2.

In the reaction of **1a**, *cis*- and *trans*-di-*p*-tolylethylene (**2a**) were afforded as the major products in yields of 21 and 38% respectively, together with ethyl *p*-tolylmethanesulfonate(**3a**) (23%), *p*-tolualdehyde azine(**4a**) (9%), and *p*-tolualdehyde(**5a**) (4%). Moreover, there was no proton signal at around δ=5 ppm[6] which could be assigned to the methylidyne proton of the corresponding *cis*- and *trans*-episulfone, 2,3-di-*p*-tolylthiirane 1,1-dioxide. This result may be ascribed to the low stability of episulfone under these reaction conditions; they might undergo decomposition to yield stilbene derivatives.[1b,7]

When **1b** or **1c** was used, the corresponding sulfonate, ethyl diphenylmethanesulfonate(**3b**) or ethyl 9-fluorenesulfonate(**3c**), was predominantly afforded. As for the structure of the reaction product of **1b**, benzhydryl ethyl sulfite(**6b**) was proposed, though not fully established, by Hesse and Majmudar.[4] This product was identified as **3b** and not the isomeric **6b** from the evidence of the mass fragmentation and the IR spectrum, in which two characteristic absorption bands of $-SO_2-$ were observed at 1168 and 1345 cm^{-1}. These observations were also made in **3c**.

On the other hand, ethyl ether, **7d** or **7e**, was exclusively afforded from the reaction of **1d** or **1e** respectively, in which an electron-withdrawing substituent is attached. This type of product is commonly obtained from the acid-catalyzed decomposition of diazo compounds in ethanol and from the thermolysis and the photolysis of diazo compounds in ethanol. In the reaction of **1d**, *p*-nitrobenzyl ethyl sulfite(**6d**) was also obtained in a very low yield(4%). Further, in the case of **1e**, the reaction did not practically proceed under the condition described above; the reaction was, instead, carried out at 40 °C for 2 h.

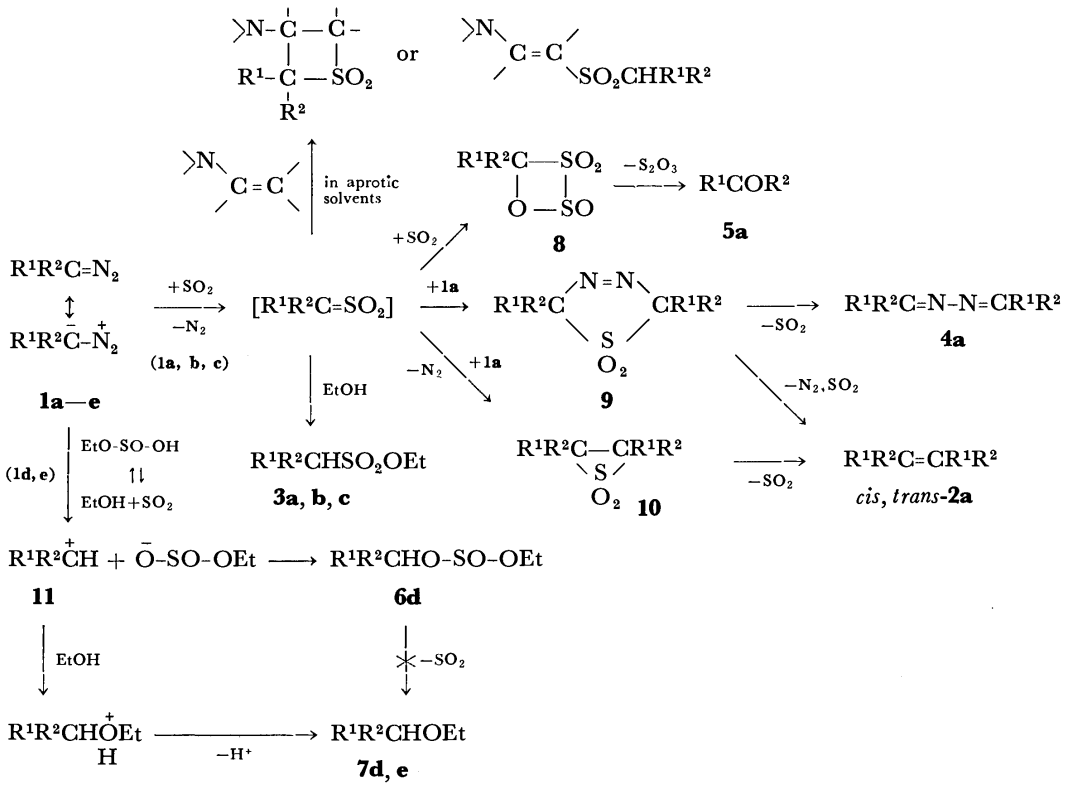
From the results presented above, it is clear that the product distribution was drastically varried with the electronic character of the substituent in **1**, that is, according to the nucleophilicity of the α-carbon atom in **1**.

Reaction Mechanism. Two different explanations are apparently possible to account for the decomposition of the diazo compounds(**1**) in the ethanol–SO_2 system and the formation of the various compounds, **2**—**7**: a reaction *via* sulfene[1] and an acid-catalyzed reaction.[8]

In the reaction of **1b**, the exclusive formation of **3b** is best explained by the process *via* the sulfene intermediate. If the decomposition proceeded by II, the reaction would result in the formation of benzhydryl ethyl ether, tetraphenylethylene, or benzhydryl ethyl sulfite as likely in a protic-acid decomposition. Hence, the possibility of acid catalysis can be ruled out. In this system, a sulfene intermediate was formed *in situ* by the electrophilic attack of SO_2 on **1b**, followed by the addition to ethanol, thus affording **3b**. This is also the case with the reaction of **1c**. As in these two cases, in the reaction of **1a**, which has a more electron-releasing substituent, sulfonate(**3a**) was also given in a 23% yield. In this instance, however, the major product was olefin, *cis*- and *trans*-**2a**(21 and 38% respectively). For the formation of this type of compound, both the sulfene process[1] and acid decomposition[8] are possible. If the latter process is involved in the present reaction, ethyl ether may be formed. Ethyl ether was not, however, obtained here. Furthermore, azine(**4a**) and aldehyde(**5a**) can not be afforded by acid decomposition.

As an alternative, the route involving a sulfene intermediate seems rather attractive as an explanation of the formation of **2a**, together with **4a** and **5a**. According to this process, sulfene was first generated *in situ* by the electrophilic attack of SO_2 on **1a**, with the loss of N_2. The further electrophilic attack of this sulfene intermediate on another, **1a**, rather than ethanol provides the transient 1,3,4-thiadiazoline 1,1-dioxide derivative(**9**), without the loss of N_2, or provides the thiirane 1,1-dioxide derivative(**10**), with the loss of N_2, which then lead to **2a** or **4a** (Scheme 3).[9] Furthermore, **5a** was afforded by the reaction of sulfene and SO_2.[1]

On the contrary, ethers are the major products in the cases bearing electron-withdrawing substituents like **1d** and **1e**. A sulfene mechanism can not give a satis-



Scheme 3.

factory explanation of the formation of **7d** and **7e**. If a sulfene intermediate is involved, the expected product is a sulfonate like **3**. Rather, **7d** or **7e** is the typical product of an acid-catalyzed decomposition of diazo compounds, as has already been mentioned. **1d** and **1e** did not show sufficient reactivity against SO_2 because of the low electron density on the α-carbon atom. Actually, **1d** showed a slower decolorization than the other diazomethanes(**1a**, **b**, and **c**). Especially, **1e** did not react against SO_2 positively under ordinary reaction conditions. Furthermore, **1e** was recovered in the reaction of **1e** with SO_2 at 20 °C in benzene in the presence of 1-morpholino-2-methylpropene, which traps the sulfene intermediate to afford the additive product.[2] Therefore, the most reasonable and acceptable mechanistic route for the formation of ether, **7d** or **7e**, is that the carbonium ion(**11**) is first formed by protonation to diazomethane with a small amount of ethyl hydrogen sulfite, which is at equilibrium with ethanol and SO_2; this is followed by the addition to ethanol, giving **7d** or **7e** in a catalytic manner. As for the formation of **7e**, Hesse and Majmudar[4] proposed a route involving the decomposition of sulfite(**6**), which is yielded by the collapse of **11** with the conuter-ion. In the current observation, **6d** was isolated in a very low yield(4%); this compound is too stable to undergo decomposition to afford **7d**.

According to the observed results and the discussions presented above, the mechanism of the decomposition of the diazomethanes and the follow-up reaction, in the ethanol–SO_2 system depend on the structures of the diazomethanes. An acid-catalyzed decomposition may be limited to the diazo compounds with a relatively strong electron-withdrawing group, while a sulfene formation is regarded as much more likely for the more nucleophilic diazomethanes: olefin or sulfonate was afforded *via* the sulfene from the diazomethane, in which the α-carbon atom has a comparatively high electron density, or from that of an intermediate electronic character, respectively. To clarify the scope and limitations of this reaction, further investigation will be necessary; however, it should be noted here that not all kinds of the diazomethanes are decomposed by a protic acid.

Experimental

The NMR spectra were recorded on a Varian EM-360 (60MHz) instrument in $CDCl_3$, with TMS as the internal standard. The IR spectra were measured with a Hitachi 215 spectrophotometer. The mass spectra were run on a VD-10001-A Hitachi spectrometer.

Materials. All the diazo compounds were prepared by known procedures: *p*-tolyldiazomethane(**1a**),[10] diphenyl diazomethane(**1b**),[11] 9-diazofluorene(**1c**),[12] *p*-nitrophenyldiazomethane(**1d**),[13] and ethyl diazoacetate(**1e**).[14] The sulfur dioxide was dried by passing it through $CaCl_2$ and P_2O_5 tubes. The ethanol was purified[15] and dried by refluxing it over magnesium metal. The carbon tetrachloride was purified by the ordinary method[15] and was dried over activated molecular sieves, MS-4A.

Procedure. *NMR Study*: The solutions to be studied were prepared by passing SO_2 slowly through ethanol until saturation. After determining the amount of SO_2, definite amounts of CCl_4 and ethanol were added to this solution. These operation were carried out under a good dry condition. The solution was then transferred into

an NMR tube, and the tightly cap-sealed tube was submitted to NMR analysis at 26 °C.

General Method for the Reaction of ***1*** *with SO_2 in Ethanol.* In a 100-ml, three-necked flask equipped with a magnetic stirrer, a gas inlet tube, a thermometer, and a calcium chloride drying tube we placed 5 mmol of **1** and 100 ml of anhydrous ethanol. Gaseous SO_2 was then introduced into this solution at 20 °C for a period of 1 h. After the decolorization of the solution and the evolution of N_2 was complete, the solvent and the excess SO_2 were removed *in vacuo* at room temperature. An aliquot of the residue was dissolved in $CDCl_3$ and analyzed by NMR; then the NMR solvent was removed, and the combined residue was separated by preparative silica gel column chromatography, if necessary. An analytically pure sample was obtained by recrystallization from suitable solvents.

The Reaction of ***1a.*** The reaction was carried out using twice the amount of **1a**. According to the NMR spectrum, five kinds of products were contained in the crude reaction mixture. These products were submitted to the preparative silica gel column chromatograph. *cis-* and *trans-***2a** were eluted first by benzene; these two geometric isomers were isolated by fractional recrystallization from ethanol. The isolated yields of *cis-* and *trans-***2a** were 21 and 38% respectively. *cis*-Di-*p*-tolylethylene (*cis-***2a**) was crystallized from ethanol; colorless prisms; mp 31—32 °C (lit, 32.3 °C).[16] NMR: δ 2.30(6H, s, methyl), 6.50(2H, s, vinyl), and 7.00 and 7.15(each 4H, d, J=8 Hz, phenyl). MS: m/e=208(M^+). *trans*-Di-*p*-tolylethylene(*trans-***2a**) was recrystallized from ethanol; colorless leaflets; mp 183—184 °C (lit, 179—180 °C).[17] NMR: δ 2.30(6H, s, methyl), 6.98 (2H, s, vinyl), and 7.10 and 7.37(each 4H, d, J=8Hz, phenyl). Found: C, 91.75; H, 7.74%. Calcd for $C_{16}H_{16}$: C, 92.26; H, 7.74%. *p*-Tolualdehyde azine(**4a**) was obtained as the second eluate by the use of benzene; its yield was estimated to be 9% from the intensity of the NMR spectrum of a reaction mixture. The recrystallization from acetone gave pale yellow prisms; mp 159—160 °C(lit, 157 °C).[18] IR(KBr): 1615 cm^{-1}(C=N). NMR: δ 2.40(6H, s, methyl), 7.26 and 7.77 (each 4H, d, J=8.5Hz, phenyl), and 8.65 (2H, s, methylidyne). Found: C, 81.32; H, 6.83; N, 11.66%. Calcd for $C_{16}H_{16}N_2$: C, 80.99; H, 6.85; N, 11.65%. *p*-Tolualdehyde(**5a**) and ethyl *p*-tolylmethanesulfonate(**3a**) were eluted by ether as the final fraction in yields of 4 and 23% respectively. The **5a** was identified by the comparison of its IR and NMR spectra with those of an authentic specimen. The **3a** was purified by further silica gel column chromatography and was recrystallized from ethanol; colorless plates; mp 40—41 °C. IR(KBr): 1170, 1175, 1350, and 1355 cm^{-1} (SO_2). NMR: δ 1.30(3H, t, J=7 Hz, $CH_2\underline{CH_3}$), 2.37 (3H, s, CH_3), 4.12 (2H, q, J=7 Hz, $\underline{CH_2}CH_3$), 4.30 (2H, s, benzylic), and 7.25 (4H, broad s, phenyl). MS: m/e=214(M^+),105 (p-CH_3-C_6H_4-CH_2^+).

Reaction of ***1b.*** The white crystalline was obtained in a 87% yield by removing the solvent; subsequent recrystallization from ethanol gave colorless needles of ethyl diphenylmethanesulfonate (**3b**); mp 70—71 °C. IR (KBr): 1168 and 1345 cm^{-1}(SO_2). NMR: δ 1.15(3H, t, J=6Hz, CH_3), 4.00(2H, q, J=6Hz, CH_2), 5.50(1H, s, methylidyne), and 7.23—7.73(10H, m, phenyl). MS: m/e=276(M^+), 167(Ph_2CH^+). Found: C, 65.12; H, 5.77%. Calcd for $C_{15}H_{16}O_3S$: C, 65.21; H, 5.84%.

Reaction of ***1c.*** In the same manner as has been described above, a white powder, ethyl 9-fluorenesulfonate (**3c**), was obtained in a 89% yield; it was subsequently recrystallized from ethanol; colorless needles; mp 94.5—95.5 °C. IR(KBr): 1175 and 1355 cm^{-1}(SO_2). NMR: δ 0.93(3H, t, J=7Hz, CH_3),3.87(2H, q, J=7Hz, CH_2), 5.37(1H, s, methylidyne), and 7.2—8.1(8H, m, aromatic). MS: m/e=274(M^+), 165($M^+-C_2H_5SO_3$). Found: C, 65.96; H, 5.24%. Calcd for $C_{15}H_{14}O_3S$: C, 65.96; H, 5.15%.

Reaction of ***1d.*** The reaction was carried out using 10 mmol of **1d**. The crude reaction mixture was chromatographed over silica gel. *p*-Nitrobenzyl ethyl ether(**7d**), fractionated as the first eluate, was purified by further column chromatography; a pale yellow oil. IR: 1515 and 1345 cm^{-1}(NO_2), 1105 cm^{-1}(C-O-C). NMR: δ1.27(3H, t, J=7 Hz, CH_3), 3.60(2H, q, J=7 Hz, OCH_2CH_3), 4.59 (2H, s, benzylic), and 7.50 and 8.18(each 2H, d, J=8.5Hz, phenyl). MS: m/e=181(M^+), 152(p-NO_2-C_6H_4-CH_2O^+), 136(p-NO_2-C_6H_4-CH_2^+), 106(p-O-C_6H_4-CH_2^+). *p*-Nitrobenzyl ethyl sulfite(**6d**) was also separated in a 4% yield by further elution with benzene; it was recrystallized from ethanol as colorless needles; mp 87—88 °C. IR(KBr): 1175 cm^{-1}(O-SO-O), 1345, 1355, 1515, and 1525 cm^{-1}(NO_2). NMR: δ 1.33(3H, t, J=7Hz, CH_3), 4.23(2H, q, J=7Hz, OCH_2CH_3), 4.41(2H, s, benzylic), and 7.60 and 8.26(each 2H, d, J=8Hz, phenyl). MS: m/e=245(M^+), 152(p-NO_2-C_6H_4-CH_2O^+), 136(p-NO_2-C_6H_4-CH_2^+), 106(p-O-C_6H_4-CH_2^+).

Reaction of ***1e.*** Although the reaction did not practically proceed under ordinary conditions, it was accomplished at 40 °C for 2 h using 15 mmol of **1e** and 60 ml of ethanol. The oily crude product, obtained in an 81% yield by fractional distillation under reduced pressure, was identified as ethyl ethoxyacetate(**7e**); a colorless oil. IR: 1753 cm^{-1} (C=O), 1138 and 1205 cm^{-1}(C-O-C). NMR: δ 1.23(3H, t, J=6.5Hz, $OCH_2\underline{CH_3}$), 1.27(3H, t, J=7Hz, $CO_2CH_2\underline{CH_3}$),3.60(2H, q, J=6.5Hz, OCH_2CH_3), 4.03(2H, s, OCH_2CO), and 4.21(2H, q, J=7Hz, $CO_2\underline{CH_2}CH_3$). MS: m/e=103($M^+-C_2H_5$), 88($M^+-C_2H_4O$).

Reaction of ***1e*** *with SO_2 in the Presence of Enamine.* The reaction was tried using 10 mmol of **1e**, 10 mmol of 1-morpholino-2-methylpropene, and 50 mmol of SO_2 in 100 ml of benzene in the manner described in the previous paper,[2] but **1e** was recovered from the reaction mixture by distillation under reduced pressure.

The Intrachain Aminolysis of a Terminal *p*-Nitrophenyl Ester Group by a Terminal 4-Pyridyl Group Attached to Both Ends of a Poly(oxyethylene) Chain*

Masahiko SISIDO, Eiichi YOSHIKAWA, Yukio IMANISHI, and Toshinobu HIGASHIMURA

Department of Polymer Chemistry, Kyoto University, Kyoto 606

(Received September 24, 1977)

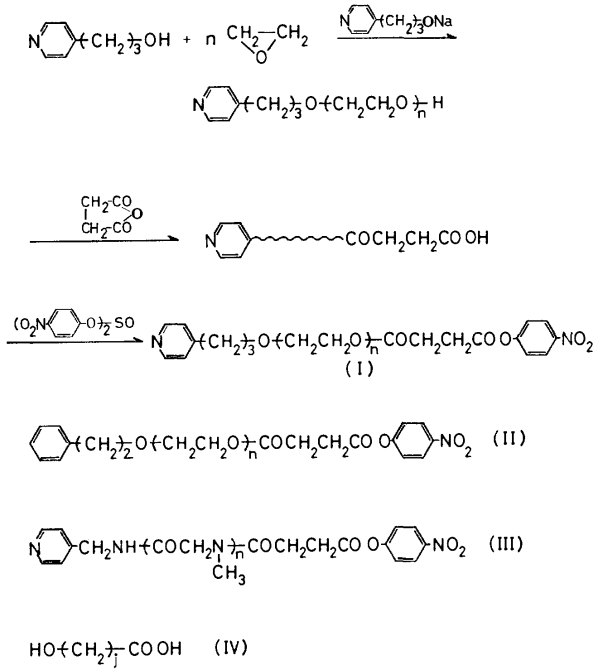
The intrachain aminolysis by a terminal 4-pyridyl group of a *p*-nitrophenyl ester group at the other terminal of a poly(oxyethylene) chain was investigated. The rate constants of the intrachain reaction were determined as a function of the degree of polymerization, *n*, of the poly(oxyethylene) chain over the range of 5—33 at 15, 25, and 35 °C. The rate constant was at its maximum at $n=7$ and decreased with an increase in the chain length. A comparison of the data with those obtained with polysarcosine chain showed that the intrachain reaction proceeded more effectively in the latter chain. Some thermodynamic considerations were made as to the cyclization process of a poly(oxyethylene) chain.

Many types of intramolecular reactions in which a polymeric molecule participates have been investigated. For a quantitative understanding of these reactions, including enzymic reactions, the investigation of the intramolecular reaction between two functional groups connected by a polymeric chain with a definite chain length is very useful.[1] The polymer molecules of this type can be shown schematically as an X–Y-type polymer, where X and Y denote the reactive groups. The intramolecular reaction of X and Y is different from the intermolecular one to an extent which is determined by the constraint imposed by the conformation of the polymer chain.

In a previous paper of this series,[2] an intrachain aminolysis on a polysarcosine chain with a terminal *p*-nitrophenoxycarbonyl group and a terminal 4-pyridyl group was investigated. The rate constant of the intrachain reaction decreased monotonously with an increase in the chain length. This observation is not in accordance with the chain length-ring-closure probability relationship predicted by the Monte Carlo calculation of the polysarcosine chain.[3] The calculation predicted a maximum intrachain rate constant at $n=7$ (*n* is the number of sarcosine units). In this study, the same sort of reaction was examined with poly(oxyethylene) chains with the degrees of polymerization, *n*, from 5 to 33. The results were compared with those obtained with the polysarcosine chain. The poly(oxyethylene) chain was employed to connect the functional groups because; (1) it readily dissolves in water; (2) it can be synthesized by anionic polymerization and the degree of polymerization is controlled by the monomer/initiator ratio;[4] and (3) its physical properties, such as the average dimensions in solution have been widely investigated.

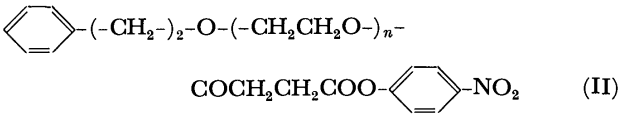
Experimental

Preparation and Characterization of Polymer Samples. Poly(oxyethylene) with a terminal *p*-nitrophenoxycarbonyl group and a terminal 4-pyridyl group (I) was synthesized as is shown in Scheme 1.[2]



Scheme 1.

Ethylene oxide was polymerized in dioxane by using a mixture of 3-(4-pyridyl)-1-propanol (3 part) and its sodium salt (1 part).[4] All the polymerization procedures, including the preparation of the catalyst solution, were carried out in a vacuum line. After the reaction mixture had been allowed to stand for a week at 60 °C, the reaction tube was opened and an excess amount of succinic anhydride was added immediately. After a few hours, a three-fold excess of bis(*p*-nitrophenyl)sulfite was added and the mixture was left overnight at 25 °C. The polymer sample was then separated from the low-molecular-weight compounds by preparative gel-chromatography using a Sephadex LH-20 column equilibrated with dioxane. The fractions containing polymer samples were freeze-dried from dioxane. A polymer sample with a terminal phenyl group instead of a pyridyl group (II) was synthesized by using phenethyl alcohol as the initiator.



Polymers with degrees of polymerization higher than 40 were precipitated from the polymer mixture with ether.

* Intrachain Reaction of a Pair of Reactive Groups Attached to Polymer Ends. Part VI.

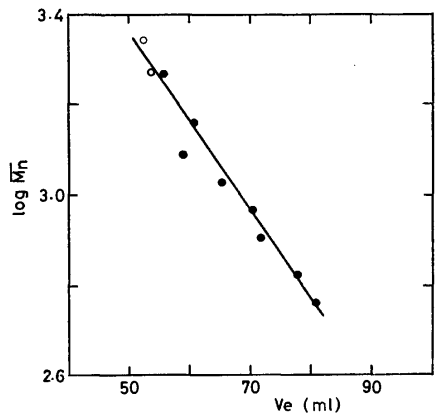


Fig. 1. Relation between the number-average molecular weight of poly(oxyethylene) and the elution volume at the peak position. The number-average molecular weight was calculated according to Eq. 1 (●) or determined by vapor-pressure osmometry (○).

The number-average molecular weight of the ether-precipitated polymers was measured by means of vapor-pressure osmometry. The low-molecular-weight samples, which were freeze-dried from the dioxane solution, usually contained trace amounts of a residual solvent and so were not suitable for the molecular-weight determination by the above method. Therefore, their molecular weight was determined on the basis of the elution volume in the gel chromatogram. Plots of the elution volume against the number-average molecular weight calculated by Eq. 1[4] are shown in Fig. 1. The

$$\bar{n} = [\text{Monomer}]/[\text{Initiator}]. \quad (1)$$

molecular weights measured by vapor-pressure osmometry are also plotted against the elution volume (open circles). Since the experimental points of different kinds (open and closed circles) lie on the same line, the following relation should hold between the elution volume, V_e, and the number-average degree of polymerization, $\bar{n}$:

$$V_e = 104 - 31 \log \bar{n}. \quad (2)$$

In the following part, the discussion will be based on the degree of polymerization calculated by Eq. 2. The number-average degrees of polymerization for polymers carrying a terminal phenyl group were determined in a similar way. The results of the polymer characterization are summarized in Table 1.

Table 1. Characterization of polymer samples

Initiator	$\bar{n}$ Calcd by Eq. 1	$\bar{n}$ Determined by VPO	$\bar{n}$ Determined by GPC
3-(4-Pyridyl)-1-propanol	5.2		4.8
	7.0		6.9
	9.7		11
	12.7		12
	15.6		17
	20.0		27
	25.7		24
	36.3		33
	31.7	35	40
	35.0	38	43
β-Phenetyl alcohol	4.6		2.4
	9.2		14
	13.4		13
	18.5		18
	18.1	28	27

The agreement of the molecular weights calculated from Eq. 1 with the observed values suggests a Poisson-type molecular-weight distribution for the polymer samples.[4] The narrow molecular-weight distribution was actually indicated by the elution diagram.

The amount of pyridyl group incorporated into a polymer end was estimated by means of the absorbance of the pyridyl group (260 nm, $\varepsilon = 2.01 \times 10^3$) for the ether-precipitated high-molecular-weight polymers. The ratios of the observed amount to the calculated amount for the complete incorporation were 0.88 ($\bar{n}=42$) and 0.95 ($\bar{n}=80$). These data show that the incorporation is nearly quantitative.

Measurements. The aminolysis reactions were carried out at pH 6.1 (phosphate buffer, $\mu=0.067$).[2] The reaction was followed by recording the absorbance (320 nm) of the *p*-nitrophenol liberated. The concentration of the terminal ester group was adjusted to about 5×10^{-5} M. At this dilute concentration the contribution from the intermolecular reactions can be ignored (see below). The iodometry[5] showed no evidence of the formation of poly(oxyethylene) micelles at this concentration. The fraction of free pyridyl groups at pH 6.1 has been estimated to be about 0.93,[2] irrespective of the reaction temperature.

Results and Discussion

Evaluation of Rate Constants of the Intrachain Reaction. The intrachain aminolysis was carried out at 15, 25, and 35 °C. Figure 2 shows a typical first-order plot for the reaction at 25 °C. The rate of the reaction depends unambiguously upon the chain length. The slope affords an apparent rate constant, k_{obsd}, which should consist of these three terms:

$$k_{obsd} = k_1 + k_s + k_2[\text{Pyr}], \quad (3)$$

where k_1, k_s, and k_2 denote the rate constants for the intrachain aminolysis, spontaneous hydrolysis, and

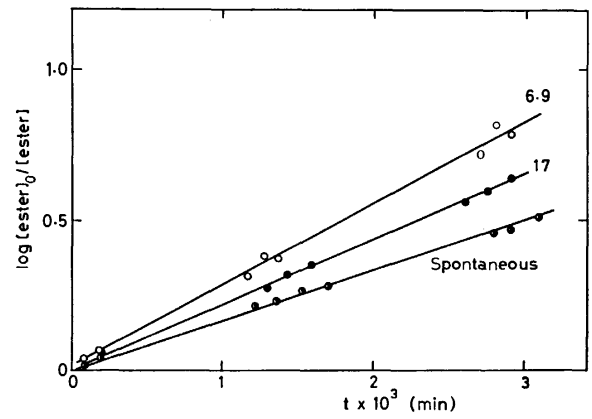

Fig. 2. Typical first-order plot for the reaction of polymer (I) having different chain lengths; 25 °C, pH=6.1. Numbers in the Figure indicate the number-average degrees of polymerization of poly(oxyethylene) chain. The bottom line represents the spontaneous hydrolysis of the polymer (II) (n=18).

Table 2. Rate constants for spontaneous hydrolysis (k_s) and intermolecular reaction by pyridine (k_2)

	$\bar{n}$	Temp (°C) 15	25	35
k_s	2.4	0.9×10^{-4}	2.9×10^{-4}	5.9×10^{-4}
(min^{-1})	7.4	0.9		
	12.5	1.0	3.5	5.4
	17.5	1.4	3.6	4.6
	27.4	1.2	3.5	4.7
	average	1.1×10^{-4}	3.3×10^{-4}	5.1×10^{-4}
k_2	2.4	2.0×10^{-2}	4.3×10^{-2}	1.3×10^{-1}
(M^{-1} min^{-1})	7.4	2.1		
	12.5	1.8	7.5	1.2
	17.5		4.4	1.5
	27.4	2.1	4.8	1.2
	average	2.0×10^{-2}	5.3×10^{-2}	1.3×10^{-1}

intermolecular aminolysis respectively. The concentration of the terminal pyridyl group is denoted as [Pyr]. The k_s value was determined from the spontaneous hydrolysis of the phenyl-terminated polymer (II) under the same conditions. The k_2 value was estimated from the pyridine-catalyzed aminolysis of the polymer (II). The results are collected in Table 2. The k_s and k_2 values were not affected by the chain length, indicating the same inherent reactivity of the terminal ester groups attached to poly(oxyethylene) with different chain lengths. The value of k_2 is so small that the contribution from the intermolecular reaction can be ignored when the polymer concentration is as low as 5×10^{-5} M.

The rate constant of the intrachain aminolysis, k_1, was calculated according to Eq. 3; it is plotted in Fig. 3 as a function of the degree of polymerization of the poly(oxyethylene) chain. It is interesting to note that the intrachain reaction is most efficient at $\bar{n}=7$. Undoubtedly the conformational constraints imposed by the poly(oxyethylene) chain caused this marked dependence on the chain length. The presence of the optimum chain length has been expected as a result of some conformational calculations and has actually been observed in some intrachain reactions.[3,6,7] The chain-length dependence of k_1 was more marked at higher temperatures. This trend indicates that the cyclic conformations, which are necessarily taken up to substantiate the intrachain reaction, have a large entropy at the optimum chain length resulting in the high intrachain reactivity. This view is consistent with the thermodynamic consideration (see below).

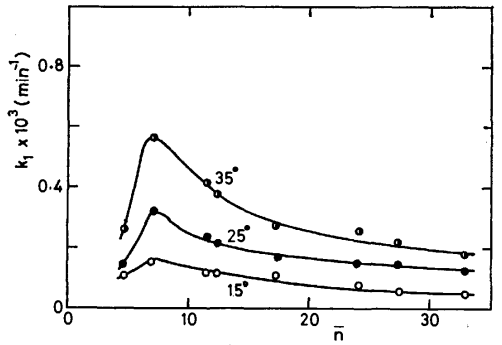

Fig. 3. Dependence of the rate constant of intrachain aminolysis k_1 on the degree of polymerization of poly(oxyethylene) at three different temperatures, pH=6.1.

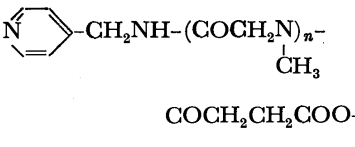
Comparison with the Intrachain Reaction on a Polysarcosine Chain. To compare the present data with those obtained with other polymer chains, the chain-length dependence of k_1/k_2, the intrachain rate constant relative to the intermolecular one, was examined. The rate-constant ratio eliminates the ambiguity arising from the different inherent reactivities of the terminal groups. The rate-constant ratios are shown in Fig. 4, together with the data obtained with the polysarcosine chain (III)[2] and the polymethylene chain (IV).[6] The data for the polymethylene chain have been obtained by the intramolecular esterification



(III)

$$HO\text{-}(\text{-}CH_2\text{-})_j\text{-}COOH \qquad \text{(IV)}$$

(lactone formation) of ω-hydroxycarboxylic acid in a benzene solution at 80 °C.[7] For the other two poly-

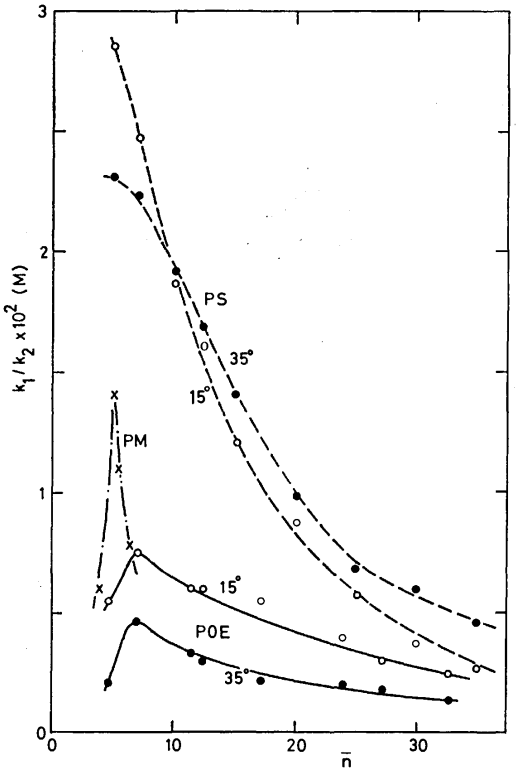


Fig. 4. Comparison of the rate-constant ratio of intrachain and intermolecular aminolyses k_1/k_2 among three polymers, *i.e.*, poly(oxyethylene) (POE), polysarcosine (PS), and polymethylene (PM). For polymethylene chains, $\bar{n}$ was calculated as $\bar{n}=(j/3)-2$.

mers, the reaction was an intrachain aminolysis. Obviously the polysarcosine and polymethylene chains are more efficient in the intrachain reaction; in other words, they take cyclic conformations more easily than poly(oxyethylene) chain. This finding is somewhat unexpected, since the latter chain appears to be more flexible due to the presence of oxygen atoms in the main chain, which are sterically less hindered than others. A Monte Carlo calculation may provide information concerning the ease of cyclization of these chains.[8] It is interesting that the population of the cyclic conformations of the poly(oxyethylene) chain increases with decreasing the temperature, whereas it increases with polysarcosines having larger chain lengths than $\bar{n}=10$ with a rise in temperature. This difference indicates the difference in the thermodynamic properties of the two chains.

Activation Parameters. The Arrehenius plots of the rate constants of the intrachain aminolysis are shown in Fig. 5. The activation parameters (ΔH_1^*, ΔS_1^*) were derived from the slope and the intercept of each straight line in Fig. 5. These parameters contain contributions from the conformational change requied for the cyclization (ΔH_c^*, ΔS_c^*) and those from the electronic change accompanying the reaction (ΔH_e^*, ΔS_e^*) as

$$\Delta H_1^* = \Delta H_c^* + \Delta H_e^*,$$
$$\Delta S_1^* = \Delta S_c^* + \Delta S_e^*. \quad (4)$$

ΔH_e^* and ΔS_e^* should be independent of the chain length. The electronic contributions can be evaluated from the activation parameters for the intermolecular reactions, ($\Delta H_2^*=14.4$ kcal/mol, $\Delta S_2^*=-15.3$ eu). Following the discussion reported previously,[2] the enthalpy for the electronic change of the intrachain reaction is equal to that of the intermolecular reaction, and the electronic entropy of the intrachain reaction is smaller by the bimolecular encounter term ($\Delta S_b^*=-3.6$ eu) than that of the intermolecular reaction. Thus, the following relations hold:

$$\Delta H_e^* = \Delta H_2^*,$$
$$\Delta S_e^* = \Delta S_2^* - \Delta S_b^*. \quad (5)$$

Using these relations, the activation parameters for the conformational change were calculated and plotted as a function of the degree of polymerization of the poly(oxyethylene) chain (Fig. 6). The activation enthalpy for conformational change is negative, irrespective of the chain length, indicating that cyclic conformations are of a lower conformational energy than linear ones. The chain-length dependence of the conformational enthalpy shows a tendency opposite to that observed in the rates of intrachain reactions; *e. g.*, at the optimum chain length ($\bar{n}=7$), the activation enthalpy is at maximum. It is, therefore, feasible to say that the chain-length dependence of the intrachain reaction of poly(oxyethylene) is governed mainly by the conformational entropy. This finding contrasts with that obtained for polysarcosine, where the conformational enthalpy was a dominant factor in the intrachain reaction.[2] As may be seen from Fig. 7, the compensation plot for ΔH_c^* and ΔS_c^* falls on a straight line, giving an isokinetic tempera-

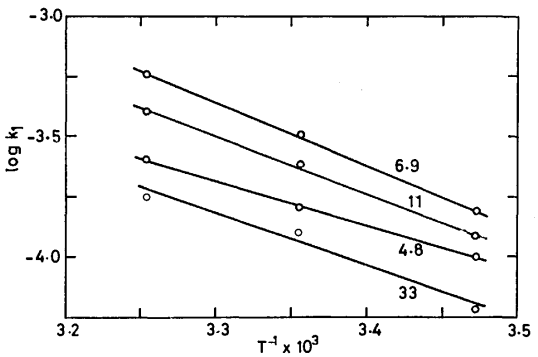

Fig. 5. Typical Arrhenius plot of the rate constants of intrachain aminolysis of poly(oxyethylene). Numbers in the Figure are the degree of polymerization of poly(oxyethylene).

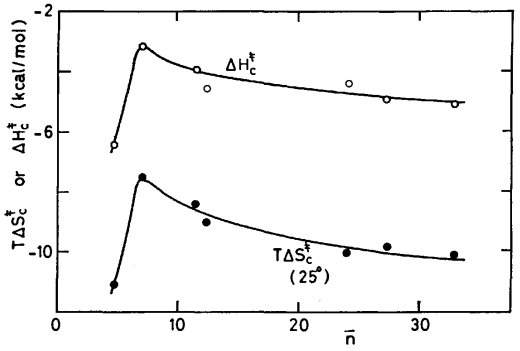

Fig. 6. Activation parameters for the conformational change accompanied with the intrachain reaction of poly(oxyethylene), plotted against the degree of polymerization.

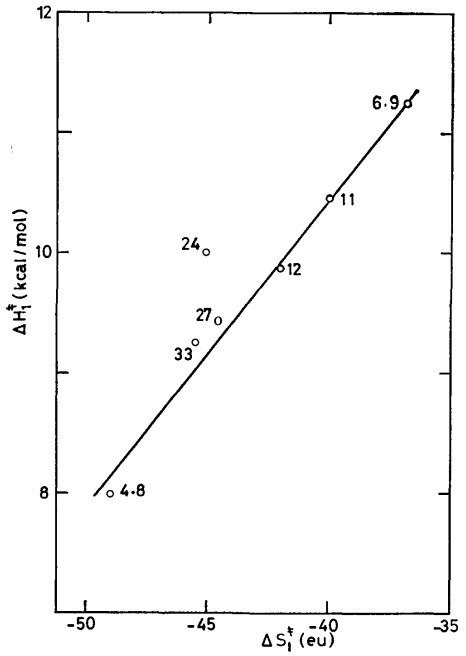

Fig. 7. Compensation plot of the activation parameters. Numbers in the Figure show the degree of polymerization of poly(oxyethylene).

ture of 2 °C. A similar relation has also been observed in the intrachain aminolysis of polysarcosine[2] and in the intrachain charge-transfer complex of polysarcosine.[9,10] Therefore, it is likely that some conformational mechanism operates to compensate for the entropy loss accompanying the cyclization, hence stabilizes the cyclized conformation. The solvation of the polymer chain has been suggested to play an important role in the compensation mechanism.[10] However, the details of the solvent effect still remain unclear in the present case.

To conclude, an optimum chain length was observed in the intrachain reaction between two terminal groups of the poly(oxyethylene) chain. Intrachain reactions on the poly(oxyethylene) chain took place less efficiently than those on polysarcosine and polymethylene chains.

A Monte Carlo Study of the Intrachain Reaction on a Poly(oxyethylene) Chain*

Masahiko Sisido, Yukio Imanishi, and Toshinobu Higashimura
Department of Polymer Chemistry, Kyoto University, Kyoto 606
(Received September 24, 1977)

Monte Carlo calculation was performed to estimate the ring-closure probability of a poly(oxyethylene) chain. The calculation was made for various chain lengths on the basis of a rotational isomeric state model in which the intrachain atomic overlaps were excluded in terms of the hard-sphere model. The chain-length dependence of the ring-closure probability thus obtained was compared with that of the rate-constant ratio of the intrachain reaction *vs.* the intermolecular reaction previously reported. For longer chains, the calculation agreed well with the experimental data. For shorter chains, the agreement was less satisfactory; this discrepancy was attributed to the effect of the bulky terminal groups of the poly(oxyethylene) chain. The thermodynamic parameters for the cyclization were determined, and it was found that the chain-length dependence of the ring-closure probability is mainly governed by the conformational enthalpy.

Intrachain reactions of X–Y-type polymers may provide information concerning the flexibility of a polymer chain, which is hard to determine quantitatively by other means. Provided that the reaction requires a moderately high activation energy, the rate of intrachain reaction on a polymer chain should be proportional to the ring-closure probability of the polymer chain.[1] The ring-closure probability of a polymer chain has been reported to be sensitive to the conformational property of the polymer chain.[2] In other words, the intrachain reaction on a polymer chain is strongly affected by the nature of the polymer chain. In this respect, a comparison of the experimental results of the intrachain reaction with the conformational calculation would seem to be interesting. This sort of comparison has been made for intrachain reactions on polymethylene chains,[1,3,4] polysarcosine chains,[5,6] and RNA chains.[7,8] The ring-closure probabilities of various condensation polymers have also been calculated in connection with the ring-chain equilibria in solution and in bulk.[9]

In our previous investigations,[7,8] a polysarcosine chain was used as a "spacer" for an intrachain aminolysis of a *p*-nitrophenyl ester group by a 4-pyridyl group in an aqueous solution. When the rate constants of the intrachain reaction were compared with those calculated by the Monte Carlo method, a fairly good agreement was found between them. This prompted us to carry out the Monte Carlo calculation for the poly(oxyethylene) chain, which has been used as a "spacer" for the same intrachain reaction.[10] Since the poly(oxyethylene) chain is different from other chains in its preference for the *gauche* conformational state for each bond, characteristic behavior in the ring-closure probability is expected. The ring-closure probability was calculated as a function of the chain length and was compared with experimental data on the rate-constant ratio of intrachain to intermolecular reactions. The agreement between them was compared with that previously obtained with polysarcosine.

Conformational calculations of poly(oxyethylene) chains have been conducted by Mark and Flory[11] and recently by Abe and Mark[12] on the basis of the *t-g* rotational isomer model. The most characteristic feature of the chain is the preference for the *gauche* rotational state, for reasons not yet completely clear. In the present calculation, therefore, the "*gauche* effect" was taken into consideration by adding a corrective energy for the *gauche* state, as was recently suggested by Abe and Mark.[12] By using these effective parameters, the conformational properties, such as the average dimensions and the dipole moment of poly(oxyethylene) chains, have been successfully reproduced.[12] Hence, the same parameters were used in the present Monte Carlo calculation.

Procedures for the Monte Carlo Calculation

Structure and Energy Parameters. As has been stated above, some ambiguity remains as to the conformational parameters for poly(oxyethylene) chains. In this study, the most recent values proposed by Abe and Mark[12] were used (Table 1). It should be noted that the rotational angles for the *gauche* states, $\phi_g\pm$, are taken as $\pm 110°$ instead of the usual value of $\pm 120°$. However, such small changes in the parameters did not cause any significant change in the ring-closure probability calculated. The bulkiness of the two terminal groups, a 4-pyridyl group and a *p*-nitrophenoxycarbonyl group, was not taken into considereation, and the computation was carried out for the skeletal structure I. It has been shown that the excluded volume effect is

$$\text{C-O-(-C-C-O-)}_m\text{-C},\ m=3\text{—}20 \qquad \text{(I)}$$

essential in the calculation of the ring-closure probability.[3] In this calculation, the skeletal overlaps were excluded in such a way that the conformations in which any pair of skeletal atoms fall within the sum of their atomic radii (Table 1) are rejected.

Table 1. Structure and energy parameters of poly(oxyethylene)

l(C-O)=1.43 Å, l(C-C)=1.53 Å,
$\angle$COC=$\angle$CCO=111.5°
ϕ_g(C-O)=ϕ_g(C-C)=$\pm$110°,
$E_{\sigma 2}$=−0.5 kcal/mol, $E_{\sigma 2'}$=0.9 kcal/mol,
$E_{\omega 2}$=0.4 kcal/mol.

For notations, see Ref. 12.

* Intrachain Reaction of a Pair of Reactive Groups Attached to Polymer Ends. Part VII.

Evaluation of the Ring-Closure Probability. The ring-closure probability is expressed as the ratio of the (conformational) partition function for ring conformations to that of the total ones. If a chain is regarded as cyclic when it takes an end-to-end distance, r, shorter than the critical distance, r_0, then the ring-closure probability is expressed as

$$W(r<r_0) = Z(r<r_0)/Z_t. \quad (1)$$

If the excluded volume effect is taken into account in the Monte Carlo calculation, the two partition functions should be estimated by generating the non-self-intersecting chains randomly. However, since the exclusion of the overlapping conformations requires a very long computation time, the exclusion process was performed after cyclic conformations were generated. For this purpose, Eq. 1 was rewritten as[6]

$$W(r<r_0) = \frac{Z(r<r_0)/Z_0}{Z_t/Z_0}, \quad (2)$$

where Z_0 is the total partition function for the conformations including any atomic overlaps. To calculate the numerator, a number of conformations were first generated without excluding the atomic overlaps, and then the check for the skeletal overlap was made only for the cyclic ($r<r_0$) conformations. The denominator represents the fraction of the non-self-intersecting conformations. This quantity can be calculated accurately from a relatively small number of Monte Carlo samples. The average value of the numerator was determined from 80000 Monte Carlo chains including skeletal overlaps. This procedure was repeated five times to obtain a total average of 400000 chains. The denominator was determined from $10000\times5=50000$ chains. In this case, the scattering among the five averages was not significant.

Results and Discussion

The ring-closure probabilities for poly(oxyethylene) chains whose chain lengths, m, range from 3 to 20 are shown in Fig. 1 for $r_0=6$ Å and in Fig. 2 for $r_0=4$ Å. The small open circles indicate the average value for 80000 chains, and the large open circles, the total average for 400000 chains. The probability shows a peak at $m=4$ or 5, indicating the presence of the optimum chain length for the intrachain reaction. In the two figures, the Monte Carlo data for polysarcosine chains[6] are also shown; they have been obtained by means of a hard-sphere model, without taking the conformational energy into account. The ring-closure probability for polysarcosine chains also shows a maximum, but the optimum chain length is considerably longer than that of poly(oxyethylene) chains. The ring-closure probability has been calculated for polymethylene chains[1] and found to reach a maximum at $j=20$, where j is the number of methylene units and corresponds approximately to 3 m. Therefore, the optimum chain length for the cyclization of poly(oxyethylene) chains is much shorter than for the other two chains. The conclusion from the calculation is undoubtedly related to the preference of a poly(oxyethylene) chain

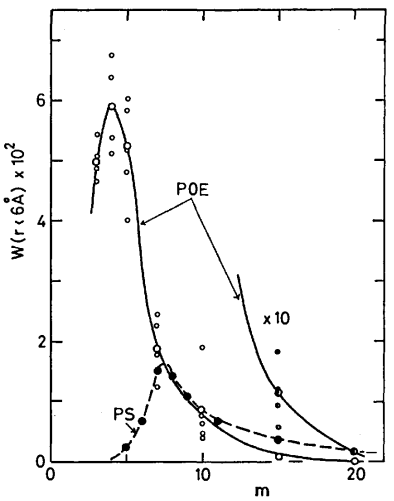

Fig. 1. Ring-closure probabilities for poly(oxyethylene) chain calculated for $r_0=6$Å. Small circles (○, ◐) indicate the local averages for 80000 chains and large circles (○, ◐) the total average for 400000 chains. (◐) and (◐) represent $W(r<6\text{Å})\times10^3$ for clarity for longer chains. Data for polysarcosine chain[6] are also shown with (●).

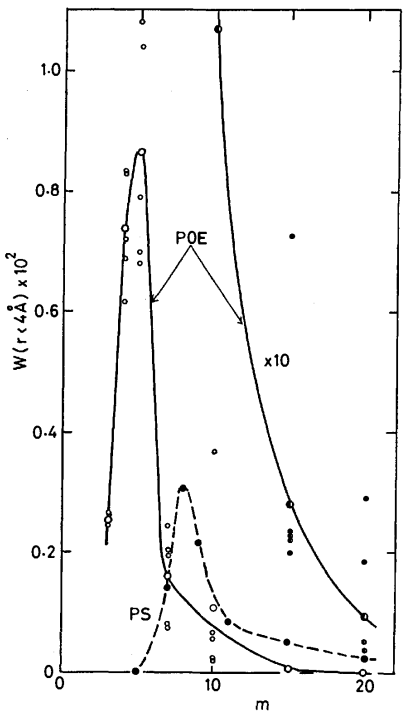

Fig. 2. Ring-closure probabilities for poly(oxyethylene) chain calculated for $r_0=4$Å. For the notations, see Fig. 1.

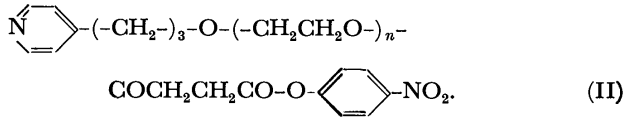
for *gauche* rotational states. Apart from the extraordinary high tendency to cyclize into a six-membered ring, which has been commonly found for various chains and is not included in the figures, the ring-closure probability at the optimum chain length is very large for poly(oxyethylene) chains. However, the probability decreases drastically with an increase in the chain length. For longer chains than $m=10$, the probability becomes smaller than that of polysarcosine chains, and

at $m=20$ it virtually vanishes.

The ratio of the rate constants for intra- and intermolecular reactions is related to the ring-closure probability, thus[1,3]

$$\frac{k_1}{k_2}=\frac{3000W(r<r_0)}{4\pi r_0^3 N_a}\ \text{mol/dm}^3, \tag{3}$$

where r_0 is the critical distance for the reaction and N_a is the Avogadro number. The ratios calculated for poly(oxyethylene) and polysarcosine chains by using the ring-closure probability for $r_0=4$ Å are shown in Fig. 3 (top), and there compared with the experimental results (bottom). The abscissa of Fig. 3 is taken as $n=m-2$ to match the actual structure (II) with the structure (I) of the poly(oxyethylene) model:



The agreement between the calculation and the experiment is fairly good for polysarcosine chain, except that the optimum chain length is not seen in the experimental data.[5] In contrast, with poly(oxyethylene) chains the optimum point is actually observed. However, the experimental rate-constant ratio at the optimum point is 10 times as small as the calculated one. For chains longer than $m=10$, the experimental rate-constant ratios for the poly(oxyethylene) chains are smaller than for the polysarcosine chains, as is to be expected from the calculation. The small ring-closure probabilities for long poly(oxyethylene) chains may be attributed to the high tendency to form small rings. In Fig. 3 the yield of cyclic n-mer in the oligomerization of ethylene oxide in dioxane initiated by BF_3 is also shown.[13] Because of the lack of detailed experimental data, however, the rate constant ratio cannot be obtained. In this case no bulky terminal group is present; hence, the yield can be compared with the k_1/k_2 calculated without considering the bulkiness of the two terminal groups. This permits a more direct comparison between the experimental and the calculated values than in the case of the intrachain reaction. In fact, a sharp maximum is seen in the yield of cyclic oligomers; this maximum is shorter by one oxyethylene unit than the calculated one. In summary, the results of the calculation on poly(oxyethylene) chains agreed with the observations of the intrachain reactions for longer chains. The deviation for shorter chains may be attributed to the steric repulsion between two terminal groups, which has not been taken into account in the calculation.

The ring-closure probabilities calculated at 15, 25, and 35 °C were used to determine thermodynamic parameters, ΔH_c and ΔS_c, for the conformational change accompanying the cyclization. The enthalpy change, ΔH_c, was determined from the temperature dependence of the ring-closure probabilities calculated for the same 80000 Monte Carlo samples. The total average for 400000 chains was calculated by using these locally averaged values. The entropy change, ΔS_c, was determined by using the total averages of the enthalpy and the ring-closure probability. The

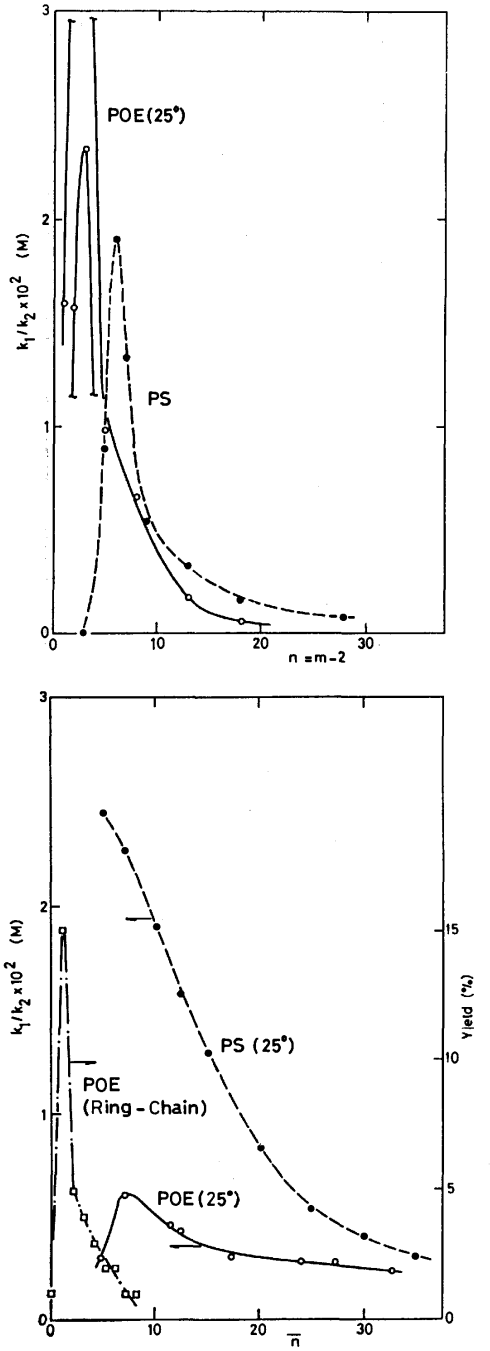


Fig. 3. Comparison of the observed (bottom) and the calculated (top) rate-constant ratio for intra- and intermolecular reactions. In the bottom, POE(Ring-Chain) represents the yield of cyclic oligomer in the ring-chain equilibrium attained in the oligomerization of ethylene oxide.[13] In the top, the data for poly(oxyethylene) chain having $n=4$ and 5 are subtracted by 3×10^{-2} for clarity. The abscissa is taken as $n=m-2$ to match the actual structure (II) with the model structure (I).

results are shown in Fig. 4, where the local average values of ΔH_c are indicated by small circles, and the total average, by a large circle. It is clear that the chain-length dependence of ΔH_c virtually determines the chain-length dependence of the ring-closure pro-

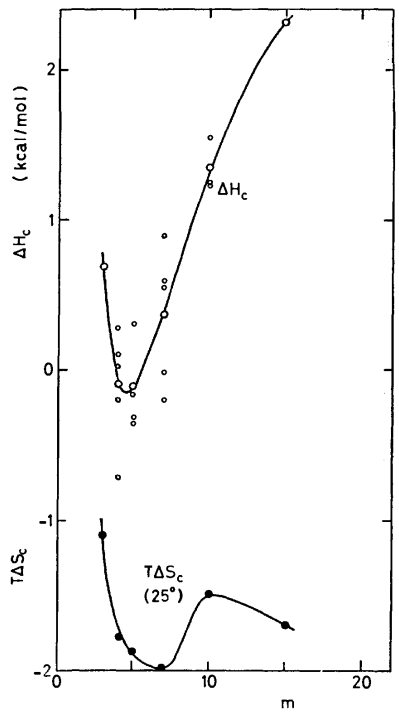

Fig. 4. Thermodynamic parameters for the cyclization and the chain length of poly(oxyethylene). Small and large open circles (○, ◯) indicate the local and the total averages of ΔH_c, respectively.

bability and, hence, the ease of the intrachain reaction. At the optimum chain length in the calculated k_1/k_2, ΔH_c is nearly zero, indicating that no excess energy is required for the optimum cyclization. The predominance of the enthalpy factor is somewhat unexpected, since it is natural to consider that the ease of the intrachain reaction is determined by the fraction of cyclic conformations and, hence, by the entropy factor. The predominance of the enthalpy factor has been found in the calculation for the ring-closure probability of polymethylene chains[3] and actually observed in some intrachain reactions on polysarcosine.[5] However, the entropy factor has been found experimentally to be important in the intrachain reaction on poly(oxyethylene) chains.[10] Since the chain-length dependence of the thermodynamic parameters has been reported to change drastically in different solvents,[14,15] the solvation of polymer chains may be another important factor in determining the thermodynamic parameters. The plot of the calculated values of ΔH_c against the calculated values of ΔS_c did not result in a straight line. This is in marked contrast with the same sort of plot between the experimental values of ΔH_c and ΔS_c, which gave a straight line.[10] This difference may also be attributed to the effect of solvation which operates in the real reaction, but which was ignored in the calculation. The solvation must compensate for the disadvantage due to the loss of entropy in a cyclic conformation and stabilize the latter, but the mechanism of solvation is not yet clear.

The authors wish to thank Mr. Eiichi Yoshikawa for his preliminary calculation of the chain conformations of poly(oxyethylene).

Syntheses and Reactions of 10-(2,2'-Biphenylylene)-9-phenanthrone Derivatives and Some Consideration of Ethyl Isomers in Their Analogous Series

Takao Ooya,* Masahiro Minabe, and Kazuo Suzuki

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Ishiicho, Utsunomiya 321-31

(Received October 3, 1977)

The Wagner-Meerwein rearrangement of 9'-methyl-9,9'-bifluoren-9-ol yielded 10-(2,2'-biphenylylene)-9-methylenephenanthrene. Ozonolysis of the phenanthrene afforded 10-(2,2'-biphenylylene)-9-phenanthrone. This pinacolone was converted into 2'-(9-fluorenyl)biphenyl-2-carboxylic acid. Oxidation of 4,9'-bifluoren-9-one, which was obtained by ring closure of the acid, gave 9'-hydroxy-, 9'-benzyl-, and 9'-benzyloxy-4,9'-bifluoren-9-one. Isomers of 2,2'-diethyl-9,9'-bifluorene-9,9'-diol were obtained by reduction of 2-ethyl-9-fluorenone. The pinacols were rearranged to the corresponding pinacolones, which were cleaved into carboxylic acids. The structural assignment of these isomers was made by spectral analyses.

It has been reported that pinacol-pinacolone rearrangement of 9,9'-bifluorene-9,9'-diol (**1a**) yields 10-(2,2'-biphenylylene)-9-phenanthrone (**2a**),[1] which does not give the corresponding oxime.[2] Spiran **2a** is cleaved into 2'-(9-fluorenyl)biphenyl-2-carboxylic acid (**3a**) by the action of potassium hydroxide in ethanol.[3]

The present paper deals, firstly, with other synthetic procedures of **2a** through 9,9'-bifluoren-9-ol derivatives, and also with the conversion of **2a** to 4,9'-bifluorene (**4**),[4] which has previously been obtained *via* ring closure of (2-biphenylyl)-(4-fluorenyl)methanol.

Ashby *et al.*[5] reported that reduction of phenyl 2-methylphenyl ketone afforded *meso*- and *dl*-1,2-diphenyl-1,2-di(2-methylphenyl)ethane-1,2-diol. Some bromo-derivatives of **1a** and **2a** have been obtained by the Clemmensen reduction of the corresponding ketones, but their isomers have not been isolated.[6] Pinacolic rearrangement of 2,3-di(2-fluorenyl)-butane-1,2-diol gave exclusively 3,3-di(2-fluorenyl)-butan-2-one.[7]

This paper is concerned, secondly, with the formation and rearrangement of *meso*-(**1b**) and *dl*-2,2'-diethyl-9,9'-bifluorene-9,9'-diol (**1c**). Finally, transformations of 2-ethyl-(**2b**) and 7-ethyl-10-(4-ethyl-2,2'-biphenylylene)-9-phenanthrone (**2c**) to 2,2-diethyl-(**5b**) and 7,2'-diethyl-4,9'-bifluoren-9-one (**5c**) are dealt with briefly here.

Results and Discussion

Synthesis and Transformations of 10-(2,2'-Biphenylylene)-9-phenanthrone (2a). A new spiran, 10-(2,2'-biphenylylene)-9-methylenephenanthrene (**6a**), was obtained by the Wagner-Meerwein rearrangement of 9'-methyl-9,9'-bifluoren-9-ol and also by dehydration of 10-(2,2'-biphenylylene)-9-methyl-9-phenanthrol (**6b**). The NMR of one of the fixed methylene protons on **6a**, H_a, appears at higher field (4.73 ppm) than that of H_b (5.20 ppm), owing to the ring current of the spiro fluorenylidene plane which lies close to the methylene group (Scheme 1).

Ozonolysis of **6a** gave the known ketone **2a**, which was also obtained by the reaction between 9'-bromo-9,9'-bifluoren-9-ol and silver oxide. The reaction of **2a** with 9-lithiofluorene gave 2-[2'-(9-fluorenyl)]-biphenylyl 9-fluorenyl ketone (**7**), as in the case[3] of **3a**. The fission between the highly-polarized carbonyl carbon and the spiro carbon atoms would be due to the stabilization of carbanion (A) resulting from an attack of the nucleophilic species, as occurs with the Haller-Bauer reaction.[8]

Scheme 1.

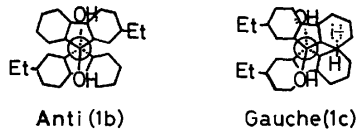
Dehydration of acid **3a** gave 4,9'-bifluoren-9-one (**5a**), which was reduced to authentic **4**. Oxidation of **5a** with Triton B-oxygen gave the expected 9'-hydroxy-4,9'-bifluoren-9-one (**8a**) in a good yield under mild conditions. If the oxidation was carried out in boiling pyridine, 9'-benzyl-(**8b**) and 9'-benzyloxy-4,9'-bifluoren-9-one (**8c**) were also obtained. Radical halogenation of **5a** with *N*-bromosuccinimide, on the other hand, did not yield 9'-bromo-4,9'-bifluoren-9-one.

These findings can be accounted for by the constrained state around the 9'-position of **5a**; the 9'-radical of **5a** may be coupled with the smaller benzyl radical,

* Present address: Institute of Pharmacology, Banyu Pharmaceutical Co., Ltd., Meguro, Tokyo 153.

but not with the larger bromine atom.

*Syntheses of 2,2'-Diethyl-9,9'-bifluorene-9,9'-diols(**1b**,**1c**).* The reduction of 2-ethyl-9-fluorenone (**9**)[9] gave the corresponding pinacol, which has a broad melting point. The NMR spectrum of the pinacol shows the existence of *meso*-(**1b**) and *dl*-isomers (**1c**) in the ratio of 1:1. A small amount of **1b** was separated by recrystallization of the mixture. Pure **1b** was isomerized to a mixture of **1b** and **1c** by UV irradiation.

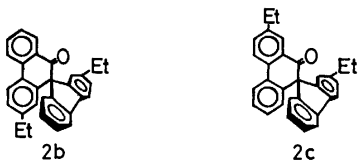


Scheme 2.

The conformation of **1b** would be represented as *anti* form because of the repulsion between the two bulky fluorene rings. Isomeric **1c** may be in *gauche* form, which twists to avoid the repulsion between two ethyl groups, as shown in Scheme 2. The assignment may be supported from the finding that the ethyl protons of **1b** are shifted to lower fields than those of **1c** due to the magnetic anisotropy effect of the aromatic rings.[10] Additionally, two protons of 8,8'-positions on **1c** locate on the shielding zone of the fluorene rings and are shifted to a higher field (6.58 ppm).[11]

*Transformations of Ethyl-substituted 10-(2,2'-Biphenylylene)-9-phenanthrones(**2b**,**2c**).* The pinacol-pinacolone rearrangement of **1b** and **1c** gave non-stereoselectively pinacolones **2b** and **2c** in the ratio of 1:1. The NMR spectra show that one ethyl group of **2b** is shifted to higher fields than the other in **2b**, higher also than those of **2c**.

The ethyl protons on the phenanthrone ring of **2b** would be more shielded than those of **2c**, because the ethyl group in the former is located in the shielding zone of the fluorenylidene ring, whereas in the latter, it undergoes a deshielding effect because of the 9-carbonyl group (Scheme 3).



Scheme 3.

Compounds **2b** and **2c** were reduced to 2-ethyl-(**10b**) and 7-ethyl-10-(4-ethyl-2,2'-biphenylylene)-9-phenanthrol (**10c**), respectively. Also, **2b** and **2c** were converted into ethyl-substituted 4,9'-bifluoren-9-ones, **5b** and **5c**, through the corresponding carboxylic acids, **3b** and **3c**. The reactions of **3b** and **3c** with copper powder gave the original **2b** and **2c**.

Experimental

All the mps are uncorrected. The IR spectra were obtained as KBr pellets using an IR-G spectrophotometer (JASCO). The MS spectra were measured with a RMU-6E apparatus (Hitachi, Ltd.) by means of a direct inlet system. The NMR spectra were obtained with a JNM-C60-HL spectrometer (JEOL), using TMS as an internal reference.

9'-Methyl-9,9'-bifluoren-9-ol. A lithium derivative of 9-methylfluorene[12] (5.4 g) was prepared in the usual manner[13] and allowed to react with fluorenone (4.3 g) in benzene (40 ml) at 5—10 °C. Upon stirring at 50 °C for 2 h, the resulting mixture was treated with aqueous NH_4Cl (5%) solution. The organic layer was dried (Na_2SO_4) and chromatographed on an alumina column to give a crystalline product, which was recrystallized from cyclohexane-benzene (1:1) to give 7.2 g (84%) of the alcohol: Mp 174—176 °C; IR: 3540 cm^{-1} (-OH); ^1H NMR (C_6D_6): δ 1.65 (1H, s), 1.95 (3H, s), 6.82—8.48 (16H, m); MS, *m/e*, 360 (M^+), 343, 181, 179, 165. Found: C, 90.31; H, 5.80%. Calcd for $C_{27}H_{20}O$: C, 89.97; H, 5.59%.

The alcohol was treated with HBr in AcOH at 20 °C to yield 9-methyl-9'-bromo-9,9'-bifluorene (90%): Mp 175 °C (dec); MS, *m/e*, 424, 422 (M^+), 343. Found: C, 76.25; H, 4.89%. Calcd for $C_{27}H_{19}Br$: C, 76.60; H, 4.52%.

This bromide (1.0 g) was refluxed for 8 h with KOH (0.264 g) in EtOH (250 ml) to give 9-methyl-9'-ethoxy-9,9'-bifluorene (0.70 g, 76%): Mp 208—210 °C; ^1H NMR (C_6D_6): δ 1.01 (3H, t, J=7.1 Hz), 2.00 (3H, s), 2.89 (2H, q), 6.70—7.42 (16H, m); MS, *m/e*, 388 (M^+), 343. Found: C, 89.75; H, 6.44%. Calcd for $C_{29}H_{24}O$: C, 89.65; H, 6.23%.

Wagner-Meerwein Rearrangement of 9'-Methyl-9,9'-bifluoren-9-ol. A mixed powder of the alcohol (0.2 g) and P_2O_5 (0.2 g) was heated at 200 °C under 2 Torr for 15 min to yield 0.15 g (79%) of **6a** as sublimate: Mp 238.5—239.5 °C; IR: 905 cm^{-1} (>C=CH_2); ^1H NMR (CCl_4): δ 4.73 (1H, s), 5.20 (1H, s), 6.38—8.02 (16H, m). Found: C, 94.87; H, 5.14%. Calcd for $C_{27}H_{18}$: C, 94.70; H, 5.30%.

*Synthesis and Dehydration of 10-(2,2'-Biphenylylene)-9-methyl-9-phenanthrol (**6b**).* A 0.34-g portion of **2a** in 70 ml of benzene was added to a MeMgI solution and the mixture was refluxed for 1 h to yield 0.28 g (78%) of **6b**: Mp 185—187 °C; IR: 3570 cm^{-1} (-OH); ^1H NMR (CCl_4): δ 1.29 (3H, s), 1.48 (1H, s), 6.54—7.95 (16H, m); MS, *m/e*, 360 (M^+), 342. Found: C, 90.12; H, 5.57%. Calcd for $C_{27}H_{20}O$ C, 89.97; H, 5.59%.

A mixed powder of **6b** (0.05 g) and P_2O_5 was heated at 200 °C under reduced pressure for 10 min to afford 0.036 g (76%) of **6a**, identical in all respects with the specimen obtained above.

*Synthesis of Pinacolone **2a**. a)*: A solution of 0.34 g of **6a** in 30 ml of $CHCl_3$ was treated with ozone at −15 °C for 1 h. Upon evaporation of the solvent, the resulting ozonide was treated with Zn-dust (0.1 g) in AcOH (10 ml) to afford 0.21 g (61%) of **2a**, identical in all respects with the sample obtained by the authentic method: Mp 256—258 °C (lit,[3] mp 256 °C, dec); IR: 1676 cm^{-1} (>C=O).

b) From 9'-Bromo-9,9'-bifluoren-9-ol: A solution of 1.73 g of 9,9'-bifluoren-9-ol[14] and 1.08 g of NBS in 100 ml of benzene was refluxed for 7 h to afford 1.82 g (86%) of 9'-bromo-9,9'-bifluoren-9-ol (mp 150.0—150.5 °C) and 0.05 g of **2a**. Found for the bromide: C, 73.18; H, 3.96%. Calcd for $C_{26}H_{17}OBr$: C, 73.42; H, 4.03%.

A solution of 0.2 g of the bromohydrin in 20 ml of dioxane was refluxed with 0.13 g of Ag_2O for 4 h; 0.09 g (56%) of **2a** was obtained.

*Ring Cleavage of **2a**. a)*: A solution of **2a** (1.4 g) in EtOH (100 ml) containing EtONa (1.36 g) was refluxed for 11 h. The reaction mixture was poured into water and neutralized with hydrochloric acid. The precipitate was collected, dried, and recrystallized from EtOH to give 1.1 g (75%) of **3a**:

Mp 244—245 °C (lit,[3] mp 243—244 °C); IR: 3370 (-OH), 1696 cm^{-1} (>C=O); MS, *m/e*, 362 (M^+), 345, 344, 317, 316, 197, 165.

A solution of **3a** (1.5 g) in MeOH (80 ml) was refluxed with concd H_2SO_4 (2 ml) for 13 h. Upon the usual treatment, 1.30 g (83%) of the methyl ester was obtained: Mp 155—157 °C; IR: 1714 cm^{-1} (>C=O); ^1H NMR (C_6D_6): δ 3.35 (3H, s), 5.07 (1H, s), 6.33—8.02 (16H, m); MS, *m/e*, 376 (M^+), 344, 316, 211, 165. Found: C, 86.24; H, 5.39%. Calcd for $C_{27}H_{20}O_2$: C, 86.14; H, 5.36%.

b): A solution of 2.1 g of **2a** in 20 ml of xylene was added to a refluxing xylene solution of 9-lithiofluorene for 20 min and the mixture was refluxed for 4 h to yield 0.08 g (3%) of **7**: Mp 286—288 °C; IR: 1653 cm^{-1} (>C=O); MS, *m/e*, 510 (M^+), 317, 316, 193, 165. Found: C, 91.96; H, 4.83%. Calcd for $C_{39}H_{26}O$: C, 91.74; H, 5.13%.

Reaction of Carboxylic Acid 3a. a): A suspension of **3a** (1.6 g) and polyphosphoric acid (PPA, 15 ml) was stirred at 130 °C for 13 h. The reaction mixture was poured into cold water and the dried precipitate was chromatographed in benzene on an alumina column to yield 1.2 g (78%) of **5a**: Mp 216.5—218 °C; IR: 1697 cm^{-1} (>C=O); ^1H NMR (CCl_4): δ 5.89 (1H, s), 6.56—8.29 (15H, m); MS, *m/e*, 344 (M^+), 316, 315, 165. Found: C, 90.49; H, 4.48%. Calcd for $C_{26}H_{16}O$: C, 90.67; H, 4.68%.

The corresponding oxime was prepared by refluxing a solution of **5a** (0.26 g), $HONH_2 \cdot HCl$ (0.06 g), NaOH (0.04 g), H_2O (5 ml) in EtOH (30 ml) for 1 h: yield 0.12 g (44%); mp 219—221 °C; IR: 3510 cm^{-1} (-OH). Found: C, 86.59; H, 4.91; N, 4.03%. Calcd for $C_{26}H_{17}NO$: C, 86.88; H, 4.77; N, 3.90%.

b): A powdered mixture of 0.40 g of sodium salt of **3a** and 2.0 g of soda lime was allowed to stand at 270 °C for 10 min. The reaction mixture was extracted with benzene to give 0.064 g (19%) of 9,9'-spirobifluorene, which was identical with that obtained by the method described in the literature:[15] Mp 199—200 °C (lit,[15] mp 198—199 °C); MS, *m/e*, 316 (M^+).

Acids **3b** and **3c** were treated in a similar way, but the corresponding spirans were not isolated.

Reduction of 5a. Ketone **5a** (3.0 g) was refluxed with HI (48 ml, 57%) and P (red, 4.8 g) in AcOH (200 ml) for 15 h. The reaction mixture was poured into water and the precipitate was washed with aqueous $Na_2S_2O_3$ (5%) solution, dried, and recrystallized from AcOH to give **4** (2.13 g, 74%), identical in all respects with an authentic sample:[4] Mp 166—168 °C; ^1H NMR (CCl_4): δ 3.95 (2H, s), 6.09 (1H, s), 6.36—8.35 (15H, m).

Oxidation of 5a with Triton B-Oxygen. a): To a solution of **5a** (1.5 g) and Triton B (40%, 1.5 ml) in pyridine (30 ml), oxygen was introduced gently at 32—38 °C with stirring for 3 h. The resulting mixture was poured into water and extracted with benzene. The organic layer was washed with water, dried (Na_2SO_4), and chromatographed on a silica gel column to yield 1.2 g (73%) of **8a**: Mp 207.5—209 °C; IR: 3465 (-OH), 1686 cm^{-1} (>C=O); ^1H NMR ($CDCl_3$): δ 2.87 (1H, s), 6.58—7.85 (15H, m). MS, *m/e*, 360 (M^+), 344. Found: C, 86.74; H, 4.18%. Calcd for $C_{26}H_{16}O_2$: C, 86.65; H, 4.48%.

b): The same reaction was carried out under boiling conditions; 0.11 g (7%) of **8a**, 0.60 g (31%) of **8b** (mp 243.5—244.5 °C), and 0.35 g (17%) of **8c** (mp 190—192 °C) were isolated by means of a method similar to the above. IR of **8b**: 1705 cm^{-1} (>C=O); ^1H NMR ($CDCl_3$): δ 3.79 (2H, s), 5.80—8.59 (20H, m); MS, *m/e*, 434 (M^+), 343, 342, 91. Found: C, 91.16; H, 4.93%. Calcd for $C_{33}H_{22}O$: C, 91.21; H, 5.10%. IR of **8c**: 1704 cm^{-1} (>C=O); ^1H NMR ($CDCl_3$): δ 4.22 (2H, s), 6.77—7.87 (20H, m): MS, *m/e*, 450 (M^+), 359, 343, 342, 91. Found: C, 88.32; H, 4.83%. Calcd for $C_{33}H_{22}O_2$: C, 87.97; H, 4.92%.

Synthesis and Photo-isomerization of 2,2'-Diethyl-9,9'-bifluorene-9,9'-diol (1b, 1c). a): Ketone **9** (11.5 g) was treated with $TiCl_4$ (15.8 g)-Zn (10.8 g) in THF (130 ml) by the procedure described elsewhere.[16] After treatment in the usual manner,[7] 9.4 g (81%) of crude pinacol was obtained, which was confirmed to be a mixture of **1b** and **1c** (1:1) by NMR: Mp 156—164 °C; IR: 3385 cm^{-1} (-OH, broad); ^1H NMR (C_6D_6): δ 1.04 (3H, t, J=7.5 Hz), 1.12 (3H, t, J=7.5 Hz), 2.44 (2H, q), 2.57 (2H, q), 3.09 (2H, s, -OH), 6.58 (1H, s), 6.80—7.48 (13H, m); MS, *m/e*, 418 (M^+), 400, 209, 193, 181, 165. Found: C, 85.97; H, 6.49%. Calcd for $C_{30}H_{26}O_2$: C, 86.09; H, 6.26%.

The crude pinacol was purified by repeated recrystallization from cyclohexane and benzene (1:1) to yield 0.9 g of **1b**: Mp 180—182 °C; IR: 3470, 3370 cm^{-1} (-OH); ^1H NMR (C_6D_6): δ 1.12 (6H, t), 2.57 (4H, q), 3.12 (2H, s), 6.80—7.48 (14H, m). Found: C, 85.99; H, 6.25%.

b): A solution of 4.2 g of **9** in 40 ml of THF was allowed to react with MeMgI (40 mmol) in the presence of $FeCl_3$ (0.1 g) by the procedure described elsewhere.[5] The resulting mixture was treated with aqueous NH_4Cl (5%) solution and extracted with benzene. The organic layer was dried (Na_2SO_4) and chromatographed on a silica gel column to afford 2.84 g (67%) of a mixture of **1b** and **1c** (1:1).

c): Pinacol **1b** (0.100 g) in ether (10 ml) was irradiated with a high pressure mercury lamp (100 W) for 8 h to give a mixture of **1b** (61%) and **1c** (39%), which were determined by means of NMR analysis.

Rearrangement of 1b and 1c. An isomeric mixture of **1b** and **1c** (0.75 g) was refluxed with concd H_2SO_4 (0.5 ml) in AcOH (15 ml) for 1 h. The mixture was poured into water to give precipitates which were submitted to NMR analysis; **2b** (49.5%) and **2c** (50.5%) were confirmed.

Fractional crystallization of the reaction mixture from EtOH gave 0.10 g (14%) of **2b**, mp 112—114.5 °C, and 0.22 g (31%) of **2c**, mp 192.5—193.5 °C. IR of **2b**: 1686 cm^{-1} (>C=O); ^1H NMR (C_6D_6) : δ 0.75 (3H, t, J=7.5 Hz), 0.93 (3H, t, J=7.5Hz), 2.03 (2H, q), 2.30 (2H, q), 6.68—8.35 (14H, m); MS, *m/e*, 400 (M^+), 372, 371, 343, 327,197, 165. Found: C, 90.12; H, 5.80%. Calcd for $C_{30}H_{24}O$: C, 89.96; H, 6.04%. IR of **2c**: 1673 cm^{-1} (>C=O); ^1H NMR (C_6D_6): δ 0.90 (3H, t, J=7.5 Hz), 0.94 (3H, t, J=7.5Hz), 2.30 (2H, q), 2.34 (2H, q), 6.73—8.20 (14H, m); MS, *m/e*, 400 (M^+), 372, 371, 343, 327, 194, 179. Found: C, 89.65; H, 6.01%.

Reduction of 2b and 2c. A mixture of **2b** (0.258 g) and $LiAlH_4$ (0.06 g) in THF (25 ml) was refluxed for 3 h. After decomposition with AcOEt (5 ml) and with hydrochloric acid (5%), the reaction mixture was extracted with benzene to yield 0.155 g (60%) of **10b**: Mp 140.5—142.5 °C; IR: 3530, 3400 cm^{-1} (-OH); ^1H NMR (C_6D_6): δ 0.80 (3H, t, J=7.8 Hz), 0.88 (3H, t, J=6.9 Hz), 1.43 (1H, d, J=6.6 Hz, -OH), 2.10 (2H, q, J=7.8 Hz), 2.26 (2H, q, J=6.9Hz), 5.15 (1H, d, J=6.6 Hz), 6.59—7.93 (14H, m) ; MS, *m/e*, 402 (M^+), 373, 345, 326. Found: C, 89.33; H, 6.74%. Calcd for $C_{30}H_{26}O$: C, 89.51; H, 6.51%.

Alcohol **10c** (0.36 g, 72%) was obtained from **2c** (0.50 g) by the method similar to that of **10b**: Mp 167—169 °C; IR: 3540 cm^{-1} (-OH); ^1H NMR (C_6D_6): δ 0.88 (3H, t, J=7.8 Hz), 1.10 (3H, t, J=7.5 Hz), 1.43 (1H, d, J=6.3 Hz, -OH), 2.26 (2H, q, J=7.8 Hz), 2.49 (2H, q, J=7.5 Hz), 5.19 (1H, d, J=6.3Hz), 6.65—7.95 (14H, m); MS, *m/e*,

402 (M^+), 373, 209. Found: C, 89.48; H, 6.54%. Calcd for $C_{30}H_{26}O$: C, 89.51; H, 6.51%.

Ring Cleavage of **2b** *and* **2c**. *a)*: A solution of **2b** (0.50 g) in EtOH (25 ml) was mixed with NaOH (0.26 g) dissolved in water (5 ml) and the mixture was refluxed for 2 h. Upon treatment in a manner similar to that employed in the cleavage of **2a**, 0.40 g (77%) of **3b** was isolated: Mp 203—204 °C; IR: 3420 (-OH), 1690 cm^{-1} (>C=O); MS, *m/e*, 418 (M^+), 400, 372, 343. Found: C, 85.73; H, 6.38%. Calcd for $C_{30}H_{26}O_2$: C, 86.09; H, 6.26%.

A mixture of **3b** (0.30 g) in MeOH (20 ml) containing concd H_2SO_4 (0.5 ml) was refluxed for 8 h. The methyl ester of **3b** (0.24 g, 77%) was obtained by recrystallization from MeOH: mp 144—146 °C; IR: 1721 cm^{-1} (>C=O); ^1H NMR (CCl_4): δ 1.11 (3H, t, J=8.1 Hz), 1.21 (3H, t, J=7.8 Hz), 2.49 (2H, q, J=8.1 Hz), 2.64(2H, q, J=7.8 Hz), 3.76 (3H, s), 4.90 (1H, s,) 6.06—8.23 (14H, m). MS, *m/e*, 432 (M^+), 400, 193, 165. Found: C, 85.98; H, 6.77%. Calcd for $C_{31}H_{28}O_2$: C, 86.08; H, 6.53%.

b): Isomeric **3c** (0.91 g, 87%) was obtained from **2c** (1.0 g) in a manner similar to that given above: Mp 195.5—197 °C; IR: 3420 (-OH), 1696 cm^{-1} (>C=O); MS, *m/e*, 418 (M^+), 400, 372, 343, 209, 193, 165. Found: C, 85.94; H, 6.22%. Calcd for $C_{30}H_{26}O_2$: C, 86.09; H, 6.26%.

Methyl ester (0.22 g, 71%) of **3c** was obtained from **3c** (0.30 g) by the same procedure as was employed above: Mp 110—112 °C; IR: 1721 cm^{-1} (>C=O); ^1H NMR (CCl_4): δ 1.22 (3H, t, J=7.5Hz), 1.32 (3H, t, J=7.2 Hz), 2.63(2H, q, J=7.5 Hz), 2.75 (2H, q, J=7.2 Hz), 3.76 (3H, s), 4.94 (1H, s), 6.32—8.02 (14H, m); MS, *m/e*, 432 (M^+), 400, 193. Found: C, 85.98; H, 6.70%. Calcd for $C_{31}H_{28}O_2$: C, 86.08; H, 6.53%.

Ring Closure of **3b** *and* **3c**. *a)*: Compound **3b** (0.45 g) was treated with PPA (10 ml), as in the case of **3a**, to afford **5b** (0.10 g, 23%): Mp 182—183.5 °C; IR: 1706 cm^{-1} (>C=O); ^1H NMR (CCl_4): δ 1.09 (3H, t, J=7.5 Hz), 1.23 (3H, t, J=8.1 Hz), 2.48 (2H, q, J=7.5 Hz), 2.71 (2H, q, J=8.1 Hz), 5.87 (1H, s, >CH-), 6.50 (1H, s), 7.09—8.26 (12H, m); MS, *m/e*, 400 (M^+), 371, 343, 327, 313. Found: C, 89.75; H, 6.26%. Calcd for $C_{30}H_{24}O$: C, 89.96; H, 6.04%.

b): Isomeric **5c** (0.03 g, 14%) was obtained from **3c** (0.25 g) by the same procedure as that described above: Mp 194.5—196 °C; IR: 1700 cm^{-1} (>C=O); ^1H NMR ($CDCl_3$): δ 1.18 (3H, t, J=7.8 Hz), 1.29 (3H, t, J=8.4 Hz), 2.58 (2H, q, J=7.8 Hz), 2.60 (2H, q, J=8.4 Hz), 5.81 (1H, s), 6.46—8.07 (13H, m); MS, *m/e*, 400 (M^+), 371, 343. Found: C, 90.09; H, 5.82%. Calcd for $C_{30}H_{24}O$: C, 89.96; H, 6.04%.

c): A mixture of **3b** (0.40 g) and copper powder (0.90 g) in quinoline (20 ml) was refluxed for 3 h. After cooling, hydrochloric acid (10%, 50 ml) was added to the solution and the resulting mixture was extracted with benzene (20 ml). The organic layer was chromatographed on a silica gel column to yield 0.25 g (65%) of **2b**.

Isomeric **3c** (0.40 g) was converted into **2c** (0.17 g, 44%) by the same procedure.

Liquid Phase Peptide Synthesis by the Fragment Condensation on Soluble Polymer Support. I. Efficient Coupling and Relative Reactivity of a Peptide Fragment with Various Coupling Reagents

Mitsuaki NARITA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184

(Received October 3, 1977)

The fragment condensation on the soluble polymer support using dicyclohexylcarbodiimide (DCCI) plus 1-hydroxy-1*H*-benzotriazole (HOBt), diethoxyphosphoryl cyanide (DEPC), and triphenylphosphine (Ph_3P) plus di-2-pyridyl disulfide ($(PyS)_2$) as coupling reagents gave rise to efficient coupling (86—99% yield) of the peptide fragment, *t*-butyloxycarbonyl-L-*O*-benzyl-tyrosylglycylglycyl-L-phenylalanine [Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH], to the amino free terminal of Leu anchored to the soluble polymer support, H-L-Leu-OCH_2-resin. Relative reactivity ratios of Boc-amino acids and Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH with H-L-Leu-OCH_2-resin in the coupling reaction using the three coupling reagent systems could be easily determined by use of amino acid ratios in the acid hydrolysates of the resulting peptide resins in which they were taken. The peptide chain length of Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH has no influence on the reactivity of *C*-terminal amino acid in the coupling reaction using DCCI plus HOBt or DEPC as a coupling reagent when Boc-L-Phe-OH was replaced with Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH. The coupling reagent, Ph_3P plus $(PyS)_2$, brought about a marked decrease in the reactivity of the fragment peptide acid.

Through progress in peptide chemistry the synthesis of several large proteins has been achieved by means of solid phase[1] and classical solution methods.[2] However, difficulties arise when these methods are applied to large molecule peptides and proteins. Heterogeneous reaction conditions in solid phase peptide synthesis cause the formation of deletion and truncated sequences,[3] diffusion, slow reaction rates[4] of coupling and removal of protecting groups, solvation problems,[5] and formidable separation of the desired peptide from a large number of similar products. There is a drastic decrease in the overall yield of synthesis, and further progress in peptide synthesis along classical lines is hindered mainly because of the low solubility of polypeptides in organic solvents and the difficulty of removing the side products in the process of synthesis.[2]

In these embarrassing situations, it is evident that a considerable modification of present techniques is necessary for the synthesis of homogeneous proteins of a defined structure. Solid phase peptide synthesis using the fragment condensation procedure is expected to be of value for the synthesis of large molecule peptides and proteins.[6] This strategy will alleviate sequence-dependent problems in coupling and deprotecting steps, formation of failure sequences, and the difficulty in purification of the desired peptide. The serious problem in this method is, however, of low yield in the coupling steps due mainly to restriction of permeability of the peptide fragment into the random closs-linked polymer support anchored amino free terminal of peptide. It can be expected that use of a soluble polymer support in the fragment condensation procedure eliminates it to attain efficient coupling.

Soluble polymer supports were used in the stepwise elongation of peptide chains.[4,7] Kinetic studies of the coupling reaction using the soluble polymer support indicate that the rate is of the same order of magnitude as that of classical liquid phase peptide synthesis,[4a] approximately 100 times faster than that of solid phase peptide synthesis.[4b]

In this paper, we wish to report that the new technique described here can achieve the efficient coupling of the fragment peptide acid using dicyclohexylcarbodiimide (DCCI) plus 1-hydroxy-1*H*-benzotriazole (HOBt),[8] triphenylphosphine (Ph_3P) plus di-2-pyridyl disulfide ($(PyS)_2$),[9] and diethoxyphosphoryl cyanide (DEPC)[10] as coupling reagents. The relative reactivity of a tetrapeptide fragment is practically the same as that of carboxylic acid of the amino acid corresponding to the carboxyl terminal of the fragment.

Results and Discussion

Fragment Condensation of Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH on the Soluble Polymer Support Using DCCI plus HOBt, DEPC, and Ph_3P plus $(PyS)_2$ as Coupling Reagents. Three systems of coupling reagents, DCCI plus HOBt, DEPC, and Ph_3P plus $(PyS)_2$, were investigated for the fragment condensation of Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH with the amino free terminal of Leu anchored to the soluble polymer support, H-L-Leu-OCH_2-resin. Soluble chloromethylated polystyrene (Cl content: 0.91 mmol/g) was prepared by the copolymerization of (chloromethyl) styrene (a mixture of *m*- and *p*-isomers 7 : 3) with styrene (molar ratios 1 : 9) using azobisisobutyronitrile as an initiator. H-L-Leu-OCH_2-resin (Leu content: 0.62 mmol/g) and Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH were prepared in the usual way.[7b,11]

On the basis of the amino component attached to the polymer, three equivalent each of the fragment peptide carboxylic acid and a coupling reagent are employed in order to pursue an efficient coupling. The reaction was performed in *N,N*-dimethylformamide (DMF) at 0—5 °C for 2 h and then at room temperature for 3 h. In the case of Ph_3P plus $(PyS)_2$, the coupling reaction was carried out with a threefold excess of the carboxyl component and a 30-fold excess each of Ph_3P and $(PyS)_2$. The reaction mixture was poured into methanol followed by the addition

Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH

$$+ \text{H-L-Leu-OCH}_2\text{-resin} \xrightarrow[\text{in DMF, 0—5 °C, 2 h and then r. t., 3 h}]{\text{coupling reagent}}$$

Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-L-Leu-OCH_2-resin

of a small amount of saturated aqueous sodium chloride. The precipitated peptide resin was filtered off and washed successively with water and methanol in order to remove the soluble reactant. In each case, recovery of the resulting peptide polymer by precipitation from the solution in DMF with methanol was more than 93% on the basis of yields. Amino acid analyses of the resulting peptide resins and coupling yields with various coupling reagents are summarized in Table 1. The average yield of the coupling reaction was calculated from the recovery of Phe and Gly in the acid hydrolysate taking the recovery of Leu as the standard. The fragment condensation on the soluble polymer support, especially when DCCI plus HOBt and DEPC were used as coupling reagents, could achieve efficient coupling (96—99% yield) of the tetrapeptide acid to the amino free terminal of Leu on the soluble polymer support.

Relative Reactivities of Boc-Amino Acids and Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH with H-L-Leu-OCH_2-resin in the Coupling Reaction. In order to find out to what extent the peptide chain length influences the reactivity of the *C*-terminal amino acid in the fragment condensation reaction, and the effect of the coupling reagent on the reactivity of the tetrapeptide acid when Boc-L-Phe-OH is replaced by Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH, the technique as given in the following was used. Relative reactivities of Boc-amino acids with H-L-Leu-OCH_2-resin were first determined with use of various coupling reagents. The results are summarized in Table 2. As a typical example (run 1), starting with 200 mg of H-L-Leu-OCH_2-resin containing 0.124 mmol of Leu, the coupling reaction was carried out with a three-fold excess each of Boc-Gly-OH, Boc-L-Val-OH, and Boc-L-Phe-OH and a nine-fold excess (an equimolar amount with the total of the

TABLE 1. AMINO ACID ANALYSES OF Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-L-Leu-OCH_2-resins AND COUPLING YIELDS WITH VARIOUS COUPLING REAGENTS

a) Determined with use of the amino acid ratios of resulting peptide resins taking the recovery of Val as a standard. b) Abbreviations; A: mixture of an equivalent each of Boc-Gly-OH, Boc-L-Val-OH, and Boc-L-Phe-OH, B: mixture of an equivalent each of Boc-L-Val-OH and Boc-L-Phe-OH, C: mixture of an equivalent each of Boc-L-Val-OH and Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH. c) A three-fold excess each of carboxyl components and an equimolar amount of the total of the carboxyl components of a coupling reagent were used. d) The coupling reaction was carried out with a three-fold excess each of carboxyl components and a two-fold excess of the total of the carboxyl components each of Ph_3P and $(PyS)_2$.

carboxyl components) of DCCI and HOBt each in 20 ml of DMF at 0—5 °C for 2 h and at room temperature for 13 h. The resulting peptide resin by precipitation from the solution in DMF with methanol was subjected to acid hydrolysis with propionic acid–12 M HCl (2: 1 v/v) at 115 °C for 35 h followed by the amino acid analysis. Relative reactivities of Boc–amino acids were determined using the amino acid ratios of the resulting peptide resin taking the recovery of Val as a standard. Relative reactivity of Boc–L-Tyr-(Bzl)–Gly–Gly–L-Phe–OH was also determined by a similar procedure using a combination of carboxyl components.

It seems that in each coupling reagent (except DCCI plus HOBt), peptide bonds involving Boc–L-Phe–OH and Boc–L-Val–OH which have bulky side chains are not formed as readily as Boc–Gly–OH forms peptide bond. A marked influence of bulky side chains on a decrease in the rate of the reaction was observed when Ph_3P plus $(PyS)_2$ was used as a coupling reagent (run Nos. 1—3, Table 2).

Relative reactivities using DCCI plus HOBt as a coupling reagent:

Boc-L-Phe-OH > Boc-Gly-OH > Boc-L-Val-OH

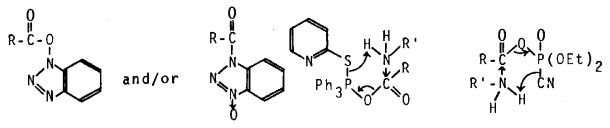
Relative reactivities using DEPC as a coupling reagent:

Boc-Gly-OH > Boc-L-Phe-OH > Boc-L-Val-OH

Relative reactivities using Ph_3P plus $(PyS)_2$ as a coupling reagent:

Boc-Gly-OH > Boc-L-Phe-OH $\gg$ Boc-L-Val-OH

The values reflect the reactivities of the intermediates formed by the reactions of coupling reagents with Boc–amino acids (Fig. 1).



I II III

Fig. 1. Intermediates for the corresponding coupling reagents (DCCI+HOBt,[12] $Ph_3P+(PyS)_2$,[9] and DEPC[10]).

The data runs 4—9, Table 2 show that the relative reactivities of Boc–L-Val–OH, Boc–L-Phe–OH, and Boc–L-Tyr(Bzl)–Gly–Gly–L-Phe–OH are as follows:

Coupling reagents: DCCI + HOBt and DEPC

Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH

= Boc-L-Phe-OH > Boc-L-Val-OH

Coupling reagent: $Ph_3P + (PyS)_2$

Boc-L-Phe-OH $\gg$ Boc-L-Val-OH >

Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH

The results indicate that the peptide chain length of Boc–L-Tyr(Bzl)–Gly–Gly–L-Phe–OH has no influence on the reactivity of the *C*-terminal amino acid in the coupling reaction using DCCI plus HOBt and DEPC as coupling reagents. A marked decrease in the reactivity of the *C*-terminal amino acid of the tetrapeptide acid was observed when Ph_3P plus $(PyS)_2$ was used as a coupling reagent. The differences due to coupling reagents can be attributed to the steric hindrance effect of the peptide chain on the intermediates I, II, and III.

Fragment condensation on the soluble polymer support could achieve efficient coupling of the tetrapeptide acid to the amino free terminal anchored to the soluble polymer support. Relative reactivities of Boc–amino acids and the peptide fragment could be easily determined by use of amino acid ratios in the acid hydrolysates of the resulting peptide resins in which they were taken. Thus it was found that the peptide chain length of Boc–tetrapeptide acid has no influence on the reactivity of the *C*-terminal amino acid in the coupling reaction using DCCI plus HOBt and DEPC as coupling reagents. However, a marked decrease in the reactivity of the *C*-terminal amino acid of the tetrapeptide was observed when Ph_3P plus $(PyS)_2$ was used as a coupling reagent.

The versatility of this new approach eliminates shortcomings of the solid phase and the classical liquid phase peptide syntheses, their merits, namely the inherent simplicity of synthesis using polymer supports and the advantage of carrying out the peptide synthesis under homogeneous conditions, being preserved. It promises the possibility of unequivocal chemical synthesis of homogeneous proteins of defined structures.

Experimental

Boc–amino acids were prepared according to Nagasawa *et al.*[13] HOBt, DEPC, and $(PyS)_2$ were prepared by the methods given by Konig and Geiger,[8] Takamizawa *et al.*[14] and Matsueda *et al.*,[18] respectively. All other reagents were commercial products. DMF was purified as follows. To benzene-dried DMF was added phenyl isothiocyanate (1% by volume) followed by distillation under reduced pressure. It was then redistilled under reduced pressure. Optical rotations were taken in a 1-dm cell on a Jasco Model ORD/UV-5 optical rotatory dispersion recorder. Amino acid analyses were performed on a Hitachi Liquid Chromatograph, Model 034. Hydrolyses of peptide resins were carried out on 20—40 mg samples of resins with propionic acid–12 M HCl (2 : 1 v/v) at 115 °C for 35 h.

Soluble Chloromethylated Polystyrene. Styrene, 28.12 g (0.27 mol), 4.58 g (0.03 mol) of (chloromethyl)styrene (Tokyo Kasei Co., a mixture of *m*- amd *p*-isomers (7 : 3)), and 0.25 g (1.5 mmol) of azobisisobutyronitrile were dissolved in 100 ml of benzene. The solution in a polymerization tube was sealed off *in vacuo* and heated in a bath maintained at 70±0.5 °C for 38 h. The solution was poured into methanol to obtain a soluble chloromethylated polystyrene. The product was dried *in vacuo* at 75—80 °C for 20 h. The yield was 20.3 g. The chlorine content of the polymer was determined by the Volhard method to get a value of 0.91 mmol per 1 g of resin.

H–L-Leu–OCH₂–resin. Esterification of the chloromethylated polystyrene with Boc–L-Leu–OH was carried out at room temperature for 7 days.[7b] Boc–L-Leu–OCH_2–resin: Leu content, 0.61 mmol/g (amino acid analysis); Cl content, 0.20 mmol/g (titrated by Volhard method). After attachment of Leu to the polymer support, residual benzylic chlorides were removed by the reaction with sodium

acetate in DMF at 105 °C for 24 h. The final chlorine content was less than 0.02 mmol/g. H-L-Leu-OCH_2-resin was prepared by a similar procedure.[7b] H-L-Leu-OCH_2-resin: Leu content, 0.62 mmol/g (amino acid analysis).

Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OCH_3. Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OCH_3 was prepared with use of DCCI plus HOBt as a coupling reagent,[11] mp 114—116 °C, $[\alpha]_D^{21}=+13.1°$ ($c=2.0$, CH_3OH) (lit,[11] mp 108—110 °C, $[\alpha]_D=+26.3°$ ($c=1.0$, CH_3OH)). It was also prepared by the following procedure. To a mixture of 3.73 g (0.01 mol) of Boc-L-Tyr(Bzl)-OH and 3.63 g (0.011 mol) of H-Gly-Gly-L-Phe-OCH_3·HCl in 30 ml of DMF was added 1.80 g (0.011 mol) of DEPC in 10 ml of DMF at 0 °C, followed by the addition of 2.1 g (0.021 mol) of triethylamine in 10 ml of DMF during 5 min. The mixture was strired at 0 °C for 1 h and then at room temperature overnight. The reaction mixture was diluted with 300 ml of ethyl acetate, successively washed three times with 5% hydrochloric acid, twice with 10% aqueous sodium chloride, three times with saturated aqueous sodium hydrogencarbonate, and twice with 10% aqueous sodium chloride, and dried over sodium sulfate. Removal of solvent *in vacuo* afforded the crude peptide (6.10 g). Recrystallization from ethyl acetate gave a substance, mp 114—116 °C, $[\alpha]_D^{21}=+12.9°$ ($c=1.0$, CH_3OH). Amino acid ratios in acid hydrolysate: Tyr 0.93, Gly 2.00, Phe 1.01 (Found: C, 64.27; H, 6.42; N, 8.87%).

Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH. To the tetrapeptide methyl ester, 3.5 g(5.0 mmol) in 60 ml of methanol, was added 12 ml of 0.5 M aqueous sodium hydroxide and stirred overnight at room temperature. Removal of solvent *in vacuo* afforded the crude peptide sodium salt, which was treated with 10% citric acid to give the tetrapeptide acid, 2.85 g. Recrystallization from water-methanol (3 : 1) gave a pure material, mp 104—107 °C, $[\alpha]_D^{21}=+21.0°$ ($c=1.0$, CH_3OH) (lit,[11] mp 95—96 °C, $[\alpha]_D=+34.3°$ ($c=0.95$, CH_3OH)). Amino acid ratios in acid hydrolysate: Tyr 0.91, Gly 2.00, Phe 1.00 (Found: C, 63.33; H, 6.15; N, 9.02%).

Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-L-Leu-OCH_2-resin. H-L-Leu-OCH_2-resin, 200 mg(Leu content: 0.124 mmol), was dissolved in 10 ml of DMF. To the solution was added 224 mg (0.37 mmol) of Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH, followed by the addition of 0.37 mmol of a coupling reagent at 0—5 °C. The reaction mixture was stirred at 0—5 °C for 2 h and then at room temperature for 3 h. To DCCI and DEPC, used as coupling reagents, were added 0.37 mmol of HOBt and 0.37 mmol of triethylamine, respectively. In the case of Ph_3P plus $(PyS)_2$, the coupling reaction was carried out with a three-fold excess of the carboxyl component and a 30-fold excess each of Ph_3P and $(PyS)_2$. The solution was poured into 200 ml of methanol followed by 30 ml of saturated aqueous sodium chloride. The precipitated peptide resin was filtered off, and washed successively with water and methanol to remove the soluble reactant. The yields were 253 mg (DCCI plus HOBt), 277 mg (DEPC), and 243 mg (Ph_3P plus $(PyS)_2$) (dried *in vacuo* for 2 days).

Relative Reactivities of Boc-Amino Acids and Boc-L-Tyr(Bzl)-Gly-Gly-L-Phe-OH in the Coupling Reaction. H-L-Leu-OCH_2-resin, 200 mg (Leu content: 0.124 mmol), and a three equivalent each of carboxyl components were dissolved in 20 ml of DMF. To the solution was added a coupling reagent, an equivalent mole with the total of the carboxyl components, under cooling with ice-cold water. When DCCI and DEPC were used as coupling reagent, an equivalent each of HOBt and triethylamine was added, respectively, after addition of the coupling reagent. In the case of Ph_3P plus $(PyS)_2$, the coupling reaction was carried out with a three-fold excess each of carboxyl components and a two-fold excess of the total of the carboxyl components each of Ph_3P and $(PyS)_2$. The reaction mixture was stirred for 2 h in an ice bath and 13 h at room temperature. The work-up was essentially the same as described above. The peptide resins were subjected to acid hydrolyses.

The work was carried out with a Grant-in-aid for Scientific Research from the Ministry of Education. Thanks are due to Prof. M. Akiyama for his support and Mrs. M. Asuke of this department for elemental analyses.

The Reactions of Group V Metal Amide with Sulfur Dioxide

Fumio Ando, Jugo Koketsu, and Yoshio Ishii
Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto, Kasugai, Aichi 487

(Received October 14, 1977)

Tris(dialkylamino)-arsines (I), -stibines (II), and -bismuthines (III) react with sulfur dioxide to give the corresponding tetraalkylsulfurous diamides and the corresponding metal oxides or polymers containing the metals. The reactivity of these metal amides in view of the fastness of the initial reactions follows the order III>II>I, however, the yields decrease in the order I>II>III. Tris(dialkylamino)phosphines, on the other hand, give hexaalkylphosphoric triamides and hexaalkylphosphorothioic triamides in a ratio of 2 : 1. The reactivity of the various phosphorus compounds toward sulfur dioxide increases with increasing nucleophilicity of the phosphorus atom; $P(NEt_2)_3 > Ph_2PNEt_2 > Ph_2POEt > PhP(OEt)_2 > P(OEt)_3$. The reaction mechanism of compounds (I), (II), and (III) with sulfur dioxide is different from that of the phosphorus amides.

Sulfur dioxide is unique in the point that it exhibits both nucleophilic and electrophilic behavior.[1] Many studies of the reaction of sulfur dioxide with organometallic compounds have been reported.[2,3] Lappert *et al.* have found that the reaction of sulfur dioxide with (dimethylamino)trimethyltin affords the insertion product,[4]

$$Me_3SnNMe_2 + SO_2 \rightarrow Me_3SnOSNMe_2 \quad (1)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad \| \; O$$

The reaction of tris(dialkylamino)boron with sulfur dioxide yields tetraalkylsulfurous diamides and tris-(dimethylamino)boroxin,[5]

$$3B(NR_2)_3 + 3SO_2 \rightarrow 3(R_2N)_2SO + (R_2NBO)_3. \quad (2)$$

The group V metal amides; $P(NR_2)_3$, $As(NR_2)_3$, $Sb(NR_2)_3$, and $Bi(NR_2)_3$ are very reactive compounds and thus are valuable as synthetic intermediates. They are known to react with ketones,[6-8] acetic anhydride,[7,9] and heterocumulenes,[7,9] but there is no report concerning their chemistry with sulfur dioxide. This paper describes the reactions of the group V metal amides with sulfur dioxide, and a reaction mechanism is proposed based on relative reactivities.

Results and Discussion

Tris(dimethylamino)-, tris(diethylamino)-, and tris-(dipropylamino)-arsine reacted with sulfur dioxide at −30 °C to give the corresponding tetraalkylsulfurous diamides and As_2O_3 which was identified by X-ray powder diffraction.

$$2As(NR_2)_3 + 3SO_2 \rightarrow 3(R_2N)_2SO + As_2O_3. \quad (3)$$

The sulfurous diamides were identified by comparison of their IR and NMR spectra with those of authentic samples obtained by the reaction of thionyl chloride with the corresponding secondary amines.[10,11] The identity of the sulfurous diamides was confirmed by the fact that their reaction with acetic anhydride gave the appropriate *N,N*-dialkylacetamides accompanied by the evolution of sulfur dioxide.[12]

The reaction of tris(dialkylamino)-stibines and -bismuthines with sulfur dioxide proceeded more vigorously, but the yield of sulfurous diamides was lower than the case of tris(dialkylamino)arsine. In addition to sulfurous diamides, in both cases polymeric residues, which were formulated on the basis of elemental analyses as $(R_2NSbO)_n$ or $(R_2NBiO)_n$, are formed. IR spectra of the residues showed a stretching mode for Sb–O–Sb at 750—715 cm^{-1} and for Bi–O–Bi at 630—620 cm^{-1}.[13]

$$M(NR_2)_3 + SO_2 \rightarrow (R_2N)_2SO + \frac{1}{n}(R_2NMO)_n. \quad (4)$$

M = Sb and Bi

These residues are hydrolyzed in the presence of hot water to afford Sb_2O_3 or Bi_2O_3 which was identified by X-ray powder diffraction.

There is a similarity between the reactions described here and the amination reactions of carbonyl compounds with group V metal amides.[8] Bismuth amides react with sulfur dioxide most vigorously. The reactivity order in view of the fastness of the initial reaction is Bi>Sb>As, whereas, the yields of sulfurous diamides decrease as follows As>Sb>Bi (Table 1). A mechanism for the reaction can be discussed in terms of the nucleophilicity of nitrogen atom and the affinity of the metal atom for oxygen. The first step involves the nucleophilic attack by the nitrogen atom of the metal amide on the sulfur atom of sulfur dioxide thus forming an insertion product.

$$(R_2N)_3M \rightarrow R_2N \quad O \| S=O \rightarrow \left[(R_2N)_2M\text{-}O \; | \; R_2N\text{-}S=O \right]$$
$$\rightarrow \left[R_2N\text{-}M\text{-}O \; | \; R_2N \;\; S(O)NR_2 \right] \rightarrow (R_2N)_2SO + \frac{1}{n}[R_2NMO]_n \quad (5)$$

The degree of ionic character of metal–nitrogen bonds increases with decreasing electronegativity of the central metal. The rates of the initial addition step are found to be parallel with the ionic degree of the metal–nitrogen bonds. On the other hand, the affinity of metal atoms

Table 1. Yields(%) of tetraalkylsulfurous diamide in the reaction of $M(NR_2)_3$ with SO_2

M	R		
	Me	Et	Pr
As	76	75	88
Sb	62	48	49
Bi	46	45	46

for oxygen decreases in the order; As>Sb>Bi.[8,14] Therefore, bismuth amides are the most reactive in the initial step, but their poor affinities for oxygen result in decreased yields of the sulfurous diamides as the result of the formation of the polymeric residues which contain the dialkylamino moieties instead of the metal oxides.

When tris(dialkylamino)phosphines were treated with sulfur dioxide, hexaalkylphosphoric triamides and hexaalkylphosphorothioic triamides were obtained in the ratio of 2:1.

$$3(R_2N)_3P + SO_2 \rightarrow 2(R_2N)_3P{=}O + (R_2N)_3P{=}S \quad (6)$$

Similarly, (diethylamino)diphenylphosphine, ethyl diphenylphosphinite and ethyl diphenylphosphinothioite gave the corresponding P=O and P=S compounds in the ratio of 2:1. The reactivity of the various trivalent phosphorus compounds toward sulfur dioxide was compared by means of GLC analysis. The order of the reactivity, $P(NEt_2)_3 > Ph_2PNEt_2 > Ph_2POEt > PhP(OEt)_2 > P(OEt)_3$, is parallel with the order of electron density on the phosphorus atom.[15,16] Tris(diethylamino)phosphine has the highest electron density on the phosphorus atom because of the (p-d)π interaction between the nitrogen atom and the phosphorus atom. In the case of phosphites, although there may be some degree of oxygen to phosphorus (p-d)π bonding, the inductive effect of oxygen atoms provide a greater influence on the reactivity. Thus it would appear most reasonable to expect that the reactive site on the aminophosphine is the phosphorus atom instead of the nitrogen atom. On this basis a tentative mechanism for the reaction is as follows.

$$(R_2N)_3P + S{=}O \rightarrow (R_2N)_3\overset{+}{P}{-}S{=}O \rightarrow (R_2N)_3P{<}\begin{matrix}S{=}O\\ O\end{matrix}$$

$$\rightarrow (R_2N)_3PO + [SO]$$

$$[SO] \rightarrow \frac{1}{2}(S) + \frac{1}{2}SO_2$$

Nucleophilic attack by the phosphorus atom on the sulfur atom of sulfur dioxide occurs as the first step of the reaction, and follows the formation of the P–O bond, generating the products. This mechanism is principally the same as that proposed by Smith *et al.* for the reaction of phosphines with sulfur dioxide.[17,18] Aminophosphines exhibit an ambident nature in their reactions with various kinds of electrophilic reagents, such as phenyl cyanate, and β-propiolactone.[19,20] In the reaction with cyclic carbonates, the nitrogen atom of the aminophosphine acts as the nucleophilic site whereas in the reaction with alkyl benzenesulfonate, the phosphorus atom attacks the electrophilic reagent forming the phosphonium salt.[21,22] Although it is very difficult to predict which atom of the aminophosphines acts as a nucleophilic site, the HSAB concept may prove helpful. Since the phosphorus atom of the aminophosphine is softer than the nitrogen atom, a soft electrophile would be expected to prefer to interact with the phosphorus atom. The striking difference in mechanism of the reaction of sulfur dioxide with aminophosphines and with aminoarsines, aminostibines and aminobismuthines is not explainable on the basis of HSAB theory. The fact that the metal sulfides of the type, $(R_2N)_3M{=}S$ where M=As, Sb, and Bi were not formed suggests that the poorer stability of the M=S bond relative to P=S may be a factor of significant importance.

Experimental

All the reactions were carried out under an argon atmosphere. The IR, NMR, and mass spectra were recorded on a Shimadzu IR-430 spectrometer, a JEOL-C60 HL spectrometer, and a JMS-D300 spectrometer, respectively. GLC analyses were carried out on a Simadzu GC 6A apparatus, using PEG 6000 (10%)-Shimalite W 301 (1 m) column with helium as the carrier gas.

Materials. Tris(dialkylamino)arsines, -stibines, and -bismuthines were prepared by the methods priviously reported[9,23]: $As(NMe_2)_3$; bp 68—72 °C/18 mmHg, $As(NEt_2)_3$; bp 62—65 °C/0.3 mmHg, $As(NPr_2)_3$; bp 82—86 °C/0.08 mmHg, $Sb(NMe_2)_3$; bp 55—61 °C/5 mmHg, $Sb(NEt_2)_3$; bp 59—62 °C/0.02 mmHg, $Sb(NPr_2)_3$; bp 107—111 °C/0.1 mmHg, $Bi(NMe_2)_3$; bp 34—36 °C/0.2 mmHg, $Bi(NEt_2)_3$; bp 75—77 °C/0.12 mmHg, $Bi(NPr_2)_3$; bp 73—77 °C/0.05 mmHg. All the phosphorus compounds used in this experiment are synthesized according to the methods described in the literature.[24] Sulfur dioxide, obtained from a commercial source, was dried by passage through concentrated sulfuric acid. Organic solvents were dried by conventional methods.[25]

Reaction of Tris(dialkylamino)arsines with Sulfur Dioxide. Dry sulfur dioxide was bubbled through tris(dimethylamino)-arsine (2.67 g, 12.9 mmol) in diethyl ether (5 ml) at −30 °C. An exothermic reaction took place to give a white precipitate. After removal of the precipitate, the solvent and excess SO_2, tetramethylsulfurous diamide (2.00 g, 76%) was obtained by distillation under reduced pressure; bp 70—73 °C/16 mmHg, mp 30—30.5 °C, IR (neat) ν(S=O) 1150, $\nu(NC_2)$ 930, 908, ν(S–N) 670, 656, 646 cm^{-1}, NMR ($CHCl_3$) δ 2.62, MS *m/e* 136 (M^+).

Similar treatment of tris(diethylamino)arsine (5.09 g, 17.5 mmol) with sulfur dioxide resulted in the formation of tetraethylsulfurous diamide (3.77 g, 75%); bp 82—84 °C/3 mmHg, n_D^{20} 1.4635, IR(neat), ν(S=O) 1110 cm^{-1}, $\nu(NC_2)$ 924, 894, 876 cm^{-1}, ν(S–N) 652 cm^{-1}, NMR ($CHCl_3$) δ 1.10 (3H, t), 3.06 (2H, q), MS *m/e* 192 (M^+). Reaction of tris-(dipropylamino)arsine (4.16 g, 11.1 mmol) with sulfur dioxide gave tetrapropylsulfurous diamide (3.63 g, 88%); bp 66—68 °C/0.03 mmHg, n_D^{20} 1.4667, IR (neat) ν(S=O) 1110 cm^{-1}, $\nu(CN_2)$ 692 cm^{-1}, NMR ($CHCl_3$); δ 0.89 (3H, t), 1.53 (2H, m), 2.94 (2H, t), MS *m/e* 248 (M^+).

Reaction of Tris(diethylamino)stibine with Sulfur Dioxide. When sulfur dioxide was passed through an ethereal solution of tris(diethylamino)stibine (1.93 g, 5.71 mmol) at −30 °C, a violent reaction took place to give a yellowish white precipitate, which was filtered and washed twice with ether. The filtrate was distilled to give tetraethylsulfurous diamide (0.79 g, 48%), bp 44—46 °C/0.02 mmHg. The polymeric residue exhibited Sb–O–Sb bands at 750, 616 cm^{-1} and several absorptions ascribed to the diethylamino moiety. (Found: C, 23.6%, H, 4.98%. Calcd for $C_4H_{10}NOSb$; C, 22.90%, H, 4.80%.)

Reaction of Tris(diethylamino)bismuthine with Sulfur Dioxide. Tris(diethylamino)bismuthine (2.85 g, 6.70 mmol) reacted readily with sulfur dioxide to give hexaethylsulfurous diamide (0.88 g, 45%) and a yellowish white precipitate; IR (KBr) 618 cm^{-1} (Bi–O–Bi). (Found: C, 16.4%, H, 3.66%, Calcd for $C_4H_{10}NOBi$; C, 16.17%, H, 3.39%)

Table 2. Spectroscopic data of the products of the reaction between several phosphorus compounds and SO_2

Reaction of Tris(dialkylamino)phosphines with Sulfur Dioxide. Sulfur dioxide was bubbled through tris(dimethylamino)phosphine (1.65 g, 10.1 mmol) in diethyl ether (5 ml) at −30 °C. After removal of the volatile materials, the reaction mixture was distilled to give a fraction having a boiling point of 53—72 °C/0.6 mmHg. The distillate showed two spots on thin layer chromatograph at $R_f=0.87$ and 0.19. Separation of the distillate by a column chromatograph (silica gel-chloroform) gave hexamethylphosphorothioic triamide (0.53 g, 27%) as a first eluate and hexamethylphosphoric triamide (0.87 g, 48%) as a second eluate, as identified by the comparison of their IR and NMR spectra with those of authentic materials.[24] Similarly, sulfur dioxide was passed through an ethereal solution of tris(diethylamino)phosphine (1.83 g, 7.40 mmol) at −30 °C, and the reaction mixture was distilled. The fraction of the bp range 36—86 °C/0.1 mmHg was collected, and column chromatograph of this fraction gave hexaethylphosphorothioic triamide (0.56 g, 27%) $R_f=0.70$, NMR ($CHCl_3$) δ 1.11 (3H, t), 3.14 (2H, m, $J_{PNCH}=11.6$ Hz). IR ν(P=S) 798, 696 cm^{-1}, and hexaethylphosphoric triamide (0.98 g, 50%), NMR ($CHCl_3$) δ 1.22 (3H, t), 3.31 (2H, m, $J_{PNCH}=16.5$ Hz), IR ν(P=O) 1205 cm^{-1}. Reaction of tris(dipropylamino)phosphine with sulfur dioxide gave hexapropylphosphorothioic triamide (0.37 g, 20%), NMR ($CHCl_3$) δ 0.86 (3H, t), 1.56 (2H, m), 2.96 (2H, m), IR ν(P=S) 796, 736 cm^{-1}, and hexapropylphosphoric triamide (0.82 g, 45%), NMR ($CHCl_3$) δ 0.91 (3H, t), 1.63 (2H, m), 3.01 (2H, m), IR ν(P=O) 1242 cm^{-1}.

The similar treatment of (diethylamino)diphenylphosphine, ethyl diphenylphosphinite and ethyl diphenylphosphinothioite with sulfur dioxide gave the corresponding P=O and P=S compounds in the ratio of 2:1. And the spectral data of these products are shown in Table 2.

Effect of Substituent on the Reactivity. A reaction of a phosphorus (III) compound (0.1 mol/l) with a large excess sulfur dioxide was initiated at −55 °C by mixing THF solutions of each reagent containing an internal standard. Aliquots of the reaction mixture were withdrawn at appropriate times, and the remaining amount of the phosphorus (III) compound was determined by GLC analysis (Table 3).

Reaction of Tetraalkylsulfurous Diamide with Acetic Anhydride. Acetic anhydride (1.3 g, 11.1 mmol) was added to an ice-cooled ethereal solution of tetramethylsulfurous diamide (1.51 g, 11.1 mmol) with stirring. An exothermic reaction took place accompanied by the evolution of a gas. After removal of the solvent, *N,N*-dimethylacetamide (17.4 g, 90%) was obtained by distillation, bp 67—70 °C/20 mmHg. Similarly an equimolar reaction of tetraethylsulfurous diamide (1.56 g, 8.13 mmol) with acetic anhydride gave *N,N*-diethylacetamide (1.63 g, 87%), bp 101—104 °C/55 mmHg.

Table 3. Remaining amount of trivalent phosphorus compounds after 40 min

Compound	Concentration (mmol/l)
$P(NEt_2)_3$	0
Ph_2PNEt_2	14.2
Ph_2POEt	21.8
$PhP(OEt)_2$	51.6
$P(OEt)_3$	98.6

The authors wish to thank Professor D. Hendricker of Ohio University for valuable discussions and correcting English.

The Reaction of 1,3,5-Triazine with Aromatic Nitrile Oxides. A New Synthesis of 3-Substituted 1,2,4-Oxadiazoles

Masahiro KURABAYASHI and Christoph GRUNDMANN

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

Department of Chemistry, Carnegie-Mellon University, 4400 Fifth Avenue, Pittsuburgh, Pennsylvania 15213

(Received October 17, 1977)

The cycloaddition of aromatic nitrile oxides(**2a**=benzo-; **2b**=*p*-tolu-; **2c**=mesitylenecarbo-) with 1,3,5-triazine(**1**) is reported. The corresponding 3-substituted 1,2,4-oxadiazoles(**3a,b,c**) are obtained in fair yields only when BF_3 is added. It was stoichiometrically confirmed that one mol of **1** behaves so as to supply three mols of azomethine radicals. A reaction scheme initiated from a two-step cycloaddition of **2** to **1** activated by BF_3 is suggested. The mixture, **1** : **2c** : BF_3=1 : 3 : 1, afforded a better yield of **3c**(69%) than an equimolar mixture of **2c** with ethyl formimidate or formamidine.

Grundmann and Kreutzberger[1-5] have investigated a variety of reactions of 1,3,5-triazine(**1**) with many kinds of nucleopiles. This paper is concerned with an unpublished reaction of **1** with nitrile oxides(**2**) which are well-known 1,3-dipoles for cycloaddition.[6a] Several aromatic **2** were treated with **1**, but 3-substituted 1,2,4-oxadiazoles(**3**), potential intermediates for organic synthesis, were obtained in fair yields only when boron trifluoride diethyl etharate(BF_3) was added to the mixtures.

2a, **3a**: R=C_6H_5
2b, **3b**: R=*p*-$CH_3C_6H_4$
2c, **3c**: R=2,4,6-$(CH_3)_3C_6H_2$

Experimental

Materials. **1** was prepared by Schaefer's method,[3] mp 81.6 °C(85—86),[3] N, 51.83% (52.13). Benzohydroximoyl chloride, mp 51.7 °C(49—50),[7] and *p*-toluhydroximoyl chloride, mp 67.2 °C, Cl, 20.90%(20.90) were obtained from the corresponding aldoximes by the usual manner.[7] **2c** was obtained by the previously reported method[8] from 2,4,6-trimethylbenzaldehyde oxime, mp 112.5—113.5 °C (114).[6] Hydrogen cyanide was generated from potassium cyanide and sulfuric acid and distilled over posphorus pentaoxide, bp 26 °C.

Typical Procedure for the Reaction of 1 with 2. An equivalent amount of triethylamine is added to a tetrahydrofuran (THF) solution of a few grams of benzohydroximoyl chloride and *p*-toluhydroximoyl chloride, respectively, to generate **2a** and **2b**, and thus precipitated triethylamine hydrochloride is removed by filtration. These procedures and the handling of the resulting solutions of **2a** and **2b** are carried out under cooling with salt and ice mixture. **2c** is stable for a long time in both solid and solution at room temperature.[6]

In the case of *Method A*, BF_3 is added dropwise to a mixture of **1** and the smallest amount of solvent under stirring. To the resulting slurry a solution of **2** is added within half an hour. In the case of *Method B*, BF_3 is added to a solution of **1** and **2**. After the stirring has been continued according to the time and temperature schedule given in Figs. 1 and 2 and Table 2, the reaction mixture is neutralized with an aqueous potassium carbonate solution, separated from the solvent by means of mild evacuation, and then shaken with heptane. The extract is analyzed by the use of gas-liquid phase chromatography(GLC) to determine the yield of **3**, and then distilled *in vacuo*. A fraction of **3** underwent further

purification on preparative GLC for supplying the analytical data given in Table 1.

Results and Discussion

The following was confirmed by a preliminary test: **1** is stable to BF_3 in inert solvents at temperatures up to 60 °C and produces an adduct of fine needles with BF_3. **2c** is unstable under the same conditions and rapidly converted into mesitylenecarbonitrile and a caramel-like polymer. When **1**, **2c**, and BF_3 are put together, the self-conversion of **2c** competes with the cycloaddition leading to **3c**.

The yield of **3c** is its maximum when the molar ratio of BF_3 to **1** is 0.3—0.5, as shown in Fig. 1; when the ratio is increased beyond this range, the yield is decreased, probably because of the extensive advance of the self-conversion of **2c**. Increase in the concentrations of the reactants and a molar ratio of **1** to **2** are effective for suppressing the self-conversion of **2**, and as a result, an increase in the yield of **3**, and also the dropwise addition of **2** to a mixture of **1** and BF_3 is similarly effective (Table 2). Use of BF_3 is also effective in the case of **2a** and **2b** in spite of their smaller steric hindrances than **2c**. The yields of **3a** and **3b** were both poor presumably because of the poor stability of **2a** and **2b**.[6b]

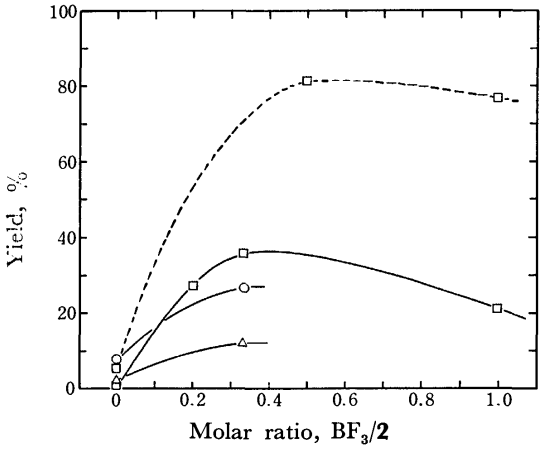

Fig. 1. Plots of yield of **3** based on **2** *vs.* molar ratio of BF_3 to **2**. —○—: **1** : **2a** : THF = 1 mol : 3 mol 1500 cm³ by reaction *Method A*, —△—: **1** : **2b** : THF = 1 mol : 3 mol : 1500 cm³ by reaction *Method A*, —□—: **1** : **2c** : benzene = 1 mol : 3 mol : 3000 cm³ by reaction *Method B*, --□--: **1** : **2c** : benzene = 1 mol : 1 mol : 1000 cm³ by reaction *Method B*.

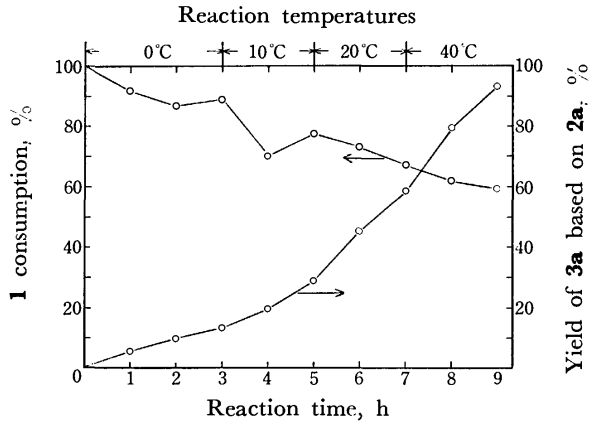

Fig. 2. Time dependence of the composition of the reaction mixture started with the ratio, **1** : **2c** : BF_3 : benzene = 1 mol : 1 mol : 0.5 mol : 1000 cm³.

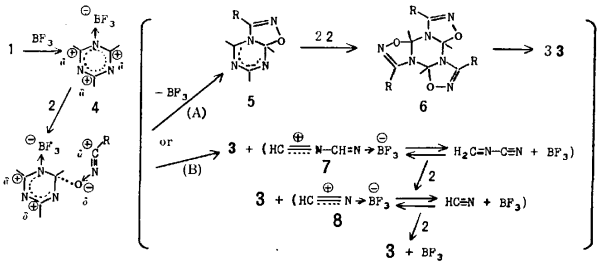
Equation 1 satisfies the experimental fact that the yield of **3c** amounted to 69% when the reaction was started with the molar ratio of **1** to **2c** as one-third (see Table 2).

$$\mathbf{1} + 3\,\mathbf{2} \longrightarrow 3\,\mathbf{3} \qquad (1)$$

It is noticeable that several dipolarophiles such as aliphatic carbonyls and nitriles without electron attractive moieties can be activated by an addition of BF_3 to undergo cycloaddition with **2**.[9] The role of BF_3 in the cycloaddition in this study is thought to activate the dipolarophile, **1**, too. The reaction scheme is inferred as Eq. 2.



(2)

4 presumed to be an activated form of **1** by BF_3 is attacked on the carbon atom by the oxygen atom of **2** and then derived to the 1:1 adduct, **5**, or split to **3** and **7** by way of a two-step cycloaddition. Additional two moles of **2** may attack the intermediates, **5** or **7** and **8**, resulting in three molecules of **3** by the route A or B. When the initial molarities of **1** and **2c** have been made equal, merely one-third mole of **1** is consumed for the formation of every one mole of **3c** during the reaction (Fig. 2). This shows that the intermediate systems containing **5** or **7** and **8** are more susceptible to the attack of **2** than **4**. Whether route A or B prevails could not be verified,[10] since these intermediates have never been isolated.

The formation of maximal 3 mol of **3** from 1 mol of **1** demonstrates the usefulness of **1** as a starting material

TABLE 3. REACTION OF **2c** WITH HYDROGEN CYANIDE AND ITS DERIVATIVES TO FORM **3c**[a]

Dipolarophile (mol/mol-**2c**)	Catalyst (mol/mol-**2c**)	Solvent	Reaction temp t/°C	Yield[b] %
HCN (3)[c]	BF_3 (0.5)	Benzene	0—60	0
$HC(NH)OC_2H_5$ (1)[d]	—	EtOH	17—40	33.4
$HC(NH)NH_2$ (1)[e]	—	EtOH	11—60	59.0

a) 2000 cm^3 of solvent was used for one mol of **2c**. b) Theoretical yield of **3c** based on **2c**. c) Hydrogen cyanide was mostly recovered unreacted. d) An equiv. amount of 1,8-diazabicyclo[5,4,0]undec-7-ene was added to the mixture of ethyl formimidate hydrochloride and **2c**. e) An equiv. amound of triethylamine was added to the mixture of formamidine hydrochloride and **2c**.

for **3**. As a comparison, hydrogen cyanide and its two derivatives were subjected to cycloaddition with **2c**.

$$\left.\begin{array}{l}\mathrm{HCN}\\ \mathrm{HC(NH)OC_2H_5}\\ \mathrm{HC(NH)NH_2}\end{array}\right\} \xrightarrow{\mathbf{2c}} \mathbf{3c} \qquad (3)$$

The results are given in Table 3. It is seen that formamidine is comparative to **1** with respect to the yield of **3c**. However, formamidine is usually prepared from hydrogen cyanide *via* formimidate. Thus it is less accessible than **1** which is prepared directry from hydrogen cyanide.[3] As regards synthesis of **3** without use of **2**, the reactions of amidoxime with acetic formic unhydride,[11] formamide,[12] trialkyl orthoformates,[14,15] and *N*,*N*-dimethyl-α,α-dimethoxymethylamine[15] have been reported to give sometimes good yields.

The authors wish to express their thanks to Mr. Jyunichi Fujishima, Tokai University, for his assistance.

The Role of the Charge-transfer Complex in the Photocopolymerization of Oxygen with Styrene and α-Methylstyrene

Toshiyuki KODAIRA, Kohzoh HASHIMOTO, Yoshihiko SAKANAKA, Sumio TANIHATA, and Katsuki IKEDA

Department of Industrial Chemistry, Faculty of Engineering, Fukui University, Fukui 910

(Received October 25, 1977)

The effect of the wavelength of irradiated light on the photocopolymerizations of oxygen with styrene (**1**) and α-methylstyrene (**2**) was investigated in connection with the charge-transfer bands observed between these monomers and oxygen, with the latter as an electron acceptor. It appeared that the excitation of the charge-transfer bands is responsible for the copolymerizations and that the photoabsorptions due to **1** and **2** do not contribute to the reactions, although the excited singlet states of these compounds were quenched by oxygen according to a Stern-Volmer plot.

The bathochromic shifts of the electronic absorption bands of several monomers including styrene (**1**) and α-methylstyrene (**2**) were observed while the electronic spectra were measured for these compounds saturated with oxygen.[1] The extra absorption bands were attributed to contact charge-transfer (CT) complexes between them and oxygen, with the latter as an electron acceptor, by taking into consideration the similar absorptions observed for various organic substances.[2] The photopolymerization of **1** in the presence of oxygen revealed that the CT-band plays an important role as a light-absorbing species in the formation of the alternating copolymer of **1** with oxygen.[1] Some contribution from the exciplex between oxygen and the excited singlet **1** to the formation of the alternating copolymer was also suggested based upon the measurements of the fluorescence spectra of **1** in the presence of oxygen under various pressures, but no detailed polymerization data were reported in connection with the excitation of **1**.[1] For this reason, the effect of the wavelength of irradiated light on the photocopolymerization of **1** with oxygen has been investigated to get further information on the contribution from the excited singlet **1** to the copolymerization. During the course of this study, it appeared that **2** also yields an alternating copolymer, with oxygen as a comonomer, on the excitation of **2** in the region of the CT-band. Therefore, similar experiments have also been carried out for **2**. Photo- and thermal-copolymerizations of these compounds by using azobisisobutyronitrile have already been reported,[3-6] but their direct photocopolymerizations have not yet been studied except for the work[1] in this laboratory.

This subject is interesting in connection with the direct photooxygenation reaction, which has been studied in only a few works,[7-9] in contrast to the extensive studies of the photosensitized oxygenation.[10]

Experimental

Materials. The monomers and oxygen were purified as has been described previously.[1]

Polymerization. The apparatus used for the copolymerization of **1** with oxygen[1] was adopted, but a polymerization tube made of quartz was used for all the copolymerizations unless otherwise noted in the text. A trap protected from atmospheric moisture by calcium chloride and immersed in a dry ice–methanol bath was added at the outlet of a refluxing condenser to collect the volatile products. After a given time, the unreacted monomers were distilled off through a vacuum line without heating. The residues were weighed in order to determine the yield of polyperoxide. The distillate was treated with an aqueous semicarbazide hydrochloride solution containing potassium acetate.

Photoirradiation. Photoirradiations were carried out using one of the following three lamps; a Riko 30-watt low-pressure mercury lamp (Model UVL-30A), a Toshiba 100-watt high-pressure mercury lamp (Model SHL-100UV2), and an Ushio 2000-watt xenon lamp (Model UXL-2003D). The wavelength was controlled by means of a Toshiba colored glass filter or a monochrometer (Ritsu Applied Optics Co., Ltd., Model MC-30). In the latter case, the distances from the lamp to the entrance slit of the monochrometer and from the exit slit to the polymerization tube were 21 and 27 cm, respectively. The width of both the slits was 8 mm.

Measurements of Light Intensities. The light intensities of the Xe-lamp at arbitrarily chosen wavelengths were determined by means of a potassium tris(oxalato)ferrate(III) actinometer,[11] using the apparatus for the copolymerization. The results are illustrated in Fig. 1. The light intensities of the low-pressure mercury lamp with and without the application of an UV-29 filter are also given in Fig. 1. The quantum efficiency at 253.7 nm of the actinometer was used for the calculation of the photointensities of the lamp, though it irradiates light of various wavelengths.

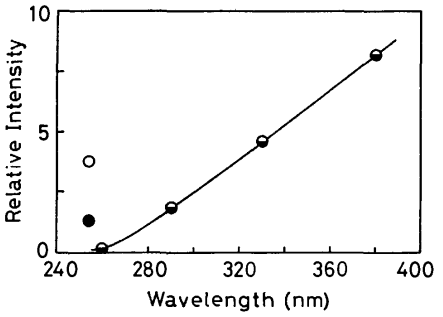

Fig. 1. Photointensities of a xenon lamp (◒) and a low pressure mercury lamp with an UV-29 filter (●) and without it (○). Light detected for the low pressure mercury lamp under the application of the filter consists of higher wavelength bands than the emission band at 253.7 nm because of the almost complete shielding of it by the filter, but the photointensity was depicted at the wavelength for convenience. Distance between light and polymerization tube was 10 cm for the mercury lamp and see experimental section for the xenon lamp.

Measurements of Spectra and Viscosity. Measured as has been described previously.[1)]

Results and Discussion

The amount of residue after the evaporation of the unreacted **1** from the reaction mixture is plotted *versus* the wavelength of the light irradiated in Fig. 2. The absorptions of **1** saturated with nitrogen and oxygen are also illustrated in Fig. 2. The yield of the copolymer increases with an increase in the wavelength of the irradiated light and then decreases after attaining a maximum at about 335 nm, though the intensity of the light increases as the wavelength becomes longer, as is shown in Fig. 1. The photointensity in the shorter-wavelength region is too weak to deduce a conclusion in connection with the intensity of light and the polymer yield. Therefore, the copolymerization was undertaken under the irradiation by the low-pressure mercury lamp. Its most prominent emission band, at 253.7 nm, is in the region where **1** has a strong absorption. The results are shown in Table 1. The emission intensity of the mercury lamp is comparable with that of the Xe-lamp at 320 nm (Fig. 1), but the polymer yield is only one-third of the yield by the Xe-lamp at that wavelength. The application of the UV-29 filter which cuts off emission at 253.7 nm did not reduce the polymer yield, as was expected from the decrease in the photointensity. Further, it must be noticed that the filter also lowers the light intensity at longer wavelengths to some extent. These results suggest that the polymer obtained by using the low-pressure mercury lamp is mainly due to the absorption of light at the longer wavelengths irradiated from the lamp. The alternating copolymer of **1** with oxygen decomposes to produce benzaldehyde and formaldehyde when exposed to ultraviolet light.[12)] The yields of benzaldehyde, determined as its semicarbazone, are also plotted *versus* the wavelength of the light irradiated in Fig. 2. The formaldehyde was qualitatively identified as paraformaldehyde when the white powder detected in the cold trap of the outlet was analyzed by comparing its IR spectrum with that of an authentic sample. It has already been confirmed that these decomposition products do not contribute to the initiation reaction of the copolymerization.[1)]

ing copolymer of **2** with oxygen, based upon its IR spectrum and that of an authentic sample.[5] The results obtained by using the low-pressure mercury lamp as a light source are given in Table 1. These results indicate that the photoabsorption of the CT-band between **2** and oxygen is responsible for the formation of the alternating copolymer, while that of **2** does not contribute to the copolymerization.

Based upon the quenching process of the fluorescence of **1** by oxygen, it has been considered that the exciplex of the excited singlet **1** with oxygen also contributes to the photoinduced alternating copolymerization of **1** with oxygen.[1] However, the results obtained in this work are in contrast to this suggestion. For this reason, the interaction of oxygen with the singlet excited state of **2** has been investigated by measuring the fluorescence spectra of **2** in the presence of oxygen under various pressures. As is shown in Figs. 4 and 5, the fluorescence of **2** is quenched by oxygen according to a Stern-Volmer plot, though it is not quenched so effectively as in the case of **1** under the conditions described. Accordingly, it appeared that the interaction between the singlet excited state and oxygen does not contribute to the initiation reaction of the copolymerization in the case of **2**, either.

The alternating copolymer of **2** with oxygen decomposes to yield acetophenone and formaldehyde on photoirradiation.[5] The former was, in fact, detected in the distillate of the unreacted monomer as its semicarbazone. The white solid precipitated in the cold trap was identified as paraformaldehyde by measuring the IR spectra. The yield of acetophenone was determined quantitatively; it is plotted against the wavelength in Fig. 3. The addition of one-fourth of the maximum yield of acetophenone to the polymerization system did not cause any change in the yield of polyperoxide as compared with the polymerization under normal conditions, *i.e.*, the copolymerization without acetophenone. The polyperoxide thus formed acts as an initiator for the photocopolymerization, as is shown in Table 2, but the results indicate that the initiation of the copolymerization proceeds more effectively through the excitation of the CT-band than the initiation through peroxide.

Thus, the photoabsorption of the CT-bands plays a fundamental role in the copolymerization of oxygen with **1** and **2**, and the excited singlet states of both the monomers do not contribute to the copolymerizations.

Table 2. Photocopolymerization of **2** with oxygen by means of a high-pressure mercury lamp in a hard glass ampoule[a]

Polyperoxide[b] %	Conv. %	APH[c] %
0	8.8	4.0
3.0	13.9[d]	7.4

a) See footnote of Table 1. b) Alternating copolymer of **2** with oxygen. c) Acetophenone. d) Polyperoxide added was not subtracted.

However, the maximum polymer yield is slightly shifted to a longer wavelength region than the wavelength expected from the CT-bands. One reason for this is the fact that the intensity of the irradiated light decreases with the decrease in the wavelength. The other is the absorption of light by **1** and **2**, which does not contribute to the reactions, because the sharp decrease in the polymer yield begins at the wavelength where the absorption bands of **1** and **2** appear.

The contribution to the copolymerizations by the triplet states excited directly by the singlet states of **1** and **2** is excluded on the basis of the following considerations. The singlet-triplet transition of **1** has been observed around 463 nm,[13] while that of **2** is expected to be detected at a longer wavelength region judging from the effect of the substituents on the transition of aromatic and olefinic compounds,[14] though the datum for the singlet-triplet transition for **2** is not available.

The reduced viscosities measured for the copolymers of oxygen with **1** and **2** were found to be in the region from 0.06 to 0.08 dl/g. The values were scattered, without any significant trend with respect to the polymerization conditions.

Financial support (Grant-in-Aid No. 975439) by the Ministry of Education, Japanese Government, is acknowledged.

Studies on the Liquid Phase Oxidation of Nitroalkylbenzenes Catalyzed by Transition Metal and Bromide Ions

Ryoichi HASEGAWA[1] and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received October 15, 1976)

The liquid phase autoxidation of nitroalkylbenzenes catalyzed by transition metal and bromide ions in acetic acid was investigated at 55—85 °C. A remarkable synergistic effect was found on the mixtures of metal catalysts composed of cobalt and other transition metals, the maximum reaction rate being observed at the molar ratio of Co : Mn : Br = 1 : 0.005—0.01 : 1—2. The rate of oxygen absorption of *p*- or *m*-nitroalkylbenzenes was affected by the partial pressure of oxygen, showing deviation from the first order dependency on the substrate concentration in contrast to the case of ordinary alkylbenzenes. The results can be explained by the retardation effect due to nitro compounds which might result from the reaction with alkyl radicals and the deactivation of metal catalysts. *o*-Nitroalkylbenzenes except nitroethylbenzene show a great resistivity against the oxidation. The retardation effect can be ascribed to the inhibiting effect due to inactive free radicals and also to the various reduced products resulting from the intramolecular reaction of nitro groups and active radicals. It was found that the autoxidation of *p*-nitrotoluene catalyzed by Co–Mn–Br catalyst proceeds very rapidly at temperatures as low as 85 °C, yeilding mostly *p*-nitrobenzoic acid along with a small amount of *p*-nitrobenzaldehyde.

The autoxidation of alkylbenzenes catalyzed by transition metal and bromide ions in acetic acid has been studied by many workers.[2-6] The liquid phase oxidation of nitroalkylbenzenes is important from the viewpoint of chemical industry, it is also interesting theoretically because of the difficulty of the reaction due to electron-withdrawing tendency of the nitro group, though this has not been clarified. Chervinskii and Kovalev reported the oxidation of *p*-nitrotoluene catalyzed by transition metal stearates and tetrabromoethane in propionic or butyric acids at 140—160 °C,[7,8] but we have confirmed that the selectivity of the reaction is low because of complicated side reactions. They reported the oxidation of nitrosubstituted *o*-xylenes,[9] but did not clarify the effect of the nitro group. Several patents which have been published for the oxidation of *p*- or *m*-nitrotoluenes[10-15] with severe conditions attached, do not furnish satisfactory data for a theoretical approach on the effect of the nitro group.

We have thoroughly studied the effect of the nitro group in the autoxidation of nitroalkylbenzenes catalyzed by transition metal and bromide ions in acetic acid and found that the oxidation proceeds easily at temperatures as low as 85 °C under restricted reaction conditions.

Experimental

Materials. Acetic acid, various metal acetates and alkali bromides of reagent grade were used. Nitrotoluenes, 2,4-dimethylnitrobenzene, *p*-nitroethylbenzene and nitrobenzene were purified by the usual method: distillation or recrystallization after washing with dilute sulfulic acid, aqueous alkali, water and drying. Chlorobenzene and *o*-dichlorobenzene were distilled after being dried over calcium chloride. *p*-Chlorotoluene, *o*-nitroethylbenzene, *o*-nitroacetophenone, *o*-nitrobenzaldehyde, *p*-nitrobenzaldehyde and other organic compounds of reagent grade were used after treatment with active alumina, when necessary.

Procedure. The rate of oxygen absorption was measured under atmospheric oxygen according to the method of Kamiya,[16,17] but in the case of the experiment under positive pressure, it was determined by measuring the very small pressure variation in a constant volume reactor.

Analysis. A gas chromatograph (Shimadzu GC-4BP-TF) was mainly used for analysis of the reaction products. The conditions were as follows, Column: 3% Silicone OV-17, on Chromosorb WHP, 1.5 m, 145 °C, Detector: FID, 250 °C, N_2-Flow rate: 40 ml/min, Injection temperature: 260 °C.

Results and Discussion

Feature of the Metal Catalyst. Oxidation of *p*-nitrotoluene and *p*-chlorotoluene was carried out in acetic acid in the presence of various catalysts. The steady state rate of oxidation is shown in Fig. 1. The general feature of the oxygen absorption curves was not affected by the concentration of catalyst or

substrate, a straight line being obtained until a considerable amount of substrate was consumed. The activity of catalysts decreased in the order, Co–Mn–Br> Co–Ce–Br> Co–Cr–Br, no appreciable catalysis being observed in other combinations of metal ions. Maximum reaction rates were obtained in metal mixtures of Co–Mn, Co–Ce, and Co–Cr at molar ratios of 99 to 1, 98 to 2 and 75 to 25, respectively. However, the Co–Mn ratio reported in the oxidation of *p*-xylene and ethylbenzene catalyzed by Co–Mn–Br is 80 to 20.[5] In the following experiments, Co–Mn–Br catalyst was mainly used at the molar ratio of Co : Mn : Br=99 : 1 : 170 because of its high activity. With regard to the molar ratio of bromide ion to total metal ions, no significant difference was observed between the ratios from 1 : 1 to 2 : 1. The effect of counter cation on bromide ion was striking. In the case of alkali earth metal ions (*e. g.* Mg^{2+}, Ca^{2+}, and Ba^{2+}), the initial reaction rate was considerably high but decreased very soon, in similar way to that in the oxidation of ordinary alkylbenzenes.[18]

Effect of Catalyst Concentration. The oxygen absorption rate is nearly of second order in catalyst at lower concentrations, but independent of the catalyst concentration above 3.6×10^{-2} M. This effect is not so significant in the oxidation of ordinary alkylbenzenes catalyzed by Co–Br catalyst.[19,20] The difference is related to the substrates, but not to catalysts, because this effect was not so remarkable in the oxidation of ethylbenzene catalyzed by Co–Mn–Br catalyst. Since odd electron density at the benzylperoxyl radical center should decrease by electron-withdrawing substituents, the reaction of *p*-nitrobenzylperoxyl radical with metal ion at low oxidation state ($Me^{2+}+RO_2\rightarrow Me^{3+}\cdot RO_2$) leading to chain termination should be accelerated. Thus no increase of oxidation rate was observed with increasing catalyst concentration.

Effect of the Partial Pressure of Oxygen. The effect of oxygen partial pressure is shown in Fig. 2,

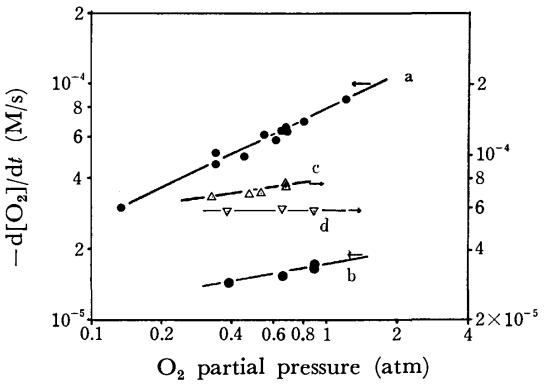

Fig. 2. The rate of oxidation of *p*-nitrotoluene, *m*-nitrotoluene, and *p*-chlorotoluene catalyzed by Co–Mn–Br catalyst in acetic acid as a function of oxygen partial pressure.
$Co(OAc)_2\cdot4H_2O$: $Mn(OAc)_2\cdot4H_2O$: NaBr=99 : 1 : 170, total metal 1.2×10^{-2} M.

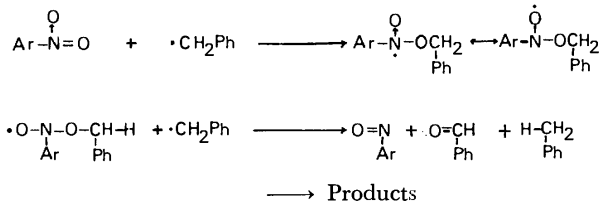
indicating a slight positive effect on the rate of oxidation of nitrotoluenes. However, in the case of ordinary alkylbenzenes below 100 °C, this effect is negligible at pressures above 0.5 atm.[5,22] Since the reaction of substituted benzyl radical with molecular oxygen has been concluded to have no significant effect due to substituents,[23,24] the effect of partial pressure of oxygen is attributable to the following inhibiting effect due to the nitro group.

According to Jackson and Waters,[25] *O,N*-dibenzyl-*N*-phenylhydroxylamines, *N*-benzylanilines, anilines and resinous materials were obtained, after toluene, aromatic nitro compounds and *t*-butyl peroxide had been allowed to react at the reflux point for 80 h. They postulated the following mechanism for the reaction.



Scheme 1.

Aromatic nitro compounds are known to be oxidizing agents which become reduced in the course of reaction, the reduced products acting as inhibitor or retarder in radical polymerization.[26–28]

Since there exist more than 1000-fold excess of nitro groups as compared with oxygen in *p*-nitrotoluene oxidation, a small portion of active radicals may react with nitro groups, even if the reaction betwen *p*-nitrobenzyl or *p*-nitrobenzoyl radicals and oxygen proceeds rapidly. Accordingly, various inhibitors could be formed in the solution, and the reaction rate would decrease by reduction in oxygen partial pressure.

Substrate Concentration. Although the rate of oxidation of *p*-nitrotoluene is of first order with respect to substrate at concentrations below 0.3 M, the order decreases with increase in concentration. However, the first order dependency is observed at high concentration region in the oxidation of ethylbenzene, *p*-xylene and toluene.[5] The inhibition effect due to nitrobenzene in the oxidation of *p*-nitrotoluene was examined, acetic acid being replaced partly by nitrobenzene. The decrease in oxidation rate of *p*-nitrotoluene by nitrobenzene addition corresponds to the negative deviation from linearity at high concentration of *p*-nitrotoluene (Fig. 3). Although chlorobenzene or *o*-dichlorobenzene was similarly treated in place of nitrobenzene, they exhibited positive effect for the *p*-nitrotoluene oxidation. When the same amount of nitrobenzene as substrate was added in the oxidation of *p*-chlorotoluene, correlation between the rate of oxidation and concentration of substrate were similar to those of *p*-nitroethylbenzene and *p*-nitrotoluene. The anomality in the oxidation of nitroalkylbenzenes compared with the case of hydrocarbons having no nitro substituent can be explained in terms of the effect of the aromatic nitro group.

Two possibilities have been suggested for the negative effect of the nitro group in *p*-nitrotoluene oxidation;[7,8] interruption of the chains, and complex formation with catalyst, which has low activity in chain initiation.

Although the reaction conditions or catalyst composition differ from those of Chervinskii and Kovalev, our results support their view.

While there is no evidence for complex formation between catalyst and nitro compounds as well as its inactivity, the aromatic nitro compounds having high dielectric constants may coordinate to metal ion and deactivate the catalyst as in the action of water. The effect of substrate concentration in the oxidation of nitroalkylbenzenes should be due to the catalyst deactivating tendency by the complex formation and the chain terminating inclination by the reaction with active radical.

Reaction Products. Main products were *p*-nitrobenzaldehyde, *p*-nitrobenzoic acid and water in the oxidation of *p*-nitrotoluene in acetic acid. Small amounts (1—2% selectivity) of *p*-nitrobenzyl bromide and *p*-nitrobenzyl acetate were formed simultaneously. The total yield of these products per reacted nitrotoluene was 101%, and 69.5% of inorganic bromide ion initially added was found to be converted into organic bromide (*p*-nitrobenzyl bromide) at 48% conversion of *p*-nitrotoluene. The relation between oxidation products of *p*-nitrotoluene and the reaction time is shown in Fig. 4. Main products in the oxidation of *p*- or *o*-nitroethylbenzene in propionic acid were nitroacetophenones, 1-(nitrophenyl)ethanols, and water. As in the case of *p*-nitrotoluene, 1-(nitrophenyl)ethyl bromides and 1-(nitrophenyl)ethyl propionates were formed. The relation between the oxidation products and the reaction time is shown in Fig. 5. In all cases, the esters are considered to be formed through the following pathways.

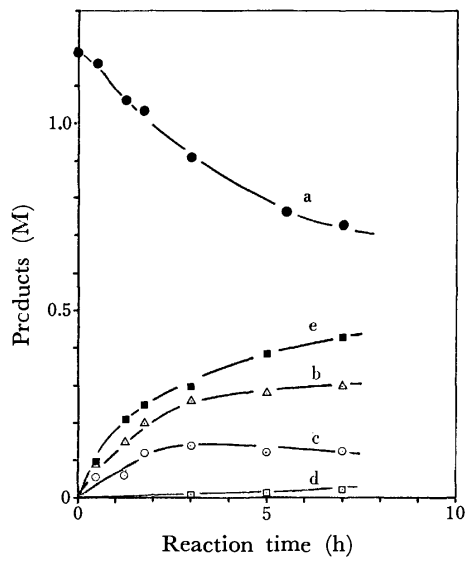

Fig. 5. Products distribution in the oxidation of *p*-nitroethylbenzene at 90 °C in propionic acid.

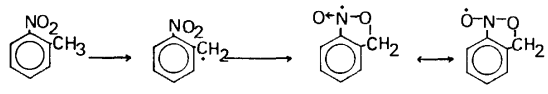
Oxidation of o-*Nitroalkylbenzenes.* When *o*-nitrotoluene was allowed to the oxidation catalyzed by Co–Mn–Br catalyst, the reaction did not proceed. As shown in Fig. 6, the oxidation of *p*-nitrotoluene in the presence of equal amounts of *o*-nitrotoluene or *o*-nitroacetophenone stops at low conversion (a few persent), as does the oxidation of 2,4-dimethylnitrobenzene. This suggests that *o*-nitrosubstituted toluene and acetophenone produce inhibitors during oxidation.

Intramolecular reaction should take place in the case of *o*-nitroalkylbenzenes. Intramolecular reaction proceeds advantageously as compared to intermolecular reaction. The reaction intermediates are supposed to form five or six membered rings.

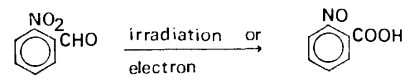


Scheme 3.

o-Nitrobenzaldehyde or *o*-nitroacetophenone formed as primary oxidation products are subjected to similar reactions. Inhibiting effect due to *o*-nitrotoluene or *o*-nitroacetophenone can be explained in terms of the intramolecular reaction between active radical and nitro group.

The oxidation of 2,4-dimethylnitrobenzene was carried out in acetic acid under the following conditions. Substrate concentration=1.51 M, molar ratio of $Co(OAc)_2 \cdot 4H_2O$, $Mn(OAc)_2 \cdot 4H_2O$ and NaBr=99 : 1 : 170, and 65 °C. When the catalyst concentration (total metal) decreased in the order 2.4×10^{-2} M, 1.2×10^{-2} M and 8×10^{-3} M, the oxidation stopped at 10 min, 70 min and did not stop over 150 min, respectively. The oxidation of 2,4-dimethylnitrobenzene stops at lower conversion as concentration of the catalyst increases. Reasons for this might be as follows. I) The metal catalyst itself stops the autoxidation chain by the reaction with peroxyl radical. II) The metal catalyst produces inhibitors in the course of the reaction.

The following reaction has been reported in studies of photochemical reaction[29] and mass spectrometry of the *o*- or *peri*-nitro substituted aromatics.[30]



Scheme 4.

The electron of the metal may enhance the rate of reaction, and a direct reaction between the catalyst and the nitro group can not be discarded.

However, when *o*-nitrobenzaldehyde or nitrobenzene was treated with equal amount of Co–Mn–Br catalyst at 80 °C in acetic acid in the absence of oxygen, no change took place. The effect of phenols which can be produced by the acid catalyzed decomposition of hydroperoxides should be negligible in acetic acid, where strong acid is absent. Thus, the inhibition effect at high concentration of catalyst on the oxidation of 2,4-dimethylnitrobenzene can be ascribed mainly to the chain termination due to metal ions. This can be correlated to the discussion on the effect of catalyst concentration.

The oxidation of *o*-nitroethylbenzene proceeded until 45% conversion. The rate of *o*-nitrocumene was extremely low as compared with that of *p*-isomer. Thus, of the *o*-nitro-substituted toluene, ethylbenzene and cumene, the oxidation of only *o*-nitroethylbenzene proceeded fairly rapidly. This can be attributed to:

I) The reactivity of *o*-nitroethylbenzene is expected to be higher than that of *o*-nitrotoluene or *o*-nitrocumene, since one of the secondary benzylic hydrogen atoms should be free from hydrogen bonding with the oxygen atom of nitro group. This would overcome the negative effect due to the nitro group.

II) The primary oxidation products, *o*-nitroacetophenone and 1-(*o*-nitrophenyl)ethanol, are relatively stable against autoxidation.

One of the authors (R.H) wishes to thank Dr. E. Niki, Mr. H. Tsutsumi, and Mr. S. Komoto for their advice and encouragement, and also to the staff of Nippon Kayaku Co., Ltd. for permission to publish this work.

1,3-Dipoles, such as phenylglyoxylonitrile oxide (**1**), benzonitrile oxide, and phenyl azide, undergo cycloadditions to the more electron-rich double bond of 2,3-bis(methoxycarbonyl)bicyclo[2.2.2]octa-2,5-diene (**5**) to afford only *endo* adducts. The cycloadditions of these 1,3-dipoles to the more electron-rich double bond of 6,7-bis(methoxycarbonyl)bicyclo[3.2.2]nona-6,8-diene (**6**) give only *exo* adducts. Benzonitrile-*N*-phenylimine (**4**) undergoes cycloadditions to both the more electron-rich and the more electron-poor double bonds of **5** or **6**. The reaction of **4** with **5** yields two *endo* adducts, and the reaction of **4** with **6** gives two *exo* adducts. However, the cycloaddition of **1** to 5,6-*endo*,*endo*-bis(methoxycarbonyl)bicyclo[2.2.2]oct-2-ene affords both the *exo*- and *endo* adducts. The reason for the predominant *endo* cycloadditions toward **5** and *exo* cycloadditions toward **6** is discussed.

In a previous paper, it was reported that 1,3-dipolar cycloadditions to norbornenes follow the "*exo* rule" of Alder and Stein, but that those to norbornadienes do not follow this rule.[2] This difference in reactivity has been ascribed to the fact that, in norbornadienes, the homoconjugations are present on their *endo* sides, while in norbornenes such interactions can not be present.[2] This assumption prompted us to examine the stereochemistry of the 1,3-dipolar cycloadditions to other bicyclic olefins with two carbon-carbon double bonds within each molecule, such as bicyclo[*n*.2.2]alkadienes($n \geqq 2$). Therefore, the 1,3-dipolar cycloadditions of phenylglyoxylonitrile oxide(**1**), benzonitrile oxide(**2**), phenyl azide(**3**), and benzonitrile-*N*-phenylimine(**4**) to 2,3-bis(methoxycarbonyl)bicyclo[2.2.2]octa-2,5-diene(**5**), or 6,7-bis(methoxycarbonyl)bicyclo[3.2.2]nona-6,8-diene (**6**) were carried out. Moreover, for comparison, the 1,3-dipolar cycloaddition of **1** to 5,6-*endo*,*endo*-bis(methoxycarbonyl)bicyclo[2.2.2]oct-2-ene(**7**), which is a corresponding monoene of **5**, was also carried out. In this paper, it will be emphasized that the interaction between the two carbon-carbon double bonds in **5** or **6** is an important factor controlling the stereochemistry of the additions of 1,3-dipoles to these double bonds.

Results

1,3-Dipolar Cycloadditions. The nitrile oxide, **1**, was easily prepared by the treatment of α-chloro-α-hydroxyiminoacetophenone(**8**) with triethylamine (TEA).[3] In order to avoid the dimerization of the nitrile oxide, **1**, to 3,4-dibenzoyl-1,2,5-oxadiazole 2-oxide(**9**), the reaction was carried out with low stationary concentrations of **1**. A dilute THF solution of TEA was slowly stirred into a solution of a mixture of **5** and **8** in THF cooled in an ice-bath.[4] This cycloaddition afforded only one *endo* adduct, 5-benzoyl-8,9-bis(methoxycarbonyl)-2,6-*endo*-3-oxa-4-azatricyclo-[5.2.2.$0^{2,6}$]undeca-4,8-diene(**10**). The cycloaddition of **1** to **6** was carried out by a similar method. In this case, the reaction gave only one *exo* adduct, 5-benzoyl-11,12-bis(methoxycarbonyl)-2,6-*exo*-3-oxa-4-azatricyclo-[5.3.2.$0^{2,6}$]dodeca-4,11-diene(**11**). The monoadducts which were produced by the addition of **1** to the more electron-poor double bonds of **5** and **6** and the bisadducts were not detected at all. These findings show that the nitrile oxide, **1**, acts as an electron-accepting 1,3-dipole toward **5** and **6**.[5]

The cycloadditions of **2** to **5** and **2** to **6** were carried out by a procedure similar to that described above. In these reactions also, the nitrile oxide, **2**, attacked the more electron-rich double bonds of **5** and **6** to give 8,9-bis(methoxycarbonyl)-5-phenyl-2,6-*endo*-3-oxa-4-azatricyclo[5.2.2.$0^{2,6}$]undeca-4,9-diene(**12**) and 11,12-bis(methoxycarbonyl)-5-phenyl-2,6-*exo*-3-oxa-4-azatricyclo[5.3.2.$0^{2,6}$]dodeca-4,11-diene(**13**) respectively. These findings show that **2** also acts as an electron-accepting 1,3-dipole toward **5** and **6**.[5]

The cycloaddition of the azide, **3**, to **5** was carried out as follows. The benzene solution of a mixture of **3** and **5** was allowed to stand in the dark for two weeks at room temperature. The subsequent usual work-up of the reaction mixture gave only one *endo* adduct, 8,9-bis(methoxycarbonyl)-5-phenyl-2,6-*endo*-3,4,5-triazatricyclo[5.2.2.$0^{2,6}$]undeca-3,8-diene(**14**). A similar treatment of **3** with **6** afforded one *exo* adduct, 11,12-bis(methoxycarbonyl)-5-phenyl-2,6-*exo*-3,4,5-triazatricyclo[5.3.2.$0^{2,6}$]dodeca-3,11-diene(**15**). These findings show that the dipole, **3**, acts as an electron-accepting 1,3-dipole toward **5** and **6**.[5] This is consistent with the fact that the dipole, **3**, acts as an electron-accepting 1,3-dipole toward norbornene and cyclopentene.[5,6]

The nitrilimine, **4**, which was prepared from *N*-phenylbenzenecarbohydrazonoyl chloride(**16**)[7] and TEA in benzene, underwent 1,3-dipolar cycloaddition

to **5** to afford a mixture of two monoadducts, 8,9-bis(methoxycarbonyl)-3,5-diphenyl-2,6-*endo*-3,4-diazatricyclo[5.2.2.$0^{2,6}$]undeca-4,8-diene(**17**) and 2-*exo*,6-*exo*-bis(methoxycarbonyl)-3,5-diphenyl-2,6-*endo*-3,4-diazatricyclo[5.2.2.$0^{2,6}$]undeca-4,8-diene(**18**). A similar treatment of **4** with **6** gave two *exo* adducts, 11,12-bis(methoxycarbonyl)-3,5-diphenyl-2,6-*exo*-3,4-diazatricyclo[5.3.2.$0^{2,6}$]dodeca-4,11-diene(**19**) and 2-*endo*,6-*endo*-bis(methoxycarbonyl)-3,5-diphenyl-2,6-*exo*-3,4-diazatricyclo[5.3.2.$0^{2,6}$]dodeca-4,11-diene(**20**). The cycloadducts, **17** and **19**, are those which were produced by the addition of **4** to the more electron-rich double bonds of **5** and **6**, while the **18** and **20** adducts are those which were produced by the addition of **4** to the more electron-poor double bonds of **5** and **6**. These results indicate that the dipole, **4**, acts both as an electron-accepting 1,3-dipole and as an electron-donating one toward **5** and **6**.[5]

The cycloaddition of **1** to **7** was carried out by the method described above. This reaction gave a mixture of the *exo*- and *endo* adducts, 5-benzoyl-8-*endo*, 9-*endo*-bis(methoxycarbonyl)-2,6-*exo*-3-oxa-4-azatricyclo[5.2.2.$0^{2,6}$]undec-4-ene(**21**) and 5-benzoyl-8-*endo*, 9-*endo*-bis(methoxycarbonyl)-2,6-*endo*-3-oxa-4-azatricyclo[5.2.2.$0^{2,6}$]undec-4-ene(**22**) in yields of 29% and 6% respectively, with a recovery of 63% of **7**.

Analyses of NMR Spectra of Adducts. The *exo*- or *endo* assignment of each adduct was based on the NMR data(Table 2). The configurations of all the adducts except for **18** and **20** could be determined from the chemical shifts of their methoxycarbonyl groups. As is shown in Table 2, for the **10**—**15** and **22** adducts, one of the two methoxycarbonyl groups of each adduct appeared in a field higher by 0.21—0.48 ppm than the other. Moreover, the low-field methoxycarbonyl groups have chemical shifts of about δ 3.7—3.8 ppm which resemble the chemical shifts of mehtoxycarbonyl goups of the referential compounds (**5**, **6**, and dimethyl maleate (**23**)). For the **17** and **19** adducts the two methoxycarbonyl groups of each adduct appeared in fields higher by about 0.3—0.4 ppm than those of

Chem.*, **42**, 926 (1964).

the referential compound, **23**. The molecular models of the adducts reveal that the high field methoxycarbonyl groups lie in the shielding cones of benzene rings attached on the heterocyclic moieties of the adducts. On the other hand, the **21** adduct exhibited the chemical shifts of the two methoxycarbonyl groups at δ 3.63 and 3.67 ppm, whose values were normal. This indicated that the adduct has the *exo* configuration. Such an assignment has also been carried out for the *exo*- and *endo* adducts, **24** and **25**, formed by the cycloaddition of **1** to 2,3-bis(methoxycarbonyl)-norbornadiene.[2] The configurations of the **18** and **20** adducts were determined as follows. The vinyl protons of these adducts appeared as AB quartets of doublets in fields higher by about 0.3—0.4 ppm than those of the referential compounds, **5**, **6**, **7**, and bicyclo[2.2.2]-oct-2-ene(**26**). These up-field shifts are probably due to the diamagnetic anisotoropy effects of the carbon-nitogen double bonds.[8] This finding indicates that the vinyl protons of these adducts are placed above the carbon-nitrogen double bonds of the heterocyclic moieties. The structures of **18** and **20** are consistent with this finding. Such an assignment has also been carried out for the *exo*- and *endo* adducts, **27** and **28**, formed by the cycloaddition of **4** to norbornadiene.[2]

Discussion

This kind of 1,3-dipolar cycloaddition has been shown to be a kinetically controlled reaction.[1,2,9] Hence, all the adducts obtained here are kinetically controlled products.

About Steric Hindrance. Two 7,8-*syn*-hydrogen atoms are present on the *exo* side of **5**, but such hydrogen atoms are absent on the *endo* side. A similar difference in steric hindrance is present between the *exo*- and *endo* sides of **6**. For this reason, it might appear that the steric hindrance is a factor which brings about the highly stereoselective cycloadditions of 1,3-dipoles toward the dienes, **5** and **6**.

From the fact that the cycloaddition of **1** to **7** gave both the *exo*- and *endo* adducts, however, we doubt the above explanation based on the steric hindrance theory. The molecular models of **5** and **7** show that the difference in steric crowding between the *exo*- and *endo* sides of **5** is smaller than that in steric crowding between the *exo* and *endo* sides of **7**. This implies that the *endo*/*exo* product ratio for the cycloaddition of **1** to **5** must become closer to unity than that for the cycloaddition of **1** to **7**, provided that the preferred direction of reaction is controlled only by the steric hindrance. As Table 1 shows, however, the *endo*/*exo* product ratio for the cycloaddition of **1** to **5** is infinity, while that for the cycloaddition of **1** to **7** is 0.21. This finding shows that the direction of the attack of the 1,3-dipole, **1**, on the double bond of **5** can not be determined only by the steric hindrance. For the same reason, the predominant *exo* cycloaddition of **1** to **6** can not be explained by the steric hindrance alone. For all the other cycloadditions carried out here as well, these findings suggest that the steric hindrance is not a main factor controlling the stereochemistry of these reactions.

The Interaction of the Two Carbon-Carbon Double Bonds.

a) For bicyclo[2.2.2]octa-2,5-diene and bicyclo-[3.2.2]nona-6,8-diene, the presence of a homoconjugation between the two non-neighboring carbon-carbon double bonds has been found by investigating the photoelectron spectroscopy of these dienes.[10]

b) The relative rate ratios of the cycloadditions of **4** to cyclohexene, cyclopentene, 1-heptene, dimethyl maleate, and dimethyl fumarate can be derived from the data of Eckell *et al.*[5c] (Table 3). Table 3 suggests that the dipole, **4**, undergoes cycloadditions to the more electron-poor double bonds of the dienes, **5** and **6**, rather than to the more electron-rich double bonds. In practice, however, the 1,3-dipolar cycloadditions occured preferentially on the more electron-rich double bonds of **5** and **6** (Table 4). This attack on the reverse site must be ascribed to the interaction between the two non-neighboring carbon-carbon

TABLE 3. RELATIVE RATES OF THE ADDITION OF 4[a)]

double bonds of **5** or **6**, as will be described below.

A Tentative Explanation of the Highly Stereoselective Cycloadditions. a) The LU-Controlled Reactions of 1,3-Dipoles with the Dienes, 5 and 6: As has described above, the 1,3-dipoles **1**—**4**, act as electron-accepting dipoles toward the more electron-rich double bonds of **5** and **6**. In Houk's terminology, these cycloadditions are called LU-controlled reactions.[5b)] In these cases, the interaction of the dipole LUMO(lowest unoccupied molecular orbital) with the dipolarophile HOMO (highest occupied molecular orbital) is greatest.[5b)] The predominant *endo* cycloadditions toward **5** and *exo* cycloadditions toward **6** can be reasonably explained by the orbital mixing rule.[11)] This rule treats the extension of an orbital at an interacting center in a certain direction. Now, we shall consider the orbital extension of the HOMO of the more electron-rich double bond (C_5–C_6) of **5** to the *exo*- and *endo* sides. The rehybridization originates from the mixing of the C_5–C_6 σ orbital in the C_5–C_6 π orbital(HOMO) under the influence of the C_2–C_3 π orbital(HOMO). The C_5–C_6 double bond interacts with the C_2–C_3 double bond on the *endo* side, as has been described above. The three orbitals and their energy relation are shown in Fig. 1.[12)] From the orbital mixing rule, it can be predicted that the HOMO of the C_5–C_6 double bond extends more to the *endo* side than to the *exo* side (Fig. 1.). Consequently, the 1,3-dipoles, **1**—**4**, attack predominantly from the *endo* side. In the same treatment, the HOMO of the C_8–C_9 double bond of **6** can be predicted to extend more greatly to the *exo* side than to the *endo* side. This explains the predominant *exo* cycloaddition to the C_8–C_9 double bond of **6**. Such a treatment has also been carried out for the HOMO of norbornene.[11a)]

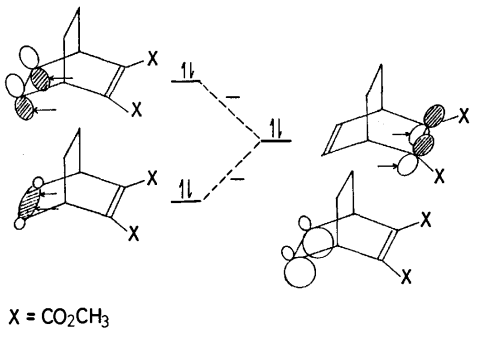

Fig. 1. Origin and direction of nonequivalent HOMO extension of **5**.

b) *The HO-Controlled Reaction of the Nitrilimine, 4, with 5 and 6*: The 1,3-dipole, **4**, acts as an electron-donating dipole toward the more electron-poor double bonds of **5** and **6**, as has been described above. In Houk's terminology, these cycloadditions are called HO-controlled reactions.[5b)] In these cases, the interaction of the dipole HOMO with the dipolarophile LUMO is greatest.[5b)] Hence, we shall consider the orbital extension of the LUMO of the more electron-poor double bond(C_2–C_3) of **5** using the orbital mixing rule in order to explain the predominant endo cycloaddition of **4** to this double bond. In this case, the interaction among the three orbitals, the C_2–C_3 σ^* orbital, the C_2–C_3 π^* orbital(LUMO), and the C_5–$C_6\pi^*$ orbital(LUMO), is taken account of on the *endo* side. The three orbitals and their energy relation are shown in Fig. 2.[14)] The orbital mixing rule predicts that the LUMO of the C_2–C_3 double bond will extend more to the *endo* side than to the *exo* side (Fig. 2.). Consequently, the dipole, **4** attacks predominantly from the *endo* side. In the same treatment, the LUMO of the C_6–C_7 double bond of **6** is predicted to extend more to the *exo* side than to the *endo* side. This reasonably explains the predominant *exo* cycloaddition of **4** to the C_6–C_7 double bond of **6**.

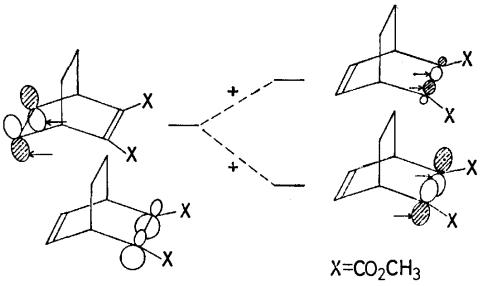

Fig. 2. Origin and direction of nonequivalent LUMO extension of **5**.

Experimental

Materials. The precursors of 1,3-dipoles (**8**,[3)] **16**,[15)] and *N*-hydroxybenzenecarboximidoyl chloride (**29**)[16)]) and the azide, **3**,[17)] were prepared by methods described in the literature. The dienes, **5**[18)] and **6**,[19)] and the monoene, **7**,[20)] were also prepared by the methods described in the literature.

Cycloaddition of 1 to 5. Into a stirred solution of **5** (1.10 g, 5.0 mmol) and **8**(0.92 g, 5.0 mmol) in dry THF (15 cm^3) cooled in an ice bath, a solution of triethylamine (TEA) (0.65 g, 6.5 mmol) in dry THF (10 cm^3) was added, drop by drop, over a period of 1 h. After an additional stirring for 1 h at the same temperature, the resulting triethylammonium chloride was removed by filtration. The TLC of the filtrate showed only one spot (elution with benzene–ether(9:1)). After the evaporation of the solvent, the yellowish residue was washed with several drops of 95%

EtOH. The solid was separated by filtration and dried under reduced pressure to give 1.79 g(98%) of the adduct, **10**. It was recrystallized from 95% EtOH to afford colorless needles: Mp 97—98 °C; IR(KBr) 1733(ester C=O), 1710(ester C=O), 1650(C=O), 1440 and 1280 cm^{-1}; NMR ($CDCl_3$) δ=1.56(4H, m, CH_2CH_2), 3.44(3H, s, 8-CO_2CH_3), 3.58(1H, m), 3.76(1H, m), 3.78(3H, s, 9-CO_2CH_3), 3.95 (1H, dd, J=10 and 4 Hz, 6-H), 4.98(1H, dd J=10 and 4 Hz, 2-H), and 7.3—8.3 ppm (5H, m).

Found: C, 65.03; H, 5.10; N, 3.56%. Calcd for $C_{20}H_{19}N_1O_6$: C, 65.03; H, 5.19; N, 3.79%.

*Cycloaddition of **1** to **6**.* A solution of **6**(710 mg, 3.0 mmol) and **8**(551 mg, 3.0 mmol) in dry THF(15cm^3) was treated with TEA(370 mg, 3.7 mmol) in dry THF(10 cm^3) as has been described above. A similar work-up of the reaction mixture and evaporation of the solvent produced a yellowish viscous oil. This oil showed, on TLC with benzene–ether(95 : 5), two marked spots, at R_f 0.45(**6**) and at R_f 0.32(**11**). The oil was chromatographed on silica gel (200—300 mesh). Elution with benzene–ether(95 : 5) gave **6**(96 mg, recovery 14%) and a white solid of **11**(877 mg, 76%). The solid was recrystallized from MeOH to afford colorless leaves: Mp 98—99 °C; IR(KBr) 1735(ester C=O), 1715(ester C=O), 1660(C=O), 1440, 1275, and 1260 cm^{-1}; NMR($CDCl_3$) δ=1.74(6H, s, $(CH_2)_3$), 3.27(1H, m), *ca.* 3.5(1H, m), 3.50(3H, s, 12-CO_2CH_3), 3.75(3H, s, 11-CO_2CH_3), 4.18(1H, dd, J=10.5 and 1.5 Hz, 6-H), 5.18(1H, dd, J=10.5 and 2.5 Hz, 2-H), and 7.1—8.2 ppm(5H, m).

Found: C, 65.75; H, 5.51; N, 3.55%. Calcd for $C_{21}H_{21}N_1O_6$: C, 65.78; H, 5.52; N, 3.65%.

*Cycloaddition of **2** to **5**.* A solution of **5**(1110 mg, 5.0 mmol) and **29**(778 mg, 5.0mmol) in dry THF(15 cm^3) was treated with TEA(610 mg, 6.0 mmol) in dry THF(10 cm^3) by a procedure like that described above. A similar work-up of the reaction mixture and evaporation of the solvent gave a yellowish viscous oil. On TLC with benzene–ether (95:5), the oil showed three spots, at R_f 0.75(3,4-diphenyl-1,2,5-oxadiazole 2-oxide (**30**)), R_f 0.40(**5**), and R_f 0.13(**12**). The oil was column chromatographed on silica gel with benzene–ether (95:5) to give a white solid of **30**(37 mg, mp 115—116 °C (lit,[21] mp 112 °C)), **5**(116 mg, recovery 10%), and a solid of **12**(1331 mg, 78%).

Adduct **12** : Mp 148—149 °C(colorless cubic crystals from MeOH); IR(KBr) 1705(ester C=O), 1433, and 1290 cm^{-1} ; NMR($CDCl_3$) δ=1.46 and 1.62(4H, ABq, J=12 Hz, CH_2CH_2), 3.38(3H, s, 8-CO_2CH_3), *ca.* 3.5(1H, m), 3.65(1H, m), 3.74(3H, s, 9-CO_2CH_3), 3.88(1H, dd, J=10 and 3 Hz, 6-H), 4.93(1H, dd, J=10 and 4.0 Hz, 2-H), and 7.2—7.8 ppm(5H, m).

Found: C, 66.91; H, 5.50; N, 4.15% Calcd for $C_{19}H_{19}N_1O_5$: C, 66.85; H, 5.61; N, 4.10%.

*Cycloaddition of **2** to **6**.* A solution of **6**(710 mg, 3.0 mmol) and **29**(476 mg, 3.0 mmol) in dry THF(15 cm^3) was treated with TEA(370 mg, 3.7 mmol) in dry THF(10 cm^3) as has been described above. A similar work-up of the reaction mixture and evaporation of the solvent afforded a yellowish viscous oil, which showed three spots on TLC with benzene–ehyl acetate(95:5). It was column chromatographed on silica gel. Elution with benzene–ethyl acetate (95:5) gave **30**(24 mg), **6**(78 mg, recovery 11%),and a solid of **13**(819 mg, 77%).

Adduct **13** : Mp 129—130 °C(colorless cubic crystals from MeOH–H_2O); IR(KBr) 1720(ester C=O), 1440, and 1295 cm^{-1}; NMR($CDCl_3$) δ=1.71(6H, s, $CH_2CH_2CH_2$), 3.11(1H, m), 3.38(1H, m), 3.49(3H, s, 12-CO_2CH_3), 3.74 (3H, s, 11-CO_2CH_3), 4.12(1H, dd, J=10.5 and 1.5 Hz, 6-H), 5.26(1H, dd, J=10.5 and 2.5 Hz, 2-H), and 7.2—7.8 ppm (5H, m).

Found: C, 67.37; H, 5.89; N, 3.98%. Calcd for $C_{20}H_{21}N_1O_5$: C, 67.59; H, 5.96; N, 3.94%.

*Cycloaddition of **3** to **5**.* A mixture of **5**(560 mg, 2.5 mmol) and **3**(298 mg, 2.5 mmol) was dissolved in dry benzene (5 cm^3). After the solution had then been allowed to stand in the dark for two weeks at room temperature, it showed two spots(**5** and **14**) on TLC with benzene–ethyl acetate(8:2). After the removal of the solvent, the residue was column chromatographed on alumina. Elution with benzene–ehtyl acetate(8:2) gave **5**(129 mg, recovery 23%). Further elution with the same solvent afforded **14** (600 mg, 70%), which was subsequently recrystallized from MeOH to give colorless prisms: Mp 151—152 °C; IR(KBr) 1715(ester C=O), 1605, 1493, 1440, and 1300 cm^{-1}; NMR($CDCl_3$) δ= 1.47 and 1.68(4H, ABq, J=11 Hz, CH_2CH_2), 3.38(3H, s, 8-CO_2CH_3), 3.75(3H, s, 9-CO_2 CH_3), 3.6—3.9(2H, m), 4.10(1H, dd, J=11.5 and 3.5 Hz, 6-H), 4.86(1H, dd, J= 11.5 and 3.5 Hz, 2-H), and 6.7—7.6 ppm(5H, m).

Found: C, 63.49; H, 5.50; N, 12.30%. $C_{18}H_{19}N_3O_4$: C, 63.33; H, 5.61; N, 12.31%.

*Cycloaddition of **3** to **6**.* A solution of **6**(708 mg, 3.0 mmol) and **3**(357 mg, 3.0 mmol) in dry benzene(3 cm^3) was allowed to stand in the dark for one week at room temperature. Then, the solution showed three spots (**3**, **6**, and **15**) on TLC with benzene–ethyl acetate(9:1). The solvent was evaporated under reduced pressure to give a residue, which was column chromatographed on alumina with benzene–ethyl acetate(9:1) to afford a trace amount of **3**, **6**(148 mg, recovery 21%), and **15**(713 mg, 67%).

Adduct **15**: Mp 137—139 °C(colorless leaves from MeOH); IR(KBr) 1710(ester C=O), 1600, 1490, 1433, and 1287 cm^{-1}; NMR($CDCl_3$) δ=1.73(6H, s, $CH_2CH_2CH_2$), 3.38 (1H, m), 3.50(3H, s, 12-CO_2CH_3), *ca.* 3.7(1H, m), 3.71(3H, s, 11-CO_2CH_3), 4.37(1H, dd, J=12 and 1.5 Hz, 6-H), 5.01(1H, dd, J=12 and 2 Hz, 2-H), and 6.8—7.6 ppm (5H, m).

Found: C, 64.26; H, 6.06; N, 11.81%. Calcd for $C_{19}H_{21}N_3O_4$: C, 64.21; H, 5.96; N, 11.83%.

*Cycloaddition of **4** to **5**.* A mixture of **5**(558 mg, 2.5 mmol) and **16**(576 mg, 2.5mmol) was dissolved in dry benzene(10 cm^3). Into the solution, TEA(940 mg, 9.3 mmol) was then added all at once, after which the solution was allowed to stand in the dark for two weeks at room temperature. The resulting ammonium chloride was removed by filtration. The filtrate showed, on TLC with benzene, four spots, at R_f 0.65(**16**), R_f 0.25(**18**), R_f 0.16(**5**), and R_f 0.09(**17**). A large amount of the solvent was removed under reduced pressure. Then, the concentrated solution was chromatographed on silica gel. Subsequent elution with benzene afforded a solid of **16**(229 mg, recovery 40%), a solid of **18**(174 mg, 17%), **5**(193 mg, recovery 35%), and a yellow solid of **17**(379 mg, 36%) in that order.

Adduct **17**: Mp 169—170 °C(yellow sticks from EtOH); IR(KBr) 1717(ester C=O), 1600, 1500, and 1300 cm^{-1}; NMR($CDCl_3$) δ=1.49 and 1.69(4H, ABq, J=10 Hz, CH_2-CH_2), 3.33(3H, s, CO_2CH_3), 3.45(3H, s, CO_2CH_3), 3.55 (1H, m), 3.89(1H, dd, J=12 and 2.5 Hz, 6-H), 3.90(1H, m), 4.45(1H, dd, J=12 and 2.5 Hz, 2-H), and 6.6—7.8 ppm(10H, m).

Found: C, 72.22; H, 5.97; N, 6.97%. Calcd for $C_{25}H_{24}N_2O_4$: C, 72.10; H, 5.81; N, 6.73%.

Adduct **18**: Mp 217—219 °C(colorless cubic crystals from hexane–benzene); IR(KBr) 1742(ester C=O), 1737(ester C=O), 1600, 1593, 1500, 1262 cm^{-1}; NMR($CDCl_3$) δ=

1.12(2H, d, J=8 Hz, 10-*syn* H and 11-*syn* H), 2.35(2H, d, J=8H, 10-*anti* H and 11-*anti* H), 3.58(3H, s, CO_2CH_3), 3.68(3H, s, CO_2CH_3), 3.5—3.7(2H, m), 5.86 and 6.01(2H, ABq of d, $J_{8,9}$=8 Hz and $J_{7,8}=J_{1,9}$=6.5 Hz, 8-H and 9-H), and 6.8—7.9 ppm(10, m).

Found: C, 71.94; H, 5.65; N, 6.68%. Calcd for $C_{25}H_{24}N_2O_4$: C, 72.10; H, 5.81; N, 6.73%.

Cycloaddition of ***4*** *to* ***6***. A mixture of **5**(710 mg, 3.0 mmol), **16**(692 mg, 3.0 mmol), and TEA(1130 mg, 11.2 mmol) was dissolved in dry benzene(10 cm³). The solution was then allowed to stand for 24 h, and the resulting triethylammonium chloride was removed by filtration. On TLC with benzene, the filtrate showed four spots, at R_f 0.79(**16**), R_f 0.36(**20**), R_f 0.25(**6**), and R_f 0.20(**19**). After the removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene gave a trace of **16**, a solid of **20**(176 mg, 14%), **6**(123 mg, recovery 17%), and a yellow solid of **19** (792 mg, 61%), in that order.

Adduct **19**: Mp 181—183 °C(yellow sticks from ethyl acetate–EtOH); IR(KBr) 1713(ester C=O), 1593, 1492, and 1285 cm⁻¹; NMR($CDCl_3$) δ=1.78(6H, s, $CH_2CH_2CH_2$), 3.30 (1H, m), 3.44(3H, s, CO_2CH_3), 3.54(3H, s, CO_2CH_3), *ca.* 3.6(1H, m), 4.18(1H, dd, J=12 and 1.5 Hz, 6-H), 4.68(1H, dd, J=12 and 2 Hz, 2-H), and 6.7—8.0 ppm(10H, m).

Found: C, 72.60; H, 6.06; N, 6.44%. Calcd for $C_{26}H_{26}N_2O_4$: C, 72.54; H, 6.09; N, 6.51%.

Synthetic Studies on Quinoxaline Antibiotics. Synthesis of Quinoxaline-2-carbonyl Tetradepsipeptide Derivatives Related to Triostin A*

Masaru SHIN, Ken INOUYE, and Hideo OTSUKA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received November 26, 1977)

The synthesis is described of four quinoxaline-2-carbonyl (Qxc) tetradepsipeptide derivatives, Qxc-D-Ser[Z-MeCys(Bzl)-MeVal]-Ala-OH, Qxc-D-Ser[Bpoc-MeCys(Bzl)-MeVal]-Ala-OBu^t (**2**), Qxc-D-Ser(Z-MeVal)-Ala-MeCys(Bzl)-OH, and Qxc-D-Ser(Bpoc-MeVal)-Ala-MeCys(Bzl)-OBu^t, corresponding to the partial structure of a quinoxaline antibiotic, triostin A. The Qxc group was introduced at the dipeptide or tripeptide stage with Qxc-ONp as acylating agent. Qxc-D-Ser-Ala-OBu^t and Qxc-D-Ser-Ala-MeCys(Bzl)-OBu^t were acylated with Z-MeVal-OH by using *p*-toluenesulfonyl chloride as activating agent to give the desired depsipeptides in excellent yields, whereas the acylation with Bpoc-MeVal-OH by the same procedure was unsuccessful. The latter could be achieved by the *N,N'*-carbonyldiimidazole method, though the yields were relatively low. The treatment of compound **2** with an aqueous acetic acid-formic acid mixture for removal of the Bpoc group brought about concomitant formation of *cyclo*[-MeCys(Bzl)-MeVal-].

The quinoxaline antibiotics[1] are produced by various species of streptomycetes including *S. aureus* and reported active against gram-positive bacteria, certain tumors and to inhibit DNA-dependent RNA synthesis. The triostins, a family of the quinoxaline antibiotics, were isolated by Shoji *et al.*[2] and their structure was determined by Otsuka and Shoji[3] to be a quinoxaline-2-carbonyl(Qxc)-peptide lactone with a bridged disulfide linkage (Fig. 1). As a result of the recent NMR and MS studies, the structure of echinomycin[4] (quinomycin A[5]), which is also a member of the quinoxaline antibiotics, has been revised,[6] while that of triostin A has rather been confirmed.[7] Some synthetic studies on these antibiotics have appeared, in which the Qxc derivatives of some amino acids,[8] peptides,[9] and related compounds[10] were prepared. Very recently Ciardelli and Olsen[11]

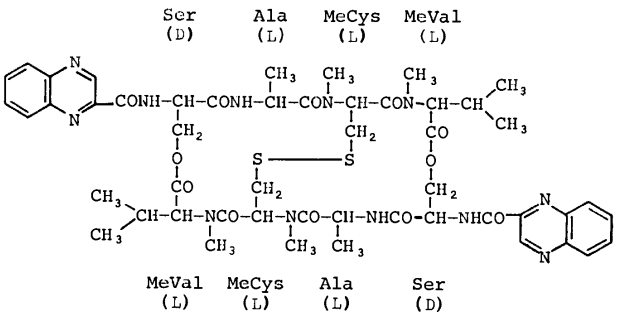

Fig. 1. Structure of triostin A.[3]

have reported the synthesis of des-*N*-tetramethyltriostin A, an analogue differing from the natural compound by lack of the *N*-methyl groups on the cysteine and valine residues. This desmethyl analogue had no activity toward *Staphylococcus aureus*, however.[11] We wish now to report the synthesis of tetradepsipeptide derivatives, Qxc-D-Ser[Z-MeCys(Bzl)-MeVal]-Ala-OH (**1**), Qxc-D-Ser[Bpoc-MeCys(Bzl)-MeVal]-Ala-OBu^t (**2**), Qxc-D-Ser(Z-MeVal)-Ala-MeCys(Bzl)-OH (**3**), and Qxc-D-Ser(Bpoc-MeVal)-Ala-MeCys-(Bzl)-OBu^t (**4**), which has been performed as a step toward the total synthesis of triostin A.

As is seen in Fig. 1, the structure of triostin A has the point of symmetry and can be split into two equal portions, each containing one Qxc group and four different amino acid residues, D-Ser, Ala, MeCys, and MeVal. Thus, the formation of the desired octadepsipeptide ring may be accomplished by combining a selected pair of the two halves, and a key to the total synthesis may be the choice of the position at which the ring is closed. The ring-closure by the lactonization between the MeVal and the D-Ser residues seems to be inadequate, because the low reactivity of the hydroxyl group of serine would require the carboxyl component highly activated,[12] and this could be a cause for some side reactions and racemization. The cyclization should, therefore, be carried out at a peptide bond. The synthesis of compounds **1**, **2**, **3**, and **4** was performed along this line.

Quinoxaline-2-carboxylic acid (Qxc-OH) as a starting material was synthesized by the method of Keller-Schierlein and Prelog[1b] from 2-methylquinoxaline *via* 2-styrylquinoxaline as intermediate. *N*-Methyl-L-valine was prepared according to the procedure of Quitt *et al.*[13] and *N*-methyl-*S*-benzyl-L-cysteine was derived from L-thiazolidine-4-carboxylic acid as described by Yamashiro *et al.*[14] As a reagent for introducing the Qxc group quinoxaline-2-carboxylic acid *p*-nitrophenyl ester (Qxc-ONp) was prepared by the treatment of Qxc-OH with *p*-nitrophenyl trifluoroacetate[15] in pyridine. Qxc-ONp was also prepared from Qxc-OH and *p*-nitrophenol by the mixed acid anhydride method using benzenesulfonyl chloride. This crystalline compound is stable, but readily reacts

---

with amines to give their Qxc derivatives. In view of the general trend that a *p*-nitrophenyl ester is less reactive toward alcohols than the corresponding acid chloride, Qxc–ONp may be more suitable than Qxc–Cl[10] for the preferential *N*-acylation in the presence of the hydroxyl group of serine residue.

Synthesis of compounds **1** and **2** was performed as illustrated in Fig. 2. Compound **5** was hydrogenolyzed to remove the Z group and the product was acylated with an equimolar amount of Qxc–ONp to give a crystalline Qxc-dipeptide (**6**) in a moderate yield. Compound **6** was also synthesized by Gerchakov and Schultz[9] from Qxc–D-Ser–OH and H–Ala–OBu^t, but the mp and $[\alpha]_D$ values reported are significantly lower than those of our product. This might be an indication of some racemization which could occur in the coupling reaction with a Qxc–amino acid as carboxyl component. The subsequent acylation of **6** with Bpoc–MeVal–OH at the hydroxyl group of serine residue could be achieved by the CDI[16] or CDMI[17] method to give compound **7**, though the yield was relatively low. This contrasts with the finding by Chen *et al.*[18] that the CDI (and the mixed anhydride) methods are unsuccessful in such depsipeptide bond formation. When the MeVal was introduced by using Z–MeVal–OH[19] and Tos–Cl in some excess, the desired depsipeptide,Qxc–D-Ser(Z–MeVal)–Ala–OBu^t, was obtained in an excellent yield. However, the same method failed to give componud **7**, probably because the symmetrical anhydride, which could be formed from Bpoc–MeVal–OH by means of Tos–Cl,[20] was sterically hindered by the bulky Bpoc

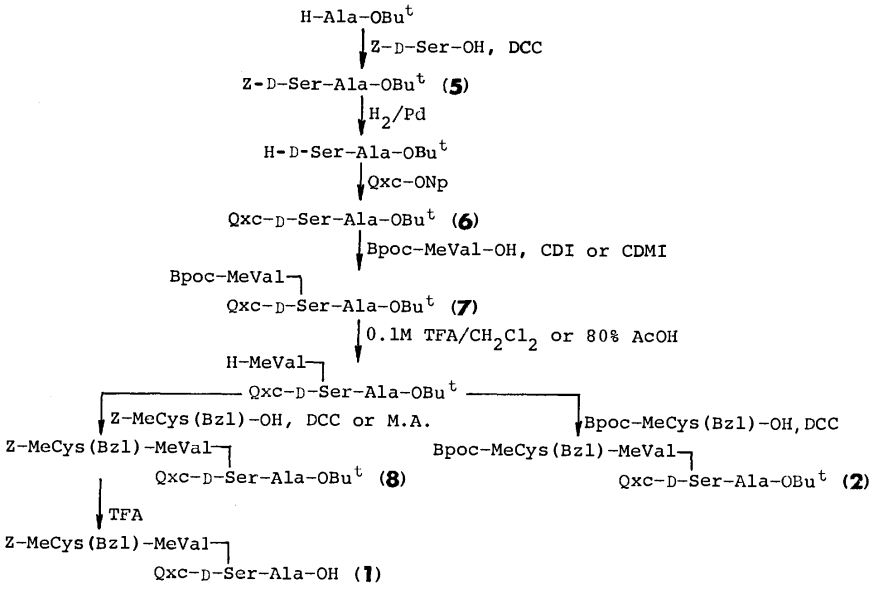

Fig. 2. Synthesis of tetradepsipeptide derivatives related to triostin A (part 1).

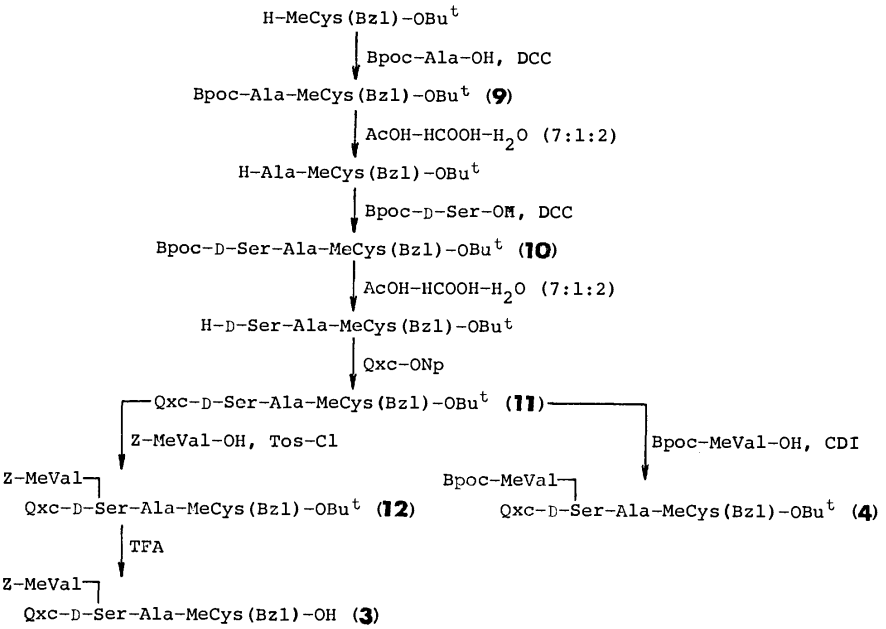

Fig. 3. Synthesis of tetradepsipeptide derivatives related to triostin A (part 2).

groups. Compound **7** was then treated with 0.1 M TFA in dichloromethane at room temperature or with 80% acetic acid at 70 °C to remove the Bpoc group. The resulting compound was coupled with Z–MeCys(Bzl)–OH[14] by the DCC or mixed anhydride method and with Bpoc–MeCys(Bzl)–OH by the DCC method to give **8** and **2**, respectively, in moderate yields. The treatment of **8** with TFA yielded **1** as desired, but the treatment of **2** with an aqueous acetic acid–formic acid mixture[21] yielded not the desired Qxc–D-Ser[H–MeCys(Bzl)–MeVal]–Ala–OBu^t but two major products, which were isolated and identified as *cyclo*[–MeCys(Bzl)–MeVal–] and **6**, respectively. The data of MS supported the structure of the cyclic compound. In view of this easy formation of the cyclic dipeptide by intramolecular aminolysis, compound **2** does not seem to be useful as intermediate for the total synthesis of triostin A. We next tried, therefore, to synthesize **3** and **4** according to the procedure illustrated in Fig. 3.

Bpoc–Ala–OH[22] and H–MeCys(Bzl)–OBu^t prepared according to Roeske[23] were coupled with DCC to give a dipeptide (**9**). The treatment of **9** with an acetic acid–formic acid–water mixture[21] yielded the N^{α}-free compound, which was coupled with Bpoc–D-Ser–OH by the DCC method. The crystalline tripeptide derivative (**10**) thus obtained was treated with acid as above, followed by acylation with Qxc–ONp to produce compound **11**. In the subsequent step Z–MeVal–OH was introduced by the use of Tos–Cl and Bpoc–MeVal–OH by the CDI method to the hydroxyl group of D-Ser residue of **11** to give **12** and **4**, respectively. As in the synthesis of **7**, Bpoc–MeVal–OH could not be introduced by the Tos–Cl method. The treatment of **12** with TFA gave **3** in a moderate yield. In the synthesis of **1**, **2**, **3**, and **4**, most of the intermediates as well as the final products resisted at crystallization, probably because of the presence of *N*-methylamino acid(s) in their molecules. These amorphous products were purified extensively by means of silica gel column chromatography. The tetradepsipeptide derivatives thus obtained, **3** and **4** in particular, would serve as intermediates for the production of triostin A. The final steps toward this goal are now in progress.

Experimental

Thin-layer chromatography (TLC) was performed on silica gel plates (Kieselgel GF_{254} or precoated Kieselgel $60F_{254}$, Merck) with the following solvent systems (ratios by volume): A, ethyl acetate; B, benzene–ethyl acetate (1 : 1); C, benzene–ethyl acetate (7 : 3); D, benzene–ethyl acetate–acetic acid (70 : 30 : 3); E, dichloromethane–ethyl acetate (9 : 1); F, dichloromethane–ethyl acetate (8 : 2); G, cyclohexane–ethyl acetate (2 : 8); H, chloroform–methanol (95 : 5); I, chloroform–methanol (8 : 2); J, chloroform–methanol–acetic acid (95 : 5 : 3); K, chloroform–methanol–acetic acid (90 : 10 : 3); L, 1-butanol–acetic acid–water (4 : 1 : 2). For column chromatography Kieselgel 60 (Merck) was used throughout unless otherwise specified.

D-Serine was purchased from Fluka AG, Buchs, Switzerland and 2-methylquinoxaline from Aldrich Chemical Co., Inc., Milwaukee, Wisconsin, U. S. A. *N*-Methyl-L-valine ($[\alpha]_D^{23}$ +32.5 ±0.8° (*c* 1.0, 6M HCl); lit,[13] $[\alpha]_D^{23}$ +33.1° (*c* 1, 6M HCl)), *N*-methyl-*S*-benzyl-L-cysteine (mp 202—203 °C dec, $[\alpha]_D^{23.5}$ +67.2 ±1.2° (*c* 1.0, 1M HCl); lit.[14] mp 205—206 °C dec, $[\alpha]_D^{20}$ +67.5° (*c* 1, 1M HCl)), and quinoxaline-2-carboxylic acid (mp 228—229 °C; lit,[4b] mp 211—212 °C) were synthesized according to the literature.

p-Nitrophenyl Quinoxaline-2-carboxylate (Qxc–ONp). *a) With p-Nitrophenyl Trifluoroacetate*: To a solution of quinoxaline-2-carboxylic acid (13.93 g, 80 mmol)[4b] in anhydrous pyridine (80 ml) was added *p*-nitrophenyl trifluoroacetate (20.69 g, 88 mmol)[15] and the mixture was stirred at 25 °C for 3.5 h. The desired product was precipitated by the addition of cold water (400 ml). Recrystallization from ethyl acetate gave needles; yield 21.57 g (91%), mp 198—199 °C. Found: C, 61.14; H, 3.13; N, 14.32%. Calcd for $C_{15}H_9N_3O_4$: C, 61.02; H, 3.07; N, 14.23%.

b) With Benzenesulfonyl Chloride and p-Nitrophenol: Quinoxaline-2-carboxylic acid (0.52 g, 3 mmol) in anhydrous pyridine (20 ml) was allowed to react with benzenesulfonyl chloride (0.77 ml, 6 mmol) at 0 °C for 5 min and to this was added *p*-nitrophenol (0.42 g, 3 mmol). The mixture was stirred at 0 °C for 60 min and then ice-cold water (100 ml) was introduced. The precipitate collected was recrystallized from ethyl acetate; yield 0.42 g (47%), mp 197—198 °C. Found: C, 60.80; H, 3.14; N, 14.35%.

Bpoc–MeVal–OH. *N*-Methyl-L-valine (3.94 g, 30 mmol)[13] was dissolved in 40% benzyltrimethylammonium hydroxide in methanol (Triton B, 13.7 ml) and the solution was evaporated *in vacuo*. The residue was, after evaporation from DMF, dissolved in DMF (15 ml) together with Bpoc–N_3 (11.25 g, 40 mmol)[21] and TEA (11.2 ml), and the mixture was stirred at 40 °C for 60 min. Some water (60 ml) was added and the mixture was washed with ether. The aqueous solution was then acidified with ice-cold M citric acid at 0 °C. The oily precipitate which separated was extracted with ether. The organic extracts were combined, dried (Na_2SO_4) and evaporated to give the desired product, which was crystallized from ethyl acetate–petroleum ether; yield 4.33 g (34%), mp 138.5—139 °C, $[\alpha]_D^{20.5}$ −60.1± 1.0° (*c* 1.0, methanol). TLC: homogeneous (H_2SO_4) in system D. Found: C, 71.66; H, 7.40; N, 4.20%. Calcd for $C_{22}H_{27}NO_4$: C, 71.52; H, 7.37; N, 3.79%.

Bpoc–MeCys(Bzl)–OH·DCHA. *N*-Methyl-*S*-benzyl-L-cysteine (9.01 g, 40 mmol)[14] was acylated with Bpoc–N_3 (13.99 g, 50 mmol) in the same manner as described above for Bpoc–MeVal–OH. The oily product was dissolved in ether (20 ml) and DCHA (4.53 g, 25 mmol) was added. The crystalline precipitate which formed was filtered off and recrystallized from methanol–ether; yield 13.55 g (53%), mp 146—148 °C, $[\alpha]_D^{20}$ −53.9 ±1.0° (*c* 1.0, methanol). TLC: homogeneous (H_2SO_4) in systems D and J. Found: C, 72.72; H, 8.20; N, 4.51; S, 4.94%. Calcd for $C_{39}H_{52}N_2O_4S$: C, 72.63; H, 8.13; N, 4.34; S, 4.97%.

Bpoc–D-Ser–OH·H$_2$O. This compound was prepared in the same manner as for Bpoc–MeVal–OH. Crystallization from chloroform–petroleum ether gave the desired product in a 73.5% yield; mp 76—77 °C, $[\alpha]_D^{23}$ +7.6 ±0.5° (*c* 1.0, methanol). TLC: homogeneous (H_2SO_4) in system M. Found: C, 63.25; H, 6.91; N, 4.12%. Calcd for $C_{19}H_{21}NO_5\cdot H_2O$: C, 63.15; H, 6.42; N, 3.88%.

The DCHA salt prepared in the usual manner showed mp 152—154 °C, $[\alpha]_D^{23}$ −4.3 ±0.5° (*c* 1.0, methanol).

H–MeCys(Bzl)–OBu^t·HCl. *N*-Methyl-*S*-benzyl-L-cysteine (2.25 g, 10 mmol)[14] was treated with 2-methylpropene in dioxane (15 ml) in the presence of sulfuric acid

(1.5 ml) according to Roeske[23] to give the corresponding *t*-butyl ester, which was isolated as the hydrochloride and recrystallized from dichloromethane-ethyl acetate; yield 1.81 g (57%), mp 153—153.5 °C, $[\alpha]_D^{23.5}$ −11.9 ±0.6° (*c* 1.0, methanol). TLC: homogeneous (H_2SO_4) in system L. Found: C, 56.53; H, 7.62; N, 4.38; S, 10.03; Cl, 11.25%. Calcd for $C_{15}H_{23}NO_2S$: C, 56.68; H, 7.61; N, 4.41; S, 10.09; Cl, 11.15%.

Z-D-Ser-Ala-OBu^t (5). Z-D-Ser-OH (4.78 g, 20 mmol)[24] and H-Ala-OBu^t (2.90 g, 20 mmol) were coupled with DCC (4.13 g, 20 mmol) in ethyl acetate-dichloromethane (2 : 5, 70 ml) at 5 °C for 20 h. After the dicyclohexylurea which had separated was filtered off, the filtrate was evaporated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with ice-cold M hydrochloric acid and M sodium hydrogencarbonate, dried (Na_2SO_4), and evaporated *in vacuo* to give the desired product, which was recrystallized from ethyl acetate-petroleum ether; yield 5.12 g (70%), mp 89—90 °C, $[\alpha]_D^{28}$ −14.4 ±0.5° (*c* 1.1, methanol). TLC: homogeneous (ninhydrin, after pretreatment with HBr) in systems A and I. Found: C, 59.32; H, 7.08; N, 7.68%. Calcd for $C_{18}H_{26}N_2O_6$: C, 59.00; H, 7.15; N, 7.64%.

Qxc-D-Ser-Ala-OBu^t (6). Compound **5** (7.33 g, 20 mmol) was hydrogenolyzed over palladium in methanol for 2 h to give H-D-Ser-Ala-OBu^t as an oil. This was then allowed to react with Qxc-ONp (5.91 g, 20 mmol) in ethyl acetate (100 ml) at 25 °C for 20 h. The product was purified on a silica gel column with chloroform-methanol (9:1) as solvent. The fractions containing the desired material as a single component, as examined by TLC, were combined and evaporated *in vacuo* to give a crystalline residue. This was recrystallized from benzene-hexane; yield 5.90 g (76%), mp 99—100 °C, $[\alpha]_D^{27}$ −114.2 ±2.9° (*c* 0.5, methanol), −100.4 ±1.7° (*c* 0.9, DMF). λ_{max}^{MeOH} 243 nm (ε 43 700), 320 nm (ε 7 450), 325 nm (ε 7 440). TLC: homogeneous (H_2SO_4) in system A. Lit: mp 94—96 °C, $[\alpha]_D^{27}$ −79.2° (*c* 5, DMF).[9] Found: C, 58.94; H, 6.18; N, 14.47%. Calcd for $C_{19}H_{24}N_4O_5$: C, 58.75; H, 6.23; N, 14.42%.

Qxc-D-Ser(Z-MeVal)-Ala-OBu^t. *a) Carbonyldiimidazole Method*: To a solution of Z-MeVal-OH (0.29 g, 1.1 mmol)[19] in anhydrous THF (4 ml) was added CDMI (0.21 g, 1.1 mmol) and the mixture was stirred at 25 °C for 25 min. To this was added compound **6** (0.43 g, 1 mmol) with some THF as solvent. After the reaction mixture had been kept at 25 °C for 2 days, the product was precipitated by the addition of water and extracted with ethyl acetate. The organic solution was dried (Na_2SO_4) and evaporated *in vacuo* to give a residue, which was purified on a silica gel column with benzene-ethyl acetate (1:1) as solvent; yield 0.19 g (30%), $[\alpha]_D^{25}$ −93.7 ±2.9° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems A and B. Found: 62.36; H, 6.45; N, 10.87%. Calcd for $C_{33}H_{41}N_5O_8$: C, 62.35; H, 6.50; N, 11.02%.

b) p-Toluenesulfonyl Chloride Method: Z-MeVal-OH (2.65 g, 10 mmol) was allowed to react with Tos-Cl (1.43 g, 7.5 mmol) in dry pyridine (10 ml) at 0 °C for 15 min. To this was added **6** (2.01 g, 5 mmol) and the mixture was stirred at 0 °C for 3 h. The product was precipitated by the addition of water and purified as described above in a); yield 2.88 g (91%), $[\alpha]_D^{25}$ −91.5 ±2.6° (*c* 0.5 methanol). TLC: homogeneous (H_2SO_4) in systems A and B. Found: C, 62.38; H, 6.21; N, 10.89%.

Qxc-D-Ser(Bpoc-MeVal)-Ala-OBu^t (7). Bpoc-MeVal-OH (3.70 g, 10 mmol) was allowed to react with CDI (1.78 g, 11 mmol) in anhydrous THF at 0 °C. When effervescence ceased compound **6** (3.88 g, 10 mmol) was added. The mixture was stirred at 25 °C for 5 h, after which the product was precipitated with water. Purification on a silica gel column with dichloromethane-ethyl acetate (8 : 2) as solvent afforded **7** as glassy material; yield 2.93 g (40%), $[\alpha]_D^{24.5}$ −62.2 ±2.1° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems D and F. Found: C, 66.34; H, 6.80; N, 9.85%. Calcd for $C_{41}H_{49}N_5O_8$: C, 66.55; H, 6.75; N, 9.61%.

Compound **7** was also synthesized under the same conditions except for the use of CDMI in place of CDI; yield 28%, $[\alpha]_D^{27}$ −60.9 ±2.1° (*c* 0.5, methanol).

Qxc-D-Ser[Z-MeCys(Bzl)-MeVal]-Ala-OBu^t (8). *a) Mixed Anhydride Method*: Compound **7** (0.44 g, 0.6 mmol) was treated with 0.1M TFA in dichloromethane (60 ml) at 25 °C for 60 min to give Qxc-D-Ser(H-MeVal)-Ala-OBu^t. The mixture was neutralized with TEA (0.75 ml, 5.4 mmol) and concentrated to *ca.* 5 ml. Z-MeCys(Bzl)-OH, derived from the DCHA salt (0.49 g, 0.9 mmol)[14] by the treatment with Dowex 50W × 8 (H^+ form) in 50% ethanol, and TEA (0.13 ml, 0.9 mmol) were dissolved in dichloromethane (5 ml) and ethyl chloroformate (0.09 ml, 0.9 mmol) was added at −10 °C. The resulting solution of the anhydride was mixed with a solution of the N^α-free tridepsipeptide obtained above and TEA (0.83 ml) was added. The reaction mixture was kept at 5 °C for 16 h. The product precipitated by the addition of water was chromatographed repeatedly on silica gel columns with chloroform-methanol (99 : 1) as solvent; yield 0.26 g (51%), $[\alpha]_D^{25}$ −146.5 ±3.7° (*c* 0.4, methanol). TLC: homogeneous (H_2SO_4) in system K. Found: C, 62.58; H, 6.34; N, 9.98; S, 4.09%. Calcd for $C_{44}H_{54}N_6O_9S$: C, 62.69; H, 6.46; N, 9.97; S, 3.80%.

b) DCC Method: Compound **7** (1.48 g, 2 mmol) was deblocked with 80% acetic acid (50 ml) at 70 °C for 60 min. The solvent was evaporated *in vacuo* and the residue was precipitated from ether-petroleum ether. The oily precipitate separated by decantation was lyophilized from 0.05M hydrochloric acid to give the N^α-free depsitripeptide hydrochloride. This was then coupled with Z-MeCys(Bzl)-OH, derived from the DCHA salt (1.08 g, 2 mmol), by means of DCC (0.41 g, 2 mmol) in dichloromethane in the presence of TEA (0.28 ml, 2 mmol) at 5 °C overnight. The reaction mixture was worked up in the usual manner and the resulting product was purified on a silica gel column with benzene and benzene-ethyl acetate systems (7:3 and 1:1) as solvent. The fractions of the last solvent system were combined and evaporated *in vacuo* to give **8** in pure form; yield 1.19 g (71%), $[\alpha]_D^{22}$ −137.7 ±3.6° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems B and C. Found: C, 62.56; H, 6.28; N, 9.74; S, 4.02%.

Qxc-D-Ser[Z-MeCys(Bzl)-MeVal]-Ala-OH (1). Compound **8** (0.84 g) was treated with anhydrous TFA (10 ml) at 25 °C for 60 min. After removal of TFA by evaporation *in vacuo* the residue was dissolved in ethyl acetate and the solution was washed with water, dried (Na_2SO_4) and evaporated *in vacuo* to give glassy material; yield 0.77 g (97%), $[\alpha]_D^{23.5}$ −142.7 ±3.6° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems B and J. Found: C, 60.81; H, 5.94; N, 10.41; S, 4.52%. Calcd for $C_{40}H_{46}N_6O_9S$: C, 61.05; H, 5.89; N, 10.68; S, 4.07%.

Qxc-D-Ser[Bpoc-MeCys(Bzl)-MeVal]-Ala-OBu^t (2). Compound **7** (0.74 g, 1 mmol) was deblocked with 80% acetic acid to give the N^α-free tridepsipeptide, which was converted into the hydrochloride as in the synthesis of **8**. This was then coupled with Bpoc-MeCys(Bzl)-OH, derived from the DCHA salt (0.65 g, 1 mmol) by shaking with M

citric acid in the presence of dichloromethane, by the DCC method as described above for compound **8**. The product was chromatographed on a silica gel column with benzene-ethyl acetate (7:3) as solvent; yield 0.57 g (60%), $[\alpha]_D^{22}$ −121.5 ±3.6° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems B and D. Found: C, 65.72; H, 6.61; N, 8.78; S, 3.76%. Calcd for $C_{52}H_{62}N_6O_9S$: C, 65.94; H, 6.60; N, 8.87; S, 3.38%.

Treatment of **2** *with Aqueous Acetic Acid-Formic Acid Mixture. Formation of* Cyclo[-*MeCys(Bzl)-MeVal*-]. Compound **2** (0.38 g, 0.4 mmol) was treated with acetic acid-formic acid-water (7:1:2, 4 ml)[21] at 25 °C for 2 h. The solvent was evaporated *in vacuo* and the oily residue was precipitated from ethyl acetate-petroleum ether. The resulting material was subjected to a column of silica gel (26 g) and eluted with benzene-ethyl acetate (7:3, 200 ml) and then with ethyl acetate (150 ml). The ethyl acetate fractions were combined and evaporated *in vacuo*. The residue (0.22 g) was rechromatographed on a silica gel column (25 g, Kieselgel H, Merck) with chloroform-methanol (95:5) as solvent. Tubes 15—17 (5 g/tube) were combined and evaporated *in vacuo* to give an oil (72 mg, 56% as *cyclo*[-MeCys(Bzl)-MeVal-]); $[\alpha]_D^{26}$ −43.5 ±1.7° (*c* 0.5, methanol). Found: C, 63.00; H, 7.59; N, 8.42; S, 9.61%. Calcd for $C_{17}H_{24}N_2O_2S$: C, 63.72; H, 7.55; N, 8.74; S, 10.00%. MS, *m/e* 320 (M), 229, 197, 183, 155, and 91.[25]

From tubes 19—24 (5 g/tube) was obtained a crystalline material, which was recrystallized from benzene-hexane (118 mg, 76% as compound **6**); mp 96—98 °C, $[\alpha]_D^{22}$ −109.0 ±0.7° (*c* 0.5, methanol). IR, identical with that of an authentic sample of **6**.

Bpoc-Ala-MeCys(Bzl)-OBu^t ***(9)***. H-MeCys(Bzl)-OBu^t·HCl (6.36 g, 20 mmol) was treated with 50% potassium carbonate at 0 °C in the presence of ether and the organic phase was dried (Na_2SO_4) and evaporated *in vacuo* to give the corresponding free base. This was then coupled with Bpoc-Ala-OH (6.55 g, 20 mmol)[22] by means of DCC (4.13 g, 20 mmol) in ethyl acetate (10 ml). The reaction mixture was worked up in the usual manner to give an oily product, which was chromatographed on a silica gel column with benzene-ethyl acetate (8:2) as solvent to give **9** in pure form; yield 11.19 g (95%), $[\alpha]_D^{22}$ −106.9 ±1.5° (*c* 1.0, methanol). TLC: homogeneous (H_2SO_4) in systems C and E. Found: C, 69.25; H, 7.24; N, 4.59; S, 5.36%. Calcd for $C_{34}H_{42}N_2O_5S$: C, 69.12; H, 7.17; N, 4.74; S, 5.43%.

Bpoc-D-Ser-Ala-MeCys(Bzl)-OBu^t ***(10)***. Compound **9** (10.63 g, 18 mmol) was treated with a mixture of acetic acid-formic acid-water (7:1:2; 100 ml) at 25 °C for 2 h. The solvent was evaporated *in vacuo* and the residue was treated with saturated potassium carbonate in the presence of ethyl acetate. The organic solution was washed with saturated sodium chloride, dried (Na_2SO_4) and evaporated *in vacuo* to give H-Ala-MeCys(Bzl)-OBu^t as an oil. This was then coupled with Bpoc-D-Ser-OH (6.18 g, 18 mmol) by the DCC method in dichloromethane in the usual manner. The product was chromatographed on a silica gel column (Kieselgel H, Merck) with ethyl acetate-cyclohexane (8:2) as solvent and crystallized from ethyl acetate-petroleum ether to give fine needles; yield 8.80 g (76%), mp 128—129 °C, $[\alpha]_D^{23}$ −42.6±1.6° (*c* 0.5, methanol). TLC: homogeneous (ninhydrin, after pretreatment with HCl) in system D. Found: C, 65.39; H, 6.95; N, 6.47; S, 4.74%. Calcd for $C_{37}H_{47}N_3O_7S$: C, 65.66; H, 6.99; N, 6.20; S, 4.73%.

Qxc-D-Ser-Ala-MeCys(Bzl)-OBu^t ***(11)***. Compound **10** (6.78 g, 10 mmol) was treated with acetic acid-formic acid-water (7:1:2) at 25 °C for 2 h to give the N^{α}-free tripeptide and this was allowed to react with Qxc-ONp (3.25 g, 11 mmol) in ethyl acetate in the presence of TEA (1.54 ml) for 20 h. The product was purified on a silica gel column with chloroform-methanol (9:1) as solvent; yield 3.90 g (65%), mp 60—70 °C, $[\alpha]_D^{22}$ −153.6±3.8° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems A and H. Found: C, 59.99; H, 6.32; N, 11.86; S, 5.29%. Calcd for $C_{30}H_{37}N_5O_6S$: C, 60.49; H, 6.26; N, 11.76; S, 5.38%.

Qxc-D-Ser(Z-MeVal)-Ala-MeCys(Bzl)-OBu^t ***(12)***. Z-MeVal-OH (0.42 g, 1.6 mmol)[19] was coupled with **11** (0.48 g, 0.8 mmol) by means of Tos-Cl (0.23 g, 1.2 mmol) in pyridine, as in the synthesis of Qxc-D-Ser(Z-MeVal)-Ala-OBu^t. The crude product was purified by repeated chromatography on silica gel columns with chloroform-methanol (95:5) and ethyl acetate-cyclohexane (8:2) as solvent; yield 0.48 g (72%), $[\alpha]_D^{22}$ −129.8±3.4° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems G and H. Found: C, 62.47; H, 6.28; N, 9.77; S, 4.03%. Calcd for $C_{44}H_{54}N_6O_9S$: C, 62.69; H, 6.46; N, 9.97; S, 3.80%.

Qxc-D-Ser(Z-MeVal)-Ala-MeCys(Bzl)-OH ***(3)***. Compound **12** (0.42 g, 0.5 mmol) was treated with TFA (5 ml) at 25 °C for 30 min. After removal of TFA by evaporation *in vacuo* the residue was dissolved in ethyl acetate and the solution was washed with water, dried (Na_2SO_4) and evaporated *in vacuo* to give a glassy material, which was purified by chromatography on a silica gel column (Kieselgel H, Merck) with chloroform-methanol-acetic acid (90:10:3) as solvent; yield 0.37 g (94%), $[\alpha]_D^{25.5}$ −126.1±3.3° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in system K. Found: C, 60.35; H, 5.81; N, 10.42; S, 4.34%. Calcd for $C_{40}H_{46}N_6O_9S$: C, 61.05; H, 5.89; N, 10.68; S, 4.07%.

Qxc-D-Ser(Bpoc-MeVal)-Ala-MeCys(Bzl)-OBu^t ***(4)***. Bpoc-MeVal-OH (0.55 g, 1.5 mmol) was allowed to react with CDI (0.29 g, 1.8 mmol) in anhydrous THF at 25 °C for 30 min. To this was added a solution of **11** (0.60 g, 1.0 mmol) in THF. The mixture was stirred at 25 °C for 22 h and evaporated *in vacuo*. The residue was, after being washed with water, purified on a silica gel column (Kieselgel H, Merck) with chloroform-methanol (98:2) as solvent; yield 0.20 g (21%), $[\alpha]_D^{26.5}$ −99.6±2.6° (*c* 0.5, methanol). TLC: homogeneous (H_2SO_4) in systems C, G, and J. Found: C, 65.62; H, 6.58; N, 8.63; S, 3.62%. Calcd for $C_{52}H_{62}N_6O_9S$: C, 65.94; H, 6.60; N, 8.87; S, 3.38%.

Reactions of Aromatic Compounds in Molten Salts. II. The Rearrangement of Phenylhydrazine to Give *o*-Phenylenediamine in a Molten Mixture of $AlCl_3$–NaCl–KCl

Hisao IMAIZUMI, Yoji HASHIDA, and Kohji MATSUI

Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received December 26, 1977)

Phenylhydrazine gave *o*-phenylenediamines as the major product upon heating in a molten mixture of $AlCl_3$–NaCl–KCl. In the molten mixture, some aromatic compounds gave the corresponding aromatic amines in good yields in the presence of phenylhydrazine, suggesting that the method provides a novel direct process for the preparation of aromatic amines.

Many derivatives of *N*-substituted aniline have been known to rearrange to give *C*-substituted anilines; as examples, Bamberger's phenylhydroxylamine[2] and phenylnitroamine rearrangement,[3] Chattaway's *N,N*-diacylaniline rearrangement,[4] Fischer-Hepp's rearrangement,[5] Hofmann-Martin's alkylaniline rearrangement,[6] and Reilly-Hickinbottom's *N*-alkylaniline rearrangement[7] can be cited.

On the other hand, phenylhydrazine is known to give *p*-phenylenediamine upon heating in the presence of hydrochloric acid; in this case, however, no detectable formation of *o*-phenylenediamine was observed.[8] Phenylhydrazine has also been known to decompose to give aniline, benzene, ammonia, and other products upon heating in the presence of Lewis acid,[9] metals[10] or phenylhydrazine hydrochloride.[11] However, the reaction to give *o*-phenylenediamine has not been reported. We have now found that, in a molten mixture of $AlCl_3$–NaCl–KCl, phenylhydrazine gives *o*-phenylendiamine and that several aromatic compounds yield the corresponding amines in the presence of phenylhydrazine in the molten mixture.

Experimental

All the melting points are uncorrected. The structural assignment of the reaction products was done by means of their NMR, MS, IR, UV spectra, and elemental analyses and by a mixed-melting-point-test with an authentic sample.

Materials. The $AlCl_3$, NaCl, KCl, and other inorganic materials used were of a reagent grade. The organic materials used were purified by distillation or recrystallization, and their purities were checked by TLC or GLC before use.

A typical example of the reaction will now be described; 5 ml of phenylhydrazine (0.051 mol) was stirred, drop by drop, into a molten mixture of $AlCl_3$–NaCl–KCl in an atmosphere of prepurified nitrogen. After stirring at a given temperature for a given time, the reaction mixture was poured into a mixture of 500 ml of 0.1 M HCl and 100 g of ice. After a small amount of the insoluble matter had then been filtered off, the filtrate was made alkaline and the reaction products were extracted with diethyl ether. The solvent was removed by distillation; then the reaction products were separated and purified by column chromatography. The quantitative determinations of the reaction products were carried out by GLC (Column:Lubrol MO 15%/Cromsorb WAW, 4 mm × 1 m).

Results and Discussion

Formation of o-*Phenylenediamine.* When phenylhydrazine (0.05 mol) was heated at 100 °C in a mixture of $AlCl_3$–NaCl–KCl (0.60:0.23:0.17 mol), aniline and *o*-phenylenediamine were both obtained in about a 30% yield; however, no *p*-phenylenediamine was detected in the reaction mixture. The yield of *o*-phenylenediamine was affected very much by the Lewis acids used. When $ZnCl_2$ was used instead of $AlCl_3$, the yield of *o*-phenylenediamine decreased considerably. However, in the reaction of phenylhydrazine in a molten mixture of CuCl–NaCl–KCl (0.60 : 0.20 : 0.20 mol) at 200 °C, aniline was the sole major product; *o*-phenylenediamine was not detected at all in the reaction mixture. Similar results were also obtained in the reactions of

TABLE 1. EFFECTS OF MOLTEN SALT COMPOSITION ON PRODUCT YIELDS IN THE REACTIONS OF PHENYLHYDRAZINE

Composition (mol)	Condition		Conv. (%)	Products (%)

PH·HCl[b1]	100	2	100	15	3	10	32
PH·HCl[b2]	100	2	100	14	2	8	33

5.0 ml (0.0508 mol) of $C_6H_5NHNH_2$ was used.

a) Phenylhydrazinium salt was insoluble in $SnCl_4$ or $TiCl_4$. b) A $AlCl_3$: NaCl : KCl mixture(=0.60 : 0.23 : 0.17) and 7.4 g (0.06 mol) of phenylhydrazine hydrochloride were used. b_1) Phenylhydrazine hydrochloride was added to a molten mixture of 100 °C. b_2) The temperature of a mixture of $AlCl_3$, NaCl, KCl, and phenylhydrazine hydrochloride was gradually raised to 100 °C.

phenylhydrazine in $SnCl_4$ and $TiCl_4$.

When phenylhydrazine hydrochloride was heated in a molten mixture of $AlCl_3$: NaCl : KCl (0.60 : 0.23 : 0.17 mol) at 100 °C, *o*-phenylenediamine was obtained only in low yields; on the contrary, benzidine became the major product in this case. These results are summarized in Table 1.

From the reaction products and their yields, *o*-phenylenediamine is assumed to be produced from the phenylhydrazine–$AlCl_3$ complex formed by the HCl–$AlCl_3$ exchange from phenylhydrazine hydrochloride. On the other hand, chloroanilines would result from the chlorination of aniline with the chlorine formed by the oxidation of hydrochloric acid by the air included in the voluminous phenylhydrazine hydrochloride powder; benzidine would be formed from the aniline produced by the decomposition of phenylhydrazine hydrochloride, as has been reported in the previous paper.[1)]

When phenylhydrazine was heated in a molten mixture of $AlCl_3$–NaCl–KCl (0.60 : 0.23 : 0.17 mol) at 120 °C, the yield of *o*-phenylenediamine varied depending upon the amount of the molten mixture employed, as is shown in Fig. 1. The results show that an excess of $AlCl_3$ is necessary for the formation of *o*-phenylenediamine in good yields.

Decomposition of Phenylhydrazine–$AlCl_3$ Complex. Phenylhydrazine is known to form a complex with $AlCl_3$ of a molar ratio of 2 : 1.[12)] Therefore, the thermal behavior of the complexes of phenylhydrazine with $AlCl_3$ were investigated in order to make clear the reaction of phenylhydrazine in the molten salt. The complexes were prepared by mixing phenylhydrazine with powdered $AlCl_3$ in benzene. When the ratio of $AlCl_3/PhNHNH_2$ is less than unity, the complex was obtained as a crystalline solid. In the range of ratios above unity, however, the complex obtained was a viscous molten mass from which the complete removal of benzene was very difficult. In some cases, the yield of aniline (based on the phenylhydrazine) was found to exceed 100% (the best yield was about 150%, in the case of a $AlCl_3/PhNHNH_2$ molar ratio of 3), suggesting that the residual benzene in the complex was aminated to give aniline. In these cases, the yields of *o*-phenylenediamine remained low.

On the other hand, in the reactions using the complexes prepared in petroleum ether the yield of *o*-phenylenediamine increased with an increase in the $AlCl_3/PhNHNH_2$ ratio until about 2 (the best yield was 30%); however, aniline was obtained only in low yields, as may be anticipated in the absence of benzene. From these results, it is obvious that the formation of *o*-phenylenediamine and the amination of benzene take place competitively.

When phenylhydrazine was heated with powdered $AlCl_3$ in benzene under reflux, the solubility of the resulting complex was found to vary depending upon the $AlCl_3/PhNHNH_2$ ratio. In the range of the ratios below 0.6, the complex was isolated as a white solid which was insoluble in the solvent. However, in the range of the ratios above 0.8, the resulting complex was soluble in the solvent to give a clear orange solution. These observations indicate that the composition of the complex varied with the change in the $AlCl_3/PhNHNH_2$.

Fig. 2 shows the results of the reactions of the phenylhydrazine–$AlCl_3$ complex in benzene. From Fig. 2, it is clear that the decomposition of phenylhydrazine takes place in the range of $AlCl_3/PhNHNH_2$ ratios above unity and that the yield of *o*-phenylenediamine increases with an increase in the ratio until 2, showing that stoichiometrically at least 1 mol of $AlCl_3$ to 1 mol of phenylhydrazine is necessary for the formation of *o*-phenylenediamine. In this case, the formation of aniline from benzene was also observed.

Decomposition of Phenylhydrazine–$AlCl_3$ Complex in Monosubstituted Benzene Derivatives. When phenylhydrazine was heated in a molten mixture of $AlCl_3$: NaCl : KCl in the presence of *p*-chloroaniline at 100 °C, no 4-chloro-*o*-phenylenediamine was detected (Table 2), indicating that the amination of aromatic amine did not take place under these reaction conditions. To get more insight into the amination in the molten mixture, the amination of several monosubstituted benzene derivatives was investigated. The results are shown in Table 3. Two noticeable points in

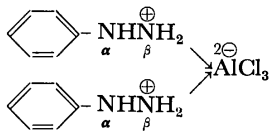
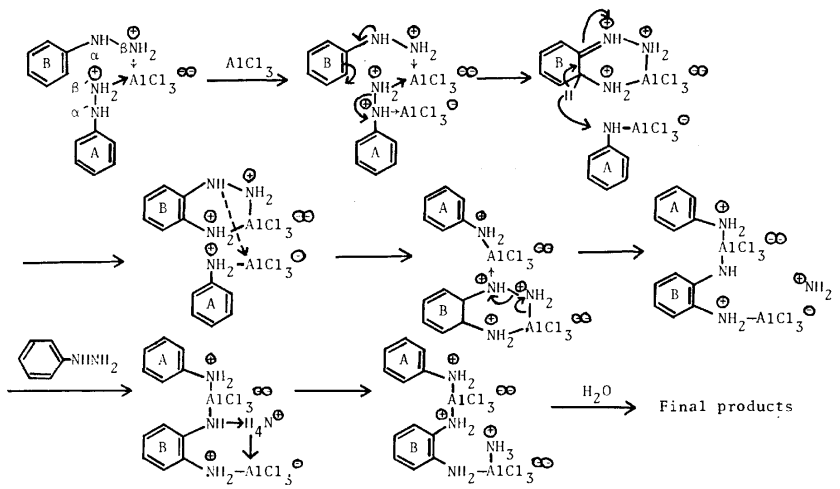
$AlCl_3$ = 0.105 mol; $C_6H_5NHNH_2$ = 0.0518 mol.
Benzene derivative, 30 ml; heated for 1 h under reflux.

Table 3 are that, even though all of these aromatic compounds were aminated, the total yield of toluidines was higher than those of chloro- and fluoroaniline, and that the amination took place at the ortho and para positions to the fluoro substituents. These results suggest that the reaction takes place by means of a mechanism of electrophilic substitution; the fact that the amination of chloroaniline did not take place may be understood to indicate that chloroaniline combines at first with $AlCl_3$ to form a inert complex towards an electrophile. Accordingly, the formation of *o*-phenylenediamine is not considered to result from the amination of aniline, but may be assumed to result from the rearrangement of the phenylhydrazine–$AlCl_3$ complex. This is because, if *o*-phenylenediamine were produced by the intermolecular amination of aniline by an electrophile such as NH_2^+, *p*-phenylenediamine should be produced at the same time.

When $AlCl_3$ was added to a solution of phenylhydrazine in dioxane, the UV spectrum of phenylhydrazine (λ_{max} 293 nm) showed a blue shift, and at the point of a $AlCl_3/PhNHNH_2$ ratio of 1/2,[12] the spectrum coincided in position with that of phenylhydrazine hydrochloride ($PhNHNH_2$: HCl = 1 : 1, λ_{max} 272 nm). In phenylhydrazine, the β-amino group is more basic than the α-amino group; therefore, a 2:1 complex between phenylhydrazine and $AlCl_3$ may be expected to possess the skeleton described below:



The fact that 1 mol of $AlCl_3$ is necessary for each mole of phenylhydrazine for the formation of *o*-phenylenediamine, as is shown in Fig. 2, suggests that an additional attack by $AlCl_3$ upon the 2 : 1 complex is essential. Thus, the reaction of the phenylhydrazine–$AlCl_3$ com-



Scheme 1.

plex to give *o*-phenylenediamine in the molten salt may be reasonably explained by a process shown in Scheme 1.

1) The formation of a 2:1 complex from phenylhydrazine and $AlCl_3$.

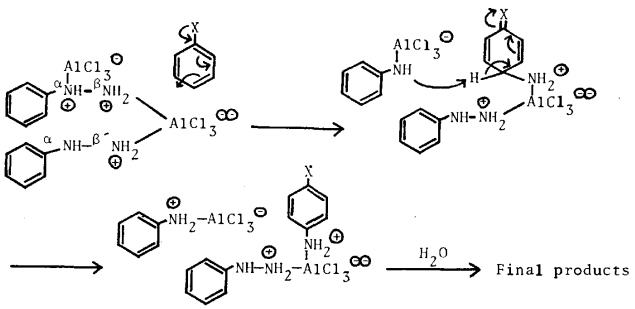
2) An additional attack by $AlCl_3$ upon one of the N_α atoms (N_α'), resulting in a new complex which has a N atom of a high electrophilicity as a result of the electrostatic repulsion between N_α' and N_β' atoms.

3) In the new complex, even though the electron-donating ability of the N_β atom is low, the electron density of the B phenyl group will be high at the ortho and para positions. Therefore, the electrophilic attack by N_β' upon the ortho carbon atom would take place without difficulty through the 6-membered transition state.

Step 3 would be the key step for the reaction; the following sequences of the reaction would proceed according to the process shown in Scheme 1, in which only the skeletons of the complexes are shown because the exact compositions of the complexes including the ligands are still uncertain. During the reaction, the nitrenium cation is assumed to be produced, even though its formation has not been confirmed; the nitrenium cation may react with phenylhydrazine to give the ammonium cation in a manner similar to that of the phenylnitrenium cation.[13] In fact, ammonia was detected during the course of the reaction.

The amination of aromatic compounds by the phenylhydrazine–$AlCl_3$ complex to give the corresponding derivatives of aniline would take place in a manner similar to that described above, as is shown in Scheme 2.

Several methods have been reported for the direct amination of aromatic compounds in the presence of Lewis acid: the aminations by hydroxylamine,[14] by hydrazoic acid,[15] and by *N*-chlorodialkylamine[16] may be cited. As to the amination by means of hydrazine, however, only the photochemical amination of cyclohexane has been reported.[17] Thus, the amination of aromatic compounds described above may provide a novel direct method for the preparation of aromatic amines; in addition, this method may be expected to develop into a general method of the amination of aromatic compounds using hydrazine and its derivatives in the presence of Lewis acid.



Scheme 2. Probable process for the amination benzene derivatives.

Polymeric Alkoxyalkylaluminum Compounds by Novel Reductive Cleavage of Saturated Cyclic Ethers. A New Organometallic Reagent in Organic Synthesis

Mitsuhiro SUMITANI, Kazuhiko KANEMITSUYA, Hajime YASUDA, and Hisaya TANI

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received November 10, 1977)

Insertion of aluminum to the C–O–C bond of saturated cyclic ethers by the $HgCl_2$–$ZnCl_2$–MeI catalyst system led to the reductive cleavage of 5, 6, and 7 membered ring ethers to give polymeric alkoxyalkylaluminum compounds. The relative rate of the reaction was increased in the order of tetrahydrofuran, 3-methyltetrahydrofuran, 2-methyltetrahydrofuran, 2,5-dimethyltetrahydrofuran, tetrahydropyran, oxepane, 7-oxabicyclo[2.2.1]-heptane, and 2-methyltetrahydropyran. The cleaved cyclic ethers are bonded with aluminum atoms bifunctionally and the resulting polymeric aluminum compound gave dideuterio alcohols upon deuterolysis. Addition reaction of allyl halides and reduction of chloral with the aluminum compound provided a novel route for the preparation of unsaturated alcohols.

A number of methods for the cleavage of saturated cyclic ethers have been reported and summarized in several reviews.[1–4] Both acid[5–8] and base[9–11] catalyzed cleavages are known and the ring opening mechanism,[12,13] ring size effects[14] and influences of the group substituted on the ring[15,16] have been extensively studied. Most of the studies reported so far are concerned with the stoichiometric reactions between cyclic ethers and ring cleaving agent. We present here a novel direct reaction of saturated cyclic ethers with aluminum which led to the reductive cleavage of 5, 6, and 7 membered cyclic ethers. Remarkable points of this reaction lie in the following points; 1) metallic aluminum, a neutral reactant, can undergo the stoichiometric reaction with cyclic ethers to give a new type of aluminum compounds, 2) the order in reactivity of the cyclic ethers follows that of the steric effects of the alkyl group on the ring and of the carbon chain consisting the ring, and 3) this method has the advantages of experimental simplicity and broad applicability for the preparation of unsaturated alcohols with elongated carbon chain from allyl halides.

Results and Discussion

Reductive Cleavage of Cyclic Ethers by Aluminum. In our search for the new method for activating main group metals, we found an unusual reductive cleavage of tetrahydrofuran(THF) with aluminum to give polymeric alkoxyalkylaluminum compounds. The reaction proceeded by employing the aluminum turnings activated not only with mercury(II) halides, in accordance with the general procedure,[17] but also with a minute quantity of organic halides. All of the mercury(II) or mercury(I) halides, $HgBr_2$, Hg_2Br_2, $HgCl_2$, Hg_2Cl_2, HgI_2, and Hg_2I_2, were effective as catalysts in various concentrations from 0.1 to 0.4 mol% when it was used simultaneously with an organic halide in concentrations of 4.0—8.0 mol% to aluminum turnings. Iodine, alkyl iodides and bromides were preferred over chloro compounds. The addition of zinc chloride to the HgX_2–RX catalyst system brought about a remarkable acceleration of the reaction. The use of the catalyst system composed of $HgCl_2$(2 mol%)–MeI(4.0 mol%)–$ZnCl_2$(4.0 mol%) resulted in the formation of the tetrahydrofuran-aluminum compound **1** in 93% yield as listed in Table 1. When an excess of THF(10 equivalent mole) reacted at 80 °C for 70 h, aluminum was consumed completely and a liquid amalgam was precipitated. The hydrolysis of the amalgam with 10 M HCl and the chemical analysis of the hydrolyzate by the 8-quinolinol method showed that 99% of mercury and 68% of zinc added to the system were reduced to metals as amalgam. As the promotors, $FeCl_3$ and $TiCl_4$ were also effective, but the use of zinc chloride was more favorable with respect to the reproducibility of the reaction. No reaction occurred when boron, magnesium, calcium or alkali metals were used in place of aluminum. It

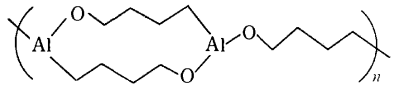
a) The g-atom/mol ratio of aluminum to THF was 1 ; 4.

may be noted that the present reaction is characteristic to cyclic ethers and, hence, acyclic ethers such as diethyl or dipropyl ether can be used as a solvent.

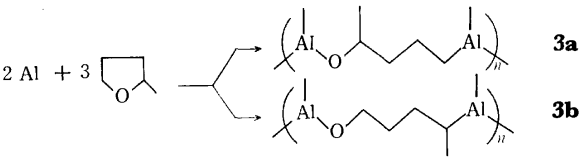
Characterization of the Aluminum Compoumds. The aluminum compound **1** thus obtained was soluble in benzene or ether. It gave terminally dideuterated 1-butanol C_4H_8DOD quantitatively upon deuterolysis and produced no detectable amount of by-product as evidenced by GC and TLC. The molecular weight of **1** determined cryoscopically in benzene corresponded to that of $(Al_2C_{12}H_{24}O_3)_n$ where $n=2$. The ratio of aluminum to 1-butanol analyzed with the 8-quinolinol method and GC was 2:3. PMR spectral data taken in benzene also agreed with the following structure. Proton signals assigned to CH_2 adjacent



1

to Al, internal CH_2, and CH_2 bonded with oxygen atoms appeared at δ 0.54, 1.84, and 3.92 ppm in 1:2:1 peak area ratio. When 4 mol% of $FeCl_3$ or $TiCl_4$ was used as a promotor instead of zinc chloride, the molecular weight of the aluminum compound increased to 1050—1105 which corresponds to $(Al_2C_{12}H_{24}O_3)_4$, but the NMR data coincided in chemical shift and peak area ratio with that of **1**. In the similar manner, 3-methyltetrahydrofuran-aluminum **2**, 2-methyltetrahydrofuran-aluminum **3**, 2,5-dimethyltetrahydrofuran-aluminum **4**, tetrahydropyran-aluminum **5**, oxepane-aluminum **6** and 7-oxabicyclo[2.2.1]-heptane-aluminum **7** compounds could be prepared individually by using the $HgCl_2$–$ZnCl_2$–MeI catalyst system. All of these aluminum compounds gave the corresponding dideuterio alcohols upon deuterolysis and have oligomeric structures similar to **1** where $n=2$ (Table 2). PMR spectral data of **5** and **6** were in accord in chemical shift with that of **1** within 10 Hz.

Steric and Ring Size Effect of the Cyclic Ethers. The reactions mentioned above were of the second order and the relative rate of reactions is listed in Table 3. A higher homologue, 2-methyltetrahydropyran, had no reactivity and was recovered quantitatively. The order in reactivity of cyclic ethers which form **1**, **2**, **3** and **4** is consistent with the half-lives for the nucleophilic cleavage of those ethers with organolithium compounds[18,19] but not consistent with the order in reactivity of cyclic ethers toward electrophiles[20] or their basicities against various acids,[21,22] nevertheless this reaction was initiated with a Lewis acid catalyst system. The substitution of THF with methyl group in α position caused to the remarkable decrease in reactivity. In case of 7-oxabicyclo[2.2.1]heptane, which may be considered as *cis*-2,5-dimethyltetrahydrofuran with methyl group bound together in a bridge, the reactivity was significantly small compared to 2,5-dimethyltetrahydrofuran. This should be ascribed to the cage effect derived from the bulky bicyclic ring.[21] In the reaction of 2-methyltetrahydrofuran, the substituted carbon atom is known to be attacked preferentially by both nucleophilic[18,19] and electrophilic[23] reagents. However, the ring cleavage of 2-methyltetrahydrofuran by the present method afforded **3a** stereoselectively (99%). The yield of **3b** was only 1%. The compound **2** also gave the abnormal product predomonantly; *i.e.*, the ratio of 2-methyl- to 3-methylbutanol was 74 : 26. These results are concordant with the reductive cleavage of 2-methyltetrahydrofuran by a bulky nucleophile, $LiAlH(OtBu)_3$-BH_3,[24] which gave only 2-methylbutanol. Thus the ring opening of cyclic ethers with aluminum was oriented mainly by the steric effect of subsituents rather than the ionic or inductive effects. The ratio of **3a** to **3b**(99 : 1) was proportional to that of relative rates of reaction between THF and 2,5-dimethyltetrahydrofuran, 92 : 8. The orientation of the ring opening of 2-methyltetrahydrofuran was, therfore, interpreted in terms of the steric effect of substituents.



3a

3b

To elucidate the ring size effect, the reaction of 3, 4, 5, 6, and 7 membered ring ethers bearing no methyl substituents was examined. Comparison of these ethers showed that the rate of reaction increased in the order of 5>6>7 membered ring. Three and four membered ring ethers are unfortunately too sensitive to the catalyst to permit the comparative studies(polymerization occurred preferentially). This order varies inversely as the order of inductive effect, 7>6>5, and is not consistent with that of pK_a values[21] of cyclic ethers or the strain energies, ΔG,[25] which

TABLE 2. CHARACTERIZATION OF ALUMINUM-CYCLIC ETHER COMPOUNDS

Compound	Mol wt Found(Calcd)	Al (%) Found(Calcd)	Hydrolysis product
1	520 (270)	19.8 (20.0)	1-butanol
2	605 (312)	17.3 (17.3)	2-methyl-1-butanol 3-methyl-1-butanol
3	620 (312)	17.1 (17.3)	2-pentanol
4	690 (354)	15.2 (15.2)	2-hexanol
5	590 (312)	16.8 (17.3)	1-pentanol
6	701 (354)	15.3 (15.2)	1-hexanol
7	705 (348)	15.7 (15.5)	cyclohexanol

TABLE 3. COMPARATIVE RATES OF REACTION OF CYCLIC ETHERS

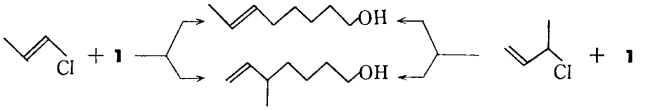
Cyclic ethers	Initial rate const $10^4 k$ (l/mol h)
Tetrahydrofuran	378.4
3-Methyltetrahydrofuran	154.5
2-Methyltetrahydrofuran	67.4
2,5-Dimethyltetrahydrofuran	15.4
Tetrahydropyran	9.1
Oxepane	8.1
7-Oxabicyclo[2.2.1]heptane	2.2

increased in order of 7>6>5. Although systematic data about the steric effect of cyclic ethers are lacking, those of linear ethers[26] clearly showed that the steric effect was reversed by the inductive effect. The order in reactivity of 5, 6, and 7 membered ring ethers should be, therfore, ascribed to the steric effect of the methylene chain on the ring.

The steric effect observed in the present system is unusually large. This unique behavior may be interpreted with the concept that the real catalyst is formed on the aluminum surface to proceed a kind of template reaction. The following examination supports this assumption; *i.e.*, aluminum turnings activated with the above mentioned catalyst at 40 °C in THF was washed thoroughly with excess of anhydrous ether to remove unreacted catalyst components. Although no ring opening had occurred at this temperature, the aluminum turnings thus treated were already activated and they maintained the activity to give **1** by the reaction with freshly introduced THF at 80 °C. In addition, aluminum chloride, methylalminum dichloride, and dimethylaluminum chloride, candidates of the real catalyst which could be formed[27,28] from the mixture of aluminum, mercury(II) chloride, zinc chloride, and methyl iodide, had no catalytic activity. The stoichiometric reaction of the catalyst, $HgCl_2$–$ZnCl_2$–MeI, with THF gave no ring opening products, unless aluminum was present in the system. On the bases of these results, we can reasonably conclude that the ring cleavage occrured certainly on the aluminum surface and the large steric effect observed in this system was caused by the metal surface reaction.

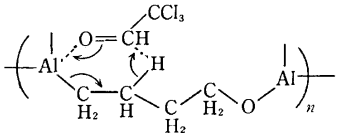
This method was less applicable to the cleavage of aromatic cyclic ethers whose ring were stabilized by the conjugation effect.[29] The reaction of 2,3-dihydrobenzofuran and 1,3-benzodioxole with aluminum resulted in the formation of 2-ethylphenol and catechol, respectively, in 10—20% yield. Desired *o*-methoxyphenol was not obtained from 1,3-benzodioxole.

Preparation of Unsaturated Alcohols from Cyclic Ethers. The cleaved cyclic ether is bonded with aluminum atoms bifunctionally, differing from the alkoxy group of the aluminum alkoxide. By taking advantage of the bifunctional nature of the cleaved cyclic ether, the addition of allyl group to the terminal methylene of the cleaved tetrahydrofuran was attempted. The addition of 2 mol. of 3-bromopropene to **1** at 80 °C resulted in the formation of 6-hepten-1-ol in only 5% yield upon hydrolysis, but the addition of cupric or cuprous compounds($CuBr_2$ or CuBr, 1 mol% to the aluminum compound) as catalyst brought about the increase of the yield to 70%. They were more effective as catalyst than Cd, Zn, Ni(II), Co(II), Pd(II), or Fe(III) compound as the latter was reduced immediately to the metal. In a similar manner, the reaction of **2** with 3-bromopropene gave 2-methyl-6-hepten-1-ol(75%) and 3-methyl-6-hepten-1-ol(25%) in 62% yield and **3** gave 7-octen-2-ol in 65% yield. The reaction of **1** with *trans*-1-chloro-2-butene in the presence of $CuBr_2$(1.0 mol%) gave 5-methyl-6-hepten-1-ol and 6-octen-1-ol with 1 : 1 ratio in 60% yield. The isomer, 3-chloro-1-butene also gave the same alcohols with 1 : 1 ratio in 63% yield under the same



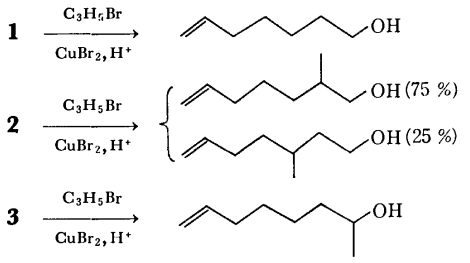
reaction conditions(80 °C for 10 h). This suggests that the ratio of two isomeric butenyl cations formed in both reactions are identical with each other. Thus the polymeric alkoxyalkylaluminum reagents are preferred for the preparation of unsaturated alcohols with elongated carbon chain from allyl halides. Elongation of the carbon chain with diiodomethane was also possible. For example, the reaction of **1** with diiodomethane at 80 °C for 20 h gave 5-iodopentanol in 49% yield upon hydrolysis.

In order to explore the reducing ability of **1**—**3**, reduction of chloral was examined. Two moles of **1** reduced three moles of chloral resulting in the formation of 2,2,2-trichloroethanol and 3-buten-1-ol in 77% yield. The following intermediate can be considered for this reaction. The reducing ability of **1** is similar



to that of triethylaluminum.[30] Acetaldehyde and acetone were not reduced with **1**. Similarly, **2** gave 2-methyl-3-buten-1-ol and 3-methyl-3-buten-1-ol in 7 : 3 ratio and **3** gave 4-penten-2-ol by the reaction with chloral.

Thus, a series of polymeric alkoxyalkylalumunum compounds obtained here has a large utility in the novel synthesis of unsaturated alcohols with or without elongated carbon chain.



Experimental

All the cyclic ethers obtained commercially were dried over sodium/potassium alloy and distilled. Aluminum foil (99.99% in purity, thickness 0.025 mm, 2.0×2.0 mm width, Nakarai Chem.), aluminum powder(99% purity, Alfa Chem.) and aluminum foil for kitchen use (97% purity, Toyo Aluminum Tech.) were used as the Aluminum turnings. Anhydrous metal halides were prepared by heating the hydrates in vacuum at the prescribed temperature. Reactions were carried out under nitrogen using the two-necked glass tube(30×150 mm, thickness 2.0 mm). GC analysis and the separation of the reaction products were made with Yanagimoto Model G-80 and Varian-Aerograph

Model 700 gas chromatographs. PMR spectra were taken with a Varian Model A-60 instrument and MS with a Hitachi RMU-7HR spectrometer. IR spectra were recorded on a Hitachi Model EPI-2 spectrometer.

*Preparation of **1** from THF.* To the aluminum turnings (2.7 g, 0.1 g-atom) in THF(40 ml, 0.4 mol), a mixture of mercury(II) chloride(0.54 g, 2.0 mol% to aluminum), zinc chloride(0.54 g, 4.0 mol%), and methyl iodide(0.25 ml, 4.0 mol%) was added as catalyst. After the tube was sealed and shaken for 70 h at 80 °C in a temperature controlled water bath equipped with a vibrator, benzene(120 ml) was added to the product. The colorless benzene solution was transferred with a hypodermic syringe to remove the residual aluminum amalgam and was evaporated to dryness to give **1** as a semi-solid substance. Any differences in reactivity were not observed among the three brands of aluminum turnings used in this experiment.

*Preparation of Aluminum Compounds **2**—**6**.* In essentially the same way as described above, the reaction of 2-methyltetrahydrofuran, 3-methyltetrahydrofuran, 2,5-dimethyltetrahydrofuran, tetrahydropyran, and oxepane(0.4 mol) with aluminum turnings(2.7 g, 0.1 g-atom) were carried out at 80 °C for 150 h. The resulting products were dissolved in benzene (120 ml) and poured into hexane(300 ml) to precipitate the compound. After decantation, the precipitates **2**—**6** were dried *in vacuo* to give semi-solid materials.

*Deuterolysis of the Compound **1**—**7**.* The aluminum compounds **1**—**7**(50 mmol) were deuterolyzed at 0 °C with deuterium oxide(5 ml) in ether(50 ml). Isomeric alcohols were separated with a preparative GC using a column(4 m) packed with 15% Silicone DC-500 on 40/60 mesh Celite 545. The position of deuteriums in the resulting alcohols was determined with IR, PMR, and MS, by reference to alcohols obtained by hydrolysis.

*Butan-4-*d-*1-ol-*d *from **1***: IR(neat) 2490(ν OD), 2180 cm^{-1} (ν CD). PMR($CDCl_3$) δ 3.68(2H, q, CH_2O), 1.52(4H, m, CH_2), 0.99(2H, m, CH_2D). MS *m/e* 76(M^+), 74, 57, 32.

*2-Methylbutan-4-*d-*1-ol-*d *from **2***: IR(neat) 2483(ν OD), 2182 cm^{-1}(ν CD). PMR($CDCl_3$) δ 3.62(2H, t, CH_2O), 1.50 (3H, m, CH_2CH), 0.93(5H, m, CH_3 and CH_2D). MS *m/e* 90(M^+), 88, 71, 32.

*3-Methylbutan-4-*d-*1-ol-*d *from **2***: IR(neat) 2485(ν OD), 2180 cm^{-1}(ν CD). PMR($CDCl_3$) δ 3.68(2H, t, CH_2O), 1.51 (3H, m, CH_2CH), 0.93(5H, d, CH_3 and CH_2D). MS *m/e* 90(M^+), 88.

*Pentan-5-*d-*2-ol-*d *from **3***: IR(neat) 2489(ν OD), 2179 cm^{-1} (ν CD). PMR($CDCl_3$) δ 3.80(1H, m, CH), 1.48(4H, m, CH_2), 1.18(3H, d, CH_3), 0.93(2H, m, CH_2D). MS *m/e* 90(M^+), 88, 75, 71, 32.

*Hexan-6-*d-*2-ol-*d *from **4***: IR(neat) 2490(ν OD), 2175 cm^{-1} (ν CD). PMR($CDCl_3$) δ 3.80(1H, m, CH), 1.31(6H, m, CH_2), 1.18(3H, d, CH_3), 0.92(2H, q, CH_2D). MS *m/e* 104 (M^+), 85, 57, 32.

*Pentan-5-*d-*1-ol-*d *from **5***: IR(neat) 2490(ν OD), 2182 cm^{-1} (ν CD). PMR($CDCl_3$) δ 3.62(2H, t, CH_2O), 1.40(6H, m, CH_2), 0.90(2H, m, CH_2D). MS *m/e* 88(M^+-2), 71, 55, 32.

*Hexan-6-*d-*1-ol-*d *from **6***: IR(neat) 2485(ν OD), 2170 cm^{-1} (ν CD). PMR($CDCl_3$) δ 3.67(2H, m, CH_2O), 1.38(8H, m, CH_2), 0.90(2H, m, CH_2D). MS *m/e* 102(M^+-2), 85, 67, 32.

*Cyclohexan-4-*d-*ol-*d *from **7***: IR(neat) 2489(ν OD), 2208, 2109 cm^{-1}(ν CD). PMR($CDCl_3$) δ 3.63(1H, m, CH), 1.78—1.32(9H, m, CH_2 and CHD). MS *m/e* 102(M^+), 83, 32.

Reaction of Aromatic Cyclic Ethers with Aluminum. To a mixture of 2,3-dihydrobenzofuran(5.7 ml, 50 mmol) and aluminum(1.4 g, 50 mg-atom) in benzene(15 ml) was added the catalyst, $HgCl_2$-$ZnCl_2$-MeI(4, 8, and 8 mol%, respectively). The mixture was heated at 80 °C for 100 h, hydrolyzed at 0 °C and then distilled. Deuterolysis of the product gave 2-ethyl-phenol-d_2 in 15% yield. IR(neat) 2558(ν OD), 2447 cm^{-1}(ν CD). PMR($CDCl_3$) δ 6.82(4H, m, CH), 2.59 (2H, q, CH_2), 1.20(2H, t, CH_2D). MS *m/e* 124(M^+). Phthalan had no reactivity toward aluminum even carrying out the reaction at 120 °C for 150 h. The reaction of 1,3-benzodioxole(6.1 g, 50 mmol) with aluminum(1.4 g) at 100 °C for 150 h resulted in the formation of catechol in 20% yield.

*Allylation of **1**—**3** with 3-Bromopropene.* To a stirred mixture of anhydrous 3-bromopropene(10.4 ml, 120 mmol) and $CuBr_2$(0.18 g, 0.8 mmol) was added compounds **1**—**3** (40 mmol) in benzene(30 ml). After the reaction was allowed to proceed at 80 °C for 20 h, products were hydrolyzed, filtered and distilled. Yields, 65—75%.

*6-Hepten-1-ol from **1***: IR(neat) 3340, 915 cm^{-1}. PMR ($CDCl_3$) δ 5.71, 4.90(3H, m, CH_2=CH), 3.65(2H, t, CH_2), 2.01(2H, m, CH_2), 1.87(1H, s, OH), 1.38(6H, m, CH_2). MS *m/e* 114(M^+).

*3-Methyl-6-hepten-1-ol from **2***. IR(neat) 3340, 915 cm^{-1}. PMR($CDCl_3$) δ 5.69, 4.95(3H, m, CH_2=CH), 3.63 (2H, t, CH_2), 2.02(2H, m, CH_2), 1.83(1H, s, OH), 1.63(1H, m, CH), 1.38(4H, m, CH_2), 0.94(3H, d, CH_3). MS *m/e* 127(M^+-1).

*2-Methyl-6-hepten-1-ol from **2***. IR(neat) 3350, 915 cm^{-1}. PMR($CDCl_3$) δ 5.68, 4.89(3H, m, CH_2=CH), 3.44(2H, d, CH_2), 2.05(2H, m, CH_2), 1.80(1H, s, OH), 1.65(1H, m, CH), 1.33(4H, m, CH_2), 0.98(3H, d, CH_3). MS *m/e* 127(M^+-1).

*7-Octen-2-ol from **3***. IR(neat) 3380, 915 cm^{-1}. PMR ($CDCl_3$) δ 5.78, 4.79(3H, m, CH_2=CH), 3.76(1H, m, CH), 1.99(2H, t, CH_2), 1.91(1H, s, OH), 1.38(6H, m, CH_2), 1.18 (3H, d, CH_3). MS *m/e* 127(M^+-1).

*Reaction of **1** with 1-Chloro-2-butene and 3-Chloro-1-butene.* A solution of **1**(5.4 g, 40 mmol) in benzene(30 ml) was added to a stirred mixture of anhydrous *trans*-1-chloro-2-butene (11.8 ml, 120 mmol) and $CuBr_2$(0.18 g, 0.8 mmol). The mixture was heated to 80 °C for 20 h and then hydrolyzed. Resulting two alcohols(with 1:1 ratio) were separated with GC. Typical yield, 63% based on **3**.

a) trans-*6-Octen-1-ol*: IR(neat) 3340(ν OH), 967(ν *trans* C=C). PMR($CDCl_3$) δ 5.42(2H, m, CH), 3.60(2H, t, CH_2O), 1.96(2H, m, CH_2), 1.82(1H, s, OH), 1.61(3H, m, CH_3), 1.38(6H, m, CH_2). MS *m/e* 128(M^+).

b) 5-Methyl-6-hepten-1-ol: IR(neat) 3370(ν OH), 920 cm^{-1}(ν C=C). PMR($CDCl_3$) δ 5.60, 4.95(3H, m, CH_2=CH), 3.63(2H, t, CH_2O), 2.05(1H, m, CH), 1.39(6H, m, CH_2), 0.99(3H, d, CH_3). MS *m/e* 128(M^+).

The same alcohols were obtained also from the reaction of 3-chloro-1-butene(12.7 ml, 120 mmol) with **1**(5.4 g) in 63% yield with 1:1 ratio.

*Addition of Methylene Iodide to **1**.* To a solution of **1** prepared from aluminum(1.4 g) and excess of tetrahydrofuran(40 ml) was added directly methylene iodide(16.1 ml, 0.2 mol) and the mixture was heated to 80° for 20 h. Distillation of the hydrolyzate gave 5-iodo-1-pentanol in 49% yield based on **1**. IR(neat) 3390(ν OH), 722 cm^{-1}(ν CI). PMR($CDCl_3$) δ 3.61(2H, t, CH_2O), 3.18(2H, t, CH_2I), 1.89 (1H, s, OH), 1.56(6H, m, CH_2). MS *m/e* 213(M^+-1).

*Reduction of Chloral with **1**—**3**.* To a solution of **1** (5.4 g, 40 mmol) in benzene(30 ml) was added dropwisely anhydrous chloral(11.8 g, 80 mmol) dried over calcium hydride with vigourous stirring at 20 °C. The mixture was heated at 60° for 3 h and then hydrolyzed. The resulting 2,2,2-trichloroethanol and 3-buten-1-ol obtained from the benzene fraction were identified with authentic samples. The yield of 3-buten-1-ol was 77% based on **1**. In the similar

manner, reduction of chloral with **2** gave 3-methyl-3-buten-1-ol(30%). Which was identified with the commercial sample, and also 2-methyl-3-buten-1-ol(70%). IR(neat) 3330 (ν OH), 905 cm^{-1}(ν CH_2=CH). PMR($CDCl_3$) δ 5.8—5.1 (3H, m, CH_2=CH), 3.68(2H, d, CH_2O), 2.01(1H, m, CH), 1.95(1H, s, OH), 1.33(3H, d, CH_3). MS *m/e* 86(M^+), 85. Typical yield was 70%. Reduction of chloral with **3** under the same reaction condition gave 4-penten-2-ol in 70% yield and it was identified with the authentic sample.

Photoreaction of 1-(1-Cycloalkenyl)-4-phenyl-1-butanone under Neutral and Acidic Conditions

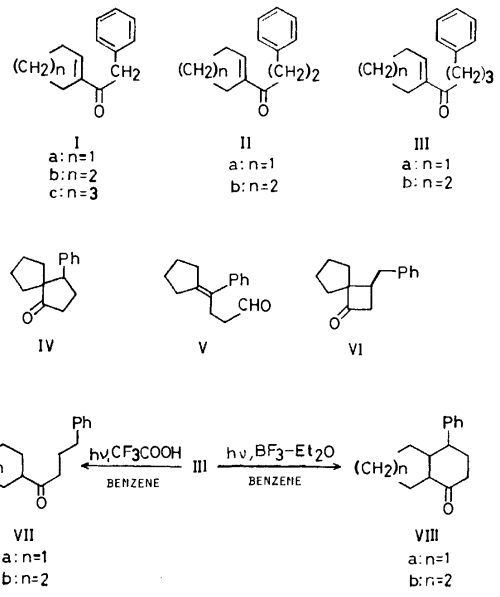
Masaru TADA, Tetsuro MAEDA, and Hiroshi SAIKI

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received October 29, 1977)

UV irradiation of 1-(1-cycloalkenyl)-4-phenyl-1-butanones gives differing products depending on the reaction conditions, neutral or acidic. In benzene 1-(1-cyclopentenyl)-4-phenyl-1-butanone gives 4-phenylspiro[4,4]-nonan-1-one, formed by the intramolecular abstraction of hydrogen, and 4-cyclopentylidene-4-phenylbutanal, formed by Norrish type I fission of the spiro ketone. 1-(1-Cyclohexenyl)-4-phenyl-1-butanone does not exibit this behavior. Both ketones give the reduction products, 1-cyclopentyl-4-phenyl-1-butanone and 1-cyclohexyl-4-phenyl-1-butanone, under the action of trifluoroacetic acid, and cyclized products, 7-phenylperhydro-4-indenone and 4-phenylperhydro-1-naphthelenone, under the action of boron trifluoride etherate. The reaction processes under acidic conditions have both an ionic and a free radical nature. The results have lead to the proposition of the mechanism involving electron transfer, proton transfer, and hydrogen abstraction.

Much attention has been paid to the intramolecular exciplex between two aromatic groups or between an aromatic moiety and a non-aromatic functional group.[1,2] It appears that the formation of the exciplex is dependent upon the length of the bridge connecting the two chromophores. Excited complexes have been postulated as the intermediates of intramolecular photochemical reactions.[3-5] Following the study on the photochemistry of 1-(1-cycloalkenyl)-2-phenyl-1-ethanones (Ia, Ib, and Ic)[6] and 1-(1-cycloalkenyl-3-phenyl-1-propanones (IIa and IIb),[7] the photoreactions of 1-(1-cycloalkenyl)-4-phenyl-1-butanones (IIIa and IIIb) having the trimethylene bridge between the enone and phenyl groups have been investigated. The UV irradiation of Ia, Ib, and Ic under acidic conditions or in protic media induces photo-coupling between the β-position of the enones and the ortho-position of the phenyl group.[6] Similarly the irradiation of IIb under acidic conditions gives the same type of photoproduct. Irradiation of IIa under neutral conditions, on the other hand, gives a product derived from the intramolecular abstraction of hydrogen by the β-carbon of the enone moiety.[7]



The 1-(1-cycloalkenyl)-4-phenyl-1-butanones (IIIa and IIIb) have a trimethylene bridge by which the two chromophores may be expected to interact more effectively than I or II.[3-5] The present study demonstrates that the photochemical behavior of III is completely different from that of I and II.

Results and Discussion

Photoreaction under Neutral Conditions. Irradiation (10 h) of a solution of 1-(1-cyclopentenyl)-4-phenyl-1-butanone (IIIa) in benzene gave a spiro ketone IV and an aldehyde V in 24 and 17% yields, respectively. The structures of IV and V were deduced from spectral data. The IR absorptions of IV at 1735, 765, and 700 cm^{-1} show the presence of a five membered ketone and a monosubstituted benzene ring. The IR absorption at 2710 cm^{-1} and NMR signal at δ 9.85 (t, J=2 Hz) of V are due to an aldehyde group, and the IR absorptions at 775 and 700 cm^{-1} show the presence of a monosubstituted benzene ring. The IR absorption of the crude product from the irradiation of IIIa showed an absorption at 1774 cm^{-1} and this indicated the product VI having a cyclobutanone structure. This minor product, which was not isolated, appears to be formed by the intramolecular abstraction of the hydrogen at C_3-methylene by the β-carbon of the enone moiety of IIIa.[7] The product IV appears to be formed by the intramolecular abstraction of the benzylic hydrogen by the β-carbon of the enone moiety of IIIa. The formation of aldehyde V showed an induction period and hence V appears to be a secondary product from IIIa through the spiro ketone IV. This was ascertained by the direct irradiation of IV. Norrish type I fission of IV and hydrogen transfer account for the transformation of IV to V.

1-(1-Cyclohexenyl)-4-phenyl-1-butanone (IIIb) in benzene, in contrast, did not react even after prolonged irradiation (24 h). This may be explained in terms of the preferential dissipation of the excited energy due to the cis-trans isomerization of the cyclohexene moiety.[8]

Photoreaction under Acidic Conditions. A solution of 1-(1-cyclopentenyl)-4-phenyl-1-butanone (IIIa) or 1-(1-cyclohexenyl)-4-phenyl-1-butanone (IIIb) in benzene

Table 1. Yield of VIIa from IIIa (0.1 M in toluene) depending upon the amount of CF_3COOH

CF_3COOH (M)	Yield of VIIa (%)
0.03	trace
0.06	44
0.12	76
0.23	84

was irradiated for 32 or 70 h in the presence of 0.05 M trifluoroacetic acid, giving the dihydro derivatives VIIa and VIIb in yields of 63 and 40%, respectively. GLC analysis of the product mixture showed the formation of 1,2-diphenylethane and carbon dioxide when the reaction of IIIa was carried out in degassed toluene. The yield of VIIa was dependent on the amount of trifluoroacetic acid used and was improved up to 84% by using two equivalents of the acid in toluene (Table 1). These results demonstrate the involvement of free radical hydrogen abstraction and the degradation of trifluoroacetic acid. The photoreaction of IIIa in 2-propanol, however, did not give the reduction product, and this suggests that the reaction takes a mechanism other than a simple hydrogen abstraction from the solvent. Under the conditions in which essentially entire incident light was absorbed in the $n\pi^*$ region of IIIa, the relative rates of the photoreduction (relative quantum yield in the approximation) were dependent on the molar polarization of the solvent used as seen in Fig. 1. The figures in parentheses in Fig. 1 are the relative rates of hydrogen abstraction by an excited benzophenone.[9] The retardation of the photo-reduction in benzene, an extremely poor hydrogen donor, explain this behavior. This suggests the polar nature of the photo-reduction and some dependence on the hydrogen donating ability of the solvent. The photo-reduction takes place only in the presence of a strong Brønsted acids such as trifluoroacetic acid (pK_a: 0.2). The weaker acids like benzoic acid (pK_a: 4.20), acetic acid (pK_a: 4.75), or phenol (pK_a: 10.00) can not induce the reaction.

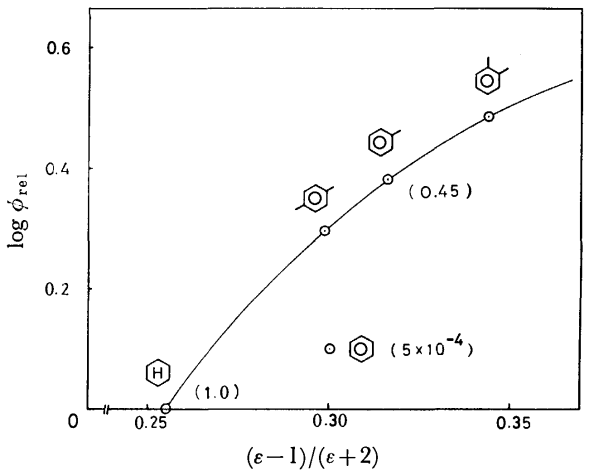


Fig. 1. Relation between the relative quantum yield of VIIa and the polarization of solvents. (The figures in parentheses are the relative rates of H-abstraction by an excited benzophenone.[9])

A solution of 1-(1-cycloalkenyl)-4-phenyl-1-butanone (IIIa and IIIb) in benzene containing 0.05 M boron trifluoride etherate was irradiated for 20 h, the cyclized products VIIIa and VIIIb were obtained in 25 and 30% yields, respectively. The structures of products VIIIa and VIIIb were deduced from permanganate oxidation which gave banzoic acid and spectroscopic data (VIIIa, 1705, 760, and 700 cm^{-1}; VIIIb, 1710, 760, and 700 cm^{-1}). These data indicate the presence of a six-membered ketone and a monosubstituted benzene ring. Though the stereochemistry of the products VIIIa and VIIIb was not defined, only one of the possible stereoisomers was detected by GLC analysis. This type of ortho-cyclization also took place under catalysis of other Lewis acids such as tin(IV) chloride and titanium(IV) chloride (0.05 M). The reaction in hydrogen donating solvents such as toluene and xylene in the presence of boron trifluoride etherate did not give the products VIIIa and VIIIb in reasonable yields but gave the reduction products VIIa and VIIb predominantly (see next section).

Reaction Mechanism. The two types of reaction do not take place in the absence of trifluoroacetic acid or a Lewis acid and do not occur intermolecularly between 1-acetylcyclopentene (0.1 M) and tuluene under the same reaction conditions as for IIIa. This result indicates that an intramolecular interaction between the phenyl group and the enone moiety, at least in the excited state, is necessary for the photoreaction of IIIa and IIIb under acidic conditions, and that the existence of an acid must enhance the interaction. The UV-spectra of IIIa and IIIb are essentially the same as the spectrum of the 1:1 mixture of 1-acetylcyclopentene or 1-acetylcyclohexene and toluene, and therefore there is no evidence for the interaction between the two chromophores in the ground state. The enone moieties of IIIa and IIIb are nonemissive and only a weak fluorescence from the aromatic moieties may be observed. The intensity is much weaker than that of toluene and this is thought due to the efficient quenching of the excited state of the aromatic moiety by the intramolecular enone group. An α,β-unsaturated ketone has the intrinsic ability to quench the excited singlet state of an aromatic molecule. Thus 1-acetylcyclopentene quenched the fluorescence of toluene, 1-methylnaphthalene, and anthracene by diffusion controlled-rates (10^9—10^{10} M^{-1} s^{-1}). The quenching rates were obtained from the slopes of Stern-Volmer plots ($k_q\tau_0$) and the reported lifetimes (τ_0) of the aromatic compounds.[10] The weak fluorescence of IIIa and IIIb is suggested due to the strong intramolecular interaction between the two chromophores in the singlet excited state. For the acid-coordinated species of IIIa and IIIb, the interaction between the two chromophores would be expected to be CT-type and the excitation of either a donor (aromatic moiety) or an acceptor (enone moiety) promotes the interaction. Though the excited state responsible for the photoreactions cannot be specified, the excitation of either chromophore must form an essentially similar CT-state. In addition it is highly possible that the photoreaction of IIIa and IIIb occurs from the new CT-excitation

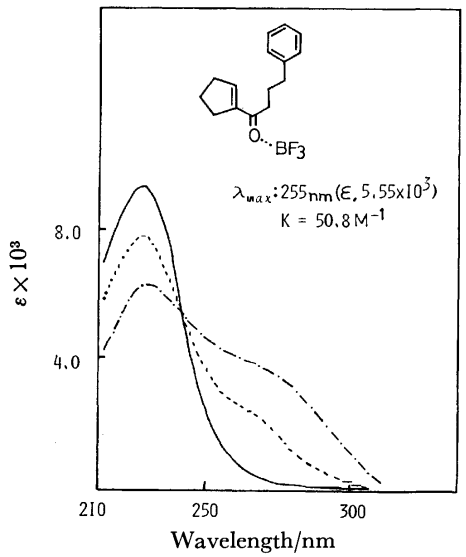

Fig. 2. UV absorption of IIIa (1.26×10^{-4} M in hexane) in the presence of BF_3-Et_2O: ——, 0 M; ----, 1.06×10^{-2} M; —·—·, 2.65×10^{-2} M.

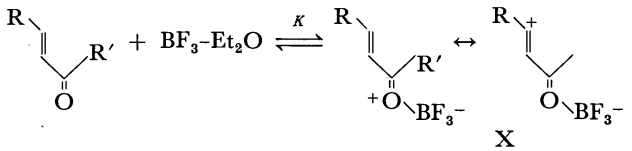
indicated by the UV spectra of IIIa and IIIb in the presence of an acid.

In the presence of boron trifluoride etherate, the UV spectrum of IIIa in hexane (2.52×10^{-4} M) shows a broad band at around 260 nm with concomitant decrease in $\pi\pi^*$ absorption at 232 nm as shown in Fig. 2. The analysis of the spectrum having an isosbestic point at 242 nm by the Rose-Drago's method,[11] monitoring at 250, 260, 270, and 280 nm, gave λ_{max}^{hexane} 255 nm (ε 5550) and the stability constant $K=50.8\ M^{-1}$ for the complex X between IIIa and boron trifluoride. The complexing of boron trifluoride to α,β-unsaturated ketones has been reported by UV,[12] IR,[13] and NMR[14] spectra. A similar behavior was observed with trifluorocetic acid (10^{-3}—10^{-2} M) in the $n\pi^*$ region of IIIa in higher concentration (1.26×10^{-2} M), though the dilute solution of IIIa (1.26×10^{-4} M) showed only a slight bathochromic shift in $\pi\pi^*$ region. These results indicate that the enone IIIa is coordinated



effectively with a Lewis acid or a strong Brønsted acid under the reaction conditions—enone III 0.1 M and acid 0.05—0.06 M. The necessity for acid in the two types of photoreactions, suggests the direct involvement of the acid-coordinated form (X) of the starting ketone. The quenching of the photo-products VIIa and VIIIa by 1,3-pentadiene gave linear Stern-Volmer plots with $k_q\tau$ value of 88 M^{-1} for VIIa and 158 M^{-1} for VIIIa. If this quenching is due to the energy transfer from the triplet enone to the diene, the quenching rates would be expected to be diffusion-controlled ($k_p=ca.\ 10^{10}\ M^{-1}\ s^{-1}$), and the lifetime ($\tau$) of the triplet enone would fall into 10^{-9}—10^{-8} s. These values are too small for the normal triplet species and hence the quenchable intermediate appears to be a singlet or triplet species with an unusually short lifetime.

TABLE 2. SOLVENT EFFECT ON THE YIELD OF VIIa AND VIIIa FROM IIIa (0.1 M)

BF_3-Et_2O (0.05 M) solvent	Yield of VIIa (%)	Yield of VIIIa (%)	CF_3COOH (0.05 M) solvent	Yield of VIIa (%)	Yield of VIIIa (%)
Benzene	1.5	25	Benzene	43	7
Toluene	18	1.0	Toluene	80	2
o-Xylene	26	0	*o*-Xylene	80	0
Cyclohexane	8	1.3	Cyclohexane	29	4
			Hexane	16	3

The photoreactions in benzene were selective with the acid used. The reaction under boron trifluoride etherate gave the cyclized product VIII whereas the reaction under trifluoroacetic acid gave largly the reduction product VII. The variation in the yields are listed in the Table 2. The reaction in the hydrogen donating solvents such as toluene and *o*-xylene gave largly the reduction product found under both trifluoroacetic acid and boron trifluoride etherate. Thus the hydrogen donating ability of the solvent appears to be an important factor in the discrimination of the two types of photoreactions.

For the photoreaction of ketone IIIa and IIIb the mechanism shown in Fig. 3 is proposed on the basis of the experimental results; (a) the radical and ionic nature of the photochemical process, (b) the degradation of trifluoroacetic acid to carbon dioxide, (c) the necessity and reality of the intramolecular interaction in the excited state, (d) the existence of acid coordination to the enone and its enhancement of the intramolecular interaction between the two chromophores, (e) quenching, and (f) the solvent effect on the yield and distribution of products.

Excitation of the acid-coordinated enone—$n\pi^*$ excitation or direct CT-excitation of the complex X—forms an intramolecular singlet excited complex (X*) having CT-character, in which the phenyl group works as as an electron donor and the enone group works as an electron accepter. An electron transfer in this excited complex gives a radical ion pair XI. When the acid A is BF_3, the loss of BF_3 and the simultaneous proton transfer from the benzylic position to oxygen gives a

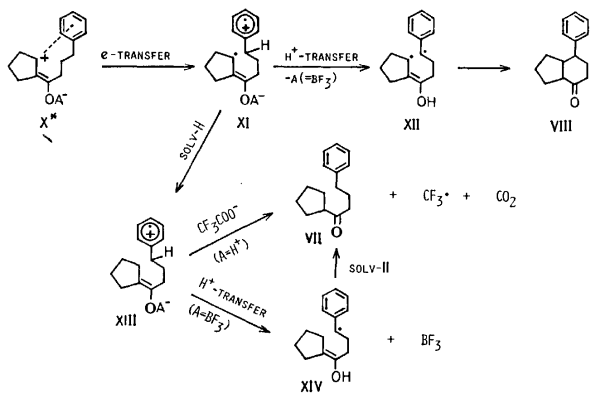


Fig. 3. Reaction scheme.

diradical XII, and the coupling of the diradical forms the photo-cyclization product VIII. In hydrogen donating solvents, the hydrogen abstraction by XI from the solvent gives a radical ion XIII. When the acid is CF_3COOH, another electron transfer from CF_3COO^- to XIII forms the reduction product VII and carbon dioxide. When the acid A in XIII is BF_3, the proton transfer from benzylic position to oxygen with simultaneous loss of BF_3 gives the benzyl radical XIV which forms the reduction product VII by another hydrogen abstraction from the solvent. This reaction mechanism accounts for solvent-polarity, the hydrogen donating ability of the solvent, and the acid—Brønsted or Lewis acid—on the product formation. The photoreactions observed for III were not observed in the case of I and II. The variation in the reactivity upon reaction conditions was again not observed with I and II. The interaction between the two chromophores in the excited state of III appeares to be stronger than that in I and II.[15] Evidently the trimethylene bridge combining the phenyl and the enone groups in III appeares to be an important factor for the different reactivity of III from those of I and II.

Experimental

Preparation of 1-(1-Cyclopentenyl)-4-phenyl-1-butanone (IIIa) and 1-(1-Cyclohexenyl)-4-phenyl-1-butanone (IIIb). Ketones IIIa and IIIb were synthesized from 4-phenylbutanoyl chloride and cycloalkene by the modified method of Cook and Hawett[16] for the synthesis of 1-(1-cyclohexenyl)-2-phenyl-1-ethanone (Ib). Dichloromethane was the solvent instead of carbon disulfide and $SnCl_4$ the acid catalyst. The reaction was carried out at a lower temperature (−80—−100 °C) under an atmosphere of nitrogen. Under these conditions clean 1-(2-chlorocycloalkyl)-4-phenyl-1-butanone was the product. 1-(2-Chlorocyclopentyl)-4-phenyl-1-butanone was dehydrochlorinated by refluxing the benzene solution in the presence of triethylamine. 1-(2-Chlorocyclohexyl)-4-phenyl-1-butanone was dehydrochlorinated in *N,N*-dimethylaniline at 180 °C. IIIa; bp 152 °C/0.3 mmHg. MS *m/e* 214 (M^+). IR(neat): 1655, 1613, 745, and 690 cm^{-1}. NMR(CCl_4): δ 7.20 (5H, m) and 6.80 (1H, br s). Semicarbazone; mp 123.5—125.0 °C. Found: C, 70.99; H, 7.85; N, 15.48%. Calcd for $C_{16}H_{21}N_3O$: C, 70.82; H, 7.80; N, 15.48%. IIIb; bp 115—120 °C/0.1 mmHg. MS *m/e* 228 (M^+). IR(neat): 1655, 1610, 750, and 700 cm^{-1}. NMR(CCl_4): δ 7.20 (5H, m), and 6.80 (1H, br s). Semicarbazone; mp 145 °C. Found: C, 71.73; H, 8.28; N, 14.96%. Calcd for $C_{17}H_{23}N_3O$: C, 71.54; H, 8.12; N, 14.73%.

Absorption and Emission Spectra of IIIa and IIIb. Hexane and cyclohexane were purified by passing over a long column of activated silica gel. The effect of BF_3-Et_2O on the absorption spectrum of IIIa was studied in hexane (IIIa, 2.52×10^{-4}M) containing 1.06—2.65×10^{-2} M BF_3-Et_2O in both sample and reference cells, and the results are shown in Fig. 2. The effect of CF_3COOH was studied in the same manner by using 1.26×10^{-4}M solution of IIIa and 1.44×10^{-3}—4.40×10^{-2}M CF_3COOH in hexane, and the $\pi\pi^*$ absorption shifted from 232 to 242 nm. The effect of CF_3COOH on $n\pi^*$ band was studied by using 1.26×10^{-2}M solution of IIIa and 2.63×10^{-3}—2.30×10^{-2}M CF_3COOH in hexane, and an isosbestic point was observed at 333 nm. Fluorescence spectra were measured by a Hitachi MPF-4 spectrophotometer using cyclohexane purged by argon as solvent. IIIa fluoresces weakly at 300—350 nm and it appeares in the same region to the $n\pi^*$ absorption of IIIa. The weakness of the fluorescence is not thought entirely due to the absorption by the enone at the concentrations for the measurement of fluorescence($<10^{-3}$ M). The concentrations of toluene and IIIa in hexane were adjusted to absorb the same quanta of light at 270nm for the measurement of the relative intensity of fluorescence. The intensity of fluorescence from IIIa under these conditions was much weaker than that of toluene, Φ(toluene)/Φ(IIIa)$>$200.

Fluorescence Quenching of Aromatic Compounds by 1-Acetylcyclopentene. The hexane solutions of (a) toluene (1.90×10^{-3} M), (b) 1-methylnaphthalene (1.45×10^{-3} M), and (c) anthracene (1.40×10^{-3}M), were used for the quenching experiments and were excited at 260nm (a), and 300 nm (b, c). The intensities of fluorescence were monitored at the emission maxima at 283 (a), 325 (b), and 400 nm (c). The concentration limits of the quencher, 1-acetylcyclopentene, were 3.64×10^{-4} to 5.82×10^{-3}M. The slopes of the Stern-Volmer plots ($k_q\tau_0$) were 427 (a), 265 (b), and 84 M^{-1} (c).

Irradiation of IIIa and IIIb under Neutral Conditions. The solution of IIIa (700 mg) in 150 ml of thiophene-free benzene was internally irradiated by a 450W high pressure mercury lamp mounted in a Pyrex cooling jacket. During the reaction the solution was stirred magnetically and kept in an atmosphere of argon. Reaction products were obtained by distillation, 100—120 °C/0.1mmHg, after evaporation of the solvent *in vacuo*. GLC analysis (5% PEG-20M on Chromosorb W, 200 °C) of the crude product showed two main peaks attributed to spiro ketone IV and aldehyde V beside small peaks attributed to the starting material IIIa and a minor product. The aldehyde V was collected by preparative GLC (120 mg, 17%). Since the spiro ketone IV was difficult to purify by preparative GLC, the aldehyde was destroyed by AgO treatment[17] of the crude product before GLC, IV (170 mg, 24%).

Irradiation of IIIb in the same manner did not give the product but recovered the starting material. IV, an oil. *MW* Found: *m/e* 214.1342. Calcd for $C_{15}H_{18}O$: *m/e* 214.1357. IR(neat): 1735, 765, and 700 cm^{-1}. NMR(CCl_4): 7.30 (5H, m). V, an oil, *MW* Found: *m/e* 214.1342. Calcd for $C_{15}H_{18}O$: *m/e* 214.1357. IR(neat): 2710, 1728, 775, and 700 cm^{-1}. NMR(CCl_4): δ 9.85 (1H, t, J=2 Hz), 7.20 (5H, m), and 2.68 (2H, t, J=7 Hz).

Photoreaction of IIIa and IIIb in the Presence of CF_3COOH.

a) Preparative Experiment: The solution of IIIa or IIIb (500 mg) in 140 ml of thiophene-free benzene was purged by argon and CF_3COOH added to make 0.05M CF_3COOH. Irradiation was carried out (32 h for IIIa and 70 h for IIIb) in the same manner as described for the photoreaction of IIIa in benzene. The reaction solution was passed through an alumina column to remove the acid and concentrated *in vacuo*. Distillation of the residue by a Kugelrohr apparatus gave product VIIa (*ca.* 110 °C/0.1 mmHg) in 63% yield and VIIb (*ca.* 120 °C/0.1 mmHg) in 40% yield. The products VIIa and VIIb were identified by IR, NMR, and GLC analyses with the authentic samples prepared by hydrogenation of IIIa and IIIb over Pd-C catalyst.

b) Detection of Carbon Dioxide: The solution of IIIa (50 mg) in toluene (4 ml) containing 0.05 M CF_3COOH was degassed by the freeze-thaw method and kept under an atomosphere of argon. After irradiation for 9 h, 3 ml of the gaseous layer was introduced into GLC (3 mm $\phi\times$

2.25 m silica gel 60/80 mesh, room temperature). The relative peak intensity of carbon dioxide from the irradiated sample and the sample kept in the dark was 16:1.

c) Solvent Effect: Enone IIIa was dissolved in cyclohexane, benzene, toluene, *p*-xylene and *o*-xylene to make the concentration of each solution to be 0.21M. This concentration was enough to absorb more than 99% of the incident light from the lamp in the $n\pi^*$ region of the enone. To each solution was added 50 μl of CF_3COOH (0.32M) and the solution in the Pyrex tube was irradiated under argon using a Rikosha merry-go-round type irradiation apparatus equiped with a 450W high pressure mercury lamp. The relative rates—the relative quantum yield—of the product were determined by GLC analysis of the product using 3-phenyl-1,3-dihydroisobenzofuran-1-one as an internal reference. The results are shown in Fig. 1.

Photoreaction of IIIa and IIIb in the Presence of Lewis Acid. a) Preparative Experiments: The solution of IIIa or IIIb (800 mg) in 150 ml of thiophene-free benzene containing a Lewis acid (0.05M) was irradiated for 20 h in the same manner as described for the reaction in benzene. The Lewis acid was removed by passing an alumina column by benzene. Alumina chromatography eluted by hexane-dichloromethane and recrystallization from hexane gave the cyclized product VIIIa (25%/BF_3–Et_2O, 63%/$SnCl_4$) or VIIIb (30%/BF_3–Et_2O). The reactions on other solvents are summarized in Table 2. VIIIa; mp 78 °C. Found: C, 84.00; H, 8.54%. Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%. MS *m/e* 214(M^+). IR(neat): 1705, 760, and 700 cm^{-1}. NMR(CCl_4): δ 7.26 (5H, m) and 3.30—3.60 (1H, m). VIIIb; mp 82 °C. Found: C, 84.11; H, 8.85%. Calcd for $C_{16}H_{20}O$: C, 84.16; H, 8.83%. MS *m/e* 228 (M^+). IR(neat): 1710, 760, and 700 cm^{-1}. NMR(CCl_4): δ 7.00 (5H, m) and 3.00—3.40 (1H, m).

b) Solvent Effect: The 0.1 M solution of IIIa in 8 ml of cyclohexane, benzene, toluen, or *o*-xylene containing 0.05 M BF_3–Et_2O was irradiated for 20 h in the same manner as the irradiation of IIIa in the presence of CF_3COOH. The products VIIa and VIIIa were analyzed by GLC (3% OV-17 on Chromosorb W, 190 °C) using an internal reference and the results are summarized in Table 2.

Permanganate Oxidation of the Product VIIIa and VIIIb. The mixture of the one of the products (10 mg) and $KMnO_4$ (36 mg) in 1 ml of water was stirred for 15 h at room temperature. The reaction mixture was extracted with benzene after addition of concd-HCl and the extract treated with an ethereal solution of diazomethane. The methyl ester was identified as methyl benzoate by GLC analysis (3% OV-17 on Chromosorb W). No trace of methyl phthalate was detected.

Quenching Experiments. a): Six Pyrex tubes containing enone IIIa (25 mg), CF_3COOH (15 μl), and dried toluene (3 ml) had 0, 3, 6, 10, 12, and 15μl of 1,3-pentadiene added. The solutions were irradiated using a merry-go-round apparatus for 2 h. After passing the solution through alumina, each sample was analyzed by GLC using an internal reference. Stern-Volmer plots of the product formation gave a linear plot with $k_q\tau$ value of 88 M^{-1}.

b): The mixture of IIIa (21.8 mg), BF_3–Et_2O (20 μl), and benzene (3 ml) containing varing amounts of 1,3-pentadiene was irradiated for 35 h in the same manner as the experiment (*a*) in this section. The product was identified by GLC using ethyl oleate as an internal reference. The Stern-Volmer plots of the product formation were found to be linear having a $k_q\tau$ value of 158 M^{-1}.

Magnitude of Mercury Levels in Fish Muscle Tissue from South Carolina Waters

Andrew K. Koli and Edward McClary

South Carolina State College, Orangeburg, South Carolina 29117 U. S. A.

(Received November 13, 1976)

Many of the world's great gastronomic materpieces are based on fish from both freshwater and saltwater. The danger for human health, due to fish consumption, has been very well recognized. A survey of mercury residues in freshwater fish was undertaken to see if the problem of the magnitude of mercury contamination was evident in the South Carolina Fishery. These investigations were initiated to determine mercury levels in fish from a variety of South Carolina Waters. Samples of fish from freshwater sources all over the state of South Carolina were collected during 1974 and 1975. The species composition of the collections generally reflects the fish populations of the water sampled. Mercury determinations were made on 100 samples of fish taken from 22 locations covering 46 South Carolina counties. Triplicate samples of fish tissues were analyzed using flameless atomic absorption procedures. Findings of this report are that magnitude of mercury levels of fish from Lake Jocassee and Edisto River have been found to be higher than other waterways surveyed. Mercury levels exceeding the U. S. Food and Drug Administration guideline of 0.5 ppm have been found in Brown Trout, Pike and Mudfish. Different patterns of mercury concentration occurred between different tissues. Larger fish contain higher concentration of mercury than do smaller fish of the same species.

A survey of mercury residues in freshwater fish was undertaken in July 1974. These investigations were initiated to determine mercury levels in fish from a variety of South Carolina waters. The survey was undertaken to see if the problem of the magnitude of mercury contamination was evident in the South Carolina Fishery. The danger for human health, due to fish consumption, has been very well recognized. The first known cases of human poisoning from fish contaminated with methylmercury were reported in Japan, on Minamata.[1,2] Samples of fish from freshwater sources all over the state of South Carolina were collected during the summers of 1974 and 1975. Mercury determinations were made on 100 samples of fish taken from 22 locations covering 46 South Carolina counties. The species composition of the collections generally reflects the fish populations of the waters sampled. Triplicate samples of fish tissue were analyzed using flameless atomic absorption procedures out-lined by Hatch and Ott.[3] The significant findings of this report are that magnitude of mercury levels of fish from Lake Jocassee and Edisto River have been found to be higher than other waterways surveyed. Mercury levels exceeding the U.S. Food and Drug Administration guideline of 0.5 ppm for muscle tissue have been found in Brown Trout, Pike and Mudfish. Different patterns of mercury concentration occurred between different tissues. Larger fish contain higher concentration of mercury than do smaller fish of the same speices as reported by Scott and Armstrong.[4]

Experimental

Sample Collection. Samples of fish from freshwater sources of lakes, rivers, streams and ponds all over the state of South Carolina were collected during the summers of 1974 and 1975. Lakes include Marion, Moultrie, Murray, Clark Hill, Keowee, Wateree, Jocassee, Greenwood, Hartwell, Wylie, Robinson, Secession, and Cherokee Falls and rivers include Edisto River and Savannah River.

The fish collected were Bluegill (*Lepomis macrochirus*), White Bass (*Roccus crysops*), Largemouth Bass (*Micropeterus salmoides*), Brown Trout (*Salmo trutta*), Channel Catfish (*Ictalurus Punctatus*), Pike (*Esox lucius*), Black Crappie (*Pomoxis nigromaculatus*), Redbreast (*Lepomis auritus*), Shad (*Alosa sapidissima*), Warmouth (*Lepomis gulosus*), Striped Bass (*Roccus saxatilis*), Mudfish (*Amia calva*), Jackfish (*Caranx hippos*), Shiner (*Notropis spp*), and Carp.

Wet Digestion. Fish tissue, 0.2 to 0.3g were weighed accurately and placed in the bottom of a clean dry Erlenmeyer flask which is closed with a polyethylene stopper. Samples were digested with 5 ml of 9M sulfuric acid and 1 ml of 5.6M nitric acid mixture. The sample flasks were incubated in a shaking water bath at 58°C until the tissue was completely dissolved giving a clear solution (50—60 min). Sample flasks were removed from the bath and allowed to cool in ice. Chemical oxidation of the samples were carried out by addition of 5 ml of 5% potassium permanganate slowly with swirling in each flask. Samples were kept overnight before analysis without apparent loss of mercury. Enough water was added to make the total volume approximately 125 ml. 1.5% Hydroxylamine hydrochloride solution, 5 ml, was added to reduce the excess permanganate. After 30 s, 5 ml of 10% Tin(II) chloride solution was added and immediately attached the flask to the aeration system.[5]

Mercury Determination by Atomic Absorption. Digests were analyzed using flameless atomic absorption spectrophotometry procedures outlined by Hatch and Ott[3] and Uthe *et al.*[5] as modified for use with a Perkin Elmer, Coleman MAS-50 mercury analyzer. Determination of mercury in fish tissue was measured in parts per million (ppm). The analytical error was $\pm 10\%$ at 0.1 ppm mercury level.

Results and Discussion

Mercury determinations were made on 100 samples taken from 22 locations covering 46 South Carolina counties. The species composition of the collections generally reflects the fish populations of the waters sampled. All South Carolina fish analyzed countained mercury. Mercury levels in fish averaged 0.13 ppm and ranged between 0.02 and 0.64 ppm.

Different species vary in mercury content and larger fish contain higher concentrations of mercury than do small fish of the same species taken from the same water. Pike, Mudfish, Brown Trout and Largemouth Bass showed higher mercury concentrations, while the pan-

fishes, including Bluegill, Redbreast, Shad, Warmouth, Catfish, Carp, Shiner often showed low concentrations.

Mercury levels exceeding the U.S. Food and Drug Administration guideline of 0.5 ppm for flesh have been found in Pike, Trout and Mudfish. No fish weighing less than a thousand grams had mercury levels above the currently accepted guideline of 0.5 ppm. Of the three fish weighing more than a thousand grams whole body weight, a Pike (1.0 kg) had muscle mercury levels of 0.64 ppm; Mudfish (2.0 kg) had muscle mercury levels of 0.63 ppm and Brown Trout (1.9 kg) had muscle mercury levels of 0.53 ppm.

Concentrations increased with increased body weight and biological amplification or magnification of mercury occurred through the food chain. Mudfish feeds on the bottom sediments and that might be the reason for higher mercury content. Pike and Trout seem to have higher mercury levels because of their predatory (carnivorous) eating habits.

Mercury levels in fish samples taken from Lake Secession ranged from 0.03 to 0.21 ppm; Lake Wylie ranged form 0.02 to 0.04 ppm; Lake Wateree ranged from 0.02 to 0.06 ppm; Lake Robinson ranged from 0.03 to 0.05 ppm; Lake Jocassee ranged from 0.02 to 0.58 ppm; Lake Moultrie ranged from 0.03 to 0.16 ppm; Edisto River ranged from 0.36 to 0.63 ppm; Lake Murray ranged from 0.06 to 0.64 ppm; Lake Hartwell ranged from 0.03 to 0.14 ppm; Lake Keowee ranged from 0.04 to 0.12 ppm; Lake Marion ranged from 0.03 to 0.18 ppm; Lake Clark Hill ranged from 0.02 to 0.07 ppm; Lake Greenwood ranged from 0.02 to 0.08 ppm; Savannah River ranged from 0.06 to 0.17 ppm and Lake Cherokee Falls ranged from 0.04 to 0.19 ppm (Table 1).

Mercury levels in Bluegill taken from Lake Jocassee and Edisto River were about one order higher than all other lakes and rivers surveyed. Matsunaga[6] has reported that mercury levels in fish taken from rivers containing mercury of 0.02 μg/l were about one order higher than natural rivers containing mercury of 0.002 μg/l. Thus, the higher levels of mercury found in both Edisto River and Lake Jocassee Fish can be related to pollution due to exposure to waters from sewege, agricultural drainage, industry waste water, and surface pollutants.

In this study, mercury in waters and in sediments was also determined (Tables 2 and 3). The mercury levels of water from Lake Jocassee and Edisto River were higher than all other Lakes and Rivers.

Relative Mercury Content of Fish Tissues. The mercury levels in different tissues, liver, kidney, muscle, skin, bone, gills, scales, fin, gonads, brain, stomach, spleen and heart of Brown Trout were determined. It seems different patterns of mercury concentration occur between tissues (Fig. 1). This was concluded from the analysis of Brown Trout from Lake Jocassee. We selected this species as an ideal to find out patterns of mercury levels in different tissues, since it had more than 0.5 ppm mercury content which is the upper limit according to Food and Drug Administration guideline.

The mercury content of fin, eye, scales, skin, bone,

Table 2. Water qtality data

Sample station	pH	Mercury level (μg/l)
Lake Jocassee	6.3	0.025
Edisto River	6.5	0.026
Lake Wylie	6.8	<0.01

Sample station	Sediment type	Mercury level in dry weight (ppm)
Lake Jocassee	Coarse sand	0.07
Edisto River	Coarse sand	0.06
Lake Wylie	Fine sand	0.02
Lake Wateree	Fine sand	0.02
Lake Robinson	Fine sand	0.02
Lake Moultrie	Fine sand	0.01
Lake Murray	Fine sand	0.01
Lake Hartwell	Fine sand	0.03
Lake Keowee	Fine sand	0.03
Lake Marion	Fine sand	0.02
Lake Clark Hill	Fine sand	0.01
Lake Greenwood	Fine sand	0.02
Savannah River	Fine sand	0.03
Cherokee Falls	Fine sand	0.01

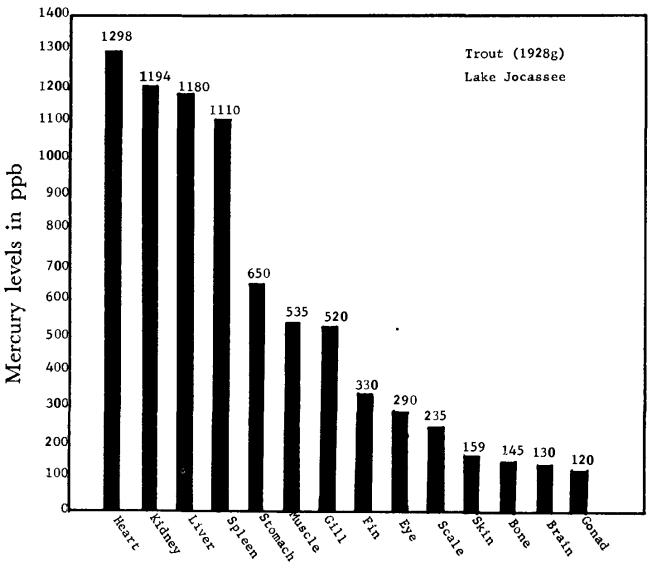

Fig. 1. Relative mercury content of fish tissues of Brown Trout.

brain and gonads was relatively low. Stomach, muscle and gills were intermediate in mercury content. Higher levels of mercury occurred in liver, kidney, spleen and heart (Fig. 1). It seems highly vascularized blood tissues had the highest mercury content than other tissues analyzed. The patterns of concentration occurred between tissues seemed characteristics of species, and suggests that patterns of uptake, accumulation and elimination differ between species.

Conclusions

The significant findings of this report are that magnitude of mercury levels of fish from Lake Jocassee and Edisto River have been found to be higher than other waterways surveyed. Carnivorous and bottom-feeding fishes are the most reliable indicators of mercury pollution. Mercury levels exceeding the U.S. Food and Drug Administration guideline of 0.5 ppm for muscle tissue have been found in Brown Trout, Pike and Mudfish. Different patterns of mercury concentration occurred between different tissues Larger fish contain higher concentration of mercury than do smaller fish of the same species.

Investigation on the Lanthanoid Chelates of 1-Phenyl-3-methyl-4-benzoyl-5-pyrazolone. An Examination of the Phenomenon of Hypersensitivity

Ajoy Roy and K. Nag*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received February 25, 1977)

1-Phenyl-3-methyl-4-benzoyl-5-pyrazolone (Hpmbp) form complexes with lanthanoids of the type $Ln(pmbp)_3 \cdot nH_2O$ ($n=4$ for La—Sm, and $n=1$ for Eu—Yb and Y), $Ln(pmbp)_3 \cdot 2pyridine \cdot 2H_2O$, $Ln(pmbp)_3 \cdot (2,2'\text{-bipyridine/}1,10\text{-phenanthroline}) \cdot C_2H_5OH$, $NH_4[Ln(pmbp)_4] \cdot C_2H_5OH$ and $Q^+[Ln(pmbp)_4] \cdot C_2H_5OH$, where Q^+ is the quaternary ammonium cation of piperidine, pyrrolidine or morpholine. These compounds have been characterized from physicochemical studies. The electronic spectra of the Nd(III) complexes have been studied in detail to investigate the phenomenon of hypersensitivity with respect to the coordination environment and solvent medium. In these compounds solvent does not play a significant role to cause variation in hypersensitivity. The oscillator strengths of the hypersensitive transition in these compounds show the following trend: $Q^+[Nd(pmbp)_4] > Nd(pmbp)_3 \cdot phen > Nd(pmbp)_3 \cdot bpy > Nd(pmbp)_3 \cdot 2py \cdot 2H_2O > Nd(pmbp)_3 \cdot 2H_2O$. In the Pr(III) complexes the band due to $^3H_4 \rightarrow {}^1D_2$ transition has been found to be hypersensitive, and the gradation of intensity due to this band follows almost the same trend as in the corresponding Nd(III) complexes.

Since the introduction of 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (Hpmbp) as a chelate-forming extractant by Jensen[1] extensive studies have been made on the use of this reagent for solvent extraction and separation of various metal ions[2,3]. The versatility of Hpmbp is comparable to the more popular extractant thenoyltrifluoroacetone (Htta).[4] In previous publications[5,6] we have reported solvent extraction behavior of the entire lanthanoid series using Hpmbp as the extractant and have noted the "tetrad effect" in the series.

Although composition and stability constants of extracted binary or ternary complexes (formed in the presence of Lewis bases during synergistic extraction) of Hpmbp with various metal ions have been determined, characterization of these compounds in the solid state have been scarcely made. To our knowledge only Cu(II) and VO^{2+} chelates have been investigated so far.[7] We wish to report here synthesis and characteristics of several types of lanthanoid chelates with Hpmbp. Our interest in these compounds stems from a desire to investigate the phenomenon of hypersensitivity which is a subject of considerable interest.

Experimental

Materials. Lanthanoids oxides (99.9% pure) were obtained from Johnson Matthey (U.K.) and A.D. Mackay (U.S.A.). Hpmbp was prepared by a modified procedure[8] of Jensen.[1] The compound in its keto form was obtained by recrystallization from (1 : 4) ethanol-water mixture (mp 120 °C, lit, 122 °C) and in the enol form from heptane (mp 91 °C, lit, 92 °C).

Preparation of the Chelates. The method adopted for the preparation of a particular type of lanthanoid chelate is the same for all the metal ions. Here preparations are described with respect to neodymium.

$Nd(pmbp)_3 \cdot 4H_2O$: Hydrated neodymium nitrate (1 mmol) and Hpmbp (3 mmol) were dissolved separately in ethanol (10 ml), then mixed together and stirred for a few minutes. Water was slowly added to the solution until precipitation of the compound occurred. After stirring the mixture for 30 min, the compound was filtered and washed thoroughly with water and petroleum ether. The compound was recrystallized from ethanol-water mixture (1 : 1).

$Nd(pmbp)_3 \cdot 2py \cdot 2H_2O$: One g (*ca.* 1 mmol) of $Nd(pmbp)_3 \cdot 4H_2O$ was dissolved in 30 ml ethanol. To it 1 g (12 mmol) of pyridine was added and the solution was refluxed on a water bath for 4 h. After filtration, the filtrate was concentrated to a small volume. The compound separated was filtered, and was washed with cold ethanol and petroleum ether.

$Nd(pmbp)_3(bpy/phen) \cdot C_2H_5OH$: To an ethanolic solution (10 ml) of hydrated neodymium nitrate (1 mmol) an ethanol solution (15 ml) containing 3 mmol of Hpmbp, 1 mmol of 2,2'-bipyridine (or 1,10-phenanthroline) and 3 mmol of sodium hydroxide was added in a dropwise manner with stirring. The mixture was stirred for 30 min and the volume was then reduced to about 5 ml, cooled and filtered. The product was washed with water, a small amount of cold ethanol and finally with benzene. The compound was recrystallized from (1 : 1) ethanol-water mixture.

*$Q^+[Nd(pmbp)_4] \cdot C_2H_5OH$***: To a stirred ethanol solution (25 ml) containing 1 mmol of hydrated neodymium nitrate and 4 mmol of Hpmbp was slowly added 4 mmol of the heterocyclic base (diluted in 5 ml of ethanol). The mixture was stirred for 30 min, evaporated to $\approx$10 ml, filtered, and the product was washed with petroleum ether and water. It was recrystallized from (2 : 1) ethanol-water mixture.

$NH_4[Nd(pmbp)_4] \cdot C_2H_5OH$: In the above preparation instead of adding a heterocyclic base ammonia gas was passed through the solution for 30 min. The mixture was filtered and the filtrate was evaporated almost to dryness. The compound separated was collected and recrystallized from (1:1) ethanol-water mixture.

All these compounds were obtained in high yield, 70—90%.

Analyses. Carbon, hydrogen and nitrogen were analysed in the microanalytical laboratory of this Institute. Lanthanoids were estimated after decomposing the compounds with acid mixtures (HNO_3-$HClO_4$) and titrating with Na_2H_2-edta using Xylenol Orange as the indicator.[9]

Physical Measurements. Conductivity measurements were carried out using a Philips PR 9500 conductivity bridge. Infrared spectra were recorded on Perkin-Elmer 225/621 spectrometers in KBr pellets (in the range 4000—400 cm^{-1}). and in nujol or hexachlorobutadiene mulls (between 700—200 cm^{-1}). Electronic spectral measurements were carried

* For correspondence.

** Q^+ is the quaternary ammonium cation of morpholine, piperidine or pyrrolidine.

out either on a Spectro MOM 201 or a Hilger UV-spek spectrophotometer. For measurements in the visible range, the solutions used mostly had a concentration $\approx 1 \times 10^{-2}$ M. The oscillator strength (P) was determined from the relation[10]

$$P = 4.31 \times 10^{-9}\left[\frac{9n}{(\eta+2)^2}\right]\varepsilon_1(\nu_1)\mathrm{d},$$

where n is the refractive index of the medium, ε_1 is the molar extinction coefficient and ν_1 is the energy of transition in cm^{-1}. The band areas were measured by a planimeter.

Results and Discussion

The analytical data of the lanthanoid complexes are summarized in Table 1. In general, the compounds are freely soluble in acetone, ethanol and chloroform, less soluble in benzene, and insoluble in hydrocarbon solvents. These compounds are generally light yellow in color, but the neodymium compounds show dichroic behavior; violet in the day light and greenish-yellow under a fluorescent lamp. The compounds of the type, $Q^+[Ln(pmbp)_4]$ and $[Ln(pmbp)_3L]$ (where L is 2,2′-bipyridine or 1,10-phenanthroline) contain one molecule of ethanol as the solvent of crystallization which can be removed by heating at *ca.* 60 °C for an hour. The tris-chelates of the lower lanthanoids (La—Sm) having the composition $Ln(pmbp)_3.4H_2O$ contain two coordinated water molecules. The two solvated water molecules may be removed by heating at 100 °C for 2 h. Thermal analysis shows that $Ln(pmbp)_3.2H_2O$ is stable up to 200°C, and beyond this temperature further loss of water molecules cause decomposition of the compound. On the other hand, the tris-chelates of the higher lanthanoids (Eu onward), $Ln(pmbp)_3 \cdot H_2O$ do not contain any water of crystallization. Conductivity measurements of the tetrakis-chelates in nitrobenzene show that Λ_M values are in the range 20—25 $ohm^{-1}\,cm^2\,mol^{-1}$ which are consistent with the 1:1 electrolytic behavior of the compounds.[11]

Hpmbp can be isolated both in keto and enol forms (Ia, Ib). The reagent is comparatively a strong acid, ($pK_a = 4.10^5$) and although its distribution constrants in various solvents have been determined[2], no information regarding the keto-enol equilibrium in organic solvents is known. Unfortunately, the reagent does not have enough solubility in major organic solvents suitable for studying NMR spectra. In an attempt to study this equilibrium the electronic spectra of Hpmbp in several organic solvents have been recorded. The pertinent data summarized in Table 2 show that the reagent has two absorption bands, but neither of these can be related to a particular tautomer. On the contrary, both the bands are composite type, having significant contribution of the either forms. It may be mentioned that the enol form is obtained by recrystallization from heptane.[1-4] On this basis one may expect that in heptane the reagent remains at least 98% in the enol form, if not exclusively. It follows from Table 2 that the decreased order of molar absorptivity of the lower wavelength band with respect to solvent is, heptane>methanol>ethanol>chloroform; whereas the corresponding order for the higher wavelength band is, chloroform>heptane>carbon tetrachloride>methanol>ethanol. It is well-known that an enol content increases with the decrease in dielectric constant of a solvent. On this basis the higher wavelength band gives an indication of the decreased order of the enol content, although the position of chloroform is confusing. Attempt was also made to determine keto-enol ratio by Meyer's bromine absorption method.[12] However, this approach was unsuccessful because bromine nonselectively gets absorbed both by

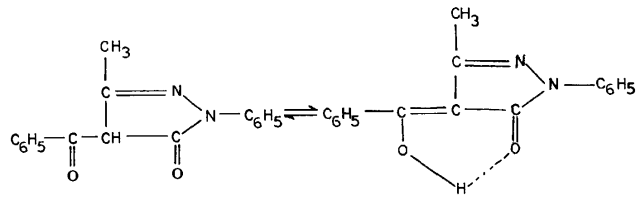
the double bond and the phenyl rings.

The IR spectrum of the enolic form of the ligand shows a broad band at 2540 cm^{-1} which is evidently due to hydrogen bonded OH. Hpmbp contains a large number of bands in the region 1700—200 cm^{-1} which rendered frequency assignments somewhat difficult. It is possible, however, to obtain some useful information regarding the metal–ligand bonding. For example, the ligand bands at 1662 and 1638 cm^{-1} are considerably shifted to lower frequency $\approx$1610 cm^{-1} in the metal chelates and thus can be related to the C=O stretching. On the other hand, a band at 1590 cm^{-1} in the ligand remains unaltered in the chelates and is therefore due to phenyl ring stretching. Similarly, another unaffected band at 1575 cm^{-1} appears to be due to C=C/C=N stretchings. The ligand band at 1545 cm^{-1} which gets displaced to 1525—1500 cm^{-1} in the complexes has major contribution due to C=O stretching. The remaining large number of bands which are mostly composite type do not undergo major shift in frequency in the complexes. A broad band in the complexes observed at 3400—3300 cm^{-1} is either due to the water molecules (in the tris-chelates) or the ethanol molecule (in the tetrakis- or the adduct type chelates). It has been observed that although the ligand has a weak band at 410 cm^{-1}, in the tris- or the adduct type chelates another new band appears at 400 cm^{-1}. In the tetrakis-chelates this band is observed at 435—440 cm^{-1}. We infer this band as due to Ln–O stretching. Indeed Liang *et al.*[13] also observed that Ln–O stretching vibration appears at 400—420 cm^{-1} in a large number of lanthanoid β-diketonates of both tris- and tetrakis-type.



Ia Ib

The electronic spectral characteristics of the compounds under discussion have been studied in detail with respect to those derived from Nd(III) and to a limited extent for the Pr(III) complexes. Admittedly useful information could have been obtained for the Ho(III) and Er(III) complexes but their hypersensitive bands appear in the region where there is considerable absorbance due to ligand/or charge-transfer tail.

Table 3 lists the oscillator strengths for several non-hypersensitive transitions in the neodymium complexes in several solvents. It may be noted from a comparison of these values with those of neodymium perchlorate[14] that the coordination environment or the solvent medium have little effect on the variation of band intensities. This is in accordance with the model proposed by Judd[15] and Oflet[16] for the intensities of f-f transitions.

In Table 4 the oscillator strengths (P) for the hypersensitive transition in the Nd(III) complexes have been summarized. It may be noted that in the $Q^+[Nd(pmbp)_4]$ type complexes P values are independent of the Q^+ cations and there is a marginal variation in hypersensitivity with respect to the solvent medium. Interestingly, in $Q^+[Nd(sdbm)_4]$ chelates (Hsdbm=1,3-diphenyl-3-thioxo-1-propanone) we noted[17] that while Q^+ ions had no effect, however, the oscillator strengths in acetone were significantly higher than in chloroform and benzene. We rationalized this variation by invoking a difference in symmetry of the dissociated (in acetone) and undissociated (in chloroform or benzene) form of the complexes. The fact that the $Q^+[Nd(pmbp)_4]$ complexes do not show such a behavior implies that dissociation of these complexes do not profoundly affect their symmetries. According to Henrie *et al.*[18] symmetry does have implication on the overall intensity but hypersensitivity *per se* can not be classified as being due to a symmetry phenomenon.

Table 4 reveals that the gradation of hypersensitivity in the compounds is $Q^+[Nd(pmbp)_4]>Nd(pmbp)_3\cdot phen > Nd(pmbp)_3\cdot bpy > Nd(pmbp)_3\cdot 2py\cdot 2H_2O > Nd(pmbp)_3\cdot 2H_2O$. The greater hypersensitivity of the tetrakis complexes over the tris species can be rationalized by invoking an important observation made by Barnes and Pincott[19] that not only are the energies of the lanthanoid charge-transfer transitions dependent on the ligand but also they increase in a stepwise manner with the stepwise addition of ligands. Similar observation as the present one was made by us[17,20] previously for β-thioxo ketonates and also by Poluektov *et al.*[21] for a number of phenolic ligands.

Table 4 shows that the addition of heterocyclic donors to the tris-chelate do as not profoundly increase hypersensitivity in the adducts. Sinha *et al.*[22] observed that hypersensitivity in neodymium complexes shows the trend phen>bpy>H_2O, but the differences are not much. Our results also show a similar trend. Sinha *et al.*[22] related the above trend to the poor donor capacity of nitrogen atom toward lanthanoid ions which indeed is an estabilshed fact.[23] Sinha and Green reported[24] that the formation constants of lanthanoid-phen or bpy complexes are extremely low, log $K_1\approx 1$.

Literature shows[25–27] that the increased order of hypersensitivity in tris-β-diketonates is hexafluoroacetylacetone < trifluoroacetylacetone < acetylacetone <benzoylacetone< thenoyltrifluoroacetone < dibenzoylmethane. In the corresponding β-thioxo ketonates also the following trend was observed by us[17,20] 4-phenyl-4-thioxo-2-butanone<4-thenoyl-4-thioxo-1,1,1-trifluoro-2-butanone < 1,3-diphenyl-3-thioxo-1-propanone. These results combined together imply that hypersensitivity

of lanthanoid complexes generally increases with the increases in pK_a value of the ligand. However, there are exceptions to this generality. For example, pK_a of Hdbm is greater than Hsdbm, but the neodymium complex of Hsdbm shows greater band intensification.[17] This is due to more covalent interaction in the thio compound as sulfur acts as a softer base. A comparison of the oscillator strengths of Hpmbp complexes (Table 4) with the β-diketonates reported in literature[25-27] reveals that in spite of weaker basicity, the oscillator strengths of Hpmbp complexes are rather high. Moreover, lanthanoid–pmbp complexes have relatively high formation constants ($\log \beta_3 \approx 12$—13)[28] which indicate that probably the complexes are stabilized to a great extent through covalent interaction. Menzel *et al.*[7] also indicated higher covalency in Cu(pmbp)$_2$ compared to Cu(II) acetylacetonate.

Henrie *et al.*[18] have recently proposed a mechanism to explain the phenomenon of hypersensitivity which suggests that hypersensitive transitions aries from metal-ligand covalency *via* charge-transfer levels. The greater the covalent interaction greater will be the hypersensitivity. On this premise Henrie *et al.*[18] further proposed a correlation between P and pK_a. From the present study we conclude that hypersensitivity indeed increases with greater covalent interaction, but a linear correlation between hypersensitive band intensity and ligand basicity appears to be an overemphasized one.

The electronic spectral characteristics of the Pr(III) complexes in chloroform have been investigated. The hypersensitive transition, $^3H_4 \rightarrow {}^3F_2$ (*ca.* 5.2×10^3 cm^{-1}) was beyond the range of measurement. Although $^3H_4 \rightarrow {}^3P_2$ and $^3H_4 \rightarrow {}^1D_2$ transitions have been reported[29] to exhibit hypersensitivity, they do not obey quadrupole selection rules. In the Pr(III)–pmbp complexes, $^3H_4 \rightarrow {}^3D_2$ transition is completely swamped by the ligand/or charge-transfer tail, which also considerably modified the bands due to $^3H_4 \rightarrow {}^3P_1$, $^1I_6$ ($\approx 21.2 \times 10^3$ cm^{-1}) transitions. The molar extinction coefficients of $^3H_4 \rightarrow {}^1D_2$ transition ($\approx 17.6 \times 10^3$ cm^{-1}) in the complexes on comparison with the corresponding value for the aquated Pr^{3+} ion reveal that there is significant increase in intensity in the complexes. In fact, the gradation in intensity is almost similar to the one observed in the Nd(III) complexes. In view of the exceptional behavior of Pr(III) in its hypersensitivity which still remains as

one of the major problems in lanthanoid intensity theory,[30] no attempt has been made to evaluate the oscillator strengths for $^3H_4 \rightarrow {}^1D_2$ transition.

The authors express their sincere thanks to Prof. B. J. Hathaway of the University College, Cork, Ireland, and Dr. P. L. Goggin of the University of Bristol for recording infrared spectra of the compounds.

Conductance Behavior of Manganese Soap Solutions in 1-Butanol and 3-Methyl-1-butanol

R. P. VARMA, K. SINGH,* and H. SINGH*

Department of Chemistry, D.A.V. College, Muzaffarnagar 251001, India

** Department of Chemistry, J.V. College, Baraut, 250611, Meerut, India*

(Received August 12, 1977)

The specific conductance of manganese soap solutions in 1-butanol and 3-methyl-1-butanol has been measured at temperatures in the range 35—50 °C. Manganese soaps form micellar aggregates and the CMC, which decreases with increase in chain length of the soaps of saturated fatty acids, was found to be independent of the nature of the solvent. Conductance behavior of soaps is given by the equation $\log \lambda_M = A + B \log C$ where A and B are constants and C is the concentration in mol/dm^3. Constant A increases with increase in temperature and chain length of the soap. Constant B is independent of temperature but varies with soap chain. Molecular conductance at infinite dilution, λ_∞, dissociation constant, K, activation energy of conductance, ΔE_λ, and heat of dissociation, $\Delta H°$, have been evaluated.

Measurement of the conductance of metal soaps involves no special problem except the application of external electrical forces. Since the mobility of the ion present as simple species resembles that of dissociated salts and differs markedly from that of aggregated ions, there is an abrupt change in specific conductance at CMC. Electrical conductance of various ionic agents has been reported.[1-4] The conductance of sodium and potassium soaps in ethanol, toluene, and pyridine was determined[5] and sodium oleate in ethanol was reported[6] to behave as simple electrolyte. Several workers[7-9] have studied the CMC of magnesium, calcium, barium, and strontium soap solutions and determined parameters such as K, λ_∞, and $\Delta H°$. From the conductance behavior[10] of magnesium soaps in lower aliphatic alcohols, it was confirmed that CMC is uneffected by change in temperature. An investigation of CMC of nickel, cobalt, and iron soaps has been made[11] by conductance measurement at different temperatures.

We have studied the conductance of manganese soaps (oleate, laurate, decanoate and octanoate) in 1-butanol and 3-methyl-1-butanol at different temperatures in order to a) determine the CMC of the soap solutions, b) confirm the effect of temperature, if any, on CMC, and c) determine dissociation constant, K, molecular conductance at infinite dilution, λ_∞ and heat of dissociation, $\Delta H°$.

Experimental

Materials. 1-Butanol, 3-methyl-1-butanol, manganese chloride, oleic acid, and octanoic, decanoic and lauric acids (Merck or B.D.H. reagent grade) were used. The fatty acids were purified by distillation under reduced pressure, the purity being confirmed by bp measurements.

Preparation of Soaps. Manganese soaps were prepared by the interaction of manganese chloride solution in a small quantity of distilled water with a hot solution of sodium soap, the latter being added drop-wise while the whole mass was continuously stirred at 50—55 °C. The precipitate was filtered and washed with hot water until the filtrate gave no reaction to manganese chloride. After initial drying in an air oven (100—105 °C) final drying was carried out under reduced pressure.

Apparatus and Procedure. All the measurements were carried out in a thermostat at constant temperature (±0.05 °C). A conductivity bridge (Phillips, PR 9500, India) and a dipping type conductivity cell were used for measuring the conductance of soap solutions. All data were obtained by concentration runs, solutions were diluted by adding the solvent in a desired proportion and the conductance was measured. The reproducibility of the results was verified by repeating the measurements.

Results and Discussion

Specific conductance, κ, of manganese soap solutions increases with increasing concentrations of soap solutions at different temperatures. The κ-C plots (Fig. 1) are characterised by an intersection of two straight lines at a definite concentration called CMC (Table 1). The values of CMC of soaps are unaffected by change in temperature but decrease with increasing chain length of the soap.

Molecular conductance, λ_M, obtained from the measured specific conductance of solutions decreases with increase in the concentration of the soap solutions. The plots (Fig. 2) of λ_M *vs.* $C^{1/2}$ are concave upward.

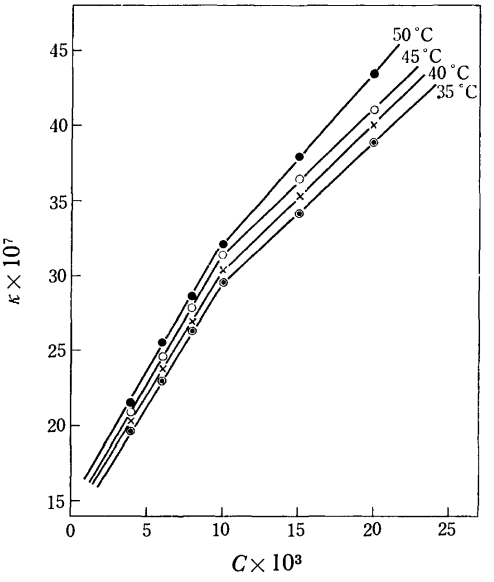

Fig. 1. Plot of specific conductivity, κ *vs.* concentration, C, of manganese oleate in 1-butanol at temperatures, 35—50 °C.

Table 1. Values of CMC and heat of dissociation, ΔH° in kcal of manganese soaps at all temperatures (35—50 °C)

Soap	1-Butanol		3-Methyl-butanol	
	CMC	ΔH°	CMC	ΔH°
Oleate	0.010 M	25.51	0.008 M	10.08
Laurate	0.007 M	27.51	0.007 M	13.29
Decanoate	0.008 M	30.25	0.008 M	39.42
Octanoate	0.009 M	33.04	0.009 M	43.54

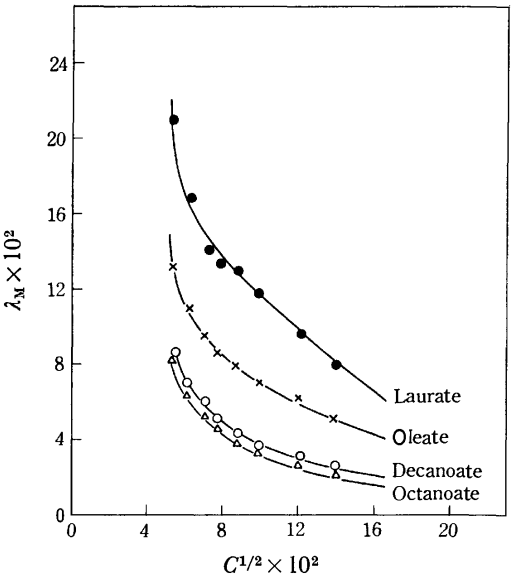

Fig. 2. Plot of molecular conductivity, λ_M, *vs.* square root of concentration, $C^{1/2}$, of manganese soaps in 3-methyl-1-butanol at 35 °C.

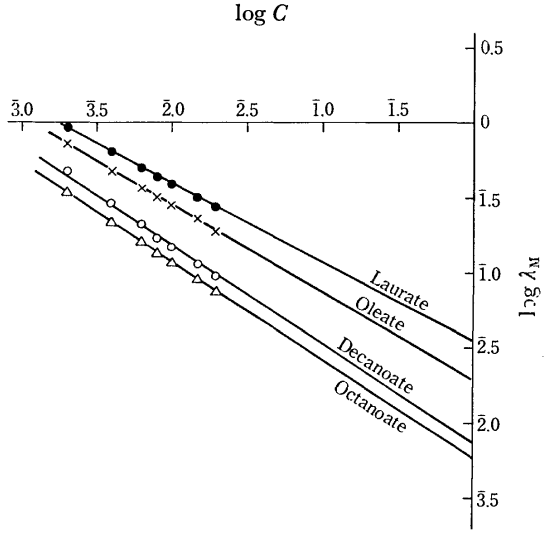

Fig. 3. Plot of $\log \lambda_M$ *vs.* $\log C$ of manganese soaps at 35 °C in 1-butanol.

This is due to the weak electrolyte behavior of the soaps.

The conductance behavior of manganese soap solutions at various temperatures (Fig. 3) is represented by

$$\log \lambda_M = A + B \log C, \quad (1)$$

where A and B are constants and C is the concentration in mol/dm^3

The values of constants A and B have been found from the slopes and intercepts of the linear plots of $\log \lambda_M$ *vs.* $\log C$ (Table 2). It is seen that constant A in 1-butanol is higher than 3-methyl-1-butanol varying with soap at different temperatures in the order

laurate>oleate>decanoate>octanoate

Constant B (Table 3) is independent of temperature which supports the idea that CMC remains unaffected by temperature.

The molecular conductance temperature variation can be expressed by

$$\lambda_M = Ae^{-\Delta E_\lambda / RT}, \quad (2)$$

where A and ΔE_λ are constants.

Constant ΔE_λ is of importance, since information can be obtained on the aggregation by measuring the activation energy of conductance. The plots of $\log \lambda_M$ *vs.* $1/T$ are straight lines in alcohols. The activation energy of conductance, ΔE_λ has been calculated from the slopes of linear plots. Table 4 indicates and appreciable difference in the values of ΔE_λ below an above CMC which supports the micellar behavior of manganese soaps in alcohols.

Dissociation Constant, Heat of Dissociation, and Molecular Conductance at Infinite Dilution. Manganese soap has been reported to behave as a weak electrolyte in dilute solutions,[13] the dissociation of soap can thus be derived as follows:

$$\underset{C(1-\alpha)}{(COOR)_2Mn} \rightleftharpoons \underset{C\alpha}{Mn^{2+}} + \underset{2C\alpha}{2RCOO^-}, \quad (3)$$

$$K = \frac{[Mn^{2+}][RCOO^-]^2}{[(COOR)_2Mn]} \quad (4)$$

$$= \frac{4C^2\alpha^3}{1-\alpha} . \quad (5)$$

The degree of dissociation, α, of soaps in solution is very small. Ionic concentration would be low and interionic effects can be neglected. On replacing $\alpha = \lambda_M/\lambda_\infty$ and rearranging, we obtain

$$C^2\lambda_M^2 = \frac{K\lambda_\infty^3}{4\lambda_M} - \frac{\lambda_\infty^2 K}{4} . \quad (6)$$

The plots of $C^2\lambda_M^2$ *vs.* $1/\lambda_M$ are linear below CMC and the equation fails above this concentration. The values of K and λ_∞ obtained from Eq. 6 at different temperatures are given in Tables 5 and 6.

The dissociation constant decreases with increase in temperature and decrease in dielectric constant of the solvent. In a medium of low dielectric constant, the electrostatic attractive forces between positive and negative ions are large, giving rise to diminished small dissociation.

The heat of dissociation, ΔH° has been calculated from the slopes of the plots of $\log K$ *vs.* $1/T$ and is given in Table 1. We see that the values of ΔH° decrease with increase in the chain length of soap.

Molecular conductance at infinite dilution, λ_∞ increases with increase in temperature which is due to the decrease in the viscosity of solvent. The rise in temperature causes increase in ionic mobility despite the fact that the addition of the soap increases the viscosity of the solvent.

Effect of Monohydroxy Alcohols and Urea on the CMC of Surfactants

H. N. SINGH and Shanti SWARUP,
Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India
(Received September 26, 1977)

The effect of monohydroxy alcohols on the critical micelle concentration (CMC) of anionic and cationic surfactants have been studied by a conductometric method. The CMC was found to decrease by adding small quantities of alcohol and raised again at higher alcohol concentrations. The CMC decreasing effect has been discussed on the basis of more ordered water cavity formed around the added alcohol molecules and their increasing effect by the partition of alcohol between the micellar and the bulk phase leading to the break-down of the micelles. The effect of urea on CMC in alcohol–water mixtures has been studied and its CMC increasing effect explained.

The properties of aqueous solutions of aliphatic monohydric alcohols are of interest in the field of surface chemistry; especially their effect on the phenomenon of micellization of surfactants. Since water–alcohol-surfactant systems are so frequently used as media in the studies of chemical equilibria and reaction rates,[1] it is very essential to investigate the nature of the alkyl groups in the alcohol on the CMC of surfactants.

The driving force for the formation of nonionic micelles in water being the hydrophobic interactions between the hydrocarbon portion of the surfactant has been treated quantitatively,[2] but this treatment in case of ionic micelles was less satisfactory.[3] The most satisfactory way of investigating the effect of hydrophobic interaction on ionic micelle formation would be to study the micellar properties of ionic surfactants in altered water structure by adding small quantities of alcohols of varying chain length. But one could not rule out the possibility of incorporation of alcohol molecules into the micelles.

The CMC decreasing effect due to incorporation of alcohol molecules between the soap micelles has been advocated by many workers.[4–6] Branched chain alcohols at low concentrations were found ineffective while the higher homologous alcohols caused depression of the CMC. Addition of various amphiphiles to micellar soap solutions caused the electrical conductivity to increase.[8] The effect of C_2—C_{10} alcohols on the CMC of soap solutions was investigated by electrical conductivity and distribution methods.[9–10] The CMC raising effect of ethanol and methanol at higher concentration is well studied.[12–19]

Virtually all substances containing hydrophobic moities decrease the concentration of an amphiphile in equilibrium with its micelles.[20] This decrease can be explained only by the incorporation of the added substances into the micelle, since simple addition of the alcohol and similar substances to the solvent must diminish the hydrophobic effect, that is, it would decrease the standard chemical potential of monomer for the micelle forming amphiphile without any effect on the standard chemical potential of micelle and would therefore increase the CMC. In related work, the effect of urea on micelle formation has been found to increase the CMC, though, it could not be incorporated into the micelle.[21–23]

From the detailed literature survey on the effect of additives, particularly alcohols and other related substances, which markedly influence the hydrophobic effect and the micelle formation,[24] it seems that there exist two different views regarding the effect of additives on micelle formation. The first deals with the solubilization of alcohols in micelle[11,21,25] and the second view is that additives have direct effect on the water structure.[26–28]

Recent investigations[29,30] further indicate that the role of alcohols in micelle formation could be explained on the basis of several factors. It may be possible that the alcohol molecules may modify water structure if present in very small concentration. At higher concentrations some other effects like the alteration in the dielectric constant of the solvent or the partition of alcohol molecules between bulk and the micellar phase[31–33] or the diminishing of the hydrophobic effect[20] may be more important. At very high alcohol concentration a shift in equilibrium between surfactant monomers and micelles towards monomer may be possible due to high solvent power of alcohol for the hydrophobic part of the surfactant ion.

The main objects of the present investigation were (a) to extend information on the influence of the solvent on the micelle formation due to alteration in water structure by gradual addition of alcohols in very small amounts and (b) to study the effect of urea on micelle formation in the altered water structure.

Experimental

Sodium dodecylsulfate (SDS) was purchased from BDH (England). It was first recrystallized from ethanol–acetone mixture. Traces of unreacted alcohol were removed by extracting it with petroleum ether (60 h) and chloroform (100 h). The surfactant was dried after filtration in a hot air oven to a constant weight. The absence of any unreacted alcohol was ascertained from the absence of OH peak in the IR spectrum. The microanalysis of the compound showed: C=49.73, H=9.02, S=11.00%; calculated values C=49.8, H=8.9, S=11.06%. The purity was also confirmed from the absence of minimum in the surface tension *vs.* log concentration plots. Cetyltrimethylammonium bromide (CTMAB) was BDH reagent grade quality. It was recrystallized from acetone, repeated thrice. Demineralized double distilled water was used throughout this work. The specific conductivity of water was 20.0×10^{-6} to 21.7×10^{-6} $ohm^{-1}\,cm^{-1}$. CMC values of SDS and CTMAB, determined by conductivity method in water at 30 °C were 8.6 and 0.97 $mmol/dm^3$ respectively, are in good agreement with literature values[12] at 25 °C. 1-Propanol, 1-butanol, 1-hexanol, and cyclohexanol were all BDH laboratory reagents while 1-pentanol and cyclopentanol were E. Merk products. These

alcohols were distilled under reduced pressure and the middle fractions of the distillate were used.

Water-alcohol mixtures of several compositions were prepared by mixing requisite quantity of alcohol in water. Stock solutions of surfactants were prepared by weighing. The conductometric measurements of surfactant solutions were made by a Philips conductivity meter model PR 9500 at a frequency of 1000 Hz using platinized electrodes of known cell constant. After measuring the conductivity of the solvent, small volumes of the stock solution (50 mmol/dm^3 surfactant solution) were added and the conductivity noted after each addition and thorough mixing to a constant reading. The specific conductivity was calculated after applying the solvent correction. The CMC values were determined at the break points of nearly two straight line portion of the specific conductivity *versus* concentration plots.

Results

The specific conductivity, K, *vs.* concentration, C, plots for SDS and CTMAB in different compositions of 1-propanol-water mixtures are shown in Fig. 1. The plots for other alcohol-water mixtures were similar. The variation of CMC with the mole fraction of alcohol, χ, are shown in Fig. 2 and the effect of urea on the CMC in alcohol-water mixtures resulting in minima in CMC, where the water is supposed to be in most ordered form, are given in Table 1. The slopes of K *vs.* C plots for SDS below and above CMC in different alcohols are given in Table 2.

Discussion

The highly structured tetrahedral arrangement of water molecules in the liquid state would have to be disrupted by the addition of any solute.[20] When alcohols are added into water, some hydrogen bonds must be broken, and new hydrogen bonds between water and alcohol would be formed. But the hydrogen bond formation between alcohol and water does not seem very tangible because in liquid alcohol the tendency for O–H···O bond formation is likely to be as strong as in water, though such hydrogen bonds cannot comprise an isotropic net work filling the entire solvent space due to the presence of alkyl side chains. However, the addition of alcohols to water, if results in the rapture of hydrogen bonds of the latter, the major contribution to the free energy of transfer of alcohol to water would be a positive enthalpy term. Instead, as reported[34] earlier, the transfer to water is actually slightly favored energetically. The positive value of change in standard chemical potential for the transfer of aliphatic alcohols from pure liquid to water resulting from a negative entropy change has been explained by the fact that the water molecules at the surface of the cavity created by a nonpolar part must be capable of rearranging themselves in order to regenerate the broken hydrogen bonds, create a higher degree of local ordering than exists in pure liquid water.[20] Hence it is reasonable to expect that the addition of higher alcohols to water may result in the ordering of water structure at concentrations lower than their lower counterparts.

In fact, the CMC lowering of surfactants by the small addition of alcohols may be due to their direct action on water structure and the subsequent addition

may cause secondary effects such as their solubilization in micelle and decrease of hydrophobic effect. A perusal of Fig. 2 shows that the CMC values of SDS decrease by the gradual increase in the mole fraction of alcohol in water and increase further after attaining a minimum value. The mole fraction of alcohols where the CMC minima occur also depend upon the length of the hydrocarbon chain. It may, therefore, be concluded from these observations and the above mentioned facts that the initial addition of alcohol to water causes the ordering of water which in turn reduces the CMC to a minimum value. From Fig. 2 it is also noted that the CMC values at the minimum decrease gradually with increase of the length of the hydrocarbon chain in the alcohol. This further supports the view[20] that the formation of the cavity of more ordered water molecules is favored by the long hydrocarbon chain of the alcohols. In presence of such a cavity a decrease in CMC is not unexpected.

In case of cyclic alcohols, *viz.*, cyclopentanol and cyclohexanol, the CMC minimum occurs at higher mole fraction of alcohols as compared with their linear-chain counterparts. This indicates that these alcohols possess less proton accepting capacity in solvent water to result in the well organized alcohol-water hydrogen bond formation or to create a cavity of more ordered water molecules. Apart from these mixtures having a more organised solvent structure, the higher CMC values at the minimum further suggest that the degree of association of the surfactant is slightly restricted due to steric reasons.

Studies have also been made with a cationic surfactant, CTMAB. The CMC values of CTMAB in different compositions of alcohols are given in Fig. 2.

In all the alcohol–water mixtures, the CMC values initially decrease, pass through a minimum and increase further, with the increase in the mole fraction of alcohols. Unlike anionic surfactant (SDS) no systemetic trend in the CMC values at the minimum is observed with the increase in the length of the hydrocarbon chain in alcohols. At this stage it is difficult to comment on the behavior of a cationic surfactant in alcohol–water mixtures.

The role of the water cavity in micelle formation has been further verified by studying the effect of urea on CMC. Urea is a strong water structure breaker, in presence of alcohols it may destroy the cavity of ordered water structure. It is, therefore, expected that the CMC should increase with the increase in the concentration of urea. Table 1 shows the effect of urea on the CMC of SDS and CTMAB in presence of constant concentration of alcohols. The percent increase in the CMC values are also included in Table 1. These results indicate that the addition of urea results in the breaking of water structure even at the concentration of alcohols where it is expected to be more ordered. This effect is so pronounced in lower alcohols that no micelle formation takes place when the concentration of urea exceeds 3 mol/dm^3. It is intresting to note that the CMC increasing effect of 1 mol/dm^3 urea is much smaller for cyclopentanol and cyclohexanol which further supports the conclusion that the water cavity formed in presence of cyclic alcohols is less ordered. However, an irregular change in the CMC values of CTMAB (Fig. 2) with the hydrophobicity of the alcohol indicates that the water molecules do not have a unique way of arranging themselves, but that different arrangements are possible depending upon the precise spatial requirements.[20] A comparison of percent increase in CMC in 3 mol/dm^3 urea (Table 1) may lead to the conclusion that the higher alcohols may be readily partitioned in cationic micelle than in an anionic micelle.

In case of anionic surfactants a further increase in CMC in higher concentration of alcohols suggests that some other factor, influencing the micelle formation, must be taken into account. A micelle formed in presence of an alcohol is likely to contain alcohol molecules in its oriented structure.[4,5] These alcohol molecules, introduced between the soap ions and the micelle, will produce a further charge separation. Owing to the lowered charge density the conditions are thus more favorable to abnormally small atmosphere and inclusion effects. This partition of additive between the solution and the micelles may be sensitive to the structure of the polar third component and the temperature. It is probably due to the above fact that no micelle formation is observed in all the alcohol–water mixtures in presence of 6 mol/dm^3 urea except in 1-hexanol which is less polar.

The inclusion and the micelle breakdown effect of alcohols[11,25,30] may further be reflected from the slopes of *K vs. C* plots below and above the CMC in different compositions of alcohols. The slopes for SDS in alcohol–water mixtures are given in Table 2.

A perusal of Table 2 shows that the slopes below the CMC remain nearly constant irrespective of the composition and the chain length of the added alcohol which indicate that alcohol molecule is not incorporated at all with the surfactant monomers. Approximately 8% higher values of slopes than in pure water may be due to modification of water structure by the added alcohols. The inclusion of alcohol molecules into the surfactant micelle is clearly reflected from the decrease in slopes above the CMC. It is also clear that the inclusion effect is stronger for alcohols with larger alkyl chains which brings about the reduction of the surface-charge density on the micelle. Similar conclusions have been given by Shirahama and Kashiwabara.[24] Larger values of slopes in higher alcohols (C_4—C_6) and their gradual increase with alcohol content indicates that the partition of alcohol into the micelle results in a slight increase in the conductivity due to release of few surfactant anions from the micellar to the bulk phase. The high solvent power of alkyl chains of the alcohol for surfactant tails may shift the equilibrium from aqueous micellar to the alcoholic environment (hydrocarbon like) in higher alcohols which could create a separate phase of reversed micelles.[35,36]

The authors are thankful to Prof. W. Rahman, Head, Department of Chemistry, for his keen interest in the work.

CNDO/2 Calculations of MeSEt, MeS-*n*-Pr, MeS-*n*-Bu, $(Et)_2S$, EtS-*n*-Pr, EtS-*n*-Bu, and $(n\text{-Pr})_2S$[1]

Masaru OHSAKU,* Norihisa BINGO, Hiroshi FUJIWARA, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received March 25, 1977)

Synopsis. CNDO/2 sp calculations were carried out for MeSEt, MeS-*n*-Pr, MeS-*n*-Bu, $(Et)_2S$, EtS-*n*-Pr, EtS-*n*-Bu, and $(n\text{-Pr})_2S$. The stable conformations of these molecules were discussed.

Conformational analyses of MeSEt have been performed extensively on the basis of the vibrational spectra and a normal coordinate treatment[2-4] and on the basis of vapor-phase electron diffraction.[5] With the MeS-*n*-Pr,[6-8] MeS-*n*-Bu,[6,7,9] $(Et)_2S$,[2,9] EtS-*n*-Pr,[6,7,9] EtS-*n*-Bu,[6,7] and $(n\text{-Pr})_2S$[6,7] molecules the conformations have also been analysed by means of IR and Raman spectroscopy. However, the interpretations of the observed results were not always consistent with each other. In particular, the conformation about the C–S bond remains vague. In the present study, in order to obtain useful information on the skeletal conformation, especially about the C–S bond, we have investigated the conformational analyses of these molecules by the aid of the CNDO/2 method.[10]

The molecular geometry used is as follows: for MeSEt–referred to the data of elctron diffraction,[5] r(C–H)=1.117, r(C–S)=1.818, r(C–C)=1.526 Å, and ϕ(CSC)=103.9°; for the other molecules, r(C–H)=1.09, r(C–S)=1.81, r(C–C)=1.54 Å, and ϕ(CSC)=105°; while the other angles were assumed to be tetrahedral. The dihedral angles of these sulfides were taken to be 180 and 60° for the T and G conformations respectively, according to the energy minima of MeSEt, to be shown later. The observed data are summarized in Table 1.

Figure 1 shows that the T form is more stable than the G form in MeSEt. The results of the present calculations, therefore, are in good agreement with our observed results,[2] but they do not agree with the

latest observations[3,4] that the G form is more stable than the T form, although the energy difference observed between the two forms is very small.

Also, for the other longer methyl substituents, the sp calculations indicate that the forms which have the T conformation around the CS–R bond are more stable than those of the G conformation, as is summarized in Fig. 2. For example, for CS–C–C–CC, the TGT and TTT forms, for example, were estimated to be more stable than the other forms, *e.g.*, GGT and GGG. The calculations, therefore, explain reasonably well the experimental results.[6,7,9] With the ethyl substituents, the calculations indicate that the forms which have the TT conformation about the CC–S–R bonds are the most stable ones. For example, for CC–S–C–CC, the TTG and TTT forms can be expected from the calculations to be more stable than the other forms. The present results agree well with the observed ones.[6,7,9] Moreover, the calculations show that the TT form about the CCC–S–CCC bonds is the most stable of all. This agrees well with our previous inference, in which the molecule may all have the *trans* form in the crystalline solid state, judging from the IR spectra of the molecule.[6,7] As has been noted previously,[7] the stable conformation around the C–C bond adjacent to the C–S bond was the T form in the crystalline state, while the conformation around the C–S bond was fairly difficult to determine from only the vibrational spectra and the normal coordinate treatment. In the present case, therefore, the sp calculations and the treatment of the molecular vibrations play complementary roles.

Generally, the present method reproduces the energy-minimum conformations of the simple normal dialkyl sulfides fairly well. Therefore, this method is a helpful method of analysing the vibrational data of these molecules.

The authors wish to thank Professor Akira Imamura of the Shiga University of Medical Science for his helpful advice. Thanks are also due to Dr. Hiroatsu Matsuura of the University of Tokyo for sending us preprints of Refs. 4 and 9.

The Verification of Three-Dimensional Aromaticity: Tricarbonyliron Complexes of Olefins

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 30, 1977)

Synopsis. Using Mingos's Hückel molecular-orbital model, polyolefins were found to be markedly aromatized by the coordination of tricarbonyliron. The Dewar-type resonance energies calculated for the title compounds are consistent with their chemistry.

In 1956, Longuet-Higgins and Orgel pointed out the possibility that quite an unstable cyclobutadiene molecule can be stabilized by combination with a suitable transition-metal compound.[1] In 1965, Pettit *et al.* first achieved such a stabilization of cyclobutadiene by adding tricarbonyliron to it.[2] The chemistry of transition-metal complexes of olefins has since been rapidly developed.[3,4] In parallel with this, two important concepts have been employed to elucidate the stability of these complexes; one is a symmetry-based molecular-orbital approach derived from perturbation-theory arguments,[5,6] and the other is the eighteen-electron (or inert-gas) rule.[4,7]

On the other hand, the present author has been developing a graph-theoretical theory of aromaticity within the framework of the Hückel molecular-orbital (HMO) theory.[8–10] The aromaticity theory is characterized by its ability to determine the Dewar-type resonance energy[11] of any conjugated compound without parametrization. Recently, Mingos reported his attempt to frame tricarbonyliron complexes of typical olefins by means of the HMO theory.[7] Accordingly, it can now be shown that the theory of aromaticity can be extended to verify the aromaticities of three-dimensional conjugated systems in these complexes.

In applying the graph-theoretical theory of aromaticity[8–10] to the tricarbonyliron complexes, Mingos's HMO model[7] was adopted in its original form. The signs of the iron-carbon resonance integrals were chosen in a way which reflects the phase changes in the set of basis orbitals. The absolute values of all the resonance integrals were taken to be equal to that of the carbon-carbon resonance integral (β_{C-C}). The Coulomb integral of iron was taken to be equal to $\alpha_C - \beta_{C-C}$, where α_C signifies the Coulomb integral of carbon. The resonance energies of typical tricarbonyliron complexes were calculated according to a procedure previously described;[8] they are presented in Table 1.

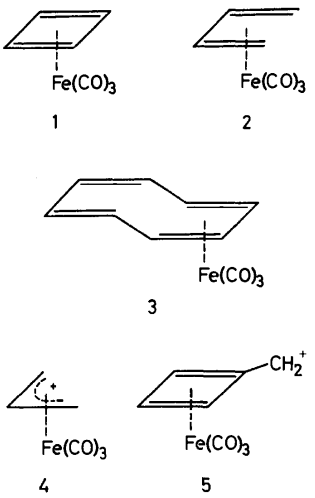

Table 1. Resonance energies of tricarbonyliron complexes of typical olefins

Complex	Resonance energy (β)
1[2,13]	0.894
2[15]	0.646
3[16]	0.671
4[17]	0.373
5[18]	0.593

Alone, the olefins investigated here are not aromatic, because they do not have positive resonance energies. The resonance energies are −1.226 for cyclobutadiene, 0.000 for butadienene, −0.594 for cyclooctatetraene, 0.000 for an allyl cation, and −0.401 for a methylenecyclobutadiene cation, all in units of β. Accordingly, it should be noted that the resonance energies of these olefins dramatically increase when they form complexes with tricarbonyliron.[12]

Since it has been fully proved that the resonance energy of this type excellently correlates with the experimental stability for a wide variety of conjugated compounds,[8,9,11] we might safely say that these olefins are markedly aromatized by the coordination of tricarbonyliron. The positive resonance energy is a distinct indication of aromaticity. This fact clearly supports the view of Pettit *et al.*,[13] who first insisted that the tricarbonyliron complex of cyclobutadiene is aromatic because of its tendency toward electrophilic substitution reactions.[14] An analogous trend in the reactivity is also found among the other tricarbonyliron complexes listed in Table 1.[15–18] The results of the present approach are, of course, consistent with Mingos's conclusion, based on the eighteen-electron rule, leading to the stabilization of these complexes.[7] The decrease in the degree of bond alternation gives further support to the aromaticities of the complexes.[7,19]

In contrast to the aromatic compounds so far identified, each of the tricarbonyliron complexes has a three-dimensional conjugated system. They can, hence, be considered to be the first examples of three-dimensional aromatic compounds ascertained in terms of

the Dewar concept of aromaticity.[8,9,11] The application of the HMO theory to the other organometallic compounds[3,4] and also to such hydrocarbons as a square-pyramidal $C_5H_5^+$ species[20] would help to extend the concept of three-dimensional aromaticity.

This work was motivated by Dr. Shigeo Yoneda's article on three-dimensional aromaticity [Kagaku Sôsetsu, **15**, 36 (1977)]. The use of the facilities of the Hokkaido University Computing Center is gratefully acknowledged.

10) A definition of resonance energy presented in a recent paper [J. Aihara, *Bull. Chem. Soc. Jpn.*, **50**, 2010 (1977)] is not used here because the original definition proposed in Ref. 8 appears most suitable for describing the stability of any conjugated system. Note that the reference energy in Ref. 8 defines the lowest energy of the reference structure relative to which aromatic stabilization is considered. For all the conjugated systems investigated here, however, both definitions of resonance energy give the same results.

12) Note that, in each of these tricarbonyliron complexes, one of the iron d orbitals and any three carbon p_π orbitals which are arranged in sequence and coordinated to the iron atom form a singly twisted conjugated ring (*i.e.*, a Möbius ring) because of the nodal characteristics of d orbitals. Such four-membered Möbius rings make a significant contribution to the aromaticity of the entire conjugated system.[9] In this context, the hypothetical Möbius cyclobutadiene can be considered to be highly aromatic. See, *e.g.*, J. Aihara, *Bull. Chem. Soc. Jpn.*, **48**, 517 (1975).
As a general rule, polyolefins do not tend to form very stable compounds in which only one double bond is coordinated to a transition metal atom. See, *e.g.*, F. A. Cotton and G. Wilkinson, "Advanced Inorganic Chemistry," 3rd ed, Wiley-Interscience, New York, N. Y. (1972), Chap. 23. This fact is consistent with the above structural consideration of conjugated systems.

Studies on Spontaneous Emulsification. III. Molecular Interaction at the Oil–Water Interface

Keizo OGINO and Hidetoshi UMETSU

Faculty of Science and Technology, Science University of Tokyo, Noda, Chiba 278

(Received August 19, 1977)

Synopsis. At the oil-water interface, measurements of the interfacial tension were performed simultaneously with the observation of spontaneous emulsification. The effects of an oil-soluble alcohol (1-dodecanol) and a water-soluble surfactant (SDS) on the interfacial tension and on the spontaneous emulsification were studied.

In previous papers,[1,2] the molecular interactions at the Nujol–water interface were studied in relation to the kinds of additives and the tendency of spontaneous emulsification.

In this study, sodium dodecyl sulfate (SDS) was used as a water-soluble surfactant and dodecane containing 1-dodecanol as an oil phase. All have 12 carbon atoms in the hydrocarbon chains, and consequently this system is advantageous for studying the details of the interactions between the molecules causing the spontaneous emulsification.

The interfacial tension showed a minimum value when the 1-dodecanol molar fraction in the oil phase was approximately from 0.05 to 0.10 for all SDS concentrations in the water phase.

Spontaneous emulsification was not observed at the minimum interfacial tension, while it was observed when the molar fraction of 1-dodecanol in dodecane exceeded 0.10 and the concentration of SDS was 6×10^{-3} M*. Spontaneous emulsification with 1-dodecanol was also observed only above an SDS concentration of 4×10^{-3} M.

Experimental

Materials. SDS obtained from the Wako Pure Chemical Industries, Ltd., was purified by recrystallization from ethanol, and extracted with petroleum ehter. Dodecane was supplied from the Nikko Petrochemical Co., Ltd., and 1-dodecanol from the Wako Pure Chemical Industries, Ltd.

Apparatus. The interfacial tension was measured using a Shimadzu Seisakusho, Ltd., Wilhelmy-type Surface Tensiometer.

Procedure. Dodecane and 1-dodecanol were mixed in various proportions to prepare the oil phase, and SDS was dissolved in distilled water. The measurement of the interfacial tension was started 10 min after the beginning of the contact between oil and water phases. Spontaneous emulsification was observed with the unaided eye and was photographed. All measurements carried out at 25 °C.

Results and Discussion

Decrease in Interfacial Tension. The interfacial tension was measured for various compositions of the oil phase consisting of dodecane and 1-dodecanol, as well as for various concentrations of SDS in the water phase. From this the effects of these variations on the interfacial tension were derived.

Figure 1 shows the effect of the variation of the SDS concentration on the interfacial tension for each composition of the oil phase. It is apparent from Fig.1 that the interfacial tension is lowered by the addition of 1-dodecanol in dodecane, and that the extent of the lowering is larger for smaller 1-dodecanol fractions in the oil phase. In this connection, the tension at the interface between the oil phase with a small molar fraction of 1-dodecanol and the water phase, including SDS, was measured. From Fig. 2, it is clear that the interfacial tension decreases greatly when the fraction of 1-dodecanol in the oil phase is in the range from 0.03 to 0.10. The interfacial tension was reduced to about 0.5 dyn**/cm for SDS concentrations

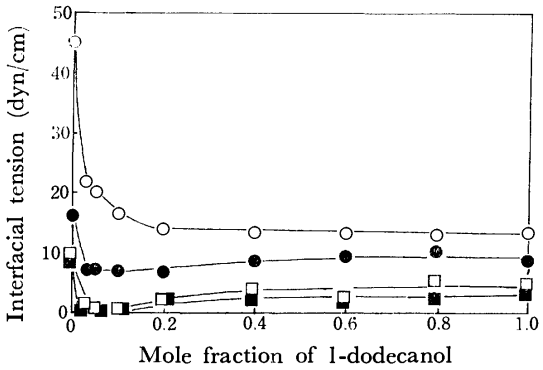

Fig. 3. The effect of composition of oil phase on the interfacial tension at the oil/SDS solution interface. Water phase ○: Water, ●: 2×10^{-3} M, □: 4×10^{-3} M, ■: 6×10^{-3} M.

above 6×10^{-3} M.

The relation between the composition of the oil phase and the interfacial tension is shown in Fig. 3. As is seen in the figure, the minimum value of the interfacial tension appears in the 1-dodecanol molar fraction range of 0.05 to 0.10 for concentrations of the SDS solution above 2×10^{-3} M. The minimum value of such a relation would be the result of molecular interaction between SDS and 1-dodecanol at the interface. When the concentration of 1-dodecanol in the oil phase is so low that no monolayer is formed, for example less than 0.05, and a solution including the other molecular species is injected, a variety of phenomena may occur.[3] If very small quantities of molecular species are present at the oil–water interface, they will eventually, by the processes of diffusion and convection, cause fluctuation, resulting in a large change in the interfacial tension.

Spontaneous Emulsification. The entire contour of the relation of the interfacial tension with the phase composition appearing separately in Figs. 1, 2, and 3 are shown together in Fig. 4. In this figure, the dotted line shows the critical SDS concentration at which spontaneous emulsification begins to occur, with the phases showing milky turbidity.

Figure 5 shows that spontaneous emulsification does not occur even for a SDS concentration in the water phase of 10×10^{-3} M, when the 1-dodecanol molar

** Throughout this paper 1 dyn = 10^{-5} N.

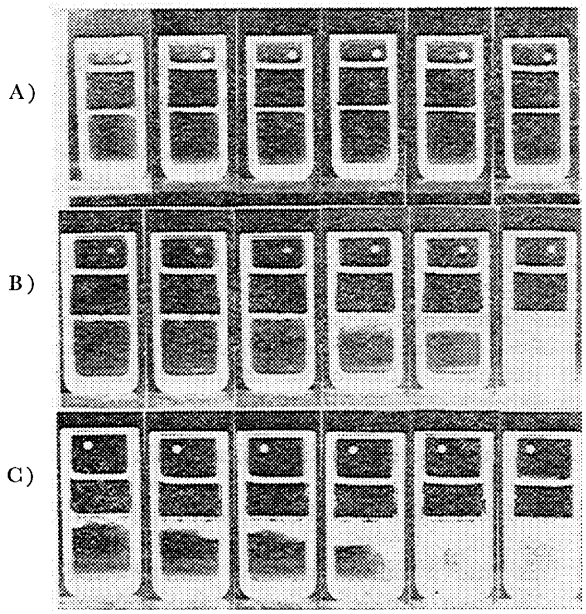

Fig. 5. Observation for spontaneous emulsification.
A) Oil phase dodecane: 1-dodecanol = 0.95 : 0.05. Water phase 10×10^{-3} M SDS solution.
B) Oil phase dodecane: 1-dodecanol = 0.90 : 0.10 Water phase 6×10^{-3} M SDS solution.
C) Oil phase dodecane: 1-dodecanol = 0.80 : 0.20 Water phase 6×10^{-3} M SDS solution.

fraction in the oil phase is 0.05. However, this occurs for SDS concentrations above 6×10^{-3} M, when the 1-dodecanol molar fraction is 0.10 and 0.20. It is apparent that the limit of the appearance of spontaneous emulsification depends on the SDS concentration and the composition of the oil phase rather than on the value of the minimum interfacial tension.

Schulman and Cockbain[4] have shown that spontaneous emulsification occurs when a complex is formed between an oil-soluble substance and a water-soluble surfactant at the oil–water interface. Mori *et al.*[5] have reported the existence of a complex between SDS and 1-dodecanol, and have shown the ratio of alcohol to sulfate to be 0.53—0.63.

In this work, no spontaneous emulsification was observed when the 1-dodecanol molar fraction was less than 0.05, although the interfacial tension showed a minimum. The amount of the complexes formed between the two components must be too small to be detectable with the unaided eye and, consequently, the visual change must be the change introduced by the complex formation.

Proton Magnetic Relaxation Time T_1 of Water in Acrylamide Gel

Seiji KATAYAMA, Yoji ARATA,* and Shizuo FUJIWARA*
Shizuoka College of Pharmacy, 2-2-1, Ojika, Shizuoka 422
**Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113*
(Received August 30, 1977)

Synopsis. Proton magnetic relaxation time T_1 of water in polyacrylamide gel was measured. The results have been interpreted in terms of the contribution from dissolved oxygen and the intrinsic nature of gel. A minimum of $1/T_1$ appears in a system with a *ca.* 2.8% concentration of acrylamide, corresponding to the lowest concentration for gel formation.

The proton spin lattice relaxation time, T_1, of water which is held in a polyacrylamide gel was measured in order to compare the motion of water molecules in the gel with that of bulk water. The gel was prepared by the copolymerization of acrylamide and *N,N'*-methylenebisacrylamide in heavy water, the mole ratio of acrylamide and *N,N'*-methylenebisacrylamide being approximately 80 to 1. The T_1 values of water were measured by the adiabatic rapid passage method using a JNM-C-60H high resolution NMR spectrometer at 60 MHz.

Samples were used under four different conditions: 1) undegassed, 2) degassed at about 10^{-5} mmHg, 3) degassed and polymerized by addition of a small amount of ammonium persulfate to accelerate polymerization, and 4) polymerized without degassing. For samples 3) and 4), no appreciable difference was observed between the values of $1/T_1$ before and immediately after the addition of ammonium persulfate. T_1 measurements were carried out in each case after sufficient elapse of time. The dissolved oxygen in each sample was thus sufficiently in equilibrium with the air pressure contacted (degassed and undegassed conditions).

Plots of $1/T_1$ against the concentration of acrylamide are shown in Figs. 1, 2, and 3. Linearity holds between the acrylamide content and $1/T_1$ of water in acrylamide solutions under atomospheric pressure (Fig. 1). We see that the $1/T_1$ values are considerably shortened by degassing. The paramagnetic effect of dissolved oxygen plays an important role in determining the relaxation.[1,2]

Polymerization causes a remarkable change in the $1/T_1$ values (Fig. 2). The $1/T_1$ values are reduced in a drastic way by polymerization of the solutions at lower concentrations of acrylamide, $1/T_1$ becoming minimum and then increasing.

In marked contrast, no such minimum can be observed in the case of degassed polymer samples (Fig. 3 A). The values of $1/T_1$ observed when the degassed samples are polymerized deviate from a straight line before polymerization (Fig. 3 B). At lower concentrations,

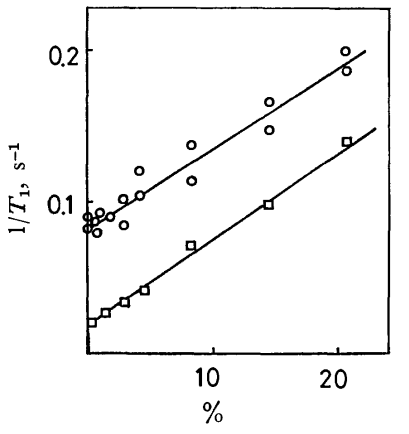

Fig. 1. Plots of $1/T_1$'s of water in acrylamide aqueous solutions *vs.* acrylamide content. —○—: Undegassed samples, —□—: degassed samples.

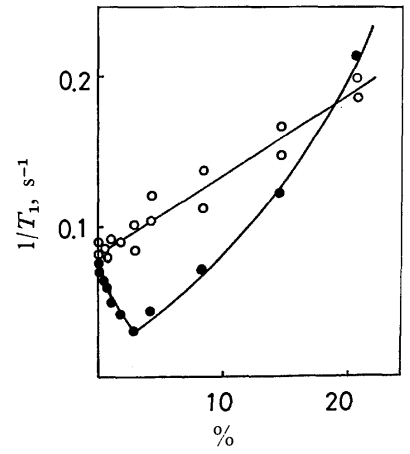

Fig. 2. Plots of $1/T_1$'s of water *vs.* acrylamide content. —○—: Undegassed samples, —●—: Undegassed polymer samples.

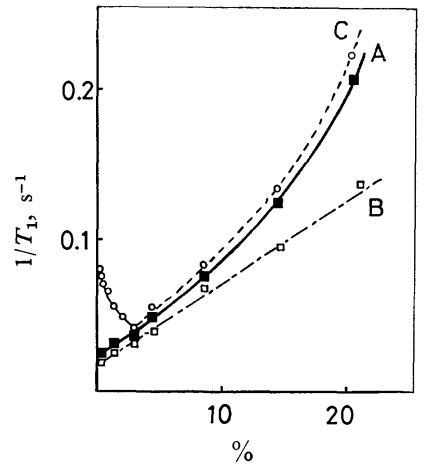

Fig. 3. Plots of $1/T_1$'s of *vs.* water acrylamide content. A —■—: Degassed polymer samples, B —□—: degassed samples, C —○—: undegassed polymer samples.

the line of $1/T_1$ for the polymerized samples (Fig. 3A) nearly coincides with that of samples before polymerization (Fig. 3B), whereas at higher concentrations, the $1/T_1$ values for the polymerized samples (Fig. 3A) increase drastically and are in accord with that for the undegassed polymer samples (Fig. 3C). The fact that very little difference can be observed in the $1/T_1$ values between both polymer samples produced from the degassed and undegassed solutions might indicate that both polymerized samples are essentially the same as regards relaxation of water.

The proton relaxation of water in the polyacrylamide gel is written as

$$(1/T_1)_{obsd} = (1/T_1)_{O_2} + (1/T_1)_{gel},$$

where $(1/T_1)_{obsd}$ is the observed value, $(1/T_1)_{O_2}$ the contribution from the oxygen molecule and $(1/T_1)_{gel}$ the term arising from the intrinsic nature of the gel. It may be concluded that in the sol phase at concentrations lower than 2.8%, the term $(1/T_1)_{O_2}$ dominantly determines T_1, with a negligible contribution from $(1/T_1)_{gel}$. The decrease of $1/T_1$ value with increase in the concentration of acrylamide in this range may be interpreted by the fact that the solubility of oxygen in the polymer solution is reduced with the increase in the concentration of acrylamide.

The above interpretation was deduced from the T_1 data and is not the final conclusion. In the gel phase, $(1/T_1)_{gel}$ becomes dominant, suggesting that the relaxation time T_1 of the water proton in a confined space of the polyacrylamide gel is considerably shortened in comparison with that in bulk water. Two types of water, "bound" and "free" have been assumed to exist in explaining a similar relaxation behavior in biological systems.[3-7] The presence of a small proportion of water having an increased relaxation rate in the bound state can produce a marked reduction in the observed relaxation times.[8-11]

It can be concluded that the minimum point of $1/T_1$ corresponds to the critical concentration at which the gel can be formed.

Complex Anion Radical Salts Derived from Dicyanomethylenetrinitrofluorene

Yoshio MATSUNAGA and Yuji YOSHIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 25, 1977)

Synopsis. Four anion radical salts of the 2 : 3 type were derived from 9-dicyanomethylene-2,4,7-trinitrofluorene. Their electronic spectra, the ESR spectra characteristic of triplet excitons, and the electrical properties were measured.

9-Dicyanomethylene-2,4,7-trinitrofluorene (DTF) has been known to form anion radical salts with a number of onium cations.[1,2] All the cations so far examined have given salts of the 1:1 type. However, Dupuis and Néel have reported the isolation of 1,2,3-trimethylbenzimidazolium salts not only of the 1:1 type, but also of the 1:2 type.[2] In addition, they have noted that the salts prepared by the reduction of DTF with onium iodides tend to include an excess of DTF, which could be eliminated by repeated recrystallizations from acetonitrile. Consequently, it seemed highly likely that some complex anion radical salts could be obtained if the preparation conditions and the cations were appropriately selected.

As has been described by Mukherjee and Levasseur,[1] DTF was prepared by a condensation reaction between 2,4,7-trinitrofluorenone, Eastman reagent-grade, and malononitrile in methanol, and was then recrystallized from acetonitrile. The anion radical salts were obtained by mixing DTF and the onium iodide, separately dissolved in hot acetonitrile, in a mole ratio of 3:2 under a nitrogen atmosphere. The mole ratio employed by Dupuis and Néel was reversed here in order to attempt the isolation of possible complex salts. The greenish-black products were recrystallized two or three times from acetonitrile. Although we examined a number of cations, only the following four complex salts could be isolated (two independent preparations were analysed for each salt). With tetrapropylammonium, Found: C, 59.19, 58.93; H, 4.90, 4.91; N, 16.18, 15.85%. Calcd for $[(C_3H_7)_4N]_2(DTF)_3$: C, 59.13; H, 4.89; N, 16.28%. With tetrabutylammonium, Found: C, 60.81, 60.68; H, 5.89, 5.77; N, 14.28, 13.63%. Calcd for $[(C_4H_9)_4N]_2(DTF)_3$: C, 61.02; H, 5.57; N, 15.12%. With propyltriphenylphosphonium, Found: C, 62.28, 63.68; H, 3.51, 3.45; N, 11.83, 12.19%. With isopropyltriphenylphosphonium, Found: C, 63.07, 63.26; H, 3.56, 3.48; N, 11.89, 12.03%. Calcd for $[C_3H_7(C_6H_5)_3P]_2(DTF)_3$: C, 63.57; H, 3.50; N, 12.36%. The composition was checked by measuring the ratio of optical density at 515 nm to that at 380 nm, following Dupuis and Néel. The optical density at the former wavelength arises solely from the anion, but that at the latter, from both the anionic and neutral species. Dupuis and Néel have found that the ratio is about 0.64 in the 1 : 1 salt and 0.34 in the 1 : 2 salt. The values observed with our salts were in the range from 0.42 to 0.48, and so seemed to be consistent with the proposed composition.

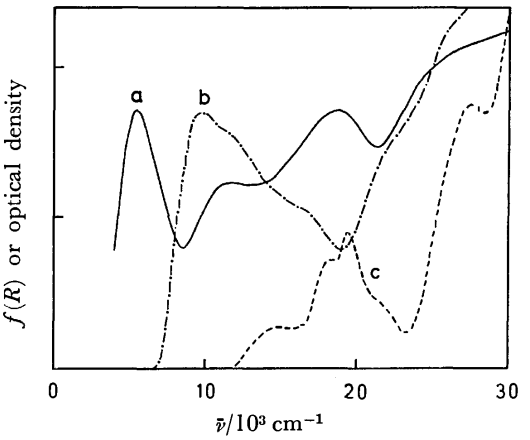

Fig. 1. Diffuse reflection spectra of (a) isopropyltriphenylphosphonium-DTF(2 : 3), (b) lithium-DTF (1 : 1), and (c) absorption spectrum of the DTF^- ion in acetone.

The solid-state spectra of the four salts, as recorded on a Beckman DK-2A spectroreflectometer, are similar to each other. In Fig. 1, the spectra of the isopropyltriphenylphosphonium salt and the simple lithium salt, plotted using the Kubelka-Munk function, are compared with the absorption spectrum of the latter dissolved in acetone. The band around 5.5×10^3 cm^{-1} appears in all the solid complex salts and may be assigned to the charge-transfer transition from the highest occupied level of the DTF anion to the lowest vacant level of the DTF molecule. The second band, located near 11×10^3 cm^{-1}, observable also with the simple salt, may arise from the charge-transfer interaction between the anions.

In the ESR spectra of the present salts taken at the X-band, the appearance of three pairs of resonance lines characteristic of triplet-spin excitons was noted in the temperature range from 30 to 120 °C. No change in the separation of the pair was detected in the measured range; however, the collapse of the inner two pairs by broadening was observed at the highest temperature employed. For the sake of simplicity, an isotropic g value was assumed to be equal to the free electron value; then, the principal axis splittings are related to the zero-field splitting parameters, D and E, by the following equations:

$$d_1 = 2|D/g\beta|,$$
$$d_2 = |D/g\beta| + 3|E/g\beta|,$$
$$d_3 = |D/g\beta| - 3|E/g\beta|,$$

where d_i is the measured separation and β is the Bohr magneton. The numbering, i, is given starting from

Table 1. Zero-field splitting parameters and singlet-triplet separation energies of the complex anion radical salts derived from dicyanomethylenetrinitofluorene

Cation	$\lvert D/g\beta \rvert$ /G	$\lvert E/g\beta \rvert$ /G	J/eV
Tetrapropylammonium	99.5	2.2	0.31
Tetrabutylammonium	97.8	3.9	0.42
Propyltriphenylphosphonium	98.3	3.7	0.28
Isopropyltriphenylphosphonium	95.2	3.4	0.32

the outermost pair of resonance lines. The estimated parameters are summarized in Table 1. The magnitude depends on the average spatial distribution of the correlated spins of the exciton. When the spins interact strongly, the parameters may be expected to increase. The values of $|D/g\beta|$ in our salts, 95—99 G, are close to those in the complex TCNQ salts of the 2:3 type, 100 G, while the simple TCNQ salts are known to give values of 140—170 G, and the complex salts of the 1:2 type, about 70 G.[3] Thus, one may be led to the conclusion that the spins in the DTF salts are as delocalized as those in the TCNQ salts and are more delocalized than those in the anion radical salts derived from 2,3-dicyano-1,4-naphthoquinone studied earlier.[4] Taking the peak height or the peak-to-peak intensity on the first derivative curve as a measure of the relative intensity of the ESR absorption for a triplet state, I, the following approximation was found to be well-obeyed;

$$I \times T \propto \exp(-J/kT),$$

where J is the energy for the singlet-triplet separation. The energies listed in Table 1 are comparable with the values for the dicyanonaphthoquinone salts. The absence of any appreciable exciton-exciton exchange in the DTF salts is consistent with such large separation energies.

The electrical resistivities, ρ, observed with polycrystalline compactions were in the order of 10^4 or 10^5 ohm cm at room temperature. These values are close to those reported by Dupuis and Néel for their simple DTF salts containing aromatic counter ions with large polarizabilities.[5] The temperature-dependence recorded employing the potential-probe method described before[6] does not fit in with the usual exponential law, $\rho=\rho_0 \exp(E/kT)$. The increase at high temperatures was found for the tetrabutylammonium and propyltriphenylphosphonium salts. Such behavior is not unexpected when the conduction is extrinsic in the measured range, but the impurity concentration is low. The intrinsic resistivities of the present complex anion radical salts at room temperature may be higher by a factor of tens or hundreds than the observed values.

The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education (No. 234028).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (5), 1549—1550 (1978)

Spectroscopic Similarity of Charge-Transfer Absorptions in Crystalline Complex Ion Radical Salts

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 29, 1977)

Synopsis. Charge-transfer transition between ion radical molecules takes place in crystalline ion radical salts. Spectroscopic similarity of the charge-transfer absorptions between certain systems of complex ion radical salts has been studied with use of a one-dimensional Hubbard model.

In most solid ion radical salts, the planar ion radical molecules are known to form, in themselves, a face-to-face stacking into infinite one-dimensional columns so as to make a large overlap between their half-occupied molecular orbitals.[1-5] In this case, since any individual radical molecule interacts through charge-transfer most strongly with two other neighboring radicals, the electronic spectrum of the solid salt differs distinctly from the monomer spectrum of the radical ion in solution, showing a charge-transfer transition between ion radicals in the low-energy region.[6,7]

Two kinds of solid ion radical salts are known:[1-7] (a) simple ion radical salts in which each ion radical molecule has one unpaired electron, considered to be a one-dimensional system of sites with half-occupied orbital; (b) complex ion radical salts, which include not only ion radicals but also formally neutral parent molecules, belonging to a one-dimensional system of sites with less than half-occupied orbital. In the present paper, it is shown that the charge-transfer absorption of the system with less than half-occupied orbital has spectroscopic properties similar to those for the system with more than half-occupied orbital.

In order to describe a narrow energy band with strong electron correlation in the crystalline ion radical salts, we consider a system of electrons expressed by the Hubbard Hamiltonian,[8]

$$\mathscr{H} = \sum_{i,j,\sigma} t_{ij} C_{i\sigma}{}^{+} C_{j\sigma} + I \sum_{i} n_{i\downarrow} n_{i\uparrow}, \tag{1}$$

where $n_{i\sigma}=C_{i\sigma}{}^{+}C_{i\sigma}$, and $C_{i\sigma}{}^{+}$ and $C_{i\sigma}$ are the creation and annihilation operators of an electron with σ-spin at the i-th site, respectively, t_{ij} is the transfer matrix element between the i-th and j-th sites, the intra-site Coulomb repulsive potential, I, appearing only when two electrons with up and down spins are at the same site. We consider one-dimensional stack of planar molecules including unpaired electrons in the solid state, and apply the one-particle Green's function given by Hubbard (often referred to as Hubbard I).[8] For the sake of simplicity, we assume non-alternant linear chain of equivalent sites for which the transfer matrix element, denoted by $T<0$, is taken only between the nearest neighbor sites. Discussion is restricted to the spectroscopic feature of the charge-transfer absorption. The charge-transfer absorption due to the transition of electrons with up spin in such one-dimensional column is given by[9]

$$\mathrm{Re}\sigma_{xx}(\omega) \propto A_{+}(\omega)\theta_{+}(\omega) + A_{-}(\omega)\theta_{-}(\omega), \tag{2}$$

$$A_{\pm}(\omega) = \frac{e^2}{2}\frac{I^2 n_{\downarrow}(1-n_{\downarrow})}{\omega^2\sqrt{\omega^2-4I^2n_{\downarrow}(1-n_{\downarrow})}}\sqrt{4T^2-\varepsilon_{\pm}(\omega)^2}, \tag{3}$$

$$\varepsilon_{\pm}(\omega) = -I(2n_{\downarrow}-1) \pm \sqrt{\omega^2-4I^2n_{\downarrow}(1-n_{\downarrow})}, \tag{4}$$

where ω is the frequency of electromagnetic wave absorbed by electrons with up spin, $n_{\downarrow}=<n_{i\downarrow}>$ being the mean number of electrons with down spin per site in the Hartree-Fock scheme.[8] $\theta_{\pm}(\omega)$ is the term related to Fermi distribution function, $f(E)$, and is given by $f(E_{\pm}{}^{L})-f(E_{\pm}{}^{U})$, where

$$E_{\pm}^{L} = \frac{1}{2}\left\{\varepsilon_{\pm}(\omega)+I-\sqrt{(\varepsilon_{\pm}(\omega)+I)^2-4I(1-n_{\downarrow})\varepsilon_{\pm}(\omega)}\right\}, \tag{5}$$

$$E_{\pm}^{U} = \frac{1}{2}\left\{\varepsilon_{\pm}(\omega)+I+\sqrt{(\varepsilon_{\pm}(\omega)+I)^2-4I(1-n_{\downarrow})\varepsilon_{\pm}(\omega)}\right\}. \tag{6}$$

If we assume a paramagnetic state (*i.e.*, $n_{\downarrow}=n_{\uparrow}$), an expression of the charge-transfer absorption similar to Eqs. 3 and 4 is obtained for electrons with down spin. Hereafter, we take only the absorption due to electrons with up spin. The character of the charge-transfer absorption of a complex ion radical salt with mean number of electrons, $n_{\downarrow}$, then depends strongly on $n_{\downarrow}$, $(0\leq n_{\downarrow}\leq 1)$.

We next consider complex ion radical salts in which the mean number of electrons with down spin is given by $1-n_{\downarrow}$. We also assume a paramagnetic state and magnitudes of I and T common to those of the $n_{\downarrow}$ system, respectively. The charge-transfer absorption of the $(1-n_{\downarrow})$ system is given by

$$\mathrm{Re}\sigma'_{xx}(\omega) \propto A_{+}'(\omega)\theta_{+}'(\omega) + A_{-}'(\omega)\theta_{-}'(\omega), \tag{7}$$

where $A_{\pm}'(\omega)$ and $\theta_{\pm}'(\omega)$ are derived from $A_{\pm}(\omega)$ and $\theta_{\pm}(\omega)$ by replacing $n_{\downarrow}$ by $1-n_{\downarrow}$, respectively. However, if we pay attention to the forms of Eqs. 3 and 4, we note that

$$A_{\pm}'(\omega) = \frac{e^2}{2}\frac{I^2 n_{\downarrow}(1-n_{\downarrow})}{\omega^2\sqrt{\omega^2-4I^2n_{\downarrow}(1-n_{\downarrow})}}\sqrt{4T^2-\varepsilon_{\pm}'(\omega)^2}, \tag{8}$$

$$\varepsilon_{\pm}'(\omega) = -\varepsilon_{\mp}(\omega). \tag{9}$$

Thus, we obtain

$$A_{\pm}'(\omega) = A_{\mp}(\omega). \tag{10}$$

The charge-transfer absorption of the $(1-n_{\downarrow})$ system is then given by

$$\mathrm{Re}\sigma_{xx}'(\omega) \propto A_{-}(\omega)\theta_{+}'(\omega) + A_{+}(\omega)\theta_{-}'(\omega). \tag{11}$$

As for the term related to the Fermi distribution function, the Fermi energy for the $(1-n_{\downarrow})$ system differs from that for the $n_{\downarrow}$ system. However, if the intra-site Coulomb repulsion energy is much greater

than the energy due to the observed temperature, we can put $\theta_{\pm}(\omega)\approx 1$ and $\theta'_{\pm}(\omega)\approx 1$. The magnitudes of I for a number of organic ion radical salts have been reported to be of the order of 1 eV.[9] This is found to be much larger than the room-temperature energy of ≈ 0.026 eV. Under these conditions, the charge-transfer absorption of $\mathrm{Re}\sigma'_{xx}(\omega)$ for the $(1-n_{\downarrow})$ system has spectroscopic properties identical with those of $\mathrm{Re}\sigma_{xx}(\omega)$ for the $n_{\downarrow}$ system, except for a difference between $\theta_{\pm}(\omega)$ and $\theta'_{\mp}(\omega)$. The symmetrical point with respect to the number of electrons with down spin is then at $n_{\downarrow}=1/2$. The system $n_{\downarrow}=1/2$ corresponds to the half-occupied orbital system of simple ion radical salt where each site has one unpaired electron. If we consider a system of complex ion radical salt with $n_{\downarrow}<1/2$, we can expect another kind of complex ion radical salt of $1-n_{\downarrow}>1/2$ with the common I and T values. Thus the spectroscopic features of the charge-transfer absorptions of both less than half-occupied orbital system (the $n_{\downarrow}$ system) and more than half-occupied orbital system (the $1-n_{\downarrow}$ system) are similar.

With respect to negatively charged ion radical salts, 7,7,8,8-tetracyanoquinodimethane (TCNQ) has been known to form a number of complex anion radical salts, as well as simple anion radical salts, with various counter cations.[1-6] Different stoichiometries of the type $(M^+)_m(TCNQ)_n^{m-}$ are obtainable even for a single cation, M^+. For example, morpholinium–TCNQ forms $(m:n)=(1:1)$, $(2:3)$, and $(3:4)$ crystalline anion radical salts,[5,10] while methyltriphenylphosphonium–TCNQ gives $(1:1)$ and $(1:2)$ salts.[1,6] The salts with $(1:1)$ composition correspond to simple anion radical salts of half-occupied orbital system, while those with other compositions are complex anion radical salts. Not only simple TCNQ anion radical salts but also complex ones show strong charge-transfer absorptions due to the transitions between unpaired electrons in the low-energy regions.[6,9] So far, only the complex salts with less than half-occupied orbital system (*i.e.*, $m<n$) are known. No experimental data have been given on the formation and thus the spectroscopic properties of the complex salts with more than half-occupied orbital system (*i.e.*, $m>n$). However, the above theoretical prediction strongly suggests that the spectroscopic features of the charge-transfer absorption of $(M^+)_m(TCNQ)_n^{m-}$, $(m<n)$, salt are very similar to those of $(M^+)_{2n-m}(TCNQ)_n^{(2n-m)-}$ salt of more than half-occupied orbital system, as long as the assumptions for deriving Eqs. 2—11 hold for these two compounds.

As for positively charged ion radical salts, few compounds are known to form crystalline complex cation radical salts with diamagnetic counter anions. For example, tetrathiafulvalene (TTF) forms such cation radical salts as $(TTF)_n^{m+}(I^-)_m$, $(m:n=0.7:1)$.[11] There should be spectroscopic similarity of the charge-transfer absorptions between complex cation radical salts of less than half-occupied and more than half-occupied orbital systems. The situation would be analogous to that of complex anion radical salts.

The author wishes to thank Dr. Kenn Kubo for his useful suggestions.

Surface Tensions of Several Rare-earth Chlorides and Binary NaCl–YCl_3 System in Molten State

Kazuo IGARASHI, Junichi MOCHINAGA, and Shiro UEDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received November 2, 1977)

Synopsis. The surface tensions of YCl_3, $LaCl_3$, $PrCl_3$, $NdCl_3$, $GdCl_3$, and $DyCl_3$, and binary NaCl–YCl_3 system in molten state were measured by a maximum bubble pressure method, and the results were represented by empirical formulas as functions of temperature. Surface enthalpies of rare-earth chlorides were calculated from the formulas.

Surface tension is important for thermodynamic considerations, since it is related to the interaction between the species in the melts and is necessary for calculating surface properties such as surface enthalpy and surface entropy. The surface tensions of binary $LaCl_3$–alkali chloride and –alkaline earth chloride systems in molten state have been reported by Smirnov and Stepanov[1] and those of binary $NdCl_3$–alkali chloride systems in molten state by Kurmaev *et al.*[2] In the present experiment, the surface tensions of YCl_3, $LaCl_3$, $PrCl_3$, $NdCl_3$, $GdCl_3$, and $DyCl_3$, and binary NaCl–YCl_3 system were measured, and represented by empirical formulas as functions of temperature. Negative deviation from the surface tension calculated by use of Guggenheim's equation[3] for ideal solution takes place in the isotherm of surface tension for binary NaCl–YCl_3 system.

Experimental

Materials. Rare-earth chlorides were prepared by the similar procedure to that given in the previous paper.[4] NaCl of analytical grade was dried by heating *in vacuo* at temperature 50 °C below the melting point for several hours. Argon gas was purified by passing through P_2O_5 and heated Ti sponges at 1000 °C.

Measurement. Maximum bubble pressure method was used. Two types of capillaries were used, one made of transparent quartz and the other of Pt-Rh(10% Rh) alloy. The surface tensions of binary NaCl–YCl_3 mixture melts were measured with the quartz capillary. The pressure of argon bubbles in the melts was measured with a manometer containing dibutyl phthalate, which was kept at 30.4±0.1 °C in a water bath. The surface tensions were calculated by means of Schrödinger's[5] equation giving the relation between bubble pressure and surface tension. The surface tension of NaCl and $CaCl_2$ in molten state were measured to check the apparatus, the observed values being in good agreement with the data given by Bloom *et al.*[6] and Grjotheim *et al.*[7]

Results and Discussion

Surface Tensions of Rare-earth Chlorides. The temperature dependence of the surface tensions for YCl_3, $LaCl_3$, $PrCl_3$, $NdCl_3$, $GdCl_3$, and $DyCl_3$ in molten state are shown in Fig. 1. The surface tension decreases linearly with increasing temperatrue within the range of measurement. The values

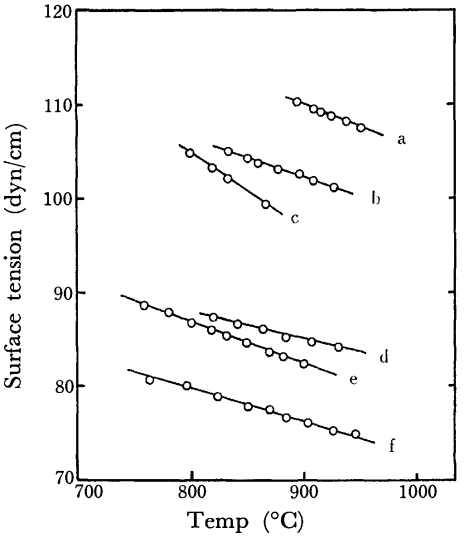

Fig. 1. Surface tensions of rare-earth chloride melts. a: $LaCl_3$, b: $PrCl_3$, c: $NdCl_3$, d: $GdCl_3$, e: $DyCl_3$, f: YCl_3.

TABLE 1. SURFACE TENSION EQUATIONS OF PURE MOLTEN SALTS

Salt	$\gamma=a+bt$ γ : (dyn/cm), t(°C)	σ (dyn/cm)	Temp range (°C)
YCl_3	$\gamma=106.3-0.0334t$	0.158	768—946
$LaCl_3$	$\gamma=147.9-0.0423t$	0.121	892—950
$PrCl_3$	$\gamma=135.9-0.0372t$	0.034	830—926
$NdCl_3$	$\gamma=173.4-0.0855t$	0.166	800—865
$GdCl_3$	$\gamma=110.1-0.0278t$	0.139	820—930
$DyCl_3$	$\gamma=124.4-0.0465t$	0.069	760—901

are represented by linear empirical formulas as functions of temperature. The formulas are given in Table 1, together with standard error, σ.

The values obtained for $LaCl_3$ melts were slightly lower than that reported by Smirnov *et al.*[8]

Surface Enthalpies of Rare-earth Chlorides. The surface enthalpies of rare-earth chlorides in molten state were calculated by the equation

$$H^s = \gamma - T\left(\frac{d\gamma}{dT}\right),$$

where H^s is the surface enthalpy in erg/cm^2, γ the surface tension of molten salt in dyn/cm, and T the absolute temperature. The results are given in Table 2. Comparing the surface enthalpies of the molten chlorides with those of other molten salts, we see that the molten chlorides have similar surface enthalpies except for YCl_3, $NdCl_3$, and $GdCl_3$ melts. The values of

Table 2. Surface enthalpies of pure molten salts

Salt	H^s (erg/cm^2)
YCl_3	115.4
$LaCl_3$	159.5
$PrCl_3$	146.1
$NdCl_3$	196.8
$GdCl_3$	117.7
$DyCl_3$	137.1

Table 3. Surface tension equations of molten binary NaCl-YCl_3 system

YCl_3 (mol%)	$\gamma=a+bt$ γ : (dyn/cm), t(°C)	σ (dyn/cm)	Temp range (°C)
0.0	$\gamma=173.1-0.0747t$	0.180	830—950
17.7	$\gamma=165.2-0.0853t$	0.332	819—910
38.1	$\gamma=140.2-0.0628t$	0.420	747—901
50.0	$\gamma=111.8-0.0346t$	0.113	787—857
63.8	$\gamma=108.0-0.0350t$	0.136	795—938
80.0	$\gamma=94.9-0.0239t$	0.166	806—876
100.0	$\gamma=106.3-0.0334t$	0.158	768—946

the molten YCl_3 and $GdCl_3$ were intermediate between those of the molten chlorides and covalent liquids such as benzene and methanol, the value of $NdCl_3$ being larger than that of the others.

Binary NaCl-YCl_3 Mixture. The isotherm of surface tension of molten binary NaCl-YCl_3 mixture at 825 °C is shown in Fig. 2. The surface tensions are represented by empirical formulas as functions of temperature. The results are given in Table 3. In binary molten salt mixtrures with a common anion, the surface tensions show a negative deviation from

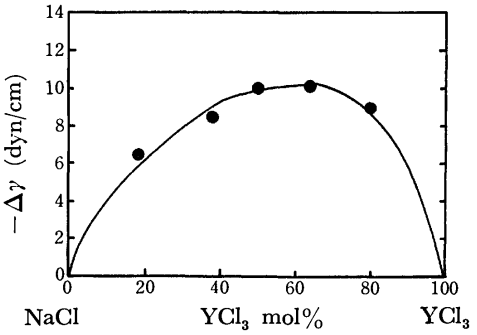

Fig. 3. Negative deviation of molten binary NaCl-YCl_3 mixture at 825 °C.

surface tension isotherms of ideal solution calculated by use of Guggenheim's equation. In this binary NaCl-YCl_3 mixture, a large negative deviation was observed. The negative deviation at 825 °C is shown in Fig. 3.

The maximum value of the deviation was observed at about 65 mol% in YCl_3. For the calculations of surface tensions, the densities of these melts were used with the data given in previous papers.[9-11]

The calculations were carried out with the computer at Chiba University.

The authors wish to thank Mr. T. Matsumaru for his kind assistance.

Characteristic Behavior of Damping Coefficient of Capillary Wave on Surfactant Solution

Minoru SASAKI, Tatsuya YASUNAGA, Minoru ASHIDA, and Haruki KAN

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Horishima 730

(Received November 15, 1977)

Synopsis. The damping coefficient of a capillary wave on decylamine hydrochloride and octylamine hydrochloride solutions decreased abruptly in the vicinity of a critical micelle concentration. The phenomenon observed was well interpreted by an equation derived on the basis of a surface mechanical impedance.

The dynamic properties of surfactants existing on a surface have been studied by means of capillary wave technique.[1-4] Most of the experimental studies have been carried out on the surfactant solutions below a critical micelle concentration (CMC) and the phenomena observed have been attributed to the diffusion and adsorption-desorption of surfactants between the surface and the bulk phase.

Preliminary measurements on decylamine hydrochloride (DeAC) solution above the CMC revealed that the damping coefficient of the wave decreases abruptly in the vicinity of the CMC. The purpose of this paper is to study the above phenomenon on the DeAC and octylamine hydrochloride (OAC) solutions above the CMC.

Experimental

The apparatus employed was the same as that reported previously.[1] The frequency range of measurement was 45 to 600 Hz at 25±0.4 °C.

The DeAC and OAC were prepared from decylamine (purity, 99.8%) and octylamine (purity, 99.9%) according to the previous procedure,[4] respectively. The CMC values of the DeAC and OAC solutions were determined to be 62 and 180 mM*, respectively.

Results and Discussion

The frequency dependence of the damping coefficient, α, was measured in the DeAC and OAC solutions above the CMC. The results are shown in Figs. 1 and 2, together with the data on the solutions below the CMC.[4] As can be seen from these figures, the α/f values on the solutions above the CMC are considerably smaller than those below the CMC, where f is the frequency. If the phenomenon is related to some chemical relaxation, the α/f value should be greater than that based on only the diffusion of surfactants between surface and bulk phase. This prediction, however, contradicts the present result.

One next considers the effect of a bending viscosity which has been observed on a highly condensed insoluble monolayer.[5] The theoretical curve of α/f based on the bending viscosity is shown by the curve

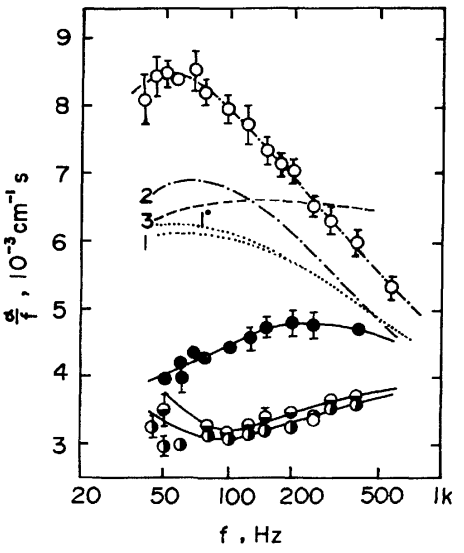

Fig. 1. Frequency dependence of α/f on the DeAC solutions. curves 1(C>CMC) and 1'(C<CMC): theoretical curves based on only the diffusion, curve 2: theoretical curve based on the relaxation, curve 3: theoretical curve based on the bending viscosity.[5] The solid lines shown the theoretical curves calculated by Eq. 3.
○: 50 mM (below the CMC), ●: 62.5 mM (G^σ = 1.8 dyn cm^{-1}, $\eta^\sigma = 3.9\times10^{-3}$ dyn cm^{-1} s), ◒: 70 mM ($G^\sigma = 3.1$ dyn cm^{-1}, $\eta^\sigma = 3.5\times10^{-3}$ dyn cm^{-1} s), ◑: 80 mM ($G^\sigma = 3.0$ dyn cm^{-1}, $\eta^\sigma = 4.3\times10^{-3}$ dyn cm^{-1} s).

3 in Fig. 1. As can be seen from this figure, the tendency of this curve differs from that of the experimental curve.

Let us introduce a surface mechanical impedance, Z, concerned with the normal stress which is proportional to the rate of change in the curvature of the surface, ζ. The boundary condition for the balance of the normal stress at the gas-liquid interface is represented by the following relation:[6]

$$\gamma\zeta + p - 2\eta\frac{\partial v}{\partial y} - Z\frac{\partial\zeta}{\partial t} = 0, \qquad (1)$$

where y is a rectangular coordinate tangent to the surface at rest, v the component in the y direction, γ the surface tension, p the hydrostatic pressure, η the viscosity, and t the time. Furthermore, one assumes that Z is given by the linear combination of the elasticity, G^σ, and the viscosity, η^σ, as follows:

$$(2i\pi fZ)^{-1} = \{G^{\sigma-1} + (2i\pi\eta^\sigma f)^{-1}\}^{-1}. \qquad (2)$$

According to the previous treatment,[6] a combination of Eqs. 1 and 2 gives the following equation for α:

* Throughout this paper, 1 mM = 10^{-3} mol dm^{-3}.

$$\frac{\alpha}{f} = \frac{4\pi}{3c}(\varepsilon_{ela}+\varepsilon_r)_{im} - \frac{4\pi^2 k G^{\sigma 2}\eta^\sigma f}{3\rho c^3\{G^{\sigma 2}+(2\pi\eta^\sigma f)^2\}}, \quad (3)$$

where ε_{ela} and ε_r are the parameters concerned with the surface viscoelaticity and the relaxation,[6] respectively; ρ is the density, k the wave number, c the propagation velocity, and the subscript im indicates the imaginary part. In the present case, ε_r was ignored because of the absence of the relaxation. The theoretical curves calculated by Eq. 3 are shown by the solid lines in Figs. 1 and 2. Here, the values of the parameters G^σ and η^σ in Eq. 3 were determined so as to reduce the residual variance about the regression line. As can be seen from these figures, the experimental values fall on the theoretical curves. This fact suggests the validity of the present theory.

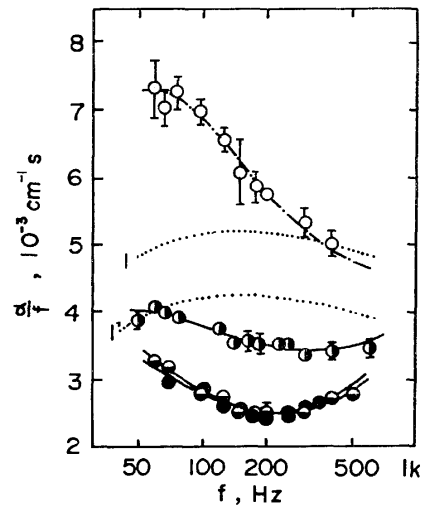

Fig. 2. Frequency dependence of α/f on the OAC solutions. curves 1(C>CMC) and 1'(C<CMC): theoretical curves based on only the diffusion. The solid lines show the theoretical curves calculated by Eq. 3.
○: 114 mM (below the CMC), ◑: 250 mM (G^σ = 2.4 dyn cm^{-1}, $\eta^\sigma = 1.0\times10^{-3}$ dyn cm^{-1} s), ◒: 280 mM (G^σ = 3.7 dyn cm^{-1}, $\eta^\sigma = 1.4\times10^{-3}$ dyn cm^{-1} s), ●: 351 mM (G^σ = 3.8 dyn cm^{-1}, $\eta^\sigma = 2.0\times10^{-3}$ dyn cm^{-1} s).

Since we have no direct measure of G^σ and η^σ, we infer their validity from the following consideration. According to the present idea, the dynamic surface tension in the case of $f \gg \eta^\sigma/G^\sigma$ is expressed by a sum of γ and G^σ. From the data of the dynamic surface tension in sodium dodecyl sulfate solution above the CMC,[7] the G^σ value was obtained to be *ca.* 3 dyn cm^{-1} (1 dyn = 10^{-5} N). This value is of the same order as that obtained in the present work (3.8 dyn cm^{-1} in the 351 mM OAC solution). This agreement in the order of magnitude gives further evidence of the validity of the present theory. No consideration for η' was made.

Further clarification for G^σ and η^σ will be reported in a subsequent paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (5), 1555—1556 (1978)

Temperature Effect on the Molecular Weight and the Optical Purity of Anhydropolyaspartic Acid Prepared by Thermal Polycondensation

Etsuo KOKUFUTA, Shinnichiro SUZUKI, and Kaoru HARADA

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki, 300-31

(Received November 16, 1977)

Synopsis. Anhydroyplyaspartic acid (APAA) was prepared by the thermal polycondensation of L-aspartic acid in the solid state at 160—220 °C for 5 h. The effect of temperature on molecular weight and optical purity of APAA was investigated. The molecular weight increases rapidly in the temperature range 180—200 °C, the yield of APAA also increasing rapidly. The optical purity decreases rapidly with rise in temperature from 160—180 °C.

In recent years, the thermal polycondensation of α-amino acids has drawn attention in view of the prebiotic formation of polypeptides. Aspartic acid yields anhydropolyaspartic acid (APAA) by thermal polycondensation in the solid state at around 200 °C.[1] APAA was converted into polyaspartic acid (PAA) having α- and β-aspartyl residues by alkaline hydrolysis.[2] Studies on the chemical structure[2–5] and potentiometric titration behavior[6] for APAA and PAA have been reported. However, little attention has been paid to the temperature effect on the physical properties of these polyamino acids prepared by thermal polycondensation.

In the present study, the effect of reaction temperature on the molecular weight, yield and optical purity of APAA was examined.

Experimental

Materials. L-Aspartic acid (10.0 g, 0.0752 mol) was packed tightly on the bottom of a 0.5 litre Erlenmeyer flask and was heated at various temperatures (160—220 °C) for 5 h under nitrogen atmosphere. The reaction time (5 h) was chosen since the yields of APAA become almost constant by heating at 180 and 200 °C for 5 h.[7] The slightly colored product was suspended in water and then dialyzed against distilled water for 5—6 days.[3] The weight losses of the products obtained at 160 and 220 °C during the dialysis are 97 and 29%, respectively. The insoluble material was collected by filtration and washed with distilled water and ethanol. APAA obtained was dried at 120 °C over phosphorus pentaoxide under reduced pressure for 4 days. PAA was prepared from APAA in the same way as described earlier.[6,7] APAA and PAA were characterized by infrared spectra and potentiometric titrations. PAA was titrated with 0.1 M NaOH, whereas APAA previously treated with 0.1 M NaOH was back-titrated with 0.1 M HCl.

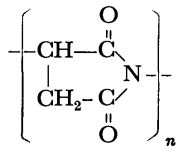
Viscometric Measurement. Viscometric measurements were carried out to investigate the change of molecular weight of APAA by reaction temperature. APAA was dissolved in 0.5 M NaOH and allowed to stand at 25 °C for 24 h. Measurements were carried out at 25±0.01 °C with a Ubbelohde capillary viscometer with 388.5 s flowing time for water at 25 °C. The reduced viscosity (η_{sp}/C) was determined at a constant concentration (C=0.179 g/dl).

Titration of N-Terminal Amino Groups with Perchloric Acid. The molecular weight of PAA derived from APAA prepared at various temperatures was determined by means of N-terminal amino group titration. PAA (20 mg) was dissolved in 5 ml of purified *N,N*-dimethylformamide. The sample solutions were titrated with 0.02 M perchloric acid with a microburet. The crystal violet was used as an indicator.

Determination of Optical Purity. APAA (20 mg) was hydrolyzed with 6 M HCl (5 ml) in a sealed tube at 110 °C for 24 h under reduced pressure. The hydrolyzate was evaporated to dryness, and the residue was dissolved in 6 M HCl. The molar ellipticity [θ] was measured with a JASCO model J-20C recording spectropolarimeter at wavelength 236 nm. On the other hand, the [θ] value at 236 nm for a standard solution of L-aspartic acid in 6 M HCl was also obtained. The concentrations of aspartic acid in the hydrolyzed samples and the standard solution (0.05—0.1 mol/l) were measured with a Yanagimoto model LC-5S amino acid analyzer. The optical purity of anhydroaspartyl residue in APAA was estimated by the ratio of the [θ] value of the sample solution to that of the standard solution.

Results and Discussion

APAA prepared by thermal polycondensation is mainly composed of the imide structure and is quantitatively hydrolyzed to aspartic acid.[2,3,7] The



structure is also supported by the results of potentiometric titration and infrared spectra. The molecular weight of repeating unit was estimated to be 99±2 for APAA and 115±1 for PAA by means of potentiometric titration. The infrared spectrum of APAA shows moderate absorption at 1780 cm^{-1}

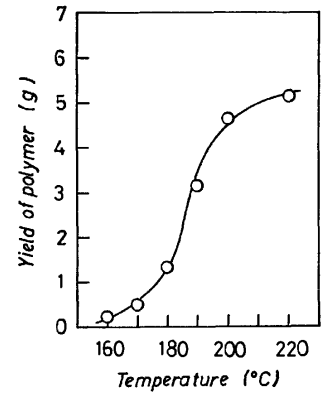


Fig. 1. Temperature effect on the yield of APAA. The yield is represented by the weight of APAA obtained from 10.0 g of L-aspartic acid.

and strong absorption at 1715 cm^{-1}, indicating the presence of 5-membered cyclic imide,[3,8] and moderate absorption at 1530 cm^{-1}(amide II). The infrared spectrum of PAA shows strong absorption at 1720 cm^{-1} (COOH), 1650 cm^{-1} (amide I), and 1530 cm^{-1} (amide II).

The relationship between the yield of APAA and the reaction temperature is shown in Fig. 1. It is seen that the yield of APAA rapidly increases with rise in reaction temperature from 180—200 °C. On the other hand, aspartic acid hardly undergoes polycondensation at all by heating below 160 °C.

The effect of reaction temperature on the molecular weight of APAA was investigated by means of viscometric measurement for APAA in 0.5M NaOH, and N-terminal amino group titration for PAA prepared from APAA. The results are shown in Fig. 2. Assuming that degradation of the polypeptide chain does not occur during the course of partial alkaline hydrolysis of the imide structure of APAA, we can estimate the molecular weight of APAA by means of the N-terminal amino group titration of PAA. The result obtained indicates that the molecular weight of APAA increases rapidly in the temperature range 180—200 °C. This is also supported by the result obtained by the viscometric measurement of APAA. It is evident that the molecular weight of APAA increases rapidly in the temperature range at which the yield of APAA increases rapidly.

The effect of reaction temperature on the optical

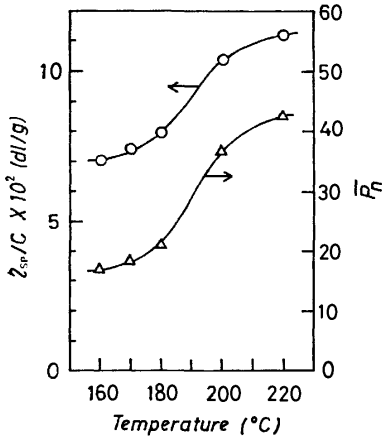

Fig. 2. Temperature effect on the molecular weight of APAA.
The reduced viscosity (η_{sp}/C) of APAA was determined in 0.5 M NaOH at C=0.175 g/dl.
The $\overline{P}_n$ represents the number-average degree of polymerization of PAA.

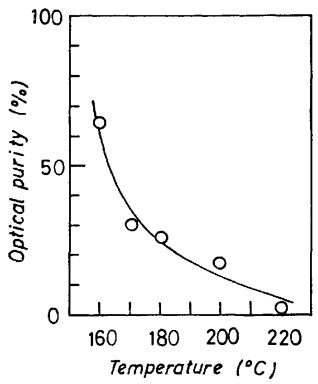

Fig. 3. Temperature effect on the optical purity of APAA.

purity of APAA is shown in Fig. 3. The optical purity decreases rapidly with rise in temperature from 160—180 °C, approaching almost zero percent in the region above 220 °C at which higher yield and higher molecular weight of APAA are obtained. The optical purity of aspartyl residue in the copolymer of aspartic acid and glutamic acid, prepared by thermal polycondensation in the molten state at 170 °C for 3 h, was also almost zero percent.[9] It seems that the racemization of L-aspartic acid by the thermal polycondensation in the molten state takes place faster than that in the solid state.

This work was partially supported by a Scientific Research Grant from the Ministry of Education.

Distribution of Trace Rare Earth Element Ions in the Crystallization Process of Alums

Hitoshi KANNO,* Hiroshi WAKITA, and Hiroshi HAMAGUCHI**

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 16, 1977)

Synopsis. The distribution coefficients of rare earth element ions between alums and aqueous solution were determined.

We have studied the effects of ionic size on the distribution of trace ions between crystal and aqueous solution. Rare earth element ions are suitable for this purpose, since they are all similar in chemical properties, differing only in ionic size.[1] In addition, the large variety of alums and the existence of more than 200 different compounds with the structure $M(I)M(III)(RO_4)_2 \cdot 12H_2O$, ($M(I)=Na^+$, K^+, NH_4^+, Rb^+, Cs^+, Tl^+ ···; $M(III)=Al^{3+}$, Ga^{3+}, In^{3+}, Cr^{3+}, ···; R=S, Se, ···)[2] provide us a good chance to clarify the effects of ion size and chemical nature on trace ion distribution.

As a first step we took up $KAl(SO_4)_2 \cdot 12H_2O$, $NH_4Al(SO_4)_2 \cdot 12H_2O$, and $NH_4Fe(SO_4)_2 \cdot 12H_2O$ as host crystals. The crystals were grown at room temperature by evaporating aqueous alum solutions containing rare earth element (REE) ions and alkali ions, the concentration of each element (other than potassium) being *ca.* 40 ppm. The contents of REE in both crystal and solution were determined by non-destructive neutron activation analysis.[3] Alkali ion contents were qualitatively measured by both atomic absorption spectroscopy[4] and neutron activation analysis (for Rb and Cs).

The distribution coefficient of REE is tentatively expressed by

$$D = \frac{X_i^s(1\text{ g of crystal})}{X_i^l(1\text{ ml of residual solution})},$$

where X_i is the content of rare earth element i in either crystal or solution, and subscripts s and l denote crystal and residual solution, respectively. The results are plotted against the ionic radius of REE. We see distinct dependence of the distribution coefficient on ionic size for potassium alum but not for ammonium alums, indicating that M(I) ion in the alum greatly affects the distribution pattern of trace ions (Fig. 1).

There are three possible mechanisms in the incorporation of trace ions in the crystallization process, *i. e.*, surface adsorption, occlusion and solid solution formation.[5] Solid solution formation is considered to be the main mechanism because the distribution coefficient is dependent on the ionic size of REE for potassium alum. In contrast to silicate minerals in which the smaller the difference in ionic size between host and guest

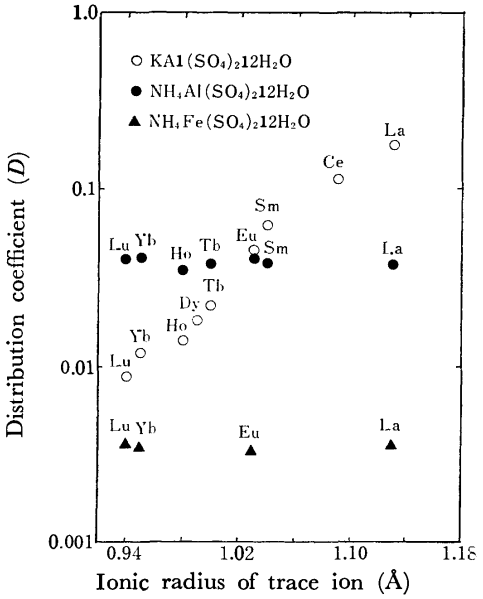

Fig. 1. Distribution coefficient of REE ion between alum and aqueous solution.

ions is the more easily the guest ions replace the host ions in the crystal,[6,7] La^{3+} ion which has the largest difference in ionic size with the host Al^{3+} ion gives the highest *D* value in potassium alum. This seems to be associated with hydration of ions and with the coordination number change of REE ions from aqueous solutions to alum crystals. In alum crystals each M(III) ion is surrounded by six water molecules, whereas in aqueous solution the lighter REE members (La^{3+}—Nd^{3+}) tend to have 9-coordination and the heavier members (Ga^{3+}—Lu^{3+}) are generally 8-coordinate.[1b] Furthermore the experimental evidence that while a smaller ion has a small number of near neighbor water molecules the larger polarizing power of the smaller ion will lead to a larger solvated radius may account for the higher *D* values for the lighter REE members than the heavier ones.

Another interesting feature is the difference in *D* values between the two ammonium alums. This apparent difference is largely due to their solubility difference, Fe-alum being soluble in cold water about 8 times larger than Al-alum.[8] In fact, the ratio (number of REE)/(number of host element) is almost the same for both Al- and Fe-crystals. This is an additional evidence for solid solution formation in the trace REE ions in the alum crystals.

As for alkali ions, the members larger in ionic radius than the host ions are found to have almost completely moved into crystal from the solution.

(Received September 26, 1977)

Synopsis. The separation of iron(III), cobalt(II), nickel(II), copper(II), zinc(II), mercury(II), lead(II), cadmium(II), and palladium(II) as their SDBM chelates has been achieved successfully on the thin layer of silica gel with such developing solvents as carbon tetrachloride, 1,1,1-trichloroethane, trichloroethylene, tetrachloroethylene, and carbon disulfide.

A new chelating reagent, 3-mercapto-1,3-diphenyl-2-propen-1-one(abbreviated as SDBM), has been found to form stable and extractable chelates of a specific color,[1,2] and it has been used for the determination of mercury(II) by means of the radioisotope dilution method[3] and for the spectrophotometric determination of iron(II, III), nickel(II), and copper(II).[4,5] In an attempt to widen the analytical application of this reagent, the metal ions have now been extracted in cyclohexane containg SDBM, and the metal chelates thus extracted have been chromatographed on the thin layer of silica gel with various organic solvents.

Experimental

The SDBM was synthesized by a modification of the method of Chaston *et al.*[6] A 5.0-g portion of dibenzoylmethane and 200 ml of absolute ethanol were put into a 500-ml flask, and then the vessel was cooled to 0—10 °C in an ice bath containing only ice or a freezing mixture with potassium chloride. The dried hydrogen chloride gas was passed through the solution for 10—30 min, after which the dried hydrogen sulfide gas was passed through for 1—2 h. There was no problem in the preparation of SDBM even if the hydrogen sulfide gas was passed into the solution first. The dehydration of ethanol, hydrogen sulfide, and hydrogen chloride might lead a worker to a successful synthesis of SDBM as in the synthesis of STTA.[7] The dark red solution was allowed to stand in an ice bath for 30—60 min and was then poured into ice water. The red crystalline product was filtered off, washed with water, and recrystallized from absolute ethanol or petroleum ether to give red crystals of the compound; yield, 60—70%; mp 76.5—78.0 °C. The developing solvents were all reagent-grade materials and were purified by the ordinary method, if necessary. The sample solutions for the thin layer chromatography were metal-SDBM chelates in cyclohexane, which were prepared as follows: a 10^{-2}—10^{-1} M salt solution was adjusted to pH 1—10, and then this solution was shaken with 10^{-3} M SDBM in cyclohexane for from 30 min to 2 h. The SDBM was found to remain mostly in the cyclohexane phase when the pH of the aqueous solution was below pH 10. Cadmium(II) and iron(III) gave large amounts of insoluble chelates in cyclohexane. Mercury(II), lead(II) and palladium(II) gave some insoluble chelates in cyclohexane. The experimental procedures and conditions for the thin layer chromatography of these metal chelates were almost the same as have previously been described.[8]

Results and Discussion

Each SDBM chelate extracted in cyclohexane showed its own specific color of the respective absorption maximum (Table 1), and was stable for at least several days. The results after the development of these SDBM metal chelates, including SDBM itself, with individual solvents on a thin layer of silica gel are given in Table 2. The compounds could be identified only by observing each specific color on the chromatoplate. The chelates may be classified into four groups in terms of their chromatographic behavior: 1) Chelates which do not migrate from the sample spot (with cyclohexane). 2) Chelates which can be developed to a moderate distance over a comparatively wide range (with carbon tetrachloride, 1,1,1-trichloroethane, trichloroethylene, tetrachloroethylene, carbon disulfide, chloroform, benzene, chlorobenzene, and *o*-dichlorobenzene). By using these solvents, the mutual separation of various metal chelates was achieved successfully. 3) Chelates which move up to the solvent front (with acetone, ethyl acetate, and diethyl ether). 4) Chelates which cause a remarkable tailing during development (with methanol and ethanol). By using a binary mixture of solvents in a 1:1 volume ratio, SDBM and its metal chelates were developed to a moderate distance (Table 3). It was observed that the Co-SDBM chelate was trans-

formed into $Co(SDBM)_3$ chelates.[8] Some representative chromatograms of SDBM and its metal chelates with pure solvents and their mixture are shown in Fig. 1. In general, the greater the polarity of the solvent, the greater the distance of the development of metal chelates on the chromatographic plate. The R_f values of the SDBM chelates with various solvents generally increased in the following order: Cd(II), Zn(II)<Hg(II)<Fe(III), Co(III)<Cu(II)<Ni(II), Pd(II)<Pb(II), (SDBM). The R_f values of the SDBM chelates of Co(II), Ni(II), Cu(II), Zn(II), and Cd(II) with the binary solvent mixture have the same tendency in their change as those of the single solvents. The R_f values of the SDBM chelates are smaller than those of the STTA chelates, while the R_f sequence of the SDBM chelates is almost the same as that of the STTA chelate series except for the Pb(II) complex, the R_f of which behaves much like the ligand; the latter sequence is: Cd(II)< Zn(II) < Pb(II), (STTA) < Hg(II) < Co(II, III) < Cu(II)<Ni(II).[9] In general, the discrepancy in the R_f values of the ligands and their metal chelates

Developing solvent: (I) Trichloroethylene, (II) carbon tetrachloride-chloroform.

may be caused by the differences in hydrogen bonding or dipole-dipole interaction among the ligands, each chelate, and silanol or siloxane on the surface of silica gel involving the competition adsorption of the developing solvents and metal chelates with or without the ligands. In conclusion, carbon tetrachloride, 1,1,1-trichloroethane, trichloroethylene, tetrachloroethylene, and carbon disulfide were found to be suitable developing solvents for the mutual separation of metals as their SDBM chelates by means of thin layer chromatography on silica gel.

An X-Ray Photoelectron Spectroscopic Study of Biuret Metal Complexes

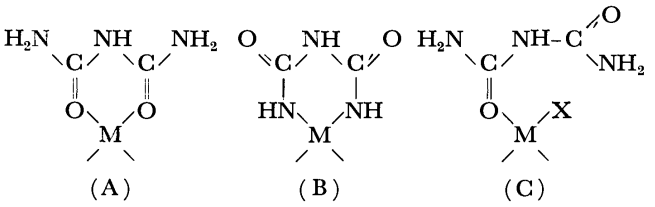
Tooru YOSHIDA, Kiyoshi YAMASAKI, and Shigemasa SAWADA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received October 21, 1977)

Synopsis. The mode of the co-ordination of biuret in biuret metal complexes has been examined by means of X-ray photoelectron spectroscopy. It has been found that the C(1s), O(1s), and N(1s) binding energies were clearly different among the bidentated, O-, and N-co-ordinated structures, and the monodentated O-co-ordinated one.

Biuret ($NH_2CONHCONH_2$) is known to form the following three types of complexes:



(A) (B) (C)

The structure (A) was found by the X-ray analysis for bis(biuret)copper(II) chloride[1] and bis(biuret)-zinc(II) chloride.[2] The structure (B) was found for dipotassium bis(biureto)cuprate(II) tetrahydrate.[1] The structure (C) was found for bis(biuret)cadmium(II) chloride.[3] The structures of the other metal complexes have been studied in the solid state by various kinds of physicochemical techniques.[4]

The purpose of this study is to examine the mode of the co-ordination of biuret in the metal complexes by means of X-ray photoelectron spectroscopy(XPS).

The X-ray photoelectron spectra were measured on an AEI ES200 spectrometer. AlK_α(1486.6 eV) X-ray radiation was used as the excitation source. The samples were ground to powder and then dusted onto double-backed adhesive tape. The measurements were run at room temperature under a vacuum of about 10^{-7} Torr. The binding energies were corrected by using the value of 285.0 eV for the C(1s) level resulting from the contaminated carbon. The reproducibilities of the values thus obtained were within ±0.1 eV. All the compounds used and their binding energies measured are given in Table 1. Biuret of an analytical grade was used after recrystallization from ethanol. All the complexes were prepared based upon the literature methods.[4c]

The C(1s), O(1s), and N(1s) electron spectra of biuret and all the biuret complexes except for K_2[M(biureto)$_2$] (M : Cu, Ni) showed approximately symmetrical single peaks, whose full-widths at the half-maximum heights were 1.8—2.0 eV in the C(1s) and O(1s) spectra, and 2.1—2.2 eV in the N(1s). These results suggest the presence of only one kind of carbon, oxygen, and nitrogen atoms. The N(1s) spectrum of dipotassium bis(biureto)niccolate(II) showed an unsymmetrical peak, as is shown in Fig. 1. This suggests the presence of two kinds of nitrogen atoms as well as dipotassium bis(biureto)cuprate(II). The two peaks, a and b, shown by the broken lines in the figure were obtained by a graphical resolution.

TABLE 1. MEASURED BINDING ENERGIES

Compond	Binding energy (eV)				
	C(1s)	N(1s)	O(1s)	Cl($2p_{3/2}$)	Metal($2p_{3/2}$)
$Cu(LH_2)_2Cl_2$	290.1	400.6	533.0	198.5	936.0
$Ni(LH_2)_2Cl_2$	289.9	400.4	532.6	198.5	856.9

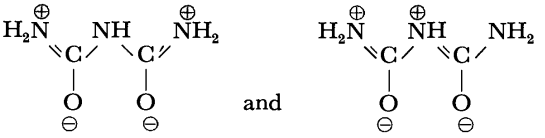
$Mn(LH_2)_2Cl_2$	289.9	400.4	532.6	198.5	642.3
$Cd(LH_2)_2Cl_2$	289.6	400.3	532.2	199.0	406.0[a]
$Hg(LH_2)_2Cl_2$	289.5	400.2	532.1	199.4	101.5[b]
K_2NiL_2	287.9	399.7; 398.2	530.8		855.0
$K_2CuL_2 \cdot 2H_2O$	288.1	399.7; 398.0	531.0		934.7
LH_2	289.5	400.2	532.2		
$NiCl_2$				199.4	856.9
$CuCl_2$				199.4	935.8
KCl				198.2	

LH_2 indicates $H_2NCONHCONH_2$. a) Cd($3d_{5/2}$). b) Hg($4f_{7/2}$).

Co-ordination through the two oxygen atoms of biuret can be expected to increase contributions from the structures of the following types:



This should result in an increase in the N(1s) binding energy of the complexes.

In fact, the N(1s) binding energies of [M(biuret)$_2$]-Cl_2 (M: Cu, Ni, Co, Mn) were 0.2—0.4 eV higher than that of biuret. The presence of only one symmetrical peak in the N(1s) spectra suggests that the differences among the charges on the three nitrogen atoms in the molecule are not large enough to be detected by XPS. The increase in the C(1s) and O(1s) binding energies of the four complexes above, 0.2—0.4 and 0.4—0.6 eV respectively, compared with those of biuret may be explained by the displacement of

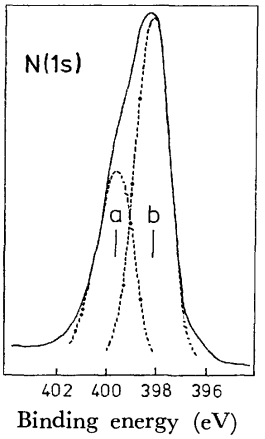


Fig. 1. N(1s) electron spectrum of dipotassium bis-(biureto)niccolate(II).

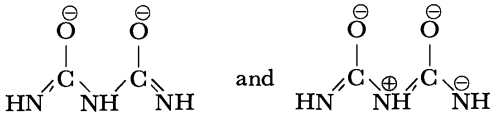
the charge through the oxygen atom to the metal ion upon the complex formation. The Cl($2p_{3/2}$) binding energies of these complexes were 0.3—0.4 eV higher than that of KCl, and 0.8—0.9 eV lower than those of $NiCl_2$ and $CuCl_2$. This indicates that the bond character between the Cl^- ion and the metal ion in these complexes is more ionic than that in $NiCl_2$ and $CuCl_2$, but not so ionic as in KCl. This does not contradict the finding[1] derived from the X-ray analysis for bis(biuret)copper(II) chloride.

The XPS results presented above lead to the conclusion that the co-ordination modes of biuret are the same in the four metal complexes above.

The C(1s), O(1s), and N(1s) binding energies and the shape of each peak of $M(biuret)_2Cl_2$ (M: Cd, Hg) were almost the same as those of the biuret, and the Cl($2p_{3/2}$) binding energies were similar to those of $NiCl_2$ and $CuCl_2$. These suggest that, in the two complexes, the charge displacement on the complex formation occurs mainly between the metal and the Cl^- ions, and that the co-ordination mode in the Hg complex is the same as that[3] in the Cd.

In the case of dipotassium bis(biureto)niccolate(II), it can be considered that two biuret molecules are co-ordinated to the metal atom, each through two nitrogen atoms of the amide groups, just as in the case of dipotassium bis(biureto)cuprate(II).[1] This co-ordination mode can be expected to increase contributions from structures of the following types:



This should result in a decrease in the O(1s) binding energy of the complex and an appreciable separation of the N(1s) binding energies for the two kinds of nitrogen atoms, central and terminal.

In fact, the C(1s) and O(1s) binding energies of the complexes were 1.6 and 1.4 eV lower in the nickel complex, and 1.4 and 1.2 eV lower in the copper complex, than those of the biuret. Furthermore, the separation energies of the two kinds of peaks with the intensity ratio of about 1 : 2 observed in the N(1s) spectra of the nickel and the copper complexes were 1.5 and 1.7 eV respectively. The two peaks in both complexes could be assigned to the central and terminal nitrogen atoms respectively.

The difference (1.9 eV) between the Ni($2p_{3/2}$) binding energies of dipotassium bis(biureto)niccolate(II) and bis(biuret)nickel(II) chloride may be mainly due to the following differecnes in the bonding types. Firstly, the former complex contains biuret in an anionic species, while the latter contains biuret in a cationic species. That is, the possibility of increasing the electron density on the metal atom is larger in the former case than in the latter. Secondly, the coordination atoms in the two complexes are different, being nitrogen atoms and oxygen atoms respectively. That is, the covalent character of the coordination bond of dipotassium bis(biureto)niccolate(II) is larger than that in bis(biuret)nickel(II) chloride; the electron density on the metal atom is larger in the former complex than in the latter. The difference (1.3 eV) between the Cu($2p_{3/2}$) binding energies of the two analogous copper complexes may be explained in the same way.

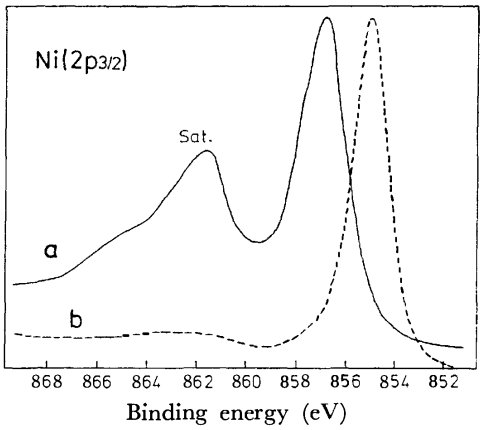


Fig. 2. Ni($2p_{3/2}$) electron region spectra.
a: Bis(biuret)nickel(II) chloride, b: dipotassium bis(biureto)niccolate(II)

XPS can differentiate specifically between the paramagnetic and diamagnetic characters of nickel(II) compounds.[5] That is, the intense shake-up satellites due to the 3d→4s, 4p transition are found on the high-energy side of the primary peak in the former in the 2p electron region, but they are absent in the latter.

Figure 2 shows the spectra of bis(biuret)nickel(II) chloride and dipotassium bis(biureto)niccolate(II) in the $2p_{3/2}$ electron region. The former complex exhibited a strong satellite peak, but the latter did not. This satellite peak was similar to those of other paramagnetic nickel compounds[6] in its intensity and its separation energy from the main peak. This suggests that the latter complex is of the low-spin type, and the former, the high-spin type. This agrees with the reported results[4c] on their magnetic properties.

Preparation of *trans*-Dichlorocobalt(III) Complexes of *N*-Alkylethylenediamines

Taku KITAMURA, Masahiko SABURI, and Sadao YOSHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 25, 1977)

Synopsis. *N*-Alkylethylenediamine ($RNHCH_2CH_2NH_2$; R=butyl, hexyl, isobutyl, and isopropyl) complexes of the type $[CoCl_2(diamine)_2]X$ prepared by usual air-oxidation method except the case of R=isopropyl. The *N*-ipren (R=isopropyl) complex was obtained by employing methanol as the solvent. A brief consideration of the steric effect of *N*-isopropyl group was given.

In the past ten years cobalt(III) complexes of *N*-methylethylenediamine(*N*-meen) and other *N*-methyl-1,2-diamines were studied extensively. The presence of secondary N atom, which provides a new asymmetric center upon coordination, opened a variety of problems in the stereochemistry of metal complexes.[1-4] However, the cobalt(III) complexes of other *N*-alkyl-1,2-diamines such as *N*-eten,* *N*-npren,* *N*-nbuen,* *etc.* were attracted little attention.[5-7]

Basolo obtained the *trans*-dichlorobis(diamine)-cobalt(III) complexes (diamine = *N*-eten, and *N*-npren) as the crystalline products.[5] However, the *N*-nbuen complex of the same type was not isolated in the pure crystalline form, though its formation could be acknowledged from the green color of a reaction mixture.[5] In this note we report the prerartion of *trans*-dichlorocobalt(III) complexes of various *N*-alkylethylenediamines including *N*-nbuen by an air-oxidation method.

Experimental

Ligands. To a solution of 2-bromoethylamine hydrobromide (52g; 0.25 mol) in ethanol (150 cm^3) was added *N*-monoalkylamine (1.3—1.5 mol) and the solution was heated under reflux for 7 h. Ethanol and excess amine were distilled off under reduced pressure and the oily residue was dissolved in a small volume of water (*ca.* 50—100 cm^3). An excess amount of sodium hydroxide (*ca.* 40 g) was added to the solution in small portions, with occasional removing of white precipitate (NaBr) by filtration through a glass filter. When the diamine separated from aqueous alkali, it was extracted with ether (total 300 cm^3). The ether extracts were combined and dried over potassium hydroxide pellets overnight. Ether was removed by distillation, and the diamine which remained was distilled at atmospheric or under reduced pressure. Yield; 45—60%. Bp: *N*-nbuen, 160 °C (atmospheric); *N*-ipren, 140 °C (atmospheric); *N*-ibuen, 160 °C (atmospheric); *N*-nhxen, 105—108 °C/17 mmHg; *N*-chxen, 115—116 °C/29 mmHg.

trans-$[CoCl_2(N\text{-}nbuen)_2]ClO_4$. To a solution of $CoCl_2 \cdot 6H_2O$ (2.38 g; 0.01 mol) in water (30 cm^3) was added *N*-nbuen (2.4 g; 0.02 mol), and the solution was aerated for 6 h at room temperature. After 15 cm^3 of concd hydrochloric acid had been added, the solution was evaporated on a water bath at 75—80 °C. When the volume was reduced to ca. 20 cm^3, 60% perchloric acid (3 cm^3) was added and the mixture was cooled in a refrigerator. Dull yellow-green crystals which deposited were collected, washed successively with cold water, ethanol, and ether, and air-dried. Yield, 1.50 g. The product was recrystallized from methanol. Found: C, 31.39; H, 7.15; N, 12.00%. Calcd for $C_{12}H_{32}N_4O_4Cl_3Co$: C, 31.22; H, 6.99; N, 12.14%.

trans-$[CoCl_2(N\text{-}ibuen)_2]ClO_4$ was obtained by the same procedure as that for the above *N*-nbuen complex, using *N*-ibuen in place of *N*-nbuen. Found: C, 30.19; H, 6.93; N, 11.96%. Calcd for $C_{12}H_{32}N_4O_4Cl_3Co$; C, 31.22; H, 6.99; N, 12.14%.

trans-$[CoCl_2(N\text{-}nhxen)_2]ClO_4$. To a solution of $CoCl_2 \cdot 6H_2O$ (1.19 g; 0.005 mol) in water (15 cm^3) was added a solution of *N*-nhxen (1.97 g; 0.012 mol) in ehtanol (15 cm^3), and the solution was aerated for 5 h, adding occationaly a few cm^3 of ethanol to dissolve deep brown oily materials. After 15 cm^3 of concd hydrochloric acid was added, the resultant solution was evaporated on a water bath at 75—80 °C. When a small amount of green crystals appeared, the mixture was cooled to room temperature, and then 60% perchloric acid (5 cm^3) was added. The oily product which deposited was separated by decantation, and crystallized from ethanol solution. Found: C, 37.11; H, 7.89; N, 10.69%. Calcd for $C_{16}H_{40}N_4O_4Cl_3Co$; C, 37.11; H, 7.79; N, 10.82%.

trans-$[CoCl_2(N\text{-}ipren)_2]_2(ZnCl_4)$. Cobalt(II) chloride hexahydrate (1.19 g; 5 mmol) dissolved in methanol (20 cm^3) was added dropwise to a solution of *N*-ipren (1.02 g; 10 mmol) in methanol (30 cm^3) with continuous bubbling of air. After the addition had been completed, air was passed through the solution for further 3 h, adding occasionally a few cm^3 of methanol to maintain the volume of reaction mixture at 40—50 cm^3. Then, methanol was rotary-evaporated and the residue was dissolved in concd hydrochloric acid (15 cm^3). The solution was heated on a boiling water bath for 30 min, and then evaporated on a rotary evaporator to a volume of 20 cm^3. After solid $ZnCl_2$ (5 g) had been added, the blue-green solution was cooled in a refrigerator overnight. Green crystals which appeared were filtered off, washed with cold hydrochloric acid, ethanol, and then ether, and dried under reduced pressure. Found: C, 27.49; H, 6.73; N, 13.08. Calcd for $C_{20}H_{56}N_8Cl_8Co_2Zn$: C, 27.44; H, 6.45; N, 12.80%.

Measurements. Absorption spectra were obtained on a Shimadzu UV-210 spectrometer.

Results and Discussion

Basolo observed that addition of *N*-ipren to an aqueous solution of coblat(II) chloride resulted in the

* Abbreviations of *N*-alkylethylenediamine ($RNHCH_2CH_2NH_2$) are as follows: *N*-eten (R=ethyl)=*N*-ethylethylenediamine, *N*-npren (R=propyl)=*N*-propylethylenediamine, *N*-nbuen (R=butyl)=*N*-butylethylenediamine, *N*-nhxen (R=hexyl)=*N*-hexylethylenediamine, *N*-ipren (R=cyclohexyl)=*N*-isopropylethylenediamine, *N*-ibuen (R=isobutyl)=*N*-isobutylethylenediamine, *N*-chxen (R=cyclohexyl)=*N*-cyclohexylethylenediamine.

separation of cobalt(II) hydroxide.[5] This implies that the introduction of the bulky isopropyl group disturbs the coordination of *N*-ipren to the Co^{2+} ion due to steric hindrances and that the Co^{2+} ion interacts with hydroxide ions to deposite as cobalt(II) hydroxide. We supposed that the coordination of *N*-ipren to the Co^{2+} ion might be permitted to give rise to *trans*-$[CoCl_2(N\text{-ipren})_2]^+$, if the coexistence of hydroxide could be prevented by using an organic solvent. It was actually observed that the air-oxidation of a mixture of Co^{2+} and *N*-ipren in methanol resulted in the formation of *trans*-$[CoCl_2(N\text{-ipren})_2]^+$ after the treatment with HCl. The addition of $ZnCl_2$ to the reaction mixture gave crystals of the *N*-ipren complex of tetrachlorozincate(II) ($ZnCl_4^{2-}$) salt, though the yield was relatively low (*ca.* 20%). A similar effect of organic solvent which improves the formation of complex ions has been noted for the *trans*-dichlorocobalt(III) complex of 1,3-diaminopropane.[8]

On the other hand, *trans*-dichlorocobalt(III) complexes of *N*-nbuen, *N*-nhxen, and *N*-ibuen were readily obtained as perchlorate salts with considerable yields according to the usual air-oxidation method in aqueous media. It was noted that *N*-ibuen behaved in the same manner as *N*-nbuen, though the isobutyl group, as well as the isopropyl group, had a branch at the alkyl substituent. This indicates that primary *N*-alkyl groups permit the coordination of *N*-substituted en to the Co^{2+} ion even in aqueous solution.

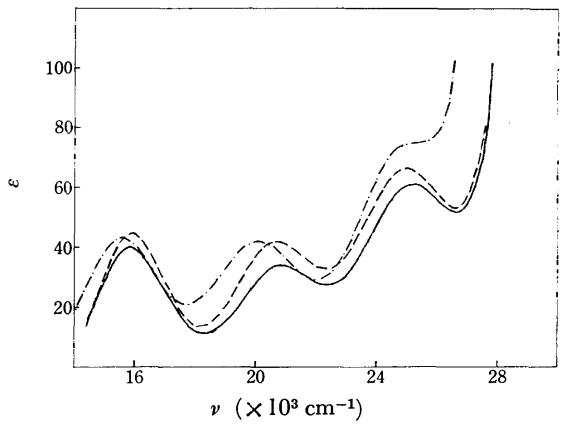

Fig. 1. Absorption spectra of *trans*-$[CoCl_2(diamine_2]^+$: *N*-nbuen (——), *N*-nhxen (— — —), and *N*-ipren (—·—·—).

The difference between isopropyl and other primary alkyl groups was also observed in the absorption spectra of *trans*-$[CoCl_2(diamine)_2]^+$ complexes. As Fig. 1 shows, the absorption maxima(15600, 20100, and 25000(sh) cm^{-1}) of the *N*-ipren compex shift to the lower energy side by 300—600 cm^{-1} than those of the other complexes (*N*-nbuen; 15900, 20800, and 25300 cm^{-1}. *N*-nhxen; 15900, 20700, and 25000 cm^{-1}. *N*-ibuen; 15900, 20700, and 25100 cm^{-1}). The red shift should be ascribed to the steric effects caused by the bulkiness of isopropyl group.

It is very suggestive that *N*-chxen no longer forms the *trans*-dichlorocobalt(III) complex according to the same method as for the *N*-ipren complex. The cyclohexyl group is also a secondary alkyl group but its bulkiness should have more significant effects than that of isopropyl. Thus, it seems likely that the isopropyl group has the critical size not to prevent the formation of Co(III) species by air-oxidation.

(Received June 24, 1977)

Synopsis. Rate constants for the solvolysis of 1-adamantyl bromide and tosylate, 2-adamantyl tosylate, and *t*-butyl chloride in the four carboxamide solvents, *i. e.*, *N,N*-dimethylacetamide, *N,N*-dimethylformamide, *N*-methylacetamide, and *N*-methylformamide, have been determined. The role of the carboxamides as solvolytic solvents has been discussed on the basis of linear free-energy relationship.

Although carboxamides, such as *N,N*-dimethylacetamide (DMA), *N,N*-dimethylformamide (DMF), *N*-methylacetamide (NMA), and *N*-methylformamide (NMF), are expected to be particularly effective solvents for S_N1 solvolyses because of their highly polar characteristics,[2] little has been studied on the solvolytic feature of these solvents.[1,3]

It has been commonly accepted that the rate of solvolysis of the adamantyl system reflects the rate of the ionization process, because, for this system, neither rate-determining elimination nor solvation at the rear side of a leaving group is possible. Thus, in the assessment of the ionizing power of solvolytic solvents, the adamantyl system, including 1-adamantyl bromide[4] (**1**) and tosylate[4b,5] (**2**), and 2-adamantyl tosylate[6] (**3**) has been used as the reference compound. In the present paper we wish to report on the ionizing powers of the carboxamides, *i.e.*, DMA, DMF, NMA, and NMF, by the use of above mentioned tertiary systems **1** and **2**, **3**, and *t*-butyl chloride (**4**).

Results and Discussion

The first-order rate constants for the solvolysis of **1**, **2**, **3**, and **4** in the carboxamide solvents are shown in Table 1 along with the *Y* and *m* values.[7] A linear relation between log k_1 and *Y* has been observed for the carboxamide solvolysis of **1**, **2**, and **3**, and another linear relation has also been observed for many other solvents, including carboxamides, with a range of solvolytic reactivities varying over 8 (for **1**), 5 (for **2**), and 6 (for **3**) powers of ten, excluding the points for carboxylic acids[5,6c,6d] for **2** and **3**, aqueous trifluoroethanols[4a,6e] for **1** and **3**, and phenolic solvents[4b] for **1** and **2**. The correlation coefficients for the latter *m*-*Y* relation are 0.996, 0.990, and 0.998, respectively for **1**, **2**, and **3**. On the basis of these linear free-energy relationships, it is expected that the four carboxamide solvents would cause the solvolytic ionization even in the solvolyses of a secondary system,[8] though their ionizing powers are comparatively low (−1.51—−4.28 as measured by *Y*-values).

The importance of the nature of a leaving group is demonstrated when the correaltion between the rates for **1** and **2** in several groups of solvents is examined (Fig. 1). The data for the different solvent systems are clearly represented by five lines in Fig. 1. A similar type of dispersion has been found by Harris *et al.*[4c] in the plots of the log k_1 for **4** against log k_1 for **1** in aqueous ethanols and aqueous trifluoroethanols, and they have suggested that this dispersion is a diagnostic for nucleophilic solvent assistance.[6c] Our findings for the adamantyl systems, in which nucleophilic solvent assistance[6c] is prohibited, suggest that, besides the factor pointed out by Harris *et al.*,[4c] the non-electrostatic contribution (*i. e.*, hydrogen-bonding to the leaving group)[4c] to the ionization is important and different from a group of solvents to

another, though the definite conclusion is to be expected in a future work.

Experimental

Substrates and Solvents. 1-Adamantyl bromide, mp 119—120 °C (lit[9] mp 119—120 °C), 1-adamantyl tosylate, mp 79—83 °C (lit[10] mp 78—83 °C), and 2-adamantyl tosylate, mp 82.3—83 °C (lit,[6e] mp 82.1—83.4 °C) were prepared following the published methods.[5,11] *t*-Butyl chloride (commercial) was dried ($CaCl_2$) and distilled immediately before use. The four carboxamides were purified by the method described in a previous paper.[1]

Kinetic Measurements. Rates of solvolysis of the tosylates **2** and **3**, and the halides **1** and **4** were respectively determined by an acid-base titration (KOH in EtOH, Thymol Blue–phenolphthalein mixed indicator) and by haldie ion titration (the Volhard method[12]), employing the usual sealed-ampoule technique. As to the run for the tosylates, an acid-catalyzed hydrolysis of the carboxamides due to water contained in the solvent even after rigorous purification, has made an experimental infinity titer greater than the theoretical one. After appropriate correction for the above difference, a good first-order behavior was observed for all kinetic runs over two to three half-lives both in the absence and presence of added pyridine, except for the solvolysis of **2** in DMA at higher temperatures in which the first-order plot showed a downward drift after 25% completion. Linearity of the Arrhenius plot held also for all cases. In the case of **4**, the rate constant was calculated using a theoretical infinity titer.

Solvolysis Products. On the basis of GLC and NMR spectroscopy, the solvolysis products of **1**, **2**, and **3** in the carboxamides were identified to be mixtures of adamantanol and adamantyl esters which were furnished by the hydrolysis of initial ion-pair intermediate and of cationic imidate,[1] respectively.

Effect of Hydration on the Thermal Denaturation of Lysozyme as Measured by Differential Scanning Calorimetry

Yukihisa FUJITA and Yukinao NODA

Department of Chemistry, Hyogo College of Medicine, Mukogawa, Nishinomiya, Hyogo 663

(Received August 31, 1977)

Synopsis. The thermal properties of the lysozyme-water system were investigated by differential scanning calorimetry under varied water contents, ranging from 0.05 to 1.6 g per g of protein. The temperature, T_d, and the enthalpy change, ΔH_d, of denaturation at water contents below 0.75 g/g showed strong dependencies on the hydration. At higher water contents, however, T_d and ΔH_d were almost independent of the degree of hydration, showing values almost identical to those in solution.

Recent studies have revealed that water plays a prominent role in the structure and biological function of proteins, but there are many problems remaining unsolved. The hydration process of proteins have been extensively studied by various techniques, such as gravimetric measurements (sorption isotherms),[1,2] IR[3] and NMR spectroscopy.[4] Calorimetric measurements of the hydrated proteins can also provide instructive information on the interaction between protein and water.

This paper will describe the effect of hydration on the thermal denaturation of lysozyme as measured by differential scanning calorimetry.

Experimental

Materials. The hen egg-white lysozyme used in the present study was a three-times-recrystallized sample(lot 74C—8040) from Sigma Chemicals Co. All the chemicals employed for the control of the relative humidities were of a reagent grade and were used without further purification.

Methods. The thermal denaturation of lysozyme was measured with a Rigaku Denki standard-type differential scanning calorimeter. The samples(5—10 mg) were packed in sealable pans and kept in humidostates at appropriate relative humidities in order to adjust the water contents by conditioning for 5 days, then the pans were sealed. The relative humidity was varied by placing saturated aqueous solutions in contact with an excess of various solutes at 293 K.[5] The samples with water contents higher than 1 g/g were prepared by adding twice-distilled water.

For calorimetric measurements, the heating rate was 2.5 K/min. This heating rate was found to be preferable in terms of the sharpness of the resulting thermograms and their reproducibility.

The water content and the dry mass of the sample were gravimetrically determined by drying the punctured sample pan at 378 K *in vacuo* for 24 h. The molecular weight of lysozyme was taken as 14300.[6]

Results and Discussion

Figure 1 shows typical thermograms measured at three different water contents. The thermal denaturation was accompanied by an endothermal heat effect. The temperature, T_d, and the enthalpy change, ΔH_d, of the denaturation were estimated

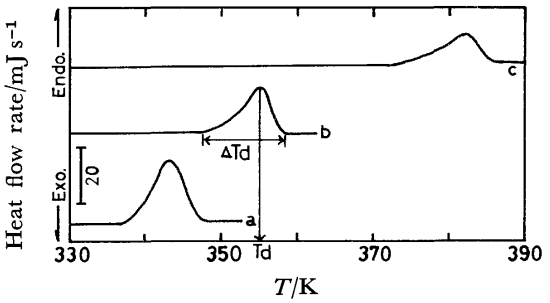

Fig. 1. DSC thermograms of lysozyme.
Water contents and sample weights are (a) 1.13, 6.2; (b) 0.27, 4.8; (c) 0.10 g/g, 4.2 mg.

from the temperature of the peak and the peak-area respectively in the thermogram obtained. The temperature width of the denaturation peak, ΔT_d, was also estimated as the temperature difference between the onset and the outset of the endothermal peak in the thermogram. Unfortunately, these values could not estimated at water contents lower than about 0.05 g/g, because these thermal decomposition occurred instead of thermal denaturation.

The T_d, ΔT_d and ΔH_d are plotted as a function of the water content in Figs. 2 and 3 respectively. These values similarly showed marked dependencies on the water content. At water contents above 0.75 g/g, both T_d and ΔH_d were slightly dependent on the water content. The mean values in this region were 341.7 K and 313 kJ/mol, almost identical to those measured for lysozyme in solution.[7,8] It seems reasonable to assume that a similar conformational change which takes place in solution occurs in a solid state containing much water; the interaction between protein

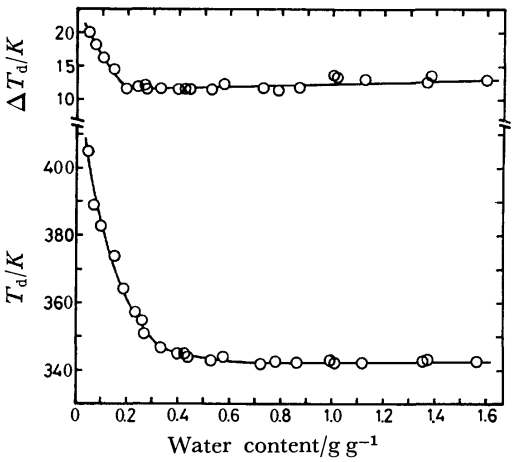

Fig. 2. Temperature of denaturation, T_d, and temperature width of denaturation peak, ΔT_d, of lysozyme as a function of water content.

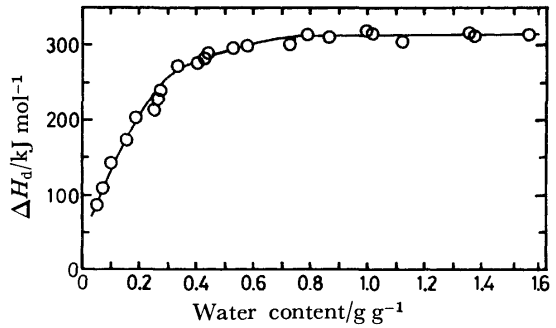

Fig. 3. Enthalpy change of denaturation, ΔH_d, of lysozyme as a function of water content.

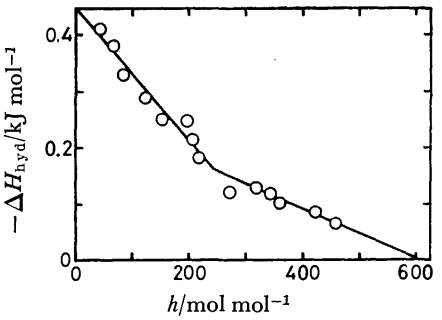

Fig. 4. The plot of the contribution by removal of the water from the hydrated protein, ΔH_{hyd}, to the enthalpy change of denaturation *vs.* the degree of hydration, h.

molecules does not influence the unfolding of the molecule. In addition, this indicates that the hydration of lysozyme, an essential process for stabilizing its spatial structure in water, is completed at about 0.75 g of water per g of protein, equivalent to about 600 moles of water per mol of protein.

Below the water content of 0.75 g/g, the T_d increased gradually with a decrease in the water content, until the increase became much more marked at water contents lower than about 0.3 g/g. The ΔH_d, on the other hand, decreased with a decrease in the water content in the same region of water content. The ΔT_d showed an almost constant value at water contents higher than about 0.15 g/g, but increased markedly at water contents lower than this value.

To analyze the experimental data we assumed that the observed enthalpy change of the thermal denaturation of lysozyme, ΔH_d, was expressed as follows:

$$\Delta H_d = \Delta H_{comp} + (600-h)\Delta H_{hyd}$$

where ΔH_{comp} is the enthalpy change of the denaturation of the completely hydrated protein, h is the degree of hydration, as expressed by the number of moles of water adsorbed per mole of protein, and ΔH_{hyd} is the contribution made by the removal of the water from the hydrated protein, as expressed on the basis of one mole of water per mol of protein. As is shown in Fig. 3, the hydration of lysozyme was completed at about 600 moles of water per mol of protein, and ΔH_d showed an almost constant value at water contents higher than 600 mol/mol, therefore, ΔH_{comp} was regarded as identical to ΔH_d, 313 kJ/mol, in this region. The plot of ΔH_{hyd} against the degree of hydration is shown in Fig. 4. The ΔH_{hyd} decreased with an increase in the h, this relationship could be represented by two segments of the straight line. This indicates that the effect of hydration on the stabilization of protein decreases with an increase in the degree of hydration; the interaction between protein and water decreases with an increase in the degree of hydration, and the dependence of protein–water interaction on the degree of hydration changes at about 240 mol/mol, equivalent to a water content of 0.3 g/g.

It is interesting to note that a break in the dependence of the protein–water interaction on the water content is seen near 0.3 g of water per g of protein. Harvey and Hoekstra[9] have reported that the dielectric properties of the adsorbed water on lysozyme changed at the same water content. A recent calorimetric study of frozen protein solutions[10] has revealed that the threshold water contents for the unfreezable and freezable water fractions with heats of fusion different from that of the bulk water are about 0.3 and 0.7 g/g respectively. The water content of 0.3 g/g corresponds to about 3.5 molecules of water per ploar amino acid residue in the lysozyme molecule. Below the water content of 0.3 g/g, the water molecules are probably bound by hydrogen bonds to the polar amino acid residues on the surface of protein. It seems likely that the exhaustive removal of these associated water molecules brings about changes in the structure of protein[11] and in the mechanism of denaturation, as suggested by the curve for ΔT_d in Fig. 2.

At water contents above 0.3 g/g, the protein–water interaction was weaker than that at lower water contents. In the range of water content between 0.3 and 0.75 g/g, some water molecules may ambivalently interact not only with the water strongly bound to hydrogen-bonding sites of the protein, but also with the normal bulk water, which probably paly an essential role in stabilizing the native conformation of the protein.

It will be interesting to study the contribution of hydration to the stabilization of protein in further detail.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (5), 1569—1570 (1978)

The Reaction of O(^{3}P) Atoms with Indene and Phenanthrene Induced by the γ-Radiolysis of Liquid Carbon Dioxide

Seizi GOTO, Akira HORI, Setsuo TAKAMUKU,* and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received October 17, 1977)

Synopsis. The γ-radiolysis of liquid CO_2 with indene and phenanthrene gives the corresponding oxirane and carbonyl compounds, together with some products which are unexpected on the basis of the reaction of (^{3}P) with aliphatic olefins: (i) the corresponding cyclic carbonate; (ii) 1*H*-2-benzopyran and a dimer for indene, and (iii) dibenz[*b*,*d*]oxepin and 2,2′-biphenyldicarbaldehyde for phenanthrene. The mechanisms of the formation of these products are discussed.

It has been shown that the γ-radiolysis of CO_2 in the liquid phase produces oxygen atoms.[1] We have recently studied the radiolysis of liquid CO_2 with various organic compounds, such as olefins,[2] saturated hydrocarbons,[3] and phenylacetylenes,[4] and have observed the formation of the corresponding oxidation products. On the basis of the reaction mechanism, it has been concluded that the most reasonable oxidizing species must be a ground-state oxygen atom. Recently, Wojnarovits *et al.*[5] also indicated the formation of O(^{3}P) atoms in the γ-radiolysis of a cyclohexene-liquid CO_2 mixture. Therefore, one may expect the radiolysis of liquid CO_2 to be useful for the generation of O(^{3}P) atoms in the liquid phase. The purpose of this work is to clarify the reactivity of O(^{3}P) atoms with condensed-ring compounds, such as indene and phenanthrene, the reactions of which with oxygen atoms are not known, and to explore the possibility of capturing CO_2 by intermediates of the reactions of O(^{3}P) atoms with the above compounds.

The irradiation of an indene-liquid CO_2 mixture was carried out using a ^{60}Co source at 0 °C; the results are summarized in Table 1. The following features were observed; (i) the products were 1H-2-benzopyran (**1**), 1,2-epoxyindan (**2**), 2-indanone (**3**), 1-indanone (**4**), 1,2-indandiyl carbonate (**5**), and an indene dimer (**6**),[6] among which **2** and **3** were the main products; (ii) the total *G* values of the oxygen-containing products were *ca.* 5.3 and 3.8 for 2 and 17 hrs irradiation respectively, which are consistent with the $G(CO)=3.5$—5.0 obtained by the γ-radiolysis of liquid CO_2 at −48 °C,[1] and hence the *G* values suggested that the oxygen atoms generated on the radiolysis of liquid CO_2 are trapped effectively by indene; (iii) on the basis of the γ-irradiation to **2** or **3** in liquid CO_2,[7] it was found that the further reactions of the main products to form their isomers and **5** are negligibly small, except for a slight isomerization of **2** to **3**, and (iv) 1*H*-2-benzopyran (**1**) was formed by the pyrolysis of **2** at 300 °C.

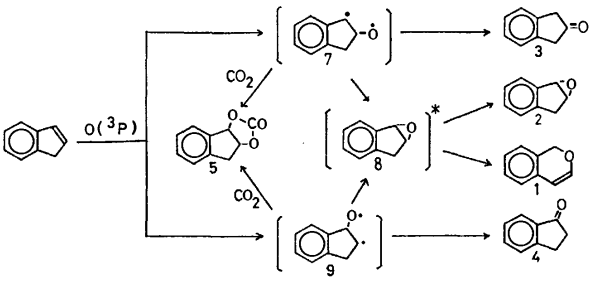
Table 1. Radiolysis of the indene-liquid CO_2 system

Irrad. time (h)	Conv. (%)	Product yield (%)[a] (*G* value)					
		1	**2**	**3**	**4**	**5**	**6**
2	4.2	2.8 (0.17)	29 (1.7)	51 (3.1)	3.3 (0.19)	1.7 (0.10)	7.8 (0.47)
17	42	1.5 (0.11)	24 (1.7)	23 (1.7)	2.7 (0.20)	1.4 (0.10)	1.0 (0.07)

a) All the products were analyzed with a 3-m PEG 20 M column at 150 °C. The product yields are based on the amount of indene consumed.

* To whom correspondence should be addressed.

On the basis of these observations, we propose the following scheme for the formation of the oxygen-containing products of indene:



In the first step, the oxygen atom adds to the double bond of indene, preferentially at the C-2 carbon atom. The biradical (**7** or **9**) thus formed undergoes ring closure to an epoxide or undergoes a rearrangement to the carbonyl compounds (**3** or **4**); 2-indanone(**3**) is also produced, partly by the further isomerization of the **2** primarily produced. The epoxide (**8**) initially formed may possess a vibrationally excess energy and may be rearranged partly to **1**. Furthermore,

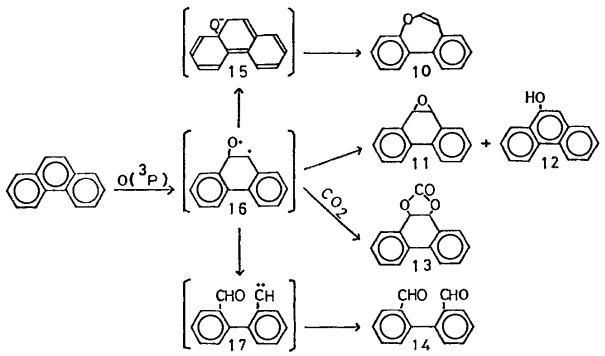
Table 2. Radiolysis of the phenanthrene-liquid CO_2 system

Irrad. time (h)	Conv. (%)	Product yield (%)[a] (*G* value)				
		10	**11**	**12**[b]	**13**	**14**
3	5	1.3 (0.04)	35 (1.1)	46 (1.4)	2.9 (0.09)	0.9 (0.03)
17	15	1.2 (0.02)	6.1 (0.10)	15 (0.24)	2.6 (0.04)	4.4[c] (0.07)

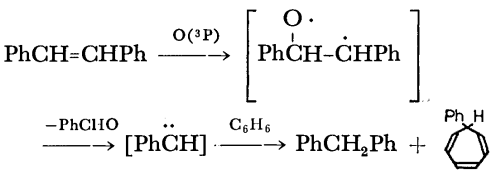
a) All the products were analyzed with a 1-m Silicone OV-17 column at 180 °C. b) This product was determined to be 9-methoxyphenanthrene. c) The addition of isopropyl alcohol (13 mmol) decreased the yield of **14** to trace amounts.

the biradical (**7** or **9**) captures CO_2 to form **5**, probably because of its dipolar character.

In the case of phenanthrene (Table 2), the products were dibenz[*b*,*d*]oxepin (**10**), 9,10-dihydro-9,10-epoxyphenanthrene (**11**), 9-phenanthrol (**12**), 9,10-dihydro-9,10-phenanthrylene carbonate (**13**), and 2,2'-biphenyldicarbaldehyde (**14**). The main products were **11** and **12**. The further reactions of the main products to form their isomers, **13** and **14**, are negligibly small, because the γ-radiolysis of liquid CO_2 in the presence of **11** or **12** gave such products in very low yields (the *G* values were all less than 0.03). Consequently, the initial reaction of the oxygen atom is the addition to the 9,10-bond of phenanthrene, the so-called K-region, to form a biradical:



The biradical (**16**) may be transformed into the products by the following possible modes: (i) the ring closure or rearrangement of **16** to give **11** or **12** respectively; (ii) the ring closure to **15**, which then undergoes thermal valence isomerization to **10**; (iii) capturing CO_2 to form **13**, or (iv) the fission of a carbon-carbon bond of **16** to form a carbene (**17**), which is then oxidized to **14**. The (ii) mode is also observed in the photorearrangement of **11** to **10**.[8] Although there is no direct evidence for the (iv) mode, it may be supported by the following facts: (a) the addition of isopropyl alcohol, which is known to react with a carbene,[9] to this reaction system resulted in a pronounced decrease in the **14**, despite the fact that the yields of the other products remained unaltered, and (b) the radiolysis of the *trans*-stilbene-benzene-liquid CO_2 system gave benzaldehyde, diphenylmethane, and 7-phenylcycloheptatriene, besides oxirane and carbonyl compounds, whose formation can be explained by the following scheme:[10]



Experimental

Procedure. The experimental procedures were essentially the same as those reported previously in the reaction of atomic oxygen with alkanes.[3] A mixture of liquid CO_2 (1.4 mol) and indene (4.3 mmol) or phenanthrene (2.8 mmol) in a stainless-steel autoclave was irradiated by means of a ^{60}Co source at 0 °C. The dose rate, as measured by ferrous sulfate dosimetry, was 1.7×10^{19} eV/g h. The products were identified by a comparison of the retention times of the GLPC and the mass spectra with those of authentic samples.

Materials. Commercial indene and phenanthrene were purified by distillation and by recrystallization from methanol respectively before use. The carbon dioxide (99.99%, Fuji Koatsu Gas Co., Ltd.) was used without further purification. Authentic samples of the products, **1**,[11] **2**,[12] **3**,[13] **4**,[14] **10**,[8] **11**,[15] **12**,[16] and **14**,[17] were prepared by the literature procedures. 1,2-Indandiyl carbonate (**5**) and **13** were prepared by reactions of *cis*-1,2-indandiol and *cis*-9,10-dihydroxy-9,10-dihydrophenanthrene with diethyl carbonate respectively, according to the method of Overberger and Drucker.[18] All the products synthesized were identified by means of their melting points and NMR spectra or by means of their mass spectra.

Syntheses of Aromatic Mannich Bases Involving Nitrogen Heterocycles by Means of Amine-exchange Reaction

Hiroyoshi KAMOGAWA, Kuniaki KUBOTA, and Masato NANASAWA

Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu, Yamanashi 400

(Received November 1, 1977)

Synopsis. Amine-exchange reactions of aliphatic Mannich bases involving nitrogen heterocycles, such as 2-(2-dimethylaminoethyl)-substituted pyridine, quinoline, benzothiazole, and 3,3-dimethyl-3*H*-indole, with arylamines readily provided the corresponding aromatic Mannich bases which are otherwise hardly accessible.

A few amine-exchange reactions involving aliphatic Mannich bases and arylamines have been reported.[1,2] In spite of their expected usefulness in organic synthesis, however, the results so far reported have been limited only to those for Mannich bases containing ketone carbonyls.

In the course of the synthetic studies of the polymerizable Mannich bases containing aromatic functional groups,[3] we have successfully attempted the amine-exchange reactions of aliphatic Mannich bases involving nitrogen heterocycles with arylamines; thereby we have isolated, in reasonable yields, the aromatic Mannich bases, which could not be synthesized directly from the corresponding 2-methyl-substituted nitrogen heterocycles, formalin, and arylamines.

Amine-exchange reactions take place as follows.

$$RCH_2CH_2NMe_2 + ArNH_2 + HCl$$

1—4

1: R =

3: R = 
2: R = 
4: R = 
$$\longrightarrow RCH_2CH_2NHAr + Me_2NH\cdot HCl$$

5a—d: R =

6a—d: R = 
7a—g: R = 
8a—e: R = 
It has been found that, by refluxing the ingredients in ethanol–water for 4—25 h, exchange reactions take place readily to afford the corresponding products (**5**—**8**). Table 1 gives the results obtained.

It may be seen that from this table that good nucleophiles, such as *p*-anisidine and *p*-toluidine generally provided better yields of the exchange products than poor nucleophiles such as *p*-nitroaniline and *p*-aminobenzoic acid. *p*-Nitroaniline, a poor nucleophile, failed even to react with 2-(2-dimethylaminoethyl)-substituted pyridine (**1**), and quinoline (**2**). Moreover, the reactivity of the Mannich base in the exchange reaction is considerably affected by the cyclic portion of the molecule, providing this decreasing order of reactivity: **3**, **4**, **2**, and **1**. The most reactive Mannich base, **3**, reacted successfully with all the arylamines employed.

Table 1. AMINE-EXCHANGE REACTIONS OF MANNICH BASES

No.		Ar	Yield, %	Mp, °C
1→	**5a**	*p*-$OCH_3\cdot C_6H_4$-	37.2[a]	Oily product
	5b	*p*-$CH_3\cdot C_6H_4$-	34.0[a]	
	5c	C_6H_5-	30.3[a]	
	5d	*p*-$NO_2\cdot C_6H_4$-	0[a]	
2→	**6a**	*p*-$OCH_3\cdot C_6H_4$-	39.1[b]	Oily product
	6b	*p*-$CH_3\cdot C_6H_4$-	35.9[b]	
	6c	C_6H_5-	31.0[b]	
	6d	*p*-$NO_2\cdot C_6H_4$-	0[b]	
3→	**7a**	*p*-$OCH_3\cdot C_6H_4$-	58.0[b]	80—82
	7b	*p*-$CH_3\cdot C_6H_4$-	60.6[b]	85—88
	7c	C_6H_5-	32.4[c]	Viscous mass
	7d		48.2[b]	151—154
	7e		57.5[b]	89—92
	7f	*p*-$NO_2\cdot C_6H_4$-	41.3[b]	85—90
	7g	*p*-$COOH\cdot C_6H_4$-	27.7[b]	70—73
4→	**8a**	*p*-$OCH_3\cdot C_6H_4$-	44.1[b]	91—93
	8b	*p*-$CH_3\cdot C_6H_4$-	62.2[b]	103—105
	8c	C_6H_5-	40.9[b]	128—131
	8d		73.7[b]	119—122
	8e	*p*-$NO_2\cdot C_6H_4$-	Trace[b]	—

a) 25 h refluxing in $EtOH/H_2O$ (1/1). b) 4 h refluxing in $EtOH/H_2O$ (1/1). c) With tar.

Although the mechanism of the reaction is not exactly known, the fact that amine-exchange reactions also took place readily between aliphatic Mannich bases containing a β-dimethylaminoethyl group attached to a nitrogen heterocycle and arylamines indicates that the synthetic procedure for aromatic Mannich bases by amine-exchange reaction is generally applicable to Mannich bases containing a β-alkylaminoethyl group.

Experimental

The infrared, ^{1}H-NMR, and mass spectra were recorded on a Hitachi 215 spectrophotometer, a JNM-PMX 60 spectrometer, and a Hitachi RMU-6 MG spectrometer, respectively, all under standard measurement conditions. The elemental analyses were carried out using a Perkin-Elmer

250 instrument.

Syntheses of Starting Mannich Bases. A conventional procedure[4] was employed. Thus, in a typical example, for obtaining 2-(β-dimethylaminoethyl)-3,3-dimethyl-3*H*-indole (**4**), 9.5 g (60 mmol) of 2,3,3-trimethyl-3*H*-indole, 4.9 g (60 mmol) of dimethylamine hydrochloride, and 6 ml (60 mmol) of 37% formalin in 30 ml of ethanol were refluxed for 4 h. The resulting dark red solution was diluted with water and extracted with ether three times. The dark aqueous layer was then basified with aqueous sodium hydroxide, and the resulting orange oil was extracted with ether, followed by washing with water, drying over anhydrous sodium sulfate, and evaporation *in vacuo* to leave a red viscous mass, which was subsequently recrystallized from ethanol–water to afford light orange crystals (mp 58—60 °C) in a 33% yield. Found: C, 77.59; H, 9.42; N, 12.99%. Calcd for $C_{14}H_{20}N_2$: C, 77.78; H, 9.26; N, 12.96%. IR(CCl_4): 2970—2860 (CH_2, CH_3), 2820, 2760 (NMe_2), 1600 (aryl), 1450 cm^{-1}. NMR(CCl_4): δ 1.3 (m, 6H, 2Me), 2.2 (s, 6H, NMe_2), 2.4—4.0 (m, 4H, $2CH_2$), 6.8—7.8 (m, 4H, ArH) ppm. Mass (*m/e*) 216(M^+).

2-(β-Dimethylaminoethyl)-pyridine (**1**), -quinoline (**2**), and -benzothiazole (**3**) were obtained in similar manners in 44% (oil), 42% (oil), and 40% (oil) yields, respectively, their analytical and spectral data also being satisfactory.

Amine-exchange Reactions. In a typical example, 0.52 g (2.5 mmol) of **3**, 0.36 g (2.5 mmol) of *p*-toluidine hydrochloride, and 10 ml of ethanol–water (1/1 v/v) were refluxed for 4 h. The resulting yellow solution, with the red oil separated, was extracted with ether and water; the yellow organic layer was then dried over anhydrous sodium sulfate and evaporated *in vacuo* at 50 °C to leave a red viscous mass, which was subjected to silica gel-column chromatography to collect benzene–ether elutes. Recrystallizations from benzene provided orange-yellow crystals (**7b**) (mp 85—88 °C) in a 60.6% yield. Found: C, 71.51; H, 6.00; N, 10.37%. Calcd for $C_{16}H_{16}N_2S$: C, 71.64; H, 5.97; N, 10.45%. IR(CCl_4): 3390 (NH), 3000—2860 (CH_3, CH_2), 1600 (aryl), 1430 cm^{-1}. NMR (CCl_4): δ 2.2 (s, 3H, CH_3), 3.0—5.0 (m, 5H, NH+$2CH_2$), 6.3—8.3(m, 8H, ArH) ppm. Mass(*m/e*): 268(M^+, 20), 120 (100).

The reactions for the other combinations in Table 1 were carried out in similar manners, the identifications of the products by CHN analyses and the infrared, NMR, and mass spectra being satisfactory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 51 (5), 1573—1574 (1978)

Studies on Heterocyclic Analogs of Azulenes. IV.[1] Behavior of 2-Chlorocyclohepta[*b*]pyrrole Derivatives toward Phosphorus Ylide

Tarozaemon NISHIWAKI, Noritaka ABE, Kozue ISHIDA, and Kaoru MIURA

Department of Chemistry, Yamaguchi University, Yamaguchi 753

(Received November 4, 1977)

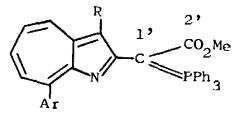
Synopsis. The transylidation reaction of methyl (triphenylphosphoranylidene)acetate with 2-chlorocyclohepta[*b*]pyrrole derivatives has been studied. 3,8-Disubstituted derivatives gave a transylidation product only, whereas 3-substituted derivatives afforded not only a transylidation products but also the compounds formed by the addition of ylide at C-8. ^{13}C NMR spectra of the transylidation products are recorded in part.

The transylidation reaction[2] has been utilized for the preparation of heterocyclic ylides[3] and alkyl- and alkenyl-substituted hetreocycles.[4] The present study was undertaken from our interest[1,5] in the reactivities of 2-chlorocyclohepta[*b*]pyrrole derivatives toward nucleophiles.

The reaction of methyl (triphenylphosphoranylidene)acetate (**5**) with 2-chloro-3-ethoxycarbonyl-8-phenyl- (**1**) and 2-chloro-3-cyano-8-*p*-methoxyphenylcyclohepta[*b*]pyrrole (**2**), respectively, proceeded to give the corresponding phosphoranes (**6**) and (**7**). However, 2-chloro-3-cyanocyclohepta[*b*]-pyrrole (**3**), when treated with **5**, gave a complex mixture of products, among which a transylidation product (**8**), 2-chloro-3-cyano-8-methylcyclohepta[*b*]-pyrrole (**10**), and 2-chloro-1-cyano-4-(methoxycarbonyl)cyclohepta[1,2,3-*hi*]indolizine (**11**) were characterized. The reaction of 2-chloro-3-(ethoxycarbonyl)-cyclohepta[*b*]pyrrole (**4**) with **5** proceeded in a similar way to give a number of compounds besides (**9**). Most of them were obtained in small quantities, too unstable to be identified.

Phosphoranes (**6**—**9**) were characterized by spectral methods. IR spectra of the products show a ν(C=O) absorption at 1650—1615 cm^{-1}, characteristic of the phosphoranes possessing an α-carboxylic ester group,[6] whereas their mass spectra contain abundant ions at *m/e* 108, 152, 183, 185, and 262 which are diagnostic of (triphenylphosphoranylidene)acetates.[7] ^{13}C NMR spectra provide a conclusive evidence in favor of the structures (**6**—**9**). The ^{13}C chemical shifts and ^{13}C- ^{31}P couplings for these products (Table 1) were easily assigned by reference to the spectra of the related azaazulenes and data on phosphoranes.[8] We see that there are long-range couplings (J=6—12 Hz) involving ^{31}P nucleus and each of the ring carbons-2 and -3; the structure in which the ylide moiety is attached to C-8 is not compatible with the observations. The phosphoranes are protonated by acid. As an example, UV spectrum of **9**, when determined for a neutral solution, displays absorptions at 272, 309, 354, and 448 nm. However, the spectrum taken in the presence of trifluoroacetic acid (265, 286^{sh}, 345, and 482 nm) resembles that of 1,2-dihydro-3-ethoxycarbonyl-2-[cyano(ethoxycarbonyl)methylene]-cyclohepta[*b*]pyrrole.[1] This fact indicates that protonation occurred at the ring nitrogen atom. The spectrum of the neutral solution was also obtained on basification of the acidified solution.

Table 1. Partial ^{13}C chemical shifts and $J_{^{31}P-^{13}C}$ values of **6**, **8**, **9**



Carbon	**6**	**8**	**9**
1′	129.4(112.3)	131.0(112.3)	131.0(129.4)

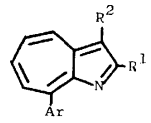
8a	154.6	157.1	158.1

Compound **10** was identified by a comparison of its melting point with that reported.[9] The NMR spectrum of **11** indicates the presence of a 2,3,8-trisubstituted cyclohepta[*b*]pyrrole ring, whereas its UV spectrum suggests the presence of a chromophore more extended than that of **3**. From these results, together with the presence of additional two sets of one-proton doublets at δ 6.58 and 6.74 (J=8 Hz) in its NMR spectrum, we assigned the structure.



1 R^1=Cl, R^2=CO_2Et, Ar=Ph
2 R^1=Cl, R^2=CN, Ar=*p*-$MeOC_6H_4$
3 R^1=Cl, R^2=CN, Ar=H
4 R^1=Cl, R^2=CO_2Et, Ar=H
6 R^1=C(CO_2Me)=PPh_3, R^2=CO_2Et, Ar=Ph
7 R^1=C(CO_2Me)=PPh_3, R^2=CN, Ar=*p*-$MeOC_6H_4$
8 R^1=C(CO_2Me)=PPh_3, R^2=CN, Ar=H
9 R^1=C(CO_2Me)=PPh_3, R^2=CO_2Et, Ar=H

11

It is concluded that the C-6 and C-8 positions of 2-chlorocyclohepta[*b*]pyrroles are reactive toward nucleophiles despite the presence of a good leaving group at the most electron deficient C-2 and reactivities of these three positions depend on the reaction conditions[1] and the nature of nucleophiles.

Experimental

Melting points were uncorrected. IR spectra were recorded for nujol mulls. ^{1}H NMR spectra were obtained with a Varian HA-100 spectrometer at 100 MHz (solvent $CDCl_3$; Me_4Si as internal standard), and ^{13}C NMR spectra with a JEOL FX-100 spectrometer (solvent $CDCl_3$). UV spectra were measured for chloroform solutions. Molecular weights were determined by mass spectrometry with a Hitachi RMU 7 spectrometer. Chromatography was performed on Kiesel gel 60. Yields are based on unrecovered starting material.

*Reaction of **1** with **5**.* A mixture of **1** (1.00 g, 3.21 mmol) and **5** (2.08 g, 6.2 mmol) in xylene (100 ml) was heated under reflux for 5.5 h, and then heated with 10% aqueous sodium carbonate solution (20 ml) for 30 min. Water was added and the mixture was extracted with chloroform, the extracts being dried and evaporated. Chromatography of the residue with chloroform afforded triphenylphosphine oxide (1.12 g). Further elution with chloroform and benzene-ethyl acetate (4:1) gave **6** (0.25 g, 66%), orange prisms (from cyclohexane), mp 183—184 °C, NMR δ=1.52 (3H, t, J=7 Hz), 3.43 (3H, s), 4.47 (2H, q, J=7 Hz), 6.82 (2H, d, J=8 Hz), 6.96—7.48 (15H, m), 7.52—7.80 (6H, m), 8.72—8.90 (1H, dm, J=8 Hz); UV_{max} 264 nm (log ε 4.35), 305 (4.30), 365 (3.84), 458 (4.18); IR 1685 (C=O), 1640 cm^{-1} (C=O). Found C, 76.57; H, 5.39; N, 2.05; P, 4.78%. Calcd for $C_{39}H_{32}NO_4P$: C, 76.84; H, 5.29; N, 2.30; P, 5.08%.

*Reaction of **2** with **5**.* A mixture of **2** (0.77 g, 2.61 mmol) and **5** (2.18 g, 6.53 mmol) in xylene (100 ml) was heated under reflux for 8.5 h and the solvent was then evaporated. Chromatography of the residue with benzene-chloroform (2:1) gave **2** (0.195 g). An oil eluted with chloroform was re-chromatographed with benzene-chloroform (1 : 2) to give **7** (0.24 g, 21%) as a red oil, which on trituration in petroleum ether-dichloromethane partly solidified, mp 115—116 °C, NMR δ=3.63 (3H, s), 3.82 (3H, s), 6.48 (2H, d, J=8 Hz), 6.83 (2H, d, J=8 Hz), 6.9—8.4 (19H, m); UV_{max} 266 nm (log ε 4.16), 312 (4.18), 360^{sh} (3.75), 383^{sh} (3.70), 464 (3.98); IR 2200 (C≡N), 1650 cm^{-1} (C=O). Found: C, 76.42; H, 5.16; N, 4.07; P, 5.74%. Calcd for $C_{38}H_{29}N_2O_3P$: C, 77.02; H, 4.93; N, 4.73; P, 5.23%.[10] Elution with chloroform-ethyl acetate gave an inseparable mixture of **5** and **7**.

*Reaction of **3** with **5**.* A mixture of **3** (2.00 g, 10.6 mmol) and **5** (7.60 g, 22.8 mmol) in xylene (150 ml) was heated under reflux for 8.5 h, hydrolyzed with 10% aqueous sodium carbonate solution (*vide supra*), and worked up as above. Chromatography with benzene gave **11** (0.084 g, 7%), brownish violet prisms (from benzene), mp 219 °C, NMR δ=3.74 (3H, s), 5.45 (1H, dd, J=11 and 8 Hz), 5.73 (1H, dd, J=12 and 8 Hz), 6.20 (1H, d, J=11 Hz), 6.58 (1H, d, J=8 Hz), 6.74 (1H, d, J=8 Hz), 7.27 (1H, d, J=12 Hz); UV_{max} 265 nm (log ε 4.43), 273 (4.45), 369 (4.03), 393 (4.08), 417 (4.09), 463 (2.96), 499 (3.03), 540 (3.04), 591 (2.94), 650 (2.65); IR 2200 (C≡N), 1690 cm^{-1} (C=O). Found: C, 63.43; H, 3.27; Cl, 12.54; N, 9.71%. Calcd for $C_{15}H_9ClN_2O_2$: C, 63.28; H, 3.19; Cl, 12.45; N, 9.84%. Elution with benzene-chloroform (3:1) gave **10** (0.083 g, 9%), mp 201 °C (lit,[9] mp 202 °C), Found: C, 65.16; H, 3.32; N, 13.92%. Further elution with benzene-chloroform (3:1) afforded **3** (1.19 g) and elution with benzene-chloroform (1:4) gave triphenylphosphine oxide (5.54 g). Elution with chloroform gave **8** (0.79 g, 38%), orange prisms (from cyclohexane-dichloromethane), mp 210 °C, NMR δ=3.65 (3H, s), 7.3—7.9 (19H, m), 8.24 (1H, d, J=9 Hz); UV_{max} 269 nm (log ε 4.34), 307 (4.31), 318^{sh} (4.23), 354 (3.76), 450 (4.22); IR 2200 (C≡N), 1650 cm^{-1} (C=O). Found: C, 76.20; H, 4.52; N, 5.72; P, 6.64%. Calcd for $C_{31}H_{23}N_2O_2P$: C, 76.53; H, 4.77; N, 5.76; P, 6.37%.

*Reaction of **4** with **5**.* A mixture of **4** (2.00 g, 8.49 mmol) and **5** (6.60 g, 20.4 mmol) in xylene (150 ml) was heated under reflux for 18.5 h, hydrolyzed (*vide supra*), and worked up as above. Elution with chloroform-ethyl acetate (1:1) gave **4** (0.296 g) and triphenylphosphine oxide (3.07 g) and elution with ethyl acetate afforded **9** (0.53 g, 14%), orange needles (from cyclohexane), mp 198 °C, NMR δ=1.46 (3H, t, J=7 Hz), 3.43 (3H, s), 4.43 (2H, q, J=7 Hz), 7.25—7.95 (19H, m), 8.75 (1H, dm, J=10 Hz); UV_{max} 272 nm (log ε 4.47), 309 (4.25), 354 (3.81), 448 (4.19); IR 1675 (C=O), 1615 cm^{-1} (C=O). Found: C, 74.16; H, 5.15; N, 2.51; P, 5.77%. Calcd for $C_{33}H_{28}NO_4P$: C, 74.28; H, 5.29; N, 2.63; P, 5.81%.

We thank Dr. A. Mori, Kyushu University, and Dr. T. Morita, Tohoku University, for NMR spectral determinations.

Electrosynthesis of Hetero-Hetero Atom Bonds. I. A Direct Preparation of Bis(dialkylthiocarbamoyl) Disulfides from Dialkylamines and Carbon Disulfide

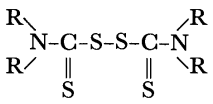
Sigeru TORII, Hideo TANAKA, and Kiyosi MISIMA

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

(Received December 3, 1977)

Synopsis. Bis(dialkylthiocarbamoyl) disulfides were synthesized directly from dialkylamines and carbon disulfide by electrolysis under constant voltage using an undivided cell. The electrochemical reaction was carried out effectively in a two-layer system of electrolysis solvents, *e. g.*, water-chloroform, water-dichloromethane, water-1,2-dichloroethane, and water-carbon disulfide. Likewise, the electrolysis could be performed in a homogeneous solution using dimethylformamide and/or acetonitrile.

Bis(dialkylthiocarbamoyl) disulfides **1** are industrial chemicals of importance for use as vulcanization accelerators[1] and fungicides.[2] Two methods of preparation have been widely used, one involving



1: R=C_1-C_4

the oxidation of ammonium dialkyldithiocarbamates[3] and the other that of alkali dialkyldithiocarbamates.[4] Both methods require stoichiometric amounts of oxidizing agents which give rise to environmental problems. A clean process using few chemical reagents is desirable. We wish to report the direct electrosynthesis of **1** form dialkylamines and CS_2 by two methods, one involving a two-layer system for the continuous extraction of **1** and the other a homogeneous solvent system.[5]

For the two-layer system the following solvent combinations are used; water–chloroform, water–dichloromethane, water–1,2-dichloroethane, and water–CS_2. A schematic sketch of the apparatus for laboratory scale electrolysis is given in Fig. 1. Electrolysis was carried out in an aqueous solution (upper layer) containing the dithiocarbamates **2**,[3] prepared *in situ*

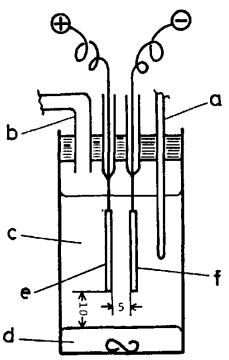


Fig. 1. Electrolysis cell.
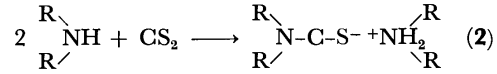
a: Thermometer; b: gas lead pipe; c: aqueous layer; d: extraction layer; e: anode; f: cathode.

by stirring a mixture of dialkylamines and CS_2, using an undivided cell fitted with platinum and/or carbon electrodes under a constant terminal voltage of 2.0 V (0.75—1.15 V *vs.* SCE).[6] The results are given in Table 1. Over 1.0—1.1 F/mol of electricity, the current becomes almost zero. During the course of the reaction,



(**2**)

electrolysis efficient extraction of **1** with dichloromethane (lower layer) proceeds spontaneously. Removal of the extracting solvent afforded the solid material **1**(R=Me, Et, and Pr) in 76—99% yields (1, 2, 5, and 7). When electrolysis of **2**(R=Et) in an aqueous solution was carried out at 2 V without using the extracting solvents, the initial current was 27 mA/cm². Soon the platinum anode became covered with **1** as a pale yellow film and about 1 h later the passage of current stopped. Work-up of the electrolytic solution afforded **1** in 5—20% yields, indicating that the presence of extracting solvents in the lower layer contributes a great deal to the continuous electrolysis of **2**.

The electrolysis of a more bulky amine such as dibutylamine with CS_2 in a water dichloromethane system gave **1** in poor yield (9), because of the low solubility of **2** (R=Bu) in water, resulting in by-products.[7] However, electrolysis in a water–CS_2 system for 60 h afforded **1** (R=Bu) in 86% yield without pro-

TABLE 1. ELECTROLYSIS OF AMMONIUM DIALKYLDITHIOCARBAMATES[a]

Entry	Amine[b] R	Amine[b] mmol	CS_2 mmol	Solvent[c] (ml)	Current mA/cm²	Temp °C	Time[d] h	Yield[e] %
1	Me	6.0	3.0	CH_2Cl_2-H_2O (3/20)	27—0.1	3— 5	26	99
2	Me	6.0	3.0	CH_2Cl_2-H_2O (3/20)	13—0.7	14—16	20	76[f]
3	Me	6.0	3.0	CH_2ClCH_2Cl-H_2O (5/20)	17—0.7	24—26	22	97
4	Me	6.0	3.0	$CHCl_3$-H_2O (3/20)	20—0.7	23—25	22	87
5	Et	5.3	2.6	CH_2Cl_2-H_2O (3/20)	23—0.1	19—21	8	99
6	Et	3.0	excess	CS_2-H_2O (3/20)	15—0.2	17—20	9	99
7	Pr	4.0	2.0	CH_2Cl_2-H_2O (3/20)	9—0.1	15—18	23	80
8	Pr	3.0	excess	CS_2-H_2O (3/20)	7—0.03	18—20	48	96
9	Bu	3.0	1.5	CH_2Cl_2-H_2O (3/20)	1—0.03	16—17	17	28
10	Bu	2.0	excess	CS_2-H_2O (3/20)	1—0.07	17—18	60	86
11	Me	9.0	3.0	MeCN (20)	19—13	12—14	3	79
12	Et	6.0	3.0	MeCN (20)	22—6	10—12	1.7	99
13	Et	6.0	3.0	DMF (20)	13—3	10—11	3.5	99
14	Pr	6.0	3.0	DMF (20)	8—0.4	10—13	6	99
15	Bu	6.0	3.0	DMF (20)	9—0.2	9—12	5	100

a) Carried out under voltage of 2 V using Pt foil electrodes (3 cm²). b) Aqueous 50% Me_2NH used. c) Containing 160 mg of NH_4Cl (1—10) or 100 mg of Et_4NClO_4 (11—15). d) 1.01—1.05 F/mol passed. e) Isolated yields based on CS_2 (1—5, 7, 9, and 11—15) or amines (6, 8, and 10). f) Carbon electrodes (3 cm²) used.

ducing by-products (10).

Choice of CS_2 for diethylamine, dipropylamine, and dibutylamine as an extracting solvent was found suitable, since electrolysis could be carried out without preparing **2** by adding appropriate amines to the aqueous solution, product **1** moving smoothly into the lower layer. Upon concentration of the CS_2 fraction, disulfides **1** were obtained in 86—99% yields as fine crystals (6, 8, and 10). It is well known that dithiocarbamate ion, upon one electron oxidation on the anode followed by the coupling of the thio radical, gives **1**.[8] In the course of electrolysis of **2**, dialkylammonium ions, upon discharge on the cathode, liberate dialkylamines, which can react with CS_2 to regenerate **2**. Consequently, most of the dialkylamines used (6, 8, and 10) could be converted into **1**.

$$R_2\overset{+}{N}H_2 \xrightarrow[-\frac{1}{2}H_2]{+e} R_2NH \xrightarrow{CS_2} \mathbf{2}$$

We further investigated the direct synthesis of **1** from dialkylamines and CS_2 in a homogeneous solvent using MeCN and/or DMF. Electrolysis of a solution of two parts of diethylamine and one part of CS_2 in MeCN was carried out by using platinum electrodes at 2 V in the presence of tetraethylammonium perchlorate as a supporting electrolyte (12). After 1.05 F/mol of electricity had been passed, work-up of the solution afforded **1** in 99% yield.

Experimental

All melting points are uncorrected. Carbon-13 NMR spectra (CMR) were taken at 25.05 MHz in the Fourier mode using a JEOL FX-100 spectrometer. Samples were dissolved in $CDCl_3$ containing Me_4Si as an internal standard.

*Preparation of **1** from Dialkylamines and Carbon Disulfide in a Two-layer Solution.* A typical procedure is as follows: A mixture of aqueous 50% Me_2NH (0.80 ml, 6.0 mmol) and CS_2 (0.18 ml, 3.0 mmol) in water (20 ml) was stirred for *ca.* 1 h at room temperature. To this solution were added NH_4Cl (160 mg) and CH_2Cl_2 (3 ml), Pt electrodes (3 cm^2) being immersed in the aqueous layer. The mixture was electrolysed at 2 V (0.79—0.90 V *vs.* SCE) at 3—5 °C for 26 h. The current densities varied from 27 to 0.1 mA/cm^2 during the course of electrolysis. The CH_2Cl_2 layer (lower layer) was separated, washed with brine, and dried (Na_2SO_4.) Removal of the solvent afforded **1** (R=Me, 357 mg, 99%): mp 143—145 °C from EtOH (lit,[4e] mp 145—146 °C); CMR ($CDCl_3$) δ 193.3 (s, C=S), 47.4, 42.2 (q, CH_3).

The reaction conditions and results are given in Table 1, 1—10. Physical and spectral data of **1** (R=Et, Pr, and Bu) are as follows.

Compound **1** (R=Et): Mp 69—70.5 °C from EtOH (lit,[4e] mp 69.5—70.5 °C); CMR ($CDCl_3$) δ 192.4 (s, C=S), 52.0, 47.6 (t, CH_2), 13.4, 11.4 (q, CH_3).

Compound **1** (R=Pr): Mp 48.5—49.5 °C from EtOH (lit,[4e] mp 49—50.5 °C); CMR ($CDCl_3$) δ 193.2 (s, C=S), 59.2, 55.1 (t, CH_2N), 21.7, 19.6 (t, CH_2), 11.3 (q, CH_3).

Compound **1** (R=Bu):[4e] CMR ($CDCl_3$) δ 192.9 (s, C=S), 57.4, 53.2 (t, CH_2N), 30.2, 28.1 (t, C_β), 20.1 (t, C_γ), 13.8 (q, CH_3).

*Preparation of **1** from Dialkylamines and Carbon Disulfide in Acetonitrile.* A mixture of Et_2NH (0.62 ml, 6.0 mmol), CS_2 (0.18 ml, 3.0 mmol), and Et_4NClO_4 (100 mg) in MeCN (20 ml) was electrolyzed at 2 V (0.75—1.10 V *vs.* SCE) at 10—12 °C using Pt electrodes (3 cm^2). After a current of 3.15×10^{-3} F had been passed for 1.7 h, the mixture was concentrated *in vacuo*. The residue was worked up to give **1** (R=Et, 99%): Mp 69—70.5 °C from EtOH (lit,[4e] mp 69.5—70.5 °C). Similarly, DMF was used for the preparation of **1** (R=Et, Pr, and Bu). The conditions and results are given in Table 1, 11—15.

*Electrolysis of Diethylammonium Diethyldithiocarbamate **2** (R=Et) in Water.* A mixture of Et_2NH (0.62 ml, 6.0 mmol), CS_2 (0.18 ml, 3.0 mmol), and NH_4Cl (160 mg) in water (20 ml) was stirred at 14 °C for 1 h to give a homogeneous solution of **2** (R=Et).[3c] The aqueous solution was electrolyzed at 2 V (0.75—0.85 V *vs.* SCE) at 13—15 °C with Pt electrodes (3 cm^2). At the beginning of the reaction the current density was 27 mA/cm^2. After 10 min, pale yellow precipitates were deposited on the anode. After 1 h the anode was covered with the precipitates as a film and the current was reduced to almost zero. Electrolysis was continued for further 2.5 h (total 0.3×10^{-3} F). After the usual work-up 35 mg (8%) of **1** (R=Et) was obtained.

5) A similar attempt involving electrolysis of an aqueous solution of sodium dithiocarbamates using an alternating current has been reported. However, the low solubility of **1** for water along with the low current efficiency (12.5%) gives rise to difficulties: J. A. Gardner, U. S. Pat., 2385410 (1945).

6) Change in the cell voltage did not affect product selectivity and yields.

7) In the course of electrolysis of **2** in water-CH_2Cl_2, methylene bis(dialkyldithiocarbamate) was obtained as a by-product (R=Me, Et, <1%; R=Pr, 5—10%; R=Bu, 65—70%). Formation of the by-product could be surpressed by use of carbon disulfide as an extracting solvent. Methylene bis(dimethyldithiocarbamate) has been prepared from CH_2Cl_2 and sodium dimethyldithiocarbamate: T. Nakai and M. Okawara, *Chem. Lett.*, **1974**, 731.

Studies on Aziridine-2-carboxylic Acid. I. Synthesis of the Optically Active L-Aziridine-2-carboxylic Acid and Its Derivatives

Kiichiro NAKAJIMA, Fumiko TAKAI, Takumi TANAKA, and Kenji OKAWA

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received December 9, 1977)

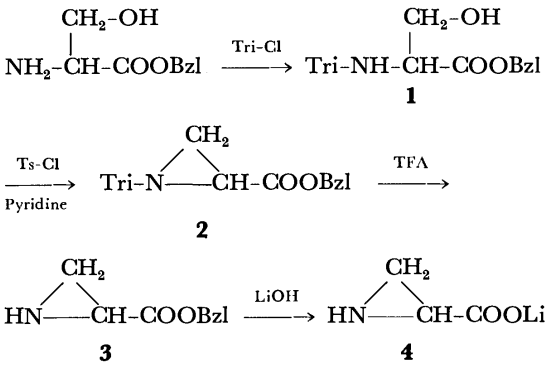
Synopsis. Lithium L-aziridine-2-carboxylate was synthesized from *N*-trityl-L-aziridine-carboxylic acid benzyl ester by the treatment with trifluoroacetic acid followed by the saponification with lithium hydroxide. Several *N*-acylaziridine-2-carboxylic acid esters were synthesized in good yield.

Due to acid labile properties of the aziridine ring, no optically active aziridine-2-carboxylic acid has been synthesized. Only racemic aziridine-2-carboxylic acid has been isolated as a lithium salt in poor yield from methyl 2,3-dibromopropionate by the treatment of liquefied ammonia.[1]

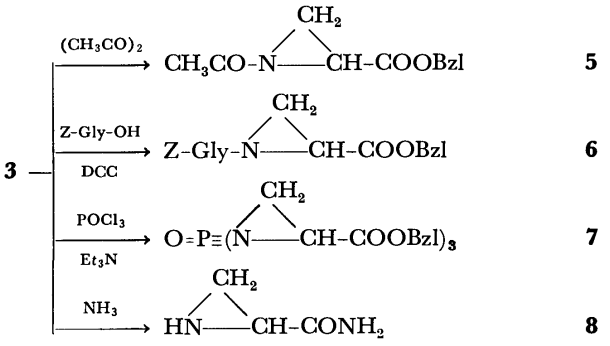
The peptide derivatives of aziridine-2-carboxylic-acid(Azy),[2] however, were prepared *via* *N*-trityl-*O*-tosyl(or *O*-mesyl)β-hydroxy amino acid peptides.[3]

We have undertaken to synthesize L-isomer of Azy since it is of great use in the synthesis of Azy containing peptides.

Lithium L-aziridine-2-carboxylate has been prepared from the corresponding *N*-trityl-*O*-tosyl-L-serine benzyl ester as shown in following Scheme 1. The key step of the detritylation procedure was accomplished by the action of trifluoroacetic acid solution at low temperature, several *N*-acyl-L-Azy–OBzl derivatives being synthesized in good yield as shown in Scheme 2.



Scheme 1.



Scheme 2.

Experimental

All the melting points are uncorrected. The IR and NMR spectra were recorded on Hitachi EPI-G3 and Hitachi R-20B spectrometers, respectively. The purity of the synthetic compounds was confirmed by thin layer chromatography on silica gel G.

Tri-L-Ser-OBzl (1): To a solution of L-Ser–OBzl benzenesulfonate (56 g, 0.15 mol) and Et_3N (42 ml, 0.3 mol) in $CHCl_3$ (100 ml) was added a solution of Tri-Cl (41.8 g, 0.15 mol) in $CHCl_3$ (80 ml) with stirring at 0 °C. After the reaction mixture had been stirred for 24 h at 0 °C, the solution was washed with 10% citric acid and water, and dried over Na_2SO_4. After removal of the solvent, **1** was obtained in theoretical yield as an oily product; $[\alpha]_D^{25}$ +64.8° (*c* 1.0, MeOH). Found: C, 79.43; H, 6.32; N, 3.42%. Calcd for $C_{29}H_{27}O_3N$: C, 79.61; H, 6.22; N, 3.20%.

Tri-L-Azy–OBzl (2): To a solution of **1** (65.6 g, 0.15 mol) in dry pyridine (200 ml) was added a solution of Ts-Cl (85.8 g, 0.45 mol) in dry pyridine (50 ml) at −10 °C for 1 h. After the reaction mixture had been stirred for 24 h at 0 °C, the solvent was removed *in vacuo* and the residual oil was partitioned between ethyl acetate and water. The organic layer was washed with 10% citric acid and water, and dried over Na_2SO_4. The ethyl acetate was removed *in vacuo* to give an oily product (84.3 g, 95% yield as a *O*-tosylate). The oil was dissolved in dry THF (100 ml), and Et_3N (39.2 ml, 0.28 mol) was added. After the THF solution had been refluxed at 75 °C for 24 h, the reaction mixture was concentrated *in vacuo* and the residue was dissolved in ethyl acetate. The organic layer was washed with 10% citric acid, 1M sodium hydrogencarbonate and water, and dried over Na_2SO_4. The solvent was removed *in vacuo*, and the product was crystallized from ethyl acetate–ether–hexane; yield, 31.4 g (57.8%); mp 114—116 °C; $[\alpha]_D^{20}$ −95.5° (*c* 1.0, THF). IR: 1722, 1590, 1095 cm^{-1}; NMR (CCl_4): δ 2.10, 1.32 (2H 2q, J_{trans}=3.1 Hz, J_{cis}=6.3 Hz, J_{gem}=1.8 Hz, β-proton); 1.87 (1H q, J_{trans}=3.1 Hz, J_{cis}=6.3 Hz, α-proton). Found: C, 82.90; H, 5.84; N, 3.25%. Calcd for $C_{29}H_{25}O_2N$: C, 83.03; H, 6.01; N, 3.34%.

L-*Azy–OBzl (3)*: To a solution of **2** (5.04 g, 12 mmol) in $CHCl_3$ (10 ml) and absolute MeOH (10 ml, used as a scavenger of trityl group), was added TFA (20 ml) with stirring at −5 °C, and the solution was stirred for 2 h. The solvent was removed *in vacuo* and the residual oil was partitioned between ether and water. Sodium hydrogencarbonate was added to the aqueous layer producing alkaline solution, and the isolated oil was extracted with ether. After being dried over Na_2SO_4, the solvent was removed *in vacuo* to give an oily product; yield, 1.92 g (90.2%); $[\alpha]_D^{23}$ −56.8° (*c* 1.0, THF). IR: 3320, 1730, 1090 cm^{-1}; NMR ($CDCl_3$): δ 2.03, 1.88 (2H 2q, J_{trans}=3.0 Hz, J_{cis}=6.0 Hz, J_{gem}=1.5 Hz, β-proton); 2.58 (1H q, J_{trans}=3.0 Hz, J_{cis}=6.0 Hz, α-proton); 1.43 (1H bs, H–N<); 5.19 (2H s, C_6H_5–

CH_2–O–); 7.36 (5H s, C_6H_5–CH_2–O–). Found: C, 67.52; H, 6.31; N, 7.76%. Calcd for $C_{10}H_{11}O_2N$: C, 67.78; H, 6.26; N, 7.91%.

L-*Azy-OLi* (**4**): To a solution of **3** (540 mg, 3.05 mmol) in absolute MeOH (3 ml) was added a solution of LiOH (115.2 mg, 2.74 mmol) in water (1 ml) with stirring at −10 °C. After the reaction mixture had been stirred for 6 h at −5 °C, the solvent was removed *in vacuo*. EtOH was added to a residual oily product and the crystals obtained were collected by filtration. The crystals (**6**) were obtained in theoretical yield; mp 260 °C dec; $[\alpha]_D^{23}$ −39.5° (*c* 1.0, H_2O). IR: 3440, 3275, 1590, 1095 cm^{-1}; NMR (D_2O): δ 1.80, 1.75 (2H 2q, J_{trans}=3.6 Hz, J_{cis}=5.8 Hz, J_{gem}=1.5 Hz, β-proton); 2.36 (1H q, J_{trans}=3.6 Hz, J_{cis}=5.8 Hz, α-proton). Found: C, 38.68; H, 4.18; N, 15.21%. Calcd for $C_3H_4O_2NLi$: C. 38.73; H, 4.34; N, 15.05%.

Ac-L-*Azy-OBzl* (**5**): To a solution of **3** (2.2 g, 12.4 mmol) and Et_3N (3.5 ml, 24.8 mmol) in $CHCl_3$ (20 ml) was added acetic anhydride (1.1 ml, 12.4 mmol) with stirring at −5 °C, followed by stirring at 0 °C for 4 h. The reaction mixture was washed with 10% citric acid and water, and dried over Na_2SO_4. The solvent was removed *in vacuo* to give an oily product; yield, 2.28 g (84.4%); $[\alpha]_D^{23}$ −39.6° (*c* 1.0, MeOH). IR: 1740, 1708, 1081 cm^{-1}; NMR ($CDCl_3$): δ 2.59, 2.48 (2H 2q, J_{trans}=2.9 Hz, J_{cis}=5.9 Hz, J_{gem}=1.5 Hz, β-proton); 3.18 (1H q, J_{trans}=2.9 Hz, J_{cis}=5.9 Hz, α-proton); 2.21 (3H s, CH_3–CO–); 5.20 (2H s, C_6H_5–CH_2–O–); 7.37 (5H s, C_6H_5–CH_2–O–). Found: C, 65.58; H, 5.86; N, 6.20%. Calcd for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98; N, 6.39%.

Z-Gly-L-*Azy-OBzl* (**6**): To a solution of Z-Gly-OH (540 mg, 2.6 mmol) and **3** (460 mg, 2.6 mmol) in $CHCl_3$ (20 ml) was added a solution of DCC (540 mg, 2.6 mmol) in $CHCl_3$ (5 ml) with stirring at −5 °C. After the reaction mixture had been stirred for 6 h, the produced *N,N'*-dicyclohexylurea was filtered off. The filtrate was washed with 1M sodium hydrogencarbonate, 10% citric acid and water, and dried over Na_2SO_4. The solvent was removed *in vacuo* to give the desired product, which was crystallized from ethyl acetate–ether– hexane; yield, 870 mg (90.8%); mp 42—43 °C; $[\alpha]_D^{23}$ −44.5° (*c* 1.0, $CHCl_3$). NMR ($CDCl_3$): δ 2.51, 2.07 (2H m, β-proton); 3.22 (1H q, J=4.8, 3.5 Hz, α-proton); 4.00 (2H d, J=5.5 Hz, –NH–CH_2–CO–); 5.09, 5.18 (4H 2s, $2C_6H_5$–CH_2–O–); 5.37 (1H bs, –NH–CO–); 7.33 (10H s, $2C_6H_5$–CH_2–O–). Found: C, 65.29; H, 5.36; N, 7.48%. Calcd for $C_{20}H_{20}O_5N_2$: C, 65.21; H, 5.47; N, 7.61%.

O=*P*≡(L-*Azy-OBzl*)$_3$ (**7**): To a solution of **3** (1.8 g, 10.1 mmol) and $POCl_3$ (0.23 ml, 2.5 mmol) in $CHCl_3$ (5 ml) at 0 °C was added a solution of Et_3N (1.06 ml, 7.63 mmol) in $CHCl_3$ (1ml) with stirring. After the reaction mixture had been stirred at 0 °C for 3 h, the solution was washed with 1M sodium hydrogencarbonate, 10% citric acid and water, and then dried over Na_2SO_4. The solvent was removed *in vacuo*, and the residual oil was subjected to column chromatography on silica gel using ethyl acetate–$CHCl_3$–benzene (5:1:1 v/v) to give a pure product; yield, 1.09 g (76.0%); $[\alpha]_D^{23}$ −94.7° (*c* 1.0, MeOH). IR: 1745, 1082, 1175—1180, 1250—1290 cm^{-1}; NMR ($CDCl_3$): δ 2.59, 2.72, 3.34 (3H 3q, J=1.6, 3.0 Hz, J=1.6, 6.0 Hz, J=3.0, 6.0Hz, aziridine ring); 2.59, 2.52, 3.09 (3H 3q, J=1.6, 3.0 Hz, J=1.6, 6.0 Hz, J=3.0, 6.0 Hz, aziridine ring); 2.36, 2.36, 2.60 (3H 3q, J=1.6, 3.0 Hz, J=1.6, 6.0 Hz, J=3.0, 6.0 Hz, aziridine ring). Found: C, 62.65; H, 5.16; N, 7.04%. Calcd for $C_{30}H_{30}O_7N_3P$: C, 62.60; H, 5.26; N, 7.29%.

L-*Azy-NH*$_2$ (**8**): Dry ammonia gas was bubbled into a solution of **3** (306.7 mg, 1.73 mmol) in absolute MeOH (10 ml) at 0 °C for 20 min. The reaction mixture was allowed to stand overnight at room temperature.. After the solvent had been removed *in vacuo*, ether was added to a residual oily product and the resulting crystals were collected; yield, 133.7 mg (89.7%); mp 141—142 °C; $[\alpha]_D^{23}$ −44.8° (*c* 1.07, DMF). NMR ($CDCl_3$): δ 1.78, 1.70 (2H 2q, J_{trans}=3.6 Hz, J_{cis}=5.7 Hz, J_{gem}=1.5 Hz, β-proton); 2.38 (1H q, J_{trans}=3.6 Hz, J_{cis}=5.7 Hz, α-proton); 1.78 (1H s, H–N<); 7.50 (2H br, –$CONH_2$). Found: C, 41.78; H, 7.16; N, 32.43%. Calcd for $C_3H_6ON_2$: C, 41.85; H, 7.02; N, 32.54%.

Rotational Isomerism and Vibrational Assignments of Monobromothioacetic Acid

H. S. RANDHAWA* and W. WALTER

Institut für Organische Chemie und Biochemie der Universität Hamburg, Federal Republic of Germany

(Received May 2, 1977)

Synopsis. The infrared and Raman spectra of monobromothioacetic acid have been recorded and vibrational assignments proposed for the two symmetrical rotational isomers present in the acid.

In our earlier paper[1] we have investigated the vibrational and NMR spectra of mono- and dichlorothioacetic acids in relation to the rotational isomerism and hydrogen bonding. As a part of the aforesaid studies we had the occasion to synthesize mono- and dibromothioacetic acids. In the present article we have characterized monobromothioacetic acid and made vibrational assignments corresponding to the two symmetrical rotational isomers present in this acid.

Experimental

Monobromothioacetic acid was prepared by the following reaction:

$$BrCH_2COCl + H_2S \xrightarrow[-15\,^\circ C]{AlCl_3} BrCH_2C\begin{Bmatrix}O\\S\end{Bmatrix}H + HCl$$

The diethyl ether extract of the reaction mixture was distilled thrice under vacuum. The deep yellow colored liquid with bp 27—28 °C/0.2 mmHg; $n_D^{20}=1.5643$ collected under dry nitrogen was used in the spectral measurements and for characterization. The yield was 35%. Elemental analysis: $BrCH_2C\begin{Bmatrix}O\\S\end{Bmatrix}H$(27—28 °C/0.2 mmHg): Found: C, 15.35; H, 2.11; Br, 51.73; S, 20.43%. Calcd: C, 15.48; H, 1.93; Br, 51.61; S, 20.64%.

The spectra were recorded by the same apparatus as described in a previous paper.[1] The infrared and Raman band frequencies (in cm^{-1}) along with the relative intensities are given in Table 1. The NMR signals (in 3% $CDCl_3$/TMS) for SH and CH_2 protons were found to be at δ values of 4.8 and 4.00 ppm respectively.

Results and Discussion

Table 1 reveals that the number of normal motions observed in the Raman (liquid) and infrared (liquid film and vapors) spectra are more than the expected number of vibrations *i.e.* $3N-6=12A'+6A''$. In transition from liquid to gaseous phase, a change in relative intensity of some of the infrared bands (Table 1) is observed. Moreover three and two bands were observed in the C–Br and C–S stretching regions respectively, while two bands were observed for each of the C=O stretching and CSH in-plane deformation regions. All these experimental observations show that there are two symmetrical rotational isomers present in the liquid and gaseous states of this acid like its chloro analogue *i. e.* $ClCH_2CO\begin{Bmatrix}O\\S\end{Bmatrix}H$.[1]

TABLE 1. INFRARED AND RAMAN BAND FREQUENCIES (in cm^{-1}) OF MONOBROMOTHIOACETIC ACID

dp, depolarized; st, strong; vst, very strong; m, medium; mw, medium weak; sh, shoulder; w, weak; vw, very weak; sym, symmetric; asym, asymmetric; str, stretch; the rotational isomers are assumed to be symmetrical.

* To whom all queries should be made: H. S. Randhawa, Department of Chemistry, Punjab Agricultural University, Ludhiana, India.

There is strong resemblance between the spectra of thioacids and their corresponding acyl halides.[1] Thus from the well known spectra of $BrCH_2COCl$[2] and $ClCH_2C\{^{O}_{S}\}H$[1] the assignments of the vibrational motions for the $BrCH_2$–C– and COSH structural parts of $BrCH_2C\{^{O}_{S}\}H$ are made and given in Table 1. The difference between the IR and Raman band frequencies (Table 1) *e. g.* for SH and C=O stretching modes may be due to the cyclic H-bonded dimers as in the carboxylic acids. The position of SH stretching motion at higher wave number in the vapor phase than in the liquid phase infrared spectrum is the normal behavior of an SH group.[3,4]

Our assignments for the normal motions of this acid are in good agreement (except for the C–C torsional frequency) with those of Nakagawa *et al.* on $BrCH_2COCl$.[2] The bands positioned at 181 cm^{-1} and 157 cm^{-1} in $BrCH_2COCl$[2] have been assigned to the in-plane bending vibration. Since the C–C torsional frequency must be influenced by the mass of the halogenated and thiocarboxyl groups, we prefer to assign the depolarized Raman bands at 180 and 153 cm^{-1} in $BrCH_2C\{^{O}_{S}\}H$ to the A'' C–C torsional vibration for each of the two rotational isomers. These bands are positioned at 205 and 180 cm^{-1} in $ClCH_2C\{^{O}_{S}\}H$.[1]

An Infrared Study of Acid Sites on Silica-Alumina Catalysts Poisoned with Sodium Hydroxide[1)]

Jun-ichiro TAKE, Toshiaki UEDA, and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo, 113

(Received July 29, 1977)

We investigated the effect of NaOH impregnation on the acidic properties (the type, strength, and amount of acid sites) of silica–alumina by means of IR spectroscopy of chemisorbed pyridine. Most acid sites on the unpoisoned catalyst were of the Lewis type. Some Lewis-bound pyridine was retained on the surface even at 400 °C, but the pyridinium ion was eliminated at 300 °C, indicating that the strong acid sites were also of the Lewis type. Impregnated NaOH affected both Lewis and Brønsted sites. An increase in the amount of NaOH resulted in the elimination of the Brønsted acid sites of medium strength, and also in a significant reduction in the number of Lewis acid sites over the whole range of acid strength. Weak Brønsted acid sites showed no marked change in number. When the NaOH-impregnated catalysts were exposed to pyridine, a new IR band appeared at about 1445 cm^{-1}; this band is attributable to pyridine associated with the Na ions on the surface.

The infrared spectroscopy of pyridine chemisorbed on solid acids permits the differentiation of Lewis acid sites from Brønsted ones.[2,3)] Since the strength of acid sites should be related to the upper limit of the temperature at which the sites are capable of holding pyridine molecules, a measure of the acid strength may be given in terms of the evacuation temperature of chemisorbed pyridine. Thus, the acid-strength distributions of Brønsted and Lewis acid sites will be determined by means of the IR spectroscopy of chemisorbed pyridine combined with its evacuation temperature, which is successively elevated. Recently, a similar IR technique has been applied to silica–alumina[4)] and Y zeolite[5)] catalysts for the purpose of investigating the influence of aluminium extraction on the surface acid properties.

Previous studies have shown that Na-poisoned silica–alumina catalysts decrease in catalytic activity for cumene cracking,[6)] the isomerization of dialkylbenzenes,[6)] and propene origomerization.[7)] A few brief studies have been reported on the effect of alkali-poisoning on the acidic properties of silica–alumina. Parry[2)] has reported that Na-poisoning (0.8 mg-ion/g) markedly reduced the number of Brønsted acid sites on silica–alumina, and also weakened the Lewis acid sites. The IR spectral data obtained by Bourne, Cannings, and Pitkethly[8)] show a partial and nonselective poisoning of the Brønsted and Lewis acid sites on "aluminium-on-silica" with sodium (0.71 wt%). Basila, Kantner, and Rhee[3)] have reported that the K-poisoning (*ca.* 1 mg-ion/g) of silica–alumina resulted in the elimination of the Brønsted sites and a severe weakening of the Lewis acid sites. The present study was undertaken in order to see, in detail, the effect of NaOH poisoning on the acidic properties of silica–alumina by means of the IR spectroscopy of pyridine, which was retained on the surface after evacuation at successively elevated temperatures.

Experimental

Materials. The Na-poisoned silica–alumina catalysts (SA-1-Na-1, -2, -3, and -4) were prepared by soaking the cracking catalyst (SA-1, 13% Al_2O_3) in an aqueous solution of sodium hydroxide and by then evaporating it to dryness.

TABLE 1. CATALYSTS

Symbol	Surface area m^2/g	Na^+ content mg-ion/g
SA-1	540	0.003
SA-1-Na-1	450	0.048
SA-1-Na-2	480	0.087
SA-1-Na-3	480	0.168
SA-1-Na-4	452	0.807

Some physical properties of these catalysts shown in Table 1 are taken from previous papers.[6,9)] The silica gel (S-3, 600 m^2/g) and γ-alumina (A-1, 170 m^2/g) were prepared by the neutral hydrolysis of ethyl orthosilicate and aluminium isopropoxide, respectively, and by calcination at 550 °C in air for 7 h. The two starting materials were distilled two or three times before use. The pyridine was distilled from a reagent of a GR grade, dried over KOH under a vacuum, and finally vacuum-distilled into a vessel containing a molecular sieve 5A, which had been evacuated *in situ* at 350 °C for 2 h before use.

Sample Preparation and IR Cell. Self-supporting 20-mm diameter wafers of the catalysts were formed by pressing about 50 mg of the samples at 3200 kg/cm^2 in a conventional KBr die. The cell was described in detail in a previous paper.[10)]

Procedures. The wafer mounted in a sample holder was pretreated first in a dry oxygen stream at 550 °C for 2 h and then in a wet oxygen stream at 150 °C for 0.5 h. Afterwards, it was activated in the cell by evacuation at 10^{-4}—10^{-5} mmHg and at 450 °C for 2 h, and then cooled to room temperature. Pyridine vapor (about 16 mmHg) was allowed to equilibrate with the wafer at 150 °C for 1 h after the background spectrum had been recorded. The wafer was evacuated at 150 °C for 1 h and then successively at the desired temperatures for 1 h. After each evacuation, the spectra were recorded on a model DS-401G grating spectrometer (Nihon Bunko) at room temperature. The spectra were scanned at a rate of 1/6 cm^{-1}/s on an expanded wave-number scale (*ca.* 3.3 mm/cm^{-1}). The spectral slit width was approximately 3 cm^{-1} in the 1300—1600 cm^{-1} region.

The band area (or integrated absorbance) was used for the quantitative measurements. The backgrounds for the integration of the bands of adsorbed pyridine were constructed in the same manner as that used by Hughes and White.[11)] The integrated absorbances were normalized so as to indicate

the absorbance per unit of "optical thickness" of the wafer. This normalized absorbance, AS/W (cm/g), corresponds to the $\varepsilon M/W$ quantity, where A and ε are, respectively, the integrated absorbance and the apparent integrated molar absorption coefficient of a band, where M is the amount (mmol) of the responsible species, and where S and W are the cross section (cm^2) and weight (g) of the wafer, respectively.

Results and Discussion

Spectra of Adsorbed Pyridine. The absorption spectrum of pyridine adsorbed on S-3 showed that the adsorbate was hydrogen-bonded (HPY) after evacuation for 1 h at room temperature. The characteristic bands appeared at around 1440 and 1600 cm^{-1}, in accordance with Parry's results.[2] The bands disappeared completely upon evacuation at 120 °C for 1 h.

The A-1 catalyst produced Lewis-bound pyridine (LPY) which gave rise to characteristic bands at 1450 and 1492 cm^{-1} when the adsorbed pyridine was evacuated at 150 °C for 1 h. The peak of the 19*b* mode of LPY was slightly shifted from 1450 to 1458 cm^{-1} as the evacuation temperature was raised from 150 to 300 °C. After evacuation at 300 °C, a weak shoulder remained at around 1452 cm^{-1}; the 19*a* mode (1492 cm^{-1}) also split into two bands at 1500 and 1492 cm^{-1}. A similar shift of the 19*b* mode has been reported for η-alumina.[2] No conversion occurred from LPY into the pyridinium ion (BPY) exhibiting characteristic bands at around 1540 and 1490 cm^{-1}, on dosing water vapor, as has been reported in the literature.[2,3,11]

The spectra of pyridine adsorbed on SA-1 and Na-poisoned SA-1 are illustrated in Fig. 1. After evacuation at 150 °C for 1 h, the pyridine adsorbed on SA-1 displayed three bands, at 1455, 1493, and 1540 cm^{-1}, indicating the coexistence of Lewis and Brønsted acid sites on the surface. The 19*b* mode (1540 cm^{-1}) of BPY disappeared upon evacuation at 300 °C for 1 h (Spectrum b). It has already been shown that this disappearance is accompanied by a partial loss of the Brønsted acid sites.[10]

The splitting of the bands at 1455 and 1493 cm^{-1} took place after evacuation at 300 °C, as was also observed for A-1. The original bands remained with reduced intensities, and additional bands appeared at 1462 and 1497 cm^{-1} (Spectrum b). The 1462 cm^{-1} band, as well as the 1458 cm^{-1} band for A-1, is probably due to another kind of pyridine bound to a Lewis acid site stronger than that characterized by the 1455 cm^{-1} band. Other researchers have reached the same conclusion.[2,4,8] The appearance of the 1497 cm^{-1} band is probably related to the same Lewis acid site as that for the band at 1462 cm^{-1}. The 19*b* mode (1455 and 1462 cm^{-1}) of LPY still remained even after evacuation at 400 °C (Spectrum c), in contrast with that of BPY. This fact implies that the strong acid sites on SA-1 are of the Lewis type. The addition of water vapor converted LPY into BPY, as is well known.

When the Na-poisoned catalysts were exposed to pyridine vapor and then evacuated at 150 °C for 1 h, the adsorbed pyridine produced the same spectra as those obtained for SA-1, except for the appearance of a new band. The new absorption occurred at 1445 cm^{-1} without the appearance of the 1600 cm^{-1} band characteristic of HPY; it was especially pronounced for SA-1-Na-4 (Fig. 1B). This band disappeared upon evacuation at 200 °C for SA-1-Na-1 or -2, but it remained even after evacuation at 300 °C for SA-1-Na-4. Additionally, the band is very similar in frequency to a band at 1438—1445 cm^{-1} due to pyridine adsorbed on the Na ion in Na-exchanged X or Y zeolites.[12] Therefore, the new band is attributable to pyridine associated with the Na ion on the surface, rather than to hydrogen-bonded pyridine. A similar band has also been found on Na-exchanged "aluminium-on-silica."[8] The three

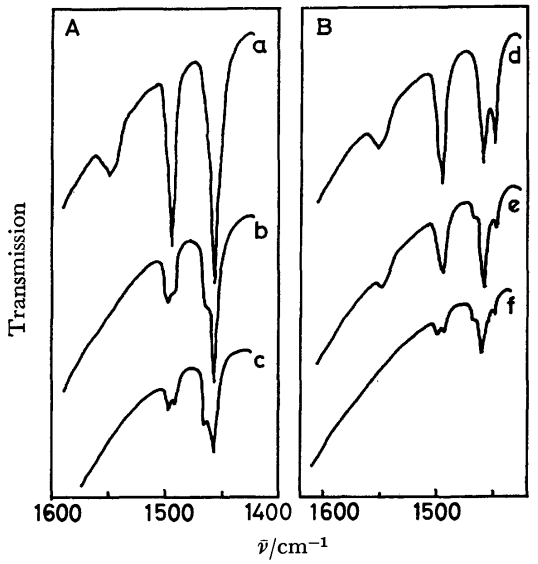

Fig. 1. Infrared spectra of pyridine chemisorbed on silica–alumina catalysts. Spectra A with SA-1 were recorded after evacuation at 150 (a), 300 (b), and 400 °C (c); spectra B with SA-1-Na-4 were obtained after evacuation at 150 (d), 200 (e), and 300 °C (f).

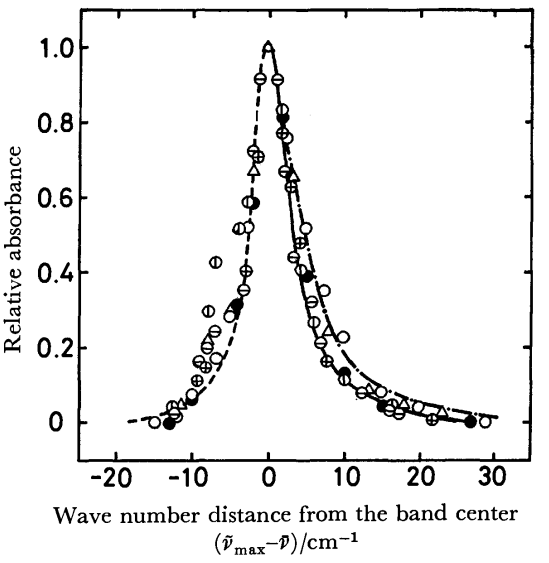

Fig. 2. Band shapes of the 19*b* mode (1455 cm^{-1}) due to Lewis-bound pyridine on various catalysts.
△, ○: SA-1 (150 °C evac.); ●: SA-1 (200 °C evac.); ◑: SA-1 (300 °C evac.); ⊖: SA-1-Na-1 (200 °C evac.); ⊕: SA-1-Na-2 (200 °C evac.).

other bands at 1455, 1490, and 1540 cm^{-1} behaved in essentially the same way as SA-1 when the evacuation temperature was raised or when water vapor was dosed. Since the 1455 cm^{-1} band overlapped to a considerable extent with the 1445 cm^{-1} band (Fig. 1B), the deconvolution of the observed band into these two components was necessary for quantitative measurements of the Lewis acid sites on the Na-poisoned catalysts. The deconvolution was carried out in the manner described below.

Deconvolution of the Overlapped Bands Near 1450 cm^{-1}. In Fig. 2, representative absorption bands at 1455 cm^{-1} are plotted in a normalized form for the catalysts which exhibit no absorption band at 1445 cm^{-1}. The solid and chain lines in Fig. 2 represent two types of Lorentz curves, whose respective half-widths are 7 and 10 cm^{-1}. Apparently, the right half of an absorption curve is fitted approximately by a Lorentz curve with a half-width of 10 cm^{-1} for the bands recorded after evacuation at 150 °C, or by one with a half-width of 7 cm^{-1} for the bands obtained after evacuation at 200 or 300 °C. A Lorentz curve (broken line) with a half-width of 5 cm^{-1} fits the left half of an absorption curve for all the bands, except for a shoulder at around 1460 cm^{-1}.

The procedure for resolving the 1455 cm^{-1} band from the 1445 cm^{-1} band is based on these findings, as illustrated in Fig. 3. First, the shape of the right half of the 1455 cm^{-1} band was determined by drawing a Lorentz curve (broken line) with a half-width of 7 or 10 cm^{-1} from the peak onto the lower-frequency side. Secondly, the absorption curve (dotted line) of the 1445 cm^{-1} band was determined by subtracting the absorption curve of the 1455 cm^{-1} band from the observed curve (solid line).

Changes in Acidic Properties. The two bands at 1455 and 1540 cm^{-1} were chosen to measure the numbers of the Lewis and Brønsted acid sites, respectively. Figure 4 shows the integrated absorbances of the two bands recorded after evacuation at the indicated temperatures for all the catalysts. These absorbances are related quantitatively to the numbers of acid sites capable of retaining the pyridine at the respective temperatures. Since the apparent integrated molar absorption coefficient is approximately the same for the two bands.[11,13] The results shown in Fig. 4 also permit a direct comparison between the Lewis and Brønsted acidities. The acid-strength distributions of the Lewis and Bronsted acids are given in Table 2, in which the number of acid sites is represented as the ratio relative to the total amount of the corresponding type of acid for each catalyst. In Table 3, the integrated absorb-

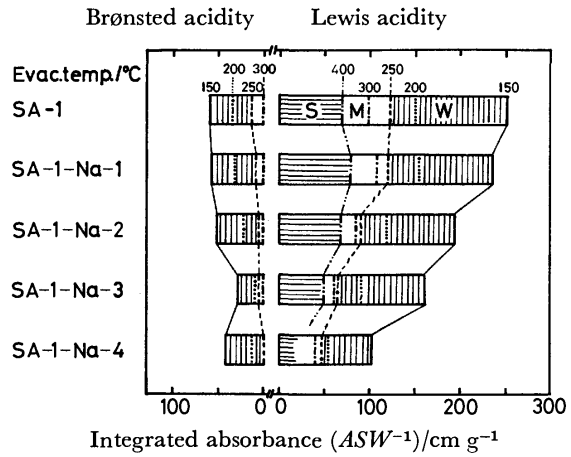

Fig. 4. Acidic properties of catalysts.
S: Strong, M: medium, W: weak.

Table 2. Acid-strength distribution

	Lewis acid			Brønsted acid		
	Weak[a)]	Medium[a)]	Strong[a)]	Weak	Medium	Strong
SA-1	0.51	0.14	0.35	0.77	0.23	0
SA-1-Na-1	0.48	0.19	0.33	0.87	0.13	0
SA-1-Na-2	0.53	0.11	0.35	0.91	0.09	0
SA-1-Na-3	0.60	0.10	0.30	0.88	0.12	0
SA-1-Na-4	0.54	0.46		1.0	0	0

a) Weak and medium sites are incapable of retaining the pyridine in the evacuation temperature (T_e) ranges of $150 < T_e/°C \leqq 250$ and $250 < T_e/°C \leqq 400$, respectively; strong sites are capable of retaining the pyridine at $T_e/°C = 400$; their amounts are given as ratios relative to the total amount of the corresponding type of acid for each catalyst.

TABLE 3. INTEGRATED ABSORBANCES[a] OF THE 1445 cm^{-1} BAND ON Na-POISONED CATALYSTS

Catalyst	Evacuation temperature/°C		
	150	200	300
SA-1-Na-1	17	0	0
SA-1-Na-2	27	0	0
SA-1-Na-3	35	7	0
SA-1-Na-4	38	13	3

a) ASW^{-1}/cm g^{-1}.

ances of the 1445 cm^{-1} band are listed for the Na-poisoned catalysts.

Figure 4 indicates that most (*ca.* 80%) of the acid sites on unpoisoned SA-1 are of the Lewis type. Of the Lewis acid sites, about 35% are so strong as to be capable of holding the pyridine even at 400 °C; about a half are weak, so the pyridine is evolved at 250 °C; the remainder are medium in acid strength. The Brønsted acid sites are not so strong as the Lewis acid sites, since they are incapable of retaining the pyridine even at 300 °C. A similar trend is also found in the results of Ballivet, Barthomeuf, and Pichat.[4] Therefore, such a trend seems general in the acidic properties of dehydroxylated silica–alumina.

The poisoning effect of the impregnated NaOH is apparent on both Lewis and Brønsted acidities, as may be seen in Fig. 4. The Lewis acid sites are markedly decreased in number as the Na^+ content is increased. However, the acid-strength distribution of Lewis acid sites shows no significant change, as is shown in Table 2. This implies that the poisoning action is exerted to an almost equal extent on the sites over the whole range of acid strength; hence, it does not mean that the impregnated NaOH weakens the Lewis acid sites, in contrast with the results of the previous researchers.[3] Of the Brønsted acid, a considerable change in the acid-strength distribution is noticed (Table 2). The Brønsted acid sites of medium strength are decreased in number with an increase in the Na^+ contents, and finally are eliminated (Fig. 4 and Table 2). The weak Bronsted acid sites show no significant change in number. Consequently, the Brønsted acid sites on the poisoned catalysts are weakened and also reduced in number with the impregnated NaOH.

Therefore, the present data confirm the general agreement in the literature[2,3,8] that alkali ions affect both Lewis and Brønsted acid sites over silica–alumina. Such behavior of alkali ions cannot be expected only as a result of their exchange with the protons of Brønsted acid sites. Many other complex chemical processes are probably involved in alkali poisoning. For example, our poisoned catalysts are probably partially hydrolyzed during the course of preparation. There are some differences in the poisoning effect between the present results and those in the literature,[2,3] as has been mentioned above. This strongly suggests that the poisoning effect of alkali ions also considerably varies depending on the preparation of poisoned catalysts. Thus, one must be careful about interpreting the results of alkali ion poisoning unless the effect of poisoning has been well characterized.

Table 3 indicates that, in the range of low Na^+ content (SA-1-Na-1 and -2), the absorbance of the 1445 cm^{-1} band after evacuation at 150 °C increases almost proportionally to the increase of Na^+ content, but its increase becomes slight more and more as the Na^+ content is additionally increased (SA-1-Na-3 and -4). This finding implies that, in the range of high Na^+ content, the number of pyridine molecules interacting with the Na ions is limited. However, the interaction is strengthened more and more with an increase in the Na^+ contents. Therefore, these findings suggest that, when the Na ions are increased in amount, they may be distributed in groups over the surface. This type of distribution may restrict sterically the number of pyridine molecules interacting with the Na ions, but may enhance electrostatically the interacting power of the Na ions.

Defect Chemistry of Barium Monoferrite, $BaFe_2O_{4-\delta}$

Akio NAKAMURA,* Shigeru YAMAUCHI, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 16, 1977)

In order to obtain information on the defects in ternary oxide systems, the nonstoichiometry and electrical conductivity of $BaFe_2O_4$ were determined at temperatures between 1050 and 1125 °C. The electrical conductivity was found to be proportional to $P_{O_2}^{-1/6}$. This relationship suggests that $BaFe_2O_4$ is an oxygen deficient n-type semiconductor at high temperatures. The nonstoichiometry was proportional to $P_{O_2}^{-1/2.88}$. In order to interpret the dependence of electrical conductivity and nonstoichiometry on the oxygen partial pressure, various defect models were examined. As a result the following equilibria were selected from among the oxygen vacancies $V_O^{\cdot\cdot}$ and V_O^{x}, and oxygen gas.

$$\text{null} = (1/2)O_2 + V_O^{x}$$
$$V_O^{x} = V_O^{\cdot\cdot} + 2e'$$

An analysis based on the above defect model explains the data well.

The defect chemistry of oxides is important for the elucidation of transport-phenomena mechanisms, such as electrical conduction, diffusion, metal oxidation, sintering and the other processes for fabricating ceramic materials and heterogeneous catalysts. Although extensive research has been carried out on point defects in simple oxides,[1-3] few studies on defects in complex oxides have been published. Most of the ternary oxide systems studied so far are spinels and perovskite-structure oxides.[4-6] In order to obtain more information about defects in ternary oxide systems of other types of crystal structure, an investigation of the nonstoichiometry δ and the electrical conductivity σ of $BaFe_2O_{4-\delta}$ of stuffed tridymite structure was carried out.

Experimental

Materials. Reagent-grade barium carbonate and hematite of 99.99% purity were mixed in a ratio of Ba/Fe= 1/2. The mixture was cold-pressed into pellets and fired in air at 1100 °C for 12 h to form barium ferrite. One of the sintered pellets was ground and the powder was cold pressed. Then, it was heated again to 1300 °C for 6 h and examined using the X-ray powder diffraction method. The powder was found to consist of β'-$BaFe_2O_4$, a low-temperature modification of barium monoferrite.[7]

The sintered pellets were crushed to grains of 1—2 mm in diameter and used as the sample for the nonstoichiometric measurements. The sintered rectangular specimen, 2× 1.5× 15 mm, was used for the mesurement of the electrical conductivity. The relative density was 88%.

Measurements. The nonstoichiometry of $BaFe_2O_{4-\delta}$ was determined gravimetrically by means of a Shimadzu RMB-50 micro balance at temperatures between 1050 and 1125 °C. The sensitivity of the balance was 1 μg. Details of the equipment have been described elesewhere.[8]

About one gram of the sample was placed in a platinum basket, which was then suspended from the balance by fine alumina fibers. The nonstoichiometry δ was assumed to be zero in 1 atm of oxygen since almost no weight change was observed even when the oxygen pressure was changed from 1 to 0.01 atm at constant temperature. The nonstoichiometry was calculated from the difference in the sample weight in CO_2–CO gas mixtures and in 1 atm of oxygen.

The electrical conductivity was measured using the d.c. four-probe method. Four platinum wires were connected to the sample using platinum paste. Details of the equipment and experimental procedure have been described elsewhere.[9]

Results and Discussion

Nonstoichiometry. A plot of $\log \delta$ against $\log P_{O_2}$ is presented in Fig. 1. The linear relationship between $\log \delta$ and $\log P_{O_2}$ indicate that δ is proportional to $P_{O_2}^{-1/m}$. The values of m calculated from the slope are

▽: 1050 °C, □: 1075 °C, △: 1100 °C, ○: 1125 °C.
The symbols for identification of the temperature is the same through Figs. 1 to 4.

Table 1. Summary of the powers of P_{O_2} from the nonstoichiometric and electric conductivity data

$\frac{t}{°C}$	m[a]	m'[b]
1050	2.88±0.02[c]	6.6±0.1
1075	2.85±0.03	6.2±0.1
1100	2.85±0.01	6.0±0.05
1125	2.95±0.01	5.5±0.1

a) m is from $\delta \propto P_{O_2}^{-1/m}$. b) m' is from $\sigma \propto P_{O_2}^{-1/m'}$. c) The errors indicated are for one standard deviation.

*Present address: Research and Development Laboratory TDK Electronics Corporation, 15-7, Higashi Owada 2-Chome, Ichikawa, Chiba 272-01.

given in the second column of Table 1. The mean value of m is 2.88. If the chemical potential of the oxygen atom in the oxide is expressed as

$$\mu_O = \mu_O^\circ + \frac{1}{2}RT \ln P_{O_2}, \quad (1)$$

the relative partial molar enthalpy of the oxygen atom at a constant composition is given by

$$\Delta H_O^\circ = \partial\left(\frac{1}{2}RT \ln P_{O_2}\right)\Big/\partial(1/T).$$

The ΔH_O° values for $BaFe_2O_{4-\delta}$ are listed in the second column of Table 2. ΔH_O° increases slightly with increasing δ.

TABLE 2. PARTIAL MOLAR ENTHALPY OF THE OXYGEN ATOM AND THE ACTIVATION ENERGY FOR ELECTRICAL CONDUCTIVITY

δ	ΔH_O° / kcal mol^{-1}	ΔH_A / kcal mol^{-1}
0.006	77.1±4.6	12.04±2.66
0.010	77.9±3.0	13.12±1.68
0.012	79.0±3.0	11.88±1.37
0.015	80.5±2.5	12.95±0.85
0.020	86.1±3.0	13.49±1.0

Electrical Conductivity. Figure 2 shows the results of the electrical conductivity measurements. The conductivity decreases with increasing oxygen partial pressure. This result indicates that $BaFe_2O_4$ is an oxygen deficient, n-type oxide and that the dependence of conductivity on the oxygen pressure is given by $\sigma = P_{O_2}^{-1/m'}$. The values of m' are given in the third column of Table 1. The values are scattered with the mean value being 6.1.

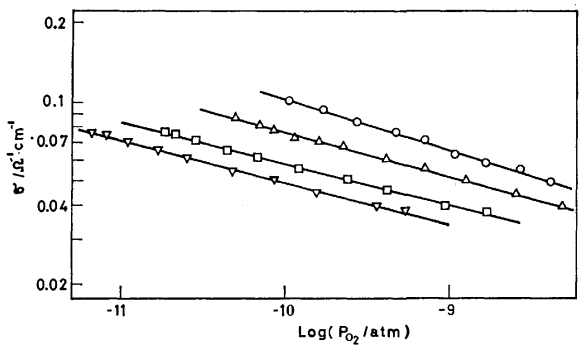

Fig. 2. Dependence of conductivity on oxygen partial pressure.

From the temperature dependence of the conductivity, the apparent activation energy for electronic conduction was calculated for a fixed composition. The results are given in the third column of Table 2. Although the standard deviations are relatively large, it appears that the apparent activation energy is independent of composition. The mean value is 12.7 kcal/mol.

Defect Models and the Expected Pressure Dependence of δ and σ. Measurements on nonstoichiometry and electrical conductivity have revealed that the dependence of the nonstoichiometry on oxygen partial pressure is different from that of the electrical conductivity, that is, the oxygen-pressure dependence is $P_{O_2}^{-1/2.88}$ for nonstoichiometry and $P_{O_2}^{-1/6.1}$ for conductivity. In order to interpret the difference in oxygen-pressure dependence consistently, a thermodynamic calculation was carried out on the defect concentration of oxygen deficit, n-type oxides on the basis of several defect models and the calculated results were compared with the data.

Interstitial cation models cannot be used to interpret the oxygen-pressure dependence, so oxygen vacancy models were examined. If V_O^x, $V_O^{\cdot}$, and $V_O^{\cdot\cdot}$ represent the neutral oxygen vacancy, the oxygen vacancy associated with one electron, and an oxygen vacancy free of electrons, respectively, the chemical equilibria relevant to these vacancies can be written as follows:

$$\text{null} = (1/2)O_2(g) + V_O^x, \quad K_1 = [V_O^x]P_{O_2}^{1/2}, \quad (2)$$

$$V_O^x = V_O^{\cdot\cdot} + 2e', \quad K_2 = n^2[V_O^{\cdot\cdot}]/[V_O^x], \quad (3)$$

$$V_O^x = V_O^{\cdot} + e', \text{ and } K_3 = n[V_O^{\cdot}]/[V_O^x], \quad (4)$$

where K_1, K_2, and K_3 are equilibrium constants, the brackets express the concentration of the respective oxygen vacancies in units of moles per mole of $BaFe_2O_{4-\delta}$ and n is the concentration of electrons in the same units. The electrical neutrality condition is

$$n = 2[V_O^{\cdot\cdot}] + [V_O^{\cdot}]. \quad (5)$$

The nonstoichiometry, δ, and electrical conductivity, σ, are related to the oxygen-vacancy concentrations by

$$\delta = [V_O^x] + [V_O^{\cdot}] + [V_O^{\cdot\cdot}] \quad (6)$$

and

$$\sigma = (N_A/V_m)ne\mu = kn, \quad (7)$$

where V_m is the molar volume of $BaFe_2O_{4-\delta}$, N_A the Avogadro number, e the electronic charge, and μ the electron mobility. k is substituted for $(N_A/V_m)eu$ for the sake of simplification.

In the following, several defect models and the results of thermodynamic calculations on the basis of these models are described.

For the "A" models, one of the three kinds of oxygen vacancies are assumed to be predominant. If $V_O^{\cdot}$ is predominant, the elimination of V_O^x and $V_O^{\cdot\cdot}$ in Eqs. 5 and 6 and combining Eqs. 2, 4, 5, and 6 result in a relation whereby both δ and σ depend on $P_{O_2}^{-1/4}$. Let us call this the "A-2" model. Two other models, "A-1" and "A-3", are also proposed. The oxygen-pressure dependence of δ and σ for the "A" models is summarized in the first three lines of Table 3.

For the "B" models, two of the three kinds of oxygen vacancies are assumed to be predominant. Three models, "B-1", "B-2", and "B-3", and the oxygen-pressure dependence of δ and σ are as shown in the fourth to sixth lines of Table 3.

All three kinds of oxygen vacancies are assumed to prevail for the "C" model. The oxygen-pressure dependence of δ and σ is given in the last line of Table 3.

The observed pressure dependence is $P_{O_2}^{-1/2.88}$ for δ and $P_{O_2}^{-1/6}$ for σ. Therefore, two kinds of models, "B-3" and "C", appear to be appropriate for interpreting the observed results.

Thermodynamic Calculations on the Basis of the "C" Model. Equation 2 gives the concentration of V_O^x as

Table 3. Models and oxygen-pressure dependence

	Model	Condition	Oxygen-pressure dependence m[a)]	m'[b)]
A	A-1	$[V_O^x] \gg [V_O^{\cdot}], [V_O^{\cdot\cdot}]$	2	
A	A-2	$[V_O^{\cdot}] \gg [V_O^x], [V_O^{\cdot\cdot}]$	4	4
A	A-3	$[V_O^{\cdot\cdot}] \gg [V_O^x], [V_O^{\cdot}]$	6	6
B	B-1	$[V_O^x], [V_O^{\cdot}] \gg [V_O^{\cdot\cdot}]$	2—4	4
B	B-2	$[V_O^{\cdot}], [V_O^{\cdot\cdot}] \gg [V_O^{\cdot}]$	4—6	4—6
B	B-3	$[V_O^x], [V_O^{\cdot\cdot}] \gg [V_O^{\cdot}]$	2—6	6
	C	$[V_O^x] \approx [V_O^{\cdot}] \approx [V_O^{\cdot\cdot}]$	2—6	4—6

a) m is from $\delta \propto P_{O_2}^{-1/m}$. b) m' is from $\sigma \propto P_{O_2}^{-1/m'}$.

$$[V_O^x] = K_1 P_{O_2}^{-1/2}. \quad (8)$$

From Eqs. 3, 4, and 7,

$$[V_O^{\cdot}] = K_3[V_O^x]/n = K_1K_2kP_{O_2}^{-1/2}\sigma^{-1}, \quad (9)$$

$$[V_O^{\cdot\cdot}] = K_2[V_O^x]/n^2 = K_1K_3k^2P_{O_2}^{-1/2}\sigma^{-2}, \quad (10)$$

and, therefore,

$$P_{O_2}^{1/2} = K_1 + K_1K_3k\sigma^{-1} + K_1K_2k^2\sigma^{-2}. \quad (11)$$

Employing the observed values of δ, σ, and P_{O_2}, a least-squares calculation was carried out for Eq. 11, but no equilibrium constants simultaneously satisfying Eq. 11 could be found. Thus, "C" model was excluded from consideration and a detailed examination of the "B-3" model was carried out.

Thermodynamic Calculations on the Basis of the "B-3" Model. Omitting $[V_O^{\cdot}]$ in the right-hand side of Eq. 5, we obtain the neutrality condition,

$$n = 2[V_O^{\cdot\cdot}]. \quad (12)$$

Combination of Eqs. 2, 3, 7, and 12 yields

$$\sigma = (2K_1K_2k^3)^{1/3}P_{O_2}^{-1/6}. \quad (13)$$

Figure 3 shows a σ-$P_{O_2}^{-1/6}$ plot for the observed data. It is seen that Eq. 13 holds for the oxygen-pressure dependence of the conductivity. The concentrations of $V_O^{\cdot\cdot}$ and V_O^x can be expressed in terms of σ using Eqs. 2, 3, 7, and 12 as follows:

$$[V_O^{\cdot\cdot}] = n/2 = \sigma/2k \quad (14)$$

and

$$[V_O^x] = n^2[V_O^{\cdot\cdot}]/K_2 = \sigma^3/2K_2k^3. \quad (15)$$

Inserting Eqs. 14 and 15 into Eq. 6, and omitting $[V_O^{\cdot}]$, we obtain

$$2\delta/\sigma = 1/k + \sigma^2/K_2k^3. \quad (16)$$

This equation implies that a plot of $2\delta/\sigma$ against σ^2 would give a straight line and the value of k and the equilibrium constant K_2 could then be determined from the intercept and the slope of the line. Figure 4 shows a plot of $2\delta/\sigma$ *vs.* σ^2. Evidently, the data at constant temperature fall along a straight line. This result supports the "B-3" model.

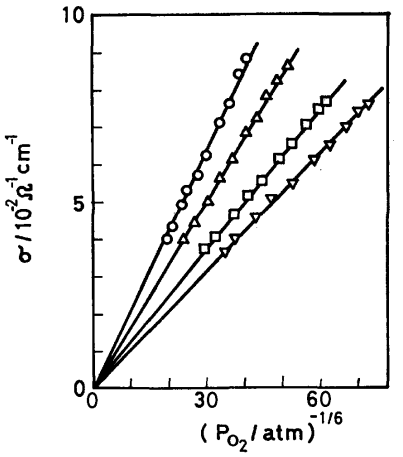

Fig. 3. The plot of σ against $P_{O_2}^{-1/6}$.

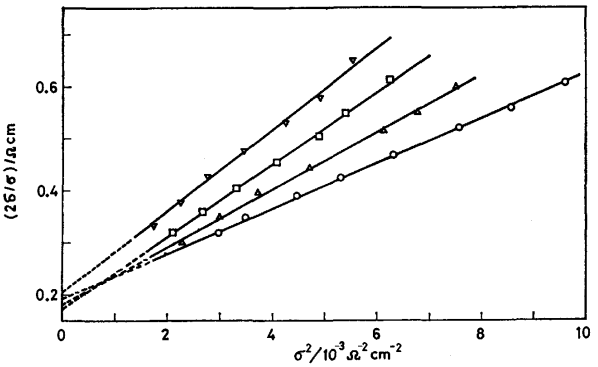

Fig. 4. The plot of $2\delta/\sigma$ against σ^2.

The k value calculated from the intercept is given in the second column of Table 4. The value of k appears to be independent of temperature in the temperature range between 1052 and 1125 °C. The average of k in this temperature range was 5.3 ± 0.4 cm^{-1} Ω^{-1}. From this value, the electron mobility was evaluated to be $(3.9\pm0.3)\times10^{-3}$ cm^2 V^{-1}.

The slope is listed in the third column of Table 4. The equilibrium constants, K_2, calculated from the slope and k are given in the fourth column of Table 4. Equa-

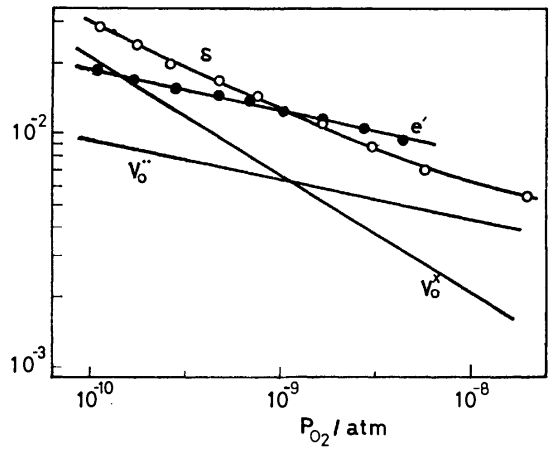

Fig. 5. Concentration of point defects in $BaFe_2O_{4-\delta}$ at 1125 °C.
○: δ, ●: concentration of conduction electron.

tion 13 indicates that the slope of the σ-$P_{O_2}^{-1/6}$ plot gives the value of $2K_1K_2k^3$, which is presented in the fifth column of Table 4. From this value and the slope obtained from Fig. 4, the equilibrium constant K_1 was calculated. The results are given in the last column of Table 4.

The concentrations of the lattice defects, V_0^x, $V_0^{\cdot\cdot}$ and electrons, and the nonstoichiometry, δ, were calculated from the values of K_1 and K_2 in Table 4. They are plotted together with δ in Fig. 5. The open circles designate the observed nonstoichiometric data and the solid circles designate the electron concentration calculated from the observed concentration data and the value of the electron mobility (3.9×10^{-3} cm^2 V^{-1}). It is seen that the oxygen vacancies V_0^x tend to dissociate into $V_0^{\cdot\cdot}$ and electrons as the oxygen partial pressure increases. The agreement is very good for both the electron concentration and the nonstoichiometry. Thus, the "B-3" model explains well the observed results.

The temperature dependence of the equilibrium constants, K_1 and K_2, can be represented by

$$K = \exp(\Delta S^\circ/R)\exp(-\Delta H^\circ/RT). \quad (17)$$

The values of ΔH° and ΔS° with one standard deviation are indicated in Table 4. The enthalpy change for Eq. 2 is 87.5 kcal/mol and that for Eq. 3 is 29.7 kcal/mol.

From these results it is concluded that the "B-3" model is best of those listed in Table 3 for interpreting the observed data for δ and σ.

Molecular Structure of 2,2-Dichloropropane as Determined by a Combined Use of the Electron-diffraction Data and the Spectroscopic Moments of Inertia

Masashi HIROTA, Takao IIJIMA,* and Masao KIMURA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 31, 1977)

The molecular structure of 2,2-dichloropropane has been determined by the joint analysis of the electron-diffraction data and the moments of inertia obtained by Matsumura and Takeo by means of microwave spectroscopy. Under the assumptions that r_g(C–H) is in the range of 1.100—1.110 Å and that φ_α(HCH) is larger than 107.0°, the structure parameter values have been determined (with the limits of error in parentheses) to be as follows: r_g(C–Cl), 1.799(3) Å; r_g(C–C), 1.523(4) Å; r_g(Cl···Cl), 2.910(1) Å; r_g(C···Cl), 2.702(1) Å; φ_{av}(ClCCl), 108.3(3)°, and φ_{av}(CCC), 113.0(4)°. The r_g-structure determined in the present study is in perfect conformity with the r_0-structure determined by Matsumura and Takeo. The C–Cl and C–C distances are shorter than the corresponding distances in 2-chloropropane.

Since Lide and Jen first pointed out the systematic elongation of C–Cl bonds in a series of molecules (methyl, ethyl, isopropyl, and *t*-butyl chlorides),[1] the environment effect on bond lengths in the halogen derivatives of alkanes has been the subject of many studies. A similar systematic elongation of the C–F bonds observed for the fluorine derivatives of alkanes may be involved in studies of the environment effect.[2] Recently, Matsumura and his collaborators have carried out extensive microwave studies of the chlorine and fluorine derivatives of methane.[3] From their results and those for halogenated ethanes and propanes quoted in the literature, they have systematized changes in the carbon-halogen bond lengths with the number of halogen atoms and methyl groups attached to the carbon atom in question. However, the comparisons of the bond lengths so far reported are, in most cases, based upon the r_s distances determined by microwave spectroscopy.[4]

In the present authors' opinion, the r_g distances are preferable to the r_s distances for comparing bond lengths, as was mentioned in the preceding paper on 2-chloropropane.[5] However, high-precision data on the r_g-structures of halogenated alkanes are rather few. The present paper will report the structure of 2,2-dichloropropane as determined by a combined use of the electron-diffraction data obtained by the present study and the moments of inertia obtained by Matsumura and Takeo by microwave spectroscopy,[6] as part of a series of studies of the molecular structures of chlorinated alkanes.

Experimental

A guaranteed reagent purchased from Nakarai Chemicals, Ltd., was used without further purification. Diffraction photographs were taken at room temperature, 20 °C, on the unit eqipped with an r^3-sector[7] under the following experimental conditions: camera lengths, 244.3 and 109.3 mm; accelerating voltage, 42 kV; beam current, 0.15 μA; exposure times, about 70 s for the short camera length and about 50 s for the long camera length; sample pressure, 50 Torr.[8] The wavelength, or the scale factor, was determined by reference to the pattern of carbon disulfide taken under the same experimental conditions. The covered s ranges were 3—19 Å^{-1} and 6—40 Å^{-1} for the long and short camera distances respectively. Two plates from the long camera distance and five plates from the short camera distance were selected for analysis.

Analysis of the Diffraction Data

The reduction of the observed total intensities to the molecular intensities[9] and the determination of the parameter values by the least-squares method were carried out following our usual procedure.[10] The following assumptions were set up with respect to the molecular geometry: (1) C_{2v} symmetry for the molecule as a whole, (2) local C_{3v} symmetry for the methyl tops, (3) zero tilt angles for the methyl tops, *i.e.*, the C_3 axes of the methyl tops coincident with the C–C bond axes, (4) staggered conformation about the C–C bonds with HCCCH in plane, as was assumed for 2-chloropropane. The mean amplitudes were fixed at values calculated using the Urey-Bradley force field proposed by Green and Harrison.[11] The calculated mean amplitudes for the main distances are shown in Table 1.

TABLE 1. CALCULATED MEAN AMPLITUDES AT 20 °C (in Å units)

Distance	Calculated mean amplitude	
C–Cl	0.0631	
C–C	0.0519	
C–H	0.0784	
Cl···Cl	0.0851	
C···Cl	0.0769	
Cl:::H_{gauche}	0.1833	H in CCC plane
	0.2113	H out of CCC plane
Cl:::H_{trans}	0.1061	
C···C	0.0788	

Starting with the r_0-structure reported by Matsumura and Takeo,[6] four distances, Cl···Cl, C–Cl, C···Cl, and C–C, were adjusted by fixing the r_a(C–H) and φ_α(HCH) at plausible values.[4,12] Since the contributions to the molecular intensities are small from the distances

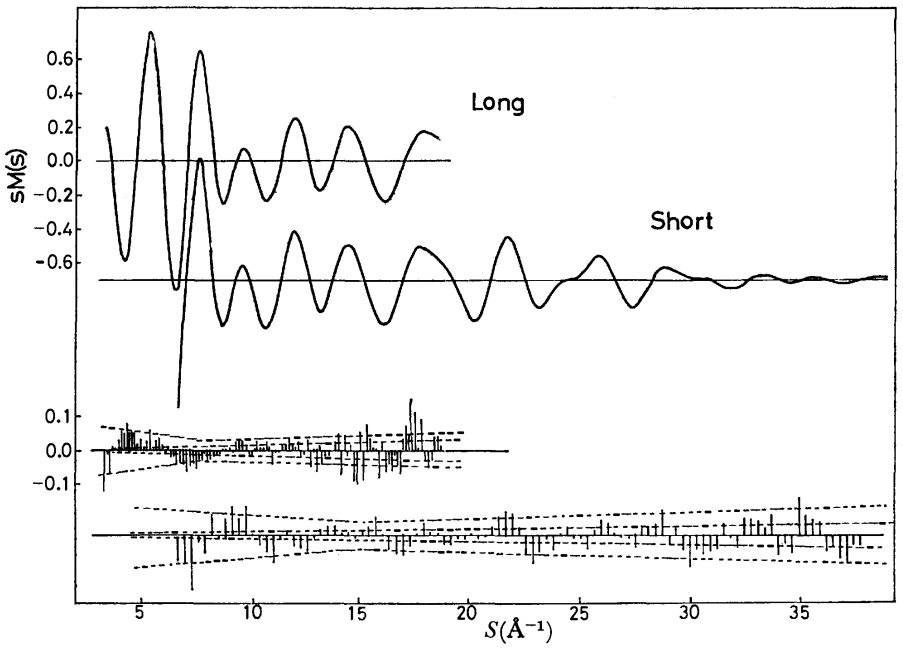

Fig. 1. The best fit theoretical molecular intensity curves, $sM(s)$, and the differences, $sM(s)^{obsd}-sM(s)^{calcd}$, for typical data from the long and the short camera distances. In the afferences, the inner broken lines indicate the limit of detection in photometry and the outer broken lines the estimated limit of errors in the observed intensities; see Ref. 5. The ordinate for the differences is taken twice as large as that for the intensity curves.

TABLE 2. RESULTS OF ELECTRON DIFFRACTION (distance in Å; angle in degree units)[a]

Distance	r_g	r_α^0 [b]
Cl···Cl	2.903(7)	2.902
C–Cl	1.797(4)	1.792
C···Cl	2.702(4)	2.700
C–C	1.519(6)	1.515
Index of resolution	0.98—1.04	

a) The values in parentheses indicate the limits of error, which were estimated from the random errors and the error in the scale factor. The uncertainty included in the scale factor is ±0.10% in the distances. The r_a(C–H) and the φ_α(HCH) were assumed to be 1.110 Å and 108.5° respectively. b) As to the conversion of r_g to r_α^0, see text. The uncertainties in the r_α^0 values are equivalent to those in the r_g values.

involving H atoms, the influence of the assumed distances on the results is insignificant; the converged values vary only by one-thousandth angstrom or less as long as the φ_α(HCH) and the r_a(C–H) values are limited within reasonable ranges (see Ref. 12 and also the next section). The final results are listed in Table 2, while the best-fit theoretical intensity curves and the residuals for the observed intensities for typical plates are shown in Fig. 1. The residuals are depicted on a double scale. The inner broken lines on the residuals indicate the limit of detection in photometry, while the outer ones indicate the boundary of the distribution of the residuals in the molecular intensities observed by a normal technique.[13]

Joint Analysis

The moments of inertia of $(CH_3)_2C^{35}Cl_2$ and $(CH_3)_2C^{35}Cl^{37}Cl$ in the ground state have been reported by Matsumura and Takeo.[6] Since the $^{35}Cl^{37}Cl$ species does not provide additional information,[5] only the moments of inertia of $(CH_3)_2C^{35}Cl_2$ were used for the joint analysis in the present study. These effective moments of inertia, $I^{(eff)}$, were corrected for the vibrational effect and converted into the moments of inertia, $I^{(z)}$, for the zero-point average structure.[14] The corrections, ΔI, were calculated by using the force constants given by Green and Harrison.[11] The barrier to the hindered rotation about the C–C axis was estimated to be about 3.4 kcal/mol.[11] In general, somewhat different ΔI values are obtained by using either one of two alternatives, the small-amplitude[14] or the large-amplitude treatment[15] for the methyl torsion. The

TABLE 3. EFFECTIVE MOMENTS OF INERTIA, THE VIBRATIONAL CORRECTION, AND THE MOMENTS OF INERTIA FOR THE ZERO-POINT AVERAGE STRUCTURE OF $(CH_3)_2C^{35}Cl_2$ (in amu Å² units)[a]

	$I^{(eff)}$ [b]	ΔI	$I^{(z)}$ [c]
a	138.056	0.108	138.164
b	205.617	0.112	205.729
c	234.154	0.044	234.198

a) The corrections were calculated by the small-amplitude treatment. See text. b) Calculated from the observed rotational constants by using, as the conversion factor, 505376 MHz amu Å². c) $I^{(z)}=I^{(eff)}+\Delta I$.

barrier to the hindered rotation of this molecule is almost the same as that of 2-chloropropane.[5] Therefore, the differencc in the r_z(C–H) value or in the φ_z(HCH) value of the 2,2-dichloropropane obtained by the two treatments is practically the same as that in the case of 2-chloropropane.[5] In the present analysis, the small-amplitude treatment was adopted; the ΔI and $I^{(z)}$ values thus obtained are listed in Table 3, together with $I^{(eff)}$. The ΔI and the $I^{(z)}$ values to be obtained by the large-amplitude treatment can be estimated by referring to the results of 2-chloropropane.[5] In either treatment, the same r_g values are finally yielded. The r_g distances determined by the electron diffraction were converted into the r_α^0 distances by correcting them for the anharmonic term, the centrifugal stretching, and the perpendicular vibration. The r_α^0 values thus obtained are also entered in Table 2. The Morse asymmetry constants, a_3, were assumed to be 2.0, 2.1, and 2.0 Å^{-1} for the C–Cl, C–C, and C–H distances respectively, and zero for all the non-bonded atom pairs.

The structure of 2,2-dichloropropane is defined by the six parameters, r(C–C), r(Cl···Cl), r(C···Cl), r(C–H), and ∠HCH, under the same assumptions with respect to the geometry as those employed in the analysis of the electron-diffraction data. In determining these six parameter values, the three moments of inertia can be used in addition to the two r_α^0 values for the bonded distances determined by the electron diffraction. Obviously these five experimental values are not sufficient for determining the six parameters of this molecule. Thus, a reasonable assumption as to the ranges of r(C–H) and ∠HCH was used and the skeletal parameters were determined with smaller uncertainties than those of the electron-diffraction results.

The analysis was done through the following steps. For the bonded distances, r(C–C) and r(C–Cl), the results obtained by the electron diffraction are illustrated in a two-dimensional space, as is shown in Fig. 2, where the axes are scaled in r_α^0 derived from r_g. In Fig. 2, the O point indicates the best-fit values determined by the electron diffraction, while the ellipse shows the boundary of the total limits of error, which were estimated from the random errors obtained by the least-squares refinement and the error included in the scale factor. The straight line S shows the direction of change in r(C–C) and r(C–Cl) with a change in the scale factor. For any pair of the C–C and C–Cl distances, the three moments of inertia give the relation among the other four parameters. When the A, B, C, and D points are chosen on the S line in Fig. 2, the relations can be represented by the corresponding parallel straight lines in the r(C–H)–∠HCH space, as is shown in Fig. 3. The relations may be described numerically as follows; (1) for any pair of r(C–C) and r(C–Cl), a variation of ±0.005 Å in r(C–H) is equivalent to variations of ±0.22° in ∠HCH, ∓0.0004 Å in r(Cl···Cl) (or ∓0.02° in ∠ClCCl), without any change in the C···Cl distance, and (2) an increase of 0.01% in both r(C–C) and

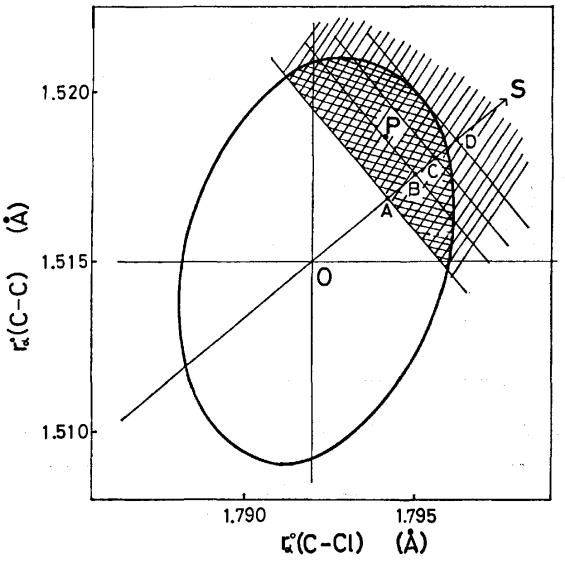

Fig. 2. The allowed range of the r_α^0(C–Cl) and r_α^0(C–C) distances. The shading indicates the range allowed by the spectroscopic moments of inertia under the conditions that the r_α^0(C–H) is in the range of 1.075—1.085 Å and the φ_α(HCH) is larger than 107.0°. The cross-shaded area is the range allowed by both electron diffraction results and the spectroscopic moments of inertia under the same conditions. The O point shows the best fit values which were obtained by converting the r_g values determined by electron diffraction into the r_α^0 values and the P point is the center of the cross-shaded area. The limits of error in the r_α^0 values are taken to be identical to those in the experimental r_g values. See text about other details.

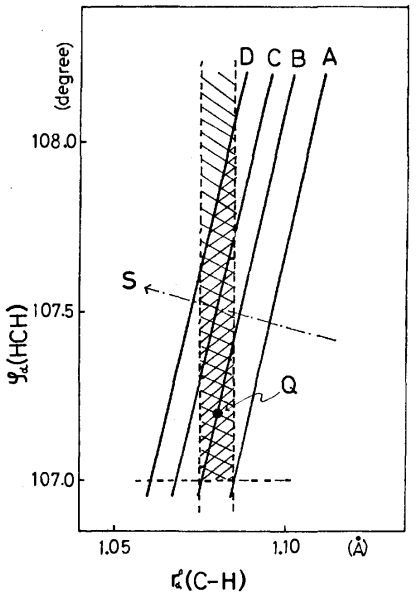

Fig. 3. The correlation diagram of the r_α^0(C–H) and the φ_α(HCH) which satisfy the three observed $I^{(z)}$. The region assumed for the r_α^0(C–H) and the φ_α(HCH) is indicated by shading. The pararell lines, A, B, C, and D, corresponds to the A, B, C, and D points in Fig. 2 respectively. The S line with an arrow indicates the direction of an increase in the scale factor. The upper boundary limited by the D line is determined by the electron diffraction results. The cross-shaded area then corresponds to that in Fig. 2. The Q point indicates the final representative values which are compatible with the P point in Fig. 2.

r(C–Cl) is equivalent to either changes of +0.11° in ∠HCH and +0.0003 Å in r(C···Cl), or changes of −0.0025 Å in r(C–H), +0.0004 Å in r(C···Cl), and +0.0002 Å in r(Cl···Cl).

Here, we put restrictions on the allowed ranges of the r(C–H) and ∠HCH. In various molecules which are about the size of the present one, the r_g(C–H) have been found in the ranges of 1.100—1.110 Å, which corresponds to the range of 1.075—1.085 Å in r_α^0(C–H), and the φ_α(HCH) have been found to be larger than 107.0°. Thus, the r_α^0(C–H) and φ_α^0(HCH) values of the present molecule were assumed to be in the ranges of values mentioned above. This region is indicated by shading in Fig. 3. It may be seen that line A in Fig. 3 is a limiting case in which the line is scarcely in contact with the region allowed by the restrictions for r(C–H) and ∠HCH. Accordingly, the A point in Fig. 2 represents the lower limit of the allowed region with respect to the scale factor. When the r(C–C) and the r(C–Cl) change along a line perpendicular to the S line, changes in the moments of inertia due to a change in the r(C–C) are almost cancelled by those due to a change in the r(C–Cl); consequently, the calculated values of the moments of inertia do not change practically. Thus, the relation between r(C–H) and ∠HCH shown by the A, B, C, and D lines in Fig. 3 holds well for any pair of the C–C and C–Cl distances on the lines perpendicular to the S line through the A, B, C, and D points in Fig. 2 respectively. In Fig. 2, the line through the A point, which corresponds to the A line in Fig. 3, is, then, the lower boundary in the r(C–C)–r(C–Cl) space. The shaded area in Fig. 2 is the region thus limited.

The upper boundary in the r(C–C)–r(C–Cl) space is formed by the error-ellipse of the electron-diffraction results. The line tangent to the ellipse and perpendicular to the S line in Fig. 2 passes through the D point. Then, the D line in Fig. 3 becomes the corresponding upper boundary in the r(C–H)–∠HCH space. The allowed regions thus determined are shown as the cross-shaded area in Figs. 2 and 3. In this procedure, the allowed ranges of the r(Cl···Cl) and the r(C···Cl) are concurrently determined, since the areas in Figs. 2 and 3 also define the ranges of these parameters, though implicitly.

The values of r(C–Cl) and r(C–C) at the approximate center, P, of the cross-shaded area in Fig. 2 were taken as the final ones. The final values for the other four parameters were chosen at the middle point of the ranges of the parameters which are compatible with the values of r(C–C) and r(C–Cl) given by the P point. The final values for r(C–H) and ∠HCH thus determined are represented by the Q point in Fig. 3. The results are summarized in Table 4. In the table, the allowed ranges for the parameters are given by the farthest separations from the respective final value in the allowed region, such as the cross-shaded area in Fig. 2. The allowed ranges for the skeletal parameters are narrower than those for the r_α^0 values determined by the electron diffraction alone. (*cf.* Table 2). This is because we assumed the C–H distance and the HCH angle to be within the limited ranges of values. The uncertainties included in the $I^{(z)}$ values are estimated to be 0.01 amu Å^2.[16] The corresponding variations in the parameter-values are only ±0.0007 Å for the C–H distance and ±0.03° for the HCH angle, and negligible for the other distances. Therefore, the uncertainties in the $I^{(z)}$ values do not affect the final allowed ranges.

TABLE 4. RESULTS OF THE COMBINED ANALYSIS[a]

	r_{av} or φ_{av}	Allowed range	r_g[c]
C–Cl	1.794	±0.003	1.799
C–C	1.519	±0.004	1.523
Cl···Cl	2.908	±0.001	2.910
C···Cl	2.700	±0.001	2.702
C–H	[1.080[b]	±0.005	1.101]
ClCCl[d]	108.3	±0.3	
CCC[d]	113.0	±0.4	
HCH	[107.2[b]	+0.9 −0.2]	
CCCl[d]	108.9	±0.4	

a) Distances in Å units, and angles in degree units. The r_{av}(C–H) and the φ_{av}(HCH) were assumed to be in the range of 1.075—1.085 Å and larger than 107.0° respectively; they are indicated by brackets. See text. b) The values obtained by the large-amplitude treatment would be 1.090 Å for the r_{av}(C–H) and 107.4° for the φ_{av}(HCH). c) The limits of error in the r_g values are equivalent to the allowed ranges of the r_{av}. d) Calculated from the distance-parameters.

Discussion

The r_0-structure determined by Matsumura and Takeo[6] is reproduced in the third column of Table 5 and compared with the result obtained by the present study in the second column of the table. The r_g(C–C) and r_g(C–Cl) values differ slightly from the r_0 values. However, if the difference in their physical meanings is taken into account,[17] such differences between r_g and r_0 as are shown in the table may be said to be reasonable. Thus, except for the structure of the methyl top, the two results are in good agreement with each other.

A comparison with the structure of 2-chloropropane

TABLE 5. COMPARISON OF THE STRUCTURES OF 2,2-DICHLOROPROPANE DETERMINED BY THE PRESENT AND THE MICROWAVE STUDIES, AND THE STRUCTURE OF 2-CHLOROPROPANE (in Å and degree units)

	2,2-Dichloropropane		2-Chloropropane
	r_g or φ_{av} (Present study)	r_0 (Matsumura *et al.*)[a]	r_g or φ_{av} (Iijima *et al.*)[b]
C–Cl	1.799 (3)	1.793 (5)	1.812 (1)
C–C	1.523 (4)	1.522 (assumed)	1.527 (1)

CCC	113.0 (0.4)	113.0 (0.5)	112.7 (0.4)
CCCl[c]	108.9 (0.4)	108.9	109.0 (0.2)

a) Ref. 6. b) Ref. 5. c) Calculated from the other parameter values.

reported previously, which is also shown in Table 5, shows that the C–C and C–Cl distances are shorter in 2,2-dichloropropane than those in 2-chloropropane. An increase in the number of Cl atoms results in the shortenings of the C–C and C–Cl bonds. In spite of the contraction of the C_2CCl_2 frame of 2,2-dichloropropane, the valence angles, CCC and CCCl, are the same as those in 2-chloropropane, while the ClCCl angle is much smaller than the tetrahedral angle. Probably, the repulsive interactions between the two methyl tops and between the methyl top and the chlorine atom overcome the interaction between the two chlorine atoms.

The numerical computations were performed on a FACOM 230-75 of the Hokkaido University Computing Center and on a FACOM 270-20 in the laboratory of Professor Kimio Ohno, to whom the authors' thanks are due. The authors also wish to thank Dr. Chi Matsumura of the National Chemical Laboratory for Industry for permitting them to use his results prior to publication.

The Molecular Structure of Ethyl Chloride as Determined by a Combined Use of the Electron-diffraction Data and the Spectroscopic Moments of Inertia

Masashi HIROTA, Takao IIJIMA,* and Masao KIMURA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 31, 1977)

The molecular structure of ethyl chloride has been determined by a joint analysis of the electron-diffraction data and the moments of inertia obtained by Schwendeman and Jacobs by means of microwave spectroscopy. In the analysis, a staggered conformation with C_s symmetry for the molecule and a local C_{3v} symmetry about the C–C axis for the methyl group were assumed. Under the further assumptions that $\varphi_{av}(HCH)_{CH_3}$ is $109.2\pm2°$ and $\varphi_{av}(CCH)_{CH_3}$ is in the range of 113.6—109.6°, the following parameter values were determined: r_g(C–C), 1.528(4) Å; r_g(C–Cl), 1.802(3) Å; r_g(C···Cl), 2.746(5) Å; $r_g(C–H)_{CH_3}$, 1.103(4) Å; $\varphi_{av}(HCH)_{CH_3}$, 110.0(1.6)°; and φ_{av}(CCCl), 110.7(0.3)°. The r_g and r_s distances for the C–Cl and C–C bonds of various chlorinated alkanes were plotted against the difference between the numbers of methyl groups and chlorine atoms, $\Delta n=n(CH_3)-n(Cl)$. In general, as the number of chlorine atoms increases, both distances become shorter, though the r_g distances are longer than the r_s distances by 0.01—0.03 Å.

In order to examine the environment effect on the bond lengths in the halogen derivatives of alkanes, precise structural determinations of chlorinated alkanes have been initiated[1] and in the preceding paper the structure of 2,2-dichloropropane has been reported.[2] As one of this series of studies, the results for ethyl chloride will be reported in the present paper.

Several microwave studies of this molecule can be found in the literature.[3–6] Among them, Schwendeman and Jacobs studied the widest variety of isotopic species and determined the r_s-structure.[6] Their data on the moments of inertia contain information necessary for our purpose, and the r_s-structure will serve for comparison with the r_g-structure determined by the present study.

According to them and also to Lide,[5] the barrier to the hindered rotation is about 3.6 kcal/mol, a value which is very close to those for propane,[7] 2-chloropropane,[8] and 2,2-dichloropropane.[9] This means that the torsional motion may be regarded as a small amplitude vibration in evaluating the vibrational correction of the present molecule as of the other molecules mentioned above; this correction is necessary to convert the r_g values determined by the electron diffraction and the observed moments of inertia, $I^{(eff)}$, into the values in the zero-point average structure, r_α^0 or $I^{(z)}$.[10] In this study, therefore, the vibrational correction has been carried out by the small-amplitude treatment[11] after the manner adopted in previous papers.[1,2]

Experimental

The sample of ethyl chloride was a guaranteed reagent purchased from Nakarai Chemicals, Ltd., and was used without further purification. Diffraction photographs were taken with a unit in our laboratory at room temperature, 20 °C. The other experimental conditions were as follows: camera length, 109 mm; accelerating voltage, 42 kV; beam current, 0.1 μA; sample pressure, 50 Torr,[12] and exposure time, 110 s. The covered s range was 6—40 $Å^{-1}$.[12] The wavelength, or the scale factor, was determined by reference to the diffraction pattern of carbon disulfide taken under the same experimental conditions. Three plates were selected for analysis.

Analysis of Electron-diffraction Data

The observed total intensities[13] were reduced to the molecular intensities, $sM(s)$, following our usual procedure.[14] The molecular intensities thus obtained were used for the refinement of the molecular parameter values by means of the least-squares method.[14] In the refinement, the following assumptions were made as to the molecular geometry: (1) a staggered conformation with C_s symmetry for the molecule as a whole; (2) a local C_{3v} symmetry for the methyl group; (3) a zero tilt angle for the methyl group, and (4) r_a(C–H) distances equal to 1.105 Å, $\varphi_\alpha(CCH)_{CH_3}=111.6°$, $\varphi_\alpha(HCH)_{CH_3}=109.2°$, and $\varphi_\alpha(HCH)_{CH_3}=108.5°$. These assumed values were taken from the r_s-structure determined by Schwendeman and Jacobs.[6] The values left to be determined are, then, the bonded C–Cl and C–C distances and the non-bonded C···Cl distance. All the mean amplitudes were fixed at values calculated using the force field proposed by Dempster and Zerbi.[15] The calculated mean amplitudes for the main distances are listed in Table 1. The Morse asymmetry constants, a_3, were assumed to be 2.0, 2.1, and 2.0 $Å^{-1}$ for the C–Cl, C–C, and C–H distances respectively, and zero for all non-bonded atom pairs, in the estimation of the asymmetry parameters, κ. As long as the distances and

a) The geometry of the methyl group was assumed at the values determined by microwave spectroscopy. See text. b) The values in parentheses indicate the limits of error, which were estimated from the random errors obtained in the least-squares adjustment and the systematic errors included in the scale factor, which was ±0.06 % in distances. c) r_α^0 were derived from r_g; see text. The errors are regarded to be the same as those for r_g.

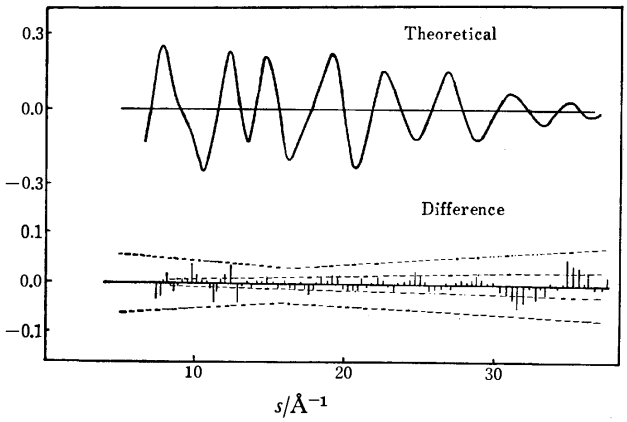

Fig. 1. The theoretical molecular intensity curve, $sM(s)$, for the best fit parameters, and the difference, $sM(s)^{obsd}-sM(s)^{calcd}$. In the difference, the inner broken lines indicate the limit of detection in photometry, and the outer broken lines the estimated limit of errors in the observed intensities; see Ref. 1. The ordinate for the difference curve is enlarged twice as large as that of the intensity curve.

angles in the methyl group are assumed to be within the ranges of plausible values (see the next section), the converged C–Cl, C–C, and C···Cl values change by only one or two thousandths Å, a value which is much smaller than the limits of error.

The results of the least-squares analyses are listed in Table 2. Figure 1 shows the theoretical molecular intensity curve for the best-fit parameters and the difference between the theoretical and observed intensities.

Joint Analysis

The r_g values obtained by the electron-diffraction were converted into the r_α^0 values using the parallel and perpendicular mean amplitudes calculated at 293 and 0 K, the centrifugal stretching, and the assumed Morse asymmetry constants. The r_α^0 values thus obtained are also entered in Table 1.

The moments of inertia have been determined by Schwendeman and Jacobs for seven isotopic species, including the parent $CH_3CH_2{}^{35}Cl$ species.[6] Among them, the ^{37}Cl-species and ^{13}C-species do not provide additional information useful for our purpose,[1] and the species containing a partially deuterated methyl group would not be helpful for the determination of the molecular structure because they have no local C_{3v} symmetry in the r_z-structure and so only increase the number of parameters to be determined. Thus, we made use of the moments of inertia of only two species, $CH_3CH_2{}^{35}Cl$ and $CH_3CD_2{}^{35}Cl$. The observed moments of inertia, $I^{(eff)}$, were corrected for the harmonic vibrations by means of the small-amplitude treatment and were converted into the zero-point moments of inertia, $I^{(z)}$. The results are listed in Table 3.[16]

Table 3. Observed and corrected moments of inertia and the vibrational corrections (in amu Å² units)[a]

		$I^{(eff)}$	ΔI	$I^{(z)}$
$CH_3CH_2{}^{35}Cl$	a	16.121	0.020	16.141
	b	91.992	0.139	92.131
	c	101.843	0.084	101.927
$CH_3CD_2{}^{35}Cl$	a	20.935	0.021	20.956
	b	94.414	0.124	94.538
	c	105.902	0.083	105.985

a) The conversion factor: 505376 MHz amu Å². b) $I^{(z)}=I^{(eff)}+\Delta I$. c) The uncertainties included in ΔI, and accordingly in $I^{(z)}$ also, are estimated to be about 10% of the corrections themselves; see Ref. 1. The joint analysis was, therefore, carried out by assuming the uncertainties in $I^{(z)}$ to be ±0.01 amu Å².

The isotope effect for the C–H distance, $\delta(C-D)=r_z(C-D)-r_z(C-H)$, was estimated and assumed to be -0.0007 ± 0.0014 Å.[17] However, the $\varphi_z(DCD)$ and the $\varphi_z(CCD)$ values were added in parameters because no appropriate method of estimation has been found. Taking all the $r_g(C-H)$ distances to be equivalent, the difference between the $r_z(C-H)_{CH_3}$ and $r_z(C-H)_{CH_2}$ distances was estimated to be 0.007 Å by converting the r_g values into the corresponding r_z values. Thus the number of parameters to be adjusted becomes nine (see Table 5 below), while the available data are two bonded distances determined by the electron diffraction and the six moments of inertia. The C···Cl distance obtained by the electron diffraction was not used, for the r_α^0 value derived from the r_g value might not be accurate enough; anharmonicity for a non-bonded atom-pair is still ambiguous. Therefore, the value of $\varphi_z(HCH)_{CH_3}$ was assumed to be $109.2\pm2°$ by referring to the reported r_s-structure[6] (see also Table 5).[18] The eight parameters to be determined are r(C–C), r(C–Cl), r(C···Cl), $r(C-H)_{CH_2}$, $\angle HCH_{CH_2}$, δ(DCD) ($=\angle DCD_{CD_2}-\angle HCH_{CH_2}$), $\angle CCH_{CH_2}$, and δ(CCD) ($=\angle CCD_{CD_2}-\angle CCH_{CH_2}$).

However, in fitting the eight parameters to the eight observed quantities, the allowed ranges for r(C–C) and r(C–Cl) could never be smaller than the limits of error of the electron-diffraction results, and the values of the other parameters may include both unreasonably large and small values. Therefore, the reported r_s-structure[6] was again used in order to restrict the $\varphi_z(CCH)_{CH_3}$ so that it was in the range of $111.6\pm2.0°$.[18]

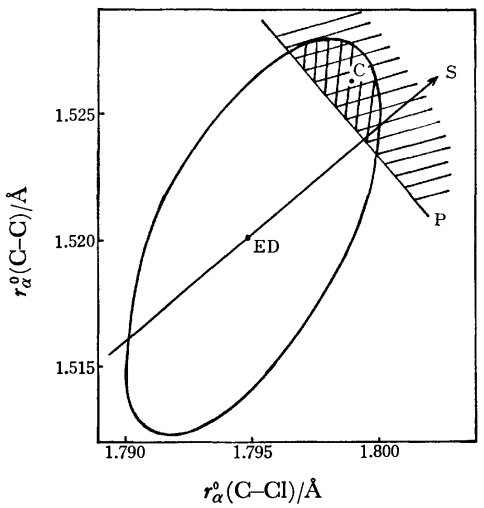

Fig. 2. The diagram of the allowable range of the C–Cl and C–C distances. The ED point indicates the best values determined by electron diffraction. The shaded area is allowed by the moments of inertia when the isotope effect, δ(C–D), is taken as −0.0007 Å and the C point indicates the final values. See text for the details. The cross-shaded area is allowed by both the electron diffraction data and the moments of inertia.

Figure 2 shows the r(C–C) and r(C–Cl) values allowed by the electron-diffraction data and the six moments of inertia under the assumptions and the restriction mentioned above. In this figure, the ED point represents the best values determined by electron diffraction, while the ellipse shows the total limits of error estimated from both the random error obtained by the least-squares adjustment and the systematic error included in the scale factor. The straight line, S, indicates the direction of change in the distances with the change in the scale factor. On the other hand, the shading in Fig. 2 indicates the area obtained by projecting the region allowed by the six moments of inertia onto the r(C–C)-r(C–Cl) plane. The P line perpendicular to the S line represents a lower bondary of the allowed region on the r(C–C)-r(C–Cl) plane, when δ(C–D) is taken to be −0.0007 Å. Thus, the cross-shaded area is the region of the r(C–C) and r(C–Cl) values allowed by both the electron-diffraction data and the moments of inertia. The final r_{av}(C–C) and r_{av}(C–Cl) values, represented by the point C in Fig. 2, were taken at the center of a rectangle which contained the allowable region and had its sides parallel to S and P. With these r_{av}(C–C) and r_{av}(C–Cl) values, and on the assumptions that $\varphi_{av}(HCH)_{CH_3}$= 109.2°, that δ(C–D) = −0.0007 Å, and that $\varphi_{av}(CCH)_{CH_3}$ was in the range of 113.6—109.6°, the final values for the other parameters were determined; with these values the six moments of inertia were satisfied best. The results are listed in the 2nd column of Table 4.

The errors listed in Table 4 were estimated as follows: ε_1 are the limits of the allowable parameter values explored with the C–C and the C–Cl values in the allowed region shown in Fig. 2; ε_2 are the limits of error due to the uncertainty included in ΔI, ±0.01 amu Å^2;[19] ε_3 were estimated by considering that the assumed $\varphi_z(HCH)_{CH_3}$ included an uncertainty of ±2°; ε_4 and ε_4' were estimated from the uncertainty included in the isotope effect for the C–H distance. As was mentioned before, the uncertainty in the δ(C–D) was estimated to be ±0.0014 Å. A change in the δ(C–D) causes the P line to shift parallel to itself in Fig. 2 and, consequently, influences the limits of error in two manners. The first influence appears as the shift of the C point, while the second one brings about a change in the width of the allowed region on the C–Cl *vs.* C–C map. A decrease in the δ(C–D) makes the P line shift in the direction of the scale factor decrease. Therefore, in order to estimate errors, it is necessary to estimate only the

influence of the decrease in the δ(C–D). ε_4 and ε_4' are uncertainties related to the shift of the C point and the increase in the allowed region respectively, when $\delta(C-D)=-0.0007-0.0014$ Å. A similar effect of the uncertainty of $\angle HCH_{CH_3}$ to the allowed region on the C–C *vs.* C–Cl was negligibly small. In order to assign the total errors, it seems safe to adopt as great error as possible in the present case. Therefore, as for ε_1 we adopted a greater value, irrespective of its sign, while for ε_4 we ignored the fact that it is applicable only in the specified direction. Then the total errors, ε_0, were estimated by considering all these errors to be independent of one another: they are listed in the last column of Table 4. Table 5 shows the final values for r_{av} and φ_{av}, their limits of error, and the r_g values derived from the r_{av}. In order to compare the C–H distances and HCH angles in various molecules, it is desirable to list these parameters in the state in which the torsional motions are eliminated.[20] Therefore, Table 5 gives the r_{av}(C–H) and the φ_{av}(HCH) for the torsionless state. They were obtained by adding 0.009 Å and 0.2° respectively to the r_{av} and φ_{av} obtained by the small-amplitude treatment.[1]

Discussion

We adopted the value of 2.746 Å as the final r_g(C···Cl) distance, the value of 2.739 Å obtained by the electron-diffraction being consistent with it within the limits of error. In deriving the r_g value from the r_{av} value, the Morse asymmetry constant a_3 for this non-bonded distance was assumed to be zero. However, the possibility of a_3 having a negative value has been pointed out in the study of 2-chloropropane[1] and also in the recent studies of $CHBr_3$, CH_2Br_2[21] and $CHCl_3$.[22] In the present case, a negative a_3 brings the r_g(C···Cl) obtained by the joint analysis closer to the diffraction value, although the large uncertainty of the latter makes it difficult to place any significance on the closeness of the two values. A similar situation was also found in the Cl···Cl distance of 2,2-dichloropropane.[2]

In the present analysis, we had to assume the symmetry of the methyl group. As a result, only the average values of the C–H distances and the HCH angles were determined for the structure of the methyl group. According to the microwave study by Zeil *et al.*, the r_s-structure of the methyl top does not have C_{3v} local symmetry.[23] However, since the method of using these r_s data in the determination of the r_g or r_{av} structure has not been established, the precise structure of the methyl group of this molecule in terms of r_g or r_{av} is left unsolved. Similar situations are probably more or less present for other molecules as well. This seems to pose a problem for the future.

The last column of Table 5 shows the r_s values reported by Schwendeman and Jacobs.[6] It should be

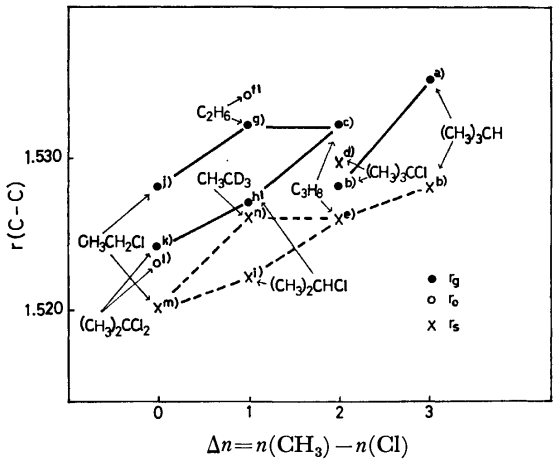

Fig. 4. The r_g(C–C) and r_s(C–C) distances of chlorinated alkanes plotted against $\Delta n=n(CH_3)-n(Cl)$; a) Ref. 30; b) Ref. 25; c) Ref. 31; d) Ref. 26; e) Ref. 32; f) Ref. 33; g) Ref. 34; h) Ref. 1; i) Ref. 8; j) the present study; k) Ref. 2; l) Ref. 24; m) Ref. 23; n) Ref. 35.

noted that the r_s distances are all shorter than the corresponding r_g distances.

Matsumura and his co-workers showed that the C–Cl and C–C r_s distances for various chlorinated alkanes exhibit systematic changes against the difference between the numbers of methyl groups and chlorine atoms attached to the carbon atom, $\Delta n = n(CH_3) - n(Cl)$.[24] Their results are reproduced in Figs. 3 and 4, together with the plotting of the r_g values. As may be seen in Fig. 3, the C–Cl distances become shorter as Δn decreases; if Δn is the same, the C–Cl distances are also the same. For the C–C distances in Fig. 4, the situation is a little more complicated. For compounds consisting of the same number of carbon atoms, the one with more chlorine atoms has a shorter C–C distance, while compounds with the same number of chlorine atoms have nearly the same C–C distance. The r_g distances show a similar tendency, but generally they are longer than the corresponding r_s distances. An exception is found in the C–C distance of *t*-butyl chloride, in which the r_s value could be unusual, for the central carbon is very close to the center of gravity of the molecule.

The numerical computations were performed on a FACOM 230-75 of the Hokkaido University Computing Center and also on a FACOM 270-20 in the laboratory of Professor Kimio Ohno, to whom the authors' thanks are due.

The Effect of Poly(oxyethylene) Alkyl Ethers, Alkanediols, and Alkanols on the Critical Micelle Concentration of Sodium Dodecyl Sulfate

Masahiro MANABE and Masaharu KODA

Department of Industrial Chemistry, Niihama Technical College, Niihama, Ehime 792

(Received September 5, 1977)

The effect of the addition of the homologues of poly(oxyethylene) alkyl ethers ($C_mH_{2m+1}(OCH_2CH_2)_nOH$: $m=3$—6, $n=1$—4), α,ω-alkanediols ($m=4$—6, 8), and 1-alkanols ($m=2$—7) on the critical micelle concentration (CMC) of sodium dodecyl sulfate (SDS) was examined. The homologous additives are appropriate for studying the effect of polar groups as well as an alkyl group. The CMC decreases with an increase in the concentration of additive. The rate of CMC-decrease estimated at the infinite dilution of the additive increases with the length of alkyl chain in each homologue. The dependence of the rate on the alkyl chain length is the same for all the homologues with longer chain ($m \geqq 4$ for ethers and alkanols, and $m > 6$ for alkanediols). This is ascribed to the complete transfer of the long alkyl chain into the interior of micelles. The dependence of rate on the number of polar groups (OH, OCH_2CH_2) is as follows. The rate for alkanediol is lower than that for alkanol with a given alkyl chain. The rate for ethers increases asymptotically with the length of oxyethylene chain. The result for alkanediol is ascribed to the pronounced hydrophilic nature, and that for ethers to the reduction of electrostatic repulsive force between ionic head groups of the surfactant in micelles.

Successive addition of a small amount of normal 1-alkanols and their isomers to a surfactant solution depresses critical micelle concentration (CMC) of several, ionic[1-3] and nonionic[4] surfactants. The rate of CMC-decrease, defined as the decrement of CMC caused by unit increase of additive concentration, increases with an increase in the number of carbon atoms of the alkyl chain. Systematic studies on the effect of additives have so far been restricted to alkanols, because of the authors' interest[1-4] in the hydrophobic behavior of the alkyl chain in the additives dissolved in the surfactant solutions. No systematic study seems to have been made on the effect of additives having various hydrophilic polar groups on the CMC of surfactant solutions. The study is necessary for finding the factor governing the micelle formation and solubilization of surfactants.

This paper deals with the effect of homologous additives, poly(oxyethylene) alkyl ethers, α,ω-alkanediols, and 1-alkanols, on the CMC of sodium dodecyl sulfate. The homologues are appropriate for studying the effect of their polar groups as well as a methylene group in their alkyl chain, since the hydrophilic property of the additives can be altered successively by the number of oxyethylene and hydroxyl groups. The present study gives information on the mixed micelle, consisting of an ionic surfactant and a poly(oxyethylene)-type nonionic one.[5-10]

Experimental

Materials. Sodium dodecyl sulfate (SDS), water, normal 1-alkanols (C_2—C_7), and poly(oxyethylene) alkyl ethers ($C_mH_{2m+1}(OCH_2CH_2)_nOH$: $m=3$, $n=1$; $m=4$, 5, $n=1$—4) were the same as given in the previous studies.[11,12] The ethers ($m=6$, $n=1$, 2, Tokyo Kasei Kogyo Co., Ltd. G. R. grade) were used without further purification. α,ω-Alkanediols (C_4—C_6, C_8) were used after distillation through a 1 m column under reduced pressure.

Determination of CMC. The conductivity of aqueous SDS solution prepared with a solvent containing a small amount of the additives was measured on a Yanagimoto Model MY-7 conductivity meter. Measurements were carried out in a water-thermostat controlled within 25± 0.01 °C. The critical micelle concentration (CMC) of SDS in an aqueous additive solution was taken as the SDS concentration at the break point in the plot of specific conductance *vs.* SDS concentration.[13] The CMC of SDS in water was determined to be 8.30 mmol/kg.

Results and Discussion

For all the additives, the CMC of SDS decreases linearly with an increase in the concentration of the additives within their low concentration regions, deviating gradually upwards from linearity at higher concentrations as shown in Fig. 1 for 1-pentanol and its derivatives. This is in line with the systems of alkanols and surfactants.[1-4] The rate of CMC-decrease, k, is determined by the limiting slope of the straight line where at least four points fall on each straight line. The values of k are given in Table 1.

The logarithm of $-k$ is plotted in Fig. 2 against the number of carbon atoms, m, in alkyl chain in each homologue. The lines are of similar form, a monotonic

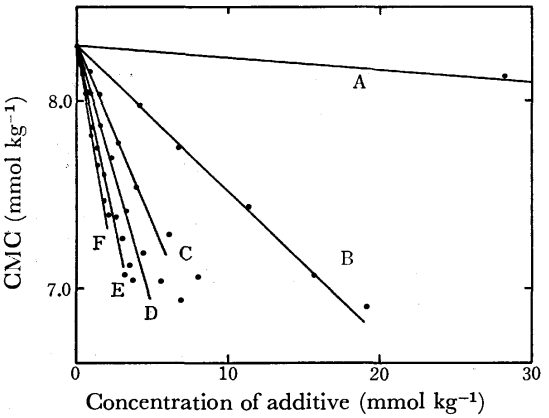

Fig. 1. The relation between CMC of SDS and concentration of additives (1-pentanol derivatives). A: Alkanediol, B: alkanol, C: ether, $n=1$, D; $n=2$, E: $n=3$, F; $n=4$.

a) Poly(oxyethylene) alkyl ether.

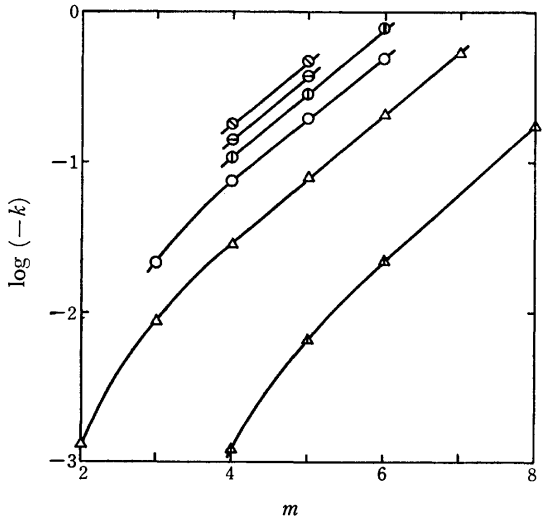

Fig. 2. The relation between log(−k) and alkyl chain length (m). Homologue of alkanediol (△), alkanol (△), ethers of n=1 (○), n=2 (◐), n=3 (⊖), n=4 (⊘).

increase in log (−k) as a function of m being found to be linear above a certain number of m. For each homologous series, a standard free energy change of transfer per methylene group, $\Delta G°(CH_2)$, from aqueous environment to micelles can be calculated by [2,3]

$$\Delta G°(CH_2) = -RT\,\mathrm{d}\ln(-k)/\mathrm{d}m \qquad (1)$$

or by its approximation

$$\Delta G°(CH_2) = -RT\{\ln(-k_{m+1}) - \ln(-k_m)\} \qquad (2)$$

as a function of m. The $\Delta G°(CH_2)$ value, calculated from each pair of neighboring k values taken from the appropriate column in Table 1, is plotted against m in Fig. 3. The plots of alkanol and its poly(oxyethylene) ethers can be regarded as giving a single curve. For all the homologues, the absolute value of $\Delta G°(CH_2)$ decreases initially with the increasing m, and then takes a constant value (−590 cal/mol CH_2)* from about m=4 for alkanols and ethers, and from about 6 for alkanediols. The value is comparable with the corresponding free energy value in the process of hydrophobic bond formation (*ca.* −600 cal/mol CH_2).[14,15] Thus, for each series of homologues including alkanediols which bears polar

* 1 cal=4.18$_4$ J.

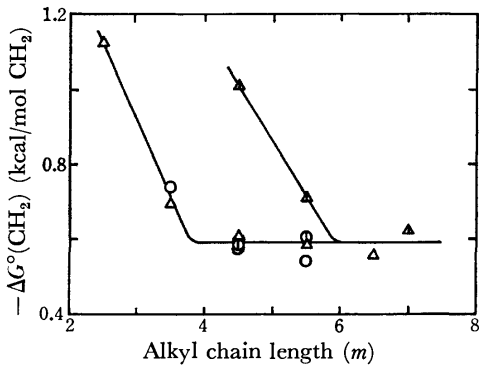

Fig. 3 The relation between $\Delta G°(CH_2)$ and alkyl chain length (m). The mark of each homologue is the same as that in the legend in Fig. 2.

groups at both end positions of the alkyl chain, the methylene groups remote from the polar group by more than about three carbon atoms can be transferred from aqueous environment to the non-polar interior of micelles. This is in line with the view that, in the process of micelle formation of surfactant alone, the hydration of the four methylene groups adjacent to its head group is retained.[16] In other words, the shorter alkyl-chain compounds are probably transferred incompletely (at most, up to the surface region of micelles) or not at all (changing only the property of aqueous medium) owing to their remarkable miscibility with water. The results are supported by the previous findings[11] that the partial molar volumes of 1-butanol and longer-chain 1-alkanols are higher in the micellar solution of SDS than in water, no difference being observed for 1-propanol and lower ones; the lower alkanols are not solubilized to a great extent.

The relation between log (−k) and the number of hydroxyl groups and oxyethylene groups (n) is shown in

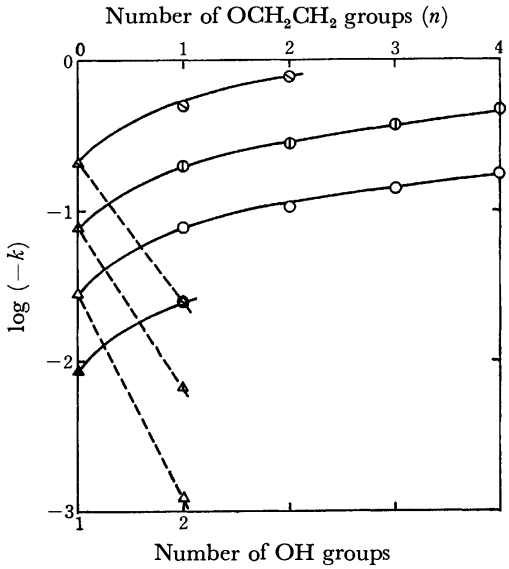

Fig. 4. The relation between log(−k) and the number of oxyethylene (n) and of hydroxyl groups. Solid line refers to ether: m=3 (●), m=4 (○), m=5 (◐), m=6 (⊘), and broken line to hydroxyl derivatives: m=3 (▲), m=4 (△), m=5 (◭), m=6 (◬).

Fig. 4. With alkanediols, log $(-k)$ is lower than that for alkanol with the same alkyl chain. However, for ethers, log $(-k)$ increases asymptotically with an increase in n, where alkanol is regarded as an ether with $n=0$. The tendencies are also seen in Fig. 1.

When a small amount of a nonionic amphiphilic substance is added to an ionic surfactant solution to form mixed micelles, the following main factors controlling the CMC-decrease can be considered: (i) thermodynamic factor by which the free energy of mixing decreases, and (ii) electrostatic factor by which the repulsive force decreases among ionic head groups in the surface region of micelles. Both hydroxyl and oxyethylene groups are hydrophilic.[12,13] From the view that an additive dissolves undergoing partition between a polar aqueous phase and a non-polar micellar one, the decreasing tendency of log $(-k)$ with the number of hydroxyl groups (Fig. 4) might be caused for the reason that alkanediol is more difficult to be transferred to the micellar phase than alkanol because of the higher hydrophilicity of the former. Thus, (i) would be the predominant factor.

The tendency of ethers to increase (Fig. 4) is explained as follows. The oxyethylene chain, which wedges off among the ionic head groups, occupies a large space in the ionic surface region of micelles to reduce ionic repulsive force. In addition, the hydrophilic nature of an oxyethylene group is less remarkable than that of a hydroxyl group.[18] The increase in the number of oxyethylene groups may not prevent effectively the solubilization of an additive in contrast with that in the number of hydroxyl groups. Thus, factor (ii) is likely to be more effective than factor (i). The present results are reasonably compared with those of the mixed micelles consisting of an ionic surfactant and a poly(oxyethylene)-type nonionic one, since the present ethers are similar to the nonionic surfactant in molecular structure. This explanation is in line with the results of potentiometric study on a mixed surfactant system: the degree of dissociation of the mixed micelles increases with an increase in the proportion of nonionic component.[8,10] It is also supported by the results obtained in the determination of CMC, in which the break in the curve of specific conductance *vs.* concentration of SDS in water becomes less sharp[5,10] with increase in the content of additive. The tendency becomes remarkable as the oxyethylene chain in ethers is lengthened. The asymptotical curve for ethers (Fig. 4) suggests that an oxyethylene group more remote from the alkyl chain has fewer occasions to approach the surface of micelle near enough to interact appreciably with ionic head groups scattering on it. Another suggestion is as follows. The longer the oxyethylene chain, the more powerful the hydrophilic nature of the ether molecule, and the more difficult the transfer of the ether molecule into micelles, as in the case of alkanediol. As a result, factor (i), the decrease of ether-concentration in micelles, may be added gradually to factor (ii).

We thank Prof. Ryohei Matuura, Kyusyu University, and Prof. Mituru Tanaka, Fukuoka University, for their encouragement.

Vibrational Spectra and Normal Coordinate Calculations for Trimethylaluminium-Ammonia

Fumio WATARI, Shigenori SHIMIZU,* Koyo AIDA, and Eiji TAKAYAMA**
Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai 980
(Received September 9, 1977)

Studies were carried out on the infrared spectra (33—4000 cm^{-1}) of four isotopic trimethylaluminium-ammonia complexes, $(CH_3)_3AlNH_3$, $(CD_3)_3AlNH_3$, $(CH_3)_3AlND_3$, and $(CD_3)_3AlND_3$, in the solid state at low temperature, and on the Raman spectra (0—4000 cm^{-1}) in the solid state and in solution of dichloromethane and of benzene at ambient temperature. Assignments for all fundamentals except internal torsion were made on the basis of C_{3v} molecular symmetry. For the sake of confirmation normal coordinate calculations were carried out utilizing a symmetry force field. The Al–N stretching force constant was found to be 1.544 mdyn/Å.

Numerous vibrational studies have been made on the coordination complexes of boron compounds with derivatives of the Group Vb elements. However, few studies are known for the addition complexes of aluminium compounds,[1-5] belonging to the same group as that of boron.

The present study was undertaken to observe the vibrational spectra of trimethylaluminium–ammonia complexes, to assign vibrational fundamentals and to calculate force constants, especially that of the Al–N bond. Complete vibrational analyses for these complexes might provide interesting information on the electron donor-acceptor bond, which in turn can be compared with other physical and chemical properties.

Experimental

All manipulation of chemical substances was done in the conventional vacuum line, because of inflammability of trimethylaluminium and sensitivity of the addition complexes to moisture.

Trimethylaluminium was prepared by the reaction of dimethylmercury(II) with aluminium powder in slight excess in a sealed tube with a break-seal, following the procedure of Wartik and Schlesinger.[6] Dimethyl-d_6-mercury-(II) was used for the preparation of trimethylaluminium-d_9. Ammonia generated by dropping commercial aqueous ammonia over solid potassium hydroxide was collected in a U-type trap immersed in liquid nitrogen. Ammonia-d_3 was prepared by the reaction of deuterium oxide with magnesium nitride[7] in the vacuum line. These substances were purified by fractional distillation in the vacuum line.

Trimethylaluminium–ammonia complex for infrared work was prepared by condensing trimethylaluminium and ammonia in a 1 : 2 mole ratio into a small reaction tube with a stopcock and a ground-joint at liquid nitrogen temperature. After closing the stopcock the tube was left to reach room temperature. It was then opened to the vacuum line for a while in order to remove volatile substances.

The aluminium content was determined by the EDTA method.[8] Calcd for $(CH_3)_3AlNH_3$: Al, 30.3%. Found: Al, 29.3%.

Infrared spectra were recorded on a Perkin-Elmer Model 337 spectrophotometer in the region 4000—400 cm^{-1}. Frequencies were read on a Hitachi QPD-33 recorder by abscissa expansion with use of a Perkin-Elmer Expanded Scale Readout Kit. The instrument was calibrated in the usual manner.[9] The spectra were obtained for the samples deposited onto a CsI plate cooled with liquid nitrogen. Before recording the spectra, the samples were annealed until the spectra showed no change.

Far infrared spectra were obtained between 400 and 33 cm^{-1} with a Hitachi FIS-III spectrophotometer which was evacuated in order to remove atmospheric water vapor. The instrument was calibrated by means of water vapor frequencies. The sample was sublimed onto a polyethylene window cooled with liquid nitrogen, and annealed in a similar manner to that for the midinfrared study. The double chopping method was used for recording the spectra to avoid the radiation effect resulting from the temperature difference between the sample and the reference beam path.

Raman spectra were recorded in the range 0—4000 cm^{-1} on a JEOL JRS-S1 laser Raman spectrophotometer equipped with an NEC GLG-108 50 mW He–Ne laser. The spectrophotometer was calibrated with the emmission lines of neon. The spectra were obtained at ambient temperature in the solid state and in the saturated solution of dichloromethane and of benzene, sealed in a capillary of about 1.5 mm o.d.

Results and Vibrational Assignments

The infrared and Raman spectra of four isotopic trimethylaluminium–ammonia complexes are shown in Figs. 1—3. The vibrational frequencies are given in Tables 1—4. A molecular symmetry of C_{3v}, with the C_3 axis coinciding with the Al–N bond, is assumed for trimethylaluminium–ammonia. From group theory, the molecule is expected to have $10A_1$, $5A_2$, and 15E modes, in which the A_2 mode is inactive in both the infrared and Raman spectra, and the A_1 and E modes are active in both.

CH_3 and CD_3 Modes. The CH_3 stretches are observed around 2900 cm^{-1} in the infrared spectra. The three asymmetric stretches are contained within a single intense absorption at 2910 cm^{-1} for $(CH_3)_3AlNH_3$ and at 2915 cm^{-1} for $(CH_3)_3AlND_3$. On deuteration of the methyl groups these stretches shift and split into two at 2184 and 2179 cm^{-1} for the NH_3 adduct, and at 2184 and 2177 cm^{-1} for the ND_3 adduct. The two symmetric methyl stretches are observed to be accidentally degenerate at 2874 cm^{-1} for $(CH_3)_3AlNH_3$ and at 2872 cm^{-1} for $(CH_3)_3AlND_3$, the modes shifting to 2089 cm^{-1} and to 2090 cm^{-1} on deuteration of the

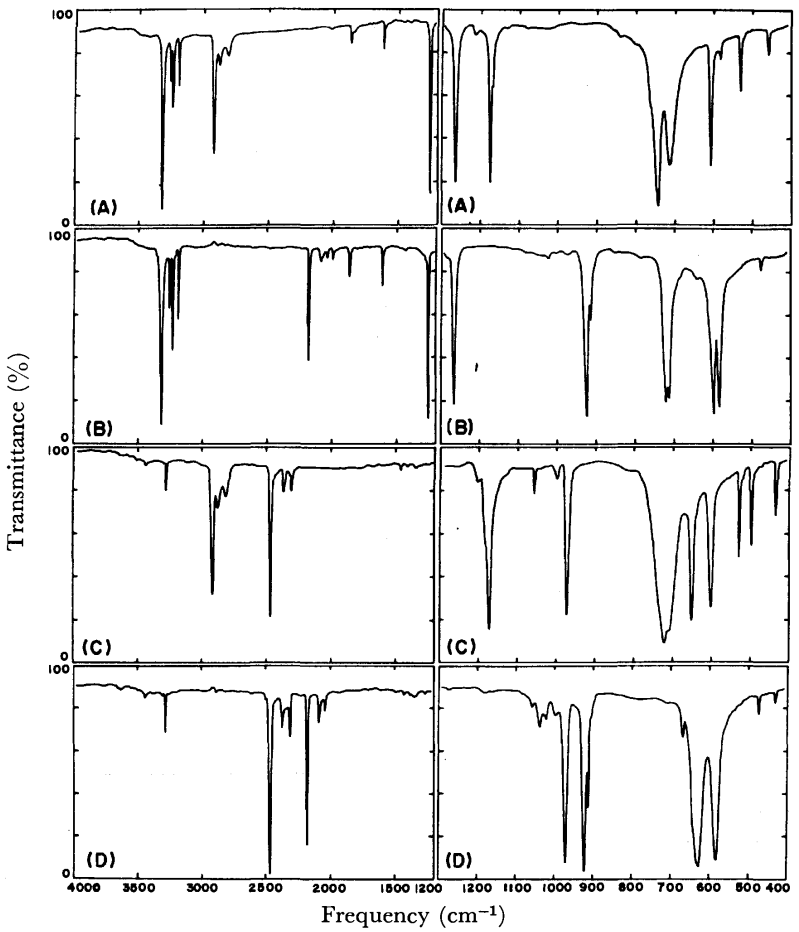

Fig. 1. Infrared spectra of (A) $(CH_3)_3AlNH_3$, (B) $(CD_3)_3AlNH_3$, (C) $(CH_3)_3AlND_3$, and (D) $(CD_3)_3$ $AlND_3$ recorded at −196 °C.

methyl groups. The Raman bands corresponding to the lower frequency infrared absorptions are polarized.

Degenerate methyl deformation is observed very weakly and broadly around 1470 and 1410 cm^{-1} in the infrared spectra. The frequencies are not definite, whereas the modes of $(CD_3)_3AlND_3$ are observed at 1038 cm^{-1} (ν_{21}) and 1021 cm^{-1} (ν_4 and ν_{22}). The deformation of $(CD_3)_3AlNH_3$ is too weak for the frequency to be defined.

Symmetric methyl deformation is observed as a singlet at 1172 cm^{-1} for $(CH_3)_3AlNH_3$ and at 1173 cm^{-1} for $(CH_3)_3AlND_3$. In the Raman spectra, the modes are observed at 1163 cm^{-1} and at 1165 cm^{-1} with a shoulder on the high-frequency side, the higher frequency bands being polarized. Consequently the 1172 and 1173 cm^{-1} infrared absorptions are assigned to the symmetric methyl deformation of A_1 symmetry, and the 1163 and 1165 cm^{-1} Raman bands, of E symmetry. The CD_3 modes are observed in the infrared spectra at 914 and 923 cm^{-1} for $(CD_3)_3AlNH_3$, and at 913 and 921 cm^{-1} for $(CD_3)_3AlND_3$, the lower frequency absorptions of which are weak. The Raman bands corresponding to the lower frequency infrared absorptions are strong and polarized.

The CH_3 rocks are assigned to absorptions at 743 cm^{-1} (ν_{25} and ν_{26}) and 712 cm^{-1} (ν_7) for $(CH_3)_3AlNH_3$, and at 720 cm^{-1} (ν_{25}) and 710 cm^{-1} (ν_7 and ν_{26}) for $(CH_3)_3AlND_3$. The CD_3 rocks are observed at 586 and 584 cm^{-1} in the infrared spectra for $(CD_3)_3AlNH_3$ and $(CD_3)_3AlND_3$, respectively, without splitting.

NH_3 and ND_3 Modes. The symmetric NH_3 stretch is assigned to an infrared absorption observed at 3254 cm^{-1} for the $(CH_3)_3Al$ and at 3252 cm^{-1} for the $(CD_3)_3Al$ adduct. On deuteration, the mode shifts from 3254 to 2369 cm^{-1} and from 3252 to 2373 cm^{-1}. The corresponding Raman bands are clearly polarized, though observed only weakly because of insufficient sensitivity of a photomultiplier in this region. The degenerate stretches are assigned to the most intense absorptions of these regions observed at 3313, 3312, 2463, and 2468 cm^{-1} for trimethylaluminium–ammonia-d_0, -d_9, -d_3, and -d_{12}, respectively.

The degenerate NH_3 deformation is observed at 1615 and 1618 cm^{-1} in the infrared spectrum for $(CH_3)_3$-$AlNH_3$ and $(CD_3)_3AlNH_3$, respectively. The ND_3 deformation shows no clear band in the infrared and Raman spectra, being observed at 1180 cm^{-1} as a shoulder on the high-frequency side of the symmetric CH_3 deformation or an extremely weak band in the infrared spectrum.

The symmetric NH_3 deformation is assigned to a band at 1263 and 1265 cm^{-1} in the infrared spectrum for $(CH_3)_3AlNH_3$ and $(CD_3)_3AlNH_3$, respectively. It shifts to 974 and 971 cm^{-1} on deuteration of the ammonia

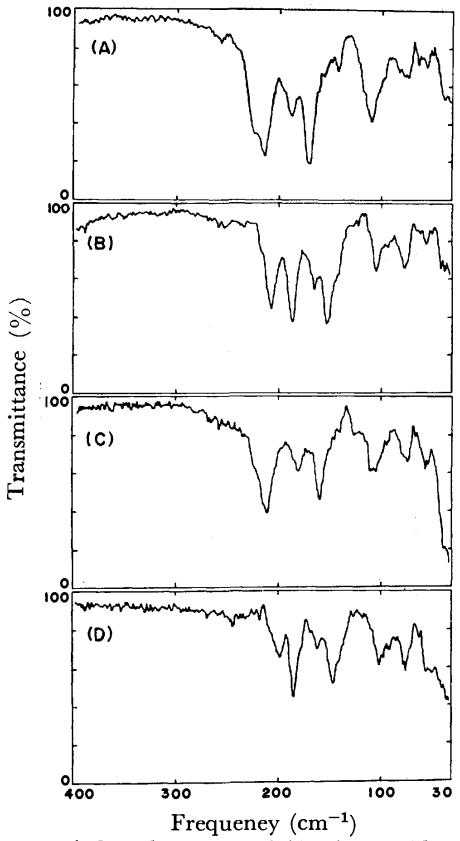

Fig. 2. Far infrared spectra of (A) $(CH_3)_3AlNH_3$, (B) $(CD_3)_3AlNH_3$, (C) $(CH_3)_3AlND_3$, and (D) $(CD_3)_3AlND_3$ recorded at −196°.

group.

The NH_3 rock is observed at 712 cm^{-1} coinciding with the CH_3 (A_1) rocking frequency for $(CH_3)_3AlNH_3$, and at 721 and 712 cm^{-1} as a doublet for $(CD_3)_3AlNH_3$. The mode shifts to 501 cm^{-1} for $(CH_3)_3AlND_3$. For $(CD_3)_3AlND_3$, no absorption is found around 500 cm^{-1}, but a shoulder is observed at 490 cm^{-1} in the Raman spectrum and assigned to the ND_3 rock.

Skeletal Modes. The symmetric AlC_3 stretches are observed at almost definite frequency of 530 cm^{-1} for the $(CH_3)_3Al$ and of 480 cm^{-1} for the $(CD_3)_3Al$ adducts. The mode gives the strongest polarized Raman line. The degenerate AlC_3 stretch, coupling with deformation of the methyl and ammonia groups, is observed in the 650—600 cm^{-1} region.

The AlC_3 deformation is observed in the 210—150 cm^{-1} region (Tables 1—4).

The Al–N stretch is observed in the 460—435 cm^{-1} region in the infrared spectrum. The absorption is weak, and not observed for $(CD_3)_3AlNH_3$. The corresponding Raman band is weak, but polarized. In a solution Raman spectrum, this mode is observed to shift toward the lower frequency than that in the solid state.

Normal Coordinate Calculations

The normal coordinate analysis was undertaken to confirm the assignments. The calculation was made by Wilson's *GF* matrix method on an ACOS 77/700 computer at the Computer Center, Tohoku University,

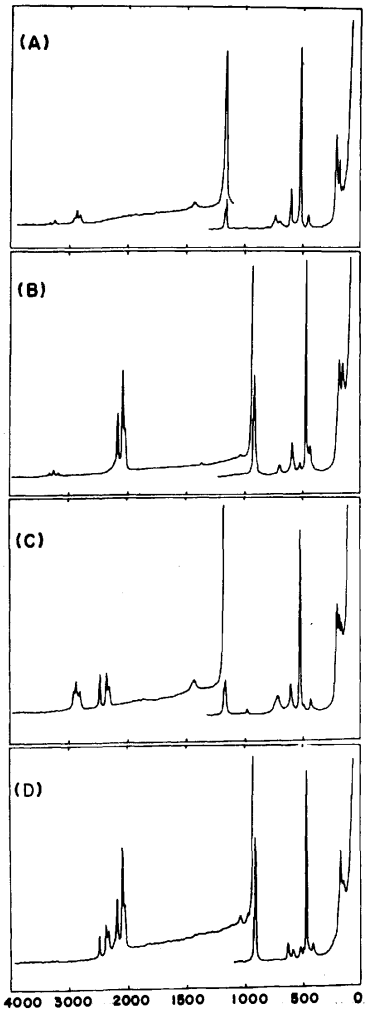

Fig. 3. Raman spectra of (A) $(CH_3)_3AlNH_3$, (B) $(CD_3)_3AlNH_3$, (C) $(CH_3)_3AlND_3$, and (D) $(CD_3)_3AlND_3$ recorded in the solid state at ambient temperature.

by means of the usual iterative least-squares procedure.

The *G* matrix was calculated using structural parameters of Cl_3AlNH_3[10] and $(CH_3)_3AlN(CH_3)_3$[11] determined by electron-diffraction studies; r(N–H)=1.03 Å (assumed), r(C–H)=1.09 Å, r(Al–C)=1.987 Å, r(Al–N)=2.099 Å (taken from $(CH_3)_3AlN(CH_3)_3$), $\angle$(H–N–H)=112.79°, $\angle$(Al–C–H)=111.8°, and $\angle$(C–Al–N)=102.3°. Symmetry coordinates similar to those for trimethylarsine-borane[12] were used.

Infrared frequencies were used for the calculations. The Raman frequencies observed in the solid state were used for vibrations which frequencies were not accurate from the infrared spectra but accurate enough from the Raman effect. The torsional mode was neglected in the E class. The frequencies were weighted by $(1/\lambda)$ in the least-squares routine, but the CH_3 degenerate deformation frequencies were weighted by 0.1 because of inaccuracy. The least-squares refinement was carried out in terms of symmetry force constants, fitted to the observed frequencies for the four isotopic species simultaneously. The calculated frequencies are given for the four isotopic species in Tables 1—4, together with the potential energy distributions, the average

errors being 0.51 and 0.97% for the A_1 and E vibrations, respectively. The sum of the weighted squares of errors, $\Sigma(\lambda_{obsd}-\lambda_{calcd})^2/\lambda_{obsd}$, was 1.83×10^{-3} for the A_1 species vibrations and 1.45×10^{-2} for the E species. The symmetry force constants and their uncertainties from the last cycle of the least-squares refinement are given in Table 5.

Discussion

In the far infrared spectra, another absorption in the skeletal deformation region was observed at around 220 cm^{-1} as a shoulder for the $(CH_3)_3Al$ adduct and at about 200 cm^{-1} for the $(CD_3)_3Al$, which remained unassigned. This may be due to the torsional mode of the methyl groups active in both the infrared and the Raman spectrum. They seem to be rather intense as being due to torsions, the deuteration shift (20 cm^{-1}) appearing to be too small.[13)] An infrared strong absorption at 604 cm^{-1} of $(CH_3)_3AlND_3$ also remained unassigned. Attempts to assign the vibrational mode was unsuccessful.

The symmetric AlC_3 stretch is mixed with the Al–N stretch, also with the CD_3 rock for the $(CD_3)_3Al$ adduct. The frequencies are in almost fixed region at 530 cm^{-1} for the $(CH_3)_3Al$ adducts and at 480 cm^{-1} for the $(CD_3)_3Al$, not being influenced on deuteration of the ammonia group, whereas the degenerate AlC_3 stretch is mixed with the NH_3 or ND_3 rock and the frequencies are higher for the ND_3 adducts than those of the NH_3.

Studies on boron adducts have shown the Raman technique to be more sensitive to the donor-acceptor bond stretching mode than the infrared technique.[14–17)] The Al–N stretch of the $(CH_3)_3AlNH_3$ molecule is weak in intensity in the infrared spectrum and also unexpectedly weak in the Raman effect.

Agreement between the observed and calculated frequencies is satisfactory. The vibrational assignments are supported by the product rule ratios given in Table 6, where the theoretical ratios were calculated from the determinant of the G matrices.

The Al–N force constant is compared with that of

a) This work.

other addition compounds containing an Al–N bond in Table 7, where their Al–N bond distances, Al–N stretching frequencies and heats of formation are also given. We can not find any trend from the frequencies of the Al–N stretching mode, probably because of its mixing with other vibrational modes. However, we find correlations between the bond distances, the Al–N force constants (except that of $H_3AlN(CH_3)_3$) and the heats of formation. Considering that ammonia is a weaker base than trimethylamine and the heat of formation of $(CH_3)_3AlNH_3$ is less than that of $(CH_3)_3AlN(CH_3)_3$, the Al–N bond distance of $(CH_3)_3AlNH_3$ would be greater than that of $(CH_3)_3AlN(CH_3)_3$. The force constant 2.321 mdyn/Å for $H_3AlN(CH_3)_3$ seems quite large as compared with the Al–N bond distances. Though we have only a limited number of data and detailed vibrational analysis would be necessary for other compounds, it appears that the Al–N force constant of 1.544 mdyn/Å is reasonable for trimethylaluminium-ammonia.

Beam Studies of the Ion-Molecule Reaction $CO_2^+ + D_2 \rightarrow DCO_2^+ + D$

Hiroshi TOCHIHARA* and Yoshitada MURATA*

Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received September 19, 1977)

Reaction cross sections of the reaction $CO_2^+ + D_2 \rightarrow DCO_2^+ + D$ have been measured over the range of the collision energies $E=0.4$ to 4 eV in the center of mass system. The cross section was obtained from relative values of the reaction $Ar^+ + D_2 \rightarrow DAr^+ + D$ by using the mixed ion beam method. The observed cross sections are about half of the Langevin-Gioumousis-Stevenson cross sections and show approximately $E^{-1/2}$ dependence.

Since the molecular beam technique has been used with great success, the ion beam technique has also been employed for ion-molecule reactions. This method has enabled the study of collision energy dependence of the reaction cross section. The following reactions have been studied extensively:[1-5]

$$Ar^+ + D_2 \longrightarrow DAr^+ + D, \quad \Delta E = -1.2\ \text{eV}, \quad (1)$$

$$CO^+ + D_2 \longrightarrow DCO^+ + D, \quad \Delta E = -2.0\ \text{eV}, \quad (2)$$

and

$$N_2^+ + D_2 \longrightarrow DN_2^+ + D, \quad \Delta E = -2.5\ \text{eV}, \quad (3)$$

where ΔE denotes the heat of reaction. These reactions are exothermic. The cross sections in these reactions are in proportional to $E^{-1/2}$ at low energies (below 1 eV in the center of mass system**) and decrease more steeply with increasing collision energy. The cross section, σ, of Reactions 1 and 2 is in good agreement with the Langevin-Gioumousis-Stevenson (LGS) cross section[6] below 1 eV.[2-4] For Reaction 3 σ is about twice as large as the LGS cross section.[1,4,5]

In this paper, the reaction

$$CO_2^+ + D_2 \longrightarrow DCO_2^+ + D, \quad \Delta E = -1.1\ \text{eV}, \quad (4)$$

was investigated. Since the incident ion of this reaction is more complex than those of Reactions 1—3, a different energy dependence of σ can be expected. This reaction has been studied by several methods such as flowing afterglow,[7] mass-spectrometry,[8,9] ion cyclotron resonance mass-spectrometry,[10,11] and energy analysis of product ions.[12] In these studies except for the last method, reaction rate constants were observed only at thermal or a little higher energies. Recently, Mahan and Schubart investigated the velocity vector distribution of DCO_2^+ in detail.[13]

Experimental

An apparatus for the study of the ion-molecule reaction was constructed chiefly to determine the collision energy dependence of σ. The beam-collison chamber method was employed and a schematic diagram of the apparatus is shown in Fig. 1. The main chamber was evacuated to a pressure around 10^{-4} Pa and operated at around 10^{-3} Pa during the experiment.

The ion source used was a Bayard-Alpert gauge type. The impact energy of the electrons was about 33 eV. The electron current was 1×10^{-5} A and the pressure of the gas

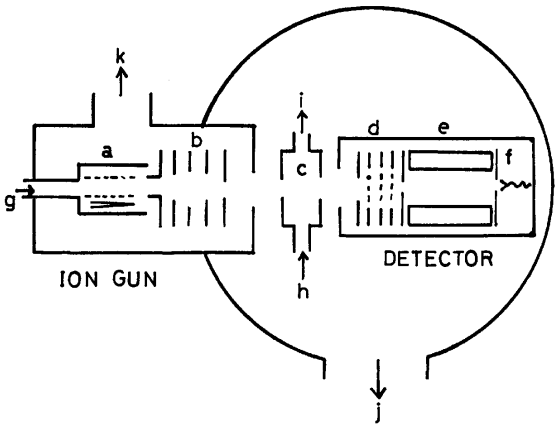

Fig. 1. Schematic diagram of the apparatus. a: Ion source, b: extracting electrode, einzel lens, and aperture, c: collision chamber, d: detection aperture and three-fold plane grids, e: quadrupole mass filter, f: channel electron multiplier, g: gas inlet to ion source, h: gas inlet to collision chamber, i: to ionization gauge, j: to 10 in. oil diffusion pump, k: to 2 in. oil diffusion pump.

introduced into the ion source was about 5×10^{-3} Pa. An attenuation experiment[14] ensured that the CO_2^+ ion beam produced by 33 eV electron impact in the present experiment did not contain any appreciable amount of metastable ions.

The collision chamber was 15 mm thick and the entrance and exit apertures were 2 and 3 mm in diameter, respectively. The distance between the center of the collision chamber and the detection aperture, 4 mm in diameter, was 20.5 mm. Hence, the detection angle was $\pm 5.6°$ at the center of the collision chamber. A quadrupole mass filter was used. In the present experiment, the transmittance of the incident and the product ions in the mass filter is almost the same, since the difference between their masses is small ($\Delta M=2$). Mass-analyzed ions were detected by a channel electron multiplier. A pulse counting system was used for detection, and the pulse height was such that the counting efficiency for all ionic species was about unity.

The pressure of the target gas in the collision chamber was measured with an ionization gauge which was mounted on the collision chamber. Since it was not suitable to keep the ionization gauge on during the collision experiment, the relationship between the reading of the ionization gauge and the revolution number of a variable leak valve was measured. During the experiment, the pressure of the target gas in the collison chamber was determined only by the revolution number of the variable leak valve. To realize the single collision condition and to obtain as many product ions as possible the pressure of D_2 was around 0.2 Pa throughout the present experiment. Under the single collision condition, σ was obtained by using the thin target formula, $\sigma = i/(INL)$

* Present address: The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106.

** Hereafter, the collision energy is in the center of mass system.

where N is the number density of the target molecules, L is the collision path length, and I and i are the intensities of the incident and the product ions respectively.

It is difficult to obtain the absolute value of N. Hence, we obtained experimentally the relative cross section of Reaction 4 with respect to Reaction 1, *i.e.*, the cross section was obtained from the equation $\sigma_4=\sigma_1 i_4 I_1/i_1 I_4$, where the subscripts 1 and 4 denote Reactions 1 and 4 respectively. The mixed ion beam of Ar^+ and CO_2^+ was employed, which was made by introducing the mixed gases of Ar and CO_2 into the ion source. The intensities, i_1/I_1 and i_4/I_4, were observed under the same scattering condition, *i.e.*, the same number density of D_2 and the same geometry.

Results and Discussion

The cross section σ_1 has been obtained in good agreement by three different groups over a wide range of collision energies.[3] Therefore, Reaction 1 was thought suitable as a reference reaction. The average value $\hat{\sigma}_1$ of σ_1's reported is shown by a solid line in Fig. 2 as a function of the collision energy. The cross section, σ_4, was obtained from the equation $\sigma_4=\hat{\sigma}_1(i_4/I_4)/(i_1/I_1)$ and was plotted as a function of the collision energy (Fig. 2). Differences, between the incident and product ions, in the transmittance of the mass filter and in the counting efficiency of the multiplier have been ignored in this experiment, as mentioned in the Experimental.

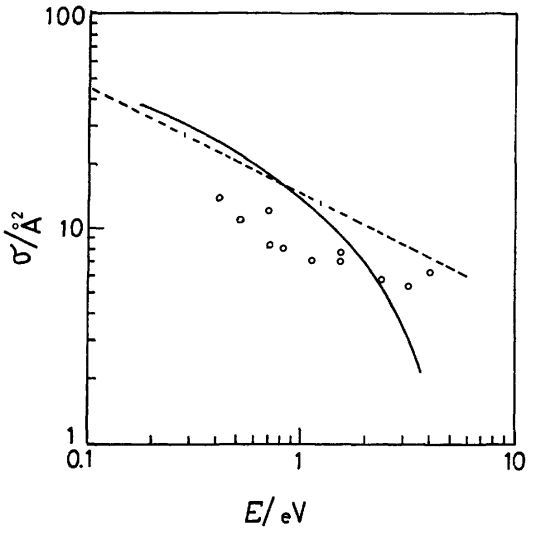

Fig. 2. Reaction cross section σ *vs.* collision energy E for Reaction 4. Open circles, observed cross sections; broken line, LGS cross section.[6] Solid line: average cross section for Reaction 1, $\hat{\sigma}_1$.[3]

In order to obtain an accurate value of σ_4, all of the product ions, DAr^+ or DCO_2^+, had to be collected in both reactions. The collection efficiency of DAr^+ for Reaction 1 in the present experiment was estimated by using data of the angular distribution observed by Herman *et al.*[15] The estimated values were about 70 and 90% at the collision energies 0.4 and 0.7 eV, respectively, and over 95% above 0.7 eV. In the estimation, the geometry mentioned above was used, and the collimated incident beam and the perfect alignment of the detection system were assumed.

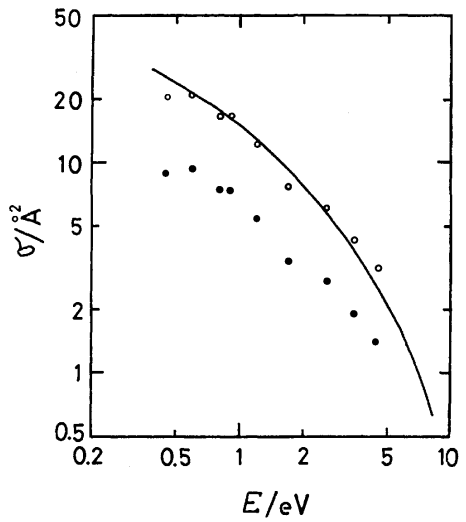

Fig. 3. Reaction cross section σ *vs.* collision energy E for Reaction 1. Solid line, average cross section, $\hat{\sigma}_1$[3]; closed circles, observed cross sections derived from the thin target formula; open circles, observed cross sections normalized to $\hat{\sigma}_1$ at 0.8 eV.

Further data on the collection efficiency in Reaction 1 has been obtained by comparing the energy dependence of the observed cross sections, the closed circles in Fig. 3, with that of $\hat{\sigma}_1$, the solid line in Fig. 3. The observed cross sections were matched to $\hat{\sigma}_1$ at 0.8 eV by multiplying by a constant. The fitted values, the open circles in Fig. 3, are in good agreement with $\hat{\sigma}_1$. This agreement may indicate that the collection efficiency of DAr^+ in the present experiment was almost the same as that of other experiments,[2-4] and that the discrepancy between the observed cross section and $\hat{\sigma}_1$ was caused by an incorrect value of the observed pressure of D_2 in the collision chamber.

The angular distribution of DCO_2^+ reported by Mahan and Schubart[13] was similar to that of DAr^+ in the laboratory system at 2 and 5 eV. Hence, the cross sections, σ_4, obtained in the present experiment give accurate values.

The magnitude of the cross section σ_4 was about 50% of $\hat{\sigma}_1$ in the low energy region and almost the same or larger at energies higher than 2.5 eV. The cross section σ_4 was approximately proportional to $E^{-1/2}$ over the energy range studied in the present experiment, and the magnitude of σ_4 was about 50% of the LGS cross section.

Mahan and Schubart detected the DCO^+ ion in the collision of CO_2^+ with D_2 above the collision energy 1 eV.[13] The peak height corresponding to DCO^+ on the contour map at 4.36 eV, at which the scattering intensity of DCO^+ was strongest, was only 5% of that corresponding to DCO_2^+. Thus, the small cross section was not caused by other reactive collisions.

The magnitude of σ_4 was observed to be about 50% of the LGS cross section which is in good agreement with that obtained by other techniques. Harrison and Myher studied Reaction 4 by mass-spectrometry and observed the reaction rate constant to be 0.6×10^{-9} $cm^3\ s^{-1}$ at a collision energy 0.3 eV.[8] McAllister and

Pitman measured the rate constant by ion cyclotron resonance mass-spectrometry and reported it to be 0.5×10^{-9} cm^3 s^{-1} at thermal energy.[11] These values are about 50% of the rate constant value predicted by the polarization theory,[6] 1.1×10^{-9} cm^3 s^{-1}. That the small rate constant is not due to charge transfer or other reactive collision has been reported.[10]

The small value of σ for Reaction 4 will be discussed by the modified polarization theory, by which the magnitude of the cross section for Reaction 3 can be explained. This will be described and presented in detail in a later paper.[16] Under this theory the incident ion is regarded as a two- or three-centered charged particle.

In Reactions 1—3, σ decreases more steeply than $E^{-1/2}$ with increasing collision energy above 1 eV,[1-5] as is illustrated by the solid line in Fig. 2 for Reaction 1. σ_4 does not illustrate this behaviour. It appears that this steep decrease of σ at the high collision energy is due to the dissociation of the product ion. In Reaction 4, the collision energy may be transferred efficiently into the internal energy of DCO_2^+ and distributed to all vibrational modes. Moreover, the minimum collision energy, above which DCO_2^+ dissociates into $CO_2 + D^+$ or $CO_2^+ + D$, is about 8 eV, if the spectator-stripping reaction occurs. The experiments of Mahan and Schubart indicate that the spectator-stripping reaction is the dominant process of Reaction 4.[13]

Linear Free Energy Relationships in Heterogeneous Catalysis. XIII. The Dehydration of Aliphatic Alcohols over Silica-Alumina

Jun-ichiro TAKE, Tadayuki MATSUMOTO, and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 5, 1977)

In order to survey the applicability of linear free-energy relationships to the catalytic dehydration of aliphatic alcohols, isopropyl alcohol and *n*-, *s*-, and *t*-butyl alcohols were dehydrated over silica-alumina at 54—166 °C. The dehydration was zero order in alcohol over the pressure range of 0.01 to 0.1 atm. The true activation energies were 32.0, 35.3, 31.7, and 29.9 kcal/mol for isopropyl alcohol and *n*-, *s*-, and *t*-butyl alcohols, respectively. The zero-order rate constants were exclusively affected by the activation energy. A linear relationship was found between the true activation energy, as well as the logarithm of the zero-order rate constant, and the heterolytic bond dissociation energy for the C–O bond in alcohols, $D(R^+OH^-)$. The activation energy increased and the rate constant decreased with an increase in the $D(R^+OH^-)$. These correlations were explained in terms of the heterolytic fission of the C–O bond in the rate-determining step.

The catalytic dehydration of alcohols on oxides has been extensively studied and reviews have appeared by Winfield,[1] Pines and Manassen,[2] Knözinger,[3] and Notari.[4] However, there have been few studies of linear free-energy relationships (LFER) and, furthermore, such studies as have been made have been restricted mainly to alumina. In previous LFER studies of the dealkylation[5] and isomerization[6] of alkylbenzenes over silica–alumina, we found that the apparent activation energies, as well as the logarithms of the first-order rate constants, have linear correlations with $\Delta H_C^+(R)$, the enthalpy change for hydride abstraction from the corresponding paraffin.

The present study was devoted to a surve of the applicability of the LFER to the catalytic dehydration of aliphatic alcohols over silica–alumina.

Experimental

Materials. The silica–alumina (SA-1, 13% Al_2O_3) in powder form was taken from the same batch as that used earlier.[6] The catalyst was calcined at 550 °C for 8 h in the atmosphere. The alcohols used were GR-grade reagents: the isopropyl alcohol and *n*- and *s*-butyl alcohols were dried over CaO and distilled; the *t*-butyl alcohol was shaken with $CaCl_2$ for 20 min and then distilled. The alcohols were finally stored over a molecular sieve 4A.

Apparatus. A continuous-flow mode was used for the reaction, as is shown in Fig. 1. Hydrogen as a carrier gas was deoxygenated with a Deoxo column (B), divided into three streams, and then dried by means of dry ice–ethanol traps (D_1—D_3). Each alcohol was introduced into the first hydrogen stream with a flow rate of about 40 STP ml/min from a microfeeder (F), vaporized, and then diluted with the second hydrogen stream, whose flow rate was usually above 600 STP ml/min. A vessel (H, with an effective volume of about 90 ml) filled with glass beads reduced a small but unnegligible cyclic fluctuation (*ca.* ±15%) in the feed rate of the reactant to a satisfactory extent (below ±5%). A conventional TCD cell (G) in the vaporizer (I) monitored the reactant pressure. The stream through a glass reactor (J) was led to a gas-sampling valve (K) of a GLC apparatus (M). A wet gas meter (N) determined the total flow rate of the carrier gas after the removal of the condensable materials with a dry ice–ethanol or an ice–NaCl trap (D_4). A column of PEG 400 (2m) or of PEG 6000 (0.7 m) was used for analysis. In some experiments, a DMS column (6 m) was also used for the analysis of olefins.

Procedures. The catalyst was held in the reactor with quartz wool plugs and activated at 450 °C for 1—2 h in a hydrogen stream with a flow rate of about 50 ml/min. The alcohol pressure was modified over the range of 0.01 to 0.1 atm by changing the feed rate of the alcohol. The alcohol were dehydrated at 120—166 °C for a primary alcohol, at 100—145 °C for a secondary one, and at 54—80 °C for a tertiary one. A proper amount of the catalyst (0.01—5.4 g) was used depending upon the reaction temperature and the reactivity of the alcohols. In all the runs, the fractional conversion was less than 0.1 (in most runs, less than 0.05), so that the reactor was regarded as differential. Under the above reaction conditions, only a dehydration reaction occurred to yield olefin, which resulted from β-elimination, and water. No other products were dected by GLC. The activity of the catalyst was almost constant during the course of the reaction.

Results

External Diffusion Effects. These experiments were performed with the most reactive *t*-butyl alcohol and moderately reactive *s*-butyl alcohol by changing the total flow rate of the carrier gas. The results are shown

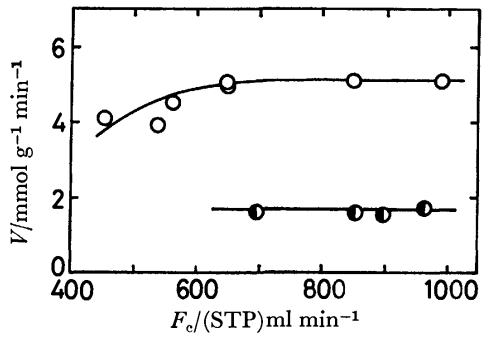

Fig. 2. Influence of flow rate of carrier on dehydration rate.
○: *t*-Butyl alcohol at 80 °C and 0.025 atm;
◐: *s*-butyl alcohol at 135 °C and 0.01 atm.

in Fig. 2. The dehydration rates of *t*-butyl alcohol at 80 °C, the highest in the present study, show no change in magnitude when the flow rate of the carrier is kept higher than about 650 STP ml/min, indicating that no external diffusion affects the reaction rate under such conditions. The carrier was, therefore, passed through at a flow rate higher than 650 STP ml/min in all subsequent runs.

Effects of Alcohol Pressure. The effect of the alcohol pressure on the dehydration rate was investigated at the high-temperature extreme for each alcohol. As is shown in Fig. 3, the dehydration rates are zero order in alcohol over the entire pressure range employed,

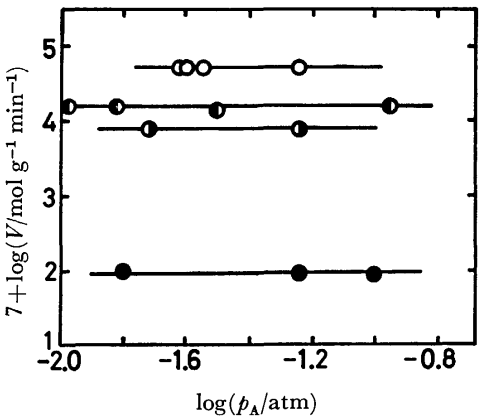

Fig. 3. Influence of alcohol pressure on dehydration rate.

implying that the rate-determining step is one which involves the reactions of adsorbed species. The zero-order kinetics should hold over the entire temperature range applied to each alcohol since the heat of adsorption is generally exothermic. With *t*- and *s*-butyl alcohols this was ascertained to be the case. The dehydration rates, therefore, give the rate constants of the dehydration of the adsorbed species.

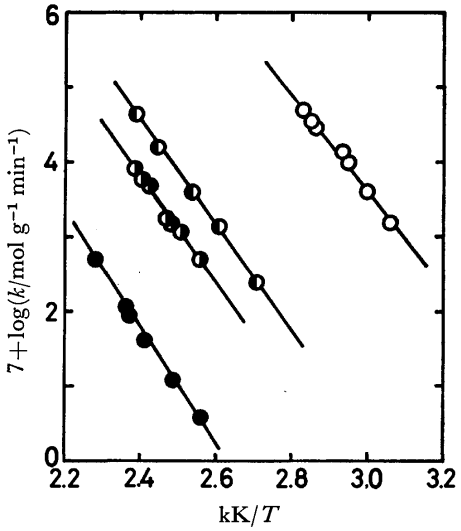

Fig. 4. Influence of temperature on dehydration rate constant.
○: *t*-Butyl alcohol; ◐: *s*-butyl alcohol; ●: butyl alcohol; ◑: isopropyl alcohol.

Effects of Reaction Temperature. The experiments were carried out at a constant alcohol pressure of about 0.02 atm. The zero-order rate constants are plotted in Arrhenius diagrams (Fig. 4). The Arrhenius parameters were determined by means of a least-squares method. The results are given in Table 1. This table also shows, as $\log(k/k_0)$, the rate constants relative to those for butyl alcohol at the low- and high-temperature extremes used. The rate constants for temperatures not covered by the experimental data were determined by extrapolation.

Internal Diffusion Effects. The effects were examined using the formula given by Weisz:[7]

$$\phi = \frac{dN}{dt}\frac{1}{C_0}\frac{R^2}{D_{eff}},$$

where dN/dt is the reaction rate in mol s^{-1} cm^{-3}; C_0,

Table 1. Rate constants and Arrhenius parameters for the dehydration of alcohols over silica–alumina

Alcohol	$\log(k/k_0)$[a] at t/°C=166	$\log(k/k_0)$[a] at t/°C=54	E_A[b] / kcal mol⁻¹	$\log\left(\frac{A}{\text{mol g}^{-1}\text{ min}^{-1}}\right)$[b]
Butyl	0	0	35.3±0.6	13.5±0.3
Isopropyl	1.85	2.41	32.0±1.3	13.7±0.7
s-Butyl	2.49	3.11	31.7±0.7	14.2±0.4
t-Butyl	5.39	6.32	29.9±0.2	16.2±0.2

a) The rate constant, k_0, is for butyl alcohol dehydration; k_0/mol g^{-1} $min^{-1}=7.8\times10^{-5}$ and 7.3×10^{-11} at t/°C=166 and 54, respectively. b) E_A is the zero-order activation energy; A, the preexponential factor.

the reactant concentration in mol cm^{-3}; R, the catalyst particle radius in cm, and D_{eff}, the effective diffusion constant in $cm^2\ s^{-1}$. In the present study, the extreme values for these coefficients are as follows: $dN/dt=10^{-4}$ mol s^{-1} cm^{-3}; $C_0=10^{-6}$ mol cm^{-3}; $R=10^{-3}$ cm. According to Weisz, the approximate value of D_{eff} is 10^{-3} for the system of a gel such as silica–alumina with a high surface area and a reactant whose molecular weight is about 150. From these data we obtain $\Phi=10^{-1}$. Weisz has shown that the diffusion effect can be excluded when $\Phi\leqslant 6$ for zero-order reactions.

Discussion

Table 1 shows that α-methylation (isopropyl to *t*-butyl) has a marked effect on the rate of dehydration, whereas the effect of β-methylation (isopropyl to *s*-butyl) is small. Thus, the reactivity of alcohols falls in the following order: butyl≪isopropyl<*s*-butyl≪*t*-butyl for dehydration. This trend is quite similar to that of the increasing stability of alkyl cations (see $\Delta H^\circ_f(R^+)$ in Table 2). Analogous rate relationships are found in the literature concerning a variety of heterogeneously or homogeneously catalyzed elimination reactions in the gas phase: the dealkylation of monoalkylbenzenes over silica–alumina;[5a] the dehydration of aliphatic alcohols over alumina[8] and hydroxyapatite,[9] or with gaseous hydrogen halide molecules;[10] the dehydrohalogenation of monohaloalkanes over salt catalysts,[11] and the dehydrosulfurization of alkyl mercaptans over silica–alumina.[12] The rate-constant data in Fig. 4 and Table 1 are for zero-order kinetics; therefore, the activation energies should not include heats of adsorprion. The major factor affecting the dehydration rates is clearly the activation energy, since the preexponential factor, A, does not vary except in the case of *t*-butyl alcohol. The activation energy decreases in the following order:

butyl > isopropyl > *s*-butyl > *t*-butyl

A similar sequence is also found in the literature.

Mochida and Yoneda[5b] obtained a linear relationship between the apparent activation energy, or the logarithm of the first-order rate constants, for the dealkylation of monoalkylbenzenes over silica–alumina and $\Delta H_C{}^+(R)$, the enthalpy change for the hydride abstraction from the corresponding paraffins. They explained this relationship in terms of the heterolytic fission of the C_{alkyl}–C_{phenyl} bond in the rate-determining step. For the gas-phase dehydrohalogenation of monohaloalkanes, Maccoll and his co-workers[10] found a linear relationship between the activation energy and the heterolytic bond dissociation energy of the C–X bond, $D(R^+\ X^-)$ (in this case, X=Cl, Br, and I). This correlation led them to the conclusion that the rate of elimination was determined by the heterolysis of the C–X bond.

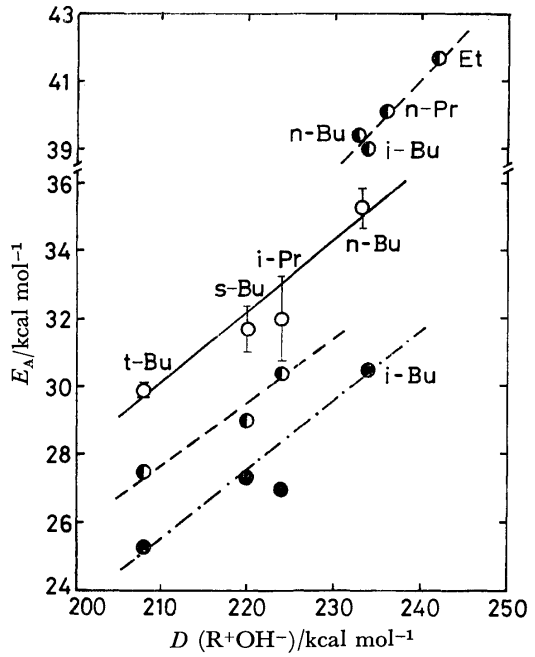

Fig. 6. Correlations of zero-order activation energy for alcohol dehydration on various catalysts with heterolytic bond dissociation energy, D(R$^+$OH$^-$), of the C–O bond.
○: The present study (on silica–alumina); ●: Knözinger and Scheglila[8] (on γ-alumina); ◐: Kibby and Hall[9] (on Ca-deficient hydroxyapatite).

Figure 5 shows the correlation between the relative rate constant of dehydration and the heterolytic bond dissociation energy, D(R$^+$OH$^-$), for alcohols. The relationship of the activation energy with D(R$^+$OH$^-$) is also shown in Fig. 6. From the definition, D(R$^+$X$^-$) is the enthalpy change of the RX→R$^+$+X$^-$ process, where R is the alkyl group, and X, the substituent, such as OH, halogen or H, so that the previous parameter, ΔH_{C^+}(R), is D(R$^+$H$^-$). The bond energy, D(R$^+$X$^-$), was calculated for X=OH and H from recent thermodynamical data, as is shown in Table 2. Although D(R$^+$X$^-$) has a linear correlation with ΔH_{C^+}(R) for each X$^-$, the former seems more attractive than the latter in that it may function as a simple parameter describing the effects of both R and X on the reactivity.

The logarithms of the rate constants relative to that for butyl alcohol have a linear relationship with D(R$^+$OH$^-$) over the range of about six orders of magnitude in the rate constants (Fig. 5), indicating that the lower the heterolytic bond dissociation energy, the higher the rate constant. The activation energies also show a linear relationship with D(R$^+$OH$^-$) (Fig. 6); that is, the activation energy increases with an increase in D(R$^+$OH$^-$). Both linear correlations can readily be explained in terms of the heterolytic rupture of the C–O bond in the rate-determining step. Yamaguchi and Tanabe[13] found no primary isotope effect of C_β–D in the zero-order dehydration of 2-propanol-d_8 on silica–alumina at 160 °C; they proposed an E1-like mechanism. Thus, the presently obtained LFER, in cooperation with the isotope-effect data, strongly supports the E1-like character of the alcohol dehydration over silica–alumina.

Knözinger and Scheglila[8] found high primary isotope effects in the zero-order dehydration of C_β-deuterated butyl alcohols, $(CH_3)_2CDCH_2OH$, $C_2D_5CH(OH)CH_3$, and $(CD_3)_3COH$, on alumina at 120—200 °C. They deduced an E2-like mechanism which contains a certain degree of ionic contributions. Their activation-energy data on undeuterated alcohols[8,14] are also plotted in Fig. 6. These activation energies also fall on a straight line, which is separate from, but nearly the same in slope as the line for silica–alumina. Comparisons of the two linear correlations provide information concerning the rate-determining participation of the heterolytic C–O bond fission during the E2-like dehydration couse. The equality in the slope indicates that the heterolytic bond strength of the C–O bond plays as important a role in determining the activation energy for the E2-like dehydration as it does for the E1-like dehydration. The heterolytic loosening of the C–O bond in the transition state may not differ much in the two modes of dehydration.

Furthermore, the activation energy on silica–alumina is approximately 5 kcal/mol higher than that on alumina for each alcohol, as is shown in Fig. 6. Knözinger and Scheglila[8] also found that the deuterium effect on the preexponential factor, A_H/A_D, was approximately 0.01 for each alcohol. More recently, this abnormally low A_H/A_D ratio was taken as evidence by the same group of researchers[14] to demonstrate a certain tunnel contribution to the β-proton abstraction. The tunnel effect is also supported, though they did not claim so, by their own experimental results that the deuterium effect on the activation energy, E_D-E_H, was about 5 kcal/mol for each alcohol.[8] This effect greatly exceeds in magnitude the zero-point energy difference between the C_β–H and C_β–D stretching vibrations in the initial state, ΔE_0, which is about 1.1 kcal/mol for the substrates in question. The $E_D-E_H<\Delta E_0$ relation also provides strong evidence for proton tunneling.[15] The difference of about 5 kcal/mol for E_D-E_H is comparable to the activation-energy difference between silica–alumina and alumina for the undeuterated alcohol dehydration. The activation energies for deuterated alcohol dehydration on alumina and those for undeuterated alcohol dehydration on silica–alumina will, therefore, fall on a single straight line if they are plotted in Fig. 6. Since tunneling should be much less in the β-deuteron abstraction than in the β-proton abstraction, the observed tunneling contribution to the β-proton abstraction presumably explains most of the slight lowering of the activation energy in the dehydration of undeuterated alcohols over alumina. In addition, the stabilization of the transition state through the interaction of β-deuterium, probably, with a basic site does not seem very large. Therefore, it is highly probable that the activation energy for the E2-like dehydration is determined primarily by the heterolytic bond strength of the C–O bond, much as with that for the E1-like dehydration.

Figure 6 also shows a plot of the activation-energy data reported by Kibby and Hall,[9] who obtained them from the zero-order reaction rates on calcium-deficient hydroxyapatite at 150—400 °C; they presumed an E1-like mechanism for tertiary alcohol and an E2-like one

with an ionic character for primary and secondary alcohols. The sequence of increasing activation energy is the same as that of increasing $D(R^+OH^-)$. Isopropyl alcohol and *s*- and *t*-butyl alcohols fall on a single straight line, which is quite similar in both slope and the magnitude of activation energy to those for silica–alumina and alumina, although primary alcohols appear to follow a separate straight line. It is clear that, on this catalyst, the activation energy is also determined by the heterolytic bond strength of the C–O bond.

In spite of the fact that these three catalysts are quite different materials, the alcohol dehydrations catalyzed by them are very similar in the magnitude of the activation energy and its dependence upon $D(R^+OH^-)$. This may be a reflection of a similarity in the nature of the active centers which first attack the oxygen atom of the C–O bond. As such active centers, Knözinger and his co-workers,[3] and Kibby and Hall[9] proposed acidic surface hydroxyls on their catalysts. With silica–alumina, Brønsted acid sites are most likely to be active centers in view of the experimental finding[16] that the response of the ethanol dehydration rates to the Na^+-poisoning of silica–alumina is very similar to that of the cumene dealkylation rates, which have been believed to be determined by the Brønsted acidity. For alumina[17,18] and even silica–alumina,[19] on the other hand, another active-center model has been proposed in which incompletely coordinated aluminium ions in the surface are responsible for attacking the oxygen atom of the C–O bond. This problem, then, requires further investigations to be solved.

Minima in the Solubilities of Normal Alkane Derivatives with a Polar Group in Water

Nobuo NISHINO and Masao NAKAMURA

Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka 259-12

(Received October 6, 1977)

The change in the solubility in water with the temperature was measured for alkanols, alkylamines, and alkanoic acids. It has been found that a minimum exists commonly on the solubility-temperature curve. This minimum dissolution point, P_m, may be regarded as a characteristic point with respect to the solute. The change in the solubility with the temperature has been explained in terms of the increase in the partial molar enthalpy of the solute in solution with an increase in the temperature, which results from the breakdown of the ice-like structure of water formed around the nonpolar alkyl group. Both the concentration, x_m, and temperature, T_m, at point P_m decrease with an increase in the number of carbon atoms in the alkyl group, m. The decrease in $\ln x_m$ by the addition of one methylene group is steeper in the order of alkanoic acids, alkylamines, and alkanols, while the corresponding decrease in T_m shows the reverse order. In addition, T_m is related to the cohesive energy of the solute in the pure state.

Aqueous nonionic surfactant solutions suddenly become turbid above a certain temperature, which is called the cloud point,[1] while nicotine and like-compounds have both upper and lower critical consolution temperatures in water,[2,3] although a substance is usually more soluble at a higher temperature in an ordinary or regular solution.[4,5] Several concepts have been presented in attempts to interpret these anomalous solubility phenomena in water. One is that the hydrogen bonding between a water molecule and a polar group of the organic solute decreases as the temperature rises,[6] and another is that a nonpolar hydrocarbon or rare gas molecule in water promotes the formation of the structure of water around it, while the structure gradually breaks down with a rise in the temperature.[7–9] The above concepts, however, cannot explain the solubility phenomena quantitatively, and the states in water of organic compounds have not yet been understood sufficiently. In the present paper, in order to study the states of organic compounds in water, the change in the solubility with the temperature was measured for several normal alkane derivatives, which have a polar group in the molecule to increase the solubilities. A minimum was commonly observed on the solubility-temperature curve.

Experimental

Normal alkane derivatives as the solutes were selected from the 1-, 2-, and 3-alkanol, alkylamine, and alkanoic acid series, each of which is liquid over the temperature range under investigation. The samples are commercially available as G. R. -grade materials from Wako Pure Chemical Industries, Ltd.; the Kanto Chemical Co., Inc.; Nakarai Chemicals, Ltd.; the Sumida Chemical Co., Ltd., and the Tokyo Kasei Kogyo Co., Ltd. They were used without further treatment except for those of 1-alkanol series, which were dried over calcium oxide and kept in ampoules in contact with magnesium powder before use. The solvent was obtained by distilling ion-exchanged water from an alkaline potassium permanganate solution after refluxing for 15 h.

Twenty to thirty glass ampoules containing aqueous solutions of *ca.* 5 cm^3 of various concentrations near the solubility at room temperature for each compound were immersed in a water thermostat. The distinction between clean and turbid ampoules was made after a time long enough for equilibrium to be established, say *ca.* 2 h, at each temperature. Observations were made at 2- to 5-K intervals from 275 to 360 K. The smooth curve drawn to separate the clean and turbid regions in the concentration-temperature diagram was regarded as the solubility curve.

The heat of evaporation was estimated according to the vapor-pressure method described in a previous paper,[10] except for using a spinning-band type of precision distillation apparatus (Tokyo Kagaku Seiki Co.).

Results and Discussion

The solubilities in the mole fraction, x_2, measured are plotted against the temperature, T, in Figs. 1 and 2. Alkanols, alkylamines, and alkanoic acids commonly show decreasing and increasing solubilities with temperature in lower- and higher-temperature regions respectively. Each curve, then, has a minimum point

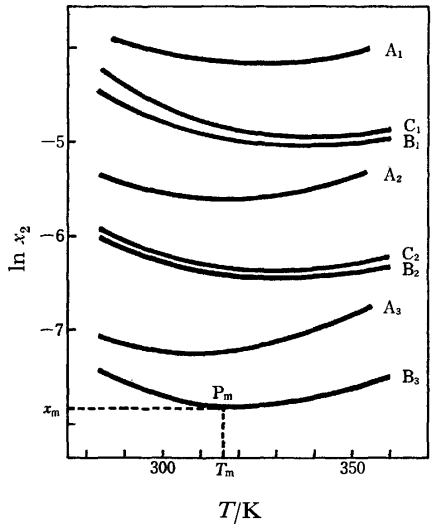

Fig. 1. Solubility of alkanol series in water as a function of temp.

in solubility, which is referred to as the minimum dissolution point, P_m, as is indicated in Fig. 1. This minimum point may be regarded as a characteristic point with respect to the solute in water as a solvent. The concentration and temperature at that point are termed the minimum dissolution concentration, x_m, and the minimum dissolution temperature, T_m, respectively. The appearance of these minima resembles the dependence of the critical micelle concentration, CMC, on the temperature, T, for aqueous surfactant solutions measured by Shinoda.[9] He has described how the iceberg formation of water molecules around the monodisperse solute rather enhances the CMC, the logarithm of which would be decreased linearly with T^{-1} if the solution behaved regularly, and the iceberg formation increases with the temperature depression.

Bohon and Claussen[11] have estimated the heat of solution from such solubility curves for aromatic compounds by assuming that the heat of solution is proportional to the tangent of the curve of $\ln x_2$ *vs.* T^{-1}. This assumption, however, is valid only when the organic phase in equilibrium with the aqueous solution contains no water or a constant amount of it, regardless of the temperature. It may be reasonable, nevertheless, to consider that the change in the solubility with the temperature shown in Figs. 1 and 2 is predominantly due to the increase in the heat of solution at an infinite dilution with the temperature, because the solubility of water in an organic phase is expected to vary less with the temperature. The heat of solution at an infinite dilution is the difference between the partial molar enthalpy of the solute in an infinitely dilute solution and the molar enthalpy in the pure state of the solute; in addition, the heat of solution is equal to the sum of the heat of evaporation of the pure solute and the heat of condensation of the solute from the vapor phase to the solution, according to Hess' law. The heat of evaporation may be assumed to be constant in the measured temperature range for each solute, because the logarithm of the vapor pressure decreases linearly with T^{-1}, as is shown in Figs. 5 and 6. The increase in the heat of solution, therefore, may be attributed mainly to the increase in the partial molar enthalpy of the solute in the solution through the heat of condensation, which shows that some endothermic changes proceed on and/or around the solute molecules with the temperature rise. Since all the solubility curves in Figs. 1 and 2 are similar in shape, regardless of the nature of the polar group, such endothermic changes may be attributed commonly to the nonpolar alkyl group. Frank and Evans[7] have described how the rare gases and hydrocarbon gases form icebergs when they dissolve in cold water; how, as the temperature is raised, these icebergs melt, giving rise to the enormous partial molar heat capacity of these gases in water, and how, at still higher temperatures, the heat of evaporation from the aqueous solution becomes negative. The solubility of most gases in water shows a minimum when plotted against the temperature. Following the above description, the solubility curves in Figs. 1 and 2 can be explained by considering that the ice-like structure of water is also formed around the nonpolar alkyl group of alkanol, alkylamine, or alkanoic acid in water, which structure breaks down as the temperature is raised.

The relations between $\ln x_m$ and the number of carbon atoms in an alkyl chain, m, for the respective series are shown in Fig. 3. The value of $\ln x_m$ decreases linearly with m for the 1- and 2-alkanol series, and these two lines are nearly parallel to each other. The decrease in $\ln x_m$ from 3-pentanol to 3-hexanol is nearly equal

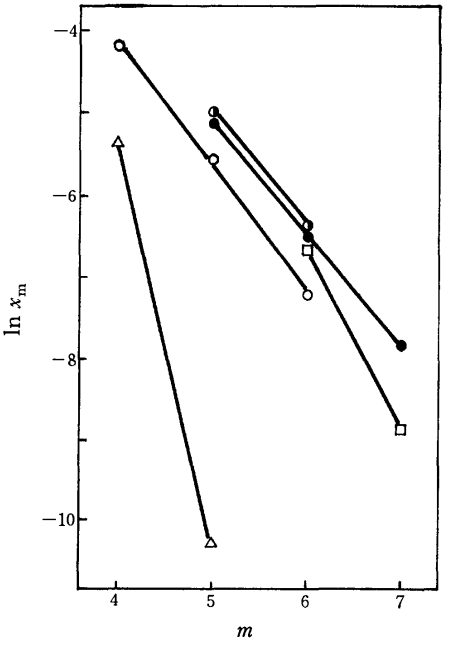

Fig. 3. Minimum dissolution concn as a function of number of carbon atom in alkyl group.
○: 1-Alkanol, ●: 2-alkanol, ◑: 3-alkanol, □: alkylamine, △: alkanoic acid.

to the slopes of the straight lines for the 1- and 2-alkanol series. The decrease of $\ln x_m$ by the addition of one methylene group is different according to the kind of polar group attached to the molecule; the order is as follows:

$$-COOH > -NH_2 > -OH.$$

It has previously been determined[12] that the slopes of the logarithm of solubility *vs.* m values of more than 9 both for the alkanoic acid series at 298 K and for the alkylamine series at 295 K are very close to the slope for the alkanol series in Fig. 3. The larger decrease for the alkylamine or alkanoic acid series in Fig. 3 can then be expected to be reduced gradually to that for the alkanol series, when m increases up to the range out of the influence of the polar group. These phenomena may be interpreted in terms of a higher free energy of a methylene group under the influence of the attached polar group than that out of the influence of the polar group.[13] The farther the methylene group is apart from the polar group, the easier is the structure of water to be formed around it, since the effect of the polar group decreases with the distance. The steeper decrease in $\ln x_m$ for the alkanoic acid series than for the alkylamine series in Fig. 3 can be explained by the smaller carbon number, m, in the former series, although the former series have slightly weaker polarities or dissociation constants.[14] In addition, in the alkanol series, the closer the OH groups are to the center, the more soluble they are when they have the same m, as is shown in Fig. 3. This may be explained in terms of the increasing number of methylene groups within the influence of an OH group as the OH group is closer to the center of the molecule, but the difference between the 2- and 3-alkanol series is not appreciable.

The minimum dissolution temperature, T_m, also decreases with an increase in the number of carbon atoms, m, for those series, as is shown in Fig. 4. The decrease in T_m upon the addition of one methylene group is steeper in the reverse order of that of $\ln x_m$ in Fig. 3. The T_m values show the following order:

3-alkanol > 2-alkanol > alkylamine > 1-alkanol > alkanoic acid,

if m is constant in the range of 5 and 6.

The characteristic point, P_m, of a solute in an aqueous solution is expected to be related to the characteristics of the solute itself, especially, for example, the cohesion between molecules. The heat of evaporation, $\Delta_e h_2^\circ$, can be considered a measure of the cohesive energy.[10] The vapor pressures, p, of the solutes in their pure states

Marks are the same as in Fig. 7.

were measured in the temperature range between 305 and 445 K. As has been mentioned above, $\ln p$ decreases linearly with T^{-1} for each solute, as is shown in Figs. 5 and 6. The heat of evaporation, $\Delta_e h_2^\circ$, was estimated from the slope according to the Clausius-Clapeyron equation. It has been found that $\Delta_e h_2^\circ$ has a certain relation to T_m except for the alkylamine series, as is shown in Fig. 7. The relation may be expressed by

$$T_m = \frac{223}{\Delta_e h_2^\circ - 41.0} + 288, \qquad (1)$$

as is shown as the straight line in Fig. 8 and as the curve in Fig. 7. It should be noted that Eq. 1 should be applied to the compounds having $\Delta_e h_2^\circ$ values higher than 41.0 kJ mol^{-1} and T_m values larger than 288 K.

A Localized Molecular Orbital Calculation of Chemically Interacting Systems. Interaction between Amines and Carbonyls

Tsutomu MINATO, Hiroshi FUJIMOTO, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 11, 1977)

The bond interchange in the course of the addition of amine to carbonyl has been studied by means of a localized molecular orbital method with a clear chemical-bond concept, and the mechanism of the addition has been elucidated theoretically. It is ascertained by the present calculation that the charge transfer interaction from the highest occupied molecular orbital of amine to the lowest unoccupied molecular orbital of carbonyl is of importance to form a new nitrogen-carbon bond. Furthermore, the stereospecificity of the nucleophilic addition to a double or triple bond has been studied. When an intermediate is created by the addition of a nucleophile to the unsaturated bond, it is suggested that the intermediate is reactive for the electrophilic attack on the side *trans* to the new bond formed by the first attack. This is reasoned in terms of the mode of orbital interaction.

Addition of amine to carbonyl is one of the simplest nucleophilic reactions.[1] Recently, the course of the addition was studied experimentally by analyzing the molecular structure of adducts of amine to ketone with presumably different strength of the interaction.[2] The path of the approach of amine to carbonyl revealed in the work is expected to provide us with valuable information for a theoretical study of chemical reactions. In general, the path of the chemical reaction is governed by various energy factors in a molecular orbital (MO) viewpoint.[3] A partitioning analysis of the interaction energy suggested that the exchange and charge transfer (CT) interactions are generally of importance in the interaction between two reagents, while the Coulomb interaction plays a dominant role in an early stage of ionic reactions.[4] Even in ionic cases, however, the CT interaction is the origin of the formation of new chemical bonds.[5]

In discussing the orientation and stereoselection in chemical reactions, the CT interaction from the highest occupied (HO) MO of electron donors to the lowest unoccupied (LU) MO of electron acceptors is usually of a particular importance.[5] The HOMO and LUMO of many molecules, however, are delocalized over p atomic orbitals (AO's) of component heavy atoms and hydrogen 1s AO's. The s AO's of first and second row atoms are found for the most part in low-lying MO's. When a configuration interaction expansion of the wavefunction of the interacting system is carried out in terms of various kinds of the electron configurations, there is non-negligible contribution of the charge transferred and locally excited configurations from low-lying MO's, in addition to the major charge transferred configurations from the HOMO to the LUMO. Therefore, the formation of new bonds and the loosening of old bonds, together with the rehybridization at the reaction centers, may be interpreted by means of orbital interactions between the isolated molecules including the HOMO-LUMO interactions.

In general, the MO's of a sizable molecule are delocalized over the constituent AO's and the bonding property of a given atom pair is discussed by means of the electron density contour,[6] the overlap population[7] and the bond energy.[8] On the other hand, the method of the Edmiston-Ruedenberg localized MO (LMO)[9] presents us an alternative way of visualizing the chemical bonds in a chemically graspable manner. It may be worthwhile to show that the application of the LMO method to chemically interacting systems is really helpful in disclosing the mechanism of bond interchange and rehybridization in the course of the reaction. These are interesting problems in organic chemistry.

In the present paper, we first apply the LMO method to the chemically interacting system composed of amine and carbonyl in order to obtain a theoretical way of representing the bond interchange and rehybridization in the course of the addition reaction. Next, the mechanism of the addition is clarified by the mode of the orbital interaction mentioned above. Furthermore, the general aspect of the nucleophilic addition to unsaturated bonds is explained schematically in terms of the shape of MO's of the isolated reactants.

Calculation of Assumed Reaction Models

Method of Calculation. In this study, a system composed of an ammonia and a formaldehyde is selected as a reaction model in the calculation of the LMO's. The canonical MO's (CMO's) of the isolated molecules and the reacting system which are transformed into the LMO's[9] are obtained by the INDO MO method.[8]

Figure 1 illustrates the geometry of assumed reaction models. In the present calculation, three variables (R, r, and θ) are changed. The geometry of ammonia[10] is kept frozen throughout the calculation, whereas that of formaldehyde[11] is deformed. The parameter, R, means the intermolecular distance between the nitrogen atom (N) of ammonia and the carbon atom (C) of formaldehyde. "r" is the distance of the C=oxygen (O) bond of formaldehyde, and "θ" is defined as the angle between the C=O bond and the methylene plane of formaldehyde. A preliminary calculation on this system gives a result which is in a fairly good agreement with the experimental reaction path.[2] In consideration of the preliminary result and the experimental reaction path, the angle between the N···C line and the C=O is fixed to be 107° in the present calculation. The N···C distance, R, is restricted to the range, 3.0—2.0 Å. At R=3.0 and 2.5 Å, the geometry of formaldehyde is not deformed (r=1.21 Å and θ=0°),[11] whereas at R=2.2

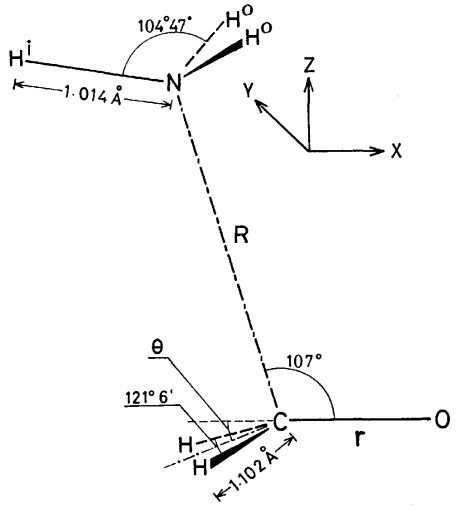

Fig. 1. The assumed reaction model employed for the calculation of the LMO.

and 2.0 Å it is deformed to give the minimum total energy of the interacting system at each value of R (r=1.25 Å, θ=10° at R=2.2 Å and r=1.27 Å, θ=15° at R=2.0Å). On these models, the LMO's of the reacting system are calculated.

The energy of each LMO (B_i) is calculated to study the formation and disappearance of the bond.[12] The energy, B_i, is represented by the sum of the electron energy (E_i^{el}) of the LMO and the nuclear repulsion energy.

$$B_i = E_i^{el} + E_i^{n}. \quad (1)$$

The nuclear repulsion energy is partitioned and assigned to the bonds according to the procedure introduced by Parks and Parr.[13] E_i^n in Eq. 1 is the partitioned nuclear repulsion energy assigned to the bond i.

Furthermore, the LMO is expanded in terms of the CMO's of ammonia and formaldehyde in order to see the origin of the bond formation, the bond cleavage and the rehybridization in the course of the reaction.[5b]

$$\phi_{LMO} = \sum_{i=1}^{7} C_i a_i + \sum_{j=1}^{10} D_j b_j. \quad (2)$$

ϕ_{LMO} is one of the LMO's of the reacting system. The CMO of ammonia is defined a_i, while that of formaldehyde is named b_j. The suffix attached to the right bottom of "a" and "b" stands for the numbering order counted from the lowest occupied MO.

Results. In Fig. 2, the CMO's of ammonia and formaldehyde are schematically depicted. In Fig. 3, the shapes of the LMO's of these are also schematically pictured. They are three N–H (hydrogen) bond orbitals and an N lone pair orbital in ammonia, and two C–H bond orbitals, two O lone pair orbitals and two C–O bent bond orbitals in formaldehyde. The upper C–O bent bond orbital is hereafter called the CO bond 1, and the lower one is called the CO bond 2. For each value of R, the energies of LMO's are calculated. The result is given in Table 1. In Table 1, it is shown that the N lone pair orbital is stabilized. This corresponds to the formation of the N···C bond. On the other hand, the two C–O bent bond orbitals are

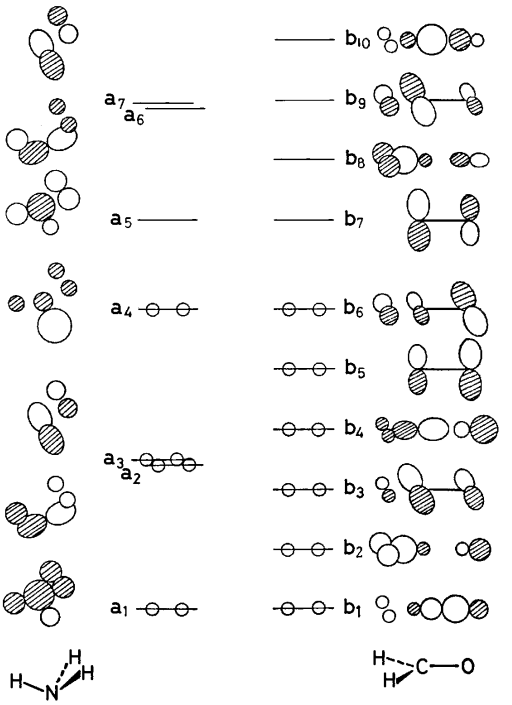

Fig. 2. The shape of the CMO's of the isolated ammonia and formaldehyde.

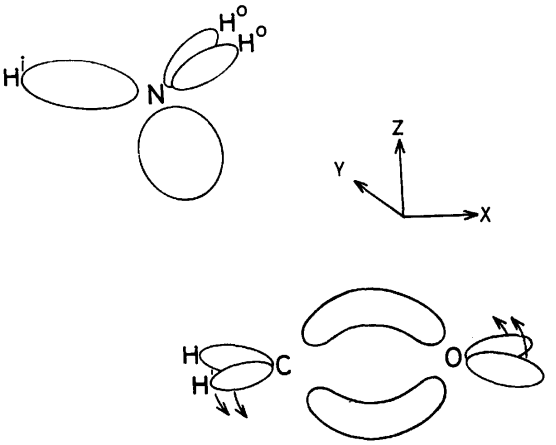

Fig. 3. The shape of the LMO's of the isolated ammonia and formaldehyde.

destabilized, indicating the weakening of the bonds. Interestingly, the CO bond 2 is loosened more easily than the CO bond 1, and the latter is even stabilized at R=2.0 Å. A more detailed discussion on this point will be given later. It is found from Table 1 that the remaining bond orbitals do not change much in comparison with the three bond orbitals mentioned above.

Let us examine the change in the LMO's for the N lone pair and the two C–O bonds. These bonds are considered to participate significantly in the addition reaction. In Fig. 4, the LMO corresponding to the N lone pair is pictured. It is shown that the N lone pair orbital begins to deform so that it would include the component of the carbon AO's. The s-nature of the N lone pair orbital of the isolated ammonia is calculated to be 35.5%, and that at R=2.0 Å is found

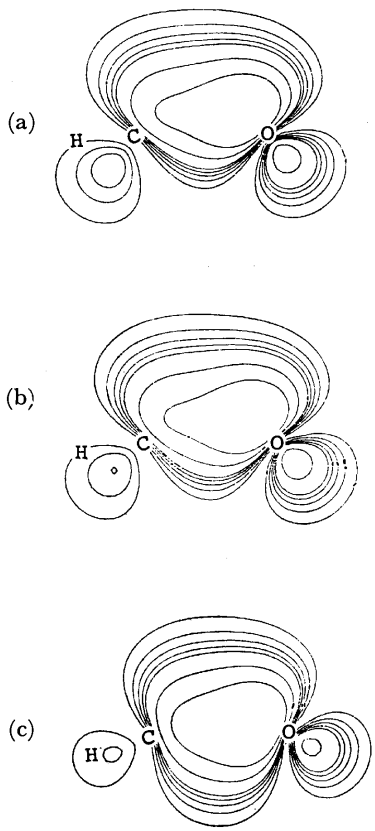
to be 35.3%. It is suggested, therefore, that ammonia gets into the interaction with formaldehyde, without changing its hybridized state significantly. The N lone pair orbital at R=2.5 Å corresponding to the N···C bond in the reacting system is expanded in terms of the CMO's of the two reactants.

$$\psi_{\text{N lone pair}} = 0.933a_4 - 0.343a_1 + 0.110b_7 + 0.020b_8 + \cdots \quad (3)$$

In Eq. 3, the coefficients larger than 0.02 (absolute value) are displayed. From Eq. 3, it is found that in addition to the dominant interaction between the HOMO (a_4) of ammonia and the LUMO (b_7) of formaldehyde, there are certain contributions of the low-lying and high-lying sigma MO's (a_1 and b_8). The former sigma MO, a_1, contributes to build up a hybridized orbital of ammonia (sp^3), and the latter, b_8, contributes to the change of the hybridization of the carbon of formaldehyde ($sp^2 \rightarrow sp^3$). The CT interaction from the HOMO (a_4) to the LUMO (b_7) is primarily important in the formation of the new N···C bond, and then the low-lying and high-lying MO's contribute to the rehybridization of the reacting centers.



(a) (b) (c)

Fig. 5. One of the bent bond orbitals of formaldehyde (CO bond 1). The contour line means the same as is used for the lone pair orbital.

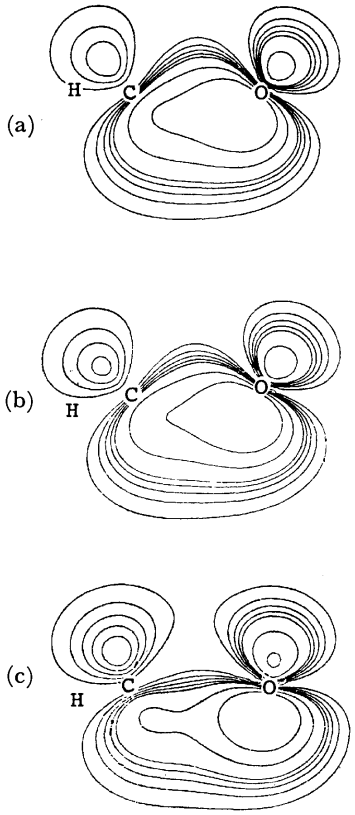

Fig. 6. The other bent bond orbital of formaldehyde (CO bond 2). The contour line means the same as is used for the lone pair orbital.
(a); The other bent bond orbital of the isolated formaldehyde. (b); The bent bond orbital at R=2.2 Å. (c); The bent bond orbital at R=2.0 Å.

In Figs. 5 and 6, the two bent bond orbitals of the C=O double bond are drawn. Let us compare Fig. 5 with Fig. 6. This comparison, together with the energy change of the bond orbitals in Table 1, shows that the CO bond 1 is converted into the CO sigma bond, whereas the CO bond 2 is transformed into the O lone pair. This result seems to be interesting in regard to the stereospecific phenomena observed in the nucleophilic additions as will be shown in the next section.

The result obtained here is explicable in terms of the orbital interaction in the following manner. In Fig. 7, the mode of the orbital interaction of the HOMO of ammonia with the π (b_5) and π^* (b_7) orbitals of formaldehyde is schematically illustrated. The interaction of the a_4 with the π and π^* leads to two occupied MO's (ψ_1 and ψ_2) and one unoccupied MO (ψ_3) of the composite system. Among the three MO's, ψ_1, ψ_2 and ψ_3, the mixing of the π and π^* through the a_4 is the largest in the ψ_2.[14] If our attention is focused on the sign of the component MO's the ψ_2 is represented[15] as

$$\psi_2 = a_4 - \pi + \pi^*.$$

The mixing of the π and π^* through the a_4 contributes to the polarization of the electrons in the direction from the carbon atom to the oxygen atom, although this mixing does not give the difference of the polarization between the upper and lower sides of the molecular

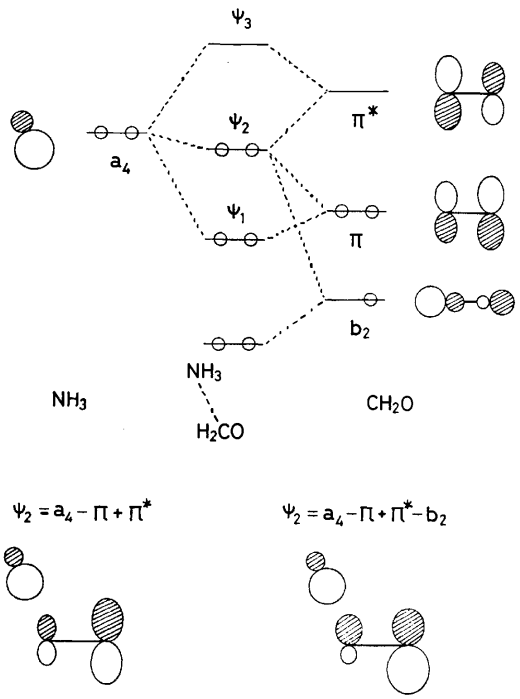

Fig. 7. The schematic representation of the electron polarization by the orbital mixing of the b_2, π, and π^* through the a_4.

plane of formaldehyde. However, the b_2 mixes into the ψ_2 through the interaction with the a_4, and then the ψ_2 is rewriten[15] as

$$\psi_2 = a_4 - \pi + \pi^* - b_2.$$

Consequently, the polarization of the C=O bond is more effective in the lower side of the molecular plane of formaldehyde than the upper side. From the above result, it is considered that in the addition of ammonia to formaldehyde one of the C=O bent bond orbitals (CO bond 1) is converted into the C–O sigma bond and the other (CO bond 2) is transformed into the O lone pair. That is, the O lone pair stays as far away from the N···C bond as possible.

In the present calculation, the LMO's representing the C–H bonds of formaldehyde are shown to be pushed down by the approach of ammonia as is indicated by the arrow in Fig. 3, whereas the O lone pair orbitals are lifted, when the nuclear framework is kept unchanged. Such rehybridizations on the carbon atom and oxygen atom are obviously in favor of the change of the CO bond 2 to the O lone pair spreading over the region opposite to the initial attack at the carbon atom. The rehybridization of the carbon is explicable in terms of the orbital mixing of the b_2, b_5, and b_7 through the interaction with the a_4. This orbital mixing is shown in Eq. 4.

$$\psi_{\text{CH bond}} = 0.238b_1 + 0.624b_2 + 0.586b_3 - 0.226b_4 + 0.018b_5 - 0.395b_6 - 0.039b_7 + \cdots. \quad (4)$$

In Eq. 4, the expansion coefficients are obtained at R=2.0 Å and the values larger than 0.015 (absolute value) are displayed. The rehybridization on the oxygen is also explicable in the way similar to that on the carbon. In Eq. 5, the expansion coefficients which

are obtained at R=2.0 Å are shown and those smaller than 0.015 (absolute value) are neglected.

$$\psi_{\text{O lone pair}} = 0.345b_1 - 0.316b_2 + 0.395b_3 - 0.491b_4 + 0.198b_5 + 0.586b_6 - 0.016b_7 + \cdots. \quad (5)$$

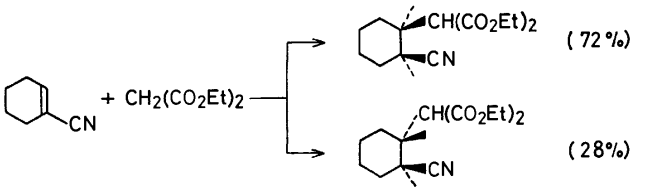
In Eqs. 4 and 5, the coefficient of the a_4 is very small, but when the CMO's of the interacting system are expanded by the use of those of the isolated molecules, the mixing of the b_2, b_5, and b_7 is shown to be due to the interaction with the a_4. It should be noted that the LMO's representing the N–H bonds are not changed markedly in the present calculation.

Let us summarize the results obtained so far. When the C=O double bond of the formaldehyde is represented by two bent bond orbitals, the attack of ammonia to the C=O bond is shown to bring about the breaking of the bent bond orbital on the side opposite to the attack. The bond orbital is shown to be converted into the O lone pair orbital having large amplitudes on the side opposite to the initial attack at the carbon atom. Furthermore, the C–H bonds and the O lone pairs are shown to rotate to assist the transformation of the bent bond orbital into the O lone pair. In the present calculation, the system composed of ammonia and formaldehyde is selected as a reaction model. It is reasonable to consider that a compound with a double bond or triple bond (A=B or A≡B) has π, π^*, and σ MO's which are delocalized over A and B. Consequently, the result obtained by the present calculation on such a simple system seems to be generalized for the nucleophilic additions to the unsaturated compounds. The electron pair dislodged from the double bond or triple bond will stay as far away from the electron pair of the nucleophile as possible. Then, the addition to an unsaturated bond initiated by a nucleophile is expected to be trans if the intermediate reacts with an electrophile without the change of its conformation. In the next section, this expectation will be compared with the experimental data reported so far.

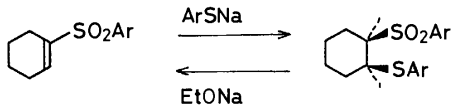
Comparison with Experimental Results

In the previous section, the change of the chemical bonds in the course of the addition of ammonia to formaldehyde was investigated by the use of the LMO method. The intermediate produced by the initial attack of the nucleophile to a double bond or triple bond is predicted to be more reactive for the *trans*-approach of the electrophile than the *cis*-approach. In this section, the validity of the prediction is checked by investigating the stereochemistry of the products of the nucleophilic additions reported so far.

First, let us investigate the nucleophilic additions to double bonds. The additions are known to be stereospecific.[16,17] In the reaction of 1-cyanocyclohexene with malonic ester, 72% of product is the *cis* and only 28% the *trans* isomer, and probably no equilibration of the products takes place.[16] Evidently, this result is attributable to the preference of *trans* addition.

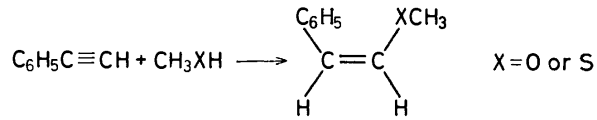


Similarly, the addition of *p*-toluenethiol to 1-(*p*-tolylsulfonyl) cyclohexene gives a *cis* product.[17]

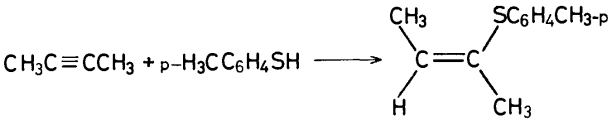


(Ar = p-$CH_3C_6H_4$-)

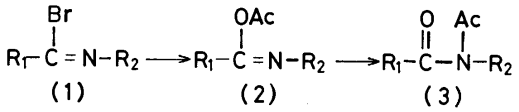
The stereochemistry of the nucleophilic addition to acetylene is known as *trans*.[18,19] The addition of sodium methoxide in methanol to phenylacetylene gives *cis*-*β*-methoxystyrene,[18] and a similar addition of sodium methanethiolate gives *cis*-*β*-(methylthio)stylene.[19]



The product obtained from sodium *p*-toluenethiolate and 2-butyne, 2-(*p*-tolylthio)-2-butene, is also assigned the *trans* structure on the basis of infrared evidence[19] and this reaction appears to involve the *trans* addition.

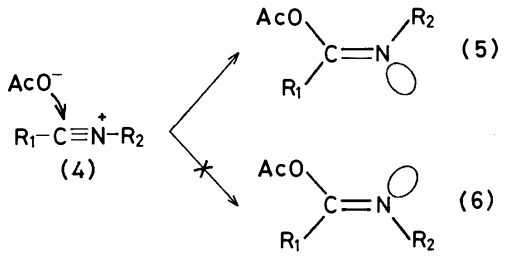


Hegarty and McCormack have suggested from the experimental result that the nucleophilic attack on alkylidyneammonium ion by acetate ion is stereospecific, giving rise to just a single imine isomer.[20]



The treatment of *N*-(α-bromoalkylidene) amine (**1**) in 1 : 1 acetone–water in the presence of sodium acetate gives the *O*-acyl compound (**2**), which is uncontaminated by the isomer (**3**). The isoimide structure is rare in organic chemistry and is generally limited to cyclic materials in which the rearrangement to the imide is inhibited.[21] They attributed the stability of the *O*-acyl structure to its existence in the configuration (**5**) in which the nucleophilic lone pair electrons on the neighboring nitrogen and the acyl group would be *trans*. It has been demonstrated that the starting bromide (**1**) reacts *via* rate-determining alkylideneammonium ion (**4**) formation in aqueous acetone.[22] They

have concluded that the nucleophilic attack by acetate ion on (**4**) must, therefore, be stereospecific as is shown in the following scheme.[20]



Their suggestion is in agreement with the prediction in the present work.

Conclusion

In this work, the LMO method is applied to the addition of ammonia to formaldehyde. The bond interchange in the course of the reaction is investigated and some comparative studies between the present results and the experimental data reported so far are made. Then, the conclusion obtained here is as follows.

In the addition of ammonia to formaldehyde, the LMO method is convenient to represent the bond interchange in the course of the reaction. In this addition reaction, the electron pair contributed by ammonia and that dislodged from the double bond of formaldehyde tend to stay as far away from each other as possible. It is suggested that this trend is general in nucleophilic additions to an unsaturated bond. Therefore, the intermediate created by the attack of a nucleophile to the unsaturated bond is more reactive at the *trans* position to the new bond than at the *cis* position.

The authors would like to express their gratitude to the Data Processing Center, Kyoto University, for its generous permission to use the FACOM 230-75 computer. The MO calculation was carried out under financial support of the Ministry of Education of Japan (Grant-in-Aid 139012).

(Received October 13, 1977)

α-Cyclodextrin (α-CDx) forms a 1: 2 crystalline complex with *m*-nitrophenol (*m*-NP). The crystal structure was determined by the X-ray method. The crystal is orthorhombic, and the space group is $P2_12_12$ with $Z=2$. The cell dimensions are $a=22.231(7)$, $b=16.865(6)$, and $c=8.152(1)$ Å. The structure was solved on the basis of the nearly isomorphous structure of the α-CDx–sodium benzenesulfonate complex by using 2246 reflections, and refined by the block-diagonal least-squares method to the final *R*-value of 0.10. The framework of the crystal is built up of a stack of α-CDx molecules with a head-to-tail arrangement along the two-fold axis, showing a channel-type structure. Two *m*-NP molecules are statistically disordered on the two-fold axis. One is located in the channel, while the other is sandwiched between the α-CDx molecules. In the channel, the nitro group of *m*-NP is inserted into the α-CDx ring from the secondary hydroxyl side, and the phenolic hydroxyl group is hydrogen-bonded to the primary hydroxyl group of the next α-CDx molecule. The enthalpy change was calculated for the complex formation in an aqueous solution. The calculated results are in qualitatively agreement with the observed values. The catalytic ability of α-CDx in the hydrolysis of substituted phenyl acetates was discussed on the basis of the structural data.

α-Cyclodextrin (α-CDx), which is a doughnut-shaped oligosaccharide consisting of α-1,4-linked six D-glucose residues, forms a number of inclusion complexes with a variety of guest molecules in aqueous solutions and in the crystalline state.[1,2] In solution, α-CDx catalyzes several chemical reactions,[3] so it has been referred to as enzyme model. The stereospecific catalysis has been observed in the hydrolysis of substituted phenyl acetates;[4] *m*-nitrophenyl acetate decomposes about fifty times faster than *p*-nitrophenyl acetate. In the previous paper,[5] it was shown that the low catalytic ability of α-CDx in the hydrolysis of *para*-substituted phenyl acetates can be ascribed to the structure of the α-CDx–ester inclusion complex. The X-ray analysis of the α-CDx–*m*-nitrophenol (1: 2) complex was carried out to investigate the geometry of inclusion in relation to the stereospecificity of the α-CDx-catalyzed reactions as well as the α-CDx–substrate interaction. The energy of the complex is calculated by using the structural data to investigate the intermolecular force for complex formation.

Experimental

A yellowish and needle-like crystal of the α-CDx–*m*-NP (1:2) complex was obtained by allowing an aqueous solution containing α-CDx and *m*-NP with a 1: 1 molar ratio to stand. The determination of lattice parameters and the intensity measurement were carried out on a Rigaku automatic four-circle diffractometer with graphite-monochromated Cu $K\alpha$ radiation. The crystal was enclosed in a quartz capillary with a small amount of water, since the crystal breaks up in the air. 2246 independent reflections with $|F_o|\geqq 3\sigma(F)$ were collected up to 120° in 2θ by using the 2θ-ω scan technique. No correction was made for absorption and extinction. The crystal data are given in Table 1.

Determination and Refinement of the Structure

The crystal of the α-CDx–*m*-NP complex is nearly isomorphous with the crystals which have the channel-type structure. A set of coordinates of α-CDx found in the α-CDx–sodium benzenesulfonate complex[6] was used to calculate the initial phases, which were refined by the block-diagonal least-squares method. The *m*-NP and water molecules were found on an electron-density map. The primary hydroxyl groups of α-CDx were found to be statistically disordered. Each occupancy factor of 0.5 was estimated from the electron-density map, but the values were not refined. The determination of the atomic parameters of the *m*-NP molecule (*m*-NP-2) located on the c axis failed, owing to the disordered structure. The position and orientation of *m*-NP-2 were then determined by the rigid-body least-squares method; the structure of *m*-NP-2 was built up by using the bond distances and angles of *p*-NP in the α-CDx–*p*-NP complex.[5] The atomic parameters of the other molecules were refined by the block-diagonal least-squares method. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$, with $w=1.0$ for all reflections. The final *R*-value was 0.10. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[7] The atomic parameters are listed in Table 2. The observed and calculated structure factors are given in Table 3.**

** Tables 3 and 4 are kept as a Document at the office of The Chemical Society of Japan (Document No. 7815).

Description and Discussion of the Structure

The structure and numbering scheme of the complex are shown in Figs. 1 and 2. The schematic drawing of the crystal structure is given in Fig. 3. The α-CDx molecules are stacked along the two-fold axis to form an endless cylinder, showing a channel-type structure. One *m*-NP molecule (*m*-NP-2) is included in the cylinder, while the other (*m*-NP-1) is located outside the α-CDx ring.

Structure of α-CDx. Bond distances, angles, and conformation angles are given in Tables 4—6. The geometrical data for α-CDx are shown in Table 7. The bond distances and angles are in good agreement with those found in the other α-CDx complexes with the channel-type structure.[6,8-10] The primary hydroxyl groups are statistically disordered, showing *gauche-trans* and *gauche-gauche* conformations. The C–O bonds of these groups are abnormally short, but a similar shortening of the disordered C–O bond has been observed in α-L-sorbose[11] and the α-CDx complexes with Methyl Orange.[9] The α-CDx ring is distorted from the regular hexagonal symmetry owing to the inclusion of the planar molecule. The diagonal O(4, G3)···O(4, G3*) distance is longer by 0.4 Å than the O(4, G2)··· O(4, G2*) distance. The distortion of the α-CDx ring

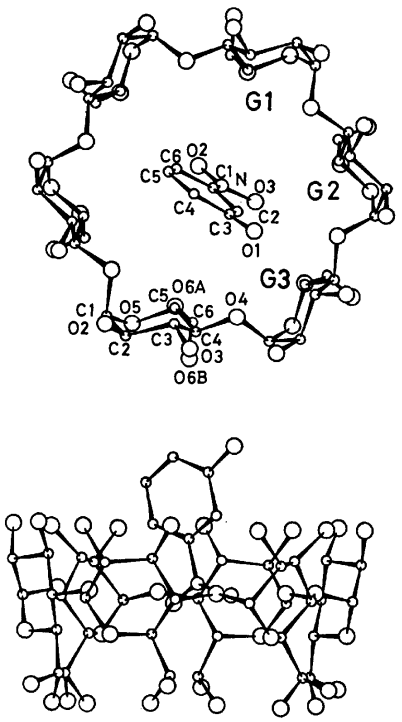

Fig. 1. The structure and numbering scheme of the α-cyclodextrin–*m*-nitorophenol complex.

Table 5. Average bond distances and angles for the glucose residue

Standard deviations given in parentheses were estimated according to $\sigma=[\sum_{i=1}^{3}(x_i-\bar{x})^2/2]^{1/2}$, where x_i is the bond distance or angle in the i-th glucose residue and $\bar{x}$ is the average value. A prime (′) indicates an atom in the adjacent glucose residue.

is small compared with the α-CDx–*p*-NP complex; the maximum difference in the O(4)···O(4) distances is 0.9 Å in the *p*-NP complex. The O(4)···O(4) distances between the adjacent glucose residues indicate that the deformation of the pyranose ring is also small in the *m*-NP complex.

O(2, N1)–N(1, N1)–O(3, N1)	120.4(24)

m-NP-1 shows the two-fold symmetry. The bond distances and angles (Table 8) are normal. The nitrophenyl group of *m*-NP-2 is not parallel to the two-fold axis, but makes an angle of 14.2°. The *m*-NP-2 molecule seems to be loosely bound, since the average thermal factor of the molecule is relatively large (22.7 Å^2).

Geometry of Inclusion. Intermolecular distances between α-CDx and *m*-NP-2 are given in Table 9. In the channel, the *m*-NP-2 molecules are located at a position similar to that of the *N,N*-dimethylaminophenyl group found in the Methyl Orange complexes.[9] The nitro group is inserted into the α-CDx cavity from the secondary hydroxyl side. The phenolic hydroxyl group is hydrogen-bonded to O(6A, G3) of the next α-CDx molecule. The benzene ring is surrounded by O(3)···O(6) hydrogen bonds. Thus, the adjacent α-CDx molecules are connected not only by the O(3)···O(6) hydrogen bonds, but also by the guest molecule. The nitro group is in close contact with the glycosidic oxygen atom.

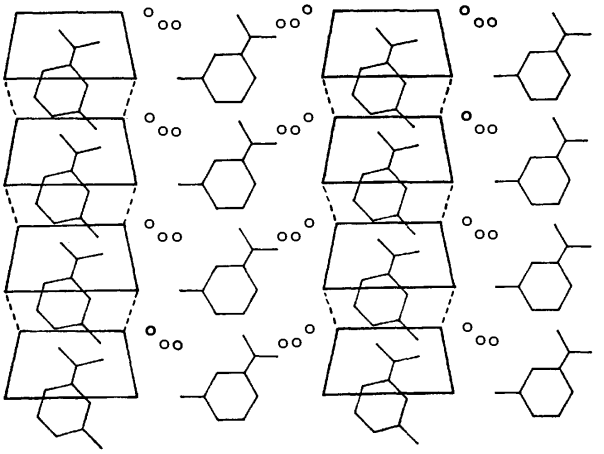

Fig. 3. A schematic drawing of the crystal structure. Circles indicate water molecules. Broken lines denote hydrogen bonds linking α-cyclodextrin molecules along the channel.

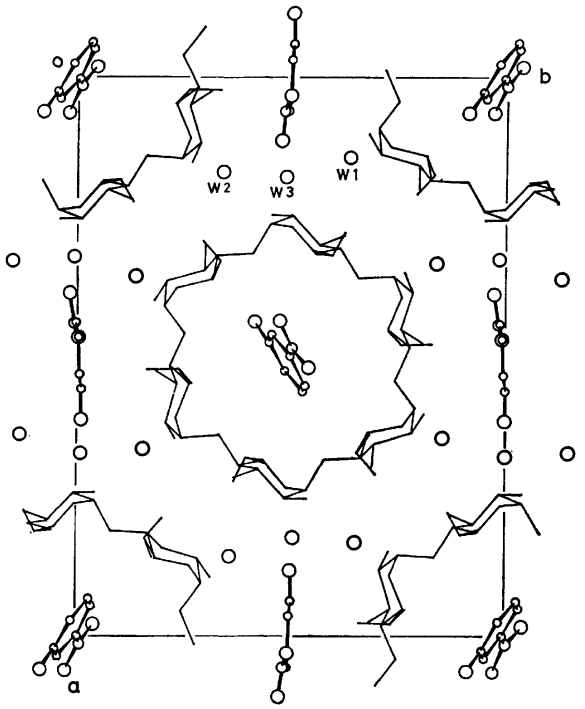

Fig. 4. The crystal structure projected to the ab plane. Circles indicate atoms in water and *m*-nitrophenol molecules.

The shortest distance is 2.922 Å, which is slightly shorter than the normal van der Waals contact of 3.04 Å.[12]

Crystal Structure. The crystal structures are shown in Figs. 4 and 5. The framework of the crystal is built up of a stack of α-CDx molecules with the head-to-tail arrangement along the two-fold axis. The *m*-NP-1 molecule is located nearly parallel to the ac plane in the space between the α-CDx molecules. The phenolic hydroxyl group forms two hydrogen bonds with O(W3) and O(2, G2) (Table 9). The benzene ring is sandwiched by the two α-CDx molecules. Water molecules are distributed in the space outside the channel, and they are linked each other by hydrogen bonds. W1 and W2 are also found in the other channel-type crystals,[6,8–10] but W3 is replaced by the sodium or potassium ion. W1 and W2 form O(2)···water···O(5) hydrogen bonds connecting the adjacent two α-CDx molecules along the channel. The space where *m*-NP-1 is located is filled with water molecules in the other channel-type crystals.

The channel-type structure with the head-to-tail arrangement of α-CDx molecules has been observed in the complexes with ionic guests. In these complexes, the primary hydroxyl groups of α-CDx form hydrogen bonds with the ionized group of the guest molecule. In the *m*-NP complex, however, the guest molecule has no ionized group. The phenolic hydroxyl group is hydrogen-bonded to the primary hydroxyl group of α-CDx. Therefore, the ionic guest is not necessarily required to form the channel-type structure, but the hydrogen bond with the primary hydroxyl group seems to be important.

Calculation of the Heat of the Complex Formation in Aqueous Solution

Method of Calculation. In the crystalline state, the uncomplexed α-CDx molecule contains two water molecules in its cavity.[13] If we assume the same structure in aqueous solution, the two water molecules will be released by the complex formation. The heat of the complex formation of α-CDx with *m*-NP and *p*-NP in aqueous solution was calculated for the following equilibrium at 25 °C:

$$\alpha\text{-CDx}\cdot 2H_2O + \text{guest} \rightleftarrows \alpha\text{-CDx–guest} + 2H_2O. \quad (1)$$

The enthalpy change is expressed as

$$\Delta H = H(\alpha\text{-CDx–guest}) + H(2H_2O) - H(\alpha\text{-CDx}\cdot 2H_2O) - H(\text{guest}), \quad (2)$$

$$= \Delta H^s + \Delta H^c + \Delta H^i, \quad (3)$$

where ΔH^s, ΔH^c, and ΔH^i are the enthalpy changes for the solvation, the conformation, and the interaction of α-CDx with the included molecules, respectively. The interaction energy and conformational energy were calculated on the basis of the non-bonded interatomic interaction.[6] The procedure of evaluating the solvation energy is generally the same as used in the earlier work,[6] but the following modifications were made: (1) the cavity term was calculated according to Pierotti[14] and (2) the dipole-dipole interaction was taken into account in the calculation of the electrostatic term (see Appendix).

Parameters. The van der Waals volumes of the

complexes were estimated from the X-ray data, and those of the other molecules were calculated by using the van der Waals volumes of atoms and groups.[12] The group dipole moments were taken from the literature[15] and the average polarizabilities were estimated from the atomic polarizabilities.[16] The coefficients of the Lennard-Jones potential function were calculated according to Goebel *et al.*[17,18] The atomic charges of the glucose residue were taken from Rao,[19] and those of *m*-NP and *p*-NP were calculated by the CNDO/2 MO method.[20]

Results of the Calculation and Discussion

The calculated enthalpy changes are given in Table 12. These values are in qualitatively agreement with the observed ones.[21] The enthalpy change of the *p*-NP complex is three times greater than that of the *m*-NP complex. In both complexes, the effect of the solvation energy is small and negative for the complex formation. The hydrogen-bond energy was not included in the calculation, but a part of it was taken into account in terms of the electrostatic energy and the van der Waals energy. The contribution of the hydrogen-bond energy to the complex formation has been considered to be small in aqueous solution.[3]

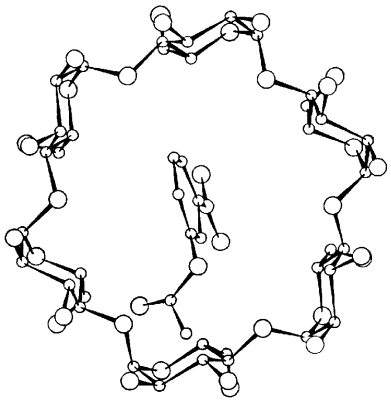

Fig. 6. An expected structure of the α-cyclodextrin–*m*-nitrophenyl acetate complex.

In the crystalline complexes, a remarkable change of the α-CDx conformation is observed between the complexed state and the uncomplexed state.[22] The calculated conformational energy of the *m*-NP complex is lower than that of the uncomplexed state, suggesting that the α-CDx conformation is stabilized by the complex formation. On the other hand, the *p*-NP complex gives a higher conformational energy than the uncomplexed α-CDx. This high energy may be due to the deformation of the α-CDx ring caused by the deep penetration of the bulky and planar molecule. Thus, the inclusion of *p*-NP makes the α-CDx conformation unstable, but the strong interaction of *p*-NP with α-CDx gives the large interaction energy. In the case of the *m*-NP complex, only the partial penetration of the guest molecule is possible because of the steric hindrance. The relatively weak interaction between α-CDx and *m*-NP gives a small deformation of the α-CDx ring. The calculated results indicate the importance of the interaction energy, and suggest that the conformational energy and the solvation energy are not the major components of the binding force in the *m*-NP and *p*-NP complexes. This has also been pointed out by Bergeron *et al.* on the basis of the spectroscopic investigations of α-CDx complexes with substituted *p*-nitrophenols.[23]

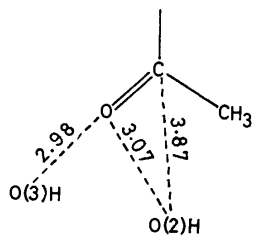

Fig. 7. A schematic drawing of the contact between the acetyl group of *m*-nitrophenyl acetate and the secondary hydroxyl groups of α-cyclodextrin.

TABLE 12. CALCULATED ENTHALPY CHANGE FOR THE COMPLEX FORMATION

	ΔH^s mol^{-1} kcal	ΔH^c mol^{-1} kcal	ΔH^i mol^{-1} kcal	ΔH mol^{-1} kcal	ΔH(obsd)[a] mol^{-1} kcal
α-CDx–*m*-NP	1.64	−0.69	−4.61	−3.66	−7.8
α-CDx–*p*-NP	1.42	0.92	−13.68	−11.34	−7.3

Catalytic Property of α-Cyclodextrin

In the α-CDx catalyzed hydrolysis of substituted phenyl acetates, the reaction mechanism has been interpreted in terms of the nucleophilic attack of the secondary hydroxyl group of α-CDx on the carbonyl carbon atom of the ester.[4] The low reactivity of α-CDx in the hydrolysis of *para*-substituted phenyl esters has been discussed on the basis of the geometry of the α-CDx–*p*-NP complex.[5] The nitrophenyl group is so rigidly fixed in the α-CDx ring that the carbonyl carbon atom of the ester could hardly have close contacts with the secondary hydroxyl groups without the large deformation of the α-CDx ring.

In the α-CDx–*m*-NP complex, the guest molecule was found to be partially inserted into the α-CDx ring from the secondary hydroxyl side. The phenolic hydroxyl group is separated by more than 4.7 Å from the secondary hydroxyl groups. When *m*-nitrophenyl acetate forms a complex in the same manner, the acetyl group may have close contacts with the secondary hydroxyl groups. The expected structure of the *m*-nitrophenyl acetate complex is shown in Fig. 6, where the conformation of the acetyl group was assumed to be the same as that found in *p*-nitrophenyl acetate.[24] The distances between the carbonyl oxygen atom and the vicinal secondary hydroxyl groups are 2.98 and 3.07 Å (Fig. 7), suggesting that the structure of the complex is stabilized by hydrogen bonds. The carbonyl carbon atom is located at the distance of 3.87 Å from the secondary hydroxyl group. Unlike *p*-NP, *m*-NP is loosely bound to the α-CDx cavity. The carbonyl carbon atom can easily approach closer to the secondary hydroxyl group by the small displacement of the guest molecule and the deformation of the α-CDx ring. The hydrolysis of the ester bond is interpreted in terms of the tetrahedral intermediate.[25,26] When the carbonyl carbon atom is attacked by the O(2) hydroxyl group (Fig. 7), which is possibly ionized in a relatively high pH condition,[4] the hydrogen bond involving the O(3) hydroxyl group may stabilize the tetrahedral intermediate and lower the activation energy. Acetyl α-CDx, which is formed by the release of *m*-NP, may be decomposed by water. Although simplified, this proposed reaction mechanism is similar to that of the chymotrypsin-catalysis,[27] indicating that α-CDx is a good enzyme model.

Appendix

The pair potential of the dipole-dipole interaction between μ_1 of the solvent molecule and μ_{2i} of the i-th group of the solute molecule is given by $-2\mu_1^2\mu_{2i}^2/(3kTr^6)$,[28] where k is the Boltzmann constant. The distance between these dipoles is

$$r = (R^2+l^2-2Rl\cos\theta)^{1/2}, \quad \text{(A1)}$$

where l and R are the distances from the center of the solute molecule to the i-th group of the solute molecule and to the solvent molecule respectively, and where θ is the angle made by the corresponding two vectors. Then, by averaging over l and θ, we obtain

$$U_{ei}(R) = \frac{-\mu_1^2\mu_{2i}^2}{kT\varepsilon(R_2-l_{2i}^\circ)^3}\int_0^{R_2-l_{2i}^\circ}\int_0^\pi \frac{l^2\sin\theta \mathrm{d}\theta\mathrm{d}l}{r^6}, \quad \text{(A2)}$$

where l_{2i}° is the radius of the i-th group. The effective dielectric constant was assumed to be

$$\varepsilon = 1 + (\varepsilon_0-1)(1-\exp[(R_1+R_2-R)/2R_1]), \quad \text{(A3)}$$

where R_1 and R_2 are the van der Waals radii of the solvent and solute molecules respectively, and where ε_0 is the dielectric constant of the solvent. Thus, the electrostatic energy is

$$H_e^s = \frac{-D}{2R_2^3}\sum_i \frac{\mu_{2i}^2}{\left(1-\frac{D\alpha_{2i}}{R_2^3}\right)} + 4\pi\rho\int_{R_0}^\infty \sum_i U_{ei}(R)R^2\mathrm{d}R, \quad \text{(A4}$$

with $D=2(\varepsilon_0-1)/(2\varepsilon_0+1)$ and $R_0=R_1+R_2$, where ρ is the number density of the solvent.

The van der Waals interaction energy is given by[29]

$$H_v^s = 4\pi\rho\left[1-\frac{3(n^2-1)}{4(n^2+2)}\right]\int_{R_0}^\infty \sum_i U_{vi}(R)R^2\mathrm{d}R. \quad \text{(A5)}$$

The pair potential of the i-th atom in the solute molecule and the solvent molecule is

$$U_{vi}(R) = \frac{3}{2(R_2-l_{2i}^\circ)^3}\int_0^{R_2-l_{2i}^\circ}\int_0^\pi\left(\frac{a_i}{r^{12}}-\frac{c_i}{r^6}\right)l^2\sin\theta\mathrm{d}\theta\mathrm{d}l, \quad \text{(A6)}$$

where a_i and c_i are the coefficients of the potential function, and where l_{2i}° is the radius of the i-th atom.

Application of Microwave Spectroscopy to Kinetic Study of the Reaction of Carbonyl Sulfide with Atomic Oxygen

Noritetsu YOSHIDA* and Shuji SAITO**

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara 229

(Received October 21, 1977)

Microwave spectroscopy has been applied to the determination of the rate constant for OCS+O→SO+CO. A short cell of a parallel-plate type was devised for the detection of the SO radicals produced in a fast flow reactor. Production of the SO radical was traced by measuring its spectral line intensity under the condition of [OCS]≫[O]. The rate constant for the reaction was determined to be $(7.1\pm0.7)\times10^9$ cm³/mol·s at room temperature (24—25) °C, in good agreement with the values obtained by other methods.

Microwave spectroscopy has been so far mainly concerned with molecular structural studies. Recently some of its applications to the studies of reaction mechanisms have been reported, examples of which are the detection of transient species and the quantitative analysis of final products. In the former studies, about forty species of free radicals, unstable molecules and molecular ions have been detected, though major interest has been focused on their structures. The latter kind of studies have been encouraged by the establishment of an improved technique[1] for measuring the relative intensities of microwave absorption lines. The catalytic hydrogen-exchange reaction of propene with deuterium or deuterium oxide has been thoroughly investigated by analyzing the geometric isomers of deuterated propenes produced. Thus the adsorbed species of propene on various catalysts have been clarified more precisely than before.[2] Other catalytic reactions have been also investigated with remarkable success.[3]

The success of these applications is entirely due to the high specificity of microwave spectroscopy with respect to the detection of molecular species and its high sensitivity. These distinctive features led to the application of microwave spectroscopy to the kinetic studies of gas-phase fast reactions reported here. The reaction investigated was

$$OCS + O \xrightarrow{k} SO + CO. \quad (1)$$

The initial step of the reaction of carbonyl sulfide with atomic oxygen has been investigated kinetically by means of ESR and MS spectroscopies.[4] Reliable values of the rate constant k reported in five seperate studies[5-9] enable the applicability of the microwave spectroscopic technique to be tested.

Experimental

The reaction of carbonyl sulfide with atomic oxygen was studied at about 0.13 Torr at room temperature (24—25) °C, by the use of a fast flow reactor with a microwave spectroscopic detection system. The apparatus used is shown schematically in Fig. 1. The reactor consisted of a flow tube (36 mm inner diameter Pyrex) coated with H_3PO_4 for reducing atom recombination, a movable injector tube (10 mm outer diameter Pyrex) with nine evenly spaced small holes on its head, and a microwave discharge tube (9 mm inner diameter quartz) equipped with an Evenson-Broida type 2a cavity operating at 2450 MHz. A Baratron capacitance manometer (MKS Instruments, Inc.) and a McLeod gauge were placed at about 10 and 94 cm upstream from the microwave absorption cell, respectively.

The atomic oxygen was produced by passing a mixture of O_2 and He through a microwave discharge tube. About 2.5% of the O_2 molecules dissociated into O atoms. Carbonyl sulfide gas, diluted with He was fed into the partially dissociated O_2 flow via the injector. The duration of the reaction was controlled by the distance between the injector head and the cell. The injector was moved less than 50 cm in each run, which covered

* Present address: Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada, Kobe 657.

** Present address: Institute for Molecular Science, Myodaiji, Okazaki 444.

the reaction range of about 50 ms. Flow rates of the gases were controlled by means of stainless steel needle valves, monitored roughly with glass flow meters, and determined accurately by measuring the pressure rise in a bulb known volume after each run. The initial concentration of oxygen atoms, $[O]_0$, was titrated with NO_2[10] in the absence of OCS, by visual observation of the greenish yellow afterglow emitted by the recombination reaction of O with NO in the presence of an excess of O atoms over NO_2 molecules.

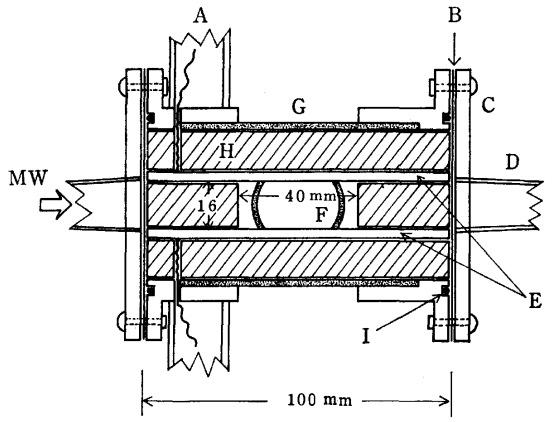

Fig. 2. Cross-sectional view of microwave absorption cell.
A: Stark input, B: mica window, C: blass flange, D: tapered transition unit, E: Stark electrodes, F: flow tube, G: Pyrex tube (55 mmϕ), H: Teflon block, I: O-ring.

The cross-sectional view of the microwave absorption cell is shown in Fig. 2, where the direction of the gas flow is perpendicular to the plane of the paper. A pair of gold-plated brass plates ($3\times30\times100$ mm), which served as Stark electrodes, were fixed 16 mm apart from each other in a Pyrex tube (55 mm outer diameter). Unessential spaces in the cell were filled up with Teflon blocks in order to obtain a smooth gas flow. The effective absorption length of the cell was 40 mm. The cell was completely vacuum-tight with O-rings and mica windows for microwave. A pair of ferrite isolators were incorporated to prevent multiple reflection of the microwave in the cell.[1] They were placed 80 cm apart from the cell (see Fig. 1) to avoid the influence of their magnetic field leakage upon the paramagnetic species SO. The microwave spectrometer used was a conventional one with 110 kHz sinusoidal Stark modulation.[11]

The SO appearance was monitored by observing a microwave absorption line at 13044 MHz, the transition $J,K=1,2\leftarrow1,1$.[12] The signal was recorded very slowly (1 MHz/min) with a time constant of 3 s in order to obtain almost true line shape. Three or four sweep runs were averaged for each signal. As the sinusoidal Stark modulation was used, the observed signal was the first derivative of the Lorenzian absorption line. The absolute intensity is proportional to $H\cdot(\Delta\nu)^2$, where H and $\Delta\nu$ denote the peak-to-peak amplitude and the width of the derivative,[13] respectively. In the determination of the rate constant k for Reaction 1, however, only the relative amplitude of the signal was sufficient to obtain relative concentration of SO, since the widths were practically constant over the reaction range. The signal intensity, H, was calibrated into the absolute concentration only to examine the stoichiometry of Reaction 1. The calibration was performed by using another source of SO, that is, the thermal decomposition of ethylene episulfoxide (CH_2CH_2SO) in He at 600 °C,[14] and by titrating with NO_2:[15] $SO+NO_2\rightarrow SO_2+NO$.

The sample gases, helium (airco, 99.9995%), oxygen (Toyo Sanso, 99.99%) and carbonyl sulfide (Matheson, 97.5%), were taken directly from their respective cylinders. Matheson NO_2 was purified by mixing it with O_2 and passing it over evaporated P_2O_5 films. This was followed by vigorous pumping of the white frozen solid at 77 K, in order to remove the impurities of H_2O and NO. Ethylene episulfoxide was prepared by the reaction of ethylen episulfide with *m*-chloroperbenzoic-acid in CH_2Cl_2[16] at −10 °C, and was purified by distillation under reduced pressure.

Results and Discussion

Performance of the Spectrometer. The quantitative steady-state experiment, such as the present one, indispensably requires a detection system which is stabilized over a long period of time and whose response is proportional to the concentration of species to be detected. This aspect was examined using a flow of OCS highly diluted with He at about 0.05 Torr. The signal amplitude of the OCS ($J=1\leftarrow0$, 12163 MHz), having a signal-to-noise ratio of about 50, was monitored over 4 h. Maximum fluctuation of the amplitude was about 3%, while that of the total pressure was only 0.5%. Figure 3

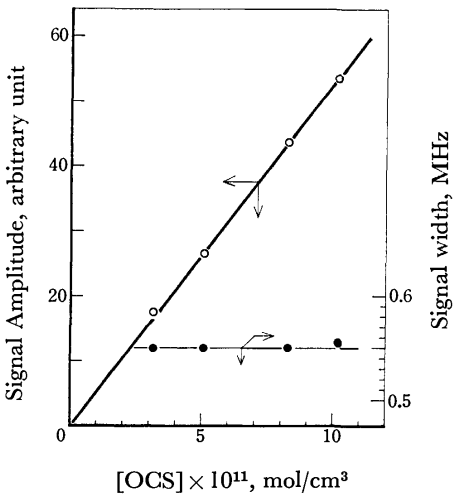

Fig. 3. Peak-to-peak amplitude and width of OCS first-derivative signal (12163 MHz) *vs.* OCS concentration. T: 27.5 °C, P: 0.0572−0.0591 Torr, He flow: 9.86 μmol/s, Noise level: 0.3 unit.

shows plots of the signal amplitudes and widths as a function of OCS concentration. The linearity of the spectrometer is clearly shown in the figure, where the signal amplitude is directly proportional to the concentration while the signal width remains constant. Figure 3 also indicates the sensitivity of the spectrometer. On the basis of the noise intensity of 0.3 unit in the above results, the OCS signal with the signal-to-noise ratio of 2 corresponds to 2×10^{-12} mol/cm³. The minimum detectable concentration of SO was proved to be 1×10^{-12} mol/cm³.

Determination of the Rate Constant k. In order to perform an exact analysis of a flow system, it would be necessary to employ a laborious treatment. In the present study it was assumed that the radial concentration gradients and axial diffusion rates were negligible

and that the parabolic velocity distribution could be replaced by an average velocity (v). Furthermore it was assumed that Reaction 1 operated simply and other side reactions were ignored. Then the solution of the rate equation becomes

$$k \cdot t = -\frac{1}{[OCS]_0 - [O]_0} \cdot \ln \frac{[O] \cdot [OCS]_0}{[O]_0 \cdot [OCS]}. \quad (2)$$

The present experiments were performed under a condition of a large excess of carbonyl sulfide, $[OCS]_0 \gg [O]_0$, so that [OCS] is essentially constant throughout the reaction. Equation 2 can be reduced under this condition, and replacement of $[O]_0$ by $[SO]_\infty$ yields

$$k \cdot [OCS]_0 \cdot t = \ln (1 - [SO]/[SO]_\infty)^{-1}, \quad (3)$$

where $[OCS]_0$ is the initial concentration of carbonyl sulfide and $[SO]_\infty$ the concentration of the SO radicals after infinite time. In Fig. 4, typical plots of $\ln(1-[SO]/[SO]_\infty)^{-1}$ *vs.* t are shown for various empirically adjusted values of $[SO]_\infty$. It may be seen that initial time, $t=0$, can be arbitrarily chosen without loss of generality. As shown in Fig. 4, plots for $[SO]_\infty=22$ (arbitrary units)

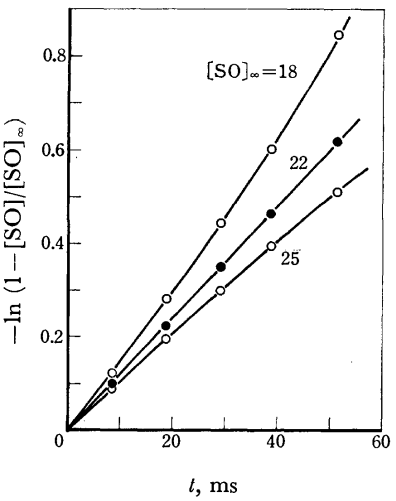

Fig. 4. Typical logarithmic plots of the SO appearance in the reaction of OCS+O→SO+CO for various empirically adjusted values of $[SO]_\infty$.
T: 24.0 °C, P: 0.1304 Torr, v: 9.6 m/s, $[OCS]_0$: 1.64×10^{-9} mol/cm³.

produced a linear curve, while the others did not. The values of k obtained from the slopes of several such linear plots are given in Table 1, and the values of k determined by other workers using MS and ESR spectrometers are also listed for comparison. The values of v and $[OCS]_0$ given in the table were determined at the pressure calculated for the center of the range of the OCS-injection point. The average k thus obtained was 7.1×10^9 cm³/mol·s, which agrees well with the values reported by other workers.

Reliability of the Observed Values. An important point in the kinetic studies by the measurement of a product species is how much the product may be lost by side reactions. The O/SO stoichiometry in Reaction 1 was thus examined by comparing $[O]_0$ and $[SO]_\infty$,

Table 1. The rate constant k for OCS+O → SO+CO

Expt No.	T (°C)	P (Torr)	v (m/s)	$[OCS]_0$ (mol/cm³)	k (cm³/mol·s)
1	25.0	0.1298	9.4	1.57×10^{-9}	7.3×10^9

8	24.0			ESR	8.5×10^9
9	24.0			ESR	7.2×10^9

a) Effect of metal surface was examined. b) The value calculated from the Arrhenius expression

because if the loss of SO by side reactions was significant, $[SO]_\infty$ should be smaller than $[O]_0$. In the case of Expt 1 in Table 1, $[O]_0$ was found to be 2.1×10^{-11} mol/cm³ by the NO_2-titration, while the adjusted $[SO]_\infty$ value was 2.0×10^{-11} mol/cm³. This good agreement confirms the stoichiometry, and hence supports the assumption of the negligible side reactions. This result is concordant with that reported by Westenberg and deHaas,[8] who confirmed this stoichiometry under highly diluted conditions by monitoring both O and SO with an ESR spectrometer.

The most serious difficulty of the microwave technique may arise from the possible effect of the metal surface of the Stark electrodes on the kinetic measurement, particularly in the case of transient species. In order to assess the error, k was determined when a gold-plated brass plate having almost the same surface area as the electrodes was inserted into the flow tube. The result is listed in Table 1 as Expt 3. Comparison of the results demonstrates that there was little difference in the values of k determined with and without the extra metal surface in the flow tube. Therefore, the surface of the Stark electrodes was considered to have little effect on the kinetic measurement.

The microwave absorption cell has a detection zone of about 3 cm. It takes about 2 ms for the flowing gas molecules to pass through the absorption cell. It is not always negiligibly small in comparison with the time range within which the reaction was monitored, but it may be reasonable to consider that the response of the spectrometer corresponds to the concentration at a fixed point in the cell.

The radial concentration gradients and the axial diffusion rate may be evaluated by the diffusion aspect of reactants, and the values of r^2/D and the ratio $k \cdot [OCS]_0 \cdot D/v^2$ are measures of them, where D denotes the diffusion coefficient of the O atoms in He and r the radius of the flow tube. Recently Goldberg and Crowe reported the value of D as 1300 cm²/s at 0.6 Torr and at 280 K.[17] The value corrected to 0.13 Torr is 6000 cm²/s, according to the relation $D=D_0(P_0/P)$ where D_0 is the diffusion coefficient at an arbitrary value of P_0,[18] the small contribution due to temperature dependence being ignored. Thus the value of r^2/D is 0.7 ms in He and $k \cdot [OCS]_0 \cdot D/v^2 \ll 1$. Therefore, the corrections for both effects may

be negligible. In the case of the viscous pressure drop, it was about 7—9% within the range where the OCS-injection point was shifted. Westenberg and deHaas reported,[19] "Simply using the pressure at the center of the measurement section to compute flow velocity and reactant concentration yielded essentially the same rate constant as was obtained with more sophisticated corrections for the pressure drop." The effect was assumed to be of the same magnitude in our experiments, since the present conditions were almost the same as theirs.

On these basis the assumptions used in determining k were considered to be reasonable. Stability of the flow system as well as of the detection system was satisfactory, as was described in the previous section. Thus the origin of the errors in the measurement may be ascribed mainly to the relative readings of the signal amplitudes and to the determination of the slopes of the pseudo-first order plots. These measurement errors were roughly estimated to be about $\pm 10\%$.

The results obtained above demonstrate that the microwave spectroscopic technique offers a reliable and powerful means for gas kinetic studies, in spite of some limitations to its applications, *e.g.*, non-polar substances cannot be detected, and the applicable pressure-range is limited normally to 10^{-1}—10^{-2} Torr. Nevertheless, high specificity of the microwave spectrum makes this technique most suitable among the available techniques (ESR, MS, *etc.*) for reactions concerned with isotopic and geometric isomers. In addition to the determination of reaction rate constants, it may be possible by this technique to determine the life-time of transient species and the diffusion coefficients of gaseous substances regardless of their stabilities.

The authors wish to express their gratitude to Professor Yonezo Morino for continuing encouragement and helpful advice, and to Mr. Fumio Makino for construction of the microwave spectrometer with great competence.

Diffusion Coefficients of Argon in Aqueous Ethanol and 1,4-Dioxane Solutions and of Methane in Aqueous Ethanol Solutions*

Yūkō Taira, Kunio Matsuda, and Koichiro Nakanishi**

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received October 24, 1977)

The diffusion coefficients of argon in water-rich regions of aqueous solutions of ethanol and of 1,4-dioxane and those of methane in aqueous solutions of ethanol have been measured by using a diaphragm cell apparatus, designed after Hildebrand *et al.*, for dissolved gases in liquid. The diffusivity of gases was found to show much anomaly which might be ascribed to the structural change of water due to the addition of another solvent. The viscosity reduced diffusion coefficient $D\eta$ (D: diffusion coefficient, η: viscosity coefficient) has a maximum value in dilute aqueous solution of both ethanol and 1,4-dioxane.

Studies have been made recently on the diffusivity of dilute solute in a variety of mixed solvents.[1-4] Iodine was used as a solute and the influence of its specific interaction with the solvents upon diffusivity was examined. Among the mixed solvents examined so far, aqueous alcohol solutions exhibit anomaly in diffusivity which is reverse in direction to that in other solvent systems.[1] It was pointed out that this anomaly may have close connection with the destruction or stabilization of water structure as revealed by solubility and other thermodynamic data.[5]

The purpose of the present study is to elucidate this phenomenon through the determination of diffusion coefficient of inert solute in aqueous solutions. Nakanishi *et al.* measured the diffusion coefficient of various gases dissolved in liquid by diaphragm cell method.[6] A diffusion apparatus has been constructed by utilizing the same diaphragm as employed previously. The diffusion coefficients of argon in water-rich regions of aqueous solution of ethanol and of 1,4-dioxane and those of methane in water-rich region of aqueous solutions of ethanol have been measured. In this paper are given the results of these measurements and a discussion based on the effect of structural change in water on gas diffusivity.

Experimental

Gases and Other Materials. Argon and methane of 99.998 and 99.95% purity were used. The gases were introduced into the apparatus after passing through a column of dehydrating agent $CaCl_2$. Guaranteed ethanol and 1,4-dioxane were used as solvent. Water was deionized and distilled three times.

Apparatus. The fundamental design of the diffusion apparatus shown in Fig. 1 is similar to that used by Hildebrand and co-workers.[6,7] The apparatus consists of three main parts, diffusion cell, gas buret and degassing device. Each of the valves used to separate the parts of the apparatus is a high vacuum glass stopcock, except for the Teflon greaseless needle valve (valve 9) used to avoid the contact of grease with solvent. The diffusion cell consists of two glass bulbs between which the diaphragm is placed. The diaphragm was cut from that prepared by Hildebrand and co-workers,[6,7b] the cross section being the same 5.65 cm^2 and the length 1.00 cm.

During the course of measurements the diffusion cell was immersed in a water thermostat kept at 25.00±0.05 °C. The gas buret was covered with a jacket in which thermostatted water (25.0±0.1 °C) was circulated.

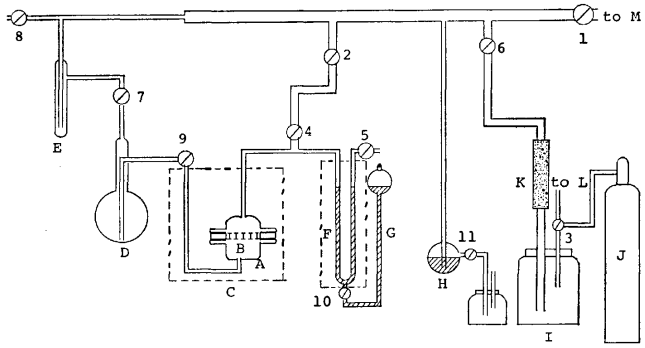

Fig. 1. Schematic diagram of diffusion apparatus.
A: Diffusion cell, B: diaphragm, C: water thermostat, D: degassing flask, E: trap, F: gas buret, G: mercury reservoir, H: open manometer, I: gas reservoir, J: cylinder, K: column of dehydrating reagent, L: gas bag, M: rotary pump, 1—11: valve or stopcock.

Operation. Before the diffusion run, *ca.* 380 ml of solvent was placed in a degassing flask (Fig. 1, D). The flask was then immersed in a Dewar vessel and the liquid was degassed thoroughly by the freeze-and-thaw method *in vacuo*. The number of the times the freeze-and-thaw procedure had to be repeated depended on the sample liquid, but usually five to seven times appeared necessary for complete degassing, which was judged from the disappearance of bubble on thawing. Valve 9 was then closed, and the diffusion cell evacuated.

After degassing was completed, a small amount of sample gas (=1/5 atm) was admitted into the diffusion cell from the gas reservoir. Valves 7 and 8 were then opened to increase the pressure in the degassing flask to ordinary pressure, and the degassed liquid was rapidly transferred to the diffusion cell by opening valve 9. When the surface of liquid layer reached about 1.0 mm above the upper end of the diaphragm, valve 9 was closed in order to complete the introduction of solvent to the diffusion cell. Next, mercury was introduced into the gas buret and the gas was admitted into the vapor space of the diffusion cell. Valve 5 was kept open and the gas pressure in the cell was made to be equal to the atmospheric pressure. The water thermostat placed on a laboratory jack was raised to immerse the diffusion cell in it, and kept at 298.15±0.05 K.

The gas above the liquid surface dissolved in the liquid layer to form a saturated solution and then diffused *via* diaphragm into the liquid phase underneath. After the concentration gradient is established in the diaphragm, diffusion takes place in a steady state and can be followed by the decrease in the

* Diffusion in Mixed Solvents. Part V.

** To whom correspondence should be addressed.

amount of gas as measured by the rise of the mercury column in the gas buret F.[8] The pressure of gas was equalized to atmospheric pressure by adjusting the amount of mercury in the gas buret. The rise Δh in mercury level was measured with a cathetometer. Thus Δh can be determined as a function of times Δt and the diffusion coefficient can be calculated from the slope of Δh *vs.* Δt plot.

Calculation of Diffusion Coefficient. For the diaphragm method, Fick's first law of diffusion can be written as

$$dn/dt = DA\Delta c/L, \quad (1)$$

where dn/dt (mol s^{-1}) is the number of mole of the diffusant which passes through the diaphragm in unit time, A (cm^2) the cross section of diaphragm, L (cm) the length of diaphragm, Δc (mol cm^{-3}) the concentration difference, and D (cm^2 s^{-1}) the diffusion coefficient.[9] If the gas can be assumed to be ideal, then the amount of gas dissolved as a result of steady progress of diffusion is given by

$$dn/dt = d(PV/RT)/dt = (P/RT)\Delta V/\Delta t, \quad (2)$$

where P is the partial pressure of gas, ΔV the volume decrease of gas due to dissolution, R the gas constant, T the temperature and Δt the time increment. Substitution of Eq. 2 into Eq. 1 gives

$$D = (LP/ART\Delta c)(\Delta V/\Delta t). \quad (3)$$

ΔV can be measured by the change in mercury level Δh in the gas buret as

$$\Delta V = A_m \Delta h, \quad (4)$$

where A_m is the cross section of gas buret. The concentration difference $\Delta c(t)$ can be expressed by

$$\Delta c(t) = (c_0 P/P_0)\Delta c^*(t), \quad (5)$$

where $c_0 = X/V_1^0$ is the concentration of the saturated solution of gas at $P = P_0$ and $\Delta c^*(t)$ a correction term due to the change in concentration difference with the advancement of diffusion of gas into lower vessel of the diffusion cell. Here X is the solubility of gas given in terms of the mole fraction in the liquid phase and V_1^0 is the molar volume of solvent. P_0 is taken to be the atmospheric pressure so that X is the solubility at 1 atmosphere.

The diffusion coefficient D can be calculated by the following equation, obtained from Eqs. 3, 4, and 5:

$$D = (LA_m P_0/ART c_0)(\Delta h/\Delta c^*\Delta t), \quad (6)$$

$$= K(\Delta h/\Delta c^*\Delta t c_0), \quad (7)$$

where K is the apparatus constant and K/c_0 is also a constant for the combination of gas and solvent. Thus we can calculate D from the slope of linear relation between $\Delta h/\Delta c^*$ and Δt.

In order to use Eq. 7 for the calculation of D, it is necessary to apply some corrections to Δh and Δc^*. Since Δh is influenced by the change in atmospheric pressure, a correction should be made by means of the equation

$$\Delta h = \Delta h_0 - (V_g/A_m)(\Delta P/P), \quad (8)$$

where V_g is the volume of vapor phase, ΔP the fluctuation of atmospheric pressre and Δh_0 the manometer (gas buret) reading. On the other hand, the correction for the concentration change can be estimated by

$$\Delta c^* = 1 - (P/RT)(A_m/V_1)(\Delta h^*(\Delta t)/c_0), \quad (9)$$

where V_1 is the volume of degassed solvent and $\Delta h^*(\Delta t)$ is the change in mercury level after the steady state was attained. The relation is somewhat ambiguous as the amount of gas dissolved before the establishment of steady state of diffusion is unknown. When V_1 is sufficiently large, the correction is negligible.

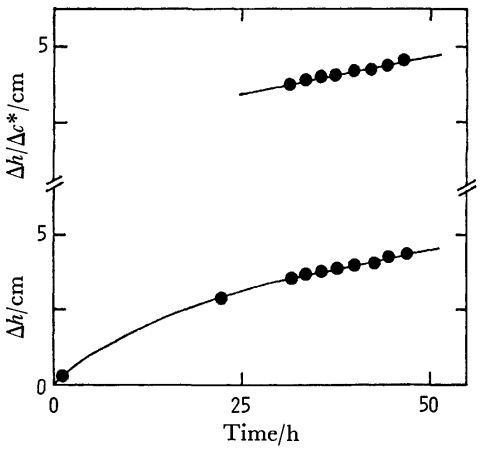

Fig. 2. Plot of height change in buret against time.

The present technique is an absolute method for the measurement of D without use of any apparatus constant determined by calibration with a gas of known D. It is in contrast to the conventional diaphragm cell technique for which the determination of cell constant is indispensable.

An example of $\Delta h/\Delta c^*$ *vs.* Δt plot is given in Fig. 2. The plot shows a downward curvature in the initial stage indicating gradual attainment of the steady concentration gradient and linearity. It requires about one day to establish a stationary state of diffusion in aqueous solutions.[10] The diffusion coefficient can be calculated from the slope of the straight line.

Apparatus Constants and Physical Constants Used. Instead of carrying out calibration measurement with a gas of known D, several apparatus constants should be determined in advance. The values of each constant used in most measurements with gases of unknown D are as follows.

$$A = 5.65\ cm^2,\ L = 1.00\ cm,\ A_m = 0.326\ cm^2,$$

$$V_1 = 257\ cm^3,\ \text{and}\ V_g = 144\ cm^3.$$

Somewhat different values of V_1 and V_g were used in part of the measurements since it was necessary to overhaul and reconstruct the apparatus during the course of the present study.

In order to calculate the diffusion coefficient, it is necessary to use physical constants such as gas solubility, vapor pressure, and density of solvent. Gas solubility data given by Ben-Naim and Baer[11] and Cargill and Morrison[12] (argon in ethanol+water solutions), Ben-Naim and Moran[13] (argon in 1,4-dioxane+water solutions) and Ben-Naim[14] (methane in ethanol +water solutions) were used. The density and vapor pressure of all the solvents have been taken from the compilation of Timmermans.[15]

Results and Discussion

Diffusion Coefficient of Argon and Methane in Water. In order to confirm the reliability of the apparatus, comparison has been made between the present data for pure solvents and those in literature. The diffusion coefficients of argon and methane have been studied extensively. Figures 3 and 4 show both data as a function of temperature. We have found that the diffusion coefficient of argon in water is 2.22×10^{-5} cm^2 s^{-1}. Literature values scatter a great deal. However, the reliable data by Duda[16] and Baird and Davidson[17] seem to converge to about 2.0×10^{-5} cm^2 s^{-1} at 25 °C. The agreement between both data is reasonable, though the present value is about 10% higher. The results for

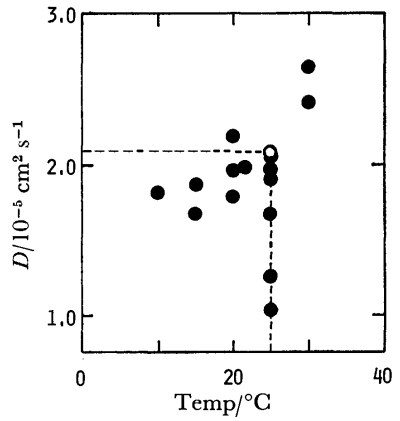

Fig. 3. Diffusion coefficient of argon in water as a function of temperature. ○: This work, ●: literature value.

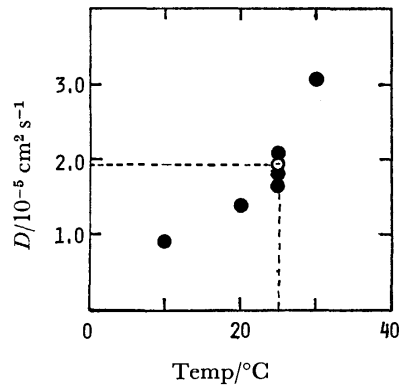

Fig. 4. Diffusion coefficient of methane in water as a function of temperature. ○: This work, ●: literature value.

methane do not scatter much, the representative datum due to Witherspoon and Saraf[18] being 1.88×10^{-5} cm^2 s^{-1} at 25 °C, in perfect agreement with the present data. It is thus concluded that the present data can be regarded as reliable.

Diffusion Coefficients in Aqueous Solutions. The diffusion coefficients of argon in aqueous solution of ethanol and in aqueous solution of 1,4-dioxane and of methane in aqueous solution of ethanol have been measured at 298.15 K. The measurements are restricted to water-rich regions. The results are given in Table 1, the values being an average of the results of two or three runs. Reproducibility is satisfactory, deviation being less than

±4%. The diffusion coefficients and the viscosity coefficient η of the mixed solvents are plotted against the mole fraction of ethanol or 1,4-dioxane in Figs. 5—7.

The viscosity of solvent increases with the addition of ethanol until the mole fraction of ethanol x_{EtOH} exceeds 0.25, at which the viscosity becomes maximum. A

similar tendency can be seen for 1,4-dioxane solutions. On the other hand, the diffusion coefficient decreases rapidly with the addition of ethanol or 1,4-dioxane, becoming minimum near $x=0.2$, and then increasing. Thus D and η are inversely proportional with each other.

Anomaly in $D\eta$ vs. x Plot. It is common practice to reduce the D value with η to examine the behavior of the product $D\eta$ as a function of the composition of mixed solvents. We have recently studied the diffusion in mixed solvents using iodine as a solute and found that $D\eta$ value of iodine becomes maximum in aqueous alcohol (ethanol and *t*-butyl alcohol) solutions near $x_{alcohol}=0.1$ to 0.2.[1] A similar anomaly has been reported by Perkins and Geankoplis[19] for acetic acid in aqueous ethanol solutions. The minimum diffusion coefficient does not necessarily correspond to maximum viscosity. It is thus of interest to examine the relation $D\eta$ *vs.* x. Figure 8 shows the plot of $D\eta$ against x for argon and methane in aqueous ethanol solutions. It should be noted that a small peak appears in the region $x_{EtOH}<0.1$. This may be characteristic of aqueous alcohol solutions and aqueous solutions of all the compounds acting as a structural maker. Although 1,4-dioxane has been regarded often as a structural breaker, it may act as a structural maker as far as diffusivity concerned.

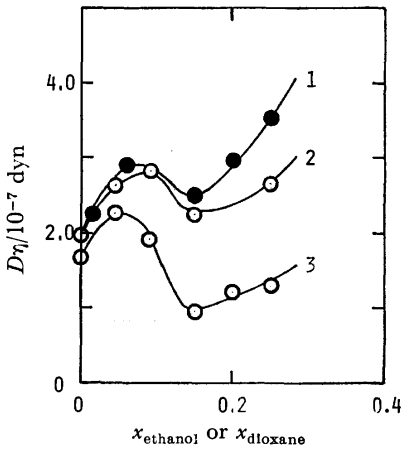

Fig. 8. Isoviscous diffusion coefficients as a function of mole fraction of ethanol or 1,4-dioxane in aqueous solutions. 1: Argon in 1,4-dioxane solutions, 2: argon in ethanol solutions, 3: methane in ethanol solutions.

Comparison between Ar and CH_4 and between Ethanol and 1,4-Dioxane Solutions. The diffusivity of gases in aqueous ethanol solution has been studied extensively.[20,21] The dependence of diffusion coefficient on the molar composition is complicated, varying with gas. In view of the complicatedness of the problem, we confine our attention to a comparison only between the three data obtained in the present study.

First we deal with the difference in the diffusivity of argon in aqueous ethanol solution and in aqueous 1,4-dioxane solution. When ethanol or 1,4-dioxane is added to water, viscosity increases a great deal to the same extent. However, the decrease in diffusivity is fairly large in ethanol solution, while that in 1,4-dioxane solution is small. This may be interpreted as follows. There should be various kinds of cavities in three dimensional hydrogen bonding structure in water. The size of these cavities is thought to be *ca.* 5.8—6.6 Å.[22] Since 1,4-dioxane shows no self-association, the cavity can be occupied by 1,4-dioxane molecule dissolved in water. In fact, the self-diffusion of 1,4-dioxane decreases distinctly with the increase in $x_{dioxane}$ in aqueous solution.[23] When argon diffuses in aqueous 1,4-dioxane solution, capture of argon molecule in the water cavity is reduced. Rapid diffusion may be energetically favorable. In spite of a large viscosity increase, the diffusion of argon would not decrease much. On the other hand, the addition of ethanol to water may enlarge and stabilize the cavity in water. Therefore, in aqueous ethanol solution, argon can be easily trapped in the cavity and its diffusion coefficient will decrease a great deal with the addition of ethanol into water.

The diffusion coefficient of methane in aqueous ethanol solutions is always smaller than that of argon in the same solutions. This reflects the difference in the size of diffusant. For the size effect on diffusivity, Ross and Hildebrand[7] have proposed an empirical relation, $D\sigma^2=$constant, where σ is the diameter of diffusant. Witherspoon and Saraf[18] showed that a relation, $D\sigma=$constant, seems to be also valid for the diffusion of gaseous hydrocarbons in water. In the present case, it can be shown that the latter gives a better fit. Thus

$$D_{Ar}\sigma_{Ar} = D_{CH_4}\sigma_{CH_4}, \qquad (10)$$

seems to be valid in water. It is of interest to examine whether D_{Ar}/D_{CH_4} is a constant in aqueous ethanol solutions. Figure 9 shows D_{Ar}/D_{CH_4} *vs.* x_{EtOH} plot. The ratio becomes maximum near $x_{EtOH}=0.1$—0.15. This indicates that the capture of solute in the cavity of water enlarged by the introduction of ethanol depends appreciably on the kind of solute and the effect can be clearly seen in the composition range where the anomaly of aqueous ethanol solution is often observed.[5] The characteristics of the diffusivity of solutes in dilute aqueous solutions is too complicated to deduce a clear-cut interpretation. It seems necessary to accumulate experimental data for various solutes in aqueous mixed solvents at different temperatures.

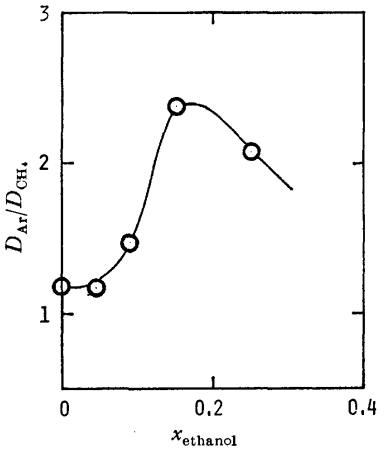

Fig. 9. Ratio of diffusion coefficient between argon and methane as a function of mole fraction of ethanol in aqueous solution.

The authors thank Mr. Soto Asakura for his cooperation in the earlier stage of the work. They are grateful to Prof. Nobuatsu Watanabe for his interest and discussion.

The Structure of the Cyclodextrin Complex. VII. The Crystal Structure of the α-Cyclodextrin-DMSO-Methanol (1: 1: 2) Dihydrate Complex A Simultaneous Inclusion of DMSO and Methanol

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari-4, Kanagawa-ku, Yokohama 221

(Received October 25, 1977)

The crystal structure of the α-cyclodextrin(α-CDx)–DMSO–methanol (1: 1: 2) dihydrate complex was determined by the X-ray method. The crystal is monoclinic, and the space group is $P2_1$ with $Z=2$. The cell dimensions are $a=9.505(1)$, $b=14.150(1)$, $c=19.738(2)$ Å, and $\beta=102.88(1)°$. The structure was solved by an inspection of a Patterson map and by a trial-and-error method, and was refined by the block-diagonal least-squares method to the final R-value of 0.083 for 3732 reflections. The α-CDx ring is nearly hexagonal, with diagonal distances of 8.40—8.53 Å between the glycosidic oxygen atoms. The α-CDx molecules are arranged to form molecular layers perpendicular to the ac plane. The DMSO molecule is located on the secondary hydroxyl side in the α-CDx cavity, forming two hydrogen bonds with the adjacent α-CDx molecules. One methanol molecule is found on the primary hydroxyl side in the cavity, while the other is located outside the cavity. Two water molecules are distributed in the space between α-CDx molecules.

Extensive studies of inclusion and catalysis by cyclodextrins have been described.[1–3] The structure and binding force of α-cyclodextrin (α-CDx) complexes have been discussed on the basis of the structure of crystalline adducts obtained from aqueous solutions.[3–5] Recently, α-CDx was found to form complexes in a DMSO solution, and lyophobic binding has been proposed.[6] From the NMR study,[7] it seems that cyclodextrins form intramolecular O(3)–H···O(2) hydrogen bonds between the adjacent glucose residues in a DMSO solution, although the α-CDx complexes crystallized from aqueous solutions show both O(2)–H···O(3) and O(3)–H···O(2) hydrogen bonds.[4,8,9] α-CDx crystallizes from a DMSO–methanol solution. The crystal structure was determined in order to investigate the conformation of α-CDx and the α-CDx-solvent interaction in non-aqueous solutions.

Experimental

A needle-like crystal of the α-CDx–DMSO–methanol (1: 1: 2) dihydrate complex was obtained from a DMSO–methanol (1: 2) solution containing α-CDx hexahydrate (*ca.* 5%). The diffraction experiments were carried out with the crystal enclosed in a quartz capillary including a drop of mother liquor, since the crystal breaks up in air. The determination of the lattice parameters and the intensity measurement were performed on a Rigaku automatic four-circle diffractometer with graphite-monochromated Cu $K\alpha$ radiation. 3732 independent reflections with $|F_o| \geqq 3\sigma(F)$ were obtained up to 150° in 2θ by using the 2θ-ω scan technique. No corrections were made for absorption or extinction.

Crystal Data: $C_{36}H_{60}O_{30}\cdot C_2H_6OS\cdot 2CH_4O\cdot 2H_2O$, *FW* 1151.1, monoclinic, space group $P2_1$, $Z=2$, $a=9.505(1)$, $b=14.150(1)$, $c=19.738(2)$ Å, $\beta=102.88(1)°$, $V=2587.0$ Å^3, $D_m=1.46$, $D_x=1.478$ g·cm^{-3}.

Determination and Refinement of the Structure

The orientation of the α-CDx molecule in the unit cell was deduced from an inspection of a Patterson map. The position of the molecule was determined by the trial-and-error method. Then, the rigid-body least-squares technique was adopted in order to refine the position and orientation of each glucose residue. DMSO, methanol, and water molecules were found on Fourier and difference-Fourier maps. The primary hydroxyl groups of the G5 residue was found to be statistically disordered. The occupancy factors were estimated from an electron-density map, but they were not refined. Fifty-four hydrogen atoms were found on a difference-Fourier map. The refinement of atomic parameters was carried out by the block-diagonal least-squares method. The thermal factors of the hydrogen atoms were fixed as isotropic ones of the carbon or oxygen atoms to which they are bonded. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$, with $w=1.0$ for all the reflections used. The final R-value was 0.083. The atomic scattering factors were taken from "International Tables for X-Ray

Crystallography."[10] The atomic parameters are listed in Tables 1 and 2,* while the observed and calculated structure factors are given in Table 3.*

Description and Discussion of the Structure

Structure of α-CDx. The structure and numbering scheme of α-CDx are shown in Fig. 1. The bond distances, angles, and conformation angles are given in Tables 4—6.* The geometrical data for the α-CDx ring are shown in Tables 7 and 8. The average bond distances and angles are in good agreement with those found in other α-CDx complexes.[5,8,9,11-21] The primary hydroxyl group of the G5 residue is statistically disordered. The occupancy factors are 0.3 for O(6A, G5) and 0.7 for O(6B, G5). The C(6)–O(6A) and C(6)–O(6B) bonds show *gauche-gauche* and *gauche-trans* conformations respectively. The other primary hydroxyl groups are in the *gauche-gauche* conformation. The C(6)–O(6A) and C(6)–O(6B) bonds are significantly short, but a similar shortening of the disordered C–O bond has been observed in α-L-sorbose[22] and α-CDx complexes with Methyl Orange[12] and *m*-nitrophenol.[15]

The six glycosidic oxygen atoms form a nearly regular hexagon. The diagonal O(4)···O(4) distances of the α-CDx ring deviate 0.08 Å at most from their average value of 8.47 Å. These six O(4) atoms are coplanar within 0.14 Å. The average O(4)···O(4) distance between the adjacent glucose residues is 4.24 Å, with a maximum deviation of 0.05 Å. The symmetrical α-CDx ring has been also found in the sodium 1-propanesulfonate complex,[14] but the torsion-angle index[23] indicates that the conformation of pyranose rings changes slightly. The torsion-angle indices (128—136°) are significantly larger than those found in the sodium 1-propanesulfonate complex (126.6—128.5°).

Intramolecular O(2)···O(3) hydrogen bonds are observed between the adjacent glucose residues (Table 7). From the NMR spectra of cyclodextrins in a DMSO solution, only the O(3)–H···O(2) hydrogen bond has been suggested.[7] In the DMSO–methanol complex there are four O(3)–H···O(2) hydrogen bonds, but a O(2)–H···O(3) hydrogen bond is also observed between the G1 and G2 residues. The O(2)···O(3) distance between the G1 and G6 residues (3.25 Å) is too large for the hydrogen bond.

TABLE 5. AVERAGE BOND DISTANCES AND ANGLES FOR THE GLUCOSE RESIDUE

The standard deviations were estimated according to $\sigma=[\sum_{i=1}^{6}(x_i-\bar{x})^2/5]^{1/2}$, where x_i referes to the bond distances or angles in the i-th residue and $\bar{x}$ is the average value. A prime indicates the atom in the adjacent glucose residue.

* Tables 2—4 and 6 are kept at the office of the Chemical Society of Japan (Document No. 7818).

Table 9. Bond distances and angles in DMSO and methanol[a)]

I.	Bond distances (l/Å)	
	S(1, DS)–C(1, DS)	1.87(3)
	S(1, DS)–C(2, DS)	1.67(3)
	S(1, DS)–O(1, DS)	1.45(1)
	C(1, M1)–O(1, M1)	1.43(2)
	C(1, M2)–O(1, M2)	1.27(3)
II.	Bond angles (ϕ/°)	
	C(1, DS)–S(1, DS)–C(2, DS)	115(1)
	C(1, DS)–S(1, DS)–O(1, DS)	100(1)
	C(2, DS)–S(1, DS)–O(1, DS)	118(1)

a) Estimated standard deviations are shown in parentheses.

Table 10. Intermolecular distances between α-cyclodextrin and included molecules[a)]

I.	α-Cyclodextrin···DMSO (l/Å)	
	O(2, G3)–O(1, DS)	3.71(1)
	O(3, G3)–O(1, DS)	3.73(1)
	C(3, G3)–O(1, DS)	3.47(2)
	O(4, G4)–O(1, DS)	3.99(1)
	O(3, G5)–C(1, DS)	3.83(3)
	C(3, G5)–C(1, DS)	3.80(3)
	O(4, G1)–C(2, DS)	3.19(3)
II.	α-Cyclodextrin···methanol (l/Å)	
	C(5, G5)–O(1, M2)	3.83(2)
	C(6, G6)–O(1, M2)	3.71(2)
	O(6B, G5)–O(1, M2)	3.73(3)
	C(5, G6)–O(1, M2)	3.77(2)

a) Estimated standard deviations are shown in parentheses.

α-CDx-Guest Interaction. The bond distances and angles in DMSO and methanol are given in Table 9. The S(1, DS)–C(1, DS) bond is longer by 0.2 Å than the S(1, DS)–C(2, DS) bond. A similar inequality of the S–C bonds has been observed in the crystal structure of DMSO.[24)] The S–O bond is shorter by 0.09 Å than that found in the crystalline DMSO. The C–O bond of M2 is shorter by 0.16 Å than that of M1. This may be due to the large thermal motion as has been found in the α-CDx–methanol complex.[8)]

The intermolecular distances between α-CDx and included guests are shown in Table 10. The sulfur atom is located at the center of the circle composed of the twelve secondary hydroxyl groups. The C(2, DS) methyl group is inserted into the α-CDx cavity, while the C(1, DS) methyl group protrudes from the cavity. The shortest contact of DMSO with α-CDx is that of 3.47 Å found between O(1, DS) and C(3, G3), suggesting van der Waals contact. The M2 methanol is located nearly parallel to the O(4) plane on the primary hydroxyl side of the cavity. In the α-CDx–methanol complex,[8)] the methanol molecule is found in a similar position, being hydrogen-bonded to the primary hydroxyl group with the *gauche-trans* conformation. In the DMSO–methanol complex, C(6, G5)–O(6B, G5) bond is in the *gauche-trans* conformation, but the O(6B, G5)···O(1, M2) distance of 3.73 Å is too large for the hydrogen bond.

Table 11. Intermolecular distances less than 3.0 Å (l/Å)[a)]

O(6, G4)–O(1, DS)	(a)	2.72
O(6B, G5)–O(2, G6)	(a)	2.66

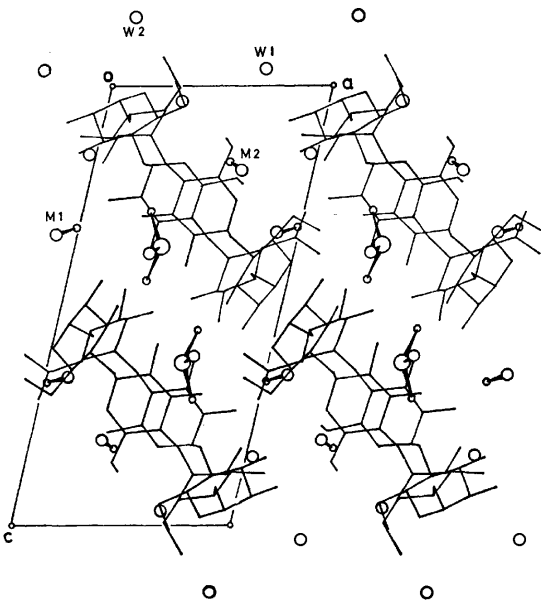

Fig. 2. The crystal structure projected on the ac plane. Circles indicate atoms in DMSO, methanol, and water molecules.

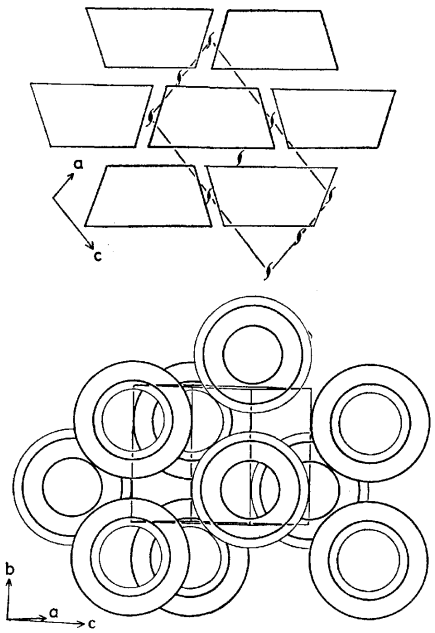

Fig. 3. A schematic drawing of the packing of α-cyclodextrin molecules.

Crystal Structure and Hydrogen Bonds. The crystal structure is shown in Fig. 2. The packing scheme of α-CDx molecules is illustrated in Fig. 3. The α-CDx molecules are arranged to form molecular layers parallel to the $(10\bar{2})$ plane. The α-CDx cavity is not connected to that of the next layer, but both ends of the cavity are open to the space between the α-CDx rings in the next layer. A similar packing of α-CDx molecules has been observed in the α-CDx complexes with *para*-disubstituted benzenes. Adjacent α-CDx molecules are linked by hydrogen bonds. In a layer, O(6, G3)–O(6, G6) (b), O(3, G1)–O(6, G2) (g), O(6, G1)–O(3, G2) (g), and O(3, G4)–O(6A, G5) (k) hydrogen bonds are observed. The adjacent layers are connected by O(6B, G5)–O(2, G6) (a), O(3, G3)–O(6, G4) (c), O(3, G1)–O(6B, G5) (c), O(2, G3)–O(3, G5) (h), and O(2, G4)–O(3, G6) (h) hydrogen bonds.

The DMSO molecule forms two hydrogen bonds with O(6, G4) (a) and O(2, G5) (j) in the next layer. The O(2)–H···DMSO hydrogen bond has also been proposed from the NMR study.[7] The methanol molecule (M2) in the α-CDx cavity is hydrogen-bonded to O(2, G1) (c), while the other methanol molecule (M1) forms two hydrogen bonds with O(2, G4) (a) and O(6, G6) (j). Thus, the DMSO and M2 methanol molecules are strongly bound to the α-CDx molecules in the next layer, although the interaction with the host α-CDx molecule seems to be weak. Each water molecule forms three hydrogen bonds with hydroxyl groups of α-CDx; O(W1) is linked to O(2, G1) (e), O(6, G3) (h) and O(6, G1) (j), while O(W2) is linked to O(6, G2) (d), O(2, G2) (f), and O(2, G6) (i).

From the DMSO methanol solution, a different crystal, which is more unstable, was obtained. The cell dimensions are $a=14.298$, $b=12.305$, $c=15.828$ Å, and $\beta=113.59°$, and the space group is $P2_1$. β-CDx crystallizes in an orthorhombic form; $a=11.428$, $b=15.549$, $c=40.025$ Å, and the space group is $P2_12_12_1$. We are attempting to elucidate these structures in order to investigate the conformation of cyclodextrins in non-aqueous solutions.

The author wishes to thank Dr. Hisashi Uedaira for supporting this study and for his helpful discussions. The computation was carried out on a HITAC 8450 computer in our laboratory.

Neutron Diffraction Study of the Structure of Liquid Water

Norio OHTOMO* and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

**Faculty of Engineering, Hokkaido University, Sapporo 060*

(Received October 28, 1977)

The structure factor for heavy water at 17 °C up to the Q value of 18 Å^{-1} has been determined by means of the time-of-flight (TOF) diffraction method using pulsed neutrons produced by LINAC. The result has been compared with structure factors calculated on the basis of the various structure models of liquid water; the "uncorrelated orientation model" and the "watery model" (Page and Powles), the "near-neighbor model" (Narten) and the "revised watery model" (authors). None of these models has been found to fit the neutron diffraction data satisfactorily over the entire range of Q, though our curve is somewhat improved in comparison with the curves for earlier models. Some discussions about the various structure models of liquid water have been made.

The neutron diffraction method has proved to be a powerful means for the determination of the structure of liquids for these two decades, and its applications into the studies of the structure of liquid water have been carried out since those by Brockhouse[1] and by Springer *et al.*[2] Recently, two remarkable studies of the liquid structure of water using the method have appeared, which have been given by Page and Powles[3] and by Narten,[4] and further, the structure factors at higher Q values have been reported.[5,6] However, the experimental data are still limited at present.

Among these studies the results[3] obtained by Page and Powles and those[4] by Narten are the most important and interesting from the view-point of the liquid structure of water. The observed structure factors obtained by both of them are found to be not so different from each other, but their conclusions on the structure models of water are largely inconsistent. It has been reported by Narten that the calculated structure factor curve based on his "near neighbor model" is in very good agreement with his observed one. However, because several arbitrarily adjustable parameters are used in his analysis, the physical reality of the model is obscured. On the other hand, any of the structure models treated in Page and Powles' paper has not fitted the diffraction data over the whole range of Q (up to the Q value of 10 Å^{-1}) and has been disproved by them.

Thus, in order to elucidate the structure of liquid water, the authors have carried out a study by the TOF diffraction technique using the electron linear accelerator as a neutron source, which has been developed recently and has turned out to be more favorable for diffraction studies of liquids than that using a reactor as the source.[7]

Experimental

i) Apparatus and Procedures. In the TOF diffraction method the analyzing actions are performed by the TOF technique, where the time-of-flight, t[μs] is measured for neutrons of various magnitudes of wavelength λ [Å] at a fixed angle 2θ [degree].[8] The momentum transfer is $\hbar Q$ and the magnitude of Q becomes

$$Q = \frac{4\pi}{\lambda}\sin\theta = 3177\frac{L_0+L}{t}\sin\theta, \qquad (1)$$

where L_0 [m] and L [m] is the flight path of the incident and scattered neutron beam, respectively. $\hbar$ is $h/2\pi$ and h is Planck constant. The schematic diagram of the apparatus is shown in Fig. 1.

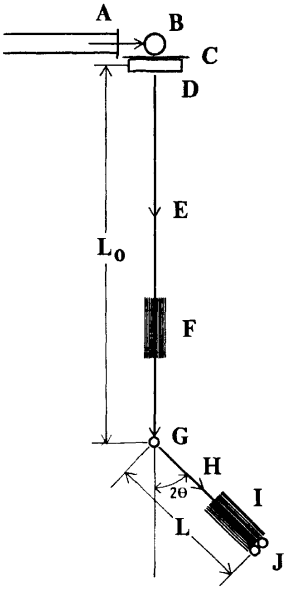

Fig. 1. Schematic diagram of the apparatus.
A: Pulsed electron beam, B: Pb target, C: Cd sheet, D: H_2O moderator assembly, E: incident neutron beam, F: Soller collimator, G: sample, H: scattered neutron beam, I: Soller collimator, and J: ^{3}He couter.

The measurement has been carried out using a pulsed neutron source which is connected to the electron linear accelerator (LINAC) at the Department of Atomic Engineering, Faculty of Engineering, Hokkaido University. In the LINAC a burst of 45 MeV (the pulse width, 3 μs and the repetition frequency of pulse, 100 pps) impinges on a water-cooled heavy metal target (lead) and pulsed photo-neutrons are produced through the (γ, n) reaction in the target. The neutrons are moderated by a water slab ($250\times250\times25$ mm^2) and become low energy neutrons in the Maxwell-Boltzmann distribution.[9] For the purpose of reducing the widening of pulse width caused by reflected neutrons a Cd sheet is inserted between the target and the water slab. The intensity and pulse width of these low energy neutrons are dependent on the shape, dimmension and arrangement of the target and the water slab, and then the neutron source system is optimized for raising up the resolution and accuracy in the present experiment.[10]

The pulsed beam of heterochromatic neutrons is scattered isotropically by the sample after passing through a flight tube set in a shielding wall and the neutrons scattered to the direction of the angle 2θ are detected by a counter. The neutron beam is collimated by two Soller collimators composed of

parallel Cd-plated sheets before and behind the sample. The slit width of the Soller collimator governs primarily the resolving power as a spectrometer, and, when the measurement is carried out at a small angle, it should be designed to be narrow enough.

The neutrons scattered by the sample are detected by a ^{3}He counter and are analyzed by a multi-channel time analyzer. Time analysis is carried out with a channel width of 20 μs and a channel number 512. The lower limit of Q in the present experiment becomes about 1 Å^{-1} at the scattered angle $2\theta=50°$ with the flight path of 7 m.

ii) Resolution. The fractional resolution $\Delta Q/Q$ is expressed as

$$\frac{\Delta Q}{Q}=\left[(\Delta\theta\cot\theta)^2+\left(\frac{\Delta t}{t}\right)^2+\left(\frac{\Delta L}{L_0+L}\right)^2\right]^{1/2}, \quad (2)$$

where $\Delta\theta$, Δt, and ΔL represent the uncertainties in θ, t, and L_0+L, respectively. $\Delta\theta$ is attributed to the widening of the beam $\Delta\theta_1$, which is determined by the slit width of the Soller collimator, as well as to the widening of the beam along the length of the detector and the sample. $\Delta\theta_1$ in the present Soller collimator becomes about 1.72° and this governs $\Delta\theta/\theta$. Δt is determined from the pulse width of the electron beam τ_p in LINAC, the mean-emission-time at the moderator τ_m and the channel width τ_c in the multi-channel time analyzer. The magnitude of τ_m is determined from theoretical and experimental considerations,[10] which becomes about 1 μs at $\lambda=0.3$ Å and increases about 25 μs at $\lambda=1.8$ Å. In the present experiment $\tau_p=3$ μs and $\tau_c=20$ μs. At small wavelength of neutrons τ_c becomes dominant in Δt. The magnitude of ΔL is calculated from the effective radius of the radiation surface of the neutron source (=15 cm) and the diameter of the detector (=2.5 cm).

Table 1. The resolving power $\Delta Q/Q$

λ[Å]	$\Delta\theta\cot\theta$	$\Delta L/(L_0+L)$	$\Delta t/t$	$\Delta Q/Q$
1.8	0.066	0.021	0.017	0.070
0.3	0.066	0.021	0.044	0.082

The resolving power $\Delta Q/Q$ is given in Table 1 for two magnitudes of wavelength. In addition to the estimation of $\Delta Q/Q$ described above the experimental determination of $\Delta Q/Q$ is also carried out, together with the calibration of Q, through the scattering experiment for polycrystalline samples such as Fe, Zr, Cu, *etc.* which have clear and known Bragg reflection peaks.

Experimental Results

Scattering measurements have been carried out at 17 °C for the sample (99.75% D_2O) which was contained in a vessel of Al foil (100 mm long, 9.0 mm in diameter; 0.017 mm wall thickness) and for a vanadium rod of the same shape and dimmension as the sample which was used as a standard and further carried out for the estimation of the contribution of background scattering. In Fig. 2 the count rate time-spectrum (the raw data of the scattering) is given, normalized in burst number of LINAC, where the spectrum for vanadium and that for background are smoothed. The magnitudes of resolution ΔQ are given as triangles along the abscissa axis. The statistical error is smaller than 1.7% in the range of $Q>2$ Å^{-1}, and becomes about 7% for $Q\approx1$ Å^{-1}. The effective range of Q in the present experiment is up to 18 Å^{-1}.

In order to determine the structure factors relevant to the molecular model of liquid, the following contributions to observed values as well as the absolute calibration should be subtracted: the multiple scattering, the absorption, the background counting and the inelastic scattering (the Placzek correction). In the present study, firstly, all data are smoothed according to the least square fitting procedure and, thereafter, the

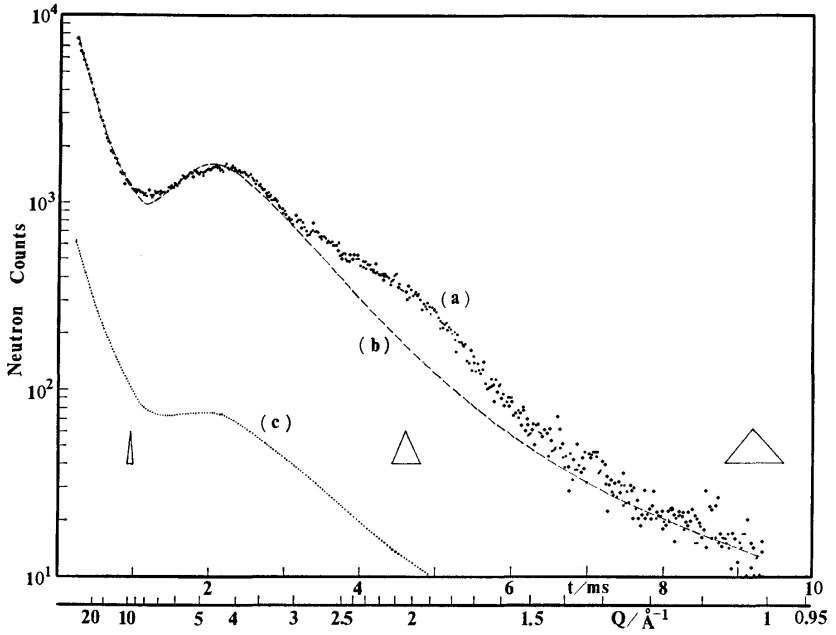

Fig. 2. Time-of-flight spectra.
(a) • : D_2O (17 °C)+background, (b) ——: vanadium rod+background, (c) ·····: background.
The magnitudes of the instrumental resolution are indicated by triangles at three points.

following corrections and reduction are made for the smoothed spectrum.

a) The multiple scattering correction: Blech and Averbach's method[11] has been used for the correction to multiple scattering. The effect of double scattering only is taken into consideration and three or more-fold scattering is ignored. We applied this correction to the scattering data of D_2O and those of vanadium rod.

b) The absorption correction: Paalman and Pings' method[12] has been applied to the absorption correction, which is used as the absorption correction in X-ray analysis for samples and vessels of cylindrical or ring shape.

c) The background correction: The background data shown in Fig. 2 has been subtracted from the scattering data for the sample and the vanadium rod after the application of the multiple scattering and absorption corrections.

d) The Placzek correction: Powles[6] proposed the method of the Placzek correction for the TOF diffraction method using the LINAC pulsed neutron source. There exist some semiempirical schemes for applying the correction, but any more rigorous numerical procedure applicable over a wide range of Q has not been discovered.[13] Then, we have applied this method in the present analysis. Page and Powles used 6.7 A.U. as the value of the effective mass M_{eff},[3] which is the mean mass of the component nuclei of a heavy water molecule. In the present analysis we have used the linearly interpolated values of M_{eff} between 2 A.U. at 20 Å^{-1} and 20 A.U. at 2 Å^{-1}. The Placzek correction rises steadily from about 2% at 2 Å^{-1} to about 8% at 10 Å^{-1}, and amounts to 16% at 18 Å^{-1}.

After the application of all corrections the calibration to the absolute cross-section scale has been carried out by comparison of the count rate time-spectrum from the sample D_2O with that from a polycrystalline vanadium rod which is usually regarded as an isotropic and incoherent scatterer. The effect of the corrections described above is seen in Fig. 3 by comparing two

Table 2. The observed absolute neutron scattering factor $S_m(Q)$ as a function of scattering vector Q [Å^{-1}] for heavy water at 17 °C

curves: the curve A (fully corrected structure factor) and the curve B (the background correction only). The difference between two curves shows the effect of the multiple scattering, the absorption and the Placzek correction. The absolute structure factor, $S_m(Q)$ for liquid D_2O thus determined after all corrections and calibration is tabulated in Table 2, and shown again in Fig. 4, together with the factors given by Page and Powles and by Narten for comparison.

Analysis of Neutron Diffraction Data

i) The Method of Analysis. It is well known that strong orientational correlations are present between adjacent water molecules in liquid water. Then, we will analyze the present data using a model in line with the correlated orientation model[3] with respect to the nearest neighbor configuration of molecules.

Firstly, under the assumption that the relative orientation of pairs of molecules is correlated in a way which is independent of molecular separarion,[14] the structure factor $S_m(Q)$ becomes[3]

$$S_m(Q) = f_1(Q) + f_{2C}(Q)[S_C(Q) - 1], \quad (3)$$

where $f_1(Q)$ and $S_C(Q)$ are the intramolecular contribution and the molecular-centre structure factor, respectively. $f_{2C}(Q)$ is a factor resulting from the orientational configuration between neighboring molecules.

Here we consider what we call the "revised watery model," that is, a revised model originating from the "watery model" proposed first by Page and Powles.[3] In the model the relative orientation of adjacent molecules is shown in Fig. 5. The water molecules constituting the tetrahedral pentamer (Fig. 5) are classified into three groups according to the manner of hydrogen-bonding: 1) a central molecule in which two OD bonds are hydrogen-bonded (Fig. 5(c)), 2) two molecules in which one OD bond is hydrogen-bonded (Fig. 5(a)), and 3) two molecules in which two OD bonds are free (Fig. 5(b)). The non-hydrogen-bonded bond length r_{OD} is 0.96 Å (the length of the bond in the vapor molecule) and the hydrogen-bonded bond length r_{OD} 1.01 Å (the length of the bond in heavy ice I). The separation r_{OO} for hydrogen bond O-D···O is taken to be 2.82 Å.[15]

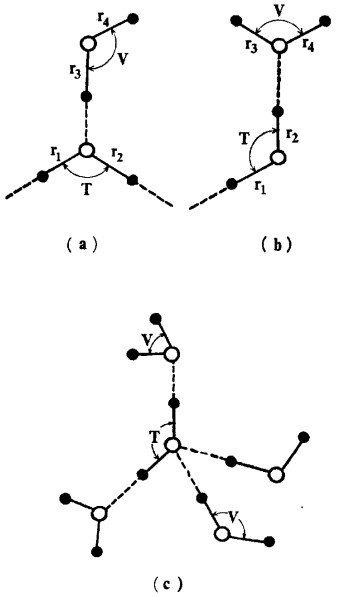

Fig. 5. The structure of the "revised watery model."
●: Deuteron nucleus, ○: oxygen nucleus.
Two types of hydrogen-bonded pairs between the central molecule and the peripheral one in the tetrahetral star-pentamer, (a): r_1, r_2, and r_3=1.01 Å, r_4=0.96 Å, (b): r_1 and r_2=1.01 Å, r_3 and r_4=0.96 Å. (c): the configuration of the tetrahedral coordination.
The four hydrogen-bonded molecules are rotating freely about each O-D···O axis. V=104.5°, T=109.5°.

The structure factor for heavy water is calculated by means of Eq. 3. The intramolecular contribution, $f_1(Q)$, consists of three varieties of factors (Fig. 5) for 1)—3) described above, and the intermolecular contribution is $f_{2C}(Q)[S_C(Q)-1]$, where the factor, $f_{2C}(Q)$, is the sum of two terms as the following equation:

$$f_{2C}(Q) = \frac{1}{2}[f^{a}_{2CW}(Q) + f^{b}_{2CW}(Q)]. \quad (4)$$

$f^{a}_{2CW}(Q)$ and $f^{b}_{2CW}(Q)$ are the structure factor for the configurations (a) and (b) in Fig. 5, respectively. These two are expressed as

$$f^{a}_{2CW}(Q) = [b_O^2 + b_O b_D\{3j_0(Qr^{i}_{OD}) \exp(-\gamma^{i}_{OD}Q^2) + j_0(Qr^{v}_{OD}) \exp(-\gamma^{v}_{OD}Q^2)\} + 2b_D^2\{j_0(Qr_s) \exp(-\gamma_s Q^2) + L(Q)\}]/(b_O + 2b_D)^2, \quad (5)$$

and

$$f^{b}_{2CW}(Q) = [b_O^2 + 2b_O b_D\{j_0(Qr^{i}_{OD}) \exp(-\gamma^{i}_{OD}Q^2) + j_0(Qr^{v}_{OD}) \exp(-\gamma^{v}_{OD}Q^2)\} + 2b_D^2\{j_0(Qr_p) \exp(-\gamma_{r,p}Q^2) + M(Q)\}]/(b_0 + 2b_D)^2, \quad (6)$$

where

$$j_0(Qr) = \frac{\sin Qr}{Qr}, \quad (7)$$

$$L(Q) = \frac{1}{\pi}\int_0^{\pi} j_0[Qh_L(\xi)] \exp(-\gamma_{h,L}Q^2)d\xi, \quad (8)$$

$$M(Q) = \frac{1}{\pi}\int_0^{\pi} j_0[Qh_M(\xi)] \exp(-\gamma_{h,M}Q^2)d\xi, \quad (9)$$

$$h_L(\xi) = \left[r^{i}_{OD}{}^2 + r^{v}_{OD}{}^2 + \frac{2}{3}r^{i}_{OD}r^{v}_{OD}\{\cos(\pi - V) - 2\sqrt{2}\cos\xi \sin(\pi - V)\}\right]^{1/2}, \quad (10)$$

$$h_M(\xi) = \left[r^{i}_{OD}{}^2 + r^{v}_{OD}{}^2 + \frac{2}{3}r^{i}_{OD}r^{v}_{OD}\left\{\cos\left(\frac{V}{2}\right) - 2\sqrt{2}\cos\xi \sin\left(\frac{V}{2}\right)\right\}\right]^{1/2}, \quad (11)$$

$$\delta = \cos^{-1}[(r^{v}_{OD}{}^2 + p^2 - r^{i}_{OD}{}^2)/2r^{v}_{OD}p], \quad (13)$$

$$p = [r^{i}_{OD}{}^2 + r^{v}_{OD}{}^2 - 2r^{i}_{OD}r^{v}_{OD}\cos T]^{1/2}, \quad (14)$$

and

$$r_s = 2r^{i}_{OD}\cos\left(\frac{T}{2}\right). \quad (15)$$

$b_0=0.577\times10^{-12}$ cm and $b_D=0.67\times10^{-12}$ cm are the coherent scattering length for oxygen and deuteron, respectively. The intramolecular oxygen-to-deuteron distance r_{OD}^{l} is the length of the O—D bond in heavy ice I and r_{OD}^{v} that in the vapor. $2\gamma_{OD}^{l}$, $2\gamma_{OD}^{v}$, $2\gamma_{h,L}$, $2\gamma_{h,M}$, $2\gamma_S$, and $2\gamma_{r,P}$ are the mean-square variation to the distance r_{OD}^{l}, r_{OD}^{v}, $h_L(\xi)$, $h_M(\xi)$, r_S, and r_P, respectively, and their magnitudes are known from various sources.[16,17] The variation is assumed to be proportional to the corresponding bond length,[18] being taken to be 0.06 Å per 1 Å for bond length. $V=104.5°$ is the DOD angle for the molecule in the vapor and T the tetrahedral angle. ξ is the average rotational angle in relation to the average of the intermolecular distance r_{DD}.[19] The molecular-centre structure factor, $S_C(Q)$, is obtained from X-ray scattering data.[16]

ii) Results and Comparison with Previous Works. The structure factor $S_m(Q)$ for the "revised watery model," which has been calculated using Eqs. 3—15 is given in Fig. 6 and compared with the experimental $S_m(Q)$ (Table 2, Fig. 4). The comparison with the calculated $S_m(Q)$ for other models is shown in Fig. 7; the "uncorrelated orientation model" and the "watery model" (Page and Powles).[3] The agreement between calculated and experimental $S_m(Q)$ is not satisfactory as seen in Fig. 6 but slightly improved in comparison with other models as seen in Fig. 7.

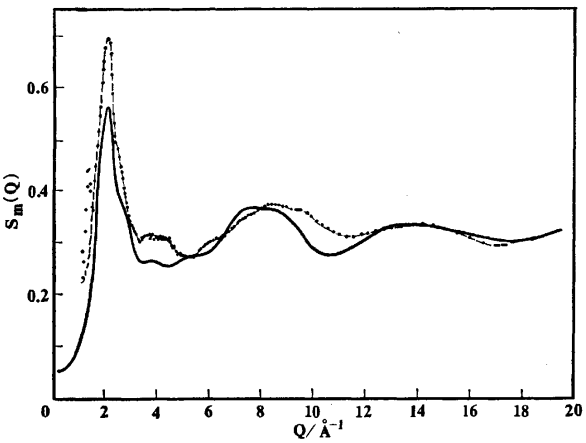

Fig. 6. The comparison between the calculated $S_m(Q)$ values for the "revised watery model" and the observed ones.
——: The calculated $S_m(Q)$ for the "revised watery model," -●-: the observed $S_m(Q)$.

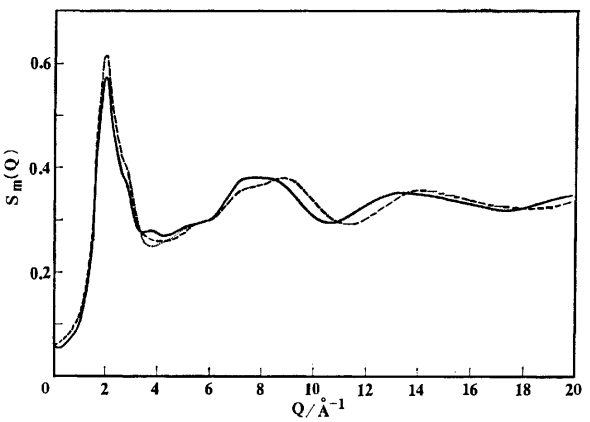

Fig. 7. The comparison between the calculated curve of $S_m(Q)$ for the "revised watery model" and the curves for other models.
——: $S_m(Q)$ for the "revised watery model," ——: $S_m(Q)$ for the "watery model," ……: $S_m(Q)$ for the "uncorrelated orientation model."

Three experimental curves, which have been given by Page and Powles, by Narten and by the authors, are compared in Fig. 4. The main features of the curves consist of the largest peak at 2 Å^{-1}, a bump about 4 Å^{-1} and a broad peak ranging over 7—10 Å^{-1}, including a rather smaller but clear shoulder at 2.8 Å^{-1}. The absolute magnitude of these peaks may be regarded as being possessed of some uncertainties, taking into consideration the fact that a certain arbitrariness is present in the application of various kinds of corrections, for example, the assignment of M_{eff} in the Placzek correction *etc.* However, the position of the peaks and shoulder is unchanged at all before and after applying the corrections, as clearly seen in Fig. 3. In analyzing the data we must take into consideration these facts. From Figs. 3, 4, 6, and 7, it can be said that the behavior of curves near 4 Å^{-1} is important in judging the adequacy of the model proposed, which has been noted by Page and Powles.[3] Our model as well as others given in Fig. 7 is not successful in this respect, though our curve is somewhat improved.

The disagreement of the first peak which is seen in Fig. 6 is attributed to the ignorance of some long range order with the period of about 3 Å, probably. This may be ascribed to the presence of unbonded water molecules which is practically ignored in the present model as well as in Page and Powles' models (except the "uncorrelated orientation model") and Narten's model, considering the fact that the first peak is the highest in the "uncorrelated orientation model" (Page and Powles). In order to improve that we must use a mixture model,[20] which is impossible without introducing some adjustable parameters in the analysis.

Narten calculated $S_m(Q)$ according to his near-neighbor model,[4,21] where one oxygen atom as an

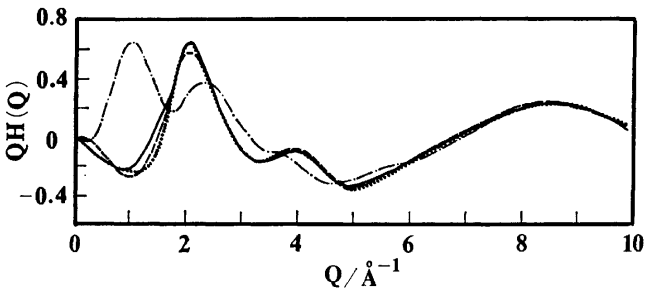

Fig. 8. The weighted structure function $QH(Q)$ calculated for Narten's model.
……: The observed curve by Narten, ——: the calculated curve by Narten, ——: the calculated curve by the authors for all $r_{o\alpha\beta}=3$ Å, -·-·-: the calculated curve by the authors for all $r_{o\alpha\beta}=5$ Å.
$H(Q)=S_m(Q)-\sum_{n=1}^{3}b_n^2/(\sum_{n=1}^{3}b_n)^2$, ($H(Q)$ is Eq. 10 in Ref. 4).

origin is surrounded by four other oxygens at the corners of a regular tetrahedron like Fig. 5 (c) and the region beyond the discrete structure is regarded as a uniform distribution of atoms, and obtained a very good fit with his experimental curve as shown in Fig. 8 which has been reprinted from his paper.[4] In order to investigate the nature of Narten's model, we have attempted to reproduce the calculation of $S_m(Q)$ according to the same procedures as described in that text, using quite identical values for molecular parameters except those for $r_{c\alpha\beta}$.[22] We have obtained the best curve for the assignment that all $r_{c\alpha\beta} \equiv 3$ Å $= r_c$, which are the separation between the nucleus α in the central molecule and the nucleus β in the continuum region. The magnitude of $r_{c\alpha\beta} \approx 3$ Å is clearly too small. It should be larger than 4.5 Å, considering the size of the discrete structure. When the larger values than 3 Å are assigned to any of $r_{c\alpha\beta}$, the shape and features of the $QH(Q)$ *vs.* Q curve are found to vary and the good fit is quite missed. Then, it is concluded for Narten's model that the assignment of implausibly small values to the parameter $r_{c\alpha\beta}$ is needed for obtaining the fit to the experimental data, and, otherwise it is not attained. Thus, the success reported in his paper[4] has turned out to be only apparent.

The authors are grateful to Associate Professor Takaaki Matsumoto and Mr. Masanobu Senda of Faculty of Engineering, Hokkaido University for their kindful cooperation in carrying out the experiment.

Light Scattering Study of Local Structures in Solutions. Structure-Forming Effect of Non-Associative Solvent on Ethanol Aggregate

Tsunetake FUJIYAMA and Masami TANAKA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received, October 31, 1977)

Light scattering spectra were observed for binary mixtures of ethanol and carbon tetrachloride, and of ethanol and cyclohexane at various concentrations. The Rayleigh intensities were reduced to concentration fluctuation values. From the observed concentration fluctuation values, the mean association numbers of ethanol at each concentration were calculated. The results were compared with that observed in ethanol–chloroform system, where associative interaction between ethanol and chloroform molecules is expected. The concentration dependencies of the mean association numbers suggested that these non-associative solvent molecules (carbon tetrachloride and cyclohexane) promote the formation of large local structure in ethanol solution.

Local fluctuation of concentration is considered to afford information which is useful to understand the mixing of liquid from a molecular viewpoint. Based upon this belief, we have planned a series of studies on analysis of temperature and concentration dependencies of concentration fluctuation through observation of light scattering spectra.[1]

First the relationship between concentration fluctuation and Rayleigh intensities has been theoretically established.[2] Then, a theory has been proposed for determining local structures existing in associated solutions from the observed concentration fluctuation in various concentrations and at various temperatures,[3,4] and the method has been applied successfully for the studies of local structures in a few kinds of binary solutions.[3–6]

In the study of the local structures which are formed in ethanol–chloroform solution, it has been emphasized that the associative interaction between chloroform and ethanol molecules arrests the growth of the local structure of ethanol and keeps the mean association number of ethanol molecules constant for all the ethanol concentrations. It is of much interest, therefore, to see the effect of non-associative solvents like cyclohexane, in place of associative solvents like chloroform, on the local structure formation of ethanol. In the present report, we will discuss the formation of local structures in ethanol–cyclohexane and ethanol–carbon tetrachloride solutions on the basis of the quantitative analysis of the concentration fluctuation measured by the light scattering spectra.

Experimental

The samples used in the present study were commercially available reagents. Ethanol was purified by distillation after elimination of water by zeolite A-3. Carbon tetrachloride and cyclohexane were purified by distillation. The binary solutions of ethanol–carbon tetrachloride and ethanol–cyclohexane were made dust-free by the use of a millipore filter FG of 0.2 μm pore size. Mole fraction of sample solutions was determined from the weight and density of each component. The refractive indices of the samples were measured by means of a Shimadzu-Bausch Lomb Abbe refractometer 3L. Density data were found in the literature.[7] The composition derivative of the refractive index at the mole fraction, x, was estimated from the refractive indices measured at $x\pm0.05$. The temperature derivative of the refractive index at the temperature, T, was estimated from the refractive indices measured at $T\pm10$ °C.

Light scattering spectra were recorded by using a spectrometer which is composed of a He–Ne gas laser source (NEC, GLG 108, 60 mW) and a pressure scanning Fabry-Perot interferometer. The spacer between the interferometer ethalon has a thickness of 6 mm, giving a free spectral range of 0.82 cm^{-1} and over-all instrumental half-width of about 0.042 cm^{-1}. Details of the spectrometer and the sampling technique have been reported elsewhere along with the reliability of the observed spectral parameters.[1,2]

The temperature of the sample solutions was controlled by a high temperature cell which was made by the authors. A temperature constancy of ±1 °C was obtained with the use of the apparatus.

Results and Discussion

Light Scattering Spectra and Concentration Fluctuation. Figure 1 shows the light scattering spectra for the ethanol–carbon tetrachloride and ethanol–cyclohexane systems. It is seen from these figures that the Rayleigh intensity increases in magnitude on passing from pure liquids to binary solutions. After separating the Rayleigh part from the observed spectra, a Rayleigh intensity was expressed relative to a Rayleigh intensity of pure ethanol. Then the concentration fluctuation,

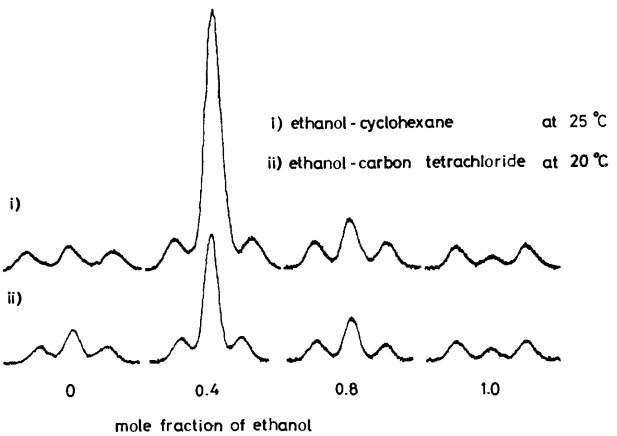

Fig. 1. Observed light scattering spectra for i) ethanol–carbon tetrachloride and ii) ethanol–cyclohexane systems. The concentration is expressed in terms of the mole fraction of ethanol.

$N\langle(\Delta x)^2\rangle$, was calculated from the relation,[2]

$$N\langle(\Delta x)^2\rangle = \frac{N_A\rho}{M}\left(\frac{\lambda_i^4}{\pi^2}\right)\frac{1}{4n^2\left(\frac{\partial n}{\partial x}\right)^2_{T,P}}\{(R_{90})_R-(R_{90})_S\}, \quad (1)$$

where N is the total number of molecules included in the field within which the concentration fluctuation is considered, N_A the Avogadro number, M the mean molecular weight, n the refractive index, ρ the density, λ_i the wavelength of the incident light, x the mole fraction of ethanol, and $(R_{90})_R$ the Rayleigh ratio for a Rayleigh line. $(R_{90})_S$ is the Rayleigh ratio for entropy fluctuation and is expressed by the relation

$$(R_{90})_S = (\pi^2/\lambda_i^4)\frac{4kn^2T^2}{C_{pg}\rho}\left(\frac{\partial n}{\partial T}\right)^2_{P,x}, \quad (2)$$

where k is the Boltzmann constant, T the absolute temperature, and C_{pg} the isobar heat capacity per gram. The C_{pg} values were found in the literature[8] only for the pure liquids studied in this work. The C_{pg} values for the binary solutions were estimated from the C_{pg} values of the pure component liquids by assuming the relation

$$C_{pg} = x_1C^1_{pg} + x_2C^2_{pg}, \quad (3)$$

where C_{pg} and x_i are the isobar heat capacity and the mole fraction of the i-th component, respectively. The error expected to the C_{pg} values thus obtained was estimated to be about a few percent by considering the C_{pg} values observed for the binary solution of ethanol and methylcyclohexane.[9] As $(R_{90})_R$ is much larger than $(R_{90})_S$ in the present binary mixture, the over-all errors which should be attached to the concentration fluctuation values are mainly determined by the uncertainties expected for the observed composition derivatives fo refractive indices (see Eq. 1).

In Figs. 2 and 3, the concentration fluctuations thus obtained are plotted against the mole fraction, x, of ethanol for ethanol–carbon tetrachloride and for ethanol–cyclohexane systems, respectively. The dashed lines in these figures correspond to the concentration fluctuation expected for an ideal binary solution. The over-all errors which should be attached to the concentration fluctuations are indicated by the vertical lines. It is seen from these figures that the observed concentration fluctuations are generally larger than that of an ideal binary solution. The concentration fluctuation takes a maximum value at $x=0.5$ for an ideal binary solution, while the observed concentration fluctuation takes maximum values at the mole fraction smaller than 0.5 for both carbon tetrachloride and cyclohexane solutions. In ethanol–carbon tetrachloride solution, the concentration fluctuation assumes much larger value for all x than that of an ideal binary solution, and takes maximum value at $x=0.3$ at 20 °C.

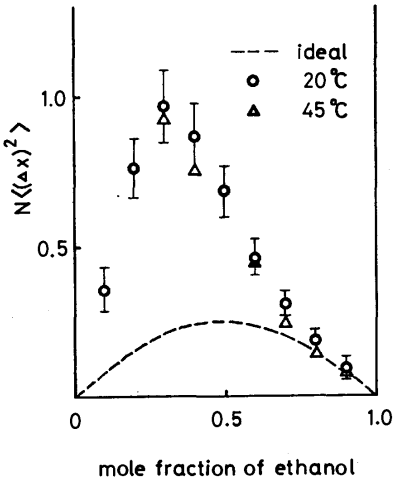

Fig. 2. Observed concentration fluctuation for ethanol–carbon tetrachloride system at the temperatures of 20 and 45 °C. Errors are indicated by the horizontal lines.

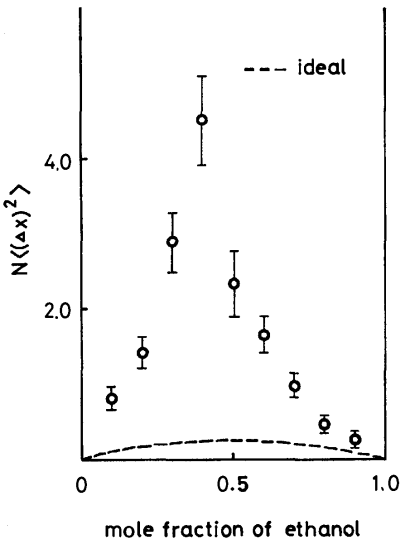

Fig. 3. Observed concentration fluctuation for ethanol–cyclohexane system at the temperature of 25 °C. Errors are indicated by the horizontal lines.

These specific concentration dependencis of the concentration fluctuation may arise from intermolecular interactions between component molecules. Taking into account the possible intermolecular interactions such as hydrogen bonding formation, we tried to estimate possible local structures expected in these ethanol solutions through theoretical consideration of the observed concentration dependencies of the concentration fluctuation.

Determination of Mean Association Number of Ethanol. In our previous reports[4,5] we have presented the associated complex model which can explain the relation between the associated complex formation and the concentration fluctuation in solutions. The associated complex formation in binary solutions would be classified into three cases: 1) the case where association between the same species occurs, 2) the case where association between different species occurs, and 3) the case where association between the same species and between different species occur simultaneously.

It has been shown that, the case 1), the concentration fluctuation takes a larger values than that of an ideal binary solution thoughout the whole concentration (see the systems "A and B_l" and "A_l and B_l" of the previous, report[4]). In the case 2), the concentration fluctuation

takes a smaller value than that of an ideal binary solution throughout the whole concentration (see the system "A and AB" or "B and AB" of the previous report[4]). In the case 3), on the other hand, the concentration fluctuation takes both larger and smaller values than that of an ideal binary solution (see the results for ethanol–chloroform system of the previous report[5]).

As the observed concentration fluctuations of Figs. 2 and 3 are always much larger than that of an ideal binary solution, the states of mixing of the solutions in question must belong to the case 1). In ethanol–carbon tetrachloride and ethanol–cyclohexane systems, it is hardly possible to imagine the associated complex formation between carbon tetrachloride molecules or between cyclohexane molecules. Therefore, we assume that l numbers of ethanol molecules associate with each other, and the resultant associated complex behaves as an independent molecule in these solutions. Then, the relation between the concentration fluctuation, $\langle(\Delta x)^2\rangle$, and the mean association number, l, of ethanol molecule is formulated to be[3,4]

$$N\langle(\Delta x)^2\rangle = x(1-x)\{x+l(1-x)\},$$

or

$$l = \frac{N\langle(\Delta x)^2\rangle - x^2(1-x)}{x(1-x)^2}, \qquad (4)$$

where x is the mole fraction of ethanol. Thus, the mean association number of ethanol can be obtained from Eq. 4 and the observed concentration fluctuation value at each concentration. The mean association numbers thus obtained for ethanol–carbon tetrachloride and ethanol–cyclohexane systems are plotted against the mole fraction of ethanol, respectively, in Figs. 4 and 5.

Local Structures in Ethanol Solutions. It is seen from Figs. 4 and 5 that the mean association number of ethanol molecules changes its magnitude with the change of the concentration. In the case of ethanol–carbon tetrachloride solution at 20 °C, the observed mean association number increases up to about 7 with the increase of ethanol mole fraction up to 0.3 and, then, gradually decreases with the successive increase in ethanol concentration. Almost the same concentration dependence can be seen in Fig. 5 for ethanol–cyclohexane solution. In this case, the maximum mean

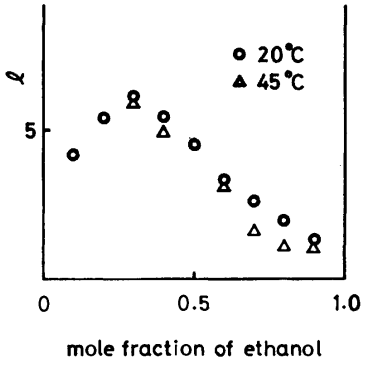

Fig. 4. Concentration dependence of mean association numbers of ethanol molecules observed in ethanol–carbon tetrachloride system.

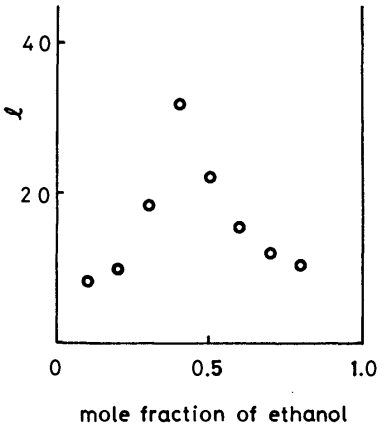

Fig. 5. Concentration dependence of mean association numbers of ethanol molecules observed in ethanol–cyclohexane system.

association number of ethanol is about 32 at 25 °C and is much larger than that observed in carbon tetrachloride solution. These results are in good contrast with the results obtained for ethanol–chloroform solution, namely, the mean association number of ethanol is about 3 for all the ethanol concentrations.[5]

It has been emphasized in the previous reports on the ethanol–chloroform system that the associative interaction between chloroform and ethanol molecules arrests the growth of the local structure of ethanol by truncating the successive growth of hydrogen bonding between ethanol molecules. The remarkable increase of the mean association number observed in the present systems is apparently consistent with this viewpoint, because the interaction between ethanol and cyclohexane or between ethanol and carbon tetrachloride is very weak in comparison with that between ethanol and chloroform molecules. However, the mean association number takes a maximum value in both cyclohexane and carbon tetrachloride solutions. At ceartain ethanol concentration the mean association number began to increase with the increase of ethanol concentration. It may be considered, therefore, that these non-associative solvent molecules promote the formation of larger local structure of ethanol molecules by surrounding and isolating the individual aggregate of ethanol molecules. Then, the decrease of the mean association number of ethanol molecules in the high ethanol concentration range can be understood reasonably, if we remind the fact that the mean association number in pure liquid ethanol is about 3—4.[10,11] As the mole fraction of ethanol increases, the number of carbon tetrachloride or cyclohexane molecules surrounding the ethanol aggregate becomes too small, and consequently neighbouring aggregates merge into more extensive aggregates, which assumes the character of pure liquid ethanol. As the mean association number of ethanol in pure liquid is about 3—4, the above situation is reflected upon the gradual decrease of the mean association number of ethanol from the maximum value down to 3—4, or the gradual breakdown of the local structure of ethanol in these solutions.

The difference between the maximum mean associa-

tion numbers observed in the ethanol–carbon tetrachloride and ethanol–cyclohexane solutions suggests the existence of very weak, but considerable degree of associative interaction between ethanol and carbon tetrachloride molecules in the binary solution of ethanol and carbon tetrachloride.

Concluding Discussion. From the discussion of the preceding paragraphs, the effects of the solvent molecules on a mean association number of ethanol may be summarized as the followings.

1) In the mixture of ethanol and the solvent which is associative with ethanol, the mean association number of ethanol does not exceed 3—4. The associative solvent molecule arrests the formation of large local structure of ethanol by truncating the seccessive hydrogen bond formation. In this sense, the associative solvent like chloroform has structure-breaking property.

2) The mean association number of ethanol increases remarkably in the mixture of ethanol and the solvent which is non-associative with ethanol. In this sense, the non-associative solvents like cyclohexane and carbon tetrachloride have structure-forming property.

The decrease of the mean association number with the increase of ethanol concentration in the ethanol-rich solution can be explained by the decrease of the structure-forming property of the non-associative solvent molecules with the decrease of the concentration of the non-associative solvent.

The Application of a Quadrupole Mass Spectrometer to a Study of Methane Oxidation in Shock Waves

Yoshiaki HIDAKA, Midori NAGAYAMA, and Masao SUGA

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received November 4, 1977)

A part of the mass-spectrometer shock-tube apparatus was improved, and its working characteristics were examined. The oxidation of methane was studied with this apparatus over the temperature range of 1800—2500 K and the total pressure range of 360—560 Torr at O_2/CH_4 ratios of 1—3. The induction period was measured by monitoring the oxygen concentration, and the following equation was found to hold:

$$\tau = 4.54 \times 10^{-10}[CH_4]^{0.37}[O_2]^{-0.64} \exp(35600/RT)\ \text{s}$$

in which the concentrations were expressed in mol per cubic centimeter.

We have previously tried to apply a quadrupole mass spectrometer to fast reactions in shock waves, and have reported the devices and characteristics of the ion source.[1] This mass-spectrometer shock-tube apparatus has since been used for the study of the decomposition of N_2O and C_2H_4.[2] However, this apparatus still has two problems. One was that the rise time of the signal on the oscillogram is suddenly prolonged by the contamination of the ion-repeller electrode. The other is the overlapping of an abnormal signal with the monitored signal of the reactant or product; this abnormal signal does not come from any of the reactants or products.[2]

The methane oxidation in a shock wave has been studied in detail by many investigators.[3-16] There is a tendency for the measured apparent activation energies to depend on the total experimental pressures, as has been mentioned by Cooke *et al.*[15] Therefore, it can be seen that the apparent activation energies previously reported may be classified roughly into two groups: about 33 kcal mol^{-1} (below 1 atm) and 50 kcal mol^{-1} (above 2 atm). The studies under low-pressure conditions (below 1 atm) are few in number than those at high pressures. It also has not become sufficiently apparent whether or not the apparent activation energy at low pressures is lower than that at high pressures.

In the present paper, we wish to report on the improvement of the apparatus and its working characteristics. Another purpose of this paper is to confirm the apparent activation energy in the oxidation of methane at relatively low pressures (below 560 Torr).

Experimental

Apparatus. The scheme of the shock tube which connects with the quadrupole mass spectrometer is given in Fig. 1. The details of the shock tube have already been described.[1,2] In the present experiment, barium titanate gauges of G_2 and G_3 were used instead of platinum resistance gauges. The barium titanate gauge G_3 was mounted flush with the inside surface of the end wall of the shock tube. A pinhole leak 20 μm in diameter was at the center of a small disk 10 mm in diameter and 1 mm thick, which was mounted flush with the inside surface of the end plate of the shock tube.

In the previous experiments, the quadrupole mass spectrometer and the shock tube were placed at right angles to one another so that the beam of gas molecules emerging from the pinhole leak entered into the ion source at right angles with the quadrupole Rod (L-type).[1] In the present experiment, though, the quadrupole mass spectrometer and shock tube

were placed at an angle of 180° to one another so that the beam of gas molecules might enter straightforwardly into the ion source from the opposite direction of the quadrupole Rod (I-type). A 4-inch oil diffusion pump with a liquid nitrogen trap was connected to the vacuum chamber, and the diffusion pump and the vacuum chamber were separated by a 4-inch butterfly valve.

A scheme of the ion source and the end section of the shock tube is shown in Fig. 2. The ion source consisted of the following parts: an ionization chamber (IC), an electron repeller (ER), a filament (F), an electron target (T), and focusing lenses (L_1, L_2, L_3, and L_4). Most of the metal parts were made of stainless steel. The tungsten filament, which was 0.2 mm in diameter, was wound in a six-turn helix. The L_1 and L_2 lens electrodes were 4 mm in inner diameter and 0.5 mm long. The ion-lens electrodes of L_3 and L_4 were constructed of pipes 4 mm and 6 mm in inner diameter, and 40 mm and 30 mm in length, respectively. They were placed at an angle of 10° to the axis of the shock tube, and also the exit of the L_3 lens was cut at an angle of 30°, as is shown in Fig. 2. The electron inlet slit (1.5 mm in diameter) was devised so as to set the edge of the leak side of the ionization chamber as near as possible. Consequently, the distance between the pinhole and the electron-inlet slit was shortened to about 4 mm. The voltage supplied to each electrode of the ion source could be changed as follows:

V_{ER}: +30—−150 V, V_{IC}: +150—+20 V,

V_T: +150—+30 V, V_{L_1}, V_{L_2}, V_{L_3}: +150—−110 V,

V_{L_4}: +150—0 V.

Sample gases behind reflected shock waves were directly introduced into the ionization chamber through the pinhole leak 20 μm in diameter and were ionized in the ionization chamber. Then, the formed ions were extracted from the ionization chamber into the ion lenses and transported into the analyzer tube (the quadrupole Rod). The ions filtered by the Rod were led to the secondary electron multiplier, and the ion-current generated from the electron multiplier was measured by means of an oscilloscope (Iwatsu DS-5158).

Materials. The compositions of the reaction mixtures used were

(A) 1% CH_4, 2% O_2, 97% Ar,

(B) 1% CH_4, 3% O_2, 96% Ar,

(C) 2% CH_4, 2% O_2, 96% Ar.

The methane, oxygen, and argon were obtained from commercial cylinders; their purities were 99.9, 99.9, and 99.99% respectively. The initial pressures of the reaction mixtures were always about 10 Torr.

Procedure. The test section of the shock tube and the vacuum chamber in which the ion source had been installed were evacuated to 2×10^{-6} Torr and 3×10^{-7} Torr respectively by two pumping systems, both of which had 4-inch oil diffusion pumps with liquid nitrogen traps. When the sample gas of about 10 Torr was admitted into the test section of the shock tube, the pressure in the vacuum chamber normally indicated a value of 4×10^{-6} Torr. The driver section was evacuated by means of a rotary pump, prior to admitting the driver gas He, until the residual gas pressure was about 1×10^{-3} Torr. Shock waves were fired within two minutes after the isolation of the pumpimg system, because the leaking and outgassing rate of the test section was about 1.57×10^{-3} Torr l/min. The operations of the pinhole leak were always checked by monitoring the inside pressure of the vacuum chamber using the ionization gauge (I). That is, before each run, the pressure in the vacuum chamber must indicate the value of 4×10^{-4} Torr when dried nitrogen gas of about 1 atm is admitted into the test section; also, the pressure must indicate the value of 4×10^{-6} Torr when a sample gas of about 10 Torr is admitted into the test section.

On the other hand, the quadrupole mass spectrometer was always adjusted and checked thus:

(1) Each electrode voltage (V_{ER}, V_{IC}, V_T, V_{L_1}, V_{L_2}, V_{L_3}, and V_{L_4}) was tentatively set up so that the detecting sensitivity of the quadrupole mass spectrometer might become a maximum.

(2) Then, a standard gas whose composition was 2% N_2 +98% Ar was heated by reflected shock waves, and the oscillogram of N_2 was observed by using the ion signal of the mass position, $m/e=28$. If necessary, the voltage, V_{L_3}, of the lens electrode (L_3) was readjusted so that the time-history curve of of N_2 could level off to a constant value during about 1000 μs.

(3) This adjustment in (2) was made for each series of experimental runs. When the detecting sensitivity of the mass spectrometer became so low that the variation in the ion-current could not be observed, the ion source had to be cleaned. The adjustment as described above was then done again.

After a series of adjustments, the reaction mixtures were heated by reflected shock waves, and the oscillogram of O_2^+ ($m/e=32$) was monitored and analyzed. With a universal counter (Iwatsu US-6141) with a precision of ±0.1 μs, the velocity of the shock waves was determined by detecting their passage between two gauges, G_2 and G_3. By assuming the gas to be ideal, the thermodynamic properties of the gas behind the reflected shock waves were calculated from the three conservation equations and from the measured incident-shock velocity.

Characteristics of Improved Ion Source. When we try to design an ion source for the study of fast reactions, the following requirements are essential, as was mentioned in a previous paper:[1]

(1) The molecules emerging from the pinhole at the end plate of the shock tube should be ionized fast.

(2) The ions thus formed should be extracted fast from

the ionization chamber.

(3) Unionized molecules should be withdrawn fast from the ionization chamber.

(4) Collisions of ions with neutral molecules emerging from the pinhole should be limited.

In the case of using the L type reported previously, ions formed by the electron bombardment needed to be forcibly extracted from the ionization chamber at right angles with the beam of the gas molecules emerging from the pinhole leak. An ion-repeller electrode had to be provided in the ion source so that the ion formed might be expelled effectively and quickly from the ionization chamber; consequently, at about 700 Torr (the pressure behind reflected shock wave) the rise time obtained was less than 10 μs. When the ion-repeller electrode was omitted from this ion source, the rise time was above 150 μs. The contamination on the ion-repeller electrode tended to increase in every experimental run and resulted in prolonging the rise time of an ion signal. This trouble happened irregularly and abruptly when the experimental runs were repeated more than 50 times. The complete adjustment of the rise time was not easy; indeed, it was the most difficult technique among the experimental procedures.

In the case of the I type, a fairly short rise time (20—50 μs) could be obtained over the pressure range of 360—560 Torr in spite of omitting the ion-repeller electrode. Since the rise time is inversely proportional to the pressure of the reflected shock wave, it can be deduced that this value is close to that in the L type. We infer that the fairly short rise time was obtained in spite of omitting the ion-repeller electrode, because the molecules emerging from the pinhole leak enter the ionization chamber, and the ions formed by an electron bombardment are expelled from that chamber. The direction of these molecules and ions is the same as in the I type; moreover, these molecules flow with a large translation energy in the direction of the ion lenses.[1)]

In the I type, the troubles in the rise time were eliminated. This may be because the ion-repeller electrode was omitted from the ionization source. The rise time did not vary even if the experimental runs were repeated more than 200 times.

There is another problem, "the abnormal signal." Since, in this kind of study, the reaction gas is generally diluted with large quantities of Ar, the high range of the detecting sensitivity of the multiplier and the amplifier needs to be employed for observing the time history of reactants or products on the oscillogram. When a high detecting sensitivity was used, an abnormal signal was observed; it always had to be subtracted in the data analysis as if it were a background signal.[2)] It was considered that this abnormal signal was not attributable to ions but to neutral species possessing a high translational energy.[2)] In order to separate the ions and neutral species, the lenses of L_3 and L_4 were designed as is shown in Fig. 2. The abnormal signal could be almost eliminated by this device. By this improvement of the ion source, the sensitivity was lowered slightly, but both the resolution of the mass spectrometer and the rise time of the ion signal did not vary at all.

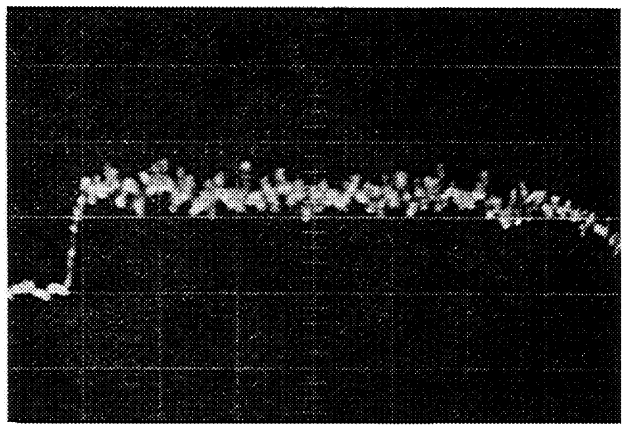

Fig. 3. Typical oscillogram of N_2^+ ($m/e=28$).
Sweep=200 μs/div., $T_5=1908$ K, $P_5=430$ Torr. Supplied voltages: $V_{ER}=+22$ V, $V_{IC}=+130$ V, $V_T=+130$ V, $V_{L_1}=+70$ V, $V_{L_3}=-116$ V, $V_{L_4}=+92$ V, $V_{L_4}=+110$ V, $V_{Rod}=+110$ V.

This apparatus had been previously checked with the time history of Ar^+ ($m/e=40$).[2)] In the present experiment, it was checked with the time history of N_2^+ ($m/e=28$) using a gas mixture (2% N_2+98% Ar). A typical time history of N_2^+ is shown in Fig. 3. In this cheking, it is necessary that the time history of N_2^+ measured on the oscillogram rise rapidly and remain constant for more than 1000 μs.

Results and Discussion

Some typical oscillograms of reactants (CH_4 and O_2) and the main products (H_2O, CO, and CO_2) near 1940 K are shown in Fig. 4. All of these are measured with a same ionizing energy of 24 eV. The time history of a product (H_2O, CO, or CO_2) keeps a base level for a certain time after shock heating, and then begins to rise gradually. On the contrary, the time history of a reactant (CH_4 or O_2) rises rapidly, keeps a nearly constant value for a while, and then falls exponentially until an equilibrium is reached. There is a lag time in the apparatus which has been defined as the time elapsing from the beginning of the reflected shock-wave signal to the beginning of the ion-current signal.[1)] If the induction period is calibrated by monitoring the time history of one of the products, the lag time needs to be measured in preliminary experiments beforehand.

In the present study, the induction period is defined as the time elapsing between the reflected shock arrival and the onset of the rapid decrease in the oxygen concentration; it is measured by monitoring the O_2^+ ($m/e=32$) signals at an ionizing energy of 110 eV, as is shown in Fig. 5. The induction period is calibrated as is shown in Fig. 6, which is obtained by averaging the noise of an observed signal (Fig. 5). Since "the lag time" of the apparatus is cancelled in the calibration in Fig. 6, it is not necessary to take account of this. This is a reason for monitoring the concentration of the O_2 reactant in a series of experimental runs.

In order to monitor the time hisroty of O_2^+, a high detecting sensitivity was required. A high ionizing energy 110 eV, was adopted in order to achieve a higher detecting sensitivity. When this high ionizing energy was adopted, many fragments appeared. When the ion signals at $m/e=16$ were monitored at the ionizing energy of 110 eV, it was the signal of CH_4^+ plus O^+ which was considered to consist of fragment ions of H_2O, CO, and CO_2. When we monitored the concentration of CH_4, the ionizing energy had to be kept lower at the expense of the detecting sensitivity. This was another reason to monitor the concentration of O_2.

Table 1 summarizes the results of the induction periods, τ, together with the conditions of the experimental runs.

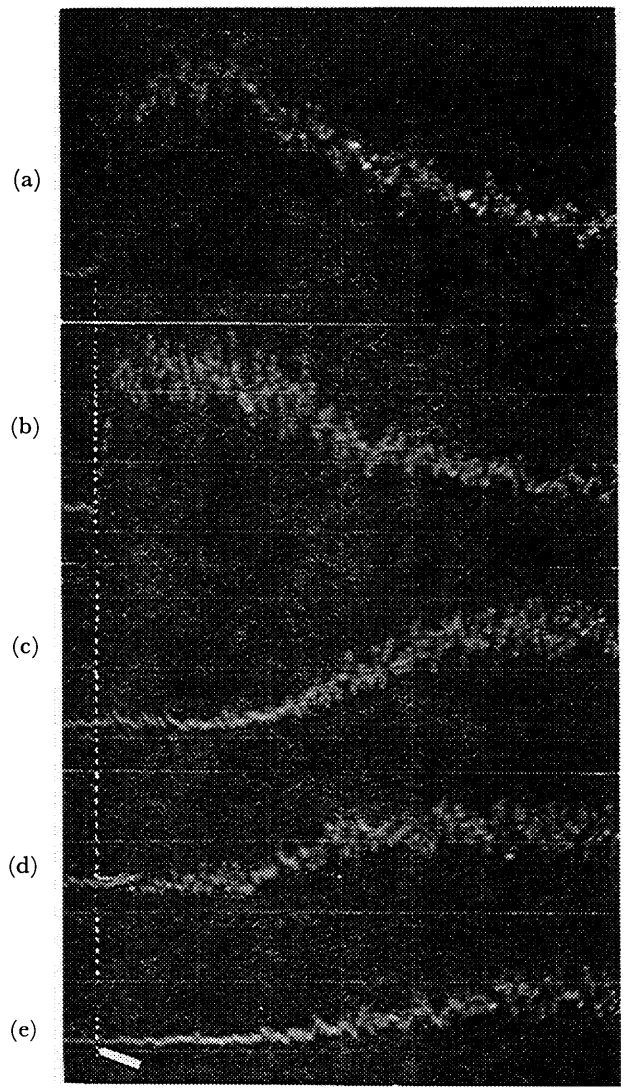

Fig. 4. Some typical oscillograms of species on the methane oxidation near 1940 K.
Sweep=200 μs/div. (a) Time history curve of O_2^+ (m/e=32), T_5=1956 K, P_5=416 Torr. (b) Time history curve of CH_4^+ (M/e=16), T_5=1944 K, P_5=413 Torr. (c) Time history curve of H_2O^+ (m/e=18), T_5=1936 K, P_5=412 Torr. (d) Time history curve of CO^+ (m/e=28), T_5=1938 K, P_5=412 Torr. (e) Time history curve of CO_2^+ (m/e=44), T_5=1947 K, P_5=414 Torr. Supplied voltages: V_{ER}=+18 V, V_{Ic}=+44 V, V_T=+45 V, V_{L_1}=+42 V, V_{L_2}=−90 V, V_{L_3}=+13 V, V_{L_4}=0 V, V_{Rod}=+23 V,

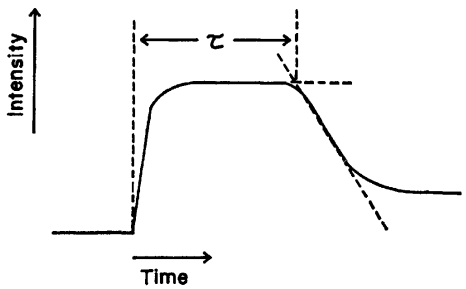

Fig. 6. Definition of the induction period.

Figure 7 shows the plot of log τ *versus* $1/T$ for three composition groups, A, B, and C. It can readily be seen that the values of log τ in each group fall on a single line and that all the lines are parallel. Figure 8 shows the plotting of log τ $[CH_4]^{-0.37}$ $[O_2]^{0.64}$ *versus* $1/T$ for the three groups of A, B, and C. All the points fit a single straight line. The temperature coefficient of the induction periods can be obtained from the slope of the line drawn in Fig. 8. Over the temperature range covered by the present experiment, the induction periods can be represented as

$$\tau = 4.54 \times 10^{-10}[CH_4]^{0.37}[O_2]^{-0.64} \exp(35600/RT)\ \text{s},$$

in which concentrations are expressed in mol per cubic centimeter.

In the study of oxidation reactions in shock waves, induction periods have been considered to be a useful parameter in elucidating a reaction mechanism. The terms "induction period of ignition" and "induction period" have been used in studies of methane oxidation

using the shock waves although there is same uncertainty in their definitions. The first study of the induction period of methane oxidation in shock waves was carried out by Skinner and Ruehrwein in 1959.[3] Afterwards, a considerable number of data have been reported by many investigators.[4-16] Most of the reported activation energies center around 50 kcal/mol (at high pressures (above 2 atm)) or 33 kcal/mol (at low pressures (below 1 atm)).

Our experimental results indicate that the reaction of methane oxidation passes through two steps: the first step (during the induction period) is characterized by a very slow decrease in the oxygen concentration, while the second step (after the induction period) is followed by a rapid decrease. The induction periods are measured by monitoring the oxygen concentration; thereby, an apparent activation energy of 35.6 kcal/mol is obtained over the pressure range of 360—560 Torr and the temperature range of 1800—2500 K. The value of the apparent activation energy obtained is in good agreement with the values obtained by Cooke *et al.*,[15] Higgin *et al.*,[10] and Kistiakowsky *et al.*[4] in spite of the differences in the method of measurement. On the other hand, although we have tried analysing the time history of the O_2 concentration after the induction period, we have not yet obtained any useful information on the methane oxidation.

Molecular Dissociation of 3-Cyclopenten-1-one Photosensitized by Excited Mercury ($^3P_1$)

Kazumoto NAKAMURA, Seiichro KODA, and Kazuo AKITA

Department of Reaction Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Hongo, Tokyo 113

(Received November 11, 1977)

The mercury photosensitized decomposition of 3-cyclopenten-1-one produced carbon monoxide and 1,3-butadiene in equal quantum yields as the exclusive products, independent on the absence or presence of nitrogen oxide. Thus the process was a molecular dissociation. The quantum yield was dependent on the pressure of argon added as a third body and revealed a maximum at the pressure of about 100 mmHg. A possible reaction scheme was proposed to explain the above kinetic behavior. It was suggested that the vibrationally excited state of 3-cyclopenten-1-one was a main precursor to decompose to carbon monoxide and 1,3-butadiene. An energy about 20 kcal·mol^{-1} was estimated to be lost before its production from the original triplet state 3-cyclopenten-1-one according to the proposed reaction scheme. This result is compared with the behaviors of excited 3-cyclopenten-1-ones produced by different excitation procedures.

Mechanisms of pyrolyses, photolyses and photosensitized reactions of saturated cyclic ketones and cyclic unsaturated hydrocarbons have been well elucidated in recent years.[1] But those of unsaturated cyclic ketones are rarely investigated. Among them is 3-cyclopenten-1-one (abbreviated as CP). Dolbier and Frey[2] studied the thermal decomposition of this ketone. Hess and Pitts[3] reported the direct photolysis at 313 nm briefly. In both cases, carbon monoxide (CO) and 1,3-butadiene (BD) were exclusive products. To our knowledge, however, there is no report on the mercury photosensitization of this ketone.

During our study of the atomic oxygen reaction with 1,3-cyclopentadiene,[4] CP was proposed as an important intermediate to decompose to CO and BD. The spin state of the intermediate cyclopentenone could be either singlet or triplet. Apart from the oxygen atom reaction, a triplet state CP is expected to be prepared through mercury photosensitization of the ketone itself. Moreover, the energy which is transferred from the excited mercury atom to the ketone should be 113 kcal·mol^{-1} or less, which is relatively close to the possible excess energy possessed by the intermediate CP of the atomic oxygen reaction with cyclopentadiene; that is about 105 kcal·mol^{-1}.[5]

Thus we are interested in the possible difference in the mechanism of decomposition of CP excited by mercury photosensitization from those of cyclopentenones excited thermally or by direct photon absorption, or prepared through the reaction of oxygen atoms with 1,3-cyclopentadiene. This matter will be discussed after the photosensitized decomposition of CP is described.

Experimental

Materials. The preparative method of 3- and 2-cyclopenten-1-one were described by Hess and Brown.[6] The crude pentenones were purified by repeated distillations. Gas-chromatographic analyses showed that the CP and the 2-cyclopenten-1-one were more than 99 and 97% pure, respectively.

Commercially obtained argon (pure grade; the purity is more than 99.99%; from Takachiho Shoji Co., Ltd.), nitrogen, CO, BD, and 1-butyne (the four gases are of research grade from Takachiho Shoji Co., Ltd.) were used without further purification. Commercially obtained dinitrogen oxide, nitrogen oxide and ethane (all, research grade; from Takachiho Shoji Co., Ltd.) were distilled several times *in vacuo* before use.

Cyclobutene (CB) was synthesized through the photoisomerization of BD according to the method described by Srinivasan[7] and purified gas-chromatographically.

Apparatus. The cyclindrical quartz photochemical cell was 5 cm in diameter and 10 cm long, equipped with a gas circulation line with a glass-made circulation pump having Teflon bearings, mercury store, a U-type trap, and a reservoir. The total volume of the reaction system mentioned above was 650 ml. A conventional vacuum system was used for gas handling.

The 253.7 nm light source was a flat-spiral low pressure mercury resonance lamp (Ushio Electric Inc., type UTL-7SQ). The light from the lamp passed through a glass filter (Toshiba Kasei Co., Ltd., UV-D25) to get rid of the radiation below 200 nm, an iris (diameter 10 mm), a quartz lens (f=10 cm) and a quartz beam splitter. The transmitted light reached the cell. The reflected light at right angles from the beam splitter reached a phototube (Hamamatsu TV Co., Ltd., R765). Thus the relative intensity of this radiation could be monitored to be corrected for any fluctuation of the radiation all through the experimental runs.

Experimental Procedure. A measured amount of CP (and nitrogen oxide, if necessary) was introduced into the reaction system. Then argon, if necessary, was added through a slightly opened stopcock until the desired total pressure was reached. The gas mixture was circulated all through the total reaction system by means of the circulation pump for at least an hour before photolysis. Within an hour, mercury vapor evaporated from the mercury store into the gas mixture until the equilibrium pressure at the temperature was reached. Irradiation was carried out for a desired period, while the gas mixture was being circulated.

After the irradiation, the gas mixture was treated as follows. In the experiments without argon, the mixture was divided to three portions. The first portion, non-condensable at liquid nitrogen temperature, was collected by a Toepler pump. The other two portions, one of which was not condensable at Dry Ice–methanol temperature (−78 °C) and the other of which, condensable at that temperature, were sampled in gas samplers cooled at the adequate temperatures, respectively. In the experiments with argon, a part of the mixture was expanded into a gas sampler. The remaining part was pumped out very slowly through several spiral traps immersed in a Dry

Iice–methanol bath. The collection efficiency of the traps was checked for BD and was found to be at least 95%.

Analyses of Products. The products were identified and analysed quantitatively by means of gas-chromatography (Yanagimoto Seisakusho Co., Ltd., G80-PT(TCD), G80-FTP (FID)) with several appropriate columns. The columns used were 3,4-dimethylsulfolane (4.5 m, 0 °C) and Squalane (3 m, 30 or 90 °C) for BD and also for lower hydrocarbons, Molecular Sieve 5A (2.25 m, 60 °C) for nitrogen and CO, bis(2-ethylhexyl)phthalate (2.25 m, 70 °C) and Polyethylene Glycol 20M (2.25 m, 100 °C) for searching for other possible products of a larger molecular weight. Usually a thermal conductivity detector was used for nitrogen and CO and a flame ionization detector for hydrocarbons.

In the experiments with argon, the product CO could not be separated from the large amount of argon by a conventional method. Thus the part which represented the total photolysed mixture correctly, and had been expanded into a gas sampler, was introduced into the gas-chromatograph after being got rid of the condensable products at Dry Ice–methanol temperature. The product CO was then separated from argon through the Molecular Sieve 5A column in the gas-chromatograph, converted to methane by the reduction with the carrier gas hydrogen at 320 °C through the nickel catalyst column (from Gasukuro Kogyo Co., Ltd.) connected to the Molecular Sieve 5A column directly, and then detected with a flame ionization detector. Carbon monoxide of more than 30 ppm in argon could be analysed quantitatively by the above procedure, provided that the total mixture of 3000 mmHg·cm^3 was introduced to the gas-chromatograph.

Measurements of the Intensity of Light Which Leaks out from the Cell. The intensity of the light coming out from the inside of the cell (transmitted light and re-emitted light from the excited mercury) was measured with a phototube at various positions around the cell. The total amount of the leaking light could be then estimated by summing the measured intensity values with taking into account the geometry of the cell.

Estimation of the Amount of Absorbed Light in the Cell. The amount of the light which leaked out from the cell was measured by the above procedure under several different experimental conditions as shown in Table 1. Thus the percentage of the absorption was always about 95%, in various experimental runs including the case of the photolysis of the mixture of dinitrogen oxide and ethane. Then the amount of absorbed light in the cell could be calculated based on the experimental nitrogen yield from the photolysis of dinitrogen oxide–ethane; the quantum yield of the nitrogen production is unity according to Ref. 8.

Results

The main products were CO and BD. Trace amounts of C_2 and C_3 hydrocarbons, 1,2-butadiene and 1-butyne were detected in some experiments, especially when the conversion was high. But they were always produced in negligibly small quantum yields. No other C_4H_6 isomers such as CB and 3-methylcyclopropene could be detected. Their quantum yields should be less than 0.002, considering from the detection limit of our analysis. Small amount of 2-cyclopenten-1-one, one of the isomers of cyclopentenones, were detected in some experiments. But quantitative analyses gave relatively poor reproducibility for this product, possibly because of its easiness to adsorb on the wall of the reaction and/or analysis systems. Thus quantitative analyses were confined to CO and BD.

The quantum yield of carbon monoxide was independent on the irradiation time as shown in Fig. 1, which guaranteed that no secondary photolysis of the products proceeded to appreciable extents under the

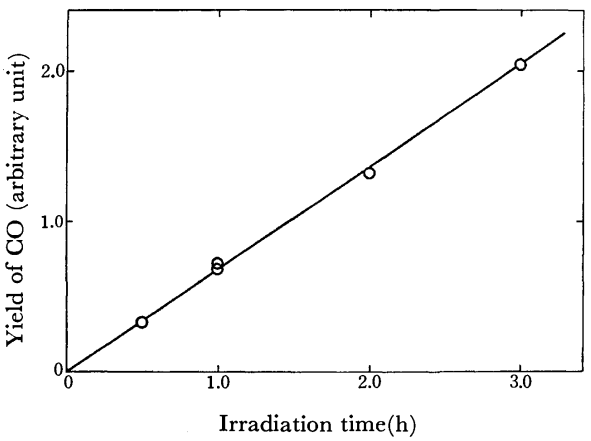

Fig. 1. Yield of carbon monoxide *versus* irradiation time
Pure CP (10.0—12.4 mmHg) was photosensitized, at 20—25 °C. The yield of CO is corrected for the variation of the light intensity.

present conditions.

Table 2 shows the quantum yields of CO and BD. In some experiments, argon was added in order to know its effect as a third body. Argon is known not to quench excited mercuries in any appreciable extent. In several experiments, nitrogen oxide as a radical scavenger[9] was added. The ratio of the quantum yield of CO versus that of BD was found to be always very close to unity under various conditions, as shown in the last column of the table.

We carried out one special experimental run where the mixture of methane (656 mmHg) and CP (10 mmHg) was photolysed. No C_4H_6 isomers other than BD could be detected. The yield of CB, if it were produced, should be less than 0.03% of that of BD produced, judging from the gas-chromatographic sensitivity.

Discussion

Molecular Dissociation. As shown in Table 2, the ratio of the quantum yield of CO to that of BD was about unity in any experiment under various conditions. Even in the experiments where nitrogen oxide was added, the ratio did not change. The decrease of the yield of CO and BD with the addition of NO should be attributed to the quenching effect of NO for the excited mercuries. These observations show that CO and BD are produced *via* a common intermediate, and no radical species seems to contribute to the production of CO and BD. Therefore, the main reaction is considered to be a molecular dissociation of a certain excited CP to produce CO and BD, under the present conditions.

Absence of Excited Cyclobutene as an Intermediate. BD is considered to be produced through a molecular dissociation as stated in the previous section. One possibility is that BD is, in fact, produced as a secondary product through isomerization from some other vibrationally excited C_4H_6 isomers which might be produced primarily. Among C_4H_6 isomers other than BD, CB seems to be the most plausible primary species, because CB could be produced as a molecular dissociation product from excited CP without any serious rearrangements of molecular structures and also because it is known to isomerize thermally to BD exclusively.[10] Thus we must determine whether BD is produced *via* the excited CB intermediate, CB*, or is produced directly. Because some part of CB* should be collisionally stabilized and analysed as CB, we can estimate the fraction of the process *via* CB*, X, based on the fraction of CB among product C_4H_6 isomers (CB+BD), β, which is experimentally obtainable. Here, the following scheme is assumed.

$$\text{Intermediate}\,(C_5H_6O) \longrightarrow CO + CB^* \quad k_a \quad (1)$$

$$\longrightarrow CO + BD \quad k_b \quad (2)$$

$$CB^* \longrightarrow BD \quad k_{iso} \quad (3)$$

$$CB^* + M \longrightarrow CB + M \quad \alpha k_\omega \quad (4)$$

(α=collisional deactivation efficiency, k_ω=kinetic collision frequency at the pressure)

X and β are equated to the rate constants, as follows.

$$X = \frac{k_a}{k_a+k_b} \quad (5)$$

$$\beta = \frac{k_a}{k_a+k_b} \times Y \quad (6)$$

Here, $Y=\alpha k_\omega/(\alpha k_\omega+k_{iso})$. Therefore, X can be calculated from β and Y.

$$X = \beta Y^{-1} \quad (7)$$

The value β is determined experimentally. The value Y can not be obtained experimentally, but may be approximately estimated by simple statistical considerations as described below. At first, the rate constant k_{iso} is calculated by the following equation when the excess energy of CB* is E.

$$k_{iso} = A(1-E_a/E)^{s-1} \quad (8)$$

By use of $s=10$, $E_a=32.9$ kcal·mol^{-1}, $A=10^{13.3}$ s^{-1} and $E=66$ kcal·mol,$^{-1}$ k_{iso} is calculated to be 1×10^{10} s^{-1}. Here, the value $s=10$ is claimed to be optimum to explain the experimental results of the thermal isomerization of CB,[10,11] and then rate parameters E_a and A are taken from the data of the thermal isomerization.[10] The excess energy E is estimated as follows. It is likely that about 105 kcal·mol^{-1} energy is transferred to CP from the $^3P_1$ mercury, referred to the experimental results of Montague and Rowland.[12] According to the simple statistical consideration, CB* possesses the excess energy which is equivalent to the available energy multiplied by the ratio of the number of internal degrees of freedom of CB(24) to that of CP(30). The available energy is equal to the transferred energy (105 kcal·mol^{-1})+ the heat of reaction of the dissociation of CP to CO and CB (-23 kcal·mol^{-1}). Its twenty four-thirtieth is 66 kcal·mol^{-1}. Secondly, the term αk_ω is estimated by adopting 1×10^7 s^{-1} as the kinetic

collision frequency at 1 mmHg and by use of appropriate α values. α is 0.24 for methane[13] and unity deactivation efficiency is assumed for CP.

Thus, the value of Y is estimated to be 0.14 in the experiment with 656 mmHg of methane (CP, 10 mmHg) and to be 0.0099 in the experiments without additive gases (CP, 10 mmHg). As described in the result section, CB could not be found both in the experiment with 656 mmHg of methane and in the experiments without additive gases. Correspondingly, the possible maximum of β is 3×10^{-4} in both cases. According to Eq. 7, the possible maximum of X should be then 2×10^{-3} in the experiment with 656 mmHg of methane and 3×10^{-2} in the experiments without additive gases.

The above discussions show that the process *via* the excited CB contributes to a very small extent, if at any. BD must be produced as the primary dissociation product from the molecular dissociation.

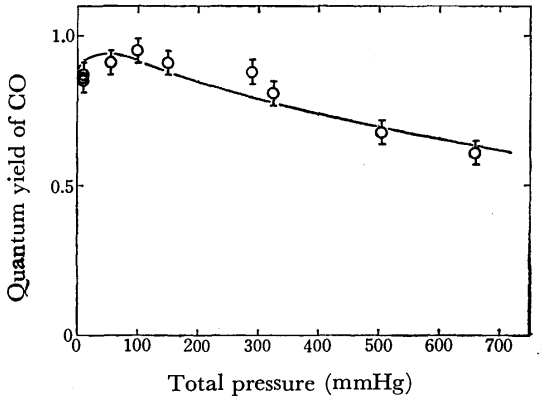

Fig. 2. Quantum yield of carbon monoxide versus total pressure.
Data are from Table 2. total pressure=Ar pressure+ CP pressure (9.8—11.3 mmHg)

Reaction Scheme. Figure 2 shows the relationship between the quantum yield of CO, ϕ_{CO}, and the total pressure. Here, the total pressure is the sum of the pressure of CP which was about 10 mmHg all through the experimental runs and the pressure of argon which was varied.

The fact that the extrapolation value of the plots to zero pressure is not unity suggests the existence of a channel through which products other than CO and BD are produced. Those products could not be clearly identified, but the isomer 2-cyclopenten-1-one is one possibility. The complex dependence of ϕ_{CO} on the pressure indicates the existence of several consecutive competitions between stabilization and dissociation to produce CO and BD. At least two independent processes which are affected by collisions are required in order to explain the positive and then negative pressure dependence of ϕ_{CO}. It is very plausible that the vibrationally excited state of CP is the immediate precursor to decompose to CO and BD, taking into account the facts that the products of pyrolysis of CP is exclusively CO and BD,[2] and that the Woodward-Hoffmann rule indicates the possibility of the production of CB from electronically excited CP's, against our observation.

As a simple model which satisfy the above considerations, we propose the following reaction scheme.

$$C_5H_6O(S_0) + Hg(^3P_1) \longrightarrow C_5H_6O(T) + Hg(^1S_0) \quad (9)$$

$$C_5H_6O(T) \longrightarrow CO + BD \quad (10)$$

$$C_5H_6O(T) \longrightarrow \text{other products except CO and BD} \quad (11)$$

$$C_5H_6O(T) + M \longrightarrow C_5H_6O(T') + M \quad (12)$$

$$C_5H_6O(T') \longrightarrow C_5H_6O(S_0^*) \quad (13)$$

$$C_5H_6O(S_0^*) \longrightarrow CO + BD \quad (14)$$

$$C_5H_6O(S_0^*) + M \longrightarrow C_5H_6O(S_0) + M \quad (15)$$

Here, M means a third body. Argon and CP are not differentiated from each other, though they may have different quenching ability. We did not vary the pressure of CP to reveal its different quenching ability from argon, because of its low vapor pressure at room temperature, which is 13 mmHg.

The reaction 10 may be a single process as described above or more plausibly a consecutive process (Eqs. 10a and 10b),

$$C_5H_6O(T) \longrightarrow C_5H_6O(S_0^\dagger), \quad (10a)$$

$$C_5H_6O(S_0^\dagger) \longrightarrow CO + BD, \quad (10b)$$

where $S_0^\dagger$ means a vibrationally excited ground state of CP with a larger excess energy than S_0^*. The process (Eq. 10a) is a collision free intersystem crossing. Because of the very large amount of excess energy of $S_0^\dagger$, its subsequent process is almost confined to the dissociation (Eq. 10b) under the present pressures. The T' state is either the vibrationally relaxed T state or any other different triplet state with a lower triplet energy. S_0^* means a vibrationally excited S_0 state, and is assumed to possess less energy than is originally transferred from the excited mercury because of the collisional deactivation (Eq. 12).

According to the above scheme, we can derive.

$$\phi_{CO} = \frac{1}{1+(k_{11}/k_{10})+(k_{12}M/k_{10})} + \frac{k_{12}M/k_{10}}{1+(k_{11}/k_{10})+(k_{12}M/k_{10})}\cdot\frac{1}{1+k_{15}M/k_{14}}. \quad (16)$$

Adoptation of appropriate values for the ratios of the rate constants is found to result in coincidence between the experimentall values and calculated values according to Eq. 16 within experimental errors. When the optimum values, $k_{11}/k_{10}=0.15$, $k_{12}/k_{10}=5\times10^{-2}$ mmHg^{-1}, $k_{15}/k_{14}=9\times10^{-4}$ mmHg^{-1} are adopted, the calculated values of ϕ_{CO} are shown as a bold line in Fig. 2. Though these rate ratios could not be determined unequivocally, the allowable range of k_{15}/k_{14} to satisfy the experimental results was found to be between 1×10^{-3} and 7×10^{-4} mmHg^{-1}. This range could be rather unequivocally determined, because the relationship between ϕ_{CO} and the pressure is determined by this ratio almost exclusively, when the pressure is above 150 mmHg.

Adoptation of a multi-step deactivation process in place of Eqs. 14 and 15 was found to result in a little better coincidence, but the improvement was minor. Thus we consider that the scheme (Eqs. 9—15) is enough to explain the experimental results. This scheme is also

compatible with the considerations of the excess energy of the intermediate S_0^* state, as will be described in the next section.

Excess Energy of the Excited Ground State 3-Cyclopenten-1-one. The experimental value of k_{15}/k_{14} gives the value of k_{14} as 1.1×10^9 s^{-1} on the basis of the assumption, $k_{15}=1\times10^6$ mmHg^{-1}·s^{-1}. Here, the k_{15} value of one-tenth (which is the collisional deactivation efficiency) of the gas kinetic collision frequency is used.[13] The excess energy of S_0^* can be estimated by use of

$$k(E) = A(1-E_a/E)^{s-1}. \quad (17)$$

Here, $k(E)$ is a rate constant of decomposition when an excess energy is E. We get $E=86.6$ kcal·mol^{-1} by using the values of A ($10^{14.5}$ s^{-1}) and E_a (51.3 kcal·mol^{-1}) taken from the experiment of Dolbier and Frey,[2] and assuming $s=15$. The possible range of the ratio k_{15}/k_{14} between 1×10^{-3} and 7×10^{-4} mmHg^{-1} corresponds to the range of the excess energy E between 86.2 and 87.1 kcal·mol^{-1}. The estimation of the excess energy is also dependent on the assumed value of the collisional deactivation efficiency. For example, unit efficiency, which is an unlikely large efficiency, result in the increase of the excess energy about 10 kcal·mol^{-1}. But even in this case, the excess energy is still smaller by about 10 kcal·mol^{-1} than the energy, about 105 kcal·mol^{-1}, which is originally transferred to CP from the excited mercury. Thus the dissociating intermediate S_0^*, and also T′ seem to be deactivated by 20 kcal·mol^{-1} or so before the dissociation. The energy loss should be due to the vibrational deactivation process (Eq. 12) in the triplet state.

Triplet State of 3-Cyclopenten-1-one. CP possesses two active chromophores which are relatively independent on each other; they are C=O and C=C double bond. Then two kinds of triplet states of low energy are expected to exist; one is $^3(n-\pi^*)$ mainly excited in the C=O chromophore (T_a) and the other is $^3(\pi-\pi^*)$ mainly excited in the C=C chromophore (T_b).

The absorption spectrum of CP measured by Hess and Pitts[3] clearly shows two different absorption systems, one of which is relatively weak ($\varepsilon\approx10$ l·mol^{-1}·cm^{-1}) and in the region from 250 to 320 nm, and the other is strong ($\varepsilon\approx10^3$ l·mol^{-1}·cm^{-1}) and in the region from 180 to 230 nm. The upper state of the first system is safely assigned to $^1(n-\pi^*)$ of the C=O chromophore. The upper state of the second system is not clear enough, but might be $^1(\pi-\pi^*)$ of the C=C chromophore. The 0–0 energies of the two systems are apparently 86 kcal·mol^{-1} and 114 kcal·mol^{-1}, respectively, judging from their absorption spectra. Considering that the difference between a $^1(n-\pi^*)$ state and the corresponding $^3(n-\pi^*)$ is usually about 5 kcal·mol^{-1} or so,[14] the T_a state may be above the ground state by about 80 kcal·mol^{-1}. The difference between a $^1(\pi-\pi^*)$ and the corresponding $^3(\pi-\pi^*)$ is usually large and also varies very much from molecule to molecule. The fact that the rotation around the C–C axis is restricted due to the ring structure in the case of CP, makes it more difficult to presume the energy of T_b.[15] It is thus difficult to decide which is the lowest triplet state. Anyhow, at least one triplet state whose triplet energy is around the same as the excess energy of the assumed T′ state seems to exist. Thus our assumption of the two-step consecutive deactivation process ((Eqs. 12, 15); the first step in the triplet vibrational manifold and the second step in the ground state vibrational maifold) is self-consistent.

Comparison among the Excited 3-Cyclopenten-1-ones from Different Excitation Methods. Hess and Pitts[3] obtained CO and BD with the quantum yield of 0.87 in the direct photolysis of CP by using 313 nm light (91.3 kcal·mol^{-1}) at 35 mmHg of total pressure. A singlet ($^1(n-\pi^*)$) CP is considered to be produced as a primary product through the direct photon absorption. Provided that the dissociation is from the vibrationally excited ground state molecule which has been prepared from the singlet excited state through internal conversion, the excess energy of the decomposing molecule is calculated to be about 90 kcal·mol^{-1} by the similar procedure as described in the fourth section, based on the above quantum yield (0.87 at 35 mmHg). The excess energy is then very near the initial excitation energy. Thus it is plausible that the singlet $^1(n-\pi^*)$ state CP changes before any appreciable collisions to a vibrationally excited ground state molecule, which then decomposes unimolecularly.

In the reaction of atomic oxygen with 1,3-cyclopentadiene, we assumed the existence of an excited CP as the intermediate to decompose to CO and BD (the corresponding process is expressed by Eq. IV in the previous paper[4]). Provided that the intermediate is a vibrationally excited ground state CP, its excess energy is estimated to be 104 kcal·mol^{-1}, by the similar calculation procedure based on the data presented in Fig. 7 of the paper. On the other hand, the heat of reaction of the process, $O(^3P)+1,3$-cyclopentadiene→ 3-cyclopenten-1-one, is 102 kcal·mol^{-1}, which is near the above estimated excess energy.

Thus in the above two excitation procedures, the collisional events do not seem to affect the processes preceding the decomposition, which should be attributed to the rapid conversion of the primary products to the corresponding vibrationally excited ground state CP's. We found a moderate pressure effect of the quantum yield of the products in the case of the mercury photosensitization, and attributed it to the collisional deactivation in the triplet state, as described before. A relatively long triplet lifetime is expected because of the possibly slow intersystem crossing.

Our reaction scheme is based on a very simple kinetic treatment of the CO quantum yield, and might be modified with future additional informations. We wish to stress, however, that the pressure dependence of ϕ_{CO} in the mercury photosensitization is somewhat different from those in the other two excitation systems even though the products are CO and BD in every case. The existence of this difference is independent on the assumption of reaction schemes.

The authors are grateful to Associate Professor S. Tsuchiya of the University of Tokyo for his encouragement.

Luminescence Properties and the Primary Process of Photochromism of 2-(2-Hydroxyphenyl)benzothiazole

Ryoichi NAKAGAKI,* Takayoshi KOBAYASHI,** and Saburo NAGAKURA*,**

**The Institute for Solid State Physics, The University of Tokyo, Minato-ku, Tokyo 106*

***The Institute of Physical and Chemical Research, Wako, Saitama 351*

(Received November 12, 1977)

The luminescence behavior of 2-(2-hydroxyphenyl)benzothiazole at 77 K was studied in detail, special attention being paid to dual fluorescence at ≈500 and ≈370 nm and also to phosphorescence at ≈500 nm. From the dependence of these emission bands upon the hydrogen-bonding ability of solvents and the excitation spectra, it is concluded that the short- and long-wavelength fluorescence bands are due to the intermolecularly hydrogen-bonded enol imine and the keto amine produced from the intramolecularly hydrogen-bonded enol, respectively, and that the phosphorescence is due to the intermolecularly hydrogen-bonded enol imine. The estimated quantum yield of the enol fluorescence gives further support to the formation scheme of the photochromic colored species previously presented. The rate constants of the intramolecular hydrogen transfer at 77 and 293 K are evaluated to be larger than 4×10^{10} s^{-1} and 3×10^{12} s^{-1}, respectively.

Photochromism of *N*-salicylideneanilines has been interpreted to be an enol-keto phototautomerization, which involves not only hydrogen transfer but a geometrical change in the molecular framework.[1-4]

In a previous paper, the photochromism of *N*-salicylideneanilines, including 2-(2-hydrophenyl)benzothiazole (HBT), was studied at room temperature.[4] From the FT infrared absorption measurement, we presented the direct evidence of the keto amine form for the colored species of *N*-salicylideneanilines. Furthermore, with the aid of picosecond time-resolved spectroscopy, we found the transient precursor from which the colored species and the *cis*-keto amine were produced.

Cohen and Flavian observed anomalously red-shifted fluorescence for *N*-salicylideneanilines and suggested from the comparison with absorption spectra that it was attributed to the keto tautomer formed during the lifetime of the enol excited state. But they could not observe separately a long-lived component (phosphorescence) appearing in the same wavelength region.[5]

In the present work, we have studied in detail the fluorescence and phosphorescence spectra, lifetimes, and fluorescence quantum yields of HBT and related heterocyclic compounds in various solvents. The main aim of the present study is to investigate the effect of hydrogen bonding upon the luminescence properties in order to obtain further support for the mechanism of photochromism, and to estimate the rate constant of intramolecular hydrogen transfer.

Experimental

The compounds employed in the present work are 2-(2-hydroxyphenyl)bonzothiazole (HBT), 2-(2-methoxyphenyl)benzothiazole (MBT), and 2-(2-hydroxyphenyl)benzoxazole (HBO). Commercially available HBT and HBO were chromatographed from benzene on activated alumina. MBT was obtained by two methods; treatment of HBT with dimethyl sulfate and synthesis according to the method in literature.[6] Solvents used in the present study are: PM (1: 1 by volume of spectro-grade isopentane and spectro-grade methylcyclohexane), DCM (dichloromethane), AN (spectro-grade acetonitrile), AA (acetic acid), EPA (5: 5: 1 by volume of spectro-grade diethyl ether, isopentane, and ethanol), EM (1: 1 by volume of spectro-grade ethanol and methanol), and DMF (*N*,*N*-dimethylformamide).

Ultraviolet absorption spectra were measured with a Cary 14 RI recording spectrophotometer. Phosphorescence spectra and their decay times were measured with a conventional phosphoroscope by employing a 1 kW Hg arc as an exciting light source. Emission spectra were measured with a Spex 1700-II grating monochromator equipped with an EMI 6256S photomultiplier and a PAR 128 lock-in amplifier. Fluorescence and phosphorescence excitation spectra were measured by exciting samples with monochromatic light at various wavelengths obtained with a 1 kW Xe lamp and the Spex monochromator, and by detecting emission intensities by the combination of a Bausch and Lomb 0.5 m monochromator with the photomultiplier and the lock-in amplifier. The quantum yield ratio between the short- and long-wavelength fluorescences was obtained by comparing the integratedintensities of the corresponding bands in the corrected emission spectra.

The fluorescence quantum yield of HBT excited at 354 nm was determined with use of a Shimadzu RF-502 spectrofluorometer. The standard material was 9,10-diphenylanthracene, the quantum yield of which was determined to be 0.93 in 3-methylpentane.[7] A flash-photolysis apparatus at room temperature and method for the determination of fluorescence lifetimes were described previously.[4] The flash photolysis experiments were carried out at 77 K with an apparatus at Institute of Applied Electricity, Hokkaido University.[8]

Results and Discussion

Fluorescence and Absorption Spectra of HBT, MBT, and HBO. The absorption and emission spectra of HBT, MBT, and HBO are given in Figs. 1, 2, and 3, respectively. HBT and MBT belong to 2-phenyl derivatives of benzothiazole and have similar molecular structures. Their emission properties, however, are quite different. In EPA at 77 K HBT shows dual fluorescence with peaks at 500 and 370 nm, while MBT exhibits single fluorescence as a mirror image of the absorption band.

The short-wavelength fluorescence of HBT shows vibrational structure pertinent to the 2-phenyl derivatives of benzothiazole like MBT,[9] and therefore is attributed to the lowest excited singlet state of the enol tautomer.

The Stokes shift amounts to 8500 cm^{-1} for the long-

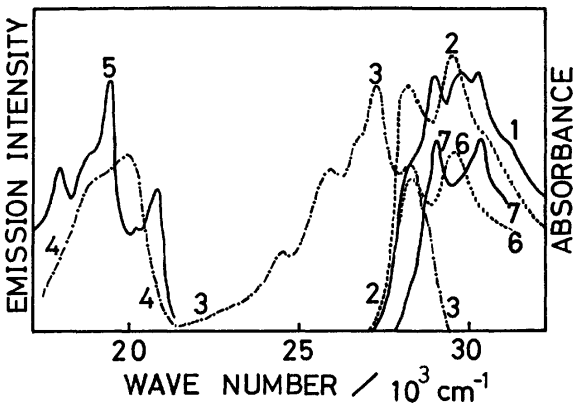

Fig. 1. The absorption, emission, and excitation spectra of HBT at 77 K: curve 1, absorption in EPA; curve 2, absorption in PM; curve 3, fluorescence of the enol imine in EPA; curve 6, fluorescence excitation spectrum of the keto amine in EPA; curve 7, fluorescence and phosphorescence excitation spectrum of the enol imine in EPA. Curves 3, 4, and 5 were measured under the excitation at 313 nm.

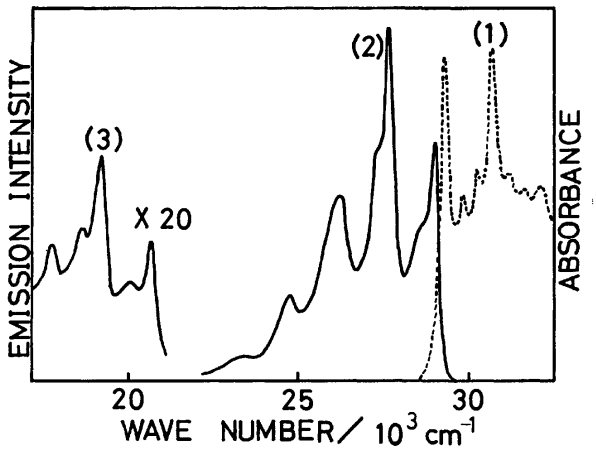

Fig. 2. The absorption (curve 1), fluorescence (curve 2), and phosphorescence (curve 3) spectra of MBT in EPA at 77 K. Curves 2 and 3 were measured under the excitation at 313 nm.

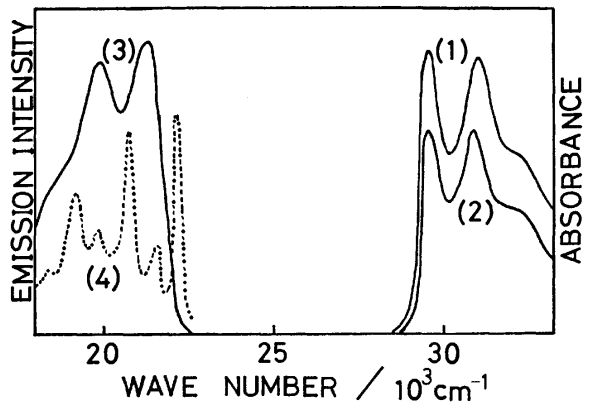

Fig. 3. The absorption and emission spectra of HBO at 77 K: curve 1, absorption in EPA; curve 2, absorption in PM curve 3, fluorescence of the keto amine in PM; curve 4, phosphorescence of the enol imine in PM. Curves 3 and 4 were measured under the excitation at 313 nm.

wavelength fluorescence of HBT. This suggests that the molecular framework changes in the excited state of the long-wavelength fluorescence. HBT can tautomerize from the enol imine to the keto amine, whereas MBT cannot. The excitation spectrum of the long-wavelength fluorescence of HBT in EPA at 77 K agrees well with the absorption spectrum of the HBT enol imine with the intramolecular hydrogen bond in PM at 77 K. This indicates that the long-wavelength fluorescence of HBT is due to the keto amine tautomer produced through hydrogen transfer in the excited state of the enol imine with the intermolecular hydrogen bond.

The relative intensities of the two fluorescence bands of HBT in solution are dependent on the solvent. The intensity of the short-wavelength fluorescence increases on going from the non-hydrogen-bonding or weakly hydrogen-bonding solvents (PM, DCM, and AN) to the strongly hydrogen-bonding solvents (AA, EPA, EM, and DMF). The fluorescence quantum yield ratios $\phi_f(E)/\phi_f(K)$ in various solvents are given in Table 1,

Table 1. $\phi_f(E)/\phi_f(K)$ in various solvents at 77K

	$\phi_f(E)/\phi_f(K)$
PM	$\leqslant 0.015$
DCM	$\leqslant 0.015$
AN	0.036 ± 0.002
AA	0.092 ± 0.005
EPA	1.6 ± 0.1
EM	3.0 ± 0.1
DMF	12 ± 1

where $\phi_f(E)$ and $\phi_f(K)$ are the fluorescence quantum yields for short- and long-wavelengths, respectively. When the short-wavelength fluorescence was too weak to be measured, an upper limit of $\phi_f(E)/\phi_f(K)$ was estimated from the limitation of detection. From these results and the discussion given above, it is concluded that the short-wavelength fluorescence of the dual emission is due to the enol imine with the intermolecular hydrogen bond, and the long-wavelength fluorescence to the keto amine produced by the hydrogen transfer in the excited state of the intramolecularly hydrogen-bonded enol imine. The absorption spectrum of HBT in EPA at 77 K is in good agreement with the superposition of the short- and long-wavelength fluorescence excitation spectra. In other words, the spectrum is interpreted as the superposition of the absorption spectra of the intramolecularly and intermolecularly hydrogen-bonded enol species of HBT.

Phosphorescence Spectra of HBT and MBT. HBT and MBT exhibit phosphorescence similar to that of 2-phenylbenzothiazole with respect to transition energy and vibrational structure.[9] The phosphorescence of HBT was observed only in the hydrogen-bonding solvents (AA, EPA, EM, and DMF). The $T_n \rightarrow T_1$ transition band of HBT was observed around 425 nm in EPA at 77 K, but not in the non-hydrogen-bonding solvent, PM at 77 K. In the HBT with the intramolecular hydrogen bond, hydrogen transfer through the bond occurs so fast that no triplet enol imine can be

formed. The excitation spectrum of HBT phosphorescence in EPA at 77 K is identical with that of the short-wavelength enol imine fluorescence. Thus the phosphorescence of HBT is assigned to the enol imine tautomer with the intermolecular hydrogen bond. The phosphorescence of the keto amine tautomer of HBT might appear above 600 nm from the position of the fluorescence band of the keto tautomer and the ordinary energy separation between π-π^* excited singlet and triplet states.

Relaxation Processes of Excited HBT in Hydrogen-bonding and Non-hydrogen-bonding Solvents. The relaxation processes after photoexciation of the HBT enol imine for HBT in non-hydrogen-bonding or weakly hydrogen-bonding solvents and in strongly hydrogen-bonding solvents are summarized in Figs. 4(a) and 4(b), respectively. In the former case in which HBT with the intramolecular hydrogen bond exists, the hydrogen transfer through the bond proceeds very fast in the excited state and the intermediate, X, is detected by picosecond time-resolved spectroscopy.[4] The photochromic state P and the *cis*-keto amine were formed from X competitively. In the latter case in which both intramolecular and intermolecular hydrogen bonded species coexist in equilibrium in the ground state, besides the processes mentioned above, the formation and decay processes of the triplet enol imine occur. "Sol" in Fig. 4(b) refers to a solvent molecule.

Electronic Spectra of HBO and HBT. The absorption spectrum of HBO in EPA at 77 K is essentially the same as that in PM (Fig. 3), showing that the dominant species in EPA at 77 K is the enol imine with the intramolecular hydrogen bond. The intramolecular hydrogen bond of HBO is more stable than that of HBT,[10] as Durmis *et al.* showed in their study of the dissociation constants.[11]

The emission spectra of HBO in PM are shown in Fig. 3. The emission properties of HBO in EPA at 77 K are very similar to those in PM at 77 K. The intensity of the keto amine fluorescence is much larger than that of the enol imine fluorescence or phosphorescence. The ratio $\phi_f(E)/\phi_f(K)$ was estimated to be less than 0.01 both in EPA and in PM at 77 K. The excitation spectra of the keto amine fluorescence and the enol imine phosphorescence agree with the absorption spectrum in PM at 77 K.

A difference between HBT and HBO is seen with respect to the yield of enol triplet formation. In PM at room temperature, the $T_n \leftarrow T_1$ transition was observed with HBO but not with HBT, while the photochromic transient absorption was observed with HBT but not with HBO. The phosphorescence of the enol imine with the internal hydrogen bond was observed with HBO but not with HBT at 77 K. These facts indicate that the intersystem crossing yield of the enol tautomer is larger for HBO than for HBT. The relaxation processes after photoexcitation of the HBO enol tautomer in EPA and in PM at 77 K are summarized in Fig. 5.

Primary Process of Photochromism. The yield $\phi_f(K)$

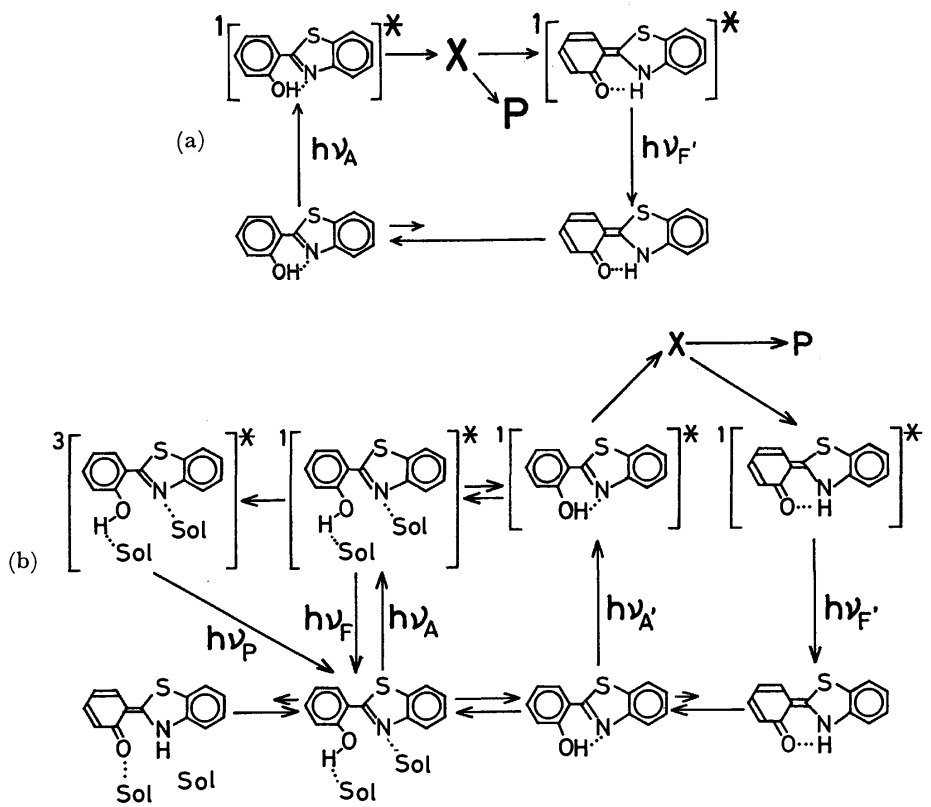

Fig. 4. Schematic diagrams representing the ground state equilibrium and relaxation processes in the excited state of HBT.
(a) In the weakly hydrogen-bonding or non-hydrogen bonding solvents.
(b) In the strongly hydrogen-bonding solvents.

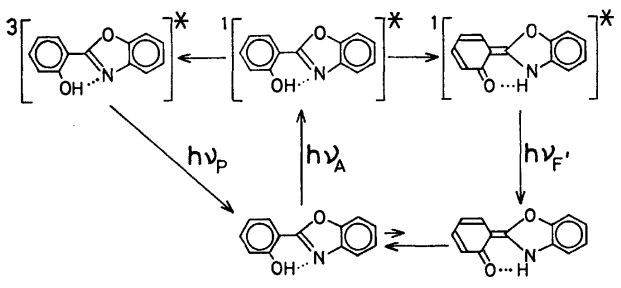

Fig. 5. Schematic diagram representing the ground state equilibrium and relaxation processes in the excited state of HBO.

of HBT in PM at 77 K was determined to be 0.36, and the ratio $\phi_f(E)/\phi_f(K)$ was estimated to be less than 0.015 (Table 1). From these values $\phi_f(E)$ at 77 K was evaluated to be less than 5.4×10^{-3}. For HBT in PM at 293 K, the yield $\phi_f(K)$ was determined to be 0.006, and the ratio $\phi_f(E)/\phi_f(K)$ was estimated to be less than 0.012. Thus the yield $\phi_f(E)$ at 293 K was evaluated to be less than 7.2×10^{-5}.

The enol fluorescence radiative rate constant k_f^e was estimated to be $2.3\times10^8\ s^{-1}$.[12] From this value and the yield $\phi_f(E)$, the lifetime of the enol imine fluorescent state was estimated to be shorter than 3.1×10^{-13} s. This is much shorter than the lifetime of the precursor, X, of the photochromic species (53 ps) determined in previous study.[4] This means that the enol imine fluorescent state is not the precursor. Thus we obtain an additional support for the scheme in which P is not formed directly from the enol excited state.

Estimation of the Rate Constant of the Intramolecular Hydrogen Transfer. The rate constants of the intramolecular hydrogen transfer at 77 and 293 K were estimated from the enol imine fluorescence quantum yield, which is given by

$$\phi_f(E) = \frac{k_f^e}{k_f^e + k_{fq}^e + k_{HT}}, \qquad (1)$$

where k_{fq}^e and k_{HT} represent the rate constants of the radiationless transition other than hydrogen transfer and of the intramolecular hydrogen transfer in the excited singlet state of the enol imine, respectively. From the decay times of the enol imine fluorescent state in the hydrogen bonding media, $(k_f^e + k_{fq}^e)$ in PM was estimated to be about $1\times10^9\ s^{-1}$ at 77 K. By putting the numerical values into Eq. 1, k_{HT} was evaluated to be larger than $4\times10^{10}\ s^{-1}$ at 77 K. At room temperature, $(k_f^e + k_{fq}^e)$ is at most of the order of $10^{11}\ s^{-1}$; k_{HT} was estimated from the values mentioned above to be larger than $3\times10^{12}\ s^{-1}$ in PM at 293 K.[13] By assuming an Arrhenius equation with a frequency factor of $10^{13}\ s^{-1}$ for k_{HT}, an upper limit of 0.9 kcal/mol was estimated for the barrier to the hydrogen transfer.[14] The value of k_{HT} at 77 K is greater than that for the 1,7-diazaindene hydrogen bonded dimer in 3-methylpentane at 77 K ($5\times10^8\ s^{-1}$) by a factor of at least 80,[15] and at 293 K it is greater than the value for 2,4-bis(dimethylamino)-6-(2-hydroxy-5-methylphenyl)-1,3,5-triazine in cyclohexane at 298 K ($1.1\times10^{10}\ s^{-1}$) by a factor of at least 270.[16] These large k_{HT} values can be explained as follows.

(1) A strong intramolecular hydrogen bond is formed in the HBT ground state, as shown by the pK_a value, NMR and IR spectroscopy and X-ray crystal analysis.[11,5,17] The O–N distances in the six-membered chelate ring are 2.605 Å for HBT, 2.584 Å for *N*-(5-chlorosalicylidene)aniline, and 2.609 Å for 2-chloro-*N*-salicylideneaniline.[18] These are examples of the shortest O–N distance in the OH···N hydrogen bond systems, the average O–N distance of which is 2.80 Å.[19] This strong intramolecular hydrogen bond favors the rapid hydrogen transfer in the excited state.

(2) Upon photoexcitation the phenolic hydroxyl group becomes more acidic and the imino nitrogen more basic than in the ground state. A similar situation has been reported for intramolecularly hydrogen-bonded salicylic acid derivatives.[20]

We are greatly indebted to Prof. Katsumi Kimura and Dr. Yohji Achiba, Hokkaido University, for their kindness in performing flash photolysis experiments at 77 K. We wish to thank Dr. Kazuo Shibata and Dr. Yorinao Inoue, the Institute of Physical and Chemical Research, for their kindness in putting the spectrofluorometer (Shimadzu RF-502) at our disposal.

12) The fluorescence radiative rate constant k_f^e was calculated by Förster's formula:

$$k_f^e = 2.88\times10^{-9}n^2\int\frac{(2\nu_0-\nu)^3}{\nu}\varepsilon(\nu)d\nu.$$

13) This value of k_{HT} is of the same order or a little larger than the usual values of the rate constants of vibrational relaxation in condensed media. This suggests that the intramolecular hydrogen transfer occurs from not only the thermalized

state in the lowest excited singlet state (S_1) but levels of S_1, and gives a plausible explanation for dependence on the excitation wavelength of the quantum yield of the photochromic colored species reported by Rosenfeld *et al.*[2c]

14) The hydrogen transfer in the enol excited state is a cooperative phenomenon, in which such particular vibrations as the stretching vibrations of the phenolic hydroxyl group and the aromatic nucleus of the salicylaldehyde moiety, participate. Consequently, it is reasonable to assume that the rate constant of phototautomerization follows the Arrhenius equation with a frequency factor of 10^{13} s^{-1}, which is commonly observed for the order of the stretching vibration frequency in the excited state.

Selective Hydrogen Atom Abstraction by H Atoms in Radiolysis and Photolysis at 77 K: Decane-d_{22}, Tetramethylsilane, and Xenon Matrices

Tetsuo MIYAZAKI,* Joji KASUGAI, Manabu WADA, and Kazuhisa KINUGAWA

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received November 19, 1977)

The selective formation of HD and solute radicals in the radiolysis of n-$C_{10}D_{22}$ doped with n-$C_{10}H_{22}$ at 77 K is explained quantitatively by the mechanism of a selective hydrogen-atom-abstraction reaction by D atoms. The selective hydrogen-atom abstraction by H atoms is found also in tetramethylsilane and xenon matrices as well as in the alkane matrix. The rate constants of the abstraction reaction by H atoms are compared with the bond energies of the solvent and solute molecules. The bond energy of the solvent molecule is always higher than that of the solute molecule. Even if the difference in the bond energy between the solvent and the solute is very small, the k(solute)/k(solvent) ratio is quite large. The k(solute)/k(*neo*-C_5H_{12}) ratios for different solutes in a neopentane matrix are not influenced by the differences in the bond energy among the solutes. Since an isotope effect on the selective hydrogen-atom abstraction reaction is small, the effect may diminish the possibility of the quantum mechanical tunneling abstraction by thermal H atoms. The energy loss of hot H atoms in a Xe matrix is discussed.

Since hydrogen and alkyl radicals are the predominant products in the radiolysis of alkanes in the solid phases, C–H bond rupture, with the resultant formation of the H atom, is one of the most important processes in the radiolysis of solid hydrocarbons. H atoms may play also an important role in the radiation effect of polymers[1] and biological solid substances.[2]

Recently Miyazaki *et al.* have found a quite interesting phenomenon concerning a hydrogen-atom abstraction reaction by H atoms in solid alkane mixtures at 77 K.[3] When H atoms are produced at 77 K by the UV-photolysis of hydrogen halide or by the radiolysis of solvent neopentane, the H atoms react selectively with the solute alkane, resulting in the formation of solute radicals. The experimental basis for the reaction of the H atoms has been described fully in previous papers.[3a,b,e] This phenomenon has also been found in several alkane matrices, such as neopentane,[3a,b] isobutane,[3a,c] 2,2,3,3-tetramethylbutane,[3c] cyclopropane,[3c] cyclohexane,[3d] pentane,[3d] and 3-methylpentane-d_{14}.[4]

Though a number of studies of the reaction of H atoms have been undertaken previously in gas and liquid phases at temperatures higher than room temperature, the studies in the solid phase at low temperatures have been limited to a few examples. The selective hydrogen-atom-abstraction reaction by H atoms in the solid phase at 77 K has raised new problems concerning its reaction kinetics. If hot H atoms are involved in the reaction, they must migrate a long distance through the alkane matrix 77 K without losing their kinetic energies. If thermal H atoms are involved, the activation energy for hydrogen-atom abstraction must be nearly zero in the alkane matrix at 77 K, though the value amounts to 7—10 kcal/mol in the gas phase.[5] Therefore, the study of the behavior of H atoms in the solid phase is important in solid-reaction kinetics as well as in solid-radiation chemistry.

The research described herein was undertaken in order to obtain further information about the reaction of the H atoms at 77 K. Answers to the following three questions have been sought: (1) Lund *et al.*[6] have reported that when n-$C_{10}D_{22}$ doped with a small amount of n-$C_{10}H_{22}$ is γ-irradiated at 77 K, solute $C_{10}H_{21}$ radicals are formed in a much higher yield than would be expected from the concentration. They ascribed this result to the excitation transfer from deuterated to protiated molecules. The results, however, can be explained also by a selective hydrogen-atom-abstraction reaction by D atoms. Recently it has been reported independently by two groups[7,8] that HD is formed selectively in the radiolysis of n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures at 77 K. The results were interpreted qualitatively by quite different mechanisms: a mechanism of excitation transfer[7] and one of selective hydrogen-atom abstraction by the D atom.[8] In order to discriminate the two mechanisms, the estimation of the yield of hydrogen *via* the molecular detachment process in the radiolysis of pure n-$C_{10}D_{22}$ and n-$C_{10}H_{22}$ at 77 K is important. In this study, the yield of hydrogen *via* the molecular detachment will be reported first. Then, we will give an answer to a question of which of the two mechanisms can best explain the absolute yields of the isotopic composition of the hydrogen gas. (2) The selective hydrogen-atom abstraction by H atoms has been found previously in alkane matrices at 77 K. Does the selective reaction take place also in matrices other than alkanes? Here we have examined tetramethylsilane (TMS) and xenon matrices at 77 K. (3) Selective hydrogen-atom abstraction reactions by H atoms have been found in several alkane matrices at 77 K. What are the rate constants of these reactions? Is there any relationship between the rate constants and the C–H bond energies?

Experimental

The D content of decane-d_{22}, supplied by Merck Sharp and Dohm, Canada, Ltd., is 99%. Tetramethylsilane (TMS), supplied by the Merck Co., is more than 99.7 mol%. Xenon, supplied by the Takachiho Shoji Co., is more than 99.9 mol%. The other reagents used in this study are the same as those used before.[3c]

UV illumination was provided by Toshiba medium-pressure

* All correspondence should be addressed.

mercury lamps. γ-Irradiation was done by Co-60 at a dose rate of 2.3×10^{19} eV/g h.

The hydrogen was analyzed by means of a gas buret connected to a Toepler pump and mass spectrometer (RMS-4 Hitachi mass spectrometer). The yields are the averages of two runs. The free radicals were measured at 77 K with a JES-3BX ESR spectrometer. The microwave power levels used did not result in the saturation of the signal of the alkyl radicals.

Results and Discussion

Selective Hydrogen-atom-abstraction Reaction in Decane-d_{22}. In order to discuss the mechanisms for the formation of hydrogen in the radiolysis of n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures, the yields of the hydrogen gas formed in an unimolecular reaction must first be estimated, though this process has been tentatively neglected in a recent paper.[7] The formation of H_2 from decane at 77 K can be represented as follows:

$$RH \begin{cases} \rightsquigarrow R\cdot + H & (1) \\ \rightsquigarrow \text{Olefin} + H_2 & (2) \end{cases}$$

$$2H \longrightarrow H_2 \quad (3)$$

$$H + RH \longrightarrow R\cdot + H_2 \quad (4)$$

Here, RH and R· represent the decane and the alkyl radicals respectively. Since the alkyl radicals produced by the radiolysis of decane at 77 K are isolated radicals,[6b,9] it is assumed here that all of the alkyl radicals are trapped at 77 K. The formation of one hydrogen molecule by an H atom produces two alkyl radicals. Therefore, a half of $G(R\cdot)$ corresponds to the amount of H_2 formation by an H-atom process. The G-value for the formation of a $C_{10}H_{21}$ radical in the radiolysis of pure n-$C_{10}H_{22}$ at 77 K has been reported as 5.4,[6b] 3.1,[9] and 6.0,[10] the mean value being 4.8. Therefore, $G(H_2)$ from the H-atom process is $4.8/2=2.4$. $G(C_{10}D_{21})$ in the radiolysis of n-$C_{10}D_{22}$ at 77 K has been reported as 4.1[6b] and 3.1,[9] the mean value being 3.6. $G(H_2)$ and $G(D_2)$ in the radiolysis of pure n-$C_{10}H_{22}$ and n-$C_{10}D_{22}$ at 77 K were measured here as 4.3 and 2.9 respectively at a dose of 3.4×10^{19} eV/g. Therefore, the molecular yields are (4.3—2.4) for n-$C_{10}H_{22}$ and (2.9—1.8) for n-$C_{10}D_{22}$. The ratios of G(hydrogen) by the molecular process to G(hydrogen) by the atomic process are 0.79 for n-$C_{10}H_{22}$ and 0.61 for n-$C_{10}D_{22}$. A similar high molecular yield was reported previously in the radiolysis of solid n-C_6H_{14} at 77 K.[11] The G-values of hydrogen in the radiolysis of n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixtures at 77 K are shown in Fig. 3. The results obtained by Lund *et al.*[7] are approximately the same as those obtained by present authors. There is a possibility that hydrogen might react with alkyl radicals during the melting of the irradiated sample, as was observed in irradiated polyethylene.[12] Since the activation energy for this reaction is 13 kcal/mol, however, it takes several hours for the reaction to occur at room temperature.[12] Therefore, we can neglect the possibility that the hydrogen produced by the radiolysis of decane might react with the alkyl radicals while the irradiated decane is warmed up.

Three mechanisms explaining the hydrogen yields will be compared: energy transfer with the resultant formation of a thermal H atom, energy transfer with the resultant formation of a hot H atom, and selective hydrogen-atom abstraction by a D atom. The hydrogen yields are calculated from the yields of the alkyl radicals, which were measured by ESR spectroscopy,[6] and are compared with the hydrogen yields obtained here experimentally.

A) Energy transfer with the resultant formation of a thermal H atom.

$$C_{10}D_{22} \rightsquigarrow C_{10}D_{22}^* \quad (1)$$

$$C_{10}D_{22}^* \longrightarrow C_{10}D_{21} + D \quad a \quad (2)$$

$$\searrow\ C_{10}D_{20} + D_2 \quad 0.305a \quad (3)$$

$$C_{10}D_{22}^* + C_{10}H_{22} \longrightarrow C_{10}D_{22} + C_{10}H_{22}^* \quad (4)$$

$$C_{10}H_{22} \rightsquigarrow C_{10}H_{22}^* \quad (5)$$

$$C_{10}H_{22}^* \longrightarrow C_{10}H_{21} + H \quad b \quad (6)$$

$$\searrow\ C_{10}H_{20} + H_2 \quad 0.395b \quad (7)$$

$$2D \longrightarrow D_2 \quad a^2/[2(a+b)] \quad (8)$$

$$2H \longrightarrow H_2 \quad b^2/[2(a+b)] \quad (9)$$

$$D + H \longrightarrow HD \quad 2ab/[2(a+b)] \quad (10)$$

Here, a and b are the yields of the $C_{10}D_{21}$ and $C_{10}H_{21}$ radicals respectively, which were obtained by ESR spectroscopy.[6] The G-value of the alkyl radicals is taken as 3.6. The excited $C_{10}D_{22}$ molecule, produced by γ-irradiation, transfers its energy to the solute $C_{10}H_{22}$ (Reactions 1 and 4). It is assumed here that the decomposition of excited decane produces thermal atoms and hydrogen molecules (Reactions 2, 3, 6, and 7). The thermal atoms recombine with each other at 77 K (Reactions 8, 9, and 10). The calculated G-values of hydrogen are shown in Fig. 1. $G(H_2)$ increases remarkably with an increase in the concentration of $C_{10}H_{22}$. G(HD) increases sharply at a low concentration of $C_{10}H_{22}$ and then reaches a plateau at a higher concentration.

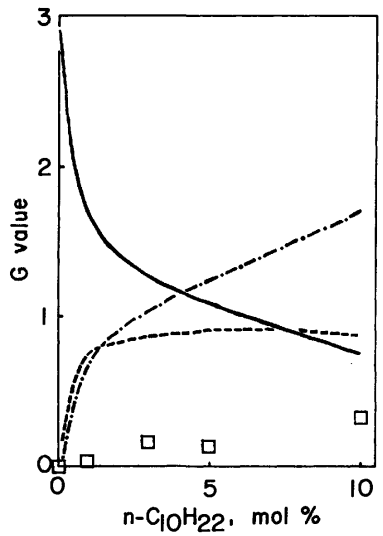

Fig. 1. Yields of hydrogen calculated by the model of energy transfer, with the resultant formation of the thermal H atom.
——, D_2; ——, HD; -·-·-, H_2; □, H_2 obtained experimentally.

The calculated G-values do not coincide at all with the experimental $G(H_2)$.

B) Energy transfer with the resultant formation of a hot H atom.

$$C_{10}D_{22} \rightsquigarrow C_{10}D_{22}^* \quad (1)$$

$$C_{10}D_{22}^* \longrightarrow C_{10}D_{21} + D \qquad c \quad (2)$$

$$\searrow\ C_{10}D_{20} + D_2 \qquad 0.61c \quad (3)$$

$$C_{10}D_{22}^* + C_{10}H_{22} \longrightarrow C_{10}D_{22} + C_{10}H_{22}^* \quad (4)$$

$$C_{10}H_{22} \rightsquigarrow C_{10}H_{22}^* \quad (5)$$

$$C_{10}H_{22}^* \longrightarrow C_{10}H_{21} + H \qquad d \quad (6)$$

$$\searrow\ C_{10}H_{20} + H_2 \qquad 0.79d \quad (7)$$

$$D + C_{10}D_{22} \longrightarrow C_{10}D_{21} + D_2 \qquad c(1-x) \quad (11)$$

$$D + C_{10}H_{22} \longrightarrow C_{10}H_{21} + HD \qquad cx \quad (12)$$

$$H + C_{10}D_{22} \longrightarrow C_{10}D_{21} + HD \qquad d(1-x) \quad (13)$$

$$H + C_{10}H_{22} \longrightarrow C_{10}H_{21} + H_2 \qquad dx \quad (14)$$

Here, c and d are the yields of hot D atoms and hot H atoms respectively, which are calculated from the yields of $C_{10}D_{21}$ and $C_{10}H_{21}$ radicals.[6] x represents the mole fraction of the solute $C_{10}H_{22}$. The excited $C_{10}D_{22}$ molecule transfers its energy to the solute $C_{10}H_{22}$ (Reaction 4). It is assumed that the decomposition of excited decane produces hot H(or D) atoms and hydrogen molecules (Reactions 2, 3, 6, and 7). The hot atoms abstract H or D atoms from decane molecules (Reactions 11, 12, 13, and 14). It is assumed here that $k_{11}=k_{12}$ and $k_{13}=k_{14}$. The G-value of the alkyl radical is taken as 3.6. Though the total alkyl-radical yields in the A and B mechanisms are the same, c(or d) is different from a(or b) because of the different mechanisms of the radical formations in the two mechanisms. The calculated G-values of hydrogen are shown in in Fig. 2. $G(D_2)$ approaches zero at 10 mol% of $C_{10}H_{22}$, while $G(HD)$ and $G(H_2)$ increase remarkably with an increase in the concentration of $C_{10}H_{22}$. The calculated

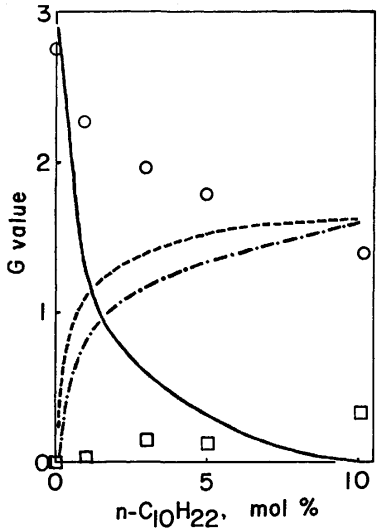

Fig. 2. Yields of hydrogen calculated by the model of energy transfer, with the resultant formation of the hot H atom.
——, D_2; ——, HD; -·-·-, H_2; ○, D_2 obtained experimentally; □, H_2 obtained experimentally.

G-values do not coincide at all with the experimental $G(D_2)$ and $G(H_2)$.

C) Selective hydrogen atom abstraction by a D atom.

Recently it has been found that H atoms, produced by the radiolysis of solvent alkane at 77 K, react selectively with solute alkane to produce solute alkyl radicals.[3] Though it has been suggested that this mechanism may play only a minor role,[6] we will discuss here the possibility.

$$C_{10}D_{22} \rightsquigarrow C_{10}D_{22}^* \quad (1)$$

$$C_{10}D_{22}^* \longrightarrow C_{10}D_{21} + D \qquad e(1-x) \quad (2)$$

$$\searrow\ C_{10}D_{20} + D_2 \qquad 0.61e(1-x) \quad (3)$$

$$C_{10}H_{22} \rightsquigarrow C_{10}H_{22}^* \quad (5)$$

$$C_{10}H_{22}^* \longrightarrow C_{10}H_{21} + H \qquad 1.33ex \quad (6)$$

$$\searrow\ C_{10}H_{20} + H_2 \qquad 1.05ex \quad (7)$$

$$D + C_{10}D_{22} \longrightarrow C_{10}D_{21} + D_2 \qquad e(1-x)^2/[Kx+1-x] \quad (11)$$

$$D + C_{10}H_{22} \longrightarrow C_{10}H_{21} + HD \qquad ex(1-x)K/[Kx+1-x] \quad (12)$$

$$H + C_{10}D_{22} \longrightarrow C_{10}D_{21} + HD \qquad 1.33ex(1-x)/[Kx+1-x] \quad (13)$$

$$H + C_{10}H_{22} \longrightarrow C_{10}H_{21} + H_2 \qquad 1.33ex^2K/[Kx+1-x] \quad (14)$$

Here, e is a half of the yield of $C_{10}D_{21}$ radicals in the radiolysis of pure n-$C_{10}D_{22}$ and is taken as 1.8 G-unit. [The amounts of Reactions 2 and 3 at $x=0$]/[the amounts of Reactions 6 and 7 at $x=1$] is equal to $[G(D_2)$ in pure n-$C_{10}D_{22}]/[G(H_2)$ in pure n-$C_{10}H_{22}]$, that is, 0.67. The D atoms produced by the radiolysis of n-$C_{10}D_{22}$ react selectively with the solute $C_{10}H_{22}$ to form $C_{10}H_{21}$ radicals. It is assumed that $k_{12}/k_{11}=k_{14}/k_{13}$, which is denoted by K. K is estimated to be 61 by using the yields[6] of the $C_{10}H_{21}$ and $C_{10}D_{21}$ radicals. The calculated yields for D_2, HD, and H_2 are shown in Fig. 3. The coincidence of the calculated curves with the experimental yields may be good, if we take into consideration of the fact that the calculation for the final products has been based upon independent results, that is to say, the yields of free radicals as measured by ESR spectroscopy. If K is taken tentatively as 27, the coincidence becomes much better, as is shown in Fig. 3.

Therefore, we can conclude that the selective formation of the solute $C_{10}H_{21}$ radical and HD in the radiolysis of the n-$C_{10}D_{22}$–n-$C_{10}H_{22}$ mixture at 77 K is not due to the energy transfer from the solvent to the solute, but to the selective hydrogen-atom abstraction from the solute by the D atom. The reaction-rate constant (k_{12}) of the D atom with n-$C_{10}H_{22}$ is 27 times greater than that (k_{11}) with n-$C_{10}D_{22}$.

Though the experimental results obtained here are approximately the same as those reported by Lund *et al.*,[7] the conclusion of this work is quite different from that of Ref. 7. This difference is caused by the following two factors. First, Lund *et al.* neglected tentatively the formation of hydrogen by a molecular detachment process. On the contrary, the yield of the molecular detachment process is estimated experimental-

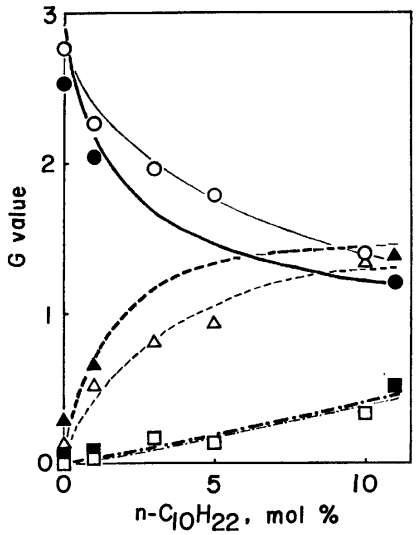

Fig. 3. Comparison of experimental hydrogen yields with the yields calculated by the model of selective hydrogen-atom abstraction by the D atom. Since the results by Lund *et al.* are relative yields, the *G*-values by Lund *et al.* are calculated by using the total *G*-value of hydrogen in this work.

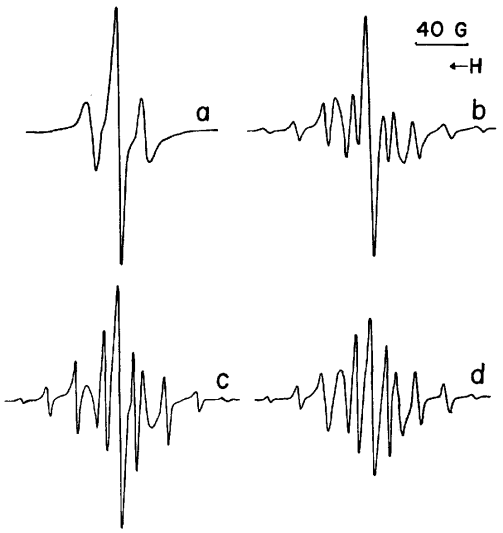

Fig. 4. ESR spectra of irradiated tetramethylsilane(TMS) at 77 K. The unit of the solute concentration is mol/100 mol of TMS.
a: γ-Irradiated TMS, b: γ-irradiated TMS-i-C_4H_{10}-(0.46), c: γ-irradiated TMS-i-C_4H_8(0.1), d: UV-irradiated TMS-i-C_4H_{10}(0.75)-HI(0.2).

ly in this paper and the process is taken into consideration in the discussion. Second, since it has been found that H atoms react quite selectively with the solute alkane in alkane mixtures at 77 K,[3] the possibility of a high selectivity for the H atom abstraction reaction by D atoms has been considered in this paper. Lund *et al.*, however, neglected the possibility of the high selective reaction of D atoms at 77 K.

Selective Hydrogen-atom-abstraction Reaction in Tetramethylsilane (TMS). Figure 4a shows the ESR spectra of γ-irradiated pure TMS at 77 K. The spectrum of the three broad lines with a separation of 20.8 G is attributable to the $(CH_3)_3\dot{S}iCH_2$ (TMS·) radical. Figures 4a and c show the ESR spectra of γ-irradiated TMS containing i-C_4H_{10} and i-C_4H_8 respectively. The spectra consist of three broad lines, which are attributable to the TMS· radical, and eight narrow lines with a separation of 22.8 G, which are attributable to the t-C_4H_9 radical. Figure 4d shows the ESR spectra of UV-illuminated TMS containing i-C_4H_{10} and HI. The spectra consist of three broad lines, ascribed to the TMS· radicals, and eight narrow lines, ascribed to the t-C_4H_9 radical.

The yields of the radicals in Fig. 4b can be estimated by the integration of the spectrum. From the decomposition of the integrated spectrum into t-C_4H_9 and TMS· radicals, the amount of the t-C_4H_9 radical is estimated to be 13% of the total radical yield. Since an electron fraction of i-C_4H_{10} in the TMS-i-C_4H_{10} (0.46 mol/100 mol of TMS) mixture is 0.0031, the formation of the t-C_4H_9 radical is sensitized 42-fold. Therefore, some activation, produced by the γ-irradiation of TMS, is transfrred to the i-C_4H_{10} solute.

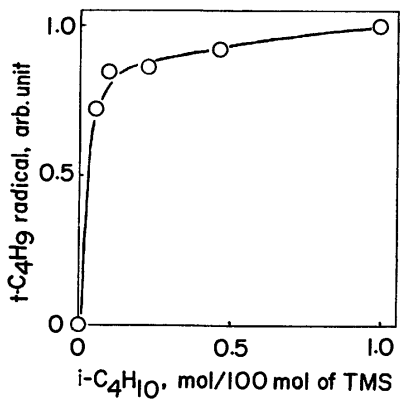

Fig. 5. Yields of the t-C_4H_9 radical against the concentration of i-C_4H_{10} in the radiolysis of TMS-i-C_4H_{10} mixtures at 77 K.

The yields of the t-C_4H_9 radicals are shown in Fig. 5 as a function of the i-C_4H_{10} concentration. The yields do not increase linearly with an increase in the i-C_4H_{10} concentration; at low concentrations they rise steeply, and then approach a plateau value at higher concentrations. This nonlinear increase in the yields indicates also that the formation of the t-C_4H_9 radical does not result from the direct absorption of the ionizing radiation by i-C_4H_{10}, but from the activation transfer from TMS to i-C_4H_{10}.

It is suggested by the following two reasons that the mechanism of the activation transfer may be due to a selective hydrogen-atom-abstraction reaction from i-

C_4H_{10} by H atoms, as is observed in the radiolysis of alkane mixtures:[3] (1) When isobutane is added to TMS, the t-C_4H_9 radical is formed by the addition of the H atom to the olefin (Fig. 4c). (2) When H atoms are produced by the photolysis of hydrogen iodide in TMS containing a small amount of i-C_4H_{10}, the H atoms react selectively with the i-C_4H_{10} solute to form t-C_4H_9 radicals (Fig. 4d).

A maximum yield of t-C_4H_9 radicals in the radiolysis of TMS–i-C_4H_{10} mixture amounts to 15% of the total radical yield. 50% of the total radical yields corresponds to the yields of TMS· radicals which are produced by the decomposition of TMS molecules (*cf.* Reactions 15 and 16). Therefore, 30% of the H atoms produced by the radiolysis of TMS migrate to the i-C_4H_{10} solute. The rest react promptly with TMS molecules (Reaction 17).

$$\text{TMS} \longrightarrow \text{TMS}\cdot + H_{ab} \quad (15)$$

$$\text{TMS} \longrightarrow \text{TMS}\cdot + H_{mig} \quad (16)$$

$$H_{ab} + \text{TMS} \longrightarrow \text{TMS}\cdot + H_2 \quad (17)$$

$$H_{mig} + i\text{-}C_4H_{10} \longrightarrow t\text{-}C_4H_9 + H_2 \quad (18)$$

$$H_{mig} + \text{TMS} \longrightarrow \text{TMS}\cdot + H_2 \quad (19)$$

H_{ab} represents an H atom which reacts promptly with TMS and does not migrate through the matrix. H_{mig} represents an H atom which can migrate through the matrix and reacts with i-C_4H_{10} or TMS during its excursion. It is uncertain at present whether the difference between H_{ab} and H_{mig} atoms is due to the difference in their kinetic energies or to that in the initial direction of their translational motions, the possibility of which was suggested in a recent paper.[13]

TABLE 1. H ATOMS PRODUCED IN THE RADIOLYSIS AND PHOTOLYSIS IN THE ALKANE MATRIX AT 77 K[a]

Matrix	Method of production of H atom	Fractions of two kinds of H atoms	
		H_{ab}, %	H_{mig}, %
neo-C_5H_{12}	radiolysis of *neo*-C_5H_{12}	54[b]—36[c]	46[b]—64[c]
neo-C_5H_{12}	photolysis of HI[d]	<10	>90
TMB[e]	radiolysis of TMB[f]	60	40
TMB[e]	photolysis of HI[g]	60	40
TMS[h]	radiolysis of TMS[i]	70	30
TMS[h]	photolysis of TMS[j]	70	30

a) The unit of the solute concentration in the footnotes is mol/100 mol of the solvent molecule. The concentrations of solute alkanes in this work are sufficient to capture almost all the H_{mig} atoms. b) The value is obtained in the radiolysis of *neo*-C_5H_{12}–i-C_4H_{10}(2). c) The value is quoted from the results by Iwasaki *et al.* in the radiolysis of *neo*-C_5H_{12}–c-C_6H_{12}(2) (*cf.* M. Iwasaki, K. Toriyama, K. Nunome, M. Fukaya, and H. Muto, *J. Phys. Chem.*, **81**, 1410 (1977)). d) The value is obtained in the photolysis of *neo*-C_5H_{12}–i-C_4H_{10}(2)–HI(0.5). e) TMB is 2,2,3,3-tetramethylbutane. f) The value is obtained in the radiolysis of TMB–C_3H_8 (4.9). g) The value is obtained in the photolysis of TMB–C_3H_8 (3.6)–HI(0.5). h) TMS is tetramethylsilane. i) The value is obtained in the radiolysis of TMS–i-C_4H_{10}(1.0). j) The value is obtained in the photolysis of TMS–i-C_4H_{10}(0.8)–HI(0.2).

Therefore, the notation of H_{ab} and H_{mig} is a phenomenological discrimination of the two kinds of hydrogen atoms; one reacts promptly with the solvent, while the other migrates through the solvent to react with a solute alkane. The presence of two kinds of H atoms is observed also in other alkane matrices. The results are summarized in Table 1. The relative yields of H_{mig} decrease in the following order: neopentane, 2,2,3,3-tetramethylbutane, and tetramethylsilane. The yields might be influenced by a crystalline structure, the rigidness of the solid, and so on.

Selective Hydrogen-atom-abstraction Reaction in Xenon.

When xenon containing a small amount of i-C_4H_{10} and HI is illuminated at 77 K by ultraviolet light, t-C_4H_9 radicals are clearly observed by ESR spectroscopy. The ESM spectra were reported in a previous paper.[14] The efficiency of the formation of butyl radicals is approximately the same as that in the photolysis of the *neo*-C_5H_{12}–i-C_4H_{10}–HI system at 77 K. H atoms, produced by the photolysis of HI, migrate through a xenon matrix and react with the i-C_4H_{10} solute (Reactions 20 and 21):

$$\text{HI} \xrightarrow{h\nu} \text{H} + \text{I} \quad (20)$$

$$\text{H} + i\text{-}C_4H_{10} \longrightarrow H_2 + t\text{-}C_4H_9 \quad (21)$$

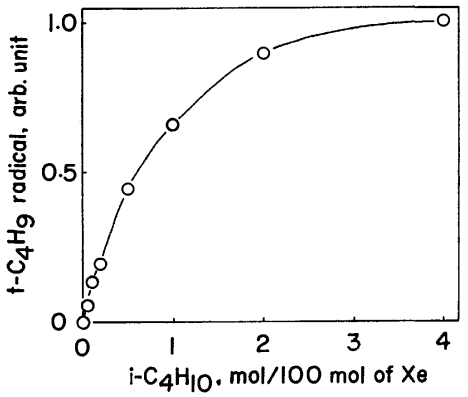

Fig. 6. Yields of the t-C_4H_9 radical against the concentration of i-C_4H_{10} in the UV-photolysis of Xe–i-C_4H_{10}–HI(0.15 mol/100 mol of Xe) at 77 K.

The yields of the t-C_4H_9 radicals are shown in Fig. 6 as a function of the i-C_4H_{10} concentration. A crude estimation of the average distance that the H atoms must be able to travel is available from the yields in Fig. 6. The simplest approach is to use a "target" model in which an H atom travels through a certain volume of the matrix where n atoms of xenon exit. When one molecule of i-C_4H_{10} exists in this volume, the H atom reacts with the i-C_4H_{10} solute. The ratio of the yield (I) of a t-C_4H_9 radical at the i-C_4H_{10} concentration (c mol/mol of Xe) to that (I_∞) at an infinite i-C_4H_{10} concentration is expected to be of the form

$$I/I_\infty = 1 - \exp(-nc). \quad (a)$$

It is assumed that I_∞ is approximately the same as the yield of a t-C_4H_9 radical at 4 mol/100 mol of Xe. Equation a can be expressed as

$$-\log\{1-(I/I_\infty)\} = nc \log e. \quad (b)$$

A good linear relationship between $-\log\{1-(I/I_\infty)\}$ and i-C_4H_{10} concentration is obtained. The actual value found for n is 114. It is concluded that the H atoms produced by the photolysis of HI migrate through 114 atoms of xenon at 77 K.

Correlation between the Rate Constant for H-atom Abstraction and the C–H Bond Energy. A selective hydrogen-atom-abstraction reaction by H atoms has been found previously in several matrices, such as n-$C_{10}D_{22}$, TMS, and Xe matrices. It is interesting to summarize the selectivities of the reactions in these matrices. H atoms which can migrate through the matrix are formed by

$$RH \rightsquigarrow H_{mig} + R\cdot \quad (22)$$

$$(HI \xrightarrow{h\nu} H_{mig} + I) \quad (23)$$

$$H_{mig} + SH \xrightarrow{k(\text{solute})} H_2 + S\cdot \quad (24)$$

$$H_{mig} + RH \xrightarrow{k(\text{solvent})} H_2 + R\cdot \quad (25)$$

the radiolysis of solvent molecules (RH) or by the photolysis of hydrogen iodide (Reactions 22 or 23). They react selectively with solute molecules (SH). It is assumed here that the H atoms may react also with solvent molecules, competing with Reaction 24. If the rate of the formation of H_{mig} is expressed as I, the following relationship is obtained by a steady-state treatment:

$$\frac{1}{r(S\cdot)} = \frac{1}{I} + \frac{k(\text{solvent})[RH]}{Ik(\text{solute})[SH]}, \quad (c)$$

where $r(S\cdot)$ is the rate of the formation of the solute radical and where k is the rate constant. The yields of the solute radical per unit of time ($r(S\cdot)$) have been measured here and in previous studies[3e] as a function of the solute concentration ([SH]). Linear relationships between $1/r(S\cdot)$ and [RH]/[SH] are obtained in many systems. The slope-to-intercept ratios give k(solvent)/k(solute), shown in Table 2.

The values of k(solute)/k(solvent) ranged from 5200 in TMS to 27 in n-$C_{10}D_{22}$. The bond-dissociation energy for the C–H bond and the difference in the bond energy between a solvent and a solute are shown in the fifth and sixth columns in Table 2 respectively. Two conclusions can be drawn from these results. First, the bond energy of the solvent molecule is always higher than that of the solute molecule. Even if the difference in the bond energy between the solvent molecule and the solute molecule is very small, the k(solute)/k(solvent) ratio is quite large. Second, the k(solute)/k(*neo*-C_5H_{12}) ratios for different solutes in a neopentane matrix are of the same order of magnitude, though the difference in the C–H bond energy between the solutes amounts to 7 kcal/mol.

The first conclusion may suggest that the selective abstraction reaction is not caused by hot H atoms with extremely high energies. In order to verify the second conclusion, the competitive reaction of H atoms with C_2H_6 and c-C_6H_{12} has been studied in the neopentane matrix at 77 K.[15] The experimental value for $k(c$-$C_6H_{12})/k(C_2H_6)$ is 3.7, though the difference in bond energy between C_2H_6 and c-C_6H_{12} is 4 kcal/mol. If the selective hydrogen-atom-abstraction reaction is caused by a thermal H atom, a small difference in a bond energy causes a large k(solute)/k(solvent) because of a reaction at a very low temperature, such as 77 K. For example, $k(C_2H_6)/k($*neo*-$C_5H_{12})$ amounts to 400—500, though the difference in the bond energy between C_2H_6 and *neo*-C_5H_{12} is only 1.3 kcal/mol. The hypothesis of the thermal H atom expects that $k(c$-$C_6H_{12})/k(C_2H_6)$ will also be very large because of the large difference of bond energies (4 kcal/mol) betweeen c-C_6H_{12} and C_2H_6. Therefore, the experimental value of $k(c$-$C_6H_{12})$/

Table 2. Rate constant for H-atom-abstraction reaction by H(or D) atom at 77 K

Radiolysis of CH_3CN at 77 K[h]	$CH_3+CH_3CN \longrightarrow CH_4+CH_2CN$ (CD_3CN)	>28000

a) Ref. 3b. b) Ref. 3a. c) This work. d) Hot H atoms have energies of 1.1—2.9 eV; G. D. Beverly and R. M. Martin, *J. Phys. Chem.*, **81**, 2063 (1976). e) Hot H atoms have an energy of 1.8 eV; K. Hong and G.J. Mains, *J. Phys. Chem.*, **76**, 3337 (1972). f) J. W. Root, W. Breckenridge, and F.S. Rowland, *J. Chem. Phys.*, **43**, 3694 (1965). g) Ref. 19b. h) Ref. 19c.

$k(C_2H_6)=3.7$ cannot be explained by the hypothesis of a thermal H atom. It is interesting to note that $k(c\text{-}C_6H_{12})/k(C_2H_6)$ is 3.5 for a hot tritium atom reaction[16] and about 6 for a hot CH_3 radical reaction in the photolysis of CH_3I.[17] The experimental value obtained in the neopentane matrix is approximately of the same order of magnitude as that in the hot-atom reaction.

Isotope Effects on the H-atom Abstraction Reaction at 77 K. The isotope effects on the hydrogen-atom-abstraction reaction are summarized in Table 3. $k(H)$ and $k(D)$ represent the rate constants of the H-abstraction and D-abstraction reactions respectively. The values in the *neo*-C_5H_{12} and Xe matrices were estimated from the yields of $t\text{-}C_4H_9$ radicals produced by the radiolysis or photolysis in *neo*-C_5H_{12} (or Xe) containing 2 mol% of $i\text{-}C_4H_{10}$ or $i\text{-}C_4H_9D$ at 77 K. The isotope effects in the neopentane matrix ranged from 1.1 to 2.5.[18] In order to confirm the isotope effect in the *neo*-C_5H_{12} matrix, a competitive reaction of H atoms with C_2H_6 and $c\text{-}C_6H_{12}$ (or $c\text{-}C_6D_{12}$) has been studied at 77 K. The experimental value for $k(H)/k(D)$ of cyclohexane in the neopentane matrix is 7.3.[15] Recently it has been reported that a thermal CH_3 radical abstracts a hydrogen atom at 77 K by mean of quantum mechanical tunneling.[19] The most important characteristic of this mechanism is a quite large isotope effect (*cf.* Table 3). The value for $k(H)/k(D)$ in the neopentane matrix is quite different from the value for quantum mechanical tunneling. On the contrary, the value in the neopentane matrix is approximately the same as the value for hot-atom reactions in the gas phase.

Energy Loss of Reactive H Atoms in the Solid Phase. Since the energy of the first excited state of alkane (7—8 eV)[20] is much larger than the bond energy of the C–H bond (4 eV),[21] and since the energy of ultraviolet light (4.9 eV) is much larger than the bond energy of HI (3.1 eV),[21] the H atom produced by the radiolysis of alkane or by the photolysis of HI must have, initially, an excess energy of 2—3 eV. Recently it has been reported that the H atoms produced in the gas phase by electron impact on hydrocarbons have kinetic energies of 1.8—3.8 eV.[22] Now, we will discuss the problem of whether or not the H atoms with the excess energy lose their energy completely during their excursion in the crystal at 77 K.

The photolysis of the Xe–$i\text{-}C_4H_{10}$–HI mixture is the simplest way to discuss the energy loss of hot H atoms. When the photolysis of HI is caused by a 2537 Å light, the initial kinetic energy of an H atom is 20 kcal/mol if the iodine atom is produced in the $^2P_{1/2}$ excited state and 41 kcal/mol if it is produced in the $^2P_{3/2}$ ground state.[23] The experimental results in Fig. 6 indicate that the H atoms produced in the photolysis of HI migrate through 114 atoms of Xe at 77 K. In order to estimate the number of H atoms colliding with Xe atoms during the excursion, three cases are considered here. First, if the collision efficiency of an H atom with solute $i\text{-}C_4H_{10}$ is the same as that of Xe, the number of collisions of the H atom with Xe is 114 until the H atom reacts with $i\text{-}C_4H_{10}$. Second, since the crystalline structure of Xe is face-centered cubic,[24] a channeling wall[25] consists of four Xe atoms. If the $i\text{-}C_4H_{10}$ solute

exists as a defect in the channeling zone, it may be assumed that the collision efficiency of an H atom with i-C_4H_{10} is four times as large as that with Xe. In this case, the collision number of the H atom with Xe is 114/4(=28.5). Third, an i-C_4H_{10} molecule may exist in a lattice of crystalline Xe. It may be assumed that H atoms react with i-C_4H_{10} whenever they approach nearest neighboring Xe atoms around i-C_4H_{10}. The collision efficiency of H atoms with i-C_4H_{10} is 12 times as large as that with Xe. In this case, the collision number of an H atom with Xe is 114/12(=9.5).

The reactive H atom loses its energy by elastic collisions with Xe molecules. The energy loss by a single collision is expressed as

$$\frac{E_0-E'}{E_0} = \frac{2M_1M_2}{(M_1+M_2)^2}(1-\cos\theta), \qquad \text{(d)}$$

where E_0 and E' are the kinetic energies before and after a collision respectively.[26] M_1 and M_2 are the masses of the H atom and the Xe atom respectively. θ is the diffraction angle of the H atom caused by the collision. The mean value of the energy loss ($\langle E'/E_0 \rangle$) is obtained by means of the following equation:

$$\left\langle \frac{E'}{E_0} \right\rangle = 1 - \int_0^{\pi/2} \frac{2M_1M_2}{(M_1+M_2)^2}(1-\cos\theta)\mathrm{d}\theta. \qquad \text{(e)}$$

When an H atom has, initially, a kinetic energy of 41 or 20 kcal/mol, the final energy of the H atom after the excursion in a xenon matrix is calculated by means of Eq. e for all three cases of the collision number. As is shown in Table 4, the final energy ranges from 11 to 39 kcal/mol, depending on the models for collisions and the initial energies of the H atoms. Since the activation energy for the hydrogen-atom-abstraction reaction of an H atom with i-C_4H_{10} is 7.4 kcal/mol,[5] the H atom has enough energy for a chemical reaction with i-C_4H_{10} after the excursion in the Xe matrix.

Table 4. Final energy of reactive H atom in Xe matrix at 77 K

	Collision efficiency with solute		
	1	4	12
Collision number	114	28.5	9.5
Final energy of H atom with 41 kcal/mol,[a] kcal/mol	23	36	39
Final energy of H atom with 20 kcal/mol,[b] kcal/mol	11	18	19

a) The H atom has initially a kinetic energy of 41 kcal/mol. b) The H atom has initially a kinetic energy of 20 kcal/mol.

The theoretically estimated energies of 11—39 kcal/mol are high in comparison with the activation energy of 7.4 kcal/mol. Therefore, there remains the important question of why the H atoms with the energies of 11—39 kcal/mol abstract selectively the tertiary H atom of i-C_4H_{10}. We cannot give a good explanation of this problem as yet. Two possibilities are plausible. One is that the real energy of the reactive H atoms is near the threshold of the hydrogen abstraction reaction. The other is that the reaction in the solid state at low temperature shows the selectivity under the influence of the crystalline fields. For example, when isobutane is exposed to γ-irradiation[27] or hot-atom attack[14] at 77 K in a polycrystalline medium, the isobutyl radical is formed, while in a glassy state the tertiary butyl radical is formed. In the radiolysis of 2,3-dimethylbutane at 77 K, the $\cdot CH_2CH(CH_3)CH(CH_3)_2$ radical is formed in crystal-I, while the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical is formed in crystal-II.[28] When glassy 3-methyl alkane are exposed to γ-irradiation, hot-atom attack, hot-radical attack, or photosensitization by aromatic solutes, radicals are formed predominantly by the rupture of secondary C–H bonds rather than by that of the weak tertiary or of the more abundant primary bonds.[29]

In conclusion, we cannot give a decisive answer to the question of whether the reactive H atoms in the radiolysis and the photolysis of solid mixtures at 77 K are thermal or hot. We will try, however, to give a probable hypothesis for further investigation. The remarkable selectivity for the reaction may diminish the possibility of hot H atoms with extremely high energies. The small isotope effect on the reaction may diminish the possibility of a quantum mechanical tunneling abstraction[19] by thermal H atoms, Since the rate constants and isotope effects for solute molecules in *neo*-C_5H_{12}-alkane mixtures are approximately the same as those for hot-atom reactions, H atoms with epithermal energy may be responsible for the reaction. When the H atoms produced by the radiolysis of the solvent alkane or by the photolysis of hydrogen halide are incident upon the channeling zone[25,3c] of the matrix, the H atoms may travel a long distance by a succession of glancing collisions with the channel walls of the solvent molecules and may then react with a solute alkane which may exist as a defect in the matrix.

The D atoms produced by the photolysis of DI react selectively with 3-methylpentane-h_{14} in 3-methylpentane-d_{14} glass at 77 K.[4] There is, however, no experimental information on the kinetic energy of the D atoms. The problem of whether the D atoms in 3-methylpentane-d_{14} glass are thermal or hot atoms requires further study in the future.

The authors wish to express their appreciation to Professor Kenji Fueki of Nagoya University for his fruitful discussions. The authors wish also to thank Dr. Kozo Matsumoto of Nagoya University for his mass spectroscopic analysis.

(Received December 1, 1977)

The influence of preparative conditions on the structure and catalytic activity of V–Cr oxide catalyst for the liquid-phase oxidation of cyclohexene has been investigated. Three series of binary oxide, V–Cr-D, V–Cr-E, and V–Cr-F, were prepared from acidic, neutral, and alkaline media, respectively. The specific activity of the catalyst was found to be in the order: V–Cr-D>V–Cr-E>V–Cr-F, the catalyst prepared from acidic medium showing the highest activity. The results of structure analysis showed the formation of several chromium isopolyvanadates, *i.e.*, chromium pyrovanadate, chromium metavanadate, and unknown phase (probably chromium polyvanadates), together with V_2O_5, Cr_2O_3, and solid solution of Cr^{6+} in V_2O_5 lattice. The formation of chromium isopolyvanadate having a higher degree of condensation of the vanadate anion was promoted by use of a more acidic medium in the catalyst preparation. The higher activity for autoxidation was obtained with the catalyst containing the more condensed isopolyvanadate. Epoxidation seems to proceed by the hydroperoxide intermediate mechanism on the active site differing from that for autoxidation.

Properties of heterogeneous catalysts in liquid-phase oxidation of cyclohexene were studied using several binary oxides containing vanadium.[1] Vanadium–chromium system (V–Cr) was found to be relatively active for the oxidation, in which epoxidation of cyclohexene also proceeded. The insoluble catalyst system seems to contain two types of active site, one effective for autoxidation of cyclohexene, *i.e.*, for radical chain reaction, and the other for selective epoxidation of cyclohexene with 1-cyclohexenyl hydroperoxide (HPO) formed by autoxidation. The activity of the V–Cr catalyst for oxidation of acrylaldehyde is considerably affected by its preparative conditions.[2] It seems that the active species is a chromium isopolyvanadate and its formation is promoted by use of an acidic medium. We have studied the effects of the methods of preparation of the V–Cr catalyst on its property. Three series of vanadium–chromium oxide were prepared from acidic, neutral, and alkaline media, and their structures and catalytic activity for oxidation of cyclohexene have been investigated in detail.

Experimental

Catalysts. Three series of binary oxide catalyst were prepared in the following way. A combination of three raw materials such as V_2O_5 hydrate+$Cr(NO_3)_3 \cdot 9H_2O$, V_2O_5 hydrate+$Cr(OH)_3$ hydrate, or NH_4VO_3+$Cr(OH)_3$ hydrate was employed in the preparation of the catalysts from acidic, neutral, or alkaline media, respectively.

The raw materials were mixed and kneaded with a small amount of water at 80 °C for 6 h, dried at 100 °C for one day, and calcined at 450 °C* for 5 h in air. The resulting three series of binary oxide, each consisting of catalysts of different compositions, are denoted by V–Cr-D (from acidic), V–Cr-E (from neutral), V–Cr-F (from alkaline medium). V_2O_5 hydrate was prepared as previously reported,[1] and $Cr(OH)_3$ hydrate was obtained as precipitate by addition of dilute ammonia to an aqueous solution of $Cr(NO_3)_3 \cdot 9H_2O$. The catalyst was pulverised and used as powder of particle size smaller than 100 mesh. The composition (in terms of atomic % of Cr/(V+Cr)), symbol, and specific surface area (S_s) are given in Table 1.

Apparatus and Procedure of Catalytic Reaction. The oxidation reaction was carried out at 60 °C for 5 h under 1 atm of O_2 pressure using a batch system.[1] 20.0 ml of cyclohexene, 50.0 ml of benzene as solvent, and 50.0 mg of the binary oxide catalyst were used in each reaction.

Analyses of Reaction Products and Catalysts. The reaction products, HPO and cyclohexene oxide (OXIDE), were determined by the iodometric method and gas-chromatography.[1]

The structure of the catalyst was studied by means of X-ray diffraction and infrared absorption, the surface area being obtained by the BET method.[1] Differential thermal analysis and thermo gravimetric analysis of the samples before calcination were carried out with a Thermoflex YGHD type thermal analyser (Rigaku Denki Co.). Electron spin resonance absorption spectra were recorded with a JES-3BX type ESR spectrometer (X-band). For removal of V_2O_5, the catalyst was immersed in 6 M ammonia for two days, separated by filtration, washed with water, and dried at 150 °C for one day.

Results

Surface Area of Catalyst. The surface area of catalyst varies a great deal with the preparative conditions and composition of catalyst (Table 1), the value being in the order: V–Cr-F>V–Cr-E>V–Cr-D. The catalyst prepared from the more alkaline medium shows a higher value.

X-Ray Diffraction of Catalyst. Typical diffraction patterns of the binary system catalysts are shown in Fig. 1. The formation of two phases, X and Y, besides V_2O_5 and Cr_2O_3 in the V–Cr catalyst used for acrylaldehyde oxidation has been recognized by X-ray diffraction analysis.[2] In the present work, these four phases were also observed. The diffraction lines are

* Formation of several chromium isopolyvanadates is expected in this binary system.[2] 450 °C was shosen as temperature of calcination so that these isopolyvanadates, *i.e.*, $Cr(VO_3)_3$,[3] $(Cr_2O)(VO_3)_4$,[4] and $Cr_4(V_2O_7)_3$,[5] might be obtained in stable form.

TABLE 1. COMPOSITION, SYMBOL, AND SPECIFIC SURFACE AREA OF CATALYST

Composition Cr/(V+Cr) (atomic %)	D-Series Symbol	S_s (m^2/g)	E-Series Symbol	S_s (m^2/g)	F-Series Symbol	S_s (m^2/g)

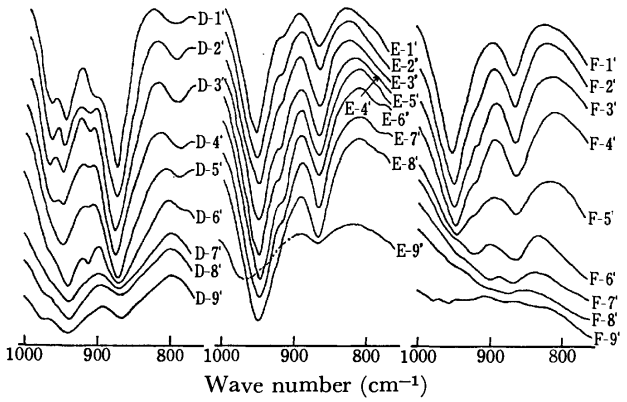

Fig. 3. Infrared spectra of V–Cr catalysts treated with NH_3.

classified into four groups; v, c, x, and y (belong to V_2O_5, Cr_2O_3, X, and Y, respectively). Several unknown lines (z) appeared in V–Cr-D catalysts of higher Cr content. The lines y were found only in V–Cr-D catalysts, while the lines *x* were observed in the other binary system, V–Cr-E and V–Cr-F. Furthermore, the *d*-spacing value of the strongest line of V_2O_5: d=4.38 Å (001 plane) increased in proportion to the Cr content, reaching 4.47 Å in D-4, only in the patterns of V–Cr-D catalysts.

Infrared Spectra. Infrared spectra of the catalysts before and after treatment with ammonia are shown in Figs. 2 and 3, respectively. Mark (') shows the catalyst treated with ammonia. The spectrum changes considerably with composition and the preparing conditions. An absorption band at about 1020 cm^{-1} (Fig. 2) is assigned to the stretching vibration of V=O bond in V_2O_5.[6] The band in D-1 and D-2 broadens toward frequency slightly lower than 1020 cm^{-1}. D-1'–D-4' show the spectra which coincide fairly well with those of chromium metavanadate ($Cr(VO_3)_3$).[7] The spectra of E-1'—E-8' and F-1'—F-5' might be due to chromium pyrovanadate ($Cr_4(V_2O_7)_3$).[7] The band observed at about 800 cm^{-1} in D-1'—D-5' is also recognized, though weak, in E-6'—E-8'.

DTA and TGA of Catalyst. In order to clarify the solid-phase reaction during the preparation of the catalysts, thermoanalyses of the samples after being dried at 100 °C (before calcination) were carried out in the range 100—750 °C. The results are shown in Fig. 4. The sharp endothermic peak at 680 °C is due to the melting of V_2O_5, and the sharp exothermic one observed with the decrease of weight at 410 °C might be due to the dehydration of $Cr(OH)_3$.[8] Several endo- and exothermic peaks observed between 100 and 200 °C with the samples of D-series are mainly due to the decomposition of chromium nitrate. An exothermic peak observed with D-0 at 320 °C seems to be due to dehydration of V_2O_5 hydrate. The peak shifted toward high temperature by addition of $Cr(NO_3)_3$. An exothermic peak at *ca.* 410 °C in D-series of high Cr content (Fig. 4, D-5) recognized with weight loss proportional to the Cr content, might be due to the dehydration of

—— DTA, ------ TGA.

$Cr(OH)_3$ formed by the partial hydrolysis of $Cr(NO_3)_3$ during the course of mixing of the raw materials. The samples of E-series show several obscure peaks with weight loss below 300 °C, and an exothermic peak in the vicinity of 500 °C (Fig. 4, E-5). The weight loss at about 320 °C decreases with increase in Cr content, that at about 500 °C being roughly proportional to the Cr content. The temperature of the latter peak was lowered with increase in Cr content. Series-F show an exothermic peak at about 210°C, two exothermic peaks at about 220 and 300 °C, and a weak endothermic peak near 500 °C (Fig. 4, F-5). The peaks at 210 and 300 °C are due to the decomposition of ammonium metavanadate. The weak endothermic peak at 500 °C is accompanied by weight loss proportional to the Cr content as in the case of V–Cr-E.

ESR Spectra of Catalyst. The form of spectra varies remarkably, depending on the preparing conditions of catalyst. Typical spectra are shown in Fig. 5. D-1—D-3 show spectra consisting of a strong narrow signal superposed on a broad one (Fig. 5, a and b), the narrow signal having a peak-to-peak line width (ΔH_{msl}) of 60—110 G and g value of 1.96. The intensity of the narrow signal is higher in the catalysts having lower Cr content, the strongest one being observed with D-1. The catalyst of low Cr content in E and F-series also show similar types of spectrum, but the intensity of the narrow signal is very weak. Furthermore, ΔH_{msl} of the broad signal varies a great deal; 300—500 G in V–Cr-D, and

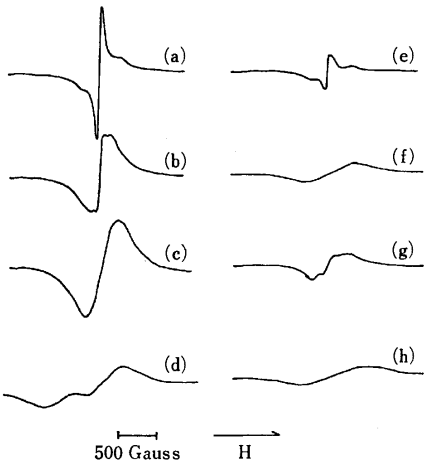

Fig. 5. ESR spectra of V–Cr catalysts.
(a) D-1, (b) D-2, (c) D-5, (d) D-7, (e) E-1, (f) E-7, (g) F-1, (h) F-7.

400—1200 G, being very broad, in both V–Cr-E and V–Cr-F. Thus, the broad signals in V–Cr-D series are clearly distinguishable from those of V–Cr-E and V–Cr-F series. In the case of D-4 and D-5, the narrow signal is probably hindered by the broad signal which is observed strongly. D-6—D-9 show spectra having additional maximum in weak fields (Fig. 5, d).

Results obtained for the single component catalysts are as follows. D-0, E-0, and F-0 show a very weak signal having ΔH_{msl} of about 80 G and g value of 1.96, while the spectra of Cr_2O_3 vary depending on the preparing conditions. D-10 shows a spectrum similar to D-7, however, the spectra of both E-10 and F-10 consist of a single broad signal.

Oxidation Reaction. The reaction results obtained for the three series of V–Cr catalysts are shown in Figs. 6 and 7. The order of specific activity shown in terms of the maximum rate of oxygen absorption per unit

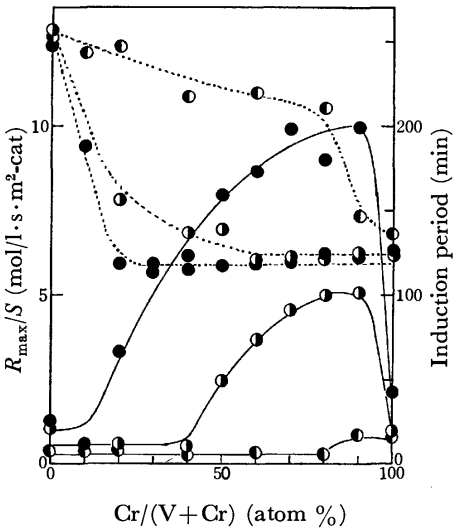

Fig. 6. Specific activities of V–Cr catalysts and induction periods of oxygen uptakes.

● V–Cr-D, ◑ V–Cr-E, ◐ V–Cr-F.

surface area of the catalyst (R_{max}/S) is: V–Cr-D>V–Cr-E>V–Cr-F (Fig. 6). The activity of each binary system is high when Cr content is high, the highest value being obtained at 90 atom % of Cr in all the three series. An induction period for oxygen uptake was 120—130 min with the relatively active catalysts, *i.e.*, D-2—D-9 and E-5—E-9, and the higher content of Cr caused decrease in its value (Fig. 6). Fig. 7 shows the yield of HPO or OXIDE per unit surface area of each catalyst (Y_{HPO}/S or Y_{OXIDE}/S). The values of Y_{HPO}/S show a very similar tendency to the oxygen uptake in Fig. 6. OXIDE was obtained only with the catalyst active for HPO formation. However, dependency of epoxidation on the catalyst composition differs clearly from that of HPO formation, the maximum value of Y_{OXIDE}/S being obtained with the catalyst with much less Cr content.

Discussion

Structure of Catalyst. Solid solution is formed in the binary oxide containing V, such as V–Mo and V–W.[6] For V–Cr system, Kurina *et al.*[9] reported that the solid solution is formed in the binary oxide prepared from NH_4VO_3 and $Cr(NO_3)_3\cdot9H_2O$.

By means of X-ray analysis, a diffraction pattern of V_2O_5, and an increase in *d*-spacing of 001 plane proportional to the Cr content, following Vegard's law were observed in D-1—D-4 catalysts. An interfacial solid solution seems to be formed in the catalysts. These catalysts show a narrow signal in their ESR spectra, the values of *g* and ΔH_{msl} being very similar to the values of the weak signal of the V_2O_5 spectra. The weak signal of V_2O_5 is thought to be due to quadrivalent vanadium ions, V^{4+}, resulting from lattice defects.[6] The narrow signal might be due to V^{4+} ions. The reduction of vanadium species is considered to occur as a result of the charge compensation of the chromium atoms (probably, Cr^{6+}) introduced into the lattice of V_2O_5 by the formation of the solid solution. This is supported by the fact, in D-1 and D-2, the infrared absorption band at 1020 cm^{-1} broadens toward lower frequency. The broadening may be due to the formation of V^{4+}=O bond, resulting from solid solution. In both series of V–Cr-E and V–Cr-F, the catalysts containing a small amount of Cr show a very weak narrow signal in their ESR spectra, its highest intensity being observed with E-1 and F-1.** However, no clear change in the *d*-spacing was observed. This suggests that the amount of solid solution is considerably smaller in both V–Cr-E and V–Cr-F than in V–Cr-D. The intensity of the narrow signal can be put in the order: V–Cr-D>V–Cr-E>V–Cr-F. It is suggested that more acidic preparative conditions are favorable for the formation of solid solution.

By means of X-ray diffraction, three phases, X, Y, and Z were observed in the catalysts. The patterns of X and Y coincide with those of $Cr_4(V_2O_7)_3$[5] and $Cr(VO_3)_3$,[3] respectively. Phases X and Y might be chromium pyrovanadate and chromium metavanadate, respectively. The *d*-spacing values of lines classified into z in V–Cr-D (Fig. 1, b) vary somewhat depending on the composition of catalyst, the lines z being hardly attributed to single component. Phase Z might be a mixture of several compounds. In order to clarify the influence of preparing conditions on the formation of these phases, the intensities of two characteristic peaks selected for two phases, $Cr_4(V_2O_7)_3$ (d=3.19 Å) and $Cr(VO_3)_3$ (d=3.87 Å), in Fig. 1, are plotted as a function of the composition of each catalyst series, together with that of both phases of V_2O_5 (d=4.37 Å) and Cr_2O_3

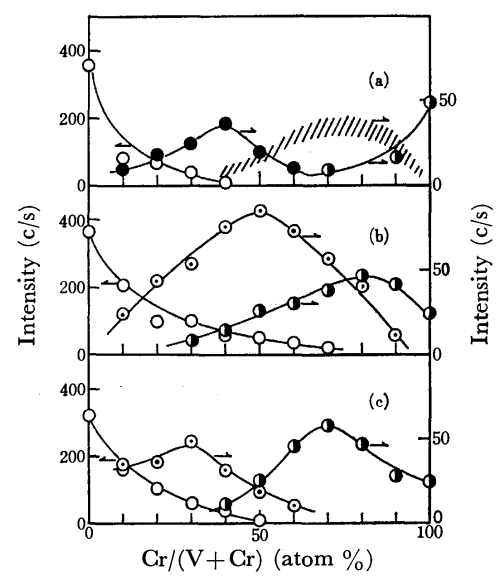

Fig. 8. Intensities of X-ray diffraction lines.
(a) V–Cr-D (b) V–Cr-E (c) V–Cr-F
○ d=4.38 Å (V_2O_5), ⊙ d=3.19 Å ($Cr_4(V_2O_7)_3$), ● d=3.87 Å ($Cr(VO_3)_3$), /// $d\simeq$3.2 Å (phase z), ◑ d=2.67 Å (Cr_2O_3).

** No narrow signal was observed in the catalyst prepared from NH_4VO_3 and $Cr(NO_3)_3\cdot9H_2O$.[2] However, Kurina *et al.*[9] reported that the binary oxide similarly prepared shows the narrow signal of V^{4+} in the solid solution, its intensity reaching maximum at 5 mol% of Cr. Disappearance of the narrrow signal seems to be due to the fact that the signal was hindered by the strong broad one, since the catalysts contain more than 17% of Cr.

(d=2.67 Å) (Fig. 8). In order to show the existence of phase Z, the line near d=3.2 Å was selected for the sake of convenience. Its intensity is indicated by shading. The intensity of the peak of $Cr(VO_3)_3$, recognized only in D-1—D-6 catalysts, was observed to reach a maximum at 40 atom % of Cr. The values of Cr content at the maximum intensity of the $Cr_4(V_2O_7)_3$ peak are *ca.* 50 and 30 atom % in V–Cr-E and V–Cr-F, respectively.

The infrared spectra suggest the formation of $Cr(VO_3)_3$ in the catalysts of D-1—D-4 and $Cr_4(V_2O_7)_3$ in E-1—E-8 and F-1—F-5. The compositions of these catalysts coincide with those classified by X-ray analysis, with respect to the formation of $Cr(VO_3)_3$ and $Cr_4(V_2O_7)_3$. However, a very weak absorption band was observed at about 800 cm^{-1} in E-6′—E-8′, in spite of the absence of $Cr(VO_3)_3$ The results suggest the formation of amorphous $Cr(VO_3)_3$. According to the report given by Olivier,[7] the absorption bands between 750 and 1050 cm^{-1} are assigned to the stretching vibrations of V–O bonds, varying markedly with the type of isopolyvanadate anion. $Cr(VO_3)_3$ has a chain structure of VO_6 octahedra connected with each other by sharing an edge,[10] the bands in its spectrum being assigned as: 970 and 945 cm^{-1} to $\nu_s VO_2$ and 915 and 800 cm^{-1}*** to VO_6. On the other hand, $Cr_4(V_2O_7)_3$ contains V_2O_7 group which consists of two VO_3 pyramids linked by a V–O–V bridge.[11] The following assignments might be made: 950 cm^{-1} to $\nu_s VO_3$ and 870 cm^{-1} to $\nu_{as} VO_3$. Catalysts D-6—D-9 containing phase Z as classified by X-ray analysis show very broad bands centered at *ca.* 940 and 870 cm^{-1} in the range of V–O stretching vibrations. No such spectra seem to have been reported. They suggest some chromium polyvanadates containing anions of higher degrees of condensation. The nature of the anionic vanadate species in alkaline, neutral, and acidic solutions has been the subject of numerous investigations. A typical example of the types of vanadate anions is as follows.[12]

pH	6.7	9.6	12.6
anion	poly→←meta→←pyro→←ortho		

It is reasonably considered that chromium polyvanadates are formed in D-6—D-9 whose preparing conditions are more acidic than those of D-1—D-5. The fact that D-6—D-9 show some randomness in the d-spacing values and the frequencies of infrared absorption might be due to the diversity of the type of polyvanadate.

Samples of the binary system show thermal changes not observed in each of the one component systems (Fig. 4). In each of the three series, the endothermic peak due to the melting of V_2O_5 was rapidly weakened with the increase in Cr content, not being observed in the sample containing less amount of V than 40 atom %. This suggests that some solid-phase reactions took place during the course of calcination. It is considered that the weight loss observed at *ca.* 500 °C especially in E and F-series is mainly due to the dehydration of $Cr_4(V_2O_7)_3 \cdot nH_2O$.[5] The dehydration is more difficult than that of $Cr(VO_3)_3 \cdot mH_2O$, requiring a long period or a higher temperature. There is a possibility that undesirable water remains in the binary catalysts. However, the infrared spectra of the catalysts show no absorption band of H–O–H bending vibration at *ca.* 1600 cm^{-1}, indicating that the dehydration is nearly completed by at 450 °C for 5 h.

The electron spin resonance spectra show broad signals whose value of ΔH_{msl} vary considerably. ΔH_{msl} of these signals were relatively small in V–Cr-D, but fairly large in both V–Cr-E and V–Cr-F. The peak-to-peak height was especially great in V–Cr-D. It is difficult to assign these broad signals. However, the relatively strong signal observed in D-2—D-6 might be assigned to a paramagnetic species included in $Cr(VO_3)_3$, since its intensity correlates fairly well with the amount of $Cr(VO_3)_3$ estimated from the results of X-ray diffraction and infrared analysis. In a similar manner, the very broad signals observed with some V–Cr-E and V–Cr-F catalysts may be assigned to a paramagnetic species in $Cr_3(V_2O_7)_4$. The broadening of these signals might be due to the dislocalization of the unpaired electron owing to the ordering of the structure containing the paramagnetic species. In the infrared spectra of E-6—E-8, a weak absorption band was observed which may be assigned to the stretching vibration of VO_6 in $Cr(VO_3)_3$. However, the electron spin resonance spectra of these catalysts show no broad signal of $Cr(VO_3)_3$, contrary to our expectation. Spectra having an additional maximum in weak fields were observed in D-7–D-10, the intensity increasing with the amount of Cr_2O_3 estimated by X-ray diffraction. This type of signal seems to be due to Cr_2O_3. However, E-10 and F-10 show only a broad signal, suggesting a difference between Cr_2O_3 prepared from $Cr(NO_3)_3$ and that from $Cr(OH)_3$.

Relationship between Structure and Catalytic Activity. The correlation of the catalyst composition to R_{max}/S differs clearly from that to Y_{OXIDE}/S, in each series of binary system (Figs. 6 and 7). The oxygen uptake is rationally assumed to be mainly due to the radical chain reaction. It is considered that the active species for autoxidation differs from that for epoxidation. Since epoxidation was observed only with the catalysts which gave HPO (Fig. 7), epoxidation is thought to proceed selectively with HPO. Thus, the results we obtained support the suggestion that epoxidation proceeds by a hydroperoxide intermediate mechanism catalyzed by the vanadium–chromium oxide having two types of active site, one effective for the autoxidation and the other for the selective epoxidation.[1]

The activity for autoxidation shown by R_{max}/S might be explained as follows. Chromium polyvanadates and $Cr(VO_3)_3$ were observed in the catalysts of D-series; $Cr(VO_3)_3$ (suggested only by the infrared absorption) and $Cr_4(V_2O_7)_3$ in those of E-series; and $Cr_4(V_2O_7)_3$ in those of F-series. From a comparison of the distribution of these isopolyvanadates in the three series with specific activities (Fig. 6), it seems that the activity for autoxidation is largely affected by the type of chromium isopolyvanadate in the catalyst, its activity being in the order: chromium polyvanadates $> Cr(VO_3)_3 > Cr_4(V_2O_7)_3$.

*** The band at about 800 cm^{-1} was assigned to the stretching of V–O–V bond.[2] However, the assignment to VO_6 octahedron may be more reasonable because of the absence of the band in the spectrum of $Cr_4(V_2O_7)_3$.

Chromium isopolyvanadate with a higher degree of condensation shows a higher activity. The long induction periods observed in all the reactions may be due to the accumulation of HPO. Thus, autoxidation is considered to be initiated by the radical decomposition of HPO with the binary catalyst. According to the results of Meyer *et al*,;[13] chromium oxide decomposes hydroperoxide, it is thought that the active species for autoxidation contains chromium.**** The correlation of catalyst composition to Y_{HPO}/S is similar to that to R_{max}/S. This is explained by the fact that HPO is the main product of the autoxidation of cyclohexene by radical chain mechanism.

Concerning epoxidation, exact discussions are difficult since it may have first-order dependence on HPO concentration. All we can say is that the active species for the epoxidation differs from that for the autoxidation. It might consist of vanadium.

Studies on the vapor-phase oxidation with V system catalysts[6] show that the formation of solid solution causes the increase of catalytic activity. However, no such phenomenon has been observed. This might result from the difference in the catalytic mechanism between liquid-phase and vapor-phase oxidation.

Higher activity of the V–Cr catalyst was obtained by use of the more acidic medium. This might result from the variety of vanadate anions formed on mixing of the raw materials. It is suggested that various isopolyvanadate anions form depending on the acidity of medium.[12] Their existence may largely influence the structure and activity of the binary oxide catalyst.

**** In order to study the surface state of the catalysts, X-ray photoelectron spectroscopy was carried out. No shift was observed in the V $2p_{3/2}$ line between $V_2O_5(V^{5+})$ and V_2O_4 (V^{4+}),[14] but some shift was recognized in the Cr $2p_{3/2}$ line between $Cr_2O_3(Cr^{3+})$ and $K_2Cr_2O_7(Cr^{6+})$.[15] The binding energies of Cr in the binary catalysts remain approximately constant, 587 eV (Cr $2p_{1/2}$) and 557 eV (Cr $2p_{3/2}$), suggesting that chromium species on the surface of the catalysts have the same charge (probably of Cr^{3+}).

Calorimetric Study of the Glassy State. XIV. Calorimetric Study on Unusual Glass Transition Phenomena in $CFCl_2$-$CFCl_2$

Kōji Kishimoto,* Hiroshi Suga, and Syûzô Seki

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 1, 1977)

The heat capacities of the glassy crystalline, plastic crystalline, and liquid phases of $CFCl_2$–$CFCl_2$ were measured by an adiabatic calorimeter over a temperature range from 13 to 310 K, with a sample of 99.93% purity. The triple point was determined to be 297.91 K, the enthalpy and entropy of fusion being 3.666 kJ mol^{-1} and 12.30 J K^{-1} mol^{-1}, respectively. Three kinds of relaxation phenomena were found during the heat capacity measurement centered at around 60, 90, and 130 K, respectively. The first was attributable to the β relaxation. The second was for primary glass transition, where overall rotation or reorientation of the molecules might be frozen. The third was analyzed by ascribing it to the freezing of conversion between the trans and the gauche conformers of the molecule. Activation enthalpy for the internal rotation and energy difference between the two conformers were determined to be 41 kJ mol^{-1} and (790 ± 60) J mol^{-1}, respectively. This experiment provides the first example in which three different freedoms of molecular motion are frozen successively at different temperatures as the crystal is cooled down. An effort to get a possible low-temperature ordered crystalline phase was partially successful by long annealing of the crystal. The extremely sluggish nature of the phase transition into the ordered phase will be related with the slow rate of the internal rotation of the molecule below the transition temperature.

In order to clarify the nature of vitrification process from molecular viewpoint, it is indispensable, at the present stage, to choose as simple a system as possible where degrees of freedom to be taken into account are so restricted in its number that rigorous treatment will be approached. Glassy crystal meets this requirement since it has three-dimensional long-range periodicity which eliminates the complication in considering positional disorder. In hopes of the elucidation of freedoms frozen below a glass transition temperature, T_g, the present material was chosen from the viewpoint of simple molecular structure with internal degrees of definite nature. Kolesov *et al.*[1] already measured the heat capacity of this material and found a type-G transition at around 90 K, according to the phenomenological classification advanced by Guthrie and McCullough.[2] They also reported that this compound has a plastic crystalline phase below its melting point. However, the detailed trend of the heat capacity in the transition region was not delineated in their calorimetric study and they did not mention any relaxational nature of the anomaly. To clarify the nature of the anomaly is the first motivation for the present study. As judged by intuitive plausibility, the transition which they called type-G transition is likely to be a glass transition from the plastic crystal to a glassy crystal. If so, a low-temperature ordered phase must be found by careful thermal treatment. This is another principal object of the study.

Experimental

Material. About 200 g of the compound purchased from E. Merck AG. was first purified by distillation at atmospherric pressure. The middle fraction was subjected to fractional melting in a thermostated bath controllable within $\pm$ 1 mK and then purified by molecular sieve (Linde 3A) to remove low molecular weight compounds as impurities, and finally fractionally distilled *in vacuo*. The calorimeter cell had been attached in advance to the purification system. The purified sample was transferred into the calorimeter cell and then an inlet capillary tubing was pinched off. The analysis of the fractional melting process of the sample, as will be described later, indicated the impurity content of 0.07%.

Heat Capacity Measurement. The heat capacity was measured by the adiabatic calorimeter reported previously.[3] The calorimeter cell was a gold-plated copper can of internal volume 30 cm^3. A sample of 48.121 g (*in vacuo*) was loaded into the cell. No exchange gas was admitted inside the cell. The density of the crystal used in buoyancy correction was calculated from an X-ray diffraction data. A working platium thermometer was calibrated against the International Practical Temperature Scale of 1968 after the completion of the measurement.

X-Ray Diffraction. Preliminary X-ray investigation of the crystal at room temperature was done by the rotating-crystal method. Single crystal was grown from the liquid within a pyrex capillary tubing. X-ray diffraction phtograph was taken at 15 °C by a cylindrical camera of diameter 5.712 cm with Cu K_α radiation

Results and Discussion

X-Ray Diffraction. The observed X-ray diffraction patterns are well indexed as those of the bcc lattice with the cell constant of (0.718 ± 0.004) nm at 15 °C. The rotation photograph has only four reflections, corresponding to (110), (200), (211), and (220) planes, even for prolonged irradiation. This arises from the rapid falling-off in intensity with increasing reflection angle and reflects the fact that the crystal is highly disordered. This behavior is one of the characteristic natures of the plastic crystal.

Determination of Purity. A fractional melting experiment was carried out to determine the melting point and the purity of the sample. In Fig. 1 the reciprocal of the fraction of the sample melted, $1/f$, is plotted against the equilibrium final temperature, T_f, for each energy input. As extremely long time was required for the establishment of thermal equilibrium during the

melting process, the extrapolated value of the temperature to the time being infinite at each energy input was taken as T_f. These values are given in Table 1. Since T_f versus $1/f$ does not yield a straight line, we employed Mastrangelo-Dornte's method[4] in which they derived a solid solution treatment for calorimetric melting point data. By use of this treatment the purity and the triple point of the sample were determined to be 99.93% and 297.91 K, respectively. The enthalpy of fusion was measured twice. These cryoscopic data are given in Table 2. The small entropy of fusion as well as its high crystallographic symmetry indicate that the crystal belongs to the category of plastic crystal originally defined by Timmermans.[5]

Heat Capacity. The experimental values of the molar heat capacities are listed in Table 3 and presented graphically in Fig. 2. These series of measurements are numbered in chronological order so that their thermal history of the sample may be followed. Also, the approximate temperature increments employed in the measurements may be deduced from the differences in the adjacent average temperatures. Curvature correction was made along the same line as in Ref. 6, whereas the vaporization correction was not made because of

lack of the vapor pressure data. As is seen in Fig. 2, the plastic crystal is easily brought into a glassy crystalline state through a glass transition region centered around 90 K. This is really a glass transition phenomenon since the characteristic enthalpy relaxation was observed at this temperature region, as will be shown later. The heat capacities of the glassy crystal plotted in Fig. 2 are for the sample cooled at the rate of 0.2 K min^{-1} from 210 K to temperatures below T_g.

Usually plastic crystal undergoes a transformation on cooling to different phase with ordered molecular orientation in accord with the third law of thermodynamics. The expected ordered phase, however, can not be realized in this crystal by a simple cooling. Therefore,

○; Rapidly cooled specimen,
●; annealed specimen for 50 days below 120 K.

the sample was first cooled down to 13 K and then annealed in the temperature range between 77 and 160 K for 50 days. This thermal treatment proves to be partially successful for inducing a low-temperature phase. The major feature of the heat capacity for this sample (solid circle in Fig. 2) is a sharp peak at 170 K which is undoubtedly the transition point T_t, separating an ordered and the plastic phases. Extremely long equilibration time was required during the phase transition, and this indicates the first order nature of the transition. The heat capacities below T_t are 0.9% smaller than those for the supercooled plastic crystalline phase, while above T_t both of the values agree within the experimental precision.

The heat capacities of the glassy crystal and its simple extrapolation to higher temperatures serve as an approximation to those for the ordered crystal. Comparing the heat capacity lowering of 0.9% with the heat capacity jump at T_g, it is estimated that 2—3% of the plastic crystalline phase was transformed into the ordered phase by the above thermal treatment. On the other hand, fewer ($\approx$0.16%) ordered phase was obtained by the same procedure except that the sample had not been cooled down to 13 K. Being cooled down to the liquid hydrogen temperature seems to be indispensable for some other kinds of materials to produce their ordered phases as suggested by Finke and Messerly.[7] The fact that the rate of nucleation is accelerated by cooling the crystal to 13 K supports the prevailing idea that some kinds of molecular rearrangement still occur even below T_g. This suggests a potential existence of another relaxation phenomenon below the primary glass transition.

tions at regular temperature intervals were obtained by numerical integration of the smoothed values of the experimental heat capacities. They are all tabulated in Table 4. In the derivation of these apparent thermodynamic functions, the glassy crystalline phase at 0 K was taken as a reference state instead of a crystalline phase which obeys the third law of thermodynamics, because of the failure in preparing pure low-temperature ordered phase. Below 13 K, the values of heat capacity contributing to the thermodynamic functions were calculated on the basis of the effective frequency distribution[8,9] given in the inset in Fig. 3.

Primary and β Relaxation. β relaxation was first observed calorimetrically in the glassy state of isopropylbenzene.[8] An analogous thermal anomaly was observed in the glassy crystalline state of the present material. Figure 4 represents the thermal drifts encountered during the course of heat capacity measurement. These drifts of the calorimeter temperature are the sum of the quasi-adiabatic drifts due to small heat leakage in the calorimetric system and the drifts due to enthalpy relaxations which are responsible for configurational or other changes possibly occurring in the sample. The values shown in this figure are corresponding to the initial drifts taken just after a uniform distribution of the calorimetric temperature which is realized about 5 min after an energy input. Changes in signs of the temperature drifts on heating from exothermic to endothermic ones characteristic of enthalpy relaxation phenomena were observed centering at around 60, 90, and 130 K. The change found around 60 K is attributed to the β relaxation. Associated with this relaxation, the heat capacity increases stepwise by amount of ≈2 J K^{-1} mol^{-1} around 60 K. Figure 3 indicates the excess heat capacity responsible for the β relaxation over those extrapolated from below T_β (see Fig. 2). This extrapolation was carried out by employing the method of effective frequency distribution[8,9] with 22 values for C_p between 14 and 52 K. The inset in this figure is the effective frequency distribution which reproduces best the heat capacity data below 52 K. The nature and the possible origins of β relaxations in glassy liquid and glassy crystal were discussed by Johari[10] based on the dielectric observation. The second found around 90 K in Fig. 4 is attributed to the primary glass transition, where overall rotation or reorientation of molecules might be frozen.

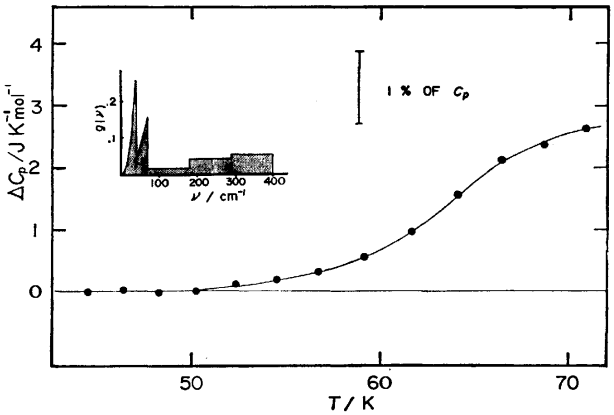

Fig. 3. Excess heat capacities responsible for β relaxation over those extrapolated from T_β.

Anomalous Heat Capacity around 130 K. The heat capacity data above 100 K are reproduced in Fig. 5 on an enlarged scale. The anomalous heat capacities observed around 130 K are accompanied by temperature drifts characteristic of those observed around glass

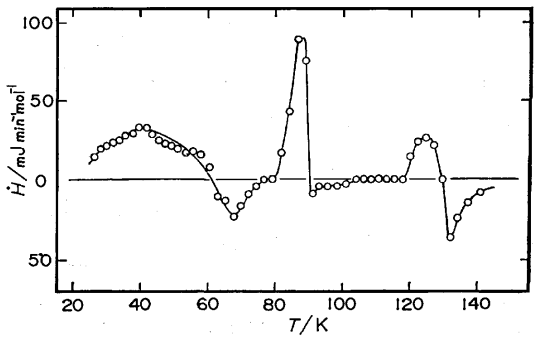

Fig. 4. Spontaneous temperature drifts of calorimeter plotted as a function of temperature.

●; Rapidly cooled specimen,
○; annealed specimen at 125 K for about 40 h.

transition region. Taking into account the step-like increase in heat capacity and the nature of temperature drifts, we can conclude that the anomaly arises from relaxational effect of some degrees of freedom. One possible candidate is freezing-in of the conversion between trans and gauche conformers of the molecule. Based on the assumptions that the frequencies of C–C torsional modes are the same for both conformers and that the conversion has little effect on the lattice vibration, the excess heat capacity due to the conversion is approximately described by the Schottky heat capacity.

Newmark and Graves[11] found that the energy of the gauche conformer was 690 J mol^{-1} above the trans conformer in a mixed solvent $CFCl_3$–CF_2Cl_2. Newmark and Sederholm[12] obtained the value 510 J mol^{-1} for the energy difference in $CFCl_3$ solution. Therefore the trans conformer was assumed to be more stable one in the plastic crystalline phase. Then, the molar Schottky heat capacity C_{sch} is given by the following equation:

$$C_{sch} = \frac{\Delta H^2 \exp(\Delta H/RT)}{2RT^2\left[1+\frac{1}{2}\exp(\Delta H/RT)\right]^2}\cdot\theta(T-T_g), \quad (1)$$

where ΔH is the enthalpy difference between the trans and the gauche conformers, R the gas constant, and θ the step function. Below T_g, there exists no contribution to the Schottky heat capacity because of the freezing-in of the conversion. Then, ΔH in this equation can be obtained from C_{sch} at T_g which is corresponding to the heat capacity jump at T_g in Fig. 5. By taking into account of the irreversible enthalpy relaxation effect, the heat capacity jump is assessed to be (1.1±0.2) J K^{-1} mol^{-1} at 130 K, which gives the value (790±60) J mol^{-1} for ΔH. The broken curve in Fig. 5 represents the heat capacities obtained by subtracting C_{sch} from the measured molar heat capacities. This broken curve gives a reasonable extrapolation of the heat capacity below 130 K up to the triple point. Comparison of our value (790±60) J mol^{-1} with the following three values, that is, (i) ΔH=800 J mol^{-1} obtained by Pethrick *et al.*[13] based on the IR and Raman data of Kagarise *et al.*,[14] (ii) ΔH=690 J mol^{-1} obtained by Newmark and Graves and (iii) ΔH=510 J mol^{-1} by Newmark and Sederholm described above, supports the validity of the proposed model for the explanation of the heat capacity anomaly appeared around 130 K.

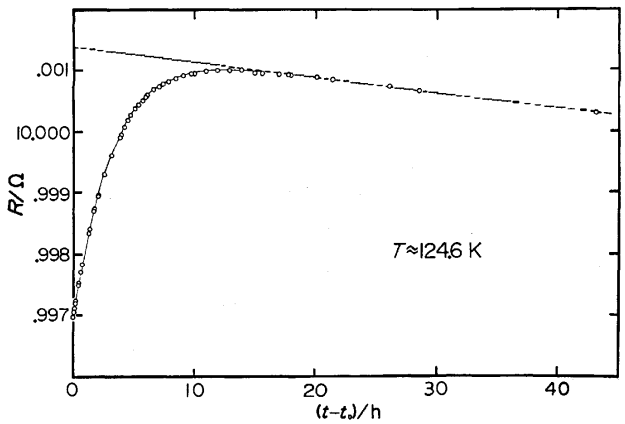

Fig. 6. The temperature drifts due to the enthalpy relaxation phenomenon are plotted as a function of time. The ordinate represents the readings of the platinum resistance thermometer.

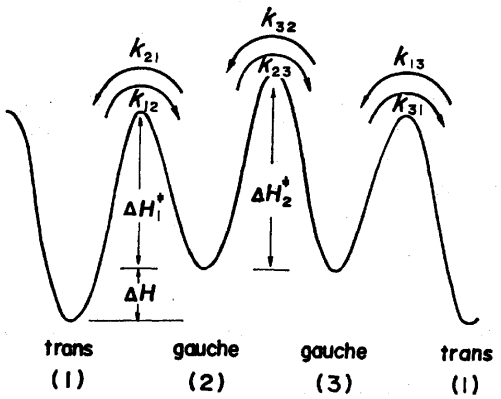

Fig. 7. The enthalpy curve as a function of the coordinate of internal rotation around the C–C bond of CCl_2F–CCl_2F.

The exothermic drifts measured at 124.6 K are plotted in Fig. 6 as a function of time. The broken line indicates the heat leakage caused by the imperfection of adiabatic control. It was assessed to be 28 μW. The difference between the solid and the broken lines is attributed to the enthalpy relaxation inside the specimen, which can be fitted considerably well to an exponential function. The relaxation time at 124.6 K turned out to be 10.4 ks. The process of trans-gauche conversion is very similar to that of unimolecular reactions. In Fig. 7, the states labeled 1, 2, and 3 correspond to trans, gauche, and gauche conformers, respectively. Dynamical equilibrium among them is established above the frozen-in temperature. The transition from state i to state j is assumed to take place with a transition probability k_{ij}.

From the symmetry of the potential function, the following relations can be obtained,

$$k_{32} = k_{23},\ k_{13} = k_{12},\ \text{and}\ k_{31} = k_{21}. \quad (2)$$

Between 1 and 2, and 2 and 3, there exist activated states whose potential barriers have heights of ΔH_1^* and ΔH_2^*, respectively. The rate equation for the occupational probablities of the states may be expressed in a matrix form,

$$\dot{P}(t) = D \cdot P(t), \quad (3)$$

where

$$P(t) = \begin{pmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \end{pmatrix}$$

$$D = \begin{bmatrix} -2k_{12} & k_{21} & k_{21} \\ k_{12} & -(k_{21}+k_{23}) & k_{23} \\ k_{12} & k_{23} & -(k_{21}+k_{23}) \end{bmatrix}. \quad (4)$$

The rate equation has the solution

$$P(t) = (\exp Dt) \cdot P(0) = Te^{\Lambda t}T^{-1}P(0). \quad (5)$$

T is the matrix that diagonalizes D, and Λ is the diagonal matrix:

$$\Lambda = T^{-1}DT = \begin{bmatrix} 0 & 0 & 0 \\ 0 & -(k_{21}+2k_{12}) & 0 \\ 0 & 0 & -(k_{21}+2k_{23}) \end{bmatrix}. \quad (6)$$

Hence $P(t)$ is readily obtained as

$$P(t) = \begin{bmatrix} P_1^\circ & 2m & 0 \\ P_2^\circ & -m & n \\ P_3^\circ & -m & -n \end{bmatrix} \cdot \begin{pmatrix} 1 \\ \exp(-t/\tau_1) \\ \exp(-t/\tau_2) \end{pmatrix}, \quad (7)$$

where $\tau_1^{-1}=k_{21}+2k_{12}$, $\tau_2^{-1}=k_{21}+2k_{23}$, the coefficients m and n are evaluated from the initial conditions, and P_i° the equilibrium occupational probability of state i.

The internal energy arising from the freedom of internal rotation, H_{int}, is given as follows by taking the trans conformer as the reference state of energy,

$$H_{\text{int}} = \Delta H(P_2+P_3) = \Delta H[2P_2^\circ - 2m\exp(t/\tau_1)]. \quad (8)$$

It is noticeable that the enthalpy relaxation is dominated by a single relaxation time, whereas the dielectric relaxation time for this system is dependent on both τ_1 and τ_2.[15] On the other hand, according to the theory of absolute reaction rate[16] k_{12} can be written in the following form by assuming a transmission coefficient of nearly unity,

$$k_{12} = \frac{kT}{h}\frac{F^*}{F_1}\exp[-(\Delta H_1^* + \Delta H)/RT] \simeq \frac{kT}{h}\left[1-\exp\left(-\frac{h\nu}{kT}\right)\right]\exp[-(\Delta H_1^* + \Delta H)/RT], \quad (9)$$

where F_1 and F^* are the partition functions of the trans conformer for the ground and the activated states, respectively. ν is the C–C torsional frequency, and the other symbols obey the conventional terminology. Similarly, k_{21} and k_{23} are of the form

$$k_{21} \simeq \frac{kT}{h}\left[1-\exp\left(-\frac{h\nu}{kT}\right)\right]\exp\left(-\frac{\Delta H_1^*}{RT}\right),$$

and

$$k_{23} \simeq \frac{kT}{h}\left[1-\exp\left(-\frac{h\nu}{kT}\right)\right]\exp\left(-\frac{\Delta H_2^*}{RT}\right). \quad (10)$$

Assuming $\Delta H \ll \Delta H_1^*$ gives $k_{12}=k_{21}$, and as a result, $\tau_1^{-1} = 3k_{21}$. Equation (8) yields the relation that the enthalpy relaxation time τ is equal to $1/3\,k_{21}$.

ΔH^* can be calculated to be 39.8 kJ mol^{-1} by use of the value 82 cm^{-1} [13] for ν together with the value for τ at 124.6 K. This result agrees well with the value of (38 ± 1) kJ mol^{-1} obtained by Newmark and Graves[11] and of (40 ± 0.4) kJ mol^{-1} obtained by Newmark and Sederholm.[12] The relaxation time at infinite temperature, τ_0, is of the order of 10^{-13} s. The large activation enthalpy in this highly halogenated ethane seems to arise from steric hindrance of the bulky halogen atoms in the eclipsed state. Since all molecules in the low-temperature ordered phase should be in only one and the same conformer, either trans or gauche form, the molecules must rearrange themselves to go to the most stable conformer by exceeding the activated state in the course of the phase transition of the plastic crystalline phase into the ordered phase. Thus one of the reasons for the extremely sluggish nature of the phase transition of the present material seems to be the slow rate of the trans-gauche conversion below T_t (170 K).

The authors express their sincere thanks to Associate Professor Yōzō Chatani for taking the X-ray diffraction photographs

Interactions of Calcium Ions with Carbohydrates: Crystal Structure of Calcium DL-Glycerate Dihydrate

Tooru TAGA, Makoto OHASHI, and Kenji OSAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 8, 1977)

The crystal structure of calcium DL-glycerate dihydrate has been determined by the heavy atom method. The crystal is monoclinic, space group $P2_1/c$, with unit cell dimensions: $a=14.40$, $b=7.63$, $c=10.40$ Å, and $\beta=98.8°$. Two independent glycerate anions have different conformations. β-Hydroxy oxygen in one conformer is trans-gauche to α-carboxy carbon and α-hydroxy oxygen, while that in the other conformer is gauche-gauche. Ca–O interactions and hydrogen bonds stabilize the crystal structure. The calcium ion is bound to three glycerate anions and two water molecules, the two glycerate anions chelating the calcium ion with the α-carboxy oxygen and α-hydroxy oxygen, and third glycerate anion bonding to the calcium ion with β-hydroxy oxygen. Seven oxygens surround a calcium ion in a distorted pentagonal biprism arrangement with Ca–O distances ranging from 2.32 to 2.47 Å.

A ^{1}H NMR study on lanthanoid complexes of polyhydroxy α-carboxylic acids in an aqueous solution indicates that the ligand anion has a conformation suitable for the complex formation with the cation and usually chelates the cation with α-carboxy oxygen, α-hydroxy oxygen, and β-hydroxy oxygen.[1,9] The same type of 'three O atoms' chelation to a calcium ion has been observed in the crystal structures of Ca-arabonate·$5H_2O$[11] and CaBr-lactobionate·$4H_2O$.[12] However, such a chelate form may not be always necessary for a stable calcium binding to β-hydroxy carboxylic acid in the crystal state, since the calcium binding features in Ca-tartrate·$3H_2O$[20] and Ca-glucarate·$4H_2O$[10] differ from that mentioned above. The calcium ion is generally coodinated with seven to nine oxygens in a crystalline state, and the oxygen polyhedra observed in a number of calcium carbohydrate crystals[8-32] are largely distorted from the idealized form. In the present investigation we were, therefore, interested in the conformation of the glycerate anion and in the chelating feature of the anion with the calcium ion; the steric arrangement of the ligand oxygens around the calcium ion in the crystal structure received special attention.

Experimental

Colorless monoclinic crystals of calcium glycerate dihydrate $Ca(C_3H_5O_4)_2\cdot 2H_2O$ were obtained by slow evaporation of the saturated aqueous solution. Prelimilary experiments indicated that the space group is $P2_1/c$, from the systematic absences of $h0l$ and $0k0$ for l and k odd, and that the unit cell dimensitions are $a=14.40(7)$, $b=7.63(4)$, $c=10.40(4)$ Å, and $\beta=98.8(3)°$, from Weissenberg photographs calibrated by NaCl standard powder lines. $V=1129$ Å^3, $Z=4$, and $D_x=1.68$ g/cm^3. Equi-inclination Weissenberg photographs were taken by rotating the crystal about the b- and c-axes, using nickel-filtered Cu $K\alpha$ radiation. Intensity data were collected on a SYNTEX AD-1 densitometer controlled by a NOVA 1200 computer acting in cooperation with a DIABLO-31 disk drive. Structure factors of 1150 independent reflections were obtained through the usual data reduction procedure.

Positional parameters of the calcium ion were determined from sharpened Patterson maps and those of carbon and oxygen atoms were determined from the Fourier maps synthesized with phases of the calcium ion. Six cycles of block-diagonal least-squares refinement with the anisotropic thermal parameters gave an R-value of 0.14.

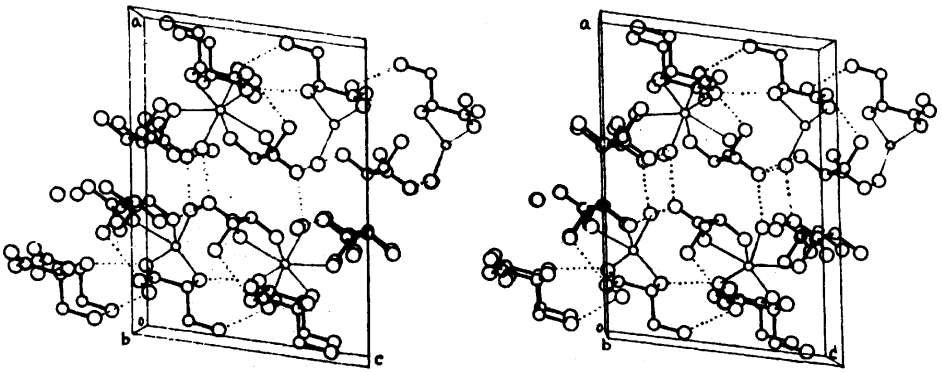

Fig. 1. Stereo-representation of the crystal structure of calcium DL-glycerate dihydrate. Ca, C, and O atoms are represented by the small, middle, and large circles, respectively. The hydrogen bonds and the Ca–O contacts are indicated by the dotted and full lines.

The hydrogen atom positions were assumed from the difference Fourier maps synthesized at this stage. After the Zachariazen extinction correction was applied for the reflection data, three more cycles of full-matrix least-squares refinement including the hydrogen atoms in the structure factor calculations reduced the R-value to 0.095. Atomic scattering factors were obtained from the International Tables for X-Ray Crystallography IV.[6] All computations for the structure analysis were undertaken by using a KPAX program system which included the UNICS programs on a FACOM M-190 in the Data Processing Center of Kyoto University.

The final atomic parameters and their estimated standard deviations are given in Table 1, and the observed and calculated structure factors at the final stage are listed in Table 2.[7]

Results and Discussion

Crystal Packing. Calcium-oxygen interactions and hydrogen bonds stabilize the crystal structure. Figure 1 shows the crystal packing and Table 3 lists the hydrogen-bond distances. All hydrogen atoms of hydroxyl groups and water molecules participate in the hydrogen bonds. The O atoms related to O(4b) and O(8) by 2_1 symmetry through 1/2, 0, 1/4, and 1/2, 0, 3/4 form an infinite hydrogen-bond chain along the b-axis. O(3), O(7), and their centrosymmetrically related O atoms form a square linkage of hydrogen-bonds about the $\bar{1}$ site, 0, 0, 0, and 0, 1/2, 1/2. Three glycerate anions and two water molecules are bound to a calcium ion, the two glycerate anions chelating the calcium ion with α-carboxy and α-hydroxy oxygens, and the one glycerate anion bonding to the calcium ion through the β-hydroxy oxygen. Figure 2 shows the environment of the calcium ion, which is surrounded by seven oxygens in a distorted pentagonal biprism arrangement, five glycerate oxygens being approximately coplanar (Table 4). The Ca–O distances range from 2.32 to 2.47 Å. The O–Ca–O angles within the pentagonal plane range from 65 to

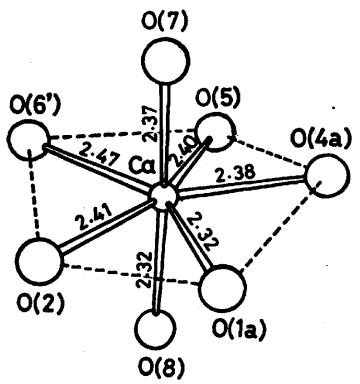

Fig. 2. The calcium ion coordination shell. Atom O(6′) is generated from O(6) by the symmetry operation $x, -1/2-y, 1/2+z$. The estimated standard deviation of a Ca–O distance is 0.02 Å.

TABLE 3. HYDROGEN-BOND DISTANCES

Donor Acceptor	Distance	Symmetry operation for acceptor O
O(2)···O(1a)	2.72 Å	$x, 1/2-y, 1/2+z$
O(3)···O(7)	2.74	$-x, 1/2+y, 1/2-z$
O(5)···O(4b)	2.71	$x, -1/2-y, 1/2+z$
O(6)···O(1b)	2.73	$x, -1+y, z$
O(7)···O(3)	2.82	$x, 1/2-y, -1/2+z$
O(7)···O(1b)	2.62	$x, -1+y, z$
O(8)···O(4b)	2.72	$1-x, -y, -z$
O(8)···O(4b)	2.92	$x, 1/2-y, 1/2+z$

TABLE 4. LEAST-SQUARES PLANE OF FIVE OXYGENS AROUND CALCIUM ION AND ATOMIC DEVIATIONS

The plane is defined by $Ax+By+Cz=D$ where x, y, and z are in Å along the axes a and b and the normal to the ab plane. An asterisk indicates an atom not used in the plane calculation.

$A=0.7703$, $B=0.5345$, $C=0.3471$, and $D=3.521$.

Atom	Deviation (Å)
Ca	−0.007
O(1a)	0.124
O(2)	−0.002
O(4a)	−0.217
O(5)	0.218
O(6′)	−0.117
O(7)*	2.355
O(8)*	−2.326

80°, while the O–Ca–O angles out of the plane range from 85 to 99°. The O(7)–Ca–O(8) angle is 175°. The estimated standard deviations of the O–Ca–O angles are less than 1°.

Geometry of the Glycerate Anions. The conformations of the two crystallographically independent glycerate anions differ from each other (Fig. 3). The bond lengths and angles, and the torsion angles about the C–C bond for each conformer are given in Tables 5 and 6. The C(3)–O(3) bond is trans to C(1)–C(2) about the C(2)–C(3) bond in one conformer, while C(6)–O(6) is gauche to C(4)–C(5) about C(5)–C(6) in the second conformer. Similar conformational dimorphism has been observed in the crystals of potassium salts of gluconic acid[8] and of calcium and potassium salts of glucaric acid.[9,10] Although in these crystals each conformer is crystallized in different crystal forms, the two conformers in the present case are crystallized together into one crystal structure. The ^{1}H NMR studies of glyceric acid in an aqueous solution[1,2] showed that the two β-protons are asymmetric in an unprotonated carboxyl state and the glycerate anion has two or more different conformations in the solution. The two conformers observed here may be therefore energetically very close to each other. For both conformers, α-hydroxy oxygen lies approximately on the same plane of the carboxyl group; the atomic deviations from the least-squares plane of the carboxyl group are given in Table 7. The nonbonding distances between α-hydroxy oxygen and one of the carboxy oxygen are 2.55 Å for O(1a)···O(2) and 2.57 Å for O(4a)···O(5). The stability of such a planar α-hydroxy carboxyl arrangement was discussed by Newton and Jeffrey.[3]

The Polyhedron of Oxygen Atoms about a Calcium Ion. Oxygen-polyhedra about a cation in inorganic crystals can be generally classified into a limited number of typically regular forms, depending on a coordination number; for instance, cube, square antiprism, and dodecahedron are usual forms for eight-coordination, and pentagonal biprism, monocapped octahedron, and monocapped trigonal biprism for seven-coordination.[4] The square antiprism for eight-coordination is the most usual form observed to data in the calcium carbohydrate crystals.[10–32] The pentagonal biprism, as observed in

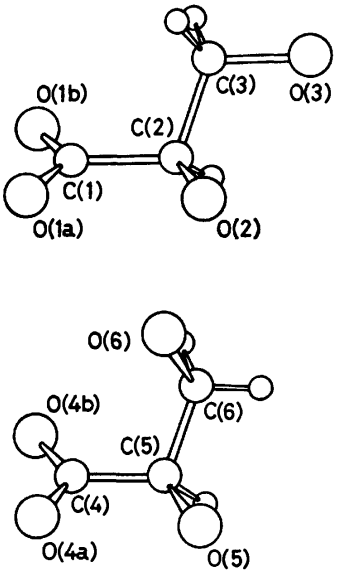

Fig. 3. Two conformations of glyceric anions. Both conformers are shown in the D-isomers.

Table 5. Bond lengths and angles, and their estimated standard deviations

the present crystal, has been found in the crystal structures of α-D-xylose $CaCl_2 \cdot 3H_2O$,[13] β-D-fructose $CaBr_2 \cdot 2H_2O$,[14] and α,α'-D-trehalose $CaBr_2 \cdot H_2O$;[15] all seven-coordinations about a calcium ion in the carbohydrate crystals are in this form. The pentagonal biprism may be therefore the most favored arrangement of oxygens about a calcium ion for the seven-coordination. This fact is evidenced by the Doyl-Britten calculations of repulsive potential energy between ligand atoms of simple seven-coordination models.[5] The Ca–O distance, averaged for those in 22 structures observed hitherto,[10–32] is 2.445 Å for Ca–O (carboxy oxygen), 2.488 Å for Ca–O (hydroxy oxygen), and 2.442 Å for Ca–O (water oxygen), the Ca–O (hydroxy oxygen) being slightly larger than the others. Thus, the partial charge and the dipole moment on the ligand oxygen apparently influence the Ca–O distance. The large distortion of the actual oxygen-polyhedron about a calcium ion may be due to such different Ca–O interactions which depend on the ligand oxygens, in addition to a steric restriction by covalent bonds bridged between two or more ligand oxygens and to the effect of crystal field, especially of the hydrogen-bonds which formed around the oxygen-polyhedron.

We wish to thank Miss Shizuko Matsumoto for her experimental assistance.

Kinetic Studies of the Dimerization Reaction of Thionine by the Laser Raman Temperature-jump Method

Wataru INAOKA, Shoji HARADA, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 23, 1977)

Kinetic studies of the dimerization reaction of thionine in an aqueous solution have been performed by the laser temperature-jump method with the use of the stimulated Raman effect in high-pressure H_2 gas. From the concentration dependence of the relaxation time, the formation and dissociation rate constants of the thionine dimer have been obtained. The data have been confirmed by the equilibrium constant, independently obtained spectrophotometrically. The formation rate constant of the dimer was very large, and the process was revealed to be a diffusion-controlled reaction, similar to those with other dyes.

The aggregation of a dye in solution is interesting not only in itself but also as a model system of molecular aggregation in the biochemical field. Many spectrophotometric[1-5] and polarographic[6] investigations have been performed. The kinetic investigations have, however, been limited in number because of their rapid aggregation rates and other experimental restrictions. The laser-heating temperature-jump method has a decisive advantage over the usual Joule-heating one for kinetic studies of the dye aggregation; it enables the measurement of a very rapid reaction with a time constant in even the nsec region and needs no addition of salts, which is undesirable for studies of the dye aggregation in solution. The recently developed method of the laser-heating T-jump with the use of a stimulated Raman effect in liquid N_2[7] or high-pressure H_2 gas[8] has much improved the applicability. In the present study, the laser T-jump method with a stimulated Raman effect in H_2 gas was applied to kinetic studies of the aggregation reaction of thionine in an aqueous solution.

Experimental

Materials. Thionine hydrochloride was purchased from Wako Pure Chemical Industries, Ltd. It was recrystallized from water and then dried at 105 °C for 12 h. The purity of the dye was confirmed by means of CHN gravimetric analysis. Distilled and deionized water was used throughout. The pH of the solution was controlled to 3.5 by the addition of nitric acid to prevent the dye decomposition.

Spectrophotometric Measurement. The equilibrium constant of the monomer-dimer reaction of thionine was determined spectrophotometrically with a Union Giken SM-401 spectrophotometer. The measurement was performed at 25 °C.

Laser Raman Temperature-jump Apparatus. The apparatus used in this study was a modification of that described by Ameen.[8] A schematic diagram of our apparatus is shown in Fig. 1. The giant pulse laser (Japan Electron Optics Laboratory Co., Ltd. Type JLS-G-3) operates in the Q-switched mode with a rotating prism. The neodymium-doped glass rod (100 mm long, 12.5 mm diam.) delivers a maximum energy of 3 J in 25 ns at a wavelength of 1060 nm. The laser beam was focused into the Raman cell by means of a $f=50$ cm quartz lens. The Raman cell consists of a stainless steel tube (100 cm long, 20 mm i.d.) with 15 mm quartz windows at the ends and filled with H_2 gas of about 80 atm. Several kinds of lights with different wavelengths are emitted. To select only the 1890 nm light, a Si-coated filter (transmittance of 1060 nm, 8.5%; 1890 nm, 93%) was used, and then the light was again focused into the sample cell by means of a $f=20$ cm quartz lens. The sample cell is made of two glass plates, with a spacer between them. Several spacers 0.1—0.5 mm thick were used. In order to prevent cavitation, a pressure of a few atm was exerted on the sample solution. The Raman cell, filter, and lens were completely covered to prevent the visible light produced by the Raman scattering from entering the photomultiplier. The laser axis was aligned by means of a conventional laser beam. The relaxation effect was monitored photometrically. The light from a 500-W xenon lamp was monochronized and focused into the sample cell. A shutter was used to prevent the decoloration of the sample. The detection axis was aligned so as to have an angle of about 30 degrees to the laser axis, –thus having a long path length in the solution. As a photomultiplier tube, 931A (Hamamatsu TV Co., Ltd.) was employed. The output signal was amplified and led to the emitter follower, the filter, and the oscilloscope. The apparatus was calibrated by means of the phenolred (1 mM)–ammonia (2.3 M) system at pH 7.9. This system is known to have a large enthalpy change and a very short relaxation

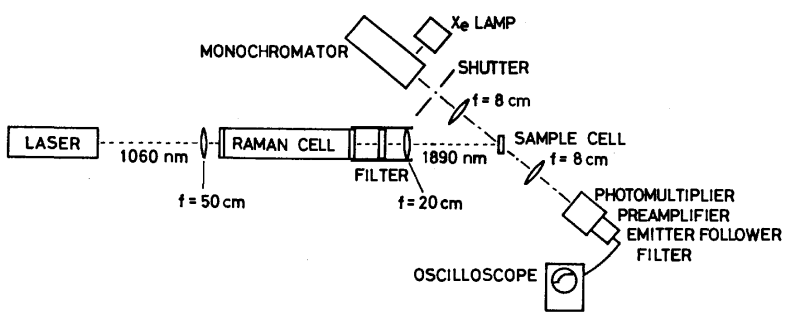

Fig. 1. Schematic diagram of the laser temperature-jump apparatus with use of the stimulated Raman effect in H_2 gas.

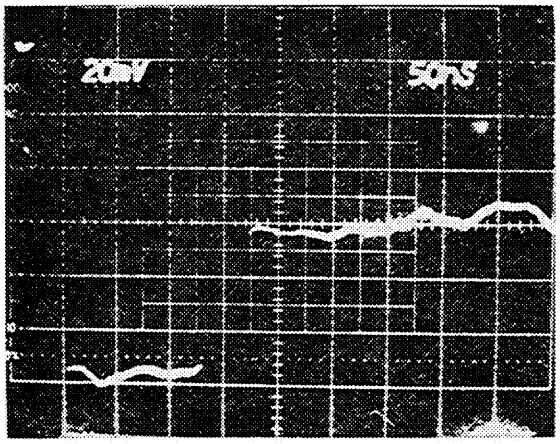

Fig. 2. Spectrum in the phenolred (1 mM)–ammonia (2.3 M) system at pH 7.9, 25 °C; sweep 50 ns/div.

time of about 10 ns.[9] The spectrum is shown in Fig. 2. In the case of a heating volume of 5 μl, the magnitudes of the temperature-jump and the heating-time constant were determined to be 3 °C and 50 ns respectively.

Results and Discussion

Thionine is known to aggregate in an aqueous solution and a monomer-dimer equilibrium is established:

$$2T \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} T_2, \qquad (1)$$

where k_1 and k_{-1} are the formation and dissociation rate constants respectively. The equilibrium constant, K, of this system is expressed by $K=[T_2]/[T]^2=k_1/k_{-1}$, where $[T]$ and $[T_2]$ denote the monomer and dimer concentrations respectively. In order to obtain the K value, spectrophotometric studies were performed with the following equation:[10]

$$\left(\frac{\varepsilon_M-\varepsilon}{C_0}\right)^{1/2} = \left(\frac{2K}{\Delta\varepsilon}\right)^{1/2}\{\Delta\varepsilon-(\varepsilon_M-\varepsilon)\}, \qquad (2)$$

where ε_M: the molar extinction coefficient of the monomer.
ε: the apparent molar extinction coefficient.
$\Delta\varepsilon$: the difference between the molar extinction coefficient of the monomer and that of the dimer.
C_0: the initial concentration of the dye.

According to Eq. 2, a plot of $\{(\varepsilon_M-\varepsilon)/C_0\}^{1/2}$ *vs.* $(\varepsilon_M-\varepsilon)$ will give a straight line with the intercept $(2K\Delta\varepsilon)^{1/2}$ on the ordinate and $\Delta\varepsilon$ on the abscissa. On this basis, we evaluated ε_M as the best choice to obtain a straight line with the measured values of ε and C_0. The value of K was obtained as 750 M^{-1} at 25 °C. In comparison with the previously reported values of this dye,[2,11,12] the present result seems to be satisfactory.

The kinetic measurements were carried out at 25 °C. The concentration of the dye was ranged from 0.2 to 2.4 mM. The concentration change was monitored at the monomer band (λ=597 nm). The relaxation phenomenon was observed over all the concentration range and was characterized by a single relaxation time. The concentration dependence of the relaxation time, τ, is expressed as follows:

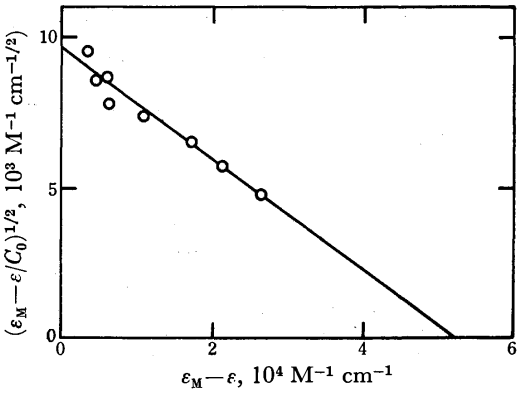

Fig. 3. Plots to determine the equilibrium constant K of dimerization at pH 3.5, 25 °C.

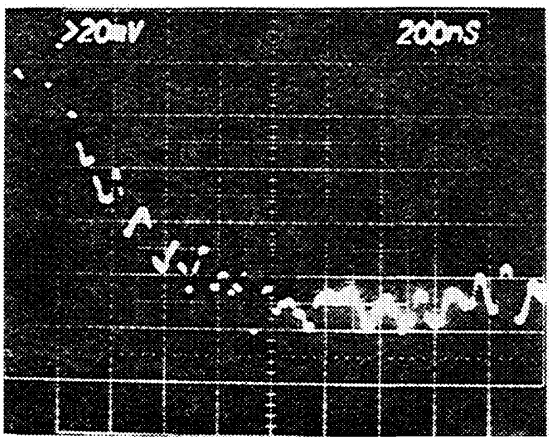

Fig. 4. Typical relaxation spectrum in 2 mM thionine at pH 3.5, 25 °C, wavelength 597 nm; sweep 200 ns/div.

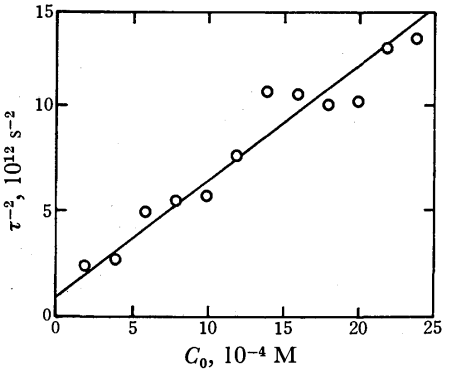

Fig. 5. Plots of τ^{-2} *vs.* C_0 at pH 3.5, 25 °C.

$$\tau^{-1} = 4k_1[T] + k_{-1}. \qquad (3)$$

This equation can be arranged more conveniently with the initial concentration of the dye:

$$\tau^{-2} = k_{-1}^2 + 8k_1k_{-1}C_0. \qquad (4)$$

The experimentally obtained values of τ^{-2} are plotted against C_0 in Fig. 5. Each value is the average of at least ten runs. The linearity of these plots indicates that the observed relaxation effect is based on the monomer-dimer reaction of the dye. The rate constants were evaluated to be $k_1=7.1\times10^8$ M^{-1} s^{-1} and $k_{-1}=9.4\times10^5$

Table 1. Summary of the rate and equilibrium constants for dimerization reactions at 25 °C

Dye	k_1 (10^8, $M^{-1}s^{-1}$)	k_{-1} (10^6, s^{-1})	K (M^{-1})	Ref.
Ethidium bromide	4.6	6.7	69	13
Proflavine	7.9	2.0	395	14
Acridine orange	2.7	0.018	15000	15
N^6,N^9-Dimethyl-adenine	9.3	50	19	16
Thionine	7.1	0.94	750	This work

s^{-1} from the slope and the intercept respectively of this straight line. The resultant equilibrium constant given by the ratio of these values is in good agreement with that derived spectrophotometrically. The rate constants were then compared with those obtained for other dyes; they are listed in Table 1. The rate and equilibrium constants of thionine are very analogous to those of proflavine. This fact is confirmed by their similar structures. As can be said for other dyes, the value of k_1 of thionine is very large and close to that of the diffusion-controlled association reaction.[17] If the dimerization process of the dye is a diffusion-controlled reaction, the value of k_1 will decrease in the case of a bulky dye molecule since the diffusion coefficient depends on the volume of the molecule. These tendencies in Table 1 show that the dye aggregation process is a diffusion-controlled reaction. In contrast to the small difference between the k_1 values, the values of k_{-1} differ remarkably; *i.e.*, the difference in the equilibrium constants is directly reflected in the values of k_{-1}. The good linear relationship between log k_{-1} and log K pointed out by Turner *et al.*[13] is here supported.

The authors gratefully acknowledge the support of the Toray Science Foundation.

Acidic Property and Catalytic Activity of Tungsten Oxide

Hideshi HATTORI, Noriyoshi ASADA, and Kozo TANABE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received January 5, 1978)

A maximum activity of tungsten oxide for the isomerization of 1-butene was observed when the catalyst was evacuated at 600 °C, the ratio of *cis*-2-butene to *trans*-2-butene being 1.4. The activity was lost by the addition of NH_3, but not affected by the addition of CO_2 or H_2O. The oxidation states of tungsten oxide treated with hydrogen at 550 and 650 °C were $WO_{2.89}$ and WO_2, respectively. The activity of $WO_{2.89}$ for the double bond isomerization of 1-butene was almost the same as that of WO_3, but the activity of WO_2 for the double bond and skeletal isomerization of 1-butene and the dehydration of isopropanol was higher than that of WO_3 or $WO_{2.89}$. The coisomerization of *cis*-2-butene-d_0/d_8 revealed that the double bond isomerization of butenes proceeds by an intermolecular hydrogen transfer mechanism. When *cis*-2-butene-d_8 was introduced to the catalyst on which *cis*-2-butene-d_0 had been preadsorbed, the reactant and the product containing much of H were obtained, no d_0-species being observed. It was concluded that the active sites for the isomerization of butenes are protons of polymerized butene formed by the adsorption on Lewis acid sites of tungsten oxide surface and the isomerization takes place *via* carbenium ion intermediates.

Tungsten oxide mixed with SiO_2 or Al_2O_3 is a well-known catalyst for the hydration[1] and disproportionation[2] of olefins. Combined with MoO_3, NiO, V_2O_5, or CeO_2, tungsten oxide becomes catalytically active for the hydrocracking,[3] hydrotreating[4] and reforming[5] of hydrocarbons, the isomerization of paraffins,[6] and the oxidative dehydrogenation of butene.[7] Thus, tungsten oxide is one component of industrially important catalysts. Tungsten oxide itself is known to catalyze the oxidation of 1-butene to carbon dioxide[8] and tungsten oxide reduced with hydrogen was reported recently to catalyze the isomerization and hydrocracking of heptane, the dealkylation of isopropyl benzene and the dehydration of isopropyl alcohol, where the change in catalytic action with the change of oxidation state and acidic property of tungsten oxide was studied.[9] The present work was initiated to learn more about the role of acid-base property of tungsten oxide for the isomerization of butenes and to elucidate the nature of active sites and the reaction mechanism.

Experimental Methods

Tungsten trioxide was prepared by calcination of ammonium paratungstate $[(NH_4)_{10}W_{12}O_{41}\cdot 5H_2O]$ at 550 °C for 10 h in air. This was used for the reaction after evacuation at different temperatures for 3 h. X-Ray diffraction patterns were recorded on a Toshiba ADG-301 with a powdered sample over the range of $2\theta = 10$—60°. Cu K_α was used as the radiation source.

1-Butene was purified by passage through 4A molecular sieves kept at −78 °C. Perdeuterated *cis*-2-butene was prepared by exchange of butenes with D_2 over MgO.[10] Isopropanol was purified by passage through 4A molecular sieves at 0 °C.

Two different types of reactors were employed. A recirculation reactor which had a volume of 270 cm^3 was used for kinetic measurements of the double bond and skeletal isomerization of 1-butene and the dehydration of isopropanol. Reaction products were periodically withdrawn from the system and analyzed by gas chromatography. For the isomerizations, a 4-m gas chromatographic column containing propylene carbonate on Celite 545 was operated at 0 °C. For the dehydration, a 1-m column packed with TPC on Celite 545 was operated at 100 °C.

In poisoning experiments, NH_3, H_2O, CO_2, and a mixture of H_2O and CO_2 were used as poisons. The catalyst that had been evacuated at 500 °C was exposed to a poison at 100 °C for 30 min (NH_3, H_2O+CO_2) or 60 min (H_2O, CO_2) and then evacuated at 100 °C for 1 or 3 h.

Oxygen and H_2 treatments were carried out as follows. To the catalyst that had been evacuated at 500 °C, 15 Torr of O_2 was admitted at 500 °C and recirculated at this temperature for 1 h, the trap attached to the recirculating loop being cooled by liquid N_2. After the treatment, the catalyst was evacuated at 500 for 30 min. Hydrogen treatment was performed at 500 and 650 °C. In the treatment at 500 °C, 50 Torr of H_2 was admitted to the catalyst that had been evacuated at 500 °C and recirculated for 1 h with a liquid N_2 trap. The catalyst was evacuated at 500 °C for 1 h. In the treatment at 650 °C, the catalyst that had been evacuated at 650 °C was exposed to 400 Torr of H_2. After H_2 was recirculated for 5 h with a liquid N_2 trap, the catalyst was evacuated with a gradual rise of temperature and finally evacuated at 700 °C for 1 h.

For the deuterium tracer experiments, a microcatalytic pulse reactor was employed. About 29 μmol of *cis*-2-butene was introduced into the He stream (flow rate, 35 ml/min) ahead of the catalyst. The produced butenes were gas chromatographically separated. The separated isomers were trapped at −196 °C and subjected to a mass spectrographic analysis. Mass spectra were recorded on Hitachi mass spectrometer RMU-2 at low ionization voltage. A deuterated catalyst was prepared by exposure of D_2O vapor at 400 °C to the catalyst that had been evacuated at 500 °C and then evacuated at 500 °C for 3 h. Another deuterated catalyst was obtained by exposure of D_2O vapor at 100 °C to the 500 °C evacuated catalyst, followed by evacuation at this temperature for several hours.

Results

Activity was expressed by percent conversion of 1-butene per unit time, min, per unit weight of catalyst, g, at the initial stage of the reaction. The variations of the activity for the isomerization of 1-butene at 100 °C and the ratio of *cis*-2-butene to *trans*-2-butene are shown in Fig. 1 as a function of evacuation temperature of the catalyst. The activity reaches a maximum value on evacuation at 600 °C. The ratio of *cis*-2-butene to *trans*-2-butene gradually decreases from 1.7 to 1.2 with

a rise of evacuation temperature.

Poisoning effects of NH_3, CO_2, H_2O, and a mixture of CO_2 and H_2O on the activity and the ratio of *cis*-2-butene to *trans*-2-butene are included in Table 1. Ammonia completely poisoned the active sites, while CO_2, H_2O, and a mixture of CO_2 and H_2O scarcely showed poisoning effect. A mixture of CO_2 and H_2O even increased a little the activity.

The catalysts evacuated at various temperatures showed yellow color and the X-ray diffraction pattern of WO_3. During the treatment with H_2 at 500 °C, 0.00048 mol/g of H_2 was consumed, which corresponds to the number of H_2 required for the change of WO_3 to $WO_{2.89}$. The catalyst became dark blue on the treatment and showed the X-ray diffraction pattern of mixture of WO_3 and $WO_{2.87}$. The treatment with H_2 at 650 °C resulted in a consumption of 0.0046 mol/g of H_2, which corresponds to the number of H_2 required for the change of WO_3 to WO_2. The resulting catalyst was brown and showed the X-ray diffraction pattern of WO_2. The effects of the treatments are given in Table 2. The treatment with H_2 or O_2 at 500 °C did not result in an appreciable effect on the activity for the double bond isomerization of 1-butene. However, the treatment with H_2 at 650 °C greatly increased the activities for the double bond and skeletal isomerizations and the dehydration of isopropanol.

Results of microcatalytic tracer experiments are given in Table 3. In the coisomerization of *cis*-2-butene-d_0/d_8 over WO_3 that had been evacuated at 500 °C, a large number of exchanged isotopic species were produced in 1-butene and *trans*-2-butene. The number of H(or D) atoms exchanged per molecule (AEM value) was calculated from the equation,[11]

$$\mathrm{AEM} = \sum_{i=0}^{4} i \cdot N_i + \sum_{i=5}^{8} (8-i) \cdot N_i,$$

where N_i is the fraction of isotopic species containing i D atoms. The AEM values of the products were close to 0.5 (see Table 3). This indicates that the double bond isomerization involves intermolecular hydrogen transfer.[11]

In the isomerization of *cis*-2-butene over the deuterated catalyst that was evacuated at 500 °C after exposed to D_2O, negligible amounts of D atoms were incorpo-

rated into butenes. However, over the deuterated catalyst that was evacuated at 100 °C after being deuterated, a considerable number of D atoms were incorporated into the products. The cumulative number of D atoms picked up by butenes till the 3rd slug was 29.2×10^{17} atoms/g.

Over the catalyst that had been evacuated at 500 °C, a slug of *cis*-2-butene-d_8 was introduced after 4 slugs of *cis*-2-butene-d_0. The products as well as the reactant contain a large number of H exchanged isotopic species. The average number of D atoms per molecule, ϕ value, was calculated from the equation,

$$\phi = \sum_{i=0}^{8} i \cdot N_i.$$

The ϕ values of 1-butene, *trans*-2-butene, and *cis*-2-butene were 0.54, 0.56 and 0.27, respectively (Table 3). There was a very small amount of d_0 species which would be detected if adsorbed butene-d_0 were replaced by butene-d_8.

Discussion

All results obtained can be explained in terms of acidic property of the catalyst.

Strong poisoning effect with NH_3 suggests that the acid sites are acting as active sites for the double bond isomerization of butene. In the acid-catalyzed isomerization of 1-butene, the ratio of *cis*-2-butene to *trans*-2-butene is usually close to unity.[12] The ratios obtained over tungusten oxide treated under different conditions were close to unity, which also supports that the acid sites are active. No poisoning effect with CO_2 indicates that the basic sites, even if present, do not participate in the reaction.

Since the reaction involves intermolecular hydrogen transfers and the active sites are acidic, it is quite plausible that the reaction intermediate is a carbenium ion. In the reaction over the deuterated catalyst that was evacuated at 500 °C after D_2O treatment, the numbers of D atoms incorporated into the products were small. On the other hand, considerable numbers of D atoms were incorporated into the products when *cis*-2-butene was reacted over the deuterated catalyst evacuated at 100 °C after D_2O treatment. Therefore, the surface OH groups on the catalyst evacuated at 100 °C participate in the reaction as a source of H^+, but the OH groups on the catalyst evacuated at 500 °C, even if they present, do not participate. Instead of surface OH groups, H^+ is provided by preadsorbed butene over the catalyst evacuated at 500 °C, since much of H^+ was contained in the reaction products of *cis*-2-butene-d_8 over the catalyst on which *cis*-2-butene-d_0 had been preadsorbed. The butene which serves as the source of H^+ may not retain the form of C_4H_8 and may be polymerized on the acid sites of Lewis type, because the preadsorbed butene-d_0 was not replaced by the introduction of butene-d_8. This type of active sites were proposed by Kimura and Ozaki for the isomerization of butenes over SiO_2–Al_2O_3.[13]

The addition of water retarded the reaction of heptane,[9] but it did not appreciably retard the isomerization of 1-butene. This is considered due to that the protons formed by the adsorption of water on Lewis acid sites act as active sites for the isomerization of 1-butene, but not for the reaction of heptane.

The treatment with H_2 at 500 °C did not result in the reduction of WO_3 to WO_2, but only to $WO_{2.87}$, while

the treatment with H_2 at 650 °C resulted in the formation of WO_2. The increase in the activity for the isomerization of butene by the treatment with H_2 at 650 °C indicates that the acidity and acid strength of WO_2 are higher than those of WO_3 or $WO_{2.87}$. The enhancement of acidic property by the treatment at 650 °C also interprets the increases of the activities for the dehydration of isopropanol and the skeletal isomerization of 1-butene, which are known as acid-catalyzed reaction.

Abnormal Hyperchromism of the n→π* Absorption Band of Acetone in Protic Solvents

Masako YUDASAKA and Haruo HOSOYA

Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo 112

(Received January 11, 1978)

Concentration dependence (1—10^{-4} molar fraction) of the UV absorption spectra of the binary mixtures of (i) acetone–water, (ii) acetone–ethanol, and (iii) diisobutyl ketone–ethanol systems was studied. In (i) and (ii) distinct spectral changes of three steps were observed in succession, while in (iii) gradual changes in two steps were observed. The intensities of the n→π* band of very dilute solutions for these systems are enhanced, respectively, by 40, 20, and 15 per cent. The results were interpreted as the following stepwise equilibria

$$A + B \rightleftarrows AB, \quad AB + B \rightleftarrows AB_2, \quad AB_2 + B \rightleftarrows AB_3$$

for (i) and (ii), while in (iii) the last step is obscured, where A and B denote, respectively, ketone and water or ethanol molecules. The structure of AB_3 is discussed.

The n→π* absorption bands of ketones have been extensively studied and known to show blue shift in protic solvents.[1,2] However, most of the studies on the solvent effect of the electronic absorption spectra have been performed using dilute solutions. Above all Bayliss and Wills-Johnson extensively measured the n→π* bands of various ketones and nitro-compounds in a number of solvents and claimed that the intensity change can be explained mainly by the dispersion force, even for the cases where hydrogen bonding exists.[3] They found that, among the various solvents studied, water has by far the most peculiar effect to increase the oscillator strength as large as 40 per cent in dilute solution, but they failed to observe the concentration dependence. Gorubunov and Naberukhin measured the concentration dependence of IR and UV spectra of acetone–water mixtures in a wide range and attributed them to the two step hydrogen bonding forming acetone–water and acetone–$(water)_2$ complexes.[4] However, their conclusions are not decisive yet, since they did not analyze the intensity change. Further, Lavrik and Naberukhin proposed that cooperative effects of the hydrogen bonding of water molecules are operative in dilute aqueous non-electrolyte solutions.[5] On the other hand, Reuben explained the concentration dependence of the NMR spectra of acetone-water mixture by the existence of two different hydrogen bonding species, *i.e.*, acetone–water and $(acetone)_2$–water.[6]

Summarizing these studies, it is plausible to assume at least the following three different hydrogen bonding species for explaining the spectral change of the acetone–water mixture.

$$R_2CO + HOH \rightleftarrows R_2CO \cdots HOH \quad (AB) \quad (1)$$

$$R_2CO \cdots HOH + R_2CO \rightleftarrows R_2CO \cdots HOH \cdots OCR_2 \quad (A_2B) \quad (2)$$

$$R_2CO \cdots HOH + HOH \rightleftarrows R_2CO \cdots (HOH)_2 \quad (AB_2) \quad (3)$$

For acetone–alcohol mixtures similar arguments may apply but without assuming the A_2B type species.

As argued from the above discussion the concentration dependence of the n→π* absorption bands of ketone in protic solvents needs to be remeasured carefully, and also the effects of the proton donating and accepting powers of the solvent and solute should be studied in order to settle the discussions above.

In this study we have performed accurate measurements of the n→π* absorption bands of the binary mixture of acetone–water, acetone–ethanol, and diisobutyl ketone–ethanol systems over the full concentration range, *i.e.*, from pure acetone liquid down to very dilute solutions as low as $\approx 10^{-4}$ molar fraction.[7] The conclusions obtained in this study are as follows.

i) The intensity of the n→π* absorption bands of ketones in protic solvents such as water and alcohols increases steadily but not monotonously as the concentration of the ketone decreases, and as yet no lower limit of the concentration is obtained below which the spectrum is stable.

ii) This concentration dependence of the n→π* absorption bands of acetone in water can be interpreted as the stepwise equilibria involving successive coordination of the protic solvent molecules through hydrogen bonding as

$$A \longrightarrow AB(A_2B) \longrightarrow AB_2 \longrightarrow AB_3.$$

Especially in the very low concentration of acetone (below 10^{-2} molar fraction), it is essential to assume the third water molecule which causes extraordinary enhancement of the n→π* absorption band by forming AB_3 species as

$$R_2CO \cdots (HOH)_2 + HOH \rightleftarrows R_2CO \cdots (HOH)_3 \quad (AB_3). \quad (4)$$

iii) Almost the same but a little different mechanism can be applied to other combinations of ketones and protic solvents, the difference being attributed to the strength of the hydrogen bonding.

iv) It became clear that any discussion on the solvent effect is liable to be in serious error unless concentration dependence in a wide range down to lower molar fraction is studied.

Experimental

Acetone and ethanol of G. R. grade were dried over molecular sieve 3A and distilled several times until the refractive indices got close to the literature values. Water for spectral measurements was passed through the ion exchange resin and distilled. Crude diisobutyl ketone was purified by the courtesy of Shimadzu Seisakusho using a preparative

gas chromatograph. It is reported that the gas chromatogram analysis assures 100% purity. The refractive index also agreed with the literature value, 1.4122. The molar fraction of the solutions was determined by weight using measuring flasks.

The UV spectra of ketones in water and ethanol of wide range of concentrations were measured with a Shimadzu D-40R recording spectrophotometer at room temperature. In order to check the linearity in the high optical density region, the influenece of the stray light of the recorded intensity was checked by using the calibrated potassium chromate in aqueous 0.05 M KOH solutions. Various fused quartz cells of the lengths, 5, 1, 0.5, and 0.1 cm, with stoppers and quartz assembling cells of 0.01 cm were used depending on the concentration of ketones. The length of the 0.01 cm cells was calibrated using a micrometer, while other cells were calibrated by measuring the standard spectra. In the case where the absorbance gets larger than 2, the reference light was diminished by using a wire net whose absorbance is nearly equal to unity in the wavelength region between 350 and 230 nm. Reproducibility of the spectra was strictly checked.

The temperature dependence of the n→π^* band of acetone in water was checked in the range 20—50 °C by using a cell jacket through which water from a constant temperature bath is circulated.

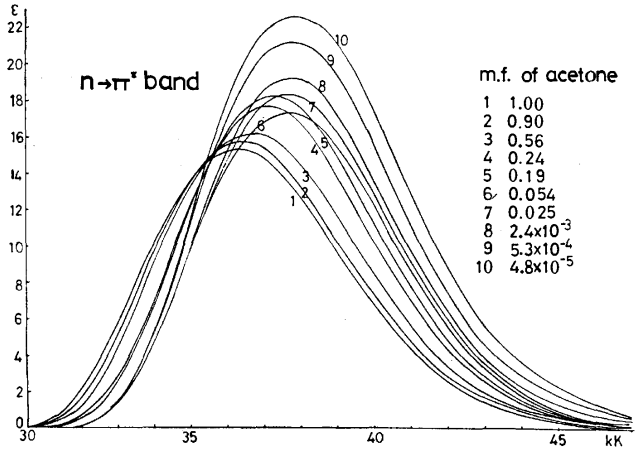

Fig. 1. The concentration dependence of the n→π^* absorption band of acetone in the binary mixtures with water.

Results

Acetone–Water System. As shown in Fig. 1, the n→π^* absorption band of the acetone-water system changes so slightly in the concentration range (Region I) between 1.0 and 0.15 molar fraction (x_A) that only a vague isosbestic point can be observed. Below 0.15 down to 0.05 of x_A (Region II) the intensity of the band slowly diminishes. Further, as the concentration gets lower (Region III) the intensity (ε_{max}) of the band monotonously increases and we could not observe the convergence limit at the infinite dilution.

In order to see the spectral change in more detail in the low concentration range, λ_{max} and ε_{max} are plotted against the logarithm of x_A as in Fig. 2.[8] It should be noted that both the curves have similar concentration dependence and their inflexion points are found nearly in the same concentration region. To see this more

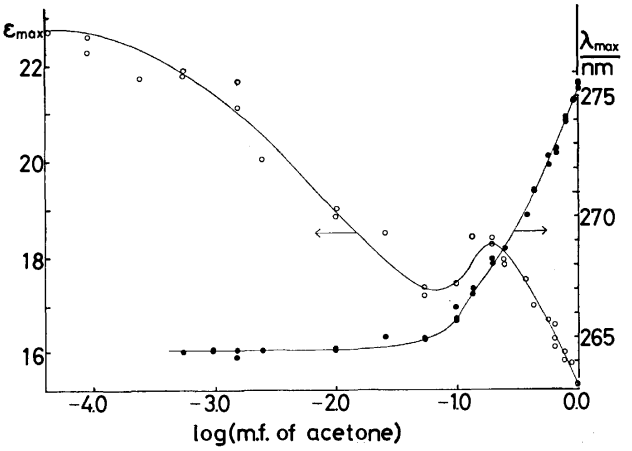

Fig. 2. The λ_{max}—log x_A and ε_{max}—log x_A plots of the acetone–water system, x_A being the molar fraction of acetone.

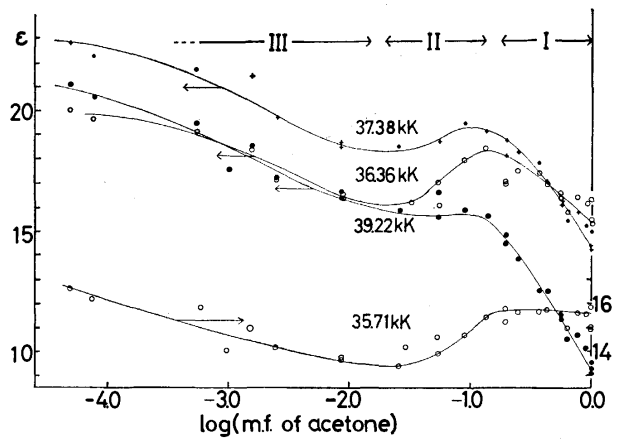

Fig. 3. The plots of ε—log x_A for the acetone–water system indicating three stepwise equilibria, Regions I—III.

quantitatively, the plots of ε—log x_A at various wavelengths are given in Fig. 3. For a single equilibrium as A+B⇌AB, the plotted curve should be something like a sigmoid one unless the wavelength is chosen at the isosbestic point.[9] For stepwise equilibria the plotted curve is expected not exactly but approximately to be a composite of the curves of the component equilibria. If a few wavelengths are carefully chosen for this plot one can easily decompose the whole change into the component equilibria.[10] This is the case with Fig. 3, where the wavelengths 35710 and 39220 cm^{-1} are so chosen from the isosbestic points for the first and second steps, respectively, that the spectral changes in the other steps clearly come out. The wavelengths 36360 and 37380 cm^{-1} are chosen so as to get zig-zag plots and are advantageous over the region above 40000 or below 34000 cm^{-1} giving monotonously increasing or decreasing curve. Now it is unambiguous that we are really observing three distinct equilibria as in Regions I—III mentioned above.

Acetone–Ethanol System. As seen in Fig. 4 the n→π^* band of acetone in ethanol does not effectively show wavelength shift (4 nm to blue) but gains only small fraction (about 20 per cent) of intensity as the concen-

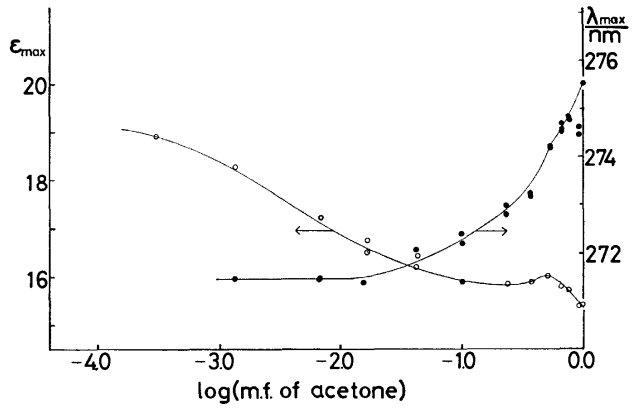

Fig. 4. The λ_{max}—log x_A and ε_{max}—log x_A plots of the acetone–ethanol system.

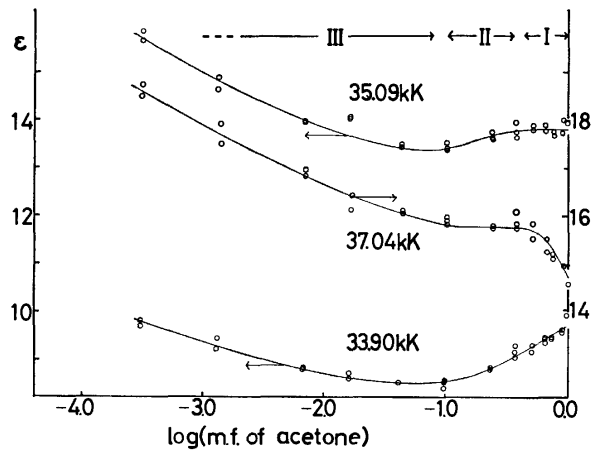

Fig. 5. The plots of ε—log x_A for the acetone–ethanol system indicating three stepwise equilibria, Regions I—III.

tration gets lower than 10^{-2} molar fraction or 0.2 M. However, if the ε—log x_A plot is taken as in Fig. 5, this spectral change also reveals three successive equilibria as in the acetone-water system. The only differences are: (i) the x_A regions in which the first and second steps occur are shifted to higher x_A values, and (ii) the degree of hyperchromism and blue shift are small. Acetone–methanol mixtures show almost the same but a little

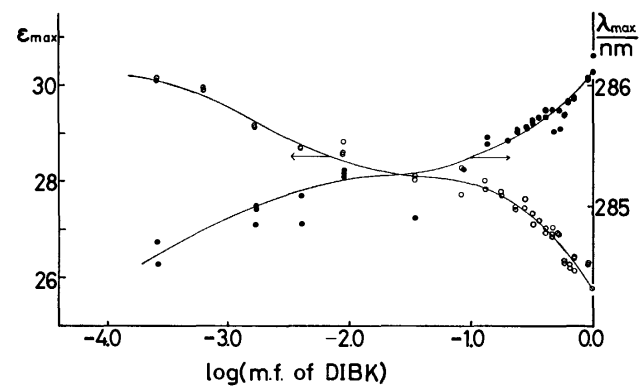

Fig. 6. The λ_{max}—log x_A and ε_{max}—log x_A plots of the diisobutyl ketone–ethanol system.

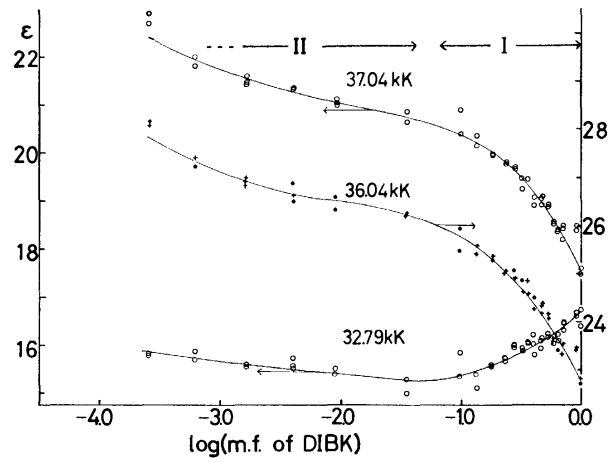

Fig. 7. The plots of ε—log x_A for the diisobutyl ketone–ethanol system.

pronounced spectral changes as the acetone–ethanol system. On the other hand, the binary mixture of acetone–dioxane does not show appreciable spectral change comparable at least with that of acetone–ethanol.[11]

Diisobutyl Ketone–Ethanol System. As shown in Figs. 6 and 7, the n→π^* band and its concentration dependence of this binary mixture is different from the case of the acetone–ethanol mixture in three points: (i) the intensity is considerably larger, (ii) in the low concentration range the intensity is monotonously growing up with small (1.5 nm) blue shift, and (iii) only two successive equilibria can be seen below and above 0.03 molar fraction indicating the low ability of diisobutyl ketone toward hydrogen bonding.

Discussion

Expected Spectral Changes of Various Hydrogen-Bonded Species. By taking account of the several mechanisms proposed by many authors, the spectral changes obtained above can be interpreted in terms of the successive change of the equilibria (1)—(4). In the following discussion the hydrogen-bonded species composed of the m ketone and n water molecules will be denoted as A_mB_n (see Chart 1). Before going into the details in the stepwise equilibria, let us try to estimate the possible change in the intensity and the wavelength at the absorption maximum.

The blue shift of AB or A_2B relative to A is known to be due to the net stabilization of the ground state by the hydrogen bonding with protic solvent molecules. Since

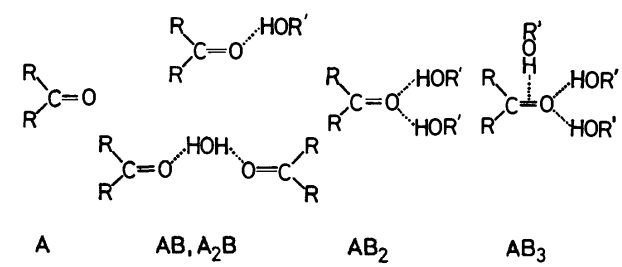

Chart 1.

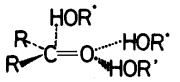
we are observing the signal from the acetone molecule, it is very difficult to distinguish between AB and A_2B, if any, from the change of the n→π* absorption band. Thus in the following discussion no attempt is tried to elucidate the relative ratio of AB to A_2B. However, this ambiguity has little effect on the discussion of the succeeding changes, *i.e.*, equilibria (3) and (4).

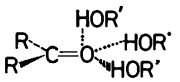
If the second solvent molecule is to attack the second lobe of the lone pairs of the carbonyl oxygen atom, further blue shift is expected for AB_2 relative to AB. According to the *ab initio* molecular orbital calculation by Iwata and Morokuma on the A, AB, and AB_2 species of formaldehyde, the same magnitude of blue shift is predicted both in the two equilibria (1) and (3).[12] It is reasonable to expect that nearly the same argument is applied to the case of acetone in water. For the case of acetone and alcohol, the magnitudes of these shifts may be smaller, reflecting the weaker hydrogen bond.

On the other hand, the intensity of the n→π* band of AB is supposed to be larger than that of AB_2 since the potential of the electrons of the carbonyl group of AB has at most the C_s symmetry rather than the C_{2v} symmetry of AB_2 and releases the n→π* transition from having the forbidden character. The intensity of the band of AB_2 may be a little larger than that of A due to the labile and fluctuating hydrogen bonds which distort the C_{2v} symmetry.

As to the position of the attack by the third solvent molecule, two possible structures, I and II, are proposed for AB_3, where the carbon and oxygen atoms are attacked, respectively.

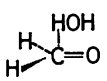


I

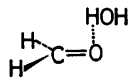


II

Since we cannot predict *a priori* which structure is more plausible for AB_3 species, let us look into the results of the *ab initio* calculation of the hydrogen bonding effect on the n→π* transition of acetone. According to Iwata and Morokuma[12] the energy of the n→π* transition is unchanged both for structures I′ and II′, in which a water molecule attacks from above the molecular plane of free formaldehyde.



I′



II′

However, there is no guaranty that this is also true for the attack of the third water molecule as in I and II. Del Bene has performed the population analysis for the species A and AB, where water molecules are situated in the formaldehyde plane, and found that the π-electron density of the oxygen atom is increased every time the first and second water molecules pulls the lone pair electrons through the σ-type hydrogen bonding.[13] This result is in favor of structure II but not decisive yet.

Anyway we can expect strong hyperchromism by the third water molecule to break the C_{2v} symmetry.

On the other hand, large blue shift is not expected for AB_3 species as the π-electron but not the lone pair electron is purturbed in either of the proposed structures.

Interpretation of the Spectral Changes in Terms of the Stepwise Equilibria. Now turn to the spectral change of the acetone–water system. In going from $x_A=1$ to 0.12, the n→π* band is shifted to blue by 0.15 eV with a moderate intensification. This change is in consistent with the expectation that the first water molecule attacks the carbonyl oxygen lone pair as in equilibrium (1) in agreement with the results of *ab initio* calculations.[12,13] The second change from $x_A=0.12$ to 0.03 is a hypochromism with a further but small blue shift (0.03 eV). The symmetrical coordination of the water molecules (equilibrium (3)) may lower the intensity of the n→π* band. Although two independent *ab initio* calculations[12,13] give much larger blue shift for AB_2 species there is no other candidate for explaining this spectral change in Region II.

For the concentration region below $x_A=0.03$ (Region III) the intensity of the n→π* band is monotonously growing up to the extraordinary large ε_{max} value without blue shift. That this sharp increase in the intensity is an abnormal phenomenon can be realized by replotting the curve in Fig. 2 against x_A, instead of log x_A. Further, as shown in Figs. 4 and 5, a similar spectral change as Regions I, II, and III is observed also for the acetone–ethanol and the acetone–methanol (not shown) system, the same mechanism should be applied to these systems. As far as we know, only water, methanol, and ethanol are the strongly perturbing solvents for the intensity of the n→π* band toward the infinite dilution without blue shift.[11]

Thus we can safely conclude that in the binary mixtures of acetone–water and acetone–alcohol the three successive hydrogen bonding equilibria (1), (3), and (4) take place. It should be noted here that although in the latter system A_2B species or equilibrium (2) is absent, the overall spectral change is essentially the same as that of the former system. This justifies the above statement that ambiguity in the ratio of AB to A_2B in the acetone–water system has little effect on the succeeding equilibria (3) and (4).

The different feature (ii) of ethanol from water stated in Results can be explained by assuming a smaller perturbation of ethanol molecule to the carbonyl group relative to that of water molecule. Whereas the main cause of the difference (i) can be attributed to the fact that, in spite of the weaker hydrogen bonding ability, ethanol molecules are more ready to associate with ketone molecules than water molecules owing to the strong tendency toward the self-association of water molecules as discussed by Gorubunov and Naberukhin.[4]

The bulky alkyl groups of a diisobutyl ketone molecule are likely to break the C_{2v} symmetry of the electronic structure of the carbonyl group reducing the forbidden character of the n→π* band more than that of acetone. These bulky alkyl groups are considered to hinder ethanol molecules from associating with the carbonyl group, so that AB_2 species is difficult to be formed and a considerable amount of AB species is seen until fairly lower concentration range. The bulky alkyl groups of the diisobutyl ketone are thus responsible for the

TABLE 1. ABSORPTION CHARACTERISTICS OF THE TYPICAL HYDROGEN-BONDED SPECIES OF KETONES AND WATER OR ETHANOL

Item		a	b	c	d

a) Spectrum of A. b) Spectrum of $AB(A_2B)$ mixed with those of A and AB_2. c) Spectrum of AB_2 mixed with those of AB and AB_3. d) Spectrum of AB_3 mixed with that of AB_2. See text for further explanation.

differences (i) and (iii) stated above. The difference (ii) is also attributed to the bulky alkyl groups. Although in the previous section, the geometry of AB_2 species does not break the C_{2v} symmetry of the carbonyl group, it is reasonable to consider that this is not the case for bulky alkyl groups which may be twisted by the two ethanol molecules to make the intensity of the n→π^* band increase accompanying blue shift. As the result the intensity of the n→π^* band increases with blue shift.

Summarizing the above discussion absorption characteristics of the typical hydrogen-bonded species of ketones and water or ethanol are given in Table 1. Note, however, that this table was prepared so as to demonstrate how the spectrum of ketones changes with the decrease of the concentration in water and alcohols. The spectra of the pure liquid acetone and diisobutyl ketone are given under item a. The values under item b do not represent the spectrum of pure AB or A_2B species but that of the liquid mixtures at the border of Regions I and II, where AB or A_2B is thought to be predominant. The value under item c corresponds to the mixture at the border of Regions II and III, where AB_2 species predominates. Since the spectra of acetone under item d are the observed limits, the intensity of the band of pure AB_3 species is expected to be larger.

Although the change in the oscillator strength is not given in Table 1, it can be estimated to be roughly proportional to the change of ε_{max} as the half-band width is kept constant in a wide range for each system.

Other Theories. Bayliss and Wills-Johnson[3] calculated the change in the oscillator strength of the n→π^* bands of ketones and nitroalkanes based on their quantum mechanical model in which the total fluctuating field

$$\boldsymbol{R}^* = \alpha_s(\nu)\boldsymbol{m}\sum_k \boldsymbol{r}_k^{-6}[\boldsymbol{m} - 3(\boldsymbol{m}\cdot\boldsymbol{r}_k)\boldsymbol{r}_k]$$

caused by the solvent molecules surrounding the cavity acts on the solute chromophore, where $\alpha_s(\nu)$ is the solvent polarizability, $\boldsymbol{m}$ is the dipole moment of the solute, and $\boldsymbol{r}_k$ is the distance vector pointing to the k-th solvent molecule from the solute molecule. Although these authors could explain the "solvent dependence" of the relative intensity of the n→π^* band even for the aqueous solution, this model cannot explain the "concentration dependence," *i.e.*, the sudden rise in the intensity in the low concentration range below 10^{-2} molar fraction in water and even in ethanol, because it is impossible for any of the quantity, $\alpha_s(\nu)$, $\boldsymbol{m}$, or $\boldsymbol{r}_k$ to change sharply in this region.[14]

According to Lavrik and Naberukhin,[5] in the binary mixtures of water and non-electrolyte the cooperative effect of the hydrogen-bonded network of the liquid water predominates below 0.05 molar fraction of the non-electrolyte and this effect is greatly diminished either in ethanol or at high temperature around 60 °C. However, we have found that the behavior of the n→π^* band observed in the acetone-ethanol system as shown in Figs. 4 and 5 is essentially the same as that for the acetone–water system and that the intensity of the n→π^* band of acetone in water is even five per cent larger than the value at 20 °C. Thus we can conclude that contrary to the case of the Raman band intensity the cooperative effect of water is not responsible for the enhancement of the n→π^* band of ketones in dilute aqueous solutions.

It is generally accepted that the "solvent effect" of the electronic absorption spectra of most organic compounds can well be understood in terms of the polarizability, dielectric constant, dipole moment of the solvent, and the relevant interactions between the solute and solvent. However, the experimental data to be considered are usually taken from the measurements on "dilute solutions," and no systematic analysis has been done on the concentration dependence rather than the solvent dependence of the solvent effect, since it has not been realized that the former effect happens to compete with the latter as in this study. Thus one of the most important consequences of the present investigation is to give a warning that any discussion on the solvent effect of the electronic spectra is liable to be in serious error unless concentration dependence in a wide range

down to lower concentrations is studied.

A preliminary work of this study was initiated by Miss Akiko Motoyama now in Japan Association for International Chemical Information, to whom the authors' hearty thanks are due. The authors also thank Dr. Koichi Ohno of the University of Tokyo, Professor Tsunetake Fujiyama of Tokyo Metropolitan University, and Professor Yusei Maruyama of Ochanomizu University for their continuous interest, criticism, and helpful suggestions. For the troublesome purification of diisobutyl ketone the authors are greatly indebted to Dr. Yoshihiko Moriyama of the University of Tokyo and Research Laboratory staffs of Shimadzu Seisakusho. The present work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

Electrical and Spectroscopic Investigations of Molecular Layers of Fatty Acids Including Carotene

Toshihiro OHNISHI, Masahiro HATAKEYAMA, Naoto YAMAMOTO, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received January 17, 1978)

Spectroscopic and electrical studies have been made for the mono- and multi-molecular layers of barium stearate mixed with carotene. The results of the electronic spectra have indicated that the carotene molecules lie parallel to the monolayer plane and are aggregated. The capacitances measured are expressed well as those of parallel plate capacitors. From these results, the structure of the layers containing carotene has been deduced.

Kuhn and his colaborators have extensively investigated the physicochemical phenomena occurring at interfaces of Langmuir films made of some organic molecules such as fatty acid salts and organic dyes.[1,2]

We have investigated the electrical and spectroscopic properties of sandwitch-type assemblies of fatty acid salt layers mixed with *all-trans*-β-carotene in order to clarify the structure of these layers and its relation with the electrical properties.

Experimental

Aluminum/Langmuir film/aluminum junctions were prepared as follows. Aluminum film was evaporated on a slide glass using 99.999% aluminum at a pressure of 10^{-5} Torr. Monolayers or multilayers were deposited on such films by means of the Langmuir-Blodgett technique.[3] Finally, aluminum was evaporated in an array of stripes on the layers as shown in Fig. 1. The effective electrode area of each

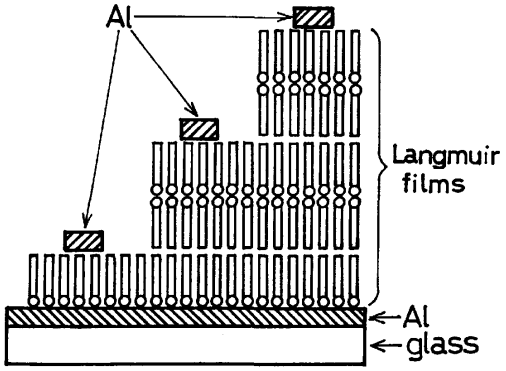

Fig. 1. The structure of Al/monolayers/Al assemblies.

of the junctions formed was about 0.1 cm^2. The monolayers were spread on an aqueous subphase containing 3×10^{-5} M barium chloride and 4×10^{-4} M potassium bicarbonate by introducing a small amount of a benzene solution of a fatty acid or a mixture of fatty acid and β-carotene. The water used as the subphase was prepared by distilling deionized water twice. Oleic acid was used as a piston oil having a surface pressure of 29.5 dyn/cm. Stearic acid from Sigma Chemical Co., 99% pure arachidic acid and 99% pure behenic acid both from Nakarai Chem. Co. were purified by recrystallization twice from distilled ethanol solutions. *All-trans*-β-carotene, 97% pure, from Merk & Co. was used without further purification. Capacitance measurements were made with a Yokogawa-Hewlett-Packard 4265B bridge at 1 kHz, 20 mV peak-to-peak. Absorption spectra were measured by use of a Cary 15 spectrophotometer.

Results and Discussion

Electronic Absorption Spectra. Figure 2 shows the electronic absorption spectra, measured at normal incidence, of various molecular layers of barium stearate mixed with β-carotene. The benzene solution of carotene is well known to have a strong absorption due to the $^1B\leftarrow{}^1A$ transition with fine structures in the region from 500 to 350 nm. The absorption spectra of the layers are somewhat different from that in solution. The peak positions of the layers, 513, 474, and 447 nm are essentially the same as those of a β-carotene film formed on glass by solvent evaporation from a benzene solution containing carotene and stearic acid at the same molar ratio, and are at slightly shorter wavelengths than those reported for a solid state carotene film by Rosenberg *et al.*[4] When the number of the superposed monolayers increased, the absorption intensity increased proportionally, but no change in the spectral shape was found.

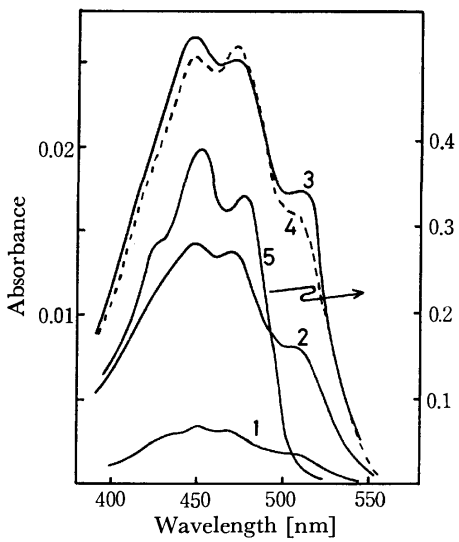

Fig. 2. Absorption spectra of Langumuir films containing *all-trans*-β-carotene taken at normal incidence: (1) monomolecular layer. (2) 3 molecular layers. (3) 5 molecular layers. (4) 5 molecular layers at an angle of incidence of 45°. (5) The hexane solution of β-carotene. All films are made of a mixture of β-carotene and barium stearate in a molar ratio of 1 : 12.3.

The $^1B\leftarrow{}^1A$ transition moment of carotene lies in the molecular plane and directs along the polyene chain. Therefore, if the carotene molecules are assumed to lie

perpendicularly on the glass plane, no absorption should be observed with light of normal incidence. On the other hand, if the carotene molecules are assumed to be randomly oriented, the absorption intensity should change with the angle of incidence, θ, being proportional to $1/\cos\theta$. Finally, if the molecules are assumed to lie parallel to the glass, the absorption intensity is expected to be proportional to $(1+\cos^2\theta)/(2\cos\theta)$, so that the ratio of the absorption intensity measured at $\theta=45°$ to that at $\theta=0°$ is calculated to be 1.06. In the present work, the absorption spectrum obtained at an angle of incidence of 45° showed no significant difference in shape and intensity from that obtained at normal incidence (Fig. 2). This result suggests that the carotene molecules lie parallel to the glass plate. The large difference between the absorption spectrum of carotene in the layers and that in solution can be explained by taking account of the aggregation of the molecules in the former. Based on these results, a plausible model for the structure of the mixed monolayers is shown schematically in Fig. 3.[5] It is reasonable to assume that the carotene molecules are stacked face to face on the glass plane in view of the π-π type molecular interaction giving a large amount of stabilization.

Capacitance Measurements. Figure 4 shows the reciprocal of capacitance per unit area measured for barium stearate layers with and without β-carotene versus the number of superposed monolayers between aluminum electrodes. The capacitance, C, of these layers, being regarded as parallel type capacitors, is expressed as a function of the number of the monolayers, n, as follows:

$$1/C = 1/C_{ox} + (d/\varepsilon_0\varepsilon)n, \quad (1)$$

where C_{ox} is the capacitance due to the oxide layer presumably formed on the aluminum electrode surface, ε_0 is the dielectric constant of vacuum, ε is the relative permittivity of the organic layers, and d is the thickness of the monolayer. As is seen from Fig. 4, a good linear relationship is obtained between $1/C$ and n for all cases.

By taking the relative permittivity of aluminum oxide to be 8,[6] the oxide thickness is calculated to be 35 Å for the stearate layer assemblies and 42 Å for the mixed layer assemblies from the $1/C$ values extrapolated to $n=0$. Similar plots were made for other fatty acid salts and the d/ε values derived from the slopes are listed in Table 1. Using the d values obtained by Kuhn *et al.*,[7] the ε values were derived for the fatty acid salts as seen in Table 1, being in good agreement with those obtained by Kuhn *et al.*[8] and Reynolds *et al.*[9]

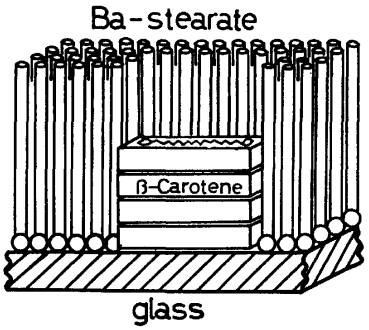

Fig. 3. Schematic representation of the mixed layer of *all-trans*-β-carotene and a fatty acid salt.

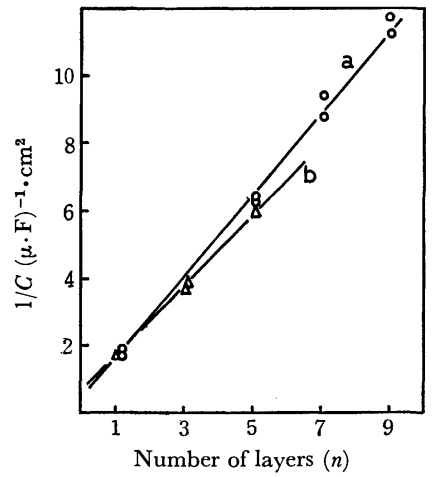

Fig. 4. Reciprocal of capacitance, $1/C$, *vs.* predicted number of layers, n; (a) for the monolayers of barium stearate and (b) for those mixed with β-carotene in a mole ratio of 1: 12.3.

Table 1. The d/ε and ε of fatty acid salts obtained from the capacitance measurements

Material	d/ε (Å)	d[a] (Å)	ε
Barium stearate	10.5	25.8	2.46
Barium arachidate	11.6	28.0	2.41
Barium behenate	13.0	30.2	2.32
Barium stearate–β-carotene	9.7		

a) Taken from Ref. 8.

Somewhat smaller d/ε values were obtained for the mixed layers than those for the pure barium stearate layers. Assuming that the electric polarization of the mixed layer is a simple sum of those by the fatty acid salt array and the carotene array indicated in Fig. 3, the capacitance of the layer can be calculated only if the stacking number of β-carotene molecules in each of the monolayer is assumed. Using the d/ε values obtained both for the fatty acid salt layers and for the mixed layers, the molecular cross-section of barium stearate of 20 Å^2, the molecular plane area of carotene of 230 Å^2, the thickness of the carotene plane of 4 Å, and ε of carotene assumed to be 2.5 or 3.0,[10] the number derived is 3.58 or 4.09, respectively. The relative actual thickness of the carotene layers is such as illustrated in Fig. 3. In the above discussion, it was assumed that there are no interstices between the molecular layers.

Surface pressure-area (π-A) curve measured for β-carotene at the air–water interface has been measured. It is in good agreement with that obtained by Leblanc and Orger.[11] The limiting area of 18.0 Å^2 per molecule was derived by extrapolating the steep part of the π-A curve. This corresponds to the cross sectional area of β-carotene calculated from the molecular structural model, indicating that the β-carotene molecules are standing perpendicularly on the surface. The π-A curves

for samples containing both carotene and fatty acid in various molar ratios have also indicated the perpendicular standing of β-carotene. Therefore, the structure proposed in Fig. 3 for the mixed Langumuir film of β-carotene with the fatty acid salt seems to be formed when the layer was transferred from the air–water interface onto the glass surface.

The Crystal and Molecular Structures of Pyrrolidinium *p*-Chlorobenzoate and Pyrrolidinium *p*-Toluate

Setsuo KASHINO, Shin-ichi KATAOKA, and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received January 27, 1978)

The crystal structures of pyrrolidinium *p*-chlorobenzoate (PYC) and pyrrolidinium *p*-toluate (PYT) have been determined from visually estimated Cu $K\alpha$ data. The crystals of PYC are orthorhombic, space group Pbca, $a=9.53(1)$, $b=27.28(3)$, $c=9.39(2)$ Å, and $Z=8$. Those of PYT are monoclinic, space group $P2_1/c$, $a=14.66(3)$, $b=9.00(2)$, $c=9.44(1)$ Å, $\beta=101.3(4)°$, and $Z=4$. The structures of PYC and PYT were refined by the block-diagonal least-squares method to R values of 0.073 and 0.089 for 855 and 1277 non-zero reflections, respectively. In both PYC and PYT, the pyrrolidinium and benzoate ions are linked together by two kinds of N–H···O hydrogen bonds to form a ribbon along the twofold screw axis. The shorter hydrogen bond [N···O 2.697(7) Å for PYC, 2.674(5) Å for PYT] lies nearly perpendicular to the twofold screw axis, and the longer bond [N···O 2.730(7) Å for PYC, 2.738(5) Å for PYT] makes an angle of about 20° with the axis. The O···N···O angle is near to the regular tetrahedral angle [105.4(2)° for PYC, 107.1(2)° for PYT]. The crystals of PYC are isomorphous with those of piperidinium *p*-chlorobenzoate, piperidinium *p*-bromobenzoate, piperidinium *p*-toluate and pyrrolidinium *p*-bromobenzoate, but PYT crystallizes in a subgroup of the space group of the others because of the cooperative effects of the bulkiness of the methyl group and the ring size of the base moiety. The pyrrolidine rings in PYC and PYT take an approximate C_S symmetry.

Previously, we have shown that the crystals of piperidinium *p*-chlorobenzoate (PIC), piperidinium *p*-bromobenzoate (PIB) and piperidinium *p*-toluate (PIT) are isomorphous.[1,2] The present investigation was undertaken in order to elucidate the effect of the ring size of the base moiety and the effect of the *para* substituent of the acid moiety on the crystal structure and on the geometry of hydrogen bond in the crystals. The conformation of the pyrrolidine ring in the solid state is of additional interest.

Experimental

The compounds were prepared by dissolving equimolar quantities of the acid and the base in dry benzene, in a similar manner described for piperidinium benzoates.[3] Crystallographic data for PYC, PYT and pyrrolidinium *p*-bromobenzoate (PYB) are listed in Table 1, and experimental details are in Table 2.

As the crystals of these compounds decomposed gradually, the specimens were sealed in glass capillaries. The intensity data were collected on the equi-inclination Weissenberg photographs using Cu $K\alpha$ radiation. Intensities were esti-

mated visually and corrected for Lorentz and polarization factors and spot shape.

Structure Determination and Refinement

The structures were solved from sharpened Patterson maps, and refined by block-diagonal least-squares calculations. For PYC an extinction correction was applied at the stage of $R=0.089$, for the four strongest reflections according to the formula $I_{corr}=I_{obsd}/(1-1.3\times 10^{-4} I_{obsd})$. In the subsequent refinements, the parameters of the H atoms attached to the C atoms of pyrrolidine ring were fixed. The weighting scheme used was $w=1.0$ for $0<|F_o|\leq F_{max}$, and $w=(F_{max}/|F_o|)^2$ for $|F_o|>F_{max}$, where F_{max} was 18.0. The final R value was 0.073 for 855 non-zero reflections.

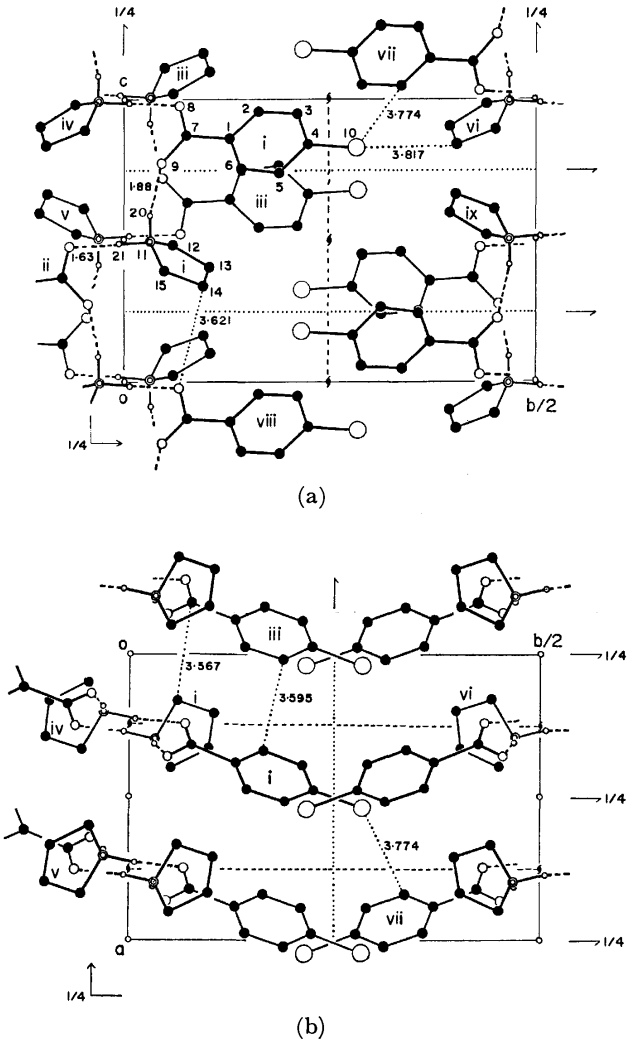

Fig. 1. Projections of the crystal structure of PYC along the a axis (a), and the c axis (b).
Broken lines show hydrogen bonds, and dotted lines intermolecular contacts.
Symmetry code: i x, y, z; ii $1/2-x, -y, -1/2+z$; iii $-1/2+x, y, 3/2-z$; iv $1/2-x, -y, 1/2+z$; v $1-x, -y, 1-z$; vi $x, 1/2-y, 1/2+z$; vii $1/2+x, 1/2-y, 2-z$; viii $x, y, -1+z$; ix $1/2+x, 1/2-y, 1-z$.

For PYT a difference Fourier map revealed all the H atoms at the stage of $R=0.104$. Further refinements gave a final R value of 0.089 for 1277 non-zero reflections. The same weighting scheme as that for PYC was used with $F_{max}=10.0$.

The final atomic parameters are listed in Table 3.[4]

The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[5] The computations were carried out on a NEAC 2200-500 computer at the Okayama University Computer Center. The programs used were HBLS-5 and DAPH.[6]

Results and Discussion

The projections of the crystal structure of PYC viewed along a and c axes are shown in Fig. 1, and those of PYT along c and b axes in Fig. 2. Some intermolecular distances are summarized in Table 4. Bond lengths and angles are listed in Table 5.

Crystal Structures. The crystals of PYC are isostructural with those of piperidinium compounds *i.e.* PIC, PIB, and PIT, and also with PYB, judging from the space group, the cell dimensions, and the intensity distribution.

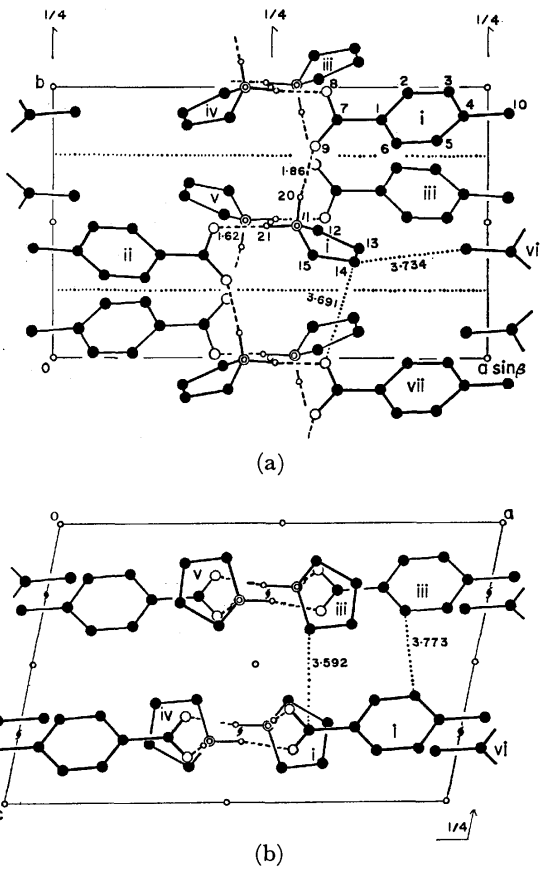

Fig. 2. Projections of the crystal structure of PYT along the c axis (a), and the b axis (b).
Broken lines show hydrogen bonds, and dotted lines intermolecular contacts.
Symmetry code: i x, y, z; ii $1-x, -1/2+y, 3/2-z$; iii $x, 3/2-y, -1/2+z$; iv $1-x, 1/2+y, 3/2-z$; v $1-x, 1-y, 1-z$; vi $2-x, -1/2+y, 3/2-z$; vii $x, -1+y, z$; viii $x, 3/2-y, 1/2+z$.

The pyrrolidinium and *p*-chlorobenzoate ions are linked together by two kinds of hydrogen bonds [N(11)–H(21)···O(8^{ii}) and N(11)–H(20)···O(9)] to form a ribbon along the twofold screw axis parallel to ***c***. The ribbons related by an a-glide plane are held together side by side by van der Waals interactions to form a sheet parallel to (010). The sheets related by a c-glide plane are stacked along ***b*** to complete a whole crystal.

In the crystals of PYT, similar hydrogen bonds to those in PYC effect a ribbon around the twofold screw axis at $x=1/2$. The ribbons related by a c-glide plane are held together to form a sheet parallel to (100). The sheets are stacked along ***a***. The axes ***a*** sin β, ***b***, and ***c*** of PYT correspond to the axes ***b***/2, ***c***, and ***a*** of PYC, respectively.

In both PYC and PYT six close contacts between the

benzene ring plane, δ_4	54	44	48	48	47

ribbons are concerned with the atoms in the pyrrolidine ring as seen from Table 4. However, the contacts around C(13) in the ring are rather loose; the closest being C(13)···C(1^{iii}) 3.866(15) Å in PYC, and C(13)···C(6^{viii}) 3.780(9) Å in PYT.

Geometry of the Hydrogen Bonds. The geometry in PYC and PYT is summarized in Table 6, along with that in the piperidinium compounds. In all these crystals the hydrogen bond N(11)···O(8^{ii}) lies nearly perpendicular to the twofold screw axis along which the ribbon extends, as seen in δ_1, and the bond N(11)···O(9) makes a constant angle of about 20° with the twofold screw axis. Thus the angle O(8^{ii})···N(11)···O(9) is near to the regular tetrahedral angle. The N(11)···O(8^{ii}) bond is shorter and hence stronger than the N(11)···O(9) bond. The former associates with the nearly tetrahedral C–N···O and C–O···N angles, and with linear N–H···O angle. Dihedral angle, δ_3, between the carboxylate group and the plane perpendicular to the twofold screw axis remains almost constant throughout the compounds, and the long axis of the acid anion lies nearly on the plane as seen from δ_2 in Table 6.

Morphotropism. In the structures of PYC, PYT and the piperidinium compounds many contacts between the ribbons are concerned with the atoms of the base moiety. Thus the effect of ring size of the bases is reflected in the thickness of the ribbons, hence in the cell dimension along ***a*** for PYC and ***c*** for PYT. The values for the pyrrolidinium compounds are smaller than those for the piperidinium compounds. Furthermore, the angle of the long axis of the acid anion with (010) in PYC, 70°, is widened from 64—61° in the piperidinium compounds. This is also the case for the corresponding angle with (100) in PYT, the angle here being 75°.

It has been shown[2] that in the piperidinium compounds the contacts around the *p*-substituents are rather loose and hence the crystal structures are little affected by the bulkiness of the substituents. On the other hand, in PYC the contacts become close as an effect of the ring size mentioned above: Cl···H(26^{vi}) 2.77 Å, Cl···H(16^{vii}) 2.97 Å. Therefore, a mode of stacking of the sheets seems to be more largely affected by the bulkiness of the substituents in the pyrrolidinium compounds than in the piperidinium compounds. The reason why PYT crystallizes in a subgroup of the space group Pbca is the disappearance of the c-glide plane by the cooperative effects of the bulkiness of the methyl group and the thickness of the ribbon.

Molecular Structures. (*a*) *Benzoate Ions*: The benzene rings are planar within 0.015 Å, as shown in Table 7. The dihedral angle between the ring and the carboxylate group is 1.9° for PYC, while is 9.7° for PYT. This difference is mainly due to the difference in δ_4 in Table 6. The inner angle at C(4) for PYT is smaller than the sp^2 angle as found in PIT and in many methyl substituted benzene derivatives.[7,8]

(*b*) *Pyrrolidinium Ions*: The torsion angles, χ_i (mod. 5), of the five bonds of the pyrrolidine rings are listed in Table 8. The χ_i in PYC corresponds to χ_{i-1} in PYT, being close to 0° for $i=3$. Hence, in PYC C(12) deviates from the plane through the other non-hydrogen atoms in the ring, while N(11) deviates in PYT, as seen from Table 7. Thus, the pyrrolidine ring in PYC and PYT take an approximate C_s (envelope) symmetry, the mirror plane passing through C(12) in PYC and N(11) in PYT.

In both PYC and PYT the C–C–C angles in the rings are slightly larger than the C–C–N angles. The C–N–C angles are close to the sp^3 angle. The C(13)–C(14) bonds are shortened by the unusually large vibrational motions of C(13) in the direction perpendicular to the ring planes, as found in prolyl residues of some oligopeptides.[9]

Charge-Transfer Character in the Intramolecular Hydrogen Bond: Vacuum Ultraviolet Spectra of Acetylacetone and Its Fluoro Derivatives

Hiroshi NAKANISHI, Hiroshi MORITA, and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received January 28, 1978)

Near and vacuum UV absorption spectra of trifluoroacetylacetone (TFAC) and hexafluoroacetylacetone (HFAC) were measured at room temperature in the vapor phase and in perfluorohexane in the 30000—80000 cm^{-1} region, together with a vacuum UV absorption spectrum of acetylacetone in the 60000—80000 cm^{-1} region. By the aid of the modified CNDO-CI calculation, each of the observed valence-shell transition bands was assigned to the π–π^*, π–σ^*, or σ–σ^* transition. The third σ–σ^* bands observed at 65200 cm^{-1} for acetylacetone, at 78000 cm^{-1} for TFAC, and at 70400 cm^{-1} for HFAC were concluded to be rich in the CT character pertinent to hydrogen bond. In particular, the third σ–σ^* band of HFAC was found to be the CT band pertinent to hydrogen bonding in the sense that the contribution of the CT configuration to the excited state amounts to 67.4%.

Importance of the charge-transfer (CT) mechanism in hydrogen bond has been recognized by many authors from theoretical[1-7] and experimental[8-10] points of view. The CT mechanism can strongly be supported by the observation of the CT band pertinent to hydrogen bond.[11] The CT character of intramolecular hydrogen bond in the ground and excited electronic states was investigated for the hydrogen maleate anion;[12,13] the theoretical and experimental results indicated that the first π-π^* band which is rich in the CT character pertinent to the hydrogen bond is covered by the strong second π-π^* band at 210 nm.[13]

The enol forms of acetylacetone, trifluoroacetylacetone (TFAC), and hexafluoroacetylacetone (HFAC) have a strong intramolecular hydrogen bond with the O···O distance of 2.38—2.55 Å as revealed from X-ray diffraction[14] and gas-phase electron diffraction studies.[15,16] In a previous paper,[17] we reported the electronic structures and spectra of the keto and enol forms of acetylacetone in the 30000—61000 cm^{-1} region, and discussed the CT character of the intramolecular hydrogen bond of the enol form. Concerning the electronic structures and spectra of the fluoroacetylacetones, only a few studies have been made.[18-20]

Our previous study[17] of the electronic structure and spectrum of acetylacetone led us to the expectation that a band rich in the CT character might appear in a higher energy region than 61000 cm^{-1}. In the present paper, we extend the spectral region to 80000 cm^{-1} in the vacuum ultraviolet (VUV) region and measure the absorption spectra of acetylacetone in the vapor phase and of TFAC and HFAC in the vapor phase and in perfluorohexane. From analysis of the experimental results by the modified CNDO-CI method[21] and the configuration analysis method,[22] the nature of the valence-shell transition and Rydberg excitation bands is discussed, special attention being paid to the identification of the CT band pertinent to the intramolecular hydrogen bond.

Experimental

Materials. TFAC (Dotait G.R. Grade) and HFAC (Dotait G. R. Grade) were purified by repeating vacuum distillation three times immediately before use. Acetylacetone and perfluorohexane were purified in the same way as reported previously.[17]

Measurement. Near UV (30000—50000 cm^{-1}) absorption spectra were measured with a Cary recording spectrophotometer Model 14. VUV (50000—80000 cm^{-1}) absorption spectra were measured with a Johnson-Onaka type VUV spectrophotometer,[23] the sample chamber and detector system of which were modified as shown in Fig. 1. A hot cathode deuterium discharge lamp and Tanaka type xenon and krypton continuum lamps driven with microwave excitation (2450 MHz) were used as VUV light sources. Cells with MgF_2 or LiF windows of 5—10 cm light path lengths and a 0.01 cm quartz cell were used for the measurement in the vapor phase and in the solution, respectively. The vapor pressure of the sample was regulated with a cryogenic bath at various temperatures.

Theoretical

The modified CNDO-CI method[21] was applied to the enol forms of acetylacetone, TFAC, and HFAC to investigate the valence-shell transitions. The semiempirical parameters of H, C, and O atoms were the same as reported previously.[17,21] The parameters of F atom were adopted as follows; the one-center Coulomb repulsion integral, γ_F=19.36 eV, the bonding parameter, β_F^0=−40.0 eV, and the $(I+A)/2$ values, 32.772 eV for the 2s AO, and 11.580 eV for the 2p AO. Preliminary calculations for such fluorinated molecules as carbon

tetrafluoride, carbonyl fluoride, trifluoroacetoaldehyde, and trifluoroacetic acid with the use of these parameters showed that the calculated transition energies and oscillator strengths agree well with the observed values. In the configuration interaction (CI) treatment of TFAC and HFAC, 40 singly excited π-π^* and σ-σ^* configurations and 40 singly excited π-σ^* and σ-π^* configurations were taken into account.

The actual calculations were made for two different geometrical structures, symmetrical and asymmetrical ones. Symmetrical molecular structures of TFAC and HFAC were taken from the results of gas-phase electron diffraction studies,[15] the linear symmetrical intramolecular hydrogen bond, O···H···O being assumed, and asymmetrical molecular structures were taken from the results by nonempirical calculations,[24,25] a non-linear asymmetrical intramolecular hydrogen bond being taken from the X-ray diffraction study.[26]

The configuration analysis was applied to the third σ-σ^* excited state (calculated at 9.02 eV)[17] of the enol form of acetylacetone. The procedure for the analysis was described in detail in the previous paper.[17]

Results and Discussion

The VUV Absorption Spectrum of Acetylacetone. Figure 2 shows the VUV spectrum in the 50000—80000 cm^{-1} region measured with acetylacetone in the vapor phase at room temperature. Since acetylacetone predominantly exists as the enol form in the vapor phase (96.2% at 20 °C),[17] the spectrum in Fig. 2 is ascribed to the enol form. We can see from Fig. 2 that strong bands appear at 65200 cm^{-1} (8.08 eV) and $\approx$79000 cm^{-1} ($\approx$9.8 eV) and shoulders at $\approx$60000 cm^{-1} ($\approx$7.4 eV) and $\approx$71000 cm^{-1} ($\approx$8.8 eV). Table 1 shows theoretical values of the transition energies and oscillator strengths of the valence-shell transition bands, together with the observed values (for the theoretical and observed results below 8 eV, see Table 1 in Ref. 17). From the comparison between the observed and calculated results, the strong 8.08 eV band (oscillator strength, $f\approx0.5$) can safely be assigned to the third σ-σ^* transition (calculated at 9.02 eV) because of its large oscillator strength among the bands calculated in 7.5—10.0 eV region. The other three observed bands at $\approx$7.4 eV, $\approx$8.8 eV, and $\approx$9.8 eV can be assigned to the third π-π^* transition (calculated at 8.46 eV), the fourth σ-σ^* transition (calculated at 9.94 eV), and the fourth π-π^* transition (calculated at 10.15 eV), respectively.

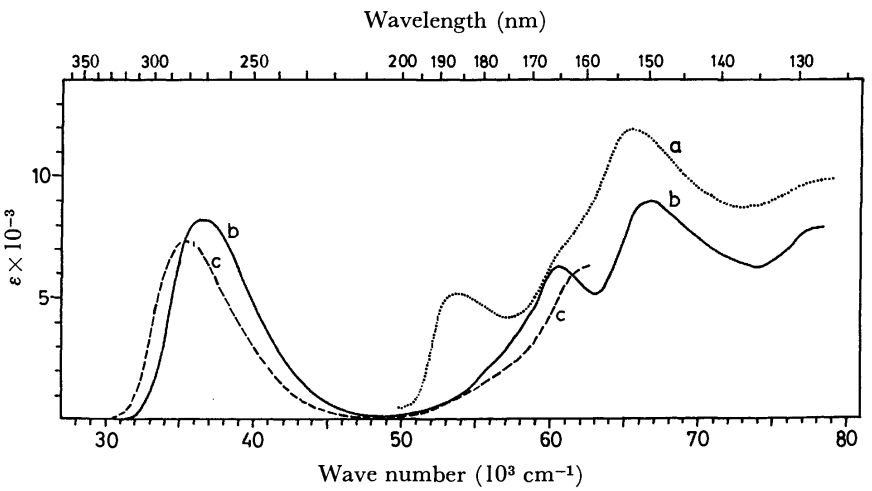

Fig. 2. Near and vacuum UV absorption spectra measured with (a) acetylacetone in the vapor phase, (b) TFAC in the vapor phase, and (c) TFAC in perfluorohexane at room temperature.

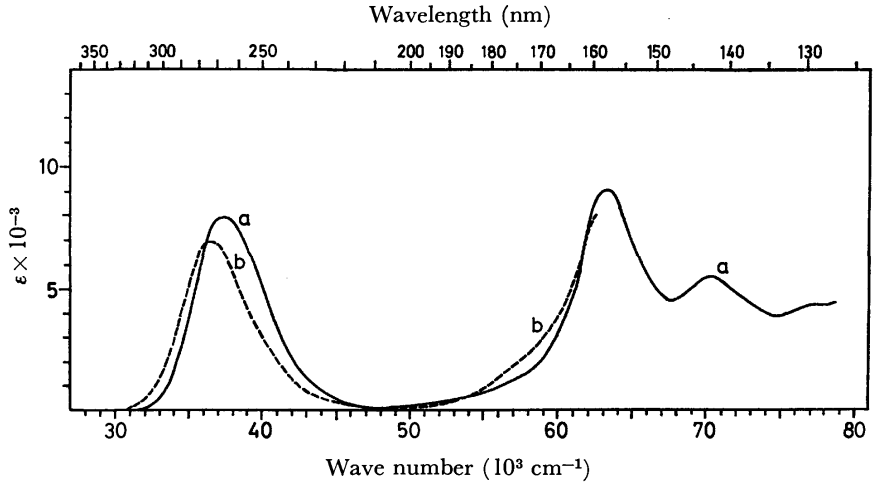

Fig. 3. Near and vacuum UV absorption spectra of HFAC measured (a) in the vapor phase and (b) in perfluorohexane at room temperature.

Electronic Absorption Spectra of TFAC and HFAC. Near and vacuum UV absorption spectra in the 30000—80000 cm^{-1} region measured with TFAC and HFAC at room temperature are shown in Figs. 2 and 3, respectively. As pointed out by the NMR studies,[27,28] substitution of the methyl group(s) in acetylacetone by the more electronegative trifluoromethyl group(s) preponderates the enol tautomer in the keto-enol equilibrium; TFAC and HFAC exist almost completely (95—100%) as the enol form in the vapor phase and in nonpolar solvents at room temperature. Therefore, the observed spectra shown in Figs. 2 and 3 are ascribed to the enol form.

The TFAC vapor spectrum in Fig. 2 has absorption peaks at 36670 cm^{-1} (4.55 eV), 60600 cm^{-1} (7.51 eV), 66700 cm^{-1} (8.27 eV), and 78000 cm^{-1} (9.7 eV), and shoulders at ≈56000 cm^{-1} (≈6.9 eV) and ≈71000 cm^{-1} (≈8.8 eV). The HFAC vapor spectrum in Fig. 3 has absorption peaks at 37450 cm^{-1} (4.64 eV), ≈57000 cm^{-1} (≈7.1 eV) (as a weak shoulder), 63700 cm^{-1} (7.90 eV), 70400 cm^{-1} (8.73 eV), and ≈77000 cm^{-1} (≈9.5 eV).

Comparison between the spectra in the vapor phase and in the solution in Fig. 2 shows that the 60600 cm^{-1} band of TFAC in the vapor phase disappears in the solution. This means that the band is assigned to the Rydberg excitation band.[29] The Rydberg excitation energy satisfies the following formula;[29]

$$h\nu = I_p - 109737/(n-\delta)^2, \quad (1)$$

where $h\nu$ is the excitation energy (cm^{-1}), I_p is the ionization potential (cm^{-1}), n is the principal quantum number, and δ is the quantum defect. By the use of the first I_p value (9.93 eV) determined by photoelectron spectroscopy,[30] the δ value of the 60600 cm^{-1} band was determined to be 0.63, corresponding to $n=3$. This strongly suggests that the band is due to the transition to the 3p Rydberg orbital from the highest occupied π orbital. The band intensity is of the same order of magnitude as the π-3p Rydberg band of acetylacetone[17] observed at 53300 cm^{-1}. The corresponding Rydberg transition band is expected to appear at ≈67000 cm^{-1} for HFAC from the first ionization potential of 10.72 eV.[30] But it is covered by strong valence-shell transition bands and cannot be observed.

Theoretical transition energies and oscillator strengths of the valence-shell transitions of the enol forms of TFAC and HFAC were calculated on the basis of two kinds of (*i.e.*, symmetrical and asymmetrical) molecular structures. The results for lower excited states of both the TFAC and HFAC molecules are rather insensitive to

a) Observed value in the vapor phase. b) Calculated value for the symmetrical molecular structure of the enol form. c) Main electron configurations of the respective excited states are shown. d) The direction of the transition moment is shown in the parentheses, the x-axis being taken to be parallel to the O···H···O bond within the molecular (x-y) plane as is shown in Fig. 8(a). e) y-Component of the transition moment contributes appreciably to x-component. f) x-Component of the transition moment contributes appreciably to y-component.

the molecular structures, and from semiquantitative view-points, the same conclusions are derived concerning the assignments and characterizations of the observed bands.

Table 2 shows the theoretical results calculated for the symmetrical molecular structure of the enol form of TFAC compared with the observed values. The 4.55 eV band can safely be assigned to the first π-π^* transition (calculated at 4.75 eV) and corresponds to the 4.72 eV band of acetylacetone. The strong 61700 cm^{-1} (7.65 eV) band in the solution is assigned to the second π-π^* transition (calculated at 7.35 eV). In the vapor phase, the second π-π^* band shifts to the shorter wavelengths. The theoretical result predicts that the weak band at $\approx$6.9 eV can be assigned to the first π-σ^* transition (calculated at 7.58 eV), and that the strong 8.27 eV band in the vapor phase is composed of the second π-π^* transition and the first σ-σ^* transition (calculated at 7.99 eV). Moreover, from the comparison between the observed and calculated results, the $\approx$8.8 eV band and the 9.7 eV band are assigned to the second (calculated at 8.97 eV) and third (calculated at 9.34 eV) σ-σ^* transitions, respectively.

Table 3 shows the theoretical results of the valence-shell transitions calculated for the symmetrical molecular structure of the enol form of HFAC, together with the observed values. The 4.64 eV band can be assigned to the first π-π^* transition (calculated at 4.48 eV). The weak band at $\approx$7.1 eV in the vapor phase is also observed in perfluorohexane, and is assigned to the first π-σ^* transition (calculated at 7.59 eV). The strong 7.90 eV band is ascribed to the superposition of the second π-π^* (calculated at 7.29 eV) and first σ-σ^* (calculated

a) The results for the first π–π^* and the first σ–σ^* excited states are shown in Table 3 of Ref. 17. b) i and j denote the 20 occupied MO's of the anion, and k and l, the 15 vacant MO's of the anion. The 1s orbital of the hydrogen-bonded hydrogen is numbered as the 36th vacant orbital. c) i–k and i, j–k,l denote the singly and doubly excited reference configurations, respectively. d) The strong band observed at 8.08 eV in Fig. 2. e) The ionic structure, $((\underline{O^+H^-O})+(\underline{OH^-O^+}))$, is also involved. f) Doubly excited configurations, i, j–k, 36.

g) The ground reference configuration coincides with the ground state of the anion. h) Singly excited configurations, i–k.

at 7.54 eV) transitions. The shift to the longer wavelengths of the second π-π^* and first σ-σ^* bands of HFAC compared to the corresponding bands of TFAC is consistent with the theoretical predictions in Tables 2 and 3. The 8.73 eV band is safely assigned to the third σ-σ^* transition (calculated at 8.87 eV). The $\approx$9.5 eV band may tentatively be assigned to the fifth σ-σ^* transition (calculated at 9.52 eV).

Electronic Structures of the Intramolecular Hydrogen Bonds of Acetylacetone, TFAC, and HFAC. The previous paper[17] shows that the CT configuration characteristic of the intramolecular hydrogen bond corresponds to the one electron excitation from the nonbonding orbital to the antibonding orbital in the hydrogen bond. In the case of acetylacetone, the 20—26 configuration is the CT configuration (see Fig. 5 in Ref. 17.), and contributes mainly to the first π-π^* band (observed at 4.72 eV) (9.8%), the third σ-σ^* band (observed at 8.08 eV) (40.3%), and the fourth π-π^* band (observed at $\approx$9.8 eV) (16.3%). In acetylacetone, the third σ-σ^* band is richest in the CT character.

The CT character in the intramolecular hydrogen bond of acetylacetone was investigated quantitatively by the configuration analysis method; the result for the third σ-σ^* band is tabulated in Table 4, together with the result for the ground state (for the purpose of comparison, also see Table 3 in Ref. 17). In this table, the CT structure corresponds to the antisymmetric covalent structure IV and antisymmetric ionic structure II. Both structures contribute considerably (30.4%) to the third σ-σ^* excited state, revealing us that the band is rich in the CT character pertinent to the hydrogen bond.

Figures 4 and 5 show the energy levels of TFAC and HFAC, respectively, calculated by the modified CNDO-CI method for some low-lying π-π^* and σ-σ^* excited states of the enol form with the symmetrical molecular structures. In the figures, i–j represents a singly excited configuration caused by the one-electron excitation from

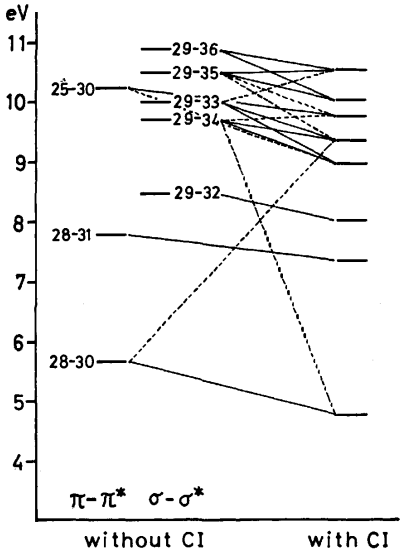

Fig. 4. Energy levels calculated with and without CI treatment for some lower π–π^* and σ–σ^* excited states of the enol form of TFAC.

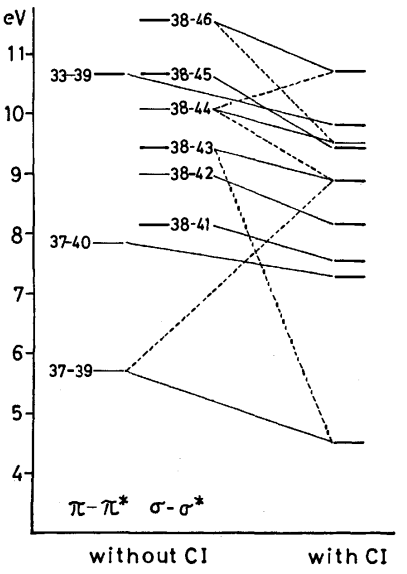

Fig. 5. Energy levels calculated with and without CI treatment for some lower π–π^* and σ–σ^* excited states of the enol form of HFAC.

the i-th occupied MO to the j-th vacant MO. From the shapes of the MO's of TFAC and HFAC (see Figs. 6 and 7), the CT configuration characteristic of the intramolecular hydrogen bond is the 29-34 configuration for TFAC and the 38-43 configuration for HFAC. As for TFAC, the 29-34 CT configuration interacts significantly with the 29-33 σ-σ^*, 25-30 π-π^*, and 28-30 π-π^* configurations, and contributes significantly to the first π-π^* (calculated at 4.75 eV), the second σ-σ^*

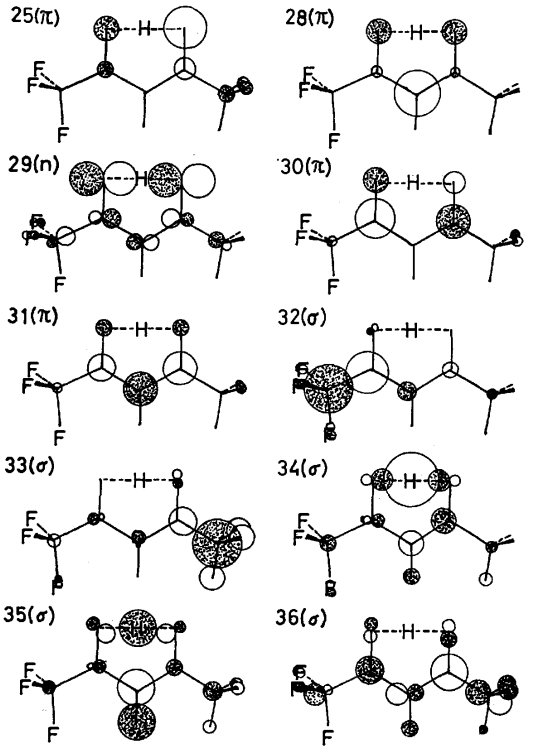

Fig. 6. Schematic shapes of some occupied and vacant MO's of the enol form of TFAC. The 29th MO is the highest occupied one.

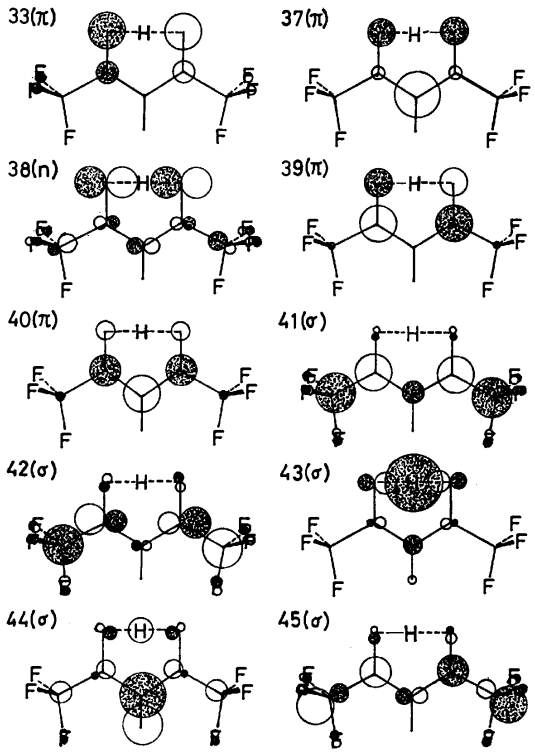

Fig. 7. Schematic shapes of some occupied and vacant MO's of the enol form of HFAC. The 38th MO is the highest occupied one.

(calculated at 8.97 eV), the third σ-σ* (calculated at 9.34 eV), and the third π-π* (calculated at 9.75 eV) excited states. The first π-π* band (observed at 4.55 eV) is mainly composed of the 28-30 π-π* (85.1%) and 29-34 CT (5.9%) configurations; the second σ-σ* band (observed at ≈8.8 eV), of the 29-34 CT (33.7%), 29-33 σ-σ* (31.8%), and 25-30 π-π* (11.4%) configurations; and the third σ-σ* band (observed at ≈9.7 eV), of the 29-33 σ-σ* (35.2%), 29-34 CT (22.0%), 29-35 σ-σ* (10.2%), and 28-30 π-π* (4.8%) configurations. The theoretical results calculated by the modified CNDO-CI method predict that the second and third σ-σ* bands are rich in the CT character pertinent to the hydrogen bond in TFAC.

In the case of HFAC, the 38-43 CT configuration interacts significantly with the 37-39 π-π* and 38-44 σ-σ* configurations, and contributes to the first π-π* (calculated at 4.48 eV) and the third σ-σ* (calculated at 8.87 eV) excited states. The first π-π* band (observed at 4.64 eV) is composed of the 37-39 π-π* (83.6%) and 38-43 CT (7.2%) configurations, and the third σ-σ* band (observed at 8.73 eV), of the 38-43 CT (67.4%), 38-44 σ-σ* (5.9%), and 37-39 π-π* (5.5%) configurations. The theoretical calculation predicts that the third σ-σ* band is the CT band characteristic of the intramolecular hydrogen bond of HFAC. It is noteworthy that the first π-π* bands of acetylacetone, TFAC, and HFAC observed at 4.5—4.7 eV have the CT character pertinent to the hydrogen bond by 5—10%.

Electron Densities of TFAC and HFAC. Figure 8 shows electron densities in the ground state calculated for the symmetrical molecular structures of the enol forms of TFAC and HFAC. By substituting the methyl

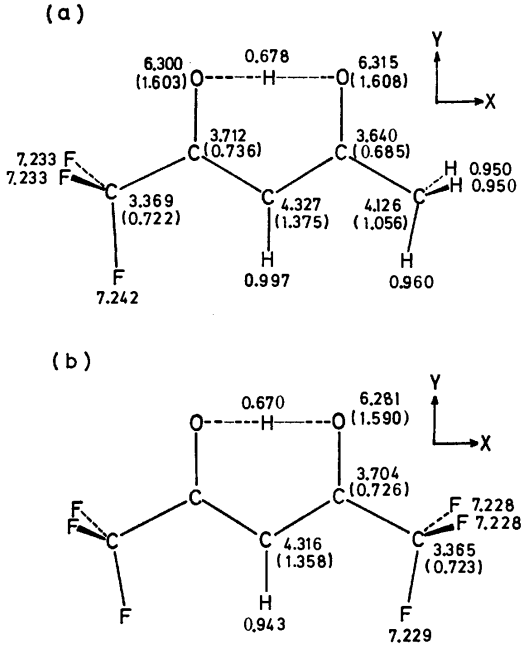

Fig. 8. Total and π-(in parentheses) electron densities calculated for the ground states of (a) TFAC and (b) HFAC.

group(s) by the trifluoromethyl group(s), the σ-electron density on the hydrogen-bonded hydrogen atom slightly decreases, and the π-electron densities increase on carbonyl carbon atoms with the decrease on oxygen atoms. The dipole moments of TFAC and HFAC were calculated to be 3.42 and 0.69 D, respectively. The cancellation between the dipole moments in the carbonyl groups and in the trifluoromethyl groups is responsible for the small dipole moment of HFAC.

The authors are indebted to Dr. J. Nakamura, the Institute of Physical and Chemical Research, for her helpful advice in modifying the VUV instrument. This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education.

(Received February 7, 1978)

The molecular structure of oxydi(carboxymethyl)bis(triphenylphosphine)palladium(II), [Pd($C_4H_4O_3$)(PPh_3)$_2$] has been determined by means of X-ray diffraction. The crystal belongs to the orthorhombic system, space group $P2_12_12_1$, with four formula units in a cell with dimensions of $a=16.320(2)$, $b=20.104(2)$, and $c=10.271(2)$ Å. $R=0.058$ for 4732 non-zero relfections. The feature of the structure is that the palladium atom is chelated by an acetic anhydride to form a six-membered ring [Pd–C=2.141(13) and 2.124(11) Å], and the palladium atom has a square-planar geometry.

Interesting studies on the synthesis and reactivity of a series of organopalladium complexes with the palladium–carbon σ-bond have been reported.[1-4] Stimulated by the stereochemical interests, X-ray molecular structures of [Pd($C_4H_4O_3$)(PPh_3)$_2$], [Pd($C_2H_2O_2$)(PPh_3)(py)],[2] [Pd(acac)$_2$(PPh_3)$_2$],[5] [Pd($C_6H_9O_3$)$_2$(MePy)$_2$][4], [PdCl($CH_2COCH_2COOCH_2Ph$)(Py)$_2$],[6] and [Pd(CH_2COOH)(acac)(PPh_3)][7] have been determined. This paper deals with the structure of [Pd($C_4H_4O_3$)(PPh_3)$_2$], of which preriminary result has been reported briefly.[2]

Experimental

Pale yellow, polyhedral crystal of [Pd($C_4H_4O_3$)(PPh_3)$_2$] were kindly supplied by Professor S. Kawaguchi and his co-workers of the Osaka City University. Preliminary X-ray work showed that the crystals belong to the orthorhombic system and that the space group is $P2_12_12_1$ (No. 16, absent reflections, $h00$; $h=2n+1$, $0k0$; $k=2n+1$, and $00l$; $l=2n+1$). Accurate unit-cell dimensions were determined by a least-squares fit using 2θ values of 20 strong reflections measured on a Rigaku automated, four-circle, single crystal diffractometer.

Crystal Data: $C_{40}H_{34}O_3P_2Pd$, *F. W.*=731.1, orthorhombic, space group, $P2_12_12_1$, $a=16.320(2)$, $b=20.104(2)$, $c=10.271(2)$ Å. $U=3369.8(8)$ Å^3, $D_m=1.41$ g·cm^{-3} (by flotation in aqueous solution of zinc iodide), $Z=4$, $D_c=1.44$ g·cm^{-3}, Mo $K\alpha_1$ ($\lambda=0.70926$ Å).

For the intensity measurement, a crystal with approximate dimensions of $0.18\times0.25\times0.30$ mm was used. Data were collected on the Rigaku diffractometer using graphite monochromatized Mo $K\alpha$ radiation. All data within a 2θ sphere of 60° ($\sin\theta/\lambda=0.70$) were measured using the θ-2θ scan technique. The integrated intensity was determined by scanning over the peak at a rate of 2°min^{-1} and subtracting the background obtained by averaging the two values measured for 10 s at both ends of a scan; the scan width of each reflection was $\Delta(2\theta)=(1.6+0.7\tan\theta_c)°$, where θ_c is the calcualated Bragg angle for Mo $K\alpha_1$ ($\lambda=0.70926$ Å). A total of 5482 independent reflections was collected, of which the number of non-zero reflections was 4732. The intensities of three standard reflections (060, 004, and 3,18,2) were measured periodically; no intensity decrease in these reflections was observed during the experiment. Usual Lorentz and polarization corrections were made, but the absorption correction was ignored ($\mu=6.73$ cm^{-1} for Mo $K\alpha$).

Solution and Refinement of the Structure

The structure was solved by the heavy atom method. The palladium and two phosphorus atoms were located from a three-dimensional Patterson function. All the remaining non-hydrogen atoms were located by successive Fourier syntheses. The structure was refined by the block-diagonal least-squares procedure. The HBLS V program[8] was used, the function minimized being $(|F_o|-k|F_c|)^2$, where k is a single scale factor. Several cycles of isotropic refinement reduced the R_1 factor ($R_1=\sum||F_o|-|F_c||/\sum|F_o|$) to 0.092 for non-zero reflections, and no abnormal thermal parameter was observed. Anisotropic thermal parameters were introduced for palladium and phosphorus atoms for several cycles of refinement, and then for all the non-hydrogen atoms. The difference synthesis, based on the final atomic parameters, did not reveal any hydrogen atoms. Finally,

Table 2. Anisotropic thermal parameters ($\times 10^4$) expressed in the form: $\exp\{-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)\}$ (estimated standard deviations in parentheses)

four cycles of refinement converged to $R_1=0.058$ ($R_2=0.070$) for 4732 non-zero reflections. The largest shifts in positional and thermal parameters were about 0.02σ and 0.3σ, respectively. The atomic scattering factors used in the calculations were those of Hanson and co-workers.[9] The final positional and thermal parameters are listed in Tables 1 and 2.**

Description of the Structure

Molecular Structure. The perspective view of the $[(Pd(C_3H_4O_3)(PPh_3)]$ molecule is given in Fig. 1, with numbering scheme of atoms. A stereoscopic drawing of the molecule and the coordination geometry around the palladium atom are given in Figs. 2 and 3, respectively. Bond lengths and bond angles are given in Table 3. Least-squares planes of various groups of atoms and

** The Table of observed and calculated structure factors are kept as Document No. 7820 at the Chemical Society of Japan.

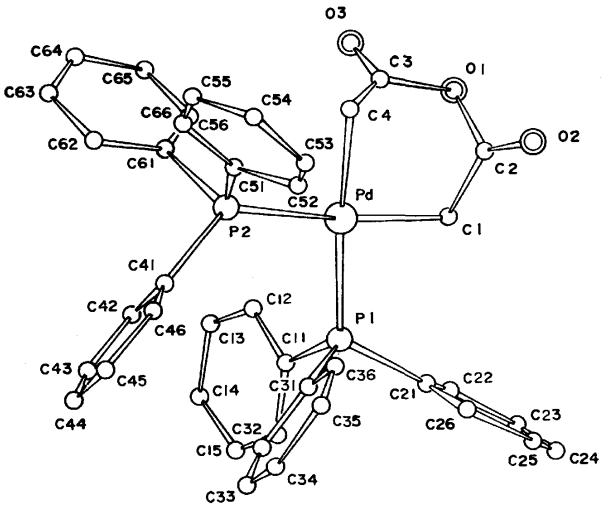

Fig. 1. Perspective view of the molecule with the numbering scheme of atoms.

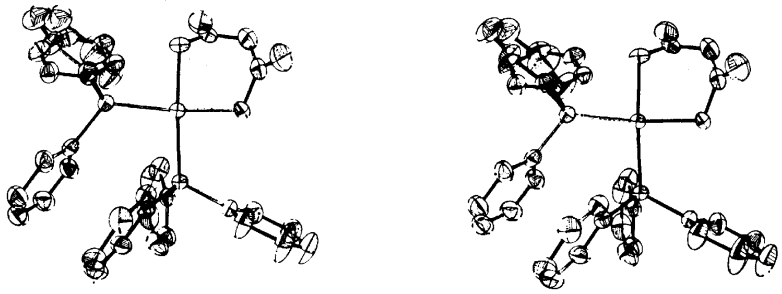

Fig. 2. A stereoscopic view of the molecule. Non-hydrogen atoms are represented by the thermal ellipsoids at 50% probability level.

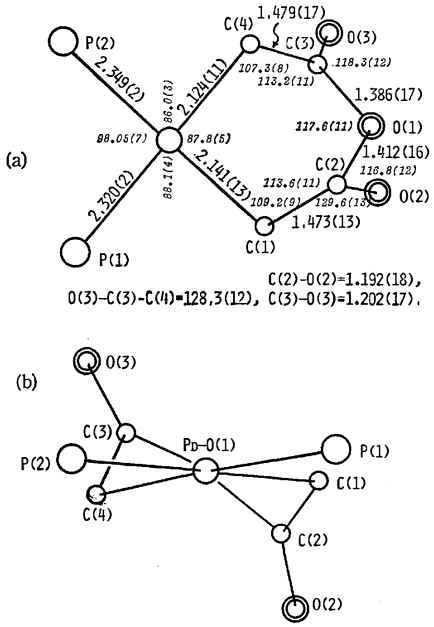

Fig. 3. The coordination geometry around the palladium atom. (a) Selected bond lengths [l/Å] and bond angles [ϕ/°]. (b) Viewed down along the Pd···O(1).

deviations of atoms from these planes are listed in Table 4.

The remarkable feature of the molecular structure is that this complex contains a carbon-bonded chelated ring of acetic anhydride (Fig. 1). The palladium atom has a square-planar geometry coordinated by two sp^3 carbon atoms (C(1) and C(4)) of the chelate ring and two phosphorus atoms: the mean and maximum deviations of atoms from the best plane being 0.023 and 0.029 Å.

The bond lengths between the palladium and two carbon atoms (C(1) and C(4)) are equal: 2.141(13) and 2.124(11) Å, which are longer ones of the Pd(II)–C-(sp^3) bonds.[6] The C(1)–Pd–C(4) angle [87.8(5)°] is slightly smaller than 90°.
